Editor: Michael Mahoney

Abstract

Community detection is the process of grouping strongly connected nodes in a network. Many community detection methods for *un*-weighted networks have a theoretical basis in a null model. Communities discovered by these methods therefore have interpretations in terms of statistical significance. In this paper, we introduce a null for weighted networks called the continuous configuration model. First, we propose a community extraction algorithm for weighted networks which incorporates iterative hypothesis testing under the null. We prove a central limit theorem for edge-weight sums and asymptotic consistency of the algorithm under a weighted stochastic block model. We then incorporate the algorithm in a community detection method called CCME. To benchmark the method, we provide a simulation framework involving the null to plant "background" nodes in weighted networks with communities. We show that the empirical performance of CCME on these simulations is competitive with existing methods, particularly when overlapping communities and background nodes are present. To further validate the method, we present two real-world networks with potential background nodes and analyze them with CCME, yielding results that reveal macro-features of the corresponding systems.

Keywords: Community detection; Multiple testing; Network models; Weighted networks; Unsupervised learning

1. Introduction

For decades, the development of graph theory and network science has produced a wide array of quantitative tools for the study of complex systems. Network-based data analysis methods have driven advances in areas as diverse as social science, systems biology, life sciences, marketing, and computer science (cf. Palla et al., 2007; Barabasi and Oltvai, 2004; Lusseau and Newman, 2004; Guimera and Amaral, 2005; Reichardt and Bornholdt, 2007; Andersen et al., 2012). Thorough surveys of the network science and methodology literature have been provided by Newman (2003) and Jacobs and Clauset (2014), among others.

A common exploratory technique for networks called "community detection" involves the search for node subsets ("communities") that are somehow internally related. Usually, it is assumed that links or "edges" between nodes in the same community are more common than those between nodes in different communities. Thus, the specific goal of community detection is often to find groups of nodes that are strongly intraconnected and weakly interconnected (Newman, 2004b), which is known as "assortative" structure. Some approaches allow for "disassortative" structure, with *weak* intraconnection and *strong* interconnection (Karrer and Newman, 2011; Aicher et al., 2014). Regardless of one's broad notion of community structure, there are hundreds of distinct criteria and methods for its discovery. Community detection most often proceeds in an *unsupervised* fashion, so that communities are found through the network edge structure alone.

Since communities in real-world networks often arise due to some explanatory systematic mechanism, community detection has been an important part of both data-driven decision-making and scientific inquiry (Danon et al., 2005). For instance, community detection has been used to facilitate recommender systems in online social networks (e.g. Sahebi and Cohen, 2011; Xin et al., 2014), and has been used to "hone in" on regions of genomes (human and otherwise) for a variety of downstream analyses (e.g. Cabreros et al., 2016; Platig et al., 2015; Fan et al., 2012). Myriad examples of community detection applications can be found in Porter et al. (2009) and Fortunato (2010), and the references therein.

Many community detection methods are based on a null model, which in this context means a random network model without explicit community structure. For un-weighted networks the most common null is the configuration model (Bollobás, 1980; Bender, 1974) or a related model like that of Chung and Lu (2002a,b). Historically, the most common approach involving a null model is the use of a node partition score that is large when nodes within the cells of the partition are highly interconnected, relative to what is expected under the null (Fortunato, 2010; Newman, 2006). Arguably the most famous example of such a criterion is modularity, introduced by Newman and Girvan (2004). Various algorithms have been created to search directly for partitions of a network with large modularity (see Clauset et al., 2004; Blondel et al., 2008), while other approaches use modularity as an auxiliary criterion (see Langone et al., 2011). More recent approaches incorporate community-specific criteria which are large when the community is preferentially intra-connected, allowing for community *extraction* algorithms (e.g. Zhao et al., 2011; Lancichinetti et al., 2011; Wilson et al., 2014).

Generally speaking, communities found by null-based community detection methods can be said to have exhibited behavior strongly departing from the null. The results of these methods therefore carry a statistical *testing* interpretation unavailable to most methods without this foundation, like spectral clustering (White and Smyth, 2005; Zhang et al., 2007) or those based on random walks (e.g. Pons and Latapy, 2006). In particular, recent methods put forth by Lancichinetti et al. (2011) and Wilson et al. (2014) for binary networks use the theoretical properties of the configuration model to detect "background" nodes that are not significantly connected to any community. These methods incorporate tail behavior of node-wise graph statistics under the configuration model in a way that others do not. Note that another class of methods capable of assessing significance are focused on specifying *alternative* (non-null) models for communities. Once fit, the models can be compared with the null-partition via likelihood ratios (e.g. Yan et al., 2014) or Bayes factors (e.g. Peixoto, 2015).

A significant drawback of null-based community detection methodology is that no explicit null model exists for edge-weighted networks. Edge weights are commonplace in network data, and can provide information that improves community detection power and specificity (Newman, 2004a). While many existing community detection methods have been established for weighted and un-weighted networks alike, due to the absence of an appropriate weighted-network null model, these methods do not provide rigorous significance assessments of weighted-network communities. For instance, the aforementioned method from Lancichinetti et al. (2011), called OSLOM, can incorporate edge weights, but uses an exponential function to calculate nominal tail probabilities for edge weight sums, a testing approach which is not based on an explicit null. As a consequence, communities in *weighted* networks identified by OSLOM may in some cases be spurious or unreliable, especially when no "true" communities exist.

The key methodological contributions in this article are as follows: (i) we provide an explicit null model for networks with weighted edges, (ii) we present a community extraction method based on hypothesis tests under the null, and (iii) we analyze the consistency properties of the method's core algorithm with respect to a weighted stochastic block model. These contributions provide the beginnings of a rigorous statistical framework with which to study communities in weighted networks. Through extensive simulations, we show that the accuracy of our proposed extraction method is highly competitive with other community detection approaches on weighted networks with both disjoint and overlapping communities, and on weighted networks with background nodes. Importantly, the weighted stochastic block model employed (in both the theoretical and empirical studies) allows for arbitrary expected degree and weighted-degree distributions, reflecting degree heterogeneity observed in real-world networks. To further validate the method, we apply it to two real data sets with (arguably) potential overlapping communities and background nodes. We show that the proposed method recovers sensible features of the real data, in contrast to other methods.

1.1 Paper organization

The rest of the paper is organized as follows. We start by introducing general notation in Section 1.2. In Section 2 we motivate and state the continuous configuration model. In Section 3, we introduce a core algorithm to search for communities using multiple hypothesis testing under the model. In Section 4, we prove both a central limit theorem and a consistency result for the primary test statistic in the core algorithm. We describe the implementation and application of the core algorithm in Section 5, and evaluate its empirical efficacy on simulations and real data in Section 6 and 7 (respectively). We close with a discussion in Section 8.

1.2 Notation and terminology

We denote an undirected weighted network on n nodes by a triple $\mathcal{G} := (N, A, W)$, where $N := \{1, \ldots, n\}$ is the node set with u, v as general elements, A is the adjacency matrix with $A_{uv} = 1$ if and only if there is an edge between u and v, and W is the weight matrix with non-negative entries W_{uv} containing edge weights between nodes u and v. Note that $A_{uv} = 0$ implies $W_{uv} = 0$, but W_{uv} may be zero even when $A_{uv} = 1$. This allows for networks with potentially zero edge weights; for instance, an online social network from which friendship

links are edges and message counts are edge weights. The degree of a node u is defined by $d(u) := \sum_{v \in N} A_{uv}$, and we denote the vector of node degrees by $\mathbf{d} = (d_1, \ldots, d_n)$. In an analogous fashion, we define the *strength* of a node by $s(u) := \sum_{v \in N} W_{uv}$, and the strength vector of the network by $\mathbf{s} = (s(1), \ldots, s(n))$. The total degree and strength of $\mathcal{G}$ are given by $d_T := \sum_{v \in N} d(v)$ and $s_T := \sum_{v \in N} s(v)$, respectively.

2. The continuous configuration model

To motivate the null model, we first explain the intuition behind the binary configuration model for unweighted networks. The binary configuration model for an n-node network is based on a given degree vector $\mathbf{d}$ corresponding to the nodes. Studied originally in Bollobás (1980) and Bender (1974), the model is equivalent to a process in which each node u receives $d(u)$ half-edges, which are paired uniformly-at-random without replacement until no half-edges remain (Molloy and Reed, 1995). In other words, the model guarantees a graph with degrees $\mathbf{d}$ but otherwise uniformly distributed edges. Therefore, given an observed network with degrees $\mathbf{d}$, a typical draw from the configuration model under $\mathbf{d}$ represents that network without any community structure.

Due to these characteristics, many community detection methods proceed by identifying node sets having intra-connectivity significantly beyond what is expected under the model. For instance, the modularity measure, introduced by Newman and Girvan (2004), scores node partitions of binary networks according to the observed versus configuration model-expected edge densities of the communities. The methods OSLOM (Lancichinetti et al., 2011) and ESSC (Wilson et al., 2014) use the configuration model to assess the statistical significance of the deviations graph statistics from their configuration model-expected values. Methods based on the configuration model are able to properly distinguish true community structure from "false positive" community structure arising from inherently high connectivity. For instance, Karrer and Newman (2011) showed that on a political blogs network, modularity maximization found communities that agreed with political affiliation, whereas the same algorithm without node degree input found a naíve split of the network into more active and less active blogs.

The degrees $\mathbf{d}$ of the configuration model can be thought of as the nodes' relative propensities to form ties. Chung and Lu made this notion explicit by defining a Bernoulli-based model for a n-node unweighted network with a given expected degree sequence (Chung and Lu, 2002b). Under this model, the probability of nodes u and v sharing an edge is exactly $d(u)d(v)/d_T$. As null models for community detection, the Chung-Lu and configuration are often interchangeable (Durak et al., 2013). Indeed, for sparse graphs it can be shown that the probability of an edge between u and v under the configuration model is approximately the Chung-Lu probability. The *continuous* configuration model, introduced below, extends the spirit of the configuration and Chung-Lu models by taking both observed degrees $\mathbf{d}$ and strengths $\mathbf{s}$ as node propensities for (respectively) edge connection and edge weight.

In the next section, we use the following notation to concisely express the model. Given a vector $\mathbf{x}$ of dimension n, we define for any indices $u, v \in N$ the ratio

$$r_{uv}(\mathbf{x}) := \frac{x(u)x(v)}{\sum_{w \in N} x(w)} \tag{1}$$

Define $\tilde{r}_{uv}(\mathbf{x}) := \min\{1, r_{uv}(\mathbf{x})\}$. Note that when $\mathbf{x}$ is a degree sequence $\mathbf{d}$, $r_{uv}(\mathbf{d})$ is the Chung-Lu probability of an edge between nodes u and v. Finally, for a vector $\mathbf{y}$ of dimension n, define $f_{uv}(\mathbf{x}, \mathbf{y}) := r_{uv}(\mathbf{y})/\tilde{r}_{uv}(\mathbf{x})$.

2.1 Model statement

The continuous configuration model on n nodes has the parameter triple $\theta := (\mathbf{d}, \mathbf{s}, \kappa)$, where $\mathbf{d} \in \{1, 2, 3, \ldots\}^n$ is a degree vector, $\mathbf{s} \in [0, \infty)^n$ is a strength vector, and $\kappa > 0$ is a variance parameter. Let F be a distribution on the non-negative real line with mean one and variance κ. The model specifies a random weighted graph $\mathcal{G} := (N, A, W)$ on n nodes as follows:

1. $\mathbb{P}(A_{uv} = 1) = \tilde{r}_{uv}(\mathbf{d})$ independently for all node pairs $u, v \in N$
2. For each node pair u, v, generate an independent random variable ξ_{uv} according to F, and assign edge weights by: $W_{uv} = \begin{cases} f_{uv}(\mathbf{d}, \mathbf{s})\xi_{uv}, & A_{uv} = 1 \\ 0, & A_{uv} = 0 \end{cases}$

The edge generation defined by step 1 is equivalent to the Chung-Lu model: edge indicators are Bernoulli, with probabilities adjusted by the propensities $\mathbf{d}$. The weight generation in step 2 mirrors this process. Edge weights follow the distribution F, with means adjusted by the propensities $\mathbf{s}$, through $f(\mathbf{d}, \mathbf{s})$. Note that $\tilde{r}_{uv}(\mathbf{d})$ differs from $r_{uv}(\mathbf{d})$ only when the degree distribution is extremely right-skewed or highly dispersed, and then only when one of u or v has a large degree. Truncating edge probabilities is standard in approaches based on the Chung-Lu model (e.g. Zhao et al., 2012).

It is easily derived from the model that

$$P(A_{uv} = 1) = \frac{d(u)d(v)}{d_T} \quad \text{and} \quad \mathbb{E}(W_{uv}) = \frac{s(u)s(v)}{s_T}, \tag{2}$$

equations which extend the binary-network notion of null behavior to edge weights. (The first equation will be approximate for any u, v for which $r_{uv}(\mathbf{d}) > 1$.) The equations in (2) imply that

$$\mathbb{E}(D(u)) = d(u) \quad \text{and} \quad \mathbb{E}(S(u)) = s(u) \ \text{ for all } \ u \in N. \tag{3}$$

where $D(u)$ and $S(u)$ are the (random) degree and strength of u under the model. Thus, the continuous configuration model can be thought of as null weighted network with given expected degrees and given expected strengths.

2.2 Null model parameter specification

When the *binary* configuration model is used for community detection, the degree parameter of the model is set to the observed degree distribution of the network. In a sense, this is an *estimation* of the nodes' connection propensities under the null. Similarly, to use the continuous configuration model in practice, we derive the parameter θ from the data at hand. Given an observed network $\mathcal{G}$, we straightforwardly use the observed degrees and strengths $\mathbf{d}$ and $\mathbf{s}$ as the first two parameters of the model. The third parameter of the continuous configuration model, κ, is also computed from the $\mathcal{G}$, and meant to capture its

observed average edge-weight variance. We use the following method-of-moments estimator to specify κ:

$$\hat{\kappa}(\mathbf{d}, \mathbf{s}) := \sum_{u,v:A_{uv}=1} (W_{uv} - f_{uv}(\mathbf{d}, \mathbf{s}))^2 \Big/ \sum_{u,v:A_{uv}=1} f_{uv}(\mathbf{d}, \mathbf{s})^2 \tag{4}$$

This estimator is derived as follows. Under the continuous configuration model with $\mathbf{d}$ and $\mathbf{s}$,

$$\text{Var}\left(W_{uv} \,\middle|\, A_{uv} = 1\right) \;=\; f_{uv}(\mathbf{d}, \mathbf{s})^2 \,\text{Var}\left(\xi_{uv}\right) \;=\; f_{uv}(\mathbf{d}, \mathbf{s})^2 \,\kappa. \tag{5}$$

Therefore

$$\begin{aligned} \mathbb{E}\left\{ \sum_{u,v:A_{uv}=1} (W_{uv} - f_{uv}(\mathbf{d}, \mathbf{s}))^2 \;\middle|\; A \right\} &= \sum_{u,v:A_{uv}=1} \text{Var}\left(W_{uv} \mid A_{uv} = 1\right) \\ &= \kappa \sum_{u,v:A_{uv}=1} f_{uv}(\mathbf{d}, \mathbf{s})^2, \end{aligned}$$

Dividing through by $\sum_{u,v:A_{uv}=1} f_{uv}(\mathbf{d}, \mathbf{s})$ motivates equation 4.

Strictly speaking, the distribution F is also a parameter of the model. However, for testing purposes we do not require a null specification of F. As we discuss in the next section, p-values from the model will be based on a central limit theorem that requires only a third-moment assumption on F. While estimating F could improve the model's efficacy as a null, in general this would require potentially costly computational procedures, and additional theoretical assumptions that might be difficult to support or verify in practice. The specification of F will be most useful for applications of the model that involve simulations or likelihood-based analyses.

In subsequent sections, we describe a procedure for testing nodal connectivity against the continuous configuration model, with parameters derived from the real data (as above). These parameters pertain only to a *null* model, and not to any particular community-laden generative network model. Our procedure (to be introduced) is built upon hypothesis testing under this estimated null. Note that this is in contrast to a broad class of community detection methods which are all based on estimating a "Stochastic Block Model" (SBM), a generative network model with parameters controlling the presence and strength of communities (e.g. Nowicki and Snijders, 2001; Karrer and Newman, 2011; Aicher et al., 2014; Peixoto, 2017). In particular, the work of Peixoto (2017) introduces a weighted-edge SBM estimation procedure which automatically chooses the number of communities, and allows for a notion of community overlap. We feature this method in our simulation experiments, introduced in Section 6.

3. Test statistic and update algorithm

In this section we introduce a core testing-based community detection algorithm based on the continuous configuration model. The algorithm *updates* an input node set via node-to-set hypothesis testing. We describe the repeated application of the algorithm as part of an iterative set-update approach to community detection, following some recently-introduced methods (e.g. Lancichinetti et al., 2011; Wilson et al., 2014).

Formally, we define the core algorithm operation as a set-update map $U_\alpha(\,\cdot\,, \mathcal{G}) : 2^N \mapsto 2^N$, indexed by a parameter $\alpha \in (0,1)$. Given a weighted network $\mathcal{G}$ and candidate set $B \subseteq N$, the update $U_\alpha(B, \mathcal{G})$ outputs a new set B' formed by the nodes from N that have statistically significant association to B at level α, after a multiple-testing correction. The node-wise hypothesis tests are based on the summary statistic

$$S(u, B, \mathcal{G}) := \sum_{v \in B} W_{uv}, \tag{6}$$

which is the sum of all weights on edges incident with u and B. When the observed value of $S(u, B, \mathcal{G})$ is much larger than its expectation under the continuous configuration model, there is evidence to support an association between u and B resulting from some form of "ground-truth" community structure in the network. We assess the strength of evidence, that is, the significance of $S(u, B, \mathcal{G})$, with the p-value

$$p(u, B, \mathcal{G}) := \mathbb{P}\left(S(u, B, \widetilde{\mathcal{G}}) > S(u, B, \mathcal{G})\right), \tag{7}$$

where $\widetilde{\mathcal{G}}$ is random with respect to $\mathbb{P}$, the distribution of the continuous configuration model with parameters $\mathbf{d}, \mathbf{s}$, and $\hat{\kappa}(\mathbf{d}, \mathbf{s})$ (see Section 2.2). The update U_α is then:

Core update U_α

1. Given: graph $\mathcal{G}$ with nodes N and input set $B \subseteq N$
2. Calculate p-values $\mathbf{p} := \{p(u, B, \mathcal{G}) : u \in N\}$
3. Obtain threshold $\tau(\mathbf{p})$ from a multiple-testing procedure
4. Output set $B' = \{u : p(u, B, \mathcal{G}) \leqslant \tau(\mathbf{p})\}$

Many methods to compute a multiple-testing threshold $\tau(\mathbf{p})$ are available, the most stringent being the well-known Bonferroni correction. The correction we employ is the false discovery rate (FDR) control procedure of Benjamini and Hochberg (1995). Given a set of p-values $\mathbf{p} := \{p_u\}_{u \in N}$ corresponding to n hypothesis tests and a target FDR $\alpha \in (0,1)$, each p-value $p_u \in \mathbf{p}$ is associated with an adjusted p-value $p_u^* := n\, p_u \,/\, j(u)$ where $j(u)$ is the rank of p_u in $\mathbf{p}$, and $\tau(\mathbf{p}) := \max\{p_u : p_u^* \leqslant \alpha\}$. Benjamini and Hochberg show that, if the p-values corresponding to true null hypotheses are independent, the threshold $\tau(\mathbf{p})$ bounds the expected number of false discoveries at α.

The update U_α is an exploratory tool for moving an input set B closer to a "target" community. Consider that, if the initial set B has a majority group of nodes from some strongly-connected community C, the statistic $S(u, B, \mathcal{G})$ will be large for $u \in C$, and small otherwise. In this case, U_α applied to B will often return many nodes in C, and few nodes in C^c. Note that U_α can *remove* nodes from B, if they are not significantly connected, as well as add them.

If C is a community with strong enough signal, we should expect $U_\alpha(C, \mathbf{D})$ to return C. This reasoning motivates an algorithm that searches for "stable communities" C satisfying $U_\alpha(C, \mathbf{D}) = C$. By definition, all interior nodes of a stable community C are significantly

connected to C, and exterior nodes are not. We define a stable community search procedure, which iteratively applies U_α until convergence:

Stable community search (SCS) algorithm

1. Given weighted graph $\mathcal{G}$ with nodes N and initial set $B_0 \subseteq N$; $t \leftarrow 0$
2. Set $B_{t+1} \leftarrow U_\alpha(B_t, \mathcal{G})$ and $t \leftarrow t + 1$.
3. If $B_t = B_{t'}$ for some $t' < t$, terminate. Else, return to step 2.

Since the number of possible node subsets B_t is finite, SCS is guaranteed to terminate. There are some technicalities regarding use of this algorithm, like how to obtain B_0, and when in rare cases $t' < t - 1$. We relegate resolution of these issues to Section 5. For now, the update U_α and SCS raise two theoretical questions:

1. Is the p-value $p(u, B, \mathcal{G})$ analytically tractable? If not, is there a useful distributional approximation based on the continuous configuration model?

2. Consistency: with what power can SCS detect ground-truth community structure?

These questions are the focus of the next section.

4. Theoretical Results

We now address the theoretical questions raised at the end of the previous section by analyzing the distribution of the test statistic $S(u, B, \mathcal{G})$ under the continuous configuration model (for question 1) and an appropriate alternative model with planted community structure (for question 2). Both analyses have an asymptotic setting consisting of a sequence of random weighted networks. Denote this sequence by $\{\mathcal{G}_n\}_{n>1}$. If $\mathcal{G}_n$ is a continuous configuration model with parameters $\theta := (\mathbf{s}, \mathbf{d}, \kappa)$, the following proposition gives general expressions for the mean and standard deviation of $S(u, B, \mathcal{G}_n)$:

Proposition 1 *Let $\mathcal{G} = (N, A, W)$ be a random network generated by the continuous configuration model with parameters $\theta = (\mathbf{s}, \mathbf{d}, \kappa)$. For any $(u, B) \in N \times 2^N$, let $\mu(u, B|\theta)$ and $\sigma(u, B|\theta)$ be, respectively, the mean and standard deviation of $S(u, B, \mathcal{G})$ under $\mathcal{G}$. Then*

$$\mu(u, B|\theta) \equiv \mu(u, B|\mathbf{s}) = \sum_{v \in B} r_{uv}(\mathbf{s}) \tag{8}$$

and

$$\sigma(u, B|\theta)^2 = \sum_{v \in B} r_{uv}(\mathbf{s}) f_{uv}(\mathbf{d}, \mathbf{s})\left(1 - \tilde{r}_{uv}(\mathbf{d}) + \kappa\right) \tag{9}$$

The proof, given in Appendix A, follows from easy calculations with the model's generating procedure (see Section 2.1). All theoretical results will make use of the expressions defined in equations 8 and 9.

4.1 Asymptotic Normality of $S(u, B, \mathcal{G})$

A central limit theorem under the null model is now established for $S(u, B, \mathcal{G})$, yielding a closed-form approximation for the p-value in equation (7). This result is motivated by the fact that, under most non-trivial null parameter specifications, the distribution of $S(u, B, \mathcal{G})$ is not analytically tractable.

In the setting of the theorem, for any $n > 1$, a random network $\mathcal{G}_n$ is generated by a continuous configuration model with parameter $\theta_n := (\mathbf{d}_n, \mathbf{s}_n, \kappa_n)$ and common weight distribution F. The following regularity conditions are required on the sequence $\{\theta_n\}_{n>1}$. Let λ_n denote the average entry of $\mathbf{d}_n$, (which is the average expected degree of $\mathcal{G}_n$). For each $r \geqslant 0$ let $L_{n,r} := n^{-1} \sum_{u \in N} (d_n(u)/\lambda_n)^r$ be the normalized r^{th}-moment of $\mathbf{d}_n$. Note that $L_{n,1} = 1$. The regularity conditions are then as follows:

Assumption 1 *Define $e_n(u|\beta) := s_n(u)/d_n(u)^{1+\beta}$. There exists $\beta > 0$ such that*

$$0 < \liminf_{n\to\infty} \min_{u \in N} e_n(u|\beta) \quad \textit{and} \quad \limsup_{n\to\infty} \max_{u \in N} e_n(u|\beta) < \infty.$$

Assumption 2 *Let β be as in Assumption 1. There exists $\varepsilon > 0$ such that, for both $r = 4\beta + 2$ and $r = 4\beta + 2 + \varepsilon$,*

$$0 < \liminf_{n\to\infty} L_{n,r} \quad \textit{and} \quad \limsup_{n\to\infty} L_{n,r} < \infty$$

Assumption 3 $\limsup_{n\to\infty} \sup_{u,v \in N} r_{uv}(\mathbf{d}_n) < \infty$.

Assumption 4 *The sequence $\{\kappa_n\}_{n\geqslant 1}$ is bounded away from zero and infinity, and F has finite third moment.*

Assumption 1 reflects the common relationship between strengths and degrees in real-world weighted networks (Barrat et al., 2004; Clauset et al., 2009). Assumptions 2-3 are needed to control the extremal behavior of the degree distribution. They exclude, for instance, cases with a few nodes having $d_n(u) \asymp n$ and the remaining nodes having $d_n(u) = O(1)$. We note that the Assumption 2 becomes more stringent as β increases, since as β increases the strength-degree power law becomes more severe.

Theorem 2 *For each $n > 1$, let $\mathcal{G}_n$ be generated by the continuous configuration model with parameter θ_n and weight distribution F. Suppose $\{\theta_n\}_{n\geqslant 1}$ and F satisfy Assumptions 1-4. Fix a node sequence $\{u_n\}_{n\geqslant 1}$ with $u_n \in N$ and a positive integer sequence $\{b_n\}_{n\geqslant 1}$ with $b_n \leqslant n$. Suppose $d_n(u_n)b_n/n \to \infty$ as $n \to \infty$. Let $B_n \subseteq N$ be a node set chosen independently of $\mathcal{G}_n$ according to the uniform distribution on all sets of size b_n. Then*

$$\frac{S(u_n, B_n, \mathcal{G}_n) - \mu_n(u_n, B_n|\theta_n)}{\sigma_n(u_n, B_n|\theta_n)} \Rightarrow \mathcal{N}(0, 1) \quad \textit{as} \quad n \to \infty \tag{10}$$

The proof is given in Appendix B. Essentially, Theorem 2 says that $S(u, B, \mathcal{G})$ is asymptotically Normal provided that B is typical (i.e. a uniform draw) and that $d(u)$ and B are sufficiently large. The theorem justifies the following approximation of the p-value in (7):

$$p(u, B) \approx 1 - \Phi\left(\frac{S(u, B, \mathcal{G}) - \mu(u, B|\theta)}{\sigma(u, B|\theta)}\right) \tag{11}$$

Above, $\theta = (\mathbf{d}, \mathbf{s}, \hat{\kappa}(\mathbf{d}, \mathbf{s}))$ is computed from $\mathcal{G}$, as described in Section 2.2. Note that the numerator $S(u, B, \mathcal{G}) - \mu(u, B|\theta)$ is the contribution of B to the standard modularity score, as will be discussed in more detail in Sections 4.2.2 and 4.2.3. The variance $\sigma(u, B|\theta)$ thus standardizes the magnitude of B's modularity, providing an appropriate test statistic for community effect.

4.2 Consistency of SCS

In this section, we evaluate the ability of the SCS algorithm to identify true communities in a planted-community model. Explicitly, we consider a sequence of networks $\{\mathcal{G}_n\}_{n>1}$ where each network in the sequence is generated by a weighted stochastic block model (WSBM). The WSBM we employ is similar to that presented in Aicher et al. (2014), but is generalized to include node-specific weight parameters. In other words, it is "strength-corrected" as well as degree-corrected, in a manner analogous to the original degree-corrected SBM (Coja-Oghlan and Lanka, 2009). The proofs of Theorem 4 and Theorem 5 are given in Appendix C.

4.2.1 The weighted stochastic block model

For fixed $K > 1$, we define a K-block WSBM on $n > 1$ nodes as follows. Let $\mathbf{c}_n$ be a community partition vector with $c_n(u) \in \{1, \ldots, K\}$ giving the community index of u. Denote community i by $C_{i,n} := \{u : c_n(u) = i\}$. Define $\pi_{i,n} := n^{-1}|C_{i,n}|$ with $\boldsymbol{\pi}_n$ the associated vector. Let $\mathbf{P}$ and $\mathbf{M}$ be fixed $K \times K$ symmetric matrices with non-negative entries encoding intra- and inter-community baseline edge probabilities and edge weight expectations, respectively. Let ϕ_n and ψ_n be arbitrary n-vectors with positive entries, which are parameters giving nodes individual propensities to form edges and assign weight (separately from $\mathbf{P}$ and $\mathbf{M}$). To ensure proper edge probabilities, we assume that $\max(\phi_n)^2 \max(\mathbf{P}) \leqslant 1$. For identifiability, we assume the vectors ϕ_n and ψ_n sum to n. Finally, let F be a distribution on the non-negative real line with mean 1 and variance $\sigma^2 \geqslant 0$. The WSBM can then be specified as follows:

1. Place an edge between nodes u and v with probability $\mathbb{P}_n(A_{uv} = 1) = r_{uv}(\phi_n)\mathbf{P}_{c_n(u)c_n(v)}$, independently across node pairs.
2. For node pair u, v with $A_{uv} = 1$, generate an independent random variable ξ_{uv} according to F. Determine edge weight W_{uv} by:

$$W_{uv} = \begin{cases} f_{uv}(\psi_n, \phi_n)\mathbf{M}_{c_n(u)c_n(v)}\xi_{uv}, & A_{uv} = 1 \\ 0, & A_{uv} = 0 \end{cases}$$

The many parameters involved with this model allow for node heterogeneity and community structure. When $\mathbf{P}$ and $\mathbf{M}$ are proportional to a $K \times K$ matrix of ones, the WSBM

reduces to the continuous configuration model with parameters $\mathbf{d} \propto \phi$, $\mathbf{s} \propto \psi$, and $\kappa = \sigma^2$. Community structure is introduced in the network by allowing the diagonal entries of $\mathbf{P}$ and $\mathbf{M}$ to be arbitrarily larger than the off-diagonals.

4.2.2 Consistency theorem

The consistency analysis of SCS involves a sequence of random networks $\{\mathcal{G}_n\}_{n>1}$, where $\mathcal{G}_n$ is generated by a K-community WSBM. In this setting, we incorporate an additional parameter ρ_n, and let $\mathbf{P}_n := \rho_n \mathbf{P}$ replace $\mathbf{P}$ for each $n > 1$. This lets us distinguish the role of the asymptotic order of the average expected degree, defined $\lambda_n := n\rho_n$, from the profile of edge densities within and between communities ($\mathbf{P}$). Importantly, our results require only that $\lambda_n / \log n \to \infty$, reflecting the sparsity of real-world networks. Throughout this section, we denote the vector of (random) strengths from $\mathcal{G}_n$ by $\mathbf{S}_n$.

We now define an explicit notion of consistency in terms of the SCS algorithm. Recall from Section 3 that for fixed FDR $\alpha \in (0,1)$, a stable community in a network $\mathcal{G}_n$ is defined as a node set $C \subseteq N$ satisfying $U_\alpha(C, \mathcal{G}_n) = C$.

Definition 3 *We say that SCS is consistent for a sequence of WSBM random networks $\{\mathcal{G}_n\}_{n>1}$ if for any FDR level $\alpha \in (0,1)$, the probability that the true communities $C_{1,n}, \ldots, C_{K,n}$ are stable approaches 1 as $n \to \infty$.*

To assess the conditions that allow a target set C to be a stable community, we seek more general conditions under which the update $U_\alpha(\,\cdot\,, \mathcal{G})$ outputs C given any initial set B. If $U_\alpha(B, \mathcal{G}_n) = C$, all nodes $u \in C$ must have significant connectivity to B, as judged by the p-value approximation defined in 11. It is clear from that p-value expression that, for the update to return C, the test statistic $S(u, B, \mathcal{G}_n)$ must be significantly larger than $\mu(u, B|\mathbf{S}_n)$, its expected value under the continuous configuration model. Therefore, our first result hinges on asymptotic analysis of that deviation, which we denote by

$$A(u, B, \mathcal{G}_n) := S(u, B, \mathcal{G}_n) - \mu_n(u, B|\mathbf{S}_n). \tag{12}$$

The asymptotics of $A(u, B, \mathcal{G}_n)$ depend on its *population* version, in which all random quantities are replaced with their expected values under the WSBM. Let $\mathbf{s}_n$ be the expected value of $\mathbf{S}_n$ under $\mathcal{G}_n$. We define the (normalized) population version of $A(u, B, \mathcal{G}_n)$ by

$$\tilde{a}_n(u, B) := \lambda_n^{-1} \left(\mathbb{E}S(u, B, \mathcal{G}_n) - \mu_n(u, B|\bar{\mathbf{s}}_n) \right), \tag{13}$$

where λ_n is the order of the average expected degree. The value $\tilde{a}_n(u, B)$ is crucial to the primary condition of Theorem 4. Given a sequence of initial sets $\{B_n\}_{n>1}$ and target sets $\{C_n\}_{n>1}$, Theorem 4 establishes that $U_\alpha(B_n, \mathcal{G}_n) = C_n$ with probability approaching 1 if $\tilde{a}_n(u, B)$ is bounded away from zero, and is positive if and only if $u \in C_n$. The theorem requires the following two assumptions:

Assumption 5 *There exist constants $m_+ > m_- > 0$ such that, for all $n > 1$, the entries of ϕ_n, ψ_n, $\mathbf{P}$, $\mathbf{M}$, and $\boldsymbol{\pi}_n$ are all bounded in the interval $[m_-, m_+]$.*

Assumption 6 *F is independent of n and has support $(0, \eta)$ with $\eta < \infty$.*

Assumption 5 is standard in consistency analyses involving block models (e.g. Zhao et al., 2012; Bickel and Chen, 2009). We note that this assumption requires the minimum community size to scale with n. Assumption 6 allows the use of Bernstein's inequality throughout the proof, but may be relaxed if there are constraints on the moments of F allowing the use of a similar inequality. We now state Theorem 4, the proof of which is given in Appendix C.

Theorem 4 *Fix $K > 1$. For each $n > 1$, let $\mathcal{G}_n$ be a n-node random network generated by a K-community WSBM with parameters satisfying Assumptions 5 - 6. Suppose $\lambda_n / \log n \to \infty$. Let $\{B_n\}_{n>1}$, $\{C_n\}_{n>1}$ be sequences of node sets satisfying the following: there exist constants $q \in (0,1]$ and $\Delta > 0$ such that for all n sufficiently large, $|B_n|, |C_n| \geqslant qn$, and*

$$\tilde{a}_n(u, B_n) \geqslant \Delta, \;\; u \in C_n, \quad \text{and} \quad \tilde{a}_n(u, B_n) \leqslant -\Delta, \;\; u \notin C_n. \tag{14}$$

Then if the update U_α uses the p-value approximation given in Equation (11),

$$\mathbb{P}_n\big(U_\alpha(B_n, \mathcal{G}_n) = C_n\big) \to 1 \text{ as } n \to \infty.$$

To prove the consistency of SCS, we show that condition 14, when it involves the community sequence, is guaranteed by a concise condition on the model parameters. Let $\tilde{\pi}_{i,n} := \sum_{v \in C_{i,n}} \psi_n(v)$, and let $\tilde{\boldsymbol{\pi}}_n$ be the vector of $\tilde{\pi}_{i,n}$'s. The consistency theorem requires the following additional assumption, an analog to which can be found in Zhao et al. (2012) for consistency of modularity under the degree-corrected SBM:

Assumption 7 *$\tilde{\boldsymbol{\pi}}_n \equiv \tilde{\boldsymbol{\pi}}$ does not depend on n.*

Assumption 7 is made mainly for clarity. Without it, the condition in (15) of Theorem 5 (below) must hold for sufficiently large n, something which is inconsequential to the proof. Define $\mathbf{H} := \mathbf{P} \cdot \mathbf{M}$, the entry-wise product, which is symmetric because $\mathbf{P}$ and $\mathbf{M}$ are each symmetric. Note that when ϕ and ψ are proportional to 1-vectors, $\mathbb{E}(W_{uv}) = \mathbf{H}_{c(u)c(v)}$ for all $u, v \in N$. Thus, the interpretation of $\mathbf{H}$ is as the baseline inter/intra-community weight expectations after integrating out edge presence. Defining $\tilde{\boldsymbol{\Pi}} := \tilde{\boldsymbol{\pi}} \tilde{\boldsymbol{\pi}}^t$, we state the consistency theorem:

Theorem 5 *Fix $K > 0$. Let $\{\mathcal{G}_n\}_{n>1}$ be a sequence of networks generated by a K-community WSBM satisfying Assumptions 5-7. Suppose that the matrix*

$$\mathcal{M} := \mathbf{H} - \frac{\mathbf{H}\tilde{\boldsymbol{\Pi}}\mathbf{H}}{\tilde{\boldsymbol{\pi}}^t \mathbf{H} \tilde{\boldsymbol{\pi}}} \tag{15}$$

has positive diagonal entries and negative off-diagonal entries. If $\lambda_n / \log n \to \infty$, SCS is consistent for $\{\mathcal{G}_n\}_{n>1}$.

The proof of Theorem 5 is given in Appendix C. Some understanding of condition 15 can be had by considering when $K = 2$, when it reduces to the requirement $\mathbf{H}_{11}\mathbf{H}_{22} > \mathbf{H}_{12}^2$. More generally, and broadly speaking, the matrix $\mathcal{M}$ reveals whether or not appropriate signal exists in the model, with respect to the continuous configuration null. Notice that this signal need not be present in both $\mathbf{P}$ and $\mathbf{M}$. For instance, the condition can be satisfied

even if $\mathbf{H}$ is a scalar multiple of $\mathbf{M}$, that is, if $\mathbf{P}$ is proportional to the $\mathbf{1}$-matrix. This entails that SCS is consistent even when the edge structure of $\mathcal{G}_n$ is Erdős-Renyi, as long as the edge weight signal (encoded in $\mathbf{M}$) is properly assortative. Of course, the opposite also holds, namely that SCS is consistent even when assortative community signal is only present in $\mathbf{P}$. In fact, one matrix may even be *disassortative* (some or all off-diagonal entries larger than diagonals) as long as the other is sufficiently assortative.

4.2.3 Connection to weighted modularity and related work

The conditions of Theorem 4 and Theorem 5 have a deep relationship to the modularity measure, discussed in Section 2. Explicitly, let the *weighted* modularity (WM) be the modularity metric with degrees replaced by strengths, as introduced in (Newman, 2004a). For fixed $n > 1$, let $\mathbf{c}$ be any partition of N. Define $K := \max\{\mathbf{c}\}$ and $C_u := \{v : c(v) = c(u)\}$. Then the (random) WM of $\mathbf{c}$ on $\mathcal{G}_n$ can be written

$$\begin{aligned} Q^w(\mathbf{c}, \mathcal{G}_n) &:= \frac{1}{S_{n,T}} \sum_{uv \in N} \{W_{uv} - r_{uv}(\mathbf{S}_n)\}\, \mathbb{1}\{c(u) = c(v)\} \\ &= \frac{1}{S_{n,T}} \sum_{i=1}^{K} \sum_{c(u)=c(v)} W_{uv} - r_{uv}(\mathbf{S}_n) = \frac{1}{S_{n,T}} \sum_{u \in N} \sum_{v \in C_u} W_{uv} - r_{uv}(\mathbf{S}_n) \\ &= \frac{1}{S_{n,T}} \sum_{u \in N} S(u, C_u, \mathcal{G}_n) - \mu_n(u, C_u | \mathbf{S}_n) = \frac{1}{S_{n,T}} \sum_{u \in N} A(u, C_u, \mathcal{G}_n) \end{aligned}$$

Thus, the contribution of u to WM with its assignment C_u is precisely the random association from u to C_u. Writing the population WM as $\bar{q}_n^w(\mathcal{C}) := n^{-1} \sum_u \tilde{a}_n(u, C_u)$, it is easily shown that condition (15) implies q_n^w is maximized by $\mathcal{C}_n$, the true community partition.

The consistency analysis of the (binary) modularity metric under the degree-corrected SBM, provided by Zhao et al. (2012), similarly hinges on maximization of population modularity. It is unsurprising, then, that the parameter condition for their result can be (analogously) expressed as a fixed $K \times K$ matrix having positive diagonals and negative off-diagonals. In fact, if the WSBM parameter $\mathbf{M}$ is proportional to a matrix of 1s, and the parameter ψ is a scalar multiple of ϕ, condition 15 in Theorem 5 is equivalent to the parameter assumptions on modularity consistency in Zhao et al. (2012). Furthermore, their analysis also requires that $\lambda_n / \log n \to \infty$. However, both the definition of consistency and proof approach for the theorems in this section are entirely novel.

5. The Continuous Configuration Model Extraction method

In the previous section, we established an asymptotic result showing that ground-truth communities are, with high probability, fixed points of the SCS algorithm. This result demonstrates the in-principle sensibility of the algorithm. In practice, we must rely on local, heuristic algorithms for initialization and termination, as with other exploratory methods. For instance, k-means is often used to initialize the EM algorithm, and modularity can be locally maximized through agglomerative pairing (Clauset et al., 2004). We incorporate SCS in a general community detection method for weighted networks entitled Continuous Configuration Model Extraction (CCME), written in loose detail as follows:

The CCME Community Detection Method for Weighted Networks

1. Given an observed weighted network $\mathcal{G}$, obtain initial node sets $\mathcal{B}_1 \subseteq 2^N$.
2. Apply SCS to each node set in $\mathcal{B}_0$, resulting in fixed points $\mathcal{C}$.
3. Remove sets from $\mathcal{C}$ that are empty or redundant.

These steps are described in more detail below. Importantly, the method has no connection to any graph-partition criteria. It proceeds solely by the SCS algorithm, which assesses communities independently. This allows CCME to adaptively return communities that share nodes ("overlap"), and, through the multiple testing procedure, ignore nodes not significantly connected to any stable communities ("background").

5.1 Step 1: Initialization

Just as mixture-models can be initialized with heuristic methods like k-means, it is possible to initialize CCME with partition-based community detection method. However, we have observed this approach to perform somewhat poorly in practice. Instead, we initialize with a novel search procedure based on the continuous configuration model. For fixed nodes $u, v \in N$, we define

$$z_u(v) := \max\left\{ \frac{W_{uv} - f_{uv}(\mathbf{s}, \mathbf{d})}{\sqrt{\theta} f_{uv}(\mathbf{s}, \mathbf{d})},\ 0 \right\}$$

The measure $z_u(v)$ acts like a truncated z-statistic, quantifying the extremity of the weight W_{uv}. The initial node set corresponding to u is formed by sampling $d(u)$ nodes with replacement from N with probability proportional to $z_u(v)$. The intuition behind this procedure is that if u is part of a highly-connected node set C, then $z_u(v)$ for nodes $v \in C$ will be larger (on average) than for other nodes.

5.2 Step 2: Application of SCS

Recall that, given an initial set B_1, SCS proceeds (via the update U_α) along a sequence of sets $B_2, B_3, \ldots, B_t, \ldots$ until $B_t = B_{t'}$ for some $t' < t$. Since the number of possible node subsets is finite, SCS is guaranteed to terminate in one of two states:

1. A stable community C, satisfying $U_\alpha(C, \mathcal{G}) = C$.
2. A stable sequence of communities $C_1, \ldots, C_J$ satisfying

$$U_\alpha(C_1, \mathcal{G}) = U_\alpha(C_2, \mathcal{G}) = \ldots = U_\alpha(C_J, \mathcal{G}) = U_\alpha(C_1, \mathcal{G}).$$

In practice, on empirical and simulated data, case 1 is the majority. Furthermore, empirically speaking, stable sequences (case 2) usually consist only of two communities that overlap. Though case 2 does not result in a clear-cut community, a stable sequence may still be of practical interest if the constituent sets have high overlap. In Appendix D.2, we give a routine to either re-initialize or terminate SCS when it encounters a stable sequence.

5.3 Step 3: Filtering of $\mathcal{C}$

The CCME community detection method returns a final collection of communities $\mathcal{C}$, containing the results of the SCS algorithm for each initial set in $\mathcal{B}_0$. By default, we remove any empty or duplicate sets from $\mathcal{C}$. In some applications, pairs of sets in $\mathcal{C}$ will have high Jaccard similarity. In Appendix D.3, we detail a method of pruning these near-duplicates from $\mathcal{C}$. Additionally, in Appendix D.3, we describe routines to suppress the application of SCS to initial sets that are "weakly" intra-connected, or with high overlap to already-extracted communities. These routines greatly reduce the runtime of CCME, and, on some simulated networks, improve accuracy.

5.4 Remarks

1. The parameter α, used in the set update operation U_α, must be specified by the user of CCME. Having a natural interpretation as the false-discovery rate for each update, α was set to 0.05 for all simulations and real data analyses introduced in this paper. We found that $\alpha = 0.05$ was a universally effective default setting, and that CCME's results change negligibly for other values of α within a reasonable window.

2. Multiple testing corrections computed within CCME are valid only for the input network. If other edge-weighted networks with the same node set are available, say, from an alternate data source or different set of node covariates, then it is necessary to apply a multiple-testing correction across communities discovered by the separate runs of CCME. The community-wise z-statistic introduced in Appendix D.3 will be useful to this end.

3. CCME can be extended to directed networks, as described in Appendix E.

6. Simulations

This section contains a performance analysis of CCME and existing methods on a benchmarking simulation framework. Simulated networks were generated from the Weighted Stochastic Block Model (see Section 4.2.1), with slight modifications to include overlapping communities and background nodes, when necessary. The performance measures, competing methods, simulation settings, and results are described below.

6.1 Performance measures and competing methods

We used three community detection method performance metrics:

1. **Overlapping Normalized Mutual Information (oNMI):** Introduced by Lancichinetti et al. (2009), oNMI is an information-based measure between 0 and 1 that approaches 1 as two covers of the same node set become similar and equals 1 when they are the same. From a method's results, we calculate oNMI with respect to the true communities *only* for the nodes the method placed into communities.

2. **Community nodes in background (%C.I.B.):** The percentage of true community nodes incorrectly assigned to background.

3. **Background nodes in communities (%B.I.C.):** The percentage of true background nodes (if present) incorrectly placed into communities.

In addition to CCME, three other weighted-network methods capable of identifying overlapping nodes were applied to our simulation ensemble. One of these was OSLOM (Lancichinetti et al., 2011), described in Section 1. Another was SLPAw, a weighted-network version of an overlapping label propagation algorithm (Xie et al., 2011). Finally, we applied the weighted Stochastic Block Model fitting procedure introduced by Peixoto (2017), which we will call "WeightedGT" after it's implementation's package ("graph-tool"). Also included were four commonly used score-based methods implemented in the `R` package `igraph` (Csárdi and Nepusz, 2006): Fast-Greedy, which performs approximate modularity optimization via a hierarchical agglomeration (Clauset et al., 2004); Louvain, an approximate modularity optimizer that proceeds through node membership swaps (Blondel et al., 2008); Walktrap, an agglomerative algorithm that locally maximizes a score based on random walk theory (Pons and Latapy, 2006); Infomap, an information-flow mapping algorithm that uses random walk transition probabilities (Rosvall and Bergstrom, 2008).

Remark. Being extraction methods, only CCME and OSLOM naturally specify background nodes, via testing. As such, we will often make direct comparative comments between OSLOM and CCME with respect to background node handling. For other methods, we take as background any nodes in singleton communities. However, these methods almost never returned singleton communities, even when the simulation had weak or non-existent signal.

6.2 Simulation settings and results

We now give an overview of the simulation procedure for the benchmarking framework. A complete account is given in Appendix F. We first describe "default" parameter settings of the WSBM; in the simulation settings below, individual parameters are toggled around their default values, to reveal the dependence of the methods to those parameters. At each unique parameter setting, 20 random networks were simulated. The points in each plot from Figure 1 show the average performance measure of the methods over the 20 repetitions.

The default WSBM setting has the number of nodes at $n = 5,000$. The community memberships were set by obtaining community sizes from a power law, then assigning nodes uniformly at random. This process produced approximately 3 to 7 communities per network. Many of these simulation features (as well as those described in what follows) mirror those used in existing frameworks (e.g. Lancichinetti et al., 2011); full details are provided in Appendix F. Recall the parameters $\mathbf{P}$ and $\mathbf{M}$, which induce baseline intra- and inter-community edge and weight signal. In the default setting, these matrices have off-diagonals equal to 1 and diagonals equal to constants $s_e = 3$ and $s_w = 3$ (respectively). In some simulation settings, overlapping and background nodes are added (as described later in this section), but the default setting includes neither overlap nor background.

Common parameter settings. For all simulated networks (regardless of the setting), the node-wise edge parameters ϕ were drawn from a power law to induce degree heterogeneity. The parameter ϕ is scaled so that the expected average degree of each network was equal to $\sqrt{n}$, which induces sparsity in the network. The parameter ψ is set by the for-

mula $\psi = \phi^{1.5}$ to ensure a non-trivial relationship between expected degrees and expected strengths (see Appendix F).

6.2.1 Networks with varying signal levels

The first simulation setting tested the methods' dependence on s_e and s_w. These values were moved along an even grid on the range $[1, 3]$. Plots A-1 and B-1 in Figure 1 show the performance measure results when s_w is fixed at 3, plots A-2 and B-2 show results when $s_e = 3$, and plots A-3 and B-3 show results when s_e and s_w are moved along $[1, 3]$ together. Many methods had large oNMI scores in this simulation setting. We transformed the oNMI scores using the function

$$\text{t-oNMI}_a(x) := (\tfrac{1}{1-x+a} - \tfrac{1}{1+a})/(\tfrac{1}{a} - \tfrac{1}{1+a})$$

with $a = 0.05$. This is a monotonic, one-to-one transformation from $[0, 1]$ to itself, which stretches the region close to 1, allowing a clearer comparison between the methods' performances. CCME consistently out-performed all competing methods, especially when either the edge or weight signal was completely absent. (The t-oNMI transformation masks the trends in lower-performing methods, so we show these plots with un-transformed oNMI in Appendix F.3.)

The plots in row B show that when either s_e or s_w were near 1, OSLOM and CCME assigned many background nodes. This is consistent with these methods' unique abilities to leave nodes unassigned when they are not significantly connected to communities. That said, %C.I.B. can be seen as a measure of sensitivity, since ideally no nodes would be assigned to background when any signal is present. In this regard, CCME outperformed OSLOM across the range of model parameters.

6.2.2 Networks with overlapping communities

The second setting involved networks with overlapping nodes. To add overlapping nodes to the default network, two parameters were introduced: o_n, the number of overlapping nodes, and o_m, the number of memberships for each overlapping node. The particular overlapping nodes and community memberships were chosen uniformly-at-random. Plots C-1 and C-2 show performance results from the setting with o_n moving away from 0 and $o_m = 2$. Plot C-3 shows results from the setting with $o_n = 500$ and $o_m \in \{1, \ldots, 4\}$. We find that CCME consistently outperforms all methods in terms of accuracy (oNMI), and outperforms OSLOM in terms of sensitivity (%C.I.B.).

6.2.3 Networks with overlapping communities and background nodes

The final simulation setting involved networks with both overlap and background nodes. The number of background nodes was fixed at 1,000, and number of community nodes varied from $n = 500$ to $n = 5,000$. For each network, $o_n = n/4$ nodes were randomly chosen to overlap $o_m = 2$ communities (also chosen at random). Background nodes were created by first simulating the n-node community sub-network, and then generating the 1,000-node background sub-network according to the continuous configuration model, using empirical degrees and strengths from the community sub-network. The complete details of this procedure are given in Appendix F.

The results of this simulation setting are shown in row D from Figure 1. From plot D-1, we see that OSLOM and CCME had the highest oNMI scores, favoring OSLOM when the number of community nodes decreased. Because this simulation setting involved background nodes, the %B.I.C. metric is relevant, and can be taken as a measure of specificity: ideally, nodes from the background sub-network should be excluded from communities. From plot D-2, we see that methods incapable of assigning background had %B.I.C. equal to 1. We found that CCME correctly ignored background nodes as the network size increased, whereas OSLOM became increasingly *anti*-conservative for larger networks. Furthermore, CCME again had lower %C.I.B. than OSLOM.

7. Applications

In this section, we discuss applications of CCME, OSLOM, and SLPAw (the methods capable of returning overlapping communities) to two real data sets.

7.1 U.S. airport network data

The first application involves commercial airline flight data, obtained from the Bureau of Transportation Statistics (www.transtats.bts.gov). For each month from January to July of 2015, we created a weighted network with U.S. airports as nodes, edges connecting airports that exchanged flights, and edges weighted by aggregate passenger count. We also constructed a year-aggregated network, formed simply by taking the union of the month-wise edge sets, and adding the month-wise weights. In Figure 2, we display the methods' results when applied to the June and year-aggregated data sets from 2015. Each discovered community (within-method) has a unique color and shape. Each overlapping node is plotted multiple times, one for each community in which it was placed. To allow for a clearer visualization of communities, background nodes are not shown.

Overall, the CCME results, in contrast to results from OSLOM and SLPAw, suggest that many airports in the U.S. airport system may not participate in meaningful community behavior. The fact that CCME performs multiple testing against an explicit null model gives this result some validity. Furthermore, airports in significant communities tend to be located near large hubs or in geographically isolated areas. We also see that, with the monthly data, OSLOM and CCME tended to find communities consistent with geography, whereas SLPAw placed most of the network into one community. With the year-aggregated data, OSLOM also agglomerated most airports, whereas CCME continued to respect the geography. Since the aggregated data is much more edge-dense, this suggests the performance of OSLOM and SLPA may suffer on weighted graphs with high or homogeneous edge-density, whereas CCME is able to detect proper community structure from the weights alone. This aligns with the simulation results described in Section 6.2.1.

7.2 ENRON email network

An email corpus from the company ENRON was made available in 2009. The unweighted network formed by linking communicating email addresses is well-studied; see www.cs.cmu.edu/~./enron for references and Leskovec et al. (2010) for the data. For the purposes of this paper, we derived a *weighted* network from the original corpus, using

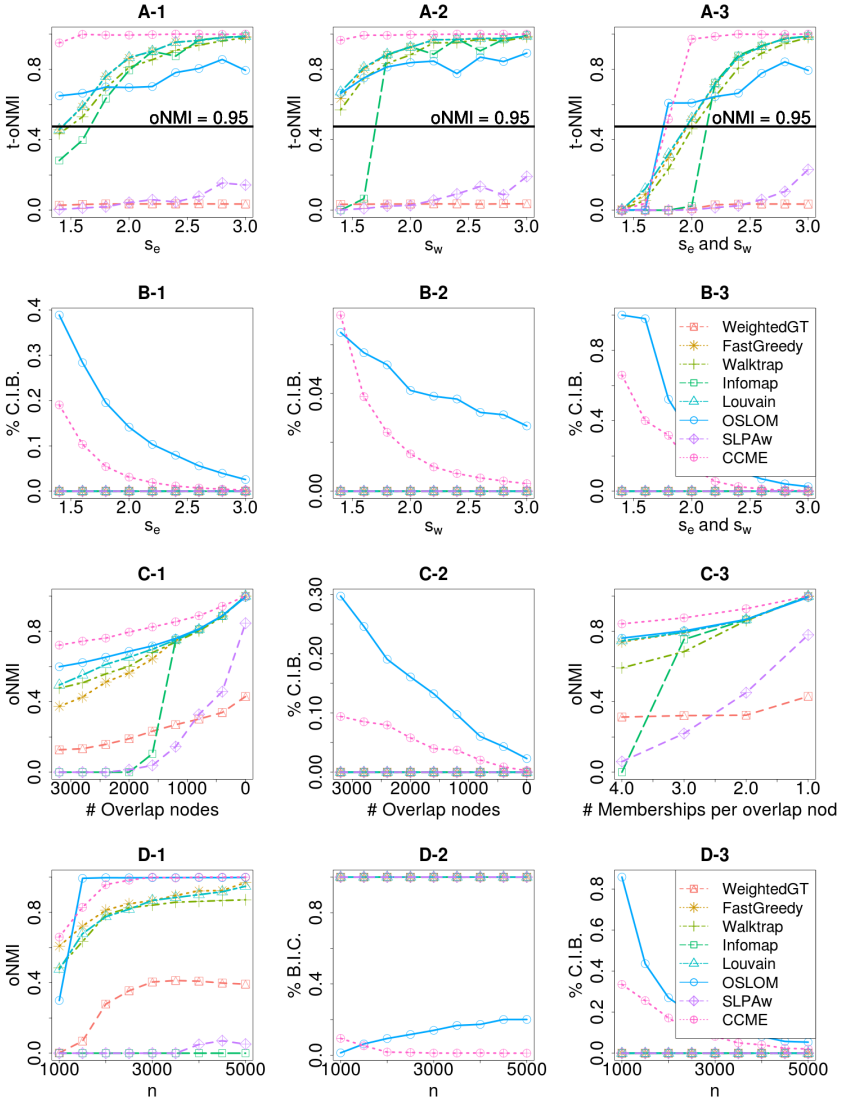

Figure 1: Simulation results described in Sections 6.2.1-6.2.3. Legends refer to all plots.

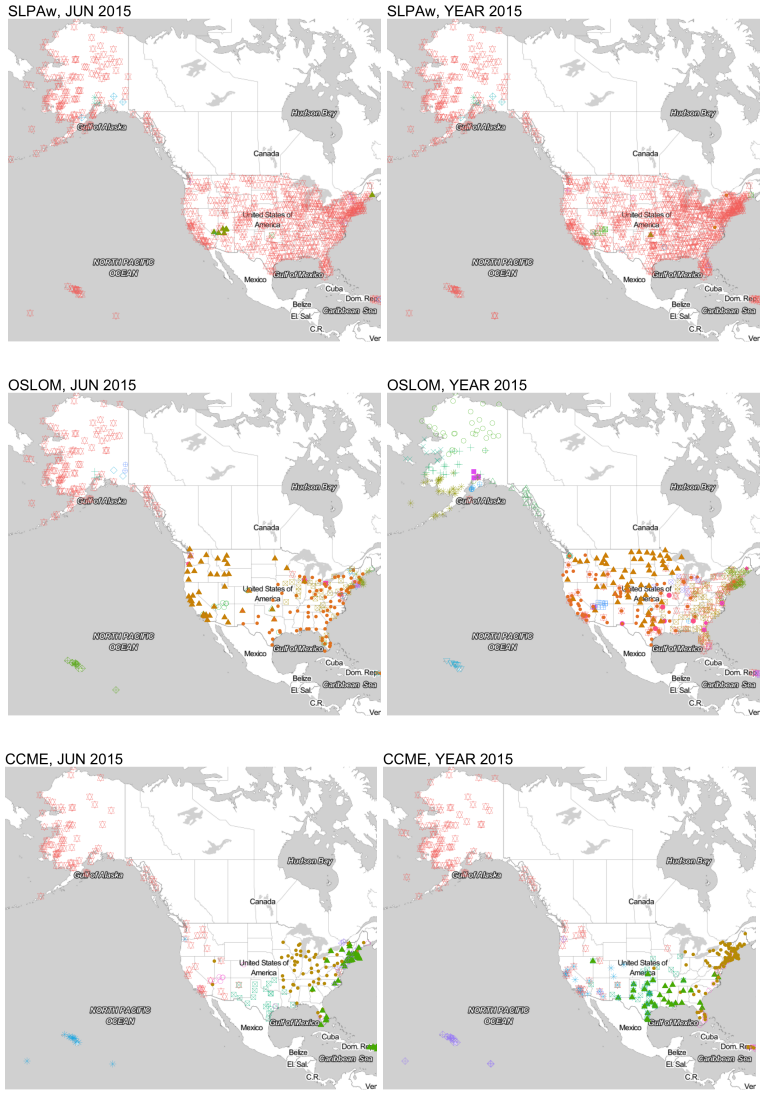

Figure 2: SLPAw, OSLOM, and CCME results from June 2015 and 2015-year-aggregated U.S. airport networks. Maps created with `ggmap` (Kahle and Wickham, 2013).

message count between addresses as edge weights. Though the corpus was formed from email folders of 150 ENRON executives, we made the network from addresses found in *any* message. This full network has 80,702 unique addresses, 47,481 of which were external to the company. Thus, the network likely has many spam or irrelevant senders, i.e. "true" background nodes. We applied CCME, OSLOM, and SLPAw to the network to see which methods best focused on company-specific areas of the data.

Tables 1 and 2 give basic summaries of the results, which show noticeable differences between the outputs of the methods. CCME placed far fewer into nodes into communities, but detected larger communities with more overlapping nodes. Notably, CCME had the highest percentage of ENRON addresses among nodes it placed into communities (see Table 3). These results suggest that CCME was more sensitive to critical relationships in the network.

Table 1: Metrics from methods' results on ENRON network: number of communities, min. comm. size, median comm. size, max. comm. size, # nodes in communities.

	Num.Comms	Min.size	Med.size	Max.size	Num.Nodes

8. Discussion

In this paper, we introduced the continuous configuration model, which is, to the best of our knowledge, the first null model for community detection on weighted networks. The explicit generative form of the null model allowed the specification of CCME, a community

extraction method based on sequential significance testing. We showed that a standardized statistic for the tests is asymptotically normal, a result which enables an analytic approximation to p-values used in the method. We also proved asymptotic consistency under a weighted stochastic block model for the core algorithm of the method.

On simulated networks the proposed method CCME is competitive with commonly-used community detection methods. CCME was the dominant method for simulated networks with large numbers of overlapping nodes. Furthermore, on networks with background nodes, CCME was the only method to correctly label true background nodes while maintaining high detection power and accuracy for nodes belonging to communities. On real data, CCME gave results that were both interpretable and revelatory with respect to the natural system under study.

We expect that the continuous configuration model will have applications outside the setting of this paper, just as the binary configuration model has been studied in diverse contexts. One may investigate the distributional properties of many different graph-based statistics under the model, as a means of assessing statistical significance in practice. For instance, an appropriate theoretical analysis could yield an approach to the assessment of statistical significance of weighted modularity. The proof approach used for Theorem 2 may serve as a basis for this endeavor. Another benefit of an explicit null for weighted networks is the potential for simulation. Using the continuous configuration model, and parts of the framework presented in this paper, one can generate weighted networks having true background nodes with arbitrary expected degree and strength distributions.

8.1 Acknowledgements and Remarks

The authors wish to thank three anonymous referees for their thoughtful suggestions, and Dr. Peter J. Mucha for helpful discussions. The `R` code for the CCME method is available in the github repository 'jpalowitch/CCME'. The code for reproducing the analyses in Sections 6 and 7 is available at the github repository 'jpalowitch/CCME_analyses'. The work of JP and ABN was supported in part by NIH grant MH101819-01. The work of SB and ABN was supported in part by NSF grant DMS-1310002. SB was also supported in part by NSF grants DMS-1105581, DMS-161307, and DMS-160683, SES grant 1357622, and ARO grant W911NF-17-1-0010. ABN was also supported in part by NSF DMS-1613072 and NIH HG009125-01.

Appendix A. Proof of Proposition 1

Equation 8 follows immediately from the observation in equation 3 and the definition of $r_{uv}(\mathbf{s})$. Next, note that

$$\mathbb{E}\left(W_{uv}|A_{uv}\right) = f_{uv}(\mathbf{d},\mathbf{s})A_{uv}, \text{ and } \mathrm{Var}(W_{uv}|A_{uv}) = \kappa f_{uv}(\mathbf{d},\mathbf{s})^2 A_{uv}.$$

Thus, using the law of total variance,

$$\begin{aligned}\mathrm{Var}(W_{uv}) &= f_{uv}(\mathbf{d},\mathbf{s})^2\mathrm{Var}(A_{uv}) + \kappa f_{uv}(\mathbf{d},\mathbf{s})^2\mathbb{E}(A_{uv}) \\ &= f_{uv}(\mathbf{d},\mathbf{s})^2\tilde{r}_{uv}(\mathbf{d})(1-\tilde{r}_{uv}(\mathbf{d})) + \kappa f_{uv}(\mathbf{d},\mathbf{s})^2\tilde{r}_{uv}(\mathbf{d}) \\ &= r_{uv}(\mathbf{s})f_{uv}(\mathbf{d},\mathbf{s})\left(1-\tilde{r}_{uv}(\mathbf{d}) + \kappa\right)\end{aligned}$$

Summing over $v \in B$ gives equation 9. ■

Appendix B. Proof of Theorem 2 and supporting lemmas.

Here we give the proof of Theorem 2 in Section 4.1. We start with supporting lemmas. Recall the definition of the average degree parameter λ_n, the normalized r^{th}-moment $L_{n,r}$, and other associated definitions from Section 4.1. For the purposes of the results below, we define the following generalization of $L_{n,r}$, given a node set $B_n \subseteq N$ with $b_n := |B_n|$:

$$L_{n,r}(B_n) := b_n^{-1} \sum_{u \in B_n} \{d_n(u)/\lambda_n\}^r$$

Note that $L_{n,r}(N) = L_{n,r}$. Recall that in the setting of Theorem 2, the node set B_n is chosen uniformly from the node set N. The first result involves a *deterministic* sequence $\{B_n\}_{n \geqslant 1}$:

Lemma 6 *For each $n > 1$, let $\mathcal{G}_n$ be generated by the continuous configuration model with parameters $\theta_n = (\mathbf{d}_n, \mathbf{s}_n, \kappa_n)$ and common weight distribution F. Fix a node sequence $\{u_n\}_{n>1}$ with $u_n \in N$ and a positive integer sequence $\{b_n\}_{n>1}$ with $b_n \leqslant n$. Suppose the parameter sequence $\{d_n(u_n)\}_{n \geqslant 1}$ satisfies*

$$\frac{d_n(u_n) b_n}{n} \to \infty \text{ as } n \to \infty$$

Fix $\varepsilon > 0$ as in Assumption 2, and choose $\delta \in (0,1)$ such that $2\beta\delta < \varepsilon$. Fix a sequence of sets $\{B_n\}_{n>1}$ with $|B_n| = b_n$ for all n, and suppose that for $r = 2\beta + 1$ and $r = \beta(2+\delta)+1$, the sequence $\{L_{n,r}(B_n)\}_{n>1}$ is bounded away from zero and infinity. Then

$$\frac{S(u_n, B_n, \mathcal{G}_n) - \mu_n(u_n, B_n|\theta_n)}{\sigma_n(u_n, B_n|\theta_n)} \Rightarrow \mathcal{N}(0,1) \quad as \quad n \to \infty$$

Proof In what follows, the functions r_{uv} and $\tilde{r}_{uv}$ from Section 1.2 will be used extensively. Note that for any nodes u, v, $\mathbb{E}W_{uv} = r_{uv}(\mathbf{s})$. Thus by the classical Lyapunov central limit theorem it suffices to show that

$$\frac{\sum_{v \in B_n} \mathbb{E}|W_{u_n,v} - r_{u_n v}(\mathbf{s}_n)|^{2+\delta}}{\left(\sqrt{\sum_{v \in B_n} \mathbb{E}\left\{(W_{u_n,v} - r_{u_n v}(\mathbf{s}_n))^2\right\}}\right)^{2+\delta}} \to 0 \tag{16}$$

as n tends to infinity. The following derivations hold for any fixed $n > 1$, so we suppress dependence on n from u_n, and B_n, and similar expressions. For the numerator of (16), we have

$$\begin{aligned}
\mathbb{E}|W_{u,v} - r_{uv}(\mathbf{s})|^{2+\delta} &= \left(\frac{r_{uv}(\mathbf{s})}{\tilde{r}_{uv}(\mathbf{d})}\right)^{2+\delta} \mathbb{E}\left(|\xi_{uv} A_{uv} - \tilde{r}_{uv}(\mathbf{d})|^{2+\delta}\right) \\
&= f_{uv}(\mathbf{d}, \mathbf{s})^{2+\delta} \cdot \mathbb{E}\left(|\xi_{uv} A_{uv} - \tilde{r}_{uv}(\mathbf{d})|^{2+\delta}\right), \qquad (17)
\end{aligned}$$

by definition of the model in Section 2.1. Moreover, by the law of total variance,

$$\begin{aligned}
\mathbb{E}(|\xi_{uv} A_{uv} - \tilde{r}_{uv}(\mathbf{d})|^{2+\delta}) &= (1 - \tilde{r}_{uv}(\mathbf{d}))\tilde{r}_{uv}(\mathbf{d})^{2+\delta} + \tilde{r}_{uv}(\mathbf{d})\mathbb{E}|\xi_{uv} - \tilde{r}_{uv}(\mathbf{d})|^{2+\delta} \\
&= \left\{(1 - \tilde{r}_{uv}(\mathbf{d}))\tilde{r}_{uv}(\mathbf{d})^{1+\delta} + \mathbb{E}|\xi_{uv} - \tilde{r}_{uv}(\mathbf{d})|^{2+\delta}\right\} \cdot \tilde{r}_{uv}(\mathbf{d}) \\
&\leqslant C \cdot \tilde{r}_{uv}(\mathbf{d}) \qquad (18)
\end{aligned}$$

for some positive constant C, by Assumption 4. Next, we note that by Assumption 1, there exist positive constants $a < c$ such that for all $v \in N$,

$$a \cdot d_n(v)^\beta \leqslant \frac{s_n(v)}{d_n(v)} \leqslant c \cdot d_n(v)^\beta,$$

for n sufficiently large. Thus, if $r_{uv}(\mathbf{d}) \leqslant 1$, $\tilde{r}_{uv}(\mathbf{d}) = r_{uv}(\mathbf{d})$, and

$$f_{uv}(\mathbf{d}, \mathbf{s}) = \frac{r_{uv}(\mathbf{s})}{\tilde{r}_{uv}(\mathbf{d})} = \left(\frac{d_T}{s_T}\right) \frac{s(u)s(v)}{d(u)d(v)} \leqslant c \cdot \left(\frac{d_T}{s_T}\right) \{d(u)d(v)\}^\beta. \tag{19}$$

If $r_{uv}(\mathbf{d}) > 1$, $\tilde{r}_{uv}(\mathbf{d}) = 1$, and by Assumption 3 there exists c' such that

$$\begin{aligned}
f_{uv}(\mathbf{d}, \mathbf{s}) = \frac{s(u)s(v)}{s_T} &\leqslant c \cdot \left(\frac{d(u)d(v)}{s_T}\right) \{d(u)d(v)\}^\beta \\
&= c \cdot \left(\frac{d_T}{s_T}\right) r_{uv}(\mathbf{d}) \{d(u)d(v)\}^\beta \leqslant c' \cdot \left(\frac{d_T}{s_T}\right) \{d(u)d(v)\}^\beta. \qquad (20)
\end{aligned}$$

Therefore, combining (18)-(20) with (17), there exists $C > 0$ such that

$$\begin{aligned}
\mathbb{E}|W_{u,v} - r_{uv}(\mathbf{s})|^{2+\delta} &\leqslant C \left(\frac{d_T}{s_T}\right)^{2+\delta} \cdot \{d(u)d(v)\}^{\beta(2+\delta)} \tilde{r}_{uv}(\mathbf{d}) \\
&= C \left(\frac{d_T}{s_T}\right)^{2+\delta} \cdot \{d(u)d(v)\}^{\beta(2+\delta)} \frac{d(u)d(v)}{d_T} \\
&\leqslant C \cdot d_T^{1+\delta} s_T^{-(2+\delta)} \cdot \{d(u)d(v)\}^{\beta(2+\delta)+1} \qquad (21)
\end{aligned}$$

A similar analysis of the summands in the denominator of (16) gives

$$\mathbb{E}\left\{(W_{u,v} - r_{uv}(\mathbf{s}))^2\right\} \geqslant C' \cdot d_T s_T^{-2} \cdot \{d(u)d(v)\}^{2\beta+1} \tag{22}$$

for appropriately chosen C'. Let $b = |B|$. Combining (21) and (22), with some algebra, we find that the left side of (16) is (up to a constant) less than

$$\begin{aligned}
&\left(\frac{d(u)}{d_T}\right)^{-\delta/2} \cdot \frac{\sum_{v \in B} d(v)^{\beta(2+\delta)+1}}{\left(\sum_{v \in B} d(v)^{2\beta+1}\right)^{1+\delta/2}} \\
&= \left(\frac{d(u)}{d_T} b\lambda\right)^{-\delta/2} \cdot \frac{b^{-1} \sum_{v \in B} (d(u)/\lambda)^{\beta(2+\delta)+1}}{\left\{b^{-1} \sum_{v \in B} (d(u)/\lambda)^{2\beta+1}\right\}^{1+\delta/2}} \\
&= \left(\frac{d(u)}{d_T} b\lambda\right)^{-\delta/2} \cdot \frac{L_{n,\beta(2+\delta)+1}(B)}{(L_{n,2\beta+1}(B))^{1+\delta/2}} = O\left\{\left(\frac{d(u)}{d_T} b\lambda\right)^{-\delta/2}\right\} \qquad (23)
\end{aligned}$$

where the final term follows from our assumptions on $L_{n,\beta(2+\delta)+1}(B_n)$ and $L_{n,2\beta+1}(B_n)$. By definition, $d_{n,T} = n\lambda_n$, so the final expression above is $O\left\{(d_n(u_n)b_n/n)^{-\delta/2}\right\} = o(1)$ by assumption. Thus (16) holds and the result follows. ■

We now proceed with the proof of Theorem 2. Proposition 6 yields the CLT for $S(u_n, B_n, \mathcal{G}_n)$ for a deterministic sequence of vertex sets $\{B_n\}_{n\geqslant 1}$ satisfying regularity properties. The remainder of the argument shows that if B_n is selected uniformly at random then, under the assumptions of Theorem 2, these regularity properties are satisfied with high probability. We begin with a few preliminary definitions and results.

Definition 7 *A sequence of random variables $\{X_n\}_{n\geqslant 1}$ is said to be* asymptotically uniformly integrable *if*

$$\lim_{M\to\infty} \limsup_{n\to\infty} \mathbb{E}\left\{|X_n|\mathbb{1}(|X_n| > M)\right\} = 0$$

Theorem 8 *Let $f : \mathbb{R}^k \mapsto \mathbb{R}^k$ be measurable and continuous at every point in a set C. Suppose $X_n \xrightarrow{w} X$ where X takes its values in an interval C. Then $\mathbb{E}f(X_n) \to \mathbb{E}f(X)$ if and only if the sequence of random variables $f(X_n)$ is asymptotically uniformly integrable.*

Proof See Asymptotic Statistics (Van der Vaart 2000), page 17. ■

We now give a technical lemma (needed for a subsequent result) which uses Theorem 8:

Lemma 9 *Let $X_1, X_2, \ldots$ be non-negative random variables and let $s, \varepsilon > 0$. If the sequences $\{\mathbb{E}X_n^s\}_{n\geqslant 1}$ and $\{\mathbb{E}X_n^{s+\varepsilon}\}_{n\geqslant 1}$ are bounded away from zero and infinity, then $\{\mathbb{E}X_n^r\}_{n\geqslant 1}$ is bounded away from zero and infinity for every $r \in (0, s+\varepsilon)$.*

Proof Suppose by way of contradiction that there exists $t \in (0, s+\varepsilon)$ such that $\liminf_n \mathbb{E}X_n^t = 0$. Then $\lim_k \mathbb{E}X_{n_k}^t = 0$ along a subsequence $\{n_k\}$. As the random variables $X_{n_k}^t$ are non-negative, $X_{n_k}^t \xrightarrow{d} 0$, and it follows from the continuous mapping theorem that $X_{n_k} \xrightarrow{w} 0$. As $M^{\varepsilon/s} X_n^s \mathbb{1}(X_n^s > M) \leqslant X_n^{s+\varepsilon}$, we find that

$$\lim_{M\to\infty} \limsup_{k\to\infty} \mathbb{E}\{X_{n_k}^s \mathbb{1}(X_{n_k}^s > M)\} \;\leqslant\; \lim_{M\to\infty} M^{-\varepsilon/s} \limsup_{k\to\infty} \mathbb{E}(X_{n_k}^{s+\varepsilon}) = 0$$

as $\mathbb{E}(X_n^{s+\varepsilon})$ is bounded by assumption. It then follows from Theorem 8 and the fact that $X_{n_k}^s \xrightarrow{w} 0$ that $\mathbb{E}X_{n_k}^s \to 0$ as $k \to \infty$, violating our assumption that $\mathbb{E}X_n^s$ is bounded away from zero. We conclude that $\mathbb{E}X_n^r$ is bounded away from zero for $r \in (0, s+\varepsilon)$. On the other hand, if $r \in (0, s+\varepsilon)$ then for each $n \geqslant 1$

$$\mathbb{E}\{X_n^r \mathbb{1}(X_n > 1)\} \;\leqslant\; \mathbb{E}\{X_n^{s+\varepsilon} \mathbb{1}(X_n > 1)\} \;\leqslant\; \sup_n \mathbb{E}\{X_n^{s+\varepsilon}\}$$

As the last term is finite by assumption and $\mathbb{E}\{X_n^r \mathbb{1}(X_n \leqslant 1)\}$ is at most one, it follows that $\mathbb{E}(X_n^r)$ is bounded. ■

Lemma 10 *Suppose a degree parameter sequence $\{\mathbf{d}_n\}_{n\geqslant 1}$ satisfies Assumption 2 from Section 4.1. For each n, let B_n be a randomly chosen subset of N of size b_n, where $b_n \to \infty$. Fix $\varepsilon > 0$ as in Assumption 2, and choose δ so that $2\beta\delta < \varepsilon$. Then for every $r \in (0,\ \beta(2+\delta)+1]$, there exists an interval $I_r = (a_r, b_r)$ with $0 < a_r < b_r < \infty$ such that $\mathbb{P}\{L_{n,r}(B_n) \in I_r\} \to 1$ as $n \to \infty$.*

Remark: Note that the function $L_{n,r}(\cdot)$ is non-random. The probability appearing in the conclusion of Lemma 10 depends only on the random choice of the vertex set B_n.

Proof Let D_n and D'_n be drawn uniformly-at-random from $\mathbf{d}_n$ without replacement, and fix $r \in (0,\ \beta(2+\delta)]$. A routine calculation gives

$$\mathrm{Var}\{L_{n,r}(B_n)\} = b_n^{-1}\lambda_n^{-2r}\left[\mathrm{Var}\{D_n^r\} + \{b_n - 1\}\mathrm{Cov}\{D_n^r, (D'_n)^r\}\right].$$

Note that $\mathbb{E}(D_n^r) = \lambda_n^r L_{n,r}$ and $\mathbb{E}(D_n^{2r}) = \lambda_n^{2r} L_{n,2r}$, so $\mathrm{Var}(D_n^r) = \lambda_n^{2r}(L_{n,2r} - L_{n,r})$. Furthermore, a simple calculation shows that $\mathrm{Cov}\{D_n^r, (D'_n)^r\}$ is negative for every r, and therefore $\mathrm{Var}\{L_{n,r}(B_n)\} \leqslant b_n^{-1}(L_{n,2r} - L_{n,r})$. Our choice of δ ensures that $2r < 4\beta + 2 + \varepsilon$, and it then follows from Lemma 9 and Assumption 2 that $L_{n,2r}$ and $L_{n,r}$ are bounded. Thus $\mathrm{Var}\{L_{n,r}(B_n)\} = O(b_n^{-1})$. Define $\Delta := \liminf_n\ L_{n,r}/2$, which is positive by Assumption 2, and let

$$I_r := \left(\liminf_{n\to\infty} L_{n,r} - \Delta,\ \limsup_{n\to\infty} L_{n,r} + \Delta\right) \tag{24}$$

As $\mathbb{E}\{L_{n,r}(B_n)\} = L_{n,r}$, an application of Chebyshev's inequality yields the bound

$$\begin{aligned}\mathbb{P}\{L_{n,r}(B_n) \notin I_r\} \;&\leqslant\; \mathbb{P}\{|L_{n,r}(B_n) - \mathbb{E}[L_{n,r}(B_n)]| > \Delta/2\} \\ &\leqslant\; \frac{4\mathrm{Var}\{L_{n,r}(B_n)\}}{\Delta^2} \;=\; O(b_n^{-1}).\end{aligned}$$

As b_n tends to infinity with n, the result follows. ■

B.1 Completing the proof of Theorem 2.

Let ε and δ be as in Proposition 6 and Lemma 10. Note that since $d_n(u_n) \leqslant n$ for all n, our assumption that $b_n d_n(u_n)/n \to \infty$ implies $|B_n| = b_n \to \infty$. Hence by lemma 10, we have that for both $r = \beta(2+\delta)+1$ and $r = 2\beta+1$, there exists a positive, finite interval I_r such that $\mathbb{P}\{L_{n,r}(B_n) \in I_r\} \to 1$ as $n \to \infty$. Thus given any subsequence $\{n_k\}_{k\geqslant 1}$ we can find a further subsequence $\{n'_k\}_{k\geqslant 1}$ such that $L_{n'_k,r}(B_{n'_k}) \in I_r$ almost surely as $k \to \infty$, which means this sequence is bounded away from zero and infinity in k. Now using Proposition 6, for almost every ω we have

$$\frac{S_{n'_k}(u_{n'_k}, B_{n'_k}, \mathcal{G}_{n'_k}) - \mu_{n'_k}(u_{n'_k}, B_{n'_k}|\theta_{n'_k})}{\sigma_{n'_k}(u_{n'_k}, B_{n'_k}|\theta_{n'_k})} \Rightarrow \mathcal{N}(0,1) \;\text{ as }\; k \to \infty$$

Applying the subsequence principle completes the proof. ■

Appendix C. Proof of Theorems 4-5 and supporting lemmas.

Throughout this section, notation and conventions from Section 4.2.1 will be used, though we suppress dependence on n for convenience. Further recall functions r and f from Section 1.2. The following additional notation will be used throughout this section:

- Define $\phi_T := \sum_{v\in N}\phi(v)$ and $\psi_T := \sum_{v\in N}\psi(v)$. For each $K \geqslant j \geqslant 1$, define $\tilde{\pi}_j^0 := \sum_{v\in\mathcal{C}_j}\phi(v)/\phi_T$ and $\tilde{\pi}_j := \sum_{v\in\mathcal{C}_j}\psi(v)/\psi_T$. Let $\tilde{\boldsymbol{\pi}}^0$ and $\tilde{\boldsymbol{\pi}}$ be the associated vectors.
- Let $\langle\cdot,\cdot\rangle$ denote the vector dot-product. For a general symmetric matrix $\mathbf{A}$, let $\mathbf{A}_{ij}$ be the i,j-th entry, and $\mathbf{A}_i$ the i-th column. Define $\mathbf{H} := \mathbf{P}\cdot\mathbf{M}$, the entry-wise product.
- Let $D(u), S(u)$ be the random degree, strength of node $u \in N$, let $\bar{d}(u)$, $\bar{s}(u)$ be the corresponding expectations, and let $\mathbf{D}, \mathbf{S}, \bar{\mathbf{d}}, \bar{\mathbf{s}}$ be the associated n-vectors. Define $\bar{s}_T := \sum_{v\in N}\bar{s}(v)$ and $\bar{d}_T := \sum_{v\in N}\bar{d}(v)$.

We now define a *empirical* population version of the variance estimate:

Definition 11 *Fix $n > 1$ and let A and W be the edge and weight matrices from $\mathcal{G}_n$, the n-th random weighted network from the sequence in the setting of Theorem 4. Let $\mathbf{x}, \mathbf{y}$ be arbitrary n-vectors with positive entries. For nodes $u, v \in N$, define*

$$V_{uv}(\mathbf{x},\mathbf{y}) := (W_{uv} - f_{uv}(\mathbf{x},\mathbf{y}))^2, \qquad v_{uv}(\mathbf{x},\mathbf{y}) := \mathbb{E}\left\{V_{uv}(\mathbf{x},\mathbf{y})\middle|A_{uv}=1\right\}.$$

Define the empirical *population variance estimator as follows:*

$$\kappa_*(\mathbf{x},\mathbf{y}) := \frac{\sum_{u,v:A_{uv}=1} v_{uv}(\mathbf{x},\mathbf{y})}{\sum_{u,v:A_{uv}=1} f_{uv}(\mathbf{x},\mathbf{y})^2}$$

The estimator $\kappa_*(\mathbf{x},\mathbf{y})$ is called "empirical" because it depends on the random edge set E. Despite this, it has a deterministic bound, a fact which is part of Lemma 12. Throughout the remaining results, denote $\Theta := (\mathbf{D}, \mathbf{S}, \hat{\kappa}(\mathbf{D},\mathbf{S}))$ and $\theta_* := (\bar{\mathbf{d}}, \bar{\mathbf{s}}, \kappa_*(\bar{\mathbf{d}}, \bar{\mathbf{s}}))$, where the estimator $\hat{\kappa}$ is the estimator from Section 2.2.

Recall the definition of the asymptotic order of the average degree $\lambda_n := n\rho_n$, from Section 4.2.2 in the main text. With this and the conventions above, Lemma 12 establishes basic facts about the WSBM:

Lemma 12 *Fix $n > 1$, and let $\mathcal{G}_n$ be a random network generated by a WSBM. For all nodes $u, v \in N$, under Assumptions 5 and 6,*

(1) $\bar{d}(u) = \lambda_n\phi(u)\langle\tilde{\boldsymbol{\pi}}^0, \mathbf{P}[c(u)]\rangle$ *and* $\bar{s}(u) = \lambda_n\psi(u)\langle\tilde{\boldsymbol{\pi}}, \mathbf{H}[c(u)]\rangle$

(2) $m_-^2 \leqslant \bar{d}(u)/\lambda_n \leqslant m_+^2$ *and* $m_-^3 \leqslant \bar{s}(u)/\lambda_n \leqslant m_+^3$

(3) $m_- \leqslant \bar{d}_T/n\lambda_n \leqslant m_+$ *and* $m_-^2 \leqslant \bar{s}_T/n\lambda_n \leqslant m_+^2$

(4) $m_-^4/m_+^1 \leqslant r_{uv}(\bar{\mathbf{d}})/\rho_n \leqslant m_+^4/m_-^1$ *and* $m_-^6/m_+^2 \leqslant r_{uv}(\bar{\mathbf{s}})/\rho_n \leqslant m_+^6/m_-^2$

(5) $m_-^2/m_+^2 \leqslant f_{uv}(\phi,\psi) \leqslant m_+^2/m_-^2$ *and* $m_-^{10}/m_+^3 \leqslant f_{uv}(\bar{\mathbf{d}},\bar{\mathbf{s}}) \leqslant m_+^{10}/m_-^3$

(6) $0 \leqslant V_{uv}(\bar{\mathbf{d}},\bar{\mathbf{s}}) \leqslant (\eta m_+^2/m_-^2 + m_+^{10}/m_-^3)^2$

(7) $0 \leqslant \kappa_*(\bar{\mathbf{d}},\bar{\mathbf{s}}) \leqslant g(\eta, m_-, m_+)$ *where g is a deterministic function.*

(8) There exist global constants $0 < m_1 < m_2 < \infty$ independent of n such that for any node set $B \subseteq N$,

$$m_1|B|\rho_n \;\leqslant\; \mu(u,B|\bar{\mathbf{s}}),\; \sigma(u,B|\theta_*)^2 \;\leqslant\; m_2|B|\rho_n$$

Proof For (1), we have

$$\begin{aligned}\bar{s}(u) := \mathbb{E}S(u) &= \sum_{j=1}^K\sum_{v\in\mathcal{C}_j}\mathbb{E}W_{uv} = \sum_{j=1}^K\sum_{v\in\mathcal{C}_j}\rho_n r_{uv}(\phi)\mathbf{H}_{c(u)j}\\ &= \rho_n\sum_{j=1}^K\phi(u)n\tilde{\pi}_j\mathbf{H}_{c(u)j} = \lambda_n\phi(u)\langle\tilde{\boldsymbol{\pi}}, \mathbf{H}_{c(u)}\rangle\end{aligned}$$

An identical calculation yields the expression for $\bar{d}(u)$. The inequalities in (2) then follow from Assumption 5. For (3), we again apply Assumption 5 to the equation

$$\bar{s}_T = \sum_{i=1}^K\sum_{v\in\mathcal{C}_i}\bar{s}(u) = \sum_{i=1}^K n\lambda_n\phi(u)\langle\tilde{\boldsymbol{\pi}}, \mathbf{H}_i\rangle = n\lambda_n\tilde{\boldsymbol{\pi}}^T\mathbf{H}\tilde{\boldsymbol{\pi}}$$

An identical equation yields the inequality for $\bar{d}_T$. (2) and (3) directly yield the inequalities in (4). Note that Assumption 5 implies $m_-^2 \leqslant nr_{uv}(\phi), nr_{uv}(\psi) \leqslant m_+^2$, which yields the first inequality of (5). The second inequality of (5) follows from (4). For part (6), note that by Assumption 6 and the first inequality in (5), we have

$$W_{uv} := f_{uv}(\phi,\psi)\xi_{uv} \leqslant (m_+^2/m_-^2)\eta \tag{25}$$

The second inequality in (5) then yields (6). For part (7), recalling the definition of $\kappa_*(\bar{\mathbf{d}},\bar{\mathbf{s}})$ from Definition 11, note first that, by (6), $0 \leqslant v_{uv}(\bar{\mathbf{d}},\bar{\mathbf{s}}) \leqslant (\eta m_+^2/m_-^2 + m_+^{10}/m_-^3)^2$. Thus, by the second inequality (5),

$$0 \leqslant \kappa_*(\bar{\mathbf{d}},\bar{\mathbf{s}}) := \frac{\sum_{u,v:A_{uv}=1} v_{uv}(\bar{\mathbf{d}},\bar{\mathbf{s}})}{\sum_{u,v:A_{uv}=1} f_{uv}(\bar{\mathbf{d}},\bar{\mathbf{s}})} \leqslant \frac{(\eta m_+^2/m_-^2 + m_+^{10}/m_-^3)^2}{m_-^{10}/m_+^3}$$

For part (8), recall that

$$\mu(u,B|\bar{\mathbf{s}}) := \sum_{v\in B} r_{uv}(\bar{\mathbf{s}})$$

The first inequality in (8) follows from applying the second inequality in (4). Similarly,

$$\sigma(u,B|\theta_*)^2 := \sum_{v\in B} r_{uv}(\bar{\mathbf{s}})f_{uv}(\bar{\mathbf{d}},\bar{\mathbf{s}})(1 - \tilde{r}_{uv}(\bar{\mathbf{d}}) + \kappa_*(\bar{\mathbf{d}},\bar{\mathbf{s}}))$$

The second inequality in part (8) follows from parts (4), (5), and (7). ■

The next lemma shows that, if the degrees and strengths of $\mathcal{G}_n$ are bounded around their expected values, the empirical estimate of variance is bounded around the conditional population estimate, and the coefficient of variation of $S_n(u,B)$ is bounded around its population value. Define $D_T := \sum_{u\in N} D(u)$ as the (random) total degree. Recall that λ_n is the asymptotic order the average of the *expected* degrees $\bar{d}_T$.

Lemma 13 *Fix $n > 1$. Suppose Assumption 5 holds. Define*

$$M(\mathbf{D}, \mathbf{S}) := \max_{u \in N} \left\{ |S(u) - \bar{s}(u)|, |D(u) - \bar{d}(u)| \right\}. \tag{26}$$

Then the following statements hold:

(1) There exists small enough $t > 0$ such that if $M(\mathbf{D}, \mathbf{S}) \leqslant \lambda_n t$,

$$\left| \hat{\kappa}(\mathbf{D}, \mathbf{S}) - \kappa_*(\bar{\mathbf{d}}, \bar{\mathbf{s}}) \right| = \left| \frac{\sum_{u,v:A_{uv}=1} V_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}) - v_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})}{\sum_{u,v:A_{uv}=1} f_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})^2 + D_T \rho_n O(t)} \right| + \rho_n O(t)$$

(2) Fix a constant $\varepsilon > 0$ independent of n. Assume $|\hat{\kappa}(\mathbf{D}, \mathbf{S}) - \kappa_*(\bar{\mathbf{d}}, \bar{\mathbf{s}})| \leqslant \varepsilon$. Then then there exists small enough $t > 0$ (not depending on ε) such that if $M(\mathbf{D}, \mathbf{S}) \leqslant t$, for all $B \subseteq N$, we have

$$\left| \frac{\mu(u, B|\Theta)}{\sigma(u, B|\Theta)} - \frac{\mu(u, B|\theta_*)}{\sigma(u, B|\theta_*)} \right| = \sqrt{|B|\rho_n} O(t)$$

Proof $M(\mathbf{D}, \mathbf{S}) \leqslant \lambda_n t$ implies there exists a n-vector $\mathbf{a}_t$ with components in the interval $[-1, 1]$ such that $S(u) = \bar{s}(u) + \lambda_n t a_t(u)$. Therefore, defining $\bar{a}_t := n^{-1} \sum_v a_t(v)$,

$$\begin{aligned}
r_{uv}(\mathbf{S}) - r_{uv}(\bar{\mathbf{s}}) &= \frac{\{\bar{s}(u) + \lambda_n a_t(u) t\}\{\bar{s}(v) + \lambda_n a_t(v) t\}}{\bar{s}_T + n\lambda_n \bar{a}_t t} - \frac{\bar{s}(u)\bar{s}(v)}{\bar{s}_T} \\
&= \frac{\bar{s}_T\{\bar{s}(u)a_t(v) + \bar{s}(v)a_t(u) + \lambda_n a_t(u)a_t(v)t\}\lambda_n t - \bar{s}(u)\bar{s}(v)n\lambda_n \bar{a}_t t}{\bar{s}_T\{\bar{s}_T + n\lambda_n \bar{a}_t t\}} \\
&= \left\{ \frac{\bar{s}(u)a_t(v) + \bar{s}(v)a_t(u) + \lambda_n a_t(u)a_t(v)t - r_{uv}(\bar{s})n\bar{a}_t}{\bar{s}_T + n\lambda_n \bar{a}_t t} \right\} \lambda_n t
\end{aligned}$$

Using parts (2)-(4) of Lemma 12, for sufficiently small t we have

$$\left| r_{uv}(\mathbf{S}) - r_{uv}(\bar{\mathbf{s}}) \right| \leqslant \frac{2\lambda_n m_+^3 + \lambda_n t + \rho_n (m_+^6/m_-^2) n}{n\lambda_n m_-^2 - n\lambda_n t} \lambda_n t = \frac{2m_+^3 + t + (m_+^6/m_-^2)}{m_-^2 - t} \rho_n t$$

Therefore,

$$|r_{uv}(\mathbf{S}) - r_{uv}(\bar{\mathbf{s}})| = \rho_n O(t) \tag{27}$$

as $t \to 0$. By a similar argument, $|r_{uv}(\mathbf{D}) - r_{uv}(\bar{\mathbf{d}})| = \rho_n O(t)$. It follows that

$$|f_{uv}(\mathbf{D}, \mathbf{S}) - f_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})| = \rho_n O(t). \tag{28}$$

Therefore, using Equations 27-28 and part (7) of Lemma 12,

$$\begin{aligned}
V_{uv}(\mathbf{D}, \mathbf{S}) &:= (W_{uv} - f_{uv}(\mathbf{D}, \mathbf{S}))^2 \\
&= (W_{uv} - f_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}))^2 + 2(W_{uv} - f_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}))(f_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}) - f_{uv}(\mathbf{D}, \mathbf{S})) \\
&\quad + (f_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}) - f_{uv}(\mathbf{D}, \mathbf{S}))^2 \\
&= V_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})^2 + 2V_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})(f_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}) - f_{uv}(\mathbf{D}, \mathbf{S})) + (f_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}) - f_{uv}(\mathbf{D}, \mathbf{S}))^2 \\
&\leqslant V_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})^2 + \rho_n O(t) + \rho_n^2 O(t^2) = V_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})^2 + \rho_n O(t)
\end{aligned}$$

Define the following:

$$V_T := \sum_{u,v:A_{uv}=1} V_{uv}(\mathbf{D}, \mathbf{S}), \quad \bar{V}_T := \sum_{u,v:A_{uv}=1} V_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}).$$

Since $D_T := \sum_{u \in N} D(u) = \sum_{u,v:A_{uv}=1} 1$, the above inequality implies that $V_T = \bar{V}_T + D_T \rho_n O(t)$. Define similarly:

$$g_T := \sum_{u,v:A_{uv}=1} f_{uv}(\mathbf{D}, \mathbf{S})^2, \quad \bar{g}_T := \sum_{u,v:A_{uv}=1} f_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})^2.$$

Similar logic gives $g_T = \bar{g}_T + D_T \rho_n O(t)$. Finally, define $\bar{v}_T := \sum_{u,v:A_{uv}=1} v_{uv}(\bar{\mathbf{s}}, \bar{\mathbf{d}})$. Then

$$\begin{aligned}
\left| \hat{\kappa}(\mathbf{D}, \mathbf{S}) - \kappa_*(\bar{\mathbf{d}}, \bar{\mathbf{s}}) \right| &= \left| \frac{V_T}{g_T} - \frac{\bar{v}_T}{\bar{g}_T} \right| = \left| \frac{\bar{V}_T + D_T \rho_n O(t)}{\bar{g}_T + D_T \rho_n O(t)} - \frac{\bar{v}_T}{\bar{g}_T} \right| \\
&= \left| \frac{\bar{V}_T + D_T \rho_n O(t) - \frac{\bar{v}_T}{\bar{g}_T} \{\bar{g}_T + D_T \rho_n O(t)\}}{\bar{g}_T + D_T \rho_n O(t)} \right| \\
&\leqslant \left| \frac{\bar{V}_T - \bar{v}_T}{\bar{g}_T + D_T \rho_n O(t)} \right| + \left| \frac{D_T \rho_n O(t) - \frac{\bar{v}_T}{\bar{g}_T} D_T \rho_n O(t)}{\bar{g}_T + D_T \rho_n O(t)} \right|
\end{aligned}$$

Note that $\bar{v}_T / D_T$ and $\bar{g}_T / D_T$ are, each, by parts (5) and (6) of Lemma 12, bounded above and below by constants independent of A, t, and n. Therefore, dividing through by D_T,

$$\left| \frac{D_T \rho_n O(t) - \frac{\bar{v}_T}{\bar{g}_T} D_T \rho_n O(t)}{\bar{g}_T + D_T \rho_n O(t)} \right| \leqslant \frac{\rho_n O(t)}{\bar{g}_T / D_T + \rho_n O(t)} = \rho_n O(t)$$

This proves part 1. For part 2, first recall that $\mu(u, B|\Theta) \equiv \mu(u, B|\mathbf{S}) := \sum_{v \in B} r_{uv}(\mathbf{S})$. Therefore by Equation 27, we have

$$|\mu(u, B|\Theta) - \mu(u, B|\theta_*)| = \left| \sum_{v \in B} r_{uv}(\mathbf{S}) - r_{uv}(\bar{\mathbf{s}}) \right| = |B| \rho_n O(t) \tag{29}$$

Recall further that

$$\sigma(u, B|\Theta)^2 := \sum_{v \in B} r_{uv}(\mathbf{S}) f_{uv}(\mathbf{D}, \mathbf{S}) \left(1 - r_{uv}(\mathbf{D}) + \hat{\kappa}(\mathbf{D}, \mathbf{S})\right)$$

Using some straightforward algebra and applying Equations 27-28, we have

$$\begin{aligned}
\left| \sigma(u, B|\Theta)^2 - \sigma(u, B|\theta_*)^2 \right| &= |B| \left(1 + \left| \hat{\kappa}(\mathbf{D}, \mathbf{S}) - \kappa_*(\bar{\mathbf{d}}, \bar{\mathbf{s}}) \right| \right) \rho_n O(t) \\
&= |B| \rho_n O(t)
\end{aligned} \tag{30}$$

where the second line follows from the assumption that $|\hat{\kappa}(\mathbf{D}, \mathbf{S}) - \kappa_*(\bar{\mathbf{d}}, \bar{\mathbf{s}})| \leqslant \varepsilon$. We will now bound $\sigma(u, B|\Theta)$ close to $\sigma(u, B|\theta_*)$ using Equation 30 and a Taylor expansion. Define the function $h(x, \sigma) := \sqrt{\sigma^2 + x}$. For fixed σ, a Taylor expansion around $x = 0$ gives

$h(x,\sigma) = \sigma + \sum_{k=1}^{\infty}(-1)^k \frac{x^k}{k!\sigma^{2k-1}}$. Setting $x = \sigma(u,B|\Theta)^2 - \sigma(u,B|\theta_*)^2$ and $\sigma = \sigma(u,B|\theta_*)$ and applying Equation 30, we obtain

$$\begin{aligned}\sigma(u,B|\Theta) &= h(x, \sigma(u,B|\theta_*)) \\ &= \sigma(u,B|\theta_*) + \sum_{k=1}^{\infty}(-1)^k \frac{|B|^k \rho_n^k O(t^k)}{k!\sigma(u,B|\theta_*)^{2k-1}} \end{aligned} \tag{31}$$

Part (8) of Lemma 12 implies that $\sigma(u,B|\theta_*) \asymp \sqrt{|B|\rho_n}$. Equation 31 therefore gives

$$\sigma(u,B|\Theta) = \sigma(u,B|\theta_*) + \sqrt{|B|\rho_n}O(t) \tag{32}$$

using Equations 29 and 32, we write

$$\left|\frac{\mu(u,B|\Theta)}{\sigma(u,B|\Theta)} - \frac{\mu(u,B|\theta_*)}{\sigma(u,B|\theta_*)}\right| = \left|\frac{\mu(u,B|\theta_*) + |B|\rho_n O(t)}{\sigma(u,B|\theta_*) + \sqrt{|B|\rho_n}O(t)} - \frac{\mu(u,B|\theta_*)}{\sigma(u,B|\theta_*)}\right| \tag{33}$$

As shorthands, define $\bar{\mu}_n := \mu(u,B|\theta_*)/|B|\rho_n$ and $\bar{\sigma}_n := \sigma(u,B|\theta_*)/\sqrt{|B|\rho_n}$. Part (8) of Lemma 12 implies that $\bar{\mu}_n, \bar{\sigma}_n \asymp 1$. Thus, using Equation 33 and dividing through by the appropriate factors,

$$\begin{aligned}\left|\frac{\mu(u,B|\Theta)}{\sigma(u,B|\Theta)} - \frac{\mu(u,B|\theta_*)}{\sigma(u,B|\theta_*)}\right| &= \sqrt{|B|\rho_n}\left|\frac{\bar{\mu}_n + O(t)}{\bar{\sigma}_n + O(t)} - \frac{\bar{\mu}_n}{\bar{\sigma}_n}\right| \\ &= \sqrt{|B|\rho_n}O(t)\end{aligned}$$

This completes part 2. ■

The proof of Lemma 4 from the main text (below) makes use of Lemma 13 by showing that its assumption holds with high probability, for appropriate t.

C.1 Proof of Theorem 4

Throughout, we will sometimes suppress dependence on n for notational convenience. Recall that $A(u,B,\mathcal{G}) := S(u,B,\mathcal{G}) - \mu(u,B|\mathbf{S})$, the deviation of the CCME test statistic from its expected value under the continuous configuration model. Recalling that $\Theta := (\mathbf{D},\mathbf{S},\hat{\kappa}(\mathbf{D},\mathbf{S}))$, define also the random Z-statistic

$$Z(u,B,\mathcal{G}|\Theta) := \frac{A(u,B,\mathcal{G})}{\sigma(u,B|\Theta)}. \tag{34}$$

Define the random p-value

$$P(u,B,\mathcal{G}|\Theta) := 1 - \Phi(Z(u,B,\mathcal{G}|\Theta)). \tag{35}$$

The random variable $P(u,B,\mathcal{G}|\Theta)$ is the random version of the p-value $p(u,B_n|\theta)$ obtained from the approximation in Equation (11). As a consequence of the Benjamini-Hochberg procedure, the event $\{U_\alpha(B_n,\mathcal{G}) = C_n\}$ will occur if

$$\begin{aligned}&P(u,B_n,\mathcal{G}_n|\Theta) \leqslant q\alpha, \quad \text{for all } u \in C_n, \quad \text{and} \\ &P(u,B_n,\mathcal{G}_n|\Theta) > q\alpha, \quad \text{for all } u \notin C_n,\end{aligned} \tag{36}$$

since by assumption $|C_n| > qn$. Let h be the density function of a standard-Normal. By a well-known inequality for the CDF of a standard-Normal, if $Z(u,B_n,\mathcal{G}_n|\Theta) > 0$,

$$P(u,B_n,\mathcal{G}_n|\Theta) \leqslant \frac{1}{Z(u,B_n,\mathcal{G}_n|\Theta)}h(Z(u,B_n,\mathcal{G}_n|\Theta)). \tag{37}$$

By symmetry, if $Z(u,B_n,\mathcal{G}_n|\Theta) < 0$, then

$$P(u,B_n,\mathcal{G}_n|\Theta) \geqslant 1 + \frac{1}{Z(u,B_n,\mathcal{G}_n|\Theta)}h(Z(u,B_n,\mathcal{G}_n|\Theta)). \tag{38}$$

We therefore analyze the concentration properties of $Z(u,B_n,\mathcal{G}_n|\Theta)$ and apply Inequalities 37 and 38 to show that for sufficiently large n, the event in Equation 36 occurs with high probability. We will focus on the first line of 36 first; the second is shown similarly. Recall that θ_* is the empirical population null parameters of $\mathcal{G}_n$, defined after Definition 11. For the derivation below we use the following shorthands: $Y \equiv S(u,B_n,\mathcal{G}_n)$, $\mu \equiv \mu(u,B_n|\mathbf{S}_n)$, $\sigma := \sigma(u,B_n|\Theta)$, $\bar{y} \equiv \mathbb{E}Y$, $\bar{\mu} \equiv \mu(u,B_n|\theta_*)$, and $\bar{\sigma} := \sigma(u,B_n|\theta_*)$. Note

$$\begin{aligned}Z(u,B_n,\mathcal{G}_n|\Theta) := \frac{Y-\mu}{\sigma} = \frac{Y-\bar{\mu}}{\bar{\sigma}} - \left(\frac{\mu}{\sigma} - \frac{\bar{\mu}}{\bar{\sigma}}\right) = \frac{\bar{y}-\bar{\mu}}{\bar{\sigma}} + \frac{Y-\bar{y}}{\bar{\sigma}} - \left(\frac{\mu}{\sigma} - \frac{\bar{\mu}}{\bar{\sigma}}\right) \\ \geqslant \frac{\bar{y}-\bar{\mu}}{\bar{\sigma}} - \left|\frac{Y-\bar{y}}{\bar{\sigma}}\right| - \left|\frac{\mu}{\sigma} - \frac{\bar{\mu}}{\bar{\sigma}}\right|\end{aligned} \tag{39}$$

Define

$$\bar{z}(u,B_n|\theta_*) := \frac{\bar{y}-\bar{\mu}}{\bar{\sigma}} = \lambda_n \frac{\tilde{a}(u,B_n|\bar{\mathbf{s}})}{\sigma(u,B_n|\theta_*)}$$

where $\tilde{a}(u,B_n|\bar{\mathbf{s}})$ is the normalized population version of $A(u,B_n|\mathbf{S})$, as defined in Equation 13 from the main text. The definition above works with Equation 39 to produce the illustrative inequality

$$Z(u,B_n,\mathcal{G}_n|\Theta) \geqslant \bar{z}(u,B_n|\theta_*) - \left|\frac{Y-\bar{y}}{\bar{\sigma}}\right| - \left|\frac{\mu}{\sigma} - \frac{\bar{\mu}}{\bar{\sigma}}\right|. \tag{40}$$

Inequality 40 exemplifies that, if the right-hand terms vanish, $Z(u,B_n,\mathcal{G}_n|\Theta)$ can be approximated by a population version. Our analysis therefore reduces to bounding the right-hand order terms in probability.

Explicitly, consider that by part (8) of Lemma 12, there exists $m_2 > 0$ such that $\sigma(u,B_n|\theta_*)^2 \leqslant m_2 n\rho_n = m_2\lambda_n$. Combining this with the crucial assumption on $\tilde{a}(u,B_n)$ from line 14 from the main text, we have that for all $u \in C_n$,

$$\bar{z}(u,B_n|\theta_*) = \lambda_n \frac{\tilde{a}(u,B_n|\bar{\mathbf{s}})}{\sigma(u,B_n|\theta_*)} \geqslant \sqrt{\lambda_n}\frac{\Delta}{\sqrt{m_2}} \tag{41}$$

Therefore, the rest of the proof is mainly dedicated to showing that the final two terms in line (40) are $o_P(\sqrt{\lambda_n})$. This will imply that $Z(u,B_n,\mathcal{G}_n|\Theta) = \Omega_P(\sqrt{\lambda_n})$ and, using Inequality 37, that $\{P(u,B_n,\mathcal{G}_n|\Theta) \leqslant q\alpha,\ \forall\ u \in C_n\}$ has probability approaching 1.

Step 1: $|\frac{\mu}{\sigma} - \frac{\bar{\mu}}{\bar{\sigma}}| = O_P(\sqrt{\log n})$

For $t > 0$, define the event

$$\mathcal{E}_1(t) := \left\{ \max_{u \in N} |S(u) - \bar{s}(u)|, \max_{u \in N} \left|D(u) - \bar{d}(u)\right| \leqslant \lambda_n t \right\} \tag{42}$$

Fix arbitrary $b > 0$ independent of all other quantities and define $t_n(b) := \sqrt{\frac{b \log n}{\lambda_n}}$. Note that $t_n(b) \to 0$ for any b, by the assumptions of the Theorem. Recall that $D_T := \sum_{u \in N} D(u)$, the (random) total degree. For notational convenience, let $E := \{\text{pairs } u, v : A_{uv} = 1\}$. By part 1 of Lemma 13, the event $\mathcal{E}_1(t_n(b))$ implies

$$\left|\hat{\kappa}(\mathbf{D}, \mathbf{S}) - \kappa_*(\bar{\mathbf{d}}, \bar{\mathbf{s}})\right| = \left| \frac{\sum_E V_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}) - v_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})}{\sum_E f_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})^2 + D_T \rho_n O(t_n(b))} \right| + \rho_n O(t_n(b)) \tag{43}$$

By Lemma 12 part (5),

$$0 \leqslant V_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}) \leqslant (\eta m_+^2 / m_-^2 + m_+^{10} / m_-^3)^2.$$

Recall that $v_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}) := \mathbb{E} V_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})$, and that the edge weights that comprise the (upper-triangle of the) weight matrix W are independent. For a fixed adjacency matrix A, Bernstein's Inequality therefore gives

$$\mathbb{P}\left(\left| \sum_E V_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}) - v_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}) \right| > \sqrt{b \log n} \;\middle|\; A \right) \leqslant 2 \exp\left\{ \frac{-2b \log n}{2a_1 + \frac{2}{3} a_2 \sqrt{b \log n}} \right\} \tag{44}$$

Now by Lemma 12 part (6), $\sum_E f_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})^2 \geqslant D_T \frac{m_-^{10}}{m_+^3}$. Thus

$$\sum_E f_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})^2 + D_T \rho_n O(t_n(b)) \geqslant D_T \frac{m_-^{10}}{m_+^3} / 2$$

for large enough n, since $\rho_n t_n(b) \to 0$. Therefore there exist constants $a_1, a_2 > 0$ depending only on m_+, m_-, and η such that

$$\mathbb{P}\left(\left| \frac{\sum_E V_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}) - v_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})}{\sum_E f_{uv}(\bar{\mathbf{s}}, \bar{\mathbf{d}})^2 + D_T \rho_n O(t_n(b))} \right| > \sqrt{\tfrac{b \log n}{D_T}} \;\middle|\; A \right) \leqslant 2 \exp\left\{ \frac{-2b \log n}{2a_1 + \frac{2}{3} a_2 \sqrt{\frac{b \log n}{D_T}}} \right\} \tag{45}$$

The above expression is conditional on a fixed adjacency matrix A. We now bound in probability the functionals of A on which the expression depends. It is easily derivable from the statement of the WSBM and Assumption 5 that there exist constants a_3, a_4 depending on m_+ and m_- such that $\mathbb{E}(D_T) = a_3 n \lambda_n$ and $\mathrm{Var}(D_T) = a_4 n \lambda_n$. Therefore, by another application of Bernstein's Inequality,

$$\mathbb{P}\left(|D_T - a_3 n \lambda_n| > \sqrt{n \lambda_n b \log n} \right) \leqslant 2 \exp\left\{ \frac{-2b \log n}{2a_4 + \frac{2}{3} \sqrt{\frac{b \log n}{n \lambda_n}}} \right\} \tag{46}$$

Applying this to inequality (45), the law of total probability gives

$$\begin{aligned}
&\mathbb{P}\left(\left| \frac{\sum_E V_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}}) - v_{uv}(\bar{\mathbf{d}}, \bar{\mathbf{s}})}{\sum_E f_{uv}(\bar{\mathbf{s}}, \bar{\mathbf{d}})^2 + D_T \rho_n O(t_n(b))} \right| > \sqrt{\frac{b \log n}{a_3 n \lambda_n - \sqrt{n \lambda_n b \log n}}} \right) \\
&\leqslant 2 \exp\left\{ \frac{-2b \log n}{2a_1 + \frac{2}{3} a_2 \sqrt{\frac{b \log n}{a_3 n \lambda_n - \sqrt{n \lambda_n b \log n}}}} \right\} + 2 \exp\left\{ \frac{-2b \log n}{2a_4 + \frac{2}{3} \sqrt{\frac{b \log n}{n \lambda_n}}} \right\} = O(n^{-b})
\end{aligned} \tag{47}$$

for sufficiently large n. Along with Equation (43), this implies there exists a constant A_0 depending on parameter constraints such that

$$\mathbb{P}\left\{ \left|\hat{\kappa}(\mathbf{D}, \mathbf{S}) - \kappa_*(\bar{\mathbf{d}}, \bar{\mathbf{s}})\right| \leqslant A_0 \left(\sqrt{\frac{b \log n}{n \lambda_n}} + \rho_n t_n(b) \right) \right\} \geqslant \mathbb{P}(\mathcal{E}_1(t_n(b))) - O(n^{-b}) \tag{48}$$

for sufficiently large n. We now assess $\mathbb{P}(\mathcal{E}_1(t_n(b)))$. Note that for all $u \in N$, $\mathrm{Var}(S(u)) = O(\lambda_n)$. Furthermore, recall from Inequality 25 (in the proof of Lemma 12) that $W_{uv} \leqslant m_+^2 \eta / m_-^2$ for all $u, v \in N$. For fixed $b > 0$, Bernstein's Inequality therefore gives, for any $u \in N$,

$$\mathbb{P}\left(|S(u) - \bar{s}(u)| > \sqrt{b \log n \lambda_n} \right) \leqslant 2 \exp\left\{ \frac{-2a_0 b \log n}{2 + \frac{2}{3} \sqrt{\frac{b \log n}{\lambda_n}}} \right\}, \tag{49}$$

where a_0 is a constant independent of n. The constant a_0 may be chosen so that, similarly,

$$\mathbb{P}\left(\left|D(u) - \bar{d}(u)\right| > \sqrt{b \log n \lambda_n} \right) \leqslant 2 \exp\left\{ \frac{-2a_0 b \log n}{2 + \frac{2}{3} \sqrt{\frac{b \log n}{\lambda_n}}} \right\} \tag{50}$$

Applying a union bound, equations (49) and (50) give

$$\begin{aligned}
\mathbb{P}(\mathcal{E}_1(t_n(b))) &\geqslant 1 - 2n \exp\left\{ \frac{-2a_0 b \log n}{2 + \frac{2}{3} \sqrt{\frac{b \log n}{\lambda_n}}} \right\} - 2n \exp\left\{ \frac{-2a_0 b \log n}{2 + \frac{2}{3} \sqrt{\frac{b \log n}{\lambda_n}}} \right\} \\
&= 1 - O(n^{-b+1})
\end{aligned} \tag{51}$$

for sufficiently large n. Returning to the inequality in (48), we therefore have

$$\begin{aligned}
\mathbb{P}\left\{ \left|\hat{\kappa}(\mathbf{D}, \mathbf{S}) - \kappa_*(\bar{\mathbf{d}}, \bar{\mathbf{s}})\right| \leqslant A_0 \left(\sqrt{\tfrac{b \log n}{n \lambda_n}} + \rho_n t_n(b) \right) \right\} &\geqslant \mathbb{P}(\mathcal{E}_1(t_n(b))) - O(n^{-b}) \\
&\geqslant 1 - O(n^{-b+1})
\end{aligned} \tag{52}$$

for sufficiently large n. Recall that by assumption, $\lambda_n / \log n \to \infty$. Thus $t_n(b) \to 0$, and

$$\sqrt{\tfrac{b \log n}{n \lambda_n}} + \rho_n t_n(b) = t_n(b) / \sqrt{n} + \rho_n t_n(b) \leqslant 1 / \sqrt{n} = o(1).$$

Thus, Inequality 52 implies that

$$\mathbb{P}\left(\left|\hat{\kappa}(\mathbf{D}, \mathbf{S}) - \kappa_*(\bar{\mathbf{d}}, \bar{\mathbf{s}})\right| \leqslant \varepsilon \right) \geqslant 1 - O(n^{-b+1}), \tag{53}$$

for sufficiently large n. For $\varepsilon > 0$, define the event $\mathcal{E}_2(\varepsilon) := \left\{\left|\hat{\kappa}(\mathbf{D},\mathbf{S}) - \kappa(\bar{\mathbf{d}},\bar{\mathbf{s}})\right| \leqslant \varepsilon\right\}$. By part 2 of Lemma 3, the event $\mathcal{E}_1(t_n(b)) \cap \mathcal{E}_2(\varepsilon)$ implies

$$\begin{aligned}\left|\frac{\mu}{\sigma} - \frac{\bar{\mu}}{\bar{\sigma}}\right| := \left|\frac{\mu(u,B_n|\mathbf{S})}{\sigma(u,B_n|\Theta)} - \frac{\mu(u,B_n|\bar{\mathbf{s}})}{\sigma(u,B_n|\theta_*)}\right| &= \sqrt{|B_n|\rho_n}O(t_n(b)) \\ &\leqslant \sqrt{\lambda_n}O(t_n(b)). \\ &= O(\sqrt{b\log n}) \end{aligned} \tag{54}$$

Therefore, there exists a constant $A_2 > 0$ such that, by Inequalities 51 and 53,

$$\mathbb{P}\left(\left|\frac{\mu}{\sigma} - \frac{\bar{\mu}}{\bar{\sigma}}\right| \leqslant A_2\sqrt{b\log n}\right) = 1 - O(n^{-b+1}) \tag{55}$$

for sufficiently large n. This completes Step 1.

Step 2: $|\frac{Y-\bar{y}}{\bar{\sigma}}| = O_P(\sqrt{\log n})$.

Note that, as for Inequality 49, Bernstein's Inequality gives

$$\mathbb{P}\left(|S(u,B_n,\mathcal{G}_n) - \mathbb{E}S(u,B_n,\mathcal{G}_n)| > \sqrt{b\log n\lambda_n}\right) \leqslant 2\exp\left\{\frac{-2a_0 b\log n}{2 + \frac{2}{3}\sqrt{\frac{b\log n}{\lambda_n}}}\right\} \tag{56}$$

By Lemma 12 part (8), there exists $m_2 > 0$ such that $\sigma(u,B_n|\theta_*)^2 \leqslant m_2\lambda_n$. Thus,

$$\left|\frac{Y-\bar{y}}{\bar{\sigma}}\right| := \left|\frac{S(u,B_n,\mathcal{G}_n) - \mathbb{E}S(u,B_n,\mathcal{G}_n)}{\sigma(u,B_n|\theta_*)}\right| \geqslant \left|\frac{S(u,B_n,\mathcal{G}_n) - \mathbb{E}S(u,B_n,\mathcal{G}_n)}{m_2\sqrt{\lambda_n}}\right|,$$

so by Inequality 56, we have for sufficiently large n that

$$\mathbb{P}\left(\left|\frac{Y-\bar{y}}{\bar{\sigma}}\right| \leqslant \sqrt{\frac{b\log n}{m_2}}\right) \geqslant 1 - O(n^{-b}). \tag{57}$$

This completes Step 2.

We now recall inequality 40:

$$Z(u,B_n,\mathcal{G}_n|\Theta) \geqslant \bar{z}(u,B_n|\theta_*) - \left|\frac{Y-\bar{y}}{\bar{\sigma}}\right| - \left|\frac{\mu}{\sigma} - \frac{\bar{\mu}}{\bar{\sigma}}\right|.$$

In step 1, we showed that there exists a constant A_2 depending only on the fixed WSBM model parameters such that for any fixed $b > 1$, for large enough n, $\left|\frac{\mu}{\sigma} - \frac{\bar{\mu}}{\bar{\sigma}}\right| \leqslant A_2\sqrt{b\log n}$ with probability $1 - O(n^{-b+1})$. In step 2, we showed that there exists a constant m_2 depending only on the fixed WSBM model parameters such that for any fixed $b > 1$, for large enough n, $|\frac{Y-\bar{y}}{\bar{\sigma}}| \leqslant \sqrt{b\log n/m_2}$ with probability $1 - O(n^{-b})$. Recall furthermore from inequality 41 that $\bar{z}(u,B_n|\theta_*) \geqslant \Delta\sqrt{\lambda_n/m_2}$, where Δ is from condition 14 in the statement of the Theorem. We can therefore write that for any fixed $b > 1$, for large enough n,

$$Z(u,B_n,\mathcal{G}_n|\Theta) \geqslant \Delta\sqrt{\lambda_n/m_2} - \sqrt{b\log n/m_2} - A_2\sqrt{b\log n} = A_3\sqrt{\lambda_n} - A_4\sqrt{b\log n}$$

with probability at least $1 - O(n^{-b+1})$. Now, by assumption, $|C_n| \geqslant qn$. Therefore, using Inequality 37 and a union bound, we can write that for any fixed $b > 1$, for large enough n,

$$\max_{u\in C_n} P(u,B_n,\mathcal{G}_n|\Theta) \leqslant \exp\{-(A_3\sqrt{\lambda_n} - A_4\sqrt{b\log n})^2\} \tag{58}$$

with probability at least $1 - O(n^{-b+2})$. Note that for any fixed b, the right-hand-side of inequality 58 vanishes, due to the assumption that $\lambda_n/\log n \to \infty$. Thus, for $b > 2$, inequality 58 implies that for large enough n (now depending on choice of b), the event $\{P(u,B_n,\mathcal{G}_n|\Theta) \leqslant q\alpha,\ \forall\ u \in C_n\}$ has probability $1 - O(n^{-b+2}) \to 1$.

It can be similarly shown that the second half of the event in (36) has probability approaching 1. Instead of Inequality 40 we (similarly) derive

$$Z(u,B_n,\mathcal{G}_n|\Theta) \leqslant \bar{z}(u,B_n|\theta_*) + \left|\frac{Y-\bar{y}}{\bar{\sigma}}\right| + \left|\frac{\mu}{\sigma} - \frac{\bar{\mu}}{\bar{\sigma}}\right| \tag{59}$$

This is useful because if $u \notin C_n$, assumption (14) ensures that $\tilde{a}_n(u,B_n)\bar{\mathbf{s}} < -\Delta$, and hence

$$\bar{z}(u,B_n|\theta_*) := \frac{\bar{y}-\bar{\mu}}{\bar{\sigma}} = \lambda_n\frac{\tilde{a}(u,B_n|\bar{\mathbf{s}})}{\sigma(u,B_n|\theta_*)} \leqslant \lambda_n\frac{-\Delta}{\sigma(u,B_n|\theta_*)} \leqslant \sqrt{\lambda_n}\frac{-\Delta}{\sqrt{m_1}}$$

where the last inequality follows from part (8) of Lemma 12. Steps 1 and 2 therefore work to show that for any fixed $b > 1$, for large enough n,

$$Z(u,B_n,\mathcal{G}_n|\Theta) \leqslant -\Delta\sqrt{\lambda_n/m_2} + \sqrt{b\log n/m_2} + A_2\sqrt{b\log n} = A_3\sqrt{\lambda_n} - A_4\sqrt{b\log n}$$

With probability $1 - O(n^{-b+1})$. Inequality 38 then implies that

$$\mathbb{P}\left(\max_{u\notin C_n} P(u,B_n,\mathcal{G}_n|\Theta) \geqslant 1 - \exp\{-(A_3\sqrt{\lambda_n} - A_4\sqrt{b\log n})^2\}\right) \geqslant 1 - O(n^{-b+2}) \tag{60}$$

With reasoning identical to the result for $u \in C_n$, this implies that for any $b > 2$, for large enough $n(b)$, the event $\{P(u,B_n,\mathcal{G}_n|\Theta) > q\alpha,\ \forall\ u \notin C_n\}$ has probability at least $1 - O(n^{-b+2}) \to 1$. Applying a union bound to the event in (36) completes the proof. ■

C.2 Proof of Theorem 5

We will show that if the condition in (15) holds, then the condition in (14) from Theorem 4 holds when $B_n = C_n = C_{j,n}$ simultaneously across all $j \in \{1,2,\ldots,K\}$. This involves representing (14) in terms of the model parameters when $B_n = C_n = C_{j,n}$. Specifically, we derive the normalized population deviation $\tilde{a}(u,C_{j,n}|\bar{\mathbf{s}}) := (\mathbb{E}S(u,C_{j,n},\mathcal{G}_n) - \mu(u,C_{j,n}|\bar{\mathbf{s}}))/\lambda_n$. First, note that for any fixed $j \leqslant K$, part (1) of Lemma 12 gives

$$\sum_{v\in C_{j,n}} \bar{s}(v) \ = \ \lambda_n\langle\tilde{\boldsymbol{\pi}},\mathbf{H}_j\rangle \cdot \sum_{v\in C_{j,n}} \psi(u) \ = \ n\lambda_n\langle\tilde{\boldsymbol{\pi}},\mathbf{H}_j\rangle\tilde{\pi}_j$$

and thus

$$\bar{s}_T := \sum_{v\in N}\bar{s}(v) = \sum_{j=1}^{K}\sum_{v\in C_{j,n}}\bar{s}(v) = n\lambda_n\sum_{j=1}^{K}\langle\tilde{\boldsymbol{\pi}},\mathbf{H}_j\rangle\tilde{\pi}_j = n\lambda_n\tilde{\boldsymbol{\pi}}^t\mathbf{H}\boldsymbol{\pi}.$$

Therefore, again applying part (1) of Lemma 12,

$$\mu(u, C_{j,n}|\bar{\mathbf{s}}) := \sum_{v \in C_{j,n}} r_{uv}(\bar{\mathbf{s}}) = \bar{s}(u) \sum_{v \in C_{j,n}} \frac{\bar{s}(v)}{\bar{s}_T} = \bar{s}(u) \frac{\langle \tilde{\boldsymbol{\pi}}, \mathbf{H}_j \rangle \tilde{\pi}_j}{\tilde{\boldsymbol{\pi}}^t \mathbf{H} \tilde{\boldsymbol{\pi}}}$$
$$= \lambda_n \psi(u) \frac{\langle \tilde{\boldsymbol{\pi}}, \mathbf{H}_{c(u)} \rangle \langle \tilde{\boldsymbol{\pi}}, \mathbf{H}_j \rangle \tilde{\pi}_j}{\tilde{\boldsymbol{\pi}}^t \mathbf{H} \tilde{\boldsymbol{\pi}}}.$$

Secondly,

$$\mathbb{E}S(u, C_{j,n}, \mathcal{G}_n) = \sum_{v \in C_{j,n}} \mathbb{E}W_{uv} = \sum_{v \in C_{j,n}} \rho_n r_{uv}(\psi) \mathbf{H}_{c(u)j} = \lambda_n \psi(u) \mathbf{H}_{c(u)j} \tilde{\pi}_j.$$

Thus,

$$\tilde{a}(u, C_{j,n}|\bar{\mathbf{s}}) := \frac{\mathbb{E}S(u, C_{j,n}, \mathcal{G}_n) - \mu(u, C_{j,n}|\bar{\mathbf{s}})}{\lambda_n}$$
$$= \psi(u) \tilde{\pi}_j \left(\mathbf{H}_{c(u)j} - \frac{\langle \tilde{\boldsymbol{\pi}}, \mathbf{H}_{c(u)} \rangle \langle \tilde{\boldsymbol{\pi}}, \mathbf{H}_j \rangle}{\tilde{\boldsymbol{\pi}}^t \mathbf{H} \tilde{\boldsymbol{\pi}}} \right). \tag{61}$$

If $u \in C_{i,n}$, the expression in the parentheses from the right-hand-side of (61) is the i,j-th element of the matrix $\mathbf{H} - \mathbf{H}\tilde{\mathbf{\Pi}}\mathbf{H}/\tilde{\boldsymbol{\pi}}^t \mathbf{H} \tilde{\boldsymbol{\pi}}$, with $\tilde{\mathbf{\Pi}} := \tilde{\boldsymbol{\pi}} \tilde{\boldsymbol{\pi}}^t$. By Assumption 5, $\psi(u) \geqslant m_-$ for all $u \in N$ and $i \leqslant K$, and $\tilde{\pi}_j$ is fixed. Thus, (15) ensures that (14) holds when $C_n = C_{j,n}$, simultaneously for $j \leqslant K$. Assumption 5 also ensures that there exists $q > 0$ such that for all $j \leqslant K$ and $n > 1$, $|C_{j,n}| > qn$. This allows us to apply Theorem 4 to the sequences $B_n = C_n = C_{j,n}$, for each $j \leqslant K$. A union bound proves the result. ■

Appendix D. Further discussion of the CCME methodology

D.1 Variance in results due to initialization

Since CCME's initialization step is stochastic, it is natural to investigate the variance of results across many applications of CCME to the same network. To do so, we (randomly) selected five replications from each fixed parameter setting of the third experiment described in 6.2.1, in which both edge and edge weight signal levels are increased from low values. At each replication, we ran CCME thirty times, and recorded the pairwise Overlapping Normalized Mutual Information (oNMI, see Section 6) scores between the thirty resulting community sets. In Figure 3, we plot the median and 5%-95% quantile bars for the oNMI scores for each replication, and jitter the lines around the corresponding parameter value. It is clear from the plot that CCME results become more stable, and eventually non-varying, as community signal becomes stronger. This follows the straightforward intuition that when in-community edge/weight signal is weak, CCME finds spurious or imperfect communities, and will find *different* such communities when it is initialized with different random starting sets.

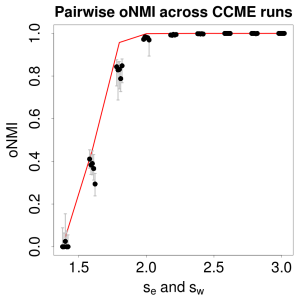

Figure 3: Stability tests for CCME.

D.2 Cycles in Fixed Point Search

As remarked in Section 5.2, it is possible for the SCS algorithm to reach a stable sequence $C_1, \ldots, C_J$ that is traversed by the update $U_\alpha(\cdot, \mathcal{G})$. If this happens, we apply the following routine to re-start the algorithm, or return the union of the sequence:

1. If $C_i \cap C_{i+1} = \phi$ for any $i \leqslant J$, or if $C_J \cap C_1 = \phi$, terminate the iterations and do not extract a community.

2. Otherwise, define $C^* = \cup_{i=1}^J C_i$, and:

   (a) If C^* has been visited previously by SCS, extract C^* into $\mathcal{C}$.

   (b) Otherwise, re-initialize with C^*.

D.3 Filtering of $\mathcal{B}_0$ and $\mathcal{C}$

To filter through $\mathcal{B}_0$ and $\mathcal{C}$, we use an inference procedure based on a set-wise z-statistic, analogous to the node-set z-statistic presented in Section 4. Define $S(B) := \sum_{v \in B} S(v, B)$. Note that $S(B)$ has an easily derivable expectation and standard deviation under the continuous configuration model, which we denote (respectively) by $\mu(B|\theta)$ and $\sigma(B|\theta)$. We define the corresponding z-statistic and an approximate p-value by

$$z(B|\theta) := \frac{S(B) - \mu(B|\theta)}{\sigma(B|\theta)}, \qquad p(B|\theta) := 1 - \Phi(z(B|\theta))$$

Before initializing the SCS algorithm on sets in $\mathcal{B}_0$, we compute the p-value above for each member set, and remove any that are not significant at FDR level $\alpha = 0.05$. This greatly reduces the number of extractions CCME must perform, and reduces the probability of convergence on small, spurious communities.

We also use $z(B|\theta)$ to filter near-matches in $\mathcal{C}$, once all SCS extractions have terminated and empty sets have been removed. To do so, we require an overlap "tolerance" parameter $\tau \in [0, 1]$. First, we create a (non-symmetric) $|\mathcal{C}| \times |\mathcal{C}|$ matrix O with general element $O_{ij} := |C_i \cap C_j|/|C_i|$, which measures the proportional overlap of C_i into C_j. After setting the diagonal of O to zero, the filtering proceeds as follows:

1. Find indices $i \neq j$ corresponding to the maximum entry of O.

2. If $O_{ij} < \tau$, terminate filtering.

3. Remove either C_i or C_j from $\mathcal{C}$, whichever has the smaller $z(B|\theta)$.

4. Re-compute O, set its diagonal to zero, and return to step 1.

For all simulations and real-data analyses in this paper, we employed this algorithm with $\tau = 0.9$. To further decrease the computation time of CCME, as we proceed through $\mathcal{B}_0$, we skip sets that were formed from nodes that have already been extracted into $\mathcal{C}$. We find that, in practice, none of these adjustments harm CCME's ability to find statistically significant overlapping communities. Indeed, the simulation results mentioned in Section 6.2.2 show that CCME outperforms competing methods with overlap capabilities.

Appendix E. Extension to directed networks

Directed networks are networks for which edges and weights carry directionality, in the sense that nodes give and receive different quantities links and edge weight. Preserving directionality can in some applications be important for appropriate analysis of a network data set. The extension of the CCME method to directed networks is straightforward. First, both "in" and "out" observed degrees and strengths, denoted $\mathbf{d}^{\rightarrow} := \{\mathbf{d}_{in}, \mathbf{d}_{out}\}$ and $\mathbf{s}^{\rightarrow} := \{\mathbf{s}_{in}, \mathbf{s}_{out}\}$, are used in the null model. Let $A^{\rightarrow}_{uv}$ be the *ordered* entry of the adjacency matrix, corresponding to the edge from u *into* v, and similarly for weights $W^{\rightarrow}_{uv}$. Let $\mathbf{d}_{T,in}$ and $\mathbf{s}_{T,in}$ be the total in-degree and in-strength. Define

$$r^{\rightarrow}_{uv}(\mathbf{d}^{\rightarrow}) := \frac{d_{out}(u)d_{in}(v)}{d_{T,in}} \tag{62}$$

Define $\tilde{r}^{\rightarrow}_{uv}(\mathbf{d}^{\rightarrow}) := \min(1, r^{\rightarrow}_{uv}(\mathbf{d}^{\rightarrow}))$ and $f^{\rightarrow}_{uv}(\mathbf{d}^{\rightarrow}, \mathbf{s}^{\rightarrow}) := r^{\rightarrow}_{uv}(\mathbf{s}^{\rightarrow})/\tilde{r}^{\rightarrow}_{uv}(\mathbf{d}^{\rightarrow})$. Then the directed continuous configuration model is as follows:

1. $\mathbb{P}(A^{\rightarrow}_{uv} = 1) = \tilde{r}^{\rightarrow}_{uv}$ independently for all ordered node pairs $(u, v) \in N \times N$
2. For each ordered node pair (u, v), generate an independent random variable ξ_{uv} according to F, and assign edge weights by:

$$W^{\rightarrow}_{uv} = \begin{cases} f^{\rightarrow}_{uv}(\mathbf{s}^{\rightarrow}, \mathbf{d}^{\rightarrow})\xi_{uv}, & A_{uv} = 1 \\ 0, & A_{uv} = 0 \end{cases}$$

For directed networks, the formula for the variance parameter is

$$\hat{\kappa}^{\rightarrow}(\mathbf{d}^{\rightarrow}, \mathbf{s}^{\rightarrow}) := \sum_{(u,v):A_{uv}=1} (W^{\rightarrow}_{uv} - f^{\rightarrow}_{uv}(\mathbf{d}^{\rightarrow}, \mathbf{s}^{\rightarrow}))^2 \Big/ \sum_{(u,v):A_{uv}=1} f^{\rightarrow}_{uv}(\mathbf{d}^{\rightarrow}, \mathbf{s}^{\rightarrow})^2, \tag{63}$$

an equation that follows from the same method-of-moments logic presented in Section 2.2. Initialization, set updates, and overlap filtering proceed through use and testing of *out*-weights and *out*-weight sums. The proof of the corresponding Central Limit Theorem proceeds similarly to the proof of Theorem 2 with trivial modifications.

Appendix F. Simulation framework

Here we describe the benchmarking simulation framework used in Section 6. In Table 4, we list and name parameters controlling the network model:

Table 4: Simulation model parameters

n: Number of nodes in communities	n_b: Number of nodes in background
$m_{\max}$: Max community size	$m_{\min}$: Min community size
τ_1: Power-law for degree parameters	τ_2: Power-law for community sizes
k: Mean of degree parameter power-law	$k_{\max}$: Maximum degree parameter
s_e: Within-community edge signal	s_w: Within-community weight signal
o_n: Number of nodes in multiple communities	o_m: Number of memberships for overlap nodes
F: Distributions of edge weights	σ^2: Variance parameter for F
β: Power-law for strength parameters	

F.1 Simulation of community nodes

The framework is capable of simulating networks with or without background nodes. We first describe the simulation procedure without background nodes, i.e. with $n_b = 0$. Later, we describe how to simulate a network with background nodes, which involves a slight modification to the procedure in this subsection. Regardless of the presence of background nodes, the first step is to determine community sizes and node memberships.

F.1.1 Community structure and node degree/strength parameters

Here we describe how to obtain a cover $\mathcal{C} := \{C_1, \dots C_K\}$ of n nodes. The following steps to obtain $\mathcal{C}$ are almost exactly as those from the LFR benchmark in Lancichinetti and Fortunato (2009), used extensively in Lancichinetti et al. (2011) and Xie et al. (2013):

1. Each of the o_n overlapping nodes will have o_m memberships. Let $n_m := n + o_n(o_m - 1)$ be the number of node *memberships* present in the network.
2. Draw community sizes from a power law with maximum value $m_{\max}$, minimum value $m_{\min}$, and exponent $-\tau_2$, until the sum of community sizes is greater than or equal to n_m. If the sum is greater than n_m, we reduce the sizes of the communities proportionally until the sum is equal to n_m.
3. Form a bipartite graph of community markers on one side and node markers on the other. Each community marker has number of empty node slots given by step (b), and each node has a number of memberships given by step (a). Sequentially pair node memberships and community node slots uniformly at random, without replacement, until every node membership is paired with a community.

With the community assignments in hand, simulation of the network proceeds according to the Weighted Stochastic Block Model as outlined in Section 6. We describe choices for particular components of this model in the following subsection.

F.1.2 Simulation of edges and weights

As described in Section 6, we set the $\mathbf{P}$ and $\mathbf{M}$ matrices to have diagonals equal to s_e and s_w (respectively, see Table 4), and off-diagonals equal to 1. We note that this homogeneity facilitates creating networks with overlapping communities. With variance in the diagonal of $\mathbf{P}$, for example, it would not be obvious with what probability to connect overlapping nodes that overlap to two of the same communities, simultaneously. It remains

to obtain the strength and degree propensity parameters ψ and ϕ; we do so analogously to the simulation framework in Lancichinetti et al. (2011). We first draw ϕ from a power law with exponent τ_1, mean k, and maximum $k_{\max}$ (see Table 4). Next we set ψ by the formula $\psi(u) = \phi(u)^{\beta+1}$.

It is worth noting here that, under the model given below, the expected degree of node u is *approximately* $\phi(u)$ and the expected strength *approximately* $\psi(u)$. Therefore, heterogeneity/skewness in ϕ and ψ induce heterogeneity/skewness in the degrees and strengths of the simulated networks. However, by scaling ϕ and ψ, we can force the total expected degree and total expected strength of the simulated networks to exactly match ϕ_T and ψ_T, respectively. The scaling constants depend on $\mathbf{P}$ and $\mathbf{M}$ and are easily derivable from the model's generative algorithm (described in Section 4.2.1).

F.1.3 Parameter settings

Here we list the "default" settings of the simulation model, mentioned in Section 6. The following choices for parameters were made regardless of the simulation setting: $\tau_2 = -2$, $k = \sqrt{n}$, $k_{\max} = 3k$ (three settings which make the degree/strength distributions skewed and the network sparse), $\beta = 0.5$ (to induce a non-trivial power law between strengths and degrees), $\tau_1 = -1$, $m_{min} = n/5$, $m_{max} = 3m_{max}/2$ (settings which produce between about 3 and 7 communities per network with skewed size distribution), and $\sigma^2 = 1/2$. Other parameter choices are specific to the simulation settings described in Section 6.

F.2 Background node simulation

If $n_b > 0$, we generate a network with n community nodes, and then add n_b background nodes, generating all remaining edges and weights according to the continuous configuration null model introduced in the main text. First, we obtain node-wise parameters for all $n+n_b$ nodes, yielding vectors ϕ and ψ as in subsection F.1. In a simulated network without background, $\phi(u)$ and $\psi(u)$ are approximately $\mathbb{E}[d(u)]$ and $\mathbb{E}[s(u)]$, respectively. To ensure that this remains the case in a network for which background nodes are added after the simulation of community nodes, we must split up each $\phi(u)$ and $\psi(u)$ into community and background portions. A few other adjustments must also be made after the simulation of community nodes. To this end, define

- $N_C := \{1, \ldots, n\}$; $N_B := \{n+1, \ldots, n+n_b\}$ (community and background node sets)
- $\phi_{C,T} := \sum_{N_C} \phi(u)$; $\phi_{B,T} := \sum_{N_B} \phi(u)$ (target total degrees of community and background nodes)
- $\phi_C(u) := \frac{\phi_{C,T}}{\phi_T}\phi(u)$; $\phi_B(u) := \frac{\phi_{B,T}}{\phi_T}\phi(u)$ (target edge-counts between u and the community and background nodes)
- $\phi_{1,T} := \sum_{N_C} \phi_C(u)$; $\phi_{2,T} := \sum_{N_B} \phi_B(u)$ (target total degrees of community and background *subnetworks*)
- $d^o_C(u) := \sum_{v \in N_C} A_{uv}$; $d^o_B(u) := \sum_{v \in N_B} A_{uv}$ (observed edge-counts between u and the community and background nodes)

The above definitions exist analogously for the strength parameters ψ (replacing "d" with "s" where appropriate). The word "target" above indicates that we will set up the background simulation model so that these values are the approximate expected values of the graph statistics they represent.

F.2.1 Adjusted community-node simulation model

The only adjustment to be made to the simulation of community nodes, described in subsection F.1.2, is that the degree and strength parameters are set to a certain *fraction* of their original values. This accounts for the eventual addition of background nodes, where the remaining (random) part of each nodes degree and strength is to be simulated. So, the community-node simulation (if background nodes are to be added later) follows the process described in subsection F.1 with degree parameters $\{\phi_C(1), \ldots, \phi_C(n)\}$ and strength parameters $\{\psi_C(1) \ldots \psi_C(n)\}$.

F.2.2 Edges and weights for background

For the simulation of the background nodes (following the community nodes) our goal is to specify adjusted degree/strength parameters ϕ' and ψ' given the observed edge-sums $\{d^o_C(1), \ldots, d^o_C(n)\}$ and weight-sums $\{s^o_C(1), \ldots, s^o_C(n)\}$ from the community nodes. In what follows we describe this specification for ϕ' only; the specification for ψ' is exactly analogous. We first represent ϕ'_T, which we have yet to determine, into community and background totals:

$$\phi'_T = \phi'_{C,T} + \phi'_{B,T}$$

Since the background subnetwork has not yet been generated, we make the specification $\phi'(u) := \phi(u)$ for all $u \in N_B$, and hence $\phi'_{B,T} = \phi_{B,T}$ is known. To address $\phi'_{C,T}$, note that for each community node $u \in N_C$, $\phi'(u)$ may be represented similarly:

$$\phi'(u) = \phi'_C(u) + \phi'_B(u)$$

This reduces the problem of specifying $\phi'(u)$ to specifying $\phi'_C(u)$ and $\phi'_B(u)$. Since the community node subnetwork has already been generated, we set $\phi'_C(u) \leftarrow d^o_C(u)$. Next, recalling that $\phi_B(u) := \frac{\phi_{B,T}}{\phi_T}\phi(u)$, we make the specification $\phi'_B(u) := \frac{\phi_{B,T}}{\phi'_T}\phi(u)$ (which must be solved for via ϕ'_T, in the following). So, in total, we have

$$\phi'(u) = \begin{cases} d^o_C(u) + \frac{\phi_{B,T}}{\phi'_T}\phi(u), & u \in N_C \\ \phi(u), & u \in N_B \end{cases}$$

Therefore we can solve for ϕ'_T with the equation

$$\begin{aligned} \phi'_T &:= \sum_{u \in N_C \cup N_B} \phi'(u) \\ &= \sum_{u \in N_C} \left[d^o_C(u) + \frac{\phi_{B,T}}{\phi'_T}\phi(u) \right] + \sum_{u \in N_B} \phi(u) \\ &= d^o_{C,T} + \frac{\phi_{B,T}}{\phi'_T}\phi_{C,T} + \phi_{B,T} \end{aligned}$$

Where $d^o_{C,T} := \sum_{u \in N_C} d^o_C(u)$. The solution for ϕ'_T from this quadratic is

$$\phi'_T = \frac{\phi_{B,T} + d^o_{C,T}}{2} + \sqrt{\frac{(\phi_{B,T} + d^o_{C,T})^2}{4} + \phi_{C,T}\phi_{B,T}} \tag{64}$$

which then immediately gives the full vector ϕ'. We can now simulate the remaining edges in the network. Specifically, for each $u \in N_B$ and each $v \in N_C \cup N_B$, we simulate an edge according to

$$\mathbb{P}(A_{uv} = 1) = \frac{\phi'(u)\phi'(v)}{\phi'_T} \text{ independent across node pairs} \tag{65}$$

We solve for ψ' analogously. Then for each $u \in N_B$ and each $v \in N$, we simulate an edge weight according to

$$W_{uv} = \begin{cases} f_{uv}(\phi', \psi')\xi_{uv}, & A_{uv} = 1 \\ 0, & A_{uv} = 1 \end{cases}$$

where $\xi \sim F$, is as it was for the generation of the community node subnetwork.

The above simulation steps correspond precisely to the continuous configuration model with parameters $(\phi', \psi', F, \sigma)$. Some basic computational trials have shown that, for large networks, the solution for ϕ'_T is quite close to ϕ_T. Therefore, for each $u \in N_B$, $\mathbb{E}(d(u))$ is almost exactly $\phi(u)$, i.e. what it would be under the model in F.1.2, without background nodes. The same holds for the strengths and expected strengths. Together with equation 65, this implies the background nodes are behaving according to the continuous configuration model, even as they are a sub-network within a larger network with communities.

To illustrate these points, we simulated a sample network from the default framework with parameters $n = 5,000$, $n_b = 1,000$, $s_e = s_w = 3$, disjoint communities, and other parameters specified by F.1.3. These settings are akin to what was used in subsection 6 of the main text. First we plotted ϕ' and ψ' against the empirical strengths and degrees with lowess curves to check the match. Figure 4 shows the fit is essentially linear. Second, for

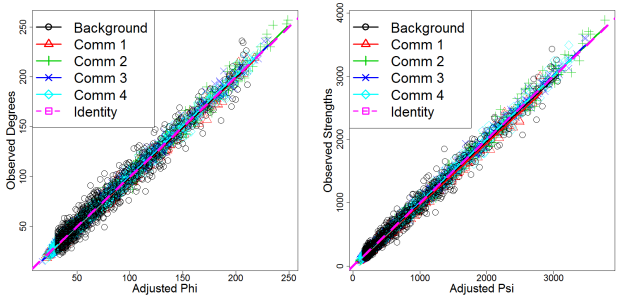

Figure 4: Empirical degrees/strengths vs. adjusted parameters for the example network

each node $u \in N$ and for each node block B (either a true community or the background

node set) we may calculate an empirical z-score for $S(u, B, \mathcal{G})$, as described in subsection 4.1 of the main text. The z-score for $S(u, B, \mathcal{G})$ is a measure of connection significance, with respect to the continuous configuration model (and also modularity, see Section 4.2.3) between u and B. Let K be the number of true communities in the network. For each $i, j = 1, \ldots, K+1$, where $K+1$ is the index of the background node block, we computed the empirical average of z-statistics between nodes u from node block i the node block B corresponding to index j. Theses empirical averages can be arranged in a $(K+1) \times (K+1)$ matrix showing the average inter-block connectivities of the network. In Figure 5 we display a visualization of this matrix, which shows preferential connection within communities, and roughly null connection between the background nodes and all blocks.

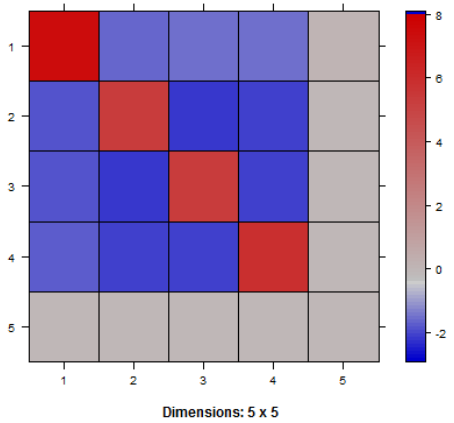

Figure 5: Average empirical z-statistics between nodes and node blocks

F.3 Additional simulation result displays

Here we display the results from our first simulation setting (described in Section 6.2.1) in plots with un-transformed y-axes. Figure 6 reveals that SLPAw seems to respond to increasing community signal, whereas WeightedGT seems to plateau, at least on this range of our parameters.

Editor: Arthur Gretton

Abstract

Topological data analysis (TDA) is an emerging mathematical concept for characterizing shapes in complicated data. In TDA, persistence diagrams are widely recognized as a useful descriptor of data, distinguishing robust and noisy topological properties. This paper introduces a kernel method for persistence diagrams to develop a statistical framework in TDA. The proposed kernel is stable under perturbation of data, enables one to explicitly control the effect of persistence by a weight function, and allows an efficient and accurate approximate computation. The method is applied into practical data on granular systems, oxide glasses and proteins, showing advantages of our method compared to other relevant methods for persistence diagrams.

Keywords: topological data analysis, persistence diagrams, kernel method, kernel embedding, persistence weighted Gaussian kernel

1. Introduction

Recent years have witnessed an increasing interest in utilizing methods of algebraic topology for statistical data analysis. In terms of algebraic topology, conventional clustering methods are regarded as charactering 0-dimensional topological features which mean connected components of data. Furthermore, higher dimensional topological features also represent informative shape of data, such as rings (1-dimension) and cavities (2-dimension). The research analyzing these topological features in data is called *topological data analysis* (TDA) (Carlsson, 2009), which has been successfully applied to various areas including information science (Carlsson et al., 2008; de Silva and Ghrist, 2007), biology (Kasson et al., 2007; Xia and Wei, 2014), brain science (Lee et al., 2011; Petri et al., 2014; Singh et al., 2008), biochemistry (Gameiro et al., 2015), material science (Hiraoka et al., 2016; Nakamura et al., 2015; Saadatfar et al., 2017), and so on. In many of these applications, data have complicated geometric structures, and thus it is important to extract informative topological features from the data.

A *persistent homology* (Edelsbrunner et al., 2002), which is a key mathematical tool in TDA, extracts robust topological information from data, and it has a compact expression called a *persistence diagram*. While it is applied to various problems such as the ones listed above, statistical or machine learning methods for analysis on persistence diagrams are still limited. In TDA, analysts often elaborate only single persistence diagram and, in particular, methods for handling many persistence diagrams, which can contain randomness from the data, are at the beginning stage (see the end of this section for related works). Hence, developing a framework of statistical data analysis on persistence diagrams is a significant issue for further success of TDA and, to this goal, this paper discusses kernel methods for persistence diagrams.

1.1 Topological Descriptor

In order to provide some intuitions for the persistent homology, let us consider a typical way of constructing persistent homology from data points in a Euclidean space, assuming that the point set lies on a submanifold. The aim is to make inference on the topology of the underlying manifold from finite data points. We consider the r-balls (balls with radius r) to recover the topology of the manifold, as popularly employed in constructing an r-neighbor graph in many manifold learning algorithms. While it is expected that, with an appropriate choice of r, the r-ball model can represent the underlying topological structures of the manifold, it is also known that the result is sensitive to the choice of r. If r is too small (resp. large), the union of r-balls consists simply of the disjoint r-balls (resp. a contractible space). Then, by considering not one specific r but all r, the persistent homology gives robust topological features of the point set.

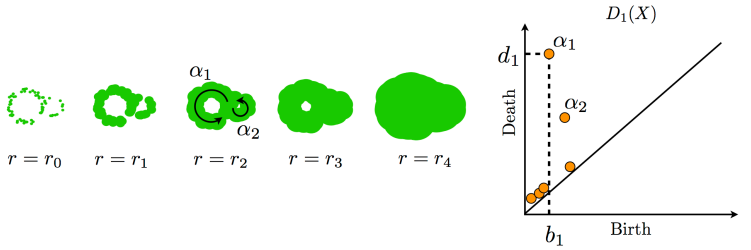

Figure 1: Unions of r-balls at data points (left) and its 1-st persistence diagram (right). The point (b_1, d_1) in the persistence diagram represents the ring α_1, which appears at $r = b_1$ and disappears at $r = d_1$. The noisy rings are plotted as the points close to the diagonal.

As a useful representation of persistent homology, a persistence diagram is often used in topological data analysis. The persistence diagram is given in the form of a multiset $D = \{(b_i, d_i) \in \mathbb{R}^2 \mid i \in I,\ b_i < d_i\}$ (Figure 1). Every point $(b_i, d_i) \in D$, called a *generator* of the persistent homology, represents a topological property (e.g., connected components, rings, cavities, etc.) which appears at $r = b_i$ and disappears at $r = d_i$ in the ball model. Then, the *persistence* $d_i - b_i$ of the generator shows the robustness of the topological property under the radius parameter. A generator with large persistence can be regarded as a reliable structure, while that with small persistence (points close to the diagonal) is likely to be a structure caused by noise. In this way, persistence diagrams encode topological and geometric information of data points.

1.2 Contributions

Since a persistence diagram is a point set of variable size, it is not straightforward to apply standard methods of statistical data analysis, which typically assume vectorial data. To vectorize persistence diagrams, we employ the framework of kernel embedding of (probability and more general) measures into reproducing kernel Hilbert spaces (RKHS). This framework has recently been developed and leading various new methods for nonparametric inference (Muandet et al., 2017; Smola et al., 2007; Song et al., 2013; Lopez-Paz et al., 2015; Szabó et al., 2016). It is known (Sriperumbudur et al., 2011) that, with an appropriate choice of kernels, a signed Radon measure can be uniquely represented by the Bochner integral of the feature vectors with respect to the measure. Since a persistence diagram can be regarded as a sum of Dirac delta measures, it can be embedded into an RKHS by the Bochner integral. Once such a vector representation is obtained, we can introduce any kernel methods for persistence diagrams systematically (see Figure 2).

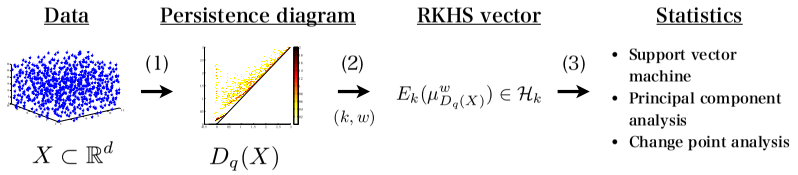

Figure 2: (1) A data set X is transformed into a persistence diagram $D_q(X)$ (Section 2.1). (2) The persistence diagram $D_q(X)$ is mapped to an RKHS vector $E_k(\mu^w_{D_q(X)})$, where k is a positive definite kernel and w is a weight function controlling the effect of persistence (Section 3.1). (3) Statistical methods are applied to those vector representations of persistence diagrams (Section 4).

Furthermore, since each generator in a persistence diagram is equipped with a persistence which indicates a robustness of the topological features, we will utilize it as a weight on the generator. For embedding persistence diagrams in an RKHS, we propose a useful class of positive definite kernels, called *persistence weighted Gaussian kernel* (PWGK). The

advantages of this kernel are as follows: (i) We can explicitly control the effect of persistence by a weight function, and hence discount the noisy generators appropriately in statistical analysis. (ii) As a theoretical contribution, the distance defined by the RKHS norm for the PWGK satisfies the stability property, which ensures the continuity from data to the vector representation of the persistence diagram. (iii) The PWGK allows efficient computation by using the random Fourier features (Rahimi and Recht, 2007), and thus it is applicable to persistence diagrams with a large number of generators.

We demonstrate the performance of the proposed kernel method with synthesized and real-world data, including granular systems (taken by X-ray Computed Tomography on granular experiments), oxide glasses (taken by molecular dynamics simulations) and protein data set (taken by NMR and X-ray crystallography experiments). We remark that these real-world problems have physical and biochemical significance in their own right, as detailed in Section 4.

1.3 Related Works

There are already some relevant works on statistical approaches to persistence diagrams. Some studies discuss how to transform a persistence diagram to a vector (Bubenik, 2015; Reininghaus et al., 2015; Adams et al., 2017; Cang et al., 2015; Robins and Turner, 2016; Donatini et al., 1998). In these methods, a transformed vector is typically expressed in a Euclidean space $\mathbb{R}^k$ or a function space L^p, and simple and ad-hoc summary statistics like means and variances are used for data analysis such as principal component analysis (PCA) and support vector machines (SVMs). In this paper, we will compare the performance among the PWGK, the persistence scale-space kernel (Reininghaus et al., 2015), the persistence landscape (Bubenik, 2015), the persistence image (Adams et al., 2017), and the molecular topological fingerprint (Cang et al., 2015) in several machine learning tasks. Furthermore, we show that our vectorization is a generalization of the persistence scale-space kernel and the persistence image although the constructions are different. We also remark that there are some works discussing statistical properties of persistence diagrams for random data points: Chazal et al. (2015) show convergence rates of persistence diagram estimation, and Fasy et al. (2014) discuss confidence sets in a persistence diagram. These works consider a different but important direction to the statistical methods for persistence diagrams.

The remaining of this paper is organized as follows: In Section 2, we review some basics on persistence diagrams and kernel embedding methods. In Section 3, the PWGK is proposed, and some theoretical and computational issues are discussed. Section 4 shows experimental results and compares the proposed kernel method with other methods.

This paper is an extended version of our ICML paper (Kusano et al., 2016). The difference from this conference version is as follows: (i) Comparisons with other relevant methods, in particular, persistence landscapes and persistence images, have been added to this version. (ii) New experimental results in comparison with other relevant methods. (iii) The theoretical results have been generalized to a class of kernels that satisfy the assumption (K) and weight functions that satisfy assumption (W1) (Propositions 8 and 10). The proofs have been modified accordingly, while the basic line of ideas are the same.

2. Backgrounds

We review the concepts of persistence diagrams and kernel methods. For readers who are not familiar with algebraic topology, we give a brief summary in Appendix A. See also Hatcher (2002) as an accessible introduction to algebraic topology.

2.1 Persistence Diagram

In order to define a persistence diagram, we transform a data set X into a filtration $\mathbb{F}\mathrm{ilt}(X)$ and compute its persistent homology $H_q(\mathbb{F}\mathrm{ilt}(X))$. In this section, we will first introduce this mathematical framework of persistence diagrams. Then, by using a ball model filtration, we will intuitively explain geometrical meanings of persistence diagrams. The ball model filtrations can be generalized toward two constructions using Čech complexes and sub-level sets. The former construction is useful for computations of persistence diagrams and the latter is useful to discuss theoretical properties.

2.1.1 Mathematical Framework of Persistence Diagrams

Let K be a coefficient field of homology.[1] Let $\mathbb{F}\mathrm{ilt} = \{F_a \mid a \in \mathbb{R}\}$ be a (right continuous) *filtration* of simplicial complexes, i.e., F_a is a subcomplex of F_b for $a \leq b$ and $F_a = \bigcap_{a<b} F_b$. Alternatively, $\mathbb{F}\mathrm{ilt}$ may be a filtration of topological spaces: in this case F_a is a subspace of F_b with the same condition as above. For $a \leq b$, the K-linear map induced from the inclusion $F_a \hookrightarrow F_b$ is denoted by $\rho_a^b : H_q(F_a) \to H_q(F_b)$, where $H_q(F_a)$ is the q-th homology of F_a. The q-th *persistent homology* $H_q(\mathbb{F}\mathrm{ilt}) = (H_q(F_a), \rho_a^b)$ of $\mathbb{F}\mathrm{ilt}$ is defined by the family of homology $\{H_q(F_a) \mid a \in \mathbb{R}\}$ and the induced linear maps $\{\rho_a^b \mid a \leq b\}$.

A *homological critical value* of $H_q(\mathbb{F}\mathrm{ilt})$ is the number $a \in \mathbb{R}$ such that the linear map $\rho_{a-\varepsilon}^{a+\varepsilon} : H_q(F_{a-\varepsilon}) \to H_q(F_{a+\varepsilon})$ is not isomorphic for any sufficiently small $\varepsilon > 0$. The persistent homology $H_q(\mathbb{F}\mathrm{ilt})$ is called *tame* if $\dim_K H_q(F_a) < \infty$ for any $a \in \mathbb{R}$ and the number of homological critical values is finite. A tame persistent homology $H_q(\mathbb{F}\mathrm{ilt})$ has a nice decomposition property:

Theorem 1 (Zomorodian and Carlsson (2005)) *A tame persistent homology can be uniquely expressed by*

$$H_q(\mathbb{F}\mathrm{ilt}) \cong \bigoplus_{i \in I} \mathbb{I}[b_i, d_i], \tag{1}$$

where $\mathbb{I}[b_i, d_i] = (U_a, \iota_a^b)$ *consists of a family of* K*-vector spaces*

$$U_a = \begin{cases} K, & b_i \leq a < d_i \\ 0, & \text{otherwise} \end{cases},$$

and $\iota_a^b = \mathrm{id}_K$ *for* $b_i \leq a \leq b < d_i$.[2]

1. In this setting, all homology are K-vector spaces. You may simply consider the case $K = \mathbb{R}$, but the theory is built with an arbitrary field.
2. To be more precise, a persistent homology can be seen as an object of the functor category from the poset category defined by $(\mathbb{R}, \leq)$ to the category of finite dimensional vector spaces. The symbols $\cong$ and $\oplus$ represent the isomorphism and the direct sum in the functor category. It is far beyond the scope of this paper to provide precise definitions of these notions. Interested readers can see Bubenik and Scott (2014) for more details.

Each summand $\mathbb{I}[b_i, d_i]$ means a topological feature in $\mathbb{F}\mathrm{ilt}$ that appears at $a = b_i$ and disappears at $a = d_i$. The birth-death pair $x = (b_i, d_i)$ is called a *generator* of the persistent homology, and $\mathrm{pers}(x) := d_i - b_i$ a *persistence* of x. We note that, when $\dim_K H_q(F_a) \neq 0$ for any $a < 0$ (resp. for any $a > 0$), the decomposition (1) should be understood in the sense that some b_i takes the value $-\infty$ (resp. $d_i = \infty$), where $-\infty, \infty$ are the elements in the extended real $\overline{\mathbb{R}} = \mathbb{R} \cup \{-\infty, \infty\}$. Through the decomposition in Theorem 1, a persistent homology $H_q(\mathbb{F}\mathrm{ilt})$, which is an algebraic object and is not suitable to be analyzed by statistical methods, is transformed into a multi-set of 2-dimensional vectors

$$D_q(\mathbb{F}\mathrm{ilt}) = \left\{ (b_i, d_i) \in \overline{\mathbb{R}}^2 \;\middle|\; i \in I \right\}$$

and we call it the *persistence diagram* of $\mathbb{F}\mathrm{ilt}$.[3]

In this paper, we assume that all persistence diagrams have finite cardinality because a tame persistent homology defines a finite persistence diagram. Moreover, we also assume that all birth-death pairs are bounded, that is, all elements in a persistence diagram take neither ∞ nor $-\infty$.[4] In the following, we also use abstract persistence diagrams (denoted by D or E) given by finite multi-sets above the diagonal $\mathbb{R}^2_{\mathrm{ad}} := \{(b, d) \in \mathbb{R}^2 \mid b < d\}$.

2.1.2 Ball Model Filtrations

The example used in Figure 1 can be expressed as follows. Let $X = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$ be a finite subset in a metric space (M, d_M) and $X_a := \bigcup_{i=1}^n B(\boldsymbol{x}_i; a)$ be a union of balls $B(\boldsymbol{x}_i; a) = \{\boldsymbol{x} \in M \mid d_M(\boldsymbol{x}_i, \boldsymbol{x}) \leq a\}$ with radius $a \geq 0$. For convenience, let $X_a := \emptyset$ $(a < 0)$. Since $\mathbb{X} = \{X_a \mid a \in \mathbb{R}\}$ is a right-continuous filtration of topological spaces and X is a finite set, $H_q(\mathbb{X})$ is tame and the persistence diagram $D_q(\mathbb{X})$ is well-defined. For notational simplicity, the persistence diagram of this ball model filtration is denoted by $D_q(X)$.

We remark that, in this model, there is only one generator in $D_0(X)$ that does not disappear in the filtration; its lifetime is ∞. From now on, we deal with $D_0(X)$ by removing this infinite lifetime generator.[5] Let $\mathrm{diam}(X)$ be the diameter of X defined by $\max_{\boldsymbol{x}_i, \boldsymbol{x}_j \in X} d_M(\boldsymbol{x}_i, \boldsymbol{x}_j)$. Then, all generators appear after $a = 0$ and disappear before $a = \mathrm{diam}(X)$ because $X_{\mathrm{diam}(X)}$ becomes a contractible space. Thus, for any dimension q, all birth-death pairs of $D_q(X)$ have finite values.

2.1.3 Geometric Complexes

We review some standard methods of constructing a filtration from finite sets in a metric space. See also Chazal et al. (2014) for more details.

Let (M, d_M) be a metric space and $X = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$ be a finite subset in M. For a fixed $a \geq 0$, we form a q-simplex $[\boldsymbol{x}_{i_0} \cdots \boldsymbol{x}_{i_q}]$ as a subset $\{\boldsymbol{x}_{i_0}, \ldots, \boldsymbol{x}_{i_q}\}$ of X whenever there exists $\bar{\boldsymbol{x}} \in M$ such that $d_M(\boldsymbol{x}_{i_j}, \bar{\boldsymbol{x}}) \leq a$ for all $j = 0, \ldots, q$, or equivalently, $\cap_{j=0}^q B(\boldsymbol{x}_{i_j}; a) \neq \emptyset$. The set of these simplices forms a simplicial complex, called the *Čech complex* of X with parameter a, denoted by $\check{\mathrm{C}}\mathrm{ech}(X; a)$. For $a < 0$, we define $\check{\mathrm{C}}\mathrm{ech}(X; a)$ as an empty set.

3. A *multi-set* is a set with multiplicity of each point. We regard a persistence diagram as a multi-set, since several generators can have the same birth-death pairs.
4. This assumption will be justified in Section 2.1.2.
5. This is called the *reduced persistence diagram*.

Since there is a natural inclusion $\check{\mathrm{C}}\mathrm{ech}(X;a) \hookrightarrow \check{\mathrm{C}}\mathrm{ech}(X;b)$ whenever $a \leq b$, $\check{\mathrm{C}}\mathrm{ech}(X) = \left\{\check{\mathrm{C}}\mathrm{ech}(X;a) \;\middle|\; a \in \mathbb{R}\right\}$ is a filtration. When M is a subspace of $\mathbb{R}^d$, from the nerve lemma (Hatcher, 2002), it is known that the topology of $\check{\mathrm{C}}\mathrm{ech}(X;a)$ is the same as X_a (Figure 3)[6], and hence $D_q(\check{\mathbb{C}}\mathrm{ech}(X)) = D_q(X)$.

As a similar concept to the Čech complex, the Rips complex (or Vietoris-Rips complex) is also often used in TDA. While the Rips complex gives different topology from the Čech complex, it can be computed much more efficiently; the Rips complex needs only pairwise distances, while the Čech complex needs all the $(q+1)$-combinations among n points for q-th homology, which easily becomes infeasible for large n. For a fixed $a \geq 0$, we form a q-simplex $[\boldsymbol{x}_{i_0} \cdots \boldsymbol{x}_{i_q}]$ as a subset $\left\{\boldsymbol{x}_{i_0}, \ldots, \boldsymbol{x}_{i_q}\right\}$ of X that satisfies $d_M(\boldsymbol{x}_{i_j}, \boldsymbol{x}_{i_k}) \leq 2a$ for all $j, k = 0, \ldots, q$. The set of these simplices forms a simplicial complex, called the *Rips complex* of X with parameter a, denoted by $\mathrm{Rips}(X;a)$. Similarly, the Rips complex also forms a filtration $\mathbb{R}\mathrm{ips}(X)$. In general, $D_q(\mathbb{R}\mathrm{ips}(X))$ is not the same as $D_q(X)$ (see Figure 3). In experiments in this paper, all persistence diagrams are computed by a ball model filtration, which is equivalent to the Čech complex filtration, and we do not use the Rips complex filtration. We remark that, however, there are also applications of Rips complexes (e.g., sensor networks (de Silva and Ghrist, 2007)), and our kernel method and stability results shown in Proposition 8 and Proposition 10 can be applied not only the ball model filtration but also any filtrations including the Rips complex filtration.

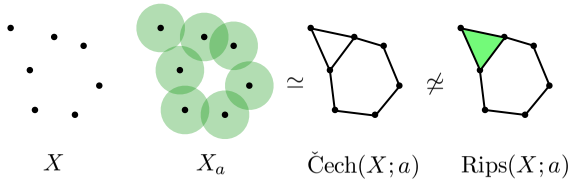

Figure 3: A point set X, the union of balls X_a, the Čech complex $\check{\mathrm{C}}\mathrm{ech}(X;a)$ and the Rips complex $\mathrm{Rips}(X;a)$. There are two rings in X_a and $\check{\mathrm{C}}\mathrm{ech}(X;a)$. However, $\mathrm{Rips}(X;a)$ has only one ring because there is a 2-simplex.

2.1.4 Sub-level Sets

Another popular way of constructing a filtration is to use sub-level sets. This is useful when data is given in the from of a function like a gray-scale image on a two dimensional region. Let M be a topological space and $f : M \to \mathbb{R}$ be a continuous map. Then, we define a *sub-level set* by $\mathrm{Sub}(f;a) := f^{-1}((-\infty, a])$ for $a \in \mathbb{R}$ and its filtration by $\mathbb{S}\mathrm{ub}(f) := \{\mathrm{Sub}(f;a) \mid a \in \mathbb{R}\}$. Here, $f : M \to \mathbb{R}$ is said to be *tame* if $H_q(\mathbb{S}\mathrm{ub}(f))$ is tame.

6. Precisely, they are *homotopy equivalent*.

For a finite set $X = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$ in a metric space (M, d_M), we define the distance function $\mathrm{dist}_X : M \to \mathbb{R}$ by

$$\mathrm{dist}_X(\boldsymbol{x}) := \min_{\boldsymbol{x}_i \in X} d_M(\boldsymbol{x}, \boldsymbol{x}_i).$$

Then, we can see $\mathrm{Sub}(\mathrm{dist}_X; a) = \bigcup_{\boldsymbol{x}_i \in X} B(\boldsymbol{x}_i; a)$ and $D_q(\mathbb{S}\mathrm{ub}(\mathrm{dist}_X)) = D_q(X)$. This means that the ball model is a special case of the sub-level set, and the Čech complex and the sub-level set with the distance function dist_X give the same persistence diagram.

2.2 Stability of Persistence Diagrams

When we consider data analysis based on persistence diagrams, it is useful to introduce a distance measure among persistence diagrams for describing their relations. In introducing a distance measure, it is desirable that, as a representation of data, the mapping from data to a persistence diagram is continuous with respect to the distance. In many cases, data involve noise or stochasticity, and thus the persistence diagrams should be stable under perturbation of data.

The *bottleneck distance* d_{W_∞} between two persistence diagrams D and E is defined by

$$d_{\mathrm{W}_\infty}(D, E) := \inf_{\gamma} \sup_{x \in D \cup \Delta} \|x - \gamma(x)\|_\infty ,$$

where $\Delta := \{(a, a) \mid a \in \mathbb{R}\}$ is the diagonal set with infinite multiplicity and γ ranges over all multi-bijections from $D \cup \Delta$ to $E \cup \Delta$.[7] Here, for $z = (z_1, z_2) \in \mathbb{R}^2$, $\|z\|_\infty$ denotes $\max\{|z_1|, |z_2|\}$. We note that there always exists such a multi-bijection γ because the cardinalities of $D \cup \Delta$ and $E \cup \Delta$ are equal by considering the diagonal set Δ with infinite multiplicity. For sets X and Y in a metric space (M, d_M), let us recall the *Hausdorff distance* d_{H} given by

$$d_{\mathrm{H}}(X, Y) := \max\left\{ \sup_{\boldsymbol{x} \in X} \inf_{\boldsymbol{y} \in Y} d_M(\boldsymbol{x}, \boldsymbol{y}), \sup_{\boldsymbol{y} \in Y} \inf_{\boldsymbol{x} \in X} d_M(\boldsymbol{x}, \boldsymbol{y}) \right\}.$$

Then, the bottleneck distance satisfies the following stability property.

Proposition 2 (Chazal et al. (2014); Cohen-Steiner et al. (2007)) *Let X and Y be finite subsets in a metric space (M, d_M). Then the persistence diagrams satisfy*

$$d_{\mathrm{W}_\infty}(D_q(X), D_q(Y)) \leq d_{\mathrm{H}}(X, Y).$$

Proposition 2 provides a geometric intuition of the stability of persistence diagrams. Assume that two point sets X and Y are close to each other with $\varepsilon = d_{\mathrm{H}}(X, Y)$. If there is a generator $(b, d) \in D_q(Y)$, then we can find at least one generator in X which is born in $(b - \varepsilon, b + \varepsilon)$ and dies in $(d - \varepsilon, d + \varepsilon)$ (see Figure 4). Thus, the stability guarantees the similarity of two persistence diagrams, and hence we can infer the true topological features from the persistence diagrams given by noisy observation (see also Fasy et al. (2014)).

7. A *multi-bijection* is a bijective map between two multi-sets counted with their multiplicity.

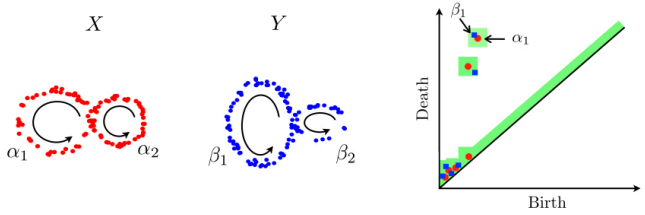

Figure 4: Two point sets X and Y (left) and their persistence diagrams (right). The green region is an ε-neighborhood of $D_q(Y)$ and all generators in $D_q(X)$ are in the ε-neighborhood.

For $1 \leq p < \infty$, the *p-Wasserstein distance* d_{W_p}, which is also used as a distance between two persistence diagrams D and E, is defined by

$$d_{\mathrm{W}_p}(D, E) = \inf_{\gamma} \left(\sum_{x \in D \cup \Delta} \|x - \gamma(x)\|_\infty^p \right)^{\frac{1}{p}},$$

where γ ranges over all multi-bijections from $D \cup \Delta$ to $E \cup \Delta$. Here, we define the *degree-p total persistence* of D by $\mathrm{Pers}_p(D) := \sum_{x \in D} \mathrm{pers}(x)^p$ for $1 \leq p < \infty$.

Proposition 3 (Cohen-Steiner et al. (2010)) *Let $1 \leq p' \leq p < \infty$, and D and E be persistence diagrams whose degree-p' total persistences are bounded from above. Then,*

$$d_{\mathrm{W}_p}(D, E) \leq \left(\frac{\mathrm{Pers}_{p'}(D) + \mathrm{Pers}_{p'}(E)}{2} \right)^{\frac{1}{p}} d_{\mathrm{W}_\infty}(D, E)^{1 - \frac{p'}{p}}.$$

For a persistence diagram D, its degree-p total persistence is bounded from above by $\mathrm{card}\,(D) \times \max_{x \in D} \mathrm{pers}(x)^p$, where $\mathrm{card}\,(D)$ denotes the number of generators in D. However, this bound may be weak because, in general, $\mathrm{card}\,(D)$ cannot be bounded from above. In particular, if data set has noise, the persistence diagram often has many generators close to the diagonal. Thus, it is desirable that the total persistence is bounded from above independently of $\mathrm{card}\,(D)$. In the case of persistence diagrams obtained from a ball model filtration, we have the following upper bound (see Appendix B for the proof):

Lemma 4 *Let M be a triangulable compact subspace in $\mathbb{R}^d$, X be a finite subset of M, and $p > d$. Then,*

$$\mathrm{Pers}_p(D_q(X)) \leq \frac{p}{p-d} C_M \mathrm{diam}(M)^{p-d},$$

where C_M is a constant depending only on M.

Hence, we have the following by combining Proposition 3 and Lemma 4.

Corollary 5 *Let M be a triangulable compact subspace in $\mathbb{R}^d$, X, Y be finite subsets of M, and $p \geq p' > d$. Then*

$$\begin{aligned} d_{\mathrm{W}_p}(D_q(X), D_q(Y)) &\leq \left(\frac{p'}{p'-d} C_M \mathrm{diam}(M)^{p'-d} \right)^{\frac{1}{p}} d_{\mathrm{W}_\infty}(D_q(X), D_q(Y))^{1 - \frac{p'}{p}} \\ &\leq \left(\frac{p'}{p'-d} C_M \mathrm{diam}(M)^{p'-d} \right)^{\frac{1}{p}} d_{\mathrm{H}}(X, Y)^{1 - \frac{p'}{p}} \end{aligned}$$

where C_M is a constant depending only on M.

2.3 Kernel Methods for Representing Signed Measures

As a preliminary to our proposal of vector representation for persistence diagrams, we briefly summarize a method for embedding signed measures with a positive definite kernel.

Let Ω be a set and $k : \Omega \times \Omega \to \mathbb{R}$ be a *positive definite kernel* on Ω, i.e., k is symmetric, and for any number of points $x_1, \ldots, x_n$ in Ω, the Gram matrix $(k(x_i, x_j))_{i,j=1,\ldots,n}$ is nonnegative definite. A popular example of positive definite kernel on $\mathbb{R}^d$ is the Gaussian kernel $k_{\mathrm{G}}(x, y) = e^{-\frac{\|x-y\|^2}{2\sigma^2}}$ $(\sigma > 0)$, where $\|\cdot\|$ is the Euclidean norm in $\mathbb{R}^d$. From the Moore-Aronszajn theorem, it is also known that every positive definite kernel k on Ω is uniquely associated with a reproducing kernel Hilbert space $\mathcal{H}_k$ (RKHS).

We use a positive definite kernel to represent persistence diagrams by following the idea of the kernel mean embedding of distributions (Muandet et al., 2017; Smola et al., 2007; Sriperumbudur et al., 2011). Let Ω be a locally compact Hausdorff space, $M_{\mathrm{b}}(\Omega)$ be the space of all finite signed Radon measures on Ω, and k be a bounded measurable kernel on Ω.[8] Since $\int \|k(\cdot, x)\|_{\mathcal{H}_k} d\mu(x)$ is finite, the integral $\int k(\cdot, x) d\mu(x)$ is well-defined as the Bochner integral (Diestel and Uhl Jr, 1977). Here, we define a mapping from $M_{\mathrm{b}}(\Omega)$ to $\mathcal{H}_k$ by

$$E_k : M_{\mathrm{b}}(\Omega) \to \mathcal{H}_k, \quad \mu \mapsto \int k(\cdot, x) d\mu(x). \tag{2}$$

For a locally compact Hausdorff space Ω, let $C_0(\Omega)$ denote the space of continuous functions vanishing at infinity.[9] A kernel k on Ω is said to be C_0-kernel if $k(\cdot, x) \in C_0(\Omega)$ for any $x \in \Omega$. If k is C_0-kernel, the associated RKHS $\mathcal{H}_k$ is a subspace of $C_0(\Omega)$. A C_0-kernel k is called *C_0-universal* if $\mathcal{H}_k$ is dense in $C_0(\Omega)$. It is known that the Gaussian kernel k_{G} is C_0-universal on $\mathbb{R}^d$ (Sriperumbudur et al., 2011). When k is C_0-universal, the vector $E_k(\mu)$ in the RKHS uniquely determines the finite signed measure μ, and thus serves as a representation of μ. We summarize the property as follows:

Proposition 6 (Sriperumbudur et al. (2011)) *Let Ω be a locally compact Hausdorff space. If k is C_0-universal on Ω, the mapping E_k is injective. Thus,*

$$d_k(\mu, \nu) = \|E_k(\mu) - E_k(\nu)\|_{\mathcal{H}_k}$$

defines a distance on $M_{\mathrm{b}}(\Omega)$.

8. A *Radon measure* μ on Ω is a Borel measure on Ω satisfying (i) $\mu(C) < \infty$ for any compact subset $C \subset \Omega$, and (ii) $\mu(B) = \sup\{\mu(C) \mid C \subset B,\ C\text{:compact}\}$ for any B in the Borel σ-algebra of Ω.
9. A function f is said to *vanish at infinity* if for any $\varepsilon > 0$ there is a compact set $K \subset \Omega$ such that $\sup_{x \in K^c} |f(x)| \leq \varepsilon$.

3. Kernel Methods for Persistence Diagrams

We propose a positive definite kernel for persistence diagrams, called the persistence weighted Gaussian kernel (PWGK), to embed the persistence diagrams into an RKHS. This vectorization of persistence diagrams enables us to apply any kernel methods to persistence diagrams and explicitly control the effect of persistence. We show the stability theorem with respect to the distance defined by the embedding and discuss the efficient and precise approximate computation of the PWGK.

3.1 Vectorization of Persistence Diagrams

We propose a method for vectorizing persistence diagrams using the kernel embedding (2) by regarding a persistence diagram as a discrete measure. In vectorizing persistence diagrams, it is desirable to have flexibility to discount the effect of generators close to the diagonal, since they often tend to be caused by noise. To this goal, we explain slightly different two ways of embeddings, which turn out to give the same inner product for two persistence diagrams.

First, for a persistence diagram D, we introduce a measure $\mu_D^w := \sum_{x\in D} w(x)\delta_x$ with a weight $w(x) > 0$ for each generator $x \in D$ (Figure 5), where δ_x is the Dirac delta measure at x. By appropriately choosing $w(x)$, the measure μ_D^w can discount the effect of generators close to the diagonal. A concrete choice of $w(x)$ will be discussed later.

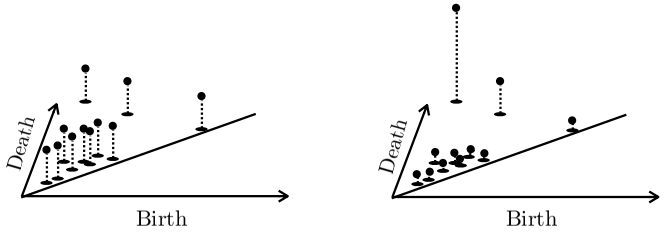

Figure 5: Unweighted (left) and weighted (right) measures.

As discussed in Section 2.3, given a C_0-universal kernel k above the diagonal $\mathbb{R}^2_{\mathrm{ad}} = \{(b,d) \in \mathbb{R}^2 \mid b < d\}$, the measure μ_D^w can be embedded as an element of the RKHS $\mathcal{H}_k$ via

$$\mu_D^w \mapsto E_k(\mu_D^w) := \sum_{x\in D} w(x)k(\cdot, x). \tag{3}$$

From the injectivity in Proposition 6, this mapping identifies a persistence diagram; in other words, it does not lose any information about persistence diagrams. Hence, $E_k(\mu_D^w) \in \mathcal{H}_k$ serves as a vector representation of the persistence diagram.

As the second construction, let

$$k^w(x,y) := w(x)w(y)k(x,y)$$

be the weighted kernel with the same weight function as above.[10] Then the mapping

$$E_{k^w} : \mu_D \mapsto \sum_{x\in D} w(x)w(\cdot)k(\cdot, x) \in \mathcal{H}_{k^w} \tag{4}$$

also defines a vectorization of persistence diagrams. The first construction may be more intuitive by directly weighting a measure, while the second one is also practically useful since all the parameter tuning is reduced to kernel choice. We note that the inner products introduced by two RKHS vectors (3) and (4) are the same:

$$\langle E_k(\mu_D^w), E_k(\mu_E^w)\rangle_{\mathcal{H}_k} = \langle E_{k^w}(\mu_D), E_{k^w}(\mu_E)\rangle_{\mathcal{H}_{k^w}}.$$

In addition, these two RKHS vectors (3) and (4) are essentially equivalent, as seen from the next proposition:

Proposition 7 *Let k be C_0-universal on $\mathbb{R}^2_{\mathrm{ad}}$ and w be a positive function on $\mathbb{R}^2_{\mathrm{ad}}$. Then the following mapping*

$$\mathcal{H}_k \to \mathcal{H}_{k^w}, \quad f \mapsto wf$$

defines an isomorphism between the RKHSs. Under this isomorphism, $E_k(\mu_D^w)$ and $E_{k^w}(\mu_D)$ are identified.

Proof Let $\tilde{\mathcal{H}} := \{wf : \mathbb{R}^2_{\mathrm{ad}} \to \mathbb{R} \mid f \in \mathcal{H}_k\}$ and define its inner product by

$$\langle wf, wg\rangle_{\tilde{\mathcal{H}}} := \langle f, g\rangle_{\mathcal{H}_k}.$$

Then, it is easy to see that $\tilde{\mathcal{H}}$ is a Hilbert space and the mapping $f \mapsto wf$ gives an isomorphism between $\tilde{\mathcal{H}}$ and $\mathcal{H}_k$ of the Hilbert spaces. In fact, we can show that $\tilde{\mathcal{H}}$ is the same as $\mathcal{H}_{k^w}$. To see this, it is sufficient to check that k^w is a reproducing kernel of $\tilde{\mathcal{H}}$ from the uniqueness property of a reproducing kernel for an RKHS. The reproducing property is proven from

$$\langle wf, k^w(\cdot, x)\rangle_{\tilde{\mathcal{H}}} = \langle f, w(x)k(\cdot, x)\rangle_{\mathcal{H}_k} = w(x)f(x) = (wf)(x).$$

The second assertion is obvious. ■

3.2 Stability with respect to the Kernel Embedding

Given a data set X, we compute the persistence diagram $D_q(X)$ and vectorize it as an element $E_k(\mu^w_{D_q(X)})$ of the RKHS. Then, for practical applications, this map $X \mapsto E_k(\mu^w_{D_q(X)})$ should be stable with respect to perturbations to the data as discussed in Section 2.2.

Let D and E be persistence diagrams and $\gamma : D \cup \Delta \to E \cup \Delta$ be any multi-bijection. Here, we partition D (resp. Δ) into D_1 and D_2 (resp. Δ_1 and Δ_2) such as

$$\gamma(D_1) \subset \mathbb{R}^2_{\mathrm{ad}},\ \gamma(D_2) \subset \Delta,\ \gamma(\Delta_1) \subset \mathbb{R}^2_{\mathrm{ad}},\ \gamma(\Delta_2) \subset \Delta.$$

10. From the facts that the product of positive definite kernels are also a positive definite kernel and $f(x,y) = w(x)w(y)$ is a positive definite kernel, k^w is actually a positive definite kernel.

Then $D_1 \cup \Delta_1$ and E are bijective under γ. Now, let a weight function w be zero on the diagonal Δ. Then, the norm of the difference between RKHS vectors is calculated as follows:

$$\begin{aligned}
&\|E_k(\mu_D^w) - E_k(\mu_E^w)\|_{\mathcal{H}_k} \\
&= \left\| \sum_{x\in D} w(x)k(\cdot,x) - \sum_{y\in E} w(y)k(\cdot,y) \right\|_{\mathcal{H}_k} \\
&= \left\| \sum_{x\in D} w(x)k(\cdot,x) - \sum_{x\in D_1\cup\Delta_1} w(\gamma(x))k(\cdot,\gamma(x)) \right\|_{\mathcal{H}_k} \\
&= \left\| \sum_{x\in D\cup\Delta_1} \Big(w(x)k(\cdot,x) - w(\gamma(x))k(\cdot,\gamma(x)) \Big) + \sum_{x\in D_2} w(\gamma(x))k(\cdot,\gamma(x)) \right\|_{\mathcal{H}_k} \\
&= \left\| \sum_{x\in D\cup\Delta_1} \Big(w(x)k(\cdot,x) - w(\gamma(x))k(\cdot,\gamma(x)) \Big) \right\|_{\mathcal{H}_k} \\
&= \left\| \sum_{x\in D} w(x) \Big(k(\cdot,x) - k(\cdot,\gamma(x)) \Big) + \sum_{x\in D\cup\Delta_1} \Big(w(x) - w(\gamma(x)) \Big) k(\cdot,\gamma(x)) \right\|_{\mathcal{H}_k} \\
&\le \sum_{x\in D} w(x) \|k(\cdot,x) - k(\cdot,\gamma(x))\|_{\mathcal{H}_k} + \sum_{x\in D\cup\Delta_1} |w(x) - w(\gamma(x))| \, \|k(\cdot,\gamma(x))\|_{\mathcal{H}_k} .
\end{aligned}$$

Here, let k be a C_0-universal kernel and satisfy the following:

(K) There exist constants $B_k, L_k > 0$ such that

$$\|k(\cdot,x)\|_{\mathcal{H}_k} \le B_k, \quad \|k(\cdot,x) - k(\cdot,y)\|_{\mathcal{H}_k} \le L_k \|x-y\|_\infty \quad (x,y\in\mathbb{R}^2).$$

Then, we have

$$\|E_k(\mu_D^w) - E_k(\mu_E^w)\|_{\mathcal{H}_k} \le L_k \sum_{x\in D} w(x) \|x-\gamma(x)\|_\infty + B_k \sum_{x\in D\cup\Delta_1} |w(x) - w(\gamma(x))| . \quad (5)$$

In this sequel, we consider the Gaussian kernel $k_{\mathrm{G}}(x,y) = e^{-\frac{\|x-y\|^2}{2\sigma^2}}$ $(\sigma > 0)$ for a C_0-universal kernel satisfying (K) by $B_{k_{\mathrm{G}}} = 1$ and $L_{k_{\mathrm{G}}} = \frac{\sqrt{2}}{\sigma}$ (Lemma 16 in Appendix C). Note that the Laplace kernel $k(x,y) = e^{-\alpha\sum_i |x_i - y_i|}$ $(\alpha > 0)$ also satisfies (K) by $B_k = 1$ and $L_k = 4\alpha$.

For a weight function, we consider the following assumption:

(W1) For any persistence diagrams D and E, and any multi-bijection $\gamma : D\cup\Delta \to E\cup\Delta$, there exist constants $B_1, L_1 > 0$ such that

$$\sum_{x\in D} |w(x)| \le B_1, \quad \sum_{x\in D\cup\Delta} |w(x) - w(\gamma(x))| \le L_1 \sup_{x\in D\cup\Delta} \|x-\gamma(x)\|_\infty . \quad (6)$$

If the weight function w satisfies (W1), from Equation (5), we have

$$\|E_k(\mu_D^w) - E_k(\mu_E^w)\|_{\mathcal{H}_k} \le (L_k B_1 + B_k L_1) \sup_{x\in D\cup\Delta} \|x-\gamma(x)\|_\infty .$$

Since this inequality holds for any multi-bijection γ, we obtain the bottleneck stability.

Proposition 8 *Let D and E be persistence diagrams, a C_0-universal kernel k satisfy (K), and a weight function w satisfy (W1). Then,*

$$\|E_k(\mu_D^w) - E_k(\mu_E^w)\|_{\mathcal{H}_k} \le (L_k B_1 + B_k L_1)\, d_{\mathrm{W}_\infty}(D,E).$$

In this paper, among many choices, we propose to use a weight function

$$w_{\mathrm{arc}}(x) = \arctan(C\mathrm{pers}(x)^p) \quad (C>0,\ p\in\mathbb{Z}_{>0}).$$

This is a bounded and increasing function of $\mathrm{pers}(x)$. The corresponding positive definite kernel is

$$k_{\mathrm{PWG}}(x,y) = w_{\mathrm{arc}}(x) w_{\mathrm{arc}}(y) e^{-\frac{\|x-y\|^2}{2\sigma^2}}. \quad (7)$$

We call it *persistence weighted Gaussian kernel* (PWGK). This function w_{arc} gives a small (resp. large) weight on a noisy (resp. essential) generator. In addition, by appropriately adjusting the parameters C and p in w_{arc}, we can control the effect of the persistence. In order to check whether w_{arc} satisfies (W1), we first have

$$\sum_{x\in D} |w_{\mathrm{arc}}(x)| \le C\mathrm{Pers}_p(D) \quad (8)$$

from the fact $w_{\mathrm{arc}}(x) \le C\mathrm{pers}(x)^p$ $(x\in\mathbb{R}^2)$, and

$$\begin{aligned}
&\sum_{x\in D\cup\Delta} |w_{\mathrm{arc}}(x) - w_{\mathrm{arc}}(\gamma(x))| \\
&\le 2pC \sum_{x\in D\cup\Delta_1} \max\{\mathrm{pers}(x)^{p-1}, \mathrm{pers}(\gamma(x))^{p-1}\} \|x-\gamma(x)\|_\infty \ \text{(Lemma 18 in Appendix C)} \\
&\le 2pC \left(\mathrm{Pers}_{p-1}(D\cup\Delta) + \mathrm{Pers}_{p-1}(\gamma(D\cup\Delta))\right) \sup_{x\in D\cup\Delta} \|x-\gamma(x)\|_\infty \\
&\le 2pC \left(\mathrm{Pers}_{p-1}(D) + \mathrm{Pers}_{p-1}(E)\right) \sup_{x\in D\cup\Delta} \|x-\gamma(x)\|_\infty . \quad (9)
\end{aligned}$$

Although total persistences in Equation (8) and Equation (9) are not constant, by restricting a class of persistence diagrams to that of a ball model filtration, w_{arc} satisfies (W1). Therefore, we obtain the bottleneck stability for PWGK:

Theorem 9 *Let M be a triangulable compact subspace in $\mathbb{R}^d$, $X, Y \subset M$ be finite subsets, $p > d+1$, and a C_0-universal kernel k satisfy (K). Then,*

$$\left\| E_k(\mu_{D_q(X)}^{w_{\mathrm{arc}}}) - E_k(\mu_{D_q(Y)}^{w_{\mathrm{arc}}}) \right\|_{\mathcal{H}_k} \le L_{k,\mathrm{arc}} d_{\mathrm{W}_\infty}(D_q(X), D_q(Y)),$$

where $L_{k,\mathrm{arc}}$ is a constant independent of X and Y.

Proof From Lemma 4, for $p-1>d$, there exists a constant $C_M>0$ such that

$$\mathrm{Pers}_p(D_q(X)) \le \frac{p}{p-d} C_M \mathrm{diam}(M)^{p-d},$$
$$\mathrm{Pers}_{p-1}(D_q(X)),\ \mathrm{Pers}_{p-1}(D_q(Y)) \le \frac{p-1}{p-1-d} C_M \mathrm{diam}(M)^{p-1-d}.$$

Thus, from Equation (8) and Equation (9), we obtain the constants in (W1) as

$$B_1 := \frac{p}{p-d} C C_M \mathrm{diam}(M)^{p-d}, \quad L_1 := \frac{4p(p-1)}{p-1-d} C C_M \mathrm{diam}(M)^{p-1-d},$$

and the statement is proven from Proposition 8. Note that

$$\begin{aligned} L_{k,\mathrm{arc}} &:= L_k B_1 + B_k L_1 \\ &= \left(\frac{\pi L_k}{2} \frac{p}{p-d} \mathrm{diam}(M) + B_k \frac{4p(p-1)}{p-1-d} \right) C C_M \mathrm{diam}(M)^{p-1-d}, \end{aligned}$$

is actually a constant independent of X and Y. ■

Let $\mathcal{P}_{\mathrm{finite}}(M)$ be the set of finite subsets in a triangulable compact subspace $M \subset \mathbb{R}^d$. Since the constant $L_{k_{\mathrm{G}},\mathrm{arc}}$ is independent of X and Y, Proposition 2 and Theorem 9 conclude that the map

$$\mathcal{P}_{\mathrm{finite}}(M) \to \mathcal{H}_{k_{\mathrm{G}}}, \quad X \mapsto E_{k_{\mathrm{G}}}(\mu^{w_{\mathrm{arc}}}_{D_q(X)})$$

is Lipschitz continuous. Note again that this implies a desirable stability property of the PWGK with the ball model: small perturbation of data points in terms of the Hausdorff distance causes only small perturbation of the persistence diagrams in terms of the RKHS distance with the PWGK. Note also that the RKHS of the PWGK is infinite dimensional. This can be seen from Proposition 7 and the fact that the Gaussian kernel defines an infinite dimensional RKHS on $\mathbb{R}^2_{\mathrm{ad}}$.

As the most relevant work to the PWGK, the persistence scale-space kernel (PSSK, Reininghaus et al. (2015)) provides another kernel method for vectorization of persistence diagrams and its stability result is shown with respect to 1-Wasserstein distance.[11] However, to the best of our knowledge, 1-Wasserstein stability with respect to the Hausdorff distance is not shown, that is, for point sets X and Y, $d_{\mathrm{W}_1}(D_q(X), D_q(Y))$ is not estimated by $d_{\mathrm{H}}(X,Y)$ such as Proposition 2 or Corollary 5. Furthermore, it is shown (Reininghaus et al., 2015, Theorem 3) that the PSSK does not satisfy the stability with respect to p-Wasserstein distance for $p>1$, including the bottleneck distance d_{W_∞}, and hence it is not ensured that results obtained from the PSSK are stable under perturbation of data points in terms of the Hausdorff distance. On the other hand, since the PWGK has the desirable stability (Theorem 9), it is one of the advantages of our method over the previous research.

For completeness of theoretical discussions, we will show some mathematical results on the the stability with respect to 1-Wasserstein distance for PWGK along the line of Reininghaus et al. (2015). Now, we consider the following assumption (W2) which is weaker than (W1).

11. See Section 4.1.1.

(W2) For any $x, y \in \mathbb{R}^2$, there exist constants $B_2, L_2 > 0$ such that

$$|w(x)| \le B_2, \quad |w(x) - w(y)| \le L_2 \|x-y\|_\infty . \tag{10}$$

Proposition 10 *Let D and E be persistence diagrams, a C_0-universal kernel k satisfy (K), and a weight function w satisfy (W2). Then,*

$$\|E_k(\mu^w_D) - E_k(\mu^w_E)\|_{\mathcal{H}_k} \le (L_k B_2 + B_k L_2)\, d_{\mathrm{W}_1}(D,E).$$

Proof From Equation (5), we have

$$\begin{aligned} \|E_k(\mu^w_D) - E_k(\mu^w_E)\|_{\mathcal{H}_k} &\le L_k \sum_{x\in D} w(x) \|x - \gamma(x)\|_\infty + B_k \sum_{x \in D \cup \Delta_1} |w(x) - w(\gamma(x))| \\ &\le L_k B_2 \sum_{x\in D} \|x-\gamma(x)\|_\infty + B_k L_2 \sum_{x \in D\cup\Delta_1} \|x-\gamma(x)\|_\infty \end{aligned}$$

Since this inequality holds for any multi-bijection γ, the statement is proven. ■

Here, we remark the relation between a weight function and stability. As a weight function, we also consider the following two natural weight functions

$$w_{\mathrm{pers}}(x) := \begin{cases} 0 & (\mathrm{pers}(x) < 0) \\ \frac{1}{L}\mathrm{pers}(x) & (0 \le \mathrm{pers}(x) \le L) \\ 1 & (\mathrm{pers}(x) > L) \end{cases}, \tag{11}$$
$$w_{\mathrm{one}}(x) \equiv 1,$$

where $L>0$ is a parameter. Similar to w_{arc}, a piecewise linear weighting function w_{pers} gives a weight to a generator dependent on its persistence, but it does not satisfy satisfies (W1) since $\sum_{x\in D} w_{\mathrm{pers}}(x) = \frac{1}{L}\mathrm{Pers}_1(D)$, which is not a constant. For an unweighted function w_{one}, it also does not satisfy (W1) since $\sum_{x\in D} w_{\mathrm{one}}(x) = \mathrm{card}\,(D)$. Thus, it is still unknown whether the bottleneck distance stability holds for w_{pers} or w_{one}. On the other hand, since w_{pers} and w_{one} satisfy (W2), the 1-Wasserstein stability holds for these weight functions.[12] Regarding w_{arc}, we proposed it to satisfy (W1) with restriction to the class of persistence diagrams, and obtained the bottleneck stability. For $p=1$, w_{arc} satisfies (W2) by $B_2 = \frac{\pi}{2}$ and $L_2 = 2C$ without any assumptions on persistence diagrams.

Corollary 11 *Let D and E be persistence diagrams and a C_0-universal kernel k satisfy (K). Then,*

$$\left\|E_k(\mu^{w_{\mathrm{pers}}}_D) - E_k(\mu^{w_{\mathrm{pers}}}_E)\right\|_{\mathcal{H}_k} \le \left(L_k + \frac{2B_k}{L}\right) d_{\mathrm{W}_1}(D,E),$$
$$\left\|E_k(\mu^{w_{\mathrm{one}}}_D) - E_k(\mu^{w_{\mathrm{one}}}_E)\right\|_{\mathcal{H}_k} \le L_k d_{\mathrm{W}_1}(D,E),$$
$$\left\|E_k(\mu^{w_{\mathrm{arc}}}_D) - E_k(\mu^{w_{\mathrm{arc}}}_E)\right\|_{\mathcal{H}_k} \le \left(\frac{\pi L_k}{2} + 2B_k C\right) d_{\mathrm{W}_1}(D,E) \quad (p=1 \text{ in } w_{\mathrm{arc}}).$$

12. Regarding w_{pers}, L_2 in (W2) is given by $\frac{2}{L}$. See Lemma 17 in Appendix C

For $p > 1$, in general, w_{arc} does not satisfy (W2) since Ct^p is not Lipschitz continuous with respect to $t \in \mathbb{R}$. Similar to Theorem 9, by restricting to the class of persistence diagrams, we have the 1-Wasserstein stability:

Corollary 12 *Let M be a triangulable compact subspace in $\mathbb{R}^d$, $X, Y \subset M$ be finite subsets, $p > d+1$, and a C_0-universal kernel k satisfy (K). Then,*

$$\left\| E_k(\mu^{w_{\mathrm{arc}}}_{D_q(X)}) - E_k(\mu^{w_{\mathrm{arc}}}_{D_q(Y)}) \right\|_{\mathcal{H}_k} \leq \left(\frac{\pi L_k}{2} + B_k \frac{4p(p-1)}{p-1-d} C C_M \mathrm{diam}(M)^{p-1-d} \right) d_{\mathrm{W}_1}(D_q(X), D_q(Y)),$$

for some constant $C_M > 0$.

Proof For any multi-bijection $\gamma : D_q(X) \cup \Delta \to D_q(Y) \cup \Delta$, we have

$$\begin{aligned} &\sum_{x \in D_q(X) \cup \Delta} |w_{\mathrm{arc}}(x) - w_{\mathrm{arc}}(\gamma(x))| \\ &\leq 2pC \left(\mathrm{Pers}_{p-1}(D_q(X)) + \mathrm{Pers}_{p-1}(D_q(Y)) \right) \sup_{x \in D_q(X) \cup \Delta} \|x - \gamma(x)\|_\infty \quad \text{(from Equation (8))} \\ &\leq \frac{4p(p-1)}{p-1-d} C C_M \mathrm{diam}(M)^{p-1-d} \sum_{x \in D_q(X) \cup \Delta} \|x - \gamma(x)\|_\infty \end{aligned}$$

From Equation (5) and $\arctan(t) \leq \frac{\pi}{2}$ $(t \in \mathbb{R})$, the statement is proven. ■

3.3 Kernel Methods on RKHS

Once persistence diagrams are represented as RKHS vectors, we can apply any kernel methods to those vectors by defining a kernel over the vector representation. In a similar way to the standard vectors, the simplest choice is to consider the inner product as a linear kernel

$$K_{\mathrm{L}}(D, E; k, w) := \langle E_k(\mu^w_D), E_k(\mu^w_E) \rangle_{\mathcal{H}_k} = \sum_{x \in D} \sum_{y \in E} w(x) w(y) k(x, y) \tag{12}$$

on the RKHS and we call it the *(k, w)-linear kernel*.

If k is a C_0-universal kernel and w is strictly positive on $\mathbb{R}^2_{\mathrm{ad}}$, from Proposition 6, $\|E_k(\mu^w_D) - E_k(\mu^w_E)\|_{\mathcal{H}_k}$ defines a distance on the persistence diagrams and it is computed as

$$\sqrt{K_{\mathrm{L}}(D, D; k, w) + K_{\mathrm{L}}(E, E; k, w) - 2K_{\mathrm{L}}(D, E; k, w)}.$$

Then, we can also consider a nonlinear kernel

$$K_{\mathrm{G}}(D, E; k, w) = \exp\left(-\frac{1}{2\tau^2} \|E_k(\mu^w_D) - E_k(\mu^w_E)\|^2_{\mathcal{H}_k} \right) \quad (\tau > 0) \tag{13}$$

on the RKHS and we call it the *(k, w)-Gaussian kernel*.

In this paper, if there is no confusion, we also refer to the $(k_{\mathrm{G}}, w_{\mathrm{arc}})$-Gaussian kernel as the PWGK. Muandet et al. (2012) observed better performance with nonlinear kernels for some complex tasks and this is one of the reasons that we will use the Gaussian kernel on the RKHS.

3.4 Computation of Gram Matrix

Let $\mathcal{D} = \{D_\ell \mid \ell = 1, \ldots, n\}$ be a collection of persistence diagrams. In many practical applications, the number of generators in a persistence diagram can be large, while n is often relatively small; in Section 4.4, for example, the number of generators is about 30000, while $n = 80$.

If the persistence diagrams contain at most m points, each element of the Gram matrix $(K_{\mathrm{G}}(D_i, D_j; k_{\mathrm{G}}, w))_{i,j=1,\ldots,n}$ involves $O(m^2)$ evaluations of $e^{-\frac{\|x-y\|^2}{2\sigma^2}}$, resulting the complexity $O(m^2 n^2)$ for obtaining the Gram matrix. Hence, reducing computational cost with respect to m is an important issue.

We solve this computational issue by using the random Fourier features (Rahimi and Recht, 2007). To be more precise, let $z_1, \ldots, z_{M_{\mathrm{rff}}}$ be random variables from the 2-dimensional normal distribution $N((0,0), \sigma^{-2} I)$ where I is the identity matrix. This method approximates $e^{-\frac{\|x-y\|^2}{2\sigma^2}}$ by $\frac{1}{M_{\mathrm{rff}}} \sum_{a=1}^{M_{\mathrm{rff}}} e^{\sqrt{-1} z_a^T x} (e^{\sqrt{-1} z_a^T y})^*$, where $*$ denotes the complex conjugate. Then, $\sum_{x \in D_i} \sum_{y \in D_j} w(x) w(y) k_{\mathrm{G}}(x, y)$ is approximated by $\frac{1}{M_{\mathrm{rff}}} \sum_{a=1}^{M_{\mathrm{rff}}} B^a_i (B^a_j)^*$, where $B^a_\ell = \sum_{x \in D_\ell} w(x) e^{\sqrt{-1} z_a^T x}$. As a result, the computational complexity of the approximated Gram matrix is $O(mn M_{\mathrm{rff}} + n^2 M_{\mathrm{rff}})$, which is linear to m. In Section 4.3 and Section 4.4, we set $M_{\mathrm{rff}} = 10^5$. For the convergence rate of this approximation with respect to M_{rff}, please see Appendix D.

We note that the approximation by the random Fourier features can be sensitive to the choice of σ. If σ is much smaller than $\|x - y\|$, the relative error can be large. For example, in the case of $x = (1, 2), y = (1, 2.1)$ and $\sigma = 0.01$, $e^{-\frac{\|x-y\|^2}{2\sigma^2}}$ is about 10^{-22} while we observed the approximated value can be about 10^{-4} with $M_{\mathrm{rff}} = 10^5$. As a whole, these m^2 errors may cause a critical error to the statistical analysis. Moreover, if σ is largely deviated from the ensemble $\|x - y\|$ for $x \in D_i, y \in D_j$, then most values $e^{-\frac{\|x-y\|^2}{2\sigma^2}}$ become close to 0 or 1.

In order to obtain a good approximation and extract meaningful values, the choice of parameters is important. For unsupervised case, we follow the heuristics proposed in Gretton et al. (2007) and set

$$\sigma = \mathrm{median}\{\sigma(D_\ell) \mid \ell = 1, \ldots, n\}, \text{ where } \sigma(D) = \mathrm{median}\{\|x_i - x_j\| \mid x_i, x_j \in D,\ i < j\},$$

so that σ takes close values to many $\|x - y\|$. For the parameter C, we also set

$$C = (\mathrm{median}\{\mathrm{pers}(D_\ell) \mid \ell = 1, \ldots, n\})^{-p}, \text{ where } \mathrm{pers}(D) = \mathrm{median}\{\mathrm{pers}(x_i) \mid x_i \in D\}.$$

Similarly, the parameter τ in the (k, w)-Gaussian kernel is defined by

$$\mathrm{median}\left\{ \left\| E_k(\mu^w_{D_i}) - E_k(\mu^w_{D_j}) \right\|_{\mathcal{H}_k} \;\middle|\; 1 \leq i < j \leq n \right\}. \tag{14}$$

For supervised learning such as SVM, we use the cross-validation (CV) approach and do not use the random Fourier features in Section 4.2 and Section 4.5.

4. Experiments

In this section, we apply the kernel method of the PWGK to synthesized and real data, and compare the performance between the PWGK and other statistical methods of persistence diagrams. All persistence diagrams are obtained from the ball model filtrations and computed by CGAL (Da et al., 2015) and PHAT (Bauer et al., 2014). With respect to the dimension of persistence diagrams, we use 2-dimensional persistence diagrams in Section 4.3 and 1-dimensional ones in other parts.

4.1 Comparisons to Previous Works

4.1.1 Persistence Scale-space Kernel

The most relevant work to our method is the one proposed by Reininghaus et al. (2015). Inspired by the heat equation, they propose a positive definite kernel called *persistence scale-space kernel* (PSSK) K_{PSS} on the persistence diagrams:

$$K_{\mathrm{PSS}}(D,E) = \langle \Phi_t(D), \Phi_t(E) \rangle_{L^2(\mathbb{R}^2)} = \frac{1}{8\pi t} \sum_{x\in D} \sum_{y\in E} e^{-\frac{\|x-y\|^2}{8t}} - e^{-\frac{\|x-\bar{y}\|^2}{8t}}, \tag{15}$$

where $\Phi_t(D)(x) = \frac{1}{4\pi t} \sum_{y\in D} e^{-\frac{\|x-y\|^2}{4t}} - e^{-\frac{\|x-\bar{y}\|^2}{4t}}$ and $\bar{y} := (y^2, y^1)$ for $y = (y^1, y^2)$. We note that $\Phi_t(D)$ also takes zero on the diagonal by subtracting the Gaussian kernels for y and $\bar{y}$.

In fact, we can verify that the (k, w)-linear kernel contains the PSSK. Let $\tilde{D} := D \cup D^*$ where $D^* = \{(d, b) \in \mathbb{R}^2 \mid (b, d) \in D\}$. Then, $\Phi_t(D)$ can also be expressed as

$$\Phi_t(D) = \frac{1}{4\pi t} \sum_{y\in \tilde{D}} w_{\mathrm{PSS}}(y) k_{\mathrm{G}}(\cdot, y) \quad \text{where} \quad w_{\mathrm{PSS}}(y) = \begin{cases} 1, & y^2 > y^1 \\ 0, & y \in \Delta \\ -1, & y^2 < y^1 \end{cases},$$

which is equal to $\frac{1}{4\pi t} E_{k_{\mathrm{G}}}(\mu_{\tilde{D}}^{w_{\mathrm{PSS}}})$. Furthermore, the inner product in $\mathcal{H}_{k_{\mathrm{G}}}$ is

$$K_{\mathrm{L}}(\tilde{D}, \tilde{E}; k_{\mathrm{G}}, w_{\mathrm{PSS}}) = \langle E_{k_{\mathrm{G}}}(\mu_{\tilde{D}}^{w_{\mathrm{PSS}}}), E_{k_{\mathrm{G}}}(\mu_{\tilde{E}}^{w_{\mathrm{PSS}}}) \rangle_{\mathcal{H}_{k_{\mathrm{G}}}} = 2 \sum_{x\in D} \sum_{y\in E} k_{\mathrm{G}}(x, y) - k_{\mathrm{G}}(x, \bar{y}). \tag{16}$$

By scaling the variance parameter σ in the Gaussian kernel k_{G} and multiplying by an appropriate scalar, Equation (15) is the same as Equation (16). Thus, the PSSK can also be approximated by the random Fourier features. When we apply the random Fourier features for the PSSK, we set $\tilde{\sigma} = \mathrm{median}\{\sigma(\tilde{D}_\ell) \mid \ell = 1, \cdots, n\}$ as before and $t = \frac{\tilde{\sigma}^2}{4}$.

While both methods discount noisy generators, the PWGK has the following advantages over the PSSK. (i) The PWGK can control the effect of the persistence by C and p in w_{arc} independently of the bandwidth parameter σ in the Gaussian factor, while in the PSSK only one parameter t cannot adjust the global bandwidth and the effect of persistence simultaneously. (ii) The PSSK does not satisfy the stability with respect to the bottleneck distance (see also remarks after Theorem 9).

4.1.2 Persistence Landscape

The *persistence landscape* (Bubenik, 2015) is a well-known approach in TDA for vectorization of persistence diagrams. For a persistence diagram D, the persistence landscape λ_D is defined by

$$\lambda_D(k, t) = k\text{-th largest value of } \min\{t - b_i, d_i - t\}_+,$$

where c_+ denotes $\max\{c, 0\}$, and it is a vector in the Hilbert space $L^2(\mathbb{N} \times \mathbb{R})$. Here, we define a positive definite kernel of persistence landscapes as a linear kernel on $L^2(\mathbb{N} \times \mathbb{R})$:

$$K_{\mathrm{PL}}(D, E) := \langle \lambda_D, \lambda_E \rangle_{L^2(\mathbb{N}\times\mathbb{R})} = \int_{\mathbb{R}} \sum_{k=1} \lambda_D(k, t) \lambda_E(k, t) dt. \tag{17}$$

Since a persistence landscape does not have any parameters, we do not need to consider the parameter tuning. However, the integral computation is required and it causes much computational time. Let $\mathcal{D} = \{D_\ell \mid \ell = 1, \ldots, n\}$ be a collection of persistence diagrams which contain at most m points. Since $\lambda_{D_i}(k, t) \equiv 0$ for any $k > m$, $t \in \mathbb{R}$, $i = 1, \cdots, n$, calculating $\{\lambda_{D_i}(k, t) \mid k \in \mathbb{Z}_{\geq 0}\}$, which needs sorting, is in $O(m \log m)$ (see also Bubenik and Dłotko (2017)). For a fixed t, we can calculate $(\sum_{k=1} \lambda_{D_i}(k, t)\lambda_{D_j}(k, t))_{i,j=1,\cdots,n}$ in $O(nm \log m + n^2 m)$, and the Gram matrix $(K_{\mathrm{PL}}(D_i, D_j))_{i,j=1,\cdots,n}$ in $O(M_{\mathrm{int}}(nm \log m + n^2 m))$, where M_{int} is the number of partitions in the integral interval. Theoretically speaking, this implies that it takes more time to calculate the Gram matrix of K_{PL} than the PWGK and the PSSK by the random Fourier features.

4.1.3 Persistence Image

As a finite dimensional vector representation of a persistence diagram, a *persistence image* is proposed in Adams et al. (2017). First, we prepare a differentiable probability density function $\phi_x : \mathbb{R}^2 \to \mathbb{R}$ with mean x and a weight function $w : \mathbb{R}^2_{\mathrm{ad}} \to \mathbb{R}$. For a persistence diagram D, the *corresponding persistence surface* is defined by

$$\rho_D(z) := \sum_{x\in D} w(x) \phi_x(z). \tag{18}$$

Then, for fixed points $a_0 < \cdots < a_M$ ($a_i \in \mathbb{R}$), the *persistence image*[13] $\mathrm{PI}(D)$ is defined by an $M \times M$ matrix whose (i, j)-element is assigned to the integral of ρ_D over the pixel $P_{i,j} := (a_{i-1}, a_i] \times (a_{j-1}, a_j]$, i.e.,

$$\mathrm{PI}(D)_{i,j} := \int_{P_{i,j}} \rho_D(z) dz.$$

Since the persistence image can be regarded as an M^2-dimensional vector, we define a vector $\mathrm{PIV}(D) \in \mathbb{R}^{M^2}$ by

$$\mathrm{PIV}(D)_{i+M(j-1)} := \mathrm{PI}(D)_{i,j}, \tag{19}$$

13. Adams et al. (2017) use a persistence diagram in birth-persistence coordinates. That is, by a linear transformation $T(b, d) = (b, d - b)$, a persistence diagram D is transformed into $T(D)$. In this paper, in order to compare with the persistence image and the PWGK, we use birth-death coordinates.

and, in this paper, call it the persistence image vector.

In Adams et al. (2017), they use the 2-dimensional Gaussian distribution $\frac{1}{2\pi\sigma^2}k_{\mathrm{G}}(x,z)$ as $\phi_x(z)$ and a piecewise linear weighting function $w_{\mathrm{pers}}(x)$. In this paper, for a collection of persistence diagrams $\mathcal{D} = \{D_\ell \mid \ell = 1,\dots,n\}$, we set a parameter L in Equation (11) as

$$L = \max\{L(D_\ell) \mid \ell = 1,\cdots,n\}, \text{ where } L(D) = \max\{d_i \mid (b_i,d_i) \in D\}.$$

For points $a_0 < \cdots < a_M$ of a pixel $P_{i,j} = (a_{i-1},a_i] \times (a_{j-1},a_j]$, we set $a_M = L$ and $a_i = \frac{i}{M}a_M$ for $0 \le i \le M$.[14]

Here, by choosing ϕ_x and w in the proposed way, we define a positive definite kernel of persistence image vector as a linear kernel on $\mathbb{R}^{M^2}$:

$$\begin{aligned} K_{\mathrm{PI}}(D,E) &:= \langle \mathrm{PIV}(D), \mathrm{PIV}(E)\rangle_{\mathbb{R}^{M^2}} \\ &= \sum_{i,j=1}^{M} \mathrm{PI}(D)_{i,j}\mathrm{PI}(E)_{i,j} \\ &= \frac{1}{(2\pi\sigma^2)^2}\sum_{x\in D}\sum_{y\in E} w_{\mathrm{pers}}(x)w_{\mathrm{pers}}(y)\sum_{i,j=1}^{M}\int_{P_{i,j}} k_{\mathrm{G}}(x,z)dz\int_{P_{i,j}} k_{\mathrm{G}}(y,z)dz. \quad (20) \end{aligned}$$

If we choose $\phi_x(z)$ as a (normalized) positive definite kernel $k(x,z)$, the corresponding persistence surface ρ_D (18) is the same as the RKHS vector $E_k(\mu_D^w)$. Thus, it may be expected that the persistence image and the PWGK show similar performance for data analysis. However, there are several differences between the persistence image and the PWGK. (i) Underlying vector spaces are different: the PWGK vector $E_k(\mu_D^w)$ is always in the RKHS and the corresponding persistence surface ρ_D is in $L^p(\mathbb{R}^2)$ with appropriate conditions. Hence, the inner product structures are also different.[15] (ii) Regarding the mapping from a persistence diagram to the corresponding persistence surface, the injectivity is not discussed in the original paper (Adams et al., 2017). On the other hand, from Proposition 6, we can easily check the injectivity of the RKHS vector $E_k(\mu_D^w)$ due to its construction based on kernel method. (iii) It is also shown that the persistence image has a stability result with respect to 1-Wasserstein distance, but it does not satisfy the bottleneck stability (Remark 1 in Adams et al. (2017)) or the Haussdorff stability as noted after Theorem 9. This instability is considered to be caused by the norm of the persistence image, which is different from the RKHS. (iv) The computational complexity of a persistence image does not depend on the number of generators in a persistence diagram, but instead, it depends on the number of pixels M^2. Precisely, the Gram matrix $(K_{\mathrm{PI}}(D_i,D_j))_{i,j=1,\cdots,n}$ is calculated in $O(n^2M^2)$. We can reduce the computational time of the persistence image by choosing a small mesh size M. However, some situations need a fine mesh (i.e., a large mesh size), and thus, we have to be careful with the choice of mesh size. In Section 4.2.2, we will discuss the effect of the mesh size on the classification performance of the persistence image.

14. Here, we set $a_0 = 0$ because all generators in the ball model filtrations are born after $b = 0$.

15. Since the persistence image vector $\mathrm{PIV}(D)$ (19) is a discretization of ρ_D, the inner product (20) can be also seen as a discretization of L^2 inner product of the corresponding persistence surfaces

$$\langle \rho_D, \rho_E\rangle_{L^2(\mathbb{R}^2)} = \frac{1}{(2\pi\sigma^2)^2}\sum_{x\in D}\sum_{y\in E} w_{\mathrm{pers}}(x)w_{\mathrm{pers}}(y)\int_{\mathbb{R}^2} k_{\mathrm{G}}(x,z)k_{\mathrm{G}}(y,z)dz.$$

Furthermore, since $\int_{\mathbb{R}^2} e^{-\frac{\|x-z\|^2}{2\sigma^2}}e^{-\frac{\|y-z\|^2}{2\sigma^2}}dz \propto e^{-\frac{\|x-y\|^2}{4\sigma^2}}$, $K_{\mathrm{PI}}(D,E)$ is also a discretization of the inner product of the RKHS vectors $K_{\mathrm{L}}(D,E;k_{\mathrm{G}},w_{\mathrm{arc}})$ by scaling the variance parameter σ in k_{G}. However, this is a special case, and it is not always to be true for any positive definite kernel.

4.2 Classification with Synthesized Data

We compare the performance among the PWGK, the PSSK, the persistence landscape, and the persistence image for a simple binary classification task with SVMs.

4.2.1 Synthesized Data

In this experiment, we design data sets so that important generators close to the diagonal must be taken into account to solve the classification task.

Let $S^1(x,y,r,N)$ be a set composed of N points sampled with equal distance from a circle in 2-dimensional Euclidean space with radius r centered at (x,y). When we compute the persistence diagram of $S^1(x,y,r,N)$ for $N > 3$, there always exists a generator whose birth time is approximately $\frac{\pi r}{N}$ (here we use $\sin\theta \approx \theta$ for small θ) and death time is r (Figure 6).

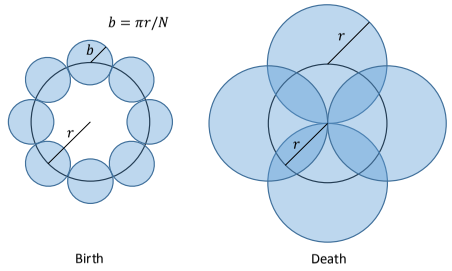

Figure 6: Birth and death of the generator for $S^1(x,y,r,N)$.

In order to add randomness on $S^1(x,y,r,N)$, we extend it into $\mathbb{R}^3$ and change $S^1(x,y,r,N)$ to $S^1_z(x,y,r,N)$ and $\tilde{S}^1_z(x,y,r,N)$ as follows:

$$\begin{aligned} S^1_z(x,y,r,N) &:= \{(z_1,z_2,z_3) \mid (z_1,z_2) \in S^1(x,y,r,N),\ z_3 \text{ is uniformly sampled from } [0,0.01]\} \\ \tilde{S}^1_z(x,y,r,N) &:= S^1_z(x+W_x^2, y+W_y^2, r+W_r^2, \lceil N+2W_N\rceil), \end{aligned}$$

where $W_x, W_y \sim N(0,2)$, $W_r, W_N \sim N(0,1)$ and $\lceil c\rceil$ is the smallest integer greater than or equal to c.[16] Then, we add $S_2 := S^1_z(x_2,y_2,r_2,N_2)$ to $S_1 := \tilde{S}^1_z(x_1,y_1,r_1,N_1)$ with probability 0.5 and use it as the synthesized data.

16. $N(\mu,\sigma^2)$ is the 1-dimensional normal distribution with mean μ and variance σ^2.

In this paper, we choose parameters by

$$r_1 = 1 + 8W^2 \quad (W \sim N(0,1)),$$
$$x_1 = y_1 = 1.5 r_1,$$
$$N_1 \ : \text{ a random integer with equal probability in } (\lceil \frac{\pi r}{2} \rceil, 4\pi r),$$

and set (x_2, y_2, r_2, N_2) as $(0, 0, 0.2, 10)$ (Figure 7).

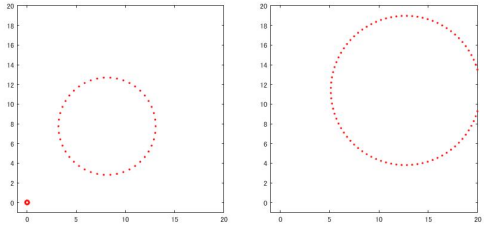

Figure 7: Examples of synthesized data. Left: S_2 exists. Right: S_2 does not exist.

For the binary classification, we introduce the following labels:

$z_0 = 1$ if there exists a generator (b, d) in the persistence diagram such that $b \leq 1$ and $d \geq 4$.

$z_1 = 1$ if S_2 exists.

The class label of the data set is then given by $\mathbf{XOR}(z_0, z_1)$. By this construction, identifying z_0 requires relatively smooth function in the area of long lifetimes, while classifying the existing of z_1 needs delicate control of the resolution around the diagonal.

4.2.2 SVM Results

SVMs are trained from persistence diagrams given by 100 data sets, and evaluated with 100 independent test data sets. As a positive definite kernel k, we choose the Gaussian kernel k_{G} and the linear kernel $k_{\mathrm{L}}(x, y) := \langle x, y \rangle_{\mathbb{R}^2}$. For a weight function w, we use the proposed function $w_{\mathrm{arc}}(x) = \arctan(C\mathrm{pers}(x)^p)$, the piecewise linear weighting function $w_{\mathrm{pers}}(x)$, and an unweighted function $w_{\mathrm{one}}(x) \equiv 1$. The hyper-parameters (σ, C) in the PWGK and t in the PSSK are chosen by the 10-fold cross-validation, and the degree p in $w_{\mathrm{arc}}(x)$ is set as $1, 5, 10$. For K_{PSS} and K_{PL}, while they originally consider only the inner product, we also apply the Gaussian kernels on RKHS following Equation (13). Since K_{PI} can be seen as a discretization of the $(k_{\mathrm{G}}, w_{\mathrm{pers}})$-linear kernel, we also construct another kernel of persistence image by replacing w_{pers} with w_{arc}, which is considered as a discretization of the PWGK. In order to check whether the persistence image with w_{arc} is an appropriate discretization of the PWGK, we try several mesh size $M = 20, 50, 100$.

In Table 1, we can see that the PWGK $\triangle$ and the Gaussian kernel on the persistence image with w_{arc} and large mesh size $\square_{100}$ show higher classification rates (85% accuracy)

		Linear	Gaussian
PWGK			
kernel	**weight**		
k_{G}	w_{arc} $(p = 1)$	75.7 ± 2.31	85.8 ± 5.19 (PWGK)
	w_{arc} $(p = 5)$	75.8 ± 2.47 ($\triangle$)	85.6 ± 5.01 (PWGK, $\square$)
	w_{arc} $(p = 10)$	76.0 ± 2.39	86.0 ± 4.98 (PWGK)
	w_{pers}	49.3 ± 2.72	52.3 ± 6.60
	w_{one}	53.8 ± 4.76	55.1 ± 8.42
k_{L}	w_{arc} $(p = 5)$	49.3 ± 6.92	51.8 ± 3.52
	w_{pers}	51.0 ± 6.84	55.7 ± 8.68
	w_{one}	50.5 ± 6.90	53.0 ± 4.89
PWGK with Persistence image			
$M = 20$	w_{arc} $(p = 5)$	48.8 ± 3.75 ($\triangle_{20}$)	52.0 ± 5.65 ($\square_{20}$)
$M = 50$	w_{arc} $(p = 5)$	49.2 ± 5.77 ($\triangle_{50}$)	51.8 ± 7.23 ($\square_{50}$)
$M = 100$	w_{arc} $(p = 5)$	75.0 ± 2.20 ($\triangle_{100}$)	85.8 ± 4.15 ($\square_{100}$)
PSSK		50.5 ± 5.60 (K_{PSS})	53.6 ± 6.69
Persistence landscape		50.6 ± 5.92 (K_{PL})	48.8 ± 4.25
Persistence image			
$M = 20$	w_{pers}	51.1 ± 4.38 (K_{PI})	51.7 ± 6.86
$M = 50$	w_{pers}	49.0 ± 6.14 (K_{PI})	52.3 ± 7.21
$M = 100$	w_{pers}	54.5 ± 8.76 (K_{PI})	52.1 ± 6.70

Table 1: Results of SVMs with the (k, w)-linear/Gaussian kernel, the PSSK, the persistence landscape, and the persistence image. Average classification rates (%) and standard deviations for 100 test data sets are shown.

than the other methods (K_{PSS} : 50%, K_{PL} : 50%, and K_{PI} : 55%). Although the $(k_{\mathrm{G}}, w_{\mathrm{pers}})$-Gaussian kernel and the persistence image with the original weight w_{pers} discount noisy generators, the classification rates are close the chance level. These unfavorable results must be caused by the difficulty in handling the local and global locations of generators simultaneously. While the result of the persistence image with a large mesh size is similar to that of the PWGK (e.g., $\square$ and $\square_{100}$), a small mesh size gives bad approximation results (e.g., $\square$ and $\square_{50}$). The reason is because a small mesh size makes rough pixels, and S_2 itself and noisy generators are treated in some rough pixel. On the other hand, we remark that a large mesh size M needs much computational time.

We observe that the classification accuracies are not sensitive to p. Thus, in the rest of this paper, we set $p = 5$ because the assumption $p > d + 1$ in Theorem 9 ensures the continuity in the kernel embedding of persistence diagrams and all data points are obtained from $\mathbb{R}^3$.

4.3 Analysis of Granular System

We apply the PWGK, the PSSK, the persistence landscape, and the persistence image to persistence diagrams obtained by experimental data in a granular packing system (Francois et al., 2013). In this example, a partially crystallized packing with 150,000 monosized beads (diameter = 1mm, polydispersity = 0.025mm) in a container is obtained by experiments, where the configuration of the beads is imaged by means of X-ray Computed Tomography. One of the fundamental interests in the study of granular packings is to understand the transition from random packings to crystallized packings. In particular, the maximum packing density ϕ_* that random packings can attain is still a controversial issue (e.g., see Torquato et al. (2000)). Here, we apply the change point analysis to detect ϕ_*.

In oder to observe configurations of various densities, we divide the original full system into 35 cubical subsets containing approximately 4000 beads. The data are provided by the authors of the paper (Francois et al., 2013). The packing densities of the subsets range from $\phi = 0.590$ to $\phi = 0.730$. Saadatfar et al. (2017) computed a persistence diagram for each subset by taking the beads configuration as a finite subset in $\mathbb{R}^3$, and found that the persistence diagrams characterize different configurations in random packings (small ϕ) and crystallized packings (large ϕ). Hence, it is expected that the change point analysis applied to these persistence diagrams can detect the maximum packing density ϕ_* as a transition from the random to crystallized packings.

Our strategy is to regard the maximum packing density as the change point and detect it from a collection $\mathcal{D} = \{D_\ell \mid \ell = 1, \ldots, n\}$ $(n = 35)$ of persistence diagrams made by beads configurations of granular systems, where ℓ is the index of the packing densities listed in the increasing order. As a statistical quantity for the change point detection, we use the kernel Fisher discriminant ratio (Harchaoui et al., 2009) defined by

$$\mathrm{KFDR}_{n,\ell,\gamma}(\mathcal{D}) = \frac{\ell(n-\ell)}{n} \left\| \left(\frac{\ell}{n} \hat{\Sigma}_{1:\ell} + \frac{n-\ell}{n} \hat{\Sigma}_{\ell+1:n} + \gamma I \right)^{-\frac{1}{2}} (\hat{\mu}_{\ell+1:n} - \hat{\mu}_{1:\ell}) \right\|_{\mathcal{H}_K}, \qquad (21)$$

where the empirical mean element $\hat{\mu}_{i:j}$ and the empirical covariance operator $\hat{\Sigma}_{i:j}$ with data D_i through D_j $(i < j)$ are given by

$$\hat{\mu}_{i:j} = \frac{1}{j-i+1} \sum_{\ell=i}^{j} K(\cdot, D_\ell),$$

$$\hat{\Sigma}_{i:j} = \frac{1}{j-i+1} \sum_{\ell=i}^{j} (K(\cdot, D_\ell) - \hat{\mu}_{i:j}) \otimes (K(\cdot, D_\ell) - \hat{\mu}_{i:j})$$

respectively, and γ is a regularization parameter (in this paper we set $\gamma = 10^{-3}$). The index ℓ achieving the maximum of $\mathrm{KFDR}_{n,\ell,\gamma}(\mathcal{D})$ corresponds to the estimated change point. In Figure 8, all the four methods detect $\ell = 23$ as the sharp maximizer of the KFDR. This result indicates that the maximum packing density ϕ_* exists in the interval $[0.604, 0.653]$ and supports the traditional observation $\phi_* \approx 0.636$ (Anonymous, 1972).

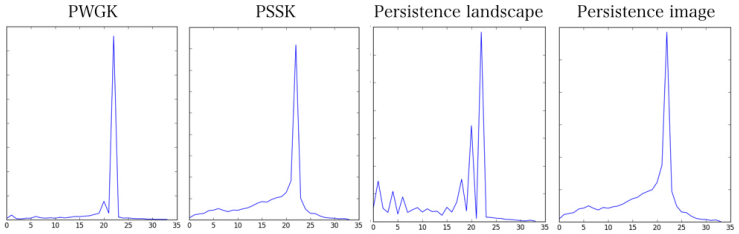

Figure 8: The KFDR graphs of the PWGK, the PSSK, the persistence landscape, and the persistence image.

We also apply kernel principal component analysis (KPCA) to the same collection of the 35 persistence diagrams. Figure 9 shows the 2-dimensional KPCA plots where each blue cross (resp. red circle) indicates the persistence diagram of random packing (resp. crystallized packing). We can see clear two-cluster structure corresponding to two physical states.

4.4 Analysis of SiO_2

When we rapidly cool down the liquid state of SiO_2, it avoids the usual crystallization and changes into a glass state. Understanding the liquid-glass transition is an important issue for the current physics and industrial applications (Greaves and Sen, 2007). Glass is an amorphous solid, which does not have a clear structure in the configuration of molecules, but it is also known that the medium distance structure such as rings have important influence on the physical properties of the material. It is thus promising to apply the persistent homology to express the topological and geometrical structure of the glass configuration. For estimating the glass transition temperature by simulations, a traditional physical method is

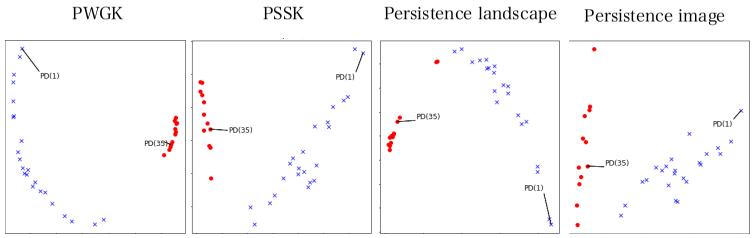

Figure 9: The KPCA plots of the PWGK (contribution rate: 92.9%), the PSSK (99.7%), the persistence landscape (83.8%), and the persistence image (98.7%).

to prepare atomic configurations of SiO_2 for a certain range of temperatures by molecular dynamics simulations, and then draw the temperature-enthalpy graph. The graph consists of two lines in high and low temperatures with slightly different slopes which correspond to the liquid and the glass states, respectively, and the glass transition temperature is conventionally estimated as an interval of the transient region combining these two lines (e.g., see Elliott (1990)). However, since the slopes of two lines are close to each other, determining the interval is a subtle problem. Usually only the rough estimate of the interval is available. Hence, we apply our framework of topological data analysis with kernels to detect the glass transition temperature.

Let $\{D_\ell \mid \ell = 1, \ldots, 80\}$ be a collection of the persistence diagrams made by atomic configurations of SiO_2 and sorted by the decreasing order of the temperature. The same data was used in the previous works by Hiraoka et al. (2016); Nakamura et al. (2015). The interval of the glass transition temperature T estimated by the conventional method explained above is $2000K \leq T \leq 3500K$, which corresponds to $35 \leq \ell \leq 50$.

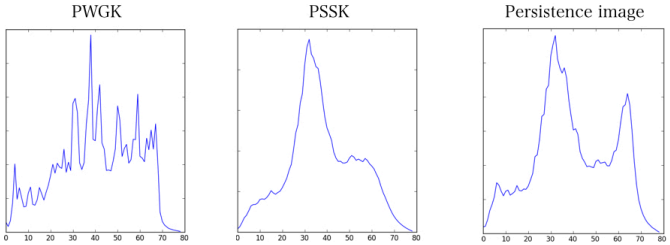

Figure 10: The KFDR graphs of the PWGK (left), the PSSK (center) and the persistence image (right).

In Figure 10, the KFDR plots show that the change point is estimated as $\ell = 39$ by the PWGK, $\ell = 33$ by the PSSK, and $\ell = 33$ by the persistence image. For the persistence landscape, we cannot obtain the KFDR or the KPCA results with reasonable computational time.

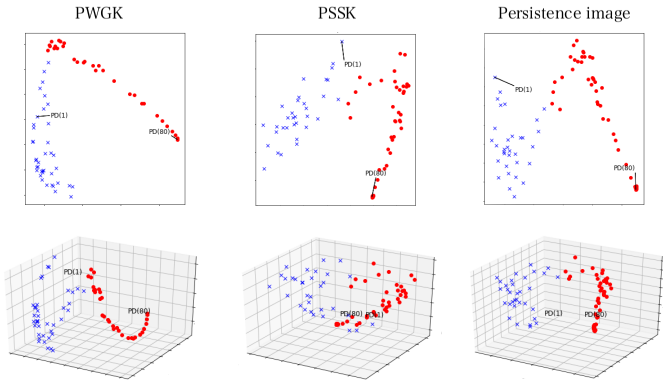

Figure 11: The 2-dimensional and 3-dimensional KPCA plots of the PWGK (contribution rates for 2-dimension: 81.7%, 3-dimension: 92.1%), the PSSK (97.2%, 99.3%) and the persistence image (99.9%, 99.9%).

As we see from the 2-dimensional plots given by KPCA (Figure 11), the PWGK presents sharp change of the gradients between before (blue cross) and after (red circle) the change point determined by the KFDR. This matches with the analysis in physics that expects a sharp change of slope in the temperature-enthalpy plane. This strongly suggests that the glass transition occurs at the detected change point. On the other hand, in the results of PSSK and persistence images we cannot observe a sharp change of the gradients at the boundary of the estimated two phases. We also remark that clearer structures are observed in the 3-dimensional KPCA plots of the PWGK.

4.5 Protein Classification

We apply the PWGK to two classification tasks studied in Cang et al. (2015). They introduced the molecular topological fingerprint (MTF) as a feature vector constructed from the persistent homology, and used it for the input to the SVM. The MTF is given by the 13-dimensional vector whose elements consist of the persistences of some specific generators

	Protein-Drug	Hemoglobin
PWGK	100	88.90
MTF	(nbd) 93.91 / (bd) 98.31	84.50

Table 2: CV classification rates (%) of SVMs with the PWGK and the MTF (cited from Cang et al. (2015)).

in persistence diagrams.[17] We compare the performance between the PWGK and the MTF method under the same setting of the SVM reported in Cang et al. (2015).

The first task is a protein-drug binding problem, where the binding and non-binding of drug to the M2 channel protein of the influenza A virus is to be classified. For each of the two forms, 15 data were obtained by NMR experiments, and 10 data are used for training and the remaining for testing. We randomly generate 100 ways of partitions and calculate the average classification rates.

In the second problem, the taut and relaxed forms of hemoglobin are to be classified. For each form, 9 data were collected by the X-ray crystallography. We select one data from each class for testing and use the remaining for training. All the 81 combinations are performed to calculate the CV classification rates.

The results of the two problems are shown in Table 4.5. We can see that the PWGK achieves better performance than the MTF in both problems.

5. Conclusion and Discussions

One of the contributions of this paper is to introduce a kernel framework to topological data analysis with persistence diagrams. We applied the kernel embedding approach to vectorize the persistence diagrams, which enables us to utilize any standard kernel methods for data analysis. Another contribution is to propose a kernel specific to persistence diagrams, that is called persistence weighted Gaussian kernel (PWGK). As a significant advantage, our kernel enables one to control the effect of persistence in data analysis. We have also proven the stability property with respect to the distance in the Hilbert space. Furthermore, we have analyzed the synthesized and real data by using the proposed kernel. The change point detection, the principal component analysis, and the support vector machine derived meaningful results for the tasks. From the viewpoint of computations, our kernel can utilize an efficient approximation to compute the Gram matrix.

One of the main theoretical results of this paper is the bottleneck stability of the PWGK (Theorem 9). It is obtained by restricting the class of persistence diagrams to that obtained from ball model filtrations. The reason of this restriction is because the total persistence can be bounded from above independent of the persistence diagram. Thus, one direction to extend this work is to examine the boundedness condition about the total persistence of other persistence diagrams, for example obtained from Rips complexes or sub-level sets.

17. The MTF method is not a general method for persistence diagrams because some elements of the MTF vector are specialized for protein data, e.g., the ninth element of the MTF vector is defined by the number of Betti 1 bars that locate at $[4.5, 5.5]$Å, divided by the number of atoms. For the details, see Cang et al. (2015).

Another direction to extend this work is to generalize the class of weight functions. The reason of the choice of w_{arc} is mainly for the stability property, but in principle, we can apply any weight function to data analysis. Even if we do not concern about stability properties, which weight function is practically good for data analysis? Suppose generators close to the diagonal are sometimes seen as important features. Then, our statistical framework can treat such small generators as significant ones by a weight function which has large weight close to the diagonal, while other statistical methods for persistence diagrams always see small generators as noisy ones. In addition, the weight function becomes better when it is constructed to satisfy the assumption (W1) or (W2), which implies the stability property.

Appendix A. Topological tools

This section summarizes some topological tools used in the paper. To study topological properties algebraically, simplicial complexes are often considered as basic objects. We start with a brief explanation of simplicial complexes, and gradually increase the generality from simplicial homology to singular and persistent homology. For more details, see Hatcher (2002).

A.1 Simplicial complex

We first introduce a combinatorial geometric model called simplicial complex to define homology. Let $P = \{1, \dots, n\}$ be a finite set (not necessarily points in a metric space). A *simplicial complex* with the vertex set P is defined by a collection S of subsets in P satisfying the following properties:

1. $\{i\} \in S$ for $i = 1, \dots, n$, and
2. if $\sigma \in S$ and $\tau \subset \sigma$, then $\tau \in S$.

Each subset σ with $q+1$ vertices is called a q-simplex. We denote the set of q-simplices by S_q. A subcollection $T \subset S$ which also becomes a simplicial complex (with possibly less vertices) is called a subcomplex of S.

We can visually deal with a simplicial complex S as a polyhedron by pasting simplices in S into a Euclidean space. The simplicial complex obtained in this way is called a geometric realization, and its polyhedron is denoted by $|S|$. In this context, the simplices with small q correspond to points ($q = 0$), edges ($q = 1$), triangles ($q = 2$), and tetrahedra ($q = 3$).

Example 1 Figure 12 shows two polyhedra of simplicial complexes

$$S = \{\{1\}, \{2\}, \{3\}, \{1,2\}, \{1,3\}, \{2,3\}, \{1,2,3\}\},$$
$$T = \{\{1\}, \{2\}, \{3\}, \{1,2\}, \{1,3\}, \{2,3\}\}.$$

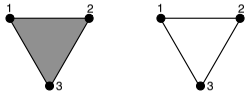

Figure 12: The polyhedra of the simplicial complexes S (left) and T (right).

A.2 Homology

A.2.1 Simplicial homology

The procedure to define homology is summarized as follows:

1. Given a simplicial complex S, build a chain complex $C_*(S)$. This is an algebraization of S characterizing the boundary.

2. Define homology by quotienting out certain subspaces in $C_*(S)$ characterized by the boundary.

We begin with the procedure 1 by assigning orderings on simplices. When we deal with a q-simplex $\sigma = \{i_0, \dots, i_q\}$ as an ordered set, there are $(q+1)!$ orderings on σ. For $q > 0$, we define an equivalence relation $i_{j_0}, \dots, i_{j_q} \sim i_{\ell_0}, \dots, i_{\ell_q}$ on two orderings of σ such that they are mapped to each other by even permutations. By definition, two equivalence classes exist, and each of them is called an oriented simplex. An oriented simplex is denoted by $\langle i_{j_0}, \dots, i_{j_q}\rangle$, and its opposite orientation is expressed by adding the minus $-\langle i_{j_0}, \dots, i_{j_q}\rangle$. We write $\langle\sigma\rangle = \langle i_{j_0}, \dots, i_{j_q}\rangle$ for the equivalence class including $i_{j_0} < \cdots < i_{j_q}$. For $q = 0$, we suppose that we have only one orientation for each vertex.

Let K be a field. We construct a K-vector space $C_q(S)$ as

$$C_q(S) = \mathrm{Span}_K\{\langle\sigma\rangle \mid \sigma \in S_q\}$$

for $S_q \neq \emptyset$ and $C_q(S) = 0$ for $S_q = \emptyset$. Here, $\mathrm{Span}_K(A)$ for a set A is a vector space over K such that the elements of A formally form a basis of the vector space. Furthermore, we define a linear map called the *boundary map* $\partial_q : C_q(S) \to C_{q-1}(S)$ by the linear extension of

$$\partial_q\langle i_0, \dots, i_q\rangle = \sum_{\ell=0}^{q} (-1)^\ell \langle i_0, \dots, \widehat{i_\ell}, \dots, i_q\rangle, \tag{22}$$

where $\widehat{i_\ell}$ means the removal of the vertex i_ℓ. We can regard the linear map ∂_q as algebraically capturing the $(q-1)$-dimensional boundary of a q-dimensional object. For example, the image of the linear map ∂_2 of a basis $\langle 1,2,3\rangle$ in the vector space $C_2(S)$ is given by

$$\partial_2\langle 1,2,3\rangle = \langle 2,3\rangle - \langle 1,3\rangle + \langle 1,2\rangle = \langle 1,2\rangle + \langle 2,3\rangle + \langle 3,1\rangle \tag{23}$$

as linear combinations of bases in the vector space $C_1(S)$. The above sentence is written only in the language of linear algebra and there is no meaning of $+$ or $-$ in Equation (23) except for its vector space structure. On the other hand, the geometric realization of $\partial_2\langle 1,2,3\rangle$ is a boundary of $\langle 1,2,3\rangle$ in a geometric sense (see Figure 12). In this way, we analyze geometric properties of a simplicial complex algebraically.

In practice, by arranging some orderings of the oriented q- and $(q-1)$- simplices, we can represent the boundary map as a matrix $M_q = (M_{\sigma,\tau})_{\sigma\in S_{q-1},\tau\in S_q}$ with the entry $M_{\sigma,\tau} = 0, \pm 1$ given by the coefficient in Equation (23). For the simplicial complex S in Example 1, the matrix representations M_1 and M_2 of the boundary maps are given by

$$M_2 = \begin{bmatrix} 1 \\ 1 \\ -1 \end{bmatrix}, \quad M_1 = \begin{bmatrix} -1 & 0 & -1 \\ 1 & -1 & 0 \\ 0 & 1 & 1 \end{bmatrix} \tag{24}$$

Here, the 1-simplices (resp. 0-simplices) are ordered by $\langle 1,2\rangle, \langle 2,3\rangle, \langle 1,3\rangle$ (resp. $\langle 1\rangle$, $\langle 2\rangle$, $\langle 3\rangle$).

We call a sequence of the vector spaces and linear maps

$$\cdots \longrightarrow C_{q+1}(S) \xrightarrow{\partial_{q+1}} C_q(S) \xrightarrow{\partial_q} C_{q-1}(S) \longrightarrow \cdots$$

the *chain complex* of S. As an easy exercise, we can show $\partial_q \circ \partial_{q+1} = 0$. Hence, the subspaces $Z_q(S) = \ker\partial_q$ and $B_q(S) = \mathrm{im}\partial_{q+1}$ satisfy $B_q(S) \subset Z_q(S)$. Then, the q-th (simplicial) *homology* is defined by taking the quotient space

$$H_q(S) = Z_q(S)/B_q(S).$$

Note that $H_q(S)$ is a K-vector space, and the dimension can be considered in a standard way. Intuitively, the dimension of $H_q(S)$ counts the number of q-dimensional holes in S and each generator of the vector space $H_q(S)$ corresponds to these holes. We remark that the homology as a vector space is independent of the orientations of simplices. For $q = 0$, each generator of $H_0(S)$ corresponds to a path-connected component of S. This can be seen from the fact that any two vertices are in the same equivalence class modulo the boundary $B_0(S)$ if and only if they are connected by a path.

For a subcomplex T of S, the inclusion map $\rho : T \hookrightarrow S$ naturally induces a linear map in homology $\rho_q : H_q(T) \to H_q(S)$. Namely, an element $[c] \in H_q(T)$ is mapped to $[c] \in H_q(S)$, where the equivalence class $[c]$ is taken in each vector space.

For example, the simplicial complex S in Example 1 has

$$Z_1(S) = \mathrm{Span}_K[\ 1 \quad 1 \quad -1\ ]^T = B_1(S)$$

from (24). Hence $H_1(S) = 0$, meaning that there are no 1-dimensional hole (ring) in S. On the other hand, since $Z_1(T) = Z_1(S)$ and $B_1(T) = 0$, we have $H_1(T) \cong K$, meaning that T consists of one ring. Hence, the induced linear map $\rho_1 : H_1(T) \to H_1(S)$ means that the ring in T disappears in S under $T \hookrightarrow S$.

A topological space X is called *triangulable* if there exists a geometric realization of a simplicial complex S whose polyhedron is homeomorphic to X.[18] For such a triangulable topological space, the homology is defined by $H_q(X) = H_q(S)$. This is well-defined, since a different geometric realization provides an isomorphic homology.

A.2.2 Singular homology

We here extend the homology to general topological spaces. Let $e_0, \ldots, e_q$ be the standard basis of $\mathbb{R}^{q+1}$ (i.e., $e_i = (0, \ldots, 0, 1, 0, \ldots, 0)$, 1 at $(i+1)$-th position, and 0 otherwise), and set

$$\Delta_q = \left\{ \sum_{i=0}^{q} \lambda_i e_i \;\middle|\; \sum_{i=0}^{q} \lambda_i = 1, \lambda_i \geq 0 \right\},$$
$$\Delta_q^\ell = \left\{ \sum_{i=0}^{q} \lambda_i e_i \;\middle|\; \sum_{i=0}^{q} \lambda_i = 1, \lambda_i \geq 0, \lambda_\ell = 0 \right\}.$$

We also denote the inclusion by $\iota_q^\ell : \Delta_q^\ell \hookrightarrow \Delta_q$.

For a topological space X, a continuous map $\sigma : \Delta_q \to X$ is called a singular q-simplex, and let X_q be the set of q-simplices. We construct a K-vector space $C_q(X)$ as

$$C_q(X) = \mathrm{Span}_K\{\sigma \mid \sigma \in X_q\}.$$

18. A continuous map $f : X \to Y$ is said to be *homeomorphic* if $f : X \to Y$ is bijective and the inverse $f^{-1} : Y \to X$ is also continuous.

The boundary map $\partial_q : C_q(X) \to C_{q-1}(X)$ is defined by the linear extension of

$$\partial_q \sigma = \sum_{\ell=0}^{q} (-1)^\ell \sigma \circ \iota_q^\ell.$$

Even in this setting, we can show that $\partial_q \circ \partial_{q+1} = 0$, and hence the subspaces $Z_q(X) = \ker\partial_q$ and $B_q(X) = \mathrm{im}\partial_{q+1}$ satisfy $B_q(X) \subset Z_q(X)$. Then, the q-th (singular) *homology* is similarly defined by

$$H_q(X) = Z_q(X)/B_q(X).$$

It is known that, for a triangulable topological space, the homology of this definition is isomorphic to that defined in A.2.1. From this reason, we hereafter identify simplicial and singular homology.

The induced linear map in homology for an inclusion pair of topological space $Y \subset X$ is similarly defined as in A.2.1.

Appendix B. Total persistence

Let (M, d_M) be a triangulable compact metric space. For a Lipschitz function $f : M \to \mathbb{R}$, we define the degree-p total persistence over t by

$$\mathrm{Pers}_p(D_q(\mathbb{S}\mathrm{ub}(f)), t) = \sum_{\substack{x \in D_q(\mathbb{S}\mathrm{ub}(f)) \\ \mathrm{pers}(x) > t}} \mathrm{pers}(x)^p$$

for $0 \leq t \leq \mathrm{Amp}(f)$, where $\mathrm{Amp}(f) := \max_{\boldsymbol{x} \in M} f(\boldsymbol{x}) - \min_{\boldsymbol{x} \in M} f(\boldsymbol{x})$ is the amplitude of f. Let S be a triangulated simplicial complex of M by a homeomorphism $\vartheta : |S| \to M$. The diameter of a simplex $\sigma \in S$ and the mesh of the triangulation S are defined by $\mathrm{diam}(\sigma) = \max_{\boldsymbol{x}, \boldsymbol{y} \in \sigma} d_M(\vartheta(\boldsymbol{x}), \vartheta(\boldsymbol{y}))$ and $\mathrm{mesh}(S) = \max_{\sigma \in S} \mathrm{diam}(\sigma)$, respectively. Furthermore, let us set $N(r) = \min_{\mathrm{mesh}(S) \leq r} \mathrm{card}\,(S)$. Then, the degree-$p$ total persistence over t is bounded from above as follows:

Lemma 13 (Cohen-Steiner et al. (2010)) *Let M be a triangulable compact metric space and $f : M \to \mathbb{R}$ be a tame Lipschitz function. Then, $\mathrm{Pers}_p(D_q(\mathbb{S}\mathrm{ub}(f)), t)$ is bounded from above by*

$$t^p N\left(\frac{t}{\mathrm{Lip}(f)}\right) + p \int_{\varepsilon=t}^{\mathrm{Amp}(f)} N\left(\frac{\varepsilon}{\mathrm{Lip}(f)}\right) \varepsilon^{p-1} d\varepsilon,$$

where $\mathrm{Lip}(f)$ is the Lipschitz constant of f.

For a compact triangulable subspace M in $\mathbb{R}^d$, the number of d-cubes with length $r > 0$ covering M is bounded from above by $O(\frac{1}{r^d})$, and hence there exists some constant C_M depending only on M such that $N(r) \leq \frac{C_M}{r^d}$.

For $p > d$, we can find the upper bounds for the both terms as follows:

$$t^p N\left(\frac{t}{\mathrm{Lip}(f)}\right) \leq t^p C_M \frac{\mathrm{Lip}(f)^d}{t^d} \;\to\; 0 \quad (t \to 0)$$

and

$$p\int_{\varepsilon=t}^{\mathrm{Amp}(f)} N\left(\frac{\varepsilon}{\mathrm{Lip}(f)}\right)\varepsilon^{p-1}d\varepsilon \le \frac{p}{p-d}C_M\mathrm{Lip}(f)^d\mathrm{Amp}(f)^{p-d}.$$

Then, the upper bound of the total persistence $\mathrm{Pers}_p(D_q(\mathbb{S}\mathrm{ub}(f))) = \mathrm{Pers}_p(D_q(\mathbb{S}\mathrm{ub}(f)),0)$ is given as follows:

Lemma 14 *Let M be a triangulable compact subspace in $\mathbb{R}^d$ and $p > d$. For any Lipschitz function $f : M \to \mathbb{R}$,*

$$\mathrm{Pers}_p(D_q(\mathbb{S}\mathrm{ub}(f))) \le \frac{p}{p-d}C_M\mathrm{Lip}(f)^d\mathrm{Amp}(f)^{p-d},$$

where C_M is a constant depending only on M.

In the case of a finite subset $X \subset \mathbb{R}^d$, there always exists an R-ball M containing X for some $R > 0$, which is a triangulable compact subspace in $\mathbb{R}^d$. Moreover, by estimating $\mathrm{Lip}(\mathrm{dist}_X)^d\mathrm{Amp}(\mathrm{dist}_X)^{p-d}$, we show Lemma 4 as a corollary of Lemma 14:

Proof [Lemma 4] The Lipschitz constant of dist_X is 1, because, for any $\boldsymbol{x}, \boldsymbol{y} \in M$,

$$\begin{aligned}\mathrm{dist}_X(\boldsymbol{x}) - \mathrm{dist}_X(\boldsymbol{y}) &= \min_{\boldsymbol{x}_i\in X} d_M(\boldsymbol{x},\boldsymbol{x}_i) - \min_{\boldsymbol{x}_i\in X} d_M(\boldsymbol{y},\boldsymbol{x}_i)\\ &\le \min_{\boldsymbol{x}_i\in X}(d_M(\boldsymbol{x},\boldsymbol{y}) + d_M(\boldsymbol{y},\boldsymbol{x}_i)) - \min_{\boldsymbol{x}_i\in X} d_M(\boldsymbol{y},\boldsymbol{x}_i)\\ &= d_M(\boldsymbol{x},\boldsymbol{y}).\end{aligned}$$

Moreover,

$$\mathrm{Amp}(\mathrm{dist}_X) \le \mathrm{diam}(M) := \max_{\boldsymbol{x}_i,\boldsymbol{x}_j\in M} d_M(\boldsymbol{x}_i,\boldsymbol{x}_j),$$

because $\min_{\boldsymbol{x}\in M}\mathrm{dist}_X(\boldsymbol{x}) = 0$ and $\max_{\boldsymbol{x}\in M}\mathrm{dist}_X(\boldsymbol{x}) \le \mathrm{diam}(M)$. Thus, for some constant C_M depending only on M, we have

$$\begin{aligned}\mathrm{Pers}_p(D_q(X)) &= \mathrm{Pers}_p(D_q(\mathbb{S}\mathrm{ub}(\mathrm{dist}_X)))\\ &\le \frac{p}{p-d}C_M\mathrm{Lip}(\mathrm{dist}_X)^d\mathrm{Amp}(\mathrm{dist}_X)^{p-d}\\ &\le \frac{p}{p-d}C_M\mathrm{diam}(M)^{p-d}.\end{aligned}$$

■

For a persistence diagram $D = \{x_1, \ldots, x_n\}$, we construct a n-dimensional vector

$$v(D) := (\mathrm{pers}(x_1), \ldots, \mathrm{pers}(x_n)).$$

Then, the degree-p total persistence is represented as

$$\mathrm{Pers}_p(D) = \|v(D)\|_p^p,$$

where $\|\cdot\|_p$ denotes the ℓ^p-norm of $\mathbb{R}^n$. Since $\|v\|_q \le \|v\|_p$ $(v \in \mathbb{R}^n,\ 1 \le p \le q < \infty)$, we have

$$\mathrm{Pers}_q(D)^{\frac{1}{q}} = \|v(D)\|_q \le \|v(D)\|_p = \mathrm{Pers}_p(D)^{\frac{1}{p}}.$$

Proposition 15 *If $1 \le p \le q < \infty$ and $\mathrm{Pers}_p(D)$ is bounded from above, $\mathrm{Pers}_q(D)$ is also bounded from above.*

Appendix C. Lemmata for Section 3.2

Lemma 16 *For any $x, y \in \mathbb{R}^2$, $\|k_{\mathrm{G}}(\cdot,x) - k_{\mathrm{G}}(\cdot,y)\|_{\mathcal{H}_{k_{\mathrm{G}}}} \le \frac{\sqrt{2}}{\sigma}\|x-y\|_\infty$.*

Proof

$$\begin{aligned}\|k_{\mathrm{G}}(\cdot,x) - k_{\mathrm{G}}(\cdot,y)\|^2_{\mathcal{H}_{k_{\mathrm{G}}}} &= k_{\mathrm{G}}(x,x) + k_{\mathrm{G}}(y,y) - 2k_{\mathrm{G}}(x,y)\\ &= 1 + 1 - 2e^{-\frac{\|x-y\|^2}{2\sigma^2}}\\ &= 2\left(1 - e^{-\frac{\|x-y\|^2}{2\sigma^2}}\right)\\ &\le \frac{1}{\sigma^2}\|x-y\|^2 \qquad (25)\\ &\le \frac{2}{\sigma^2}\|x-y\|_\infty^2. \qquad (26)\end{aligned}$$

We have used the fact $1 - e^{-t} \le t$ $(t \in \mathbb{R})$ in Equation (25) and $\|x\|^2 \le 2\|x\|_\infty^2$ $(x \in \mathbb{R}^2)$ in Equation (26). ■

Lemma 17 *For any $x, y \in \mathbb{R}^2$, the difference of persistences $|\mathrm{pers}(x) - \mathrm{pers}(y)|$ is less than or equal to $2\|x-y\|_\infty$.*

Proof For $x = (x_1, x_2), y = (y_1, y_2)$, we have

$$\begin{aligned}|\mathrm{pers}(x) - \mathrm{pers}(y)| &= |(x_2 - x_1) - (y_2 - y_1)|\\ &\le |x_2 - y_2| + |x_1 - y_1|\\ &\le 2\|x-y\|_\infty.\end{aligned}$$

■

Lemma 18 *For any $x, y \in \mathbb{R}^2$, we have*

$$|w_{\mathrm{arc}}(x) - w_{\mathrm{arc}}(y)| \le 2pC\max\{\mathrm{pers}(x)^{p-1}, \mathrm{pers}(y)^{p-1}\}\|x-y\|_\infty.$$

Proof

$$\begin{aligned}&|w_{\mathrm{arc}}(x) - w_{\mathrm{arc}}(y)|\\ &= |\arctan(C\mathrm{pers}(x)^p) - \arctan(C\mathrm{pers}(y)^p)| \qquad (27)\\ &\le C|\mathrm{pers}(x)^p - \mathrm{pers}(y)^p|\\ &\le C|\mathrm{pers}(x) - \mathrm{pers}(y)|\,p\max\{\mathrm{pers}(x)^{p-1}, \mathrm{pers}(y)^{p-1}\} \qquad (28)\\ &\le 2pC\max\{\mathrm{pers}(x)^{p-1}, \mathrm{pers}(y)^{p-1}\}\|x-y\|_\infty. \qquad (29)\end{aligned}$$

We have used the fact that the Lipschitz constant of arctan is 1 in Equation (27),

$$\begin{aligned} s^p - t^p &= (s-t)(s^{p-1} + s^{p-2}t + \cdots + t^{p-1}) \\ &\leq (s-t)p\max\{s^{p-1}, t^{p-1}\} \end{aligned}$$

for any $s, t > 0$ in Equation (28), and Lemma 17 in Equation (29). ■

Appendix D. The number of the random Fourier features

Let $\mathcal{M}$ be a compact subset of $\mathbb{R}^2$ and $\delta > 0$ be a positive number, then it is known (Rahimi and Recht, 2007) that

$$\sup_{x,y\in\mathcal{M}} \left| \mathrm{Re}\left(\frac{1}{M_{\mathrm{rff}}} \sum_{a=1}^{M_{\mathrm{rff}}} \xi_{z_a}(x)\xi_{z_a}(y)^* \right) - e^{-\frac{\|x-y\|^2}{2\sigma^2}} \right| \leq \delta$$

where $\xi_{z_a}(x) = e^{\sqrt{-1}z_a^T x}$ and $M_{\mathrm{rff}} = \Omega(\frac{2}{\delta^2}\log\frac{\sqrt{2}\mathrm{diam}(\mathcal{M})}{\sigma\delta})$. For a collection $\mathcal{D} = \{D_\ell \mid \ell = 1, \ldots, n\}$ of persistence diagrams, the absolute error between the (k_{G}, w)-linear kernel $K_{\mathrm{L}}(D_i, D_j; k_{\mathrm{G}}, w)$ and its random Fourier feature approximation is given by

$$\begin{aligned} &\left| \sum_{x\in D_i}\sum_{y\in D_j} w(x)w(y)\mathrm{Re}\left(\frac{1}{M_{\mathrm{rff}}} \sum_{a=1}^{M_{\mathrm{rff}}} \xi_{z_a}(x)\xi_{z_a}(y)^* \right) - \sum_{x\in D_i}\sum_{y\in D_j} w(x)w(y)e^{-\frac{\|x-y\|^2}{2\sigma^2}} \right| \\ &\leq \sum_{x\in D_i} w(x) \sum_{y\in D_j} w(y) \left| \mathrm{Re}\left(\frac{1}{M_{\mathrm{rff}}} \sum_{a=1}^{M_{\mathrm{rff}}} \xi_{z_a}(x)\xi_{z_a}(y)^* \right) - e^{-\frac{\|x-y\|^2}{2\sigma^2}} \right|. \end{aligned} \tag{30}$$

In order to make the Equation (30) bounded by an arbitrary $\varepsilon > 0$, M_{rff} is given by $\Omega(\frac{2W_{i,j}^2}{\varepsilon^2}\log\frac{\sqrt{2}W_{i,j}\mathrm{diam}(\mathcal{M})}{\sigma\varepsilon})$ where $W_{i,j} := \sum_{x\in D_i} w(x)\sum_{y\in D_j} w(y)$. In this case, we can define the subset $\mathcal{M}$ by $\bigcup_{\ell=1}^n D_\ell$. When we calculate several $K_{i,j} := K_{\mathrm{L}}(D_i, D_j; k_{\mathrm{G}}, w)$ of Section 4.3 without approximation, we observed $K_{i,j} \approx 10^8$.[19] Since the true values are huge, we consider 5% relative error for Equation (30) and set $\varepsilon := 0.05K_{i,j}$. Then,

$$\frac{2W_{i,j}^2}{\varepsilon^2}\log\frac{\sqrt{2}W_{i,j}\mathrm{diam}(\mathcal{M})}{\sigma\varepsilon} = \frac{800W_{i,j}^2}{K_{i,j}^2}\log\frac{20\sqrt{2}W_{i,j}\mathrm{diam}(\mathcal{M})}{\sigma K_{i,j}} =: M_{i,j}.$$

In Section 4.3 and Section 4.4, we observed $\frac{W_{i,j}}{K_{i,j}} \approx 2.5$ and $\frac{\mathrm{diam}(\mathcal{M})}{\sigma} \approx 10$ from several computation without approximation, and $M_{i,j} \approx 800 \cdot (2.5)^2\log(20\sqrt{2}\cdot 3\cdot 10) \approx 3\cdot 10^4$. Thus, the approximation (30) with $M_{\mathrm{rff}} = 10^5$, which is used in our experiments, gives 95% accuracy in the sense of the relative error.

19. Even though a single $K_{i,j}$ can be computed in several hours on MacBook Pro, 2.6 GHz Intel Core i5, 8 GB 1600 MHz DDR3, the total $\frac{1}{2}n(n-1)$ computations of $K_{i,j}$ for the Gram matrix cause huge computational time.

Editor: Geoff Holmes

Abstract

We introduce `pycobra`, a Python library devoted to ensemble learning (regression and classification) and visualisation. Its main assets are the implementation of several ensemble learning algorithms, a flexible and generic interface to compare and blend any existing machine learning algorithm available in Python libraries (as long as a `predict` method is given), and visualisation tools such as Voronoi tessellations. `pycobra` is fully `scikit-learn` compatible and is released under the MIT open-source license. `pycobra` can be downloaded from the Python Package Index (PyPi) and Machine Learning Open Source Software (MLOSS). The current version (along with Jupyter notebooks, extensive documentation, and continuous integration tests) is available at https://github.com/bhargavvader/pycobra and official documentation website is https://modal.lille.inria.fr/pycobra.

Keywords: ensemble methods, machine learning, Voronoi tesselation, Python, open source software

1. Introduction

Combined statistical procedures, also known as ensemble or aggregation methods, are very popular in Machine Learning competitions – the celebrated Netflix Challenge (as are repeatedly Kaggle competitions) was won by an ensemble technique (see for example Bell and Koren, 2007, for a discussion). In a nutshell, ensemble methods combine different predictors (each trained on the same dataset) to improve performance. `scikit-learn` offers implementations of some ensemble methods but it does not ship with a specific analysis toolbox for aggregation. `pycobra` attempts to fill this gap by providing to the `scikit-learn` environment a toolbox to analyse and visualise the different preliminary predictors (also called machines hereafter), in addition to providing pythonic implementations of several ensemble algorithms (the COBRA algorithm introduced by Biau et al., 2016; the Exponential Weighted Aggregate (EWA) introduced by Vovk, 1990; a COBRA-flavored majority vote inspired by Mojirsheibani, 1999). All these algorithms are supported by oracle bounds which prove that the risk of the aggregated predictor is upper-bounded by the smallest risk of the initial pool of predictors, up to a remainder term which decays to zero (typically at a rate $\mathcal{O}(1/\sqrt{n})$ or faster).

COBRA (standing for COmBined Regression Alternative) is a nonlinear ensemble method designed for regression problems. To predict the response for a new data point, COBRA operates in two steps. First, it retains data points for which the prediction made by preliminary machines is close (in the Euclidean sense) to the prediction made for the new point. This is called the *consensus step*. Second, the final prediction is then formed by averaging responses over the retained points' indices. COBRA outputs a predictor which outperforms any combination of the preliminary predictors (as shown by see Theorem 2.1 in Biau et al., 2016). We describe the COBRA algorithm as implemented in `pycobra` in Algorithm 1. Exponential weights have been used for a long time in statistical learning theory (Vovk, 1990). The EWA algorithm implemented in Pycobra is inspired by the description of Dalalyan and Tsybakov (2007). EWA amounts to forming an exponentially weighted average of preliminary predictors, where the weights include a measure of each predictor's performance. COBRA has been inspired by the work of Mojirsheibani (1999) in classification, and therefore `pycobra` includes a classification version of COBRA called `ClassifierCobra`. The consensus step shares a similar philosophy to what is done in COBRA regression but the final prediction is delivered by a majority vote among the labels of the retained data points.

`pycobra` allows the user to gauge the performance of the preliminary predictors used in the aggregation, with built-in methods to easily plot boxplots and QQ-plots. A salient feature of `pycobra` is using Voronoi tessellations for generic visualisation. By implementing ensemble algorithms which were not represented in the Python machine learning community, and providing a variety of tools to visualise and analyse their behavior and performance, we present to the machine learning open source community a toolbox designed for ensemble learning and visualisation.

2. The `pycobra` library

Our toolbox is written in Python and uses `NumPy` (Walt et al., 2011) and `scikit-learn` (Pedregosa et al., 2011) for computation and linear algebra operations. `Matplotlib` (Hunter, 2007) is used for visualisation purposes, and `SciPy` (Jones et al., 2001) is used to help create Voronoi tessellations. Tutorials and examples are created using Jupyter IPython notebooks (Pérez and Granger, 2007). Currently `pycobra` supports any machine learning algorithm with a `predict` method, casting our procedure into a very flexible and generic framework. By default, `pycobra` relies on `scikit-learn` implementations of Lasso, Random Forest, Decision Trees and Ridge regression for the `EWA` and `COBRA` implementations. As for `ClassifierCobra`, `scikit-learn` implementations of SVM classifier, KNN, Decision Tree classifier, and a classifier which implements regularised linear models with SGD (SGDClassifier object). `pycobra` itself and all software it relies on is open source, with no dependence on proprietary software. Algorithm 1 presents the pseudo-code of the COBRA implementation. All the pycobra estimators are `scikit-learn` compatible and can be used as part of the existing `scikit-learn` ecosystem, such as `[GridSearchCV]` and `[Pipeline]`. While hyperparameter initialisation is systematically done using `scikit-learn`'s `GridSearchCV`, `pycobra`'s `Diagnostics` class allows us to compare between different combinations of the constituent predictors and data-splitting, among other basic parameters.

Algorithm 1: The original COBRA algorithm from Biau et al. (2016).

Data: input vector $\mathbf{X}$, `epsilon`, `alpha`, `basic-machines`, `training-set-responses`, `training-set`
`training-set` is the set composed of all `data_point` and the responses. `training-set-responses` is the set composed of the responses.
Result: prediction $\mathbf{Y}$
for *machine j in basic-machines* **do**
  `machine_set` = ;
  # *machine_set is a dictionary mapping each machine M to a set* `machine_set`$[M]$;
  `pred` $= r_j(\mathbf{X})$; # *where $r_j(x)$ denotes the prediction made by machine j at point x*;
  for *response in training-set-responses* **do**
    if $|$`data_point` $-$ `pred`$| \leq$ `epsilon`, collect `response` in `machine_set`$[M]$;
  end
end
array = [ ] ;
for *data_point in training-set* **do**
  if at least `alpha` machines out of M have collected `data_point` in their `set`, store point in array ;
end
result = average(array) ;

The `visualisation` class allows the user to compare all the machines used to create aggregates, as well as visualise the results, for all `pycobra` estimators. `pycobra` ships with [a notebook on visualisation] to illustrate this.

QQ-plots and boxplots. Once all the basic machines are initialized and trained, the user can easily compare their performance with boxplots and QQ-plots. All the plotting details are handled by both the `diagnostics` and `visualisation` classes. An example is given in Figure 1.

Visualisation through Voronoi tessellations. Voronoi tessellations can be used to visualise the selection of optimal machines for COBRA, as well as visualising outputs from clustering algorithms, as illustrated by the [tutorial notebook]. An example is reproduced Figure 2.

3. Project Focus

Community-based development. We intend `pycobra` to be an ongoing collaborative project. To that matter, it is referenced on [Python Package Index (PyPi)] and [Machine Learning Open Source Software]. Moreover, `pycobra` is under active development and available on [GitHub] to promote collaborative programming, issue tracking and idea discussions.

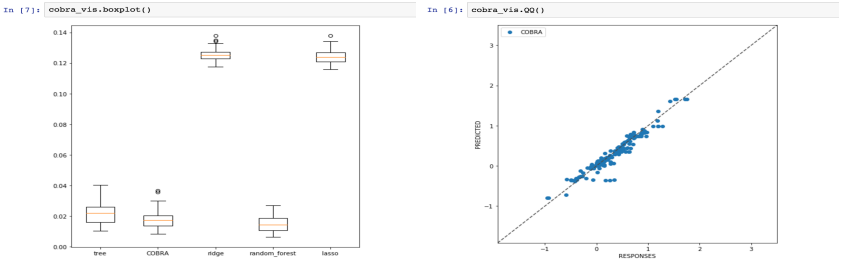

Figure 1: Assessing the performance of regression machines and COBRA.

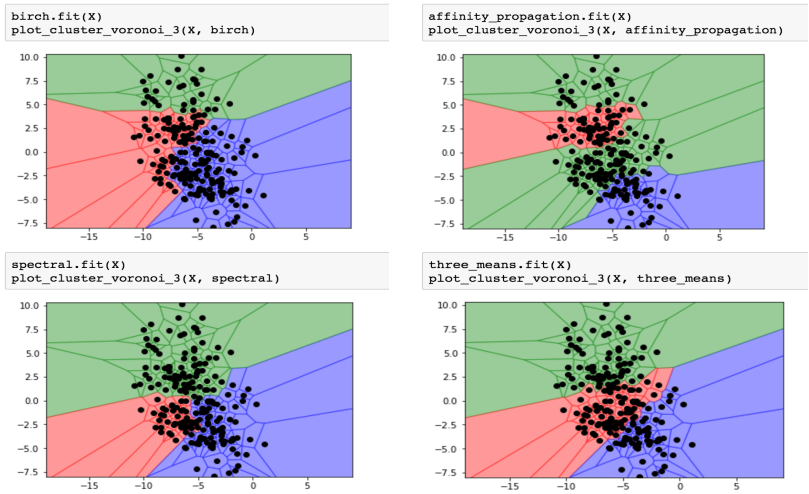

Figure 2: Visualising clustering through Voronoi tessellations.

Documentation and Jupyter Notebooks. A consistent API documentation is provided, along with an additional installation guide and examples. The documentation website is available at https://modal.lille.inria.fr/pycobra. The [notebooks directory] contains Jupyter notebooks which serve as both a documentation tool and a tutorial resource. These notebooks cover use-cases of Pycobra, from solving regression and classification problems to using Voronoi tesselations.

Ease of use and quality assurance. Ensemble learning with `pycobra` is as simple as loading trained `scikit-learn` machines – or any machine which has a `predict` method. Visualising involves little to no parameters, and after loading machines it is straightforward to analyse their performance on a particular dataset. In order to ensure code quality, a set of unit tests is provided for all classes in `pycobra`, and continuous integration via [Travis CI] ensures all commits are tested. The package follows the PEP8 convention, keeping the code easy to read and contribute to.

4. Conclusion and Future Work

The future of `pycobra` would be to grow its user base by adding new ways to add predictors, as well as further implement ensemble learning techniques and visualisation tools. Statistical aggregation and ensemble learning are an important part of the machine learning literature and are widely used by practitioners, yet it seems under-represented in the machine learning open source community. By creating `pycobra` and releasing it to the community, we intend to enrich the existing ecosystem with ensemble algorithms, a generic toolbox for ensemble learning on-the-go, along with analysis and visualisation tools.

Abstract

KeLP is a Java framework that enables fast and easy implementation of kernel functions over discrete data, such as strings, trees or graphs and their combination with standard vectorial kernels. Additionally, it provides several kernel-based algorithms, e.g., online and batch kernel machines for classification, regression and clustering, and a Java environment for easy implementation of new algorithms. KeLP is a versatile toolkit, very appealing both to experts and practitioners of machine learning and Java language programming, who can find extensive documentation, tutorials and examples of increasing complexity on the accompanying website. Interestingly, KeLP can be also used without any knowledge of Java programming through command line tools and JSON/XML interfaces enabling the declaration and instantiation of articulated learning models using simple templates. Finally, the extensive use of modularity and interfaces in KeLP enables developers to easily extend it with their own kernels and algorithms.

Keywords: Kernel Machines, Structured Data and Kernels, Java Framework.

1. Introduction

Kernel methods for discrete structures (Shawe-Taylor and Cristianini, 2004) are popular and effective techniques for the design of learning algorithms on non-vectorial data, such as strings (Lodhi et al., 2002), trees (Collins and Duffy, 2002; Moschitti, 2006; Aiolli et al., 2009; Croce et al., 2011; Annesi et al., 2014) and graphs (Gärtner, 2003; Borgwardt and Kriegel, 2005; Shervashidze, 2011). These kernels are very valuable to model complex relations in real-world applications, where data naturally has a structured form, e.g., strings and graphs are used to represent DNA and chemical compounds, or parse trees can encode syntactic and semantic information expressed in text.

However, current software for structural kernels is mainly limited to specific research, and is often not made publicly available or easily adaptable to new application domains. SVM-Light-TK toolkit by Moschitti (2006) is one of few exceptions that provides the user with different string and tree kernels but no graph kernels. It is written in C language thus extending it with new kernels can be costly, especially when new data structures are required. This may also prevent non programmers to use it for their specific applications.

In designing KeLP, we have capitalized on our previous experience with SVM-Light-TK and other toolkits to foster the reuse of previous software and models as well as their extendibility. We provide a software platform for learning on structured data, which is both easy to use for unexperienced users and easily extendable for developers. KeLP includes many standard kernel algorithms for classification, regression and clustering as well as popular kernel functions for strings, trees and graphs. Additionally, it includes kernel functions for modeling relations between pairs of objects, which are, e.g., required in paraphrasing detection, textual entailment and question answering (Moschitti and Zanzotto, 2007; Filice et al., 2015; Tymoshenko and Moschitti, 2015). Most importantly, new data structures, models, algorithms and kernels can be easily added on top of the previous code, facilitating and promoting the development of a library of kernel-based algorithms for structured data.

The KeLP source code is distributed under the terms of Apache 2.0 License. No additional software is required to be installed in order to use it, the Apache Maven project management tool resolves all module dependencies automatically. We also provide and maintain a website with updated tutorials and documentation.

2. The KeLP Framework: an Overview

KeLP is written in Java and uses three different Maven projects to logically separate its three main components: (*i*) the framework backbone implements classification, regression and clustering algorithms operating on vector-based kernels. These core modules along with SVMs[1] are always part of any framework instantiation. (*ii*) Additional-algorithm packages, e.g., online kernel machines, Nyström method (Williams and Seeger, 2001) and label sequence learning (Altun et al., 2003), and (*iii*) additional-kernel packages, which include kernel functions for sequences, trees and graphs. A complete and up-to-date list of algorithms and kernel functions, a full Javadoc API documentation in PDF, and tutorials for both end-users and developers are hosted on the KeLP website, `http://www.kelp-ml.org`.

2.1 Machine Learning Algorithms

Learning algorithms in KeLP are implemented following *implementation contracts* provided by specific Java interfaces for different scenarios, i.e., classification, regression and clustering, according to two main learning paradigms, i.e., batch and online. New learning algorithms can implement these interfaces, thus becoming fully integrated with the other library functions. More in detail: (*i*) The `ClassificationLearningAlgorithm` interface supports the definition of classification learning methods, such as SVMs (Chang and Lin, 2011) or the Dual Coordinate Descent (Hsieh et al., 2008). (*ii*) The `RegressionLearningAlgorithm` interface supports the definition of regressors, such as ϵ-SVR (Chang and Lin, 2011). (*iii*) The `ClusteringAlgorithm` interface enables the implementation of clustering algorithms, such as (Kulis et al., 2005). (*iv*) The `OnlineLearningAlgorithm` interface supports the definition of online learning algorithms, e.g., Passive Aggressive (Crammer et al., 2006), or the Soft Confidence Weighted (Wang et al., 2012) algorithms. Finally, (*v*) the `MetaLearningAlgorithm` interface enables the design of committees, such as the multi-classification schemas, e.g., One-VS-One and One-VS-All.

1. We include it because of its wide use.

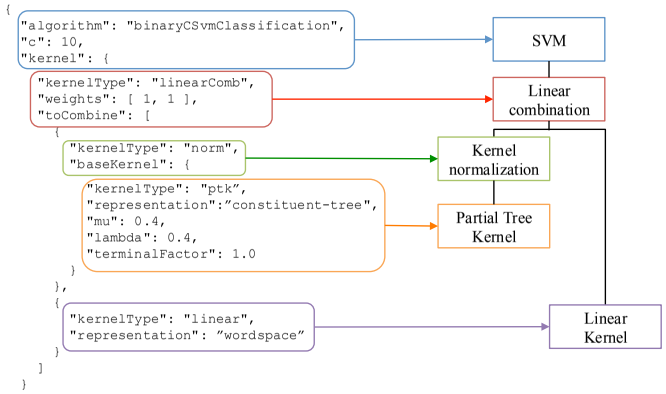

Figure 1: A JSON description of a SVM classifier.

2.2 Data Representation

In KeLP, data is represented by the `Example` class, which is constituted by (*i*) a set of `Labels` and (*ii*) a set of `Representations`. The former enables the design of single or multi-label classifiers and multi-variate regressors. The latter model examples in terms of vectors (e.g., `DenseVector` and `SparseVector`) or structures (e.g., `SequenceRepresentation`, `TreeRepresentation` or `GraphRepresentation`). In particular, kernels can be defined over examples encoded by multiple representations (e.g., multiple parse trees, strings, graphs and feature vectors). This makes the experimentation with multiple kernel combinations easy, just requiring negligible changes in the code or the JSON description (see Section 2.4), without the need of modifying the input data sets. Additionally, the examples can be combined in more complex structures, e.g., `ExamplePair`, useful to learn relations between objects, e.g., pairs representing question and answer text in QA, or text and hypothesis in textual entailment tasks. Building other types of data format is extremely simple, e.g., KeLP includes the SVM-Light-TK input format for trees and provides many scripts to use the popular gspan format for graphs (and indirectly for the 111 openBabel formats[2]).

2.3 Building Kernels from Kernels

KeLP enables (*i*) kernel composition, i.e., $K_{ab}(s_1, s_2) = (\phi_a \circ \phi_b)(s_1) \cdot (\phi_a \circ \phi_b)(s_2)$ from $K_a(s_1, s_2) = \phi_a(s_1) \cdot \phi_a(s_2)$ and $K_b(s_1, s_2) = \phi_b(s_1) \cdot \phi_b(s_2)$; and (*ii*) kernel combinations, e.g., $\lambda_1 K_a(s_1, s_2) + \lambda_2 K_b(s_1, s_2) \times K_a(s_1, s_2)$. These operations are coded using three abstractions of the `Kernel` class: (*i*) `DirectKernel` directly operates on a specified `Representation` object, derived from the `Example` object (e.g., implementing kernels for vectors, sequences, trees and graphs). (*ii*) The `KernelComposition` class composes `Kernel` objects, e.g., `PolynomialKernel`, `RBFKernel` and `NormalizationKernel`. (*iii*) `KernelCombination` class enables the combination of different `Kernels`, e.g., the `LinearKernelCombination` class applies a weighted kernel sum. (*iv*) `KernelOnPair` class operates on `ExamplePair`, e.g., to learn similarity functions between sentences (Filice et al., 2015) or to implement ranking algorithms with the `PreferenceKernel` class.

2. `http://openbabel.org`

```java
public static void run(String trainPath, String testPath, String learningAlgoPath){
        //Define (load) the learning algorithm  (see the JSON in Fig. 1)
        JacksonSerializerWrapper serializer = new JacksonSerializerWrapper();
        ClassificationLearningAlgorithm learningAlgo;
        learningAlgo = serializer.readValue(new File(learningAlgoPath),
                                        ClassificationLearningAlgorithm.class);
        //Load the datasets
        SimpleDataset trainDataset = new SimpleDataset();
        trainDataset.populate(trainPath);
        SimpleDataset testDataset = new SimpleDataset();
        testDataset.populate(testPath);
        //Learn the classifier
        List<Label> classes = trainDataset.getClassificationLabels();
        learningAlgo.setLabels(classes);
        learningAlgo.learn(trainDataset);
        //Classify and Evaluate
        Classifier classifier = learningAlgo.getPredictionFunction();
        Evaluator evaluator = new MulticlassClassificationEvaluator(classes);
        for(Example ex: testDataset.getExamples()){
                evaluator.addCount(ex, classifier.predict(ex));
        }
        System.out.println("ACC:" + evaluator.getPerformanceMeasure("accuracy"));
}
```

Listing 1: The Java instantiation (and evaluation) of the SVM classifier specified in Figure 1.

2.4 A User-friendly Interfacing with JSON

Each object, kernel function or algorithm, is serializable in JSON or XML. Thus, new algorithms can be implemented with a JSON description exploiting already implemented building blocks. The JSON interpreter of KeLP instantiates the corresponding objects without requiring any Java coding. Note that once a new kernel or learning algorithm is coded in Java, it will also be automatically available in the JSON format. Thus, it can be combined and composed with any kernel and algorithm available in KeLP by simply using JSON specifications. For example, Figure 1 provides a JSON description of an SVM classifier using a linear combination of a tree kernel with a linear kernel. The procedure for training and evaluating such classifier can be written in less than 20 code lines, as shown in Listing 1. Additionally, new kernels can be designed by combining JSON files and used in the framework by executing terminal commands (runnable jars). This enables experimenting with most KeLP features without writing any Java code.

3. Related Work and Conclusions

Most kernel-based software assumes data is represented by feature vectors (Hall et al., 2009; Chang and Lin, 2011; Abeel et al., 2009). Notable exceptions are SVM-Light-TK (Moschitti, 2006) and JKernelMachines (Picard et al., 2013). SVM-Light-TK is entirely written in C language and its main feature is the high computation speed. Unfortunately, C does not allow for fast prototyping of new kernel functions and machines. In contrast, KeLP enables fast and easy implementation of new kernel methods. JKernelMachines is a Java based package primarily designed to deal with custom kernels that cannot be easily found in standard libraries. However, many features offered by KeLP are not available in JKernelMachines, e.g., tree and graph kernels and regression algorithms. Moreover, KeLP supports easier composition and combination of kernels and learning algorithms.

Abstract

We design a new nonparametric method that allows one to estimate the matrix of integrated kernels of a multivariate Hawkes process. This matrix not only encodes the mutual influences of each node of the process, but also disentangles the causality relationships between them. Our approach is the first that leads to an estimation of this matrix *without any parametric modeling and estimation of the kernels themselves*. As a consequence, it can give an estimation of causality relationships between nodes (or users), based on their activity timestamps (on a social network for instance), without knowing or estimating the shape of the activities lifetime. For that purpose, we introduce a moment matching method that fits the second-order and the third-order integrated cumulants of the process. A theoretical analysis allows us to prove that this new estimation technique is consistent. Moreover, we show, on numerical experiments, that our approach is indeed very robust with respect to the shape of the kernels and gives appealing results on the MemeTracker database and on financial order book data.

Keywords: Hawkes Process, Causality Inference, Cumulants, Generalized Method of Moments

1. Introduction

In many applications, one needs to deal with data containing a very large number of irregular timestamped events that are recorded in continuous time. These events can reflect, for instance, the activity of users on a social network, see Subrahmanian et al. (2016), the high-frequency variations of signals in finance, see Bacry et al. (2015), the earthquakes and aftershocks in geophysics, see Ogata (1998), the crime activity, see Mohler et al. (2011) or the position of genes in genomics, see Reynaud-Bouret and Schbath (2010). The succession of the precise timestamps carries a great deal of information about the dynamics of the underlying systems. In this context, multidimensional counting processes based models play a paramount role. Within this framework, an important task is to recover the mutual influence of the nodes (i.e., the different components of the counting process), by leveraging on their timestamp patterns, see, for instance, Bacry and Muzy (2016); Lemonnier and Vayatis (2014); Lewis and Mohler (2011); Zhou et al. (2013a); Gomez-Rodriguez et al. (2013); Farajtabar et al. (2015); Xu et al. (2016).

Consider a set of nodes $I = \{1, \dots, d\}$. For each $i \in I$, we observe a set Z^i of *events*, where each $\tau \in Z^i$ labels the occurrence time of an event related to the activity of i. The events of all nodes can be represented as a vector of counting processes $\boldsymbol{N}_t = [N_t^1 \cdots N_t^d]^\top$, where N_t^i counts the number of events of node i until time $t \in \mathbb{R}^+$, namely $N_t^i = \sum_{\tau \in Z^i} \mathbb{1}_{\{\tau \leq t\}}$. The vector of stochastic intensities $\boldsymbol{\lambda}_t = [\lambda_t^1 \cdots \lambda_t^d]^\top$ associated with the multivariate counting process $\boldsymbol{N}_t$ is defined as

$$\lambda_t^i = \lim_{dt \to 0} \frac{\mathbb{P}(N_{t+dt}^i - N_t^i = 1 | \mathcal{F}_t)}{dt}$$

for $i \in I$, where the filtration $\mathcal{F}_t$ encodes the information available up to time t. The coordinate λ_t^i gives the expected instantaneous rate of event occurrence at time t for node i. The vector $\boldsymbol{\lambda}_t$ characterizes the distribution of $\boldsymbol{N}_t$, see Daley and Vere-Jones (2003), and patterns in the events time-series can be captured by structuring these intensities.

The Hawkes process introduced in Hawkes (1971) corresponds to an autoregressive structure of the intensities in order to capture self-excitation and cross-excitation of nodes, which is a phenomenon typically observed, for instance, in social networks, see for instance Crane and Sornette (2008). Namely, $\boldsymbol{N}_t$ is called a *Hawkes point process* if the stochastic intensities can be written as

$$\lambda_t^i = \mu^i + \sum_{j=1}^d \int_0^t \phi^{ij}(t - t') dN_{t'}^j,$$

where $\mu^i \in \mathbb{R}^+$ is an exogenous intensity and ϕ^{ij} are positive, integrable and causal *i.e.* with support in $\mathbb{R}_+$ (so that effects don't happen before their cause) functions called *kernels* encoding the impact of an action by node j on the activity of node i. Note that when all kernels are zero, the process is a simple homogeneous multivariate Poisson process.

Most of the literature uses a parametric approach for estimating the kernels. Without a doubt, the most popular parametrization form is the exponential kernel $\phi^{ij}(t) = \alpha_{ij}\beta_{ij}e^{-\beta_{ij}t}$ because it definitely simplifies the inference algorithm (e.g., the complexity needed for computing the likelihood is much smaller). When d is large, in order to reduce the number of parameters, some authors choose to arbitrarily share the kernel shapes across the different nodes. Thus, for instance, in Yang and Zha (2013); Zhou et al. (2013b); Farajtabar et al. (2015), they choose $\phi^{ij}(t) = \alpha_{ij}h(t)$ with $\alpha_{ij} \in \mathbb{R}^+$ quantifies the intensity of the influence of j on i and $h(t)$ a (normalized) function that characterizes the time-profile of this influence and that is *shared* by all couples of nodes (i, j) (most often, it is chosen to be either exponential $h(t) = \beta e^{-\beta t}$ or power law $h(t) = \beta t^{-(\beta+1)}$). Both approaches are, most of the time, non-realistic. On the one hand there is a priori no reason for assuming that the time-profile of the influence of a node j on a node i does not depend on the pair (i, j). On the other

hand, assuming an exponential shape or a power law shape for a kernel arbitrarily imposes an event impact that is always instantly maximal and that can only decrease with time, while in practice, there may exist a latency between an event and its maximal impact.

In order to have more flexibility on the shape of the kernels, nonparametric estimation can be considered. Expectation-Maximization algorithms can be found in Lewis and Mohler (2011) (for $d = 1$) or in Zhou et al. (2013a) ($d > 1$). An alternative method is proposed in Bacry and Muzy (2016) where the nonparametric estimation is formulated as a numerical solving of a Wiener-Hopf equation. Another nonparametric strategy considers a decomposition of kernels on a dictionary of function $h_1, \dots, h_K$, namely $\phi^{ij}(t) = \sum_{k=1}^{K} a_k^{ij} h_k(t)$, where the coefficients a_k^{ij} are estimated, see Hansen et al. (2015); Lemonnier and Vayatis (2014) and Xu et al. (2016), where group-lasso is used to induce a sparsity pattern on the coefficients a_k^{ij} that is shared across $k = 1, \dots, K$.

Such methods are computationally-intensive when d is large, since they rely on likelihood maximization or least squares minimization within an over-parametrized space in order to gain flexibility on the shape of the kernels. This is problematic, since the original motivation for the use of Hawkes processes is to estimate the influence and causality of nodes, the knowledge of the full parametrization of the model being of little interest for causality purpose.

Our paper solves this problem with a different and more direct approach. Instead of trying to estimate the kernels ϕ^{ij}, we focus on the direct estimation of their *integrals*. Namely, we want to estimate the matrix $\boldsymbol{G} = [g^{ij}]$ where

$$g^{ij} = \int_0^{+\infty} \phi^{ij}(u)\, du \geq 0 \;\text{ for }\; 1 \leq i, j \leq d. \tag{1}$$

As it can be seen from the cluster representation of Hawkes processes (Hawkes and Oakes (1974)), this integral represents the mean total number of events of type i directly triggered by an event of type j, and then encodes a notion of *causality*. Actually, as detailed below (see Section 2.1), such integral can be related to the Granger causality (Granger (1969)).

The main idea of the method we developed in this paper is to estimate the matrix $\boldsymbol{G}$ directly using a matching cumulants (or moments) method. Apart from the mean, we shall use second and third-order cumulants which correspond respectively to centered second and third-order moments. We first compute an estimation $\widetilde{\boldsymbol{M}}$ of these centered moments $M(\boldsymbol{G})$ (they are uniquely defined by $\boldsymbol{G}$). Then, we look for a matrix $\widehat{\boldsymbol{G}}$ that minimizes the L^2 error $\|M(\widehat{\boldsymbol{G}}) - \widetilde{\boldsymbol{M}}\|^2$. Thus the integral matrix $\widehat{\boldsymbol{G}}$ is directly estimated without making hardly any assumptions on the shape the involved kernels. As it will be shown, this approach turns out to be particularly robust to the kernel shapes, which is not the case of all previous Hawkes-based approaches that aim causality recovery. We call this method NPHC (Non Parametric Hawkes Cumulant), since our approach is of nonparametric nature. We provide a theoretical analysis that proves the consistency of the NPHC estimator. Our proof is based on ideas from the theory of Generalized Method of Moments (GMM) but requires an original technical trick since our setting strongly departs from the standard parametric statistics with i.i.d observations. Note that moment and cumulant matching techniques proved particularly powerful for latent topic models, in particular Latent Dirichlet Allocation, see Podosinnikova et al. (2015). A small set of previous works, namely Da Fonseca and Zaatour (2014); Aït-Sahalia et al. (2010), already used method of moments with Hawkes processes, but only in a parametric setting. Our work

is the first to consider such an approach for a nonparametric counting processes framework.

The paper is organized as follows: in Section 2, we provide the background on the integrated kernels and the integrated cumulants of the Hawkes process. We then introduce the method, investigate its complexity and explain the consistency result we prove. In Section 3, we estimate the matrix of Hawkes kernels' integrals for various simulated datasets and for real datasets, namely the MemeTracker database and financial order book data. We then provide in Appendix B the technical details skipped in the previous parts and the proof of our consistency result. Section 4 contains concluding remarks.

2. NPHC: The Non Parametric Hawkes Cumulant method

In this Section, we provide the background on integrals of Hawkes kernels and integrals of Hawkes cumulants. We then explain how the NPHC method enables estimating $\boldsymbol{G}$.

2.1 Branching structure and Granger causality

From the definition of Hawkes process as a Poisson cluster process, see Jovanović et al. (2015) or Hawkes and Oakes (1974), g^{ij} can be simply interpreted as the average total number of events of node i whose *direct* ancestor is a given event of node j (by direct we mean that interactions mediated by any other intermediate event are not counted). In that respect, $\boldsymbol{G}$ not only describes the mutual influences between nodes, but it also quantifies their *direct causal* relationships. Namely, introducing the counting function $N_t^{i \leftarrow j}$ that counts the number of events of i whose direct ancestor is an event of j, we know from Bacry et al. (2015) that

$$\mathbb{E}[dN_t^{i \leftarrow j}] = g^{ij} \mathbb{E}[dN_t^j] = g^{ij} \Lambda^j dt, \tag{2}$$

where we introduced Λ^i as the intensity expectation, namely satisfying $\mathbb{E}[dN_t^i] = \Lambda^i dt$. Note that Λ^i does not depend on time by stationarity of $\boldsymbol{N}_t$, which is known to hold under the *stability condition* $\|\boldsymbol{G}\| < 1$, where $\|\boldsymbol{G}\|$ stands for the spectral norm of $\boldsymbol{G}$. In particular, this condition implies the non-singularity of $\boldsymbol{I_d} - \boldsymbol{G}$.

Since the question of a *real causality* is too complex in general, see Imbens and Rubin (2015); Pearl (2009), most econometricians agreed on the simpler definition of Granger causality Granger (1969). Its mathematical formulation is a statistical hypothesis test: X causes Y *in the sense of Granger causality* if forecasting future values of Y is more successful while taking X past values into account.

Definition 1 (Granger causality for time series) *Given two time series X and Y, we denote $\mathcal{H}(t)$ the set of all information available prior to t, $\mathcal{H}_{-X}(t)$ the previous set in which information coming from X is excluded, and A an arbitrary non-empty set. We say that X Granger-causes Y if*

$$\mathbb{P}[Y(t+1) \in A | \mathcal{H}(t)] \neq \mathbb{P}[Y(t+1) \in A | \mathcal{H}_{-X}(t)].$$

Existing works mainly focus on learning Granger causality for time series, see Arnold et al. (2007); Eichler (2012); Basu et al. (2015), such as vector autoregressive models (VAR), where Granger causality is formulated as a statistical test of the VAR coefficients. In Eichler et al. (2016), the authors extend the definition of Granger (non-)causality to the case of Hawkes processes.

Definition 2 (Granger causality for Hawkes processes) *For $\boldsymbol{N}_t$ a multivariate Hawkes process, N_t^j does not Granger-cause N_t^i w.r.t $\boldsymbol{N}_t$ if and only if $\phi^{ij}(u) = 0$ for $u \in \mathbb{R}^+$.*

Since the kernels take positive values, the latter condition is equivalent to $\int_0^\infty \phi^{ij}(u)du = 0$. In the following, we'll refer to *learning the kernels' integrals* as *uncovering causality* since each integral encodes the notion of Granger causality, and is also linked to the number of events directly caused from a node to another node, as described above at Eq. (2).

2.2 Integrated cumulants of the Hawkes process

A general formula for the integral of the cumulants of a multivariate Hawkes process is provided in Jovanović et al. (2015). As explained below, for the purpose of our method, we only need to consider cumulants up to the third order. Given $1 \leq i, j, k \leq d$, the first three integrated cumulants of the Hawkes process can be defined as follows thanks to stationarity:

$$\Lambda^i dt = \mathbb{E}(dN_t^i) \tag{3}$$

$$C^{ij}dt = \int_{\tau\in\mathbb{R}} \Big(\mathbb{E}(dN_t^i dN_{t+\tau}^j) - \mathbb{E}(dN_t^i)\mathbb{E}(dN_{t+\tau}^j)\Big) \tag{4}$$

$$\begin{aligned} K^{ijk}dt = \iint_{\tau,\tau'\in\mathbb{R}^2} \Big(&\mathbb{E}(dN_t^i dN_{t+\tau}^j dN_{t+\tau'}^k) + 2\mathbb{E}(dN_t^i)\mathbb{E}(dN_{t+\tau}^j)\mathbb{E}(dN_{t+\tau'}^k) \\ &- \mathbb{E}(dN_t^i dN_{t+\tau}^j)\mathbb{E}(dN_{t+\tau'}^k) - \mathbb{E}(dN_t^i dN_{t+\tau'}^k)\mathbb{E}(dN_{t+\tau}^j) - \mathbb{E}(dN_{t+\tau}^j dN_{t+\tau'}^k)\mathbb{E}(dN_t^i)\Big), \end{aligned} \tag{5}$$

where Eq. (3) is the mean intensity of the Hawkes process, the second-order cumulant (4) refers to the integrated covariance density matrix and the third-order cumulant (5) measures the skewness of $\boldsymbol{N}_t$. Using the martingale representation from Bacry and Muzy (2016) or the Poisson cluster process representation from Jovanović et al. (2015), one can obtain an explicit relationship between these integrated cumulants and the matrix $\boldsymbol{G}$. If one sets

$$\boldsymbol{R} = (\boldsymbol{I_d} - \boldsymbol{G})^{-1}, \tag{6}$$

straightforward computations (see Appendix B) lead to the following identities:

$$\Lambda^i = \sum_{m=1}^d R^{im}\mu^m \tag{7}$$

$$C^{ij} = \sum_{m=1}^d \Lambda^m R^{im} R^{jm} \tag{8}$$

$$K^{ijk} = \sum_{m=1}^d (R^{im}R^{jm}C^{km} + R^{im}C^{jm}R^{km} + C^{im}R^{jm}R^{km} - 2\Lambda^m R^{im}R^{jm}R^{km}). \tag{9}$$

Equations (8) and (9) are proved in Appendix B. Our strategy is to use a convenient subset of Eqs. (3), (4) and (5) to define $\boldsymbol{M}$, while we use Eqs. (7), (8) and (9) in order to construct the operator that maps a candidate matrix $\boldsymbol{R}$ to the corresponding cumulants $M(\boldsymbol{R})$. By looking for $\widehat{\boldsymbol{R}}$ that minimizes $\boldsymbol{R} \mapsto \|M(\boldsymbol{R}) - \widehat{\boldsymbol{M}}\|^2$, we obtain, as illustrated below, good recovery of the ground truth matrix $\boldsymbol{G}$ using Equation (6).

The simplest case $d = 1$ has been considered in Hardiman and Bouchaud (2014), where it is shown that one can choose $M = \{C^{11}\}$ in order to compute the kernel integral. Eq. (8) then reduces to a simple second-order equation that has a unique solution in $\boldsymbol{R}$ (and consequently a unique $\boldsymbol{G}$) that accounts for the stability condition ($\|\boldsymbol{G}\| < 1$).

Unfortunately, for $d > 1$, the choice $M = \{C^{ij}\}_{1\leq i\leq j\leq d}$ is not sufficient to uniquely determine the kernels integrals. In fact, the integrated covariance matrix provides $d(d+1)/2$ independent coefficients, while d^2 parameters are needed. It is straightforward to show that the remaining $d(d-1)/2$ conditions can be encoded in an orthogonal matrix $\boldsymbol{O}$, reflecting the fact that Eq. (8) is invariant under the change $\boldsymbol{R} \to \boldsymbol{OR}$, so that the system is under-determined.

Our approach relies on using the third order cumulant tensor $\boldsymbol{K} = [K^{ijk}]$ which contains $(d^3 + 3d^2 + 2d)/6 > d^2$ independent coefficients that are sufficient to uniquely fix the matrix $\boldsymbol{G}$. This can be justified intuitively as follows: while the integrated covariance only contains symmetric information, and is thus unable to provide causal information, *the skewness given by the third order cumulant in the estimation procedure can break the symmetry between past and future so as to uniquely fix $\boldsymbol{G}$*. Thus, our algorithm consists of selecting d^2 third-order cumulant components, namely $M = \{K^{iij}\}_{1\leq i,j\leq d}$. Note that the choice of K^{iij} is arbitrary, our method and the theory developed below is unchanged for any choice of d^2 distinct components among the d^3 third-order cumulant. In particular, we define the estimator of $\boldsymbol{R}$ as $\widehat{\boldsymbol{R}} \in \operatorname{argmin}_{\boldsymbol{R}} \mathcal{L}(\boldsymbol{R})$, where

$$\mathcal{L}(\boldsymbol{R}) = (1-\kappa)\|\boldsymbol{K^c}(\boldsymbol{R}) - \widehat{\boldsymbol{K^c}}\|_2^2 + \kappa\|\boldsymbol{C}(\boldsymbol{R}) - \widehat{\boldsymbol{C}}\|_2^2, \tag{10}$$

where $\|\cdot\|_2$ stands for the Frobenius norm, $\boldsymbol{K^c} = \{K^{iij}\}_{1\leq i,j\leq d}$ is the matrix obtained by the contraction of the tensor $\boldsymbol{K}$ to d^2 indices, $\boldsymbol{C}$ is the covariance matrix, while $\widehat{\boldsymbol{K^c}}$ and $\widehat{\boldsymbol{C}}$ are their respective estimators, see Equations (12), (13) below. It is noteworthy that the above mean square error approach can be seen as a peculiar Generalized Method of Moments (GMM), see Hall (2005). This framework allows us to determine the optimal weighting matrix involved in the loss function. However, this approach is unusable in practice, since the associated complexity is too high. Indeed, since we have d^2 parameters, this matrix has d^4 coefficients and GMM calls for computing its inverse leading to a $O(d^6)$ complexity. In this work, we use the coefficient κ to scale the two terms, as

$$\kappa = \frac{\|\widehat{\boldsymbol{K^c}}\|_2^2}{\|\widehat{\boldsymbol{K^c}}\|_2^2 + \|\widehat{\boldsymbol{C}}\|_2^2},$$

see Section B.4 for an explanation about the link between κ and the weighting matrix. Finally, the estimator of $\boldsymbol{G}$ is straightforwardly obtained as

$$\widehat{\boldsymbol{G}} = \boldsymbol{I_d} - \widehat{\boldsymbol{R}}^{-1},$$

from the inversion of Eq. (6). Let us mention an important point: the matrix inversion in the previous formula is not the bottleneck of the algorithm. Indeed, its has a complexity $O(d^3)$ that is cheap compared to the computation of the cumulants when $n = \max_i |Z^i| \gg d$, which is the typical scaling satisfied in applications. Solving the considered problem on a larger scale, say $d \gg 10^3$, is an open question, even with state-of-the-art parametric and nonparametric approaches, see for instance Zhou et al. (2013a); Xu et al. (2016); Zhou et al. (2013b); Bacry and Muzy (2016), where the number of components d in experiments is always around 100 or smaller. Note that, actually, our approach leads to a *much faster* algorithm than the considered state-of-the-art baselines, see Tables 1–4 from Section 3 below.

2.3 Estimation of the integrated cumulants

In this section we present explicit formulas to estimate the three moment-based quantities listed in the previous section, namely, $\mathbf{\Lambda}$, $\boldsymbol{C}$ and $\boldsymbol{K}$. We first assume there exists $H > 0$ such that the truncation from $(-\infty, +\infty)$ to $[-H, H]$ of the domain of integration of the quantities appearing in Eqs. (4) and (5), introduces only a small error. In practice, this amounts to neglecting border effects in the covariance density and in the skewness density that is a good approximation if the support of the kernel $\phi^{ij}(t)$ is smaller than H and the spectral norm $\|\boldsymbol{G}\|$ satisfies $\|\boldsymbol{G}\| < 1$.
In this case, given a realization of a stationary Hawkes process $\{\boldsymbol{N}_t : t \in [0, T]\}$, as shown in Appendix B, we can write the estimators of the first three cumulants (3), (4) and (5) as

$$\widehat{\Lambda}^i = \frac{1}{T} \sum_{\tau \in Z^i} 1 = \frac{N_T^i}{T} \tag{11}$$

$$\widehat{C}^{ij} = \frac{1}{T} \sum_{\tau \in Z^i} \left(N_{\tau+H}^j - N_{\tau-H}^j - 2H\widehat{\Lambda}^j \right) \tag{12}$$

$$\begin{aligned} \widehat{K}^{ijk} = & \frac{1}{T} \sum_{\tau \in Z^i} \left(N_{\tau+H}^j - N_{\tau-H}^j - 2H\widehat{\Lambda}^j \right) \cdot \left(N_{\tau+H}^k - N_{\tau-H}^k - 2H\widehat{\Lambda}^k \right) \\ & - \frac{\widehat{\Lambda}^i}{T} \sum_{\tau \in Z^j} \sum_{\tau' \in Z^k} (2H - |\tau' - \tau|)^+ + 4H^2 \widehat{\Lambda}^i \widehat{\Lambda}^j \widehat{\Lambda}^k. \end{aligned} \tag{13}$$

Let us mention the following facts.

Bias. While the first cumulant $\hat{\Lambda}^i$ is an unbiased estimator of Λ^i, the other estimators $\widehat{C}^{ij}$ and $\widehat{K}^{ijk}$ introduce a bias. However, as we will show, in practice this bias is small and hardly affects numerical estimations (see Section 3). This is confirmed by our theoretical analysis, which proves that if H does not grow too fast compared to T, then these estimated cumulants are consistent estimators of the theoretical cumulants (see Section 2.6).

Complexity. The computations of all the estimators of the first, second and third-order cumulants have complexity respectively $O(nd)$, $O(nd^2)$ and $O(nd^3)$, where $n = \max_i |Z^i|$. However, our algorithm requires a lot less than that: it computes only d^2 third-order terms, of the form $\widehat{K}^{iij}$, leaving us with only $O(nd^2)$ operations to perform.

Symmetry. While the values of Λ^i, C^{ij} and K^{ijk} are symmetric under permutation of the indices, their estimators are generally not symmetric. We have thus chosen to symmetrize the estimators by averaging their values over permutations of the indices. Worst case is for the estimator of $\boldsymbol{K^c}$, which involves only an extra factor of 2 in the complexity.

2.4 The NPHC algorithm

The objective to minimize in Equation (10) is non-convex. More precisely, the loss function is a polynomial of $\boldsymbol{R}$ of degree 6. However, the expectations of cumulants $\mathbf{\Lambda}$ and $\boldsymbol{C}$ defined in Eq. (4) and (5) that appear in the definition of $\mathcal{L}(\boldsymbol{R})$ are unknown and should be replaced with $\widehat{\mathbf{\Lambda}}$ and $\widehat{\boldsymbol{C}}$. We denote $\widetilde{\mathcal{L}}(\boldsymbol{R})$ the objective function, where the expectations of cumulants Λ^i and C^{ij} have been replaced with their estimators in the right-hand side of Eqs. (8) and (9):

$$\widetilde{\mathcal{L}}(\boldsymbol{R}) = (1-\kappa)\|\boldsymbol{R}^{\odot 2}\widehat{\boldsymbol{C}}^\top + 2[\boldsymbol{R} \odot (\widehat{\boldsymbol{C}} - \boldsymbol{R}\widehat{\boldsymbol{L}})]\boldsymbol{R}^\top - \widehat{\boldsymbol{K^c}}\|_2^2 + \kappa\|\boldsymbol{R}\widehat{\boldsymbol{L}}\boldsymbol{R}^\top - \widehat{\boldsymbol{C}}\|_2^2 \tag{14}$$

As explained in Choromanska et al. (2015), the loss function of a typical multilayer neural network with simple nonlinearities can be expressed as a polynomial function of the weights in the network, whose degree is the number of layers. Since the loss function of NPHC writes as a polynomial of degree 6, we expect good results using optimization methods designed to train deep multilayer neural networks. We use AdaGrad from Duchi et al. (2011), a variant of the Stochastic Gradient Descent with adaptive learning rates. AdaGrad scales the learning rates coordinate-wise using the online variance of the previous gradients, in order to incorporate second-order information during training. As detailed in Section 2.5, the optimization step is negligible compared to the computation of the cumulants whenever $n = \max_i |Z^i| \gg d$, which is the typical scaling in applications. The NPHC method is summarized schematically in Algorithm 1.

Algorithm 1 Non Parametric Hawkes Cumulant method

Input: $\boldsymbol{N}_t$
Output: $\widehat{\boldsymbol{G}}$

1: Estimate $\widehat{\Lambda}^i$, $\widehat{C}^{ij}$, $\widehat{K}^{iij}$ from Eqs. (11, 12, 13)
2: Design $\widetilde{\mathcal{L}}(\boldsymbol{R})$ using the computed estimators.
3: Minimize numerically $\widetilde{\mathcal{L}}(\boldsymbol{R})$ so as to obtain $\widehat{\boldsymbol{R}}$
4: Return $\widehat{\boldsymbol{G}} = \boldsymbol{I_d} - \widehat{\boldsymbol{R}}^{-1}$.

Our problem being non-convex, the choice of the starting point has a major effect on the convergence. Here, the key is to notice that the matrices $\boldsymbol{R}$ that match Equation (8) write $\boldsymbol{C}^{1/2}\boldsymbol{O}\boldsymbol{L}^{-1/2}$, with $\boldsymbol{L} = \mathrm{diag}(\mathbf{\Lambda})$ and $\boldsymbol{O}$ an orthogonal matrix. Our starting point is then simply chosen by setting $\boldsymbol{O} = \boldsymbol{I_d}$ in the previous formula, leading to nice convergence results. Even though our main concern is to retrieve the matrix $\boldsymbol{G}$, let us notice we can also obtain an estimation of the baseline intensities' from Eq. (3), which leads to $\widehat{\boldsymbol{\mu}} = \widehat{\boldsymbol{R}}^{-1}\widehat{\mathbf{\Lambda}}$. An efficient implementation of this algorithm with TensorFlow, see Abadi et al. (2016), is available on GitHub: `https://github.com/achab/nphc`.

The optimization problem can be regularized by adding to the function $\mathcal{L}(\boldsymbol{R})$ a regularizing term of the form $\lambda N(\boldsymbol{G})$ that encodes a prior assumption on the structure of $\boldsymbol{G}$. As long as $\boldsymbol{R}$ matches Equation (8) the penalty term can be written as a function of $\boldsymbol{R}$ since $\lambda N(\boldsymbol{G}) = \lambda N(\boldsymbol{I_d} - \boldsymbol{C}^{-1}\boldsymbol{L}\boldsymbol{R}^\top)$. Since the algorithms we compare our method to optimize different objective functions (negative log-likelihood, least-squares, etc.), adding $\lambda N(\boldsymbol{G})$ with the same λ to these functions would trigger different behaviors. Then, in the rest of the document we focus on the unregularized problem, for which we prove the convergence's consistency in the Section 2.6.

2.5 Complexity of the algorithm

Compared with existing state-of-the-art methods to estimate the kernel functions, e.g., the ordinary differential equations-based (ODE) algorithm in Zhou et al. (2013a), the Granger Causality-based algorithm in Xu et al. (2016), the ADM4 algorithm in Zhou et al. (2013b), and the Wiener-Hopf-based algorithm in Bacry and Muzy (2016), our method has a very competitive complexity. This can be understood by the fact that those methods estimate the kernel functions, while in NPHC we only estimate their integrals. The ODE-based algorithm is an EM algorithm that parametrizes the kernel function with M basis functions, each being discretized to L points. The basis functions are updated after solving M Euler-Lagrange equations. If n denotes the maximum number of events per component (i.e. $n = \max_{1 \le i \le d} |Z^i|$) then the complexity of one iteration of the algorithm is

$O(Mn^3d^2 + ML(nd + n^2))$. The Granger Causality-based algorithm is similar to the previous one, without the update of the basis functions, that are Gaussian kernels. The complexity per iteration is $O(Mn^3d^2)$. The algorithm ADM4 is similar to the two algorithms above, as EM algorithm as well, with only one exponential kernel as basis function. The complexity per iteration is then $O(n^3d^2)$. The Wiener-Hopf-based algorithm is not iterative, on the contrary to the previous ones. It first computes the empirical conditional laws on many points, and then invert the Wiener-Hopf system, leading to a $O(nd^2L + d^4L^3)$ computation. Similarly, our method first computes the integrated cumulants, then minimize the objective function with N_{iter} iterations, and invert the resulting matrix $\widehat{\boldsymbol{R}}$ to obtain $\widehat{\boldsymbol{G}}$. In the end, the complexity of the NPHC method is $O(nd^2 + N_{\text{iter}}d^3)$. According to this analysis, summarized in Table 1 below, one can see that in the regime $n \gg d$, the NPHC method outperforms all the other ones.

Table 1: Complexity of state-of-the-art methods. NPHC's complexity is very low, especially in the regime $n \gg d$.

Method	Total complexity
ODE Zhou et al. (2013a)	$O(N_{\text{iter}}M(n^3d^2 + L(nd + n^2)))$
GC Xu et al. (2016)	$O(N_{\text{iter}}Mn^3d^2)$
ADM4 Zhou et al. (2013b)	$O(N_{\text{iter}}n^3d^2)$
WH Bacry and Muzy (2016)	$O(nd^2L + d^4L^3)$
NPHC	$O(nd^2 + N_{\text{iter}}d^3)$

2.6 Theoretical guarantee: consistency

The NPHC method can be phrased using the framework of the Generalized Method of Moments (GMM). GMM is a generic method for estimating parameters in statistical models. In order to apply GMM, we have to find a vector-valued function $g(X, \theta)$ of the data, where X is distributed with respect to a distribution $\mathbb{P}_{\theta_0}$, which satisfies the *moment condition*: $\mathbb{E}[g(X, \theta)] = 0$ if and only if $\theta = \theta_0$, where θ_0 is the "ground truth" value of the parameter. Based on i.i.d. observed copies $x_1, \dots, x_n$ of X, the GMM method minimizes the norm of the empirical mean over n samples, $\|\frac{1}{n}\sum_{i=1}^n g(x_i, \theta)\|$, as a function of θ, to obtain an estimate of θ_0.

In the theoretical analysis of NPHC, we use ideas from the consistency proof of the GMM, but the proof actually relies on very different arguments. Indeed, the integrated cumulants estimators used in NPHC are not unbiased, as the theory of GMM requires, but asymptotically unbiased. Moreover, the setting considered here, where data consists of a single realization $\{\boldsymbol{N}_t\}$ of a Hawkes process strongly departs from the standard i.i.d setting. Our approach is therefore based on the GMM idea but the proof is actually not using the theory of GMM.

In the following, we use the subscript T to refer to quantities that only depend on the process $(\boldsymbol{N_t})$ in the interval $[0, T]$ (e.g., the truncation term H_T, the estimated integrated covariance $\widehat{\boldsymbol{C}}_T$ or the estimated kernel norm matrix $\widehat{\boldsymbol{G}}_T$). In the next equation, $\odot$ stands for the Hadamard product and $\odot 2$ stands for the entrywise square of a matrix. We denote $\boldsymbol{G}_0 = \boldsymbol{I_d} - \boldsymbol{R}_0^{-1}$ the true value of $\boldsymbol{G}$, and

the $\mathbb{R}^{2d\times d}$ valued vector functions

$$g_0(\boldsymbol{R}) = \begin{bmatrix} \boldsymbol{C} - \boldsymbol{R}\boldsymbol{L}\boldsymbol{R}^\top \\ \boldsymbol{K^c} - \boldsymbol{R}^{\odot 2}\boldsymbol{C}^\top - 2[\boldsymbol{R} \odot (\boldsymbol{C} - \boldsymbol{R}\boldsymbol{L})]\boldsymbol{R}^\top \end{bmatrix}$$

$$\widehat{g}_T(\boldsymbol{R}) = \begin{bmatrix} \widehat{\boldsymbol{C}}_T - \boldsymbol{R}\widehat{\boldsymbol{L}}_T\boldsymbol{R}^\top \\ \widehat{\boldsymbol{K^c_T}} - \boldsymbol{R}^{\odot 2}\widehat{\boldsymbol{C}}_T^\top - 2[\boldsymbol{R} \odot (\widehat{\boldsymbol{C}}_T - \boldsymbol{R}\widehat{\boldsymbol{L}}_T)]\boldsymbol{R}^\top \end{bmatrix}.$$

Using these notations, $\widetilde{\mathcal{L}}_T(\boldsymbol{R})$ can be seen as the weighted squared Frobenius norm of $\widehat{g}_T(\boldsymbol{R})$. Moreover, when $T \to +\infty$, one has $\widehat{g}_T(\boldsymbol{R}) \xrightarrow{\mathbb{P}} g_0(\boldsymbol{R})$ under the conditions of the following theorem, where $\xrightarrow{\mathbb{P}}$ stands for convergence in probability.

Theorem 3 (Consistency of NPHC) *Suppose that $(\boldsymbol{N_t})$ is observed on $\mathbb{R}^+$ and assume that*

1. *$g_0(\boldsymbol{R}) = 0$ if and only if $\boldsymbol{R} = \boldsymbol{R}_0$;*
2. *$\boldsymbol{R} \in \Theta$, where Θ is a compact set;*
3. *the spectral radius of the kernel norm matrix satisfies $\|\boldsymbol{G}_0\| < 1$;*
4. *$H_T \to \infty$ and $H_T^2/T \to 0$.*

Then

$$\widehat{\boldsymbol{G}}_T = \boldsymbol{I_d} - \left(\arg\min_{\boldsymbol{R}\in\Theta} \widetilde{\mathcal{L}}_T(\boldsymbol{R})\right)^{-1} \xrightarrow{\mathbb{P}} \boldsymbol{G}_0.$$

The proof of the Theorem is given in the subsection B.5 below. Assumption 3 is mandatory for stability of the Hawkes process, and Assumptions 3 and 4 are sufficient to prove that the estimators of the integrated cumulants defined in Equations (11), (12) and (13) are asymptotically consistent. Assumption 2 is a very mild standard technical assumption allowing to prove consistency for estimators based on moments. Assumption 1 is a standard asymptotic moment condition, that allows to identity parameters from the integrated cumulants.

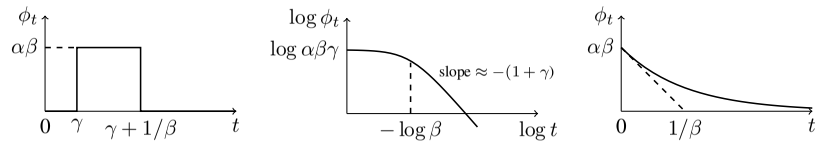
3. Numerical Experiments

In this Section, we provide a comparison of NPHC with the state-of-the art, on simulated datasets with different kernel shapes, the MemeTracker dataset (social networks) and the order book dynamics dataset (finance).

Simulated datasets. We simulated several datasets with Ogata's Thinning algorithm Ogata (1981) using the open-source library `tick`[1], each corresponding to a shape of kernel: rectangular, exponential or power law kernel, see Figure 1 below.

The integral of each kernel on its support equals α, $1/\beta$ can be regarded as a characteristic time-scale and γ is the scaling exponent for the power law distribution and a delay parameter for the rectangular one. We consider a non-symmetric block-matrix $\boldsymbol{G}$ to show that our method can effectively uncover causality between the nodes, see Figure 3. The matrix $\boldsymbol{G}$ has constant entries α on the three blocks - $\alpha = g^{ij} = 1/6$ for dimension 10 and $\alpha = g^{ij} = 1/10$ for dimension 100 -,

1. `https://github.com/X-DataInitiative/tick`



(a) Rectangular kernel $\phi_t = \alpha\beta \mathbb{1}_{[0,1/\beta]}(t-\gamma)$

(b) Power law kernel on log-log scale $\phi_t = \alpha\beta\gamma(1+\beta t)^{-(1+\gamma)}$

(c) Exponential kernel $\phi_t = \alpha\beta \exp(-\beta t)$

Figure 1: The three different kernels used to simulate the datasets.

and zero outside. The two other parameters' values are the same for dimensions 10 and 100. The parameter γ is set to $1/2$ on the three blocks as well, but we set three very different β_0, β_1 and β_2 from one block to the other, with ratio $\beta_{i+1}/\beta_i = 10$ and $\beta_0 = 0.1$. The number of events is roughly equal to 10^5 on average over the nodes. We ran the algorithm on three simulated datasets: a 10-dimensional process with rectangular kernels named Rect10, a 10-dimensional process with power law kernels named PLaw10 and a 100-dimensional process with exponential kernels named Exp100.

MemeTracker dataset. We use events of the most active sites from the MemeTracker dataset[2]. This dataset contains the publication times of articles in many websites/blogs from August 2008 to April 2009, and hyperlinks between posts. We extract the top 100 and the top 200 media sites with the largest number of documents, with about 7 million of events. We name MemeTracker100 the 100-dimensional dataset, and MemeTracker200 the 200-dimensional one. We use the links to trace the flow of information and establish an estimated ground truth for the matrix $\boldsymbol{G}$. Indeed, when an hyperlink j appears in a post in website i, the link j can be regarded as a direct ancestor of the event. Then, Eq. (2) shows g^{ij} can be estimated by $N_T^{i\leftarrow j}/N_T^j = \#\{\text{links } j \to i\}/N_T^j$.

Order book dynamics. We apply our method to financial data, in order to understand the self and cross-influencing dynamics of all event types in an order book. An order book is a list of buy and sell orders for a specific financial instrument, the list being updated in real-time throughout the day. This model has first been introduced in Bacry et al. (2016), and models the order book via the following 8-dimensional point process: $N_t = (P_t^{(a)}, P_t^{(b)}, T_t^{(a)}, T_t^{(b)}, L_t^{(a)}, L_t^{(b)}, C_t^{(a)}, C_t^{(b)})$, where $P^{(a)}$ (resp. $P^{(b)}$) counts the number of upward (resp. downward) price moves, $T^{(a)}$ (resp. $T^{(b)}$) counts the number of market orders at the ask[3] (resp. at the bid) that do not move the price, $L^{(a)}$ (resp. $L^{(b)}$) counts the number of limit orders at the ask[4] (resp. at the bid) that do not move the price, and $C^{(a)}$ (resp. $C^{(b)}$) counts the number of cancel orders at the ask[5] (resp. at the bid) that do not move the price. The financial data has been provided by QuantHouse EUROPE/ASIA, and consists of DAX future contracts between 01/01/2014 and 03/01/2014.

2. https://www.memetracker.org/data.html
3. That is buy orders that are executed and removed from the list.
4. That is buy orders added to the list.
5. That is the number of times a limit order at the ask is canceled: in our dataset, almost 95% of limit orders are canceled before execution.

Baselines. We compare NPHC to state-of-the art baselines: the ODE-based algorithm (ODE) by Zhou et al. (2013a), the Granger Causality-based algorithm (GC) by Xu et al. (2016), the ADM4 algorithm (ADM4) by Zhou et al. (2013b), and the Wiener-Hopf-based algorithm (WH) by Bacry and Muzy (2016).

Metrics. We evaluate the performance of the proposed methods using the computing time, the Relative Error

$$\text{RelErr}(\boldsymbol{A}, \boldsymbol{B}) = \frac{1}{d^2} \sum_{i,j} \frac{|a^{ij} - b^{ij}|}{|a^{ij}|} \mathbb{1}_{\{a^{ij} \neq 0\}} + |b^{ij}| \mathbb{1}_{\{a^{ij}=0\}}$$

and the Mean Kendall Rank Correlation

$$\text{MRankCorr}(\boldsymbol{A}, \boldsymbol{B}) = \frac{1}{d} \sum_{i=1}^{d} \text{RankCorr}([a^{i\bullet}], [b^{i\bullet}]),$$

where $\text{RankCorr}(x, y) = \frac{2}{d(d-1)}(N_{\text{concordant}}(x, y) - N_{\text{discordant}}(x, y))$ with $N_{\text{concordant}}(x, y)$ the number of pairs (i, j) satisfying $x_i > x_j$ and $y_i > y_j$ or $x_i < x_j$ and $y_i < y_j$ and $N_{\text{discordant}}(x, y)$ the number of pairs (i, j) for which the same condition is not satisfied.

Note that RankCorr score is a value between -1 and 1, representing rank matching, but can take smaller values (in absolute value) if the entries of the vectors are not distinct.

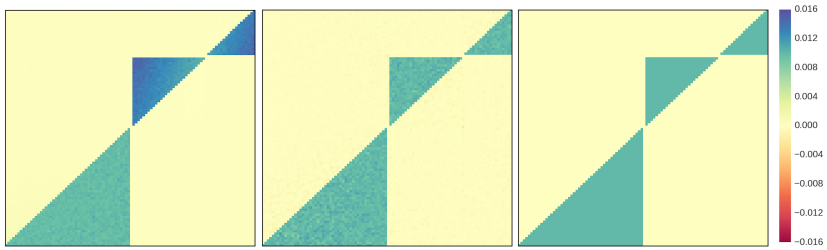


Figure 2: On Exp100 dataset, estimated $\widehat{\boldsymbol{G}}$ with ADM4 (left), with NPHC (middle) and the ground-truth matrix $\boldsymbol{G}$ (right). Both ADM4 and NPHC estimates recover the three blocks. However, ADM4 overestimates the integrals on two of the three blocks, while NPHC gives the same value on each blocks.

Discussion. We perform the ADM4 estimation, with exponential kernel, by giving the exact value $\beta = \beta_0$ of one block. Let us stress that this helps a lot this baseline, in comparison to NPHC where nothing is specified on the shape of the kernel functions. We used $M = 10$ basis functions for both ODE and GC algorithms, and $L = 50$ quadrature points for WH. We did not run WH on the 100-dimensional datasets, for computing time reasons, because its complexity scales with d^4. We ran multi-processed versions of the baseline methods on 56 cores, to decrease the computing time.

Our method consistently performs better than all baselines, on the three synthetic datasets, on MemeTracker and on the financial dataset, both in terms of Kendall rank correlation and estimation

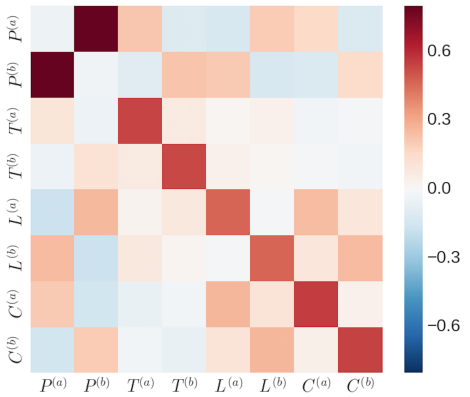

Figure 3: Estimated $\widehat{\boldsymbol{G}}$ via NPHC on DAX order book data.

error. Moreover, we observe that our algorithm is roughly 50 times faster than all the considered baselines.

On Rect10, PLaw10 and Exp100 our method gives very impressive results, despite the fact that it does not uses any prior shape on the kernel functions, while for instance the ADM4 baseline do. On Figure 3, we observe that the matrix $\widehat{\boldsymbol{G}}$ estimated with ADM4 recovers well the block for which $\beta = \beta_0$, i.e. the value we gave to the method, but does not perform well on the two other blocks, while the matrix $\widehat{\boldsymbol{G}}$ estimated with NPHC approximately reaches the true value for each of the three blocks. On these simulated datasets, NPHC obtains a comparable or slightly better Kendall rank correlation, but improves a lot the relative error.

On MemeTracker100, the baseline methods obtain a high relative error between 9% and 19% while our method achieves a relative error of 7% which is a strong improvement. Moreover, NPHC reaches a much better Kendall rank correlation, which proves that it leads to a much better recovery of the relative order of estimated influences than all the baselines. On MemeTracker200, NPHC outperforms again the baselines, with smaller Kendall rank correlation. The comparison of the computation times for both experiments shows that NPHC scales better than other methods. Plus, it has been shown in Zhou et al. (2013a) that kernels of MemeTracker data are not exponential, nor power law. This partly explains why our approach behaves better.

On the financial data, the estimated kernel norm matrix obtained via NPHC, see Figure 3, gave some interpretable results (see also Bacry et al. (2016)):

1. Any 2×2 sub-matrix with same kind of inputs (i.e. Prices changes, Trades, Limits or Cancels) is symmetric. This shows empirically that ask and bid have symmetric roles.

2. The prices are mostly cross-excited, which means that a price increase is very likely to be followed by a price decrease, and conversely. This is consistent with the wavy prices we observe on financial markets.

3. The market, limit and cancel orders are strongly self-excited. This can be explained by the persistence of order flows, and by the splitting of meta-orders into sequences of smaller orders. Moreover, we observe that orders impact the price without changing it. For example, the increase of cancel orders at the bid causes downward price moves.

4. Conclusion

In this paper, we introduce a simple nonparametric method (the NPHC algorithm) that leads to a fast and robust estimation of the matrix $\boldsymbol{G}$ of the kernel integrals of a Multivariate Hawkes process that encodes Granger causality between nodes. This method relies on the matching of the integrated order 2 and order 3 empirical cumulants, which represent the simplest set of global observables containing sufficient information to recover the matrix $\boldsymbol{G}$. Since this matrix fully accounts for the self- and cross- influences of the process nodes (that can represent agents or users in applications), our approach can naturally be used to quantify the degree of endogeneity of a system and to uncover the causality structure of a network.

By performing numerical experiments involving very different kernel shapes, we show that the baselines, involving either parametric or non-parametric approaches are very sensible to model misspecification, do not lead to accurate estimation, and are numerically expensive, while NPHC provides fast, robust and reliable results. This is confirmed on the MemeTracker database, where we show that NPHC outperforms classical approaches based on EM algorithms or the Wiener-Hopf equations. Finally, the NPHC algorithm provided very satisfying results on financial data, that are consistent with well-known stylized facts in finance.

Acknowledgments

This work benefited from the support of the chair "Changing markets", CMAP École Polytechnique and École Polytechnique fund raising - Data Science Initiative. The authors want to thank Marcello Rambaldi for fruitful discussions on order book data's experiments.

Appendix A. Additional experiments

We propose below additional experiments and technical details on the theoretical study of the NPHC procedure.

A.1 Convergence curves versus dimension

The NPHC procedure is divided into two parts: the first is the computation of the integrated cumulants' estimators, the second is the minimization of the loss function. As highlighted in the Section 2.5, the bottleneck of the algorithm is the computation of the cumulants' estimators. However, we can still wonder how fast the optimization algorithm converges with respect to the dimensionality of the point process. To answer that question, we simulated ten datasets corresponding to dimensions $d \in \{10, 20, \dots, 100\}$ with $\mu_i = 0.01$ for $i \in [d]$, $g^{ij} = 0.9/d$ for $(i, j) \in [d]^2$ (such that $\|\boldsymbol{G}\| = 0.9 < 1$), and $T = 10^7$. We then ran the NPHC method and recorded the loss function's evolution over the iterations, rescaled between 0 and 1. One can see on Figure 4 how the dimension influences the convergence curve: using the same hyperparameters for AdaGrad Duchi et al. (2011), the higher the dimension the more oscillating the convergence curve. Plus, the loss function seems to be flatter in lower dimension ($d = 10$ for instance) since AdaGrad needs more iterations to reach a minimum compared to higher-dimensional cases ($d = 70$ or $d = 100$ for instance).

A.2 Relative error versus number of events

The estimation of the integrated cumulants becomes more accurate when the amount of training data increases. The consistency of the estimators given in Equations (7), (8) and (9) is indeed proved in the theorem's proof in Appendix B. A natural question that arises is then to evaluate the precision of the parameter's estimation when the number of points increases, all other things remaining equal. To quantify this effect, we simulated several datasets similar to Rect10 - described in Section 3 - with

Table 5: Metrics on MemeTracker100: strong improvement in relative error, rank correlation and computing time.

Method	ODE	GC	ADM4	NPHC
RelErr	0.162	0.19	0.092	**0.071**
MRankCorr	0.07	0.053	0.081	**0.095**
Time (s)	2944	2780	2217	**38**

Table 6: Metrics on MemeTracker200: strong improvement in relative error, rank correlation and computing time.

Method	ODE	GC	ADM4	NPHC
RelErr	0.173	0.212	0.109	**0.084**
MRankCorr	0.062	0.048	0.077	**0.085**
Time (s)	11786	11210	8903	**164**

different simulation's durations. The only difference between those datasets is then the number of points per node. We ran NPHC ten times per dataset to loosely evaluate the variance of the estimate.

We only focus on the relative error metric which gives more interpretable results. The results summarized on the Figure 5 show the decrease of the relative error as the average (over the ten dimensions) number of points per node becomes larger. This decrease comes along with a variance decrease of the estimates.

A.3 Random choice of d^2 third integrated cumulant's entries

The NPHC method arbitrarily computes the d^2 *iij* entries of the third integrated cumulant, among the d^3 entries available, and then minimizes the distance between theoretical and empirical cumulants. We numerically show in this subsection than the computation of d^2 random entries followed by the minimization of the loss function reachs the same performance than NPHC's method. We sampled three sets of random d^2 indices ijk, and ran the methods on the dataset Rect10 introduced in Section 3.

Table 7: Metrics on Rect10: similar relative errors and rank correlations for the different methods.

Set of indices	Random set 1	Random set 2	Random set 3	*iij* (NPHC)
RelErr	0.0013	0.0014	0.0013	0.0013
MRankCorr	0.34	0.34	0.33	0.34

The results summarized on the Table 7 show that, to our knowledge, the procedure is not very sensitive to the selection of the d^2 entries from the third integrated cumulant tensor.

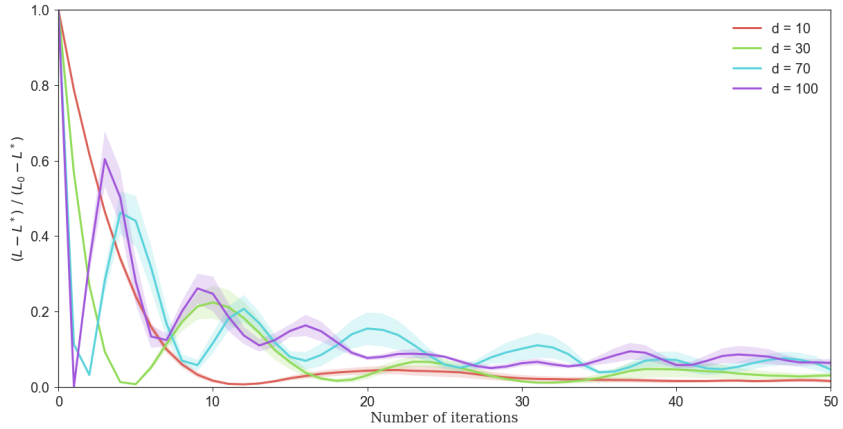

Figure 4: Convergence curves versus dimension.

Appendix B. Technical details

We show in this section how to obtain the equations stated above, the estimators of the integrated cumulants and the scaling coefficient κ that appears in the objective function. We then prove the theorem of the paper.

B.1 Proof of Equation (8)

We denote $\boldsymbol{\nu}(z)$ the matrix

$$\nu^{ij}(z) = \mathcal{L}_z\Big(t \to \frac{\mathbb{E}(dN_u^i dN_{u+t}^j)}{dudt} - \Lambda^i \Lambda^j\Big),$$

where $\mathcal{L}_z(f)$ is the Laplace transform of f, and $\psi_t = \sum_{n\geq 1} \phi_t^{(\star n)}$, where $\phi_t^{(\star n)}$ refers to the n^{th} auto-convolution of ϕ_t. Then we use the characterization of second-order statistics, first formulated in Hawkes (1971) and fully generalized in Bacry and Muzy (2016),

$$\boldsymbol{\nu}(z) = (\boldsymbol{I_d} + \mathcal{L}_{-z}(\boldsymbol{\Psi}))\boldsymbol{L}(\boldsymbol{I_d} + \mathcal{L}_z(\boldsymbol{\Psi}))^\top,$$

where $\boldsymbol{L}^{ij} = \Lambda^i \delta^{ij}$ with δ^{ij} the Kronecker symbol. Since $\boldsymbol{I_d} + \mathcal{L}_z(\boldsymbol{\Psi}) = (\boldsymbol{I_d} - \mathcal{L}_z(\boldsymbol{\Phi}))^{-1}$, taking $z = 0$ in the previous equation gives

$$\begin{aligned}\boldsymbol{\nu}(0) &= (\boldsymbol{I_d} - \boldsymbol{G})^{-1}\boldsymbol{L}(\boldsymbol{I_d} - \boldsymbol{G}^\top)^{-1},\\ \boldsymbol{C} &= \boldsymbol{RLR}^\top,\end{aligned}$$

which gives us the result since the entry (i,j) of the last equation gives $C^{ij} = \sum_m \Lambda^m R_{im} R_{jm}$.

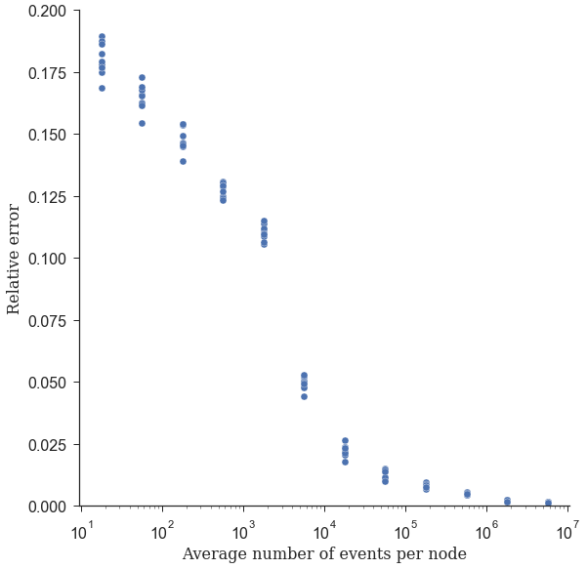

Figure 5: Relative error versus number of events.

B.2 Proof of Equation (9)

We start from Jovanović et al. (2015), cf. Eqs. (48) to (51), and group some terms:

$$\begin{aligned}K^{ijk} = &\sum_m \Lambda^m R_{im} R_{jm} R_{km}\\ &+ \sum_m R_{im} R_{jm} \sum_n \Lambda^n R_{kn} \mathcal{L}_0(\psi^{mn})\\ &+ \sum_m R_{im} R_{km} \sum_n \Lambda^n R_{jn} \mathcal{L}_0(\psi^{mn})\\ &+ \sum_m R_{jm} R_{km} \sum_n \Lambda^n R_{in} \mathcal{L}_0(\psi^{mn}).\end{aligned}$$

Using the relations $\mathcal{L}_0(\psi^{mn}) = R_{mn} - \delta^{mn}$ and $C^{ij} = \sum_m \Lambda^m R_{im} R_{jm}$, proves Equation (9).

B.3 Integrated cumulants estimators

For $H > 0$ let us denote $\Delta_H N_t^i = N_{t+H}^i - N_{t-H}^i$. Let us first remark that, if one restricts the integration domain to $(-H, H)$ in Eqs. (4) and (5), one gets by permuting integrals and expectations:

$$\begin{aligned}
\Lambda^i dt &= \mathbb{E}(dN_t^i) \\
C^{ij} dt &= \mathbb{E}\left(dN_t^i(\Delta_H N_t^j - 2H\Lambda^j)\right) \\
K^{ijk} dt &= \mathbb{E}\left(dN_t^i(\Delta_H N_t^j - 2H\Lambda^j)(\Delta_H N_t^k - 2H\Lambda^k)\right) \\
&\quad - dt\Lambda^i \mathbb{E}\left((\Delta_H N_t^j - 2H\Lambda^j)(\Delta_H N_t^k - 2H\Lambda^k)\right).
\end{aligned}$$

The estimators (11) and (12) are then naturally obtained by replacing the expectations by their empirical counterparts, notably

$$\frac{\mathbb{E}(dN_t^i f(t))}{dt} \to \frac{1}{T} \sum_{\tau \in Z^i} f(\tau).$$

For the estimator (13), we shall also notice that

$$\begin{aligned}
&\mathbb{E}((\Delta_H N_t^j - 2H\Lambda^j)(\Delta_H N_t^k - 2H\Lambda^k)) \\
&\quad = \int\int \mathbb{1}_{[-H,H]}(t) \mathbb{1}_{[-H,H]}(t') C_{t-t'}^{jk} dt dt' \\
&\quad = \int (2H - |t|)^+ C_t^{jk} dt.
\end{aligned}$$

We estimate the last integral with the remark above.

B.4 Choice of the scaling coefficient κ

Following the theory of GMM, we denote $m(X, \theta)$ a function of the data, where X is distributed with respect to a distribution $\mathbb{P}_{\theta_0}$, which satisfies the *moment conditions* $g(\theta) = \mathbb{E}[m(X, \theta)] = 0$ if and only if $\theta = \theta_0$, the parameter θ_0 being the *ground truth*. For $x_1, \dots, x_N$ observed copies of X, we denote $\widehat{g}_i(\theta) = m(x_i, \theta)$, the usual choice of weighting matrix is $\widehat{W}_N(\theta) = \frac{1}{N} \sum_{i=1}^N \widehat{g}_i(\theta) \widehat{g}_i(\theta)^\top$, and the objective to minimize is then

$$\left(\frac{1}{N} \sum_{i=1}^N \widehat{g}_i(\theta)\right) \left(\widehat{W}_N(\theta_1)\right)^{-1} \left(\frac{1}{N} \sum_{i=1}^N \widehat{g}_i(\theta)\right), \tag{15}$$

where θ_1 is a constant vector. Instead of computing the inverse weighting matrix, we rather use its projection on $\{\alpha \boldsymbol{I_d} : \alpha \in \mathbb{R}\}$. It can be shown that the projection choses α as the mean eigenvalue of $\widehat{W}_N(\theta_1)$. We can easily compute the sum of its eigenvalues:

$$\mathrm{Tr}(\widehat{W}_N(\theta_1)) = \frac{1}{N} \sum_{i=1}^N \mathrm{Tr}(\widehat{g}_i(\theta_1) \widehat{g}_i(\theta_1)^\top) = \frac{1}{N} \sum_{i=1}^N \mathrm{Tr}(\widehat{g}_i(\theta_1)^\top \widehat{g}_i(\theta_1)) = \frac{1}{N} \sum_{i=1}^N ||\widehat{g}_i(\theta_1)||_2^2.$$

In our case, $\widehat{g}(\boldsymbol{R}) = \left[\mathbf{vec}[\widehat{\boldsymbol{K^c}} - \boldsymbol{K^c}(\boldsymbol{R})], \mathbf{vec}[\widehat{\boldsymbol{C}} - \boldsymbol{C}(\boldsymbol{R})]\right]^\top \in \mathbb{R}^{2d^2}$. Considering a block-wise weighting matrix, one block for $\widehat{\boldsymbol{K^c}} - \boldsymbol{K^c}(\boldsymbol{R})$ and the other for $\widehat{\boldsymbol{C}} - \boldsymbol{C}(\boldsymbol{R})$, the sum of the eigenvalues of the first block becomes $\|\widehat{\boldsymbol{K^c}} - \boldsymbol{K^c}(\boldsymbol{R})\|_2^2$, and $\|\widehat{\boldsymbol{C}} - \boldsymbol{C}(\boldsymbol{R})\|_2^2$ for the second. We compute the previous terms with $\boldsymbol{R}_1 = 0$. All together, the objective function to minimize is

$$\frac{1}{\|\widehat{\boldsymbol{K^c}}\|_2^2} \|\boldsymbol{K^c}(\boldsymbol{R}) - \widehat{\boldsymbol{K^c}}\|_2^2 + \frac{1}{\|\widehat{\boldsymbol{C}}\|_2^2} \|\boldsymbol{C}(\boldsymbol{R}) - \widehat{\boldsymbol{C}}\|_2^2. \tag{16}$$

Dividing this function by $\left(1/\|\widehat{\boldsymbol{K^c}}\|_2^2 + 1/\|\widehat{\boldsymbol{C}}\|_2^2\right)^{-1}$, and setting $\kappa = \|\widehat{\boldsymbol{K^c}}\|_2^2 / (\|\widehat{\boldsymbol{K^c}}\|_2^2 + \|\widehat{\boldsymbol{C}}\|_2^2)$, we obtaind the loss function given in Equation (10).

B.5 Proof of the Theorem

The main difference with the usual Generalized Method of Moments, see Hansen (1982), relies in the relaxation of the moment conditions, since we have $\mathbb{E}[\widehat{g}_T(\theta_0)] = m_T \neq 0$. We adapt the proof of consistency given in Newey and McFadden (1994).

We can relate the integral of the Hawkes process's kernels to the integrals of the cumulant densities, from Jovanović et al. (2015). Our cumulant matching method would fall into the usual GMM framework if we could estimate - without bias - the integral of the covariance on $\mathbb{R}$, and the integral of the skewness on $\mathbb{R}^2$. Unfortunately, we can't do that easily. We can however estimate without bias $\int f_t^T C_t^{ij} dt$ and $\int f_t^T K_t^{ijk} dt$ with f^T a compact supported function on $[-H_T, H_T]$ that weakly converges to 1, with $H_T \longrightarrow \infty$. In most cases we will take $f_t^T = \mathbb{1}_{[-H_T, H_T]}(t)$. Denoting $\widehat{C}^{ij,(T)}$ the estimator of $\int f_t^T C_t^{ij} dt$, the term $|\mathbb{E}[\widehat{C}^{ij,(T)}] - C^{ij}| = |\int f_t^T C_t^{ij} dt - C^{ij}|$ can be considered a proxy to the *distance to the classical GMM*. This distance has to go to zero to make the rest of GMM's proof work: the estimator $\widehat{C}^{ij,(T)}$ is then asymptotically unbiased towards C^{ij} when T goes to infinity.

B.5.1 NOTATIONS

We observe the multivariate point process $(\boldsymbol{N}_t)$ on $\mathbb{R}^+$, with Z^i the events of the i^{th} component. We will often write covariance / skewness instead of integrated covariance / skewness. In the rest of the document, we use the following notations.

Hawkes kernels' integrals $\boldsymbol{G}^{\text{true}} = \int \boldsymbol{\Phi}_t dt = (\int \phi_t^{ij} dt)_{ij} = \boldsymbol{I_d} - (\boldsymbol{R}^{\text{true}})^{-1}$

Theoretical mean matrix $\boldsymbol{L} = \mathrm{diag}(\Lambda^1, \dots, \Lambda^d)$

Theoretical covariance $\boldsymbol{C} = \boldsymbol{R}^{\text{true}} \boldsymbol{L} (\boldsymbol{R}^{\text{true}})^\top$

Theoretical skewness $\boldsymbol{K^c} = (K^{iij})_{ij} = (\boldsymbol{R}^{\text{true}})^{\odot 2} \boldsymbol{C}^\top + 2[\boldsymbol{R}^{\text{true}} \odot (\boldsymbol{C} - \boldsymbol{R}^{\text{true}} \boldsymbol{L})](\boldsymbol{R}^{\text{true}})^\top$

Filtering function $f^T \geq 0 \qquad \mathrm{supp}(f^T) \subset [-H_T, H_T] \qquad F^T = \int f_s^T ds \qquad \widetilde{f}_t^T = f_{-t}^T$

Events sets $Z^{i,T,1} = Z^i \cap [H_T, T + H_T] \qquad Z^{j,T,2} = Z^j \cap [0, T + 2H_T]$

Estimators of the mean $\widehat{\Lambda}^i = \frac{N_{T+H_T}^i - N_{H_T}^i}{T} \qquad \widetilde{\Lambda}^j = \frac{N_{T+2H_T}^j}{T+2H_T}$

Estimator of the covariance $\widehat{C}^{ij,(T)} = \frac{1}{T}\sum_{\tau\in Z^{i,T,1}}\left(\sum_{\tau'\in Z^{j,T,2}} f_{\tau'-\tau} - \widetilde{\Lambda}^j F^T\right)$

Estimator of the skewness[6]

$$\widehat{K}^{ijk,(T)} = \frac{1}{T}\sum_{\tau\in Z^{i,T,1}}\left(\sum_{\tau'\in Z^{j,T,2}} f_{\tau'-\tau} - \widetilde{\Lambda}^j F^T\right)\left(\sum_{\tau''\in Z^{k,T,2}} f_{\tau'-\tau} - \widetilde{\Lambda}^k F^T\right) - \frac{\widehat{\Lambda}^i}{T+2H_T}\sum_{\tau'\in Z^{j,T,2}}\left(\sum_{\tau''\in Z^{k,T,2}} (f^T\star\widetilde{f}^T)_{\tau'-\tau''} - \widetilde{\Lambda}^k (F^T)^2\right)$$

GMM RELATED NOTATIONS

$$\begin{aligned}
\theta &= \boldsymbol{R} \quad \text{and} \quad \theta_0 = \boldsymbol{R}^{\text{true}}\\
g_0(\theta) &= \textbf{vec}\begin{bmatrix}\boldsymbol{C} - \boldsymbol{R}\boldsymbol{L}\boldsymbol{R}^\top\\ \boldsymbol{K^c} - \boldsymbol{R}^{\odot^2}\boldsymbol{C}^\top - 2[\boldsymbol{R}\odot(\boldsymbol{C}-\boldsymbol{R}\boldsymbol{L})]\boldsymbol{R}^\top\end{bmatrix} \in \mathbb{R}^{2d^2}\\
\widehat{g}_T(\theta) &= \textbf{vec}\begin{bmatrix}\widehat{\boldsymbol{C}}^{(T)} - \boldsymbol{R}\widehat{\boldsymbol{L}}\boldsymbol{R}^\top\\ \widehat{\boldsymbol{K}^{\boldsymbol{c}}}^{(T)} - \boldsymbol{R}^{\odot^2}(\widehat{\boldsymbol{C}}^{(T)})^\top - 2[\boldsymbol{R}\odot(\widehat{\boldsymbol{C}}^{(T)} - \boldsymbol{R}\widehat{\boldsymbol{L}})]\boldsymbol{R}^\top\end{bmatrix} \in \mathbb{R}^{2d^2}\\
Q_0(\theta) &= g_0(\theta)^\top W g_0(\theta)\\
\widehat{Q}_T(\theta) &= \widehat{g}_T(\theta)^\top \widehat{W}_T \widehat{g}_T(\theta)
\end{aligned}$$

B.5.2 CONSISTENCY

First, let's remind a useful theorem for consistency in GMM from Newey and McFadden (1994).

Theorem 4 *If there is a function $Q_0(\theta)$ such that (i) $Q_0(\theta)$ is uniquely maximized at θ_0; (ii) Θ is compact; (iii) $Q_0(\theta)$ is continuous; (iv) $\widehat{Q}_T(\theta)$ converges uniformly in probability to $Q_0(\theta)$, then $\widehat{\theta}_T = \arg\max \widehat{Q}_T(\theta) \xrightarrow{\mathbb{P}} \theta_0$.*

We can now prove the consistency of our estimator.

Theorem 5 *Suppose that $(\boldsymbol{N_t})$ is observed on $\mathbb{R}^+$, $\widehat{W}_T \xrightarrow{\mathbb{P}} W$, and*

1. *W is positive semi-definite and $Wg_0(\theta) = 0$ if and only if $\theta = \theta_0$,*
2. *$\theta \in \Theta$, which is compact,*
3. *the spectral radius of the kernel norm matrix satisfies $||\boldsymbol{\Phi}||_* < 1$,*
4. *$\forall i,j,k \in [d]$, $\int f_u^T C_u^{ij} du \to \int C_u^{ij} du$ and $\int f_u^T f_v^T K_{u,v}^{ijk} du dv \to \int K_{u,v}^{ijk} du dv$,*
5. *$(F^T)^2/T \xrightarrow{\mathbb{P}} 0$ and $||f||_\infty = O(1)$.*

6. When $f_t^T = \mathbb{1}_{[-H_T,H_T]}(t)$, we remind that $(f^T\star\widetilde{f}^T)_t = (2H_T - |t|)^+$. This leads to the estimator we showed in the article.

Then

$$\widehat{\theta}_T \xrightarrow{\mathbb{P}} \theta_0.$$

Remark 6 *In practice, we use a constant sequence of weighting matrices: $\widehat{W}_T = \boldsymbol{I_d}$.*

Proof Proceed by verifying the hypotheses of Theorem 2.1 from Newey and McFadden (1994). Condition 2.1(i) follows by (i) and by $Q_0(\theta) = [W^{1/2}g_0(\theta)]^\top[W^{1/2}g_0(\theta)] > 0 = Q_0(\theta_0)$. Indeed, there exists a neighborhood N of θ_0 such that $\theta \in N\backslash\{\theta_0\}$ and $g_0(\theta) \neq 0$ since $g_0(\theta)$ is a polynom. Condition 2.1(ii) follows by (ii). Condition 2.1(iii) is satisfied since $Q_0(\theta)$ is a polynom. Condition 2.1(iv) is harder to prove. First, since $\widehat{g}_T(\theta)$ is a polynom of θ, we prove easily that $\mathbb{E}[\sup_{\theta\in\Theta}|\widehat{g}_T(\theta)|] < \infty$. Then, by Θ compact, $g_0(\theta)$ is bounded on Θ, and by the triangle and Cauchy-Schwarz inequalities,

$$\begin{aligned}
&\left|\widehat{Q}_T(\theta) - Q_0(\theta)\right|\\
&\quad\le \left|(\widehat{g}_T(\theta) - g_0(\theta))^\top \widehat{W}_T(\widehat{g}_T(\theta) - g_0(\theta))\right|\\
&\quad+ \left|g_0(\theta)^\top(\widehat{W}_T + \widehat{W}_T^\top)(\widehat{g}_T(\theta) - g_0(\theta))\right| + \left|g_0(\theta)^\top(\widehat{W}_T - W)g_0(\theta)\right|\\
&\quad\le \|\widehat{g}_T(\theta) - g_0(\theta)\|^2\|\widehat{W}_T\| + 2\|g_0(\theta)\|\|\widehat{g}_T(\theta) - g_0(\theta)\|\|\widehat{W}_T\| + \|g_0(\theta)\|^2\|\widehat{W}_T - W\|.
\end{aligned}$$

To prove $\sup_{\theta\in\Theta}\left|\widehat{Q}_T(\theta) - Q_0(\theta)\right| \xrightarrow{\mathbb{P}} 0$, we should now prove that $\sup_{\theta\in\Theta}\|\widehat{g}_T(\theta) - g_0(\theta)\| \xrightarrow{\mathbb{P}} 0$. By Θ compact, it is sufficient to prove that $\|\widehat{\boldsymbol{L}} - \boldsymbol{L}\| \xrightarrow{\mathbb{P}} 0$, $\|\widehat{\boldsymbol{C}}^{(T)} - \boldsymbol{C}\| \xrightarrow{\mathbb{P}} 0$, and $\|\widehat{\boldsymbol{K^c}}^{(T)} - \boldsymbol{K^c}\| \xrightarrow{\mathbb{P}} 0$.

PROOF THAT $\|\widehat{\boldsymbol{L}} - \boldsymbol{L}\| \xrightarrow{\mathbb{P}} 0$

The estimator of $\boldsymbol{L}$ is unbiased so let's focus on the variance of $\widehat{\boldsymbol{L}}$.

$$\begin{aligned}
\mathbb{E}[(\widehat{\Lambda}^i - \Lambda^i)^2] &= \mathbb{E}\left[\left(\frac{1}{T}\int_{H_T}^{T+H_T}(dN_t^i - \Lambda^i dt)\right)^2\right]\\
&= \frac{1}{T^2}\int_{H_T}^{T+H_T}\int_{H_T}^{T+H_T}\mathbb{E}[(dN_t^i - \Lambda^i dt)(dN_{t'}^i - \Lambda^i dt')]\\
&= \frac{1}{T^2}\int_{H_T}^{T+H_T}\int_{H_T}^{T+H_T} C_{t'-t}^{ii} dt dt'\\
&\le \frac{1}{T^2}\int_{H_T}^{T+H_T} C^{ii} dt = \frac{C^{ii}}{T} \longrightarrow 0
\end{aligned}$$

By Markov inequality, we have just proved that $\|\widehat{\boldsymbol{L}} - \boldsymbol{L}\| \xrightarrow{\mathbb{P}} 0$.

PROOF THAT $\|\widehat{\boldsymbol{C}}^{(T)} - \boldsymbol{C}\| \xrightarrow{\mathbb{P}} 0$

First, let's remind that $\mathbb{E}(\widehat{\boldsymbol{C}}^{(T)}) \neq \boldsymbol{C}$. Indeed,

$$\begin{aligned}
\mathbb{E}\left(\widehat{C}^{ij,(T)}\right) &= \mathbb{E}\left(\frac{1}{T}\int_{H_T}^{T+H_T} dN_t^i \int_0^{T+2H_T} dN_{t'}^j f_{t'-t} - \widehat{\Lambda}^i\widetilde{\Lambda}^j F^T\right) \\
&= \mathbb{E}\left(\frac{1}{T}\int_{H_T}^{T+H_T} dN_t^i \int_{-t}^{T+2H_T-t} dN_{t+s}^j f_s - \Lambda^i\Lambda^j F^T\right) + \epsilon^{ij,T,H_T}F^T \\
&= \frac{1}{T}\int_{H_T}^{T+H_T}\int_{-H_T}^{H_T} f_s \mathbb{E}\left(dN_t^i dN_{t+s}^j - \Lambda^i\Lambda^j ds\right) + \epsilon^{ij,T,H_T}F^T \\
&= \int f_s C_s^{ij} ds + \epsilon^{ij,T,H_T}F^T
\end{aligned}$$

Now,

$$\begin{aligned}
\epsilon^{ij,T,H_T} &= \mathbb{E}\left(\Lambda^i\Lambda^j - \widehat{\Lambda}^i\widetilde{\Lambda}^j\right) \\
&= -\frac{1}{T^2}\int_{H_T}^{T+H_T}\int_0^{T+2H_T} \mathbb{E}\left(dN_t^i dN_{t'}^j - \Lambda^i\Lambda^j dt dt'\right) \\
&= -\frac{1}{T^2}\int_{H_T}^{T+H_T}\int_0^{T+2H_T} C_{t-t'}^{ij} dt dt' \\
&= -\frac{1}{T}\int\left(1 + \left(\frac{H_T - |t|}{T}\right)^-\right)^+ C_t^{ij} dt
\end{aligned}$$

Since f satisfies $F^T = o(T)$, we have $\mathbb{E}(\widehat{\boldsymbol{C}}^{(T)}) \longrightarrow \boldsymbol{C}$. It remains now to prove that $\|\widehat{\boldsymbol{C}}^{(T)} - \mathbb{E}(\widehat{\boldsymbol{C}}^{(T)})\| \xrightarrow{\mathbb{P}} 0$.
Let's now focus on the variance of $\widehat{C}^{ij,(T)}$: $\quad \mathbb{V}(\widehat{C}^{ij,(T)}) = \mathbb{E}\left((\widehat{C}^{ij,(T)})^2\right) - \mathbb{E}(\widehat{C}^{ij,(T)})^2$.
Now,

$$\begin{aligned}
&\mathbb{E}\left((\widehat{C}^{ij,(T)})^2\right) \\
&= \mathbb{E}\left(\frac{1}{T^2}\sum_{(\tau,\eta,\tau',\eta')\in(Z^{i,T,1})^2\times(Z^{j,T,2})^2}(f_{\tau'-\tau} - F^T/(T+2H_T))(f_{\eta'-\eta} - F^T/(T+2H_T))\right) \\
&= \mathbb{E}\left(\frac{1}{T^2}\int_{t,s\in[H_T,T+H_T]}\int_{t',s'} dN_t^i dN_{t'}^j dN_s^i dN_{s'}^j (f_{t'-t} - F^T/(T+2H_T))(f_{s'-s} - F^T/(T+2H_T))\right) \\
&= \frac{1}{T^2}\int_{t,s\in[H_T,T+H_T]}\int_{t',s'\in[0,T+2H_T]} \mathbb{E}\left(dN_t^i dN_{t'}^j dN_s^i dN_{s'}^j\right) \\
&\qquad\qquad \cdot (f_{t'-t} - F^T/(T+2H_T))(f_{s'-s} - F^T/(T+2H_T))
\end{aligned}$$

And,

$$\begin{aligned}
&\mathbb{E}(\widehat{C}^{ij,(T)})^2 \\
&= \frac{1}{T^2}\int_{t,s\in[H_T,T+H_T]}\int_{t',s'\in[0,T+2H_T]} \mathbb{E}\left(dN_t^i dN_{t'}^j\right)\mathbb{E}\left(dN_s^i dN_{s'}^j\right) \\
&\qquad\qquad \cdot (f_{t'-t} - F^T/(T+2H_T))(f_{s'-s} - F^T/(T+2H_T))
\end{aligned}$$

Then, the variance involves the integration towards the difference of moments $\mu^{r,s,t,u} - \mu^{r,s}\mu^{t,u}$.
Let's write it as a sum of cumulants, since cumulants density are integrable.

$$\begin{aligned}
\mu^{r,s,t,u} - \mu^{r,s}\mu^{t,u} &= \kappa^{r,s,t,u} + \kappa^{r,s,t}\kappa^u[4] + \kappa^{r,s}\kappa^{t,u}[3] + \kappa^{r,s}\kappa^t\kappa^u[6] + \kappa^r\kappa^s\kappa^t\kappa^u - (\kappa^{r,s} + \kappa^r\kappa^s)(\kappa^{t,u} + \kappa^t\kappa^u) \\
&= \kappa^{r,s,t,u} \\
&\quad + \kappa^{r,s,t}\kappa^u + \kappa^{u,r,s}\kappa^t + \kappa^{t,u,r}\kappa^s + \kappa^{s,t,u}\kappa^r \\
&\quad + \kappa^{r,t}\kappa^{s,u} + \kappa^{r,u}\kappa^{s,t} \\
&\quad + \kappa^{r,t}\kappa^s\kappa^u + \kappa^{r,u}\kappa^s\kappa^t + \kappa^{s,t}\kappa^r\kappa^u + \kappa^{s,t}\kappa^r\kappa^u
\end{aligned}$$

In the rest of the proof, we denote $a_t = \mathbb{1}_{t\in[H_T,T+H_T]}$, $b_t = \mathbb{1}_{t\in[0,T+2H_T]}$, $c_t = \mathbb{1}_{t\in[-H_T,H_T]}$, $g_t = f_t - \frac{1}{T+2H_T}F^T$
Before starting the integration of each term, let's remark that:

1. $\boldsymbol{\Psi}_t = \sum_{n\geq 1}\boldsymbol{\Phi}_t^{(\star n)} \geq 0$ since $\boldsymbol{\Phi}_t \geq 0$.
2. The regular parts of C_u^{ij}, $K_{u,v}^{ijk}$ (skewness density) and $M_{u,v,w}^{ijkl}$ (fourth cumulant density) are positive as polynoms of integrals of $\psi_\cdot^{ab}$ with positive coefficients. The integrals of the singular parts are positive as well.
3. (a) $\int a_t b_{t'} f_{t'-t} dt dt' = TF^T$
   (b) $\int a_t b_{t'} g_{t'-t} dt dt' = 0$
   (c) $\int a_t b_{t'} |g_{t'-t}| dt dt' \leq 2TF^T$
4. $\forall t \in \mathbb{R}, a_t(b \star \widetilde{g})_t = 0$, where $\widetilde{g}_s = g_{-s}$.

Fourth cumulant We want here to compute $\int \kappa_{t,t',s,s'}^{i,j,i,j} a_t b_{t'} a_s b_{s'} g_{t'-t} g_{s'-s} dt dt' ds ds'$.
We remark that $|g_{t'-t}g_{s'-s}| \leq (||f||_\infty(1 + 2H_T/T))^2 \leq 4||f||_\infty^2$.

$$\begin{aligned}
\left|\frac{1}{T^2}\int \kappa_{t,t',s,s'}^{i,j,i,j} a_t b_{t'} a_s b_{s'} g_{t'-t} g_{s'-s} dt dt' ds ds'\right| &\leq \left(\frac{2||f||_\infty}{T}\right)^2 \int dt a_t \int dt' b_{t'} \int ds a_s \int ds' b_{s'} M_{t'-t,s-t,s'-t}^{ijij} \\
&\leq \left(\frac{2||f||_\infty}{T}\right)^2 \int dt a_t \int dt' b_{t'} \int ds a_s \int dw M_{t'-t,s-t,w}^{ijij} \\
&\leq \left(\frac{2||f||_\infty}{T}\right)^2 \int dt a_t \int M_{u,v,w}^{ijij} du dv dw \\
&\leq \frac{4||f||_\infty^2}{T} M^{ijij} \underset{T\to\infty}{\longrightarrow} 0
\end{aligned}$$

Third $\times$ First We have four terms, but only two different forms since the roles of (s, s') and (t, t') are symmetric.
First form

$$\begin{aligned}\int \kappa^{i,j,i}_{t,t',s}\Lambda^j G_{\boldsymbol{t}} d\boldsymbol{t} &= \frac{\Lambda^j}{T^2}\int \kappa^{i,j,i}_{t,t',s} a_t b_{t'} a_s b_{s'} g_{t'-t} g_{s'-s} dt dt' ds ds' \\ &= \frac{\Lambda^j}{T^2}\int \kappa^{i,j,i}_{t,t',s} a_t b_{t'} a_s (b \star \widetilde{g})_s g_{t'-t} dt dt' ds \\ &= 0 \qquad \text{since } a_s(b\star\widetilde{g})_s = 0\end{aligned}$$

Second form

$$\begin{aligned}\Big|\int \kappa^{i,j,j}_{t,t',s'}\Lambda^i G_{\boldsymbol{t}} d\boldsymbol{t}\Big| &= \Big|\frac{\Lambda^i}{T^2}\int \kappa^{i,j,j}_{t,t',s'} a_t b_{t'} a_s b_{s'} g_{t'-t} g_{s'-s} dt dt' ds ds'\Big| \\ &= \Big|\frac{\Lambda^i}{T^2}\int \kappa^{i,j,j}_{t,t',s'} a_t b_{t'} g_{t'-t} b_{s'} (a\star g)_{s'} dt dt' ds'\Big| \\ &\leq \frac{\Lambda^i}{T^2} 2||f||_\infty \int ds' b_{s'}(a\star|g|)_{s'} \int dt a_t \int dt' b_{t'} K^{ijj}_{t'-s',t-s'} \\ &\leq 4||f||_\infty K^{ijj}\Lambda^i \frac{F^T}{T} \underset{T\to\infty}{\longrightarrow} 0\end{aligned}$$

Second $\times$ Second
First form

$$\begin{aligned}\Big|\int \kappa^{i,i}_{t,s}\kappa^{j,j}_{t',s'} G_{\boldsymbol{t}} d\boldsymbol{t}\Big| &\leq \frac{2||f||_\infty}{T^2}\int C^{ii}_{t-s} C^{jj}_{t'-s'} a_t b_{t'} |g_{t'-t}| a_s b_{s'} dt dt' ds ds' \\ &\leq \frac{2||f||_\infty}{T^2} C^{ii} C^{jj} \int a_t b_{t'} |g_{t'-t}| dt dt' \\ &\leq 4||f||_\infty C^{ii} C^{jj} \frac{F^T}{T} \underset{T\to\infty}{\longrightarrow} 0\end{aligned}$$

Second form

$$\Big|\int \kappa^{i,j}_{t,s'}\kappa^{i,j}_{t',s} G_{\boldsymbol{t}} d\boldsymbol{t}\Big| \leq 4||f||_\infty (C^{ij})^2 \frac{F^T}{T} \underset{T\to\infty}{\longrightarrow} 0$$

Second $\times$ First $\times$ First
First form

$$\int \kappa^{i,j}_{t,t'}\Lambda^i\Lambda^j G_{\boldsymbol{t}} d\boldsymbol{t} = \frac{\Lambda^i\Lambda^j}{T^2}\int \kappa^{i,j}_{t,t'} a_t b_{t'} g_{t'-t} dt dt' \int a_s b_{s'} g_{s'-s} ds ds' = 0$$

Second form

$$\int \kappa^{i,i}_{t,s}\Lambda^j\Lambda^j G_{\boldsymbol{t}} d\boldsymbol{t} = \left(\frac{\Lambda^j}{T}\right)^2 \int \kappa^{i,i}_{t,s} a_t b_{t'} g_{t'-t} a_s (b\star\widetilde{g})_s dt dt' ds = 0$$

We have just proved that $\mathbb{V}(\widehat{\boldsymbol{C}}^{(T)}) \xrightarrow{\mathbb{P}} 0$. By Markov inequality, it ensures us that $\|\widehat{\boldsymbol{C}}^{(T)} - \mathbb{E}(\widehat{\boldsymbol{C}}^{(T)})\| \xrightarrow{\mathbb{P}} 0$, and finally that $\|\widehat{\boldsymbol{C}}^{(T)} - \boldsymbol{C}\| \xrightarrow{\mathbb{P}} 0$. ■

PROOF THAT $\|\widehat{\boldsymbol{K}^{\boldsymbol{c}}}^{(T)} - \boldsymbol{K}^{\boldsymbol{c}}\| \xrightarrow{\mathbb{P}} 0$

The scheme of the proof is similar to the previous one. The upper bounds of the integrals involve the same kind of terms, plus the new term $(F^T)^2/T$ that goes to zero thanks to the assumption 5 of the theorem.

Editor: Qiang Liu

Abstract

This survey provides a comprehensive overview of the landscape of crowdsourcing research, targeted at the machine learning community. We begin with an overview of the ways in which crowdsourcing can be used to advance machine learning research, focusing on four application areas: 1) data generation, 2) evaluation and debugging of models, 3) hybrid intelligence systems that leverage the complementary strengths of humans and machines to expand the capabilities of AI, and 4) crowdsourced behavioral experiments that improve our understanding of how humans interact with machine learning systems and technology more broadly. We next review the extensive literature on the behavior of crowdworkers themselves. This research, which explores the prevalence of dishonesty among crowdworkers, how workers respond to both monetary incentives and intrinsic forms of motivation, and how crowdworkers interact with each other, has immediate implications that we distill into best practices that researchers should follow when using crowdsourcing in their own research. We conclude with a discussion of additional tips and best practices that are crucial to the success of any project that uses crowdsourcing, but rarely mentioned in the literature.

Keywords: crowdsourcing, data generation, model evaluation, hybrid intelligence, behavioral experiments, incentives, mechanical turk

1. Introduction

Crowdsourcing allows us to harness the power of human computation to solve tasks that are notoriously difficult to solve with computers alone, such as determining whether or not an image contains a tree, rating the quality of a website, or verifying the phone number of a business. The machine learning community was early to embrace crowdsourcing as a tool for quickly and inexpensively obtaining the vast quantities of labeled data needed to train machine learning systems. Crowdsourcing has been used to generate the image annotations that are needed to train computer vision systems (Deng et al., 2009; Patterson and Hays, 2012; Raykar et al., 2010; Wah et al., 2011), provide the linguistic annotations needed for common natural language processing tasks (Callison-Burch and Dredze, 2010; Snow et al., 2008), and collect the relevance judgments needed to optimize search engines (Alonso, 2013; Alonso et al., 2008). This simple idea—that crowds could be used to generate training data for machine learning algorithms—inspired a flurry of algorithmic work on how to best elicit and aggregate potentially noisy labels (e.g., Ghosh et al., 2011; Karger et al., 2011; Khetan and Oh, 2016; Liu et al., 2012a; Sheng et al., 2008; Welinder et al., 2010; Zhang et al., 2016b; Zhou et al., 2012), still an active area of research (Zheng et al., 2017). Meanwhile, machine learning researchers have begun to put crowdsourcing to use in other ways, most commonly as a tool to evaluate and debug machine learning models (Chang et al., 2009; Ribeiro et al., 2016).

Crowdsourcing has flourished as a research tool outside of the machine learning community as well. In human-computer interaction and related fields, researchers are building "hybrid intelligence systems" with the goal of expanding the capabilities of current AI technology by incorporating humans in the loop (e.g., Bernstein et al., 2010; Kamar, 2016; Lasecki et al., 2017; Zhang et al., 2012). And psychologists and social scientists have increasingly moved experiments that traditionally would have been run in physical labs onto crowdsourcing platforms (Buhrmester et al., 2011; Mason and Suri, 2012). While these bodies of research are less well known within the machine learning community, there are countless opportunities for machine learning research to both influence and benefit from these lines of work. For example, human-in-the-loop clustering algorithms have been designed that produce better clusters by drawing on the common sense knowledge and experience of the crowd (Gomes et al., 2011; Heikinheimo and Ukkonen, 2013; Tamuz et al., 2011), while behavioral experiments run on the crowd offer insight about how to encourage human trust in algorithmic predictions (Dietvorst et al., 2015, 2016; Dzindolet et al., 2002).

The first goal of this survey is to expand the horizons of how machine learning researchers think about crowdsourcing, providing a broad overview of ways in which crowdsourcing can benefit (and sometimes benefit from) machine learning research. Unlike other surveys, which go into greater depth on algorithms for aggregating crowdsourced labels (Zhang et al., 2016a; Zheng et al., 2017), we address the label aggregation problem only briefly, devoting relatively more attention and detail to applications that are less well known within the machine learning community, in the hope of inspiring new connections and directions of research. We break the applications into four broad categories:

- **Data generation.** (Section 2) Crowdsourcing platforms are well suited to generating data, but challenges arise since the data supplied by crowdworkers can be prone to errors. We start with a brief review of two lines of research aimed at improving the quality of crowdsourced labels. The first assumes that data points are redundantly assigned to multiple workers and seeks algorithms for aggregating workers' responses that take into account the quality of individual workers (e.g., Zhang et al., 2016a; Zheng et al., 2017). Though there are many notable exceptions, much of this work builds on the influential model and expectation-maximization framework of Dawid and Skene (1979). The second line of work focuses on developing incentive schemes to motivate high quality responses. Much of this work builds on the literature on peer prediction, a framework in which crowdworkers' payments are a function of their own reported labels and the labels of other workers (Jurca and Faltings, 2009; Miller et al., 2005; Radanovic et al., 2016). We then review ways in which crowdsourcing has been applied to generate other forms of data, including transcriptions of printed text (von Ahn et al., 2008), translations of sentences from one language to another (Zaidan and Callison-Burch, 2011), and image annotations (Kovashka et al., 2016).

- **Evaluating and debugging models.** (Section 3) Crowdsourcing is also commonly used to evaluate or debug models, including unsupervised learning models, which can

be difficult to evaluate objectively since there is often no clear notion of ground truth. Along these lines, we discuss the use of crowdsourcing to evaluate the coherence of topic models, generative models used to discover and explore the thematic topics discussed in a set of documents (Chang et al., 2009). We also explore ways in which crowdsourcing has been used to evaluate the interpretability of explanations of predictions in supervised learning settings (Ribeiro et al., 2016) and to debug the components of a pipeline in a complex computer vision system (Mottaghi et al., 2013, 2016; Parikh and Zitnick, 2011).

- **Hybrid intelligence systems.** (Section 4) Hybrid intelligence or "human-in-the-loop" systems advance the capabilities of current AI technology by leveraging the complementary strengths of humans and machines. We explore several compelling examples of hybrid systems that suggest their great potential: hybrid systems for clustering data points (Gomes et al., 2011; Heikinheimo and Ukkonen, 2013; Tamuz et al., 2011), transcribing speech in real time (Kushalnagar et al., 2012; Lasecki and Bigham, 2012; Lasecki et al., 2012, 2013, 2017; Naim et al., 2013), scheduling conference sessions (André et al., 2013; Bhardwaj et al., 2014; Chilton et al., 2014; Kim et al., 2013), and forecasting geopolitical or economic events (Atanasov et al., 2017; Baron et al., 2014; Mellers et al., 2015b). These systems are able to achieve more than would be possible with state-of-the-art machine learning or AI systems alone because they can make use of people's common sense knowledge, life experience, subjective beliefs, and flexible reasoning skills.

- **Behavioral studies to inform machine learning research.** (Section 5) As machine learning becomes a larger part of people's everyday lives, interest in understanding how real people interact with machine learning systems continues to grow. There has been a surge of recent research on questions like how to design machine learning models that are more interpretable (Doshi-Velez and Kim, 2017; Lipton, 2016) or how to understand the ways that algorithmic decisions impact people's lives (Angwin et al., 2016; Barocas and Selbst, 2016). These questions are interdisciplinary in nature and require gaining a better understanding of the underlying principles behind humans' interactions with machine learning and other technological systems. At the same time, psychologists and social scientists have started using crowdsourcing platforms as a fast and easy way to gain access to large pools of subjects for behavioral experiments. This presents a natural opportunity for researchers to conduct studies on crowdsourcing platforms that improve our understanding of how humans interact with technology broadly and machine learning algorithms in particular. Rather than evaluating the way in which people interact with one particular algorithm, this line of research aims to develop an understanding of components of human behavior that could inform the use and design of machine learning systems more broadly. We walk through illustrative examples of behavioral studies aimed at understanding user trust in algorithmic predictions (Dietvorst et al., 2015, 2016; Dzindolet et al., 2002; Poursabzi-Sangdeh et al., 2018) and how users react to online advertising (Goldstein et al., 2013, 2014). The latter study, while not directly motivated by a machine learning question, could provide insights that inform the design of better machine learning algorithms for ad pricing and display.

Having explored these applications and motivated the use of crowdsourcing in machine learning research, the remainder of the survey addresses our second goal: to provide the reader with best practices for crowdsourcing by drawing deeply on the vast and cross-disciplinary literature aimed at studying and understanding the behavior of the crowd itself. In Section 6, we describe several studies that quantify and measure the prevalence of dishonest or spammy behavior on crowdsourcing platforms (Chandler and Paolacci, 2017; Suri et al., 2011; Wessling et al., 2017). We discuss how to set payments for tasks in light of both ethical considerations (Williamson, 2016) and a body of research that explores how the quality and quantity of crowdwork are impacted by monetary incentives (e.g., Buhrmester et al., 2011; Ho et al., 2015; Mason and Watts, 2009; Shaw et al., 2011). We examine how workers react to intrinsic sources of motivation, such as gamification (von Ahn and Dabbish, 2008) or the satisfaction of performing meaningful work (Chandler and Kapelner, 2013; Rogstadius et al., 2011), and how intrinsically motivating workers can increase workers' willingness to complete tasks. Finally, we explore communication and collaboration patterns of workers and see that crowdworkers are not independent and isolated, but rather part of a rich communication network (Gray et al., 2016; Yin et al., 2016). We discuss the implications of this work on the practice of using crowdsourcing for research, outlining best practices that should be followed whether one wishes to use crowdsourcing for data generation, model evaluation, building hybrid systems, running behavioral studies, or beyond.

Section 7 concludes with a discussion of additional tips and tricks that are crucial for the success of any crowdsourcing-based project, but rarely discussed in the literature.

1.1 A Note on Scope

As described above, this survey was written with two overarching goals in mind. The first is to inspire machine learning researchers to discover unexpected applications of crowdsourcing in their own research. Because of this, relatively more space is devoted to applications that may be less familiar to the machine learning community, such as hybrid intelligence systems and behavioral studies of users interacting with technology, compared with more familiar applications like data generation and model evaluation. Full surveys have been written just on the problem of aggregating noisy labels from a crowd; readers who are most interested in this problem are encouraged to look at Zheng et al. (2017), Zhang et al. (2016a), or the comprehensive summary of related work in Zhang et al. (2016b).

The second goal is to introduce machine learning researchers to the extensive cross-disciplinary literature on crowd behavior and motivate why understanding this literature is crucial for successfully employing crowdsourcing in research. Because of this, Section 6 draws heavily on work from outside the machine learning community, and emphasizes experimental work over pure theory.

Several other crowdsourcing surveys have been published, each focused on a different set of themes and problems. Readers interested in gaining a broader perspective on crowdsourcing may be interested in recent surveys and guides from the computer vision community (Kovashka et al., 2016), the databases community (Li et al., 2016), and the marketing community (Goodman and Paolacci, 2017), or the older but still widely cited and applicable how-to guides on crowdsourcing user studies (Kittur et al., 2008) and behavioral research (Mason and Suri, 2012).

1.2 Background on Mechanical Turk and Other Crowdsourcing Platforms

In this survey, we use the term crowdsourcing very generally to encompass both paid and volunteer crowdwork, done by experts or nonexperts, on any general or specialized crowdsourcing platform. Regardless, the majority of research covered was conducted using paid crowdworkers, and the majority of that on one particular platform, Amazon Mechanical Turk.

Amazon Mechanical Turk[1] is the most commonly used crowdsourcing platform among researchers. It is designed for crowdsourcing relatively small "microtasks" (often referred to as "HITs," for human intelligence tasks) such as labeling a set of images or completing a survey, though it can also be used for more complex short-term tasks, such as participating in behavioral experiments (Mason and Suri, 2012) or even writing fiction (Kim et al., 2017). Task requesters come to Mechanical Turk to post their tasks, stating up front the amount of money that they are willing to pay to have their tasks completed. Requesters can also specify certain criteria that a crowdworker must meet to be eligible for their task, such as having an approval rate of more than a particular amount (say, 97%) on previous tasks or being located in a particular country. Crowdworkers can then browse the set of tasks available and choose the tasks they would like to work on. After a crowdworker completes a task, the requester approves her work and a payment is made.

Although Mechanical Turk is used broadly in the research community, it is not the right choice for everyone. In particular, it can be difficult to use from outside of the United States. Luckily, many alternatives are available. For example:

- CrowdFlower[2] is a crowdsourcing platform widely used in both industry and research. CrowdFlower offers specialized enterprise solutions for businesses with artificial intelligence and data science needs including search relevance evaluation, sentiment analysis, and data classification.
- ClickWorker[3] is a German crowdsourcing platform that attracts European workers. It provides support for specialized tasks such as translation, web research, and web content generation. It also provides tools for mobile crowdsourcing.
- Prolific Academic[4] is a UK-based crowdsourcing platform focused primarily on connecting researchers with participants for behavioral or user studies.
- Upwork[5] is an online freelancer marketplace focused not on microtasks but rather on larger scale jobs such as writing an article or designing a website.
- TopCoder[6] hosts crowdsourcing contests (Chawla et al., 2015; DiPalantino and Vojnovic, 2009; Gao et al., 2012) in which coders design and develop software in response to specific challenges and compete for prizes. Unlike on the other sites mentioned, only those who create the top-judged submissions are paid.

2. https://www.crowdflower.com
3. https://www.clickworker.com
4. https://www.prolific.ac
5. https://www.upwork.com
6. https://www.topcoder.com

Several researchers have compared commercially available platforms along different dimensions. Vakharia and Lease (2015) provided a thorough qualitative content analysis of seven platforms: ClickWorker, CrowdComputing Systems (now WorkFusion), CloudFactory, CrowdFlower, CrowdSource, MobileWorks (now LeadGenius), and oDesk (now Upwork), examining factors like infrastructure and tools, support for fraud protection, and quality of work. Peera et al. (2017) provided a detailed experimental comparison of three platforms: Mechanical Turk, CrowdFlower, and Prolific Academic. They compared dropout rates, response rates, workers' performance on attention-check questions, workers' reliability, workers' familiarity with common psychology studies (which would signal an overused population of subjects), and the ability to replicate classic psychology studies on each platform. They found, for example, that workers on both CrowdFlower and Prolific Academic were less familiar with common psychology studies and less dishonest than workers on Mechanical Turk, with Prolific Academic producing higher quality data than CrowdFlower.

2. Data Generation

Perhaps the most common application of crowdsourcing within the machine learning community is data generation. We first describe techniques for crowdsourcing binary or categorical labels, reviewing the literature on how to improve label quality through redundancy and incentives. We then discuss several examples of ways in which crowdsourcing has been used to generate more complex forms of data, such as image annotations and translations of text. As mentioned above, entire surveys could be written on the topic of crowdsourced data generation alone, and indeed some have (Zhang et al., 2016a; Zheng et al., 2017). Our treatment of this topic is comparatively brief, intended only to give the reader the flavor of this work with pointers to the literature for readers who wish to learn more.

2.1 Generating Binary or Categorical Labels

We start with the setting in which crowdworkers are presented with unlabeled data instances (for instance, websites) and are asked to supply labels (for instance, a binary label indicating whether or not the website contains profanity). The main challenge arises from the fact that the supplied labels are often noisy or inaccurate, either because workers are imperfect or because workers are unmotivated to put high effort into the labeling task. There are two primary lines of work aimed at improving the quality of crowdsourced labels. The first assumes that each instance is presented to multiple crowdworkers and explores algorithmic techniques for aggregating the workers' responses (e.g., Abraham et al., 2016; Aydin et al., 2014; Demartini et al., 2012; Fan et al., 2015; Gao et al., 2016; Ghosh et al., 2011; Ho et al., 2013; Karger et al., 2011, 2014; Khetan and Oh, 2016; Kim and Ghahramani, 2012; Li et al., 2014a,b; Liu et al., 2012a,b; Ma et al., 2015; Raykar et al., 2010; Shah and Lee, 2018; Sheng et al., 2008; Tian and Zhu, 2015; Venanzi et al., 2014; Welinder et al., 2010; Whitehill et al., 2009; Zhang et al., 2016b; Zhou et al., 2012). The second explores the use of well-designed incentives to encourage higher quality work (e.g., Dasgupta and Ghosh, 2013; Ho et al., 2016; Kamar and Horvitz, 2012; Kamble et al., 2015; Radanovic et al., 2016; Shah et al., 2015; Shah and Zhou, 2016a,b).

Much of the research on label aggregation builds on the model proposed in the seminal paper of Dawid and Skene (1979). The basic Dawid-Skene model assumes that instances are

homogeneous. A worker's probability of labeling any given instance correctly is controlled by one or more worker-specific quality parameters. In the original model, each worker's quality is governed by a latent confusion matrix that specifies the worker's probability of choosing each possible label conditioned on the true label of the instance. A variety of extensions have been studied. For example, several papers have explored models in which difficulty varies by instance (Khetan and Oh, 2016; Ma et al., 2015; Whitehill et al., 2009; Zhou et al., 2012) or workers have diverse sets of skills (Fan et al., 2015; Ho et al., 2013; Welinder et al., 2010). Most of this work assumes a fixed assignment of instances to workers, but some assumes that workers arrive online and are assigned to instances upon arrival (Abraham et al., 2016; Ho and Vaughan, 2012; Ho et al., 2013; Karger et al., 2011, 2014). Some work requires the existence of "gold-standard" or "control" tasks (Le et al., 2010; Liu et al., 2013; Oleson et al., 2011), data instances for which ground truth labels are known a priori, while some does not. Extensions of the Dawid-Skene model have also been applied to the problem of aggregating ordinal labels or rankings (Zhou et al., 2014).

While there are exceptions, much of this research builds on the general expectation-maximization (EM) algorithmic framework that Dawid and Skene (1979) proposed. This framework is outlined in Algorithm 1. The basic approach involves iteratively updating estimates of both workers' quality parameters and the labels of each instance. At each step, quality parameters are updated treating the current label estimates as ground truth. The instance labels are then updated to their most likely values treating the quality parameters as ground truth. The details of these updates vary. Zheng et al. (2017) provide a thorough survey and empirical comparison of seventeen algorithms that are based on this general framework, characterizing them in terms of the way in which instances and workers are modeled as well as the specifics of how the calculations of quality parameters and label assignments are made (through what they call direct computation, using optimization methods, or using probabilistic graphical models). While their experiments reveal that different algorithms perform best on different data sets, they show that the original Dawid-Skene algorithm is itself fairly robust in practice.

Algorithm 1 The basic EM framework of Dawid and Skene (1979).

Input: Sets of worker-generated labels for each instance
Initialize each instance's label based on a simple majority vote
repeat
  for all Workers w **do**
    Calculate w's quality parameter(s), treating each instance's current label as ground truth
  end for
  for all Instances i **do**
    Calculate the most likely label for i, treating each worker's approximated quality parameter(s) as ground truth
  end for
until Label assignments have converged
Output: The current label assignments for each instance

One broadly studied class of incentive schemes for crowdsourcing is built on the literature on peer prediction (e.g., Dasgupta and Ghosh, 2013; Jurca and Faltings, 2009; Kamar and Horvitz, 2012; Kamble et al., 2015; Miller et al., 2005; Prelec, 2004; Prelec et al., 2017; Radanovic and Faltings, 2013; Waggoner and Chen, 2014; Witkowski and Parkes, 2012), a framework in which workers are rewarded based on a function of their own reported labels and the reports of others. Under many peer prediction mechanisms, higher rewards are given to reports that are "surprisingly common" among workers, where "surprise" could be measured, for example, in terms of a common prior or the frequency of a label. As just one example, to determine the payment for a worker w who labels a particular instance as x, the mechanism proposed by Radanovic et al. (2016) selects another worker w' at random and compares the label provided by w to the label provided by w'. If w' reports x (so the two workers' labels agree), then w receives payment $1/f$ where f is the empirical frequency with which other workers have reported the label x over all instances. If w' does not report x, then w receives no payment. Radanovic et al. (2016) showed that under some assumptions on workers' beliefs, truthful reporting (i.e., each worker reporting the label they think is most likely) is an equilibrium under this mechanism.

The primary benefit of peer prediction style methods is that there is no need to know ground truth labels in order to calculate payments. One major drawback is that most such methods leave open the opportunity for workers to benefit by coordinating and colluding on incorrect reports, behavior that has been observed when these methods were tested on real workers (Gao et al., 2014). There is an active line of research on developing peer prediction techniques for which such undesirable equilibria do not exist, or at least are less profitable than truth telling (Agarwal et al., 2017; Dasgupta and Ghosh, 2013; Shnayder et al., 2016).

When gold-standard labels are available for some instances, workers can be rewarded directly for the quality of labels they supply for these instances, using either simple bonuses for accuracy (Ho et al., 2015; Shaw et al., 2011) or more complex incentive schemes (Ho et al., 2016; Shah et al., 2015; Shah and Zhou, 2016a,b). See Section 6.3 for a more detailed discussion of how workers respond to monetary incentives in practice.

2.2 Generating Transcriptions, Translations, and Image Annotations

Crowdsourcing is also used to generate more complex and free-form labels, such as transcriptions, translations of language, or image annotations.

Perhaps the best known example of a crowdsourcing system for transcription is reCAPTCHA (von Ahn et al., 2008). CAPTCHAs (or Completely Automated Public Turing tests to tell Computers and Humans Apart) are security tools designed to prevent bots from accessing online services (von Ahn et al., 2003, 2004). People attempting to access a website or create an account are asked to perform a task that is difficult for computers to perform but that humans find easy, such as reading and transcribing distorted characters. CAPTCHAs are used to stop ticket scalpers from using bots to buy out popular shows and to prevent spammers from opening arbitrary numbers of email accounts.

Von Ahn et al. (2008) found a way to put the vast quantities of human effort exerted on solving CAPTCHAs to use, harnessing this effort to digitize old books that current optical character recognition (OCR) systems were unable to handle. Their reCAPTCHA system presents two images of words, both taken from scanned text on which state-of-the-

art OCR systems have failed. One of these images is a gold-standard data point for which the correct transcription is already known. This is the image used to test whether or not the transcriber is human. The true label of the second image is unknown. By completing the CAPTCHA, the human is essentially entering a label for this data. Since reCAPTCHA was acquired by Google, similar techniques have been used to annotate images and build other large-scale machine learning data sets.[7]

Within the natural language processing community, crowdsourcing has been successfully used to generate translations of sentences from one language to another (Ambati et al., 2012; Callison-Burch and Dredze, 2010; Pavlick et al., 2014; Post et al., 2012; Zaidan and Callison-Burch, 2011; Zbib et al., 2012). This approach is especially effective for language pairs for which not much data exists. As one example, Zaidan and Callison-Burch (2011) used crowdsourcing to generate translations of sentences from Urdu to English. They assigned crowdworkers different jobs such as translating a sentence, editing other workers' translations to make them more fluent and grammatical, or ranking the quality of a translation. Finally, they used machine learning methods to predict the highest quality translation based on sentence-level features, worker-level features, and worker-generated ranks. The crowd-generated translations collected by this and other systems can then be used as training data for machine translation tasks.

Within the computer vision community, crowdsourcing is commonly used to collect human-generated labels and annotations for images and video (e.g., Deng et al., 2009; Gebru et al., 2017; Patterson and Hays, 2012; Patterson et al., 2014; Raykar et al., 2010; Russakovsky et al., 2015b; Sorokin and Forsyth, 2008; Su et al., 2012; Vijayanarasimhan and Grauman, 2009; Welinder et al., 2010). For example, the widely used ImageNet database[8] was constructed by leveraging workers on Mechanical Turk to perform tasks such as verifying image annotations and generating bounding boxes (Deng et al., 2009; Russakovsky et al., 2015a; Su et al., 2012). Other data generation and labeling tasks appropriate for crowdsourcing include object classification, attribute (or feature) generation, and image segmentation. A full taxonomy of applications of crowdsourcing to computer visions tasks is beyond the scope of this paper; see instead the comprehensive survey of Kovashka et al. (2016).

3. Evaluating and Debugging Models

Aside from data generation, the most common use of crowdsourcing within the machine learning community is to evaluate or debug models. Crowdsourced evaluation is especially common for unsupervised models, which generally cannot be evaluated in terms of simple metrics like accuracy or precision because there is no objective notion of ground truth. More recently, crowdsourcing has been used to evaluate human-centric properties of supervised models, such as model interpretability. In this section, we review several examples of applications of crowdsourcing to model evaluation and debugging. This list of examples is not intended to be exhaustive, but to give a flavor of different ways in which crowdsourcing can be used in this context.

7. `https://www.google.com/recaptcha`
8. `http://www.image-net.org`

3.1 Evaluating Unsupervised Models

It is increasingly common to see crowdsourcing used to evaluate unsupervised models, such as topic models (e.g., Chang et al., 2009; Hu et al., 2014; Newman et al., 2011; Paul and Dredze, 2014). Topic models are widely used to discover thematic topics from a set of documents such as New York Times articles from the past year or transcripts of Supreme Court hearings (Blei and Lafferty, 2009; Blei et al., 2003; Boyd-Graber et al., 2017). In this context, a topic is a distribution over words in a vocabulary. Every word in the vocabulary occurs in every topic, but with a different probability or weight. For example, a topic model might produce a food topic that places high weight on `cheese`, `kale`, and `bread`, or a politics topic that places high weight on `election`, `senate`, and `bill`. Each document is then represented as a distribution over topics.

Topic models are often used for data exploration and summarization, especially in the social sciences (Boyd-Graber et al., 2017). In order to be useful in these contexts, the inferred topics must be meaningful to end users. For example, if the set of words that appear with high weight in an individual topic are not coherent, the topic will not be useful to end users trying to understand the content of their documents. However, "meaningfulness" is hard to measure analytically, leading many researchers to instead evaluate topic models in terms of easier to quantify criteria, such as predictive power. To address this problem, Chang et al. (2009) proposed using crowdsourcing to measure the quality of a set of topics. The researchers designed a word intrusion task in which a crowdworker is presented with a randomly ordered list of the most common words from a topic. Included in that list is one intruder word that has low weight for the topic but high weight for another topic. The worker is then asked to identify the intruder. If the topic is coherent, then picking out the intruder should be easy (think {`cheese`, `bread`, `steak`, `election`, `mushroom`, `kale`}). If a topic is incoherent, identifying the intruder would be harder. The average error that crowdworkers make on this task can thus be used as a proxy for how coherent topics are. The researchers found that previous measures of success like high log likelihood of held out data do not necessarily imply coherence, illustrating the value of crowd-based evaluation over other techniques.

3.2 Evaluating Model Interpretability

In supervised learning, models are often evaluated in terms of objective performance metrics such as accuracy, precision, or recall. However, even if a model performs well in terms of these criteria, users may hesitate to rely on the model if they do not understand the model's predictions, especially in critical domains like health or criminal justice. Because of this, there is now wide interest in developing models that are human-interpretable (e.g., Doshi-Velez and Kim, 2017; Jung et al., 2017; Koh and Liang, 2017; Lipton, 2016; Lou et al., 2012, 2013; Paul, 2016; Ribeiro et al., 2016; Ustun and Rudin, 2016). Because of the subjective and inherently human-centric nature of interpretability, it is natural to use crowdsourcing to evaluate the interpretability of models.

As one example, Ribeiro et al. (2016) proposed an algorithm, Local Interpretable Model-agnostic Explanations, or LIME, that generates simple, locally faithful explanations for individual predictions made by potentially complex black-box models. They used crowdsourcing to test how how these explanations impact people's ability to perform tasks such as as-

sessing the classifier's quality or determining instances on which the classifier will make a mistake. In one study, the researchers presented crowdworkers with predictions from two SVM classifiers trained on different data sets along with explanations for their predictions. Workers were asked to select the classifier they believed would have better performance. The researchers found that explanations improved workers' ability to choose the best classifier and that LIME produced more effective explanations than a greedy technique. In another study, the researchers used crowdworkers to test which explanations best helped people find flaws in a trained model by identifying features used in the explanation that are irrelevant for the prediction task.

In this example, the researchers compared the effectiveness of specific techniques for generating explanations of predictions. In Section 5.1, we contrast this with crowdsourcing approaches that can be used to gain a better general understanding of how various properties associated with the "interpretability" of a model impact different aspects of human behavior in different scenarios.

3.3 Debugging Components of a Pipeline

In fields like computer vision, speech recognition, translation, and natural language processing, systems often consist of several discrete components linked together to perform a complex task. For example, consider the problem of semantic segmentation, which involves partitioning an image into semantically meaningful parts and labeling each part with a class. There are promising approaches to this problem that use machine learning models such as conditional random fields (CRFs) to integrate feedback from independent components that perform various scene understanding tasks like object detection, scene recognition, and segmentation. If a system designer wants to improve performance, it is not always clear which component to focus attention on.

To solve this problem, Parikh and Zitnick (2011) proposed the idea of "human debugging," in which humans are used to uncover bottlenecks in AI systems. The goal of human debugging is to identify which component in a system is the "weakest link." The basic idea is simple. To quantify how much potential improvements to a particular component would benefit the system as a whole, we could imagine replacing the component with something (close to) perfectly accurate and testing how much the system improves. Since for many vision and language tasks human performance is an upper bound on what we might expect from a machine, we can instead replace the component with a human.

Mottaghi et al. (2013, 2016) applied this idea in order to analyze the performance of a CRF that has been used in the computer vision community for scene understanding (Yao et al., 2012). They replaced each component with crowdworkers from Mechanical Turk and measured the change in performance of both the component in isolation and the system as a whole. One of their most interesting findings was that humans are actually less accurate than machines at one particular task (classifying super-pixels), yet when human classifications were plugged into the CRF, the system performance improved. One interpretation of this result is that perhaps making fewer mistakes classifying super-pixels is not enough. Rather it may be more important that the classifier makes the right kind of mistakes—the kind made by humans. This kind of feedback helps designers know where to focus their effort.

Recently, Nushi et al. (2017) took this idea one step further, allowing crowdworkers to propose targeted fixes to the machine components of a larger system and then evaluating the effect of various component fixes on the overall system performance.

4. Hybrid Intelligence Systems

Despite the current hype around AI and the great technological advances that have been made in recent years, AI systems are still far from perfect. In some cases, AI systems can benefit by involving humans in the loop to perform tasks that rely on life experience, judgment, or domain knowledge (Kamar, 2016). Such hybrid intelligence systems can leverage the complementary strengths of humans and machines to accomplish more than would be possible using humans or machines alone.

Hybrid systems have been designed to perform tasks from grading students' work (Kulkarni et al., 2014; Wright et al., 2015) to writing essays or novels (Bernstein et al., 2010; Kim et al., 2017; Kittur et al., 2011; Salehi et al., 2017; Teevan et al., 2016) to building better topic models (Hu et al., 2014). In this section, we walk through four illustrative examples: hybrid systems for clustering data points (Gomes et al., 2011; Heikinheimo and Ukkonen, 2013; Tamuz et al., 2011), transcribing speech in real time (Kushalnagar et al., 2012; Lasecki and Bigham, 2012; Lasecki et al., 2012, 2013, 2017; Naim et al., 2013), scheduling conference sessions (André et al., 2013; Bhardwaj et al., 2014; Chilton et al., 2014; Kim et al., 2013), and forecasting geopolitical or economic events (Atanasov et al., 2017; Baron et al., 2014; Mellers et al., 2015b).

4.1 Hybrid Clustering

Hybrid intelligence systems can be put to use to solve traditional machine learning problems like clustering in scenarios in which data points are easier for humans to understand and categorize than they are for machines. For example, given a data set of celebrity images, a human could potentially use their life experience and background knowledge to categorize them into sets like "actors" or "politicians," while a machine without access to this knowledge and experience could not.

Many hybrid clustering techniques have been proposed (Davidson et al., 2014; Gomes et al., 2011; Karaletsos et al., 2016; Mazumdar and Saha, 2016; Tamuz et al., 2011; Vesdapunt et al., 2014; Vinayak and Hassibi, 2016; Vinayak et al., 2014; Wah et al., 2014; Wang et al., 2012b; Wauthier et al., 2012; Yi et al., 2012a,b), the majority of which solicit human judgments or comparisons in order to actively generate a similarity matrix or other similarity function. Approaches vary in terms of the types of queries given to human judges, the algorithms used to aggregate their responses, and whether or not additional features of each object are available to the algorithm. Some researchers focus primarily on the entity resolution setting, in which the goal is to cluster together objects that refer to the same entity (e.g., Marcus et al., 2011; Mazumdar and Saha, 2016; Vesdapunt et al., 2014; Wang et al., 2012b), while others consider clustering more broadly.

Tamuz et al. (2011) designed an adaptive algorithm that estimates a similarity matrix from human judgments based on comparisons of triples ("*Is object A more similar to object B or object C?*"). Their approach requires only a relatively small number of human judgments to obtain a good approximation. Using this approach, they were able to answer questions

like which necktie would be a good substitute for another, a task that would perhaps be difficult for a machine without specialized human knowledge. As a complement to this algorithmic work, Wilber et al. (2014) outlined and studied several user interface techniques that allow high quality comparisons of triples to be collected faster.

Gomes et al. (2011) proposed a crowd-clustering approach in which each member of a crowd is presented a relatively small set of objects and asked to cluster just these objects. The sets of objects presented to different workers are distinct but overlap. The partial clusterings generated by the workers are then aggregated into one full clustering of all objects using an algorithm based on Bayesian inference.

Heikinheimo and Ukkonen (2013) took a different approach to hybrid clustering, proposing a crowd-powered version of the k-means algorithm. Running the standard k-means algorithm (Lloyd, 1982) requires the ability to perform two main operations:

1. Given a set S of objects and one new object x, find the object in S that is closest to x.
2. Find the center of a set of objects S, that is, the object in S with the lowest sum of distances to other objects in S.

Heikinheimo and Ukkonen (2013) showed how to perform each of these operations with a crowd. The first operation is straight-forward, assuming the size of the set S (which, in this case, is the number of clusters k since S is the set of cluster representatives) is sufficiently small: they simply present a worker with S and x and ask the worker which object in S is closest to x. (Noisy responses from multiple workers can be combined using standard techniques.) To perform the second operation, the researchers proposed the following simple algorithm, which they call `crowd-median`. Each crowdworker is presented with a set of three objects from the set S and asked which object is the outlier. After many such triples have been presented to workers, the object chosen least often as the outlier is selected as the center. The researchers gave both theoretical and empirical evidence that the output of `crowd-median` coincides with existing definitions of a centroid, and empirical evidence that the resulting crowd-powered k-means algorithms produces coherent clusters.

4.2 Hybrid Speech Recognition

Quickly and reliably converting speech to text requires a level of contextual understanding beyond the capabilities of machines and a level of speed beyond the capabilities of most humans. Closed captioning systems that rely on automatic speech recognition work very well under ideal circumstances (for example, when the voice recording is high quality and the system has been trained on data from the particular speaker), but can fail when presented with low quality audio, speakers with novel accents, or language with technical jargon that falls outside the vocabulary on which the system was trained. In these scenarios, professional stenographers produce the best results, but high quality stenographers can be prohibitively expensive and are not available on demand.

With this in mind, Lasecki et al. developed Scribe (Kushalnagar et al., 2012; Lasecki and Bigham, 2012; Lasecki et al., 2012, 2013, 2017; Naim et al., 2013), a hybrid speech recognition system that provides relatively inexpensive, real-time, and on-demand closed captioning to deaf or hard of hearing users to help them understand lectures, meetings, or other day-to-day conversations. As illustrated in Figure 1, Scribe combines algorithmic

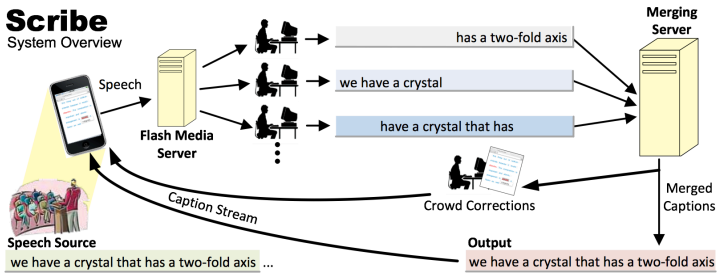

Figure 1: The architecture of Scribe. Image originally appeared in Lasecki et al. (2012).

techniques with the power of the crowd. As soon as a user starts recording, the recorded audio is sent simultaneously to several crowdworkers. These workers are not expected to fully transcribe the speech, which is generally not possible without a specialized stenotype keyboard. Instead, each worker transcribes sentence fragments. Scribe adjusts the speed and volume of the speech adaptively for each worker in order to focus workers' attention on distinct, overlapping components. It then uses multiple sequence alignment techniques (Edgar and Batzoglou, 2006; Lermen and Reinert, 2000; Naim et al., 2013) to combine the workers' text into one complete and coherent stream that is delivered back to the user with a delay of only a few seconds.

More recently, Gaur et al. (2015, 2016) developed an approach in which a single crowdworker is used to correct mistakes made by an automatic speech recognition system in real time. The crowdworker views the transcription output by a speech recognition system while listening to the corresponding audio. She then types out corrections to mistakes in the transcription as she notices them. These corrections are automatically incorporated into the appropriate spot in the transcription. Initial experiments showed that when this system was run with crowdworkers from Mechanical Turk, the word error rate improved. However, only 30% of possible corrections were made, leaving significant room for improvement in future work (Gaur et al., 2015).

As new breakthroughs continue to improve automatic speech recognition (Yu and Deng, 2014), this hybrid approach may eventually become unnecessary. However, the ability for speech recognition systems to achieve true human parity under nonideal conditions likely remains far in the future (Bigham, 2017). This example shows that crowdsourcing can be an effective way of compensating for a lack of sufficient machine learning or AI solutions until a time when the technology improves.

4.3 Hybrid Scheduling

Several researchers have explored the potential use of hybrid intelligence systems to solve complex tasks with global constraints or consistency requirements. Examples of such tasks include itinerary planning (Zhang et al., 2012), taxonomy creation (Bragg et al., 2013;

Chilton et al., 2013), and writing (Bernstein et al., 2010; Kim et al., 2017; Kittur et al., 2011; Salehi et al., 2017; Teevan et al., 2016). In this section we describe Cobi[9] (André et al., 2013; Bhardwaj et al., 2014; Chilton et al., 2014; Kim et al., 2013), a hybrid conference scheduling system. Rather than enlisting the help of anonymous crowdworkers, Cobi is based on the idea of "communitysourcing." It draws on the specialized expertise of people within a research community.

The problem of scheduling conference sessions can be viewed as a constrained optimization problem in which the solver has no direct access to the constraints. The goal of conference organizers is to group similar talks together in sessions while minimizing conflicts between talks that are scheduled at the same time, but conference organizers generally do not know which sets of talks attendees want to see. This optimization problem can be large; for example, Cobi was used to map out the schedule of the Conference on Human Factors in Computing Systems (CHI) in 2013, which required scheduling 400 talks in 16 parallel tracks.

Cobi was designed to efficiently collect information about attendee preferences from the community and use this information to optimize the conference schedule. (It is worth noting that the conference chairs always retain control and can choose to overwrite the optimized schedule.) As one example, their "authorsourcing" component presents authors with papers that are potentially similar to their own and asks which ones would be a good fit to appear in the same session. In order to generate the lists of potentially similar papers in the first place, their "committeesourcing" component makes use of hybrid clustering techniques like those discussed in Section 4.1 (André et al., 2013).

Communitysourcing can be especially effective because the same people who are asked to provide information also benefit from high quality end results. Although participants were not directly compensated, when Cobi was first deployed at CHI, the authors of 87% of accepted submissions opted to engage with the system.

Cobi was subsequently deployed several times for scheduling at both CHI and the ACM Conference on Computer-Supported Cooperative Work and Social Computing (CSCW). Anecdotally, users of the system found that the constraints generated by the authorsourcing component were crucial for producing a schedule of coherent and nonconflicting sessions; without this input the scheduler performed poorly.

4.4 Hybrid Forecasting

Significant resources are devoted to producing forecasts about geopolitical events and economic indicators. Humans are flexible in their ability to reason about arbitrary events, but human forecasts can be limited by cognitive biases or the inability to digest and process information at scale. Statistical and data-driven models, on the other hand, are able to take advantage of vast quantities of available data, but are difficult to design and train for one-of-a-kind events. Hybrid forecasting systems aim to combine the computational power of machines with the flexibility of humans to produce accurate forecasts.

In the most basic hybrid forecasting systems, algorithmic techniques are used primarily as a way to elicit and aggregate human-generated forecasts. One common example is a prediction market (Berg et al., 2008; Wolfers and Zitzewitz, 2004), a financial market in which traders can buy or sell securities with payoffs that are linked to future events. For

9. http://projectcobi.com

example, in an election market, traders might buy or sell a security that is worth \$1 if the incumbent candidate wins and nothing otherwise. If a trader believes that the probability of this candidate winning is p and wants to maximize her expected payoff, then she should be willing to buy this security at any price less than \$$p$, since with probability p she would get \$1. Similarly, she should be willing to sell at any price greater than \$$p$. For this reason, we can think of the current market price of this security as capturing traders' collective beliefs about how likely it is that the incumbent will win. Prediction markets can be operated as continuous double auctions, much like the stock market, requiring very little algorithmic ingenuity. However, when the level of trade is low, there can be advantages to operating prediction markets using algorithmic market makers that automatically set prices based on the history of trade (Chen and Pennock, 2007; Hanson, 2003). Prediction markets have recently gained more attention in the machine learning community due to the discovery of strong mathematical connections between these algorithmic market makers and no-regret online learning algorithms (Abernethy et al., 2013; Chen and Vaughan, 2010).

As part of the Good Judgment Project (Schoemaker and Tetlock, 2016; Tetlock et al., 2017; Ungar et al., 2012), a large-scale project funded by U.S. Intelligence, researchers evaluated and compared a wide range of algorithmic techniques for eliciting and aggregating human forecasts, including prediction markets and prediction polls, in which forecasters are asked to directly provide a probability estimate about the likelihood of an event. Through a series of randomized controlled trials, they found that prediction markets produce more accurate forecasts than those obtained by simply averaging forecasts from prediction polls. However, even higher accuracy could be obtained by aggregating prediction poll forecasts using more clever statistical methods (Atanasov et al., 2017) and extremizing aggregated forecasts (Baron et al., 2014). They also studied the importance of identifying and teaming up the top-performing individual forecasters (Mellers et al., 2015b) as well as the psychological traits shared by these top forecasters (Mellers et al., 2015a).

Building on lessons learned from the Good Judgment Project, the U.S. Office of the Director of National Intelligence has recently launched a new program aimed at producing hybrid forecasting systems that more comprehensively integrate modern data-driven approaches with human forecasting capabilities.[10]

4.5 Hybrid Intelligence Systems in Industry

So far we have focused on hybrid intelligence systems that have come out of the research community, but it is worth mentioning that human-in-the-loop systems are widely used in industry as well. To name just a few examples, Stitch Fix, which provides personalized style recommendations, trains machine learning algorithms to suggest items that a user might like and then sends the output of these algorithms to a human expert to curate and pare down.[11] Twitter employs contract workers to interpret search terms that suddenly spike in meaning, often due to recent mentions in the media or pop culture that an algorithm trained on stale data would miss.[12] PatternEx uses machine learning to identify suspicious activity that could indicate a security threat. This suspicious activity is then examined by a

11. http://multithreaded.stitchfix.com/blog/2016/03/29/hcomp1/
12. http://nyti.ms/2gzOo4K

human, who determines whether there is a real attack, and the human's feedback is used to improve the system.[13] And even search engines like Google and Bing can be viewed as hybrid intelligence systems, since the relevance judgments that are used to adaptively improve the systems are generated by humans (Alonso, 2013; Alonso et al., 2008; Kazai, 2011).

5. Behavioral Studies to Inform Machine Learning Research

Within the past few years, there has been an increased interest, both from within and outside the machine learning community, in understanding how humans interact with machine learning systems. Researchers are striving to make machine learning models human-interpretable (Doshi-Velez and Kim, 2017; Jung et al., 2017; Koh and Liang, 2017; Lipton, 2016; Lou et al., 2012, 2013; Paul, 2016; Ribeiro et al., 2016; Ustun and Rudin, 2016), to make machine learning tools easier to use (Brooks et al., 2015; Patel et al., 2010; Simard et al., 2017), and to understand how algorithmic decisions impact people's lives (Angwin et al., 2016; Barocas and Selbst, 2016; Campolo et al., 2017; Chouldechova, 2017; Corbett-Davies et al., 2017; Sweeney, 2013).

During the same time period, psychologists and social scientists have increasingly turned to crowdsourcing platforms to run behavioral experiments that traditionally would have been conducted on undergraduates in a physical lab. One of the papers frequently credited with introducing Mechanical Turk to the psychology community, Buhrmester et al.'s "Amazon's Mechanical Turk: A New Source of Inexpensive, Yet High-Quality, Data?" (Buhrmester et al., 2011), has been cited almost 5500 times according to Google Scholar, and this number continues to rise. Crowdsourcing platforms provide fast and easy access to large pools of subjects, and promote faster iteration between the development of new theories and experimentation, allowing researchers to speed up their overall research process (Mason and Suri, 2012). Additionally, studies have shown that classic psychology and behavioral economics results can be replicated using crowdworkers (Horton et al., 2011; Paolacci et al., 2010; Simons and Chabris, 2012; Suri and Watts, 2011). On the down side, there are some concerns about overuse of subjects (Chandler et al., 2014; Peera et al., 2017), with the same crowdworkers participating in many variants of the same standard psychology experiments, with which they have become familiar.

These developments open up the opportunity for interdisciplinary research that uses behavioral experiments conducted on crowdsourcing platforms to improve our understanding of how humans interact with machine learning and AI systems. This line of work goes beyond the idea of using crowdsourcing to evaluate one particular machine learning model or user interface, as discussed in Section 3, and instead seeks a general understanding of the components of human behavior that could inform the use and design of machine learning systems more broadly. Such experiments can help us develop better models of human behavior that could be used, in turn, to develop better algorithms and interfaces (Chen et al., 2016).

It is worth noting that behavioral experiments and other crowdsourced user studies could benefit other subfields of computer science as well, and there are already examples where it has. For example, Mechanical Turk experiments have been used to study lay people's perceptions of password security (Ur et al., 2016) and perceptions of graphics and visualizations (Heer and Bostock, 2010).

13. http://tek.io/1Vy01KB

Compared with the bodies of work on crowdsourcing for data generation, model evaluation, and hybrid intelligence, there is relatively little research in this area to date. In this section, we describe a few examples of behavioral studies using crowdsourcing platforms that have the potential to change the way we think about applications of machine learning in the hope that these examples will inspire additional research.

5.1 Understanding Trust in Predictive Models

There is a large body of work cutting across psychology, management, and other research communities that studies human trust in algorithmic predictions and models (Dietvorst et al., 2015, 2016; Dzindolet et al., 2002; Logg, 2017; Promberger and Baron, 2006; Sinha and Swearingen, 2001; Yeomans et al., 2017). While the earlier work was performed in traditional labs, the newer studies primarily rely on crowdworkers or a mix of crowdworkers and in-person participants (Dietvorst et al., 2015, 2016; Logg, 2017; Yeomans et al., 2017). This body of work provides invaluable insights about how real end users interact with machine learning systems in practice that can be put to use immediately in the design of models and user interfaces.

As one example, there is significant evidence in the literature of algorithm aversion, a phenomenon in which people fail to trust an algorithm once they have seen the algorithm make a mistake, even if the algorithm outperforms human predictors (Dietvorst et al., 2015; Dzindolet et al., 2002). This is worrisome since essentially all machine learning models make errors at least occasionally. Dietvorst et al. (2016) ran a sequence of experiments, some on crowdworkers and some on students, to examine the question of whether algorithm aversion can be overcome using simple interventions. In particular, the researchers asked whether people would choose to use an algorithm more if they were given the ability to intervene and make minor adjustments to the algorithm's prediction when they believed it to be wrong.

In one study, they asked crowdworkers to predict students' test scores on a standardized test using nine features such as the student's favorite subject in school and the region of the country the student lives in. Workers would be paid based on the accuracy of their predictions. The workers were told that analysts had trained a model to make the same predictions and were given the average error of the model (and thus explicitly told that the model was not perfect). They were then asked to decide whether they wanted to use the model or not. The workers were assigned to one of four randomized conditions. In the first, workers were told that if they chose to use the model they would not be allowed to adjust the predictions of the model at all. In the other three, workers were told that they would be given the ability to adjust each prediction of the model by up to 2 points, 5 points, or 10 points respectively. The researchers found that participants were indeed significantly more likely to choose to use the model if they were given the ability to intervene and adjust the model's prediction. In both the adjust-by-5 and adjust-by-10 conditions, 71% of participants chose to use the model, along with 68% in the adjust-by-2 condition. On the other hand, those who would not have the opportunity to intervene only chose to use the model 47% of the time.

Participants in the conditions in which adjustments were allowed also had significantly better predictive accuracy than those who were not allowed to adjust the model. This is not because their adjustments helped; on the contrary, participants would have done better

by always following the model exactly. They were more accurate because they were more willing to rely on the model.

This finding has immediate implications about which strategies might help gain user trust in machine learning models. In particular, users might be more willing to trust a model if they have the ability to intervene. Even if this human intervention leads to a worse prediction, allowing the intervention may still be beneficial because the user will be more likely to use the model in the first place.

It is natural to imagine that similar ideas could be applied to study model interpretability. As one very recent step in this direction, Poursabzi-Sangdeh et al. (2018) ran a large-scale human-subject experiment on Mechanical Turk that was designed to test how two different attributes of a model (the number of features and whether the details of the model are presented to the user or the model is presented as a black box) impact either users' understanding of the model or users' trust in the model. Unlike the experiments described in Section 3.2, in which crowdworkers were used to evaluate the interpretability of one specific model, Poursabzi-Sangdeh et al. (2018) tried to uncover how different factors of a model influence different aspects of interpretability more broadly, with the goal of providing general guidance on how to develop future interpretable models.

5.2 Understanding Reactions to Ads

Internet advertising is a huge business. Revenues from internet advertising in the U.S. alone hit $72.5 billion in 2016, up 22% from the previous year.[14] Naturally, significant effort is devoted to developing and optimizing machine learning algorithms for online advertising, especially in industry. New algorithms are generally put through rigorous A-B testing before deployment to quantify and measure their impact when run on real users. However, one might ask whether it is possible to design better algorithms using general insights about human behavior that transcend any one particular algorithm.

Goldstein et al. (2013; 2014) set out to quantify the impact of "annoying" display ads on user behavior, under the hypothesis that web publishers might be losing money and driving away users by displaying annoying ads. They designed a two-stage experiment run on Mechanical Turk. The first stage was designed to identify examples of "good" and "bad" ads. To do this, they presented crowdworkers with overlapping sets of display ads and asked for judgments of how annoying the ads were, a standard data labeling task as discussed in Section 2.1. By aggregating these judgments across workers, they produced lists of the most and least annoying banner ads.

In the second stage, Goldstein et al. (2013; 2014) ran a behavioral experiment aimed at estimating how much monetary value web users get from not being subjected to annoying ads. They posted another Mechanical Turk task in which workers were asked to label emails from the Enron email database as either spam or not spam. Workers were randomly assigned to different experimental conditions. Some workers saw good ads (as determined in stage 1) next to each email, while others saw bad, annoying ads. A third group saw no ads at all. The researchers also randomly varied how much users were paid for labeling each email. Workers were free to label as many emails as they wanted. By comparing the number of emails that workers chose to classify in each experimental condition, the

14. https://read.bi/2Ks0StR

researchers produced an estimate of the amount of extra money it would be necessary to pay workers who were exposed to bad ads in order to get them to perform the same number of email classification tasks as those exposed to good ads or no ads at all. From that, they were able to measure people's annoyance at bad ads.

They found that people were willing to classify almost as many emails when shown good ads compared with no ads at all, suggesting that displaying good ads does not hurt publishers. The same was not true for annoying ads. The researchers estimated that they would have to pay approximately $1 extra to generate 1000 views using a bad ad compared with a good ad or no ad. This is a significant amount as a typical banner ad might cost $1-$5 per 1000 views. In other words, publishers may very well be losing money by displaying annoying ads unless they charge significantly more per view.

While there are some limitations to the applicability of these results (for example, it is plausible that people react differently to ads when performing classification tasks than they would when browsing the news), it is a valuable step towards a model of user reactions to annoying ads. It is easy to imagine that such a model would prove useful when designing machine learning algorithms for pricing and displaying banner ads.

6. Understanding the Crowd

In the previous section, we argued that crowdsourced studies of human behavior can be valuable for understanding how lay people interact with machine learning systems. In this section, we argue that such studies are also useful for understanding the behavior of the crowd itself. This understanding helps us better model the crowd and allows us to define concrete recommendations of best practices that can be put to use whether using the crowd for data generation, model evaluation, hybrid intelligence systems, behavioral research, or any other purpose.

The studies described in this section help us understand how real crowdworkers respond to incentives, yielding immediately applicable guidelines for setting payments in addition to more accurate ways of modeling crowd behavior in theoretical work on incentive design. They tell us how to most effectively gamify crowdwork and provide other sources of intrinsic motivation for workers. They help us get a grip on the question of how widespread dishonesty is on crowdsourcing platforms, and how dishonest behavior can be mitigated. And they show us that crowdworkers are not independent and isolated workers, but have a rich social network.

6.1 Crowdworker Demographics

Over the years there have been several studies published that examine the demographics of workers on Mechanical Turk. We mention only a few key statistics that help paint a picture of the worker pool. These are based on a November 2016 snapshot from MTurk Tracker,[15] a project aimed at tracking the demographics of Mechanical Turk over time by continually releasing tasks containing demographic surveys on Mechanical Turk to obtain up-to-date information about workers (Difallah et al., 2015).

15. http://www.behind-the-enemy-lines.com/2015/04/demographics-of-mechanical-turk-now.html

These statistics should be taken with a grain of salt for several reasons. First, worker demographics change over time. For example, there is evidence that the worker pool on Mechanical Turk is shifting to be more heavily composed of American workers due to changes in Amazon's rules and regulations (Silberman et al., 2015). Second, not all workers on Mechanical Turk choose to work on surveys, so these statistics perhaps better reflect the population of workers who do survey work. That said, these demographics are more or less in line with those reported in other contemporaneous studies.

According to the MTurk Tracker data:

- About 70-80% of Mechanical Turk workers are from the United States, while about 10-20% are from India, but the breakdown of workers varies significantly throughout the day. The prevalence of workers from the U.S. and India makes sense because Mechanical Turk offers payment only in U.S. dollars, Indian rupees, or Amazon credit.
- The breakdown between male and female workers is fairly close to even, though it varies a bit by country.
- For crowdworkers in the U.S., the (self-reported) median household income is in the range of $40K-$60K, which is in line with the median U.S. household income. The median for Indian workers is less than $15K, with many Indian workers reporting a household income of less than $10K per year.

There is evidence that other crowdsourcing platforms, such as CrowdFlower and Prolific Academic, attract more European workers and lower income workers than Mechanical Turk (Peera et al., 2017).

Goodman and Paolacci (2017) provide a nice overview of the similarities and differences between the population of Mechanical Turk workers and the U.S. population as a whole, as well as the populations traditionally used for consumer studies.

The demographics of available workers vary widely based on the time of day and, to a lesser extent, day of the week. Through a large study of intertemporal demographic differences on Mechanical Turk, Casey et al. (2017) found that, even restricting attention to workers from the U.S., the demographics of available workers change dramatically over the course of a day. For example, they found that workers who completed their task at night were more likely to be single than those who completed it in the morning, and more likely to be completing the task on a smartphone.

6.2 Dishonesty Among Workers

Researchers may be deterred from using crowdsourcing due to concerns about the prevalence of dishonest workers. In this section, we discuss the results of behavioral experiments aimed at quantifying the presence of dishonest behavior on Mechanical Turk.

Suri et al. (2011) borrowed a trick from a lab study run by Fischbacher and Föllmi-Heusi (2013) that allowed them to measure how trustworthy crowdworkers are on the whole without the ability to detect individual lies. They posted a task on Mechanical Turk in which each worker was asked to roll a die (or simulate rolling a die on an external website) and report the value of her roll, a random number between 1 and 6. For completing this task, the worker received a base payment of $0.25 plus an additional bonus of $0.25 times her reported roll. For example, if a worker reported rolling a 4, she would receive a total

payment of $1.25. Thus the workers, who knew that there was no way for the outcomes of their rolls to be verified, were given a direct incentive to lie.

If all workers honestly reported the outcome of a die roll, the mean of the reported rolls of the 175 participants in the study would be close to 3.5. The researchers instead observed a mean reported roll of 3.91. On the whole, workers had a tendency to overreport rolls of 5 and 6 and underreport rolls of 1 and 2. In fact, it is possible that roughly a third of participants who rolled a 1 or 2 chose to misreport. (It is also possible that some participants ignored the instructions to roll a die at all, choosing to report an arbitrary number.)

Suri et al. (2011) next examined whether increasing the ability of the task requester to detect cheating would lead to higher levels of honesty. They conducted a variant of the die rolling experiment in which each worker was asked to report the results of a sequence of thirty die rolls instead of just one. Workers in this experiment received a base payment of $0.25 plus the sum of their reported die rolls, for a total payment between $0.55 and $2.05. This time, the mean reported role of the 232 participants was 3.57—still statistically significantly higher than the expected mean of 3.5, but practically much closer. Only three of the 232 experiment participants were found to have an average report significantly greater than what would be expected if they reported their rolls honestly, and only one reported the payoff-maximizing sequence of thirty rolls of 6. This suggests that dishonest behavior may be less prevalent when there is a chance that this behavior will be detected (though the results of the two experiments are not directly comparable since they were performed at different times on potentially different populations).

Two recent contemporaneous studies (Chandler and Paolacci, 2017; Wessling et al., 2017) examined whether crowdworkers misrepresent themselves in order to satisfy the eligibility criteria of tasks. Chandler and Paolacci (2017) asked over two thousand crowdworkers to report whether they are the parent or guardian of a child with autism. Workers were randomly assigned to one of two experimental conditions. In one, workers were told that this question was part of a prescreening test for a subsequent study, while in another (the control), they were not. 7.8% of workers in the prescreening condition reported being the parent or guardian of a child with autism, compared with 4.3% in the control, suggesting that at least 3.5% of workers in the prescreening condition provided a fraudulent response. While 3.5% of workers may seem small, note that due to the low number of workers who would truly qualify for a follow-up study based on this question, this level of dishonesty would lead to a high prevalence of impostors (45%) in a follow-up study. In a separate study, the same researchers found that when payments were sufficiently high, 16% of participants made a second attempt to pass a prescreening survey, identifying themselves as a different gender after initially being blocked. Similarly, Wessling et al. (2017) provided additional evidence of misrepresentation in prescreening tests.

Based on these findings, both papers include detailed discussions of best practices that can be followed to mitigate dishonesty in prescreening tests. One recommendation is to collect screening data as part of a stand-alone task ahead of time and call back eligible participants later. As an alternative, when costs are not prohibitive, all workers can be allowed to perform a task and those who do not meet the screening criteria can be filtered out after all data have been collected.

All of this work suggests that the rate of dishonest behavior and spam depends on the particular task and the motivation to lie. There is some anecdotal evidence that spammers

are especially drawn to surveys (Mason and Suri, 2012) and multiple-choice questions (Rao and Michel, 2016) since these are especially easy tasks to complete, so rates of spam may be even higher on these questions.

It is worth noting that requesters on crowdsourcing platforms can be dishonest or otherwise malicious too. For example, requesters may ask workers to create social media accounts to post specific content or engage in other dodgy Internet marketing practices. It fact, there are now entire crowdsourcing platforms in China specifically devoted to these "crowdturfing" tasks (Wang et al., 2012a).

6.3 Monetary Incentives

One of the first questions that many researchers have when they decide to incorporate crowdsourcing into their work is how much to pay per task. When crowdsourcing first began to gain popularity among researchers, part of the appeal was the ability to generate data or run experiments cheaply. For example, Snow et al. (2008) boasted that they were able to offer workers $0.02 to complete a set of 30 annotations, obtaining 1500 annotations per dollar. However, over the last decade, the views of the community have shifted as the ethics of crowdsourcing have received more attention (Kittur et al., 2013; Salehi et al., 2015; Silberman et al., 2010; Williamson, 2016). Although crowdworkers are legally considered contractors, making minimum wage laws inapplicable, guidelines put forth by the Dynamo project[16] (Salehi et al., 2015) recommend paying the equivalent of the current U.S. federal minimum wage or more. An effective and widely used method of setting the payment for a task is to first estimate the time it takes to complete the task (for example, by asking colleagues or students to try out the task, or by posting a small test batch of tasks) and then use that estimate to ensure that the per-hour payment is higher than U.S. minimum wage.

A natural question is whether paying higher wages increases the quality of work. There is evidence that, at least in some scenarios, the answer is no. Several behavioral studies examining the impact of payments on quality found that setting higher payments increased the quantity of work that crowdworkers were willing to do, but not the quality (Buhrmester et al., 2011; Litman et al., 2014; Mason and Watts, 2009; Rogstadius et al., 2011). Mason and Watts (2009) conjectured that this might be due, at least in part, to an anchoring effect: workers' opinions about fair payment rates are anchored by the payments they are offered. In one of their experiments, workers were asked to sort sets of images and were randomly assigned to experimental conditions in which they received $0.01 per task, $0.05 per task, or $0.10 per task respectively. (All tasks were advertised at a rate of $0.01 and additional payments were made via bonuses to avoid selection effects.) In a post-hoc survey, workers who were paid $0.01 felt they should have received $0.05 for the task on average, while workers who were paid $0.05 felt they should have received $0.08, and workers who were paid $0.10 felt they should have received $0.13.

On the other hand, two recent studies have shown that in other scenarios, higher payments do increase work quality (Ho et al., 2015; Ye et al., 2017). There are several possible reasons for this discrepancy. One is that the type of task being performed might impact the effectiveness of increased payments. Ho et al. (2015) and Ye et al. (2017) both used "effort-responsive tasks"—tasks for which workers are able to improve their output by spending

16. `http://wiki.wearedynamo.org/index.php/Guidelines_for_Academic_Requesters`

more time or effort—in their studies, whereas the study mentioned above used a task that was fairly easy to complete without much effort. Mason and Watts (2009) did use an effort-responsive task (solving word puzzles) in a second study, but found that for this particular task, worker quality was more correlated with enjoyment of word puzzles than the rate of pay offered, an argument that intrinsic motivation (the topic of Section 6.4) can overpower monetary incentives. Another possibility is that in some studies, payments were so low that the differences between conditions were not salient. Buhrmester et al. (2011) offered either $0.02, $0.10, or $0.50 for up to 30 minutes of work, while Ho et al. (2015) and Ye et al. (2017) aimed to pay at least minimum wage and had larger per-hour gaps between payments in different experimental conditions.

While this research is somewhat inconclusive, it does appear that paying higher wages consistently increases the number of tasks that crowdworkers are willing to perform and therefore speeds up the rate at which a requester's tasks are completed.

Another body of work is aimed at answering the question of whether the quality of crowdwork can be improved through the use of performance-based payments, payment schemes that explicitly reward crowdworkers for higher quality work (Harris, 2011; Ho et al., 2015; Shaw et al., 2011; Yin et al., 2013, 2014). While in theory, such payment schemes could be arbitrarily complex (Ho et al., 2016), in practice they are generally implemented in the form of a bonus payment awarded for exceeding a particular quality threshold. Bonus payments of this form are common on Mechanical Turk.

Here, too, results have been mixed. Harris (2011) asked workers to evaluate the relevance of resumes and found that performance-based payments increased both quality and the amount of time that workers spent on the task. On the other hand, Shaw et al. (2011) compared fourteen incentives schemes, including four that involved performance-based payments, and did not find significant increases in quality, and Yin et al. (2013) varied the bonus sizes offered to workers and found no significant difference in quality between experimental conditions.

The most comprehensive experimental study of performance-based payments was performed by Ho et al. (2015). They showed that performance-based payments can improve quality for particular tasks (again, those that are effort-responsive). They found that the effectiveness of performance-based payments is not heavily dependent on the precise quality threshold chosen. They also tested how sensitive their results were to the size of the bonus offered and found that as long as the bonus offered was big enough, quality improved. Offering a very small bonus (say, $0.05 on a $0.50 base payment) actually led to a small apparent decrease in performance, though this decrease is not statistically significant. This may explain the negative results of Shaw et al. (2011), since their bonus payments were very small ($0.03 on a base payment of $0.30). It may also explain the results of Yin et al. (2013), who considered only bonuses that were relatively large compared with the base, a regime in which Ho et al. (2015) also saw no statistically significant differences in quality when varying the bonus size.

It is not always immediately apparent whether or not a task is effort-responsive. As an example, Ho et al. (2015) were surprised to find that handwriting recognition is not. When they gave workers a handwriting recognition task, the majority of workers were able to identify most words with little effort. When workers could not make out a word, additional time spent did not help. The researchers suggest that to determine whether or not a task

is effort-responsive, a requester should run a pilot experiment in which they ask workers to complete the task for a fixed payment and examine the relationship between time spent and quality of results. The results of such a pilot could be used to determine an appropriate payment scheme for the task.

6.4 Intrinsic Motivation

In addition to monetary incentives, researchers have also explored the ways in which intrinsic sources of motivation, such as having fun or doing meaningful work, affect the quantity and quality of work that crowdworkers perform. This research is important for informing the design of volunteer-based or citizen science platforms, like the Zooniverse[17] and Science at Home[18], as well as paid crowdsourcing platforms like Mechanical Turk.

In one study, Chandler and Kapelner (2013) found that crowdworkers are more active when the tasks they are asked to perform are framed as meaningful. The researchers recruited workers on Mechanical Turk to label medical images. In one experimental condition, workers were told that they were labeling tumor cells and that the results of their work would be used to assist medical researchers. In the control condition, they were given no context for the task at all. In a third condition, they were given no context and additionally told that the labels they generated would not be recorded; that is, all of their work would be discarded. The researchers found that when workers were told their work would benefit medical research, the quantity of work that they produced increased compared with the control, but their work was not significantly more accurate. On the other hand, when workers were told their work would be discarded, the quality of their work was worse than the control, but the quantity of work produced was similar. Similar effects were observed by Rogstadius et al. (2011), who compared the behavior of workers who were told they were performing work for a nonprofit organization "dedicated to saving lives by improving health throughout the world" with workers who were told they were working for a for-profit pharmaceutical manufacturer. This work suggests that when the task being performed has the potential to do good in the world, it is worth emphasizing this to the workers.

Gamification is an another effective way of increasing crowdworkers' motivation that can be applied in both paid and unpaid crowdsourcing settings (Feyisetan et al., 2015; Lee et al., 2013; von Ahn and Dabbish, 2008). Von Ahn and Dabbish (2008) pioneered the study of "games with a purpose," computer games in which players, as a side effect of their play, accomplish tasks that are difficult for machines, such as generating training data for machine learning algorithms. For example, in the ESP Game (von Ahn and Dabbish, 2004) (now the Google Image Labeler), randomly matched pairs of players are presented with an image and asked to type in words that describe it (i.e., labels), as in Figure 2. The players receive points if both members of the pair produce the same word. Since players are unable to communicate with each other, their best strategy for producing the same word is to type in words that are relevant to the image, thus providing useful labels. As another example, Verbosity (von Ahn et al., 2006) is a game designed to collect common-sense facts about objects. Players are again randomly paired, with one partner serving as a describer and the other as a guesser. The describer is given an object (such as a sock) and asked to list

17. https://www.zooniverse.org
18. https://www.scienceathome.org

Figure 2: A screenshot of the ESP Game. Image originally appeared in von Ahn and Dabbish (2008).

facts about the object ("it is a kind of clothing" or "it is related to feet"). The guesser is shown these facts and must try to guess the object as quickly as possible. To win, it is in the describer's best interest to come up with facts that succinctly and accurately describe the object, which then become a part of a database of common knowledge statements.

Von Ahn and Dabbish (2008) credit the success of these games in part to following known game-design principles, such as incorporating extra challenges through game features like timed responses, score keeping and leaderboards, and randomness (Malone, 1980, 1982). However, there are some caveats of gamification. Hamari et al. (2014) recently conducted an extensive survey of the literature on gamification and found that it is more successful with some types of users than others, and may generally be less effective in scenarios in which people are prone towards exhibiting rational behavior, which may include paid crowdsourcing sites since at least some crowdworkers are already be in the mindset of maximizing pay.

Law et al. (2016) examined the possibility of appealing to workers' curiosity as a source of intrinsic motivation. Their work was inspired by the information gap theory of curiosity, which suggests that when people are made aware that there is a gap in their knowledge, they actively seek out the information needed to fill in this gap. They suggested several "curiosity interventions" aimed at stoking workers' curiosity and showed that these interventions led to workers completing more tasks and performing better. Curiosity interventions are especially effective on tasks that are inherently less interesting.

6.5 Crowdworker Communication and Forum Usage

Finally, several recent papers have explored the questions of how, why, and to what extent crowdworkers communicate with each other.

Gray et al. (2016) conducted a mixed-method study to understand communication among crowdworkers on four crowdsourcing platforms. Through extensive ethnographic fieldwork and in-person interviews with 118 crowdworkers in India, the researchers uncov-

ered three common categories of communication among workers. First, workers help each other with administrative overhead in order to reduce their costs. For example, a crowdworker might seek help figuring out how to receive her payments from a crowdsourcing platform, which can be nontrivial for Indian workers. Second, crowdworkers share information about good tasks and reputable (or irreputable) task requesters. Third, crowdworkers help each other complete specific tasks. More generally, crowdworkers seek each other out to recreate the social connections and support structures that are common in most traditional jobs but missing from crowdwork. This idea that crowdworkers communicate and collaborate with each other is supported by the work of Gupta et al. (2014), who also conducted interviews of crowdworkers in India.

This line of work suggests that crowdworkers are not independent, but rather that there is a hidden communication network among workers. Yin et al. (2016) attempted to quantify and map the hidden network of workers on Mechanical Turk in order to better understand its scale and structure as well as how is it used. To do this, the researchers designed and launched a task on Mechanical Turk. When a worker accepted the task, she was first asked to create a nickname for herself. She then filled out a brief demographic survey and was asked to answer two free-form questions about her experiences on Mechanical Turk: why she started Turking and what motivated her to keep Turking. (These questions were selected based on the results of a pilot study in which crowdworkers were asked what they most wanted to know about other crowdworkers, with the goal of generating interesting questions.) The worker was then asked to pause and swap nicknames with other workers she knows who had already completed the task or might be interested in completing it. If she entered another worker's nickname, she was asked several questions about their communication patterns, and an edge was created between them in the network. Finally, the worker was given the chance to explore the partially constructed network, viewing basic information on all workers (including their answers to the two free-form questions above), and more extensive information about those workers with whom she had exchanged nicknames. She was also given a personalized link she could use to return to the network later and add more connections.

The resulting communication network is shown in Figure 3. Over a period of several weeks, 10,354 workers completed the task. (Stewart et al. 2015 estimated the number of active workers on Mechanical Turk to be only 7,300, so it is likely that this task was completed by a large fraction of active workers, mitigating potential issues with sample bias.) These 10,354 workers reported a total of 5,268 connections. Since workers were not financially incentivized to add connections, this number is probably an underestimate of the true number of connected pairs. Roughly 13% of workers were connected to at least one other worker. On average these workers had 7.6 connections, and the maximum degree of any worker was 321. The largest connected component contained 994 workers, or about 72% of connected workers.

While many different methods of communicating were reported, by far the most common was through online forums. In fact, 90% of all edges were between pairs of workers who communicate via forums. This finding is in line with other work that examined the important role that forums play in crowdsourcing (Martin et al., 2014). Different online forums create different but overlapping subcommunities in the network, as illustrated in Figure 4. The researchers' analysis showed that these subcommunities differ in terms of topo-

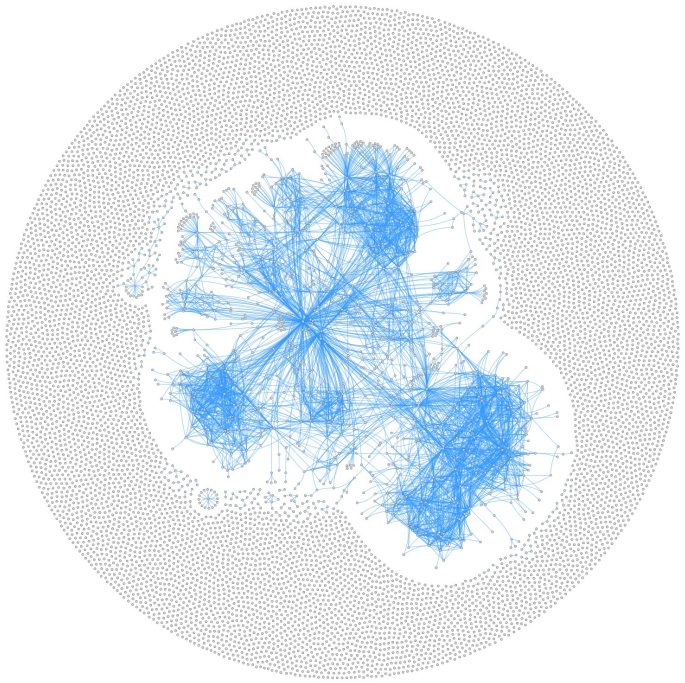

Figure 3: The communication network among Amazon Mechanical Turk workers. Image originally appeared in Yin et al. (2016).

logical structure, dynamics, and the content of communication, with some acting more as social communities and others more like broadcasting platforms.

Although it is impossible to establish causal claims on the basis of their study, Yin et al. (2016) did find correlations between a worker's connectivity and different measures of success on Mechanical Turk. In particular, they found that connected workers tended to find their task faster, were more likely to have been active on Mechanical Turk longer, were more likely to have achieved Mechanical Turk's "Master" qualification, and had a higher approval rate on average.

The high level of communication among crowdworkers and widespread use of forums have several immediate implications for researchers. First, researchers should keep in mind that the set of crowdworkers who choose to do a task may not be an independent sample of the worker pool since workers often share good tasks. Second, it can be in a researcher's best

interest to monitor popular forums such as Turker Nation[19], MTurk Forum[20], and Reddit HITs Worth Turking For[21] while their tasks are running to be aware of any potential issues that workers are discussing.

7. Discussion and Additional Best Practices

We have explored examples of four different ways in which machine learning researchers can put crowdsourcing to use in their own research: to generate data, to evaluate and debug models, to build hybrid intelligence systems, and to run behavioral experiments that inform the design of future machine learning systems. We have also reviewed the results of a variety of behavioral and user studies aimed at understanding the crowd and have discussed the implications of these studies for researchers who use crowdsourcing in their own research.

We conclude this survey with a discussion of additional crowdsourcing best practices that are rarely mentioned in the literature, despite their importance to the success of a project.

7.1 Maintain a Good Relationship With Crowdworkers

There are several reasons why it can be valuable for a researcher to build a relationship with the community of crowdworkers and maintain a good reputation among them. As discussed in Section 6.5, workers share information about both tasks and requesters among themselves, especially through forums. Workers will be discouraged from accepting a task if other workers have complained about bugs, slow payments, or other issues. Experienced Mechanical Turk workers also commonly use tools like TurkOpticon[22] that allow them to view requester ratings broken down by communicativity, generosity, fairness, and promptness (Irani and Silberman, 2013). There are also tools available that allow workers to be notified when a favorite requester posts a new task. Being known as a good requester therefore brings more attention to one's tasks, while being known as a bad requester can deter experienced workers.

To maintain a good reputation, researchers should actively monitor and respond to any email or questions from workers so that any potential problems or bugs can be caught quickly. It is worth planning in advance to make sure that someone will be available to communicate with workers while a new task is running.

Researchers should pay fair wages (at least the equivalent of U.S. federal minimum wage, as discussed in Section 6.3) and approve work quickly since on many platforms workers are not paid until their work is approved. It is also good practice to avoid rejecting work. On Mechanical Turk, for example, a lowered approval rate can have a damaging effect on a worker's ability to find new work. Rejecting the work of a well-meaning worker who makes a mistake can therefore harm that worker's future income (Mason and Suri, 2012).

Finally, researchers should strive to be a ethical requesters. A good way to start is by reviewing the Dynamo project's guidelines for academic requesters[23] (Salehi et al., 2015).

7.2 Good Task Design Matters

Crowdworkers cannot be expected to excel at a task with unclear instructions or a confusing user interface. Any ambiguity will increase the rate of errors since it is difficult and time consuming for workers to ask clarifying questions (Rao and Michel, 2016). Both the instructions and UI should be piloted on a small batch of workers to make sure that they are clear before launching a task at a large scale. Some evidence suggests that including examples in a task's description or instructions is correlated with lower levels of confusion among workers and with workers more quickly accepting the task (Jain et al., 2017). Including quiz questions can also be an effective way to check for clarity. In addition to increased clarity, an attractive and easy-to-use UI may help keep workers engaged.

7.3 Pilot, Pilot, Pilot

Last but not least, the effective use of pilots is crucial to a project's success. Crowdsourcing platforms allow for quick and easy iteration of task design and experimentation (Mason and Suri, 2012). One of the primary benefits of crowdsourcing platforms is the ability to quickly pilot new or modified task designs on small batches of crowdworkers before making a commitment. As is the case with any software system, tasks often have bugs that are

22. https://turkopticon.ucsd.edu
23. http://wiki.wearedynamo.org/index.php/Guidelines_for_Academic_Requesters

hard to catch until they are deployed on real users. It is often best to launch a task slowly, iterating as many times as necessary to ensure that the task is clear and bug-free.

Acknowledgments

This survey grew out of lecture notes that were originally prepared to accompany my tutorial "Crowdsourcing: Beyond Label Generation" at NIPS 2016. Thanks to all of the people—far too many to name—who sent pointers and suggestions of research to include. Thanks to Dan Goldstein, Chien-Ju Ho, Jake Hofman, Andrew Mao, Roozbeh Mottaghi, Sid Suri, Jaime Teevan, Ming Yin, and Haoqi Zhang for discussing their research and sending along slides and other material while I was preparing the tutorial. Thanks to the authors of Lasecki et al. (2012) and von Ahn and Dabbish (2004) and to my coauthors on Yin et al. (2016) for allowing me to include images from their papers. Thanks to Chien-Ju Ho, Andrew Mao, Joelle Pineau, Sid Suri, Hanna Wallach, and especially Ming Yin for extended discussions and valuable feedback on previous versions of this survey. Finally, huge thanks to the four anonymous JMLR reviewers who went above and beyond their duty to give countless valuable comments, suggestions, and references that greatly improved the breadth and structure of this survey. This was a crowdsourced effort.

Editor: Peter Spirtes

Abstract

Causal models communicate our assumptions about causes and effects in real-world phenomena. Often the interest lies in the identification of the effect of an action which means deriving an expression from the observed probability distribution for the interventional distribution resulting from the action. In many cases an identifiability algorithm may return a complicated expression that contains variables that are in fact unnecessary. In practice this can lead to additional computational burden and increased bias or inefficiency of estimates when dealing with measurement error or missing data. We present graphical criteria to detect variables which are redundant in identifying causal effects. We also provide an improved version of a well-known identifiability algorithm that implements these criteria.

Keywords: causal inference, identifiability, causal model, pruning, algorithm

1. Introduction

A formal framework for causal inference is provided by the probabilistic causal model (Pearl, 2009) that encodes our knowledge of the variables of interest and their mutual relationships. In observational studies experimentation is not available, but through the causal model framework we can still symbolically intervene on variables, forcing them to take certain values as if an experiment had taken place. The question is whether we can make inferences about the effect of the intervention in the post-intervention model using only the observed probability distribution of the variables in the model before the intervention took place. This question is formally defined as identifiability of causal effects, and it has received considerable attention in literature, including a number of algorithmic solutions (Huang and Valtorta, 2006; Shpitser and Pearl, 2006; Tian and Pearl, 2002).

A causal model can be associated with a directed acyclic graph (DAG) that represents the functional relationships of the variables included in the model. The graphical representation provides us with the concept of d-separation (Geiger et al., 1990), that can be used to infer conditional independences between variables from the graph. If the distribution of the variables implies no conditional independence statements other than those already encoded in the graph, we say that the distribution is faithful (Spirtes et al., 2000).

The use of d-separation in the post-intervention model is the basis of do-calculus (Pearl, 1995), which consists of a set of inference rules for manipulating interventional distributions. The purpose of do-calculus is to derive formulas for causal effects and other causal queries, and it has been shown to be complete with respect to the identifiability of causal effects (Huang and Valtorta, 2006; Shpitser and Pearl, 2006). The derived formulas provide recipes for estimating the causal effects from observational data.

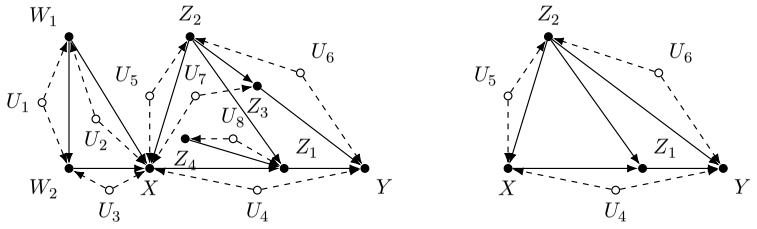
When computing causal effect formulas, we often apply an identifiability algorithm, such as the ID algorithm by Shpitser and Pearl (2006). Criteria for identifiability such as the back-door criterion and front-door criterion are available for manual derivations (Pearl, 2009) but the ID algorithm is more general and thus more suitable for automated processing. The ID algorithm splits the original problem into smaller subproblems which are then solved and aggregated as the final expression for the causal effect.

Complicated expressions are likely to arise in situations where we have included variables in our model that do not provide further benefit for the identification of the causal effect of interest. It is often the case that these variables nonetheless appear in the resulting formula, and deriving a simpler expression with the variable eliminated can be non-trivial. It is hard to specify what makes one expression simpler than another, but we can consider a number of criteria to evaluate simplicity. For example, we can compare the number of sums and fractions and the number of variables present in the expression.

In this paper we propose a number of graphical criteria to infer which variables in our causal model are in fact not necessary for identification. These criteria allow us to prune the graph, which in practice means removing specific vertices and considering identification in a latent projection. A significantly simpler expression can be obtained by pruning alone, but we may also combine pruning with simplification procedures that operate symbolically on the interventional distribution as presented in (Tikka and Karvanen, 2017b). Applying these methods in conjunction often provides additional benefits.

We present an identifiability algorithm that is able to recognize and eliminate unnecessary variables from the graph based on our criteria resulting in a simpler expression. When a large number of graphs and identifiability queries are processed, evaluating simpler expressions has apparent computational benefits. First, it is more efficient to evaluate a simpler expression repeatedly especially when some variables have been completely removed which further reduces the complexity of the task. Second, in practical applications that involve real-world data, variables often contain missing data or are affected by bias. Obtaining expression that do not involve such variables can be of great benefit in estimation. Third, a simpler expression is easier to communicate.

An introductory example motivates the use of the improved algorithm. We are interested in the causal effect of X on Y in graph G of Figure 1(a). Here, open circles denote unobserved variables. A more in-depth overview of graph theoretic concepts used in this paper is provided in Section 2. The causal effect is identifiable and the output of the ID algorithm is



(a) Graph G. (b) Graph G after pruning.

Figure 1: Graph G before and after pruning for the introductory example.

$$\sum_{z_2,z_4,z_3,z_1}\left(\sum_{w_1,w_2,x'}P(y|w_1,z_2,z_4,w_2,z_3,x',z_1)P(x'|w_1,z_2,z_4,w_2,z_3)\times P(z_3|w_1,z_2,z_4,w_2)P(w_2|w_1,z_2,z_4)P(z_2|w_1)P(w_1)\right)\Bigg/$$
$$\left(\sum_{w_1,w_2,x',y'}P(y'|w_1,z_2,z_4,w_2,z_3,x',z_1)P(x'|w_1,z_2,z_4,w_2,z_3)\times P(z_3|w_1,z_2,z_4,w_2)P(w_2|w_1,z_2,z_4)P(z_2|w_1)P(w_1)\right)\times$$
$$\left(\sum_{w_1,w_2,z_3',x',y'}P(y'|w_1,z_2,z_4,w_2,z_3',x',z_1)P(x'|w_1,z_2,z_4,w_2,z_3')\times P(z_3'|w_1,z_2,z_4,w_2)P(w_2|w_1,z_2,z_4)P(z_2|w_1)P(w_1)\right)\times$$
$$P(z_1|w_1,z_2,z_4,w_2,x)P(z_3|z_2)P(z_4).$$

This expression is very cumbersome and complicated. However, it turns out that a simpler expression exists for the causal effect. By exploiting the structure of the graph and using standard probability calculus the following expression can be obtained

$$\sum_{z_2,z_1}\left(\sum_{x'}P(y|z_2,z_1,x')P(x'|z_2)P(z_2)\right)P(z_1|z_2,x).$$

This expression is simpler in every regard compared to the original output. It contains fewer terms and no fractions. Also, we have completely removed the variables w_1, w_2 and z_4 from the expression. It can be shown that identifying the causal effect in the original graph is

equivalent to identifying it in the graph depicted in Figure 1(b). By running our improved algorithm we are able to prune the original graph and obtain this simpler expression directly. The algorithm works recursively and the pruning is carried out at each stage of the recursion. The recursive pruning provides significant benefits over pruning as a pre-processing step as demonstrated later.

The paper is structured as follows. In Section 2 we review crucial definitions and concepts related to graph theory and causal models. In Section 3 we focus on semi-Markovian causal models and present the original formulation of the ID algorithm. Our main results are presented in Section 4 and they are implemented into an improved identifiability algorithm in Section 5. Examples on the benefits of recursive pruning are provided in Section 6. Section 7 concludes with a discussion.

2. Definitions

We assume the reader to be familiar with a number of graph theoretic concepts and refer them to works such as (Koller and Friedman, 2009). We use capital letters to denote vertices and the respective variables, and small letters to denote their values. Bold letters are used to denote sets. A directed graph with a vertex set $\mathbf{V}$ and an edge set $\mathbf{E}$ is denoted by $\langle \mathbf{V}, \mathbf{E}\rangle$. For a graph $G = \langle \mathbf{V}, \mathbf{E}\rangle$ and a set of vertices $\mathbf{W} \subseteq \mathbf{V}$ the sets $\mathrm{Pa}(\mathbf{W})_G, \mathrm{Ch}(\mathbf{W})_G, \mathrm{An}(\mathbf{W})_G$ and $\mathrm{De}(\mathbf{W})_G$ denote a set that contains $\mathbf{W}$ in addition to its parents, children, ancestors and descendants in G, respectively. We also define the set $\mathrm{Co}(\mathbf{W})_G$ to denote the set of vertices that are connected to $\mathbf{W}$ in G via paths where the directionality of the edges is ignored, including $\mathbf{W}$. The root set of a graph G is the set of vertices without any descendants $\{X \in V \mid \mathrm{De}(X)_G \setminus \{X\} = \emptyset\}$, where $\setminus$ denotes the set difference. A subgraph of a graph $G = \langle \mathbf{V}, \mathbf{E}\rangle$ induced by a set of vertices $\mathbf{W} \subset \mathbf{V}$ is denoted by $G[\mathbf{W}]$. This subgraph retains all edges $V \to W$ of G such that $V, W \in \mathbf{W}$. The graph obtained from G by removing all incoming edges of $\mathbf{X}$ and all outgoing edges of $\mathbf{Z}$ is written as $G_{\overline{\mathbf{X}},\underline{\mathbf{Z}}}$. To facilitate analysis of causal effects we must first define the probabilistic causal model (Pearl, 2009).

Definition 1 (Probabilistic Causal Model) *A* probabilistic causal model *is a quadruple*

$$M = \langle \mathbf{U}, \mathbf{V}, \mathbf{F}, P(\mathbf{u})\rangle,$$

where

1. $\mathbf{U}$ *is a set of unobserved (exogenous) variables that are determined by factors outside the model.*
2. $\mathbf{V}$ *is a set* $\{V_1, V_2, \ldots, V_n\}$ *of observed (endogenous) variables that are determined by variables in* $\mathbf{U} \cup \mathbf{V}$.
3. $\mathbf{F}$ *is a set of functions* $\{f_{V_1}, f_{V_2}, \ldots, f_{V_n}\}$ *such that each* f_{V_i} *is a mapping from (the respective domains of)* $\mathbf{U} \cup (\mathbf{V} \setminus \{V_i\})$ *to* V_i*, and such that the entire set* $\mathbf{F}$ *forms a mapping from* $\mathbf{U}$ *to* $\mathbf{V}$.
4. $P(\mathbf{u})$ *is a joint probability distribution of the variables in the set* $\mathbf{U}$.

Each causal model induces a causal diagram which is a directed graph that provides a graphical means to convey our assumptions of the causal mechanisms involved. The induced graph is constructed by adding a vertex for each variable in $\mathbf{U} \cup \mathbf{V}$ and a directed edge from $V_i \in \mathbf{U} \cup \mathbf{V}$ into $V_j \in \mathbf{V}$ whenever f_{V_j} is defined in terms of V_i.

Causal inference often focuses on a sub-class of models that satisfy additional assumptions: each $U \in \mathbf{U}$ appears in at most two functions of $\mathbf{F}$, the variables in $\mathbf{U}$ are mutually independent and the induced graph of the model is acyclic. Models that satisfy these additional assumptions are called *semi-Markovian causal models*. A graph associated with a semi-Markovian model is called a *semi-Markovian graph* (SMG). In SMGs every $U \in \mathbf{U}$ has at most two children. When semi-Markovian models are considered it is common not to depict background variables in the induced graph explicitly. Unobserved variables with exactly two children are not denoted as $V_i \leftarrow U \rightarrow V_j$ but as a bidirected edge $V_i \leftrightarrow V_j$ instead. Furthermore, unobserved variables with only one or no children are omitted entirely. We also adopt these abbreviations. For SMGs the sets $\mathrm{Pa}(\cdot)_G, \mathrm{Ch}(\cdot)_G, \mathrm{An}(\cdot)_G, \mathrm{De}(\cdot)_G$ and $\mathrm{Co}(\cdot)_G$ contain only observed vertices. Additionally, a subgraph $G[\mathbf{W}]$ of an SMG G will also retain any bidirected edges between vertices in $\mathbf{W}$.

Any DAG can be associated with an SMG by constructing its *latent projection* (Verma, 1993).

Definition 2 (latent projection) *Let $G = \langle \mathbf{V} \cup \mathbf{L}, \mathbf{E} \rangle$ be a DAG such that the vertices in $\mathbf{V}$ are observed and the vertices in $\mathbf{L}$ are latent. The* latent projection *$L(G, \mathbf{V})$ is a DAG $\langle \mathbf{V}, \mathbf{E}_L \rangle$, where for every pair of distinct vertices $Z, W \in \mathbf{V}$ it holds that:*

1. *$L(G, \mathbf{V})$ contains an edge $Z \rightarrow W$ if there exists a directed path $Z \rightarrow \cdots \rightarrow W$ in G on which every vertex except Z and W is in $\mathbf{L}$.*
2. *$L(G, \mathbf{V})$ contains an edge $Z \leftrightarrow W$ if there exists a path from Z to W in G that does not contain the pattern $Z \rightarrow M \leftarrow W$ (a collider) and on which every vertex except Z and W is in $\mathbf{L}$ and the first edge has an arrowhead pointing into W and the last edge has an arrowhead pointing into Z.*

From the construction it is easy to see that a latent projection is in fact an SMG. The induced graph of a probabilistic causal model can also be used to derive conditional independences among the variables in the model using a concept known as d-separation. We provide a definition for d-separation (Shpitser and Pearl, 2008) which takes into account the presence of bidirected edges and is thus suitable for SMGs.

Definition 3 (d-separation) *A path P in an SMG G is said to be d-separated by a set $\mathbf{Z}$ if and only if either*

1. *P contains one of the following three patterns of edges: $I \rightarrow M \rightarrow J$, $I \leftrightarrow M \rightarrow J$ or $I \leftarrow M \rightarrow J$, such that $M \in \mathbf{Z}$, or*
2. *P contains one of the following three patterns of edges: $I \rightarrow M \leftarrow J$, $I \leftrightarrow M \leftarrow J$, $I \leftrightarrow M \leftrightarrow J$, such that $De(M)_G \cap \mathbf{Z} = \emptyset$.*

Disjoint sets $\mathbf{X}$ and $\mathbf{Y}$ are said to be d-separated by $\mathbf{Z}$ in G if every path from $\mathbf{X}$ to $\mathbf{Y}$ is d-separated by $\mathbf{Z}$ in G.

Whenever we can decompose the joint distribution of the observed variables $\mathbf{V}$ and the unobserved variables $\mathbf{U}$ as $P(\mathbf{v}, \mathbf{u}) = \prod_{W \in \mathbf{V} \cup \mathbf{U}} P(w|\mathrm{Pa}^*(w)_G)$, where $\mathrm{Pa}^*(\cdot)$ also contains the unobserved parents but not the argument itself, we say that G is an I-map of $P(\mathbf{v}, \mathbf{u})$ (Pearl, 2009). If sets $\mathbf{X}$ and $\mathbf{Y}$ are d-separated by $\mathbf{Z}$ in G, then $\mathbf{X}$ is independent of $\mathbf{Y}$ given $\mathbf{Z}$ in every P for which G is an I-map (Pearl, 1988). We use the notation of (Dawid, 1979) to denote this d-separation and conditional independence statement as $(\mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{Z})_G$. It is clear that the graph induced by any semi-Markovian causal model is an I-map for the joint distribution $P(\mathbf{v}, \mathbf{u})$ induced by the model.

Our interest lies in the effects of actions imposing changes to the model. An action that forces $\mathbf{X}$ to take a specific value $\mathbf{x}$ is called an *intervention* and it is denoted by $\mathrm{do}(\mathbf{x})$ (Pearl, 2009). An intervention $\mathrm{do}(\mathbf{x})$ on a model M creates a new sub-model, denoted by $M_{\mathbf{x}}$, where the functions in $\mathbf{F}$ that determine the value of $\mathbf{X}$ have been replaced with constant functions. The *interventional distribution* of a set of variables $\mathbf{Y}$ in the model $M_{\mathbf{x}}$ is denoted by $P_{\mathbf{x}}(\mathbf{y})$. This distribution is also known as the *causal effect* of $\mathbf{X}$ on $\mathbf{Y}$.

Multiple causal models can share the same graph, and thus the same sub-model resulting from an intervention. The question is, are our assumptions encoded in the causal model sufficient to uniquely specify an interventional distribution of interest. This notion is captured by the following definition (Shpitser and Pearl, 2006).

Definition 4 (identifiability) *Let $G = \langle \mathbf{V}, \mathbf{E} \rangle$ be an SMG and let $\mathbf{X}$ and $\mathbf{Y}$ be disjoint sets of variables such that $\mathbf{X}, \mathbf{Y} \subset \mathbf{V}$. The causal effect of $\mathbf{X}$ on $\mathbf{Y}$ is said to be* identifiable *from P in G if $P_{\mathbf{x}}(\mathbf{y})$ is uniquely computable from $P(\mathbf{V})$ in any causal model that induces G.*

In order to show the identifiability of a given effect we have to express the interventional distribution in terms of observed probabilities only. The link between observed probabilities and interventional distributions is provided by three inference rules known as *do-calculus* (Pearl, 1995):

1. Insertion and deletion of observations:

$$P_{\mathbf{x}}(\mathbf{y}|\mathbf{z}, \mathbf{w}) = P_{\mathbf{x}}(\mathbf{y}|\mathbf{w}), \text{ if } (\mathbf{Y} \perp\!\!\!\perp \mathbf{Z}|\mathbf{X}, \mathbf{W})_{G_{\overline{\mathbf{X}}}}.$$

2. Exchanging actions and observations:

$$P_{\mathbf{x},\mathbf{z}}(\mathbf{y}|\mathbf{w}) = P_{\mathbf{x}}(\mathbf{y}|\mathbf{z}, \mathbf{w}), \text{ if } (\mathbf{Y} \perp\!\!\!\perp \mathbf{Z}|\mathbf{X}, \mathbf{W})_{G_{\overline{\mathbf{X}},\underline{\mathbf{Z}}}}.$$

3. Insertion and deletion of actions:

$$P_{\mathbf{x},\mathbf{z}}(\mathbf{y}|\mathbf{w}) = P_{\mathbf{x}}(\mathbf{y}|\mathbf{w}), \text{ if } (\mathbf{Y} \perp\!\!\!\perp \mathbf{Z}|\mathbf{X}, \mathbf{W})_{G_{\overline{\mathbf{X}},Z(\overline{\mathbf{W}})}},$$

   where $Z(\mathbf{W}) = \mathbf{Z} \setminus \mathrm{An}(\mathbf{W})_{G_{\overline{\mathbf{X}}}}$.

Completeness of do-calculus was established independently by Huang and Valtorta (2006) and Shpitser and Pearl (2006). In this paper we focus on the solution provided by Shpitser and Pearl (2006). They constructed an identifiability algorithm called ID, which in essence applies the rules of do-calculus and breaks the problem into smaller sub-problems repeatedly.

3. ID Algorithm

In order to present the ID algorithm, we first need some additional definitions that are used to construct the graphical criterion for non-identifiability (Shpitser and Pearl, 2006).

Definition 5 (C-component) *Let G be an SMG and let $C \subseteq G$. If every pair of vertices in C is connected by a bidirected path, that is a path consisting entirely of bidirected edges, then C is a* C-component *(confounded component). Furthermore, C is a* maximal C-component *if C contains every vertex connected to C via bidirected paths in G and C is an induced subgraph of G.*

No restrictions are imposed on the directed edges of a C-component. The same is not true for the maximal C-components (also known as districts) of an SMG G, which are assumed to be induced subgraphs of G. This requirement guarantees the uniqueness of the maximal C-components.

Maximal C-components are an important tool for identifying causal effects. The set of maximal C-components of a semi-Markovian graph G is denoted by $C(G)$. A result in (Tian, 2002) states that if $C = \langle \mathbf{C}, \mathbf{E} \rangle$ is a maximal C-component and $C \subset G$ then the causal effect $P_{\mathbf{v}\setminus\mathbf{c}}(\mathbf{c})$ is identifiable from P in G. A distribution P of a semi-Markovian model also factorizes with respect to the maximal C-components of the induced graph G such that $P(\mathbf{v}) = \prod_{\langle \mathbf{C},\mathbf{E}\rangle \in C(G)} P_{\mathbf{v}\setminus\mathbf{c}}(\mathbf{c})$ (Shpitser and Pearl, 2006). It is precisely this factorization that the ID algorithm takes advantage of. A specific type of C-component is used to characterize problematic structures for identifiability.

Definition 6 (C-forest) *Let G be an SMG and let $\mathbf{Y}$ be the root set of G. If G is a C-component and all observed vertices have at most one child, then G is a* $\mathbf{Y}-$rooted C-forest.

The complete criterion for non-identifiability uses a structure formed by two C-forests:

Definition 7 (hedge) *Let $\mathbf{X}, \mathbf{Y} \subset \mathbf{V}$ be disjoint sets of variables and let G be an SMG. Let $F = \langle \mathbf{V}_F, \mathbf{E}_F \rangle$ and $F' = \langle \mathbf{V}_{F'}, \mathbf{E}_{F'} \rangle$ be $\mathbf{R}$-rooted C-forests in G such that $\mathbf{V}_F \cap \mathbf{X} \neq \emptyset$, $\mathbf{V}_{F'} \cap \mathbf{X} = \emptyset$, $F' \subseteq F$, and $\mathbf{R} \subseteq An(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$. Then F and F' form a hedge for $P_{\mathbf{x}}(\mathbf{y})$ in G.*

Intuitively hedges are a difficult concept. Whenever a hedge is present, there exists two causal models with the same probability distribution over $\mathbf{V}$ but their interventional distributions do not agree. Observational data can not be used to estimate causal effects in this scenario. We are now ready to present the ID algorithm.

Shpitser and Pearl (2006) showed that whenever Algorithm 1 returns an expression for a causal effect, it is correct. Additionally whenever line 5 is triggered there exists a hedge for the causal effect currently being identified. This result establishes the completeness of the algorithm and also the completeness of do-calculus, since the soundness of each line of the algorithm can be shown with do-calculus and standard probability calculus alone.

Algorithm 1 The causal effect of intervention $do(\mathbf{X} = \mathbf{x})$ on $\mathbf{Y}$ (ID).

INPUT: Value assignments $\mathbf{x}$ and $\mathbf{y}$, joint distribution $P(\mathbf{v})$ and an SMG $G = \langle \mathbf{V}, \mathbf{E} \rangle$. G is an I-map of P.

OUTPUT: Expression for $P_{\mathbf{x}}(\mathbf{y})$ in terms of $P(\mathbf{v})$ or **FAIL**(F, F').

function ID$(\mathbf{y}, \mathbf{x}, P, G)$

1: **if** $\mathbf{x} = \emptyset$,
  return $\sum_{v \in \mathbf{v}\setminus\mathbf{y}} P(\mathbf{v})$.
2: **if** $\mathbf{V} \neq \mathrm{An}(\mathbf{Y})_G$,
  return ID$(\mathbf{y}, \mathbf{x} \cap \mathrm{An}(\mathbf{y})_G, P(\mathrm{An}(\mathbf{Y})_G), G[\mathrm{An}(\mathbf{Y})_G])$.
3: **let** $\mathbf{W} = (\mathbf{V} \setminus \mathbf{X}) \setminus \mathrm{An}(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$.
  if $\mathbf{W} \neq \emptyset$,
  return ID$(\mathbf{y}, \mathbf{x} \cup \mathbf{w}, P, G)$.
4: **if** $C(G[\mathbf{V} \setminus \mathbf{X}]) = \{G[\mathbf{S}_1], \ldots, G[\mathbf{S}_k]\}$,
  return $\sum_{v \in \mathbf{v}\setminus(\mathbf{y}\cup\mathbf{x})} \prod_{i=1}^{k}$ **ID**$(\mathbf{s}_i, \mathbf{v} \setminus \mathbf{s}_i, P, G)$.
  if $C(G[\mathbf{V} \setminus \mathbf{X}]) = \{G[\mathbf{S}]\}$,
5: **if** $C(G) = \{G\}$,
    throw FAIL$(G, G[\mathbf{S}])$.
6: **if** $G[\mathbf{S}] \in C(G)$,
    return $\sum_{v \in \mathbf{s}\setminus\mathbf{y}} \prod_{V_i \in \mathbf{S}} P(v_i | v_\pi^{(i-1)})$.
7: **if** $(\exists \mathbf{S}')\mathbf{S} \subset \mathbf{S}'$ **such that** $G[\mathbf{S}'] \in C(G)$,
    return ID$(\mathbf{y}, \mathbf{x} \cap \mathbf{s}', \prod_{V_i \in \mathbf{S}'} P(V_i | V_\pi^{(i-1)} \cap \mathbf{S}', v_\pi^{(i-1)} \setminus \mathbf{s}'), G[\mathbf{S}'])$.

4. Pruning of Variables

In this section we present a number of results that deal with variables that are not necessary for identification either by removing them from the graph or by considering them latent. When the causal effect $P_{\mathbf{x}}(\mathbf{y})$ is considered in an SMG we can present an outline of the pruning process:

1. Removal of non-ancestors of $\mathbf{Y}$.
2. Removal of ancestors of $\mathbf{X}$ that are connected to $\mathbf{Y}$ only via $\mathbf{X}$ under certain conditions.
3. Removal of vertices connected to other vertices only through a single vertex.
4. Identification in a latent projection under certain conditions.

Steps 2–4 are new and they are based on the results of this section. Step 1 is derived from a useful result by Shpitser and Pearl (2006) which states that for a causal effect $P_{\mathbf{x}}(\mathbf{y})$ we can always ignore non-ancestors of $\mathbf{Y}$.

Lemma 8 *Let $\mathbf{X}' = \mathbf{X} \cap An(\mathbf{Y})_G$. Then $P_{\mathbf{x}}(\mathbf{y})$ obtained from P in G is equal to $P'_{\mathbf{x}'}(\mathbf{y})$ obtained from $P' = P(An(\mathbf{Y})_G)$ in $G[An(\mathbf{Y})_G]$.*

Lemma 8 is implemented on line 2 of Algorithm 1. Not all ancestors of $\mathbf{Y}$ are always necessary for identification. The next result states that we may sometimes remove ancestors of $\mathbf{X}$ that are connected to $\mathbf{Y}$ only through $\mathbf{X}$.

Theorem 9 *Let G be an SMG and let $\mathbf{Z} \subset \mathbf{V}$ be the set of all vertices such that $\mathbf{X}$ intercepts all paths from $\mathbf{Z}$ to $\mathbf{Y}$. Then the causal effect $P_{\mathbf{x}}(\mathbf{y})$ obtained from P in G is equal to $P'_{\mathbf{x}}(\mathbf{y})$ obtained from $P' = P(\mathbf{V} \setminus \mathbf{Z})$ in $G[\mathbf{V} \setminus \mathbf{Z}]$ if $\mathbf{Z}$ contains no members of $\mathbf{X}$ and if $G[\mathbf{V} \setminus \mathbf{Z}] = L(G, \mathbf{V} \setminus \mathbf{Z})$.*

Proof Let $G' = G[\mathbf{V} \setminus \mathbf{Z}]$ and assume that $G' = L(G, \mathbf{V} \setminus \mathbf{Z})$. Let $\mathbf{U_Z}$, $\mathbf{U_{V \setminus Z}}$ and $\mathbf{U_X}$ be sets of unobserved variables such that for all $U \in \mathbf{U_Z}$ it holds that $\mathrm{Ch}(U)_{G_{\overline{\mathbf{X}}}} \subseteq \mathbf{Z}$, for all $U \in \mathbf{U_{V \setminus Z}}$ it holds that $\mathrm{Ch}(U)_{G_{\overline{\mathbf{X}}}} \subseteq \mathbf{V} \setminus \mathbf{Z}$ and for all $U \in \mathbf{U_X}$ it holds that $\mathrm{Ch}(U)_G \in \mathbf{X}$. The sets $\mathbf{U_Z}$, $\mathbf{U_{V \setminus Z}}$ and $\mathbf{U_X}$ partition $\mathbf{U}$ because $\mathbf{X}$ intercepts all paths from $\mathbf{Z}$ to $\mathbf{Y}$. According to the third rule of do-calculus $P_{\mathbf{x}}(\mathbf{y}) = P_{\mathbf{x},\mathbf{z}}(\mathbf{y})$ because the condition $(\mathbf{Y} \perp\!\!\!\perp \mathbf{Z}|\mathbf{X})_{G_{\overline{\mathbf{X}}}}$ holds as removing the edges incoming to $\mathbf{X}$ separates $\mathbf{X}$ from its ancestors. Applying the truncated factorization formula (Pearl, 2009) we have that

$$P_{\mathbf{x},\mathbf{z}}(\mathbf{y}) = \sum_{\mathbf{U}} \sum_{\mathbf{V} \setminus (\mathbf{Y} \cup \mathbf{X} \cup \mathbf{Z})} \prod_{\mathbf{V} \setminus (\mathbf{X} \cup \mathbf{Z})} P(v_i | \mathrm{Pa}(v_i)_G \setminus \{v_i\}) \prod_{\mathbf{U}} P(u_i).$$

Since variables in $\mathbf{U_Z}$ can only be parents of variables in $\mathbf{Z}$ or $\mathbf{X}$ in G, we can sum them out from the previous expression and obtain

$$P_{\mathbf{x},\mathbf{z}}(\mathbf{y}) = \sum_{\mathbf{U_{V \setminus Z}} \cup \mathbf{U_X}} \sum_{\mathbf{V} \setminus (\mathbf{Y} \cup \mathbf{X} \cup \mathbf{Z})} \prod_{\mathbf{V} \setminus (\mathbf{X} \cup \mathbf{Z})} P(v_i | \mathrm{Pa}(v_i)_G \setminus \{v_i\}) \prod_{\mathbf{U_{V \setminus Z}} \cup \mathbf{U_X}} P(u_i).$$

Similarly, variables in $\mathbf{U_X}$ can only be parents of variables in $\mathbf{X}$ in G, so we can also sum them out of the expression to obtain

$$P_{\mathbf{x},\mathbf{z}}(\mathbf{y}) = \sum_{\mathbf{U_{V \setminus Z}}} \sum_{\mathbf{V} \setminus (\mathbf{Y} \cup \mathbf{X} \cup \mathbf{Z})} \prod_{\mathbf{V} \setminus (\mathbf{X} \cup \mathbf{Z})} P(v_i | \mathrm{Pa}(v_i)_G \setminus \{v_i\}) \prod_{\mathbf{U_{V \setminus Z}}} P(u_i).$$

We let $\mathbf{V}' = \mathbf{V} \setminus \mathbf{Z}$. Verma (1993) showed that a graph and its latent projection have the same set of conditional independence relations among the observed variables. Because we have assumed that $G' = L(G, \mathbf{V} \setminus \mathbf{Z})$ every conditional independence between variables in $\mathbf{V}'$ and $\mathbf{U_{V'}}$ applies in both G and G'. We have that for all $V_i \in \mathbf{V}' \setminus \mathbf{X}$ it holds that $P(v_i|\mathrm{Pa}(v_i)_G \setminus \{v_i\}) = P'(v_i|\mathrm{Pa}(v_i)_{G'} \setminus \{v_i\})$ and for all $U_i \in \mathbf{U_{V'}}$ it holds that $P(u_i) = P'(u_i)$. Finally we obtain

$$P_{\mathbf{x},\mathbf{z}}(\mathbf{y}) = \sum_{\mathbf{U_{V'}}} \sum_{\mathbf{V}' \setminus (\mathbf{Y} \cup \mathbf{X})} \prod_{\mathbf{V}' \setminus \mathbf{X}} P'(v_i | \mathrm{Pa}(v_i)_{G'} \setminus \{v_i\}) \prod_{\mathbf{U_{V'}}} P'(u_i) = P'_{\mathbf{x}}(\mathbf{y}).$$

■

Theorem 9 can also be applied in a more general setting where a subset of $\mathbf{X}$ intercepts all paths from a set $\mathbf{Z}$ to $\mathbf{Y}$

Corollary 10 *Let G be an SMG and let $\mathbf{Z} \subset \mathbf{V}$ be the set of all vertices such that a set $\mathbf{W} \subseteq \mathbf{X}$ intercepts all paths from $\mathbf{Z}$ to $\mathbf{Y}$ and no member of $\mathbf{X} \setminus \mathbf{W}$ is a descendant of $\mathbf{W}$. Then the causal effect $P_{\mathbf{x}}(\mathbf{y})$ obtained from P in G is equal to $P'_{\mathbf{x}\setminus\mathbf{z}}(\mathbf{y})$ obtained from $P' = P(\mathbf{V} \setminus \mathbf{Z})$ in $G[\mathbf{V} \setminus \mathbf{Z}]$ if $\mathbf{Z}$ contains no members of $\mathbf{W}$ and if $G[\mathbf{V} \setminus \mathbf{Z}] = L(G, \mathbf{V} \setminus \mathbf{Z})$.*

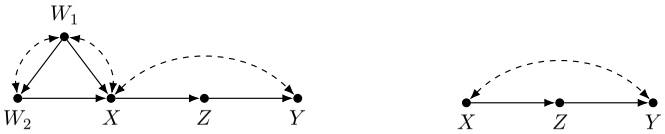
Proof Since $\mathbf{W}$ intercepts all paths from $\mathbf{Z}$ to $\mathbf{Y}$ and no member of $\mathbf{X} \setminus \mathbf{W}$ is a descendant of $\mathbf{W}$, it follows that no member of $\mathbf{W}$ is in $\mathbf{Z}$. According to the third rule of do-calculus we have that $(\mathbf{Y} \perp\!\!\!\perp \mathbf{Z}|\mathbf{X} \setminus \mathbf{Z})_{G_{\overline{\mathbf{X}\setminus\mathbf{Z}}}}$ and $P_{\mathbf{x}}(\mathbf{y}) = P_{\mathbf{x}\setminus\mathbf{z}}(\mathbf{y})$. The claim now follows by applying Theorem 9 to $P_{\mathbf{x}\setminus\mathbf{z}}(\mathbf{y})$. ■

Corollary 11 *When the causal effect $P_{\mathbf{x}}(\mathbf{y})$ is considered in graph G, a set of vertices $\mathbf{Z} = An(\mathbf{Y})_G \setminus Co(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$ can be removed from G if $G[\mathbf{V} \setminus \mathbf{Z}] = L(G, \mathbf{V} \setminus \mathbf{Z})$.*

Proof The set $\mathrm{An}(\mathbf{Y})_G$ contains $\mathbf{Y}$ in addition to the ancestors of $\mathbf{Y}$, and the set $\mathrm{Co}(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$ contains $\mathbf{Y}$ and all vertices that are connected to $\mathbf{Y}$ via a path that does not contain edges incoming to $\mathbf{X}$. Therefore, $\mathbf{Z}$ contains such ancestors of $\mathbf{Y}$ that all paths from $\mathbf{Z}$ to $\mathbf{Y}$ contain $\mathbf{X}$. The removal of $\mathbf{Z}$ from G is now licensed by Corollary 10. ■

Corollary 11 provides a constructive criterion for the set $\mathbf{Z}$ described in Corollary 10 when G consists only of $\mathbf{Y}$ and its ancestors. If a vertex Z_i is a member of $\mathrm{An}(\mathbf{Y})_G \setminus \mathrm{Co}(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$ then it must be connected to $\mathbf{Y}$ only through paths containing some $\mathbf{W}_{Z_i} \subseteq \mathbf{X}$. We can always choose the sets $\mathbf{W}_{Z_i}$ in such a way that the union $\mathbf{W} = \cup \mathbf{W}_{Z_i}$ over the members Z_i of $\mathrm{An}(\mathbf{Y})_G \setminus \mathrm{Co}(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$ has no descendants in $\mathbf{X} \setminus \mathbf{W}$. The set $\mathbf{W}$ intercepts all paths from $\mathbf{Z} = \cup \{Z_i\}$ to $\mathbf{Y}$. Conversely, if Z_i is a vertex such that a set $\mathbf{W} \subseteq \mathbf{X}$ intercepts all paths from Z_i to $\mathbf{Y}$, then Z_i cannot be connected to $\mathbf{Y}$ in $G_{\overline{\mathbf{X}}}$. If we assume that $G = G[\mathrm{An}(\mathbf{Y})_G]$ it follows that Z_i is a member of $\mathrm{An}(\mathbf{Y})_G \setminus \mathrm{Co}(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$.

We present a simple example to motivate the usefulness of Corollary 11. We apply the ID algorithm to identify the causal effect of X on Y in graph G of Figure 2(a). Applying



(a) Graph G. (b) Subgraph $G[\{X, Y, Z\}]$.

Figure 2: A graph for an example where Corollary 11 allows us to remove vertices W_1 and W_2 when the causal effect of X on Y is considered.

the ID algorithm results in the following expression for the causal effect

$$\sum_z P(z|w_1, w_2, x) \left(\sum_{w_1, w_2, x'} P(y|w_1, w_2, x', z) P(x'|w_1, w_2) P(w_2|w_1) P(w_1) \right).$$

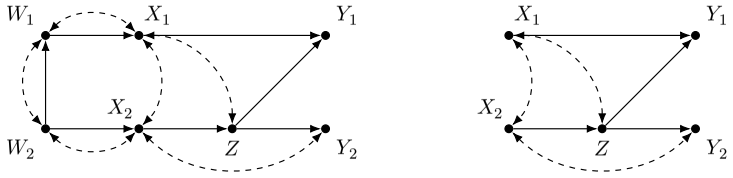
Applying Corollary 11 in this case would result in the removal of the vertices W_1 and W_2 from the graph, since they are ancestors of Y in G but not connected to Y in $G_{\overline{X}}$ and the corresponding latent projection is the subgraph $G[\{X, Y, Z\}]$ of Figure 2(b). Running the

ID algorithm in this subgraph provides us the following expression

$$\sum_z P(z|x)\left(\sum_{x'} P(y|x',z)P(x')\right).$$

We may consider this expression simpler compared to the previous output by noting that W_1 and W_2 do not appear in the expression and it has fewer unique terms. The same expression can also be obtained manually by applying the front-door criterion (Pearl, 2009).

Often the question of identifiability can not be answered directly by neither the back-door nor the front-door criterion which leads us to more general methods, such as the ID algorithm. We are interested in the causal effect of W_1, X_1 and X_2 on Y_1 and Y_2 in the graph of Figure 3(a).



(a) Graph G. (b) Subgraph $G[\{X_1, X_2, Z, Y_1, Y_2\}]$.

Figure 3: A graph for an example where the back-door and front-door criteria are unavailable, but Corollary 11 allows us to remove vertices W_1 and W_2 even when W_1 is part of the intervention.

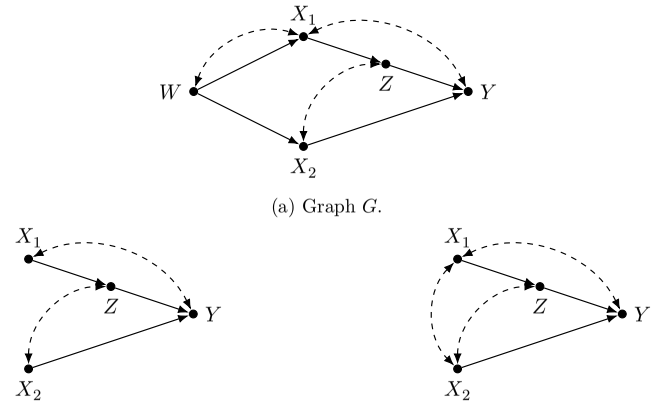
Direct application of the ID algorithm provides us with the following expression

$$\sum_z P(y_1|w_2,w_1,x_2,x_1,z)P(z|w_2,x_2)\left(\sum_{w_2,x_2'} P(y_2|w_2,x_2',z)P(x_2'|w_2)P(w_2)\right).$$

Corollary 11 licenses the removal of W_1 and W_2 from the graph. By running ID again in the resulting subgraph $G[\{X_1, X_2, Z, Y_1, Y_2\}]$ as shown in Figure 3(b) we obtain a simpler expression for the causal effect

$$\sum_z P(y_1|x_1,x_2,z)P(z|x_2)\left(\sum_{x_2'} P(y_2|x_2',z)P(x_2')\right).$$

The next example illustrates the necessity of the assumption $G[\mathbf{V}\setminus\mathbf{Z}] = L(G, \mathbf{V}\setminus\mathbf{Z})$ of Theorem 9 and Corollary 10. We are interested in the causal effect of X_1 and X_2 on Y in graph G of Figure 4(a). In this graph W is connected to Y only through X_1 and X_2, but the corresponding latent projection does not match the subgraph with W removed as seen in Figures 4(b) and 4(c). In G the causal effect is identifiable, but it is not identifiable in the latent projection $G' = L(G, \{X_1, X_2, Z, Y\})$. In this latent projection a bidirected edge exists between X_1 and X_2 and a hedge is formed by the C-forests G' and $G[\{Y\}]$.



(a) Graph G.

(b) Subgraph $G[\{X_1, X_2, Z, Y\}]$. (c) Latent projection $L(G, \{X_1, X_2, Z, Y\})$.

Figure 4: An example where the assumptions of Corollary 10 are not met because the subgraph in panel (b) and the latent projection in panel (c) differ from each other.

We may also remove sets of vertices that are connected to the rest of the graph only through a single vertex even when no intervention on the corresponding variable has taken place.

Theorem 12 *Let G be an SMG such that $G = G[An(\mathbf{Y})_G]$ for a set of vertices $\mathbf{Y}$ and let W be a vertex of G. If there exists a set $\mathbf{Z}$ such that $\mathbf{Z}\cap(\mathbf{Y}\cup\mathbf{X}) = \emptyset$ and $\mathbf{Z}$ is connected to $\mathbf{V}\setminus\mathbf{Z}$ only through W. Then the causal effect $P_{\mathbf{x}}(\mathbf{y})$ obtained from P in G is equal to $P'_{\mathbf{x}}(\mathbf{y})$ obtained from $P' = P(\mathbf{V}\setminus\mathbf{Z})$ in $G[\mathbf{V}\setminus\mathbf{Z}]$.*

Proof Let $G' = G[\mathbf{V}\setminus\mathbf{Z}]$ and let $\mathbf{U}_{\mathbf{Z}}$ and $\mathbf{U}_{\mathbf{V}\setminus\mathbf{Z}}$ be sets of unobserved variables such that for all $U\in\mathbf{U}_{\mathbf{Z}}$ it holds that $\mathrm{Ch}(U)_G \in \mathbf{Z}\cup\{W\}$ and for all $U\in\mathbf{U}_{\mathbf{V}\setminus\mathbf{Z}}$ it holds that $\mathrm{Ch}(U)_G \in (\mathbf{V}\setminus\mathbf{Z})\cup\{W\}$. Sets $\mathbf{U}_{\mathbf{Z}}$ and $\mathbf{U}_{\mathbf{V}\setminus\mathbf{Z}}$ partition $\mathbf{U}$ because $\mathbf{Z}$ is connected to $\mathbf{V}\setminus\mathbf{Z}$ only through W. Applying the truncated factorization formula yields

$$P_{\mathbf{x}}(\mathbf{y}) = \sum_{\mathbf{U}}\sum_{\mathbf{V}\setminus(\mathbf{Y}\cup\mathbf{X})} P(w|\mathrm{Pa}(w)_G\setminus\{w\}) \prod_{\mathbf{V}\setminus(\mathbf{X}\cup\{W\})} P(v_i|\mathrm{Pa}(v_i)_G\setminus\{v_i\}) \prod_{\mathbf{U}} P(u_i).$$

Since variables in $\mathbf{U}_{\mathbf{Z}}$ and $\mathbf{Z}$ can be connected to the other vertices of G only through W we can complete the marginalization over $\mathbf{Z}$ and $\mathbf{U}_{\mathbf{Z}}$

$$P_{\mathbf{x}}(\mathbf{y}) = \sum_{\mathbf{U}_{\mathbf{V}\setminus\mathbf{Z}}}\sum_{\mathbf{V}\setminus(\mathbf{Y}\cup\mathbf{X}\cup\mathbf{Z})} P(w|\mathrm{Pa}(w)_G\setminus(\mathbf{z}\cup\{w\})) \prod_{\mathbf{V}\setminus(\mathbf{X}\cup\mathbf{Z}\cup\{W\})} P(v_i|\mathrm{Pa}(v_i)_G\setminus\{v_i\}) \prod_{\mathbf{U}_{\mathbf{V}\setminus\mathbf{Z}}} P(u_i).$$

Because we have assumed that $\mathbf{Z}$ is disconnected from $\mathbf{V}\setminus\mathbf{Z}$ in $G_{\overline{W}}$ we have that $G[\mathbf{V}\setminus\mathbf{Z}] = L(G, \mathbf{V}\setminus\mathbf{Z})$. Therefore, just as in the proof of Theorem 9, we have that $P(v_i|\mathrm{Pa}(v_i)_G\setminus\{v_i\}) =$

$P'(v_i|\text{Pa}(v_i)_{G'} \setminus \{v_i\})$ for all $V_i \in \mathbf{V} \setminus (\mathbf{X} \cup \mathbf{Z} \cup \{W\})$ and $P(u_i) = P'(u_i)$ for all $U_i \in \mathbf{U}_{\mathbf{V}\setminus\mathbf{Z}}$. Additionally, we have $P(w|\text{Pa}(w)_G \setminus (\mathbf{z} \cup \{w\})) = P(w|Pa(w)_{G'} \setminus \{w\})$. Finally we obtain

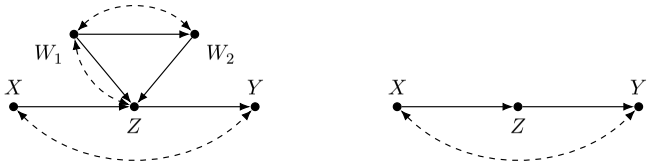
$$\begin{aligned} P_{\mathbf{x}}(\mathbf{y}) &= \sum_{\mathbf{U}_{\mathbf{V}\setminus\mathbf{Z}}} \sum_{\mathbf{V}\setminus(\mathbf{Y}\cup\mathbf{X}\cup\mathbf{Z})} P(w|\text{Pa}(w)_{G'} \setminus \{w\}) \prod_{\mathbf{V}\setminus(\mathbf{X}\cup\mathbf{Z}\cup\{W\})} P(v_i|\text{Pa}(v_i)_{G'} \setminus \{v_i\}) \prod_{\mathbf{U}_{\mathbf{V}\setminus\mathbf{Z}}} P(u_i) \\ &= \sum_{\mathbf{U}_{\mathbf{V}\setminus\mathbf{Z}}} \sum_{\mathbf{V}\setminus(\mathbf{Y}\cup\mathbf{X}\cup\mathbf{Z})} \prod_{\mathbf{V}\setminus(\mathbf{X}\cup\mathbf{Z})} P(v_i|\text{Pa}(v_i)_{G'} \setminus \{v_i\}) \prod_{\mathbf{U}_{\mathbf{V}\setminus\mathbf{Z}}} P(u_i) \\ &= P'_{\mathbf{x}}(\mathbf{y}). \end{aligned}$$

■

Corollary 13 *Let W be a vertex of an SMG G and let $\mathbf{R} = An(W)_{G_{\overline{\mathbf{X}}}} \setminus De(\mathbf{X})_G$. When the causal effect $P_{\mathbf{x}}(\mathbf{y})$ is considered in graph G, the set of vertices $\mathbf{T} = \mathbf{R} \setminus Co(\mathbf{V} \setminus \mathbf{R})_{G_{\overline{W}}}$ can be removed from the graph if $G = G[An(\mathbf{Y})_G]$.*

Proof No descendant of $\mathbf{X}$ can be removed via theorem 12 since they are connected to $\mathbf{X}$ and the set to be removed cannot itself contain $\mathbf{X}$. By removing descendants of $\mathbf{X}$ and $\mathbf{X}$ itself, and assuming that $G = G[\text{An}(\mathbf{Y})_G]$, we have that $\mathbf{T} \cap (\mathbf{X} \cup \mathbf{Y}) = \emptyset$. Thus it remains to remove those vertices from $\mathbf{R}$ that are connected to $\mathbf{V} \setminus \mathbf{R}$ through a path that does not contain W. Removal of the resulting set $\mathbf{T}$ from the graph is now licensed by theorem 12. ■

In the following example we consider the causal effect of X on Y in graph G of Figure 5(a) and show how Corollary 13 can be applied. The ID algorithm succeeds in identifying the



(a) Graph G. (b) Subgraph $G[\{X, Y, Z\}]$.

Figure 5: First example of Corollary 13.

causal effect and returns following expression for it

$$\sum_{w_1,w_2,z} P(z|x, w_1, w_2)P(w_2|x, w_1)P(w_1|x) \left(\sum_{x'} P(y|x', w_1, w_2, z)P(x') \right).$$

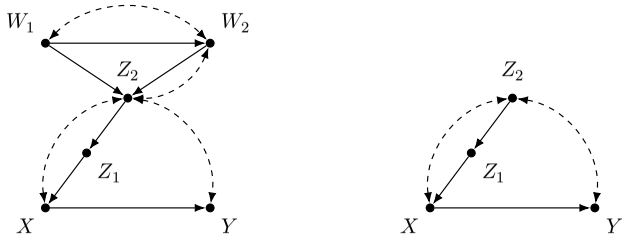
We apply Corollary 13 which allows us to remove W_1 and W_2 from the graph, since they are connected to other vertices of the graph through a single vertex Z. Applying the ID

algorithm in the resulting subgraph $G[\{X, Y, Z\}]$ of Figure 5(b) provides us the following expression

$$\sum_z P(z|x) \left(\sum_{x'} P(y|x', z)P(x') \right).$$

The same expression can be obtained manually by applying the front-door criterion.

We provide another example on Corollary 13 with a slightly more complicated graph. We are interested in the causal effect of X on Y in graph G of Figure 6(a) We obtain a



(a) Graph G. (b) Subgraph $G[\{X, Y, Z_1, Z_2\}$.

Figure 6: Second example of Corollary 13.

formula for the causal effect using the ID algorithm

$$\frac{\sum_{w_2,z_2} P(y|w_1, w_2, z_2, z_1, x)P(x|w_1, w_2, z_2, z_1)P(z_2|w_1, w_2)P(w_2|w_1)}{\left(\sum_{w_2,z_2,y} P(y|w_1, w_2, z_2, z_1, x)P(x|w_1, w_2, z_2, z_1)P(z_2|w_1, w_2)P(w_2|w_1)\right)}.$$

Vertices W_1 and W_2 are connected to other vertices only through Z_2 which allows us to remove them from the graph. We obtain a simpler formula for the causal effect from the subgraph $G[\{X, Y, Z_1, Z_2\}]$ of Figure 6(b)

$$\frac{\sum_{z_2} P(y|z_2, z_1, x)P(x|z_2, z_1)P(z_2)}{\sum_{z_2,y} P(y|z_2, z_1, x)P(x|z_2, z_1)P(z_2)}.$$

The previous results have allowed us to completely remove specific vertices from the graph. Next we will consider cases where a vertex is present in the graph, but it is not necessary to observe it. This means that instead of the original graph we may consider identifiability in the corresponding latent projection, as characterized by the following lemma.

Lemma 14 *Let $G = \langle \mathbf{V}, \mathbf{E} \rangle$ be an SMG and let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be disjoint sets of variables. Let $P(\mathbf{V})$ be the joint distribution of $\mathbf{V}$. Then the causal effect of $\mathbf{X}$ on $\mathbf{Y}$ is identifiable from P' in the latent projection $L(G, \mathbf{V} \setminus \mathbf{Z})$ where $P' = P(\mathbf{V} \setminus \mathbf{Z})$, if and only if it is identifiable from P' in G.*

Proof Tian (2002) showed that the latent projection has the same topological relations over the observables and that it has the same set of maximal C-components. Thus if $P_{\mathbf{x}}(\mathbf{y})$

is identifiable from P' in G it is also identifiable from P' in $L(G, \mathbf{V} \setminus \mathbf{Z})$ with the same expression and vice versa. ■

In situations where $\mathbf{X}$ is a singleton we can exploit the following sufficient condition for identifiability by Tian and Pearl (2002).

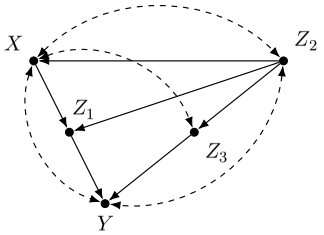
Theorem 15 *The causal effect $P_x(\mathbf{y})$ is identifiable if there is no bidirected path between X and any of its children in $G[An(\mathbf{Y})_G]$.*

We can regard any variable as latent when $\mathbf{X}$ is a singleton if the respective latent projection does not induce such a bidirected path.

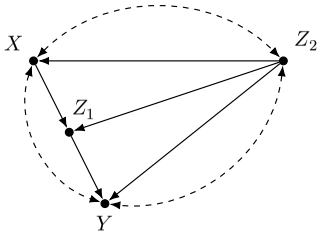
Corollary 16 *Let G be an SMG and let $\mathbf{Y}$ be a set of vertices. Let $X, W \in \mathbf{V}$ such that $X \neq W$, $W \notin \mathbf{Y}$ and $X, W \in An(\mathbf{Y})_G$. The causal effect $P_x(\mathbf{y})$ obtained from P in G is equal to $P'_x(\mathbf{y})$ obtained from $P' = P(An(\mathbf{Y})_G \setminus \{w\})$ and $G' = L(G[An(\mathbf{Y})_G], An(\mathbf{Y})_G \setminus \{W\})$ if there is no bidirected path from X to any of its children in G'.*

Proof By Theorem 15 the causal effect $P'_x(\mathbf{y})$ is identifiable from P' in G'. By Lemma 14 $P'_x(\mathbf{y})$ is now identifiable from P' in G. $P_x(y)$ obtained from P' in G is equal to $P^*_x(y)$ obtained from $P^* = P(\mathrm{An}(\mathbf{Y})_G)$ in $G[\mathrm{An}(\mathbf{Y})]$ since identifiability from P' implies identifiability from P. Finally, $P^*_x(\mathbf{y})$ obtained from $P^* = P(\mathrm{An}(\mathbf{Y})_G)$ in $G[\mathrm{An}(\mathbf{Y})_G]$ is equal to $P_x(y)$ obtained from P in G. ■

We continue with an example on how Corollary 16 can be applied in practice. We consider the causal effect of X on Y in the graph G of Figure 7(a). The causal effect is



(a) Graph G.



(b) Latent projection $L(G, \{X, Y, Z_1, Z_2\})$.

Figure 7: A graph for an example where Corollary 16 allows us to make variable Z_3 latent.

identifiable and the output of the ID algorithm is

$$\sum_{z_2,z_3,z_1} P(z_1|z_2,x)\frac{\left(\sum_{x'} P(y|z_2,x',z_3,z_1)P(z_3|z_2,x')P(x'|z_2)P(z_2)\right)}{\left(\sum_{x',y'} P(y'|z_2,x',z_3,z_1)P(z_3|z_2,x')P(x'|z_2)P(z_2)\right)}\times \left(\sum_{x',z_3,y'} P(y'|z_2,x',z_3,z_1)P(z_3|z_2,x')P(x'|z_2)P(z_2)\right)P(z_3|z_2).$$

We may apply Corollary 16 by noting that $G = G[\mathrm{An}(Y)_G]$ and that there is no bidirected path between X and its only child Z_1 in the latent projection $L(G, \mathbf{V} \setminus \{Z_3\})$ as depicted in Figure 7(b).

Running the ID algorithm in $L(G, \mathbf{V} \setminus \{Z_3\})$ results in the following expression

$$\sum_{z_2,z_1}\left(\sum_{x'} P(y|z_2,x',z_1)P(x'|z_2)P(z_2)\right)P(z_1|z_2,x).$$

5. Pruning Identifiability Algorithm

Corollaries 11, 13 and 16 can be implemented as additional steps for the ID algorithm. For Algorithm 2, line 3 implements Corollary 11, line 4 implements Corollary 13 and line 5 implements Corollary 16. Other lines are identical to the ID algorithm. This algorithm is provided by the R package *causaleffect* which implements various causal inference algorithms such as the original ID algorithm (Tikka and Karvanen, 2017a).

The ordering of the variables in the loop on line 4 has no effect on the resulting expression, but the ordering does matter on line 5. Choosing a different ordering may lead to a different expression. For example, when identifying the causal effect of X on Y in graph G of Figure 8 one may obtain either the back-door formula or the front-door formula by proceeding in either the topological ordering or the reverse-topological ordering of the vertices, respectively.

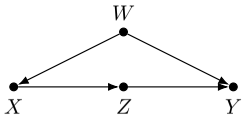


Figure 8: Graph G where different latent projections lead to different expressions for $P_x(y)$.

Algorithm 2 A pruning identifiability algorithm (PID) for causal effects.

INPUT: Value assignments $\mathbf{x}$ and $\mathbf{y}$, joint distribution $P(\mathbf{v})$ and an SMG $G = \langle \mathbf{V}, \mathbf{E} \rangle$. G is an I-map of P.

OUTPUT: Expression for $P_{\mathbf{x}}(\mathbf{y})$ in terms of $P(\mathbf{v})$ or **FAIL**(F, F').

function PID$(\mathbf{y}, \mathbf{x}, P, G)$
1: **if** $\mathbf{x} = \emptyset$,
  return $\sum_{v \in \mathbf{v} \setminus \mathbf{y}} P(\mathbf{v})$.
2: **if** $\mathbf{V} \neq \mathrm{An}(\mathbf{Y})_G$,
  return PID$(\mathbf{y}, \mathbf{x} \cap \mathrm{An}(\mathbf{y})_G, P(\mathrm{An}(\mathbf{Y})_G), G[\mathrm{An}(\mathbf{Y})_G])$
3: **let** $\mathbf{Z} = \mathrm{An}(\mathbf{Y})_G \setminus \mathrm{Co}(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$.
  if $\mathbf{Z} \neq \emptyset$ **and** $G[\mathbf{V} \setminus \mathbf{Z}] = L(G, \mathbf{V} \setminus \mathbf{Z})$,
  return PID$(\mathbf{y}, \mathbf{x} \setminus \mathbf{z}, P(\mathbf{V} \setminus \mathbf{Z}), G[\mathbf{V} \setminus \mathbf{Z}])$
4: **for** $W \in \mathbf{V} \setminus \mathbf{X}$ **do**
  let $\mathbf{R} = \mathrm{An}(W)_{G_{\overline{\mathbf{X}}}} \setminus \mathrm{De}(\mathbf{X})_G$.
  let $\mathbf{T} = \mathbf{T} \cup (\mathbf{R} \setminus \mathrm{Co}(\mathbf{V} \setminus \mathbf{R})_{G_{\overline{W}}})$.
  if $\mathbf{T} \neq \emptyset$,
  return PID$(\mathbf{y}, \mathbf{x}, P(\mathbf{V} \setminus \mathbf{T}), G[\mathbf{V} \setminus \mathbf{T}])$
5: **if** $\mathbf{X} = \{X\}$,
  let $G[\mathbf{S}_X] \in C(G), X \in \mathbf{S}_X$.
  if $\mathrm{Ch}(\mathbf{X})_{G[\mathbf{S}_X]} \setminus \mathbf{X} = \emptyset$,
    for $W \in \mathbf{V} \setminus (\mathbf{Y} \cup \mathbf{X})$ **do**
      let $G' = L(G, \mathbf{V} \setminus \{W\})$.
      let $G'[\mathbf{S}'_X] \in C(G'), X \in \mathbf{S}'_X$.
      if $\mathrm{Ch}(\mathbf{X})_{G'[\mathbf{S}'_X]} \setminus \mathbf{X} = \emptyset$,
        $P \leftarrow P(\mathbf{V} \setminus \{W\})$.
        $G \leftarrow G'$.
        $\mathbf{V} \leftarrow \mathbf{V} \setminus \{W\}$.
6: **let** $\mathbf{W} = (\mathbf{V} \setminus \mathbf{X}) \setminus \mathrm{An}(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$.
  if $\mathbf{W} \neq \emptyset$,
  return PID$(\mathbf{y}, \mathbf{x} \cup \mathbf{w}, P, G)$.
7: **if** $C(G[\mathbf{V} \setminus \mathbf{X}]) = \{G[\mathbf{S}_1], \ldots, G[\mathbf{S}_k]\}$,
  return $\sum_{v \in \mathbf{v} \setminus (\mathbf{y} \cup \mathbf{x})} \prod_{i=1}^{k}$ **PID**$(\mathbf{s}_i, \mathbf{v} \setminus \mathbf{s}_i, P, G)$.
  if $C(G[\mathbf{V} \setminus \mathbf{X}]) = \{G[\mathbf{S}]\}$,
8: **if** $C(G) = \{G\}$,
    throw FAIL$(G, G[\mathbf{S}])$.
9: **if** $G[\mathbf{S}] \in C(G)$,
    return $\sum_{v \in \mathbf{s} \setminus \mathbf{y}} \prod_{V_i \in \mathbf{S}} P(v_i | v_\pi^{(i-1)})$.
10: **if** $(\exists \mathbf{S}')\mathbf{S} \subset \mathbf{S}'$ **such that** $G[\mathbf{S}'] \in C(G)$,
    return PID$(\mathbf{y}, \mathbf{x} \cap \mathbf{s}', \prod_{V_i \in \mathbf{S}'} P(V_i | V_\pi^{(i-1)} \cap \mathbf{S}', v_\pi^{(i-1)} \setminus \mathbf{s}'), G[\mathbf{S}'])$.

On line 5 we first check whether the set $\mathbf{X}$ is a singleton. If so, we determine whether any children of X belong the same C-component as X. If no such children exist, we iterate over

the possible latent projections in an attempt to find one that does not induce a bidirected path between X and any of its children in the projection. After the new pruning steps have been carried out, we attempt identification using the original formulation of the ID algorithm.

We return to the example presented in the introduction and show how Algorithm 2 operates to derive the expression for $P_x(y)$ in the graph of Figure 1(a). We choose the topological ordering to be $Y > Z_1 > X > Z_3 > W_2 > Z_4 > Z_2 > W_1$. We begin on line 3, since $\mathbf{Z} = \mathrm{An}(Y)_G \setminus \mathrm{Co}(Y)_{G_{\overline{X}}} = \mathbf{V} \setminus \{W_1, W_2\}$ and continue by calling $\mathrm{PID}(y, x, P(\mathbf{V} \setminus \{W_1, W_2\}), G[\mathbf{V} \setminus \{W_1, W_2\}])$. In the presentation below, $\mathbf{V}$ and G refer to the set of vertices and graph in the current call of PID, respectively.

Next we enter the loop on line 4. When $W = Z_1$ we obtain $\mathbf{R} = \mathrm{An}(Z_1)_{G_{\overline{X}}} \setminus \mathrm{De}(X)_G = \{Z_2, Z_4\}$ and $\mathbf{R} \setminus \mathrm{Co}(\mathbf{V} \setminus \mathbf{R})_{G_{\overline{Z}_1}} = \{Z_2, Z_4\} \setminus \{Z_2\} = \{Z_4\}$ since Z_4 is an ancestor of Z_1 and it is disconnected from other vertices in $G_{\overline{Z}_1}$. Other choices of W result in an empty set. When the loop is completed we have $\mathbf{T} = \{Z_4\}$ and we continue by calling $\mathrm{PID}(y, x, P(\mathbf{V} \setminus \{Z_4\}), G[\mathbf{V} \setminus \{Z_4\}])$.

Since $\mathbf{X}$ is a singleton we end up on line 5 and find no children of X in the same C-component as X. We assume a reverse-topological ordering for the loop and begin with the latent projection $L(G, \mathbf{V} \setminus \{Z_2\})$. This projection creates a bidirected edge between X and Z_1 bringing them into the same C-component in the projection. Thus we continue with $L(G, \mathbf{V} \setminus \{Z_1\})$. This projection is also unsuitable, since Y is a child of X in the projection and there is a bidirected arc connecting them. We continue with $L(G, \mathbf{V} \setminus \{Z_3\})$ and find that X is not connected to its children via bidirected paths in the projection. Thus we set $P \leftarrow P(\mathbf{V} \setminus \{Z_3\})$, $G \leftarrow L(G, \mathbf{V} \setminus \{Z_3\})$ and $\mathbf{V} \leftarrow \mathbf{V} \setminus \{Z_3\}$. This projection is identical to the graph depicted in Figure 7(b). After these steps, only lines of the original ID algorithm are called, which results in the expression

$$\sum_{z_2, z_1} \left(\sum_{x'} P(y | z_2, z_1, x') P(x' | z_2) P(z_2) \right) P(z_1 | z_2, x).$$

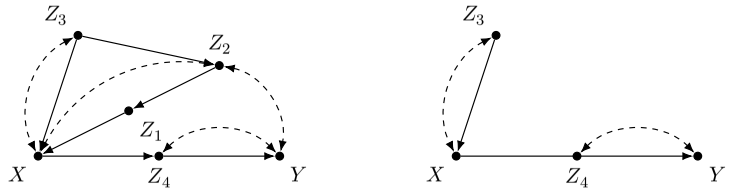
6. Examples on Recursive Pruning

Corollaries 10, 13 and 16 often provide direct benefits when applied before the ID algorithm. The following examples show why they are also useful as recursive steps as implemented in the PID algorithm.

We are tasked with identifying the causal effect of X on Y in graph G depicted in Figure 9(a)
Initially there are no vertices that are connected to other vertices only through X. As a recursive step of the ID algorithm, we are tasked with identifying $P'_{z_3,x}(y)$ from P', where

$$P' = \sum_{z_2} P(y | z_3, z_2, z_1, x) P(x | z_3, z_2, z_1) P(z_2 | z_3) P(z_3),$$

in the subgraph $G[\{Z_3, X, Y\}]$ shown in Figure 9(b). In this graph Z_3 is connected to other vertices only through X and it can be removed according to Corollary 11, since the corresponding latent projection is the subgraph $G[\{X, Y\}]$. Thus we sum out Z_3 from P'



(a) Graph G. (b) Subgraph $G[\{Z_3, X, Y\}]$.

Figure 9: A graph for the example of recursive application of Corollary 11 within the ID algorithm.

and the resulting expression for the causal effect is

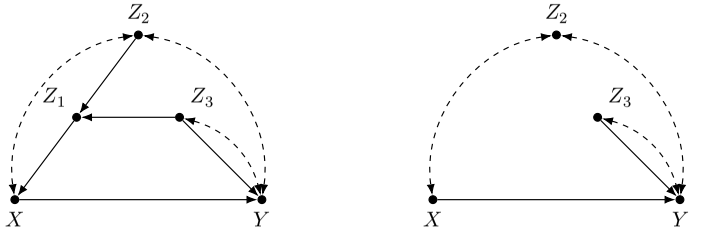
$$\sum_{z_4} \frac{\sum_{z_2,z_3} P(y|z_3,z_2,z_1,x,z_4)P(z_4|z_3,z_2,z_1,x)P(x|z_3,z_2,z_1)P(z_2|z_3)P(z_3)}{\sum_{z_2,z_3,y'} P(y'|z_3,z_2,z_1,x,z_4)P(z_4|z_3,z_2,z_1,x)P(x|z_3,z_2,z_1)P(z_2|z_3)P(z_3)}.$$

If Corollary 11 is not applied at this stage, the final expression is instead

$$\sum_{z_4} \left(\frac{\sum_{z_2} P(y|z_3,z_2,z_1,x,z_4)P(z_4|z_3,z_2,z_1,x)P(x|z_3,z_2,z_1)P(z_2|z_3)P(z_3)}{\sum_{z_2,y'} P(y'|z_3,z_2,z_1,x,z_4)P(z_4|z_3,z_2,z_1,x)P(x|z_3,z_2,z_1)P(z_2|z_3)P(z_3)} \times \frac{\sum_{z_2,y'} P(y'|z_3,z_2,z_1,x,z_4)P(z_4|z_3,z_2,z_1,x)P(x|z_3,z_2,z_1)P(z_2|z_3)P(z_3)}{\sum_{z_2,y',z_4} P(y'|z_3,z_2,z_1,x,z_4)P(z_4|z_3,z_2,z_1,x)P(x|z_3,z_2,z_1)P(z_2|z_3)P(z_3)} \right).$$

Using Corollary 11 provides us with a simpler expression in this situation by completely removing the second term from the product inside the summation.

Next we show how Corollary 13 can also be applied at a recursive step. Our interest lies in the causal effect of X on Y in graph G of Figure 10(a)



(a) Graph G. (b) Subgraph $G[\{Z_2, Z_3, X, Y\}]$.

Figure 10: A graph for the example of recursive application of Corollary 13 within the ID algorithm.

There are no vertices that are connected to other vertices in the graph via a single vertex. When the ID algorithm is applied we eventually reach a step where the causal effect of

$P'_{z_2,x}(y)$ is to be identified from P', where

$$P' = P(y|z_2,z_3,z_1,x)P(x|z_2,z_3,z_1)P(z_3|z_2)P(z_2),$$

in the subgraph $G[\{Z_2, Z_3, X, Y\}]$ which is depicted in Figure 10(b).

In this graph Z_3 can be removed according to Corollary 13, since Z_3 is connected to other vertices of the subgraph only through Y. The resulting distribution is obtained by summing out Z_3 from P'. The final expression for the causal effect is now

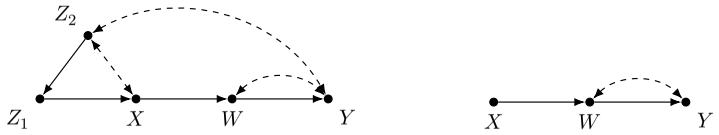
$$\frac{\sum_{z_2,z_3} P(y|z_2,z_3,z_1,x)P(x|z_2,z_3,z_1)P(z_3|z_2)P(z_2)}{\sum_{z_2,z_3,y'} P(y'|z_2,z_3,z_1,x)P(x|z_2,z_3,z_1)P(z_3|z_2)P(z_2)}. \quad (1)$$

If Corollary 13 is not applied, the resulting expression is instead

$$\sum_{z_3} \left(\frac{\sum_{z_2} P(y|z_2,z_3,z_1,x)P(x|z_2,z_3,z_1)P(z_3|z_2)P(z_2)}{\sum_{z_2,y'} P(y'|z_2,z_3,z_1,x)P(x|z_2,z_3,z_1)P(z_3|z_2)P(z_2)} \times \sum_{z_2,x,y'} P(y'|z_2,z_3,z_1,x)P(x|z_2,z_3,z_1)P(z_3|z_2)P(z_2) \right).$$

As in the previous example, the benefit of applying Corollary 13 is apparent.

We can also take advantage of latent projections recursively via Corollary 16 as shown in the next example. Our interest lies in the causal effect of X on Y in graph G of Figure 11.



(a) Graph G. (b) Subgraph $G[\{X, W, Y\}]$.

Figure 11: A graph for the example of recursive application of Corollary 16 within the ID algorithm.

Here X is connected to its child W via a bidirected path and thus they belong to the same C-component rendering Corollary 16 unusable at this time. However, as a recursive step of the ID algorithm we have to identify $P'_x(y)$ from P', where

$$P' = \sum_{z_2} P(y|z_2,z_1,x,w)P(w|z_2,z_1,x)P(x|z_2,z_1)P(z_2)$$

in the subgraph $G[\{X, W, Y\}]$. In this subgraph X is not connected to its child W via a bidirected path. We also find that the latent projection $L(G[\{X, W, Y\}], \{X, Y\})$ does not induce such a path between X and Y. We can now continue identification in this latent projection and sum out W from P'. The resulting expression for the causal effect is

$$\frac{\sum_{z_2,w} P(y|z_2,z_1,x,w)P(w|z_2,z_1,x)P(x|z_2,z_1)P(z_2)}{\sum_{z_2,w,y'} P(y'|z_2,z_1,x,w)P(w|z_2,z_1,x)P(x|z_2,z_1)P(z_2)},$$

whereas the expression without applying the corollary is instead

$$\sum_w \left(\frac{\sum_{z_2} P(y|z_2,z_1,x,w)P(w|z_2,z_1,x)P(x|z_2,z_1)P(z_2)}{\sum_{z_2,y'} P(y'|z_2,z_1,x,w)P(w|z_2,z_1,x)P(x|z_2,z_1)P(z_2)} \times \frac{\sum_{z_2,y'} P(y'|z_2,z_1,x,w)P(w|z_2,z_1,x)P(x|z_2,z_1)P(z_2)}{\sum_{z_2,w',y'} P(y'|z_2,z_1,x,w)P(w'|z_2,z_1,x)P(x|z_2,z_1)P(z_2)} \right).$$

Additional examples are provided as an R script (R Core Team, 2017) at the JMLR online paper repository. The script also includes all of the examples presented in this paper.

An interesting question is how pruning works together with simplification presented in (Tikka and Karvanen, 2017b). We return to the example on identifying the causal effect of X on Y in the graph of Figure 10. If we apply the ID algorithm without pruning and perform simplification as a post-processing step, then the resulting expression is

$$\sum_{z_3} \frac{\sum_{z_2} P(y|z_2,z_3,z_1,x)P(x|z_2,z_3,z_1)P(z_3|z_2)P(z_2)}{\sum_{z_2} P(x|z_2,z_3,z_1)P(z_3|z_2)P(z_2)} P(z_3|z_2). \tag{2}$$

This expression is in some aspects simpler than expression (1) obtained using pruning alone, but does contain a sum over Z_3 that was not originally present.

When pruning is introduced to the ID algorithm and simplification is again applied, the resulting expression is instead

$$\frac{\sum_{z_3,z_2} P(y|z_2,z_3,z_1,x)P(x|z_2,z_3,z_1)P(z_3|z_2)P(z_2)}{\sum_{z_2} P(x|z_2,z_1)P(z_2)},$$

which is noticeably simpler than expressions (1) and (2). This example shows, that when pruning methods are employed together with simplification, a simpler expression can be reached than what is possible with either pruning or simplification alone.

7. Discussion

We have presented criteria for removing variables from causal models that are not necessary to achieve identifiability for a given causal effect, and showed how these criteria can be applied in practice. We integrated our results into a new version of the ID algorithm called PID as presented in Algorithm 2 to facilitate automatic processing of identifiability queries. It should be noted that the ID algorithm already performs some pruning such as removing non-ancestors of $\mathbf{Y}$.

The pruning operations carried out by Algorithm 2 can significantly simplify the resulting expression compared to the traditional ID algorithm. Benefits of simplification can be realized in various settings. A simpler expression is easier to understand and to evaluate, since the dimensionality of the problem has been reduced. This is especially true for settings where the expression has to be evaluated repeatedly. Simplification can also help dealing with data where some variables are affected by bias or contain missing data. Obtaining an expression that does not contain these variables has clear advantages. It may also be of interest to obtain a different expression for the same causal effect.

The choice of variable ordering on line 5 of Algorithm 2 is not arbitrary. However, available external knowledge may guide our selection to prefer certain orderings. For example, in a situation where two latent projections are mutually exclusive, we may prefer an ordering where the variable that is associated with the smallest cost, or of which we have the most accurate measurements is not considered latent.

When PID is applied in conjunction with simplification methods described in (Tikka and Karvanen, 2017b), various situations that lead to complex expressions can be taken into account. These methods complement each other, since the results in this paper deal with completely removing variables from the resulting expression, whereas the simplification methods focus on symbolic summation of so-called atomic expressions, which are expression consisting of a single sum and a number of product terms. An expression for a causal effect may consist of multiple atomic expressions, some of which can be simplified and some of which can not.

We showed via examples that our improvements are not simply pre-processing steps to be carried out before calling the ID algorithm, but actually provide significant benefits when applied recursively. As the ID algorithm manipulates the original graph it often enables the application of our results as well. As hedges characterize identifiability, it is possible to consider latent projections in a more general manner, but this is not necessarily beneficial for simplification. One could construct an algorithm that performs a search over the possible subsets of $\mathbf{V}$, and checks whether identifiability is retained in the corresponding latent projection. However, as we have shown via examples, this may not be enough to obtain a simpler expression, and the recursive structure of the ID algorithm needs to be taken advantage of. Instead, we could consider a variant of the PID algorithm, where line 5 is replaced by this procedure. However, one must be careful when applying this method, so that the computation does not become intractable when the number of vertices increases due to the complexity of the search.

Acknowledgments

We wish to thank Professor Jukka Nyblom for his comments that greatly helped to improve this paper. We also thank the anonymous reviewers for their insightful feedback. The work belongs to the profiling area "Decision analytics utilizing causal models and multiobjective optimization" (DEMO) supported by Academy of Finland (grant number 311877).

Abstract

We propose a pool-based non-parametric active learning algorithm for general metric spaces, called MArgin Regularized Metric Active Nearest Neighbor (MARMANN), which outputs a nearest-neighbor classifier. We give prediction error guarantees that depend on the noisy-margin properties of the input sample, and are competitive with those obtained by previously proposed passive learners. We prove that the label complexity of MARMANN is significantly lower than that of any passive learner with similar error guarantees. MARMANN is based on a generalized sample compression scheme, and a new label-efficient active model-selection procedure.

Keywords: Nearest-neighbors, active learning, metric spaces, non-parametric learning

1. Introduction

Active learning is a framework for reducing the amount of label supervision for prediction tasks. While labeling large amounts of data can be expensive and time-consuming, unlabeled data is often much easier to come by. In this paper we propose a non-parametric pool-based active learning algorithm for general metric spaces, which outputs a nearest-neighbor classifier.

In pool-based active learning (McCallum and Nigam, 1998), a collection of random examples is provided, and the algorithm can interactively query an oracle to label some of the examples. The goal is good prediction accuracy, while keeping the label complexity — that is, the number of labels queried — low. Our algorithm, MArgin Regularized Metric Active Nearest Neighbor (MARMANN), receives a pool of unlabeled examples in a general metric space, and outputs a variant of the 1-nearest-neighbor classifier, implemented by a 1-nearest-neighbor rule. The algorithm obtains a prediction error guarantee that depends on a noisy-margin property of the input sample, and has a provably smaller label complexity than any passive learner with a similar guarantee.

Active learning has been mostly studied in a parametric setting, in which learning takes place with respect to a fixed hypothesis class with a bounded capacity. There has also been some work on analyzing non-parametric active learning strategies under certain distributional assumptions (see Section 1.1 for more discussion on this). However, the question of whether active querying strategies can yield label savings for non-parametric methods in a general setting, without distributional assumptions, had not been analyzed prior to this work. Here, we provide a first demonstration that this is indeed possible. We discuss related work in detail in Section 1.1 below.

Our contributions. MARMANN is a new non-parametric pool-based active learning algorithm, which obtains an error guarantee competitive with that of a noisy-margin-based passive learner. Additionally, it provably uses significantly fewer labels in nontrivial regimes. As far as the authors are aware, this is the first non-parametric active learner for general metric spaces, which achieves competitive prediction error guarantees to the passive learner, while provably improving label complexity. The guarantees of MARMANN are given in Theorem 4 in Section 3. We further provide a passive learning lower bound (Theorem 5), which together with Theorem 4 shows that MARMANN can have a significantly reduced label complexity compared to any passive learner. The passive lower bound is more general than previous lower bounds, relies on a novel technique, and may be of independent interest. Additionally, we give an active label complexity lower bound (Theorem 6), which holds for any active learner with similar error guarantees as MARMANN. The proof of this active lower bound relies on a new No-Free-Lunch type result, which holds for active learning algorithms.

Our approach. Previous passive learning approaches to classification using nearest-neighbor rules under noisy-margin assumptions (Gottlieb et al., 2014b, 2017) provide statistical guarantees using sample compression bounds (Graepel et al., 2005). Their finite-sample guarantees depend on the number of noisy labels relative to an optimal margin scale.

A central challenge in the active setting is performing model selection to select a margin scale with a low label complexity. A key insight that we exploit in this work is that by designing a new labeling scheme for the compression set, we can construct the compression set and estimate its error with label-efficient procedures. We obtain statistical guarantees for this approach using generalization bounds for sample compression with side information.

We derive a label-efficient, as well as computationally efficient, active model-selection procedure. This procedure finds a good scale by estimating the sample error for some scales, using a small number of active querying rounds. Crucially, unlike cross-validation, our model-selection procedure does not require a number of labels that depends on the worst possible scale, nor does it test many scales. This allows our label complexity bounds to be low, and to depend only on the final scale selected by the algorithm. Our error guarantee is a constant factor over the error guarantee of the passive learner of Gottlieb et al. (2017). An approach similar to Gottlieb et al. (2017), proposed in Gottlieb et al. (2014a), has been shown to be Bayes consistent (Kontorovich and Weiss, 2015). The Bayes-consistency of the passive version of our approach has recently been established (Kontorovich et al., 2017).

Paper structure. Related work is discussed in Section 1.1. We lay down the preliminaries in Section 2. In Section 3 we provide our main result: Theorem 4, which gives error and label complexity guarantees for MARMANN. Additionally we state the passive and active lower bounds, Theorem 5 and Theorem 6. The rest of the paper is devoted to the description and analysis of MARMANN, and proof of the main results. Section 4 shows how MARMANN defines the nearest neighbor rule for a given scale, and Section 5 describes the model selection procedure of MARMANN. Theorem 4 is proved in Section 6, based on a framework for compression with side information. The passive lower bound in Theorem 5 is proved in Section 7. The active lower bound Theorem 6 is proved in Section 8. We conclude with a discussion in Section 9.

1.1 Related Work

The theory of active learning has received considerable attention in the past decade (e.g., Dasgupta, 2004; Balcan et al., 2007, 2009; Hanneke, 2011; Hanneke and Yang, 2015). Active learning theory has been mostly studied in a parametric setting (that is, learning with respect to a fixed hypothesis class with a bounded capacity). Benefits and limitations of various active querying strategies have been proven in the realizable setting (Dasgupta, 2004; Balcan et al., 2007; Gonen et al., 2013) as well as in the agnostic case (Balcan et al., 2009; Hanneke, 2011; Awasthi et al., 2014). It has also been shown that active queries can also be beneficial for regression tasks (Castro et al., 2005; Sabato and Munos, 2014). Further, an active model selection procedure has been developed for the parametric setting (Balcan et al., 2010).

The potential benefits of active learning for non-parametric settings are less well understood. Practical Bayesian graph-based active learning methods (Zhu et al., 2003; Wei et al., 2015) rely on generative model assumptions, and therefore come without distribution-free performance guarantees. From a theoretical perspective, the label complexity of graph based active learning has mostly been analyzed in terms of combinatorial graph parameters (Cesa-Bianchi et al., 2010; Dasarathy et al., 2015). While the latter work provides some statistical guarantees under specific conditions on the data-generating distribution, this type of analysis does not yield distribution-free statistical performance guarantees.

Castro et al. (2005); Castro and Nowak (2008) analyze minimax rates for non-parametric regression and classification respectively, for a class of distributions in Euclidean space, characterized by decision boundary regularity and noise conditions with uniform marginals. The paradigm of cluster-based active learning (Dasgupta and Hsu, 2008) has been shown to provide label savings under some distributional clusterability assumptions (Urner et al., 2013; Kpotufe et al., 2015). Dasgupta and Hsu (2008) showed that a suitable cluster-tree can yield label savings in this framework, and papers following up (Urner et al., 2013; Kpotufe et al., 2015) quantified the label savings under distributional clusterability assumptions. However, no active non-parametric strategy has been proposed so far that has label complexity guarantees for i.i.d. data from general distributions and general metric spaces. Here, we provide the first such algorithm and guarantees.

The passive nearest-neighbor classifier, introduced by Fix and Hodges (1951, 1989), is popular among theorists and practitioners alike (Fix and Hodges, 1989; Cover and Hart, 1967; Stone, 1977; Kulkarni and Posner, 1995; Boiman et al., 2008). This paradigm is applicable in general metric spaces, and its simplicity is an attractive feature for both implementation and analysis. When appropriately regularized — either by taking a majority vote among the k nearest neighbors (Stone, 1977; Devroye and Györfi, 1985; Zhao, 1987), or by enforcing a *margin* separating the classes (von Luxburg and Bousquet, 2004; Gottlieb et al., 2014a; Kontorovich and Weiss, 2015; Kontorovich et al., 2017) — this type of learner can be made Bayes-consistent. Another desirable property of nearest-neighbor-based methods is their ability to generalize at a rate that scales with the intrinsic data dimension, which can be much lower than that of the ambient space (Kpotufe, 2011; Gottlieb et al., 2014a, 2016; Chaudhuri and Dasgupta, 2014). Furthermore, margin-based regularization makes nearest neighbor classifiers ideally suited for sample compression, which yields a compact representation, faster classification runtime, and improved generalization performance (Gottlieb et al., 2014b). The resulting error guarantees can be stated in terms of the sample's noisy-margin, which depends on the distances between differently-labeled examples in the input sample.

Active learning strategies specific to nearest neighbor classification have recently received attention. It has been shown that certain active querying rules maintain Bayes consistency for nearest neighbor classification, while other, seemingly natural, rules do not lead to a consistent algorithm (Dasgupta, 2012). A selective querying strategy has been shown to be beneficial for nearest neighbors under covariate shift (Berlind and Urner, 2015), where one needs to adapt to a change in the data generating process. However, the querying rule in that work is based solely on information in the unlabeled data, to account for a shift in the distribution over the covariates. It does not imply any label savings in the standard learning setting, where training and test distribution are identical. In contrast, our current work demonstrates how an active learner can take label information into account, to reduce the label complexity of a general nearest neighbor method in the standard setting.

1.2 A Remark on Bayes-Consistency

We remark on the Bayes-consistency of the margin-based passive 1-NN methods. In Gottlieb et al. (2014a), a PAC-style generalization bound was given. At a given scale t, the algorithm first ensured t-separation of the sample by solving solving a minimum vertex cover problem to eliminate the t-blocking pairs. Following that, the hypothesis was constructed as a Lipschitz extension from the remaining sample; the latter is computationally implemented as a nearest neighbor classifier. Structural Risk Minimization (SRM) was used to select the optimal scale t. A very close variant of this learner was shown to be Bayes-consistent by Kontorovich and Weiss (2015). The only difference between the two is that the former analyzed the hypothesis complexity in terms of fat-shattering dimension while the latter via Rademacher averages. Thus, a margin-regularized 1-NN classifier was shown to be Bayes-consistent; however, no compression was involved.

A compression-based alternative to Lipschitz extension was proposed in Gottlieb et al. (2014b). The idea is again to ensure t-separation via vertex cover and then compress the remaining sample down to a t-net. We conjecture that this latter algorithm is also Bayes-consistent, but currently have no proof. If instead one considers a compression-based passive learner implemented as in this paper (by taking majority vote in each Voronoi region rather than enforcing t-separation via vertex cover), the resulting classifier is indeed Bayes-consistent, as was recently shown by Kontorovich et al. (2017).

2. Preliminaries

In this section we lay down the necessary preliminaries. We formally define the setting and necessary notation in Section 2.1. We discuss nets in metric spaces in Section 2.2, and present the guarantees of the compression-based passive learner of Gottlieb et al. (2017) in Section 2.3.

2.1 Setting and Notation

For positive integers n, denote $[n] := \{1, \ldots, n\}$. We consider learning in a general metric space $(\mathcal{X}, \rho)$, where $\mathcal{X}$ is a set and ρ is the metric on $\mathcal{X}$. Our problem setting is that of classification of the instance space $\mathcal{X}$ into some finite label set $\mathcal{Y}$. Assume that there is some distribution $\mathcal{D}$ over $\mathcal{X} \times \mathcal{Y}$, and let $S \sim \mathcal{D}^m$ be a labeled sample of size m, where m is an integer. Denote the sequence of unlabeled points in S by $\mathbb{U}(S)$. We sometimes treat S and $\mathbb{U}(S)$ as multisets, since the order is

unimportant. For a labeled multiset $S \subseteq \mathcal{X} \times \mathcal{Y}$ and $y \in \mathcal{Y}$, denote $S^y := \{x \mid (x,y) \in S\}$; in particular, $\mathbb{U}(S) = \cup_{y \in \mathcal{Y}} S^y$.

The error of a classifier $h : \mathcal{X} \to \mathcal{Y}$ on $\mathcal{D}$, for any fixed h, is denoted

$$\mathrm{err}(h, \mathcal{D}) := \mathbb{P}[h(X) \neq Y],$$

where $(X,Y) \sim \mathcal{D}$. The empirical error on a labeled sample S instantiates to

$$\mathrm{err}(h, S) = \frac{1}{|S|} \sum \mathbb{I}[h(X) \neq Y].$$

A passive learner receives a labeled sample S_{in} as input. An active learner receives the unlabeled part of the sample $U_{\text{in}} := \mathbb{U}(S_{\text{in}})$ as input, and is allowed to interactively select examples from U_{in} and request their label from S_{in}. In other words, the active learner iteratively selects an example and requests its label, wherein all the labels requested so far can be used to make the next selection.

When either learner terminates, it outputs a classifier $\hat{h} : \mathcal{X} \to \mathcal{Y}$, with the goal of achieving a low $\mathrm{err}(\hat{h}, \mathcal{D})$. An additional goal of the active learner is to achieve a performance competitive with that of the passive learner, while querying considerably fewer labels.

The diameter of a set $A \subseteq \mathcal{X}$ is defined by

$$\mathsf{diam}(A) := \sup_{a,a' \in A} \rho(a,a').$$

For a finite set $U = \{u_1, \ldots, u_{|U|}\} \subseteq \mathcal{X}$ with some fixed numbering of its elements,[1] denote the index of the closest point in U to $x \in \mathcal{X}$ by

$$\kappa(x, U) := \operatorname*{argmin}_{i : x_i \in U} \rho(x, x_i).$$

We assume here and throughout this work that when there is more than one minimizer for $\rho(x, x_i)$, ties are broken arbitrarily (but in a consistent and deterministic fashion). Any labeled sample $S = ((x_i, y_i))_{i \in [k]}$ naturally induces the 1-nearest-neighbor classifier $h_S^{\text{nn}} : \mathcal{X} \to \mathcal{Y}$, via $h_S^{\text{nn}}(x) := y_{\kappa(x, \mathbb{U}(S))}$. For a set $Z \subseteq \mathcal{X}$, denote by

$$\kappa(Z, U) := \{\kappa(z, U) \mid z \in Z\}$$

the set of all the indices $\kappa(z, U)$, as defined above. For $x \in \mathcal{X}$, and $t > 0$, denote by $\mathsf{ball}(x,t)$ the (closed) ball of radius t around x:

$$\mathsf{ball}(x,t) := \left\{x' \in \mathcal{X} \mid \rho(x,x') \leq t\right\}.$$

2.2 Nets

A set $A \subseteq \mathcal{X}$ is *t-separated* if $\inf_{a,a' \in A : a \neq a'} \rho(a,a') \geq t$. For $A \subseteq B \subseteq \mathcal{X}$, the set A is a *t-net* of B if A is t-separated and $B \subseteq \bigcup_{a \in A} \mathsf{ball}(a,t)$. Thus, A is a t-net of B if it is both a t-covering and a t-packing.

1. Invoking the well-ordering principle, we may assume $\mathcal{X}$ to be well-ordered and then any $U \subseteq \mathcal{X}$ inherits the ordering of $\mathcal{X}$.

The size of a t-net of a metric space is strongly related to its *doubling dimension*. The doubling dimension is the effective dimension of the metric space, which controls generalization and runtime performance of nearest-neighbors (Kpotufe, 2011; Gottlieb et al., 2014a). It is defined as follows. Let $\lambda = \lambda(\mathcal{X})$ be the smallest number such that every ball in $\mathcal{X}$ can be covered by λ balls of half its radius, where all balls are centered at points of $\mathcal{X}$. Formally,

$$\lambda(\mathcal{X}) := \min\{\lambda \in \mathbb{N} : \forall x \in \mathcal{X}, r > 0, \quad \exists x_1, \ldots, x_\lambda \in \mathcal{X} : \mathsf{ball}(x,r) \subseteq \cup_{i=1}^{\lambda} \mathsf{ball}(x_i, r/2)\}.$$

Then the doubling dimension of $\mathcal{X}$ is defined by $\mathsf{ddim}(\mathcal{X}) := \log_2 \lambda$. In line with modern literature, we work in the low-dimension, large-sample regime, where the doubling dimension is assumed to be constant, and hence sample complexity and algorithmic runtime may depend on it exponentially. This exponential dependence is unavoidable, even under margin assumptions, as previous analyses (Kpotufe, 2011; Gottlieb et al., 2014a) indicate. Generalization bounds in terms of the doubling dimension of the hypothesis space were established in Bshouty et al. (2009), while runtime and generalization errors in terms of $\mathsf{ddim}(\mathcal{X})$ were given in Gottlieb et al. (2014a).

As shown in Gottlieb and Krauthgamer (2013), the doubling dimension is "almost hereditary" in the sense that for $A \subset \mathcal{X}$, we have $\mathsf{ddim}(A) \leq c\mathsf{ddim}(\mathcal{X})$ for some universal constant $c \leq 2$ (Feldmann et al., 2015, Lemma 6.6). In the works cited above, where generalization bounds are stated in terms of $\mathsf{ddim}(\mathcal{X})$, one can obtain tighter bounds in terms of $\mathsf{ddim}(\mathbb{U}(S))$ when the latter is substantially lower than that of the ambient space, and it is also possible to perform metric dimensionality reduction, as in Gottlieb et al. (2016).

Constructing a minimum size t-net for a general set B is NP-hard (Gottlieb and Krauthgamer, 2013). However, a simple greedy algorithm constructs a (not necessarily minimal) t-net in time $O(m^2)$ (Gottlieb et al., 2014b, Algorithm 1). There is also an algorithm for constructing a t-net in time $2^{O(\mathsf{ddim}(\mathcal{X}))} m \log(1/t)$ (Krauthgamer and Lee, 2004; Gottlieb et al., 2014b). The size of any t-net of a metric space $A \subseteq \mathcal{X}$ is at most

$$\lceil \mathsf{diam}(A)/t \rceil^{\mathsf{ddim}(\mathcal{X})+1} \tag{1}$$

(Krauthgamer and Lee, 2004). In addition, the size of any t-net is at most $2^{\mathsf{ddim}(A)+1}$ times the size of the minimal t-net, as the following easy lemma shows.

Lemma 1 (comparison of two nets) *Let $t > 0$ and suppose that M_1, M_2 are t-nets of $A \subseteq \mathcal{X}$. Then $|M_1| \leq 2^{\mathsf{ddim}(A)+1} |M_2|$.*

Proof Suppose that $|M_1| \geq k|M_2|$ for some positive integer k. Since $M_1 \subseteq \bigcup_{x \in M_2} \mathsf{ball}(x,t)$, it follows from the pigeonhole principle that at least one of the points in M_2 must cover at least k points in M_1. Thus, suppose that $x \in M_2$ covers the set $Z = \{z_1, \ldots, z_l\} \subseteq M_1$, meaning that $Z \subseteq \mathsf{ball}(x,t)$, where $l = |Z| \geq k$. By virtue of belonging to the t-net M_1, the set Z is t-separated. Therefore Z is a t-net of Z. Since Z is contained in a t-ball, we have $\mathsf{diam}(Z) \leq 2t$. It follows from Eq. (1) that $|Z| \leq 2^{\mathsf{ddim}(A)+1}$, whence the claim. ■

Throughout the paper, we fix a deterministic procedure for constructing a t-net, and denote its output for a multiset $U \subseteq \mathcal{X}$ by $\mathsf{Net}(U,t)$. Let $\mathsf{Par}(U,t)$ be a partition of $\mathcal{X}$ into regions induced by $\mathsf{Net}(U,t)$, that is: for $\mathsf{Net}(U,t) = \{x_1, \ldots, x_N\}$, define $\mathsf{Par}(U,t) := \{P_1, \ldots, P_N\}$, where

$$P_i = \{x \in \mathcal{X} \mid \kappa(x, \mathsf{Net}(U,t)) = i\}.$$

For $t > 0$, let $\mathcal{N}(t) := |\mathsf{Net}(U_{\text{in}}, t)|$ be the size of the t-net for the input sample.

2.3 Passive Compression-Based Nearest-Neighbors

Non-parametric binary classification admits performance guarantees that scale with the sample's noisy-margin (von Luxburg and Bousquet, 2004; Gottlieb et al., 2014a, 2017). The original margin-based methods of von Luxburg and Bousquet (2004) and Gottlieb et al. (2014a) analyzed the generalization performance via the technique of Lipschitz extension. Later, it was noticed in Gottlieb et al. (2014b) that the presence of a margin allows for compression — in fact, nearly optimally so.

We say that a labeled multiset S is (ν, t)-*separated*, for $\nu \in [0,1]$ and $t > 0$ (representing a margin t with noise ν), if one can remove a ν-fraction of the points in S, and in the resulting multiset, any pair of differently labeled points is separated by a distance of at least t. Formally, we have the following definition.

Definition 2 *S is (ν, t)-separated if there exists a subsample $\tilde{S} \subseteq S$ such that*

1. $|S \setminus \tilde{S}| \leq \nu |S|$ *and*
2. $\forall y_1 \neq y_2 \in \mathcal{Y}, a \in \tilde{S}^{y_1}, b \in \tilde{S}^{y_2}$, *we have* $\rho(a,b) \geq t$.

For a given labeled sample S, denote by $\nu(t)$ the smallest value ν such that S is (ν, t)-separated. Gottlieb et al. (2017) propose a passive learner with the following guarantees[2] as a function of the separation of S. Setting $\alpha := m/(m-N)$, define the following form of a generalization bound:

$$\mathrm{GB}(\epsilon, N, \delta, m, k) := \alpha\epsilon + \frac{2}{3}\frac{(N+1)\log(mk) + \log(\frac{1}{\delta})}{m-N} + \frac{3}{\sqrt{2}}\sqrt{\frac{\alpha\epsilon((N+1)\log(mk) + \log(\frac{1}{\delta}))}{m-N}}.$$

Further, for an integer m and $\delta \in (0,1)$, denote

$$G_{\min}(m, \delta) := \min_{t>0} \mathrm{GB}(\nu(t), \mathcal{N}(t), \delta, m, 1).$$

The quantity $G_{\min}(m,\delta)$ is small for datasets where we only need to remove few points to obtain a reasonably well separated subset. As an example, consider data generated by two well separated Gaussians (one generating the positively labeled points, and one generating the negatively labeled points). Then, most of the data points will be close to their respective means, but some will be farther, and may lie closer to the mean of the other Gaussian. Removing those few will result in a separated set.

Theorem 3 (Gottlieb et al. 2017) *Let m be an integer, $\delta \in (0,1)$. There exists a passive learning algorithm that returns a nearest-neighbor classifier $h^{\mathrm{nn}}_{S_{\mathrm{pas}}}$, where $S_{\mathrm{pas}} \subseteq S_{\mathrm{in}}$, such that, with probability $1-\delta$,*

$$\mathrm{err}(h^{\mathrm{nn}}_{S_{\mathrm{pas}}}, \mathcal{D}) \leq G_{\min}(m, \delta).$$

The bound above is data-dependent, meaning that the strength of the generalization guarantee depends on the quality of the random sample. Specifically, the passive algorithm of Gottlieb et al. (2017) generates S_{pas} of size approximately $\mathcal{N}(t)$ for the optimal scale $t > 0$ (found by searching over all scales), by removing the $|S_{\mathrm{in}}|\nu(t)$ points that obstruct the t-separation between different labels in S_{in}, and then selecting a subset of the remaining labeled examples to form S_{pas}, so that the examples are a t-net for S_{in} (not including the obstructing points). For the binary classification case ($|\mathcal{Y}| = 2$) an efficient algorithm is shown in Gottlieb et al. (2017). However, in the general multi-class case, it is not known how to find a minimal t-separation efficiently — a naive approach requires solving the NP-hard problem of vertex cover. Our approach, which we detail below, circumvents this issue, and provides an efficient algorithm also for the multiclass case.

2. The guarantees hold for the more general case of semimetrics.

3. Main Results

We propose a novel approach for generating a subset for a nearest-neighbor rule. This approach, detailed in the following sections, does not require finding and removing all the obstructing points in S_{in}, and can be implemented in an active setting using a small number of labels. The resulting active learning algorithm, MARMANN, has an error guarantee competitive with that of the passive learner, and a label complexity that can be significantly lower. We term the subset used by the nearest-neighbor rule a *compression set.*

Algorithm 1 MARMANN: MArgin Regularized Metric Active Nearest Neighbor

input Unlabeled sample U_{in} of size m, $\delta \in (0,1)$.
$\hat{t} \leftarrow \mathsf{SelectScale}(\delta)$. # SelectScale is given in Section 5, Alg. 4.
$\hat{S} \leftarrow \mathsf{GenerateNNSet}(\hat{t}, [\mathcal{N}(\hat{t})], \delta)$. # GenerateNNSet is given in Section 4, Alg. 2.
Output $h^{\mathrm{nn}}_{\hat{S}}$.

MARMANN, listed in Alg. 1, operates as follows. First, a scale $\hat{t} > 0$ is selected, by calling $\hat{t} \leftarrow \mathsf{SelectScale}(\delta)$, where SelectScale is our model selection procedure. SelectScale has access to U_{in}, and queries labels from S_{in} as necessary. It estimates the generalization error bound GB for several different scales, and executes a procedure similar to binary search to identify a good scale. The binary search keeps the number of estimations (and thus requested labels) small. Crucially, our estimation procedure is designed to prevent the search from spending a number of labels that depends on the net size of the smallest possible scale t, so that the total label complexity of MARMANN depends only on the error of the selected $\hat{t}$. Second, the selected scale $\hat{t}$ is used to generate the compression set by calling $\hat{S} \leftarrow \mathsf{GenerateNNSet}(\hat{t}, [\mathcal{N}(\hat{t})], \delta)$, where GenerateNNSet is our procedure for generating the compression set, and $[\mathcal{N}(\hat{t})] \equiv \{1, \ldots, \mathcal{N}(\hat{t})\}$. Our main result is the following guarantee for MARMANN.

Theorem 4 (Main result; Guarantee for MARMANN) *Let $S_{\mathrm{in}} \sim \mathcal{D}^m$, where $m \geq \max(6, |\mathcal{Y}|)$, $\delta \in (0, \frac{1}{4})$. Let $h^{\mathrm{nn}}_{\hat{S}}$ be the output of $\mathsf{MARMANN}(U_{\mathrm{in}}, \delta)$, where $\hat{S} \subseteq \mathcal{X} \times \mathcal{Y}$, and let $\hat{N} := |\hat{S}|$. Let $\hat{h} := h^{\mathrm{nn}}_{\hat{S}}$ and $\hat{\epsilon} := \mathrm{err}(\hat{h}, S_{\mathrm{in}})$, and denote $\hat{G} := \mathrm{GB}(\hat{\epsilon}, \hat{N}, \delta, m, 1)$. With a probability of $1-\delta$ over S_{in} and randomness of MARMANN,*

$$\mathrm{err}(\hat{h}, \mathcal{D}) \leq 2\hat{G} \leq O\left(G_{\min}(m, \delta)\right),$$

and the number of labels from S_{in} requested by MARMANN is at most

$$O\left(\log^3(\frac{m}{\delta})\left(\frac{1}{\hat{G}}\log(\frac{1}{\hat{G}}) + m\hat{G}\right)\right). \tag{2}$$

Here the $O(\cdot)$ notation hides only universal multiplicative constants.

Our error guarantee is thus a constant factor over the error guarantee of the passive learner of (Gottlieb et al., 2017), given in Theorem 3. The constant factor that we derive in our analysis is in the order of 2000 (this can be seen in the proof of Theorem 15). Note that we did not focus on optimizing it, opting instead for a more streamlined analysis. As the lower bound in Theorem 6 shows, the additive term $m\hat{G}$ in Eq. (2) is essentially unavoidable. Whether the dependence on $1/\hat{G}$ is indeed necessary is currently an open problem.

To observe the advantages of MARMANN over a passive learner, consider a scenario in which the upper bound $G_{\min}$ of Theorem 3, as well as the Bayes error of $\mathcal{D}$, are of order $\tilde{\Theta}(1/\sqrt{m})$. Then $\hat{G} = \Theta(1/\sqrt{m})$ as well. Therefore, MARMANN obtains a prediction error guarantee of $\tilde{\Theta}(1/\sqrt{m})$, similarly to the passive learner, but it uses only $\tilde{\Theta}(\sqrt{m})$ labels instead of m. In contrast, the following result shows that no learner that selects labels uniformly at random from S_{in} can compete with MARMANN: Theorem 5 below shows that for any passive learner that uses $\tilde{\Theta}(\sqrt{m})$ random labels from S_{in}, there exists a distribution $\mathcal{D}$ with the above properties, for which the prediction error of the passive learner in this case is $\tilde{\Omega}(m^{-1/4})$, a decay rate which is almost quadratically slower than the $\tilde{O}(1/\sqrt{m})$ rate achieved by MARMANN. Thus, the guarantees of MARMANN cannot be matched by any passive learner.

Theorem 5 (Passive lower bound) *Let $m > 0$ be an integer, and suppose that $(\mathcal{X}, \rho)$ is a metric space such that for some $\bar{t} > 0$, there is a $\bar{t}$-net T of $\mathcal{X}$ of size $\Theta(\sqrt{m})$. Consider any passive learning algorithm that maps i.i.d. samples $S_\ell \sim \mathcal{D}^\ell$ from some distribution $\mathcal{D}$ over $\mathcal{X} \times \{-1, 1\}$, to functions $\hat{h}_\ell : \mathcal{X} \to \{-1, 1\}$. For any such algorithm and any $\ell = \tilde{\Theta}(\sqrt{m})$, there exists a distribution $\mathcal{D}$ such that:*

i. The Bayes error of $\mathcal{D}$ is $\Theta(1/\sqrt{m})$;

ii. With at least a constant probability, both of the following events occur:

(a) The passive learner achieves error $\operatorname{err}(\hat{h}_\ell, \mathcal{D}) = \tilde{\Omega}(m^{-1/4})$,

(b) $G_{\min}(m, \delta) = \tilde{\Theta}(1/\sqrt{m})$.

Furthermore, i. and ii. continue to hold when the learning algorithm has access to the full marginal distribution over $\mathcal{X}$.

Thus, MARMANN even improves over a semi-supervised learner: its label savings stem from actively selecting labels, and are not achievable by merely exploiting information from unlabeled data or by randomly selecting examples to label.

We deduce Theorem 5 from a more general result, which might be of independent interest. Theorem 18, given in Section 7, improves existing passive learning sample complexity lower bounds. In particular, our result removes the restrictions of previous lower bounds on the relationship between the sample size, the VC-dimension, and the noise level, which render existing bounds inapplicable to our parameter regime. The proof of Theorem 5 is given thereafter in Section 7, as a consequence of Theorem 18.

We further provide a label complexity lower bound, in Theorem 6 below, which holds for any active learner that obtains similar guarantees to those of MARMANN. The lower bound shows that any active learning algorithm which guarantees a multiplicative accuracy over $G_{\min}(m, \delta)$ has a label complexity which is $\tilde{\Omega}(mG_{\min}(m, \delta))$, for a wide range of values of $G_{\min}(m, \delta)$ — essentially, as long as $G_{\min}(m, \delta)$ is not trivially large or trivially small. This implies that the term $m\hat{G}$ in the upper bound of the label complexity of MARMANN in Theorem 4 cannot be significantly improved.

Theorem 6 (Active lower bound) *Let $\mathcal{X} = \mathbb{R}$, $\delta \in (0, 1/14)$. Let $C \geq 1$, and let $\mathcal{A}$ be an active learning algorithm that outputs $\hat{h}$. Suppose that for any distribution $\mathcal{D}$ over $\mathcal{X} \times \mathcal{Y}$, if the input unlabeled sample is of size m, then $\operatorname{err}(\hat{h}, \mathcal{D}) \leq CG_{\min}(m, \delta)$ with probability at least $1 - \delta$. Then for any $\alpha \in (\frac{\log(m)+\log(28)}{8\sqrt{2m}}, \frac{1}{240C})$ there exists a distribution $\mathcal{D}$ such with probability at least $\frac{1}{28}$ over $S \sim \mathcal{D}^m$ and the randomness of $\mathcal{A}$, both of the following events hold:*

1. *$\alpha \leq G_{\min}(m, \delta) \leq 30\alpha$*
2. *$\mathcal{A}$ queries at least $\frac{1}{2}\left\lfloor \frac{mG_{\min}(m,\delta) - \log(\frac{m}{\delta})}{30\log(m)} \right\rfloor \equiv \tilde{\Omega}(mG_{\min}(m, \delta))$ labels.*

The proof of this lower bound is provided in Section 8. In the rest of the paper, the components of MARMANN are described in detail, and the main results are proved.

4. Active Nearest-Neighbor at a Given Scale

A main challenge for active learning in our non-parametric setting is performing model selection, that is, selecting a good scale t similarly to the passive learner of Gottlieb et al. (2017). In the passive supervised setting, the approach developed in several previous works (Gottlieb et al., 2014b; Kontorovich and Weiss, 2014; Gottlieb et al., 2014a; Kontorovich and Weiss, 2015) performs model selection by solving a minimum vertex cover problem for each considered scale t, so as to eliminate all of the *t-blocking pairs* — i.e., pairs of differently labeled points within a distance t. The passive algorithm generates a compression set by first finding and removing from S_{in} all points that obstruct (ν, t)-separation at a given scale $t > 0$. This incurs a computational cost but no significant sample complexity increase, aside from the standard logarithmic factor that comes from stratifying over data-dependent hierarchies (Shawe-Taylor et al., 1998).

While this approach works for passive learning, in the active setting we face a crucial challenge: estimating the error of a nearest-neighbor rule at scale t using a small number of samples. A key insight that we exploit in this work is that instead of eliminating the blocking pairs, one may simply relabel some of the points in the compression set, and this would also generate a low-error nearest neighbor rule. This new approach enables estimation of the sample accuracy of a (possibly relabeled) t-net by label-efficient active sampling. In addition, this approach is significantly simpler than estimating the size of the minimum vertex cover of the t-blocking graph. Moreover, we gain improved algorithmic efficiency, by avoiding the relatively expensive vertex cover procedure.

A small technical difference, which will be evident below, is that in this new approach, examples in the compression set might have a different label than their original label in S_{in}. Standard sample compression analysis (e.g. Graepel et al., 2005) assumes that the classifier is determined by a small number of labeled examples from S_{in}. This does not allow the examples in the compression set to have a different label than their original label in S_{in}. Therefore, we require a slight generalization of previous compression analysis (following previous works on compression, see details in Section 6.1), which allows adding side information to the compression set. This side information will be used to set the label of each of the examples in the compression set. The generalization incurs a small statistical penalty, which we quantify in Section 6, as a preliminary to proving Theorem 4.

We now describe our approach to generating a compression set for a given scale $t > 0$. Recall that $\nu(t)$ is the smallest value for which S_{in} is (ν, t)-separated. We define two compression sets. The first one, denoted $S_{\text{a}}(t)$, represents an ideal compression set, constructed (solely for the sake of analysis) so that it induces an empirical error of at most $\nu(t)$. Calculating $S_{\text{a}}(t)$ might require many labels, thus it is only used for analysis purposes; the algorithm never constructs it. The second compression set, denoted $\hat{S}_{\text{a}}(t)$, represents an approximation to $S_{\text{a}}(t)$, which can be constructed using a small number of labels, and induces a sample error of at most $4\nu(t)$ with high probability.

We first define the ideal set $S_{\text{a}}(t) := \{(x_1, y_1), \ldots, (x_N, y_N)\}$. The examples in $S_{\text{a}}(t)$ are the points in $\mathsf{Net}(U_{\text{in}}, t/2)$, and the label of each example is the majority label, out of the labels of the examples in S_{in} to which x_i is closest. Formally, $\{x_1, \ldots, x_N\} := \mathsf{Net}(U_{\text{in}}, t/2)$, and for $i \in [N]$, $y_i := \operatorname{argmax}_{y \in \mathcal{Y}} |S^y \cap P_i|$, where $P_i = \{x \in \mathcal{X} \mid \kappa(x, \mathsf{Net}(U, t/2)) = i\} \in \mathsf{Par}(U_{\text{in}}, t/2)$.

Lemma 7 *Let S be a labeled sample of size m, and let $\{P_1, \ldots, P_N\}$ be a partition of $\mathbb{U}(S)$, with $\max_i \mathsf{diam}(P_i) \le t$ for some $t \ge 0$. For $i \in [N]$, let $\Lambda_i := S^{y_i} \cap P_i$. Then*

$$\nu(t) \ge 1 - \frac{1}{m} \sum_{i \in [N]} |\Lambda_i|.$$

Proof Let $\tilde{S} \subseteq S$ be a subsample that witnesses the $(\nu(t), t)$-separation of S, so that $|\tilde{S}| \ge m(1 - \nu(t))$, and for any two points $(x, y), (x', y') \in \tilde{S}$, if $\rho(x, x') \le t$ then $y = y'$. Denote $\tilde{U} := \mathbb{U}(\tilde{S})$. Since $\max_i \mathsf{diam}(P_i) \le t$, for any $i \in [N]$ all the points in $\tilde{U} \cap P_i$ must have the same label in $\tilde{S}$. Therefore,

$$\exists y \in \mathcal{Y} \text{ s.t. } \tilde{U} \cap P_i \subseteq \tilde{S}^y \cap P_i.$$

Hence $|\tilde{U} \cap P_i| \le |\Lambda_i|$. It follows

$$|S| - \sum_{i \in [N]} |\Lambda_i| \le |S| - \sum_{i \in [N]} |\tilde{U} \cap P_i| = |S| - |\tilde{S}| = m \cdot \nu(t).$$

Dividing by m we get the statement of the lemma. ■

From Lemma 7, we get Cor. 8, which upper bounds the empirical error of $h^{\text{nn}}_{S_{\text{a}}(t)}$ by $\nu(t)$.

Corollary 8 *For every $t > 0$, $\operatorname{err}(h^{\text{nn}}_{S_{\text{a}}(t)}, S_{\text{in}}) \le \nu(t)$.*

This corollary is immediate from Lemma 7, since for any $P_i \in \mathsf{Par}(U_{\text{in}}, t/2)$, $\mathsf{diam}(P_i) \le t$, and

$$\operatorname{err}(h^{\text{nn}}_{S_{\text{a}}(t)}, S_{\text{in}}) = 1 - \frac{1}{m} \sum_{i \in [N]} |\Lambda_i|.$$

Now, calculating $S_{\text{a}}(t)$ requires knowing most of the labels in S_{in}. MARMANN constructs instead an approximation $\hat{S}_{\text{a}}(t)$, in which the examples are the points in $\mathsf{Net}(U_{\text{in}}, t/2)$ (so that $\mathbb{U}(\hat{S}_{\text{a}}(t)) = \mathbb{U}(S_{\text{a}}(t))$), but the labels are determined using a bounded number of labels requested from S_{in}. The labels in $\hat{S}_{\text{a}}(t)$ are calculated by the simple procedure GenerateNNSet given in Alg. 2. The empirical error of the output of GenerateNNSet is bounded in Theorem 9 below.[3]

3. In the case of binary labels ($|\mathcal{Y}| = 2$), the problem of estimating $S_{\text{a}}(t)$ can be formulated as a special case of the benign noise setting for parametric active learning, for which tight lower and upper bounds are provided in Hanneke and Yang (2015). However, our case is both more general (as we allow multiclass labels) and more specific (as we are dealing with a specific "hypothesis class"). Thus we provide our own procedure and analysis.

A technicality in Alg. 2 requires explanation: In MARMANN, the generation of $\hat{S}_{\text{a}}(t)$ will be split into several calls to GenerateNNSet, so that different calls determine the labels of different points in $\hat{S}_{\text{a}}(t)$. Therefore GenerateNNSet has an additional argument I, which specifies the indices of the points in $\mathsf{Net}(U_{\text{in}}, t/2)$ for which the labels should be returned this time. Crucially, if during the run of MARMANN, GenerateNNSet is called again for the same scale t and the same point in $\mathsf{Net}(U_{\text{in}}, t/2)$, then GenerateNNSet returns the same label that it returned before, rather than recalculating it using fresh labels from S_{in}. This guarantees that despite the randomness in GenerateNNSet, the full $\hat{S}_{\text{a}}(t)$ is well-defined within any single run of MARMANN, and is distributed like the output of $\mathsf{GenerateNNSet}(t, [\mathcal{N}(t/2)], \delta)$, which is convenient for the analysis. Define

$$Q(m) := \lceil 18 \log(4m^3/\delta) \rceil . \tag{3}$$

Algorithm 2 $\mathsf{GenerateNNSet}(t, I, \delta)$

input Scale $t > 0$, a target set $I \subseteq [\mathcal{N}(t/2)]$, confidence $\delta \in (0, 1)$.
output A labeled set $S \subseteq \mathcal{X} \times \mathcal{Y}$ of size $|I|$
  $\{x_1, \ldots, x_N\} \leftarrow \mathsf{Net}(U_{\text{in}}, t/2)$, $\{P_1, \ldots, P_N\} \leftarrow \mathsf{Par}(U_{\text{in}}, t/2)$, $S \leftarrow ()$
  for $i \in I$ **do**
    if $\hat{y}_i$ has not already been calculated for U_{in} with this value of t **then**
      Draw $Q(m)$ points uniformly at random from P_i and query their labels.
      Let $\hat{y}_i$ be the majority label observed in these $Q(m)$ queries.
    end if
    $S \leftarrow S \cup \{(x_i, \hat{y}_i)\}$.
  end for
  Output S

Theorem 9 *Let $\hat{S}_{\text{a}}(t)$ be the output of $\mathsf{GenerateNNSet}(t, [\mathcal{N}(t/2)], \delta)$. With a probability at least $1 - \frac{\delta}{2m^2}$, the following event, which we denote by $E(t)$, holds:*

$$\operatorname{err}(h^{\text{nn}}_{\hat{S}_{\text{a}}(t)}, S_{\text{in}}) \le 4\nu(t).$$

Proof By Cor. 8, $\operatorname{err}(h^{\text{nn}}_{S_{\text{a}}(t)}, S_{\text{in}}) \le \nu(t)$. In $S_{\text{a}}(t)$, the labels assigned to each point in $\mathsf{Net}(U_{\text{in}}, t/2)$ are the majority labels (based on S_{in}) of the points in the regions in $\mathsf{Par}(U_{\text{in}}, t/2)$. As above, we denote the majority label for region P_i by $y_i := \operatorname{argmax}_{y \in \mathcal{Y}} |S^y \cap P_i|$. We now compare these labels to the labels $\hat{y}_i$ assigned by Alg. 2. Let $p(i) = |\Lambda_i|/|P_i|$ be the fraction of points in P_i which are labeled by the majority label y_i, where Λ_i is as defined in Lemma 7. Let $\hat{p}(i)$ be the fraction of labels equal to y_i out of those queried by Alg. 2 in round i. Let $\beta := 1/6$. By Hoeffding's inequality and union bounds, we have that with a probability of at least

$$1 - 2\mathcal{N}(t/2) \exp(-\frac{Q(m)}{18}) \ge 1 - \frac{\delta}{2m^2},$$

we have $\max_{i \in [\mathcal{N}(t/2)]} |\hat{p}(i) - p(i)| \le \beta$. Denote this "good" event by E'. We now prove that $E' \Rightarrow E(t)$. Let $J = \{i \in [\mathcal{N}(t/2)] \mid \hat{p}(i) > \frac{1}{2}\}$. It can be easily seen that $\hat{y}_i = y_i$ for all $i \in J$. Therefore, for all x such that $\kappa(x, \mathbb{U}(S_{\text{a}}(t))) \in J$, $h^{\text{nn}}_{\hat{S}_{\text{a}}(t)}(x) = h^{\text{nn}}_{S_{\text{a}}(t)}(x)$, and hence

$$\operatorname{err}(h^{\text{nn}}_{S'}, S_{\text{in}}) \le \mathbb{P}_{X \sim S_{\text{in}}}[\kappa(X, \mathbb{U}(S_{\text{a}}(t))) \notin J] + \operatorname{err}(h^{\text{nn}}_{S_{\text{a}}(t)}, U_{\text{in}}).$$

The second term is at most $\nu(t)$ by Cor. 8, and it remains to bound the first term, on the condition that E' holds. We have $\mathbb{P}_{X\sim U}[\kappa(X,\mathbb{U}(S_{\rm a}(t)))\notin J] = \frac{1}{m}\sum_{i\notin J}|P_i|$. If E' holds, then for any $i\notin J$, $p(i)\leq\frac{1}{2}+\beta$, therefore

$$|P_i|-|\Lambda_i| = (1-p(i))|P_i| \geq (\frac{1}{2}-\beta)|P_i|.$$

Recall that, by Lemma 7, $\nu(t)\geq 1-\frac{1}{m}\sum_{i\in[\mathcal{N}(t/2)]}|\Lambda_i|$. Therefore,

$$\begin{aligned}\nu(t) &\geq 1-\frac{1}{m}\sum_{i\in[\mathcal{N}(t/2)]}|\Lambda_i| \\ &= \frac{1}{m}\sum_{i\in[\mathcal{N}(t/2)]}(|P_i|-|\Lambda_i|) \\ &\geq \frac{1}{m}\sum_{i\notin J}(|P_i|-|\Lambda_i|) \\ &\geq \frac{1}{m}\sum_{i\notin J}(\frac{1}{2}-\beta)|P_i|.\end{aligned}$$

Thus, under E',

$$\mathbb{P}_{X\sim U}[\kappa(X,\mathbb{U}(S_{\rm a}(t)))\notin J] \leq \frac{\nu(t)}{\frac{1}{2}-\beta} = 3\nu(t).$$

It follows that under E', $\mathrm{err}(h^{\rm nn}_S, U_{\rm in})\leq 4\nu(t)$. ■

5. Model Selection

We now show how to select the scale $\hat{t}$ that will be used to generate the output nearest-neighbor rule. The main challenge is to do this with a low label complexity: Generating the full classification rule for scale t requires a number of labels that depends on $\mathcal{N}(t)$, which might be very large. We would like the label complexity of MARMANN to depend only on $\mathcal{N}(\hat{t})$ (where $\hat{t}$ is the selected scale), which is of the order $m\hat{G}$. Therefore, during model selection we can only invest a bounded number of labels in each tested scale. In addition, to keep the label complexity low, we would like to avoid testing all scales. In Section 5.1 we describe how we estimate the error on a given scale. In Section 5.2 we provide a search procedure, resembling binary search, which uses the estimation procedure to select a single scale $\hat{t}$.

5.1 Estimating the Error at a Given Scale

For $t>0$, let $\hat{S}_{\rm a}(t)$ be the compressed sample that MARMANN would generate if the selected scale were set to t. Our model selection procedure performs a search, similar to binary search, over the possible scales. For each tested scale t, the procedure estimates the empirical error $\epsilon(t) := \mathrm{err}(h^{\rm nn}_{\hat{S}_{\rm a}(t)}, S)$ within a certain accuracy, using an estimation procedure given below, called EstimateErr. EstimateErr outputs an estimate $\hat{\epsilon}(t)$ of $\epsilon(t)$, up to a given threshold $\theta>0$, using labels requested from $S_{\rm in}$.

To estimate the error, we sample random labeled examples from $S_{\rm in}$, and check the prediction error of $h^{\rm nn}_{\hat{S}_{\rm a}(t)}$ on these examples. The prediction error of any fixed hypothesis h on a random labeled example from $S_{\rm in}$ is an independent Bernoulli variable with expectation $\mathrm{err}(h, S_{\rm in})$. EstimateErr is implemented using the following procedure, EstBer, which adaptively estimates the expectation of a Bernoulli random variable to an accuracy specified by the parameter θ, using a small number of random independent Bernoulli experiments. Let $B_1, B_2, \ldots \in \{0,1\}$ be i.i.d. Bernoulli random variables. For an integer n, denote $\hat{p}_n = \frac{1}{n}\sum_{i=1}^n B_i$. The estimation procedure EstBer is given in Alg. 3. We prove a guarantee for this procedure in Theorem 10. Note that we assume that the threshold parameter is in $(0,1]$, since for $\theta\geq 1$ one can simply output 1 using zero random draws to satisfy Theorem 10.

Algorithm 3 EstBer(θ,β,δ)

input A threshold parameter $\theta\in(0,1]$, a budget parameter $\beta\geq 7$, confidence $\delta\in(0,1)$
  $S\leftarrow\{B_1,\ldots,B_4\}$
  $K\leftarrow\frac{4\beta}{\theta}\log(\frac{8\beta}{\delta\theta})$
  for $i=3:\lceil\log_2(\beta\log(2K/\delta)/\theta)\rceil$ **do**
    $n\leftarrow 2^i$
    $S\leftarrow S\cup\{B_{n/2+1},\ldots,B_n\}$.
    if $\hat{p}_n>\beta\log(2n/\delta)/n$ **then**
      break
    end if
  end for
  Output $\hat{p}_n$.

The following theorem states that Alg. 3 essentially estimates p, the expectation of the i.i.d. Bernoulli variables $B_1, B_2, \ldots$, up to a multiplicative constant, except if p is smaller than a value proportional to the threshold θ, in which case the algorithm simply returns a value at most θ. Moreover, the theorem shows that the number of random draws required by the algorithm is inversely proportional to the maximum of the threshold θ and the expectation p. Thus, if p is very small, the number of random draws does not increase without bound. The parameter β controls the trade-off between the accuracy of estimation and the number of random draws.

Theorem 10 *Let $\delta\in(0,1)$, $\theta\in(0,1]$, $\beta\geq 7$. Let $B_1, B_2, \ldots\in\{0,1\}$ be i.i.d Bernoulli random variables with expectation p. Let p_o be the output of* EstBer(θ,β,δ). *The following holds with a probability of $1-\delta$, where $f(\beta) := 1+\frac{8}{3\beta}+\sqrt{\frac{2}{\beta}}$.*

1. *If $p_o\leq\theta$, then $p\leq f(\beta)\theta$. Otherwise, $\frac{p}{f(\beta)}\leq p_o\leq\frac{p}{2-f(\beta)}$.*
2. *Let $\psi := \max(\theta, p/f(\beta))$. The number of random draws in* EstBer *is at most $\frac{4\beta\log(\frac{8\beta}{\delta\psi})}{\psi}$.*

Proof First, consider any single round i with $n=2^i$. By the empirical Bernstein bound (Maurer and Pontil, 2009, Theorem 4), with a probability of $1-\delta/n$, for $n\geq 8$, we have[4]

$$|\hat{p}_n - p| \leq \frac{8\log(2n/\delta)}{3n} + \sqrt{\frac{2\hat{p}_n\log(2n/\delta)}{n}}. \tag{4}$$

4. This follows from Theorem 4 of Maurer and Pontil (2009) since $\frac{7}{3(n-1)}\leq\frac{8}{3n}$ for $n\geq 8$.

Define $g := (\beta + 8/3 + \sqrt{2\beta})$, so that $f(\beta) = g/\beta$. Conditioned on Eq. (4), there are two cases:

(a) $\hat{p}_n \leq \beta \log(2n/\delta)/n$. In this case, $p \leq g \log(2n/\delta)/n$.

(b) $\hat{p}_n > \beta \log(2n/\delta)/n$. In this case, $n \geq \beta \log(2n/\delta)/\hat{p}_n$. Thus, by Eq. (4),

$$|\hat{p}_n - p| \leq \hat{p}_n(\frac{8}{3\beta} + \sqrt{2/\beta}) = \hat{p}_n(g/\beta - 1).$$

Therefore

$$\frac{\beta p}{g} \leq \hat{p}_n \leq \frac{p}{2 - g/\beta}.$$

Taking a union bound on all the rounds, we have that the guarantee holds for all rounds with a probability of at least $1 - \delta$.

Condition now on the event that these guarantees all hold. First, we prove the label complexity bound. Note that since $\beta \geq 7$, $K \geq 28$, thus we have $2\log(2K) > 8$, therefore there is always at least one round. Let n_o be the value of n in the last round that the algorithm runs, and let $p_o = \hat{p}_{n_o}$. Let i such that $n_o = 2^{i+1}$, thus the algorithm stops during round $i + 1$. This implies $\hat{p}_n \leq \beta \log(2n/\delta)/n$ for $n = 2^i$, therefore case (a) holds for n, which means $n \leq g \log(2n/\delta)/p$. It follows that $n \leq 2g \log(4g/\delta)/p$, therefore $n_o \leq 4g \log(4g/(\delta p))/p$. In addition, the number of random draws in the algorithm is n_0, which is bounded by

$$n_0 \leq 2^{\lceil \log_2(\beta \log(2K/\delta)/\theta) \rceil} \leq 2 \cdot 2^{\log_2(\beta \log(2K/\delta)/\theta)} \leq 2\beta \log(2K/\delta)/\theta.$$

Therefore we have the following bound on the number of random draws:

$$n_o \leq \min\left(\frac{2\beta \log(2K/\delta)}{\theta}, \frac{4g \log(4g/(\delta p))}{p}\right).$$

Plugging in the definition of K and substituting $\beta \cdot f(\beta)$ for g yields

$$\begin{aligned} n_0 \leq & \beta \min\left(\frac{2\log(\frac{8\beta}{\delta\theta}\log(\frac{8\beta}{\delta\theta}))}{\theta}, \frac{4f(\beta)\log(\frac{4\beta f(\beta)}{\delta p})}{p}\right) \leq \\ & \beta \min\left(\frac{4\log(\frac{8\beta}{\delta\theta})}{\theta}, \frac{4f(\beta)\log(\frac{4\beta f(\beta)}{\delta p})}{p}\right) \leq \\ & 4\beta \min\left(\frac{1}{\theta}(\log(\frac{8\beta}{\delta}) + \log(\frac{1}{\theta})), \frac{f(\beta)}{p}(\log(\frac{4\beta}{\delta}) + \log(\frac{f(\beta)}{p}))\right). \end{aligned}$$

Using the definition of ψ, we get that the number of draws is at most $\frac{4\beta \log(\frac{8\beta}{\delta\psi})}{\psi}$.

Next, we prove the accuracy of p_o (item 1 in the theorem statement) by considering two cases.

(I) If $p_o > \beta \log(2n_o/\delta)/n_o$, then case (b) above holds for n_o, thus

$$\frac{\beta p}{g} \leq p_o \leq \frac{p}{2 - g/\beta}.$$

In addition, if $p_o \leq \theta$, the LHS implies $p \leq f(\beta)\theta$. Thus item 1 in the theorem statement holds in this case.

(II) If $p_o \leq \beta \log(2n_o/\delta)/n_o$, then EstBer could not have ended by breaking out of the loop, thus it ran until the last round. Therefore $n_o \geq \beta \log(2K/\delta)/\theta$. In addition, case (a) holds for n_0, therefore

$$p \leq \frac{g \log(2n_o/\delta)}{n_o} \leq \frac{g\theta \log(2n_0/\delta)}{\beta \log(2K/\delta)}. \tag{5}$$

Now, for any possible value of n_o,

$$n_o \leq 2\beta \log(2K/\delta)/\theta \leq K.$$

The first inequality follows from the bound on i in EstBer, and the second inequality holds since, as defined in EstBer, $K \geq \frac{4\beta}{\theta}\log(\frac{8\beta}{\theta\delta})$. Since $n_0 \leq K$, Eq. (5) implies that

$$p \leq \frac{g\theta}{\beta} = f(\beta)\theta.$$

In addition, we have

$$p_o \leq \beta \log(2n_o/\delta)/n_o \leq \frac{\theta \log(2n_0/\delta)}{\log(2K/\delta)} \leq \theta.$$

Therefore in this case, necessarily $p_o \leq \theta$ and $p \leq f(\beta)\theta$, which satisfies item 1 in the theorem statement.

In both cases item 1 holds, thus the theorem is proved. ■

The procedure $\mathsf{EstimateErr}(t, \theta, \delta)$ is then implemented as follows:

- Call $\mathsf{EstBer}(\theta, 52, \delta/(2m^2))$, where the random variables B_i are independent copies of the Bernoulli variable
$$B := \mathbb{I}[h^{\mathrm{nn}}_{\hat{S}_{\mathrm{a}}(t)}(X) \neq Y]$$
and $(X, Y) \sim S_{\mathrm{in}}$.
- To draw a single B_i, sample a random pair (x', y') from S_{in}, set
$$i := \kappa(x', \mathsf{Net}(U_{\mathrm{in}}, t/2)),$$
and get $S \leftarrow \mathsf{GenerateNNSet}(t, \{i\}, \delta)$. This returns $S = ((x_i, \hat{y}_i))$ where $\hat{y}_i$ is the label of x_i in $\hat{S}_{\mathrm{a}}(t)$. Then $B_i := \mathbb{I}[\hat{y}_i \neq y']$. Note that B_i is indeed distributed like B, and $\mathbb{E}[B] = \epsilon(t)$. Note further that this call to $\mathsf{GenerateNNSet}(t, \{i\}, \delta)$ uses $Q(m)$ label queries. Therefore the overall label complexity of a single draw of a B_i is $Q(m) + 1$.

Cor. 11 gives a guarantee for the accuracy and label complexity of EstimateErr. The proof is immediate from Theorem 10, by setting $\beta = 52$, which implies $f(\beta) \leq 5/4$.

Corollary 11 *Let $t, \theta > 0$ and $\delta \in (0, 1)$, and let $\hat{\epsilon}(t) \leftarrow \mathsf{EstimateErr}(t, \theta, \delta)$. Let $Q(m)$ as defined in Eq. (3) The following properties hold with a probability of $1 - \frac{\delta}{2m^2}$ over the randomness of* EstimateErr *(and conditioned on $\hat{S}_{\mathrm{a}}(t)$).*

1. *If* $\hat{\epsilon}(t) \le \theta$, *then* $\epsilon(t) \le 5\theta/4$. *Otherwise,*

$$\frac{4\epsilon(t)}{5} \le \hat{\epsilon}(t) \le \frac{4\epsilon(t)}{3}.$$

2. *Let* $\psi' := \max(\theta, \epsilon(t))$. *The number of labels that* EstimateErr *requests is at most*

$$\frac{260(Q(m)+1)\log(\frac{1040m^2}{\delta\psi'})}{\psi'}.$$

To derive item 2. above from Theorem 10, note that for $\beta = 52$,

$$\psi' = \max(\theta, \epsilon(t)) \le f(\beta)\max(\theta, \epsilon(t)/f(\beta)) = f(\beta)\psi \le \frac{5}{4}\psi,$$

where ψ is as defined in Theorem 10. Below we denote the event that the two properties in Cor. 11 hold for t by $V(t)$.

5.2 Selecting a Scale

The model selection procedure SelectScale, given in Alg. 4, implements its search based on the guarantees in Cor. 11. First, we introduce some notation. We would like MARMANN to obtain a generalization guarantee that is competitive with $G_{\min}(m, \delta)$. Denote

$$\phi(t) := \frac{(\mathcal{N}(t)+1)\log(m) + \log(\frac{1}{\delta})}{m}, \tag{6}$$

and let

$$G(\epsilon, t) := \epsilon + \frac{2}{3}\phi(t) + \frac{3}{\sqrt{2}}\sqrt{\epsilon\phi(t)}.$$

Note that for all ϵ, t,

$$\mathrm{GB}(\epsilon, \mathcal{N}(t), \delta, m, 1) = \frac{m}{m - \mathcal{N}(t)}G(\epsilon, t).$$

When referring to $G(\nu(t), t), G(\epsilon(t), t)$, or $G(\hat{\epsilon}(t), t)$ we omit the second t for brevity.

Instead of directly optimizing $G(\nu(t))$, we will select a scale based on our estimate $G(\hat{\epsilon}(t))$ of $G(\epsilon(t))$. Let Dist denote the set of pairwise distances in the unlabeled dataset U_{in} (note that $|\text{Dist}| < \binom{m}{2}$). We remove from Dist some distances, so that the remaining distances have a net size $\mathcal{N}(t)$ that is monotone non-increasing in t. We also remove values with a very large net size. Concretely, define

$$\text{Dist}_{\text{mon}} := \text{Dist} \setminus \{t \mid \mathcal{N}(t) + 1 > m/2\} \setminus \{t \mid \exists t' \in \text{Dist}, t' < t \text{ and } \mathcal{N}(t') < \mathcal{N}(t)\}.$$

Then for all $t, t' \in \text{Dist}_{\text{mon}}$ such that $t' < t$, we have $\mathcal{N}(t') \ge \mathcal{N}(t)$. The output of SelectScale is always a value in Dist_{mon}. The following lemma shows that it suffices to consider these scales.

Lemma 12 *Assume* $m \ge 6$ *and let* $t^*_m \in \operatorname{argmin}_{t\in\text{Dist}} G(\nu(t))$. *If* $G_{\min}(m, \delta) \le 1/3$ *then* $t^*_m \in \text{Dist}_{\text{mon}}$.

Algorithm 4 SelectScale(δ)

input $\delta \in (0, 1)$
output Scale $\hat{t}$

$\mathcal{T} \leftarrow \text{Dist}_{\text{mon}}$, # $\mathcal{T}$ maintains the current set of possible scales
while $\mathcal{T} \neq \emptyset$ **do**
  $t \leftarrow$ the median value in $\mathcal{T}$ # break ties arbitrarily
  $\hat{\epsilon}(t) \leftarrow \mathsf{EstimateErr}(t, \phi(t), \delta)$.
  if $\hat{\epsilon}(t) < \phi(t)$ **then**
    $\mathcal{T} \leftarrow \mathcal{T} \setminus [0, t]$ # go right in the binary search
  else if $\hat{\epsilon}(t) > \frac{11}{10}\phi(t)$ **then**
    $\mathcal{T} \leftarrow \mathcal{T} \setminus [t, \infty)$ # go left in the binary search
  else
    $t_0 \leftarrow t, \mathcal{T}_0 \leftarrow \{t_0\}$.
    break from loop
  end if
end while
if $\mathcal{T}_0$ was not set yet **then**
  If the algorithm ever went to the right, let t_0 be the last value for which this happened, and let $\mathcal{T}_0 := \{t_0\}$. Otherwise, $\mathcal{T}_0 := \emptyset$.
end if
Let $\mathcal{T}_L$ be the set of all t that were tested and made the search go left
Output $\hat{t} := \operatorname{argmin}_{t\in\mathcal{T}_L\cup\mathcal{T}_0} G(\hat{\epsilon}(t))$

Proof Assume by way of contradiction that $t^*_m \in \text{Dist} \setminus \text{Dist}_{\text{mon}}$. First, since $G(\nu(t^*_m)) \le G_{\min}(m, \delta) \le 1/3$ we have

$$\frac{\mathcal{N}(t^*_m)+1}{m - \mathcal{N}(t^*_m)}\log(m) \le \frac{1}{2}.$$

Therefore, since $m \ge 6$, it is easy to verify $\mathcal{N}(t^*_m) + 1 \le m/2$. Therefore, by definition of Dist_{mon} there exists a $t \le t^*_m$ with $\phi(t) < \phi(t^*_m)$. Since $\nu(t)$ is monotone over all of $t \in \text{Dist}$, we also have $\nu(t) \le \nu(t^*_m)$. Now, $\phi(t) < \phi(t^*_m)$ and $\nu(t) \le \nu(t^*_m)$ together imply that $G(\nu(t)) < G(\nu(t^*_m))$, a contradiction. Hence, $t^*_m \in \text{Dist}_{\text{mon}}$. ■

SelectScale follows a search procedure similar to binary search, however the conditions for going right and for going left are not exhaustive, thus it is possible that neither condition holds. The search ends either when neither conditions hold, or when no additional scale should be tested. The final output of the algorithm is based on minimizing $G(\hat{\epsilon}(t))$ over some of the values tested during search.

For $c > 0$, define

$$\gamma(c) := 1 + \frac{2}{3c} + \frac{3}{\sqrt{2c}} \text{ and } \tilde{\gamma}(c) := \frac{1}{c} + \frac{2}{3} + \frac{3}{\sqrt{2c}}.$$

For all $t, \epsilon > 0$ we have the implications

$$\epsilon \ge c\phi(t) \;\Rightarrow\; \gamma(c)\epsilon \ge G(\epsilon, t) \quad \text{and} \quad \phi(t) \ge c\epsilon \;\Rightarrow\; \tilde{\gamma}(c)\phi(t) \ge G(\epsilon, t). \tag{7}$$

The following lemma uses Eq. (7) to show that the estimate $G(\hat{\epsilon}(t))$ is close to the true $G(\epsilon(t))$.

Lemma 13 *Let $t > 0$, $\delta \in (0,1)$, and suppose that* SelectScale *calls $\hat{\epsilon}(t) \leftarrow$ EstimateErr$(t, \phi(t), \delta)$. Suppose that $V(t)$ as defined in Cor. 11 holds. Then*

$$\frac{1}{6}G(\hat{\epsilon}(t)) \leq G(\epsilon(t)) \leq 6.5G(\hat{\epsilon}(t)).$$

Proof Under $V(t)$, we have that if $\hat{\epsilon}(t) < \phi(t)$ then $\epsilon(t) \leq \frac{5}{4}\phi(t)$. In this case,

$$G(\epsilon(t)) \leq \tilde{\gamma}(4/5)\phi(t) \leq 4.3\phi(t),$$

by Eq. (7). Therefore

$$G(\epsilon(t)) \leq \frac{3 \cdot 4.3}{2} G(\hat{\epsilon}(t)).$$

In addition, $G(\epsilon(t)) \geq \frac{2}{3}\phi(t)$ (from the definition of G), and by Eq. (7) and $\tilde{\gamma}(1) \leq 4$,

$$\phi(t) \geq \frac{1}{4}G(\hat{\epsilon}(t)).$$

Therefore $G(\epsilon(t)) \geq \frac{1}{6}G(\hat{\epsilon}(t))$. On the other hand, if $\hat{\epsilon}(t) \geq \phi(t)$, then by Cor. 11

$$\frac{4}{5}\epsilon(t) \leq \hat{\epsilon}(t) \leq \frac{4}{3}\epsilon(t).$$

Therefore $G(\hat{\epsilon}(t)) \leq \frac{4}{3}G(\epsilon(t))$ and $G(\epsilon(t)) \leq \frac{5}{4}G(\hat{\epsilon}(t))$. Taking the worst-case of both possibilities, we get the bounds in the lemma. ■

The next theorem bounds the label complexity of SelectScale. Let $\mathcal{T}_{\text{test}} \subseteq \text{Dist}_{\text{mon}}$ be the set of scales that are tested during SelectScale (that is, their $\hat{\epsilon}(t)$ was estimated).

Theorem 14 *Suppose that the event $V(t)$ defined in Cor. 11 holds for all $t \in \mathcal{T}_{\text{test}}$ for the calls $\hat{\epsilon}(t) \leftarrow$ EstimateErr$(t, \phi(t), \delta)$. If the output of* SelectScale *is $\hat{t}$, then the number of labels requested by* SelectScale *is at most*

$$9620|\mathcal{T}_{\text{test}}|(Q(m)+1)\frac{1}{G(\epsilon(\hat{t}))}\log(\frac{38480m^2}{\delta G(\epsilon(\hat{t}))}).$$

Proof The only labels used by the procedure are those used by calls to EstimateErr. Let $\psi_t := \max(\phi(t), \epsilon(t))$, and $\psi_{\min} := \min_{t \in \mathcal{T}_{\text{test}}} \psi_t$. Denote also $\hat{\psi}_t := \max(\phi(t), \hat{\epsilon}(t))$. From Cor. 11 we have that the total number of labels in all the calls to EstimateErr in SelectScale is at most

$$\sum_{t \in \mathcal{T}_{\text{test}}} \frac{260(Q(m)+1)\log(\frac{1040m^2}{\delta\psi_t})}{\psi_t} \leq |\mathcal{T}_{\text{test}}| \frac{260(Q(m)+1)\log(\frac{1040m^2}{\delta\psi_{\min}})}{\psi_{\min}}. \tag{8}$$

We now lower bound $\psi_{\min}$ using $G(\epsilon(\hat{t}))$. By Lemma 13 and the choice of $\hat{t}$,

$$G(\epsilon(\hat{t})) \leq 6.5G(\hat{\epsilon}(\hat{t})) = 6.5 \min_{t \in \mathcal{T}_L \cup T_0} G(\hat{\epsilon}(t)).$$

From the definition of G, for any $t > 0$,

$$G(\hat{\epsilon}(t)) \leq \gamma(1)\max(\phi(t), \hat{\epsilon}(t)) \leq 25\hat{\psi}_t.$$

Therefore

$$G(\epsilon(\hat{t})) \leq 25 \min_{t \in \mathcal{T}_L \cup \mathcal{T}_0} \hat{\psi}_t. \tag{9}$$

We will show a similar upper bound when minimizing over all of $\mathcal{T}_{\text{test}}$, not just over $\mathcal{T}_L \cup \mathcal{T}_0$. This is trivial if $\mathcal{T}_{\text{test}} = \mathcal{T}_L \cup \mathcal{T}_0$. Consider the case $\mathcal{T}_L \cup \mathcal{T}_0 \subsetneq \mathcal{T}_{\text{test}}$. For any $t \in \mathcal{T}_{\text{test}}$, we have one of:

- The search went left on t (step 8), hence $t \in \mathcal{T}_L$.
- The search went nowhere on t and the loop broke (step 11), hence $t = t_0 \in \mathcal{T}_0$.
- The search went right on t (step 6) and this was the last value for which this happened, hence $t = t_0 \in \mathcal{T}_0$.
- The search went right on t (step 6) and this was *not* the last value for which this happened. Hence $t \in \mathcal{T}_{\text{test}} \setminus (\mathcal{T}_L \cup \mathcal{T}_0)$.

Set some $t_1 \in \mathcal{T}_{\text{test}} \setminus (\mathcal{T}_L \cup \mathcal{T}_0)$. Since the search went right on t_1, then t_0 also exists, since the algorithm did go to the right for some t (see step 15). Since the binary search went right on t_1, we have $\hat{\epsilon}(t_1) \leq \phi(t_1)$. Since the binary search did *not* go left on t_0 (it either broke from the loop or went right), $\hat{\epsilon}(t_0) \leq \frac{11}{10}\phi(t_0)$.

In addition, $t_0 \geq t_1$ (since the search went right at t_1, and t_0 was tested later than t_1), thus $\phi(t_0) \leq \phi(t_1)$ (since $t_0, t_1 \in \text{Dist}_{\text{mon}}$). Therefore,

$$\hat{\psi}_{t_0} = \max(\phi(t_0), \hat{\epsilon}(t_0)) \leq \frac{11}{10}\phi(t_0) \leq \frac{11}{10}\phi(t_1) = \frac{11}{10}\max(\phi(t_1), \hat{\epsilon}(t_1)) = \hat{\psi}_{t_1}.$$

It follows that for any such t_1,

$$\min_{t \in \mathcal{T}_L \cup \mathcal{T}_0} \hat{\psi}_t \leq \frac{11}{10}\hat{\psi}_{t_1}.$$

Therefore

$$\min_{t \in \mathcal{T}_L \cup \mathcal{T}_0} \hat{\psi}_t \leq \frac{11}{10} \min_{t \in \mathcal{T}_{\text{test}}} \hat{\psi}_t.$$

Therefore, by Eq. (9)

$$G(\epsilon(\hat{t})) \leq 27.5 \min_{t \in \mathcal{T}_{\text{test}}} \hat{\psi}_t.$$

By Cor. 11, $\hat{\epsilon}(t) \leq \max(\phi(t), 4\epsilon(t)/3)$, therefore $\hat{\psi}_t \leq \frac{4}{3}\psi_t$. Therefore $G(\epsilon(\hat{t})) \leq 37\psi_{\min}$. Therefore, from Eq. (8), the total number of labels is at most

$$9620|\mathcal{T}_{\text{test}}|(Q(m)+1)\frac{1}{G(\epsilon(\hat{t}))}\log(\frac{38480m^2}{\delta G(\epsilon(\hat{t}))}).$$

■

The following theorem provides a competitive error guarantee for the selected scale $\hat{t}$.

Theorem 15 *Suppose that $V(t)$ and $E(t)$, defined in Cor. 11 and Theorem 9, hold for all values $t \in \mathcal{T}_{\text{test}}$, and that $G_{\min}(m,\delta) \le 1/3$. Then* SelectScale *outputs $\hat{t} \in \text{Dist}_{\text{mon}}$ such that*

$$\text{GB}(\epsilon(\hat{t}), \mathcal{N}(\hat{t}), \delta, m, 1) \le O(G_{\min}(m,\delta)),$$

Where the $O(\cdot)$ notation hides only universal multiplicative constants.

The full proof of this theorem is given below. The idea of the proof is as follows: First, we show (using Lemma 13) that it suffices to prove that $G(\nu(t_m^*)) \ge O(G(\hat{\epsilon}(\hat{t})))$ to derive the bound in the theorem. Now, SelectScale ends in one of two cases: either $\mathcal{T}_0$ is set within the loop, or $\mathcal{T} = \emptyset$ and $\mathcal{T}_0$ is set outside the loop. In the first case, neither of the conditions for turning left and turning right holds for t_0, so we have $\hat{\epsilon}(t_0) = \Theta(\phi(t_0))$ (where Θ hides numerical constants). We show that in this case, whether $t_m^* \ge t_0$ or $t_m^* \le t_0$, $G(\nu(t_m^*)) \ge O(G(\hat{\epsilon}(t_0)))$. In the second case, there exist (except for edge cases, which are also handled) two values $t_0 \in \mathcal{T}_0$ and $t_1 \in \mathcal{T}_L$ such that t_0 caused the binary search to go right, and t_1 caused it to go left, and also $t_0 \le t_1$, and $(t_0, t_1) \cap \text{Dist}_{\text{mon}} = \emptyset$. We use these facts to show that for $t_m^* \ge t_1$, $G(\nu(t_m^*)) \ge O(G(\hat{\epsilon}(t_1)))$, and for $t_m^* \le t_0$, $G(\nu(t_m^*)) \ge O(G(\hat{\epsilon}(t_0)))$. Since $\hat{t}$ minimizes over a set that includes t_0 and t_1, this gives $G(\nu(t_m^*)) \ge O(G(\hat{\epsilon}(\hat{t})))$ in all cases.

Proof First, note that it suffices to show that there is a constant C, such that for the output $\hat{t}$ of SelectScale, we have $G(\epsilon(\hat{t})) \le CG(\nu(t_m^*))$. This is because of the following argument: From Lemma 12 we have that if $G_{\min}(m,\delta) \le 1/3$, then $t_m^* \in \text{Dist}_{\text{mon}}$. Now

$$G_{\min}(m,\delta) = \frac{m}{m - \mathcal{N}(t_m^*)} G(\nu(t_m^*)) \ge G(\nu(t_m^*)).$$

And, if we have the guarantee on $G(\epsilon(\hat{t}))$ and $G_{\min}(m,\delta) \le 1/3$ we will have

$$\text{GB}(\epsilon(\hat{t}), \mathcal{N}(\hat{t}), \delta, m, 1) = \frac{m}{m - \mathcal{N}(\hat{t})} G(\epsilon(\hat{t})) \le 2G(\epsilon(\hat{t})) \le 2CG(\nu(t_m^*)) \le 2CG_{\min}(m,\delta). \tag{10}$$

We now prove the existence of such a guarantee and set C. Denote the two conditions checked in SelectScale during the binary search by Condition 1: $\hat{\epsilon}(t) < \phi(t)$ and Condition 2: $\hat{\epsilon}(t) > \frac{11}{10}\phi(t)$. The procedure ends in one of two ways: either $\mathcal{T}_0$ is set within the loop (Case 1), or $\mathcal{T} = \emptyset$ and $\mathcal{T}_0$ is set outside the loop (Case 2). We analyze each case separately.

In Case 1, none of the conditions 1 and 2 hold for t_0. Therefore

$$\phi(t_0) \le \hat{\epsilon}(t_0) \le \frac{11}{10}\phi(t_0).$$

Therefore, by Eq. (7),

$$\phi(t_0) \ge G(\hat{\epsilon}(t_0))/\tilde{\gamma}(\frac{10}{11}).$$

By Cor. 11, since $\hat{\epsilon}(t_0) > \phi(t_0)$,

$$\frac{3}{4}\phi(t_0) \le \frac{3}{4}\hat{\epsilon}(t_0) \le \epsilon(t_0) \le \frac{5}{4}\hat{\epsilon}(t_0) \le \frac{55}{40}\phi(t_0).$$

Suppose $t_m^* \ge t_0$, then

$$G(\nu(t_m^*)) \ge \nu(t_m^*) \ge \nu(t_0) \ge \frac{1}{4}\epsilon(t_0) \ge \frac{3}{16}\phi(t_0).$$

here we used $\epsilon(t_0) \le 4\nu(t_0)$ by Theorem 9. Therefore, from Eq. (7) and Lemma 13,

$$G(\nu(t_m^*)) \ge \frac{3}{16}\phi(t_0) \ge \frac{3}{16\tilde{\gamma}\left(\frac{40}{55}\right)} G(\epsilon(t_0)) \ge \frac{\frac{1}{2}}{16\tilde{\gamma}(\frac{40}{55})} G(\hat{\epsilon}(t_0)).$$

Now, suppose $t_m^* < t_0$, then

$$G(\nu(t_m^*)) \ge \frac{2}{3}\phi(t_m^*) \ge \frac{2}{3}\phi(t_0) \ge \frac{2}{3\tilde{\gamma}(\frac{10}{11})} G(\hat{\epsilon}(t_0)).$$

In this inequality we used the fact that $t_m^*, t_0 \in \text{Dist}_{\text{mon}}$, hence $\phi(t_m^*) \ge \phi(t_0)$. Combining the two possibilities for t_m^*, we have in Case 1,

$$G(\hat{\epsilon}(t_0)) \le \max(32\tilde{\gamma}(\frac{40}{55}), \frac{3\tilde{\gamma}(\frac{10}{11})}{2}) G(\nu(t_m^*)).$$

Since $\hat{t}$ minimizes $G(\hat{\epsilon}(t))$ on a set that includes t_0, we have, using Lemma 13

$$G(\epsilon(\hat{t})) \le 6.5 G(\hat{\epsilon}(\hat{t})) \le 6.5 G(\hat{\epsilon}(t_0)).$$

Therefore, in Case 1,

$$G(\epsilon(\hat{t})) \le 6.5 \max(32\tilde{\gamma}(\frac{40}{55}), \frac{3\tilde{\gamma}(\frac{10}{11})}{2}) G(\nu(t_m^*)). \tag{11}$$

In Case 2, the binary search halted without satisfying Condition 1 nor Condition 2 and with $\mathcal{T} = \emptyset$. Let t_0 be as defined in this case in SelectScale (if it exists), and let t_1 be the smallest value in $\mathcal{T}_L$ (if it exists). At least one of these values must exist. If both values exist, we have $t_0 \le t_1$ and $(t_0, t_1) \cap \text{Dist}_{\text{mon}} = \emptyset$.

If t_0 exists, it is the last value for which the search went right. We thus have $\hat{\epsilon}(t_0) < \phi(t_0)$. If $t_m^* \le t_0$, from condition 1 on t_0 and Eq. (7) with $\tilde{\gamma}(1) \le 4$,

$$G(\nu(t_m^*)) \ge \frac{2}{3}\phi(t_m^*) \ge \frac{2}{3}\phi(t_0) \ge \frac{1}{6} G(\hat{\epsilon}(t_0)).$$

Here we used the monotonicity of ϕ on $t_m^*, t_0 \in \text{Dist}_{\text{mon}}$, and Eq. (7) applied to condition 1 for t_0.

If t_1 exists, the search went left on t_1, thus $\hat{\epsilon}(t_1) > \frac{11}{10}\phi(t_1)$. By Cor. 11, it follows that $\hat{\epsilon}(t_1) \le \frac{4}{3}\epsilon(t_1)$. Therefore, if $t_m^* \ge t_1$,

$$G(\nu(t_m^*)) \ge \nu(t_m^*) \ge \nu(t_1) \ge \frac{1}{4}\epsilon(t_1) \ge \frac{3}{16}\hat{\epsilon}(t_1) \ge \frac{3}{16\gamma(11/10)} G(\hat{\epsilon}(t_1)).$$

Here we used $\epsilon(t_1) \le 4\nu(t_1)$ by Theorem 9 and Eq. (7). Combining the two cases for t_m^*, we get that if t_0 exists and $t_m^* \le t_0$, or t_1 exists and $t_m^* \ge t_1$,

$$G(\nu(t_m^*)) \ge \min(\frac{1}{6}, \frac{3}{16\gamma(11/10)}) \min_{t \in T_E} G(\hat{\epsilon}(t)).$$

where we define $T_E = \{t \in \{t_0, t_1\} \mid t \text{ exists}\}$. We now show that this covers all possible values for t_m^*: If both t_0, t_1 exist, then since $(t_0, t_1) \cap \text{Dist}_{\text{mon}} = \emptyset$, it is impossible to have $t_m^* \in (t_0, t_1)$.

If only t_0 exists, then the search never went left, which means $t_0 = \max(\mathrm{Dist}_{\mathrm{mon}})$, thus $t^*_m \le t_0$. If only t_1 exists, then the search never went right, which means $t_1 = \min(\mathrm{Dist}_{\mathrm{mon}})$, thus $t^*_m \ge t_1$.

Since $\hat{t}$ minimizes $G(\hat{\epsilon}(t))$ on a set that has T_E as a subset, we have, using Lemma 13 $G(\epsilon(\hat{t})) \le 6.5G(\hat{\epsilon}(\hat{t})) \le 6.5 \min_{t\in T_E} G(\hat{\epsilon}(t))$. Therefore in Case 2,

$$G(\nu(t^*_m)) \ge \frac{1}{6.5} \min\left(\frac{1}{6}, \frac{3}{16\gamma(11/10)}\right) G(\epsilon(\hat{t}). \tag{12}$$

From Eq. (11) and Eq. (12) we get that in both cases

$$G(\nu(t^*_m)) \ge \frac{1}{6.5} \min\left(\frac{1}{6}, \frac{3}{16\gamma(11/10)}, \frac{2}{3\tilde{\gamma}(10/11)}, \frac{1}{32\tilde{\gamma}(\frac{40}{55})}\right) G(\epsilon(\hat{t})) \ge G(\epsilon(\hat{t}))/865.$$

Combining this with Eq. (10) we get the statement of the theorem. ■

6. Bounding the Label Complexity of MARMANN

We are now almost ready to prove Theorem 4. Our last missing piece is quantifying the effect of side information on the generalization of sample compression schemes in Section 6.1. We then prove Theorem 4 in Section 6.2.

6.1 Sample Compression with Side Information

It appears that compression-based generalization bounds were independently discovered by Littlestone and Warmuth (1986) and Devroye et al. (1996); some background is given in Floyd and Warmuth (1995). As noted in Section 4, our algorithm relies on a generalized sample compression scheme, which requires side information. This side information is used to represent the labels of the sample points in the compression set. A similar idea appears in Floyd and Warmuth (1995) for hypotheses with short description length. Here we provide a generalization that is useful for the analysis of MARMANN.

Let Σ be a finite alphabet, and define a mapping $\mathsf{Rec}_N : (\mathcal{X} \times \mathcal{Y})^N \times \Sigma^N \to \mathcal{Y}^{\mathcal{X}}$.[5] This is a *reconstruction* function mapping a labeled sequence of size N with side information $T \in \Sigma^N$ to a classifier. For $I \subseteq [|S|]$, denote by $S[I]$ the subsequence of S indexed by I. For a labeled sample S, define the set of possible hypotheses reconstructed from a compression of S of size N with side information in Σ: $\mathcal{H}_N(S) := \left\{h : \mathcal{X} \to \mathcal{Y} \mid h = \mathsf{Rec}_N(S[I], T), I \in [m]^N, T \in \Sigma^N\right\}$. The following result closely follows the sample compression arguments in Graepel et al. (2005, Theorem 2), and Gottlieb et al. (2017, Theorem 6), but incorporates side information.

Theorem 16 *Let m be an integer and $\delta \in (0,1)$. Let $S \sim \mathcal{D}^m$. With probability at least $1-\delta$, if there exist $N < m$ and $h \in \mathcal{H}_N(S)$ with $\epsilon := \mathrm{err}(h,S) \le \frac{1}{2}$, then $\mathrm{err}(h,\mathcal{D}) \le \mathrm{GB}(\epsilon, N, \delta, m, |\Sigma|)$.*

Proof We recall a result of Dasgupta and Hsu (2008, Lemma 1): if $\hat{p} \sim \mathrm{Bin}(n,p)/n$ and $\delta > 0$, then the following holds with probability at least $1-\delta$:

$$p \le \hat{p} + \frac{2}{3n}\log\frac{1}{\delta} + \sqrt{\frac{9\hat{p}(1-\hat{p})}{2n}\log\frac{1}{\delta}}. \tag{13}$$

5. If $\mathcal{X}$ is infinite, replace $\mathcal{Y}^{\mathcal{X}}$ with the set of measurable functions from $\mathcal{X}$ to $\mathcal{Y}$.

Now fix $N < m$, and suppose that $h \in \mathcal{H}_{\mathcal{N}}(S)$ has $\hat{\epsilon} \le \frac{1}{2}$. Let $I \in [m]^N, T \in \Sigma^N$ such that $h = \mathsf{Rec}_N(S[I], T)$. We have $\mathrm{err}(h, S[[m] \setminus I]) \le \frac{\hat{\epsilon} m}{m-N} = \theta\hat{\epsilon}$. Substituting into (13) $p := \mathrm{err}(h,\mathcal{D})$, $n := m-N$ and $\hat{p} := \mathrm{err}(h, S[[m]\setminus I]) \le \theta\hat{\epsilon}$, yields that for a fixed $S[I]$ and a random $S[[m]\setminus I] \sim \mathcal{D}^{m-N}$, with probability at least $1-\delta$,

$$\mathrm{err}(h,\mathcal{D}) \le \theta\hat{\epsilon} + \frac{2}{3(m-N)}\log\frac{1}{\delta} + \sqrt{\frac{9\theta\hat{\epsilon}}{2(m-N)}\log\frac{1}{\delta}}. \tag{14}$$

To make (14) hold simultaneously for all $(I,T) \in [m]^N \times \Sigma^N$, divide δ by $(m|\Sigma|)^N$. To make the claim hold for all $N \in [m]$, stratify (as in Graepel et al. (2005, Lemma 1)) over the (fewer than) m possible choices of N, which amounts to dividing δ by an additional factor of m. ■

For MARMANN, we use the following sample compression scheme with $\Sigma = \mathcal{Y}$. Given a subsequence $S' := S[I] := (x'_1, \ldots, x'_N)$ and $T = (t_1, \ldots, t_N) \in \mathcal{Y}^N$, the reconstruction function $\mathsf{Rec}_N(S[I], T)$ generates the nearest-neighbor rule induced by the labeled sample $\psi(S', T) := ((x'_i, t_i))_{i\in[N]}$. Formally, $\mathsf{Rec}_N(S', T) = h^{\mathrm{nn}}_{\psi(S',T)}$. Note the slight abuse of notation: formally, the y_i in $S_{\mathrm{a}}(t)$ should be encoded as side information T, but for clarity, we have opted to "relabel" the examples $\{x_1, \ldots, x_N\}$ as dictated by the majority in each region. The following corollary is immediate from Theorem 16 and the construction above.

Theorem 17 *Let $m \ge |\mathcal{Y}|$ be an integer, $\delta \in (0, \frac{1}{4})$. Let $S_{\mathrm{in}} \sim \mathcal{D}^m$. With probability at least $1-\delta$, if there exist $N < m$ and $S \subseteq (\mathcal{X}\times\mathcal{Y})^N$ such that $\mathbb{U}(S) \subseteq U_{\mathrm{in}}$ and $\epsilon := \mathrm{err}(h^{\mathrm{nn}}_S, S_{\mathrm{in}}) \le \frac{1}{2}$, then $\mathrm{err}(h^{\mathrm{nn}}_S, \mathcal{D}) \le \mathrm{GB}(\epsilon, N, \delta, m, |\mathcal{Y}|) \le 2\mathrm{GB}(\epsilon, N, 2\delta, m, 1)$.*

If the compression set includes only the original labels, the compression analysis of Gottlieb et al. (2017) gives the bound $\mathrm{GB}(\epsilon, N, \delta, m, 1)$. Thus the effect of allowing the labels to change is only logarithmic in $|\mathcal{Y}|$, and does not appreciably degrade the prediction error.

6.2 Proof of Theorem 4

The proof of the main theorem, Theorem 4, which gives the guarantee for MARMANN, is almost immediate from Theorem 17, Theorem 9, Theorem 15 and Theorem 14.

Proof [of Theorem 4] We have $|\mathrm{Dist}_{\mathrm{mon}}| \le \binom{m}{2}$. By a union bound, the events $E(t)$ and $V(t)$ of Theorem 9 and Cor. 11 hold for all $t \in \mathcal{T}_{\mathrm{test}} \subseteq \mathrm{Dist}_{\mathrm{mon}}$ with a probability of at least $1-\delta/2$. Under these events, we have by Theorem 15 that if $G_{\min}(m,\delta) \le 1/3$,

$$\mathrm{GB}(\epsilon(\hat{t}), \mathcal{N}(\hat{t}), \delta, m, 1) \le O\left(\min_t \mathrm{GB}(\nu(t), \mathcal{N}(t), \delta, m, 1)\right).$$

By Theorem 17, with a probability at least $1-\delta/2$, if $\epsilon(\hat{t}) \le \frac{1}{2}$ then

$$\mathrm{err}(\hat{h}, \mathcal{D}) \le 2\mathrm{GB}(\epsilon(\hat{t}), \mathcal{N}(\hat{t}), \delta, m, 1).$$

The statement of the theorem follows. Note that the statement trivially holds for $G_{\min}(m,\delta) \ge 1/3$ and for $\epsilon(\hat{t}) \ge \frac{1}{2}$, thus these conditions can be removed. To bound the label complexity, note that the total number of labels used by MARMANN is at most the number of labels used by SelectScale plus the number of labels used by GenerateNNSet when the final compression set is generated.

By Theorem 14, since $Q(m) = O(\log(m/\delta))$, the number of labels used by SelectScale is at most

$$O\left(|\mathcal{T}_{\text{test}}|\frac{\log^2(m/\delta)}{G(\epsilon(\hat{t}))}\log\left(\frac{1}{G(\epsilon(\hat{t}))}\right)\right).$$

In addition,

$$G(\epsilon(\hat{t})) \geq \text{GB}(\epsilon(\hat{t}), \mathcal{N}(\hat{t}), \delta, m, 1) = \hat{G}.$$

The number of tested scales in SelectScale is bounded by

$$|\mathcal{T}_{\text{test}}| \leq \lfloor \log_2(|\text{Dist}_{\text{mon}}|) + 1 \rfloor \leq 2\log_2(m)$$

Therefore the number of labels used by SelectScale is

$$O\left(\frac{\log^3(m/\delta)}{\hat{G}}\log\left(\frac{1}{\hat{G}}\right)\right).$$

The number of labels used by GenerateNNSet is at most $Q(m)\mathcal{N}(\hat{t})$, where $Q(m) \leq O(\log(m/\delta)$, and from the definition of $\hat{G}$, $\mathcal{N}(\hat{t}) \leq O(m\hat{G}/\log(m))$. Summing up the number of labels used by SelectScale and the number used by GenerateNNSet, this gives the bound in the statement of the theorem. ■

7. Passive Learning Lower Bounds

Theorem 5 lower bounds the performance of a passive learner who observes a limited number ℓ of random labels from S_{in}. The number ℓ is chosen so that it is of the same order as the number of labels MARMANN observes for the case analyzed in Section 3. We deduce Theorem 5 from a more general result pertaining to the sample complexity of passive learning. The general result is given as Theorem 18 in Section 7.1. The proof of Theorem 5 is provided in Section 7.2.

We note that while the lower bounds below assume that the passive learner observes only the random labeled sample of size ℓ, in fact their proofs hold also if the algorithm has access to the full unlabeled sample of size m of which S_ℓ is sampled. This is because the lower bound is based on requiring the learner to distinguish between distributions that all have the same marginal. Under this scenario, access to unlabeled examples does not provide any additional information to the learner.

7.1 A General Lower Bound

In this section we show a general sample complexity lower bound for passive learning, which may be of independent interest. We are aware of two existing lower bounds for agnostic PAC with bounded Bayes error: Devroye et al. (1996, Theorem 14.5) and Audibert (2009, Theorem 8.8). Both place restrictions on the relationship between the sample size, VC-dimension, and Bayes error level, which render them inapplicable as stated to some parameter regimes, including the one needed for proving Theorem 5.

Let $\mathcal{H}$ be a hypothesis class with VC-dimension d and suppose that $\mathcal{L}$ is a passive learner[6] mapping labeled samples $S_\ell = (X_i, Y_i)_{i\in[\ell]}$ to hypotheses $\hat{h}_\ell \in \mathcal{H}$. For any distribution $\mathcal{D}$ over

6. We allow $\mathcal{L}$ access to an independent internal source of randomness.

$\mathcal{X} \times \{-1, 1\}$, define the *excess risk* of $\hat{h}_\ell$ by

$$\Delta(\hat{h}_\ell, \mathcal{D}) := \text{err}(\hat{h}_\ell, \mathcal{D}) - \inf_{h\in\mathcal{H}} \text{err}(h, \mathcal{D}).$$

Let $\mathscr{D}(\eta)$ be the collection of all *η-bounded agnostic error* distributions $\mathcal{D}$ over $\mathcal{X}\times\{-1,1\}$ that satisfy $\inf_{h\in\mathcal{H}} \text{err}(h, \mathcal{D}) \leq \eta$. We say that $Z \in \{-1, 1\}$ has Rademacher distribution with parameter $b \in [-1, 1]$, denoted $Z \sim \text{R}_b$, if

$$\mathbb{P}[Z = 1] = 1 - \mathbb{P}[Z = -1] = \frac{1}{2} + \frac{b}{2}.$$

All distributions on $\{-1, 1\}$ are of this form. For $k \in \mathbb{N}$ and $b \in [0, 1]$, define the function

$$\text{bayes}(k, b) = \tfrac{1}{2}\left(1 - \tfrac{1}{2}\left\|\text{R}_b^k - \text{R}_{-b}^k\right\|_1\right),$$

where $\text{R}_{\pm b}^k$ is the corresponding product distribution on $\{-1, 1\}^k$ and $\frac{1}{2}\|\cdot\|_1$ is the total variation norm. This expression previously appeared in Berend and Kontorovich (2015, Equation (25)) in the context of information-theoretic lower bounds; the current terminology was motivated in Kontorovich and Pinelis (2016), where various precise estimates on $\text{bayes}(\cdot)$ were provided. In particular, the function $\text{baÿes}(\kappa, b)$ was defined as follows: for each fixed $b \in [0, 1]$, $\text{baÿes}(\cdot, b)$ is the largest convex minorant on $[0, \infty)$ of the function $\text{bayes}(\cdot, b)$ on $\{0, 1, \dots\}$. It was shown in Kontorovich and Pinelis (2016, Proposition 2.8) that $\text{baÿes}(\cdot, b)$ is the linear interpolation of $\text{bayes}(\cdot, b)$ at the points $0, 1, 3, 5, \dots$.

Theorem 18 *Let $0 < \eta < \frac{1}{2}$, $\ell \geq 1$, and $\mathcal{H}$ be a hypothesis class with VC-dimension $d > 1$. Then, for all $0 < b, p < 1$ satisfying*

$$p\left(\frac{1}{2} - \frac{b}{2}\right) \leq \eta, \tag{15}$$

we have

$$\inf_{\hat{h}_\ell} \sup_{\mathcal{D}\in\mathscr{D}(\eta)} \mathop{\mathbb{E}}_{\mathcal{D}^\ell}\left[\Delta(\hat{h}_\ell, \mathcal{D})\right] \;\geq\; bp\,\text{baÿes}(\ell p/(d-1), b). \tag{16}$$

Furthermore, for $0 \leq u < 1$,

$$\inf_{\hat{h}_\ell} \sup_{\mathcal{D}\in\mathscr{D}(\eta)} \mathbb{P}\left[\Delta(\hat{h}_\ell, \mathcal{D}_{\sigma,b,p}) > bpu\right] \;>\; \text{baÿes}(\ell p/(d-1), b) - u. \tag{17}$$

Proof This proof uses ideas from Devroye et al. (1996, Theorem 14.5), Anthony and Bartlett (1999, Theorem 5.2) and Kontorovich and Pinelis (2016, Theorem 2.2).

We will construct adversarial distributions supported on a shattered subset of size d, and hence there is no loss of generality in taking $\mathcal{X} = [d]$ and $\mathcal{H} = \{-1, 1\}^{\mathcal{X}}$. A random distribution $\mathcal{D}_{\sigma,b,p}$ over $\mathcal{X} \times \{-1, 1\}$, parametrized by a random $\sigma \sim \text{Unif}(\{-1, 1\}^{d-1})$ and scalars $b, p \in (0, 1)$ to be specified later, is defined as follows. The point $x = d \in \mathcal{X}$ gets a marginal weight of $1 - p$ where p is a parameter to be set; the remaining $d - 1$ points each get a marginal weight of $p/(d - 1)$:

$$\mathop{\mathbb{P}}_{X\sim\mathcal{D}_{\sigma,b,p}}[X = d] = 1 - p, \qquad \mathop{\mathbb{P}}_{X\sim\mathcal{D}_{\sigma,b,p}}[X < d] = \frac{p}{d-1}. \tag{18}$$

The distribution of Y conditional on X is given by $\mathbb{P}_{(X,Y)\sim\mathcal{D}_{\sigma,b,p}}[Y=1\,|\,X=d]=1$ and

$$\mathop{\mathbb{P}}_{(X,Y)\sim\mathcal{D}_{\sigma,b,p}}[Y=\pm 1\,|\,X=j<d]=\frac{1}{2}\pm\frac{b\sigma_j}{2}. \tag{19}$$

Suppose that $(X_i,Y_i)_{i\in[\ell]}$ is a sample drawn from $\mathcal{D}^{\ell}_{\sigma,b,p}$. The assumption that $\mathcal{D}_{\sigma,b,p}\in\mathscr{D}(\eta)$ implies that b and p must satisfy the constraint (15).

A standard argument (e.g., Anthony and Bartlett (1999) p. 63 display (5.5)) shows that, for any hypothesis $\hat{h}_\ell$,

$$\begin{aligned}
\Delta(\hat{h}_\ell,\mathcal{D}_{\sigma,b,p}) &= \mathrm{err}(\hat{h}_\ell,\mathcal{D}_{\sigma,b,p})-\inf_{h\in\mathcal{H}}\mathrm{err}(h,\mathcal{D}_{\sigma,b,p})\\
&= \mathop{\mathbb{P}}_{X\sim\mathcal{D}_{\sigma,b,p}}[X=d,\hat{h}_\ell(X)\neq 1]+b\mathop{\mathbb{P}}_{X\sim\mathcal{D}_{\sigma,b,p}}[X<d,\hat{h}_\ell(X)\neq\sigma(X)]\\
&\geq b\mathop{\mathbb{P}}_{X\sim\mathcal{D}_{\sigma,b,p}}[X<d,\hat{h}_\ell(X)\neq\sigma(X)]\\
&= bp\mathop{\mathbb{P}}_{X\sim\mathcal{D}_{\sigma,b,p}}[\hat{h}_\ell(X)\neq\sigma(X)|X<d].
\end{aligned}\tag{20}$$

It follows from Kontorovich and Pinelis (2016, Theorems 2.1, 2.5) that

$$\begin{aligned}
\mathop{\mathbb{E}}_{\sigma}\mathop{\mathbb{P}}_{X\sim\mathcal{D}_{\sigma,b,p}}[\hat{h}_\ell(X)\neq\sigma(X)|X<d] &\geq \mathop{\mathbb{E}}_{N\sim\mathrm{Bin}(\ell,p/(d-1))}[\mathrm{bayes}(N,b)]\\
&\geq \mathop{\mathbb{E}}_{N\sim\mathrm{Bin}(\ell,p/(d-1))}[\mathrm{ba\check{y}es}(N,b)]\\
&\geq \mathrm{ba\check{y}es}(\mathbb{E}[N],b)=\mathrm{ba\check{y}es}(\ell p/(d-1),b),
\end{aligned}\tag{21}$$

where the second inequality holds because $\mathrm{ba\check{y}es}$ is, by definition, a convex minorant of bayes, and the third follows from Jensen's inequality. Combined with (20), this proves (16).

To show (17), define the random variable

$$Z=Z(\sigma,\mathcal{L})=\mathop{\mathbb{P}}_{X\sim\mathcal{D}_{\sigma,b,p}}[\hat{h}_\ell(X)\neq\sigma(X)|X<d].$$

Since $Z\in[0,1]$, Markov's inequality implies

$$\mathbb{P}[Z>u]\geq\frac{\mathbb{E}[Z]-u}{1-u}>\mathbb{E}[Z]-u,\qquad 0\leq u<1.$$

Now (20) implies that $\Delta(\hat{h}_\ell,\mathcal{D}_{\sigma,b,p})\geq bpZ$ and hence, for $0\leq u<1$,

$$\begin{aligned}
\inf_{\hat{h}_\ell}\sup_{\mathcal{D}\in\mathscr{D}(\eta)}\mathbb{P}\left[\Delta(\hat{h}_\ell,\mathcal{D}_{\sigma,b,p})>bpu\right] &= \inf_{\hat{h}_\ell}\sup_{\mathcal{D}\in\mathscr{D}(\eta)}\mathbb{P}[Z>u]\\
&> \inf_{\hat{h}_\ell}\sup_{\mathcal{D}\in\mathscr{D}(\eta)}\mathbb{E}[Z]-u\\
&\geq \frac{1}{bp}\inf_{\hat{h}_\ell}\sup_{\mathcal{D}\in\mathscr{D}(\eta)}\mathbb{E}[\Delta(\hat{h}_\ell,\mathcal{D}_{\sigma,b,p})]-u\\
&\geq \mathrm{ba\check{y}es}(\ell p/(d-1),b)-u.
\end{aligned}$$

■

7.2 Proof of Theorem 5

We break down the proof into several steps. For now, we assume that the labeled examples are sampled i.i.d. as per the classic PAC setup. At the end, we show how to extend the proof to the semi-supervised setting.

(i) Defining a family of adversarial distributions. Let T be a $\bar{t}$-net of $\mathcal{X}$ of size $\Theta(\sqrt{m})$ and $\eta=\Theta(1/\sqrt{m})$. For any passive learning algorithm mapping i.i.d. samples of size $\ell=\tilde{\Theta}(\sqrt{m})$ to hypotheses $\hat{h}_\ell:\mathcal{X}\to\{-1,1\}$, we construct a random adversarial distribution $\mathcal{D}_{\sigma,b,p}$ with agnostic error η. We accomplish this via the construction described in the proof of Theorem 18, with $|T|=d=\Theta(\sqrt{m})$. The marginal distribution over $T=\{x_1,\ldots,x_d\}$ puts a mass of $1-p$ on $x_d\in T$ and spreads the remaining mass uniformly over the other points, as in (18). The "heavy" point has a deterministic label and the remaining "light" points have noisy labels drawn from a random distribution with symmetric noise level b, as in (19). We proceed to choose b and p; namely,

$$p=\frac{d-1}{2\ell}\sqrt{\eta}=\tilde{\Theta}(m^{-1/4}),\qquad b=1-\frac{2\eta}{p}=1-\tilde{\Theta}(m^{-1/4}),$$

which makes the constraint in (15) hold with equality; this means that the agnostic error is exactly η and in particular, establishes (i).

(ii.a) Lower-bounding the passive learner's error. Our choice of p implies that $\ell p/(d-1)=\sqrt{\eta}/2=:\kappa<1$. For this range of κ, Kontorovich and Pinelis (2016, Proposition 2.8) implies that $\mathrm{ba\check{y}es}(\kappa,b)=\frac{1}{2}(1-\kappa b)=\Theta(1)$. Choosing $u=\frac{1}{4}(1-\kappa b)=\Theta(1)$ in (17), Theorem 18 implies that

$$\inf_{\hat{h}_\ell}\sup_{\mathcal{D}\in\mathscr{D}(\eta)}\mathbb{P}[\Delta(\hat{h}_\ell,\mathcal{D})>\tilde{\Omega}(m^{-1/4})]>\Omega(1).$$

In more formal terms, there exist constants $c_0,c_1>0$ such that

$$\inf_{\hat{h}_\ell}\sup_{\mathcal{D}\in\mathscr{D}(\eta)}\mathbb{P}[\Delta(\hat{h}_\ell,\mathcal{D})>c_0 p]>c_1. \tag{22}$$

(ii.b) Upper-bounding $\nu(\bar{t})$. To establish (ii.b), it suffices to show that for $(X_i,Y_i)_{i\in[\ell]}\sim\mathcal{D}^{\ell}_{\sigma,b,p}$, we will have $\nu(\bar{t})=O(m^{-1/2})$ with sufficiently high probability. Indeed, the latter condition implies the requisite upper bound on $\min_{t>0:\mathcal{N}(t)<m}\mathrm{GB}(\nu(t),\mathcal{N}(t),\delta,m,1)$, while (i) implies the lower bound, since the latter quantity cannot be asymptotically smaller than the Bayes error (which coincides with the agnostic error for $\mathcal{H}=\{-1,1\}^{\mathcal{X}}$).

Recall that the $\bar{t}$-net points $\{x_1,\ldots,x_{d-1}\}$ are the "light" ones (i.e., each has weight $p/(d-1)$) and define the random sets $J_j\subset[\ell]$ by

$$J_j=\{i\in[\ell]:X_i=x_j\},\qquad j\in[d-1].$$

In words, J_j consists of the indices i of the sample points for which X_i falls on the net point x_j. For $y\in\{-1,1\}$, put $\tau_j^y=\sum_{i\in J_j}\mathbb{I}[Y_i=y]$ and define the *minority count* ξ_j at the net point x_j by

$$\xi_j=\min_{y\in\{-1,1\}}\tau_j^y=\tfrac{1}{2}(|\tau_j^+-\tau_j^-|-|\tau_j^++\tau_j^-|).$$

Observe that by virtue of being a $\bar{t}$-net, T is $\bar{t}$-separated and hence the only contribution to $\nu(\bar{t})$ is from the minority counts (to which the "heavy" point x_d does not contribute due to its deterministic

label):

$$\nu(\bar{t}) = \frac{1}{\ell}\sum_{j=1}^{d-1}\xi_j.$$

Now

$$\mathbb{E}\,|\tau_j^+ + \tau_j^-| = \mathbb{E}\,|J_j| = \frac{\ell p}{d-1} = \Theta(m^{-1/4})$$

and

$$\begin{aligned}\mathbb{E}\,|\tau_j^+ - \tau_j^-| &= \mathop{\mathbb{E}}_{\sigma_j}\mathbb{E}[|\tau_j^+ - \tau_j^-|\,|\sigma_j] \\ &\geq \mathop{\mathbb{E}}_{\sigma_j}\left|\mathbb{E}[\tau_j^+ - \tau_j^-\,|\sigma_j]\right|.\end{aligned}$$

Computing

$$\mathbb{E}[\tau_j^+|\sigma_j = +1] = (\frac{1}{2}+\frac{b}{2})\frac{\ell p}{d-1}, \qquad \mathbb{E}[\tau_j^-|\sigma_j = +1] = (\frac{1}{2}-\frac{b}{2})\frac{\ell p}{d-1},$$

with an analogous calculation when conditioning on $\sigma_j = -1$, we get

$$\mathbb{E}\,|\tau_j^+ - \tau_j^-| \geq \frac{b\ell p}{d-1}$$

and hence

$$\begin{aligned}\mathbb{E}[\xi_j] &\leq \frac{1}{2}\left(\frac{\ell p}{d-1} - b\frac{\ell p}{d-1}\right) \\ &= (1-b)\frac{\ell p}{2(d-1)} = \frac{2\eta}{p}\cdot\frac{\ell p}{2(d-1)} = \frac{\eta\ell}{d-1}.\end{aligned}$$

It follows that

$$\begin{aligned}\mathbb{E}[\nu(\bar{t})] &= \frac{1}{\ell}\sum_{j=1}^{d-1}\mathbb{E}[\xi_j] \\ &\leq \frac{d-1}{\ell}\cdot\frac{\eta\ell}{d-1} = \eta = \Theta(m^{-1/2}).\end{aligned}$$

To give tail bounds on $\nu(\bar{t})$, we use Markov's inequality: for all $c_2 > 0$,

$$\mathbb{P}[\nu(\bar{t}) > c_2\,\mathbb{E}[\nu(\bar{t})] \leq \frac{1}{c_2}.$$

Choosing c_2 sufficiently large that $1 - 1/c_2 > c_1$ (the latter from (22)) implies the existence of constants $c_0, c_2, c_3 > 0$ such that

$$\inf_{\hat{h}_\ell}\sup_{\mathcal{D}\in\mathscr{D}(\eta)}\mathbb{P}\left[\left(\Delta(\hat{h}_\ell,\mathcal{D}) > c_0 p\right) \wedge (\nu(\bar{t}) \leq c_2\eta)\right] > c_3.$$

Since $p = \tilde{\Theta}(m^{-1/4})$ and $\eta = \Theta(m^{-1/2})$, this establishes (ii) and concludes the proof of Theorem 5.

(iii) Extending to the semi-supervised setting. Providing the learner with the exact weights of $\mathcal{X} = [d]$ under our adversarial distribution does not give it any additional power. Indeed, the information-theoretic excess risk lower bound in Eq. (21) hinges on the fact that to estimate $\sigma(x)$ with some desired certainty, the point x must be sampled some minimal number of times. The marginal probability of x does not enter that calculation, and hence knowing its value does not afford the learner an improved performance.

8. Active Learning Lower Bound

We now prove the active learning lower bound stated in Theorem 6. To prove the theorem, we first prove a result which is similar to the classical No-Free-Lunch theorem, except it holds for active learning algorithms. The proof follows closely the proof of the classical No-Free-Lunch theorem given in Shalev-Shwartz and Ben-David (2014, Theorem 5.1), with suitable modifications.

Theorem 19 *Let $\beta \in [0, \frac{1}{2})$, and m be an integer. Let $\mathcal{A}$ any active learning algorithm over a finite domain $\mathcal{X}$ which gets as input a random labeled sample $S \sim \mathcal{D}^m$ (with hidden labels) and outputs $\hat{h}$. If $\mathcal{A}$ queries fewer than $\mathcal{X}/2$ labels from S, then there exists a distribution $\mathcal{D}$ over $\mathcal{X}\times\{0,1\}$ such that*

- *Its marginal on $\mathcal{X}$ is uniform, and for each $x \in \mathcal{X}$, $\mathbb{P}[Y = 1 \mid X = x] \in \{\beta, 1-\beta\}$.*
- $\mathbb{E}[\mathrm{err}(\hat{h},\mathcal{D})] \geq \frac{1}{4}$.

Proof Let $\mathcal{F} = \{f_1,\ldots,f_T\}$ be the set of possible functions $f_i : \mathcal{X} \to \{0,1\}$. Let $\mathcal{D}_i$ to be a distribution with a uniform marginal over $\mathcal{X}$, and $\mathbb{P}_{(X,Y)\sim\mathcal{D}_i}[Y = 1 \mid X = x] = f_i(x)(1-\beta) + (1-f_i(x))\beta$. Consider the following random process: First, draw an unlabeled sample $X = (x_1,\ldots,x_m)$ i.i.d. from $\mathcal{D}_X^m$. Then, draw $B = (b_1,\ldots,b_m)$ independently from a Bernoulli distribution with $\mathbb{P}[b_i = 1] = \beta$. For $i \in [T]$, let $S^i(X,B) = ((x_1,y_1),\ldots,(x_m,y_m))$ such that x_i are set by X, and $y_i = f_i(x)$ if $b_i = 0$ and $1 - f_i(x)$ otherwise. Clearly, $S^i(X,B)$ is distributed according to $\mathcal{D}_i^m$. Let $h_i(S)$ be the output of $\mathcal{A}$ when the labeled sample is S. Denote by $\hat{h}_i$ the (random) output of $\mathcal{A}$ when the sample is drawn from $\mathcal{D}_i$. Clearly

$$\mathbb{E}[\mathrm{err}(\hat{h}_i,\mathcal{D}_i)] = \mathop{\mathbb{E}}_{X,B}[\mathrm{err}(h_i(S(X,B)),\mathcal{D}_i)].$$

Therefore (as in (5.4) in Shalev-Shwartz and Ben-David (2014)), for some j, X, B it holds that

$$\mathbb{E}[\mathrm{err}(\hat{h}_j,\mathcal{D}_j)] \geq \frac{1}{T}\sum_{i=1}^{T}\mathbb{E}[\mathrm{err}(\hat{h}_i,\mathcal{D}_i)] \geq \frac{1}{T}\sum_{i=1}^{T}\mathrm{err}(h_i(S(X,B)),\mathcal{D}_i). \tag{23}$$

Fix X, B, j as above, and denote for brevity $h_i := h_i(S(X,B))$. Let V_i be the set of examples $x \in \mathcal{X}$ for which that $\mathcal{A}$ does not observe their label if the labeled sample is $S^i(X,B)$ (this includes both examples that are not in the sample at all as well as examples that are in the sample but their label is not requested by $\mathcal{A}$). We have $|V_i| > |\mathcal{X}|/2$ by assumption. Then (as in Eq. (5.6) therein)

$$\frac{1}{T}\sum_{i=1}^{T}\mathrm{err}(h_i,\mathcal{D}_i) \geq \frac{1}{T}\sum_{i=1}^{T}\frac{1}{2|V_i|}\sum_{x\in V_i}\mathbb{I}[h_i(x) \neq f_i(x)]. \tag{24}$$

Since $\mathcal{A}$ is active, it selects which examples to request, which can depend on the labels observed by $\mathcal{A}$ so far. Therefore, V_i can be different for different i. However, an argument similar to that of the No-Free-Lunch theorem for the passive case still goes through, as follows.

Let i, i' such that $f_i(x) = f_{i'}(x)$ for all $x \notin V_i$, and $f_i(x) = 1 - f_{i'}(x)$ for all $x \in V_i$. Since X, B are fixed, $\mathcal{A}$ observes the same labels for all $x \notin V_i$ for both $S^{i'}(X,B)$ and $S^i(X,B)$, thus all its decisions and requests are identical for both samples, and so $V_i = V_{i'}$, and $h_i = h_{i'}$. Therefore, it is possible to partition T into $T/2$ pairs of indices i, i' such that for each such pair,

$$\begin{aligned}
&\frac{1}{2|V_i|}\sum_{x\in V_i}\mathbb{I}[h_i(x)\neq f_i(x)] + \frac{1}{2|V_{i'}|}\sum_{x\in V_{i'}}\mathbb{I}[h_{i'}(x)\neq f_{i'}(x)] \\
&= \frac{1}{2|V_i|}\sum_{x\in V_i}\mathbb{I}[h_i(x)\neq f_i(x)] + \mathbb{I}[h_i(x)\neq 1-f_i(x)] \\
&= \frac{1}{2}.
\end{aligned}$$

Therefore, $\frac{1}{T}\sum_{i=1}^{T}\mathrm{err}(h_i,\mathcal{D}_i) \geq \frac{1}{4}$. Therefore, from Eq. (24), $\frac{1}{T}\sum_{i=1}^{T}\mathrm{err}(h_i,\mathcal{D}_i) \geq \frac{1}{4}$. Combining this with Eq. (23), it follows that $\mathbb{E}[\mathrm{err}(\hat{h}_j,\mathcal{D}_j)] \geq \frac{1}{4}$. ■

We will also make use of the following simple lemma.

Lemma 20 *Let $\beta \in [0,1]$. Let $\mathcal{D}$ be a distribution over $\mathcal{X}\times\{0,1\}$ such that for $(X,Y)\sim\mathcal{D}$, for any x in the support of $\mathcal{D}$, $\mathbb{P}[Y=1 \mid X=x] \in \{\beta, 1-\beta\}$. Let N be the size of the support of $\mathcal{D}$. Let $S\sim\mathcal{D}^m$. Denote by n_x the number of sample pairs (x',y') in S where $x'=x$, and let n_x^+ be the number of sample pairs (x',y') where $x'=x$ and $y'=1$. Let $\hat{p}_x^+ = n_x^+/n_x$ (or zero if $n_x=0$). Then*

$$2\beta(1-\beta)(m-N) \leq \sum_{x\in\mathcal{X}}\mathbb{E}[2n_x\hat{p}_x^+(1-\hat{p}_x^+)] \leq 2\beta(1-\beta)m.$$

Proof We have

$$\mathbb{E}[2n_x\hat{p}_x^+(1-\hat{p}_x^+)] = \sum_{i=1}^{\infty}\mathbb{P}[n_x=i]\cdot i\cdot\mathbb{E}[2\hat{p}_x^+(1-\hat{p}_x^+)\mid n_x=i].$$

Note that $\mathbb{E}[2\hat{p}_x^+(1-\hat{p}_x^+)\mid n_x=1]=0$. For $i>1$, let $y_1,\ldots,y_i$ be the labels of the examples that are equal to x in S, then

$$\sum_{j,k\in[i]}\mathbb{I}[y_k\neq y_j] = 2n_x^+(i-n_x^+) = i^2\cdot 2\hat{p}_x^+(1-\hat{p}_x^+).$$

Therefore, letting $(X_1,Y_1),(X_2,Y_2)\sim\mathcal{D}^2$,

$$\begin{aligned}
\mathop{\mathbb{E}}_{S\sim\mathcal{D}^m}[2\hat{p}_x^+(1-\hat{p}_x^+)\mid n_x=i] &= \frac{1}{i^2}\mathop{\mathbb{E}}_{S\sim\mathcal{D}^m}[\sum_{j,k\in[n_x]}\mathbb{I}[y_k\neq y_j]\mid n_x=i] \\
&= \frac{i^2-i}{i^2}\,\mathbb{P}[Y_1\neq Y_2\mid X_1=X_2=x] \\
&= 2(1-\frac{1}{i})\beta(1-\beta),
\end{aligned}$$

Thus

$$\begin{aligned}
\mathbb{E}[2n_x\hat{p}_x^+(1-\hat{p}_x^+)] &= 2\beta(1-\beta)\sum_{i=2}^{\infty}(i-1)\,\mathbb{P}[n_x=i] \\
&= 2\beta(1-\beta)(\mathbb{E}[n_x]+\mathbb{P}[n_x=0]-1).
\end{aligned}$$

To complete the proof, sum over all x in the support of $\mathcal{D}$, and note that $\sum_x\mathbb{E}[n_x]=m$, and $\sum_x(\mathbb{P}[n_x=0]-1)\in[-N,0]$. ■

We now prove our lower bound, stated in Theorem 6, on the number of queries required by any active learning with competitive guarantees similar to ours.

Proof [of Theorem 6] Let $N = \left\lfloor \frac{m\alpha - \log(\frac{m}{\delta})}{\log(m)} \right\rfloor$. Let $\beta = 8\alpha \leq \frac{1}{2}$. Consider a marginal distribution $\mathcal{D}_X$ over $\mathcal{X}$ which is uniform over N points $1,\ldots,N\in\mathbb{R}$. Consider the following family of distributions: $\mathcal{D}$ such that its marginal over $\mathcal{X}$ is $\mathcal{D}_X$, and for each $x\in\mathcal{X}$, $\mathbb{P}[Y=1\mid X=x]\in\{\beta,1-\beta\}$. Thus the Bayes optimal error for each of these distributions is β.

Let $S\sim\mathcal{D}^m$. If one example in S is changed, $\nu(\frac{1}{2})$ changes by at most $1/m$. Hence, by McDiarmid's inequality (McDiarmid, 1989), with probability at least $1-\frac{1}{28}$, $\left|\nu(\frac{1}{2})-\mathbb{E}[\nu(\frac{1}{2})]\right| \leq \sqrt{\frac{\log(28)}{2m}}$. Denote the event that this holds E_M. Since $\beta = 8\alpha \geq \frac{\log(m)+\log(28)}{\sqrt{2m}}$, it follows that under E_M,

$$|\nu(1/2)-\mathbb{E}[\nu(1/2)]| \leq \beta/8. \tag{25}$$

We now bound $\mathbb{E}[\nu(\frac{1}{2})]$. Using the notation $\hat{p}_x^+, n_x, n_x^+$ as in Lemma 20, we have

$$\nu(1/2) = \frac{1}{m}\sum_{x\in\mathcal{X}}\min(n_x^+, n_x-n_x^+) = \frac{1}{m}\sum_{x\in\mathcal{X}}n_x\min(p_x^+,1-p_x^+)$$

Also, for all $p\in[0,1]$, $\min(p,1-p)\leq 2p(1-p)\leq 2\min(p,1-p)$. Therefore

$$\frac{1}{2m}\sum_{x\in\mathcal{X}}2n_xp_x^+(1-p_x^+) \leq \nu(1/2) \leq \frac{1}{m}\sum_{x\in\mathcal{X}}2n_xp_x^+(1-p_x^+).$$

By Lemma 20, it follows that

$$\frac{m-N}{m}\beta(1-\beta) \leq \mathbb{E}[\nu(1/2)] \leq 2\beta(1-\beta).$$

Since $N\leq m/2$ and $\beta\in[0,\frac{1}{2}]$, $\mathbb{E}[\nu(\frac{1}{2})]\in(\beta/4,2\beta)$. Combining this with Eq. (25), we get that under E_M, $\alpha=\beta/8\leq\nu(\frac{1}{2})\leq\frac{17}{8}\beta=17\alpha$.

Now, we bound $G_{\min}$ from above and below assuming E_M holds. Denote

$$G(t) := \mathrm{GB}(\nu(t),\mathcal{N}(t),\delta,m,1).$$

To establish a lower bound on $G_{\min}(m,\delta)$, note that $G_{\min}(m,\delta)=\min_{t>0}G(t)\geq\min_{t>0}\nu(t)$. For $t\in(0,\frac{1}{2})$, $\nu(t)=\nu(\frac{1}{2})$ (since the distances between any two distinct points in S is at least 1). In addition, since ν is monotonically increasing, we have $\nu(t)\geq\nu(\frac{1}{2})$ for $t\geq\frac{1}{2}$. Hence $\min_{t>0}\nu(t)\geq\nu(\frac{1}{2})\geq\beta/8=\alpha$.

To show an upper bound on $G_{\min}(m,\delta)$, we upper bound $G(\frac{1}{2})$. Note that $\mathcal{N}(\frac{1}{2}) \leq N$. Recall the definition of $\phi(t)$ in Eq. (6). We have

$$\phi(\frac{1}{2}) = \frac{(N+1)\log(m) + \log(\frac{1}{\delta})}{m} \leq \alpha.$$

Then, since $\nu(\frac{1}{2}) \leq 17\alpha$,

$$G(1/2) \leq \frac{m}{m-N}(\nu(\frac{1}{2}) + \frac{2}{3}\alpha + \frac{3}{\sqrt{2}}\sqrt{\nu(\frac{1}{2})\alpha}) \leq 30\alpha.$$

In the last inequality we used the fact that $\frac{m}{m-N} \leq 10/9$. So if E_M holds, $G_{\min}(m,\delta) \leq G(\frac{1}{2}) \leq 30\alpha$.

From the assumption on $\mathcal{A}$, with probability at least $1-\delta$, we have $\mathrm{err}(\hat{h},\mathcal{D}) \leq CG_{\min}(m,\delta) \leq 30C\alpha \leq 1/8$ (since $\alpha \leq \frac{1}{240C}$). Let $E_L(\mathcal{D})$ denote the event that $\mathcal{A}$ queries fewer than $N/2$ labels, where the probability is over the randomness of S and $\mathcal{A}$. Let h' be the output of an algorithm that behaves like $\mathcal{A}$ in cases where $E_L(\mathcal{D})$ holds, and queries at most $N/2$ otherwise. By Theorem 19, there exists some $\mathcal{D}$ in the family of distributions such that $\mathbb{E}[\mathrm{err}(h',\mathcal{D})] \geq \frac{1}{4}$. By Markov's inequality, $\mathbb{P}[\mathrm{err}(h',\mathcal{D}) \geq \frac{1}{8}] \geq 1/7$. Also, $\mathbb{P}[h' = \hat{h}] \geq \mathbb{P}[E_L(\mathcal{D})]$. Therefore

$$\mathbb{P}[\mathrm{err}(\hat{h},\mathcal{D}) \geq 1/8] \geq \mathbb{P}[\mathrm{err}(h',\mathcal{D}) \geq 1/8] + \mathbb{P}[E_L(\mathcal{D})] - 1 = \mathbb{P}[E_L(\mathcal{D})] - 6/7.$$

Therefore $\mathbb{P}[E_L(\mathcal{D})] - 6/7 \leq \mathbb{P}[\mathrm{err}(\hat{h},\mathcal{D}) \geq \frac{1}{8}] \leq \delta$. Since by assumption $\delta \leq 1/14$, it follows that $\mathbb{P}[E_L(\mathcal{D})] \leq 6/7 + \delta \leq 13/14$. It follows that with a probability of at least $1/14$, the negation of $E_L(\mathcal{D})$ holds. Since also E_M holds with probability at least $1 - \frac{1}{28}$, it follows that with a probability of at least $\frac{1}{28}$, both E_M and the negation of $E_L(\mathcal{D})$ hold. Now, as shown above, E_M implies the bounds on $G_{\min}(m,\delta)$ (item 1 in the theorem statement). In addition, the negation of $E_L(\mathcal{D})$ implies that $\mathcal{A}$ queries at least $N/2 = \frac{1}{2}\left\lfloor \frac{m\alpha - \log(\frac{m}{\delta})}{\log(m)} \right\rfloor$ labels (item 2 in the theorem statement). This completes the proof. ■

9. Discussion

We have presented an efficient fully empirical proximity-based non parametric active learner. Our approach provides competitive error guarantees for general distributions, in a general metric space, while keeping label complexity significantly lower than any passive learner with the same guarantees. MARMANN yields fully empirical error estimates, easily computable from finite samples. This is in contrast with classic techniques, that present bounds and rates that depend on unknown distribution-dependent quantities.

An interesting question is whether the guarantees can be related to the Bayes error of the distribution. Our error guarantees give a constant factor over the error guarantees of Gottlieb et al. (2017). A variant of this approach (Gottlieb et al., 2014a) was shown to be Bayes-consistent (Kontorovich and Weiss, 2015), and we conjecture that this holds also for the algorithm of Gottlieb et al. (2017). The passive component of our learning algorithm is indeed Bayes-consistent (Kontorovich et al., 2017). Since in our analysis MARMANN achieves a constant factor over the error of the passive

learner, Bayes-consistency of the active learner cannot be inferred from our present techniques; we leave this problem open for future research.

Another important issue is one of efficient implementation. We mentioned that the naive $O(m^2)$ runtime for constructing a t-net may be improved to $2^{O(\mathsf{ddim}(\mathcal{X}))}m\log(1/t)$, as shown in Krauthgamer and Lee (2004); Gottlieb et al. (2014b). The fast t-net construction was the algorithmic work-horse of Gottlieb et al. (2014a,b, 2017) and inspired the passive component of our learner. We note that implementing even this passive component efficiently is far from trivial; this formed the core of a Master's thesis (Korsunsky, 2017). The remaining obstacle to making our algorithm fully practical is the magnitude of some of the constants. We believe these to be artifacts of the proof and intend to bring them down to manageable values in future work.

Abstract

Missing data is a common problem in real-world settings and for this reason has attracted significant attention in the statistical literature. We propose a flexible framework based on formal optimization to impute missing data with mixed continuous and categorical variables. This framework can readily incorporate various predictive models including K-nearest neighbors, support vector machines, and decision tree based methods, and can be adapted for multiple imputation. We derive fast first-order methods that obtain high quality solutions in seconds following a general imputation algorithm `opt.impute` presented in this paper. We demonstrate that our proposed method improves out-of-sample accuracy in large-scale computational experiments across a sample of 84 data sets taken from the UCI Machine Learning Repository. In all scenarios of missing at random mechanisms and various missing percentages, `opt.impute` produces the best overall imputation in most data sets benchmarked against five other methods: mean impute, K-nearest neighbors, iterative knn, Bayesian PCA, and predictive-mean matching, with an average reduction in mean absolute error of 8.3% against the best cross-validated benchmark method. Moreover, `opt.impute` leads to improved out-of-sample performance of learning algorithms trained using the imputed data, demonstrated by computational experiments on 10 downstream tasks. For models trained using `opt.impute` single imputations with 50% data missing, the average out-of-sample R^2 is 0.339 in the regression tasks and the average out-of-sample accuracy is 86.1% in the classification tasks, compared to 0.315 and 84.4% for the best cross-validated benchmark method. In the multiple imputation setting, downstream models trained using `opt.impute` obtain a statistically significant improvement over models trained using multivariate imputation by chained equations (`mice`) in 8/10 missing data scenarios considered.

Keywords: missing data imputation, K-NN, SVM, optimal decision trees

1. Introduction

The missing data problem is arguably the most common issue encountered by machine learning practitioners when analyzing real-world data. In many applications ranging from gene expression in computational biology to survey responses in social sciences, missing data is present to various degrees. As many statistical models and machine learning algorithms rely on complete data sets, it is key to handle the missing data appropriately.

Method Name	Category	Software	Reference
Mean impute (`mean`)	Mean		Little and Rubin (1987)
Expectation-Maximization (`EM`)	EM		Dempster et al. (1977)
EM with Mixture of Gaussians and Multinomials	EM		Ghahramani and Jordan (1994)

Table 1: List of Imputation Methods

In some cases, simple approaches may suffice to handle missing data. For example, complete-case analysis uses only the data that is fully known and omits all observations with missing values to conduct statistical analysis. This works well if only a few observations contain missing values, and when the data is missing completely at random, complete-case analysis does not lead to biased results (Little and Rubin, 1987). Alternately, some machine learning algorithms naturally account for missing data, and there is no need for preprocessing. For instance, CART and K-means have been adapted for problems with missing data (Breiman et al., 1984; Wagstaff, 2004).

In many other situations, missing values need to be imputed prior to running statistical analyses on the complete data set. The benefit of the latter approach is that once a set (or multiple sets) of complete data has been generated, practitioners can easily apply their own learning algorithms to the imputed data set. We focus on methods for missing data imputation in this paper.

Concretely, assume that we are given data $\mathbf{X} = \{\mathbf{x}_1, \ldots, \mathbf{x}_n\}$ with missing entries $x_{id}, (i,d) \in \mathcal{M}$. The objective is to impute the values of the missing data that resemble the underlying complete data as closely as possible. This way, when one conducts statistical inference or pattern recognition using machine learning methods on the imputed data, the results should be similar to those obtained if full data were given. We outline some of the state-of-the-art methods for imputation in Table 1 and describe them briefly below. Part of the list is adapted from a review paper by Liew et al. (2011).

1.1 Related Work

The simplest method is mean impute, in which each missing value x_{id} is imputed as the mean of all observed values in dimension d. Mean impute underestimates the variance, ignores the correlation between the features, and thus often leads to poor imputation (Little and Rubin, 1987).

Joint modeling asserts some joint distribution on the entire data set. It assumes a parametric density function (e.g., multivariate normal) on the data given model parameters. In practice, model parameters are typically estimated using an Expectation-Maximization (EM) approach. It finds a solution (often non-optimal) of missing values and model parameters to maximize the likelihood function. Many software tools such as the R package `Amelia 2` implement the EM method with bootstrapping, assuming that the data is drawn from a multivariate normal distribution (Honaker et al., 2011). Joint modeling provides useful theoretical properties but lacks the flexibility for processing data types seen in many real applications (Van Buuren, 2007). For example, when the data includes continuous and categorical variable types, standard multivariate density functions often fail at modeling the complexity of mixed data types. However, under the assumption that the categorical variables are independent, we can use mixture models of Gaussians and Multinomials for imputation (Ghahramani and Jordan, 1994).

In contrast to joint modeling, fully conditional specification is a more flexible alternative where one specifies the conditional model for each variable; it is especially useful in mixed data types (Van Buuren, 2007). To generalize to multivariate settings, a chained equation process — initializing using random sampling and conducting univariate imputations sequentially until convergence — is typically used (Buuren and Groothuis-Oudshoorn, 2011). Each iteration is a Gibbs sampler that draws from the conditional distribution on the imputed values.

A simple example of conditional specification is based on regression. Least-Squares (LS) imputation constructs single univariate regressions, regressing features with missing values on all of the other dimensions in the data. Each missing value x_{id} is then imputed as the weighted average of these regression predictions (Bø et al., 2004; Raghunathan et al., 2001). Alternatively, in the Predictive-Mean Matching method (`pmm`), imputations are random samples drawn from a set of observed values close to regression predictions (Buuren and Groothuis-Oudshoorn, 2011). Imputation methods that use Support Vector Regression in place of LS for the regression step have also been explored (Wang et al., 2006).

When there is non-linear relationship between the variables, linear regression based imputation may perform poorly. Burgette and Reiter (2010) propose using Classification and Regression Trees (CART) as the conditional model for imputation. Extensions to random forests have also shown promising results (Stekhoven and Bühlmann, 2012). These decision tree based imputation methods are non-parametric approaches that do not rely upon distributional assumptions on the data.

One of the most commonly used non-parametric approaches is K-Nearest Neighbors (K-NN) based imputation. This method imputes each missing entry x_{id} as the mean of the dth dimension of the K-nearest neighbors that have observed values in dimension d (Troyanskaya et al., 2001). Some extensions of K-NN include sequential K-NN, which starts by imputing missing values from observations with the fewest missing dimensions and continues imputing the next unknown entries reusing the previously imputed values (Kim et al., 2004). Iterative K-NN uses an iterative process to refine the estimates and choose the nearest neighbors based on the estimates from the previous iteration (Caruana, 2001; Brás and Menezes, 2007). The Local-Least Squares method combines ideas from K-NN and LS, imputing each missing value x_{id} using regression models trained on the K-nearest neighbors of the point

$\mathbf{x}_i$ (Kim et al., 2005). Sequential and iterative variations of Local-Least Squares resemble their K-NN imputation counterparts (Zhang et al., 2008; Cai et al., 2006).

Low dimensional representation-based imputation assumes that the data represents a noisy observation of a linear combination of a small set of principal components or factor variables. In the basic method, singular value decomposition (SVD) is used on the entire data set to determine the principal eigenvectors. The missing values are imputed as a linear combination of these eigenvectors. This process is iteratively repeated until convergence (Troyanskaya et al., 2001; Mazumder et al., 2010). Bayesian Principal Component Analysis is similar to SVD imputation but extends the method to incorporate information from a prior distribution on the model parameters (Oba et al., 2003; Mohamed et al., 2009). Some recent development of a variant of the EM algorithm for factor analysis also provides a missing data imputation method for mixed data (Khan et al., 2010).

Thus far, we have only discussed methods for single imputation which generate one set of completed data that will be used for further statistical analyses. Multiple imputation, on the other hand, imputes multiple times (each set is possibly different), runs the statistical analyses on each, and pools the results (Little and Rubin, 1987). Such method is able to capture the variability in the missing data and therefore generate potentially more accurate estimates to the larger statistical problem. However, multiple imputation methods are slower and require pooling results, which may not be appropriate for certain applications.

Within the multiple imputation framework, the procedure for generating multiple estimates of missing values varies. Multivariate imputation by chained equations (`mice`), a popular multiple imputation method, generates estimates using: predictive mean matching, Bayesian linear regression, logistic regression, and others (Buuren and Groothuis-Oudshoorn, 2011). In all cases, the method initializes using random sampling and conducts univariate imputations sequentially until convergence. Each iteration is a Gibbs sampler that draws from the conditional distribution on the imputed values.

Because of its importance, missing data imputation remains an active research area. Although there are numerous methods, many of them have serious shortcomings. Joint modeling methods are not as effective when data sets violate normality assumptions, and a naïve implementation often crashes during the computation of a singular covariance matrix (Honaker et al., 2011). Some conditional specification methods such as `pmm` are practically reliable, but lack theoretical foundation and have no explicit formulation as an optimization problem. This stands in stark contrast to other areas of machine learning, where statistical models and optimization problems are deeply intertwined.

Evidence from recent literature suggests that recent advances in optimization have driven significant progress in machine learning. Integer and convex optimization have been applied successfully to median and sparse regression problems (Bertsimas and Van Parys, 2017; Bertsimas and Mazumder, 2014). Recent work on Optimal Decision Trees for classification leverages integer and robust optimization (Bertsimas and Dunn, 2017; Bertsimas et al., 2017). In this paper, we reconsider the missing data problem from this perspective, in order to develop optimization-based methods for imputation with improved out-of-sample performance.

1.2 Contributions

We summarize our contributions in this paper below:

1. We pose the missing data problem under a general optimization framework. The framework produces an optimization problem with a predictive model-based cost function that explicitly handles both continuous and categorical variables and can be used to generate multiple imputations. We present three cost functions derived from K-nearest neighbors, support vector machines, and optimal decision tree models. This optimization perspective provides fresh insight into the classical missing data problem and leads to new algorithms for more accurate data imputation.

2. For each imputation model, we derive first-order methods to find high-quality solutions to the missing data problem following a general imputation algorithm `opt.impute` presented in this paper. These methods easily scale to data sets with n in the 100,000s and p in the 1,000s on a standard desktop computer and converge within a few iterations. In addition, the first-order methods are robust and reliable for arbitrary missing patterns and mixed data types.

3. We evaluate the methods in computational experiments using 84 real-world data sets taken from the UCI Machine Learning Repository. Benchmarked against existing imputation methods including mean impute, K-nearest neighbors, iterative knn, Bayesian PCA, and predictive-mean matching, `opt.impute` produces the best overall imputation in more than 75.8% of all data sets, and results in an average reduction in mean absolute error of 8.3% against the best cross-validated benchmark method.

4. We demonstrate that the improved data imputations generated by `opt.impute` give rise to improved performance on 10 downstream classification and regression tasks. With 50% of missing data, classification models trained on data imputed via `opt.impute` have an average testing accuracy of 86.1% compared to 84.4% for the best cross-validated benchmark method. In addition, regression models trained on data imputed via `opt.impute` have an average out-of-sample R^2 value of 0.339 compared to 0.315 for the best cross-validated benchmark method. Finally, downstream models trained on multiple imputations produced by `opt.impute` significantly outperform multiple imputations produced by `mice` in 3/5 missing data scenarios for classification and 5/5 scenarios for regression.

The structure of the paper is as follows. In Section 2, we formulate the missing data imputation problem as an optimization problem, present a general first-order method `opt.impute` that can be used to find high-quality solutions, and derive the algorithms for each model: K-NN, SVM, and trees. We also discuss a cross-validation procedure and extensions of `opt.impute` to multiple imputation. In Section 3, we compare the imputation quality and performance on downstream tasks of `opt.impute` to benchmark imputation methods on a wide range of real data sets. In Section 4, we discuss the benefits from adopting such framework and suggest areas for future work. We conclude in Section 5.

2. Methods for Optimal Imputation

In this section, we pose the missing data problem as an optimization problem in which we optimize the missing values in all data points and dimensions simultaneously. We introduce a general imputation framework on mixed data (continuous and categorical) based upon first-order methods applied to this problem. Within this framework, we use K-nearest neighbors, SVM, and decision tree based imputation as examples to define three specific optimization problems. For each problem, we present two first-order methods used to find high-quality solutions: block coordinate descent (BCD) and coordinate descent (CD).

Let $\mathbf{X} = \{\mathbf{x}_i\}_{i=1}^n$ be the data set given with p variables. Without loss of generality, we assume each data vector $\mathbf{x}_i$ contains continuous variables indexed by $d \in \{1, 2, \ldots, p_0\}$ and categorical variables indexed by $d \in \{p_0 + 1, \ldots, p_0 + p_1\}$ with $p_0 + p_1 = p$. As a pre-processing step, we transform all continuous variables to have unit standard deviation. We leave all categorical variables unchanged, and assume the dth categorical variable $d \in \{p_0 + 1, \ldots, p_0 + p_1\}$ takes values among k_d classes. Note that if all data is continuous $p_0 = 0$, while if all data is categorical $p_1 = 0$. The missing and known values are specified by the following sets:

$$\begin{aligned}
\mathcal{M}_0 &= \{(i,d) : \text{entry } x_{id} \text{ is missing, } 1 \le d \le p_0\},\\
\mathcal{N}_0 &= \{(i,d) : \text{entry } x_{id} \text{ is known, } 1 \le d \le p_0\},\\
\mathcal{M}_1 &= \{(i,d) : \text{entry } x_{id} \text{ is missing, } p_0 + 1 \le d \le p_0 + p_1\},\\
\mathcal{N}_1 &= \{(i,d) : \text{entry } x_{id} \text{ is known, } p_0 + 1 \le d \le p_0 + p_1\}.
\end{aligned}$$

We also refer to the full missing pattern as $\mathcal{M} := \mathcal{M}_0 \cup \mathcal{M}_1$. Let $\mathbf{W} \in \mathbb{R}^{n \times p_0}$ be the matrix of imputed continuous values, where w_{id} is the imputed value for entry x_{id}, $d \in \{1, \ldots, p_0\}$. Similarly, let $\mathbf{V} \in \{1, \ldots, k_1\} \times \ldots \times \{1, \ldots, k_{p_1}\}$ be the matrix of imputed categorical values, where v_{id} is the imputed value for entry x_{id}, $d \in \{p_0 + 1, \ldots, p_0 + p_1\}$. We refer to the full imputation for observation $\mathbf{x}_i$ as $(\mathbf{w}_i, \mathbf{v}_i)$ in the following sections.

2.1 General Problem Formulation

As the task is to impute the missing values, for each model the key decision variables are the imputed values $\{w_{id} : (i,d) \in \mathcal{M}_0\}$ and $\{v_{id} : (i,d) \in \mathcal{M}_1\}$. We also introduce auxiliary decision variables as well; denote these as $\mathbf{U}$. For instance, in a K-NN based approach, indicator variables $z_{ij}, 1 \le i, j \le n$ are introduced to identify the neighbor assignment for each pair of points $\mathbf{x}_i$, $\mathbf{x}_j$. For a given set of imputed values and a given model, there is a cost function $c(\cdot)$ associated with it. Our goal is to solve the following optimization problem:

$$\begin{aligned}
\min \quad & c(\mathbf{U}, \mathbf{W}, \mathbf{V}; \mathbf{X}) \\
\text{s.t.} \quad & w_{id} = x_{id} \quad (i,d) \in \mathcal{N}_0, \\
& v_{id} = x_{id} \quad (i,d) \in \mathcal{N}_1, \\
& (\mathbf{U}, \mathbf{W}, \mathbf{V}) \in \mathcal{U},
\end{aligned} \tag{1}$$

where $\mathcal{U}$ is the set of all feasible combinations $(\mathbf{U}, \mathbf{W}, \mathbf{V})$ of auxiliary vectors and imputations. For example, in a K-NN based approach, this includes the constraints that each

point has exactly K neighbors and the assignment variables are binary. We list the auxiliary variables and cost functions corresponding to each of the imputation models K-NN, SVM, and trees in Table 2. Note that the cost function can be different for continuous and categorical variables. We can introduce a parameter that controls the relative contribution to the cost between the continuous and categorical variables, or scale continuous variables appropriately. For the remainder of the paper the latter is assumed for simplicity of notation.

Model	U	$c(\mathbf{U}, \mathbf{W}, \mathbf{V}; \mathbf{X})$
K-NN	$\mathbf{Z}$	$\sum_{i\in\mathcal{I}}\sum_{j=1}^{n} z_{ij}\Big[\sum_{d=1}^{p_0}(w_{id}-w_{jd})^2 + \sum_{d=p_0+1}^{p_0+p_1}\mathbb{1}_{\{v_{id}\neq v_{jd}\}}\Big]$
SVM	$[\boldsymbol{\beta}, \boldsymbol{\theta}, \boldsymbol{\gamma}, \boldsymbol{\gamma}^*, \boldsymbol{\xi}]$	$\frac{1}{2}(\|\boldsymbol{\beta}\|_{\mathcal{H}}^2 + \|\boldsymbol{\theta}\|_{\mathcal{H}}^2) + C\sum_{i=1}^{n}\left(\sum_{d=1}^{p_0}(\gamma_{id}+\gamma_{id}^*) + \sum_{d=p_0+1}^{p_0+p_1}\xi_{id}\right)$
Trees	$\mathbf{T}$	$\sum_{i=1}^{n}\sum_{j=1}^{n}\Big[\sum_{d=1}^{p_0} t_{ij}^d(w_{id}-w_{jd})^2 + \sum_{d=p_0+1}^{p_0+p_1} t_{ij}^d\mathbb{1}_{\{v_{id}\neq v_{jd}\}}\Big]$

Table 2: Variables and cost functions for each imputation model. Variables for K-NN, SVM, and trees are defined in Sections 2.3, 2.4, and 2.5 respectively.

This problem is non-convex for K-NN, SVM, and tree models. To obtain a certifiable optimal solution, one can reformulate the problem with integer variables and solve it using a mixed integer solver. We ran computational experiments and found that solving such mixed integer problems requires a long time to reach a certifiably optimal solution. As a result, we present a general imputation algorithm `opt.impute` which approximates the solution to Problem (1) very fast using first-order methods.

2.2 First-Order Method for the General Problem

To obtain high-quality solutions to Problem (1), we can use first-order methods with random warm starts. In particular, we will focus on block coordinate descent (BCD) and coordinate descent (CD) (Bertsekas, 1999). Algorithm 1, which we refer to as `opt.impute`, implements BCD or CD for Problem (1). The variables $\mathbf{U}, \mathbf{W}, \mathbf{V}$, and $\mathbf{X}$ as well as the cost function $c(\cdot)$ are summarized in Table 2 for K-NN, SVM, and trees. The detailed solution methods for Problems (2), (3), (4), and (5) for K-NN, SVM, and tree imputation models are described in Sections 2.3-2.5, respectively.

By construction, the objective function value strictly decreases by at least δ_0 until termination. It follows that the number of steps needed for the algorithm to terminate is $\lceil \frac{1}{\delta_0} c(\mathbf{U}^0, \mathbf{W}^0, \mathbf{V}^0; \mathbf{X}) \rceil$, where $\mathbf{W}^0, \mathbf{V}^0$ are the initialization values, $\mathbf{X}$ is data, and $\mathbf{U}^0$ is the argmin in Equation (2). However, the algorithm is not guaranteed to find a global minimum for Problem (1) (Wright, 2015).

In the next sections, we discuss three example models and the optimization problem formulations. For each model and each first-order method, we derive the specific updates

Algorithm 1 `opt.impute`

Input: $\mathbf{X} \in \mathbb{R}^{n\times p_0} \times \{1,\ldots,k_1\} \times \ldots \times \{1,\ldots,k_{p_1}\}$, a data matrix with some missing entries $\mathcal{M} = \{(i,d) : x_{id} \text{ is missing}\}$, $\delta_0 > 0$, and warm start $\mathbf{W}^0 \in \mathbb{R}^{n\times p_0}$, $\mathbf{V}^0 \in \{1,\ldots,k_1\} \times \ldots \times \{1,\ldots,k_{p_1}\}$.

Output: $\mathbf{X}^{imp}$ a full matrix with imputed values.

Procedure:

Initialize $\delta \leftarrow \infty$, $\mathbf{W}^{old} \leftarrow \mathbf{W}^0$, $\mathbf{V}^{old} \leftarrow \mathbf{V}^0$.

while $\delta > \delta_0$ **do**

① Update $\mathbf{U}^*$ using model dependent information:

$$\begin{aligned} \mathbf{U}^* \leftarrow \arg\min_{\mathbf{U}} \;& c(\mathbf{U}, \mathbf{W}^{old}, \mathbf{V}^{old}; \mathbf{X}) \\ \text{s.t.} \;& (\mathbf{U}, \mathbf{W}^{old}, \mathbf{V}^{old}) \in \mathcal{U}. \end{aligned} \tag{2}$$

② Update the imputation $\mathbf{W}^*$, $\mathbf{V}^*$, following either:

②a block coordinate descent (BCD):

$$\begin{aligned} \mathbf{W}^*, \mathbf{V}^* \leftarrow \arg\min_{\mathbf{W},\mathbf{V}} \;& c(\mathbf{U}^*, \mathbf{W}, \mathbf{V}; \mathbf{X}) \\ \text{s.t.} \;& w_{id} = x_{id} \qquad (i,d) \in \mathcal{N}_0, \\ & v_{id} = x_{id} \qquad (i,d) \in \mathcal{N}_1, \\ & (\mathbf{U}^*, \mathbf{W}, \mathbf{V}) \in \mathcal{U}, \end{aligned} \tag{3}$$

or

②b coordinate descent (CD):

$$\begin{aligned} w_{jr}^* \leftarrow \arg\min_{w_{jr}} \;& c(\mathbf{U}^*, \mathbf{W}, \mathbf{V}; \mathbf{X}) \\ \text{s.t.} \;& w_{id} = x_{id} \qquad (i,d) \in \mathcal{N}_0, \\ & v_{id} = x_{id} \qquad (i,d) \in \mathcal{N}_1, \\ & w_{id} = w_{id}^* \qquad (i,d) \in \mathcal{M}_0 \backslash (j,r), \\ & v_{id} = v_{id}^* \qquad (i,d) \in \mathcal{M}_1, \\ & (\mathbf{U}^*, \mathbf{W}, \mathbf{V}) \in \mathcal{U}, \end{aligned} \tag{4}$$

$$\begin{aligned} v_{jr}^* \leftarrow \arg\min_{v_{jr}} \;& c(\mathbf{U}^*, \mathbf{W}, \mathbf{V}; \mathbf{X}) \\ \text{s.t.} \;& w_{id} = x_{id} \qquad (i,d) \in \mathcal{N}_0, \\ & v_{id} = x_{id} \qquad (i,d) \in \mathcal{N}_1, \\ & w_{id} = w_{id}^* \qquad (i,d) \in \mathcal{M}_0, \\ & v_{id} = v_{id}^* \qquad (i,d) \in \mathcal{M}_1 \backslash (j,r), \\ & (\mathbf{U}^*, \mathbf{W}, \mathbf{V}) \in \mathcal{U}. \end{aligned} \tag{5}$$

③ $\delta \leftarrow c(\mathbf{U}^*, \mathbf{W}^*, \mathbf{V}^*; \mathbf{X}) - c(\mathbf{U}^{old}, \mathbf{W}^{old}, \mathbf{V}^{old}; \mathbf{X})$.

④ $(\mathbf{U}^{old}, \mathbf{W}^{old}, \mathbf{V}^{old}) \leftarrow (\mathbf{U}^*, \mathbf{W}^*, \mathbf{V}^*)$.

end while

$\mathbf{X}^{imp} \leftarrow [\mathbf{W}^*; \mathbf{V}^*]$

for $\mathbf{U}, \mathbf{W}, \mathbf{V}$ that we use in our optimization-based imputation procedure. After, we describe a cross-validation procedure to select the specific model and parameters for the imputation.

2.3 K-NN Based Imputation

We first define a distance metric between rows $(\mathbf{w}_i, \mathbf{v}_i)$ and $(\mathbf{w}_j, \mathbf{v}_j)$ as

$$d_{ij} := \sum_{d=1}^{p_0} (w_{id} - w_{jd})^2 + \sum_{d=p_0+1}^{p_0+p_1} \mathbb{1}_{\{v_{id} \neq v_{jd}\}}. \tag{6}$$

Next, we introduce the binary variables:

$$z_{ij} = \begin{cases} 1, & \text{if } (\mathbf{w}_j, \mathbf{v}_j) \text{ is among the } K\text{-nearest neighbors of } (\mathbf{w}_i, \mathbf{v}_i) \\ & \text{with respect to distance metric (6)}, \\ 0, & \text{otherwise.} \end{cases}$$

We further define the set of indices $\mathcal{I} := \{i : \mathbf{x}_i \text{ has at least one missing coordinate}\}$. The optimization problem for the K-NN based imputation model is:

$$\begin{aligned} \min \quad & c(\mathbf{Z}, \mathbf{W}, \mathbf{V}; \mathbf{X}) := \sum_{i \in \mathcal{I}} \sum_{j=1}^{n} z_{ij} \Big[\sum_{d=1}^{p_0} (w_{id} - w_{jd})^2 + \sum_{d=p_0+1}^{p_0+p_1} \mathbb{1}_{\{v_{id} \neq v_{jd}\}} \Big] \\ \text{s.t.} \quad & w_{id} = x_{id} && (i,d) \in \mathcal{N}_0, \\ & v_{id} = x_{id} && (i,d) \in \mathcal{N}_1, \\ & z_{ii} = 0 && i \in \mathcal{I}, \\ & \sum_{j=1}^{n} z_{ij} = K && i \in \mathcal{I}, \\ & \mathbf{Z} \in \{0,1\}^{|\mathcal{I}| \times n}. \end{aligned} \tag{7}$$

By optimality, it follows that $z_{ij} = 1$ if and only if $(\mathbf{w}_j, \mathbf{v}_j)$ is among the K-nearest neighbors of $(\mathbf{w}_i, \mathbf{v}_i)$. Therefore, solving Problem (7) produces the missing value imputation which minimizes the sum of distances from each point $(\mathbf{w}_i, \mathbf{v}_i), i \in \mathcal{I}$ to its K-nearest neighbors. Note that the relation $\mathbb{1}_{\{v_{id} \neq v_{jd}\}}$ can be modeled with binary variables. Problem (7) is a nonconvex optimization problem with both continuous and binary variables. Correspondingly, it is difficult to solve to provable optimality, even if the data set contains continuous variables only.

Next, we describe the updates in Algorithm 1 for K-NN based imputation. We refer to this specific imputation method as `opt.knn`.

2.3.1 `OPT.KNN`

In step (1), to update the auxiliary variables $\mathbf{Z}$, first fix all imputed values $\mathbf{W}$, $\mathbf{V}$. Problem (2) decomposes by $i \in \mathcal{I}$ into the assignment problems:

$$\begin{aligned} \min_{\mathbf{z}_i} \quad & \sum_{j=1}^{n} z_{ij} d_{ij} \\ \text{s.t.} \quad & z_{ii} = 0, \\ & \sum_{j=1}^{n} z_{ij} = K, \\ & \mathbf{z}_i \in \{0,1\}^n. \end{aligned} \tag{8}$$

The optimal solution to Problem (8) can be found using a simple sorting procedure on the distances $\{d_{ij}\}_{j=1}^n$. For each $i \in \mathcal{I}$, we find the K-nearest neighbors of $(\mathbf{w}_i, \mathbf{v}_i)$ and set $z_{ij} = 1$ for these neighbors, $z_{ij} = 0$, otherwise.

Next, we fix $\mathbf{Z}$ and update the imputed values $\mathbf{W}, \mathbf{V}$ using either BCD or CD. In step (2a), the BCD update, Problem (3) decomposes by dimension $d = 1, \ldots, p$. For each continuous dimension $d = 1, \ldots, p_0$, we consider the following quadratic optimization problem:

$$\begin{aligned} \min_{\mathbf{w}^d} \quad & \sum_{i \in \mathcal{I}} \sum_{j=1}^{n} z_{ij} (w_{id} - w_{jd})^2 \\ \text{s.t.} \quad & w_{id} = x_{id} && (i,d) \in \mathcal{N}_0, \end{aligned}$$

where $\mathbf{w}^d \in \mathbb{R}^n$ are the imputed values in the dth dimension. Taking partial derivative of the objective function with respect to w_{id} for some missing entry $(i,d) \in \mathcal{M}_0$ and setting it to zero, we obtain after some simplifications:

$$(K + \sum_{j \in \mathcal{I}} z_{ji}) w_{id} - \sum_{(j,d) \in \mathcal{M}_0} (z_{ij} + z_{ji}) w_{jd} - \sum_{(j,d) \in \mathcal{N}_0} (z_{ij} + \mathbb{1}_{\{j \in \mathcal{I}\}} z_{ji}) x_{jd} = 0. \tag{9}$$

For each continuous dimension d, we have a system of equations of the form (9) which we can solve to determine the optimal imputed values $w_{id}, (i,d) \in \mathcal{M}_0$. To simplify notation, suppose that the missing values for dimension d are $\widetilde{\mathbf{w}} := (\widetilde{w}_{1d}, \ldots, \widetilde{w}_{ad})$ and the known values are $\widetilde{\mathbf{x}} := (\widetilde{x}_{(a+1)d}, \ldots, \widetilde{x}_{nd})$. Then, the set of optimal imputed missing values $\widetilde{\mathbf{w}}$ is the solution to the linear system $\mathbf{Q}\widetilde{\mathbf{w}} = \mathbf{R}\widetilde{\mathbf{x}}$, where

$$\mathbf{Q} = \begin{bmatrix} K + \sum_{j \in \mathcal{I}} z_{j1} - 2z_{11} & -z_{12} - z_{21} & \cdots & -z_{1a} - z_{a1} \\ -z_{21} - z_{12} & K + \sum_{j \in \mathcal{I}} z_{j2} - 2z_{22} & \cdots & -z_{2a} - z_{a2} \\ \vdots & & \ddots & \vdots \\ -z_{a1} - z_{1a} & -z_{a2} - z_{2a} & \cdots & K + \sum_{j \in \mathcal{I}} z_{ja} - 2z_{aa} \end{bmatrix},$$

$$\mathbf{R} = \begin{bmatrix} z_{1(a+1)} + \mathbb{1}_{\{(a+1)\in\mathcal{I}\}} z_{(a+1)1} & \cdots & z_{1n} + \mathbb{1}_{\{n\in\mathcal{I}\}} z_{n1} \\ \vdots & & \vdots \\ z_{a(a+1)} + \mathbb{1}_{\{(a+1)\in\mathcal{I}\}} z_{(a+1)a} & \cdots & z_{an} + \mathbb{1}_{\{n\in\mathcal{I}\}} z_{na} \end{bmatrix}.$$

Note that when K is sufficiently large, the matrix $\mathbf{Q}$ is positive semidefinite and therefore invertible. If $\mathbf{Q}$ is singular, then we may add a small positive perturbation to the diagonal of $\mathbf{Q}$ so that the matrix becomes positive semidefinite. Therefore, without loss of generality there is a closed-form solution $\widetilde{\mathbf{w}} = \mathbf{Q}^{-1}\mathbf{R}\widetilde{\mathbf{x}}$ to this system of equations for each continuous dimension d.

In order to update $\mathbf{V}$, we solve the following integer linear optimization problem for each categorical dimension $d = (p_0+1), \ldots, p$:

$$\begin{aligned} \min_{\mathbf{v}^d} \quad & \sum_{i\in\mathcal{I}} \sum_{j=1}^{n} z_{ij} y_{ij} \\ \text{s.t.} \quad & v_{id} = x_{id} && (i,d) \in \mathcal{N}_1, \\ & v_{id} - v_{jd} \le y_{ij} k_d && i = 1,\ldots,n, j = 1,\ldots,n, \\ & v_{jd} - v_{id} \le y_{ij} k_d && i = 1,\ldots,n, j = 1,\ldots,n, \\ & y_{ij} \in \{0,1\}^{n\times n}, \end{aligned}$$

where $\mathbf{v}^d \in \{1,\ldots,k_d\}^n$ are the imputed values for the dth dimension. Here, the indicator variables y_{ij} take values equal to $\mathbb{1}_{\{v_{jd}\neq v_{jd}\}}$ in the optimal solution.

In step (2b), following the CD method, we update the missing imputed values one at a time. Each $w_{id}, (i,d) \in \mathcal{M}_0$ is imputed as the minimizer of the following:

$$\min_{w_{id}} \quad \sum_{j=1}^{n} z_{ij}(w_{id} - w_{jd})^2 + \sum_{j\in\mathcal{I}} z_{ji}(w_{jd} - w_{id})^2.$$

Solving the above gives

$$w_{id} = \frac{\sum_{j=1}^{n} z_{ij} w_{jd} + \sum_{j\in\mathcal{I}} z_{ji} w_{jd}}{K + \sum_{j\in\mathcal{I}} z_{ji}}. \tag{10}$$

We can interpret the missing value imputation (10) as a weighted average of the K nearest neighbors of $\mathbf{x}_i$, along with all points $\mathbf{x}_j$ which include $\mathbf{x}_i$ as a neighbor. Similarly, each categorical variable $v_{id}, (i,d) \in \mathcal{M}_1$ is imputed as the minimizer of the following:

$$\min_{v_{id}} \quad \sum_{j=1}^{n} z_{ij} \mathbb{1}_{\{v_{id}\neq v_{jd}\}} + \sum_{j\in\mathcal{I}} z_{ji} \mathbb{1}_{\{v_{jd}\neq v_{jd}\}}.$$

The solution is

$$v_{id} = \text{mode}\big(\{\{v_{jd} : z_{ij} = 1\}, \{v_{jd} : z_{ji} = 1\}\}\big).$$

Here, we set v_{id} to be the highest frequency category among the K nearest neighbors of $\mathbf{x}_i$, along with all points $\mathbf{x}_j$ which include $\mathbf{x}_i$ as a nearest neighbor. In practice, we use this update for $v_{id}, (i,d) \in \mathcal{M}_1$ in place of the update for $\mathbf{V}$ in BCD because it is much faster computationally.

2.4 Mixed SVM Based Imputation

In this section, we consider a second model for imputation, based upon SVM regression for imputing continuous features and SVM classification for imputing categorical features. First, define $\widetilde{\mathbf{v}}_i \in \{-1,1\}^{p_2}$ to be a dummy encoded representation of $\mathbf{v}_i$, where $p_2 = \sum_{d=p_0+1}^{p_0+p_1} k_d - p_1$. Let $\widetilde{v}_{id}^{fixed}, (i,d) \in \mathcal{N}_2$ be the known dummy encoded values. For each continuous feature $d \in \{1,\ldots,p_0\}$, let $(\boldsymbol{\beta}_d, \beta_{d0}) \in \mathbb{R}^{p_0+p_2+1}$ be the coefficients for an SVM regression model regressing feature d on the other features with the dummy encoding. Let $(\boldsymbol{\theta}_d, \theta_{d0}) \in \mathbb{R}^{p_0+p_2+1}$ be the coefficients for an SVM classification model predicting dummy feature d based upon the other features. Note that it is also possible to use a multi-class SVM model to predict each categorical feature directly, as described by Crammer and Singer (2001), using parameters of the form $\mathbf{M} \in \mathbb{R}^{k_d\times(p_0+p_2+1)}$ for each feature $d \in \{p_0+1,\ldots,p_0+p_1\}$. In this case, we would keep the dummy encoded decision variables as covariates to predict the other features and add constraints relating $v_{id}, (i,d) \in \mathcal{M}_1$ and $\widetilde{v}_{id}, (i,d) \in \mathcal{M}_2$. For illustrative purposes and simplicity of notation, we present the formulation using binary SVM to predict each dummy variable d.

We consider the following optimization problem:

$$\begin{aligned} \min \quad & c([\boldsymbol{\beta},\boldsymbol{\theta}], \mathbf{W}, \widetilde{\mathbf{V}}; \mathbf{X}) := \frac{1}{2}\left(\|\boldsymbol{\theta}\|^2 + \|\boldsymbol{\beta}\|^2\right) + C\left(\sum_{i=1}^{n}\sum_{d=1}^{p_0}(\gamma_{id} + \gamma_{id}^*) + \sum_{i=1}^{n}\sum_{d=p_0+1}^{p_0+p_1}\xi_{id}\right) \\ \text{s.t.} \quad & x_{id} = w_{id} && (i,d) \in \mathcal{N}_0, \\ & \widetilde{v}_{id} = \widetilde{v}_{id}^{fixed} && (i,d) \in \mathcal{N}_2, \\ & \beta_{dd} = 0 && d = 1,\ldots,p_0, \\ & \theta_{dd} = 0 && d = 1,\ldots,p_2, \\ & \gamma_{id} \ge w_{id} - (\boldsymbol{\beta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \beta_{d0}) - \epsilon && d = 1,\ldots,p_0, i = 1\ldots,n, \\ & \gamma_{id}^* \ge (\boldsymbol{\beta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \beta_{d0}) - w_{id} - \epsilon && d = 1,\ldots,p_0, i = 1\ldots,n, \\ & \xi_{id} \ge 1 - \widetilde{v}_{id}(\boldsymbol{\theta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \theta_{d0}) && d = 1,\ldots,p_2, i = 1\ldots,n, \\ & \gamma_{id} \ge 0 && d = 1,\ldots,p_0, i = 1\ldots,n, \\ & \gamma_{id}^* \ge 0 && d = 1,\ldots,p_0, i = 1\ldots,n, \\ & \xi_{id} \ge 0 && d = 1,\ldots,p_2, i = 1\ldots,n, \\ & \widetilde{v}_{id} \in \{-1,1\} && d = 1,\ldots,p_2, i = 1\ldots,n. \end{aligned} \tag{11}$$

This formulation is based upon SVM with a linear kernel; however we can extend Problem (11) to arbitrary kernels, including the multi-class cases, using the modified objective function

$$c([\boldsymbol{\beta},\boldsymbol{\theta}], \mathbf{W}, \mathbf{V}; \mathbf{X}) := \frac{1}{2}(\|\boldsymbol{\beta}\|_{\mathcal{H}}^2 + \|\boldsymbol{\theta}\|_{\mathcal{H}}^2) + C\left(\sum_{i=1}^{n}\sum_{d=1}^{p_0}(\gamma_{id} + \gamma_{id}^*) + \sum_{i=1}^{n}\sum_{d=p_0+1}^{p_0+p_1}\xi_{id}\right),$$

where $\|\cdot\|_{\mathcal{H}}$ is the norm in a given Reproducing Kernel Hilbert Space $\mathcal{H}$.

Another important aspect of Problem (11) is the compound objective function, which is the summation of objective functions derived from both SVM regression and SVM classification methods. Observe that if we fix a single imputed entry w_{id} or $\widetilde{v}_{id}$, the contribution to the objective function scales linearly as $(\boldsymbol{\beta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \beta_{d0})$ if d is continuous or scales linearly as $(\boldsymbol{\theta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \theta_{d0})$ if d is categorical. This is desirable because we do not wish to weight continuous and categorical variables unequally in our imputation. Next, we describe the updates in Algorithm 1 for mixed SVM based imputation, which we refer to as `opt.svm`.

2.4.1 `opt.svm`

In step (1), we fix the imputed values $\mathbf{W}, \mathbf{V}$ and update the auxiliary variables $[\boldsymbol{\beta}, \boldsymbol{\beta}_0, \boldsymbol{\theta}, \boldsymbol{\theta}_0]$. Independent of the choice of kernel, Problem (2) decomposes by dimension p into p_0 SVM regression problems and p_2 SVM classification problems for the categorical variables. For each continuous feature $d \in \{1, \ldots, p_0\}$, we update $\boldsymbol{\beta}_d, \beta_{d0}$ by solving

$$\begin{aligned}
\min \quad & \frac{1}{2}\|\boldsymbol{\beta}\|^2 + C\sum_{i=1}^{n}(\gamma_{id} + \gamma_{id}^*) \\
\text{s.t.} \quad & \beta_{dd} = 0 \\
& \gamma_{id} \geq w_{id} - (\boldsymbol{\beta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \beta_{d0}) - \epsilon \quad i = 1 \ldots, n, \\
& \gamma_{id}^* \geq (\boldsymbol{\beta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \beta_{d0}) - w_{id} - \epsilon \quad i = 1 \ldots, n, \\
& \gamma_{id} \geq 0 \qquad\qquad\qquad\qquad i = 1, \ldots, n, \\
& \gamma_{id}^* \geq 0 \qquad\qquad\qquad\qquad i = 1, \ldots, n.
\end{aligned} \tag{12}$$

Similarly, for each dummy feature $d \in \{p_0 + 1, \ldots, p_0 + p_2\}$, we update $\boldsymbol{\theta}_d, \theta_{d0}$ by solving

$$\begin{aligned}
\min \quad & \frac{1}{2}\|\boldsymbol{\theta}\|^2 + C\sum_{i=1}^{n}\xi_{id} \\
\text{s.t.} \quad & \theta_{dd} = 0 \\
& \xi_{id} \geq 1 - \widetilde{v}_{id}(\boldsymbol{\theta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \theta_{d0}) \quad i = 1 \ldots, n, \\
& \xi_{id} \geq 0 \qquad\qquad\qquad\qquad i = 1, \ldots, n.
\end{aligned} \tag{13}$$

Taking the Lagrangian duals, both Problems (12) and (13) can be reformulated as quadratic optimization problems which can be solved efficiently (Cortes and Vapnik, 1995).

Next, we fix the auxiliary variables $[\boldsymbol{\beta}, \boldsymbol{\beta}_0, \boldsymbol{\theta}, \boldsymbol{\theta}_0]$ and update the imputed values $\mathbf{W}, \mathbf{V}$ using BCD or CD. In step (2a), Problem (2) decomposes by observation i into n nonlinear

integer optimization problems. For each i we solve

$$\begin{aligned}
\min_{\mathbf{w}_i, \widetilde{\mathbf{v}}_i} \quad & \sum_{d=1}^{p_0}(\gamma_{id} + \gamma_{id}^*) + \sum_{d=p_0+1}^{p_0+p_1}\xi_{id} \\
\text{s.t.} \quad & x_{id} = w_{id} \qquad\qquad\qquad\qquad (i,d) \in \mathcal{N}_0, \\
& \gamma_{id} \geq w_{id} - (\boldsymbol{\beta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \beta_{d0}) - \epsilon \quad d = 1, \ldots, p_0, \\
& \gamma_{id}^* \geq (\boldsymbol{\beta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \beta_{d0}) - w_{id} - \epsilon \quad d = 1, \ldots, p_0, \\
& \xi_{id} \geq 1 - \widetilde{v}_{id}(\boldsymbol{\theta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \theta_{d0}) \qquad d = 1, \ldots, p_2, \\
& \gamma_{id} \geq 0 \qquad\qquad\qquad\qquad d = 1, \ldots, p_0, \\
& \gamma_{id}^* \geq 0 \qquad\qquad\qquad\qquad d = 1, \ldots, p_0, \\
& \xi_{id} \geq 0 \qquad\qquad\qquad\qquad d = 1, \ldots, p_2,
\end{aligned} \tag{14}$$

where $(\mathbf{w}_i, \widetilde{\mathbf{v}}_i) \in \mathbb{R}^{p_0} \times \{-1, 1\}^{p_2}$ is the imputation for observation $\mathbf{x}_i$. Note that if all features are continuous, Problem (14) reduces to a linear optimization problem. Because we are using the dummy encoding in this formulation, it is possible to obtain an imputation in which multiple classes are selected for a single categorical entry. In this case, when `opt.svm` terminates, we select the imputation among the set of potential candidates which minimizes the objective function of Problem (14).

In step (2b), we update the imputed values one at a time. To update $w_{id}, (i,d) \in \mathcal{M}_0$, we solve the one-dimensional linear optimization problem:

$$\begin{aligned}
\min_{w_{id}} \quad & \sum_{d=1}^{p_0}(\gamma_{id} + \gamma_{id}^*) + \sum_{d=p_0+1}^{p_0+p_1}\xi_{id} \\
\text{s.t.} \quad & \gamma_{id} \geq w_{id} - (\boldsymbol{\beta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \beta_{d0}) - \epsilon \quad d = 1, \ldots, p_0, \\
& \gamma_{id}^* \geq (\boldsymbol{\beta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \beta_{d0}) - w_{id} - \epsilon \quad d = 1, \ldots, p_0, \\
& \xi_{id} \geq 1 - \widetilde{v}_{id}(\boldsymbol{\theta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \theta_{d0}) \qquad d = 1, \ldots, p_2, \\
& \gamma_{id} \geq 0 \qquad\qquad\qquad\qquad d = 1, \ldots, p_0, \\
& \gamma_{id}^* \geq 0 \qquad\qquad\qquad\qquad d = 1, \ldots, p_0, \\
& \xi_{id} \geq 0 \qquad\qquad\qquad\qquad d = 1, \ldots, p_2.
\end{aligned}$$

We update $\widetilde{v}_{id}, (i,d) \notin \mathcal{N}_2$ by solving the binary optimization problem:

$$\begin{aligned}
\min_{\widetilde{v}_{id} \in \{-1,1\}} \quad & \sum_{i=1}^{n}\sum_{d=1}^{p_0}\big(\max\{w_{id} - (\boldsymbol{\beta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \beta_{d0}) - \epsilon, 0\} + \max\{(\boldsymbol{\beta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \beta_{d0}) - w_{id} - \epsilon, 0\}\big) + \\
& \sum_{i=1}^{n}\sum_{d=1}^{p_2}\big(1 - \widetilde{v}_{id}(\boldsymbol{\theta}_d^T \begin{bmatrix} \mathbf{w}_i \\ \widetilde{\mathbf{v}}_i \end{bmatrix} + \theta_{d0})\big).
\end{aligned}$$

2.5 Tree Based Imputation

Finally, we consider an imputation model based on classification and regression trees. For each dimension we train a decision tree to predict the missing values, using the other features as covariates. We train regression trees to predict each of the continuous variables and classification trees to predict each of the categorical variables. Given a regression tree for continuous dimension d, we will impute $x_{id}, (i,d) \in \mathcal{M}_0$ to be the mean in dimension d of all points in the same leaf node as $\mathbf{x}_i$. Similarly, given a classification tree for dimension d, we will impute $x_{id}, (i,d) \in \mathcal{M}_1$ to be the mode in dimension d of all points in the same leaf node as $\mathbf{x}_i$.

For general prediction tasks, we can use greedy (Breiman et al., 1984) or globally optimal (Bertsimas and Dunn, 2017) solution methods to train the decision trees. In this case, we consider the latter approach because it admits a clear optimization model with mixed integer decision variables which fits into our framework for imputation. For each dimension d, let $\mathbf{T}^d \in \{0,1\}^{n \times n}$ denote the set of indicator variables

$$t_{ij}^d = \begin{cases} 1, & \text{if } (\mathbf{w}_i, \mathbf{v}_i), (\mathbf{w}_j, \mathbf{v}_j) \text{ are in the same leaf node} \\ & \text{of the decision tree for dimension } d, \\ 0, & \text{otherwise.} \end{cases}$$

Let $(\mathbf{T}^d, \mathbf{W}, \mathbf{V}) \in \mathcal{T}^d$ denote the set of optimal decision tree constraints for dimension d as described in (Bertsimas and Dunn, 2017). We consider the following optimization problem:

$$\begin{aligned} \min \quad & c(\mathbf{T}, \mathbf{W}, \mathbf{V}; \mathbf{X}) := \sum_{i=1}^n \sum_{j=1}^n \Big[\sum_{d=1}^{p_0} t_{ij}^d (w_{id} - w_{jd})^2 + \sum_{d=p_0+1}^{p_0+p_1} t_{ij}^d \mathbb{1}_{\{v_{id} \neq v_{jd}\}} \Big] \\ \text{s.t.} \quad & w_{id} = x_{id} && (i,d) \in \mathcal{N}_0, \\ & v_{id} = x_{id} && (i,d) \in \mathcal{N}_1, \\ & (\mathbf{T}^d, \mathbf{W}, \mathbf{V}) \in \mathcal{T}^d && d = 1, \ldots, p, \end{aligned} \tag{15}$$

Next, we describe the updates in Algorithm 1 for decision tree based imputation, which we refer to as `opt.tree`.

2.5.1 `opt.tree`

In step ①, we fix the imputed values $\mathbf{W}, \mathbf{V}$ and update the decision tree variables $\mathbf{T}$. For each continuous feature, we fit a regression tree to predict $\mathbf{w}^d$ based upon the other features. Similarly, for each categorical feature, we fit a classification tree to predict $\mathbf{v}^d$ based upon the other features. In practice, we may use greedy or optimal methods to find these trees; however, if we use greedy trees then the objective function value $c(\mathbf{T}, \mathbf{W}, \mathbf{V}; \mathbf{X})$ is not guaranteed to be monotonically decreasing over the course of the algorithm.

Next, we fix $\mathbf{T}$ and update the imputed values $\mathbf{W}, \mathbf{V}$ using BCD or CD. In step (2a), Problem (3) decomposes by dimension into p_0 quadratic optimization problems and p_1

integer optimization problems. For each continuous dimension $d = 1, \ldots, p_0$, we solve:

$$\begin{aligned} \min_{\mathbf{w}^d} \quad & \sum_{i=1}^n \sum_{j=1}^n t_{ij}^d (w_{id} - w_{jd})^2 \\ \text{s.t.} \quad & w_{id} = x_{id} && (i,d) \in \mathcal{N}_0, \end{aligned}$$

where $\mathbf{w}^d \in \mathbb{R}^n$ are the imputed values in the dth dimension. This is a quadratic optimization problem with an explicit optimum. For each $w_{id}, (i,d) \in \mathcal{M}_0$, an optimal solution is

$$w_{id} = \begin{cases} \dfrac{\sum_{(j,d) \in \mathcal{N}_0^d} t_{ij}^d x_{jd}}{\sum_{(j,d) \in \mathcal{N}_0^d} t_{ij}^d}, & \text{if} \quad \sum_{(j,d) \in \mathcal{N}_0^d} t_{ij}^d \geq 1, \\ \dfrac{1}{|\mathcal{N}_0^d|} \displaystyle\sum_{(j,d) \in \mathcal{N}_0^d} x_{jd}, & \text{otherwise,} \end{cases}$$

where $\mathcal{N}_0^d := \{(i,r) \in \mathcal{N}_0 : r = d\}$. This solution corresponds to setting each missing entry equal to the mean of all observed values in the same leaf node. If the number of non-missing values in the same leaf node as w_{id} is zero, i.e., $\sum_{(j,d) \in \mathcal{N}_0^d} t_{ij}^d = 0$, then we set all of the values in that leaf node to the mean impute solution.

For each categorical dimension $d = p_0 + 1, \ldots, p_0 + p_1$, we solve the following integer optimization problem:

$$\begin{aligned} \min_{\mathbf{v}^d} \quad & \sum_{i=1}^n \sum_{j=1}^n t_{ij}^d \mathbb{1}_{\{v_{id} \neq v_{jd}\}} \\ \text{s.t.} \quad & v_{id} = x_{id}, && (i,d) \in \mathcal{N}_1, \end{aligned}$$

where $\mathbf{v}^d \in \{1, \ldots, k_d\}^n$ are the imputed values for the dth dimension. An optimal solution is

$$v_{id} = \begin{cases} \text{mode}\big(\{x_{jd} : t_{ij}^d = 1, (j,d) \in \mathcal{N}_1\}\big) & \text{if} \quad |\{x_{jd} : t_{ij}^d = 1, (j,d) \in \mathcal{N}_1\}| \geq 1, \\ \text{mode}\big(\{x_{jd} : (j,d) \in \mathcal{N}_1\}\big) & \text{otherwise.} \end{cases}$$

In step (2b), we update the missing imputed values one at a time, which results in slightly different closed form solutions for $w_{id}, (i,d) \in \mathcal{M}_0$ and $v_{id}, (i,d) \in \mathcal{M}_1$. First, we update the continuous variables $w_{id}, (i,d) \in \mathcal{M}_0$ by solving:

$$\min_{w_{id}} \quad 2 \sum_{j=1}^n t_{ij}^d (w_{id} - w_{jd})^2. \tag{16}$$

An optimal solution to Problem (16) is

$$w_{id} = \begin{cases} \dfrac{\sum_{j \neq i} t_{ij}^d w_{jd}}{\sum_{j \neq i} t_{ij}^d}, & \text{if} \quad \sum_{j \neq i} t_{ij}^d \geq 1, \\ \dfrac{1}{|\mathcal{N}_0^d|} \displaystyle\sum_{(j,d) \in \mathcal{N}_0^d} x_{jd}, & \text{otherwise.} \end{cases}$$

Next, we update the categorical variables $v_{id}, (i,d) \in \mathcal{M}_1$ one at a time by solving:

$$\min_{v_{id}} \quad 2\sum_{j=1}^{n} t_{ij}^{d} \mathbb{1}_{\{v_{id} \neq v_{jd}\}}. \tag{17}$$

An optimal solution to Problem (17) is

$$v_{id} = \begin{cases} \text{mode}\big(\{v_{jd} : t_{ij}^{d} = 1\}\big), & \text{if} \quad |\{v_{jd} : t_{ij}^{d} = 1\}| \geq 1, \\ \text{mode}\big(\{x_{jd} : (j,d) \in \mathcal{N}_1\}\big), & \text{otherwise.} \end{cases}$$

Both of these updates coincide with the predicted values from the decision trees constructed.

2.6 Model Selection Procedure

Each of the above methods and choice of hyperparameters generates some imputed values. For single imputation, a single set of imputed values should be generated in the end. We propose the following procedure for model selection.

Given $\mathbf{X}$ with existing missing data $\mathcal{M}_0, \mathcal{M}_1$, we generate an additional fixed percentage of data missing $\mathcal{M}_0^{valid}, \mathcal{M}_1^{valid}$, with the known values as the hold-out set, and perform each of the imputation methods under the combined missing pattern. We evaluate the imputation quality on the hold-out validation set by measuring how closely the imputed values resemble the ground truth values. In particular, the mean absolute error (MAE) between true and imputed values for each imputation method is calculated. The validation MAE is defined to be

$$\frac{1}{|\mathcal{M}_0^{valid}|} \sum_{(i,d) \in \mathcal{M}_0^{valid}} |w_{id} - x_{id}| + \frac{1}{|\mathcal{M}_1^{valid}|} \sum_{(i,d) \in \mathcal{M}_1^{valid}} \mathbb{1}_{\{v_{id} \neq x_{id}\}}.$$

Lower values indicate closer imputation, and perfect imputation corresponds to an MAE of zero. Another metric of imputation quality is root mean squared error (RSME), which is given by

$$\sqrt{\frac{1}{|\mathcal{M}_0^{valid}|} \sum_{(i,d) \in \mathcal{M}_0^{valid}} (w_{id} - x_{id})^2 + \frac{1}{|\mathcal{M}_1^{valid}|} \sum_{(i,d) \in \mathcal{M}_1^{valid}} \mathbb{1}_{\{v_{id} \neq x_{id}\}}}.$$

For each imputation method, the combination of hyperparameters that achieves the lowest MAE in validation (or RMSE) is selected, and the $\mathbf{X}$ is again imputed but under the original missing patterns $\mathcal{M}_0$, $\mathcal{M}_1$. This set of imputed values is now ready to be evaluated or used for downstream tasks.

The hyperparameters that we tune via this method are summarized in Table 3. In addition, we also use this cross-validation procedure to select the best method out of `opt.knn`, `opt.svm`, and `opt.tree`. We refer to this composite method as `opt.cv`. Similarly, we may use the cross-validation procedure for model selection for any set of imputations. We define `benchmark.cv` to be the procedure that selects the best method out of: `mean`, `pmm`, `bpca`, `knn`, and `iknn` that will be later used in computational comparisons (see Section 3.1 for descriptions of these individual methods).

Method	Hyperparameters
K-NN	K
SVM	C, σ^2
Trees	cp

Table 3: Hyperparameters tuned via the model selection procedure outlined in Section 2.6. σ^2 is a parameter in the radial basis function kernel, $K(\mathbf{x}_i, \mathbf{x}_j) = \exp(\frac{\|\mathbf{x}_i - \mathbf{x}_j\|}{\sigma^2})$. cp is a complexity parameter related to the depth of the decision tree.

2.7 Extensions to Multiple Imputation

Thus far, we have described `opt.impute` methods for single imputation which output a single completed data set. On the other hand, multiple imputation methods output $m \geq 2$ different completed data sets for a single missing data problem. Afterwards, analysis is performed on each of the m data sets separately, and the results are pooled (Little and Rubin, 1987). For some applications, multiple imputation is preferred because it captures the variation in missing data imputation, which enables us to compute confidence intervals for downstream models trained on the imputed data sets. In addition, the pooled results from models fit on multiple imputed data sets may provide better point estimates than models fit on a single imputed data set in some cases.

To extend `opt.impute` to produce multiple imputations, we generate m warm starts using a probabilistic procedure, run `opt.knn`, `opt.svm`, or `opt.tree` from these starting points, and output the full set of m completed data sets. These warm starts can be generated from sample draws under a previously estimated posterior distribution; an example would be using outputs from the `mice` procedure. This provides us with a representative set of imputations found by the `opt.impute` algorithm, which converges to local optima. We refer to the multiple imputation method as `opt.mi`. In the computational experiments, we use the benchmark multiple imputation method `mice` to generate the warm starts.

Note that there are other possible ways of adapting `opt.impute` to the multiple imputation schema. We may introduce m instances of artificial noise in the observed values, and solve the resulting optimization problems. Alternatively, we may run `opt.impute` on m bootstrapped samples of the original data set. Afterwards, we can analyze each of the m imputed data sets separately and pool the results as before.

3. Real-World Data Experiments

In this section, we evaluate the performance of `opt.impute` on many real-world data sets. Our comparisons include 1) the effect on imputation accuracy, and 2) the effect on the performance of downstream machine learning tasks. We compare to the most commonly used state-of-the-art methods on a large sample of data sets from the UCI Machine Learning Repository. For data sets that include categorical variables, we impute the discrete values directly using our specialized imputation methods for categorical variables and benchmark methods.

3.1 Experimental Setup

To test the accuracy of the proposed missing data imputation method, we run a series of computational experiments on data sets taken from the UCI Machine Learning Repository for both regression and classification tasks. The data sets cover a range of number of observations n and number of features p, potentially mixed with both continuous and categorical variables. The numbers of continuous (p_0) and categorical (p_1) variables in each of these data sets are given in Table 10.

In these experiments, we use full data sets in which all entries are known, and we generate patterns of missing data for various percentages ranging from 10% to 50%. We take the full data sets $\mathbf{X}$ that have no missing entries to be the ground truth. We run some of the most commonly-used and state-of-the-art methods for data imputation on these data sets to predict the missing values and compare against our optimization based imputation methods. The individual methods in this comparison are:

1. **Mean Impute** (`mean`): The simplest imputation method. For each missing value x_{id}, imputes the mean of all known values in dimension d.

2. **Predictive-Mean Matching** (`pmm`): An iterative method which imputes missing values from known values in a given dimension using linear regressions. It is commonly used for multiple imputation and can be generalized to multiple missing dimensions using the chained equations process (Buuren and Groothuis-Oudshoorn, 2011). Implemented using the `MICE` package in R.

3. **Bayesian PCA** (`bpca`): A missing data estimation method based on Bayesian principal component analysis (Oba et al., 2003). Implemented using the `pcaMethods` package in R.

4. K-**Nearest Neighbors** (`knn`): A single-step, greedy method which imputes missing values using the K-nearest neighbors of an observation based upon Euclidean distance. The candidate neighbors must have non-missing values in the imputed feature. Averaged distance is used if some other coordinates are missing. Implemented using the `impute` package in R.

5. **Iterative** K-**Nearest Neighbors** (`iknn`): Implemented in R and Julia, based on the description in the original papers (Brás and Menezes, 2007; Caruana, 2001) .

6. **Optimal Impute** (`opt.impute`): All sub-methods below use warm starts including: `mean`, `knn`, `bpca` and five random starts where the values are imputed by a random sampling of the non-missing observations of that feature. The imputation which results in the lowest objective value is selected for each method.

   (a) K-NN based (`opt.knn`): This method solves the optimal K-nearest neighbors problem (7). Convergence time depends upon the quality of the initial warm start. We run both block coordinate descent and coordinate descent for small data sets of size $n \leq 10{,}000$, and only coordinate descent for large data sets with higher n. The implementation was in the programming language Julia with fast algorithms for K-nearest neighbor calculations.

   (b) SVM Regression and Classification based (`opt.svm`): This method solves the maximum margin support vector machine problem (11) using a radial basis function kernel. For continuous variables, we use ϵ-support vector regression; for categorical variables, we use classical support vector machines. These problems were solved using coordinate descent methods. The implementation was in Julia using the `scikit-learn` package in Python.

   (c) Decision Tree based (`opt.tree`): This method solves the optimal decision-tree problem (15). For continuous variables, a single-leaf regularized regression tree is used; for categorical variables, a fast coordinate descent-based algorithm for solving Optimal Classification Trees is used (Bertsimas and Dunn, 2017). We run coordinate descent for the imputation problems. The implementation was in Julia using the packages `glmnet` and `OptimalTrees`.

In addition, we consider two composite methods: `opt.cv`, which selects the best method from `opt.knn`, `opt.svm`, and `opt.tree`; and `benchmark.cv`, which selects the best method from `mean`, `pmm`, `bpca`, `knn`, and `iknn`. These composite methods use the cross-validation procedure described in Section 2.6. To generate the validation set for each missing data problem, we randomly sample an additional 10% of the entries to be hidden under the MCAR assumption. After running each individual method, we select the one that gives the lowest MAE on the validation set. We re-run this method on the original missing data set to obtain the final imputation.

Each imputation method was run for a maximum time limit of 12 hours on each data set. The quality of the imputations is evaluated using the same MAE and RMSE metrics defined in Section 2.6. For each of the `opt.impute` methods, we also record and present the convergence in objective value and MAE to show the progress over the iterations.

3.1.1 Missing Pattern

Because the mechanism which generates the pattern of missing data can affect imputation quality, we run experiments under two different missing data mechanisms: missing completely at random (MCAR) and not missing at random (NMAR). These statistical assumptions are summarized in Table 4. The MCAR assumption implies that the missing pattern is completely independent from both the missing and observed values. The NMAR assumption implies that the missing pattern depends upon the missing values. There is an intermediate type of assumption, missing at random (MAR), which implies that the missing pattern depends only upon the observed values, but not upon the missing values. Because this assumption is less general than NMAR, we do not consider this mechanism for our experiments.

To generate MCAR patterns of missing data, we randomly sample a subset of the entries in $\mathbf{X}$ to be missing, assuming that each entry is equally likely to be chosen. The NMAR patterns are generated by sampling missingness indicators as independent Bernoulli random variables where each probability p_{id} equals the probability that a normal random variable $N(x_{id}, \epsilon)$ is greater than a particular threshold for dimension d. The threshold for each dimension d is the quantile of $\mathbf{X}^d$ which corresponds to the desired missing percentage level.

Mechanism of Missing Data	Assumption
Missing Completely at Random (MCAR)	$f(\mathcal{M}\|\mathbf{X}^{obs},\mathbf{X}^{miss}) = f(\mathcal{M})$
Missing at Random (MAR)	$f(\mathcal{M}\|\mathbf{X}^{obs},\mathbf{X}^{miss}) = f(\mathcal{M}\|\mathbf{X}^{obs})$
Not Missing at Random (NMAR)	$f(\mathcal{M}\|\mathbf{X}^{obs},\mathbf{X}^{miss})$ is a function of $\mathbf{X}^{miss}$

Table 4: Statistical assumptions of mechanisms used to generate patterns of missing data $\mathcal{M}$ for data set $\mathbf{X}$. Here, we suppose that f is the underlying density of the missing pattern, and $\mathbf{X}^{obs}, \mathbf{X}^{miss}$ are the observed and missing components of the data set, respectively.

Note that regardless of the missing data scenarios generated for the experiments, in order to make fair comparisons, we always use MCAR as the generating mechanism for cross-validation.

3.1.2 Downstream Tasks

For 10 data sets from the UCI Machine Learning Repository, we run further experiments to evaluate the impact of these imputations on the intended downstream machine learning tasks. This selection includes a representative sample of 5 data sets for regression and 5 data sets for classification, with dependent variable observations $\mathbf{Y} \in \mathbb{R}^n$ and $\mathbf{Y} \in \{0,1\}^n$ respectively. We evaluate both single and multiple imputation methods in these experiments.

For single imputation, we consider `opt.cv` and `benchmark.cv`. First, we divide each downstream data set using a 50% training/testing split. Next, we randomly sample a fixed percentage of the entries in $\mathbf{X}$ to be missing completely at random, ranging from 10% to 50%. For each missing percentage, we impute the missing values in the training set and then fit standard machine learning algorithms to obtain a classification or regression model. We impute the missing values in the testing set by running the imputation methods on the full data set. For the regression tasks, we fit cross-validated LASSO and SVR models and compute the out-of-sample accuracy on the imputed testing set. For the classification tasks, we fit cross-validated SVM and Optimal Trees models and compute the out-of-sample R^2 on the imputed testing set.

We also evaluate the performance of multiple imputation methods on the downstream tasks. In these experiments, we consider the following methods:

1. **Multivariate Imputation by Chained Equations** (`mice`): An iterative method which imputes each dimension with missing values one at a time drawing from distributions fully conditional on the other variables. We use predictive mean matching for continuous variables and logistic regression for categorical variables. This process is repeated to generate m fully imputed data sets. Implemented via the `MICE` package in R.

2. **Optimal Impute for Multiple Imputation** (`opt.mi`): Starting from m warm starts, we run `opt.knn`, `opt.svm`, or `opt.tree` to generate a new set of m fully imputed data sets. We use warm starts produced by `mice`, and the best model among K-NN, SVM, and trees is selected initially via cross-validation.

For both `mice` and `opt.mi`, we generate $m = 5$ multiple imputations for the training set and fit an ensemble of predictive models on these completed training sets. We make predictions on the test set by averaging the predictions from the model ensemble. For the classification tasks, we use a threshold value of 0.5. We run this experiment 100 times with different training/testing splits and distributions of missing values for each data set and report the averaged out-of-sample of the predictive models.

3.2 Results

We run the methods on 84 data sets from the UCI Machine Learning Repository. These data sets range in size from $n = 23$ to 5,875 observations and dimension $p = 2$ to 124. In the following sections, we first show the convergence for each of the `opt.impute` methods is fast and generally leads to a decrease in MAE. Next, we demonstrate that the quality of the imputations is significantly higher for `opt.impute` compared to the reference methods, and that this leads to improved performance on downstream classification and regression tasks. We further discuss the sensitivity of imputation quality to the model parameters (K, cp, C), warm starts, descent method (BCD or CD), and data characteristics including the missing pattern. Finally, we compare the computational burden of each method.

3.2.1 Convergence

Figure 1 represents the change in objective value and MAE over the iterations for each of the `opt.impute` methods based on mean warm start, using `iris` data set as an example. We present results for `opt.knn` (CD and BCD), `opt.svm` (CD), and `opt.tree` (CD). The convergence is relatively fast for all methods; in particular, the BCD algorithm for K-NN converges significantly faster than the CD algorithm. When comparing the change in MAE, the value generally monotonically decreases with each iteration in concordance with the change in objective, especially during the first few iterations. In some paths, MAE increases slightly after a certain point. RMSE exhibits the same behavior and is therefore not plotted. This suggests a potential issue of overfitting to the known observations, which may be remedied by regularization or early stopping. In summary, the solution paths illustrate: 1) convergence is often fast, and 2) the objective functions are decent proxies for out-of-sample MAEs, and 3) imputation quality for each first-order method generally improves until convergence.

In general, we found that the BCD algorithm for `opt.knn` did not significantly improve upon imputation accuracy compared to the CD algorithm, but only improved upon speed. Because the BCD algorithms do not scale as well, we restricted our analysis to the CD algorithms for `opt.svm` and `opt.tree`.

3.2.2 Imputation Accuracy

The imputation accuracy for each data set is presented in Table 10 for the scenario in which 30% of the entries are missing, assuming MCAR. We compare the benchmark ones and each individual `opt.impute` method (not cross-validated); the method with the lowest

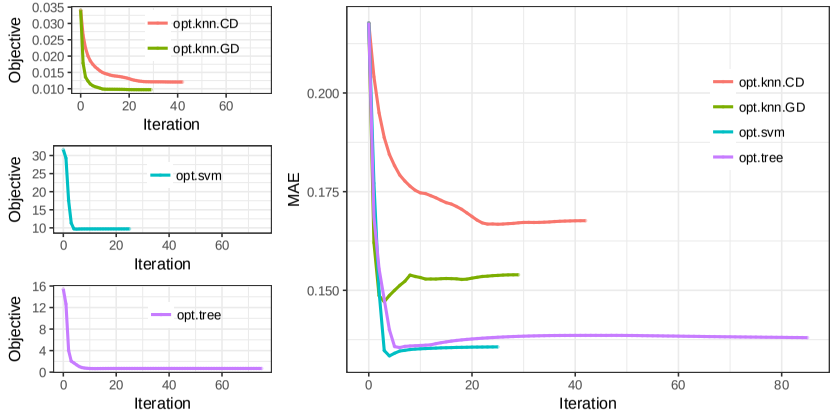

Figure 1: Solution paths of `opt.impute` methods on the `iris` data set. These plots show the objective value and mean absolute error (MAE) of the imputation over the course of the algorithm. Each path represents a different algorithm: `opt.knn` (BCD and CD), `opt.svm` (CD), and `opt.tree` (CD). Mean imputation warm start is used.

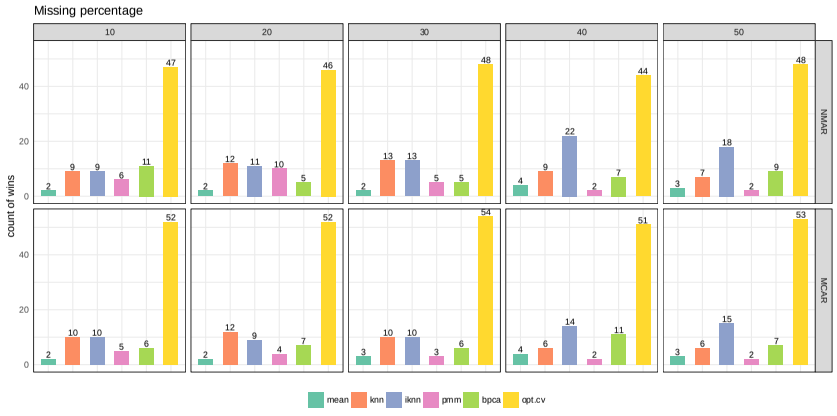
MAE (i.e., best imputation accuracy) is bolded. Among all data sets, at least one of the `opt.impute` methods obtains the lowest MAE in 76.2% of the data sets, followed by `iknn` and `bpca` imputation methods with 9 and 4 wins each. Comparatively, `mean`, `knn`, and `pmm` impute have the weakest performances. Among the `opt.impute` methods, the tree based model achieves the lowest MAE in most data sets.

We repeat this experiment for other percentages of missing data with the winning counts summarized in Figure 2, using `opt.cv` as our proposed method. We show the number of times that each method achieves the best overall imputation with lowest MAE and RMSE under five different missing data percentages, as well MCAR and NMAR scenarios. In all missing data scenarios, our proposed method produces the best imputations in more than half of the data sets according to both performance metrics. Among the comparator methods, `mean` and `pmm` are generally among the weaker ones. When MAE is the metric, the heuristic method `iknn` performs the best among the benchmark methods, suggesting that the idea of iteratively updating the imputed values have merits. At higher percentages of missing values (the right-most subfigures), `bpca` improves in its performance when RMSE is the metric of evaluation, but still not as strong as `opt.cv`.

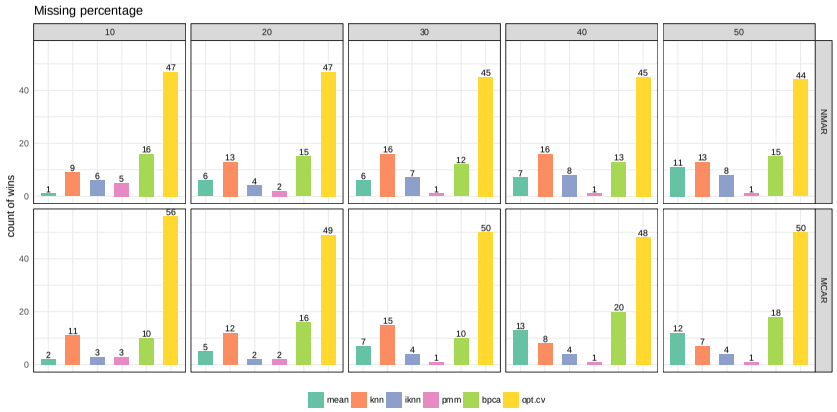
In Figure 3, we present summary results of the MAE and RMSE values as geometric means across all data sets for each missing percentage and missing data mechanism, with the confidence bands representing one geometric standard deviation multiplied above and divided below by the mean. Comparatively, `opt.cv` achieves the lowest average MAE and RMSE values for all missing percentages. At the 10% missing data percentage, the average MAE of the `opt.cv` imputations is 0.100, a reduction of 14.9% from the average MAE of 0.118 obtained by the best benchmark method `knn`. As missing percentages increase, `opt.cv` remains the most accurate imputation method, with the average MAE of 0.142 at 50% missing, a reduction of 12.1% from the average MAE of 0.172 obtained by the next best method `knn`. The performance of `opt.cv` relative to benchmark ones does not appear to differ drastically between the MCAR and NMAR scenarios, with overall higher MAE for NMAR across most methods, as expected.

To isolate the effect of each individual method from the cross-validation procedure, we further summarize the results by comparing one method at a time against the benchmark ones. Table 5 presents the statistical comparisons between each `opt.impute` method and each benchmark method. We conduct pairwise Wilcoxon signed rank tests and paired t-tests between each pair of methods. When comparing `opt.cv` against the benchmark methods, our proposed cross-validated method achieves statistically significant lower rank and lower MAE compared to each benchmark. For each individual `opt.impute` method, with the exception of `opt.svm` against heuristic `iknn`, the `opt.impute` one has statistically significant lower rank than every benchmark. The decrease in MAE is still statistically significant when `mean`, `bpca`, and `pmm` are comparators, but no longer statistically significant when compared to `knn` or `iknn`. This suggests that each of the proposed methods holds its own against most benchmark ones, especially under rank comparisons, but the cross-validation procedure adds another layer of improvement in imputation quality.

Finally, we compare against the same cross-validated procedure introduced in Section 2.6 applied on all the benchmark methods (`benchmark.cv`) with results in Figure 2b. At 30% missing data, we observe 10.1% average improvement in MAE down to 0.118 from 0.131.



(a) Counts based on lowest MAE



(b) Counts based on lowest RMSE

Figure 2: Number of data sets in which each missing data imputation method achieves lowest mean absolute error (MAE) or root mean squared error (RMSE) from true value, with ties included. Each panel represents a different missing percentage ranging from 10% to 50%. Panels in the top row are for not missing at random scenarios, whereas the ones in the bottom row are for missing completely at random scenarios.

Table 5: Pairwise Wilcoxon signed-rank tests and t-tests between `opt.impute` and benchmark methods, with the p-values adjusted for multiple comparisons.

`opt.impute`	**Benchmark**	Δ rank (adjusted p-value)	Δ MAE (adjusted p-value)
opt.cv	mean	-0.7855 (<0.001***)	-0.0502 (<0.001***)
opt.cv	pmm	-0.8355 (<0.001***)	-0.0399 (<0.001***)
opt.cv	bpca	-0.6329 (<0.001***)	-0.0214 (0.0019**)
opt.cv	knn	-0.6281 (<0.001***)	-0.0134 (0.0499*)
opt.cv	iknn	-0.5352 (<0.001***)	-0.0199 (0.0046**)
opt.knn	mean	-0.6424 (<0.001***)	-0.0419 (<0.001***)
opt.knn	pmm	-0.6091 (<0.001***)	-0.0316 (<0.001***)
opt.knn	bpca	-0.4875 (<0.001***)	-0.0131 (0.0601)
opt.knn	knn	-0.3850 (<0.001***)	-0.0051 (0.4574)
opt.knn	iknn	-0.3611 (<0.001***)	-0.0116 (0.1011)
opt.svm	mean	-0.5852 (<0.001***)	-0.0355 (<0.001***)
opt.svm	pmm	-0.4875 (<0.001***)	-0.0252 (<0.001***)
opt.svm	bpca	-0.2515 (<0.001***)	-0.0067 (0.3335)
opt.svm	knn	-0.1371 (0.0033**)	+0.0013 (0.8485)
opt.svm	iknn	-0.0322 (0.0884)	-0.0052 (0.4589)
opt.tree	mean	-0.7139 (<0.001***)	-0.0454 (<0.001***)
opt.tree	pmm	-0.7712 (<0.001***)	-0.0351 (<0.001***)
opt.tree	bpca	-0.5137 (<0.001***)	-0.0165 (0.0176*)
opt.tree	knn	-0.4136 (<0.001***)	-0.0086 (0.2152)
opt.tree	iknn	-0.3135 (<0.001***)	-0.0151 (0.0337*)

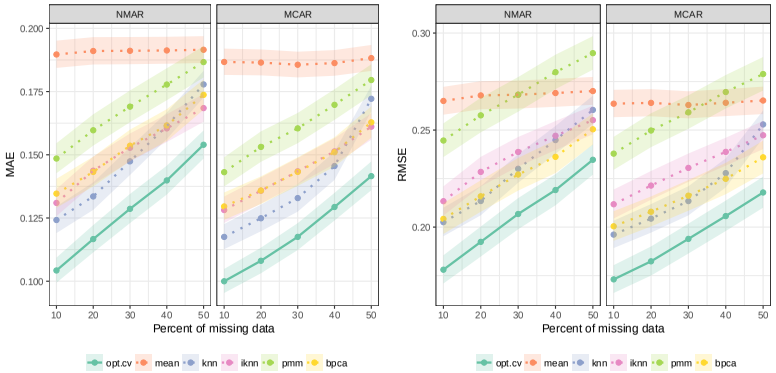
Further, `opt.cv` achieves highest imputation accuracy in more than 78.6% of the data sets compared to `benchmark.cv`.

3.2.3 Performance on Downstream Tasks

Next, we evaluate the performance of standard machine learning algorithms for classification and regression trained on the imputed data. We consider the data sets in Table 6, which were selected as a representative subsample from the UCI Machine Learning Repository data sets. These data sets range in size, having $n = 150$ to 5,875 observations and $p = 4$ to 16 features. The difficulty of the regression or classification task on the completely known data set also varies widely. The baseline out-of-sample accuracy of an SVM model for the binary classification problems ranges from 77% to 100%, and the baseline out-of-sample R^2 of a LASSO model for the regression problems ranges from 0.09 to 0.82. For each of these data sets, the downstream tasks become more difficult as the missing data percentage increases.

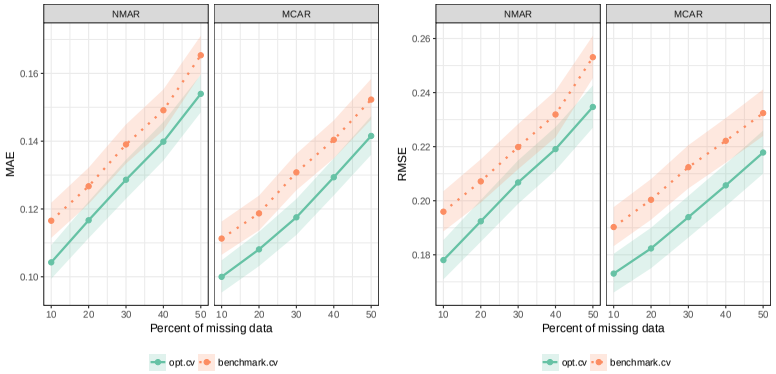
In Figure 4, we show how the imputation method chosen impacts the performance for downstream tasks, across different data sets and different missing data percentages. In Tables 7 and 8, we show pairwise t-test results, aggregating out-of-sample performance results by downstream task and missing percentage. These results include comparisons for both single and multiple imputation methods.

For the single imputation methods, we observe that the improvement of `opt.cv` over the best cross-validated benchmark method is statistically significant for all missing percentages in both classification and regression tasks. Moreover, this improvement in out-of-sample



(a) Average MAE

(b) Average RMSE



(c) Average RMSE

(d) Average RMSE

Figure 3: Mean absolute error (MAE) and root mean squared error (RMSE) across 84 data sets for each imputation method, comparing `opt.cv` against all benchmark methods and against the cross-validated best benchmark method, `benchmark.cv`. The center lines are geometric mean with one geometric standard deviation multiplied above and divided below. The x-axis corresponds to the percentage of missing entries.

Downstream Task	Name	(n,p)	Baseline Accuracy or R^2
Classification	climate-model-crashes	(540, 18)	0.95
	connectionist-bench	(990, 10)	0.93
	ecoli	(336, 8)	0.96
	iris	(150, 4)	1.00
	pima-indians-diabetes	(768, 8)	0.77
Regression	abalone	(4177, 7)	0.51
	auto-mpg	(392, 8)	0.82
	housing	(506, 13)	0.71
	parkinsons-telemonitoring-total	(5875, 16)	0.09
	wine-quality-white	(4898, 11)	0.27

Table 6: Data sets considered for downstream regression and classification tasks. For classification tasks, we list the average baseline out-of-sample accuracy of an SVM model fit on the full data set, and for regression tasks, we list the average baseline out-of-sample R^2 of a LASSO model fit on the full data set.

accuracy and R^2 is monotonically increasing with the missing percentage. At 50% missing data, the average improvement in out-of-sample accuracy is 1.7% for classification tasks, and the average improvement in out-of-sample R^2 is 0.024 for regression tasks.

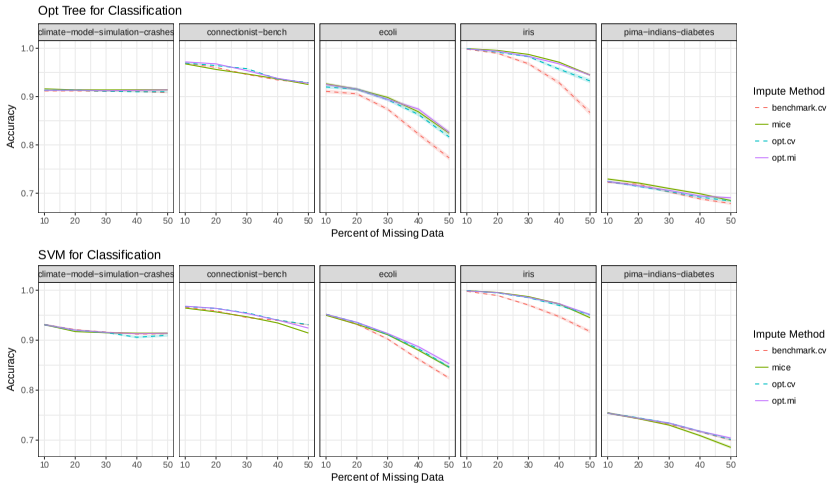
For the multiple imputation methods, we observe that the improvement of `opt.mi` over `mice` is statistically significant for all missing percentages in the regression tasks, and 3/5 missing percentages in the classification tasks. At the 50% missing percentage, the average improvement is 0.5% in out-of-sample accuracy for classification tasks and 0.010 in out-of-sample R^2 for regression tasks. While these improvements are smaller than those for single imputation, they are significant at the $p = 0.001$ level.

Overall, these results suggest that `opt.impute` leads to gains in out-of-sample performance in both single and multiple imputation settings. The relative improvements are consistently greatest at the highest missing percentages, where the imputation method selected has the largest impact on the downstream performance.

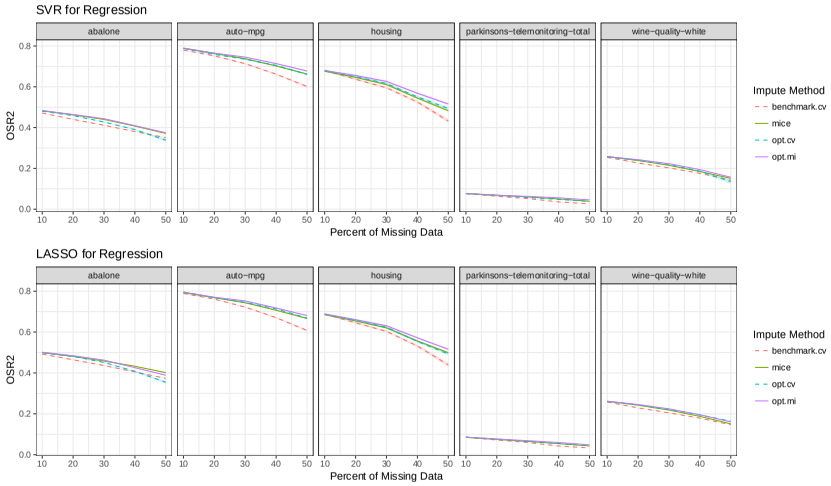
Finally, we compare the performance of single vs multiple imputation for `opt.impute`. We observe that the improvement of `opt.mi` over `opt.cv` is statistically significant in 8/10 scenarios, with the largest improvements occurring at the highest missing percentages. At the 50% missing percentage, the average improvement is 0.4% in out-of-sample accuracy for classification tasks and 0.017 in out-of-sample R^2 for regression tasks. These improvements are similar to the gains in performance over `mice`.

3.2.4 Sensitivity to Parameters

Model performance can be impacted by various parameters. For a specific data set and model, the performance can be sensitive to hyperparameters such as the number of neighbors K in K-NN and the trade-off parameter C for SVM. It is also affected by the number of random starts and choice of algorithm between block coordinate descent and coordinate descent. Data characteristics such as sample size n, feature dimension p, and missing data



(a) Average out-of-sample accuracy values with standard errors of Optimal Trees and SVM models



(b) Average out-of-sample R^2 values with standard errors of SVR and LASSO models

Figure 4: Average out-of-sample performance of downstream models trained on data imputed via `opt.impute` and benchmark methods across a sample of classification and regression problems and a range of missing data percentages. Multiple and single imputation methods are solid and dotted lines respectively.

	Δ Out-of-Sample Accuracy (adjusted p-value)		
Missing %	`opt.mi - mice`	`opt.cv - benchmark.cv`	`opt.mi - opt.cv`
10	-0.0001 (1.0000)	0.0016 (0.0059**)	0.0006 (0.2076)
20	0.0018 (0.0059**)	0.0026 (<0.001***)	0.0008 (0.2076)
30	0.0005 (0.9858)	0.0082 (<0.001***)	0.0002 (1.0000)
40	0.0018 (0.0491*)	0.0113 (<0.001***)	0.0043 (<0.001***)
50	0.0052 (<0.001***)	0.0171 (<0.001***)	0.0038 (<0.001***)

Table 7: Pairwise t-tests between `opt.impute` and benchmark methods for downstream classification tasks, with the p-values adjusted for multiple comparisons.

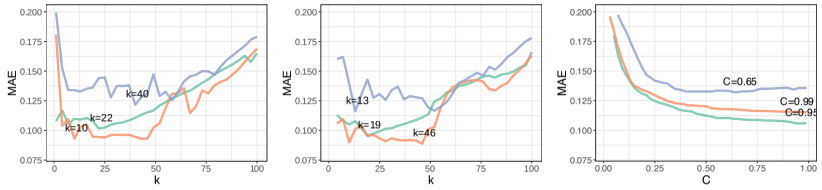
	Δ Out-of-Sample R^2 (adjusted p-value)		
Missing %	`opt.mi - mice`	`opt.cv - benchmark.cv`	`opt.mi - opt.cv`
10	0.0014 (<0.001***)	0.0034 (<0.001***)	0.0013 (<0.001***)
20	0.0029 (<0.001***)	0.0113 (<0.001***)	0.0027 (<0.001***)
30	0.0071 (<0.001***)	0.0161 (<0.001***)	0.0077 (<0.001***)
40	0.0085 (<0.001***)	0.0195 (<0.001***)	0.0108 (<0.001***)
50	0.0097 (<0.001***)	0.0237 (<0.001***)	0.0174 (<0.001***)

Table 8: Pairwise t-tests between `opt.impute` and benchmark methods for downstream regression tasks, with the p-values adjusted for multiple comparisons.

percentage may affect the imputation quality as well. This section explores how these parameters impact the imputation quality.

We found that all of the imputation model hyperparameters that we investigated affect imputation accuracy. Figure 5 shows the relationship between the hyperparameters and MAE for various data sets and missing patterns. For `opt.knn` (CD and BCD), the out-of-sample MAE first decreases and then increases as the hyperparameter increases. When K reaches the sample size, the imputation is equivalent to mean imputation. For `opt.svm`, the imputation accuracy remains relatively constant with respect to changes in parameter C after a certain threshold. There were no external parameters for trees, as the trees in each step were pruned during the training process. Overall, these plots suggest that the `opt.impute` methods are relatively robust even if their hyperparameters are not known exactly.

For `opt.knn`, the performances of block coordinate descent and coordinate descent are comparable. Under most missing data scenarios, block coordinate descent achieves the lower MAE in a few more data sets. As the missing data percentage increases, in many problems both block coordinate descent and coordinate descent methods find the same solutions, thus resulting in a tie. Comparing between the two, there is no clear dominant strategy; in practice we recommend running both methods and then selecting the imputation which yields the lowest objective value.



(a) K in `opt.knn.CD` (b) K in `opt.knn.BCD` (c) C for `opt.svm`

Figure 5: Sensitivity of MAE to the choice of K for the number of neighbors for K-NN coordinate descent, K-NN block coordinate descent, and the trade-off parameter C for SVM in data set `iris`. The colors represent different missing data percentages. The parameter value that achieves lowest MAE is labeled for each missing data percentage.

3.2.5 Computational Speed

Next, we compare the computational time required for all imputation methods across a selection of six UCI data sets and missing data patterns. Each method was run on a single thread of a machine with an Intel Xeon CPU E5-2650 (2.00 GHz) Processor and limited to 8 GB RAM with a time limit of 4 hours. For various `opt.impute` methods, we report the running times for `mean` warm starts, as multiple warm starts can be trivially parallelized. The results are shown below in Table 9.

Mean imputation is almost instantaneous and is therefore not presented in the table. For small-scale problems on the `iris` data set, all imputation methods finish quickly. As the data dimension p increases (for example, in the `libras-movement` data set), most `opt.impute` methods scale better than the `pmm` method. As the sample size n increases, `opt.knn.CD` also scales better than `pmm`, as seen in `banknote-authentication` and `skin-segmentation`. Among the `opt.impute` methods, tree based imputation scales very well with respect to sample size n but not dimension p. Despite its high imputation quality, SVM based imputation scales relatively poorly with respect to both n and p. Among the proposed methods, `opt.knn.CD` has the best scalability in both n and p.

In particular, when comparing coordinate descent and block coordinate descent methods, the former performs best when the data size is large. When n is in the 100,000s, the coordinate descent method still converges within one hour (see `skin-segmentation`). For the block coordinate descent method, each iteration requires solving a separate system of linear equations for each continuous dimension, or an integer optimization problem for each of the categorical dimensions. On the other hand, the main bottleneck of `opt.knn.CD` is computing the K-NN assignment on $\mathbf{X}$ to update $\mathbf{Z}$ each iteration, which requires only $O(n \log n)$ time. When the problem size is small, the running times of the two methods are comparable, and the block coordinate descent method is slightly faster because it converges in fewer iterations. However, when the number of data entries to be imputed exceeds a certain threshold, the block coordinate descent method slows down and takes much longer.

			Time (in seconds)

Table 9: Computational time comparison of benchmark and `opt.impute` imputation methods. Blank entries indicate that the method failed to converge with the 4 hour time limit.

In practice, we recommend running both when $n \leq 10{,}000$ and performing model selection between the two, and running only coordinate descent when n is larger.

4. Discussion

One of the primary contributions of this paper is the formulation of the missing data problem as a family of optimization problems. This framework accommodates almost any predictive model that describes the conditional relationship within the data, ranging from parametric to fully non-parametric models. By design, these formulations admit arbitrary missing pattern and mixed data types and do not require specific joint distributional assumptions on the data. In addition, we show how these methods can be used to generate multiple imputations.

The first-order methods that we developed to solve these optimization problem are highly scalable and produce high quality solutions. These methods are computationally fast; for example, the coordinate descent method for SVM solves problems with 100,000s of data points and 1,000s of features in seconds on a standard desktop computer. With more random starts, we obtain solutions which continue to improve upon the objective. Since random warm starts can be trivially parallelized, increasing the number of warm starts does not change the computational times materially if implemented efficiently.

For single imputation, we propose `opt.cv`, a combination method which uses cross-validation to select the best imputation objective function from K-NN, SVM, and decision tree models. We provide evidence on `opt.cv`'s strong empirical performance against benchmark single imputation methods in large scale computational experiments on 84 real-world data sets. For all of the missing data scenarios considered, `opt.cv` produces the best overall imputation for the largest number of data sets. In addition, `opt.cv` produces the lowest average MAE and RMSE for the majority of missing data scenarios. Our proposed cross-validation procedure generates additional missing pattern under MCAR, which may be further improved by adapting the generative procedure for more accurate reflection of imputation quality in the original data missing.

Further, we demonstrate that using the imputations produced by `opt.cv` with values closer to the ground truth leads to gains in out-of-sample performance on downstream regression and classification tasks. This suggests that at medium-to-high missing percentage scenarios, machine learning practitioners will benefit significantly by adopting this framework for single imputation.

For multiple imputation, we propose `opt.mi`, a method which runs `opt.impute` on a set of probabilistically generated warm starts. We show that this method offers a statistically significant improvement over both `mice` and `opt.cv` in the downstream tasks. However, the multiple imputation methods have drawbacks because they are computationally slower, require pooling after analyzing multiple data sets, and produce an ensemble of models which is less interpretable than a single model. Therefore, unless statistical inference is required, `opt.cv` may be preferable for many applications.

Given the optimization formulations introduced in this paper, there are multiple open questions for future research. We may consider alternate cost functions for missing data imputation that reflect out-of-sample performance better. For example, in the K-NN based model, we could add a regularizer term or use the L_1 distance or Mahalanobis distance

metric instead of the squared Euclidean distance metric. The tree based imputation method invites future development in fast optimal trees for convergence and better performance. Finally, solving the global optimization problem (1) fast and accurately for any of the three examples of non-convex, non-linear cost functions $c(\mathbf{U}, \mathbf{W}, \mathbf{V}; \mathbf{X})$ proposed in this paper remains an open question.

5. Conclusions

In summary, we frame the classical missing data problem as a non-convex optimization problem based upon a variety of predictive models. We propose a family of new imputation methods, `opt.impute`, which finds high quality solutions to this problem using fast first-order methods. Through extensive computational experiments on 84 data sets from the UCI Machine Learning Repository, we show that `opt.impute` yields statistically significant gains in imputation quality over state-of-the-art imputation methods, which leads to improved out-of-sample performance on downstream tasks. This approach scales to large problem sizes, generalizes to multiple imputation, and improves over state-of-the-art methods across a broad range of missing data scenarios.

Abstract

We extend the adaptive regression spline model by incorporating *saturation*, the natural requirement that a function extend as a constant outside a certain range. We fit saturating splines to data via a convex optimization problem over a space of measures, which we solve using an efficient algorithm based on the conditional gradient method. Unlike many existing approaches, our algorithm solves the original infinite-dimensional (for splines of degree at least two) optimization problem without pre-specified knot locations. We then adapt our algorithm to fit generalized additive models with saturating splines as coordinate functions and show that the saturation requirement allows our model to simultaneously perform feature selection and nonlinear function fitting. Finally, we briefly sketch how the method can be extended to higher order splines and to different requirements on the extension outside the data range.

Keywords: Convex optimization, feature selection, splines, lasso, regression

1. Introduction

Splines—piecewise polynomials with continuity constraints—are widely used to fit data (Hastie et al., 2001, §5.1). One issue with piecewise polynomials is that they behave erratically beyond their boundary knot points, and (typically) grow without bound outside of that range (Hastie et al., 2001, §5.2). This instability makes extrapolation dangerous; practitioners must take care to avoid querying spline models near or outside of the range of the training data.

Smoothing spline algorithms (De Boor, 2001; Wahba, 1990; Green and Silverman, 1994) ameliorate this problem by fitting *natural splines*, which reduce to a lower-degree polynomial beyond the boundary knots. The most commonly used varieties of smoothing splines are cubic smoothing splines (degree-three splines that reduce to linear outside the boundary knots) and linear smoothing splines, which extend as constant. The saturating splines we propose are closely related to linear smoothing splines.

Smoothing splines use an ℓ_2 or quadratic notion of complexity, and hence fit models with a predetermined and dense set of knot points (Hastie et al., 2001, §5.4). *Adaptive regression splines* (Mammen and van de Geer, 1997), on the other hand, use an ℓ_1-type penalty, which can result in a sparse set of adaptively chosen knots. However, adaptive regression splines do not reduce to lower degree outside of the range of their largest knots, and hence may suffer from instability.

We propose fitting adaptive regression splines with explicit constraints on the degree of the spline outside of a certain interval. We call such splines *saturating splines*. While the approach we take can be extended to fitting splines of arbitrary degree with constraints on arbitrary derivatives, in this paper we focus on fitting linear splines that are flat (constant) outside the data range; we mention the extension to higher degree splines in §8. We show that saturating splines inherit the knot-selection property of adaptive regression splines, while at the same time behave like natural splines near the boundaries of the data.

We also show a very important benefit of our approach in the context of fitting generalized additive models (Hastie and Tibshirani, 1990) with saturating spline coordinate functions: the saturation constraint naturally results in variable selection. Not only do we control the complexity of each coordinate function through knot selection, but with the saturation condition, no knots on a variable means the variable is out of the model. This is not true for adaptive splines, since the linear term is unpenalized and hence each variable would always be in the model. The lack of feature selection can hurt interpretability and, in certain cases, generalization. The saturation constraint we propose precludes linear functions, and in concert with the adaptive spline ℓ_1 penalty encourages coordinate functions to be identically zero. As a result, generalized additive models fit with saturating spline component functions often depend on only a few input features.

Like smoothing splines and adaptive regression splines, saturating splines arise as solutions to certain natural functional regression problems. We solve the saturating spline fitting problem by reformulating it as a convex optimization problem over a space of measures, roughly speaking, the second derivative of the fitted function. To the best of our knowledge, this approach is novel. We then apply a variant of the classical conditional gradient method (Jaggi, 2013.; Boyd et al., 2017) to this problem. At each iteration of our algorithm, an atomic measure is produced; moreover, we can uniformly bound the number of atoms, which corresponds to the number of knot points in the spline function. (While we manipulate atomic measures, we solve the problem over the space of all measures with finite total variation.) In contrast to standard coordinate descent methods, in each iteration of the conditional gradient method the weights of *two* knot points are adjusted. In the fully corrective step, we solve a finite-dimensional convex optimization problem with ℓ_1

and simple linear constraints. Numerical experiments show that the method is extremely effective in practice.

Our optimization method can exploit warm starts, i.e., it can use an initial guess for the fitted function. This allows us to compute an entire regularization path efficiently, at a cost typically just a small multiple of the effort to solve the problem for one value of the regularization parameter. Because our algorithm is based on the conditional gradient method, we can use the framework of Giesen et al. (2012) to compute a provably ϵ-suboptimal approximate regularization path. When fitting generalized additive models, the regularization path has attractive features: at critical values of the regularization parameter, new regressors are brought into (or, occasionally, out of) the model, or new knot points are added to (or deleted from) one of the existing coordinate functions. Thus our approach combines feature selection and knot point selection.

1.1 Outline

In §2 we introduce a univariate function fitting problem, inspired by the adaptive spline estimation problem of Mammen and van de Geer (1997), that includes the additional requirement that the fitted function saturate. In §3 we make the connection between our function estimation problem and standard adaptive splines, and pose the saturating spline fitting problem as a convex optimization problem over measures. In §4 we modify the classical conditional gradient method to solve this optimization problem. In §5 we extend the optimization problem and algorithm to fit generalized additive models to multivariate data. We illustrate the effectiveness of the method with several examples in §7. We discuss generalizations to higher-degree splines in §8. Finally, we discuss potential extensions and variations in §9. The appendix includes implementation details and proofs.

2. Univariate Function Fitting

We wish to fit a continuous bounded function $f : \mathbf{R} \to \mathbf{R}$ from data $(x_i, y_i) \in \mathbf{R} \times \mathcal{Y}$, $i = 1, \ldots, n$, $x_i \in [0, 1]$. To do this we will choose f to minimize a data mismatch or loss function subject to a constraint that encourages regularity in f, and an additional constraint, saturation, that we describe below.

The loss is given by

$$L(f) = \sum_{i=1}^{n} \ell(f(x_i), y_i),$$

where $\ell : \mathbf{R} \times \mathcal{Y} \to \mathbf{R}$ is nonnegative, twice differentiable, and strictly convex in its first argument. Typical loss functions include $\ell(z, w) = (z-w)^2/2$ (standard regression, $\mathcal{Y} = \mathbf{R}$), or $\ell(z, w) = \log(1 + \exp -(zw))$ (logistic regression, with $\mathcal{Y} = \{-1, 1\}$). The loss L is a convex functional of the function f that only depends on the values of f at the data points x_i. The smaller the loss, the better f fits the given data.

We constrain the function f to be simple by limiting the value of a nonnegative regularization functional R. In this paper, we take R to be the total variation of the derivative of f,

$$R(f) = \mathrm{TV}(f'),$$

a convex functional of f. For a twice-differentiable function f, recall that

$$\mathrm{TV}(f') = \int |f''(x)| \, dx, \tag{1}$$

i.e., the regularization is the ℓ_1 norm of the second derivative. (As we review in the following section, the modern definition of total variation extends this equality to nondifferentiable functions.) The total variation limit we impose on f is $R(f) \leq \tau$, where τ is a parameter that we use to trade off model fit and model regularity. This regularization constraint implicitly constrains f to be differentiable almost everywhere, with its derivative having finite total variation.

Our model f will be subject to one more constraint, that it saturates (outside the interval $[0, 1]$), which means that it is a (possibly different) constant on the two intervals outside $[0, 1]$: $f(x) = f(0)$ for $x \leq 0$, and $f(x) = f(1)$ for $x \geq 1$. In other words, f extends as a constant outside the nominal data range of $[0, 1]$. In terms of the derivative, this is equivalent to the requirement that f' exists and is zero outside $[0, 1]$.

The fitting problem is then

$$\begin{array}{ll} \text{minimize} & L(f) \\ \text{subject to} & R(f) \leq \tau, \\ & f'(x) = 0 \text{ for } x \notin [0, 1], \end{array} \tag{2}$$

where $\tau \geq 0$ is the regularization parameter. The variable to be determined is the function f, which is in the vector space of continuous functions with derivatives of finite total variation. This fitting problem is an infinite-dimensional convex optimization problem.

In applications the problem (2) is solved for a range of values of τ, which yields the regularization path. The final model is selected using a hold-out set or cross-validation. For $\tau = 0$, f must be constant and the problem (2) reduces to fitting the best constant to the data. As τ increases, f is less constrained, and our fitted model becomes more complex; eventually we expect overfitting. For example, in the case of regression, with a loss function that satisfies $\ell(u, u) = 0$ and data with distinct x_i, the fitting function is the piecewise-linear function that interpolates the data, for large enough τ.

3. Splines and Functions of Bounded Variation

In this section we explore the connection between our fitting problem and degree-one splines, i.e., piecewise-linear continuous functions, which have the form

$$f(x) = c + \sum_{i=1}^{K} w_i (x - t_i)_+, \tag{3}$$

where $(z)_+ = \max\{z, 0\}$. We assume that the t_i are distinct, and refer to them as knot points or simply knots. The scalars w_i are the weights, and c is the offset. We refer to the function $x \mapsto (x - t_i)_+$ as a hinge function, so a degree-one spline is a finite linear combination of hinge functions, plus a constant.

3.1 Functions of Bounded Variation

A right-continuous function $h : [0,1] \to \mathbf{R}$ is of bounded variation if and only if there exists a signed measure μ on $[0,1]$ with

$$h(z) = \int 1(y \le z)\, d\mu(y), \tag{4}$$

where $1(y \le z) = 1$ for $y \le z$ and 0 otherwise. The measure μ is unique; we can think of it as the derivative of h. That is, (4) is essentially the second fundamental theorem of calculus with h' replaced by μ.

We also have $\mathrm{TV}(h) = \int d|\mu|$. (This is called the total variation of the measure μ.) We will denote this using the notation $\|\mu\|_1$, to emphasize the similarity with the finite-dimensional case, or the case when h is differentiable: $\mathrm{TV}(h) = \|h'\|_1$. When the measure μ is atomic, the function h is piecewise constant with jumps at the points in the support of μ.

3.2 Splines and Derivatives with Bounded Variation

Now suppose that $f : [0,1] \to \mathbf{R}$ has a right-continuous *derivative* of bounded variation. From (4), with $h = f'$, and the fundamental theorem of calculus, we have

$$f(x) = f(0) + \int_0^x f'(z)\, dz = f(0) + \int_0^x \int 1(y \le z)\, d\mu(y)\, dz \tag{5}$$

$$= f(0) + \int \int_0^x 1(y \le z)\, dz\, d\mu(y) \tag{6}$$

$$= f(0) + \int (x-y)_+\, d\mu(y). \tag{7}$$

This shows that any such function is a (possibly infinite) linear combination of hinge functions, plus a constant (i.e., $f(0)$). In this case, the measure μ can be thought of as the *second* derivative of f.

When μ is atomic and supported on a finite set, that is,

$$\mu = \sum_{i=1}^{K} w_i \delta_{t_i},$$

f is a degree-one spline of the form (3), with $c = f(0)$. So degree-one splines correspond exactly to the case where the measure μ (roughly, the second derivative) has finite support.

We introduce the notation

$$f_\mu(x) = \int_0^x \int 1(t \le z)\, d\mu(t)\, dz = \int (x-t)_+\, d\mu(t) \tag{8}$$

to denote the function derived from the measure μ. It is, roughly speaking, the double integral of the measure μ, or the (potentially infinite) linear combination of hinge functions associated with the measure μ. The mapping from μ to f_μ is linear, and we have $\mathrm{TV}(f'_\mu) = \|\mu\|_1$. A simple example of f_μ, its first derivative f'_μ, and its (atomic measure) second derivative μ is shown in Figure 1.

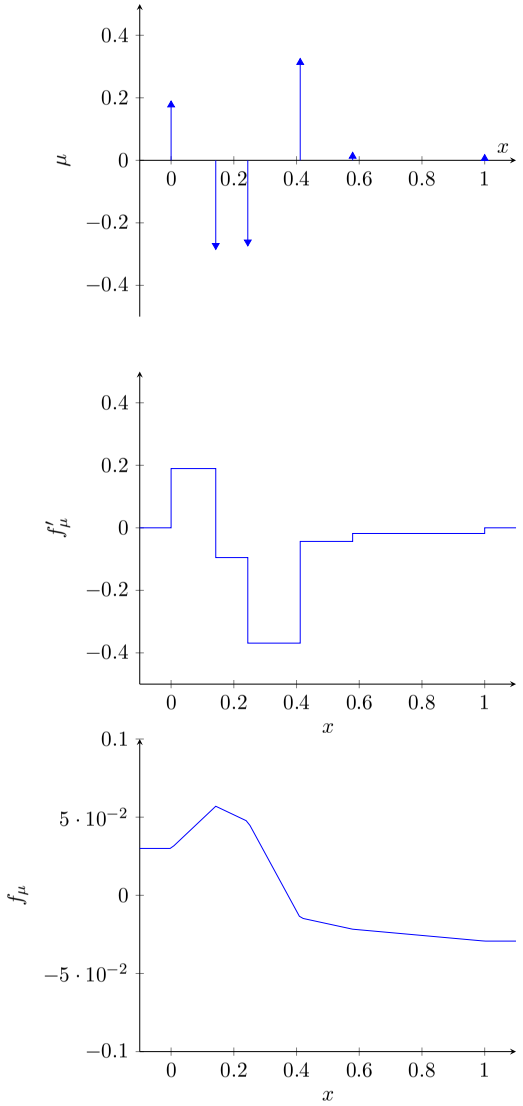

Figure 1: f_μ and f'_μ generated by the atomic measure μ (f''_μ). The regularization functional, $\mathrm{TV}(f'_\mu)$, is the sum of the absolute values of the spikes in μ. Note that the (signed) sum of the spikes in μ is zero: that is, $\int d\mu = 0$, which implies that f_μ saturates.

3.3 Fitting Splines by Optimizing Over Measures

Identifying $f = c + f_\mu$, we can solve the fitting problem (2) by minimizing over the bounded measure μ on $[0,1]$, and the constant c. The measure μ is the second derivative of f, and the constant c corresponds to $f(0)$. The total variation regularization constraint $\mathrm{TV}(f') \leq \tau$ corresponds to $\|\mu\|_1 \leq \tau$. The saturation condition holds by construction for $x < 0$; to ensure that $f'(x) = 0$ for $x > 1$, we need

$$f'(1) = f'(0) + \int_0^1 d\mu = 0.$$

In other words, saturation of f corresponds to μ having total (net) mass zero. Thus (2) can be rephrased as

$$\begin{array}{ll} \text{minimize} & L(E_x\mu + c) \\ \text{subject to} & \|\mu\|_1 \leq \tau, \\ & \int d\mu = 0 \end{array} \tag{9}$$

over the bounded measure μ on $[0,1]$, and $c \in \mathbf{R}$. Note the slight abuse of notation here: we now (and for the remainder of the paper) consider L as a functional on $\mathbf{R}^n$. In the above, E_x is the linear operator that maps μ to the vector $(f_\mu(x_1), \ldots, f_\mu(x_n))$, given by (8). E_x is clearly linear, as it is the integral of the function $\psi : \mathbf{R} \to \mathbf{R}^n$:

$$\psi(t) = ((x_1 - t)_+, \ldots, (x_n - t)_+)$$

against μ. We will apply the conditional gradient method directly to this problem.

To gain intuition about the optimization problem (9), we can consider it as a infinite-dimensional analogue of the standard lasso (Tibshirani, 1994). The lasso is the solution to the optimization problem

$$\begin{array}{ll} \text{minimize} & \frac{1}{2}\|Aw - y\|_2^2 \\ \text{subject to} & \|w\|_1 \leq \tau. \end{array} \tag{10}$$

Here w is a vector in $\mathbf{R}^d$, and $A \in \mathbf{R}^{(n,d)}$ is a matrix. Ignoring the constant term c, we see that (9) looks very similar to (10), where E_x plays the role of A; indeed, E_x is essentially a matrix with n rows and infinitely many columns. Our intuition from the lasso suggests that there should be solutions of (9) that are sparse, which here means that μ is atomic. In terms of f_μ, sparsity means there are solutions of the original functional fitting problem (2) that are degree-one splines. This is indeed the case. Theorem 1 shows that there is a solution of (9) with μ atomic, supported on no more than $n+2$ points; in other words, f_μ is a degree-one spline with $K \leq n+2$. Moreover, in practice the solution of (9) will exhibit selection, that is, it will be supported on far fewer than $n+2$ points.

Theorem 1 *Fix $x_1, \ldots, x_n \in [0,1]$ and $f : \mathbf{R} \to \mathbf{R}$ with f' (right-continuous) of bounded total variation, and f constant outside of $[0,1]$. Then there exists a degree-one saturating spline $\hat{f}$ (with an most $n+2$ knots) that matches f on x_i with $\mathrm{TV}(\hat{f}') \leq \mathrm{TV}(f')$.*

For the remainder of the paper we will ignore the constant term c. It is not difficult to adapt the algorithms we present to handle the constant term, but doing so does add some notational complexity. It's also possible to minimize out c, as it does not affect the regularization term; the resulting problem is still convex in w.

4. The Conditional Gradient Method for Fitting Splines

In this section we outline our algorithm for solving (9) (and therefore also (2)). To that end, we briefly review the classical conditional gradient method (Jaggi, 2013.) and the measure-theoretic version proposed in (Boyd et al., 2017).

The optimization problem we need to solve, (9), (without the constant term c) is

$$\begin{array}{ll} \text{minimize} & L(E_x\mu) \\ \text{subject to} & \int d\mu = 0, \\ & \|\mu\|_1 \leq \tau. \end{array} \tag{11}$$

As noted in the last section, (11) is a convex optimization problem over a space of measures. We closely follow the approach taken in Boyd et al. (2017) and apply the conditional gradient method to this problem directly.

The main benefit of this approach is that we can restrict our attention to *atomic* measures, i.e., μ of the form

$$\mu = \sum_{j=1}^K w_j \delta_{t_j}.$$

Measures of this form are easily representable in a computer, by simply storing a list of (w_j, t_j) pairs. Theorem 1 ensures that the number of knots we need to store is absolutely bounded, i.e., that our algorithm runs in bounded memory. While we manipulate atomic measures, we solve the problem (11) over all bounded measures.

One thing to note about finitely-supported atomic measures is that we can easily optimize over the weights w_j with the knot locations t_j fixed, since this corresponds to a finite-dimensional convex optimization problem amenable to any standard algorithm. Our algorithm makes use of this fact, and alternates between adding pairs of knots and optimizing over the weights w at each iteration. In this latter step knots can be (and indeed eventually must be) removed. In an additional and optional step the knot points can be moved continuously within $[0,1]$, or to neighboring data points. This step is not needed for theoretical convergence but can improve convergence and the sparsity of the final solution in practice.

4.1 The Conditional Gradient Method

The conditional gradient method (CGM) solves constrained convex optimization problems of the form

$$\begin{array}{ll} \text{minimize} & f(x) \\ \text{subject to} & x \in \mathcal{C}, \end{array} \tag{12}$$

with variable $x \in \mathbf{R}^d$. In the above, it is always assumed that the (convex) function f is differentiable. At each iteration of the CGM we form the standard linear approximation to the function f at the current iterate x_m:

$$\hat{f}(x; x_m) = f(x_m) + f'(x - x_m; x_m).$$

Here $f'(d; x)$ is the directional derivative of the function f at x in the direction d, defined by

$$f'(d; x) = \lim_{t \searrow 0} \frac{f(x + td) - f(x)}{t}.$$

Our use of the directional derivative here may seem surprising: for differentiable functions on $\mathbf{R}^d$, $f'(d;x)$ is always equal to $\langle \nabla f(x), d\rangle$. The direct applicability of directional derivatives to convex functionals of measures motivates us to prefer the directional derivative.

Convexity of f implies that $\hat{f}$ is a *lower* bound on f, that is:

$$\hat{f}(x; x_m) \leq f(x). \tag{13}$$

In the next step of the CGM, we minimize this first-order approximation over the feasible set $\mathcal{C}$:

$$s_m \in \arg\min_{s\in\mathcal{C}} \hat{f}(s; x_m) = \arg\min_{s\in\mathcal{C}} f'(s; x_m).$$

The point s_m is called the conditional gradient of f. Note that s_m provides a lower bound on $f(x_\star)$:

$$\hat{f}(s_m; x_m) \leq f(x_\star).$$

In particular, we can bound the sub-optimality of the point x_m:

$$f(x_m) - f(x_\star) \leq -f'(s_m - x_m; x_m). \tag{14}$$

One can show (Jaggi, 2013.) that this bound decreases to zero, which means that it can be used as a (non-heuristic) termination criterion. After determining s_m, there are several options for updating x_m. In this paper, we will use the fully-corrective variant of the CGM, which chooses x_{m+1} to minimize f over the convex hull of $\{s_1, s_2, \ldots, s_m\}$. Note that this last step may become computationally intensive as k grows, and indeed limits the applicability of the conditional gradient method to problems where this step is computationally feasible. One option is to remove previous conditional gradients as soon as they are not selected in the minimization step. Caratheodory's theorem ensures us that the set of previous conditional gradients we need to track is then bounded by $d+1$. In practice, however, the algorithm is usually terminated well before $d+1$ iterations.

Algorithm 1 Fully-corrective conditional gradient method

For $m = 1, \ldots$

1. Linearize: $\hat{f}(s; x_m) \leftarrow f(x_m) + f'(s - x_m; x_m)$.
2. Minimize: $s_m \in \arg\min_{s\in\mathcal{C}} \hat{f}(s; x_m)$.
3. Update: $x_m \in \arg\min_{x\in\mathrm{conv}(s_1,\ldots,s_m)} f(s)$.

4.2 Conditional Gradient for Measures

In this subsection, we apply the conditional gradient method to the infinite-dimensional problem (11), which we repeat here:

$$\begin{array}{ll} \text{minimize} & L(E_x\mu) \\ \text{subject to} & \int d\mu = 0, \\ & \|\mu\|_1 \leq \tau. \end{array} \tag{15}$$

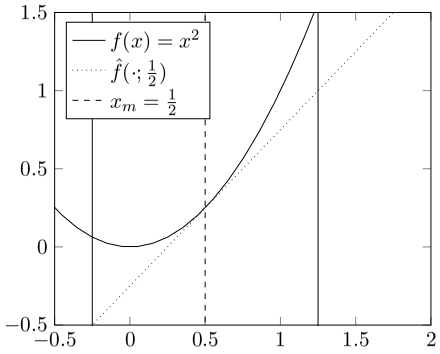

Figure 2: An illustration of a single iteration of the conditional gradient method on the function $f(x) = x^2$ at the point $\frac{1}{2}$. The set $\mathcal{C}$ is the interval $[-0.25, 1.25]$, indicated by the solid vertical lines. The first order approximation $\hat{f}(\cdot; \frac{1}{2})$ is plotted as the dotted line tangential to $f(x)$ at $\frac{1}{2}$. The conditional gradient s_m is the point -0.25.

First we'll show that the conditional gradient, i.e., the measure s_m, can be chosen to be supported on exactly two points, and is computable in time linear in n. The directional derivative of the objective function in the direction of the measure s at the point μ is given by

$$\begin{aligned} &\lim_{t\searrow 0} \frac{L(E_x(\mu + ts)) - L(E_x\mu)}{t} \\ &= \lim_{t\searrow 0} \frac{L(E_x\mu + tE_x s) - L(E_x\mu)}{t} \\ &= L'(E_x s; E_x\mu) \\ &= \langle \nabla L(E_x\mu), E_x s\rangle_{\mathbf{R}^n}. \end{aligned}$$

We can then interchange the inner-product in $\langle \nabla L(E_x\mu), E_x s\rangle$ with the integral in $E_x s = \int \psi(t)\, ds(t)$:

$$\langle \nabla L(E_x\mu), E_x s\rangle = \int \langle \nabla L(E_x\mu), \psi(t)\rangle\, ds(t). \tag{16}$$

Let $g = \nabla L(E_x\mu) \in \mathbf{R}^n$. Note that in the case $\ell(x,y) = \frac{(x-y)^2}{2}$, g is simply the residual $E_x\mu - y$ and $\langle g, \psi(t)\rangle$ is the correlation between the residual and a single hinge function located at t. A conditional gradient is any solution to the following optimization problem

$$\begin{array}{ll} \text{minimize} & \int \langle g, \psi(t)\rangle\, ds(t) \\ \text{subject to} & \int ds = 0, \\ & \|s\|_1 \leq \tau. \end{array} \tag{17}$$

Without the integral constraint, we would expect there to be a solution to (17) that is a single point-mass: the objective function is the integral of a scalar-valued function against a bounded measure. We'll show that there is always a solution to (17) that is supported on exactly two points. Furthermore, we'll show that those two points can be computed in time linear in n.

First we'll construct a particular feasible point for (17) and then we'll show that it achieves the optimal value. Let

$$t_+ \in \arg\min_t \langle g, \psi(t)\rangle, \quad t_- \in \arg\min_t -\langle g, \psi(t)\rangle.$$

Define

$$s_\star = \frac{\tau}{2}\delta_{t_+} - \frac{\tau}{2}\delta_{t_-}.$$

The objective value achieved by $s_\star$ is

$$o_\star = \frac{\tau}{2}\left(\langle g, \psi(t_+)\rangle - \langle g, \psi(t_-)\rangle\right).$$

We'll show that either any measure s that is feasible for (17) has objective value bounded below by $o_\star$ or μ is optimal for (11). Let s be any feasible measure for (17). Decompose s into the difference of two mutually singular non-negative measures: $s = s_+ - s_-$. Then as s is feasible we have $\|s_+\|_1 = \|s_-\|_1 \leq \frac{\tau}{2}$. The objective value achieved by s can be bounded below as follows

$$\begin{aligned}\int \langle g, \psi(t)\rangle ds(t) &= \int \langle g, \psi(t)\rangle ds_+(t) + \int -\langle g, \psi(t)\rangle ds_-(t) \\ &\geq \|s_+\|_1 \left(\min_t \langle g, \psi(t)\rangle\right) + \|s_-\|_1 \left(\min_t -\langle g, \psi(t)\rangle\right) \\ &\geq \|s_+\|_1 \left(\min_t \langle g, \psi(t)\rangle + \min_t -\langle g, \psi(t)\rangle\right).\end{aligned}$$

Suppose $(\min_t \langle g, \psi(t)\rangle + \min_t -\langle g, \psi(t)\rangle) \geq 0$. Then the argument above implies $s_\star = 0$ is a conditional gradient for (11), and thus (14) implies μ is optimal. Otherwise we have

$$\left(\min_t \langle g, \psi(t)\rangle + \min_t -\langle g, \psi(t)\rangle\right) < 0,$$

which implies

$$\|s_+\|_1 \left(\min_t \langle g, \psi(t)\rangle + \min_t -\langle g, \psi(t)\rangle\right) \geq \frac{\tau}{2}\left(\min_t \langle g, \psi(t)\rangle + \min_t -\langle g, \psi(t)\rangle\right) = o_\star.$$

This proves the assertion.

Note that finding t_- and t_+ involves two *separate* optimization problems over $[0, 1]$ instead of one over $[0, 1] \times [0, 1]$. These problems are readily solved by gridding, though in this case they can be solved exactly in time linear in n if we have access to a sorted vector of the data points x_i. To see this, we expand the objective function for t_+ above,

$$t_+ = \arg\min_{0\leq t\leq 1} \sum_{i=1}^n g_i(x_i - t)_+ = \arg\min_t \sum_{i:x_i\geq t} g_i(x_i - t).$$

If x_i are sorted, we can compute the minimizer between each pair of consecutive data points exactly, since this is simply computing the minimizer of a linear functional over an interval. Thus in a single pass over the data we can compute the global minimizer exactly.

Immediately after computing t_- and t_+ we can use (14) to bound the suboptimality of μ by

$$L(E_x\mu) - L(E_x\mu_\star) \leq -\int \langle g, \psi(t)\rangle d(s_\star - \mu)(t).$$

With this choice of conditional gradient, the fully-corrective step is a finite-dimensional convex problem. Fixing the knot locations encountered as conditional gradients so far, $t_1, \ldots, t_{2k}$, we can do at least as well as the fully-corrective algorithm by solving the following optimization problem:

$$\begin{array}{ll}\text{minimize} & L(E_x\mu) \\ \text{subject to} & \int d\mu = 0, \\ & \|\mu\|_1 \leq \tau, \\ & \text{supp}(\mu) \subset \{t_1, \ldots, t_{2k}\}.\end{array} \tag{18}$$

This is equivalent to the following optimization problem in $\mathbf{R}^{2k}$:

$$\begin{array}{ll}\text{minimize} & L(\sum_j w_j E_x \delta_{t_j}) \\ \text{subject to} & 1^T w = 0, \\ & \|w\|_1 \leq \tau.\end{array} \tag{19}$$

We can solve this using any of a number of existing algorithms (Boyd et al., 2011; den Berg and Friedlander, 2011). In our implementation we use the conditional gradient method with line-search for simplicity.

By warm starting with an increasing sequence of τ's, we can efficiently compute an approximate regularization path. Indeed we can even provide a provably ϵ-suboptimal path using the approach of Giesen et al. (2012).

4.3 Convergence

As in the case of ADCG (Boyd et al., 2017) convergence follows immediately from the conditional gradient method proof in general Banach spaces (Dunn and Harshbarger, 1978; Demyanov and Rubinov, 1973; Jaggi, 2013.). The convergence of the conditional gradient method depends on a curvature parameter C_f. C_f is a constant such that the following inequality is satisfied for all $x, s \in \mathcal{S}$ and $\eta \in (0, 1)$:

$$f(x + \eta(s - x)) \leq f(x) + \eta f'(s - x; x) + \frac{C_f}{2}\eta^2.$$

For our purposes $f : \mathbf{R}^n \to \mathbf{R}$ is simply L and $\mathcal{S} = \{E_x\mu : \|\mu\|_1 \leq \tau, \int d\mu = 0\}$. A simple sufficient condition for C_f to be finite is that ℓ is differentiable with Lipschitz gradient. If C_f is finite, the conditional gradient method converges (in terms of function value) at a rate of at least $1/m$ where m is the iteration counter.

5. Generalized Additive Models

One natural application of univariate splines is fitting generalized additive models (Hastie and Tibshirani, 1990) to multivariate data: $(x_i, y_i) \in \mathbf{R}^D \times \mathcal{Y}$, $i = 1, \ldots, n$. That is, fitting a function of the form

$$f(x) = \sum_{d=1}^{D} f_d(x[d])$$

where each f_d is a simple function from $\mathbf{R}$ to $\mathbf{R}$ (here $x[d]$ is the d-th coordinate of the vector x). We can mimic our approach in the scalar case with the following optimization problem:

$$\begin{array}{ll} \text{minimize} & L(f) \\ \text{subject to} & \sum_d R(f_d) \leq \tau, \\ & f_d'(x) = 0 \ \forall x \notin [0,1], d. \end{array} \tag{20}$$

Here R is the same regularizer used in the scalar case, namely

$$R(g) = \mathrm{TV}(g') \simeq \|g''\|_1.$$

As in the scalar case, one can show that there is always an optimal f with each coordinate function f_d a degree-one saturating spline.

This allows us to rephrase (20) as an optimization problem over measures. The only change from the scalar case is that the measure is over the set $\{1, \ldots, D\} \times [0, 1]$—each knot is now attached to a particular coordinate. In other words, we search for a function of the following form:

$$f_\mu(x) = \int (x[d] - t)_+ d\mu(d, t).$$

We again have equality between the ℓ_1 norm of μ and the regularization term:

$$\sum_d R((f_\mu)_d) = \|\mu\|_1.$$

The analogue of (11) is then

$$\begin{array}{ll} \text{minimize} & L(E_x \mu) \\ \text{subject to} & \int 1(d = \hat{d})\ d\mu(d, t) = 0, \ \forall \hat{d} \\ & \|\mu\|_1 \leq \tau. \end{array} \tag{21}$$

The conditional gradient algorithm from the scalar case generalizes immediately to fitting generalized additive models—the only difference is that we now need to find a pair of knots for the same coordinate. This involves solving d pairs of nonconvex optimization problems over $[0, 1]$—again this can be done by gridding or by sorting the training data.

Saturating splines gain an additional advantage over standard adaptive splines when fitting generalized additive models. The addition of the saturation constraint (that f_d be constant outside of $[0, 1]$) naturally leads to variable selection when fitting generalized additive models. What we mean by variable selection is that the functions f_d are often exactly 0. This is because the saturation constraint means that linear coordinate functions no longer escape the regularization (indeed, they are impossible). This is very different

from the standard adaptive spline setup without the saturation constraint. In that case, linear functions, i.e., $f_d(x[d]) = wx[d]$ completely escape the regularization, and as a result are essentially always included in the model. Linear functions are *not* free with saturation constraints (in fact, outside of the function 0, they are not feasible). When we solve (21) we simultaneously fit nonlinear coordinate functions while doing variable selection.

6. Prior and Related Work

Smoothing splines also have an interpretation as the solution of an infinite-dimensional optimization problem (Hastie et al., 2001, §5.4). In fact, (degree-one) smoothing splines solve

$$\begin{array}{ll} \text{minimize} & L(f) \\ \text{subject to} & \hat{R}(f) \leq \tau, \end{array} \tag{22}$$

where

$$\hat{R}(f) = \int f'(x)^2\ dx.$$

The solution to (22) is *also* a degree-one natural spline that saturates outside of $[0, 1]$. However, the solutions to (22) and (2) are *very* different. Roughly, (22) is analogous to ridge regression, while (2) is analogous to the lasso. That is, (22) fits functions with as many knots as datapoints, while (2) often fits splines with very few knots.

Another type of spline, that is adaptive but does not saturate, are adaptive regression splines (Mammen and van de Geer, 1997). These splines also arise as solutions to a functional regression problem:

$$\begin{array}{ll} \text{minimize} & L(f) \\ \text{subject to} & \hat{R}(f) \leq \tau, \end{array} \tag{23}$$

where

$$\hat{R}(f) = TV(f'(x)).$$

Note that this is (2) without the saturation constraint. Algorithms for solving (23) (for degree-one splines) are based on an extension of Theorem 1, that shows there is a solution to (23) which is actually supported on the data points x_i. Hence a lasso algorithm can be used to find the solution. This also suggests a very simple method to solve our problem (9): we fix the n knot points to be the values of the data x_i, and solve the finite-dimensional convex optimization problem to find the weights. While simple coordinate-descent methods like GLMNet (Friedman et al., 2010) will not immediately work because of the saturation constraint, they could be modified to handle the constraint.

This method does work, but can be much slower than ours since in practice the number of knots is typically much smaller than n for useful values of the regularization parameter τ, and the finite-dimensional problem with n basis functions is very poorly conditioned. With that said, the algorithm we propose—for the piecewise linear case—can be interpreted as a forward active set method for the finite dimensional problem, where we avoid explicitly evaluating all basis functions. One advantage of our measure-theoretic approach is that it immediately generalizes to higher-degree splines, where the support of μ need not be on data points, as we will see in §9. In this case (9) is truly infinite-dimensional, yet our algorithm can still be directly applied.

Trend filtering is a nonparametric function estimation technique, first introduced by Kim et al. (2009), that is very similar to adaptive splines. Indeed, as discussed by Tibshirani (2014), the trend filtering estimate in the constant or piecewise-linear case is exactly the same as the adaptive spline estimate. Trend filtering is increasingly popular as it admits extremely efficient, robust algorithms (Tibshirani, 2014; Ramdas and Tibshirani, 2015). Indeed, some of these algorithms (especially those adapted to fit GAMs, Petersen, Witten, and Simon (2015)) may be adapted to efficiently fit saturating trend filter estimates, which would benefit from the feature selection properties of saturating splines and the computational efficiency of trend filtering.

There are a number of methods for fitting generalized additive models with spline component functions. One approach (Lin and Zhang, 2006) is to use the group-lasso version of (6):

$$R(f) = \sum_d \sqrt{\int f_d'(x)^2 \, dx}.$$

Extending this idea, Chouldechova and Hastie (2015) use an overlap group-lasso that facilitates selection between zero, linear and nonlinear terms. The differences between these approaches and ours are analogous to the differences between the standard group-lasso and the lasso. While both do feature selection, the penalty functional (6) does not do knot-selection within each coordinate function.

One very similar approach to fitting splines that does not require knot selection (but does not incorporate saturation) is discussed by Rosset et al. (2007).

7. Examples

In all examples we affinely preprocess the data so that all training features lie in $[0, 1]$, and apply the same transformation to the test features (which thus may have values outside of $[0, 1]$). All plots are in terms of the standardized features. For the bone density and abalone data sets we select τ to minimize error on the validation sets. For the Spam and ALS data sets we use cross-validation to estimate τ. We hold out a random subset of size 100 from the training set and train on the remaining data. For each random validation/train split we estimate τ to minimize hold-out error and take our final estimate of τ as the mean over 50 trials.

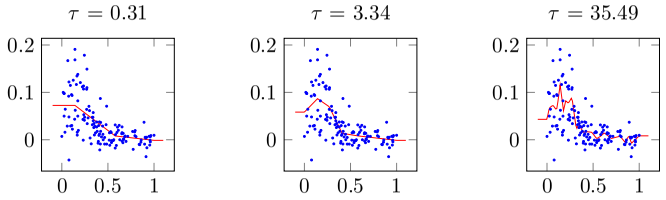

Figure 3: Saturating splines fit to bone density data (shown as scattered points) for 3 values of the regularization parameter τ. *Top:* $\tau = 0.31$; *Middle:* $\tau = 3.34$; *Bottom:* $\tau = 35.45$.

7.1 Bone Density

We start with a simple univariate data set from (Hastie et al., 2001, §5.4). The response variable for this data set is the change in spinal bone density between two doctor visits for female adolescents as a function of age. There are 259 data points, of which we hold out 120 for validation, leaving 139 data points to which we fit a saturating spine. We start with the square loss.

The results are shown in figure 3, for three values of the regularization parameter τ. The scattered points are the training data, the solid line is the saturating spline fit by our algorithm. The figure demonstrates the clear link between τ and the complexity of the optimized spline. Out-of-sample validation suggests setting $\tau \simeq 3.34$, which achieves a validation RMSE of 0.036.

To demonstrate that our proposed method works with more general loss functions, we add 30 simulated outliers to the training set and fit with the pseudo-Huber loss (Charbonnier et al., 1997), a smooth approximation to the Huber loss function given by

$$l_\delta(u) = \delta \left(\sqrt{1 + \frac{u^2}{\delta}} - 1 \right),$$

where $\delta > 0$ is a parameter that interpolates between the absolute value loss and the squared loss. For our experiment we take $\delta = 0.0015$; roughly speaking, the transition between square and linear loss occurs around $\sqrt{\delta} = 0.039$. The results are shown in figure 4. These plots demonstrate that our algorithm can fit losses other than the square loss, and confirms that the pseudo-Huber loss is far more robust to outliers than the basic square loss function. Indeed, on the validation set the least-squares fit achieves a minimum RMSE of 0.096, while the pseudo-Huber fit achieves 0.038, only slightly worse than the fit obtained before the outliers were added to the training data. While this one-dimensional problem is very easy, it shows one advantage of the adaptive spline penalty over smoothing splines: the optimal model has only 5 knot points.

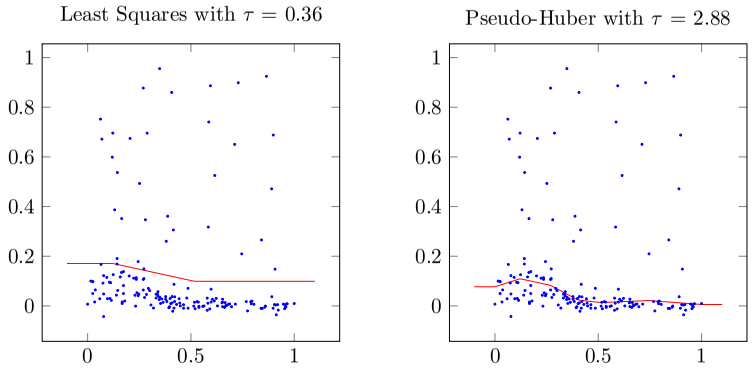

Figure 4: Saturating splines fit to bone density data (shown as scattered points) with simulated outliers for square loss function (left) and pseudo-Huber loss function (right), each for the value of τ that minimizes RMSE on the test set.

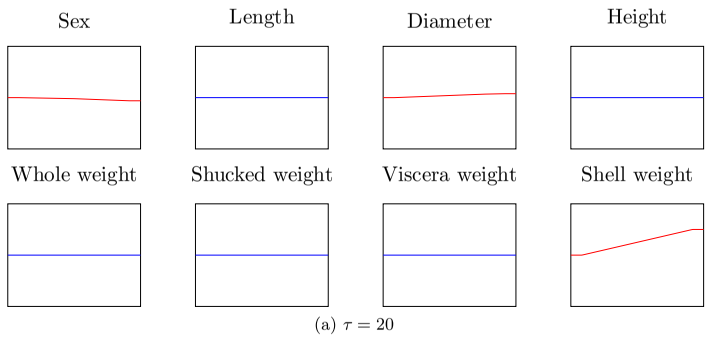
7.2 Abalone

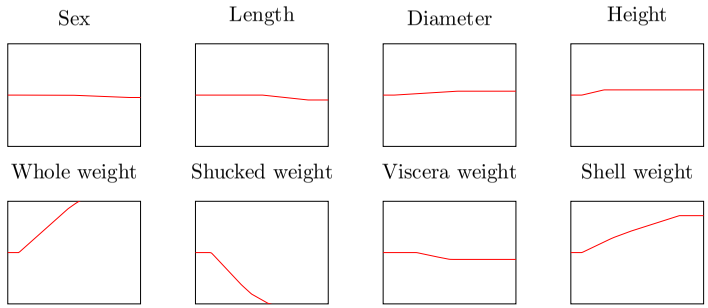
We fit a generalized additive model with saturating spline coordinate functions to the Abalone data set from the UCI Machine Learning Repository (Lichman, 2013). The data consists of 4177 observations of 8 features of abalone along with the target variable, the age of the abalone. We hold out 400 data points as a validation set, leaving 3777 data points to fit the model. The first feature (labeled sex) has three values: Male, Female, and Juvenile, which are coded with values $0, 1, 2$; the other 7 are (directly) real numbers. The task is to estimate the age of the abalone from the features.

Cross-validation suggests we choose $\tau \simeq 200$, which achieves a validation set RMSE of 2.131. Because the number of features is low, we can plot the entire generalized additive model. Each plot shows one coordinate function f_d for $d = 1, \ldots, 8$ as a function of the standardized feature in $[0, 1]$. The coordinate functions are shown for three values of τ, with the middle one corresponding to the value that minimizes cross-validation RMSE. When a coordinate function is zero, which means that the feature is not used in the model, it is shown in blue. We can see that in the case of strong regularization ($\tau = 20$), several coordinates are not used; for the best model ($\tau = 200$), all features are used, with a few having only a small effect. It is interesting to see how the sex factors into the optimal model. It is neutral on Male or Female, but subtracts a small fixed amount from its age prediction for a Juvenile abalone.

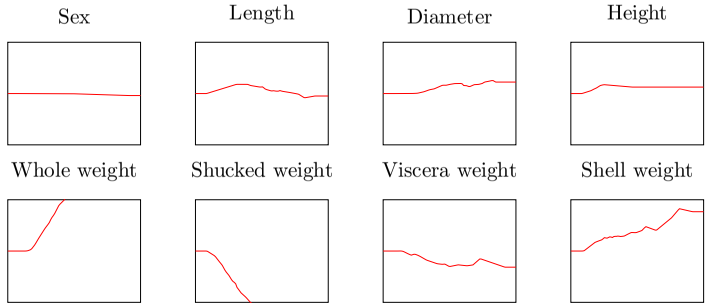
This data set is small enough that we can compare against standard adaptive splines fit using a coarse grid of $[0, 1]$. For this experiment, we fit a GAM with standard adaptive spline component functions using GLMNET (Friedman et al., 2010). The standard adaptive GAM fit, which does no variable selection, achieves a validation set RMSE of 2.137, not significantly worse than the saturating spline model. Our algorithm, however, selects many fewer knot points. The increased number of knots when fitting with GLMNET is perhaps due to the poor conditioning of the gridded problem.



(a) $\tau = 20$



(b) $\tau = 200$



(c) $\tau = 2000$

Figure 5: Coordinate functions for saturating spline generalized additive models fit to Abalone data for three values of the regularization parameter τ.

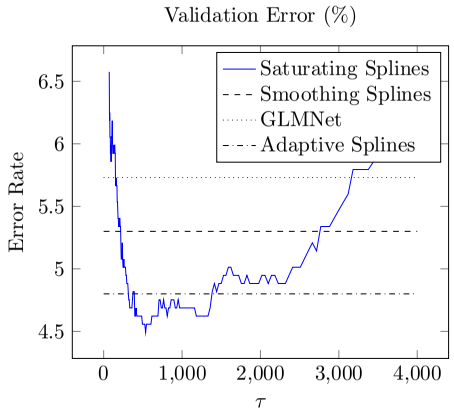


Figure 6: Validation error for saturating spline generalized additive model fit to Spam data set versus regularization parameter τ.

7.3 Spam

We consider the problem of classifying email into spam/not spam, with a data set taken from ESL (Hastie et al., 2001). The data set consists of 57 word-frequency features from 4601 email messages, along with their labels as spam or not spam. Following the approach in ESL (Hastie et al., 2001) we log-transform the features and use the standard train/validation split, with a training set of size 3065, and test set with 1536 samples. We fit a saturating spline generalized additive model with standard logistic loss.

Figure 6 shows the validation error versus the regularization parameter τ. Cross-validation suggests the choice $\tau \simeq 1100$. To show the benefit of nonlinear coordinate functions, we also include the best validation error achieved using a linear model (fit using GLMNet Friedman, Hastie, and Tibshirani (2010)).

With regularization parameter $\tau = 500$, the model selects 55 of the 57 features. We note that our saturating spline generalized additive model modestly outperforms many methods from ESL (Hastie et al., 2001); for example, smoothing splines yield 5.3% error, while our model has an error rate well below 5%. Figure 7 shows (some of) the coordinate functions for the model with $\tau = 500$. The coordinate functions use very few knots, making them readily interpretable.

For comparison, we fit a GAM with standard adaptive spline coordinate functions. To do so, we grid each dimension with 20 knots and solve the resulting finite-dimensional problem with GLMNET (Friedman et al., 2010). Note that adaptive splines do not penalize linear functions, so there is no feature selection. Adaptive splines achieve a minimum error of 4.8%, significantly worse than saturating splines.

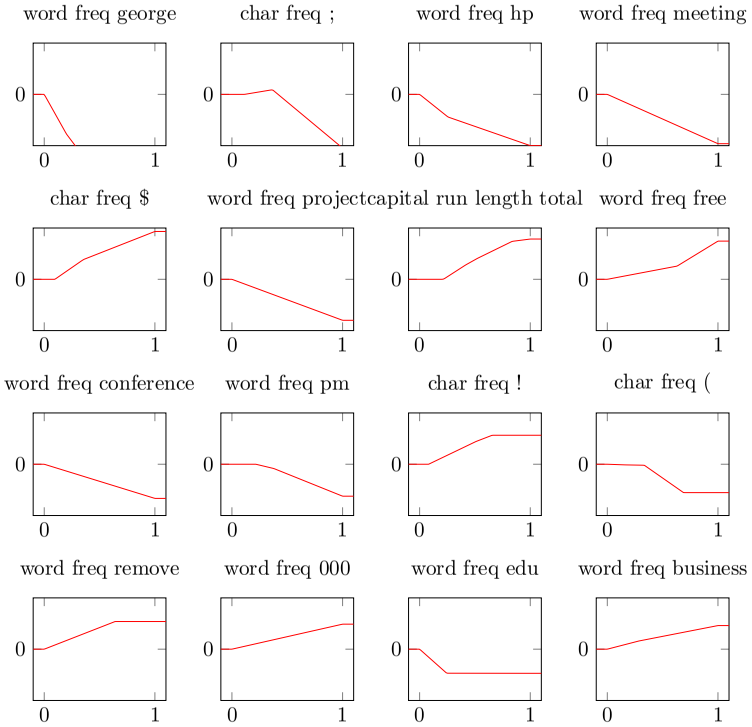

Figure 7: 16 coordinate functions for $\tau = 500$, labeled with the corresponding feature name.

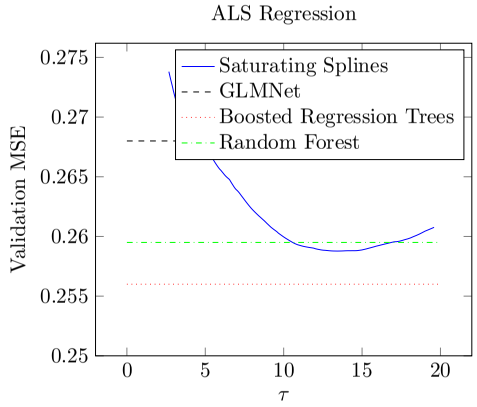

Figure 8: Validation MSE on ALS data set versus regularization parameter τ.

7.4 ALS

Using this data set we try to predict the rate of progression of ALS (amyotrophic lateral sclerosis) in medical patients, as measured by the rate of change in their functional rating score, a measurement of functional impairment. The data set is split into a training set of 1197 examples and a validation set of 625 additional patients. Each datapoint has dimension 369. We fit a generalized additive model with saturating spline component functions to the data using a least-squares objective function. Following (Efron and Hastie, 2016, §17.2), we measure performance using mean-squared error.

We estimate the optimal value of τ using cross validation with a hold-out size of 100 examples and 50 samples; this procedure suggests $\tau = 13$. Figure 8 shows the validation error versus the regularization parameter τ; the value of τ selected by cross validation achives low error. On the same plot, we also show the results from Efron and Hastie (2016) using boosted regression trees and random forests. The optimal saturating spline GAM model selects only 50 out of the 369 features, in contrast to boosted regression trees, which use 267. The saturating spline GAM model performs comparably to boosted regression trees and random forests. This is surprising as the saturating spline GAM has no interaction terms. It also uses substantially fewer features, further improving interpretability.

Again we fit a GAM with standard adaptive spline coordinate functions (using GLMNET) to show the advantage of saturation. The standard adaptive spline fit achieves an MSE of 0.547, substantially worse than any other model. We speculate that this is because the unpenalized linear functions lead to immediate overfitting. Indeed, removing the unpenalized linear functions and fitting a model with only hinges gives very similar performance to the saturating spline fit, suggesting that the main advantage of saturation for this application is the removal of the unpenalized linear functions.

Practical advantages of saturating splines These experiments show that saturating splines achieve competitive performance on small classification and regression data sets. In addition, the experiments demonstrate that saturating splines exhibit both knot selection and feature selection—in the context of fitting GAMs. While it is no surprise that saturating splines select fewer knots than smoothing splines (which choose a fully-dense set of knots), it is somewhat surprising that our algorithm selects fewer knots than even *adaptive* splines fit with GLMNET. Finally, the Spam and ALS data sets demonstrate a major advantage of saturating splines over adaptive splines: they simultaneously perform non-linear coordinate function fitting and feature selection. This aids in generalization performance and interpretability. In particular, for the ALS data set saturating spline GAMs achieve *half* the test MSE of adaptive spline GAMs by selecting only 50 of 369 available features.

8. Higher-degree Splines

In the majority of this paper we focused on the functional regression problem (2), with a total variation constraint on the first derivative and a saturation constraint on the zeroth derivative (the function itself). In this section, we consider constraints on higher order derivatives, which lead to solutions that are splines of higher degrees.

$$\begin{array}{ll} \text{minimize} & L(f) \\ \text{subject to} & \mathrm{TV}(f^{(k)}) \leq \tau, \\ & f^{(k-j)}(x) = 0, \ \forall x \notin [0,1]. \end{array} \tag{24}$$

We consider the family of nonparametric function estimation problems indexed by $0 \leq j \leq k$. This is the analogue of the functional regression problem (2) with a total variation constraint on the k-th derivative and a saturation constraint on the $(k-j)$-th derivative. The saturating spline case from the rest the paper is the special case of (24) with $k = 1$, $j = 0$. Widely used cubic natural splines correspond to $k = 3$, $j = 1$. Note that unlike natural splines, which are only defined for some values of j and k, there are no constraints on j and k.

We now show that higher-degree saturating splines solve (24) in general. As $f^{(k)}$ is of bounded TV, there exists a measure μ s.t. $f^{(k)}(x) = \int 1(t \leq x)\, d\mu(t)$. Then we have

$$\begin{aligned} f^{(k-j)}(x) &= \int \dots \int f^{(k)}(x) dx \dots dx \\ &= \int \dots \int \int 1(t \leq x)\, d\mu(t) dx \dots dx \\ &= j! \int (x-t)_+^j \, d\mu(t) + \sum_{l=0}^{j-1} w_l x^l \end{aligned}$$

for some w_l. In the above, all iterated integrals take place j times.

Note that the constraint that $f^{(k-j)}(x) = 0$ for all $x < 0$ implies that the polynomial term, $\sum_{l=0}^{j-1} w_l x^l$ is identically zero. So, we have

$$f^{(k-j)}(x) = j! \int (x-t)_+^j \, d\mu(t).$$

For $x > 1$, we can remove the nonlinearity, that is, for $x > 1$, $f^{(k-j)}(x)$ is simply the integral of a polynomial in x. We can pull terms involving x out of the integral to get a polynomial in x whose coefficients are nonzero multiples of the first j moments of μ:

$$f^{(k-j)}(x) = j! \sum_{l=0}^{j} \binom{j}{l} x^{j-k} \int (-t)^k \, d\mu(t).$$

Again, we note that as this polynomial is identically zero for infinitely many points, all of the coefficients must be zero. In terms of the measure μ, this means:

$$\int t^l \, d\mu(t) = 0 \quad \text{for } l = 0, \dots, j.$$

This shows that the constraint that the $(k-j)$-th derivative of f saturate translates to constraints on all moments of μ up to the j-th moment.

While the conditional gradient step becomes more complex with the addition of more moment constraints, the approach taken in this paper can still be applied to (24) as long as j is fairly small—the conditional gradient step for (24) involves a nonconvex optimization problem over $[0,1]^{j+2}$. This is because we need at least $(j+2)$ point-masses to satisfy the moment constraints. So, fitting quadratic splines that saturate to linear is very easy—in fact the code to do so is essentially identical to that for fitting piecewise linear saturating splines splines—but fitting quadratic splines that saturate to constant is slightly more difficult due to the additional linear constraint on the measure μ. Unfortunately for larger values of j and k, we can no longer hope to find the conditional gradient analytically and must resort to recursive gridding or other global optimization algorithms to find the locations of the new knots.

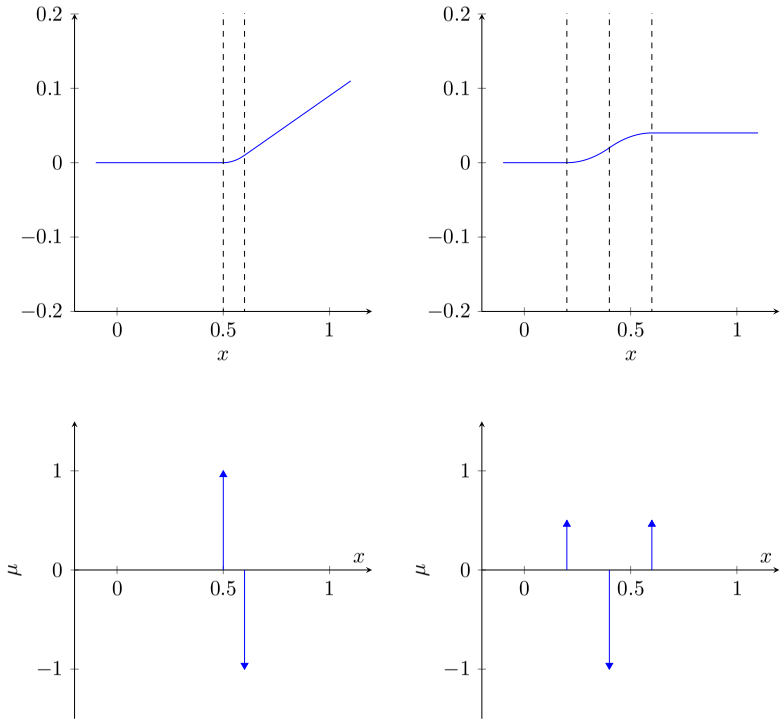

Figure 9: The top two plots show conditional gradients for $k = 2$ with $j = 0$ and $j = 1$ respectively. The dashed lines denote the locations of the point masses: when $j = 1$, the conditional gradient consists of three point masses. The bottom plots show the corresponding measures.

9. Variations and Extensions

While saturation is often a natural prior, the approach we take in this paper can also be applied to other (convex) variations on (9). For example, we could add the constraint that the fitted function is monotone nondecreasing, or takes values in a given interval.

A simple algorithmic extension would be to incorporate nonconvex optimization in the spirit of Boyd et al. (2017). At each iteration we adjust the weights of the atomic measure (w), but we could also adjust the knot locations (t). The objective in (19) is nonconvex in t_i, but we can still attempt to find a local minimum. As long as we do not increase the objective function the algorithm is still guaranteed to converge (Boyd et al., 2017). In the case of degree one splines, we can use the fact that the knot points can, without loss of generality, be chosen to be on the data points to make discrete adjustments to the knot locations.

To fit vector-valued functions, for example in multiclass classification, we would need to extend (9) to use *vector-valued* measures. This is the natural measure-theoretic analogue to the group-lasso.

In multivariate fitting problems with significant interactions between features generalized additive models may underfit. One possible solution is to use single-layer neural networks: i.e., learn functions of the form

$$x \mapsto \sum_{i=1}^{K} w_i (v_i^T x - t_i)_+.$$

In the above, v_i are constrained to lie in the unit ball. Unfortunately, the conditional gradient step for networks of this form is NP-hard (Bach, 2017). In many practical applications, however, we might expect that the degree of the interaction is bounded. That is, each v_i has bounded cardinality. If we assume $\|v_i\|_0 \leq 2$, i.e., we only fit pairwise interactions, we can still apply the conditional gradient method. In this case, the fitting function is a sum of functions of pairs of the variables, formed from the basis elements

$$((\cos\theta)x_p + (\sin\theta)x_q - t)_+,$$

with (continuous) parameters θ and t and (index) parameters p and q (i.e., $v = (\cos\theta)e_p + (\sin\theta)e_q$). (This is practical only if d is small enough.) Such functions capture nonlinear relationships between (pairs of) variables.

10. Conclusion

In this paper we propose a modification of the adaptive spline regression model—namely saturation constraints. We show that saturating splines inherit knot-selection from adaptive splines, and have a very important quality in the context of generalized additive models: feature selection. This allows saturating spline generalized additive models to remain interpretable and (crucially) avoid overfitting when applied to multivariate data. We also propose a simple, effective algorithm based on the standard conditional gradient method for solving the saturating spline estimation problem with arbitrary convex losses. Finally, we apply our algorithm to several data sets, demonstrating the simplicity of the resulting models.

Appendix A. Implementation Details

We provide a simple, unoptimized implementation in the Rust language. The runtime of our algorithm is dominated by the fully-corrective step, that is, solving the finite-dimensional convex optimization problem (19). We solve (19) using a proximal Newton method and the standard conditional gradient method with exact linesearch. To be precise, at each iteration, we form the second-order approximation to the objective function

$$f(w) \simeq C + (w - \hat{w})^T \nabla_w f(\hat{w}) + \frac{1}{2}(w - \hat{w})^T \nabla^2 f(\hat{w})(w - \hat{w})$$

which we then minimize (over the constraint set) using the standard conditional gradient method with (exact) linesearch. Note that this is a Newton step with fixed step-length of 1: as in GLMNET (Friedman et al., 2010), we omit a line search in the interest of speed.

We chose to use a proximal Newton method because of its relative simplicity; other standard convex optimization algorithms may give much better practical performance, especially when the number of data points, n, is extremely large.

Appendix B. Saturating Hinges

In this section we introduce a heuristic for solving an approximation to (9) using existing algorithms for the lasso. Here we consider the case where $\hat{R}(f) = TV(f'(x))$, and hence as pointed out in Section 6 the solution is an expansion in piecewise linear splines with knots at the unique data points. Let h_j be a hinge function at knot t_j: $h_j(x) = (x - t_j)_+$, and suppose we have knots $t_1 < t_t < \cdots < t_k$. Define $f(x) = w_0 + \sum_{j=1}^k w_j h_j(x)$. Given a sample $T = \{(x_i, y_i)\}_1^N$, solving (9) amounts to solving

$$\underset{w_0, w}{\text{minimize}} \left\{ \sum_{i=1}^N \ell(y_i, f(x_i)) + \lambda \|w\|_1 \right\} \quad \text{s.t. } f'(t_k) = 0. \tag{25}$$

Here we've exchanged a constraint on the total variation of $TV(f'(x))$ with a penalty. The condition $f'(t_k) = 0$ is equivalent to $\sum_{j=1}^k w_j = 0$. If the points x_i are unique, then $k = n$; irrespective $t_1 = \min(x_i)$, $t_k = \max(x_i)$ and by construction the estimate $\hat{f}$ is constant beyond the data.

Without the gradient condition $f'(t_k) = 0$, solving (25) amounts to a large lasso problem, for which efficient software is available. Here our goal is to transform the problem to get rid of this constraint. For more generality we do this for an arbitrary set of ordered knots.

Suppose $k < n$ and the right-most knot is inside the range of the data. Consider the following formulation. Let $s_j(x) = h_j(x) - h_k(x)$, a "saturating" hinge function. It looks like a piecewise linear sigmoid, and goes horizontal at t_k (see figure 10).

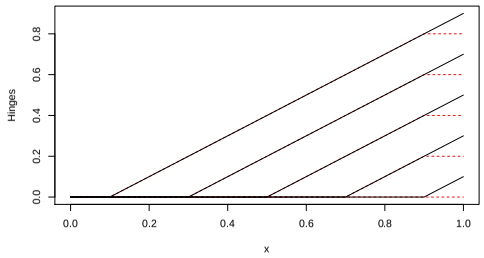

Figure 10: Hinges and saturating hinges.

Without the ℓ_1 constraint (or when $\lambda = 0$) the solution to (25) is equivalent to the solution to the problem with the reduced basis $g(x) = \theta_0 + \sum_{j=1}^{k-1} \theta_j s_j(x)$:

$$\underset{\theta_0, \theta}{\text{minimize}} \sum_{i=1}^N \ell(y_i, g(x_i)). \tag{26}$$

This is easy to see. f is an affine expansion in the h_j, and hence any nonsingular $k \times k$ transformation C of the vector of functions $h(x) = (h_1(x), h_2(x), \ldots, h_k(x))$ spans the same space. It is easy to see that with $s(x) = C^T h(x)$, and

$$C = \begin{bmatrix} 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \\ -1 & -1 & \cdots & -1 & -1 \end{bmatrix}$$

that $s_j(x)$ are as described (and $s_k(x) = -h_k(x)$). Now $h(x)^T w = h(x)^T C C^{-1} w = s(x)^T \theta$, with $\theta = C^{-1} w$. However, in this case $C^{-1} = C$, and hence $\theta_j = w_j$, $j = 1, \ldots, k-1$ and $\theta_k = \sum_{j=1}^k w_j$. In this new basis, imposing the constraint amounts to setting $\theta_k = 0$, or simply deleting the last basis function. So fitting the linear model f subject to $f'(t_k) = 0$ is equivalent to fitting the model g without constraints, and in fact the $\theta_j = w_j$, $j = 1, \ldots, k-1$.

So in summary, fitting a constrained optimization with the hinge functions is equivalent to fitting an unconstrained optimization with the reduced set of saturating hinges. The remaining question is does this also work with the penalty $\lambda\|w\|$ as in (25). Not quite, but close. It turns out we are still missing a penalty term $\lambda|\sum_{j=1}^{k-1} \theta_j|$. Hence the transformed problem is

$$\underset{\theta_0, \theta \in \mathbf{R}^{k-1}}{\text{minimize}} \left\{ \sum_{i=1}^N \ell(y_i, g(x_i)) + \lambda\|\theta\| + \lambda|\textstyle\sum_{j=1}^{k-1} \theta_j| . \right\} \tag{27}$$

If we are willing to ignore this last penalty, we can fit the saturated spline model using a fast lasso solver, such as `glmnet`. By generating such a basis for each variable in a GAM, this same approach can be used to fit a saturated GAM regularization path.

The impact is that one could fit a saturated gam model by running say `glmnet` on the $\{s\}$ bases. An example is given on the spam data in figure 11, where the regularization path was computed at a 100 values of λ in seconds. There are of course some caveats.

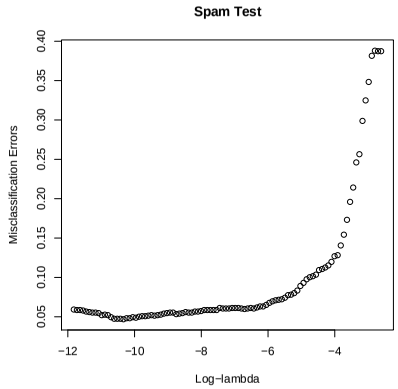

Figure 11: Performance on the spam test data, with 20 knots per variable. Increasing to 50 did not make much difference. Minimum error is 0.047.

- If you use all the knots for each of p variables, you end up with a data matrix of dimension $N \times Np$, which does not scale too well. So instead one might use a smaller grid of knots; e.g., map the variables onto $[0, 1]$, and then use a grid of say 50 evenly spaced knots on this grid, including the end knots.

- With a large number of knots, the "variables" are highly correlated, and this can cause numerical issues. The main issue we see is that active sets tend to be larger than they should be.

Nevertheless, this is an alternative algorithm, which is closer in spirit to the adaptive splines algorithm.

Appendix C. Proof of Theorem 1

Theorem 1 *Fix $x_1, \ldots, x_n \in [0, 1]$ and $f : \mathbf{R} \to \mathbf{R}$ with f' (right-continuous) of bounded total variation, and f constant outside of $[0, 1]$. Then there exists a degree-one saturating spline $\hat{f}$ that matches f on x_i with $\mathrm{TV}(\hat{f}') \leq \mathrm{TV}(f')$.*

Proof Without loss of generality, we will assume $f(0) = 0$. Let $\tau = \mathrm{TV}(f')$. As f' has bounded total variation, there exists a measure μ on $[0, 1]$ such that $f(x) = f_\mu$:

$$f(x) = \int (x - t)_+ \, d\mu(t).$$

That is, f is a spline with infinitely many knots. The idea is to use Caratheodory's theorem for convex hulls to see that, as we only care about μ in terms of its action on a finite number of functions (basically, we only care about the values of f at x_i), we can replace μ with a measure supported on finitely many points.

To make this idea rigorous, note that the vector

$$v = (f(x_1), \ldots, f(x_n), 0) = \int ((x_1 - t)_+, \ldots, (x_n - t)_+, 1) \, d\mu(t)$$

must lie in convex hull of the (convex) set

$$C = \{\pm(\tau(x_1 - t)_+, \ldots, \tau(x_n - t)_+, \tau) : t \in [0, 1]\} \subset \mathbf{R}^{n+1}$$

as $\|\mu\|_1 = \tau$. Caratheodory's theorem for convex hulls ensures us that v can be represented as a convex combination of at most $n + 2$ points from C. Letting these $n + 2$ points be represented by their indicies, $t_1, \ldots, t_{n+2}$, and their weights $\alpha_1, \ldots, \alpha_{n+2}$ we define $w_j = \alpha_j \tau$ to obtain:

$$f(x_i) = \sum_j w_j (x_i - t_j)_+ = f_\mu(x_i)$$
$$\sum_j w_j = 0.$$

Here $\mu = \sum_j w_j \delta_{t_j}$. As $\sum_j |w_j| = \tau$, we have $\mathrm{TV}(f'_\mu) = \|\mu\|_1 = \tau$. ■

Abstract

A popular approach for solving stochastic optimization problems is the stochastic gradient descent (SGD) method. Although the SGD iteration is computationally cheap and its practical performance may be satisfactory under certain circumstances, there is recent evidence of its convergence difficulties and instability for unappropriate choice of parameters. To avoid some of the drawbacks of SGD, stochastic proximal point (SPP) algorithms have been recently considered. We introduce a new variant of the SPP method for solving stochastic convex problems subject to (in)finite intersection of constraints satisfying a linear regularity condition. For the newly introduced SPP scheme we prove new nonasymptotic convergence results. In particular, for convex Lipschitz continuous objective functions, we prove nonasymptotic convergence rates in terms of the expected value function gap of order $\mathcal{O}\left(\frac{1}{k^{1/2}}\right)$, where k is the iteration counter. We also derive better nonasymptotic convergence rates in terms of expected quadratic distance from the iterates to the optimal solution for smooth strongly convex objective functions, which in the best case is of order $\mathcal{O}\left(\frac{1}{k}\right)$. Since these convergence rates can be attained by our SPP algorithm only under some natural restrictions on the stepsize, we also introduce a restarting variant of SPP that overcomes these difficulties and derive the corresponding nonasymptotic convergence rates. Numerical evidence supports the effectiveness of our methods in real problems.

Keywords: Stochastic convex optimization, intersection of convex constraints, stochastic proximal point, nonasymptotic convergence analysis, rates of convergence.

1. Introduction

The randomness in most of the practical optimization applications led the stochastic optimization field to become an essential tool for many applied mathematics areas, such as machine learning (Polyak and Juditsky, 1992), distributed optimization (Necoara et al., 2011), control (Karimi and Kammer, 2017), and sensor networks problems (Blatt and Hero, 2006). Since the randomness usually enters the problem through the cost function and/or the constraints set, in this paper we approach both randomness sources and consider stochastic objective functions subject to stochastic constraints. Usually, in the literature, the following unconstrained stochastic model has been considered:

$$\min_{x\in\mathbb{R}^n} F(x) = (\mathbb{E}[f(x;S)]), \tag{1}$$

where the expectation is taken w.r.t. the random variable S. In the following subsections, we recall some popular numerical optimization algorithms for solving the previous unconstrained stochastic optimization problem and set the context for our contributions.

1.1 Previous work

A very popular approach for solving the unconstrained stochastic problem (1) is the stochastic gradient method (SGD) (Nemirovski et al., 2009; Moulines and Bach, 2011; Rosasco et al., 2014; Polyak and Juditsky, 1992). At each iteration k, the SGD algorithm randomly samples S and takes a step along the gradient of the chosen individual function:

$$x^{k+1} = x^k - \mu_k \nabla f(x^k; S_k),$$

where μ_k is a positive stepsize. Convergence behavior of SGD for the last iterate sequence has been analyzed in (Nemirovski et al., 2009) and for the average of the iterates sequence has been given in (Polyak and Juditsky, 1992). However, there is a recent nonasymptotic convergence analysis of SGD provided in (Moulines and Bach, 2011), under various differentiability assumptions on the objective function. While the SGD scheme is the method of choice in practice for many machine learning applications due to its superior empirical performance, the theoretical estimates obtained in (Moulines and Bach, 2011) highlights several difficulties regarding its practical limitations and robustness. For example, the stepsize is highly constrained to small values by an exponential term from the convergence rate which could be catastrophically increased by uncontrolled variations of the stepsize. More precisely, the convergence rates of SGD with decreasing stepsize $\mu_k = \frac{\mu_0}{k}$, given for the quadratic mean $\{\mathbb{E}[\|x^k - x^*\|^2]\}_{k\geq 0}$, where x^* is the optimal solution of (1), contains certain exponential terms (depending on the initial stepsize) of the following form (Moulines and Bach, 2011):

$$\mathbb{E}[\|x^k - x^*\|^2] \leq \frac{C_1 e^{C_2\mu_0^2}}{k^{\alpha\mu_0}} + \mathcal{O}\left(\frac{1}{k}\right), \tag{2}$$

for $\mu_0 > 2/\alpha$ and for appropriate positive constants C_1, C_2 and α. Note that this convergence rate holds under strong convexity and gradient Lipschitz assumptions on the objective function F. From (2) we observe that $\{\mathbb{E}[\|x^k - x^*\|^2]\}_{k\geq 0}$ can grow exponentially until the stepsizes becomes sufficiently small, a behavior which can be also observed in practical simulations.

Since these drawbacks are naturally introduced by the SGD iteration, other essential modifications of this scheme have been applied for avoiding the issues. One resulted method is the stochastic proximal point (SPP) algorithm for solving the unconstrained stochastic problem (1) having the following iteration (Ryu and Boyd, 2016; Toulis et al., 2016; Bianchi, 2016):

$$x^{k+1} = \arg\min_{z\in\mathbb{R}^n} \left[f(z;S_k) + \frac{1}{2\mu_k}\|z - x^k\|^2 \right].$$

Note that SGD represents a particular SPP iteration applied to the linearization of $f(z;S_k)$ in x^k, that is to the linear function $l_f(z;x^k,S_k)=f(x^k;S_k)+\langle\nabla f(x^k;S_k),z-x^k\rangle$. Of course, when f has an easily computable proximal operator, it is natural to use f instead of its linearization l_f. In (Ryu and Boyd, 2016), the SPP algorithm has been applied to problems with the objective function having Lipschitz continuous gradient and the following *restricted strong convexity* property:

$$f(x;S)\geq f(y;S)+\langle\nabla f(y;S),x-y\rangle+\frac{1}{2}\langle M_S(x-y),x-y\rangle\quad\forall x,y\in\mathbb{R}^n, \tag{3}$$

for some matrix $M_S\succeq 0$, satisfying $\lambda=\lambda_{\min}(\mathbb{E}[M_S])>0$. In (Ryu and Boyd, 2016) the asymptotic global convergence of SPP with decreasing stepsize $\mu_k=\frac{\mu_0}{k}$ is derived, followed by a nonasymptotic analysis for the SPP with constant stepsize. In particular, it has been proven that SPP converges linearly to a noise-dominated region around the optimal solution. Moreover, the following *asymptotic* (i.e. for a *sufficiently large* k) convergence rate in the quadratic mean have been given:

$$\mathbb{E}[\|x^k-x^*\|^2]\leq\left(\frac{1}{e}\right)^{\mu_0\lambda\ln(k+1)}C_1+\begin{cases}\frac{C_2}{(\mu_0\lambda-1)k} & \text{if}\quad \mu_0\lambda>1\\ \frac{C_2\ln(k)}{k} & \text{if}\quad \mu_0\lambda=1\\ \frac{C_2}{(1-\mu_0\lambda)k^{\mu_0\lambda}} & \text{if}\quad \mu_0\lambda<1,\end{cases}$$

where C_1 and C_2 are some positive constants. With the essential difference that no exponential terms depending on μ_0 are encountered, these rates of convergence have similar orders with those for the variable stepsize SGD method. Although in this paper we make similar assumptions on the objective function, we additionally assume the presence of *convex constraints* and provide a *nonasymptotic* convergence analysis of the SPP for a more general stepsize $\mu_k=\frac{\mu_0}{k^\gamma}$, with $\gamma>0$. Moreover, the Moreau smoothing framework used in our paper leads to more elegant and intuitive proofs. Another paper related to the SPP algorithm is (Toulis et al., 2016), where the considered stochastic model involves minimization of the expectation of random particular components $f(x;S)$ defined by the composition of a smooth function and a linear operator, i.e.:

$$f(x;S)=f(a_S^Tx),$$

where $a_S\in\mathbb{R}^n$. Moreover, the objective function $F(x)=\mathbb{E}[f(a_S^Tx)]$ needs to satisfy $\lambda_{\min}\left(\nabla^2F(x)\right)\geq\lambda>0$ for all $x\in\mathbb{R}^n$. The nonasymptotic convergence of the SPP with decreasing stepsize $\mu_k=\frac{\mu_0}{k^\gamma}$, with $\gamma\in(1/2,1]$, has been analyzed in the quadratic mean and the following convergence rate has been derived in (Toulis et al., 2016):

$$\mathbb{E}[\|x^k-x^*\|^2]\leq C\left(\frac{1}{1+\lambda\mu_0\alpha}\right)^{k^{1-\gamma}}+\mathcal{O}\left(\frac{1}{k^\gamma}\right),$$

where C and α are some positive constants. However, the analysis used in (Toulis et al., 2016) cannot be extended to general convex objective functions and complicated constraints, since it is essential in the proofs that each component of the objective function has the form $f(a_S^Tx)$, where $a_S\in\mathbb{R}^n$. In our paper we consider general convex objective functions, which lack the previously discussed structure, with (in)finite number of convex constraints.

Further, in (Bianchi, 2016) a general asymptotic convergence analysis of several variants of SPP scheme within operator theory settings has been provided, under mild convexity assumptions. A particular optimization model instance analyzed in (Bianchi, 2016), related to our paper, is:

$$\min_x\ f(x)\quad\text{s.t.}\ \ x\in\cap_{i=1}^m X_i,$$

for which has been derived the following SPP type algorithm:

$$x^{k+1}=\begin{cases}\arg\min_{z\in\mathbb{R}^n}\left[f(z)+\frac{1}{2\mu_k}\|z-x^k\|^2\right] & \text{if } S_k=0\\ \Pi_{X_{S_k}}(x^k) & \text{otherwise,}\end{cases}$$

where S_k is randomly chosen in $\Omega=\{0,1,\cdots,m\}$ according to a probability distribution $\mathbb{P}$. Although this scheme is very similar to the SPP algorithm, only the almost sure asymptotic convergence has been provided in (Bianchi, 2016). Convergence results of order $\mathcal{O}\left(\frac{1}{k}\right)$ in the strongly convex case, as well as almost sure convergence results under weaker assumptions, are also provided in (Rosasco et al., 2017) for the stochastic proximal gradient algorithm on convex composite optimization problems. In (Combettes and Pesquet, 2016) the asymptotic behavior of a stochastic forward-backward splitting algorithm for finding a zero of the sum of a maximally monotone set-valued operator and a co-coercive operator in Hilbert spaces is investigated. Weak and strong almost sure convergence properties of the iterates are established under mild conditions on the underlying stochastic processes.

A particular case of the stochastic optimization problem (1) is the discrete stochastic model, where the random variable S is discrete and thus, usually the objective function is given as a finite sum of functional components. There exists a large amount of work in the literature on deterministic and randomized algorithms for the finite sum optimization problem. Linear convergence of SGD for solving convex feasibility problems is proven recently in (Necoara, 2017). Convergence analysis of SGD for minimizing an objective function subject to a finite number of convex constraints is provided e.g. in (Necoara, 2017; Nedic, 2011). Linear convergence results on a restarted variant of SGD for finite-sum problems is given in (Yang and Lin, 2016). On the deterministic side, the cyclic incremental gradient methods were extensively analyzed e.g. in (Bertsekas, 2011). Recently, highly efficient algorithms with improved convergence estimates (compared to SGD) for finite sums have been developed using aggregated (averaged) or variance reduction techniques. The first category is based on the common idea of updating the current iterate along the aggregated (averaged) gradient step: e.g. incremental aggregated gradient (IAG) (Vanli et al., 2017), stochastic averaged gradient (SAG) (Roux et al., 2012) and its generalization SAGA (Defazio et al., 2014). Regarding the second category, there are simpler schemes, but memory intensive, such as stochastic variance reduced gradient (SVRG) method introduced in (Johnson and Zhang, 2013). It has been proved that all these schemes can achieve linear convergence under strong convexity and gradient Lipschitz assumptions on the finite sum objective function. Similar optimal performances on finite sum minimization, as for the previous two classes of algorithms, are obtained also for the stochastic dual coordinate ascent (SDCA) method, which has been analyzed in (Shalev-Shwartz and Zhang, 2013).

Other stochastic proximal (gradient) schemes together with their theoretical guarantees are studied in several recent papers as we further exemplify. In (Atchade et al., 2014) a perturbed proximal gradient method is considered for solving composite optimization

problems, where the gradient is intractable and approximated by Monte Carlo methods. Conditions on the stepsize and the Monte Carlo batch size are derived under which the convergence is guaranteed. Two classes of stochastic approximation strategies (stochastic iterative Tikhonov regularization and the stochastic iterative proximal point) are analyzed in (Koshal et al., 2013) for monotone stochastic variational inequalities and almost sure convergence results are presented. A new stochastic optimization method is analyzed in (Yurtsever et al., 2016) for the minimization of the sum of three convex functions, one of which has Lipschitz continuous gradient and satisfies a restricted strong convexity condition. In (Xu, 2011) a finite sample analysis for the averaged SGD is provided, which shows that it usually takes a huge number of samples for averaged SGD to reach its asymptotic region, for improperly chosen learning rate (stepsize). Moreover, simple strategies to properly set the learning rate are derived in the same paper so that it takes a reasonable amount of data for averaged SGD to reach its asymptotic region. In (Niu et al., 2011) it is shown through a novel theoretical analysis that SGD can be implemented in a parallel fashion without any locking. Moreover, for sparse optimization problems (meaning that the most gradient updates only modify small parts of the decision variable) the developed scheme achieves a nearly optimal rate of convergence. A regularized stochastic version of the BFGS method is proposed in (Mokhtari and Ribeiro, 2014) to solve convex optimization problems. Convergence analysis shows that lower and upper bounds on the Hessian eigenvalues of the sample functions are sufficient to guarantee convergence of order $\mathcal{O}\left(\frac{1}{k}\right)$. A comprehensive survey on modern optimization algorithms for machine learning problems is given recently in (Bottou et al., 2016). Based on experience, theoretical results are presented on a straightforward, yet versatile SGD algorithm, its practical behavior is discussed, and opportunities are highlighted for designing new algorithms with improved performance.

1.2 Contributions

In this paper we consider both randomness sources (i.e. objective function and constraints) and thus our problem of interest involves stochastic objective functions subject to (in)finite intersection of constraints. Given the clear superior features of SPP algorithm over the classical SGD scheme, we consider the SPP scheme for solving our problem of interest. The main contributions of this paper are:

(i) More general stochastic optimization model and a new stochastic proximal point algorithm: While most of the existing papers from the stochastic optimization literature consider convex models without constraints or simple (easy projection onto) constraints, in this paper we consider stochastic convex optimization problems subject to (in)finite intersection of constraints satisfying a linear regularity type condition. It turns out that many practical applications, including those from machine learning, fits into this framework: e.g. classification, regression, finite sum minimization, portfolio optimization, convex feasibility, optimal control problems. For this general stochastic optimization model we introduce a new stochastic proximal point (SPP) algorithm. It is worth to mention that although the analysis of an SPP method for stochastic models with complicated constraints is nontrivial and does not follow from the analysis corresponding to the unconstrained setting, our framework allows us to deal with even an infinite number of constraints. To the best of our knowledge, our SPP method is the first stochastic proximal point algorithm that can tackle optimization problems with complicated constraints.

(ii) New nonasymptotic convergence results for the SPP method: For the newly introduced SPP scheme we prove new nonasymptotic convergence results. In particular, for convex and Lipschitz continuous objective functions, we prove nonasymptotic estimates for the rate of convergence of the SPP scheme in terms of the expected value function gap and feasibility violation of order $\mathcal{O}\left(\frac{1}{k^{1/2}}\right)$, where k is the iteration counter. We also derive better nonasymptotic bounds for the rate of convergence of SPP scheme with decreasing stepsize $\mu_k = \frac{\mu_0}{k^\gamma}$, with $\gamma \in (0,1]$, for smooth strongly convex objective functions. For this case the convergence rates are given in terms of expected quadratic distance from the iterates to the optimal solution and are of order:

$$\mathbb{E}[\|x^k - x^*\|^2] \leq C\left(\mathbb{E}\left[\frac{1}{1+\bar{\alpha}_S\mu_0}\right]\right)^{k^{1-\gamma}} + \mathcal{O}\left(\frac{1}{k^\gamma}\right),$$

where C and $\bar{\alpha}_S$ are appropriate nonnegative constants. Note that the derived rates of convergence do not contain any exponential term in μ_0, as it is the case for the SGD scheme, which makes SPP more robust than SGD even in the constrained case. This can be also observed in numerical simulations, see Section 7 below.

(iii) Restarted variant of SPP algorithm and the corresponding convergence analysis: Since the best complexity of our basic SPP scheme can be attained only under some natural restrictions on the initial stepsize μ_0, we also introduce a restarting stochastic proximal point algorithm that overcomes these difficulties. The main advantage of this restarted variant of SPP algorithm is that it is parameter-free and thus it is easily implementable in practice. Under strong convexity and smoothness assumptions on the objective function, for $\gamma > 0$ and epoch counter t, the restarting SPP scheme with the constant stepsize (per epoch) $\frac{1}{t^\gamma}$ provides a nonasymptotic complexity of order $\mathcal{O}\left(\frac{1}{\epsilon^{1+\frac{1}{\gamma}}}\right)$.

Paper outline. The paper is organized as follows. In Section 2 the problem of interest is formulated and analyzed. Further in Section 3, a new stochastic proximal point algorithm is introduced and its relations with the previous work are highlighted. We provide in Section 4 the first main result of this paper regarding the nonasymptotic convergence of SPP in the convex case. Further, stronger convergence results are presented in Section 5 for smooth strongly convex objective functions. In order to improve the convergence of the simple SPP scheme, in Section 6 we introduce a restarted variant of SPP algorithm. In Section 7 we provide some preliminary numerical simulations to highlight the empirical performance of our schemes. Some long proofs are moved in the Appendix.

Notations. We consider the space $\mathbb{R}^n$ composed by column vectors. For $x, y \in \mathbb{R}^n$ denote the scalar product $\langle x, y\rangle = x^T y$ and Euclidean norm by $\|x\| = \sqrt{x^T x}$. The projection operator onto the nonempty closed convex set X is denoted by $\Pi_X(\cdot)$ and the distance from a given x to the set X is denoted by $\text{dist}_X(x) = \min_{z\in X}\|x - z\|$. Given any convex set X, the function $\text{dist}_X(\cdot)$ is convex and the squared distance function $\text{dist}_X^2(\cdot)$ has Lipschitz gradient with constant 1. For some function f, we denote by $\partial f(x)$ the subdifferential set

at x. We also use the following definition of the indicator function of a set X:

$$\mathbb{I}_X(x) = \begin{cases} 0, & \text{if } x \in X \\ \infty, & \text{otherwise.} \end{cases}$$

Finally, we define the function $\varphi_\alpha : (0, \infty) \to \mathbb{R}$ as:

$$\varphi_\alpha(x) = \begin{cases} (x^\alpha - 1)/\alpha, & \text{if } \alpha \neq 0 \\ \log(x), & \text{if } \alpha = 0. \end{cases}$$

2. Problem formulation

In many machine learning applications randomness usually enters the problem through the cost function and/or the constraint set. Minimization of problems having complicating constraints can be very challenging. This is usually alleviated by approximating the feasible set by an (in)finite intersection of simple sets (Necoara, 2017; Necoara et al., 2017; Nedic, 2011). Therefore, in this paper we tackle the following stochastic convex constrained optimization problem:

$$\begin{aligned} F^* = \min_{x \in \mathbb{R}^n} F(x) \quad (:= \mathbb{E}[f(x;S)]) \\ \text{s.t.} \quad x \in X \quad (:= \cap_{S \in \Omega} X_S), \end{aligned} \tag{4}$$

where $f(\cdot; S) : \mathbb{R}^n \to \mathbb{R}$ are convex functions with full domain $\text{dom} f = \mathbb{R}^n$, X_S are nonempty closed convex sets, and S is a random variable with its associated probability space $(\Omega, \mathbb{P})$. Notice that this formulation allows us to include (in)finite number of constraints. We denote the set of optimal solutions with X^* and x^* any optimal point for (4). For the optimization problem (4) we make the following assumptions.

Assumption 1 *For any $S \in \Omega$, the function $f(\cdot; S)$ is proper, closed, convex and Lipschitz continuous, that is there exists $L_{f,S} > 0$ such that*

$$|f(x;S) - f(y;S)| \leq L_{f,S}\|x - y\| \qquad \forall x, y \in \mathbb{R}^n.$$

Notice that Assumption 1 implies that any subgradient $g_f(x;S) \in \partial f(x;S)$ is bounded, that is $\|g_f(x;S)\| \leq L_{f,S}$ for all $x \in \mathbb{R}^n$ and $S \in \Omega$. For the sets we assume:

Assumption 2 *Given $S \in \Omega$, the following two properties hold:*
(i) X_S are simple convex sets (i.e. projections onto these sets are easy).
(ii) There exists $\zeta > 0$ such that the feasible set X satisfies linear regularity:

$$dist_X^2(x) \ \leq \zeta \, \mathbb{E}[dist_{X_S}^2(x)] \qquad \forall x \in \mathbb{R}^n.$$

Assumption 2 (ii) is known in the literature as the *linear regularity property* and it is essential for proving linear convergence for (alternating) projection algorithms, see (Necoara, 2017; Necoara et al., 2017; Nedic, 2011). For example, when X_S are hyperplanes, halfspaces or when X has nonempty interior, then the linear regularity property holds. In particular, if the set X contains a ball of radius $\bar{r}$ and X is contained in a ball of radius $\bar{R}$, then the

ratio $\bar{R}/\bar{r}$ can be taken as the linear regularity constant ζ (Necoara et al., 2017). The linear regularity property is related to the relaxation of strong convexity, the so-called quadratic functional growth condition for an objective function, for smooth convex optimization introduced in (Necoara et al., 2017). In (Necoara et al., 2017) it has been proved that several first order methods converge linearly under functional growth condition and smoothness of the objective function.
Notice that this general optimization model (4) covers a long range of applications from various fields, such as optimization, machine learning, statistics, control, which we discuss in more details below.

2.1 Convex feasibility problem

Let us consider the following objective function and constraints (Necoara, 2017):

$$f(x;S) := \frac{\lambda}{2}\|x\|^2 \quad \forall S \in \Omega \quad \text{and} \quad X = \cap_{S \in \Omega} X_S,$$

where $\lambda > 0$. Then, we obtain the least norm convex feasibility problem:

$$\min_{x \in \mathbb{R}^n} \frac{\lambda}{2}\|x\|^2 \quad \text{s.t.} \ \ x \in \cap_{S \in \Omega} X_S.$$

We can also consider another reformulation of the least norm convex feasibility problem:

$$f(x;S) := \frac{\lambda_S}{2}\|x\|^2 + \mathbb{I}_{X_S}(x) \quad \forall S \in \Omega,$$

where $\lambda_S \geq 0$ and $\mathbb{E}[\lambda_S] = \lambda$. Then, this leads to the stochastic optimization model:

$$\min_{x \in \mathbb{R}^n} \ \mathbb{E}\left[\frac{\lambda_S}{2}\|x\|^2 + \mathbb{I}_{X_S}(x)\right].$$

Finding a point in the intersection of a collection of closed convex sets represents a modeling paradigm for solving important applications such as data compression, neural networks and adaptive filtering, see (Censor et al., 2012) for a complete list.

2.2 Regression problem

Let us consider the matrix $A \in \mathbb{R}^{m \times n}$. For any $S \in \Omega \subseteq \mathbb{R}$, let us define:

$$f(x;S) := \ell(A_S^T x),$$

where ℓ is some loss function and $A_S \in \mathbb{R}^n$. This results in the following constrained optimization model:

$$\min_{x \in \mathbb{R}^n} \quad \mathbb{E}[\ell(A_S^T x)] \quad \text{s.t.} \ \ x \in \cap_{S \in \Omega} X_S.$$

Many learning problems can be modeled into this form, see e.g. (Toulis et al., 2016; Shalev-Shwartz and Zhang, 2013). This type of optimization model has been also considered in (Bianchi, 2016; Rosasco et al., 2014).

2.3 Finite sum problem

Let $\Omega = \{1, \cdots, m\}$ and $\mathbb{P}$ be the uniform discrete probability distribution on Ω. Further, we consider convex functions $f(x; i) = \ell_i(x)$. Then, the following constrained finite sum problem is recovered:

$$\min_{x \in \mathbb{R}^n} \quad \frac{1}{m} \sum_{i=1}^{m} \ell_i(x) \quad \text{s.t. } x \in \cap_{i=1}^{m} X_i.$$

This constrained optimization model appears often in statistics and machine learning applications, where the functions $\ell_i(\cdot)$ typically represent loss functions associated to a given estimator and the feasible set comes from physical constraints, see e.g. (Defazio et al., 2014; Roux et al., 2012; Vanli et al., 2017; Yurtsever et al., 2016). It is also a particular problem of a more general optimization model considered in (Bianchi, 2016).

2.4 Multiple kernel learning problem

In many classification problems we want to learn a convex combination of kernels $\kappa(x, x') = \sum_{j=1}^{M} \beta_j \kappa_j(x, x')$ (Bach et al., 2004). This approach is useful in complex classification problems, where we use polynomial kernels of different degrees or kernels on different domains. The goal is to learn the weights β_j and they are usually found through SVM optimization:

$$\begin{aligned}
&\min_{(w,\beta,\xi,b)} \ \frac{1}{2} \left(\sum_{j=1}^{M} \beta_j \|w_j\| \right)^2 + C \sum_{i=1}^{N} \xi_i \\
&w = (w_1, \cdots, w_M), \ w_j \in \mathbb{R}^{n_j}, \ \beta = (\beta_1, \cdots, \beta_M), \ \xi = (\xi_1, \cdots, \xi_N) \\
&y_i \left(\sum_{j=1}^{M} \beta_j w_j^T x_{ij} + b \right) \geq 1 - \xi_i \ \forall i = 1 : N, \ \xi \geq 0, \ \beta \geq 0, \ \sum_{j=1}^{M} \beta_j = 1.
\end{aligned}$$

Note that this formulation is equivalent to linear SVM for $M = 1$. We usually obtain a sparse solution in β, where each component β_j corresponds to one kernel κ_j. The dual of this optimization problem takes the form:

$$\begin{aligned}
&\min_{(\gamma,\alpha)} \ \frac{1}{2}\gamma^2 - \sum_{i=1}^{N} \alpha_i \\
&0 \leq \alpha \leq C, \ \sum_{i=1}^{N} \alpha_i y_i = 0, \ \sum_{p=1}^{N} \sum_{q=1}^{N} \alpha_p \alpha_q y_p y_q \kappa_j(x_p, x_q) \leq \gamma^2 \ \ \forall j = 1 : M.
\end{aligned}$$

This convex Quadratic Optimization problem with Quadratic Constraints can be easily reformulated as a Linear Program with infinite number of simple constraints by introducing the notation $Q_j(\alpha) = \sum_{p=1}^{N} \sum_{q=1}^{N} \alpha_p \alpha_q y_p y_q \kappa_j(x_p, x_q)$ (Sonnenburg et al., 2006):

$$\begin{aligned}
&\max_{(\theta,\beta)} \ \theta \\
&\theta \in \mathbb{R}, \ \ \beta \geq 0, \ \ \sum_{j=1}^{M} \beta_j = 1, \ \ \sum_{j=1}^{M} \beta_j \left(\frac{1}{2} Q_j(\alpha) - \sum_{i=1}^{N} \alpha_i \right) \geq \theta \quad \forall \alpha \in \Omega(y),
\end{aligned}$$

where we use the notation

$$\Omega(y) = \left\{ \alpha : \ 0 \leq \alpha \leq C, \ \sum_{i=1}^{N} \alpha_i y_i = 0 \right\}.$$

There are many methods for solving Linear Programs with infinite number of constraints, in particular algorithms related to boosting (Sonnenburg et al., 2006). Note that in this Linear Program formulation the sets X_S are simple hyperplanes.

2.5 Optimal control problem

In this section we briefly present the H_2 optimal control problem for linear systems (see (Karimi and Kammer, 2017) for a detailed exposition). In this application one aims at finding a stabilizing controller K for a linear system which minimize an H_2 performance indicator. This problem can be formulated as:

$$\begin{aligned}
&\min_{K(\omega),\Gamma(\omega)} \int_{-\frac{\pi}{T}}^{\frac{\pi}{T}} \text{trace}[\Gamma(\omega)] d\omega \\
&\text{s.t. : } W(\omega)[(I_n + G(\omega)K(\omega))^*(I_n + G(\omega)K(\omega))]^{-1} W^*(\omega) \preceq \Gamma(\omega) \quad \forall \omega \in \Omega,
\end{aligned}$$

where the frequencies ω are taken in the interval $\Omega = \left[-\frac{\pi}{T}, \frac{\pi}{T}\right]$, $G(\omega), W(\omega)$ are the parameters associated with the linear dynamical system under consideration, $\Gamma(\omega)$ is a positive semidefinite matrix and $K(\omega)$ is the controller that needs to be identified. Note that the previous H_2 optimal control problem requires that the constraints, expressed through matrix inequalities, to hold for all frequencies ω in the interval Ω. Moreover, the objective function can be expressed as an expectation over the same interval Ω. In control theory, $\Gamma(\omega)$ and $K(\omega)$ are taken as polynomial matrices in the frequencies ω. Moreover, the previous matrix inequalities are usually convexified using Schur complement and linearization techniques and then the interval Ω is discretized to get a finite number of constraints (linear matrix inequalities) (Karimi and Kammer, 2017).

3. Stochastic Proximal Point algorithm

In this section we propose solving the optimization problem (4) through stochastic proximal point type algorithms. It has been proven in (Necoara et al., 2017) that the optimization problem (4) can be equivalently reformulated under Assumption 2 into the following stochastic optimization problem:

$$\min_{x \in \mathbb{R}^n} \ \mathbb{E}\left[f(x; S) + \mathbb{I}_{X_S}(x) \right]. \tag{5}$$

Since each component of the stochastic objective is nonsmooth, a first possible approach is to apply stochastic subgradient methods (Duchi and Singer, 2009; Moulines and Bach, 2011), which would yield simple algorithms, but having usually a relatively slow sublinear convergence rate. Therefore, for more robustness, one can deal with the nonsmoothness through the Moreau smoothing framework. However, there are multiple potential approaches in

this direction. For a given smoothing parameter $\mu > 0$, we can smooth each functional component and the associated indicator function together to obtain the following smooth approximation for the nonsmooth convex function $f(\cdot;S) + \mathbb{I}_{X_S}$:

$$\bar{f}_\mu(x;S) := \min_{z\in\mathbb{R}^n} \; f(z;S) + \mathbb{I}_{X_S}(z) + \frac{1}{2\mu}\|z-x\|^2.$$

Let us denote the corresponding prox operator by $\bar{z}_\mu(x;S) = \arg\min_{z\in\mathbb{R}^n} f(z;S) + \mathbb{I}_{X_S}(z) + \frac{1}{2\mu}\|z-x\|^2$. It is known that any Moreau approximation $\bar{f}_\mu(\cdot;S)$ is differentiable having the gradient $\nabla \bar{f}_\mu(x;S) = \frac{1}{\mu}(x - \bar{z}_\mu(x;S))$ (Rockafellar and Wets, 1998). Moreover, the gradient is Lipschitz continuous with constants bounded by $\frac{1}{\mu}$. Then, instead of solving the nonsmooth problem (5) we can consider solving the smooth approximation:

$$\min_{x\in\mathbb{R}^n} \; \bar{F}_\mu(x) \quad \left(:= \mathbb{E}[\bar{f}_\mu(x;S)]\right).$$

Notice that we can easily apply the classical SGD strategy to the newly created smooth objective function, which results in the following iteration:

$$\begin{aligned} x^{k+1} &= x^k - \mu_k \nabla \bar{f}_{\mu_k}(x^k;S_k) = \bar{z}_{\mu_k}(x^k;S_k) \\ &= \arg\min_{z\in\mathbb{R}^n} \; f(z;S_k) + \mathbb{I}_{X_{S_k}}(z) + \frac{1}{2\mu_k}\|z-x^k\|^2. \end{aligned}$$

However, the nonasymptotic analysis technique considered in our paper encounters difficulties with this variant of the algorithm. The main difficulty consists in proving the bound $\|\nabla \bar{f}_\mu(x;S)\| \leq \|g_{f(\cdot;S)+\mathbb{I}_{X_S}}(x)\|$ for all $x \in \mathbb{R}^n$, where $g_{f(\cdot;S)+\mathbb{I}_{X_S}}(x) \in \partial(f(\cdot;S) + \mathbb{I}_{X_S})(x)$. We believe that such a bound is essential in our convergence analysis and we leave for future work the analysis of this iterative scheme. Therefore, we considered a second approach based on a smooth Moreau approximation only for the functional component $f(\cdot;S)$ and keeping the indicator function $\mathbb{I}_{X_S}$ in its original form, that is:

$$f_\mu(x;S) := \min_{z\in\mathbb{R}^n} \; f(z;S) + \frac{1}{2\mu}\|z-x\|^2$$

for some smoothing parameter $\mu > 0$. Then, instead of solving nonsmooth problem (5), we solve the following composite approximation:

$$\min_{x\in\mathbb{R}^n} \; F_\mu(x) \quad (:= \mathbb{E}[f_\mu(x;S) + \mathbb{I}_{X_S}(x)]). \tag{6}$$

Let us denote the corresponding prox operator by:

$$z_\mu(x;S) = \arg\min_{z\in\mathbb{R}^n} f(z;S) + \frac{1}{2\mu}\|z-x\|^2.$$

Further, on the stochastic composite approximation (6) we can apply the stochastic projected gradient method, which leads to a stochastic proximal point like scheme for solving the original problem (4):

Algorithm SPP $(x_0, \{\mu_k\}_{k\geq 0})$

For $k \geq 1$ compute:
1. Choose randomly $S_k \in \Omega$ w.r.t. probability distribution $\mathbb{P}$
2. Update: $y^k = z_{\mu_k}(x^k;S_k)$ and $x^{k+1} = \Pi_{X_{S_k}}(y^k)$

where $x^0 \in \mathbb{R}^n$ is some initial starting point and $\{\mu_k\}_{k\geq 0}$ is a nonincreasing positive sequence of stepsizes. We assume that the algorithm SPP returns either the last point x^k or the average point $\hat{x}^k = \frac{1}{\sum_{i=0}^{k-1}\mu_i}\sum_{i=0}^{k-1}\mu_i x^i$ when it is called as a subroutine. Since the update rule of the positive smoothing (stepsize) sequence $\{\mu_k\}_{k\geq 0}$ strongly contributes to the convergence of the scheme, we discuss in the following sections the most advantageous choices. We first prove the following useful auxiliary result:

Lemma 3 *Let $\mu > 0$, $S \in \Omega$. Then, for any $g_f(x;S) \in \partial f(x;S)$, the following holds:*

$$\|\nabla f_\mu(x;S)\| \leq \|g_f(x;S)\| \qquad \forall x \in \mathbb{R}^n.$$

Proof The optimality condition of problem $\min_{z\in\mathbb{R}^n} f(z;S) + \frac{1}{2\mu}\|x-z\|^2$ is given by:

$$\frac{1}{\mu}(x - z_\mu(x;S)) \in \partial f(z_\mu(x;S);S).$$

The above inclusion easily implies that there is $g_f(z_\mu(x;S);S) \in \partial f(z_\mu(x;S);S)$ such that:

$$\begin{aligned} \frac{1}{\mu}\|z_\mu(x;S) - x\|^2 &= \langle g_f(z_\mu(x;S);S), x - z_\mu(x;S)\rangle \\ &= \langle g_f(x;S), x - z_\mu(x;S)\rangle + \langle g_f(z_\mu(x;S);S) - g_f(x;S), x - z_\mu(x;S)\rangle \\ &\leq \langle g_f(x;S), x - z_\mu(x;S)\rangle, \end{aligned}$$

where in the last inequality we used the convexity of f. Lastly, by applying the Cauchy-Schwarz inequality in the right hand side we get the above statement. ■

The following two well-known inequalities, which can be found in (Bullen, 2003), will be also useful in the sequel:

(*i*) **[Bernoulli]** Let $t \in [0,1]$ and $x \in [-1,\infty)$, then the following holds:

$$(1+x)^t \leq 1 + tx. \tag{7}$$

(*ii*) **[Minkowski]** Let x and y be two random variables. Then, for any $1 \leq p < \infty$, the following inequality holds:

$$(\mathbb{E}[|x+y|^p])^{1/p} \leq (\mathbb{E}[|x|^p])^{1/p} + (\mathbb{E}[|y|^p])^{1/p}. \tag{8}$$

4. Nonasymptotic complexity of SPP: convex objective function

In this section we analyze, under Assumptions 1 and 2, the iteration complexity of SPP scheme with nonincreasing stepsize rule to approximately solve the optimization problem (4). In order to prove this nonasymptotic result, we define $\hat{\mu}_{1,k}=\sum\limits_{i=0}^{k-1}\mu_i$, $\hat{\mu}_{2,k}=\sum\limits_{i=0}^{k-1}\mu_i^2$ and the averaged sequences $\hat{x}^k=\frac{1}{\hat{\mu}_{1,k}}\sum_{i=0}^{k-1}\mu_i x^i$ and $\hat{y}^k=\frac{1}{\hat{\mu}_{1,k}}\sum_{i=0}^{k-1}\mu_i y^i$. Moreover, denote by $\mathcal{F}_k$ the history of random choices $\{S_k\}_{k\geq 0}$, i.e. $\mathcal{F}_k=\{S_0,\cdots,S_k\}$.

Lemma 4 *Let Assumptions 1 and 2 hold and the sequences $\{x^k,y^k\}_{k\geq 0}$ be generated by SPP scheme with positive stepsize $\{\mu_k\}_{k\geq 0}$. Then the following relation holds:*

$$\mathbb{E}\left[dist^2_{X_{S_k}}(\hat{y}^k)\right]\geq\frac{1}{\zeta}\mathbb{E}\left[dist^2_X(\hat{x}^k)\right]-\frac{\hat{\mu}_{2,k}}{\hat{\mu}_{1,k}}\sqrt{\mathbb{E}[dist^2_X(\hat{x}^k)]}\sqrt{\mathbb{E}[L^2_{f,S}]}.$$

Proof See Appendix for the proof. ■

Now, we are ready to derive the convergence rate of SPP in the average sequence $\hat{x}^k$:

Theorem 5 *Under Assumptions 1 and 2, let the sequence $\{x^k\}_{k\geq 0}$ be generated by the algorithm SPP with nonincreasing positive stepsize $\{\mu_k\}_{k\geq 0}$. Define $\mathcal{R}_\mu=\mu_0\zeta(\|x^0-x^*\|^2+\mathbb{E}[L^2_{f,S}]\hat{\mu}_{2,k})$, then the following estimates for suboptimality and feasibility violation hold:*

$$\begin{aligned}-\zeta\mathbb{E}[L^2_{f,S}]\left(\frac{\hat{\mu}_{2,k}}{\hat{\mu}_{1,k}}+2\mu_0\right)-\sqrt{\mathbb{E}[L^2_{f,S}]\,\frac{\mathcal{R}_\mu}{\hat{\mu}_{1,k}}}\leq\mathbb{E}[F(\hat{x}^k)]-F^*\leq\frac{\mathcal{R}_\mu}{2\mu_0\zeta\hat{\mu}_{1,k}}\\ \mathbb{E}[dist^2_X(\hat{x}^k)]\leq 2\zeta^2\mathbb{E}[L^2_{f,S}]\left(\frac{\hat{\mu}_{2,k}}{\hat{\mu}_{1,k}}+2\mu_0\right)^2+\frac{2\mathcal{R}_\mu}{\hat{\mu}_{1,k}}.\end{aligned}\tag{9}$$

Proof See Appendix for the proof. ■

Note that the right suboptimality bound (9), obtained for the SPP algorithm, is similar with the one given for the standard subgradient method (Nesterov, 2004). Below we provide the convergence estimates for the algorithm SPP with constant stepsize for a desired accuracy $\epsilon>0$. For simplicity, assume that $\|x^0-x^*\|\geq 1$ and $\mathbb{E}[L^2_{f,S}]\geq 2$.

Corollary 6 *Under the assumptions of Theorem 5, let $\{x^k\}_{k\geq 0}$ be the sequence generated by algorithm SPP with constant stepsize $\mu_k=\mu>0$. Also let $\epsilon>0$ be the desired accuracy, K be an integer satisfying:*

$$K\geq\frac{\mathbb{E}[L^2_{f,S}]\|x^0-x^*\|^2}{\epsilon^2}\max\left\{1,(3\zeta+\sqrt{2\zeta})^2\right\},$$

and the stepsize be chosen as:

$$\mu=\frac{\epsilon}{\mathbb{E}[L^2_{f,S}](3\zeta+\sqrt{2\zeta})}.$$

Then, after K iterations, the average point $\hat{x}^K=\frac{1}{K}\sum\limits_{i=0}^{K-1}x^i$ satisfies:

$$\left|\mathbb{E}[F(\hat{x}^K)]-F^*\right|\leq\epsilon\quad\text{and}\quad\sqrt{\mathbb{E}[dist^2_X(\hat{x}^K)]}\leq\epsilon.$$

Proof We consider $k=K$ in Theorem 5 and, by taking into account that $\mu_k=\mu$ for all $k\geq 0$, we aim to obtain the lowest value of the right hand side of (9) by minimizing over $\mu>0$. Thus, by denoting that $r_0=\|x^0-x^*\|$, we obtain for the optimal smoothing parameter:

$$\mu=\sqrt{\frac{r_0^2}{K\mathbb{E}[L^2_{f,S}]}}$$

the optimal rate

$$\mathbb{E}[F(\hat{x}^K)]-F^*\leq\sqrt{\frac{\mathbb{E}[L^2_{f,S}]r_0^2}{K}}.\tag{10}$$

Also using the optimal parameter $\tilde{\mu}$ into the other relations of Theorem 5 result in:

$$\mathbb{E}[\text{dist}^2_X(\hat{x}^K)]\leq\frac{r_0^2}{K}\left(18\zeta^2+4\zeta\right)\tag{11}$$

and

$$\mathbb{E}[F(\hat{x}^K)]-F^*\geq-(3\zeta+\sqrt{2\zeta})\sqrt{\frac{\mathbb{E}[L^2_{f,S}]r_0^2}{K}}.\tag{12}$$

From the upper and lower suboptimality bounds (10), (12) and feasibility bound (11), we deduce the following bound:

$$K\geq\frac{\mathbb{E}[L^2_{f,S}]r_0^2}{\epsilon^2}\max\left\{1,(3\zeta+\sqrt{2\zeta})^2\right\}$$

which confirms our result. ■

In conclusion, Corollary 6 states that for a desired accuracy ϵ, if we choose a constant stepsize $\mu=\mathcal{O}(\epsilon)$ and perform a number of SPP iterations $\mathcal{O}\left(\frac{1}{\epsilon^2}\right)$ we obtain an ϵ-optimal solution for our original stochastic constrained convex problem (4). Note that for convex problems with objective function having bounded subgradients the previous convergence estimates derived for the SPP algorithm are similar to those corresponding to the classical deterministic proximal point method (Guler, 1991) and subgradient method (Nesterov, 2004).

5. Nonasymptotic complexity of SPP: strongly convex objective function

In this section we analyze the convergence behavior of the SPP scheme under smoothness and strong convexity assumptions on the objective function of constrained problem (4). Therefore, in this section the Assumption 1 is replaced by the following assumptions:

Assumption 7 *Each function $f(\cdot;S)$ is differentiable and $\sigma_{f,S}$-strongly convex, that is there exists strong convexity constant $\sigma_{f,S}\geq 0$ such that:*

$$f(x;S)\geq f(y;S)+\langle\nabla f(y;S),x-y\rangle+\frac{\sigma_{f,S}}{2}\|x-y\|^2 \qquad \forall x,y\in\mathbb{R}^n.$$

Moreover, the strong convexity constants $\sigma_{f,S}$ satisfy $\sigma_F=\mathbb{E}[\sigma_{f,S}]>0$.

Notice that if for some function $f(\cdot;S)$ the corresponding constant $\sigma_{f,S}=0$, then $f(\cdot;S)$ is only convex. However, relation $\mathbb{E}[\sigma_{f,S}]=\sigma_F>0$ implies that the whole objective function F of problem (4) is strongly convex with constant $\sigma_F>0$. In the sequel we will analyze the SPP scheme under the following additional smoothness assumption:

Assumption 8 *Each function $f(\cdot;S)$ has Lipschitz gradient, that is there exists Lipschitz constant $L_{f,S}>0$ such that:*

$$\|\nabla f(x;S)-\nabla f(y;S)\|\leq L_{f,S}\|x-y\| \qquad \forall x,y\in\mathbb{R}^n.$$

Note that Assumptions 7 and 8 are standard for the convergence analysis of SPP like schemes, see e.g. (Moulines and Bach, 2011; Ryu and Boyd, 2016). We first present an auxiliary result on the behavior of the proximal mapping $z_\mu(\cdot;S)$.

Lemma 9 *Let $f(\cdot;S)$ satisfy Assumption 7. Further, for any $S\in\Omega$ and $\mu>0$, we define $\theta_S(\mu)=\frac{1}{1+\mu\sigma_{f,S}}$. Then, the following contraction inequality holds for the prox operator:*

$$\|z_\mu(x;S)-z_\mu(y;S)\|\leq\theta_S(\mu)\|x-y\| \qquad \forall x,y\in\mathbb{R}^n.$$

Proof See Appendix for the proof. ■

Notice that if all the functions $f(\cdot;S)$ are just convex, that is they satisfy Assumption 7 with $\sigma_{f,S}=0$, then Lemma 9 highlights the nonexpansiveness property of the proximal operator $z_\mu(\cdot;S)$. We will further keep using the notation $\theta_S(\mu)$ for the contraction factor of the operator $z_\mu(\cdot;S)$. Moreover, in all our proofs below, regarding the results in expectation, we use the standard technique of applying first expectation with respect to S_k conditioned on $\mathcal{F}_{k-1}$ and then apply the expectation over the entire history $\mathcal{F}_{k-1}$ (see the proof of Theorem 5). For simplicity of the exposition and for saving space, we omit these details below.

5.1 Linear convergence to noise dominated region for constant stepsize SPP

Next we analyze the sequence generated by the SPP scheme with constant stepsize $\mu>0$ and provide a nonasymptotic bound on the quadratic mean $\{\mathbb{E}[\|x^k-x^*\|^2]\}_{k\geq 0}$.

Theorem 10 *Under Assumption 7, let the sequence $\{x^k\}_{k\geq 0}$ be generated by the algorithm SPP with constant stepsize $\mu>0$. Further, assume $\sigma_f^{\max}=\sup_{S\in\Omega}\sigma_{f,S}<\infty$. Then, $\mathbb{E}[\theta_S^2(\mu)]\leq\mathbb{E}[\theta_S(\mu)]<1$ and the following linear convergence to some region around the optimal point in the quadratic mean holds:*

$$\mathbb{E}[\|x^k-x^*\|^2]\leq 2\left(\mathbb{E}\left[\theta_S^2(\mu)\right]\right)^k\|x^0-x^*\|^2+\frac{2\mu^2\mathbb{E}[\|\nabla f(x^*;S)\|^2]}{\left(1-\sqrt{\mathbb{E}[\theta_S^2(\mu)]}\right)^2}.$$

Proof First, it can be easily seen that for any $\mu>0$ and $S\in\Omega$ we have $\theta_S^2(\mu)\leq\theta_S(\mu)\leq 1$ and assuming that $\sigma_f^{\max}<\infty$ we obtain:

$$0\leq\mathbb{E}[\theta_S^2(\mu)]\leq\mathbb{E}[\theta_S(\mu)]=\mathbb{E}\left[\frac{1}{1+\mu\sigma_{f,S}}\right]=1-\mathbb{E}\left[\frac{\mu\sigma_{f,S}}{1+\mu\sigma_{f,S}}\right]\leq 1-\frac{\mu\sigma_F}{1+\mu\sigma_f^{\max}}<1.$$

Then, by applying Lemma 9 with $S=S_k, x=x^k$ and $z=x^*$, results in:

$$\left\|z_\mu(x^k;S_k)-z_\mu(x^*;S_k)\right\|\leq\theta_{S_k}(\mu)\|x^k-x^*\|,$$

which, by the triangle inequality, further implies:

$$\left\|z_\mu(x^k;S_k)-x^*\right\|\leq\theta_{S_k}(\mu)\|x^k-x^*\|+\|z_\mu(x^*;S_k)-x^*\|.$$

By using the nonexpansiveness property of the projection operator we get that $\|x^{k+1}-x^*\|\leq\|y^k-x^*\|$, then the last inequality leads to the reccurent relation:

$$\left\|x^{k+1}-x^*\right\|\leq\left\|z_\mu(x^k;S_k)-x^*\right\|\leq\theta_{S_k}(\mu)\|x^k-x^*\|+\|z_\mu(x^*;S_k)-x^*\|. \tag{13}$$

The relation (13), Minkowski inequality and Lemma 3 lead to the following recurrence:

$$\begin{aligned}\sqrt{\mathbb{E}[\|x^{k+1}-x^*\|^2]}&\overset{(13)}{\leq}\sqrt{\mathbb{E}\left[\left(\theta_{S_k}(\mu)\|x^k-x^*\|+\|z_\mu(x^*;S_k)-x^*\|\right)^2\right]}\\&\overset{(8)}{\leq}\sqrt{\mathbb{E}\left[\theta_{S_k}^2(\mu)\|x^k-x^*\|^2\right]}+\sqrt{\mathbb{E}\left[\|z_\mu(x^*;S_k)-x^*\|^2\right]}\\&=\sqrt{\mathbb{E}\left[\theta_S^2(\mu)\right]}\sqrt{\mathbb{E}\left[\|x^k-x^*\|^2\right]}+\mu\sqrt{\mathbb{E}\left[\|\nabla f_\mu(x^*;S)\|^2\right]}\\&\overset{\text{Lemma 3}}{\leq}\sqrt{\mathbb{E}\left[\theta_S^2(\mu)\right]}\sqrt{\mathbb{E}[\|x^k-x^*\|^2]}+\mu\sqrt{\mathbb{E}\left[\|\nabla f(x^*;S)\|^2\right]}.\end{aligned}$$

This yields the following relation valid for all $\mu>0$ and $k\geq 0$:

$$\sqrt{\mathbb{E}[\|x^{k+1}-x^*\|^2]}\leq\sqrt{\mathbb{E}\left[\theta_S^2(\mu)\right]}\sqrt{\mathbb{E}[\|x^k-x^*\|^2]}+\mu\sqrt{\mathbb{E}\left[\|\nabla f(x^*;S)\|^2\right]}, \tag{14}$$

Denote $r_k=\sqrt{\mathbb{E}[\|x^k-x^*\|^2]}$, $\eta=\sqrt{\mathbb{E}\left[\|\nabla f(x^*;S)\|^2\right]}$ and $\theta(\mu)=\sqrt{\mathbb{E}\left[\theta_S^2(\mu)\right]}$. Then, we get:

$$r_{k+1}\leq\theta(\mu)r_k+\mu\eta.$$

Finally, a simple inductive argument leads to:

$$\begin{aligned}r_k&\leq r_0\theta(\mu)^k+\mu\eta\left[1+\theta(\mu)+\cdots+\theta(\mu)^{k-1}\right]\\&=r_0\theta(\mu)^k+\mu\eta\frac{1-\theta(\mu)^k}{1-\theta(\mu)}\\&\leq r_0\theta(\mu)^k+\frac{\mu\eta}{1-\theta(\mu)}.\end{aligned}$$

By squaring and returning to our basic notations, we recover our statement. ■

Theorem 10 proves a linear convergence rate in expectation, without assuming any kind of smoothness on the objective function, for the sequence $\{x^k\}_{k\geq 0}$ generated by SPP with constant stepsize $\mu > 0$ when the iterates are outside of a *noise dominated* neighborhood of the optimal set of radius $\frac{\mu\sqrt{\mathbb{E}[\|\nabla f(x^*;S)\|^2]}}{1-\sqrt{\mathbb{E}[\theta_S^2(\mu)]}}$. It also establishes the boundedness of the sequence $\{x^k\}_{k\geq 0}$ when the stepsize is constant. Notice that in (Ryu and Boyd, 2016) a similar result has been given for an unconstrained optimization model with the difference that the convergence rate was provided for $\mathbb{E}[\|x^k - x^*\|]$. However, our proof is simpler and more elegant, based on the properties of Moreau approximation, despite the fact that we consider the constrained case.

5.2 Nonasymptotic sublinear convergence rate of variable stepsize SPP

In this section we derive sublinear convergence rate of order $\mathcal{O}(1/k^\gamma)$ for the variable stepsize SPP scheme, in a nonasymptotic fashion. We first prove the boundedness of $\{x^k\}_{k\geq 0}$ when the stepsize is nonincreasing, which will be useful for the subsequent convergence results.

Lemma 11 *Under Assumption 7, let the sequence $\{x^k\}_{k\geq 0}$ be generated by the algorithm SPP with nonincreasing positive stepsize $\{\mu_k\}_{k\geq 0}$. Then, the following relation holds:*

$$\mathbb{E}\left[\|x^k - x^*\|\right] \leq \sqrt{\mathbb{E}[\|x^k - x^*\|^2]} \leq \max\left\{\|x^0 - x^*\|, \frac{\mu_0\sqrt{\mathbb{E}\left[\|\nabla f(x^*;S)\|^2\right]}}{1-\sqrt{\mathbb{E}\left[\theta_S^2(\mu_0)\right]}}\right\}.$$

Proof See Appendix for the proof. ■

Furthermore, we need an upper bound on the sequence $\{\mathbb{E}[\|\nabla f(x^k;S)\|]\}_{k\geq 0}$:

Lemma 12 *Under Assumptions 7 and 8, let the sequence $\{x^k\}_{k\geq 0}$ be generated by the algorithm SPP with nonincreasing positive stepsizes $\{\mu_k\}_{k\geq 0}$. Then, the following holds:*

$$\mathbb{E}[\|\nabla f(x^k;S)\|^2] \leq 2\mathbb{E}[\|\nabla f(x^*;S)\|^2] + 2\mathbb{E}[L_{f,S}^2]\mathcal{A}^2,$$

where $\mathcal{A} = \max\left\{\|x^0 - x^*\|, \frac{\mu_0\sqrt{\mathbb{E}[\|\nabla f(x^*;S)\|^2]}}{1-\sqrt{\mathbb{E}\left[\theta_S^2(\mu_0)\right]}}\right\}$.

Proof From the Lipschitz continuity of $\nabla f(\cdot;S)$ we have that $\|\nabla f(x;S) - \nabla f(x^*;S)\| \leq L_{f,S}\|x - x^*\|$ for all $x \in \mathbb{R}^n$, which implies:

$$\|\nabla f(x^k;S)\|^2 \leq (\|\nabla f(x^*;S)\| + L_{f,S}\|x^k - x^*\|)^2 \leq 2\|\nabla f(x^*;S)\|^2 + 2L_{f,S}^2\|x^k - x^*\|^2.$$

By taking expectation in both sides we get:

$$\mathbb{E}[\|\nabla f(x^k;S)\|^2] \leq 2\mathbb{E}[\|\nabla f(x^*;S)\|^2] + 2\mathbb{E}[L_{f,S}^2]\mathbb{E}[\|x^k - x^*\|^2].$$

Lastly, by using Lemma 11 we obtain our statement. ■

Finally, we provide a non-trivial upper bound on the feasibility gap, which automatically leads to a iterative descent in the distance to the feasible set of the sequence $\{x^k\}_{k\geq 0}$, generated by the SPP scheme with nonincreasing stepsizes.

Lemma 13 *Under Assumptions 2, 7 and 8, let the sequence $\{x^k\}_{k\geq 0}$ be generated by SPP scheme with nonincreasing stepsizes $\{\mu_k\}_{k\geq 0}$. Then, the following relation holds:*

$$\sqrt{\mathbb{E}[dist_X^2(x^k)]} \leq \left(1 - \frac{1}{\zeta}\right)^{k/2}\left[dist_X(x^0) + 2\mu_0\zeta\mathcal{B}\right] + 2\mu_{k-\lceil\frac{k}{2}\rceil}\zeta\mathcal{B},$$

where $\mathcal{B} = \sqrt{2\mathbb{E}[\|\nabla f(x^*;S)\|^2]} + \mathcal{A}\sqrt{2\mathbb{E}[L_{f,S}^2]}$.

Proof See Appendix for the proof. ■

Now, we are ready to derive the nonasymptotic convergence rate of the Algorithm SPP with nonincreasing stepsizes. For simplicity, we denote $\eta = \sqrt{\mathbb{E}[\|\nabla f(x^*;S)\|^2]}$ and keep the notations for $\mathcal{A}$ from Lemma 12 and for $\mathcal{B}$ from Lemma 13.

Theorem 14 *Under Assumptions 2, 7 and 8, let the sequence $\{x^k\}_{k\geq 0}$ be generated by the algorithm SPP with the stepsize $\mu_k = \frac{\mu_0}{k^\gamma}$ for all $k \geq 1$, with $\mu_0 > 0$ and $\gamma \in (0,1]$, and denote $\theta_0 = \mathbb{E}\left[\theta_S^2(\mu_0)\right] = \mathbb{E}\left[\frac{1}{(1+\mu_0\sigma_{f,S})^2}\right]$. Then, the following relations hold:*
(i) If $\gamma \in (0,1)$, then we have the following nonasymptotic convergence rates:

$$\mathbb{E}[\|x^k - x^*\|^2] \leq \theta_0^{\varphi_{1-\gamma}(k)} r_0^2 + \mathcal{D}\theta_0^{\varphi_{1-\gamma}(k) - \varphi_{1-\gamma}(\frac{k+1}{2})}\mu_0^2\left[\varphi_{1-2\gamma}\left(\frac{k+1}{2}\right) + 2\right] + \frac{\mathcal{D}\mu_0^2 4^\gamma}{(1-\theta_0)k^\gamma}.$$

(ii) If $\gamma = 1$, then we have the following nonasymptotic convergence rate:

$$\mathbb{E}[\|x^k - x^*\|^2] \leq \begin{cases} \theta_0^{\varphi_0(k)} r_0^2 + \frac{2\mu_0^2}{k\left(\ln\left(\frac{1}{\theta_0}\right)-1\right)} & \text{if} \quad \theta_0 < \frac{1}{e} \\ \theta_0^{\varphi_0(k)} r_0^2 + \frac{2\mu_0^2 \ln k}{k} & \text{if} \quad \theta_0 = \frac{1}{e} \\ \theta_0^{\varphi_0(k)} r_0^2 + \left(\frac{2}{k}\right)^{\ln\left(\frac{1}{\theta_0}\right)} \frac{\mu_0^2}{1-\ln\left(\frac{1}{\theta_0}\right)} & \text{if} \quad \theta_0 > \frac{1}{e}, \end{cases}$$

where $\mathcal{D} = 4\|\nabla F(x^*)\|\left[\frac{dist_X(x^0)+2\mu_0\zeta\mathcal{B}}{\mu_0\ln(\zeta/(\zeta-1))} + 3^\gamma\mathcal{B}\zeta\right] + 2\eta\sqrt{2\eta^2 + 2\mathbb{E}[L_{f,S}^2]\mathcal{A}^2} + 2\eta\mathcal{A}\sqrt{\mathbb{E}[L_{f,S}^2]}$.

Proof See Appendix for the proof. ■

For more clear estimates of the convergence rates obtained in Theorem 14, we provide in the next corollary a summary given in terms of the dominant terms:

Corollary 15 *Under the assumptions of Theorem 14 the following convergence rates hold:*
(i) If $\gamma \in (0,1)$, then we have convergence rate of order:

$$\mathbb{E}[\|x^k - x^*\|^2] \leq \mathcal{O}\left(\frac{1}{k^\gamma}\right)$$

(ii) If $\gamma = 1$, then we have convergence rate of order:

$$\mathbb{E}[\|x^k - x^*\|^2] \leq \begin{cases} \mathcal{O}\left(\frac{1}{k}\right) & \text{if } \theta_0 < \frac{1}{e} \\ \mathcal{O}\left(\frac{\ln k}{k}\right) & \text{if } \theta_0 = \frac{1}{e} \\ \mathcal{O}\left(\frac{1}{k}\right)^{2\ln\left(\frac{1}{\theta_0}\right)} & \text{if } \theta_0 > \frac{1}{e}. \end{cases}$$

Proof First assume that $\gamma \in (0, \frac{1}{2})$. This assumption implies that $1 - 2\gamma > 0$ and that:

$$\varphi_{1-2\gamma}\left(\frac{k}{2}+2\right) = \frac{\left(\frac{k}{2}+2\right)^{1-2\gamma} - 1}{1-2\gamma} \leq \frac{\left(\frac{k}{2}+2\right)^{1-2\gamma}}{1-2\gamma}. \tag{15}$$

On the other hand, by using the inequality $e^{-x} \leq \frac{1}{1+x}$ for all $x \geq 0$, we obtain:

$$\begin{aligned}
&\theta_0^{\varphi_{1-\gamma}(k+1) - \varphi_{1-\gamma}\left(\frac{k+1}{2}\right)} \varphi_{1-2\gamma}\left(\frac{k}{2}+2\right) = e^{\left(\varphi_{1-\gamma}(k+1) - \varphi_{1-\gamma}\left(\frac{k+1}{2}\right)\right)\ln\theta_0} \varphi_{1-2\gamma}\left(\frac{k}{2}+2\right) \\
&\leq \frac{\varphi_{1-2\gamma}\left(\frac{k}{2}+2\right)}{1 + [\varphi_{1-\gamma}(k+1) - \varphi_{1-\gamma}(\frac{k}{2}+1)]\ln\frac{1}{\theta_0}} \overset{(15)}{\leq} \frac{\frac{(k+4)^{1-2\gamma}}{2^{1-2\gamma}(1-2\gamma)}}{\frac{1}{1-\gamma}[(k+1)^{1-\gamma} - (\frac{k}{2}+1)^{1-\gamma}]\ln\frac{1}{\theta_0}} \\
&= \frac{\frac{(k+4)^{1-2\gamma}}{2^{1-2\gamma}(1-2\gamma)}}{\frac{(k+2)^{1-\gamma}}{1-\gamma}[(\frac{2}{3})^{1-\gamma} - (\frac{1}{2})^{1-\gamma}]\ln\frac{1}{\theta_0}} = \frac{1-\gamma}{1-2\gamma}\frac{2^\gamma(k+4)^{-\gamma}}{[(\frac{2}{3})^{1-\gamma} - (\frac{1}{2})^{1-\gamma}]\ln\frac{1}{\theta_0}} \approx \mathcal{O}\left(\frac{1}{k^\gamma}\right).
\end{aligned}$$

Therefore, in this case, the overall rate will be given by:

$$r_{k+1}^2 \leq \theta_0^{\mathcal{O}(k^{1-\gamma})} r_0^2 + \mathcal{O}\left(\frac{1}{k^\gamma}\right) \approx \mathcal{O}\left(\frac{1}{k^\gamma}\right).$$

If $\gamma = \frac{1}{2}$, then the definition of $\varphi_{1-2\gamma}(\frac{k}{2}+2)$ provides that:

$$r_{k+1}^2 \leq \theta_0^{\mathcal{O}(\sqrt{k})} r_0^2 + \theta_0^{\mathcal{O}(\sqrt{k})}\mathcal{O}(\ln k) + \mathcal{O}\left(\frac{1}{\sqrt{k}}\right) \approx \mathcal{O}\left(\frac{1}{\sqrt{k}}\right).$$

When $\gamma \in (\frac{1}{2}, 1)$, it is obvious that $\varphi_{1-2\gamma}\left(\frac{k}{2}+2\right) \leq \frac{1}{2\gamma-1}$ and therefore the order of the convergence rate changes into:

$$r_{k+1}^2 \leq \theta_0^{\mathcal{O}(k^{1-\gamma})}[r_0^2 + \mathcal{O}(1)] + \mathcal{O}\left(\frac{1}{k^\gamma}\right) \approx \mathcal{O}\left(\frac{1}{k^\gamma}\right).$$

Lastly, if $\gamma = 1$, by using $\theta_0^{\ln k + 1} \leq \left(\frac{1}{k}\right)^{\ln\frac{1}{\theta_0}}$ we obtain the second part of our result. ■

Notice that the above results state that our SPP algorithm with variable stepsize $\frac{\mu_0}{k^\gamma}$ converges with $\mathcal{O}\left(\frac{1}{k^\gamma}\right)$ rate. Similar results have been obtained in (Toulis et al., 2016) for a particular objective function of the form $f(a_S^T x)$ without any constraints and for $\gamma \in (1/2, 1]$. Moreover, for $\gamma = 1$ similar convergence rate, but in asymptotic fashion and for unconstrained problems, has been derived in (Ryu and Boyd, 2016). As we have already mentioned in the introduction section, the convergence rate for the SGD scheme contains an exponential term of the form $\frac{e^{C_2\mu_0^2}}{k^{\alpha\mu_0}}$, which for a given iteration counter k grows exponentially in the initial stepsize μ_0, see (Moulines and Bach, 2011). Thus, although the SGD method achieves a rate $O(\frac{1}{k})$ for a variable stepsize $\frac{\mu_0}{k}$, if μ_0 is chosen too large, then it can induce catastrophic effects in the convergence rate. However, one should notice that for our SPP method, Theorem 14 does not contain this kind of exponential term, therefore SPP is more robust than SGD scheme even in the constrained case. This can be also observed in numerical simulations, see Section 7 below. Clearly, Corollary 15 directly implies the following complexity estimates for attaining a suboptimal point x^k satisfying $\mathbb{E}[\|x^k - x^*\|^2] \leq \epsilon$.

Corollary 16 *Under the assumptions of Theorem 14 and $\epsilon > 0$ the following estimates hold. For $\gamma \in (0,1)$, if we perform:*

$$\left\lceil \mathcal{O}\left(\frac{1}{\epsilon^{1/\gamma}}\right) \right\rceil$$

iterations of SPP scheme with variable stepsize, then the sequence $\{x^k\}_{k\geq 0}$ satisfies $\mathbb{E}[\|x^k - x^*\|^2] \leq \epsilon$. Moreover, for $\gamma = 1$ and $\theta_0 < \frac{1}{e}$, if we perform:

$$\left\lceil \mathcal{O}\left(\frac{1}{\epsilon}\right) \right\rceil$$

iterations of SPP scheme with variable stepsize, then we have $\mathbb{E}[\|x^k - x^*\|^2] \leq \epsilon$.

Proof The proof follows immediately from Corollary 15. ■

6. A restarted variant of Stochastic Proximal Point algorithm

From previous section we easily notice that an $\mathcal{O}\left(\frac{1}{\epsilon}\right)$ convergence rate is obtained for the SPP algorithm with variable stepsize $\mu_k = \frac{\mu_0}{k}$ only when the initial stepsize μ_0 is chosen sufficiently large such that $\theta_0 = \mathbb{E}\left[\frac{1}{(1+\mu_0\sigma_{f,S})^2}\right] < \frac{1}{\sqrt{e}}$. However, this condition is not easy to check. Therefore, if μ_0 is not chosen adequately, we can encounter the case $\theta_0 > \frac{1}{\sqrt{e}}$, which leads to a worse convergence rate for the SPP scheme of order $\mathcal{O}\left(\epsilon^{-\frac{1}{2\ln(1/\theta_0)}}\right)$, that is implicitly dependent on the choice of the initial stepsize μ_0. In conclusion, in order to remove this dependence on the initial stepsize of the simple SPP scheme, we develop a restarting variant of it. This variant consists of running the SPP algorithm (as a routine) for multiple times (epochs) and restarting it each time after a certain number of iterations. In each epoch t, the SPP scheme runs for an estimated number of iterations K_t, which may vary over the epochs, depending on the assumptions made on the objective function.

More explicitly, the Restarted Stochastic Proximal Point (RSPP) scheme has the following iteration:

Algorithm RSPP

Let $\mu_0 > 0$ and $x^{0,0} \in \mathbb{R}^n$. For $t \geq 1$ do:

1. Compute stepsize μ_t and number of inner iterations K_t
2. Set $x^{K_t,t}$ the average output of SPP$(x^{K_{t-1},t-1}, \mu_t)$ runned for K_t iterations with constant stepsize μ_t
3. If an outer stopping criterion is satisfied, then **STOP**, otherwise $t := t+1$ and go to step 1.

We analyze below the nonasymptotic convergence rate of the RSPP algorithm under Assumptions 7 and 8.

6.1 Nonasymptotic sublinear convergence of algorithm RSPP

In this section we analyze the convergence rate of the sequence generated by the RSPP scheme, which repeatedly calls the subroutine SPP with a constant stepsize, in multiple epochs. We consider that SPP runs in epoch $t \geq 1$ with the constant stepsize μ_t for K_t iterations. As in previous sections, we first provide a descent lemma for the feasibility gap. For simplicity, we keep the notations of $\mathcal{A}$ from Lemma 12 and $\mathcal{B}$ from Lemma 13.

Lemma 17 *Let Assumptions 2, 7 and 8 hold. Also let the sequence $\{x^{K_t,t}\}_{t\geq 0}$ be generated by RSPP scheme with nonincreasing stepsizes $\{\mu_t\}_{t\geq 0}$ and nondecreasing epoch lengths $\{K_t\}_{t\geq 1}$ such that $K_t \geq 1$ for all $t \geq 1$. Then, the following relation holds:*

$$\sqrt{\mathbb{E}[dist_X^2(x^{K_t,t})]} \leq \left(1-\frac{1}{\zeta}\right)^{\sum_{i=1}^{t}\frac{K_i}{2}} dist_X(x^{0,0}) + 2\left(1-\frac{1}{\zeta}\right)^{\sum_{i=t-\lceil \frac{t}{2}\rceil}^{t}\frac{K_i}{2}} \mu_0\zeta^2\mathcal{B} + 2\mu_{t-\lceil\frac{t}{2}\rceil}\zeta^2\mathcal{B}.$$

Proof See Appendix for the proof. ■

Next, we provide the non-asymptotic bounds on the iteration complexity of RSPP scheme.

Theorem 18 *Let Assumptions 2, 7 and 8 hold and $\epsilon, \mu_0 > 0$. Also let $\gamma > 0$ and $\{x^{K_t,t}\}_{t\geq 0}$ be generated by RSPP scheme with $\mu_t = \frac{\mu_0}{t^\gamma}$ and $K_t = \lceil t^\gamma \rceil$. If we perform the following number of epochs:*

$$T = \left\lceil \max\left\{ \ln\left(\frac{2r_{0,0}^2}{\epsilon}\right)\frac{1}{\ln(1/\theta_0)}, \left(\frac{2^{\gamma+1}\mathcal{D}_r}{\epsilon}\mathcal{C}\right)^{1/\gamma}\right\}\right\rceil,$$

then after a total number of SPP iterations of $\frac{T^{1+\gamma}}{1+\gamma}$, which is bounded by

$$\left\lceil \frac{1}{1+\gamma}\max\left\{ \ln\left(\frac{2r_{0,0}^2}{\epsilon}\right)^{1+\gamma}\frac{1}{\ln(1/\theta_0)^{1+\gamma}}, \left(\frac{2^{\gamma+1}\mathcal{D}_r}{\epsilon}\mathcal{C}\right)^{1+\frac{1}{\gamma}}\right\}\right\rceil,$$

where $\mathcal{D}_r = 4\|\nabla F(x^*)\|\left[\frac{dist_X(x^{0,0})+2\mu_0\zeta^2\mathcal{B}}{\mu_0\ln(\zeta/(\zeta-1))} + 3^\gamma\mathcal{B}\zeta^2\right] + 2\eta\sqrt{2\eta^2+2\mathbb{E}[L_{f,S}^2]\mathcal{A}^2} + 2\eta\mathcal{A}\sqrt{\mathbb{E}[L_{f,S}^2]}$ and $\mathcal{C} = \frac{1}{2(1-\gamma)\ln 1/\sqrt{\theta_0}} + \frac{\mu_1^2}{(1-\theta_0)^2}$, we have $\mathbb{E}[\|x^{K_T,T}-x^*\|^2] \leq \epsilon$.

Proof See Appendix for the proof. ■

In conclusion Theorem 18 states that the RSPP algorithm with the choices $(\mu_t, K_t) = \left(\frac{\mu_0}{t^\gamma}, \frac{t^\gamma}{2}\right)$ requires $\mathcal{O}\left(\epsilon^{-\left(1+\frac{1}{\gamma}\right)}\right)$ simple SPP iterations to reach an ϵ optimal point. It is important to observe that this convergence rate is achieved when the stepsize and the epoch length are not dependent on any inaccessible constant, making our restarting scheme easily implementable. Moreover, the parameter γ can be chosen in $(0,\infty)$, i.e. our RSPP scheme allows also stepsizes $\frac{\mu_0}{t^\gamma}$, with $\gamma > 1$. By comparison, an $\mathcal{O}\left(\epsilon^{-1}\right)$ complexity is obtained for SPP with stepsize $\mu_k = \frac{\mu_0}{k}$ only when μ_0 is chosen sufficiently large such that $\theta_0 < \frac{1}{e}$. However, this condition is not easy to check. Moreover, we may fall in the case when $\theta_0 > \frac{1}{e}$, which leads to a complexity of $\mathcal{O}\left(\epsilon^{-\frac{1}{2\ln(1/\theta_0)}}\right)$ of the variable stepsize SPP scheme. Observe that the last convergence rate is implicitly dependent on the constant μ_0 and can be arbitrarily bad, while for $\gamma > 1$ sufficiently large the RSPP scheme achieves the optimal convergence rate $\mathcal{O}\left(\epsilon^{-1}\right)$.

Remark 19 *Notice that there exists a connection between the quadratic mean residual $\mathbb{E}[\|x^k - x^*\|^2]$ and the function value residual in a certain point. To obtain this relation, denote $v^k = [x^k - \frac{1}{L_F}\nabla F(x^k)]_X$ and observe that for some constant $L_F \geq \mathbb{E}[L_{f,S}]$ we have:*

$$\begin{aligned} F(v^k) &\leq F(x^k) + \langle \nabla F(x^k), v^k - x^k\rangle + \frac{L_F}{2}\|v^k - x^k\|^2 \\ &= \min_{y\in X} F(x^k) + \langle \nabla F(x^k), y - x^k\rangle + \frac{L_F}{2}\|y - x^k\|^2 \\ &\leq \min_{y\in X} F(y) + \frac{L_F}{2}\|y - x^k\|^2 \\ &\leq F(x^*) + \frac{L_F}{2}\|x^k - x^*\|^2, \end{aligned}$$

where in the second inequality we used the convexity relation. The last relation leads to $F(v^k) - F(x^*) \leq \frac{L_F}{2}\|x^k - x^*\|^2$.

7. Numerical experiments

We present numerical evidence to assess the theoretical convergence guarantees of the SPP algorithm. We provide three numerical examples: constrained stochastic least-square with

random generated data (Moulines and Bach, 2011; Toulis et al., 2016), Markowitz portfolio optimization using real data (Brodie et al., 2009; Yurtsever et al., 2016) and logistic regression using real data (Platt, 1998). In all our figures the results are averaged over 20 Monte-Carlo simulations for an algorithm.

7.1 Stochastic least-square problems using random data

In this section we evaluate the practical performance of the SPP schemes on finite large scale least-squares models. To do so, we follow a simple normal (constrained) linear regression example from (Moulines and Bach, 2011; Toulis et al., 2016). Let $m = 10^5$ be the number of observations, and $n = 20$ be the number of features. Let x^* be a randomly a priori chosen ground truth. The feature vectors $a_1, \cdots, a_m \approx \mathcal{N}_n(0, H)$ are i.i.d. normal random variables, and H is a randomly generated symmetric matrix with eigenvalues $1/k$, for $k = 1, \cdots, n$. The outcome b_S is sampled from a normal distribution as $b_S|a_S \approx \mathcal{N}(a_S^T x^*, 1)$, for $S = 1, \cdots, m$. Since the typical loss function is defined as the elementary squared residual $(a_S^T x - b_S)^2$, which is not strongly convex, we consider batches of residuals to form our loss functions, i.e we consider $\ell(x, S)$ of two forms:

$$\ell(x, S) = \|A_{j(S):j(S)+n}x - b_{j(S):j(S)+n}\|^2 \quad \text{or} \quad \ell(x, S) = (a_S^T x - b_S)^2,$$

where a_S is the Sth row of A and $A_{j(S):j(S)+n} \in \mathbb{R}^{n\times n}$ is a submatrix containing n rows of A so that the function $x \mapsto \|A_{j(S):j(S)+n}x - b_{j(S):j(S)+n}\|^2$ is strongly convex. In our tests we used $\texttt{round}(m/2n)$ batches of dimension n and we let the rest as elementary residuals, thus having in total $p = m/2 + m/n$ loss functions. Additionally, we impose on the estimator x also p linear inequality constraints $\{x \mid Cx \leq d\}$. This constraints can be found in many applications and they come from physical constraints, see e.g. (Censor et al., 2012; Rosasco et al., 2014). We choose randomly the matrix C for the constraints and $d = C \cdot x^* + [0\ 0\ 0\ v^T]^T$, where $v \geq 0$ is a random vector of appropriate dimension, i.e. three inequalities are active at the solution x^*. Besides the SPP and RSPP algorithms analyzed in the previous sections of our paper, we also implemented SGD and the averaged variant of SPP algorithm (A-SPP), which has the same SPP iteration, but outputs the average of iterates: $\hat{x}^k = (1/\sum_{i=1}^k \mu_i)\sum_{i=1}^k \mu_i x_i$. Convergence behavior of the averaged iterates of stochastic gradient has been initially proposed in the seminal paper (Polyak and Juditsky, 1992).

In Figure 1 we run algorithms SPP, RSPP, A-SPP and SGD for two values of the initial stepsize: $\mu_0 = 0.5$ and $\mu_0 = 1$. Each scheme runs for two stepsize exponents: $\gamma_1 = 1$ (left) and $\gamma_2 = 1/2$ (right). From Figure 1 we can asses one conclusion of Theorem 15: the best performance for SPP is achieved for stepsize exponent $\gamma = 1$. Moreover, we can observe that algorithm RSPP has the fastest behavior, while the averaged variant A-SPP is more robust to changes in the initial stepsize μ_0. The performance of SGD is much worse as exponent γ decreases and it is also sensitive to the learning rate μ_0. Notice that both tests are performed over m iterations (i.e. one pass through data).

In the second set of experiments, we generate random least-square problems of the form $\min_{x:Cx\leq d}\ 1/2\|Ax - b\|^2$, where both matrices A and C have $m = 10^3$ rows and generated randomly. Now, we do not impose the solution x^* to have the form given in the first test. We let SPP and RSPP algorithms to do one pass through data for various stepsize exponents

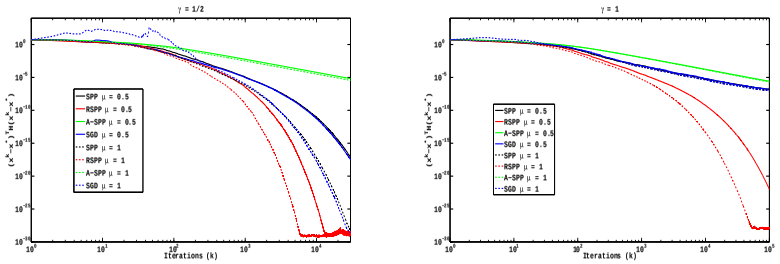

Figure 1: Performance comparison of SPP, A-SPP, RSPP and SGD for two values of initial stepsize $\mu_0 = 0.5$ and $\mu_0 = 1$ and for two values of exponent $\gamma = 1/2$ (left) and $\gamma = 1$ (right).

γ. From Figure 2 we can assess the empirical evidence of the $\mathcal{O}(1/\epsilon^{1/\gamma})$ convergence rate of Theorem 15 for SPP and $\mathcal{O}(1/\epsilon^{1+1/\gamma})$ convergence rate of Theorem 19 for RSPP, by presenting squared relative distance to the optimum solution. Moreover, the simulation results match other conclusions of Theorems 15 and 19 regarding the stepsize exponent γ: (i) the performance of SPP deteriorates with the decrease in the value of the stepsize exponent γ; (ii) from our preliminary numerical experiments we observed that RSPP scheme runs faster for higher values of γ and it has a more robust performance with respect to the variation of γ than SPP algorithm.

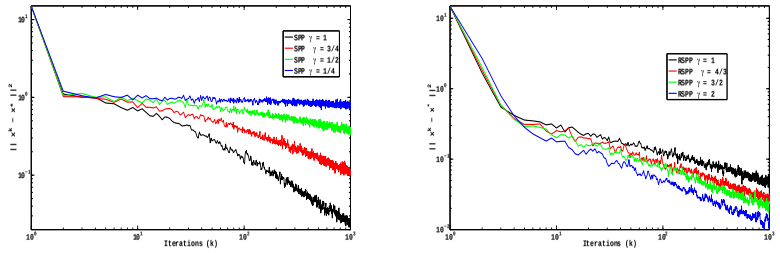

Figure 2: Performance of: SPP for four values of the stepsize exponent $\gamma = 1,\ 3/4,\ 1/2$ and $1/4$ (left); RSPP for four values of the stepsize exponent $\gamma = 1,\ 4/3,\ 3/2$ and 2 (right).

7.2 Markowitz portfolio optimization using real data

Markowitz portfolio optimization aims to reduce the risk by minimizing the variance for a given expected return. This can be mathematically formulated as a convex optimization

problem (Brodie et al., 2009; Yurtsever et al., 2016):

$$\min_{x\in\mathbb{R}^n} \mathbb{E}[(a_S^T x - b)^2] \quad \text{s.t.} \quad x \in X = \{x:\ x \geq 0,\ e^T x \leq 1,\ a_{av}^T x \geq b\},$$

where $a_{av} = \mathbb{E}[a_S]$ is the average returns for each asset that is assumed to be known (or estimated), and b represents a minimum desired return. Since new data points are arriving on-line, one cannot access the entire dataset at any moment of time, which makes the stochastic setting more favorable. For simulations, we approximate the expectation with the empirical mean as follows:

$$\min_{x\in\mathbb{R}^n} \frac{1}{m}\sum_{S=1}^{m}(a_S^T x - b)^2 \quad \text{s.t.} \quad x \in X = X_1 \cap X_2 \cap X_3,$$

where $X_1 = \{x:\ x \geq 0\}$, $X_2 = \{x:\ e^T x \leq 1\}$ and $X_3 = \{x:\ a_{av}^T x \geq b\}$. In this application we have the number of samples m larger than the number of constraints. However, by taking a certain partition of $[m] = \Omega_1 \cup \Omega_2 \cup \Omega_3$, then one can consider: $X_S = X_i$ for all $S \in \Omega_i$, with $i \in \{1, 2, 3\}$. We use 2 different real portfolio datasets: Standard & Poor's 500 (SP500, with 25 stocks for 1276 days) and one dataset by Fama and French (FF100, with 100 portfolios for 23.647 days) that is commonly used in financial literature, see e.g. (Brodie et al., 2009). We split all the datasets into test (10%) and train (90%) partitions randomly. We set the desired return a_{av} as the average return over all assets in the training set and $b = \text{mean}(a_{av})$. The results of this experiment are presented in Figure 3. We plot the value of the objective function over the datapoints in the test partition F_{test} along the iterations. We observe that SGD is very sensitive to both parameters, initial stepsize (μ_0) and stepsize exponent (γ), while SPP is more robust to changes in both parameters and also performs better over one pass through data in the train partition.

7.3 Logistic regression using real data

Finally, we consider the logistic regression problem. In this task we train an estimator over a given dataset (A, b), where $A \in \mathbb{R}^{m\times n}$ is the observations matrix and $b \in \mathbb{R}^m$ is the labels vector. For any $S \in \{1, \cdots, m\}$ we define the logistic loss function:

$$\ell(a_S^T x) = \log\left(1 + e^{-b_S(a_S^T x)}\right),$$

where $a_S \in \mathbb{R}^n$ is the Sth row of matrix A. Notice that the logistic loss function $\ell(a_S^T x)$ is only convex and smooth. However, in logistic regression we also consider a quadratic regularization term (Toulis et al., 2016; Bach, 2010):

$$\min_{x\in\mathbb{R}^n} \frac{1}{m}\sum_{S=1}^{m}\log\left(1 + e^{-b_S(a_S^T x)}\right) + \frac{\lambda}{2}\|x\|^2,$$

where $\lambda > 0$ is taken small, which makes the objective function λ-strongly convex. We have tested the four schemes (SGD, SPP, ASPP and RSPP), on the Adult datasets (a2a with $m = 2265, n = 123$ and a5a with $m = 6414, n = 123$) from LIBSVM/UCI database (Platt, 1998). We set the initial stepsize at value $\mu_0 = 0.6$ and the regularization parameter

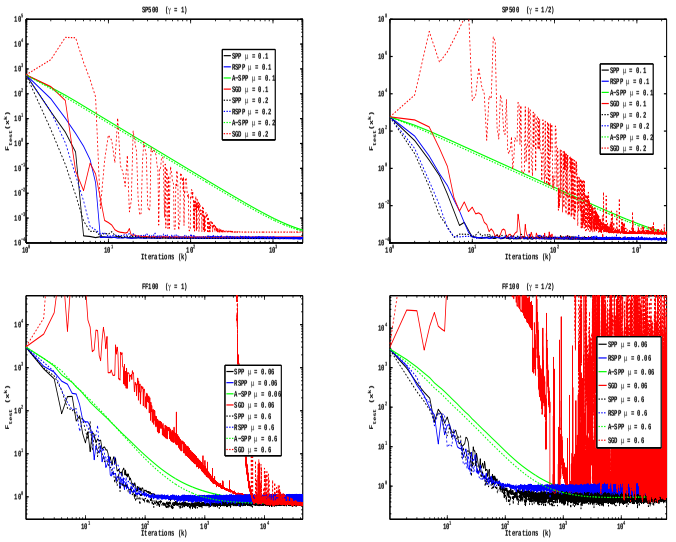

Figure 3: Performance on Markowitz portfolio using real datasets (SP500 - top and FF100 - bottom) for the SPP, A-SPP, RSPP and SGD schemes for several values of the initial stepsize μ_0 and for two values of the exponent ($\gamma = 1/2$ - left and $\gamma = 1$ - right).

$\lambda = 10^{-3}$. Once an approximate solution $\tilde{x}^*$ of the logistic regression problem is obtained, we evaluate the resulted estimator on the test dataset, i.e. $\frac{1}{2p}\sum_{S=1}^{p}|sgn(\tilde{a}_S^T\tilde{x}^*) - \tilde{b}_S|$, where $\tilde{A} \in \mathbb{R}^{p\times n}$ and $\tilde{b}$ are the testing dataset. The results are displayed in Figure 4. We observe that for large stepsize ($\gamma = 1/2$) the performances of all four methods (SGD, SPP, A-SPP and RSPP) are similar. However, when we use a smaller stepsizes ($\gamma = 1$), the RSPP algorithm outperforms the other methods. We also observe that the variation of stepsize exponent γ does not influence too much the performance of RSPP algorithm, showing once more the robustness of this scheme against variations in the stepsize choices μ_0/k^γ.

Since we used different parameter values in our experiments, we want to provide some details on the parameter choices. From the theoretical viewpoint, Theorems 15 and 19 show that the stepsize exponent γ has to be chosen as large as possible to obtain the best convergence rate. Let us consider for simplicity that $\sigma_{f,S} = \sigma > 0$ for all $S \in \Omega$. Then, for the initial stepsize μ_0 Corollary 16 indicates that the best convergence rate is obtained for $\mu_0 > \frac{\sqrt{e}-1}{\sigma}$. Therefore, in the case when σ is known (e.g. regularized logistic regression) we can choose μ_0 appropriately so that we obtain the best convergence. However, when this parameter σ is not known, then there is an inherent need for parameter tuning. From practical point of view, our plots show that the performance of SPP/RSPP deteriorates with the decrease

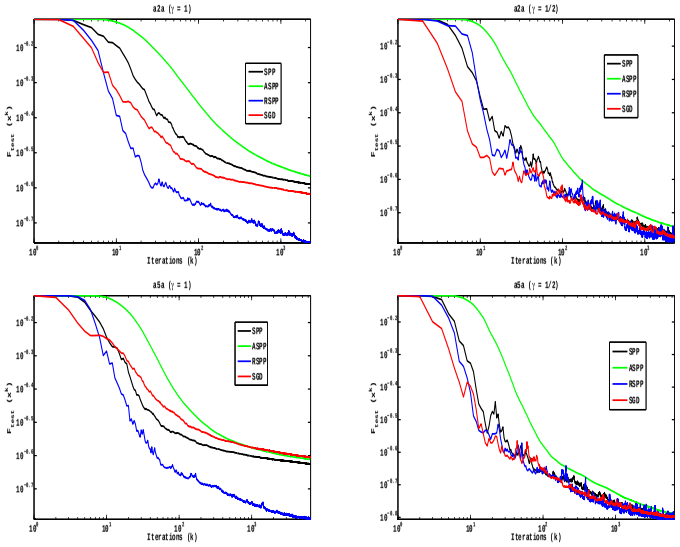

Figure 4: Performance on logistic regression using real datasets (a2a - top and a5a - bottom) for the SPP, A-SPP, RSPP and SGD schemes for two values of the exponent ($\gamma = 1/2$ - left and $\gamma = 1$ - right).

in value of the exponent γ. That is, they indicate that the higher values of this parameter the better performance. However, there is empirical evidence in the literature regarding the SGD performance which shows that values $\gamma < 1$ provide a better performance than the choice $\gamma = 1$. In these cases, the choice of initial stepsize μ_0 requires a detailed tuning procedure. As a general conclusion of our experiments, we can state that both parameters μ_0 and γ are strongly linked to the problem conditioning and, up to some extent, they have to be tuned accordingly to the problem datasets.

8. Appendix

To make the paper more readable, in this Appendix we provide the proofs of some lemmas and theorems.

Proof of Lemma 4:

Proof By using the convexity of the function $\mathbb{I}_{\mu,S}(x) = \frac{1}{2\mu}\text{dist}^2_{X_S}(x)$ and taking the conditional expectation w.r.t. S_k over the history $\mathcal{F}_{k-1} = \{S_0, \cdots, S_{k-1}\}$, we get:

$$\mathbb{E}[\mathbb{I}_{1,S_k}(\hat{y}^k)|\mathcal{F}_{k-1}] \geq \mathbb{E}\left[\mathbb{I}_{1,S_k}(\hat{x}^k) + \langle \nabla \mathbb{I}_{1,S_k}(\hat{x}^k), \hat{y}^k - \hat{x}^k\rangle |\mathcal{F}_{k-1}\right].$$

Taking further the expectation over $\mathcal{F}_{k-1}$ we obtain:

$$\begin{aligned}
\mathbb{E}[\mathbb{I}_{1,S_k}(\hat{y}^k)] &\geq \mathbb{E}\left[\mathbb{I}_{1,S_k}(\hat{x}^k)\right] + \mathbb{E}\left[\langle \nabla \mathbb{I}_{1,S_k}(\hat{x}^k), \hat{y}^k - \hat{x}^k\rangle\right] \\
&= \mathbb{E}\left[\mathbb{I}_{1,S_k}(\hat{x}^k)\right] + \frac{\mathbb{E}\left[\langle \nabla \mathbb{I}_{1,S_k}(\hat{x}^k), \sum_{i=0}^{k-1} \mu_i^2 \nabla f_{\mu_i}(x^i;S_i)\rangle\right]}{\hat{\mu}_{1,k}} \\
&\geq \mathbb{E}\left[\mathbb{I}_{1,S_k}(\hat{x}^k)\right] - \mathbb{E}\left[\frac{\hat{\mu}_{2,k}}{\hat{\mu}_{1,k}}\|\nabla \mathbb{I}_{1,S_k}(\hat{x}^k)\|\left\|\sum_{i=0}^{k-1}\frac{\mu_i^2}{\hat{\mu}_{2,k}}\nabla f_{\mu_i}(x^i;S_i)\right\|\right] \\
&\geq \mathbb{E}\left[\mathbb{I}_{1,S_k}(\hat{x}^k)\right] - \frac{\hat{\mu}_{2,k}}{\hat{\mu}_{1,k}}\mathbb{E}\left[\|\nabla \mathbb{I}_{1,S_k}(\hat{x}^k)\|\sum_{i=0}^{k-1}\frac{\mu_i^2}{\hat{\mu}_{2,k}}\|\nabla f_{\mu_i}(x^i;S_i)\|\right],
\end{aligned}$$

where in the second inequality we used the Cauchy-Schwarz inequality and in the third the convexity relation regarding $\|\cdot\|$. Further, using as well Lemma 3, Assumption 2 and Cauchy-Schwarz inequality, we have:

$$\begin{aligned}
\mathbb{E}\left[\frac{1}{2}\text{dist}^2_{X_{S_k}}(\hat{y}^k)\right] &\overset{\text{Lemma 3}}{\geq} \mathbb{E}\left[\frac{1}{2}\text{dist}^2_{X_{S_k}}(\hat{x}^k)\right] - \frac{\hat{\mu}_{2,k}}{2\hat{\mu}_{1,k}}\mathbb{E}\left[\text{dist}_{X_{S_k}}(\hat{x}^k)L_{f,S_k}\right] \\
&\overset{\text{Assump. 2}}{\geq} \frac{1}{2\zeta}\mathbb{E}\left[\text{dist}^2_X(\hat{x}^k)\right] - \frac{\hat{\mu}_{2,k}}{2\hat{\mu}_{1,k}}\sqrt{\mathbb{E}[\text{dist}^2_X(\hat{x}^k)]}\sqrt{\mathbb{E}[L^2_{f,S}]},
\end{aligned}$$

which proves the statement of the lemma. ■

Proof of Theorem 5:

Proof Since the function $z \to f(z;S) + \frac{1}{2\mu}\|z - x\|^2$ is strongly convex, we have:

$$\begin{aligned}
f(z;S) + \frac{1}{2\mu}\|z - x\|^2 &\geq f(z_\mu(x;S);S) + \frac{1}{2\mu}\|z_\mu(x;S) - x\|^2 + \frac{1}{2\mu}\|z_\mu(x;S) - z\|^2 \\
&= f_\mu(x;S) + \frac{1}{2\mu}\|z_\mu(x;S) - z\|^2 \quad \forall z \in \mathbb{R}^n. \qquad (16)
\end{aligned}$$

By taking $x = x^k, S = S_k, z = x^*, \mu = \mu_k$ in (16) and using the strictly nonexpansive property of the projection operator, see e.g. (Nedic, 2011):

$$\|x - \Pi_{X_{S_k}}(x)\|^2 \leq \|x - z\|^2 - \|z - \Pi_{X_{S_k}}(x)\|^2 \qquad \forall z \in X_{S_k},\ x \in \mathbb{R}^n, \qquad (17)$$

then these lead to:

$$\begin{aligned}
f(x^*;S_k) + \frac{1}{2\mu_k}\|x^k - x^*\|^2 &\geq f_{\mu_k}(x^k;S_k) + \frac{1}{2\mu_k}\|y^k - x^*\|^2 \\
&\overset{(17)}{\geq} f_{\mu_k}(x^k;S_k) + \frac{1}{2\mu_k}\|\Pi_{X_{S_k}}(y^k) - x^*\|^2 + \frac{1}{2\mu_k}\|y^k - \Pi_{X_{S_k}}(y^k)\|^2 \\
&= f_{\mu_k}(x^k;S_k) + \frac{1}{2\mu_k}\|x^{k+1} - x^*\|^2 + \frac{1}{2\mu_k}\|y^k - x^{k+1}\|^2, \qquad (18)
\end{aligned}$$

where in the second inequality we used (17) with $x = y^k$ and $z = x^*$. For simplicity we denote $\mathbb{I}_{\mu,S}(x) = \frac{1}{2\mu}\|x - \Pi_{X_S}(x)\|^2$. From relation (18), it can be easily seen that:

$$\begin{aligned}
&\mu_k(f(x^k;S_k) - f(x^*;S_k)) + \mathbb{I}_{1,S_k}(y^k) - \frac{\mu_k^2}{2}L_{f,S_k}^2 \\
&\leq \mu_k(f(x^k;S_k) - f(x^*;S_k)) + \mathbb{I}_{1,S_k}(y^k) - \frac{\mu_k^2}{2}\|\nabla f(x^k;S_k)\|^2 \\
&= \mu_k(f(x^k;S_k) - f(x^*;S_k)) + \mathbb{I}_{1,S_k}(y^k) + \min_{z\in\mathbb{R}^n}\left[\mu_k\langle\nabla f(x^k;S_k), z - x^k\rangle + \frac{1}{2}\|z - x^k\|^2\right] \\
&\leq \mu_k(f(x^k;S_k) - f(x^*;S_k)) + \mathbb{I}_{1,S_k}(y^k) + \mu_k\langle\nabla f(x^k;S_k), y^k - x^k\rangle + \frac{1}{2}\|y^k - x^k\|^2 \\
&= \mu_k(f(x^k;S_k) + \langle\nabla f(x^k;S_k), y^k - x^k\rangle + \frac{1}{2\mu_k}\|y^k - x^k\|^2 - f(x^*;S_k)) + \mathbb{I}_{1,S_k}(y^k) \\
&\overset{\text{conv. f}}{\leq} \mu_k(f_{\mu_k}(x^k;S_k) - f(x^*;S_k)) + \mathbb{I}_{1,S_k}(y^k) \\
&\overset{(18)}{\leq} \frac{1}{2}\|x^k - x^*\|^2 - \frac{1}{2}\|x^{k+1} - x^*\|^2.
\end{aligned}$$

Taking now the conditional expectation in S_k w.r.t. the history $\mathcal{F}_{k-1} = \{S_0, \cdots, S_{k-1}\}$ in the last inequality we have:

$$\begin{aligned}
\mu_k(F(x^k) - F(x^*)) + \mathbb{E}[\mathbb{I}_{1,S_k}(y^k)|\mathcal{F}_{k-1}] - \frac{\mu_k^2}{2}\mathbb{E}[L_{f,S_k}^2] \\
\leq \frac{1}{2}\|x^k - x^*\|^2 - \frac{1}{2}\mathbb{E}[\|x^{k+1} - x^*\|^2|\mathcal{F}_{k-1}].
\end{aligned}$$

Taking further the expectation over $\mathcal{F}_{k-1}$ and summing over $i = 0, \cdots, k-1$, results in:

$$\begin{aligned}
\frac{\|x^0 - x^*\|^2}{2\sum_{i=0}^{k-1}\mu_i} &\geq \frac{1}{\sum_{i=0}^{k-1}\mu_i}\sum_{i=0}^{k-1}\mathbb{E}[\mu_i(F(x^i) - F(x^*))] + \mathbb{E}[\mathbb{I}_{1,S}(y^i)] - \frac{\mu_i^2}{2}\mathbb{E}[L_{f,S}^2] \\
&= \frac{1}{\sum_{i=0}^{k-1}\mu_i}\sum_{i=0}^{k-1}\mathbb{E}[\mu_i(F(x^i) - F(x^*))] + \mu_i\mathbb{E}[\mathbb{I}_{\mu_i,S}(y^i)] - \frac{\mu_i^2}{2}\mathbb{E}[L_{f,S}^2] \\
&\geq \frac{1}{\sum_{i=0}^{k-1}\mu_i}\sum_{i=0}^{k-1}\mathbb{E}[\mu_i(F(x^i) - F(x^*))] + \mu_i\mathbb{E}[\mathbb{I}_{\mu_0,S}(y^i)] - \frac{\mu_i^2}{2}\mathbb{E}[L_{f,S}^2] \\
&\overset{\text{Jensen}}{\geq} \mathbb{E}[F(\hat{x}^k) - F(x^*)] + \mathbb{E}[\mathbb{I}_{\mu_0,S}(\hat{y}^k)] - \frac{\mathbb{E}[L_{f,S}^2]\hat{\mu}_{2,k}}{2\hat{\mu}_{1,k}},
\end{aligned} \tag{19}$$

where in the second inequality we used that $\mathbb{I}_{\mu_i,S}(y) \geq \mathbb{I}_{\mu_0,S}(y)$ for all $S \in \Omega, i \geq 0$. The relation (19) implies the following upper bound on the suboptimality gap:

$$\mathbb{E}[F(\hat{x}^k) - F(x^*)] \leq \frac{\|x^0 - x^*\|^2 + \mathbb{E}[L_{f,S}^2]\hat{\mu}_{2,k}}{2\hat{\mu}_{1,k}}. \tag{20}$$

On the other hand, recalling $\nabla F(x^*) = \mathbb{E}[\nabla f(x^*;S)]$, we use the following fact:

$$\begin{aligned}
\mathbb{E}[F(\hat{x}^k)] - F(x^*) &\geq \mathbb{E}[\langle\nabla F(x^*), \hat{x}^k - x^*\rangle] \\
&= \mathbb{E}[\langle\nabla F(x^*), \Pi_X(\hat{x}^k) - x^*\rangle] + \mathbb{E}[\langle\nabla F(x^*), \hat{x}^k - \Pi_X(\hat{x}^k)\rangle] \\
&\geq -\mathbb{E}[L_{f,S}]\mathbb{E}[\text{dist}_X(\hat{x}^k)] \\
&\overset{\text{Jensen}}{\geq} -\sqrt{\mathbb{E}[L_{f,S}^2]\ \mathbb{E}[\text{dist}_X^2(\hat{x}^k)]} \qquad \forall k \geq 0,
\end{aligned} \tag{21}$$

which is derived from the optimality conditions $\langle\nabla F(x^*), z - x^*\rangle \geq 0$ for all $z \in X$, the Cauchy-Schwarz and Jensen inequalities. By denoting $r_0 = \|x^0 - x^*\|$ and combining (19) with Lemma 4 and the last inequality (21), we obtain:

$$\begin{aligned}
\mathbb{E}[\text{dist}_X^2(\hat{x}^k)] - \zeta\sqrt{\mathbb{E}[L_{f,S}^2]}\left(\frac{\hat{\mu}_{2,k}}{\hat{\mu}_{1,k}} + 2\mu_0\right)\sqrt{\mathbb{E}[\text{dist}_X^2(\hat{x}^k)]} \\
\overset{\text{Lemma 4+(21)}}{\leq} 2\mu_0\zeta\mathbb{E}[F(\hat{x}^k) - F(x^*)] + 2\mu_0\zeta\mathbb{E}[\mathbb{I}_{\mu_0,S}(\hat{y}^k)] \\
\overset{(20)}{\leq} \frac{\mu_0\zeta r_0^2 + \mu_0\zeta\mathbb{E}[L_{f,S}^2]\hat{\mu}_{2,k}}{\hat{\mu}_{1,k}}.
\end{aligned}$$

This last relation clearly implies an upper bound on the feasibility residual:

$$\sqrt{\mathbb{E}[\text{dist}_X^2(\hat{x}^k)]} \leq \zeta\sqrt{\mathbb{E}[L_{f,S}^2]}\left(\frac{\hat{\mu}_{2,k}}{\hat{\mu}_{1,k}} + 2\mu_0\right) + \sqrt{\frac{\mu_0\zeta r_0^2 + \mu_0\zeta\mathbb{E}[L_{f,S}^2]\hat{\mu}_{2,k}}{\hat{\mu}_{1,k}}}. \tag{22}$$

Also, combining (21) and (22) we obtain the lower bound on the suboptimality gap:

$$\mathbb{E}[F(\hat{x}^k)] - F^* \geq -\zeta\mathbb{E}[L_{f,S}^2]\left(\frac{\hat{\mu}_{2,k}}{\hat{\mu}_{1,k}} + 2\mu_0\right) - \sqrt{\mathbb{E}[L_{f,S}^2]}\sqrt{\frac{\mu_0\zeta r_0^2 + \mu_0\zeta\mathbb{E}[L_{f,S}^2]\hat{\mu}_{2,k}}{\hat{\mu}_{1,k}}}. \tag{23}$$

From the upper and lower suboptimality bounds (20), (23) and feasibility bound (22), we deduce our convergence rate results. ■

Proof of Lemma 9:

Proof Let $\sigma_{f,S} \geq 0$ be the strong convexity constant of the function $f(\cdot;S)$. Notice that we allow the convex case, that is $\sigma_{f,S} = 0$ for some S. Then, it is known that the Moreau approximation $f_\mu(\cdot;S)$ is also a $\hat{\sigma}_{f,S}$-strongly convex function with strong convexity constant, see e.g. (Rockafellar and Wets, 1998):

$$\hat{\sigma}_{f,S} = \frac{\sigma_{f,S}}{1 + \mu\sigma_{f,S}}.$$

Clearly, in the simple convex case, that is $\sigma_{f,S} = 0$, we also have $\hat{\sigma}_{f,S} = 0$. By denoting $\hat{L}_{f,S} = \frac{1}{\mu}$ the Lipschitz constant of the gradient of $f_\mu(\cdot;S)$, the following well-known relation holds for the smooth and (strongly) convex function $f_\mu(\cdot;S)$, see e.g. (Nesterov, 2004):

$$\begin{aligned}
\langle\nabla f_\mu(x;S) - \nabla f_\mu(y;S), x - y\rangle \geq \frac{1}{\hat{\sigma}_{f,S} + \hat{L}_{f,S}}\|\nabla f_\mu(x;S) - \nabla f_\mu(y;S)\|^2 \\
+ \frac{\hat{\sigma}_{f,S}\hat{L}_{f,S}}{\hat{L}_{f,S} + \hat{\sigma}_{f,S}}\|x - y\|^2 \quad \forall x, y \in \mathbb{R}^n.
\end{aligned} \tag{24}$$

By using Assumption 7, then it can be also obtained that:

$$\|\nabla f_\mu(x;S)-\nabla f_\mu(y;S)\|\geq \hat{\sigma}_{f,S}\|x-y\| \qquad \forall x,y\in\mathbb{R}^n. \tag{25}$$

Using this relation, we further derive that:

$$\begin{aligned}
&\|z_\mu(x;S)-z_\mu(y;S)\|^2=\|x-y+\mu(\nabla f_\mu(y;S)-\nabla f_\mu(x;S))\|^2\\
&=\|x-y\|^2+2\mu\langle\nabla f_\mu(y;S)-\nabla f_\mu(x;S),x-y\rangle+\mu^2\|\nabla f_\mu(x;S)-\nabla f_\mu(y;S)\|^2\\
&\overset{(24)}{\leq}\left(1-\frac{2\mu\hat{\sigma}_{f,S}\hat{L}_{f,S}}{\hat{L}_{f,S}+\hat{\sigma}_{f,S}}\right)\|x-y\|^2+\mu\left(\mu-\frac{2}{\hat{L}_{f,S}+\hat{\sigma}_{f,S}}\right)\|\nabla f_\mu(x;S)-\nabla f_\mu(y;S)\|^2\\
&\overset{(25)}{\leq}\left[1+\hat{\sigma}_{f,S}^2\left(\mu^2-\frac{2\mu}{\hat{\sigma}_{f,S}+\hat{L}_{f,S}}\right)-\frac{2\mu\hat{\sigma}_{f,S}\hat{L}_{f,S}}{\hat{L}_{f,S}+\hat{\sigma}_{f,S}}\right]\|x-y\|^2\\
&=(1-\hat{\sigma}_{f,S}\mu)^2\|x-y\|^2 \qquad \forall x,y\in\mathbb{R}^n,
\end{aligned}$$

which implies our result. ■

Proof of Lemma 11:
Proof By taking $\mu=\mu_k$ in relation (14), we obtain:

$$\sqrt{\mathbb{E}[\|x^{k+1}-x^*\|^2]}\leq\sqrt{\mathbb{E}\left[\theta_S^2(\mu_k)\right]}\sqrt{\mathbb{E}[\|x^k-x^*\|^2]}+\mu_k\sqrt{\mathbb{E}\left[\|\nabla f(x^*;S)\|^2\right]}.$$

By using the notations $r_k=\sqrt{\mathbb{E}[\|x^k-x^*\|^2]}$, $\theta_k=\sqrt{\mathbb{E}\left[\theta_S^2(\mu_k)\right]}$ and $\eta=\sqrt{\mathbb{E}\left[\|\nabla f(x^*;S)\|^2\right]}$, the last inequality leads to:

$$\begin{aligned}
r_{k+1}&\leq\theta_k r_k+(1-\theta_k)\frac{\mu_k}{1-\theta_k}\eta\\
&\leq\max\left\{r_k,\frac{\mu_k}{1-\theta_k}\eta\right\}\leq\max\left\{r_0,\frac{\mu_0}{1-\theta_0}\eta,\cdots,\frac{\mu_k}{1-\theta_k}\eta\right\}.
\end{aligned}\tag{26}$$

By observing the fact that $t\mapsto\mathbb{E}\left[\frac{\sigma_{f,S}}{(1+t\sigma_{f,S})^2}+\frac{\sigma_{f,S}}{1+t\sigma_{f,S}}\right]$ is nonincreasing in t, and implicitly:

$$\begin{aligned}
\frac{\mu_{k-1}}{1-\theta_{k-1}}&=\frac{1}{\mathbb{E}\left[\frac{\sigma_{f,S}}{(1+\mu_{k-1}\sigma_{f,S})^2}+\frac{\sigma_{f,S}}{1+\mu_{k-1}\sigma_{f,S}}\right]}\\
&\geq\frac{1}{\mathbb{E}\left[\frac{\sigma_{f,S}}{(1+\mu_k\sigma_{f,S})^2}+\frac{\sigma_{f,S}}{1+\mu_k\sigma_{f,S}}\right]}=\frac{\mu_k}{1-\theta_k},
\end{aligned}$$

then we have $\max\limits_{0\leq i\leq k}\frac{\mu_i}{1-\theta_i}=\frac{\mu_0}{1-\theta_0}$ and the relation (26) becomes:

$$r_k\leq\max\left\{r_0,\frac{\mu_0}{1-\theta_0}\eta\right\}\quad\forall k\geq 0, \tag{27}$$

which implies our result. ■

We also present the following useful auxiliary result:

Lemma 20 *Let $\gamma\in(0,1]$ and the integers $p,q\in\mathbb{N}$ with $q\geq p\geq 1$. Given the sequence of stepsizes $\mu_k=\frac{\mu_0}{k^\gamma}$ for all $k\geq 1$, where $\mu_0>0$, then the following relation holds:*

$$\prod_{i=p}^{q}\mathbb{E}[\theta_S^2(\mu_i)]\leq\left(\mathbb{E}\left[\theta_S^2(\mu_0)\right]\right)^{\varphi_{1-\gamma}(q+1)-\varphi_{1-\gamma}(p)}$$

Proof From definition of $\theta_S(\mu)$ for any $k\geq 1$ we have:

$$\begin{aligned}
\mathbb{E}[\theta_S^2(\mu_k)]&=\mathbb{E}\left[\left(\frac{1}{1+\mu_k\sigma_{f,S}}\right)^2\right]=\mathbb{E}\left[\frac{1}{\left(1+\frac{\mu_0}{k^\gamma}\sigma_{f,S}\right)^2}\right]\\
&\overset{(7)}{\leq}\mathbb{E}\left[\left(\frac{1}{1+\mu_0\sigma_{f,S}}\right)^{\frac{2}{k^\gamma}}\right]\leq\left(\mathbb{E}\left[\frac{1}{(1+\mu_0\sigma_{f,S})^2}\right]\right)^{\frac{1}{k^\gamma}}=\left(\mathbb{E}[\theta_S^2(\mu_0)]\right)^{\frac{1}{k^\gamma}}.
\end{aligned}\tag{28}$$

By taking into account that $\mathbb{E}[\theta_S^2(\mu_0)]=\mathbb{E}\left[\frac{1}{(1+\mu_0\sigma_{f,S})^2}\right]\leq 1$ and that

$$\sum_{i=p}^{q}\frac{1}{i^\gamma}\geq\varphi_{1-\gamma}(q+1)-\varphi_{1-\gamma}(p)=\int_p^{q+1}\frac{1}{t^\gamma}dt=\begin{cases}\ln\frac{q+1}{p} & \text{if}\quad\gamma=1\\ \frac{(q+1)^{1-\gamma}-p^{1-\gamma}}{1-\gamma} & \text{if}\quad\gamma<1,\end{cases}$$

then the relation (28) implies:

$$\begin{aligned}
\prod_{i=p}^{q}\mathbb{E}[\theta_S^2(\mu_i)]&\leq\left(\mathbb{E}\left[\theta_S^2(\mu_0)\right]\right)^{\sum\limits_{i=p}^{q}\frac{1}{i^\gamma}}\leq\left(\mathbb{E}\left[\theta_S^2(\mu_0)\right]\right)^{\varphi_{1-\gamma}(q+1)-\varphi_{1-\gamma}(p)}\\
&=\begin{cases}\left(\mathbb{E}\left[\theta_S^2(\mu_0)\right]\right)^{\ln\frac{q+1}{p}} & \text{if}\quad\gamma=1\\ \left(\mathbb{E}\left[\theta_S^2(\mu_0)\right]\right)^{\frac{(q+1)^{1-\gamma}-p^{1-\gamma}}{1-\gamma}} & \text{if}\quad\gamma<1,\end{cases}
\end{aligned}\tag{29}$$

which immediately implies the above statement. ■

Proof of Lemma 13:
Proof By using the strictly nonexpansive property of the projection operator (17), with $z=\Pi_X(y^k), x=y^k$, and the linear regularity assumption, we obtain:

$$\begin{aligned}
\mathbb{E}[\text{dist}_X^2(x^{k+1})]&\leq\mathbb{E}[\|x^{k+1}-\Pi_X(y^k)\|^2]\overset{(17)}{\leq}\mathbb{E}[\|y^k-\Pi_X(y^k)\|^2]-\mathbb{E}[\|y^k-x^{k+1}\|^2]\\
&\overset{\text{As. 2}}{\leq}\mathbb{E}[\|y^k-\Pi_X(y^k)\|^2]-\frac{1}{\zeta}\mathbb{E}[\|y^k-\Pi_X(y^k)\|^2]\\
&=\left(1-\frac{1}{\zeta}\right)\mathbb{E}[\text{dist}_X^2(y^k)].
\end{aligned}\tag{30}$$

On the other hand, from triangle inequality and Minkowski inequality, we obtain:

$$\begin{aligned}\sqrt{\mathbb{E}[\mathrm{dist}_X^2(y^k)]} &\leq \sqrt{\mathbb{E}[\|y^k-\Pi_X(x^k)\|^2]} \leq \sqrt{\mathbb{E}[(\|y^k-x^k\|+\mathrm{dist}_X(x^k))^2]}\\ &\overset{(8)}{\leq} \sqrt{\mathbb{E}[\|z_{\mu_k}(x^k;S_k)-x^k\|^2]}+\sqrt{\mathbb{E}[\mathrm{dist}_X^2(x^k)]}\\ &= \sqrt{\mathbb{E}[\mathrm{dist}_X^2(x^k)]}+\mu_k\sqrt{\mathbb{E}[\|\nabla f_{\mu_k}(x^k;S_k)\|^2]}\\ &\overset{\text{Lemma 3}}{\leq} \sqrt{\mathbb{E}[\mathrm{dist}_X^2(x^k)]}+\mu_k\sqrt{\mathbb{E}[\|\nabla f(x^k;S_k)\|^2]}\\ &\overset{\text{Lemma 12}}{\leq} \sqrt{\mathbb{E}[\mathrm{dist}_X^2(x^k)]}+\mu_k\left(\sqrt{2\mathbb{E}[\|\nabla f(x^*;S)\|^2]}+\mathcal{A}\sqrt{2\mathbb{E}[L_{f,S}^2]}\right). \quad (31)\end{aligned}$$

For simplicity we use notations: $\alpha=\sqrt{1-\frac{1}{\zeta}}$, $d_k=\sqrt{\mathbb{E}[\mathrm{dist}_X^2(x^k)]}$ and $\mathcal{B}=\sqrt{2\mathbb{E}[\|\nabla f(x^*;S)\|^2]}+\mathcal{A}\sqrt{2\mathbb{E}[L_{f,S}^2]}$. Combining (30) and (31) yields:

$$d_{k+1}\leq \alpha d_k+\alpha\mu_k\mathcal{B}\leq \alpha^{k+1}d_0+\mathcal{B}\sum_{i=1}^{k+1}\alpha^i\mu_{k-i+1}. \quad (32)$$

Define $m=\lceil\frac{k+1}{2}\rceil$. By dividing the sum from the right side of (32) in two parts and by taking into account that $\{\mu_k\}_{k\geq 0}$ is nonincreasing, then results in:

$$\begin{aligned}\sum_{i=1}^{k+1}\alpha^i\mu_{k-i+1} &= \sum_{i=1}^{m}\alpha^i\mu_{k-i+1}+\sum_{i=m+1}^{k+1}\alpha^i\mu_{k-i+1}\\ &\leq \mu_{k-m+1}\sum_{i=1}^{m}\alpha^i+\alpha^{m+1}\sum_{i=0}^{k-m}\alpha^i\mu_{k-i-m}\\ &\leq \mu_{k-m+1}\frac{\alpha(1-\alpha^m)}{1-\alpha}+\mu_0\alpha^{m+1}\frac{1-\alpha^{k-m+1}}{1-\alpha}\\ &\leq \mu_{k-m+1}\frac{\alpha}{1-\alpha}+\alpha^{m+1}\frac{\mu_0}{1-\alpha}.\end{aligned}$$

By using the last inequality into (32) and using the bound $\frac{\alpha}{1-\alpha}\leq 2\zeta$, then these facts imply the statement of the lemma. ■

Proof of Theorem 14:
Proof Let $\mu>0, x\in\mathbb{R}^n$ and $S\in\Omega$, then we have:

$$\begin{aligned}&\frac{1}{2}\|z_\mu(x;S)-x^*\|^2\\ &=\frac{1}{2}\|z_\mu(x;S)-z_\mu(x^*;S)\|^2+\langle z_\mu(x;S)-z_\mu(x^*;S),z_\mu(x^*;S)-x^*\rangle+\frac{1}{2}\|z_\mu(x^*;S)-x^*\|^2\\ &\leq \frac{\theta_S^2(\mu)}{2}\|x-x^*\|^2-\mu\langle\nabla f(x^*;S),x-x^*\rangle+\langle z_\mu(x^*;S)-x^*+\mu\nabla f(x^*;S),x-x^*\rangle\\ &\qquad+\langle z_\mu(x;S)-x,z_\mu(x^*;S)-x^*\rangle-\frac{\mu^2}{2}\|\nabla f_\mu(x^*;S)\|^2. \quad (33)\end{aligned}$$

Now we take expectation in both sides and consider $x=x^k$ and $\mu=\mu_k$. We thus seek a bound for each term from the right hand side in (33). For the second term, by using the optimality conditions $\langle\nabla F(x^*),z-x^*\rangle\geq 0$ for all $z\in X$, we have:

$$\begin{aligned}\mathbb{E}[\langle\nabla f(x^*;S),x^*-x^k\rangle] &= \mathbb{E}[\langle\nabla F(x^*),x^*-\Pi_X(x^k)\rangle]+\mathbb{E}[\langle\nabla F(x^*),\Pi_X(x^k)-x^k\rangle]\\ &\leq \mathbb{E}[\langle\nabla F(x^*),\Pi_X(x^k)-x^k\rangle]\\ &\overset{\text{C.-S.}}{\leq} \|\nabla F(x^*)\|\,\mathbb{E}[\mathrm{dist}_X(x^k)]\leq\|\nabla F(x^*)\|\sqrt{\mathbb{E}[\mathrm{dist}_X^2(x^k)]}\\ &\overset{\text{Lemma 13}}{\leq} \|\nabla F(x^*)\|\left[\left(1-\frac{1}{\zeta}\right)^{\frac{k}{2}}\left(\mathrm{dist}_X(x^0)+2\mu_0\zeta\mathcal{B}\right)+2\mu_{k-\lceil\frac{k}{2}\rceil}\zeta\mathcal{B}\right],\end{aligned}$$

where in the second inequality we used the Cauchy-Schwarz inequality. By using that $e^x\geq 1+x$, for all $x\geq 0$, and the fact that $\frac{1}{k}\leq\frac{1}{k^\gamma}$ when $k\geq 1$ and $\gamma\in(0,1]$, then the last inequality implies:

$$\begin{aligned}\mathbb{E}[\langle\nabla f(x^*;S),x^*-x^k\rangle] &\leq \|\nabla F(x^*)\|\left[\frac{2\mathrm{dist}_X(x^0)+4\mu_0\zeta\mathcal{B}}{k\ln(\zeta/(\zeta-1))}+2\mu_{k-\lceil\frac{k}{2}\rceil}\mathcal{B}\zeta\right]\\ &\leq \mu_k\|\nabla F(x^*)\|\left[\frac{2\mathrm{dist}_X(x^0)+4\mu_0\zeta\mathcal{B}}{\mu_0\ln(\zeta/(\zeta-1))}+\frac{2\mu_{k-\lceil\frac{k}{2}\rceil}\mathcal{B}\zeta}{\mu_k}\right]. \quad (34)\end{aligned}$$

For the third term in (33) we observe from the optimality conditions for $z_{\mu_k}(x^*;S)$ that:

$$\begin{aligned}\left\|\frac{1}{\mu_k}\left(z_{\mu_k}(x^*;S)-x^*\right)+\nabla f(x^*;S)\right\| &= \|\nabla f(z_{\mu_k}(x^*;S);S)-\nabla f(x^*;S)\|\\ &\overset{\text{As.1}}{\leq} L_{f,S}\|z_{\mu_k}(x^*;S)-x^*\|=\mu_k L_{f,S}\|\nabla f_{\mu_k}(x^*;S)\|\\ &\overset{\text{Lemma 3}}{\leq} \mu_k L_{f,S}\|\nabla f(x^*;S)\|,\end{aligned}$$

which yields the following bound:

$$\begin{aligned}&\langle z_{\mu_k}(x^*;S)-x^*+\mu_k\nabla f(x^*;S),x^k-x^*\rangle\leq\|z_{\mu_k}(x^*;S)-x^*+\mu_k\nabla f(x^*;S)\|\cdot\|x^k-x^*\|\\ &\leq\|\mu_k\nabla f(x^*;S)-\mu_k\nabla f(z_{\mu_k}(x^*;S);S)\|\cdot\|x^k-x^*\|\overset{\text{As.1}}{\leq}\mu_k L_{f,S}\|x^*-z_{\mu_k}(x^*;S)\|\cdot\|x^k-x^*\|\\ &\leq\mu_k^2L_{f,S}\|\nabla f_{\mu_k}(x^*;S)\|\cdot\|x^k-x^*\|\overset{\text{Lemma 3}}{\leq}\mu_k^2L_{f,S}\|\nabla f(x^*;S)\|\cdot\|x^k-x^*\|,\end{aligned}$$

where in the first inequality we used the Cauchy-Schwarz. By taking expectation in both sides and using Lemma 11, we obtain the refinement:

$$\begin{aligned}\mathbb{E}[\langle z_{\mu_k}(x^*;S)-x^*+\mu_k\nabla f(x^*;S),x^k-x^*\rangle] &= \mu_k\mathbb{E}[\langle\nabla f(x^*;S)-\nabla f(z_{\mu_k}(x^*;S);S),x^k-x^*\rangle]\\ &\leq \mu_k\mathbb{E}[\|\nabla f(x^*;S)-\nabla f(z_{\mu_k}(x^*;S);S)\|\|x^k-x^*\|] \quad (35)\end{aligned}$$

$$\begin{aligned}
&\overset{\text{As. 1}}{\leq} \mu_k\mathbb{E}[L_{f,S}\|x^*-z_{\mu_k}(x^*;S)\|\|x^k-x^*\|]\\
&=\mu_k\mathbb{E}[L_{f,S}\|\nabla f_{\mu_k}(x^*;S)\|\|x^k-x^*\|]\\
&\overset{\text{Lemma 3}}{\leq} \mu_k\mathbb{E}[L_{f,S}\|\nabla f(x^*;S)\|\|x^k-x^*\|]\\
&\leq \mu_k^2\sqrt{\mathbb{E}[L_{f,S}^2]}\sqrt{\mathbb{E}[\|\nabla f(x^*;S)\|^2]}\mathbb{E}[\|x^k-x^*\|]\\
&\leq \mu_k^2\sqrt{\mathbb{E}[L_{f,S}^2]}\sqrt{\mathbb{E}[\|\nabla f(x^*;S)\|^2]}\mathbb{E}[\|x^k-x^*\|]\\
&\overset{\text{Lemma 11}}{\leq} \mu_k^2\sqrt{\mathbb{E}[L_{f,S}^2]}\eta\mathcal{A}, \qquad (36)
\end{aligned}$$

where in the first inequality we again used Cauchy-Schwarz relation and in the second we used Assumption 1. Finally, for the fourth term in (33) we use Lemma 12:

$$\begin{aligned}
&\mathbb{E}[\langle z_{\mu_k}(x^k;S)-x^k, z_{\mu_k}(x^*;S)-x^*\rangle] = \mu_k^2\mathbb{E}[\langle\nabla f_{\mu_k}(x^k;S),\nabla f_{\mu_k}(x^*;S)\rangle]\\
&\leq \mu_k^2\mathbb{E}[\|\nabla f_{\mu_k}(x^k;S)\|\|\nabla f_{\mu_k}(x^*;S)\|]\\
&\overset{\text{Lemma 3}}{\leq} \mu_k^2\mathbb{E}[\|\nabla f(x^k;S)\|\|\nabla f(x^*;S)\|] \leq \mu_k^2\sqrt{\mathbb{E}[\|\nabla f(x^k;S)\|^2]\mathbb{E}[\|\nabla f(x^*;S)\|^2]}\\
&\overset{\text{Lemma 12}}{\leq} \mu_k^2\eta\sqrt{2\eta^2+2\mathbb{E}[L_{f,S}^2]\mathcal{A}^2}, \qquad (37)
\end{aligned}$$

where in the first inequality we used Cauchy-Schwarz. By taking expectation in (33), using the relations (34)-(37) and taking into account that $\frac{\mu_k}{\mu_{k-\lceil\frac{k}{2}\rceil}}\leq 3^\gamma$ for all $k\geq 1$, we obtain:

$$\begin{aligned}
&\mathbb{E}[\|z_{\mu_k}(x^k;S)-x^*\|^2]\\
&\leq \mathbb{E}\left[\theta_S^2(\mu_k)\|x^k-x^*\|^2\right]+4\mu_k^2\|F(x^*)\|\left[\frac{\operatorname{dist}_X(x^0)+2\mu_0\zeta\mathcal{B}}{\mu_0\ln\left(\zeta/(\zeta-1)\right)}+3^\gamma\mathcal{B}\zeta\right]\\
&\qquad +2\mu_k^2\eta\sqrt{2\eta^2+2\mathbb{E}[L_{f,S}^2]\mathcal{A}^2}+2\mu_k^2\eta\mathcal{A}\sqrt{\mathbb{E}[L_{f,S}^2]}\\
&=\mathbb{E}\left[\theta_S^2(\mu_k)\right]\mathbb{E}[\|x^k-x^*\|^2]+\mu_k^2\mathcal{D}.
\end{aligned}$$

For simplicity, we use further in the proof the following notations: $r_k=\sqrt{\mathbb{E}[\|x^k-x^*\|^2]}$ and $\theta_k=\mathbb{E}[\theta_S^2(\mu_k)]$. Then, through the nonexpansiveness property of the projection operator, the previous inequality turns into:

$$\begin{aligned}
r_{k+1}^2 &\leq \mathbb{E}[\|z_{\mu_k}(x^k;S)-x^*\|^2]\leq \theta_k r_k^2+\mu_k^2\mathcal{D}\\
&\leq r_0^2\prod_{i=0}^k\theta_i+\mathcal{D}\sum_{i=0}^k\left(\prod_{j=i+1}^k\theta_j\right)\mu_i^2. \qquad (38)
\end{aligned}$$

To further refine the right hand side in (38), we first notice from Lemma 20 that we have $\prod_{i=0}^k\theta_i\leq\theta_0^{\varphi_{1-\gamma}(k+1)}$. Then, from (38) we can derive different upper bounds for the two cases of the parameter γ: $\gamma<1$ and $\gamma=1$.

Case (i) $\gamma<1$. From Lemma 20, we derive an upper approximation for the second term in the right hand side of (38). Therefore, if we let $m=\lceil\frac{k}{2}\rceil$ we obtain:

$$\begin{aligned}
\sum_{i=0}^k\mu_i^2\left(\prod_{j=i+1}^k\theta_j\right) &= \sum_{i=0}^m\mu_i^2\left(\prod_{j=i+1}^k\theta_j\right)+\sum_{i=m+1}^k\mu_i^2\left(\prod_{j=i+1}^k\theta_j\right)\\
&\overset{\text{Lemma 20}}{\leq} \sum_{i=0}^m\mu_i^2\theta_0^{\varphi_{1-\gamma}(k+1)-\varphi_{1-\gamma}(i+1)}+\mu_{m+1}\sum_{i=m+1}^k\mu_i\left(\prod_{j=i+1}^k\theta_j\right)\\
&\leq \theta_0^{\varphi_{1-\gamma}(k+1)-\varphi_{1-\gamma}(m+1)}\sum_{i=0}^m\mu_i^2+\mu_{m+1}\sum_{i=m+1}^k\mu_i\left(\prod_{j=i+1}^k\theta_j\right)\\
&= \theta_0^{\varphi_{1-\gamma}(k+1)-\varphi_{1-\gamma}(m+1)}\sum_{i=0}^m\mu_i^2+\mu_{m+1}\sum_{i=m+1}^k\frac{\mu_i}{1-\theta_i}(1-\theta_i)\left(\prod_{j=i+1}^k\theta_j\right). \qquad (39)
\end{aligned}$$

We will further refine the right hand side of (39) by noticing the following two facts. First, the constant $\frac{\mu_i}{1-\theta_i}$ can be upper bounded by:

$$\frac{\mu_i}{1-\theta_i}=\frac{1}{\mathbb{E}\left[\frac{\sigma_S}{(1+\mu_i\sigma_S)^2}+\frac{\sigma_S}{1+\mu_i\sigma_S}\right]}\leq\frac{\mu_{i-1}}{1-\theta_{i-1}}\leq\cdots\leq\frac{\mu_0}{1-\theta_0}.$$

Second, the sum of products is upper bounded as:

$$\sum_{i=m+1}^k(1-\theta_i)\left(\prod_{j=i+1}^k\theta_j\right)=\sum_{i=m+1}^k\left(\prod_{j=i+1}^k\theta_j-\prod_{j=i}^k\theta_j\right)=1-\prod_{j=m+1}^k\theta_j\leq 1.$$

By using the last two inequalities into (39), we have:

$$\sum_{i=0}^k\mu_i^2\left(\prod_{j=i+1}^k\theta_j\right)\leq\theta_0^{\varphi_{1-\gamma}(k+1)-\varphi_{1-\gamma}(m+1)}\sum_{i=0}^m\mu_i^2+\mu_{m+1}\frac{\mu_0}{1-\theta_0}. \qquad (40)$$

Since $\sum_{i=0}^m\mu_i^2\leq\mu_0^2(\varphi_{1-2\gamma}(m)+2)\leq\mu_0^2(\varphi_{1-2\gamma}(m)+2)\leq\mu_0^2[\varphi_{1-2\gamma}\left(\frac{k}{2}+1\right)+2]$ and using (40) into (38), we obtain the above result.

Case (ii) $\gamma=1$. In this case we have:

$$\begin{aligned}
&\sum_{i=1}^k\mu_i^2\left(\prod_{j=i+1}^k\theta_j\right)\overset{\text{Lemma 20}}{\leq}\sum_{i=1}^k\mu_i^2\theta_0^{\varphi_0(k+1)-\varphi_0(i+1)}\\
&=\sum_{i=1}^k\frac{\mu_1^2}{i^2}\theta_0^{\ln\frac{k+1}{i+1}}=\sum_{i=1}^k\frac{\mu_1^2}{i^2}\left(\frac{k+1}{i+1}\right)^{\ln\theta_0}\leq\left(\frac{1}{k}\right)^{\ln\left(\frac{1}{\theta_0}\right)}\sum_{i=1}^k\frac{\mu_1^2}{i^{2-\ln\frac{1}{\theta_0}}}\\
&\leq\left(\frac{1}{k}\right)^{\ln\left(\frac{1}{\theta_0}\right)}\mu_0^2\varphi_{\ln\frac{1}{\theta_0}-1}(k).
\end{aligned}$$

Therefore, the variation of θ_0 leads to the following cases:

$$\sum_{i=1}^{k}\mu_i^2\left(\prod_{j=i+1}^{k}\theta_j\right)\leq\begin{cases}\frac{\mu_0^2}{k\left(\ln\left(\frac{1}{\theta_0}\right)-1\right)} & \text{if } \theta_0<\frac{1}{e}\\ \frac{\mu_0^2\ln k}{k} & \text{if } \theta_0=\frac{1}{e}\\ \left(\frac{1}{k}\right)^{\ln\left(\frac{1}{\theta_0}\right)}\frac{\mu_0^2}{1-\ln\left(\frac{1}{\theta_0}\right)} & \text{if } \theta_0>\frac{1}{e},\end{cases}$$

which leads to the second part of the result. ■

Proof of Lemma 17:

Proof The proof follows similar lines with the one of Lemma 30. Therefore, by using notations: $\alpha=\sqrt{1-\frac{1}{\zeta}}$ and $d_{k,t}=\sqrt{\mathbb{E}[\mathrm{dist}_X^2(x^{k,t})]}$ results in:

$$\begin{aligned}d_{k+1,t}&\leq\alpha d_{k,t}+\alpha\mu_t\mathcal{B}\leq\alpha^{k+1}d_{0,t}+\mu_t\mathcal{B}\sum_{i=1}^{k+1}\alpha^i\\&\leq\alpha^{k+1}d_{0,t}+\mu_t\mathcal{B}\frac{\alpha}{1-\alpha}.\end{aligned}$$

By setting $k=K_t-1$, then the last inequality implies:

$$\begin{aligned}d_{K_t,t}&\leq\alpha^{K_t}d_{K_{t-1},t-1}+\mu_t\mathcal{B}\frac{\alpha}{1-\alpha}\\&\leq\alpha^{\sum_{i=1}^{t}K_i}d_{0,0}+\mathcal{B}\frac{\alpha}{1-\alpha}\sum_{j=0}^{t-1}\alpha^{\sum_{i=t-j+1}^{t}K_i}\mu_{t-j}.\end{aligned}$$

Now set $m=\lceil\frac{t}{2}\rceil$. By dividing the sum from the right side of (32) in two parts, by taking into account that $\{\mu_t\}_{t\geq0}$ is nonincreasing and $\{K_t\}_{t\geq0}$ is nondecreasing, then results in:

$$\begin{aligned}\sum_{j=0}^{t-1}\alpha^{\sum_{i=t-j+1}^{t}K_i}\mu_{t-j}&=\sum_{j=0}^{m}\alpha^{\sum_{i=t-j+1}^{t}K_i}\mu_{t-j}+\sum_{j=m+1}^{t-1}\alpha^{\sum_{i=t-j+1}^{t}K_i}\mu_{t-j}\\&\leq\mu_{t-m}\sum_{j=0}^{m}\alpha^{\sum_{i=t-j+1}^{t}K_i}+\mu_0\alpha^{K_t}\sum_{j=m+1}^{t-1}\alpha^{\sum_{i=t-j+1}^{t-1}K_i}\\&\leq\mu_{t-m}\frac{1-\alpha^{m+1}}{1-\alpha}+\mu_0\alpha^{\sum_{i=t-m}^{t}K_i}\frac{1-\alpha^{t-m+2}}{1-\alpha}\\&\leq\frac{\mu_{t-m}}{1-\alpha}+\frac{\mu_0\alpha^{\sum_{i=t-m}^{t}K_i}}{1-\alpha}.\end{aligned}$$

By using the last inequality into (32) and using the bound $\frac{\alpha}{1-\alpha}\leq2\zeta$, then these facts imply the statement of the lemma. ■

Proof of Theorem 18:

Proof First notice that from $e^x\geq1+x$ for all $x\geq0$, we have $\left(1-\frac{1}{\zeta}\right)^{\sum_{i=1}^{t}\frac{K_i}{2}}\leq\left(1-\frac{1}{\zeta}\right)^{\frac{K_t}{2}}\leq\frac{2}{K_t\ln(\zeta/\zeta-1)}$ and $\left(1-\frac{1}{\zeta}\right)^{\sum_{i=t-\lceil\frac{t}{2}\rceil}^{t}\frac{K_i}{2}}\leq\left(1-\frac{1}{\zeta}\right)^{\frac{K_t}{2}}\leq\frac{2}{K_t\ln(\zeta/\zeta-1)}$, which imply that Lemma 2 becomes

$$\sqrt{\mathbb{E}[\mathrm{dist}_X^2(x^{K_t,t})]}\leq\mu_t\frac{2\mathrm{dist}_X(x^{0,0})}{\mu_0\ln(\zeta/\zeta-1)}+\mu_t\frac{4\zeta^2\mathcal{B}}{\ln(\zeta/\zeta-1)}+2\mu_{t-\lceil\frac{t}{2}\rceil}\zeta^2\mathcal{B}.\tag{41}$$

It can be seen that by combining (41) with a similar argument as in Theorem 14 we obtain a similar descent as (38). Therefore, let $k\geq0$ and $x^{k,t}$ be the kth iterate from the tth epoch. Then, by denoting $r_{k,t}^2=\mathbb{E}[\|x^{k,t}-x^*\|^2]$, results in:

$$r_{k+1,t}^2\leq\mathbb{E}[\theta_S(\mu_t)^2]r_{k,t}^2+\mu_t^2\mathcal{D}_r.$$

Now taking $k=K_t$ results in:

$$r_{0,t+1}^2=r_{K_t,t}^2\leq r_{0,t}^2\theta_t^{K_t}+\mathcal{D}_r\mu_t^2\sum_{i=0}^{k}\theta_t^i\leq r_{0,t}^2\theta_t^{K_t}+\frac{\mathcal{D}_r\mu_t^2}{1-\theta_t}.\tag{42}$$

Recalling that we chose $\mu_t=\frac{\mu_0}{t^\gamma}$ and $K_t=\lceil t^\gamma\rceil$, then (7) leads to:

$$\theta_t^{K_t}\leq\left(\mathbb{E}\left[\frac{1}{(1+\mu_0\sigma_{f,S})^2}\right]\right)^{\frac{K_t}{t^\gamma}}\leq\theta_0.$$

Therefore, (42) leads to:

$$r_{0,t+1}\overset{(42)}{\leq}\theta_0r_{0,t}^2+\frac{\mathcal{D}_r\mu_t^2}{1-\theta_t}\leq\theta_0^tr_{0,1}^2+\mathcal{D}_r\sum_{i=1}^{t}\frac{\mu_i^2\theta_0^{t-i}}{1-\theta_i}.\tag{43}$$

Note that $\frac{\mu_i^2}{1-\theta_i}$ is nonincreasing in i. Then, if we fix $m=\lceil\frac{t}{2}\rceil$, then the sum $\sum_{i=1}^{t}\frac{\mu_i^2\theta_0^{t-i}}{1-\theta_i}$ can be bounded as follows:

$$\begin{aligned}\sum_{i=1}^{t}\frac{\mu_i^2\theta_0^{t-i}}{1-\theta_i}&\leq\theta_0^m\sum_{i=1}^{m}\frac{\mu_i^2}{1-\theta_i}+\sum_{i=m}^{t}\frac{\mu_i^2\theta_0^{t-i}}{1-\theta_i}\\&\leq\theta_0^m\sum_{i=1}^{m}\frac{\mu_i^2}{1-\theta_i}+\frac{\mu_m^2}{1-\theta_m}\sum_{i=1}^{t-m}\theta_0^i\\&\leq\frac{\theta_0^m\mu_1}{1-\theta_0}\left(\sum_{i=1}^{m}\mu_i\right)+\frac{\mu_m^2}{(1-\theta_m)(1-\theta_0)}\\&\leq\frac{\theta_0^m\mu_1}{1-\theta_0}\left(\sum_{i=1}^{m}\mu_i\right)+\mu_m\frac{\mu_1}{(1-\theta_0)^2}.\end{aligned}\tag{44}$$

Taking into account that $\sum_{i=1}^{m}\mu_i \leq \int_1^m \frac{1}{s^\gamma}ds \leq \frac{2^{\gamma-1}}{(1-\gamma)t^{\gamma-1}}$ and that $\theta_0^m \leq \frac{1}{1+\frac{t}{2}\ln\frac{1}{\theta_0}}$, the previous relation (44) implies:

$$\sum_{i=1}^{t}\frac{\mu_i^2\theta_0^{t-i}}{1-\theta_i} \leq \left(\frac{2}{t}\right)^{\gamma}\left[\frac{1}{2(1-\gamma)\ln 1/\sqrt{\theta_0}}+\frac{\mu_1^2}{(1-\theta_0)^2}\right]. \tag{45}$$

By using this bound in relation (44), then in order to obtain $r_{0,t+1}^2 \leq \epsilon$ it is sufficient that the number of epochs t to satisfy:

$$t \geq \max\left\{\ln\left(\frac{2r_{0,0}^2}{\epsilon}\right)\frac{1}{\ln(1/\theta_0)}, \left(\frac{2^{\gamma+1}\mathcal{D}_r}{\epsilon}\mathcal{C}\right)^{1/\gamma}\right\}. \tag{46}$$

Finally, the total number of SPP iterations performed by RSPP algorithm satisfies:

$$\begin{aligned}\sum_{i=1}^{t}K_t &\geq \sum_{i=1}^{t}i^\gamma \geq \int_0^t s^\gamma ds = \frac{t^{1+\gamma}}{1+\gamma}\\ &\geq \frac{1}{1+\gamma}\max\left\{\ln\left(\frac{2r_{0,0}^2}{\epsilon}\right)^{1+\gamma}\frac{1}{\ln(1/\theta_0)^{1+\gamma}}, \left(\frac{2^{\gamma+1}\mathcal{D}_r}{\epsilon}\mathcal{C}\right)^{1+\frac{1}{\gamma}}\right\},\end{aligned}$$

which proves the statement of the theorem. ■

Abstract

We consider data in the form of pairwise comparisons of n items, with the goal of identifying the top k items for some value of $k < n$, or alternatively, recovering a ranking of all the items. We analyze the Borda counting algorithm that ranks the items in order of the number of pairwise comparisons won, and show it has three attractive features: (a) it is an optimal method achieving the information-theoretic limits up to constant factors; (b) it is robust in that its optimality holds without imposing conditions on the underlying matrix of pairwise-comparison probabilities, in contrast to some prior work that applies only to the BTL parametric model; and (c) its computational efficiency leads to speed-ups of several orders of magnitude. We address the problem of exact recovery, and for the top-k recovery problem we also extend our results to obtain sharp guarantees for approximate recovery under the Hamming distortion metric, and more generally, to any arbitrary error requirement that satisfies a simple and natural monotonicity condition. In doing so, we introduce a general framework that allows us to treat a variety of problems in the literature in an unified manner.

Keywords: Pairwise comparisons, Ranking, Set recovery, Approximate recovery, Borda count, Permutation-based models, Occam's razor

1. Introduction

Ranking problems involve a collection of n items, and some unknown underlying total ordering of these items. In many applications, one may observe noisy comparisons between various pairs of items. Examples include matches between football teams in tournament play; consumer's preference ratings in marketing; and certain types of voting systems in politics. Given a set of such noisy comparisons between items, it is often of interest to find the true underlying ordering of all n items, or more generally, given some given positive integer $k \leq n$, to find the subset of k most highly rated items. These two problems are the focus of this paper.

There is a substantial literature on the problem of finding approximate rankings based on noisy pairwise comparisons. A number of papers (e.g., Kenyon-Mathieu and Schudy, 2007; Braverman and Mossel, 2008; Eriksson, 2013) consider models in which the probability of a pairwise comparison agreeing with the underlying order is identical across all pairs. These results break down when, for one or more pairs, the probability of agreeing with the underlying ranking is close to or exactly equal to $\frac{1}{2}$. Another set of papers (Hunter, 2004; Negahban et al., 2012; Hajek et al., 2014; Soufiani et al., 2014; Shah et al., 2016a) work using parametric models of pairwise comparisons, and address the problem of recovering the parameters associated to every individual item. A more recent line of work (Chatterjee, 2014; Shah et al., 2017a, 2016d) studies a more general class of models based on the notion of strong stochastic transitivity (SST), and derives conditions on recovering the pairwise comparison probabilities themselves. However, it remains unclear whether or not these results can directly extend to tight bounds for the problem of recovery of the top k items. Another line of work (Jagabathula and Shah, 2008; Mitliagkas et al., 2011; Ammar and Shah, 2012; Ding et al., 2015) focuses on mixture models, in which every pairwise comparison is associated to a certain individual making the comparison, and it is assumed that the preferences across individuals can be described by a low-dimensional model.

Most related to our work are the papers by Wauthier et al. (2013); Rajkumar and Agarwal (2014); Rajkumar et al. (2015), and Chen and Suh (2015), which we briefly discuss here and in a more detailed manner in the sequel. Wauthier et al. (2013) analyze a weighted counting algorithm to recover approximate rankings; their analysis applies to a specific model in which the pairwise comparison between any pair of items remains faithful to their relative positions in the true ranking with a probability common across all pairs. They consider recovery of an approximate ranking under Kendall's tau and maximum displacement metrics, but do not provide results on exact recovery. As the analysis of this paper shows, their bounds are quite loose: more precisely, their results are tight only when there are a total of at least $\Theta(n^2)$ comparisons. Two other papers (Rajkumar and Agarwal, 2014; Rajkumar et al., 2015) consider ranking under several models and several metrics. In the part that is common with our setting, they show that the counting algorithm is consistent in terms of recovering the full ranking, which automatically implies consistency in exactly recovering the top k items. They obtain upper bounds on the sample complexity in terms of a separation threshold that is identical to a parameter Δ_k defined subsequently in this paper (see Section 3). However, as our analysis shows, their bounds are loose by at least an order of magnitude. They also assume a certain high-SNR condition on the probabilities, an assumption that is not imposed in our analysis.

Finally, in very recent work on this problem, Chen and Suh (2015) proposed an algorithm called the Spectral MLE for exact recovery of the top k items. They showed that, if the pairwise observations are assumed to drawn according to the Bradley-Terry-Luce (BTL) parametric model (Bradley and Terry, 1952; Luce, 1959), the Spectral MLE algorithm recovers the k items correctly with high probability under certain regularity conditions. In addition, they also show, via matching lower bounds, that their regularity conditions are tight up to constant factors. While these guarantees are attractive, it is natural to ask how such an algorithm behaves when the data is *not* drawn from the BTL model. In real-world instances of pairwise ranking data, it is often found that parametric models, such as the BTL model and its variants, fail to provide accurate fits (for instance, see the papers Davidson and Marschak, 1959; McLaughlin and Luce, 1965; Tversky, 1972; Ballinger and Wilcox, 1997 and references therein).

With this context, the main contribution of this paper is to analyze a classical counting-based method for ranking, often called the Borda count method (de Borda, 1781), and to show that it is optimal and robust. Our analysis does not require that the data-generating mechanism follow either the BTL or other parametric assumptions, nor other regularity conditions such as stochastic transitivity. We show that the Borda counting algorithm has the following properties:

- Simplicity: The algorithm is simple, as it just orders the items by the number of pairwise comparisons won. As we will subsequently see, the execution time of this counting algorithm is several orders of magnitude lower as compared to prior work on ranking from noisy pairwise comparisons.
- Optimality: We derive conditions under which the counting algorithm achieves the stated goals, and by means of matching information-theoretic lower bounds, show that these conditions are tight.
- Robustness: The guarantees that we prove do not require any assumptions on the pairwise-comparison probabilities, and the counting algorithm performs well for various classes of data sets. In contrast, we find that the spectral MLE algorithm performs poorly when the data is not drawn from the BTL model.

In doing so, we consider three different instantiations of the problem of set-based recovery:

(i) Recovering the top k items perfectly;

(ii) Recovering the top k items allowing for a certain Hamming error tolerance; and

(iii) A more general recovery problem for set families that satisfy a natural "set-monotonicity" condition. In order to tackle this general problem, we introduce a general framework that allows us to treat a variety of problems in the literature in an unified manner.

The remainder of this paper is organized as follows. We begin in Section 2 with background and a more precise formulation of the problem. Section 3 presents our main theoretical results on top-k recovery under various requirements. Section 4 provides the results of experiments on both simulated and real-world data sets. We provide all proofs in Section 5. The paper concludes with a discussion in Section 6.

2. Background and problem formulation

In this section, we provide a more formal statement of the problem along with background on various types of ranking models.

2.1 Problem statement

Given an integer $n \geq 2$, we consider a collection of n items, indexed by the set $[n] := \{1, \ldots, n\}$. For each pair $i \neq j$, we let M_{ij} denote the probability that item i wins the comparison with item j. We assume that each comparison necessarily results in one winner, meaning that

$$M_{ij} + M_{ji} = 1, \qquad \text{and} \quad M_{ii} = \frac{1}{2}, \tag{1}$$

where we set the diagonal as $\frac{1}{2}$ for concreteness.

For any item $i \in [n]$, we define an associated score τ_i as

$$\tau_i(M) := \frac{1}{n} \sum_{j=1}^{n} M_{ij}. \tag{2}$$

In words, the score $\tau_i(M)$ of any item $i \in [n]$ corresponds to the probability that item i beats an item chosen uniformly at random from all n items. In the sequel, we will use the shorthand τ_i for the score of any item i, and drop the dependence on M from the notation wherever the value of M is clear from context.

Given a set of noisy pairwise comparisons, our goals are (a) to recover the k items with the maximum values of their scores; and (b) to recover the full ordering of all the items as defined by the score vector. The notion of ranking items via their scores (2) generalizes the explicit rankings under popular models in the literature. Indeed, as we discuss shortly, most models of pairwise comparisons considered in the literature either implicitly or explicitly assume that the items are ranked according to their scores. Note that neither the scores $\{\tau_i\}_{i \in [n]}$ nor the matrix $M := \{M_{ij}\}_{i,j \in [n]}$ of probabilities are assumed to be known.

More concretely, we consider a random-design observation model defined as follows. Each pair is associated with a random number of noisy comparisons, following a binomial distribution with parameters (r, p), where $r \geq 1$ is the number of trials and $p \in (0, 1]$ is the probability of making a comparison on any given trial. Thus, each pair (i, j) is associated with a binomial random variable with parameters (r, p) that governs the number of comparisons between the pair of items. We assume that the observation sequences for different pairs are independent. Note that in the special case $p = 1$, this random binomial model reduces to the case in which we observe exactly r observations of each pair; in the special case $r = 1$, the set of pairs compared form an (n, p) Erdős-Rényi random graph.

In this paper, we begin in Section 3.1 by analyzing the problem of exact recovery. More precisely, for a given matrix M of pairwise probabilities, suppose that we let $\mathcal{S}_k^*$ denote the (unknown) set of k items with the largest values of their respective scores, assumed to be unique for concreteness.

Given noisy observations specified by the pairwise probabilities M, our goal is to establish conditions under which there exists some algorithm $\widehat{\mathcal{S}}_k$ that identifies k items based on the outcomes of various comparisons such that the probability $\mathbb{P}_M(\widehat{\mathcal{S}}_k = \mathcal{S}_k^*)$ is very close to one. In the case of recovering the full ranking, our goal is to identify conditions which ensure that the probability $\mathbb{P}_M\big(\bigcap_{k \in [n]} (\widehat{\mathcal{S}}_k = \mathcal{S}_k^*)\big)$ is close to one.

In Section 3.2, we consider the problem of recovering a set of k items that approximates $\mathcal{S}_k^*$ with a minimal Hamming error. For any two subsets of the set $[n]$, we define their Hamming distance D_{H}, also referred to as their Hamming error, to be the number of items that belong to exactly one of the two sets—that is

$$D_{\mathrm{H}}(A, B) = \mathrm{card}\Big(\{A \cup B\} \backslash \{A \cap B\}\Big). \tag{3}$$

For a given user-defined tolerance parameter $h \geq 0$, we derive conditions that ensure that $D_{\mathrm{H}}(\widehat{\mathcal{S}}_k, \mathcal{S}_k^*) \leq 2h$ with high probability.

Finally, we generalize our results to the problem of satisfying any a general class of requirements on set families. These requirement are specified in terms of which k-sized

subsets of the items are allowed, and is required to satisfy only one natural condition, that of set-monotonicity, meaning that replacing an item in an allowed set with a higher rank item should also be allowed. See Section 3.3 for more details on this general framework.

2.2 A range of pairwise comparison models

Our work makes minimal assumptions on the the pairwise comparison probabilities. Our model is based on a "permutation-based" approach, and is described below (see Shah et al., 2017a, 2016d,c, 2017b for other uses of permutation-based models and Shah, 2017, Chapter 1 and Part 1 for a general treatment). In order to put our work in context of the literature, we also briefly review some standard models used for pairwise comparison data – all of these models form special cases of our general model.

Our model: We assume that any requirements or metrics for recovery of a partial or total order of the items are governed by the scores of the items defined in equation (2). In other words, any item i is considered as ranked higher than any item j when their scores satisfy $\tau_i > \tau_j$. We make no other assumptions on the probabilities $\{M_{ij}\}_{i,j\in[n]}$. In what follows, we show that several other popular classes of models arise as special cases of our model.

Parametric models: A broad class of parametric models, including the Bradley-Terry-Luce (BTL) model (Bradley and Terry, 1952; Luce, 1959) as a special case, are based on assuming the existence of "quality" parameter $w_i \in \mathbb{R}$ for each item $i \in [n]$, and requiring that the probability of an item beating another is a specific function of the difference between their values. In the BTL model, the probability M_{ij} that i beats j is given by the logistic model

$$M_{ij} = \frac{1}{1 + e^{-(w_i - w_j)}}. \tag{4a}$$

More generally, parametric models assume that the pairwise comparison probabilities take the form

$$M_{ij} = F(w_i - w_j), \tag{4b}$$

where $F : \mathbb{R} \to [0, 1]$ is some strictly increasing cumulative distribution function. The function F is typically assumed to be known. By construction, any parametric model has the following property: if $w_i > w_j$ for some pair of items (i, j), then we are also guaranteed that $M_{i\ell} > M_{j\ell}$ for every item ℓ. As a consequence, we are guaranteed that $\tau_i > \tau_j$, which implies that ordering of the items in terms of their quality vector $w \in \mathbb{R}^n$ is identical to their ordering in terms of the score vector $\tau \in \mathbb{R}^n$. Consequently, if the data is actually drawn from a parametric model, then recovering the top k items according to their scores is the same as recovering the top k items according their respective quality parameters.

Strong Stochastic Transitivity (SST) class: The class of strong stochastic transitivity (SST) models is a superset of parametric models (Shah et al., 2017a). It does not assume the existence of a quality vector, nor does it assume any specific form of the probabilities as in equation (4a). Instead, the SST class is defined by assuming the existence of a total ordering of the n items, and imposing the inequality constraints $M_{i\ell} \geq M_{j\ell}$ for every pair of items (i, j) in which i is ranked above j in the ordering, and every item ℓ. One can verify

that an ordering by the scores $\{\tau_i\}_{i\in[n]}$ of the items lead to an ordering of the items that is consistent with that defined by the SST class.

Thus, we see that in a broad class of models for pairwise ranking, the total ordering defined by the score vector (2) coincides with the underlying ordering used to define the models. In this paper, we analyze the performance of a counting algorithm, essentially without imposing any modeling conditions on the family of pairwise probabilities. The next three sections establish theoretical guarantees on the recovery of the top k items under various requirements.

2.3 Borda counting algorithm

The analysis of this paper focuses on a simple counting-based algorithm, often called the Borda count method (de Borda, 1781). We employ this method here for the setting of pairwise comparisons, noting that the Borda count method more generally also supports comparisons between more than two items.

More precisely, for each distinct $i, j \in [n]$ and every integer $\ell \in [r]$, let $Y_{ij}^{\ell} \in \{-1, 0, +1\}$ represent the outcome of the ℓ^{th} comparison between the pair i and j, defined as

$$Y_{ij}^{\ell} = \begin{cases} 0 & \text{no comparison between } (i,j) \text{ in trial } \ell \\ +1 & \text{if comparison is made and item } i \text{ beats } j \\ -1 & \text{if comparison is made and item } j \text{ beats } i. \end{cases} \tag{5}$$

Note that this definition ensures that $Y_{ij}^{\ell} = -Y_{ji}^{\ell}$. For each $i \in [n]$, the quantity

$$N_i := \sum_{j\in[n]} \sum_{\ell\in[r]} \mathbf{1}\{Y_{ij}^{\ell} = 1\} \tag{6}$$

corresponds to the number of pairwise comparisons won by item i. Here we use $\mathbf{1}\{\cdot\}$ to denote the indicator function that takes the value 1 if its argument is true, and the value 0 otherwise. For each integer k, the vector $\{N_i\}_{i=1}^n$ of number of pairwise wins defines a k-sized subset

$$\widetilde{\mathcal{S}}_k = \Big\{ i \in [n] \mid N_i \text{ is among the } k \text{ highest number of pairwise wins} \Big\}, \tag{7}$$

corresponding to the set of k items with the largest values of N_i. In other words, the set $\widetilde{\mathcal{S}}_k$ corresponds to the rank statistics of the top k-items in the pairwise win ordering. (If there are any ties, we resolve them by choosing the indices with the smallest value of i.)

3. Main results

In this section, we present our main theoretical results on top-k recovery under the three settings described earlier. Note that the three settings are ordered in terms of increasing generality, with the advantage that the least general setting leads to the simplest form of theoretical claim. We also discuss optimal exact recovery of the full ranking.

3.1 Thresholds for exact recovery of the top k items

We begin with the goal of exactly recovering the k top-ranked items. As one might expect, the difficulty of this problem turns out to depend on the degree of separation between the top k items and the remaining items. More precisely, let us use (k) and $(k+1)$ to denote the indices of the items that are ranked k^{th} and $(k+1)^{th}$ respectively. With this notation, the *k-separation threshold* Δ_k is given by

$$\Delta_k(M) := \tau_{(k)}(M) - \tau_{(k+1)}(M) = \underbrace{\frac{1}{n}\sum_{i=1}^{n} M_{(k)i}}_{\text{Term (i)}} - \underbrace{\frac{1}{n}\sum_{i=1}^{n} M_{(k+1)i}}_{\text{Term (ii)}}. \tag{8}$$

In words, the quantity $\Delta_k(M)$ is the difference between (i) the probability of item (k) beating another item chosen uniformly at random, and (ii) the same probability for item $(k+1)$.

As shown by the following theorem, success or failure in recovering the top k entries is determined by the size of $\Delta_k(M)$ relative to the number of items n, observation probability p and number of repetitions r. In particular, consider the family of matrices

$$\mathcal{F}_k(\alpha; n, p, r) := \left\{ M \in [0,1]^{n \times n} \mid M + M^T = 11^T, \text{ and } \Delta_k(M) \geq \alpha \sqrt{\frac{\log n}{npr}} \right\}. \tag{9}$$

To simplify notation, we often adopt $\mathcal{F}_k(\alpha)$ as a convenient shorthand for this set, where its dependence on (n, p, r) should be understood implicitly.

With this notation, the achievable result in part (a) of the following theorem is based on the estimator that returns the set $\widetilde{\mathcal{S}}_k$ of the the k items defined by the number of pairwise comparisons won, as defined in equation (7). On the other hand, the lower bound in part (b) applies to *any estimator*, meaning any measurable function of the observations.

Theorem 1 *(a) Consider any $n \geq 2$, $r \geq 1$ and $p \in (0, 1]$. Then if $\alpha \geq 8$, the set $\widetilde{\mathcal{S}}_k$ of top k items (7) given by the Borda counting algorithm satisfies*

$$\sup_{M \in \mathcal{F}_k(\alpha)} \mathbb{P}_M\big[\widetilde{\mathcal{S}}_k \neq \mathcal{S}_k^*\big] \leq \frac{1}{n^{14}}. \tag{10a}$$

(b) Conversely, suppose that $n \geq 7$ and $p \geq \frac{\log n}{2nr}$. Then for any $\alpha \leq \frac{1}{7}$, the error probability of any *estimator $\widehat{\mathcal{S}}_k$ is lower bounded as*

$$\sup_{M \in \mathcal{F}_k(\alpha)} \mathbb{P}_M\big[\widehat{\mathcal{S}}_k \neq \mathcal{S}_k^*\big] \geq \frac{1}{7}. \tag{10b}$$

Remarks: First, it is important to note that the negative result in part (b) holds even if the supremum is further restricted to a particular parametric sub-class of $\mathcal{F}_k(\alpha)$, such as the pairwise comparison matrices generated by the BTL model, or by the SST model. The proof for the lower bound constructs a packing set of possible pairwise comparison probabilities

and then applies Fano's inequality. The construction ensures that every element of the packing set also lies in the parametric and SST models. The packing set is based on a generalization of a construction introduced by Chen and Suh (2015) for the BTL model, which we adapt to the general definition (8) of the separation threshold Δ_k.

Second, we note that in the regime $p < \frac{\log n}{2nr}$, standard results from random graph theory (Erdős and Rényi, 1960) can be used to show that there are at least $\sqrt{n}$ items (in expectation) that are never compared to any other item. Of course, estimating the rank is impossible in this pathological case, so we omit it from consideration.

Third, the two parts of the theorem in conjunction show that the counting algorithm is essentially optimal. The only room for improvement is in the difference between inequality $\alpha \geq 8$ in the achievable result, and $\alpha \leq \frac{1}{7}$ in the lower bound.

Theorem 1 can also be used to derive guarantees for recovery of other functions of the underlying ranking. Here we consider the problem of identifying the ranking of all n items, which we denote by the permutation π^*. In this case, we require that each of the separations $\{\Delta_j\}_{j=1}^{n-1}$ are suitably lower bounded: more precisely, we study models M that belong to the intersection $\cap_{j=1}^{n-1}\mathcal{F}_j(\alpha)$.

Theorem 2 *Consider any $n \geq 2$, $r \geq 1$ and $p \in (0, 1]$. Let $\widetilde{\pi}$ be the permutation of the items specified by the Borda counting algorithm in order of the number of pairwise comparisons won. Then for any $\alpha \geq 8$, we have*

$$\sup_{M \in \cap_{j=1}^{n-1}\mathcal{F}_j(\alpha)} \mathbb{P}_M\big[\widetilde{\pi} \neq \pi^*\big] \leq \frac{1}{n^{13}}.$$

Conversely, if $n \geq 9$, then the separation condition on $\{\Delta_j\}_{j=1}^{n-1}$ that defines the set $\cap_{j=1}^{n-1}\mathcal{F}_j(\alpha)$ is unimprovable beyond constant factors.

The upper bound of Theorem 2 follows from the equivalence of the correct recovery of the ranking with the recovery of the top k items for every value of $k \in [n]$. The proof of the lower bound requires a markedly different set of arguments; the proof does not follow from Theorem 1(b) since for any given value of k a condition of the form $\min_{j \in [n-1]} \Delta_j \leq \alpha$ in general does not imply $\Delta_k \leq \alpha$ which would otherwise be required to use Theorem 1(b).

Detailed comparison to related work: In the remainder of this subsection, we make a detailed comparison to the related works (Wauthier et al., 2013; Rajkumar and Agarwal, 2014; Rajkumar et al., 2015; Chen and Suh, 2015) that were briefly discussed in Section 1.

Wauthier et al. (2013) analyze a weighted counting algorithm for approximate recovery of rankings; they work under a model in which $M_{ij} = \frac{1}{2} + \gamma$ whenever item i is ranked above item j in an assumed underlying ordering. Here the parameter $\gamma \in (0, \frac{1}{2}]$ is independent of (i, j), and as a consequence, the best ranked item is assumed to be as likely to beat the worst item as it is to beat the second ranked item, for instance. They analyze approximate ranking under Kendall tau and maximum displacement metrics. In order to have a displacement upper bounded by by some $\delta > 0$, their bounds require the order of $\frac{n^5}{\delta^2\gamma^2}$ pairwise comparisons. In comparison, our model is more general in that we do not impose the γ-condition on the pairwise probabilities When specialized to the γ-model, the

quantities $\{\Delta_j\}_{j=1}^n$ in our analysis takes the form $\Delta_j = \frac{2\gamma}{n}$, and Theorem 2 shows that $\frac{n \log n}{\min_{j \in [n]} \Delta_j^2} = \frac{n^3 \log n}{\gamma^2}$ observations are sufficient to recover the exact total ordering. Thus, for any constant δ, Theorem 2 guarantees exact recovery with a sample complexity that is a multiplicative factor of order $\frac{n^2}{\log n}$ smaller than that established by Wauthier et al. (2013).

The two papers by Rajkumar and Agarwal (2014) and Rajkumar et al. (2015) consider ranking under several models and several metrics. For the subset of their models common with our setting—namely, Bradley-Terry-Luce and the so-called low noise models—they show that the counting algorithm is consistent in terms of recovering the full ranking or the top subset of items. The guarantees are obtained under a low-noise assumption: namely, that the probability of any item i beating j is at least $\frac{1}{2} + \gamma$ whenever item i is ranked higher than item j in an assumed underlying ordering. Their guarantees are based on a sample size of at least $\frac{\log n}{\gamma^2 \mu^2}$, where μ is a parameter lower bounded as $\mu \geq \frac{1}{n^2}$. Once again, our setting allows for the parameter γ to be arbitrarily close to zero, and furthermore as one can see from the discussion above, our bounds are much stronger. Moreover, while Rajkumar et al. focus on upper bounds alone, we also prove matching lower bounds on sample complexity showing that our results are unimprovable beyond constant factors. It should be noted that Rajkumar et al. also provide results for other types of ranking problems that lie outside the problem class treated in the current paper.

Most recently, Chen and Suh (2015) consider a random-design setting and show that if the pairwise observations are assumed to drawn according to the Bradley-Terry-Luce (BTL) parametric model (4a), then their proposed Spectral MLE algorithm recovers the k items correctly with high probability when a certain separation condition on the parameters $\{w_i\}_{i=1}^n$ of the BTL model is satisfied. Their random-design setting is similar to ours except that they first choose a set of pairs of items with each pair chosen with probability p, and then make r comparisons between the two items in every chosen pair. We believe our random-design setting is more natural; the two are identical when $r = 1$. Chen and Suh also show, via matching lower bounds, that the separation condition they derive for the BTL model is tight up to constant factors. In real-world instances of pairwise ranking data, it is often found that parametric models, such as the BTL model and its variants, fail to provide accurate fits (Davidson and Marschak, 1959; McLaughlin and Luce, 1965; Tversky, 1972; Ballinger and Wilcox, 1997). Our results make no such assumptions on the noise, and furthermore, our notion of the ordering of the items in terms of their scores (2) strictly generalizes the notion of the ordering with respect to the BTL parameters. In empirical evaluations presented subsequently, we see that the counting algorithm is significantly more robust to various kinds of noise, and takes several orders of magnitude lesser time to compute.

Finally, in addition to the notion of exact recovery considered so far, in the next two subsections we also derive tight guarantees for the Hamming error metric and more general metrics inspired by the requirements of many relevant applications (Ilyas et al., 2008; Michel et al., 2005; Babcock and Olston, 2003; Metwally et al., 2005; Kimelfeld and Sagiv, 2006; Fagin et al., 2003).

3.2 Approximate recovery under Hamming error

In the previous section, we analyzed performance in terms of exactly recovering the top-k subset. Although exact recovery is suitable for some applications (e.g., a setting with high stakes, in which any single error has a large price), there are other settings in which it may be acceptable to return a subset that is "close" to the correct k-ranked subset. In this section, we analyze this problem of approximate recovery when closeness is measured under the Hamming error. More precisely, for a given threshold $h \in [0, k)$, suppose that our goal is to output a set k-sized set $\widehat{\mathcal{S}}_k$ such that its Hamming distance to the set $\mathcal{S}_k^*$ of the true top k items, as defined in equation (3), is bounded as

$$D_{\mathrm{H}}(\widehat{\mathcal{S}}_k, \mathcal{S}_k^*) \leq 2h. \tag{11}$$

Our goal is to establish conditions under which it is possible (or impossible) to return an estimate $\widehat{\mathcal{S}}_k$ satisfying the bound (11) with high probability.[1]

As before, we use $(1), \ldots, (n)$ to denote the permutation of the n items in decreasing order of their scores. With this notation, the following quantity plays a central role in our analysis:

$$\Delta_{k,\,h}(M) := \tau_{(k-h)}(M) - \tau_{(k+h+1)}(M). \tag{12a}$$

The quantity $\Delta_{k,\,h}$ measures the difference between the scores associated to the items which are h positions on either side of our desired boundary between the k^{th} and $(k+1)^{\text{th}}$ items. Observe that $\Delta_{k,\,h}$ is a generalization of the quantity Δ_k defined previously in equation (8); and the quantity Δ_k corresponds to $\Delta_{k,\,h}$ with $h = 0$. We then define a generalization of the family $\mathcal{F}_k(\alpha; n, p, r)$, namely

$$\mathcal{F}_{k,h}(\alpha; n, p, r) := \left\{ M \in [0,1]^{n \times n} \;\middle|\; M + M^T = 11^T, \text{ and } \Delta_{k,\,h} \geq \alpha \sqrt{\frac{\log n}{npr}} \right\}. \tag{12b}$$

As before, we adopt the shorthand $\mathcal{F}_{k,h}(\alpha)$, with the dependence on (n, p, r) being understood implicitly.

Theorem 3 *(a) Consider any $n \geq 2$, $r \geq 1$ and $p \in (0, 1]$. Then if $\alpha \geq 8$, the set $\widetilde{\mathcal{S}}_k$ of top k items (7) given by the Borda counting algorithm satisfies*

$$\sup_{M \in \mathcal{F}_{k,h}(\alpha)} \mathbb{P}_M\big[D_{\mathrm{H}}(\widetilde{\mathcal{S}}_k, \mathcal{S}_k^*) > 2h\big] \leq \frac{1}{n^{14}}. \tag{13a}$$

(b) Conversely, in the regime $p \geq \frac{\log n}{2nr}$ and for given constants $\nu_1, \nu_2 \in (0, 1)$, suppose that $2h \leq \frac{1}{1+\nu_2} \min\{n^{1-\nu_1}, k, n-k\}$. Then for any $\alpha \leq \frac{\sqrt{\nu_1 \nu_2}}{14}$, any estimator $\widehat{\mathcal{S}}_k$ has error at least

$$\sup_{M \in \mathcal{F}_{k,h}(\alpha)} \mathbb{P}_M\big[D_{\mathrm{H}}(\widehat{\mathcal{S}}_k, \mathcal{S}_k^*) > 2h\big] \geq \frac{1}{7}, \tag{13b}$$

for all n larger than a constant $c(\nu_1, \nu_2)$.

1. The requirement $h < k$ is sensible because if $h \geq k$, the problem is trivial: any two k-sized sets $\widehat{\mathcal{S}}_k$ and $\mathcal{S}_k^*$ satisfy the bound $D_{\mathrm{H}}(\widehat{\mathcal{S}}_k, \mathcal{S}_k^*) \leq 2k \leq 2h$.

This result is similar to that of Theorem 1, except that the relaxation of the exact recovery condition allows for a less constrained definition of the separation threshold $\Delta_{k,h}$. As with Theorem 1, the lower bound in part (b) applies even if probability matrix M is restricted to lie in a parametric model (such as the BTL model), or the more general SST class. The counting algorithm is thus optimal for estimation under the relaxed Hamming metric as well.

The proof of the upper bound involves a transformation of the Hamming error requirement into one of exact recovery requirement, and then transforming the result of Theorem 1(a) to that required here via certain algebraic arguments. The lower bound is significantly more intricate: we carefully design a packing set using a coding-theoretic result due to Levenshtein (1971), which we then employ in Fano's inequality.

Finally, it is worth making a few comments about the constants appearing in these claims. We can weaken the lower bound on Δ_k required in Theorem 3(a) at the expense of a lower probability of success; for instance, if we instead require that $\alpha \geq 4$, then the probability of error is guaranteed to be at most n^{-2}. Subsequently in the paper, we provide the results of simulations with $n = 500$ items and $\alpha = 4$. On the other hand, in Theorem 3(b), if we impose the stronger upper bound $\alpha = \mathcal{O}(1/\sqrt{h \log n})$, then we can remove the condition $h \leq n^{1-\nu_1}$.

3.3 An abstract form of k-set recovery

In earlier sections, we investigated recovery of the top k items either exactly or under a Hamming error. Exact recovery may be quite strict for certain applications, whereas the property of Hamming error allowing for a few of the top k items to be replaced by *arbitrary* items may be undesirable. Indeed, many applications have requirements that go beyond these metrics; for instance, see the papers Ilyas et al. (2008); Michel et al. (2005); Babcock and Olston (2003); Metwally et al. (2005); Kimelfeld and Sagiv (2006); Fagin et al. (2003) and references therein for some examples. In this section, we generalize the notion of exact or Hamming-error recovery in order to accommodate a fairly general class of requirements.

Both the exact and approximate Hamming recovery settings require the estimator to output a set of k items that are either exactly or approximately equal to the true set of top k items. When is the estimate deemed successful? One way to think about the problem is as follows. The specified requirement of exact or approximate Hamming recovery is associated to a set of k-sized subsets of the n possible ranks. The estimator is deemed successful if the true ranks of the chosen k items equals one of these subsets. In our notion of generalized recovery, we refer to such sets as *allowed sets*. For example, in the case $k = 3$, we might say that the set $\{1, 4, 10\}$ is allowed, meaning that an output consisting of the items that are ranked "first", "fourth" and "tenth" in the ground truth is considered correct.

In more generality, let $\mathfrak{S}$ denote a family of k-sized subsets of $[n]$, which we refer to as *family of allowed sets*. Notice that any allowed set is defined by the *positions* of the items in the true ordering and not the items themselves.[2] Once some true underlying ordering of the n items is fixed, each element of the family $\mathfrak{S}$ then specifies a set of the items themselves. We use these two interpretations depending on the context — the definition in terms of

2. In case of two or more items with identical scores, the choice of any of these items is considered valid.

positions to specify the requirements, and the definition in terms of the items to evaluate an estimator for a given underlying probability matrix M.

We let $\mathcal{S}_k^\dagger$ denote a k-set estimate, meaning a function that given a set of observations as input, returns a k-sized subset of $[n]$ as output.

Definition 4 ($\mathfrak{S}$-respecting estimators) *For any family $\mathfrak{S}$ of allowed sets, a k-set estimate $\mathcal{S}_k^\dagger$* respects *its structure if the set of k positions of the items in $\mathcal{S}_k^\dagger$ belongs to the set family $\mathfrak{S}$.*

Our goal is to determine conditions on the set family $\mathfrak{S}$ under which there exist estimators $\mathcal{S}_k^\dagger$ that respect its structure. In order to illustrate this definition, let us return to the examples treated thus far.

Example 1 (Exact and approximate Hamming recovery) *The requirement of exact recovery of the top k items has $\mathfrak{S}$ consisting of exactly one set, the set of the top k positions $\mathfrak{S} = \{[k]\}$. In the case of recovery with a Hamming error at most $2h$, the set $\mathfrak{S}$ of all allowed sets consists all k-sized subsets of $[n]$ that contain at least $(k - h)$ positions in the top k positions. For instance, in the case $h = 1$, $k = 2$ and $n = 4$, we have*

$$\mathfrak{S} = \Big\{\{1,2\},\{1,3\},\{1,4\},\{2,3\},\{2,4\}\Big\}.$$

Apart from these two requirements, there are several other requirements for top-k recovery popular in the literature (Carmel et al., 2001; Fagin et al., 2003; Babcock and Olston, 2003; Michel et al., 2005; Metwally et al., 2005; Kimelfeld and Sagiv, 2006; Ilyas et al., 2008). Let us illustrate them with another example:

Example 2 *Let $\pi^* : [n] \to [n]$ denote the true underlying ordering of the n items. The following are four popular requirements on the set $\mathcal{S}_k^\dagger$ for top-k identification, with respect to the true permutation π^*, for a pre-specified parameter $\epsilon \geq 0$.*

(i) All items in the set $\mathcal{S}_k^\dagger$ must be contained contained within the top $(1+\epsilon)k$ entries:

$$\max_{i \in \mathcal{S}_k^\dagger} \pi^*(i) \leq (1+\epsilon)k. \tag{14a}$$

(ii) The rank of any item in the set $\mathcal{S}_k^\dagger$ must lie within a multiplicative factor $(1+\epsilon)$ of the rank of any item not in the set $\mathcal{S}_k^\dagger$:

$$\max_{i \in \mathcal{S}_k^\dagger} \pi^*(i) \leq (1+\epsilon) \min_{j \in [n] \setminus \mathcal{S}_k^\dagger} \pi(j). \tag{14b}$$

(iii) The rank of any item in the set $\mathcal{S}_k^\dagger$ must lie within an additive factor ϵ of the rank of any item not in the set $\mathcal{S}_k^\dagger$:

$$\max_{i \in \mathcal{S}_k^\dagger} \pi^*(i) \leq \min_{j \in [n] \setminus \mathcal{S}_k^\dagger} \pi^*(j) + \epsilon. \tag{14c}$$

(iv) The sum of the ranks of the items in the set $\mathcal{S}_k^\dagger$ *must be contained within a factor* $(1+\epsilon)$ *of the sums of ranks of the top* k *entries:*

$$\sum_{i \in \mathcal{S}_k^\dagger} \pi^*(i) \le (1+\epsilon)\frac{1}{2}k(k+1). \tag{14d}$$

Note that each of these requirements reduces to the exact recovery requirement when $\epsilon = 0$. *Moreover, each of these requirements can be rephrased in terms of families of allowed sets. For instance, if we focus on requirement (i), then any* k*-sized subset of the top* $(1+\epsilon)k$ *positions is an allowed set.*

In this paper, we derive conditions that govern k-set recovery for allowed set systems that satisfy a natural "monotonicity" condition. Informally, the monotonicity condition requires that the set of k items resulting from replacing an item in an allowed set with a higher ranked item must also be an allowed set. More precisely, for any set $\{t_1, \ldots, t_k\} \subseteq [n]$, let $\Lambda(\{t_1, \ldots, t_k\}) \subseteq 2^{[n]}$ be the set defined by all of its monotone transformations—that is

$$\Lambda(\{t_1, \ldots, t_k\}) := \Big\{\{t'_1, \ldots, t'_k\} \subseteq [n] \mid t'_j \le t_j \text{ for every } j \in [k]\Big\}.$$

Using this notation, we have the following:

Definition 5 (Monotonic set systems) *The set* $\mathfrak{S}$ *of allowed sets is a* monotonic set system *if*

$$\Lambda(T) \subseteq \mathfrak{S} \quad \textit{for every } T \in \mathfrak{S}. \tag{15}$$

One can verify that condition (15) is satisfied by the settings of exact and Hamming-error recovery, as discussed in Example 1. The condition is also satisfied by all four requirements discussed in Example 2.

Our next result establishes conditions under which one can (or cannot) produce an estimator that respects an allowed set requirement. In order to state the result, we recall the score $\tau_i(M) := \frac{1}{n}\sum_{j=1}^n M_{ij}$, as previously defined in equation (2) for each $i \in [n]$. For notational convenience, we also define $\tau_i(M) := -\infty$ for every $i > n$ and every M. Consider any monotonic family of allowed sets $\mathfrak{S}$, and for some integer $\beta \ge 1$, let $T^1, \ldots, T^\beta \in \mathfrak{S}$ such that $\mathfrak{S} = \bigcup_{b \in [\beta]} \Lambda(T^b)$. For every $b \in [\beta]$, let $t_1^b < \cdots < t_k^b$ denote the entries of T^b. We then define the critical threshold based on the scores:

$$\Delta_{\mathfrak{S}}(M) := \max_{b \in [\beta]} \min_{j \in [k]} \big(\tau_{(j)}(M) - \tau_{(k + t_j^b - j + 1)}(M)\big). \tag{16}$$

The term $\Delta_{\mathfrak{S}}$ is a further generalization of the quantities Δ_k and $\Delta_{k,h}$ defined in earlier sections. For example, for the exact recovery setting we have $\beta = 1$ and $T^1 = \{1, \ldots, k\}$, and after some algebraic simplifications of (16), we obtain that the critical threshold $\Delta_{\mathfrak{S}}$ reduces exactly to the threshold Δ_k defined earlier in (8). As a second example, the setting allowing a Hamming error at most $2h$ can be described with the choice $\beta = 1$ and $T^1 = \{h+1, \ldots, k,\ n-h+1, \ldots, n\}$. Some algebraic simplifications of (16) reduce $\Delta_{\mathfrak{S}}$ to the threshold $\Delta_{k,h}$ defined in (12a). As an example with $\beta > 1$, consider requirement (ii) in Example 2. For simplicity of exposition, assume that $\epsilon > \frac{1}{k-1}$ and $n \ge 2k(1+\epsilon)$. For this requirement, we have $\beta = (k - \lceil \frac{k}{1+\epsilon} \rceil)$, and for every $b \in \{\lceil \frac{k}{1+\epsilon} \rceil + 1, \ldots, k\}$, we have $T^{b - \lceil \frac{k}{1+\epsilon} \rceil} = \{1, \ldots, b-1, \lceil (1+\epsilon)b - (k-b) \rceil, \ldots, \lceil (1+\epsilon)b \rceil\}$. Then some algebraic simplifications of equation (16) yield that the critical threshold for this requirement is given by $\Delta_{\mathfrak{S}}(M) = \max_{b \in \{\lceil \frac{k}{1+\epsilon} \rceil + 1, \ldots, k\}} \min\{\tau_{(b-1)}(M) - \tau_{(k+1)}(M), \tau_{(k)}(M) - \tau_{(\lceil (1+\epsilon)b \rceil + 1)}(M)\}$.

With the definition of the critical threshold $\Delta_{\mathfrak{S}}$ in place, we now define a generalization $\mathcal{F}_{\mathfrak{S}}(\cdot)$ of the families $\mathcal{F}_k(\cdot)$ and $\mathcal{F}_{k,h}(\cdot)$ as

$$\mathcal{F}_{\mathfrak{S}}(\alpha; n, p, r) := \left\{ M \in [0,1]^{n \times n} \mid M + M^T = 11^T \text{ and } \Delta_{\mathfrak{S}}(M) \ge \alpha \sqrt{\frac{\log n}{npr}} \right\}. \tag{17}$$

As before, we use the shorthand $\mathcal{F}_{\mathfrak{S}}(\alpha)$, with the dependence on (n, p, r) being understood implicitly.

Theorem 6 *Consider any allowed set requirement specified by a monotonic set class* $\mathfrak{S}$.

(a) For any $\alpha \ge 8$, *the set* $\widetilde{\mathcal{S}}_k$ *of top* k *items (7) given by the Borda counting algorithm satisfies*

$$\sup_{M \in \mathcal{F}_{\mathfrak{S}}(\alpha)} \mathbb{P}_M\big[\widetilde{\mathcal{S}}_k \notin \mathfrak{S}\big] \le \frac{1}{n^{13}}.$$

(b) Conversely, in the regime $p \ge \frac{\log n}{2nr}$, *and for given constants* $\mu_1 \in (0,1), \mu_2 \in (\frac{3}{4}, 1]$, *suppose that* $\max_{b \in [\beta]} t^b_{\lceil \mu_2 k \rceil} \le \frac{n}{2}$ *and* $8(1-\mu_2)k \le n^{1-\mu_1}$. *Then for any* α *smaller than a constant* $c_u(\mu_1, \mu_2) > 0$, *any estimator* $\widehat{\mathcal{S}}_k$ *has error at least*

$$\sup_{M \in \mathcal{F}_{\mathfrak{S}}(\alpha)} \mathbb{P}_M\big[\widetilde{\mathcal{S}}_k \notin \mathfrak{S}\big] \ge \frac{1}{15}, \tag{18}$$

for all n *larger than a constant* $c_0(\mu_1, \mu_2)$.

A few remarks on the bounds are in order. For the lower bound, first, it continues to hold even if the probability matrix M is restricted to follow a parametric model such as BTL or restricted to lie in the SST class. Second, in terms of the threshold for α, the lower bound holds with $c_u(\mu_1, \mu_2) = \frac{1}{15}\sqrt{\mu_1 \min\left\{\frac{1}{4(1-\mu_2)-1}, \frac{1}{2}\right\}}$. Third, it is worth noting that one must necessarily impose some conditions for the lower bound, along the lines of those required in Theorem 6(b) for the allowed sets to be "interesting" enough. As a concrete illustration of the necessity of this condition, consider the requirement defined by the parameters $b = 1$, $k = 1$ and $\mathfrak{S} = \Lambda(\{n - \sqrt{n}\})$. For $\mu_1 = \mu_2 = \frac{9}{10}$, this requirement satisfies the condition $8(1-\mu_2)k \le n^{1-\mu_1}$ but violates the condition $t_{\lceil \mu_2 k \rceil} \le \frac{n}{2}$. Now, a selection of $k = 1$ item made uniformly at random (independent of the data) satisfies this allowed set requirement with probability $1 - \frac{1}{\sqrt{n}}$. Given the success of such a random selection algorithm in this parameter regime, we see that the lower bounds therefore cannot be universal, but must require some conditions on the allowed sets.

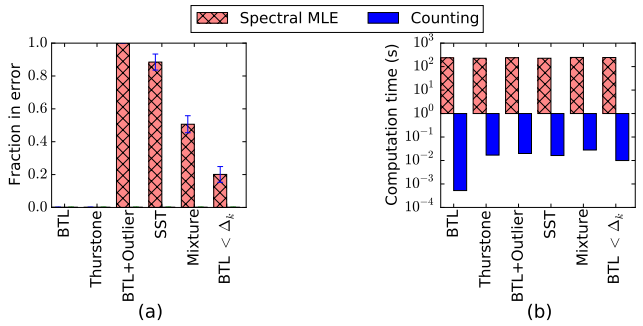

Figure 1. Simulation results comparing Spectral MLE and the counting algorithm in terms of error rates for exact recovery of the top k items, and computation time. (a) Histogram of fraction of instances where the algorithm failed to recover the k items correctly, with each bar being the average value across 50 trials. The counting algorithm has 0% error across all problems, while the spectral MLE is accurate for parametric models (BTL, Thurstone), but not very accurate for other models. (b) Histogram plots of the maximum computation time taken by the counting algorithm and the minimum computation time taken by Spectral MLE across all trials. Even though this maximum-to-minimum comparison is unfair to the counting algorithm, it involves five or more orders of magnitude less computation.

4. Simulations and experiments

In this section, we empirically evaluate the performance of the counting algorithm and compare it with the Spectral MLE algorithm via simulations on synthetic data, as well as experiments using datasets from the Amazon Mechanical Turk crowdsourcing platform.

4.1 Simulated data

We begin with simulations using synthetically generated data with $n = 500$ items and observation probability $p = 1$, and with pairwise comparison models ranging over six possible types. Panel (a) in Figure 1 provides a histogram plot of the associated error rates (with a bar for each one of these six models) in recovering the $k = n/4 = 125$ items for the counting algorithm versus the Spectral MLE algorithm. Each bar corresponds to the average over 50 trials. Panel (b) compares the CPU times of the two algorithms. The value of α (and in turn, the value of r) in the first five models is as derived in Section 3.1. In more detail, the six model types are given by:

(I) *Bradley-Terry-Luce (BTL) model:* Recall that the theoretical guarantees for the Spectral MLE algorithm (Chen and Suh, 2015) are applicable to data that is generated from the BTL model (4a), and as guaranteed, the Spectral MLE algorithm gives a 100% accuracy under this model. The counting algorithm also obtains a 100% accuracy, but importantly, the counting algorithm requires a computational time that is five orders of magnitude lower than that of Spectral MLE.

(II) *Thurstone model:* The Thurstone model (Thurstone, 1927) is another parametric model, with the function F in equation (4b) set as the cumulative distribution function of the standard Gaussian distribution. Both Spectral MLE and the counting algorithm gave 100% accuracy under this model.

(III) *BTL model with one (non-transitive) outlier:* This model is identical to BTL, with one modification. Comparisons among $(n-1)$ of the items follow the BTL model as before, but the remaining item always beats the first $\frac{n}{4}$ items and always loses to each of the other items. We see that the counting algorithm continues to achieve an accuracy of 100% as guaranteed by Theorem 1. The departure from the BTL model however prevents the Spectral MLE algorithm from identifying the top k items.

(IV) *Strong stochastic transitivity (SST) model:* We simulate the "independent diagonals" construction of Shah et al. (2017a) in the SST class. Spectral MLE is often unsuccessful in recovering the top k items, while the counting algorithm always succeeds.

(V) *Mixture of BTL models:* Consider two sets of people with opposing preferences. The first set of people have a certain ordering of the items in their mind and their preferences follow a BTL model under this ordering. The second set of people have the opposite ordering, and their preferences also follow a BTL model under this opposite ordering. The overall preference probabilities is a mixture between these two sets of people. In the simulations, we observe that the counting algorithm is always successful while the Spectral MLE method often fails.

(VI) *BTL with violation of separation condition:* We simulate the BTL model, but with a choice of parameter r small enough that the value of α is about one-tenth of its recommended value in Section 3.1. We observe that the counting algorithm continues to incur a lower error than the Spectral MLE algorithm, thereby demonstrating its robustness.

To summarize, the performance of the two algorithms can be contrasted in the following way. When our stated lower bounds on α are satisfied, then consistent with our theoretical claims, the Borda counting algorithm succeeds irrespective of the form of the pairwise probability distributions. The Spectral MLE algorithm performs well when the pairwise comparison probabilities are faithful to parametric models, but is often unsuccessful otherwise. Even when the condition on α is violated, the performance of the counting algorithm remains superior to that of the Spectral MLE.[3] In terms of computational complexity, for every instance we simulated, the counting algorithm took several orders of magnitude less time as compared to Spectral MLE.

Simulations with adversarial, imbalanced choice of pairs: The theoretical results in the earlier sections addressed a random design setting where the pairs to be compared are chosen at random in a homogeneous manner. While such a random design setting is widespread in various applications such as crowdsourcing and others, and is also the focus of a bulk of past literature on related topics, it is also of interest to understand situations where the

3. Note that part (b) of Theorem 1 is a minimax converse meaning that it appeals to the worst case scenario.

comparisons may be imbalanced. With this goal, we new present simulations that contrast the behavior of the counting algorithm in a random-design setting with an adversarial-design setting.

In this set of simulations, we consider the problem of recovering the top item (that is, $k = 1$). Moreover, we adopt a parametric model in which every item $i \in [n]$ is assumed to be governed by a parameter $w_i^* \in [0, 1]$, and the probability of any item i beating item j is set as $M_{ij} = \frac{1+w_i^*-w_j^*}{2}$. As before, the number of times any pair of items (i, j) is compared is drawn as a binomial distribution with parameters r and p. In the standard random-design setting studied throughout the remainder of this paper, the choice of the number of comparisons is unrelated to the choice of the parameters w^*. However in the adversarial setting, we make w^* adversarially misaligned to the number of comparisons between various pairs. In particular, the parameters associated to the items are chosen as follows for the random and the adversarial settings:

1. Random: $w_1^* = 1$ and $w_2^* = 0.9$ are the top two items. For every $i \in \{3, \ldots, n\}$, we draw w_i^* uniformly at random from the set $\{0.1, 0.7\}$.

2. Adversarial: $w_1^* = 1$ and $w_2^* = 0.9$ are the top two items. For every $i \in \{3, \ldots, n\}$, we set $w_i^* = 0.7$ if item i is compared more often to item 1 than to item 2, set $w_i^* = 0.1$ if item i is compared more often to item 2 than to item 1, and draw w_i^* uniformly at random from the set $\{0.1, 0.7\}$ otherwise.

The results of applying the counting algorithm are shown in Figure 2. From these simulations we observe that the simple counting algorithm is indeed sensitive to the imbalanced choice of pairs to be compared (that is, when the top item is compared more often to higher ranked items and the second item is compared more often to lower ranked items). Designing algorithms for ranking from pairwise comparisons that can optimally handle such imbalanced, adversarial-design settings is left as a problem for future work.

4.2 Experiments on data from Amazon Mechanical Turk

In this section, we describe experiments on real world datasets collected from the Amazon Mechanical Turk (`mturk.com`) commercial crowdsourcing platform.

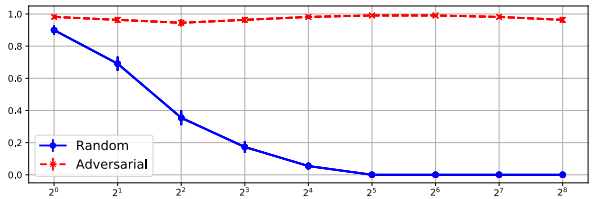

Figure 2. Performance of the counting algorithm for top $k = 1$ recovery when the pairs to be compared are chosen randomly and when they are chosen adversarially to create an imbalanced setting.

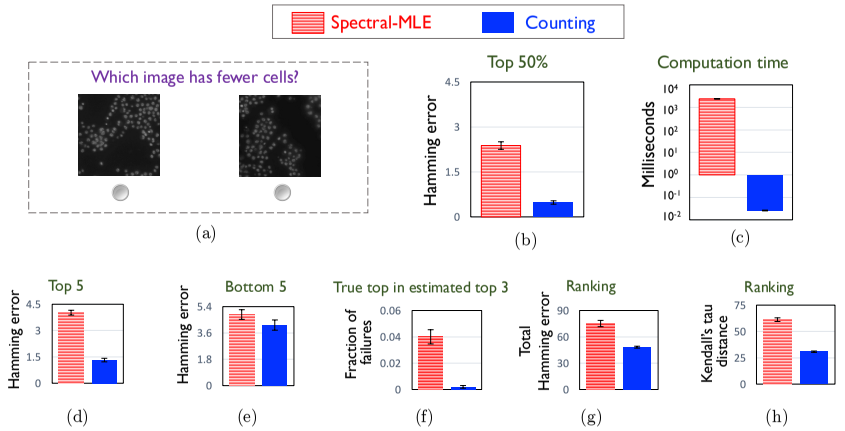

Figure 3. An illustration of the cell counting experiment (panel a) and results comparing Spectral MLE and the counting algorithm in terms of accuracy and computation time (panels b–h).

4.2.1 Experiment on counting cells

We begin with an experiment on counting (biological) cells in images.

Data. We employed a dataset of 23 images, each comprising several (biological) cells. The images of the cells and the ground truth counts of the numbers of cells in each image were obtained from the dataset collected by Carpenter et al. (2006).

On the Amazon Mechanical Turk crowdsourcing platform, we recruited a total of 64 workers and showed multiple pairs of such images to each worker – see Figure 3(a) for an illustrative example. For each pair of images, the worker was asked to select the image that the worker considered to have fewer cells. For each worker, the pairs were chosen by permuting the 23 images uniformly at random and asking for a comparison between the first and second images, between the third and fourth images and so on, for a total of 11 pairs of images per worker. In the raw data, 9.8% of the responses provided by the workers were erroneous. In the raw data we also observed that unsurprisingly, the number of errors increase as the actual cell counts in the pair of images come closer. The interface seen by the workers as well as the raw data obtained from Amazon Mechanical Turk is available on the website of the first author.

The goal of any algorithm is to take this set of noisy pairwise comparisons from the workers and estimate the images with the fewest cells. Such estimates are useful to detect various conditions, for instance, a low count of red blood cells in images of human cells indicates anemia. To this end, we executed the Spectral MLE algorithm (Chen and Suh, 2015) and the Borda counting algorithm on the set of pairwise comparisons obtained from the workers.

Results. We compared the performance of the two algorithms on a variety of metrics. In what follows, we subsample the responses with $p = 0.5$, that is, for each response for each question, we keep the response independently with probability 0.5 and discard it otherwise. We execute the two algorithms on this subsampled data. We repeat this process for 100 trials and plot the mean of the metric under consideration along with error bars representing the standard error of the mean.

We first consider recovering the set of top $k = \frac{n}{2}$ items. The natural metric of error here is the Hamming error, that is, the number of images that are misclassified. For this objective, while Spectral MLE does quite well, counting incurs a significantly lower Hamming error – see Figure 3(b). As one may expect, the count estimator also requires a much lower computation time – see Figure 3(c) for a comparison. In Figures 3(d) to (h), we see that counting also performs quite well for other exact or approximate requirements of top k or ranking recovery.

4.2.2 Data from earlier experiments on Amazon Mechanical Turk

We now describe three additional experiments using data collected from Amazon Mechanical Turk in our past work Shah et al. (2016a).

Data. In order to evaluate the accuracy of the algorithms under consideration, we require datasets consisting of pairwise comparisons in which the questions can be associated with an objective and verifiable ground truth. To this end, we used the "cardinal versus ordinal" dataset from our past work Shah et al. (2016a); three of the experiments performed in that paper are suitable for the evaluations here—namely, ones in which each question has a ground truth, and the pairs of items are chosen uniformly at random. The three experiments tested the workers' general knowledge, audio, and visual understanding, and the respective tasks involved: (i) identifying the pair of cities with a greater geographical distance, (ii) identifying the higher frequency key of a piano, and (iii) identifying spelling mistakes in a paragraph of text. The number of items n in the three experiments were 16, 10 and 8 respectively. The total number of pairwise comparisons were 408, 265 and 184 respectively. The fraction of pairwise comparisons whose outcomes were incorrect (as compared to the ground truth) in the raw data are 17%, 20% and 40% respectively.

Results. We compared the performance of the counting algorithm with that of the Spectral MLE algorithm. For each value of a "subsampling probability" $q \in \{0.1, 0.2, \ldots, 1.0\}$, we subsampled a fraction q of the data and executed both algorithms on this subsampled data. We evaluated the performance of the algorithms on their ability to recover the top $k = \lceil \frac{n}{4} \rceil$ items under the Hamming error metric.

Figure 4 shows the results of the experiments. Each point in the plots is an average across 100 trials. Observe that the counting algorithm consistently outperforms Spectral MLE. (We think that the erratic fluctuations in the spelling mistakes data are a consequence of a high noise and a relatively small problem size.) Moreover, the Spectral MLE algorithm required about 5 orders of magnitude more computation time (not shown in the figure) as compared to counting. Thus the counting algorithm performs well on simulated as well as real data. It outperforms Spectral MLE not only when the number of items is large (as in the simulations) but also when the problem sizes are small as seen in these experiments.

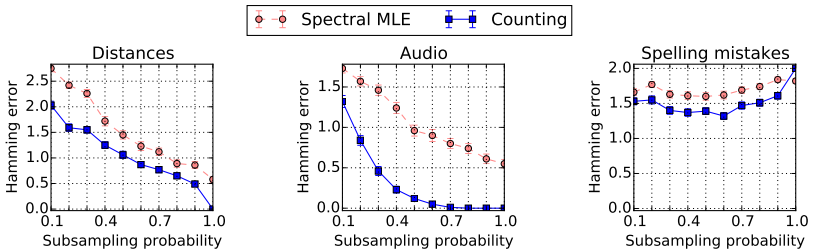

Figure 4. Evaluation of Spectral MLE and the counting algorithm on three datasets (from left to right: Distances, Audio, Spelling mistakes) from Amazon Mechanical Turk in terms of the error rates for top k-subset recovery. The three panels plot the Hamming error when recovering the top k items in the three datasets when a q^{th} fraction of the total data is used, for various values of subsampling probability $q \in (0, 1]$.

5. Proofs

We now turn to the proofs of our main results. We continue to use the notation $[i]$ to denote the set $\{1, \ldots, i\}$ for any integer $i \geq 1$. We ignore floor and ceiling conditions unless critical to the proof. All logarithms are taken to the base e.

Our lower bounds are based on a standard form of Fano's inequality (Cover and Thomas, 2012; Tsybakov, 2008) for lower bounding the probability of error in an L-ary hypothesis testing problem. We state a version here for future reference. For some integer $L \geq 2$, fix some collection of distributions $\{\mathbb{P}^1, \ldots, \mathbb{P}^L\}$. Suppose that we observe a random variable Y that is obtained by first sampling an index A uniformly at random from $[L] = \{1, \ldots, L\}$, and then drawing $Y \sim \mathbb{P}^A$. (As a result, the variable Y is marginally distributed according to the mixture distribution $\bar{\mathbb{P}} = \frac{1}{L} \sum_{a=1}^{L} \mathbb{P}^a$.) Given the observation Y, our goal is to "decode" the value of A, corresponding to the index of the underlying mixture component. Using $\mathcal{Y}$ to denote the sample space associated with the observation Y, Fano's inequality asserts that any test function $\phi : \mathcal{Y} \to [L]$ for this problem has error probability lower bounded as

$$\mathbb{P}[\phi(Y) \neq A] \geq 1 - \frac{I(Y; A) + \log 2}{\log L},$$

where $I(Y; A)$ denotes the mutual information between Y and A. A standard convexity argument for the mutual information yields the weaker bound

$$\mathbb{P}[\phi(Y) \neq A] \geq 1 - \frac{\max\limits_{a,b \in [L]} D_{\mathrm{KL}}(\mathbb{P}^a \| \mathbb{P}^b) + \log 2}{\log L}, \tag{19}$$

We make use of this weakened form of Fano's inequality in several proofs.

5.1 Proof of Theorem 1

We begin with the proof of Theorem 1, dividing our argument into two parts.

5.1.1 Proof of part (a)

For any pair of items (i, j), let us encode the outcomes of the r trials by an i.i.d. sequence $V_{ij}^{(\ell)} = [X_{ij}^{(\ell)} \quad X_{ji}^{(\ell)}]^T$ of random vectors, indexed by $\ell \in [r]$. Each random vector follows the distribution

$$\mathbb{P}\big[x_{ij}^{(\ell)},\, x_{ji}^{(\ell)}\big] = \begin{cases} 1-p & \text{if } (x_{ij}^{(\ell)},\, x_{ji}^{(\ell)}) = (0,0) \\ pM_{ij} & \text{if } (x_{ij}^{(\ell)},\, x_{ji}^{(\ell)}) = (1,0) \\ p(1-M_{ij}) & \text{if } (x_{ij}^{(\ell)},\, x_{ji}^{(\ell)}) = (0,1) \\ 0 & \text{otherwise.} \end{cases}$$

With this encoding, the variable $W_a := \sum_{\ell\in[r]} \sum_{z\in[n]\setminus\{a\}} X_{aj}^{(r)}$ encodes the number of wins for item a.

Consider any item $a \in \mathcal{S}_k^*$ which ranks among the top k in the true underlying ordering, and any item $b \in [n]\setminus\mathcal{S}_k^*$ which ranks outside the top k. We claim that with high probability, item a will win more pairwise comparisons than item b. More precisely, let $\mathcal{E}_{ba}$ denote the event that item b wins at least as many pairwise comparisons than a. We claim that

$$\mathbb{P}(\mathcal{E}_{ba}) \overset{(i)}{\leq} \exp\left(-\frac{\frac{1}{2}(rpn\Delta_k)^2}{rpn(2-\Delta_k)+\frac{2}{3}rpn\Delta_k}\right) \overset{(ii)}{\leq} \frac{1}{n^{16}}. \tag{20}$$

Given this bound, the probability that the counting algorithm will rank item b above a is no more than n^{-16}. Applying the union bound over all pairs of items $a \in \mathcal{S}_k^*$ and $b \in [n]\setminus\mathcal{S}_k^*$ yields $\mathbb{P}\big[\widehat{\mathcal{S}}_k \neq \mathcal{S}_k^*\big] \leq n^{-14}$ as claimed.

We note that inequality (ii) in equation (20) follows from inequality (i) combined with the condition on Δ_k that arises by setting $\alpha \geq 8$ as assumed in the hypothesis of the theorem. Thus, it remains to prove inequality (i) in equation (20). By definition of $\mathcal{E}_{ba}$, we have

$$\mathbb{P}(\mathcal{E}_{ba}) = \mathbb{P}\Big(\underbrace{\sum_{\ell\in[r]}\sum_{z\in[n]\setminus\{b\}} X_{bz}^{(\ell)}}_{W_b} - \underbrace{\sum_{\ell\in[r]}\sum_{z\in[n]\setminus\{a\}} X_{az}^{(\ell)}}_{W_a} \geq 0\Big). \tag{21}$$

It is convenient to recenter the random variables. For every $\ell \in [r]$ and $z \in [n]\setminus\{a,b\}$, define the zero-mean random variables

$$\overline{X}_{az}^{(\ell)} = X_{az}^{(\ell)} - \mathbb{E}[X_{az}^{(\ell)}] = X_{az}^{(\ell)} - pM_{az} \;\text{ and }\; \overline{X}_{bz}^{(\ell)} = X_{bz}^{(\ell)} - \mathbb{E}[X_{bz}^{(\ell)}] = X_{bz}^{(\ell)} - pM_{bz}.$$

Also, let

$$\overline{X}_{ab}^{(\ell)} = (X_{ab}^{(\ell)} - X_{ba}^{(\ell)}) - \mathbb{E}[X_{ab}^{(\ell)} - X_{ba}^{(\ell)}] \;=\; (X_{ab}^{(\ell)} - X_{ba}^{(\ell)}) - (pM_{ab} - pM_{ba}).$$

We then have

$$\mathbb{P}(\mathcal{E}_{ba}) = \mathbb{P}\Bigg(\sum_{\ell\in[r]}\Big(\sum_{z\in[n]\setminus\{a,b\}} \overline{X}_{bz}^{(\ell)} - \sum_{z\in[n]\setminus\{a,b\}} \overline{X}_{az}^{(\ell)} - \overline{X}_{ab}^{(\ell)}\Big) \geq rp\sum_{z\in[n]}\Big(M_{az} - M_{bz}\Big)\Bigg).$$

Since $a \in \mathcal{S}_k^*$ and $b \in [n]\setminus\mathcal{S}_k^*$, from the definition of Δ_k, we have $n\Delta_k \leq \sum_{z\in[n]}(M_{az} - M_{bz})$, and consequently

$$\mathbb{P}\left(\mathcal{E}_{ba}\right) \leq \mathbb{P}\left(\sum_{\ell\in[r]}\Big(\sum_{z\in[n]\setminus\{a,b\}} \overline{X}_{bz}^{(\ell)} - \sum_{z\in[n]\setminus\{a,b\}} \overline{X}_{az}^{(\ell)} - \overline{X}_{ab}^{(\ell)}\Big) \geq rpn\Delta_k\right). \tag{22}$$

By construction, all the random variables in the above inequality are zero-mean, mutually independent, and bounded in absolute value by 2. These properties alone would allow us to obtain a tail bound by Hoeffding's inequality; however, in order to obtain the stated result (20), we need the more refined result afforded by Bernstein's inequality (e.g., Boucheron et al., 2013). In order to derive a bound of Bernstein type, the only remaining step is to bound the second moments of the random variables at hand. Some straightforward calculations yield

$$\mathbb{E}[(-\overline{X}_{az}^{(\ell)})^2] \leq pM_{az}, \qquad \mathbb{E}[(\overline{X}_{bz}^{(\ell)})^2] \leq pM_{bz}, \quad \text{and} \quad \mathbb{E}[(\overline{X}_{ab}^{(\ell)})^2] \leq pM_{ab} + pM_{ba}.$$

It follows that

$$\begin{aligned} \sum_{z\in[n]\setminus\{a,b\}} \mathbb{E}[(-\overline{X}_{az}^{(\ell)})^2] + \sum_{z\in[n]\setminus\{a,b\}} \mathbb{E}[(\overline{X}_{bz}^{(\ell)})^2] + \mathbb{E}[(\overline{X}_{ab}^{(\ell)})^2] & \\ \leq p\left(\sum_{z\in[n]\setminus\{a,b\}}(M_{az}+M_{bz}) + M_{ab} + M_{ba}\right) & \\ \overset{(iii)}{\leq} p\left(2\sum_{z\in[n]} M_{az} - n\Delta_k\right) & \\ \overset{(iv)}{<} pn(2-\Delta_k), & \end{aligned}$$

where the inequality (iii) follows from the definition of Δ_k, and step (iv) follows because $M_{az} \leq 1$ for every z and $M_{aa} = \frac{1}{2}$. Applying the Bernstein inequality now yields the stated bound (20)(i).

5.1.2 Proof of part (b)

We prove the claim by constructing a packing set that satisfies our general requirements as well as also lies within the SST model and all parametric models, and subsequently using the packing set in an application of Fano's inequality. We then carefully bound the Kullback-Leibler divergence between the probability distributions on the outcomes induced by any pair of elements in the packing set in order to obtain a tractable bound.

In more detail, the symmetry of the problem allows us to assume, without loss of generality, that $k \leq \frac{n}{2}$. We first construct an ensemble of $n-k+1$ different problems, and considering the problem of distinguishing between them. For each $a \in \{k, \ldots, n\}$, let us define the k-sized subset $\mathcal{S}^*[a] := \{1, \ldots, k-1\} \cup \{a\}$, and the associated matrix of pairwise

probabilities

$$M^a_{ij} := \begin{cases} \frac{1}{2} & \text{if } i,j \in \mathcal{S}^*[a], \text{ or } i,j \notin \mathcal{S}^*[a] \\ \frac{1}{2}+\delta & \text{if } i \in \mathcal{S}^*[a] \text{ and } j \notin \mathcal{S}^*[a] \\ \frac{1}{2}-\delta & \text{if } i \notin \mathcal{S}^*[a] \text{ and } j \in \mathcal{S}^*[a], \end{cases}$$

where $\delta \in (0, \frac{1}{2})$ is a parameter to be chosen. We use $\mathbb{P}^a$ to denote probabilities taken under pairwise comparisons drawn according to the model M^a.

One can verify that the construction above falls in the intersection of parametric models and the SST model. In the parametric case, this construction amounts to having the parameters associated to every item in $\mathcal{S}^*_k$ to have the same value, and those associated to every item in $[n]\backslash\mathcal{S}^*_k$ to have the same value. Also observe that for every such distribution $\mathbb{P}^a$, the associated k-separation threshold is $\Delta_k = \delta$.

Any given set of observations can be described by the collection of random variables $Y = \{Y^{(\ell)}_{ij}, j > i \in [n], \ell \in [r]\}$. When the true underlying model is $\mathbb{P}^a$, the random variable $Y^{(\ell)}_{ij}$ follows the distribution

$$Y^{(\ell)}_{ij} = \begin{cases} 0 & \text{with probability } 1-p \\ i & \text{with probability } pM^a_{ij} \\ j & \text{with probability } p(1-M^a_{ij}). \end{cases}$$

The random variables $\{Y^{(\ell)}_{ij}\}_{i,j\in[n],i<j,\ell\in[r]}$ are mutually independent, and the distribution $\mathbb{P}^a$ is a product distribution across pairs $\{i > j\}$ and repetitions $\ell \in [r]$.

Let $A \in \{k, \ldots, n\}$ follow a uniform distribution over the index set, and suppose that given $A = a$, our observations Y has components drawn according to the model $\mathbb{P}^a$. Consequently, the marginal distribution of Y is the mixture distribution $\frac{1}{n-k+1}\sum_{a=k}^n \mathbb{P}^a$ over all $(n-k+1)$ models. Based on observing Y, our goal is to recover the correct index $A = a$ of the underlying model, which is equivalent to recovering the planted subset $\mathcal{S}^*[a]$. We use the Fano bound (19) to lower bound the error bound associated with any test for this problem. In order to apply Fano's inequality, the following result provides control over the Kullback-Leibler divergence between any pair of probabilities involved.

Lemma 7 *For any distinct pair $a, b \in \{k, \ldots, n\}$, we have*

$$D_{\mathrm{KL}}(\mathbb{P}^a \| \mathbb{P}^b) \leq \frac{2npr}{\frac{1}{4\delta^2}-1}. \tag{23}$$

See the end of this section for the proof of this claim.

Given this bound on the Kullback-Leibler divergence, Fano's inequality (19) implies that any estimator ϕ of A has error probability lower bounded as

$$\mathbb{P}[\phi(Y) \neq A] \geq 1 - \frac{\frac{2npr}{\frac{1}{4\delta^2}-1} + \log 2}{\log(n-k+1)} \;\geq\; \frac{1}{7}.$$

Here the final inequality holds whenever $\delta \leq \frac{1}{7}\sqrt{\frac{\log n}{npr}}$, $p \geq \frac{\log n}{2nr}$, $n \geq 7$ and $k \leq \frac{n}{2}$. The condition $p \geq \frac{\log n}{2nr}$ also ensures that $\delta < \frac{1}{2}$ thereby ensuring that our construction is valid. It only remains to prove Lemma 7.

5.1.3 Proof of Lemma 7

Since the distributions $\mathbb{P}^a$ and $\mathbb{P}^b$ are formed by components that are independent across edges $i > j$ and repetitions $\ell \in [r]$, we have

$$D_{\mathrm{KL}}(\mathbb{P}^a \| \mathbb{P}^b) = \sum_{\ell\in[r]} \sum_{1\leq i<j\leq n} D_{\mathrm{KL}}(\mathbb{P}^a(X^{(\ell)}_{ij}) \| \mathbb{P}^b(X^{(\ell)}_{ij})) \;=\; r \sum_{1\leq i<j\leq n} D_{\mathrm{KL}}(\mathbb{P}^a(X^{(1)}_{ij}) \| \mathbb{P}^b(X^{(1)}_{ij})),$$

where the second equality follows since the r trials are all independent and identically distributed.

We now evaluate each individual term in right hand side of the above equation. Consider any $i, j \in [n]$. We divide our analysis into three disjoint cases:

Case I: Suppose that $i, j \in [n]\backslash\{a, b\}$. The distribution of $X^{(1)}_{ij}$ is identical across the distributions $\mathbb{P}^a$ and $\mathbb{P}^b$. As a result, we find that

$$D_{\mathrm{KL}}(\mathbb{P}^a(X^{(1)}_{ij}) \| \mathbb{P}^b(X^{(1)}_{ij})) = 0.$$

Case II: Suppose that $i = a,\ j \in [n]\backslash\{a, b\}$ or $i = b,\ j \in [n]\backslash\{a, b\}$. We then have

$$D_{\mathrm{KL}}(\mathbb{P}^a(X^{(1)}_{ij}) \| \mathbb{P}^b(X^{(1)}_{ij})) \leq p\frac{\delta^2}{(\frac{1}{2}-\delta)(\frac{1}{2}+\delta)}.$$

Case III: Suppose that $i = a,\ j = b$. We then have

$$D_{\mathrm{KL}}(\mathbb{P}^a(X^{(1)}_{ij}) \| \mathbb{P}^b(X^{(1)}_{ij})) \leq p\frac{(2\delta)^2}{(\frac{1}{2}-\delta)(\frac{1}{2}+\delta)}.$$

Combining the bounds from all three cases, we find that the KL divergence is upper bounded as

$$\frac{1}{r}D_{\mathrm{KL}}(\mathbb{P}^a \| \mathbb{P}^b) \leq 2(n-2)p\frac{\delta^2}{(\frac{1}{2}-\delta)(\frac{1}{2}+\delta)} + p\frac{(2\delta)^2}{(\frac{1}{2}-\delta)(\frac{1}{2}+\delta)}.$$

Some simple algebraic manipulations yield the claimed result.

5.2 Proof of Theorem 2

We now turn to the proof of Theorem 2. Beginning with the claim of sufficiency, it is easy to see that the ranking is correctly recovered whenever the top k items are correctly recovered for every value of $k \in [n]$. Consequently, one can apply the union bound to (10a) over all values of $k \in [n]$ and this gives the desired upper bound.

Now turning to the claim of necessity, we first introduce some notation to aid in subsequent discussion. Defining the parameter $\Delta_0 := \min_{j\in[n-1]}(\tau_{(j)} - \tau_{(j+1)})$, we have shown that the lower bound

$$\Delta_0 \geq 8\sqrt{\frac{\log n}{npr}}$$

is sufficient to guarantee exact recovery of the full ranking. Further, one must also have

$$\Delta_0 \leq \frac{1}{n-1}\sum_{j=1}^{n-1}(\tau_{(j)} - \tau_{(j+1)}) = \frac{1}{n-1}(\tau_{(1)} - \tau_{(n)}) \leq \frac{1}{n-1}.$$

Here we show that this pair of requirements is jointly tight up to constant factors, meaning that for any value of Δ_0 satisfying $\Delta_0 \leq \frac{1}{9}\sqrt{\frac{\log n}{npr}}$ and $\Delta_0 \leq \frac{1}{9}\frac{1}{n-1}$, there are instances where recovery of the underlying ranking fails with probability at least $\frac{1}{70}$ for any estimator.

Consider the following ensemble of $(n-1)$ different problems, indexed by $a \in [n-1]$. For every value of $a \in [n-1]$, define a permutation π^a of the n items as

$$\pi^a(i) = \begin{cases} i+1 & \text{if } i = a \\ i-1 & \text{if } i = a+1 \\ i & \text{otherwise.} \end{cases}$$

In words, the permutation π^a equals the identity permutation except for the swapping of items a and $(a+1)$. Define an associated matrix of pairwise-comparison probabilities M^a as

$$M^a_{ij} = \frac{1}{2} - (\pi^a(i) - \pi^a(j))\Delta_0,$$

and $M^a_{ji} = 1 - M^a_{ij}$. Let $\mathbb{P}^a$ denote the probabilities taken under pairwise comparisons drawn according to the model M^a. The condition $\Delta_0 \leq \frac{1}{9}\frac{1}{n-1}$ ensures that this construction is a valid probability distribution. One can then compute that under distribution $\mathbb{P}^a$, the score τ^a_i of any item i equals

$$\tau^a_i = \frac{1}{2} - \big(\pi^a(i) - \frac{n+1}{2}\big)\Delta_0.$$

One can also verify that for any $a \in [n-1]$, and any $i \in [n-1]$, we have

$$\tau^a_{\pi^a(i)} - \tau^a_{\pi^a(i+1)} = \Delta_0,$$

where we have used the fact that $\pi^a(\pi^a(i)) = i$. The requirement imposed by the hypothesis is thus satisfied.

We now use Fano's inequality (19) obtain the claimed lower bound. In order to apply this result, we first obtain an upper bound on the Kullback-Leibler divergence between the probability distributions of the observed data under any pair of problems constructed above.

Lemma 8 *For any distinct pair $a, b \in [n-1]$, we have*

$$D_{\mathrm{KL}}(\mathbb{P}^a \| \mathbb{P}^b) \leq 50npr\Delta_0^2.$$

See the end of this section for the proof of this claim.

Given this bound on the Kullback-Leibler divergence, the Fano bound (19) implies that any method ϕ for identifying the true ranking has error probability

$$\mathbb{P}[\phi(Y) \neq A] \geq 1 - \frac{50npr\Delta_0^2 + \log 2}{\log(n-1)} \geq \frac{1}{70},$$

where the final inequality holds whenever $\Delta_0 \leq \frac{1}{9}\sqrt{\frac{\log n}{npr}}$ and $n \geq 9$.

The only remaining detail is the proof of Lemma 8.

5.2.1 Proof of Lemma 8

Since the distributions $\mathbb{P}^a$ and $\mathbb{P}^b$ are formed by components that are independent across edges $i > j$ and repetitions $\ell \in [r]$, we have

$$D_{\mathrm{KL}}(\mathbb{P}^a \| \mathbb{P}^b) = \sum_{\ell \in [r]} \sum_{1 \leq i < j \leq n} D_{\mathrm{KL}}(\mathbb{P}^a(X^{(\ell)}_{ij}) \| \mathbb{P}^b(X^{(\ell)}_{ij})) \;=\; r \sum_{1 \leq i < j \leq n} D_{\mathrm{KL}}(\mathbb{P}^a(X^{(1)}_{ij}) \| \mathbb{P}^b(X^{(1)}_{ij})),$$

where the second equality follows since the r trials are all independent and identically distributed.

We now evaluate each individual term in right hand side of the above equation. Consider any $i, j \in [n]$. We divide our analysis into three disjoint cases:

Case I: Suppose that $i, j \in [n] \backslash \{a, a+1, b, b+1\}$. The distribution of $X^{(1)}_{ij}$ is identical across the distributions $\mathbb{P}^a$ and $\mathbb{P}^b$. As a result, we find that

$$D_{\mathrm{KL}}(\mathbb{P}^a(X^{(1)}_{ij}) \| \mathbb{P}^b(X^{(1)}_{ij})) = 0.$$

Case II: Alternatively, suppose $i \in \{a, a+1, b, b+1\}$ and $j \in [n] \backslash \{a, a+1, b, b+1\}$ or if $j \in \{a, a+1, b, b+1\}$ and $i \in [n] \backslash \{a, a+1, b, b+1\}$. Then we have

$$D_{\mathrm{KL}}(\mathbb{P}^a(X^{(1)}_{ij}) \| \mathbb{P}^b(X^{(1)}_{ij})) \leq 5p\Delta_0^2,$$

where we have used the fact that $\mathbb{P}^a(X^{(1)}_{ij})$ and $\mathbb{P}^b(X^{(1)}_{ij})$ both take values in $[\frac{7}{18}, \frac{11}{18}]$ since $\Delta_0 \leq \frac{1}{9}\frac{1}{n-1}$.

Case III: Otherwise, suppose that both $i, j \in \{a, a+1, b, b+1\}$. Then we have

$$D_{\mathrm{KL}}(\mathbb{P}^a(X^{(1)}_{ij}) \| \mathbb{P}^b(X^{(1)}_{ij})) \leq 20p\Delta_0^2.$$

Combining the bounds from the three cases, we find that the KL divergence is upper bounded as

$$\frac{1}{r} D_{\mathrm{KL}}(\mathbb{P}^a \| \mathbb{P}^b) \leq 40(n-4)p\Delta_0^2 + 240p\Delta_0^2 \leq 50np\Delta_0^2,$$

where we have used the assumption $n \geq 9$ to obtain the final inequality.

5.3 Proof of Theorem 3

We now turn to the proof of Theorem 3, beginning with part (a).

5.3.1 Proof of part (a)

Without loss of generality, we can assume that the true underlying ranking is the identity ranking, that is, item i is ranked at position i for every $i \in [n]$. Given the the lower bound $\alpha \geq 8$ is satisfied, Theorem 1 ensures that with probability at least $1 - n^{-16}$, the counting estimator $\widetilde{\mathcal{S}}_k$ ranks every item in $\{1, \ldots, k-h\}$ higher than every item in the set $\{k+h+1, \ldots, n\}$. Thus, we are guaranteed that either $\widetilde{\mathcal{S}}_k \subseteq [k+h]$ and/or $[k-h] \subseteq \widetilde{\mathcal{S}}_k$. One can verify either case leads to $|\widetilde{\mathcal{S}}_k \cap [k]| \geq k-h$, thereby proving the claimed result.

5.3.2 Proof of part (b)

At a higher level, the crux of this proof is the construction of a packing set of pairwise comparison probability matrices, where every element of the set is also guaranteed to lie in the parametric classes and the SST class. The packing set is constructed via a careful application of a coding theoretic result due to Levenshtein (1971), such that the pairwise Kullback-Leibler divergence is small but the pairwise Hamming error is large enough, and that the packing set is also large enough. An application of Fano's inequality and some algebra yields the claimed result.

In more detail, we assume without loss of generality that $k \leq \frac{n}{2}$. (Otherwise, one can equivalently study the problem of recovering the last k items.) Since the case $h = 0$ is already covered by Theorem 1(b), we may also assume that $h \geq 1$.

The proof involves construction of $L \geq 1$ sets of probability matrices $\{M^a\}_{a \in [L]}$ of the pairwise comparisons with the following two properties:

(i) For every $a \in [L]$, let $S_k^a \subseteq [n]$ denote the set of the top k items under the a^{th} set of distributions. Then for every k-sized set $S \in [n]$,

$$\sum_{a=1}^{L} \mathbf{1}\{D_{\mathrm{H}}(S, S_k^a) \leq 2h\} \leq 1.$$

(ii) If the underlying distribution a is chosen uniformly at random from this set of L distributions, then any estimator that attempts to identify the underlying distribution $a \in [L]$ errs with probability at least $\frac{1}{7}$.

Now consider any estimator $\widehat{\mathcal{S}}_k$ for identifying the top k items $\mathcal{S}_k^*$. Given property (i), whenever the estimator is successful under the Hamming error requirement $D_{\mathrm{H}}(\widehat{\mathcal{S}}_k, \mathcal{S}_k^*) \leq 2h$, it must be able to uniquely identify the index $a \in [L]$ of the underlying distribution of pairwise comparison probabilities. However, property (ii) mandates that any estimator for identifying the underlying distribution errs with a probability at least $\frac{1}{7}$. Assuming that such sets of probability distributions satisfying these two properties exist, putting these results together yields the claimed result.

We now proceed to construct probability distributions satisfying the two aforementioned properties. Consider any positive number Δ_0 satisfying the upper bound

$$\Delta_0 \leq \frac{1}{14}\sqrt{\frac{\nu_1 \nu_2 \log n}{npr}}. \tag{24}$$

The L matrices $\{M^a\}_{a \in [L]}$ of probability distributions we construct differ only in a permutation of their rows and columns, and modulo this permutation, have identical values. In other words, these L distributions differ only in the identities of the n items and the values of the pairwise-comparison probabilities $M^a_{(i)(j)}$ among the ordered sequence of the n items are identical across all distributions $a \in [L]$.

For any ordering $(1), \ldots, (n)$ of the n items, for every $a \in [L]$, set

$$M^a_{(i)(j)} = \begin{cases} \frac{1}{2} + \Delta_0 & \text{if } i \in [k] \text{ and } j \notin [k] \\ \frac{1}{2} - \Delta_0 & \text{if } i \notin [k] \text{ and } j \in [k] \\ \frac{1}{2} & \text{otherwise.} \end{cases} \tag{25}$$

Note that the upper bound (24) on Δ_0, coupled with the assumption $p \geq \sqrt{\frac{\log n}{2nr}}$, ensures that $\Delta_0 < \frac{1}{3}$ and hence that our definition (25) leads to a valid set of probabilities. Given this construction, the scores of the n items are $\tau_{(1)} = \cdots = \tau_{(k)} = \tau_{(k+1)} + \Delta_0 = \cdots = \tau_{(n)} + \Delta_0$. The bound (24) ensures that the condition $\alpha \leq \frac{\sqrt{\nu_1 \nu_2}}{14}$ required by the hypothesis of the theorem is satisfied.

It remains to specify the ordering of the n items in each set of probability distributions. This specification relies on the following lemma, that in turn uses a coding-theoretic result due to Levenshtein (1971). It applies in the regime $2h \leq \frac{1}{1+\nu_2} \min\{n^{1-\nu_1}, k, n-k\}$ for some constants $\nu_1 \in (0,1)$ and $\nu_2 \in (0,1)$, and when n is larger than a (ν_1, ν_2)-dependent constant. For any pair of binary vectors b, b' of the same length, we define the Hamming error as $D_{\mathrm{H}}(b, b') = \sum_i \mathbf{1}\{b_i \neq b'_i\}$. We also let $\mathbf{0}$ denote the all-zero vector.

Lemma 9 *Under the previously given conditions, there exists a subset $\{b^1, \ldots, b^L\} \subseteq \{0,1\}^{n/2}$ with cardinality $L \geq e^{\frac{9}{10}\nu_1\nu_2 h \log n}$, such that*

$$D_{\mathrm{H}}(b^j, \mathbf{0}) = 2(1+\nu_2)h, \quad \textit{and} \quad D_{\mathrm{H}}(b^j, b^\ell) > 4h \quad \textit{for all } j \neq \ell \in [L].$$

We prove this lemma at the end of this section. Given this lemma, we now complete the proof of the theorem. Map the $\frac{n}{2}$ items $\{\frac{n}{2}+1, \ldots, n\}$ to the $\frac{n}{2}$ bits in each of the strings given by Lemma 9. For each $\ell \in [e^{\frac{9}{10}\nu_1\nu_2 h \log n}]$, let B_ℓ denote the $2(1+\nu_2)h$-sized subset of $\{\frac{n}{2}+1, \ldots, n\}$ corresponding to the $2(1+\nu_2)h$ positions equaling 1 in the ℓ^{th} string. Also define sets $A_\ell = \{1, \ldots, k - 2(1+\nu_2)h\}$ and $C_\ell = [n] \backslash (A_\ell \cup B_\ell)$. We note that this construction is valid since $2h \leq \frac{1}{1+\nu_2} k$.

We now construct $L = e^{\frac{9}{10}\nu_1\nu_2 h \log n}$ sets of pairwise comparison probability distributions $M^1, \ldots, M^L$ and show that these sets satisfy the two required properties. As mentioned earlier, each matrix of comparison-probabilities M^ℓ takes values as given in (25), but differs in the underlying ordering of the n items. In particular, associate the set $\ell \in [L]$ of distributions to any ordering of the n items that ranks every item in A_ℓ higher than every

item in B_ℓ, and every item in B_ℓ in turn higher than every item in C_ℓ. Then for any ℓ, the set of top k items is given by $A_\ell \cup B_\ell$. From the guarantees provided by Lemma 9, for any distinct $\ell, m \in [L]$, we have $D_{\mathrm{H}}(A_\ell \cup B_\ell, A_m \cup B_m) \geq 4h+1$. This construction consequently satisfies the first required property.

We now show that the construction also satisfies the second property: namely, it is difficult to identify the true index. We do so using Fano's inequality (19), for which we denote the probability distribution of the observations due to any matrix M^ℓ, $\ell \in [L]$, as $\mathbb{P}^\ell$.

We first derive an upper bound on the Kullback-Leibler divergence between any two distributions $\mathbb{P}^\ell$ and $\mathbb{P}^m$ of the observations. Observe that $[M^\ell]_{ij} \neq [M^m]_{ij}$ only if $i \in B_\ell \cup B_m$ or $j \in B_\ell \cup B_m$. In this case, we have $D_{\mathrm{KL}}([M^\ell]_{ij} \| [M^m]_{ij}) \leq \frac{4\Delta_0^2}{\frac{1}{4}-\Delta_0^2}$. Since both sets B_ℓ and B_m have a cardinality of $2(1+\nu_2)h$, aggregating over all possible observations across all pairs, we obtain that

$$D_{\mathrm{KL}}(\mathbb{P}^\ell \| \mathbb{P}^m) \leq 4(1+\nu_2)hnpr \frac{4\Delta_0^2}{\frac{1}{4}-\Delta_0^2}. \tag{26}$$

In the regime $p \geq \frac{\log n}{2nr}$ and $\Delta_0 \leq \frac{1}{14}\sqrt{\frac{\nu_1\nu_2 \log n}{npr}}$, we have $\Delta_0 \leq \frac{1}{14\sqrt{2}}$. Substituting the inequality $\Delta_0 \leq \frac{1}{14}\sqrt{\frac{\nu_1 \log n}{npr}}$ in the numerator and $\frac{1}{4} - \Delta_0^2 \geq \frac{1}{4} - \big(\frac{1}{14\sqrt{2}}\big)^2$ in the denominator of the right hand side of the bound (26), we find that

$$D_{\mathrm{KL}}(\mathbb{P}^\ell \| \mathbb{P}^m) \leq \frac{3}{4}\nu_1\nu_2 h \log n.$$

Now suppose that we draw Y from some distribution chosen uniformly at random from $\{\mathbb{P}^1, \ldots, \mathbb{P}^L\}$. Applying Fano's inequality (19) ensures that any test ϕ for estimating the index A of the chosen distribution must have error probability lower bounded as

$$\mathbb{P}\big[\phi(Y) \neq A\big] \geq \left(1 - \frac{\frac{3}{4}\nu_1\nu_2 h \log n + \log 2}{\frac{9}{10}\,\nu_1\nu_2 h \log n}\right) \geq \frac{1}{7}.$$

Here the final inequality holds as long as n is larger than some universal constant.

5.3.3 Proof of Lemma 9

We divide the proof into two cases depending on the value of h.

Case I: $h \geq \frac{1}{2\nu_1\nu_2}$: Let L denote the number of binary strings of length m_0 such that each has a Hamming weight w_0 and each pair has a Hamming distance at least d_0. It is known (Levenshtein, 1971; Jiang and Vardy, 2004) that L can be lower bounded as:

$$L \geq \frac{\binom{m_0}{w_0}}{\sum_{i=0}^{\lfloor \frac{d_0-1}{2} \rfloor} \binom{w_0}{j}\binom{m_0-w_0}{j}} \geq \frac{\big(\frac{m_0}{w_0}\big)^{w_0}}{\frac{d_0+1}{2}\big(\frac{ew_0}{\min\{d_0,w_0\}/2}\big)^{\min\{d_0,w_0\}/2}\big(\frac{em_0}{\min\{d_0,m_0\}/2}\big)^{\min\{d_0,m_0\}/2}}.$$

Note that for the setting at hand, we have $m_0 = \frac{n}{2}$, $w_0 = 2(1+\nu_2)h$ and $d_0 = 4h+1$. Since $\nu_1 \in (0,1)$ and $\nu_2 \in (0,1)$, we have the chain of inequalities

$$w_0 < d_0 \leq 4n^{1-\nu_1} \overset{(i)}{<} \frac{n}{2} = m_0,$$

where the inequality (i) holds when n is large enough. These relations allow for the simplification:

$$\begin{aligned}\log L &\geq \log\left\{\frac{\big(\frac{m_0}{w_0}\big)^{w_0}}{\frac{d_0+1}{2}\big(\frac{ew_0}{w_0/2}\big)^{w_0/2}\big(\frac{em_0}{d_0/2}\big)^{d_0/2}}\right\} \\ &= (w_0 - d_0/2)\log m_0 - w_0 \log w_0 + \frac{d_0}{2}\log d_0 - \frac{d_0+w_0}{2}\log(2e) - \log((d_0+1)/2).\end{aligned}$$

Substituting the values of w_0, d_0 and m_0 and then simplifying yields

$$\begin{aligned}\log L &\geq (2\nu_2 h - \frac{1}{2})\log\frac{n}{2} - 2(1+\nu_2)h\log(2(1+\nu_2)h) + (2h+\frac{1}{2})\log(4h+1) \\ &\quad - (((3+\nu_2)h) + \frac{1}{2})\log(2e) - \log(2h+1) \\ &\geq (2\nu_2 h - \frac{1}{2})\log\frac{n}{2} - 2\nu_2 h\log(2(1+\nu_2)h) - c_1' h,\end{aligned}$$

where c_1' is a constant whose value depends only on (ν_1, ν_2). In the regime $\frac{1}{\nu_1\nu_2} \leq 2h \leq \frac{n^{1-\nu_1}}{1+\nu_2}$, some algebraic manipulations then yield

$$\log L \geq (2\nu_1\nu_2 h - \frac{1}{2})\log\frac{n}{2} - c_2' h \geq \nu_1\nu_2 h(\log n - \log 2 - c_3') \geq \frac{9}{10}\nu_1\nu_2 h \log n,$$

where the final inequality holds when n is large enough, and where c_2' and c_3' are (ν_1, ν_2)-dependent positive constants.

Case II: $h < \frac{1}{2\nu_1\nu_2}$ Consider a partition of the $\frac{n}{2}$ bits into $\frac{n}{4(1+\nu_2)h}$ sets of size $2(1+\nu_2)h$ each. Define an associated set of $\frac{n}{4(1+\nu_2)h}$ binary strings, each of length $\frac{n}{2}$, with the i^{th} string having ones in the positions corresponding to the i^{th} set in the partition and zeros elsewhere. Then each of these strings have a Hamming weight of $2(1+\nu_2)h$, and every pair has a Hamming distance at least $4(1+\nu_2)h > 4h$. The total number of such strings equals

$$\exp\big(\log\frac{n}{4(1+\nu_2)h}\big) \overset{(i)}{\geq} \exp\big(\log n - \log(\frac{2(1+\nu_2)}{\nu_1\nu_2})\big) \overset{(ii)}{\geq} \exp\big(\frac{9}{10}\log n\big) \overset{(iii)}{>} \exp\big(1.8\nu_1\nu_2 h \log n\big),$$

where the inequalities (i) and (iii) are a result of operating in the regime $h < \frac{1}{2\nu_1\nu_2}$ and the inequality (ii) assumes that n is greater than a (ν_1, ν_2)-dependent constant.

5.4 Proof of Theorem 6

We now turn to the proof of Theorem 6.

5.4.1 Proof of part (a)

For every $i \in [n]$, let (i) denote the item ranked i according to their latent scores, as defined in equation (2). Recall from the proof of Theorem 1 that for any $u < v \in [n]$, the condition

$$\tau_{(u)} - \tau_{(v)} \geq 8\sqrt{\frac{\log n}{npr}}$$

ensures that with probability at least $1 - n^{-14}$, every item in the set $\{(1), \ldots, (u)\}$ wins more comparisons than every item in the set $\{(v), \ldots, (n)\}$. Consequently, if the set $\widetilde{\mathcal{S}}_k$ contains any item in $\{(v), \ldots, (n)\}$, then it must contain the entire set $\{(1), \ldots, (u)\}$. In other words, at least one of the following must be true: either $\{(1), \ldots, (u)\} \subseteq \widetilde{\mathcal{S}}_k$ or $\widetilde{\mathcal{S}}_k \subseteq \{(1), \ldots, (v-1)\}$. Consequently, in the regime $v = k + t - u + 1$ for any $1 \leq u \leq k$ and $u \leq t \leq n$, we have that

$$|\widetilde{\mathcal{S}}_k \cap \{(1), \ldots, (t)\}| \geq u. \tag{27}$$

Now consider any $b \in [\beta]$ that satisfies the condition

$$\min_{j \in [k]} (\tau_{(j)} - \tau_{(k + t_j^b - j + 1)}) \geq 8\sqrt{\frac{\log n}{npr}}.$$

For any $j \in [k]$, setting $u = j$ and $v = (k + t_j^b - j + 1)$ in (27), and applying the union bound over all values of $j \in [k]$ yields that

$$|\widetilde{\mathcal{S}}_k \cap \{(1), \ldots, (t_j^b)\}| \geq j \quad \text{for every } j \in [k],$$

with probability at least $1 - n^{-13}$. Consequently, we have that

$$\mathbb{P}\big(\widetilde{\mathcal{S}}_k \in \Lambda(T_b)\big) \geq 1 - n^{-13},$$

completing the proof of the claim.

5.4.2 Proof of part (b)

In the regime $t^b_{\mu_2 k} \leq \frac{n}{2}$ for every $b \in [\beta]$, it suffices to show that any estimator $\widehat{\mathcal{S}}_k$ will incur an error lower bounded as

$$\mathbb{P}\big(|\widehat{\mathcal{S}}_k \cap \{(1), \ldots, (n/2)\}| < \mu_2 k\big) \geq \frac{1}{15},$$

where (i) denotes the item ranked i according to their latent scores according to equation (2).

Our proof relies on the result and proof of the Hamming error case analyzed in Theorem 3(b). To this end, let us set the parameter h of Theorem 3(b) as $h = 2(1 - \mu_2)k$. We claim that this value of h lies in the regime $h \leq \frac{1}{2(1+\nu_2)} \min\{k, n-k, n^{1-\nu_1}\}$ for some values $\nu_1 \in (0,1)$ and $\nu_2 \in (0,1)$, as required by Theorem 3(b). This claim follows from the fact that

$$h = 2(1 - \mu_2)k \leq \frac{1}{2(1+\nu_2)} k,$$

for $\nu_2 = \min\{\frac{1}{4(1-\mu_2)} - 1, \frac{1}{2}\} \in (0,1)$. Furthermore,

$$h = 2(1-\mu_2)k \overset{(i)}{\leq} \frac{n^{1-\mu_1}}{4} \overset{(ii)}{\leq} \frac{1}{2(1+\nu_2)} n^{1-\nu_1}$$

for $\nu_1 = \frac{9}{10}\mu_1 \in (0,1)$, where (i) is a result of our assumption $8(1-\mu_2)k \leq n^{1-\mu_1}$ and (ii) holds when n is large enough. This assumption also implies that $k \leq n - k$ for a large enough value of n. We have now verified operation in the regime required by Theorem 3(b).

The construction in the proof of Theorem 3 is based on setting

$$\tau_{(1)} = \cdots \tau_{(k)} = \tau_{(k+1)} + \Delta_0 = \cdots = \tau_{(n)} + \Delta_0,$$

for any real number Δ_0 in the interval $\Big(0, \frac{1}{14}\sqrt{\frac{\nu_1\nu_2 \log n}{npr}}\Big]$. This condition is also satisfied in our construction due to the assumed upper bound $\alpha \leq \frac{1}{15}\sqrt{\mu_1 \min\big\{\frac{1}{4(1-\mu_2)-1}, \frac{1}{2}\big\}}$. Consequently, the result of Theorem 3(b) implies that in this setting, any estimator $\widehat{\mathcal{S}}_k$ will incur a Hamming error greater than $h = 2(1-\mu_2)k$ with probability at least $\frac{1}{7}$, or equivalently,

$$\mathbb{P}\big(|\widehat{\mathcal{S}}_k \cap \{(1), \ldots, (k)\}| < (2\mu_2 - 1)k\big) \geq \frac{1}{7}.$$

Under this event, the estimator $\widehat{\mathcal{S}}_k$ contains at most $(2\mu_2 - 1)k - 1$ items from the set of top k items. In order to ensure it gets at least $\mu_2 k$ items from $\{(1), \ldots, (n/2)\}$, the remaining $2(1-\mu_2)k + 1$ chosen items must have at least $(1-\mu_2)k + 1$ items from $\{(k+1), \ldots, (n/2)\}$. However, in the construction, items $(k+1), \ldots, (n)$ are indistinguishable from each other, and hence by symmetry these $2(1-\mu_2)k+1$ chosen items must contain at least $(1-\mu_2)k+1$ items from the set $\{(n/2+1), \ldots, (n)\}$ with probability at least $\frac{1}{2}$. Putting these arguments together, we obtain that under this construction, any estimator $\widehat{\mathcal{S}}_k$ has error probability lower bounded as

$$\mathbb{P}\big(|\widehat{\mathcal{S}}_k \cap \{(1), \ldots, (n/2)\}| < \mu_2 k\big) \geq \frac{1}{14}. \tag{28}$$

It remains to deal with a subtle technicality. The construction above involves items $(k+1), \ldots, (n)$ with identical scores. Recall that in the definition of the user-defined requirement, in case of multiple items with identical scores, we considered the choice of either of such items as valid. The following lemma helps overcome this issue.

Lemma 10 *Consider any two $(n \times n)$ matrices M^a and M^b of pairwise probabilities such that*

$$\max_{(i,j) \in [n]^2} |[M^a]_{ij} - [M^b]_{ij}| \leq \epsilon, \tag{29a}$$

for some $\epsilon \in [0,1]$. Then for any k-sized sets of items $T_1, \ldots, T_\beta \subseteq [n]$*, and any estimator $\widehat{\mathcal{S}}_k$, we have*

$$|\, \mathbb{P}_{M^a}(\widehat{\mathcal{S}}_k \in \{T_1, \ldots, T_\beta\}) - \mathbb{P}_{M^b}(\widehat{\mathcal{S}}_k \in \{T_1, \ldots, T_\beta\}) \,| \leq 6^{n^2 r}\epsilon. \tag{29b}$$

See Section 5.4.3 for the proof of this claim.

Now consider an $(n \times n)$ pairwise probability matrix M' whose entries take values

$$M'_{(i)(j)} = \begin{cases} \frac{1}{2} + \Delta_0 + \epsilon & \text{if } i \in [k] \text{ and } j \in [n] \backslash [n/2] \\ \frac{1}{2} + \Delta_0 & \text{if } i \in [k] \text{ and } j \in [n/2] \backslash [k] \\ \frac{1}{2} + \epsilon & \text{if } i \in [n/2] \backslash [k] \text{ and } j \in [n] \backslash [n/2] \\ \frac{1}{2} & \text{otherwise,} \end{cases}$$

and $M'_{ji} = 1 - M'_{ij}$, whenever $i \leq j$. Set $\epsilon = 7^{-n^2 r}$.

One can verify that under the probability matrix M', the scores of the n items satisfy the relations

$$\tau_{(1)} = \cdots = \tau_{(k)} = \tau_{(k+1)} + \Delta_0 = \cdots = \tau_{(n/2)} + \Delta_0 = \tau_{(n/2+1)} + \Delta_0 + \epsilon = \cdots = \tau_{(n)} + \Delta_0 + \epsilon.$$

The set of items $\{(1), \ldots, (n/2)\}$ are thus explicitly distinguished from the items $\{(n/2+1), \ldots, (n)\}$. We now call upon Lemma 10 with $M^a = M'$, and M^b as the matrix of probabilities constructed in the proof of Theorem 3, where both sets have the same ordering of the items. This assignment is valid given that $\Delta_0 < \frac{1}{3}$ and $\epsilon = 7^{-n^2 r}$. Lemma 10 then implies that any estimator that is $\mathfrak{S}$-respecting with probability at least $1 - \frac{1}{15}$ under M^b must also be $\mathfrak{S}$-respecting with probability at least $1 - \frac{1}{14.5}$ under M^a. But by equation (28), the latter condition is impossible, which implies our claimed lower bound.

5.4.3 Proof of Lemma 10

Let $\mathbb{P}^a$ and $\mathbb{P}^b$ denote the probabilities induced by the matrices M^a and M^b respectively. Consider any fixed observation $Y_1 \subseteq \{0, 1, \phi\}^{n \times n \times r}$, where ϕ denotes the absence of an observation. Let $\mathbb{P}^a(Y = Y_1)$ and $\mathbb{P}^b(Y = Y_1)$ denote the probabilities of observing Y_1 under $\mathbb{P}^a$ and $\mathbb{P}^b$, respectively. Given the bounds (29a), some algebra leads to

$$\begin{aligned}
| \, \mathbb{P}^a(Y = Y_1) - \mathbb{P}^b(Y = Y_1) \, | &\leq \max_{u \in [0, 1-\epsilon]^{n^2 r}} \Big(\prod_{i=1}^{n^2 r} (u_i + \epsilon) - \prod_{i=1}^{n^2 r} u_i \Big) \\
&\leq \max_{u \in [0, 1-\epsilon]^{n^2 r}} \Big(u_{n^2 r} \big(\prod_{i=1}^{n^2 r - 1} (u_i + \epsilon) - \prod_{i=1}^{n^2 r - 1} u_i \big) + \epsilon \Big) \\
&\vdots \\
&\leq n^2 r \epsilon. \qquad (30)
\end{aligned}$$

Now consider any estimator $\widehat{\mathcal{S}}_k$, which is permitted to be randomized. Let $L \leq 3^{n^2 r}$ denote the total number of possible values of the observation Y, and let $\{Y_1, \ldots, Y_L\} = \{0, 1, \phi\}^{n \times n \times r}$ denote the set of all possible valid values of the observation. For each $i \in [L]$, let $q_i \in [0, 1]$ denote the probability that the estimator $\widehat{\mathcal{S}}_k$ succeeds in satisfying the given requirement when the data observed equals Y_i. (Recall that the given requirement is in terms of the actual items and not their positions.) Then we have

$$\begin{aligned}
\big| \mathbb{P}^1(\widehat{\mathcal{S}}_k \in \{T_1, \ldots, T_\beta\}) - \mathbb{P}^2(\widehat{\mathcal{S}}_k \in \{T_1, \ldots, T_\beta\}) \big| &= \big| \sum_{i=1}^{L} \mathbb{P}^1(Y = Y_i) q_i - \sum_{i=1}^{L} \mathbb{P}^2(Y = Y_i) q_i \big| \\
&\leq \sum_{i=1}^{L} | \, \mathbb{P}^1(Y = Y_i) - \mathbb{P}^2(Y = Y_i) \, | \, q_i \\
&\overset{(i)}{\leq} \sum_{i=1}^{L} n^2 r \epsilon q_i \overset{(ii)}{\leq} 6^{n^2 r} \epsilon,
\end{aligned}$$

as claimed, where step (i) follows from our earlier bound (30) and step (ii) uses the bounds $L \leq 3^{n^2 r}$ and $n^2 r \leq 2^{n^2 r}$.

6. Discussion

In this paper, we analyzed the problem of recovering the k most highly ranked items based on observing noisy comparisons. We proved that an algorithm that simply selects the items that win the maximum number of comparisons is, up to constant factors, an information-theoretically optimal procedure. Our results also extend to recovering the entire ranking of the items. The results of this paper thus underscore the philosophy of *Occam's razor* that the simplest answer is often correct.

Empirical evaluations reveal the superior performance of the counting algorithm that we analyzed through our "permutation-based" approach as compared to the Spectral MLE algorithm. The intuition is that Spectral MLE is too tied to the restrictive parameter-based model and the model mismatch in this crowdsourcing data causes the high amount of error. On the other hand, the robustness and accuracy guarantees of the count estimator due to our permutation-based approach carry over to practice. More generally, parameter-based models are popular in many applications in part because they are quite intuitive to write down, and in part because they are sometimes analytically more tractable. However, instead if one were to consider rich enough models like permutation-based models then they may yield a broader perspective and richer insights into the problem that can lead to superior results (Shah, 2017, Chapter 1, Part 1).

There are number of open questions suggested by our work. The notion of allowed sets introduced in this paper apply to recovery of k-sized subsets of the items; such a formulation and associated results may apply to recovery of partial or total orderings of the items. The observation model considered here is based on a random number of observations for all pairs of comparisons. It would be interesting to extend our results to cases in which only specific subsets of pairs are observed, and particularly when these pairs are chosen adversarially. A parallel line of literature (e.g., Kaufmann and Kalyanakrishnan, 2013; Busa-Fekete et al., 2013; Jamieson et al., 2015; Heckel et al., 2016) studies settings in which the pairs to be compared can be chosen sequentially in a data-dependent manner, but to the best of our knowledge, this line of literature considers only the metric of exact recovery of the top k items. It is of interest to investigate the Hamming and allowed set recovery problems in such an active setting. Finally, it will also be useful to obtain analogous results for ranking problems where the identity of the person making the comparison is known and influences the outcomes of the comparison, for instance, in applications of peer-grading (Shah et al., 2013; Song et al., 2017) and peer-reviews (Shah et al., 2017c).

Acknowledgments

We would like to thank the AE Sujay Sanghavi for the efficient handling of the paper and the anonymous reviewers for their valuable comments. Abstract

We analyze dropout in deep networks with rectified linear units and the quadratic loss. Our results expose surprising differences between the behavior of dropout and more traditional regularizers like weight decay. For example, on some simple data sets dropout training produces negative weights even though the output is the sum of the inputs. This provides a counterpoint to the suggestion that dropout discourages co-adaptation of weights. We also show that the dropout penalty can grow exponentially in the depth of the network while the weight-decay penalty remains essentially linear, and that dropout is insensitive to various re-scalings of the input features, outputs, and network weights. This last insensitivity implies that there are no isolated local minima of the dropout training criterion. Our work uncovers new properties of dropout, extends our understanding of why dropout succeeds, and lays the foundation for further progress.

Keywords: Dropout, deep neural networks, regularization, learning theory.

1. Introduction

The 2012 ImageNet Large Scale Visual Recognition challenge was won by the University of Toronto team by a surprisingly large margin. In an invited talk at NIPS, Hinton (2012) credited the dropout training technique for much of their success. Dropout training is a variant of stochastic gradient descent (SGD) where, as each example is processed, the network is temporarily perturbed by randomly "dropping out" nodes of the network. The gradient calculation and weight updates are performed on the reduced network, and the dropped out nodes are then restored before the next SGD iteration. Since the ImageNet competition, dropout has been successfully applied to a variety of domains (Dahl, 2012; Deng et al., 2013; Dahl et al., 2013; Kalchbrenner et al., 2014; Chen and Manning, 2014), and is widely used (Schmidhuber, 2015; He et al., 2015; Szegedy et al., 2015; Yang et al., 2016; Havaei et al., 2017); for example, it is incorporated into popular packages such as TensorFlow, Torch, and Caffe. It is intriguing that crippling the network during training often leads to such dramatically improved results, and dropout has also sparked substantial research on related methods (for example, (Goodfellow et al., 2013; Wan et al., 2013; Gal and Ghahramani, 2016)).

In this work, we examine the effect of dropout on the inductive bias of the learning algorithm. A match between dropout's inductive bias and some important applications could explain the success of dropout, and its popularity also motivates the study of its properties.

Weight decay training optimizes the empirical error plus an L_2 regularization term, $\frac{\lambda}{2}||\mathbf{w}||_2^2$, so we call $\frac{\lambda}{2}||\mathbf{w}||_2^2$ the *L_2 penalty* of $\mathbf{w}$ since it is the difference between training criterion evaluated at $\mathbf{w}$ and the empirical loss of $\mathbf{w}$. By analogy, we define the *dropout penalty* of $\mathbf{w}$ to be the difference between the dropout training criterion and the empirical loss of $\mathbf{w}$ (see Section 2). Dropout penalties measure how much dropout discriminates against weight vectors, so they are key to understanding dropout's inductive bias.

Even in one-layer networks, conclusions drawn from (typically quadratic) approximations of the dropout penalty can be misleading (Helmbold and Long, 2015). Therefore we focus on exact formal analysis of dropout in multi-layer networks. Theoretical analysis of deep networks is notoriously difficult, so we might expect that a thorough understanding of dropout in deep networks must be achieved in stages. In this paper we further the process by exposing some of the surprising ways that the inductive bias of dropout differs from L_2 and other standard regularizers. These include the following:

- We show that dropout training can lead to negative weights *even when the output is a positive multiple of the the inputs.* Arguably, such use of negative weights constitutes co-adaptation – this adds a counterpoint to previous analyses showing that dropout discourages co-adaptation (Srivastava et al., 2014; Helmbold and Long, 2015).

- Unlike weight decay and other p-norm regularizers, dropout training is insensitive to the rescaling of input features, and largely insensitive to rescaling of the outputs; this may play a role in dropout's practical success. Dropout is also unaffected if the weights in one layer are scaled up by a constant c, and the weights of another layer are scaled down by c; this implies that dropout training does not have isolated local minima.

- The dropout penalty grows exponentially in the depth of the network in cases where the L_2 regularizer grows linearly. This may enable dropout to penalize the complexity of the network in a way that more meaningfully reflects the richness of the network's behaviors. (The exponential growth with d of the dropout penalty is reminiscent of some regularizers for deep networks studied by Neyshabur et al. (2015).)

- Dropout in deep networks has a variety of other behaviors different from standard regularizers. In particular: the dropout penalty for a set of weights can be negative; the dropout penalty of a set of weights depends on both the training instances and the labels; and although the dropout probability intuitively measures the strength of dropout regularization, the dropout penalties are often non-monotonic in the dropout probability. In contrast, Wager et al. (2013) show that when dropout is applied to generalized linear models, the dropout penalty is always non-negative and does not depend on the labels.

Our analysis is for multilayer neural networks with the square loss at the output node. The hidden layers use the popular rectified linear units (Nair and Hinton, 2010) outputting $\sigma(a) = \max(0, a)$ where a is the node's activation (the weighted sum of its inputs). We study the minimizers of a criterion that may be viewed as the objective function when using dropout. This abstracts away sampling and optimization issues to focus on the inductive bias, as in some previous work (Breiman, 2004; Zhang, 2004; Bartlett et al., 2006; Long and Servedio, 2010; Helmbold and Long, 2015). See Section 2 for a complete explanation.

Related work

A number of possible explanations have been suggested for dropout's success. Hinton et al. (2012) suggest that dropout controls network complexity by restricting the ability to co-adapt weights and illustrate how it appears to learn simpler functions at the second layer. Others (Baldi and Sadowski, 2013; Bachman et al., 2014) view dropout as an ensemble method combining the different network topologies resulting from the random deletion of nodes. Wager et al. (2014) observe that in 1-layer networks dropout essentially forces learning on a more challenging distribution akin to 'altitude training' of athletes.

Most formal analysis of the inductive bias of dropout has concentrated on the single-layer setting, where a single neuron combines the (potentially dropped-out) inputs. Wager et al. (2013) considered the case that the distribution of label y given feature vector $\mathbf{x}$ is a member of the exponential family, and the log-loss is used to evaluate models. They pointed out that, in this situation, the criterion optimized by dropout can be decomposed into the original loss and a term that does not depend on the labels. They then gave approximations to this dropout regularizer and discussed its relationship with other regularizers. As we have seen, many aspects of the behavior of dropout and its relationship to other regularizers are qualitatively different when there are hidden units.

Wager et al. (2014) considered dropout for learning topics modeled by a Poisson generative process. They exploited the conditional independence assumptions of the generative process to show that the excess risk of dropout training due to training set variation has a term that decays more rapidly than the straightforward empirical risk minimization, but also has a second additive term related to document length. They also discussed situations where the model learned by dropout has small bias.

Baldi and Sadowski (2014) analyzed dropout in linear networks, and showed how dropout can be approximated by normalized geometric means of subnetworks in the nonlinear case. Gal and Ghahramani (2015) described an interpretation of dropout as an approximation to a deep Gaussian process.

The impact of dropout (and its relative dropconnect) on generalization (roughly, how much dropout restricts the search space of the learner) was studied in (Wan et al., 2013).

In the on-line learning with experts setting, Van Erven et al. (2014) showed that applying dropout in on-line trials leads to algorithms that automatically adapt to the input sequence without requiring doubling or other parameter-tuning techniques.

The rest of the paper is organized as follows. Section 2 introduces our notation and formally defines the dropout model. We prove that dropout enjoys several scaling invariances that weight-decay doesn't in Section 3, and that dropout requires negative weights even in very simple situations in Section 4. Section 5 uncovers various properties of the

dropout penalty function. Section 6 describes some simulation experiments. We provide some concluding remarks in Section 7.

2. Preliminaries

Throughout, we will analyze fully connected layered networks with K inputs, one output, d layers (counting the output, but not the inputs), and n nodes in each hidden layer. We assume that n is a positive multiple of K and that K is a perfect square and a power of two to avoid unilluminating floor/ceiling clutter in the analysis. We will call this the *standard architecture*. We use $\mathcal{W}$ to denote a particular setting of the weights and biases in the network and $\mathcal{W}(\mathbf{x})$ to denote the network's output on input $\mathbf{x}$ using $\mathcal{W}$. The hidden nodes are ReLUs, and the output node is linear. $\mathcal{W}$ can be decomposed as $(W_1, \mathbf{b}_1, ..., W_{d-1}, \mathbf{b}_{d-1}, \mathbf{w}, b)$, where each W_j is the matrix of weights on connections from the $j-1$st into the jth hidden layer, each $\mathbf{b}_j$ is the vector of bias inputs into the jth hidden layer, $\mathbf{w}$ are the weights into the output node, and b is the bias into the output node.

An *example distribution* is a joint probability distribution over $(\mathbf{x}, y)$ pairs We focus on square loss, so the loss of $\mathcal{W}$ on example $(\mathbf{x}, y)$ is $(\mathcal{W}(\mathbf{x}) - y)^2$. The *risk* is the expected loss with respect to an example distribution P, we denote the risk of $\mathcal{W}$ as $R_P(\mathcal{W}) \stackrel{\text{def}}{=} \mathbf{E}_{(\mathbf{x},y)\sim P}\left((\mathcal{W}(\mathbf{x}) - y)^2\right)$. The subscript will often be omitted when P is clear from the context.

The goal of L_2 training is to find weights and biases minimizing the *L_2 criterion* with regularization strength λ: $J_2(\mathcal{W}) \stackrel{\text{def}}{=} R(\mathcal{W}) + \frac{\lambda}{2}||\mathcal{W}||^2$. Here and throughout, we use $||\mathcal{W}||^2$ to denote the sum of the squares of the weights of $\mathcal{W}$. (As usual, the biases are not penalized.) We use $\mathcal{W}_{L_2}$ to denote a minimizer of this criterion. The L_2 penalty, $\frac{\lambda}{2}||\mathcal{W}||^2$, is non-negative. This is useful, for example, to bound the risk of a minimizer $\mathcal{W}_{L_2}$ of J_2, since $R(\mathcal{W}) \le J_2(\mathcal{W})$.

Dropout training independently removes nodes in the network. In our analysis each non-output node is dropped out with the same probability q, so $p = 1 - q$ is the probability that a node is kept. (The output node is always kept; dropping it out has the effect of cancelling the training iteration.) When a node is dropped out, the node's output is set to 0. To compensate for this reduction, the values of the kept nodes are multiplied by $1/p$. With this compensation, the dropout can be viewed as injecting zero-mean additive noise at each non-output node (Wager et al., 2013). [1]

A *dropout pattern* is a boolean vector indicating the choices, for each node in the network, of whether the node is kept (1) or dropped out (0). For a network $\mathcal{W}$, an input $\mathbf{x}$, and dropout pattern $\mathcal{R}$, let $\mathcal{D}(\mathcal{W}, \mathbf{x}, \mathcal{R})$ be the output of $\mathcal{W}$ when nodes are dropped out or not following $\mathcal{R}$ (including the $1/p$ rescaling of kept nodes' outputs). The goal of dropout training on an example distribution P is to find weights and biases minimizing the *dropout criterion* for a given dropout probability:

$$J_D(\mathcal{W}) \stackrel{\text{def}}{=} \mathbf{E}_{\mathcal{R}}\mathbf{E}_{(\mathbf{x},y)\sim P}\left((\mathcal{D}(\mathcal{W}, \mathbf{x}, \mathcal{R}) - y)^2\right).$$

1. Some authors use a similar adjustment where the weights are scaled down at prediction time instead of inflating the kept nodes' outputs at training time.

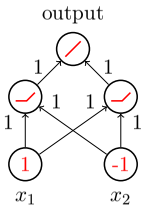

Figure 1: A network where the dropout penalty is negative.

This criterion is equivalent to the expected risk of the dropout-modified network, and we use $\mathcal{W}_D$ to denote a minimizer of it. Since the selection of dropout pattern and example from P are independent, the order of the two expectations can be swapped, yielding

$$J_D(\mathcal{W}) = \mathbf{E}_{(\mathbf{x},y)\sim P}\mathbf{E}_{\mathcal{R}}\left((\mathcal{D}(\mathcal{W},\mathbf{x},\mathcal{R})-y)^2\right). \quad (1)$$

Equation (1) is a key property of the dropout criterion. It indicates when something is true about the dropout criterion for a family of distributions concentrated on single examples, then (usually) the same thing will be true for any mixture of these single-example distributions.

Consider now the example network in Figure 1. The weight parameters W_1 and $\mathbf{w}$ are all-1's, and all of the biases are 0. $\mathcal{W}(1,-1)=0$ as each hidden node computes 0. Each dropout pattern indicates the subset of the four lower nodes to be kept, and when $q=p=1/2$ each subset is equally likely to be kept. If $\mathcal{R}$ is the dropout pattern where input x_2 is dropped and the other nodes are kept, then the network computes $\mathcal{D}(\mathcal{W},(1,-1),\mathcal{R})=8$ (recall that when $p=1/2$ the values of non-dropped out nodes are doubled). Only three dropout patterns produce a non-zero output, so if P is concentrated on the example $\mathbf{x}=(1,-1), y=8$ the dropout criterion is:

$$J_D(\mathcal{W}) = \frac{1}{16}(8-8)^2 + \frac{2}{16}(4-8)^2 + \frac{13}{16}(0-8)^2 = 54.$$

As mentioned in the introduction, the *dropout penalty* of a weight vector for a given example distribution and dropout probability is the amount that the dropout criterion exceeds the risk, $J_D(\mathcal{W}) - R(\mathcal{W})$. Wager et al. (2013) show that for 1-layer generalized linear models, the dropout penalty is non-negative.

Since $\mathcal{W}(1,-1)=0$, we have $R(\mathcal{W})=64$, and the dropout penalty is negative in our example. This is because the variance in the output due to dropout causes the network to better fit the data (on average) than the network's non-dropout evaluation. In Section 5.2, we give a necessary condition for this variance to be beneficial. As with the dropout criterion, the dropout penalty decomposes into an expectation of penalties over single examples:

$$J_D(\mathcal{W}) - R(\mathcal{W}) = \mathbf{E}_{(\mathbf{x},y)\sim P}\left(\mathbf{E}_{\mathcal{R}}\left((\mathcal{D}(\mathcal{W},\mathbf{x},\mathcal{R})-y)^2\right) - (\mathcal{W}(\mathbf{x})-y)^2\right).$$

Definition 1 *Define $P_{(\mathbf{x},y)}$ as the distribution with half of its weight on example $(\mathbf{x},y)$ and half of its weight on example $(\mathbf{0},0)$.*

Unless indicated otherwise, we assume $p=q=1/2$ for simplicity, although this is not crucial for our results.

3. Scaling inputs, weights and outputs

This section compares the sensitivity of dropout and weight decay on the scale of the training data.

3.1 Dropout is scale-free

Here we prove that dropout regularizes deep networks in a manner that is independent of the scale of the input features. In other words, training under dropout regularization does not penalize the use of large weights when needed to compensate for small input values.

Definition 2 *For any example distribution P, define the dropout aversion of P to be the maximum, over minimizers $\mathcal{W}_\mathcal{D}$ of the dropout criterion $J_\mathcal{D}(\mathcal{W}_\mathcal{D})$, of $R_P(\mathcal{W}_\mathcal{D})-\inf_\mathcal{W} R_P(\mathcal{W})$.*

The dropout aversion of P measures the extent to which P is incompatible with the inductive bias of dropout, measured by the risk gap between the true risk minimizer and the optimizers of the dropout criterion.

Definition 3 *For example distribution P and square matrix A, denote by $A\circ P$ the distribution obtained by sampling $(\mathbf{x},y)$ from P, and outputting $(A\mathbf{x},y)$.*

When A is diagonal and has full rank, then $A\circ P$ is a rescaling of the inputs, like changing one input from minutes to seconds and another from feet to meters.

Theorem 4 *For any example distribution P, and any diagonal full-rank $K\times K$ matrix A, the dropout aversion of P equals the dropout aversion of $A\circ P$.*

Proof: Choose a network

$$\mathcal{W} = (W_1, \mathbf{b}_1, ..., W_{d-1}, \mathbf{b}_{d-1}, \mathbf{w}, b).$$

Let

$$\mathcal{W}' = (W_1A^{-1}, \mathbf{b}_1..., W_{d-1}, \mathbf{b}_{d-1}, \mathbf{w}, b).$$

For any $\mathbf{x}$, $\mathcal{W}(\mathbf{x}) = \mathcal{W}'(A\mathbf{x})$, as A^{-1} undoes the effect of A before it gets to the rest of the network, which is unchanged. Furthermore, for any dropout pattern $\mathcal{R}$, we have $\mathcal{D}(\mathcal{W},\mathbf{x},\mathcal{R}) = \mathcal{D}(\mathcal{W}',A\mathbf{x},\mathcal{R})$. Once again A^{-1} undoes the effects of A on kept nodes (since A is diagonal), and the rest of the network $\mathcal{W}'$ is modified by $\mathcal{R}$ an a manner paralleling $\mathcal{W}$. Thus, there is bijection between networks $\mathcal{W}$ and networks $\mathcal{W}'$ with $J_\mathcal{D}(\mathcal{W}') = J_\mathcal{D}(\mathcal{W})$ and $R(\mathcal{W}') = R(\mathcal{W})$, yielding the theorem. ■

Theorem 4 indicates that some common normalizations of the input features (for example, to have unit variance) do not affect the quality of the dropout criterion minimizers, but normalization might change the speed of convergence and which minimizer is reached. Centering the features has slightly different properties. Although it is easy to use the biases to define a $\mathcal{W}'$ that "undoes" the centering in the non-dropout computation, different $\mathcal{W}'$ appear to be required for different dropout patterns, breaking the bijection exploited in Theorem 4.

As we will see in Section 3.4, weight decay does not enjoy such scale-free status.

3.2 Dropout's invariance to parameter scaling

Next, we describe an equivalence relation among parameterizations for dropout networks of depth $d \geq 2$. Basically, scaling the parameters at a level creates a corresponding scaling of the output. (A similar observation was made in a somewhat different context by Neyshabur et al. (2015).)

Theorem 5 *For any input* $\mathbf{x}$*, dropout pattern* $\mathcal{R}$*, any network*

$$\mathcal{W} = (W_1, \mathbf{b}_1, ..., W_{d-1}, \mathbf{b}_{d-1}, \mathbf{w}, b),$$

and any positive $c_1, ..., c_d$*, if*

$$\mathcal{W}' = \left(c_1 W_1, c_1 \mathbf{b}_1, c_2 W_2, c_1 c_2 \mathbf{b}_2, ..., c_{d-1} W_{d-1}, \left(\prod_{j=1}^{d-1} c_j \right) \mathbf{b}_{d-1}, c_d \mathbf{w}, \left(\prod_{j=1}^{d} c_j \right) b \right), \quad (2)$$

then $\mathcal{D}(\mathcal{W}', \mathbf{x}, \mathcal{R}) = \left(\prod_{j=1}^{d} c_j \right) \mathcal{D}(\mathcal{W}, \mathbf{x}, \mathcal{R})$*. In particular, if* $\prod_{j=1}^{d} c_j = 1$*, then for any example distribution* P*, networks* $\mathcal{W}$ *and* $\mathcal{W}'$ *have the same dropout criterion, dropout penalty, and expected loss.*

Note that the re-scaling of the biases at layer j depends not only on the rescaling of the connection weights at layer j, but also the re-scalings at lower layers.

Proof: Choose an input $\mathbf{x}$ and a dropout pattern $\mathcal{R}$. Define $\mathcal{W}'$ as in (2). For each hidden layer j, let $(h_{j1}, ..., h_{jn})$ be the jth hidden layer when applying $\mathcal{W}$ to $\mathbf{x}$ with $\mathcal{R}$, and let $(\tilde{h}_{j1}, ..., \tilde{h}_{jn})$ be the jth hidden layer when applying $\mathcal{W}'$ instead. By induction, for all i, $\tilde{h}_{ji} = \left(\prod_{\ell \leq j} c_\ell \right) h_{ji}$; the key step is that the pre-rectified value used to compute $\tilde{h}_{ji}$ has the same sign as for h_{ji}, since rescaling by c_j preserves the sign. Thus the same units are zeroed out in $\mathcal{W}$ and $\mathcal{W}'$ and $\mathcal{D}(\mathcal{W}, \mathbf{x}, \mathcal{R}) = (\prod_j c_j) \mathcal{D}(\mathcal{W}', \mathbf{x}, \mathcal{R})$. When $\prod_j c_j = 1$, this implies $\mathcal{D}(\mathcal{W}, \mathbf{x}, \mathcal{R}) = \mathcal{D}(\mathcal{W}', \mathbf{x}, \mathcal{R})$. Since this is true for all $\mathbf{x}$ and $\mathcal{R}$, we have $J_{\mathcal{D}}(\mathcal{W}) = J_{\mathcal{D}}(\mathcal{W}')$. Since, similarly, $\mathcal{W}(\mathbf{x}) = \mathcal{W}'(\mathbf{x})$ for all $\mathbf{x}$, so $R(\mathcal{W}) = R(\mathcal{W}')$, the dropout penalities for $\mathcal{W}$ and $\mathcal{W}'$ are also the same. ■

Theorem 5 implies that the dropout criterion never has isolated minimizers, since one can continuously up-scale the weights on one layer with a compensating down-scaling at another layer to get a contiguous family of networks computing the same function and having the same dropout criterion. It may be possible to exploit the parameterization equivalence of Theorem 5 in training by using canonical forms for the equivalent networks or switching to an equivalent networks whose gradients have better properties. We leave this question for future work.

3.3 Output scaling with dropout

Scaling the output values of an example distribution P does affect the aversion, but in a very simple and natural way.

Theorem 6 *For any example distribution* P*, if* P' *is obtained from* P *by scaling the outputs of* P *by a positive constant* c*, the dropout aversion of* P' *is* c^2 *times the dropout aversion of* P*.*

Proof: If a network $\mathcal{W}$ minimizes the dropout criterion for P, then the network $\mathcal{W}'$ obtained by scaling up the weights and bias for the output unit by c minimizes the dropout criterion for P', and for any $\mathbf{x}$, y, and dropout pattern $\mathcal{R}$, $(\mathcal{D}(\mathcal{W}, \mathbf{x}, \mathcal{R}) - y)^2 = (\mathcal{D}(\mathcal{W}', \mathbf{x}, \mathcal{R}) - cy)^2 / c^2$. ■

3.4 Scaling properties of weight decay

Weight decay is not scale-free. Define the *weight-decay aversion* analogously to the dropout aversion: the weight-decay aversion with P is the maximum, over minimizers $\mathcal{W}^*$ of $J_2(\mathcal{W}^*)$, of $R_P(\mathcal{W}^*) - \inf_{\mathcal{W}} R_P(\mathcal{W})$.

We analyze the L_2 criterion for depth-2 networks in Appendix B, resulting in the following theorem. Our proof shows that, despite the non-convexity of the L_2 criterion, it is still possible to identify a closed form for one of its optimizers.

Theorem 7 *Choose an arbitrary number* n *of hidden nodes,* $\lambda > 0$ *and* $\mathbf{x} \in \mathbf{R}^K$ *other than* $(0, 0, ..., 0)$*.*

The weight-decay aversion of $P_{(\mathbf{x},1)}$ *is* $\min(\frac{1}{4}, \frac{\lambda^2}{\mathbf{x} \cdot \mathbf{x}})$*.*

Theorem 7 shows that, unlike dropout, the weight decay aversion *does* depend on the scaling of the input features.

Furthermore, when $2\lambda > \sqrt{\mathbf{x} \cdot \mathbf{x}}$, the weight-decay criterion for $P_{(\mathbf{x},1)}$ has only a single isolated optimum weight setting[2] – all weights set to zero and bias $1/2$ at the output node. This means that weight-decay in 2-layer networks can completely regularize away significant signal in the sample *even when* λ *is finite*, contrasting starkly with weight-decay's behavior in 1-layer networks.

The "vertical" flexibility to rescale weights between layers enjoyed by dropout (Theorem 5) does not hold for L_2: one can always drive the L_2 penalty to infinity by scaling one layer up by a large enough positive c, even while scaling another down by c. On the other hand, the proof of Theorem 7 shows that the L_2 criterion has an alternative "horizontal" flexibility involving the rescaling of weights across nodes on the hidden layer (under the theorem's assumptions). Lemma 31 shows that at the optimizers each hidden node's contributions to the output are a constant (depending on the input) times their contribution to the the L_2 penalty. Shifting the magnitudes of these contributions between hidden nodes leads to alternative weights that compute the same value and have the same weight decay penalty. This is a more general observation than the permutation symmetry between hidden nodes because any portion of a hidden node's contribution can be shifted to another hidden node.

2. Since the output node puts weight 0 on each hidden node and the biases are unregularized, this optimum actually represents a class of networks differing only in the irrelevant biases at the hidden nodes. One can easily construct other cases when weight-decay has isolated minima in this sense, for example when $n = 2$ and there is equal probability on $\mathbf{x}$ and $-\mathbf{x}$, both with label 1.

4. Negative weights for monotone functions

If the weights of a unit are non-negative, then the unit computes a monotone function, in the sense that increasing any input while keeping the others fixed increases the output. The bias does not affect a node's monotonicity. A network of monotone units is also monotone.

We first present our theoretical results for many features (Section 4.1) and few features (Section 4.2), and then discuss the implication of these results in Section 4.3.

4.1 The basic case – many features

In this section, we analyze the simple distribution $P_{(\mathbf{1},1)}$ that assigns probability 1/2 to the example $(0,...,0),0$, and probability 1/2 to the example $(1,...,1),1$. The support of $P_{(\mathbf{1},1)}$ is arguably the simplest monotone function. Nevertheless, we prove that dropout uses negative weights to fit this data.

The key intuition is that optimizing the dropout criterion requires controlling the variance. Negative weights at the hidden nodes can be used to control the variance due to dropout at the input layer. When there are enough hidden nodes this becomes so beneficial that every minimizer of the dropout criterion uses such negative weights.

Theorem 8 *For the standard architecture, if $K > 18$ and n is large enough relative to K and d, every optimizer of the dropout criterion for $P_{(\mathbf{1},1)}$ uses at least one negative weight.*

To prove Theorem 8, we first calculate $J_{\mathcal{D}}(\mathcal{W}_{\text{neg}})$ for a network $\mathcal{W}_{\text{neg}}$ that uses negative weights, and then prove a lower bound greater than this value that holds for all networks using only non-negative weights.

All of the biases in $\mathcal{W}_{\text{neg}}$ are 0.

A key building block in the definition of $\mathcal{W}_{\text{neg}}$ is a block of hidden units that we call the *first-one gadget*. Each such block has K hidden nodes, and takes its input from the K input nodes. The ith hidden node in the block takes the value 1 if the ith input node is 1, and all inputs $x_{i'}$ for $i' < i$ are 0; otherwise it takes the value 0. This can be accomplished with a weight vector $\mathbf{w}$ with $w_{i'} = -1$ for $i' < i$, with $w_i = 1$, and with $w_{i'} = 0$ for $i' > i$. The first hidden layer of $\mathcal{W}_{\text{neg}}$ comprises n/K copies of the first-one gadget.

Informally, this construction removes most of the variance in the number of $1's$ in the input, as recorded in the following lemma.

Lemma 9 *On any input $\mathbf{x} \in \{0,1\}^n$ except $(0,0,...,0)$, the sum of the values on the first hidden layer of $\mathcal{W}_{\text{neg}}$ is exactly n/K.*

The weights into the remaining hidden layers of $\mathcal{W}_{\text{neg}}$ are all 1, and all the weights into the output layer take a value $c \stackrel{\text{def}}{=} \frac{K^2}{2n^{d-1}\left(1+\frac{K}{n}\right)\left(1+\frac{1}{n}\right)^{d-2}}$, chosen to minimize the dropout criterion for the network. The following lemma analyzes $\mathcal{W}_{\text{neg}}$.

Lemma 10 $J_{\mathcal{D}}(\mathcal{W}_{\text{neg}}) = \frac{1}{2}\left(1 - \frac{(1-2^{-K})}{\left(1+\frac{K}{n}\right)\left(1+\frac{1}{n}\right)^{d-2}}\right)$.

When n is large relative to K and d, the $\left(1+\frac{K}{n}\right)\left(1+\frac{1}{n}\right)^{d-2}$ denominator in Lemma 10 approaches 1, so $J_{\mathcal{D}}(\mathcal{W}_{\text{neg}})$ approaches $2^{-K}/2$ in this case. Lemma 16 below gives a larger

lower bound for any network with all positive weights. In the concrete case when $d = 2$ and $n = K^3$, then Lemma 10 implies $J_{\mathcal{D}}(\mathcal{W}_{\text{neg}}) < 1/K^2$.

Proof (of Lemma 10): Consider a computation of $\mathcal{W}_{\text{neg}}(1,1,...,1)$ under dropout and let $\hat{y}$ be the (random) output. Let k_0 be the number of input nodes kept, and, for each $j \geq 2$, let k_j be the number of nodes in the jth hidden layer kept. Call the node in each first-one gadget that computes 1 a *key* node, and if no node in the gadget computes 1 because the input is all dropped, arbitrarily make the gadget's first hidden node the key node. This ensures there is exactly one key node per gadget, and every non-key node computes 0. Let k_1 be the number of kept key nodes on the first hidden layer. If $k_0 = 0$, the output $\hat{y}$ of the network is 0. Otherwise, $\hat{y} = c2^d \prod_{j=1}^{d-1} k_j$.

Note that k_0 is zero with probability 2^{-K}. Whenever $k_0 \geq 1$, k_1 is distributed as $B(n/K, 1/2)$. Each other k_j is distributed as $B(n, 1/2)$, and $k_1, k_2, ..., k_{d-1}$ are independent of one another.

$$\begin{aligned}\mathbf{E}(\hat{y}) &= \mathbf{Pr}(k_0 \geq 1)c2^d \mathbf{E}[k_1 | k_0 \geq 1] \prod_{j=2}^{d-1} \mathbf{E}[k_j] \\ &= (1-2^{-K})c2^d \left(\frac{n}{2K}\right)\left(\frac{n}{2}\right)^{d-2} = \frac{2c}{K}(1-2^{-K})n^{d-1}.\end{aligned}$$

Using the value of the second moment of the binomial, we get

$$\begin{aligned}\mathbf{E}(\hat{y}^2) &= \mathbf{E}\left[\left(\mathbb{1}_{k_0 \geq 1} c2^d \prod_{j=1}^{d-1} k_j\right)^2\right] = 4c^2(1-2^{-K})\left(\frac{n}{K}\right)\left(\frac{n}{K}+1\right)n^{d-2}(n+1)^{d-2} \\ &= \frac{4c^2(1-2^{-K})}{K^2} n^{2(d-1)} \left(1+\frac{K}{n}\right)\left(1+\frac{1}{n}\right)^{d-2}.\end{aligned}$$

Thus,

$$\begin{aligned}J_{\mathcal{D}}(\mathcal{W}_{\text{neg}}) &= \frac{1}{2}\left(1 - 2\mathbf{E}(\hat{y}) + \mathbf{E}(\hat{y}^2)\right) \\ &= \frac{1}{2}\left(1 - \frac{4c}{K}(1-2^{-K})n^{d-1} + \frac{4c^2(1-2^{-K})}{K^2} n^{2(d-1)} \left(1+\frac{K}{n}\right)\left(1+\frac{1}{n}\right)^{d-2}\right) \\ &= \frac{1}{2}\left(1 - \frac{(1-2^{-K})}{\left(1+\frac{K}{n}\right)\left(1+\frac{1}{n}\right)^{d-2}}\right),\end{aligned}$$

since $c = \frac{K}{2n^{d-1}\left(1+\frac{K}{n}\right)\left(1+\frac{1}{n}\right)^{d-2}}$, completing the proof. ■

Next we prove a lower bound on $J_{\mathcal{D}}$ for networks with nonnegative weights. Let $\mathcal{W}$ be an arbitrary such network.

Our lower bound will use a property of the function computed by $\mathcal{W}$ that we now define.

Definition 11 *A function $\phi : \mathbf{R}^K \to \mathbf{R}$ is* supermodular *if for all $\mathbf{x}, \boldsymbol{\delta}_1, \boldsymbol{\delta}_2 \in \mathbf{R}^K$ where $\boldsymbol{\delta}_1, \boldsymbol{\delta}_2 \geq \mathbf{0}$*

$$\phi(\mathbf{x}) + \phi(\mathbf{x} + \boldsymbol{\delta}_1 + \boldsymbol{\delta}_2) \geq \phi(\mathbf{x} + \boldsymbol{\delta}_1) + \phi(\mathbf{x} + \boldsymbol{\delta}_2),$$

or equivalently:

$$\phi(\mathbf{x}+\boldsymbol{\delta}_1+\boldsymbol{\delta}_2)-\phi(\mathbf{x}+\boldsymbol{\delta}_2)\geq\phi(\mathbf{x}+\boldsymbol{\delta}_1)-\phi(\mathbf{x})$$

The latter indicates that adding $\boldsymbol{\delta}_1$ to the bigger input $\mathbf{x}+\boldsymbol{\delta}_2$ has at least as large an effect as adding it to the smaller input $\mathbf{x}$.

Since $\mathcal{W}$ has all non-negative weights, it computes a supermodular function of its inputs. (This fact may be of independent interest.)

Lemma 12 *If a network has non-negative weights and its activation functions $\sigma(\cdot)$ are convex, continuous, non-decreasing, and differentiable except on a finite set, then the network computes a supermodular function of its input $\mathbf{x}$.*

Proof: We will prove by induction over the layers that, for any unit h in the network, if $h(\mathbf{x})$ is the output of unit h when $\mathbf{x}$ is the input to $\mathcal{W}$, then $h(\cdot)$ is a supermodular function of its input.

The base case holds since each input node h outputs the corresponding component of the input, and $(\mathbf{x}+\boldsymbol{\delta}_1)-\mathbf{x}=(\mathbf{x}+\boldsymbol{\delta}_1+\boldsymbol{\delta}_2)-(\mathbf{x}+\boldsymbol{\delta}_2)$.

Now, for the inductive step, let $\mathbf{w}$ be the weight vector for node h, let b be its bias, and $\sigma(\cdot)$ be its activation function. Let $I(\mathbf{x})$, $I(\mathbf{x}+\boldsymbol{\delta}_1)$, $I(\mathbf{x}+\boldsymbol{\delta}_2)$, and $I(\mathbf{x}+\boldsymbol{\delta}_1+\boldsymbol{\delta}_2)$ be the inputs to node h when the inputs to the network are $\mathbf{x}$, $\mathbf{x}+\boldsymbol{\delta}_1$, $\mathbf{x}+\boldsymbol{\delta}_2$ and $\mathbf{x}+\boldsymbol{\delta}_1+\boldsymbol{\delta}_2$ respectively.

By induction, these inputs to node h (componentwise) satisfy

$$I(\mathbf{x}+\boldsymbol{\delta}_1)-I(\mathbf{x})\leq I(\mathbf{x}+\boldsymbol{\delta}_1+\boldsymbol{\delta}_2)-I(\mathbf{x}+\boldsymbol{\delta}_2).$$

Therefore, since $\mathbf{w}$, $\boldsymbol{\delta}_1$, and $\boldsymbol{\delta}_2$ are non-negative, the interval $[\mathbf{w}\cdot I(\mathbf{x}+\boldsymbol{\delta}_2)+b, \mathbf{w}\cdot I(\mathbf{x}+\boldsymbol{\delta}_1+\boldsymbol{\delta}_2)+b]$ is at least as long and starts at least as high as the interval $[\mathbf{w}\cdot I(\mathbf{x})+b, \mathbf{w}\cdot I(\mathbf{x}+\boldsymbol{\delta}_1)+b]$. Since σ is continuous and differentiable except on a finite set, we have

$$\begin{aligned}h(I(\mathbf{x}+\boldsymbol{\delta}_1))-h(I(\mathbf{x}))&=\int_{\mathbf{w}\cdot I(\mathbf{x})+b}^{\mathbf{w}\cdot I(\mathbf{x}+\boldsymbol{\delta}_1)+b}\sigma'(z)dz\\&\leq\int_{\mathbf{w}\cdot I(\mathbf{x}+\boldsymbol{\delta}_2)+b}^{\mathbf{w}\cdot I(\mathbf{x}+\boldsymbol{\delta}_1+\boldsymbol{\delta}_2)+b}\sigma'(z)dz\quad\text{(since }\sigma'\text{ is non-decreasing)}\\&=h(I(\mathbf{x}+\boldsymbol{\delta}_1+\boldsymbol{\delta}_2))-h(I(\mathbf{x}+\boldsymbol{\delta}_2)).\end{aligned}$$

■

Definition 13 *Let $\mathbf{r}_0\in\{0,1\}^K$ be the dropout pattern concerning the input layer, and let $\mathcal{R}'$ be the dropout pattern concerning the rest of the network, so that the dropout pattern $\mathcal{R}=(\mathbf{r}_0,\mathcal{R}')$.*

For each $\ell\in\{0,...,K\}$, let $\psi_{\mathcal{W}}(\ell)$ be the average output of $\mathcal{W}$ under dropout when ℓ of the inputs are kept: that is,

$$\psi_{\mathcal{W}}(\ell)=\mathbf{E}\left(\mathcal{D}(\mathcal{W},1^K,(\mathbf{r}_0,\mathcal{R}'))\middle|\sum_j r_{0j}=\ell\right).$$

Lemma 14 *For any $\ell\in\{1,...,K-1\}$,*

$$\psi_{\mathcal{W}}(\ell+1)-\psi_{\mathcal{W}}(\ell)\geq\psi_{\mathcal{W}}(\ell)-\psi_{\mathcal{W}}(\ell-1).$$

Proof: Generate $\mathbf{u}$, i and j randomly by, first choosing $\mathbf{u}$ uniformly at random from among bit vectors with ℓ ones, then choosing i uniformly from the 0-components of $\mathbf{u}$, and j uniformly from the 1-components of $\mathbf{u}$. By Lemma 12,

$$\mathcal{W}(\mathbf{u}+\mathbf{e}_i)-\mathcal{W}(\mathbf{u})\geq\mathcal{W}(\mathbf{u}-\mathbf{e}_j+\mathbf{e}_i)-\mathcal{W}(\mathbf{u}-\mathbf{e}_j)\tag{3}$$

always holds. Furthermore, $\mathbf{u}+\mathbf{e}_i$ is uniformly distributed among bit vectors with $\ell+1$ ones, $\mathbf{u}-\mathbf{e}_j$ is uniformly distributed among bit vectors with $\ell-1$ ones, and $\mathbf{u}+\mathbf{e}_i-\mathbf{e}_j$ is uniformly distributed among bit vectors with ℓ ones. This is true for $\mathcal{W}$, but it is also true for any network obtained by dropping out some of the hidden nodes of $\mathcal{W}$. Thus

$$\begin{aligned}&\psi_{\mathcal{W}}(\ell+1)-\psi_{\mathcal{W}}(\ell)\\&=\mathbf{E}(\mathcal{D}(\mathcal{W},1^K,(\mathbf{r}_0,\mathcal{R}')|\sum_j r_{0j}=\ell+1))-\mathbf{E}(\mathcal{D}(\mathcal{W},1^K,(\mathbf{r}_0,\mathcal{R}')|\sum_j r_{0j}=\ell))\\&=\mathbf{E}(\mathcal{D}(\mathcal{W},\mathbf{r}_0,(1^K,\mathcal{R}')|\sum_j r_{0j}=\ell+1))-\mathbf{E}(\mathcal{D}(\mathcal{W},\mathbf{r}_0,(1^K,\mathcal{R}')|\sum_j r_{0j}=\ell))\\&\geq\mathbf{E}(\mathcal{D}(\mathcal{W},\mathbf{r}_0,(1^K,\mathcal{R}')|\sum_j r_{0j}=\ell))-\mathbf{E}(\mathcal{D}(\mathcal{W},\mathbf{r}_0,(1^K,\mathcal{R}')|\sum_j r_{0j}=\ell-1)),\end{aligned}$$

by (3)) and the distributions of $\mathbf{u}+\mathbf{e}_i$, $\mathbf{u}-\mathbf{e}_j+\mathbf{e}_i$ and $\mathbf{u}-\mathbf{e}_j$. Since

$$\begin{aligned}&\mathbf{E}(\mathcal{D}(\mathcal{W},\mathbf{r}_0,(1^K,\mathcal{R}')|\sum_j r_{0j}=\ell))-\mathbf{E}(\mathcal{D}(\mathcal{W},\mathbf{r}_0,(1^K,\mathcal{R}')|\sum_j r_{0j}=\ell-1))\\&=\psi_{\mathcal{W}}(\ell)-\psi_{\mathcal{W}}(\ell-1),\end{aligned}$$

this completes the proof. ■

We will use the following lower bound on the tail of the binomial. (Many similar lower bounds are known.)

Lemma 15 *If X is distributed according to* $\mathrm{Bin}(n,1/2)$*, then*

$$\mathbf{Pr}(X<n/2-\sqrt{n}/4)=\mathbf{Pr}(X>n/2+\sqrt{n}/4)\geq 1/4.$$

Proof: Using the fact that, for any i, $\mathbf{Pr}(X=i)\leq 1/\sqrt{n}$, we get $\mathbf{Pr}(|X-n/2|<\sqrt{n}/4)\leq 1/2$, so $\mathbf{Pr}(X<n/2-\sqrt{n}/4)\geq 1/4$. ■

Now we are ready for the lower bound on $J_{\mathcal{D}}(\mathcal{W})$.

Lemma 16 *If $K>18$ and the weights in $\mathcal{W}$ are non-negative, then $J_{\mathcal{D}}(\mathcal{W})\geq\frac{1}{36K}$.*

Proof: Assume to the contrary that $J_{\mathcal{D}}(\mathcal{W})<\frac{1}{36K}$. First, note that $\psi_{\mathcal{W}}(0)\leq\sqrt{\frac{1}{18K}}$, or else the contribution to $J_{\mathcal{D}}(\mathcal{W})$ due to the $(0,0),0$ example is at least $\frac{1}{36K}$. Applying Lemma 15, we have

$$\psi_{\mathcal{W}}(K/2-\sqrt{K}/4)>1-\sqrt{\frac{2}{9K}}\text{ and }\psi_{\mathcal{W}}(K/2+\sqrt{K}/4)<1+\sqrt{\frac{2}{9K}}\tag{4}$$

as otherwise the contribution of one of the tails to $J_{\mathcal{D}}(\mathcal{W})$ will be at least $\frac{1}{36K}$ for the $(1,\ldots,1),1$ example. We will contradict this small variation of $\psi_{\mathcal{W}}(\ell)$ around $K/2$. The bounds on $\psi_{\mathcal{W}}(0)$ and $\psi(K/2-\sqrt{K}/4)$ and Lemma 14 imply that $\psi_{\mathcal{W}}(\ell)$ grows rapidly when ℓ is around $K/2$, in particular:

$$\psi(K/2-\sqrt{K}/4+1)-\psi(K/2-\sqrt{K}/4) \geq \frac{1-\sqrt{\frac{2}{9K}}-\sqrt{\frac{1}{18K}}}{K/2-\sqrt{K}/4} > \frac{1}{\sqrt{9/32}K},$$

since $K>18$. Now using Lemma 14 repeatedly shows that

$$\psi(K/2+\sqrt{K}/4)-\psi(K/2-\sqrt{K}/4) > \frac{\sqrt{K}}{2}\times\frac{1}{\sqrt{9/32}K} = 2\sqrt{\frac{2}{9K}},$$

which contradicts (4), completing the proof. ■

Putting together Lemmas 10 and 16 immediately proves Theorem 8, since for $K>18$ and large enough n, the criterion for $\mathcal{W}_{\text{neg}}$ must be less than the criterion for any network with all non-negative weights.

4.2 The case when $K=2$

Theorem 8 uses the assumption that $K>18$ and n is large enough; is the lower bound on K really necessary? Here we show that it is not, by treating the case that $K=2$.

Theorem 17 *For the standard architecture, if $K=2$, for any fixed d and large enough n, every optimizer of the dropout criterion for $P_{(1,1),1}$ uses negative weights.*

Proof: Define $\mathcal{W}_{\text{neg}}$ as in the proof of Lemma 10, except that the output layer has a bias of $1/5$.

We claim that

$$\lim_{n\to\infty} J_{\mathcal{D}}(\mathcal{W}_{\text{neg}}) = 1/10. \tag{5}$$

To see this, consider the joint input/label distribution under dropout:

$$\begin{aligned}
\mathbf{Pr}((0,0),0) &= 1/2\\
\mathbf{Pr}((0,0),1) &= 1/8\\
\mathbf{Pr}((2,0),1) &= 1/8\\
\mathbf{Pr}((0,2),1) &= 1/8\\
\mathbf{Pr}((2,2),1) &= 1/8.
\end{aligned}$$

Due to the bias of $1/5$ on the output, $\mathcal{W}_{\text{neg}}(0,0)=1/5$. Thus, contribution to $J_{\mathcal{D}}$ from examples with $\mathbf{x}=(0,0)$ in this joint distribution is $1/2\times(1/5)^2+1/8\times(4/5)^2=1/10$.

Now, choose $\mathbf{x}\neq(0,0)$. If, after dropout, the input is $\mathbf{x}$, each node in the hidden layer closest to the input computes 1. Arguing exactly as in the proof of Lemma 10, in such cases,

$$\mathbf{E}((\hat{y}-1)^2) = 1-\frac{1}{\left(1+\frac{2}{n}\right)\left(1+\frac{1}{n}\right)^{d-2}}.$$

This proves (5).

Now, let $\mathcal{W}$ be an arbitrary network with non-negative weights.

For our distribution,

$$J_{\mathcal{D}}(\mathcal{W}) = \frac{\mathbf{E}_{\mathcal{R}}\left((\mathcal{D}(\mathcal{W},(0,0),\mathcal{R})-0)^2\right)+\mathbf{E}_{\mathcal{R}}\left((\mathcal{D}(\mathcal{W},(1,1),\mathcal{R})-1)^2\right)}{2}.$$

Let $V_{00}=\mathbf{E}(\mathcal{W}(0,0)), V_{22}=\mathbf{E}(\mathcal{W}(2,2)), V_{20}=\mathbf{E}(\mathcal{W}(2,0)), V_{02}=\mathbf{E}(\mathcal{W}(0,2))$ where the expectations are taken with respect to the dropout patterns at the hidden nodes (with no dropout at the inputs). Since each dropout pattern over the hidden nodes defines a particular network, and Lemma 12 holds for all of them, the relationships also hold for the expectations, so

$$V_{22} \geq V_{20}+V_{02}-V_{00}.$$

Using this V notation, handling the dropout at the input explicitly, and the bias-variance decomposition keeping just the bias terms we get:

$$\begin{aligned}
J_{\mathcal{D}}(\mathcal{W}) &\geq \frac{(V_{00}-0)^2+\left((V_{00}-1)^2+(V_{22}-1)^2+(V_{20}-1)^2+(V_{02}-1)^2\right)/4}{2}\\
8J_{\mathcal{D}}(\mathcal{W}) &\geq 4(V_{00}-0)^2+(V_{00}-1)^2+(V_{22}-1)^2+(V_{20}-1)^2+(V_{02}-1)^2.
\end{aligned}$$

We will continue lower bounding the RHS. We can re-write V_{22} as $V_{20}+V_{02}-V_{00}+\epsilon$ where $\epsilon\geq 0$. This is convex and symmetric in V_{02} and V_{20} so they both take the same value at the minimizer of the RHS, so we proceed using V_{20} for this common minimizing value.

$$8J_{\mathcal{D}}(\mathcal{W}) \geq (2V_{20}-V_{00}+\epsilon-1)^2+2(V_{20}-1)^2+(V_{00}-1)^2+4V_{00}^2.$$

Differentiating with respect to V_{20}, we see that the RHS is minimized when $V_{20}=(2+V_{00}-\epsilon)/3$, giving

$$8J_{\mathcal{D}}(\mathcal{W}) \geq \frac{(V_{00}-\epsilon-1)^2}{3}+(V_{00}-1)^2+4V_{00}^2.$$

If $V_{00}\geq 1$, then $J_{\mathcal{D}}\geq 1/2$ (just from the (0,0),0 example) and when $V_{00}<1$ the RHS of the above is minimized for non-negative ϵ when $\epsilon=0$. Using this substitution, the minimizing value of V_{00} is $1/4$ giving

$$\begin{aligned}
8J_{\mathcal{D}}(\mathcal{W}) &\geq 1\\
J_{\mathcal{D}}(\mathcal{W}) &\geq 1/8.
\end{aligned}$$

Combining this with (5) completes the proof. ■

4.3 More general distributions and implications

In the previous sub-section we analyzed the distribution P over the 2-feature examples $(1,1),1$ and $(0,0),0$. However, these two examples can be embedded in a larger feature space by using any fixed vector of additional feature values, creating, for instance, a distribution over $(\underline{0,1},0,0,\underline{0,1/2,1}),0$ and $(\underline{0,1},1,1,\underline{0,1/2,1}),1$ (with the additional features underlined) The results of Section 4.2 still apply to distribution over these extended examples after defining $\mathcal{W}_{\text{neg}}$ network to have zero weight on the additional features, and noticing that any weight on the additional features in the positive-weight network $\mathcal{W}$ can be simulated using the biases at the hidden nodes.

It is particularly interesting when the additional features all take the value 0, we call these *zero-embeddings*. Every network $\mathcal{W}$ with non-negative weights has $J_{\mathcal{D}}(\mathcal{W}) \geq 1/8$ on each of these *zero-embeddings* of P. On the other hand, a single $\mathcal{W}_{\text{neg}}$ network with n/K copies of the K-input first-one gadget has $J_{\mathcal{D}}(\mathcal{W}_{\text{neg}}) \approx 1/10$ simultaneously for all of these zero-embeddings of P (when $n >> K$).

Any source distribution over $\{0,1\}^K \times \{0,1\}$ that puts probability $1/2$ on the the $\mathbf{0},0$ example and distributes the other $1/2$ probability over examples where exactly two inputs are one is a mixture of zero-embeddings of P, and thus $J_{\mathcal{D}}(\mathcal{W}) \geq 1/8$ while $J_{\mathcal{D}}(\mathcal{W}_{\text{neg}}) \approx 1/10$ for this mixture and optimizing the dropout criterion requires negative weights.

In our analysis the negative weights used by dropout are counterintuitive for fitting monotone behavior, but are needed to control the variance due to dropout. This suggests that dropout may be less effective when layers with sparse activation patterns are fed into wider layers, as dropout training can hijack part of the expressiveness of the wide layer to control the artificial variance due to dropout rather than fitting the underlying patterns in the data.

5. Properties of the dropout penalty

This section examines some properties of the dropout penalty applied to deep networks with ReLUs and the quadratic loss, which are often different than the case of networks without hidden layers.

5.1 Growth of the dropout penalty as a function of d

Weight-decay penalizes large weights, while Theorem 5 shows that compensating rescaling of the weights does not affect the dropout penalty or criterion. On the other hand, dropout can be more sensitive to the calculation of large outputs than weight decay, and large outputs can be produced in deep networks using only small weights. We make this observation concrete by exhibiting a family of networks where the depth and desired output are linked while the size of individual weights remains constant. For this family, the dropout penalty grows exponentially in the depth d (as opposed to linearly for weight-decay), suggesting that dropout training is less willing to fit the data in this kind of situation.

Theorem 18 *If $\mathbf{x} = (1,1,...,1)$ and $0 \leq y \leq Kn^{d-1}$, for $P_{\mathbf{x},y}$ there are weights $\mathcal{W}$ for the standard architecture with $R(\mathcal{W}) = 0$ such that (a) every weight has magnitude at most one, but (b) $J_{\mathcal{D}}(\mathcal{W}) \geq \frac{y^2}{K}$, whereas (c) $J_2(\mathcal{W}) \leq \frac{\lambda y^{2/d}}{2}(Kn + n^2(d-2) + n)$.*

Proof: Let $\mathcal{W}$ be the network whose weights are all $c = \frac{y^{1/d}}{K^{1/d}n^{(d-1)/d}}$ and biases are all 0, so that the L_2 penalty is the number of weights times $\lambda c^2/2$. It is a simple induction to show that, for these weights and input $(1,1,...,1)$, the value computed at each hidden node on level j is $c^j Kn^{j-1}$, so the the network outputs $c^d Kn^{d-1}$, and has zero square loss (since $\mathcal{W}(\mathbf{x}) = c^d Kn^{d-1} = y$).

Consider now dropout on this network. This is equivalent to changing all of the weights from c to $2c$ and, independently with probability $1/2$, replacing the value of each node with 0. For a fixed dropout pattern, each node on a given layer has the same weights, and receives the same (kept) inputs. Thus, the value computed at every node on the same layer is the same. For each j, let H_j be the value computed by the units in the jth hidden layer.

If k_0 is the number of input nodes kept under dropout, and, for each $j \in \{1,...,d-1\}$, k_j is the number of hidden nodes kept in layer j, a straightforward induction shows that, for all ℓ, we have $H_\ell = (2c)^\ell \prod_{j=0}^{\ell-1} k_j$, so that the output $\hat{y}$ of the network is $(2c)^d \prod_{j=0}^{d-1} k_j$.

Using a bias-variance decomposition,

$$\mathbf{E}((\hat{y}-y)^2) = (\mathbf{E}[\hat{y}]-y)^2 + \mathbf{Var}(\hat{y}).$$

Since each k_j is binomially distributed, and $k_0,...,k_{d-1}$ are independent, we have

$$\mathbf{E}(\hat{y}) = (2c)^d(K/2)(n/2)^{d-1} = c^d Kn^{d-1} = y,$$

so

$$\mathbf{E}((\hat{y}-y)^2) = \mathbf{Var}(\hat{y}).$$

Since

$$\mathbf{E}(\hat{y}^2) = (2c)^{2d}(K(K+1)/4)(n(n+1)/4)^{d-1} = y^2(1+1/K)(1+1/n)^{d-1},$$

we have

$$\mathbf{Var}(\hat{y}) = \mathbf{E}(\hat{y}^2) - \mathbf{E}(\hat{y})^2 = y^2((1+1/K)(1+1/n)^{d-1} - 1) \geq y^2/K,$$

completing the proof. ■

Theorem 18 shows that if $y = \exp(\Theta(d))$, the dropout penalty grows exponentially in d, whereas the L_2 penalty grows polynomially. Since the dropout penalty of a distribution decomposes into the expectation over single examples, the dropout penalty for any distribution P that puts positive probability on this $((1,1,\ldots,1),y)$ example has a term that grows exponentially in the depth.

5.2 A necessary condition for negative dropout penalty

Section 2 contains an example where the dropout penalty is negative. The following theorem provides a necessary condition.

Theorem 19 *The dropout penalty can be negative. For all example distributions, a necessary condition for this in rectified linear networks is that either a weight, input, or bias is negative.*

Proof: Baldi and Sadowski (2014) show that for networks of linear units (as opposed to the non-linear rectified linear units we focus on) the network's output without dropout equals the expected output over dropout patterns, so in our notation: $\mathcal{W}(\mathbf{x})$ equals $\mathbf{E}_{\mathcal{R}}(\mathcal{D}(\mathcal{W},\mathbf{x},\mathcal{R}))$. Assume for the moment that the network consists of linear units and the example distribution is concentrated on the single example $(\mathbf{x},y)$. Using the bias-variance decomposition for square loss and this property of linear networks,

$$J_D(\mathcal{W}) = \mathbf{E}_{\mathcal{R}}\left((\mathcal{D}(\mathcal{W},\mathbf{x},\mathcal{R})-y)^2\right) = (\mathbf{E}_{\mathcal{R}}(\mathcal{D}(\mathcal{W},\mathbf{x},\mathcal{R})-y)^2 + \mathbf{Var}_{\mathcal{R}}(\mathcal{D}(\mathcal{W},\mathbf{x},\mathcal{R})) \geq (\mathcal{W}(\mathbf{x})-y)^2$$

and the dropout penalty is again non-negative. Since the same calculations go through when averaging over multiple examples, we see that the dropout penalty is always non-negative for networks of linear nodes. When all the weights, biases and inputs in a network of rectified linear units are positive, then the rectified linear units behave as linear units, so the dropout penalty will again be non-negative. ■

5.3 Multi-layer dropout penalty does depend on labels

In contrast with its behavior on a variety of linear models including logistic regression (Wager et al., 2013), the dropout penalty can depend on the value of the response variable in deep networks with ReLUs and the quadratic loss. Thus in a fundamental and important respect, dropout differs from traditional regularizers like weight-decay or an L_1 penalty.

Theorem 20 *There are joint distributions P and Q, and weights $\mathcal{W}$ such that, for all dropout probabilities $q \in (0,1)$, (a) the marginals of P and Q on the input variables are equal, but (b) the dropout penalties of $\mathcal{W}$ with respect to P and Q are different.*

We will prove Theorem 20 by describing a general, somewhat technical, condition that implies that P and Q are witnesses to Theorem 20.

For each input $\mathbf{x}$ and dropout pattern $\mathcal{R}$, let $\mathcal{H}(\mathcal{W},\mathbf{x},\mathcal{R})$ be the values presented to the output node with dropout. As before, let $\underline{\mathbf{w}} \in \overline{\mathbf{R}^n}$ be those weights of $\mathcal{W}$ on connections directly into the output node and let b be the bias at the output node. Let $\underline{\mathbf{r}} \in \{0,1\}^n$ be the indicator variables for whether the various nodes connecting to the output node are kept.

Proof (of Theorem 20): Suppose that P is concentrated on a single $(\mathbf{x},y)$ pair. We will then get Q by modifying y.

Let $\mathbf{h}$ be the values coming into the output node in the non-dropped out network. Therefore the output of the non-dropout network is $\mathbf{w}\cdot\mathbf{h}+b$ while the output of the network with dropout is $\mathbf{w}\cdot\mathcal{H}(\mathcal{W},\mathbf{x},\mathcal{R})+b$. We now examine the dropout penalty, which is the expected dropout loss minus the non-dropout loss. We will use δ as a shorthand for $\mathbf{w}\cdot(\mathcal{H}(\mathcal{W},\mathbf{x},\mathcal{R})-\mathbf{h})$.

$$\begin{aligned}\text{dropout penalty} &= \mathbf{E}\left((\mathbf{w}\cdot\mathcal{H}(\mathcal{W},\mathbf{x},\mathcal{R})+b-y)^2\right) - (\mathbf{w}\cdot\mathbf{h}+b-y)^2 \\ &= \mathbf{E}\left((\mathbf{w}\cdot\mathcal{H}(\mathcal{W},\mathbf{x},\mathcal{R})+b-\mathbf{w}\cdot\mathbf{h}+\mathbf{w}\cdot\mathbf{h}-y)^2\right) - (\mathbf{w}\cdot\mathbf{h}+b-y)^2 \\ &= \mathbf{E}\left(\delta^2\right) + 2(\mathbf{w}\cdot\mathbf{h}+b-y)\mathbf{E}(\delta)\end{aligned}$$

which depends on the label y unless $\mathbf{E}(\delta)=0$.

Typically $\mathbf{E}(\delta)\neq 0$. To prove the theorem, consider the case where

- there are two inputs and one hidden layer,
- $\mathbf{x} = (1,-2)$,
- all weights in the network are 1, and
- all biases are 0.

Without dropout $\mathbf{h}=(0,0)$, but with dropout the hidden nodes are never negative and compute positive values when only the negative input is dropped, so that the expectation of δ is positive. ■

6. Experiments

To complement our theoretical results we performed two sets of experiments. The first set tests the scale dependence of dropout and weight decay, while the the second set examines its promotion of negative weights even when learning monotone functions. The code is accessible at

`https://www.dropbox.com/sh/6s2lcfrq17zshmp/AAAQO6uDa4gOAuAnw2MAghEMa?dl=0`

6.1 Scale (in)sensitivity

The scale dependence simulations were implemented using Torch. Our experiment used the standard architecture with $K=5$ inputs, depth $d=2$, $n=5$ hidden nodes. We used stochastic gradient using the `optim` package for Torch, with learning rate $\frac{0.01}{1+0.00001t}$ and momentum of 0.5, and a maximum of 100000 iterations.

We performed 10 sets of training runs. In each run:

- Ten training examples were generated uniformly at random from $[-1,1]^K$.
- Target outputs were assigned using $y=\prod_i \text{sign}(x_i)$.
- Five training sets $S_1,...,S_5$ with ten examples each were obtained by rescaling the inputs by $\{0.5, 0.75, 1, 1.25, 1.5\}$ and leaving the outputs unchanged.
- The weights of a network $\mathcal{W}_{\text{init}}$ were initialized using the default initialization from Torch.
- For each S_i:
  - $\mathcal{W}_{\text{init}}$ was cloned three times to produce $\mathcal{W}_D$, $\mathcal{W}_2$ and $\mathcal{W}_{\text{none}}$ with identical starting parameters.
  - $\mathcal{W}_D$ was trained with dropout probability 1/2 and no weight decay.
  - $\mathcal{W}_2$ was trained with weight decay with $\lambda = 1/2$ and no dropout.
  - $\mathcal{W}_{\text{none}}$ was trained without any regularization.

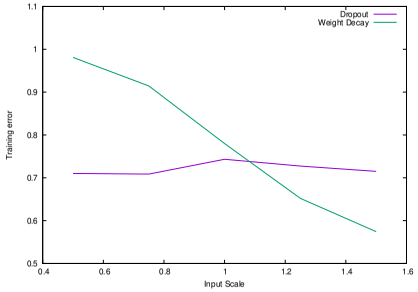

Figure 2: Training error as a function of the scale of the inputs for Dropout and Weight Decay in the experiment of Section 3.

The average training losses of $\mathcal{W}_D$ and $\mathcal{W}_2$, over the 10 runs, are shown in Figure 2. (The average training loss of $\mathcal{W}_{\text{none}}$ was less than 0.05 at all scales.)

The theoretical insensitivity of dropout to the scale of the inputs described in Theorem 4 is also seen here, along with the contrast with weight decay analyzed in Theorem 7.

The scale of the inputs also affects the dynamics of stochastic gradient descent. With very small inputs, convergence is very slow, and with very large inputs, SGD is unstable. The effects of the scale of the inputs on inductive bias analyzed in this paper are visible at the scales where optimization can be done effectively.

6.2 Negative Weights

Here we demonstrate dropout's propensity to use negative weights even when the function to be learned is monotonic. These experiments were implemented with Keras on top of TensorFlow and using SGD optimization with a learning rate of 0.005. Weight decay learning used a parameter of 0.05, and dropout training used a dropout rate of 0.5. We used the standard architecture with six inputs, 12 hidden nodes, and one output. The training set consists of six inputs as follows:

inputs	label	multiplicity
(0,0,0,0,0,0)	0	$\times 3$
(1,1,0,0,0,0)	1	$\times 1$
(0,0,1,1,0,0)	1	$\times 1$
(0,0,0,0,1,1)	1	$\times 1$

A natural network for this data uses all weights set to the same value $w = \sqrt{1/24}$ (with the biases set to 0). This network computes the correct labels for all of the training inputs. We ran each of dropout and weight-decay for 10,000 epochs from 10 different initial weight settings created by by sampling the weights independently from the uniform distribution

Table 1: Summary of weights resulting from noisy "all same" initialization

weights from	num neg	below -1.0	-1.0 to -0.1	-0.1 to -0.001	-0.001 to 0	0 to 0.001	0.001 to 0.1	0.1 to 1.0	above 1.0
initial wts	76	0	0	75	1	1	166	597	0
weight-decay	7	0	0	0	7	1	276	556	0
dropout	82	0	70	12	0	0	146	612	0

Table 2: Summary of weights resulting from noisy "first-one" initialization

weights from	num neg	below -1.0	-1.0 to -0.1	-0.1 to -0.001	-0.001 to 0	0 to 0.001	0.001 to 0.1	0.1 to 1.0	above 1.0
initial wts	204	90	80	34	180	1	47	232	176
weight-decay	111	0	0	57	68	68	298	349	0
dropout	303	91	93	119	5	0	168	189	175

over $[-0.2w, 2.2w]$. This randomization gives a one-in-twelve chance of changing the weight's sign.

Table 1 summarizes the initial weights, weights learned by weight-decay, and weights learned by dropout aggregated over the 10 initializations. This table shows that dropout not only (slightly) increases the number of negative weights, but also tends to greatly increase their magnitude. As expected, weight-decay eliminates almost all negative weights, and the few remaining negative weights have very small magnitudes.

We also ran a similar experiment based on the "first-one" gadget construction of Section 4.1. The hidden nodes are organized into six groups of two, with each group implementing three first-one gadgets – one for each of the input "pairs". Now the uncorrupted weights into the hidden layer are 0, 1, or -1, and those at the output node are $1/6$ so that the network computes the labels in the training set. As before, 10 noisy initial weight settings are chosen by selecting each weight uniformly from $[-0.2w, 2.2w]$, where w is the corresponding uncorrupted weight.

Table 2 summarizes the initial weights, weights learned by weight-decay, and weights learned by dropout aggregated over the 10 initializations. From this initialization, dropout tends to preserve the magnitudes of the negative weights. Although dropout increases the number of small-magnitude negative weights, much of this increase can be explained by half of the 180 weights initialized to exactly zero becoming negative. Again, weight-decay dramatically decreases both the number of the negative weights and their magnitudes.

7. Conclusions

The reasons behind dropout's surprisingly good performance in training deep networks across a variety of applications are somewhat mysterious and there is relatively little existing formal analysis. A variety of explanations have been offered (Bachman et al., 2014; Baldi and Sadowski, 2014, 2013; Gal and Ghahramani, 2015; Wager et al., 2014), including the

possibility that dropout reduces the amount of coadaptation in a network's weights (Hinton et al., 2012).

The dropout criterion is an expected loss over dropout patterns, and the variance in the output values over dropout patterns contributes to this expected loss. Therefore dropout may co-adapt weights in order to reduce this (artificial) variance. We prove that this happens even in very simple situations where nothing in the training data justifies negative weights (Theorem 8). This indicates that the relationship between dropout and co-adaption is not a simple one.

The effects of dropout in deep neural networks are rather complicated, and approximations can be misleading since the dropout penalty is very non-convex even in 1-layer networks (Helmbold and Long, 2015). In Section 3 we show that dropout does enjoy several scale-invariance properties that are not shared by weight-decay. A perhaps surprising consequence of these invariances is that there are never isolated local minima when learning a deep network with dropout. Further exploration of these scale invariance properties is warranted to see if they are a contributor to dropout's empirical success or can be exploited to facilitate training. While contrasting dropout to weight-decay in simple situations, we found that a degenerate all-zero network results (Theorem 7) when the L_2 regularization parameter is above a threshold. This is in dramatic contrast to our previous intuition from the 1-layer case.

In (Wager et al., 2013), dropout was viewed as a regularization method, adding a data dependent penalty to the empirical loss of (presumably) undesirable solutions. Section 5 shows that, unlike the generalized linear models case analyzed there, the dropout penalty in deeper networks can be negative and depends on the labels in the training data, and thus behaves unlike most regularizers. On the other hand, the dropout penalty can grow exponentially in the depth of the network, and thus may better reflect the complexity of the underlying model space than L_2 regularization.

This paper uncovers a number of dropout's interesting fundamental properties using formal analysis of simple cases. However, the effects of using dropout training in deep networks are subtle and complex, and we hope that this paper lays a foundation to promote further formal analysis of dropout's properties and behavior.

Appendix A. Table of Notation

Notation	Meaning
$\mathbb{1}_{\text{set}}$	indicator function for "set"
$(\mathbf{x}, y)$	an example with feature vector $\mathbf{x}$ and label y
$\sigma(\cdot)$	the rectified linear unit computing $\max(0, \cdot)$
$\mathcal{W}$	an arbitrary weight setting for the network
w, v	specific weights, often subscripted
$\mathcal{W}(\mathbf{x})$	the output value produced by weight setting $\mathcal{W}$ on input $\mathbf{x}$
P	an arbitrary source distribution over $(\mathbf{x}, y)$ pairs
$P_{\mathbf{x},y}$	the source distribution concentrated on the single example $(\mathbf{x}, y)$
$R_P(\mathcal{W})$	the risk (expected square loss) of $\mathcal{W}$ under source P
q, p	probabilities that a node is dropped out (q) or kept (p)
$\mathcal{R}$	a dropout pattern, indicates the kept nodes
$\mathbf{r}, \mathbf{s}$	dropout patterns on subsets of the nodes
$\mathcal{D}(\mathcal{W}, \mathbf{x}, \mathcal{R})$	Output with weights $\mathcal{W}$, input $\mathbf{x}$, and dropout pattern $\mathcal{R}$
$J_D(\mathcal{W})$	the dropout criterion
$J_2(\mathcal{W})$	the L_2 criterion
λ	the L_2 regularization strength parameter
$\mathcal{W}_D$	an optimizer of the dropout criterion
$\mathcal{W}_{L_2}$	an optimizer of the L_2 criterion
n, d	the network width and depth
K	the number of input nodes

Appendix B. Proof of Theorem 7

Here we prove Theorem 7, showing that the weight-decay aversion depends on the values of the inputs and the number of input nodes K. Furthermore, unlike the single-layer case, the L_2 regularization strength has a threshold where the minimizer of the L_2 criterion degenerates to the all-zero network.

We will focus on the standard architecture with depth $d = 2$. Recall that we are analyzing the distribution $P_{(\mathbf{x},1)}$ that assigns probability $1/2$ to $(\mathbf{x}, 1)$ and probability $1/2$ to $(\mathbf{0}, 0)$.

Also, recall that, for $P_{(\mathbf{x},1)}$, the weight-decay aversion is the maximum risk incurred by a minimizer of J_2.

The proof of Theorem 7 involves a series of lemmas, in which we show that there is a minimizer of J_2 of a special form, and then relate any hidden node's effect on the output to the regularization penalty on the weights in and out of that node. This will allow us to treat optimizing the L_2 criterion as a one-dimensional problem, whose solution yields the theorem.

For some minimizer $\mathcal{W}_{L_2}$ of J_2, let $\underline{\mathbf{v}_j^*}$ denote the vector of weights into hidden node j and $\underline{w_j^*}$ denote the weight from j to the output node. Let $\underline{a_j^*}$ be the bias for hidden node j and let $\underline{b^*}$ be the bias for the output node. Let $\underline{h_j}$ be the function computed by hidden node j.

Lemma 21 *We may assume without loss of generality that for each hidden node j, there is an input $\tilde{\mathbf{x}} \in \{\mathbf{0}, \mathbf{x}\}$ such that $h_j(\tilde{\mathbf{x}}) = 0$.*

Proof: Suppose neither of $h_j(\mathbf{0})$ or $h_j(\mathbf{x})$ was 0. If $w_j^* = 0$, then replacing both with 0 does not affect the output of $\mathcal{W}_{L_2}$, and does not increase the penalty. If $w_j^* \neq 0$, then subtracting $\min\{h_j(\mathbf{0}), h_j(\mathbf{x})\}$ from a_j^* and adding $w_j^* \cdot \min\{h_j(\mathbf{0}), h_j(\mathbf{x})\}$ to b does not affect the output of $\mathcal{W}_{L_2}$ or the penalty, but, after this transformation, $\min\{h_j(\mathbf{0}), h_j(\mathbf{x})\} = 0$. ■

Lemma 22 *We may assume without loss of generality that for each hidden node j, we have $|\mathbf{v}_j^* \cdot \mathbf{x}| = \max\{h_j(\mathbf{0}), h_j(\mathbf{x})\}$.*

Proof: If $h_j(\mathbf{x}) \geq h_j(\mathbf{0}) = 0$, then bias $a_j^* = 0$, and $h_j(\mathbf{x}) = \mathbf{v}_j^* \cdot \mathbf{x}$.

If $h_j(\mathbf{0}) > h_j(\mathbf{x}) = 0$. Then, $a_j^* > 0$, and $\mathbf{v}_j^* \cdot \mathbf{x} \leq -a_j^*$. If needed, the magnitude of $\mathbf{v}_j^*$ can be decreased to make $\mathbf{v}_j^* \cdot \mathbf{x} = -a_j^*$. This decrease does not affect $\mathcal{W}_{L_2}(\mathbf{x})$ or $\mathcal{W}_{L_2}(\mathbf{0})$, and can only reduce the L_2 penalty. ■

Lemma 23 *We may assume without loss of generality that for each hidden node j, we have $h_j(\mathbf{0}) = 0$.*

Proof: Suppose $h_j(\mathbf{0}) > 0$. Let z be this old value of $h_j(\mathbf{0})$. Then $h_j(\mathbf{x}) = 0$ and $z = h_j(\mathbf{0}) = -\mathbf{v}_j^* \cdot \mathbf{x}$. If we negate $\mathbf{v}^*$ and set $a_j = 0$, then Lemma 22 implies that we swap the values of $h_j(\mathbf{x})$ and $h_j(\mathbf{0})$.

Then, by adding zw_j^* to b^* and negating w_j^*, we correct for this swap at the output node and do not affect the function computed by $\mathcal{W}_{L_2}$ or the penalty. ■

Note that Lemma 23 implies that, without loss of generality, $a_1^* = ... = a_K^* = 0$. We continue with that assumption.

Lemma 24 *For all j, $\mathbf{v}_j^* \cdot \mathbf{x} \geq 0$.*

Proof: Since $a_j^* = 0$, if $\mathbf{v}_j^* \cdot \mathbf{x} < 0$, we could make $\mathcal{W}_{L_2}$ compute the same function with a smaller penalty by replacing $\mathbf{v}_j^*$ with $\mathbf{0}$. ■

Lemma 24 implies that the optimal $\mathcal{W}_{L_2}$ computes the linear function:

$$\mathcal{W}_{L_2}(\tilde{\mathbf{x}}) = (\mathbf{w}^*)^T V^* \tilde{\mathbf{x}} + b^*,$$

when $\tilde{\mathbf{x}}$ is a non-negative multiple of $\mathbf{x}$. Later we will call $(\mathbf{w}^*)^T V^* \tilde{\mathbf{x}}$ the <u>activation</u> at the output node.

Lemma 25 $b^* = \frac{1-(\mathbf{w}^*)^T V^* \mathbf{x}}{2}$.

Proof: Minimize J_2 (wrt distribution $P_{(\mathbf{x},1)}$) as a function of b using Calculus. ■

Now, for $\tilde{\mathbf{x}}$ a non-negative multiple of $\mathbf{x}$,

$$\mathcal{W}_{L_2}(\tilde{\mathbf{x}}) = \frac{1}{2} + (\mathbf{w}^*)^T V^* (\tilde{\mathbf{x}} - \mathbf{x}/2) \tag{6}$$

which immediately implies

$$\mathcal{W}_{L_2}(\mathbf{0}) = 1 - \mathcal{W}_{L_2}(\mathbf{x}). \tag{7}$$

Lemma 26 *Each $\mathbf{v}_j^*$ is a (positive) rescaling of $\mathbf{x}$.*

Proof: Projecting $\mathbf{v}_j^*$ onto the span of $\mathbf{x}$ does not affect h_j, and cannot increase the penalty. ■

Lemma 27 $\mathcal{W}_{L_2}(\mathbf{x}) \leq 1$.

Proof: By (7), if $\mathcal{W}_{L_2}(\mathbf{x}) > 1$ then $\mathcal{W}_{L_2}(\mathbf{0}) < 0$ and the loss and the penalty would both be reduced by scaling down $\mathbf{w}^*$. ■

Lemma 28 *$\mathcal{W}_{L_2}$ maximizes $\mathcal{W}(\mathbf{x})$ over those weight vectors $\mathcal{W}$ that have the same penalty as $\mathcal{W}_{L_2}$ and compute a function of the form $\mathcal{W}(\tilde{x}) = \frac{1}{2} + (\mathbf{w})^T V(\tilde{\mathbf{x}} - \mathbf{x}/2)$ (that is, Equation 6).*

Proof: Let $\mathcal{W}$ maximize $\mathcal{W}(\mathbf{x})$ over the networks considered. If $\mathcal{W}_{L_2}(\mathbf{x}) < \mathcal{W}(\mathbf{x}) \leq 1$, then $\mathcal{W}$ would have the same penalty as $\mathcal{W}_{L_2}$ but smaller error, contradicting the optimality of $\mathcal{W}_{L_2}$.

If $\mathcal{W}(\mathbf{x}) > 1$, then the network $\widetilde{\mathcal{W}}$ obtained by scaling down the weights in the output layer so that $\widetilde{\mathcal{W}}(\mathbf{x}) = 1$ has a smaller penalty than $\mathcal{W}_{L_2}$ and smaller error, again contradicting $\mathcal{W}_{L_2}$'s optimality. ■

Informally, Lemmas 27 and 28 engender a view of the learner straining against the yolk of the L_2 penalty to produce a large enough output on $\mathbf{x}$. This motivates us to ask how large $\mathcal{W}(\mathbf{x})$ can be, for a given value of $||\mathcal{W}||_2^2$ (recall that Lemma 24 allows us to assume that the biases at the hidden nodes are all 0).

Definition 29 *For each hidden node j, let $\underline{\alpha_j}$ be the constant such $\mathbf{v}_j^* = \alpha_j \mathbf{x}$, so that $h_j(\mathbf{x}) = \alpha_j \mathbf{x} \cdot \mathbf{x}$.*

Recall that the *activation* at the output node on input $\mathbf{x}$ is the weighted sum of the hidden-node outputs, $(\mathbf{w}^*)^T V^* \mathbf{x}$.

Definition 30 *The <u>contribution to the activation</u> at the output due to hidden node j is*

$$w_j^* h_j(\mathbf{x}) = w_j^* \alpha_j \mathbf{x} \cdot \mathbf{x}$$

and the <u>contribution to the L_2 penalty</u> from these weights is

$$\frac{\lambda}{2}\left((w_j^*)^2 + \alpha_j^2 \mathbf{x} \cdot \mathbf{x}\right).$$

We now bound the contribution to the activation in terms of the contribution to the L_2 penalty. Note that as the L_2 "budget" increases, so does the the maximum possible contribution to the output node's activation.

Lemma 31 *If B is hidden node j's weight-decay contribution, $(w_j^*)^2+\alpha_j^2\mathbf{x}\cdot\mathbf{x}$, then hidden node j's contribution to the output node's activation is maximized when $w_j^* = \sqrt{\frac{B}{2}}$ and $\alpha_j = \sqrt{\frac{B}{2\mathbf{x}\cdot\mathbf{x}}}$, where it achieves the value $B\sqrt{\mathbf{x}\cdot\mathbf{x}}/2$*

Proof: Since $\alpha_j^2\mathbf{x}\cdot\mathbf{x}+(w_j^*)^2 = B$, we have $w_j^* = \sqrt{B-\alpha_j^2\mathbf{x}\cdot\mathbf{x}}$, so the contribution to the activation can be re-written as $\alpha_j\mathbf{x}\cdot\mathbf{x}\sqrt{B-\alpha_j^2\mathbf{x}\cdot\mathbf{x}}$. Taking the derivative with respect to α_j, and solving, we get $\alpha_j = \pm\sqrt{\frac{B}{2\mathbf{x}\cdot\mathbf{x}}}$ and we want the positive solution (otherwise the node outputs 0). When $\alpha_j = \sqrt{\frac{B}{2\mathbf{x}\cdot\mathbf{x}}}$ we have $w_j^* = \sqrt{\frac{B}{2}}$ and thus the node's maximum contribution to the activation is

$$\sqrt{\frac{B}{2}}\sqrt{\frac{B}{2\mathbf{x}\cdot\mathbf{x}}}\,(\mathbf{x}\cdot\mathbf{x}) = \frac{B\sqrt{\mathbf{x}\cdot\mathbf{x}}}{2}.$$

■

Lemma 32 *The minimum sum-squared weights for a network $\mathcal{W}$ (without biases at the hidden nodes) that has an activation A at the output node on input $\mathbf{x}$ is $\frac{2A}{\sqrt{\mathbf{x}\cdot\mathbf{x}}}$.*

Proof: When maximized, the contribution of each hidden node to the activation at the output is $\sqrt{\mathbf{x}\cdot\mathbf{x}}/2$ times the hidden node's contribution to the sum of squared-weights. Since each weight in $\mathcal{W}$ is used in exactly one hidden node's contribution to the output node's activation, this completes the proof. ■

Note that this bound is independent of n, the number of hidden units, but does depend on the input $\mathbf{x}$.

Proof (of Theorem 7): Let $A \geq 0$ be the activation at the output node for $\mathcal{W}_{L_2}$ on input $\mathbf{x}$. From Lemma 25 we get that $b^* = \frac{1-A}{2}$. Combining Lemmas 27 , 28 and 32, we can re-write the J_2 criterion for $\mathcal{W}_{L_2}$ and distribution $P_{(\mathbf{x},1)}$ in terms of A as follows.

$$\begin{aligned} J_2(\mathcal{W}_{L_2}) &= \frac{1}{2}\left(b^*-0\right)^2 + \frac{1}{2}\left(\mathcal{W}_{L_2}(\mathbf{x})-1\right)^2 + \frac{\lambda}{2}||\mathcal{W}||_2^2 \\ &= \frac{1}{2}\left(\left(\frac{1-A}{2}\right)^2 + \left(\frac{1+A}{2}-1\right)^2 + \lambda\frac{2A}{\sqrt{\mathbf{x}\cdot\mathbf{x}}}\right). \end{aligned} \tag{8}$$

Differentiating with respect to A, we see that the criterion is minimized when

$$\begin{aligned} A &= 1-\frac{2\lambda}{\sqrt{\mathbf{x}\cdot\mathbf{x}}} && \text{when } \frac{2\lambda}{\sqrt{\mathbf{x}\cdot\mathbf{x}}} \leq 1 \\ A &= 0 && \text{when } \frac{2\lambda}{\sqrt{\mathbf{x}\cdot\mathbf{x}}} > 1 \end{aligned}$$

since we assumed $A \geq 0$; when $A = 0$ then $\mathcal{W}_{L_2}$ has all zero weights with a bias of $1/2$ at the output.

The risk part of (8) simplifies to

$$\frac{(1-A)^2}{4} = \frac{\lambda^2}{\mathbf{x}\cdot\mathbf{x}},$$

so the overall the risk of $\mathcal{W}_{L_2}$, which minimizes J_2, is $\min\left\{\frac{1}{4}, \frac{\lambda^2}{\mathbf{x}\cdot\mathbf{x}}\right\}$. ■

Abstract

We study the problem of learning description logic (DL) ontologies in Angluin et al.'s framework of exact learning via queries. We admit membership queries ("is a given subsumption entailed by the target ontology?") and equivalence queries ("is a given ontology equivalent to the target ontology?"). We present three main results: (1) ontologies formulated in (two relevant versions of) the description logic DL-Lite can be learned with polynomially many queries of polynomial size; (2) this is not the case for ontologies formulated in the description logic $\mathcal{EL}$, even when only acyclic ontologies are admitted; and (3) ontologies formulated in a fragment of $\mathcal{EL}$ related to the web ontology language OWL 2 RL can be learned in polynomial time. We also show that neither membership nor equivalence queries alone are sufficient in cases (1) and (3).

Keywords: Exact Learning, Description Logic, Complexity

1. Introduction

In many subfields of artificial intelligence, ontologies are used to provide a common vocabulary for the application domain of interest and to give a meaning to the terms in the vocabulary, and to describe the relations between them. Description logics (DLs) are a prominent family of ontology languages with a long history that goes back to Brachman's famous knowledge representation system KL-ONE in the early 1980s (Brachman and Schmolze, 1985). Today, there are several widely used families of DLs that differ in expressive power, computational complexity, and intended application. The most important ones are the $\mathcal{ALC}$ family which aims at high expressive power, the $\mathcal{EL}$ family (Baader et al., 2005) which aims to provide scalable reasoning, and the DL-Lite family (Calvanese et al., 2007; Artale et al., 2009) which is tailored specifically towards applications in data access. In 2004, the World Wide Web Committee (W3C) has standardised a DL of the $\mathcal{ALC}$ family as an ontology language for the web, called OWL. The standard was updated to OWL 2 in 2009, and since then comprises a family of five languages including the OWL 2 profiles OWL 2 EL, OWL 2 QL, and OWL 2 RL. While OWL 2 EL is based on $\mathcal{EL}$ and OWL 2 QL on DL-Lite, OWL 2 RL is closely related to the fragment of $\mathcal{EL}$ that is obtained by allowing only concept names on the right-hand side of concept inclusions. In this paper we study DLs from the $\mathcal{EL}$ and DL-Lite families. Designing an ontology for an application domain is a subtle, error-prone, and time consuming task. From its beginnings, DL research was driven by the aim to provide various forms of support for ontology engineers, assisting them in the design of high-quality ontologies; examples include the ubiquitous task of ontology classification (Baader et al., 2017), reasoning support for debugging ontologies (Wang et al., 2005; Schlobach et al., 2007), support for modular ontology design (Stuckenschmidt et al., 2009), and checking the completeness of the modelling in a systematic way (Baader et al., 2007). The same aim is pursued by the field of ontology learning, where the goal is to use machine learning techniques for various ontology engineering tasks such as to identify the relevant vocabulary of the application domain (Cimiano et al., 2010; Wong et al., 2012), to learn an initial version of the ontology that is then refined manually (Borchmann and Distel, 2011; Ma and Distel, 2013; Jiménez-Ruiz et al., 2015), and to learn concept expressions as building blocks of an ontology (Lehmann and Hitzler, 2010). For details we refer the reader to a collection of articles in ontology learning edited by Lehmann and Völker (2014) and Section 7.

In this paper we concentrate on learning the full logical structure of a description logic ontology. Our starting point is the observation that building a high-quality ontology relies on the successful communication between an ontology engineer and a domain expert because the former is typically not sufficiently familiar with the domain and the latter is rarely an expert in ontology engineering. We study the foundations of this communication process in terms of a simple communication model and analyse, within this model, the complexity of constructing a correct and complete domain ontology. Our model rests on the following assumptions:

1. The domain expert has perfect knowledge of the domain, but is not able to formalise or communicate the target ontology $\mathcal{O}$ to be constructed.

2. The domain expert is able to communicate the vocabulary (predicate symbols, which in the case of DLs take the form of concept and role names) of $\mathcal{O}$ and shares it with the ontology engineer. The ontology engineer knows nothing else about the domain.

3. The ontology engineer can pose queries to the domain expert which the domain expert answers truthfully. The main queries posed by the ontology engineer are of the form

   "Is the concept inclusion $C \sqsubseteq D$ entailed by $\mathcal{O}$?"

4. In addition, the ontology engineer needs a way to find out whether the ontology $\mathcal{H}$ that has been constructed so far, called the hypothesis ontology, is complete. If not, he requests an example illustrating the incompleteness. The engineer can thus ask:

   "Is the ontology $\mathcal{H}$ complete? If not, then return a concept inclusion $C \sqsubseteq D$ entailed by $\mathcal{O}$ but not by $\mathcal{H}$."

JMLR 18(201):1-63, 2018

We are then interested in whether the target ontology $\mathcal{O}$ can be constructed with only polynomially many queries of polynomial size (polynomial query learnability) or, even better, with overall polynomial time (polynomial time learnability). In both cases, the polynomial is in the size of the ontology to be constructed plus the size of the counterexamples returned by the domain expert. Without taking into account the latter, one can never expect to achieve polynomial time learnability because the domain expert could provide unnecessarily large counterexamples. Note that polynomial time learnability implies polynomial query learnability, but that the converse is false because polynomial query learnability allows the ontology engineer to run computationally costly procedures between posing queries.

The above model is an instance of Angluin et al.'s framework of exact learning via queries (Angluin, 1987b). In this context, the queries mentioned in Point 3 above are called *membership queries*. The queries in Point 4 are a form of *equivalence queries*. In Angluin's framework, however, such queries are slightly more general:

> "Is the hypothesis ontology $\mathcal{H}$ equivalent to the target ontology $\mathcal{O}$? If not, then return a concept inclusion $C \sqsubseteq D$ entailed by $\mathcal{O}$ but not by $\mathcal{H}$ (a *positive counterexample*) or vice versa (a *negative counterexample*)."

In our upper bounds (that is, polynomial learnability results), we admit only queries of the more restricted form in Point 4 above: the learning algorithm is designed in a way so that the hypothesis ontology $\mathcal{H}$ is a consequence of the target ontology $\mathcal{O}$ at all times, and thus the only meaningful equivalence query is a query of the form "Is $\mathcal{H}$ already complete?". Our lower bounds (results saying that polynomial learnability is impossible), in contrast, apply to unrestricted equivalence queries, that is, they do not assume that the hypothesis is implied by the target. In this way, we achieve maximum generality.

Within the setup outlined above, we study the following description logics:

(a) DL-Lite$^{\exists}_{\mathcal{R}}$, which is a member of the DL-Lite family that admits role inclusions and allows nested existential quantification on the right-hand side of concept inclusions;

(b) the extension DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ of DL-Lite$^{\exists}_{\mathcal{R}}$ with conjunction on the left-hand side of concept inclusions;

(c) the basic member $\mathcal{EL}$ of the $\mathcal{EL}$ family;

(d) the fragment $\mathcal{EL}_{\mathsf{lhs}}$ of $\mathcal{EL}$ where only concept names (but no compound concept expressions) are admitted on the right-hand side of concept inclusions.

We remark that DL-Lite$^{\exists}_{\mathcal{R}}$ is closely related to OWL 2 QL, which is based on the fragment of DL-Lite$^{\exists}_{\mathcal{R}}$ that does not allow nested existential quantification on the right-hand side of concept inclusions. In this more restricted case, though, polynomial learnability is uninteresting. In fact, the number of concept inclusions formulated in a fixed finite vocabulary Σ is bounded polynomially in the size of Σ instead of being infinite as in the description logics studied in this paper; consequently, TBoxes are trivially learnable in polynomial time, even when only membership queries (but no equivalence queries) are available or vice versa. The extension DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ of DL-Lite$^{\exists}_{\mathcal{R}}$ is not part of the OWL 2 QL standard, but admitting conjunctions on the left-hand side of concept inclusions is a useful and widely considered extension of basic DL-Lite dialects (Artale et al., 2009). $\mathcal{EL}_{\mathsf{lhs}}$ is a significant part

Not polynomial query learnable	⋯›	$\mathcal{EL}$
Polynomial query learnable	⋯›	DL-Lite$^{\exists}_{\mathcal{R}}$ DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$
Polynomial time learnable	⋯›	$\mathcal{EL}_{\mathsf{rhs}}$ $\mathcal{EL}_{\mathsf{lhs}}$

Figure 1: Summary of main results

of the OWL 2 RL language and can be viewed as a natural fragment of Datalog. An even better approximation of OWL 2 RL would be the extension of $\mathcal{EL}_{\mathsf{lhs}}$ with inverse roles, but polynomial learnability in that language remains an open problem. And finally, unrestricted $\mathcal{EL}$ can be viewed as a logical core of the OWL 2 EL language.

After introducing preliminaries in Section 2, we study exact learning of DL-Lite$^{\exists}_{\mathcal{R}}$ ontologies in Section 3, establishing polynomial query learnability. We strengthen this result to DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ in Section 4, using a significantly more subtle algorithm. It remains open whether DL-Lite$^{\exists}_{\mathcal{R}}$ and DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ admit polynomial time learnability. Our algorithms do not yield such a stronger result since they use subsumption checks to analyse counterexamples provided by the oracle and to integrate them into the current hypothesis ontology, and subsumption is NP-complete in these DLs (Kikot et al., 2011). In Section 5, we show that $\mathcal{EL}_{\mathsf{lhs}}$ ontologies are learnable in polynomial time, a result that extends the known polynomial time learnability of propositional Horn formulas (Angluin et al., 1992), which correspond to $\mathcal{EL}$ ontologies without existential restrictions. In fact, our algorithms take inspiration from learning algorithms for propositional Horn formulas and combine the underlying ideas with modern concepts from DL such as canonical models, simulations, and products. The algorithm for $\mathcal{EL}_{\mathsf{lhs}}$ also uses subsumption checks, which in this case does not get in the way of polynomial time learnability since subsumption in $\mathcal{EL}_{\mathsf{lhs}}$ can be decided in polynomial time.

In Section 6, we then establish that $\mathcal{EL}$ ontologies are not polynomial query learnable. Note that the fragment $\mathcal{EL}_{\mathsf{rhs}}$ of $\mathcal{EL}$, which is symmetric to $\mathcal{EL}_{\mathsf{lhs}}$ and only admits concept names on the *left*-hand side of concept inclusions is a fragment of DL-Lite$^{\exists}_{\mathcal{R}}$. Together, our upper bounds for DL-Lite$^{\exists}_{\mathcal{R}}$ and $\mathcal{EL}_{\mathsf{lhs}}$ thus establish that failure of polynomial query learnability of $\mathcal{EL}$ ontologies is caused by the interaction between existential restrictions on the left- and right-hand sides of concept inclusions. Interestingly, our result already applies to acyclic $\mathcal{EL}$ TBoxes, which disallow recursive definitions of concepts and are of a rather restricted syntactic form. However, the result does rely on concept inclusions as counterexamples that are of a form not allowed in acyclic TBoxes. We also show that ontologies formulated in DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ and in $\mathcal{EL}_{\mathsf{lhs}}$ are neither polynomial query learnable with membership queries alone nor with equivalence queries alone; corresponding results for propositional Horn formulas are well known (Frazier and Pitt, 1993; Angluin et al., 1992; Angluin, 1987a; Arias and Balcázar, 2011). Figure 1 summarises the main results obtained in this paper.

In Section 7 we provide an extensive discussion of related work on the exact learning of logical formulas and theories, and we close the paper with a discussion of open problems. A small number of proofs are deferred to an appendix.

2. Preliminaries

We introduce the description logics studied in this paper, then consider a representation of concept expressions in terms of labelled trees and show how important semantic notions such as subsumption between concept expressions can be characterised by homomorphisms between the corresponding trees. This also involves introducing canonical models, which are an important tool throughout the paper. Finally, we formally introduce the framework of exact learning.

2.1 Description Logics

Let $\mathsf{N_C}$ be a countably infinite set of *concept names* (denoted by upper case letters A, B, etc) and let $\mathsf{N_R}$ be a countably infinite set of *role names* disjoint from $\mathsf{N_C}$ (denoted by lower case letters r, s, etc). Concept and role names can be regarded as unary and binary predicates, respectively. In description logic, constructors are used to define compound concept and role expressions from concept and role names. In this paper, the only role constructor is the inverse role constructor: for $r \in \mathsf{N_R}$, the expression r^- is the *inverse role* of r. Semantically, r^- represents the converse of the binary relation r. A *role expression* is a role name or an inverse role. We set $r^- := s$ if $r = s^-$ for a role name s. For brevity, we will typically speak of *roles* rather than of role expressions. The concept constructors used in this paper are $\top$ (*everything*), $\sqcap$ (*conjunction*), and $\exists r.C$ (*qualified existential restriction*). Formally, *concept expressions* C are defined according to the following syntactic rule:

$$C, D \quad := \quad \top \quad | \quad A \quad | \quad C \sqcap D \quad | \quad \exists r.C$$

where A is a concept name and r is a role. For example, $\exists \mathsf{hasChild}.\top \sqcap \exists \mathsf{gender}.\mathsf{Male}$ denotes the class of individuals who have a child and whose gender is male.

Terminological knowledge is captured by finite sets of *inclusions* between concept expressions or roles. Specifically,

- a *concept inclusion (CI)* takes the form $C \sqsubseteq D$, where C and D are concept expressions, and
- a *role inclusion (RI)* takes the form $r \sqsubseteq s$, where r and s are roles.

An *ontology* or *TBox* is a finite set of CIs and RIs.[1] We use $C \equiv D$ as an abbreviations for the two CIs $C \sqsubseteq D$ and $D \sqsubseteq C$ and likewise for $r \equiv s$; we speak of *concept equivalences (CEs)* and *role equivalences (REs)*, respectively.

1. In the description logic literature, CIs of the form introduced here are often called $\mathcal{ELI}$ CIs to distinguish them from CIs that use concept expressions formulated in other description logics. The TBoxes are called $\mathcal{ELIH}$ TBoxes (TBoxes that consist of $\mathcal{ELI}$ CIs and RIs).

Example 1 *Consider the following TBox:*

$$\begin{aligned}
\mathsf{Prof} &\sqsubseteq \exists \mathsf{supervisor_of}.\mathsf{Student} \sqcap \exists \mathsf{conduct_research}.\top && (1)\\
\mathsf{Graduate} &\equiv \exists \mathsf{has_degree}.\top && (2)\\
\mathsf{GraduateStudent} &\equiv \mathsf{Student} \sqcap \mathsf{Graduate} && (3)\\
\mathsf{GraduateStudent} &\sqsubseteq \exists \mathsf{supervisor_of}^-.\mathsf{Prof} && (4)\\
\mathsf{supervisor_of} &\sqsubseteq \mathsf{advisor_of} && (5)\\
\mathsf{CS_Graduate} &\equiv \exists \mathsf{has_degree}.\mathsf{CS_Degree} && (6)
\end{aligned}$$

The CI in Line 1 states that every professor supervises students and conducts research. Notice that we do not specify the specific area of research, hence we use an unqualified existential restriction of the form $\exists r.\top$. The CE in Line 2 defines a graduate as anyone who has a degree. The CE in Line 3 defines a graduate student as a student who is a graduate. The CI in Line 4 states that graduate students are supervised by professors. Notice that we use the inverse role of supervisor_of *here. Line 5 shows an RI which states that every supervisor is an advisor. The CE in the last line defines a computer science graduate as someone with a degree in computer science.*

A *signature* is a set of concept and role names and we use $\Sigma_{\mathcal{T}}$ to denote the signature of the TBox $\mathcal{T}$, that is, the set of concept and role names that occur in it. The *size* $|C|$ of a concept expression C is the length of the string that represents C, where concept names and role names are considered to be of length one. The *size* $|\mathcal{T}|$ of a TBox $\mathcal{T}$ is defined as $\sum_{C \sqsubseteq D \in \mathcal{T}} |C| + |D|$.

The semantics of concept expressions and TBoxes is defined as follows (Baader et al., 2017). An *interpretation* $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$ is given by a non-empty set $\Delta^{\mathcal{I}}$ (the *domain* of $\mathcal{I}$) and a mapping $\cdot^{\mathcal{I}}$ that maps every concept name A to a subset $A^{\mathcal{I}}$ of $\Delta^{\mathcal{I}}$ and every role name r to a subset $r^{\mathcal{I}}$ of $\Delta^{\mathcal{I}} \times \Delta^{\mathcal{I}}$. The *interpretation* $r^{\mathcal{I}}$ of an inverse role $r = s^-$ is given by $r^{\mathcal{I}} = \{(d, d') \mid (d', d) \in s^{\mathcal{I}}\}$ and the *interpretation* $C^{\mathcal{I}}$ of a concept expression C is defined inductively by

$$\begin{aligned}
\top^{\mathcal{I}} &= \Delta^{\mathcal{I}}\\
(C_1 \sqcap C_2)^{\mathcal{I}} &= C_1^{\mathcal{I}} \cap C_2^{\mathcal{I}}\\
(\exists r.C)^{\mathcal{I}} &= \{d \in \Delta^{\mathcal{I}} \mid \text{there exists } d' \in C^{\mathcal{I}} \text{ with } (d, d') \in r^{\mathcal{I}}\}.
\end{aligned}$$

An interpretation $\mathcal{I}$ *satisfies* a concept expression C if $C^{\mathcal{I}}$ is not empty. It satisfies the CI $C \sqsubseteq D$ if $C^{\mathcal{I}} \subseteq D^{\mathcal{I}}$, written as $\mathcal{I} \models C \sqsubseteq D$. Similarly, $\mathcal{I}$ satisfies RI $r \sqsubseteq s$ if $r^{\mathcal{I}} \subseteq s^{\mathcal{I}}$, written as $\mathcal{I} \models r \sqsubseteq s$. $\mathcal{I}$ is a *model of a TBox* $\mathcal{T}$ if it satisfies all CIs and RIs in $\mathcal{T}$. A TBox $\mathcal{T}$ *entails* a CI or RI α, in symbols $\mathcal{T} \models \alpha$, if α is satisfied in every model of $\mathcal{T}$. Concept expressions C and D are *equivalent w.r.t.* $\mathcal{T}$, written $\mathcal{T} \models C \equiv D$, if $\mathcal{T} \models C \sqsubseteq D$ and $\mathcal{T} \models D \sqsubseteq C$; equivalence of roles r and s is defined accordingly, written $\mathcal{T} \models s \equiv r$. TBoxes $\mathcal{T}$ and $\mathcal{T}'$ are *logically equivalent*, in symbols $\mathcal{T} \equiv \mathcal{T}'$, if $\mathcal{T} \models \alpha$ for all $\alpha \in \mathcal{T}'$ and vice versa.

JMLR 18(201):1-63, 2018

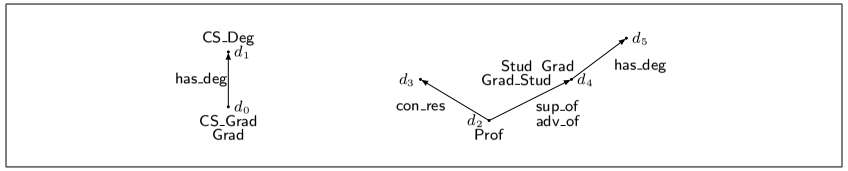

Figure 2: Illustration to Example 2.

Example 2 *Consider the TBox $\mathcal{T}$ from Example 1 and the interpretation $\mathcal{I}$ that is illustrated in Figure 2 and defined by setting $\Delta^{\mathcal{I}} = \{d_0, \ldots, d_5\}$ and*

$$\begin{aligned}
\mathsf{Prof}^{\mathcal{I}} &= \{d_2\}, & \mathsf{conduct_research}^{\mathcal{I}} &= \{(d_2, d_3)\}\\
\mathsf{Student}^{\mathcal{I}} &= \{d_4\}, & \mathsf{supervisor_of}^{\mathcal{I}} &= \{(d_2, d_4)\},\\
\mathsf{Graduate_Student}^{\mathcal{I}} &= \{d_4\}, & \mathsf{advisor_of}^{\mathcal{I}} &= \{(d_2, d_4)\},\\
\mathsf{Graduate}^{\mathcal{I}} &= \{d_4, d_0\}, & \mathsf{has_degree}^{\mathcal{I}} &= \{(d_4, d_5), (d_0, d_1)\},\\
\mathsf{CS_Graduate}^{\mathcal{I}} &= \{d_0\}, & \mathsf{CS_Degree}^{\mathcal{I}} &= \{d_1\}.
\end{aligned}$$

It is easy to see that $\mathcal{I}$ is a model of $\mathcal{T}$. Moreover, $\mathcal{I} \not\models \mathsf{Graduate} \sqsubseteq \mathsf{CS\_Graduate}$ as $\mathsf{Graduate}^{\mathcal{I}} = \{d_4, d_0\}$ but $\mathsf{CS\_Graduate}^{\mathcal{I}} = \{d_0\}$, thus $\mathcal{T} \not\models \mathsf{Graduate} \sqsubseteq \mathsf{CS\_Graduate}$. It can be shown that $\mathcal{T} \models \mathsf{CS\_Graduate} \sqsubseteq \mathsf{Graduate}$.

It is ExpTime-complete to decide, given a TBox $\mathcal{T}$ and a concept inclusion $C \sqsubseteq D$, whether $\mathcal{T} \models C \sqsubseteq D$ (Baader et al., 2008); this reasoning problem is known as *subsumption*. Because of this high complexity, the profiles of OWL 2 are based on syntactically more restricted description logics in which subsumption is less complex. We next introduce a few relevant such logics. A *basic concept* is a concept name or a concept expression of the form $\exists r.\top$, where r is a role. For example, $\exists \mathsf{hasChild}^-.\top$ is a basic concept, but $\exists \mathsf{hasChild}^-.\mathsf{Graduate}$ is not.

DL-Lite$^{\exists}_{\mathcal{R}}$. A *DL-Lite$^{\exists}_{\mathcal{R}}$ CI* takes the form

$$B \sqsubseteq C$$

where B is a basic concept and C is a concept expression. A *DL-Lite$^{\exists}_{\mathcal{R}}$ inclusion* is a DL-Lite$^{\exists}_{\mathcal{R}}$ CI or an RI. A *DL-Lite$^{\exists}_{\mathcal{R}}$ TBox* is a finite set of DL-Lite$^{\exists}_{\mathcal{R}}$ inclusions.

Example 3 *Lines* (1), (4), *and* (5) *of Example 1 are DL-Lite$^{\exists}_{\mathcal{R}}$ inclusions and Line* (2) *abbreviates the two DL-Lite$^{\exists}_{\mathcal{R}}$ CIs* $\mathsf{Graduate} \sqsubseteq \mathsf{has\_degree}.\top$ *and* $\mathsf{has\_degree}.\top \sqsubseteq \mathsf{Graduate}$. *Lines* (3) *and* (6) *do not fall within DL-Lite$^{\exists}_{\mathcal{R}}$.*

DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$. In the extension DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ of DL-Lite$^{\exists}_{\mathcal{R}}$, CIs take the form

$$B_1 \sqcap \cdots \sqcap B_n \sqsubseteq C$$

where $B_1, \ldots, B_n$ are basic concepts and C is a concept expression. A *DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ TBox* $\mathcal{T}$ is a finite set of DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ CIs and RIs. Both DL-Lite$^{\exists}_{\mathcal{R}}$ and DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ have been investigated in detail (Artale et al., 2009).

Example 4 *As Lines* (1), (2), (4) *and* (5) *from Example 1 fall within DL-Lite$^{\exists}_{\mathcal{R}}$, they also fall within DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$. Line* (3) *falls within DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$. Line* (6) *is not in DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$.*

$\mathcal{EL}$. An $\mathcal{EL}$ *concept expression* is a concept expression that does not use inverse roles. An $\mathcal{EL}$ *concept inclusion* is a CI of the form

$$C \sqsubseteq D$$

where C and D are $\mathcal{EL}$ concept expressions. An $\mathcal{EL}$ *TBox* is a finite set of $\mathcal{EL}$ CIs. Thus, $\mathcal{EL}$ does neither admit role inclusions nor inverse roles. In contrast to DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$, however, it allows existential restrictions $\exists r.C$ with $C \neq \top$ on the left-hand side of CIs.

Example 5 *Inclusions* (1), (2), (3) *and* (6) *from Example 1 are $\mathcal{EL}$ inclusions. Inclusion* (5) *is not an $\mathcal{EL}$ inclusion.*

Subsumption is NP-complete in DL-Lite$^{\exists}_{\mathcal{R}}$ and in DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ (Kikot et al., 2011; Calvanese et al., 2007; Artale et al., 2009). Subsumption in $\mathcal{EL}$ is in PTime (Baader et al., 2005) and this is still true if RIs that do not use inverse roles are admitted in the TBox. Given a TBox $\mathcal{T}$ and an RI $r \sqsubseteq s$, deciding whether $\mathcal{T} \models r \sqsubseteq s$ is possible in PTime in all description logics considered in this paper. In fact, $\mathcal{T} \models r \sqsubseteq s$ if, and only if, there exists a sequence $r_0, \ldots, r_n$ of roles such that $r = r_0$, $s = r_n$, and for every $i < n$ either $r_i \sqsubseteq r_{i+1} \in \mathcal{T}$ or $r_i^- \sqsubseteq r_{i+1}^- \in \mathcal{T}$. Our learning algorithms will carry out various subsumption checks as a subprocedure, as detailed later on.

2.2 Tree Representation of Concept Expressions

To achieve an elegant and succinct exposition of our learning algorithms, it will be convenient to represent concept expressions C as a finite directed tree T_C whose nodes are labelled with sets of concept names and whose edges are labelled with roles, and to describe manipulations of concept expressions in terms of manipulations of the corresponding tree such as merging nodes, replacing subgraphs, modifying node and edge labels, etc. We generally use ρ_C to denote the root node of the tree T_C. In detail, T_C is defined as follows. For $C = \top$, the tree T_C has a single node d with label $l(d) = \emptyset$; if $C = A$, where A is a concept name, then T_C has a single node d with $l(d) = \{A\}$; if $C = \exists r.D$, then T_C is obtained from T_D by adding a new root d_0 and an edge from d_0 to the root d of T_D with label $l(d_0, d) = r$ (we then call d an *r-successor* of d_0); if $C = D_1 \sqcap D_2$, then T_C is obtained by identifying the roots of T_{D_1} and T_{D_2}.

Example 6 *For $C = \mathsf{Student} \sqcap \exists \mathsf{has\_degree}.\exists \mathsf{has\_degree}^-.\mathsf{Graduate\_Student}$, T_C has three nodes, e_0, e_1, e_2, where e_0 is the root ρ_C of T_C, e_1 is a successor of e_0 and e_2 is a successor of e_1, the labelling of the nodes is given by $l(e_0) = \{\mathsf{Student}\}$, $l(e_1) = \emptyset$, and $l(e_2) = \{\mathsf{Graduate\_Student}\}$, and the labelling of the edges is given by $l(e_0, e_1) = \mathsf{has\_degree}$ and $l(e_1, e_2) = \mathsf{has\_degree}^-$, see Figure 3 (left).*

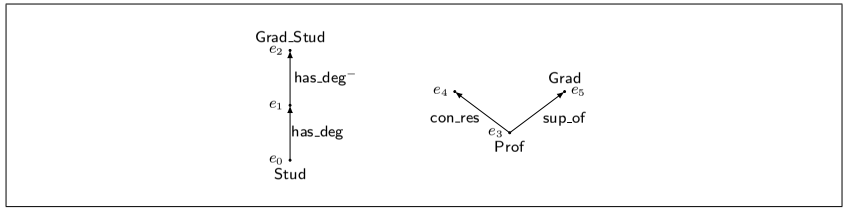

Figure 3: Illustration to Examples 6 (left) and 7 (right).

Conversely, every labelled finite directed tree T of the described form gives rise to a concept expression C_T in the following way: if T has a single node d labelled by $\{A_1, \dots, A_n\}$, then $C_T = A_1 \sqcap \dots \sqcap A_n$ (we treat $\top$ as the empty conjunction here, so if $l(d) = \emptyset$ then $C_T = \top$). Inductively, let d be the root of T labelled with $l(d) = \{A_1, \dots, A_n\}$, let $d_1, \dots, d_m$ be the successors of d, and let $l(d, d_1) = r_1, \dots, l(d, d_m) = r_m$. Assume $C_{d_1}, \dots, C_{d_m}$ are the concept expressions corresponding to the subtrees of T with roots $d_1, \dots, d_m$, respectively. Then $C_T = A_1 \sqcap \dots \sqcap A_n \sqcap \exists r_1.C_{d_1} \sqcap \dots \sqcap \exists r_m.C_{d_m}$.

Example 7 *Let T be the tree with root e_3 labelled by $\{\mathsf{Prof}\}$ and successors e_4, e_5 labelled by $\emptyset$ and $\{\mathsf{Graduate}\}$, respectively, and with edge labelling given by $l(e_3, e_4) = \mathsf{conduct\_research}$ and $l(e_3, e_5) = \mathsf{supervisor\_of}$. Then*

$$C_T = \mathsf{Prof} \sqcap \exists \mathsf{conduct\_research}.\top \sqcap \exists \mathsf{supervisor\_of}.\mathsf{Graduate};$$

see Figure 3 (right).

In what follows, we will not always distinguish explicitly between C and its tree representation T_C which allows us to speak, for example, about the nodes and subtrees of a concept expression.

One important use of the tree representation of concept expressions is that both the truth relation '$d \in C^{\mathcal{I}}$' and the entailment '$\mathcal{T} \models C \sqsubseteq D$' can be characterised in terms of homomorphisms between labelled trees and interpretations. A mapping h from a tree T_C corresponding to a concept expression C to an interpretation $\mathcal{I}$ is a *homomorphism* if $A \in l(d)$ implies $h(d) \in A^{\mathcal{I}}$ for every concept name A and $r = l(d, d')$ implies $(h(d), h(d')) \in r^{\mathcal{I}}$ for all role names r. The following characterisation of the truth relation $d \in C^{\mathcal{I}}$ by means of homomorphisms is well-known.

Lemma 8 *Let $\mathcal{I}$ be an interpretation, $d \in \Delta^{\mathcal{I}}$, and C a concept expression. Then $d \in C^{\mathcal{I}}$ if, and only if, there is a homomorphism from T_C to $\mathcal{I}$ mapping ρ_C to d.*

The proof is by a straightforward induction on the structure of C (Baader et al., 1999).

Example 9 *Consider the interpretation $\mathcal{I}$ from Example 2 and the tree representations of the concept expressions given in Figure 3. It can be seen that functions g and h defined as $g(e_0) = d_4$, $g(e_1) = d_5$, $g(e_2) = d_4$ and $h(e_3) = d_2$, $h(e_4) = d_3$, $h(e_5) = d_4$ are homomorphisms and so, by Lemma 8, $d_4 \in (\mathsf{Student} \sqcap \exists \mathsf{has\_degree}.\exists \mathsf{has\_degree}^-.\mathsf{Graduate\_Student})^{\mathcal{I}}$ and $d_2 \in (\mathsf{Prof} \sqcap \exists \mathsf{conduct\_research}.\top \sqcap \exists \mathsf{supervisor\_of}.\mathsf{Graduate})^{\mathcal{I}}$.*

It is also standard to characterise the subsumption relation $\emptyset \models C \sqsubseteq D$ (that is, subsumption relative to the empty TBox) by means of homomorphisms between the tree representations T_D and T_C. A *homomorphism* h from labelled tree T_1 to labelled tree T_2 is a mapping from the nodes of T_1 to the nodes of T_2 such that $A \in l(d)$ implies $A \in l(h(d))$ for every concept name A and $r = l(d, d')$ implies $r = l(h(d), h(d'))$ for every role r.

Lemma 10 *Let C and D be concept expressions. Then $\emptyset \models C \sqsubseteq D$ if, and only if, there is a homomorphism from T_D to T_C that maps ρ_D to ρ_C.*

The 'if' direction is essentially a consequence of Lemma 8 and the fact that the composition of two homomorphisms is again a homomorphism. For the 'only if' direction, one can consider T_C as an interpretation $\mathcal{I}$ and apply Lemma 8 (Baader et al., 1999).

Next, we characterise subsumption in the presence of TBoxes in terms of homomorphisms. To achieve this, we make use of the *canonical model* $\mathcal{I}_{C_0,\mathcal{T}}$ of a concept expression C_0 and a TBox $\mathcal{T}$. If $\mathcal{T} = \emptyset$, then we want $\mathcal{I}_{C_0,\mathcal{T}}$ to be T_{C_0} viewed as a tree-shaped interpretation which we denote by $\mathcal{I}_{C_0}$ rather than by $\mathcal{I}_{C_0,\mathcal{T}}$. More precisely, the domain of $\mathcal{I}_{C_0}$ is the set of nodes of T_{C_0} and

$$\begin{aligned} d \in A^{\mathcal{I}_{C_0}} \quad &\text{iff} \quad A \in l(d), \text{ for all } d \in \Delta^{\mathcal{I}_{C_0}} \text{ and concept names } A \\ (d, d') \in r^{\mathcal{I}_{C_0}} \quad &\text{iff} \quad r = l(d, d'), \text{ for all } d, d' \in \Delta^{\mathcal{I}_{C_0}} \text{ and roles names } r \end{aligned}$$

We call the root ρ_{C_0} of T_{C_0} the *root of* $\mathcal{I}_{C_0}$. If $\mathcal{T} \neq \emptyset$, then $\mathcal{I}_{C_0,\mathcal{T}}$ is obtained by extending $\mathcal{I}_{C_0}$ so that the CIs in $\mathcal{T}$ are satisfied. For example, if $\mathcal{T} = \{A \sqsubseteq \exists r.B\}$ and $C_0 = A$, then $\mathcal{I}_{C_0}$ is a single node ρ_{C_0} with $A^{\mathcal{I}_{C_0}} = \{\rho_{C_0}\}$ and $X^{\mathcal{I}_{C_0}} = \emptyset$ for all concept and role names X distinct from A. To define $\mathcal{I}_{C_0,\mathcal{T}}$ we add a node d to $\Delta^{\mathcal{I}_{C_0}}$ and set $B^{\mathcal{I}_{C_0,\mathcal{T}}} = \{d\}$ and $r^{\mathcal{I}_{C_0,\mathcal{T}}} = \{(\rho_{C_0}, d)\}$. In general, $\mathcal{I}_{C_0,\mathcal{T}}$ is defined as the limit of a sequence $\mathcal{I}_0, \mathcal{I}_1, \dots$ of interpretations, where $\mathcal{I}_0 = \mathcal{I}_{C_0}$. For the inductive definition of the sequence, assume that $\mathcal{I}_n$ has been defined. Then obtain $\mathcal{I}_{n+1}$ by applying one of the following rules once:

1. if $C \sqsubseteq D \in \mathcal{T}$ and $d \in C^{\mathcal{I}_n}$ but $d \notin D^{\mathcal{I}_n}$, then take the interpretation $\mathcal{I}_D$ and add it to $\mathcal{I}_n$ by identifying its root ρ_C with d. In more detail, assume that $\Delta^{\mathcal{I}_n} \cap \Delta^{\mathcal{I}_C} = \{d\}$ and $d = \rho_C$ and define $\mathcal{I}_{n+1}$ by setting, for all concept names A and role names r:

$$\Delta^{\mathcal{I}_{n+1}} = \Delta^{\mathcal{I}_n} \cup \Delta^{\mathcal{I}_C}, \quad A^{\mathcal{I}_{n+1}} = A^{\mathcal{I}_n} \cup A^{\mathcal{I}_C}, \quad r^{\mathcal{I}_{n+1}} = r^{\mathcal{I}_n} \cup r^{\mathcal{I}_C};$$

2. if $r \sqsubseteq s \in \mathcal{T}$ and $(d, d') \in r^{\mathcal{I}_n}$ but $(d, d') \notin s^{\mathcal{I}_n}$, then define $\mathcal{I}_{n+1}$ as $\mathcal{I}_n$ except that $s^{\mathcal{I}_{n+1}} := s^{\mathcal{I}_n} \cup \{(d, d')\}$ if s is a role name; otherwise there is a role name s_0 with $s = s_0^-$ and we define $\mathcal{I}_{n+1}$ as $\mathcal{I}_n$ except that $s_0^{\mathcal{I}_{n+1}} = s_0^{\mathcal{I}_n} \cup \{(d', d)\}$.

We assume that rule application is fair, that is, if a rule is applicable in a certain place, then it will indeed eventually be applied there. If for some $n > 0$ no rule is applicable then we set $\mathcal{I}_{n+1} = \mathcal{I}_n$. We obtain $\mathcal{I}_{C_0,\mathcal{T}}$ by setting for all concept names A and role names r:

$$\Delta^{\mathcal{I}_{C_0,\mathcal{T}}} = \bigcup_{n \geq 0} \Delta^{\mathcal{I}_n}, \quad A^{\mathcal{I}_{C_0,\mathcal{T}}} = \bigcup_{n \geq 0} A^{\mathcal{I}_n}, \quad r^{\mathcal{I}_{C_0,\mathcal{T}}} = \bigcup_{n \geq 0} r^{\mathcal{I}_n}.$$

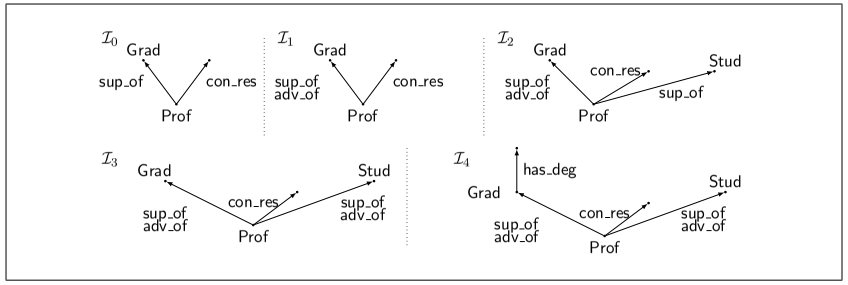

Figure 4: Canonical model construction for Example 11.

Note that the interpretation $\mathcal{I}_{C_0,\mathcal{T}}$ obtained in the limit is tree-shaped and might be infinite.[2] The following example illustrates the definition of $\mathcal{I}_{C_0,\mathcal{T}}$.

Example 11 *Consider the following TBox $\mathcal{T}$:*

$$\mathsf{Prof} \sqsubseteq \exists \mathsf{supervisor\_of}.\mathsf{Student} \quad (7)$$

$$\mathsf{Prof} \sqsubseteq \exists \mathsf{conduct\_research}.\top \quad (8)$$

$$\mathsf{Graduate} \sqsubseteq \exists \mathsf{has\_degree}.\top \quad (9)$$

$$\exists \mathsf{has\_degree}.\top \sqsubseteq \mathsf{Graduate} \quad (10)$$

$$\mathsf{supervisor\_of} \sqsubseteq \mathsf{advisor\_of} \quad (11)$$

and the concept expression

$$C_0 = \mathsf{Prof} \sqcap \exists \mathsf{conduct\_research}.\top \sqcap \exists \mathsf{supervisor\_of}.\mathsf{Graduate}.$$

Figure 4 illustrates the steps of the canonical model construction with $\mathcal{I}_0$ being $\mathcal{I}_{C_0}$ and $\mathcal{I}_4$ being the canonical model $\mathcal{I}_{C_0,\mathcal{T}}$.

The following lemma provides the announced characterisation of subsumption in the presence of TBoxes.

Lemma 12 *Let $\mathcal{T}$ be a TBox and C a concept expression. Then $\mathcal{I}_{C,\mathcal{T}}$ is a model of $\mathcal{T}$ and the following conditions are equivalent, for every concept expression D:*

1. *$\mathcal{T} \models C \sqsubseteq D$;*
2. *$\rho_C \in D^{\mathcal{I}_{C,\mathcal{T}}}$;*
3. *there is a homomorphism from T_D to $\mathcal{I}_{C,\mathcal{T}}$ that maps ρ_D to ρ_C.*

2. The exact shape of $\mathcal{I}_{C_0,\mathcal{T}}$ depends on the order of rule applications. However, all possible resulting interpretations $\mathcal{I}_{C_0,\mathcal{T}}$ are homomorphically equivalent and, as a consequence, the order of rule application is not important for our purposes.

The proof is completely standard, see, for example, the introduction by Krötzsch (2012). We only give a high-level overview. Using the construction of $\mathcal{I}_{C,\mathcal{T}}$, it is not hard to show that $\mathcal{I}_{C,\mathcal{T}}$ is a model of $\mathcal{T}$ and that $\rho_C \in C^{\mathcal{I}_{C,\mathcal{T}}}$. This implies '1 $\Rightarrow$ 2' and '2 $\Rightarrow$ 3' follows from Lemma 8. For '3 $\Rightarrow$ 1', one can show that for any model $\mathcal{I}$ of $\mathcal{T}$ and any $d \in C^{\mathcal{I}}$, there is a homomorphism from $\mathcal{I}_{C,\mathcal{T}}$ to $\mathcal{I}$ that maps ρ_C to d. In fact, one constructs a homomorphism to $\mathcal{I}$ from each of the interpretations $\mathcal{I}_0, \mathcal{I}_1, \ldots$ built during the construction of $\mathcal{I}_{C,\mathcal{T}}$, which is not hard by analysing the rules applied during that construction. The homomorphism built for each $\mathcal{I}_{n+1}$ extends that for $\mathcal{I}_n$ and thus we can take the unions of all those homomorphisms to obtain a homomorphism from $\mathcal{I}_{C,\mathcal{T}}$ to $\mathcal{I}$. It remains to compose homomorphisms and apply Lemma 8.

We are only going to use canonical models and Lemma 12 in the context of DL-Lite$^{\exists}_{\mathcal{R}}$ and DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$. Next, we identify a more subtle property of canonical models of DL-Lite$^{\exists}_{\mathcal{R}}$ and DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ TBoxes that we need later on. Very roughly speaking, it states a form of locality which is due to the fact that existential restrictions on the left-hand side of CIs in DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ are unqualified. Assume that $d \in (\exists r.D)^{\mathcal{I}_{C,\mathcal{T}}}$ for the canonical model $\mathcal{I}_{C,\mathcal{T}}$ of a concept expression C and TBox $\mathcal{T}$. Assume $d \in \Delta^{\mathcal{I}_C}$. We know that there exists a homomorphism h from $T_{\exists r.D}$ to $\mathcal{I}_{C,\mathcal{T}}$ mapping $\rho_{\exists r.D}$ to d. Then either h maps some elements of T_D into $\Delta^{\mathcal{I}_C}$ or it maps the whole tree T_D into $\Delta^{\mathcal{I}_{C,\mathcal{T}}} \setminus \Delta^{\mathcal{I}_C}$. We are interested in the latter case. The following lemma states that if $\mathcal{T}$ is a DL-Lite$^{\exists}_{\mathcal{R}}$ TBox, then there is a basic concept B with $d \in B^{\mathcal{I}_C}$ such that $\mathcal{T} \models B \sqsubseteq \exists r.D$. Thus, the question whether $d \in (\exists r.D)^{\mathcal{I}_{C,\mathcal{T}}}$ only depends on the concept names A with $d \in A^{\mathcal{I}_C}$ and the roles r with $d \in (\exists r.\top)^{\mathcal{I}_C}$. If $\mathcal{T}$ is a DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ TBox, it might not be sufficient to take a single basic concept but at least a set of basic concepts suffices (corresponding to the fact that DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ admits conjunctions on the left-hand side of CIs). This observation does not hold for $\mathcal{EL}$ TBoxes and is ultimately the reason for the fact that one cannot polynomially learn $\mathcal{EL}$ TBoxes. The following example illustrates this observation.

Example 13 *Consider the $\mathcal{EL}$ TBox $\mathcal{T} = \{\exists r.A \sqsubseteq A, A \sqsubseteq \exists r.B\}$ and let $C = \exists r.\exists r.A$. Then $\rho_C \in (\exists r.B)^{\mathcal{I}_{C,\mathcal{T}}}$ since $\mathcal{T} \models C \sqsubseteq \exists r.B$. We therefore find a homomorphism h from $T_{\exists r.B}$ to $\mathcal{I}_{C,\mathcal{T}}$ mapping $\rho_{\exists r.B}$ to ρ_C. This homomorphism maps T_B (which has a single node only) into $\Delta^{\mathcal{I}_C} \setminus \Delta^{\mathcal{I}_{C,\mathcal{T}}}$. The only basic concept B with $\rho_C \in B^{\mathcal{I}_C}$ is $\exists r.\top$ but clearly $\mathcal{T} \not\models \exists r.\top \sqsubseteq \exists r.B$ and so the observation we sketched above does not hold for $\mathcal{EL}$.*

We present this result in a more formal way. Let T_1 and T_2 be trees with labelling functions l_1 and l_2, respectively. We call T_1 a *subtree of* T_2 if the following conditions hold: $T_1 \subseteq T_2$, l_1 is the restriction of l_2 to T_1, and if $d \in T_1$ and d' is a successor of d in T_2, then d' is a successor of d in T_1 as well. The *one-neigbourhood* $N_{\mathcal{I}_C}(d)$ *of* $d \in \Delta^{\mathcal{I}_C}$ is the set of concept names A with $d \in A^{\mathcal{I}_C}$ and basic concepts $\exists r.\top$ such that there exists $d' \in \Delta^{\mathcal{I}_C}$ with $(d, d') \in r^{\mathcal{I}_C}$.

Lemma 14 *Let $\mathcal{T}$ be a DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ TBox, $D = \exists r.D'$ and assume $h : T_D \to \mathcal{I}_{C,\mathcal{T}}$ is such that $h(\rho_D) = d \in \Delta^{\mathcal{I}_C}$ and the image of the subtree $T_{D'}$ of T_D under h is included in $\Delta^{\mathcal{I}_{C,\mathcal{T}}} \setminus \Delta^{\mathcal{I}_C}$. Then there exists $I \subseteq N_{\mathcal{I}_C}(d)$ such that $\mathcal{T} \models \bigsqcap_{E \in I} E \sqsubseteq D$. Moreover, if $\mathcal{T}$ is a DL-Lite$^{\exists}_{\mathcal{R}}$ TBox, then there exists such a set $I \subseteq N_{\mathcal{I}_C}(d)$ with a single concept.*

Proof (sketch) This property of canonical models for DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ has been proved implicitly in many papers, for example the work of Artale et al. (2009). We give a sketch. Let N be the conjunction of all $E \in N_{\mathcal{I}_C}(d)$ and assume $\mathcal{T} \not\models N \sqsubseteq D$. Consider the canonical model $\mathcal{I}_{N,\mathcal{T}}$. By definition, the one-neighbourhoods of ρ_N in $\mathcal{I}_{N,\mathcal{T}}$ and d in $\mathcal{I}_{C,\mathcal{T}}$ coincide. Now observe that the canonical model of any concept expression C_0 and TBox $\mathcal{T}$ is obtained from $\mathcal{I}_{C_0}$ by hooking tree-shaped interpretations $\mathcal{I}_d$ with root d to every d in $\mathcal{I}_{C_0}$. As in DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ the concept expressions on the left-hand side of CIs are basic concepts, the interpretations $\mathcal{I}_d$ only depend on the one-neighbourhood $N_{\mathcal{I}_{C_0}}(d)$ of d in $\mathcal{I}_{C_0}$. Thus, the tree-shaped interpretations hooked to ρ_N in $\mathcal{I}_{N,\mathcal{T}}$ and to d in $\mathcal{I}_{C,\mathcal{T}}$ coincide and the homomorphism h given in Lemma 14 provides a homomorphism $h : \mathcal{I}_D \to \mathcal{I}_N$ such that $h(\rho_D) = \rho_N$. By Lemma 12, $\mathcal{T} \models N \sqsubseteq D$. We have derived a contradiction. For DL-Lite$^{\exists}_{\mathcal{R}}$ one only requires a single member of $N_{\mathcal{I}_C}(d)$ since the left-hand side of CIs in DL-Lite$^{\exists}_{\mathcal{R}}$ consists of a single basic concept only. ❑

We close the introduction of description logics with some comments about the choice of our languages. In the DL literature it is not uncommon to consider the weaker variant DL-Lite$_{\mathcal{R}}$ of DL-Lite$^{\exists}_{\mathcal{R}}$ in which only basic concepts are admitted on the right-hand side of CIs, but compound concepts are not. This is often without loss of generality since every DL-Lite$^{\exists}_{\mathcal{R}}$ TBox can be expressed in DL-Lite$_{\mathcal{R}}$ by using additional role names; in this way, standard DL-Lite$^{\exists}_{\mathcal{R}}$ reasoning tasks such as subsumption and conjunctive query answering can be reduced in polynomial time to the corresponding tasks for DL-Lite$_{\mathcal{R}}$. Such a reduction is not possible in the framework of exact learning that we are concerned with in this paper. In fact, in contrast to DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes, TBoxes in DL-Lite$_{\mathcal{R}}$ are trivially polynomial time learnable using either membership queries only or equivalence queries only as there are only polynomially many CIs and RIs over a given signature.

2.3 Exact Learning

We introduce the relevant notation for exact learning. A *learning framework* $\mathfrak{F}$ is a triple $(X, \mathcal{L}, \mu)$, where X is a set of *examples* (also called *domain* or *instance space*), $\mathcal{L}$ is a set of *concepts*,[3] and μ is a mapping from $\mathcal{L}$ to 2^X. We say that $x \in X$ is a *positive example* for $l \in \mathcal{L}$ if $x \in \mu(l)$ and a *negative example* for l if $x \notin \mu(l)$.

We give a formal definition of polynomial query and time learnability within a learning framework. Let $\mathfrak{F} = (X, \mathcal{L}, \mu)$ be a learning framework. We are interested in the exact identification of a *target* concept representation $l \in \mathcal{L}$ by posing queries to oracles. Let $\mathsf{MEM}_{\mathfrak{F},l}$ be the oracle that takes as input some $x \in X$ and returns 'yes' if $x \in \mu(l)$ and 'no' otherwise. A *membership query* is a call to the oracle $\mathsf{MEM}_{\mathfrak{F},l}$. Similarly, for every $l \in \mathcal{L}$, we denote by $\mathsf{EQ}_{\mathfrak{F},l}$ the oracle that takes as input a *hypothesis* concept representation $h \in \mathcal{L}$ and returns 'yes' if $\mu(h) = \mu(l)$ and a *counterexample* $x \in \mu(h) \oplus \mu(l)$ otherwise, where $\oplus$ denotes the symmetric set difference. There is no assumption regarding which counterexample in $\mu(h) \oplus \mu(l)$ is chosen by the oracle. An *equivalence query* is a call to the oracle $\mathsf{EQ}_{\mathfrak{F},l}$.

A *learning algorithm* for $\mathfrak{F}$ is a deterministic algorithm that takes no input, is allowed to make queries to $\mathsf{MEM}_{\mathfrak{F},l}$ and $\mathsf{EQ}_{\mathfrak{F},l}$ (without knowing what the target l to be learned is), and that eventually halts and outputs some $h \in \mathcal{L}$ with $\mu(h) = \mu(l)$. We say that $\mathfrak{F}$ is *exact learnable* if there is a learning algorithm for $\mathfrak{F}$ and that $\mathfrak{F}$ is *polynomial query learnable* if it is exact learnable by an algorithm A such that at every step the sum of the sizes of the inputs to membership and equivalence queries made by A up to that step is bounded by a polynomial $p(|l|, |x|)$, where l is the target and $x \in X$ is the largest counterexample seen so far (Arias, 2004). Finally, $\mathfrak{F}$ is *polynomial time learnable* if it is exact learnable by an algorithm A such that at every step (we count each call to an oracle as one step of computation) of computation the time used by A up to that step is bounded by a polynomial $p(|l|, |x|)$, where $l \in \mathcal{L}$ is the target and $x \in X$ is the largest counterexample seen so far. Clearly, a learning framework $\mathfrak{F}$ that is polynomial time learnable is also polynomial query learnable.

The aim of this paper is to study learnability of description logic TBoxes. In this context, each DL L gives rise to a learning framework $(X, \mathcal{L}, \mu)$, as follows: $\mathcal{L}$ is the set of all TBoxes formulated in L, X is the set of all CIs and RIs formulated in L, and $\mu(\mathcal{T}) = \{\alpha \in X \mid \mathcal{T} \models \alpha\}$ for every $\mathcal{T} \in \mathcal{L}$. Observe that $\mu(\mathcal{T}) = \mu(\mathcal{T}')$ iff $\mathcal{T} \equiv \mathcal{T}'$, for all TBoxes $\mathcal{T}$ and $\mathcal{T}'$. We say that L *TBoxes are polynomial query learnable* if the learning framework defined by L is polynomial query learnable, and likewise for polynomial time learnability. What does not show up directly in this representation is our assumption that the signature of the target TBox is known to the learner. Note that this is a standard assumption. For example, when learning propositional Horn formulas, it is common to assume that the variables in the target formula are known to the learner.

3. Learning DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes

We prove that DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes are polynomial query learnable. If inverse roles are disallowed in CIs and RIs of the target TBox then our algorithm runs in polynomial time and thus shows that TBoxes in this restricted language are polynomial time learnable. Without this restriction, polynomial time learnability remains open.

To simplify the presentation, we make two minor assumptions about the target TBox $\mathcal{T}$. We will show later how these assumptions can be overcomed. First, we assume that $\mathcal{T}$ does not entail non-trivial role equivalences, that is, there do not exist distinct roles r and s such that $\mathcal{T} \models r \equiv s$. This allows us to avoid dealing with classes of equivalent roles, simplifying notation. The second requirement is a bit more subtle. A concept inclusion is in *reduced form* if it is between basic concepts or its left-hand side is a concept name. A TBox $\mathcal{T}$ is in *named form* if all CIs in it are in reduced form and it contains a concept name A_r such that $A_r \equiv \exists r.\top \in \mathcal{T}$, for each role r. We assume that the target TBox is in named form and that all CIs considered by the learner are in reduced form. In particular, counterexamples returned by the oracle are immediately converted into this form.

Example 15 *Although the TBox $\mathcal{T}$ from Example 11 does not entail role equivalences and all its CIs are in reduced form, it is not in named form. To fix this, we introduce concept names $A_{\mathsf{supervisor\_of}}$, $A_{\mathsf{conduct\_research}}$ and $A_{\mathsf{advisor\_of}}$ and extend $\mathcal{T}$ with the following equivalences:*

$$A_{\mathsf{supervisor\_of}} \equiv \exists \mathsf{supervisor\_of}.\top \quad (12)$$

$$A_{\mathsf{conduct\_research}} \equiv \exists \mathsf{conduct\_research}.\top \quad (13)$$

3. The similarity of this name to 'concept expression' is accidental and should not be taken to mean that these two notions are closely related. Both is standard terminology in the respective area.

JMLR 18(201):1-63, 2018

Algorithm 1 Naïve learning algorithm for DL-Lite$^{\exists}_{\mathcal{R}}$

Input: A DL-Lite$^{\exists}_{\mathcal{R}}$ TBox $\mathcal{T}$ in named form given to the oracle; $\Sigma_{\mathcal{T}}$ given to the learner.
Output: TBox $\mathcal{H}$, computed by the learner, such that $\mathcal{T} \equiv \mathcal{H}$.

1: Compute $\mathcal{H}_{basic} = \{r \sqsubseteq s \mid \mathcal{T} \models r \sqsubseteq s\} \cup \{B_1 \sqsubseteq B_2 \mid \mathcal{T} \models B_1 \sqsubseteq B_2,\ B_1, B_2 \text{ basic}\}$
2: Set $\mathcal{H}_{add} = \emptyset$
3: **while** $\mathcal{H}_{basic} \cup \mathcal{H}_{add} \not\equiv \mathcal{T}$ **do**
4: Let $A \sqsubseteq C$ be the returned positive counterexample for $\mathcal{T}$ relative to $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$
5: **if** there is $A \sqsubseteq C' \in \mathcal{H}_{add}$ **then**
6: Replace $A \sqsubseteq C'$ by $A \sqsubseteq C \sqcap C'$ in $\mathcal{H}_{add}$
7: **else**
8: Add $A \sqsubseteq C$ to $\mathcal{H}_{add}$
9: **end if**
10: **end while**
11: **return** $\mathcal{H} = \mathcal{H}_{basic} \cup \mathcal{H}_{add}$

$$A_{\mathsf{advisor\_of}} \quad \equiv \quad \exists \mathsf{advisor\_of}.\top. \tag{14}$$

Notice that Graduate *acts as a name for* $\exists$has_degree.$\top$ *so no new definition is needed for the role* has_degree. *The TBox* $\mathcal{T}' = \mathcal{T} \cup \{(12), (13), (14)\}$ *is in named form.*

To develop the learning algorithm it is instructive to start with a naïve version that does not always terminate but which can be refined to obtain the desired algorithm. This version is presented as Algorithm 1. Given the signature $\Sigma_{\mathcal{T}}$ of the target TBox $\mathcal{T}$, the learner starts with computing the set $\mathcal{H}_{basic}$ by posing to the oracle the membership query '$\mathcal{T} \models r \sqsubseteq s$?' for all $r, s \in \Sigma_{\mathcal{T}}$ and '$\mathcal{T} \models B_1 \sqsubseteq B_2$?' for all basic concept B_1, B_2 over $\Sigma_{\mathcal{T}}$. Observe that $\mathcal{T} \models \mathcal{H}_{basic}$. Then it enters the main **while** loop. Note that the condition '$\mathcal{H}_{basic} \cup \mathcal{H}_{add} \not\equiv \mathcal{T}$?' in Line 3 is implemented using an equivalence query to the oracle, and that $A \sqsubseteq C$ in Line 4 refers to the counterexample returned by the oracle in the case that equivalence does not hold. The counterexample must be positive since we maintain the invariant $\mathcal{T} \models \mathcal{H}_{basic} \cup \mathcal{H}_{add}$ throughout the run of the algorithm. If there is no CI of the form $A \sqsubseteq C'$ in $\mathcal{H}_{add}$ then $A \sqsubseteq C$ is added to $\mathcal{H}_{add}$, otherwise $A \sqsubseteq C \sqcap C'$ is (Lines 6 and 8). The algorithm terminates when $\mathcal{H}_{basic} \cup \mathcal{H}_{add} \equiv \mathcal{T}$, implying that the target TBox has been learned.

Example 16 For the TBox $\mathcal{T}'$ from Example 15, Algorithm 1 first computes $\mathcal{H}_{basic}$ which coincides with $\mathcal{T}'$ except that Prof $\sqsubseteq \exists$supervisor_of.Student is not included since the concept $\exists$supervisor_of.Student is not basic. In the main loop the only counterexamples to $\mathcal{H}_{basic} \cup \mathcal{H}_{add} \equiv \mathcal{T}'$ are (up to logical equivalence modulo $\mathcal{H}_{basic}$) the CIs

$$\mathsf{Prof} \sqsubseteq \exists \mathsf{supervisor\_of.Student}, \quad \mathsf{Prof} \sqsubseteq \exists \mathsf{advisor\_of.Student}.$$

If the oracle returns the first CI in the first iteration, the algorithm terminates immediately having learned $\mathcal{T}'$. Otherwise the oracle first returns the second CI and then returns the first CI in the second iteration. The algorithm terminates with

$$\mathcal{H}_{add} = \{\mathsf{Prof} \sqsubseteq \exists \mathsf{supervisor\_of.Student} \sqcap \exists \mathsf{advisor\_of.Student}\}$$

which is equivalent to $\mathcal{T}'$.

We now consider five examples on which this naïve algorithm fails to terminate after polynomially many steps (or at all), each example motivating a different *modification step* that is added to Algorithm 1 after Lines 4 and 5. The final, corrected algorithm is given as Algorithm 2 below. Each modification step takes as input a counterexample $A \sqsubseteq C$ against the equivalence $\mathcal{H}_{basic} \cup \mathcal{H}_{add} \equiv \mathcal{T}$ and modifies it by posing membership queries to the oracle to obtain a CI $A' \sqsubseteq C'$ which is still a counterexample and has additional desired properties. CIs satisfying all five additional properties will be called $\mathcal{T}$*-essential*. The five modification steps are of three different types:

1. two *saturations steps*: the underlying tree of T_C is left unchanged but the labelling is modified by adding concept names to node labels or replacing roles in edge labels;

2. two *merging steps*: nodes in the tree T_C are merged, resulting in a tree with fewer nodes;

3. a *decomposition step*: T_C is replaced by a subtree or a subtree is removed from T_C, and the concept name A on the left-hand side might be replaced.

The saturation and merging steps do not change the left-hand side A of the CI $A \sqsubseteq C$ and result in a logically stronger CI $A \sqsubseteq C'$ in the sense that $\emptyset \models C' \sqsubseteq C$. In contrast, the decomposition step can be regarded as a reset operation in which also the left-hand side can change and which is logically not related to $A \sqsubseteq C$. We start with an example which motivates the first saturation step.

Example 17 *Let*

$$\mathcal{T} = \{A \sqsubseteq \exists r.A\} \cup \mathcal{T}_{\text{NF}},$$

where $\mathcal{T}_{\text{NF}} = \{A_r \equiv \exists r.\top\}$ *ensures that* $\mathcal{T}$ *is in named form. First, Algorithm 1 computes* $\mathcal{H}_{basic}$*. Afterwards the oracle can provide for the n-th equivalence query in the while loop the positive counterexample* $A \sqsubseteq \exists r^{n+1}.\top$*, for any* $n \geq 1$ *(here we set inductively* $\exists r^{m+1}.\top = \exists r.\exists r^m.\top$ *and* $\exists r^1.\top = \exists r.\top$*). Thus, the algorithm does not terminate.*

Informally, the problem for the learner in Example 17 is that the concepts $\exists r^n.\top$ used in the counterexamples $A \sqsubseteq \exists r^n.\top$ get larger and larger, but still none of the counterexamples implies $A \sqsubseteq \exists r.A$. We address this problem by saturating T_C with implied concept names. For the following discussion, recall that we do not distinguish between the concept expression C and its tree representation T_C. For example, if we say that C' is obtained from C by adding a concept name B to the label of node d in C, then this stands for: C' is the concept expression corresponding to the tree obtained from T_C by adding B to the label of d in T_C.

Definition 18 (Concept saturation for $\mathcal{T}$) *A CI* $A \sqsubseteq C$ *is* concept saturated for $\mathcal{T}$ *if* $\mathcal{T} \models A \sqsubseteq C$ *and* $\mathcal{T} \not\models A \sqsubseteq C'$ *for any* C' *obtained from* C *by adding a concept name to the label of some node of* C*. A CI* $A \sqsubseteq C'$ *is a* concept saturation for $\mathcal{T}$ *of a CI* $A \sqsubseteq C$ *if it is concept saturated for* $\mathcal{T}$ *and* C' *is obtained from* C *by adding concept names to the labels of some nodes in* C*.*

Observe that the learner can compute a concept saturation $A \sqsubseteq C'$ for $\mathcal{T}$ from a counterexample $A \sqsubseteq C$ by posing polynomially many membership queries to the oracle: it simply asks for any node d in T_C and concept name $E \in \Sigma_{\mathcal{T}}$ whether $\mathcal{T} \models A \sqsubseteq C^{E,d}$, where $C^{E,d}$ is obtained from C by adding E to the label of d. If the answer is positive, it replaces C by $C^{E,d}$ and proceeds. Note that there can be several concept saturations of a given CI $A \sqsubseteq C$ for a TBox $\mathcal{T}$. Consider, for example, $\mathcal{T} = \{A \sqsubseteq \exists r.(B \sqcap \exists r.\top), A \sqsubseteq \exists r.\exists r.B\}$ and the CI $A \sqsubseteq \exists r.\exists r.\top$. Then both $A \sqsubseteq A \sqcap \exists r.(B \sqcap \exists r.\top)$ and $A \sqsubseteq A \sqcap \exists r.\exists r.B$ are concept saturations of $A \sqsubseteq \exists r.\exists r.\top$ for $\mathcal{T}$ since $\mathcal{T} \not\models A \sqsubseteq \exists r.(B \sqcap \exists r.B)$.

Example 19 (Example 17 continued) *The CIs $A \sqsubseteq \exists r^n.\top$ are not concept saturated for $\mathcal{T}$. For example, for $n = 2$, a concept saturation of $A \sqsubseteq \exists r.\exists r.\top$ for $\mathcal{T}$ is given by $A \sqsubseteq A \sqcap A_r \sqcap \exists r.(A \sqcap A_r \sqcap \exists r.(A_r \sqcap A))$ (in fact, this is the only concept saturation for $\mathcal{T}$ of $A \sqsubseteq \exists r.\exists r.\top$). Now observe that if the CI $A \sqsubseteq C$ returned by the oracle to the first equivalence query is transformed by the learner into a concept saturated CI (after Line 4), then the TBox $\mathcal{T} = \{A \sqsubseteq \exists r.A\} \cup \mathcal{T}_{\text{NF}}$ is learned in one step: the only possible counterexamples returned by the oracle to the equivalence query $\mathcal{H}_{basic} \equiv \mathcal{T}$ are of the form $A \sqsubseteq C_1 \sqcap \exists r.C_2$ for some concepts C_1 and C_2. Concept saturation results in a concept of the form $C_1' \sqcap \exists r.(A \sqcap C_2')$ and $\{A \sqsubseteq C_1' \sqcap \exists r.(A \sqcap C_2')\} \models A \sqsubseteq \exists r.A$.*

The following example motivates the second saturation step. Here and in the subsequent examples we do not transform the TBoxes into named form as this does not effect the argument and simplifies presentation.

Example 20 *Consider for $n \geq 1$ the TBoxes*

$$\mathcal{T}_n \quad = \quad \{A \sqsubseteq \exists e_1.\exists e_2. \ldots \exists e_n.\top\} \cup \{e_i \sqsubseteq r_i, e_i \sqsubseteq s_i \mid 1 \leq i \leq n\}.$$

For $M \subseteq \{1, \ldots, n\}$, set $C_M = \exists t_1.\exists t_2. \ldots \exists t_n.\top$, where $t_i = r_i$ if $i \in M$ and $t_i = s_i$ if $i \notin M$. Then for the first 2^n equivalence queries in the while loop the oracle can provide a positive counterexample $A \sqsubseteq C_M$ by always choosing a fresh set $M \subseteq \{1, \ldots, n\}$.

Intuitively, the problem for the learner in Example 20 is that there are exponentially many logically incomparable CIs that are entailed by $\mathcal{T}_n$ but do not entail $A \sqsubseteq \exists e_1.\exists e_2. \ldots \exists e_n.\top$. A step towards resolving this problem is to replace the roles r_i and s_i by the roles e_i in the counterexamples $A \sqsubseteq C_M$.

Definition 21 (Role saturation for $\mathcal{T}$) *A CI $A \sqsubseteq C$ is* role saturated for $\mathcal{T}$ *if $\mathcal{T} \models A \sqsubseteq C$ and $\mathcal{T} \not\models A \sqsubseteq C'$ for any C' obtained from C by replacing in some edge label a role r by a role $s \neq r$ with $\mathcal{T} \models s \sqsubseteq r$. A CI $A \sqsubseteq C'$ is a* role saturation for $\mathcal{T}$ *of a CI $A \sqsubseteq C$ if it is role saturated for $\mathcal{T}$ and C' is obtained from C by replacing in some edge labels a role r by a role s with $\mathcal{T} \models s \sqsubseteq r$.*

Similarly to concept saturation, the learner can compute a role saturated $A \sqsubseteq C'$ from a counterexample $A \sqsubseteq C$ by posing polynomially many membership queries. Again, there can be several role saturations of a given $A \sqsubseteq C$ for a TBox $\mathcal{T}$. For example, if

$$\mathcal{T} = \{s_1 \sqsubseteq r, s_2 \sqsubseteq r, A \sqsubseteq \exists s_1.B, A \sqsubseteq \exists s_2.B\},$$

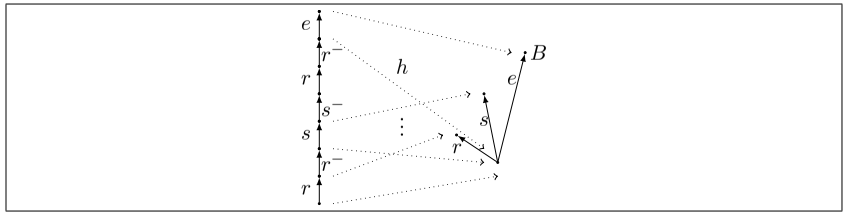

Figure 5: Tree representation of $C_{\{1,3\}}$ and homomorphism to $\exists r.\top \sqcap \exists s.\top \sqcap \exists e.B$.

then $A \sqsubseteq \exists s_1.B$ and $A \sqsubseteq \exists s_2.B$ are role saturations of $A \sqsubseteq \exists r.B$ for $\mathcal{T}$. Observe that in Example 20 the single role saturation of any $A \sqsubseteq C_M$ is $A \sqsubseteq \exists e_1.\exists e_2. \ldots \exists e_n.\top$. Thus, if the counterexample $A \sqsubseteq C_M$ returned by the first equivalence query is transformed into a role saturated CI, then the algorithm terminates after one step. We now introduce and motivate our two merging rules.

Example 22 Consider the TBox

$$\mathcal{T} = \{A \sqsubseteq \exists r.\top \sqcap \exists s.\top \sqcap \exists e.B\}.$$

and fix an $n \geq 1$. For $M \subseteq \{1, \ldots, n\}$, set $C_M = \exists t_1.\exists t_1^-.\exists t_2.\exists t_2^-. \ldots \exists t_n.\exists t_n^-.\exists e.\top$, where $t_i = r$ if $i \in M$ and $t_i = s$ if $i \notin M$. Figure 5 (left) illustrates the concept expression $C_{\{1,3\}}$, assuming $n = 3$. By Lemma 10, $\mathcal{T} \models A \sqsubseteq C_M$ since there is a homomorphism h from T_{C_M} to the labelled tree that corresponds to $\exists r.\top \sqcap \exists s.\top \sqcap \exists e.B$, as shown in Figure 5. Thus, the oracle can provide for the first 2^n equivalence queries a positive counterexample $A \sqsubseteq C_M$ by always choosing a fresh set $M \subseteq \{1, \ldots, n\}$.

The problem for the learner in Example 22 is similar to that in Example 20: there are exponentially many logically incomparable CIs that are entailed by $\mathcal{T}$ but do not entail $A \sqsubseteq \exists r.\top \sqcap \exists s.\top \sqcap \exists e.B$. A step towards solving this problem is to merge the predecessor and successor nodes of a node if the edge labels are inverse to each other and the resulting CI is still implied by the TBox.

Definition 23 (Parent/Child Merging for $\mathcal{T}$) *A concept C' is* obtained from a concept C by parent/child merging *if C' is obtained from C by choosing nodes d, d', d'' such that d is an r-successor of d', and d'' is an r^--successor of d, for some role r, and then removing d'', setting $l(d') = l(d') \cup l(d'')$, and making every s-successor e of d'' in C an s-successor of d', for any role s.*

Let $A \sqsubseteq C$ be a CI with $\mathcal{T} \models A \sqsubseteq C$. A CI $A \sqsubseteq C'$ is obtained from $A \sqsubseteq C$ by parent/child merging *if $\mathcal{T} \models A \sqsubseteq C'$ and C' is obtained from C by parent/child merging. We say that $A \sqsubseteq C$ is* parent/child merged for $\mathcal{T}$ *if there is no $A \sqsubseteq C'$ with $C \neq C'$ that can be obtained from $A \sqsubseteq C$ by parent/child merging.*

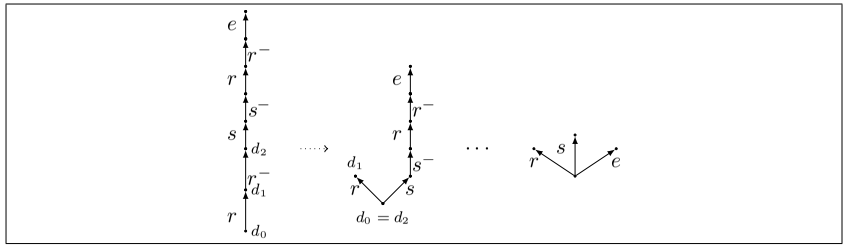

Figure 6: Parent/Child Merging of $C_{\{1,3\}}$ for $\mathcal{T}$

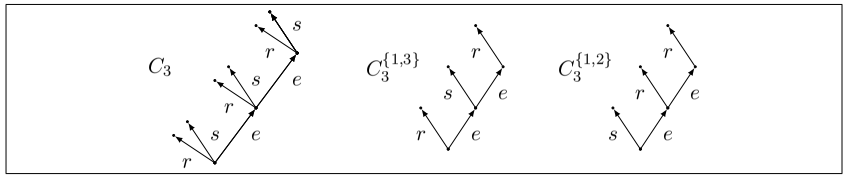

Figure 7: Tree representation of the concept expressions C_3, $C_3^{\{1,3\}}$ and $C_3^{\{1,2\}}$.

Note that when C' is obtained from C by parent/child merging with d' and d'' as in Definition 23, then $\emptyset \models C' \sqsubseteq C$. To show this, one can use Lemma 10 and the natural homomorphism h from T_C to $T_{C'}$, that is, the identity except that $h(d'') = d'$.

Similarly to the saturation operations, the learner can compute a parent/child merged $A \sqsubseteq C'$ by posing polynomially many membership queries. In Example 22 the parent/child merging of any $A \sqsubseteq C_M$ with $\emptyset \neq M \neq \{1, \dots, n\}$ is $A \sqsubseteq \exists r.\top \sqcap \exists s.\top \sqcap \exists e.\top$, as illustrated in Figure 6: in the first step the nodes d_0 and d_2 are merged, two additional merging steps give $\exists r.\top \sqcap \exists s.\top \sqcap \exists e.\top$. The following example motivates the second merging operation.

Example 24 *Define concept expressions C_i by induction as follows:*

$$C_1 = \exists r.\top \sqcap \exists s.\top, \quad C_{i+1} = C_1 \sqcap \exists e.C_i$$

and let

$$\mathcal{T}_n = \{A \sqsubseteq \exists e.C_n\}.$$

For $M \subseteq \{1, \dots, n\}$, set $C_1^M = \exists r.\top$ if $1 \in M$ and $C_1^M = \exists s.\top$ if $1 \notin M$. Also, let $C_{i+1}^M = \exists r.\top \sqcap \exists e.C_i^M$ if $i+1 \in M$ and $C_{i+1}^M = \exists s.\top \sqcap \exists e.C_i^M$ if $i+1 \notin M$, $1 \leq i < n$. Figure 7 illustrates concept expressions of the form C_n and C_n^M.

As an answer to the first 2^n equivalence queries the oracle can compute a positive counterexample $A \sqsubseteq \exists e.C_n^M$ by always choosing a fresh set $M \subseteq \{1, \dots, n\}$.

To deal with this example we introduce a modification step that identifies siblings in C rather than a parent and a child.

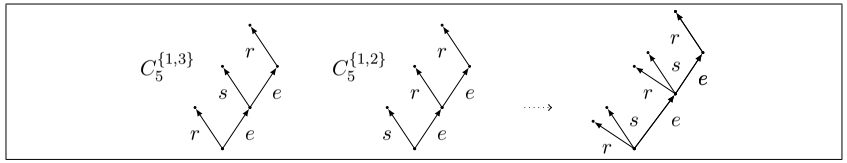

Figure 8: Sibling Merging $C_3^{\{1,3\}}$ and $C_3^{\{1,2\}}$ for $\mathcal{T}$.

Definition 25 (Sibling Merging for $\mathcal{T}$) *A concept C' is* obtained from a concept C by sibling merging *if C' is obtained from C by choosing nodes d, d', d'' such that d' and d'' are r-successors of d, for some role r, and then removing d'', setting $l(d') = l(d') \cup l(d'')$, and making every s-successor e of d'' in T_C an s-successor of d', for any role s.*

Let $A \sqsubseteq C$ be a CI with $\mathcal{T} \models A \sqsubseteq C$. A CI $A \sqsubseteq C'$ is obtained from $A \sqsubseteq C$ by sibling merging *if $\mathcal{T} \models A \sqsubseteq C'$ and C' is obtained from C by sibling merging. We say that $A \sqsubseteq C$ is* sibling merged for $\mathcal{T}$ *if there is no $A \sqsubseteq C'$ with $C \neq C'$ that can be obtained from $A \sqsubseteq C$ by sibling merging.*

It can be verified that when C' is obtained from C by sibling merging, then $\emptyset \models C' \sqsubseteq C$.

In Example 24 the counterexamples $A \sqsubseteq C_n^M$ are actually sibling merged for $\mathcal{T}_n$. Thus, producing a sibling merged $A \sqsubseteq C'$ directly from the counterexamples returned by the oracle does not overcome the problem illustrated by the example. Instead, we apply sibling merging after Line 5 of the algorithm: instead of adding $A \sqsubseteq C \sqcap C'$ to $\mathcal{H}_{add}$, the learner computes a sibling merged $A \sqsubseteq D$ from this CI and adds it to $\mathcal{H}_{add}$. For Example 24, this is illustrated in Figure 8. Clearly, after at most $n+1$ counterexamples, the learner has added $A \sqsubseteq \exists e.C_n$, as required.

Finally, we need a decomposition rule. The following variant of Example 17 illustrates that the four modification steps introduced so far do not yet lead to a polynomial learning algorithm even if they are applied both after Line 4 and after Line 5 in Algorithm 1.

Example 26 *Let*

$$\mathcal{T} = \{A \sqsubseteq B, B \sqsubseteq \exists r.B\}.$$

The oracle can provide for the n-th equivalence query the positive counterexample $A \sqsubseteq C_{B,n}$, where $C_{B,n} = A \sqcap D_{B,n}$ and, inductively, $D_{B,0} = B$ and $D_{B,n+1} = B \sqcap \exists r.D_{B,n}$, for any $n \geq 0$. The algorithm does not terminate even with the four modification steps introduced above applied after Lines 4 and 5: the CIs $A \sqsubseteq C_{B,n}$ are concept and role saturated and they are parent/child and sibling merged.

The problem illustrated in Example 26 is that so far the learning algorithm attempts to learn $\mathcal{T}$ without ever considering to add to $\mathcal{H}_{add}$ a CI whose left-hand side is B (rather than A). To deal with this problem we introduce a 'reset step' that, in contrast to the previous modification steps, can lead to a different left-hand side and also to a CI that does not imply the original CI given $\mathcal{T}$, as in all previous modification steps.

Definition 27 (Decomposed CI for $\mathcal{T}$) *Let $A \sqsubseteq C$ be a CI with $\mathcal{T} \models A \sqsubseteq C$. We say that $A \sqsubseteq C$ is* decomposed for $\mathcal{T}$ *if for every non-root node d in C, every concept name*

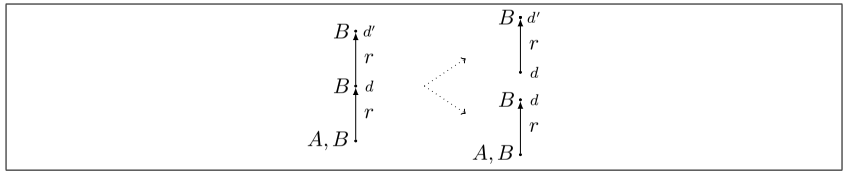

Figure 9: Illustration of decomposition of CIs. Here $C|^{-}_{d'\downarrow} = A \sqcap B \sqcap \exists r.B$ and $C' = B$.

$A' \in l(d)$, and every r-successor d' of d in C, we have $\mathcal{T} \not\models A' \sqsubseteq \exists r.C'$ where C' corresponds to the subtree of C rooted at d'.

In contrast to the previous four modification steps, the membership queries used by the learner to obtain a decomposed CI do not only depend on $\mathcal{T}$ but also on the hypothesis $\mathcal{H}_{add} \cup \mathcal{H}_{basic}$ computed up to that point: starting from CI $A \sqsubseteq C$, the learner takes a non-root node d in C, a concept name $A' \in l(d)$, and an r-successor d' of d in C, and then checks using a membership query whether $\mathcal{T} \models A' \sqsubseteq \exists r.C'$, where C' is the subtree rooted at d' in C. If the check succeeds, $A \sqsubseteq C$ is replaced by

(a) $A' \sqsubseteq \exists r.C'$ if $\mathcal{H}_{basic} \cup \mathcal{H}_{add} \not\models A' \sqsubseteq \exists r.C'$; and otherwise by

(b) $A \sqsubseteq C|^{-}_{d'\downarrow}$, where $C|^{-}_{d'\downarrow}$ is obtained from C by removing the subtree rooted in d' from C.

Note that $\{A \sqsubseteq C|^{-}_{d'\downarrow}, A' \sqsubseteq \exists r.C'\} \models A \sqsubseteq C$. Thus, one of the CIs $A \sqsubseteq C|^{-}_{d'\downarrow}$ and $A' \sqsubseteq \exists r.C'$ is not entailed by $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$, and this is the CI that replaces the original CI.

In Example 26, assume that the oracle returns $A \sqsubseteq C$ with $C = A \sqcap B \sqcap \exists r.(B \sqcap \exists r.B)$ as the first counterexample. The tree T_C corresponding to C is shown on the left-hand side of Figure 9. This CI is not decomposed for $\mathcal{T}$: the label of node d contains B, the concept C' rooted in d' in C is B and $\mathcal{T} \models B \sqsubseteq \exists r.B$. Since $\mathcal{H} \cup \mathcal{H}_{add} \not\models B \sqsubseteq \exists r.B$, Case (a) applies and $A \sqsubseteq B$ is replaced by $B \sqsubseteq \exists r.B$.

This finishes the description of the modification steps. It turns out that they cure all problems with the initial version of the algorithm and enable polynomial query learnability.

Definition 28 *A DL-Lite$^{\exists}_{\mathcal{R}}$ CI is* $\mathcal{T}$-essential *if it is concept saturated, role saturated, parent/child merged, sibling merged, and decomposed for $\mathcal{T}$.*

After Lines 4 and 5 of Algorithm 1, we need to make the CI currently considered $\mathcal{T}$-essential, by exhaustively applying the modification steps described above in all possible orders. The resulting refined version of the learning algorithm is shown as Algorithm 2. We next analyse the properties of this algorithm.

Polynomial Query Bound on the Algorithm

If Algorithm 2 terminates, then it obviously has found a TBox $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$ that is logically equivalent to $\mathcal{T}$. It thus remains to show that the algorithm terminates after polynomially many polynomial size queries. Observe that $\mathcal{H}_{add}$ contains at most one CI $A \sqsubseteq C$ for each concept name A. At each step in the while loop, either some $A' \sqsubseteq C'$ is added to $\mathcal{H}_{add}$ such

Algorithm 2 The learning algorithm for DL-Lite$^{\exists}_{\mathcal{R}}$

Input: A DL-Lite$^{\exists}_{\mathcal{R}}$ TBox $\mathcal{T}$ in named form given to the oracle; $\Sigma_{\mathcal{T}}$ given to the learner.
Output: TBox $\mathcal{H}$, computed by the learner, such that $\mathcal{T} \equiv \mathcal{H}$.

1: Compute $\mathcal{H}_{basic} = \{r \sqsubseteq s \mid \mathcal{T} \models r \sqsubseteq s\} \cup \{B_1 \sqsubseteq B_2 \mid \mathcal{T} \models B_1 \sqsubseteq B_2,\ B_1, B_2 \text{ basic}\}$
2: Set $\mathcal{H}_{add} = \emptyset$
3: **while** $\mathcal{H}_{basic} \cup \mathcal{H}_{add} \not\equiv \mathcal{T}$ **do**
4: Let $A \sqsubseteq C$ be the returned positive counterexample for $\mathcal{T}$ relative to $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$
5: Find a $\mathcal{T}$-essential CI $A' \sqsubseteq C'$ such that $\mathcal{H}_{basic} \cup \mathcal{H}_{add} \not\models A' \sqsubseteq C'$
6: **if** there is $A' \sqsubseteq C'' \in \mathcal{H}_{add}$ **then**
7: Find $\mathcal{T}$-essential CI $A' \sqsubseteq C^*$ such that $\emptyset \models C^* \sqsubseteq C'' \sqcap C'$
8: Replace $A' \sqsubseteq C''$ by $A' \sqsubseteq C^*$ in $\mathcal{H}_{add}$
9: **else**
10: Add $A' \sqsubseteq C'$ to $\mathcal{H}_{add}$
11: **end if**
12: **end while**
13: **return** $\mathcal{H} = \mathcal{H}_{basic} \cup \mathcal{H}_{add}$

that no CI with A' on the left-hand side existed in $\mathcal{H}_{add}$ before (Line 10) or an existing CI $A' \sqsubseteq C''$ in $\mathcal{H}_{add}$ is replaced by a fresh CI $A' \sqsubseteq C^*$ with $\emptyset \models C^* \sqsubseteq C''$.

We start with showing that Lines 5 and 7 can be implemented with polynomially many membership queries. The next lemma addresses Line 5.

Lemma 29 *Given a positive counterexample $A \sqsubseteq C$ for $\mathcal{T}$ relative to $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$, one can construct a $\mathcal{T}$-essential counterexample $A' \sqsubseteq C'$ using only polynomially many polynomial size membership queries in $|C| + |\mathcal{T}|$.*

Proof Let $A \sqsubseteq C$ be a positive counterexample for $\mathcal{T}$ relative to $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$ and assume the five modification steps introduced above are applied exhaustively by posing membership queries to the oracle. Observe that the number of applications of modifications steps is bounded polynomially in $|C| \times |\mathcal{T}|$. To show this, let n_C be the number of nodes in T_C. Then $n_{C''} = n_{C'}$ if $A'' \sqsubseteq C''$ is obtained from $A' \sqsubseteq C'$ by a concept or role saturation step and $n_{C''} < n_{C'}$ if $A'' \sqsubseteq C''$ is obtained from $A' \sqsubseteq C'$ by a merging or decomposition step. Thus, the number of applications of merging and decomposition steps is bounded by n_C and the number of applications of concept and role saturated steps is bounded by $|\Sigma_{\mathcal{T}}| \times n_C$ and $|\Sigma_{\mathcal{T}}| \times n_C^2$, respectively. Thus, after at most $n_C + |\Sigma_{\mathcal{T}}| \times n_C + |\Sigma_{\mathcal{T}}| \times n_C^2$ steps no modification step is applicable and the final CI is $\mathcal{T}$-essential. We verify that it is also a positive counterexample for $\mathcal{T}$ relative to $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$. It suffices to show that the CI resulting from each single modification step is entailed by $\mathcal{T}$, but not by $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$. The former has been shown when we introduced the modification steps. Regarding the latter, in the first four modification steps we have $\mathcal{H}_{basic} \models C' \sqsubseteq C$ if $A \sqsubseteq C$ is replaced by $A \sqsubseteq C'$. Hence $\mathcal{H}_{basic} \cup \mathcal{H}_{add} \not\models A \sqsubseteq C'$. For the decomposition step, we have already argued, after Definition 27, that the added CI is not entailed by $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$. ❑

The following lemma addresses Line 7.

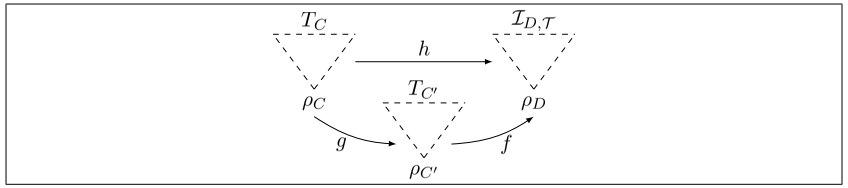

Figure 10: Homomorphisms in Lemma 31.

Lemma 30 *Assume that $A \sqsubseteq C_1$ and $A \sqsubseteq C_2$ are $\mathcal{T}$-essential. Then one can construct a $\mathcal{T}$-essential $A \sqsubseteq C$ such that $\emptyset \models C \sqsubseteq C_1 \sqcap C_2$ using polynomially many polynomial size membership queries in $|C_1| + |C_2|$.*

Proof We start with $A \sqsubseteq C_1 \sqcap C_2$. Using the fact that C_1 and C_2 are both $\mathcal{T}$-essential, one can show that this CI is (i) concept saturated for $\mathcal{T}$, (ii) role saturated for $\mathcal{T}$, (iii) parent/child merged for $\mathcal{T}$, and (iv) decomposed for $\mathcal{T}$. Assume, for example, that $A \sqsubseteq C_1 \sqcap C_2$ is not concept saturated. Then one can add a new concept name A' to the label $l(d)$ for some node d in $T_{C_1 \sqcap C_2}$ and $\mathcal{T} \models A \sqsubseteq C'$ for the resulting concept C'. Clearly d is a node in T_{C_1} or in T_{C_2}. Assume without loss of generality that d is in T_{C_1} and let C_1' be the concept obtained from C_1 by adding A' to $l(d)$. Then $\mathcal{T} \models A \sqsubseteq C_1'$ since $\mathcal{T} \models A \sqsubseteq C'$ which contradicts the assumption that $A \sqsubseteq C_1$ is concept saturated. The remaining three modification steps are considered similarly. We now exhaustively apply the modification step 'Sibling merging for $\mathcal{T}$' and use the resulting CI as the desired $A \sqsubseteq C$. Similarly to the argument above one can show that a CI with properties (i)–(iv) still has those properties after applying sibling merging. Thus, $A \sqsubseteq C$ is $\mathcal{T}$-essential. We have argued in the proof of Lemma 29 already that the number of applications of a sibling merging step to a CI of the form $A \sqsubseteq D$ is bounded by the number of nodes in T_D. Thus, the number of modification steps is bounded polynomially in $|C_1| + |C_2|$. ❑

To analyse the algorithm further we first prove a polynomial upper bound on the size of $\mathcal{T}$-essential CIs. To this end, we require the notion of an isomorphic embedding and an auxiliary lemma. A homomorphism $h : T_C \to \mathcal{I}$ is an *isomorphic embedding for* $\mathcal{T}$ if it is injective, $A \in l(d)$ if $h(d) \in A^{\mathcal{I}}$ for all concept names A, and for $r = l(d, d')$ it holds that $\mathcal{T} \models r \sqsubseteq s$ for all $(h(d), h(d')) \in s^{\mathcal{I}}$. The following lemma shows that for $\mathcal{T}$-essential CIs $A \sqsubseteq C$ and any D that interpolates between A and C (meaning that $\mathcal{T} \models A \sqsubseteq D$ and $\mathcal{T} \models D \sqsubseteq C$) the homomorphism h from T_C to $\mathcal{I}_{D,\mathcal{T}}$ that witnesses $\rho_D \in C^{\mathcal{I}_{D,\mathcal{T}}}$ (see Lemma 12) is an isomorphic embedding.

Lemma 31 *Assume the $A \sqsubseteq C$ is $\mathcal{T}$-essential, $\mathcal{T} \models A \sqsubseteq D$ and $\mathcal{T} \models D \sqsubseteq C$. Then any homomorphism $h : T_C \to \mathcal{I}_{D,\mathcal{T}}$ that maps ρ_C to ρ_D is an isomorphic embedding.*

Proof Assume first that h is not injective. Then there is a parent/child or sibling merging C' of C and a homomorphism $f : T_{C'} \to \mathcal{I}_{D,\mathcal{T}}$ such that $h = f \circ g$ for the natural homomorphism $g : T_C \to T_{C'}$ (Figure 10). By Lemma 12, $\mathcal{T} \models D \sqsubseteq C'$. Thus, $\mathcal{T} \models A \sqsubseteq C'$ and we have derived a contradiction to the assumption that C is parent/child and sibling merged.

Now let T' be the following labelled tree: the nodes in T' are the same as in T, $A \in l'(d)$ iff $h(d) \in A^{\mathcal{I}_{D,\mathcal{T}}}$, and for any two nodes d, d' with d' a successor of d: $l'(d, d') = r$ for the unique role r with $\mathcal{T} \models r \sqsubseteq s$ for all s with $(d, d') \in s^{\mathcal{I}_{D,\mathcal{T}}}$. Let C' be the concept expression that corresponds to T'. Then $\rho_D \in C'^{\mathcal{I}_{D,\mathcal{T}}}$ and so, by Lemma 12, $\mathcal{T} \models D \sqsubseteq C'$. Thus $\mathcal{T} \models A \sqsubseteq C'$. But then $A \sqsubseteq C'$ can be obtained from $A \sqsubseteq C$ by concept and role saturation steps. As $A \sqsubseteq C$ is concept and role saturated already, $C = C'$ and so h is an isomorphic embedding. ❑

We are now able to prove that $\mathcal{T}$-essential CIs are of polynomial size in $\mathcal{T}$. For a concept C, let n_C denote the number of nodes in the tree representation T_C of C and let

$$A^{\mathcal{T}} = \{A\} \cup \{B \mid A \sqsubseteq B \in \mathcal{H}_{basic}\} \cup \{D \mid \mathcal{T} \models A \sqsubseteq B, B \sqsubseteq D \in \mathcal{T}\}.$$

Lemma 32 *If $A \sqsubseteq C$ is $\mathcal{T}$-essential, then $n_C \leq \sum_{D \in A^{\mathcal{T}}} n_D$.*

Proof Assume $A \sqsubseteq C$ is $\mathcal{T}$-essential. Let $D_0 := \bigsqcap_{D \in A^{\mathcal{T}}} D$ and $\mathcal{I}_{D_0,\mathcal{T}}$ be the canonical model of D_0 and $\mathcal{T}$. By Lemma 12, there is a homomorphism $h : T_C \to \mathcal{I}_{D_0,\mathcal{T}}$ mapping ρ_C to ρ_{D_0}. By Lemma 31, h is an isomorphic embedding. Using that $A \sqsubseteq C$ is decomposed for $\mathcal{T}$, we now show that h maps T_C into the restriction of $\mathcal{I}_{D_0,\mathcal{T}}$ to $\Delta^{\mathcal{I}_{D_0}}$ from which the lemma follows since h is injective.

For a proof by contradiction, assume that there exists d' in T_C with $h(d') \notin \Delta^{\mathcal{I}_{D_0}}$. As $h(\rho_C) \in \Delta^{\mathcal{I}_{D_0}}$, we may assume that all d' on the path from ρ_C to d' are mapped to $\Delta^{\mathcal{I}_{D_0}}$ (if this is not the case, we can replace d' by the first element on the path from ρ_C to d' not mapped into $\Delta^{\mathcal{I}_{D_0}}$). In particular, the parent d of d' in T_C is mapped into $\Delta^{\mathcal{I}_{D_0}}$. Let $l(d, d') = r$. Observe that the whole subtree rooted in d' must be mapped into $\Delta^{\mathcal{I}_{D_0,\mathcal{T}}} \setminus \Delta^{\mathcal{I}_{D_0}}$ since otherwise h would not be injective.

Let $C' = \exists r.C''$, where C'' corresponds to the subtree rooted in d' in C. By Lemma 14, there exists a basic concept B such that $h(d) \in B^{\mathcal{I}_{D_0,\mathcal{T}}}$ and $\mathcal{T} \models B \sqsubseteq C'$. As $\mathcal{T}$ is in named form there exists a concept name E with $\mathcal{T} \models E \equiv B$. Thus, $h(d) \in E^{\mathcal{I}_{D_0,\mathcal{T}}}$ and $\mathcal{T} \models E \sqsubseteq C'$. As h is an isomorphic embedding, $E \in l(d)$. We make a case distinction:

- $h(d) \neq \rho_{D_0}$. Then $A \sqsubseteq C$ is not decomposed for $\mathcal{T}$ since C contains an edge (d, d') such that E is in the node label of d, $l(d, d') = r$, and $\mathcal{T} \models E \sqsubseteq \exists r.C''$. We have derived a contradiction.

- $h(d) = \rho_{D_0}$. As $h(d') \in \Delta^{\mathcal{I}_{D_0,\mathcal{T}}} \setminus \Delta^{\mathcal{I}_{D_0}}$, by construction of $\mathcal{I}_{D_0,\mathcal{T}}$, there exists a CI $B_0 \sqsubseteq D \in \mathcal{T}$ with B_0 a basic concept such that $\rho_{D_0} \in B_0^{\mathcal{I}_{D_0,\mathcal{T}}}$ and $h(d')$ is in the copy of the tree-shaped interpretation $\mathcal{I}_D$ which was attached to ρ_{D_0} in the construction of $\mathcal{I}_{D_0,\mathcal{T}}$. But since $\mathcal{T} \models A \sqsubseteq B_0$ we have $D \in A^{\mathcal{T}}$ and so $\rho_{D_0} \in D^{\mathcal{I}_{D_0}}$. But then, by the construction of $\mathcal{I}_{D_0,\mathcal{T}}$, no fresh $\mathcal{I}_D$ was attached to ρ_{D_0} because D is already satisfied in $\mathcal{I}_{D_0}$ and we have derived a contradiction.

❑

We are now in the position to prove that the learning algorithm terminates after posing a polynomial number of queries.

Lemma 33 *For every concept name A, the number of replacements of a CI $A \sqsubseteq C$ in $\mathcal{H}_{add}$ by a CI of the form $A \sqsubseteq C'$ is bounded polynomially in $|\mathcal{T}|$.*

Proof We aim to show that when $A \sqsubseteq C$ is replaced with $A \sqsubseteq C'$, then the number of nodes in the tree representation of C' is strictly larger than the number of nodes in the tree representation of C. Since any CI $A \sqsubseteq C$ ever added to $\mathcal{H}_{add}$ is $\mathcal{T}$-essential, Lemma 32 then yields that the number of replacements is bounded by $\sum_{D \in A^{\mathcal{T}}} n_D$, which is polynomial in $|\mathcal{T}|$.

A straightforward analysis of Algorithm 2 reveals that when $A \sqsubseteq C$ is replaced with $A \sqsubseteq C'$, then $\emptyset \models C' \sqsubseteq C$ and $\emptyset \not\models C \sqsubseteq C'$ (otherwise the positive counterexample returned by the oracle would be a consequence of $\mathcal{H}_{basic} \cup \mathcal{H}_{add}$). Moreover, both $A \sqsubseteq C$ and $A \sqsubseteq C'$ are consequences of $\mathcal{T}$. It thus suffices to establish the following.

Claim. If $A \sqsubseteq C$ is $\mathcal{T}$-essential, $\mathcal{T} \models A \sqsubseteq C'$, $\emptyset \models C' \sqsubseteq C$, and $\emptyset \not\models C \sqsubseteq C'$, then T_C is obtained from $T_{C'}$ by removing at least one subtree.

We prove the claim. Since $\emptyset \models C' \sqsubseteq C$, by Lemma 12 there is a homomorphism h from T_C to the canonical model $\mathcal{I}_{C'}$ that maps ρ_C to $\rho_{C'}$. Then h is also a homomorphism into the canonical model $\mathcal{I}_{C',\mathcal{T}}$. Since $A \sqsubseteq C$ is $\mathcal{T}$-essential, $\mathcal{T} \models A \sqsubseteq C'$, and $\emptyset \models C' \sqsubseteq C$, Lemma 31 yields that h is an isomorphic embedding into $\mathcal{I}_{C',\mathcal{T}}$. Then, trivially, h is also an isomorphic embedding into $\mathcal{I}_{C'}$ which means that T_C is obtained from $T_{C'}$ by removing subtrees. Since $\emptyset \not\models C \sqsubseteq C'$, at least one subtree must in fact have been removed. ❑

We have obtained the following main result of this section.

Theorem 34 *DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes are polynomial query learnable using membership and equivalence queries. Moreover, DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes without inverse roles can be learned in polynomial time using membership and equivalence queries.*

Proof Recall that our algorithm requires the target TBox to be in named form. We first show Theorem 34 under that assumption and then argue that the assumption can be dropped.

In each iteration of Algorithm 2, either a CI is added to $\mathcal{H}_{add}$ or a CI is replaced in $\mathcal{H}_{add}$. Since the number of times the former happens is bounded by $|\Sigma_{\mathcal{T}}|$ and (by Lemma 33) the number of times the latter happens is polynomial in $|\mathcal{T}|$, the number of iterations of Algorithm 2 is polynomial in $|\mathcal{T}|$. For polynomial query learnability of DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes, it remains to show that in each iteration Algorithm 2 makes only polynomially many polynomial size queries in $|\mathcal{T}|$ and the size of the largest counterexample seen so far. We start with equivalence queries, made only in Line 3. We have already argued that the number of iterations is polynomial in $|\mathcal{T}|$ and thus so is the number of equivalence queries made. Regarding their size, we observe that there are at most $|\Sigma_{\mathcal{T}}|^2$ CIs in $\mathcal{H}_{basic}$ and at most $|\Sigma_{\mathcal{T}}|$ CIs in $\mathcal{H}_{add}$, that the size of CIs in $\mathcal{H}_{basic}$ is constant and by Lemma 32 the size of CIs in $\mathcal{H}_{add}$ is polynomial in $|\mathcal{T}|$. Membership queries are made only in Lines 5 and 7 for which it suffices to invoke Lemmas 29 and 30.

Now for the "moreover" part of Theorem 34. Observe that since each (membership or equivalence) query counts as one step of computation, the only potentially costly step of Algorithm 2 is the implementation of the decomposition step in Line 5, which relies on making subsumption checks of the form $\mathcal{H}_{basic} \cup \mathcal{H}_{add} \models A \sqsubseteq C$. As discussed in Section 2, deciding subsumption in DL-Lite$^{\exists}_{\mathcal{R}}$ is NP-complete while in $\mathcal{EL}$ with role inclusions subsumption is in PTime. As DL-Lite$^{\exists}_{\mathcal{R}}$ without inverse roles is a fragment of $\mathcal{EL}$ with role inclusions, we obtain polynomial time learnability for TBoxes in this case.

To drop the requirement that the target TBox is in named form, we show that any polynomial (query or time) learning algorithm for TBoxes in named form can be transformed into the same kind of algorithm for unrestricted target TBoxes. In fact, the learner can use at most $\mathcal{O}(|\Sigma_{\mathcal{T}}|^2)$ membership queries "Does $\mathcal{T}$ entail $r \sqsubseteq s$?" to compute for every role r the class $[r]_{\mathcal{T}}$ of roles s with $\mathcal{T} \models s \equiv r$ and choose a representative $r_{\mathcal{T}}$ for this class. Then whenever some $s \in [r]_{\mathcal{T}}$ is used in any counterexample returned by the oracle, it gets replaced with $r_{\mathcal{T}}$. Likewise, whenever $\mathcal{T}$ does not have a name for some $\exists r.\top$, the algorithm still uses the concept name A_r in its internal representations (although they are no longer included in the signature $\Sigma_{\mathcal{T}}$ of the target TBox) and replaces $\exists r.\top$ with A_r in the counterexamples returned by the oracle. It also replaces each A_r with $\exists r.\top$ in membership queries to the oracle and in the hypothesis used for posing equivalence queries. ❑

4. Learning DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ TBoxes

We study exact learnability of TBoxes in DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$, the extension of DL-Lite$^{\exists}_{\mathcal{R}}$ that admits conjunctions of basic concepts on the left-hand side of CIs. This language is a generalisation of both DL-Lite$^{\exists}_{\mathcal{R}}$ and propositional Horn logic. In fact, the algorithm we present combines the classical algorithms for propositional Horn logic (Angluin et al., 1992; Frazier and Pitt, 1993) with the algorithm for DL-Lite$^{\exists}_{\mathcal{R}}$ presented in Section 3. The resulting algorithm is quite subtle and indeed this is the reason why we treated the DL-Lite$^{\exists}_{\mathcal{R}}$ case separately in Section 3.

To simplify the presentation, we make the same assumptions as in Section 3 about the target TBox $\mathcal{T}$ with signature $\Sigma_{\mathcal{T}}$. In particular, we assume that $\mathcal{T}$ is in named form, suitably generalised to DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$: there are no distinct roles r and s such that $\mathcal{T} \models r \equiv s$, for each role r the TBox $\mathcal{T}$ contains an equivalence $A_r \equiv \exists r.\top$ and all CIs of $\mathcal{T}$ are either CIs between basic concepts or contain no concept expressions of the form $\exists r.\top$ on the left-hand side, for any role r. Denote by $\mathsf{lhs}(\alpha)$ the set of concept names that occur as conjuncts on the left-hand side of a CI α and denote by $\mathsf{rhs}(\alpha)$ the set of concept expressions that occur as top-level conjuncts on the right-hand side of α (that is, they are not nested inside restrictions). We often do not distinguish between the set $\mathsf{lhs}(\alpha)$ and the conjunction over all its concept expressions, and similarly for $\mathsf{rhs}(\alpha)$. For example, if $\alpha_1 = C_1 \sqsubseteq D_1$ and $\alpha_2 = C_2 \sqsubseteq D_2$ then $\mathsf{lhs}(\alpha_1) \sqsubseteq \mathsf{rhs}(\alpha_2)$ stands for $C_1 \sqsubseteq D_2$. Also, if $\mathsf{lhs}(\alpha_1) = \{A_1, A_2, A_3\}$ and $\mathsf{lhs}(\alpha_2) = \{A_2, A_3, A_4\}$ then $\mathsf{lhs}(\alpha_1) \cap \mathsf{lhs}(\alpha_2) \sqsubseteq D$ stands for $A_2 \sqcap A_3 \sqsubseteq D$.

The algorithm for learning DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ TBoxes is shown as Algorithm 3. Like Algorithm 2, Algorithm 3 first determines the set $\mathcal{H}_{basic}$ that contains all CIs $B_1 \sqsubseteq B_2$ with B_1, B_2 basic concepts such that $\mathcal{T} \models B_1 \sqsubseteq B_2$ and all RIs $r \sqsubseteq s$ such that $\mathcal{T} \models r \sqsubseteq s$. The hypothesis $\mathcal{H}$ is the union of $\mathcal{H}_{basic}$ and $\mathcal{H}_{add}$. In contrast to Algorithm 2, $\mathcal{H}_{add}$ is an *ordered list* of CIs rather than a set. We write α_i to denote the CI α at position i in the list $\mathcal{H}_{add}$. In

Algorithm 3 The learning algorithm for DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ TBoxes

Input: A DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ TBox $\mathcal{T}$ in named form given to the oracle; $\Sigma_{\mathcal{T}}$ given to the learner.
Output: TBox $\mathcal{H}$, computed by the learner, such that $\mathcal{T} \equiv \mathcal{H}$.

1: Compute $\mathcal{H}_{basic} = \{r \sqsubseteq s \mid \mathcal{T} \models r \sqsubseteq s\} \cup \{B_1 \sqsubseteq B_2 \mid \mathcal{T} \models B_1 \sqsubseteq B_2,\ B_1, B_2 \text{ basic}\}$
2: Set $\mathcal{H}_{add}$ to be the empty list and $\mathcal{H} = \mathcal{H}_{basic} \cup \mathcal{H}_{add}$
3: **while** $\mathcal{H} \not\equiv \mathcal{T}$ **do**
4: Let γ be the returned positive counterexample for $\mathcal{T}$ and $\mathcal{H}$
5: Find a $\mathcal{T}$-essential γ' with $\mathcal{H} \not\models \gamma'$ and $|\{\exists r.F \mid \exists r.F \in \mathsf{rhs}(\gamma')\}| \leq 1$
6: Left saturate γ' for $\mathcal{H}$
7: **if** there is $A \in \mathsf{N_C}$ such that $\mathcal{T} \models \mathsf{lhs}(\gamma') \sqsubseteq A$ and $\mathcal{H} \not\models \mathsf{lhs}(\gamma') \sqsubseteq A$ **then**
8: $\mathcal{H}$:=CN-Refine$(\mathcal{H}, \mathsf{lhs}(\gamma') \sqsubseteq A)$
9: **else**
10: $\mathcal{H}$:=$\exists$-Refine$(\mathcal{H}, \gamma')$
11: **end if**
12: Set $\mathcal{H} = \mathcal{H}_{basic} \cup \mathcal{H}_{add}$
13: **end while**
14: **return** $\mathcal{H}$

the learning algorithm, working with an ordered list of CIs allows the learner to pick the first α_i in $\mathcal{H}_{add}$ with a certain property and merge it with a new CI, a technique we adopt from the work of Angluin et al. (1992) and Frazier and Pitt (1993). As in Algorithm 2, $\mathcal{T} \models \mathcal{H}$ is a loop invariant, thus, γ is necessarily positive. The algorithm terminates when $\mathcal{H} \equiv \mathcal{T}$.

Algorithm 4 Function CN-Refine$(\mathcal{H}, \gamma)$

1: **if** there is $A \in \mathsf{N_C}$ and $\alpha_i \in \mathcal{H}_{add}$ such that $\mathcal{T} \models \mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \sqsubseteq A$,
2: and $\mathcal{H} \not\models \mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \sqsubseteq A$ **then**
3: Concept saturate $\gamma' = \mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \sqsubseteq A$ for $\mathcal{T}$
4: Replace the first such α_i in $\mathcal{H}_{add}$ by γ'
5: **else**
6: Concept saturate γ for $\mathcal{T}$
7: Append γ to the list $\mathcal{H}_{add}$
8: **end if**
9: **return** $\mathcal{H}$

Algorithm 3 uses membership queries to compute a $\mathcal{T}$-essential counterexample γ such that $\mathsf{rhs}(\gamma)$ contains at most one concept expression of the form $\exists r.F$ (Line 5) and which is 'Left saturated for $\mathcal{H}$' (Line 6); here, a CI is left saturated for $\mathcal{H}$ if its left-hand side contains all subsuming concept names w.r.t. $\mathcal{H}$ (Definition 35 below) and $\mathcal{T}$-essential if it satisfies the conditions for $\mathcal{T}$-essential CIs from Section 3, appropriately modified for CIs with conjunctions of concept names on the left-hand side (Definition 37 below). Then, the algorithm checks whether there is a concept name A such that $\mathsf{lhs}(\gamma) \sqsubseteq A$ is a positive counterexample. If so, then it calls Function CN-Refine (Algorithm 4) and updates the hypothesis either by refining some α_i in $\mathcal{H}_{add}$ or by appending a new CI to $\mathcal{H}_{add}$. The

Algorithm 5 Function $\exists$-Refine$(\mathcal{H}, \gamma)$

1: **if** there is $C \in \mathsf{rhs}(\gamma)$ of the form $\exists r.D$ and $\alpha_i \in \mathcal{H}_{add}$ such that $\mathcal{T} \models \mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \sqsubseteq C$
2: and $\mathcal{H} \not\models \mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \sqsubseteq C$ **then**
3: **if** $\mathcal{T} \models \mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \sqsubseteq C \sqcap \mathsf{rhs}(\alpha_i)$ **then**
4: Find a $\mathcal{T}$-essential $\mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \sqsubseteq D^*$ with $\emptyset \models D^* \sqsubseteq C \sqcap \mathsf{rhs}(\alpha_i)$
5: Replace the first such α_i in $\mathcal{H}_{add}$ by $\mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \sqsubseteq D^*$
6: **else**
7: Concept saturate $\gamma' = \mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \sqsubseteq C$ for $\mathcal{T}$
8: Replace the first such α_i in $\mathcal{H}_{add}$ by γ'
9: **end if**
10: **else**
11: Append γ to the list $\mathcal{H}_{add}$
12: **end if**
13: **return** $\mathcal{H}$

number of replacements of any given α_i in $\mathcal{H}_{add}$ in CN-Refine is bounded by $|\Sigma_{\mathcal{T}}|$ since whenever α_i is replaced in CN-Refine$(\mathcal{H}, \gamma)$, then $\mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \subsetneq \mathsf{lhs}(\alpha_i)$.[4]

If there is no concept name A such that $\mathsf{lhs}(\gamma) \sqsubseteq A$ is a positive counterexample then Algorithm 3 calls Function $\exists$-Refine (Algorithm 5). In this case one considers the existential restrictions that occur on top-level on the right-hand side of γ. Note that $\exists$-Refine can be viewed as a variation of the body of the while loop in Algorithm 2 in which one considers sets of concept names on the left-hand side of CIs rather than a single concept name. Recall that in Algorithm 2, the new CI γ and a CI α in $\mathcal{H}_{add}$ are merged if they have the same concept name on the left-hand side. In contrast, now they are merged if the intersection of their left-sides is still subsumed by some existential restriction C from $\mathsf{rhs}(\gamma)$ (Lines 1 and 2). There are two cases: if the intersection is also subsumed by $\mathsf{rhs}(\alpha)$ (checked in Line 3), then in the next line a $\mathcal{T}$-essential counterexample is computed and the first such α_i is replaced by the new CI. Otherwise it follows that $\mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \subsetneq \mathsf{lhs}(\alpha_i)$ and the first such α_i is replaced by the CI computed in Line 7. Note that the latter can happen at most $|\Sigma_{\mathcal{T}}|$ times for each CI in $\mathcal{H}_{add}$ (and the former can happen at most $|\mathcal{T}|$ times for each CI in $\mathcal{H}_{add}$, see Lemma 43 below). If no CI can be refined with γ then $\exists$-Refine appends γ to $\mathcal{H}_{add}$.

We now define the step 'left-saturate γ for $\mathcal{H}$' used in Line 6 of Algorithm 3. Observe that this step is meaningless for DL-Lite$^{\exists}_{\mathcal{R}}$.

Definition 35 (Left saturation for $\mathcal{H}$) *A CI γ' is obtained from a CI γ by* left saturation for $\mathcal{H}$ *if* $\mathsf{rhs}(\gamma') = \mathsf{rhs}(\gamma)$ *and* $\mathsf{lhs}(\gamma') = \{A \in \Sigma_{\mathcal{T}} \mid \mathcal{H} \models \mathsf{lhs}(\gamma) \sqsubseteq A\}$. *A CI γ is* left saturated for $\mathcal{H}$ *if it coincides with its left saturation for $\mathcal{H}$.*

One can clearly left saturate any CI γ for $\mathcal{H}$ by checking whether $\mathcal{H} \models \mathsf{lhs}(\gamma) \models A$ for every $A \in \Sigma_{\mathcal{T}}$. The following example shows that Line 6 is necessary for Algorithm 3 to be polynomial. A similar step is also necessary in Frazier et al.'s algorithm learning propositional Horn logic from entailments (Frazier and Pitt, 1993).

4. This is a consequence of the fact that $\mathcal{H}_{add}$ only contains concept saturated CIs (defined essentially as in the previous section, see Definition 37 below): $\mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) = \mathsf{lhs}(\alpha_i)$ and $\mathcal{T} \models \mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \sqsubseteq A$ implies $A \in \mathsf{rhs}(\alpha_i)$ by concept saturatedness, thus contradicting $\mathcal{H} \not\models \mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \sqsubseteq A$.

Example 36 Assume Line 6 of Algorithm 3 is omitted. Let for $n \geq 2$,

$$\mathcal{T}_n \quad = \quad \{E_1 \sqcap \cdots \sqcap E_n \sqsubseteq A\} \cup \{A_i \sqsubseteq E_i, B_i \sqsubseteq E_i \mid 1 \leq i \leq n\}.$$

For $M \subseteq \{1, \ldots, n\}$, set $C_M = \bigsqcap_{i \leq n} C_i$, where $C_i = A_i$ if $i \in M$ and $C_i = B_i$ if $i \notin M$. Then the oracle can provide for the first 2^n equivalence queries in the while loop of Algorithm 3 a positive counterexample $C_M \sqsubseteq A$ by always choosing a fresh set $M \subseteq \{1, \ldots, n\}$.

For the refinements on the right-hand side, we extend to DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ the notion of $\mathcal{T}$-essential CIs introduced in the previous section:

1. (Concept saturation for $\mathcal{T}$) A CI γ is *concept saturated for* $\mathcal{T}$ if $\mathcal{T} \models \gamma$ and $\mathcal{T} \not\models \gamma'$ for any γ' with $\mathsf{lhs}(\gamma) = \mathsf{lhs}(\gamma')$ such that $\mathsf{rhs}(\gamma')$ is obtained from $\mathsf{rhs}(\gamma)$ by adding a concept name to the label of some node of $\mathsf{rhs}(\gamma)$. A CI γ' is a *concept saturation for* $\mathcal{T}$ of a CI γ if it is concept saturated for $\mathcal{T}$, $\mathsf{lhs}(\gamma) = \mathsf{lhs}(\gamma')$, and $\mathsf{rhs}(\gamma')$ is obtained from $\mathsf{rhs}(\gamma)$ by adding concept names to the labels of some nodes of $\mathsf{rhs}(\gamma)$.

2. (Role saturation for $\mathcal{T}$) A CI γ is *role saturated for* $\mathcal{T}$ if $\mathcal{T} \models \gamma$ and $\mathcal{T} \not\models \gamma'$ for any γ' with $\mathsf{lhs}(\gamma) = \mathsf{lhs}(\gamma')$ such that $\mathsf{rhs}(\gamma')$ is obtained from $\mathsf{rhs}(\gamma)$ by replacing in some edge label a role r by a role $s \neq r$ with $\mathcal{T} \models s \sqsubseteq r$. A CI γ' is a *role saturation for* $\mathcal{T}$ of a CI γ if it is role saturated for $\mathcal{T}$, $\mathsf{lhs}(\gamma) = \mathsf{lhs}(\gamma')$, and $\mathsf{rhs}(\gamma')$ is obtained from $\mathsf{rhs}(\gamma)$ by replacing in some edge labels a role r by a role $s \neq r$ with $\mathcal{T} \models s \sqsubseteq r$.

3. (Parent/child merged for $\mathcal{T}$) A CI γ' is *obtained from a CI* γ *by parent/child merging for* $\mathcal{T}$ if $\mathsf{lhs}(\gamma) = \mathsf{lhs}(\gamma')$, $\mathsf{rhs}(\gamma')$ is obtained from $\mathsf{rhs}(\gamma')$ by parent/child merging (as in Definition 23), and $\mathcal{T} \models \gamma'$. A CI γ is *parent/child merged for* $\mathcal{T}$ if $\mathcal{T} \models \gamma$ and there is no γ' with $\gamma \neq \gamma'$ that can be obtained from γ by parent/child merging for $\mathcal{T}$.

4. (Sibling merged for $\mathcal{T}$) A CI γ' is *obtained from a CI* γ *by sibling merging for* $\mathcal{T}$ if $\mathsf{lhs}(\gamma) = \mathsf{lhs}(\gamma')$, $\mathsf{rhs}(\gamma')$ is obtained from $\mathsf{rhs}(\gamma')$ by sibling merging (as in Definition 25), and $\mathcal{T} \models \gamma'$. A CI γ is *sibling merged for* $\mathcal{T}$ if $\mathcal{T} \models \gamma$ and there is no γ' with $\gamma \neq \gamma'$ that can be obtained from γ by sibling merging for $\mathcal{T}$.

5. (Decomposed CI for $\mathcal{T}$) A CI γ is *decomposed for* $\mathcal{T}$ if $\mathcal{T} \models \gamma$ and for every non-root node d in $\mathsf{rhs}(\gamma)$, every role r, and every r-successor d' of d in $\mathsf{rhs}(\gamma)$ we have $\mathcal{T} \not\models l(d) \sqsubseteq \exists r.C'$, where C' corresponds to the subtree of $\mathsf{rhs}(\gamma)$ rooted at d'.

Definition 37 *A DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ CI is* $\mathcal{T}$-essential *if it is concept saturated, role saturated, parent/child merged, sibling merged, and decomposed for* $\mathcal{T}$.

The saturation, merging and decomposition steps defined above are straightforward generalisations of Definitions 18 to 27 to CIs with conjunctions on the left-hand side. One can easily generalise the arguments from DL-Lite$^{\exists}_{\mathcal{R}}$ to show that for any CI γ with $\mathcal{H} \not\models \gamma$ one can compute a $\mathcal{T}$-essential γ' with $\mathcal{H} \not\models \gamma'$ using polynomially many membership queries and entailment checks relative to $\mathcal{H}$. For the analysis of the learning algorithm it is crucial that all CIs in the ordered list $\mathcal{H}_{add}$ are $\mathcal{T}$-essential at all times, which we prove next.

Lemma 38 *At any point in the execution of Algorithm 3, all CIs in* $\mathcal{H}_{add}$ *are* $\mathcal{T}$*-essential.*

Proof If a CI γ is of the form $A_1 \sqcap \cdots \sqcap A_n \sqsubseteq A$ with A a concept name, then the set $\mathsf{rhs}(\gamma')$ of the concept saturation γ' of γ for $\mathcal{T}$ contains concept names only. Thus, γ' is $\mathcal{T}$-essential. It follows that the CIs added to $\mathcal{H}_{add}$ in Lines 4 and 7 of CN-Refine are $\mathcal{T}$-essential. Also, it is easy to see that if γ is $\mathcal{T}$-essential and $C \in \mathsf{rhs}(\gamma)$ then the concept saturation of $\mathsf{lhs}(\gamma) \sqsubseteq C$ for $\mathcal{T}$ is $\mathcal{T}$-essential as well. Thus, the CI γ' in Line 8 of $\exists$-Refine is $\mathcal{T}$-essential. ❑

Polynomial Query Bound on the Algorithm

As in the previous section it is immediate that upon termination the algorithm has found a TBox $\mathcal{H} = \mathcal{H}_{basic} \cup \mathcal{H}_{add}$ that is logically equivalent to the target TBox $\mathcal{T}$. It thus remains to show that it issues only polynomially many queries of polynomial size. We first discuss how Lines 5 and 6 of Algorithm 3 and Line 4 of $\exists$-Refine can be implemented. The next lemma addresses Lines 5 and 6 of Algorithm 3.

Lemma 39 *Given a positive counterexample* γ *for* $\mathcal{T}$ *relative to* $\mathcal{H}$*, one can construct with polynomially many polynomial size membership queries in* $|\gamma|$ *and* $|\mathcal{T}|$*, a counterexample* γ' *that is left saturated for* $\mathcal{H}$*,* $\mathcal{T}$*-essential and such that* $|\{\exists r.F \mid \exists r.F \in \mathsf{rhs}(\gamma')\}| \leq 1$.

The proof of Lemma 39 is a straightforward extension of the proof of Lemma 29 and uses the observation that a left-saturated γ' for $\mathcal{H}$ can be computed from γ by adding all concept names $A \in \Sigma_{\mathcal{T}}$ with $\mathcal{H} \models \mathsf{lhs}(\gamma) \sqsubseteq A$ to $\mathsf{lhs}(\gamma)$. This lemma also requires that $|\{\exists r.F \mid \exists r.F \in \mathsf{rhs}(\gamma')\}| \leq 1$. If there is $A \in \mathsf{rhs}(\gamma')$ such that $\mathcal{H} \not\models \mathsf{lhs}(\gamma') \sqsubseteq A$ then we can simply drop all conjuncts of the form $\exists r.F$ from $\mathsf{rhs}(\gamma')$. Otherwise, we can satisfy the condition by simply choosing a conjunct $\exists r.F \in \mathsf{rhs}(\gamma')$ such that $\mathcal{H} \not\models \mathsf{lhs}(\gamma') \sqsubseteq \exists r.F$ and then apply 'Concept saturation for $\mathcal{T}$' to $\mathsf{lhs}(\gamma') \sqsubseteq \exists r.F$. The resulting γ' is left saturated for $\mathcal{H}$, $\mathcal{T}$-essential and has at most one conjunct of the form $\exists r.F$ in $\mathsf{rhs}(\gamma')$.

The following lemma addresses Line 4 of $\exists$-Refine.

Lemma 40 *Assume that* α *and* γ *are* $\mathcal{T}$*-essential and there is* $C \in \mathsf{rhs}(\gamma)$ *such that* $\mathcal{T} \models \mathsf{lhs}(\alpha) \sqcap \mathsf{lhs}(\gamma) \sqsubseteq \mathsf{rhs}(\alpha) \sqcap C$*. Then one can construct, with polynomially many polynomial size membership queries in* $|\mathsf{rhs}(\alpha)|$ *and* $|C|$*, a* $\mathcal{T}$*-essential* $\mathsf{lhs}(\alpha) \sqcap \mathsf{lhs}(\gamma) \sqsubseteq D^*$ *such that* $\emptyset \models D^* \sqsubseteq \mathsf{rhs}(\alpha) \sqcap C$.

Proof Assume $\mathcal{T} \models \mathsf{lhs}(\alpha) \sqcap \mathsf{lhs}(\gamma) \sqsubseteq \mathsf{rhs}(\alpha) \sqcap C$. Then, similar to Lemma 30, one can show that the only property of $\mathcal{T}$-essential CIs that can fail is being sibling merged for $\mathcal{T}$ and that after applying the step 'Sibling merging for $\mathcal{T}$' to $\mathsf{lhs}(\alpha) \sqcap \mathsf{lhs}(\gamma) \sqsubseteq \mathsf{rhs}(\alpha) \sqcap C$ the resulting CI is $\mathcal{T}$-essential, as required. ❑

We also have to show that the number of CIs in $\mathcal{H}_{add}$ is bounded polynomially in $|\mathcal{T}|$ and for each position of $\mathcal{H}_{add}$ the number of replacements is bounded polynomially in $|\mathcal{T}|$. These properties follow from the following lemma.

Lemma 41 *Let* $\mathcal{H}_{add}$ *be a ordered list of CIs computed at some point of an execution of Algorithm 3. Then*

(i) the length of $\mathcal{H}_{add}$ *is bounded by the number of CIs in* $\mathcal{T}$ *and*

(ii) The number of replacements of an existing CI $\alpha \in \mathcal{H}_{add}$ is bounded polynomially in $|\mathcal{T}|$.

The rest of the section is devoted to proving Lemma 41. We first show Point (ii) of Lemma 41 and start by generalising Lemma 32 on the size of $\mathcal{T}$-essentials CIs. For any conjunction C of concept names we set

$$\begin{aligned} C^{\mathcal{T}} \;=\; & \{D \mid \mathcal{T} \models C \sqsubseteq A_1 \sqcap \cdots \sqcap A_k \text{ and } A_1 \sqcap \cdots \sqcap A_k \sqsubseteq D \in \mathcal{T}\} \cup \\ & \{B \mid \mathcal{T} \models C \sqsubseteq B, B \text{ basic concept over } \Sigma_{\mathcal{T}}\} \end{aligned}$$

Recall that for any concept expression C we denote by n_C the number of nodes in the tree T_C corresponding to C.

Lemma 42 *If α is $\mathcal{T}$-essential, then $n_{\mathsf{rhs}(\alpha)} \leq \sum_{D \in \mathsf{lhs}(\alpha)^{\mathcal{T}}} n_D$.*

Proof The proof is almost the same as the proof of Lemma 32. Assume α is $\mathcal{T}$-essential. Let $D_0 := \bigsqcap_{D \in \mathsf{lhs}(\alpha)^{\mathcal{T}}} D$ and let $\mathcal{I}_{D_0,\mathcal{T}}$ be the canonical model of D_0 and $\mathcal{T}$. Now one can prove in almost the same way as in the proof of Lemma 32 that the homomorphism h from $T_{\mathsf{rhs}(\alpha)}$ into $\mathcal{I}_{D_0,\mathcal{T}}$ mapping $\rho_{\mathsf{rhs}(\alpha)}$ to $\rho_{D_0,\mathcal{T}}$ is an injective mapping into $\mathcal{I}_{D_0}$ (using Lemma 14 for DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ instead of DL-Lite$^{\exists}_{\mathcal{R}}$). ❑

We are now in the position to prove Point (ii) of Lemma 41.

Lemma 43 *The number of replacements of an existing CI $\alpha \in \mathcal{H}_{add}$ is bounded polynomially in $|\mathcal{T}|$.*

Proof A CI $\alpha \in \mathcal{H}_{add}$ can be replaced in Line 4 of CN-Refine or in Lines 5 or 8 of $\exists$-Refine. If α is replaced by α' in Line 4 of CN-Refine or in Line 8 of $\exists$-Refine then $\mathsf{lhs}(\alpha') \subsetneq \mathsf{lhs}(\alpha)$, so the number of replacements is bounded by $|\Sigma_{\mathcal{T}}|$. If α is replaced by α' in Line 5 of $\exists$-Refine, then either $\mathsf{lhs}(\alpha') \subsetneq \mathsf{lhs}(\alpha)$ or $\mathsf{lhs}(\alpha') = \mathsf{lhs}(\alpha)$. For the latter case one can show as in the proof of Lemma 33 for DL-Lite$^{\exists}_{\mathcal{R}}$, the following

Claim. If $A_1 \sqcap \cdots \sqcap A_n \sqsubseteq C$ and $A_1 \sqcap \cdots \sqcap A_n \sqsubseteq C'$ are $\mathcal{T}$-essential, and $\emptyset \models C' \sqsubseteq C$, then T_C is obtained from $T_{C'}$ by removing subtrees.

Thus, each time $\alpha \in \mathcal{H}_{add}$ is replaced in Line 5 of $\exists$-Refine without decreasing the number of concept names in $\mathsf{lhs}(\alpha)$, the number $n_{\mathsf{rhs}(\alpha)}$ of nodes in the tree representation of $\mathsf{rhs}(\alpha)$ strictly increases. By Lemma 42, $n_{\mathsf{rhs}(\alpha)}$ is bounded polynomially in $|\mathcal{T}|$ and the lemma follows. ❑

We now come to the proof of Point (i) of Lemma 41. To formulate an upper bound on the length of $\mathcal{H}_{add}$ in terms of $\mathcal{T}$ it is convenient to assume that the right-hand side of every CI in $\mathcal{T}$ is *primitive*, that is, either a concept name or a concept expression of the form $\exists r.D$. This assumption is w.l.o.g. since one can equivalently transform every CI $C \sqsubseteq D_1 \sqcap D_2$ into two CIs $C \sqsubseteq D_1$ and $C \sqsubseteq D_2$. We call such a TBox *rhs-primitive*. Note that CIs in $\mathcal{H}$ may still have multiple concepts on the right-hand side.

A concept C is called *concept saturated for* $\mathcal{T}$ if $\mathcal{T} \models C \sqsubseteq C'$ whenever C' results from C by adding a new concept name A' to the label of some node in T_C. Denote by C^{sat} the (unique) concept obtained from C by adding concept names to the node labels of T_C until it is concept saturated for $\mathcal{T}$. The following definition enables us to link the CIs in $\mathcal{H}_{add}$ to the CIs in $\mathcal{T}$.

Definition 44 *Let $\mathcal{T}$ be rhs-primitive. We say that a CI α* has target $\beta \in \mathcal{T}$ *if*

1. $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha)$ *and*
2. *there exists $D \in \mathsf{rhs}(\alpha) \setminus \mathsf{lhs}(\alpha)$ such that $\emptyset \models \mathsf{rhs}(\beta)^{\mathsf{sat}} \sqsubseteq D$.*

We aim to show that Algorithm 3 maintains the invariant that

(iii) every $\alpha \in \mathcal{H}_{add}$ has some target $\beta \in \mathcal{T}$ and

(iv) every $\beta \in \mathcal{T}$ is the target of at most one $\alpha \in \mathcal{H}_{add}$.

Then Point (i) of Lemma 41 clearly follows.

Example 45 To illustrate Definition 44, suppose that

$$\mathcal{T} = \{A_1 \sqcap A_4 \sqsubseteq A_2,\ A_2 \sqsubseteq \exists r.A_3,\ A_3 \sqsubseteq A_4,\ A_r \equiv \exists r.\top\}$$

is the target TBox. $\mathcal{T}$ is rhs-primitive. To simplify notation, we use β_i to denote the i-th CI occurring in $\mathcal{T}$ above. Assume $\mathcal{H}_{basic} = \{\beta_3, \beta_4\}$ and $\mathcal{H}_{add} = \emptyset$. Let $\alpha_1 = A_1 \sqcap A_3 \sqsubseteq A_2$. Then there is no $\beta_i \in \mathcal{T}$ such that α_1 has target β_i. However, by applying left saturation for $\mathcal{H}$ to α_1 we obtain $\alpha_1' = A_1 \sqcap A_3 \sqcap A_4 \sqsubseteq A_2$ and since $\mathsf{lhs}(\beta_1) \subseteq \mathsf{lhs}(\alpha_1')$ and $A_2 \notin \mathsf{lhs}(\alpha_1')$, α_1' has target β_1. For $\alpha_2 = A_1 \sqcap A_4 \sqsubseteq \exists r.A_3$, there is no $\beta_i \in \mathcal{T}$ such that α_2 has target β_i. But α_2 is not $\mathcal{T}$-essential and making it $\mathcal{T}$-essential results in $\alpha_2' = A_1 \sqcap A_4 \sqsubseteq A_r \sqcap A_1 \sqcap A_2 \sqcap A_4 \sqcap \exists r.(A_3 \sqcap A_4)$ which again has target β_1. Finally, let $\alpha_3 = A_2 \sqsubseteq \exists r.A_4$. As $\mathsf{lhs}(\beta_2) \subseteq \mathsf{lhs}(\alpha_3)$ and $\emptyset \models A_r \sqcap \exists r.(A_3 \sqcap A_4) \sqsubseteq \exists r.A_4$, α_3 has target β_2. Note that α_3 is not $\mathcal{T}$-essential, but the result of making it $\mathcal{T}$-essential also has target β_2.

Point (iii) is a consequence of the following lemma.

Lemma 46 *Let $\mathcal{T}$ be rhs-primitive and let γ be a $\mathcal{T}$-essential CI such that $\emptyset \not\models \gamma$. Then γ has some target $\beta \in \mathcal{T}$.*

Proof Assume γ is $\mathcal{T}$-essential and $\emptyset \not\models \gamma$. Assume for a proof by contradiction that γ has no target in $\mathcal{T}$. We first show the following

Claim 1. If γ has no target in $\mathcal{T}$ and $\mathcal{T} \models \mathsf{lhs}(\gamma) \sqsubseteq A$ then $A \in \mathsf{lhs}(\gamma)$, for all $A \in \mathsf{N_C}$.

For the proof of Claim 1, consider the canonical model $\mathcal{I}_{\mathsf{lhs}(\gamma),\mathcal{T}}$ of $\mathsf{lhs}(\gamma)$ and $\mathcal{T}$. Recall that $\rho_{\mathsf{lhs}(\gamma),\mathcal{T}}$ denotes the root of $\mathcal{I}_{\mathsf{lhs}(\gamma),\mathcal{T}}$. By Lemma 12, $\rho_{\mathsf{lhs}(\gamma),\mathcal{T}} \in D^{\mathcal{I}_{\mathsf{lhs}(\gamma),\mathcal{T}}}$ iff $\mathcal{T} \models \mathsf{lhs}(\gamma) \sqsubseteq D$, for any concept D. Thus, it suffices to prove that $\rho_{\mathsf{lhs}(\gamma),\mathcal{T}} \in A^{\mathcal{I}_{\mathsf{lhs}(\gamma),\mathcal{T}}}$ implies $A \in \mathsf{lhs}(\gamma)$, for all concept names A. The proof is by induction over the sequence $\mathcal{I}_0, \ldots$ used to construct $\mathcal{I}_{\mathsf{lhs}(\gamma),\mathcal{T}}$, where $\mathcal{I}_0 = \mathcal{I}_{\mathsf{lhs}(\gamma)}$. For $\mathcal{I}_{\mathsf{lhs}(\gamma)}$ this is the case by definition. Now suppose the claim holds for $\mathcal{I}_n$ and $\rho_{\mathsf{lhs}(\gamma),\mathcal{T}} \in A^{\mathcal{I}_{n+1}} \setminus A^{\mathcal{I}_n}$. Then there either exist concept names $A_1, \ldots, A_k$ with $A_1 \sqcap \cdots \sqcap A_k \sqsubseteq A \in \mathcal{T}$ and $\rho_{\mathsf{lhs}(\gamma),\mathcal{T}} \in (A_1 \sqcap \cdots \sqcap A_k)^{\mathcal{I}_n}$ or there exists $\exists r.\top$ with $\exists r.\top \sqsubseteq A \in \mathcal{T}$ and $\rho_{\mathsf{lhs}(\gamma),\mathcal{T}} \in (\exists r.\top)^{\mathcal{I}_n}$. In the first case, we have $\{A_1, \ldots, A_k\} \subseteq \mathsf{lhs}(\gamma)$ by induction hypothesis and so $A \in \mathsf{lhs}(\gamma)$ because otherwise $A_1 \sqcap \cdots \sqcap A_k \sqsubseteq A$ would be a target of γ. In the second case there must be an $\mathcal{I}_m$ with $m < n$ such that there are $E_1 \sqcap \cdots \sqcap E_k \sqsubseteq \exists s.D \in \mathcal{T}$ and $s \sqsubseteq r \in \mathcal{T}$ with $\rho_{\mathsf{lhs}(\gamma),\mathcal{T}} \in (E_1 \sqcap \cdots \sqcap E_k)^{\mathcal{I}_m}$ (the case $s = r$ is similar and omitted). It follows that $A \in \mathsf{lhs}(\gamma)$ because otherwise $E_1 \sqcap \cdots \sqcap E_k \sqsubseteq \exists s.D$ would

be a target of γ since, by induction hypothesis, $\{E_1, \ldots, E_k\} \subseteq \mathsf{lhs}(\gamma)$ and $A \in (\exists s.D)^{\mathsf{sat}}$. This finishes the proof of Claim 1.

By Claim 1, as $\emptyset \not\models \gamma$, there is a conjunct of the form $\exists r.F$ in $\mathsf{rhs}(\gamma)$. Let $(\mathsf{lhs}(\alpha))^{\mathcal{T}}$ be as above and $\mathcal{I}_{D_0,\mathcal{T}}$ be the canonical model of $D_0 = \bigsqcap_{D \in (\mathsf{lhs}(\alpha))^{\mathcal{T}}} D$ and $\mathcal{T}$. As $\exists r.F \in \mathsf{rhs}(\gamma)$ and γ is $\mathcal{T}$-essential one can show in the same way as in the proof of Lemma 32 that there is an injective homomorphism from the labelled tree $T_{\exists r.F}$ corresponding to $\exists r.F$ into the restriction of $\mathcal{I}_{D_0,\mathcal{T}}$ to $\Delta^{\mathcal{I}_{D_0}}$ mapping the root of $T_{\exists r.F}$ to the root $\rho_{D_0,\mathcal{T}}$ of $\mathcal{I}_{D_0,\mathcal{T}}$. Thus, by definition of $(\mathsf{lhs}(\alpha))^{\mathcal{T}}$, there is $\beta \in \mathcal{T}$ such that $\mathcal{T} \models \mathsf{lhs}(\alpha) \sqsubseteq \mathsf{lhs}(\beta)$ and $\emptyset \models \mathsf{rhs}(\beta)^{\mathsf{sat}} \sqsubseteq \exists r.F$. By Lemma 12, $\rho_{\mathsf{lhs}(\gamma),\mathcal{T}} \in A^{\mathcal{I}_{\mathsf{lhs}(\gamma),\mathcal{T}}}$, for all $A \in \mathsf{lhs}(\beta)$. Hence, by Claim 1 and again Lemma 12, $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\gamma)$. We have shown that γ has target β and so derived a contradiction. ❏

Point (iii) is a direct consequence of Lemma 46 and the fact that all CIs in $\mathcal{H}_{add}$ are $\mathcal{T}$-essential (Lemma 38). To prove Point (iv), we first establish the following intermediate Lemmas 47 and 48.

Lemma 47 *Let $\mathcal{T}$ be rhs-primitive and let $\mathcal{H}, \gamma$ be inputs to CN-Refine. Let $\alpha_i \in \mathcal{H}_{add}$, $\beta \in \mathcal{T}$, and concept name $A \notin \mathsf{lhs}(\gamma)$ satisfy the following conditions: (a) $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\gamma)$; (b) $\mathcal{T} \models \mathsf{lhs}(\beta) \sqsubseteq A$; (c) $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_i)$. Then there is some $j \leq i$ such that α_j is replaced in Line 4 of CN-Refine.*

Proof Assume $\mathcal{H}$, γ, α_i, β, and A satisfy the conditions of the lemma. If CN-Refine replaces some α_j with $j < i$ then we are done. Suppose this does not happen. Then we need to show that α_i is replaced. By Conditions (a), (b), and (c), $\mathcal{T} \models \mathsf{lhs}(\gamma) \sqcap \mathsf{lhs}(\alpha_i) \sqsubseteq A$. As γ is left saturated for $\mathcal{H}$, $A \notin \mathsf{lhs}(\gamma)$ implies that $\mathcal{H} \not\models \mathsf{lhs}(\gamma) \sqsubseteq A$. So $\mathcal{H} \not\models \mathsf{lhs}(\gamma) \sqcap \mathsf{lhs}(\alpha_i) \sqsubseteq A$. Then, the condition in Lines 1 and 2 of CN-Refine is satisfied and α_i is replaced. ❏

Lemma 48 *Let $\mathcal{T}$ be rhs-primitive and let $\mathcal{H}, \gamma$ be inputs to $\exists$-Refine. If γ has target $\beta \in \mathcal{T}$ and $\alpha_i \in \mathcal{H}_{add}$ satisfies $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_i)$, then there is some $j \leq i$ such that α_j is replaced in Line 5 or 8 of $\exists$-Refine.*

Proof Let $\mathcal{H}$, γ, β, and α_i satisfy the conditions of the lemma. If $\exists$-Refine replaces some α_j with $j < i$ then we are done. Suppose this does not happen. We need to show that α_i is replaced. We first show that there is a concept C of the form $\exists r.F$ in $\mathsf{rhs}(\gamma)$ such that $\mathsf{lhs}(\gamma) \sqsubseteq C$ has target β. Note that if Algorithm 3 calls $\exists$-Refine then there is no concept name A such that $\mathcal{T} \models \mathsf{lhs}(\gamma) \sqsubseteq A$ and $\mathcal{H} \not\models \mathsf{lhs}(\gamma) \sqsubseteq A$ (Line 10). As γ is left saturated for $\mathcal{H}$ and $\mathcal{T}$-essential, this implies $\mathsf{N_C} \cap \mathsf{rhs}(\gamma) \subseteq \mathsf{lhs}(\gamma)$. But then any $C \in \mathsf{rhs}(\gamma) \setminus \mathsf{lhs}(\gamma)$ with $\emptyset \models \mathsf{rhs}(\beta)^{\mathsf{sat}} \sqsubseteq C$ is compound. As γ has target β it follows that $\mathsf{lhs}(\gamma) \sqsubseteq C$ has target β for some C of the form $\exists r.F$ in $\mathsf{rhs}(\gamma)$. By Line 5 of Algorithm 3, there is only one such conjunct C in $\mathsf{rhs}(\gamma)$. From $\emptyset \models \mathsf{rhs}(\beta)^{\mathsf{sat}} \sqsubseteq C$ we obtain $\mathcal{T} \models \mathsf{lhs}(\beta) \sqsubseteq C$. Since $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\gamma) \cap \mathsf{lhs}(\alpha_i)$, we have that $\mathcal{T} \models \mathsf{lhs}(\gamma) \cap \mathsf{lhs}(\alpha_i) \sqsubseteq C$. As γ is a positive counterexample, $\mathcal{H} \not\models \gamma$. From $\mathsf{N_C} \cap \mathsf{rhs}(\gamma) \subseteq \mathsf{lhs}(\gamma)$ we thus obtain $\mathcal{H} \not\models \mathsf{lhs}(\gamma) \sqsubseteq C$, and so, $\mathcal{H} \not\models \mathsf{lhs}(\alpha_i) \cap \mathsf{lhs}(\gamma) \sqsubseteq C$. Hence, the condition in Lines 1 and 2 of $\exists$-Refine is satisfied and α_i is replaced (in Line 5 or 8). ❏

Point (iv) above is now a direct consequence of the following lemma.

Lemma 49 *At any point in the execution of Algorithm 3, if $\alpha_j \in \mathcal{H}_{add}$ has target $\beta \in \mathcal{T}$ then $\mathsf{lhs}(\beta) \not\subseteq \mathsf{lhs}(\alpha_i)$, for all $i < j$.*

Proof The proof is by induction on the number k of iterations. For $k = 1$ the lemma is vacuously true. Assume it holds for $k = n$, $n \geq 1$. Now the algorithm modifies $\mathcal{H}_{add}$ in response to receiving a positive counterexample in iteration $k = n + 1$. We make a case distinction:

Case 1. Algorithm 3 calls CN-Refine: Let $\mathcal{H}, \gamma$ be the inputs to CN-Refine. Assume first that the condition in Lines 1 and 2 is not satisfied. Then CN-Refine appends the result of concept saturating γ for $\mathcal{T}$ to $\mathcal{H}_{add}$. Call this CI γ'. Suppose that the lemma fails to hold. This can only happen if γ' has a target $\beta \in \mathcal{T}$ and there is $\alpha_i \in \mathcal{H}_{add}$ such that $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_i)$. Then, since $\mathsf{lhs}(\gamma') = \mathsf{lhs}(\gamma)$, we have that $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\gamma)$ and, since $\mathsf{rhs}(\gamma') \subseteq \mathsf{N_C}$, there is a concept name $A \notin \mathsf{lhs}(\gamma)$ such that $\emptyset \models \mathsf{rhs}(\beta)^{\mathsf{sat}} \sqsubseteq A$. So $\mathcal{T} \models \mathsf{lhs}(\beta) \sqsubseteq A$. Then Lemma 47 applies to $\mathcal{H}$, γ, α_i, β and A which contradicts the assumption that CN-Refine did not replace any $\alpha_j \in \mathcal{H}_{add}$, $j \leq i$.

Now assume that the condition in Lines 1 and 2 is satisfied. Suppose that the lemma fails to hold. This can only happen if there are $\alpha_i, \alpha_j \in \mathcal{H}_{add}$ with $i < j$ such that either (a) α_i is replaced by α_i', $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_i')$ and α_j has target β; or (b) α_j is replaced by α_j', α_j' has target β and $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_i)$. In case (a), from $\mathsf{lhs}(\gamma) \cap \mathsf{lhs}(\alpha_i) = \mathsf{lhs}(\alpha_i')$, we obtain $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\gamma) \cap \mathsf{lhs}(\alpha_i)$. Thus, $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_i)$. This contradicts the induction hypothesis. Now assume case (b). Since α_j' has target β, we obtain:

1. $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_j')$; and
2. as $\mathsf{rhs}(\alpha_j') \subseteq \mathsf{N_C}$, there is $A \in \mathsf{N_C}$ with $A \in \mathsf{rhs}(\alpha_j') \setminus \mathsf{lhs}(\alpha_j')$ and $\emptyset \models \mathsf{rhs}(\beta)^{\mathsf{sat}} \sqsubseteq A$.

Since $\mathsf{lhs}(\gamma) \cap \mathsf{lhs}(\alpha_j) = \mathsf{lhs}(\alpha_j')$, it follows from Point 1 that $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_j)$ and $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\gamma)$. From $\emptyset \models \mathsf{rhs}(\beta)^{\mathsf{sat}} \sqsubseteq A$ we obtain $\mathcal{T} \models \mathsf{lhs}(\beta) \sqsubseteq A$. If $A \in \mathsf{rhs}(\alpha_j') \setminus \mathsf{lhs}(\alpha_j')$ then either $A \in \mathsf{rhs}(\alpha_j) \setminus \mathsf{lhs}(\alpha_j)$ or $A \notin \mathsf{lhs}(\gamma)$. So either α_j has target β or $A \notin \mathsf{lhs}(\gamma)$. α_j does not have target β as this would contradict the induction hypothesis. Thus, $A \notin \mathsf{lhs}(\gamma)$ and the conditions of Lemma 47 are satisfied by $\mathcal{H}$, γ, α_i, β, and A. Thus, some $\alpha_{i'}$ with $i' \leq i$ is replaced which contradicts the assumption that α_j is replaced.

Case 2. Algorithm 3 calls $\exists$-Refine: Let $\mathcal{H}, \gamma$ be the inputs to $\exists$-Refine. Assume first that the condition in Lines 1 and 2 is not satisfied. Then $\exists$-Refine appends γ to $\mathcal{H}_{add}$. Suppose the lemma fails to hold. This can only happen if γ has a target $\beta \in \mathcal{T}$ and there is $\alpha_i \in \mathcal{H}_{add}$ such that $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_i)$. By Lemma 48, this contradicts the assumption that $\exists$-Refine did not replace any $\alpha_j \in \mathcal{H}_{add}$, $j \leq i$.

Assume now that the condition in Lines 1 and 2 is satisfied. Suppose that the lemma fails to hold. This can only happen if there are $\alpha_i, \alpha_j \in \mathcal{H}_{add}$ with $i < j$ such that either (a) α_i is replaced by α_i', $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_i')$ and α_j has target β; or (b) α_j is replaced by α_j', α_j' has target β and $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_i)$. For case (a) we argue as above: from $\mathsf{lhs}(\gamma) \cap \mathsf{lhs}(\alpha_i) = \mathsf{lhs}(\alpha_i')$, we obtain $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\gamma) \cap \mathsf{lhs}(\alpha_i)$. Thus, $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_i)$, which contradicts the induction hypothesis. Now assume case (b). As α_j' has target β, we obtain the following:

1. $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha'_j)$; and

2. there is $D \in \mathsf{rhs}(\alpha'_j) \setminus \mathsf{lhs}(\alpha'_j)$ and $\emptyset \models \mathsf{rhs}(\beta)^{\mathsf{sat}} \sqsubseteq D$.

Since $\mathsf{lhs}(\gamma) \cap \mathsf{lhs}(\alpha_j) = \mathsf{lhs}(\alpha'_j)$, it follows from Point 1 that $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\alpha_j)$ and $\mathsf{lhs}(\beta) \subseteq \mathsf{lhs}(\gamma)$. Recall that if Algorithm 3 calls $\exists$-Refine then there is no $A \in \mathsf{N_C}$ such that $\mathcal{T} \models \mathsf{lhs}(\gamma) \sqsubseteq A$ and $\mathcal{H} \not\models \mathsf{lhs}(\gamma) \sqsubseteq A$. So $\mathsf{N_C} \cap \mathsf{rhs}(\gamma) \subseteq \mathsf{lhs}(\gamma)$ (by left saturation of γ for $\mathcal{H}$). Assume $D \in \mathsf{N_C}$. Since $D \in \mathsf{rhs}(\alpha'_j) \setminus \mathsf{lhs}(\alpha'_j)$ (Point 2), it follows that $D \notin \mathsf{lhs}(\alpha_j)$. As $\mathsf{lhs}(\alpha'_j) \subseteq \mathsf{lhs}(\alpha_j)$, we have that $D \in \mathsf{rhs}(\alpha_j)$. So $D \in \mathsf{rhs}(\alpha_j) \setminus \mathsf{lhs}(\alpha_j)$. This means that α_j has target β, which contradicts the induction hypothesis. Otherwise, D is of the form $\exists r.F$. Then, either $D \in \mathsf{rhs}(\gamma)$ or there is $D' \in \mathsf{rhs}(\alpha_j)$ such that $\emptyset \models D \sqsubseteq D'$. In the latter case, $D' \in \mathsf{rhs}(\alpha_j) \setminus \mathsf{lhs}(\alpha_j)$ and $\emptyset \models \mathsf{rhs}(\beta)^{\mathsf{sat}} \sqsubseteq D'$, so α_j has target β, which contradicts the induction hypothesis. In the former case, γ has target β. Then $\mathcal{H}$, γ, and α_i satisfy the conditions of Lemma 48. Thus, some $\alpha_{i'}$ with $i' \leq i$ is replaced which contradicts the assumption that α_j is replaced. ❑

We have proved the main result of this section.

Theorem 50 *DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ TBoxes are polynomial query learnable using membership and equivalence queries. Moreover, DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ TBoxes without inverse roles can be learned in polynomial time using membership and equivalence queries.*

Proof Polynomial query learnability of DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ TBoxes follows from Lemma 41 and the analysis of the number of membership queries in Lemmas 39 and 40, see the proof of Theorem 34. For the second part observe that the only potentially costly steps are entailment checks of the form $\mathcal{H} \models \alpha$, where $\mathcal{H}$ is a DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ TBox and α a DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ CI, both without inverse roles. Then both $\mathcal{H}$ and α are in $\mathcal{EL}$ with role inclusions for which entailment is known to be in PTIME (Baader et al., 2005). ❑

5. Learning $\mathcal{EL}_{\mathsf{lhs}}$ TBoxes

We study polynomial learnability of TBoxes in the restriction $\mathcal{EL}_{\mathsf{lhs}}$ of $\mathcal{EL}$ in which only concept names are allowed on the right-hand side of CIs. We assume that CIs used in membership queries and in equivalence queries and those returned as counterexamples are also of this restricted form and show that under this assumption $\mathcal{EL}_{\mathsf{lhs}}$ TBoxes can be learned in polynomial time. As in the previous section, our learning algorithm is an extension of the polynomial time algorithm for learning propositional Horn theories presented by Angluin et al. (1992) and Arias and Balcázar (2011).

There is a certain similarity between the learning algorithm of this section and the DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ learning algorithm introduced in Section 4. In both cases the left-hand side of inclusions can contain complex concept expressions, which, unless addressed, might lead to several counterexamples with unnecessarily strong left-hand sides targeting the same inclusion in the target TBox. In Algorithm 3 storing multiple such counterexamples in $\mathcal{H}_{add}$ is prevented by taking the intersection of the set of conjuncts of the left-hand sides. To deal with the more complex left-hand sides of inclusions in $\mathcal{EL}_{\mathsf{lhs}}$, a more sophisticated way of 'taking the intersection' of concept expressions is required. To define it, we identify concept

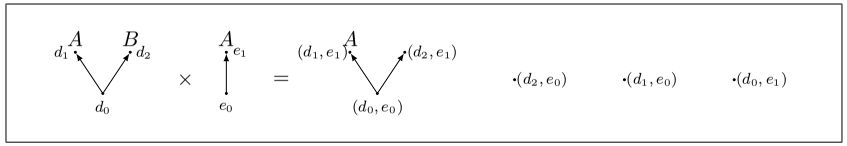

Figure 11: Illustration to Example 52.

expressions with tree-shaped interpretations and then take their product. Products have also been employed in the construction of least common subsumers (Baader et al., 1999).

In detail, we say that an interpretation $\mathcal{I}$ is a *ditree interpretation* if the directed graph $(\Delta^{\mathcal{I}}, E)$ with $E = \bigcup_{r \in \mathsf{N_R}} r^{\mathcal{I}}$ is a directed tree and $r^{\mathcal{I}} \cap s^{\mathcal{I}} = \emptyset$ for all distinct $r, s \in \mathsf{N_R}$. We denote the root of a ditree interpretation $\mathcal{I}$ with $\rho_{\mathcal{I}}$. The interpretation $\mathcal{I}_C$ corresponding to an $\mathcal{EL}$ concept expression C is a ditree interpretation with root ρ_C. Conversely, every ditree interpretation $\mathcal{I}$ can be viewed as an $\mathcal{EL}$ concept expression $C_{\mathcal{I}}$ in the same way as any labelled tree T with edge labels that are role names (rather than arbitrary roles) can be seen as an $\mathcal{EL}$ concept expression.

An interpretation $\mathcal{I}$ is a *$\mathcal{T}$-countermodel* for a given $\mathcal{EL}_{\mathsf{lhs}}$ TBox $\mathcal{T}$ if $\mathcal{I} \not\models \mathcal{T}$. Notice that for any $\mathcal{EL}_{\mathsf{lhs}}$ inclusion $C \sqsubseteq A$ with $\mathcal{T} \models C \sqsubseteq A$ and $\emptyset \not\models C \sqsubseteq A$ the interpretation $\mathcal{I}_C$ is a $\mathcal{T}$-countermodel. Indeed, by construction of $\mathcal{I}_C$, we have $\rho_C \in C^{\mathcal{I}_C}$ and, as $\emptyset \not\models C \sqsubseteq A$, we have $\rho_C \notin A^{\mathcal{I}_C}$. So $\mathcal{I}_C \not\models C \sqsubseteq A$ and, as $\mathcal{T} \models C \sqsubseteq A$, we have $\mathcal{I}_C \not\models \mathcal{T}$. Conversely, given a $\mathcal{T}$-countermodel $\mathcal{I}$, a learning algorithm can construct in polynomial time in $|\Sigma_{\mathcal{T}}|$ all inclusions of the form $C_{\mathcal{I}} \sqsubseteq A$, where A is a concept name, such that $\mathcal{T} \models C_{\mathcal{I}} \sqsubseteq A$ by posing membership queries to the oracle. Thus a learning algorithm can use inclusions and $\mathcal{T}$-countermodels interchangeably. We prefer working with interpretations as we can then use the notion of products to define the 'intersection of concept expressions' and the results of Section 2 linking homomorphisms with entailment in a direct way.

The *product* of two interpretations $\mathcal{I}$ and $\mathcal{J}$ is the interpretation $\mathcal{I} \times \mathcal{J}$ with

$$\begin{aligned} \Delta^{\mathcal{I}\times\mathcal{J}} &= \Delta^{\mathcal{I}} \times \Delta^{\mathcal{J}} \\ A^{\mathcal{I}\times\mathcal{J}} &= \{(d,e) \mid d \in A^{\mathcal{I}}, e \in A^{\mathcal{J}}\} \\ r^{\mathcal{I}\times\mathcal{J}} &= \{((d,e),(d',e')) \mid (d,d') \in r^{\mathcal{I}}, (e,e') \in r^{\mathcal{J}}\} \end{aligned}$$

Products preserve the membership in $\mathcal{EL}$ concept expressions (Lutz et al., 2011):

Lemma 51 *For all interpretations $\mathcal{I}$ and $\mathcal{J}$, all $d \in \Delta^{\mathcal{I}}$ and $e \in \Delta^{\mathcal{J}}$, and for all $\mathcal{EL}$ concept expressions C the following holds: $d \in C^{\mathcal{I}}$ and $e \in C^{\mathcal{J}}$ if, and only if, $(d,e) \in C^{\mathcal{I}\times\mathcal{J}}$.*

One can easily show that the product of ditree interpretations is a disjoint union of ditree interpretations. If $\mathcal{I}$ and $\mathcal{J}$ are ditree interpretations, we denote by $\mathcal{I} \times_\rho \mathcal{J}$ the maximal ditree interpretation that is a subinterpretation of $\mathcal{I} \times \mathcal{J}$ and contains $(\rho_{\mathcal{I}}, \rho_{\mathcal{J}})$.

Example 52 *Figure 11 depicts the product of the ditree interpretations $\mathcal{I}$ with root d_0 and $\mathcal{J}$ with root e_0. The ditree interpretation $\mathcal{I} \times_\rho \mathcal{J}$ has root (d_0, e_0) and does not contain the nodes (d_2, e_0), (d_1, e_0) and (d_0, e_1) from $\mathcal{I} \times \mathcal{J}$.*

Observe that the product $\mathcal{I}_C \times \mathcal{I}_D$ of concept expressions $C = A_1 \sqcap \cdots \sqcap A_n$ and $D = B_1 \sqcap \cdots \sqcap B_m$, where $A_1, \ldots, A_n$ and $B_1, \ldots, B_m$ are concept names, coincides with the interpretation $\mathcal{I}_E$, where E is the conjunction of all concept names in $\{A_1, \ldots, A_n\} \cap \{B_1, \ldots, B_m\}$. Thus, products can be seen as a generalisation of taking the intersection of the concept names from the left-hand side of DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ concept inclusions used in Section 4.

We will now describe a class of $\mathcal{T}$-countermodels that are in a sense minimal and central to our learning algorithm. Let $\mathcal{T}$ be the $\mathcal{EL}_{\mathsf{lhs}}$ TBox to be learned, and assume that its signature $\Sigma_{\mathcal{T}}$ is known to the learner. For a ditree interpretation $\mathcal{I}$, we use $\mathcal{I}|^{-}_{\rho}$ to denote the interpretation obtained from $\mathcal{I}$ by removing the root $\rho_{\mathcal{I}}$ of $\mathcal{I}$. For any $d \in \Delta^{\mathcal{I}} \setminus \{\rho_{\mathcal{I}}\}$, we use $\mathcal{I}|^{-}_{d\downarrow}$ to denote $\mathcal{I}$ with the subtree rooted at d removed. A $\mathcal{T}$-countermodel is *essential* if the following conditions are satisfied:

1. $\mathcal{I}|^{-}_{\rho} \models \mathcal{T}$;
2. $\mathcal{I}|^{-}_{d\downarrow} \models \mathcal{T}$ for all $d \in \Delta^{\mathcal{I}} \setminus \{\rho_{\mathcal{I}}\}$.

Intuitively, Condition 1 states that $\mathcal{I}$ contradicts $\mathcal{T}$ only at the root, that is, the only reason for why $\mathcal{I}$ does not satisfy $\mathcal{T}$ is that for at least one CI $C \sqsubseteq A \in \mathcal{T}$, we have that $\rho_{\mathcal{I}} \in C^{\mathcal{I}}$ and $\rho_{\mathcal{I}} \notin A^{\mathcal{I}}$. Condition 2 is a minimality condition which states that for any such $C \sqsubseteq A \in \mathcal{T}$, $\rho_{\mathcal{I}}$ is no longer in $C^{\mathcal{I}}$ if we remove any node from $\mathcal{I}$. Example 61 at the end of this section shows that working with essential $\mathcal{T}$-countermodels is needed for our learning algorithm to be in polynomial time.

The algorithm for learning $\mathcal{EL}_{\mathsf{lhs}}$ TBoxes is given as Algorithm 6. It maintains an ordered list $\mathfrak{I}$ of ditree interpretations that intuitively represents the TBox $\mathcal{H}$ constructed in Line 13. In Line 6 we write $\mathcal{I} \to_{\rho} \mathcal{J}$ if there is a homomorphism from a ditree interpretation $\mathcal{I}$ to a ditree interpretation $\mathcal{J}$ mapping $\rho_{\mathcal{I}}$ to $\rho_{\mathcal{J}}$. $\mathcal{I} \not\to_{\rho} \mathcal{J}$ denotes that no such homomorphism exists. By Lemma 10, $\mathcal{I} \to_{\rho} \mathcal{J}$ iff $\emptyset \models C_{\mathcal{J}} \sqsubseteq C_{\mathcal{I}}$ which can be checked in polynomial time in the size of $\mathcal{I}$ and $\mathcal{J}$. In Line 8, we write $\mathcal{J}' \subseteq \mathcal{I} \times_{\rho} \mathcal{J}$ as shorthand for the condition that $\mathcal{J}'$ is a subinterpretation of $\mathcal{I} \times_{\rho} \mathcal{J}$ that is obtained from $\mathcal{I} \times_{\rho} \mathcal{J}$ by removing subtrees. Note that the assumption in Line 4 that a *positive* counterexample is returned is justified by the construction of $\mathcal{H}$ in Lines 2 and 13, which ensures that, at all times, $\mathcal{T} \models \mathcal{H}$.

We now provide additional details on how to realise lines 5, 8 and 13. Line 13 is the easiest: we simply use membership queries '$\mathcal{T} \models C_{\mathcal{I}} \sqsubseteq A$?' with $\mathcal{I} \in \mathfrak{I}$ and $A \in \Sigma_{\mathcal{T}}$ to find all CIs $C_{\mathcal{I}} \sqsubseteq A$ entailed by $\mathcal{T}$. We will later show that the length of $\mathfrak{I}$ is bounded polynomially in $|\mathcal{T}|$ and that each interpretation in $\mathfrak{I}$ is replaced only polynomially many times, therefore polynomially many membership queries suffice. Lines 5 and 8 are addressed by Lemmas 53 and 54 below.

Lemma 53 *Given a positive counterexample $C \sqsubseteq A$ for $\mathcal{T}$ relative to $\mathcal{H}$, one can construct an essential $\mathcal{T}$-countermodel $\mathcal{I}$ with $\mathcal{I} \models \mathcal{H}$ using only polynomially many membership queries in $|\mathcal{T}| + |C|$.*

Proof Let $C \sqsubseteq A$ be a positive counterexample for $\mathcal{T}$ relative to $\mathcal{H}$. Let $\mathcal{I}_C$ be the ditree interpretation of C. First observe that $\mathcal{I}_C \not\models \mathcal{T}$: since $\mathcal{H} \not\models C \sqsubseteq A$, we know that A does not occur as a top-level conjunct in C. Consequently, $\rho_C \in C^{\mathcal{I}_C} \setminus A^{\mathcal{I}_C}$ and thus $\mathcal{I}_C \not\models \mathcal{T}$.

We construct an essential $\mathcal{T}$-countermodel $\mathcal{I}$ with $\mathcal{I} \models \mathcal{H}$ by applying the following rules to $\mathcal{I} := \mathcal{I}_C$.

Algorithm 6 The learning algorithm for $\mathcal{EL}_{\mathsf{lhs}}$ TBoxes

Input: $\mathcal{EL}_{\mathsf{lhs}}$ TBox $\mathcal{T}$ given to the oracle; $\Sigma_{\mathcal{T}}$ given to the learner.

Output: TBox $\mathcal{H}$, computed by the learner, such that $\mathcal{T} \equiv \mathcal{H}$.

15: return ℋ
```

1. Saturate $\mathcal{I}$ by exhaustively applying the CIs from $\mathcal{H}$ as rules: if $D \sqsubseteq B \in \mathcal{H}$ and $d \in D^{\mathcal{I}}$, then add d to $B^{\mathcal{I}}$.
2. Replace $\mathcal{I}$ by a minimal subtree of $\mathcal{I}$ refuting $\mathcal{T}$ to address Condition 1 of essential $\mathcal{T}$-countermodels. To describe how this can be achieved using membership queries denote for $d \in \Delta^{\mathcal{I}}$ by $\mathcal{I}|_d$ the ditree interpretation obtained from $\mathcal{I}$ by taking the subtree of $\mathcal{I}$ rooted in d. Now check using membership queries for any $d \in \Delta^{\mathcal{I}} \setminus \{\rho_{\mathcal{I}}\}$ and concept name B whether $\mathcal{T} \models C_{\mathcal{I}|_d} \sqsubseteq B$. Then replace $\mathcal{I}$ by any $\mathcal{I}|_d$ such that there exists a B with $\mathcal{T} \models C_{\mathcal{I}|_d} \sqsubseteq B$ and $d \notin B^{\mathcal{I}|_d}$ but there does not exist a d' in $\Delta^{\mathcal{I}|_d}$ and a B' with $\mathcal{T} \models C_{\mathcal{I}|_{d'}} \sqsubseteq B'$ and $d' \notin B^{\mathcal{I}|_{d'}}$. If no such d and B exist, then $\mathcal{I}$ is not replaced.
3. Exhaustively remove subtrees from $\mathcal{I}$ until Condition 2 of essential $\mathcal{T}$-countermodels is also satisfied: if $\mathcal{I}|^{-}_{d\downarrow} \not\models \mathcal{T}$, then replace $\mathcal{I}$ by $\mathcal{I}|^{-}_{d\downarrow}$. This can again be achieved using the membership queries $\mathcal{T} \models C_{\mathcal{I}|^{-}_{d\downarrow}} \sqsubseteq B$ for B a concept name.

Now we show that the interpretation $\mathcal{J}$ constructed above has the required properties. First observe that $\mathcal{J} \models \mathcal{H}$: clearly, the interpretation $\mathcal{I}$ constructed in Step 1 is a model of $\mathcal{H}$. As taking subtrees and removing subtrees from $\mathcal{I}$ preserves being a model of $\mathcal{H}$, we conclude that $\mathcal{J} \models \mathcal{H}$. Next we show that $\mathcal{J} \not\models \mathcal{T}$: the interpretation $\mathcal{I}$ constructed in Step 1 is not a model of $\mathcal{T}$. In fact, we can use $C_{\mathcal{I}} \sqsubseteq A$ as a positive counterexample for $\mathcal{T}$ relative to $\mathcal{H}$ instead of $C \sqsubseteq A$. Observe that $\emptyset \models C_{\mathcal{I}} \sqsubseteq C$, and thus $\mathcal{T} \models C \sqsubseteq A$ implies $\mathcal{T} \models C_{\mathcal{I}} \sqsubseteq A$. On the other hand, $\rho_{\mathcal{I}} \in B^{\mathcal{I}}$ implies $\mathcal{H} \models C \sqsubseteq B$ for all concept names B. Consequently and since $\mathcal{H} \not\models C \sqsubseteq A$, we have $\rho_{\mathcal{I}} \notin A^{\mathcal{I}}$. Thus $\mathcal{I} \not\models \mathcal{T}$. By construction, Steps 2 and 3 preserve the condition that $\mathcal{I}$ is not a model of $\mathcal{T}$ and so $\mathcal{J} \not\models \mathcal{T}$. It remains to argue that $\mathcal{J}$

satisfies Conditions 1 and 2 for essential $\mathcal{T}$-countermodels for $\mathcal{H}$. But Condition 1 is ensured by Step 2 and Condition 2 is ensured by Step 3, respectively. ❑

Lemma 54 *Given essential $\mathcal{T}$-countermodels $\mathcal{I}$ and $\mathcal{J}$ with $\mathcal{I} \times_\rho \mathcal{J} \not\models \mathcal{T}$, one can construct an essential $\mathcal{T}$-countermodel $\mathcal{J}' \subseteq \mathcal{I} \times_\rho \mathcal{J}$ using only polynomially many membership queries in $|\mathcal{T}| + |\mathcal{I}| + |\mathcal{J}|$.*

Proof Let $\mathcal{I}$ and $\mathcal{J}$ be essential $\mathcal{T}$-countermodels with $\mathcal{I} \times_\rho \mathcal{J} \not\models \mathcal{T}$. Obtain the interpretation $\mathcal{J}'$ from $\mathcal{I} \times_\rho \mathcal{J}$ by exhaustively applying Rule 3 from the proof of Lemma 53. As argued above, applying Rule 3 can be implemented using membership queries and $\mathcal{J}'$ is a $\mathcal{T}$-countermodel. Thus, it remains to argue that it satisfies Conditions 1 and 2 for $\mathcal{T}$-essential countermodels. For Condition 1, we have to show that $\mathcal{J}'|_\rho^- \models \mathcal{T}$. We know that $\mathcal{I}|_\rho^- \models \mathcal{T}$ and $\mathcal{J}|_\rho^- \models \mathcal{T}$. Thus, by Lemma 51, $\mathcal{I}|_\rho^- \times \mathcal{J}|_\rho^- \models \mathcal{T}$. Now $\mathcal{J}'|_\rho^-$ is obtained from $\mathcal{I}|_\rho^- \times \mathcal{J}|_\rho^-$ by removing subtrees and removing subtrees preserves being a model of an $\mathcal{EL}_{\mathsf{lhs}}$ TBox. Thus, $\mathcal{J}'|_\rho^- \models \mathcal{T}$. For Condition 2, we have to show that $\mathcal{J}'|_{d\downarrow}^- \models \mathcal{T}$ for all $d \in \Delta^{\mathcal{J}'} \setminus \{\rho_{\mathcal{J}'}\}$. But if this is not the case, then the subtree rooted at d would have been removed during the construction of $\mathcal{J}'$ from $\mathcal{I} \times_\rho \mathcal{J}$ using Rule 3. ❑

If Algorithm 6 terminates, then it obviously returns a TBox $\mathcal{H}$ that is equivalent to the target TBox $\mathcal{T}$. It thus remains to prove that the algorithm terminates after polynomially many steps, which is a consequence of the following lemma.

Lemma 55 *Let $\mathfrak{I}$ be a list computed at some point of an execution of Algorithm 6. Then (i) the length of $\mathfrak{I}$ is bounded by the number of CIs in $\mathcal{T}$ and (ii) each interpretation in each position of $\mathfrak{I}$ is replaced only $|\mathcal{T}| + |\mathcal{T}|^2$ often with a new interpretation.*

The rest of this section is devoted to proving Lemma 55. For easy reference, assume that at each point of the execution of the algorithm, $\mathfrak{I}$ has the form $\mathcal{I}_0, \dots, \mathcal{I}_k$ for some $k \geq 0$. To establish Point (i) of Lemma 55, we closely follow the argument given by Angluin et al. (1992) and show that

(iii) for every $\mathcal{I}_i$, there is a $D_i \sqsubseteq A_i \in \mathcal{T}$ with $\mathcal{I}_i \not\models D_i \sqsubseteq A_i$ and

(iv) if $i \neq j$, then $D_i \sqsubseteq A_i$ and $D_j \sqsubseteq A_j$ are not identical.

In fact, Point (iii) is immediate since whenever a new $\mathcal{I}_i$ is added to $\mathfrak{I}$ in the algorithm, then $\mathcal{I}_i$ is a $\mathcal{T}$-countermodel. To prove Point (iv), we first establish the intermediate Lemma 56 below. For a ditree interpretation $\mathcal{I}$ and a CI $C \sqsubseteq A$, we write $\mathcal{I} \models^\rho C \sqsubseteq A$ if $\rho_\mathcal{I} \notin C^\mathcal{I}$ or $\rho_\mathcal{I} \in A^\mathcal{I}$; that is, the CI $C \sqsubseteq A$ is satisfied at the root of $\mathcal{I}$, but not necessarily at other points in $\mathcal{I}$. It is easy to see that if some interpretation $\mathcal{I}$ is a $\mathcal{T}$-countermodel, then there is $C \sqsubseteq A \in \mathcal{T}$ such that $\mathcal{I} \not\models^\rho C \sqsubseteq A$.

The following lemma shows under which conditions Algorithm 6 replaces an interpretation in the list $\mathfrak{I}$.

Lemma 56 *If the interpretation $\mathcal{I}$ constructed in Line 5 of Algorithm 6 satisfies $\mathcal{I} \not\models^\rho C \sqsubseteq A \in \mathcal{T}$ and $\rho_{\mathcal{I}_j} \in C^{\mathcal{I}_j}$ for some j, then $\mathcal{J} = \mathcal{I}_i$ is replaced with $\mathcal{J}'$ in Line 9 for some $i \leq j$.*

Proof Assume that the interpretation $\mathcal{I}$ constructed in Line 5 of Algorithm 6 satisfies $\mathcal{I} \not\models^\rho C \sqsubseteq A \in \mathcal{T}$ and that there is some j with $\rho_{\mathcal{I}_j} \in C^{\mathcal{I}_j}$. If there is some $i < j$ such that $\mathcal{I}_i \not\to_\rho (\mathcal{I} \times_\rho \mathcal{I}_i)$ and $\mathcal{I} \times_\rho \mathcal{I}_i \not\models \mathcal{T}$, then $\mathcal{J} = \mathcal{I}_{i'}$ will be replaced with $\mathcal{J}'$ in Line 9 for some $i' \leq i$ and we are done. Thus assume that there is no such i. We aim to show that $\mathcal{J} = \mathcal{I}_j$ is replaced with $\mathcal{J}'$ in Line 9. To this end, it suffices to prove that $\mathcal{I}_j \not\to_\rho (\mathcal{I} \times_\rho \mathcal{I}_j)$ and $\mathcal{I} \times_\rho \mathcal{I}_j \not\models \mathcal{T}$. The latter is a consequence of $\mathcal{I} \not\models^\rho C \sqsubseteq A$ and $\rho_{\mathcal{I}_j} \in C^{\mathcal{I}_j}$.

Assume to the contrary of what we have to show that $\mathcal{I}_j \to_\rho (\mathcal{I} \times_\rho \mathcal{I}_j)$. We establish a contradiction against $\mathcal{I} \models \mathcal{H}$ (which holds by construction of $\mathcal{I}$ in the algorithm) by showing that

1. $\mathcal{I} \not\models^\rho C_{\mathcal{I}_j} \sqsubseteq A$ and
2. $C_{\mathcal{I}_j} \sqsubseteq A \in \mathcal{H}$.

For Point 1, $\mathcal{I}_j \to_\rho (\mathcal{I} \times_\rho \mathcal{I}_j)$ and $\rho_{\mathcal{I}_j} \in (C_{\mathcal{I}_j})^{\mathcal{I}_j}$ imply $\rho_{\mathcal{I} \times_\rho \mathcal{I}_j} \in (C_{\mathcal{I}_j})^{\mathcal{I} \times_\rho \mathcal{I}_j}$, which gives $\rho_\mathcal{I} \in (C_{\mathcal{I}_j})^\mathcal{I}$, by Lemma 51. It remains to observe that $\mathcal{I} \not\models^\rho C \sqsubseteq A$ implies $\rho_\mathcal{I} \notin A^\mathcal{I}$.

In view of the construction of $\mathcal{H}$ in the algorithm, Point 2 can be established by showing that $\mathcal{T} \models C_{\mathcal{I}_j} \sqsubseteq A$. Since $C \sqsubseteq A \in \mathcal{T}$, it suffices to prove that $\emptyset \models C_{\mathcal{I}_j} \sqsubseteq C$. This, however, is an immediate consequence of the fact that $\rho_{\mathcal{I}_j} \in C^{\mathcal{I}_j}$ and the definition of $C_{\mathcal{I}_j}$. ❑

Now, Point (iv) above is a consequence of the following.

Lemma 57 *At any time of the algorithm execution, the following condition holds: if $\mathcal{I}_i \not\models^\rho C \sqsubseteq A \in \mathcal{T}$ and $j < i$, then $\rho_{\mathcal{I}_j} \notin C^{\mathcal{I}_j}$.*

Proof We prove the invariant formulated in Lemma 57 by induction on the number of iterations of the while loop. Clearly, the invariant is satisfied before the loop is entered. We now consider the two places where $\mathfrak{I}$ is modified, that is, Line 9 and Line 11, starting with the latter.

In Line 11, $\mathcal{I}$ is appended to $\mathfrak{I}$. Assume that $\mathcal{I} \not\models^\rho C \sqsubseteq A \in \mathcal{T}$. We have to show that, before $\mathcal{I}$ was added to $\mathfrak{I}$, there was no $\mathcal{I}_i \in \mathfrak{I}$ with $\rho_{\mathcal{I}_i} \in C^{\mathcal{I}_i}$. This, however, is immediate by Lemma 56.

Now assume that $\mathcal{J}$ was replaced in Line 9 with $\mathcal{J}'$. We have to show two properties:

1. If $\mathcal{J}' = \mathcal{I}_i \not\models^\rho C \sqsubseteq A \in \mathcal{T}$ and $j < i$, then $\rho_{\mathcal{I}_j} \notin C^{\mathcal{I}_j}$.

   Assume to the contrary that $\rho_{\mathcal{I}_j} \in C^{\mathcal{I}_j}$. Since $\mathcal{J}'$ is obtained from $\mathcal{I} \times \mathcal{J}$ by removing subtrees (see Lemma 54), $\mathcal{J}' \not\models^\rho C \sqsubseteq A$ implies $\mathcal{I} \times \mathcal{J} \not\models^\rho C \sqsubseteq A$. Consequently, $\mathcal{I} \not\models^\rho C \sqsubseteq A$ or $\mathcal{J} \not\models^\rho C \sqsubseteq A$. The former and $\rho_{\mathcal{I}_j} \in C^{\mathcal{I}_j}$ yields $i \leq j$ by Lemma 56, in contradiction to $j < i$. In the latter case, since $\mathcal{I}_i = \mathcal{J}$ before the replacement of $\mathcal{J}$ with $\mathcal{J}'$, we have a contradiction against the induction hypothesis.

2. If $\mathcal{J}' = \mathcal{I}_j$ and $\mathcal{I}_i \not\models^\rho C \sqsubseteq A \in \mathcal{T}$ with $i > j$, then $\rho_{\mathcal{I}_j} \notin C^{\mathcal{I}_j}$.

   Assume to the contrary that $\rho_{\mathcal{I}_j} \in C^{\mathcal{I}_j}$. Since $\mathcal{J}'$ is obtained from $\mathcal{I} \times_\rho \mathcal{J}$ by removing subtrees, we then have $\rho_{\mathcal{I} \times_\rho \mathcal{J}} \in C^{\mathcal{I} \times_\rho \mathcal{J}}$, thus $\rho_\mathcal{J} \in C^\mathcal{J}$. Since $\mathcal{I}_j = \mathcal{J}$ before the replacement of $\mathcal{J}$ with $\mathcal{J}'$, we have a contradiction against the induction hypothesis.

❑

We now turn towards proving Point (ii) of Lemma 55. It is a consequence of Lemma 59 below.

Lemma 58 *If $\mathcal{I}$ is an essential $\mathcal{T}$-countermodel, then $|\Delta^{\mathcal{I}}| \leq |\mathcal{T}|$.*

Proof Let $\mathcal{I}$ be an essential $\mathcal{T}$-countermodel. Then $\mathcal{I} \not\models \mathcal{T}$, but $\mathcal{I}|_\rho^- \models \mathcal{T}$. It follows that there is a $C \sqsubseteq A \in \mathcal{T}$ such that $\rho_{\mathcal{I}} \in C^{\mathcal{I}} \setminus A^{\mathcal{I}}$. By Lemma 8, there is a homomorphism h from $\mathcal{I}_C$ to $\mathcal{I}$ mapping $\rho_{\mathcal{I}_C}$ to $\rho_{\mathcal{I}}$. We show that $|\Delta^{\mathcal{I}}| \leq |C|$, from which $|\Delta^{\mathcal{I}}| \leq |\mathcal{T}|$ follows. It suffices to show that h is surjective. Assume that this is not the case and let $d \in \Delta^{\mathcal{I}}$ be outside the range of h. Then h is a homomorphism from $\mathcal{I}_C$ to $\mathcal{J} := \mathcal{I}|_{d\downarrow}^-$. Therefore, $\rho^{\mathcal{J}} \in C^{\mathcal{J}}$ by Lemma 8, which implies $\mathcal{J} \not\models C \sqsubseteq A$. But $\mathcal{J} \not\models C \sqsubseteq A$ contradicts the assumption that $\mathcal{I}$ is an essential $\mathcal{T}$-countermodel as it violates Condition 2 of being an essential $\mathcal{T}$-countermodel. ❑

Lemma 59 *Let $\mathcal{I}_0, \ldots, \mathcal{I}_n$ be a list of interpretations such that $\mathcal{I}_{i+1}$ replaces $\mathcal{I}_i$ in Line 9 for all $i < n$. Then $n \leq |\mathcal{T}| + |\mathcal{T}|^2$.*

Proof Let $\mathcal{I}$ and $\mathcal{J}$ be ditree interpretations. We set $\mathcal{I} \leq_\rho \mathcal{J}$ if $\rho_{\mathcal{I}} \in A^{\mathcal{I}}$ implies $\rho_{\mathcal{J}} \in A^{\mathcal{J}}$ for all concept names A. We first show that for every $i < n$ either

(a) $\mathcal{I}_i \not\leq_\rho \mathcal{I}_{i+1}$ or

(b) $\mathcal{I}_{i+1} \to_\rho \mathcal{I}_i$ via a surjective homomorphism.

For a proof by contradiction assume that there is $i < n$ such that neither (a) nor (b) holds. Since $\mathcal{I}_{i+1}$ is obtained from some $\mathcal{I} \times_\rho \mathcal{I}_i$ by removing subtrees and $(\mathcal{I} \times_\rho \mathcal{I}_i) \to_\rho \mathcal{I}_i$ we obtain that $\mathcal{I}_{i+1} \to_\rho \mathcal{I}_i$. Since $\mathcal{I}_{i+1}$ is an essential $\mathcal{T}$-countermodel, there is a $C \sqsubseteq A \in \mathcal{T}$ such that $\mathcal{I}_{i+1} \not\models^\rho C \sqsubseteq A$. Let $\mathcal{J}$ be the subinterpretation of $\mathcal{I}_i$ determined by the range of the homomorphism h from $\mathcal{I}_{i+1}$ to $\mathcal{I}_i$ mapping $\rho_{\mathcal{I}_{i+1}}$ to $\rho_{\mathcal{I}_i}$. By Lemma 8, $\rho_{\mathcal{J}} \in C^{\mathcal{J}}$ and so, since $\rho_{\mathcal{J}} \notin A^{\mathcal{J}}$ because (a) does not hold, $\mathcal{J} \not\models^\rho C \sqsubseteq A$. $\mathcal{I}_i$ is an essential $\mathcal{T}$-countermodel and so $\mathcal{J} = \mathcal{I}$. But then h is surjective and we have derived a contradiction.

In addition to the property stated above, we also have for all $i < n$:

(c) $\mathcal{I}_{i+1} \leq_\rho \mathcal{I}_i$ and

(d) $\mathcal{I}_i \not\to_\rho \mathcal{I}_{i+1}$.

It follows that for any $i < n$ with $\mathcal{I}_i \leq_\rho \mathcal{I}_{i+1}$ either $|\Delta^{\mathcal{I}_i}| < |\Delta^{\mathcal{I}_{i+1}}|$ or $|A^{\mathcal{I}_i}| < |A^{\mathcal{I}_{i+1}}|$ for some concept name A. By Lemma 58 we have $|\Delta^{\mathcal{I}_i}| \leq |\mathcal{T}|$ for all $i \leq n$. Hence $k - j \leq |\mathcal{T}|^2$ for any subsequence $\mathcal{I}_j \ldots, \mathcal{I}_k$ of $\mathcal{I}_0, \ldots, \mathcal{I}_n$ with $\mathcal{I}_i \leq_\rho \mathcal{I}_{i+1}$ for all $j \leq i < k$. It follows that $n \leq |\mathcal{T}| + |\mathcal{T}|^2$. ❑

We have thus established the main result of this section. Note that we obtain a polynomial time learning algorithm since checking $\mathcal{T} \models \alpha$ is in polynomial times for $\mathcal{EL}$ TBoxes $\mathcal{T}$ and $\mathcal{EL}$ CIs α (as discussed in Section 2).

Theorem 60 *$\mathcal{EL}_{\mathsf{lhs}}$ TBoxes are polynomial time learnable using membership and equivalence queries.*

The following example shows that Algorithm 6 does not terminate in polynomial time if in Line 5 it does not transform the given counterexample into an essential $\mathcal{T}$-countermodel.

Example 61 Assume that Line 5 of Algorithm 6 does not modify the counterexample $C \sqsubseteq A$ given in Line 4 if the second condition for essential $\mathcal{T}$-countermodels ($\mathcal{I}_C|_{d\downarrow}^- \models \mathcal{T}$ for all $d \in \Delta^{\mathcal{I}_C} \setminus \{\rho_{\mathcal{I}_C}\}$) is satisfied but the first condition ($\mathcal{I}_C|_\rho^- \models \mathcal{T}$) does not hold. Then for the target TBox $\mathcal{T} = \{\exists r.A \sqsubseteq A\}$ the oracle can return the infinite sequence of positive counterexamples $\exists r^n.A \sqsubseteq A$, with n a prime number. In fact, Algorithm 6 would simply construct the list $\mathfrak{I}$ of interpretations $\mathcal{I}_{\exists r^n.A}$, n a prime number, and would not terminate. To show this observe that Algorithm 6 would never replace a CI in the list $\mathfrak{I}$ by another CI since $\mathcal{I}_{\exists r^n.A} \times_\rho \mathcal{I}_{\exists r^{n+m}.A} = \mathcal{I}_{\exists r^n.\top}$ and $\mathcal{I}_{\exists r^n.\top} \models \mathcal{T}$.

Now assume that Line 5 of Algorithm 6 does not modify the counterexample $C \sqsubseteq A$ given in Line 4 if the first condition for essential $\mathcal{T}$-countermodels is satisfied but the second condition does not hold. Let $\mathcal{T}$ be a TBox containing $\exists r.A \sqsubseteq A$ and some CIs containing the concept names B_1 and B_2, say, for simplicity, $B_1 \sqsubseteq B_1$ and $B_2 \sqsubseteq B_2$. Let $\varphi^1 = \exists r.(B_1 \sqcap B_2)$ and $\varphi^{n+1} = \exists r.(\varphi^n \sqcap B_1 \sqcap B_2)$. Then the oracle can return n positive counterexamples $\exists r.A \sqcap C_i \sqsubseteq A$, where the tree T_{C_i} corresponding to C_i is the result of identifying the i-th node of the tree T_{φ^i} corresponding to φ_i with the root of the tree corresponding to $\exists r.(B_1 \sqcap \varphi^n) \sqcap \exists r.(B_2 \sqcap \varphi^n)$. Note that the product of $\mathcal{I}_{C_1}, \ldots, \mathcal{I}_{C_n}$ is an interpretation with $O(2^n)$ elements. Then, at the n-th iteration, Algorithm 6 computes an interpretation of exponential size in n.

6. Limits of Polynomial Learnability

The main result of this section is that $\mathcal{EL}$ TBoxes are not polynomial query learnable using membership and equivalence queries. We also show that DL-Lite$_{\mathcal{R}}^{\exists}$ TBoxes are not polynomial query learnable using membership or equivalence queries alone. The latter result also holds for $\mathcal{EL}_{\mathsf{lhs}}$ TBoxes. In this case, however, it follows already from the fact that propositional Horn logic is not polynomial query learnable from entailments using membership or equivalence queries alone (Frazier and Pitt, 1993; Angluin et al., 1992; Angluin, 1987a).

We start by proving the non-polynomial query learnability result for $\mathcal{EL}$ TBoxes. On our way, we also prove non-polynomial query learnability of DL-Lite$_{\mathcal{R}}^{\exists}$ TBoxes using membership queries only. Our proof shows that even acyclic $\mathcal{EL}$ TBoxes are not polynomial query learnable and, in fact, heavily relies on the additional properties of acyclic TBoxes. Recall that an $\mathcal{EL}$ TBox is called *acyclic* if it satisfies the following conditions (Baader et al., 2017; Konev et al., 2012):

- all CIs and CEs are of the form $A \sqsubseteq C$ or $A \equiv C$, where A is a concept name;
- no concept name occurs more than once on the left-hand side of a CI;
- there are no cyclic definitions: there is no sequence $\alpha_0, \ldots, \alpha_n$ of CIs such that the concept name on the left-hand side of α_0 occurs in α_n and the concept name on the left-hand side of α_{i+1} occurs in the right-hand side of α_i for all $i < n$.

Our non-polynomial query learnability proof is inspired by Angluin's lower bound for the following abstract learning problem (Angluin, 1987b): a learner aims to identify one of N distinct sets $L_1, \dots, L_N$ which have the property that there exists a set $L_\cap$ for which $L_i \cap L_j = L_\cap$, for any $i \neq j$. It is assumed that $L_\cap$ is not a valid argument to an equivalence query. The learner can pose membership queries "$x \in L$?" and equivalence queries "$H = L$?". Then in the worst case it takes at least $N-1$ membership and equivalence queries to exactly identify a hypothesis L_i from $L_1, \dots, L_N$. The proof proceeds as follows. At every stage of computation, the oracle (which here should be viewed as an adversary) maintains a set of hypotheses S, which the learner is not able to distinguish based on the answers given so far. Initially, $S = \{L_1, \dots, L_N\}$. When the learner asks a membership query x, the oracle returns 'Yes' if $x \in L_\cap$ and 'No' otherwise. In the latter case, the (unique) L_i such that $x \in L_i$ is removed from S. When the learner asks an equivalence query H, the oracle returns 'No' and a counterexample $x \in L_\cap \oplus H$ (the symmetric difference of $L_\cap$ and H). This always exists as $L_\cap$ is not a valid query. If the counterexample x is not a member of $L_\cap$, (at most one) $L_i \in S$ such that $x \in L_i$ is eliminated from S. In the worst case, the learner has to reduce the cardinality of S to one to exactly identify a hypothesis, which takes $N-1$ queries.

Similarly to the method outlined above, in our proof we maintain a set of acyclic $\mathcal{EL}$ TBoxes whose members the learning algorithm is not able to distinguish based on the answers obtained so far. For didactic purposes, we first present a set of acyclic TBoxes $S_N = \{\mathcal{T}_1, \dots, \mathcal{T}_N\}$, where N is superpolynomial in the size of every TBox $\mathcal{T}_i$, for which the oracle can respond to membership queries in the way described above but which is polynomial time learnable when equivalence queries are also allowed. We then show how the TBoxes can be modified to obtain a family of acyclic TBoxes that is not polynomial query learnable using membership and equivalence queries.

To present the TBoxes in S_N, fix two role names r and s. We use the following abbreviation. For any sequence $\sigma = \sigma^1\sigma^2 \dots \sigma^n \in \{r, s\}^n$, the expression $\exists \boldsymbol{\sigma}.C$ stands for $\exists \sigma^1.\exists \sigma^2 \dots \exists \sigma^n.C$. Then for every such sequence $\boldsymbol{\sigma}$, of which there are $N = 2^n$ many, consider the acyclic $\mathcal{EL}$ TBox $\mathcal{T}_\sigma$ defined as

$$\begin{array}{rcl} \mathcal{T}_{\boldsymbol{\sigma}} & = & \{A \sqsubseteq \exists \boldsymbol{\sigma}.M \sqcap X_0\} \cup \mathcal{T}_0 \text{ with} \\ \mathcal{T}_0 & = & \{X_i \sqsubseteq \exists r.X_{i+1} \sqcap \exists s.X_{i+1} \mid 0 \leq i < n\}. \end{array}$$

Observe that the canonical model $\mathcal{I}_{X_0,\mathcal{T}_0}$ of X_0 and $\mathcal{T}_0$ consists of a full binary tree whose edges are labelled with the role names r and s and with X_0 at the root ρ_{X_0}, X_1 at level 1, and so on. In the canonical model $\mathcal{I}_{A,\mathcal{T}_{\boldsymbol{\sigma}}}$ of A and $\mathcal{T}_{\boldsymbol{\sigma}}$, the root is labelled by A and X_0 and, *in addition to* the binary tree, there is a path given by the sequence $\boldsymbol{\sigma}$ whose endpoint is marked by the concept name M.

One can use Angluin's strategy to show that TBoxes from the set S_N of all such TBoxes $\mathcal{T}_{\boldsymbol{\sigma}}$ cannot be learned using polynomially many polynomial size membership queries only: notice that for no sequence $\boldsymbol{\sigma}' \neq \boldsymbol{\sigma}$ of length n, we have $\mathcal{T}_{\boldsymbol{\sigma}} \models A \sqsubseteq \exists \boldsymbol{\sigma}'.M$. Thus a membership query of the form $A \sqsubseteq \exists \boldsymbol{\sigma}.M$ eliminates at most one TBox from the set of TBoxes that the learner cannot distinguish. This observation can be generalised to arbitrary membership queries $C \sqsubseteq D$ in $\mathcal{EL}$; however, we instead observe that the TBoxes $\mathcal{T}_{\boldsymbol{\sigma}}$ are formulated in DL-Lite$^\exists_\mathcal{R}$ and prove a stronger result. The proof, given in the appendix, uses the canonical model construction introduced in Section 2.

Lemma 62 *For every DL-Lite$^\exists_\mathcal{R}$ CI $B \sqsubseteq D$ over the signature of $\mathcal{T}_{\boldsymbol{\sigma}}$,*

- *either $\mathcal{T}_{\boldsymbol{\sigma}} \models B \sqsubseteq D$ for every $\mathcal{T}_{\boldsymbol{\sigma}} \in S_N$*
- *or there is at most one $\mathcal{T}_{\boldsymbol{\sigma}} \in S_N$ such that $\mathcal{T}_{\boldsymbol{\sigma}} \models B \sqsubseteq D$.*

The argument outlined above immediately gives us the following side result.

Theorem 63 *DL-Lite$^\exists_\mathcal{R}$ TBoxes (even without inverse roles) are not polynomial query learnable using only membership queries.*

We return now to our proof that $\mathcal{EL}$ TBoxes are not polynomial query learnable using both membership and equivalence queries. Notice that the set of TBoxes S_N is not suitable as a single equivalence query is sufficient to learn any TBox from S_N in two steps: given the equivalence query $\{A \sqsubseteq X_0\} \cup \mathcal{T}_0$, the oracle has no other option but to reveal the target TBox $\mathcal{T}_{\boldsymbol{\sigma}}$ as $A \sqsubseteq \exists \boldsymbol{\sigma}.M$ can be found 'inside' every counterexample.

Our strategy to rule out equivalence queries with the 'intersection TBox' is to modify $\mathcal{T}_1, \dots, \mathcal{T}_N$ in such a way that although a TBox $\mathcal{T}_\cap$ axiomatising the intersection over the set of consequences of each $\mathcal{T}_i$, $i \leq N$, exists, its size is superpolynomial and so it cannot be used as an equivalence query by a polynomial query learning algorithm.

For every $n > 0$ and every n-tuple $L = (\boldsymbol{\sigma}_1, \dots, \boldsymbol{\sigma}_n)$, where every $\boldsymbol{\sigma}_i$ is a role sequence of length n as above, we define an acyclic $\mathcal{EL}$ TBox $\mathcal{T}_L$ as the union of $\mathcal{T}_0$ and the following CIs and CEs:[5]

$$\begin{array}{ccc} A_1 \sqsubseteq \exists \boldsymbol{\sigma}_1.M \sqcap X_0 & & A_n \sqsubseteq \exists \boldsymbol{\sigma}_n.M \sqcap X_0 \\ B_1 \sqsubseteq \exists \boldsymbol{\sigma}_1.M \sqcap X_0 & \cdots & B_n \sqsubseteq \exists \boldsymbol{\sigma}_n.M \sqcap X_0 \end{array}$$

$$A \equiv X_0 \sqcap \exists \boldsymbol{\sigma}_1.M \sqcap \dots \sqcap \exists \boldsymbol{\sigma}_n.M.$$

Observe that every $\mathcal{T}_L$ contains the TBoxes $\mathcal{T}_{\boldsymbol{\sigma}_i}$, $1 \leq i \leq n$, discussed above with A replaced by any of the three concept names A, A_i, B_i. In addition, *every* $\mathcal{T}_L$ entails, among other CIs, $\bigsqcap_{i=1}^n C_i \sqsubseteq A$, where every C_i is either A_i or B_i. There are 2^n different such CIs, which indicates that every representation of the 'intersection TBox' requires superpolynomially many axioms. It follows from Lemma 67 below that this is indeed the case.

Let $\mathfrak{L}_n$ be a set of n-tuples such that for $1 \leq i \leq n$ and every $L, L' \in \mathfrak{L}_n$ with $L = (\boldsymbol{\sigma}_1, \dots, \boldsymbol{\sigma}_n)$, $L' = (\boldsymbol{\sigma}'_1, \dots, \boldsymbol{\sigma}'_n)$, if $\boldsymbol{\sigma}_i = \boldsymbol{\sigma}'_j$ then $L = L'$ and $i = j$. Then for any sequence $\boldsymbol{\sigma}$ of length n there exists at most one $L \in \mathfrak{L}_n$ and at most one $i \leq n$ such that $\mathcal{T}_L \models A_i \sqsubseteq \exists \boldsymbol{\sigma}.M$ and $\mathcal{T}_L \models B_i \sqsubseteq \exists \boldsymbol{\sigma}.M$. We can choose $\mathfrak{L}_n$ such that there are $N = \lfloor 2^n/n \rfloor$ different tuples in $\mathfrak{L}_n$. Notice that the size of each $\mathcal{T}_L$ with $L \in \mathfrak{L}_n$ is polynomial in n and so N is superpolynomial in the size of each $\mathcal{T}_L$ with $L \in \mathfrak{L}_n$. Let the set of TBoxes that the learner cannot distinguish initially be $S_\mathfrak{L} = \{\mathcal{T}_L \mid L \in \mathfrak{L}_n\}$. We use Σ_n to denote the signature of $\mathcal{T}_L$.

For the proof of non-polynomial query learnability, we show that the oracle has a strategy to answer both membership and equivalence queries without eliminating too many TBoxes from $S_\mathfrak{L}$. We start with the former.

5. In fact, to prove non-polynomial query learnability, it suffices to consider $\exists \boldsymbol{\sigma}_1.M \sqcap \dots \sqcap \exists \boldsymbol{\sigma}_n.M \sqsubseteq A$ in place of the concept equivalence; however, CIs of this form are not allowed in acyclic TBoxes. CIs with a complex left-hand side or concept equivalences are essential for non-polynomial query learnability as any acyclic TBox containing expressions of the form $A \sqsubseteq C$ only is a DL-Lite$^\exists_\mathcal{R}$ TBox and thus polynomially learnable with membership and equivalence queries (Section 3).

Unlike the DL-Lite$^{\exists}_{\mathcal{R}}$ case presented above, membership query can eliminate more than one TBox from $S_{\mathfrak{L}}$. Consider, for example, two TBoxes $\mathcal{T}_L$ and $\mathcal{T}_{L'}$, where $\{L, L'\} \subseteq \mathfrak{L}_n$ with $L = (\boldsymbol{\sigma}_1, \ldots, \boldsymbol{\sigma}_n)$ and $L' = (\boldsymbol{\sigma}'_1, \ldots, \boldsymbol{\sigma}'_n)$. Then the CI

$$X_0 \sqcap \exists \boldsymbol{\sigma}_1.M \sqcap \exists \boldsymbol{\sigma}'_1.M \sqcap A_2 \sqcap \cdots \sqcap A_n \sqsubseteq A$$

is entailed by both $\mathcal{T}_L$ and $\mathcal{T}_{L'}$ but not by any other $\mathcal{T}_{L''}$ with $L'' \in \mathfrak{L}_n$. We prove, however, that the number of TBoxes eliminated from $S_{\mathfrak{L}}$ by a single membership query can be linearly bounded by the size of the query.

Lemma 64 *For all $\mathcal{EL}$ CIs $C \sqsubseteq D$ over Σ_n:*

- *either $\mathcal{T}_L \models C \sqsubseteq D$ for every $L \in \mathfrak{L}_n$*
- *or the number of $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models C \sqsubseteq D$ does not exceed $|C|$.*

The proof of Lemma 64 is technical and is deferred to the appendix. To illustrate our proof method here we consider a particular case that deals with membership queries of the form $C \sqsubseteq \exists \boldsymbol{\sigma}.M$ and is used in the proof of the general case. Both proofs rely on the following lemma from the study of the logical difference between ontologies (Konev et al., 2012). It characterises CIs entailed by acyclic $\mathcal{EL}$ TBoxes.

Lemma 65 (Konev et al. (2012)) *Let $\mathcal{T}$ be an acyclic $\mathcal{EL}$ TBox, r a role name and D an $\mathcal{EL}$ concept expression. Suppose that $\mathcal{T} \models \bigsqcap_{1 \leq i \leq n} A_i \sqcap \bigsqcap_{1 \leq j \leq m} \exists r_j.C_j \sqsubseteq D$, where A_i are concept names for $1 \leq i \leq n$, C_j are $\mathcal{EL}$ concept expressions for $1 \leq j \leq m$, and $m, n \geq 0$. Then the following holds:*

- *if D is a concept name such that $\mathcal{T}$ does not contain any CE $D \equiv C$ for any concept expression C, then there exists A_i, $1 \leq i \leq n$, such that $\mathcal{T} \models A_i \sqsubseteq D$;*
- *if D is of the form $\exists r.D'$ then either (i) there exists A_i, $1 \leq i \leq n$, such that $\mathcal{T} \models A_i \sqsubseteq \exists r.D'$ or (ii) there exists r_j, $1 \leq j \leq m$, such that $r_j = r$ and $\mathcal{T} \models C_j \sqsubseteq D'$.*

The following lemma considers membership queries of the form $C \sqsubseteq \exists \boldsymbol{\sigma}.M$.

Lemma 66 *For any $0 \leq m \leq n$, any sequence of role names $\boldsymbol{\sigma} = \sigma^1 \ldots \sigma^m \in \{r, s\}^m$, and any $\mathcal{EL}$ concept expression C over Σ_n:*

- *either $\mathcal{T}_L \models C \sqsubseteq \exists \boldsymbol{\sigma}.M$ for every $\mathcal{T}_L$ with $L \in \mathfrak{L}_n$;*
- *or there is at most one $\mathcal{T}_L$ such that $\mathcal{T}_L \models C \sqsubseteq \exists \boldsymbol{\sigma}.M$.*

Proof The lemma follows from the following claim.

Claim. Let $L = (\boldsymbol{\sigma}_1, \ldots, \boldsymbol{\sigma}_n) \in \mathfrak{L}_n$ be such that $\mathcal{T}_L \models C \sqsubseteq \exists \boldsymbol{\sigma}.M$. Then *either* (1) there exists $i \leq n$ such that $\boldsymbol{\sigma} = \boldsymbol{\sigma}_i$ and C is of the form $A \sqcap C'$, $A_i \sqcap C'$ or $B_i \sqcap C'$, for some $\mathcal{EL}$ concept expression C'; *or* (2) we have $\emptyset \models C \sqsubseteq \exists \boldsymbol{\sigma}.M$.

Proof of Claim. We prove the claim by induction on m. If $m = 0$, by Lemma 65, the concept expression C is of the form $Z \sqcap C'$, for some concept name Z and concept expression C' such that $\mathcal{T}_L \models Z \sqsubseteq M$. As $\mathcal{T}_L \models Z \sqsubseteq M$ does not hold for any concept name Z distinct from M, we obtain $Z = M$. Thus, $\emptyset \models C \sqsubseteq M$ and Point (2) follows.
Let $m > 0$. By Lemma 65 we have one of the following two cases:

- C is of the form $X \sqcap C'$, for some concept name X and concept expression C' such that $\mathcal{T}_L \models X \sqsubseteq \exists \boldsymbol{\sigma}.M$. But then there exists $i \leq n$ such that $\boldsymbol{\sigma} = \boldsymbol{\sigma}_i$ and $X \in \{A, A_i, B_i\}$ and Point (1) follows.
- C is of the form $\exists \sigma^1.C' \sqcap C''$, for some concept expressions C' and C'', and $\mathcal{T}_L \models C' \sqsubseteq \exists \sigma^2. \cdots \exists \sigma^m.M$. Notice that the length of the sequence $\sigma^2 \ldots \sigma^n$ is strictly less than n. Thus, by induction hypothesis, $\emptyset \models C' \sqsubseteq \exists \sigma^2. \cdots \exists \sigma^m.M$. But then $\emptyset \models C \sqsubseteq \exists \boldsymbol{\sigma}.M$ and Point (2) follows.

This finishes the proof of the claim. To see that the claim entails the lemma observe that at most one $L \in \mathfrak{L}_n$ can satisfy Point (1). Point (2) entails that $\mathcal{T}_L \models C \sqsubseteq \exists \boldsymbol{\sigma}.M$ for every $\mathcal{T}_L$ with $L \in \mathfrak{L}_n$. ❑

We now show how the oracle can answer equivalence queries, aiming to show that for any polynomial size equivalence query $\mathcal{H}$, the oracle can return a counterexample $C \sqsubseteq D$ such that either (i) $\mathcal{H} \models C \sqsubseteq D$ and $\mathcal{T}_L \models C \sqsubseteq D$ for at most one $L \in \mathfrak{L}_n$ or (ii) $\mathcal{H} \not\models C \sqsubseteq D$ and $\mathcal{T}_L \models C \sqsubseteq D$ for every $L \in \mathfrak{L}_n$. Thus, such a counterexample eliminates at most one $\mathcal{T}_L$ from the set $S_{\mathfrak{L}}$ of TBoxes that the learner cannot distinguish. In addition, however, we have to take extra care of the size of counterexamples as the learning algorithm is allowed to formulate queries polynomial not only in the size of the target TBox but also in the size of the counterexamples returned by the oracle. For instance, if the hypothesis TBox $\mathcal{H}$ contains a CI $C \sqsubseteq D$ which is not entailed by any $\mathcal{T}_L$, one cannot simply return $C \sqsubseteq D$ as a counterexample since the learner will be able to 'pump up' its capacity by asking a sequence of equivalence queries $\mathcal{H}_i = \{C_i \sqsubseteq D_i\}$ such that the size of $C_{i+1} \sqsubseteq D_{i+1}$ is twice the size of $C_i \sqsubseteq D_i$. Then at every stage in a run of the learning algorithm, the query size will be polynomial in the size of the input and the size of the largest counterexample received so far, but exponential size queries will become available to the learner. The following lemma addresses this issue.

Lemma 67 *For any $n > 1$ and any $\mathcal{EL}$ TBox $\mathcal{H}$ in Σ_n with $|\mathcal{H}| < 2^n$, there exists an $\mathcal{EL}$ CI $C \sqsubseteq D$ over Σ_n such that the size of $C \sqsubseteq D$ does not exceed $6n$ and*

- *if $\mathcal{H} \models C \sqsubseteq D$, then $\mathcal{T}_L \models C \sqsubseteq D$ for at most one $L \in \mathfrak{L}_n$;*
- *if $\mathcal{H} \not\models C \sqsubseteq D$, then $\mathcal{T}_L \models C \sqsubseteq \ D$ for every $L \in \mathfrak{L}_n$.*

Proof We define an exponentially large TBox $\mathcal{T}_\cap$ and use it to prove that one can select the required $\mathcal{EL}$ CI $C \sqsubseteq D$ in such a way that either $\mathcal{H} \models C \sqsubseteq D$ and $\mathcal{T}_\cap \not\models C \sqsubseteq D$, or vice versa.

To define $\mathcal{T}_\cap$, denote for any sequence $\boldsymbol{b} = b_1 \dots b_n \in \{0,1\}^n$ by $C_{\boldsymbol{b}}$ the conjunction $\bigsqcap_{i \leq n} C_i$, where $C_i = A_i$ if $b_i = 1$ and $C_i = B_i$ if $b_i = 0$. Then we define

$$\mathcal{T}_\cap = \mathcal{T}_0 \cup \{C_{\boldsymbol{b}} \sqsubseteq A \sqcap X_0 \mid \boldsymbol{b} \in \{0,1\}^n\}.$$

Consider the following cases for $\mathcal{H}$ and $\mathcal{T}_\cap$.

1. Suppose $\mathcal{H} \not\models \mathcal{T}_\cap$. Then there exists a CI $C \sqsubseteq D \in \mathcal{T}_\cap$ such that $\mathcal{H} \not\models C \sqsubseteq D$. Clearly, $C \sqsubseteq D$ is entailed by every $\mathcal{T}_L$, for $L \in \mathfrak{L}_n$, and the size of $C \sqsubseteq D$ does not exceed $6n$. Thus $C \sqsubseteq D$ is as required.

2. Suppose there exist $\boldsymbol{b} \in \{0,1\}^n$ and a concept expression of the form $\exists t.D'$ such that $\mathcal{H} \models C_{\boldsymbol{b}} \sqsubseteq \exists t.D'$ and $\mathcal{T}_0 \not\models C_{\boldsymbol{b}} \sqsubseteq \exists t.D'$. It can be seen (Lemma 73 in the appendix), that there exists a sequence of role names $t_1, \dots, t_l \in \{r,s\}^l$ with $0 \leq l \leq n+1$ and $Y \in \{\top\} \cup \mathsf{N_C}$ such that $\emptyset \models \exists t.D' \sqsubseteq \exists t_1. \cdots \exists t_l.Y$. Thus, $\mathcal{H} \models C_{\boldsymbol{b}} \sqsubseteq \exists t_1. \cdots \exists t_l.Y$ and $\mathcal{T}_0 \not\models X_0 \sqsubseteq \exists t_1. \cdots \exists t_l.Y$. We show that the inclusion $C_{\boldsymbol{b}} \sqsubseteq \exists t_1. \cdots \exists t_l.Y$ is as required. Clearly, the size of $C_{\boldsymbol{b}} \sqsubseteq \exists t_1. \cdots \exists t_l.Y$ does not exceed $6n$. It remains to prove that $\mathcal{T}_L \models C_{\boldsymbol{b}} \sqsubseteq \exists t_1 \cdots \exists t_l.Y$ for at most one $L \in \mathfrak{L}_n$.

   Suppose there exists $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models C_{\boldsymbol{b}} \sqsubseteq \exists t_1. \cdots \exists t_l.Y$. By Lemma 65, there exists A_j or B_j such that $\mathcal{T}_L \models A_j \sqsubseteq \exists t_1. \cdots \exists t_l.Y$ or $\mathcal{T}_L \models B_j \sqsubseteq \exists t_1. \cdots \exists t_l.Y$, respectively. As $\mathcal{T}_0 \not\models X_0 \sqsubseteq \exists t_1. \cdots \exists t_l.Y$ it is easy to see that $l = n$, $t_1 t_2 \dots t_n = \boldsymbol{\sigma}_j$, and $Y = M$ follow. As $\mathcal{T}_{L'} \not\models C_{\boldsymbol{b}} \sqsubseteq \exists \boldsymbol{\sigma}_j.M$ for any $L' \in \mathfrak{L}_n$ such that $L' \neq L$, it follows that $\mathcal{T}_L \models C_{\boldsymbol{b}} \sqsubseteq \exists t_1 \cdots \exists t_l.Y$ for at most one $L \in \mathfrak{L}_n$

3. Finally, suppose that neither Case 1 nor 2 above apply. Then $\mathcal{H} \models \mathcal{T}_\cap$ and for every $\boldsymbol{b} \in \{0,1\}^n$ and every $\mathcal{EL}$ concept expression over Σ_n of the form $\exists t.D'$: if $\mathcal{H} \models C_{\boldsymbol{b}} \sqsubseteq \exists t.D'$ then $\mathcal{T}_0 \models X_0 \sqsubseteq \exists t.D'$. We show that unless there exists a CI $C \sqsubseteq D$ satisfying the conditions of the lemma, $\mathcal{H}$ contains at least 2^n different CIs (and thus derive a contradiction).

   Fix some $\boldsymbol{b} = b_1 \dots b_n \in \{0,1\}^n$. From $\mathcal{H} \models \mathcal{T}_\cap$ we obtain $\mathcal{H} \models C_{\boldsymbol{b}} \sqsubseteq A$. Then there must exist at least one CI $C \sqsubseteq A \sqcap D \in \mathcal{H}$ such that $\mathcal{H} \models C_{\boldsymbol{b}} \sqsubseteq C$ and $\emptyset \not\models C \sqsubseteq A$. Let $C = Z_1 \sqcap \dots \sqcap Z_m \sqcap \exists t_1.C'_1 \sqcap \dots \sqcap \exists t_l.C'_l$, where $Z_1, \dots, Z_m$ are different concept names. As $\mathcal{H} \models C_{\boldsymbol{b}} \sqsubseteq \exists t_j.C'_j$ we have $\mathcal{T}_0 \models X_0 \sqsubseteq \exists t_j.C'_j$, for $j = 1, \dots l$. As $\mathcal{H} \models \mathcal{T}_\cap$ we have $\mathcal{H} \models X_0 \sqsubseteq \exists t_j.C'_j$, for $j = 1, \dots l$. So $\mathcal{H} \models Z_1 \sqcap \dots \sqcap Z_m \sqcap X_0 \sqsubseteq A$.

   - Suppose there exists i such that there is no $Z_j \in \{A_i, B_i\}$. Then we have $\mathcal{T}_L \not\models Z_1 \sqcap \dots \sqcap Z_m \sqcap X_0 \sqsubseteq A$, for any $L \in \mathfrak{L}_n$. Notice that $Z_1 \sqcap \dots \sqcap Z_m$ contains at most all concepts names in Σ_n, except A_i, B_i. Thus, the size of $Z_1 \sqcap \dots \sqcap Z_m \sqcap X_0 \sqsubseteq A$ does not exceed $6n$, and $Z_1 \sqcap \dots \sqcap Z_m \sqcap X_0 \sqsubseteq A$ is as required.
   - Assume that $Z_0 \sqcap \dots \sqcap Z_m \sqcap X_0$ contains a conjunct B_i such that $b_i \neq 0$. Then $\mathcal{H} \models C_{\boldsymbol{b}} \sqsubseteq B_i$ and there is no $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models C_{\boldsymbol{b}} \sqsubseteq B_i$. The size of $C_{\boldsymbol{b}} \sqsubseteq B_i$ does not exceed $6n$, so $C_{\boldsymbol{b}} \sqsubseteq B_i$ is as required.
   - Assume that $Z_0 \sqcap \dots \sqcap Z_m \sqcap X_0$ contains a conjunct A_i such that $b_i \neq 1$. Then $\mathcal{H} \models C_{\boldsymbol{b}} \sqsubseteq A_i$ and there is no $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models C_{\boldsymbol{b}} \sqsubseteq A_i$. The size of $C_{\boldsymbol{b}} \sqsubseteq A_i$ does not exceed $6n$, so $C_{\boldsymbol{b}} \sqsubseteq A_i$ is as required.
   - If none of the above applies, then $Z_1 \sqcap \dots \sqcap Z_m \sqcap X_0$ contains exactly the A_i with $b_i = 1$ and exactly the B_i with $b_i = 0$.

   This argument applies to arbitrary $\boldsymbol{b} \in \{0,1\}^n$. Thus, if there exists no CI $C \sqsubseteq D$ satisfying the conditions of the lemma then, by the final case, $\mathcal{H}$ contains at least 2^n CIs.

❑

Now we have all the ingredients to prove that $\mathcal{EL}$ TBoxes are not polynomial query learnable using membership and equivalence queries.

Theorem 68 *$\mathcal{EL}$ TBoxes are not polynomial query learnable using membership and equivalence queries.*

Proof Assume that TBoxes are polynomial query learnable. Then there exists a learning algorithm whose query complexity (the sum of the sizes of the inputs to membership and equivalence queries made by the algorithm up to a computation step) is bounded at any stage by a polynomial $p(n,m)$. Choose n such that $\lfloor 2^n/n \rfloor > (p(n,6n))^2$ and let $S_{\mathfrak{L}} = \{\mathcal{T}_L \mid L \in \mathfrak{L}_n\}$. We follow Angluin's strategy of letting the oracle remove TBoxes from $S_{\mathfrak{L}}$ in such a way that the learner cannot distinguish between any of the remaining TBoxes. Given a membership query $C \sqsubseteq D$, if $\mathcal{T}_L \models C \sqsubseteq D$ for every $L \in \mathfrak{L}_n$, then the answer is 'yes'; otherwise the answer is 'no' and all $\mathcal{T}_L$ with $\mathcal{T}_L \models C \sqsubseteq D$ are removed from $S_{\mathfrak{L}}$ (by Lemma 64, there are at most $|C|$ such TBoxes). Given an equivalence query $\mathcal{H}$, the answer is 'no', a counterexample $C \sqsubseteq D$ guaranteed by Lemma 67 is produced, and (at most one) $\mathcal{T}_L$ such that $\mathcal{T}_L \models C \sqsubseteq D$ is removed from $S_{\mathfrak{L}}$.

As all counterexamples produced are smaller than $6n$, the overall query complexity of the algorithm is bounded by $p(n,6n)$. Hence, the learner asks no more than $p(n,6n)$ queries and the size of every query does not exceed $p(n,6n)$. By Lemmas 64 and 67, at most $(p(n,6n))^2$ TBoxes are removed from $S_{\mathfrak{L}}$ during the run of the algorithm. But then, the algorithm cannot distinguish between any remaining TBoxes and we have derived a contradiction. ❑

We conclude this section by showing that DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes cannot be learned using polynomially many polynomial size equivalence queries only. We use the following result on non-polynomial query learnability of monotone DNF formulas, that is, DNF formulas that do not use negation, using equivalence queries due to Angluin (1990). Here, equivalence queries take a hypothesis ψ in the form of a monotone DNF formula and return as a counterexample either a truth assignment that satisfies ψ but not the target formula ϕ or vice versa. Let $M(n,t,s)$ denote the set of all monotone DNF formulas whose variables are $x_1, \dots, x_n$, that have exactly t conjunctions, and where each conjunction contains exactly s variables.

Theorem 69 (Angluin (1990)) *For any polynomial $q(\cdot)$ there exist constants t_0 and s_0 and a strategy [6] for the oracle $\mathfrak{O}$ to answer equivalence queries posed by a learning*

6. The existence of this strategy is a direct consequence of Theorem 8 by Angluin (1990), which states that the class of DNF formulae has the *approximate fingerprint* property, and the proof of Theorem 1

JMLR 18(201):1-63, 2018

algorithm in such a way that for sufficiently large n any learning algorithm that asks at most $q(n)$ equivalence queries, each bounded in size by $q(n)$, cannot exactly identify elements of $M(n, t_0, s_0)$.

To employ Theorem 69, we associate with every monotone DNF formula

$$\phi = \bigvee_{i=1}^{t} (x_1^i \wedge \cdots \wedge x_{s^i}^i),$$

where $\{x_1^i, \ldots, x_{s^i}^i\} \subseteq \{x_1, \ldots, x_n\}$, a DL-Lite$_{\mathcal{R}}^{\exists}$ TBox $\mathcal{T}_\phi$ as follows. With each conjunct $x_1^i \wedge \cdots \wedge x_{s^i}^i$ we associate a concept expression

$$C_i := \exists \rho_1^i . \exists \rho_2^i . \ldots \exists \rho_n^i . \top,$$

where $\rho_j^i = r$ if x_j occurs in $x_1^i \wedge \cdots \wedge x_{s^i}^i$ and $\rho_j^i = \bar{r}$ otherwise (r and $\bar{r}$ are role names). Let A be a concept name and set

$$\mathcal{T}_\phi = \{A \sqsubseteq \textstyle\prod_{i=1}^{t} C_i, \quad \bar{r} \sqsubseteq r\}.$$

For example, for $n = 4$ and $\phi = (x_1 \wedge x_4) \vee x_2$ we have

$$\mathcal{T}_\phi = \{A \sqsubseteq \exists r . \exists \bar{r} . \exists \bar{r} . \exists r . \top,\ A \sqsubseteq \exists \bar{r} . \exists r . \exists \bar{r} . \exists \bar{r} . \top,\ \bar{r} \sqsubseteq r\}.$$

We say that a TBox $\mathcal{T}$ *has a DNF-representation for n* if it is obtained by the translation of a monotone DNF-formula with n variables; that is, if $\mathcal{T}$ is of the following form, for some $\Gamma \subseteq \{r, \bar{r}\}^n$:

$$\{A \sqsubseteq \prod_{\rho_1 \cdots \rho_n \in \Gamma} \exists \rho_1 . \exists \rho_2 . \ldots \exists \rho_n . \top, \quad \bar{r} \sqsubseteq r\}.$$

A truth assignment I (for the variables $x_1 \ldots, x_n$) also corresponds to a concept expression

$$C_I := \exists \rho_1^i . \exists \rho_2^i . \ldots \exists \rho_n^i . \top,$$

where $\rho_j^i = r$ if I makes x_j true and $\rho_j^i = \bar{r}$ otherwise. Then

$$I \models \phi \text{ if, and only if, } \mathcal{T}_\phi \models A \sqsubseteq C_I$$

holds for all truth assignments I.

Note that $\bar{r}$ represents that a variable is false and r that a variable is true. Thus, the RI $\bar{r} \sqsubseteq r$ captures the monotonicity of the DNF formulas considered. For any fixed values n, s and t, we set

$$T(n, t, s) = \{\mathcal{T}_\phi \mid \phi \in M(n, t, s)\}.$$

Note that the TBoxes in $T(n, t, s)$ are exactly those TBoxes that have a DNF-representation for n and satisfy additionally the conditions that the DNF represented by $\mathcal{T}_\phi$ has exactly t conjunctions each conjunction of which has exactly s variables.

by Angluin (1990), where such a strategy is explicitly constructed for any class having approximate fingerprints.

We describe now the strategy for the oracle $\mathfrak{O}'$ to answer equivalence queries so that no learning algorithm is able to exactly identify members of $T(n, t, s)$ based on the answers to polynomially many equivalence queries of polynomial size. If the TBox in the equivalence query is 'obviously' not within the class $T(n, t, s)$, then we will explicitly produce a counterexample that the oracle can return. If, on the other hand, the TBox $\mathcal{H}$ from the equivalence query is 'similar' to TBoxes that have a DNF-representation for n, then we approximate $\mathcal{H}$ by a TBox $\mathcal{H}'$ that has a DNF-representation for n and return the counterexample $A \sqsubseteq C_I$ corresponding to the truth assignment I that the oracle $\mathfrak{O}$ from Theorem 69 would return when given ψ.

In detail the strategy is as follows. Assume q is the given polynomial in Theorem 69 and that t_0, s_0 and the strategy of the oracle $\mathfrak{O}$ are chosen so that for sufficiently large n no learning algorithm for DNF formulas that asks at most $q(n)$ equivalence queries, each bounded in size by $q(n)$, can distinguish all members of $M(n, t_0, s_0)$. Choose a sufficiently large n. Let $\mathcal{H}$ be an equivalence TBox query issued by a learning algorithm. Then $\mathfrak{O}'$ does the following:

1. If $\mathcal{H}$ entails some $A \sqsubseteq \exists \rho_1 . \exists \rho_2 . \ldots \exists \rho_{n+1} . \top$ with $\rho_i \in \{r, \bar{r}\}$ for $1 \leq i \leq n+1$, then return this CI as a negative counterexample;

2. If $\mathcal{H}$ entails some $\exists \rho_1 . \top \sqsubseteq \exists \rho_2 . \top$ such that $\{\rho_1, \rho_2\} \subseteq \{r, \bar{r}, r^-, \bar{r}^-\}$ and $\{\bar{r} \sqsubseteq r\} \not\models \exists \rho_1 . \top \sqsubseteq \exists \rho_2 . \top$, then return this CI as a negative counterexample;

3. If $\mathcal{H} \models \exists \rho_1 . \top \sqsubseteq \exists \rho_2 . \exists \rho_3 . \top$ such that $\{\rho_1, \rho_2, \rho_3\} \subseteq \{r, \bar{r}\}$, then return this CI as a negative counterexample;

4. If there exists no $\rho_1, \ldots, \rho_n \in \{r, \bar{r}\}^n$ such that $\mathcal{H} \models A \sqsubseteq \exists \rho_1 . \cdots \exists \rho_n . \top$ then return $A \sqsubseteq \underbrace{\exists r \cdots \exists r}_{n} . \top$ as a positive counterexample.

5. Suppose now that none of the above applies. We say that a sequence $\rho_1, \ldots, \rho_n \in \{r, \bar{r}\}^n$ is *r-minimal for $\mathcal{H}$* if $\mathcal{H} \models A \sqsubseteq \exists \rho_1 . \cdots \exists \rho_n . \top$ and whenever $\rho_i = r$, for $1 \leq i \leq n$, we have $\mathcal{H} \not\models \exists \rho_1 . \cdots \exists \rho_{i-1} . \exists \bar{r} . \exists \rho_{i+1} . \cdots \exists \rho_n . \top$. We obtain a TBox $\mathcal{H}'$ with a DNF representation by setting

$$\mathcal{H}' = \{A \sqsubseteq \prod_{\substack{\rho_1, \ldots, \rho_n \text{ is} \\ r\text{-minimal for } \mathcal{H}}} \exists \rho_1 . \cdots \exists \rho_n . \top, \quad \bar{r} \sqsubseteq r\}.$$

   Observe that for any sequence $\rho_1, \ldots, \rho_n \in \{r, \bar{r}\}^n$ we have $\mathcal{H} \models A \sqsubseteq \exists \rho_1 . \cdots \exists \rho_n . \top$ if, and only if, $\mathcal{H}' \models A \sqsubseteq \exists \rho_1 . \cdots \exists \rho_n . \top$. We convert $\mathcal{H}'$ into its corresponding monotone DNF formula $\phi_{\mathcal{H}'}$ by reversing the translation from monotone DNF formulas into DL-Lite$_{\mathcal{R}}^{\exists}$ TBoxes of the above form in the obvious way. Note that the size of $\phi_{\mathcal{H}'}$ is linear in the size of $\mathcal{H}'$. Given $\phi_{\mathcal{H}'}$ the oracle $\mathfrak{O}$ returns a (positive or negative) counterexample (a truth assignment) I. Then return the counterexample in the form of the CI $A \sqsubseteq C_I$.

Observe that the answers given in Points 1 to 3 are correct in the sense that if an inclusion α is returned as a negative example then $\mathcal{T} \not\models \alpha$ for any $\mathcal{T} \in T(n, t, s)$. Point 4 is trivially correct, since any monotone DNF is satisfied by the truth assignment that makes every variable true. We analyse the size of the TBox $\mathcal{H}'$ computed in Point 5.

Lemma 70 *Assume that Points 1 to 4 do not apply to $\mathcal{H}$. Then the number of sequences $\rho_1, \dots, \rho_n \in \{r, \bar{r}\}^n$ which are r-minimal for $\mathcal{H}$ is bounded by $|\mathcal{H}|$.*

Proof We first show that if $\rho_1, \dots, \rho_n \in \{r, \bar{r}\}^n$ is r-minimal for $\mathcal{H}$, then there exists a CI $A \sqsubseteq C \in \mathcal{H}$ such that

(∗) there are concept expressions $C_0, \dots, C_n$ with $C_0 = C$ and $\exists \rho_{i+1}.C_{i+1}$ a top-level conjunct of C_i, for all $i < n$.

For the proof we require the canonical model $\mathcal{I}_{A,\mathcal{H}}$ of A and $\mathcal{H}$ (Lemma 12). Denote the root of $\mathcal{I}_{A,\mathcal{H}}$ by ρ_A. Let $\rho_1, \dots, \rho_n \in \{r, \bar{r}\}^n$ be r-minimal for $\mathcal{H}$. Then there are $d_0, \dots, d_n \in \Delta^{\mathcal{I}_{A,\mathcal{H}}}$ with $d_0 = \rho_A$ such that $(d_i, d_{i+1}) \in \rho_i^{\mathcal{I}_{A,\mathcal{H}}}$ for all $i < n$. By the canonical model construction and the assumption that Points 2 and 3 do not hold, there either exists $d_i \in A^{\mathcal{I}_{A,\mathcal{H}}}$ or there is a CI $A \sqsubseteq C \in \mathcal{H}$ such that (∗) holds. We show that the first condition does not hold. Assume for a prove by contradiction that $d_i \in A^{\mathcal{I}_{A,\mathcal{H}}}$. By Lemma 12, $\mathcal{H} \models A \sqsubseteq \exists \rho_1 \cdots \exists \rho_i.A$. But then $\mathcal{H} \models A \sqsubseteq \exists (\rho_1 \cdots \rho_i)^n.\top$ for all $n > 0$ which contradicts the assumption that Point 1 does not apply to $\mathcal{H}$.

It follows that the number of distinct r-minimal sequences is bounded by the number of distinct sequences $C_0, \dots, C_n$ with $A \sqsubseteq C_0 \in \mathcal{H}$ and $\exists \rho_{i+1}.C_{i+1}$ a top-level conjunct of C_i for all $i < n$. Thus, the number of distinct r-minimal sequences is bounded by $|\mathcal{H}|$. ❑

It follows from Lemma 70 that the size of the TBox $\mathcal{H}'$ computed in Point 5 is bounded by $4n|\mathcal{H}| + 2$.

Theorem 71 *DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes (even without inverse roles) are not polynomial query learnable using only equivalence queries.*

Proof Suppose that the query complexity of a learning algorithm $\mathfrak{A}$ for DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes in $\Sigma = \{A, r, \bar{r}\}$ is bounded at every stage of computation by a polynomial $p(x, y)$, where x is the size of the target TBox, and y is the maximal size of a counterexample returned by the oracle up to the current stage of computation. Let $q(n) = (p(n^2, 4n + 6))^2$, and let constants t_0 and s_0 be as guaranteed by Lemma 69. We claim that, for sufficiently large n, $\mathfrak{A}$ cannot distinguish some $\mathcal{T}_\phi$ and $\mathcal{T}_\psi$ for $\phi, \psi \in M(n, t_0, s_0)$.

Assuming that $n > 11$ (the maximal size of counterexamples given under Point 2 and 3), the largest counterexample returned by our strategy described above is of the form $A \sqsubseteq \exists \rho_1 . \cdots \exists \rho_{n+1}.\top$, so for sufficiently large n the maximal size of any counterexample in any run of $\mathfrak{A}$ is bounded by $4n + 6 = 4(n + 1) + 2$. Similarly, the size of every potential target TBox $\mathcal{T}_\phi \in T(n, t_0, s_0)$ does not exceed $t_0 \cdot (4n + 2)$ and, as t_0 is a constant, for sufficiently large n it is bounded by n^2. Thus, for sufficiently large n the total query complexity of $\mathfrak{A}$ on any input from $T(n, t_0, s_0)$ is bounded by $p(n^2, 4n + 6)$. Obviously, the size of each query is bounded by the query complexity of the learning algorithm. So, the size of a DNF equivalence query forwarded to the strategy $\mathfrak{O}$ guaranteed by Lemma 69 is bounded by $4n \times p(n^2, 4n + 6) + 2 \leq q(n)$, and there will be at most $q(n)$ queries forwarded. But then $\mathfrak{O}$ can return answers such that some ϕ and ψ from $M(n, t_0, s_0)$ cannot be distinguished. It remains to observe that $\mathfrak{A}$ cannot distinguish $\mathcal{T}_\phi$ and $\mathcal{T}_\psi$. ❑

7. Related Work

Some related work has already been discussed in the introduction to this paper. Here we discuss in more detail related work from *ontology learning* in general and *exact learning of ontologies* in particular. We start with the former.

Ontology Learning. Research in ontology learning has a rich history that we cannot discuss here in full detail. The collection edited by Lehmann and Völker (2014) and surveys authored by Cimiano et al. (2010) and Wong et al. (2012) provide an excellent introduction to the state of the art in this field. The techniques applied in ontology learning range from information extraction and text mining to interactive learning and inductive logic programming (ILP). Of particular relevance for this paper are the approaches to learning logical expressions (rather than subsumption hierarchies between concept names). For example, the work of Lehmann and Haase (2009), Lehmann and Hitzler (2010), and Bühmann et al. (2014) applies techniques from ILP to learn description logic concept expressions. ILP is applied as well by Lisi (2011) for learning logical rules for ontologies. The learning of fuzzy DLs has been considered by Lisi and Straccia (2015). Other machine learning methods which have been applied to learn ontology axioms include Association Rule Mining (ARM) (Völker and Niepert, 2011; Fleischhacker et al., 2012; Völker et al., 2015) and Formal Concept Analysis (FCA) (Rudolph, 2004; Baader et al., 2007; Distel, 2011; Borchmann, 2014; Ganter et al., 2016). Recently, learnability of lightweight DL TBoxes from finite sets of interpretations has been investigated (Klarman and Britz, 2015).

Exact Learning of Description Logic Concept Expressions. Rather than aiming to learn a TBox here one is interested in learning a target concept expression C_*. This was first studied by Cohen and Hirsh (1994a,b) and Frazier and Pitt (1996). The standard learning protocol is as follows:

- a membership query asks whether a concept expression C is subsumed by the target concept expression C_* (in symbols, $\emptyset \models C \sqsubseteq C_*$?);
- an equivalence query asks whether a concept expression C is equivalent to the target concept expression C_* (in symbols, $\emptyset \models C \equiv C_*$?). If C and C_* are not equivalent then the oracle gives a counterexample, that is, a concept expression C' such that either $\emptyset \models C' \sqsubseteq C_*$ and $\emptyset \not\models C' \sqsubseteq C$ or $\emptyset \not\models C' \sqsubseteq C_*$ and $\emptyset \models C' \sqsubseteq C$.

Cohen and Hirsh (1994a,b) and Frazier and Pitt (1996) consider concept expressions in (variations of) the now largely historic description logic Classic (Borgida et al., 1989; Patel-Schneider et al., 1991; Borgida and Patel-Schneider, 1994). The expressive power of Classic and its variants is incomparable to the expressive power of modern lightweight description logics. Classic only shares conjunction and unqualified existential restrictions of the form $\exists r.\top$ with the DLs considered in this paper. It additionally admits *value restrictions* $\forall r.C$ whose interpretation is given as

$$(\forall r.C)^{\mathcal{I}} = \{d \in \Delta^{\mathcal{I}} | d' \in C^{\mathcal{I}} \text{ for all } d' \text{ with } (d, d') \in r^{\mathcal{I}}\}$$

and *unqualified number restrictions* $(\leq n\ r)$ and $(\geq n\ r)$ interpreted as

$$\begin{aligned} (\leq nr)^{\mathcal{I}} &= \{d \in \Delta^{\mathcal{I}} \mid |\{d' \mid (d, d') \in r^{\mathcal{I}}\}| \leq n\} \\ (\geq nr)^{\mathcal{I}} &= \{d \in \Delta^{\mathcal{I}} \mid |\{d' \mid (d, d') \in r^{\mathcal{I}}\}| \geq n\} \end{aligned}$$

as well as various constructors using individual names. For example, if $a_1, \ldots, a_n$ are names for individual objects, then ONE-OF$(a_1, \ldots, a_n)$ is a CLASSIC concept denoting the set $\{a_1^{\mathcal{I}}, \ldots, a_n^{\mathcal{I}}\}$, where $a_i^{\mathcal{I}}$ denotes the individual with name a_i in interpretation $\mathcal{I}$. It is proved by Cohen and Hirsh (1994a,b) and Frazier and Pitt (1996) that in many fragments of CLASSIC concept expressions cannot be learned polynomially using only membership or equivalence queries but that they can be learned in polynomial time using both. Exact learning of concept expressions in modern lightweight description logics has not yet been investigated.

Exact Learning of TBoxes using Concept Inclusions as Queries. First results on exact learning of description logic TBoxes using concept inclusions as queries were presented by Konev et al. (2013, 2014). This paper is an extension. In contrast to the work of Konev et al. (2013, 2014), we make the distinction between polynomial time and polynomial query learnability which enables us to formulate and prove results on a more fine grained level. TBoxes in DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$, for which we prove polynomial query learnability, were not considered by Konev et al. (2013, 2014). The current paper is also closely related to the PhD thesis of the third author (Ozaki, 2016). In addition to the results presented here, it is shown there that even in the extension of $\mathcal{EL}_{\mathsf{lhs}}$ with role inclusions, TBoxes can be learned in polynomial time. The learning algorithm is a non-trivial extension of the algorithm presented here for $\mathcal{EL}_{\mathsf{lhs}}$ TBoxes.

Exact Learning of TBoxes using Certain Answers. In recent years, data access mediated by ontologies has become one of the most important applications of DLs (Poggi et al., 2008; Bienvenu et al., 2014; Kontchakov and Zakharyaschev, 2014; Bienvenu and Ortiz, 2015) and references therein. The idea is to use a TBox to specify semantics and background knowledge for the data and use it for deriving more complete answers to queries over the data. In this context, the data is stored in an *ABox* consisting of a finite set of assertions of the form $A(a)$ or $r(a, b)$, where A is a concept names, r a role name, and a, b are individual names. Given a query $q(\vec{x})$ (typically a conjunctive query), a TBox $\mathcal{T}$, and an ABox $\mathcal{A}$, a tuple of individual names $\vec{a}$ from $\mathcal{A}$ and of the same length as $\vec{x}$ is called a certain answer to $q(\vec{x})$ over $\mathcal{A}$ w.r.t. $\mathcal{T}$, in symbols $\mathcal{T}, \mathcal{A} \models q(\vec{a})$, if every model $\mathcal{I}$ of $\mathcal{T}$ and $\mathcal{A}$ satisfies $q(\vec{a})$. Motivated by this setup, Konev et al. (2016) and Ozaki (2016) study polynomial learnability of TBoxes using membership queries that ask whether a tuple of individuals names is a certain answer to a query over an ABox w.r.t. the target TBox. This is a natural alternative to learning using concept inclusions since domain experts are often more familiar with querying data in a particular domain than with the logical notion of subsumption between concept expressions. In detail, the learning protocol is as follows:

- a membership query takes the form $(\mathcal{A}, q(\vec{a}))$ and asks whether the tuple $\vec{a}$ of individual names is a certain answer to the query $q(\vec{x})$ over the ABox $\mathcal{A}$ w.r.t. the target TBox $\mathcal{T}$;

- an equivalence query asks whether a TBox $\mathcal{H}$ is equivalent to the target TBox $\mathcal{T}$. If $\mathcal{T}$ and $\mathcal{H}$ are not equivalent then a counterexample of the form $(\mathcal{A}, q(\vec{a}))$ is given such that $\mathcal{T}, \mathcal{A} \models q(\vec{a})$ and $\mathcal{H}, \mathcal{A} \not\models q(\vec{a})$ (a positive counterexample) or $\mathcal{T}, \mathcal{A} \not\models q(\vec{a})$ and $\mathcal{H}, \mathcal{A} \models q(\vec{a})$ (a negative counterexample).

In the learning protocol above we have not yet specified the class of queries from which the $q(\vec{x})$ are drawn and which strongly influences the classes of TBoxes that can be learned. In the context of data access using TBoxes the two most popular classes of queries are:

- conjunctive queries (CQs), that is, existentially quantified conjunctions of atoms; and

- instance queries (IQs), which take the form $C(x)$ or $r(x, y)$ with C a concept expression from the DL under consideration and r a role name.

Konev et al. (2016) and Ozaki (2016) study exact learning of TBoxes in the languages $\mathcal{EL}$, $\mathcal{EL}_{\mathsf{lhs}}$ and DL-Lite$^{\exists}_{\mathcal{R}}$ for both IQs and CQs in queries. The positive learnability results are proved by polynomial reductions to the learnability results presented in this paper and also by Ozaki (2016). The basic link between learning using concept inclusions as queries and learning by certain answers is as follows: if $\mathcal{T}$ is a TBox and C, D are concept expressions in any of the DLs discussed above then one can regard the labelled tree T_C corresponding to C as an ABox $\mathcal{A}_C$ with root ρ_C and it holds that $\mathcal{T} \models C \sqsubseteq D$ if, and only if, $\mathcal{T}, \mathcal{A}_C \models D(\rho_C)$. The converse direction (obtaining a concept expression from an ABox) is more involved since ABoxes are not tree-shaped and an additional unfolding step is needed to compute a corresponding concept expression. Using this link it is proved by Konev et al. (2016) and Ozaki (2016) that DL-Lite$^{\exists}_{\mathcal{R}}$ and $\mathcal{EL}_{\mathsf{lhs}}$ TBoxes with role inclusions can be learned with polynomially many queries using certain answers to IQs. It is also proved that $\mathcal{EL}$ is still not learnable with polynomially many queries using certain answers with neither IQs nor CQs as the query language and that DL-Lite$^{\exists}_{\mathcal{R}}$ TBoxes cannot be learned with polynomially many queries using certain answers with CQs as the query language.

Exact Learning in (other) Fragments of FO Horn. We discuss results on exact learning of finite sets of FO Horn clauses or fragments of this logic, where a *FO Horn clause* is a universally quantified clause with at most one positive literal (Page Jr, 1993; Arimura, 1997; Reddy and Tadepalli, 1998; Arias and Khardon, 2002; Arias et al., 2007; Selman and Fern, 2011). Depending on what is used as membership queries and as counterexamples to equivalence queries, one can distinguish between exact learning FO Horn clauses using interpretations and using entailments. As learning using entailments is closer to our approach we focus on that setting. The exact learning protocol is then as follows:

- a membership query asks whether an FO Horn clause is entailed by the target set T of FO Horn clauses;

- an equivalence query asks whether a set H of FO Horn clauses is equivalent to the target set T. If H and T are not equivalent then a counterexample is given, that is, an FO Horn clause entailed by T but not by H (a positive counterexample) or vice versa.

Considering how terms (with function symbols allowed) can appear in an FO Horn clause, two main restrictions have been studied in the literature:

1. *Range restricted clauses*: when the set of terms in the positive literal (if existent) is a subset of the terms in the negative literals and their subterms; and

2. *Constrained clauses*: when the set of terms and subterms in the positive literal (if existent) is a superset of the terms in the negative literals.

For example, the FO Horn clause $\forall x(\neg P(f(x)) \vee P(x))$ is range restricted but not constrained and the FO Horn clause $\forall x(\neg P(x) \vee P(f(x)))$ is constrained but not range restricted, where P is a predicate symbol and f a function symbol. Reddy and Tadepalli (1998) and Arimura (1997), it is shown that under certain acyclicity conditions FO Horn with range restricted clauses and, respectively, constrained clauses are polynomial time learnable from entailments if the arity of predicates is bounded by a constant. A learning algorithm for a fragment of FO Horn (called closed FO Horn) that subsumes the two languages defined above is presented by Arias and Khardon (2002). The algorithm is polynomial in the number of clauses, terms and predicates and the size of the counterexamples, but exponential not only in the arity of predicates but also in the number of variables per clause. In fact, it is an open question whether there exists a learning algorithm for closed FO Horn that is polynomial in the number of variables per clause.

We relate the learnability results for FO Horn to the learnability results for lightweight description logics presented in this paper. Observe that most DLs (and in particular all DLs investigated in this paper) can be translated into FO (Baader et al., 2003). For example, a translation of the $\mathcal{EL}_{\mathsf{lhs}}$ CI $\exists r.A \sqsubseteq B$ is $\forall x \forall y(\neg r(x,y) \vee \neg A(y) \vee B(x))$ and a translation of the DL-Lite$^{\exists}_{\mathcal{R}}$ CI $A \sqsubseteq \exists r.A$ is $\forall x(A(x) \rightarrow \exists y.(r(x,y) \wedge A(y)))$. Under this translation, every $\mathcal{EL}_{\mathsf{lhs}}$ TBox can be regarded as a set of range restricted FO Horn clauses, where the arity of predicates is bounded by 2. In contrast, since in DL-Lite$^{\exists}_{\mathcal{R}}$ existential quantifiers can be nested in the right side of CIs, DL-Lite$^{\exists}_{\mathcal{R}}$ CIs cannot be translated into FO Horn clauses. We can now summarise the relationship between our learnability results for $\mathcal{EL}_{\mathsf{lhs}}$, DL-Lite$^{\exists}_{\mathcal{R}}$ and DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$ and the results on exact learnability of FO Horn from entailments as follows: since the arity of DL predicates is at most 2 and since no function symbols are admitted in DLs, none of the DLs considered in this paper can express the fragments of FO Horn discussed above. On the other hand, we do not impose an acyclicity condition on the TBoxes (in contrast to the work by Reddy and Tadepalli (1998); Arimura (1997)) and our algorithms are polynomial in the number of variables permitted in any clause (in contrast to the work by Arias and Khardon (2002)). Thus, the results discussed above for FO Horn do not translate into polynomial learning algorithms for $\mathcal{EL}_{\mathsf{lhs}}$ and are not applicable to DL-Lite$^{\exists}_{\mathcal{R}}$ nor DL-Lite$^{\exists}_{\mathcal{R},\mathsf{horn}}$. Our results thus cover new fragments of FO that have not yet been considered for exact learning. This is not surprising, given the fact that the fragments of FO considered previously were not motivated by applications in ontology learning.

Also related to exact learning of Horn FO is recent work on exact learning of schema mappings in data exchange (ten Cate et al., 2012). Schema mappings are tuples (S,T,M) where S is a source schema (a finite set of predicates), T is a target schema (a finite set of predicates), and M is a finite set of sentences of the form $\forall \vec{x}(\varphi(\vec{x}) \rightarrow \exists \vec{y} \psi(\vec{x},\vec{y}))$ where $\varphi(\vec{x})$ and $\psi(\vec{x},\vec{y})$ are conjunctions of atoms over S and T, respectively (Fagin et al., 2005). (S,T,M) is a GAV schema mapping if $\vec{y}$ is empty and $\psi(\vec{x},\vec{y})$ is an atom. The authors study exact learnability of GAV schema mappings from data examples (I,J) consisting of a database I over the source schema S and a database J over the target schema T. Such a data example satisfies M if $I \cup J \models M$. The authors present both polynomial query learnability results for protocols using membership and equivalence queries and non-polynomial query learnability results if either only membership or only equivalence queries are allowed. These results are not applicable to the setting considered in this paper since the learning protocol uses data examples instead of entailments.

8. Conclusion

We have presented the first study of learnability of DL ontologies in Angluin et al's framework of exact learning, obtaining both positive and negative results. Several research questions remain to be explored. One immediate question is whether acyclic $\mathcal{EL}$ TBoxes can be learned in polynomial time using queries and counterexamples of the form $A \equiv C$ and $A \sqsubseteq C$ only. Note that our non-polynomial query learnability result for acyclic $\mathcal{EL}$ TBoxes relies heavily on counterexamples that are not of this form. Another immediate question is whether the extension of $\mathcal{EL}_{\mathsf{lhs}}$ with inverse roles (which is a better approximation of OWL2 RL than $\mathcal{EL}_{\mathsf{lhs}}$ itself) can still be learned in polynomial time, or at least with polynomially many queries of polynomial size. Other interesting research directions are non-polynomial time learning algorithms for $\mathcal{EL}$ TBoxes and the admission of different types of membership queries and counterexamples in the learning protocol. For example, one could replace CIs as counterexamples with interpretations.

Appendix A. Proofs for Section 6

We supply proofs for Lemma 62 and Lemma 64. In addition, we prove a claim used in the proof of Lemma 67. We start by giving the proof of Lemma 62.

Lemma 62 *For every DL-Lite$^{\exists}_{\mathcal{R}}$ CI $B \sqsubseteq D$ over the signature of $\mathcal{T}_{\boldsymbol{\sigma}}$,*

- *either $\mathcal{T}_{\boldsymbol{\sigma}} \models B \sqsubseteq D$ for every $\mathcal{T}_{\boldsymbol{\sigma}} \in S_N$*
- *or there is at most one $\mathcal{T}_{\boldsymbol{\sigma}} \in S_N$ such that $\mathcal{T}_{\boldsymbol{\sigma}} \models B \sqsubseteq D$.*

Proof Assume the CI $B \sqsubseteq D$ is given. If $B \neq A$ or M does not occur in D, then the claim can be readily checked. Thus, we assume that $B = A$ and M occurs in D. Assume there exists $\boldsymbol{\sigma}_0$ such that $\mathcal{T}_{\boldsymbol{\sigma}_0} \models A \sqsubseteq D$ (if no such $\boldsymbol{\sigma}_0$ exists, we are done). For any $\boldsymbol{\sigma}$, let $\mathcal{I}_{A,\mathcal{T}_{\boldsymbol{\sigma}}}$ be the canonical model of A and $\mathcal{T}_{\boldsymbol{\sigma}}$ (Lemma 12). Apply the following restricted form of parent/child merging exhaustively to the concept expression D:

- if there are nodes $d, d_1, d_2 \in T_D$ with $l(d_1,d) = \sigma$ and $l(d,d_2) = \sigma^-$ for some $\sigma \in \{r,s\}$, then replace D by the resulting concept expression after d_1 and d_2 are merged in D.

Let D' be the resulting concept expression. Recall from Lemma 12 that $\mathcal{T}_{\boldsymbol{\sigma}} \models A \sqsubseteq D$ iff there is a homomorphism from T_D to $\mathcal{I}_{A,\mathcal{T}_{\boldsymbol{\sigma}}}$ mapping ρ_D to ρ_A. Using the fact that $\mathcal{I}_{A,\mathcal{T}_{\boldsymbol{\sigma}}}$ is a ditree interpretation, one can readily check that any homomorphism h from T_D to $\mathcal{I}_{A,\mathcal{T}_{\boldsymbol{\sigma}}}$ mapping ρ_D to ρ_A factors through $T_{D'}$ and that D' is an $\mathcal{EL}$ concept expression. Thus, if there is an additional $\boldsymbol{\sigma}' \neq \boldsymbol{\sigma}_0$ such that $\mathcal{T}_{\boldsymbol{\sigma}'} \models A \sqsubseteq D$, then there are two homomorphisms

$h_{\boldsymbol{\sigma}_0}$ and $h_{\boldsymbol{\sigma}'}$ with the same domain $T_{D'}$ into $\mathcal{I}_{A,\mathcal{T}_{\boldsymbol{\sigma}_0}}$ and $\mathcal{I}_{A,\mathcal{T}_{\boldsymbol{\sigma}'}}$ and mapping the root of $T_{D'}$ to the roots of $\mathcal{I}_{A,\mathcal{T}_{\boldsymbol{\sigma}_0}}$ and $\mathcal{I}_{A,\mathcal{T}_{\boldsymbol{\sigma}'}}$, respectively. Since M occurs in D' and D' is an $\mathcal{EL}$ concept expression we find a sequence $D_0, \ldots, D_m$ with $D_0 = D'$ and $D_m = M$ such that $\exists s_{i+1}.D_{i+1}$ is a top-level conjunct of D_i for $s_i \in \{r, s\}$ and all $i < m$. But then $s_1 \cdots s_m = \boldsymbol{\sigma}_0$ and $s_1 \cdots s_m = \boldsymbol{\sigma}'$ and we have derived a contradiction to the assumption that $\boldsymbol{\sigma}_0$ and $\boldsymbol{\sigma}'$ are distinct. ❑

To prove Lemma 64 we require the following observation.

Lemma 72 *For any acyclic $\mathcal{EL}$ TBox $\mathcal{T}$, any CI $A \sqsubseteq C \in \mathcal{T}$ and any concept expression of the form $\exists t.D$ we have $\mathcal{T} \models A \sqsubseteq \exists t.D$ if, and only if, $\mathcal{T} \models C \sqsubseteq \exists t.D$.*

We are now ready to prove Lemma 64.

Lemma 64 *For every $\mathcal{EL}$ CI $C \sqsubseteq D$ over Σ_n:*

- *either $\mathcal{T}_L \models C \sqsubseteq D$ for every $L \in \mathfrak{L}_n$*
- *or the number of $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models C \sqsubseteq D$ does not exceed $|C|$.*

Proof We prove the lemma by induction on the structure of D. We assume throughout the proof that there exists some $L_0 \in \mathfrak{L}_n$ such that $\mathcal{T}_{L_0} \models C \sqsubseteq D$.

Base case: D is a concept name. We make the following case distinction.

- $D \in \{X_i, A_i, B_i \mid 1 \leq i \leq n\}$ or $D = M$. By Lemma 65, C is of the form $Z \sqcap C'$, for some concept name Z, and $\mathcal{T}_{L_0} \models Z \sqsubseteq D$. But then $Z = D$ and it follows that $\mathcal{T}_L \models C \sqsubseteq D$ for every $L \in \mathfrak{L}_n$.
- $D = X_0$. By Lemma 65, C is of the form $Z \sqcap C'$, for some concept name Z, and $\mathcal{T}_{L_0} \models Z \sqsubseteq X_0$. This is the case if either $Z = X_0$, or $Z \in \{A, A_1, B_1, \ldots, A_n, B_n\}$. In either case, $\mathcal{T}_L \models C \sqsubseteq X_0$ for every $L \in \mathfrak{L}_n$.
- $D = A$. If C is of the form $A \sqcap C'$ or for all i such that $1 \leq i \leq n$, A_i or B_i is a conjunct of C, then $\mathcal{T}_L \models C \sqsubseteq A$ for every $L \in \mathfrak{L}_n$. Assume now that C is not of this form. Then for some j such that $1 \leq j \leq n$, C is neither of the form $A \sqcap C'$ nor of the form $A_j \sqcap C'$ nor of the form $B_j \sqcap C'$. Let $L = (\boldsymbol{\sigma}_1, \ldots, \boldsymbol{\sigma}_n) \in \mathfrak{L}_n$ be such that $\mathcal{T}_L \models C \sqsubseteq A$. Notice that $\mathcal{T}_L \models C \sqsubseteq A$, for $L = (\boldsymbol{\sigma}_1, \ldots, \boldsymbol{\sigma}_n) \in \mathfrak{L}_n$, if, and only if, $\mathcal{T}_L \models C \sqsubseteq X_0 \sqcap \exists \boldsymbol{\sigma}_1.M \sqcap \cdots \sqcap \exists \boldsymbol{\sigma}_n.M$. By the claim in the proof of Lemma 66, for such a $\mathcal{T}_L$ we must have $\emptyset \models C \sqsubseteq \exists \boldsymbol{\sigma}_j.M$. Clearly, the number of $L = (\boldsymbol{\sigma}_1, \ldots, \boldsymbol{\sigma}_n) \in \mathfrak{L}_n$ with $\emptyset \models C \sqsubseteq \exists \boldsymbol{\sigma}_j.M$ does not exceed $|C|$.

  Thus, either $\mathcal{T}_L \models C \sqsubseteq A$ for every $L \in \mathfrak{L}_n$ or the number of $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models C \sqsubseteq A$ does not exceed $|C|$.

Induction step. If $D = D_1 \sqcap D_2$, then $\mathcal{T}_L \models C \sqsubseteq D$ if, and only if, $\mathcal{T} \models C \sqsubseteq D_i$, $i = 1, 2$. By induction hypothesis, for $i = 1, 2$ either $\mathcal{T}_L \models C \sqsubseteq D_i$ for every $L \in \mathfrak{L}_n$ or there exist at most $|C|$ different $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models C \sqsubseteq D_i$. Thus either $\mathcal{T}_L \models C \sqsubseteq D$ for every $L \in \mathfrak{L}_n$ or the number of $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models C \sqsubseteq D$ also does not exceed $|C|$.

Now assume that $D = \exists t.D'$. Suppose that $\mathcal{T}_L \models C \sqsubseteq D$ for some $L \in \mathfrak{L}_n$. Then, by Lemma 65, either there exists a conjunct Z of C, Z a concept name, such that $\mathcal{T}_L \models Z \sqsubseteq \exists t.D'$ or there exists a conjunct $\exists t.C'$ of C with $\mathcal{T}_L \models C' \sqsubseteq D'$. We analyse for every conjunct of C of the form Z or $\exists t.C'$ the number of $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models Z \sqsubseteq \exists t.D'$ or $\mathcal{T}_L \models \exists t.C' \sqsubseteq \exists t.D'$, respectively.

(i) Let Z be a conjunct of C such that Z is a concept name and $\mathcal{T}_L \models Z \sqsubseteq \exists t.D'$. Notice that $Z \neq M$ as there is no $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models M \sqsubseteq \exists t.D'$. We consider the remaining cases.

- $Z = X_i$, for some $i \geq 0$. It is easy to see that for $L, L' \in \mathfrak{L}_n$ we have $\mathcal{T}_L \models X_i \sqsubseteq \exists t.D'$ if, and only if $\mathcal{T}_{L'} \models X_i \sqsubseteq \exists t.D'$. Thus, $\mathcal{T}_L \models Z \sqsubseteq \exists t.D'$ for every $L \in \mathfrak{L}_n$.
- $Z \in \{A_i, B_i \mid 1 \leq i \leq n\}$. By Lemma 72, $\mathcal{T}_L \models Z \sqsubseteq \exists t.D'$ if, and only if, $\mathcal{T}_L \models X_0 \sqcap \exists \boldsymbol{\sigma}_i.M \sqsubseteq \exists t.D'$. By Lemma 65, either $\mathcal{T}_L \models X_0 \sqsubseteq \exists t.D'$ or $\mathcal{T}_L \models \exists \boldsymbol{\sigma}_i.M \sqsubseteq \exists t.D'$. If $\mathcal{T}_L \models X_0 \sqsubseteq \exists t.D'$ then, as above, for $\mathcal{T}_L \models C \sqsubseteq \exists t.D'$ every $L \in \mathfrak{L}_n$. Suppose that $\exists t.D'$ is such that $\mathcal{T}_L \not\models X_0 \sqsubseteq \exists t.D'$ and $\mathcal{T}_L \models \exists \boldsymbol{\sigma}_i.M \sqsubseteq \exists t.D'$. By inductive applications of Lemma 65, this is only possible if $\exists t.D' = \exists \boldsymbol{\sigma}_i.M$. Thus, there is exactly one $L \in \mathfrak{L}_n$ (namely, $L = L_0$) such that $\mathcal{T}_L \models Z \sqsubseteq \exists \boldsymbol{\sigma}_i.M$.
- $Z = A$. Suppose that for some $L = (\boldsymbol{\sigma}_1, \ldots, \boldsymbol{\sigma}_n) \in \mathfrak{L}_n$ we have $\mathcal{T}_L \models A \sqsubseteq \exists t.D'$. Equivalently, $\mathcal{T}_L \models X_0 \sqcap \exists \boldsymbol{\sigma}_1.M \sqcap \ldots \boldsymbol{\sigma}_n.M \sqsubseteq \exists t.D'$. By Lemma 65, either $\mathcal{T}_L \models X_0 \sqsubseteq \exists t.D'$ or $\mathcal{T}_L \models \exists \boldsymbol{\sigma}_i.M \sqsubseteq \exists t.D'$ for some i with $1 \leq i \leq n$. Thus, as above, unless $\mathcal{T}_L \models X_0 \sqsubseteq \exists t.D'$ we have $\exists t.D'$ is $\exists \boldsymbol{\sigma}_i.M$. But then $L = L_0$.

(ii) Let $\exists t.C'$ be a conjunct of C with $\mathcal{T}_L \models C' \sqsubseteq D'$. The induction hypothesis implies that the number of $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models C' \sqsubseteq D'$ does not exceed $|C'|$.

To summarise, either $\mathcal{T}_L \models C \sqsubseteq \exists t.D'$ for every $L \in \mathfrak{L}_n$ or for every conjunct C_0 of C of the form Z or $\exists t.C'$, the number of $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models C_0 \sqsubseteq \exists t.D'$ does not exceed $|C_0|$. Hence the number of $L \in \mathfrak{L}_n$ such that $\mathcal{T}_L \models C \sqsubseteq \exists t.D'$ does not exceed $|C|$. ❑

The next result is used in the proof of Lemma 67.

Lemma 73 *For any $0 \leq i \leq n$ and concept expression D over Σ_n, if $\mathcal{T}_0 \not\models X_i \sqsubseteq D$ then there exists a sequence of role names $t_1, \ldots t_l \in \{r, s\}^l$ such that $\emptyset \models D \sqsubseteq \exists t_1. \cdots \exists t_l.Y$ and $\mathcal{T}_0 \not\models X_i \sqsubseteq \exists t_1. \cdots \exists t_l.Y$, where Y is either $\top$ or a concept name and $0 \leq l \leq n - i + 1$.*

Proof We prove the lemma by induction on i from $i = n$ to $i = 0$. If $i = n$, then $\mathcal{T}_0 \not\models X_i \sqsubseteq D$ if either $\emptyset \models D \sqsubseteq \exists t.\top$, for some role name t, or $\emptyset \models D \sqsubseteq Y$, for some concept name $Y \neq X_i$.

Suppose that the lemma is proved for $0 < j \leq n$ and let $i = j - 1$. We proceed by induction on the structure of D. If D is a concept name, we are done as $\mathcal{T}_0 \models X_i \sqsubseteq Z$ does not hold for any concept name $Z \neq X_i$. If D is of the form $\exists t.D'$, where $t \in \{r, s\}$, then $\mathcal{T}_0 \not\models X_{i+1} \sqsubseteq D'$, and so, by induction hypothesis, there exists a sequence of role names $t_1, \ldots, t_l$, with $l \leq n - i$, such that $\mathcal{T}_0 \not\models X_{i+1} \sqsubseteq \exists t_1. \cdots \exists t_l.Y$ and $\emptyset \models D' \sqsubseteq \exists t_1. \cdots \exists t_l.Y$. But then, by Lemma 72 and Lemma 65, $\mathcal{T}_0 \not\models X_i \sqsubseteq \exists t.\exists t_1. \cdots \exists t_l.Y$ and $\emptyset \models \exists t.D' \sqsubseteq \exists t.\exists t_1. \cdots \exists t_l.Y$. If D is of the form $D = D_1 \sqcap D_2$, there there exists D_i, $i = 1, 2$, such that $\mathcal{T}_0 \not\models X_i \sqsubseteq D_i$ and the lemma holds by induction hypothesis. ❑

Abstract

To find optimal decision rule, Fan et al. (2016) proposed an innovative concordance-assisted learning algorithm which is based on maximum rank correlation estimator. It makes better use of the available information through pairwise comparison. However the objective function is discontinuous and computationally hard to optimize. In this paper, we consider a convex surrogate loss function to solve this problem. In addition, our algorithm ensures sparsity of decision rule and renders easy interpretation. We derive the L_2 error bound of the estimated coefficients under ultra-high dimension. Simulation results of various settings and application to STAR*D both illustrate that the proposed method can still estimate optimal treatment regime successfully when the number of covariates is large.

Keywords: concordance-assisted learning, optimal treatment regime, L_1 norm, support vector machine, variable selection.

1. Introduction

A treatment regime is a decision rule that tailors treatment for each individual. Instead of randomly assigning treatments, we can select a specific treatment among a few options for each patient based on his or her clinical, genetic and other health information. A decision rule is a procedure to decide which treatment should be picked and it is a function of available information for each patient. Optimal treatment regime aims to find the decision rule that would yield the most favorable outcome. Besides treatment type, treatments of interest also include different treatment combinations and dosage level variation. In reality, it often occurs that large number of patient level covariates are available. However, many of them have no qualitative interaction with treatment effect. Covariates may also be correlated with each other. Under such circumstances, variable selection for optimal treatment regime is necessary to avoid overfitting and increase model interpretation.

Many learning algorithms have been proposed to estimate optimal treatment regime (Qian et al. 2012). Watkins and Dayan (1992) modeled the conditional expectation of outcome (Q-function) and obtained the optimal treatment regime through maximizing the Q-function. Qian and Murphy (2011) extended Q-learning using l_1-penalized least square (PLS). The estimator derived from the two-step procedure may not be consistent if the conditional mean is misspecified. Instead of modeling the outcome, Murphy (2003) proposed the advantage learning (A-learning) algorithm, which is based on modeling contrast function. A contrast function is the difference in potential outcome given different treatments. Lu et al. (2011) considered model selection for estimating optimal treatment regime via penalized least square. A-learning is more robust than Q-learning since it does not require a correct specification of the baseline function but a correct model of interaction term is still needed. In literature, it is common to adopt parametric models for Q-function or contract function. As a result, the corresponding decision rule derived from Q-learning or A-learning may be biased.

To further reduce the impact of model misspecification, Zhang et al. (2012) proposed a value function estimator using inverse probability weighting. The optimal decision rule is derived by maximizing the value function estimator. Zhao et al. (2012) proposed the outcome weighted learning (OWL) algorithm. The OWL approximates optimal treatment decision estimation by transforming an objective function in Zhang et al. (2012) to a classification loss. Larger reward observed indicates higher chance that the optimal decision rule would recommend the same treatment as the patient actually received. Song et al. (2015) extended this method to penalized outcome weighted learning (POWL). Penalty functions include lasso (Tibshirani 1996) and SCAD (Fan and Li 2001).

Value search methods suffer from slow convergence and computation difficulties. Fan et al. (2016) proposed a novel concordance-assisted learning (CAL) algorithm to estimate optimal decision rule. Concordance function is motivated by maximizing value function using pairwise comparison between patients. Since concordance function can be estimated by a much smoother function, better asymptotic results can be obtained.

In this paper, we show that concordance-assisted learning algorithm can be transformed to a classification problem. We replace 0-1 loss by a continuous surrogate function. In order to improve the accuracy of optimal treatment regime and interpretation of decision rule, we conduct variable selection by adding lasso penalty to the objective function. We derive error bound of the proposed estimator under ultra-high dimension. We illustrate that the proposed estimator has better performance than existing popular methods under different scenarios together with a clinical trial study.

In Section 2, we reviewed and developed the concordance-assisted learning algorithm. We continued to derive the L_2 error bound of coefficient estimation in Section 3. Section 4 demonstrates the performance of sparse concordance-assisted learning at different settings. We present results of the proposed method for the STAR*D clinical trial in Section 5. The proofs of all lemmas and theorems are provided in the Appendix.

2. Method

In this section, we first introduce notations and explain its usage. It is followed by a concordance-assisted learning overview. We then propose the sparse concordance-assisted learning algorithm and provide an algorithm to calculate the proposed estimator using Douglas-Rachford splitting method.

2.1 Notation

Let $\boldsymbol{X}_i = (X_{i1}, X_{i2}, ..., X_{ip})^T$ denote the vector of covariates measured for the i-th patient, A_i the assigned treatment and Y_i the outcome after treatment. Let $\boldsymbol{X} = (\boldsymbol{X}_1, \boldsymbol{X}_2, ..., \boldsymbol{X}_n)^T$ denote the feature matrix. Assume that $(\boldsymbol{X}_i, A_i, Y_i)$ are independent, identically distributed. Y is a continuous variable and larger value of Y indicates better treatment effect. Denote $g(\boldsymbol{X})$ as the individualized treatment regime (ITR), P^g as the joint distribution of $(\boldsymbol{X}, A = g(\boldsymbol{X}), Y)$, $E^g(Y)$ as the expected outcome if all treatments follow $g(\boldsymbol{X})$. From now on we consider the case of a binary treatment, i.e., A takes values in {0,1}. Denote $\mu(a, \boldsymbol{X}) = E(Y|A = a, \boldsymbol{X})$, Zhang et al. (2012) shows that $g^{opt}(\boldsymbol{X}) = I\{\mu(1, \boldsymbol{X}) > \mu(0, \boldsymbol{X})\}$. Here $g^{opt}(\boldsymbol{X})$ represents optimal treatment regime.

We also assume stable unit treatment value assumption (SUTVA) and no-unmeasured-confounders assumption holds. SUTVA(Rubin 1980), i.e., $Y = I(A = 0)Y^*(0) + I(A = 1)Y^*(1)$, assumes that no interference exists between treatments of different units and no same treatment variation exists for different units. $Y_i^*(a)$ is the potential outcome after receiving treatment a for subject i. The no-unmeasured-confounders condition, i.e., $\{Y_i^*(0), Y_i^*(1)\} \perp A_i|\boldsymbol{X}_i$, implies all variables that affect treatment assignment or treatment-specific outcomes are observed. The second assumption holds in a randomized trial.

2.2 Concordance-assisted Learning Overview

Concordance-assisted learning estimates optimal treatment regime by comparing the outcome gain of different treatments between individuals. Maximum Rank Correlation (MRC) estimator (Kendall 1938, Han 1987, Cavanagh and Sherman 1998) is chosen to estimate the concordance function. CAL further relaxes parametric assumptions and allows for more flexibility. Fan et al. (2016) showed that under certain conditions, optimal treatment regime estimated by concordance-assisted learning is the same as optimal treatment regime estimated by maximizing value functions.

The true optimal decision rule may not be linear, however, throughout the paper, we only search the optimal decision rule within the class of linear decision rules, i.e. $g(\boldsymbol{X}) = I(\boldsymbol{\beta}^T\boldsymbol{X} \geq \beta_0)$. This is partly because that linear decision rules are much easier to compute and interpret compared with nonlinear decision rules, and they generally can achieve high accuracy. CAL is a two-step procedure that first estimates the prescriptive index, i.e., a set of decision rules with fixed covariate weights by maximizing the concordance function:

$$C(\boldsymbol{\beta}) = E\Big\{\{[Y_i^*(1) - Y_i^*(0)] - [Y_j^*(1) - Y_j^*(0)]\}I(\boldsymbol{\beta}^T\boldsymbol{X}_i > \boldsymbol{\beta}^T\boldsymbol{X}_j)\Big\}$$

and then threshold estimator is optimized based on the prescriptive index estimator. Let $D(\boldsymbol{X}_i)$ be the expected outcome gain of treatment 1 for the i^{th} subject, i.e. $D(\boldsymbol{X}_i) = E(Y_i|A_i = 1, \boldsymbol{X}_i) - E(Y_i|A_i = 0, \boldsymbol{X}_i)$. Concordance function is motivated by the following

idea: for pairwise subjects i and j, larger $D(\boldsymbol{X}_i) - D(\boldsymbol{X}_j)$, which means subject i would benefit more by taking treatment 1 compared to subject j, requires larger $\boldsymbol{\beta}^T\boldsymbol{X}_i$ compared to $\boldsymbol{\beta}^T\boldsymbol{X}_j$.

Define $w_i = \frac{\{Y_i - \nu(\boldsymbol{X}_i)\}\{A_i - \pi(\boldsymbol{X}_i)\}}{\pi(\boldsymbol{X}_i)\{1-\pi(\boldsymbol{X}_i)\}}$,here $\nu(\boldsymbol{X}_i)$ is any arbitrary function and $\pi(\boldsymbol{X}_i) = P(A_i = 1|\boldsymbol{X}_i)$ is the propensity score. In practice we choose $\nu(\boldsymbol{X}_i)$ to be the mean response of the patients who receive treatment 0. Given $\boldsymbol{X}_i$, w_i is an unbiased estimator of $D(\boldsymbol{X}_i)$. The proof is given in Appendix C. Concordance-assisted learning can be summarized as follows:

1 Estimate the prescriptive index:

$$\hat{\boldsymbol{\beta}} = \underset{||\boldsymbol{\beta}||=1}{argmax} \frac{1}{n(n-1)} \sum_{i \neq j} (w_i - w_j) I(\boldsymbol{\beta}^T\boldsymbol{X}_i > \boldsymbol{\beta}^T\boldsymbol{X}_j).$$

2 Estimate the threshold using the inverse probability weighted estimator (IPW) proposed by Zhang et al. (2012):

$$\hat{\beta}_0 = \underset{\beta_0}{argmax} \frac{1}{n} \sum_{i=1}^{n} \frac{\{Y_i - \nu(\boldsymbol{X}_i)\} I\{A_i = \hat{g}(\boldsymbol{X}_i)\}}{A_i\pi(\boldsymbol{X}_i) + (1 - A_i)\{1 - \pi(\boldsymbol{X}_i)\}},$$
$$\hat{g}(\boldsymbol{X}_i) = I(\hat{\boldsymbol{\beta}}^T\boldsymbol{X}_i > \beta_0).$$

Although in general the concordance-based estimator does not always lead to the actual optimal decision rule, under certain conditions, concordance-based estimator is the maximizer of value function (Fan et al. 2016). Concordance-based estimator has attractive properties, including faster convergence rates, known asymptotic distribution (normal) and easy optimization. It is a very promising approach for optimal treatment regime estimation. In the next section, we will introduce sparse concordance-assisted learning (SCAL). Compared to CAL, it is easier to optimize and can achieve satisfactory accuracy under high dimension.

2.3 Sparse Concordance-assisted Learning

Notice that solving for $\hat{\boldsymbol{\beta}}$ is equivalent to minimize:

$$\frac{1}{n(n-1)} \sum_{i \neq j} (w_i - w_j) I(\boldsymbol{\beta}^T\boldsymbol{X}_i < \boldsymbol{\beta}^T\boldsymbol{X}_j), \quad \text{subject to } ||\boldsymbol{\beta}|| = 1. \tag{1}$$

(1) is equivalent to minimizing (see Appendix B):

$$\sum_{w_i > w_j} (w_i - w_j) I(\boldsymbol{\beta}^T\boldsymbol{X}_i < \boldsymbol{\beta}^T\boldsymbol{X}_j), \quad \text{subject to } ||\boldsymbol{\beta}|| = 1.$$

This alternative expression reduces computation cost and ensures the convexity of the objective function. We replace the indicator loss function with the hinge loss. Hinge loss is

a convex upper bound of the 0-1 loss function. It is often used for support vector machine (Cortes and Vapnik 1995), a popular classification method with good performance (Gordon 2004). The optimization of hinge loss function can be solved in polynomial time. Due to the high dimension of p, we use lasso penalty to estimate the optimal treatment regime and perform variable selection simultaneously. Lasso penalty also helps reduce the variance of the fitted coefficients (Zhu et al. 2004). The prescriptive index estimated by the sparse concordance-assisted learning algorithm (SCAL) is:

$$\hat{\boldsymbol{\beta}} = \underset{\boldsymbol{\beta}}{\operatorname{argmin}} \frac{2}{n(n-1)} \sum_{w_i > w_j} (w_i - w_j)\Big[1 - \boldsymbol{\beta}^T(\boldsymbol{X}_i - \boldsymbol{X}_j)\Big]_+ + \lambda \sum_{j=1}^{p} |\beta_j|.$$

We then estimate the threshold parameter β_0 by:

$$\hat{\beta}_0 = \underset{\beta_0}{\operatorname{argmax}} \frac{1}{n} \sum_{i=1}^{n} w_i I(\hat{\boldsymbol{\beta}}^T \boldsymbol{X}_i > \beta_0).$$

The threshold parameter β_0 is estimated through grid search. In practice, the search range is $[\min(\hat{\boldsymbol{\beta}}^T \boldsymbol{X}_i), \max(\hat{\boldsymbol{\beta}}^T \boldsymbol{X}_j)]$, $1 \le i, j \le n$.

We sort the subjects by descending order of w_i. Therefore,

$$\sum_{i=1}^{n}\sum_{j=1}^{n}(w_i - w_j)I(w_i - w_j > 0) = \sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i - w_j). \tag{2}$$

The objective function of SCAL can be written as:

$$\hat{\boldsymbol{\beta}} = argmin_{\boldsymbol{\beta}} \frac{2}{n(n-1)} \sum_{i=1}^{\binom{n}{2}} \delta w_i (1 - \boldsymbol{\beta}^T \boldsymbol{D}_i)_+ + \lambda \sum_{j=1}^{p} |\beta_j|.$$

$$\boldsymbol{D} = \begin{pmatrix} \boldsymbol{X}_1^T - \boldsymbol{X}_2^T \\ \boldsymbol{X}_1^T - \boldsymbol{X}_3^T \\ \cdots \\ \boldsymbol{X}_1^T - \boldsymbol{X}_n^T \\ \boldsymbol{X}_2^T - \boldsymbol{X}_3^T \\ \boldsymbol{X}_2^T - \boldsymbol{X}_4^T \\ \cdots \end{pmatrix}, \quad \delta w = \begin{pmatrix} w_1 - w_2 \\ w_1 - w_3 \\ \cdots \\ w_1 - w_n \\ w_2 - w_3 \\ w_2 - w_4 \\ \cdots \end{pmatrix}.$$

The optimization problem in step 1 is a weighted L_1-SVM problem. The objective function is convex and piecewise linear and many algorithms have been proposed to solve this problem. It can be solved by various linear programming and convex packages. Zhu et al. (2004) proposed an algorithm to compute the whole solution path. Iterative algorithm like Spingarn's Method is another good way to solve this problem. We use three methods: CVX, a package for specifying and solving convex programs (Michael and Stephen 2014, Grant and Boyd 2008), GLPK (GNU Linear Programming Kit, glp 2016) and the method proposed by Spingarn (1985) to find the minimizer. Spingarn's method of partial inverses

implements Douglas-Rachford splitting for equality constrained convex problem (Douglas and Rachford 1956). We add ancillary variables $\boldsymbol{\theta}$ and reformulate (1) as:

$$min f_1(\boldsymbol{\beta}) + f_2(\boldsymbol{\theta})$$
$$subject\ to\ \boldsymbol{\theta} = \boldsymbol{D}\boldsymbol{\beta}$$

where $f_1(\boldsymbol{\beta}) = \lambda||\boldsymbol{\beta}||_1, f_2(\boldsymbol{\theta}) = \sum_{i=1}^{\binom{n}{2}} \delta w_i (1 - \boldsymbol{D}_i\boldsymbol{\beta})_+$.
The iterative algorithm is as follows:

Repeat

1. $\boldsymbol{V}_1^+ = \Big(prox_{tf_1}(\boldsymbol{\beta}), prox_{tf_2}(\boldsymbol{\theta})\Big)$, where
   $[prox_{tf_1}(\boldsymbol{\beta})]_j = S(\beta_j, t\lambda)$,
   S is soft thresholding operator: $S(x, \lambda) = sgn(x)(|x| - \lambda)_+$.
   $[prox_{tf_2}(\boldsymbol{\beta})]_i = \begin{cases} 1 & \theta \in [1 - t\delta w_i, 1], \\ \theta_i & \theta > 1, \\ \theta_i + t\delta w_i & \theta < 1 - t\delta w_i. \end{cases}$
2. $\boldsymbol{V}_2^+ = \begin{pmatrix} \boldsymbol{I} \\ \boldsymbol{D} \end{pmatrix} \boldsymbol{R}^{-T}\boldsymbol{R}^{-1}\Big[P_1(2\boldsymbol{V}_1^+ - \boldsymbol{V}_3) + \boldsymbol{D}^T P_2(2\boldsymbol{V}_1^+ - \boldsymbol{V}_3)\Big]$,
   $P_1(\boldsymbol{\beta}, \boldsymbol{\theta}) = \boldsymbol{\beta}$, $P_2(\boldsymbol{\beta}, \boldsymbol{\theta}) = \boldsymbol{\theta}$, $\boldsymbol{R}\boldsymbol{R}^T = \boldsymbol{I} + \boldsymbol{D}^T\boldsymbol{D}$ is Cholesky decomposition.
3. $\boldsymbol{V}_3^+ = \boldsymbol{V}_3 + \boldsymbol{V}_2^+ - \boldsymbol{V}_1^+$.

until convergence.
Output: $\boldsymbol{\beta}$

We keep step-size parameter t fixed at 1. The convergence is guaranteed (Spingarn 1985). The iterative algorithm greatly reduces memory and time cost. Under the case of ultra-high dimension, preprocessing requires $O(p^3)$ work to form and compute Cholesky decomposition and $O(p^2)$ work per iteration. In summary, CVX is the least computational efficient way to estimate prescriptive index and Spingarn's Method is the only approach that can handle STAR*D trial in terms of its scale.

3. Error Bound for Order-2 U Statistics

Define $\boldsymbol{\beta}^* = argmin_{\boldsymbol{\beta}} L(\boldsymbol{\beta})$ where

$$L(\boldsymbol{\beta}) = E\Big\{(w_i - w_j)I(w_i - w_j > 0)[1 - (\boldsymbol{X}_i - \boldsymbol{X}_j)^T\boldsymbol{\beta}]_+\Big\}.$$

Then the gradient vector and Hessian matrix of the loss function $L(\boldsymbol{\beta})$ are:

$$S(\boldsymbol{\beta}) = -E\Big\{(w_i - w_j)I(w_i - w_j > 0)I[1 - (\boldsymbol{X}_i^T - \boldsymbol{X}_j^T)\boldsymbol{\beta} \ge 0](\boldsymbol{X}_i - \boldsymbol{X}_j)\Big\},$$
$$H(\boldsymbol{\beta}) = E\Big\{(w_i - w_j)I(w_i - w_j > 0)Dirac\delta[1 - (\boldsymbol{X}_i^T - \boldsymbol{X}_j^T)\boldsymbol{\beta}](\boldsymbol{X}_i - \boldsymbol{X}_j)(\boldsymbol{X}_i^T - \boldsymbol{X}_j^T)\Big\},$$

where $Dirac\delta$ is the Dirac delta function. Denote the index set of active features as $T = \{1 \le j \le p : \beta_j^* \neq 0\}$ and $|T| = q$. $\hat{\boldsymbol{\beta}}(\lambda) = \underset{\boldsymbol{\beta}}{argmin}\ l_n(\boldsymbol{\beta}, \lambda)$ is an estimator of $\boldsymbol{\beta}^*$, where

$$l_n(\boldsymbol{\beta}, \lambda) = \frac{2}{n(n-1)} \sum_{i=1}^{n} \sum_{j=1}^{n} (w_i - w_j) I(w_i - w_j > 0)[1 - (\boldsymbol{X}_i^T - \boldsymbol{X}_j^T)\boldsymbol{\beta}]_+ + \lambda ||\boldsymbol{\beta}||_1.$$

We assume the following regularity conditions:

(A1) The densities of $\boldsymbol{X}_i$, i = 1, 2, ... are continuous and have common support in $\boldsymbol{R}^p$, and there exists a constant $M_0 > 0$ such that $|\boldsymbol{X}_{ij}| \le M_0$, $i \in R^+,\ j \in 1, ..., p$
(A2) Denote $\boldsymbol{Z}_{ij} = \boldsymbol{X}_i^T - \boldsymbol{X}_j^T$ with probability density function $f^*(z)$. There exists $B(0, \delta_0)$, a ball centered at 0 with radius $\delta_0 > 0$ such that $E[(w_i - w_j) I(w_i - w_j > 0) | \boldsymbol{Z}_{ij} = \boldsymbol{z}_{ij}] f^*(\boldsymbol{z}_{ij}) > C_3$ for every $\boldsymbol{z}_{ij} \in B(0, \delta_0)$.
(A3) $\int E[(w_i - w_j) I(w_i - w_j > 0) | \boldsymbol{z}] z_k f^*(\boldsymbol{z}) d\boldsymbol{z} \neq 0$ for some k.
(A4) There exists a constant M_1 s.t. $\underset{\boldsymbol{d} \in \boldsymbol{R}^p : ||\boldsymbol{d}||_0 \le 2q}{max} \frac{\boldsymbol{d}^T \boldsymbol{D}^T \boldsymbol{D} \boldsymbol{d}}{\frac{n(n-1)}{2} ||\boldsymbol{d}||_2^2} \le M_1$ almost surely.
(A5) Denote $\bar{c} = \frac{c-1}{c+1}$ where c is a constant satisfying $\lambda \ge c||S(\hat{\boldsymbol{\beta}}^*)||_\infty$, T is the set of significant coefficients (non-zero coefficients). There exists a constant $M_2 > 0$ such that $\underset{\boldsymbol{d} \in \boldsymbol{R}^p : ||d||_0 \le q, ||\boldsymbol{d}_T||_1 \ge \bar{c}||\boldsymbol{d}_{T^c}||_1}{min} \frac{\boldsymbol{d}^T H(\boldsymbol{\beta}^*) \boldsymbol{d}}{||\boldsymbol{d}||_2^2} \ge M_2$.
(A6) $q = O(n^{c_1})$ for some $0 \le c_1 < \frac{1}{2}$.
(A7) There exists a constant M_3 such that for any w_M, $P(|w_i| > w_M) < \exp(-\frac{w_M}{M_3})$.

Condition (A1) ensures $H(\boldsymbol{\beta})$ is well-defined and continuous in $\boldsymbol{\beta}$. Condition (A2) is similar to condition (A2) in Koo et al. (2008). It guarantees $L(\boldsymbol{\beta}) \to \infty$ as $||\boldsymbol{\beta}|| \to \infty$ and further guarantees the existence of $\boldsymbol{\beta}^*$. Condition (A3) implies that $\boldsymbol{\beta}^* \neq 0$. Condition (A4) gives the upper bound of restricted eigenvalue (RE). It can guarantee the Gram matrix is positive definite over a subset of vectors (Bickel et al. 2009). Condition (A5) gives the lower bound for restricted eigenvalue of $H(\boldsymbol{\beta}^*)$. Condition (A6) restricts the divergence rate for the number of none-zero variables. Condition (A7) is a popular distribution assumption in literature.

Lemma 1: *Assume condition (A1) and (A7) satisfied. Suppose* $\lambda = c\sqrt{32A(\alpha)(\log p)^3/n}$, *c is some given constant,* α *is a small probability and* $A(\alpha)$ *is a constant such that* $(2 + n)p^{-A(\alpha)^{1/3} M_0^{-2/3} M_3^{-2/3} + 1} \le \alpha$, *we have*

$$P(\lambda \ge c||\hat{S}(\boldsymbol{\beta}^*)||_\infty) \ge 1 - \alpha.$$

Lemma 2: *Assume conditions (A1), (A4), (A6) and (A7) are satisfied,* $p > n$. *Let*

$$\begin{aligned} B(h) = \frac{2}{n(n-1)} \Big| & \sum_{i=1}^{n} \sum_{j=1}^{n} (w_i - w_j) I(w_i - w_j > 0)[1 - (\boldsymbol{X}_i^T - \boldsymbol{X}_j^T)(\boldsymbol{\beta}^* - h)]_+ \\ & - \sum_{i=1}^{n} \sum_{j=1}^{n} (w_i - w_j) I(w_i - w_j > 0)[1 - (\boldsymbol{X}_i^T - \boldsymbol{X}_j^T)\boldsymbol{\beta}^*]_+ \\ & - \sum_{i=1}^{n} \sum_{j=1}^{n} E\{(w_i - w_j) I(w_i - w_j > 0)[1 - (\boldsymbol{X}_i^T - \boldsymbol{X}_j^T)(\boldsymbol{\beta}^* - h)]_+ \\ & - \sum_{i=1}^{n} \sum_{j=1}^{n} (w_i - w_j) I(w_i - w_j > 0)[1 - (\boldsymbol{X}_i^T - \boldsymbol{X}_j^T)\boldsymbol{\beta}^*]_+ \} \Big|. \end{aligned}$$

Then for sufficiently large n,

$$P\Big(\underset{||\boldsymbol{h}||_0 \le q, ||\boldsymbol{h}||_2 \neq 0}{sup} \frac{B(\boldsymbol{h})}{||\boldsymbol{h}||_2} \ge (1 + C_2\sqrt{M_1}) q \sqrt{\frac{32 \log p}{n}} [M_3 q(C_2^2 - 2) \log p + M_3 \log 2n] \Big) \le 3p^{-q(C_2^2 - 2)}$$

Lemma 2 guarantees that with high probability,

$$\frac{2}{n(n-1)} \sum_{i=1}^{n} \sum_{j=1}^{n} (w_i - w_j) I(w_i - w_j > 0) \Big\{ [1 - (\boldsymbol{X}_i^T - \boldsymbol{X}_j^T)(\boldsymbol{\beta}^* - h)]_+ - [1 - (\boldsymbol{X}_i^T - \boldsymbol{X}_j^T)\boldsymbol{\beta}^*]_+ \Big\}.$$

is within a small range of its expectation. From now on, we choose h to be $h = \boldsymbol{\beta}^* - \hat{\boldsymbol{\beta}}(\lambda)$.

Lemma 3: *For* $\lambda \ge c||S(\hat{\boldsymbol{\beta}}^*)||_\infty$,

$$||\boldsymbol{h}_T||_1 \ge \bar{c}||\boldsymbol{h}_{T^c}||_1,$$

where $\bar{c} = \frac{c-1}{c+1}$, *T is the set of significant coefficients (non-zero coefficients) and* $|T| \le q$.

Theorem 4: *Suppose (A1) - (A7) hold, then* $\hat{\boldsymbol{\beta}}$ *satisfies*

$$||\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^*||_2 \le \sqrt{1 + \frac{1}{\bar{c}}} [\frac{2\lambda\sqrt{q}}{M_2} + \frac{2C_4}{M_2} q^2 \sqrt{\frac{(\log p)^3}{n}} (\frac{5}{4} + \frac{1}{\bar{c}})]$$

with probability at least $1 - 3p^{-q(C_2^2 - 2) + 1}$, *where* C_4 *is a constant.*

When $\lambda = c\sqrt{32A(\alpha)(\log p)^3/n}$, the first term has order $\sqrt{(\log p)^3 q/n}$ and the second term has order $q^2\sqrt{(\log p)^3/n}$. Therefore, with high probability,

$$||\hat{\boldsymbol{\beta}}(\lambda) - \boldsymbol{\beta}^*||_2 = O_p(q^2\sqrt{(\log p)^3/n}).$$

The proofs of the lemmas and theorems are given in the Appendix. We first show the existence of $\boldsymbol{\beta}^*$ and it is non-trivial (formally stated and proved in Appendix A). Lemma 1

indicates a certain λ to bound the infinity norm of gradient vector with large probability. Lemma 2, and Lemma 3 are stepping stones on the path to proving Theorem 4. To be specific, Lemma 2 establishes the relationship between difference in loss functions and its expectation. Lemma 3. Similar results can be found in Zhang et al. (2016) and Peng et al. (2016). Compared to their proofs, our proof uses Hoeffding's inequality for u-statistics of order 2. Another difference is that an unbounded weight exists in our objective function. To handle this challenge, we make assumptions on the tail distribution of weights and adjust the bound correspondingly.

4. Simulation Studies

In this section, we demonstrate the numerical performance of the proposed method. We simulate data from a randomized experiment and evaluate the estimated optimal treatment regimes using sparse concordance-assisted learning and penalized outcome weighted learning. Objective function of POWL is:

$$\frac{1}{n}\sum_{i=1}^{n}\Big\{\frac{Y_i}{A_i\pi(\boldsymbol{X_i})+(1-A_i)[1-\pi(\boldsymbol{X_i})]}[1-(2A_i-1)g(\boldsymbol{X}_i)]_+\Big\}+\lambda\sum_{j=1}^{p}|\beta_j|. \qquad (3)$$

Here g is a linear function, i.e. $g(\boldsymbol{\beta},\boldsymbol{X}_i)=\boldsymbol{\beta}^T\boldsymbol{X}_i+\beta_0$. Notice that the solution to (2) will remain the same if every Y_i is added to a constant c. In order to guarantee the objective function is convex and the optimization problem is feasible, we add a constant to all Y_i to make sure the smallest response is positive. The constant is chosen so that the smallest shifted response is 0.01. POWL is implemented using convex toolbox in MATLAB. We compute the IPW estimator using Monte Carlo simulations with 1000 replicates and select the tuning parameter λ with the largest $\hat{Y}_{\hat{opt}}$.

To evaluate the estimated decision rule, we report the mean outcome following the estimated optimal treatment regime (Estimated Value) and the percentage of correct decision (PCD) of the estimated optimal treatment regime. The mean of value function following estimated treatment regime is calculated by plugging estimated decisions in the real model using Monte Carlo simulations with 1000 replicates. The mean of value function following the true optimal treatment regime (True Value) is also listed. In addition, we report the mean square error of $\hat{\boldsymbol{\beta}}$. For variable selection, we report correct number of zero coefficients (Corr0) and incorrect number of zero coefficients (Incorr0) compared to the true optimal treatment regime. Results are evaluated and compared under various settings. The associated sample standard deviations are included in the parentheses.

4.1 Low Dimension

We follow the first simulation scenario in Zhao et al. (2012): $X_{i1}, X_{i2}, ..., X_{i50}$ are generated independently from a uniform distribution on $[-1,1]$, $i=1,\cdots,n$. The treatment indicator A is generated from Bernoulli distribution with $p=0.5$. The conditional density of the response Y given $\boldsymbol{X}$ and A is normal, with mean $Q_0(\boldsymbol{X}_i)=1+2X_{i1}+X_{i2}+0.5X_{i3}+0.442(1-X_{i1}-X_{i2})(2A_i-1)$ and variance 1. Here only X_{i1} and X_{i2} have linear interaction

with treatment. We ran 100 simulations with n=30, 100 and 200 respectively to estimate the individualized treatment rule using SCAL and POWL. Table 1 summarizes the results.

From Table 1 we have the following observations. First, sparse concordance-assisted learning leads to more accurate estimates of $\boldsymbol{\beta}$ and better variable selection results. Sparse concordance-assisted learning achieves smaller mean square error (MSE) smaller Incorr0 and smaller Corr0 than that of penalized outcome weighted learning. Although the model size of POWL is smaller and closer to the real model size, its value function estimation is smaller. This further demonstrates that SCAL can select covariates that have strong interaction with treatment and compensate for the influence of model complexity.

The mean of value function following the estimated treatment regime gets closer to the real optimal value as sample size increases. We also notice that SCAL estimator does not vary much from sample to sample: both PCD and value function estimated by SCAL have smaller variance.

In general two methods lead to comparable results. The difference between methods are small, and this is especially true when the sample size is large. When n=30, SCAL leads to much closer value function estimation to true optimal value function estimation than that of POWL. But when n=200, the difference between value functions estimated from SCAL and POWL is only 1.39% of the true value function estimation. It is not surprising since compared to concordance-assisted learning, outcome weighted learning uses information less efficiently, which, can be made up of by increasing available information.

	n	MSE	Incorr0(0)	Corr0(48)	PCD	Estimated Value	True Value
POWL	30	1.60	1.70	42.23	0.615(0.02)	1.09(0.02)	1.44
	100	1.27	1.94	46.64	0.768(0.02)	1.27(0.02)	1.44
	200	1.09	1.99	47.78	0.786(0.02)	1.30(0.03)	1.44

	200	0.19	0.01	46.03	0.749(0.01)	1.32(0.01)	1.44

Table 1: Simulation results of sparse concordance-assisted learning (SCAL) and penalized outcome weighted learning (POWL): low-dimensional case

4.2 High Dimension

We consider the following six models to generate simulation data:

Model I: $\boldsymbol{Y}=\boldsymbol{X}\gamma_1+\boldsymbol{X}\boldsymbol{\beta}A+\epsilon$, $\gamma_1=(3,-1,1,\mathbf{0_{p-2}})^T$, $\boldsymbol{\beta}=(2,1.8,0,0,0,-1.6,\mathbf{0_{p-6}})^T$.

Model II: $\boldsymbol{Y}=3-0.5(\boldsymbol{X}\gamma_1)^2+0.625(\boldsymbol{X}\gamma_2)^2+\boldsymbol{X}\boldsymbol{\beta}A+\epsilon$, $\gamma_1=(1,0.5,\mathbf{0_{p-2}})^T$, $\gamma_2=(0,1,\mathbf{0_{p-2}})^T$,$\boldsymbol{\beta}=(2,1.8,0,0,0,-1.6,\mathbf{0_{p-6}})^T$.

Model III: $\boldsymbol{Y}=1-\sin(\boldsymbol{X}\gamma_1)+\sin(\boldsymbol{X}\gamma_2)+\boldsymbol{X}\boldsymbol{\beta}A+\epsilon$, $\gamma_1=(1,\mathbf{0_{p-1}})^T$,$\gamma_2=(0,1,\mathbf{0_{p-2}})^T$, $\boldsymbol{\beta}=(2,1.8,0,0,0,-1.6,\mathbf{0_{p-6}})^T$.

Model IV: $\boldsymbol{Y}=\boldsymbol{X}\gamma_1+(\boldsymbol{X}\boldsymbol{\beta})^3A+\epsilon$, $\gamma_1=(3,-1,1,\mathbf{0_{p-2}})^T$, $\boldsymbol{\beta}=(1,0.9,0,0,0,-0.8,\mathbf{0_{p-6}})^T$.

Model V: $\boldsymbol{Y}=3-0.5(\boldsymbol{X}\gamma_1)^2+0.625(\boldsymbol{X}\gamma_2)^2+(\boldsymbol{X}\boldsymbol{\beta})^3A+\epsilon$, $\gamma_1=(1,0.5,\mathbf{0_{p-2}})^T$, $\gamma_2=(0,1,\mathbf{0_{p-2}})^T$,$\boldsymbol{\beta}=(1,0.9,0,0,0,-0.8,\mathbf{0_{p-6}})^T$.

Model VI: $\boldsymbol{Y}=1-\sin(\boldsymbol{X}\gamma_1)+\sin(\boldsymbol{X}\gamma_2)+(\boldsymbol{X}\boldsymbol{\beta})^3A+\epsilon$, $\gamma_1=(1,\mathbf{0_{p-1}})^T$,$\gamma_2=(0,1,\mathbf{0_{p-2}})^T$, $\boldsymbol{\beta}=(1,0.9,0,0,0,-0.8,\mathbf{0_{p-6}})^T$.

There are three baseline functions: Models I and III share the same linear baseline function; Models II and IV share the same higher order polynomial baseline function; Models III and VI share the same complex baseline function. In the first three models there is a linear interaction between covariates and treatment; in the last three models treatment and a cubic function of prescriptive index are interacted with each other. All six models have the same important variables $\boldsymbol{X}_{i1}$, $\boldsymbol{X}_{i2}$ and $\boldsymbol{X}_{i6}$. Covariates $\boldsymbol{X}_i = (X_{i1}, X_{i2}, ..., X_{ip})^T$ are generated from a multivariate normal distribution: each entry is standard normal and the correlation between covariates is $Corr(X_{ij}, X_{ik}) = \rho^{|j-k|}$ for $1 \leq j \neq k \leq p$. ρ is chosen to be 0 and 0.2 respectively. The error term ϵ is generated from standard normal distribution. We ran 100 simulations for each scenario with n=100 and p=500, 1000 respectively.

We consider randomized studies where A is generated from Bernoulli distribution with p = 0.5. The performance of variable selection and treatment regime estimation of both methods are summarized in Tables 2 and 3. Conclusions are similar to low-dimensional case. SCAL selects more important variables and fewer unimportant variables than POWL. SCAL also provides more accurate decision rule estimation. Its value function estimate is 0.73 higher than POWL, which is 18.3% of true optimal value function estimate and its PCD is 22.4% higher. The comparison between MSE of $\boldsymbol{\beta}$ estimate further supports the advantage of SCAL.

The performance of SCAL continues to improve as magnitude of interaction between treatment and covariates increases. However we are unable to see this trend from POWL. In general, SCAL can recover important variables better under cubic prescriptive index and treatment interaction than under linear interaction. When $\rho = 0$ and $p = 500$, comparing Model 1 with Model 4, we can see that MSE and Incorr0 dropped a lot. On the contrary, for POWL under the same circumstances, MSE remains almost the same and Incorr0 even increases. Results of Corr0 as well as PCD agree with this statement.

SCAL has demonstrated its performance under high dimension. It also shows the potential to identify important variables when p goes even larger. Performance of variable selection and optimal treatment regime estimation become slightly worse when p increases from 500 to 1000. In reality it is common that hundreds of covariates are available for each patient. Reliable results can still be obtained by SCAL under such circumstances.

The PCD slightly increases when the correlation between covariates increases, suggesting that correlated covariate structure can reduce the impact of falsely selected unimportant variables and missing important variables. When ρ increases from 0 to 0.5, $p = 500$, the PCD of Model 1 increases 4.2% for SCAL and 0.9% for POWL. Due to the fact that correlation exists in most of the real-world data, SCAL proves itself to be a desirable approach.

Next, we consider observational studies where the propensity score is estimated from data. To be specific, the treatment indicator A is generated from Bernoulli($\frac{1}{1+e^{-u}}$), where $u(\boldsymbol{X}) = 0.01 - 0.5 * X_1 + 0.4 * X_{10}$. Here, we consider the same high-dimensional settings with $p = 500$ and $\rho = 0.2$, and the propensity score is estimated using the l_1-penalized logistic regression. The results of SCAL and POWL are summarized in Table 4. Overall, SCAL outperforms POWL in terms of variable selection and estimating optimal treatment regime in all cases as observed for randomization studies.

5. Application to STAR*D Study

We apply the proposed method to STAR*D Study, the largest and longest study ever conducted to assess effectiveness of depression treatments. 4041 outpatients who are diagnosed with major depressive disorder (MDD), representing of various ethnic and socioeconomic groups are collected. There are four levels in this clinical trial and at each level different treatments are evaluated and compared. See Fava et al. (2003) for design and measurement details of STAR*D study.

In the data analysis, we focus on patients who received bupropion (BUP) or sertraline (SER) in the second level to illustrate our method. Among the 309 selected subjects, 153 of them received bupropion (BUP) and 166 received sertraline (SER). In order to be consistent with our previous notation, we use 0 to represent SER and 1 to represent BUP. We consider all 305 covariates collected from enrollment, IVR call, ROA interviews, clinic visit and other events (such as suicide, non-serious adverse event and protocol deviation) to recommend individualized treatment for each patient. We choose negative 16-item Quick Inventory of Depressive Symptomatology-Clinician-Rated (QIDS-C16) as our response variable. QIDS-C16 is reverse coded so that it satisfies larger outcome indicates better treatment effect. The negative QIDS-C16 is in the range of -24 to 0.

We apply SCAL using Spingarn's method to this data set. λ_{opt} is tuned using 5-fold cross validation. A pre-defined range (0, 4) is searched and λ is chosen based on the IPW estimator. Propensity score is estimated by proportion of subjects who receive treatment 1 in the training data set. For comparison, we also evaluate the performance of POWL using 5-fold cross validation. The response is shifted with the smallest value to be 0.01. Note that the adjusted response is only used to optimize objective function; Value function is estimated using original response.

To compare the estimated treatment regimes on STAR*D data, we draw bootstrap samples over 1,000 times and estimate the 95% confident interval of difference between expected outcome following estimated treatment regime from SCAL and the non-dynamic treatment regimes. The expected outcome difference between SCAL and POWL is also calculated. See Table 5 for estimate of value function based on estimated optimal treatment regime and 95% confident interval of the differences.

Treatment Regime	Estimated Value	Diff	95% CI on Diff
Optimal Regime(SCAL)	-6.77		
Optimal Regime(POWL)	-9.46	2.69	(1.18, 4.24)
BUP	-10.52	3.75	(2.38, 5.19)
SER	-10.74	3.97	(2.57, 5.50)

Table 5: Estimated values, difference in estimated values and its 95% CI

The estimated value function by SCAL is significantly larger than either of the non-dynamic treatment regimes. It is also significantly larger than the expected outcome following the optimal treatment regime based on POWL at $\alpha = 0.05$. Compared to POWL, SCAL achieves a reasonable model size. It keeps good balance of including important features and controlling the complexity of the model. Estimate based on POWL is too sparse and many covariates which have interaction with treatment effects are missed. Table 6 and

Table 7 are summaries of treatment actually received versus estimated optimal treatment. We can see that estimated optimal treatment regime based on SCAL tends to be more balance. Based on SCAL, among all 171 subjects who were assigned to SER, 92 of them should stay in the same treatment and 79 of them should be assigned to BUP. While the result of POWL indicates 111 of them were assigned to the optimal treatment and only 56 patients should switch to BUP.

	Estimated treatment: SER	Estimated treatment: BUP

6. Conclusion

We propose a variable selection method based on concordance-assisted learning for estimating optimal treatment regime. Our method can minimize the weighted misclassification rate and select prescriptive index simultaneously. The proposed method gives much more accurate decision rule and value function estimation than existing popular methods under various simulation settings. Moreover, inputs that are correlated with treatments effects are also successfully identified. Sparse concordance-assisted learning achieves promising result in constructing real-world decision. We also study the error bound of SCAL in ultra-high dimension.

The proposed method does not require model specification except for propensity score. It is based on an estimate of contrast function which can be defined easily under binary treatment circumstance. SCAL can solve problems in other fields as well. One popular example is to determine the best move in a game. SCAL can be implemented to choose the best action. In the future, one interesting direction of our study would be to extend the definition of contrast function when more than two treatment arms are available. We may also replace linear support vector machine by other kernels to see whether a better treatment regime can be found.

Acknowledgments

We would like to acknowledge support for this project from National Institute of Mental Health for providing the STAR*D data. We would also like to thank Dr. Eric Chi for his help in developing Spingarn's method.

Appendix A.

In this appendix we first state and prove two fundamental lemmas.

Lemma 0.1: *If condition (A1) and (A2) are satisfied, $\boldsymbol{\beta}^*$ exists.*

Proof. of Lemma 0.1:

$$\begin{aligned}
&E\Big\{(w_i-w_j)I(w_i-w_j>0)[1-\boldsymbol{\beta}^*(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)]_+\Big\}\\
=&E\Big(E\{(w_i-w_j)I(w_i-w_j>0)[1-\boldsymbol{\beta}^*(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)]_+|\boldsymbol{X}_i^T-\boldsymbol{X}_j^T\}\Big)
\end{aligned}$$

$$\begin{aligned}
L(\boldsymbol{\beta})=&\int E\Big[(w_i-w_j)I(w_i-w_j>0)|\boldsymbol{z}\Big](1-\boldsymbol{z}^T\boldsymbol{\beta})_+f^*(\boldsymbol{z})d\boldsymbol{z}\\
\geq&\int I(\boldsymbol{z}^T\boldsymbol{\beta}\leq 0)E\Big[(w_i-w_j)I(w_i-w_j>0)|\boldsymbol{z}\Big](1-\boldsymbol{z}^T\boldsymbol{\beta})f^*(\boldsymbol{z})d\boldsymbol{z}\\
\geq&\int I(\boldsymbol{z}^T\boldsymbol{\beta}\leq 0)E\Big[(w_i-w_j)I(w_i-w_j>0)|\boldsymbol{z}\Big](-\boldsymbol{z}^T\boldsymbol{\beta})f^*(\boldsymbol{z})d\boldsymbol{z}\\
\geq&C_3\int_{B(0,\delta_0)}I(\boldsymbol{z}^T\boldsymbol{\beta}\leq 0)(-\boldsymbol{z}^T\boldsymbol{\beta})d\boldsymbol{z}\\
=&C_3||\boldsymbol{\beta}||\int_{B(0,\delta_0)}I(\boldsymbol{z}^Tw\leq 0)(-\boldsymbol{z}^Tw)d\boldsymbol{z}\\
\geq&C_3||\boldsymbol{\beta}||vol\Big(B(0,\delta_0)\bigcap\{-\boldsymbol{z}^Tw\geq\epsilon\}\Big)\epsilon,
\end{aligned}$$

where $w=\boldsymbol{\beta}/||\boldsymbol{\beta}||$ and vol is short for volume. Note that $vol\Big(B(0,\delta_0)\bigcap\{-\boldsymbol{z}^Tw\geq\epsilon\}\Big)>0$ for some $\epsilon<\delta_0$ and $vol\Big(B(0,\delta_0)\bigcap\{-\boldsymbol{z}^Tw\geq\epsilon\}\Big)$ is independent of $\boldsymbol{\beta}$. Thus $L(\beta)\to\infty$ as $||\boldsymbol{\beta}||\to\infty$. Since $L(\boldsymbol{\beta})$ is convex in $\boldsymbol{\beta}$, the solution $\boldsymbol{\beta}^*$ exists.■

Lemma 0.2: *Condition (A3) implies $\boldsymbol{\beta}^*\neq 0$.*

Proof. of Lemma 0.2:

Without loss of generality, suppose $\int E[(w_i-w_j)I(w_i-w_j>0)|\boldsymbol{z}]z_kf^*(\boldsymbol{z})d\boldsymbol{z}>0$, then for $\beta_k^*>0$,

$$\begin{aligned}
L(0,...,\beta_k^*,0,...0)=&\int E[(w_i-w_j)I(w_i-w_j>0)|\boldsymbol{z}](1-\beta_k^*z_k)I(1-\beta_k^*z_k>0)f^*(\boldsymbol{z})d\boldsymbol{z}\\
=&\int E[(w_i-w_j)I(w_i-w_j>0)|\boldsymbol{z}]I(z_k<\frac{1}{\beta_k^*})f^*(\boldsymbol{z})d\boldsymbol{z}\\
&-\beta_k^*\int E[(w_i-w_j)I(w_i-w_j>0)|\boldsymbol{z}]z_kI(z_k<\frac{1}{\beta_k^*})f^*(\boldsymbol{z})d\boldsymbol{z}.
\end{aligned}$$

The second term is non-negative for a sufficient small $\beta_k^*>0$.
Therefore,

$$L(0,...,\beta_k^*,0,...0)<\int E[(w_i-w_j)I(w_i-w_j>0)|\boldsymbol{z}]f^*(\boldsymbol{z})d\boldsymbol{z}=L(0,...,0).\blacksquare$$

Now we prove all lemmas and theorems from Section 3.

Proof of Lemma 1: Recall that

$$\hat{S}(\boldsymbol{\beta})=\frac{-2}{n(n-1)}\sum_{i=1}^n\sum_{j=i+1}^n(w_i-w_j)I[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}\geq 0](\boldsymbol{X}_i-\boldsymbol{X}_j).$$

Note that

$$\begin{aligned}
&\frac{2}{n(n-1)}\sum_{i=1}^n\sum_{j=i+1}^n(w_i-w_j)I[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}\geq 0](X_{ik}-X_{jk})\\
&\qquad=\frac{1}{n(n-1)}\sum_{i\neq j}q_1\Big((w_i,\boldsymbol{X}_i),(w_j,\boldsymbol{X}_j)\Big),
\end{aligned}$$

where

$$q_1\Big((w_i,\boldsymbol{X}_i),(w_j,\boldsymbol{X}_j)\Big)=\begin{cases}(w_i-w_j)I[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}\geq 0](\boldsymbol{X}_{ik}-\boldsymbol{X}_{jk}) & if\ i<j,\\ q_1\Big((w_j,\boldsymbol{X}_j),(w_i,\boldsymbol{X}_i)\Big) & if\ i>j.\end{cases}$$

By Hoeffding's inequality for u-statistics of order 2, which can be found in Peel et al. (2010):

$$\begin{aligned}
P\Big(\sqrt{32A(\alpha)(\log p)^3/n}\leq&\frac{2}{n(n-1)}\Big|\sum_{i=1}^n\sum_{j=i+1}^n(w_i-w_j)I[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}\geq 0](X_{ik}-X_{jk})\Big|\Big)\\
&\leq 2\exp\Big(-\frac{32A(\alpha)n(\log p)^3}{2n(4M_0w_M)^2}\Big)+n\exp(-\frac{w_M}{M_3}).
\end{aligned}$$

Let $w_M=A(\alpha)^{1/3}\log pM_0^{-2/3}M_3^{1/3}$, then

$$\exp\Big(-\frac{32A(\alpha)n(\log p)^3}{32nM_0^2w_M^2}\Big)=\exp(-\frac{w_M}{M_3}),$$

$$\begin{aligned}
P\Big(\sqrt{32A(\alpha)(\log p)^3/n}\leq&\frac{2}{n(n-1)}\Big|\sum_{i=1}^n\sum_{j=i+1}^n(w_i-w_j)I[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}\geq 0](X_{ik}-X_{jk})\Big|\Big)\\
&\leq(2+n)p^{-A(\alpha)^{1/3}M_0^{-2/3}M_3^{-2/3}},
\end{aligned}$$

$$P\Big(c\sqrt{32A(\alpha)(\log p)^3/n} \le c||\hat{S}(\boldsymbol{\beta}^*)||_\infty\Big)$$
$$\le \sum_{k=1}^{p} P\Big(\sqrt{32A(\alpha)(\log p)^3/n} \le$$
$$\frac{2}{n(n-1)}\Big|\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)I[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}\ge 0](\boldsymbol{X}_{ik}-\boldsymbol{X}_{jk})\Big|\Big)$$
$$\le (2+n)p^{-A(\alpha)^{1/3}M_0^{-2/3}M_3^{-2/3}+1} \le \alpha.\blacksquare$$

Proof of Lemma 2:
Let $q_2\Big((w_i,\boldsymbol{X}_i),(w_j,\boldsymbol{X}_j)\Big) =$

$$\begin{cases}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-h)]_+-(w_i-w_j)[1-(X_i^T-X_j^T)\boldsymbol{\beta}^*]_+ & if\ i<j,\\ q_2\Big((w_j,\boldsymbol{X}_j),(w_i,\boldsymbol{X}_i)\Big) & if\ i>j.\end{cases}$$

and $\hat{U}_{q_2}(\mathcal{W}_n,\boldsymbol{\mathcal{X}}_n)=\frac{1}{n(n-1)}\sum_{i\neq j}q_2\Big((w_i,\boldsymbol{X}_i),(w_j,\boldsymbol{X}_j)\Big)$. It is a u-statistics of order 2.

$$\Big|(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-h)]_+-(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}^*]_+\Big| \le \Big|2w_M(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)h\Big|$$

holds with at least probability $1-ne^{-\frac{w_M}{M_3}}$, $\forall\ 1\le i,j\le n$.

By Hoeffding's inequality,

$$P\Big(\sup_{h\in R^p:||\boldsymbol{h}||_0\le q,||\boldsymbol{h}||_2\neq 0}\frac{B(\boldsymbol{h})}{||\boldsymbol{h}||_2}\ge\frac{t}{\sqrt{n}}|\boldsymbol{X}\Big)\le 2\exp(-\frac{t^2}{32M_0^2w_M^2q})$$

holds with at least probability $1-ne^{-\frac{w_M}{M_3}}$, $\forall\ 1\le i,j\le n$. Let $t=C\sqrt{32\log p}qw_M$, then

$$P\Big(\sup_{h\in R^p:||\boldsymbol{h}||_0\le q,||\boldsymbol{h}||_2\neq 0}\frac{B(\boldsymbol{h})}{||\boldsymbol{h}||_2}\ge C\sqrt{\frac{32\log p}{n}}qw_M\Big)\le 2p^{-\frac{qC^2}{M_0^2}},$$
$$P\Big(\sup_{\boldsymbol{h}\in N}\frac{B(\boldsymbol{h})}{||\boldsymbol{h}||_2}\ge C\sqrt{\frac{32\log p}{n}}qw_M\Big)\le 2(\frac{3}{\epsilon}p^{1-\frac{C^2}{M_0^2}})^q,$$

where N is a ϵ-net to cover $\{\boldsymbol{h}\in R^p,||\boldsymbol{h}||_0\le q,||\boldsymbol{h}||_2\neq 0\}$, for any $\boldsymbol{h}_1$, $\boldsymbol{h}_2$ within the same ϵ-ball and $||\boldsymbol{h}_1||_2\neq 0$ and $||\boldsymbol{h}_2||_2\neq 0$, $\Big|\frac{\boldsymbol{h}_1}{||\boldsymbol{h}_1||_2}-\frac{\boldsymbol{h}_2}{||\boldsymbol{h}_2||_2}\Big|\le\epsilon$ holds.

We also have

$$\sup_{\boldsymbol{h}_1,\boldsymbol{h}_2\in R^p,||\boldsymbol{h}_1-\boldsymbol{h}_2||_0\le 2q,||\boldsymbol{h}_1||_2\neq 0,||\boldsymbol{h}_2||_2\neq 0}\Big|\frac{B(\boldsymbol{h}_1)}{||\boldsymbol{h}_1||_2}-\frac{B(\boldsymbol{h}_2)}{||\boldsymbol{h}_2||_2}\Big|\le\frac{8w_M}{n(n-1)}\Big|\Big|D(\frac{\boldsymbol{h}_1}{||\boldsymbol{h}_1||_2}-\frac{\boldsymbol{h}_2}{||\boldsymbol{h}_2||_2})\Big|\Big|_1$$
$$\le\frac{8w_M}{\sqrt{\frac{n(n-1)}{2}}}\Big|\Big|D(\frac{\boldsymbol{h}_1}{||\boldsymbol{h}_1||_2}-\frac{\boldsymbol{h}_2}{||\boldsymbol{h}_2||_2})\Big|\Big|_2\le 8w_M\sqrt{M_1}\epsilon$$

holds with probability at least $1-ne^{-\frac{w_M}{M_3}}$.

$$\sup_{||\boldsymbol{h}||_0\le q,||\boldsymbol{h}||_2\neq 0}\frac{B(\boldsymbol{h})}{||\boldsymbol{h}||_2}\le\sup_{\boldsymbol{h}\in N}\frac{B(\boldsymbol{h})}{||\boldsymbol{h}||_2}+8w_M\sqrt{M_1}\epsilon$$

holds with probability at least $1-ne^{-\frac{w_M}{M_3}}$.

Let $\epsilon=q\sqrt{\frac{32\log p}{n}}\frac{1}{8\sqrt{M_1}}$, we have that

$$P\Big(\sup_{||\boldsymbol{h}||_0\le q,||\boldsymbol{h}||_2\neq 0}\frac{B(\boldsymbol{h})}{||\boldsymbol{h}||_2}\ge Cq\sqrt{\frac{32\log p}{n}}w_M\Big)\le$$
$$P\Big(\sup_{\boldsymbol{h}\in N}\frac{B(\boldsymbol{h})}{||\boldsymbol{h}||_2}\ge(C-1)q\sqrt{\frac{32\log p}{n}}w_M\Big)+2n\exp(-\frac{w_M}{M_3}).$$

Since $p>n$ and take $C=1+C_2M_0$ for some $C_2\ge\sqrt{2}$, for sufficiently large n:

$$P\Big(\sup_{||\boldsymbol{h}||_0\le q,||\boldsymbol{h}||_2\neq 0}\frac{B(\boldsymbol{h})}{||\boldsymbol{h}||_2}\ge(1+C_2M_0)q\sqrt{\frac{32\log p}{n}}w_M\Big)\le 2p^{-q(C_2^2-2)}+\exp(\log 2n-\frac{w_M}{M_3}).$$

Take $w_M=M_3q(C_2^2-2)\log p+M_3\log 2n$, we have that $P\Big(\sup_{||\boldsymbol{h}||_0\le q,||\boldsymbol{h}||_2\neq 0}\frac{B(\boldsymbol{h})}{||\boldsymbol{h}||_2}\ge(1+C_2M_0)q\sqrt{\frac{32\log p}{n}}[M_3q(C_2^2-2)\log p+M_3\log 2n]\Big)\le 3p^{-q(C_2^2-2)}.\blacksquare$

Proof of Lemma 3.
By the definition of $\boldsymbol{\beta}^*$, we have

$$\begin{aligned}&\frac{2}{n(n-1)}\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\hat{\boldsymbol{\beta}}]_+ +\lambda||\hat{\boldsymbol{\beta}}||_1\le\\ &\frac{2}{n(n-1)}\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}^*]_+ +\lambda||\boldsymbol{\beta}^*||_1\\ &\frac{2}{n(n-1)}\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\hat{\boldsymbol{\beta}}]_+\\ &-\frac{2}{n(n-1)}\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}^*]_+\le\lambda||\boldsymbol{\beta}^*||_1-\lambda||\hat{\boldsymbol{\beta}}||_1.\end{aligned}\tag{4}$$

We can also show that

$$||\boldsymbol{\beta}^*||_1-||\hat{\boldsymbol{\beta}}||_1\le||\boldsymbol{h}_T||_1-||\boldsymbol{h}_{T^c}||_1,\tag{5}$$

$$\frac{2}{n(n-1)}\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\hat{\boldsymbol{\beta}}]_+$$
$$-\frac{2}{n(n-1)}\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}^*]_+$$
$$\geq \hat{S}^T(\boldsymbol{\beta}^*)\boldsymbol{h}\geq -||\boldsymbol{h}||_1||\hat{S}(\boldsymbol{\beta}^*)||_\infty\geq -\frac{\lambda}{c}(||\boldsymbol{h}_T||_1+||\boldsymbol{h}_{T^c}||_1). \quad (6)$$

Based on (4),(6) and (6), we have

$$||\boldsymbol{h}_T||_1\geq\frac{c-1}{c+1}||\boldsymbol{h}_{T^c}||_1.\blacksquare$$

Proof. of Theorem 4:
Assume $|h_1|\geq|h_2|\geq ...\geq|h_p|$, then for the partition: $S_0=\{1,2,..,q\},S_1=\{q+1,q+2,..,2q\},...,$

$$||\boldsymbol{h}_{S_0}||_1\geq||\boldsymbol{h}_T||_1\geq\bar{c}||\boldsymbol{h}_{T^C}||_1\geq\bar{c}||\boldsymbol{h}_{S_0^C}||_1$$

holds. We have

$$\frac{2}{n(n-1)}\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-\boldsymbol{h})]_+-$$
$$\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}^*]_+$$
$$=\frac{2}{n(n-1)}\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-\boldsymbol{h}_{S_0})]_+-$$
$$\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}^*]_+$$
$$+\frac{2}{n(n-1)}\sum_{l\geq1}\Big\{\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-\sum_{k=0}^{l}\boldsymbol{h}_{S_k})]_+$$
$$-\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-\sum_{k=0}^{l-1}\boldsymbol{h}_{S_k})]_+\Big\}.$$

By Lemma 2 we have with at least probability $1-3p^{-q(C_2^2-2)}$,

$$E\Big\{(w_i-w_j)I(w_i-w_j>0)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-\sum_{k=1}^{l}\boldsymbol{h}_{S_k})]_+\Big\}$$
$$-E\Big\{(w_i-w_j)I(w_i-w_j>0)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-\sum_{k=1}^{l-1}\boldsymbol{h}_{S_k})]_+\Big\}$$
$$\leq\frac{2}{n(n-1)}\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-\sum_{k=1}^{l}\boldsymbol{h}_{S_k})]_+$$
$$-\frac{2}{n(n-1)}\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-\sum_{k=1}^{l-1}\boldsymbol{h}_{S_k})]_++C_4q^2\sqrt{\frac{(\log p)^3}{n}}||\boldsymbol{h}_{S_l}||_2.$$

It holds for every l, therefore

$$\frac{2}{n(n-1)}E\Big\{\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-\boldsymbol{h})]_+-$$
$$\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}^*]_+\Big\}$$
$$\leq\frac{2}{n(n-1)}\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-\boldsymbol{h})]_+$$
$$-\frac{2}{n(n-1)}\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}^*]_++C_4q^2\sqrt{\frac{(\log p)^3}{n}}\sum_{j\geq0}||\boldsymbol{h}_{S_j}||_2$$
$$\leq\lambda(||\boldsymbol{h}_T||_1-||\boldsymbol{h}_{T^C}||_1)+C_4q^2\sqrt{\frac{(\log p)^3}{n}}||\boldsymbol{h}_{S_0}||_2+\sum_{j\geq1}C_4q^2\sqrt{\frac{(\log p)^3}{n}}||\boldsymbol{h}_{S_j}||_2$$
$$\leq\lambda\sqrt{q}||\boldsymbol{h}_{S_0}||_2+C_4q^2\sqrt{\frac{(\log p)^3}{n}}(\frac{5}{4}+\frac{1}{\bar{c}})||\boldsymbol{h}_{S_0}||_2$$

holds with probability at least $1-3p^{-q(C_2^2-2)+1}$.

The last inequality holds by,

$$\sum_{j\geq1}||\boldsymbol{h}_{S_j}||_2\leq\sum_{j\geq1}\frac{||\boldsymbol{h}_{S_j}||_1}{\sqrt{q}}+\frac{\sqrt{q}}{4}|h_q|\leq\frac{||\boldsymbol{h}_{S_0^C}||_1}{\sqrt{q}}+\frac{||\boldsymbol{h}_{S_0}||_1}{4\sqrt{q}}$$
$$\leq(\frac{1}{\sqrt{q}\bar{c}}+\frac{1}{4\sqrt{q}})||\boldsymbol{h}_{S_0}||_1\leq(\frac{1}{4}+\frac{1}{\bar{c}})||\boldsymbol{h}_{S_0}||_2.$$

And more details can be found in Cai et al. (2010).
By Taylor expansion of $L(\boldsymbol{\beta})$ around $\boldsymbol{\beta}^*$:

$$\begin{aligned}\frac{2}{n(n-1)}E\Big\{&\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)(\boldsymbol{\beta}^*-\boldsymbol{h})]_+-\\&\sum_{i=1}^{n}\sum_{j=i+1}^{n}(w_i-w_j)[1-(\boldsymbol{X}_i^T-\boldsymbol{X}_j^T)\boldsymbol{\beta}^*]_+\Big\}\\=&\frac{1}{2}\boldsymbol{h}^TH(\boldsymbol{\beta}^*)\boldsymbol{h}+o_p(||\boldsymbol{h}||_2^2)\geq\frac{1}{2}M_2||\boldsymbol{h}||_2^2+o_p(||\boldsymbol{h}||_2^2).\end{aligned}$$

Then we have

$$\frac{1}{2}M_2||\boldsymbol{h}||_2^2+o_p(||\boldsymbol{h}||_2^2)\leq\lambda\sqrt{q}||\boldsymbol{h}_{S_0}||_2+C_4q^2\sqrt{\frac{(\log p)^3}{n}}(\frac{5}{4}+\frac{1}{\bar{c}})||\boldsymbol{h}_{S_0}||_2.$$

On the other hand,

$$\begin{aligned}||\boldsymbol{h}||_2^2=&||\mathbf{h}_{S_0}||_2^2+\sum_{j\geq1}||\boldsymbol{h}_{S_j}||_2^2\leq||\boldsymbol{h}_{S_0}||_2^2+|h_q|\sum_{j\geq1}||\boldsymbol{h}_{S_j}||_1\\\leq&||\boldsymbol{h}_{S_0}||_2^2+\frac{1}{\bar{c}}||\boldsymbol{h}_{S_0}||_1|h_q|\leq(1+\frac{1}{\bar{c}})||\boldsymbol{h}_{S_0}||_2^2.\end{aligned}$$

Therefore,

$$\begin{aligned}&||\boldsymbol{h}_{S_0}||_2^2\leq||\boldsymbol{h}||_2^2\leq(1+\frac{1}{\bar{c}})||\boldsymbol{h}_{S_0}||_2^2,\\&o(||\boldsymbol{h}||_2^2)=o(||\boldsymbol{h}_{S_0}||_2^2).\end{aligned}$$

Hence

$$\begin{aligned}&\frac{1}{2}M_2||\boldsymbol{h}_{S_0}||_2+o_p(||\boldsymbol{h}_{S_0}||_2)\leq\lambda\sqrt{q}+C_4q^2\sqrt{\frac{(\log p)^3}{n}}(\frac{5}{4}+\frac{1}{\bar{c}}),\\&||\boldsymbol{h}||_2+o_p(||\boldsymbol{h}||_2)\leq\sqrt{1+\frac{1}{\bar{c}}}[\frac{2\lambda\sqrt{q}}{M_2}+\frac{2C_4}{M_2}q^2\sqrt{\frac{(\log p)^3}{n}}(\frac{5}{4}+\frac{1}{\bar{c}})].\end{aligned}$$

That is,

$$||\hat{\boldsymbol{\beta}}-\boldsymbol{\beta}^*||_2\leq\sqrt{1+\frac{1}{\bar{c}}}[\frac{2\lambda\sqrt{q}}{M_2}+\frac{2C_4}{M_2}q^2\sqrt{\frac{(\log p)^3}{n}}(\frac{5}{4}+\frac{1}{\bar{c}})]$$

with probability at least $1-3p^{-q(C_2^2-2)+1}$.■

Appendix B.

We now show that

$$\begin{aligned}&min\sum_{i\neq j}(w_i-w_j)I(\boldsymbol{\beta}^T\boldsymbol{X}_i<\boldsymbol{\beta}^T\boldsymbol{X}_j),\\&\text{subject to }||\boldsymbol{\beta}||=1.\end{aligned}$$

is equivalent to

$$\begin{aligned}&min\sum_{w_i>w_j}(w_i-w_j)I(\boldsymbol{\beta}^T\boldsymbol{X}_i<\boldsymbol{\beta}^T\boldsymbol{X}_j),\\&\text{subject to }||\boldsymbol{\beta}||=1.\end{aligned}$$

Suppose $\boldsymbol{\beta}^T\boldsymbol{X}_i\neq\boldsymbol{\beta}^T\boldsymbol{X}_j,\forall i,j$, we have

$$\begin{aligned}&\sum_{i\neq j}(w_i-w_j)I(\boldsymbol{\beta}^T\boldsymbol{X}_i<\boldsymbol{\beta}^T\boldsymbol{X}_j)\\&\sum_{w_i>w_j}(w_i-w_j)I(\boldsymbol{\beta}^T\boldsymbol{X}_i<\boldsymbol{\beta}^T\boldsymbol{X}_j)+\sum_{w_i>w_j}(w_j-w_i)I(\boldsymbol{\beta}^T\boldsymbol{X}_j<\boldsymbol{\beta}^T\boldsymbol{X}_i)\\&\sum_{w_i>w_j}(w_i-w_j)[I(\boldsymbol{\beta}^T\boldsymbol{X}_i-\boldsymbol{\beta}^T\boldsymbol{X}_j<0)-I(\boldsymbol{\beta}^T\boldsymbol{X}_i-\boldsymbol{\beta}^T\boldsymbol{X}_j>0)]\\&\sum_{w_i>w_j}(w_i-w_j)[I(\boldsymbol{\beta}^T\boldsymbol{X}_i-\boldsymbol{\beta}^T\boldsymbol{X}_j<0)-1+I(\boldsymbol{\beta}^T\boldsymbol{X}_i-\boldsymbol{\beta}^T\boldsymbol{X}_j<0)]\\&\sum_{w_i>w_j}(w_i-w_j)[2I(\boldsymbol{\beta}^T\boldsymbol{X}_i-\boldsymbol{\beta}^T\boldsymbol{X}_j<0)-1].\blacksquare\end{aligned}$$

Appendix C.

We now show that given $\boldsymbol{X}_i$, w_i is an unbiased estimator of $D(\boldsymbol{X}_i)$. Specifically,

$$\begin{aligned}&E\{\frac{[Y_i-\nu(\boldsymbol{X}_i)][A_i-\pi(\boldsymbol{X}_i)]}{\pi(\boldsymbol{X}_i)[1-\pi(\boldsymbol{X}_i)]}|\boldsymbol{X}_i\}\\=&E\left\{\frac{[Y_i-\nu(\boldsymbol{X}_i)][1-\pi(\boldsymbol{X}_i)]}{\pi(\boldsymbol{X}_i)[1-\pi(\boldsymbol{X}_i)]}|A_i=1,\boldsymbol{X}_i\right\}\pi(\boldsymbol{X}_i)\\+&E\left\{\frac{[Y_i-\nu(\boldsymbol{X}_i)][-\pi(\boldsymbol{X}_i)]}{\pi(\boldsymbol{X}_i)[1-\pi(\boldsymbol{X}_i)]}|A_i=0,\boldsymbol{X}_i\right\}[1-\pi(\boldsymbol{X}_i)]\\=&E[Y_i|A_i=1,\boldsymbol{X}_i]-E[Y_i|A_i=0,\boldsymbol{X}_i]=D(\boldsymbol{X}_i).\blacksquare\end{aligned}$$

Abstract

We propose a novel class of time-varying nonparanormal graphical models, which allows us to model high dimensional heavy-tailed systems and the evolution of their latent network structures. Under this model we develop statistical tests for presence of edges both locally at a fixed index value and globally over a range of values. The tests are developed for a high-dimensional regime, are robust to model selection mistakes and do not require commonly assumed minimum signal strength. The testing procedures are based on a high dimensional, debiasing-free moment estimator, which uses a novel kernel smoothed Kendall's tau correlation matrix as an input statistic. The estimator consistently estimates the latent inverse Pearson correlation matrix uniformly in both the index variable and kernel bandwidth. Its rate of convergence is shown to be minimax optimal. Our method is supported by thorough numerical simulations and an application to a neural imaging data set.

Keywords: graphical model selection, nonparanormal graph, time-varying network analysis, hypothesis test, regularized rank-based estimator

1. Introduction

We consider the problem of inferring time-varying undirected graphical models from high dimensional non-Gaussian distributions. Undirected graphical models have been widely used as a powerful tool for exploring the dependency relationships between variables. We are interested in graphical models which have non-static graphical structures and can handle heavy-tail distributions as well as data contaminated with outliers. To that end, we develop a class of time-varying nonparanormal models, which can be used to explore Markov dependencies of a random vector $\boldsymbol{X}$ given the index variable Z. Specifically, we assume the random variables $(\boldsymbol{X}, Z)$ follow the following joint distribution: the conditional distribution

of $\boldsymbol{X} \mid Z = z$ follows a nonparanormal distribution

$$\boldsymbol{X} \mid Z = z \sim \mathsf{NPN}_d(\mathbf{0}, \boldsymbol{\Sigma}(z), f) \tag{1}$$

where $f = \{f_1, \ldots, f_d\}$ is a set of d univariate, strictly increasing functions and Z is a random variable with a continuous density. A variable follows a nonparanormal distribution $\boldsymbol{Y} \sim \mathsf{NPN}_d(\boldsymbol{\mu}, \boldsymbol{\Sigma}, f)$ if $f(\boldsymbol{Y}) \sim N(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ (Liu et al., 2009). Graphical modeling with nonparanormal distribution is studied in Liu et al. (2009), Liu et al. (2012a) and Xue and Zou (2012), however, their graph structure is static. Time-varying graphical models are studied in Talih and Hengartner (2005), Xuan and Murphy (2007), Zhou et al. (2010), Kolar and Xing (2011), Kolar and Xing (2012), Yin et al. (2010), Kolar et al. (2010b), Ahmed and Xing (2009), Kolar et al. (2010a) and Kolar and Xing (2009). However, these papers assume that conditionally on the index, the distribution of $\boldsymbol{X}$ is parametric, which is not adequate for applications to heavy-tailed data sets in finance, neuroscience and genomics (Qiu et al., 2016). Moreover, inferential methods for the time-varying graphical models have not been developed so far.

Primary motivation for proposing the model in (1) and developing corresponding estimation and inferential procedures comes from an application in neuroscience. Graphical models are widely used to estimate and explore functional connectivity between different brain regions from functional magnetic resonance imaging (fMRI) data (Wang et al., 2010; Bullmore and Bassett, 2011; Smith et al., 2011). There is evidence that that the brain connectivity network evolves over time (Bartzokis et al., 2001; Gelfand et al., 2003) and current techniques are not adequate for capturing evolving nature of brain networks. For example, work of Kolar et al. (2010a) assumes that data are Gaussian, which is rarely satisfied in practice. Qiu et al. (2016) need replicated observations at each time point, which are not available in most of the time-varying fMRI data sets. Furthermore, current procedures are solely focused on estimation of networks, while the question of inference and quantification of uncertainty is left unanswered. We address these drawbacks in the current work.

The focus of the paper is on the inferential analysis about parameters in the model given in (1), as well as the Markov dependencies between observed variables. The inference procedures we develop are uniformly valid in a high-dimensional regime and robust to model selection mistakes. In particular, the inference does not depend on the oracle support recovery properties of the estimator. As a foundation for inference, we develop an estimation procedure for the high-dimensional latent time-varying inverse correlation matrix based on a novel kernel smoothed Kendall's tau statistic. The estimator is uniformly consistent in both the bandwidth and the index variable, and furthermore is optimal in a minimax sense. Obtaining rate of convergence for the estimator is technically challenging and requires development of new uniform bounds for the U-processes, careful characterization of the leading terms in the expansion of the estimator in the presence of high-dimensionality and approximation errors arising from the local approximation of nonlinear curves. The proof that the rate of convergence is optimal involves application of Le Cam's method on a carefully chosen function valued high dimensional matrices class. These technical details are novel and of independent interest, as discussed in Section 4.2.

We consider three types of hypothesis tests: (1) the edge presence test for whether there is an edge in the Markov graph at z_0, (2) the super graph test for whether the true graph is a subgraph of a fixed graph at z_0, and (3) the uniform edge presence test for whether

the true graph is a subgraph of a given graph over a range of index values. The first test was studied in the context of static Gaussian graphical models in Janková and van de Geer (2015, 2017) and Ren et al. (2015), however, their approach cannot handle time-varying models. The second test was considered in Wasserman et al. (2014), Yang et al. (2014b) and Gu et al. (2015) also in the context of static graphical models. Cai et al. (2013b) considered a statistical test for whether the correlation matrix is an identity, which is a special case of the super graph test. The third test is a generalization of the above two local tests to a global test over a range of index values, which allows for identifying whether certain connections in graphical models exist for a period of time. We illustrate the super graph test in an application to the ADHD-200 data set containing fMRI data from subjects with and without attention deficit hyperactive disorder (ADHD) (Biswal et al., 2010), which allows us to uncover how the brain networks change with age.

This paper makes two major contributions to the literature on statistical inference for graphical models. First, we develop a general inferential procedure for a wide family of high dimensional graphical model estimation methods. Many existing high dimensional inference methods are specifically designed for concrete estimators. For example, Zhang and Zhang (2013), van de Geer et al. (2014), Javanmard and Montanari (2014), and Ning and Liu (2017) design inference procedures for specific M-estimators, while Neykov et al. (2015) developed an inferential procedure for the method of moments estimators like Dantzig selector (Candés and Tao, 2007) and CLIME (Cai et al., 2011). Barber and Kolar (2018) design a procedure for constructing confidence intervals in high-dimensional elliptical copula models. In contrast to that, we propose a nonparametric score-type statistic, which uses any estimator of $\mathbf{\Sigma}(z)^{-1}$ with fast enough rate of convergence as an input. Therefore, our inference procedure does not depend on a particular estimate of $\mathbf{\Sigma}(z)^{-1}$ and can be applied to both M-estimators, like graphical Lasso, and method of moments estimators, like CLIME. Second, to the best of our knowledge, this paper considers for the first time presence of the edges test uniformly over the index z for high dimensional graphical models. Computing quantiles of the test statistic requires development a new Gaussian multiplier bootstrap procedure for a U-process.

1.1 Related Literature

High-dimensional Gaussian graphical models are studied in Meinshausen and Bühlmann (2006), Yuan and Lin (2007), Rothman et al. (2008), Friedman et al. (2008), d'Aspremont et al. (2008), Fan et al. (2009), Lam and Fan (2009), Yuan (2010), Cai et al. (2011), Liu and Wang (2017), and Zhao and Liu (2014), with an extension to covariate-adjusted graphical models given in Dondelinger et al. (2010), Li et al. (2012), Cai et al. (2013a), Chen et al. (2016), and Yin and Li (2013). Semiparametric extensions using copulas are developed in Liu et al. (2009), Liu et al. (2012a), Xue and Zou (2012), and Liu et al. (2012b), and extended for mixed data in Fan et al. (2015). Guo et al. (2011a), Guo et al. (2011b), Lee and Hastie (2015), Cheng et al. (2017), Yang et al. (2012), and Yang et al. (2014a) study the mixed exponential family graphical models where a node conditional distribution is a member of an exponential family distribution. Danaher et al. (2014), Qiu et al. (2016), Mohan et al. (2014) consider joint estimation of multiple graphical models.

All of the above mentioned work assumes that the graphical structure is static. However, in analysis of many complex systems, such an assumption is not valid. There are two major types of time-varying graphical model: directed and undirected. The directed time-varying graphical models are mainly studied in the context of autoregressive models with time-varying parameters (Punskaya et al., 2002; Fujita et al., 2007; Rao et al., 2007; Grzegorczyk and Husmeier, 2011; Song et al., 2009; Robinson and Hartemink, 2010; Jia and Huan, 2010; Lébre et al., 2010; Husmeier et al., 2010; Wang et al., 2011; Grzegorczyk and Husmeier, 2012; Dondelinger et al., 2013; Lébre et al., 2010). For the time-varying undirected graphical models, Zhou et al. (2010), Kolar and Xing (2011), Yin et al. (2010), Kolar et al. (2010b) and Kolar et al. (2010a) consider the kernel- smoothed type estimator for graphical models. Kolar and Xing (2012) assume the graphical model evolves in a piecewise-constant fashion and estimate it by the temporally smoothed ℓ_1 penalized regression. Talih and Hengartner (2005) and Xuan and Murphy (2007) consider a Bayesian framework to model the time-varying of graphs and estimate the graph by Markov chain Monte Carlo methods. All the above works show the statistical rates for graphical models for fixed time points. Our work contributes to this literature by studying the uniform properties of estimators and developing inferential procedures. For estimation, we prove a rate of convergence that is uniform over z and show it matches the minimax rate. Instead of the kernel smoothed sample covariance, we propose the kernel smoothed U-statistics as a robust estimator. For inference, we study the presence of edges for a range of index values instead of the local tests in the literature.

Our paper also contributes to the literature on high dimensional inference. Hypothesis testing and confidence intervals for the high dimensional M-estimators are studied in Zhang and Zhang (2013), van de Geer et al. (2014); Javanmard and Montanari (2014), Belloni et al. (2013), Belloni et al. (2016), Javanmard and Montanari (2014) and Meinshausen (2015). Lu et al. (2015) considered the confidence bands for the high dimensional nonparametric models. Neykov et al. (2015) proposed the inference for high dimensional method of moments estimators. Lee et al. (2016) and Tibshirani et al. (2016) consider the conditional inference based on post-selection methods. Our work considers a new inferential framework involving both discrete graph structures and the nonparametric index variable, which provides more flexibility in the modeling of modern data sets.

Finally, we develop novel probabilistic tools to study the high dimensional U-statistics. Classical analysis for fixed dimensional U-statistics is built on the Hoeffding decomposition (Hoeffding, 1948). Concentration inequalities for high dimensional U-statistics are studied in Giné et al. (2000) and Adamczak (2006). However, existing methods based on uniform entropy numbers are too loose to be applicable (Nolan and Pollard, 1987). We develop a new peeling method to control suprema of our kernel smoothed U-process uniformly over three aspects: dimension, index variable and bandwidth. The uniform consistency over the bandwidth shown in the paper also generalizes a data-driven bandwidth-tuning method to U-statistics from the kernel-type estimator considered in Einmahl and Mason (2005). This provides more flexibility in the tuning procedure of our method. Moreover, to study the limiting distribution of the U-statistics, we generalize the Gaussian multiplier bootstrap proposed in Chernozhukov et al. (2013) and Chernozhukov et al. (2014a) to nonparametric U-process by considering a new type of nonlinear Gaussian multiplier U-processes.

1.2 Notation

Let $[n]$ denote the set $\{1, \ldots, n\}$ and let $\mathbb{1}\{\cdot\}$ denote the indicator function. For a vector $a \in \mathbb{R}^d$, we let $\text{supp}(a) = \{j \,:\, a_j \neq 0\}$ be the support set (with an analogous definition for matrices $A \in \mathbb{R}^{n_1 \times n_2}$), $||a||_q$, $q \in [1, \infty)$, the ℓ_q-norm defined as $||a||_q = (\sum_{i\in[n]} |a_i|^q)^{1/q}$ with the usual extensions for $q \in \{0, \infty\}$, that is, $||\mathbf{a}||_0 = |\text{supp}(\mathbf{a})|$ and $||\mathbf{a}||_\infty = \max_{i\in[n]} |a_i|$. For a matrix $\mathbf{A} \in \mathbb{R}^{n_1 \times n_2}$, we use the notation $\text{vec}(A)$ to denote the vector in $\mathbb{R}^{n_1 n_2}$ formed by stacking the columns of $\mathbf{A}$. We write $\mathbf{A} = [\mathbf{A}_{jk}]$ if the (j,k)-th entry of $\mathbf{A}$ is $\mathbf{A}_{jk}$. Let $\boldsymbol{A}_{\setminus j,k}$ be the sub-vector of the k-th column $\mathbf{A}$ with $\mathbf{A}_{jk}$ removed. We denote the Frobenius norm of $\mathbf{A}$ by $||\mathbf{A}||_F^2 = \sum_{i\in[n_1],j\in[n_2]} \mathbf{A}_{ij}^2$, the max-norm $\|\mathbf{A}\|_{\max} = \max_{i\in[n_1],j\in[n_2]} |\mathbf{A}_{ij}|$, the ℓ_1-norm $\|\mathbf{A}\|_1 = \max_{j\in[n_2]} \sum_{i\in[n_1]} |\mathbf{A}_{ij}|$, and the operator norm $\|\mathbf{A}\|_2 = \sup_{\|\mathbf{v}\|_2=1} \|\mathbf{A}\mathbf{v}\|_2$. The Hadamard product of two matrices is the matrix $\mathbf{A} \circ \mathbf{B}$ with elements $(\mathbf{A} \circ \mathbf{B})_{jk} = \mathbf{A}_{jk} \cdot \mathbf{B}_{jk}$. Given two functions f and g, we denote their convolution as $(f * g)(t) = \int f(t-x)g(x)dx$. For $1 \leq p < \infty$, let $\|f\|_p = (\int f^p)^{1/p}$ denote the L^p-norm of f and $\|f\|_\infty = \sup_x |f(x)|$. The total variation of f is defined as $\text{TV}(f) = \|f'\|_1$. For two sequences of numbers $\{a_n\}_{n=1}^\infty$ and $\{b_n\}_{n=1}^\infty$, we use $a_n = O(b_n)$ or $a_n \lesssim b_n$ to denote that $a_n \leq C b_n$ for some finite positive constant C, and for all n large enough. If $a_n = O(b_n)$ and $b_n = O(a_n)$, we use the notation $a_n \asymp b_n$. The notation $a_n = o(b_n)$ is used to denote that $a_n/b_n \to 0$ as n goes infinity. We also define $a \vee b = \max(a, b)$ and $a \wedge b = \min(a, b)$ for any two scalars a and b. We use $\xrightarrow{P}$ for convergence in probability and $\rightsquigarrow$ for convergence in distribution. Throughout the paper, we let c, C be two generic absolute constants, whose values will vary at different locations.

We use the notation $\mathbb{E}_n[\cdot]$ to denote the empirical average, $\mathbb{E}_n[f] = n^{-1} \sum_{i\in[n]} f(X_i)$. We also use $\mathbb{G}_n[f] = \sqrt{n}\left(\mathbb{E}_n[f(X_i)] - \mathbb{E}[f(X_i)]\right) = n^{-1/2} \sum_{i\in[n]} \left(f(X_i) - \mathbb{E}[f(X_i)]\right)$. For a bivariate function $H(x, x')$, we define the U-statistic $\mathbb{U}_n[H] = [n(n-1)]^{-1} \sum_{i\neq i'} H(X_i, X_{i'})$.

Appendix J collects all the notation in a table format with reference to where they appear first.

2. Preliminaries

We start by providing background on the nonparanormal distribution and discuss how it relates to the time-varying nonparanormal graphical model in (1). The nonparanormal distribution was introduced in Liu et al. (2009). A random variable $\boldsymbol{X} = (X_1, \ldots, X_d)^T$ is said to follow a nonparanormal distribution if there exists a set of monotone univariate functions $f = \{f_1, \ldots, f_d\}$ such that $f(\boldsymbol{X}) := (f_1(X_1), \ldots, f_d(X_d))^T \sim N(\mathbf{0}, \boldsymbol{\Sigma})$, where $\boldsymbol{\Sigma}$ is a latent correlation matrix satisfying $\text{diag}(\boldsymbol{\Sigma}) = 1$. We denote $\boldsymbol{X} \sim \mathsf{NPN}_d(\mathbf{0}, \boldsymbol{\Sigma}, f)$.

Given n independent copies of $\boldsymbol{X} \sim \mathsf{NPN}_d(\mathbf{0}, \boldsymbol{\Sigma}, f)$, Liu et al. (2012a) study how to estimate the latent correlation matrix $\boldsymbol{\Sigma}$. The key idea lies in relating the Kendall's tau correlation matrix with the Pearson correlation. The Kendall's tau correlation between X_j and X_k, two coordinates of $\boldsymbol{X}$, is defined as

$$\tau_{jk} = \mathbb{E}\left[\text{sign}\left((X_j - \widetilde{X}_j)(X_k - \widetilde{X}_k)\right)\right],$$

where $(\widetilde{X}_j, \widetilde{X}_k)$ is an independent copy of (X_j, X_k). It can be related to the latent correlation matrix using the fact that $\tau_{jk} = (2/\pi) \arcsin\left(\boldsymbol{\Sigma}_{jk}\right)$ when $\boldsymbol{X}$ follows a nonparanormal distribution (Fang et al., 1990). The inverse covariance matrix $\boldsymbol{\Omega} = \boldsymbol{\Sigma}^{-1}$ encodes the graph

structure of a nonparanormal distribution (Liu et al., 2009). Specifically $\boldsymbol{\Omega}_{jk} = 0$ if and only if X_j is independent of X_k conditionally on $\boldsymbol{X}_{\setminus\{j,k\}}$.

The above observations lead naturally to the following estimation procedure for $\boldsymbol{\Omega}$. We estimate the Kendall's tau correlation matrix $\widehat{\mathbf{T}} = [\widehat{\tau}_{jk}] \in \mathbb{R}^{d\times d}$ elementwise using the following U-statistic

$$\widehat{\tau}_{jk} = \frac{2}{n(n-1)} \sum_{1\leq i<i'\leq n} \text{sign}(X_{ij} - X_{i'j})\,\text{sign}(X_{ik} - X_{i'k}).$$

An estimate of the latent correlation matrix is given as $\widehat{\boldsymbol{\Sigma}} = \sin\left(\pi\widehat{\mathbf{T}}/2\right)$, where $\sin(\cdot)$ is applied elementwise. Finally, the estimate of the latent correlation matrix $\widehat{\boldsymbol{\Sigma}}$ is used as a plug-in statistic in the CLIME estimator (Cai et al., 2011), or calibrated CLIME estimator (Zhao and Liu, 2014), to obtain the inverse covariance estimator $\widehat{\boldsymbol{\Omega}}$.

The CLIME estimator solves the following optimization program

$$\widehat{\boldsymbol{\Omega}}_j^{\text{CLIME}} = \underset{\boldsymbol{\beta}\in\mathbb{R}^d}{\text{argmin}} \|\boldsymbol{\beta}\|_1 \qquad \text{subject to} \qquad \|\widehat{\boldsymbol{\Sigma}}\boldsymbol{\beta} - \mathbf{e}_j\|_\infty \leq \lambda, \tag{2}$$

where $\mathbf{e}_j$ is the j-th canonical basis in $\mathbb{R}^d$ and the penalty parameter λ that controls the sparsity of the resulting estimator is commonly chosen as $\lambda \asymp \|\boldsymbol{\Omega}\|_1 \sqrt{\log d/n}$ (Cai et al., 2011). Note that the tuning parameter depends on the unknown $\boldsymbol{\Omega}$ through $\|\boldsymbol{\Omega}\|_1$, which makes practical selection of λ difficult. The calibrated CLIME is a tuning-insensitive estimator, which alleviates this problem. The calibrated CLIME estimator solves

$$\left(\widehat{\boldsymbol{\Omega}}_j^{\text{CCLIME}}, \widehat{\kappa}_j\right) = \underset{\boldsymbol{\beta}\in\mathbb{R}^d, \kappa\in\mathbb{R}}{\text{argmin}} \|\boldsymbol{\beta}\|_1 + \gamma\kappa \qquad \text{subject to} \qquad \|\widehat{\boldsymbol{\Sigma}}\boldsymbol{\beta} - \mathbf{e}_j\|_\infty \leq \lambda\kappa,\ \|\boldsymbol{\beta}\|_1 \leq \kappa, \tag{3}$$

where γ is any constant in $(0, 1)$ and the tuning parameter can be chosen as $\lambda = C\sqrt{\log d/n}$ with C being a universal constant independent of the problem parameters. In what follows, we will adapt the calibrated clime to estimation of the parameters of the model in (1).

2.1 Time-Varying Nonparanormal Graphical Model

The time-varying nonparanormal graphical model in (1) is an extension of the nonparanormal distribution. For every fixed value of the index variable $Z = z$, we have a static nonparanormal distribution $\boldsymbol{X} \mid Z = z \sim \mathsf{NPN}_d(\mathbf{0}, \boldsymbol{\Sigma}(z), f)$ that can be easily interpreted. However, as the index variable changes, the conditional distribution of $\boldsymbol{X} \mid Z$ can change in an unspecified way. In this sense, time-varying nonparanormal graphical models extend nonparanormal graphical models in the same way varying coefficient models extend linear regression models.

Let $Y = (\boldsymbol{X}, Z)$ denote a random pair distributed according to the time-varying nonparanormal distribution. Specifically $Z \sim f_Z(z)$ with $f_Z(\cdot)$ being a continuous density function supported on $[0, 1]$ and $\boldsymbol{X} \mid Z = z \sim \mathsf{NPN}_d(\mathbf{0}, \boldsymbol{\Sigma}(z), f)$ for all $z \in [0, 1]$. For any fixed $z \in [0, 1]$, we denote the inverse of the correlation matrix as $\boldsymbol{\Omega}(z) = \boldsymbol{\Sigma}^{-1}(z)$. Both $f_Z(z)$ and each entry of $\boldsymbol{\Omega}(z)$ are second-order differentiable (we will formalize assumptions in Section 4). We denote the undirected graph encoding the conditional independence of $\boldsymbol{X} \mid Z = z$ as $G^*(z) = (V, E^*(z))$, with $(j, k) \in E^*(z)$ when $\boldsymbol{\Omega}_{jk}(z) \neq 0$. As in the static

case, we relate the Kendall's tau correlation matrix with the latent correlation matrix. Let $\mathbf{T}(z) = [\tau_{jk}(z)]_{jk}$ be the Kendall's tau correlation matrix corresponding to $\boldsymbol{X} \mid Z = z$ with elements defined as

$$\tau_{jk}(z) = \mathbb{E}\left[\operatorname{sign}\left((X_j - \widetilde{X}_j)(X_k - \widetilde{X}_k)\right) \mid Z = z\right],$$

where $\widetilde{\boldsymbol{X}}$ is an independent copy of $\boldsymbol{X}$ conditionally on $Z = z$. Given n independent copies of $Y = (\boldsymbol{X}, Z)$, $\{Y_i = (\boldsymbol{X}_i, Z_i)\}_{i\in[n]}$, we estimate an element of the Kendall's tau correlation matrix using the following kernel estimator

$$\widehat{\tau}_{jk}(z) = \frac{n^{-2}\sum_{i<i'}\omega_z(Z_i, Z_{i'})\operatorname{sign}(X_{ij} - X_{i'j})\operatorname{sign}(X_{ik} - X_{i'k})}{n^{-2}\sum_{i<i'}\omega_z(Z_i, Z_{i'})}, \text{ where} \tag{4}$$

$$\omega_z(Z_i, Z_{i'}) = K_h(Z_i - z)\, K_h(Z_{i'} - z) \tag{5}$$

with the kernel function $K(\cdot)$ being a symmetric density function, $K_h(\cdot) = h^{-1}K(\cdot/h)$ and $h > 0$ is the bandwidth parameter. We can choose the kernel function as long as it satisfies some regularity conditions, which will be specified in Assumption 4.3. The kernel U-statistic in (4) is a generalization of classical kernel regression (Opsomer and Ruppert, 1997; Fan and Jiang, 2005). For example, given i.i.d. samples $\{Y_i, Z_i\}_{i=1}^n$ from the model $Y = f(Z) + \epsilon$, the Nadaraya-Watson estimator (Bierens, 1988) is

$$\widehat{f}(z) = \frac{n^{-1}\sum_{i=1}^n K_h(Z_i - z)Y_i}{n^{-1}\sum_{i=1}^n K_h(Z_i - z)}, \tag{6}$$

where we take the weighted average of Y_i's and the weight $K_h(Z_i - z)$ is related to the distance between Z_i and z. In order to normalize the weights, we add the denominator in (6), which is the kernel density estimator for the density of Z. Comparing (4) with the Nadaraya-Watson estimator, since the kernel U-statistic involves both $\boldsymbol{X}_i$ and $\boldsymbol{X}_{i'}$, we need to multiply the weights as (5) to ensure that both Z_i and $Z_{i'}$ are in the neighborhood of z. We also normalize the weights by dividing the denominator $n^{-2}\sum_{i<i'}\omega_z(Z_i, Z_{i'})$ which is the estimator of $f_Z^2(z)$. The denominator $n^{-2}\sum_{i<i'}\omega_z(Z_i, Z_{i'})$ is also related to the density $f_Z(z)$. In fact, it is the estimator of $f_Z^2(z)$. Intuitively, we can see it from

$$\mathbb{E}\Big[\frac{1}{n^2}\sum_{i<i'}\omega_z(Z_i, Z_{i'})\Big] = \iint K(t_1)K(t_2)f_Z(z + t_1h)f_Z(z + t_2h)dt_1dt_2 = f_Z^2(z) + O(h^2).$$

Lemma 14 provides the details and is given in the supplementary material.

Based on the above estimator, we obtain the corresponding latent correlation matrix for any index value $z \in (0, 1)$ as

$$\widehat{\boldsymbol{\Sigma}}(z) = \sin\left(\frac{\pi}{2}\widehat{\mathbf{T}}(z)\right), \tag{7}$$

where $\widehat{\mathbf{T}}(z) = [\widehat{\tau}_{jk}(z)] \in \mathbb{R}^{d\times d}$.

Finally, similar to the static case, we can plug $\widehat{\boldsymbol{\Sigma}}(z)$ into a procedure that gives an estimate of the inverse correlation matrix, such as the CLIME in (2) or calibrated CLIME in (3). Due to practical advantages of the calibrated CLIME, we will use it for our simulations. However, at this point we note that the inferential framework only requires the estimator of the inverse correlation matrix to converge at a fast enough rate. Therefore, in what follows, we denote $\widehat{\boldsymbol{\Omega}}(z)$ a generic estimator of $\boldsymbol{\Omega}(z)$. Concrete statistical properties required of the calibrated CLIME will be discussed in details in Section 4.2.

3. Inferential Methods

In this section, we develop a framework for statistical inference about the parameters in a time-varying nonparanormal graphical model. We focus on the following three testing problems:

- **Edge presence test:** $H_0 : \boldsymbol{\Omega}_{jk}(z_0) = 0$ for a fixed $z_0 \in (0, 1)$ and $j, k \in [d]$;
- **Super-graph test:** $H_0 : G^*(z_0) \subset G$ for a fixed $z_0 \in (0, 1)$ and a fixed graph G;
- **Uniform edge presence test:** $H_0 : G^*(z) \subset G$ for all $z \in [z_L, z_U] \subset (0, 1)$ and a fixed graph G.

For all the testing problems, the alternative hypotheses is the negation of the null. The edge presence test is concerned with a local hypothesis that X_j and X_k are conditionally independent given $\boldsymbol{X}_{\setminus\{j,k\}}$ for a particular value of the index z_0. Equivalently, under the null hypothesis of the edge presence test, the nodes j and k are not connected at a particular index value z_0. The null hypothesis under the super-graph test postulates that the true graph is a subgraph of a given graph G for $Z = z_0$. It can also be interpreted as multiple-edge presence tests, since

$$H_0 : \boldsymbol{\Omega}_{jk}(z_0) = 0, \qquad \text{for all } (j, k) \in E^c, \tag{8}$$

where E is the edge set of the graph G. The null hypothesis under the uniform edge presence test postulates that the true graph is a subgraph of G for all index values in the range $[z_L, z_U]$. It is a generalization of the first two local tests to a global test over a range of index values. Similar to the super-graph test, this hypothesis is equivalent to the following

$$H_0 : \sup_{z\in[z_L, z_U]} |\boldsymbol{\Omega}_{jk}(z)| = 0, \qquad \text{for all } (j, k) \in E^c.$$

If the graph G consists of the edge set $E = \{(a, b) \in V \times V \mid (a, b) \neq (j, k)\}$, the uniform edge presence test becomes a uniform single-edge test $H_0 : \sup_{z\in[z_L, z_U]} |\boldsymbol{\Omega}_{jk}(z)| = 0$.

Next, we provide details on how to construct tests for the above three hypothesis.

3.1 Edge Presence Testing

We consider the hypothesis $H_0 : \boldsymbol{\Omega}_{jk}(z_0) = 0$, for a fixed $z_0 \in (0, 1)$ and $j, k \in [d]$. In order to construct a test for this hypothesis, we introduce the score function

$$\widehat{S}_{z|(j,k)}(\boldsymbol{\beta}) = \widehat{\boldsymbol{\Omega}}_j^T(z)\big(\widehat{\boldsymbol{\Sigma}}(z)\boldsymbol{\beta} - \mathbf{e}_k\big). \tag{9}$$

The argument $\boldsymbol{\beta}$ of the score function corresponds to the k-th column of $\boldsymbol{\Omega}(z)$. Our test is based on the score function evaluated at $\widehat{\boldsymbol{\Omega}}_{k\setminus j}$ which is an estimator of $\boldsymbol{\Omega}_k(z)$ under the null hypothesis, defined as

$$\widehat{\boldsymbol{\Omega}}_{k\setminus j}(z) = \big(\widehat{\boldsymbol{\Omega}}_{1k}(z), \ldots, \widehat{\boldsymbol{\Omega}}_{(j-1)k}(z), 0, \widehat{\boldsymbol{\Omega}}_{(j+1)k}(z), \ldots, \widehat{\boldsymbol{\Omega}}_{dk}(z)\big)^T \in \mathbb{R}^d,$$

where $\widehat{\boldsymbol{\Omega}}(z)$ is an estimator of $\boldsymbol{\Omega}(z)$. That is, we use $\widehat{S}_{z|(j,k)}\big(\widehat{\boldsymbol{\Omega}}_{k\setminus j}(z)\big)$ as the score statistic. We establish statistical properties of this statistic later. We first develop intuition for

why $\widehat{S}_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\big)$ is a good testing statistic for $H_0 : \mathbf{\Omega}_{jk}(z_0) = 0$. If we replace $\widehat{\mathbf{\Omega}}$ and $\widehat{\mathbf{\Sigma}}$ by the truth $\mathbf{\Omega}$ and $\mathbf{\Sigma}$ in (9), we can find the score statistic $\widehat{S}_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\big) \approx \mathbf{\Omega}_j^T(z)\big(\mathbf{\Sigma}(z)\mathbf{\Omega}_{k\backslash j}(z) - \mathbf{e}_k\big) = \mathbf{\Omega}_{jk}(z)$. Therefore, the score statistic is close to zero under the null, and $\widehat{S}_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z_0)\big) \approx \widehat{\mathbf{\Omega}}_{jk}(z_0)$ under the alternative. In specific, under H_0, the testing statistic is close to

$$\widehat{S}_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}\big) \approx \mathbf{\Omega}_j^T(z)\big(\widehat{\mathbf{\Sigma}}(z) - \mathbf{\Sigma}(z)\big)\mathbf{\Omega}_k(z) \approx \mathbf{\Omega}_j^T(z)\big[\dot{\mathbf{\Sigma}}(z) \circ \big(\widehat{\mathbf{T}}(z) - \mathbf{T}(z)\big)\big]\mathbf{\Omega}_k(z), \quad (10)$$

where $\dot{\mathbf{\Sigma}}_{jk}(z) = (\pi/2)\cos\big((\pi/2)\tau_{jk}(z)\big)$ is the derivative of $\mathbf{\Sigma}_{jk}(\cdot)$ and "$\approx$" denotes equality up to a smaller order term. The first approximation in (10) is due to replacing $\widehat{\mathbf{\Omega}}$ with the truth and the second approximation is due to the Taylor expansion. A rigorous derivation of this argument can be found in Appendix B.1. We note that the right-hand side of (10) is a linear function of $\widehat{\mathbf{T}}(z)$, which is a U-statistic. By applying the central limit theorem for U-statistics, we will show the asymptotic normality of $\widehat{S}_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}\big)$. See Theorem 1 for details.

Under the null, we have that

$$\sqrt{nh}\cdot\sigma_{jk}^{-1}(z_0)\widehat{S}_{z_0|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z_0)\big) \rightsquigarrow N(0,1),$$

where $\sigma_{jk}^2(z_0) = f_Z^{-4}(z_0)\mathrm{Var}(\mathbf{\Omega}_j^S(z_0)\mathbf{\Theta}_{z_0}\mathbf{\Omega}_k(z_0))$, and $\mathbf{\Theta}_z$ is a random matrix with elements

$$(\mathbf{\Theta}_z)_{jk} = \pi\cos\big((\pi/2)\tau_{jk}(z)\big)\tau_{jk}^{(1)}(Y), \quad \text{where} \quad (11)$$

$$\tau_{jk}^{(1)}(\boldsymbol{x}, z) = \sqrt{h}\cdot\mathbb{E}\left[K_h\left(z - z_0\right)K_h\left(Z - z_0\right)\left(\mathrm{sign}(X_j - x_j)\,\mathrm{sign}(X_k - x_k) - \tau_{jk}(z_0)\right)\right], \quad (12)$$

where the expectation is taken for Z and $\boldsymbol{X}$. For simplicity, we denote $y = (\boldsymbol{x}^T, z)^T$ and write $\tau_{jk}^{(1)}(y) := \tau_{jk}^{(1)}(\boldsymbol{x}, z)$. The form of the asymptotic variance comes from the Hoeffding decomposition of the U-statistics in (4), with $\tau_{jk}^{(1)}$ being the leading term of the decomposition. Technical details will be provided in Section 4.1 and Section B.1. The score statistic is a generalization of Rao's score tests in fixed dimensional parametric models. We can apply a one-step debiased estimator of $\mathbf{\Omega}_{jk}(z)$ from the score statistic $\widehat{S}_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\big)$ following the procedure similar to (Ning and Liu, 2017). They show that the one-step estimation procedure is asymptotically equivalent to the score statistic and we choose to use score statistic in this paper. Janková and van de Geer (2017) considered a similar debiasing procedure specific for the nodewise regression estimator. On the other hand, we will show in Theorem 1 that the score statistic $\widehat{S}_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\big)$ can be applied to any estimator $\widehat{\mathbf{\Omega}}$ has sharp enough statistical rate.

In order to use the score function as a test statistic, we need to estimate its asymptotic variance $\sigma_{jk}^2(z_0)$. For any $1 \le s \le n$ and $1 \le j, k \le d$, let

$$q_{s,jk}(z) = \frac{\sqrt{h}}{n-1}\sum_{s'\neq s}\left[\omega_z(Z_s, Z_{s'})\left(\mathrm{sign}\left((X_{sj} - X_{s'j})(X_{sk} - X_{s'k})\right) - \widehat{\tau}_{jk}(z)\right)\right], \quad (13)$$

$$\widehat{\mathbf{\Theta}}_{jk}^{(s)}(z) = \pi\cos\left((\pi/2)\widehat{\tau}_{jk}(z)\right)q_{s,jk}(z).$$

With this notation, the leave-one-out Jackknife estimator for $\sigma_{jk}^2(z_0)$ is given as

$$\widehat{\sigma}_{jk}^2(z_0) = [\mathbb{U}_n(\omega_{z_0})]^{-2}\cdot\frac{1}{n}\sum_{s=1}^{n}\left(\widehat{\mathbf{\Omega}}_j^S(z_0)\widehat{\mathbf{\Theta}}^{(s)}(z_0)\widehat{\mathbf{\Omega}}_k(z_0)\right)^2, \quad (14)$$

where the matrix $\widehat{\mathbf{\Theta}}^{(s)}(z) = [\widehat{\mathbf{\Theta}}_{jk}^{(s)}(z)]$. As we have remarked in Section 2.1, $\widehat{\sigma}_{jk}^2(z_0)$ is an estimator for $f_Z^2(z)$. We divide $[\mathbb{U}_n(\omega_{z_0})]^{-2}$ in (14) in order to normalized the weights $\omega_z(Z_s, Z_{s'})$ in the U-statistics $q_{s,jk}(z)$ defined in (13). The Jackknife estimator is widely used when estimating the variance of a U-statistics, which is not an average of independent random variables. The leave-one-out statistic $q_{s,jk}(z)$ in (13) is estimates the expectation in (12) by leaving Y_s out of the summation in $q_{s,jk}(z)$.

Finally, a level α test for $H_0 : \mathbf{\Omega}_{jk}(z_0) = 0$ is given as

$$\psi_{z_0|(j,k)}(\alpha) = \begin{cases} 1 & \text{if } \sqrt{nh}\cdot\left|\widehat{S}_{z_0|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z_0)\big)/\widehat{\sigma}_{jk}(z_0)\right| > \Phi^{-1}(1-\alpha/2); \\ 0 & \text{if } \sqrt{nh}\cdot\left|\widehat{S}_{z_0|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z_0)\big)/\widehat{\sigma}_{jk}(z_0)\right| \le \Phi^{-1}(1-\alpha/2), \end{cases}$$

where $\Phi(\cdot)$ is the cumulative distribution function of a standard normal distribution. The single-edge presence test is a cornerstone of more general hypothesis tests described in the next two sections. The properties of the test are given in Theorem 1.

3.2 Super-Graph Testing

In this section, we discuss super-graph testing. Recall that for a fixed z_0 and a predetermined graph $G = (V, E)$, the null hypothesis is

$$H_0 : G^*(z_0) \subset G. \quad (15)$$

From (8), we have that the super-graph test can be seen as a multiple test for presence of several edges. Therefore, we propose the following testing statistic based on the score function in (9):

$$S(z_0) = \sqrt{nh}\cdot\mathbb{U}_n(\omega_{z_0})\max_{(j,k)\in E^c}\widehat{S}_{z_0|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z_0)\big). \quad (16)$$

In order to estimate the quantile of $S(z_0)$, we develop a novel Gaussian multiplier bootstrap for U-statistics. Let $\{\xi_i\}_{i\in[n]}$ be n independent copies of $N(0,1)$. Let $\widehat{\mathbf{T}}^B(z) = \big[\widehat{\tau}_{jk}^B(z)\big]$ where

$$\widehat{\tau}_{jk}^B(z) = \frac{\sum_{i\neq i'}K_h\left(Z_i - z\right)K_h\left(Z_{i'} - z\right)\mathrm{sign}\left((X_{ij} - X_{i'j})(X_{ik} - X_{i'k})\right)(\xi_i + \xi_{i'})}{\sum_{i\neq i'}K_h\left(Z_i - z\right)K_h\left(Z_{i'} - z\right)(\xi_i + \xi_{i'})}, \quad (17)$$

$$\widehat{\mathbf{\Sigma}}^B(z) = \sin\left(\frac{\pi}{2}\widehat{\mathbf{T}}^B(z)\right). \quad (18)$$

The Gaussian multiplier bootstrap statistic in (19) is motivated by the method developed in Chernozhukov et al. (2013), who proposed a bootstrap procedure to estimate a quantile of the supremum of high dimensional empirical processes. Their method, however, cannot be directly applied to our kernel Kendall's tau estimator in (4), which is a ratio of two

U-statistics. If we compare (17) with (4), we add $\xi_i + \xi_{i'}$ into the bootstrap estimator in order to simulate the distribution of $\widehat{\tau}_{jk}(z)$ in (4).

The bootstrap estimator of the test statistic $S(z_0)$ in (16) is

$$S^B(z_0) = \sqrt{nh} \cdot \mathbb{U}_n[\omega^B_{z_0}] \max_{(j,k)\in E^c} \widehat{\mathbf{\Omega}}^S_j(z_0)\big(\widehat{\mathbf{\Sigma}}^B(z_0)\widehat{\mathbf{\Omega}}_{k\backslash j} - \mathbf{e}_k^T\big), \text{ where} \tag{19}$$

$$\mathbb{U}_n[\omega^B_{z_0}] = \frac{2}{n(n-1)} \sum_{i\neq i'} K_h\left(Z_i - z_0\right) K_h\left(Z_{i'} - z_0\right)(\xi_i + \xi_{i'}). \tag{20}$$

Here we multiply $\mathbb{U}_n[\omega^B_{z_0}]$ in (19) in order to eliminate the denominator in (17) such that the leading term of the bootstrap statistic $S^B(z_0)$ is a Gaussian multiplier bootstrap U-statistic. The correlation estimator in (7) has an additional sin transform. Therefore, a new nonlinear type of multiplier bootstraps in (17) and (19) are introduced to overcome these problems and novel technical tools are then developed to study statistical properties. See Theorem 3 for the statement of statistical properties.

Denote the conditional $(1-\alpha)$-quantile of $S^B(z_0)$ given $\{Y_i\}_{i=1}^n$ as $\widehat{c}_T(1-\alpha, \{Y_i\}_{i=1}^n)$. The level-$\alpha$ super-graph test is constructed as

$$\psi_{z_0|G}(\alpha) = \begin{cases} 1 & \text{if } S(z_0) > \widehat{c}_T(1-\alpha, \{Y_i\}_{i=1}^n); \\ 0 & \text{if } S(z_0) \leq \widehat{c}_T(1-\alpha, \{Y_i\}_{i=1}^n). \end{cases} \tag{21}$$

Note that the quantile $\widehat{c}_T(1-\alpha, \{Y_i\}_{i=1}^n)$ can be estimated by a Monte-Carlo method.

An alternative approach for the super-graph test in (15) is the multiple hypothesis testing. We can apply the Holm's multiple testing procedure (Holm, 1979) to control the family-wise error for the hypotheses set $\{H_{0,(jk)}\}_{(j,k)\in E^c}$ where $H_{0,(jk)} : \mathbf{\Omega}_{jk}(z_0) = 0$ and $G^*(z_0) \subset G = (V, E)$. However, it is not straightforward to obtain the nominal probability for the family-wise error in Holm's method. Moreover, we will show in Theorem 3 that our testing procedure is nominal.

3.3 Uniform Edge Presence Testing

In this section, we develop the uniform presence test for which the null hypothesis is given as

$$H_0 : G^*(z) \subset G \text{ for all } z \in [z_L, z_U].$$

This test is a generalization of the edge presence test to the uniform version over both edges and index. We again use the score function in (9) to construct the test statistic

$$W_G = \sqrt{nh} \sup_{z\in[z_L,z_U]} \max_{(j,k)\in E^c} \mathbb{U}_n[\omega_z]\widehat{S}_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\big) \tag{22}$$

and estimate a quantile of W_G by developing a Gaussian multiplier bootstrap. Let

$$W^B_G = \sqrt{nh} \sup_{z\in[z_L,z_U]} \max_{(j,k)\in E^c} \mathbb{U}_n[\omega^B_z] \cdot \widehat{\mathbf{\Omega}}^T_j(z)\big(\widehat{\mathbf{\Sigma}}^B(z)\widehat{\mathbf{\Omega}}_{k\backslash j}(z) - \mathbf{e}_k^T\big), \tag{23}$$

where $\widehat{\mathbf{\Sigma}}^B(z)$ is defined in (18). Let $\widehat{c}_W(1-\alpha, \{Y_i\}_{i=1}^n)$ denote the conditional $(1-\alpha)$-quantile of W^B_G given $\{Y_i\}_{i=1}^n$. Similar to (21), the level α uniform edge presence test is constructed as

$$\psi_G(\alpha) = \begin{cases} 1 & \text{if } W_G > \widehat{c}_W(1-\alpha, \{Y_i\}_{i=1}^n); \\ 0 & \text{if } W_G \leq \widehat{c}_W(1-\alpha, \{Y_i\}_{i=1}^n). \end{cases} \tag{24}$$

Theorem 4 provides statistical properties of the test. The statistics W_G in (22) and W^B_G in (23) involve taking supreme over $z \in [z_L, z_U]$. In practice, we approximate the suprema by evenly dividing $[z_L, z_U]$ into discrete grids and taking the maximum of the statistic over these discrete values in $[z_L, z_U]$.

4. Theoretical Properties

In this section, we establish the validity of tests proposed in the previous sections. Validity of tests rely on existence of estimators for the latent inverse correlation matrix with fast enough convergence. We show that the calibrated CLIME satisfy the testing requirements and, in addition, show that it achieves the minimax rate of convergence for a large class of models.

To facilitate the argument, we need the regularity and smoothness of the density function of Z and the time-varying correlation matrix $\mathbf{\Sigma}(z)$. Let us first introduce the Hölder class $\mathcal{H}(\gamma, L)$ of smooth functions. The Hölder class $\mathcal{H}(\gamma, L)$ on $(0,1)$ is the set of $\ell = \lfloor\gamma\rfloor$ times differentiable functions $g : \mathcal{X} \mapsto \mathbb{R}$ whose derivative $g^{(\ell)}$ satisfies

$$|g^{(\ell)}(x) - g^{(\ell)}(y)| \leq L|x-y|^{\gamma-\ell}, \quad \text{for any } x, y \in \mathcal{X}$$

and $\lfloor\gamma\rfloor$ denotes the largest integer smaller than γ. In this paper, we need some regularity conditions for the functions in our model.

Assumption 4.1 (Density function of Z) *There exist constants $0 < \underline{f}_Z < \bar{f}_Z < \infty$ such that the marginal density f_Z of the index variable Z has its image in $[\underline{f}_Z, \bar{f}_Z]$ and $f_Z \in \mathcal{H}(2, \bar{f}_Z)$.*

Assumption 4.2 (Regularization of $\mathbf{\Sigma}_{jk}(\cdot)$) *The correlations $\mathbf{\Sigma}_{jk}(\cdot) \in \mathcal{H}(2, M_\sigma)$ for some constant $M_\sigma < \infty$ given any $1 \leq j, k \leq d$.*

The above two assumptions are standard assumptions on the marginal distribution of Z (Pagan and Ullah, 1999) and time-varying graphical models (see, for example, Kolar et al., 2010a).

Assumption 4.3 (Kernel function) *Through this paper, we assume the kernel function K, used in (4), is a symmetric density function supported on $[-1, 1]$ with bounded variation, i.e., $||K||_\infty \vee \mathrm{TV}(K) < \infty$,*

$$\int_{-1}^{1} K(u)du = 1 \text{ and } \int_{-1}^{1} uK(u)du = 0.$$

These properties are also required in Zhou et al. (2010). Many widely used kernels, including the uniform kernel $K(u) = 0.5\mathbb{1}(|u| < 1)$, the triangular kernel $K(u) = (1-|u|)\mathbb{1}(|u| < 1)$, and the Epanechnikov kernel $K(u) = 0.75(1-u^2)\mathbb{1}(|u| < 1)$, satisfy this assumption.

Finally, we list a generic assumption on the properties of $\widehat{\mathbf{\Sigma}}(z)$ in (7) and the an inverse correlation matrix estimator $\widehat{\mathbf{\Omega}}(z)$.

Assumption 4.4 (Statistical rates) *There are sequences $r_{1n}, r_{2n}, r_{3n} = o(1)$ such that*

$$\sup_{z\in(0,1)} \|\widehat{\mathbf{\Sigma}}(z) - \mathbf{\Sigma}(z)\|_{\max} \le r_{1n}, \quad \sup_{z\in(0,1)} \|\widehat{\mathbf{\Omega}}(z) - \mathbf{\Omega}(z)\|_1 \le r_{2n}, \text{ and}$$
$$\sup_{z\in(0,1)} \max_{j\in[d]} \|\widehat{\mathbf{\Sigma}}(z)\widehat{\mathbf{\Omega}}_j(z) - \mathbf{e}_j\|_\infty \le r_{3n},$$

with probability at least $1 - 1/d$.

Assumption 4.4 is a generic condition on the consistency of $\widehat{\mathbf{\Sigma}}(z)$ and $\widehat{\mathbf{\Omega}}(z)$. We aim to show that our testing methods are independent to any specific procedure to estimate $\mathbf{\Omega}(\cdot)$. The three rates in Assumption 4.4 are sufficient for the validity of our tests. Our inferential framework can thus be easily generalized to other inverse correlation matrix estimators as long as their rates satisfy Assumption 4.4. Under this assumption, the score statistic used for testing can be approximated by an asymptotically normal leading term. For our estimators $\widehat{\mathbf{\Sigma}}(\cdot)$ in (7) and $\widehat{\mathbf{\Omega}}(\cdot)$ in (2) or (3), we will show in Theorems 5 and 6 that

$$r_{1n} = O(\sqrt{\log(d/h)/(nh)}), \quad r_{2n} = O(s\sqrt{\log(d/h)/(nh)}) \text{ and } r_{3n} = O(\sqrt{\log(d/h)/(nh)}). \tag{25}$$

See Section 4.2 for more details.

4.1 Validity of Tests

In this section, we state theorems on asymptotic validity of the tests considered in Section 3. We first define the parameter space

$$\mathcal{U}_s(M,\rho) = \Big\{\mathbf{\Omega} \in \mathbb{R}^{d\times d} \Big| \, \mathbf{\Omega} \succ 1/\rho, \|\mathbf{\Omega}\|_2 \le \rho, \max_{j\in[d]} \|\mathbf{\Omega}_j\|_0 \le s, \|\mathbf{\Omega}\|_1 \le M\Big\}. \tag{26}$$

This matrix class was considered in the literature on inverse covariance matrix estimation (Cai et al., 2016) and time-varying covariance estimation (Chen and Leng, 2016).

The following theorem gives us the limiting distribution of the score function defined in (9).

Theorem 1 (Edge presence test) *For a fixed $z_0 \in (0,1)$, suppose $\mathbf{\Omega}(z_0) \in \mathcal{U}_s(M,\rho)$, Assumption 4.4 holds with $\sqrt{nh}\cdot(r_{2n}(r_{1n}+r_{3n})) = o(1)$ and the bandwidth h satisfies*

$$\sqrt{nh}\big(\log(dn)/(nh) + h^2\big) + s^3/\sqrt{nh} = o(1). \tag{27}$$

Furthermore, for a fixed and $j,k \in [d]$, suppose there exists $\theta_{\min} > 0$ such that

$$\mathbb{E}(\mathbf{\Omega}_j^T(z_0)\mathbf{\Theta}_{z_0}\mathbf{\Omega}_k(z_0))^2 \ge \theta_{\min}\|\mathbf{\Omega}_j(z_0)\|_2^2\|\mathbf{\Omega}_k(z_0)\|_2^2,$$

then under $H_0 : \mathbf{\Omega}_{jk}(z_0) = 0$, we have that

$$\sqrt{nh}\cdot\sigma_{jk}^{-1}(z_0)\widehat{S}_{z_0|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z_0)\big) \rightsquigarrow N(0,1),$$

where $\sigma_{jk}^2(z_0) = f_Z^{-4}(z_0)\mathrm{Var}(\mathbf{\Omega}_j^T(z_0)\mathbf{\Theta}_{z_0}\mathbf{\Omega}_k(z_0))$ and $\mathbf{\Theta}_{z_0}$ is defined in (11).

We have two sets of scaling conditions in the above theorem. Under the condition $\sqrt{nh}(r_{2n}(r_{1n}+r_{3n})) = o(1)$, the first heuristic approximation "$\approx$" in (10) is valid. The condition in (27) guarantees that the leading term on the right hand side of (10) is asymptotically normal. In particular, the first term of (27) makes the second heuristic approximation in (10) valid and allows for control of the higher order term of the Hoeffding decomposition of the U-statistics in (4). If r_{1n}, r_{2n} and r_{3n} have the rates as in (25) (see Theorems 5 and 6 for more details), this condition becomes $\sqrt{nh}\cdot s(h^2 + \sqrt{\log(dn)/(nh)})^2 = o(1)$. We choose $h \asymp n^{-\nu}$, where $\nu > 1/5$ in order to remove the bias. The two scaling conditions in Theorem 1 can be replaced by $(s^3 + s\log(dn))/n^{(1-\nu)/2} = o(1)$. This is similar to the condition $s^2\log d/\sqrt{n}$ in the inference for the Lasso estimator (Zhang and Zhang, 2013; van de Geer et al., 2014; Javanmard and Montanari, 2014). Here, the slower $n^{-(1-\nu)/2}$ term originates from the nonparametric relationship between the index and correlation matrix. The additional s^2 term comes from the matrix structure and is ignorable if $s = o\Big(\sqrt{\log(dn)}\Big)$.

The following lemma shows that the asymptotic variance of the score function can be consistently estimated.

Lemma 2 *Suppose the conditions of Theorem 1 hold. If $r_{2n}/h = o(1)$ and $\log(dn)/(nh^3) = o(1)$, then the variance estimator $\widehat{\sigma}_{jk}^2(z_0)$ in (14) has $\widehat{\sigma}_{jk}^2(z_0) \xrightarrow{P} \sigma_{jk}^2(z_0)$.*

The proofs of Theorem 1 and Lemma 2 are deferred to Appendix B.1 and G.4 respectively. Stronger scaling conditions are needed for consistent estimation of variance as its estimator in (14) relies on controlling higher moments. Under the rates in (25) with $h \asymp n^{-\nu}$, for some $\nu > 1/5$, the scaling $(s^3 + s^2\log(dn))/n^{(1-\nu)/2} = o(1)$ suffices for the estimator to consistently estimate the variance.

We also have the following theorems on the asymptotic validity of the super-graph test.

Theorem 3 (Super-graph test) *Let $z_0 \in (0,1)$ and $j,k \in [d]$ be fixed. Assume the conditions of Theorem 1 hold. Suppose there exists $\theta_{\min} > 0$ such that for all $j \ne k \in [d]$, $\mathbb{E}(\mathbf{\Omega}_j^T(z_0)\mathbf{\Theta}_{z_0}\mathbf{\Omega}_k(z_0))^2 \ge \theta_{\min}\|\mathbf{\Omega}_j(z_0)\|_2^2\|\mathbf{\Omega}_k(z_0)\|_2^2$, and there exists a constant $\epsilon > 0$ such that $\sqrt{nh}(r_{2n}(r_{1n}+r_{3n})) = O(n^{-\epsilon})$ and*

$$\sqrt{nh}\big(\log(dn)/(nh) + h^2\big) + \log d/(nh^2) + (\log(dn))^7/(nh) = O(n^{-\epsilon}). \tag{28}$$

Let $G = (V,E)$ be any fixed graph and $G^*(z_0)$ is the Markov graph corresponding to the index value z_0. Under the null hypothesis $H_0 : G^*(z_0) \subset G$, the test $\psi_{z_0|G}(\alpha)$ defined in (21) satisfies

$$\sup_{\alpha\in(0,1)} \Big|\mathbb{P}_{H_0}\big(\psi_{z_0|G}(\alpha) = 1\big) - \alpha\Big| = O(n^{-c}) \tag{29}$$

for some universal constant c.

The next theorem shows the asymptotic validity of the uniform edge presence test.

Theorem 4 (Uniform edge presence test) *Assume that $\mathbf{\Omega}(z) \in \mathcal{U}(M,\rho)$ for any $z \in (0,1)$ and Assumption 4.4 is true. Suppose there exists $\theta_{\min} > 0$ such that for all $j \ne k \in [d]$ and $z \in (0,1)$, $\mathbb{E}(\mathbf{\Omega}_j^T(z)\mathbf{\Theta}_z\mathbf{\Omega}_k(z))^2 \ge \theta_{\min}\|\mathbf{\Omega}_j(z)\|_2^2\|\mathbf{\Omega}_k(z)\|_2^2$, and there exists a constant $\epsilon > 0$ such that $\sqrt{nh}(r_{2n}(r_{1n}+r_{3n})) = O(n^{-\epsilon})$ and*

$$\sqrt{nh}\big(\log(dn)/(nh) + h^2\big) + \log d/(nh^2) + (\log(dn))^8/(nh) = O(n^{-\epsilon}). \tag{30}$$

Under the null hypothesis $H_0 : G^*(z) \subset G$ *for all* $z \in [z_L, z_U]$*, the test* $\psi_G(\alpha)$ *defined in* (24) *satisfies*

$$\sup_{\alpha\in(0,1)} \left|\mathbb{P}_{H_0}\big(\psi_G(\alpha) = 1\big) - \alpha\right| = O(n^{-c}) \tag{31}$$

for some universal constant $c > 0$.

We defer the proof of Theorem 3 to Appendix B.2 and the proof of Theorem 4 to Appendix F.

Theorems 3 and 4 only depend on the estimation rates of $\widehat{\mathbf{\Sigma}}(z)$ and $\widehat{\mathbf{\Omega}}(z)$ through Assumption 4.4. This implies that our inferential framework does not rely on exact model selection. We have $O(n^{-\epsilon})$ in (28) and (30) instead of $o(1)$ in (27) to achieve the polynomial convergence rate for type I error in (29) and (31). Comparing the scaling condition in (28) with the one in (27), the second term in (28) is dominated by the first term under a mild bandwidth rate $h = o(n^{-1/3})$. The third term $(\log(dn))^7/(nh)$ in (28) comes from a Berry-Essen bound on the suprema of increasing dimensional U-processes. Such a scaling condition is similar to the one in Chernozhukov et al. (2013). They showed that for the empirical process $\boldsymbol{W} = (W_1, \ldots, W_d)^T$ having the same covariance as the centered Gaussian vector $\boldsymbol{U} = (U_1, \ldots, U_d)^T$, the following Berry-Essen bound holds

$$\sup_{t\in\mathbb{R}} \left|\mathbb{P}\big(\max_j W_j \le t\big) - \mathbb{P}\big(\max_j U_j \le t\big)\right| = O\left(\big((\log(dn))^7/n\big)^{1/6}\right).$$

Comparing with our condition that $(\log(dn))^7/(nh) = O(n^{-\epsilon})$, the additional term nh in the denominator comes from the nonparametric part of our estimator. Furthermore, Theorem 4 requires a stronger scaling condition in (30), where the term $(\log(dn))^8/(nh) = O(n^{-\epsilon})$ arises from the additional supremum over $z \in [z_L, z_U]$ in the uniform edge presence test.

4.2 Consistency of Estimation

In this section, we show that the Assumption 4.4 holds under mild conditions on the data generating process. We give explicit rates for r_{1n}, r_{2n} and r_{3n} under concrete estimation procedures. We first show the estimation rate of $\widehat{\mathbf{\Sigma}}$ given in (7). Next, we give the rate of convergence for $\mathbf{\Omega}(z)$ when using the (calibrated) CLIME estimator.

We establish rates of convergence that are uniform in bandwidth h. Uniform in bandwidth results are important as they ensure consistency of our estimators even when the bandwidth is chosen in a data-driven way, which is the case in practice, including the cross-validation over integrated squared error Hall (1992) and other risks (Muller and Stadtmuller, 1987; Ruppert et al., 1995; Fan and Gijbels, 1995). See Jones et al. (1996) for a survey of other methods. Existing literature on uniform in bandwidth consistency focuses on low dimensional problems (see, for example, Einmahl and Mason, 2005). High dimensional statistical methods usually have more tuning parameters and it is hard to guarantee that the selected bandwidth satisfies an optimal scaling condition. To the best of our knowledge this is the first result established in a high-dimensional regime that shows uniform consistency for a wide range of possible bandwidths.

The following theorem shows the rate of the covariance matrix estimator.

Theorem 5 *Assume* $\log d/n = o(1)$ *and the bandwidths* $0 < h_l < h_u < 1$ *satisfy*

$$h_l n/\log(dn) \to \infty \quad \text{and} \quad h_u = o(1).$$

There exists a universal constant $C_{\mathbf{\Sigma}} > 0$ *such that for any* $\delta \in (0,1)$*, we have*

$$\sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \frac{\big\|\widehat{\mathbf{\Sigma}}(z) - \mathbf{\Sigma}(z)\big\|_{\max}}{h^2 + \sqrt{(nh)^{-1}\big[\log(d/h) \vee \log\big(\delta^{-1}\log\big(h_u h_l^{-1}\big)\big)\big]}} \le C_{\mathbf{\Sigma}} \tag{32}$$

with probability $1 - \delta$.

The proof of this theorem is deferred to Appendix A.1. Using (32), we can determine the rate of r_{1n} in Assumption 4.4. The supremum over the bandwidth h in (32) implies that if a data-driven bandwidth $\widehat{h}_n$ satisfies $\mathbb{P}(h_l \le \widehat{h}_n \le h_u) \longrightarrow 1$, then with high probability,

$$\sup_{z\in(0,1)} \big\|\widehat{\mathbf{\Sigma}}(z) - \mathbf{\Sigma}(z)\big\|_{\max} \le C_{\mathbf{\Sigma}} \left(\widehat{h}_n^2 + \sqrt{\frac{\log(d/\widehat{h}_n)}{n\widehat{h}_n}}\right). \tag{33}$$

The first term in the rate is the bias and the second is the variance. Our result is sharper than the rate $O\left(h^2\sqrt{\log d} + \sqrt{\log d/(nh)}\right)$ established in Lemma 9 of Chen and Leng (2016). The uniform consistency result $\sup_{h_l\le h\le h_u}\sup_{z\in(0,1)}\big\|\widehat{\mathbf{\Sigma}}(z) - \mathbf{\Sigma}(z)\big\|_{\max} = o_P(1)$ holds for a wide range of bandwidths satisfying $h_l n/\log(dn) \to \infty$ and $h_u = o(1)$, which allows flexibility for data-driven methods. In fact, such h_l is the smallest to make the variance (33) converge and h_u is the largest for the convergence of bias. When $d = 1$, the range $[h_l, h_u]$ is the same as for the kernel-type function estimators (Einmahl and Mason, 2005).

Due to the large capacity of the estimator $\widehat{\mathbf{\Sigma}}(z)$ in (32), which varies with both the bandwidth h and the index z, the routine proof based on uniform entropy numbers does not easily apply here. We use the peeling method (Van de Geer, 2000) by slicing the range of h into smaller intervals, for which the uniform entropy number is controllable. Finally, we assemble the interval specific bounds to obtain (32). See Section E.1 for more details.

Next, we give a result on the estimation consistency of the inverse correlation matrix. Let $\widehat{\mathbf{\Omega}}(z) = (\widehat{\mathbf{\Omega}}_1(z), \ldots, \widehat{\mathbf{\Omega}}_d(z))$ where each column $\widehat{\mathbf{\Omega}}_j(z)$ is constructed either by using the CLIME in (2) or calibrated CLIME in (3) We recommend using the calibrated CLIME in practice due to the tuning issues discussed in Section 2.1.

Theorem 6 *Suppose* $\mathbf{\Omega}(z) \in \mathcal{U}_s(M, \rho)$ *for all* $z \in (0,1)$*. Assume* $\log d/n = o(1)$*, the bandwidths* $0 < h_l < h_u < 1$ *satisfy* $h_l n/\log(dn) \to \infty$ *and* $h_u = o(1)$*. The regularization parameter* λ *is chosen to satisfy* $\lambda \ge \lambda_{n,h} := C_{\mathbf{\Sigma}}\big(h^2 + \sqrt{\log(d/h)/(nh)}\big)$*, where* $C_{\mathbf{\Sigma}}$ *is the constant in* (32)*, for the calibrated CLIME and* $\lambda \ge M\lambda_{n,h}$ *for the CLIME estimator. Then there exists a universal constant* $C > 0$ *such that*

$$\sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \frac{1}{\lambda M^2}\big\|\widehat{\mathbf{\Omega}}(z) - \mathbf{\Omega}(z)\big\|_{\max} \le C; \tag{34}$$

$$\sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \frac{1}{\lambda s M}\big\|\widehat{\mathbf{\Omega}}(z) - \mathbf{\Omega}(z)\big\|_1 \le C;$$

$$\sup_{z\in(0,1)} \max_{j\in[d]} \frac{1}{\lambda M} \cdot \|\widehat{\mathbf{\Omega}}_j^T\widehat{\mathbf{\Sigma}} - \mathbf{e}_j\|_\infty \le C, \tag{35}$$

with probability $1 - 1/d$.

The proof is deferred to Appendix A.2. From this theorem, we can see that (34) determines r_{2n} and (35) determines r_{3n} in Assumption 4.4. We can plug the r_{1n}, r_{2n} and r_{3n} given in (32), (34) and (35) into the condition $\sqrt{nh}(r_{2n}(r_{1n} + r_{3n})) = O(n^{-\epsilon})$ stated in Theorems 1, 3 and 4 to get an explicit condition for n, h, s, d.

Corollary 7 *Let* $\widehat{\mathbf{\Omega}}(z)$ *be the calibrated CLIME estimator with* $\lambda \geq \lambda_{n,h} = C_{\mathbf{\Sigma}}\big(h^2 + \sqrt{\log(d/h)/(nh)}\big)$ *or the CLIME estimator with* $\lambda \geq M\lambda_{n,h}$. *Then the Assumption 4.4 and all conditions on* r_{1n}, r_{2n} *and* r_{3n} *in Theorems 1, 3 and 4 can be replaced with* $\sqrt{nh} \cdot s\left(h^2 + \sqrt{\log(dn)/(nh)}\right)^2 = o(1)$.

Theorem 6 implies that if the bandwidth satisfies $h \asymp (\log(dn)/n)^{1/5}$, then

$$\sup_{z\in(0,1)} \big\|\widehat{\mathbf{\Omega}}(z) - \mathbf{\Omega}(z)\big\|_{\max} \leq CM^2\left(\frac{\log d + \log n}{n}\right)^{2/5};$$
$$\sup_{z\in(0,1)} \big\|\widehat{\mathbf{\Omega}}(z) - \mathbf{\Omega}(z)\big\|_{1} \leq CMs\left(\frac{\log d + \log n}{n}\right)^{2/5}$$

with probability $1 - 1/d$. When $\log d \gg \log n$, the optimal bandwidth for selection is larger than the standard scaling $h \asymp (\log n/n)^{1/5}$ for univariate nonparametric regression (Tsybakov, 2009). This is because we need to over-regularize each entry of $\widehat{\mathbf{\Sigma}}(z)$ to reduce the variance of entire matrix. The optimal bandwidth is also larger than the scaling for inference $h \asymp n^{-\nu}$ for some $\nu > 1/5$ in (27), since we also need to over-regularize to remove bias for inference.

4.2.1 Optimality of Estimation Rate

The following theorem shows that the rate in (34) is minimax optimal.

Theorem 8 *Consider the following class of the inverse correlation matrices*

$$\overline{\mathcal{U}}_s(M, \rho, L) := \{\mathbf{\Omega}(\cdot) \mid \mathbf{\Omega}(z) \in \mathcal{U}_s(M, \rho) \text{ for any } z \in (0,1), \text{ and } \mathbf{\Omega}_{jk}(\cdot) \in \mathcal{H}(2, L) \text{ for } j, k \in [d]\},$$

where $\mathcal{U}_s(M, \rho)$ *is defined in* (26). *We have the following two results on the minimax risk:*

1. *If* $\log(dn)/n = o(1)$, *then*

$$\inf_{\widehat{\mathbf{\Omega}}(z)} \sup_{\mathbf{\Omega}(\cdot)\in\overline{\mathcal{U}}_s(M,\rho,L)} \mathbb{E}\left[\sup_{z\in(0,1)} \|\widehat{\mathbf{\Omega}}(z) - \mathbf{\Omega}(z)\|_{\max}\right] \geq c\left(\frac{\log d + \log n}{n}\right)^{2/5}. \tag{36}$$

2. *If* $s^2 \log(dn)/n = o(1)$ *and* $s^{-v}d \leq 1$ *for some* $v > 2$, *then*

$$\inf_{\widehat{\mathbf{\Omega}}(z)} \sup_{\mathbf{\Omega}(\cdot)\in\overline{\mathcal{U}}_s(M,\rho,L)} \mathbb{E}\left[\sup_{z\in(0,1)} \|\widehat{\mathbf{\Omega}}(z) - \mathbf{\Omega}(z)\|_{1}\right] \geq cs\left(\frac{\log d + \log n}{n}\right)^{2/5}. \tag{37}$$

The proof is deferred to Appendix C. We prove it by applying Le Cam's lemma (Le Cam, 1973) and constructing a finite collection $\mathbf{\Omega}(\cdot)$ from the function value matrices space $\overline{\mathcal{U}}_s(M, \rho, L)$. If we take the dimension $d = 1$, our problem degenerates to the univariate twice differentiable function estimation. The risk on the left hand side of (36) becomes to the supreme norm between the estimated function and truth. The right hand side of (36) degenerates to $O((\log n/n)^{2/5})$ which matches the typical minimax rate for nonparametric regression in $\|\cdot\|_\infty$ risk (Tsybakov, 2009). This indicates the reason why we have the power $2/5$ in the rates.

5. Numerical Experiments

In this section, we explore finite sample performance of our estimation procedure and test using simulations. Furthermore, we also apply the super graph test to the brain image network.

5.1 Synthetic Data

We illustrate finite sample properties of the estimator in (3) on synthetic data. We consider three other competing methods: (1) the kernel Pearson CLIME estimator (Zhou et al., 2010; Yin et al., 2010), (2) the kernel graphical Lasso estimator (Zhou et al., 2010), and (3) the kernel neighborhood selection estimator (Kolar et al., 2010a). Zhou et al. (2010) and Yin et al. (2010) consider the correlation matrix estimator at z as a weighted summation of Pearson's correlations

$$\widehat{\mathbf{\Sigma}}_P(z) = \frac{\sum_{i=1}^n K_h(Z_i - z)\boldsymbol{X}_i\boldsymbol{X}_i^T}{\sum_{i=1}^n K_h(Z_i - z)}.$$

This estimate can be plugged into the calibrated CLIME estimator in (3) to obtain the kernel Pearson inverse correlation estimator $\widehat{\mathbf{\Omega}}_{(1)}(z)$. Zhou et al. (2010) proposed to estimate the inverse correlation matrix by plugging $\widehat{\mathbf{\Sigma}}_P$ into the graphical lasso (Yuan and Lin, 2007) objective

$$\widehat{\mathbf{\Omega}}_{(2)}(z) = \operatorname*{argmax}_{\mathbf{\Omega}\succ 0} \Big\{\log\det\mathbf{\Omega} - \operatorname{tr}\left(\mathbf{\Omega}\widehat{\mathbf{\Sigma}}_P(z)\right) - \lambda\|\mathbf{\Omega}\|_1\Big\},$$

resulting in the kernel graphical Lasso estimator. Kolar et al. (2010a) proposed to combine the neighborhood selection procedure Meinshausen and Bühlmann (2006) with local kernel smoothing. To estimate the j-th column of $\mathbf{\Omega}(z)$ they use

$$\widehat{\boldsymbol{\beta}}_j(z) = \operatorname*{argmin}_{\boldsymbol{\beta}\in\mathbb{R}^{d-1}} \frac{1}{nh}\sum_{i=1}^n K\left(\frac{Z_i - z}{h}\right)(\boldsymbol{X}_{ij} - \boldsymbol{X}_{i\setminus j}\boldsymbol{\beta})^2 + \lambda\|\boldsymbol{\beta}\|_1,$$

where $\boldsymbol{X}_{i\setminus j}$ is a $(d-1)$-dimensional vector with the j-th entry of $\boldsymbol{X}_i$ removed. The kernel neighborhood selection estimator $\widehat{\mathbf{\Omega}}_{(3)}(z)$ is then obtained as as

$$\big[\widehat{\mathbf{\Omega}}_{(3)}(z)\big]_{jj} = 1 \text{ and } \big[\widehat{\mathbf{\Omega}}_{(3)}(z)\big]_{\setminus j,j} = \widehat{\boldsymbol{\beta}}_j(z), \text{ for all } j \in [d].$$

We describe a procedure to generate the graph $G^*(z)$ and inverse correlation matrix $\mathbf{\Omega}(z)$ at each $z \in (0,1)$. At any index $z \in (0,1)$, we generate a graph with $d = 50$

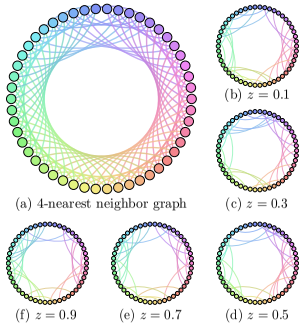

Figure 1: The 4-nearest neighbor graph and the time-varying graph for various index values z. The thickness of edges represents the magnitude of the inverse correlation matrix corresponding to that edge for a specific value z.

nodes and $e = 25$ by selecting edge from the 4-nearest neighbor graph illustrated in Figure 1(a). We first generate $Z_1, \ldots, Z_n$ independently from Uniform$(0, 1)$ with the sample size $n \in \{200, 500, 800\}$ and then generate $\mathbf{\Omega}(z)$ at each index value Z_i as follows.

1. Randomly select 25 edges from the 4-nearest neighbor graph and generate the initial graph $G^{(0)}$. The structure of the underlying graph will change at the following anchor points $z = 0.2, 0.4, 0.6, 0.8$. At the ℓ-th anchor point, we randomly remove 10 edges from the previous graph $G^{(\ell-1)}$ and randomly add 10 edges from the 4-nearest neighbor graph that did not belong to the previous graph $G^{(k-1)}$. We therefore generate 5 anchor graphs $G^{(0)}, \ldots, G^{(4)}$. On the ℓ-th interval $[(\ell-1)/5, \ell/5]$, the graph structure stays constant and equal to $G^{(\ell-1)}$ for $\ell = 1, \ldots, 5$.

2. Given the graph structure we generate $\mathbf{\Omega}(z)$. At the middle of each interval, that is, for index values $z = 0.1, 0.3, 0.5, 0.7, 0.9$, if the edge (j, k) belongs to the graph at that time, we randomly generate $\mathbf{\Omega}_{jk}(z)$ from Uniform$[\mu, 0.9]$, where μ is the minimal signal strength, otherwise we set $\mathbf{\Omega}_{jk}(z)$ to be zero. For $1 \leq \ell \leq 4$, if the edge (j, k) belongs to both $G^{(\ell)}$ and $G^{(\ell+1)}$, we let $\mathbf{\Omega}_{jk}(z_\ell)$ be generated from Uniform$[\mu, 0.9]$, otherwise we set it to be zero. We also generate $\mathbf{\Omega}_{jk}(0)$ from Uniform$[\mu, 0.9]$ if the edge (j, k) is in $G^{(0)}$ and similarly for $\mathbf{\Omega}_{jk}(1)$ using $G^{(4)}$. The signal strength is set to $\mu = 0.5$.

3. For any $z \in (0, 1)$, if $z \in [\ell/10, (\ell+1)/10]$ for some $\ell = 0, \ldots, 9$, $\mathbf{\Omega}_{jk}(z)$ is set to be an linear interpolation of $\mathbf{\Omega}_{jk}(\ell/10)$ and $\mathbf{\Omega}_{jk}((\ell+1)/10)$. We first rescale the diagonal of $\mathbf{\Omega}(z)$ by $\mathbf{\Omega}(z) + (1 - \lambda_{\min}(\mathbf{\Omega}(z)))\mathbf{I}_d$, where $\lambda_{\min}(\mathbf{\Omega}(z))$ is the minimum eigenvalue of $\mathbf{\Omega}(z)$ in order to make its minimum eigenvalue equal to one for each time $z \in (0, 1)$. We then get the covariance matrix $\mathbf{\Sigma}(z) = \mathbf{\Omega}^{-1}(z)$ and normalize its diagonal to all

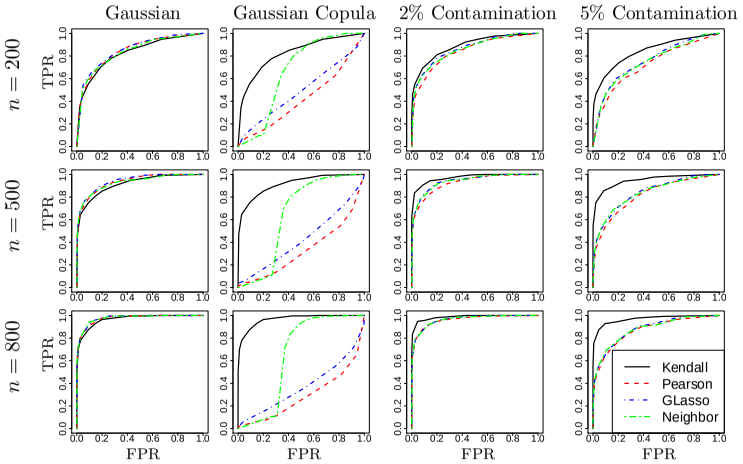

Figure 2: ROC curves for different estimators of the inverse correlation matrix estimator. The number of nodes is $d = 50$, the number of edges for each index value is $e = 25$ and the sample size is varied in $n \in \{200, 500, 800\}$. Each curve is obtained by averaging 100 simulation runs.

ones. An illustration of the time-varying graphical model is shown in Figure 1(b) - Figure 1(f).

Given the inverse correlation matrix $\mathbf{\Omega}(z)$, we consider four data generation schemes:

1. Gaussian, where $\boldsymbol{X} \mid Z = z \sim N(\mathbf{0}, \mathbf{\Sigma}(z))$;

2. Gaussian Copula, where $\boldsymbol{X} \mid Z = z \sim (\Phi(\boldsymbol{Y}_1(z)), \ldots, \Phi(\boldsymbol{Y}_d(z)))^T$, $\boldsymbol{Y} \mid Z = z \sim N(\mathbf{0}, \mathbf{\Sigma}(z))$ and $\Phi(\cdot)$ is the cumulative density function of standard normal distribution;

3. Gaussian with 2% contamination, where $\boldsymbol{X} \mid Z = z \sim N(\mathbf{0}, \mathbf{\Sigma}(z))$ and then 2% of locations are randomly chosen and replaced by $\pm N(3, 3)$;

4. Gaussian with 5% contamination, is uses the same data generating mechanism as before, but more of the observations are contaminated.

All the methods under consideration require a specification of the kernel function satisfying Assumption 4.3. We choose the Epanechnikov kernel $K(u) = 0.75(1 - u^2)\mathbb{1}(|u| < 1)$ which can be easily checked that it satisfies Assumption 4.3. The bandwidth parameter is set as $h = 0.35/n^{1/5}$ for all four methods in order to facilitate easier comparison. For the calibrated CLIME, we choose $\gamma = 0.5$ in (3). We then estimate a sequence of inverse correlation matrices and graphs by changing the penalty parameter λ over a large range of values. Let $\widehat{E}(z)$ be the estimated edge set and $E^*(z)$ is the true edge set at the index value

n	$\mu_0 = 0$	$\mu_0 = 0.4$	$\mu_0 = 0.6$	$\mu_0 = 0.9$
600	**0.108**	0.722	0.892	0.994
800	**0.090**	0.822	0.900	0.998
1,000	**0.056**	0.736	0.968	1.000

Table 1: Size (bold) and power of the local edge presence test $H_0 : \mathbf{\Omega}_{12}(0.5) = 0$ at significance level 95% with various signal strength μ_0. Results reported based on 500 simulation runs.

z. The true positive rate (TPR) and false positive rate (FPR) are defined as

$$\text{TPR}(z) = \frac{|\widehat{E}(z) \bigcap E^*(z)|}{|E^*(z)|} \qquad \text{and} \qquad \text{FPR}(z) = \frac{|\widehat{E}(z) \backslash E^*(z)|}{d(d-1)/2 - |E^*(z)|},$$

where $|S|$ denotes cardinality of the set S. To measure the quality of graph estimation for $z \in (0,1)$, we randomly choose 10 data points from $\{Z_i\}_{i\in[n]}$ and compute the averaged TPR and FPR on these 10 points as the overall TPR and FPR of the graph estimation. Figure 2 illustrates the ROC curves of the overall TPR and FPR for the four competing methods under four schemes for $n = 200, 500$ and 800. We can observe that the proposed estimator is slightly worse compared to other three estimators when the data are Gaussian conditionally on the index value. In this setting the data generating assumptions are satisfied for the other three procedures. On the other hand, when the data are generated according to the Gaussian copula distribution, the Gaussian assumption is violated and our estimator performs better compared to the other three estimators. The third and fourth columns of Figure 2 further illustrate that our estimator is more robust to corruption of data.

In addition to graph estimation accuracy, we consider the numerical performance of testing procedures proposed in the paper. We first focus on the local edge presence test introduced in Section 3.1. Consider the following null hypothesis $H_0 : \mathbf{\Omega}_{12}(0.5) = 0$. We choose the bandwidth $h = 0.9n^{-1/5}$, $\gamma = 0.5$ in (3) and the penalty parameter $\lambda = 0.2\big(h^2 + \sqrt{\log(d/h)/(nh)}\big)$ for the sample size $n \in \{600, 800, 1000\}$. The data generating process is the same as before, except that we set $\mathbf{\Omega}_{21}(z) = \mu_0$ for all $z \in (0,1)$ where $\mu_0 \in \{0, 0.4, 0.6, 0.9\}$. We use (21) to test the null hypothesis at significance level 95% and estimate the power based on 500 repetitions. The Q-Q plots of the testing statistic

	$n = 600$			$n = 800$			$n = 1,000$		
	$\mu = 0$	$\mu = 0.4$	$\mu = 0.9$	$\mu = 0$	$\mu = 0.4$	$\mu = 0.9$	$\mu = 0$	$\mu = 0.4$	$\mu = 0.9$
$k = 0$	**0.118**	0.954	0.958	**0.088**	0.958	0.976	**0.068**	0.977	0.992
$k = 2$	**0.128**	0.900	0.926	**0.090**	0.944	0.964	**0.070**	0.970	0.982
$k = 4$	**0.098**	**0.089**	**0.058**	**0.082**	**0.068**	**0.054**	**0.066**	**0.052**	**0.048**
$k = 8$	**0.090**	**0.074**	**0.054**	**0.066**	**0.058**	**0.048**	**0.054**	**0.052**	**0.050**

Table 2: Size (bold) and power of local edge present test $H_0 : G^*(z) \subset G$ for all $z \in (0,1)$ at significance level 95% with the super graph G being a k-nearest neighbor graph for $k \in \{0, 2, 4, 8\}$. Results reported based on 500 simulation runs.

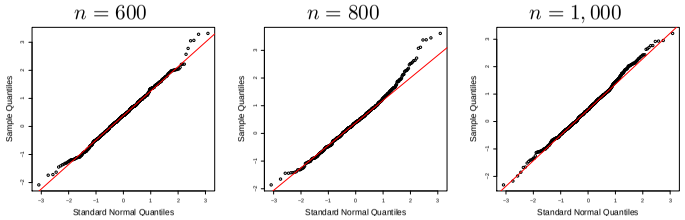

Figure 3: Q-Q plot of the testing statistic under the null hypothesis $H_0 : \mathbf{\Omega}_{12}(0.5) = 0$.

for various sample sizes are shown in Figure 3. The empirical distribution of the testing statistic is close to standard normal distribution. The results on the power of these tests are summarized in Table 5.1. When the signal strength $\mu_0 = 0$, the size of the test approaches the nominal value 0.05. When $\mu \geq 0.4$, the power approaches 1, showing validity of the proposed test.

We also conduct a simulation for the uniform edge presence test introduced in Section 3.3. We consider the null hypothesis $H_0 : G^*(z) \subset G$ for all $z \in (0,1)$, where the super graph G is a k-nearest neighbor graph for $k \in \{0, 2, 4, 8\}$. Here a k-nearest neighbor graph has edges only connecting a vertex to its closest k nodes. See Figure 1(a) for an illustration of a 4-nearest neighbor graph. When $k = 0$, it is a null graph whose adjacency matrix is identity. In order to illustrate the power of our test, we generate the nonzero entries of the inverse correlation matrix at anchor points from Uniform$[\mu, \max(\mu + 0.2, 0.9)]$ for $\mu = 0.4$ and 0.9. We also consider the setting where $\mathbf{\Omega}(z) = \mathbf{I}$ for all $z \in (0,1)$. The sample size is varied as $n \in \{600, 800, 1000\}$. The bandwidth and tuning parameter are set in the same way as for the local edge presence test. When computing the test statistic in (22) the suprema over $z \in (0,1)$ is approximated by taking the maximum of the statistic over 100 evenly spaced values in $(0,1)$, and similarly for the bootstrapped statistic in (23). The size and power of the test are summarized in Table 5.1. From the data generating mechanism, we see that the true graph is always a subgraph of the 4-nearest graph. Therefore, the null hypothesis is true when the number of nearest neighbors is $k \in \{4, 8\}$ or $\mathbf{\Omega}(z) = \mathbf{I}$. From the results reported in Table 5.1, we observe that the uniform edge presence test has the correct size as the sample size increases. The alternative hypothesis is true when $k \in \{0, 2\}$ and $\mathbf{\Omega}(z) \neq \mathbf{I}$. In this setting, the less edges the super graph has, the more powerful the test is. That is because we take maximum over more edges in (16).

5.2 Super Brain Test

We apply the super graph test in Section 3.2 to the ADHD-200 brain imaging data set (Biswal et al., 2010). The ADHD-200 data set is a collection of resting-state functional MRI (R-fMRI) of subjects with and without attention deficit hyperactive disorder (ADHD) (Eloyan et al., 2012; The ADHD-200 Consortium, 2012). The data set contains 776 subjects: 491 controls, 195 cases diagnosed with ADHD of various types and 88 subjects with withheld diagnosis for the purpose of a prediction competition. For each subject there are between 76 and 276 R-fMRI scans. We focus on 264 voxels as the regions of interest (ROI) extracted by Power et al. (2011). These voxels are representative of the functional areas corresponding

	$H_0 : G(8) \subset G(11.75)$	$H_0 : G(11.75) \subset G(20)$
Statistics	2.793	3.548
Quantiles	1.899	2.154

Table 3: Results on the super brain hypothesis tests at 95% significant level. The row named "Statistics" are the values of the testing statistic in (16). The row named "Quantiles" are the 95%-quantile estimators obtained by the bootstrap estimator in (19).

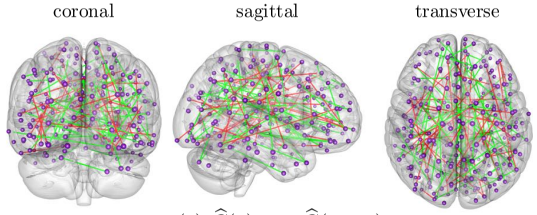
to the cerebral cortex and cerebellum. For each subject we also have covariates that include age, IQ, gender and handedness. For illustration purposes, we focus on 491 controls and explore how the structure of the neural network varies with age of subjects, which range from 7.08 to 21.83. Using the kernel smoothing technique to estimate the varying neural networks, Qiu et al. (2016) found that the connections tend to be denser at the age 21.83 than at ages 11.75 and 7.09. Such a discovery is also supported by Bartzokis et al. (2001) and Gelfand et al. (2003).

Based on these discoveries, a more interesting conjecture is whether the neural network is always growing with age. We can use our testing framework to investigate the claim that a neural network in a younger subject is a subgraph of a neural network in an older subject. Specifically, we choose three ages: 8, 11.75 and 20, and we are interested in the graphs $G(8)$, $G(11.75)$ and $G(20)$, where $G(z)$ is the true neural network at age z. The age 11.75 is chosen as the median age of subjects. We call the neural networks at ages 8, 11.75 and 20 as the junior, median and senior neural network, respectively. As we do not have access to the true networks, we will estimate them using the calibrated CLIME in (3). We first map the ages onto the interval $(0, 1)$ and set the tuning parameters for our procedure as $\gamma = 0.5$, the bandwidth $h = 0.002$ and the penalty parameter $\lambda = 0.03\big(h^2 + \sqrt{d/h}/(nh)\big)$, where the last two parameters are chosen through cross-validation. We estimate the neural networks $\widehat{G}(8)$, $\widehat{G}(11.75)$ and $\widehat{G}(20)$ by (3) at ages 8, 11.75 and 20. The estimated graphs are used as super graphs in defining the null hypothesis. In particular, we have the following two tests: $H_0 : G(8) \subset \widehat{G}(11.75)$ and $H_0 : G(11.75) \subset \widehat{G}(20)$. Although we use the random estimators as the super graphs in these hypotheses, the testing procedure is still valid. This is because of the small bandwidth $h = 0.002$ making the data used in network estimation independent to the data used in these two tests. Therefore, the test can still be reduced as a super graph test.

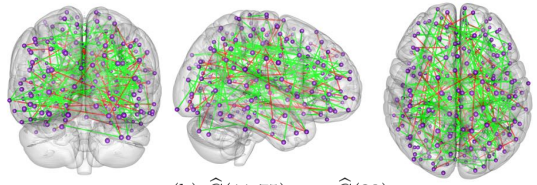
Figure 4 shows the differences among the junior, median and senior brains. We observe that even if a later neural network has more edges compared to the earlier one, many edges existing at an earlier stage disappear later in the development. This implies that the conjecture that neural networks grow with age is not supported by the data. Table 5.2 quantifies evidence against the null hypothesis.

6. Discussion

In this paper, we consider the time-varying graphical model under the framework of nonparanormal distribution. Although it contains many examples of heavy-tailed distributions, there are many other cases uncovered in this family. It will be interesting to explore the



(a) $\widehat{G}(8)$ v.s. $\widehat{G}(11.75)$



(b) $\widehat{G}(11.75)$ v.s. $\widehat{G}(20)$

Figure 4: The differences between junior, median and senior neural networks. $\widehat{G}(8)$, $\widehat{G}(11.75)$ and $\widehat{G}(20)$ denote the estimated graphs at age 8, 11.75 and 20. The first row is the difference between $\widehat{G}(8)$ and $\widehat{G}(11.75)$. The green lines are the edges existing in $\widehat{G}(11.75)$ but not in $\widehat{G}(8)$ and the red edges only exist in $\widehat{G}(8)$ but not $\widehat{G}(11.75)$. The second row is the difference between $\widehat{G}(11.75)$ and $\widehat{G}(20)$. The green edges only exist in $\widehat{G}(20)$ and the red edges only exist in $\widehat{G}(11.75)$.

estimation and inference methods for the time-varying graphical model under general heavy-tailed distributions with certain moment conditions. It is possible to incorporate existing methods including the Catoni's estimator (Catoni, 2012) and the median-of-means estimator (Hsu and Sabato, 2014) into the framework of this paper and conduct inference for the general heavy-tailed time-varying graphical models.

Appendix A. Proof of Estimation Consistency

In the appendix, we use $c, C, c_1, C_1, c_2, C_2, \ldots$ to denote universal constants, independent of n and d, whose values may change from line to line.

In this section, we prove uniform rates of convergence for the covariance matrix estimator $\widehat{\mathbf{\Sigma}}(z)$ and the inverse covariance estimator $\widehat{\mathbf{\Omega}}(z)$. These rates are uniformly valid over both the index z and the kernel bandwidth h used for the estimator $\widehat{\tau}_{jk}(z)$ in (4).

A.1 Proof of Theorem 5

We apply the bias-variance decomposition for the kernel smoothed Kendall's tau statistic in the following two lemmas. The first lemma controls the variance term $|\widehat{\tau}_{jk}(z) - \mathbb{E}[\widehat{\tau}_{jk}(z)]|$ uniformly in $j, k \in [d]$, $z \in (0,1)$, and $h \in [h_l, h_u]$. The second lemma controls the bias term $|\mathbb{E}[\widehat{\tau}_{jk}(z)] - \tau_{jk}(z)|$.

Lemma 9 (Variance of Kendall's tau estimator) *Assume that $n^{-1}\log d = o(1)$ and the bandwidths $0 < h_l < h_u < 1$ satisfy $h_l n/\log(dn) \to \infty$ and $h_u = o(1)$. There exists a universal constant $C > 0$ such that, with probability $1-\delta$, for sufficiently large n,*

$$\sup_{j,k\in[d]} \sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \frac{\sqrt{nh}}{\sqrt{\log(d/h) \vee \log\left(\delta^{-1}\log\left(h_u h_l^{-1}\right)\right)}} |\widehat{\tau}_{jk}(z) - \mathbb{E}\left[\widehat{\tau}_{jk}(z)\right]| \leq C.$$

Lemma 10 (Bias of Kendall's tau estimator) *Assume that the bandwidths $0 < h_l < h_u < 1$ satisfy $h_u = o(1)$. There exists a constant $C > 0$ such that*

$$\sup_{j,k\in[d]} \sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \frac{|\mathbb{E}[\widehat{\tau}_{jk}(z)] - \tau_{jk}(z)|}{h^2 + 1/(nh)} \leq C.$$

We defer the proof of these two lemmas to Appendix D.

By the definition of $\widehat{\mathbf{\Sigma}}(z)$ in (7), for any $j, k \in [d]$ and $z \in (0,1)$, we have

$$\left|\widehat{\mathbf{\Sigma}}_{jk}(z) - \mathbf{\Sigma}_{jk}(z)\right| = \left|\sin\left(\pi\widehat{\tau}_{jk}(z)/2\right) - \sin\left(\pi\tau_{jk}(z)/2\right)\right| \leq \frac{\pi}{2}\left|\widehat{\tau}_{jk}(z) - \tau_{jk}(z)\right|, \tag{38}$$

where the last inequality is due to $|\sin(x) - \sin(y)| \leq |x - y|$ for any $x, y \in [-\pi/2, \pi/2]$. Therefore, the rate of $\widehat{\mathbf{\Sigma}}(z)$ can be bounded by the rate of $\widehat{\tau}_{jk}(z)$ up to a constant. Recall that $\mathbf{T} = [\tau_{jk}]_{jk}$ and $\widehat{\mathbf{T}} = [\widehat{\tau}_{jk}]_{jk}$. We have

$$\|\widehat{\mathbf{T}}(z) - \mathbf{T}(z)\|_{\max} \leq \sup_{j,k\in[d]} |\widehat{\tau}_{jk}(z) - \mathbb{E}\widehat{\tau}_{jk}(z)| + \sup_{j,k\in[d]} |\mathbb{E}\widehat{\tau}_{jk}(z) - \tau_{jk}(z)|.$$

Lemma 9 and Lemma 10 together with (38) give us

$$\sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \frac{\left\|\widehat{\mathbf{\Sigma}}(z) - \mathbf{\Sigma}(z)\right\|_{\max}}{h^2 + \sqrt{(nh)^{-1}\left[\log(d/h) \vee \log\left(\delta^{-1}\log\left(h_u h_l^{-1}\right)\right)\right]}}$$

$$\leq \sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \frac{\left\|\widehat{\mathbf{T}}(z) - \mathbf{T}(z)\right\|_{\max}}{h^2 + \sqrt{(nh)^{-1}\left[\log(d/h) \vee \log\left(\delta^{-1}\log\left(h_u h_l^{-1}\right)\right)\right]}} \leq 2\pi(C_1 + C_2),$$

with probability $1-\delta$, since $1/(nh) = o(1)$. We complete the proof of the theorem by setting $C_{\mathbf{\Sigma}} = 2\pi(C_1 + C_2)$.

A.2 Proof of Theorem 6

Using the uniform rate of convergence of $\widehat{\mathbf{\Sigma}}(z)$ established in Theorem 5, we establish the corresponding rate for $\widehat{\mathbf{\Omega}}(z)$ when estimated using the CLIME (Cai et al., 2011) or the calibrated CLIME (Zhao and Liu, 2014). Modifying the proofs in the above two papers, we can establish a bound on $\left\|\widehat{\mathbf{\Omega}} - \mathbf{\Omega}\right\|_{\max}$, if $\left\|\widehat{\mathbf{\Sigma}} - \mathbf{\Sigma}\right\|_{\max}$ is controlled. For simplicity, we recall the results for the calibrated CLIME estimator. Similar results for the CLIME estimator can be found in the proof of Theorem 6 in Cai et al. (2011).

Theorem 11 (Adapted from Zhao and Liu 2014) *Suppose $\mathbf{\Omega} \in \mathcal{U}_s(M, \rho)$ and the tuning parameter satisfies $s\lambda = o(1)$. On the event $\left\{\|\widehat{\mathbf{\Sigma}} - \mathbf{\Sigma}\|_{\max} \leq \lambda\right\}$, there exist universal constants C_1, C_2, C_3 such that the output of the calibrated CLIME satisfies*

$$\left\|\widehat{\mathbf{\Omega}} - \mathbf{\Omega}\right\|_{\max} \leq C_1 M^2 \lambda, \quad \left\|\widehat{\mathbf{\Omega}} - \mathbf{\Omega}\right\|_1 \leq C_2 s M \lambda \quad \text{and} \quad \max_{j\in[d]} \|\widehat{\mathbf{\Sigma}}\widehat{\mathbf{\Omega}}_j - \mathbf{e}_j\|_\infty \leq C_3 \lambda M.$$

The formal statements of Theorem IV.1 and Theorem IV.2 in Zhao and Liu (2014) are not the same as the statement above. The result of Theorem 11 is more general and directly follows from the proofs of Theorem IV.1 and Theorem IV.2 in Zhao and Liu (2014). For example, the last inequality in Theorem 11 follows from Equation (E.12) of Zhao and Liu (2014).

Let $\lambda_{n,h} = C_{\mathbf{\Sigma}}\left(h^2 + \sqrt{\log(dn)/(nh)}\right)$ and define the event

$$\mathcal{E} = \left\{\sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \lambda_{n,h}^{-1}\left\|\widehat{\mathbf{\Sigma}}(z) - \mathbf{\Sigma}(z)\right\|_{\max} \leq 1\right\}.$$

Since the constants C_1, C_2 and C_3 in Theorem 11 are universal and the penalty parameter $\lambda \geq \lambda_{n,h}$, it follows that

$$\sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \lambda^{-1}\left\|\widehat{\mathbf{\Omega}}(z) - \mathbf{\Omega}(z)\right\|_{\max} \leq C_1 M^2;$$

$$\sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \lambda^{-1}\left\|\widehat{\mathbf{\Omega}}(z) - \mathbf{\Omega}(z)\right\|_1 \leq C_2 s M;$$

$$\sup_{z\in(0,1)} \max_{j\in[d]} \lambda^{-1} \cdot \|\widehat{\mathbf{\Omega}}_j^T\widehat{\mathbf{\Sigma}} - \mathbf{e}_j\|_\infty \leq C_3 M,$$

on the event $\mathcal{E}$. Theorem 5 gives us $\mathbb{P}(\mathcal{E}) \geq 1 - 1/d$, which completes the proof.

Appendix B. Asymptotic Properties of Testing Statistics

In this section, we prove asymptotic properties of the testing statistics for three kinds of hypothesis tests: (1) edge presence test in Theorem 1, (2) super-graph test in Theorem 3 and (3) uniform edge presence test in Theorem 4.

Let $\mathcal{S}_{j,z} = \{k \in [d] \mid \mathbf{\Omega}_{kj}(z) \neq 0\}$. For any index sets $\mathcal{S}, \mathcal{S}' \subset [d]$, we define $\mathbf{\Omega}_{\mathcal{S}\mathcal{S}'} \in \mathbb{R}^{|\mathcal{S}|\times|\mathcal{S}'|}$ to be the submatrix of $\mathbf{\Omega}$ obtained from rows indexed by $\mathcal{S}$ and columns indexed by $\mathcal{S}'$. For any function $f(x)$, we define

$$\mathbb{G}_n^\xi[f] = \frac{1}{\sqrt{n}}\sum_{i=1}^n f(X_i)\cdot\xi_i, \tag{39}$$

where $\xi_1, \ldots, \xi_n \sim N(0,1)$. We also define $\mathbb{P}_\xi(\cdot) := \mathbb{P}(\cdot|\{Y_i\}_{i\in[n]})$ and $\mathbb{E}_\xi[\cdot] := \mathbb{E}[\cdot|\{Y_i\}_{i\in[n]}]$.

At a high-level, we establish the asymptotic results by carefully studying the Hoeffding decomposition of the kernel smoothed Kendall's tau estimator. From (4), we observe that $\widehat{\tau}_{jk}(z)$ is a quotient of two U-statistics. To study this quotient, we introduce some additional notation. For a fixed $j,k \in [d]$, we define the following bivariate function

$$g_{z|(j,k)}(y_i, y_{i'}) = \omega_z(z_i, z_{i'}) \operatorname{sign}(x_{ij} - x_{i'j}) \operatorname{sign}(x_{ik} - x_{i'k}), \tag{40}$$

for $y_i = (z_i, \boldsymbol{x}_i)$ and $y_{i'} = (z_{i'}, \boldsymbol{x}_{i'})$. Recalling the definition of $\omega_z(z_i, z_{i'})$ in (5), we have that

$$\widehat{\tau}_{jk}(z) = \mathbb{U}_n[g_{z|(j,k)}]/\mathbb{U}_n[\omega_z].$$

Let us define the Hoeffding decomposition of $g_{z|(j,k)}$ as

$$g^{(1)}_{z|(j,k)}(y) = \mathbb{E}[g_{z|(j,k)}(y,Y)] - \mathbb{E}\left[\mathbb{U}_n[g_{z|(j,k)}]\right], \tag{41}$$

$$g^{(2)}_{z|(j,k)}(y_1,y_2) = g_{z|(j,k)}(y_1,y_2) - g^{(1)}_{z|(j,k)}(y_1) - g^{(1)}_{z|(j,k)}(y_2) - \mathbb{E}\left[\mathbb{U}_n[g_{z|(j,k)}]\right]. \tag{42}$$

Then we can reformulate the centered U-statistic as

$$\mathbb{U}_n\left[g_{z|(j,k)}\right] - \mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right] = 2\mathbb{E}_n\left[g^{(1)}_{z|(j,k)}(Y_i)\right] + \mathbb{U}_n\left[g^{(2)}_{z|(j,k)}\right]. \tag{43}$$

In the above display, we decomposed the centered U-statistic into an empirical process and a higher order U-statistic. Our proof strategy is to study the asymptotic property of the leading empirical process term $2\mathbb{E}_n\left[g^{(1)}_{z|(j,k)}(Y_i)\right]$ and show that the higher order term can be ignored. Similarly, let

$$\omega^{(1)}_z(s) = \mathbb{E}[\omega_z(s,Z)] - \mathbb{E}\left[\mathbb{U}_n[\omega_z]\right], \tag{44}$$

$$\omega^{(2)}_z(s,t) = \omega_z(s,t) - \omega^{(1)}_z(s) - \omega^{(1)}_z(t) - \mathbb{E}\left[\mathbb{U}_n[\omega_z]\right], \tag{45}$$

which leads to the following Hoeffding decomposition

$$\mathbb{U}_n[\omega_z] - \mathbb{E}\left[\mathbb{U}_n[\omega_z]\right] = 2\mathbb{E}_n\left[\omega^{(1)}_z\right] + \mathbb{U}_n\left[\omega^{(2)}_z\right], \tag{46}$$

According to the heuristic approximation of $\widehat{S}_{z|(j,k)}\big(\widehat{\boldsymbol{\Omega}}_{k\setminus j}(z_0)\big)$ in (10), we have

$$\begin{aligned}
&\widehat{S}_{z|(j,k)}\big(\widehat{\boldsymbol{\Omega}}_{k\setminus j}(z)\big) \approx \boldsymbol{\Omega}_j^T(z)\big[\dot{\boldsymbol{\Sigma}}(z) \circ \big(\widehat{\mathbf{T}}(z) - \mathbf{T}(z)\big)\big]\boldsymbol{\Omega}_k(z) \\
&\approx [\mathbb{U}_n[\omega_z]]^{-1} \sum_{u,v\in[d]} \boldsymbol{\Omega}_{ju}(z)\boldsymbol{\Omega}_{kv}(z)\pi\cos\Big(\tau_{uv}(z)\frac{\pi}{2}\Big) \cdot \left[\mathbb{U}_n[g_{z|(u,v)}] - \mathbb{E}[\mathbb{U}_n[g_{z|(u,v)}]] \cdot \mathbb{U}_n[\omega_z]\right],
\end{aligned} \tag{47}$$

where the last "$\approx$" comes from (4) and Lemma 10. Combining (43) and (46) with (47),

$$\sqrt{nh} \cdot \widehat{S}_{z|(j,k)} \approx [\mathbb{U}_n[\omega_z]]^{-1}\mathbb{G}_n\big[J_{z|(j,k)}\big],$$

where the leading term of the Hoeffding decomposition is defined as

$$J_{z|(j,k)}(y') := \sum_{u,v\in[d]} \boldsymbol{\Omega}_{ju}(z)\boldsymbol{\Omega}_{kv}(z)\pi\cos\Big(\tau_{uv}(z)\frac{\pi}{2}\Big)\sqrt{h} \cdot \left[g^{(1)}_{z|(u,v)}(y') - \tau_{uv}(z)\omega^{(1)}_z(z')\right], \tag{48}$$

for any $y' = (z', \boldsymbol{x}')$. We find the asymptotic distribution of $[\mathbb{U}_n[\omega_z]]^{-1}\mathbb{G}_n\big[J_{z|(j,k)}\big]$ in the next part.

B.1 Proof of Theorem 1

Let the operator $u_n[\cdot]$ be defined as

$$u_n[H] = \sqrt{n} \cdot \big(\mathbb{U}_n[H] - \mathbb{E}[\mathbb{U}_n[H]]\big) \tag{49}$$

for any bivariate function $H(x,x')$. In order to prove Theorem 1, we need the convergence rate of terms related to the Kendall's tau estimator, especially the two lemmas below.

Lemma 12 *Suppose that $n^{-1}\log d = o(1)$ and the bandwidths $0 < h_l < h_u < 1$ satisfy $h_l n/\log(dn) \to \infty$ and $h_u = o(1)$. There exists a universal constant $C > 0$ such that with probability $1-\delta$,*

$$\sup_{j,k\in[d]} \sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \left| \frac{\sqrt{h}}{\sqrt{\log(d/h) \vee \log\left(\delta^{-1}\log\left(h_u h_l^{-1}\right)\right)}} \Big(u_n\left[\omega_z\right] \vee u_n\left[g_{z|(j,k)}\right] \Big) \right| \le C, \tag{50}$$

for large enough n.

Lemma 13 *Suppose the bandwidths $0 < h_l < h_u < 1$ satisfy $h_u = o(1)$. Then*

$$\sup_{z\in(0,1)} \left|\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right] - f_Z^2(z)\tau_{jk}(z)\right| = O(h^2), \tag{51}$$

$$\sup_{z\in(0,1)} \left|\mathbb{E}\left[\mathbb{U}_n\left[\omega_z\right]\right] - f_Z^2(z)\right| = O(h^2), \tag{52}$$

$$\sup_{z\in(0,1)} n^{-1}\mathbb{E}\left[u_n\left[g_{z|(j,k)}\right] \cdot u_n\left[\omega_z\right]\right] = O\big((nh)^{-1}\big), \tag{53}$$

$$\sup_{z\in(0,1)} n^{-1}\mathbb{E}\big[\left(u_n\left[\omega_z\right]\right)^2\big] = O\big((nh)^{-1}\big). \tag{54}$$

We defer the proof of the above two lemmas to Appendix E in the supplementary material.

Using Lemma 12 and Lemma 13, we have

$$\begin{aligned}
\inf_{z\in(0,1)} \mathbb{U}_n[\omega_z] &\ge \inf_{z\in(0,1)} \mathbb{E}[\mathbb{U}_n[\omega_z]] - \sup_{z\in(0,1)} n^{-1/2}|u_n[\omega_z]| \ge \underline{f}_Z^2/2, \\
\sup_{z\in(0,1)} \mathbb{U}_n[\omega_z] &\le \sup_{z\in(0,1)} \mathbb{E}[\mathbb{U}_n[\omega_z]] + \sup_{z\in(0,1)} n^{-1/2}|u_n[\omega_z]| \le 2\bar{\mathrm{f}}_Z^2,
\end{aligned} \tag{55}$$

with probability $1 - 1/d$ for sufficiently large n. The last inequality is due to the fact that f_Z is bounded from above and below, $h = o(1)$ and $\log(1/h)/nh = o(1)$.

Combining the above display with Lemma 19, we have

$$\begin{aligned}
&\left|\sqrt{nh} \cdot \widehat{S}_{z|(j,k)}\big(\widehat{\boldsymbol{\Omega}}_{k\setminus j}(z)\big) - [\mathbb{U}_n[\omega_z]]^{-1}\mathbb{G}_n\big[J_{z|(j,k)}\big]\right| \\
&\quad\le \left|\sqrt{nh} \cdot \mathbb{U}_n[\omega_z]\widehat{S}_{z|(j,k)}\big(\widehat{\boldsymbol{\Omega}}_{k\setminus j}(z)\big) - \mathbb{G}_n\big[J_{z|(j,k)}\big]\right| \cdot \Big(\inf_{z\in(0,1)} \mathbb{U}_n[\omega_z]\Big)^{-1} \le 2\underline{\mathrm{f}}_Z^{-2}n^{-c}.
\end{aligned} \tag{56}$$

Therefore, it suffices to derive the limiting distribution of $\mathbb{G}_n\big[J_{z|(j,k)}\big]$.

In order to apply central limit theorem to $\mathbb{G}_n\big[J_{z|(j,k)}\big]$ we check Lyapunov's condition. By the definition of $g^{(1)}_{z|(j,k)}$ in (41) and $\omega^{(1)}_z$ in (44), we have $\mathbb{E}[J_{z|(j,k)}(Y_i)] = 0$ for all $i \in [n]$. The matrix $\mathbf{\Theta}_z$ defined in (11) can be rewritten as

$$(\mathbf{\Theta}_z)_{jk} = \pi \cos\left(\tau_{jk}(z)\frac{\pi}{2}\right)\sqrt{h}\cdot\left[g^{(1)}_{z|(j,k)}(Y) - \tau_{jk}(z)\omega^{(1)}_z(Z)\right]. \tag{57}$$

In order to apply the Lyapunov condition to show the asymptotic normality, we begin to control the third moments of $\omega^{(1)}_z$ and $g^{(1)}_{z|(j,k)}$. We bound the third moment of $\omega^{(1)}_z(Z)$ by

$$\begin{aligned}
\sup_z \mathbb{E}\Big[\big|\omega^{(1)}_z(Z)\big|^3\Big] &= \sup_z |\mathbb{E}[K_h(z-Z)]|^3\mathbb{E}\Big[\big|K_h(z-Z) - \mathbb{E}[K_h(z-Z)]\big|^3\Big] \\
&\le \sup_z 8|\mathbb{E}[K_h(z-Z)]|^3\mathbb{E}\Big[\big|K_h(z-Z)\big|^3\Big] \\
&= \sup_z 8\big|f_Z(z) + O(h^2)\big|^3\cdot h^{-2}\int |K^3(t)|f_Z(z+th)dt \\
&\lesssim h^{-2}\cdot \bar{\mathrm{f}}_Z^4\int |K^3(t)|dt,
\end{aligned} \tag{58}$$

where we used that $(1+x)^3 \le 4(1+x^3)$ for $x > 0$ and $|\mathbb{E}[K_h(z-Z)]|^3 \le \mathbb{E}[|K_h(z-Z)|^3]$. By the definition of $g^{(1)}_{z|(j,k)}$, we also have

$$\mathbb{E}\Big[\big|g^{(1)}_{z|(j,k)}(Y)\big|^3\Big] \le 4\mathbb{E}\Big[\big|\mathbb{E}[g_{z|(j,k)}(Y',Y)\mid Y']\big|^3\Big] + 4\Big|\mathbb{E}\big[g_{z|(j,k)}(Y',Y)\big]\Big|^3, \tag{59}$$

where Y' is an independent copy of Y. Using (99),

$$\sup_z\Big|\mathbb{E}\big[g_{z|(j,k)}(Y',Y)\big]\Big|^3 = \sup_z\big|f_Z^2(z)\tau_{jk}(z) + O(h^2)\big|^3 \lesssim \bar{\mathrm{f}}_Z^6. \tag{60}$$

We now bound the conditional expectation in (59). From (A.3) of Mitra and Zhang (2014), denoting $\boldsymbol{x}' = (x'_1,\ldots,x'_d)^T$ and $y' = (z', \boldsymbol{x}')$, we have

$$\begin{aligned}
&\mathbb{E}\left[g_{z|(j,k)}(y',Y)|Z=s\right] = K_h(z'-z)K_h(s-z)\varphi\left(x'_j, x'_k, \mathbf{\Sigma}_{jk}(s)\right), \text{ where} \\
&\qquad \varphi(u,v,\rho) = 2\int \mathrm{sign}(u-x)\phi(x)\cdot\Phi\left(\frac{v-\rho x}{\sqrt{1-\rho^2}}\right)dx,
\end{aligned} \tag{61}$$

with $\phi(\cdot)$ and $\Phi(\cdot)$ being the probability density and cumulative distribution function of a standard normal variable, respectively. From (41), we have

$$\begin{aligned}
\mathbb{E}\left[g_{z|(j,k)}(y',Y)\right] &= \mathbb{E}\big[\mathbb{E}\left[g_{z|(j,k)}(y',Y)|Z\right]\big] \\
&= K_h(z'-z)\int K_h(s-z)\varphi\left(x'_j, x'_k, \mathbf{\Sigma}_{jk}(s)\right)f_Z(s)ds.
\end{aligned} \tag{62}$$

Let $\phi_\rho(x,y)$ be the density function of bivariate normal distribution with mean zero, variance one and correlation ρ. Notice that $\sup_{x,y,\rho}|\varphi(x,y,\rho)| \le 2$. Since the minimum eigenvalue

of $\mathbf{\Sigma}(z)$ is strictly positive for any z, there exists a $\gamma_\sigma < 1$ such that $\sup_z|\mathbf{\Sigma}_{jk}(z)| \le \gamma_\sigma < 1$ for any $j \ne k$. We also have $\sup_{x,y,\rho}|\phi_\rho(x,y)| \le (2\pi\sqrt{1-\gamma_\sigma^2})^{-1}$. By (62), for any $z \in (0,1)$

$$\begin{aligned}
&\mathbb{E}\Big[\big|\mathbb{E}[g_{z|(j,k)}(Y',Y)\mid Y']\big|^3\Big] \\
&= \frac{2}{\pi}\int h^{-2}K^3(t_1)f_Z(z+t_1h)\times \\
&\qquad\qquad \times\left|\int K(t_2)f_Z(z+t_2h)\varphi\left(u,v,\mathbf{\Sigma}_{jk}(z+t_2h)\right)dt_2\right|^3\phi_{\mathbf{\Sigma}_{jk}(z+t_1h)}(u,v)dt_1 \\
&\lesssim \frac{1}{h^2\pi\sqrt{1-\gamma_\sigma^2}}\int K^3(t_1)f_Z(z+t_1h)|f_Z(z)+O(h^2)|^3dt_1 \le h^{-2}\cdot\frac{\bar{\mathrm{f}}_Z^4\|K\|_3^3}{\pi\sqrt{1-\gamma_\sigma^2}}.
\end{aligned} \tag{63}$$

Combining (60), (63) with (59), we have

$$\mathbb{E}\Big[\big|g^{(1)}_{z|(j,k)}(Y)\big|^3\Big] \lesssim h^{-2}\left(\frac{\bar{\mathrm{f}}_Z^4\|K\|_3^3}{\pi\sqrt{1-\gamma_\sigma^2}}\right). \tag{64}$$

By the assumption of Theorem 4, there exists a $\theta_{\min} > 0$ such that

$$\mathrm{Var}(J_{z_0|(j,k)}(Y)) = \mathbb{E}(\mathbf{\Omega}_j^T(z_0)\mathbf{\Theta}_{z_0}\mathbf{\Omega}_k(z_0))^2 \ge \theta_{\min}\|\mathbf{\Omega}_j(z_0)\|_2^2\|\mathbf{\Omega}_k(z_0)\|_2^2. \tag{65}$$

We are now ready to check the Lyapunov's condition. We have

$$\begin{aligned}
\frac{\sum_{i=1}^n\mathbb{E}|J_{z_0|(j,k)}(Y_i)|^3}{n^{3/2}\mathrm{Var}^{3/2}(J_{z_0|(j,k)}(Y))} &\overset{(65)}{\le} \frac{(\theta_{\min}n)^{-3/2}}{\|\mathbf{\Omega}_j^T\|_2^3\|\mathbf{\Omega}_k\|_2^3}\sum_{i=1}^n\mathbb{E}|J_{z_0|(j,k)}(Y_i)|^3 \\
&\lesssim \frac{1}{n^{3/2}}\sum_{i=1}^n\mathbb{E}\|\mathrm{Vec}((\mathbf{\Theta}_{z_0})_{\mathcal{S}_{j,z_0},\mathcal{S}_{k,z_0}})\|_2^3.
\end{aligned} \tag{66}$$

Since $|\mathbf{\Theta}^{(i)}_{jk}| \le \pi\sqrt{h}|g^{(1)}_{z_0|(j,k)}(Y)| + \pi\sqrt{h}|\tau_{jk}(z_0)\omega^{(1)}_{z_0}(Z)|$, we have

$$\begin{aligned}
&\mathbb{E}\|\mathrm{Vec}((\mathbf{\Theta}_{z_0})_{\mathcal{S}_{j,z_0},\mathcal{S}_{k,z_0}})\|_2^3 \\
&\qquad \le |\mathcal{S}_{j,z_0}|^{3/2}|\mathcal{S}_{k,z_0}|^{3/2}\pi^3h^{3/2}\Big(\mathbb{E}\Big[\big|g^{(1)}_{z_0|(j,k)}(Y)\big|^3\Big] + |\tau_{jk}(z_0)|^3\mathbb{E}\Big[\big|\omega^{(1)}_{z_0}(Z)\big|^3\Big]\Big).
\end{aligned}$$

Using (58) and (64), together with $s^3/\sqrt{nh} = o(1)$,

$$\frac{\sum_{i=1}^n\mathbb{E}|J_{z_0|(j,k)}(Y_i)|^3}{n^{3/2}\mathrm{Var}^{3/2}(J_{z_0|(j,k)}(Y))} \lesssim \frac{s^3}{\sqrt{nh}} = o(1),$$

which implies that the Lyapunov's condition is satisfied. Moreover, by Lemma 12, for any $z_0 \in (0,1)$, $\mathbb{U}_n[\omega_{z_0}] - \mathbb{E}[\mathbb{U}_n[\omega_{z_0}]]$ converges to 0 in probability. Combining this with (52) and $h = o(1)$, we have that $\mathbb{U}_n[\omega_{z_0}]$ converges to $f_Z^2(z_0)$ in probability. Therefore, by the central limit theorem and Slutsky's theorem, for any $j,k \in [d]$,

$$\frac{[\mathbb{U}_n[\omega_{z_0}]]^{-1}\mathbb{G}_n\big[J_{z_0|(j,k)}\big]}{f_Z^{-2}(z_0)\big\{\mathbb{E}\big[\big(\mathbf{\Omega}_j^T\mathbf{\Theta}_{z_0}\mathbf{\Omega}_k\big)^2\big]\big\}^{1/2}} \rightsquigarrow N(0,1).$$

Combining with (56), the proof is complete.

B.2 Proof of Theorem 3

The strategy is to apply the theory for multiplier bootstrap developed in Chernozhukov et al. (2013) to the score function in (16). A similar strategy is applied to prove Theorem 4, whose proof is deferred to Section F.

Let $T_0(z) := \max_{(j,k)\in E^c} \mathbb{G}_n[J_{z|(j,k)}]$ and

$$S_0^B(z_0) = \max_{(j,k)\in E^c} \mathbb{G}_n^{\xi}\left[J_{z_0|(j,k)}\right] = \max_{(j,k)\in E^c} \frac{1}{\sqrt{n}} \sum_{i=1}^{n} J_{z_0|(j,k)}(Y_i)\cdot \xi_i$$

be the bootstrap counterpart to $T_0(z_0)$. Recall that $S^B(z)$ is defined in (19). We denote

$$\Delta_z := \max_{(j,k),(j',k')\in E^c} \left| \frac{1}{n}\sum_{i=1}^{n} \Big(J_{z|(j,k)}(Y_i)J_{z|j'k'}(Y_i) - \mathbb{E}[J_{z|(j,k)}(Y_i)J_{z|j'k'}(Y_i)] \Big) \right|.$$

In order to Use Theorem 3.2 in Chernozhukov et al. (2013), we check four conditions.

1. With probability $1-1/d$,
$$|S(z_0) - T_0(z_0)| \le \sup_{j,k\in[d]} \left| \sqrt{nh}\cdot \mathbb{U}_n[\omega_{z_0}]\widehat{S}_{z_0|(j,k)} \left(\widehat{\mathbf{\Omega}}_{k\backslash j}(z_0)\right) - \mathbb{G}_n\left[J_{z_0|(j,k)}\right] \right| \le n^{-c}.$$
2. With probability $1-1/d$, $\mathbb{P}_\xi\big(|S^B(z_0) - S_0^B(z_0)| \le n^{-c}\big) \ge 1 - 1/d$.
3. There exists a constant $c>0$, such that $\mathrm{Var}(\mathbb{G}_n\big[J_{z_0|(j,k)}\big]) > c$.
4. There exists a constant $c>0$, such that $\mathbb{P}(\Delta_{z_0} > n^{-c}) \le n^{-c}$.

The first condition is proven in Lemma 19. We defer the proof of the second condition in Lemma 20. The third condition is due to (65). The following of the proof verifies the last condition.

Define

$$\gamma_{z|(j,k,j',k')}(Y_i) = J_{z|(j,k)}(Y_i)J_{z_0|(j',k')}(Y_i) - \mathbb{E}[J_{z|(j,k)}(Y_i)J_{z|(j',k')}(Y_i)]. \tag{67}$$

We will apply Lemma A.1 in van de Geer (2008) on the concentration of empirical processes. For the self-consistence, we has restated the lemma in Lemma 34. In order to apply Lemma 34, we need to bound $\|\gamma_{z|(j,k,j',k')}\|_\infty$ and $n^{-1}\sum_{i=1}^n \mathbb{E}[\gamma^2_{z|(j,k,j',k')}(Z_i)]$. By the definition of $J_{z_0|(j,k)}$ in (48), we have for any $z_0\in(0,1)$,

$$\begin{aligned}
&\max_{(j,k),(j',k')\in E^c} \|\gamma_{z_0|(j,k,j',k')}\|_\infty \\
&\quad\le \max_{i\in[n]} \max_{(j,k)\in E^c} 2|J_{z_0|(j,k)}(Y_i)|^2 \\
&\quad\le \max_{(j,k)\in E^c} 2\|\mathbf{\Omega}_j(z_0)\|_1^2 \|\mathbf{\Omega}_k(z_0)\|_1^2 \cdot \pi^2 h \cdot \left(\|g^{(1)}_{z_0|(j,k)}(Y_i)\|_\infty + \|\omega^{(1)}_{z_0}(Z_i)\|_\infty \right)^2 \\
&\quad\le CM^2h^{-1},
\end{aligned} \tag{68}$$

where the second inequality follows from Hölder's inequality, similar to (66), and the final inequality is due to (84) and (94). Since the right hand size of (68) does not depend on z_0, we also have

$$\max_{z\in(0,1)} \max_{(j,k),(j',k')\in E^c} \|\gamma_{z|(j,k,j',k')}\|_\infty \le CM^2h^{-1} \text{ and} \tag{69}$$

$$\max_{z\in(0,1)} \max_{(j,k),(j',k')\in E^c} \mathbb{E}[\gamma^2_{z|(j,k,j',k')}(Z_i)] \le \max_{z\in(0,1)} \max_{(j,k),(j',k')\in E^c} \|\gamma_{z|(j,k,j',k')}\|_\infty^2 \le CM^4h^{-2}. \tag{70}$$

According to Lemma 34, the expectation of Δ_{z_0} is bounded by

$$\mathbb{E}[\Delta_{z_0}] \lesssim \sqrt{\frac{2M^4\log(2d)}{nh^2}} + \frac{M^2\log(2d)}{nh}.$$

Since $\log d/(nh^2) = o(n^{-\epsilon})$, there exists $c_1>0$ such that $\mathbb{E}[\Delta_{z_0}] \le n^{-2c_1}$ for sufficiently large n. By Markov's inequality, $\mathbb{P}(\Delta_{z_0} > n^{-c_1}) \le n^{c_1}\mathbb{E}[\Delta_{z_0}] \le n^{-c_1}$ for sufficiently large n, which verifies the last condition.

By Theorem 3.2 in Chernozhukov et al. (2013),

$$\sup_{\alpha\in(0,1)} \left| \mathbb{P}_{H_0}\big(\psi_{z_0|G}(\alpha)=1\big) - \alpha \right| \lesssim n^{-c},$$

for some constant $c>0$, which completes the proof.

Appendix C. Proof of Theorem 8

In this section, we prove the minimax rate of convergence for estimating time-varying inverse covariance matrices. Section C.1 proves the minimax rate in terms of $\|\cdot\|_{\max}$ norm, while Section C.2 establishes the minimax rate for the $\|\cdot\|_1$ norm.

At a high-level, both results will use Le Cam's lemma applied to a finite collection of time-varying inverse covariance matrices. Given a time-varying inverse covariance matrix $\mathbf{\Omega}(\cdot)$, let $\mathbb{P}_{\mathbf{\Omega}}$ be the joint distribution of $(\boldsymbol{X}_1, Z_1), \ldots, (\boldsymbol{X}_n, Z_n)$ where $(\boldsymbol{X}_i, Z_i)$ are independent copies of $(\boldsymbol{X}, Z)$ with $Z \sim \mathrm{Unif}((0,1))$ and $\boldsymbol{X} \mid Z \sim N(0, \mathbf{\Omega}(z)^{-1})$. Let $\mathcal{U}_0 = \{\mathbf{\Omega}_0(\cdot), \mathbf{\Omega}_1(\cdot), \ldots, \mathbf{\Omega}_m(\cdot)\}$ be a collection of time-varying inverse covariance matrices, which are going to be defined later. With these we define the mixture distribution $\overline{\mathbb{P}} = m^{-1}\sum_{\ell=1}^m \mathbb{P}_{\mathbf{\Omega}_\ell}$. For two measures $\mathbb{P}$ and $\mathbb{Q}$, the total variation is given as $\|\mathbb{P}\wedge\mathbb{Q}\| := \int (d\mathbb{P}/d\mu)\wedge(d\mathbb{Q}/d\mu)d\mu$, where $d\mu$ is the Lebesgue measure. Now, Le Cam's lemma (Le Cam, 1973) gives us the following lower bound.

Lemma 14 *Let $\widehat{\mathbf{\Omega}}(\cdot)$ be any estimator of $\mathbf{\Omega}(\cdot)$ based on the data generated from the distribution family $\{\mathbb{P}_{\mathbf{\Omega}} \mid \mathbf{\Omega}\in\mathcal{U}_0\}$. Then*

$$\max_{1\le\ell\le m} \mathbb{E}\left[\sup_{z\in(0,1)} \|\widehat{\mathbf{\Omega}}(z) - \mathbf{\Omega}_\ell(z)\|_{\max} \right] \ge r_{\min} \|\overline{\mathbb{P}} \wedge \mathbb{P}_{\mathbf{\Omega}_0}\|,$$

where $r_{\min} = \min_{1\le\ell\le m} \sup_{z\in(0,1)} \|\mathbf{\Omega}_0(z) - \mathbf{\Omega}_\ell(z)\|_{\max}$.

We will use the above lemma in the following two subsections.

C.1 Proof of Maximum Norm in (36)

We start by constructing the collection of inverse covariance matrices $\mathcal{U}_0$. Let $\mathbf{\Omega}_0(\cdot) \equiv \mathbf{I}$. Let $M_0 = \lceil c_0(n/\log(dn))^{1/5} \rceil$ where c_0 is some constant to be determined. Then

$$\mathcal{U}_0 = \Big\{ \mathbf{\Omega}_{(j,m)}(\cdot) \mid \mathbf{\Omega}^{-1}_{(j,m)}(z) = \mathbf{\Sigma}_{(j,m)}(z) = \mathbf{I} + \tau_m(z)\mathbf{E}_{jj}, z \in (0,1), j \in [d-1], m \in [M_0] \Big\},$$

where $\mathbf{E}_{jj} = \mathbf{e}_j \mathbf{e}_{j+1}^T + \mathbf{e}_{j+1}\mathbf{e}_j^T$, $\mathbf{e}_j$ is the j-th canonical basis in $\mathbb{R}^d$ and for any $m \in [M_0]$,

$$\tau_m(z) = Lh^2 K_0\Big(\frac{z - z_m}{h}\Big), \quad z_m = \frac{m - 1/2}{M_0}, \quad h = 1/M_0. \tag{71}$$

Here, $K_0(\cdot)$ is any function supported on $(-1/2, 1/2)$ and satisfying $\|K_0\|_{\sup} \le K_{\max}$. For example, consider $K_0(\cdot) = a\psi(2z)$, where $\psi(z) = \exp(-1/(1-z^2))\mathbb{1}(|z| \le 1)$, for some sufficiently small a (Tsybakov, 2009). It is easy to check that $\mathcal{U}_0 \subset \overline{\mathcal{U}}_s(M, \rho, L)$ if $n^{-1}\log(dn) = o(1)$.

For any $j \in [d-1]$, $m \in [M_0]$, we have

$$\sup_{z \in (0,1)} \|\mathbf{\Omega}_{(j,m)}(z) - \mathbf{\Omega}_0(z)\|_{\max} \ge \Big\| \frac{\tau_m(\cdot)}{1 - \tau_m^2(\cdot)} \Big\|_{\sup} \ge \|\tau_m\|_{\sup} \ge Lh^2 K_0(0)$$

by direct calculation, which gives us $r_{\min} \ge Lh^2 K_0(0) \asymp (\log(dn)/n)^{2/5}$.

In the remainder of the proof we show that for $\overline{\mathbb{P}} = ((d-1)M_0)^{-1} \sum_{j \in [d], m \in [M_0]} \mathbb{P}_{\mathbf{\Omega}_{(j,m)}}$, we have $\|\mathbb{P}_{\mathbf{\Omega}_0} \wedge \overline{\mathbb{P}}\| \ge 1/2$. Let f_{jm} be the density of $\mathbb{P}_{\mathbf{\Omega}_{(j,m)}}$ for $j \in [d-1], m \in [M_0]$ and f_0 the density of $\mathbb{P}_0$. Under our setting,

$$f_{jm}((\boldsymbol{x}_i, z_i)_{i=1}^n) = \prod_{i=1}^n g_{jm}(\boldsymbol{x}_i)\mathbb{1}\{z_i \in (0,1)\},$$

where g_{jm} is the density function of $N(0, \mathbf{\Sigma}_{(j,m)})$. Note that for any two densities f and f'

$$\int (f \wedge f') d\mu = 1 - \frac{1}{2}\int |f - f'| d\mu \ge 1 - \frac{1}{2}\Big(\int \frac{f^2}{f'} d\mu - 1 \Big)^{1/2}.$$

Therefore, it suffices to show that

$$\Delta := \int \Big(((d-1)M_0)^{-1} \sum_{j,m} f_{jm} \Big)^2 / f_0 \, d\mu - 1 \to 0. \tag{72}$$

Expanding the square of the mixture in (72), we have

$$\frac{1}{((d-1)M_0)^2} \Bigg\{ \sum_{j=1}^{d-1}\sum_{m=1}^{M_0} \int \frac{f_{jm}^2}{f_0} d\mu + \sum_{j=1}^{d-1} \sum_{m_1 \ne m_2} \int \frac{f_{jm_1} f_{jm_2}}{f_0} d\mu + \sum_{j_1 \ne j_2} \sum_{m_1, m_2 \in [M_0]} \int \frac{f_{j_1 m_1} f_{j_2 m_2}}{f_0} d\mu \Bigg\} - 1.$$

To proceed, we recall the following result of Ren et al. (2015) given in their equation (94). Let g_i be the density function of $N(0, \mathbf{\Sigma}_i)$ for $i = 0, 1, 2$. Then

$$\int \frac{g_1 g_2}{g_0} = \Big[\det\Big(\mathbf{I} - \mathbf{\Sigma}_0^{-1}(\mathbf{\Sigma}_1 - \mathbf{\Sigma}_0)\mathbf{\Sigma}_0^{-1}(\mathbf{\Sigma}_2 - \mathbf{\Sigma}_0) \Big) \Big]^{-1/2}. \tag{73}$$

Using the above display, for $j_1 \ne j_2$ and $m_1, m_2 \in [M_0]$, since $(\mathbf{\Sigma}_{j_1} - \mathbf{I})(\mathbf{\Sigma}_{j_2} - \mathbf{I}) = 0$, we have $\int f_{j_1 m_1} f_{j_2 m_2} / f_0 d\mu = 1$. For $|j_1 - j_2| = 1$, we have $\int f_{j_1 m_1} f_{j_2 m_2}/f_0 d\mu = [\det(\mathbf{I}_3 - \mathbf{M}_3)]^{-n/2} = 1$, where $\mathbf{M}_3 \in \mathbb{R}^{3\times 3}$ with $(\mathbf{M}_3)_{13} = \tau_{m_1}(z)\tau_{m_2}(z)$ and the other entries are zero. For any $m_1, m_2 \in [M_0]$ and $j \in [d-1]$, we have

$$\int \frac{f_{jm_1} f_{jm_2}}{f_0} d\mu = \prod_{1 \le i \le n} \int_0^1 \big(1 - \tau_{m_1}(z_i)\tau_{m_2}(z_i)\big)^{-1} dz_i \;\; = \Big[\int_0^1 \big(1 - \tau_{m_1}(z)\tau_{m_2}(z)\big)^{-1} dz \Big]^n. \tag{74}$$

If $m_1 \ne m_2$, since the supports of $\tau_{m_1}(\cdot)$ and $\tau_{m_2}(\cdot)$ are disjoint, (74) implies

$$\int f_{jm_1} f_{jm_2} / f_0 d\mu = 1.$$

Finally, if $m_1 = m_2 = m$, we have

$$\begin{aligned} \int \frac{f_{jm}^2}{f_0} d\mu &\le \Big[\int_0^1 \big(1 - \tau_m^2(z)\log^{4/5}(dn)\big)^{-1} dz \Big]^n \\ &\le \Big[\frac{M_0 - 1}{M_0} + \frac{1}{M_0}(1 - L^2h^4K_{\max}^2)^{-1} \Big]^n = \Big[1 + \frac{L^2h^4K_{\max}^2}{M_0(1 - L^2h^4K_{\max}^2)} \Big]^n. \end{aligned} \tag{75}$$

In summary,

$$\begin{aligned} \Delta &= \frac{1}{((d-1)M_0)^2} \sum_{j=1}^{d-1}\sum_{m=1}^{M} \Big(\int \frac{f_{jm}^2}{f_0} d\mu - 1 \Big) \\ &\le \exp\Big[-\log((d-1)M_0) + n\log\Big(1 + \frac{L^2h^4K_{\max}^2}{M_0(1 - L^2h^4K_{\max}^2)} \Big) \Big] - \frac{1}{(d-1)M_0}. \end{aligned}$$

Recall that $M_0 = \lceil c_0(n/\log(dn))^{1/5} \rceil$ and $h = 1/M_0$. We choose c_0 sufficiently large such that $c_0^5 > 1 - L^2K_{\max}^2$. Using $\log(1+x) \le x$ and $x/(1-x) \le 2x$ for $x \in (0, 1/2)$, we have

$$\Delta \le \exp\Big[-\log(d(c_0 n/\log(dn))^{1/5}) + c_0^{-5}L^2K_{\max}^2 \log(dn) \Big] - \frac{1}{c_0 dn^{1/5}} \to 0.$$

Since $r_{\min} \ge Lh^2K_0(0) \asymp (\log(dn)/n)^{2/5}$, the proof of (36) is complete by Lemma 14.

C.2 Proof of ℓ_1 Norm in (37)

In order to show the lower bound for $\|\cdot\|_1$, we need to construct a different $\mathcal{U}_0$. We still choose $\mathbf{\Omega}_0(\cdot) \equiv \mathbf{I}$. Let $\mathcal{B}$ be the set of matrices defined as

$$\mathcal{B} = \Big\{ \mathbf{B} \in \mathbb{R}^{d\times d} \Big| \, B = \begin{pmatrix} 0 & \boldsymbol{v} \\ \boldsymbol{v} & 0 \end{pmatrix} \text{ s.t. } \boldsymbol{v} \in \{0,1\}^{d-1}, \|\boldsymbol{v}\|_0 = s, \boldsymbol{v}_2 = 0 \Big\}.$$

With this, we define

$$\mathcal{U}_0' = \{\mathbf{\Omega}_{(j,m)}(\cdot) \mid \mathbf{\Omega}_{(j,m)}^{-1}(z) = \mathbf{\Sigma}_{(j,m)}(z) = \mathbf{I} + \tau_m(z)B_j, \text{ for } z \in (0,1), B_j \in \mathcal{B}, m \in [M_0]\},$$

where the index j corresponds to an element in the set $\mathcal{B}$ and the function $\tau_m(\cdot)$ is defined in (71). Let $D := |\mathcal{B}| = \binom{d-2}{s}$. We still choose $M_0 = \lceil c_0(n/\log(dn))^{1/5} \rceil$ for some constant c_0. It can be easily shown that $\mathcal{U}_0 \subset \overline{\mathcal{U}}_s(M, \rho, L)$ if $s^2 \log(dn)/n^{4/5} = o(1)$.

The rest of the proof is similar to the proof in Section C.1. For any $j \in [D]$, $m \in [M_0]$,

$$\sup_{z \in (0,1)} \|\mathbf{\Omega}_{(j,m)}(z) - \mathbf{\Omega}_0(z)\|_1 \geq s\|\tau_m\|_{\sup} \geq sLh^2 K_0(0),$$

giving $r_{\min} \geq sLh^2K_0(0) \asymp s(\log(dn)/n)^{2/5}$. We proceed to show $\|\mathbb{P}_{\mathbf{\Omega}_0} \wedge \overline{\mathbb{P}}\| \geq 1/2$, where $\overline{\mathbb{P}} = (DM_0)^{-1} \sum_{j \in [D], m \in [M_0]} \mathbb{P}_{\mathbf{\Omega}_{(j,m)}}$, by proving

$$\Delta := \int \Big(\frac{1}{DM_0} \sum_{j,m} f_{jm}\Big)^2 / f_0 \, d\mu - 1 \to 0.$$

We establish the above display by modifying the proof of Lemma 2 in Ren et al. (2015).

Let $J(j_1, j_2) = \text{Vec}(B_{j_1})^T \text{Vec}(B_{j_2})/2$, where $\text{Vec}(\mathbf{M}) = (\mathbf{M}_1^T, \ldots, \mathbf{M}_d^T)^T$ for any matrix $\mathbf{M} = [\mathbf{M}_1, \ldots, \mathbf{M}_d]$. From (73) and the definition of $\mathcal{B}$, we have

$$\begin{aligned} \int \frac{f_{j_1 m_1} f_{j_1 m_2}}{f_0} d\mu &= \Big[\int_0^1 \Big[\det\Big(\mathbf{I} - \tau_{m_1}(z)\tau_{m_2}(z) B_{j_1} B_{j2}\Big)\Big]^{-1/2} dz\Big]^n \\ &= \Big[\int_0^1 (1 - J(j_1, j_2)\tau_{m_1}(z)\tau_{m_2}(z))^{-1} dz\Big]^n. \end{aligned} \tag{76}$$

Similar to (74), when $m_1 \neq m_2$, (76) yields that $\int f_{j_1 m_1} f_{j_2 m_2}/f_0 d\mu = 1$. Similar to (75), we also have

$$\int \frac{f_{j_1 m} f_{j_2 m}}{f_0} d\mu \leq \Big[1 + \frac{2J(j_1, j_2) L^2 h^4 K_{\max}^2}{M_0}\Big]^n.$$

Since

$$\big|\{(j_1, j_2) \in [D]^2 \mid J(j_1, j_2) = j\}\big| = \binom{d-2}{s}\binom{s}{j}\binom{d-2-s}{s-j},$$

we have

$$\begin{aligned} \Delta &= \frac{1}{D^2 M_0^2} \sum_{m=1}^{M_0} \sum_{0 \leq j \leq s} \sum_{J(j_1, j_2) = j} \Big(\int \frac{f_{j_1 m} f_{j_2 m}}{f_0} d\mu - 1\Big) \\ &\leq \frac{1}{D^2 M_0^2} \sum_{m=1}^{M_0} \sum_{0 \leq j \leq s} \sum_{J(j_1, j_2) = j} \Big(\Big[1 + \frac{2jL^2 h^4 K_{\max}^2}{M_0}\Big]^n - 1\Big) \\ &\leq \frac{1}{D^2 M_0^2} \sum_{m=1}^{M_0} \sum_{0 \leq j \leq s} \binom{d-2}{s}\binom{s}{j}\binom{d-2-s}{s-j} \Big[1 + \frac{2jL^2 h^4 K_{\max}^2}{M_0}\Big]^n. \end{aligned}$$

Let $a_0 = 2c_0^{-5} L^2 K_{\max}^2$. Similar to the proof of Lemma 6 in Ren et al. (2015), we have

$$\Big[1 + \frac{2jL^2 h^4 K_{\max}^2 \log(dn)}{M_0}\Big]^n \leq \exp\big(2nM^{-1} jL^2 h^4 K_{\max}^2\big) \leq (nd)^{a_0 j}.$$

This further gives us

$$\begin{aligned} \Delta &\leq \frac{1}{M_0^2} \sum_{m=1}^{M_0} \sum_{1 \leq j \leq s} \binom{s}{j}\binom{d-2-s}{s-j} (nd)^{a_0 j} \Big/ \binom{d-2}{s} \\ &= \frac{1}{M_0^2} \sum_{m=1}^{M_0} \sum_{0 \leq j \leq s} \frac{1}{j!} \Big(\frac{s!(d-s)!}{(s-j)!}\Big)^2 \frac{(nd)^{a_0 j}}{(d-2)!(d-2s+j-2)!} \\ &\leq \frac{1}{M_0} \sum_{1 \leq j \leq s} \Big(\frac{s^2 (nd)^{a_0}}{d-s}\Big)^j, \end{aligned}$$

where the last inequality is due to $\frac{s!}{(s-j)!} \leq s^j$ and $\frac{(d-2)!(d-2s+j-2)!}{[(d-s)!]^2} \geq (d-s)^j$. By assumption $s^{-v} d \geq 1$ for some $v > 2$, and therefore

$$\Delta \leq \frac{1}{c_0(n/\log n)^{1/5}} \sum_{0 \leq j \leq s} (2d^{2/v-1}(dn)^{a_0})^j \leq \frac{2c_0(n/\log(dn))^{-1/5} d^{2/v-1+a_0} n^{a_0}}{(1 - 2d^{2/v-1+2a_0})},$$

for sufficiently large d, $d - s \geq d/2$, $d \geq n$. By choosing c_0 in $a_0 = 2c_0^{-5} L^2 K_{\max}^2$ sufficiently small, so that $a_0 < \min(1/5, 1/v - 1/2)$, we have $\Delta \to 0$. This completes the proof.

Appendix D. Convergence Rate of Kendall's Tau Estimator

In this section, we study the rate of convergence of kernel Kendall's tau estimator $\widehat{\tau}_{jk}(z)$ in (4) to $\tau_{jk}(z)$ uniformly in the bandwidth $h \in [h_l, h_u]$, the index $z \in (0,1)$ and the dimension $j, k \in [d]$. We start by establishing the bias-variance decomposition for $\widehat{\tau}_{jk}(z)$ and then show how to bound the bias and variance separately.

Recall that in (40), we define

$$g_{z|(j,k)}(y_i, y_{i'}) = \omega_z(z_i, z_{i'}) \operatorname{sign}(x_{ia} - x_{i'a}) \operatorname{sign}(x_{ib} - x_{i'b}),$$

and $\omega_z(z_i, z_{i'})$ is defined in (5). The estimator $\widehat{\tau}_{jk}(z)$ can be written as a quotient of two U-statistics

$$\widehat{\tau}_{jk}(z) = \mathbb{U}_n[g_{z|(j,k)}]/\mathbb{U}_n[\omega_z].$$

Recall that the operator $u_n[\cdot]$ is defined as

$$u_n[H] = \sqrt{n} \cdot \big(\mathbb{U}_n[H] - \mathbb{E}[\mathbb{U}_n[H]]\big)$$

for any bivariate function $H(x, x')$. With this, following an argument similar to that in Equation (3.45) of Pagan and Ullah (1999), we have the following decomposition

$$\begin{aligned} \widehat{\tau}_{jk}(z) &= \frac{\mathbb{E}[\mathbb{U}_n\left[g_{z|(j,k)}\right]] + \mathbb{U}_n\left[g_{z|(j,k)}\right] - \mathbb{E}[\mathbb{U}_n\left[g_{z|(j,k)}\right]]}{\mathbb{E}[\mathbb{U}_n[\omega_z]]} \left[1 + \frac{\mathbb{U}_n[\omega_z] - \mathbb{E}[\mathbb{U}_n[\omega_z]]}{\mathbb{E}[\mathbb{U}_n[\omega_z]]}\right]^{-1} \\ &= \frac{\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right]}{\mathbb{E}[\mathbb{U}_n[\omega_z]]} + \frac{u_n\left[g_{z|(j,k)}\right]}{\sqrt{n}\,\mathbb{E}[\mathbb{U}_n[\omega_z]]} - \frac{\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right] \cdot u_n\left[\omega_z\right]}{\sqrt{n}\left(\mathbb{E}[\mathbb{U}_n[\omega_z]]\right)^2} \\ &\quad + n^{-1} O\left(u_n\left[g_{z|(j,k)}\right] \cdot u_n\left[\omega_z\right] + \left(u_n\left[\omega_z\right]\right)^2\right), \end{aligned} \tag{77}$$

under the condition that

$$\left|\frac{u_n\left[\omega_z\right]}{\sqrt{n}\mathbb{E}[\mathbb{U}_n[\omega_z]]}\right| < 1 \quad \text{and} \quad \mathbb{E}[\mathbb{U}_n[\omega_z]] \neq 0. \tag{78}$$

Taking expectation on both sides of (77), we obtain

$$\mathbb{E}\left[\widehat{\tau}_{jk}(z)\right] = \frac{\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right]}{\mathbb{E}\left[\mathbb{U}_n[\omega_z]\right]} + n^{-1}O\bigg(\mathbb{E}\Big[u_n\left[g_{z|(j,k)}\right]\cdot u_n\left[\omega_z\right]\Big] + \mathbb{E}\left[\left(u_n\left[\omega_z\right]\right)^2\right]\bigg). \tag{79}$$

With this, we are ready to prove Lemma 9 and Lemma 10.

D.1 Proof of Lemma 9

We first check that the condition in (78) is satisfied under the assumptions. Using (50) and (52), for sufficiently large n,

$$\sup_{j,k\in[d]}\sup_{z\in(0,1)}\left|\frac{u_n\left[\omega_z\right]}{\sqrt{n}\mathbb{E}[\mathbb{U}_n[\omega_z]]}\right| \lesssim \sqrt{\frac{\log(d/h)\vee\log\left(\delta^{-1}\log\left(h_uh_l^{-1}\right)\right)}{nh}}\cdot\frac{1}{f_Z^2(z)+O(h^2)} < 1.$$

Since f_Z is bounded from below, $\mathbb{E}[\mathbb{U}_n[\omega_z]] = f_Z^2(z)+O(h^2) \geq \mathrm{f}_Z/2 > 0$ for large enough n. Therefore, condition in (78) holds and the expansion in (77) is valid.

From (77) and (79), we have

$$\widehat{\tau}_{jk}(z,h) - \mathbb{E}\left[\widehat{\tau}_{jk}(z,h)\right] = \underbrace{\frac{u_n\left[g_{z|(j,k)}\right]}{\sqrt{n}\,\mathbb{E}[\mathbb{U}_n[\omega_z]]}}_{I_1} - \underbrace{\frac{\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right]\cdot u_n\left[\omega_z\right]}{\sqrt{n}\left(\mathbb{E}[\mathbb{U}_n[\omega_z]]\right)^2}}_{I_2} + I_3, \tag{80}$$

where

$$I_3 = n^{-1}O\left(u_n\left[g_{z|(j,k)}\right]\cdot u_n\left[\omega_z\right] + \left(u_n\left[\omega_z\right]\right)^2 + \mathbb{E}\Big[u_n\left[g_{z|(j,k)}\right]\cdot u_n\left[\omega_z\right]\Big] + \mathbb{E}\left[\left(u_n\left[\omega_z\right]\right)^2\right]\right).$$

We bound I_1, I_2 and I_3 separately. Using (50) and (52), we have that

$$\begin{aligned}&\sup_{j,k\in[d]}\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\frac{\sqrt{nh}\cdot|I_1|}{\sqrt{\log(d/h)\vee\log\left(\delta^{-1}\log\left(h_uh_l^{-1}\right)\right)}}\right|\\ &\leq \sup_{j,k\in[d]}\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\frac{\sqrt{h}}{\sqrt{\log(d/h)\vee\log\left(\delta^{-1}\log\left(h_uh_l^{-1}\right)\right)}}\frac{|u_n\left[g_{z|(j,k)}\right]|}{f_Z^2(z)+O(h^2)}\right| \leq C,\end{aligned}$$

with probability $1-\delta$ for large enough n. Similarly, using (50), (51) and (52), we also have

$$\begin{aligned}&\sup_{j,k\in[d]}\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\frac{\sqrt{nh}\cdot|I_2|}{\sqrt{\log(d/h)\vee\log\left(\delta^{-1}\log\left(h_uh_l^{-1}\right)\right)}}\right|\\ &\leq \sup_{j,k\in[d]}\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\frac{\sqrt{h}}{\sqrt{\log(d/h)\vee\log\left(\delta^{-1}\log\left(h_uh_l^{-1}\right)\right)}}\frac{|u_n\left[\omega_z\right]|(f_Z^2(z)\tau_{jk}(z)+O(h^2))}{(f_Z^2(z)+O(h^2))^2}\right| \leq C,\end{aligned}$$

with probability $1-\delta$. Finally, using (50), (53) and (54), we have

$$\begin{aligned}&\sup_{j,k\in[d]}\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\frac{nh\cdot|I_3|}{\log(d/h)\vee\log\left(\delta^{-1}\log\left(h_uh_l^{-1}\right)\right)}\right|\\ &\lesssim \sup_{j,k\in[d]}\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\frac{2h}{\log(d/h)\vee\log\left(\delta^{-1}\log\left(h_uh_l^{-1}\right)\right)}\Big(u_n\left[\omega_z\right]\vee u_n\left[g_{z|(j,k)}\right]\Big)^2\right|\\ &\quad+\sup_{j,k\in[d]}\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\frac{nh\cdot O((nh)^{-1})}{\log(d/h)\vee\log\left(\delta^{-1}\log\left(h_uh_l^{-1}\right)\right)}\right| \leq C,\end{aligned}$$

with probability $1-\delta$.

Combining the above three displays with (80) completes the proof.

D.2 Proof of Lemma 10

It follows from Lemma 13 and the decomposition in (79) that

$$\begin{aligned}&\sup_{j,k\in[d]}\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\frac{|\mathbb{E}[\widehat{\tau}_{jk}(z)]-\tau_{jk}(z)|}{h^2+1/(nh)}\\ &\leq \sup_{j,k\in[d]}\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left[\frac{f_Z^2(z)\tau_{jk}(z)+O(h^2)}{f_Z^2(z)+O(h^2)}-\tau_{jk}(z)+O((nh)^{-1})\right]\frac{1}{h^2+(nh)^{-1}}\\ &\leq \sup_{j,k\in[d]}\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left[\frac{O(h^2+(nh)^{-1})}{f_Z^2(z)+O(h^2)}\right]\frac{1}{h^2+(nh)^{-1}} \leq C.\end{aligned}$$

Appendix E. Concentration of U-statistics

In this section, we study certain properties of the U-statistics used in this paper. We state and prove Lemma 12 and Lemma 13, which were used to establish results on the rate of convergence of Kendall's tau estimator in Appendix D. In particular, we will prove the following two results in this section, with the notations on U-statistics and empirical processes defined in Appendix D.

E.1 Proof of Lemma 12

At a high-level, we will use the Hoeffding decomposition to represent the U-statistics $\mathbb{U}_n[\omega_z]$ and $\mathbb{U}_n[g_{z|(j,k)}]$ defined in (43) and (46). Next, we will use concentration inequalities for suprema of empirical processes and U-statistics to bound individual terms in the decomposition.

Recall that (43) and (46) give

$$n^{-1/2}\cdot u_n\left[g_{z|(j,k)}\right] = \mathbb{U}_n\left[g_{z|(j,k)}\right] - \mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right] = 2\mathbb{E}_n\left[g^{(1)}_{z|(j,k)}(Y_i)\right] + \mathbb{U}_n\left[g^{(2)}_{z|(j,k)}\right]$$

and

$$n^{-1/2}\cdot u_n\left[\omega_z\right] = \mathbb{U}_n[\omega_z] - \mathbb{E}\left[\mathbb{U}_n[\omega_z]\right] = 2\mathbb{E}_n\left[\omega_z^{(1)}\right] + \mathbb{U}_n\left[\omega_z^{(2)}\right].$$

In order to bound $u_n[\omega_z]$ and $u_n\left[g_{z|(j,k)}\right]$ it is sufficient to bound $g^{(1)}_{z|(j,k)}$, $g^{(2)}_{z|(j,k)}$, $\omega^{(1)}_z$ and $\omega^{(2)}_z$. We do so in the following lemmas.

Lemma 15 *We assume $n^{-1}\log d = o(1)$ and the bandwidths $0 < h_l < h_u < 1$ satisfy $h_l n/\log(dn) \to \infty$ and $h_u = o(1)$. There exist a universal constant $C > 0$ such that*

$$\sup_{j,k\in[d]}\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\mathbb{G}_n\left[\frac{\sqrt{h}g^{(1)}_{z|(j,k)}}{\sqrt{\log(d/h)\vee\log\left(\delta^{-1}\log\left(h_u h_l^{-1}\right)\right)}}\right]\right| \le C \tag{81}$$

with probability $1-\delta$.

Proof The general strategy to show (81) can be separated into two steps.

Step 1. Splitting the supreme over $h \in [h_l, h_u]$ into smaller intervals such that the empirical process (81) is easier to bound for each interval. Let S be the smallest integer such that $2^S h_l \ge h_u$. Note that $S \le \log_2(h_u/h_l)$ and $[h_l, h_u] \subseteq \cup_{\ell=1}^S [2^{\ell-1}h_l, 2^\ell h_l] =: \mathcal{H}_\ell$. Then

$$\mathbb{P}\left[\sup_{z,j,k}\sup_{h\in[h_l,h_u]}\left|\mathbb{G}_n\left[\sqrt{h}g^{(1)}_{z|(j,k)}\right]\right| \ge t\right] \le \sum_{\ell=1}^S \mathbb{P}\left[\sup_{j,k\in[d]}\sup_{h\in\mathcal{H}_\ell}\sup_{z\in(0,1)}\left|\mathbb{G}_n\left[\sqrt{h}g^{(1)}_{z|(j,k)}\right]\right| \ge t\right]. \tag{82}$$

Step 2. We apply Talagrand's inequality (Bousquet, 2002) to each term in the summation on the right hand side of (82).

Consider the class of functions

$$\mathcal{F}_\ell = \left\{\sqrt{h}g^{(1)}_{z|(j,k)}\,\middle|\, h\in\mathcal{H}_\ell, z\in(0,1), j,k\in[d]\right\}.$$

In order to apply Talagrand's inequality to functions in the class $\mathcal{F}_\ell$, we have to check three conditions:

- The class $\mathcal{F}_\ell$ is uniformly bounded;
- Bounding the variance of $g^{(1)}_{z|(j,k)}$;
- Bounding the covering number of $\mathcal{F}_\ell$

We verify the above three conditions next. First, we show that the class $\mathcal{F}_\ell$ is uniformly bounded.

Recall that in (62), we show that

$$\mathbb{E}\left[g_{z|(j,k)}(y', Y)\right] = K_h(z'-z)\int K_h(s-z)\varphi\left(x'_j, x'_k, \mathbf{\Sigma}_{jk}(s)\right) f_Z(s)ds, \tag{83}$$

where $\varphi(\cdot)$ is defined in (61). Since $|\varphi(u,v,\rho)| \le 2$ for any u, v, and ρ, and $h \in \mathcal{H}_\ell$, the above display gives us

$$\begin{aligned}\sup_{z\in(0,1)}\max_{j,k\in[d]}\left\|g^{(1)}_{z|(j,k)}\right\|_\infty &\le \frac{2\|K\|_\infty}{h}\sup_{z\in(0,1)}\int K_h(s-z)f_Z(s)ds + \sup_{z\in(0,1)}\max_{j,k\in[d]}\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right]\\ &\le \frac{2\|K\|_\infty}{h}\sup_{z\in(0,1)}\left(f_Z(z)+O(h^2)\right) + \bar{\mathrm{f}}_Z^2 + O(h^2) \le \frac{3\|K\|_\infty\bar{\mathrm{f}}_Z}{h},\end{aligned} \tag{84}$$

where the second inequality is due to (51). This results shows that the class $\mathcal{F}_\ell$ is uniformly bounded by $(2^\ell h_l)^{-1/2}3\|K\|_\infty\bar{\mathrm{f}}_Z$ and has the envelope $F_\ell = 3(2^{\ell-1}h_l)^{-1/2}\|K\|_\infty\bar{\mathrm{f}}_Z$.

Next, we bound the variance of $g^{(1)}_{z|(j,k)}$. Let $\bar{\varphi}_{u,v}(s) = \varphi(u,v,\mathbf{\Sigma}_{jk}(s))f_Z(s)$. We can rewrite (83) as

$$\mathbb{E}\left[g_{z|(j,k)}(y', Y)\right] = K_h(z'-z)\cdot(K_h * \bar{\varphi}_{u,v})(z),$$

where "$*$" denotes the convolution operator. Then we bound the convolution by

$$\sup_{u,v}\|K_h * \bar{\varphi}_{u,v}\|_\infty \le \sup_{u,v}\|K_h\|_1\|\bar{\varphi}_{u,v}\|_\infty \le 2\bar{\mathrm{f}}_Z, \tag{85}$$

where the first inequality follows using the Young's inequality for convolution. Now, for any fixed $h \in \mathcal{H}_\ell$ and $z \in (0,1)$, we have

$$\begin{aligned}&\sup_{z,j,k}\mathbb{E}\left[\left(\sqrt{h}g^{(1)}_{z|(j,k)}\right)^2\right] \le \sup_{z,j,k}\mathbb{E}\left[\max_{u,v}\left(\sqrt{h}g^{(1)}_{z|(u,v)}\right)^2\right]\\ &\le \sup_z 2\mathbb{E}\left[h\left(K_h(Z-z)\right)^2\right]\sup_{u,v}\|K_h * \bar{\varphi}_{u,v}\|^2_\infty + \sup_{z,j,k}2h\left\{\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right]\right\}^2\\ &\le C\bar{\mathrm{f}}_Z^2\cdot\sup_z\left(\int\frac{1}{h}K^2\left(\frac{x-z}{h}\right)f_Z(x)dx\right) + Ch\bar{\mathrm{f}}_Z^2 + O(h^3)\\ &\le C\bar{\mathrm{f}}_Z^2\sup_z(f_Z(z)\|K\|_2^2 + O(h^2)) \le C\bar{\mathrm{f}}_Z^3||K||_2^2.\end{aligned} \tag{86}$$

The reason why we show a stronger result above on the expectation of maximal is because we need (86) in the proof of Section F.

Using the above display, we can bound the variance for any $\ell \in [S]$,

$$\sigma_\ell^2 := \sup_{f\in\mathcal{F}_\ell}\mathbb{E}\left[f^2\right] \le C\bar{\mathrm{f}}_Z^3||K||_2^2. \tag{87}$$

Finally, we need a bound on the covering number of $\mathcal{F}_\ell$. Using Lemma 28 we have that

$$\sup_Q N(\mathcal{F}_\ell, L_2(Q), \epsilon) \le \frac{Cd^2}{(2^{\ell-1}h_\ell)^{v+9}\epsilon^{v+6}}.$$

Theorem 3.12 of Koltchinskii (2011) then gives us that for some universal constant C,

$$\mathbb{E}\left[\sup_{f\in\mathcal{F}_\ell}|n\mathbb{E}_n[f]|\right] \le C\sqrt{n\log\left(\frac{Cd}{2^{\ell-1}h_\ell}\right)} + \frac{C}{(2^{\ell-1}h_l)^{1/2}}\log\left(\frac{Cd}{2^{\ell-1}h_\ell}\right).$$

Furthermore, since $h_l n/\log(dn) \to \infty$, the above display simplifies to

$$\mathbb{E}\left[\sup_{f\in\mathcal{F}_\ell}|n\mathbb{E}_n[f]|\right] \le C\sqrt{n\log\left(\frac{Cd}{2^{\ell-1}h_l}\right)}. \tag{88}$$

Using Theorem 2.3 of Bousquet (2002) together with (87), (88), and $n^{-1}\log\left(dh^{-1}\right) = o(1)$, we obtain

$$\sup_{j,k\in[d]}\sup_{h\in\mathcal{H}_\ell}\sup_{z\in(0,1)}\left|\mathbb{G}_n\left[\sqrt{h}g^{(1)}_{z|(j,k)}\right]\right| \le C\left(\sqrt{\log\left(\frac{Cd}{2^{\ell-1}h_l}\right)} + \sqrt{\log(1/\delta)}\right) \tag{89}$$

with probability $1-\delta$. Observe that $2^{\ell-1}h_l \geq h/2$ for any $h \in \mathcal{H}_\ell$. Therefore, combining (89), (82), we obtain that for some constant $C > 0$

$$\sup_{j,k\in[d]} \sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \left| \mathbb{G}_n \left[\frac{\sqrt{h} g^{(1)}_{z|(j,k)}}{\sqrt{\log(d/h) \vee \log\left(\delta^{-1}\log\left(h_u h_l^{-1}\right)\right)}} \right] \right| \leq C,$$

with probability $1-\delta$. ■

Lemma 16 *We assume $n^{-1}\log d = o(1)$ and the bandwidths $0 < h_l < h_u < 1$ satisfy $h_l n/\log(dn) \to \infty$ and $h_u = o(1)$. There exists a universal constant $C > 0$ such that*

$$\sup_{j,k\in[d]} \sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \left| \frac{nh}{\log(d/h) \vee \log\left(\delta^{-1}\log\left(h_u h_l^{-1}\right)\right)} \mathbb{U}_n \left[g^{(2)}_{z|(j,k)} \right] \right| \leq C$$

with probability $1-\delta$.

Proof The method to prove this lemma is similar to the proof of Lemma 15. The only difference is that instead of bounding the empirical process, we bound a suprema of a U-statistic process. Therefore, we will use Theorem 33 instead of Talagrand's inequality.

We apply the trick of splitting $[h_l, h_u]$ again. Let S be the smallest integer such that $2^S h_l \geq h_u$. We have that $S \leq \log_2(h_u/h_l)$ and $[h_l, h_u] \subseteq \cup_{\ell=1}^S [2^{\ell-1}h_l, 2^\ell h_l]$. For simplicity, we define $\mathcal{H}_\ell = [2^{\ell-1}h_l, 2^\ell h_l]$. Therefore,

$$\mathbb{P}\left[\sup_{z,j,k} \sup_{h\in[h_l,h_u]} \left| h\mathbb{U}_n \left[g^{(2)}_{z|(j,k)} \right] \right| \geq t \right] \leq \sum_{j=1}^S \mathbb{P}\left[\sup_{z,j,k} \sup_{h\in\mathcal{H}_\ell} \left| h\mathbb{U}_n \left[g^{(2)}_{z|(j,k)} \right] \right| \geq t \right]. \tag{90}$$

As $g^{(2)}_{z|(j,k)}$ is a degenerate kernel, we can use Theorem 33 to bound the right hand side of (90). Consider the class of functions

$$\mathcal{F}^{(2)}_{\ell|(j,k)} = \left\{ (2^{\ell-1}h_l L) h g^{(2)}_{z|(j,k)} \,\middle|\, h \in \mathcal{H}_\ell, z \in (0,1) \right\} \text{ and } \mathcal{F}^{(2)}_\ell = \left\{ f \in \mathcal{F}^{(2)}_{\ell|(j,k)} \mid j,k \in [d] \right\}.$$

where $L^{-1} := 7\|K\|_\infty^2 \bar{\mathrm{f}}_Z^2$. From the expansion in (42), with (84) and (51), we have

$$\sup_{z\in(0,1)} \max_{j,k\in[d]} \left\| g^{(2)}_{z|(j,k)} \right\|_\infty \leq C\|K\|_\infty^2 \bar{\mathrm{f}}_Z^2 h^{-2}, \qquad \text{for } h \in [h_l, h_u].$$

Therefore, the class $\mathcal{F}^{(2)}_\ell$ is uniformly bounded by 1 and has the envelope $F^{(2)}_\ell = 1$, which verifies the condition in (159). Furthermore, by (86) and (51), we can bound the variance

as

$$\begin{aligned}
&\sup_{z,j,k} \mathbb{E}\left[\left(h g^{(2)}_{z|(j,k)} \right)^2 \right] \\
&\quad \lesssim \sup_{z,j,k} \left\{ 4h^2 \mathbb{E}\left[\left(g_{z|(j,k)}(Y_i, Y_{i'}) \right)^2 \right] + h\mathbb{E}\left[\left(\sqrt{h} g^{(1)}_{z|(j,k)} \right)^2 \right] + 4\{ h\mathbb{E}[\mathbb{U}_n[g_{z|(j,k)}]] \}^2 \right\} \\
&\quad \lesssim \sup_z h^{-2}\mathbb{E}\left[K\left((Z_i - z)/h \right)^2 K\left((Z_{i'} - z)/h \right)^2 \right] + \bar{\mathrm{f}}_Z^3 h + \bar{\mathrm{f}}_Z^2 h^2 \\
&\quad \lesssim \sup_z \left(h^{-1} \int K\left((x-z)/h \right)^2 f_Z(x) dx \right)^2 + \bar{\mathrm{f}}_Z^3 h + \bar{\mathrm{f}}_Z^2 h^2 \\
&\quad \lesssim \bar{\mathrm{f}}_Z^2 \|K\|_2^4 + \bar{\mathrm{f}}_Z^3 h + \bar{\mathrm{f}}_Z^2 h^2 \lesssim \bar{\mathrm{f}}_Z^2 \|K\|_2^4.
\end{aligned}$$

Therefore, for any $\ell \in [S]$,

$$\sup_{f\in\mathcal{F}^{(2)}_\ell} \mathbb{E}\left[f^2 \right] \lesssim 2\bar{\mathrm{f}}_Z^2 \|K\|_2^4 (2^{\ell-1}h_l L)^2 := \sigma_\ell^2 < 1.$$

According to Lemma 28, we have that

$$\sup_Q N(\mathcal{F}^{(2)}_{\ell|(j,k)}, L_2(Q), \epsilon) \leq C \frac{(2^{\ell-1}h_l L)^{-4v-15}}{(2^{\ell-1}h_l)^{2v+18} \epsilon^{4v+15}}.$$

By setting $t = C(2^{\ell-1}h_l)[\log\left(C/(2^{\ell-1}h_l)\right) \vee \log(C/\delta)]$ in (160) for a sufficiently large constant C, as $h_l n/\log(dn) \to \infty$, we have

$$\begin{aligned}
n\sigma_\ell^2 = n(2^{\ell-1}h_l)^2 &\geq \log\left(1/(2^{\ell-1}h_l)\right) \vee \log(1/\delta) \\
&= \frac{t}{\sigma_\ell} \geq C' \left(\frac{\log(1/(2^{\ell-1}h_l))}{\log n} \right)^{3/2} \log\left(\frac{2}{2^{\ell-1}h_l} \right),
\end{aligned}$$

for some constant $C' > 0$. This verifies the condition (161). Now (160) gives us that with probability $1 - [(2^{\ell-1}h_\ell) \vee \delta]$,

$$\sup_{h\in\mathcal{H}_\ell} \sup_{z\in(0,1)} (2^{\ell-1}h_l L) h \mathbb{U}_n \left[g^{(2)}_{z|(j,k)} \right] \leq Cn^{-1}(2^{\ell-1}h_l)[\log\left(1/(2^{\ell-1}h_l)\right) \vee \log(1/\delta)]. \tag{91}$$

Since $2^{\ell-1}h_l \geq h/2$ for any $h \in \mathcal{H}_\ell$, applying (90) and (91) with the union bound over $j,k \in [d]$, we obtain

$$\sup_{j,k\in[d]} \sup_{h\in[h_l,h_u]} \sup_{z\in(0,1)} \left| \frac{nh}{\log(d/h) \vee \log\left(\delta^{-1}\log\left(h_u h_l^{-1}\right)\right)} \mathbb{U}_n \left[g^{(2)}_{z|(j,k)} \right] \right| \leq C, \tag{92}$$

with probability $1-(h_u \vee \delta)$. As $h_u = o(1)$, (92) follows with probability larger than $1-\delta$. ■

Lemma 17 *We suppose $n^{-1}\log d = o(1)$ and the bandwidths $0 < h_l < h_u < 1$ satisfy $h_l n/\log(dn) \to \infty$ and $h_u = o(1)$. There exists a universal constant $C > 0$ such that*

$$\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\mathbb{G}_n\left[\frac{\sqrt{h}\omega_z^{(1)}}{\sqrt{\log(1/h)\vee\log\left(\delta^{-1}\log\left(h_u h_l^{-1}\right)\right)}}\right]\right| \le C$$

with probability $1-\delta$.

Proof The proof is similar to that of Lemma 15. We again decompose $[h_l, h_u] \subseteq \cup_{\ell=1}^{S}\mathcal{H}_\ell$, where $\mathcal{H}_\ell = [2^{\ell-1}h_l, 2^\ell h_l]$ and S is the smallest integer such that $2^S h_l \ge h_u$. By the union bound,

$$\mathbb{P}\left[\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\mathbb{G}_n\left[h^2\omega_z^{(1)}\right]\right| \ge t\right] \le \sum_{j=1}^{S}\mathbb{P}\left[\sup_{h\in\mathcal{H}_\ell}\sup_{z\in(0,1)}\left|\mathbb{G}_n\left[h^2\omega_z^{(1)}\right]\right| \ge t\right]. \tag{93}$$

Talagrand's inequality (Bousquet, 2002) is applied once again to control (93). Consider the class of functions

$$\mathcal{K}_\ell = \left\{\sqrt{h}\omega_z^{(1)} \mid h\in\mathcal{H}_\ell, z\in(0,1)\right\}.$$

According to the definition of $\omega_z^{(1)}$ in (44), we have

$$\omega_z^{(1)}(s) = K_h(s-z)\mathbb{E}[K_h(z-Z)] - (\mathbb{E}[K_h(z-Z)])^2.$$

We can bound the supremum norm by

$$\sup_{z\in(0,1)}\|\omega_z^{(1)}\|_\infty \le 2\bar{\mathrm{f}}_Z\|K\|_\infty h^{-1}, \tag{94}$$

which implies that the envelope function is $F_\ell = 2\bar{\mathrm{f}}_Z\|K\|_\infty(2^{\ell-1}h_\ell)^{-1/2}$. Similar to (86), we can also bound the variance by

$$\begin{aligned}\sup_z\mathbb{E}\left[\left(\sqrt{h}\omega_z^{(1)}\right)^2\right] &\le \sup_z 2\mathbb{E}\left[h\left(K_h(Z-z)\right)^2\right]\cdot(\mathbb{E}[K_h(z-Z)])^2 + \sup_z 2h\left\{\mathbb{E}\left[\mathbb{U}_n\left[\omega_z\right]\right]\right\}^2\\ &\le 2(\bar{\mathrm{f}}_Z^3\|K\|_2^2 + O(h^2)) + 2h\bar{\mathrm{f}}_Z^2 + O(h^3) \le 2\bar{\mathrm{f}}_Z^3||K||_2^2 := \sigma_\ell^2.\end{aligned} \tag{95}$$

Using Lemma 29 we have

$$\sup_Q N(\mathcal{K}_\ell, L_2(Q), \epsilon) \le \frac{C}{(2^{\ell-1}h_\ell)^4\epsilon^{2v+1}}\cdot\frac{\|F_\ell\|_{L_2}}{2\|K\|_\infty(2^{\ell-1}h_\ell)^{-1/2}},$$

which combined with Theorem 3.12 of Koltchinskii (2011) with $h_l n/\log(dn)\to\infty$ implies that

$$\mathbb{E}\left[\sup_{f\in\mathcal{K}_\ell}|n\mathbb{E}_n[f]|\right] \le C\sqrt{n\log\left(\frac{C}{2^{\ell-1}h_l}\right)}.$$

Theorem 2.3 of Bousquet (2002) derives that for some constant $C > 0$

$$\sup_{h\in\mathcal{H}_\ell}\sup_{z\in(0,1)}\left|\mathbb{G}_n\left[\sqrt{h}\omega_z^{(1)}\right]\right| \le C\left(\sqrt{\log\left(\frac{C}{2^{\ell-1}h_l}\right)} + \sqrt{\log(1/\delta)}\right) \tag{96}$$

with probability $1-\delta$. Using the union bound in (96) with (93), we have

$$\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\mathbb{G}_n\left[\frac{\sqrt{h}\omega_z^{(1)}}{\sqrt{\log(1/h)\vee\log\left(\delta^{-1}\log\left(h_u h_l^{-1}\right)\right)}}\right]\right| \le C,$$

for some constant $C > 0$ with probability $1-\delta$. ■

Lemma 18 *We assume $n^{-1}\log d = o(1)$ and the bandwidths $0 < h_l < h_u < 1$ satisfy $h_l n/\log(dn)\to\infty$ and $h_u = o(1)$. There exists a universal constant $C > 0$ such that for sufficiently large n,*

$$\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\frac{nh}{\log(1/h)\vee\log\left(\delta^{-1}\log\left(h_u h_l^{-1}\right)\right)}\mathbb{U}_n\left[\omega_z^{(2)}\right]\right| \le C$$

with probability $1-\delta$.

Proof The proof is similar to that of Lemma 16. Instead of applying Lemma 29, we use Lemma 28. We omit the details of the proof. ■

Let

$$r(d,n,h,\delta,h_u,h_l) = \frac{\log(d/h)\vee\log\left(\delta^{-1}\log\left(h_u h_l^{-1}\right)\right)}{nh}.$$

Applying Lemma 15, Lemma 16, Lemma 17 and Lemma 18 to (43) and (46), we obtain that with probability $1-\delta$, there exists a constant $C > 0$ such that

$$\sup_{j,k\in[d]}\sup_{h\in[h_l,h_u]}\sup_{z\in(0,1)}\left|\frac{n^{-1/2}\cdot u_n\left[\omega_z\right]\vee u_n\left[g_{z|(j,k)}\right]}{r^{1/2}(d,n,h,\delta,h_u,h_l)+r(d,n,h,\delta,h_u,h_l)}\right| \le C/2. \tag{97}$$

Since $\log(dn)/(nh_l) = o(1)$ and $h_u = o(1)$, we have $r(d,n,h,\delta,h_u,h_l) \le r^{1/2}(d,n,h,\delta,h_u,h_l)$ for sufficiently large n. Using this in (97), we have Lemma 12 proved.

E.2 Proof of Lemma 13

The high-level idea for proving this lemma is to write the expectations as the integrals and apply Taylor expansions to the density functions and other nonparametric functions. Afterwards, we bound the remainder terms of the Taylor expansions.

We compute $\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right]$ first. Using Corollary 32, we have

$$\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right] = \frac{2}{\pi}\mathbb{E}\left[K_h(Z_1-z)K_h(Z_2-z)\arcsin\left(\frac{\mathbf{\Sigma}_{jk}(Z_1)+\mathbf{\Sigma}_{jk}(Z_2)}{2}\right)\right], \tag{98}$$

where Z_1, Z_2 are independent and equal to Z in distribution. After a change of variables, we can further expand the right hand side of (98) as

$$\frac{2}{\pi}\iint K(t_1)K(t_2)f_Z(z+t_1h)f_Z(z+t_2h)\arcsin\left(\frac{\mathbf{\Sigma}_{jk}(z+t_1h)+\mathbf{\Sigma}_{jk}(z+t_2h)}{2}\right)dt_1dt_2.$$

Using the Taylor series expansion of $\arcsin(\cdot)$, we have

$$\arcsin\left(\frac{\mathbf{\Sigma}_{jk}(z+t_1h)+\mathbf{\Sigma}_{jk}(z+t_2h)}{2}\right)$$
$$=\arcsin\left(\mathbf{\Sigma}_{jk}(z)\right)+\left(\frac{t_1h\dot{\mathbf{\Sigma}}_{jk}(z)+t_2h\dot{\mathbf{\Sigma}}_{jk}(z)}{2}+\frac{(t_1h)^2\ddot{\mathbf{\Sigma}}_{jk}(\bar{z})+(t_2h)^2\ddot{\mathbf{\Sigma}}_{jk}(\bar{z})}{4}\right)\frac{1}{\sqrt{1-\bar{\rho}^2}},$$

where $\bar{z}$ is between z and $z+t_1h$, and $\bar{\rho}$ is between $\mathbf{\Sigma}_{jk}(z)$ and $(\mathbf{\Sigma}_{jk}(z+t_1h)+\mathbf{\Sigma}_{jk}(z+t_2h))/2$. Since the minimum eigenvalue of $\mathbf{\Sigma}(z)$ is strictly positive for any z, there exists a $\gamma_\sigma<1$ such that $\sup_z|\mathbf{\Sigma}_{jk}(z)|\leq\gamma_\sigma<1$ for any $j\neq k$. We thus have $(1-\bar{\rho}^2)^{-1/2}\leq(1-\gamma_\sigma^2)^{-1/2}<\infty$. Similarly, we can expand $f_Z(z+th)=f_Z(z)+th\dot{f}_Z(z)+(th)^2\ddot{f}_Z(\widetilde{z})/2$, where $\widetilde{z}\in(z,z+th)$. Therefore, using regularity conditions on f_Z and $\mathbf{\Sigma}(\cdot)$, we obtain

$$\max_{j,k\in[d]}\sup_{z\in(0,1)}\left|\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right]-f_Z^2(z)\tau_{jk}(z)\right|\leq\frac{M_\sigma\bar{f}_Z}{\sqrt{1-\gamma_\sigma^2}}h^2 \tag{99}$$

as desired. Proof of (52) follows in the same way since

$$\begin{aligned}\mathbb{E}\left[\mathbb{U}_n\left[K_h(Z_i-z)K_h(Z_{i'}-z)\right]\right]&=\iint K(t_1)K(t_2)f_Z(z+t_1h)f_Z(z+t_2h)dt_1dt_2\\&=f_Z^2(z)+O(h^2).\end{aligned}$$

Similarly, we can also bound the expectation of the cross product term

$$\begin{aligned}&n^{-1}\mathbb{E}\left[u_n\left[g_{z|(j,k)}\right]\times u_n\left[K_h(z_i-z)K_h(z_i-z)\right]\right]\\&=\mathbb{E}[\mathbb{U}_n\left[g_{z|(j,k)}\right]\mathbb{U}_n\left[K_h(z_i-z)K_h(z_{i'}-z)\right]]-\mathbb{E}[\mathbb{U}_n\left[g_{z|(j,k)}\right]]\mathbb{E}[\mathbb{U}_n\left[K_h(z_i-z)K_h(z_{i'}-z)\right]]\\&=\frac{4}{n^2(n-1)^2}\sum_{i\neq j,s\neq t}\mathbb{E}\left[K_h(z_i-z)K_h(z_j-z)g_{z|(j,k)}(y_s,y_t)\right]-(f_Z^2(z)\tau_{jk}(z)+O(h^2))^2\\&=\frac{24}{n^2(n-1)^2}\left\{\binom{n}{4}\mathbb{E}^2\left[K_h(z_i-z)\right]\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right]\right.\\&\quad+\binom{n}{3}\mathbb{E}\left[K_h(z_i-z)\right]\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}(y_i,y_j)K_h(z_i-z)\right]\right]\\&\quad\left.+\binom{n}{3}\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}(y_i,y_j)K_h(z_i-z)K_h(z_j-z)\right]\right]\right\}-(f_Z^2(z)+O(h^2))^2=O\left(\frac{1}{nh}\right).\end{aligned}$$

and the expectation of the square term

$$\begin{aligned}&n^{-1}\mathbb{E}\left[\left(u_n\left[K_h(z_i-z)K_h(z_i-z)\right]\right)^2\right]\\&=\mathbb{E}[\mathbb{U}_n^2\left[K_h(z_i-z)K_h(z_{i'}-z)\right]]-\mathbb{E}^2[\mathbb{U}_n\left[K_h(z_i-z)K_h(z_{i'}-z)\right]]\\&=\frac{4}{n^2(n-1)^2}\sum_{i\neq j,s\neq t}\mathbb{E}\left[K_h(z_i-z)K_h(z_j-z)K_h(z_s-z)K_h(z_t-z)\right]-(f_Z^2(z)+O(h^2))^2\\&=\frac{24}{n^2(n-1)^2}\left\{\binom{n}{4}\mathbb{E}^4\left[K_h(z_i-z)\right]+\binom{n}{3}\mathbb{E}^2\left[K_h(z_i-z)\right]\mathbb{E}\left[K_h(z_i-z)\right]^2\right.\\&\qquad\left.+\binom{n}{3}\mathbb{E}\left[K_h(z_i-z)\right]^4\right\}-(f_Z^2(z)+O(h^2))^2=O\left(\frac{1}{nh}\right).\end{aligned}$$

This completes the proof.

Appendix F. Proof of Theorem 4

The proof is similar to the proof of Theorem 3. Instead of only bounding the maximum over $(j,k)\in E^c$, we also need to control the supremum over $z\in[z_L,z_U]$. Without loss of generality, we consider the case $E=\emptyset$ and $[z_L,z_U]=(0,1)$. We will apply the multiplier bootstrap theory for continuous suprema developed in Chernozhukov et al. (2014a). Let W_0 and its bootstrap counterpart W_0^B be defined as

$$W_0=\max_{j,k\in[d]}\sup_{z\in(0,1)}\frac{1}{\sqrt{n}}\sum_{i=1}^n J_{z|(j,k)}(Y_i)\text{ and }W_0^B=\max_{j,k\in[d]}\sup_{z\in(0,1)}\frac{1}{\sqrt{n}}\sum_{i=1}^n J_{z|(j,k)}(Y_i)\cdot\xi_i.$$

Step 1. We aim to approximate W_0 by a Gaussian process. In order to apply Theorem A.1 of Chernozhukov et al. (2014a), we need to study the variance of $J_{z|(j,k)}$ and covering number of the function class $\mathcal{J}=\left\{J_{z|(j,k)}\mid z\in(0,1),j,k\in[d]\right\}$.

By the definition of $J_{z|(j,k)}$ in (48), we have

$$\begin{aligned}\sup_{z,j,k}\mathbb{E}[J_{z|(j,k)}^2(Y)]&\leq\sup_{z,j,k}4\|\mathbf{\Omega}_j(z)\|_1^2\|\mathbf{\Omega}_k(z)\|_1^2\cdot\pi^2h\cdot\left(\mathbb{E}[\max_{u,v}g_{z|(u,v)}^{(1)}(Y_i)]^2+\mathbb{E}[\omega_z^{(1)}(Z_i)]^2\right)\\&\leq CM^2:=\sigma_J^2,\end{aligned}\tag{100}$$

where the last inequality is due to (86) and (95). Similar to (68), we also have for some constant $C>0$,

$$\sup_{z,j,k}\|J_{z|(j,k)}^2(Y)\|_\infty\leq C/h:=b_J.$$

Furthermore, by Lemma 30, the covering number of $\mathcal{J}$ satisfies

$$\sup_Q N(\mathcal{J},L_2(Q),b_J\epsilon)\leq\left(\frac{Cd}{\epsilon h}\right)^c.$$

Therefore $\mathcal{J}$ is a $\mathrm{VC}(b_J,C(d/h)^c,c)$ type class (see, for example, Definition 3.1 Chernozhukov et al., 2014a) and we can apply Theorem A.1 in Chernozhukov et al. (2014a). Let $K_n=C\left(\log n\vee\log(d/h)\right)$ for some sufficiently large $C>0$. Using Theorem A.1 of Chernozhukov et al. (2014a), there exists a random variable W^0 such that for any $\gamma\in(0,1)$,

$$\mathbb{P}\Big(|W_0-W^0|\geq\frac{K_n/\sqrt{h}}{(\gamma n)^{1/2}}+\frac{(\sigma_J/\sqrt{h})^{1/2}K_n^{3/4}}{\gamma^{1/2}n^{1/4}}+\frac{h^{-1/6}\sigma_J^{2/3}K_n^{2/3}}{\gamma^{1/3}n^{1/6}}\Big)\leq C\Big(\gamma+\frac{\log n}{n}\Big).$$

Choosing $\gamma=(\log^4(dn)/(nh))^{1/8}$, we have

$$\mathbb{P}\big(|W_0-W^0|>C(\log^4(dn)/(nh))^{1/8}\big)\leq C(\log^4(dn)/(nh))^{1/8}.\tag{101}$$

Step 2. We next bound the difference between W_0^B and W^0. Define

$$\psi_n=\sqrt{\frac{\sigma_J^2K_n}{n}}+\left(\frac{\sigma_J^2K_n^3}{nh}\right)^{1/4}\qquad\text{and}\qquad\gamma_n(\delta)=\frac{1}{\delta}\left(\frac{\sigma_J^2K_n^3}{nh}\right)^{1/4}+\frac{1}{n}.$$

Since $K_n/h\lesssim(\log(dn))/h\lesssim n\sigma_J^2$, Theorem A.2 of Chernozhukov et al. (2014a) gives us

$$\mathbb{P}\Big(|W_0^B-W^0|>\psi_n+\delta\,\Big|\,\{Y_i\}_{i\in[n]}\Big)\leq C\gamma_n(\delta),$$

with probability $1-3/n$. Choosing $\delta = (\log(dn))^3/(nh))^{1/8}$, with probability $1-3/n$,

$$\mathbb{P}\Big(|W_0^B - W^0| > C((\log(dn))^3/(nh))^{1/8} \mid \{Y_i\}_{i\in[n]}\Big) \leq C((\log d)^3/(nh))^{1/8}. \tag{102}$$

Step 3. The last step is to assemble the above results to quantify the difference between W and W^B. According to Lemma 19 and Lemma 20, there exists a constant $c>0$ such that

$$\mathbb{P}(|W - W_0| > n^{-c}) \leq n^{-c} \qquad \text{and} \qquad \mathbb{P}(\mathbb{P}_\xi\big(|W_G^B - W_0^B| > n^{-c}\big) > n^{-c}\big) \leq n^{-c}. \tag{103}$$

Let $q_n := [(\log(dn))^3/(nh)]^{1/8}$. From (103) and (101), we have

$$\mathbb{P}\big(|W - W^0| > q_n\big) \leq q_n. \tag{104}$$

Define the event

$$\mathcal{W} = \Big\{\mathbb{P}\big(|W_G^B - W^0| > q_n \,\Big|\, \{Y_i\}_{i\in[n]}\big) \leq q_n\Big\}. \tag{105}$$

Using (103) and (102), $\mathbb{P}(\mathcal{W}) \geq 1-n^{-c}$. Recall that $\widehat{c}_W(1-\alpha, \{Y_i\}_{i=1}^n)$ is $(1-\alpha)$-quantile of W_G^B conditionally on $\{Y_i\}_{i=1}^n$. Let

$$W_0^B(\{Y_i\}_{i=1}^n) = \max_{j,k\in[d]} \sup_{z\in(0,1)} n^{-1/2}\sum_{i=1}^n J_{z|(j,k)}(Y_i)\cdot\xi_i$$

and define $W^B(\{Y_i\}_{i=1}^n)$ similarly. Let $\widehat{\sigma}^2_{z,j,k} = n^{-1}\sum_{i=1}^n J^2_{z|(j,k)}(Y_i)$, $\underline{\sigma}_J = \inf_{z,j,k}\widehat{\sigma}_{z,j,k}$ and $\overline{\sigma}_J = \sup_{z,j,k}\widehat{\sigma}_{z,j,k}$. Using the triangle inequality, we have

$$\begin{aligned}
&\mathbb{P}\big(W \leq \widehat{c}_W(1-\alpha, \{Y_i\}_{i=1}^n)\big) \overset{(104)}{\geq} \mathbb{P}\big(W^0 \leq \widehat{c}_W(1-\alpha, \{Y_i\}_{i=1}^n) - q_n\big) - q_n \\
&\overset{(105)}{\geq} \mathbb{P}\big(W_0^B(\{Y_i\}_{i=1}^n) \leq \widehat{c}_W(1-\alpha, \{Y_i\}_{i=1}^n) - 2q_n\big) - 2q_n \\
&\geq \mathbb{P}\big(W^B(\{Y_i\}_{i=1}^n) \leq \widehat{c}_W(1-\alpha, \{Y_i\}_{i=1}^n)\big) \\
&\qquad - C(\underline{\sigma}_J, \overline{\sigma}_J)q_n(\mathbb{E}_\xi[W_0^B] + \sqrt{1\vee\log(n\underline{\sigma}_J)}) - Cq_n,
\end{aligned} \tag{106}$$

where the last inequality follows from the anti-concentration for suprema of Gaussian processes, given in Lemma A.1 of Chernozhukov et al. (2014b), and $C(\underline{\sigma}_J, \overline{\sigma}_J)$ is a constant that only depends on $\underline{\sigma}_J$ and $\overline{\sigma}_J$.

In the following of the proof, we will bound the right hand side of (106). We first show the constant $C(\underline{\sigma}_J, \overline{\sigma}_J)$ is independent to h, n or d and then bound $\mathbb{E}_\xi[W^B]$. We bound $\mathbb{E}_\xi[W^B]$ by bounding $\mathbb{E}_\xi[W_0^B]$ and $\mathbb{E}_\xi[|W^B - W_0^B|]$. Since W_0^B is a supreme of a Gaussian process given data, we can bound its expectation by quantifying its conditional variance and related covering number. We first bound its conditional variance $n^{-1}\sum_{i=1}^n J^2_{z|(j,k)}(Y_i)$. Using the notation defined in (67), we have

$$\sup_{z,j,k}\frac{1}{n}\sum_{i=1}^n (J^2_{z|(j,k)}(Y_i) - \mathbb{E}[J^2_{z|(j,k)}(Y_i)]) = \sup_{z,j,k}\frac{1}{n}\sum_{i=1}^n \gamma_{z|(j,k,j,k)}(Y_i).$$

Therefore, (69) and (70) give an upper bound and variance of $(J^2_{z|(j,k)}(Y_i) - \mathbb{E}[J^2_{z|(j,k)}(Y_i)])$. Define the function class $\mathcal{J}_{(2)} = \Big\{J^2_{z|(j,k)} \mid z\in(0,1), j,k\in[d]\Big\}$. Using Lemma 26 and Lemma 30,

$$\sup_Q N(\mathcal{J}_{(2)}, \|\cdot\|_{L_2(Q)}, \epsilon/\sqrt{h}) \leq \left(\frac{Cd}{h\epsilon}\right)^c.$$

As the upper bound, variance and covering number are quantified above, similar to (88), we apply Theorem 3.12 of Koltchinskii (2011) to get

$$\mathbb{E}\left[\sup_{z,j,k}\frac{1}{n}\sum_{i=1}^n (J^2_{z|(j,k)}(Y_i) - \mathbb{E}[J^2_{z|(j,k)}(Y_i)])\right] \lesssim \sqrt{\frac{\log(2d/h)}{nh^2}} + \frac{\log(2d/h)}{nh}.$$

Under the assumptions of the theorem, $\sqrt{\log(2d/h)/(nh^2)} + \log(2d/h)/(nh) = O(n^{-2c})$ and the Markov's inequality give

$$\mathbb{P}\left(\sup_{z,j,k}\frac{1}{n}\sum_{i=1}^n (J^2_{z|(j,k)}(Y_i) - \mathbb{E}[J^2_{z|(j,k)}(Y_i)]) > n^{-c}\right) \leq Cn^{-c}.$$

Combining with (100),

$$\overline{\sigma}_J^2 = \sup_{z,j,k}\frac{1}{n}\sum_{i=1}^n J^2_{z|(j,k)}(Y_i) \leq \sigma_J^2 + n^{-c} \leq 2\sigma_J^2,$$

with probability $1-Cn^{-c}$. By the assumption in Theorem 4,

$$\inf_{z,j,k}\mathbb{E}[J^2_{z|(j,k)}(Y)] = \inf_{z,j,k}\mathrm{Var}(\mathbf{\Omega}_j(z)\mathbf{\Theta}_z\mathbf{\Omega}_k(z)) > c > 0.$$

Therefore, we have

$$\begin{aligned}
\underline{\sigma}_J &= \inf_{z,j,k}\frac{1}{n}\sum_{i=1}^n J^2_{z|(j,k)}(Y_i) \\
&\geq \inf_{z,j,k}\mathbb{E}[J^2_{z|(j,k)}(Y)] - \sup_{z,j,k}\frac{1}{n}\sum_{i=1}^n (J^2_{z|(j,k)}(Y_i) - \mathbb{E}[J^2_{z|(j,k)}(Y_i)]) \geq c/2 > 0
\end{aligned}$$

with probability $1-Cn^{-c}$. The constant $C(\underline{\sigma}_J, \overline{\sigma}_J)$ does not depend on n, d and h.

Combining Lemma 2.2.8 in van der Vaart and Wellner (1996) and Lemma 30, we have

$$\mathbb{E}_\xi[W_0^B] \leq C\sigma_J\sqrt{\log\left(Cd\sigma_J^{-1}/h\right)} \leq C\sqrt{\log(d/h)}.$$

From Lemma 20, we have $\mathbb{E}_\xi[W^B] \leq \mathbb{E}_\xi[W_0^B] + \mathbb{E}_\xi[|W^B - W_0^B|] \leq C\sqrt{\log(d/h)}$, since $q_n\sqrt{\log(d/h)} = (\log^8(d/h)/(nh))^{1/8} = O(n^{-c})$. Due to (106) and the fact that $\mathbb{P}(\mathcal{W}) \geq 1-n^{-c}$, we have $\mathbb{P}\big(W \leq c_W(1-\alpha)\big) \geq 1-\alpha-3n^{-c}$. Similarly, we can also show that $\mathbb{P}\big(W \geq \widehat{c}_W(1-\alpha, \{Y_i\}_{i=1}^n)\big) \geq \alpha - 3n^{-c}$, which completes the proof.

Appendix G. Auxiliary Lemmas for Score Statistics

In this section, we provide the auxiliary results for proving auxiliary lemmas on the asymptotic properties on the score statistics.

G.1 Approximation Error for Score Statistics

In this section, we prove Lemma 19 and Lemma 20, which approximate the score statistics by a leading linear term.

Lemma 19 *Under the same conditions as Theorem 4, there exists a universal constant $c > 0$ such that*

$$\sup_{j,k\in[d]}\sup_{z\in(0,1)}\left|\sqrt{nh}\cdot\mathbb{U}_n[\omega_z]\widehat{S}_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\big)-\mathbb{G}_n\big[J_{z|(j,k)}\big]\right|\leq n^{-c}, \tag{107}$$

with probability $1-c/d$.

Proof We have

$$\begin{aligned}
&\left|\sqrt{nh}\cdot\mathbb{U}_n[\omega_z]\widehat{S}_{z|(j,k)}\left(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\right)-\mathbb{G}_n\left[J_{z|(j,k)}\right]\right| \\
&\quad\leq\underbrace{\sqrt{nh}\cdot\mathbb{U}_n[\omega_z]\left|\widehat{S}_{z|(j,k)}\left(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\right)-\mathbf{\Omega}_j^T(z)\left(\widehat{\mathbf{\Sigma}}(z)\mathbf{\Omega}_k(z)-\mathbf{e}_k^T\right)\right|}_{I} \\
&\qquad+\underbrace{\left|\sqrt{nh}\cdot\mathbb{U}_n[\omega_z]\mathbf{\Omega}_j^T(z)\left(\widehat{\mathbf{\Sigma}}(z)\mathbf{\Omega}_k(z)-\mathbf{e}_k^T\right)-\mathbb{G}_n\left[J_{z|(j,k)}\right]\right|}_{II}
\end{aligned}$$

A bound on I is obtained in Lemma 21. Here, we proceed to obtain a bound on II.

To simplify the notation, we sometimes omit the argument z_0, that is, we write $\mathbf{\Omega}(z_0)$ as $\mathbf{\Omega}$ and similarly for other parameters indexed by z. Applying the Taylor expansion to $\sin(\cdot)$ we obtain

$$\begin{aligned}
&\sqrt{nh}\cdot\mathbf{\Omega}_j^T(z)\left(\widehat{\mathbf{\Sigma}}(z)\mathbf{\Omega}_k(z)-\mathbf{e}_k\right)=\sqrt{nh}\cdot\mathbf{\Omega}_j^T(z)\left(\widehat{\mathbf{\Sigma}}(z)-\mathbf{\Sigma}(z)\right)\mathbf{\Omega}_k(z) \\
&=\sqrt{nh}\sum_{a,b\in[d]}\mathbf{\Omega}_{ja}\mathbf{\Omega}_{bk}\left(\sin\left(\widehat{\tau}_{ab}\frac{\pi}{2}\right)-\sin\left(\tau_{ab}\frac{\pi}{2}\right)\right) \\
&=\underbrace{\sqrt{nh}\sum_{a,b\in[d]}\mathbf{\Omega}_{ja}\mathbf{\Omega}_{bk}\cos\left(\tau_{ab}\frac{\pi}{2}\right)\frac{\pi}{2}\left(\widehat{\tau}_{ab}-\tau_{ab}\right)}_{T_1} \\
&\qquad\underbrace{-\frac{\sqrt{nh}}{2}\sum_{a,b\in[d]}\mathbf{\Omega}_{ja}\mathbf{\Omega}_{bk}\sin\left(\widetilde{\tau}_{ab}\frac{\pi}{2}\right)\left(\frac{\pi}{2}\left(\widehat{\tau}_{ab}-\tau_{ab}\right)\right)^2}_{T_2},
\end{aligned} \tag{108}$$

where $\widetilde{\tau}_{ij}=(1-\alpha)\widehat{\tau}_{ij}+\alpha\tau_{ij}$ for some $\alpha\in(0,1)$.

In order to study the properties of T_1 and T_2, we first analyze the $\sqrt{nh}(\widehat{\tau}_{ab}-\tau_{ab})$ shared by both terms. Let

$$r_{z|(a,b)}(Y_i,Y_{i'}):=g_{z|(a,b)}(Y_i,Y_{i'})-\tau_{ab}(z)\omega_z(Z_i,Z_{i'}), \tag{109}$$

where $g_{z|(a,b)}$ is defined in (40). From (4), we have

$$\sqrt{nh}\big(\widehat{\tau}_{ab}(z)-\tau_{ab}(z)\big)=\frac{\sqrt{nh}\cdot\sum_{i\neq i'}r_{z|(a,b)}(Y_i,Y_{i'})}{\sum_{i\neq i'}\omega_z(Z_i,Z_{i'})}.$$

We divide the U-statistic in the numerator into two parts

$$\frac{1}{\sqrt{nh}(n-1)}\sum_{i\neq i'}r_{z|(a,b)}(Y_i,Y_{i'})=\sqrt{h}\cdot u_n[r_{z|(a,b)}]+\sqrt{nh}\cdot\mathbb{E}[r_{z|(a,b)}(Y_i,Y_{i'})].$$

For any $z\in(0,1)$ and $a,b\in[d]$, using Lemma 13 we obtain

$$\begin{aligned}
&\sqrt{nh}\cdot\mathbb{E}[r_{z|(a,b)}(Y_i,Y_{i'})] \\
&\quad=\sqrt{nh}\cdot\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(a,b)}\right]\right]-\sqrt{nh}\cdot\tau_{ab}(z)\mathbb{E}\left[\mathbb{U}_n\left[K_h(Z_i-z)K_h(Z_{i'}-z)\right]\right] \\
&\quad=\sqrt{nh}\big[f_Z^2(z)\tau_{ab}(z)+O(h^2)\big]-\sqrt{nh}\tau_{ab}(z)\big[f_Z^2(z)+O(h^2)\big] \\
&\quad=O(\sqrt{nh^5}).
\end{aligned} \tag{110}$$

For the leading term $\sqrt{h}\cdot u_n[r_{z|(a,b)}]$, we combine (109) with (43) and (46), to obtain

$$\sqrt{h}\cdot u_n[r_{z|(a,b)}]=2\sqrt{nh}\cdot\mathbb{E}_n\left[g^{(1)}_{z|(a,b)}-\tau_{ab}(z)\omega_z^{(1)}\right]+\sqrt{nh}\cdot\mathbb{U}_n\left[g^{(2)}_{z|(a,b)}-\tau_{ab}(z)\omega_z^{(2)}\right],$$

where $g^{(1)}_{z|(a,b)}$, $g^{(2)}_{z|(a,b)}$, $\omega_z^{(1)}$, $\omega_z^{(2)}$ are defined in (41), (42), (44), (45) respectively. With this,

$$\begin{aligned}
T_1&=[\mathbb{U}_n[\omega_z]]^{-1}\sum_{a,b\in[d]}\mathbf{\Omega}_{ja}\mathbf{\Omega}_{bk}\frac{\pi}{2}\cos\left(\tau_{ab}\frac{\pi}{2}\right)\left(\sqrt{h}\cdot u_n[r_{z|(a,b)}]+\sqrt{nh}\cdot\mathbb{E}[r_{z|(a,b)}(Y_i,Y_{i'})]\right) \\
&=[\mathbb{U}_n[\omega_z]]^{-1}(T_{11}+T_{12}+T_{13}),
\end{aligned}$$

where

$$\begin{aligned}
T_{11}&=\sqrt{nh}\sum_{a,b\in[d]}\mathbf{\Omega}_{ja}\mathbf{\Omega}_{bk}\pi\cos\left(\tau_{ab}\frac{\pi}{2}\right)\mathbb{E}_n\left[g^{(1)}_{z|(a,b)}-\tau_{ab}(z)\omega_z^{(1)}\right], \\
T_{12}&=\sqrt{nh}\sum_{a,b\in[d]}\mathbf{\Omega}_{ja}\mathbf{\Omega}_{bk}\frac{\pi}{2}\cos\left(\tau_{ab}\frac{\pi}{2}\right)\mathbb{U}_n\left[g^{(2)}_{z|(a,b)}-\tau_{ab}(z)\omega_z^{(2)}\right] \quad\text{and} \\
T_{13}&=\sqrt{nh}\sum_{a,b\in[d]}\mathbf{\Omega}_{ja}\mathbf{\Omega}_{bk}\frac{\pi}{2}\cos\left(\tau_{ab}\frac{\pi}{2}\right)\mathbb{E}[r_{z|(a,b)}(Y_i,Y_{i'})].
\end{aligned}$$

From (48), we have that $T_{11}=\mathbb{G}_n[J_{z|(j,k)}]$. We proceed to bound the other terms. Using Lemma 16 and Lemma 18, we have

$$\sup_{z,j,k}|T_{12}|\leq\sup_{z,j,k}\sqrt{nh}\cdot\|\mathbf{\Omega}_j\|_1\|\mathbf{\Omega}_k\|_1\max_{a,b\in[d]}\left(\left|\mathbb{U}_n\left[g^{(2)}_{z|(a,b)}\right]\right|+\left|\mathbb{U}_n\left[\omega_z^{(2)}\right]\right|\right)\lesssim\frac{\log(d/h)}{\sqrt{nh}}, \tag{111}$$

with probability $1-1/d$. Using (110), we can bound T_{13} as

$$\sup_{z,j,k}|T_{13}|\lesssim\frac{\pi}{2}\|\mathbf{\Omega}_j\|_1\|\mathbf{\Omega}_k\|_1\cdot(\sqrt{nh^5})\leq\pi M^2\sqrt{nh^5}. \tag{112}$$

The final step is to bound T_2. Using Lemma 9 and Lemma 10,

$$\sup_{z,j,k}|T_2| \le \frac{\pi^2}{8}\|\mathbf{\Omega}_j\|_1\|\mathbf{\Omega}_k\|_1 \max_{z,a,b}\sqrt{nh}\cdot|\widehat{\tau}_{ab}(z)-\tau_{ab}(z)|^2$$
$$\le CM^2\sqrt{nh}\cdot\left(\frac{\log(d/h)}{nh}+h^4+\frac{1}{n^2h^2}\right) \quad (113)$$

with probability $1-1/d$.

Combining (55), (111), (112), and (113) with (108), we finally have

$$\sup_{j,k\in[d]}\sup_{z\in(0,1)}\left|\sqrt{nh}\cdot\mathbb{U}_n[\omega_z]\widehat{S}_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\big)-\mathbb{G}_n\big(J_{z|(j,k)}\big)\right|$$
$$\le \sup_{j,k\in[d]}\sup_{z\in(0,1)}\big(|T_{12}|+|T_{13}|+|\mathbb{U}_n[\omega_z]||T_2|\big)\lesssim\frac{\log(d/h)}{\sqrt{nh}}+\sqrt{nh^5}.$$

with probability $1-1/d$. Under the assumptions of the lemma, there exists a constant $c>0$ such that $\log(d/h)/\sqrt{nh}=o(n^{-c})$ and $\sqrt{nh^5}=o(n^{-c})$, which completes the proof. ■

The following lemma states a result analogous to Lemma 19 for the bootstrap test statistic.

Lemma 20 *Under the same conditions as Theorem 4, there exists a universal constant $c>0$ such that for sufficiently large n,*

$$\mathbb{P}_\xi\left(\sup_{j,k\in[d]}\sup_{z\in(0,1)}\left|\sqrt{nh}\cdot\mathbb{U}_n[\omega_z^B]\widehat{S}^B_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\big)-\mathbb{G}_n^\xi\big[J_{z|(j,k)}\big]\right|\le n^{-c}\right)\ge 1-c/d.$$

Proof We have

$$\left|\sqrt{nh}\cdot\mathbb{U}_n[\omega_z^B]\widehat{S}^B_{z|(j,k)}\left(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\right)-\mathbb{G}_n^\xi\left(J_{z|(j,k)}\right)\right|$$
$$\le\underbrace{\sqrt{nh}\cdot\mathbb{U}_n[\omega_z^B]\left|\widehat{S}^B_{z|(j,k)}\left(\widehat{\mathbf{\Omega}}^B_{k\backslash j}(z)\right)-\mathbf{\Omega}_j^T(z)\left(\widehat{\mathbf{\Sigma}}(z)\mathbf{\Omega}_k(z)-\mathbf{e}_k^T\right)\right|}_{I}$$
$$+\underbrace{\left|\sqrt{nh}\cdot\mathbb{U}_n[\omega_z^B]\mathbf{\Omega}_j^T(z)\left(\widehat{\mathbf{\Sigma}}^B(z)\mathbf{\Omega}_k(z)-\mathbf{e}_k^T\right)-\mathbb{G}_n^\xi\left[J_{z|(j,k)}\right]\right|}_{II}.$$

Lemma 22 gives a bound on I. Here, we focus on obtaining a bound on II. That is, we show that $\sqrt{nh}\cdot\mathbb{U}_n[\omega_z^B]\mathbf{\Omega}_j^T(z)\big(\widehat{\mathbf{\Sigma}}^B(z)\mathbf{\Omega}_k(z)-\mathbf{e}_k^T\big)$ is close to the linear leading term

$$T_0^B:=\mathbb{G}_n^\xi\left[J_{z|(j,k)}\right]=\frac{1}{\sqrt{n}}\sum_{i=1}^n J_{z|(j,k)}(Y_i)\cdot\xi_i.$$

Similar to (108), we have

$$\max_{j,k\in[d]}\sup_{z\in(0,1)}\sqrt{nh}\cdot\mathbb{U}_n[\omega_z^B]\mathbf{\Omega}_j(z_0)^T\Big(\widehat{\mathbf{\Sigma}}^B(z)\mathbf{\Omega}_k(z)-\mathbf{e}_k^T\Big)=T_1^B+T_2^B,$$

where

$$T_1^B=\sqrt{nh}\sum_{a,b\in[d]}\mathbf{\Omega}_{ja}\mathbf{\Omega}_{bk}\cos\left(\tau_{ab}\frac{\pi}{2}\right)\frac{\pi}{2}\mathbb{U}_n[\omega_z^B]\left(\widehat{\tau}_{ab}^B-\tau_{ab}\right)$$

and

$$T_2^B=-\frac{\sqrt{nh}}{2}\sum_{a,b\in[d]}\mathbf{\Omega}_{ja}\mathbf{\Omega}_{bk}\sin\left(\tau_{ab}\frac{\pi}{2}\right)\mathbb{U}_n[\omega_z^B]\left(\frac{\pi}{2}\left(\widehat{\tau}_{ab}^B-\tau_{ab}\right)\right)^2.$$

We bound T_2^B first. Note that

$$\underline{\mathrm{f}}_Z^2-\sup_{z\in(0,1)}|\mathbb{U}_n[\omega_z^B]-f_Z^2(z)|\le\inf_{z\in(0,1)}\mathbb{U}_n[\omega_z^B]\le\sup_{z\in(0,1)}\mathbb{U}_n[\omega_z^B]\le\bar{\mathrm{f}}_Z^2+\sup_{z\in(0,1)}|\mathbb{U}_n[\omega_z^B]-f_Z^2(z)|.$$

Using Lemma 24 and $\log(h^{-1})/(nh^2)=o(1)$, we have

$$\underline{\mathrm{f}}_Z^2/2\le\inf_{z\in(0,1)}\mathbb{U}_n[\omega_z]\le\sup_{z\in(0,1)}\mathbb{U}_n[\omega_z]\le 2\bar{\mathrm{f}}_Z^2, \quad (114)$$

with probability at least $1-1/n$. Similar to (113), (114) and the Hölder's inequality give us

$$|T_2^B|\le\frac{\pi^2}{4\underline{\mathrm{f}}_Z^2}\|\mathbf{\Omega}_j\|_1\|\mathbf{\Omega}_k\|_1\max_{a,b\in[d]}\sqrt{nh}\cdot|\mathbb{U}_n[\omega_z^B](\widehat{\tau}_{ab}^B-\tau_{ab})|^2.$$

Under the assumptions, $h\asymp n^{-\delta}$ for $\delta\in(1/5,1/4)$, and Lemma 23 gives us

$$\mathbb{P}_\xi\Big(\max_{z,j,k}|T_2^B|\le C\log(d/h)/\sqrt{nh^3}\Big)\ge 1-1/d \quad (115)$$

for some constant $C>0$ with probability $1-c/d$.

Next, we handle the difference between T_1^B and T_0^B. We denote

$$\Delta W_{z|(a,b)}=\mathbb{U}_n[\omega_z^B]\left(\widehat{\tau}_{ab}^B(z)-\tau_{ab}(z)\right)-\frac{2}{n}\sum_{i=1}^n\left[g^{(1)}_{z|(a,b)}(Y_i)-\tau_{ab}(z)\omega_z^{(1)}(Z_i)\right]\xi_i. \quad (116)$$

Using the Hölder's inequality, we have

$$|T_1^B-T_0^B|\le\left|\sqrt{nh}\sum_{a,b\in[d]}\mathbf{\Omega}_{ja}\mathbf{\Omega}_{bk}\cos\left(\tau_{ab}\frac{\pi}{2}\right)\frac{\pi}{2}\cdot\Delta W_{z|(a,b)}\right|\le CM^2\sqrt{nh}\max_{a,b}|\Delta W_{z|(a,b)}|.$$

Combining with (123), there exists a constant $c>0$ such that with probability $1-c/d$

$$\mathbb{P}_\xi\big(\sup_{z\in(0,1)}\max_{j,k\in[d]}|T_1^B-T_0^B|\ge C\sqrt{\log(d/h)/(nh^2)}\big)\le 1/d. \quad (117)$$

If $\log(d/h)/(nh^2)\asymp n^{-c}$, (120), (115) and (117) give us with probability $1-c/d$

$$\mathbb{P}_\xi\Big(\sup_{z\in(0,1)}\max_{j,k\in[d]}|\widehat{S}^B_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\big)-T_0^B|\le n^{-c}\Big)\ge 1-1/d,$$

which completes the proof of the lemma. ■

G.2 First Step Approximation Results

Here we establish results needed for the first step in the proofs of Lemma 19 and Lemma 20.

Lemma 21 *Under the same conditions as Theorem 4, there exists a universal constant $c > 0$ such that*

$$\sup_{j,k\in[d]}\sup_{z\in(0,1)}\sqrt{nh}\cdot\Big|\widehat{S}_{z|(j,k)}\Big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\Big)-\mathbf{\Omega}_j^T(z)\Big(\widehat{\mathbf{\Sigma}}(z)\mathbf{\Omega}_k(z)-\mathbf{e}_k^T\Big)\Big|\le n^{-c}$$

with probability $1-c/d$.

Proof For any matrix $\mathbf{A}=(\mathbf{A}_1,\ldots,\mathbf{A}_d)\in\mathbb{R}^{d\times d}$, we define

$$\mathbf{A}_{-j}:=(\mathbf{A}_1,\ldots,\mathbf{A}_{j-1},\mathbf{A}_{j+1},\ldots,\mathbf{A}_d)\in\mathbb{R}^{d\times(d-1)},$$

which is a submatrix of $\mathbf{A}$ with column j removed. We also denote

$$\begin{aligned}\boldsymbol{\gamma}^*(z)&=(\mathbf{\Omega}_{k1}(z),\ldots,\mathbf{\Omega}_{k(j-1)}(z),\mathbf{\Omega}_{k(j+1)}(z)\ldots\mathbf{\Omega}_{kd}(z))^T\in\mathbb{R}^{d-1}\quad\text{and}\\ \widehat{\boldsymbol{\gamma}}(z)&=(\widehat{\mathbf{\Omega}}_{k1}(z),\ldots,\widehat{\mathbf{\Omega}}_{k(j-1)}(z),\widehat{\mathbf{\Omega}}_{k(j+1)}(z),\ldots,\widehat{\mathbf{\Omega}}_{kd}(z))^T\in\mathbb{R}^{d-1}.\end{aligned}$$

To simplify the notation, we sometimes omit the varying variable z in the proof.

We start by decomposing the score function into two parts. We will then identify the leading term and bound the remainder. With the above introduced notation, we have

$$\begin{aligned}&\sqrt{nh}\cdot\widehat{S}_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}\big)\\&\quad=\sqrt{nh}\cdot\widehat{\mathbf{\Omega}}_j^T\big(\widehat{\mathbf{\Sigma}}_{-j}\widehat{\boldsymbol{\gamma}}-\mathbf{e}_k^T\big)\\&\quad=\sqrt{nh}\cdot\mathbf{\Omega}_j^T\big(\widehat{\mathbf{\Sigma}}_{-j}\boldsymbol{\gamma}^*-\mathbf{e}_k^T\big)+\underbrace{\sqrt{nh}\cdot\big(\widehat{\mathbf{\Omega}}_j^T-\mathbf{\Omega}_j^T\big)\big(\widehat{\mathbf{\Sigma}}_{-j}\boldsymbol{\gamma}^*-\mathbf{e}_k^T\big)}_{I_1}+\underbrace{\sqrt{nh}\cdot\widehat{\mathbf{\Omega}}_j^T\widehat{\mathbf{\Sigma}}_{-j}\big(\widehat{\boldsymbol{\gamma}}-\boldsymbol{\gamma}^*\big)}_{I_2}.\end{aligned}$$

The first term in the display above is the leading term on the right hand side of (107) as desired. The remaining part of the proof is to bound I_1 and I_2. By the Hölder's inequality, we have

$$|I_1|=\sqrt{nh}\cdot\big(\widehat{\mathbf{\Omega}}_j-\mathbf{\Omega}_j\big)^T\big(\widehat{\mathbf{\Sigma}}_{-j}-\mathbf{\Sigma}_{-j}\big)\boldsymbol{\gamma}^*\le\sqrt{nh}\cdot\big\|\widehat{\mathbf{\Omega}}_j-\mathbf{\Omega}_j\big\|_1\big\|\widehat{\mathbf{\Sigma}}-\mathbf{\Sigma}\big\|_{\max}\|\mathbf{\Omega}_k\|_1.$$

Assumption 4.4 together with the display above gives

$$\sup_{z\in(0,1)}\max_{j,k\in[d]}|I_1|\le M\sqrt{nh}\cdot r_{1n}r_{2n}\tag{118}$$

with probability $1-1/d$. Next, using the Hölder's inequality we have

$$|I_2|\le\sqrt{nh}\cdot\|\widehat{\mathbf{\Omega}}_j^T\widehat{\mathbf{\Sigma}}_{-j}\|_\infty\big\|\widehat{\boldsymbol{\gamma}}-\boldsymbol{\gamma}^*\big\|_1.$$

From Assumption 4.4, we have $\|\widehat{\mathbf{\Omega}}_j^T\widehat{\mathbf{\Sigma}}_{-j}\|_\infty\le\|\widehat{\mathbf{\Omega}}_j^T\widehat{\mathbf{\Sigma}}\|_\infty\le r_{3n}$ with probability $1-1/d$ and, therefore,

$$\sup_{z\in(0,1)}\max_{j,k\in[d]}|I_2|\le\sqrt{nh}\cdot r_{3n}r_{2n}\tag{119}$$

with probability $1-1/d$. Combining (118) and (119), we have

$$\sup_{j,k\in[d]}\sup_{z\in(0,1)}\big(|I_1|+|I_2|\big)\le\sqrt{nh}\cdot r_{2n}(r_{1n}+r_{3n})\le n^{-c}$$

with probability $1-2/d$, which completes the proof. ■

Lemma 22 *Under the same conditions as Theorem 4, there exists a universal constant $c>0$ such that with probability $1-1/d$,*

$$\mathbb{P}_\xi\Big(\max_{j,k\in[d]}\sup_{z\in(0,1)}\sqrt{nh}\cdot\Big|\widehat{S}^B_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\big)-\mathbf{\Omega}_j^T(z)\Big(\widehat{\mathbf{\Sigma}}^B(z)\mathbf{\Omega}_k(z)-\mathbf{e}_k^T\Big)\Big|\le n^{-c}\Big)\ge1-1/d.\tag{120}$$

Proof The proof is similar to the proof of Lemma 21. Compared to the proof in Lemma 21, there are two differences: (1) we need to bound $\mathbb{U}_n[\omega_z^B]\|\widehat{\mathbf{\Sigma}}^B-\mathbf{\Sigma}\|_{\max}$ instead of $\|\widehat{\mathbf{\Sigma}}-\mathbf{\Sigma}\|_{\max}$ and (2) obtain a rate for $\mathbb{U}_n[\omega_z^B]\|\widehat{\mathbf{\Omega}}_j^T\widehat{\mathbf{\Sigma}}^B\|_\infty$ instead of $\|\widehat{\mathbf{\Omega}}_j^T\widehat{\mathbf{\Sigma}}\|_\infty$.

According to Lemma 23 and (114), we have

$$\begin{aligned}&\mathbb{P}_\xi\Big(\sup_{z\in(0,1)}\mathbb{U}_n[\omega_z^B]\|\widehat{\mathbf{\Sigma}}^B-\mathbf{\Sigma}\|_{\max}>C\sqrt{\log(d/h)/(nh^2)}\Big)\\&\le\mathbb{P}_\xi\Big(\max_{j,k\in[d]}\sup_{z\in(0,1)}\Big|\mathbb{U}_n[\omega_z^B]\big(\widehat{\tau}^B_{jk}(z)-\tau_{jk}(z)\big)\Big|>C\sqrt{\log(d/h)/(nh^2)}\Big)\le1/d.\end{aligned}\tag{121}$$

Next, (114) and the Hölder's inequality, give us

$$\mathbb{U}_n[\omega_z^B]\|\widehat{\mathbf{\Omega}}_j^T\widehat{\mathbf{\Sigma}}^B\|_\infty\le2\bar{\mathrm{f}}_Z\Big(\|\widehat{\mathbf{\Omega}}_j^T\widehat{\mathbf{\Sigma}}\|_\infty+\big(\|\widehat{\mathbf{\Omega}}_j-\mathbf{\Omega}_j\|_1+\|\mathbf{\Omega}_j\|_1\big)\mathbb{U}_n[\omega_z^B]\|\widehat{\mathbf{\Sigma}}^B-\widehat{\mathbf{\Sigma}}\|_{\max}\Big).$$

Therefore, by Assumption 4.4, (121) and Theorem 6, with probability $1-1/d$,

$$\mathbb{P}_\xi\Big(\mathbb{U}_n[\omega_z^B]\|\widehat{\mathbf{\Omega}}_j\widehat{\mathbf{\Sigma}}^B\|_\infty>C\big(M\lambda+M\sqrt{\log(d/h)/(nh^2)}\big)\Big)\le1/d.\tag{122}$$

Compared to the rate on I_1 in (118), we have

$$I_{12}^B:=\sqrt{nh}\cdot\big(\widehat{\mathbf{\Omega}}_j-\mathbf{\Omega}_j\big)^T\big(\widehat{\mathbf{\Sigma}}^B_{-j}-\mathbf{\Sigma}_{-j}\big)\boldsymbol{\gamma}^*\le\sqrt{nh}\cdot\big\|\widehat{\mathbf{\Omega}}_j-\mathbf{\Omega}_j\big\|_1\big\|\widehat{\mathbf{\Sigma}}^B-\mathbf{\Sigma}\big\|_{\max}\|\boldsymbol{\gamma}^*\|_1.$$

For $\lambda=\kappa\sqrt{\log(dn)}\cdot(h^2+1/\sqrt{nh})$ and $h=n^{-\delta}$, for $1/5<\delta<1/4$, by (121), we have with probability $1-1/d$, there exists a constant c such that

$$\mathbb{P}_\xi\Big(\sup_{z,j,k}|I_{12}^B|>sM^2\lambda\sqrt{\log(d/h)/h}\Big)\le1/d.$$

Instead of I_2 in (119), we define $I_2^B:=\sqrt{nh}\cdot\mathbb{U}_n^B(\omega_z)\|\widehat{\mathbf{\Omega}}_j\widehat{\mathbf{\Sigma}}^B\|_\infty\big\|\widehat{\boldsymbol{\gamma}}-\boldsymbol{\gamma}^*\big\|_1$. By (122) and Theorem 6, we have with probability $1-1/d$,

$$\mathbb{P}_\xi\Big(\sup_{z,j,k}|I_2^B|\le C\sqrt{nh}\cdot sM^2\lambda(\lambda+\sqrt{\log(d/h)(nh^2)})\Big)\le1/d.$$

For $\lambda = C_{\mathbf{\Sigma}}\big(h^2 + \sqrt{\log(d/h)/(nh)}\,\big)$, as $s\log d/\sqrt{nh^3} = o(n^{-c})$ and $\sqrt{nh^5} = o(n^{-c})$, we have with probability $1 - 1/d$,

$$\mathbb{P}_\xi\left(\sup_{j,k\in[d]}\sup_{z\in(0,1)}\sqrt{nh}\cdot\Big|\widehat{S}^B_{z|(j,k)}\big(\widehat{\mathbf{\Omega}}_{k\backslash j}(z)\big) - \mathbf{\Omega}_j^T(z)\Big(\widehat{\mathbf{\Sigma}}^B(z)\mathbf{\Omega}_k(z) - \mathbf{e}_k^T\Big)\Big| > n^{-c}\right)$$
$$\leq \mathbb{P}_\xi\left(\sup_{j,k\in[d]}\sup_{z\in(0,1)}\big(|I^B_{12}| + |I^B_2|\big) > n^{-c}\right) \leq 1/d,$$

following the same proof of Lemma 21. The proof is therefore complete. ∎

G.3 Properties of Bootstrap Score Statistics

In this section, we focus on establishing certain properties of the Gaussian multiplier bootstrap statistics introduced in this paper. The main goal is to prove Lemma 20, which states the approximation rate of a leading linear term to the bootstrap score statistic. To that end, we establish a rate of convergence for the bootstrap Kendall's tau estimator $\widehat{\tau}^B_{jk}(z)$ parallel to the results for $\widehat{\tau}^B_{jk}(z)$ in Lemma 12.

Recall from (17) and (20) that

$$\widehat{\tau}^B_{jk}(z) = \frac{\sum_{i\neq i'} K_h\left(Z_i - z\right) K_h\left(Z_{i'} - z\right)\operatorname{sign}(X_{ij} - X_{i'j})\operatorname{sign}(X_{ik} - X_{i'k})(\xi_i + \xi_{i'})}{\sum_{i\neq i'} K_h\left(Z_i - z\right) K_h\left(Z_{i'} - z\right)(\xi_i + \xi_{i'})},$$

and

$$\mathbb{U}_n[\omega^B_z] = \frac{2}{n(n-1)}\sum_{i\neq i'} K_h\left(Z_i - z_0\right) K_h\left(Z_{i'} - z_0\right)(\xi_i + \xi_{i'}).$$

The following lemma presents a convergence rate of the bootstrap Kendall's tau estimator $\widehat{\tau}^B_{jk}(z)$.

Lemma 23 *Under the conditions of Lemma 20, with probability* $1 - c/d$,

$$\mathbb{P}_\xi\left(\max_{j,k\in[d]}\sup_{z\in(0,1)}\Big|[\mathbb{U}_n[\omega^B_z]]\big(\widehat{\tau}^B_{jk}(z) - \tau_{jk}(z)\big)\Big| > C\sqrt{\log(d/h)/(nh^2)}\right) \leq 1/d$$

and

$$\mathbb{P}_\xi\left(\max_{j,k\in[d]}\sup_{z\in(0,1)}\sqrt{nh}|\Delta W_{z|(j,k)}| > C\sqrt{\log(d/h)/(nh^2)}\right) \leq 1/d, \tag{123}$$

with $\Delta W_{z|(j,k)}$ *defined in* (116).

Proof We first introduce some notation to simplify the proof. Let

$$W_{z|(j,k)}(Y_i) = \frac{2}{n-1}\sum_{i'\neq i}\omega_z(Z_i, Z_{i'})\Big(\operatorname{sign}(X_{ij} - X_{i'j})\operatorname{sign}(X_{ik} - X_{i'k}) - \tau_{jk}(z)\Big). \tag{124}$$

From the definition of $\widehat{\tau}^B_{jk}(z)$ in (17), conditionally on $\{Y_i\}_{i\in[n]}$, we have

$$\sqrt{n}\cdot\mathbb{U}_n[\omega^B_{z_0}]\Big(\widehat{\tau}^B_{jk}(z) - \tau_{jk}(z)\Big) = \frac{1}{\sqrt{n}}\sum_{i=1}^n W_{z|(j,k)}(Y_i)\xi_i \sim N\Big(0, \frac{1}{n}\sum_{i=1}^n W^2_{z|(j,k)}(Y_i)\Big). \tag{125}$$

Since the bootstrap process in (124) is a Gaussian process, we bound its supreme using the Borell's inequality (see Proposition A.2.1, van der Vaart and Wellner (1996)). The Borell's inequality requires us bound the following three quantities:

1. the variance of $n^{-1}\sum_{i=1}^n W^2_{z|(j,k)}(Y_i)$;
2. the supremum norm of $n^{-1}\sum_{i=1}^n W^2_{z|(j,k)}(Y_i)$;
3. the L^2 norm covering number of the function class

$$\mathcal{F}_W = \left\{\omega^{(i)}_{z|(j,k)} \mid z\in(0,1), j,k\in[d]\right\}, \tag{126}$$

under the empirical measure $\mathbb{P}_n = n^{-1}\sum_{i=1}^n \delta_{Y_i}$, where

$$\omega^{(i)}_{z|(j,k)} := \frac{1}{n-1}\sum_{i'\neq i}\omega_z(Z_i, Z_{i'})\operatorname{sign}(X_{ij} - X_{i'j})\operatorname{sign}(X_{ik} - X_{i'k}).$$

To bound the variance, we first study $W_{z|(j,k)}(Y_i)$ for each single $i\in[n]$. For any bivariate function $f(y_1, y_2)$, define the operator

$$\mathbb{G}^{(i)}_{n-1}[f] = \frac{1}{\sqrt{n-1}}\sum_{i'\neq i}^n\left(f(Y_{i'}, Y_i) - \mathbb{E}\left[f(Y_{i'}, Y_i)\mid Y_i\right]\right).$$

Now, can be written as

$$W_{z|(j,k)}(Y_i) = \mathbb{E}[W_{z|(j,k)}(Y_i)] + \frac{2}{\sqrt{n-1}}\underbrace{\Big(\mathbb{G}^{(i)}_{n-1}(g_{z|(j,k)}) - \tau_{jk}(z)\mathbb{G}^{(i)}_{n-1}(\omega_z)\Big)}_{J^{(1)}(Y_i)}$$
$$+ \underbrace{2\left(g^{(1)}_{z|(j,k)}(Y_i) - \tau_{jk}(z)\omega^{(1)}_z(Z_i)\right)}_{J^{(2)}(Y_i)}. \tag{127}$$

From (84) and (94), we have that almost surely

$$\max_{i\in[n]}\sup_{j,k\in[d]}\sup_{z\in(0,1)} J^{(2)}(Y_i) \leq Ch^{-1}. \tag{128}$$

Using Lemma 13, we have

$$\sup_{z,j,k}\mathbb{E}[W_{z|(j,k)}(Y_i)] \leq \sup_{z,j,k} 2\Big(\big|\mathbb{E}\left[\mathbb{U}_n\left[g_{z|(j,k)}\right]\right] - f^2_Z(z)\tau_{jk}(z)\big| + \big|\mathbb{E}\left[\mathbb{U}_n\left[\omega_z\right]\right] - f^2_Z(z)\big|\Big) \leq Ch^2. \tag{129}$$

Similar to the proof of Lemma 15 and Lemma 17, with probability $1-\delta$, we have

$$\max_{i\in[n]}\sup_{j,k\in[d]}\sup_{z\in(0,1)}\left|\mathbb{G}_{n-1}^{(i)}\left[\frac{h^{3/2}\big(g_{z|(j,k)}-\tau_{jk}(z)\omega_z\big)}{\sqrt{\log(d/h)\vee\log(n/\delta)}}\right]\right|\le C. \tag{130}$$

Plugging (128), (129) and (130) into (127), with probability $1-1/d$, we have

$$\max_{j,k\in[d]}\sup_{z\in(0,1)}\frac{1}{n}\sum_{i=1}^{n}W_{z|(j,k)}^2(Y_i)\le\max_{i\in[n]}\max_{j,k\in[d]}\sup_{z\in(0,1)}W_{z|(j,k)}^2(Y_i)\le Ch^{-2}, \tag{131}$$

as $\log(d/h)/(nh)=o(1)$ and $h=o(1)$.

Next, we bound the covering number of the function class $\mathcal{F}_W$ defined in (126). For some M_0 to be determined later, let $\{K_h(z_\ell-\cdot)\}_{\ell\in[M_0]}$ be the ϵ-net of

$$\mathcal{K}=\{K\left((s-\cdot)/h\right)\mid s\in(0,1)\}.$$

That is, for any $z\in(0,1)$, there exists a z_ℓ such that $\|K_h(z_\ell-\cdot)-K_h(z-\cdot)\|_{L^2(\mathbb{P}_n)}^2\le\epsilon$. For this z_ℓ, we also have

$$\begin{aligned}\|\omega_{z|(j,k)}^{(i)}-\omega_{z_\ell|(j,k)}^{(i)}\|_{L^2(\mathbb{P}_n)}^2&\le\frac{1}{n}\sum_{i=1}^{n}\left(\frac{1}{n-1}\sum_{i'\neq i}|\omega_z(Z_i,Z_{i'})-\omega_{z'}(Z_i,Z_{i'})|\right)^2\\&\le\frac{1}{n}\sum_{i=1}^{n}(K_h(z-Z_i))^2\left(\frac{1}{n-1}\sum_{i'\neq i}|K_h(z-Z_{i'})-K_h(z_\ell-Z_{i'})|^2\right)\\&\quad+\frac{1}{n}\sum_{i=1}^{n}\big(K_h(z-Z_i)-K_h(z_\ell-Z_i)\big)^2\left(\frac{1}{n-1}\sum_{i'\neq i}|K_h(z_\ell-Z_{i'})|^2\right)\\&\le C\epsilon^2h^{-2}.\end{aligned}$$

Therefore, as $M_0\le(C/\epsilon)^v$, we have $N(\mathcal{F}_W,\|\cdot\|_{L^2(\mathbb{P}_n)},h^{-1}\epsilon)\le d^2(C/\epsilon)^{3v}$.

Similarly, for the function class

$$\mathcal{F}_W'=\big\{W_{z|(j,k)}(Y_i)\mid z\in(0,1),j,d\in[d]\big\}$$

we have

$$N(\mathcal{F}_W',\|\cdot\|_{L^2(\mathbb{P}_n)},h^{-1}\epsilon)\le N(\mathcal{F}_W,\|\cdot\|_{L^2(\mathbb{P}_n)},h^{-1}\epsilon)\le d^2(C/\epsilon)^{6v}. \tag{132}$$

This bound follows by combining the the fact that $\tau_{jk}(\cdot)$ is Lipschitz (since $\mathbf{\Sigma}_{jk}(\cdot)\in\mathcal{H}(2,L)$) with Lemma 26 and Lemma 27.

Now, the Dudley's inequality (see Lemma 2.2.8 in van der Vaart and Wellner, 1996), together with the fact that $\mathbb{U}_n[\omega_{z_0}^B](\widehat{\tau}_{jk}^B(z)-\tau_{jk}(z))$ is normally distributed conditionally on data (see (125)), the upper bound and variance bound in (131) and the covering number on $\mathcal{F}_W'$ above, gives us

$$\mathbb{E}\left[\sup_{z\in(0,1)}\max_{j,k\in[d]}\mathbb{U}_n[\omega_{z_0}^B]\Big(\widehat{\tau}_{jk}^B(z)-\tau_{jk}(z)\Big)\right]\le C\sqrt{\frac{\log(d/h)}{nh^2}}.$$

Using the Borell's inequality, on the event that (131) is true, we have

$$\mathbb{P}_\xi\left(\sup_{z\in(0,1)}\max_{j,k\in[d]}\mathbb{U}_n[\omega_{z_0}^B]\Big(\widehat{\tau}_{jk}^B(z)-\tau_{jk}(z)\Big)\ge C\sqrt{\frac{\log(d/h)}{nh^2}}\right)\ge1/d.$$

Since (131) is true with probability $1-1/d$, the first part of the lemma is proved.

Similarly, we can bound $\Delta W_{z|(j,k)}$. By (127), we have

$$\Delta W_{z|(j,k)}=\bar{\xi}\cdot\mathbb{E}[W_{z|(j,k)}(Y)]+\frac{1}{n}\sum_{i=1}^{n}\frac{2J^{(1)}(Y_i)}{\sqrt{n-1}}\xi_i, \tag{133}$$

where $\bar{\xi}=n^{-1}\sum_{i=1}^n\xi_i$. From the concentration of sub-Gaussian random variables, we have $\mathbb{P}(|\bar{\xi}|<C\sqrt{\log d/n})\ge1-1/d$. Combining with (129), we have

$$\mathbb{P}_\xi\left(\sup_{z\in(0,1)}\max_{j,k\in[d]}\bar{\xi}\cdot\mathbb{E}[W_{z|(j,k)}(Y_i)]\ge\sqrt{\frac{Ch^4\log d}{n}}\right)\le1/d. \tag{134}$$

According to (130), with probability $1-1/d$, we have

$$\sup_{z\in(0,1)}\max_{j,k\in[d]}\frac{1}{n}\sum_{i=1}^{n}\left(\frac{2J^{(1)}(Y_i)}{\sqrt{n-1}}\right)^2\le\max_{i\in[n]}\sup_{z\in(0,1)}\max_{j,k\in[d]}\left(\frac{2J^{(1)}(Y_i)}{\sqrt{n-1}}\right)^2\le\frac{C\log(d/h)}{nh^3}. \tag{135}$$

Define the function class $\widetilde{F}_W=\{J^{(1)}(\cdot)\mid z\in(0,1),j,k\in[d]\}$. By the definition of $J^{(1)}$ in (127), we apply Lemma 26 to the covering number of function classes consisting of $W_{z|(j,k)}$, $g_{z|(j,k)}^{(1)}$ and $\omega_z^{(1)}$ in (132), (144) and (153) to obtain

$$N(\widetilde{\mathcal{F}}_W,\|\cdot\|_{L^2(\mathbb{P}_n)},h^{-1}\epsilon)\le d^2(C/\epsilon)^{cv}.$$

The Borell's inequality, on the event that (135) is true, gives us

$$\mathbb{P}_\xi\left(\max_{j,k\in[d]}\sup_{z\in(0,1)}\frac{1}{n}\sum_{i=1}^{n}J^{(1)}(Y_i)\xi_i\ge C\sqrt{\frac{\log(d/h)}{n^2h^3}}\right)\le1/d. \tag{136}$$

Plugging (134) and (136) into (133), the proof of the second part is complete. ■

The following lemma presents a convergence rate of $\mathbb{U}^B(\omega_z)$ to $f_Z^2(z)$.

Lemma 24 *Under the conditions of Lemma 20, with probability* $1-1/n$,

$$\mathbb{P}_\xi\left(\sup_{z\in(0,1)}\big|\mathbb{U}_n[\omega_z^B]]-f_Z^2(z)\big|>C\sqrt{\log(1/h)/(nh^2)}\right)\le1/n.$$

Proof The proof is similar to that of Lemma 23. We define

$$\overline{W}_{z|(j,k)}(Z_i)=\frac{2}{n-1}\sum_{i'\neq i}\Big(\omega_z(Z_i,Z_{i'})-f_Z^2(z)\Big).$$

Conditionally on the data $\{Y_i\}_{i\in[n]}$,

$$\sqrt{n}\cdot(\mathbb{U}_n[\omega_z^B]-f_Z^2(z))=\frac{1}{\sqrt{n}}\sum_{i=1}^n\overline{W}_{z|(j,k)}(Z_i)\xi_i\sim N\Big(0,\frac{1}{n}\sum_{i=1}^n\overline{W}^2_{z|(j,k)}(Z_i)\Big).$$

Note that

$$\overline{W}_{z|(j,k)}(Y_i)=\mathbb{E}[\overline{W}_{z|(j,k)}(Y_i)]+2(n-1)^{-1/2}\mathbb{G}^{(i)}_{n-1}[\omega_z]+2\omega_z^{(1)}(Z_i).$$

Similar to the proof of Lemma 17 and (130), with probability $1-\delta$,

$$\max_{j,k\in[d]}\sup_{z\in(0,1)}\frac{1}{n}\sum_{i=1}^n\overline{W}^2_{z|(j,k)}(Y_i)\le\max_{i\in[n]}\max_{j,k\in[d]}\sup_{z\in(0,1)}\overline{W}^2_{z|(j,k)}(Y_i)\le Ch^{-2}. \tag{137}$$

Using Lemmas 29, 26 and 27, we can bound the covering number of the function class

$$\mathcal{F}''_W=\{\overline{W}_{z|(j,k)}(Y_i)|z\in(0,1)\}$$

by $N(\mathcal{F}''_W,\|\cdot\|_{L^2(\mathbb{P}_n)},h^{-1}\epsilon)\le(C/\epsilon)^{6v}$.

The remained of the proof follows the proof of Lemma 23. Using the Dudley's and Borell's inequality (see Lemma 2.2.8 and Proposition A.2.1 van der Vaart and Wellner, 1996)), on the event that (137) is true, we have

$$\mathbb{P}_\xi\left(\sup_{z\in(0,1)}\big(\mathbb{U}_n[\omega_z^B]-f_Z^2(z)\big)\ge C\sqrt{\frac{\log(n/h)}{nh^2}}\right)\ge 1/n.$$

The lemma follows since (137) holds with probability $1-1/n$. ∎

G.4 Proof of Lemma 2

Recall that we defined the matrix $\mathbf{\Theta}^{(i)}$ in (57) with elements

$$\mathbf{\Theta}^{(i)}_{jk}(z)=\pi\cos\big((\pi/2)\tau_{jk}(z)\big)\cdot\frac{1}{n-1}\sum_{i'\neq i}\tau^{(1)}_{jk}(Y_{i'}),$$

and $\tau^{(1)}_{jk}$ defined in (12). The strategy of the proof is to establish

$$\frac{1}{n}\sum_{i=1}^n\Big(\widehat{\mathbf{\Omega}}_j^T(z_0)\widehat{\mathbf{\Theta}}^{(i)}(z_0)\widehat{\mathbf{\Omega}}_k(z_0)\Big)^2\xrightarrow{P}\mathrm{Var}(\mathbf{\Omega}_j^T(z_0)\mathbf{\Theta}_{z_0}\mathbf{\Omega}_k(z_0))\qquad\text{and}\tag{138}$$

$$[\mathbb{U}_n[\omega_{z_0}]]^2\xrightarrow{P}f_Z^4(z_0).\tag{139}$$

The lemma then follows from the Slutsky's theorem.

We first establish (138). Let

$$\Delta_1=\frac{1}{n}\sum_{i=1}^n\Big(\widehat{\mathbf{\Omega}}_j^T(z_0)\widehat{\mathbf{\Theta}}^{(i)}(z_0)\widehat{\mathbf{\Omega}}_k(z_0)\Big)^2-\frac{1}{n}\sum_{i=1}^n\Big(\mathbf{\Omega}_j^T(z_0)\widehat{\mathbf{\Theta}}^{(i)}(z_0)\widehat{\mathbf{\Omega}}_k(z_0)\Big)^2\text{ and}$$

$$\Delta_2=\frac{1}{n}\sum_{i=1}^n\Big(\mathbf{\Omega}_j^T(z_0)\widehat{\mathbf{\Theta}}^{(i)}(z_0)\widehat{\mathbf{\Omega}}_k(z_0)\Big)^2-\frac{1}{n}\sum_{i=1}^n\Big(\mathbf{\Omega}_j^T(z_0)\widehat{\mathbf{\Theta}}^{(i)}(z_0)\mathbf{\Omega}_k(z_0)\Big)^2.$$

We can bound Δ_1 as

$$\begin{aligned}|\Delta_1|&=\left|(\widehat{\mathbf{\Omega}}_j(z_0)-\mathbf{\Omega}_j(z_0))^T\cdot\frac{1}{n}\sum_{i=1}^n\widehat{\mathbf{\Theta}}^{(i)}(z_0)\widehat{\mathbf{\Omega}}_k(z_0)\widehat{\mathbf{\Omega}}_k^T(z_0)\widehat{\mathbf{\Theta}}^{(i)}(z_0)\cdot(\widehat{\mathbf{\Omega}}_j(z_0)+\mathbf{\Omega}_j(z_0))^T\right|\\&\le\big\|\widehat{\mathbf{\Omega}}_j(z_0)-\mathbf{\Omega}_j(z_0)\big\|_1\big\|\widehat{\mathbf{\Omega}}_j(z_0)+\mathbf{\Omega}_j(z_0)\big\|_1\big\|\widehat{\mathbf{\Omega}}_k(z_0)\big\|_1^2\big\|\widehat{\mathbf{\Theta}}^{(i)}(z_0)\big\|^2_{\max}\\&=O_P\big(M^4r_{2n}(2\pi)^2h^{-1}\big)=o_P(1),\end{aligned}\tag{140}$$

where the second equality is by Assumption 4.4 and $\big\|\widehat{\mathbf{\Theta}}^{(i)}(z_0)\big\|_{\max}\le 2\pi h^{-1/2}$ with probability $1-c/d$. Similarly,

$$|\Delta_2|=O_P\big(M^4r_{2n}(2\pi)^2h^{-1}\big)=o_P(1).\tag{141}$$

Next, $\max_{i\in[n]}h^{1/2}\|\widehat{\mathbf{\Theta}}^{(i)}-\mathbf{\Theta}^{(i)}\|_{\max}\le\Delta_{31}+\Delta_{32}$, where

$$\Delta_{31}=\max_{i\in[n],j,k\in[d]}\pi\left|\cos\left((\pi/2)\widehat{\tau}_{jk}(z_0)\right)-\cos\left((\pi/2)\tau_{jk}(z_0)\right)\right|\cdot\left|\frac{h^{1/2}}{n-1}\sum_{i'\neq i}\tau^{(1)}_{jk}(Y_{i'})\right|;$$

$$\Delta_{32}=\max_{i\in[n],j,k\in[d]}\pi\left|\cos\left((\pi/2)\tau_{jk}(z_0)\right)\right|\cdot h^{1/2}\left|q_{i,jk}(z_0)-\frac{1}{n-1}\sum_{i'\neq i}\tau^{(1)}_{jk}(Y_{i'})\right|,$$

where $q_{i,jk}$ is defined in (13). Using Lemma 9 and Lemma 10, with probability $1-c/d$

$$\Delta_{31}\le\pi^2\|K\|_\infty\cdot\max_{j,k}|\widehat{\tau}_{jk}(z_0)-\widehat{\tau}_{jk}(z_0)|\lesssim\left(h^2+\sqrt{\log(dn)/(nh)}\right).$$

Let $\bar{q}_{i,jk}=q_{i,jk}+\widehat{\tau}_{jk}(z_0)$. By the Hoeffding's inequality and union bound, we have

$$\mathbb{P}\left(\max_{i,j,k}h^{3/2}|\bar{q}_{i,jk}-\mathbb{E}[\bar{q}_{i,jk}]|>t\,\middle|\,Y_i\right)\le 2nd^2\exp\left(-(n-1)t^2/2\right).$$

Setting $t=\sqrt{\log(dn)/n}$ and taking the expectation above, with probability $1-c/d$,

$$\max_{i,j,k}h^{1/2}|\bar{q}_{i,jk}-\mathbb{E}[\bar{q}_{i,jk}]|\le\sqrt{\log(dn)/n}.$$

Similarly, with probability $1-c/d$,

$$\Delta_{32}\le\pi h^{1/2}\max_{j,k}|\widehat{\tau}_{jk}(z_0)-\widehat{\tau}_{jk}(z_0)|+\max_{i,j,k}h^{1/2}|\bar{q}_{i,jk}-\mathbb{E}[\bar{q}_{i,jk}]|\lesssim\sqrt{\log(dn)/n}+h^{3/2}.$$

Therefore,

$$\begin{aligned}\Delta_3&:=\frac{1}{n}\sum_{i=1}^n\Big(\mathbf{\Omega}_j^T(z_0)\widehat{\mathbf{\Theta}}^{(i)}(z_0)\mathbf{\Omega}_k(z_0)\Big)^2-\frac{1}{n}\sum_{i=1}^n\Big(\mathbf{\Omega}_j^T(z_0)\mathbf{\Theta}^{(i)}(z_0)\mathbf{\Omega}_k(z_0)\Big)^2\\&\le 4M^4\pi h^{-1/2}\max_{i\in[n]}\|\widehat{\mathbf{\Theta}}^{(i)}-\mathbf{\Theta}^{(i)}\|_{\max}=O_P\Big(h+\sqrt{\log(dn)/(nh^3)}\Big)=o_P(1).\end{aligned}\tag{142}$$

Finally, by the law of large numbers,

$$\frac{1}{n}\sum_{i=1}^{n}\left(\mathbf{\Omega}_j^T(z_0)\mathbf{\Theta}^{(i)}(z_0)\mathbf{\Omega}_k(z_0)\right)^2 \xrightarrow{P} \mathbb{E}[\mathbf{\Omega}_j^T(z_0)\mathbf{\Theta}^{(i)}(z_0)\mathbf{\Omega}_k(z_0)]^2 = \mathrm{Var}(\mathbf{\Omega}_j^T(z_0)\mathbf{\Theta}_{z_0}\mathbf{\Omega}_k(z_0)).$$

Combining (140), (141) and (142), we prove (138).

Using Lemma 24 and the continuous mapping theorem, we also prove (139). By the Slutsky's theorem, we have $\widehat{\sigma}_{jk}(z_0) \xrightarrow{P} \sigma_{jk}(z_0)$.

Appendix H. Results on Covering Number

In this section, we present several results on the covering number of certain function classes. The first two lemmas, Lemmas 26 and 27, are preliminary technical lemmas that will be used to prove Lemmas 28, 29 and 30. Lemma 26 provides bounds on the covering numbers for function classes generated from products and additions of two function classes. Lemma 27 provides a bound on the covering number of a class of constant functions.

Before presenting these lemmas, we first state a result on the covering number of kernel functions.

Lemma 25 *(Lemma 22 of Nolan and Pollard, 1987). Let $K : \mathbb{R} \mapsto \mathbb{R}$ be a bounded variation function. The following function class*

$$\mathcal{K} = \left\{ K\left(\frac{s-\cdot}{h}\right) \,\middle|\, h > 0, s \in \mathbb{R} \right\}$$

indexed by the kernel bandwidth satisfies the uniform entropy condition

$$\sup_Q N(\mathcal{K}, L_2(Q), \epsilon) \le C\epsilon^{-v}, \quad \text{for all } \epsilon \in (0,1), \tag{143}$$

for some $C > 0$ and $v > 0$.

The following lemma is about the covering number of summation and product of functions.

Lemma 26 *Let $\mathcal{F}_1$ and $\mathcal{F}_2$ be two function classes satisfying*

$$N(\mathcal{F}_1, \|\cdot\|_{L_2(Q)}, a_1\epsilon) \le C_1\epsilon^{-v_1} \qquad \text{and} \qquad N(\mathcal{F}_2, \|\cdot\|_{L_2(Q)}, a_2\epsilon) \le C_2\epsilon^{-v_2}$$

for some $C_1, C_2, a_1, a_2, v_1, v_2 > 0$ and any $0 < \epsilon < 1$. Define $\|\mathcal{F}_\ell\|_\infty = \sup\{\|f\|_\infty, f \in \mathcal{F}_\ell\}$ for $\ell = 1, 2$ and $U = \|\mathcal{F}_1\|_\infty \vee \|\mathcal{F}_2\|_\infty$. For the function classes $\mathcal{F}_\times = \{f_1 f_2 \mid f_1 \in \mathcal{F}_1, f_2 \in \mathcal{F}_2\}$ and $\mathcal{F}_+ = \{f_1 + f_2 \mid f_1 \in \mathcal{F}_1, f_2 \in \mathcal{F}_2\}$, we have for any $\epsilon \in (0,1)$,

$$N(\mathcal{F}_\times, \|\cdot\|_{L_2(Q)}, \epsilon) \le C_1C_2\left(\frac{2a_1U}{\epsilon}\right)^{v_1}\left(\frac{2a_2U}{\epsilon}\right)^{v_2};$$
$$N(\mathcal{F}_+, \|\cdot\|_{L_2(Q)}, \epsilon) \le C_1C_2\left(\frac{2a_1}{\epsilon}\right)^{v_1}\left(\frac{2a_2}{\epsilon}\right)^{v_2}.$$

Proof For any $\epsilon \in (0,1)$, let $N_1 = \{f_{11}, \ldots, f_{1N_1}\}$ and $N_2 = \{f_{21}, \ldots, f_{2N_2}\}$ be the $\epsilon/(2U)$-net of $\mathcal{F}_1$ and $\mathcal{F}_2$ respectively with

$$N_1 \le C_1\left(\frac{2a_1U}{\epsilon}\right)^{v_1} \text{ and } N_2 \le C_2\left(\frac{2a_2U}{\epsilon}\right)^{v_2}.$$

Define the set $N = \{f_{1j}f_{2k} \mid f_{1j} \in N_1, f_{2k} \in N_2\}$. We now show that N is an ϵ-net for $\mathcal{F}_\times$. For any $f_1f_2 \in \mathcal{F}$, there exist two functions $f_{1j} \in N_1$ and $f_{2k} \in N_2$ such that $\|f_1 - f_{1j}\|_{\|\cdot\|_{L_2(Q)}} \le \epsilon/(2U)$ and $\|f_2 - f_{2k}\|_{\|\cdot\|_{L_2(Q)}} \le \epsilon/(2U)$. Moreover, we have $f_{1j}f_{2k} \in N$ and

$$\|f_1f_2 - f_{1j}f_{2k}\|_{\|\cdot\|_{L_2(Q)}} \le \|\mathcal{F}_2\|_\infty\|f_1 - f_{1j}\|_{\|\cdot\|_{L_2(Q)}} + \|\mathcal{F}_1\|_\infty\|f_2 - f_{2k}\|_{\|\cdot\|_{L_2(Q)}} \le \epsilon.$$

Therefore N is the ϵ-net for $\mathcal{F}_\times$. Similarly, we also have

$$\|(f_1 + f_2) - (f_{1j} + f_{2k})\|_{\|\cdot\|_{L_2(Q)}} \le \|f_1 - f_{1j}\|_{\|\cdot\|_{L_2(Q)}} + \|f_2 - f_{2k}\|_{\|\cdot\|_{L_2(Q)}} \le \epsilon/U.$$

So $N' = \{f_{1j} + f_{2k} \mid f_{1j} \in N_1, f_{2k} \in N_2\}$ is the ϵ/U-net of $\mathcal{F}_+$. We finally complete the proof by showing that

$$|N'| = |N| = N_1N_2 \le C_1C_2\left(\frac{2a_1U}{\epsilon}\right)^{v_1}\left(\frac{2a_2U}{\epsilon}\right)^{v_2}.$$

■

Lemma 27 *Let $f(s)$ be a Lipschitz function defined on $[a,b]$ such that $|f(s) - f(s')| \le L_f|s - s'|$ for any $s, s' \in [a,b]$. We define the constant function class $\mathcal{F}_c = \{g_s(\cdot) \equiv f(s) \mid s \in [a,b]\}$. For any probability measure Q, the covering number of $\mathcal{F}_c$ satisfies for any $\epsilon \in (0,1)$,*

$$N(\mathcal{F}_c, \|\cdot\|_{L_2(Q)}, \epsilon) \le L_f \cdot \frac{|b-a|}{\epsilon}.$$

Proof Let $N = \{a + i\epsilon/L_f \mid i = 0, \ldots, \lfloor L_f|b-a|/\epsilon \rfloor\}$. For any $g_{s_0} \in \mathcal{F}_c$, there exists a $s \in N$ such that $|s_0 - s| \le \epsilon/L_f$ and we have

$$\|g_{s_0} - g_s\|_{L^2(Q)} = |f(s_0) - f(s)| \le L_f|s_0 - s| \le \epsilon.$$

Therefore $\{g_s \mid s \in N\}$ is the ϵ-net of $\mathcal{F}_c$. As $|N| \le L_f|b-a|/\epsilon$, the lemma is proved. ■

The following lemma presents the covering number of function classes consisting of $g^{(1)}_{z|(j,k)}(\cdot)$ or $g^{(2)}_{z|(j,k)}(\cdot)$ defined in (41) and (42).

Lemma 28 *For some $0 < \underline{h} < \overline{h} < 1$, we consider the class of functions*

$$\mathcal{F}^{(1)} = \left\{\sqrt{h}\cdot g^{(1)}_{z|(j,k)} \,\middle|\, h \in [\underline{h}, \overline{h}], z \in (0,1), j, k \in [d]\right\}; \tag{144}$$
$$\mathcal{F}^{(2)} = \left\{h\cdot g^{(2)}_{z|(j,k)} \,\middle|\, h \in [\underline{h}, \overline{h}], z \in (0,1), j, k \in [d]\right\},$$

where $g^{(1)}_{z|(j,k)}$ *and* $g^{(2)}_{z|(j,k)}$ *are defined in* (41) *and* (42). *There exist constants* $C_{(1)}$ *and* $C_{(2)}$ *such that for any* $\epsilon \in (0,1)$

$$\sup_Q N(\mathcal{F}^{(1)}, \|\cdot\|_{L_2(Q)}, \epsilon) \leq \frac{d^2 C_{(1)}}{\underline{\mathrm{h}}^{v+9}\epsilon^{v+6}} \quad \text{and} \quad \sup_Q N(\mathcal{F}^{(2)}, \|\cdot\|_{L_2(Q)}, \epsilon) \leq \frac{d^2 C_{(2)}}{\underline{\mathrm{h}}^{2v+18}\epsilon^{4v+15}}.$$

Proof Recall that

$$g^{(1)}_{z|(j,k)}(y) = \mathbb{E}[g_{z|(j,k)}(y,Y)] - \mathbb{E}\left[\mathbb{U}_n(g_{z|(j,k)})\right] \qquad \text{and}$$
$$g^{(2)}_{z|(j,k)}(y_1,y_2) = g_{z|(j,k)}(y_1,y_2) - g^{(1)}_{z|(j,k)}(y_1) - g^{(1)}_{z|(j,k)}(y_2) - \mathbb{E}\left[\mathbb{U}_n(g_{z|(j,k)})\right].$$

Our proof strategy for bounding the covering numbers of $\mathcal{F}^{(1)}$ and $\mathcal{F}^{(2)}$ is to decompose them into the following three auxiliary function classes:

$$\mathcal{F}^{(1)}_{1,jk} = \left\{\mathbb{E}[g_{z|(j,k)}(y,Y)] \mid h \in [\underline{\mathrm{h}}, \overline{\mathrm{h}}], z \in (0,1)\right\};$$
$$\mathcal{F}^{(1)}_{2} = \{\mathbb{E}\left[\mathbb{U}_n(g_{h,z})\right] \mid h \in [\underline{\mathrm{h}}, \overline{\mathrm{h}}], z \in (0,1)\};$$
$$\mathcal{F}^{(2)}_{jk} = \{g_{z|(j,k)}(y_1,y_2) \mid h \in [\underline{\mathrm{h}}, \overline{\mathrm{h}}], z \in (0,1)\}.$$

Observe that we can write

$$\mathcal{F}^{(1)} = \{\sqrt{h}\cdot(f_1 - f_2) \mid h \in [\underline{\mathrm{h}}, \overline{\mathrm{h}}], f_1 \in \mathcal{F}^{(1)}_{1,jk}, f_2 \in \mathcal{F}^{(1)}_2, j,k \in [d]\};$$
$$\mathcal{F}^{(2)} = \{h\cdot(f_1 - f_2 - f_3 - f_4) \mid h \in [\underline{\mathrm{h}}, \overline{\mathrm{h}}], f_1 \in \mathcal{F}^{(2)}_{jk}, f_2, f_3 \in \mathcal{F}^{(1)}_{1,jk}, f_4 \in \mathcal{F}^{(1)}_2, j,k \in [d]\}.$$

Therefore, we can apply Lemma 26 on the addition and product of functions classes and Lemma 27 on the constant functions to bound the covering numbers of $\mathcal{F}^{(1)}$ and $\mathcal{F}^{(2)}$.

Covering number of $\mathcal{F}^{(1)}_{1,jk}$. We bound the covering number of $\mathcal{F}^{(1)}_{1,jk}$ first. Recall from (62) that for $y' = (z', \boldsymbol{x}')$

$$\mathbb{E}\left[g_{z|(j,k)}(y',Y)\right] = K_h(z'-z)\int K_h(s-z)\varphi\left(x'_j, x'_k, \boldsymbol{\Sigma}_{jk}(s)\right) f_Z(s)ds.$$

We have $\mathcal{F}^{(1)}_{1,jk} = \left\{f_1 \cdot f_2 \mid f_1 \in \{K_h(\cdot - z)\}, f_2 \in \mathcal{F}^{(1)}_{3,jk}\right\}$ where

$$\mathcal{F}^{(1)}_{3,jk} = \left\{q_{z,h}(x,y) = \int K_h(s-z)\varphi\left(x,y,\boldsymbol{\Sigma}_{jk}(s)\right) f_Z(s)ds, h \in [\underline{\mathrm{h}}, \overline{\mathrm{h}}], z \in (0,1)\right\}. \quad (145)$$

Let $\bar{\varphi}_{x,y}(s) = \varphi\left(x,y,\boldsymbol{\Sigma}_{jk}(s)\right) f_Z(s)$. Then $\mathcal{F}^{(1)}_{3,jk}$ is the class of functions generated by the convolution $q_{z,h}(x,y) = (K_h * \bar{\varphi}_{x,y})(z)$. The L_1 norm of the derivative of K_h can be bounded by

$$\|K'_h\|_1 = \int \frac{1}{h^2}\left|K'\left(\frac{t}{h}\right)\right| dt = h^{-1}\int |K'(t)|dt = h^{-1}\mathrm{TV}(K), \quad (146)$$

where $\mathrm{TV}(K)$ is the total variation of the kernel K. Similarly we have for any $h \in [\underline{\mathrm{h}}, \overline{\mathrm{h}}]$,

$$\left\|\frac{\partial}{\partial h}K_h\right\|_1 \leq \int h^{-2}|K(t/h)|dt + \int h^{-3}|K'(t/h)|dt = h^{-1}\|K\|_1 + h^{-2}\mathrm{TV}(K).$$

We can apply a similar argument as in (85) and derive that

$$\sup_{z_0,h,x,y}\left|\frac{\partial}{\partial z}q_{z,h}(x,y)\Big|_{z=z_0}\right| = \sup_{h,x,y}\|K'_h * \bar{\varphi}_{x,y}\|_\infty \leq \sup_{h,x,y}\|K'_h\|_1\|\bar{\varphi}_{x,y}\|_\infty \leq 2\underline{\mathrm{h}}^{-1}\mathrm{TV}(K)\bar{\mathrm{f}}_Z, \quad (147)$$

where the first equality is due to the property of the derivative of a convolution, the first inequality is because of Young's inequality and the last inequality is by (146). Similarly, we have

$$\begin{aligned}\sup_{z,h_0,x,y}\left|\frac{\partial}{\partial h}q_{z,h}(x,y)\Big|_{h=h_0}\right| &= \sup_{h_0,x,y}\|\nabla_{h=h_0}K_h * \bar{\varphi}_{x,y}\|_\infty \\ &\leq \sup_{h_0,x,y}\|\nabla_{h=h_0}K_h\|_1\|\bar{\varphi}_{x,y}\|_\infty \\ &\leq 2\bar{\mathrm{f}}_Z(\underline{\mathrm{h}}^{-1}\|K\|_1 + \underline{\mathrm{h}}^{-2}\mathrm{TV}(K)).\end{aligned} \quad (148)$$

Therefore for any $z_1, z_2 \in (0,1)$, $h_1, h_2 \in [\underline{\mathrm{h}}, \overline{\mathrm{h}}]$, denoting $C_h := 2\bar{\mathrm{f}}_Z[(\underline{\mathrm{h}}^{-1} + \underline{\mathrm{h}}^{-2})\mathrm{TV}(K) + \underline{\mathrm{h}}^{-1}\|K\|_1]$, we have

$$\sup_{x,y}|q_{z_1,h_1}(x,y) - q_{z_2,h_2}(x,y)| \leq C_h\max(|z_1 - z_2|, |h_1 - h_2|).$$

Given any measure Q on $\mathbb{R}^2$, let $\mathcal{Z}$ be the ϵ/C_h-net of $(0,1)\times[\underline{\mathrm{h}}, \overline{\mathrm{h}}]$ under $\|\cdot\|_\infty$. For any $z \in (0,1), h \in [\underline{\mathrm{h}}, \overline{\mathrm{h}}]$, choose $(z_0, h_0) \in \mathcal{Z}$ such that $\max(|z - z_0|, |h - h_0|) \leq \epsilon/C_h$ and we have

$$\|q_{z,h} - q_{z_0,h_0}\|_{\|\cdot\|_{L_2(Q)}} \leq \|q_{z,h} - q_{z_0,h_0}\|_\infty \leq \epsilon.$$

This shows that $\{q_{z,h} \mid (z,h) \in \mathcal{Z}\}$ is the ϵ-net of $\mathcal{F}^{(1)}_{3,jk}$ and

$$\sup_Q N(\mathcal{F}^{(1)}_{3,jk}, \|\cdot\|_{L_2(Q)}, \epsilon) \leq |\mathcal{Z}| \leq \left(\frac{C_h}{\epsilon}\right)^2. \quad (149)$$

According to the formulation in (62) and Lemma 26 and (143), we have

$$\sup_Q N(\mathcal{F}^{(1)}_{1,jk}, \|\cdot\|_{L_2(Q)}, \epsilon) \leq C\left(\frac{1}{\underline{\mathrm{h}}\epsilon}\right)^v\left(\frac{\overline{\mathrm{h}} - \underline{\mathrm{h}}}{\underline{\mathrm{h}}^2\epsilon}\right)\left(\frac{C_h}{\underline{\mathrm{h}}\epsilon}\right)^2 \leq \frac{CC_h^2}{\underline{\mathrm{h}}^{v+4}\epsilon^{v+3}}. \quad (150)$$

Covering number of $\mathcal{F}^{(1)}_2$. According to (51) and Assumptions (**T**) and (**D**), we have that for any $z_1, z_2 \in (0,1), h_1, h_2 \in [\underline{\mathrm{h}}, \overline{h}]$

$$\begin{aligned}\left|\mathbb{E}\left[\mathbb{U}_n(g^{(1)}_{z_1|(j,k)})\right] - \mathbb{E}\left[\mathbb{U}_n(g^{(1)}_{z_2|(j,k)})\right]\right| &\leq \left|f^2_Z(z_1)\tau_{jk}(z_1) - f^2_Z(z_2)\tau_{jk}(z_2)\right| + C|h_1^2 - h_2^2| \\ &\leq \bar{\mathrm{f}}^2_Z C_\tau|z_1 - z_2| + 2C\overline{\mathrm{h}}|h_1 - h_2|.\end{aligned}$$

Using Lemma 27, we have

$$\sup_Q N(\mathcal{F}^{(1)}_2, \|\cdot\|_{L_2(Q)}, \epsilon) \leq \left(\frac{\bar{\mathrm{f}}^2_Z C_\tau + 2C\overline{\mathrm{h}}}{\epsilon}\right)^2. \quad (151)$$

Covering number of $\mathcal{F}^{(1)}$. Observe that the function $g(h) = \sqrt{h}$ is Lipschitz on $[\underline{h}, \overline{h}]$ with Lipschitz constant $(\underline{h})^{-1/2}/2$. Combining (150) and (151) with Lemma 26, we have

$$\sup_Q N(\mathcal{F}^{(1)}, \|\cdot\|_{L_2(Q)}, \epsilon) \leq d^2 \cdot \frac{2CC_h^2(\bar{f}_Z^2 C_\tau + 2C\overline{h})^2}{\underline{h}^{v+5}\epsilon^{v+6}}. \tag{152}$$

Here the additional d^2 on the right hand side of (152) is because we also take supreme over $j, k \in [d]$ in the definition of $\mathcal{F}^{(1)}$. As $C_h \leq 2\bar{f}_Z(2\mathrm{TV}(K) + \|K\|_1) \cdot \underline{h}^{-2}$, defining

$$C_{(1)} := 4C\bar{f}_Z(2\mathrm{TV}(K) + \|K\|_1)(\bar{f}_Z^2 C_\tau + 2C)^2$$

and the first part of lemma in (144) is proved.

Covering numbers of $\mathcal{F}_{jk}^{(2)}$ and $\mathcal{F}^{(2)}$. Let $N_K = \{K_h(x-z)K_h(y-z) \mid z \in \mathcal{Z}_K, h \in \mathcal{H}_K\}$ be the ϵ-net of the function class $\mathcal{K}^2 = \{K_h(x-z)K_h(y-z) \mid h \in [\underline{h}, \overline{h}], z \in (0,1)\}$. According to Lemma 26 and (143), we have $|N_K| \leq C^2(2\|K\|_\infty/\epsilon)^{2v}$. Given any $g_{h_0,z_0} \in \mathcal{F}_{jk}^{(2)}$, there exist $h_1 \in \mathcal{Z}_K, z_1 \in \mathcal{H}_K$ such that

$$\|g_{h_0,z_0} - g_{h_1,z_1}\|_{\|\cdot\|_{L_2(Q)}} \leq \|K_{h_0}(\cdot - z_0)K_{h_0}(\cdot - z_0) - K_{h_1}(\cdot - z_1)K_{h_1}(\cdot - z_1)\|_{\|\cdot\|_{L_2(Q)}} \leq \epsilon.$$

Therefore $N_g = \{g_{z|(j,k)}(y_1, y_2) \mid z \in \mathcal{Z}_K, h \in \mathcal{H}_K\}$ is an ϵ-net of $\mathcal{H}$ and $|N_g| = |N_K| \leq C^2(2\|K\|_\infty/\epsilon)^{2v}$. Applying Lemma 26 again with (151) and (152), we have

$$\begin{aligned}\sup_Q N(\mathcal{F}^{(2)}, \|\cdot\|_{L_2(Q)}, \epsilon) &\leq d^2C^2\left(\frac{\overline{h}-\underline{h}}{\epsilon}\right)\left(\frac{2\|K\|_\infty}{\epsilon}\right)^{2v}\left(\frac{C_{(1)}}{\underline{h}^{v+9}\epsilon^{v+6}}\right)^2\left(\frac{\bar{f}_Z^2 C_\tau + 2C\overline{h}}{\epsilon}\right)^2 \\ &\leq \frac{d^2 C_{(2)}}{\underline{h}^{2v+18}\epsilon^{4v+15}},\end{aligned}$$

where $C_{(2)} := C^2 4^v \|K\|_\infty^{2v} C_{(1)}^2 (\bar{f}_Z^2 C_\tau + 2C)^2$. Therefore, we complete the proof of the lemma. ■

Similar to Lemma 28, we can also establish the covering number for function classes consisting of $\omega_z^{(1)}$ or $\omega_z^{(2)}$ in the following lemma.

Lemma 29 *For some $0 < \underline{h} < \overline{h} < 1$, we consider the class of functions*

$$\begin{aligned}\mathcal{K}^{(1)} &= \left\{\sqrt{h} \cdot \omega_z^{(1)} \,\middle|\, h \in [\underline{h}, \overline{h}], z \in (0,1)\right\}; \\ \mathcal{K}^{(2)} &= \left\{h \cdot \omega_z^{(2)} \,\middle|\, h \in [\underline{h}, \overline{h}], z \in (0,1)\right\},\end{aligned} \tag{153}$$

where $\omega_z^{(1)}$ and $\omega_z^{(2)}$ are defined in (44) *and* (45)*. There exist constants $C'_{(1)}$ and $C'_{(2)}$ such that for any $\epsilon \in (0,1)$*

$$\sup_Q N(\mathcal{K}^{(1)}, \|\cdot\|_{L_2(Q)}, \epsilon) \leq \frac{C'_{(1)}}{\underline{h}^{2v+7}\epsilon^{v+3}} \quad \text{and} \quad \sup_Q N(\mathcal{K}^{(2)}, \|\cdot\|_{L_2(Q)}, \epsilon) \leq \frac{C'_{(2)}}{\underline{h}^{4v+14}\epsilon^{4v+8}}.$$

Proof The proof is similar to Lemma 28. We first bound $\sup_Q N(\mathcal{K}^{(1)}, \|\cdot\|_{L_2(Q)}, \epsilon)$. We have

$$\begin{aligned}\omega_z^{(1)}(s) &= \mathbb{E}[K_h(s-z)K_h(Z-z)] - \mathbb{E}\left[\mathbb{U}_n(K_h(Z_i - z)K_h(Z_{i'} - z))\right] \\ &= K_h(s-z)\mathbb{E}[K_h(z-Z)] - \{\mathbb{E}[K_h(z-Z)]\}^2.\end{aligned}$$

We first study the covering number of the function class

$$\mathcal{C}_K = \{\mathbb{E}[K_h(z-Z)] = (K_h * f_Z)(z) \mid h \in [\underline{h}, \overline{h}], z \in (0,1)\},$$

where "$*$" denotes the convolution. Just as (145), $\mathcal{C}_K$ is also generated by convolutions. Similar to (147) and (148), we have

$$\begin{aligned}\sup_{z_0,h}\left|\nabla_z \mathbb{E}[K_h(z-Z)]\Big|_{z=z_0}\right| &\leq 2\underline{h}^{-1}\mathrm{TV}(K)\bar{f}_Z \text{ and} \\ \sup_{z,h_0}\left|\nabla_h \mathbb{E}[K_h(z-Z)]\Big|_{h=h_0}\right| &\leq 2\bar{f}_Z(\underline{h}^{-1}\|K\|_1 + \underline{h}^{-2}\mathrm{TV}(K)).\end{aligned}$$

Therefore, following the derivation of (149), for any $z_1, z_2 \in (0,1)$, $h_1, h_2 \in [\underline{h}, \overline{h}]$, we have

$$\left|\mathbb{E}[K_{h_1}(z_1 - Z)] - \mathbb{E}[K_{h_2}(z_2 - Z)]\right| \leq C_h \max(|z_1 - z_2|, |h_1 - h_2|),$$

where $C_h := 2\bar{f}_Z[(\underline{h}^{-1} + \underline{h}^{-2})\mathrm{TV}(K) + \underline{h}^{-1}\|K\|_1]$. From Lemma 27, we have

$$\sup_Q N(\mathcal{C}_K, \|\cdot\|_{L_2(Q)}, \epsilon) \leq C_h/\epsilon \quad \text{and}$$

$$\sup_Q N\big(\{(\mathbb{E}[K_h(z-Z)])^2 \mid z, h\}, \|\cdot\|_{L_2(Q)}, \epsilon\big) \leq C_h/\epsilon.$$

Using the fact that the function $q(h) = 1/\sqrt{h}$ is Lipschitz on $[\underline{h}, \overline{h}]$ with Lipschitz constant $(\underline{h})^{-3/2}/2$ together with Lemma 26, Lemma 27 and (143), we have

$$\sup_Q N(\mathcal{K}^{(1)}, \|\cdot\|_{L_2(Q)}, \epsilon) \leq C\left(\frac{1}{\underline{h}^2\epsilon}\right)^v\left(\frac{C_h}{\underline{h}\epsilon}\right)\left(\frac{C_h}{\epsilon}\right)\left(\frac{\overline{h}-\underline{h}}{\underline{h}^{3/2}\epsilon}\right) \leq \frac{C'_{(1)}}{\underline{h}^{2v+7}\epsilon^{v+3}},$$

where $C'_{(1)} := [2\bar{f}_Z(2\mathrm{TV}(K) + \|K\|_1)C]^2$. Function class $\mathcal{K}^{(2)}$ contains functions in the form

$$\omega_z^{(2)}(s,t) = K_h(s-z)K_h(t-z) - \omega_z^{(1)}(s) - \omega_z^{(1)}(t) - \mathbb{E}\left[\mathbb{U}_n(K_h(Z_i - z)K_h(Z_i - z))\right].$$

By Lemma 26, it suffices to study the covering number of

$$\mathcal{C}'_K = \{K_h(s-z)K_h(t-z) \mid h \in [\underline{h}, \overline{h}], z \in (0,1)\}.$$

Using Lemma 26 and (143) again, we have

$$\sup_Q N(\mathcal{C}'_K, \|\cdot\|_{L_2(Q)}, \epsilon) \leq C^2\left(\frac{2\|K\|_\infty}{\epsilon}\right)^{2v},$$

and therefore combining with the covering number in (153) and (151)

$$\sup_Q N(\mathcal{K}^{(2)}, \|\cdot\|_{L_2(Q)}, \epsilon) \leq C^2\left(\frac{2\|K\|_\infty}{\epsilon}\right)^{2v}\left(\frac{C'_{(1)}}{\underline{h}^{2v+7}\epsilon^{v+3}}\right)^2\left(\frac{C_h}{\epsilon}\right)\left(\frac{\overline{h}-\underline{h}}{\epsilon}\right) \leq \frac{C'_{(2)}}{\underline{h}^{4v+14}\epsilon^{4v+8}},$$

where $C'_{(2)} := C^2 4^v \|K\|_\infty^{2v}(C'_{(1)})^2(\bar{f}_Z^2 C_\tau + 2C)^2$. This completes the proof. ■

Lemma 30 *Suppose $\mathbf{\Omega}(z) \in \mathcal{U}(c, M, \rho)$ for all $z \in (0,1)$. Consider the class of functions $\mathcal{J} = \left\{J_{z|(j,k)} \mid z \in (0,1), j, k \in [d]\right\}$, where $J_{z|(j,k)}$ is defined in (48). There exists positive constants C and c such that*

$$\sup_Q N(\mathcal{J}, \|\cdot\|_{L_2(Q)}, \epsilon/\sqrt{h}) \leq \left(\frac{Cd}{h\epsilon}\right)^c.$$

Proof We denote for any $u, v \in [d]$ and $z \in (0,1)$ that

$$\mathbf{\Phi}_{uv}(z; Y) = \pi \cos\left(\tau_{uv}(z)\frac{\pi}{2}\right)\sqrt{h} \cdot \left[g^{(1)}_{z|(u,v)}(Y) - \tau_{uv}(z)\omega^{(1)}_z(Z)\right] \tag{154}$$

and the matrix $\mathbf{\Phi}(z; Y) = [\mathbf{\Phi}_{uv}(z; Y)]_{u,v\in[d]}$. In order to bound the covering number of $\mathcal{J}$, we define a larger function class

$$\mathcal{J}' = \left\{\mathbf{\Omega}_j^T(z)\mathbf{\Phi}(x; \cdot)\mathbf{\Omega}_k(z) \mid z, x \in (0,1), j, k \in [d]\right\}.$$

Given any measure Q, $j, k \in [d]$ and $x_1, x_2, z_1, z_2 \in (0,1)$, we first bound the difference

$$\begin{aligned}
&\|\mathbf{\Omega}_j^T(z_1)\mathbf{\Phi}(x_1; Y)\mathbf{\Omega}_k(z_1) - \mathbf{\Omega}_j^T(z_2)\mathbf{\Phi}(x_2; Y)\mathbf{\Omega}_k(z_2)\|^2_{L_2(Q)} \\
&\leq 3\|\mathbf{\Omega}_j(z_1) - \mathbf{\Omega}_j(z_2)\|_1^2 \max_{u,v}\|\mathbf{\Phi}_{uv}(x_1; Y)\|^2_{L_2(Q)}\|\mathbf{\Omega}_k(z_1)\|_1^2 \\
&\quad + 3\|\mathbf{\Omega}_j(z_2)\|_1^2 \max_{u,v}\|\mathbf{\Phi}_{uv}(z_1; Y) - \mathbf{\Phi}_{uv}(z_2; Y)\|^2_{L_2(Q)}\|\mathbf{\Omega}_k(z_1)\|_1^2 \\
&\quad + 3\|\mathbf{\Omega}_j(z_2)\|_1^2 \max_{u,v}\|\mathbf{\Phi}_{uv}(x_2; Y)\|^2_{L_2(Q)}\|\mathbf{\Omega}_k(z_1) - \mathbf{\Omega}_k(z_2)\|_1^2.
\end{aligned} \tag{155}$$

Since $\mathbf{\Omega}(z) \in \mathcal{U}(c, M, \rho)$ for any $z \in (0,1)$, we have $\sup_z \|\mathbf{\Omega}_j(z)\|_1 \leq M$. Next, using Theorem 2.5 of Stewart et al. (1990), for any $z_1, z_2 \in (0,1)$,

$$\|\mathbf{\Omega}(z_1) - \mathbf{\Omega}(z_2)\|_2 \leq \|\mathbf{\Omega}(z_1)\|_2\|\mathbf{\Omega}(z_2)(\mathbf{\Sigma}(z_1) - \mathbf{\Sigma}(z_2))\|_2.$$

Since $\mathbf{\Omega}(z) \in \mathcal{U}(c, M, \rho)$ for any $z \in (0,1)$, we further have

$$\|\mathbf{\Omega}(z_1) - \mathbf{\Omega}(z_2)\|_1 \leq \sqrt{d}\|\mathbf{\Omega}(z_1) - \mathbf{\Omega}(z_2)\|_2 \leq \rho^2\|\mathbf{\Sigma}(z_1) - \mathbf{\Sigma}(z_2)\|_2 \leq \rho^2 d^{3/2}\|\mathbf{\Sigma}(z_1) - \mathbf{\Sigma}(z_2)\|_{\max}.$$

Since $\mathbf{\Sigma}_{jk}(\cdot) \in \mathcal{H}(2, M_\sigma)$, we have

$$\begin{aligned}
\|\mathbf{\Omega}(z_1) - \mathbf{\Omega}(z_2)\|_1 &\leq \rho^2 d^{3/2}\|\mathbf{\Sigma}(z_1) - \mathbf{\Sigma}(z_2)\|_{\max} \\
&\leq \rho^2 d^{3/2}\|\mathbf{T}(z_1) - \mathbf{T}(z_2)\|_{\max} \leq \rho^2 M_\sigma d^{3/2}|z_1 - z_2|.
\end{aligned} \tag{156}$$

We next study the covering number of the function class $\mathcal{J}_{uv} = \{\mathbf{\Phi}_{uv}(z; \cdot) \mid z \in (0,1)\}$. By (84) and (94), we have

$$\max_{u,v,x}\|\mathbf{\Phi}_{uv}(x; Y)\|^2_{L_2(Q)} \leq \max_{u,v,x}\|\mathbf{\Phi}_{uv}(x; Y)\|^2_\infty \leq Ch^{-1}. \tag{157}$$

According to the definition in (154), $\mathbf{\Phi}_{uv}(z; \cdot)$ is obtained from products and summations of functions with known covering numbers, quantified in Lemmas 28 and 29. By Lemmas 27 and 26 and fixing the bandwidth $h = \underline{h} = \overline{h}$, $\sup_Q N(\mathcal{J}_{uv}, \|\cdot\|_{L_2(Q)}, \epsilon) \leq C/(h\epsilon)^{v_1}$ for any $u, v \in [d]$. Notice that the construction of covering sets in the proofs of Lemmas 28, and 29 is independent to the indices j, k. Therefore, we can construct a set $N_{(2)} \subset (0,1)$ with $|N_{(2)}| \leq C/(h\epsilon)^c$ such that for any $x \in (0,1)$, there exists a $x_\ell \in N_{(2)}$ with

$$\max_{u,v}\|\mathbf{\Phi}_{uv}(x; Y) - \mathbf{\Phi}_{uv}(x_\ell; Y)\|_{L_2(Q)} \leq \epsilon. \tag{158}$$

With this, we construct the covering set for $\mathcal{J}'$ as

$$N_{(3)} = N_{(2)} \times \{\ell\epsilon\sqrt{h} | \ell = 0, \ldots, \lfloor 1/(\epsilon\sqrt{h})\rfloor\}.$$

For any $(x, z) \in (0,1)^2$, we select $(x_\ell, z_\ell) \in N_{(3)}$ such that (158) holds and $|z - z_\ell| \leq \epsilon\sqrt{h}$. Therefore, by (155), (156) and (157), we have

$$\|\mathbf{\Omega}_j^T(z)\mathbf{\Phi}(x; Y)\mathbf{\Omega}_k(z) - \mathbf{\Omega}_j^T(z_\ell)\mathbf{\Phi}(x_\ell; Y)\mathbf{\Omega}_k(z_\ell)\|^2_{L_2(Q)} \leq Cd^3M^4\epsilon^2$$

and $\sup_Q N(\mathcal{J}', \|\cdot\|_{L_2(Q)}, d^{3/2}M^2\epsilon) \leq d^2|N_{(3)}| = (Cd/(h\epsilon))^c$. ■

Appendix I. Some Useful Results

Lemma 31 *Let $(Y_1, Y_2, Y_3, Y_4)^T \sim N_4(\mathbf{0}, \mathbf{K})$ with $\mathbf{K} = [K_{ab}]_{ab}$. We then have*

$$\mathbb{E}\left[\operatorname{sign}(Y_1 - Y_2)\operatorname{sign}(Y_3 - Y_4)\right] = \frac{2}{\pi}\arcsin\left(\frac{K_{13} + K_{24} - K_{23} - K_{14}}{\sqrt{(K_{11} + K_{22} - 2K_{12})(K_{33} + K_{44} - 2K_{34})}}\right).$$

Proof Observe that $(Y_1 - Y_2, Y_3 - Y_4)^T$ is distributed according to a bivariate Gaussian distribution with mean zero and Pearson correlation coefficient

$$\operatorname{Corr}\left[\mathrm{Y}_1 - \mathrm{Y}_2, \mathrm{Y}_3 - \mathrm{Y}_4\right] = \frac{\mathrm{K}_{13} + \mathrm{K}_{24} - \mathrm{K}_{23} - \mathrm{K}_{14}}{\sqrt{(\mathrm{K}_{11} + \mathrm{K}_{22} - 2\mathrm{K}_{12})(\mathrm{K}_{33} + \mathrm{K}_{44} - 2\mathrm{K}_{34})}}.$$

The result follows directly from the correspondence between Pearson correlation and Kendall's tau (Fang et al., 1990). ■

Corollary 32 *Let $(\boldsymbol{X}_1, Z_1), (\boldsymbol{X}_2, Z_2)$ be independently distributed according to the model in (1). Then we have*

$$\mathbb{E}\left[\operatorname{sign}(X_{1a} - x_{2a})\operatorname{sign}(X_{1b} - x_{2b}) \mid Z_1 = z_1, Z_2 = z_2\right] = \frac{2}{\pi}\arcsin\left(\frac{\mathbf{\Sigma}_{ab}(z_1) + \mathbf{\Sigma}_{ab}(z_2)}{2}\right).$$

Proof Follows directly from Lemma 31 by observing that

$$\operatorname{sign}(X_{1a} - X_{2a}) = \operatorname{sign}(f(X_{1a}) - f(X_{2a})),$$

since f is monotone, and using the fact that $f(\boldsymbol{X}_i)$ follows a Gaussian distribution. ■

Let $H : S^2 \mapsto \mathbb{R}$ be a symmetric kernel function. In the setting of our paper, we have $S^2 = \mathbb{R}^2 \times (0,1)$. A kernel is completely degenerate if

$$\mathbb{E}[H(Y_1, Y_2) \mid Y_2] = 0.$$

U-statistic based on the kernel H is called degenerate of order 1. See, for example, Serfling (2001).

Theorem 33 (Theorem 2, Major (2006)) *Let $\{Y_i\}_{i\in[n]}$ be independent and identically distributed random variables on a probability space $(S, \mathcal{S}, \mu)$. Let $\mathcal{F}$ be a separable space (with respect to μ) of $\mathcal{S}$-measurable μ-degenerate kernel functions that satisfies*

$$N(\epsilon, \mathcal{F}, L_2(\mu)) \le A\epsilon^{-v}, \quad \text{for all } 1 \ge \epsilon > 0,$$

where A and v are some fixed constants. Furthermore, we assume that the envelope function is bounded by 1, that is,

$$\sup_{y_1,y_2} |H(y_1, y_2)| \le 1, \quad \text{for all } H \in \mathcal{F} \text{ and} \tag{159}$$

$$\sup_{H\in\mathcal{F}} \mathbb{E}\left[H^2(Y_1, Y_2)\right] \le \sigma^2$$

for some $0 < \sigma \le 1$. Then there exist constants C_1, C_2, C_3 that depend only on A and v, such that

$$\mu\left[\sup_{H\in\mathcal{F}} \left|\frac{1}{n}\sum_{i\neq i'} H(Y_i, Y_{i'})\right| \ge t\right] \le C_1 \exp\left(-C_2 \frac{t}{\sigma}\right) \tag{160}$$

for all t such that

$$n\sigma^2 \ge \frac{t}{\sigma} \ge C_3\Big(v + \frac{\log A}{\log n}\Big)^{3/2} \log\left(\frac{2}{\sigma}\right). \tag{161}$$

Lemma 34 (Lemma A.1, van de Geer 2008) *Let $X_1, \ldots, X_n$ be independent random variables. The $\gamma_1, \ldots, \gamma_d$ be real-valued bounded functions satisfying*

$$\mathbb{E}[\gamma_j(Z_i)] = 0, \text{ for any } i \in [n], j \in [d]; \quad \|\gamma_k\|_\infty \le \eta_n \quad \text{and} \quad \max_{j\in[d]} \frac{1}{n}\sum_{i=1}^n \mathbb{E}\gamma_j^2(Z_i) \le \tau_n^2.$$

We have

$$\mathbb{E}\left[\max_{j\in[d]} \left|\frac{1}{n}\sum_{i=1}^n \gamma_j(Z_i)\right|\right] \le \sqrt{\frac{2\tau_n^2 \log(2d)}{n}} + \frac{\eta_n \log(2m)}{n}.$$

Appendix J. Notation Table

The following table collects notation used in the paper, their meanings and where they first appear.

Notation	Meaning	Page No.
$\boldsymbol{X}$	d-dimensional nonparanormal random vector	2
Z	index variable	2
Y	$Y = (\boldsymbol{X}, Z)$ denotes the full data variable	2
$\boldsymbol{\Sigma}(z)$	true correlation matrix	2
f	marginal transform	2
$\boldsymbol{\Omega}(z)$	inverse correlation matrix	2
$[n], [d]$	discrete sets $[n] = \{1, \ldots, n\}$, $[d] = \{1, \ldots, d\}$	5
$\mathbf{A} \circ \mathbf{B}$	Hadamard product $(\mathbf{A} \circ \mathbf{B})_{jk} = \mathbf{A}_{jk} \cdot \mathbf{B}_{jk}$	5
$f * g$	convolution $(f * g)(t) = \int f(t-x)g(x)dx$	5
$\mathrm{TV}(f)$	total variation of f	5
$\vee, \wedge$	$a \vee b = \max(a, b)$ and $a \wedge b = \min(a, b)$	5
$c, C, c_1, C_1, \ldots$	universal constants whose values may change from line to line	5
$\rightsquigarrow$	converge in distribution	5
$\xrightarrow{P}$	converge in probability	5
$\mathbb{1}(\cdot)$	indicator function	5
$\mathbb{E}_n[f]$	$= n^{-1}\sum_{i\in[n]} f(X_i)$	5
$\mathbb{G}_n[f]$	$= n^{-1/2}\sum_{i\in[n]} (f(X_i) - \mathbb{E}[f(X_i)])$	5
$\mathbb{U}_n[H]$	$= [n(n-1)]^{-1}\sum_{i\neq i'} H(X_i, X_{i'})$	5
$G^*(z)$	true graph	6
$E^*(z)$	true edge set	6
$\mathbf{e}_j$	the j-th canonical basis in $\mathbb{R}^d$	6
$\widehat{\boldsymbol{\Omega}}(z)$	a generic inverse correlation estimator	6
$\widehat{\boldsymbol{\Omega}}^{\mathrm{CLIME}}(z)$	CLIME inverse correlation estimator	6
$\widehat{\boldsymbol{\Omega}}^{\mathrm{CCLIME}}(z)$	calibrated CLIME inverse correlation estimator	6
λ	$\|\cdot\|_\infty$-tuning parameter calibrated CLIME	6
γ	$\|\cdot\|_1$-tuning parameter calibrated CLIME	6
$\tau_{jk}(z)$	Kendall's tau correlation	7
$\widehat{\tau}_{jk}(z)$	Kendall's tau estimator	7
h	bandwidth	7
K_h	The rescaled kernel $K_h(\cdot) = h^{-1}K(\cdot/h)$	7
ω_z	double kernel function $\omega_z(Z_i, Z_{i'}) = K_h(Z_i - z)K_h(Z_{i'} - z)$	7
$\widehat{\boldsymbol{\Sigma}}(z)$	correlation matrix estimator	7
$\widehat{\mathbf{T}}(z)$	Kendall's tau matrix estimator	7
$[z_L, z_U]$	interval for uniform edge test	8
$\widehat{S}_{z\mid(j,k)}(\boldsymbol{\beta})$	$= \widehat{\boldsymbol{\Omega}}_j^T(z)\big(\widehat{\boldsymbol{\Sigma}}(z)\boldsymbol{\beta} - \mathbf{e}_k\big)$	8
f_Z	the density of Z	9
σ_{jk}^2	variance of the score statistic	9
$\widehat{\boldsymbol{\Theta}}_z$	random matrix for the definition of σ_{jk}^2	9
$\tau_{jk}^{(1)}(y)$	$= \sqrt{h} \cdot \mathbb{E}\Big[K_h(z - z_0)K_h(Z - z_0)\big(\mathrm{sign}(X_j - x_j)\mathrm{sign}(X_k - x_k) - \tau_{jk}(z_0)\big)\Big]$	9
ξ_i	i.i.d. sample of standard normal $N(0,1)$	10
$\widehat{\tau}_{jk}^B(z)$	bootstrap Kendall's tau estimator	10
$\widehat{\boldsymbol{\Sigma}}_{jk}^B(z)$	bootstrap correlation estimator	10
$\mathcal{H}(\gamma, L)$	the Hölder class on $(0,1)$	12
$\underline{f}_Z, \bar{f}_Z$	lower and upper bounds of f_Z	12
M_σ	the Hölder constant such that $\boldsymbol{\Sigma}_{jk}(\cdot) \in \mathcal{H}(2, M_\sigma)$	12
r_{1n}, r_{2n}, r_{3n}	the statistical rates of $\widehat{\boldsymbol{\Sigma}}(z)$ and $\widehat{\boldsymbol{\Omega}}(z)$	12
M	upper bound of column ℓ_1-norm of $\boldsymbol{\Omega}(z)$	13
ρ	maximum eigenvalue of $\boldsymbol{\Omega}(z)$	13

$\mathcal{U}_s(M,\rho)$	the class of matrices $\mathbf{\Omega} \succ 1/\rho, \|\mathbf{\Omega}\|_2 \le \rho, \max_{j\in[d]} \|\mathbf{\Omega}_j\|_0 \le s, \|\mathbf{\Omega}\|_1 \le M$	13
h_l, h_u	lower and upper bounds of bandwidth	15
$C_{\mathbf{\Sigma}}$	universal constant in the rate of $\widehat{\mathbf{\Sigma}}(z)$	16
$\overline{\mathcal{U}}_s(M,\rho,L)$	time-varying matrix class $\mathbf{\Omega}(z) \in \mathcal{U}_s(M,\rho)$	17
$g_{z\|(j,k)}(y_i, y_{i'})$	$= \omega_z(z_i, z_{i'}) \operatorname{sign}(x_{ia} - x_{i'a}) \operatorname{sign}(x_{ib} - x_{i'b})$	27
$g^{(1)}_{z\|(j,k)}(y)$	$= \mathbb{E}[g_{z\|(j,k)}(y,Y)] - \mathbb{E}\left[\mathbb{U}_n[g_{z\|(j,k)}]\right]$	27
$g^{(2)}_{z\|(j,k)}(y_1,y_2)$	$= g_{z\|(j,k)}(y_1,y_2) - g^{(1)}_{z\|(j,k)}(y_1) - g^{(1)}_{z\|(j,k)}(y_2) - \mathbb{E}\left[\mathbb{U}_n[g_{z\|(j,k)}]\right]$	27
$\omega^{(1)}_z(s)$	$= \mathbb{E}[\omega_z(s,Z)] - \mathbb{E}\left[\mathbb{U}_n[\omega_z]\right]$	27
$\omega^{(2)}_z(s,t)$	$= \omega_z(s,t) - \omega^{(1)}_z(s) - \omega^{(1)}_z(t) - \mathbb{E}\left[\mathbb{U}_n[\omega_z]\right]$	27
$\mathbb{G}^{\xi}_n[f]$	$= n^{-1/2} \sum_{i=1}^n f(X_i) \cdot \xi_i$	26
$\mathbb{P}_\xi$, $\mathbb{E}_\xi$	$\mathbb{P}_\xi(\cdot) := \mathbb{P}(\cdot \| \{Y_i\}_{i\in[n]})$ and $\mathbb{E}_\xi[\cdot] := \mathbb{E}[\cdot \| \{Y_i\}_{i\in[n]}]$	26
$J_{z\|(j,k)}(y')$	$= \sum_{u,v\in[d]} \mathbf{\Omega}_{ju}(z)\mathbf{\Omega}_{kv}(z)\pi \cos\left(\tau_{uv}(z)\frac{\pi}{2}\right) \sqrt{h} \cdot \left[g^{(1)}_{z\|(u,v)}(y') - \tau_{uv}(z)\omega^{(1)}_z(z')\right]$	27
$u_n[H]$	$= \sqrt{n} \cdot \left(\mathbb{U}_n[H] - \mathbb{E}[\mathbb{U}_n[H]]\right)$	28
$N(\mathcal{F}, d, \epsilon)$	covering number of function class $\mathcal{F}$ of ϵ-ball in metric d	61

Abstract

To model categorical response variables given their covariates, we propose a permuted and augmented stick-breaking (paSB) construction that one-to-one maps the observed categories to randomly permuted latent sticks. This new construction transforms multinomial regression into regression analysis of stick-specific binary random variables that are mutually independent given their covariate-dependent stick success probabilities, which are parameterized by the regression coefficients of their corresponding categories. The paSB construction allows transforming an arbitrary cross-entropy-loss binary classifier into a Bayesian multinomial one. Specifically, we parameterize the negative logarithms of the stick failure probabilities with a family of covariate-dependent softplus functions to construct nonparametric Bayesian multinomial softplus regression, and transform Bayesian support vector machine (SVM) into Bayesian multinomial SVM. These Bayesian multinomial regression models are not only capable of providing probability estimates, quantifying uncertainty, increasing robustness, and producing nonlinear classification decision boundaries, but also amenable to posterior simulation. Example results demonstrate their attractive properties and performance.

Keywords: Discrete choice models, logistic regression, nonlinear classification, softplus regression, support vector machines

1. Introduction

Inferring the functional relationship between a categorical response variable and its covariates is a fundamental problem in physical and social sciences. To address this problem, it is common to use either multinomial logistic regression (MLR) (McFadden, 1973; Greene, 2003; Train, 2009) or multinomial probit regression (Albert and Chib, 1993; McCulloch and Rossi, 1994; McCulloch et al., 2000; Imai and van Dyk, 2005), both of which can be expressed as a latent-utility-maximization model that lets an individual make the decision by comparing its random utilities across all categories at once. In this paper, we address the problem via a new stick-breaking construction of the multinomial distribution, which defines a one-to-one random mapping between the category and stick indices. Rather than assuming an individual compares its random utilities across all categories at once, we assume an individual makes a sequence of stick-specific binary random decisions. The choice of the individual is the category mapped to the stick that is the first to choose "1," or the category mapped to stick S if all the first $S-1$ sticks choose "0." This framework transforms the problem of regression analysis of categorical variables into the problem of inferring the one-to-one mapping between the category and stick indices, and performing regression analysis of binary stick-specific random variables.

Both MLR and the proposed stick-breaking models link a categorical response variable to its covariate-dependent probability parameters. While MLR is invariant to the permutation of category labels, given a fixed category-stick mapping, the proposed stick-breaking models purposely destruct that invariance. We are motivated to introduce this new framework for discrete choice modeling mainly to facilitate efficient Bayesian inference via data augmentation, introduce nonlinear decision boundaries, and relax a well-recogonized restrictive model assumption of MLR, as described below.

An important motivation is to extend efficient Bayesian inference available to binary regression to multinomial one. In the proposed stick-breaking models, the binary stick-specific random variables of an individual are conditionally independent given their stick-specific covariate-dependent probabilities. Under this setting, one can solve a multinomial regression by solving conditionally independent binary ones. The only requirement is that the underlying binary regression model uses the cross entropy loss. In other words, we require each stick-specific binary random variable to be linked via the Bernoulli distribution to its corresponding stick-specific covariate-dependent probability parameter.

Another important motivation is to improve the model capacity of MLR, which is a linear classifier in the sense that if the total number of categories is S, then MLR uses the intersection of $S-1$ linear hyperplanes to separate one class from the others. By choosing nonlinear binary regression models, we are able to enhance the capacities of the proposed stick-breaking models. We are also motivated to relax the *independence of irrelevant alternative* (IIA) assumption, an inherent property of MLR that requires the probability ratio of any two choices to be independent of the presence or characteristics of any other alternatives (McFadden, 1973; Greene, 2003; Train, 2009). By contrast, the proposed stick-breaking models make the probability ratio of two choices depend on other alternatives, as long as the two sticks that both choices are mapped to are not next to each other.

In light of these considerations, we will first extend the softplus regressions recently proposed in Zhou (2016), a family of cross-entropy-loss binary classifiers that can introduce nonlinear decision boundaries and can recover logistic regression as a special case, to construct Bayesian multinomial softplus regressions (MSRs). We then consider a multinomial generalization of the widely used support vector machine (SVM) (Boser et al., 1992; Cortes and Vapnik, 1995; Schölkopf et al., 1999; Cristianini and Shawe-Taylor, 2000), a max-margin binary classifier that uses the hinge loss. While there has been significant effort in extending binary SVMs into multinomial ones (Crammer and Singer, 2002; Lee et al., 2004; Liu and Yuan, 2011), the resulted extensions typically only provide the predictions of deterministic class labels. By contrast, we extend the Bayesian binary SVMs in Sollich (2002) and Mallick et al. (2005) under the proposed framework to construct Bayesian multinomial SVMs (MSVMs), which naturally provide predictive class probabilities.

We will show that the proposed Bayesian MSRs and MSVMs, which all generalize the stick-breaking construction to perform Bayesian multinomial regression, are not only capable of placing nonlinear decision boundaries between different categories, but also amenable

to posterior simulation via data augmentation. Another attractive feature shared by all these proposed Bayesian algorithms is that they can not only predict class probabilities but also quantify model uncertainty. In addition, we will show that robit regression, a robust cross-entropy-loss binary classifier proposed in Liu (2004), can be extended into a robust Bayesian multinomial classifier under the proposed stick-breaking construction.

The remainder of the paper is organized as follows. In Section 2 we briefly review MLR and discuss the restrictions of its stick-breaking construction. In Section 3 we propose the permuted and augmented stick breaking (paSB) to construct Bayesian multi-class classifiers, present the inference, and show how the IIA assumption is relaxed. Under the paSB framework, we show how to transform softplus regressions and support vector machines into Bayesian multinomial regression models in Sections 4 and 5, respectively. We provide experimental results in Section 6 and conclude the paper in Section 7.

2. Multinomial Logistic Regression and Stick Breaking

In this section we first briefly review multinomial logistic regression (MLR). We then use the stick-breaking construction to show how to generate a categorical random variable as a sequence of dependent binary variables, and further discuss a naive approach to transform binary logistic regression under stick breaking into multinomial regression. In the following discussion, we use $i \in \{1, \ldots, N\}$ to index the individual/observation, $s \in \{1, \ldots, S\}$ to index the choice/category, and the prime symbol to denote the transpose operation.

2.1 Multinomial Logistic Regression

MLR that parameterizes the probability of each category given the covariates as

$$P(y_i = s \,|\, \boldsymbol{x}_i, \{\boldsymbol{\beta}_s\}_{1,S}) = p_{is},\ p_{is} = e^{\boldsymbol{x}_i'\boldsymbol{\beta}_s} / \big(\textstyle\sum_{j=1}^{S} e^{\boldsymbol{x}_i'\boldsymbol{\beta}_j}\big) \tag{1}$$

is widely used, where $\boldsymbol{x}_i \in \mathbb{R}^{P+1}$ consists of $x_{i1} = 1$ and P covariates, and $\boldsymbol{\beta}_s \in \mathbb{R}^{P+1}$ consists of the regression coefficients for the sth category (McCullagh and Nelder, 1989; Albert and Chib, 1993; Holmes and Held, 2006). Without loss of generality, one may choose category S as the reference category by setting all the elements of $\boldsymbol{\beta}_S$ as 0, making $e^{\boldsymbol{x}_i'\boldsymbol{\beta}_S} = 1$ almost surely (a.s.). For MLR, if data i is assigned to the category with the largest p_{is}, then one may consider that category s resides within a convex polytope (Grünbaum, 2013), defined by the set of solutions to $S-1$ inequalities as $\boldsymbol{x}'(\boldsymbol{\beta}_j - \boldsymbol{\beta}_s) \le 0$, where $j \in \{1, \ldots, s-1, s+1, \ldots, S\}$.

Despite its popularity, MLR is a linear classifier in the sense that it uses the intersection of $S-1$ linear hyperplanes to separate one class from the others. As a classical discrete choice model in econometrics, it makes the independence of irrelevant alternatives (IIA) assumption, implying that the unobserved factors for choice making are both uncorrelated and having the same variance across all alternatives (McFadden, 1973; Train, 2009). Moreover, while its log-likelihood is convex and there are efficient iterative algorithms to find the maximum likelihood or maximum a posteriori solutions of $\boldsymbol{\beta}_s$, the absence of conjugate priors on $\boldsymbol{\beta}_s$ makes it difficult to derive efficient Bayesian inference. For Bayesian inference, Polson et al. (2013) have introduced the Pólya-Gamma data augmentation for logit models, and combined it with the data augmentation technique of Holmes and Held (2006) for the multinomial likelihood to develop a Gibbs sampling algorithm for MLR. This algorithm, however, has to update $\boldsymbol{\beta}_s$ one at a time while conditioning on all $\boldsymbol{\beta}_j$ for $j \neq s$. Thus it may not only lead to slow convergence and mixing, especially when the number of categories S is large, but also prevent us from parallelizing the sampling of $\{\boldsymbol{\beta}_s\}_{1,S}$ within each MCMC iteration.

2.2 Stick Breaking

Suppose y_i is a random variable drawn from a categorical distribution with a finite vector of probability parameters $(p_{i1}, \ldots, p_{iS})$, where $S < \infty$, $p_{is} \ge 0$, and $\sum_{s=1}^{S} p_{is} = 1$. Instead of directly using $y_i \sim \sum_{s=1}^{S} p_{is}\delta_s$, one may consider generating y_i using the multinomial stick-breaking construction that sequentially draws binary random variables

$$b_{is} \,\big|\, \{b_{ij}\}_{j<s} \sim \text{Bernoulli}\Big[\Big(1 - \textstyle\sum_{j<s} b_{ij}\Big)\,\pi_{is}\Big],\quad \pi_{is} = \dfrac{p_{is}}{1 - \sum_{j<s} p_{ij}} \tag{2}$$

for $s = 1, 2, \ldots, S$. Note that $\pi_{iS} = 1$ and $b_{iS} = 1 - \sum_{j=1}^{S-1} b_{ij}$ by construction. Defining $y_i = s$ if and only if $b_{is} = 1$ and $b_{ij} = 0$ for all $j \neq s$, then one has a strick-breaking representation for the multinomial probability parameter as

$$P(y_i = s \,|\, \{\pi_{is}\}_{1,S}) = P(b_{is} = 1) \textstyle\prod_{j \neq s} P(b_{ij} = 0) = \pi_{is} \prod_{j<s} (1 - \pi_{ij}), \tag{3}$$

which, as expected, recovers p_{is} by substituting the definitions of π_{is} shown in (2).

The finite stick-breaking construction in (3) can be further generalized to an infinite setting, as widely used in Bayesian nonparametrics (Hjort et al., 2010). For example, the stick-break construction of Sethuraman (1994) represents the length of the kth stick using the product of k stick-specific probabilities that are independent, and identically distributed (i.i.d.) beta random variables. It represents a size-biased random permutation of a Dirichlet process (DP) (Ferguson, 1973) random draw, which includes countably infinite atoms whose weights sum to one. The stick-breaking construction of Sethuraman (1994) has also been generalized to represent a draw from a random probability measure that is more general than the DP (Pitman, 1996; Ishwaran and James, 2001; Wang et al., 2011a).

Related to this paper, one may further consider making the stick-specfic probabilities depend on the covariates (Dunson and Park, 2008; Chung and Dunson, 2009; Ren et al., 2011). For example, the logistic stick-breaking process of Ren et al. (2011) uses the product of k covariate-dependent logistic functions to parameterize the probability of the kth stick. To implement a stick-breaking process mixture model, truncated stick-breaking representations with a finite number of sticks are commonly used, with inference developed via both Gibbs sampling (Ishwaran and James, 2001; Dunson and Park, 2008; Rodriguez and Dunson, 2011) and variational approximation (Blei and Jordan, 2006; Kurihara et al., 2007; Ren et al., 2011).

Another related work is the order-based dependent Dirichlet processes of Grifin and Steel (2006), which use an ordered stick-breaking construction for mixture modeling, encouraging the data samples close to each other in the covariate space to share similar orders of the sticks and hence similar mixture weights. We will show that the proposed stick-breaking construction is distinct in that all data samples share the same category-stick mapping inferred from the data, with the category labels mapped to lower-indexed sticks subject to fewer geometric constraints on their decision boundaries.

2.3 Logistic Stick Breaking

The stick-breaking construction parameterizes each p_{is} with the product of s probability parameters and links each y_i with a unit-norm binary vector $(b_{i1}, \ldots, b_{iS})$, where $b_{iy_i} = 1$ and $b_{ij} = 0$ a.s. if $j \neq y_i$. Following the logistic stick-breaking construction of Ren et al. (2011), one may represent p_{is} with (3) and parameterize the logit of each π_{is} with a latent Gaussian variable w_{is} as $\pi_{is} = e^{w_{is}}/\sum_{j=1}^{S} e^{w_{ij}}$. To model observed or latent multinomial variables, a stick-breaking procedure, closely related to that of Ren et al. (2011), is used in Khan et al. (2012) to transform the modeling of multinomial probability parameters into the modeling of the logits of binomial probability parameters using Gaussian latent variables. As shown in Linderman et al. (2015), this procedure allows using the Pólya-Gamma data augmentation, without requiring the assistance of the technique of Holmes and Held (2006), to construct Gibbs sampling that simultaneously updates all categories in each MCMC iteration, leading to improved performance over the one proposed in Polson et al. (2013).

The simplification brought by the stick-breaking representation, which stochastically arranges its categories in decreasing order, comes with a clear change in that it removes the invariance of the multinomial distribution to label permutation. While the loss of invariance to label permutation may not pose a major issue for Bayesian mixture models inferred with MCMC (Jasra et al., 2005; Kurihara et al., 2007), it appears to be a major obstacle when applying stick breaking for multinomial regression, where the performance is often found to be sensitive to how the labels of the S categories are ordered. In particular, if one constructs a logistic stick breaking model by letting $\text{logit}(\pi_{is}) = w_{is} = \boldsymbol{x}_i'\boldsymbol{\beta}_s$, which means $\pi_{is} = (1 + e^{-\boldsymbol{x}_i'\boldsymbol{\beta}_s})^{-1}$, then one has

$$p_{is} = \left(1 + e^{-\boldsymbol{x}_i'\boldsymbol{\beta}_s}\right)^{-1} \prod_{j<s} \left(1 + e^{\boldsymbol{x}_i'\boldsymbol{\beta}_j}\right)^{-1},$$

which clearly tends to impose fewer geometric constraints on the classification decision boundaries of a category with a smaller s. For example, $p_{i1} = \left(1 + e^{-\boldsymbol{x}_i'\boldsymbol{\beta}_1}\right)^{-1}$ is larger than 50% if $\boldsymbol{x}_i'\boldsymbol{\beta}_1 > 0$ while $p_{i2} = \left(1 + e^{\boldsymbol{x}_i'\boldsymbol{\beta}_1}\right)^{-1}\left(1 + e^{-\boldsymbol{x}_i'\boldsymbol{\beta}_2}\right)^{-1}$ is possible to be larger than 50% only if both $\boldsymbol{x}_i'\boldsymbol{\beta}_1 < 0$ and $\boldsymbol{x}_i'\boldsymbol{\beta}_2 > 0$. We will use an example to illustrate this type of geometric constraints in Section 6.1.

Under the logistic stick-breaking construction, not only could the performance be sensitive to how the S different categories are ordered, but the imposed geometric constraints could also be overly restrictive even if the categories are appropriately ordered. Below we address the first issue by introducing a permuted and augmented stick-breaking representation for a multinomial model, and the second issue by adding the ability to model nonlinearity.

3. Permuted and Augmented Stick Breaking

To turn the seemingly undesirable sensitivity of the stick-breaking construction to label permutation into a favorable model property, when label asymmetry is desired, and mitigate performance degradation, when label symmetry is desired, we introduce a permuted and augmented stick-breaking (paSB) construction for a multinomial distribution, making it straightforward to extend an arbitrary binary classifier with cross entropy loss into a

Bayesian multinomial one. The paSB construction infers a one-to-one mapping between the labels of the S categories and the indices of the S latent sticks, transforming the problem from modeling a multinomial random variable into modeling S conditionally independent binary ones. It not only allows for parallel computation within each MCMC iteration, but also improves the mixing of MCMC in comparison to the one used in Polson et al. (2013), which updates one regression-coefficient vector conditioning on all the others, as will be shown in Section 6.5. Note that the number of distinct one-to-one label-stick mappings is $S!$, which quickly becomes too large to exhaustively search for the best mapping as S increases. Our experiments will show that the proposed MCMC algorithm can quickly escape from a purposely poorly initialized mapping and subsequently switch between many different mappings that all lead to similar performance, suggesting an effective search space that is considerably smaller than $S!$.

3.1 Category-Stick Mapping and Data Augmentation

The proposed paSB construction randomly maps a category to one and only one of the S latent sticks and makes the augmented Bernoulli random variables $\{b_{is}\}_{1,S}$ conditionally independent to each other given $\{\pi_{is}\}_{1,S}$. Denote $\boldsymbol{z} = (z_1, \ldots, z_S)$ as a permutation of $(1, \ldots, S)$, where $z_s \in \{1, \ldots, S\}$ is the index of the stick that category s is mapped to. Given the label-stick mapping $\boldsymbol{z}$, let us denote $p_{is}(\boldsymbol{z})$ as the multinomial probability of category s, and $\pi_{iz_s}(\boldsymbol{x}_i, \boldsymbol{\beta}_s)$ as the covariate-dependent stick probability that is associated with the covariates of observation i and the stick that category s is mapped to. For notational convenience, we will write $\pi_{iz_s}(\boldsymbol{x}_i, \boldsymbol{\beta}_s)$ as π_{iz_s} and $\pi_{ij}(\boldsymbol{x}_i, \boldsymbol{\beta}_{s:z_s=j})$ as π_{ij}. We emphasize that here the sth regression-coefficient vector $\boldsymbol{\beta}_s$ is always associated with both category s and the corresponding stick probabily π_{iz_s}, a construction that will facilitate the inference of the label-stick mapping $\boldsymbol{z}$. The following Theorem shows how to generate a categorical random variable of S categories with a set of S conditionally independent Bernoulli random variables. This is key to transforming the problem from solving multinomial regression into solving S binary regressions independently.

Theorem 1 *Suppose* $y_i \sim \sum_{s=1}^{S} p_{is}(\boldsymbol{z})\delta_s$, *where* $[p_{i1}(\boldsymbol{z}), \ldots, p_{iS}(\boldsymbol{z})]$ *is a multinomial probability vector whose elements are constructed as*

$$p_{is}(\boldsymbol{z}) = (\pi_{iz_s})^{\mathbf{1}(z_s \neq S)} \prod_{j<z_s} (1 - \pi_{ij}), \tag{4}$$

then y_i *can be equivalently generated under the permuted and augmented stick-breaking (paSB) construction as*

$$y_i \sim \sum_{s=1}^{S} \left\{ [\mathbf{1}(b_{iz_s} = 1)]^{\mathbf{1}(z_s \neq S)} \prod_{j<z_s} \mathbf{1}(b_{ij} = 0) \right\} \delta_s\,, \tag{5}$$

$$b_{ij} \sim \text{Bernoulli}(\pi_{ij}), \quad j \in \{1, \ldots, S\}. \tag{6}$$

Distinct from the conventional stick breaking in (2) that maps category s to stick s and makes b_{is} depend on $b_{ij}, j = 1, \ldots, s-1$, under the new construction in (5)-(6), the S categories are now randomly permuted and then one-to-one mapped to S sticks, and

the augmented binary random variables $\{b_{ij}\}_j$ become mutually independent given $\{\pi_{ij}\}_j$. Given y_i, we still have $b_{ij} = 0$ for $j < z_{y_i}$ and $b_{iz_{y_i}} = 1$ a.s., but impose no restriction on any b_{ij} for $j > z_{y_i}$, whose conditional posteriors given y_i and π_{ij} remain the same as their priors. These changes are key to appropriately ordering the latent sticks, more flexibly parameterizing π_{iz_s} and hence $p_{is}(\boldsymbol{z})$, and maintaining tractable inference.

With paSB, the problem of inferring the functional relationship between the categorical response y_i and the corresponding covariates $\boldsymbol{x}_i$ is now transformed into the problem of modeling S conditionally independent binary regressions as

$$b_{iz_s} \,|\, \boldsymbol{x}_i, \boldsymbol{\beta}_s \sim \text{Bernoulli}[\pi_{iz_s}(\boldsymbol{x}_i, \boldsymbol{\beta}_s)],\ i = 1, \ldots, N,\ s = 1, \ldots, S.$$

Note that the only requirement for the binary regression model under paSB is that it uses the Bernoulli likelihood. In other words, it uses the cross entropy loss (Murphy, 2012) as

$$-\sum_{i=1}^{N} \ln P(b_{iz_s} \,|\, \boldsymbol{x}_i, \boldsymbol{\beta}_s) = \sum_{i=1}^{N} \big\{ -b_{iz_s} \ln \pi_{iz_s}(\boldsymbol{x}_i, \boldsymbol{\beta}_s) - (1 - b_{iz_s}) \ln[1 - \pi_{iz_s}(\boldsymbol{x}_i, \boldsymbol{\beta}_s)] \big\}.$$

A basic choice is paSB logistic regression that lets

$$\pi_{iz_s}(\boldsymbol{x}_i, \boldsymbol{\beta}_s) = 1/(1 + e^{-\boldsymbol{x}_i \boldsymbol{\beta}_s}),$$

which becomes the same as the logistic stick breaking construction described in Section 2.3 if $z_s = s$ for all $s \in \{1, \ldots, S\}$. Another choice is paSB-robit regression that extends robit regression of Liu (2004), a robust binary classifier using cross entropy loss, into a robust Bayesian multinomial classifier. In robit regression, observation i is labeled as 1 if $\boldsymbol{x}_i'\boldsymbol{\beta} + \varepsilon_i > 0$ and as 0 otherwise, where ε_i are independently drawn from a t-distribution with κ degrees of freedom, denoted as $\varepsilon_i \overset{iid}{\sim} t_\kappa$. Consequently, the conditional class probability function of robit regression is $P(y_i = 1 \,|\, \boldsymbol{x}_i, \boldsymbol{\beta}) = F_\kappa(\boldsymbol{x}_i'\boldsymbol{\beta})$, where F_κ is the cumulative density function of t_κ. The robustness is attributed to the heavy-tail property of $F_\kappa(\boldsymbol{x}_i'\boldsymbol{\beta})$, which, if $\kappa < 7$, imposes less penalty than the conditional class probability function of logistic regression does on misclassified observations that are far from the decision boundary. Applying Theorem 1, the category probability of paSB-robit regression with κ degrees of freedom is shown in (4), where $\pi_{iz_s}(\boldsymbol{x}_i, \boldsymbol{\beta}_s) = F_\kappa(\boldsymbol{x}_i'\boldsymbol{\beta}_s)$. The paSB-robit regression provides a simple solution to robust multiclass classification; with $\{b_{ij}\}_{i,j}$ defined in Theorem 1, we run independent binary robit regressions using the Gibbs sampler proposed in Liu (2004).

In addition to paSB, we define permuted and augmented reverse stick breaking (parSB) in the following Corollary.

Corollary 2 *Suppose* $y_i \sim \sum_{s=1}^{S} p_{is}\delta_s$ *and*

$$p_{is}(\boldsymbol{z}) = (1 - \pi_{iz_s})^{\mathbf{1}(z_s \neq S)} \textstyle\prod_{j<z_s} \pi_{ij}\,,$$

then y_i *can also be generated under the permuted and augmented reverse stick-breaking (parSB) representation as*

$$y_i \sim \sum_{s=1}^{S} \Big\{ [\mathbf{1}(b_{iz_s} = 0)]^{\mathbf{1}(z_s \neq S)} \textstyle\prod_{j<z_s} \mathbf{1}(b_{ij} = 1) \Big\} \delta_s\,, \qquad (7)$$
$$b_{ij} \sim \text{Bernoulli}(\pi_{ij}), \quad j \in \{1, \ldots, S\}.$$

Generally speaking, if $\pi_{iz_s}(\boldsymbol{x}_i, -\boldsymbol{\beta}_s) = 1 - \pi_{iz_s}(\boldsymbol{x}_i, \boldsymbol{\beta}_s)$, which is the case for logistic stick breaking and robit stick breaking, where π_{iz_s} are defined as $(1 + e^{-\boldsymbol{x}_i'\boldsymbol{\beta}_s})^{-1}$ and $F_\kappa(\boldsymbol{x}_i'\boldsymbol{\beta}_s)$, respectively, and Bayesian multinomial SVMs to be discussed in Section 5, then there is no need to introduce parSB as an addition to paSB. Otherwise, there are potential benefits, such as for softplus regressions to be introduced in Section 4, to combine parSB with paSB.

3.2 Inference of Stick Variables and Category-Stick Mapping

Below we first describe Gibbs sampling for the augmented stick variables $\{b_{ij}\}_{1,S}$, and then introduce a Metropolis-Hastings (MH) step to infer the category-stick mapping $\boldsymbol{z}$. Given the category label y_i, stick probability π_{ij}, and $\boldsymbol{z}$, we sample b_{ij} as

$$(b_{ij} \,|\, y_i, \pi_{ij}, \boldsymbol{z}) \sim \mathbf{1}(j = z_{y_i}) + \mathbf{1}(j > z_{y_i})\text{Bernoulli}(\pi_{ij}),$$

for $j = 1, \ldots, S-1$, and let

$$b_{iS} = \mathbf{1}(z_{y_i} = S).$$

This means we let $b_{ij} = 0$ if $j < z_{y_i}$, $b_{ij} = 1$ if $j = z_{y_i}$, draw b_{ij} from Bernoulli(π_{ij}) if $z_{y_i} < j < S$, and let $b_{iS} = 1$ if and only if $z_{y_i} = S$. Note that stick S is used as a reference stick and π_{iS} is not used in defining $p_{is}(\boldsymbol{z})$ in (4). Despite having no impact on computing $\{p_{is}\}_{1,S}$, we infer π_{iS} (*i.e.*, sample the regression-coefficient vector $\boldsymbol{\beta}_{s':z_{s'}=S}$) under the likelihood $\prod_{i=1}^{N} \text{Bernoulli}(b_{iS}; \pi_{iS})$ and use it in a Metropolis-Hastings step, as described in (8) shown below, to decide whether to switch the mappings of two different categories, if one of which is mapped to the reference stick S. Once we have an MCMC sample of $\{b_{ij}\}_{1,S}$, we then essentially solve independently S binary classification problems, the jth of which can be expressed as $b_{ij} \,|\, \boldsymbol{x}_i, \boldsymbol{\beta}_{s:z_s=j} \sim \text{Bernoulli}[\pi_{ij}(\boldsymbol{x}_i, \boldsymbol{\beta}_{s:z_s=j})]$.

Analogously, for parSB, $\{b_{ij}\}_{1,S}$ can be sampled as $(b_{ij} \,|\, y_i, \pi_{ij}, \boldsymbol{z}) \sim \mathbf{1}(j < z_{y_i}) + \mathbf{1}(j > z_{y_i})\text{Bernoulli}(\pi_{ij})$ for $j = 1, \ldots, S-1$, and $b_{iS} = 1 - \mathbf{1}(z_{y_i} = S)$, which means we let $b_{ij} = 1$ if $j < z_{y_i}$, let $b_{ij} = 0$ if $j = z_{y_i}$, draw b_{ij} from Bernoulli(π_{ij}) if $z_{y_i} < j < S$, and let $b_{iS} = 0$ if and only if $z_{y_i} = S$.

Since stick-breaking multinomial classification is not invariant to the permutation of its class labels, it may perform substantially worse than it could be if the inherent geometric constraints implied by the current ordering of the labels make it difficult to adapt the decision boundaries to the data. Our solution to this problem is to infer the one-to-one mapping between the category labels and stick indices from the data. We construct a Metropolis-Hastings (MH) step within each Gibbs sampling iteration, with a proposal of switching two sticks that categories c and c', $1 \leq c < c' \leq S$, are mapped to, by changing the current category-stick one-to-one mapping from $\boldsymbol{z} = (z_1, \ldots, z_c, \ldots, z_{c'}, \ldots, z_S)$ to $\boldsymbol{z}' = (z_1', \ldots, z_S') := (z_1, \ldots, z_{c'}, \ldots, z_c, \ldots, z_S)$. Assuming a uniform prior on $\boldsymbol{z}$ and proposing (c, c') uniformly at random from one of the $\binom{S}{2} = S(S-1)/2$ possibilities, we would accept the proposal with probability

$$\min\left\{ \prod_i \frac{\prod_{s=1}^{S} [p_{is}(\boldsymbol{z}')]^{\mathbf{1}(y_i=s)}}{\prod_{s=1}^{S} [p_{is}(\boldsymbol{z})]^{\mathbf{1}(y_i=s)}},\ 1 \right\} = \min\left\{ \prod_i \frac{\prod_{s=1}^{S} \left[(\pi_{iz_s'})^{\mathbf{1}(z_s' \neq S)} \prod_{j<z_s'} (1 - \pi_{ij}) \right]^{\mathbf{1}(y_i=s)}}{\prod_{s=1}^{S} \left[(\pi_{iz_s})^{\mathbf{1}(z_s \neq S)} \prod_{j<z_s} (1 - \pi_{ij}) \right]^{\mathbf{1}(y_i=s)}},\ 1 \right\}. \qquad (8)$$

3.3 Sequential Decision Making

Random utility models, including both the logit and probit models as special examples, are widely used to infer the functional relationship between a categorical response variable and its covariates. For discrete choice analysis in econometrics (Hanemann, 1984; Greene, 2003; Train, 2009), these models assume that among a set of S alternatives, an individual makes the choice that maximizes his/her utility $U_{is} = V_{is} + \varepsilon_{is}$, where V_{is} and ε_{is} represent the observable and unobservable parts of U_{is}, respectively. If V_{is} is set as $V_{is} = \boldsymbol{x}_i'\boldsymbol{\beta}_s$, then marginalizing out $\boldsymbol{\varepsilon}_i = (\varepsilon_{i1}, \ldots, \varepsilon_{iS})'$ leads to MLR if all ε_{is} follow the extreme value distribution (McFadden, 1973; Greene, 2003; Train, 2009), and multinomial probit regression if all $\boldsymbol{\varepsilon}_i$ follow a multivariate normal distribution (Albert and Chib, 1993; McCulloch and Rossi, 1994; McCulloch et al., 2000; Imai and van Dyk, 2005).

Instead of examining the utilities of all choices before making the decision, the paSB construction is characterized by a sequential decision making process, described as follows. In step one, an individual decides whether to select the choice mapped to stick 1, or to select a choice among the remaining alternatives, *i.e.*, choices $\{s : z_s \in \{2, \ldots, S\}\}$. If the individual selects the choice mapped to stick 1, then the sequential process is terminated. Otherwise this choice is eliminated and the individual proceeds to step two, in which he/she would follow the same procedure to either select the choice mapped to stick 2 or proceed to the next step to select a choice among the remaining alternatives, *i.e.*, choices $\{s : z_s \in \{3, \ldots, S\}\}$. The individual, reconsidering none of the eliminated choices, will keep making a *one-vs-remaining* decision at each step until the termination of the sequential decision making process.

This unique sequential decision making procedure relaxes the independence of irrelevant alternatives (IIA) assumption, as described in the following Lemma.

Lemma 3 *Under the paSB construction, the probability ratio of two choices are influenced by the success probabilities of the sticks that lie between these two choices' corresponding sticks. In other words, the probability ratio of two choices will be influenced by some other choices if they are not mapped to adjacent sticks.*

As in Lemma 3, the paSB construction could adjust how two choices' probability ratio depends on the other alternatives by controlling the distance between the two sticks that they are mapped to, and hence provide a unique way to relax the IIA assumption. While the widely used MLR can be considered as a random-utility-maximization model with the IIA assumption, the paSB multinomial logistic model performs sequential random utility maximization that relaxes this assumption, as described in Lemma 5 in the Appendix.

4. Bayesian Multinomial Softplus Regression

Logistic regression is a cross-entropy-loss binary classifier that can be straightforwardly extended to paSB multinomial logistic regression (paSB-MLR). However, it is a linear classifier that uses a single hyperplane to separate one class from the other. To introduce nonlinear classification decision boundaries, we consider extending softplus regression of Zhou (2016), a multi-hyperplane binary classifier that uses the cross entropy loss, into multinomial softplus regression (MSR) under paSB.

Softplus regression uses the interaction of multiple hyperplanes to construct a union of convex-polytope-like confined spaces to enclose the data labeled as "1," which are hence separated from the data labeled as "0". It is constructed under a Bernoulli-Poisson link (Zhou, 2015) that thresholds at one a latent Poisson count, with the distribution of the Poisson rate defined as the convolution of the probability density functions of K experts, each of which corresponds to the stack of T gamma distributions with covariate-dependent scale parameters. The number of experts K and the number of layers T can be considered as the two model parameters that determine the nonlinear capacity of the model. More specifically, for expert k, denoting r_k as its weight and $\boldsymbol{\beta}_k^{t+1}$ as its tth regression-coefficient vector, the conditional class probability can be expressed as

$$P(y_i = 1 \,|\, \boldsymbol{x}_i, \{r_k, \{\boldsymbol{\beta}_k^{(t+1)}\}_{1,T}\}_{1,K}) = 1 - \prod_{k=1}^{K}(1 - p_{ik}),$$
$$p_{ik} = 1 - \left(1 + e^{\boldsymbol{x}_i'\boldsymbol{\beta}_k^{(T+1)}} \ln\left\{1 + e^{\boldsymbol{x}_i'\boldsymbol{\beta}_k^{(T)}} \ln\left[1 + \ldots \ln\left(1 + e^{\boldsymbol{x}_i'\boldsymbol{\beta}_k^{(2)}}\right)\right]\right\}\right)^{-r_k};$$

when $K = T = 1$, the conditional class probability reduces to

$$P(y_i = 1 \,|\, \boldsymbol{x}_i, r, \boldsymbol{\beta}) = 1 - \left(\frac{1}{1 + e^{\boldsymbol{x}_i'\boldsymbol{\beta}}}\right)^{r};$$

and when $K = T = r = 1$, it becomes the same as that of binary logistic regression. Note that a gamma process, a random draw from which is expressed as $G = \sum_{k=1}^{\infty} r_k \delta_{\{\boldsymbol{\beta}_k^{t+1}\}_{1,T}}$, can be used to support a potentially countably infinite number of experts for softplus regression. For this reason, one can set K as large as permitted by computation and relies on the gamma process's inherent shrinkage mechanism to turn off unneeded model capacity (not all K experts will be used if K is set to be sufficiently large).

4.1 paSB and parSB Extensions of Softplus Regressions

We first follow Zhou (2016) to define

$$\varsigma(x_1, \ldots, x_t) = \ln\left(1 + e^{x_t} \ln\left\{1 + e^{x_{t-1}} \ln\left[1 + \ldots \ln\left(1 + e^{x_1}\right)\right]\right\}\right)$$

as the stack-softplus function. Note that if $t = 1$, the stack-softplus function reduces to softplus function $\varsigma(x) = \ln(1 + e^x)$, which is often considered as a smoothed version of the rectifier function, expressed as $\text{rectifier}(x) = \max(0, x)$, that has become the dominant nonlinear activation function for deep neural networks (Nair and Hinton, 2010; Glorot et al., 2011; Krizhevsky et al., 2012; LeCun et al., 2015). We then parameterize $\lambda_{iz_s} = -\ln(1 - \pi_{iz_s})$, the negative logarithms of the failure probabilities of the stick that category s is mapped to, as

$$\lambda_{iz_s} = \sum_{k=1}^{\infty} r_{sk}\, \varsigma\left(\boldsymbol{x}'\boldsymbol{\beta}_{sk}^{(2)}, \ldots, \boldsymbol{x}'\boldsymbol{\beta}_{sk}^{(T+1)}\right), \tag{9}$$

where the countably infinite atoms $(\boldsymbol{\beta}_{sk}^{(2)}, \ldots, \boldsymbol{\beta}_{sk}^{(T+1)})$ and their weights $\{r_{sk}\}_k$ constitute a draw from a gamma process $G_s \sim \text{GaP}(G_0, 1/c_s)$ (Ferguson, 1973), with G_0 as a finite and

continuous base distribution over a complete separable metric space Ω and $1/c_s$ as a scale parameter. In other words, we let $b_{iz_s} \sim \text{Bernoulli}(\pi_{iz_s})$ or

$$b_{iz_s} \sim \text{Bernoulli}\left[1-\prod_{k=1}^{\infty}\left(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{sk}^{(T+1)}}\ln\Big\{1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{sk}^{(T)}}\ln\Big[1+\ldots\ln\Big(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{sk}^{(2)}}\Big)\Big]\Big\}\right)^{-r_{sk}}\right]. \tag{10}$$

As shown in Theorem 10 of Zhou (2016), b_{iz_s} can be equivalently generated from a hierarchical model that convolves countably infinite stacked gamma distributions, with covariate-dependent scales, as

$$\begin{aligned}
\theta_{isk}^{(T)} &\sim \text{Gamma}\left(r_{sk}, e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{sk}^{(T+1)}}\right),\\
&\cdots\\
\theta_{isk}^{(t)} &\sim \text{Gamma}\left(\theta_{isk}^{(t+1)}, e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{sk}^{(t+1)}}\right),\\
&\cdots\\
\theta_{isk}^{(1)} &\sim \text{Gamma}\left(\theta_{isk}^{(2)}, e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{sk}^{(2)}}\right),\\
b_{iz_s} = \mathbf{1}(m_{is}\geq 1),\ m_{is} &= \sum_{k=1}^{\infty} m_{isk}^{(1)},\ m_{isk}^{(1)} \sim \text{Pois}(\theta_{isk}^{(1)}),
\end{aligned} \tag{11}$$

the marginalization of whose latent variables lead to (10). Note the gamma distribution $\theta \sim \text{Gamma}(r, 1/c)$ is defined such that $\mathbb{E}[\theta] = r/c$ and $\text{var}[\theta] = r/c^2$, and the hierarchical structure in (11) can also be related to the augmentable gamma belief network proposed in Zhou et al. (2016). We consider the combination of (11) and either paSB in (5) or parSB in (7) as the Bayesian nonparametric hierarchical model for multinomial softplus regression (MSR) that is defined below.

Definition 1 (Multinomial Softplus Regression) *With a draw from a gamma process for each category that consists of countably infinite atoms $\boldsymbol{\beta}_{sk}^{(2:T+1)}$ with weights $r_{sk} > 0$, where $\boldsymbol{\beta}_{sk}^{(t)} \in \mathbb{R}^{P+1}$, given the covariate vector $\boldsymbol{x}_i$ and category-stick mapping $\boldsymbol{z}$, MSR parameterizes p_{is}, the multinomial probability of category s, under the paSB construction as*

$$\begin{aligned}
p_{is}(\boldsymbol{z}) &= \left[1-\textstyle\prod_{k=1}^{\infty}\left(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{sk}^{(T+1)}}\ln\Big\{1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{sk}^{(T)}}\ln\Big[1+\ldots\ln\Big(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{sk}^{(2)}}\Big)\Big]\Big\}\right)^{-r_{sk}}\right]^{\mathbf{1}(z_s\neq S)}\\
&\times\textstyle\prod_{j:z_j<z_s}\left[\prod_{k=1}^{\infty}\left(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{jk}^{(T+1)}}\ln\Big\{1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{jk}^{(T)}}\ln\Big[1+\ldots\ln\Big(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{jk}^{(2)}}\Big)\Big]\Big\}\right)^{-r_{jk}}\right],
\end{aligned}$$

and parameterizes p_{is} under the parSB construction as

$$\begin{aligned}
p_{is}(\boldsymbol{z}) &= \left[\prod_{k=1}^{\infty}\left(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{sk}^{(T+1)}}\ln\Big\{1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{sk}^{(T)}}\ln\Big[1+\ldots\ln\Big(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{sk}^{(2)}}\Big)\Big]\Big\}\right)^{-r_{sk}}\right]^{\mathbf{1}(z_s\neq S)}\\
&\times\textstyle\prod_{j:z_j<z_s}\left[1-\prod_{k=1}^{\infty}\left(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{jk}^{(T+1)}}\ln\Big\{1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{jk}^{(T)}}\ln\Big[1+\ldots\ln\Big(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_{jk}^{(2)}}\Big)\Big]\Big\}\right)^{-r_{jk}}\right].
\end{aligned}$$

For the convenience of implementation, we truncate the number of atoms of the gamma process at K by choosing a discrete base measure for each category as $G_{s0} = \sum_{k=1}^{K}\frac{\gamma_{s0}}{K}\delta_{\boldsymbol{\beta}_{sk}^{(2:T+1)}}$, under which we have $r_{sk} \sim \text{Gamma}(\gamma_{s0}/K, 1/c_{s0})$ as the prior distribution for the weight of expert k in category s. For each category, we expect only some of its K experts to have non-negligible weights if K is set large enough, and we may use $\sum_k \mathbf{1}\big(\sum_i m_{isk}^{(1)} > 0\big)$, where $m_{isk}^{(1)}$ is defined in (11), to measure the number of active experts inferred from the data.

4.2 Geometric Constraints for MSR

Since by definition we have $p_{is}(\boldsymbol{z}) = \pi_{iz_s}\big(1-\sum_{j<s}p_{is}(\boldsymbol{z})\big) = \pi_{iz_s}\prod_{j<z_s}(1-\pi_{ij})$ in MSR, it is clear that if π_{ij} for all $j < z_s$ are small and π_{iz_s} is the first one to have a large probability value close to one, y_i will be likely assigned to category s regardless of how large the values of $\{\pi_{ij}\}_{j>z_s}$ are. To motivate the use of the seemingly over-parameterized sum-stack-softplus function in (9), we first consider the simplest case of $K = T = 1$. Without loss of generality, let us assume that the category-stick mapping is fixed at $\boldsymbol{z} = (1, \ldots, S)$.

Lemma 4 *For paSB-MSR with $K = T = 1$ and $\boldsymbol{z} = (1, \ldots, S)$, the set of solutions to $p_{is}(\boldsymbol{z}) > p_0$ in the covariate space are bounded by a convex polytope defined by the intersection of s linear hyperplanes.*

Note that the binary softplus regression with $K = T = 1$ is closely related to logistic regression, and reduces to logistic regression if $r = 1$ (Zhou, 2016). With Lemma 4, it is clear that even if an optimal category-stick mapping $\boldsymbol{z}$ is provided, paSB-MSR with $K = T = 1$ may still clearly underperform MLR. This is because category s uses a single hyperplane to separate itself from the remaining $S - s$ categories, and hence uses the interaction of at most s hyperplanes to separate itself from the other $S - 1$ categories. By contrast, MLR uses a convex polytope bounded by at most $S - 1$ hyperplanes for each of the S categories.

When $K > 1$ and/or $T > 1$, an exact theoretical analysis is beyond the scope of this paper. Instead we provide some qualitative analysis by borrowing related geometric-constraint analysis for softplus regressions in Zhou (2016). Note that Equation (10) indicates that a noisy-or model (Pearl, 2014; Srinivas, 1993), commonly appearing in causal inference, is used at each step of the sequential one-vs-remaining decision process; at each step, the binary outcome of an observation is attributed to the disjunctive interaction of many possible hidden causes. Roughly speaking, to enclose category s to separate it from the remaining $S-s$ categories in the covariate space, paSB-MSR with $K > 1$ and $T = 1$ uses the complement of a convex-polytope-bounded space, paSB-MSR with $K = 1$ and $T > 1$ uses a convex-polytope-like confined space, and paSB-MSR with both $K > 1$ and $T > 1$ uses a union of convex-polytope-like confined spaces. For parSB-MSR with $K + T > 1$, the interpretation is the same except a convex polytope in paSB will be replaced with the complement of a convex polytope, and vise versa. In contrast to SVMs using the kernel trick, MSRs using the original covariates might be more appealing in research areas, like biostatistics and sociology, where the interpretation of regression coefficients and investigation of causal relationships are of interest. In addition, we find that the classification capability of MSRs could be further enhanced with data transformation, as will be discussed in Section 6.4.

5. Bayesian Multinomial Support Vector Machine

Support vector machines (SVMs) are max-margin binary classifiers that typically minimize a regularized hinge loss objective function as

$$l(\boldsymbol{\beta}, \nu) = \sum_{i=1}^{N} \max(1 - b_i \boldsymbol{x}_i'\boldsymbol{\beta}, 0) + \nu R(\boldsymbol{\beta}),$$

where $b_i \in \{-1, 1\}$ represents the binary label for the ith observation, $R(\boldsymbol{\beta})$ is a regularization function that is often set as the L_1 or L_2 norm of $\boldsymbol{\beta}$, ν is a tuning parameter, and $\boldsymbol{x}_i'$ is the ith row of the design matrix $\mathbf{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)'$. For linear SVMs, $\boldsymbol{x}_i$ is the covariate vector of the ith observation, whereas for nonlinear SVMs, one typically set the (i, j)th element of $\mathbf{X}$ as the kernel distance between the covariate vector of the ith observation and the jth support vector. The decision boundary of a binary SVM is $\{\boldsymbol{x} : \boldsymbol{x}'\boldsymbol{\beta} = 0\}$ and an observation is assigned the label $y_i = \text{sign}(\boldsymbol{x}'\boldsymbol{\beta})$, which means $b_i = 1$ if $\boldsymbol{x}'\boldsymbol{\beta} \geq 0$ and $b_i = -1$ if $\boldsymbol{x}'\boldsymbol{\beta} < 0$.

5.1 Bayesian Binary SVMs

It is shown in Polson and Scott (2011) that the exponential of the negative of the hinge loss can be expressed as a location-scale mixture of normals as

$$\begin{aligned} L(b_i \,|\, \boldsymbol{x}_i, \boldsymbol{\beta}) &= \exp\left[-2\max(1 - b_i \boldsymbol{x}_i'\boldsymbol{\beta}, 0)\right] \\ &= \int_0^\infty \frac{1}{\sqrt{2\pi\omega_i}} \exp\left[-\frac{1}{2}\frac{(1 + \omega_i - b_i \boldsymbol{x}_i'\boldsymbol{\beta})^2}{\omega_i}\right] d\omega_i. \end{aligned}$$

Consequently, $L(\boldsymbol{b} \,|\, \mathbf{X}, \boldsymbol{\beta}) = \prod_i L(b_i \,|\, \boldsymbol{x}_i, \boldsymbol{\beta}) = \exp\{-2\sum_i \max(1 - b_i \boldsymbol{x}_i'\boldsymbol{\beta}, 0)\}$ can be regarded as a pseudo likelihood in the sense that it is unnormalized with respect to $\boldsymbol{b} = (b_1, \ldots, b_N)' \in \{-1, 1\}^N$. This location-scale normal mixture representation of the hinge loss allows developing close-form Gibbs sampling update equations for the regression coefficients $\boldsymbol{\beta}$ via data augmentation, as discussed in detail in Polson and Scott (2011) and further generalized in Henao et al. (2014) to construct nonlinear SVMs amenable to Bayesian inference. While data augmentation has made it feasible to develop Bayesian inference for SVMs, it has not addressed a common issue that SVMs provide the predictions of deterministic class labels but not class probabilities. For this reason, below we discuss how to allow SVMs to predict class probabilities while maintaining tractable Bayesian inference via data augmentation.

Following Sollich (2002) and Mallick et al. (2005), by defining the joint distribution of $\boldsymbol{\beta}$ and $\{\boldsymbol{x}_i\}_i$ to be proportional to $\prod_i [L(1 \,|\, \boldsymbol{x}_i, \boldsymbol{\beta}) + L(-1 \,|\, \boldsymbol{x}_i, \boldsymbol{\beta})]$, one may define the conditional distribution of the binary label $b_i \in \{-1, 1\}$ as

$$P(b_i \,|\, \boldsymbol{x}_i, \boldsymbol{\beta}) = \begin{cases} \dfrac{1}{1 + e^{-2b_i \boldsymbol{x}_i'\boldsymbol{\beta}}}, & \text{for } |\boldsymbol{x}_i'\boldsymbol{\beta}| \leq 1; \\ \dfrac{1}{1 + e^{-b_i[\boldsymbol{x}_i'\boldsymbol{\beta} + \text{sign}(\boldsymbol{x}_i'\boldsymbol{\beta})]}}, & \text{for } |\boldsymbol{x}_i'\boldsymbol{\beta}| > 1; \end{cases} \tag{12}$$

which defines a probabilistic inference model that has the same maximum a posteriori (MAP) solution as that of a binary SVM for a given data set. Note that for MAP inference, the penalty term $\nu R(\boldsymbol{\beta})$ of the regularized hinge loss can be related to a corresponding prior distribution imposed on $\boldsymbol{\beta}$, such as Gaussian, Laplace, and spike-and-slab priors (Polson and Scott, 2011).

5.2 paSB Multinomial Support Vector Machine

Generalizing previous work in constructing Bayesian binary SVMs, we propose multinomial SVM (MSVM) under the paSB framework that is distinct from previously proposed MSVMs (Crammer and Singer, 2002; Lee et al., 2004; Liu and Yuan, 2011). A Bayesian MSVM that predicts class probabilities has also been proposed before in Zhang and Jordan (2006), which, however, does not have a data augmentation scheme to sample the regression coefficients in closed form, and consequently, relies on a random-walk Metropolis-Hastings procedure that may be difficult to tune.

Redefining the label sample space from $b_i \in \{-1, 1\}$ to $b_i \in \{0, 1\}$, we may rewrite (12) as $b_i \,|\, \boldsymbol{x}_i, \boldsymbol{\beta} \sim \text{Bernoulli}[\pi_{i,\text{svm}}(\boldsymbol{x}_i, \boldsymbol{\beta})]$, where

$$\pi_{i,\text{svm}}(\boldsymbol{x}_i, \boldsymbol{\beta}) = \begin{cases} \dfrac{1}{1 + e^{-2\boldsymbol{x}_i\boldsymbol{\beta}}}, & \text{for } |\boldsymbol{x}_i'\boldsymbol{\beta}| \leq 1; \\ \dfrac{1}{1 + e^{-\boldsymbol{x}_i\boldsymbol{\beta} - \text{sign}(\boldsymbol{x}_i'\boldsymbol{\beta})}}, & \text{for } |\boldsymbol{x}_i'\boldsymbol{\beta}| > 1. \end{cases} \tag{13}$$

The Bernoulli likelihood based cross-entropy-loss binary classifier, whose covariate-dependent probabilities are parameterized as in (13), is exactly what we need to extend the binary SVM into a multinomial classifier under paSB introduced in Theorem 1. More specifically, given the category-stick mapping $\boldsymbol{z}$, with the success probabilities of the stick that category s is mapped to parameterized as $\pi_{iz_s,\text{svm}}(\boldsymbol{x}_i, \boldsymbol{\beta}_s)$ and binary stick variables drawn as $b_{iz_s} \sim \text{Bernoulli}[\pi_{iz_s,\text{svm}}(\boldsymbol{x}_i, \boldsymbol{\beta}_s)]$, we have the following definition.

Definition 2 (paSB multinomial SVM) *Under the paSB construction, given the covariate vector $\boldsymbol{x}_i$ and category-stick mapping $\boldsymbol{z}$, multinomial support vector machine (MSVM) parameterizes p_{is}, the multinomial probability of category s, as*

$$p_{is}(\boldsymbol{z}) = [\pi_{iz_s,\text{svm}}(\boldsymbol{x}_i, \boldsymbol{\beta}_s)]^{\mathbf{1}(z_s \neq S)} \prod\nolimits_{j:z_j < z_s} \pi_{iz_j,\text{svm}}(\boldsymbol{x}_i, \boldsymbol{\beta}_j).$$

Note that there is no need to introduce parSB-MSVM in addition to paSB-MSVM, since by definition, we have $\pi_{iz_s,\text{svm}}(\boldsymbol{x}_i, -\boldsymbol{\beta}_s) = 1 - \pi_{iz_s,\text{svm}}(\boldsymbol{x}_i, \boldsymbol{\beta}_s)$ for all s.

6. Example Results

Constructed under the paSB framework, a multinomial regression model of S categories is characterized by not only how the S stick-specific binary classifiers with cross entropy loss parameterize their covariate-dependent probability parameters, but also how its S categories are one-to-one mapped to S latent sticks. To investigate the unique properties of a paSB multinomial regression model, we will study the benefits of both inferring an appropriate mapping $\boldsymbol{z}$ and increasing the modeling capacity of the underlying binary regression model. For illustration purpose, we will focus on multinomial softplus regression (MSR) whose capacity and complexity are both explicitly controlled by K and T.

6.1 Influence of Binary Regression Model Capacity

We first consider the Iris data set with $S = 3$ categories. We choose the sepal and petal lengths as the two dimensional covariates to illustrate the performance of MSR under four different settings. We fix $\boldsymbol{z} = (1, 2, 3)$, which means category s is mapped to stick s for all s, but choose different model capacities by varying K and T.

Examining the relative 2D spatial locations of the observations, where the blue, black, and gray points are labeled as category 1, 2, and 3, respectively, one can imagine that setting $\boldsymbol{z} = (2, 1, 3)$, which means mappings categories 2, 1, and 3 to the 1st, 2nd, and 3rd sticks, respectively, will already lead to excellent class separations for MSR with $K = T = 1$, according to the analysis in Section 4.2 and also confirmed by our experimental results (not shown for brevity). More specifically, with the 2nd, 1st, and 3rd categories mapped to the 1st, 2nd, and 3rd sticks, respectively, one can first use a single hyperplane to separate category 2 (black points) from both categories 1 (blue points) and 3 (gray points), and then use another hyperplane to separate category 1 (blue points) from category 3 (gray points).

However, when the mapping is fixed at $\boldsymbol{z} = (1, 2, 3)$, as shown in the first row of Figure 1, MSR with $K = T = 1$ performs poorly and fails to separate out category 1 (blue points) right in the beginning. This is not surprising since MSR with $K = T = 1$ is only equipped with a single hyperplane to separate the category that the first stick is mapped to (category $z_1 = 1$ in this case) from the others, whereas for this data set it is apparent at least two hyperplanes are required to separate the blue from the black and gray points. MSR with $K = 5$ and $T = 1$ also fails to work with $\boldsymbol{z} = (1, 2, 3)$, as shown in the third row of Figure 1, which is also not surprising since it can only use the complementary of a convex-polytope-bound confined space to enclose category $z_1 = 1$, but the blue points can not be enclosed in such a manner. Despite purposely enforcing an unfavorable category-stick mapping, once we increase T, the performance quickly improves, which is expected since $T > 1$ allows using a single (if $K = 1$ as in the second row) or a union (if $K > 1$ as in the fourth row) of convex-polytope-like confined spaces to separate one category from the others (by enclosing the positively labeled observations in each stick-specific binary classification task).

The results in Figure 1 show that even an unoptimized category-stick mapping, which is unfavorable to MSR with small K and/or T, is enforced, empowering each stick-specific binary regression model with a higher capacity (using larger K and/or T) can still allow MSR to achieve excellent separations. It is also simple to show that for the data set in Figure 1, even if one chooses low-capacity stick-specific binary regression models by setting $T = 1$, one can still achieve good performance with MSR if the category-stick mapping is set as $\boldsymbol{z} = (2, 1, 3)$, $\boldsymbol{z} = (3, 1, 2)$, $\boldsymbol{z} = (2, 3, 1)$, or $\boldsymbol{z} = (3, 2, 1)$. That is to say, as long as it is not category 1 (blue points) that is mapped to stick 1, MSR with $T = 1$ is able to provide satisfactory performance.

6.2 Influence of Category-Stick Mapping and its Inference

The Iris data set in Figure 1 provides an instructive example to show not only the importance of increasing the model capacity if a poor category-stick mapping is imposed, but also the importance of optimizing the category-stick mapping if the capacities of these stick-specific binary regression models are limited. To further illustrate the benefits of inferring an appropriate category-stick mapping $\boldsymbol{z}$, we consider the *square* data set shown in Figure 2.

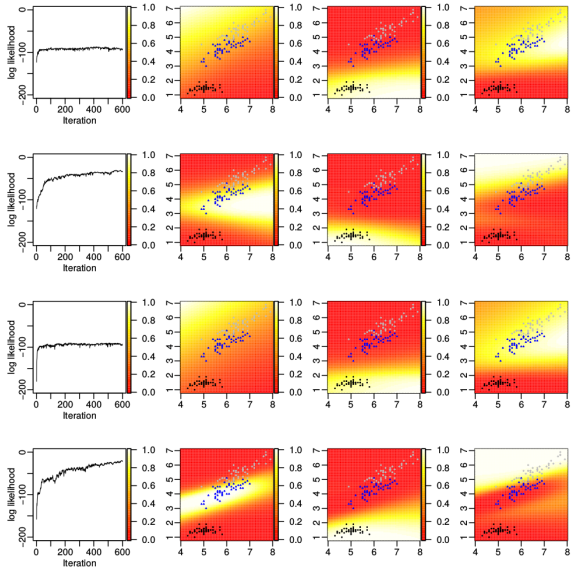

Figure 1: Log-likelihood plots and predictive probability heat maps for the 2-D iris data with a fixed category-stick mapping $\boldsymbol{z} = (1, 2, 3)$. Blue, black, and gray points are labeled as categories 1, 2, and 3, respectively. For the first row, $K = 1$ and $T = 1$, second row, $K = 1$ and $T = 3$, third row, $K = 5$ and $T = 1$, and fourth row, $K = 5$ and $T = 3$. The log-likelihood plots are shown in Column 1, and the predictive probability heat maps of categories 1 (blue), 2 (black), and 3 (gray) are shown in Columns 2, 3, and 4, respectively.

We show that for MSR, even if both K and T are sufficiently large to allow each stick-specific binary regression model to have a high enough capacity, whether an optimal category-stick mapping is selected may still clearly matter for the performance.

As shown in the first three rows of Figure 2, with $K = T = 10$, three different $\boldsymbol{z}$'s are considered and $\boldsymbol{z} = (1, 2, 3)$ (shown in the first row) is found to perform the best. As shown in the fourth row, we sample $\boldsymbol{z}$ using (8) within each MCMC iteration and achieve a result that seems as good as fixing $\boldsymbol{z} = (1, 2, 3)$. In fact, we find that our inferred mappings switch between $\boldsymbol{z} = (1, 2, 3)$ and $\boldsymbol{z} = (1, 3, 2)$ during MCMC iterations, indicating that the Markov chain is mixing well. These results suggest the importance of both learning the mapping $\boldsymbol{z}$ from the data and allowing the stick-specific binary classifiers to have enough capacities to model nonlinear classification decision boundaries.

When sampling $\boldsymbol{z} = (z_1, \ldots, z_S)$ that the S categories are mapped to, although $S!$ permutations of $(1, \ldots, S)$ can become enormous as S increases, the effective search space could be much smaller if many different mappings imply similar likelihoods and if these extremely poor mappings can be easily avoided. Rather than searching for the best mapping,

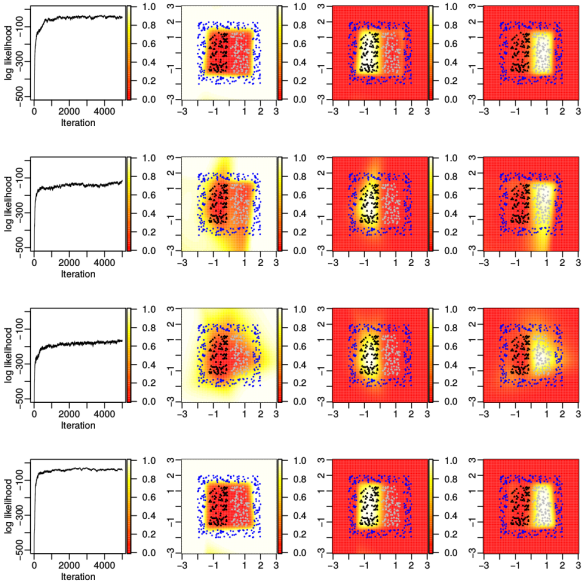

Figure 2: Log-likelihood plots and predictive probability heat maps for the square data with $K = T = 10$. The blue, black, and gray points are labeled as categories 1, 2, and 3, respectively. We fix the category-stick mapping as $\boldsymbol{z} = (1, 2, 3)$ for Row 1, $(2, 1, 3)$ for Row 2, and $(3, 1, 2)$ for Row 3, and sample $\boldsymbol{z}$ for Row 4. The log-likelihood plots are shown in Column 1, and the predictive probability heat maps of categories 1 (blue), 2 (black), and 3 (gray) are shown in Columns 2, 3, and 4, respectively.

the proposed MH step, proposing two indices z_j and $z_{j'}$ to switch in each iteration, is a simple but effective strategy to escape from the mappings that lead to poor fits. Note that the probability of a z_j not being proposed to switch after t MCMC iterations is $[(S-2)/S]^t$. Even if S is as large as 100, this probability is less than 10^{-8} at $t = 1000$. Also note the iteration at which z_j is proposed to switch at the first time follows a geometric distribution, with success probability $2/S$. Thus $S/2$ is the expected number of iterations for a z_j to be proposed to switch once.

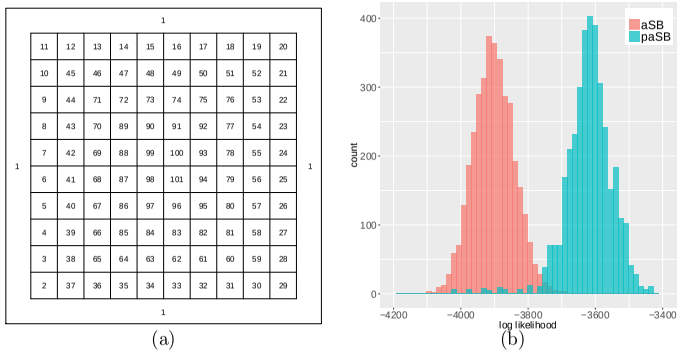
To demonstrate the efficiency of our permutation scheme, we construct square101, a synthetic two-dimensional data set consisting of 101 categories. We generate 8000 data points that are uniformly at random distributed within the 12×12 spatial region occupied by all 101 categories. The decision boundaries of different classes are displayed in Figure 3(a), where the data points placed within the outside square frame, whose outer and inner dimensions are 12 and 10, respectively, are assigned to category 1, and these placed within the sth unit square, where $s \in \{2, \ldots, 101\}$, inside the square frame are assigned to category s.

Although it is almost impossible to search for the best category-stick mapping $\boldsymbol{z}$ giving rise to the highest likelihood from all $101! \approx 10^{160}$ possible mappings, we show our permutation scheme is very effective in escaping from poor mappings, leading to a performance that is comparable to the best of those obtained with pre-fixed suboptimal mappings. More specifically, applying the analysis in Section 4.2 to Figure 3(a), we expect an aSB-MSR to perform well under a fixed suboptimal category-stick mapping $\boldsymbol{z}$, where $z_1 = 1$, which means the outside square frame is mapped to stick 1, and the squares closer to the inner boundary of the square frame are mapped to the sticks broken at earlier stages; the mapping $\boldsymbol{z} = (1, 2, \cdots, 101)$ is such an example. In other words, we first separate the frame from all the other squares, and then sequentially separate the squares from the remainders; the closer a square is from the frame, the earlier it is separated. The total number of suboptimal mappings $\boldsymbol{z}$'s constructed in this manner is as large as $36! \times 28! \times 20! \times 12! \times 4! \approx 10^{99.5}$.

First, we uniformly at random generate 3600 different suboptimal mappings $\boldsymbol{z}$'s under this construction, run aSB-MSR with $K = T = 4$, and plot the histogram of the 3600 log-likelihoods in Figure 3(b). Second, we start from 3600 randomly initialized $\boldsymbol{z}$, run paSB-MSR with $K = T = 4$, and also plot the histogram of the 3600 log-likelihoods in Figure 3(b). For each run, we choose 20,000 MCMC iterations and collect the last 1000 MCMC samples. Each log-likelihood is averaged over those of the corresponding model's collected MCMC samples. As in Figure 3(b), the log-likelihood from a paSB-MSR is in general clearly larger than that of an aSB-MSR with a fixed suboptimal $\boldsymbol{z}$, and there is little overlap between their corresponding histograms. Further examining the 3600 $\boldsymbol{z}$'s inferred by paSB at its last MCMC iteration shows that 3482 of them have $z_1 = 1$ and all of them have $z_1 \leq 5$. Suppose $z_1 \notin \{1, 2, 3, 4, 5\}$ at the current iteration, which means category 1 is mapped to none of the first five sticks, then the probability of not only selecting stick z_1, but also switching it with one of the first five sticks in the MH proposal is $\frac{1}{101} \times \frac{5}{100}$. Thus the probability that category 1 has never been proposed to mapped to one of the first five sticks after t iterations is $[1 - 5/(101 \times 100)]^t$, which becomes as small as 0.005% at $t = 20,000$, demonstrating the effectiveness of our permutation scheme in dealing with a large number of categories. Note we have also tried 3600 aSB-MSR, each of which is provided with a randomly initialized $\boldsymbol{z}$. The log-likelihoods, however, are all far below -4000 and hence not included for comparison. This phenomenon is not surprising, as the probability for a randomly initialized $\boldsymbol{z}$ to be suboptimal is as tiny as $36! \times 28! \times 20! \times 12! \times 4!/101! \approx 10^{-60.5}$.

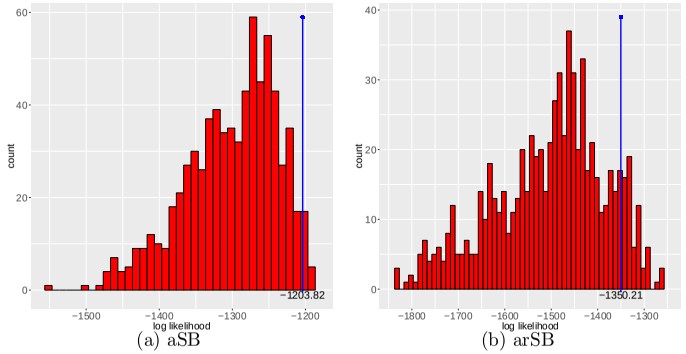
Figure 4 empirically demonstrates the effectiveness of permuting $\boldsymbol{z}$ on the satimage data set, using MSRs with $K = 5$, $T = 3$, and $\boldsymbol{z}$ fixed at each of the $6! = 720$ possible one-to-one category-stick mappings. Panels (a) and (b) show the log-likelihood histograms for MSRs constructed under augmented SB (aSB) and augmented reversed SB (arSB), respectively. Both histograms are clearly left skewed, indicating under both aSB and arSB, only a small proportion of the 720 different category-stick mappings lead to very poor fits. The blue vertical lines at -1203.82 in (a) and -1350.21 in (b) are the log-likelihoods by paSB and parSB, respectively, in both of which the category-stick mapping $\boldsymbol{z}$ is updated by a MH step in each MCMC iteration. Only 20 (97) out of 720 aSB-MSRs (arSB-MSRs) have a higher likelihood than paSB-MSR (parSB-MSR).

Since in the stick-breaking construction, the binary classifier that separates a category mapped to a smaller-indexed stick from the others utilizes fewer constraints, the classification can be poor if the complexity of the decision boundary goes beyond the nonlinear



(a) (b)

Figure 3: (a) Illustration of the square101 data and (b) log-likelihood histograms, by aSB-MSR with 3600 random suboptimal category-stick mappings and by paSB-MSR with 3600 randomly initialized category-stick mappings.



(a) aSB (b) arSB

Figure 4: Log-likelihood histograms for MSRs using all 720 possible category-stick mappings, constructed under (a) augmented stick breaking (aSB) and (b) augmented and reversed stick breaking (arSB). The blue lines in (a) and (b) correspond to the log-likelihoods of paSB-MSR and parSB-MSR, respectively.

modeling capacity of the binary classifier. However, even with a low-capacity binary classifier, the performance could be significantly improved if that difficult-to-separate category is mapped to a larger-indexed stick, for which there are fewer categories left to be separated in its "one-vs-remaining" binary classification problem. Examining the $\boldsymbol{z}$'s associated with the 100 lowest log-likelihoods in Figure 4, we find there are 51 mappings belonging to the set $\{\boldsymbol{z} : z_5 = 1 \text{ or } z_6 = 1\}$ in aSB, and 77 belonging to $\{\boldsymbol{z} : z_3 = 1 \text{ or } z_6 = 1\}$ in arSB. It suggests that separating Categories 5 or 6 (Categories 3 or 6) from all the other categories might be beyond the capacity of a binary softplus regression with $K = 5$ and $T = 3$ under

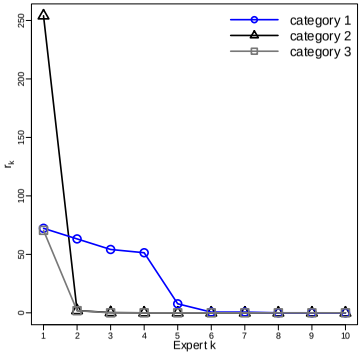


Figure 5: Inferred expert weights r_k in descending order for each category of the square data with $K = T = 10$.

the aSB (arSB) construction. But if breaking the sticks associated with these categories at late stages, we only need to separate them from fewer remaining categories, which could be much easier. We have further examined the other 620 arrangements, and found no evident patterns. These observations suggest that the effective search space of the mapping $\boldsymbol{z}$ is considerably smaller than $S!$, and the proposed MH step is effective in escaping from poor category-stick mappings.

In paSB-MSVM, we use a Gaussian radial basis function kernel, whose kernel width is cross validated from a set of predefined candidates. We find its performance to be sensitive to the setting of the kernel width, which is a common issue for SVMs (Cherkassky and Ma, 2004; Soares et al., 2004; Chang et al., 2005). If an appropriate kernel width could be identified through cross validation, we find that learning the mapping $\boldsymbol{z}$ becomes less important for paSB-MSVM to perform well. However, we find that if the kernel width is not well selected, which can happen if all candidate kernel widths are far from the optimal value, the binary classifier for each category may not have enough capacity for nonlinear classification and the learning of the category-stick mapping $\boldsymbol{z}$ could then become important.

6.3 Turning Off Unneeded Model Capacities

While one can adjust both K and T to control the capacity of binary softplus regression, for MSR, the total number of experts K is a truncation level that can be set as large as permitted by the computation budget. This is because the truncated gamma process used by each stick-specific binary softplus regression shrinks the weights of unnecessary experts towards zeros. Figure 5 shows in decreasing order the inferred weights of the experts belonging to each of the 3 categories of the square data set. These weights are inferred by MSR with $K = T = 10$ and the learning of $\boldsymbol{z}$, as in the fourth row of Figure 2. It is clear from Figure 5 that only a small number of experts are inferred with non-negligible weights in the posterior, and the number of active experts and their weights indicate the complexity

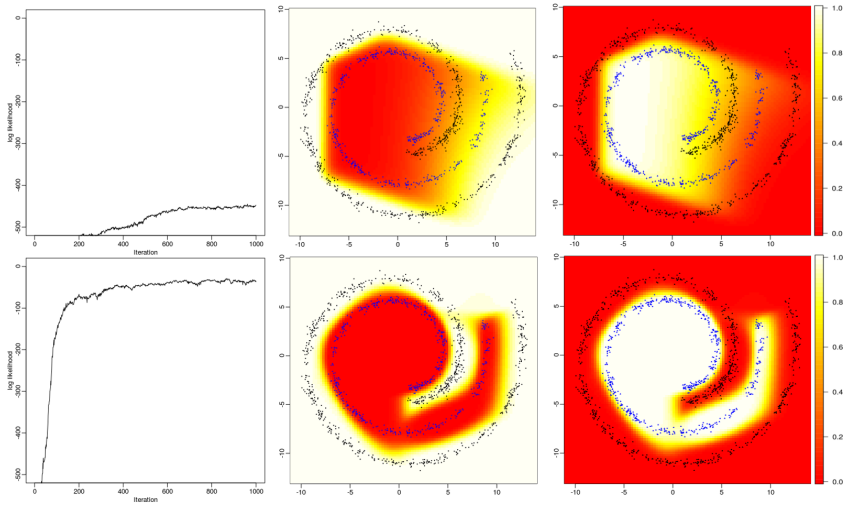

Figure 6: First row: classification of a 2-D swiss roll data by paSB-MSR with $K = 5$, $T = 3$, using the original covariates. Second row: paSB-MSR with $K = 5$, $T = 1$ trained on the covariates transformed via the paSB-MSR used in the first row. In each row, the left column plot the log-likelihood against MCMC iteration, and the middle and right columns show the predictive probability heatmaps for Category 1 (black points) and Category 2 (blue points), respectively.

of the corresponding classification decision boundaries shown in the fourth row of Figure 2. We note that while T is a parameter to be set by the user, we find increasing it increases model capacity, without observing clear signs of overfitting for all the data considered here.

6.4 MSR with Data Transformation

Kernel SVMs transform the data to make different categories more linearly separable in the transformed covariate space. While kernel SVMs may provide high nonlinear modeling capacity, its performance could be sensitive to the kernel width, which often needs to be cross validated, and its number of support vectors often increases linearly in the size of the training set. By contrast, MSRs rely on the interactions of linear hyperplanes to construct nonlinear decision boundaries, as discussed in Section 4.2, and hence may have insufficient capacity for highly complex nonlinearity. However, we may simply stack another MSR on a previously trained MSR to quickly enhance its nonlinear modeling capacity. In particular, we may first run a MSR to obtain a finite set of hyperplanes denoted by $\tilde{\boldsymbol{\beta}}_{jk}^{(t+1)}$. We may

then augment the original covariate vector $\boldsymbol{x}_i$ as

$$\tilde{\boldsymbol{x}}_i := \left[\boldsymbol{x}_i', \log\left(1 + e^{\boldsymbol{x}_i'\tilde{\boldsymbol{\beta}}_{11}^{(2)}}\right), \cdots, \log\left(1 + e^{\boldsymbol{x}_i'\tilde{\boldsymbol{\beta}}_{jk}^{(t+1)}}\right), \cdots, \log\left(1 + e^{\boldsymbol{x}_i'\tilde{\boldsymbol{\beta}}_{SK}^{(T+1)}}\right)\right]' \tag{14}$$

and run another MSR with the transformed covariates $\tilde{\boldsymbol{x}}_i$.

For illustration, we show the efficacy of this data-transformation strategy on a 2-D swiss roll data in Figure 6. The first row shows the results of MSR with $K = 5$ and $T = 3$, using the original covariates $\boldsymbol{x}_i$, while the second row shows MSR with $K = 5$ and $T = 1$, using the transformed covariates $\tilde{\boldsymbol{x}}_i$ defined by (14), where the regression coefficient vectors $\tilde{\boldsymbol{\beta}}_{jk}^{(t+1)}$ are learned using the MSR illustrated in the first row. It is evident that the classification is greatly improved in terms of both training log-likelihood and out-of-sample predictions.

6.5 Results on Benchmark Data Sets

To further evaluate the performance of the proposed paSB multinomial regression models, we consider paSB multinomial logistic regression (paSB-MLR), paSB multinomial robit with $\kappa = 6$ degrees of freedom (paSB-robit), paSB multinomial support vector machine (paSB-MSVM), and MSRs. We compare their performance with those of L_2 regularized multinomial logistic regression (L_2-MLR), support vector machine (SVM), and adaptive multi-hyperplane machine (AMM), and consider the following benchmark multi-class classification data sets: iris, wine, glass, vehicle, waveform, segment, dna, and satimage. We also include the synthetic square data shown in Figure 2 for comparison. For SVM we use the LIBSVM package, which trains $S(S-1)/2$ one-vs-one binary classifiers and makes prediction using majority voting (Chang and Lin, 2011). We run LIBSVM in `R` with package `e1071` (Meyer et al., 2015). We consider MSRs with (K, T) as $(1, 1)$, $(1, 3)$, $(5, 1)$, and $(5, 3)$, respectively. We also consider MSR with data transformation (DT-MSR), in which we first train a MSR with $K = 5$ and $T = 3$ to transform the covariates and then stack another MSR with $K = 5$ and $T = 1$. We provide detailed descriptions on the data and experimental settings in the Appendix.

With the number of categories in parentheses right after the data set names, we summarize in Table 1 the classification error rates by various models, where those of MSRs are calculated by averaging over paSB and parSB. Table 1 shows that an MSR with K or T sufficiently large generally outperforms paSB-MLR, paSB-robit, L_2-MLR, and AMM, and using another MSR on the transformed covariates can in general further reduce the error rate. This is especially evident when there are nonlinearly separable categories, as indicated by a clearly higher error rate of L_2-MLR in contrast to that of SVM. One may notice that paSB-robit, paSB-MLR, and MSR with $K = T = 1$ are similar to L_2-MLR in terms of performance, suggesting the effectiveness of the proposed permutation scheme, which helps mitigate the potential adverse effects of having asymmetric class labels. One may also note that paSB-robit outperforms paSB-MLR on glass, vehicle, waveform, dna, and satimage, indicating there are benefits in using a robust classifier on these data sets. Comparable error rates of paSB-MSVM to SVM and better performance of MSRs on most data sets demonstrate the success of the paSB framework in transforming a binary classifier with cross entropy loss into a Bayesian multinomial one.

To further check whether a paSB model is attractive when fast out-of-sample prediction is desired, we consider using only the MCMC sample that has the highest training likelihood

Data (S)	paSB-MLR	paSB-robit	paSB-MSVM	$K=1$ $T=1$	$K=1$ $T=3$	$K=5$ $T=1$	$K=5$ $T=3$	DT-MSR	L_2-MLR	SVM	AMM

Table 1: Comparison of the classification error rates (%) of paSB-MLR, paSB-robit, paSB-MSVM, MSRs with various K and T (columns 5 to 8), MSR with data transformation (DT-MSR), L_2-MLR, SVM, and AMM.

among the collected ones for all paSB models, and summarize in Table 4 of the Appendix the classification error rates of various models, with the number of inferred support vectors or active hyperplanes included in parenthesis. Following the definition of active experts in Zhou (2016), we define for MSRs the number of active hyperplanes as $T\sum_s^S \widetilde{K}_s$ where $\widetilde{K}_s$ is the number of active experts for class s. The number of active hyperplanes determines the computational complexity for out-of-sample prediction with a single MCMC sample, which is $O(T\sum_s^S \widetilde{K}_s)$. Since the error rates of MSRs in Table 4 are calculated by averaging over both paSB and parSB, the number of active hyperplanes is $T\sum_s^S(\widetilde{K}_s^{(paSB)} + \widetilde{K}_s^{(parSB)})$.

Shown in Figure 8 in the Appendix are boxplots of the number of each category's active experts for MSR with $K = 5$ and $T = 3$. Except for several categories of satimage that require all $K = 5$ experts for parSB-MSR, $K = 5$ is large enough to provide the needed model capacity under all the other scenarios. As shown in Table 4, MSRs with sufficiently large K and/or T are comparable to both SVM and paSB-MSVM in terms of the error rates, while clearly outperforming them in terms of the number of (active) hyperplanes/support vectors and hence computational complexity for out-of-sample predictions. While MSR with $K = T = 1$, paSB-MLR, and paSB-robit generally perform worse than SVM in terms of the error rates, they use much fewer hyperplanes and hence have significantly lower computation for out-of-sample predictions. In summary, MSR whose upper-bound for the number of active expects K and number of layers for each expert T can both be adjusted to control its capacity of modeling nonlinearity, can achieve a good compromise between the accuracy and computational complexity for out-of-sample prediction of multinomial class probabilities, and can be further improved by training an additional MSR on the transformed covariates.

We further measure how well the Gibbs sampler is mixing using effective sample size (ESS) for both paSB-MLR and Bayesian multinomial logistic regression (Bayes MLR) of Polson et al. (2013). For both algorithms we let $\boldsymbol{\beta}_j \sim \mathcal{N}\left(0, \text{diag}(\alpha_{j0}^{-1}, \ldots, \alpha_{jV}^{-1})\right)$, where $\alpha_{jv} \sim \text{Gamma}(0.001, 1/0.001)$. The ESS (Holmes and Held, 2006) of a parameter or a function of parameters is defined as $\text{ESS} = L/\left[1 + 2\sum_{h=1}^{\infty}\rho(h)\right]$, where L is the number of post-burn-in samples, $\rho(h)$ is the hth autocorrelation of the parameter or the function of parameters. It describes how quickly an MCMC algorithm generates independent samples.

Table 2: Comparison of the ESS of the conditional class probability between Bayes MLR and paSB-MLR.

Since the Gibbs sampler of Bayes MLR samples one $\boldsymbol{\beta}_j$ conditioning on all $\boldsymbol{\beta}_{j'}$ for $j' \neq j$, which may lead to strong dependencies between different categories and hence slow down the mixing of the Markov chain. By contrast, the $\boldsymbol{\beta}_j$'s are conditionally independent given the augmented variables b_{ij}'s in paSB-MLR, which may lead to faster mixing. For both Bayes MLR and paSB-MLR, we consider five independent random trials, in each of which we randomly initialize the model parameters, run 10,000 Gibbs sampling iterations, and collect the last 1,000 MCMC samples of $\boldsymbol{\beta}_j$. We use the `mcmcse` package (Flegal et al., 2016) to estimate the ESS of each p_{ij} in a random trial using the 1,000 collected MCMC samples. For the training set, we calculate the 10% quantile, median, and 90% quantile of the ESSs of all p_{ij} for each random trial, and then report their averages over the five random trials in Table 2. For the testing set, we follow the same steps and report the results in Table 2. While paSB-MLR underperforms Bayes MLR on some of the data sets for the 10% ESS quantile, they consistently outperform Bayes MLR on all data sets for both the ESS median and 90% ESS quantile, for both training and testing.

6.6 Robustness of paSB-Robit Regression

We use the contaminated vehicle data to demonstrate the robustness of paSB-robit. As discussed by Liu (2004), the heavy-tailed conditional class probability function of robit regression can robustify the decision boundary when there exist outliers. We use the vehicle training set as inliers, synthesize outliers that are far from inliers, combine both as the new training set, and keep the testing set unchanged. We generate different numbers of outliers so that the ratio of outliers to inliers varies from 0, 0.1, 0.2, 0.3, to 0.5, at each of which we randomly simulate 10 different sets of outlier covariates. We provide the details on how we generate outliers in the Appendix.

We compare L_2-MLR and paSB-robit with $\kappa = 1$ degree of freedom on the contaminated vehicle data. Figure 7 shows the prediction error rate (mean $\pm$ standard deviation) of the testing set for different outlier-inlier ratios. When there are no outliers, both approaches delivers comparable performances. As the ratio increases, paSB-robit with $\kappa = 1$ more and more clearly outperforms L_2-MLR, which justifies the robustness of paSB-robit.

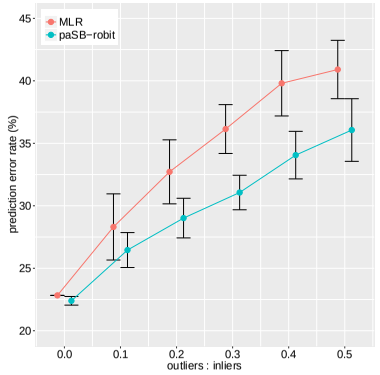

Figure 7: Prediction error rates (%, mean ± standard deviation) for different ratios of outliers to inliers.

7. Conclusions

To transform a cross-entropy-loss binary classifier into a Bayesian multinomial regression model and derive efficient Bayesian inference, we develop a permuted and augmented stick-breaking construction. With permutation, we one-to-one map the categories to sticks to escape from poor category-stick mappings that impose restrictive geometric constraints on the decision boundaries, and with augmentation, we link a category outcome to conditionally independent stick-specific covariate-dependent Bernoulli random variables. We illustrate this general framework by extending binary softplus regression, robit regression, and support vector machine into multinomial ones. Experiment results validate our contributions and show that the proposed multinomial softplus regressions achieve a good compromise between interpretability, complexity, and predictability.

Appendix A. Additional Lemma and Proofs

Proof [Proof of Theorem 1] The conditional probability of y_i given $\{z_s, \pi_{is}\}_{1,S}$ can be expressed as

$$P(y_i = s \,|\, \{z_s, \pi_{is}\}_{1,S}) = \textstyle\sum_{b_{ij}:j>z_s} [P(b_{iz_s}=1)]^{\mathbf{1}(z_s\neq S)} \left[\prod_{j<z_s} P(b_{ij}=0)\right] \left[\prod_{j>z_s} P(b_{ij})\right]$$
$$= [P(b_{iz_s}=1)]^{\mathbf{1}(z_s\neq S)} \left[\prod_{j<z_s} P(b_{ij}=0)\right] \textstyle\sum_{b_{ij}:j>z_s} \left[\prod_{j>z_s} P(b_{ij})\right],$$

which becomes the same as (4) by applying (5) and $\sum_{b_{ij}:j>z_s}\left[\prod_{j>z_s} P(b_{ij})\right]=1$. ■

Proof [Proof of Lemma 3] Under the paSB construction, the probability ratio of categories (choices) s and $s+d$ is a function of the stick success probabilities $\pi_{z_s}, \pi_{z_{(s+1)}}, \cdots, \pi_{z_{(s+d)}}$. More specifically,

$$\frac{p_{i(s+d)}(\boldsymbol{z})}{p_{is}(\boldsymbol{z})} = \frac{\pi_{iz_{(s+d)}}^{\mathbf{1}(z_{(s+d)}\neq S)} \left[\prod_{z_s\leq j<z_{(s+d)}}(1-\pi_{ij})\right]^{\delta(z_s\leq z_{(s+d)})}}{\pi_{iz_s}^{\mathbf{1}(z_s\neq S)} \left[\prod_{z_{(s+d)}\leq j<z_s}(1-\pi_{ij})\right]^{\delta(z_s>z_{(s+d)})}}.$$

■

Proof [Proof of Lemma 4] Since $p_{is}(\boldsymbol{z}) = \left[1-\left(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_s}\right)^{-r_s}\right]^{\mathbf{1}(s\neq S)} \prod_{j<s}\left(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_j}\right)^{-r_j}$ when $K=T=1$ and $\boldsymbol{z}=(1,\ldots,S)$, the set of solutions to $p_{is}>p_0$ are bounded by the set of solutions to $\left(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_j}\right)^{-r_s}>p_0$, $j\in\{1,\ldots,s-1\}$, and $1-\left(1+e^{\boldsymbol{x}_i'\boldsymbol{\beta}_s}\right)^{-r_s}>p_0$, and hence bounded by the convex polytope defined by the set of solutions to the s inequalities as

$$\boldsymbol{x}_i'[(-1)^{\mathbf{1}(j=s)}\boldsymbol{\beta}_j] < (-1)^{\mathbf{1}(j=s)} \ln\left\{\left[p_0^{\mathbf{1}(j\neq s)}(1-p_0)^{\mathbf{1}(j=s)}\right]^{-\frac{1}{r_j}}-1\right\}, \quad j\in\{1,\ldots,s\}.$$

■

Lemma 5 *Without loss of generality, let us assume that the category-stick mapping is fixed at $\boldsymbol{z}=(1,2,\cdots,S)$. The paSB multinomial logistic model that assigns choice $s\in\{1,\ldots,S\}$ for individual i with probability $p_{is}=(\pi_{is})^{\mathbf{1}(s\neq S)}\prod_{j<s}(1-\pi_{ij})$, where $\pi_{is}=1/(1+e^{-W_{is}})$, can be considered as a sequential random utility maximization model. This model selects choice s once $U_{is}>\sum_{j\geq s}U_{ij}$ is observed for $s=1,\ldots,S$, where U_{is} are defined as*

$$\begin{aligned} U_{i1} &= U_{i2}+\cdots+U_{iS}+W_{i1}+\varepsilon_{i1},\\ &\cdots\\ U_{is} &= \sum_{j>s}U_{ij}+W_{is}+\varepsilon_{is},\\ &\cdots\\ U_{i(S-1)} &= W_{i(S-1)}+\varepsilon_{i(S-1)},\\ U_{iS} &= 0, \end{aligned}$$

and $\varepsilon_{is}\overset{i.i.d.}{\sim}\text{Logistic}(0,1)$ are independent, and identically distributed (i.i.d.) random variables following the standard logistic distribution.

Proof [Proof of Lemma 5] Note that $P(\varepsilon<x)=1/(1+e^{-x})$ if $\varepsilon\sim\text{Logistic}(0,1)$. First consider the choice of individual i be $y_i=1$, which would happen with probability

$$P(y_i=1)=P\left(U_{i1}>\sum\nolimits_{j\geq 1}U_{ij}\right)=P(\varepsilon_{i1}>-W_{i1})=1/(1+e^{-W_{i1}})=\pi_{i1}=p_{i1}.$$

Table 3: Multi-class classification data sets used in experiments for model comparison.

Then for $s = 2, \cdots, S-1$,

$$\begin{aligned} P(y_i = s) &= P(y_i = s \,|\, y_i > s-1) P(y_i > s-1) \\ &= P\left(U_{is} > \sum\nolimits_{j>s} U_{ij}\right) \prod\nolimits_{j \le s-1} P\left(U_{ij} < \sum\nolimits_{j'>j} U_{ij'}\right) \\ &= P(\varepsilon_{is} > -W_{is}) \prod\nolimits_{j \le s-1} P(\varepsilon_{ij} < -W_{ij}) \\ &= \pi_{is} \prod\nolimits_{j \le s-1} (1 - \pi_{ij}) \\ &= p_{is}. \end{aligned}$$

Finally, $P(y_i = S) = 1 - \sum_{j<S} P(y_i = j) = \prod_{j<S}(1 - \pi_{ij}) = p_{iS}$. ■

Appendix B. Experimental Settings and Additional Results

The table below summarizes the sizes of both training and testing sets, and the number of covariates and categories. The training and testing sets are predefined for vehicle, dna, and satimage. Note that the training and validation sets are combined as training. We divide the other data sets into training and testing as follows. For iris, wine, and glass, five random partitions are taken such that for each partition the training set accounted for 80% of the whole data set while the testing set 20%. The classification error rate is calculated by averaging the error rates of all five random partitions. For square, waveform, and segment, only one random partition is taken, where 70% of the square data set are used as training and the remaining 30% as testing, and 10% of both the waveform and segment datas are used as training and the remaining 90% as testing.

We compare paSB-MLR, paSB-robit with $\kappa = 6$, paSB-MSVM, and MSR with three other models, including L_2 regularized multinomial logistic regression (L_2-MLR), support vector machine (SVM), and adaptive multi-hyperplane machine (AMM). For paSB-robit, we run 8,000 iterations and discard the first 5,000 as burn-in (this setting is unchanged for experiments in Section 6.6). For paSB-MSVM, we use the spike-and-slab prior to select the kernel bases and set 0.5 as the probability of spike at 0, which is referred to as a uniform prior by Polson and Scott (2011). A Gaussian radial basis function (RBF) kernel is used and the kernel width is selected by 3-fold cross validation from $(2^{-10}, 2^{-9}, \ldots, 2^{10})$. We run 1000 MCMC iterations and discard the first 500 as burn-in samples. For MSR, we try both paSB and parSB with (K, T) set as $(1,1)$, $(1,3)$, $(5,1)$, or $(5,3)$. We run 10000 MCMC iterations and discard the first 5000 as burn-in samples. The predictive probability is calculated by averaging the Monte Carlo average predictive probabilities from paSB and

Table 4: Comparison of classification error rates (%) of paSB-MLR, paSB-robit, paSB-MSVM, MSRs with various K and T (results column 3 to 6), MSR with data transformation (DT-MSR), L_2-MLR, SVM, and AMM, using the collected MCMC sample with the highest log-likelihood. The number of active hyperplanes/support vectors used for out-of-sample predictions are shown in parenthesis.

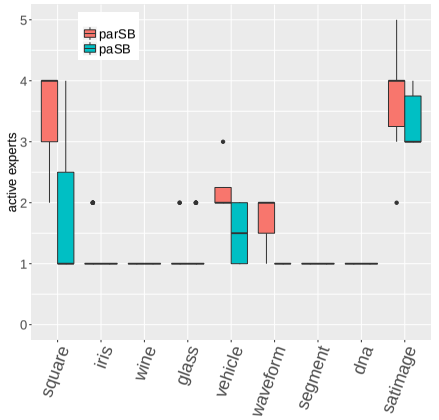

Figure 8: Boxplots of the number of active experts inferred by paSB/parSB MSRs with $K = 5$ and $T = 3$.

parSB MSRs. An observation in the testing set is classified to the category associated with the largest predictive probability.

For MSRs on benchmark data with data transformation, in the first step, we run paSB-MSR and parSB-MSR with $K = 5$ and $T = 3$ on the original covariates for 3,000 iterations to learn $\boldsymbol{z}$, $\{r_{jk}\}$, $\{\boldsymbol{\beta}_{jk}^{(t)}\}$. We then transform the covariates by Equation (6.4), where $\boldsymbol{\beta}_{jk}^{(t)}$ are associated with active experts. In the last step, we use $\boldsymbol{z}$ learned in the first step, and run paSB-MSR and parSB-MSR with $K = 5$ and $T = 1$ for 10,000 iterations and collect the last 5,000 samples to compute the predictive probabilities.

We use the L_2-MLR provided in the LIBLINEAR package (Fan et al., 2008) to train a linear classifier, where a bias term is included and the regularization parameter is five-

fold cross-validated on the training set from $(2^{-10}, 2^{-9}, \ldots, 2^{15})$. We run the LIBLINEAR package in R via `R` package `LiblineaR` (Helleputte, 2015). We also classify an observation to the category associated with the largest predictive probability. For SVM, we use the LIBSVM package (Chang and Lin, 2011) and run it in R with `R` package `e1071` (Meyer et al., 2015). A Gaussian RBF kernel is used and three-fold cross validation is adopted to tune both the regularization parameter and kernel width from $(2^{-10}, 2^{-9}, \ldots, 2^{10})$ on the training set. For paSB-MSVM, we use three-fold cross validation on the training set to select a kernel width from $(2^{-10}, 2^{-9}, \ldots, 2^{10})$. We choose the default LIBSVM settings for all the other parameters. We consider adaptive multi-hyperplane machine (AMM) of Wang et al. (2011b), as implemented in the BudgetSVM[1] (Version 1.1) software package (Djuric et al., 2013). We use the batch version of the algorithm. Important parameters of the AMM include both the regularization parameter ν and training epochs E. As also mentioned by Kantchelian et al. (2014), we do not observe the testing errors of AMM to strictly decrease as E increased. Thus, in addition to cross validating the regularization parameter ν on the training set from $\{10^{-7}, 10^{-6}, \ldots, 10^{-2}\}$, as done in Wang et al. (2011b), for each ν, we try $E \in \{5, 10, 20, 50, 100\}$ sequentially until the cross-validation error begins to decrease, *i.e.*, under the same ν, we choose $E = 20$ if the cross-validation error of $E = 50$ is greater than that of $E = 20$. We use the default settings for all the other parameters, and calculate average classification error rates.

We add an outlier to the vehicle data in Section 6.6 as follows. There are 18 covariates, whose values range from -1 to 1, in this data set. To simulate an outlier, since the MLR regression coefficients associated with the 4th, 5th, and 6th covariates all have large absolute values, we first draw three uniform random numbers from $(-3, -2) \cup (2, 3)$ and assign them to these three covariates, and then assign each of the 12 remaining covariates a uniform random number from $(-1, 1)$. Finally, we draw the category label y uniformly from $\{1, 2, 3, 4\}$.

Abstract

User engagement in online social networking depends critically on the level of *social activity* in the corresponding platform—the number of online *actions*, such as posts, shares or replies, taken by their users. Can we design data-driven algorithms to increase social activity? At a user level, such algorithms may increase activity by helping users decide when to take an action to be more likely to be *noticed* by their peers. At a network level, they may increase activity by *incentivizing* a few influential users to take more actions, which in turn will trigger additional actions by other users.

In this paper, we model social activity using the framework of marked temporal point processes, derive an alternate representation of these processes using stochastic differential equations (SDEs) with jumps and, exploiting this alternate representation, develop two efficient online algorithms with provable guarantees to steer social activity both at a user and at a network level. In doing so, we establish a previously unexplored connection between optimal control of jump SDEs and doubly stochastic marked temporal point processes, which is of independent interest. Finally, we experiment both with synthetic and real data gathered from Twitter and show that our algorithms consistently steer social activity more effectively than the state of the art.

Keywords: marked temporal point processes, stochastic optimal control, stochastic differential equations with jumps, social networks, information networks

. *Preliminary version of this work appeared in Zarezade et al. (2017).

1. Introduction

People perform a wide variety of online actions in a growing number of online social networking sites. In most cases, these online actions can be broadly categorized into *exogenous* actions, taken by users at their own initiative, and *endogenous* actions, taken by users as a *response* to previous actions by other users. For example, users often post small pieces of information at their own initiative, which can then trigger additional posts, shares or replies by other users. In this paper, our goal is designing online algorithms that, by steering exogenous actions, are able to increase the number of endogenous actions and thus the overall user activity.

We first address the above problem from the perspective of an individual user whose posts compete for *attention* with dozens, if not hundreds, of posts *simultaneously* shared by other users that her *followers* follow (Backstrom et al., 2011; Gomez-Rodriguez et al., 2014). In this context, recent empirical studies have shown that stories at the top of their followers' feed are more likely to be *noticed* and consequently liked, shared or replied to (Hodas and Lerman, 2012; Kang and Lerman, 2015; Lerman and Hogg, 2014). Therefore, we design an online algorithm, RedQueen, to help a user decide when-to-post to increase her chances to stay at the top, increasing her *visibility*. Then, we tackle the problem from the perspective of an entire online social networking site, where an endless stream of stories posted by its users are constantly eliciting a variable number of likes, shares or replies by other users (Goel et al., 2012; Farajtabar et al., 2014; Rizoiu et al., 2017). Here, we design another online algorithm, Cheshire, to find how much should we incentivize a small number of influential users to post more over time to increase the overall number of additional posts, shares or replies in the site.

More specifically, we represent users' actions using the framework of marked temporal point processes, which characterizes the continuous time interval between actions using conditional intensity functions (Aalen et al., 2008), and model endogenous and exogenous actions using multidimensional Hawkes processes (Hawkes, 1971). Then, we derive an alternate representation of these processes using stochastic differential equations (SDEs) with jumps and, exploiting this alternate representation, address the design of both algorithms from the perspective of optimal control for SDEs with jumps (Hanson, 2007). Our approach differs from previous literature in two key technical aspects, which are of independent interest:

I. The control signals are conditional (posting) intensities, which are used to sample stochastic events (*i.e.*, stories to post). In contrast, previous work considered the control signal to be a time-varying real vector. As a consequence, our approach requires another layer of stochasticity.

II. The (posting) intensities are stochastic Markov processes and thus the dynamics are doubly stochastic. This requires us to redefine the cost-to-go to incorporate the instantaneous value of these intensities as additional arguments. Previous work has typically considered constant intensities until very recently (Wang et al., 2016, 2017).

These technical aspects have implications beyond steering social activity since they enable us to establish a previously unexplored connection between optimal control of jump SDEs

and doubly stochastic temporal point processes (*e.g.*, Hawkes processes), which have been increasingly used to model social activity (Farajtabar et al., 2014, 2015b; Zhao et al., 2015).

In both cases, we find that the solution to the corresponding optimal control problem is surprisingly simple. At a user level, the optimal posting intensity for a user to achieve high visibility depends linearly on the position of her most recent post on each of her follower's feed and, at a network level, the optimal level of incentivized actions depends linearly on the current level of overall actions. Moreover, at a user level, the coefficients of the linear relationship only depend on tunable parameters, which are predefined, and, at a network level, the coefficients can be found by solving a matrix Riccati differential equation (Garrett, 2013) and a first order differential equation, which has a closed form solution. As a consequence, both RedQueen and Cheshire are simple and highly efficient online procedures, which can be implemented in a few lines of code (refer to Algorithms 1 and 3). Finally, we perform experiments on both synthetic and real-data gathered from Twitter and show that our algorithms can consistently steer social activity at a user and at a network level more effectively than the state of the art.

1.1 Related Work

Our work relates to previous work on the when-to-post problem, the activity shaping problem, stochastic optimal control, and temporal point processes.

The "when-to-post" problem was first studied by Spasojevic et al. (2015), who performed a large empirical study on the best times for a user to post in Twitter and Facebook, measuring attention a user elicits by means of the number of responses to her posts. Moreover, they designed several heuristics to pinpoint at the times that elicit the greatest attention in a training set and showed that these times also lead to more responses in a held-out set. Since then, algorithmic approaches to the "when-to-post" problem with provable guarantees have been largely lacking. Only very recently, Karimi et al. (2016) introduced a convex optimization framework to find optimal broadcasting strategies, measuring attention a user elicits as the time that at least one of her posts is among the k most recent stories received in her followers' feed. However, their algorithm requires expensive data pre-processing, it does not adapt to changes in the users' feeds dynamics, and in practice, it is less effective than our algorithm RedQueen, as shown in Section 5.

The "activity shaping" problem was first studied by Farajtabar et al. (2015a), who derived a time dependent linear relation between the *intensity* of exogenous actions and the overall intensity of actions in a social network under a model of actions based on multidimensional Hawkes processes and, exploiting this connection, developed a convex optimization framework for activity shaping. One of the main shortcomings of their framework is that it provides deterministic exogenous intensities that do not adapt to changes in the users' intensities and, as a consequence, it is less effective than our algorithm Cheshire, as shown in Section 5. More recently, Farajtabar et al. (2016) developed a heuristic method that splits the time window of interest into stages and adapts to changes in the users' intensities at the beginning of each stage. However, their method is suboptimal, it does not have *provable* guarantees, and it achieves lower performance than our method.

In the traditional control literature (Hanson, 2007), two key aspects of our approach—intensities as control signals and stochastic intensities—have been largely understudied.

Only very recently, Wang et al. (2016) and Wang et al. (2017) have considered these aspects. However, in Wang et al. (2016), the intensities are not stochastic and the resulting algorithm needs to know the future actions, hindering its applicability, and, in Wang et al. (2017), the solution is open-loop and the control policy depends on the expectation of the uncontrolled dynamics, which needs to be calculated approximately by a time consuming sampling process. In contrast, our framework consider double stochastic intensities, our solution is closed-loop, our control policies only depend on the current state of the dynamics, and the feedback coefficients only need to be calculated once off-line.

Temporal point processes have been increasingly used for representation and modeling in a wide range of applications in social and information systems, *e.g.*, information propagation (Gomez-Rodriguez et al., 2011; Du et al., 2013; Zhao et al., 2015), opinion dynamics (De et al., 2016), product competition (Valera and Gomez-Rodriguez, 2015; Zarezade et al., 2016b), spatiotemporal social activity (Jankowiak and Gomez-Rodriguez, 2017; Zarezade et al., 2016a), information reliability (Tabibian et al., 2017), or human learning (Mavroforakis et al., 2017). However, in such context, algorithms based on stochastic optimal control of temporal point processes have been lacking.

2. Preliminaries

In this section, we first revisit the framework of temporal point processes (Aalen et al., 2008) and then describe how to use such framework to represent actions and feeds (Karimi et al., 2016) as well as to model endogenous and exogenous actions in social networks (Farajtabar et al., 2014).

2.1 Temporal Point Processes

A univariate temporal point process is a stochastic process whose realization consists of a sequence of discrete events localized in time, $\mathcal{H} = \{t_i \in \mathbb{R}^+ \,|\, i \in \mathbb{N}^+, t_i < t_{i+1}\}$. It can also be represented as a counting process $N(t)$, which counts the number of events before time t, *i.e.*,

$$N(t) = \sum_{t_i \in \mathcal{H}} \mathbb{I}(t - t_i \geq 0),$$

where $\mathbb{I}(\cdot)$ is the indicator function. Then, we can characterize the counting process using the conditional intensity function $\lambda^*(t)$, which is the conditional probability of observing an event in an infinitesimal window $[t, t + dt)$ given the history of event times up to time t, $\mathcal{H}(t) = \{t_i \in \mathcal{H} \,|\, t_i < t\}$, *i.e.*,

$$\lambda^*(t)\, dt = \mathbb{P}\left\{\text{event in } [t, t + dt) \,|\, \mathcal{H}(t)\right\} = \mathbb{E}[dN(t) \,|\, \mathcal{H}(t)],$$

where $dN(t) := N(t+dt) - N(t) \in \{0, 1\}$, the sign * means that the intensity may depend on the history $\mathcal{H}(t)$. Moreover, given a function $f(t)$, it will be useful to define the convolution with respect to $dN(t)$ as

$$f(t) \star dN(t) := \int_0^t f(t - s) dN(s) = \sum_{t_i \in \mathcal{H}(t)} f(t - t_i).$$

One can readily extend the above definitions to multivariate (or multidimensional) temporal point processes, which have been recently used to represent many different types of event data produced in social networks, such as the times of tweets (Farajtabar et al., 2014), retweets (Zhao et al., 2015), or links (Farajtabar et al., 2015b). More specifically, a realization of an m-dimensional temporal point process, $\mathcal{H} = \{(t_i, u_i) \,|\, i \in \mathbb{N}^+, t_i \in \mathbb{R}_+, u_i \in [m], t_i < t_{i+1}\}$, consists of m sequences of discrete events localized in time, $\mathcal{H} = \cup_{u\in[m]}\mathcal{H}_u$, where $\mathcal{H}_u = \{(t_i, u_i) \in \mathcal{H} \,|\, u_i = u\}$. Equivalently, it can be represented by an m-dimensional counting process $\mathbf{N}(t)$, where $N_u(t)$ counts the number of events in the u-th sequence before time t, and this counting process can be characterized by m intensity functions, *i.e.*,

$$\boldsymbol{\lambda}^*(t)dt = \mathbb{E}[d\boldsymbol{N}(t)|\mathcal{H}(t)],$$

where $\mathcal{H}(t) = \{(t_i, u_i) \in \mathcal{H} \,|\, t_i < t\}$, $d\boldsymbol{N}(t) := (dN_u(t))_{u\in[m]} := (N_u(t + dt) - N_u(t))_{u\in[m]}$, and $\boldsymbol{\lambda}^*(t) := (\lambda_u^*(t))_{u\in[m]}$ denotes the associated intensities, which may depend on history $\mathcal{H}(t)$. Finally, given a function $f(t)$, one can define the convolution with respect to $d\boldsymbol{N}(t)$ as

$$f(t) \star d\boldsymbol{N}(t) := \int_0^t f(t-s)d\boldsymbol{N}(s) = \left(\sum_{t_i\in\mathcal{H}_u(t)} f(t-t_i)\right)_{u\in[m]}.$$

In the remainder of the paper, to simplify the notation, we drop the sign * from the intensities.

2.2 Representation of Actions and Feeds

Given a (directed) social network $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ with $|\mathcal{V}| = n$ users, we assume that each user i can take a variety of online actions, *e.g.*, posting, sharing or replying, and she will be exposed to the online actions taken by the users she *follows* through her feed. Here, we assume that user i follows user j if and only if $(i, j) \in \mathcal{E}$.

Then, we represent the times when users take online actions as a multidimensional counting process $\boldsymbol{N}(t)$, where the i-th dimension, $N_i(t)$, counts the number of actions taken by user i up to time t. Here, we denote the history of times of the actions taken by user i by time t as $\mathcal{H}_i(t)$, the entire history of times as $\mathcal{H}(t) = \cup_{i\in\mathcal{V}}\mathcal{H}_i(t)$, and characterize this multidimensional process using n intensity functions, *i.e.*, $\mathbb{E}[d\boldsymbol{N}(t)|\mathcal{H}(t)] = \boldsymbol{\lambda}(t)\, dt$.

Given the adjacency matrix $\boldsymbol{A} \in \{0, 1\}^{n\times n}$, where $\boldsymbol{A}_{ij} = 1$ indicates that user j follows user i, we can represent the times of the actions users are exposed to through their feeds as a sum of counting processes, $\boldsymbol{A}^T\boldsymbol{N}(t)$, and calculate the corresponding conditional intensities as $\boldsymbol{\gamma}(t) = \boldsymbol{A}^T\boldsymbol{\lambda}(t)$. Here, we denote the history of times of the actions user j is exposed to by time t as $\mathcal{F}_j(t) := \cup_{i\in\mathcal{N}(j)}\mathcal{H}_i(t)$, where $\mathcal{N}(j)$ is the set of users that j follows.

Finally, from the perspective of a user i, it is useful to define the multidimensional counting process $\boldsymbol{M}_{\setminus i}(t) = \boldsymbol{A}^T\boldsymbol{N}(t) - \boldsymbol{A}_i N_i(t)$, in which the j-th dimension, $M_{j\setminus i}(t)$, counts the number of actions taken by other users that user j follows up to time i, and $\boldsymbol{A}_i$ is the i-th row of the adjacency matrix $\boldsymbol{A}$. Moreover, for each dimension, the conditional intensity is given by $\gamma_{j\setminus i}(t) = \gamma_j(t) - \lambda_i(t)$ and the history is given by $\mathcal{F}_{j\setminus i}(t) := \mathcal{F}_j(t)\setminus\mathcal{H}_i(t)$. When there is no ambiguity, we will omit the subscript i and write $\boldsymbol{M}_{\setminus i}(t) = \boldsymbol{M}(t)$ and $\boldsymbol{\gamma}_{\setminus i}(t) = \boldsymbol{\gamma}(t)$.

2.3 Modeling Endogenous and Exogenous Actions

Following previous work (Farajtabar et al., 2014, 2015b; Zhao et al., 2015; De et al., 2016; Rizoiu et al., 2017), we model endogenous and exogenous actions using multidimensional Hawkes processes (Hawkes, 1971). More specifically, we proceed as follows.

From the perspective of an individual user i, we assume we observe the online actions her followers are exposed to through their feeds. Then, consider the following functional form for the intensities $\boldsymbol{\gamma}_{\setminus i}(t) = \boldsymbol{\gamma}(t)$ of the followers' feeds from Section 2.2:

$$\boldsymbol{\gamma}(t) = \boldsymbol{\gamma}_0(t) + \boldsymbol{D}\,\kappa_\omega(t) \star d\boldsymbol{M}(t) = \boldsymbol{\gamma}_0(t) + \boldsymbol{D}\int_0^t \kappa_\omega(t-s)\, d\boldsymbol{M}(s) \tag{1}$$

where $\boldsymbol{\gamma}_0(t)$ are time-varying functions that model exogenous actions, *i.e.*, actions users take at their own initiative, the second term, with $\boldsymbol{D} = \mathrm{diag}(\alpha_j), \alpha_j \geq 0$, models endogenous actions, *i.e.*, actions users take as *response* to previous actions (their own as well as the ones taken by others), and $\kappa_\omega(t) = e^{-\omega t}\,\mathbb{I}(t \geq 0)$ is an exponential kernel modeling the decay on influence over time[1].

From the perspective of an entire online social networking site, we assume we observe the online actions taken by all the users[2]. Thus, we consider the following functional form for the users' intensities $\boldsymbol{\lambda}(t)$ from Section 2.2:

$$\boldsymbol{\lambda}(t) = \boldsymbol{\lambda}_0(t) + \boldsymbol{B}\,\kappa_\omega(t) \star d\boldsymbol{N}(t) = \boldsymbol{\lambda}_0(t) + \boldsymbol{B}\int_0^t \kappa_\omega(t-s)\, d\boldsymbol{N}(s), \tag{2}$$

where $\boldsymbol{\lambda}_0(t) \geq 0$ are time-varying functions that model exogenous actions and the second term models endogenous actions—actions users take as response to the actions taken by the users they follow. Here, we parameterize the strength of *influence* between users using a sparse nonnegative *influence matrix* $\boldsymbol{B} = (\beta_{uv}) \in \mathbb{R}_+^{m\times m}$, where β_{uv} means user u's actions directly triggers *follow-ups* from user v and we assume $\beta_{uv} = 0$ if $(u, v) \notin \mathcal{E}$.

In both cases, the second term makes the intensity dependent on the history and a stochastic process itself. Moreover, the following alternative representation of multidimensional Hawkes processes will be useful to design our stochastic optimal control algorithms (proven in Appendix A):

Proposition 1 *Let $\boldsymbol{N}(t)$ be an m-dimensional Hawkes process with an associated intensity $\boldsymbol{\lambda}(t) = \boldsymbol{\lambda}_0(t) + \boldsymbol{C}\int_0^t \kappa_\omega(t-s)\, d\boldsymbol{N}(s)$, where $\lambda_0(t) \geq 0$ is a differentiable time-varying function, $\kappa_\omega(t) = e^{-\omega t}\,\mathbb{I}(t \geq 0)$ is an exponential triggering kernel, and $\omega \geq 0$ and $\boldsymbol{C} \in \mathbb{R}_+^{m\times m}$ are given parameters. Then, the tuple $(\boldsymbol{N}(t), \boldsymbol{\lambda}(t))$ is a doubly stochastic Markov process, whose dynamics can be defined by the following jump SDEs:*

$$d\boldsymbol{\lambda}(t) = \left[\boldsymbol{\lambda}_0'(t) + \omega\boldsymbol{\lambda}_0(t) - \omega\boldsymbol{\lambda}(t)\right] dt + \boldsymbol{C}\, d\boldsymbol{N}(t), \tag{3}$$

1. Exponential kernels have been shown to provide relatively good predictive performance (Farajtabar et al., 2014, 2015b; Zhao et al., 2015; De et al., 2016; Rizoiu et al., 2017), however, we acknowledge that power-law may have higher predictive performance in some scenarios, as recently shown by Mishra et al. (2016). Here, we opt for exponential kernels since, in such case, the dynamics of the corresponding intensity can be expressed by a linear SDE with jumps and this will be helpful in the derivation of our stochastic optimal control algorithms.
2. We acknowledge that there may be scenarios in which one only has access to a subset of the online actions taken by the users. However, in those cases, one could resort to an increasing number of methods to fit multidimensional Hawkes processes from incomplete observations, *e.g.*, refer to Xu et al. (2017)

with the initial condition $\boldsymbol{\lambda}(0) = \boldsymbol{\lambda}_0(0)$.

Remark. From the perspective of an individual user, we assume the user has a local view, *i.e.*, she only observes the online actions her followers are exposed to through their feeds. Alternatively, if the user would have a global view, one could naturally opt for the following functional form for the intensities $\boldsymbol{\gamma}(t)$ of the followers' feeds:

$$\boldsymbol{\gamma}(t) = \boldsymbol{A}^T \boldsymbol{\lambda}(t) = \boldsymbol{A}^T \boldsymbol{\lambda}_0(t) + \boldsymbol{A}^T \boldsymbol{B} \int_0^t \kappa_\omega(t-s)\, d\boldsymbol{N}(s). \tag{4}$$

However, for simplicity, from the perspective of an individual user, we will assume the user has a local view and thus consider the functional form defined by Eq. 1. Considering an individual user has a global view is an interesting, albeit challenging venue for future work.

3. A Local Problem: When-to-post

In this section, we take the perspective of an individual user and design an online algorithm to help her decide when-to-post to be *noticed*—achieve high *visibility*. To this aim, we first define our visibility measure and then derive a jump stochastic differential equation that links our measure to the user's posting intensity and the feeds' intensities due to other users her followers follow. Finally, we formally state the when-to-post problem for this visibility measure and address the problem from the perspective of stochastic optimal control of SDEs with jumps. For ease of exposition, we assume users can only take one type of exogenous and endogenous action—posting stories. Moreover, throughout the section, we refer to users who posts stories as *broadcasters*.

3.1 Visibility Definition and Dynamics

Given a broadcaster i and one of her followers j, we define the visibility function $r_{ij}(t)$ as the position or *rank* of the most recent story posted by i in j's feed by time t, which clearly depends on the feed ranking mechanism in the corresponding social network. Here, for simplicity, we assume each user's feed ranks stories in reverse chronological order[3]. However, our framework can be easily extended to any feed ranking mechanisms, as long as its rank dynamics can be expressed as a jump SDE[4].

Under the reverse chronological ordering assumption, position at time t is simply the number of stories that other broadcasters posted in j's feed from the time of the most recent story posted by i until t. Then, when a new story arrives to a user's feed, it appears at the top of the feed and the other stories are shifted down by one. If we denote the time of the most recent story posted by i by time t as $\tau_i(t) = \max\{t_k \in \mathcal{H}_i(t)\}$, then the visibility is formally defined as

$$r_{ij}(t) = M_{j\setminus i}(t) - M_{j\setminus i}(\tau_i(t)). \tag{5}$$

Note that, if the last story posted by i is at the top of j's feed at time t, then $r_{ij}(t) = 0$.

3. At the time of writing, Weibo rank stories in reverse chronological order by default and Twitter and Facebook allow choosing such an ordering.
4. This would require either having access to the corresponding feed ranking mechanism or reverse engineering it, which is out of the scope of this work.

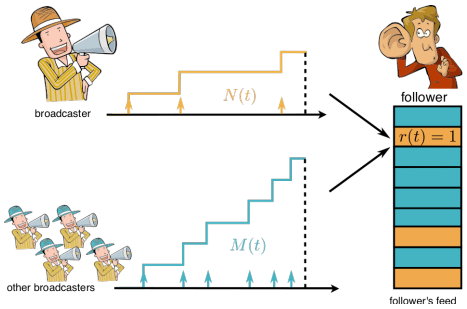

Figure 1: The dynamics of visibility. A broadcaster i posts $N_i(t) = N(t)$ stories with intensity $\lambda_i(t) = u(t)$. Her stories accumulate in her follower j's feed, competing for attention with $M_{j\setminus i}(t) = M(t)$ other stories posted by other broadcasters user j follows with intensity $\gamma_{j\setminus i}(t) = \gamma(t)$. The visibility function $r_{ij}(t) = r(t)$ is the position or rank of the most recent story posted by broadcaster i in the follower j's feed by time t.

Dynamics of visibility. Given a broadcaster i with broadcasting counting process $N_i(t)$ and one of her followers j with feed counting process due to other broadcasters $M_{j\setminus i}(t)$, the rank of i in j's feed $r_{ij}(t)$ satisfies the following equation:

$$r_{ij}(t+dt) = \underbrace{(r_{ij}(t)+1)dM_{j\setminus i}(t)(1-dN_i(t))}_{\text{1. Increases by one}} + \underbrace{0}_{\text{2. Becomes zero}} + \underbrace{r_{ij}(t)(1-dM_{j\setminus i}(t))(1-dN_i(t))}_{\text{3. Remains the same}},$$

where each term models one of the three possible situations:

1. The other broadcasters post a story in $(t, t+dt]$, $dM_{j\setminus i}(t) = 1$, and broadcaster i does not post, $dN_i(t) = 0$. The position of the last story posted by i in j's feed steps down by one, *i.e.*, $r_{ij}(t+dt) = r_{ij}(t) + 1$.
2. Broadcaster i posts a story in $(t, t+dt]$, $dN_i(t) = 1$, and the other broadcasters do not, $dM_{j\setminus i}(t) = 0$. No matter what the previous rank was, the new rank is $r_{ij}(t+dt) = 0$ since the newly posted story appears at the top of j's feed.
3. No one posts any story in $(t, t+dt]$, $dN_i(t) = 0$ and $dM_{j\setminus i}(t) = 0$. The rank remains the same, *i.e.*, $r_{ij}(t+dt) = r_{ij}(t)$.

We skip the case in which $M_{j\setminus i}(t) = 1$ and $dN_i(t) = 1$ in the same time interval $(t, t+dt]$ because, by the Blumenthal zero-one law (Blumenthal, 1957), it has zero probability. Now, by rearranging terms and using that $dN_i(t)dM_{j\setminus i}(t) = 0$, we uncover the following jump SDE for the visibility (or rank) dynamics:

$$dr_{ij}(t) = -r_{ij}(t)\, dN_i(t) + dM_{j\setminus i}(t), \tag{6}$$

where $dr_{ij}(t) = r_{ij}(t+dt) - r_{ij}(t)$. Figure 1 illustrates the concept of visibility for one broadcaster and one follower.

3.2 Problem Formulation

Given a broadcaster i and her followers $\mathcal{N}(i)$, our goal is to find the optimal posting intensity $\lambda_i(t) = u(t)$ that minimizes the expected value of a particular nondecreasing convex loss

function $\ell(\boldsymbol{r}(t), u(t))$ of the broadcaster's visibility on each of her follower's feed, $\boldsymbol{r}(t) = [r_{ij}(t)]_{j \in \mathcal{N}(i)}$, and the intensity itself, $u(t)$, over a time window $(t_0, t_f]$, *i.e.*,

$$\begin{aligned} \underset{u(t_0,t_f]}{\text{minimize}} \quad & \mathbb{E}_{(N_i, \boldsymbol{M}_{\setminus i})(t_0,t_f]} \left[\phi(\boldsymbol{r}(t_f)) + \int_{t_0}^{t_f} \ell(\boldsymbol{r}(s), u(s)) ds \right] \\ \text{subject to} \quad & u(t) \geq 0 \quad \forall t \in (t_0, t_f], \end{aligned} \tag{7}$$

where $u(t_0, t_f]$ denotes the broadcaster i's intensity from t_0 to t_f, the expectation is taken over all possible realizations of the counting processes associated to the broadcaster i and all other broadcasters from t_0 to t_f, denoted as $(N_i, \boldsymbol{M}_{\setminus i})(t_0, t_f]$, and $\phi(\boldsymbol{r}(t_f))$ is an arbitrary penalty function[5]. Here, by considering a loss which is nondecreasing in the rank $r(t)$ and the posting intensity $u(t)$, we penalize times when the position of the most recent story on each of the follower's feeds is high (*i.e.*, the most recent story does not stay *at the top*) and we limit the posting intensity, which in turn limits the number of stories the broadcaster can post. Finally, note that the optimal intensity $u(t)$ for broadcaster i at time t may depend on the visibility $\boldsymbol{r}(t)$ with respect to each of her followers and, thus, the associated counting process $N_i(t)$ may be doubly stochastic.

3.3 Stochastic Optimal Control Algorithm

In this section, we tackle the when-to-post problem defined by Eq. 7 from the perspective of stochastic optimal control of jump SDEs (Hanson, 2007). More specifically, we first derive a solution to the problem considering only one follower, provide an efficient practical implementation of the solution and then generalize it to the case of multiple followers. We conclude this section by deriving a solution to the problem given an (idealized) oracle that knows the times of all stories in the followers' feeds *a priori*, which we will use as baseline in our experiments (refer to Section 5.1).

Optimizing for one follower. Given a broadcaster i with $N_i(t) = N(t)$ and $\lambda_i(t) = u(t)$ and only one of her followers j with $M_{j \setminus i}(t) = M(t)$ and $\gamma_{j \setminus i}(t) = \gamma(t)$, we can rewrite the when-to-post problem defined by Eq. 7 as

$$\begin{aligned} \underset{u(t_0,t_f]}{\text{minimize}} \quad & \mathbb{E}_{(N,M)(t_0,t_f]} \left[\phi(r(t_f)) + \int_{t_0}^{t_f} \ell(r(s), u(s))\, ds \right] \\ \text{subject to} \quad & u(t) \geq 0 \quad \forall t \in (t_0, t_f], \end{aligned} \tag{8}$$

where, using Eqs. 1, 3 and 6, the dynamics of $M(t)$ and $r(t)$ are given by the following two coupled jump SDEs:

$$\begin{aligned} d\gamma(t) &= \left[\gamma_0'(t) + \omega\gamma_0(t) - \omega\gamma(t)\right] dt + \alpha\, dM(t), \\ dr(t) &= -r(t)\, dN(t) + dM(t), \end{aligned} \tag{9}$$

with initial conditions $r(t_0) = r_0$ and $\gamma(t_0) = \gamma_0$, and the dynamics of $N(t)$ are given by the intensity $u(t)$ that we aim to optimize.

5. The final penalty function $\phi(\boldsymbol{r}(t_f))$ is necessary to derive the optimal intensity $u^*(t)$ in Section 3.3. However, the actual optimal intensity $u^*(t)$ will not depend on the particular choice of terminal condition.

Next, we will define a novel optimal cost-to-go function that accounts for the above unique aspects of our problem, showing that the Bellman's principle of optimality still follows, and finally find the optimal solution using the corresponding Hamilton-Jacobi-Bellman (HJB) equation.

Definition 2 *The optimal cost-to-go $J(r(t), \gamma(t), t)$ is defined as the minimum of the expected value of the cost of going from state $r(t)$ with intensity $\gamma(t)$ at time t to a final state at time t_f,* i.e.*,*

$$J(r(t), \gamma(t), t) = \min_{u(t,t_f]} \mathbb{E}_{(N,M)(t,t_f]} \left[\phi(r(t_f)) + \int_t^{t_f} \ell(r(s), u(s))\, ds \right], \tag{10}$$

where the expectation is taken over all trajectories of the control and noise jump process, N and M, in the $(t, t_f]$ interval, given the initial values of $r(t)$, $\gamma(t)$ and $u(t)$.

To find the optimal control $u(t, t_f]$ and cost-to-go J, we break the problem into smaller subproblems, using the Bellman's principle of optimality (Bertsekas, 1995), which the above definition allows (proven in Appendix B):

Lemma 3 (Bellman's Principle of Optimality) *The optimal cost satisfies the following recursive equation:*

$$J(r(t), \gamma(t), t) = \min_{u(t,t+dt]} \left\{ \mathbb{E}\left[J(r(t+dt), \gamma(t+dt), t+dt) \right] + \ell(r(t), u(t))\, dt \right\}, \tag{11}$$

where the expectation is taken over all trajectories of the control and noise jump processes, N and M, in $(t, t+dt]$. Then, we use the Bellman's principle of optimality to derive a partial differential equation on J, often called the Hamilton-Jacobi-Bellman (HJB) equation (Hanson, 2007). To do so, we first assume J is continuous and then rewrite Eq. 11 as

$$\begin{aligned} J(r(t), \gamma(t), t) &= \min_{u(t,t+dt]} \left\{ \mathbb{E}\left[J(r(t), \gamma(t), t) + dJ(r(t), \gamma(t), t) \right] + \ell(r(t), u(t))\, dt \right\} \\ 0 &= \min_{u(t,t+dt]} \left\{ \mathbb{E}\left[dJ(r(t), \gamma(t), t) \right] + \ell(r(t), u(t))\, dt \right\}, \end{aligned} \tag{12}$$

where $dJ(r(t), \gamma(t), t) = J(r(t+dt), \gamma(t+dt), t+dt) - J(r(t), \gamma(t), t)$. Then, we differentiate J with respect to time t, $r(t)$ and $\gamma(t)$ using to following Lemma (proven in the Appendix C):

Lemma 4 *The differential $dJ(r(t), \gamma(t), t)$ of the cost-to-go function $J(r(t), \gamma(t), t)$, as defined by Eq. 10, is given by*

$$\begin{aligned} dJ(r(t), \gamma(t), t) = {} & J_t(r(t), \gamma(t), t) dt + \left[\gamma_0'(t) + \omega\gamma_0(t) - \omega\gamma(t)\right] J_\gamma(r(t), \gamma(t), t) dt \\ & + \left[J(0, \gamma(t), t) - J(r(t), \gamma(t), t) \right] dN(t) \\ & + \left[J(r(t) + 1, \gamma(t) + \alpha, t) - J(r(t), \gamma(t), t) \right] dM(t), \end{aligned}$$

where J_t and J_γ are derivatives of J with respect to t and γ, respectively.

Algorithm 1: RedQueen for fixed s, q and one follower.

Input: parameters q and s ;
Output: Returns time for the next post ;
$t \leftarrow \infty$; $\tau \leftarrow othersNextPost(\,)$;
while $\tau < t$ **do**
  $\Delta \sim Sample(\sqrt{s/q})$;
  $t \leftarrow \min(t,\, \tau + \Delta)$;
  $\tau \leftarrow othersNextPost(\,)$;
return t;

Next, if we plug in the above equation in Eq. 12, it follows that

$$\begin{aligned} 0 = \min_{u(t,t+dt]} \Big\{ & J_t(r(t),\gamma(t),t)dt + \left[\gamma_0'(t) + \omega\gamma_0(t) - \omega\gamma(t)\right] J_\gamma(r(t),\gamma(t),t)dt \\ & + [J(0,\gamma(t),t) - J(r(t),\gamma(t),t)]\mathbb{E}[dN(t)] \\ & + [J(r(t)+1,\gamma(t)+\alpha,t) - J(r(t),\gamma(t),t)]\mathbb{E}[dM(t)] + \ell(r(t),u(t))\,dt \Big\}. \end{aligned}$$

Now, using $\mathbb{E}[dN(t)] = u(t)dt$ and $\mathbb{E}[dM(t)] = \gamma(t)dt$, and rearranging terms, the HJB equation follows:

$$\begin{aligned} 0 = {} & J_t(r(t),\gamma(t),t) + \left[\gamma_0'(t) + \omega\gamma_0(t) - \omega\gamma(t)\right] J_\gamma(r(t),\gamma(t),t) \\ & + [J(r(t)+1,\gamma(t)+\alpha,t) - J(r(t),\gamma(t),t)]\gamma(t) \\ & + \min_{u(t,t+dt]} \ell(r(t),u(t)) + [J(0,\gamma(t),t) - J(r(t),\gamma(t),t)]u(t). \end{aligned} \tag{13}$$

To be able to continue further, we need to define the loss ℓ and the penalty ϕ. Following the literature on stochastic optimal control (Hanson, 2007), we consider the following quadratic forms, which will turn out to be a tractable choice[6]:

$$\phi(r(t_f)) = \frac{1}{2} r^2(t_f) \quad \text{and} \quad \ell(r(t),u(t)) = \frac{1}{2} s(t)\, r^2(t) + \frac{1}{2} q\, u^2(t),$$

where $s(t)$ is a time significance function $s(t) \geq 0$, which favors some periods of times (*e.g.*, times in which the follower is online[7]), and q is a given parameter, which trade-offs visibility and number of broadcasted posts.

Under these definitions, we take the derivative with respect to $u(t)$ of Eq. 13 and uncover the relationship between the optimal intensity and the optimal cost:

$$u^*(t) = q^{-1}\left[J(r(t),\gamma(t),t) - J(0,\gamma(t),t)\right]. \tag{14}$$

Finally, we substitute the above expression in Eq. 13 and find that the optimal cost J needs to satisfy the following nonlinear differential equation:

$$\begin{aligned} 0 = {} & J_t(r(t),\gamma(t),t) + \frac{1}{2} s(t)\, r^2(t) - \frac{1}{2} q^{-1}\left[J(r(t),\gamma(t),t) - J(0,\gamma(t),t)\right]^2 \\ & + \left[\gamma_0'(t) + \omega\gamma_0(t) - \omega\gamma(t)\right] J_\gamma(r(t),\gamma(t),t) + [J(r(t)+1,\gamma(t)+\alpha,t) - J(r(t),\gamma(t),t)]\gamma(t) \end{aligned} \tag{15}$$

6. Considering other losses with a specific semantic meaning (*e.g.*, $\mathbb{I}(r(t) \leq k)$) is a challenging direction for future work.
7. Such information may be hidden but one can use the followers' posting activity or geographic location as a proxy (Karimi et al., 2016).

with $J(r(t_f),\gamma(t_f),t_f) = \phi(r(t_f))$ as the terminal condition. The following technical lemma provides us with a solution to the above equation (proven in Appendix D):

Lemma 5 *In the space of m-degree polynomials, the following polynomial is the only solution to Eq. 15:*

$$J(r(t),\gamma(t),t) = f(t) + \sqrt{s(t)q}\, r(t) + \sum_{j=1}^{m} g_j(t)\gamma^j(t),$$

where $f(t)$ and $g_j(t)$ are time-varying functions which can be found by solving a linear system of differential equations.

Given the above Lemma and Eq. 14, the optimal intensity is readily given by following theorem:

Theorem 6 *The optimal intensity for the when-to-post problem defined by Eq. 8 with quadratic loss and penalty function is given by $u^*(t) = \sqrt{s(t)/q}\, r(t)$.*

The optimal intensity only depends on the position of the most recent post by broadcaster i in her follower's feed and, thus, allows for a very efficient procedure to sample posting times, which exploits the superposition theorem (Kingman, 1992). The key idea is as follows: at any given time t, we can view the process defined by the optimal intensity as a superposition of $r(t)$ inhomogeneous Poisson processes with intensity $\sqrt{s(t)/q}\, r(t)$ which starts at jumps of the rank $r(t)$, and find the next sample by computing the minimum across all samples from these processes. Algorithm 1 summarizes our (sampling) method, which we name RedQueen (Carroll, 1917). Within the algorithm, $Sample(\sqrt{s/q})$ samples from a Poisson process with intensity $\sqrt{s/q}$ and $othersNextPost(\,)$ returns the time of the next event by other broadcasters in the followers' feeds, once the event happens. In practice, we only need to know if the event happens before we post. Remarkably, it only needs to sample $M(t_f)$ times from a (in)homogeneous Poisson process (if significance is time varying) and requires $O(1)$ space.

Optimizing for multiple followers. Given a broadcaster i with $N_i(t) = N(t)$ and $\lambda_i(t) = u(t)$ and her followers $\mathcal{N}(i)$ with $\boldsymbol{M}_{\setminus i}(t) = \boldsymbol{M}(t)$ and $\boldsymbol{\gamma}_{\setminus i}(t) = \boldsymbol{\gamma}(t)$, we can write the dynamics of $\boldsymbol{M}(t)$ and $\boldsymbol{r}(t)$, which we need to solve Eq. 7, using Eqs. 1, 3 and 6:

$$\begin{aligned} d\boldsymbol{\gamma}(t) &= \left[\boldsymbol{\gamma}_0'(t) + w\boldsymbol{\gamma}_0(t) - w\boldsymbol{\gamma}(t)\right] dt + \boldsymbol{D}\, d\boldsymbol{M}(t) \\ d\boldsymbol{r}(t) &= -\boldsymbol{r}(t)\, dN(t) + d\boldsymbol{M}(t). \end{aligned}$$

Then, consider the following quadratic forms for the loss ℓ and the penalty ϕ:

$$\begin{aligned} \phi(\boldsymbol{r}(t_f)) &= \sum_{i=1}^{n} \frac{1}{2} r_i^2(t_f) \\ \ell(\boldsymbol{r}(t),u(t),t) &= \sum_{i=1}^{n} \frac{1}{2} s_i(t) r_i^2(t) + \frac{1}{2} q\, u^2(t). \end{aligned}$$

Algorithm 2: Optimal posting times with an oracle.

Input: Initial state r_0, interval widths $w_1, \ldots, w_{m+1}$, parameter q and significance $s(t) = s$;
Output: Overall cost $J(r_0, 0)$, optimal control $u_0^*, \ldots, u_m^*$;
for $r \leftarrow r_0 + m$ **to** 0 **do**
  $J(r, m+1) \leftarrow \frac{1}{2} r^2$;
for $k \leftarrow m$ **to** 0 **do**
  for $r \leftarrow r_0 + k - 1$ **to** 0 **do**
    $J(r,k) = \min\{\frac{1}{2}q + J(0, k+1),\ \frac{1}{2} s w_{k+1} (r+1)^2 + J(r+1, k+1)\}$;
for $k \leftarrow 0$ **to** m **do**
  if $\frac{1}{2}q + J(0, k+1) < \frac{1}{2} s w_{k+1} (r_k + 1)^2 + J(r_k + 1, k+1)$ **then**
    $u_k^* \leftarrow 1$; $r_{k+1} \leftarrow 0$;
  else
    $u_k^* \leftarrow 0$; $r_{k+1} \leftarrow r_k + 1$;
return $J(r_0, 0)$, $u_0^*, \ldots, u_m^*$

where $s_i(t)$ is the time significance function for follower i, as defined above, and q is a given parameter. Proceeding similarly as in the case of one follower, we can show that:

$$u^*(t) = \sum_{i=1}^{n} \sqrt{s_i(t)/q}\, r_i(t), \tag{16}$$

which only depends on the position of the most recent post by broadcaster i in her followers' feeds. Finally, we can readily adapt RedQueen (Algorithm 1) to efficiently sample the posting times using the above intensity—it only needs to sample $|\cup_{j \in \mathcal{N}(i)} \mathcal{F}_{j \setminus i}(t_f)|$ values from an (in)homogeneous Poisson process (if significance is time varying) and requires $O(|\mathcal{N}(i)|)$ space.

Optimizing with an oracle. In this section, we consider a broadcaster i with $N_i(t) = N(t)$ and $\lambda_i(t) = u(t)$, only one of her followers j with $M_{j \setminus i}(t) = M(t)$, and a constant significance $s(t) = s$. The derivation can be easily adapted to the case of multiple followers and time-varying significance.

Suppose there is an (idealized) oracle that reveals $M(t)$ from t_0 to t_f, *i.e.*, the history $\mathcal{F}_{j \setminus i}(t_f) = \mathcal{F}(t_f)$ is given, and $M(t_f) = |\mathcal{F}(t_f)| = m$. Then, we can rewrite Eq. 7 as

$$\begin{aligned} \underset{u(t_0, t_f]}{\text{minimize}} \quad & \mathbb{E}_{N(t_0,t_f]} \left[\phi(r(t_f)) + \int_{t_0}^{t_f} \ell(r(s), u(s))\, ds \right] \\ \text{subject to} \quad & u(t) \geq 0 \quad \forall t \in (t_0, t_f], \end{aligned}$$

where the expectation is only taken over all possible realizations of the counting process $N(t_0, t_f]$ since $M(t_0, t_f]$ is revealed by the oracle and, thus, deterministic.

Similar to the previous sections, assume the loss ℓ and penalty ϕ are quadratic. The best times for user i to post will always coincide with one of the times in $\mathcal{F}(t_f)$ since, given a posting time $\tau_i \in (t_k, t_{k+1})$, where $t_k, t_{k+1} \in \mathcal{F}(t_f)$, one can reduce the cost by $(1/2)q(\tau_i - t_k) r^2(t_k)$ by choosing instead to post at t_k. As a consequence, we can discretize the dynamics of $r(t)$ in times $\mathcal{F}(t_f)$, and write $r_{k+1} = r_k + 1 - (r_k + 1)u_k$, where $r_k = r(t_k^-)$,

$u_k = u(t_k^+) \in \{0, 1\}$, $t_k \in \mathcal{F}(t_f)$. We can easily see that r_k is bounded by $0 \leq r_k < r_0 + m$. Similarly, we can derive the optimal cost-to-go in discrete-time as

$$J(r_k, k) = \min_{u_k, \ldots, u_m} \frac{1}{2} r_{m+1}^2 + \sum_{i=k}^{m} \frac{1}{2} q\, w_{i+1}\, r_{i+1}^2 + \frac{1}{2} s\, u_i^2,$$

where $w_i = t_i - t_{i-1}$. Next, we can break the minimization and use Bellman's principle of optimality,

$$J(r_k, k) = \min_{u_k} \frac{1}{2} q\, w_{k+1}\, r_{k+1}^2 + \frac{1}{2} s\, u_k^2 + J(r_{k+1}, k+1),$$

and, since $u_k \in \{0, 1\}$, the above recursive equation can be written as

$$J(r_k, k) = \min \left\{ \frac{1}{2} s + J(0, k+1),\ \frac{1}{2} q\, w_{k+1} (r_k + 1)^2 + J(r_k + 1, k+1) \right\}.$$

Finally, we can find the optimal control u_k^*, $k = 0, \ldots, m$ and cost $J(r_0, 0)$ by backtracking from the terminal condition $J(r_{m+1}, m+1) = r_{m+1}^2/2$ to the initial state r_0, as summarized in Algorithm 2, which can be adapted to multiple followers. Note that, in this case, the optimal strategy is not stochastic and consists of a set of optimal posting times, as one could have guessed. However, for multiple followers, the complexity of the algorithm is $O(m^2)$, where $m = |\cup_{j \in \mathcal{N}(i)} \mathcal{F}_{j \setminus i}(t_f)|$.

4. A Global Problem: Activity Maximization

In this section, we take the perspective of an entire online social networking site and design an online algorithm to find how much should we incentivize a small number of influential users to post more over time to increase the overall number of additional posts, shares or replies in the site. To this aim, we first describe how to formally model such incentive mechanism in social networks. Then, we state the activity shaping problem and address the problem from the perspective of stochastic optimal control of SDEs with jumps, similarly as in Section 3.

4.1 Triggering Additional Endogenous Actions

Given a social network $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ with $|\mathcal{V}| = n$ users, we trigger additional endogenous user actions by directly incentivizing (*e.g.*, paying) for $\boldsymbol{P}(t)$ actions, where $P_i(t)$ counts the number of directly incentivized actions taken by user $i \in \mathcal{V}$ before time t and we can characterize $\boldsymbol{P}(t)$ by means of n intensity functions $\boldsymbol{u}(t)$, *i.e.*, $\mathbb{E}[d\boldsymbol{P}(t)] = \boldsymbol{u}(t)dt$. Then, if we assume the strength of influence $\boldsymbol{B}$ between users is the same both for organic and incentivized actions[8], as previous work (Farajtabar et al., 2014, 2016), we can rewrite the

8. This assumption seems reasonable in some scenarios, *e.g.*, it is often difficult to notice whether an influential user is being paid for posting a message. However, one could relax this assumption by considering a different influence matrix $C \neq B$ for the additional endogenous actions in Eq. 17, change the SDE, Eq. 18 and HJB, Eq. 22 accordingly, and derived the new optimal control in Theorem 11.

users' intensities $\boldsymbol{\lambda}(t)$, given by Eq. 2, as

$$\boldsymbol{\lambda}(t) = \boldsymbol{\lambda}_0(t) + \boldsymbol{B}\int_0^t \kappa_\omega(t-s)\, d\boldsymbol{N}(s) + \underbrace{\boldsymbol{B}\int_0^t \kappa_\omega(t-s)\, d\boldsymbol{P}(s)}_{\text{Additional endogenous actions}}. \tag{17}$$

Here, note that treating directly incentivized actions as a different counting process $\boldsymbol{P}(t)$ prevents the intensities $\boldsymbol{\lambda}(t)$ from including their intensity but instead including only the intensity of their follow-ups (*i.e.*, additional endogenous actions), which we aim to maximize. Then, it is easy to derive the following alternative representation, similarly as in Proposition 1, which we will use in our stochastic optimal control algorithm:

Proposition 7 *Let $\boldsymbol{N}(t)$ and $\boldsymbol{P}(t)$ be two multidimensional counting processes with associated intensities $\boldsymbol{\lambda}(t)$, given by Eq. 17, and $\boldsymbol{u}(t)$, respectively. Then, the dynamics of the intensity $\boldsymbol{\lambda}(t)$ can be expressed using the following jump SDEs:*

$$d\boldsymbol{\lambda}(t) = \left[\boldsymbol{\lambda}_0'(t) + \omega\boldsymbol{\lambda}_0(t) - \omega\boldsymbol{\lambda}(t)\right] dt + \boldsymbol{B}\, d\boldsymbol{N}(t) + \boldsymbol{B}\, d\boldsymbol{P}(t) \tag{18}$$

with the initial condition $\boldsymbol{\lambda}(0) = \boldsymbol{\lambda}_0(0)$.

In the remainder of the section, for ease of exposition, we assume $\boldsymbol{\lambda}_0(t) = \boldsymbol{\lambda}_0$ and thus $\boldsymbol{\lambda}_0'(t) = 0$.

4.2 Problem Formulation

Given a social network $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ with $|\mathcal{V}| = n$ users, our goal is to find the optimal users' intensities for directly incentivized actions $\boldsymbol{u}(t)$ (for short, control intensities) that minimize the expected value of a particular loss function $\ell(\boldsymbol{u}(t), \boldsymbol{\lambda}(t))$ of the control intensities and the users' intensities for not directly incentivized actions over a time window $(t_0, t_f]$, *i.e.*,

$$\begin{aligned} &\underset{\boldsymbol{u}(t_0,t_f]}{\text{minimize}} \quad \mathbb{E}_{(\boldsymbol{N},\boldsymbol{P})(t_0,t_f]}\left[\phi(\boldsymbol{\lambda}(t_f)) + \int_{t_0}^{t_f} \ell(\boldsymbol{\lambda}(s), \boldsymbol{u}(s))\, ds\right] \\ &\text{subject to} \quad u_i(t) \geq 0,\ \forall t \in (t_0, t_f],\ i = 1, \ldots, n \end{aligned} \tag{19}$$

where $\boldsymbol{u}(t_0, t_f]$ denotes the control intensities from t_0 to t_f, the dynamics of $\boldsymbol{N}(t)$ are given by Eq. 18, and the expectation is taken over all possible realizations of the two counting processes $\boldsymbol{N}(t)$ and $\boldsymbol{P}(t)$ during interval $(t_0, t_f]$. Here, by considering a loss that is nonincreasing (nondecreasing) with respect to the intensities $\boldsymbol{\lambda}(t)$ ($\boldsymbol{u}(t)$), we will trade-off number of directly incentivized actions and number of additional endogenous actions. Finally, note that the optimal intensities $\boldsymbol{u}(t)$ at time t may depend on the intensities $\boldsymbol{\lambda}(t)$ and thus the associated counting process $\boldsymbol{P}(t)$ may be doubly stochastic.

4.3 Stochastic Optimal Control Algorithm

In this section, we proceed similarly as in Section 3.3 and tackle the activity maximization problem defined by Eq. 19 from the perspective of stochastic optimal control of SDEs with jumps (Hanson, 2007). More specifically, we first define a novel optimal cost-to-go function specially designed for this global problem and then derive and solve the corresponding HJB equation to find the optimal control intensities.

Definition 8 *The optimal cost-to-go $J(\boldsymbol{\lambda}(t), t)$ is defined as the minimum of the expected value of the cost of going from the state with intensity $\boldsymbol{\lambda}(t)$ at time t to the final state at time t_f,* i.e.,

$$J(\boldsymbol{\lambda}(t), t) = \min_{\boldsymbol{u}(t,t_f]} \mathbb{E}_{(\boldsymbol{N},\boldsymbol{P})(t,t_f]}\left[\phi(\boldsymbol{\lambda}(t_f)) + \int_t^{t_f} \ell(\boldsymbol{\lambda}(s), \boldsymbol{u}(s))\, ds\right], \tag{20}$$

where the expectation is taken over all trajectories of the counting processes $\boldsymbol{N}$ and $\boldsymbol{P}$ in the $(t, t_f]$ interval, given the initial values of $\boldsymbol{\lambda}(t)$ and $\boldsymbol{u}(t)$.

Next, we use the Bellman's principle of optimality (Bertsekas, 1995), which the above cost-to-go $J(\boldsymbol{\lambda}(t), t)$ also allows for (proof is similar to that of Lemma 3)), to break the problem into smaller subproblems and rewrite Eq. 20 as

$$\begin{aligned} J(\boldsymbol{\lambda}(t), t) &= \min_{\boldsymbol{u}(t,t+dt]} \left\{\mathbb{E}\left[J(\boldsymbol{\lambda}(t), t) + dJ(\boldsymbol{\lambda}(t), t)\right] + \ell(\boldsymbol{u}(t), \boldsymbol{\lambda}(t))\, dt\right\} \\ 0 &= \min_{\boldsymbol{u}(t,t+dt]} \left\{\mathbb{E}\left[dJ(\boldsymbol{\lambda}(t), t)\right] + \ell(\boldsymbol{u}(t), \boldsymbol{\lambda}(t))\, dt\right\}, \end{aligned} \tag{21}$$

where $dJ(\boldsymbol{\lambda}(t), t) = J(\boldsymbol{\lambda}(t+dt), t+dt) - J(\boldsymbol{\lambda}(t), t)$. Then, we explicitly differentiate J with respect to time t and $\lambda(t)$ using the following Lemma (proven in the Appendix E):

Lemma 9 *The differential $dJ(\boldsymbol{\lambda}(t), t)$ of the cost-to-go function $J(\boldsymbol{\lambda}(t), t)$, as defined by Eq. 20, is given by*

$$\begin{aligned} J_t(\boldsymbol{\lambda}(t), t)\, dt + [w\boldsymbol{\lambda}_0 - w\boldsymbol{\lambda}(t)]^T \nabla_{\boldsymbol{\lambda}} J(\boldsymbol{\lambda}(t), t)\, dt + \sum_i \left[J(\boldsymbol{\lambda}(t) + \boldsymbol{b}_i, t) - J(\boldsymbol{\lambda}(t), t)\right] dN_i(t) \\ + \sum_i \left[J(\boldsymbol{\lambda}(t) + \boldsymbol{b}_i, t) - J(\boldsymbol{\lambda}(t), t)\right] dP_i(t), \end{aligned}$$

where $\boldsymbol{b}_i$ is the i'th column of $\boldsymbol{B}$, J_t is derivative of J with respect to t and $\nabla_{\boldsymbol{\lambda}} J$ is the gradient of J with respect to $\boldsymbol{\lambda}(t)$.

Next, if we plug the above equation in Eq. 21 and use that $\mathbb{E}[N_i(t)] = \lambda_i(t)\, dt$ and $\mathbb{E}[P_i(t)] = u_i(t)\, dt$, the HJB equation follows:

$$0 = J_t(\boldsymbol{\lambda}(t), t) + [w\boldsymbol{\lambda}_0 - w\boldsymbol{\lambda}(t)]^T \nabla_{\boldsymbol{\lambda}} J(\boldsymbol{\lambda}(t), t) + \boldsymbol{\lambda}^T(t)\, \Delta_B J + \min_{\boldsymbol{u}(t)} \ell(\boldsymbol{u}(t), \boldsymbol{\lambda}(t)) + \boldsymbol{u}^T(t)\, \Delta_B J, \tag{22}$$

where $\Delta_B J$ denotes a vector whose i'th element is given by $(\Delta_B J)_i = J(\boldsymbol{\lambda}(t) + \boldsymbol{b}_i, t) - J(\boldsymbol{\lambda}(t), t)$.

To solve the above equation, we need to define the loss and penalty functions, ℓ and ϕ. Similarly as in Section 3, we consider the following quadratic forms, which will turn out to be a tractable choice:

$$\ell(\boldsymbol{u}(t), \boldsymbol{\lambda}(t)) = -\frac{1}{2}\boldsymbol{\lambda}^T(t)\, \boldsymbol{Q}\, \boldsymbol{\lambda}(t) + \frac{1}{2}\boldsymbol{u}^T(t)\, \boldsymbol{S}\, \boldsymbol{u}(t) \quad \text{and} \quad \phi(\boldsymbol{\lambda}(t_f)) = -\frac{1}{2}\boldsymbol{\lambda}^T(t_f)\, \boldsymbol{F}\, \boldsymbol{\lambda}(t_f),$$

where $\boldsymbol{Q}$, $\boldsymbol{F}$ and $\boldsymbol{S}$ are given symmetric matrices[9] with $q_{ij} \geq 0$, $f_{ij} \geq 0$ and $s_{ij} \geq 0$ for all $i, j \in [n]$. These matrices allow us to trade-off the number of directly incentivized actions

9. In practice, we will consider diagonal matrices.

Algorithm 3: CHESHIRE: it returns user i and time τ for the next incentivized action

1: **Initialization:**
2: Compute $\boldsymbol{H}(t)$ and $\mathbf{g}(t)$;
3: $\mathbf{u}(t) \leftarrow -\boldsymbol{S}^{-1}\big[\boldsymbol{B}^T(\boldsymbol{g}(t) + \boldsymbol{H}(t)\boldsymbol{\lambda}_0) + \frac{1}{2}\operatorname{diag}(\boldsymbol{B}^T\boldsymbol{H}(t)\boldsymbol{B})\big]$;
4: **General subroutine:**
5: $(i, \tau) \leftarrow \mathit{Sample}(\mathbf{u}(t))$;
6: $(j, s) \leftarrow \mathit{NextAction}(\,)$;
7: **while** $s < \tau$ **do**
8: $\quad \boldsymbol{\lambda}_N(t) \leftarrow \boldsymbol{B}\mathbf{e}_j\kappa_\omega(t - s)$;
9: $\quad \mathbf{u}_N(t) \leftarrow -\boldsymbol{S}^{-1}\boldsymbol{B}^T\boldsymbol{H}(t)\boldsymbol{\lambda}_N(t)$;
10: $\quad (k, r) \leftarrow \mathit{Sample}(\mathbf{u}_N(t))$;
11: $\quad$ **if** $r < \tau$ **then**
12: $\quad\quad \tau \leftarrow r$;
13: $\quad\quad i \leftarrow k$;
14: $\quad \mathbf{u}(t) \leftarrow \mathbf{u}(t) + \mathbf{u}_N(t)$;
15: $\quad (j, s) \leftarrow \mathit{NextAction}(\,)$;
16: $\boldsymbol{\lambda}_P(t) \leftarrow \boldsymbol{B}\mathbf{e}_i\kappa_\omega(t - \tau)$;
17: $\mathbf{u}_P(t) \leftarrow -\boldsymbol{S}^{-1}\boldsymbol{B}^T\boldsymbol{H}(t)\boldsymbol{\lambda}_P(t)$;
18: $\mathbf{u}(t) \leftarrow \mathbf{u}(t) + \mathbf{u}_P(t)$;
19: **return** (i, τ)

over time and the number of additional endogenous actions, both over time and at time t_f. Under these definitions, we can find the relationship between the optimal intensity and the optimal cost by solving the minimization in the HJB equation:

$$\underset{\boldsymbol{u}(t)}{\text{minimize}} \quad \boldsymbol{u}^T(t)\,\Delta_B J + \frac{1}{2}\boldsymbol{u}^T(t)\,\boldsymbol{S}\,\boldsymbol{u}(t) \quad \text{subject to} \quad u_i(t) \geq 0,\ i = 1, \ldots, n.$$

By taking the differentiation with respect to $\boldsymbol{u}(t)$, the solution of the unconstrained minimization is given by

$$\boldsymbol{u}^*(t) = -\boldsymbol{S}^{-1}\Delta_B J, \tag{23}$$

which is the same as the solution to the constrained problem given that $s_{ij} \geq 0$, by definition, and $(\Delta_B J)_i \leq 0$, as proved in the Appendix F. Then, we substitute Eq. 23 into Eq. 22 and find that the optimal cost J needs to satisfy the following partial differential equation:

$$0 = J_t(\boldsymbol{\lambda}(t), t) + [w\boldsymbol{\lambda}_0 - w\boldsymbol{\lambda}(t)]^T\nabla_{\boldsymbol{\lambda}}J(\boldsymbol{\lambda}(t), t) + \boldsymbol{\lambda}^T(t)\,\Delta_B J - \frac{1}{2}\boldsymbol{\lambda}^T(t)\,\boldsymbol{Q}\,\boldsymbol{\lambda}(t) - \frac{1}{2}\Delta_B J^T\boldsymbol{S}^{-1}\Delta_B J, \tag{24}$$

with $J(\boldsymbol{\lambda}(t_f), t_f) = \phi(\boldsymbol{\lambda}(t_f))$ as the terminal condition. The following lemma provides us with a solution to the above equation (proven in Appendix G):

Lemma 10 *In the space of m-degree degree polynomials, the following quadratic form is the only solution to Eq. 24:*

$$J(\boldsymbol{\lambda}(t), t) = f(t) + \boldsymbol{g}(t)^T\boldsymbol{\lambda}(t) + \frac{1}{2}\boldsymbol{\lambda}(t)^T\boldsymbol{H}(t)\boldsymbol{\lambda}(t).$$

where $\boldsymbol{g}(t)$ and $\boldsymbol{H}(t)$ can be found by solving the following differential equations:

$$\dot{\boldsymbol{H}}(t) = (\omega\boldsymbol{I} - \boldsymbol{B})^T\boldsymbol{H}(t) + \boldsymbol{H}(t)(\omega\boldsymbol{I} - \boldsymbol{B}) + \boldsymbol{H}(t)\boldsymbol{B}\boldsymbol{S}^{-1}\boldsymbol{B}^T\boldsymbol{H}(t) + \boldsymbol{Q}$$

$$\dot{\boldsymbol{g}}(t) = [\omega\boldsymbol{I} - \boldsymbol{B}^T + \boldsymbol{H}(t)\boldsymbol{B}\boldsymbol{S}^{-1}\boldsymbol{B}^T]\boldsymbol{g}(t) - \omega\boldsymbol{H}(t)\boldsymbol{\lambda}_0 + \frac{1}{2}\left[\boldsymbol{H}(t)\boldsymbol{B}\boldsymbol{S}^{-1} - \boldsymbol{I}\right]\operatorname{diag}(\boldsymbol{B}^T\boldsymbol{H}(t)\boldsymbol{B}).$$

In the above lemma, note that the first differential equation is a matrix Riccati differential equation, which can be solved using many well-known efficient numerical solvers (Garrett, 2013), and the second one is a first order differential equation which has closed form solution. Both equations are solved backward in time with final conditions $\boldsymbol{g}(t_f) = \mathbf{0}$ and $\boldsymbol{H}(t_f) = -\boldsymbol{F}$.

Finally, given the above cost-to-go function, the optimal intensity is given by the following theorem:

Theorem 11 *The optimal intensity for the activity maximization problem defined by Eq. 19 with quadratic loss and penalty function is given by*

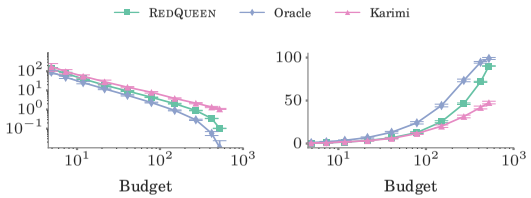
$$\boldsymbol{u}^*(t) = -\boldsymbol{S}^{-1}\big[\boldsymbol{B}^T\boldsymbol{g}(t) + \boldsymbol{B}^T\boldsymbol{H}(t)\boldsymbol{\lambda}(t) + \frac{1}{2}\operatorname{diag}(\boldsymbol{B}^T\boldsymbol{H}(t)\boldsymbol{B})\big].$$

Since the optimal intensity is linear in $\boldsymbol{\lambda}(t)$, it allows for an efficient procedure to sample the times of the users' directly incentivized actions: at any given time t, we can view the multidimensional control signal $\boldsymbol{u}(t)$ as a superposition of inhomogeneous multidimensional Poisson processes, one per non incentivized action, which start when the actions take place. Algorithm 3 summarizes our method, which we name CHESHIRE (Carroll, 1917).

Within the algorithm, *NextAction*() returns the time of the next (non directly incentivized) action in the network as well as the identity of the user who takes the action, once the action happens, $\boldsymbol{e}_j$ is an indicator vector where the entry corresponding to user j is 1, and *Sample*($\boldsymbol{u}(t)$) samples from a multidimensional inhomogeneous Poisson process with intensity $\boldsymbol{u}(t)$ and it returns both the sampled time and dimension (*i.e.*, user). Moreover, note that the algorithm initially plans a user i and time τ for the next directly incentivized action, however, if before τ, a new organic action takes place at $s < \tau$ and the intensity $\boldsymbol{\lambda}(t)$ changes, then the algorithm updates the user and time for the next directly incentivized action using the superposition principle. To sample from a multidimensional inhomogeneous Poisson process, there exist multiple methods *e.g.*, refer to Lewis and Shedler (1979). Finally, note that one can precompute most of the quantities the algorithm needs, *e.g.*, lines 2-3, $\boldsymbol{B}\boldsymbol{e}_j$ in line 8, and $\boldsymbol{S}^{-1}\boldsymbol{B}^T\boldsymbol{H}(t)$ in line 9. Given these precomputations, the algorithm only needs to perform $O(n)$ operations and sample $\mathbf{1}^T\boldsymbol{N}(t_f)$ times from an inhomogeneous Poisson process.

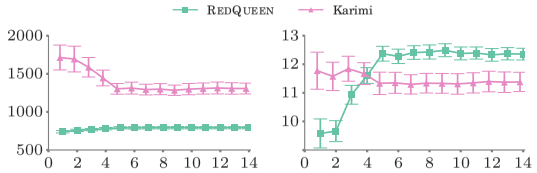
5. Experiments

In this section, we validate REDQUEEN (Algorithm 1) and CHESHIRE (Algorithm 3) using both synthetic and real data gathered from Twitter and compare their performance with several state of the art methods and competitive baselines He et al. (2012).



(a) Position over time (b) Time at the top

Figure 2: Optimizing for one follower. Performance of RedQueen in comparison with the oracle and the method by Karimi et al. (2016) against number of broadcasted events. The feeds counting processes $M(t)$ due to other broadcasters are Hawkes processes with $\gamma_0 = 10$, $\alpha = 1$ and $w = 10$. In all cases, the time horizon $t_f - t_0$ is chosen such that the number of stories posted by other broadcasters is ∼1000. Error bars are too small to be seen.



(a) Position over time (b) Time at the top

Figure 3: Optimizing for multiple followers. Performance of RedQueen in comparison with the method by Karimi et al. (2016) against number of followers. The feeds counting processes $M(t)$ due to other broadcasters follow piecewise constant intensities, where the intensity of each follower remains constant within each piece, it varies as a half-sinusoid across pieces and it starts with a random initial phase. The performance of both methods stays constant upon addition of more followers.

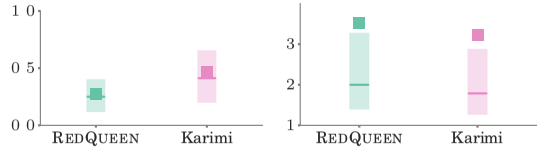
5.1 When-to-post

5.1.1 Experiments on synthetic data

Experimental setup. We evaluate the performance via two quality measures: position over time, $\int_0^T r(t)dt$, and time at the top, $\int_0^T \mathbb{I}(r(t)<1)dt$ and compare the performance of RedQueen against the oracle, described in Section 3.3, and the method by Karimi et al. (2016), which, to the best of our knowledge, is the state of the art. Unless otherwise stated, we set the significance $s_i(t) = 1, \forall t, i$ and use the parameter q to control the number of posts by RedQueen[10].

Optimizing for one follower. We first experiment with one broadcaster and one follower against an increasing number of events (or budget). We generate the counting processes

10. The expected number of posts by RedQueen are a decreasing function of q. Hence, we can use binary search to guess q and then use averaging over multiple simulation runs to estimate the number of posts made.



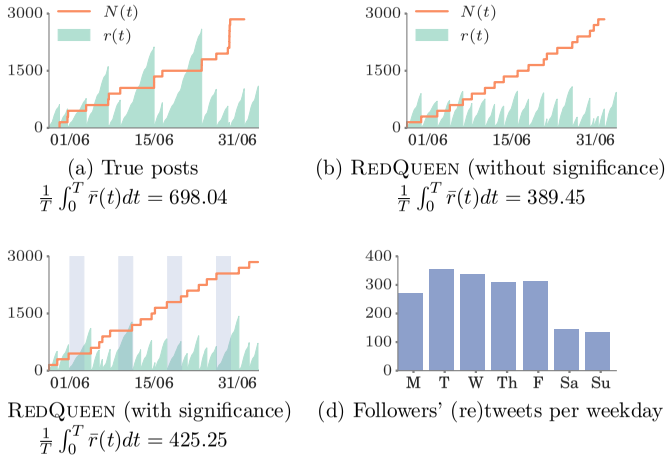
(a) Position over time (b) Time at the top

Figure 4: Performance of RedQueen and the method by Karimi et al. (2016) for 2000 Twitter users, picked at random. The solid horizontal line (square) shows the median (mean) quality measure, normalized with respect to the value achieved by the users' actual *true* posts, and the box limits correspond to the 25%-75% percentiles.

$M(t)$ due to other broadcasters using Hawkes processes, as defined by Eq. 1. We perform 10 independent simulation runs and compute the average and standard error (or standard deviation) of the quality measures. Fig. 2 summarizes the results, which show that our method: (i) consistently outperforms the method by Karimi et al. by large margins; (ii) achieves at most 3× higher position over time than the oracle as long as the budget is <30% of the posted events by all other broadcasters; and, (iii) achieves >40% of the value of time at the top that the oracle achieves.

Optimizing for multiple followers. Next, we experiment with one broadcaster and multiple followers. In this case, we generate the counting processes $M(t)$ due to other broadcasters using piece-wise constant intensity functions. More specifically, we simulate the feeds of each follower for 1 day, using 24 1-hour long segments, where the rate of posts remains constant per follower in each segment and the rate itself varies as a half-sinusoid (*i.e.*, from $\sin 0$ to $\sin \pi$), with each follower starting with a random initial phase. This experimental setup reproduces volume changes throughout the day across followers' feeds in different time-zones and closely resembles the settings in previous work (Karimi et al., 2016). The total number of posts by the RedQueen broadcaster is kept nearly constant and is used as the budget for the other baselines. Additionally, for Karimi's method, we provide as input the true empirical rate of tweets per hour for each user. Here, we do not compare with the oracle since, due to its quadratic complexity, it does not scale.

Figure 3 summarizes the results. In terms of position over time, RedQueen outperforms Karimi's method by a factor of 2. In terms of time at the top, RedQueen achieves ∼18% lower values than Karimi's method for 1-4 followers but ∼10% higher values for >5 followers. A potential reason Karimi's method performs best in terms of time at the top for a low number of followers and piecewise constant intensities is that, while the number of followers is low, there are segments which are clearly favorable and thus Karimi's method concentrates posts on those. However, as the number of followers increases, there are no clear favorable segments and advance planning does not give Karimi's method any advantage. On the other hand, RedQueen, due to its online nature, is able to adapt to transient variations in the feeds.



(a) True posts
$\frac{1}{T}\int_0^T \bar{r}(t)dt = 698.04$

(b) RedQueen (without significance)
$\frac{1}{T}\int_0^T \bar{r}(t)dt = 389.45$

(c) RedQueen (with significance)
$\frac{1}{T}\int_0^T \bar{r}(t)dt = 425.25$

(d) Followers' (re)tweets per weekday

Figure 5: A broadcaster chosen from real data. Panels compares the position over time $\bar{r}(t) = \sum_{i=0}^{\mathcal{N}} r(t)/\mathcal{N}$ (in green; lower is better) for the most recent tweet posted by a real user against the most recent one *posted* by a simulation run of RedQueen without and with significance. Here, the orange staircases represent the counts $N(t)$ of the tweets posted by the real user and RedQueen over time. The shaded area in panel (c) highlights weekends. We can see that RedQueen avoided tweeting on weekends, when the followers are less likely to be active/logged-in, as seen in panel (d).

5.1.2 Experiments on real data

Dataset description and experimental setup. We use data gathered from Twitter as reported in previous work (Cha et al., 2010), which comprises profiles of 52 million users, 1.9 billion directed follow links among these users, and 1.7 billion public tweets posted by the collected users. The follow link information is based on a snapshot taken at the time of data collection, in September 2009. Here, we focus on the tweets published during a two month period, from July 1, 2009 to September 1, 2009, in order to be able to consider the social graph to be approximately static, and sample 2000 users uniformly at random as broadcasters and record all the tweets they posted. Then, for each of these broadcasters, we track down their followers and record all the (re)tweets they posted as well as reconstruct their timelines by collecting all the (re)tweets published by the people they follow. We assign equal significance to each follower but filter out those who follow more than 500 people since, otherwise, they would dominate the optimal strategy. Finally, we tune q such that the total number of tweets posted by our method is equal to the number of tweets the broadcasters tweeted during the two month period (with a tolerance of 10%).

Solution quality. We only compare the performance of our method against the method by Karimi et al. (2016) since the oracle does not scale to the size of real data. Moreover,

for the method by Karimi et al., we divide the two month period into ten segments of approximately one week to fit the piecewise constant intensities of the followers' timelines, which the method requires. Fig. 4 summarizes the results by means of box plots, where position over time and time at the top are normalized with respect to the value achieved by the broadcasters' actual *true* posts during the two month period. That means, if $y = 1$, the optimized intensity achieves the same position over time or time at the top as the broadcaster's true posts. In terms of position over time and time at the top, RedQueen consistently outperforms competing methods by large margins and achieves 0.28× lower average position and 3.5× higher time at the top, in average, than the broadcasters' true posts—in fact, it achieves lower position over time (higher time at the top) for 100% (99.1%) of the users.

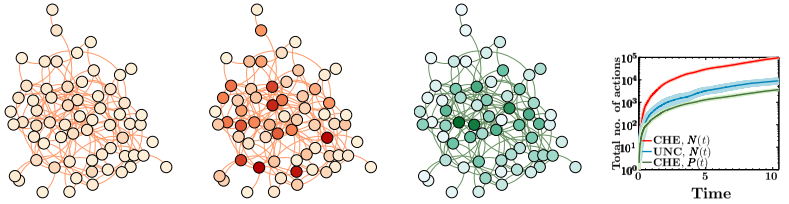
Time significance. We look at the actual broadcasting strategies for one real user and investigate the effect of a time varying significance. We define $s_i(t)$ to be the probability that follower i is online on that weekday, estimated empirically using the (re)tweets the follower posted as in Karimi et al. (2016). Fig. 5 compares the position over time for the most recent tweet posted by a real user against the most recent one *posted* by a simulation run of RedQueen with and without time varying significance. We can see that without significance information, RedQueen posts at nearly an even pace. However, when we supply empirically estimated significance, RedQueen avoids tweeting at times the followers are unlikely to be active, *i.e.*, the weekends, denoted by the shaded areas in panel (c) of Fig. 5. Due to this, the average position (maximum position) falls from 389.45 (1085.17) to 425.25 (1431.0), but is still lower than 698.04 (2597.9) obtained by the user's original posting schedule.

5.2 Activity Maximization

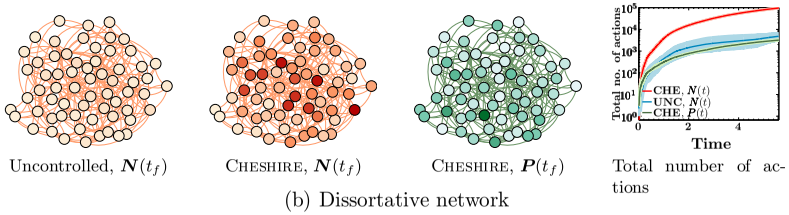
5.2.1 Experiments on Synthetic Data

In this section, we first shed light on Cheshire's sampling strategy in two small Kronecker networks (Leskovec et al., 2010) by recording, on the one hand, the number of directly incentivized actions per node and, on the other hand, the number of not directly incentivized actions per node in comparison with an uncontrolled setup. Then, we compare the performance of our method against several baselines and state of the art methods (Farajtabar et al., 2014, 2016) on a variety of large Kronecker networks and provides a scalability analysis.

Sampling strategy. We generate two small Kronecker networks with 64 nodes, a small core-periphery (parameter matrix $[0.96, 0.3; 0.3, 0.96]$) and a dissortative network (param. matrix $[0.3, 0.96; 0.96, 0.3]$), shown in Figure 6. For each network, we draw $\boldsymbol{B}$ from a uniform distribution $U(0, 10)$, $\boldsymbol{\lambda}_0$ also from a uniform distribution $U(0, 10)$ for 20% of the nodes and $\boldsymbol{\lambda}_0 = 0$ for the remaining 80%, and set $\omega = 16$, $t_0 = 0$ and $t_f = 5.5$. Then, we compare the number of actions $\boldsymbol{N}(t)$ over time under uncontrolled dynamics (Eq. 2; without Cheshire) and controlled dynamics (Eq. 17; with Cheshire). In both cases, we perform 20 simulation runs and sample non directly incentivized actions using Ogata's thinning algorithm (Ogata, 1981). In the case of controlled dynamics, we sample directly incentivized actions using Algorithm 3.



(a) Core-Periphery network

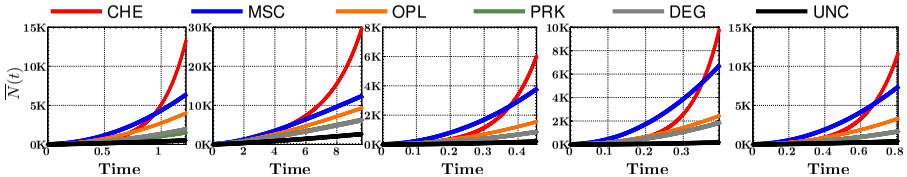


(b) Dissortative network

Figure 6: Activity on two 64-node networks, G_1 (top) and G_2 (bottom) under uncontrolled (Eq. 2; without Cheshire) and controlled (Eq. 17; with Cheshire) dynamics. The first and second columns visualize the final number of non incentivized actions $\boldsymbol{N}(t_f)$ under uncontrolled and controlled dynamics, where darker red corresponds to higher number of actions. The third column visualizes the final number of incentivized actions $\boldsymbol{P}(t_f)$ under controlled dynamics, where darker green corresponds to higher number of actions. The fourth column shows the temporal evolution of the number of incentivized and non incentivized actions across the whole networks for controlled and uncontrolled dynamics, where the solid line is the average across simulation runs and the shadowed region represents the standard error. By incentivizing a relatively small number of actions (∼3,600 actions), Cheshire is able to increase the overall number of (non incentivized) actions dramatically (∼96,000 vs ∼4,800 actions).

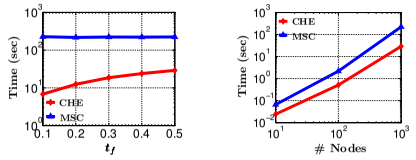
Figure 6 summarizes the results in terms of the number of non directly incentivized and incentivized actions, which show that: (i) a relatively small number of incentivized actions (fourth column; ∼3,600 actions) result in a dramatic increase in the overall number of (non directly incentivized) actions with respect the uncontrolled setup (fourth column; ∼96,000 vs ∼4,800 actions); (ii) the majority of the incentivized actions concentrate in a small set of influential nodes (third column; nodes in dark green); and, (iii) the variance of the overall number of actions (fourth column; shadowed regions) is consistently reduced when using Cheshire, in other words, the networks become more robust.

Performance. We experiment with five different types of large Kronecker networks (Leskovec et al., 2010) with 512 nodes: (i) homophily (assortative) networks (parameter matrix $[0.96, 0.3; 0.3, 0.96]$); (ii) heterophily (dissortative) networks ($[0.3, 0.96; 0.96, 0.3]$); (iii) random networks ($[0.7, 0.7; 0.7, 0.7]$); (iv) hierarchical networks ($[0.9, 0.1; 0.1, 0.9]$); and, (v)



(a) Core-periphery (b) Hierarchical (c) Homophily (d) Heterophily (e) Random

Figure 7: Performance over time of Cheshire against several competitors for several types of Kronecker networks. Performance is measured in terms of overall number of tweets $\bar{N}(t) = \sum_{u \in \mathcal{V}} \mathbb{E}[N_u(t)]$. In all cases, we tune the parameters Q, S and F such that the total number of incentivized tweets *posted* by our method is equal to the budget used in the competing methods and baselines.



(a) Running time vs t_f (b) Running time vs #nodes

Figure 8: Scalability of Cheshire against several competitors. Panel (a) shows the running time against the cut-off time t_f for a 1,000 node Kronecker network. Panel (b) shows the running time for several Kronecker networks of increasing size with $t_f = 0.5$. In both panels, the average degree per node is 10. The experiments are carried out in a single machine with 24 cores and 64 GB of main memory.

core-periphery networks ($[0.9, 0.5; 0.5, 0.3]$). For each network, we draw $\boldsymbol{\lambda}_0$ and $\boldsymbol{B}$ from a uniform distribution $U(0, 1)$ and set $\omega = 100$. We compare the performance of our algorithm, Cheshire, with two state of the art methods, which we denote as OPL (Farajtabar et al., 2014) and MSC (Farajtabar et al., 2016), and three baselines, which we denote as PRK, DEG, and UNC. OPL is a provably optimal algorithm for the offline setting and MSC is a suboptimal algorithm that discretizes the time window of interest in several rounds and, at any given round, it computes the control signal using the feedback from previous rounds to maximize the activity. PRK and DEG distribute the users' control intensities $\mathbf{u}(t)$ proportionally to the user's page rank and outgoing degree in the network, respectively. UNC simply considers all control intensities to be zero, *i.e.*, it represents the uncontrolled dynamics.

For the large Kronecker networks, Figure 7 compares the performance of our algorithm against others in terms of overall average number of tweets $\bar{N}(t) = \sum_{u \in \mathcal{V}} \mathbb{E}[N_u(t)]$ for a fixed budget $\bar{P}(t_f) = \sum_{u \in \mathcal{V}} \mathbb{E}[P_u(t_f)] \approx 6.1\text{K}$. We find that: (i) our algorithm consistently outperforms competing methods by large margins at time t_f; (ii) it triggers up to 50%–100% more posts than the second best performer by time t_f; (iii) MSC tends to use the

budget too early, as a consequence, although it initially beats our method, it eventually gets outperformed by time t_f; and, (iv) the baselines PRK and DEG have an underwhelming performance, suggesting that the network structure alone is not an accurate measure of influence.

Scalability. Figure 8 shows that our algorithm scales to large networks and is almost an order of magnitude faster than the second best performer, MSC (Farajtabar et al., 2016). For example, our algorithm takes ∼30 seconds to steer a network with 1,000 nodes and average degree of 10 while MSC takes ∼4 minutes.

5.2.2 Experiments on Real Data

In this section, we experiment with data gathered from Twitter and show that our model can maximize the number of online actions more effectively than several baselines and state of the art methods (Farajtabar et al., 2014, 2016).

Experimental setup. We experiment with five Twitter data sets about current real-world events, where actions are tweets (and retweets). To create each data set, we used the Twitter search API[11] to collect all the tweets (corresponding to a 2-3 weeks period around the event date) that contain hashtags related to:

- **Elections:** British election, from May 7 to May 15, 2015.
- **Verdict:** Verdict for the corruption-case against Jayalalitha, an Indian politician, from May 6 to May 17, 2015.
- **Club:** Barcelona getting the first place in La-liga, from May 8 to May 16, 2016.
- **Sports:** Champions League final in 2015, between Juventus and Real Madrid, from May 8 to May 16, 2015.
- **TV Show:** The promotion on the TV show "Games of Thrones", from May 4 to May 12, 2015.

We then built the follower-followee network for the users that posted the collected tweets using the Twitter rest API[12]. Finally, we filtered out users that posted less than 200 tweets during the account lifetime, follow less than 100 users, or have less than 50 followers. An account of the data set statistics is given in Table 1.

Similarly as in the synthetic experiments, we compare the performance of our algorithm with two state of the art methods, OPL (Farajtabar et al., 2014) and MSC (Farajtabar

Figure 9: Performance over time of Cheshire against several competitors for each Twitter data set. Performance is measured in terms of overall number of tweets $\bar{N}(t) = \sum_{u \in \mathcal{V}} \mathbb{E}[N_u(t)]$. In all cases, we tune the parameters $\boldsymbol{Q}$, $\boldsymbol{S}$ and $\boldsymbol{F}$ to be diagonal matrices such that the total number of incentivized tweets *posted* by our method is equal to the budget used in the competing methods and baselines. Cheshire (in red) consistently outperforms competing methods over time and it triggers up to 100%–400% more posts than the second best performer (in blue) as time goes by.

et al., 2016), and three baselines, PRK, DEG and UNC. More in detail, we proceed as follows.

For each data set, we estimate the influence matrix $\boldsymbol{B}$ of the multidimensional Hawkes process defined by Eq. 2 using maximum likelihood, as elsewhere (Farajtabar et al., 2014; Valera and Gomez-Rodriguez, 2015). Moreover, we set the decay parameter ω of the corresponding exponential triggering kernel $\kappa(t)$ by cross-validation. Then, we perform 20 simulation runs for each method and baseline, where we sample non directly incentivized actions from the multidimensional Hawkes process learned from the corresponding Twitter data set using Ogata's thinning algorithm (Ogata, 1981). For the competing methods and baselines, the control intensities $\boldsymbol{u}(t)$ are deterministic and thus we only need to sample incentivized actions from inhomogeneous Poisson processes (Lewis and Shedler, 1979). For our method, the control intensities are stochastic and thus we sample incentivized actions using Algorithm 3. Here, we compare their performance in terms of the (empirical) average number of tweets $\mathbb{E}[\boldsymbol{N}(t)]$. In the above procedure, for a fair comparison, we tune the parameters $\boldsymbol{Q}$, $\boldsymbol{S}$ and $\boldsymbol{F}$ to be diagonal matrices such that the total number of incentivized tweets *posted* by our method is equal to the budget used in the state of the art methods and baselines.

Results. We first compare the performance of our algorithm against others in terms of overall average number of tweets $\bar{N}(t) = \sum_{u \in \mathcal{V}} \mathbb{E}[N_u(t)]$ for a fixed budget $\bar{P}(t_f) = \sum_{u \in \mathcal{V}} P_u(t_f)$. Figure 9 summarizes the results, which show that: (i) our algorithm consistently outperforms competing methods by large margins; (ii) it triggers up to 100%–400% more posts than the second best performer as time goes by; and, (iii) the baselines PRK and DEG have an underwhelming performance, suggesting that the network structure alone is not an accurate measure of influence.

Next, we evaluate the performance of our algorithm against others with respect to the available budget. To this aim, we compute the average time $\bar{t}_{30K}$ required by each method to reach a milestone of 30,000 tweets against the number of directly incentivized tweets

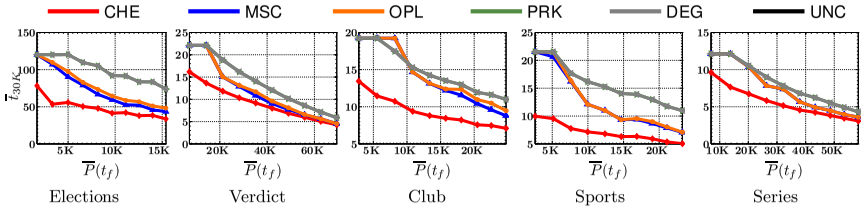

Figure 10: Performance vs. number of directly incentivized tweets for each Twitter data set. Performance is measured in terms of the average time $\bar{t}_{30K}$ required by each method to reach a milestone of 30,000 tweets. Cheshire (in red) consistently reaches the milestone faster than the competing methods, *e.g.*, 20%–50% faster than the second best performer (in blue) for low budgets.

$\bar{P}(t_f)$ (*i.e.*, the budget). Here, we do not report the results for the uncontrolled dynamics (UNC) since it did not reach the milestone after 10× the time the slowest competitor took to reach it. Figure 10 summarizes the results, which show that: (i) our algorithm consistently reaches the milestone faster than the competing methods; (ii) it exhibits a greater competitive advantage when the budget is low; and, (iii) it reaches the milestone 20%–50% faster than the second best performer for low budgets.

6. Conclusions

In this paper, we developed efficient online algorithms for steering social activity, both at a user (local) and network (global) level, based on stochastic optimal control of stochastic differential equations (SDEs) with jumps. In doing so, we established a previously unexplored connection between optimal control of jump SDEs and doubly stochastic marked temporal point processes, which is of independent interest. We experimented with synthetic and real-world data gathered from Twitter and showed that our algorithms can consistently steer social activity more effectively than the state of the art.

Our work also opens many venues for future work. For example, from the perspective of an individual user, we considered social networks that sort stories in the users' feeds in reverse chronological order (*e.g.*, Twitter, Weibo). Extending our methodology to social networks that sort stories algorithmically (*e.g.*, Facebook) is a natural next step. Moreover, we assume that only one broadcaster is using RedQueen. A very interesting follow-up would be augmenting our framework to consider multiple broadcasters under cooperative, competitive and adversarial environments. From the perspective of an entire social networking site, our experimental evaluation is based on simulation, using models whose parameters ($\boldsymbol{B}$, ω) are learned from data. It would be very interesting to evaluate our method using actual interventions in a social network. From both perspectives, our algorithms optimize quadratic losses and assume the model parameters do not change over time, however, it would be useful to derive optimal broadcasting intensities for other losses with well-defined semantics and time-varying model parameters. Finally, optimal control of jump SDEs with doubly stochastic temporal point processes can be potentially applied to design online algorithms for a wide variety of control problems in social and information systems, such as human learning (Reddy et al., 2016) or rumor control (Friggeri et al., 2014).

Appendix A. Proof of Proposition 1

Using the left continuity of Poisson processes and the definition of derivative $d\boldsymbol{\lambda}(t) = \boldsymbol{\lambda}(t + dt) - \boldsymbol{\lambda}(t)$ we can find the dynamics of the process using Ito's calculus (Hanson, 2007) as follows:

$$
\begin{aligned}
d\boldsymbol{\lambda}(t) &= \boldsymbol{\lambda}_0'(t)\,dt + \boldsymbol{C}\int_0^{t+dt} \kappa_\omega(t+dt-s)\,d\boldsymbol{N}(s) - \boldsymbol{C}\int_0^{t} \kappa_\omega(t-s)\,d\boldsymbol{N}(s) \\
&= \boldsymbol{\lambda}_0'(t)\,dt + \boldsymbol{C}\int_0^{t+dt} (\kappa_\omega(t-s) + \kappa_\omega'(t-s)\,dt)\,d\boldsymbol{N}(s) - \boldsymbol{C}\int_0^{t} \kappa_\omega(t-s)\,d\boldsymbol{N}(s) \\
&= \boldsymbol{\lambda}_0'(t)\,dt + \boldsymbol{C}\int_t^{t+dt} \kappa_\omega(t-s)\,d\boldsymbol{N}(s) + dt\,\boldsymbol{C}\int_0^{t+dt} \kappa_\omega'(t-s)\,d\boldsymbol{N}(s) \\
&= \boldsymbol{\lambda}_0'(t)\,dt + \boldsymbol{C}\,\kappa_\omega(0)\,d\boldsymbol{N}(t) - \omega\,dt\,\boldsymbol{C}\int_0^{t+dt} \kappa_\omega(t-s)\,d\boldsymbol{N}(s) \\
&= \boldsymbol{\lambda}_0'(t)\,dt + \boldsymbol{C}\,d\boldsymbol{N}(t) - \omega\,dt\,\boldsymbol{C}\int_0^{t} \kappa_\omega(t-s)\,d\boldsymbol{N}(s) \\
&= \left[\boldsymbol{\lambda}_0'(t) + \omega\boldsymbol{\lambda}_0(t) - \omega\boldsymbol{\lambda}(t)\right]dt + \boldsymbol{C}\,d\boldsymbol{N}(t).
\end{aligned}
$$

Appendix B. Proof of Lemma 3

$$
\begin{aligned}
&J(\gamma(t), r(t), t) = \min_{u(t,t_f]} \mathbb{E}_{(N,M)(t,t_f]}\left[\phi(r(t_f)) + \int_t^{t_f} \ell(r(\tau), u(\tau))\,d\tau\right] \\
&= \min_{u(t,t_f]} \mathbb{E}_{(N,M)(t,t_f]}\left[\phi(r(t_f)) + \int_t^{t+dt} \ell(r(\tau), u(\tau))\,d\tau + \int_{t+dt}^{t_f} \ell(r(\tau), u(\tau))\,d\tau\right] \\
&= \min_{u(t,t_f]} \mathbb{E}_{(N,M)(t,t+dt]}\left[\mathbb{E}_{(N,M)(t+dt,t_f]}\left[\phi(r(t_f)) + \ell(t,r,u)\,dt + \int_{t+dt}^{t_f} \ell(r(\tau), u(\tau))\,d\tau\right]\right] \\
&= \min_{u(t,t+dt]} \min_{u(t+dt,t_f]} \mathbb{E}_{(N,M)(t,t+dt]}\left[\ell(r(t),\gamma(t),t)\,dt + \mathbb{E}_{(N,M)(t+dt,t_f]}\left[\phi(r(t_f)) + \int_{t+dt}^{t_f} \ell(r(\tau), u(\tau))\,d\tau\right]\right] \\
&= \min_{u(t,t+dt]} \mathbb{E}_{(N,M)(t,t+dt]}\left[J(\gamma(t+dt), r(t+dt), t+dt)\right] + \ell(r(t), u(t))\,dt.
\end{aligned}
$$

Appendix C. Proof of Lemma 4

According to the definition of differential,

$$
\begin{aligned}
dJ(r(t),\gamma(t),t) &:= J(r(t+dt),\gamma(t+dt),t+dt) - J(r(t),\gamma(t),t) \\
&= J(r(t)+dr(t),\gamma(t)+d\gamma(t),t+dt) - J(r(t),\gamma(t),t).
\end{aligned}
$$

To evaluate the first term in the right hand side of the above equality we substitute $dr(t)$ and $d\gamma(t)$ using Eq. 9. Then, using the zero-one jump law (Kingman, 1992) we can write:

$$\begin{aligned} dJ = {} & J\big(0, \gamma(t) + m(t)dt, t + dt\big)\, dN(t) + J\big(r(t) + g(t), \gamma(t) + m(t)dt + \alpha, t + dt\big)\, dP(t) \\ & + J\big(r, \gamma(t) + m(t)dt, t + dt\big)\,(1 - dN(t))(1 - dP(t)) - J\big(r(t), \gamma(t), t\big), \end{aligned}$$

where $m(t) = \gamma_0'(t) + \omega\gamma_0(t) - \omega\gamma(t)$. Then, we can expand the first three terms in the right hand sides:

$$\begin{aligned} J\big(0, \gamma + m(t)dt, t + dt\big) &= J(0, \gamma(t), t) + J_\gamma(0, \gamma(t), t)m(t)dt + J_t(0, \gamma(t), t)dt \\ J\big(r(t) + 1, \gamma(t) + m(t)dt + \alpha, t + dt\big) &= J(r(t) + 1, \gamma(t) + \alpha, t) + J_\gamma(r + 1, \gamma(t) + \alpha, t)m(t)dt \\ J\big(r(t), \gamma(t) + m(t)dt, t + dt\big) &= J(r(t), \gamma(t), t) + J_\gamma(r(t), \gamma(t), t)m(t)dt + J_t(r(t), \gamma(t), t)dt, \end{aligned}$$

using that the bilinear differential form $dt\, dN(t) = 0$ (Hanson, 2007) and $dN(t)dP(t) = 0$ by the zero-one jump law. Finally,

$$\begin{aligned} dJ(r(t), \gamma(t), t) = {} & J_t(r(t), \gamma(t), t)dt + \big[\gamma_0'(t) + \omega\gamma_0(t) - \omega\gamma(t)\big]\, J_\gamma(r(t), \gamma(t), t)dt \\ & + [J(0, \gamma(t), t) - J(r(t), \gamma(t), t)]dN(t) \\ & + [J(r(t) + 1, \gamma(t) + \alpha, t) - J(r(t), \gamma(t), t)]dP(t), \end{aligned}$$

which concludes the proof.

Appendix D. Proof of Lemma 5

Consider the following proposal for the cost-to-go:

$$J(r(t), \gamma(t), t) = \sum_{i=0}^{n} \sum_{j=0}^{m} f_{ij}(t) r^i(t) \gamma^j(t),$$

where m and n are arbitrary large numbers and $f_{ij}(t)$ are time-varying functions. Now, substitute this proposal in to Eq. 15:

$$\begin{aligned} 0 = {} & \sum_{i=1}^{n} f_{i0}'\, r^i + f_{i0}\,(r+1)^i\gamma - f_{i0}\, r^i\gamma + \sum_{j=1}^{m} f_{0j}'\gamma^j + j(\gamma_0' + w\gamma_0 - w\gamma)f_{0j}\gamma^{j-1} + f_{0j}(\gamma+\alpha)^j\gamma - f_{0j}\gamma^{j+1} \\ & + \sum_{i=1}^{n}\sum_{j=1}^{m} j(\gamma_0' + w\gamma_0 - w\gamma)f_{ij} r^i\gamma^{j-1} + \sum_{i=1}^{n}\sum_{j=1}^{m} f_{ij}(r+1)^i(\gamma+\alpha)^j\gamma - f_{ij} r^i\gamma^{j+1} \\ & - \frac{1}{2}q^{-1}\Big[\sum_{i=1}^{n} f_{i0} r^i + \sum_{i=1}^{n}\sum_{j=1}^{m} f_{ij} r^i\gamma^j\Big]^2 + \frac{1}{2}s\, r^2 + f_{00}' \end{aligned}$$

where for notational simplicity we omitted the time argument of functions. To find the unknown functions $f_{ij}(t)$, we equate the coefficient of different variables. If we consider the coefficient of r^{2n}, we have $f_{n0}(t) = 0$. We can continue this argument for $n-1, n-2, \cdots, 2$ to show that $\forall i \geq 2$; $f_{i0}(t) = 0$. Similar reasoning for coefficients of $r^{2i}\gamma^{2j}$ shows that $\forall j, i \geq 2$; $f_{ij}(t) = 0$. Finally, the coefficient of r^2 is $s(t)/2 - q^{-1}f_{10}^2(t)/2 = 0$, so $f_{10}(t) = \sqrt{s(t)q}$. If we rename $f_{0j}(t)$ to $g_j(t)$ and $f_{00}(t)$ to $f(t)$, then it follows that

$$J(r(t), \gamma(t), t) = f(t) + \sqrt{s(t)q}\, r(t) + \sum_{j=1}^{m} g_j(t)\gamma^j(t).$$

We can continue the previous method to find the remaining coefficients and completely define the cost-to-go function. If we equate the coefficient of γ^j to zero we would have a system of first oder differential equation which its j'th row for $j > 1$ is

$$g_j'(t) - g_{j-1}(t) + j(\alpha - w)g_j(t) + (j+1)\big(\gamma_0'(t) + w\gamma_0(t) + \frac{j}{2}\alpha^2\big)g_{j+1}(t) + \sum_{k=2}^{m-j}\binom{j+k}{k+1}\alpha^{k+1}g_{j+k}(t) = 0$$

We can also evaluate the corresponding differential equation for $j = 1$. When $\gamma_0(t) = \gamma_0$, we can express these differential equations using a matrix differential equation $\boldsymbol{g}'(t) = A\boldsymbol{g}(t)$. and its solution is $\boldsymbol{g}(t) = c_1 e^{\zeta_1 t}\boldsymbol{u}_1 + c_2 e^{\zeta_2 t}\boldsymbol{u}_2 + \cdots + c_n e^{\zeta_n t}\boldsymbol{u}_n$ where ζ_i and $\boldsymbol{u}_i$ are eigenvalue and eigenvector of matrix A and c_i is a constant found using the terminal conditions. Since in triangular matrices diagonal entries are eigenvalues, we have $\boldsymbol{g}(t) = \sum_{j=1}^{m} c_i e^{j(w-\alpha)}\boldsymbol{u}_i$. We can approximate general time varying $\gamma_0(t)$ using piecewise function and repeat the above procedure for each piece.

Appendix E. Proof of Lemma 9

According to the definition of differential,

$$dJ(\boldsymbol{\lambda}(t), t) := J(\boldsymbol{\lambda}(t + dt), t + dt) - J(\boldsymbol{\lambda}(t), t) = J(\boldsymbol{\lambda}(t) + d\boldsymbol{\lambda}(t), t + dt) - J(\boldsymbol{\lambda}(t), t).$$

To evaluate the first term in the right hand side of the above equality we substitute $d\boldsymbol{\lambda}(t)$ using Eq. 18. Then, using the zero-one jump law (Kingman, 1992) we can write:

$$\begin{aligned} & J(\boldsymbol{\lambda}(t) + d\boldsymbol{\lambda}(t), t + dt) = J(\boldsymbol{\lambda}(t) + m(t)\, dt + \boldsymbol{B}\, d\boldsymbol{N}(t) + \boldsymbol{B}\, d\boldsymbol{P}(t), t + dt) \\ & = \sum_i J(\boldsymbol{\lambda}(t) + m(t)\, dt + \boldsymbol{b}_i, t + dt)dN_i(t) + \sum_i J(\boldsymbol{\lambda}(t) + m(t)\, dt + \boldsymbol{b}_i, t + dt)dP_i(t) \\ & \quad + J(\boldsymbol{\lambda}(t) + m(t)\, dt, t + dt)\prod_i [1 - dN_i(t)][1 - dP_i(t)] \\ & = J(\boldsymbol{\lambda}(t) + m(t)\, dt, t + dt)[1 - \sum_i dN_i(t) + dP_i(t)] + \sum_i J(\boldsymbol{\lambda}(t) + m(t)\, dt + \boldsymbol{b}_i, t + dt)[dN_i(t) + dP_i(t)] \\ & = J(\boldsymbol{\lambda}(t) + m(t)\, dt, t + dt) + \sum_i [J(\boldsymbol{\lambda}(t) + m(t)\, dt + \boldsymbol{b}_i, t + dt) - J(\boldsymbol{\lambda}(t) + m(t)\, dt, t + dt)][dN_i(t) + dP_i(t)] \end{aligned}$$

where $m(t) := \omega\boldsymbol{\lambda}_0 - \omega\boldsymbol{\lambda}(t)$ and we used that the bilinear differential form $dt\, dN(t) = 0$ (Hanson, 2007). By total derivative rule, it follows that

$$\begin{aligned} J(\boldsymbol{\lambda}(t) + m(t)\, dt + \boldsymbol{b}_i, t + dt) &= J(\boldsymbol{\lambda}(t) + \boldsymbol{b}_i, t) + \nabla_{\boldsymbol{\lambda}} J(\boldsymbol{\lambda}(t) + \boldsymbol{b}_i, t)m(t)\, dt + J_t(\boldsymbol{\lambda}(t) + \boldsymbol{b}_i, t)\, dt \\ J(\boldsymbol{\lambda}(t) + m(t)\, dt, t + dt) &= J(\boldsymbol{\lambda}(t), t) + \nabla_{\boldsymbol{\lambda}} J(\boldsymbol{\lambda}(t), t)m(t)\, dt + J_t(\boldsymbol{\lambda}(t), t)\, dt. \end{aligned}$$

Then, the differential is given by:

$$dJ(\boldsymbol{\lambda}(t) + d\boldsymbol{\lambda}(t), t + dt) = J(\boldsymbol{\lambda}(t), t) + (\omega\boldsymbol{\lambda}_0 - \omega\boldsymbol{\lambda}(t))^T \nabla_{\boldsymbol{\lambda}} J(\boldsymbol{\lambda}(t), t)\, dt + J_t(\boldsymbol{\lambda}(t), t)\, dt + \sum_i \left[J(\boldsymbol{\lambda}(t) + \boldsymbol{b}_i, t) - J(\boldsymbol{\lambda}(t), t)\right] \left[dN_i(t) + dP_i(t)\right],$$

which completes the proof.

Appendix F. Proof of $(\Delta_B J)_i \leq 0$

Lets $t < s$, then according to the definition we can write,

$$\boldsymbol{\lambda}(s) = \boldsymbol{\lambda}_0 + \int_0^s \kappa_\omega(s-\tau)\, \boldsymbol{B}\, d\boldsymbol{N}(\tau) = \boldsymbol{\lambda}_0 + \int_0^t \kappa_\omega(s-\tau)\, \boldsymbol{B}\, d\boldsymbol{N}(\tau) + \int_t^s \kappa_\omega(s-\tau)\, \boldsymbol{B}\, d\boldsymbol{N}(\tau).$$

For the exponential kernel $\kappa_\omega(t) = e^{-wt}$ we have,

$$\int_0^t \kappa_\omega(s-\tau)\, \boldsymbol{B}\, d\boldsymbol{N}(\tau) = \int_0^t e^{-w(s-\tau)}\, \boldsymbol{B}\, d\boldsymbol{N}(\tau) = e^{-w(s-t)} \int_0^t e^{-w(t-\tau)}\, \boldsymbol{B}\, d\boldsymbol{N}(\tau) = e^{-w(s-t)}(\boldsymbol{\lambda}(t) - \boldsymbol{\lambda}_0)$$

so given the value of $\boldsymbol{\lambda}(t)$ at time t then we can write $\boldsymbol{\lambda}(s)$ for later times as

$$\boldsymbol{\lambda}(s) = \boldsymbol{\lambda}_0 + e^{-w(s-t)}(\boldsymbol{\lambda}(t) - \boldsymbol{\lambda}_0) + \int_t^s \kappa_\omega(s-\tau)\, \boldsymbol{B}\, d\boldsymbol{N}(\tau)$$

Lets consider a process $\boldsymbol{\xi}(s)$ with intensity value at time t equal to $\boldsymbol{\lambda}(t) + \boldsymbol{b}_i$ as,

$$\boldsymbol{\xi}(s) = \boldsymbol{\lambda}_0 + e^{-w(s-t)}(\boldsymbol{\lambda}(t) + \boldsymbol{b}_i - \boldsymbol{\lambda}_0) + \int_t^s \kappa_\omega(s-\tau)\, \boldsymbol{B}\, d\boldsymbol{N}(\tau).$$

Since $\boldsymbol{b}_i \succeq 0$, then given the same history in interval (t, s), we have $\boldsymbol{\xi}(s) \succeq \boldsymbol{\lambda}(s)$. Then, we have:

$$\ell(\boldsymbol{\xi}(s), \boldsymbol{u}(s)) \leq \ell(\boldsymbol{\lambda}(s), \boldsymbol{u}(s)).$$

Now, taking the integration, then expectation (over all histories) and finally the minimization from the above inequality does not change the direction of inequality. So it readily follows the required result.

$$J(\boldsymbol{\lambda}(t) + \boldsymbol{b}_i, t) \leq J(\boldsymbol{\lambda}(t), t).$$

Appendix G. Proof of Lemma 10

Consider the following proposal of degree three for the cost-to-go function:

$$J(\boldsymbol{\lambda}(t), t) = f(t) + \sum_i g_i(t)\lambda_i(t) + \sum_i \sum_j \lambda_i(t)\lambda_j(t) H_{ij}(t) + \sum_i \sum_j \sum_k \lambda_i(t)\lambda_j(t)\lambda_k(t) H_{ijk}(t)$$

If we plug this proposal in Eq. 22, and evaluate the coefficient of fourth degree terms like $\lambda_i^2(t)\lambda_j^2(t)$ and equate them to zero, then we can find the unknown coefficients $H_{ijk}(t)$'s as follows:

$$\forall i, j, t: \ \sum_k \big(\sum_\ell B_{\ell k}^2\big) H_{ijk}^2(t) = 0$$

Since the sum of positives terms is zero if and only if they all be zero, then $H_{ijk}(t)$ and consequently the terms with degree three in the proposal are all zero. So the proposal reduces to a quadratic proposal.

It is quite straightforward to extend this argument for proposals with order $m > 3$ and by equating the degree $2m-1$ terms, similarly conclude that coefficients of degree m terms in the proposal are zero. If we repeat this argument for $m-1, \ldots, 3$, we deduce that any proposal with arbitrary degree $m \geq 2$, would result in a quadratic optimal cost.

Abstract

We consider the task of learning the parameters of a *single* component of a mixture model, for the case when we are given *side information* about that component; we call this the "search problem" in mixture models. We would like to solve this with computational and sample complexity lower than solving the overall original problem, where one learns parameters of all components.

Our main contributions are the development of a simple but general model for the notion of side information, and a corresponding simple matrix-based algorithm for solving the search problem in this general setting. We then specialize this model and algorithm to four common scenarios: Gaussian mixture models, LDA topic models, subspace clustering, and mixed linear regression. For each one of these we show that if (and only if) the side information is informative, we obtain parameter estimates with greater accuracy, and also improved computation complexity than existing moment based mixture model algorithms (e.g. tensor methods). We also illustrate several natural ways one can obtain such side information, for specific problem instances. Our experiments on real data sets (NY Times, Yelp, BSDS500) further demonstrate the practicality of our algorithms showing significant improvement in runtime and accuracy.

Keywords: mixture models, search, side information, semi-supervised, method of moments

1. Introduction

Mixture models denote the statistical setting where observed samples can come from one of several distinct underlying populations—each typically with its own probability distribution—but are not labeled as separate in the data presented. They have been used to model a wide variety of phenomena, and have seen great success in practice, going back as far as Pearson (1894). In this paper we consider (what we call) the **search problem** in the mixture model setting: given some *special side information* about one of the mixture components, is it possible to efficiently learn the parameters of that component only? Given that there are known methods for learning the entire set of parameters of various mixture models, "efficient" here means more efficient (statistically and/or computationally) than existing methods for learning all the parameters.

As an example, we consider the "latent Dirichlet allocation" model for document generation. In this model, "underlying population" means the set of topics in a document, which determines the frequencies of different words in the document. "Side information" could be a word that is more common in the topic of interest than it is in any other topic: for example, the word "semi-supervised" might work if the topic of interest is machine learning.

Side information could also consist of a small number of labelled examples. We might have a small collection of documents about machine learning and also a much larger corpus that includes documents from many topics. Our methods will allow us to leverage the large, unlabelled corpus to obtain good estimates for word frequencies in machine learning articles—and these estimates will be much better than anything that could be learned from the small labelled sample.

Main contributions: We propose a general setting for side information in mixture models, and show how to solve the search problem by estimating certain matrices of moments. We prove error bounds on the resulting estimates; our rates have a sharp dependence on the sample size (although they are possibly not sharp in the other parameters).

We then specialize our approach to four popular families of mixture models: Gaussian mixture models with spherical covariances, latent Dirichlet allocation for topic models, mixed linear regression, and subspace clustering. We give concrete algorithms for these four families. Our results also include new moment derivations for mixed linear regression and subspace clustering models.

Finally, we simulate our algorithm on both real and synthetic data sets for the Gaussian mixture model, topic model, and subspace clustering applications. For synthetic data set we compare its performance to the tensor decomposition methods discussed by Anandkumar et al. (2014) in both GMM and LDA models, and k-means for subspace clustering. We show that our methods outperform the baseline when the side information is informative. We also demonstrate the practical applicability of our algorithms on three real data sets—the NY Times data set of news articles, Yelp data set of business reviews, and BSDS500 data set of images. In the first two text corpus, we show our algorithm recovers more coherent topics than topic modeling algorithm by Arora et al. (2013). In the BSDS500 data set, we demonstrate how our algorithm can be used for parallel image segmentation. In all three cases, our algorithm also exhibits significant computational gains over competing unsupervised and semi-supervised algorithms.

1.1 Related Work

There is a vast literature on mixture models; too much to even summarize here. We will therefore focus this section on two more closely related areas: method of moments estimators for mixture models, and learning with side information.

Mixture models and method of moments: A common method for learning mixture models is the EM algorithm of Dempster et al. (1977), which outputs a complete set of model parameters. However, EM may converge slowly (or not at all) [Redner and Walker 1984]; this weakness of EM has spurred a resurgence in method-of-moments estimators for mixture models. Although these methods go back to the pioneering work of Pearson (1894) on Gaussian mixture models, the last several years have seen important advances. Moitra and Valiant (2010), and Hardt and Price (2015) showed that Gaussian mixture models with two components can be learned in polynomial time. Hsu and Kakade (2013) considered mixtures of more Gaussians, but constrained to have spherical covariances. They gave a method based on third-order tensor decompositions, which was later generalized to other models in Anandkumar et al. (2014).

Learning with side information: As has been observed many times, often in practice one has access to a set of data that is somewhat richer than standard models of data in learning theory. The term *side information* is used as a catch-all for extra data that doesn't fit into pre-existing models; as such, the literature contains many incomparable models of side information.

Xing et al. (2002) and Yang et al. (2010) took unsupervised clustering as their starting point. For them, side information arrived as pairs of points that were known to belong to the same cluster; they showed how this extra information could substantially improve the performance of the k-means algorithm.

Kuusela and Ocone (2004) developed a framework for side information in the PAC learning model, in which extra samples with a particular dependence on the original samples could sometimes give a substantial benefit.

Many different types of metadata have been proposed for the *latent Dirichlet allocation* (LDA) model of document generation. Mcauliffe and Blei (2008) introduced the *supervised LDA* model, in which each document comes with an additional response variable from a generalized linear model. On the other hand Rosen-Zvi et al. (2004) proposed the *author-topic model*, in which the metadata (author names) affects the distribution of the documents themselves. From a more experimental point of view, Lu and Zhai (2008) used long, detailed product reviews as side information for categorizing short snippets and blog entries.

The notion of *semi-supervised learning* (see the book by Chapelle et al. (2006)) is also related to our framework of side information. In semi-supervised learning, the learner has access to a small number of labelled examples and a large number of unlabelled examples. This setting is useful for us too, although our general method does not strictly require data of this form.

2. Basic Idea and Algorithm

We now first briefly describe the basic mixture model setting, and then describe our method. These descriptions cover several popular specific examples for mixture models, and we detail the application to each of them in Section 3.

Setting: We are interested in the standard statistical setting of (parametric) mixture models: that is, samples are drawn i.i.d. from a distribution f given by

$$f(x) \;=\; \sum_{i=1}^{k} \alpha_i \, g(x;\mu_i).$$

Here g corresponds to a known parametric class of distributions, and k is the number of mixture components. The corresponding parameter vectors are $\mu_1, \ldots, \mu_k$, and their mixture weights / probabilities are $\alpha_1, \ldots, \alpha_k$. So, for example, in the case of the standard (spherical) Gaussian mixture model, $g(x;\mu_i)$ is the Gaussian pdf $\mathcal{N}(\mu_i, I)$. Thus each sample can be considered to be drawn by first selecting a mixture component μ_i with probability α_i, and then drawing the sample x according to $g(x;\mu_i)$. We assume all the μ_i's are *linearly independent*. This is a common assumption for learning mixture models using spectral methods.

Search problem: The standard parameter estimation problem is to find all the μ_i vectors given samples. In this paper we are interested in the search problem: we are given *side information* about one of the vectors—say μ_1, without loss of generality—and we would like to recover *only* μ_1. Of course, we would like to do this with sample and computational complexity lower than what would be required to estimate all parameter vectors (i.e., lower complexity than the standard case).

Side information: Our general procedure requires the following model for side information: we assume that we have access to a vector v such that the inner product with the parameter vector μ_1—the special one we are searching for—is higher than the inner product with any of the other μ_i; i.e. there exists $\delta > 0$ such that;

$$\langle \mu_1, v\rangle \geq \; (1+\delta)\langle \mu_i, v\rangle \quad \text{for all } i \neq 1$$

Section 3 shows how to obtain such side information in some specific models of interest: spherical Gaussian mixture models, mixed linear regression, subspace clustering and the LDA topic model.

We remark that it's also possible (and perhaps more intuitive in some situations) to ask for side information satisfying $|\langle \mu_1, v\rangle| \geq (1+\delta)|\langle \mu_i, v\rangle|$. However, our assumption above is slightly weaker, since for any v satisfying the latter assumption, either v or $-v$ satisfies the former assumption. Later, we show the above condition is sufficient for uniquely identifying the required parameter μ_1 (but it may not be necessary). We refer side information vector v as *informative* about μ_1 if it satisfies the above condition.

2.1 General Procedure

The main idea behind method of moments is to use samples to estimate certain moments of the distribution $f(x)$, using which we can recover the parameters of interest. For many mixture models (including the four common examples we detail), it is possible to easily and directly estimate using first and second order moments, given sufficient samples, the vector

$$m := \sum_{i=1}^{k} \alpha_i \mu_i. \tag{1}$$

and the matrix

$$A := \sum_{i=1}^{k} \alpha_i \mu_i \mu_i^T. \tag{2}$$

For example, in many models the estimate of vector m is simply the sample mean, and matrix A can be derived from the sample covariance matrix. The exact procedure for estimating m and A varies according to the particular parametric model g. The fact that m and A (and also higher-order tensors) can be estimated from samples is well known for many models, see Anandkumar et al. (2014) for a treatment of several different models, and for other pointers to the literature.

Typically, all mixture model components cannot be identified from just the first and second order moments (or m and A). It is often necessary to compute even higher order moment terms. In our search problem, given the side information, **we develop** procedures to estimate an alternative matrix B, using higher order moments, given by

$$B := \sum_{i=1}^{k} \alpha_i \langle \mu_i, v \rangle \mu_i \mu_i^T \tag{3}$$

Again, the exact procedure for estimating B from samples depends on the particular parametric model g.

For this section, we assume we are able to estimate A, B, m to within some accuracy. We will use the notation $\hat{A}, \hat{B}, \hat{m}$ to denote these finite sample estimates of A, B, m respectively, and n denotes the number of samples used to compute these estimates. With this in hand, we outline two general procedures for estimating μ_1 (i.e. the component that we are interested in). The first procedure is based on a whitening step, much like the one that is used in the spectral algorithms in Hsu and Kakade (2013); Anandkumar et al. (2012), and tensor decomposition methods of Anandkumar et al. (2014) (please see remarks in Section 3 for the differences for specific models). The second procedure uses a line search instead, and may be computationally favorable when k is large, because it avoids the need to invert a $k \times k$ matrix. Both Algorithms 1 and 2 take as input the estimates $\hat{A}, \hat{B}, \hat{m}$ (where $\hat{B}$ is constructed using side information vector v) and they output estimates of the first mixture component $\hat{\mu}_1$, and also the proportion of the first component $\hat{\alpha}_1$.

2.1.1 The Whitening Method

Our main result about Algorithm 1 is that if $\hat{A}$ and $\hat{B}$ are good estimates of A and B then Algorithm 1 outputs good estimates for μ_1 and α_1. In order to interpret Theorem 1 as an error rate, note that if all parameters but ϵ are fixed then the error is $O(\epsilon)$. Since standard concentration results yield $\epsilon = O(n^{-1/2})$, where n is the number of samples; our error rate in terms of n is also $O(n^{-1/2})$. This rate is sharp, since it is also the rate for estimating the mean of a single Gaussian vector (i.e. a GMM with only one component).

Theorem 1 *Suppose that $\mu_1, \ldots, \mu_k$ are linearly independent, and that $\hat{A}$ is positive semi-definite. Also suppose that $\langle \mu_1, v \rangle \geq (1+\delta)\langle \mu_i, v \rangle$ for all $i \neq 1$. Assume that*

$$\max\{\|A - \hat{A}\|, \|B - \hat{B}\|, \|m - \hat{m}\|\} \leq \epsilon < \sigma_k(A)/4,$$

Algorithm 1 Extracting a mixture component from side information: the whitening method.

Input: $\hat{A}, \hat{B}, \hat{m}$

Output: $\hat{\mu}_1, \hat{\alpha}_1$

1: let $\{\sigma_j, v_j\}$ be the singular values and singular vectors of $\hat{A}$, in non-increasing order
2: let V be the $d \times k$ matrix whose jth column is v_j
3: let D be the $k \times k$ diagonal matrix with $D_{jj} = \sigma_j$
4: let u be the largest eigenvector of $D^{-1/2} V^T \hat{B} V D^{-1/2}$
5: let $w = V D^{1/2} u$
6: let E be the span of $\{V D^{1/2} v : v \perp u\}$
7: write $V V^T \hat{m}$ (uniquely) as $aw + y$, where $y \in E$
8: return w/a and a^2

and that the right hand side of (4) *is at most α_1. Then*

$$\|\mu_1 - \hat{\mu}_1\| \leq CR|\alpha_1^{-1/2} - \hat{\alpha}_1^{-1/2}| + C\frac{\sqrt{\sigma_1(A)}}{\sqrt{\alpha_1}}\eta \quad , \text{ and}$$

$$|\alpha_1 - \hat{\alpha}_1| \leq \frac{C\sqrt{\alpha_1}(\alpha_1 R + \eta)}{\sigma_k(A)} \left(\eta + R\frac{\epsilon}{\sigma_k(A)} + \epsilon \right) \tag{4}$$

where $\eta = \frac{\epsilon \sigma_1}{\delta \sigma_k^{5/2}}$, $R = \max_i \|\mu_i\|$, $\sigma_1(A) \geq \cdots \geq \sigma_k(A) > 0$ are the non-zero singular values of $A = \sum_i \alpha_i \mu_i \mu_i^T$, and C is a universal constant.

Our error bounds are somewhat complicated, and depend on many different parameters, so let us elaborate on them slightly. First of all, the dependence on $\sigma_1(A)$ and $\sigma_k(A)$ is of the order $\|\mu_1 - \hat{\mu}_1\| \lesssim \sigma_1(A)^{3/2}/\sigma_k(A)^{5/2}$, which is probably an artifact of the analysis, and not the true behavior of the algorithm. On the other hand, our dependence on ϵ is optimal: we have $|\alpha_1 - \hat{\alpha}_1| \lesssim \epsilon$ and $\|\mu_1 - \hat{\mu}_1\| \lesssim \epsilon$. Note also that our bound has no explicit dependence on k; this feature comes from the fact that our method is targeted at a single mixture component. By comparison, other methods typically give bounds in which the *averaged* per-mixture-component error does not depend on k. In terms of dependence on k, therefore, our bounds are better than previous bounds if there is only one component of interest.

Finally, let us remark on the assumption that the right hand side of (4) is at most α_1. This amounts to an assumption that ϵ is sufficiently small compared to all the other parameters. Without this assumption, the bound in (4) would not be very interesting, since $|\alpha_1 - \hat{\alpha}_1| \leq \alpha_1$ is too weak to give useful information about $\hat{\alpha}_1$ (it could even be zero).

We defer the actual analysis of Algorithm 1 to the appendix, but we will motivate the algorithm and give the basic idea of the proof by showing that if $\hat{A}, \hat{B}$, and $\hat{m}$ are equal to A, B and m respectively then Algorithm 1 outputs μ_1 and α_1 exactly.

Lemma 2 *Let m, A, and B be defined by in* (1), (2), *and* (3), *where $\mu_1, \ldots, \mu_k$ are linearly independent. If $\langle \mu_1, v \rangle > \langle \mu_i, v \rangle$ for all $i \neq 1$ and we apply Algorithm 1 to A, B, and m, then it returns μ_1 and α_1.*

Proof Let V and D be as defined in Algorithm 1. Since A has rank k,

$$\sum_{i=1}^{k} \alpha_i D^{-1/2} V^T \mu_i \mu_i^T V D^{-1/2} = D^{-1/2} V^T A V D^{-1/2} = I_k.$$

Defining $u_i := \sqrt{\alpha_i} D^{-1/2} V^T \mu_i$, we have $\sum_i u_i u_i^T = I_k$, which implies that the u_i are orthonormal in $\mathbb{R}^k$. Now,

$$D^{-1/2} V^T B V D^{-1/2} = \sum_{i=1}^{k} \alpha_i \langle \mu_i, v \rangle D^{-1/2} V^T \mu_i \mu_i^T V D^{-1/2} = \sum_{i=1}^{k} \langle \mu_i, v \rangle u_i u_i^T.$$

Since $\langle \mu_1, v \rangle$ was assumed to be larger than all other $\langle \mu_i, v \rangle$, it follows that u_1 is the largest eigenvector of $D^{-1/2} V^T B V D^{-1/2}$. Now, if $w = V D^{1/2} u_1$ then $w = \sqrt{\alpha_1}\mu_1$.

Now, note that since the μ_i are linearly independent, there is a unique way to write $m = V V^T m = \sum_i \alpha_i \mu_1$ as $aw + y$, where y belongs to the span of $\{\mu_2, \ldots, \mu_k\}$ (which is the same as the span of $\{V D^{1/2} u_i : i \geq 2\}$. Moreover, the unique choice of a that allows this representation must satisfy $aw = \alpha_1 \mu_1$, which implies that $a = \sqrt{\alpha_1}$. Therefore, $w/a = \mu_1$ and $a^2 = \alpha_1$. ■

The proof of Lemma 2 is crucial to understanding the algorithm, and also the broader message of this article: if we can get hold of two different normalizations of something, then we can learn something about it. In the proof of Lemma 2, this happens twice: first, we use the fact that A and B contain the same components (but with differing normalizations) to extract the span of a single component of interest. The differing normalization is crucial, because A by itself does not uniquely determine the set $\{\mu_1, \ldots, \mu_k\}$, much less single out a specific component of interest.

In the second step of Lemma 2, we know $\sqrt{\alpha_1}\mu_1$, which is not enough to determine either α_1 or μ_1. However, we also have access to m, which involves a contribution of $\alpha_1 \mu_1$. Exploiting the difference between these two normalizations, we recover both α_1 and μ_1.

2.1.2 The Cancellation Method

Our second method avoids the matrix inversion in Algorithm 1, preferring a line search instead.

In the above Algorithm 2, we assume $\langle \mu_1, v \rangle > 0$. When this is not the case and B is a negative semi-definite matrix, we simply have to change the line search step to search for the smallest $\lambda < 0$ such that $\widehat{V}\widehat{V}^T(\widehat{A} - \lambda \widehat{B})\widehat{V}\widehat{V}^T$ is PSD. Theorem 3 shows that with m, A, B estimated up to $O(\epsilon)$ error, the parameter estimation error in Algorithm 2 is also bounded as $O(\epsilon)$.

Theorem 3 *Suppose $\{\mu_1, \ldots, \mu_k\}$ are linearly independent and v satisfies $\langle \mu_1, v \rangle \geq (1 + \delta)\langle \mu_i, v \rangle$ for all $i \neq 1$. Suppose that $\max\{\|\widehat{A} - A\|, \|\widehat{B} - B\|, \|\hat{m} - m\|\} < \epsilon$, and $\lambda_1 := 1/\langle \mu_1, v \rangle$. Then Algorithm 2 returns $\hat{\mu}_1, \hat{\alpha}_1$ with*

$$\begin{aligned} \|\hat{\mu}_1 - \mu_1\| &< \frac{C\epsilon}{\alpha_1^2 a_1^2}\left(\sigma_1(A)\left(1 + \frac{\alpha_1 a_1}{\sigma_{k-1}(Z_{\lambda_1})}\right) + \frac{\sigma_1(A)\eta_3 R}{\sigma_{k-1}(Z_{\lambda_1})}\right) \\ |\hat{\alpha}_1 - \alpha_1| &< \frac{C\sigma_1(A)\epsilon}{\alpha_1 a_1^3}\left(\eta_1 + \frac{\eta_2 R \eta_3}{\sigma_{k-1}(Z_{\lambda_1})}\right) \end{aligned}$$

Algorithm 2 Extracting a mixture component from side information: the cancellation method.

Input: $\hat{A}, \hat{B}, \hat{m}$
Output: $\hat{\mu}_1, \hat{\alpha}_1$

1: let $\widehat{V}$ be the $d \times k$ matrix of k largest eigenvectors of $\hat{A}$;
2: search over λ to find the largest $\lambda = \lambda^*$ such that $\widehat{V}\widehat{V}^T(\widehat{A} - \lambda\widehat{B})\widehat{V}\widehat{V}^T$ is PSD;
3: let $\widehat{Z}_{\lambda^*} = \widehat{A} - \lambda^* \widehat{B}$, and let $\{v_2, \ldots, v_k\}$ be the top $k-1$ singular vectors of $\widehat{Z}_{\lambda^*}$
4: let $V_{1:(k-1)}$ be the $d \times (k-1)$ matrix with columns $\{v_2, \ldots, v_k\}$
5: let $x_1 = \hat{m} - V_{1:(k-1)} V_{1:(k-1)}^T \hat{m}$
6: let $v_1 = x_1 / \|x_1\|$
7: compute $c_i = v_1^T \widehat{A} v_i$ for $i = 1$ to k
8: let $a_i = c_i / \|x_1\|$ for $i = 1$ to k
9: return $\hat{\mu}_1 = \sum_{i=1}^{k} a_i v_i$ and $\hat{\alpha}_1 = c_1 / a_1^2$

where $\eta_1 := \max\{\alpha_1 a_1 (2a_1 + 1), 20\}$, $\eta_2 := \max\{\alpha_1 a_1^2, 10\}$, $\eta_3 = \max\{1, \lambda_1, \sigma_1(B)\}$, $R = \max \|\mu_i\|$, $a_1 = \|\mu_1 - \prod_{\mathcal{V}} \mu_1\|$, where $\mathcal{V} = span\{\mu_2, \ldots, \mu_k\}$, and C is an universal constant.

Again, we will defer the actual analysis to the appendix, and instead show that Algorithm 2 returns the exact answer when fed exact initial data. We will do this in two lemmas: Lemmas 4 and 5.

Lemma 4 *Let $Z = \sum_{i=1}^{k} \gamma_i \mu_i \mu_i^T$ where $\{\mu_1, \ldots, \mu_k\}$ are linearly independent, $\mu_i \in \mathbb{R}^d, \gamma_i \in \mathbb{R}$ and $d > k$. If $\gamma_1 < 0$ and $\gamma_i > 0$ for all $i \neq 1$ then Z is not positive semi-definite.*

Proof Let Π denote the projection onto the orthogonal complement of $\text{span}\{\mu_2, \ldots, \mu_k\}$. Let $x = \Pi \mu_1$, and note that $\langle x, \mu_1 \rangle > 0$ but $\langle x, \mu_i \rangle = 0$ for all $i \neq 1$. Hence, $x^T Z x = \gamma_1 \langle x, \mu_1 \rangle^2 < 0$ and so Z is not positive semi-definite. ■

Lemma 5 *Let m, A, and B be defined by in (1), (2), and (3), where $\mu_1, \ldots, \mu_k$ are linearly independent. If $\langle \mu_1, v \rangle > \langle \mu_i, v \rangle$ for all $i \neq 1$ and we apply Algorithm 2 to A, B, and m, then it returns μ_1 and α_1.*

Proof Define $w_i = \langle \mu_i, v \rangle$ and let $\gamma_i = \alpha_i(1 - \lambda w_i)$, so that

$$Z_\lambda = A - \lambda B = \sum_{i=1}^{k} \gamma_i \mu_i \mu_i^T.$$

Note that, in our case where $\widehat{A} = A$, and $\widehat{B} = B$, columns of $\widehat{V}$ simply form a common orthonormal bases of the row/column space of both matrices A, B. Therefore the matrix $\widehat{V}\widehat{V}^T(A - \lambda B)\widehat{V}\widehat{V}^T = A - \lambda B = Z_\lambda$. Now for $\lambda > \frac{1}{w_1}$, $\gamma_1 < 0$ and for all $\lambda \leq \frac{1}{w_1}$, $\gamma_i \geq 0$ for all i since $w_1 > w_i$, for every $i \neq 1$. By Lemma 4, $\lambda^* = \frac{1}{w_1}$ is the largest λ such that Z_λ is PSD; hence,

$$Z_{\lambda^*} = \sum_{i=2}^{k} \alpha_i (1 - \lambda^* w_i) \mu_i \mu_i^T.$$

From Lemma 26 in Appendix E.2 it follows that $k-1$ singular vectors $\{v_2, \ldots, v_k\}$ of Z_{λ^*} form a basis of the subspace $\mathcal{V} = \text{span}\{\mu_2, \ldots, \mu_k\}$. Let $\mathcal{V}_\perp$ be the perpendicular space of $\mathcal{V}$, and write $\Pi = I - V_{1:(k-1)} V_{1:(k-1)}^T$ for the orthogonal projection onto $\mathcal{V}_\perp$. Since $\Pi\mu_i = 0$ for $i \neq 1$, we have $x_1 = \Pi m = \alpha \Pi \mu_1$.

Now define $b_1, \ldots, b_k$ by $\mu_1 = \sum_{i=1}^k b_i v_i$. In order to prove that the algorithm returns μ_1 correctly, we need to show that $b_i = a_i := c_i/\|x_1\|$. Indeed,

$$c_i := v_1^T A v_i = \sum_{j=1}^k \alpha_j v_1^T \mu_j \mu_j^T v_i = \alpha_1 b_1 b_i,$$

since $v_1^T \mu_j = 0$ for $j \neq 1$. On the other hand, $\|x_1\| = \alpha \|\Pi \mu_1\| = \alpha b_1$, and so $b_i = a_i$, as claimed. Moreover, $\hat{\alpha}_1 = \frac{c_1}{a_1^2} = \alpha_1$, as claimed. ■

Optimization for λ^*: The first step of Algorithm 2 involves finding a smallest λ^* such that $\widehat{Z}'_{\lambda^*} = \widehat{V}\widehat{V}^T(\widehat{A} - \lambda^* \widehat{B})\widehat{V}\widehat{V}^T$ is PSD using line search. Although $\widehat{Z}'_\lambda$ is a $d \times d$ matrix, this step can be performed efficiently as follows. Instead of searching for λ directly for $\widehat{Z}'_\lambda$, we do this for a smaller $k \times k$ matrix $\widehat{V}^T \widehat{Z}'_\lambda \widehat{V} = \widehat{V}^T(\widehat{A} - \lambda^* \widehat{B})\widehat{V}$. This optimization step using line search can be performed in just $O(k^3 \log |\lambda^*|)$ time.

3. Specific Models

In this section we discuss how the search algorithms can be applied in four specific mixture models.

3.1 Gaussian Mixture Model with Spherical Covariance

The model: Besides the mixture parameters $\alpha_1, \ldots, \alpha_k$, the Gaussian mixture model (GMM) has mean parameters $\mu_1, \ldots, \mu_k \in \mathbb{R}^d$ and variance parameters $\sigma_1, \ldots, \sigma_k \in \mathbb{R}$. The conditional densities $g(\cdot; \mu_i, \sigma_i)$ are Gaussian, with mean μ_i and covariance $\sigma_i^2 I_d$. Explicitly,

$$g(x; \mu_i, \sigma_i) = \frac{1}{(2\pi\sigma_i^2)^{d/2}} e^{-\frac{\|x-\mu_i\|^2}{2\sigma_i^2}}.$$

Matrices A and B: We fix a vector $v \in \mathbb{R}^d$, with the assumption that $\langle v, \mu_1 \rangle > \langle v, \mu_i \rangle$ for $i \neq 1$. Recall (from Section 2.1) that $m = \mathbb{E}[x] = \sum_i \alpha_i \mu_i$, $A = \sum_{i=1}^k \alpha_i \mu_i \mu_i^T$, and $B = \sum_{i=1}^k \alpha_i \langle \mu_i, v \rangle \mu_i \mu_i^T$. To compute these quantities, we first define σ^2 to be the $(k+1)$th-largest eigenvalue of the mixture covariance matrix $\mathbb{E}[(x-m)(x-m)^T]$, and let u be a corresponding eigenvector. Then let $\widetilde{m} = \mathbb{E}[x(u^T(x-m))^2]$. Then it follows from moment computations (see Hsu and Kakade (2013)) that:

$$\begin{aligned} A &= \mathbb{E}[xx^T] - \sigma^2 I_d \\ B &= \mathbb{E}[\langle x, v \rangle xx^T] - \widetilde{m}v^T - v\widetilde{m}^T - \langle \widetilde{m}, v \rangle I_d, \end{aligned}$$

Given the samples $\{\hat{x}_i\}$, we can now empirically evaluate these quantities (denoted by $\hat{m}, \hat{A}, \hat{B}$ respectively) by replacing expectations above by the corresponding sample averages; for instance we replace $\mathbb{E}[xx^T]$ by $\widehat{\mathbb{E}}[xx^T] \doteq (1/n) \sum_{j=1}^n \hat{x}_j \hat{x}_j^T$.

Examples of v: Assuming that $\|\mu_1\|^2 > \langle \mu_1, \mu_i \rangle$ for all $i \neq 1$—this will be true, for example, if $\|\mu_i\|$ are all the same—one can find a suitable vector v given a relatively small number of samples from the first mixture component. Specifically, if $\|\mu_1\|^2 \geq \langle \mu_1, \mu_i \rangle + \delta$ and $\|\mu_i\| \leq R$ for all $i \neq 1$ then standard Gaussian tail bounds imply the following: if $v := \ell^{-1} \sum_{j=1}^\ell x_j$ where $\ell = \Omega(R^2 \delta^{-2} \log k)$ and $x_1, \ldots, x_m$ are drawn independently from the distribution $g(\cdot; \mu_1, \sigma_1)$ then with high probability v satisfies $\langle v, \mu_1 \rangle > \langle v, \mu_i \rangle$ for all $i \neq 1$. Here, "high probability" means probability converging to 1 as the hidden constant in $\ell = \Omega(\cdot)$ grows. Note here that the number of tagged samples is nowhere near sufficient to estimate μ_1 by direct averaging; indeed to do so would require the number of samples to grow with the size of the underlying dimension.

Remarks: We note that spectral algorithms which uses the whitening procedure has been proposed before in the context of GMM e.g. Hsu and Kakade (2013). The primary difference between the algorithm in Hsu and Kakade (2013) and Algorithm 1 is that the former, in absence of side information, takes a projection of the third order moment tensor M_3 on a random unit vector to obtain the second matrix, where as our matrix B can be viewed as a projection of M_3 on the side information vector v. The main advantage of projecting onto v is that, when we have reliable side information, this will give a good singular value separation resulting in better empirical performance. The Cancellation algorithm however is distinctly different from both and has not been studied before.

3.2 Latent Dirichlet Allocation

The model: In the LDA model with k topics and a dictionary of size d, the parameters $\mu_1, \ldots, \mu_k \in \Delta_{d-1}$ are the probability distributions corresponding to each topic (Δ_{d-1} denotes the probability simplex $\{y \in \mathbb{R}^d : \sum_i y_i = 1, \min_i y_i \geq 0\}$). The LDA model introduced in Blei et al. (2003) differs slightly from the other models as the mixture distribution cannot be expressed exactly in the parametric form in Section 2. Instead we have a two level hierarchy as follows. Given $\bar{\alpha} = (\alpha_1, \ldots, \alpha_k)$, we first draw a topic distribution θ from the Dirichlet$(\bar{\alpha})$ distribution. Given this $\theta = (\theta_1, \ldots, \theta_k)$ each word in the document is drawn i.i.d. from the distribution $\sum_{i=1}^k \theta_i \mu_i$. However still we can compute the vector m and the matrices A, B as shown below. Then with an appropriate v our algorithms can recover the topic distribution μ_1.

Matrices A and B: Let x_1 denote the random vector with $x_1(w) = 1$ if the first word is w, and 0 otherwise. Similarly define vectors x_2, x_3 corresponding to the second and third word respectively, and let $\alpha_0 = \sum_{i=1}^k \alpha_i$. Then, moment computations under the LDA distribution yields the following expressions for (m, A, B), defined in (1), (2), (3):

$$\begin{aligned} &m = \alpha_0 \mathbb{E}[x_1], \quad A = \alpha_0(\alpha_0+1)\mathbb{E}[x_1 x_2^T] - mm^T \\ &B = \frac{\alpha_0(\alpha_0+1)(\alpha_0+2)}{2} \mathbb{E}[\langle x_3, v \rangle x_1 x_2^T] - \frac{\alpha_0(\alpha_0+1)}{2} \left(\langle m, v \rangle \mathbb{E}[x_1 x_2^T] + \mathbb{E}[\langle x_3, v \rangle x_1 m^T] \right. \\ &\quad \left. + \mathbb{E}[\langle x_3, v \rangle m x_2^T] \right) + \langle m, v \rangle mm^T. \end{aligned}$$

With the given document samples, let $\hat{x}_i$ denote the normalized empirical word frequencies in the document i. Then, $\hat{m} = \frac{\alpha_0}{n} \sum_{i=1}^n \hat{x}_i$, and $\widehat{A}, \widehat{B}$ can be immediately estimated using the above expressions by replacing expectations with sample averages.

Using labeled words to find v: In order to recover the topic distribution μ_1 we now require a vector v which satisfies $\langle \mu_1, v\rangle > \langle \mu_i, v\rangle$ for $i \neq 1$. Now suppose we are given a *labeled word* ℓ such that its occurrence probability in topic 1 is the highest, i.e., $\mu_1(\ell) > \mu_i(\ell)$ for $i \neq 1$ (note that this does not mean ℓ is the most frequent word in topic 1, there may be words with higher occurrence probability in this topic). Then we can simply choose $v = e_\ell$ (the standard basis element with 1 in the ℓ-th coordinate). For most topics of practical interest it is possible to find such labeled words. For example the word "ball" can be a labeled word for topic sport, "party" is a labeled word for topic politics and so on. However, a labeled word is merely indicative of a topic and is not exclusive to a topic (e.g. the word "ball" can occur in other contexts as well). In this sense, the labelled word is quite different from the "anchor word" described in Arora et al. (2013). Note however that anchor words are also labeled words (but *not* vice-versa) since for an anchor word ℓ, $\mu_1(\ell) > 0$ and $\mu_i(\ell) = 0$ for $i \neq 1$.

Using labeled documents to find v: If the different topics are not too similar, then we can estimate a suitable vector v from a small collection of documents that are mostly about the topic of interest. For example, if $\langle \mu_i, \mu_j\rangle \leq \eta\|\mu_i\|\|\mu_j\|$ for all $i \neq j$, and if we observe a total of m words from some collection of documents with $\theta_1 \geq (1+\delta)(1/2+\eta)$ then about $m = \Omega(\delta^{-2}\log k)$ words will suffice to find a suitable vector v.

Remarks: Similar to the case of GMM, a spectral algorithm using whitening procedure to estimate LDA components have been presented before in Anandkumar et al. (2012). Again the main difference with our Whitening algorithm being the fact that in Anandkumar et al. (2012) the second matrix is constructed by taking a random projection of the third order moment tensor *Triples*, and in Algorithm 1 this is constructed as a projection onto v. Empirically this results is a more stable algorithm due to guaranteed singular value separation. The Cancellation algorithm has not been previously studied in LDA model.

3.3 Mixed Regression

The model: In mixed linear regression the mixture samples generated are of the form $y = \langle x, \mu_i\rangle + \xi$, where $x \sim \mathcal{N}(0, I)$ and noise $\xi \sim \mathcal{N}(0, \sigma^2)$. As before, a sample is generated using the i-th linear component μ_i, with probability α_i. We have access to the observations (y, x) but the particular μ_i and ξ are unknown. Hence the conditional density $g(x, y; \mu_i, \sigma)$ is a multivariate Gaussian where $x \sim \mathcal{N}(0, I)$, $y \sim \mathcal{N}(0, \|\mu_i\|^2 + \sigma^2)$, and $\mathrm{Cov}(x, y) = \mu_i$.

Matrices A and B: To compute A and B, we consider the following moments (for more detailed derivations, see Appendix C):

$$M_{1,1} = \mathbb{E}[yx] = \sum_{i=1}^{k} \alpha_i \mu_i$$

$$M_{2,2} = \mathbb{E}[y^2 xx^T] = 2\sum_{i=1}^{k} \alpha_i \mu_i \mu_i^T + \sum_{i=1}^{k} \alpha_i(\sigma^2 + \|\mu_i\|^2) I$$

$$M_{3,1} = \mathbb{E}[y^3 x] = 3\sum_{i=1}^{k} \alpha_i(\sigma^2 + \|\mu_i\|^2)\mu_i$$

$$M_{3,3} = \mathbb{E}[y^3\langle x, v\rangle xx^T] = 6\sum_{i=1}^{k} \alpha_i \langle \mu_i, v\rangle \mu_i \mu_i^T + \left(M_{3,1}v^T + vM_{3,1}^T + \langle M_{3,1}, v\rangle I\right)$$

Let τ^2 be the smallest singular value of the matrix $M_{2,2}$. Then we can compute m, A, B as follows.

$$\begin{aligned} m &= M_{1,1}, \quad A = \frac{1}{2}(M_{2,2} - \tau^2 I) \\ B &= \frac{1}{6}(M_{3,3} - (M_{3,1}v^T + vM_{3,1}^T + \langle M_{3,1}, v\rangle I)) \end{aligned}$$

As in the previous cases with finite samples the estimates $\hat{m}, \widehat{A}, \widehat{B}$ can be computed by taking their empirical expectations e.g., $\widehat{M}_{1,1} = \widehat{\mathbb{E}}[yx] = \frac{1}{n}\sum_{i=1}^{n} \hat{y}_i \hat{x}_i$ and so on, where $(\hat{y}_i, \hat{x}_i)$ denote the i-th sample.

Examples of v: Suppose we are given a few random labeled examples from the first component. Then assuming $\|\mu_1\|^2 > \langle \mu_1, \mu_i\rangle + \delta$, $\|\mu_i\|^2 \leq R$, similar to the GMM case we can estimate a $v := \frac{1}{\ell}\sum_{j=1}^{\ell} \hat{y}_j \hat{x}_j$ using only $\ell = \Omega\left(R^4\delta^{-2}\log k\right)$ labeled samples so that $\langle \mu_1, v\rangle > \langle \mu_i, v\rangle$ holds with high probability.

Remarks: Our construction of the second matrix B is a consequence of some new moment results for the mixed linear regression model. We present these detailed moment derivations in Appendix C.4. This also results in improved sample complexity bounds over previous moment based algorithms (discussed in Section 3.5).

3.4 Subspace Clustering

The model: Besides the mixture parameters $\alpha_1, \ldots, \alpha_k$, the subspace clustering model has parameters $U_1, \ldots, U_k \in \mathbb{R}^{d\times m}$ and $\sigma \in \mathbb{R}$, where the matrices $U_1, \ldots, U_k$ have orthonormal columns. The conditional distribution $g(\cdot; U_i)$ is a standard Gaussian variable supported on the column space of U_i, plus independent Gaussian noise. More precisely, we sample $y \sim \mathcal{N}(0, I_d)$ and set $x = U_i U_i^T y + \xi$, where $\xi \sim \mathcal{N}(0, \sigma^2 I_d)$ is independent of y.

Matrices A and B: The subspace clustering model does not quite fit into the basic method of Section 2; one motivation for presenting it is to show that the basic ideas in Section 2 are more flexible than they first appear. Suppose $v \in \mathbb{R}^d$ satisfies $\|U_1^T v\| > \|U_i^T v\|$

for all $i \neq 1$. We consider

$$\begin{aligned} A &:= \mathbb{E}[xx^T] - \sigma^2 I_d = \sum_{i=1}^{k} \alpha_i U_i U_i^T \\ B &:= \mathbb{E}[\langle x, v\rangle^2 xx^T] - \sigma^2 v^T A v I_d - \sigma^2 \|v\|^2 A - \sigma^4(\|v\|^2 I_d + vv^T) - 2\sigma^2(Avv^T + vv^T A) \\ &= \sum_{i=1}^{k} \alpha_i \|U_i^T v\|^2 U_i U_i^T + 2\sum_{i=1}^{k} \alpha_i U_i U_i^T vv^T U_i U_i^T \end{aligned}$$

and their empirical versions $\hat{A}$ and $\hat{B}$ (the computation giving the claimed formula for B is carried out in Appendix C). Now with these $\hat{A}$ and $\hat{B}$, we can recover the subspace U_1 using Algorithm 3. This algorithm uses the same principle behind the whitening method in Section 2.1.1, the key difference is that here we pick the top m eigenvectors of the whitened B matrix.

Algorithm 3 Subspace clustering algorithm

Input: $\hat{A}, \hat{B}$
Output: $\hat{U}$

1: let $\{\sigma_j, v_j\}$ be the singular values and singular vectors of $\hat{A}$, in non-increasing order
2: let V be the $d \times mk$ matrix whose jth column is v_j
3: let D be the $mk \times mk$ diagonal matrix with $D_{jj} = \sigma_j$
4: let $Y = [u_1, \ldots, u_m]$ be the matrix of m largest eigenvectors of $D^{-1/2}V^T\hat{B}VD^{-1/2}$
5: let $Z = VD^{1/2}Y$
6: let the columns of $\hat{U}$ be the m eigenvectors of the matrix ZZ^T

The following perturbation theorem guarantees that if the side information vector v is substantially more aligned with the subspace spanned by U_1 than it is with any other subspace, and the matrices A, B are estimated within ϵ accuracy, then Algorithm 3 can recover the required subspace with a small error.

Theorem 6 *Suppose that $\|\hat{A} - A\| \leq \epsilon$ and $\|\hat{B} - B\| \leq \epsilon$. Suppose that the side information vector v satisfies $\|U_i v\|^2 \leq (1/3 - \delta)\|U_1 v\|^2$. Then output $\hat{U}$ of Algorithm 3 satisfies*

$$\|\hat{U}\hat{U}^T - U_1 U_1^T\| \leq C\epsilon\alpha_1^{-1}\sigma_1(A)^2\sigma_{mk}(A)^{-2}\delta^{-1}.$$

We prove Theorem 6 in Appendix F. Note that the conditions on v can be satisfied if the spaces U_i satisfy a certain affinity condition and we have a few labelled samples from U_1. Specifically, suppose that $\langle u, w\rangle < (\frac{1}{\sqrt{3}} - \eta)\|u\|\|w\|$ for every $u \in U_1$ and $w \in U_i$, $i \neq 1$. Then any $v \in U_1$ will satisfy the assumption of Theorem 6. Hence, a single labelled sample from U_1 (or several—depending on η—noisy samples) is enough to find a suitable v.

Remarks: To the best of our knowledge Algorithm 3 is the first moment based algorithm for the subspace clustering model. The detailed moment derivations are presented in Appendix C.5. Also our generative model allows samples to be noisy, hence they do not lie exactly on the subspace but close to it. Such a setting has not been considered in most subspace clustering literature.

3.5 Comparison

In this section we compare the theoretical performance of the Whitening and Cancellation algorithms with other algorithms. Both Whitening and Cancellation algorithms require estimating the quantities m, A, B by computing moments from the samples. Therefore the sample complexity primarily depends on how well these quantities concentrate. We compute the specific sample complexities for each model in Appendix G.

For Gaussian mixture model the sample complexity of our algorithm scales as $\tilde{\Omega}(d\epsilon^{-2}\log d)$ similar to moment based algorithm by Hsu and Kakade (2013) and tensor decomposition based algorithm by Anandkumar et al. (2014). In terms of runtime the Whitening algorithm is faster than the tensor decomposition based algorithm by Anandkumar et al. (2014). This can be viewed as follows. The first step in both the algorithms take $O(d^2k)$ time to compute the whitening matrix and in subsequent whitening steps. However, computing the largest eigenvector in Algorithm 1 takes only $O(k^2)$ time, faster than $O(k^5 \log k)$ time required for rank-k tensor power iteration (we also verify this in our experiments in Section 4).

In LDA topic model our algorithms have a sample complexity of $\tilde{\Omega}(\epsilon^{-2}\log d)$, again similar to tensor decomposition based algorithm by Anandkumar et al. (2014), and non-negative matrix factorization (NMF) based algorithm by Arora et al. (2013). The Whitening algorithm again is faster than tensor decomposition as argued for GMM case. The NMF based algorithm using optimization based RecoverKL/RecoverL2 procedures also has a runtime of $O(d^2k)$ similar to our algorithms (in Section 4 again we observe our algorithm to be faster in practice). The spectral topic modeling algorithm in Anandkumar et al. (2012) also has a computation complexity $O(d^2k)$ similar to our algorithms. However, its sample complexity has a high $\Omega(k^5)$ dependence on the number of components. This spectral algorithm also suffer from instability in practice due to the random projection step (as noted in Anandkumar et al. 2014).

In the case of mixed linear regression again our method has a sample complexity of $\tilde{\Omega}(d\epsilon^{-2}\log d)$ similar (upto log factors) to the convex optimization based approach by Chen et al. (2014), alternating minimization based approach by Yi et al. (2014), but better than tensor decomposition based method of Sedghi et al. (2016) which has a sample complexity of $\tilde{\Omega}(d^3\epsilon^{-2})$. However unlike the convex optimization and alternating minimization based techniques our method is also applicable when the number of components $k > 2$. As argued in GMM case the Whitening algorithm is again faster than the tensor algorithm by Sedghi et al. (2016).

Subspace clustering algorithms like greedy subspace clustering by Park et al. (2014), optimization based algorithms by Elhamifar and Vidal (2009), Soltanolkotabi and Candes (2012), requires the samples to exactly lie on a subspace. In contrast our moment based algorithm works even when the samples are noisy and perturbed from the actual subspace. Our subspace clustering algorithm also has a sample complexity of $\tilde{\Omega}(m\epsilon^{-2}\log d)$ which is similar (up to log factors) to greedy subspace clustering algorithm by Park et al. (2014).

We note that it is possible to use approximation methods like randomized svd to further speed up the Whitening, Cancellation and tensor decomposition based algorithms by Anandkumar et al. (2014), however this will result in decreased accuracy in both algorithms. We refer to Huang et al. (2015) for such stochastic optimization, and parallelization techniques used to speed up the tensor algorithms.

In a setting where side information is provided on each of the k components, observe that we can run the Whitening algorithm independently for each of the k components, possibly in parallel. Hence we can recover all k components, without loosing the runtime advantage of the Whitening algorithm. We demonstrate this application on real data set in Section 4.2. In terms of the overall computation time, it can be shown that running the Whitening algorithm for all k components is still faster than the tensor decomposition based algorithm by Anandkumar et al. (2014), when $k = \Omega(n^{\frac{1}{3}} d^{\frac{1}{3}})$.

4. Experiments

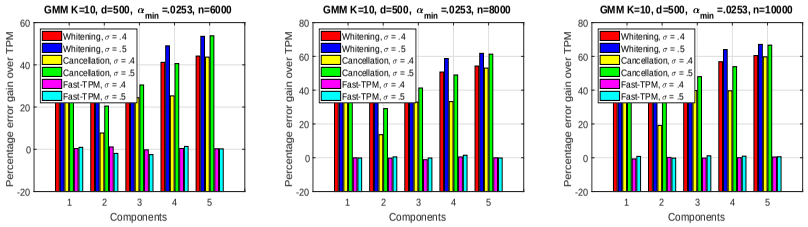
In this section we present the empirical performance of our Whitening, Cancellation, and Subspace clustering algorithms. We consider three of the settings: the Gaussian Mixture Model (GMM), and Latent Dirichlet Allocation (LDA), and Subspace clustering, and validate our algorithms on both real and synthetic data sets.

4.1 Synthetic Data Set

First we compare the sample complexity and runtime of our algorithms with the robust tensor decomposition algorithm by Anandkumar et al. (2014), which is based on tensor power iteration, for learning mixture models (we refer to this as the TPM algorithm). Our second baseline algorithm is a faster heuristic of TPM where we start the tensor power iterations initialized with side information vector v, and recover just the first component. We refer this as the Fast-TPM algorithm. For the Cancellation algorithm we compute the optimum λ for cancellation using two different techniques as follows. First, let $\widehat{Z}'_\lambda = V^T \widehat{Z}_\lambda V$, where V is the matrix of top k singular vectors of $\widehat{A}$. In the first method, we perform a line search over positive λ to find the minimum λ such that $\sigma_k(\widehat{Z}'_\lambda)$ falls below certain threshold. This method works well in GMM case. In a second method we minimize the convex function $\|\widehat{Z}'_\lambda\|_* + \lambda$, subject to $\lambda \geq 0$. This method performs better in the case of LDA. Note that for the Cancellation algorithm after estimating λ, instead of using m and A to find μ_1 we can follow the same steps using $m' = Av$ and B to recover μ_1. Theoretically it has the same performance, however empirically we observe this to work slightly better and we use this version for our experiments. We implement all algorithms for our synthetic data experiments using MATLAB.

Performance metric: We compute the estimation error of parameter μ_1 as $\mathcal{E} = \|\hat{\mu}_1 - \mu_1\|$. In our figures we plot the quantity "percentage relative error gain" which is defined as $G = 100(\mathcal{E}_T - \mathcal{E}_A)/\mathcal{E}_T$, where $\mathcal{E}_T$ is the TPM error and $\mathcal{E}_A$ is the error for Whitening / Cancellation / Fast-TPM algorithm. Note that a positive error gain implies that the TPM error is greater than that of the competing algorithm. In the subspace clustering model we plot similar percentage relative error gain over the baseline k-means algorithm.

Gaussian mixture model: We generate synthetic data sets for GMM with different k, d, α_i, σ, and v. Figure 1 shows the percentage relative error gains of the Whitening, Cancellation, and Fast-TPM algorithms over the TPM algorithm in a GMM with various values of k, d, α_i, σ, and n. The μ_i were generated randomly over the sphere of norm $r = 10$. We define $\alpha_{min} := \min_i \alpha_i$. The side information vector v was chosen as follows. Let $\{v_1, \ldots, v_k\}$ be a orthonormal basis of span$\{\mu_1, \ldots, \mu_k\}$, such that $\{v_2, \ldots, v_k\} \in$ span$\{\mu_2, \ldots, \mu_k\}$. Then we



(a) (b) (c)

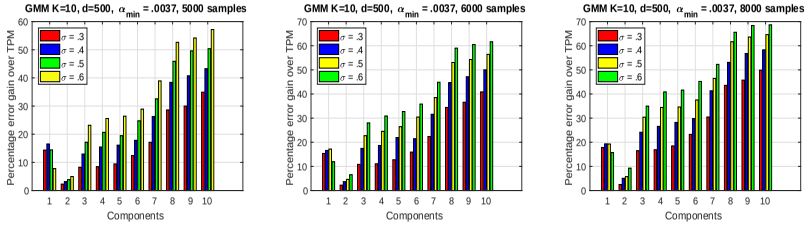
Figure 1: Figure showing the percentage relative error gain by the Whitening, Cancellation, and Fast-TPM algorithm over the TPM algorithm for 5 components of increasing size, in a GMM with $k = 10, d = 500, \sigma \in \{.4, .5\}$, and three different sample complexities (a) $n = 6000$ (b) $n = 8000$ (c) $n = 10000$. Our algorithms shows increasingly better gain over TPM and Fast-TPM as α_i, σ and n increase.

choose $v = \sqrt{\gamma} v_1 + \sqrt{(1-\gamma)/(k-1)} \sum_{i=2}^{k} v_i$ for some $\gamma \in (0, 1)$ such that the condition $\langle \mu_1, v \rangle > \langle \mu_i, v \rangle$ is satisfied. We observe that in all the cases, our algorithms have lower error (positive error gain) than both the tensor algorithms. Moreover, our methods' advantage increases with increasing proportion α_i, increasing sample size n, and increasing variance σ. We also observe that the Fast-TPM algorithm has the same error performance as TPM (error gain close to zero).

Figure 2 gives an example where the Whitening algorithm can successfully recover even rare components. Here we consider a GMM with $k = 10, d = 500$ with the rarest component having probability $\alpha_{min} = .0037$. Again we observe positive relative error gains over TPM algorithm for increasing number of samples n.

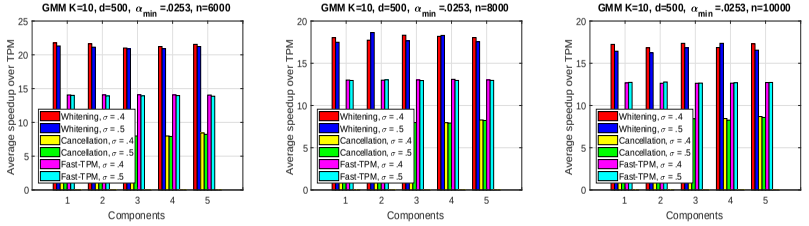
In Figure 3 we plot the speedup of the algorithms over TPM, and observe that the Whitening and Cancellation algorithms are much faster (high speedup) than the TPM algorithm. We also observe that the Fast-TPM algorithm is faster than TPM and Cancellation algorithms, but slower than Whitening algorithm. Note that, while it is also possible to speed up the basic TPM algorithm compared here using techniques such as randomized svd and stochastic tensor gradient descent [Huang et al. 2015], such approximate methods will reduce the overall accuracy. Moreover the randomized svd techniques can also be applied to the search algorithms presented in this paper, to obtain further speedups.

Topic Modeling: We generate a synthetic LDA document corpus according to the model in Blei et al. (2003). The lengths of the documents are generated using a Poission(L) distribution where L is the mean document length. In Figure 4 we plot the percentage relative error gain of the Whitening, Cancellation, and Fast-TPM algorithms over the TPM algorithm. Our side information was a labeled word w satisfying $\mu_1(w) > \mu_i(w)$ for $i \neq 1$. Again we observe positive error gains over the TPM algorithm. Although the Fast-TPM algorithm sometimes perform better than TPM for more frequent topics, the Whitening



(a) (b) (c)

Figure 2: Figure showing the percentage relative error gain of the Whitening algorithm over the TPM algorithm in presence of rare components ($\alpha_{min} = .0037$), for a GMM with $k = 10, d = 500, \sigma \in \{.3, .4, .5, .6\}$, and number of samples (a) $n = 5000$ (b) $n = 6000$ (c) $n = 8000$. The Whitening algorithm recovers even the rarest component with increasing error gain over TPM as the number of samples increase.

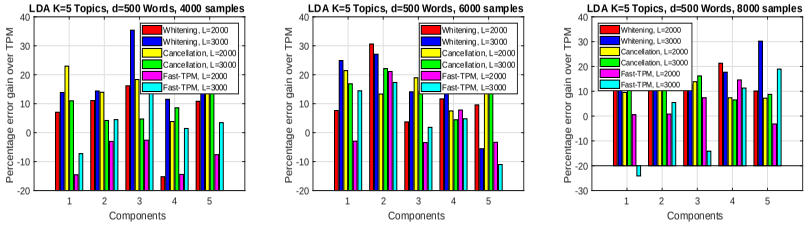


(a) (b) (c)

Figure 3: Figure showing the average speedup of Whitening, Cancellation, and Fast-TPM algorithms over TPM, for 5 components of increasing size, in a GMM with $k = 10, d = 500, \sigma \in \{.4, .5\}$, and three different sample complexities (a) $n = 6000$ (b) $n = 8000$ (c) $n = 10000$. The Whitening algorithm is the fastest.

algorithm still outperforms it. Note that the performance varies across topics since the probability of the labeled word is different for each topic.

Subspace Clustering: We generate synthetic data for the subspace clustering model described in section 3.4 using parameters $d = 500, k = 5, m = 10$, and $\alpha_i \in [.1, .3]$. First we generate $k = 5$ random subspaces with orthonormal basis $\{U_i\}_{i=1}^k$, each of dimension $m = 10$. Then we generate random points on these subspaces, and add white Gaussian perturbations with $\sigma \in \{.1, .2\}$. We choose the side information vector v similar to the sensitivity experiment in GMM, and ensuring $\|U_1^T v\| > \|U_i^T v\|$, for $i \neq 1$. Note that due to the added Gaussian noise, our samples do not lie exactly on the subspaces $\{U_i\}_{i=1}^k$, but close



(a) (b) (c)

Figure 4: Figure showing the percentage relative error gain in each component of the Whitening, Cancellation, and Fast-TPM algorithms over the TPM algorithm in an LDA model with $k = 5, d = 500$, mean document length $L \in \{2000, 3000\}$, and number of documents (a) $n = 4000$ (b) $n = 6000$ (c) $n = 8000$. The Whitening algorithm show an improvement over TPM and Fast-TPM with increasing samples.

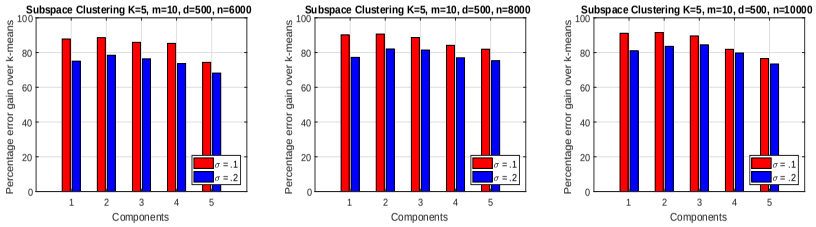
to it. Traditional subspace clustering algorithms, which assume points to lie exactly on the subspace, may not perform well. The TPM algorithm is also not well suited for this model since (a) the required moment tensor will be of 4^{th} order resulting in high computation cost (b) even if mk basis of the tensor are recovered, finding the target subspace will involve a further combinatorial search of $\binom{mk}{m}$ subspaces and finding the one having the strongest projection of v. Therefore we choose the k-means algorithm as our baseline for this model and compare with Algorithm 3. First we compute k clusters using k-means, then we find an m dimensional basis for each cluster using svd, finally we choose the target subspace as the one having the largest projection of v. If $\widehat{U}_1$ is the estimated orthonormal basis for the target subspace U_1, we compute the error as $\mathcal{E} = \|\widehat{U}_1\widehat{U}_1^T - U_1U_1^T\|/\|U_1U_1^T\|$.

Figure 5 shows that Algorithm 3 has a much better error performance over k-means. In the speedup plots in Figure 6 we also observe that our subspace search algorithm is over $4X$ times faster than k-means.

4.2 Real Data Sets

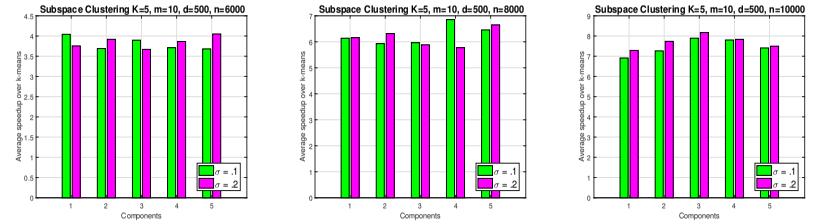
Topic Modeling: In this section we compare the performance of Whitening algorithm with a recent non-negative matrix factorization based topic modeling algorithm by Arora et al. (2013) (we refer this as NMF algorithm), and also the semi-supervised version of this NMF algorithm (we refer to this as SS-NMF). We test on two real large data sets; (a) New York Times news article data set [UCI 2008] (300,000 articles) (b) Yelp data set of business reviews [Yelp 2014] (335,022 reviews). We run both algorithms for $k = 100$ topics. For this experiment we do not consider the TPM algorithm by Anandkumar et al. (2014) since its runtime with $k = 100$ topics becomes extremely large on these data sets.[1]

1. To be more precise, with just $k = 10$ topics, the tensor algorithm takes 908 seconds in NY Times data set, compared to just 188 seconds for the Whitening algorithm (using MATLAB).



(a) (b) (c)

Figure 5: Figure showing the percentage relative error gain by our subspace search algorithm (Algorithm 3) over k-means for 5 components of increasing size, in a subspace clustering model with $k = 5, m = 10, d = 500, \sigma \in \{.1, .2\}$, and three different sample complexities (a) $n = 6000$ (b) $n = 8000$ (c) $n = 10000$. Our algorithm shows much better error performance than k-means.



(a) (b) (c)

Figure 6: Figure showing the average speedup of our subspace search algorithm (Algorithm 3) over k-means, for 5 components of increasing size, in a subspace clustering model with $k = 5, m = 10, d = 500, \sigma \in \{.1, .2\}$, and three different sample complexities (a) $n = 6000$ (b) $n = 8000$ (c) $n = 10000$. Our subspace clustering algorithm shows high speedup over k-means.

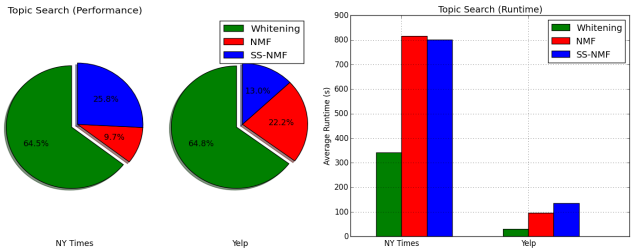
In contrast, the NMF algorithm is known to be faster, and produce topics of comparable quality to more popular variational inference based algorithms [Blei et al. 2003]. The side information for this experiment are chosen as follows. First from the set of topics produced by NMF algorithm we choose a subset of interpretable topics, then we choose labeled words representative of these topics. We test with a set of 62 labeled words for NY Times data set and 54 labeled words for Yelp data set. Note that given labeled word w_l the whitening algorithm produces one topic distribution μ_1, but the NMF algorithm finds k topics. Therefore for NMF algorithm the target topic i is the one which has the highest probability of the labeled word i.e., $\mu_i(w_l)$. For the semi-supervised NMF we first compute

the weighted word-word co-occurrence matrix Q_w where we re-weigh each document by the normalized frequency of the labeled word w_l. Then we apply the NMF algorithm [Arora et al. 2013] on this weighted matrix Q_w. All three algorithms were implemented in Python.

Performance metric: We compare the quality of the topics returned by Whitening, NMF, and SS-NMF algorithms using the pointwise mutual information (PMI) score, known to be a good metric for topic coherence [Newman et al. 2010; Röder et al. 2015]. However in order to also capture the relevance of the estimated topic to the labeled word we compute PMI score for topic i as,

$$PMI(\text{topic i}) = \frac{1}{20} \sum_{w \in \mathcal{T}_{20}^i} \log \frac{p(w_l, w)}{p(w_l)p(w)}$$

where w_l is the labeled word, $\mathcal{T}_{20}^i$ is the set of top 20 words in the i-th topic. The probabilities $p(w_l, w), p(w), p(w_l)$ are computed over a larger data set of English Wikipedia articles to reduce noise [Newman et al. 2011]. For whitening algorithm we choose $\alpha_0 = .01$. Note that other supervised topic modeling algorithms e.g. supervised LDA by Mcauliffe and Blei (2008), labeled LDA by Ramage et al. (2009) require a much stronger notion of side-information than just labeled words, hence we could not compare with them.



(a) (b)

Figure 7: Figure comparing the performance of Whitening, NMF [Arora et al. 2013], and semi-supervised NMF (SS-NMF) algorithms on NY Times and Yelp data sets. (a) Topics estimated by Whitening algorithm have the best PMI score in 40 out of 62 labeled words for NY Times data set, and 35 out of 54 labeled words in Yelp data set. (b) Whitening shows more than 2X speedup over competing algorithm in both data sets.

In Figure 7 (a) we plot the percentage of labeled words for which each algorithm has the best PMI score. Observe that for most labeled words (40 out of 62 labeled words for NY Times data set, and 35 out of 54 labeled words in Yelp data set) the Whitening algorithm estimates topic with better PMI score over NMF and SS-NMF algorithms. The Whitening algorithm is also more than twice as fast as NMF and SS-NMF[2] as shown in Figure 7 (b).

2. For large corpus the NMF algorithm runs much faster than Gibbs sampling and variational inference based algorithms [Arora et al. 2013].

A complete list of topics and PMI scores returned by the algorithms for every labeled word is presented in Tables 2, 3 of Appendix B. Notice that the Whitening algorithm often estimates more coherent topics which are more relevant to the given labeled word than topics produced by the NMF/SS-NMF algorithm. For example in NY Times data set with the labeled word *student* the Whitening algorithm returns top five words in the topic as *student, school, teacher, percent, program*; however those returned by NMF algorithm are *test, school, student, ignore, export*; and those by SS-NMF algorithm are *student, university, shooting, shot, rampage*.

Parallel image segmentation: One method to perform image segmentation is to use GMM clustering. In this experiment we demonstrate how GMM search algorithm can be used to parallelize image segmentation in vision applications. For this we consider the BSDS500 data set introduced in Arbelaez et al. (2011) and choose a subset of 70 images having less than 4 segments in the ground truth. Note that this data set has up to six ground truth segmentation by human users for each image. We randomly choose one pixel from each segment in ground truth as side-information v. We compare our Whitening algorithm with the seeded k-means clustering [Basu et al. 2002] where the centers are initialized by these side-information pixels (we refer to this as s-Kmeans). The Whitening algorithm uses one pixel from the i-th cluster to compute μ_i, in parallel for every i, and then it assigns each pixel to its closest μ_i. The segmentation quality is compared using normalized mutual information (NMI) metric [Manning et al. 2008]. To avoid local minimum in s-Kmeans we consider the maximum NMI over 5 initializations of side-information for each ground truth, and then we compute average NMI over all ground truths for an image.

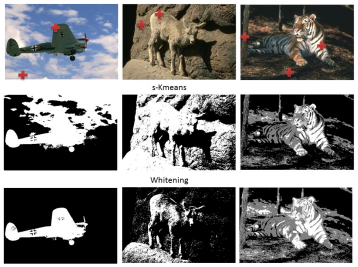


Figure 8: Figure comparing the performance of image segmentation by Whitening (row 3) and s-Kmeans (row 2) algorithms, with images selected from the BSDS500 data set. The side-information pixels are shown in red plus in the original image (row 1). In the segmented images (rows 2, 3) the segments are shown in different shades. Observe that the Whitening algorithm often isolates the foreground segment better than s-Kmeans.

We summarize our result in Table 1. Observe that the Whitening algorithm has a slightly better NMI performance over s-Kmeans in the BSDS test data set and similar performance

Data set	N	N_W	N_K	T_W (s)	T_K (s)	$\overline{NMI}_W$	$\overline{NMI}_K$
BSDS test	30	17	13	6.7	81.5	0.17	0.13
BSDS train	25	12	13	8.2	89.8	0.15	0.15
BSDS val	15	8	7	10.6	117.2	0.11	0.09

Table 1: Table comparing the performance of Whitening and s-Kmeans algorithm on BSDS data set. N is the total number of images, N_W is the number of images where segmentation produced by Whitening has a better NMI than s-Kmeans, and N_K is the number of images where segmentation of s-Kmeans has a better NMI. T_W is the median runtime of Whitening algorithm and T_K is the median runtime of s-Kmeans. $\overline{NMI}_W$ and $\overline{NMI}_K$ are the median NMI scores for the Whitening and s-Kmeans algorithms respectively. Whitening runs much faster than s-Kmeans.

in BSDS train and BSDS val data sets. However the Whitening algorithm runs an order of magnitude faster than s-Kmeans.

5. Conclusion and Discussion

In this paper we developed a new, simple and flexible framework for incorporating side information into mixture model learning. The underlying motivation was to provide a principled way to take into account extra input (e.g. generated by human data analysts etc.). Even for cases where this input is very limited compared to the size/dimensionality of the data, we show meaningful statistical and computational performance improvement over baseline unsupervised and semi-supervised methods. More generally, developing methods which work with very limited human input is a promising research endeavor, in our opinion.

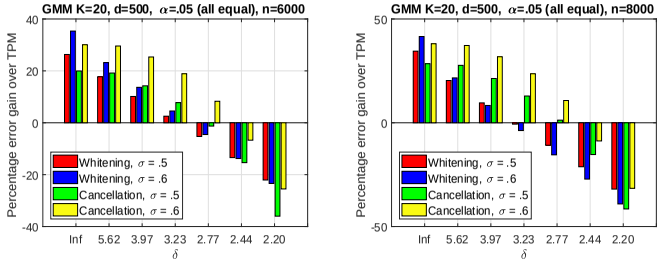
Appendix A. More Experiments for Gaussian Mixture Models

In Figure 9 we show the sensitivity of the Whitening and Cancellation algorithms in GMM with $k = 20, d = 500$, all equal probability components, and two different values of σ and n. Observe that the percentage error gain of the algorithms decreases with decreasing values of $\delta = \min_{i \neq 1} \frac{\langle \mu_1, v \rangle}{\langle \mu_i, v \rangle}$, as we would expect, and it eventually becomes negative when the performance become worse than TPM algorithm. Also here the Cancellation algorithm shows lesser sensitivity, hence better performance compared to the Whitening algorithm.



(a) (b)

Figure 9: Sensitivity plots showing how the percentage relative error gain of the Whitening and Cancellation algorithms over the TPM algorithm decrease with decreasing values of the parameter $\delta = \min_{i \neq 1} \frac{\langle \mu_1, v \rangle}{\langle \mu_i, v \rangle}$, in GMM with $k = 20, d = 500$, all equal probability components, for different values of variance $\sigma \in \{.5, .6\}$, and two different sample complexities (a) $n = 6000$ (b) $n = 8000$.

Appendix B. Complete Results on New York Times and Yelp Data Set

In this section we provide more detailed result of our experiments on NY Times and Yelp data sets. In Tables 2, 3 we show for every labeled word, the top five words in the topics computed by Whtening, NMF, and SS-NMF algorithms along with their corresponding PMI scores.

Table 2: Results of topic search by Whitening and NMF algorithms on NYtimes data set of 300,000 news articles using $K = 100$ topics and 62 labeled words.
