Appendix C. Computation of A, B for Different Models

This section outlines the construction of matrices A, B in various models via different moment computations. First we introduce some notations which we use in Appendices C, D, E, F, and G.

C.1 Notations

For a vector x, $\|x\|$ denotes its ℓ_2 norm. For a matrix X, $\|X\|$ represents the spectral norm of the matrix. We use the notation $\widehat{X}$ or $\widehat{\mathbb{E}}[X]$ to represent the sample estimate of a quantity X, unless mentioned otherwise. For a matrix M let $\sigma_k(M)$ denote the $k-$th largest singular value of M, and $\tilde{\sigma}_k(M)$ denote the $k-$th largest eigenvalue. n represents the number of samples used to obtain the sample estimates. Next, we introduce some basic tensor notations. Let $x, y, z \in \mathbb{R}^d$ be three d dimensional vectors. Then the order-3 tensor $T_3 = x \otimes y \otimes z$ is defined as $T_3(i,j,k) = x(i)y(j)z(k)$, for $i,j,k \in [d]$. Similarly the order-2 tensor $T_2 = x \otimes y$ is equivalent to the matrix outer product $T_2 = xy^T$. Finally let $v \in \mathbb{R}^d$ be another d dimensional vector, I be the d dimensional identity matrix. The tensor contraction $T_3(I,I,v)$ is equal to the order-2 tensor $T_3(I,I,v) = \langle z, v\rangle x \otimes y$, which is again equivalent to the matrix $T_3(I,I,v) = \langle z, v\rangle xy^T$. For order-2 tensors we will use the tensor and matrix notations interchangeably.

C.2 GMM Moments

In this section we prove how the required matrices A, B can be computed in the GMM model. We restate the following useful theorem from Hsu and Kakade (2013) which computes three tensor moments for the GMM model.

Theorem 7 (Hsu and Kakade (2013)) *Consider the GMM model with means $\{\mu_1, \ldots, \mu_k\}$ and corresponding variances $\{\sigma_1^2, \ldots, \sigma_k^2\}$, and α_i denote the proportion of the i-th component in the mixture. Let $\sigma^2 = \sum_{i=1}^k \alpha_i \sigma_i^2$ be the smallest eigenvalue of the covariance matrix $\mathbb{E}[(x - \mathbb{E}[x])(x - \mathbb{E}[x])^T]$ (note that since $\sum \alpha_i \mu_i \mu_i^T$ has rank k, this is the same as the $k+1$th-largest eigenvalue), and u be a unit norm eigenvector corresponding to the eigenvalue σ^2. Define*

$$\begin{aligned} \widetilde{m} &= \mathbb{E}[x(u^T(x - \mathbb{E}[x]))^2], \quad M_2 = \mathbb{E}[x \otimes x] - \sigma^2 I \\ M_3 &= \mathbb{E}[x \otimes x \otimes x] - \sum_{i=1}^d (\widetilde{m} \otimes e_i \otimes e_i + e_i \otimes \widetilde{m} \otimes e_i + e_i \otimes e_i \otimes \widetilde{m}) \end{aligned}$$

where $\{e_1, \ldots, e_d\}$ form standard basis of $\mathbb{R}^d$. Then,

$$\widetilde{m} = \sum_{i=1}^k \alpha_i \sigma_i^2 \mu_i, \quad M_2 = \sum_{i=1}^k \alpha_i \mu_i \otimes \mu_i, \quad M_3 = \sum_{i=1}^k \alpha_i \mu_i \otimes \mu_i \otimes \mu_i.$$

Theorem 8 *In the GMM model define*

$$\begin{aligned} m &= \mathbb{E}[x], \quad A = \mathbb{E}[xx^T] - \sigma^2 I_d \\ B &= \mathbb{E}[\langle x, v\rangle xx^T] - \widetilde{m}v^T - v\widetilde{m}^T - \langle \widetilde{m}, v\rangle I_d \end{aligned}$$

Then, $m = \sum_i \alpha_i \mu_i$, $A = \sum_{i=1}^k \alpha_i \mu_i \mu_i^T$ and $B = \sum_{i=1}^k \alpha_i \langle \mu_i, v\rangle \mu_i \mu_i^T$

Proof The expression for m, A follows directly from Theorem 7 by noting that $A = M_2$ and $\mu_i \otimes \mu_i = \mu_i \mu_i^T$. To compute B consider the tensor contraction $M_3(I,I,v)$, M_3 as in Theorem 7. Then,

$$\begin{aligned} M_3(I,I,v) &= \mathbb{E}[\langle x, v\rangle x \otimes x] - \sum_{i=1}^d (v(i)\widetilde{m} \otimes e_i + v(i) e_i \otimes \widetilde{m} + \langle \widetilde{m}, v\rangle e_i \otimes e_i) \\ &= \mathbb{E}[\langle x, v\rangle xx^T] - \sum_{i=1}^d (v(i)\widetilde{m} e_i^T + v(i) e_i \widetilde{m}^T + \langle \widetilde{m}, v\rangle e_i e_i^T) \\ &= \mathbb{E}[\langle x, v\rangle xx^T] - \widetilde{m}v^T - v\widetilde{m}^T - \langle \widetilde{m}, v\rangle I_d = B \end{aligned}$$

Also from Theorem 7, $M_3(I,I,v) = \sum_{i=1}^k \alpha_i \langle \mu_i, v\rangle \mu_i \otimes \mu_i = \sum_{i=1}^k \alpha_i \langle \mu_i, v\rangle \mu_i \mu_i^T$. Therefore $B = \sum_{i=1}^k \alpha_i \langle \mu_i, v\rangle \mu_i \mu_i^T$. ■

C.3 LDA Moments

In this section we show the m, A, B computation corresponding to the LDA model. Again we restate the following theorem from Anandkumar et al. (2014) which computes the first three tensor moments for LDA distribution.

Theorem 9 (Anandkumar et al. (2014)) *In an LDA model with parameters $\bar{\alpha} = (\alpha_1, \ldots, \alpha_k)$, topic distributions $\mu_1, \ldots, \mu_k$. Let $\alpha_0 = \sum_{i=1}^k \alpha_i$. Define*

$$\begin{aligned} M_1 &= \mathbb{E}[x_1], \quad M_2 = \mathbb{E}[x_1 \otimes x_2] - \frac{\alpha_0}{1+\alpha_0} M_1 \otimes M_1 \\ M_3 &= \mathbb{E}[x_1 \otimes x_2 \otimes x_3] - \frac{\alpha_0}{\alpha_0 + 2} (\mathbb{E}[x_1 \otimes x_2 \otimes M_1] + \mathbb{E}[x_1 \otimes M_1 \otimes x_3] + \mathbb{E}[M_1 \otimes x_2 \otimes x_3]) \\ &\quad + \frac{2\alpha_0^2}{(\alpha_0+1)(\alpha_0+2)} M_1 \otimes M_1 \otimes M_1 \end{aligned}$$

Then,

$$\begin{aligned} M_1 &= \sum_{i=1}^k \frac{\alpha_i}{\alpha_0} \mu_i, \quad M_2 = \sum_{i=1}^k \frac{\alpha_i}{\alpha_0(\alpha_0+1)} \mu_i \otimes \mu_i \\ M_3 &= \sum_{i=1}^k \frac{2\alpha_i}{\alpha_0(\alpha_0+1)(\alpha_0+2)} \mu_i \otimes \mu_i \otimes \mu_i \end{aligned}$$

Theorem 10 *For an LDA model for any $v \in \mathbb{R}^d$ suppose m, A, B be defined as*

$$\begin{aligned} m &= \alpha_0 \mathbb{E}[x_1] \\ A &= \alpha_0(\alpha_0+1)\mathbb{E}[x_1 x_2^T] - mm^T \\ B &= \frac{\alpha_0(\alpha_0+1)(\alpha_0+2)}{2} \mathbb{E}[\langle x_3, v\rangle x_1 x_2^T] - \frac{\alpha_0(\alpha_0+1)}{2} \left(\langle m, v\rangle \mathbb{E}[x_1 x_2^T] + \mathbb{E}[\langle x_3, v\rangle x_1 m^T] \right. \\ &\quad \left. + \mathbb{E}[\langle x_3, v\rangle m x_2^T]\right) + \langle m, v\rangle mm^T. \end{aligned}$$

Then we can express m, A, B as follows.

$$m = \sum_{i=1}^{k} \alpha_i \mu_i, \quad A = \sum_{i=1}^{k} \alpha_i \mu_i \mu_i^T, \quad B = \sum_{i=1}^{k} \alpha_i \langle \mu_i, v \rangle \mu_i \mu_i^T$$

Proof The expressions for m and A follows easily from Theorem 9 since $m = \alpha_0 M_1$ and $A = \alpha_0(\alpha_0+1)M_2$. To show the expression for B consider the tensor contraction $M_3(I, I, v)$, M_3 defined as in Theorem 9. Then we have

$$\begin{aligned} M_3(I,I,v) &= \mathbb{E}[\langle x_3, v\rangle x_1 \otimes x_2] - \frac{\alpha_0}{\alpha_0+2}\left(\mathbb{E}[\langle M_1, v\rangle x_1 \otimes x_2] + \mathbb{E}[\langle x_3, v\rangle x_1 \otimes M_1]\right. \\ &\quad \left. + \mathbb{E}[\langle x_3, v\rangle M_1 \otimes x_2 \otimes x_3]\right) + \frac{2\alpha_0^2}{(\alpha_0+1)(\alpha_0+2)}\langle M_1, v\rangle \otimes M_1 \otimes M_1 \\ &= \frac{2}{\alpha_0(\alpha_0+1)(\alpha_0+2)} B \end{aligned}$$

where we used $x_1 \otimes x_2$ is same as $x_1 x_2^T$ and so on. We also get from Theorem 9 $M_3(I, I, v) = \sum_{i=1}^{k} \frac{2\alpha_i}{\alpha_0(\alpha_0+1)(\alpha_0+2)} \langle \mu_i, v\rangle \mu_i \otimes \mu_i$. Therefore we have

$$B = \frac{\alpha_0(\alpha_0+1)(\alpha_0+2)}{2} M_3(I,I,v) = \sum_{i=1}^{k} \alpha_i \langle \mu_i, v\rangle \mu_i \mu_i^T.$$

■

C.4 Mixed Regression Moments

Recall in mixed regression we have $y = \langle x, \mu_i\rangle + \xi$ where $x \sim \mathcal{N}(0, I)$ and $\xi \sim \mathcal{N}(0, \sigma^2)$. In the following Lemmas we compute the various moments $M_{1,1}, M_{2,2}, M_{3,1}, M_{3,3}$ and show how they are used to compute m, A, B.

Lemma 11 *In mixed linear regression define $M_{1,1} = \mathbb{E}[yx]$, $M_{2,2} = \mathbb{E}[y^2 xx^T]$, $M_{3,1} = \mathbb{E}[y^3 x]$ and $M_{3,3} = \mathbb{E}[y^3 \langle x, v\rangle xx^T]$. Then,*

$$\begin{aligned} M_{1,1} &= \sum_{i=1}^{k} \alpha_i \mu_i \\ M_{2,2} &= 2\sum_{i=1}^{k} \alpha_i \mu_i \mu_i^T + (\sigma^2 + \sum_{i=1}^{k} \alpha_i \|\mu_i\|^2) I \\ M_{3,1} &= 3\sum_{i=1}^{k} \alpha_i (\sigma^2 + \|\mu_i\|^2)\mu_i \\ M_{3,3} &= 6\sum_{i=1}^{k} \alpha_i \langle \mu_i, v\rangle \mu_i \mu_i^T + \left(M_{3,1} v^T + v M_{3,1}^T + \langle M_{3,1}, v\rangle I\right) \end{aligned}$$

Proof

We compute the moments as shown below.

$$M_{1,1} = \mathbb{E}[yx] = \sum_{i=1}^{k} \alpha_i \mathbb{E}[x^T \mu_i x + \xi x] = \sum_{i=1}^{k} \alpha_i \mu_i$$

$$\begin{aligned} M_{2,2} &= \mathbb{E}[y^2 xx^T] = \sum_{i=1}^{k} \alpha_i \mathbb{E}[\langle \mu_i, x\rangle^2 xx^T] + \mathbb{E}[\xi^2]\mathbb{E}[xx^T] \\ &= \sum_{i=1}^{k} \alpha_i \mathbb{E}[\langle \mu_i, x\rangle^2 xx^T] + \sigma^2 I \\ &= \sum_{i=1}^{k} \alpha_i (2\mu_i \mu_i^T + \|\mu_i\|^2 I) + \sigma^2 I \\ &= 2\sum_{i=1}^{k} \alpha_i \mu_i \mu_i^T + \sum_{i=1}^{k} \alpha_i (\sigma^2 + \|\mu_i\|^2) I \end{aligned}$$

Using the fact that all odd moments of normal random variable are zero.

$$\begin{aligned} M_{3,1} &= \mathbb{E}[y^3 x] = \sum_{i=1}^{k} \alpha_i \mathbb{E}[(\langle x, \mu_i\rangle + \xi)^3 x] \\ &= \sum_{i=1}^{k} \alpha_i \mathbb{E}[\langle x, \mu_i\rangle^3 x] + 3\sum_{i=1}^{k} \alpha_i \mathbb{E}[\xi^2]\mathbb{E}[\langle x, \mu_i\rangle x] \\ &= 3\sum_{i=1}^{k} \alpha_i \|\mu_i\|^2 \mu_i + 3\sum_{i=1}^{k} \alpha_i \sigma^2 \mu_i = 3\sum_{i=1}^{k} \alpha_i (\sigma^2 + \|\mu_i\|^2)\mu_i \end{aligned}$$

We use the fact that for even p the moment $\mathbb{E}[z^p] = (p-1)!!$ for a standard normal random variable z and !! denote the double factorial. Next we compute $M_{3,3}$.

$$\begin{aligned} M_{3,3} &= \mathbb{E}[y^3 \langle x, v\rangle xx^T] = \sum_{i=1}^{k} \alpha_i \mathbb{E}[(\langle x, \mu_i\rangle + \xi)^3 \langle x, v\rangle xx^T] \\ &= \sum_{i=1}^{k} \alpha_i \mathbb{E}[\langle x, \mu_i\rangle^3 \langle x, v\rangle xx^T] + 3\sum_{i=1}^{k} \alpha_i \mathbb{E}[\xi^2]\mathbb{E}[\langle x, v\rangle \langle x, \mu_i\rangle xx^T] \\ &= \sum_{i=1}^{k} \alpha_i \mathbb{E}[\langle x, \mu_i\rangle^3 \langle x, v\rangle xx^T] + 3\sigma^2 \sum_{i=1}^{k} \alpha_i \mathbb{E}[\langle x, v\rangle \langle x, \mu_i\rangle xx^T] \end{aligned} \tag{5}$$

Now we compute these individual moments.

$$\mathbb{E}[\langle x, v\rangle \langle x, \mu_i\rangle xx^T] = \mu_i^T v + v\mu_i^T + \langle \mu_i, v\rangle I$$

Using the fact that any odd combination of the variables in x will be zero in expectation. Also,

$$\mathbb{E}[\langle x,\mu_i\rangle^3\langle x,v\rangle xx^T] = 6\langle v,\mu_i\rangle\mu_i\mu_i^T + 3\|\mu_i\|^2[\mu_i^Tv + v\mu_i^T + \langle\mu_i,v\rangle I]$$

Again by using the moments of standard normal variable. This can be verified by considering the (a,b)-th entry of the matrix on the right as a polynomial in $\mu_i(l)$, the l-th component of μ_i, and matching the corresponding coefficients from both sides of the equation.

Combining with equation (5) we get,

$$\begin{aligned}
M_{3,3} &= \sum_{i=1}^k \alpha_i\left[6\langle v,\mu_i\rangle\mu_i\mu_i^T + 3\|\mu_i\|^2(\mu_i^Tv + v\mu_i^T + \langle\mu_i,v\rangle I)\right] \\
&\quad +3\sigma^2\sum_{i=1}^k\alpha_i[\mu_i^Tv + v\mu_i^T + \langle\mu_i,v\rangle I] \\
&= 6\sum_{i=1}^k\alpha_i\langle v,\mu_i\rangle\mu_i\mu_i^T + 3\sum_{i=1}^k\alpha_i(\sigma^2+\|\mu_i\|^2)[\mu_i^Tv + v\mu_i^T + \langle\mu_i,v\rangle I] \\
&= 6\sum_{i=1}^k\alpha_i\langle v,\mu_i\rangle\mu_i\mu_i^T + \left(M_{3,1}v^T + vM_{3,1}^T + \langle M_{3,1},v\rangle I\right)
\end{aligned}$$

■

Theorem 12 *Let m, A, B be defined as*

$$\begin{aligned}
m &= M_{1,1}, \quad A = \frac{1}{2}(M_{2,2} - \tau^2 I), \\
B &= \frac{1}{6}(M_{3,3} - (M_{3,1}v^T + vM_{3,1}^T + \langle M_{3,1},v\rangle I))
\end{aligned}$$

where τ^2 is the smallest singular value of $M_{2,2}$. Then,

$$m = \sum_{i=1}^k\alpha_i\mu_i, \quad A = \sum_{i=1}^k\alpha_i\mu_i\mu_i^T, \quad B = \sum_{i=1}^k\alpha_i\langle\mu_i,v\rangle\mu_i\mu_i^T$$

Proof The proof follows directly from Lemma 11. Note that since μ_i-s are linearly independent the smallest singular vector τ^2 of $M_{2,2}$ is equal to $\sum_{i=1}^k\alpha_i(\sigma^2+\|\mu_i\|^2)$. Then $A = \frac{1}{2}\left(M_{2,2} - \tau^2 I\right) = \sum_{i=1}^k\alpha_i\mu_i\mu_i^T$. Similarly the expression for B holds. ■

C.5 Subspace Clustering Moments

In this section we derive the necessary moments required for subspace clustering. Recall that in the subspace clustering model we have k dimension—m subspaces $U_1,\ldots,U_k \in \mathbb{R}^{d\times m}$ (matrices $U_1,\ldots,U_k$ have orthonormal columns). The data is generated as follows. We sample $y\sim\mathcal{N}(0,I_d)$ and set $x = U_iU_i^Ty + \xi$, where $\xi\sim\mathcal{N}(0,\sigma^2I_d)$ is additive noise.

Theorem 13 *Consider the subspace clustering model. Let M_2, A, B be defined as,*

$$\begin{aligned}
M_2 &:= \mathbb{E}[xx^T], \quad A := M_2 - \sigma^2I_d \\
B &:= \mathbb{E}[\langle x,v\rangle^2xx^T] - \sigma^2(v^TAv)I_d - \sigma^2\|v\|^2A - \sigma^4(\|v\|^2I_d + vv^T) - 2\sigma^2(Avv^T + vv^TA)
\end{aligned}$$

where $\sigma^2 = \sigma_{mk+1}(M_2)$. Then,

$$\begin{aligned}
A &= \sum_{i=1}^k\alpha_iU_iU_i^T \\
B &= \sum_{i=1}^k\alpha_i\|U_i^Tv\|^2U_iU_i^T + 2\sum_{i=1}^k\alpha_iU_iU_i^Tvv^TU_iU_i^T
\end{aligned}$$

Proof First we compute M_2.

$$M_2 = \mathbb{E}(xx^T) = \sum_{i=1}^k\alpha_i\mathbb{E}\left[U_iU_i^Tyy^TU_iU_i^T\right] + \mathbb{E}[\xi\xi^T] = \sum_{i=1}^k\alpha_iU_iU_i^T + \sigma^2I_d$$

Using $\mathbb{E}[yy^T] = I$ as $y\sim\mathcal{N}(0,I)$ and $U_i^TU_i = I$ since the columns are orthogonal. Since $\alpha_i > 0$, the $mk+1$-th singular value of M_2, $\sigma_{mk+1}(M_2) = \sigma^2$. Therefore it follows that,

$$A = M_2 - \sigma^2I_d = \sum_{i=1}^k\alpha_iU_iU_i^T$$

Now we compute the moment $\mathbb{E}[\langle x,v\rangle^2xx^T]$. Given a sample $x = U_iU_i^Ty + \xi$ from the i-th subspace we have,

$$\begin{aligned}
\langle x,v\rangle^2 &= v^TU_iU_i^Tyy^TU_iU_i^Tv + v^T\xi\xi^Tv + 2v^T\xi v^TU_iU_i^Ty \\
xx^T &= U_iU_i^Tyy^TU_iU_i^T + U_iU_i^Ty\xi^T + \xi y^TU_iU_i^T + \xi\xi^T
\end{aligned}$$

Then we can write,

$$\begin{aligned}
&\mathbb{E}[\langle x,v\rangle^2xx^T] \\
&= \sum_{i=1}^k\alpha_i\left(\mathbb{E}[v^TU_iU_i^Tyy^TU_iU_i^TvU_iU_i^Tyy^TU_iU_i^T] + \mathbb{E}[v^TU_iU_i^Tyy^TU_iU_i^Tv]\mathbb{E}[\xi\xi^T]\right. \\
&\quad +\mathbb{E}[v^T\xi\xi^Tv]\mathbb{E}[U_iU_i^Tyy^TU_iU_i^T] + \mathbb{E}[v^T\xi\xi^Tv\xi\xi^T] + 2\mathbb{E}[(v^T\xi v^TU_iU_i^Ty)U_iU_i^Ty\xi^T] \\
&\quad \left.+2\mathbb{E}[(v^T\xi v^TU_iU_i^Ty)\xi y^TU_iU_i^T]\right) \\
&= T_1 + T_2 + T_3 + T_4 + T_5 + T_6 \qquad (6)
\end{aligned}$$

where $T_1, \ldots, T_6$ are as follows. We define $v_i := U_i U_i^T v$, we use the Gaussian moment results $\mathbb{E}[\langle v, z\rangle z] = \sigma^2 v$, and $\mathbb{E}[\langle v, z\rangle^2 z z^T] = \sigma^4(\|v\|^2 I_d + vv^T)$ whenever $z \sim \mathcal{N}(0, \sigma^2 I_d)$.

$$\begin{aligned}
T_1 &= \sum_{i=1}^k \alpha_i \mathbb{E}\left[v^T U_i U_i^T y y^T U_i U_i^T v U_i U_i^T y y^T U_i U_i^T\right] \\
&= \sum_{i=1}^k \alpha_i \mathbb{E}[\langle y, v_i\rangle^2 U_i U_i^T y y^T U_i U_i^T] = \sum_{i=1}^k \alpha_i U_i U_i^T \mathbb{E}[\langle y, v_i\rangle^2 y y^T] U_i U_i^T \\
&= \sum_{i=1}^k \alpha_i U_i U_i^T (\|v_i\|^2 I_d + 2 v_i v_i^T) U_i U_i^T \\
&= \sum_{i=1}^n \alpha_i \|v_i\|^2 U_i U_i^T + 2\sum_{i=1}^k \alpha_i U_i U_i^T v v^T U_i U_i^T \\
&= \sum_{i=1}^k \alpha_i \|U_i^T v\|^2 U_i U_i^T + 2\sum_{i=1}^k \alpha_i U_i U_i^T v v^T U_i U_i^T
\end{aligned}$$

since $\|v_i\| = \|U_i U_i^T v\| = \|U_i^T v\|$.

$$\begin{aligned}
T_2 &= \sum_{i=1}^k \alpha_i \mathbb{E}[v^T U_i U_i^T y y^T U_i U_i^T v]\mathbb{E}[\xi\xi^T] = \sum_{i=1}^k \alpha_i v^T U_i U_i^T v \times \sigma^2 I_d = \sigma^2 (v^T A v) I_d \\
T_3 &= \sum_{i=1}^k \alpha_i \mathbb{E}[v^T \xi\xi^T v]\mathbb{E}[U_i U_i^T y y^T U_i U_i^T] = \sigma^2 \|v\|^2 \sum_{i=1}^k \alpha_i U_i U_i^T = \sigma^2 \|v\|^2 A \\
T_4 &= \sum_{i=1}^k \alpha_i \mathbb{E}[v^T \xi\xi^T v \xi\xi^T] = \mathbb{E}[\langle v, \xi\rangle^2 \xi\xi^T] = \sigma^4(\|v\|^2 I_d + 2vv^T) \\
T_5 &= \sum_{i=1}^k \alpha_i 2\mathbb{E}[(v^T \xi v^T U_i U_i^T y) U_i U_i^T y \xi^T] = 2\sum_{i=1}^k \alpha_i \mathbb{E}[(v^T U_i U_i^T y) U_i U_i^T y]\mathbb{E}[\langle v, \xi\rangle \xi^T] \\
&= 2\sum_{i=1}^k \alpha_i \mathbb{E}[(v^T U_i U_i^T y) U_i U_i^T y] \times \sigma^2 v^T = 2\sigma^2 \sum_{i=1}^k \alpha_i \mathbb{E}[(v^T U_i U_i^T y) U_i U_i^T y v^T] \\
&= 2\sigma^2 \sum_{i=1}^k \alpha_i \mathbb{E}[U_i U_i^T \langle v, y\rangle y v^T] = 2\sigma^2 \sum_{i=1}^k \alpha_i U_i U_i^T v v^T = 2\sigma^2 A v v^T \\
T_6 &= 2\sum_{i=1}^k \alpha_i \mathbb{E}[(v^T \xi v^T U_i U_i^T y)\xi y^T U_i U_i^T] = 2\sum_{i=1}^k \alpha_i \mathbb{E}[\langle v, \xi\rangle \xi]\mathbb{E}[\langle v_i, y\rangle y^T U_i U_i^T] \\
&= 2\sigma^2 \sum_{i=1}^k \alpha_i v v_i^T U_i U_i^T = \sigma^2 \sum_{i=1}^k \alpha_i v v^T U_i U_i^T = \sigma^2 v v^T \sum_{i=1}^k \alpha_i U_i U_i^T = 2\sigma^2 v v^T A
\end{aligned}$$

Therefore,

$$\begin{aligned}
B &= \mathbb{E}[\langle x, v\rangle^2 x x^T] - \sigma^2 (v^T A v) I_d - \sigma^2 \|v\|^2 A - \sigma^4(\|v\|^2 I_d + vv^T) - 2\sigma^2(Avv^T + vv^T A) \\
&= \mathbb{E}[\langle x, v\rangle^2 x x^T] - T_2 - T_3 - T_4 - T_5 - T_6 = T_1 \\
&= \sum_{i=1}^k \alpha_i \|U_i^T v\|^2 U_i U_i^T + 2\sum_{i=1}^k \alpha_i U_i U_i^T v v^T U_i U_i^T
\end{aligned}$$

■

Appendix D. Finite-sample Analysis of the Whitening Method

Suppose that

$$\begin{aligned}
A &= \sum_i \alpha_i \mu_i \mu_i^T \\
B &= \sum_i \beta_i \mu_i \mu_i^T \\
\|A - \hat{A}\| &\le \epsilon \\
\|B - \hat{B}\| &\le \epsilon,
\end{aligned}$$

where σ_k is the kth singular value of A. Let V be the $n \times k$ matrix whose columns are the first k singular vectors of A, and let $\hat{V}$ be the same for $\hat{A}$. Let D be the diagonal matrix of singular values of A, and let $\hat{D}$ be the diagonal matrix of the first k singular values of $\hat{A}$. Then $A = VDV^T$ and $V^T V = \hat{V}^T \hat{V} = I_k$. This entire section is under the assumptions of Theorem 1; in particular, recall that $\epsilon \le \sigma_k(A)/4$.

It will be technically convenient for us to assume that $\|B\| \le \|A\| = \sigma_1(A)$. This assumption holds without loss of generality: if not, simply rescale the side information, setting $v^{\text{new}} = v\frac{\|A\|}{\|B\|}$. This has the effect of rescaling B, so that $\|B^{\text{new}}\| = \|A\|$; define also $\hat{B}^{\text{new}} = \hat{B}\frac{\|A\|}{\|B\|}$. Note that

$$\|B^{\text{new}} - \hat{B}^{\text{new}}\| = \|B - \hat{B}\|\frac{\|A\|}{\|B\|} \le \epsilon$$

under the assumption $\|B - \hat{B}\| \le \epsilon$. Now, the algorithm is homogeneous in $\hat{B}$: it will produce the same output given either $\hat{B}$ or $\hat{B}^{\text{new}}$; hence, it suffices to prove Theorem 1 with v, B, and $\hat{B}$ replaced by their new versions. Since the new versions satisfy $\|B^{\text{new}}\| \le \|A\|$, we may assume this without loss of generality. From now on, we will drop the notation B^{new}, and we will simply prove Theorem 1 under the assumption $\|B\| \le \|A\|$.

Our basic tool is Wedin's theorem:

Theorem 14 *For a matrix A, let $P^A_{\ge s}$ be the orthogonal projection onto the subspace spanned by singular vectors of A with singular value at least s. Let $P^A_{\le s}$ be the orthogonal projection onto the subspace spanned by singular vectors with singular value at most s. Then for any matrices A and B, and for any $s < t$,*

$$\|P^A_{\le s} P^B_{\ge t}\| \le \frac{2\|A - B\|}{t - s}.$$

In applying Wedin's theorem, the following geometric lemma will be useful. In what follows, P_E denotes the orthogonal projection onto E.

Lemma 15 *Let E and F be subspaces of $\mathbb{R}^n$ with $\|P_{E^\perp} P_F\| \leq \delta$. Then $\|P_F v\|^2 \leq \|P_E v\|^2 + 3\delta\|v\|^2$ for every $v \in \mathbb{R}^n$.*

Lemma 16 *If $\epsilon < \sigma_k/4$ then for any $u \in \mathbb{R}^k$,*

$$\sqrt{1 - \frac{16\epsilon^2}{\sigma_k^2}}\|u\| \leq \|\hat{V}^T V u\| \leq \|u\|.$$

By a simple change of variables, if we define

$$O = D^{-1/2}\hat{V}^T V D^{1/2}$$

then O is also an almost-isometry: for every $u \in \mathbb{R}^k$,

$$\sqrt{1 - \frac{16\epsilon^2}{\sigma_k^2}}\|u\| \leq \|Ou\| \leq \|u\|. \tag{7}$$

Proof First, note that $\sigma_k(\hat{A}) \geq \sigma_k(A) - \|A - \hat{A}\| \geq \sigma_k - \epsilon$. If $\epsilon < \sigma_k/4$, we also have $\sigma_{k+1}(\hat{A}) \leq \sigma_{k+1}(A) + \epsilon \leq \sigma_k/4 < \sigma_k - \epsilon$, which implies that $\hat{V}\hat{V}^T = P^{\hat{A}}_{\geq \sigma_k - \epsilon}$.

Let $\hat{W}$ be a $d \times (d-k)$ matrix whose columns form an orthonormal basis for the orthogonal complement of the column span of $\hat{V}$. Note that if $\epsilon < \sigma_k/2$ then the kth singular value of $\hat{A}$ is strictly larger than $\sigma_k/2$ and the $(k+1)$th singular value is at most ϵ. Then $P^{\hat{A}}_{\leq \epsilon} = \hat{W}\hat{W}^T$. By Wedin's theorem,

$$\|\hat{W}\hat{W}^T V V^T\| = \|P^{\hat{A}}_{\leq \epsilon} P^A_{\geq \sigma_k}\| \leq \frac{2\epsilon}{\sigma_k - \epsilon} \leq \frac{4\epsilon}{\sigma_k}$$

Now, $\hat{W}^T$ and V have norm 1, and so it follows that

$$\|\hat{W}^T V\| = \|\hat{W}^T(\hat{W}\hat{W}^T V V^T)V\| \leq \frac{4\epsilon}{\sigma_k}.$$

For any $u \in \mathbb{R}^k$ with $\|u\| = 1$, we have

$$\|\hat{V}^T V u\|^2 = 1 - \|\hat{W}^T V u\|^2 \geq 1 - 16\epsilon^2/\sigma_k^2,$$

from which the claimed lower bound follows. On the other hand, $\|\hat{V}^T V u\| \leq u$ because both $\hat{V}^T$ and V have norm 1. ■

Let $M = D^{-1/2}V^T B V D^{-1/2}$ and $\hat{M} = \hat{D}^{-1/2}\hat{V}^T\hat{B}\hat{V}\hat{D}^{-1/2}$. Then M is the infinite-sample version of A's whitening matrix applied to B, and $\hat{M}$ is the finite-sample analogue. Recall from (7) that $O = D^{-1/2}\hat{V}^T V D^{1/2}$ is an almost-isometry of $\mathbb{R}^k$.

Lemma 17

$$\|OMO^T - \hat{M}\| \leq C\frac{\epsilon\sigma_1}{\sigma_k^2}.$$

Proof The first step is to approximate OMO^T by $D^{-1/2}\hat{V}^T B\hat{V}D^{-1/2}$. To this end, note that

$$OMO^T = D^{-1/2}\hat{V}^T V V^T B V V^T \hat{V} D^{-1/2}.$$

Now, $\hat{V}$ is an isometry of $\mathbb{R}^k$ into $\mathbb{R}^n$; hence,

$$\|\hat{V}^T V V^T - \hat{V}^T\| = \|\hat{V}\hat{V}^T V V^T - \hat{V}\hat{V}^T\| = \|P^{\hat{A}}_{\geq \sigma_k - \epsilon} P^A_{\geq \sigma_k} - P^{\hat{A}}_{\geq \sigma_k - \epsilon}\| = \|P^{\hat{A}}_{\geq \sigma_k - \epsilon} P^A_{\leq 0}\|,$$

where the last equality used the fact that A has rank exactly k, and hence $I - P^A_{\geq \sigma_k} = P^A_{\leq 0}$. Now, Wedin's theorem applied to the computation above implies that

$$\|\hat{V}^T V V^T - \hat{V}^T\| \leq \frac{2\epsilon}{\sigma_k - \epsilon} \leq \frac{4\epsilon}{\sigma_k}$$

(recalling that $\epsilon \leq \sigma_k/4$).

Now, for general matrices $X, Y, \tilde{Y}, Z$ we have

$$\begin{aligned}\|X^T Y^T Z Y X - X^T \tilde{Y}^T Z \tilde{Y} X\| &\leq \|X^T(Y - \tilde{Y})^T Z Y X\| + \|X^T \tilde{Y}^T Z (Y - \tilde{Y}) X\| \\ &\leq \|Y - \tilde{Y}\|\|X\|^2\|Z\|(\|Y\| + \|\tilde{Y}\|).\end{aligned}$$

We apply this with $X = D^{-1/2}$, $Y = \hat{V}$, $\tilde{Y} = \hat{V}VV^T$, and $Z = B$; since $\|D^{-1/2}\| = \sigma_k^{-1/2}$, $\|B\| \leq \sigma_1$, and $\|\hat{V}\|, \|V\|, \|V^T\| = 1$,

$$\|OMO^T - D^{-1/2}\hat{V}^T B\hat{V}D^{-1/2}\| \leq \frac{8\epsilon\sigma_1}{\sigma_k^2}$$

Next, we will replace B by $\hat{B}$ in the above inequality. Since $\|\hat{V}\| = \|\hat{V}^T\| = 1$ and $\|D^{-1/2}\| = \sigma_k^{-1/2}$,

$$\begin{aligned}\|D^{-1/2}\hat{V}^T B\hat{V}D^{-1/2} - D^{-1/2}\hat{V}^T\hat{B}\hat{V}D^{-1/2}\| &= \|D^{-1/2}\hat{V}^T(B - \hat{B})\hat{V}D^{-1/2}\| \\ &\leq \sigma_k^{-1}\|B - \hat{B}\| \leq \frac{\epsilon}{\sigma_k}.\end{aligned}$$

Putting this together with the previous bound yields

$$\|OMO^T - D^{-1/2}\hat{V}^T\hat{B}\hat{V}D^{-1/2}\| \leq \frac{\epsilon}{\sigma_k} + \frac{8\epsilon\sigma_1}{\sigma_k^2} \tag{8}$$

It remains to relate $D^{-1/2}\hat{V}^T\hat{B}\hat{V}D^{-1/2}$ to $\hat{M}$ (which is the same, but with $\hat{D}$ instead of D). Now, Weyl's inequality implies that

$$\|D^{-1/2} - \hat{D}^{-1/2}\| \leq \sigma_k^{-1/2} - (\sigma_k - \epsilon)^{-1/2} \leq \epsilon\sigma_k^{-3/2},$$

where the second inequality follows from a first-order Taylor expansion and the fact that $\epsilon \leq \sigma_k/2$. Hence,

$$\begin{aligned}\|D^{-1/2}\hat{V}^T\hat{B}\hat{V}D^{-1/2} - \hat{M}\| &\leq \|D^{-1/2} - \hat{D}^{-1/2}\|\|\hat{V}^T\hat{B}\hat{V}D^{-1/2}\| \\ &\quad + \|\hat{D}^{-1/2}\hat{V}^T\hat{B}\hat{V}\|\|D^{-1/2} - \hat{D}^{-1/2}\| \\ &\leq 4\epsilon\sigma_1\sigma_k^{-2}.\end{aligned}$$

Combining this with (8) and the triangle inequality, we have

$$\|OMO^T - \hat{M}\| = \frac{\epsilon}{\sigma_k} + 12\frac{\epsilon\sigma_1}{\sigma_k^2} \leq C\frac{\epsilon\sigma_1}{\sigma_k^2}.$$

■

Since O is almost an isometry, it follows that there is an orthogonal matrix $\tilde{O}$ that is close to O (for example, if $UDV^T = O$ is an SVD, let $\tilde{O} = UV^T$). In this way, we may find an orthogonal $\tilde{O}$ such that

$$\|O - \tilde{O}\| \leq 1 - \sqrt{1 - \frac{16\epsilon^2}{\sigma_k^2}} \leq \frac{16\epsilon^2}{\sigma_k^2}.$$

Now let u be the top eigenvector of M and let u_O be the top eigenvector of OMO^T. Then $\tilde{O}u$ is the top eigenvector of $\tilde{O}M\tilde{O}^T$. The triangle inequality implies that

$$\|OMO^T - \tilde{O}M\tilde{O}^T\| \leq 2\|M\|\|O - \tilde{O}\| \leq \frac{32\epsilon^2}{\sigma_k^2}\|M\|.$$

On the other hand, M was assumed to have a spectral gap of $\delta\|M\|$. By Wedin's theorem, it follows that

$$\|u - \tilde{O}^T u_O\| = \|\tilde{O}u - u_O\| \leq \frac{64\epsilon^2}{\delta\sigma_k^2}.$$

Finally, let $\hat{u}$ be the top eigenvector of $\hat{M}$. By Lemma 17 and Wedin's theorem,

$$\|\hat{u} - u_O\| \leq \frac{C\epsilon\sigma_1}{\delta\sigma_k^2}.$$

Then

$$\|Ou - \hat{u}\| \leq \|O - \tilde{O}\| + \|\tilde{O}u - \hat{h}\| \leq C\max\left\{\frac{\epsilon\sigma_1}{\delta\sigma_k^2}, \frac{\epsilon^2}{\delta\sigma_k^2}\right\} \leq \frac{C\epsilon\sigma_1}{\delta\sigma_k^2}, \tag{9}$$

where the last inequality follows because $\epsilon \leq \sigma_k/2 \leq \sigma_1/2$.

Next, we unpack O. Weyl's inequality implies that

$$\|D^{-1/2} - \hat{D}^{-1/2}\| \leq \sigma_k^{-1/2} - (\sigma_k - \epsilon)^{-1/2} \leq \epsilon\sigma_k^{-3/2},$$

where the second inequality follows from a first-order Taylor expansion and the fact that $\epsilon \leq \sigma_k/4$. Hence,

$$\|O - \hat{D}^{-1/2}\hat{V}^T V D^{1/2}\| \leq \|D^{1/2}\|\|D^{-1/2} - \hat{D}^{-1/2}\| \leq \frac{\epsilon\sqrt{\sigma_1}}{\sigma_k^{3/2}}.$$

The right hand side is smaller than $\frac{\epsilon\sigma_1}{\sigma_k^2}$, and so we may plug it into (9) to obtain

$$\|\hat{D}^{-1/2}\hat{V}^T V D^{1/2}u - \hat{u}\| \leq \frac{C\epsilon\sigma_1}{\delta\sigma_k^2}.$$

Finally, (again because $\epsilon \leq \sigma_k/2$), $\|\hat{D}^{-1/2}\| \leq (\sigma_k/2)^{-1/2}$, and so

$$\|VD^{1/2}u - \hat{V}\hat{D}^{1/2}\hat{u}\| \leq \frac{C\epsilon\sigma_1}{\delta\sigma_k^{5/2}}. \tag{10}$$

Setting $w = VD^{1/2}u$ and $\hat{w} = \hat{V}\hat{D}^{1/2}\hat{u}$ and comparing this to the setting of Algorithm 1, (10) shows that the finite-sample algorithm gets almost the same w as the infinite-sample version.

It remains to check the last few lines of Algorithm 1; i.e., to see that we recover the right scaling of w.

Lemma 18 *Let M be a symmetric matrix of rank $k-1$ and let E be the span of its columns. Then $\|w\|\operatorname{dist}(w, E) \geq \sigma_k(M + ww^T)$.*

Proof It suffices to consider the case $\|w\| = 1$ (for a general w, apply the special case of the lemma to $w/\|w\|$ and $M/\|w\|^2$). Let P_E denote the orthogonal projection onto E, and note that $\|w - P_E w\| = \operatorname{dist}(w, E)$ Let $F = \operatorname{span}\{E, w\}$. Since F has dimension k and $y \in F^\perp$ implies $\|(M + ww^T)y\| = 0$, it suffices to find some $y \in F$ such that $\|(M + ww^T)y\| \leq \operatorname{dist}(w, E)\|y\|$. Choose $y = w - P_E w$. Then $My = 0$ and so

$$\|(M + ww^T)y\| = |w^T y| = \|w - P_E w\|^2 = \operatorname{dist}(w, E)\|y\|.$$

■

Lemma 19 *Let E be a subspace and take $w \notin E$. For $x \in \operatorname{span}\{E, w\}$, let $a(x) \in \mathbb{R}$ be the unique solution to $x = aw + e$, $e \in E$. Then $|a(x) - a(y)| \leq \|x - y\|/\operatorname{dist}(w, E)$.*

Proof Given $x, y \in \operatorname{span}\{E, w\}$, we can write $x - y = (a(x) - a(y))w + e$, where $e \in E$. It follows that

$$\begin{aligned}\|x - y\| &= \|(a(x) - a(y))w + e\| \geq \inf_{e \in E}\|(a(x) - a(y))w + e\| \\ &= |a(x) - a(y)|\operatorname{dist}(w, E).\end{aligned}$$

■

Finally, we apply the preceding two lemmas to show that $\hat{\alpha}_1$ is accurate in Algorithm 1. Together with (10) (whose right hand side provides the value of η that we will use), this completes the proof of Theorem 1.

Lemma 20 *Let $m = \sum_i \alpha_i\mu_i$. If $\|\hat{A} - A\| \leq \epsilon$, $\|\hat{m} - m\| \leq \epsilon$ and $\|\hat{w} - \sqrt{\alpha_1}\mu_1\| \leq \eta$ then*

$$|\hat{\alpha}_1 - \alpha_1| \leq \frac{C\sqrt{\alpha_1}|\alpha_1 R + \eta|}{\sigma_k}\left(\eta + R\frac{\epsilon}{\sigma_k} + \epsilon\right),$$

where $R = \max_i \|\mu_i\|$, provided that the right hand side above is at most α_1.

Proof By Wedin's theorem,

$$\|VV^T - \hat{V}\hat{V}^T\| \leq \frac{2\|\hat{A} - A\|}{\sigma_k - \|\hat{A} - A\|} \leq 4\frac{\epsilon}{\sigma_k}$$

if $\epsilon \leq \sigma_k/2$. Hence,

$$\begin{aligned} \|m - \hat{V}\hat{V}^T\hat{m}\| &= \|VV^T m - \hat{V}\hat{V}^T\hat{m}\| \\ &\leq \|(VV^T - \hat{V}\hat{V}^T)m\| + \|\hat{V}\hat{V}^T(m - \hat{m})\| \\ &\leq 4\frac{\epsilon}{\sigma_k}\|m\| + \epsilon. \end{aligned}$$

Now, let $y = \sqrt{\alpha_1}\hat{w} + \hat{V}\hat{V}^T\sum_{i=2}^k \alpha_i\mu_i$. Then

$$\begin{aligned} \|m - y\| &\leq \sqrt{\alpha_1}\|\hat{w} - \sqrt{\alpha_1}\mu_1\| + \left\|\sum_{i=2}^k \alpha_i(\mu_i - \hat{V}\hat{V}^T\mu_i)\right\| \\ &\leq \eta + \max_i \|\mu_i\|\|VV^T - \hat{V}\hat{V}^T\| \\ &\leq \eta + 4\max_i \|\mu_i\|\frac{\epsilon}{\sigma_k}. \end{aligned}$$

Defining $R = \max_i \|\mu_i\|$, we have

$$\|y - \hat{V}\hat{V}^T\hat{m}\| \leq \eta + 8R\frac{\epsilon}{\sigma_k} + \epsilon.$$

Now, let $\hat{E}$ be the span of $\{\hat{V}\hat{D}^{1/2}v : v \in \mathbb{R}^k, v \perp \hat{u}\}$, and note that $\hat{E}$ may also be written as the column space of $\hat{V}\hat{D}^{1/2}(I_k - \hat{u}\hat{u}^T)\hat{D}^{1/2}\hat{V}^T = \hat{V}\hat{D}\hat{V}^T - \hat{w}\hat{w}^T$. Since $\hat{V}\hat{D}^{1/2}$ is injective, $\hat{E}$ has dimension $k-1$ and does not contain $\hat{w} = \hat{V}\hat{D}^{1/2}\hat{u}$. Hence, $y = \sqrt{\alpha_1}\hat{w} + e$ is the unique way to decompose y in $\text{span}\{\hat{w}\} \oplus \hat{E}$. If we define a by the decomposition $\hat{m} = a\hat{w} + e$ then Lemma 19 implies

$$\begin{aligned} |a - \sqrt{\alpha_1}| &\leq \|y - \hat{m}\|/\operatorname{dist}(\hat{w}, \hat{E}) \\ &\leq \frac{1}{\operatorname{dist}(\hat{w}, \hat{E})}\left(\eta + 8R\frac{\epsilon}{\sigma_k} + \epsilon\right). \end{aligned}$$

On the other hand, Lemma 18 applied to $\hat{V}\hat{D}\hat{V}^T - \hat{w}\hat{w}^T$ and $\hat{w}$ implies (because the kth singular value of $\hat{V}\hat{D}\hat{V}^T \geq \sigma_k - \epsilon \geq \sigma_k/2$) that $\|\hat{w}\|\operatorname{dist}(\hat{w}, \hat{E}) \geq \sigma_k/2$. Therefore,

$$|a - \sqrt{\alpha_1}| \leq \frac{2\|\hat{w}\|}{\sigma_k}\left(\eta + 8R\frac{\epsilon}{\sigma_k} + \epsilon\right) \leq \frac{2(\alpha_1\|\mu_1\| + \eta)}{\sigma_k}\left(\eta + 8R\frac{\epsilon}{\sigma_k} + \epsilon\right).$$

Finally, note that $|\hat{\alpha}_1 - \alpha_1| = |a^2 - \alpha_1| = |a - \sqrt{\alpha_1}|(a + \sqrt{\alpha_1})$. We consider two cases: if $a \leq C\sqrt{\alpha_1}$ then $|\hat{\alpha}_1 - \alpha_1| \leq (1 + C)\sqrt{\alpha_1}|a - \sqrt{\alpha_1}|$, which completes the proof. In the other case, we have

$$|\hat{\alpha}_1 - \alpha_1| \sim \hat{\alpha}_1 \leq C\sqrt{\hat{\alpha}_1}|a - \sqrt{\alpha_1}|,$$

which implies that

$$|\hat{\alpha}_1 - \alpha_1| \leq C|a - \sqrt{\alpha_1}|^2$$

for some other constant C. This implies

$$|\hat{\alpha}_1 - \alpha_1| \leq C\left[\frac{(\alpha_1 R + \eta)}{\sigma_k}\left(\eta + R\frac{\epsilon}{\sigma_k} + \epsilon\right)\right]^2 \leq C\sqrt{\alpha_1}\left[\frac{(\alpha_1 R + \eta)}{\sigma_k}\left(\eta + R\frac{\epsilon}{\sigma_k} + \epsilon\right)\right],$$

where the second inequality comes from the assumption that the right hand side in the lemma is bounded by α_1. ■

As we pointed out in Section 2, spectral algorithms similar to Algorithm 1 has been proposed before for GMM [Hsu and Kakade 2013] and LDA [Anandkumar et al. 2012] models, the main difference being how the second matrix (equivalent to B) is constructed. Since the underlying whitening procedure is the same in all these algorithms, the proof approach presented above is similar to those in Hsu and Kakade (2013); Anandkumar et al. (2012). The proofs diverge when computing the perturbation of the second matrix, matrix B in our algorithm, which introduces different dependence on various parameter models in the overall error bound. For example the error bound in Theorem 4.1 of Anandkumar et al. (2012) has a slightly worse dependence on k and σ_k than Theorem 1.

Appendix E. Finite-sample Analysis of the Cancellation Method

In this section we analyze the performance of Algorithm 2 when we have finite sample estimates of the matrices A, B and vector m. For ease of exposition we replaced the quantities $V_{1:(k-1)}, v_i, a_i, c_i$ in Algorithm 2 with the notation representing estimate $\widehat{V}_{1:(k-1)}, \hat{v}_i, \hat{a}_i, \hat{c}_i$ respectively, since these are computed from sample estimates $\widehat{A}, \widehat{B}$. First, we show in Lemma 21 that we can have a good estimate for $\widehat{Z}_{\lambda^*}$ using good estimates for A, B and λ_1.

Lemma 21 *Let $\widehat{Z}_\lambda = \widehat{A} - \lambda\widehat{B}, Z_\lambda = A - \lambda B$. Suppose $\max\{\|\widehat{A} - A\|, \|\widehat{B} - B\|\} < \epsilon$ and $\lambda_1 = 1/w_1$. Then,*

$$\|\widehat{Z}_\lambda - Z_{\lambda_1}\| < \epsilon\left(2 + \frac{1}{w_1}\right) + \epsilon_1\sigma_1(B)$$

when $|\lambda_1 - \lambda| < \epsilon_1 < 1$.

Proof We have,

$$\begin{aligned} \|\widehat{Z}_\lambda - Z_{\lambda_1}\| &\leq \|\widehat{A} - A\| + \|\lambda\widehat{B} - \lambda_1 B\| \\ &< \|\widehat{A} - A\| + \lambda_1\|\widehat{B} - B\| + |\lambda_1 - \lambda|\|\widehat{B}\| \\ &\leq \epsilon + \lambda_1\epsilon + \epsilon_1(\sigma_1(B) + \epsilon) \\ &< \epsilon(1 + 1/w_1 + \epsilon_1) + \epsilon_1\sigma_1(B) < \epsilon\left(2 + \frac{1}{w_1}\right) + \epsilon_1\sigma_1(B) \end{aligned}$$

since $\epsilon_1 < 1$. ■

The following lemma will show that even with noisy estimates of A, B, the estimated λ^* is close to λ_1.

Lemma 22 *Let* $\max\{\|\widehat{A}-A\|, \|\widehat{B}-B\|\} < \epsilon < \sigma_k(A)/2$, *and* $\lambda_1 = 1/w_1 > 0$. *Then,*

$$|\lambda^* - \lambda_1| = O(\epsilon)$$

Proof Define $Z'_\lambda = VV^TAVV^T - \lambda VV^TBVV^T$, V being the $d \times k$ matrix of top k eigenvectors of A. The corresponding empirical estimate $\widehat{Z}'_\lambda = \widehat{V}\widehat{V}^T\widehat{A}\widehat{V}\widehat{V}^T - \lambda\widehat{V}\widehat{V}^T\widehat{B}\widehat{V}\widehat{V}^T$. The main proof idea is the following. We try to find $\lambda_2, \lambda_3 > 0$ such that:

1. $\forall \lambda > \lambda_2$, $\widehat{Z}'_\lambda$ is not PSD.
2. $\forall \lambda < \lambda_3$, $\widehat{Z}'_\lambda$ is PSD.

The above two conditions imply that the optimum λ^* is bounded as $\lambda_3 \le \lambda^* \le \lambda_2$. We then simply bound $\lambda^* - \lambda_1$ as $\lambda_3 - \lambda_1 \le \lambda^* - \lambda_1 \le \lambda_2 - \lambda_1$. We now elaborate the above two steps. First, we bound the perturbation of empirical matrix $\widehat{Z}'_\lambda$ as follows. Using Wedin's theorem we have $\|\widehat{V}\widehat{V}^T - VV^T\| \le \frac{4\epsilon}{\sigma_k(A)}$. Using this and the theorem assumptions we can compute the following bounds.

$$\begin{aligned}
\|\widehat{V}\widehat{V}^T\widehat{A}\widehat{V}\widehat{V}^T - VV^TAVV^T\| &\le 13\epsilon \\
\|\widehat{V}\widehat{V}^T\widehat{B}\widehat{V}\widehat{V}^T - VV^TBVV^T\| &\le \left(1 + \frac{12\sigma_k(B)}{\sigma_k(A)}\right)\epsilon
\end{aligned}$$

Combining, we have

$$\|\widehat{Z}'_\lambda - Z'_\lambda\| \le \|\widehat{V}\widehat{V}^T\widehat{A}\widehat{V}\widehat{V}^T - VV^TAVV^T\| + \lambda\|\widehat{V}\widehat{V}^T\widehat{B}\widehat{V}\widehat{V}^T - VV^TBVV^T\| \le c_1(1+\lambda)\epsilon \quad (11)$$

where $c_1 = \max\{13, 1 + \frac{12\sigma_k(B)}{\sigma_k(A)}\}$.

Step 1: Since matrices A and B share the same column and row space, $VV^TAVV^T = A$, $VV^TBVV^T = B$, and $Z'_\lambda = Z_\lambda = \sum_{i=1}^k (1 - \lambda w_i)\alpha_i\mu_i\mu_i^T$, $w_i = \langle \mu_i, v\rangle$. Recall, $\mathcal{V} = \text{span}\{\mu_2, \ldots, \mu_k\}$ and Π denote the projection onto $\mathcal{V}_\perp$, its perpendicular space. Let $x_1 = \Pi\mu_1/\|\Pi\mu_1\|$, and $x_1 = V\tilde{x}_1$, $\|x_1\| = \|\tilde{x}_1\| = 1$. Consider the eigenvalues of the $k \times k$ Hermitian matrix $V^TZ_\lambda V$. Using variational theorem we can write:

$$\tilde{\sigma}_k(V^TZ_\lambda V) = \min_{x \ne 0, \|x\|=1} x^TV^TZ_\lambda Vx \le \tilde{x}_1^TV^TZ_\lambda V\tilde{x}_1 = x_1^TZ_\lambda x_1 = (1 - \lambda w_1)\alpha_1 a'_1 \quad (12)$$

where $a'_1 = |\langle x_1, \mu_1\rangle|^2 > 0$. Now note that the matrices $Z'_\lambda = VV^TZ_\lambda VV^T$ and $V^TZ_\lambda V$ have the same set of non-zero eigenvalues since V forms an orthonormal basis of the row/column space of Z_λ. Therefore we can write from above,

$$\tilde{\sigma}_k(Z'_\lambda) = \tilde{\sigma}_k(V^TZ_\lambda V) \le (1 - \lambda w_1)\alpha_1 a'_1 \quad (13)$$

For $\lambda = \lambda_1 = 1/w_1$, Z'_{λ_1} is a rank $k-1$ matrix, and for any $\lambda > \lambda_1$, Z'_λ has at least one negative eigenvalue. Consider $\lambda_2 > \lambda_1$ such that Z'_{λ_2} has one negative eigenvalue and $k-1$ positive eigenvalues. Since $\widehat{Z}'_{\lambda_2}, Z'_{\lambda_2}$ are symmetric matrices, using Weyl's inequality we get,

$$\begin{aligned}
\tilde{\sigma}_k(\widehat{Z}'_{\lambda_2}) &\le \tilde{\sigma}_k(Z'_{\lambda_2}) + \|\widehat{Z}'_{\lambda_2} - Z'_{\lambda_2}\| \le \tilde{\sigma}_k(Z'_{\lambda_2}) + c_1(1+\lambda_2)\epsilon \\
&\le (1 - \lambda_2 w_1)\alpha_1 a'_1 + c_1(1+\lambda_2)\epsilon \\
&\le a'_1[(\alpha_1 + \epsilon) - \lambda_2(w_1\alpha_1 - \epsilon)] \quad (14)
\end{aligned}$$

using equations (11), (13), and assuming $a'_1 > c_1$ (else we can simply rescale ϵ). Now for any $\lambda > \lambda_2 = \frac{\alpha_1+\epsilon}{\alpha_1 w_1 - \epsilon}$ we get

$$\tilde{\sigma}_k(\widehat{Z}'_\lambda) \le a'_1[(\alpha_1 + \epsilon) - \lambda(w_1\alpha_1 - \epsilon)] \le a'_1[(\alpha_1 + \epsilon) - \lambda_2(w_1\alpha_1 - \epsilon)] = 0$$

Therefore, when $\lambda > \lambda_2 = \frac{\alpha_1+\epsilon}{\alpha_1 w_1 - \epsilon}$, $\widehat{Z}'_\lambda$ is not PSD. This implies that $\lambda_2 \ge \lambda^*$. Then,

$$\lambda^* - \lambda_1 \le \lambda_2 - \lambda_1 = \frac{\alpha_1 + \epsilon}{\alpha_1 w_1 - \epsilon} - \frac{1}{w_1} = \frac{\epsilon(w_1 + 1)}{(\alpha_1 w_1 - \epsilon)w_1} \quad (15)$$

Step 2: Consider $\lambda_3 < \lambda_1$ such that Z'_{λ_3} is PSD. Then we lower bound $\tilde{\sigma}_k(Z'_{\lambda_3})$ as follows. Let $\tilde{v}_{k,\lambda_3}$ be the $k-$th eigenvector of Z'_{λ_3} having eigenvalue $\tilde{\sigma}_k(Z'_{\lambda_3})$. Then,

$$\begin{aligned}
\tilde{\sigma}_k(Z'_{\lambda_3}) &= \tilde{v}_{k,\lambda_3}^TZ'_{\lambda_3}\tilde{v}_{k,\lambda_3} = \sum_{i=1}^k \alpha_i(1 - \lambda_3 w_i)\tilde{v}_{k,\lambda_3}^T\mu_i\mu_i^T\tilde{v}_{k,\lambda_3} \\
&\ge (1 - \lambda_3 w_1)\sum_{i=1}^k \alpha_i|\langle \tilde{v}_{k,\lambda_3}, \mu_i\rangle|^2 \ge (1 - \lambda_3 w_1)a'_2 \quad (16)
\end{aligned}$$

since $w_1 > w_i$, $i \ne 1$, and where $a'_2 = \inf_{\lambda \ge 0}\sum_{i=1}^k \alpha_i|\langle \tilde{v}_{k,\lambda}, \mu_i\rangle|^2 > 0$. Now using the lower bound of Weyl's inequality,

$$\begin{aligned}
\tilde{\sigma}_k(\widehat{Z}'_{\lambda_3}) &\ge \tilde{\sigma}_k(Z'_{\lambda_3}) - \|\widehat{Z}'_{\lambda_3} - Z'_{\lambda_3}\| \\
&\ge \tilde{\sigma}_k(Z'_{\lambda_3}) - c_1(1 + \lambda_3)\epsilon \\
&\ge (1 - \lambda_3 w_1)a'_2 - c_1(1 + \lambda_3)\epsilon \\
&\ge c_1[(1 - \epsilon) - \lambda_3(w_1 + \epsilon)]
\end{aligned}$$

using equation (16), and assuming $c_1 < a'_2$ (else we can simply rescale ϵ). Then, for any $\lambda < \lambda_3 = \frac{(1-\epsilon)}{(w_1+\epsilon)}$ we have $\tilde{\sigma}_k(\widehat{Z}'_\lambda) > 0$, or $\widehat{Z}'_\lambda$ is PSD. This implies $\lambda^* > \lambda_3$. Therefore,

$$\lambda^* - \lambda_1 \ge \lambda_3 - \lambda_1 = \frac{(1 - \epsilon)}{(w_1 + \epsilon)} - \frac{1}{w_1} = -\frac{(w_1 + 1)\epsilon}{(w_1 + \epsilon)w_1} \quad (17)$$

Combining equations (15), (17) we get,

$$|\lambda^* - \lambda_1| \le c_3\epsilon = O(\epsilon)$$

where $c_3 = \max\left(\frac{(w_1+1)}{(w_1+\epsilon)w_1}, \frac{(w_1+1)}{(\alpha_1 w_1 - \epsilon)w_1}\right)$. ■

In Lemma 22 we assume $w_1 = \langle \mu_1, v\rangle$ is positive. When $w_1 < 0$, we have to modify the line search and find the smallest $\lambda < 0$ such that $\widehat{Z}'_\lambda$ is PSD. However we can still apply similar arguments and prove that as long as the estimates of A, B, are within ϵ in spectral norm, Algorithm 2 can estimate λ^* within an $O(\epsilon)$ accuracy of λ_1. Lemma 21 and 22

together implies that $\|\widehat{Z}_{\lambda^*} - Z_{\lambda_1}\| = O(\epsilon)$ as follows, which will be used to prove Theorem 3. We have,

$$\begin{aligned}\|\widehat{Z}_{\lambda^*} - Z_{\lambda_1}\| &< \epsilon\left(2 + \frac{1}{w_1}\right) + \epsilon_1\sigma_1(B) \\ &\leq \epsilon\left(2 + \frac{1}{w_1}\right) + c_3\epsilon\sigma_1(B) \\ &\leq 3\eta_3\epsilon \end{aligned} \tag{18}$$

where in the last inequality we assume $\epsilon < \alpha_1 w_1/2$, and $\eta_3 = \max\left\{2, \frac{1}{w_1}, c_3\sigma_1(B)\right\}$.

Lemma 23 *Let $\|\hat{m} - m\| < \epsilon$, $\|\widehat{Z}_{\lambda^*} - Z_{\lambda_1}\| < \epsilon_2 < \sigma_{k-1}(Z_{\lambda_1})/2$ for $\lambda_1 = \alpha_1/\beta_1$. $V_{1:(k-1)}$ denote the $d \times (k-1)$ matrix of $k-1$ largest singular vectors of Z_{λ_1} and $\widehat{V}_{1:(k-1)}$ be the $d \times (k-1)$ matrix of $k-1$ largest singular vectors of $\widehat{Z}_{\lambda^*}$. Then,*

$$\begin{aligned}\|\hat{x}_1 - x_1\| &< 2\epsilon + \frac{4\epsilon_2 R}{\sigma_{k-1}(Z_{\lambda_1})} = \epsilon_3 \\ \|\hat{v}_1 - v_1\| &< \frac{2\epsilon_3}{\alpha_1 a_1} = \epsilon_4\end{aligned}$$

where $R = \max_{i\in[k]} \|\mu_i\|$.

Proof Since, $\|\widehat{Z}_{\lambda^*} - Z_{\lambda_1}\| < \epsilon_2 < \sigma_{k-1}(Z_{\lambda_1})/2$, applying Wedin's theorem we get,

$$\|\widehat{V}_{1:(k-1)}\widehat{V}_{1:(k-1)}^T - V_{1:(k-1)}V_{1:(k-1)}^T\| \leq \frac{2\|\widehat{Z}_{\lambda^*} - Z_{\lambda_1}\|}{\sigma_{k-1}(Z_{\lambda_1}) - \|\widehat{Z}_{\lambda^*} - Z_{\lambda_1}\|} \leq \frac{4\epsilon_2}{\sigma_{k-1}(Z_{\lambda_1})} \tag{19}$$

since $\epsilon_2 < \sigma_{k-1}(Z_{\lambda_1})/2$. Now,

$$\begin{aligned}\|\hat{x}_1 - x_1\| &= \|\hat{m} - \widehat{V}_{1:(k-1)}\widehat{V}_{1:(k-1)}^T\hat{m} - m + V_{1:(k-1)}V_{1:(k-1)}^T m\| \\ &\leq \|\hat{m} - m\| + \|(\widehat{V}_{1:(k-1)}\widehat{V}_{1:(k-1)} - V_{1:(k-1)}V_{1:(k-1)}^T)m\| + \|\widehat{V}_{1:(k-1)}\widehat{V}_{1:(k-1)}^T(m - \hat{m})\| \\ &< 2\|m - \hat{m}\| + \frac{4\epsilon_2\|m\|}{\sigma_{k-1}(Z_{\lambda_1})} < 2\epsilon + \frac{4\epsilon_2 R}{\sigma_{k-1}(Z_{\lambda_1})} := \epsilon_3\end{aligned}$$

where we used equation 19 and $\|m\| \leq R$. Recall that $x_1 = \alpha_1 \prod_{\mathcal{V}} \mu_1 = \alpha_1 a_1 v_1$, where $\mathcal{V} = \text{span}\{\mu_2, \ldots, \mu_k\}$ and $a_1 = \langle \mu_1, v_1 \rangle$. To show the second bound,

$$\begin{aligned}\|\hat{v}_1 - v_1\| &= \left\|\frac{\hat{x}_1}{\|\hat{x}_1\|} - \frac{x_1}{\|x_1\|}\right\| \\ &\leq \frac{\|\hat{x}_1 - x_1\|}{\|x_1\|} + \|\hat{x}_1\|\left|\frac{1}{\|x_1\|} - \frac{1}{\|\hat{x}_1\|}\right| \\ &< \frac{\|\hat{x}_1 - x_1\|}{\|x_1\|} + \frac{|\|\hat{x}_1\| - \|x_1\||}{\|x_1\|} \leq 2\frac{\|\hat{x}_1 - x_1\|}{\|x_1\|} \\ &< \frac{2\epsilon_3}{\alpha_1 a_1} := \epsilon_4\end{aligned}$$

■

Lemma 24 *Let $\|\widehat{A} - A\| < \epsilon, \|\hat{v}_1 - v_1\| < \epsilon_4$. Define $d \times k$ matrices $V = [v_1 V_{1:(k-1)}]$ and $\widehat{V} = [\hat{v}_1 \widehat{V}_{1:(k-1)}]$. Then,*

$$\|\widehat{V}\widehat{V}^T\widehat{A}\hat{v}_1 - VV^TAv_1\| < \sigma_1(A)\left(3\epsilon_4 + \frac{4\epsilon}{\sigma_{k-1}(Z_{\lambda_1})}\right) + \epsilon(1 + \epsilon_4)$$

Proof Similar to Lemma 23 we have from Wedin's theorem $\|\widehat{V}_{1:(k-1)}\widehat{V}_{1:(k-1)}^T - V_{1:(k-1)}V_{1:(k-1)}^T\| < \frac{4\epsilon}{\sigma_{k-1}(Z_{\lambda_1})}$. Then we can bound,

$$\begin{aligned}\|\widehat{V}\widehat{V}^T - VV^T\| &\leq \|\hat{v}_1\hat{v}_1^T - v_1v_1^T\| + \|\widehat{V}_{1:(k-1)}\widehat{V}_{1:(k-1)} - V_{1:(k-1)}V_{1:(k-1)}^T\| \\ &< 2\|\hat{v}_1 - v_1\| + \frac{4\epsilon}{\sigma_{k-1}(Z_{\lambda_1})} \\ &< 2\epsilon_4 + \frac{4\epsilon}{\sigma_{k-1}(Z_{\lambda_1})}\end{aligned} \tag{20}$$

Now,

$$\begin{aligned}\|\widehat{V}\widehat{V}^T\widehat{A}\hat{v}_1 - VV^TAv_1\| &\leq \|(\widehat{V}\widehat{V}^T - VV^T)Av_1\| + \|\widehat{V}\widehat{V}^T(A - \widehat{A})v_1\| \\ &\quad + \|\widehat{V}\widehat{V}^T\widehat{A}(v_1 - \hat{v}_1)\| \\ &\leq \|\widehat{V}\widehat{V}^T - VV^T\|\|A\| + \|A - \widehat{A}\| + \|\widehat{A}\|\|v_1 - \hat{v}_1\| \\ &< \sigma_1(A)\left(2\epsilon_4 + \frac{4\epsilon}{\sigma_{k-1}(Z_{\lambda_1})}\right) + \epsilon + (\sigma_1(A) + \epsilon)\epsilon_4\end{aligned}$$

where we use inequality (20), $\|Av_1\| \leq \sigma_1(A)$ as v_1 is unit norm, $\|\widehat{V}\widehat{V}^T\| < 1$ since $\widehat{V}$ is orthonormal, and $\|\widehat{A}\| < \|A\| + \epsilon$. Combining,

$$\|\widehat{V}\widehat{V}^T\widehat{A}\hat{v}_1 - VV^TAv_1\| < \sigma_1(A)\left(3\epsilon_4 + \frac{4\epsilon}{\sigma_{k-1}(Z_{\lambda_1})}\right) + \epsilon(1 + \epsilon_4)$$

■

Lemma 25 *Let $\|\widehat{A} - A\| < \epsilon$, $\|\hat{x}_1 - x_1\| < \epsilon_3 < \frac{\alpha_1 a_1}{2}$, and $\|\hat{v}_1 - v_1\| < \epsilon_4$. Then,*

$$|\hat{a}_1 - a_1| < \frac{\alpha_1 a_1\left(2\sigma_1(A)\epsilon_4 + \epsilon(1 + \epsilon_4)\right) + 2(\sigma_1(A) + \epsilon)\epsilon_3}{\alpha_1^2 a_1^2}$$

Proof We first compute,

$$\begin{aligned}|\hat{v}_1^T\widehat{A}\hat{v}_1 - v_1^TAv_1| &\leq |(v_1^T - \hat{v}_1^T)Av_1| + |\hat{v}_1^T(A - \widehat{A})v_1| + |\hat{v}_1^T\widehat{A}(v_1 - \hat{v}_1)| \\ &\leq \|v_1^T - \hat{v}_1^T\|\sigma_1(A) + \|A - \widehat{A}\| + \sigma_1(\widehat{A})\|v_1 - \hat{v}_1\| \\ &< \sigma_1(A)\epsilon_4 + \epsilon + (\sigma_1(A) + \epsilon)\epsilon_4 = 2\sigma_1(A)\epsilon_4 + \epsilon(1 + \epsilon_4)\end{aligned} \tag{21}$$

using the fact that $v_1, \hat{v}_1$ have unit norms. Now we can bound the error $|\hat{a}_1 - a_1|$ as follows.

$$\begin{aligned}|\hat{a}_1 - a_1| &= \left|\frac{\hat{v}_1^T \widehat{A}\hat{v}_1}{\|\hat{x}_1\|} - \frac{v_1^T A v_1}{\|x_1\|}\right| \\ &\leq \frac{1}{\|x_1\|}|\hat{v}_1^T\widehat{A}\hat{v}_1 - v_1^T A v_1| + |\hat{v}_1^T\widehat{A}\hat{v}_1|\frac{|\|x_1\| - \|\hat{x}_1\||}{\|x_1\|\|\hat{x}_1\|}\end{aligned}$$

From equation (21) and using $|\|x_1\| - \|\hat{x}_1\|| < \|\hat{x}_1 - x_1\| < \epsilon_3, \|x_1\| = \alpha_1 a_1$ we get,

$$\begin{aligned}|\hat{a}_1 - a_1| &< \frac{2\sigma_1(A)\epsilon_4 + \epsilon(1+\epsilon_4)}{\alpha_1 a_1} + \frac{(\sigma_1(A)+\epsilon)\epsilon_3}{\alpha_1 a_1(\alpha_1 a_1 - \epsilon_3)} \\ &< \frac{\alpha_1 a_1\left(2\sigma_1(A)\epsilon_4 + \epsilon(1+\epsilon_4)\right) + 2(\sigma_1(A)+\epsilon)\epsilon_3}{\alpha_1^2 a_1^2}\end{aligned}$$

since $\epsilon_3 < \frac{\alpha_1 a_1}{2}$. ■

Note that from Lemma 23 taking $\frac{2\epsilon_3}{\alpha_1 a_1} = \epsilon_4$ the above bound becomes $|\hat{a}_1 - a_1| < \frac{6\sigma_1(A)\epsilon_3 + \epsilon\alpha_1 a_1 + 4\epsilon\epsilon_3}{\alpha_1^2 a_1^2}$.

E.1 Proof of Theorem 3

We now proof Theorem 3. Assume $\|\widehat{Z}_{\lambda^*} - Z_{\lambda_1}\| \leq \epsilon_2$. Under the assumptions we have using Lemma 23 $\|\hat{x}_1 - x_1\| < \epsilon_3 = 2\epsilon + \frac{4\epsilon_2 R}{\sigma_{k-1}(Z_{\lambda_1})}$, $\|\hat{v}_1 - v_1\| < \epsilon_4 = \frac{2\epsilon_3}{\alpha_1 a_1}$. Also from Lemma 24 we have $\|\widehat{V}\widehat{V}^T\widehat{A}\hat{v}_1 - VV^T A v_1\| < \sigma_1(A)\left(3\epsilon_4 + \frac{4\epsilon}{\sigma_{k-1}(Z_{\lambda_1})}\right) + \epsilon(1+\epsilon_4)$. Using these we compute the first bound as follows.

$$\begin{aligned}\|\hat{\mu}_1 - \mu_1\| &= \left\|\frac{\widehat{V}\widehat{V}^T\widehat{A}\hat{v}_1}{\|\hat{x}_1\|} - \frac{VV^T A v_1}{\|x_1\|}\right\| \\ &\leq \|\widehat{V}\widehat{V}^T\widehat{A}\hat{v}_1\|\left|\frac{1}{\|\hat{x}_1\|} - \frac{1}{\|x_1\|}\right| + \frac{1}{\|x_1\|}\|\widehat{V}\widehat{V}^T\widehat{A}\hat{v}_1 - VV^T A v_1\| \\ &\leq \|\widehat{A}\|\frac{\|\hat{x}_1 - x_1\|}{\|\hat{x}_1\|\|x_1\|} + \frac{1}{\|x_1\|}\|\widehat{V}\widehat{V}^T\widehat{A}\hat{v}_1 - VV^T A v_1\|\end{aligned}$$

Now using bounds from Lemma 23, 24 we get,

$$\begin{aligned}\|\hat{\mu}_1 - \mu_1\| &< \frac{(\sigma_1(A)+\epsilon)\epsilon_3}{\alpha_1 a_1(\alpha_1 a_1 - \epsilon_3)} + \frac{\sigma_1(A)\left(3\epsilon_4 + \frac{4\epsilon}{\sigma_{k-1}(Z_{\lambda_1})}\right) + \epsilon(1+\epsilon_4)}{\alpha_1 a_1} \\ &< \frac{2}{\alpha_1^2 a_1^2}\left[(\sigma_1(A)+\epsilon)\epsilon_3 + \alpha_1 a_1\left((3\sigma_1(A)+\epsilon)\epsilon_4\right.\right. \\ &\quad \left.\left. +\epsilon\left(1 + 4\sigma_1(A)/\sigma_{k-1}(Z_{\lambda_1})\right)\right)\right] \\ &< \frac{2}{\alpha_1^2 a_1^2}\left[(\sigma_1(A)+\epsilon)\epsilon_3 + 2\left(3\sigma_1(A)+\epsilon\right)\epsilon_3\right. \\ &\quad \left. +\alpha_1 a_1\epsilon\left(1 + 4\sigma_1(A)/\sigma_{k-1}(Z_{\lambda_1})\right)\right] \\ &\leq 2\frac{10\sigma_1(A)\epsilon_3 + 5\alpha_1 a_1\epsilon\frac{\sigma_1(A)}{\sigma_{k-1}(Z_{\lambda_1})}}{\alpha_1^2 a_1^2}\end{aligned}$$

assuming $\epsilon_3 \leq \frac{\alpha_1 a_1}{2}$, $\sigma_1(A) \geq \epsilon$, and $\sigma_1(A) > \sigma_{k-1}(Z_{\lambda_1})$. Now expanding ϵ_3 and rearranging terms we have,

$$\begin{aligned}\|\hat{\mu}_1 - \mu_1\| &< \frac{1}{\alpha_1^2 a_1^2}\left(\left(40 + 10\frac{\alpha_1 a_1}{\sigma_{k-1}(Z_{\lambda_1})}\right)\sigma_1(A)\epsilon + 80\frac{\sigma_1(A)R\epsilon_2}{\sigma_{k-1}(Z_{\lambda_1})}\right) \\ &< \frac{80}{\alpha_1^2 a_1^2}\left(\sigma_1(A)\epsilon\left(1 + \frac{\alpha_1 a_1}{\sigma_{k-1}(Z_{\lambda_1})}\right) + \frac{\sigma_1(A)\epsilon_2 R}{\sigma_{k-1}(Z_{\lambda_1})}\right) \qquad (22)\end{aligned}$$

To prove the second bound from Lemma 25 and assuming $\epsilon < \sigma_1(A)$ we have $|\hat{a}_1 - a_1| \leq \frac{10\sigma_1(A)\epsilon_3 + \alpha_1 a_1\epsilon}{\alpha_1^2 a_1^2}$. Then,

$$\begin{aligned}\hat{a}_1(\alpha_1 - \hat{\alpha}_1) &= \hat{a}_1\alpha_1 - \hat{a}_1\hat{\alpha}_1 \\ &= a_1\alpha_1 - \hat{a}_1\hat{\alpha}_1 + \hat{a}_1\alpha_1 - a_1\alpha_1 \\ \hat{a}_1|\alpha_1 - \hat{\alpha}_1| &\leq |a_1\alpha_1 - \hat{a}_1\hat{\alpha}_1| + \alpha_1|\hat{a}_1 - a_1| \\ |\alpha_1 - \hat{\alpha}_1| &\leq \frac{1}{\hat{a}_1}\left(\|x_1 - \hat{x}_1\| + \alpha_1|\hat{a}_1 - a_1|\right) \\ &< \frac{\epsilon_3 + \alpha_1|\hat{a}_1 - a_1|}{a_1 - |\hat{a}_1 - a_1|} \\ &\leq 2\frac{\epsilon_3 + \frac{(10\sigma_1(A)\epsilon_3 + \alpha_1 a_1\epsilon)}{\alpha_1 a_1^2}}{a_1}\end{aligned}$$

using $|\hat{a}_1 - a_1| < \frac{a_1}{2}$. We have,

$$\begin{aligned}|\alpha_1 - \hat{\alpha}_1| &\leq 2\frac{\alpha_1 a_1^2\epsilon_3 + 10\sigma_1(A)\epsilon_3 + \alpha_1 a_1\epsilon}{\alpha_1 a_1^3} \\ &< \frac{2}{\alpha_1 a_1^3}\left(\left(\alpha_1 a_1^2 + 10\sigma_1(A)\right)\left(2\epsilon + 4R\epsilon_2/\sigma_{k-1}(Z_{\lambda_1})\right) + \alpha_1 a_1\epsilon\right) \\ &\leq \frac{4\sigma_1(A)}{\alpha_1 a_1^3}\left(\eta_1\epsilon + \frac{\eta_2 R\epsilon_2}{\sigma_{k-1}(Z_{\lambda_1})}\right) \qquad (23)\end{aligned}$$

where $\eta_1 := \max\{\alpha_1 a_1(2a_1 + 1), 20\}$, and $\eta_2 := \max\{\alpha_1 a_1^2, 10\}$.

Finally using equation (18) we can bound $\|\widehat{Z}_{\lambda^*} - Z_{\lambda_1}\| \leq \epsilon_2 \leq 3\eta_3\epsilon$, where $\eta_3 = \max\left\{1, \frac{1}{w_1}, c_3\sigma_1(B)\right\}$. Using this in equations (22) and (23) proves the theorem.

E.2 Related Lemmas

In this section we prove a supporting lemma for Lemma 5.

Lemma 26 *Let $\{\mu_2, \ldots, \mu_k\}$ be linearly independent. Suppose matrix Z_{λ^*} be expressed as,*

$$Z_{\lambda^*} = \sum_{i=2}^{k}\alpha_i(1 - \lambda^* w_i)\mu_i\mu_i^T = V_{1:(k-1)}\Sigma_{1:(k-1)}V_{1:(k-1)}^T = \sum_{i=2}^{k}\sigma_{i-1}(Z_{\lambda^*})v_i v_i^T, \qquad (24)$$

where $w_i = \langle\mu_i, v\rangle$, $V_{1:(k-1)} = [v_2, \ldots, v_k]$ the matrix of $k-1$ singular vectors, and $\Sigma_{1:(k-1)}$ is a diagonal matrix of singular values of Z_{λ^*}. Then $\{v_2, \ldots, v_k\}$ forms a basis of span$\{\mu_2, \ldots, \mu_k\}$.

Proof Define $\mathcal{V}_{Z_{\lambda^*}}$ as the **column space** of matrix Z_{λ^*}. First observe that from equation (24) each column of Z_{λ^*} can be written as a linear combination of $\{\mu_2, \ldots, \mu_k\}$. Therefore any vector in the column space $\mathcal{V}_{Z_{\lambda^*}}$ can be written as a linear combination of $\{\mu_2, \ldots, \mu_k\}$. this implies,

$$\mathcal{V}_{Z_{\lambda^*}} \subseteq span\{\mu_2, \ldots, \mu_k\} \tag{25}$$

Now any vector $y \in \mathcal{V}_{Z_{\lambda^*}}$ can be written as $y = Z_{\lambda^*}x = \sum_{i=2}^{k} \sigma_{i-1}(Z_{\lambda^*})\langle v_i, x\rangle v_i$ using equation (24). This implies,

$$\mathcal{V}_{Z_{\lambda^*}} \subseteq span\{v_2, \ldots, v_k\} \tag{26}$$

Conversely any vector $s \in span\{v_2, \ldots, v_k\}$ can be written as $s = V_{1:(k-1)}r = Z_{\lambda^*}V_{1:(k-1)}\Sigma^{-1}_{1:(k-1)}r = Z_{\lambda^*}r'$, using equation (24), where $r' = V_{1:(k-1)}\Sigma^{-1}_{1:(k-1)}r$. This implies,

$$span\{v_2, \ldots, v_k\} \subseteq \mathcal{V}_{Z_{\lambda^*}} \tag{27}$$

Therefore combining equations (25),(26),(27) we get,

$$span\{v_2, \ldots, v_k\} = \mathcal{V}_{Z_{\lambda^*}} \subseteq span\{\mu_2, \ldots, \mu_k\} \tag{28}$$

Note that both the vector spaces $span\{v_2, \ldots, v_k\}$ and $span\{\mu_2, \ldots, \mu_k\}$ have rank $k-1$ since $\{v_2, \ldots, v_k\}$ are orthonormal, and $\{\mu_2, \ldots, \mu_k\}$ are linearly independent. Then from this rank constraint and equation (28) we must have:

$$span\{v_2, \ldots, v_k\} = span\{\mu_2, \ldots, \mu_k\}$$

This implies $\{v_2, \ldots, v_k\}$ forms a basis of $span\{\mu_2, \ldots, \mu_k\}$. ■

Appendix F. Subspace Clustering Proofs

In this section we prove Theorem 6 and the necessary lemmas. The main point is the following infinite-sample analysis, which shows that the top m eigenvectors of the whitened matrix B can be used to recover the subspace $\mathcal{U}_1$.

Theorem 27 *Suppose that there is some $\delta > 0$ such that $\|U_i v\|^2 \leq (1/3 - \delta)\|U_1 v\|^2$ for all $i \neq 1$. Let $Y = [u_1, ..., u_m]$ be the matrix of top m eigenvectors of $R = D^{-1/2}V^T BVD^{-1/2}$ and $Z = VD^{1/2}Y$. Let $\mathcal{Z}$ be the subspace spanned by columns of Z. Then,*

1. *$\mathcal{Z} = \mathcal{U}_1$*
2. *$\sigma_m(R) - \sigma_{m+1}(R) \geq 3\delta\|U_1 v\|^2$*

Proof Define $w_i = \|U_i U_i^T v\| = \|U_i^T v\|$, and $\tilde{U}_i := \sqrt{\alpha_i}D^{-1/2}V^T U_i$; note that $\sum_{i=1}^{k} \tilde{U}_i\tilde{U}_i^T$ is the $(km) \times (km)$ identity matrix, which implies that each $\tilde{U}_i$ has orthonormal columns. Consider the whitened B matrix. Using Theorem 13,

$$\begin{aligned} D^{-1/2}V^T BVD^{-1/2} &= \sum_{i=1}^{k} w_i^2 \tilde{U}_i\tilde{U}_i^T + 2\sum_{i=1}^{k} \tilde{U}_i U_i^T vv^T U_i\tilde{U}_i^T \\ &= \sum_{i=1}^{k} w_i^2 \tilde{U}_i\tilde{U}_i^T + 2\sum_{i=1}^{k} \tilde{v}_i\tilde{v}_i^T = \sum_{i=1}^{k}(w_i^2\tilde{U}_i\tilde{U}_i^T + 2\tilde{v}_i\tilde{v}_i^T) \end{aligned}$$

where $\tilde{v}_i = \tilde{U}_i U_i^T v$. Note that $\tilde{v}_i$ are orthogonal to each other and each $\tilde{v}_i$ is in the space $\tilde{\mathcal{U}}_i$, the span of corresponding $\tilde{U}_i$. Moreover, $\|\tilde{v}_i\| = w_i$. Now for each i consider a different orthonormal basis $\tilde{V}_i$ of $\tilde{\mathcal{U}}_i$ such that in this basis the first unit vector is aligned along $\tilde{v}_i$. Define a rotation R_i such that $\tilde{V}_i = \tilde{U}_i R_i$. Then $\tilde{V}_i\tilde{V}_i^T = \tilde{U}_i\tilde{U}_i^T$. Therefore we can write the above equation as

$$R = D^{-1/2}V^T BVD^{-1/2} = \sum_{i=1}^{k} \tilde{V}_i\tilde{D}_i\tilde{V}_i^T \tag{29}$$

where each $\tilde{D}_i$ is a diagonal matrix with one maximum value of $3w_i^2$ and all other values w_i^2, and also the matrices $\tilde{V}_i$ are orthogonal. Under the assumption that $w_i^2 \leq (1/3 - \delta)w_1^2$, it follows that the top m eigenvectors of R are the columns of $\tilde{V}_i$, and that the corresponding eigenvalues are $3w_1^2$ and then w_1^2 repeated $m-1$ times. Therefore we can write $Y = \tilde{U}_i O$, where O is an $m \times m$ orthogonal matrix. Then,

$$Z = VD^{1/2}Y = VD^{1/2}\tilde{U}_i O = \sqrt{\alpha_1}U_1 O$$

This proves the first statement that $\mathcal{Z}$, the span of the columns of Z, is the subspace $\mathcal{U}_1$, the span of columns of U_1. The second statement follows from equation (29) since the maximum value of the $m+1$-th eigenvalue is $3w_i^2$ for some $i \neq 1$. Hence,

$$\sigma_m(R) - \sigma_{m+1}(R) \geq w_1^2 - 3\max_{i \neq 1} w_i^2 \geq 3\delta w_1^2 = 3\delta\|U_1 v\|^2.$$

■

Lemma 28 *Let $\|\hat{A} - A\| < \epsilon < \sigma_{mk}(A)/4$. $A = VDV^T$ and $\hat{A} = \hat{V}\hat{D}\hat{V}^T$ be the eigen decompositions of $A, \hat{A}$. Let $\hat{W} = \hat{V}\hat{D}^{-1/2}$ be the whitening matrix. Then,*

$$\|I_k - (\hat{W}^T A\hat{W})^{-1/2}\| \leq \frac{4\epsilon}{\sigma_{mk}(A)}$$

Proof We prove this along the lines in Hsu and Kakade (2013). The matrix $\hat{W}$ whitens $\hat{A}$ since,

$$\hat{W}^T\hat{A}\hat{W} = \hat{D}^{-1/2}\hat{V}^T\hat{A}\hat{V}\hat{D}^{-1/2} = I_k$$

Also $\epsilon < \sigma_{mk}(A)/2$, hence using Weyl's inequality $\sigma_{mk}(\hat{A}) \geq \sigma_{mk}(A)/2$. This implies

$$\begin{aligned} \|I_k - \hat{W}^T A\hat{W}\| &= \|\hat{W}^T(\hat{A} - A)\hat{W}\| \leq \|\hat{W}\|^2\|\hat{A} - A\| \\ &< \frac{2\epsilon}{\sigma_{mk}(A)} \end{aligned}$$

Therefore all eigenvalues of the matrix $\hat{W}^T A\hat{W}$ lie in the interval $(1 - 2\epsilon/\sigma_{mk}(A), 1 + 2\epsilon/\sigma_{mk}(A))$. This implies the eigenvalues of $(\hat{W}^T A\hat{W})^{-1}$ lie in the interval $(1/(1 + 2\epsilon/\sigma_{mk}(A)), 1/(1 - 2\epsilon/\sigma_{mk}(A)))$. Then,

$$\begin{aligned}(I_k - (\hat{W}^T A\hat{W})^{-1/2})(I_k + (\hat{W}^T A\hat{W})^{-1/2}) &= I_k - (\hat{W}^T A\hat{W})^{-1} \\ I_k - (\hat{W}^T A\hat{W})^{-1/2} &= \left(I_k - (\hat{W}^T A\hat{W})^{-1}\right)(I_k + (\hat{W}^T A\hat{W})^{-1/2})^{-1} \\ \|I_k - (\hat{W}^T A\hat{W})^{-1/2}\| &\leq \|I_k - (\hat{W}^T A\hat{W})^{-1}\| \\ &\leq \frac{1}{1 - 2\epsilon/\sigma_{mk}(A)} - 1 \leq \frac{4\epsilon}{\sigma_{mk}(A)}\end{aligned}$$

■

Lemma 29 (Whitening matrix perturbation) *Assume $\|\hat{A} - A\| < \epsilon < \sigma_{mk}(A)/4$. Let $\hat{W} = \hat{V}\hat{D}^{-1/2}$ be the whitening matrix. Define $W := \hat{W}(\hat{W}^T A\hat{W})^{-1/2}$. Then,*

$$\|\hat{W} - W\| \leq \frac{8\epsilon}{\sigma_{mk}(A)^{3/2}}$$

Proof We note that the matrix W whitens the matrix A, since

$$W^T AW = (\hat{W}^T A\hat{W})^{-1/2}\hat{W}^T A\hat{W}(\hat{W}^T A\hat{W})^{-1/2} = I_k$$

We can bound the perturbation as follows.

$$\begin{aligned}\|\hat{W} - W\| &= \|\hat{W}(I_k - (\hat{W}^T A\hat{W})^{-1/2})\| \\ &\leq \|\hat{W}\|\|I_k - (\hat{W}^T A\hat{W})^{-1/2}\| \\ &\leq \frac{2}{\sqrt{\sigma_{mk}(A)}}\frac{4\epsilon}{\sigma_{mk}(A)} = \frac{8\epsilon}{\sigma_{mk}(A)^{3/2}}\end{aligned}$$

where the last inequality follows from Lemma 28. ■

Lemma 30 *Let $\max\{\|\hat{A} - A\|, \|\hat{B} - B\|\} < \epsilon$, and also let $\epsilon < \min\{\sigma_1(B)/2, \frac{\sigma_{mk}(A)}{16}\}$. $W = \hat{W}(\hat{W}^T A\hat{W})^{-1/2}$ be the whitening matrix. Define $R = W^T BW$ as the whitened B matrix, and $\hat{R} = \hat{W}^T\hat{B}\hat{W}$ is its estimate. Then,*

$$\|\hat{R} - R\| < \frac{51\sigma_1(B)\epsilon}{\sigma_{mk}(A)^2} := \epsilon_1$$

Proof From Lemma 29 we have $\|\hat{W} - W\| \leq \frac{8\epsilon}{\sigma_{mk}(A)^{3/2}} < \|\hat{W}\|/2$. Also we know $\|\hat{W}\| \leq \sqrt{2/\sigma_{mk}(A)}$. We obtain the required bound as follows.

$$\begin{aligned}\|\hat{R} - R\| &= \|\hat{W}^T\hat{B}\hat{W} - W^T BW\| \\ &\leq \|(\hat{W} - W)^T\hat{B}\hat{W}\| + \|W^T(\hat{B} - B)\hat{W}\| + \|W^T B(\hat{W} - W)\| \\ &\leq \frac{3}{2}\|\hat{W} - W\|\|B\|\|\hat{W}\| + \frac{3}{2}\|\hat{W}\|^2\|\hat{B} - B\| + \frac{3}{2}\|\hat{W}^T\|\|B\|\|\hat{W} - W\| \\ &= 3\|\hat{W} - W\|\|B\|\|\hat{W}\| + \frac{3}{2}\|\hat{W}\|^2\|\hat{B} - B\| \\ &< 48\frac{\sigma_1(B)\epsilon}{\sigma_{mk}(A)^2} + \frac{3\epsilon}{\sigma_{mk}(A)} < \frac{51\sigma_1(B)\epsilon}{\sigma_{mk}(A)^2}\end{aligned}$$

■

Lemma 31 *Suppose $Y = [u_1, \ldots, u_m]$ be the matrix of m largest eigenvectors of $R = W^T BW$, and $\hat{Y}$ be that of $\hat{R} = \hat{W}^T\hat{B}\hat{W}$. Let $\hat{Z} = \hat{V}\hat{D}^{1/2}\hat{Y}$. Then,*

$$\|\hat{Z}\hat{Z}^T - ZZ^T\| \leq C_1\frac{\sigma_1(A)\sigma_1(B)\epsilon}{(\sigma_m(R) - \sigma_{m+1}(R))\sigma_{mk}(A)^2}$$

where Z satisfies $Y = W^T Z$, and C_1 is a constant.

Proof First using Wedin's theorem for the matrix A and $\hat{A}$ we get

$$\|\hat{V}\hat{V}^T - VV^T\| < \frac{4\epsilon}{\sigma_{mk}(A)}. \tag{30}$$

From Lemma 30 we have $\|\hat{R} - R\| < \frac{51\sigma_1(B)\epsilon}{\sigma_{mk}(A)^2} = \epsilon_1$. Therefore we can again use Wedin's theorem on the matrices $R, \hat{R}$ to bound the perturbation of the subspace spanned by Y.

$$\begin{aligned}\|\hat{Y}\hat{Y}^T - YY^T\| &\leq \frac{4\|\hat{R} - R\|}{\sigma_m(R) - \sigma_{m+1}(R)} \\ &= \frac{4\epsilon_1}{\sigma_m(R) - \sigma_{m+1}(R)}.\end{aligned} \tag{31}$$

We now bound the following term.

$$\begin{aligned}\|\hat{V}\hat{D}^{1/2}W^T - \hat{V}\hat{V}^T\| &= \|\hat{V}\hat{D}^{1/2}(\hat{W}^T A\hat{W})^{-1/2}\hat{W}^T - \hat{V}\hat{V}^T\| \\ &= \|\hat{V}\hat{D}^{1/2}(\hat{W}^T A\hat{W})^{-1/2}\hat{D}^{-1/2}\hat{V}^T - \hat{V}\hat{V}^T\| \\ &\leq \|\hat{D}^{1/2}(\hat{W}^T A\hat{W})^{-1/2}\hat{D}^{-1/2} - I_k\| \\ &\leq \|\hat{D}^{1/2}\|\|(\hat{W}^T A\hat{W})^{-1/2} - I_k\|\|\hat{D}^{-1/2}\| \\ &\leq \sqrt{\frac{\sigma_1(\hat{A})}{\sigma_{mk}(\hat{A})}}\frac{4\epsilon}{\sigma_{mk}(A)} \leq \frac{8\sigma_1(A)^{1/2}\epsilon}{\sigma_{mk}(A)^{3/2}}\end{aligned} \tag{32}$$

where the second to last inequality follows from Lemma 28. Next we show that $\hat{Z}\hat{Z}^T$ is close to the projection of ZZ^T onto the subspace $\hat{V}\hat{V}^T$.

$$
\begin{aligned}
& \|\hat{Z}\hat{Z}^T - \hat{V}\hat{V}^T ZZ^T \hat{V}\hat{V}^T\| \\
= \; & \|\hat{V}\hat{D}^{1/2}\hat{Y}\hat{Y}^T\hat{D}^{1/2}\hat{V}^T - \hat{V}\hat{V}^T ZZ^T\hat{V}\hat{V}^T\| \\
\leq \; & \|\hat{V}\hat{D}^{1/2}(\hat{Y}\hat{Y}^T - YY^T)\hat{D}^{1/2}\hat{V}^T\| + \|\hat{V}\hat{D}^{1/2}YY^T\hat{D}^{1/2}\hat{V}^T - \hat{V}\hat{V}^T ZZ^T\hat{V}\hat{V}^T\| \\
\leq \; & \sigma_1(\hat{A})\|\hat{Y}\hat{Y}^T - YY^T\| + \|\hat{V}\hat{D}^{1/2}W^T ZZ^T W\hat{D}^{1/2}\hat{V}^T - \hat{V}\hat{V}^T ZZ^T\hat{V}\hat{V}^T\| \qquad (33)
\end{aligned}
$$

We bound the second term as follows. Observe that the matrix $D^{-1/2}V^T$ also whitens the matrix A. Therefore Z can be expressed as $Z = VD^{1/2}U'$ where U' is a matrix with orthonormal columns. This implies $\|ZZ^T\| = \|VD^{1/2}U'U'^T D^{1/2}V^T\| \leq \sigma_1(A)$.

$$
\begin{aligned}
& \|\hat{V}\hat{D}^{1/2}W^T ZZ^T W\hat{D}^{1/2}\hat{V}^T - \hat{V}\hat{V}^T ZZ^T\hat{V}\hat{V}^T\| \\
\leq \; & \|(\hat{V}\hat{D}^{1/2}W^T - \hat{V}\hat{V}^T)ZZ^T W\hat{D}^{1/2}\hat{V}^T\| + \|\hat{V}\hat{V}^T ZZ^T(W\hat{D}^{1/2}\hat{V}^T - \hat{V}\hat{V}^T)\| \\
\leq \; & \|(\hat{V}\hat{D}^{1/2}W^T - \hat{V}\hat{V}^T)ZY^T\hat{D}^{1/2}\hat{V}^T\| + \|ZZ^T\|\|W\hat{D}^{1/2}\hat{V}^T - \hat{V}\hat{V}^T\| \\
\leq \; & \|\hat{V}\hat{D}^{1/2}W^T - \hat{V}\hat{V}^T\|\|Z\|\|\hat{D}^{1/2}\| + \|ZZ^T\|\|W\hat{D}^{1/2}\hat{V}^T - \hat{V}\hat{V}^T\| \\
\leq \; & \frac{8\sigma_1(A)^{1/2}\epsilon}{\sigma_{mk}(A)^{3/2}} \times 2\sigma_1(A) + \sigma_1(A) \times \frac{8\sigma_1(A)^{1/2}\epsilon}{\sigma_{mk}(A)^{3/2}} \\
= \; & 24\frac{\sigma_1(A)^{3/2}\epsilon}{\sigma_{mk}(A)^{3/2}}
\end{aligned}
$$

The second to last step follows from equation 32. Now using the above bound in equation 33 we get,

$$
\begin{aligned}
\|\hat{Z}\hat{Z}^T - \hat{V}\hat{V}^T ZZ^T\hat{V}\hat{V}^T\| &\leq \sigma_1(\hat{A})\|\hat{Y}\hat{Y}^T - YY^T\| + 24\frac{\sigma_1(A)^{3/2}\epsilon}{\sigma_{mk}(A)^{3/2}} \\
&\leq \frac{8\sigma_1(A)\epsilon_1}{\sigma_m(R) - \sigma_{m+1}(R)} + 24\frac{\sigma_1(A)^{3/2}\epsilon}{\sigma_{mk}(A)^{3/2}} \qquad (34)
\end{aligned}
$$

where the last step follows from inequalities (31). We compute the required bound by combining equations (30) and (34) as follows.

$$
\begin{aligned}
\|\hat{Z}\hat{Z}^T - ZZ^T\| &= \|\hat{Z}\hat{Z}^T - VV^T ZZ^T VV^T\| \\
&\leq \|\hat{Z}\hat{Z}^T - \hat{V}\hat{V}^T ZZ^T\hat{V}\hat{V}^T\| + 3\|VV^T - \hat{V}\hat{V}^T\|\|ZZ^T\| \\
&\leq \frac{8\sigma_1(A)\epsilon_1}{\sigma_m(R) - \sigma_{m+1}(R)} + 24\frac{\sigma_1(A)^{3/2}\epsilon}{\sigma_{mk}(A)^{3/2}} + \frac{12\sigma_1(A)\epsilon}{\sigma_{mk}(A)} \\
&\leq C_1\frac{\sigma_1(A)\sigma_1(B)\epsilon}{(\sigma_m(R) - \sigma_{m+1}(R))\sigma_{mk}(A)^2}
\end{aligned}
$$

where C_1 is a constant. ■

F.1 Proof of Theorem 6

The proof follows from Theorem 27 and Lemma 31. Note that the matrix Z has all singular values equal to $\sqrt{\alpha_1}$, therefore ZZ^T has singular values α_1. Under the affinity condition from Theorem 27, we have

$$\sigma_m(R) - \sigma_{m+1}(R) \geq 3\delta\|U_1 v\|^2$$

Combining with Lemma 31 we get

$$\|\hat{Z}\hat{Z}^T - ZZ^T\| \leq \frac{C_2\sigma_1(A)\sigma_1(B)\epsilon}{\delta\|U_1 v\|^2\sigma_{mk}(A)^2}$$

where C_2 is a constant. Finally applying Wedin's theorem for the matrices $\hat{Z}\hat{Z}^T$ and ZZ^T, we have

$$\|\hat{U}\hat{U}^T - U_1 U_1^T\| \leq \frac{C_3\sigma_1(A)\sigma_1(B)\epsilon}{\alpha_1\delta\|U_1 v\|^2\sigma_{mk}(A)^2} \leq \frac{C\sigma_1(A)^2\epsilon}{\alpha_1\delta\sigma_{mk}(A)^2}$$

where $C_3 = 4C_2$.

Appendix G. Sample Complexity Analysis

Since the basic application of our method requires the estimation of certain covariance matrices, we need to show that one can estimate these matrices. There is a large literature on estimating covariance matrices, but for simplicity we will only focus on the simplest estimator: the sample covariance matrix. By well-known matrix concentration inequalities, one can show that the sample covariance matrix will be close to the covariance matrix with high probability if the sample size is large enough:

Theorem 32 *Tropp (2015) Let $A_1, \ldots, A_n$ be i.i.d. symmetric random $d \times d$ matrices. If $\|A_1\| \leq L$ a.s. then*

$$\Pr\left(\left\|\frac{1}{n}\sum_{i=1}^n A_i - \mathbb{E}A_i\right\| \geq t\right) \leq 8d\exp\left(-\frac{nt^2}{L^2}\right).$$

G.1 Truncation

Unfortunately, the matrices we will be dealing with do not usually have almost sure bounds on their norm. Here, we develop some straightforward truncation arguments in order to adapt Theorem 32.

Theorem 33 *Suppose that $A_1, \ldots, A_n$ are i.i.d. symmetric random $d \times d$ matrices satisfying the tail bound*

$$\Pr(\|A_1\| \geq t) \leq Ce^{-ct^\alpha}$$

for some $\alpha > 0$. Then for any $\epsilon, \delta > 0$, if $n \geq \tilde{\Omega}_\alpha(\epsilon^{-2}\log(d/\delta))$ then

$$\Pr(\|\hat{\mathbb{E}}A - \mathbb{E}A\| \geq \epsilon) \leq \delta,$$

where $\tilde{\Omega}_\alpha(k)$ means $C(\alpha)\Omega(k\log^{C(\alpha)}k)$.

Proof Fix $L > 0$ (to be determined later) and define the random matrix B_i by $B_i = A_i 1_{\{\|A_i\| \le L\}}$. Then Theorem 32 applies to B_i: if $n \ge \Omega(L^2\epsilon^{-2}\log(d/\delta))$ then

$$\Pr(\|\hat{\mathbb{E}}B - \mathbb{E}B\| \ge \epsilon) \le \delta.$$

To compare this with the similar quantity involving A, we will consider $\hat{\mathbb{E}}(A-B)$ and $\mathbb{E}(A-B)$ separately.

First, note that $\Pr(A_i \ne B_i) = \Pr(\|A\| \ge L) \le C\exp(-cL^\alpha)$. If $L = \Omega(\log^{1/\alpha}(n/\delta))$ then $\Pr(A_i \ne B_i) \le \delta/n$. By a union bound,

$$\Pr(\hat{\mathbb{E}}A \ne \hat{\mathbb{E}}B) \le \delta. \tag{35}$$

Now we fix $L = C'\log^{1/\alpha}(n/(\delta \vee \epsilon))$ and we consider $\|\mathbb{E}(A-B)\|$. By the triangle inequality,

$$\|\mathbb{E}(A-B)\| = \|\mathbb{E}A1_{\{\|A\|\ge L\}}\| \le \mathbb{E}\|A\|1_{\{\|A\|\ge L\}}.$$

On the other hand, we can bound

$$\mathbb{E}\|A\|1_{\{\|A\|\ge L\}} = \int_L^\infty \Pr(\|A\| \ge t)\,dt \le C\int_L^\infty e^{-ct^\alpha}\,dt.$$

With the change of variables $t = u^{1/\alpha}$, we have

$$\mathbb{E}\|A\|1_{\{\|A\|\ge L\}} \le \frac{1}{\alpha}\int_{L^\alpha}^\infty u^{1/\alpha}e^{-cu}\,du.$$

Now, if $u \ge C''\frac{1}{\alpha}\log\frac{1}{\alpha}$ for large enough C'' then $u^{1/\alpha}e^{-cu} \le e^{-cu/2}$. Hence, if $L^\alpha \ge C''\frac{1}{\alpha}\log\frac{1}{\alpha}$ then

$$\mathbb{E}\|A\|1_{\{\|A\|\ge L\}} \le \frac{1}{\alpha}\int_{L^\alpha}^\infty e^{-cu/2}\,du \le C(\alpha)e^{-cL^\alpha/2} \le C(\alpha)\epsilon$$

where the last inequality holds if the constant C' in the definition of L is large enough compared to c. On the other hand, if $L^\alpha < C''\frac{1}{\alpha}\log\frac{1}{\alpha}$ then we must have $\epsilon > c(\alpha)$ for some $c(\alpha) > 0$. In this case, $\mathbb{E}\|A\|1_{\{\|A\|\ge L\}} \le C \le C(\alpha)\epsilon$ trivially. To summarize, in every case we have

$$\|\mathbb{E}(A-B)\| \le C(\alpha)\epsilon.$$

Putting this together with (35), we have that if $n \ge \Omega(L^2\epsilon^{-2}\log(d/\delta))$ then with probability at least $1-2\delta$,

$$\begin{aligned}\|\hat{\mathbb{E}}A - \mathbb{E}A\| &\le \|\hat{\mathbb{E}}B - \mathbb{E}B\| + \|\hat{\mathbb{E}}A - \hat{\mathbb{E}}B\| + \|\mathbb{E}A - \mathbb{E}B\| \\ &\le (1 + C(\alpha))\epsilon.\end{aligned}$$

Finally, recalling that $L = \mathrm{polylog}(n, 1/\epsilon, 1/\delta)$ (with the polynomial depending on α), we see that $n = \tilde{\Omega}_\alpha(\epsilon^{-2}\log(d/\delta))$ suffices. Finally, we can absorb the constant $C(\alpha)$ into ϵ. ■

We will now show how Theorem 33 bounds the error in estimating the various matrices that we had to estimate for the various different models we considered. Essentially, we will repeatedly use the observation that if z is a standard Gaussian variable then $z^{2/\alpha}$ has a tail that decays like e^{-ct^α}. In other words, moments of Gaussians will naturally lead to a condition that the one assumed in Theorem 33.

G.2 Gaussian Mixture Model

For the following theorem, we revert to the notation of the Gaussian mixture model.

Theorem 34 *Fix $\epsilon, \delta > 0$. Let $\hat{A} = \hat{\mathbb{E}}[xx^T]$ and $\hat{B} = \hat{\mathbb{E}}[\langle x, v\rangle xx^T]$, where $\hat{\mathbb{E}}$ is taken with n i.i.d. samples. If $n \ge \tilde{\Omega}(d\epsilon^{-2}\log(d/\delta))$ then with probability at least $1-\delta$, $\|\hat{\mathbb{E}}A - \mathbb{E}A\| \le \epsilon$ and $\|\hat{\mathbb{E}}B - \mathbb{E}B\| \le \epsilon$.*

Proof To estimate A, first note that $\|xx^T\| = \|x\|^2$. Now, $\mathbb{E}\|x\|^2 \le R^2 + d\sigma^2$, where $R = \max_i \|\mu_i\|$, and also $\Pr(\|x\|^2 \ge \mathbb{E}\|x\|^2 + t\sqrt{d}) \le Ce^{-ct}$. Hence, we may apply Theorem 33 with $A_i = x_i x_i^T/\sqrt{d}$ and $\alpha = 1$; this yields the claimed bound on $\|\hat{\mathbb{E}}A - \mathbb{E}A\|$.

To estimate B, note that $\|\langle x, v\rangle^2 xx^T\| = \langle x, v\rangle^2\|x\|^2$. Now, the triangle inequailty implies that $\langle x, v\rangle^2\|x\|^2$ is stochastically dominated by

$$4R^4 + 4\mathbb{E}[\langle z, v\rangle^2\|z\|^2] = 4R^4 + 4\mathbb{E}[z_1^2\|z\|^2],$$

where z is a standard (i.e., centered) Gaussian vector. Then $\mathbb{E}[z_1^2\|z\|^2] = 2 + d$, and $z_1^2\|z\|^2$ has tails of order $e^{-ct^{1/2}}$; that is it satisfies the assumptions of Theorem 33 with $\alpha = 1/2$. Applying Theorem 33 with $A_i = \langle x_i, v\rangle^2 x_i x_i^T/\sqrt{d}$ then yields the claimed bound on $\|\hat{\mathbb{E}}B - \mathbb{E}B\|$. ■

G.3 LDA Topic Model

For the following theorem, we revert to the notation of the LDA topic model, where d is the size of the dictionary.

Theorem 35 *Fix $\epsilon, \delta > 0$. Let $\hat{A} = \hat{\mathbb{E}}[x_1 x_2^T]$ and $\hat{B} = \hat{E}[\langle x_3, v\rangle x_1 x_2^T]$, where $\hat{\mathbb{E}}$ is taken with n i.i.d. samples. If $n \ge \Omega(\epsilon^{-2}\log(d/\delta))$ then with probability at least $1-\delta$, $\|\hat{A} - \mathbb{E}A\| \le \epsilon$ and $\|\hat{B} - \mathbb{E}B\| \le \epsilon$.*

Proof We can apply Theorem 32 directly, since $\|x_1 x_2^T\| \le 1$ and $\langle x_3, v\rangle x_1 x_2^T \le 1$. ■

G.4 Mixed Regression

For the following theorem, we revert to the notation of the mixed regression model.

Theorem 36 *Fix $\epsilon, \delta > 0$. Let $\hat{A} = \hat{\mathbb{E}}[y^2 xx^T]$ and $\hat{B} = \hat{\mathbb{E}}[y^3\langle x, v\rangle xx^T]$, where $\hat{\mathbb{E}}$ is taken with n i.i.d. samples. Let $R = \max_i \|\mu_i\|$. If $n \ge \tilde{\Omega}((R^2 + \sigma^2)\epsilon^{-2}d\log(d/\delta))$ then with probability at least $1-\delta$, $\|\hat{A} - \mathbb{E}A\| \le \epsilon$ and $\|\hat{B} - \mathbb{E}B\| \le \epsilon$.*

Proof Recalling that in cluster i we have $y = \langle x, \mu_i\rangle + \xi$, we have

$$\|y^2 xx^T\| \le 2\langle x, \mu_i\rangle^2\|x\|^2 + 2\xi^2\|x\|^2.$$

Hence, $\mathbb{E}\|y^2 xx^T\| \le 2R^2(2+d) + \sigma^2 d$, with tails that decay at the rate $e^{-ct^{1/2}}$. Applying Theorem 33 implies the claimed bounds for A. The case of B is analogous, except that since it involves sixth moments the tails will decay at the rate $e^{-ct^{1/3}}$; this only effects the poly-logarithmic terms hidden in the $\tilde{\Omega}$ notation. ■

G.5 Subspace Clustering

For the following theorem, we revert to the notation of the subspace clustering model. We assume for simplicity that σ is known, since if it isn't then it can be easily and accurately learnt.

Theorem 37 *Fix $\epsilon, \delta > 0$. Let $\hat{A} = \hat{\mathbb{E}}[xx^T] - \sigma^2 I_d$ and*

$$\hat{B} = \hat{\mathbb{E}}[\langle x, v\rangle^2 xx^T] - \sigma^2(v^T\hat{A}v)I_d - \sigma^2\|v\|^2\hat{A} - \sigma^4(\|v\|^2 I_d + vv^T) - 2\sigma^2(\hat{A}vv^T + vv^T\hat{A})$$

where $\hat{\mathbb{E}}$ is taken with respect to n i.i.d. samples. If $n \geq \tilde{\Omega}(\epsilon^{-2}(1+\sigma^2)\|v\|^2 m\log(d/\delta))$ then with probability at least $1-\delta$, $\|\hat{A} - A\| \leq \epsilon$ and $\|\hat{B} - B\| \leq \epsilon$.

Proof Since x/σ is an m-dimensional Gaussian vector, $\|x\|^2/(\sigma^2 m)$ is concentrated around its mean (1) with tails of order e^{-ct}. In other words, Theorem 33 (with $\alpha = 1$) implies our claim for A. The claim for B is analogous, except that since it involves fourth moments, the tails will decay at the rate $e^{-ct^{1/2}}$. ■

Abstract

In statistics and machine learning, we are interested in the eigenvectors (or singular vectors) of certain matrices (e.g. covariance matrices, data matrices, etc). However, those matrices are usually perturbed by noises or statistical errors, either from random sampling or structural patterns. The Davis-Kahan $\sin\theta$ theorem is often used to bound the difference between the eigenvectors of a matrix A and those of a perturbed matrix $\widetilde{A} = A + E$, in terms of ℓ_2 norm. In this paper, we prove that when A is a low-rank and incoherent matrix, the ℓ_∞ norm perturbation bound of singular vectors (or eigenvectors in the symmetric case) is smaller by a factor of $\sqrt{d_1}$ or $\sqrt{d_2}$ for left and right vectors, where d_1 and d_2 are the matrix dimensions. The power of this new perturbation result is shown in robust covariance estimation, particularly when random variables have heavy tails. There, we propose new robust covariance estimators and establish their asymptotic properties using the newly developed perturbation bound. Our theoretical results are verified through extensive numerical experiments.

Keywords: Matrix perturbation theory, Incoherence, Low-rank matrices, Sparsity, Approximate factor model

1. Introduction

The perturbation of matrix eigenvectors (or singular vectors) has been well studied in matrix perturbation theory (Wedin, 1972; Stewart, 1990). The best known result of eigenvector perturbation is the classic Davis-Kahan theorem (Davis and Kahan, 1970). It originally emerged as a powerful tool in numerical analysis, but soon found its widespread use in other fields, such as statistics and machine learning. Its popularity continues to surge in recent years, which is largely attributed to the omnipresent data analysis, where it is a common practice, for example, to employ PCA (Jolliffe, 2002) for dimension reduction, feature extraction, and data visualization.

The eigenvectors of matrices are closely related to the underlying structure in a variety of problems. For instance, principal components often capture most information of data and extract the latent factors that drive the correlation structure of the data (Bartholomew et al., 2011); in classical multidimensional scaling (MDS), the centered squared distance matrix encodes the coordinates of data points embedded in a low dimensional subspace (Borg and Groenen, 2005); and in clustering and network analysis, spectral algorithms are used to reveal clusters and community structure (Ng et al., 2002; Rohe et al., 2011). In those problems, the low dimensional structure that we want to recover, is often 'perturbed' by observation uncertainty or statistical errors. Besides, there might be a sparse pattern corrupting the low dimensional structure, as in approximate factor models (Chamberlain et al., 1983; Stock and Watson, 2002) and robust PCA (De La Torre and Black, 2003; Candès et al., 2011).

A general way to study these problems is to consider

$$\widetilde{A} = A + S + N, \tag{1}$$

where A is a low rank matrix, S is a sparse matrix, and N is a random matrix regarded as random noise or estimation error, all of which have the same size $d_1 \times d_2$. Usually A is regarded as the 'signal' matrix we are primarily interested in, S is some sparse contamination whose effect we want to separate from A, and N is the noise (or estimation error in covariance matrix estimation).

The decomposition (1) forms the core of a flourishing literature on robust PCA (Chandrasekaran et al., 2011; Candès et al., 2011), structured covariance estimation (Fan et al., 2008, 2013), multivariate regression (Yuan et al., 2007) and so on. Among these works, a standard condition on A is matrix incoherence (Candès et al., 2011). Let the singular value decomposition be

$$A = U\Sigma V^T = \sum_{i=1}^{r} \sigma_i u_i v_i^T, \tag{2}$$

where r is the rank of A, the singular values are $\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_r > 0$, and the matrices $U = [u_1, \ldots, u_r] \in \mathbb{R}^{d_1 \times r}$, $V = [v_1, \ldots, v_r] \in \mathbb{R}^{d_2 \times r}$ consist of the singular vectors. The coherences $\mu(U), \mu(V)$ are defined as

$$\mu(U) = \frac{d_1}{r} \max_i \sum_{j=1}^{r} U_{ij}^2, \qquad \mu(V) = \frac{d_2}{r} \max_i \sum_{j=1}^{r} V_{ij}^2, \tag{3}$$

where U_{ij} and V_{ij} are the (i,j) entry of U and V, respectively. It is usually expected that $\mu_0 := \max\{\mu(U), \mu(V)\}$ is not too large, which means the singular vectors u_i and v_i are incoherent with the standard basis. This incoherence condition (3) is necessary for us to separate the sparse component S from the low rank component A; otherwise A and S are not identifiable. Note that we do not need any incoherence condition on UV^T, which is different from Candès et al. (2011) and is arguably unnecessary (Chen, 2015).

Now we denote the eigengap $\gamma_0 = \min\{\sigma_i - \sigma_{i+1} : i = 1, \ldots, r\}$ where $\sigma_{r+1} := 0$ for notational convenience. Also we let $E = S + N$, and view it as a perturbation matrix to the matrix A in (1). To quantify the perturbation, we define a rescaled measure as $\tau_0 := \max\{\sqrt{d_2/d_1}\|E\|_1, \sqrt{d_1/d_2}\|E\|_\infty\}$, where

$$\|E\|_1 = \max_j \sum_{i=1}^{d_1} |E_{ij}|, \quad \|E\|_\infty = \max_i \sum_{j=1}^{d_2} |E_{ij}|, \tag{4}$$

which are commonly used norms gauging sparsity (Bickel and Levina, 2008). They are also operator norms in suitable spaces (see Section 2). The rescaled norms $\sqrt{d_2/d_1}\|E\|_1$ and $\sqrt{d_1/d_2}\|E\|_\infty$ are comparable to the spectral norm $\|E\|_2 := \max_{\|u\|_2=1}\|Eu\|_2$ in many cases; for example, when E is an all-one matrix, $\sqrt{d_2/d_1}\|E\|_1 = \sqrt{d_1/d_2}\|E\|_\infty = \|E\|_2$.

Suppose the perturbed matrix $\widetilde{A}$ also has the singular value decomposition:

$$\widetilde{A} = \sum_{i=1}^{d_1\wedge d_2} \widetilde{\sigma}_i \widetilde{u}_i \widetilde{v}_i^T, \tag{5}$$

where $\widetilde{\sigma}_i$ are nonnegative and in the decreasing order, and the notation $\wedge$ means $a \wedge b = \min\{a, b\}$. Denote $\widetilde{U} = [\widetilde{u}_1, \ldots, \widetilde{u}_r], V = [\widetilde{v}_1, \ldots, \widetilde{v}_r]$, which are counterparts of top r singular vectors of A.

We will present an ℓ_∞ matrix perturbation result that bounds $\|\widetilde{u}_i - u_i\|_\infty$ and $\|\widetilde{v}_i - v_i\|_\infty$ up to sign.[1] This result is different from ℓ_2 bounds, Frobenius-norm bounds, or the $\sin\Theta$ bounds, as the ℓ_∞ norm is not orthogonal invariant. The following theorem is a simplified version of our main results in Section 2.

Theorem 1 *Let $\widetilde{A} = A + E$ and suppose the singular decomposition in (2) and (5). Denote $\gamma_0 = \min\{\sigma_i - \sigma_{i+1} : i = 1, \ldots, r\}$ where $\sigma_{r+1} := 0$. Then there exists $C(r, \mu_0) = O(r^4\mu_0^2)$ such that, if $\gamma_0 > C(r, \mu_0)\tau_0$, up to sign,*

$$\max_{1\le i\le r}\|\widetilde{u}_i - u_i\|_\infty \le C(r,\mu_0)\frac{\tau_0}{\gamma_0\sqrt{d_1}} \quad \text{and} \quad \max_{1\le i\le r}\|\widetilde{v}_i - v_i\|_\infty \le C(r,\mu_0)\frac{\tau_0}{\gamma_0\sqrt{d_2}}, \tag{6}$$

where $\mu_0 = \max\{\mu(U), \mu(V)\}$ is the coherence given after (3) and $\tau_0 := \max\{\sqrt{d_2/d_1}\|E\|_1, \sqrt{d_1/d_2}\|E\|_\infty\}$.

When A is symmetric, $\tau_0 = \|E\|_\infty$ and the condition on the eigengap is simply $\gamma_0 > C(r, \mu_0)\|E\|_\infty$. The incoherence condition naturally holds for a variety of applications, where the low rank structure emerges as a consequence of a few factors driving the data matrix. For example, in Fama-French factor models, the excess returns in a stock market are driven by a few common factors (Fama and French, 1993); in collaborative filtering, the ratings of users are mostly determined by a few common preferences (Rennie and Srebro, 2005); in video surveillance, A is associated with the stationary background across image frames (Oliver et al., 2000). We will have a detailed discussion in Section 2.3.

The eigenvector perturbation was studied by Davis and Kahan (1970), where Hermitian matrices were considered, and the results were extended by Wedin (1972) to general rectangular matrices. To compare our result with these classical results, assuming $\gamma_0 \ge 2\|E\|_2$, a combination of Wedin's theorem and Mirsky's inequality (Mirsky, 1960) (the counterpart of Weyl's inequality for singular values) implies

$$\max_{1\le k\le r}\left\{\|v_k - \widetilde{v}_k\|_2 \vee \|u_k - \widetilde{u}_k\|_2\right\} \le \frac{2\sqrt{2}\|E\|_2}{\gamma_0}. \tag{7}$$

where $a \vee b := \max\{a, b\}$.

1. 'Up to sign' means we can appropriately choose an eigenvector or singular vector u to be either u or $-u$ in the bounds. This is becuase eigenvectors and singular vectors are not unique.

Yu et al. (2015) also proved a similar bound as in (7), and that result is more convenient to use. If we are interested in the ℓ_∞ bound but naively use the trivial inequality $\|x\|_\infty \le \|x\|_2$, we would have a suboptimal bound $O(\|E\|_2/\gamma_0)$ in many situations, especially in cases where $\|E\|_2$ is comparable to $\|E\|_\infty$. Compared with (6), the bound is worse by a factor of $\sqrt{d_1}$ for u_k and $\sqrt{d_2}$ for v_k. In other words, converting the ℓ_2 bound from Davis-Kahan theorem directly to the ℓ_∞ bound does not give a sharp result in general, in the presence of incoherent and low rank structure of A. Actually, assuming $\|E\|_2$ is comparable with $\|E\|_\infty$, for square matrices, our ℓ_∞ bound (6) matches the ℓ_2 bound (7) in terms of dimensions d_1 and d_2. This is because $\|x\|_2 \le \sqrt{n}\,\|x\|_\infty$ for any $x \in \mathbb{R}^n$, so we expect to gain a factor $\sqrt{d_1}$ or $\sqrt{d_2}$ in those ℓ_∞ bounds. The intuition is that, when A has an incoherent and low-rank structure, the perturbation of singular vectors is not concentrated on a few coordinates.

To understand how matrix incoherence helps, let us consider a simple example with no matrix incoherence, in which (7) is tight up to a constant. Let $A = d(1, 0, \ldots, 0)^T(1, 0, \ldots, 0)$ be a d-dimensional square matrix, and $E = d(0, 1/2, 0, \ldots, 0)^T(1, 0, \ldots, 0)$ of the same size. It is apparent that $\gamma_0 = d, \tau_0 = d/2$, and that $v_1 = (1, 0, \ldots, 0)^T, \widetilde{v}_1 = (2/\sqrt{5}, 1/\sqrt{5}, 0, \ldots, 0)^T$ up to sign. Clearly, the perturbation $\|\widetilde{v}_1 - v_1\|_\infty$ is not vanishing as d tends to infinity in this example, and thus, there is no hope of a strong upper bound as in (6) without the incoherence condition.

The reason that the factor $\sqrt{d_1}$ or $\sqrt{d_2}$ comes into play in (7) is that, the error $u_k - \widetilde{u}_k$ (and similarly for v_k) spreads out evenly in d_1 (or d_2) coordinates, so that the ℓ_∞ error is far smaller than the ℓ_2 error. This, of course, hinges on the incoherence condition, which in essence precludes eigenvectors from aligning with any coordinate.

Our result is very different from the sparse PCA literature, in which it is usually assumed that the leading eigenvectors are sparse. In Johnstone and Lu (2009), it is proved that there is a threshold for p/n (the ratio between the dimension and the sample size), above which PCA performs poorly, in the sense that $\langle\widetilde{v}_1, v_1\rangle$ is approximately 0. This means that the principal component computed from the sample covariance matrix reveals nothing about the true eigenvector. In order to mitigate this issue, in Johnstone and Lu (2009) and subsequent papers (Vu and Lei, 2013; Ma, 2013; Berthet and Rigollet, 2013), sparse leading eigenvectors are assumed. However, our result is different, in the sense that we require a stronger eigengap condition $\gamma_0 > C(r, \mu_0)\|E\|_\infty$ (i.e. stronger signal), whereas in Johnstone and Lu (2009), the eigengap of the leading eigenvectors is a constant times $\|E\|_2$. This explains why it is plausible to have a strong uniform eigenvector perturbation bound in this paper.

We will illustrate the power of this perturbation result using robust covariance estimation as one application. In the approximate factor model, the true covariance matrix admits a decomposition into a low rank part A and a sparse part S. Such models have been widely applied in finance, economics, genomics, and health to explore correlation structure.

However, in many studies, especially financial and genomics applications, it is well known that the observations exhibit heavy tails (Gupta et al., 2013). This problem can be resolved with the aid of recent results of concentration bounds in robust estimation (Catoni, 2012; Hsu and Sabato, 2014; Fan et al., 2017a), which produces the estimation error N in (1) with an optimal entry-wise bound. It nicely fits our perturbation results, and we can tackle it easily by following the ideas in Fan et al. (2013).

Here are a few notations in this paper. For a generic d_1 by d_2 matrix, the matrix max-norm is denoted as $\|M\|_{\max} = \max_{i,j} |M_{ij}|$. The matrix operator norm induced by vector ℓ_p norm is $\|M\|_p = \sup_{\|x\|_p=1} \|Mx\|_p$ for $1 \le p \le \infty$. In particular, $\|M\|_1 = \max_j \sum_{i=1}^{d_1} |M_{ij}|$; $\|M\|_\infty = \max_i \sum_{j=1}^{d_2} |M_{ij}|$; and $\|\cdot\|$ denotes the spectral norm, or the matrix 2-norm $\|\cdot\|_2$ for simplicity. We use $\sigma_j(M)$ to denote the j^{th} largest singular value. For a symmetric matrix M, denote $\lambda_j(M)$ as its j^{th} largest eigenvalue. If M is a positive definite matrix, then $M^{1/2}$ is the square root of M, and $M^{-1/2}$ is the square root of M^{-1}.

2. The ℓ_∞ perturbation results

2.1 Symmetric matrices

First, we study ℓ_∞ perturbation for symmetric matrices (so $d_1 = d_2$). The approach we study symmetric matrices will be useful to analyze asymmetric matrices, because we can always augment a $d_1 \times d_2$ rectangular matrix into a $(d_1+d_2)\times(d_1+d_2)$ symmetric matrix, and transfer the study of singular vectors to the eigenvectors of the augmented matrix. This augmentation is called *Hermitian dilation*. (Tropp, 2012; Paulsen, 2002)

Suppose that $A \in \mathbb{R}^{d\times d}$ is an d-dimensional symmetric matrix. The perturbation matrix $E \in \mathbb{R}^{d\times d}$ is also d-dimensional and symmetric. Let the perturbed matrix be $\widetilde{A} := A + E$. Suppose the spectral decomposition of A is given by

$$A = [V, V_\perp] \begin{pmatrix} \Lambda_1 & 0 \\ 0 & \Lambda_2 \end{pmatrix} [V, V_\perp]^T = \sum_{i=1}^{r} \lambda_i v_i v_i^T + \sum_{i>r} \lambda_i v_i v_i^T, \tag{8}$$

where $\Lambda_1 = \mathrm{diag}\{\lambda_1, \ldots, \lambda_r\}$, $\Lambda_2 = \mathrm{diag}\{\lambda_{r+1}, \ldots, \lambda_n\}$, and where $|\lambda_1| \ge |\lambda_2| \ge \ldots \ge |\lambda_n|$. Note the best rank-$r$ approximation of A under the Frobenius norm is $A_r := \sum_{i\le r} \lambda_i v_i v_i^T$.[2] Analogously, the spectral decomposition of $\widetilde{A}$ is

$$\widetilde{A} = \sum_{i=1}^{r} \widetilde{\lambda}_i \widetilde{v}_i \widetilde{v}_i^T + \sum_{i>r} \widetilde{\lambda}_i \widetilde{v}_i \widetilde{v}_i^T,$$

and write $\widetilde{V} = [\widetilde{v}_1, \ldots, \widetilde{v}_r] \in \mathbb{R}^{d\times r}$, where $|\widetilde{\lambda}_1| \ge |\widetilde{\lambda}_2| \ge \ldots \ge |\widetilde{\lambda}_n|$. Recall that $\|E\|_\infty$ given by (4) is an operator norm in the ℓ_∞ space, in the sense that $\|E\|_\infty = \sup_{\|u\|_\infty \le 1} \|Eu\|_\infty$. This norm is the natural counterpart of the spectral norm $\|E\|_2 := \sup_{\|u\|_2\le 1} \|Eu\|_2$.

We will use notations $O(\cdot)$ and $\Omega(\cdot)$ to hide absolute constants.[3] The next theorem bounds the perturbation of eigenspaces up to a rotation.

Theorem 2 *Suppose $|\lambda_r| - \varepsilon = \Omega(r^3\mu^2\|E\|_\infty)$, where $\varepsilon = \|A - A_r\|_\infty$, which is the approximation error measured under the matrix ∞-norm and $\mu = \mu(V)$ is the coherence of V defined in (3). Then, there exists an orthogonal matrix $R \in \mathbb{R}^{r\times r}$ such that*

$$\|\widetilde{V}R - V\|_{\max} = O\left(\frac{r^{5/2}\mu^2\|E\|_\infty}{(|\lambda_r| - \varepsilon)\sqrt{d}}\right).$$

This result involves an unspecified rotation R, due to the possible presence of multiplicity of eigenvalues. In the case where $\lambda_1 = \cdots = \lambda_r > 0$, the individual eigenvectors of V are only identifiable up to rotation. However, assuming an eigengap (similar to Davis-Kahan theorem), we are able to bound the perturbation of individual eigenvectors (up to sign).

Theorem 3 *Assume the conditions in Theorem 2. In addition, suppose δ satisfies $\delta > \|E\|_2$, and for any $i \in [r]$, the interval $[\lambda_i - \delta, \lambda_i + \delta]$ does not contain any eigenvalues of A other than λ_i. Then, up to sign,*

$$\max_{i\in[r]} \|\widetilde{v}_i - v_i\|_\infty = \|\widetilde{V} - V\|_{\max} = O\left(\frac{r^4\mu^2\|E\|_\infty}{(|\lambda_r| - \varepsilon)\sqrt{d}} + \frac{r^{3/2}\mu^{1/2}\|E\|_2}{\delta\sqrt{d}}\right).$$

To understand the above two theorems, let us consider the case where A has exactly rank r (i.e., $\varepsilon = 0$), and r and μ are not large (say, bounded by a constant). Theorem 2 gives a uniform entrywise bound $O(\|E\|_\infty/|\lambda_r|\sqrt{d})$ on the eigenvector perturbation. As a comparison, the Davis–Kahan $\sin\Theta$ theorem (Davis and Kahan, 1970) gives a bound $O(\|E\|_2/|\lambda_r|)$ on $\|\widetilde{V}R - V\|_2$ with suitably chosen rotation R.[4] This is an order of $\sqrt{d}$ larger than the bound given in Theorem 2 when $\|E\|_\infty$ is of the same order as $\|E\|_2$. Thus, in scenarios where $\|E\|_2$ is comparable to $\|E\|_\infty$, this is a refinement of Davis-Kahan theorem, because the max-norm bound in Theorem 2 provides an entry-wise control of perturbation. Although $\|E\|_\infty \ge \|E\|_2$,[5] there are many settings where the two quantities are comparable; for example, if E has a submatrix whose entries are identical and has zero entries otherwise, then $\|E\|_\infty = \|E\|_2$.

Theorem 3 provides the perturbation of individual eigenvectors, under a usual eigengap assumption. When r and μ are not large, we incur an additional term $O(\|E\|_2/\delta\sqrt{d})$ in the bound. This is understandable, since $\|\widetilde{v}_i - v_i\|_2$ is typically $O(\|E\|_2/\delta)$.

When the rank of A is not exactly r, we require that $|\lambda_r|$ is larger than the approximation error $\|A - A_r\|_\infty$. It is important to state that this assumption is more restricted than the eigengap assumption in the Davis-Kahan theorem, since $\|A - A_r\|_\infty \ge \|A - A_r\|_2 = |\lambda_{r+1}|$. However, different from the matrix max-norm, the spectral norm $\|\cdot\|_2$ only depends on the eigenvalues of a matrix, so it is natural to expect ℓ_2 perturbation bounds that only involve λ_r and λ_{r+1}. It is not clear whether we should expect an ℓ_∞ bound that involves λ_{r+1} instead of ε. More discussions can be found in Section 5.

We do not pursue the optimal bound in terms of r and $\mu(V)$ in this paper, as the two quantities are not large in many applications, and the current proof is already complicated.

2. This is a consequence of Wielandt-Hoffman theorem.
3. We write $a = O(b)$ if there is a constant $C > 0$ such that $a < Cb$; and $a = \Omega(b)$ if there is a constant $C' > 0$ such that $a > C'b$.
4. To see how the Davis-Kahan $\sin\Theta$ theorem relates to this form, we can use the identity $\|\sin\Theta(\widetilde{V}, V)\|_2 = \|\widetilde{V}\widetilde{V}^T - VV^T\|_2$ (Stewart, 1990), and the (easily verifiable) inequality $2\min_R \|\widetilde{V}R - V\|_2 \ge \|\widetilde{V}\widetilde{V}^T - VV^T\|_2 \ge \min_R \|\widetilde{V}R - V\|_2$ where R is an orthogonal matrix.
5. Since $\|E\|_1\|E\|_\infty \ge \|E\|_2^2$ (Stewart, 1990), the inequality follows from $\|E\|_1 = \|E\|_\infty$ by symmetry.

2.2 Rectangular matrices

Now we establish ℓ_∞ perturbation bounds for general rectangular matrices. The results here are more general than those in Section 1, and in particular, we allow the matrix A to be of approximate low rank. Suppose that both A and E are $d_1 \times d_2$ matrices, and $\widetilde{A} := A + E$. The rank of A is at most $d_1 \wedge d_2$ (where $a \wedge b = \min\{a, b\}$). Suppose an integer r satisfies $r \le \mathrm{rank}(A)$. Let the singular value decomposition of A be

$$A = \sum_{i=1}^{r} \sigma_i u_i v_i^T + \sum_{i=r+1}^{d_1 \wedge d_2} \sigma_i u_i v_i^T,$$

where the singular values are ordered as $\sigma_1 \ge \sigma_2 \ge \ldots \ge \sigma_{d_1 \wedge d_2} \ge 0$, and the unit vectors $u_1, \ldots, u_{d_1 \wedge d_2}$ (or unit vectors $v_1, \ldots, v_{d_1 \wedge d_2}$) are orthogonal to each other. We denote $U = [u_1, \ldots, u_r] \in \mathbb{R}^{d_1 \times r}$ and $V = [v_1, \ldots, v_r] \in \mathbb{R}^{d_2 \times r}$. Analogously, the singular value decomposition of $\widetilde{A}$ is

$$\widetilde{A} = \sum_{i=1}^{r} \widetilde{\sigma}_i \widetilde{u}_i \widetilde{v}_i^T + \sum_{i=r+1}^{d_1 \wedge d_2} \widetilde{\sigma}_i \widetilde{u}_i \widetilde{v}_i^T,$$

where $\widetilde{\sigma}_1 \ge \ldots \ge \widetilde{\sigma}_{d_1 \wedge d_2}$. Similarly, columns of $\widetilde{U} = [\widetilde{u}_1, \ldots, \widetilde{u}_r] \in \mathbb{R}^{d_1 \times r}$ and $\widetilde{V} = [\widetilde{v}_1, \ldots, \widetilde{v}_r] \in \mathbb{R}^{d_2 \times r}$ are orthonormal.

Define $\mu_0 = \max\{\mu(V), \mu(U)\}$, where $\mu(U)$ (resp. $\mu(V)$) is the coherence of U (resp. V). This μ_0 will appear in the statement of our results, as it controls both the structure of left and right singular spaces. When, specially, A is a symmetric matrix, the spectral decomposition of A is also the singular value decomposition (up to sign), and thus μ_0 coincides with μ defined in Section 2.1.

Recall the definition of matrix ∞-norm and 1-norm of a rectangular matrix (4). Similar to the matrix ∞-norm, $\|\cdot\|_1$ is an operator norm in the ℓ_1 space. An obvious relationship between matrix ∞-norm and 1-norm is $\|E\|_\infty = \|E^T\|_1$. Note that the matrix ∞-norm and 1-norm have different number of summands in their definitions, so we are motivated to consider $\tau_0 := \max\{\sqrt{d_1/d_2}\|E\|_\infty, \sqrt{d_2/d_1}\|E\|_1\}$ to balance the dimensions d_1 and d_2.

Let $A_r = \sum_{i \le r} \sigma_i u_i v_i^T$ be the best rank-r approximation of A under the Frobenius norm, and let $\varepsilon_0 = \sqrt{d_1/d_2}\|A - A_r\|_\infty \vee \sqrt{d_2/d_1}\|A - A_r\|_1$, which also balances the two dimensions. Note that in the special case where A is symmetric, this approximation error ε_0 is identical to ε defined in Section 2.1. The next theorem bounds the perturbation of singular spaces.

Theorem 4 *Suppose that $\delta_0 - \varepsilon_0 = \Omega(r^3 \mu_0^2 \tau_0)$. Then, there exists orthogonal matrices $R_U, R_V \in \mathbb{R}^{r \times r}$ such that,*

$$\|\widetilde{U} R_U - U\|_{\max} = O\Big(\frac{r^{5/2}\mu_0^2\tau_0}{(\sigma_r - \epsilon_0)\sqrt{d_1}}\Big), \qquad \|\widetilde{V} R_V - V\|_{\max} = O\Big(\frac{r^{5/2}\mu_0^2\tau_0}{(\sigma_r - \epsilon_0)\sqrt{d_2}}\Big).$$

Similar to Theorem 3, under an assumption of gaps between singular values, the next theorem bounds the perturbation of individual singular vectors.

Theorem 5 *Suppose the same assumptions in Theorem 4 hold. In addition, suppose δ_0 satisfies $\delta_0 > \|E\|_2$, and for any $i \in [r]$, the interval $[\sigma_i - \delta_0, \sigma_i + \delta_0]$ does not contain any eigenvalues of A other than σ_i. Then, up to sign,*

$$\max_{i \in [r]} \|\widetilde{u}_i - u_i\|_\infty = O\Big(\frac{r^4\mu_0^2\tau_0}{(\sigma_r - \varepsilon_0)\sqrt{d_1}} + \frac{r^{3/2}\mu_0^{1/2}\|E\|_2}{\delta_0\sqrt{d_1}}\Big), \tag{9}$$

$$\max_{i \in [r]} \|\widetilde{v}_i - v_i\|_\infty = O\Big(\frac{r^4\mu_0^2\tau_0}{(\sigma_r - \varepsilon_0)\sqrt{d_2}} + \frac{r^{3/2}\mu_0^{1/2}\|E\|_2}{\delta_0\sqrt{d_2}}\Big). \tag{10}$$

As mentioned in the beginning of this section, we will use dilation to augment all $d_1 \times d_2$ matrices into symmetric ones with size $d_1 + d_2$. In order to balance the possibly different scales of d_1 and d_2, we consider a weighted max-norm. This idea will be further illustrated in Section 5.

2.3 Examples: which matrices have such structure?

In many problems, low-rank structure naturally arises due to the impact of pervasive latent factors that influence most observed data. Since observations are imperfect, the low-rank structure is often 'perturbed' by an additional sparse structure, gross errors, measurement noises, or the idiosyncratic components that can not be captured by the latent factors. We give some motivating examples with such structure.

Panel data in stock markets. Consider the excess returns from a stock market over a period of time. The driving factors in the market are reflected in the covariance matrix as a low rank component A. The residual covariance of the idiosyncratic components is often modeled by a sparse component S. Statistical analysis including PCA is usually conducted based on the estimated covariance matrix $\widetilde{A} = \widehat{\Sigma}$, which is perturbed from the true covariance $\Sigma = A + S$ by the estimation error N (Stock and Watson, 2002; Fan et al., 2013). In Section 3.1, we will develop a robust estimation method in the presence of heavy-tailed return data.

Video surveillance. In image processing and computer vision, it is often desired to separate moving objects from static background before further modeling and analysis (Oliver et al., 2000; Hu et al., 2004). The static background corresponds to the low rank component A in the data matrix, which is a collection of video frames, each consisting of many pixels represented as a long vector in the data matrix. Moving objects and noise correspond to the sparse matrix S and noise matrix N. Since the background is global information and reflected by many pixels of a frame, it is natural for the incoherence condition to hold.

Wireless sensor network localization. In wireless sensor networks, we are usually interested in determining the location of sensor nodes with unknown position based on a few (noisy) measurements between neighboring nodes (Doherty et al., 2001; Biswas and Ye, 2004). Let $\mathbb{X}$ be an r by n matrix such that each column x_i gives the coordinates of each node in a plane ($r = 2$) or a space ($r = 3$). Assume the center of the sensors has been relocated at origin. Then the low rank matrix $A = \mathbb{X}^T\mathbb{X}$, encoding the true distance information, has to satisfy distance constraints given by the measurements. The noisy distance matrix $\widetilde{A}$ after centering, equals to the sum of A and a matrix N consisting of measurement

errors. Suppose that each node is a random point uniformly distributed in a rectangular region. It is not difficult to see that with high probability, the top r eigenvalues of $\mathbb{X}^T\mathbb{X}$ and their eigengap scales with the number of sensors n and the leading eigenvectors have a bounded coherence.

In our theorems, we require that the coherence μ is not too large. This is a natural structural condition associated with the low rank matrices. Consider the following very simple example: if the eigenvectors $v_1, \ldots, v_r$ of the low rank matrix A are uniform unit vectors in a sphere, then with high probability, $\max_i \|v_i\|_\infty = O(\sqrt{\log n})$, which implies $\mu = O(\log n)$. An intuitive way to understand the incoherence structure is that no coordinates of v_1 (or $v_2, \ldots v_r$) are dominant. In other words, the eigenvectors are not concentrated on a few coordinates.

In all our examples, the incoherence structure is natural. The factor model satisfies such structure, which will be discussed in Section 3. In the video surveillance example, ideally, when the images are static, A is a rank one matrix $x\mathbf{1}^T$. Since usually a majority of pixels (coordinates of x) help to display an image, the vector x often has dense coordinates with comparable magnitude, so A also has an incoherence structure in this example. Similarly, in the sensor localization example, the coordinates of all sensor nodes are comparable in magnitude, so the low rank matrix A formed by $\mathbb{X}^T\mathbb{X}$ also has the desired incoherence structure.

2.4 Other perturbation results

Although the eigenvector perturbation theory is well studied in numerical analysis, there is a renewed interest among statistics and machine learning communities recently, due to the wide applicability of PCA and other eigenvector-based methods. In Cai and Zhang (2016); Yu et al. (2015), they obtained variants or improvements of Davis-Kahan theorem (or Wedin's theorem), which are user-friendly in the statistical contexts. These results assume the perturbation is deterministic, which is the same as Davis-Kahan theorem and Wedin's theorem. In general, these results are sharp, even when the perturbation is random, as evidenced by the BBP transition (Baik et al., 2005).

However, these classical results can be suboptimal, when the perturbation is random and the smallest eigenvalue gap $\lambda_1 - \lambda_2$ does not capture particular spectrum structure. For example, Vu (2011); O'Rourke et al. (2013) showed that with high probability, there are bounds sharper than the Wedin's theorem, when the signal matrix is low-rank and satisfies certain eigenvalue conditions.

In this paper, our perturbation results are deterministic, thus the bound can be suboptimal when the perturbation is random with certain structure (e.g. the difference between sample covariance and population one for i.i.d. samples). However, the advantage of a deterministic result is that it is applicable to any random perturbation. This is especially useful when we cannot make strong random assumptions on the perturbation (e.g., the perturbation is an unknown sparse matrix). In Section 3, we will see examples of this type.

3. Application to robust covariance estimation

We will study the problem of robust estimation of covariance matrices and show the strength of our perturbation result. Throughout this section, we assume both rank r and the coherence $\mu(V)$ are bounded by a constant, though this assumption can be relaxed. We will use C to represent a generic constant, and its value may change from line to line.

3.1 PCA in spiked covariance model

To initiate our discussions, we first consider sub-Gaussian random variables. Let $X = (X_1, \ldots, X_d)$ be a random d-dimensional vector with mean zero and covariance matrix

$$\Sigma = \sum_{i=1}^{r} \lambda_i v_i v_i^T + \sigma^2 I_d := \Sigma_1 + \Sigma_2, \qquad (\lambda_1 \geq \ldots \geq \lambda_r > 0), \tag{11}$$

and $\mathbb{X}$ be an n by d matrix, whose rows are independently sampled from the same distribution. This is the spiked covariance model that has received intensive study in recent years. Let the empirical covariance matrix be $\widehat{\Sigma} = \mathbb{X}^T\mathbb{X}/n$. Viewing the empirical covariance matrix as its population version plus an estimation error, we have the decomposition

$$\widehat{\Sigma} = \Sigma_1 + \Sigma_2 + \Big(\frac{1}{n}\mathbb{X}^T\mathbb{X} - \Sigma\Big),$$

which is a special case of the general decomposition in (1). Here, Σ_2 is the sparse component, and the estimation error $\mathbb{X}^T\mathbb{X}/n - \Sigma$ is the noise component. Note that $v_1, \ldots, v_r$ are just the top r leading eigenvectors of Σ and we write $V = [v_1, \ldots, v_r]$. Assume the top r eigenvectors of $\widehat{\Sigma}$ are denoted by $\widehat{v}_1, \ldots, \widehat{v}_r$. We want to find an ℓ_∞ bound on the estimation error $\widehat{v}_i - v_i$ for all $i \in [r]$.

When the dimension d is comparable to or larger than n, it has been shown by Johnstone and Lu (2009) that the leading empirical eigenvector $\widehat{v}_1$ is not a consistent estimate of the true eigenvector v_1, unless we assume larger eigenvalues. Indeed, we will impose more stringent conditions on λ_i's in order to obtain good ℓ_∞ bounds.

Assuming the coherence $\mu(V)$ is bounded, we can easily see $\mathrm{Var}(X_j) \leq \sigma^2 + C\lambda_1/d$ for some constant C. It follows from the standard concentration result (e.g., Vershynin (2010)) that if rows of $\mathbb{X}$ contains i.i.d sub-Gaussian vectors and $\log d = O(n)$, then with probability greater than $1 - d^{-1}$,

$$\|\frac{1}{n}\mathbb{X}^T\mathbb{X} - \Sigma\|_{\max} \leq C\big(\sigma^2 + \frac{\lambda_1}{d}\big)\sqrt{\frac{\log d}{n}}. \tag{12}$$

To apply Theorem 3, we treat Σ_1 as A and $\widehat{\Sigma} - \Sigma_1$ as E. If the conditions in Theorem 3 are satisfied, we will obtain

$$\max_{1\leq k\leq r} \|\widehat{v}_k - v_k\|_\infty = O(\|E\|_\infty/(\lambda_r\sqrt{d}) + \|E\|_2/(\delta\sqrt{d})). \tag{13}$$

Note there are simple bounds on $\|E\|_\infty$ and $\|E\|_2$:

$$\|E\|_2 \leq \|E\|_\infty \leq \sigma^2 + d\,\|\frac{1}{n}\mathbb{X}^T\mathbb{X} - \Sigma\|_{\max} \leq C\Big\{1 + \big(d\sigma^2 + \lambda_1\big)\sqrt{\frac{\log d}{n}}\Big\}.$$

By assuming a strong uniform eigengap, the conditions in Theorem 3 are satisfied, and the bound in (13) can be simplified. Define the uniform eigengap as

$$\gamma = \min\{\lambda_i - \lambda_{i+1} : 1 \le i \le r\}, \qquad \lambda_{r+1} := 0.$$

Note that $\gamma \le \min\{\lambda_r, \delta\}$, so if $\gamma > C(1 + \big(d\sigma^2 + \lambda_1\big)\sqrt{\log d/n})$, we have

$$\max_{1\le k\le r} \|\widehat{v}_k - v_k\|_\infty = O_P\Big(\frac{\|E\|_\infty}{\gamma\sqrt{d}}\Big) = O_P\Big(\frac{1 + \big(d\sigma^2 + \lambda_1\big)\sqrt{\log d/n}}{\gamma\sqrt{d}}\Big),$$

In particular, when $\lambda_1 \asymp \gamma$ and $\gamma \gg \max\{1, \sigma^2 d\sqrt{\log d/n}\}$, we have

$$\max_{1\le k\le r} \|\widehat{v}_k - v_k\|_\infty = o_P\Big(\frac{1}{\sqrt{d}}\Big).$$

The above analysis pertains to the structure of sample covariance matrix. In the following subsections, we will estimate the covariance matrix using more complicated robust procedure. Our perturbation theorems in Section 2 provide a fast and clean approach to obtain new results.

3.2 PCA for robust covariance estimation

The usefulness of Theorem 3 is more pronounced when the random variables are heavy-tailed. Consider again the covariance matrix Σ with structure (11). Instead of assuming sub-Gaussian distribution, we assume there exists a constant $C > 0$ such that $\max_{j\le d} EX_j^4 < C$, i.e. the fourth moments of the random variables are uniformly bounded.

Unlike sub-Gaussian variables, there is no concentration bound similar to (12) for the empirical covariance matrix. Fortunately, thanks to recent advances in robust statistics (e.g., Catoni (2012)), robust estimate of Σ with guaranteed concentration property becomes possible. We shall use the method proposed in Fan et al. (2017a). Motivated by the classical M-estimator of Huber (1964), Fan et al. (2017a) proposed a robust estimator for each element of $\widehat{\Sigma}$, by solving a Huber loss based minimization problem

$$\widehat{\Sigma}_{ij} = \mathrm{argmin}_\mu \sum_{t=1}^n l_\alpha(X_{ti}X_{tj} - \mu), \tag{14}$$

where l_α is the Huber loss defined as

$$l_\alpha(x) = \begin{cases} 2\alpha|x| - \alpha^2, & |x| \ge \alpha, \\ x^2, & |x| \le \alpha. \end{cases}$$

The parameter α is suggested to be $\alpha = \sqrt{nv^2/\log(\epsilon^{-1})}$ for $\epsilon \in (0,1)$, where v is assumed to satisfy $v \ge \max_{ij}\sqrt{\mathrm{Var}(X_iX_j)}$. If $\log(\epsilon^{-1}) \le n/8$, Fan et al. (2017a) showed

$$P\Big(|\widehat{\Sigma}_{ij} - \Sigma_{ij}| \le 4v\sqrt{\frac{\log(\epsilon^{-1})}{n}}\Big) \ge 1 - 2\epsilon.$$

From this result, the next proposition is immediate by taking $\epsilon = d^{-3}$.

Proposition 1 *Suppose that there is a constant C with $\max_{j\le d} EX_j^4 < C$. Then with probability greater than $1 - d^{-1}(1 + d^{-1})$, the robust estimate of covariance matrix with $\alpha = \sqrt{3nv^2\log(d)}$ satisfies*

$$\|\widehat{\Sigma} - \Sigma\|_{\max} \le 4v\sqrt{\frac{3\log d}{n}},$$

where v is a pre-determined parameter assumed to be no less than $\max_{ij}\sqrt{Var(X_iX_j)}$.

This result relaxes the sub-Gaussianity assumption by robustifying the covariance estimate. It is apparent that the ℓ_∞ bound in the previous section is still valid in this case. To be more specific, suppose $\mu(V)$ is bounded by a constant. Then, (13) holds for the PCA based on the robust covariance estimation. When $\lambda_1 \asymp \gamma$ and $\gamma \gg \max\{1, \sigma^2 d\sqrt{\log d/n}\}$, we again have

$$\max_{1\le k\le r} \|\widehat{v}_k - v_k\|_\infty = O_P\Big(\frac{1 + \big(d\sigma^2 + \lambda_1\big)\sqrt{\log d/n}}{\gamma\sqrt{d}}\Big) = o_P\Big(\frac{1}{\sqrt{d}}\Big).$$

Note that an entrywise estimation error $o_p(1/\sqrt{d})$ necessarily implies consistency of the estimated eigenvectors, since we can easily convert an ℓ_∞ result into an ℓ_2 result. The minimum signal strength (or magnitude of leading eigenvalues) for such consistency is shown to be $\sigma^2 d/n$ under the sub-Gaussian assumption (Wang and Fan, 2017).

If the goal is simply to prove consistency of $\widehat{v}_k$, the strategy of using our ℓ_∞ perturbation bounds is not optimal. However, there are also merits: our result is nonasymptotic; it holds for more general distributions (beyond sub-Gaussian distributions); and its entrywise bound gives stronger guarantee. Moreover, the ℓ_∞ perturbation bounds provide greater flexibility for analysis, since it is straightforward to adapt analysis to problems with more complicated structure. For example, the above discussion can be easily extended to a general Σ_2 with bounded $\|\Sigma_2\|_\infty$ rather than a diagonal matrix.

3.3 Robust covariance estimation via factor models

In this subsection, we will apply Theorem 3 to robust large covariance matrix estimation for approximate factor models in econometrics. With this theorem, we are able to extend the data distribution in factor analysis beyond exponentially decayed distributions considered by Fan et al. (2013), to include heavy-tailed distributions.

Suppose the observation y_{it}, say, the excess return at day t for stock i, admits a decomposition

$$y_{it} = b_i^T f_t + u_{it}, \qquad i \le d, t \le n, \tag{15}$$

where $b_i \in \mathbb{R}^r$ is the unknown but fixed loading vector, $f_t \in \mathbb{R}^r$ denotes the unobserved factor vector at time t, and u_{it}'s represent the idiosyncratic noises. Let $y_t = (y_{1t}, \ldots, y_{dt})^T$ and $u_t = (u_{1t}, \ldots, u_{dt})^T$ so that $y_t = Bf_t + u_t$, where $B = (b_1, \ldots, b_d)^T \in \mathbb{R}^{d\times r}$. Suppose that f_t and u_t are uncorrelated and centered random vectors, with bounded fourth moments, i.e., the fourth moments of all entries of f_t and u_t are bounded by some constant. We assume $\{f_t, u_t\}$ are independent for t, although it is possible to allow for weak temporal

dependence as in Fan et al. (2013). From (15), we can decompose $\Sigma = \mathrm{Cov}(y_t)$ into a low rank component and a residual component:

$$\Sigma = BB^T + \Sigma_u, \tag{16}$$

where $\Sigma_u := \mathrm{Cov}(u_t)$. To circumvent the identifiability issue common in latent variable models, here we also assume, without loss of generality, $\mathrm{Cov}(f_t) = I_r$ and that B^TB is a diagonal matrix, since rotating B will not affect the above decomposition (16).

We will need two major assumptions for our analysis: (1) the factors are *pervasive* in the sense of Definition 2, and (2) there is a constant $C > 0$ such that $\|\Sigma_u^{-1}\|_2, \|\Sigma_u\|_2 \le C$, which are standard assumptions in the factor model literature. The pervasive assumption is reasonable in financial applications, since the factors have impacts on a large fraction of the outcomes (Chamberlain et al., 1983; Bai, 2003). If the factor loadings $\{b_i\}_{i=1}^d$ are regarded as random realizations from a bounded random vector, the assumption holds (Fan et al., 2013).

Definition 2 *In the factor model (15), the factors are called pervasive if there is a constant $C > 0$ such that $\|B\|_{\max} \le C$ and the eigenvalues of the r by r matrix B^TB/d are distinct and bounded away from zero and infinity.*

Let $\{\lambda_i, v_i\}_{i=1}^r$ be the top r eigenvalues and eigenvectors of Σ, and similarly, $\{\overline{\lambda}_i, \overline{v}_i\}_{i=1}^r$ for BB^T. In the following proposition, we show that pervasiveness is naturally connected to the incoherence structure. This connects the econometrics and machine learning literature and provide a good interpretation on the concept of the incoherence. Its proof can be found in the appendix.

Proposition 3 *Suppose there exists a constant $C > 0$ such that $\|\Sigma_u\| \le C$. The factors f_t are pervasive if and only if the coherence $\mu(V)$ for $V = (v_1, \ldots, v_r) \in \mathbb{R}^{d\times r}$ is bounded by some constant, and $\lambda_i = \lambda_i(\Sigma) \asymp d$ for $i \le r$ so that $\min_{1\le i\ne j\le r} |\lambda_i - \lambda_j|/\lambda_j > 0$.*

Our goal is to obtain a good covariance matrix estimator by exploiting the structure (16). Our strategy is to use a generalization of the principal orthogonal complement thresholding (POET) method proposed in Fan et al. (2013). The generic POET procedure encompasses three steps:

(1) Given three pilot estimators $\widehat{\Sigma}, \widehat{\Lambda} = \mathrm{diag}(\widehat{\lambda}_1, \ldots, \widehat{\lambda}_r), \widehat{V} = (\widehat{v}_1, \ldots, \widehat{v}_r)$ respectively for true covariance Σ, leading eigenvalues $\Lambda = \mathrm{diag}(\lambda_1, \ldots, \lambda_r)$ and leading eigenvectors $V = (v_1, \ldots, v_r)$, compute the principal orthogonal complement $\widehat{\Sigma}_u$:

$$\widehat{\Sigma}_u = \widehat{\Sigma} - \widehat{V}\widehat{\Lambda}\widehat{V}^T. \tag{17}$$

(2) Apply the correlation thresholding to $\widehat{\Sigma}_u$ to obtain thresholded estimate $\widehat{\Sigma}_u^\top$ defined as follows:

$$\widehat{\Sigma}_{u,ij}^\top = \begin{cases} \widehat{\Sigma}_{u,ij}, & i = j \\ s_{ij}(\widehat{\Sigma}_{u,ij}) I(|\widehat{\Sigma}_{u,ij}| \ge \tau_{ij}), & i \ne j \end{cases}, \tag{18}$$

where $s_{ij}(\cdot)$ is the generalized shrinkage function (Antoniadis and Fan, 2001; Rothman et al., 2009) and $\tau_{ij} = \tau(\hat{\sigma}_{u,ii}\hat{\sigma}_{u,jj})^{1/2}$ is an entry-dependent threshold. τ will be determined later in Theorem 6. This step exploits the sparsity of Σ_u.

(3) Construct the final estimator $\widehat{\Sigma}^\top = \widehat{V}\widehat{\Lambda}\widehat{V}^T + \widehat{\Sigma}_u^\top$.

The key feature in the above procedure lies in the flexibility of choosing the pilot estimators in the first step. We will choose $\widehat{\Sigma}$ according to data generating distribution. Typically we can use $\hat{\lambda}_i, \hat{v}_i$ for $i \le r$ as the eigenvalues/vectors of $\widehat{\Sigma}$. However, $\hat{\Lambda}$ and $\hat{V}$ in general do not have to come from the spectral information of $\widehat{\Sigma}$ and can be obtained separately via different methods.

To guide the selection of proper pilot estimators, Fan et al. (2017+) provided a high level sufficient condition for this simple procedure to be effective, and its performance is gauged, in part, through the sparsity level of Σ_u, defined as $m_d := \max_{i\le d} \sum_{j\le d} |\Sigma_{u,ij}|^q$. When $q = 0$, m_d corresponds to the maximum number of nonzero elements in each row of Σ_u. For completeness, we present the theorem given by Fan et al. (2017+) in the following.

Theorem 6 *Let $w_n = \sqrt{\log d/n} + 1/\sqrt{d}$. Suppose there exists $C > 0$ such that $\|\Sigma_u^{-1}\|, \|\Sigma_u\| \le C$ and we have pilot estimators $\widehat{\Sigma}, \widehat{\Lambda}, \widehat{V}$ satisfying*

$$\|\widehat{\Sigma} - \Sigma\|_{\max} = O(\sqrt{\log d/n}), \tag{19}$$

$$|\widehat{\lambda}_i/\lambda_i - 1| = O(\sqrt{\log d/n}), \tag{20}$$

$$\|\widehat{v}_i - v_i\|_\infty = O(w_n/\sqrt{d}). \tag{21}$$

Under the pervasiveness condition of the factor model (15), with $\tau \asymp w_n$, if $m_d w_n^{1-q} = o(1)$, the following rates of convergence hold with the generic POET procedure:

$$\|\widehat{\Sigma}_u^\top - \Sigma_u\|_2 = O\Big(m_d w_n^{1-q}\Big) = \|(\widehat{\Sigma}_u^\top)^{-1} - {\Sigma_u}^{-1}\|_2, \tag{22}$$

and

$$\begin{aligned} \|\widehat{\Sigma}^\top - \Sigma\|_{\max} &= O\Big(w_n\Big), \\ \|\widehat{\Sigma}^\top - \Sigma\|_\Sigma &= O\Big(\frac{\sqrt{d}\log d}{n} + m_d w_n^{1-q}\Big), \\ \|(\widehat{\Sigma}^\top)^{-1} - \Sigma^{-1}\|_2 &= O\Big(m_d w_n^{1-q}\Big), \end{aligned} \tag{23}$$

where $\|A\|_\Sigma = d^{-1/2}\|\Sigma^{-1/2}A\Sigma^{-1/2}\|_F$ is the relative Frobenius norm.

We remark that the additional term $1/\sqrt{d}$ in w_n, is due to the estimation of unobservable factors and is negligible when the dimensional d is high. The optimality of the above rates of convergence is discussed in details in Fan et al. (2017+). Theorem 6 reveals a profound deterministic connection between the estimation error bound of the pilot estimators with the rate of convergences of the POET output estimators. Notice that the eigenvector estimation error is under the ℓ_∞ norm, for which our ℓ_∞ perturbation bounds will prove to be useful.

In this subsection, since we assume only bounded fourth moments, we choose $\widehat{\Sigma}$ to be the robust estimate of covariance matrix Σ defined in (14). We now invoke our ℓ_∞ bounds to show that the spectrum properties (eigenvalues and eigenvectors) are stable to perturbation.

Let us decompose $\widehat{\Sigma}$ into a form such that Theorem 3 can be invoked:

$$\widehat{\Sigma} = \sum_{i=1}^{r} \overline{\lambda}_i \overline{v}_i \overline{v}_i^T + \Sigma_u + (\widehat{\Sigma} - \Sigma),$$

where $\widehat{\Sigma}$ is viewed as $\widetilde{A}$, the low-rank part $\sum_{i=1}^r \overline{\lambda}_i \overline{v}_i \overline{v}_i^T$, which is also BB^T, is viewed as A, and the remaining terms are treated as E. The following results follow immediately.

Proposition 4 *Assume that there is a constant $C > 0$ such that $\|\Sigma_u\| \le C$. If the factors are pervasive, then with probability greater than $1 - d^{-1}$, we have (19) – (21) hold with $\widehat{\lambda}_i, \widehat{v}_i$ as the leading eigenvalues/vectors of $\widehat{\Sigma}$ for $i \le r$. In addition, (22) and (23) hold.*

The inequality (19) follows directly from Proposition 1 under the assumption of bounded fourth moments. It is also easily verifiable that (20), (21) follow from (19) by Weyl's inequality and Theorem 3 (noting that $\|\Sigma_u\|_\infty \le \sqrt{d}\|\Sigma_u\|$). See Section 3.2 for more details.

Note that in the case of sub-Gaussian variables, sample covariance matrix and its leading eigenvalues/vectors will also serve the same purpose due to (12) and Theorem 3 as discussed in Section 3.1.

We have seen that the ℓ_∞ perturbation bounds are useful in robust covariance estimation, and particularly, they resolve a theoretical difficulty in the generic POET procedure for factor model based covariance matrix estimation.

4. Simulations

4.1 Simulation: the perturbation result

In this subsection, we implement numerical simulations to verify the perturbation bound in Theorem 3. We will show that the error behaves in the same way as indicated by our theoretical bound.

In the experiments, we let the matrix size d run from 200 to 2000 by an increment of 200. We fix the rank of A to be 3 ($r = 3$). To generate an incoherence low rank matrix, we sample a $d \times d$ random matrix with iid standard normal variables, perform singular value decomposition, and extract the first r right singular vectors $v_1, v_2, \ldots, v_r$. Let $V = (v_1, \ldots, v_r)$ and $D = \mathrm{diag}(r\gamma, (r-1)\gamma, \ldots, \gamma)$ where γ as before represents the eigengap. Then, we set $A = VDV^T$. By orthogonal invariance, v_i is uniformly distributed on the unit sphere $\mathbb{S}^{d-1}$. It is not hard to see that with probability $1 - O(d^{-1})$, the coherence of V $\mu(V) = O(\sqrt{\log d})$.

We consider two types of sparse perturbation matrices E: (a) construct a $d \times d$ matrix E_0 by randomly selecting s entries for each row, and sampling a uniform number in $[0, L]$ for each entry, and then symmetrize the perturbation matrix by setting $E = (E_0 + E_0^T)/2$; (b) pick $\rho \in (0, 1), L' > 0$, and let $E_{ij} = L'\rho^{|i-j|}$. Note that in (b) we have $\|E\|_\infty \le 2L'/(1-\rho)$, and thus we can choose suitable L' and ρ to control the ℓ_∞ norm of E. This covariance structure is common in cases where correlations between random variables depend on their "distance" $|i - j|$, which usually arises from autoregressive models.

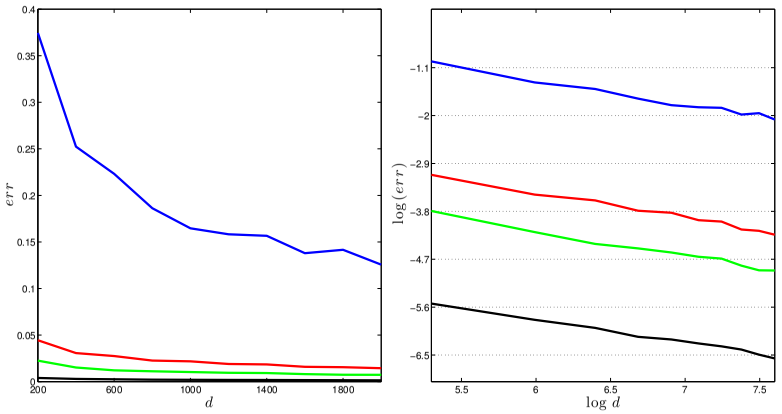

Figure 1: *The left plot shows the perturbation error of eigenvectors against matrix size d ranging from* 200 *to* 2000*, with different eigengap γ. The right plot shows* $\log(err)$ *against* $\log(d)$*. The slope is around* -0.5*. Blue lines represent $\gamma = 10$; red lines $\gamma = 50$; green lines $\gamma = 100$; and black lines $\gamma = 500$. We report the largest error over* 100 *runs.*

The perturbation of eigenvectors is measured by the element-wise error:

$$err := \max_{1 \le i \le r} \min_{\eta_i \in \{\pm 1\}} \|\eta_i \widetilde{v}_i - v_i\|_\infty,$$

where $\{\widetilde{v}_i\}_{i=1}^r$ are the eigenvectors of $\widetilde{A} = A + E$ in the descending order.

To investigate how the error depends on γ and d, we generate E according to mechanism (a) with $s = 10, L = 3$, and run simulations in different parameter configurations: (1) let the matrix size d range from 200 to 2000, and choose the eigengap γ in $\{10, 50, 100, 500\}$ (Figure 1); (2) fix the product $\gamma\sqrt{d}$ to be one of $\{2000, 3000, 4000, 5000\}$, and let the matrix size d run from 200 to 2000 (Figure 2).

To find how the errors behave for E generated from different methods, we run simulations as in (1) but generate E differently. We construct E through mechanism (a) with $L = 10, s = 3$ and $L = 0.6, s = 50$, and also through mechanism (b) with $L' = 1.5, \rho = 0.9$ and $L' = 7.5, \rho = 0.5$ (Figure 3). The parameters are chosen such that $\|E\|_\infty$ is about 30.

In Figure 1 – 3, we report the largest error based on 100 runs. Figure 1 shows that the error decreases as d increases (the left plot); and moreover, the logarithm of the error is linear in $\log(d)$, with a slope -0.5, that is, $err \propto 1/\sqrt{d}$ (the right plot). We can take the eigengap γ into consideration and characterize the relationship in a more refined way. In Figure 2, it is clear that err almost falls on the same horizontal line for different configurations of d and γ, with $\gamma\sqrt{d}$ fixed. The right panel clearly indicates that $err \times \gamma\sqrt{d}$ is a constant, and therefore $err \propto 1/(\gamma\sqrt{d})$. In Figure 3, we find that the errors behave almost the

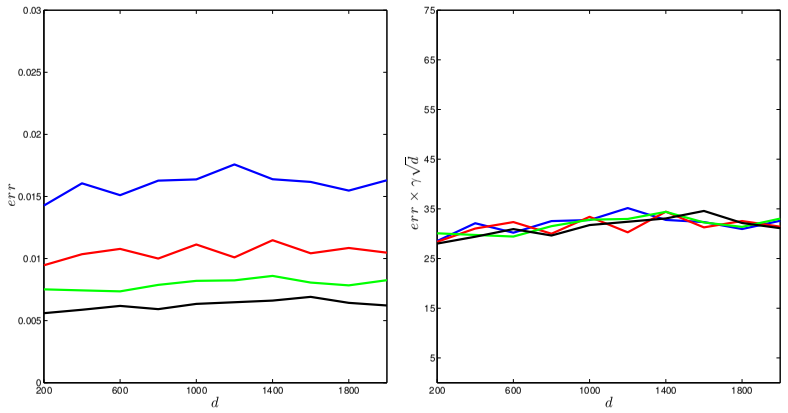

Figure 2: *The left plot shows the perturbation error of eigenvectors against matrix size* d *ranging from* 200 *to* 2000*, when* $\gamma\sqrt{d}$ *is kept fixed, with different values. The right plot shows the error multiplied by* $\gamma\sqrt{d}$ *against* d*. Blue lines represent* $\gamma\sqrt{d} = 2000$*; red lines* $\gamma\sqrt{d} = 3000$*; green lines* $\gamma\sqrt{d} = 4000$*; and black lines* $\gamma\sqrt{d} = 5000$*. We report the largest error over* 100 *runs.*

same regardless of how E is generated. These simulation results provide stark evidence supporting the ℓ_∞ perturbation bound in Theorem 3.

4.2 Simulation: robust covariance esitmation

We consider the performance of the generic POET procedure in robust covariance estimation in this subsection. Note that the procedure is flexible in employing any pilot estimators $\widehat{\Sigma}, \widehat{\Lambda}, \widehat{V}$ satisfying the conditions (19) – (21) respectively.

We implemented the robust procedure with four different initial trios: (1) the sample covariance $\widehat{\Sigma}^S$ with its leading r eigenvalues and eigenvectors as $\widehat{\Lambda}^S$ and $\widehat{V}^S$; (2) the Huber's robust estimator $\widehat{\Sigma}^R$ given in (14) and its top r eigen-structure estimators $\widehat{\Lambda}^R$ and $\widehat{V}^R$; (3) the marginal Kendall's tau estimator $\widehat{\Sigma}^K$ with its corresponding $\widehat{\Lambda}^K$ and $\widehat{V}^K$; (4) lastly, we use the spatial Kendall's tau estimator to estimate the leading eigenvectors instead of the marginal Kendall' tau, so $\widehat{V}^K$ in (3) is replaced with $\widetilde{V}^K$. We need to briefly review the two types of Kendall's tau estimators here, and specifically give the formula for $\widehat{\Sigma}^K$ and $\widetilde{V}^K$.

Kendall's tau correlation coefficient, for estimating pairwise comovement correlation, is defined as

$$\hat{\tau}_{jk} := \frac{2}{n(n-1)} \sum_{t<t'} \mathrm{sgn}((y_{tj} - y_{t'j})(y_{tk} - y_{t'k})) \,. \tag{24}$$

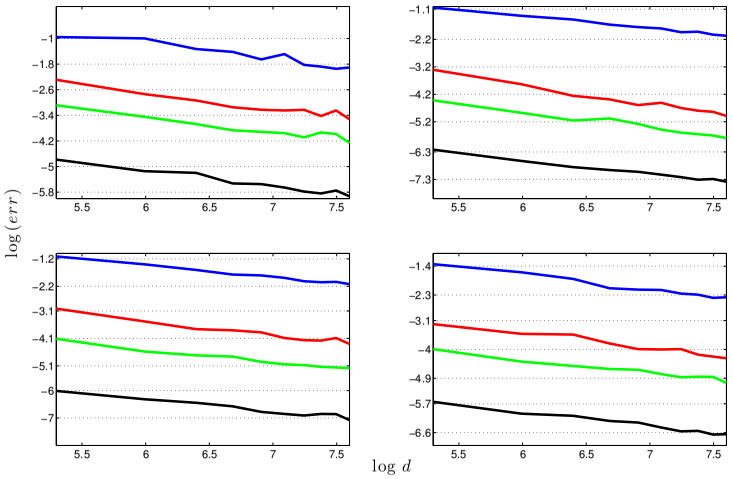

Figure 3: *These plots show* $\log(err)$ *aginst* $\log(d)$*, with matrix size* d *ranging from* 200 *to* 2000 *and different eigengap* γ*. The perturbation* E *is generated from different ways. Top left:* $L = 10, s = 3$*; top right:* $L = 0.6, s = 50$*; bottom left:* $L' = 1.5, \rho = 0.9$*; bottom right:* $L' = 7.5, \rho = 0.5$*. The slopes are around* -0.5*. Blue lines represent* $\gamma = 10$*; red lines* $\gamma = 50$*; green lines* $\gamma = 100$*; and black lines* $\gamma = 500$*. We report the largest error over* 100 *runs.*

Its population expectation is related to the Pearson correlation via the transform $r_{jk} = \sin\left(\frac{\pi}{2} E[\hat{\tau}_{jk}]\right)$ for elliptical distributions (which are far too restrictive for high-dimensional applications). Then $\hat{r}_{jk} = \sin\left(\frac{\pi}{2}\hat{\tau}_{jk}\right)$ is a valid estimation for the Pearson correlation r_{jk}. Letting $\widehat{R} = (\hat{r}_{jk})$ and $\widehat{D} = \mathrm{diag}(\sqrt{\widehat{\Sigma}^R_{11}}, \ldots, \sqrt{\widehat{\Sigma}^R_{dd}})$ containing the robustly estimated standard deviations, we define the marginal Kendall's tau estimator as

$$\widehat{\Sigma}^K = \widehat{D}\,\widehat{R}\,\widehat{D}\,. \tag{25}$$

In the above construction of $\widehat{D}$, we still use the robust variance estimates from $\widehat{\Sigma}^R$.

The spatial Kendall's tau estimator is a second-order U-statstic, defined as

$$\widetilde{\Sigma}^K := \frac{2}{n(n-1)} \sum_{t<t'} \frac{(y_t - y_{t'})(y_t - y_{t'})^T}{\|y_t - y_{t'}\|_2^2} \,. \tag{26}$$

Then $\widetilde{V}^S$ is constructed by the top r eigenvectors of $\widetilde{\Sigma}^K$. It has been shown by Fan et al. (2017+) that under elliptical distribution, $\widehat{\Sigma}^K$ and its top r eigenvalues $\widehat{\Lambda}^K$ satisfy (19) and (20) while $\widetilde{V}^S$ suffices to conclude (21). Hence Method (4) indeed provides good initial estimators if data are from elliptical distribution. However, since $\widehat{\Sigma}^K$ attains (19) for elliptical distribution, by similar argument for deriving Proposition 4 based on our ℓ_∞ pertubation bound, $\widehat{V}^K$ consisting of the leading eigenvectors of $\widehat{\Sigma}^K$ is also valid for the generic POET procedure. For more details about the two types of Kendall's tau, we refer the readers to Fang et al. (1990); Choi and Marden (1998); Han and Liu (2014); Fan et al. (2017+) and references therein.

In summary, Method (1) is designed for the case of sub-Gaussian data; Method (3) and (4) work under the situation of elliptical distribution; while Method (2) is proposed in this paper for the general heavy-tailed case with bounded fourth moments without further distributional shape constraints.

We simulated n samples of $(f_t^T, u_t^T)^T$ from two settings: (a) a multivariate t-distribution with covariance matrix $\mathrm{diag}\{I_r, 5I_d\}$ and various degrees of freedom ($\nu = 3$ for very heavy tail, $\nu = 5$ for medium heavy tail and $\nu = \infty$ for Gaussian tail), which is one example of the elliptical distribution (Fang et al., 1990); (b) an element-wise iid one-dimensional t distribution with the same covariance matrix and degrees of freedom $\nu = 3, 5$ and ∞, which is a non-elliptical heavy-tailed distribution.

Each row of coefficient matrix B is independently sampled from a standard normal distribution, so that with high probability, the pervasiveness condition holds with $\|B\|_{\max} = O(\sqrt{\log d})$. The data is then generated by $y_t = Bf_t + u_t$ and the true population covariance matrix is $\Sigma = BB^T + 5I_d$.

For d running from 200 to 900 and $n = d/2$, we calculated errors of the four robust estimators in different norms. The tuning for α in minimization (14) is discussed more throughly in Fan et al. (2017b). For the thresholding parameter, we used $\tau = 2\sqrt{\log d/n}$. The estimation errors are gauged in the following norms: $\|\widehat{\Sigma}_u^\top - \Sigma_u\|$, $\|(\widehat{\Sigma}^\top)^{-1} - \Sigma^{-1}\|$ and $\|\widehat{\Sigma}^\top - \Sigma\|_\Sigma$ as shown in Theorem 6. The two different settings are separately plotted in Figures 4 and 5. The estimation errors of applying sample covariance matrix $\widehat{\Sigma}^S$ in Method (1) are used as the baseline for comparison. For example, if relative Frobenius norm is used to measure performance, $\|(\widehat{\Sigma}^\top)^{(k)} - \Sigma\|_\Sigma / \|(\widehat{\Sigma}^\top)^{(1)} - \Sigma\|_\Sigma$ will be depicted for $k = 2, 3, 4$, where $(\widehat{\Sigma}^\top)^{(k)}$ are generic POET estimators based on Method (k). Therefore if the ratio curve moves below 1, the method is better than naive sample estimator (Fan et al., 2013) and vice versa. The more it gets below 1, the more robust the procedure is against heavy-tailed randomness.

The first setting (Figure 4) represents a heavy-tailed elliptical distribution, where we expect Methods (2), (3), (4) all outperform the POET estimator based on the sample covariance, i.e. Method (1), especially in the presence of extremely heavy tails (solid lines for $\nu = 3$). As expected, all three curves under various measures show error ratios visibly smaller than 1. On the other hand, if data are indeed Gaussian (dotted line for $\nu = \infty$), Method (1) has better behavior under most measures (error ratios are greater than 1). Nevertheless, our robust Method (2) still performs comparably well with Method (1), whereas the median error ratios for the two Kendall's tau methods are much worse. In addition, the IQR (interquartile range) plots reveal that Method (2) is indeed more stable than two Kendall's tau Methods (3) and (4). It is also noteworthy that Method (4), which

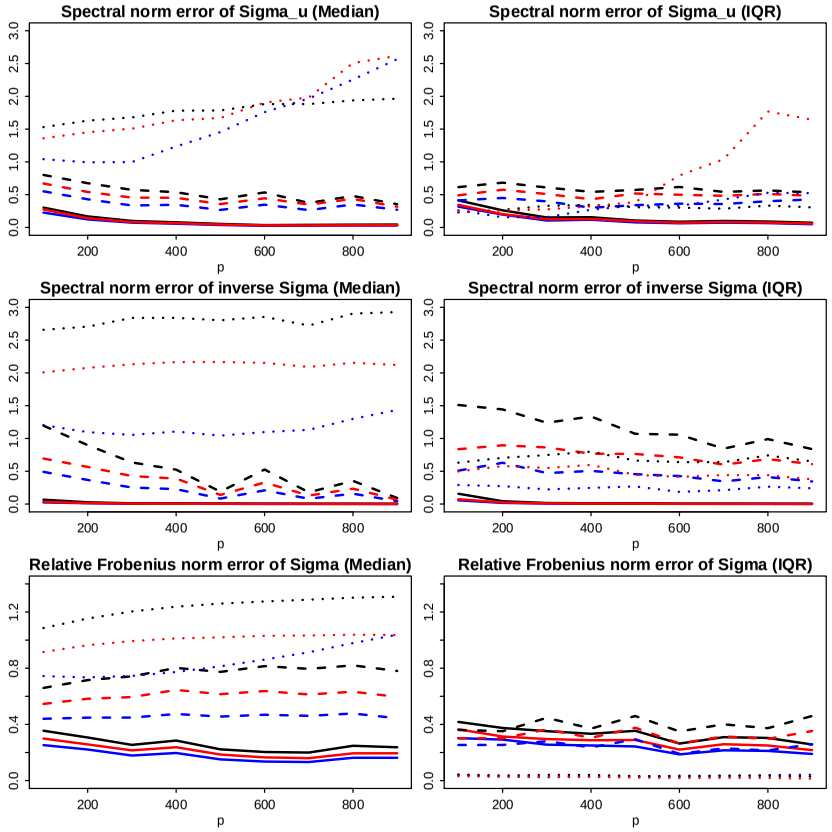

Figure 4: *Error ratios of robust estimates against varying dimension. Blue lines represent errors of Method (2) over Method (1) under different norms; black lines errors of Method (3) over Method (1); red lines errors of Method (4) over Method (1).* (f_t^T, u_t^T) *is generated by multivariate t-distribution with df* $= 3$ *(solid),* 5 *(dashed) and* ∞ *(dotted). The median errors and their IQR's (interquartile range) over* 100 *simulations are reported.*

leverages the advantage of spatial Kendall's tau, performs more robustly than Method (3), which solely base its estimation of the eigen-structure on marginal Kendall's tau.

The second setting (Figure 5) provides an example of non-elliptical distributed data. We can see that the performance of the general robust Method (2) dominates the other three methods, which verifies the benefit of robust estimation for a general heavy-tailed distribu-

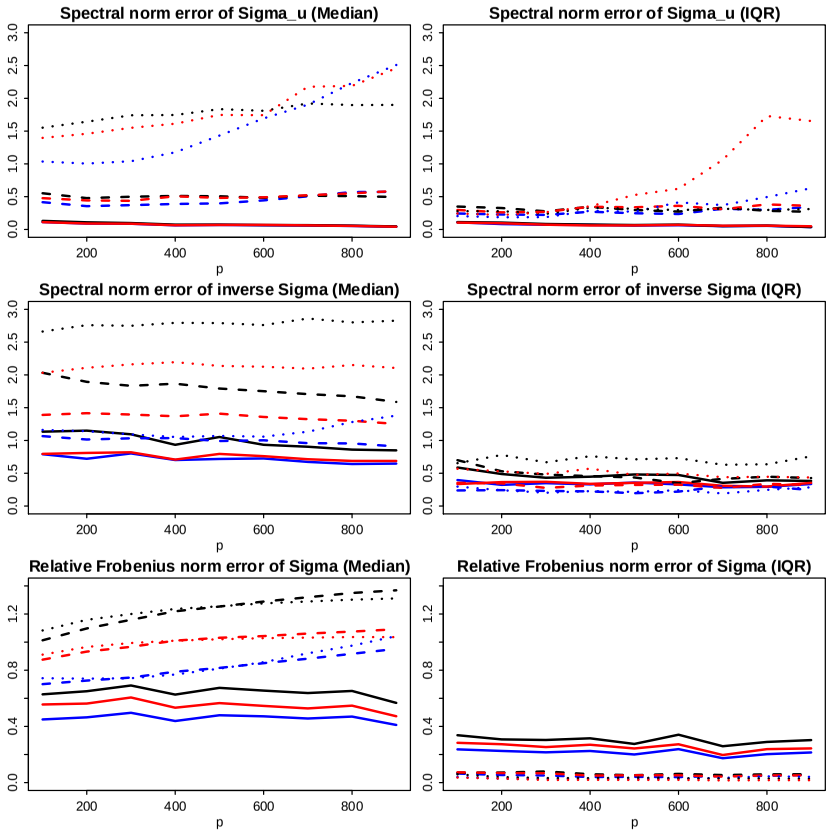

Figure 5: *Error ratios of robust estimates against varying dimension. Blue lines represent errors of Method (2) over Method (1) under different norms; black lines errors of Method (3) over Method (1); red lines errors of Method (4) over Method (1).* (f_t^T, u_t^T) *is generated by element-wise iid t-distribution with df* $= 3$ *(solid),* 5 *(dashed) and* ∞ *(dotted). tion. Note that Kendall's tau methods do not apply to distributions outside the elliptical family, excluding even the element-wise iid t distribution in this setting. Nonetheless, even in the first setting where the data are indeed elliptical, with proper tuning, the proposed robust method can still outperform Kendall's tau by a clear margin.

5. Proof organization of main theorems

5.1 Symmetric Case

For shorthand, we write $\tau = \|E\|_\infty$, and $\kappa = \sqrt{d}\,\|EV\|_{\max}$. An obvious bound for κ is $\kappa \le \sqrt{r\mu}\,\tau$ (by Cauchy-Schwarz inequality). We will use these notations throughout this subsection.

Recall the spectral decomposition of A in (8). Expressing E in terms of the column vectors of V and $V_\perp$, which form an orthogonal basis in $\mathbb{R}^n$, we write

$$[V, V_\perp]^T E [V, V_\perp] =: \begin{pmatrix} E_{11} & E_{12} \\ E_{21} & E_{22} \end{pmatrix}. \tag{27}$$

Note that $E_{12} = E_{21}^T$ since E is symmetric. Conceptually, the perturbation results in a rotation of $[V, V_\perp]$, and we write a candidate orthogonal basis as follows:

$$\overline{V} := (V + V_\perp Q)(I_r + Q^T Q)^{-1/2}, \qquad \overline{V}_\perp := (V_\perp - V Q^T)(I_{d-r} + Q Q^T)^{-1/2}, \tag{28}$$

where $Q \in \mathbb{R}^{(d-r)\times r}$ is to be determined. It is straightforward to check that $[\overline{V}, \overline{V}_\perp]$ is an orthogonal matrix. We will choose Q in a way such that $(\overline{V}, \overline{V}_\perp)^T \widetilde{A} (\overline{V}, \overline{V}_\perp)$ is a block diagonal matrix, i.e., $\overline{V}_\perp^T \widetilde{A} \overline{V} = 0$. Substituting (28) and simplifying the equation, we obtain

$$Q(\Lambda_1 + E_{11}) - (\Lambda_2 + E_{22})Q = E_{21} - Q E_{12} Q. \tag{29}$$

The approach of studying perturbation through a quadratic equation is known. See Stewart (1990) for example. Yet, to the best of our knowledge, existing results study perturbation under orthogonal-invariant norms (or unitary-invariant norms in the complex case), which includes a family of matrix operator norms and Frobenius norm, but excludes the matrix max-norm. The advantages of orthogonal-invariant norms are pronounced: such norms of a symmetric matrix only depend on its eigenvalues regardless of eigenvectors; moreover, with suitable normalization they are *consistent* in the sense $\|AB\| \le \|A\| \cdot \|B\|$. See Stewart (1990) for a clear exposition.

The max-norm, however, does not possess these important properties. An imminent issue is that it is not clear how to relate Q to $V_\perp Q$, which will appear in (29) after expanding E according to (27), and which we want to control. Our approach here is to study $\overline{Q} := V_\perp Q$ directly through a transformed quadratic equation, obtained by left multiplying $V_\perp$ to (29). Denote $H = V_\perp E_{21}, \overline{Q} = V_\perp Q, \overline{L}_1 = \Lambda_1 + E_{11}, \overline{L}_2 = V_\perp(\Lambda_2 + E_{22})V_\perp^T$. If we can find an appropriate matrix $\overline{Q}$ with $\overline{Q} = V_\perp Q$, and it satisfies the quadratic equation

$$\overline{Q}\,\overline{L}_1 - \overline{L}_2 \overline{Q} = H - \overline{Q} H^T \overline{Q}, \tag{30}$$

then Q also satisfies the quadratic equation (29). This is because multiplying both sides of (30) by $V_\perp^T$ yields (29), and thus any solution $\overline{Q}$ to (30) with the form $\overline{Q} = V_\perp Q$ must result in a solution Q to (29).

Once we have such $\overline{Q}$ (or equivalently Q), then $(\overline{V}, \overline{V}_\perp)^T \widetilde{A} (\overline{V}, \overline{V}_\perp)$ is a block diagonal matrix, and the span of column vectors of $\overline{V}$ is a candidate space of the span of first r

eigenvectors, namely span$\{\widetilde{v}_1, \ldots, \widetilde{v}_r\}$. We will verify the two spaces are identical in Lemma 7. Before stating that lemma, we first provide bounds on $\|\overline{Q}\|_{\max}$ and $\|\overline{V} - V\|_{\max}$.

Lemma 5 *Suppose $|\lambda_r| - \varepsilon > 4r\mu(\tau + 2r\kappa)$. Then, there exists a matrix $Q \in \mathbb{R}^{(d-r)\times r}$ such that $\overline{Q} = V_\perp Q \in \mathbb{R}^{d\times r}$ is a solution to the quadratic equation (30), and $\overline{Q}$ satisfies $\|\overline{Q}\|_{\max} \le \omega/\sqrt{d}$. Moreover, if $r\omega < 1/2$, the matrix $\overline{V}$ defined in (28) satisfies*

$$\|\overline{V} - V\|_{\max} \le 2\sqrt{\mu}\,\omega r/\sqrt{d}\,. \tag{31}$$

Here, ω is defined as $\omega = 8(1 + r\mu)\kappa/(|\lambda_r| - \varepsilon)$.

The second claim of the lemma (i.e., the bound (31)) is relatively easy to prove once the first claim (i.e., the bound on $\|\overline{Q}\|_{\max}$) is proved. To understand this, note that we can rewrite $\overline{V}$ as $\overline{V} = (V + \overline{Q})(I_r + \overline{Q}^T\overline{Q})^{-1/2}$, and $\|\overline{Q}^T\overline{Q}\|_{\max}$ can be controlled by a trivial inequality $\|\overline{Q}^T\overline{Q}\|_{\max} \le d\|\overline{Q}\|_{\max}^2 \le w^2$. To prove the first claim, we construct a sequence of matrices through recursion that converges to the fixed point $\overline{Q}$, which is a solution to the quadratic equation (30). For all iterates of matrices, we prove a uniform max-norm bound, which leads to a max-bound on $\|\overline{Q}\|_{\max}$ by continuity. To be specific, we initialize $\overline{Q}^0 = 0$, and given $\overline{Q}^t$, we solve a linear equation:

$$\overline{Q}\,\overline{L}_1 - \overline{L}_2\overline{Q} = H - \overline{Q}^t H^T \overline{Q}^t, \tag{32}$$

and the solution is defined as $\overline{Q}^{t+1}$. Under some conditions, the iterate $\overline{Q}^t$ converges to a limit $\overline{Q}$, which is a solution to (30). The next general lemma captures this idea. It follows from Stewart (1990) with minor adaptations.

Lemma 6 *Let T be a bounded linear operator on a Banach space $\mathcal{B}$ equipped with a norm $\|\cdot\|$. Assume that T has a bounded inverse, and define $\beta = \|T^{-1}\|^{-1}$. Let $\varphi : \mathcal{B} \to \mathcal{B}$ be a map that satisfies*

$$\|\varphi(x)\| \le \eta\|x\|^2, \qquad \text{and} \qquad \|\varphi(x) - \varphi(y)\| \le 2\eta\max\{\|x\|, \|y\|\}\|x - y\| \tag{33}$$

for some $\eta \ge 0$. Suppose that $\mathcal{B}_0$ is a closed subspace of $\mathcal{B}$ such that $T^{-1}(\mathcal{B}_0) \subseteq \mathcal{B}_0$ and $\varphi(\mathcal{B}_0) \subseteq \mathcal{B}_0$. Suppose $y \in \mathcal{B}_0$ that satisfies $4\eta\|y\| < \beta^2$. Then, the sequence initialized with $x_0 = 0$ and iterated through

$$x_{k+1} = T^{-1}(y + \varphi(x_k)), \quad k \ge 0 \tag{34}$$

converges to a solution $x^\star$ to $Tx = y + \varphi(x)$. Moreover, we have $x^\star \subseteq \mathcal{B}_0$, and $\|x^\star\| \le 2\|y\|/\beta$.

To apply this lemma to the equation (30), we view $\mathcal{B}$ as the space of matrices $\mathbb{R}^{d\times r}$ with the max-norm $\|\cdot\|_{\max}$, and $\mathcal{B}_0$ as the subspace of matrices of the form $V_\perp Q$ where $Q \in \mathbb{R}^{(d-r)\times r}$. The linear operator T is set to be the $T(\overline{Q}) = \overline{Q}\,\overline{L}_1 - \overline{L}_2\overline{Q}$, and the map φ is set to be the quadratic function $\varphi(\overline{Q}) = -\overline{Q}H^T\overline{Q}$. Roughly speaking, under the assumption of Lemma 6, the nonlinear effect caused by φ is weak compared with the linear operator T. Therefore, it is crucial to show T is invertible, i.e. to give a good lower bound on $\|T^{-1}\|_{\max}^{-1} = \inf_{\|\overline{Q}\|_{\max}=1}\|T(\overline{Q})\|_{\max}$. Since the norm is not orthogonal-invariant, a subtle

issue arises when A is not of exact low rank, which will be discussed at the end of the subsection.

If there is no perturbation (i.e., $E = 0$), all the iterates $\overline{Q}^t$ are simply 0, so $\overline{V}$ is identical to V. If the perturbation is not too large, the next lemma shows that the column vectors of $\overline{V}$ span the same space as span$\{\widetilde{v}_1, \ldots, \widetilde{v}_r\}$.

In other words, with a suitable orthogonal matrix R, the columns of $\overline{V}R$ are $\widetilde{v}_1, \ldots, \widetilde{v}_r$.

Lemma 7 *Suppose $|\lambda_r| - \varepsilon > \max\{3\tau, 64(1 + r\mu)r^{3/2}\mu^{1/2}\kappa\}$. Then, there exists an orthogonal matrix $R \in \mathbb{R}^{r\times r}$ such that the column vectors of $\overline{V}R$ are $\widetilde{v}_1, \ldots, \widetilde{v}_r$.*

Proof of Theorem 2 It is easy to check that under the assumption of Theorem 2, the conditions required in Lemma 5 and Lemma 7 are satisfied. Hence, the two lemmas imply Theorem 2. ■

To study the perturbation of individual eigenvectors, we assume, in addition to the condition on $|\lambda_r|$, that $\lambda_1, \ldots, \lambda_r$ satisfy a uniform gap, (namely $\delta > \|E\|_2$). This additional assumption is necessary, because otherwise, the perturbation may lead to a change of relative order of eigenvalues, and we may be unable to match eigenvectors from the order of eigenvalues. Suppose $R \in \mathbb{R}^{r\times r}$ is an orthogonal matrix such that $\overline{V}R$ are eigenvectors of $\widetilde{A}$. Now, under the assumption of Theorem 2, the column vectors of $\widetilde{V}$ and $\overline{V}R$ are identical up to sign, so we can rewrite the difference $\widetilde{V} - V$ as

$$\widetilde{V} - V = \overline{V}(R - I_r) + (\overline{V} - V). \tag{35}$$

We already provided a bound on $\|\overline{V} - V\|_{\max}$ in Lemma 5. By the triangular inequality, we can derive a bound on $\|\overline{V}\|_{\max}$. If we can prove a bound on $\|R - I_r\|_{\max}$, it will finally leads to a bound on $\|\widetilde{V} - V\|_{\max}$. In order to do so, we use the Davis-Kahan theorem to obtain an bound on $\langle\widetilde{v}_i, v_i\rangle$ for all $i \in [r]$. This will lead to a max-norm bound on $R - I_r$ (with the price of potentially increasing the bound by a factor of r). The details about the proof of Theorem 3 are in the appendix.

We remark that the conditions on $|\lambda_r| - \epsilon$ in Theorem 2 and Theorem 3 are only useful in cases where $|\lambda_r| > \|A - A_r\|_\infty$. Ideally, we would like to have results with assumptions only involving λ_r and λ_{r+1}, like in the Davis-Kahan theorem. Unfortunately, unlike orthogonal-invariant norms that only depend on the eigenvalues of a matrix, the max-norm $\|\cdot\|_{\max}$ is not orthogonal-invariant, and thus it also depends on the eigenvectors of a matrix. For this reason, it is not clear whether we could obtain a lower bound on $\|T^{-1}\|_{\max}^{-1}$ using only the eigenvalues λ_r and λ_{r+1} so that Lemma 6 could be applied. The analysis appears to be difficult if we do not have a bound on $\|T^{-1}\|_{\max}^{-1}$, considering that even in the analysis of linear equations, we need invertibility and a well-controlled condition number.

5.2 Asymmetric case

Let A^d, E^d be $d_1 + d_2$ square matrices defined as

$$A^d := \begin{pmatrix} 0 & A \\ A^T & 0 \end{pmatrix}, \qquad E^d := \begin{pmatrix} 0 & E \\ E^T & 0 \end{pmatrix}.$$

Also denote $\widetilde{A}^d := A^d + E^d$. This augmentation of an asymmetric matrix into a symmetric one is called Hermitian dilation. Here the superscript d means the Hermitian dilation. We also use this notation to denote quantities corresponding to A^d and $\widetilde{A}^d$.

An important observation is that

$$\begin{pmatrix} 0 & A \\ A^T & 0 \end{pmatrix} \begin{pmatrix} u_i \\ \pm v_i \end{pmatrix} = \pm \sigma_i \begin{pmatrix} u_i \\ \pm v_i \end{pmatrix}.$$

From this identity, we know that A^d have nonzero eigenvalues $\pm\sigma_i$ where $1 \le i \le \mathrm{rank}(A)$, and its corresponding eigenvectors are $(u_i^T, \pm v_i^T)^T$. For a given r, we stack these (normalized) eigenvectors with indices $i \in [r]$ into a matrix $V^d \in \mathbb{R}^{(d_1+d_2)\times 2r}$:

$$V^d := \frac{1}{\sqrt{2}} \begin{pmatrix} U & U \\ V & -V \end{pmatrix}.$$

Through the augmented matrices, we can transfer eigenvector results for symmetric matrices to singular vectors of asymmetric matrices. However, we cannot directly invoke the results proved for symmetric matrices, due to an issue about the coherence of V^d: when d_1 and d_2 are not comparable, the coherence $\mu(V^d)$ can be very large even when $\mu(V)$ and $\mu(U)$ are bounded. To understand this, consider the case where $r = 1$, $d_1 \gg d_2$, and all entries of U are $O(1/\sqrt{d_1})$, and all entries of V are $O(1/\sqrt{d_2})$. Then, the coherences $\mu(U)$ and $\mu(V)$ are $O(1)$, but $\mu(V^d) = O((d_1+d_2)/d_2) \gg 1$.

This unpleasant issue about the coherence, nevertheless, can be tackled if we consider a different matrix norm. In order to deal with the different scales of d_1 and d_2, we define the weighted max-norm for any matrix M with $d_1 + d_2$ rows as follows:

$$\|M\|_w := \left\| \begin{pmatrix} \sqrt{d_1} I_{d_1} & 0 \\ 0 & \sqrt{d_2} I_{d_2} \end{pmatrix} M \right\|_{\max}. \tag{36}$$

In other words, we rescale the top d_1 rows of M by a factor of $\sqrt{d_1}$, and rescale the bottom d_2 rows by $\sqrt{d_2}$. This weighted norm serves to balance the potential different scales of d_1 and d_2.

The proofs of theorems in Section 2.2 will be almost the same with those in the symmetric case, with the major difference being the new matrix norm. Because the derivation is slightly repetitive, we will provide concise proofs in the appendix . Similar to the decomposition in (2.1),

$$A^d = \begin{pmatrix} 0 & A_r \\ A_r^T & 0 \end{pmatrix} + \begin{pmatrix} 0 & A - A_r \\ A^T - A_r^T & 0 \end{pmatrix} =: A_r^d + (A^d - A_r^d),$$

where A_r^d is has rank $2r$. Equivalently,

$$A_r^d = \sum_{i=1}^r \sigma_i (u_i^T, v_i^T)^T (u_i^T, v_i^T) - \sum_{i=1}^r \sigma_i (u_i^T, -v_i^T)^T (u_i^T, -v_i^T).$$

Analogously, we define notations in (28)–(30) and use d in the superscript to signify that they are augmented through Hermitian dilation. It is worthwhile to note that $\Lambda_1^d = \mathrm{diag}\{\sigma_1, \ldots, \sigma_r, -\sigma_r, \ldots, -\sigma_1\}$, and that $\min\{|\pm\sigma_i| : i \in [r]\} = \sigma_r$ (a similar quantity as $|\lambda_r|$). Recall $\mu_0 = \mu(U) \vee \mu(V)$, $\tau_0 = \sqrt{d_1/d_2}\|E\|_\infty \vee \sqrt{d_2/d_1}\|E\|_1$ and $\varepsilon_0 = \sqrt{d_1/d_2}\|A - A_r\|_\infty \vee \sqrt{d_2/d_1}\|A - A_r\|_1$. In the proof, we will also use $\kappa_0 = \max\{\sqrt{d_1}\,\|EV\|_{\max}, \sqrt{d_2}\,\|E^T U\|_{\max}\}$, which is a quantity similar to κ.

The next key lemma, which is parallel to Lemma 5, provides a bound on the solution $\overline{Q}^d$ to the quadratic equation

$$\overline{Q}^d \overline{L}_1^d - \overline{L}_2^d \overline{Q}^d = H^d - \overline{Q}^d (H^d)^T \overline{Q}^d. \tag{37}$$

Lemma 8 *Suppose $\sigma_r - \varepsilon_0 > 16 r\mu_0(\tau_0 + r\kappa_0)$. Then, there exists a matrix $Q^d \in \mathbb{R}^{(d_1+d_2-2r)\times 2r}$ such that $\overline{Q}^d = V_\perp^d Q^d \in \mathbb{R}^{(d_1+d_2)\times 2r}$ is a solution to the quadratic equation (37), and $\overline{Q}^d$ satisfies $\|\overline{Q}^d\|_w \le \omega_0$. Moreover, if $r\omega_0 < 1/2$, the matrix $\overline{V}^d$ defined in (28) satisfies*

$$\|\overline{V}^d - V^d\|_w \le 6\sqrt{\mu_0}\, r\omega_0. \tag{38}$$

Here, ω_0 is defined as $\omega_0 = 8(1 + r\mu_0)\kappa_0/3(\sigma_r - \varepsilon_0)$.

In this lemma, the bound (38) bears a similar form to (31): if we consider the max-norm, the first d_1 rows of $\overline{V}^d - V^d$ correspond to the left singular vectors u_i's, and they scale with $1/\sqrt{d_1}$; and the last d_2 rows correspond to the right singular vectors v_i's, which scale with $1/\sqrt{d_2}$. Clearly, the weighted max-norm $\|\cdot\|_w$ indeed helps to balance the two dimensions.

The rest of the proofs can be found in the appendix.

A. Proofs for Section 2.1

Denote the column span of a matrix M by $\mathrm{span}(M)$. Suppose two matrices $M_1, M_2 \in \mathbb{R}^{n\times m}$ ($m \le n$) have orthonormal column vectors. It is known that (Stewart, 1990)

$$d(M_1, M_2) := \|M_1 M_1^T - M_2 M_2^T\|_2 = \|\sin\Theta(M_1, M_2)\|_2. \tag{39}$$

where $\Theta(M_1, M_2)$ are the canonical angles between $\mathrm{span}(M_1)$ and $\mathrm{span}(M_2)$. Recall the notations defined in (27), and also recall $\kappa = \sqrt{d}\|EV\|_{\max}$, $\Lambda_1 = \mathrm{diag}\{\lambda_1, \ldots, \lambda_r\}$, $\Lambda_2 = \mathrm{diag}\{\lambda_{r+1}, \ldots, \lambda_n\}$, $\overline{L}_1 = \Lambda_1 + E_{11}$, $\overline{L}_2 = V_\perp(\Lambda_2 + E_{22})V_\perp^T$ and $H = V_\perp E_{21}$. The first lemma bounds $\|H\|_{\max}$.

Lemma 9 *We have the following bound on $\|H\|_{\max}$:*

$$\|H\|_{\max} \le (1 + r\mu)\kappa/\sqrt{d}.$$

Proof Using the definition $E_{21} = V_\perp^T EV$ in (27), we can write $H = V_\perp V_\perp^T EV$. Since the columns of V and $V_\perp$ form an orthogonal basis in $\mathbb{R}^d$, clearly

$$VV^T + V_\perp V_\perp^T = I_d\,. \tag{40}$$

By Cauchy-Schwarz inequality and the definition of μ, for any $i, j \in [d]$,

$$|(VV^T)_{ij}| = \sum_{k=1}^r |V_{ik}V_{jk}| \le \big(\sum_{k=1}^r V_{ik}^2\big)^{1/2} \cdot \big(\sum_{k=1}^r V_{jk}^2\big)^{1/2} \le \frac{r\mu}{d}\,.$$

Using the identity (40) and the above inequality, we derive

$$\begin{aligned}\|H\|_{\max} &\le \|EV\|_{\max} + \|VV^T EV\|_{\max} \\ &\le (1 + d\|VV^T\|_{\max})\,\|EV\|_{\max} \le (1 + r\mu)\|EV\|_{\max}\,,\end{aligned}$$

which completes the proof. ∎

Lemma 10 *If $|\lambda_r| > \kappa r\sqrt{\mu}$, then $\overline{L}_1$ is an invertible matrix. Furthermore,*

$$\inf_{\|Q_0\|_{\max}=1} \|Q_0\overline{L}_1 - \overline{L}_2 Q_0\|_{\max} \ge |\lambda_r| - 3r\mu(\tau + r\kappa) - \varepsilon\,, \tag{41}$$

where Q_0 is an $d \times r$ matrix.

Proof Let Q_0 be any $d \times r$ matrix with $\|Q_0\|_{\max} = 1$. Note

$$Q_0\overline{L}_1 - \overline{L}_2 Q_0 = Q_0\Lambda_1 + Q_0E_{11} - \overline{L}_2 Q_0.$$

We will derive upper bounds on Q_0E_{11} and $\overline{L}_2Q_0$, and a lower bound on $Q_0\Lambda_1$. Since $E_{11} = V^TEV$ by definition, we expand Q_0E_{11} and use a trivial inequality to derive

$$\|Q_0E_{11}\|_{\max} \le d\,\|Q_0V^T\|_{\max}\|EV\|_{\max}\,. \tag{42}$$

By Cauchy-Schwarz inequality and the definition of μ in (3), for $i, j \in [d]$,

$$|(Q_0V^T)_{ij}| \le \sum_{k=1}^r |(Q_0)_{ik}V_{jk}| \le \big(\sum_{k=1}^r (Q_0)_{ik}^2\big)^{1/2}\big(\sum_{k=1}^r V_{jk}^2\big)^{1/2} \le \sqrt{r}\cdot\sqrt{\frac{r\mu}{d}}\,,$$

Substituting $\|EV\|_{\max} = \kappa/\sqrt{d}$ into (42), we obtain an upper bound:

$$\|Q_0E_{11}\|_{\max} \le \kappa r\sqrt{\mu}\,. \tag{43}$$

To bound $\overline{L}_2Q_0 = (V_\perp E_{22}V_\perp^T + (A - A_r))Q_0$, we use the identity (40) and write

$$V_\perp E_{22}V_\perp^T Q_0 = V_\perp V_\perp^T EV_\perp V_\perp^T Q_0 = (I_d - VV^T)E(I_d - VV^T)Q_0\,.$$

Using two trivial inequalities $\|EQ_0\|_{\max} \le \|E\|_\infty\|Q_0\|_{\max} = \|E\|_\infty$ and $\|V^TQ_0\|_{\max} \le \|V^T\|_\infty\|Q_0\|_{\max} \le \sqrt{d}$, we have

$$\begin{aligned}\|E(I_d - VV^T)Q_0\|_{\max} &\le \|EQ_0\|_{\max} + r\|EV\|_{\max}\|V^TQ_0\|_{\max} \\ &\le \|E\|_\infty + r\sqrt{d}\,\|EV\|_{\max} = \tau + r\kappa\,.\end{aligned}$$

In the proof of Lemma 9, we showed $\|VV^T\|_{\max} \le r\mu/d$. Thus,

$$\|V_\perp E_{22}V_\perp^TQ_0\|_{\max} \le (1 + d\,\|VV^T\|_{\max})\cdot\|E(I_d - VV^T)Q_0\|_{\max} \le (1 + r\mu)(\tau + r\kappa)\,.$$

Moreover, $\|(A - A_r)Q_0\|_{\max} \le \|A - A_r\|_\infty\|Q_0\|_{\max} = \varepsilon$. Combining the two bounds,

$$\|\overline{L}_2Q_0\|_{\max} \le (1 + r\mu)(\tau + r\kappa) + \varepsilon. \tag{44}$$

It is straightforward to obtain a lower bound on $\|Q_0\Lambda_1\|_{\max}$: since there is an entry of Q_0, say $(Q_0)_{ij}$, that has an absolute value of 1, we have

$$\|Q_0\Lambda_1\|_{\max} \ge |(Q_0)_{ij}\lambda_j| \ge |\lambda_r|. \tag{45}$$

To show $\overline{L}_1$ is invertible, we use (42) and (45) to obtain

$$\|Q_0\overline{L}_1\|_{\max} \ge \|Q_0\Lambda_1\|_{\max} - \|Q_0E_{11}\|_{\max} \ge |\lambda_r| - \kappa r\sqrt{\mu}\,.$$

When $|\lambda_r| - \kappa r\sqrt{\mu} > 0$, $\overline{L}_1$ must have full rank, because otherwise we can choose an appropriate Q_0 in the null space of $\overline{L}_1^T$ so that $Q_0\overline{L}_1 = 0$, which is a contradiction. To prove the second claim of the lemma, we combine the lower bound (45) with upper bounds (43) and (44) to derive

$$\begin{aligned}\|Q_0\overline{L}_1 - \overline{L}_2Q_0\|_{\max} &\ge \|Q_0L_1\|_{\max} - \|Q_0E_{11}\|_{\max} - \|\overline{L}_2Q_0\|_{\max} \\ &\ge |\lambda_r| - \kappa r\sqrt{\mu} - (1 + r\mu)(\tau + r\kappa) - \varepsilon \\ &\ge |\lambda_r| - 3r\mu(\tau + r\kappa) - \varepsilon\,,\end{aligned}$$

which is exactly the desired inequality. ∎

Next we prove Lemma 6. This lemma follows from Stewart (1990), with minor changes that involves $\mathcal{B}_0$. We provide a proof for the sake of completeness.

Proof of Lemma 6 Let us write $\alpha = \|y\|$ for shorthand and recall $\beta = \|T^{-1}\|^{-1}$. As the first step, we show that the sequence $\{x_k\}_{k=0}^{\infty}$ is bounded. By construction in (34), we bound $\|x_{k+1}\|$ using $\|x_k\|$:

$$\|x_{k+1}\| \le \|T^{-1}\|(\|y\| + \|\varphi(x_k)\|) \le \frac{\alpha}{\beta} + \frac{\eta}{\beta}\|x_k\|^2.$$

We use this inequality to derive an upper bound on $\{x_k\}$ for all k. We define $\xi_0 = 0$ and

$$\xi_{k+1} = \frac{\alpha}{\beta} + \frac{\eta}{\beta}\xi_k^2, \quad k \ge 0,$$

then clearly $\|x_k\| \le \xi_k$ (which can be shown by induction). It is easy to check (by induction) that the sequence $\{\xi_k\}_{k=1}^{\infty}$ is increasing. Moreover, since $4\alpha\eta < \beta^2$, the quadratic function

$$\phi(\xi) = \frac{\alpha}{\beta} + \frac{\eta}{\beta}\xi^2,$$

has two fixed points (namely solutions to $\phi(\xi) = \xi$), and the smaller one satisfies

$$\xi_\star = \frac{2\alpha}{\beta + \sqrt{\beta^2 - 4\eta\alpha}} < \frac{2\alpha}{\beta}.$$

If $\xi_k < \xi_\star$, then $\xi_{k+1} = \phi(\xi_k) \le \phi(\xi_\star) = \xi_\star$. Thus, by induction, all ξ_k are bounded by $\xi_\star$. This implies $\|x_k\| \le \xi_\star < 2\alpha/\beta$. The next step is to show that the sequence $\{x_k\}$ converges. Using the recursive definition (34) again, we derive

$$\begin{aligned}\|x_{k+1} - x_k\| &\le \|T^{-1}\|\|\varphi(x_k) - \varphi(x_{k-1})\| \\ &\le 2\beta^{-1}\eta \max\{\|x_k\|, \|x_{k-1}\|\}\|x_k - x_{k-1}\| \\ &\le \frac{4\alpha\eta}{\beta^2}\|x_k - x_{k-1}\|.\end{aligned}$$

Since $4\alpha\eta/\beta^2 < 1$, the sequence $\{x_k\}_{k=0}^{\infty}$ is a Cauchy sequence, and convergence is secured. Let $x^\star \in \mathcal{B}$ be the limit. It is clear by assumption that $x_k \in \mathcal{B}_0$ implies $x_{k+1} \in \mathcal{B}_0$, so $x^\star \in \mathcal{B}_0$ and $\|x^\star\| \le 2\alpha/\beta$ by continuity.

The final step is to show $x^\star$ is a solution to $Tx = y + \phi(x)$. Because $\{x_k\}_{k=0}^{\infty}$ is bounded and ϕ satisfies (33), the sequence $\{\phi(x_k)\}_{k=0}^{\infty}$ converges to $\phi(x^\star)$ by continuity and compactness. The linear operator T is also continuous, so we can take limits on both sides of $Tx_{k+1} = y + \phi(x_k)$, we conclude that $x^\star$ is a solution to $Tx = y + \phi(x)$. ■

With all the preparations, we are now ready to present the key lemma. As discussed in Section 5, we set

$$\mathcal{B}_0 := \{\overline{Q} \in \mathbb{R}^{d\times r} : \overline{Q} = V_\perp Q \text{ for some } Q \in \mathbb{R}^{(d-r)\times r}\}.$$

which is a subspace of $\mathcal{B} = \mathbb{R}^{d\times r}$. Consider the matrix max-norm $\|\cdot\|_{\max}$ in $\mathcal{B}$.

Lemma 11 *Suppose $|\lambda_r| - \varepsilon > 4r\mu(\tau + 2r\kappa)$. Then there exists a solution $\overline{Q} \in \mathcal{B}_0$ to the equation (30) with*

$$\|\overline{Q}\|_{\max} \le \frac{8(1 + r\mu)\kappa}{(|\lambda_r| - \varepsilon)\sqrt{d}}.$$

Proof We will invoke Lemma 6 and apply it to the quadratic equation (30). To do so, we first check the conditions required in Lemma 6.

Let the linear operator $\mathcal{T}$ be $\mathcal{T}\overline{Q} = \overline{Q}\overline{L}_1 - \overline{L}_2\overline{Q}$. By Lemma 10, $\mathcal{T}$ has a bounded inverse, and $\beta := \|\mathcal{T}^{-1}\|_{\max}^{-1}$ is bounded from below:

$$\beta \ge |\lambda_r| - 3r\mu(\tau + r\kappa) - \varepsilon. \tag{46}$$

Let us define φ by $\varphi(\overline{Q}) = \overline{Q}H^T\overline{Q}$. To check the inequalities in (33), observe that

$$\|\varphi(\overline{Q})\|_{\max} \le rd\|\overline{Q}\|_{\max}\|H\|_{\max}\|\overline{Q}\|_{\max} \le (1 + r\mu)\kappa r\sqrt{d}\,\|\overline{Q}\|_{\max}^2$$

where we used Lemma 9. We also observe

$$\begin{aligned}\|\varphi(\overline{Q}_1) - \varphi(\overline{Q}_2)\|_{\max} &= \|\overline{Q}_1 H^T(\overline{Q}_1 - \overline{Q}_2) + (\overline{Q}_1 - \overline{Q}_2)H^T\overline{Q}_2\|_{\max} \\ &\le rd\|\overline{Q}_1\|_{\max}\|H\|_{\max}\|\overline{Q}_1 - \overline{Q}_2\|_{\max} + rd\|\overline{Q}_1 - \overline{Q}_2\|_{\max}\|H\|_{\max}\|\overline{Q}_2\|_{\max} \\ &\le 2(1 + r\mu)\kappa r\sqrt{d}\,\max\{\|\overline{Q}_1\|_{\max}, \|\overline{Q}_2\|_{\max}\}\|\overline{Q}_1 - \overline{Q}_2\|_{\max}.\end{aligned}$$

Thus, if we set $\eta = (1 + r\mu)\kappa r\sqrt{d}$, then inequalities required in (33) are satisfied. For any $\overline{Q}$ with $\overline{Q} = V_\perp Q \in \mathcal{B}_0$, obviously $\varphi(\overline{Q}) = V_\perp QH^T\overline{Q} \in \mathcal{B}_0$. To show $\mathcal{T}^{-1}(\overline{Q}) \in \mathcal{B}_0$, let $Q_0 = \mathcal{T}^{-1}(\overline{Q})$ and observe that

$$Q_0\overline{L}_1 - \overline{L}_2 Q_0 = \overline{Q} \in \mathcal{B}_0.$$

By definition, we know $\overline{L}_2 Q_0 = V_\perp(E_{22} + \Lambda_2)V_\perp^T Q_0 \in \mathcal{B}_0$, so we deduce $Q_0\overline{L}_1 \in \mathcal{B}_0$. Our assumption implies $|\lambda_r| > \kappa r\sqrt{\mu}$, so by Lemma 10, the matrix $\overline{L}_1$ is invertible, and thus $Q_0 \in \mathcal{B}_0$. The last condition we check is $4\eta\|H\|_{\max} < \beta^2$. By Lemma 9 and (46), this is true if

$$4(1 + r\mu)^2\kappa^2 r < \big[|\lambda_r| - 3r\mu(\tau + r\kappa) - \varepsilon\big]^2.$$

The above inequality holds when $|\lambda_r| > 4r\mu(V)(\tau + 2r\kappa) + \varepsilon$. Under this condition, we have, by Lemma 6,

$$\|\overline{Q}\|_{\max} \le \frac{2(1 + r\mu)\kappa}{\big(|\lambda_r| - 3r\mu(\tau + r\kappa) - \varepsilon\big)\sqrt{d}} \le \frac{8(1 + r\mu)\kappa}{(|\lambda_r| - \varepsilon)\sqrt{d}},$$

where, the second inequality is due to $3r\mu(\tau + r\kappa) \le 3(|\lambda_r| - \varepsilon)/4$. ■

The next lemma is a consequence of Lemma 11. We define, as in Lemma 5, that $\omega = 8(1 + r\mu)\kappa/(|\lambda_r| - \varepsilon)$.

Lemma 12 *If $r\omega^2 < 1/2$, then*

$$\|(I_r + \overline{Q}^T\overline{Q})^{-1/2} - I_r\|_{\max} \le r\omega^2, \qquad \|(I_r + \overline{Q}^T\overline{Q})^{-1/2}\|_{\max} \le \frac{3}{2}.$$

Proof By the triangular inequality, the second inequality is immediate from the first one. To prove the first inequality, suppose the spectral decomposition of $\overline{Q}^T\overline{Q}$ is $\overline{Q}^T\overline{Q} = \overline{U}\,\overline{\Sigma}\,\overline{U}^T$, where $\overline{\Sigma} = \mathrm{diag}\{\overline{\lambda}_1, \ldots, \overline{\lambda}_r\}$ where $\overline{\lambda}_1 \ge \ldots \ge \overline{\lambda}_r$, and $\overline{U} = [\overline{u}_1, \overline{u}_2, \ldots, \overline{u}_r]$ where $\overline{u}_1, \ldots, \overline{u}_r$ are orthonormal vectors in $\mathbb{R}^r$. Since $\overline{Q}^T\overline{Q}$ has nonnegative eigenvalues, we have $\overline{\lambda}_r \ge 0$. Using these notations, we can rewrite the matrix as

$$(I_r + \overline{Q}^T\overline{Q})^{-1/2} - I_r = \sum_{i=1}^{r} \big((1+\overline{\lambda}_i)^{-1/2} - 1\big)\overline{u}_i\overline{u}_i^T\,.$$

Note that $\overline{\lambda}_1 \le \|\overline{Q}^T\overline{Q}\| \le rd\|\overline{Q}\|_{\max}^2 \le r\omega^2$, which implies $\overline{\lambda}_1 < 1/2$. It is easy to check that $1+|x| \ge (1+x)^{-1/2} \ge 1-|x|$ whenever $|x| < 1/2$. From this fact, we know $|(1+\overline{\lambda}_i)^{-1/2} - 1| \le \overline{\lambda}_i \le r\omega^2$. Using Cauchy-Schwarz inequality, we deduce that for any $j, k \in [d]$,

$$\begin{aligned}
\big|[(I_r + \overline{Q}^T\overline{Q})^{-1/2} - I_r]_{jk}\big| &\le \sum_{i=1}^{r} \big|(1+\overline{\lambda}_i)^{-1/2} - 1\big| \cdot |\overline{U}_{ji}\overline{U}_{ki}| \\
&\le r\omega^2 \cdot \Big(\sum_{i=1}^{r} \overline{U}_{ji}^2\Big)^{1/2}\Big(\sum_{i=1}^{r} \overline{U}_{ki}^2\Big)^{1/2} \\
&\le r\omega^2.
\end{aligned}$$

This leads to the desired max-norm bound. ■

Proof of Lemma 5 The first claim of the lemma (the existence of $\overline{Q}$ and its max-norm bound) follows directly from Lemma 11. To prove the second claim, we split $\overline{V} - V$ into two parts:

$$\begin{aligned}
\overline{V} - V &= V\Big((I_r + Q^TQ)^{-1/2} - I_r\Big) + V_\perp Q(I_r + Q^TQ)^{-1/2} \\
&= V\Big((I_r + \overline{Q}^T\overline{Q})^{-1/2} - I_r\Big) + \overline{Q}(I_r + \overline{Q}^T\overline{Q})^{-1/2}, \qquad (47)
\end{aligned}$$

where we used identity $V_\perp^T V_\perp = I_{d-r}$. Note that $r\omega < 1/2$ implies $r\omega^2 = (r\omega)^2/r < 1/(4r) < 1/2$. Thus, we can use Lemma 12 and derive

$$\Big\|V\Big((I_r + \overline{Q}^T\overline{Q})^{-1/2} - I_r\Big)\Big\|_{\max} \le \sqrt{\frac{r^2\mu}{d}}\|(I_r + \overline{Q}^T\overline{Q})^{-1/2} - I_r\|_{\max} \le \sqrt{\frac{\mu}{d}}\, r^2\omega^2.$$

where we used Cauchy-Schwarz inequality. Using the above inequality and the bound on $\|Q\|_{\max}$ (namely, the first claim in the lemma),

$$\begin{aligned}
\|\overline{V} - V\|_{\max} &\le \sqrt{\frac{\mu}{d}}\, r^2\omega^2 + r\|\overline{Q}\|_{\max}\|(I_r + \overline{Q}^T\overline{Q})^{-1/2}\|_{\max} \\
&\le (\sqrt{\mu}\,\omega^2 r^2 + 3\omega r/2)/\sqrt{d}.
\end{aligned}$$

Simplifying the bound using $r\omega \le 1/2$ and a trivial bound $\mu \ge 1$, we obtain (31). ■

Proof of Lemma 7 Using the identity in (39), it follows from Davis-Kahan $\sin\Theta$ theorem (Davis and Kahan, 1970) and Weyl's inequality that

$$d(\widetilde{V}, V) \le \frac{\|E\|_2}{\delta_r - \|E\|_2},$$

when $\delta_r > \|E\|_2$, where $\delta_r = |\lambda_r| - |\lambda_{r+1}|$. Since $\lambda_{r+1} \le \|A - A_r\|_2 \le \varepsilon$ and $\|E\|_2 \le \tau$, the condition $|\lambda_r| - \varepsilon > 3\tau$ implies $\delta_r > 3\|E\|_2$. Hence, we have $d(\widetilde{V}, V) < 1/2$. Moreover,

$$\begin{aligned}
d(\overline{V}, V) &= \|\overline{V}\overline{V}^T - VV^T\|_2 \le \|\overline{V}(\overline{V} - V)^T\|_2 + \|(\overline{V} - V)V^T\|_2 \\
&\le 2\|\overline{V} - V\|_2 \le 2\sqrt{rd}\,\|\overline{V} - V\|_{\max} \\
&\le 4r^{3/2}\sqrt{\mu}\,\omega,
\end{aligned}$$

where we used a trivial inequality $\|M\|_2 \le \|M\|_F \le \sqrt{rd}\,\|M\|_{\max}$ for any $M \in \mathbb{R}^{d\times r}$. Under the condition $|\lambda_r| - \epsilon > 64(1+r\mu)r^{3/2}\mu^{1/2}\kappa$, it is easy to check that $4r^{3/2}\sqrt{\mu}\,\omega \le 1/2$. Thus, we obtain $d(\overline{V}, V) < 1/2$. By the triangular inequality,

$$d(\widetilde{V}, \overline{V}) \le d(\widetilde{V}, V) + d(\overline{V}, V) < 1.$$

Since $(\overline{V}, \overline{V}_\perp)^T\widetilde{A}(\overline{V}, \overline{V}_\perp)$ is a block diagonal matrix, $\mathrm{span}(\overline{V})$ is the same as the subspace spanned by r eigenvectors of $\widetilde{A}$. We claim that $\mathrm{span}(\overline{V}) = \mathrm{span}(\widetilde{v}_1, \ldots, \widetilde{v}_r)$. Otherwise, there exists an eigenvector $u \in \mathrm{span}(\overline{V})$ whose associated eigenvalue is distinct from $\widetilde{\lambda}_1, \ldots, \widetilde{\lambda}_r$ (since $\delta_r > 3\|E\|_2$), and thus u is orthogonal to $\widetilde{v}_1, \ldots, \widetilde{v}_r$. Therefore,

$$\|(\widetilde{V}\widetilde{V}^T - \overline{V}\overline{V}^T)u\|_2 = \|\overline{V}\overline{V}^T u\|_2 = \|u\|_2.$$

This implies $d(\widetilde{V}, \overline{V}) \ge 1$, which is a contradiction. ■

Proof of Theorem 3 We split $\widetilde{V} - V$ into two parts—see (35). In the following, we first obtain a bound on $\|R - I_r\|_{\max}$, which then results in a bound on $\|\widetilde{V} - V\|_{\max}$.

Under the assumption of the theorem, $r\omega < 1/2$, so

$$\|\overline{V}\|_{\max} \le \|\overline{V} - V\|_{\max} + \|V\|_{\max} \le (2\sqrt{\mu}\,r\omega)/\sqrt{d} + \sqrt{r\mu}/\sqrt{d} \le 2\sqrt{r\mu/d}\,. \qquad (48)$$

To bound $\|R - I_r\|_{\max}$, we rewrite R as $R = \overline{V}^T \overline{V} R = \overline{V}^T \widetilde{V}$. Expand $\overline{V}$ according to (28),

$$R = (I_r + \overline{Q}^T \overline{Q})^{-1/2} (V + \overline{Q})^T \widetilde{V} \,.$$

Let us make a few observations: (a) $\|\overline{Q}^T \widetilde{V}\|_{\max} \le \sqrt{d} \|\overline{Q}\|_{\max} \le \omega$ by Cauchy-Schwarz inequality; (b) $\|\widetilde{V}^T V\|_{\max} \le 1$ by Cauchy-Schwarz inequality again; and (c) $\|(I_r + \overline{Q}^T \overline{Q})^{-1/2} - I_r\|_{\max} \le r\omega^2$ by Lemma 12. Using these inequalities, we have

$$\begin{aligned} \|R - (V + \overline{Q})^T \widetilde{V}\|_{\max} &\le r \|(I_r + \overline{Q}^T \overline{Q})^{-1/2} - I_r\|_{\max} \, \|(V + \overline{Q})^T \widetilde{V}\|_{\max} \\ &\le r^2 \omega^2 (1 + \omega) \,. \end{aligned} \tag{49}$$

Furthermore, by Davis-Kahn $\sin\Theta$ theorem (Davis and Kahan, 1970) and Weyl's inequality, for any $i \in [r]$,

$$\sin\theta(v_i, \widetilde{v}_i) = \sqrt{1 - \langle v_i, \widetilde{v}_i \rangle^2} \le \frac{\|E\|_2}{\delta - \|E\|_2} \,. \tag{50}$$

when $\delta > \|E\|_2$ (δ is defined in Theorem 3). This leads to the bound $\sin\theta(v_i, \widetilde{v}_i) \le 2\|E\|_2/\delta$ (which is a simplified bound). This is because when $\delta \ge 2\|E\|_2$, the bound is implied by (50); when $\delta < 2\|E\|_2$, the bound trivially follows from $\sin\theta(v_i, \widetilde{v}_i) \le 1$. We obtain, up to sign, for $i \le r$,

$$\sqrt{1 - \langle v_i, \widetilde{v}_i \rangle} \le \sqrt{1 - \langle v_i, \widetilde{v}_i \rangle^2} \le \frac{2\|E\|_2}{\delta} \,. \tag{51}$$

In other words, each diagonal entry of $I_r - V^T \widetilde{V}$, namely $1 - \langle v_i, \widetilde{v}_i \rangle$, is bounded by $4\|E\|_2^2/\delta^2$. Since $\{\widetilde{v}_i\}_{i=1}^r$ are orthonormal vectors, we have $1 - \langle v_i, \widetilde{v}_i \rangle^2 \ge \sum_{i' \ne i} \langle v_i, \widetilde{v}_{i'} \rangle^2 \ge \langle v_i, \widetilde{v}_j \rangle^2$ for any $i \ne j$, which leads to bounds on off-diagonal entries of $V^T \widetilde{V} - I_r$. We will combine the two bounds. Note that when $\delta \ge 2\|E\|_2$,

$$\|V^T \widetilde{V} - I_r\|_{\max} \le \max\Big\{ \frac{4\|E\|_2^2}{\delta^2}, \frac{2\|E\|_2}{\delta} \Big\} = \frac{2\|E\|_2}{\delta};$$

and when $\delta < 2\|E\|_2$, $\|V^T \widetilde{V} - I_r\|_{\max}$ is trivially bounded by 1 (up to sign), which is trivially bounded by $2\|E\|_2/\delta$. In either case, we deduce

$$\|V^T \widetilde{V} - I_r\|_{\max} \le \frac{2\|E\|_2}{\delta}. \tag{52}$$

Using the bounds in (49) and (52) and $\|\overline{Q}^T \widetilde{V}\|_{\max} \le \omega$, we obtain

$$\begin{aligned} \|R - I_r\|_{\max} &\le \|R - (V + \overline{Q})^T \widetilde{V}\|_{\max} + \|V^T \widetilde{V} - I_r\|_{\max} + \|\overline{Q}^T \widetilde{V}\|_{\max} \\ &\le r^2 \omega^2 (1 + \omega) + \frac{2\|E\|_2}{\delta} + \omega \,. \end{aligned}$$

We use the inequality $r\omega < 1/2$ to simplify the above bound:

$$\begin{aligned} \|R - I_r\|_{\max} &\le r^2 \omega^2 (1 + \omega) + \omega + 2\|E\|_2/\delta \le (\frac{1}{2} + \frac{1}{4} + 1) r\omega + 2\|E\|_2/\delta \\ &\le 2r\omega + 2\|E\|_2/\delta \,. \end{aligned} \tag{53}$$

We are now ready to bound $\|\widetilde{V} - V\|_{\max}$. In (35), we use the bounds (48), (53), (31) to obtain

$$\begin{aligned} \|\widetilde{V} - V\|_{\max} &= \|\overline{V}(R - I_r) + (\overline{V} - V)\|_{\max} \le r\|\overline{V}\|_{\max} \|R - I_r\|_{\max} + \|\overline{V} - V\|_{\max} \\ &\le 2r\sqrt{r\mu/d}\,(2r\omega + 2\|E\|_2/\delta) + 2r\sqrt{\mu}\,\omega/\sqrt{d} \\ &\le \frac{(4r^{5/2}\mu^{1/2} + 2r\mu^{1/2})\omega}{\sqrt{d}} + \frac{4r^{3/2}\mu^{1/2}\|E\|_2}{\delta\sqrt{d}} \\ &\le \frac{48(1 + r\mu) r^{5/2} \mu^{1/2} \kappa}{(|\lambda_r| - \varepsilon)\sqrt{d}} + \frac{4r^{3/2}\mu^{1/2}\|E\|_2}{\delta\sqrt{d}}. \end{aligned}$$

Using a trivial inequality $\kappa \le \sqrt{r\mu}\,\tau$, the above bound leads to

$$\|\widetilde{V} - V\|_{\max} = O\Big(\frac{r^4 \mu^2 \tau}{(|\lambda_r| - \varepsilon)\sqrt{d}} + \frac{r^{3/2}\mu^{1/2}\|E\|_2}{\delta\sqrt{d}} \Big).$$

■

B. Proofs for Section 2.2

Recall the definitions of μ_0, τ_0, κ_0 and ε_0 in Section 5.2. Similar to the symmetric case, we will use the following easily verifiable inequalities.

$$\kappa_0 \le \sqrt{r\mu_0}\,\tau_0, \qquad \|E\|_2 \le \Big(\sqrt{d_1/d_2}\,\|E\|_\infty \cdot \sqrt{d_2/d_1}\,\|E\|_1 \Big)^{1/2} \le \tau_0. \tag{54}$$

Lemma 13 *Parallel to Lemma 9, we have*

$$\|H^d\|_w \le (1 + r\mu_0)\kappa_0 \,,$$

where $\kappa_0 = \sqrt{d_1}\,\|EV\|_{\max} \vee \sqrt{d_2}\|E^T U\|_{\max}$ *as defined.*

Proof Recall $H^d = V_\perp^d (V_\perp^d)^T E^d V^d = E^d V^d - V^d (V^d)^T E^d V^d$. Note $V^d (V^d)^T = \mathrm{diag}(UU^T, VV^T)$ and $\|UU^T\|_{\max} \le r\mu(U)/d_1$, $\|VV^T\|_{\max} \le r\mu(V)/d_2$. Thus,

$$\begin{aligned} \|H^d\|_w &\le \|E^d V^d\|_w + \|V^d (V^d)^T E^d V^d\|_w \\ &\le (1 + d_1 \|UU^T\|_{\max} \vee d_2 \|VV^T\|_{\max}) \, \|E^d V^d\|_w \le (1 + r\mu_0)\kappa_0 \,. \end{aligned}$$

■

Lemma 14 *Parallel to Lemma 10, if $\sigma_r > 2\kappa_0 r\sqrt{\mu_0}$, then $\overline{L}_1^d$ is a non-degenerate matrix. Furthermore, we have the following bound*

$$\inf_{\|Q_0^d\|_w=1} \|Q_0^d \overline{L}_1^d - \overline{L}_2^d Q_0^d\|_w \geq \sigma_r - 4r\mu_0(\tau_0 + r\kappa_0) - \varepsilon_0\,, \tag{55}$$

where $Q_0^d \in \mathbb{R}^{(d_1+d_2)\times 2r}$.

Proof Following similar derivations with Lemma 10, we have $\|Q_0^d E_{11}^d\|_w \leq 2\kappa_0 r\sqrt{\mu_0}$, and for any matrix $Q_0^d \in \mathbb{R}^{(d_1+d_2)\times 2r}$ with $\|Q_0^d\|_w = 1$,

$$\|\overline{L}_2^d Q_0^d\|_w = \|(A^d - A_r^d)Q_0^d + V_\perp^d (V_\perp^d)^T E^d V_\perp^d (V_\perp^d)^T Q_0^d\|_w \leq \varepsilon_0 + (1 + r\mu_0)(\tau_0 + r\kappa_0).$$

This can be checked by expressing Q_0^d as a block matrix and expand the matrix multiplication. In particular, one can verify that (i) $\|(A^d - A_r^d)Q_0^d\|_w \leq \varepsilon_0$; (ii) For any matrix M with $d_1 + d_2$ rows, $\|V^d(V^d)^T M\|_w \leq r\mu_0\|M\|_w$; (iii) $\|E^d Q_0^d\|_w \leq \tau_0$; (iv) $\|E^d V^d (V^d)^T Q_0^d\|_w \leq r\kappa_0$. Moreover, $\|Q_0^d \Lambda_1^d\|_w \geq \sigma_r \|Q_0^d\|_w \geq \sigma_r$. Thus,

$$\inf_{\|Q_0^d\|_w=1} \|Q_0^d \overline{L}_1^d - \overline{L}_2^d Q_0^d\|_w \geq \sigma_r - 4r\mu_0(\tau_0 + r\kappa_0) - \varepsilon_0\,,$$

which is the desired inequality in the lemma. In addition, $\overline{L}_1^d$ is non-degenerate if $\sigma_r > 2\kappa_0 r\sqrt{\mu_0} > 0$. ■

Lemma 15 *Parallel to Lemma 11, there is a solution $\overline{Q}^d \in \mathcal{B}_0$ to the system (37) such that if $\sigma_r - \varepsilon_0 > 16r\mu_0(\tau_0 + r\kappa_0)$, then*

$$\|\overline{Q}^d\|_w \leq \frac{8(1 + r\mu_0)\kappa_0}{3(\sigma_r - \varepsilon_0)}\,.$$

Proof We again invoke Lemma 6. Let $\mathcal{B}$ be the space $\mathbb{R}^{(d_1+d_2)\times 2r}$ equipped with the weighted max-norm $\|\cdot\|_w$. We also define $\mathcal{B}_0$ as a subspace of $\mathcal{B}$ consisting of matrices of the form $V_\perp^d Q^d$ where Q^d has size $(d_1 + d_2 - 2r) \times 2r$. Let the linear operator $\mathcal{T}^d$ be $\mathcal{T}^d \overline{Q}^d := \overline{Q}^d \overline{L}_1^d - \overline{L}_2^d \overline{Q}^d$. First notice from Lemma 14, $\mathcal{T}^d$ is a linear operator with bounded inverse, i.e., $\beta := \|(\mathcal{T}^d)^{-1}\|_w^{-1}$ is bounded from below by

$$\beta \geq \sigma_r - 4r\mu_0(\tau_0 + r\kappa_0) - \varepsilon_0\,.$$

Let φ be a map given by $\varphi(\overline{Q}^d) = \overline{Q}^d (H^d)^T \overline{Q}^d$. Note that $H^d \in \mathcal{B}$. Using the (easily verifiable) inequality

$$\|M_1 M_2^T M_3\|_w \leq 2r\|M_1\|_w \|M_2^T M_3\|_{\max} \leq 4r\|M_1\|_w \|M_2\|_w \|M_3\|_w \quad \forall\, M_1, M_2, M_3 \in \mathcal{B}, \tag{56}$$

we derive, by the bound on $\|H^d\|_w$ (Lemma 13), that

$$\|\varphi(\overline{Q}^d)\|_w \leq 4r\|H^d\|_w \|\overline{Q}^d\|_w^2 \leq 4r(1 + r\mu_0)\kappa_0 \|\overline{Q}^d\|_w^2\,.$$

Moreover, using the inequality (56) and the bound on $\|H^d\|_w$ (Lemma 13),

$$\begin{aligned}\|\varphi(\overline{Q}_1^d) - \varphi(\overline{Q}_2^d)\|_w &\leq 4r\|\overline{Q}_1^d\|_w \|H^d\|_w \|\overline{Q}_1^d - \overline{Q}_2^d\|_w + 4r\|\overline{Q}_1^d - \overline{Q}_2^d\|_w \|H^d\|_w \|\overline{Q}_2^d\|_w \\ &\leq 8r(1 + r\mu_0)\kappa_0 \max\{\|\overline{Q}_1^d\|_w, \|\overline{Q}_2^d\|_w\} \|\overline{Q}_1^d - \overline{Q}_2^d\|_w.\end{aligned}$$

Thus, we can choose $\eta = 4r(1 + r\mu_0)\kappa_0$, and the condition (33) in Lemma 6 is satisfied. To ensure $4\eta\|H^d\|_w < \beta^2$, it suffices to require (again by Lemma 13),

$$16r(1 + r\mu_0)^2 \kappa_0^2 < \big[\sigma_r - 4r\mu_0(\tau_0 + r\kappa_0) - \varepsilon_0\big]^2.$$

It is easily checkable that the above inequality holds when $\sigma_r - \varepsilon_0 > 16r\mu_0(\tau_0 + r\kappa_0)$. Under this condition, by Lemma 6,

$$\|\overline{Q}^d\|_w \leq \frac{2\|H^d\|_w}{\beta} \leq \frac{2(1 + r\mu_0)\kappa_0}{\sigma_r - 4r\mu(\tau_0 + r\kappa_0) - \varepsilon_0} \leq \frac{2(1 + r\mu_0)\kappa_0}{\sigma_r - \varepsilon_0 - (\sigma_r - \varepsilon_0)/4} \leq \frac{8(1 + r\mu_0)\kappa_0}{3(\sigma_r - \varepsilon_0)}\,,$$

which completes the proof. ■

Proof of Lemma 8 The first claim of the lemma (existence of $\overline{Q}^d$ and its max-norm bound) follows from Lemma 15. To prove the second claim, we split $\overline{V}^d - V^d$ into two parts:

$$\overline{V}^d - V^d = V^d \Big((I_{2r} + (\overline{Q}^d)^T \overline{Q}^d)^{-1/2} - I_{2r}\Big) + \overline{Q}^d (I_{2r} + (\overline{Q}^d)^T \overline{Q}^d)^{-1/2}, \tag{57}$$

Note $\kappa_0 \leq \tau_0\sqrt{r\mu_0}$ (see (54)). It can be checked that the condition $\sigma_r - \varepsilon_0 > 16r\mu_0(\tau_0 + r\kappa_0)$ implies $r\omega_0 < 1/3$. Since $\|(\overline{Q}^d)^T \overline{Q}^d\|_{\max} \leq 2\omega_0^2$ and $\|(\overline{Q}^d)^T \overline{Q}^d\|_2 \leq 2r\|(\overline{Q}^d)^T \overline{Q}^d\|_{\max} \leq 4r\omega_0^2 < 1/2$, similar to Lemma 12, we have

$$\begin{aligned}&\|(I_{2r} + (\overline{Q}^d)^T \overline{Q}^d)^{-1/2} - I_{2r}\|_{\max} \leq 4r\omega_0^2, \\ &\|(I_{2r} + (\overline{Q}^d)^T \overline{Q}^d)^{-1/2}\|_{\max} \leq 3/2.\end{aligned} \tag{58}$$

This yields

$$\begin{aligned}\|\overline{V}^d - V^d\|_w &= \|V^d \Big((I_{2r} + (\overline{Q}^d)^T \overline{Q}^d)^{-1/2} - I_{2r}\Big)\|_w + \|\overline{Q}^d (I_{2r} + (\overline{Q}^d)^T \overline{Q}^d)^{-1/2}\|_w \\ &\leq \sqrt{2r^2\mu_0}\, 4r\omega_0^2 + 2r \cdot 3/2 \cdot \|\overline{Q}^d\|_w \leq 8\sqrt{\mu_0}\,\omega_0^2 r^2 + 3\,\omega_0 r \qquad (59) \\ &\leq 8\sqrt{\mu_0}\,\omega_0 r/3 + 3\sqrt{\mu_0}\,\omega_0 r \leq 6\sqrt{\mu_0}\, r\omega_0. \qquad (60)\end{aligned}$$

■

Lemma 16 *Suppose $\sigma_r - \varepsilon_0 > \max\{16r\mu_0(\tau_0 + r\kappa_0), 64r^{3/2}\mu_0^{1/2}(1 + r\mu_0)\kappa_0\}$. Then, there exists an orthogonal matrix $R_V \in \mathbb{R}^{r\times r}$ (or R_U) such that the column vectors of $\overline{V}R_V$ (and $\overline{U}R_U$) are the top r right (and left) singular vectors of $\widetilde{A}$.*

Proof Similar to the proof of Lemma 7, we will prove $d(\overline{V},V) < 1/2$ and $d(\widetilde{V},V) \le 1/2$, which would then imply that $\overline{V}$ and $\widetilde{V}$ are the same only up to an orthogonal transformation. The same is true for $\overline{U}$ and $\widetilde{U}$, and we will leave out its proof.

By Weyl's inequality for singular values (also known as Mirsky's theorem (Mirsky, 1960)), for any i, $|\overline{\sigma}_i - \sigma_i| \le \|E\|$. By Wedin's perturbation bounds for singular vectors (Wedin, 1972),

$$d(\widetilde{V},V) \le \frac{\|E\|_2}{\sigma_r - \|E\|_2}.$$

Note that $\|E\|_2 \le \tau_0$ (see (54)) Under the assumption in the lemma, clearly $\sigma_r - \varepsilon_0 > 3\tau_0$, and we have $d(\widetilde{V},V) \le 1/2$. Moreover, by Lemma 8, we have $\|\overline{V}^d - V^d\|_w \le 6r\omega_0\sqrt{\mu_0}$. Note that each column vector of V^d and $\overline{V}^d$ are (d_1+d_2)-dimensional. Looking at the last d_2 dimensions, we have $\|\overline{V} - V\|_{\max} \le 6r\omega_0\sqrt{\mu_0/d_1}$.

$$d(\overline{V},V) \le 2\|\overline{V} - V\| \le 2\sqrt{rd_1}\|\overline{V} - V\|_{\max} \le 12r^{3/2}\mu_0^{1/2}\omega_0.$$

Under the assumption of the lemma, $d(\overline{V},V) \le 1/2$. Therefore, we deduce $d(\widetilde{V},\overline{V}) = 0$, and conclude that there exists an orthogonal matrix $R_V \in \mathbb{R}^{r\times r}$ such that $\widetilde{V} = \overline{V}R_V$.

■

Proof of Theorem 4 Lemma 8, together with Lemma 16, implies Theorem 4. ■

Proof of Theorem 5 Similar to the proof of Theorem 3, we first split the difference $\widetilde{V}^d - V^d$:

$$\widetilde{V}^d - V^d = \overline{V}^d(R^d - I_{2r}) + (\overline{V}^d - V^d). \tag{61}$$

To bound the first term, note that under our assumption, $r\omega_0 < 1/3$ (derived in the proof of Lemma 8), it is easy to check $\|\overline{V}^d\|_w \le 3\sqrt{r\mu_0}$. We rewrite the matrix R^d as

$$R^d = (I_{2r} + (\overline{Q}^d)^T\overline{Q}^d)^{-1/2}(V^d + \overline{Q}^d)^T\widetilde{V}^d.$$

Notice that $\|(\overline{Q}^d)^T\widetilde{V}^d\|_{\max} \le \sqrt{2}\|\overline{Q}^d\|_w \le \sqrt{2}\,\omega_0$, $\|(\widetilde{V}^d)^TV^d\|_{\max} \le 1$ and

$$\begin{aligned}\|R^d - (V^d + \overline{Q}^d)^T\widetilde{V}^d\|_{\max} &\le 2r\|(I_{2r} + (\overline{Q}^d)^T\overline{Q}^d)^{-1/2} - I_{2r}\|_{\max}\,\|(V^d + \overline{Q}^d)^T\widetilde{V}^d\|_{\max}\\ &\le 8r^2\omega_0^2(1+\sqrt{2}\,\omega_0).\end{aligned}$$

where we used (58). Following the same derivations as in the proof of Theorem 3, and using the (easily verifiable) fact $\|E^d\|_2 = \|E\|_2$, we can bound $\|(V^d)^T\widetilde{V}^d - I_{2r}\|_{\max}$ by $2\|E\|_2/\delta_0$. Thus, using $r\omega_0 \le 1/3$, under $\delta_0 > 2\|E\|_2$, we have

$$\begin{aligned}\|R^d - I_{2r}\|_{\max} &\le \|R^d - (V^d + \overline{Q}^d)^T\widetilde{V}^d\|_{\max} + \|(V^d)^T\widetilde{V}^d - I_{2r}\|_{\max} + \|(\overline{Q}^d)^T\widetilde{V}^d\|_{\max}\\ &\le 8r^2\omega_0^2(1+\sqrt{2}\,\omega_0) + \frac{2\|E\|_2}{\delta_0} + \sqrt{2}\,\omega_0 < 4\sqrt{2}\,r\omega_0 + \frac{2\|E\|_2}{\delta_0}.\end{aligned} \tag{62}$$

Finally, in order to bound $\|\widetilde{V}^d - V^d\|_w$, we use (60), (61) and (62), and derive

$$\begin{aligned}\|\widetilde{V}^d - V^d\|_w &= \|\overline{V}^d(R^d - I_{2r}) + (\overline{V}^d - V^d)\|_w \le 2r\|\overline{V}^d\|_w\|R^d - I_{2r}\|_{\max} + \|\overline{V}^d - V^d\|_w\\ &\le 6r\sqrt{r\mu_0}\Big(4\sqrt{2}\,r\omega_0 + \frac{2\|E\|_2}{\delta_0}\Big) + 6r\sqrt{\mu_0}\,\omega_0 \le \Big(40r^{5/2}\,\omega_0 + 12r^{3/2}\,\frac{\|E\|_2}{\delta_0}\Big)\cdot\sqrt{\mu_0}\\ &\le \frac{107r^{5/2}\mu_0^{1/2}(1+r\mu_0)\kappa_0}{\sigma_r - \varepsilon_0} + \frac{12r^{3/2}\mu_0^{1/2}\|E\|_2}{\delta_0}\\ &= O\Big(\frac{r^4\mu_0^2\tau_0}{\sigma_r - \varepsilon_0} + \frac{r^{3/2}\mu_0^{1/2}\|E\|_2}{\delta_0}\Big).\end{aligned}$$

This completes the proof. ■

C. Proofs for Section 3

Proof of Proposition 3 Note first by Weyl's inequality, $|\lambda_i - \overline{\lambda}_i| \le \|\Sigma_u\| \le C$. So this implies that $\overline{\lambda}_i = \lambda_i(B^TB) \asymp d$ if and only if $\lambda_i = \lambda_i(\Sigma) \asymp d$ for $i \le r$. And furthermore the eigenvalues of B^TB/d are distinct if and only if $\min_{1\le i\ne j\le r}|\lambda_i(\Sigma) - \lambda_j(\Sigma)|/\lambda_j(\Sigma) > 0$.

To prove the equivalency of bounded $\|B\|_{\max}$ and bounded coherence. We first prove the necessary condition. Again from Weyl's inequality, $\lambda_i(\Sigma) \le C$ for $i \ge r+1$. If $\mu(V)$ is bounded, Σ_{ii} must also be bounded, since $\Sigma_{ii} \le \sum_{j=1}^r v_{ij}^2\lambda_j(\Sigma) + \lambda_{r+1}(\Sigma) \le C(\mu(V)+1)$. Therefore $\|b_i\|^2 \le \|b_i\|^2 + (\Sigma_u)_{ii} = \Sigma_{ii}$ implies $\|B\|_{\max}$ is bounded. Namely, the factors are pervasive.

On the contrary, if pervasiveness holds, we need to prove that $\mu(V)$ is bounded. Let $B = (\widetilde{b}_1,\ldots,\widetilde{b}_r)$. Obviously $\overline{\lambda}_i = \|\widetilde{b}_i\|^2 \asymp d$ and $\overline{v}_i = \widetilde{b}_i/\|\widetilde{b}_i\|$. Without loss of generality, assume $\overline{\lambda}_i$'s are decreasing. So $\|\overline{v}_i\|_\infty \le \|B\|_{\max}/\|\widetilde{b}_i\| \le C/\sqrt{d}$ and $\mu(\overline{V}) \le C$ where $\overline{V} = (\overline{v}_1,\ldots,\overline{v}_r)$. By Theorem 3,

$$\|\overline{v}_i - v_i\|_\infty \le C\frac{\|\Sigma_u\|_\infty}{\overline{\gamma}\sqrt{d}},$$

where $\overline{\gamma} = \min\{\overline{\lambda}_i - \overline{\lambda}_{i+1} : 1 \le i \le r\} \asymp d$ with the convention $\overline{\lambda}_{r+1} = 0$. Hence, we have $\|v_i\|_\infty \le C/\sqrt{d}$, which implies bounded coherence $\mu(V)$. ■

Abstract

This paper is concerned with the hard thresholding operator which sets all but the k largest absolute elements of a vector to zero. We establish a *tight* bound to quantitatively characterize the deviation of the thresholded solution from a given signal. Our theoretical result is universal in the sense that it holds for all choices of parameters, and the underlying analysis depends only on fundamental arguments in mathematical optimization. We discuss the implications for two domains:

Compressed Sensing. On account of the crucial estimate, we bridge the connection between the restricted isometry property (RIP) and the sparsity parameter for a vast volume of hard thresholding based algorithms, which renders an improvement on the RIP condition especially when the true sparsity is unknown. This suggests that in essence, many more kinds of sensing matrices or fewer measurements are admissible for the data acquisition procedure.

Machine Learning. In terms of large-scale machine learning, a significant yet challenging problem is learning accurate sparse models in an efficient manner. In stark contrast to prior work that attempted the ℓ_1-relaxation for promoting sparsity, we present a novel stochastic algorithm which performs hard thresholding in each iteration, hence ensuring such parsimonious solutions. Equipped with the developed bound, we prove the *global linear convergence* for a number of prevalent statistical models under mild assumptions, even though the problem turns out to be non-convex.

Keywords: sparsity, hard thresholding, compressed sensing, stochastic optimization

1. Introduction

Over the last two decades, pursuing sparse representations has emerged as a fundamental technique throughout bioinformatics (Olshausen and Field, 1997), statistics (Tibshirani, 1996; Efron et al., 2004), signal processing (Chen et al., 1998; Donoho et al., 2006; Donoho, 2006; Candès and Wakin, 2008) and mathematical science (Chandrasekaran et al., 2012), to name just a few. In order to obtain a sparse solution, a plethora of practical algorithms have been presented, among which two prominent examples are greedy pursuit and convex relaxation (Tropp and Wright, 2010). For instance, as one of the earliest greedy algorithms, orthogonal matching pursuit (OMP) (Pati et al., 1993) repeatedly picks a coordinate as the potential support of a solution. While OMP may fail for some deterministic sensing matrices, Tropp (2004); Tropp and Gilbert (2007) showed that it recovers the true signal with high probability when using random matrices such as Gaussian. Inspired by the success of OMP, the two concurrent work of compressive sampling matching pursuit (CoSaMP) (Needell and Tropp, 2009) and subspace pursuit (SP) (Dai and Milenkovic, 2009) made improvement by selecting multiple coordinates followed by a pruning step in each iteration, and the recovery condition was framed under the restricted isometry property (RIP) (Candès and Tao, 2005). Interestingly, the more careful selection strategy of CoSaMP and SP leads to an optimal sample complexity. The iterative hard thresholding (IHT) algorithm (Daubechies et al., 2004; Blumensath and Davies, 2008, 2009) gradually refines the iterates by gradient descent along with truncation. Foucart (2011) then developed a concise algorithm termed hard thresholding pursuit (HTP), which combined the idea of CoSaMP and IHT, and showed that HTP is superior to both in terms of the RIP condition. Jain et al. (2011) proposed an interesting variant of the HTP algorithm and obtained a sharper RIP result. Recently, Bahmani et al. (2013) and Yuan et al. (2018) respectively extended CoSaMP and HTP to general objective functions, for which a global convergence was established.

Since the sparsity constraint counts the number of non-zero components which renders the problem non-convex, the ℓ_1-norm was suggested as a convex relaxation dating back to basis pursuit (Chen et al., 1998; Donoho and Tsaig, 2008) and Lasso (Tibshirani, 1996). The difference is that Lasso looks for an ℓ_1-norm constrained solution that minimizes the residual while the principle of basis pursuit is to find a signal with minimal ℓ_1-norm that fits the observation data. Candès and Tao (2005) carried out a detailed analysis on the recovery performance of basis pursuit. Another popular estimator in the high-dimensional statistics is the Dantzig selector (Candès and Tao, 2007) which, instead of constraining the residual of the linear model, penalizes the maximum magnitude of the gradient. From a computational perspective, both basis pursuit and Dantzig selector can be solved by linear programming, while Lasso is formulated as a quadratic problem. Interestingly, under the RIP condition or the uniform uncertainty assumption (Candès et al., 2006), a series of work showed that exact recovery by convex programs is possible as soon as the observation noise vanishes (Candès and Tao, 2005; Candès, 2008; Wainwright, 2009; Cai et al., 2010; Foucart, 2012).

In this paper, we are interested in the hard thresholding (HT) operator underlying a large body of the developed algorithms in compressed sensing (e.g., IHT, CoSaMP, SP), machine learning (Yuan and Zhang, 2013), and statistics (Ma, 2013). Our motivation is two-fold. From a high level, compared to the convex programs, these HT-based algorithms are always orders of magnitude computationally more efficient, hence more practical for large-scale problems (Tropp and Wright, 2010). Nevertheless, they usually require a more stringent condition to guarantee the success. This naturally raises an interesting question of whether we can derive milder conditions for HT-based algorithms to achieve the best of the two worlds. For practitioners, to address the huge volume of data, a popular strategy in machine learning is to appeal to stochastic algorithms that sequentially update the solution. However, as many researchers observed (Langford et al., 2009; Duchi and Singer, 2009; Xiao, 2010), it is hard for the ℓ_1-based stochastic algorithms to preserve the sparse structure of the solution as the batch solvers do. This immediately poses the question of whether we are able to apply the principal idea of hard thresholding to stochastic algorithms while still ensuring a fast convergence.

To elaborate the problem more precisely, let us first turn to some basic properties of hard thresholding along with simple yet illustrative cases. For a general vector $\boldsymbol{b} \in \mathbb{R}^d$, the hard thresholded signal $\mathcal{H}_k(\boldsymbol{b})$ is formed by setting all but the largest (in magnitude) k elements of $\boldsymbol{b}$ to zero. Ties are broken lexicographically. Hence, the hard thresholded signal $\mathcal{H}_k(\boldsymbol{b})$ is always k-sparse, i.e., the number of non-zero components does not exceed k. Moreover, the resultant signal $\mathcal{H}_k(\boldsymbol{b})$ is a best

k-sparse approximation to $\boldsymbol{b}$ in terms of any ℓ_p norm ($p \geq 1$). That is, for any k-sparse vector $\boldsymbol{x}$

$$\|\mathcal{H}_k(\boldsymbol{b}) - \boldsymbol{b}\|_p \leq \|\boldsymbol{x} - \boldsymbol{b}\|_p.$$

In view of the above inequality, a broadly used bound in the literature for the deviation of the thresholded signal is as follows:

$$\|\mathcal{H}_k(\boldsymbol{b}) - \boldsymbol{x}\|_2 \leq 2\|\boldsymbol{b} - \boldsymbol{x}\|_2. \tag{1.1}$$

To gain intuition on the utility of (1.1) and to spell out the importance of offering a tight bound for it, let us consider the compressed sensing problem as an example for which we aim to recover the true sparse signal $\boldsymbol{x}$ from its linear measurements. Here, $\boldsymbol{b}$ is a good but dense approximation to $\boldsymbol{x}$ obtained by, e.g., full gradient descent. Then (1.1) justifies that in order to obtain a structured (i.e., sparse) approximation by hard thresholding, the distance of the iterate to the true signal $\boldsymbol{x}$ is upper bounded by a multiple of 2 to the one before. For comparison, it is worth mentioning that ℓ_1-based convex algorithms usually utilize the soft thresholding operator which enjoys the non-expansiveness property (Defazio et al., 2014), i.e., the iterate becomes closer to the optimum after projection. This salient feature might partially attribute to the wide range of applications of the ℓ_1-regularized formulations. Hence, to derive comparable performance guarantee, tightening the bound (1.1) is crucial in that it controls how much deviation the hard thresholding operator induces. This turns out to be more demanding for stochastic gradient methods, where the proxy $\boldsymbol{b}$ itself is affected by the randomness of sample realization. In other words, since $\boldsymbol{b}$ does not minimize the objective function (it only optimizes the objective in expectation), the deviation (1.1) makes it more challenging to analyze the convergence behavior. As an example, Nguyen et al. (2014) proposed a stochastic solver for general sparsity-constrained programs but suffered a non-vanishing optimization error due to randomness. This indicates that to mitigate the randomness barrier, we have to seek a better bound to control the precision of the thresholded solution and the variance.

1.1 Summary of Contributions

In this work, we make three contributions:

1. We examine the tightness of (1.1) that has been used for a decade in the literature and show that the equality therein will never be attained. We then improve this bound and quantitatively characterize that the deviation is inversely proportional to the value of $\sqrt{k}$. Our bound is tight, in the sense that the equality we build can be attained for specific signals, hence cannot be improved if no additional information is available. Our bound is universal in the sense that it holds for all choices of k-sparse signals $\boldsymbol{x}$ and for general signals $\boldsymbol{b}$.

2. Owing to the tight estimate, we demonstrate how the RIP (or RIP-like) condition assumed by a wide range of hard thresholding based algorithms can be relaxed. In the context of compressed sensing, it means that in essence, many more kinds of sensing matrices or fewer measurements can be utilized for data acquisition. For machine learning, it suggests that existing algorithms are capable of handling more difficult statistical models.

3. Finally, we present an computationally efficient algorithm that applies hard thresholding in large-scale setting and we prove its linear convergence to a global optimum up to the statistical precision of the problem. We also prove that with sufficient samples, our algorithm identifies the true parameter for prevalent statistical models. Returning to (1.1), our analysis shows that only when the deviation is controlled below the multiple of 1.15 can such an algorithm succeed. This immediately implies that the conventional bound (1.1) is not applicable in the challenging scenario.

1.2 Notation

Before delivering the algorithm and main theoretical results, let us instate several pieces of notation that are involved throughout the paper. We use bold lowercase letters, e.g., $\boldsymbol{v}$, to denote a vector (either column or row) and its ith element is denoted by v_i. The ℓ_2-norm of a vector $\boldsymbol{v}$ is denoted by $\|\boldsymbol{v}\|_2$. The support set of $\boldsymbol{v}$, i.e., indices of non-zeros, is denoted by $\operatorname{supp}(\boldsymbol{v})$ whose cardinality is written as $|\operatorname{supp}(\boldsymbol{v})|$ or $\|\boldsymbol{v}\|_0$. We write bold capital letters such as $\boldsymbol{M}$ for matrices and its (i,j)-th entry is denoted by m_{ij}. The capital upright letter C and its subscript variants (e.g., $\mathrm{C}_0, \mathrm{C}_1$) are reserved for absolute constants whose values may change from appearance to appearance.

For an integer $d > 0$, suppose that Ω is a subset of $\{1,\ 2,\ \ldots,\ d\}$. Then for a general vector $\boldsymbol{v} \in \mathbb{R}^d$, we define $\mathcal{P}_\Omega(\cdot)$ as the orthogonal projection onto the support set Ω which retains elements contained in Ω and sets others to zero. That is,

$$\left(\mathcal{P}_\Omega(\boldsymbol{v})\right)_i = \begin{cases} v_i, & \text{if } i \in \Omega, \\ 0, & \text{otherwise.} \end{cases}$$

In particular, let Γ be the support set indexing the k largest absolute components of $\boldsymbol{v}$. In this way, the hard thresholding operator is given by

$$\mathcal{H}_k(\boldsymbol{v}) = \mathcal{P}_\Gamma(\boldsymbol{v}).$$

We will also use the orthogonal projection of a vector $\boldsymbol{v}$ onto an ℓ_2-ball with radius ω. That is,

$$\Pi_\omega(\boldsymbol{v}) = \frac{\boldsymbol{v}}{\max\{1, \|\boldsymbol{v}\|_2/\omega\}}.$$

1.3 Roadmap

We present the key tight bound for hard thresholding in Section 2, along with a justification why the conventional bound (1.1) is not tight. We then discuss the implications of the developed tight bound to compressed sensing and machine learning in Section 3, which shows that the RIP or RIP-like condition can be improved for a number of popular algorithms. Thanks to our new estimation, Section 4 develops a novel stochastic algorithm which applies hard thresholding to large-scale problems and establishes the global linear convergence. A comprehensive empirical study on the tasks of sparse recovery and binary classification is carried out in Section 5. Finally, We conclude the paper in Section 6 and all the proofs are deferred to the appendix.

2. The Key Bound

We argue that the conventional bound (1.1) is not tight, in the sense that the equality therein can hardly be attained. To see this, recall how the bound was derived for a k-sparse signal $\boldsymbol{x}$ and a general one $\boldsymbol{b}$:

$$\|\mathcal{H}_k(\boldsymbol{b}) - \boldsymbol{x}\|_2 = \|\mathcal{H}_k(\boldsymbol{b}) - \boldsymbol{b} + \boldsymbol{b} - \boldsymbol{x}\|_2 \overset{\xi}{\leq} \|\mathcal{H}_k(\boldsymbol{b}) - \boldsymbol{b}\|_2 + \|\boldsymbol{b} - \boldsymbol{x}\|_2 \leq 2\|\boldsymbol{b} - \boldsymbol{x}\|_2,$$

where the last inequality holds because $\mathcal{H}_k(\boldsymbol{b})$ is a best k-sparse approximation to $\boldsymbol{b}$. The major issue occurs in ξ. Though it is the well-known triangle inequality and the equality could be attained if there is no restriction on the signals $\boldsymbol{x}$ and $\boldsymbol{b}$, we remind here that the signal $\boldsymbol{x}$ does have a specific structure – it is k-sparse. Note that in order to fulfill the equality in ξ, we must have $\mathcal{H}_k(\boldsymbol{b}) - \boldsymbol{b} = \gamma(\boldsymbol{b} - \boldsymbol{x})$ for some $\gamma \geq 0$, that is,

$$\mathcal{H}_k(\boldsymbol{b}) = (\gamma+1)\boldsymbol{b} - \gamma\boldsymbol{x}. \tag{2.1}$$

One may verify that the above equality holds *if and only if*

$$\boldsymbol{x} = \boldsymbol{b} = \mathcal{H}_k(\boldsymbol{b}). \tag{2.2}$$

To see this, let Ω be the support set of $\mathcal{H}_k(\boldsymbol{b})$ and $\overline{\Omega}$ be the complement. Let $\boldsymbol{b}_1 = \mathcal{P}_\Omega(\boldsymbol{b}) = \mathcal{H}_k(\boldsymbol{b})$ and $\boldsymbol{b}_2 = \mathcal{P}_{\overline{\Omega}}(\boldsymbol{b})$. Likewise, we define $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ as the components of $\boldsymbol{x}$ supported on Ω and $\overline{\Omega}$ respectively. Hence, (2.1) indicates $\boldsymbol{x}_1 = \boldsymbol{b}_1$ and $\boldsymbol{x}_2 = (1+\gamma^{-1})\boldsymbol{b}_2$ where we assume $\gamma > 0$ since $\gamma = 0$ immediately implies $\mathcal{H}_k(\boldsymbol{b}) = \boldsymbol{b}$ and hence the equality of (1.1) does not hold. If $\|\boldsymbol{b}_1\|_0 < k$, then we have $\boldsymbol{x}_2 = \boldsymbol{b}_2 = \boldsymbol{0}$ since $\boldsymbol{b}_1$ contains the k largest absolute elements of $\boldsymbol{b}$. Otherwise, the fact that $\|\boldsymbol{x}\|_0 \leq k$ and $\boldsymbol{x}_1 = \boldsymbol{b}_1$ implies $\boldsymbol{x}_2 = \boldsymbol{0}$, and hence $\boldsymbol{b}_2$. Therefore, we obtain (2.2).

When (2.2) happens, however, we in reality have $\|\mathcal{H}_k(\boldsymbol{b}) - \boldsymbol{x}\|_2 = \|\boldsymbol{b} - \boldsymbol{x}\|_2 = 0$. In other words, the factor of 2 in (1.1) can essentially be replaced with an *arbitrary constant*! In this sense, we conclude that the bound (1.1) is not tight. Our new estimate for hard thresholding is as follows:

Theorem 1 (Tight Bound for Hard Thresholding) *Let $\boldsymbol{b} \in \mathbb{R}^d$ be an arbitrary vector and $\boldsymbol{x} \in \mathbb{R}^d$ be any K-sparse signal. For any $k \geq K$, we have the following bound:*

$$\|\mathcal{H}_k(\boldsymbol{b}) - \boldsymbol{x}\|_2 \leq \sqrt{\nu}\,\|\boldsymbol{b} - \boldsymbol{x}\|_2, \quad \nu = 1 + \frac{\rho + \sqrt{(4+\rho)\,\rho}}{2}, \quad \rho = \frac{\min\{K, d-k\}}{k - K + \min\{K, d-k\}}.$$

In particular, our bound is tight in the sense that there exist specific vectors of $\boldsymbol{b}$ and $\boldsymbol{x}$ such that the equality holds.

Remark 2 (Maximum of ν) *In contrast to the constant bound* (1.1)*, our result asserts that the deviation resulting from hard thresholding is inversely proportional to $\sqrt{k}$ (when $K \leq d-k$) in a universal manner. When k tends to d, ρ is given by $(d-k)/(d-K)$ which is still decreasing with respect to k. Thus, the maximum value of ρ equals one. Even in this case, we find that $\sqrt{\nu_{\max}} = \sqrt{1 + \frac{\sqrt{5}+1}{2}} = \frac{\sqrt{5}+1}{2} \approx 1.618$.*

Remark 3 *Though for some batch algorithms such as IHT and CoSaMP, the constant bound* (1.1) *suffices to establish the convergence due to specific conditions, we show in Section 4 that it cannot ensure the global convergence for stochastic algorithms.*

Remark 4 *When $\boldsymbol{x}$ is not exactly K-sparse, we still can bound the error by $\|\mathcal{H}_k(\boldsymbol{b}) - \boldsymbol{x}\|_2 \leq \|\mathcal{H}_k(\boldsymbol{b}) - \mathcal{H}_k(\boldsymbol{x})\|_2 + \|\mathcal{H}_k(\boldsymbol{x}) - \boldsymbol{x}\|_2$. Thus, without loss of generality, we assumed that the signal $\boldsymbol{x}$ is K-sparse.*

Proof (Sketch) Our bound follows from fully exploring the sparsity pattern of the signals and from fundamental arguments in optimization. Denote

$$\boldsymbol{w} := \mathcal{H}_k(\boldsymbol{b}).$$

Let Ω be the support set of $\boldsymbol{w}$ and let $\overline{\Omega}$ be its complement. We immediately have $\mathcal{P}_\Omega(\boldsymbol{b}) = \boldsymbol{w}$. Let Ω' be the support set of $\boldsymbol{x}$. Define

$$\boldsymbol{b}_1 = \mathcal{P}_{\Omega\setminus\Omega'}(\boldsymbol{b}), \quad \boldsymbol{b}_2 = \mathcal{P}_{\Omega\cap\Omega'}(\boldsymbol{b}), \quad \boldsymbol{b}_3 = \mathcal{P}_{\overline{\Omega}\setminus\Omega'}(\boldsymbol{b}), \quad \boldsymbol{b}_4 = \mathcal{P}_{\overline{\Omega}\cap\Omega'}(\boldsymbol{b}).$$

Likewise, we define $\boldsymbol{x}_i$ and $\boldsymbol{w}_i$ for $1 \leq i \leq 4$. Due to the construction, we have $\boldsymbol{w}_1 = \boldsymbol{b}_1, \boldsymbol{w}_2 = \boldsymbol{b}_2, \boldsymbol{w}_3 = \boldsymbol{w}_4 = \boldsymbol{x}_1 = \boldsymbol{x}_3 = \boldsymbol{0}$. Our goal is to estimate the maximum value of $\|\boldsymbol{w} - \boldsymbol{x}\|_2^2 / \|\boldsymbol{b} - \boldsymbol{x}\|_2^2$. It is easy to show that when attaining the maximum, $\|\boldsymbol{b}_3\|_2$ must be zero. Denote

$$\gamma := \frac{\|\boldsymbol{w} - \boldsymbol{x}\|_2^2}{\|\boldsymbol{b} - \boldsymbol{x}\|_2^2} = \frac{\|\boldsymbol{b}_1\|_2^2 + \|\boldsymbol{b}_2 - \boldsymbol{x}_2\|_2^2 + \|\boldsymbol{x}_4\|_2^2}{\|\boldsymbol{b}_1\|_2^2 + \|\boldsymbol{b}_2 - \boldsymbol{x}_2\|_2^2 + \|\boldsymbol{b}_4 - \boldsymbol{x}_4\|_2^2}. \tag{2.3}$$

Note that the variables here only involve $\boldsymbol{x}$ and $\boldsymbol{b}$. Arranging the equation we obtain

$$(\gamma-1)\,\|\boldsymbol{b}_2 - \boldsymbol{x}_2\|_2^2 + \gamma\,\|\boldsymbol{b}_4 - \boldsymbol{x}_4\|_2^2 - \|\boldsymbol{x}_4\|_2^2 + (\gamma-1)\,\|\boldsymbol{b}_1\|_2^2 = 0. \tag{2.4}$$

It is evident that for specific choices of $\boldsymbol{b}$ and $\boldsymbol{x}$, we have $\gamma = 1$. Since we are interested in the maximum of γ, we assume $\gamma > 1$ below. Fixing $\boldsymbol{b}$, we can view the left-hand side of the above equation as a function of $\boldsymbol{x}$. One may verify that the function has a positive definite Hessian matrix and thus it attains the minimum at stationary point given by

$$\boldsymbol{x}_2^* = \boldsymbol{b}_2, \quad \boldsymbol{x}_4^* = \frac{\gamma}{\gamma-1}\boldsymbol{b}_4. \tag{2.5}$$

On the other hand, (2.4) implies that the minimum function value should not be greater than zero. Plugging the stationary point back gives

$$\|\boldsymbol{b}_1\|_2^2\gamma^2 - (2\,\|\boldsymbol{b}_1\|_2^2 + \|\boldsymbol{b}_4\|_2^2)\gamma + \|\boldsymbol{b}_1\|_2^2 \leq 0.$$

Solving the above inequality with respect to γ, we obtain

$$\gamma \leq 1 + \left(2\,\|\boldsymbol{b}_1\|_2^2\right)^{-1}\left(\|\boldsymbol{b}_4\|_2^2 + \sqrt{\left(4\,\|\boldsymbol{b}_1\|_2^2 + \|\boldsymbol{b}_4\|_2^2\right)\|\boldsymbol{b}_4\|_2^2}\right). \tag{2.6}$$

To derive an upper bound that is uniform over the choice of $\boldsymbol{b}$, we recall that $\boldsymbol{b}_1$ contains the largest absolute elements of $\boldsymbol{b}$ while $\boldsymbol{b}_4$ has smaller values. In particular, the average in $\boldsymbol{b}_1$ is larger than that in $\boldsymbol{b}_4$, which gives

$$\|\boldsymbol{b}_4\|_2^2/\|\boldsymbol{b}_4\|_0 \leq \|\boldsymbol{b}_1\|_2^2/\|\boldsymbol{b}_1\|_0.$$

Note that $\|\boldsymbol{b}_1\|_0 = k - \|\boldsymbol{b}_2\|_0 = k - (K - \|\boldsymbol{b}_4\|_0)$. Hence, combining with the fact that $0 \leq \|\boldsymbol{b}_4\|_0 \leq \min\{K, d-k\}$ and optimizing over $\|\boldsymbol{b}_4\|_0$ in the above inequality gives

$$\|\boldsymbol{b}_4\|_2^2 \leq \frac{\min\{K, d-k\}}{k - K + \min\{K, d-k\}}\,\|\boldsymbol{b}_1\|_2^2. \tag{2.7}$$

Finally, we arrive at a uniform upper bound

$$\gamma \leq 1 + \frac{\rho + \sqrt{(4+\rho)\,\rho}}{2}, \quad \rho = \frac{\min\{K, d-k\}}{k - K + \min\{K, d-k\}}.$$

See Appendix B for the full proof. ■

Remark 5 (Tightness) *We construct proper vectors $\boldsymbol{b}$ and $\boldsymbol{x}$ to establish the tightness of our bound by a backward induction. Note that γ equals ν if and only if $\|\boldsymbol{b}_4\|_2^2 = \rho\,\|\boldsymbol{b}_1\|_2^2$. Hence, we pick*

$$\|\boldsymbol{b}_4\|_2^2 = \rho\,\|\boldsymbol{b}_1\|_2^2, \quad \boldsymbol{x}_2 = \boldsymbol{b}_2, \quad \boldsymbol{x}_4 = \frac{\nu}{\nu-1}\boldsymbol{b}_4, \tag{2.8}$$

where $\boldsymbol{x}_2$ and $\boldsymbol{x}_4$ are actually chosen as the stationary point as in (2.5)*. We note that the quantity of ν only depends on d, k and K, not on the components of $\boldsymbol{b}$ or $\boldsymbol{x}$. Plugging the above back to* (2.3) *justifies $\gamma = \nu$.*

It remains to show that our choices in (2.8) *do not violate the definition of $\boldsymbol{b}_i$'s, i.e., we need to ensure that the elements in $\boldsymbol{b}_1$ or $\boldsymbol{b}_2$ are equal to or greater than those in $\boldsymbol{b}_3$ or $\boldsymbol{b}_4$. Note that there is no such constraint for the K-sparse vector $\boldsymbol{x}$. Let us consider the case $K < d-k$ and $\|\boldsymbol{b}_4\|_0 = K$, so that $\|\boldsymbol{b}_1\|_0 = k$ and $\rho = K/k$. Thus, the first equality of* (2.8) *holds as soon as all the entries of $\boldsymbol{b}$ have same magnitude. The fact $\|\boldsymbol{b}_4\|_0 = K$ also implies Ω' is a subset of $\overline{\Omega}$ due to the definition of $\boldsymbol{b}_4$ and the sparsity of $\boldsymbol{x}$, hence we have $\boldsymbol{x}_2 = \boldsymbol{0} = \boldsymbol{b}_2$. Finally, picking $\boldsymbol{x}_4$ as we did in* (2.8) *completes the reasoning since it does not violate the sparsity constraint on $\boldsymbol{x}$.*

As we pointed out and just verified, the bound given by Theorem 1 is tight. However, if there is additional information for the signals, a better bound can be established. For instance, let us further assume that the signal $\boldsymbol{b}$ is r-sparse. If $r \le k$, then $\boldsymbol{b}_4$ is a zero vector and (2.6) reads as $\gamma \le 1$. Otherwise, we have $\|\boldsymbol{b}_4\|_0 \le \min\{K, r-k\}$ and (2.7) is improved to

$$\|\boldsymbol{b}_4\|_2^2 \le \frac{\min\{K, r-k\}}{k - K + \min\{K, r-k\}}\,\|\boldsymbol{b}_1\|_2^2\,.$$

Henceforth, we can show that the parameter ρ is given by

$$\rho = \frac{\min\{K, r-k\}}{k - K + \min\{K, r-k\}}.$$

Note that the fact $r \le d$ implies that the above is a tighter bound than the one in Theorem 1.

We would also like to mention that in Lemma 1 of Jain et al. (2014), a closely related bound was established:

$$\|\mathcal{H}_k(\boldsymbol{b}) - \boldsymbol{b}\|_2 \le \sqrt{\frac{d-k}{d-K}}\,\|\boldsymbol{b} - \boldsymbol{x}\|_2\,. \tag{2.9}$$

One may use this nice result to show that

$$\|\mathcal{H}_k(\boldsymbol{b}) - \boldsymbol{x}\|_2 \le \|\mathcal{H}_k(\boldsymbol{b}) - \boldsymbol{b}\|_2 + \|\boldsymbol{b} - \boldsymbol{x}\|_2 \le \left(1 + \sqrt{\frac{d-k}{d-K}}\right)\|\boldsymbol{b} - \boldsymbol{x}\|_2\,, \tag{2.10}$$

which also improves on (1.1) provided $k > K$. However, one shortcoming of (2.10) is that the factor depends on the dimension. For comparison, we recall that in the regime $K \le d-k$, our bound is free of the dimension. This turns out to be a salient feature to integrate hard thresholding into stochastic methods, and we will comment on it more in Section 4.

3. Implications to Compressed Sensing

In this section, we investigate the implications of Theorem 1 for compressed sensing and signal processing. Since most of the HT-based algorithms utilize the deviation bound (1.1) to derive the convergence condition, they can be improved by our new bound. We exemplify the power of our theorem on two popular algorithms: IHT (Blumensath and Davies, 2009) and CoSaMP (Needell and Tropp, 2009). We note that our analysis also applies to their extensions such as Bahmani et al. (2013). To be clear, the purpose of this section is not dedicated to improving the best RIP condition for which recovery is possible by any methods (either convex or non-convex). Rather, we focus on two broadly used greedy algorithms and illustrate how our bound improves on previous results.

We proceed with a brief review of the problem setting in compressed sensing. Compressed sensing algorithms aim to recover the true K-sparse signal $\boldsymbol{x}^* \in \mathbb{R}^d$ from a set of its (perhaps noisy) measurements

$$\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x}^* + \boldsymbol{\varepsilon}, \tag{3.1}$$

where $\boldsymbol{\varepsilon} \in \mathbb{R}^d$ is some observation noise and $\boldsymbol{A}$ is a known $n \times d$ sensing matrix with $n \ll d$, hence the name compressive sampling. In general, the model is not identifiable since it is an underdetermined system. Yet, the prior knowledge that $\boldsymbol{x}^*$ is sparse radically changes the premise. That is, if the geometry of the sparse signal is preserved under the action of the sampling matrix $\boldsymbol{A}$ for a restricted set of directions, then it is possible to invert the sampling process. Such a novel idea was quantified as the kth restricted isometry property of $\boldsymbol{A}$ by Candès and Tao (2005), which requires that there exists a constant $\delta \ge 0$, such that for all k-sparse signals $\boldsymbol{x}$

$$(1-\delta)\,\|\boldsymbol{x}\|_2^2 \le \|\boldsymbol{A}\boldsymbol{x}\|_2^2 \le (1+\delta)\,\|\boldsymbol{x}\|_2^2\,. \tag{3.2}$$

The kth restricted isometry constant (RIC) δ_k is then defined as the smallest one that satisfies the above inequalities. Note that $\delta_{2k} < 1$ is the minimum requirement for distinguishing all k-sparse signals from the measurements. This is because for two arbitrary k-sparse vectors $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ and their respective measurements $\boldsymbol{y}_1$ and $\boldsymbol{y}_2$, the RIP condition reads as

$$(1-\delta_{2k})\,\|\boldsymbol{x}_1 - \boldsymbol{x}_2\|_2^2 \le \|\boldsymbol{y}_1 - \boldsymbol{y}_2\|_2^2 \le (1+\delta_{2k})\,\|\boldsymbol{x}_1 - \boldsymbol{x}_2\|_2^2\,,$$

for which $\delta_{2k} < 1$ guarantees that $\boldsymbol{x}_1 \ne \boldsymbol{x}_2$ implies $\boldsymbol{y}_1 \ne \boldsymbol{y}_2$. To date, there are three quintessential examples known to exhibit a profound restricted isometry behavior as long as the number of measurements is large enough: Gaussian matrices (optimal RIP, i.e., very small δ_k), partial Fourier matrices (fast computation) and Bernoulli ensembles (low memory footprint). Notably, it was shown in recent work that random matrices with a heavy-tailed distribution also satisfy the RIP with overwhelming probability (Adamczak et al., 2011; Li et al., 2014).

Equipped with the standard RIP condition, many efficient algorithms have been developed. A partial list includes ℓ_1-norm based convex programs, IHT, CoSaMP, SP and regularized OMP (Needell and Vershynin, 2010), along with much interesting work devoted to improving or sharpening the RIP condition (Wang and Shim, 2012; Mo and Shen, 2012; Cai and Zhang, 2013; Mo, 2015). To see why relaxing RIP is of central interest, note that the standard result (Baraniuk et al., 2008) asserts that the RIP condition $\delta_k \le \delta$ holds with high probability over the draw of $\boldsymbol{A}$ provided

$$n \ge \mathrm{C}_0\delta^{-2}k\log(d/k). \tag{3.3}$$

Hence, a slight relaxation of the condition $\delta_k \le \delta$ may dramatically decrease the number of measurements. That being said, since the constant C_0 above is unknown, in general one cannot tell

the precise sample size for greedy algorithms. Estimating the constant is actually the theme of phase transition (Donoho and Tanner, 2010; Donoho et al., 2013). While precise phase transition for ℓ_1-based convex programs has been well understood (Wainwright, 2009), an analogous result for greedy algorithms remains an open problem. Notably, in Blanchard and Tanner (2015), phase transition for IHT/CoSaMP was derived using the constant bound (1.1). We believe that our tight bound shall sharpen these results and we leave it as our future work. In the present paper, we focus on the ubiquitous RIP condition. In the language of RIP, we establish improved results.

3.1 Iterative Hard Thresholding

The IHT algorithm recovers the underlying K-sparse signal $\boldsymbol{x}^*$ by iteratively performing a full gradient descent on the least-squares loss followed by a hard thresholding step. That is, IHT starts with an arbitrary point $\boldsymbol{x}^0$ and at the t-th iteration, it updates the new solution as follows:

$$\boldsymbol{x}^t = \mathcal{H}_k\left(\boldsymbol{x}^{t-1} + \boldsymbol{A}^\top(\boldsymbol{y} - \boldsymbol{A}\boldsymbol{x}^{t-1})\right). \tag{3.4}$$

Note that Blumensath and Davies (2009) used the parameter $k = K$. However, in practice one may only know to an upper bound on the true sparsity K. Thus, we consider the projection sparsity k as a parameter that depends on K. To establish the global convergence with a geometric rate of 0.5, Blumensath and Davies (2009) applied the bound (1.1) and assumed the RIP condition

$$\delta_{2k+K} \le 0.18. \tag{3.5}$$

As we have shown, (1.1) is actually not tight and hence, their results, especially the RIP condition can be improved by Theorem 1.

Theorem 6 *Consider the model* (3.1) *and the IHT algorithm* (3.4)*. Pick $k \ge K$ and let $\{\boldsymbol{x}^t\}_{t\ge1}$ be the iterates produced by IHT. Then, under the RIP condition $\delta_{2k+K} \le 1/\sqrt{8\nu}$, for all $t \ge 1$*

$$\left\|\boldsymbol{x}^t - \boldsymbol{x}^*\right\|_2 \le 0.5^t \left\|\boldsymbol{x}^0 - \boldsymbol{x}^*\right\|_2 + \mathrm{C}\left\|\boldsymbol{\varepsilon}\right\|_2,$$

where ν is given by Theorem 1.

Let us first study the vanilla case $k = K$. Blumensath and Davies (2009) required $\delta_{3K} \le 0.18$ whereas our analysis shows $\delta_{3K} \le 0.22$ suffices. Note that even a little relaxation on RIP is challenging and may require several pages of mathematical induction (Candès, 2008; Cai et al., 2010; Foucart, 2012). In contrast, our improvement comes from a direct application of Theorem 1 which only modifies several lines of the original proof in Blumensath and Davies (2009). See Appendix C for details. In view of (3.3), we find that the necessary number of measurements for IHT is dramatically reduced with a factor of 0.67 by our new theorem in that the minimum requirement of n is inversely proportional to the square of δ_{2k+K}.

Another important consequence of the theorem is a characterization on the RIP condition and the sparsity parameter, which, to the best of our knowledge, has not been studied in the literature. In Blumensath and Davies (2009), when gradually tuning k larger than K, it always requires $\delta_{2k+K} \le 0.18$. Note that due to the monotonicity of RIC, i.e., $\delta_r \le \delta_{r'}$ if $r \le r'$, the condition turns out to be more and more stringent. Compared to their result, since ν is inversely proportional to $\sqrt{k}$, Theorem 6 is powerful especially when k becomes larger. For example, suppose $k = 20K$. In this

case, Theorem 6 justifies that IHT admits the linear convergence as soon as $\delta_{41K} \le 0.32$ whereas Blumensath and Davies (2009) requires $\delta_{41K} \le 0.18$. Such a property is appealing in practice, in that among various real-world applications, the true sparsity is indeed unknown and we would like to estimate a conservative upper bound on it.

On the other hand, for a given sensing matrix, there does exist a fundamental limit for the maximum choice of k. To be more precise, the condition in Theorem 6 together with the probabilistic argument (3.3) require

$$1/\sqrt{8\nu} \ge \delta_{2k+K}, \quad \mathrm{C}_1\nu(2k+K)\log\left(d/(2k+K)\right) \le n.$$

Although it could be very interesting to derive a quantitative characterization for the maximum value of k, we argue that it is perhaps intractable owing to two aspects: First, it is known that one has to enumerate all the combinations of the $2k+K$ columns of $\boldsymbol{A}$ to compute the restricted isometry constant δ_{2k+K} (Bah and Tanner, 2010, 2014). This suggests that it is NP-hard to estimate the largest admissible value of k. Also, there is no analytic solution of the stationary point for the left-hand side of the second inequality.

3.2 Compressive Sampling Matching Pursuit

The CoSaMP algorithm proposed by Needell and Tropp (2009) is one of the most efficient algorithms for sparse recovery. Let $F(\boldsymbol{x}) = \|\boldsymbol{y} - \boldsymbol{A}\boldsymbol{x}\|_2^2$. CoSaMP starts from an arbitrary initial point $\boldsymbol{x}^0$ and proceeds as follows:

$$\begin{aligned}
\Omega^t &= \mathrm{supp}\left(\nabla F(\boldsymbol{x}^{t-1}),\ k\right) \cup \mathrm{supp}\left(\boldsymbol{x}^{t-1}\right),\\
\boldsymbol{b}^t &= \arg\min_{\boldsymbol{x}}\ F(\boldsymbol{x}),\ \text{s.t. supp}\left(\boldsymbol{x}\right) \subset \Omega^t,\\
\boldsymbol{x}^t &= \mathcal{H}_k\left(\boldsymbol{b}^t\right).
\end{aligned}$$

Compared to IHT which performs hard thresholding after gradient update, CoSaMP prunes the gradient at the beginning of each iteration, followed by solving a least-squares program restricted on a small support set. In particular, in the last step, CoSaMP applies hard thresholding to form a k-sparse iterate for future updates. The analysis of CoSaMP consists of bounding the estimation error in each step. Owing to Theorem 1, we advance the theoretical result of CoSaMP by improving the error bound for its last step, and hence the RIP condition.

Theorem 7 *Consider the model* (3.1) *and the CoSaMP algorithm. Pick $k \ge K$ and let $\{\boldsymbol{x}^t\}_{t\ge1}$ be the iterates produced by CoSaMP. Then, under the RIP condition*

$$\delta_{3k+K} \le \frac{\left(\sqrt{32\nu+49}-9\right)^{1/2}}{4\sqrt{\nu-1}},$$

it holds that for all $t \ge 1$

$$\left\|\boldsymbol{x}^t - \boldsymbol{x}^*\right\|_2 \le 0.5^t \left\|\boldsymbol{x}^0 - \boldsymbol{x}^*\right\|_2 + \mathrm{C}\left\|\boldsymbol{\varepsilon}\right\|_2,$$

where ν is given by Theorem 1.

Roughly speaking, the bound is still inversely proportional to $\sqrt{\nu}$. Hence, it is monotonically increasing with respect to k, indicating our theorem is more effective for a large quantity of k. In fact, for the CoSaMP algorithm, our bound above is superior to the best known result even when $k = K$. To see this, we have the RIP condition $\delta_{4K} \leq 0.31$. In comparison, Needell and Tropp (2009) derived a bound $\delta_{4K} \leq 0.1$ and Foucart and Rauhut (2013, Theorem 6.27) improved it to $\delta_{4K} < 0.29$ for a geometric rate of 0.5. We notice that for binary sparse vectors, Jain et al. (2014) presented a different proof technique and obtained the RIP condition $\delta_{4K} \leq 0.35$ for CoSaMP.

4. Hard Thresholding in Large-Scale Optimization

Now we move on to the machine learning setting where our focus is pursuing an optimal sparse solution that minimizes a given objective function based on a set of training samples $Z_1^n := \{Z_i\}_{i=1}^n$. Different from compressed sensing, we usually have sufficient samples which means n can be very large. Therefore, the computational complexity is of primary interest. Formally, we are interested in optimizing the following program:

$$\min_{\boldsymbol{x}\in\mathbb{R}^d} F(\boldsymbol{x}; Z_1^n) = \frac{1}{n}\sum_{i=1}^n f(\boldsymbol{x}; Z_i), \quad \text{s.t. } \|\boldsymbol{x}\|_0 \leq K,\ \|\boldsymbol{x}\|_2 \leq \omega. \tag{4.1}$$

The global optimum of the above problem is denoted by $\boldsymbol{x}_{\rm opt}$. We note that the objective function is presumed to be decomposable with respect to the samples. This is quite a mild condition and most of the popular machine learning models fulfill it. Typical examples include (but not limited to) the sparse linear regression and sparse logistic regression:

- Sparse Linear Regression: For all $1 \leq i \leq n$, we have $Z_i = (\boldsymbol{a}_i, y_i) \in \mathbb{R}^d \times \mathbb{R}$ and the loss function $F(\boldsymbol{x}; Z_1^n) = \frac{1}{2n}\|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{y}\|_2^2$ is the least-squares and can be explained by $f(\boldsymbol{x}; Z_i) = \frac{1}{2}\|\boldsymbol{a}_i \cdot \boldsymbol{x} - y_i\|_2^2$.
- Sparse Logistic Regression: For all $1 \leq i \leq n$, we have $Z_i = (\boldsymbol{a}_i, y_i) \in \mathbb{R}^d \times \{+1, -1\}$ and the negative log-likelihood is penalized, i.e., $F(\boldsymbol{x}; Z_1^n) = \frac{1}{n}\sum_{i=1}^n \log\left(1 + \exp\left(-y_i \boldsymbol{a}_i \cdot \boldsymbol{x}\right)\right)$ for which $f(\boldsymbol{x}; Z_i) = \log\left(1 + \exp\left(-y_i \boldsymbol{a}_i \cdot \boldsymbol{x}\right)\right)$.

To ease notation, we will often write $F(\boldsymbol{x}; Z_1^n)$ as $F(\boldsymbol{x})$ and $f(\boldsymbol{x}; Z_i)$ as $f_i(\boldsymbol{x})$ for $i = 1, 2, \cdots, n$. It is worth mentioning that the objective function $F(\boldsymbol{x})$ is allowed to be non-convex. Hence, in order to ensure the existence of a global optimum, a natural option is to impose an ℓ_p-norm ($p \geq 1$) constraint (Loh and Wainwright, 2012, 2015). Here we choose the ℓ_2-norm constraint owing to its fast projection. Previous work, e.g., Agarwal et al. (2012) prefers the computationally less efficient ℓ_1-norm to promote sparsity and to guarantee the existence of optimum. In our problem, yet, we already have imposed the hard sparsity constraint so the ℓ_2-norm constraint is a better fit.

The major contribution of this section is a computationally efficient algorithm termed hard thresholded stochastic variance reduced gradient method (HT-SVRG) to optimize (4.1), tackling one of the most important problems in large-scale machine learning: producing sparse solutions by stochastic methods. We emphasize that the formulation (4.1) is in stark contrast to the ℓ_1-regularized programs considered by previous stochastic solvers such as Prox-SVRG (Xiao and Zhang, 2014) and SAGA (Defazio et al., 2014). We target here a stochastic algorithm for the *non-convex* problem that is less exploited in the literature. From a theoretical perspective, (4.1) is more difficult to analyze but it always produces sparse solutions, whereas performance guarantees for convex programs

are fruitful but one cannot characterize the sparsity of the obtained solution (usually the solution is not sparse). When we appeal to stochastic algorithms to solve the convex programs, the ℓ_1-norm formulation becomes much less effective in terms of sparsification, naturally owing to the randomness. See Langford et al. (2009); Xiao (2010); Duchi and Singer (2009) for more detailed discussion on the issue. We also remark that existing work such as Yuan et al. (2018); Bahmani et al. (2013); Jain et al. (2014) investigated the sparsity-constrained problem (4.1) in a batch scenario, which is not practical for large-scale learning problems. The perhaps most related work to our new algorithm is Nguyen et al. (2014). Nonetheless, the optimization error therein does not vanish for noisy statistical models.

Our main result shows that for prevalent statistical models, our algorithm is able to recover the true parameter with a linear rate. Readers should distinguish the optimal solution $\boldsymbol{x}_{\rm opt}$ and the true parameter. For instance, consider the model (3.1). Minimizing (4.1) does not amount to recovering $\boldsymbol{x}^*$ if there is observation noise. In fact, the convergence to $\boldsymbol{x}_{\rm opt}$ is only guaranteed to an accuracy reflected by the *statistical precision* of the problem, i.e., $\|\boldsymbol{x}^* - \boldsymbol{x}_{\rm opt}\|_2$, which is the best one can hope for any statistical model (Agarwal et al., 2012). We find that the global convergence is attributed to both the tight bound and the variance reduction technique to be introduced below, and examining the necessity of them is an interesting future work.

Algorithm 1 Hard Thresholded Stochastic Variance Reduced Gradient Method (HT-SVRG)

Require: Training samples $\{Z_i\}_{i=1}^n$, maximum stage count S, sparsity parameter k, update frequency m, learning rate η, radius ω, initial solution $\widetilde{\boldsymbol{x}}^0$.
Ensure: Optimal solution $\widetilde{\boldsymbol{x}}^S$.

4.1 Algorithm

Our algorithm (Algorithm 1) applies the framework of Johnson and Zhang (2013), where the primary idea is to leverage past gradients for the current update for the sake of variance reduction – a technique that has a long history in statistics (Owen and Zhou, 2000). To guarantee that each iterate is k-sparse, it then invokes the hard thresholding operation. Note that the orthogonal projection for $\boldsymbol{r}^t$ will not change the support set, and hence $\boldsymbol{x}^t$ is still k-sparse. Also note that our sparsity constraint in (4.1) reads as $\|\boldsymbol{x}\|_0 \leq K$. What we will show below is that when the parameter k is properly chosen (which depends on K), we obtain a globally convergent sequence of iterates.

The most challenging part on establishing the global convergence comes from the hard thresholding operation $\mathcal{H}_k\left(\boldsymbol{r}^t\right)$. Note that it is $\boldsymbol{b}^t$ that reduces the objective value in expectation. If $\boldsymbol{b}^t$ is not k-sparse (usually it is dense), $\boldsymbol{x}^t$ is not equal to $\boldsymbol{b}^t$ so it does not decrease the objective function. In addition, compared with the convex proximal operator (Defazio et al., 2014) which enjoys the non-expansiveness of the distance to the optimum, the hard thresholding step can enlarge the distance up to a multiple of 2 if using the bound (1.1). What makes it a more serious issue is that these inaccurate iterates $\boldsymbol{x}^t$ will be used for future updates, and hence the error might be progressively propagated at an exponential rate.

Our key idea is to first bound the curvature of the function from below and above to establish RIP-like condition, which, combined with Theorem 1, downscales the deviation resulting from hard thresholding. Note that ν is always greater than one (see Theorem 1), hence the curvature bound is necessary. Due to variance reduction, we show that the optimization error vanishes when restricted on a small set of directions as soon as we have sufficient samples. Moreover, with hard thresholding we are able to control the error per iteration and to obtain near-optimal sample complexity.

4.2 Deterministic Analysis

We will first establish a general theorem that characterizes the progress of HT-SVRG for approximating an arbitrary K-sparse signal $\widehat{\boldsymbol{x}}$. Then we will discuss how to properly choose the hyper-parameters of the algorithm. Finally we move on to specify $\widehat{\boldsymbol{x}}$ to develop convergence results for a global optimum of (4.1) and for a true parameter (e.g., $\boldsymbol{x}^*$ of the compressed sensing problem).

4.2.1 ASSUMPTION

Our analysis depends on two properties of the curvature of the objective function that have been standard in the literature. Readers may refer to Bickel et al. (2009); Negahban et al. (2009); Jain et al. (2014) for a detailed description.

Definition 8 (Restricted Strong Convexity) *A differentiable function $g:\ \mathbb{R}^d \to \mathbb{R}$ is said to satisfy the property of restricted strong convexity (RSC) with parameter $\alpha_r > 0$, if for all vectors $\boldsymbol{x}$, $\boldsymbol{x}' \in \mathbb{R}^d$ with $\|\boldsymbol{x}-\boldsymbol{x}'\|_0 \le r$, it holds that*

$$g(\boldsymbol{x}') - g(\boldsymbol{x}) - \left\langle \nabla g(\boldsymbol{x}), \boldsymbol{x}'-\boldsymbol{x}\right\rangle \ge \frac{\alpha_r}{2}\left\|\boldsymbol{x}'-\boldsymbol{x}\right\|_2^2.$$

Definition 9 (Restricted Smoothness) *A differentiable function $g:\ \mathbb{R}^d \to \mathbb{R}$ is said to satisfy the property of restricted smoothness (RSS) with parameter $L_r > 0$, if for all vectors $\boldsymbol{x}$, $\boldsymbol{x}' \in \mathbb{R}^d$ with $\|\boldsymbol{x}-\boldsymbol{x}'\|_0 \le r$, it holds that*

$$\left\|\nabla g(\boldsymbol{x}') - \nabla g(\boldsymbol{x})\right\|_2 \le L_r\left\|\boldsymbol{x}'-\boldsymbol{x}\right\|_2.$$

With these definitions, we assume the following:

$(A1)$ $F(\boldsymbol{x})$ satisfies the RSC condition with parameter α_{k+K}.

$(A2)$ For all $1 \le i \le n$, $f_i(\boldsymbol{x})$ satisfies the RSS condition with parameter L_{3k+K}.

Here, we recall that K was first introduced in (4.1) and the parameter k was used in our algorithm. Compared to the convex algorithms such as SAG (Roux et al., 2012), SVRG (Johnson and Zhang, 2013) and SAGA (Defazio et al., 2014) that assume strong convexity and smoothness everywhere, we only assume these in a restricted sense. This is more practical especially in the high dimensional regime where the Hessian matrix could be degenerate (Agarwal et al., 2012). We also stress that the RSS condition is imposed on each $f_i(\boldsymbol{x})$, whereas prior work requires it for $F(\boldsymbol{x})$ which is milder than ours (Negahban et al., 2009).

4.2.2 UPPER BOUND OF PROGRESS

For brevity, let us denote

$$L := L_{3k+K}, \quad \alpha := \alpha_{k+K}, \quad c := L/\alpha,$$

where we call the quantity c as the condition number of the problem. It is also crucial to measure the ℓ_2-norm of the gradient restricted on sparse directions, and we write

$$\left\|\nabla_{3k+K}F(\boldsymbol{x})\right\|_2 := \max_{\Omega}\left\{\left\|\mathcal{P}_{\Omega}\left(\nabla F(\boldsymbol{x})\right)\right\|_2:\ |\Omega| \le 3k+K\right\}.$$

Note that for convex programs, the above evaluated at a global optimum is zero. As will be clear, $\left\|\nabla_{3k+K}F(\boldsymbol{x})\right\|_2$ reflects how close the iterates returned by HT-SVRG can be to the point $\boldsymbol{x}$. For prevalent statistical models, it vanishes when there are sufficient samples. Related to this quantity, our analysis also involves

$$Q(\boldsymbol{x}) := \left(16\nu\eta^2 L\omega m + \frac{2\omega}{\alpha}\right)\left\|\nabla_{3k+K}F(\boldsymbol{x})\right\|_2 + 4\nu\eta^2 m\left\|\nabla_{3k+K}F(\boldsymbol{x})\right\|_2^2,$$

where we recall that ν is the expansiveness factor given by Theorem 1, η and m are used in the algorithm and ω is a universal constant that upper bounds the ℓ_2-norm of the signal we hope to estimate. Virtually, with an appropriate parameter setting, $Q(\boldsymbol{x})$ scales as $\left\|\nabla_{3k+K}F(\boldsymbol{x})\right\|_2$ which will be clarified. For a particular stage s, we denote $\mathcal{I}^s := \{i_1, i_2, \cdots, i_m\}$, i.e., the samples randomly chosen for updating the solution.

Theorem 10 *Consider Algorithm 1 and a K-sparse signal $\widehat{\boldsymbol{x}}$ of interest. Assume $(A1)$ and $(A2)$. Pick the step size $0 < \eta < 1/(4L)$. If $\nu < 4L/(4L-\alpha)$, then it holds that*

$$\mathbb{E}\left[F(\widetilde{\boldsymbol{x}}^s) - F(\widehat{\boldsymbol{x}})\right] \le \beta^s\left[F(\widetilde{\boldsymbol{x}}^0) - F(\widehat{\boldsymbol{x}})\right] + \tau(\widehat{\boldsymbol{x}}),$$

where the expectation is taken over $\{\mathcal{I}^1, j^1, \mathcal{I}^2, j^2, \cdots, \mathcal{I}^s, j^s\}$ and $0 < \beta < 1$ provided that m is large enough. In particular, for $1/(1-\eta\alpha) < \nu < 4L/(4L-\alpha)$, we have

$$\beta = \beta_1 := \frac{1}{\left(2\nu\eta\alpha - 2\nu\eta^2\alpha L - \nu + 1\right)m} + \frac{2\nu\eta^2\alpha L}{2\nu\eta\alpha - 2\nu\eta^2\alpha L - \nu + 1},$$
$$\tau(\widehat{\boldsymbol{x}}) = \tau_1(\widehat{\boldsymbol{x}}) := \frac{\alpha Q(\widehat{\boldsymbol{x}})}{2(2\nu\eta\alpha - 2\nu\eta^2\alpha L - \nu + 1)(1-\beta_1)m}.$$

For $\nu \le 1/(1-\eta\alpha)$, we have

$$\beta = \beta_2 := \frac{1}{\nu\eta\alpha(1-2\eta L)m} + \frac{2\eta L}{1-2\eta L}, \quad \tau(\widehat{\boldsymbol{x}}) = \tau_2(\widehat{\boldsymbol{x}}) := \frac{Q(\widehat{\boldsymbol{x}})}{2\nu\eta\alpha(1-2\eta L)(1-\beta_2)m}.$$

The proof can be found in Appendix D.1.

Remark 11 *For the theorem to hold,* $\sqrt{\nu} < \sqrt{4L/(4L-\alpha)} \leq \sqrt{4/3} \approx 1.15$ *due to* $L \geq \alpha$. *Hence, the conventional bound* (1.1) *is not applicable. In contrast, Theorem 1 asserts that this condition can be fulfilled by tuning* k *slightly larger than* K.

Remark 12 *With the conditions on* η *and* ν, *the coefficient* β *is always less than one provided that* m *is sufficiently large.*

Remark 13 *The theorem does* not *assert convergence to an arbitrary sparse vector* $\widehat{\boldsymbol{x}}$. *This is because* $F(\widetilde{\boldsymbol{x}}^s) - F(\widehat{\boldsymbol{x}})$ *might be less than zero. However, specifying* $\widehat{\boldsymbol{x}}$ *does give convergence results, as to be elaborated later.*

4.2.3 HYPER-PARAMETER SETTING

Before moving on to the convergence guarantee, let us discuss the minimum requirement on the hyper-parameters k, m and η, and determine how to choose them to simplify Theorem 10.

For the sake of success of HT-SVRG, we require $\nu < 4c/(4c-1)$, which implies $\rho < 1/(16c^2 - 4c)$. Recall that ρ is given in Theorem 1. In general, we are interested in the regime $K \leq k \ll d$. Hence, we have $\rho = K/k$ and the minimum requirement for the sparsity parameter is

$$k > (16c^2 - 4c)K. \tag{4.2}$$

To our knowledge, the idea of relaxed sparsity was first introduced in Zhang (2011) for OMP and in Jain et al. (2014) for projected gradient descent. However, the relaxed sparsity here emerges in a different way in that HT-SVRG is a stochastic algorithm, and their proof technique cannot be used.

We also contrast our tight bound to the inequality (2.10) that is obtained by combining the triangle inequality and Lemma 1 of Jain et al. (2014). Following our proof pipeline, (2.10) gives

$$k \geq \left(1 - \left(\sqrt{4c(4c-1)^{-1}} - 1\right)^2\right) d + \left(\sqrt{4c(4c-1)^{-1}} - 1\right)^2 K$$

which grows with the dimension d, whereas using Theorem 1 the sparsity parameter k depends only on the desired sparsity K. In this regard, we conclude that for the stochastic case, our bound is vital.

Another component of the algorithm is the update frequency m. Intuitively, HT-SVRG performs m number of stochastic gradient update followed by a full gradient evaluation, in order to mitigate the variance. In this light, m should not be too small. Otherwise, the algorithm reduces to the full gradient method which is not computationally efficient. On the other spectrum, a large m leads to a slow convergence that is reflected in the convergence coefficient β. To quantitatively analyze how m should be selected, let us consider the case $\nu \leq 1/(1-\eta\alpha)$ for example. The case $1/(1-\eta\alpha) < \nu < 4L/(4L-\alpha)$ follows in a similar way. In order to ensure $\beta_2 < 1$, we must have $m > 1/\left(\nu\eta\alpha(1-4\eta L)\right)$. In particular, picking

$$\eta = \frac{\eta'}{L}, \quad \eta' \in (0, 1/4), \tag{4.3}$$

we find that the update frequency m has to satisfy

$$m > \frac{c}{\nu\eta'(1-\eta')}, \tag{4.4}$$

which is of the same order as in the convex case (Johnson and Zhang, 2013) when $\eta' = \Theta(1)$. Note that the way we choose the learning rate $\eta = \eta'/L$ is also a common practice in convex optimization (Nesterov, 2004).

With (4.2), (4.3) and (4.4) in mind, we provide detailed choices of the hyper-parameters. Due to $0 < \eta < 1/(4L)$, β_1 is monotonically increasing with respect to ν. By Theorem 1, we know that ν is decreasing with respect to k. Thus, a larger quantity of k results in a smaller value of β_1, and hence a faster rate. Interestingly, for β_2 we discover that the smaller the k is, the faster the algorithm concentrates. Hence, we have the following consequence:

Proposition 14 *Fix* η *and* m. *Then the optimal choice of* ν *in Theorem 10 is* $\nu = 1/(1-\eta\alpha)$ *in the sense that the convergence coefficient* β *attains the minimum.*

In light of the proposition, in the sections to follow, we will only consider the setting $\nu = 1/(1-\eta\alpha)$. But we emphasize that our analysis and results essentially apply to any $\nu \leq 4L/(4L-\alpha)$.

Now let

$$\eta = \frac{1}{8L}, \quad m = 4(8c-1), \quad k = 8c(8c-1)K. \tag{4.5}$$

This gives

$$\beta = \frac{2}{3}, \quad \tau(\widehat{\boldsymbol{x}}) = \frac{5\omega}{\alpha}\left\|\nabla_{3k+K}F(\widehat{\boldsymbol{x}})\right\|_2 + \frac{1}{\alpha L}\left\|\nabla_{3k+K}F(\widehat{\boldsymbol{x}})\right\|_2^2. \tag{4.6}$$

4.2.4 GLOBAL LINEAR CONVERGENCE

We are in the position to state the global linear convergence to an optimum of the sparsity-constrained optimization program (4.1).

Corollary 15 *Assume* $(A1)$ *and* $(A2)$. *Consider the HT-SVRG algorithm with hyper-parameters given in* (4.5). *Then the sequence* $\{\widetilde{\boldsymbol{x}}^s\}_{s\geq 1}$ *converges linearly to a global optimum* $\boldsymbol{x}_{\rm opt}$ *of* (4.1)

$$\begin{aligned}\mathbb{E}\left[F(\widetilde{\boldsymbol{x}}^s) - F(\boldsymbol{x}_{\rm opt})\right] \leq &\left(\frac{2}{3}\right)^s \left[F(\widetilde{\boldsymbol{x}}^0) - F(\boldsymbol{x}_{\rm opt})\right] \\ &+ \frac{5\omega}{\alpha}\left\|\nabla_{3k+K}F(\boldsymbol{x}_{\rm opt})\right\|_2 + \frac{1}{\alpha L}\left\|\nabla_{3k+K}F(\boldsymbol{x}_{\rm opt})\right\|_2^2.\end{aligned}$$

Proof This is a direct consequence of Theorem 10. ■

Whenever $\nabla_{3k+K}F(\boldsymbol{x}_{\rm opt}) = \boldsymbol{0}$, the corollary reads as

$$\mathbb{E}\left[F(\widetilde{\boldsymbol{x}}^s) - F(\boldsymbol{x}_{\rm opt})\right] \leq \left(\frac{2}{3}\right)^s \left[F(\widetilde{\boldsymbol{x}}^0) - F(\boldsymbol{x}_{\rm opt})\right].$$

It implies that if one is solving a convex problem without the sparsity constraint but the optimal solution happens to be sparse, it is safe to perform hard thresholding without loss of optimality. We exemplify such behavior with another algorithm SAGA (Defazio et al., 2014) in Appendix E. In the noiseless compressed sensing setting where $\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x}^*$, the corollary guarantees that HT-SVRG exactly recovers the underlying true signal $\boldsymbol{x}^*$ when $F(\boldsymbol{x})$ is chosen as the least-squares loss in that $\boldsymbol{x}_{\rm opt} = \boldsymbol{x}^*$ and $\nabla F(\boldsymbol{x}^*) = \boldsymbol{A}^\top(\boldsymbol{A}\boldsymbol{x}^* - \boldsymbol{y}) = \boldsymbol{0}$.

On the other side, the RSC property implies that

$$\left\|\widetilde{\boldsymbol{x}}^s - \widehat{\boldsymbol{x}}\right\|_2 \leq \sqrt{\frac{2\max\{F(\widetilde{\boldsymbol{x}}^s) - F(\widehat{\boldsymbol{x}}), 0\}}{\alpha}} + \frac{2\left\|\nabla_{k+K}F(\widehat{\boldsymbol{x}})\right\|_2}{\alpha}.$$

The proof is straightforward and can be found in Lemma 14 of Shen and Li (2017a). Now we specify $\widehat{\boldsymbol{x}}$ as the true parameter of some statistical model, for instance, $\boldsymbol{x}^*$ in (3.1). It is hence possible to establish recovery guarantee of $\boldsymbol{x}^*$, which is known as the problem of parameter estimation.

Corollary 16 *Assume* $(A1)$ *and* $(A2)$. *Let* L' *be the RSS parameter of* $F(\boldsymbol{x})$ *at the sparsity level* $3k+K$. *Consider the HT-SVRG algorithm with hyper-parameters given in* (4.5). *Then the sequence* $\{\widetilde{\boldsymbol{x}}^s\}_{s\geq 1}$ *recovers a* K*-sparse signal* $\boldsymbol{x}^*$ *with a geometric rate*

$$\mathbb{E}\left[\left\|\widetilde{\boldsymbol{x}}^s-\boldsymbol{x}^*\right\|_2\right] \leq \sqrt{\frac{2L'}{\alpha}}\cdot\left(\frac{2}{3}\right)^{\frac{s}{2}}\left\|\widetilde{\boldsymbol{x}}^0-\boldsymbol{x}^*\right\|_2+\sqrt{\frac{10\omega}{\alpha^2}\left\|\nabla_{3k+K}F(\boldsymbol{x}^*)\right\|_2} + \left(\sqrt{\frac{2}{\alpha^3}}+\frac{3}{\alpha}\right)\left\|\nabla_{3k+K}F(\boldsymbol{x}^*)\right\|_2.$$

The proof can be found in Appendix D.2.

Remark 17 *The RSS parameter* L' *of* $F(\boldsymbol{x})$ *always ranges in* $[\alpha, L]$, *which is simply by definition.*

4.2.5 COMPUTATIONAL COMPLEXITY

We compare the computational complexity of HT-SVRG to that of projected gradient descent (PGD) studied in Jain et al. (2014), which is a batch counterpart to HT-SVRG. First, we remark that the analysis of PGD is based on the smoothness parameter L' of $F(\boldsymbol{x})$ at sparsity level $2k+K$. We write $c'=L'/\alpha$. To achieve a given accuracy $\epsilon>0$, PGD requires $\mathcal{O}\left(c'\log(1/\epsilon)\right)$ iterations. Hence the total computational complexity is $\mathcal{O}\left(nc'd\log(1/\epsilon)\right)$. For HT-SVRG, in view of Corollary 15, the convergence coefficient is a constant. Hence, HT-SVRG needs $\mathcal{O}\left(\log(1/\epsilon)\right)$ iterations where we note that the error term $\left\|\nabla_{3k+K}F(\boldsymbol{x}^*)\right\|_2$ can be made as small as ϵ with sufficient samples (to be clarified in the sequel). In each stage, HT-SVRG computes a full gradient $\widetilde{\boldsymbol{\mu}}$ followed by m times stochastic updates. Therefore, the total complexity of HT-SVRG is given by $\mathcal{O}\left((n+c)d\log(1/\epsilon)\right)$ by noting the fact $m=\mathcal{O}\left(c\right)$. In the scenario $c<n(c'-1)$, HT-SVRG significantly improves on PGD in terms of time cost.

4.3 Statistical Results

The last ingredient of our theorem is the term $\tau(\widehat{\boldsymbol{x}})$ which measures how close the iterates could be to a given sparse signal $\widehat{\boldsymbol{x}}$. With appropriate hyper-parameter settings, the quantity relies exclusively on $\left\|\nabla_{3k+K}F(\widehat{\boldsymbol{x}})\right\|_2$, as suggested by (4.6). Thereby, this section is dedicated to characterizing $\left\|\nabla_{3k+K}F(\widehat{\boldsymbol{x}})\right\|_2$. We will also give examples for which HT-SVRG is computationally more efficient than PGD. For the purpose of a concrete result, we study two problems: sparse linear regression and sparse logistic regression. These are two of the most popular statistical models in the literature and have found a variety of applications in machine learning and statistics (Raskutti et al., 2011). Notably, it is known that similar statistical results can be built for low-rank matrix regression, sparse precision matrix estimation, as suggested in Negahban et al. (2009); Agarwal et al. (2012).

4.3.1 SPARSE LINEAR REGRESSION

For sparse linear regression, the observation model is given by

$$\boldsymbol{y}=\boldsymbol{A}\boldsymbol{x}^*+\boldsymbol{\varepsilon},\quad \left\|\boldsymbol{x}^*\right\|_0\leq K,\ \left\|\boldsymbol{x}^*\right\|_2\leq\omega, \tag{4.7}$$

where $\boldsymbol{A}\in\mathbb{R}^{n\times d}$ is the design matrix, $\boldsymbol{y}\in\mathbb{R}^n$ is the response, $\boldsymbol{\varepsilon}\in\mathbb{R}^n$ is some noise, and $\boldsymbol{x}^*$ is the K-sparse true parameter we hope to estimate from the knowledge of $\boldsymbol{A}$ and $\boldsymbol{y}$. Note that when we have the additional constraint $n\ll d$, the model above is exactly that of compressed sensing (3.1).

In order to (approximately) estimate the parameter, a natural approach is to optimize the following non-convex program:

$$\min_{\boldsymbol{x}}\ F(\boldsymbol{x}):=\frac{1}{2n}\sum_{i=1}^{n}\left\|y_i-\boldsymbol{a}_i\cdot\boldsymbol{x}\right\|_2^2,\quad \text{s.t. } \left\|\boldsymbol{x}\right\|_0\leq K,\ \left\|\boldsymbol{x}\right\|_2\leq\omega. \tag{4.8}$$

For our analysis, we assume the following on the design matrix and the noise:

$(A3)$ $\boldsymbol{a}_1,\boldsymbol{a}_2,\ldots,\boldsymbol{a}_n$ are independent and identically distributed (i.i.d.) Gaussian random vectors $N(\boldsymbol{0},\boldsymbol{\Sigma})$. All the diagonal elements of $\boldsymbol{\Sigma}$ satisfy $\Sigma_{jj}\leq 1$. The noise $\boldsymbol{\varepsilon}$ is independent of $\boldsymbol{A}$ and its entries are i.i.d. Gaussian random variables $N(0,\sigma^2)$.

Proposition 18 *Consider the sparse linear regression model* (4.7) *and the program* (4.8). *Assume* $(A3)$. *Then for a sparsity level* r,

- *with probability at least* $1-\exp(-\mathrm{C}_0 n)$,

$$\alpha_r=\lambda_{\min}(\boldsymbol{\Sigma})-\mathrm{C}_1\frac{r\log d}{n},\quad L_r'=\lambda_{\max}(\boldsymbol{\Sigma})+\mathrm{C}_2\frac{r\log d}{n};$$

- *with probability at least* $1-\mathrm{C}_3 r/d$

$$L_r=\mathrm{C}_4 r\log d;$$

- *and with probability at least* $1-\mathrm{C}_5/d$

$$\left\|\nabla_r F(\boldsymbol{x}^*)\right\|_2\leq\mathrm{C}_6\sigma\sqrt{\frac{r\log d}{n}},\quad \left\|\nabla_r F(\boldsymbol{x}_{\mathrm{opt}})\right\|_2\leq L_r'\left\|\boldsymbol{x}_{\mathrm{opt}}-\boldsymbol{x}^*\right\|_2+\mathrm{C}_6\sigma\sqrt{\frac{r\log d}{n}}.$$

Above, $\lambda_{\min}(\boldsymbol{\Sigma})$ *and* $\lambda_{\max}(\boldsymbol{\Sigma})$ *are the minimum and maximum singular values of* $\boldsymbol{\Sigma}$ *respectively.*

We recall that α_r and L_r are involved in our assumptions $(A1)$ and $(A2)$, and L_r' is the RSS parameter of $F(\boldsymbol{x})$. The estimation for α_r, L_r' and $\left\|\nabla_r F(\boldsymbol{x}^*)\right\|_2$ follows from standard results in the literature (Raskutti et al., 2011), while that for L_r follows from Proposition E.1 in Bellec et al. (2016) by noting the fact that bounding L_r amounts to estimating $\max_i\left\|\mathcal{H}_r(\boldsymbol{a}_i)\right\|_2^2$. In order to estimate $\left\|\nabla_r F(\boldsymbol{x}_{\mathrm{opt}})\right\|_2$, notice that

$$\begin{aligned}\left\|\nabla_r F(\boldsymbol{x}_{\mathrm{opt}})\right\|_2 &\leq \left\|\nabla_r F(\boldsymbol{x}_{\mathrm{opt}})-\nabla_r F(\boldsymbol{x}^*)\right\|_2+\left\|\nabla_r F(\boldsymbol{x}^*)\right\|_2\\ &\leq \left\|\nabla F(\boldsymbol{x}_{\mathrm{opt}})-\nabla F(\boldsymbol{x}^*)\right\|_2+\left\|\nabla_r F(\boldsymbol{x}^*)\right\|_2\\ &\leq L_r'\left\|\boldsymbol{x}_{\mathrm{opt}}-\boldsymbol{x}^*\right\|_2+\left\|\nabla_r F(\boldsymbol{x}^*)\right\|_2,\end{aligned}$$

where we use the definition of RSS in the last inequality.

Now we let $r=3k+K=\mathrm{const}\cdot c^2K$ and get $\alpha=\lambda_{\min}(\boldsymbol{\Sigma})-\mathrm{C}_1\frac{c^2K\log d}{n}$, $L=\mathrm{C}_4c^2K\log d$. Suppose that $\lambda_{\min}(\boldsymbol{\Sigma})=2\mathrm{C}_4(K\log d)^2$ and $n=q\cdot\frac{\mathrm{C}_1}{\mathrm{C}_4}K\log d$ with $q\geq 1$. Then our assumptions $(A1)$ and $(A2)$ are met with high probability with

$$\alpha=\mathrm{C}_4(K\log d)^2,\ L=\mathrm{C}_4(K\log d)^3,\ \text{and } c=K\log d.$$

For Corollary 15, as far as

$$s \geq \mathrm{C}_7 \log\left(\frac{F(\widetilde{\boldsymbol{x}}^0) - F(\boldsymbol{x}_{\mathrm{opt}})}{\epsilon}\right),\ n = \mathrm{C}_7\left(\omega\sigma\right)^2 \epsilon^{-2} K \log d,$$

we have

$$\mathbb{E}\left[F(\widetilde{\boldsymbol{x}}^s) - F(\boldsymbol{x}_{\mathrm{opt}})\right] \leq \epsilon + \frac{\lambda_{\max}(\boldsymbol{\Sigma})}{\lambda_{\min}(\boldsymbol{\Sigma})}\left\|\boldsymbol{x}_{\mathrm{opt}} - \boldsymbol{x}^*\right\|_2 + \left(\frac{\lambda_{\max}(\boldsymbol{\Sigma})}{\lambda_{\min}(\boldsymbol{\Sigma})}\left\|\boldsymbol{x}_{\mathrm{opt}} - \boldsymbol{x}^*\right\|_2\right)^2$$

for some accuracy parameter $\epsilon > 0$. This suggests that it is possible for HT-SVRG to approximate a global optimum of (4.1) up to $\left\|\boldsymbol{x}_{\mathrm{opt}} - \boldsymbol{x}^*\right\|_2$, namely the statistical precision of the problem.

Returning to Corollary 16, to guarantee that

$$\mathbb{E}\left[\left\|\widetilde{\boldsymbol{x}}^s - \boldsymbol{x}^*\right\|_2\right] \leq \epsilon,$$

it suffices to pick

$$s \geq \mathrm{C}_8 \log(\omega\sqrt{c'}/\epsilon), \quad n = \mathrm{C}_8(\omega\sigma)^2\epsilon^{-4} K \log d.$$

Finally, we compare the computational cost to PGD. It is not hard to see that under the same situation $\lambda_{\min}(\boldsymbol{\Sigma}) = 2\mathrm{C}_4(K\log d)^2$ and $n = \frac{\mathrm{C}_1}{\mathrm{C}_4} K \log d$,

$$L' = \mathrm{C}_4(K\log d)^3,\ c' = K\log d,\ \text{provided that } \lambda_{\max}(\boldsymbol{\Sigma}) = \mathrm{C}_4(K\log d)^3 - \frac{\mathrm{C}_2\mathrm{C}_4}{\mathrm{C}_1}(K\log d)^2.$$

Thus $c < n(c'-1)$, i.e., HT-SVRG is more efficient than PGD. It is also possible to consider other regimes of the covariance matrix and the sample size, though we do not pursue it here.

4.3.2 SPARSE LOGISTIC REGRESSION

For sparse logistic regression, the observation model is given by

$$\Pr(y_i \mid \boldsymbol{a}_i;\, \boldsymbol{x}^*) = \frac{1}{1+\exp(-y_i\boldsymbol{a}_i\cdot\boldsymbol{x}^*)}, \quad \|\boldsymbol{x}^*\|_0 \leq K,\ \|\boldsymbol{x}\|_2 \leq \omega,\ \forall\, 1 \leq i \leq n, \tag{4.9}$$

where y_i is either 0 or 1. It then learns the parameter by minimizing the negative log-likelihood:

$$\min_{\boldsymbol{x}}\ F(\boldsymbol{x}) \coloneqq \frac{1}{n}\sum_{i=1}^{n}\log\left(1+\exp(-y_i\boldsymbol{a}_i\cdot\boldsymbol{x})\right), \quad \text{s.t. } \|\boldsymbol{x}\|_0 \leq K,\ \|\boldsymbol{x}\|_2 \leq \omega. \tag{4.10}$$

There is a large body of work showing that the statistical property is rather analogous to that of linear regression. See, for example, Negahban et al. (2009). In fact, the statistical results apply to generalized linear models as well.

4.4 A Concurrent Work

After we posted the first version Shen and Li (2016) on arXiv, Li et al. (2016) made their work public where a similar algorithm to HT-SVRG was presented. Their theoretical analysis applies to convex objective functions while we allow the function $F(\boldsymbol{x})$ to be non-convex. We also fully characterize the convergence behavior of the algorithm by showing the trade-off between the sparsity parameter k and the convergence coefficient β (Proposition 14).

5. Experiments

In this section, we present a comprehensive empirical study for the proposed HT-SVRG algorithm on two tasks: sparse recovery (compressed sensing) and image classification. The experiments on sparse recovery is dedicated to verifying the theoretical results we presented, and we visualize the classification models learned by HT-SVRG to demonstrate the practical efficacy.

5.1 Sparse Recovery

To understand the practical behavior of our algorithm as well as to justify the theoretical analysis, we perform experiments on synthetic data. The experimental settings are as follows:

- **Data Generation.** The data dimension d is fixed as 256 and we generate an $n \times d$ Gaussian random sensing matrix $\boldsymbol{A}$ whose entries are i.i.d. with zero mean and variance $1/n$. Then 1000 K-sparse signals $\boldsymbol{x}^*$ are independently generated, where the support of each signal is uniformly chosen. That is, we run our algorithm and the baselines for 1000 trials. The measurements $\boldsymbol{y}$ for each signal $\boldsymbol{x}^*$ is obtained by $\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x}^*$ which is noise free. In this way, we are able to study the convergence rate by plotting the logarithm of the objective value since the optimal objective value is known to be zero.

- **Baselines.** We mainly compare with two closely related algorithms: IHT and PGD. Both of them compute the full gradient of the least-squares loss followed by hard thresholding. Yet, PGD is more general, in the sense that it allows the sparsity parameter k to be larger than the true sparsity K ($k = K$ for IHT) and also considers a flexible step size η ($\eta = 1$ for IHT). Hence, PGD can be viewed as a batch counterpart to our method HT-SVRG.

- **Evaluation Metric.** We say a signal $\boldsymbol{x}^*$ is successfully recovered by a solution $\boldsymbol{x}$ if

$$\frac{\|\boldsymbol{x} - \boldsymbol{x}^*\|_2}{\|\boldsymbol{x}^*\|_2} < 10^{-3}.$$

  In this way, we can compute the percentage of success over the 1000 trials for each algorithm.

- **Hyper-Parameters.** If not specified, we use $m = 3n$, $k = 9K$, and $S = 10000$ for HT-SVRG. We also use the heuristic step size $\eta = 2/\mathrm{svds}(\boldsymbol{A}\boldsymbol{A}^\top)$ for HT-SVRG and PGD, where $\mathrm{svds}(\boldsymbol{A}\boldsymbol{A}^\top)$ returns the largest singular value of the matrix $\boldsymbol{A}\boldsymbol{A}^\top$. Since for each stage, HT-SVRG computes the full gradient for $(2m/n+1)$ times, we run the IHT and PGD for $(2m/n+1)S$ iterations for fair comparison, i.e., all of the algorithms have the same number of full gradient evaluations.

5.1.1 PHASE TRANSITION

Our first simulation aims at offering a big picture on the recovery performance. To this end, we vary the number of measurements n from 1 to 256, roughly with a step size 8. We also study the performance with respect to the true sparsity parameter K, which ranges from 1 to 26, roughly with step size 2. The results are illustrated in Figure 1, where a brighter block means a higher percentage of success and the brightest ones indicate exact sparse recovery. It is apparent that PGD and HT-SVRG require fewer measurements for an accurate recovery than IHT, possibly due to the flexibility in choosing the sparsity parameter and the step size. We also observe that as a stochastic algorithm,

HT-SVRG performs comparably to PGD. This suggests that HT-SVRG is an appealing solution to large-scale sparse learning problems in that HT-SVRG is computationally more efficient.

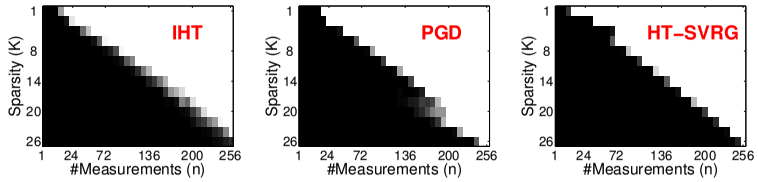

Figure 1: **Percentage of successful recovery under various sparsity and sample size.** The values range from 0 to 100, where a brighter color means a higher percentage of success (the brightest blocks correspond to the value of 100). PGD admits a higher percentage of recovery compared to IHT because it flexibly chooses the step size and sparsity parameter. As a stochastic variant, HT-SVRG performs comparably to the batch counterpart PGD.

In Figure 2, we exemplify some of the results obtained from HT-SVRG by plotting two kinds of curves: the success of percentage against the sample size n and that against the signal sparsity K. In this way, one can examine the detailed values and can determine the minimum sample size for a particular sparsity. For instance, the left panel tells that to ensure that 80% percents of the 16-sparse signals are recovered, we have to collect 175 measurements. We can also learn from the right panel that using 232 measurements, any signal whose sparsity is 22 or less can be reliably recovered.

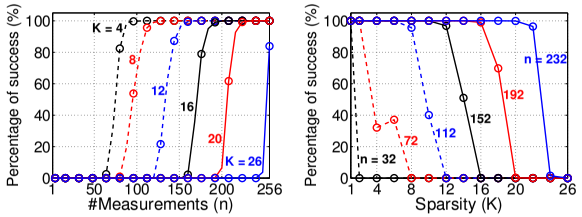

Figure 2: **Percentage of success of HT-SVRG against the number of measurements (left) and the sparsity (right).**

Based on the results in Figure 1 and Figure 2, we have an approximate estimation on the minimum requirement of the sample size which ensures accurate (or exact) recovery. Now we are to investigate how many measurements are needed to guarantee a success percentage of 95% and 99%. To this end, for each signal sparsity K, we look for the number of measurements n_0 from Figure 1 where 90 percents of success are achieved. Then we carefully enlarge n_0 with step size 1 and run the algorithms. The empirical results are recorded in Figure 3, where the circle markers represent the empirical results with different colors indicating different algorithms, e.g., red circle for empirical observation of HT-SVRG. Then we fit these empirical results by linear regression, which are

plotted as solid or dashed lines. For example, the green line is a fitted model for IHT. We find that n is almost linear with K. Especially, the curve of HT-SVRG is nearly on top of that of PGD, which again verifies HT-SVRG is an attractive alternative to the batch method.

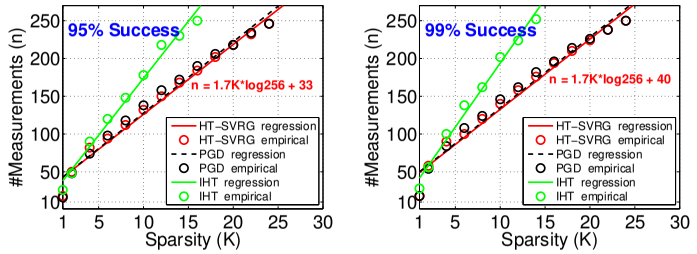

Figure 3: **Minimum number of measurements to achieve 95% and 99% percentage of success.** Red equation indicates the linear regression of HT-SVRG. The markers and curves for HT-SVRG are almost on top of PGD, which again justifies that HT-SVRG is an appealing stochastic alternative to the batch method PGD.

5.1.2 INFLUENCE OF HYPER-PARAMETERS

Next, we turn to investigate the influence of the hyper-parameters, i.e., the sparsity parameter k, update frequency m and step size η on the convergence behavior of HT-SVRG. We set the true sparsity $K = 4$ and collect 100 measurements for each groundtruth signal, i.e., $n = 100$. Note that the standard setting we employed is $k = 9K = 36$, $m = 3n = 300$ and $\eta = 2/\mathrm{svds}(\boldsymbol{A}\boldsymbol{A}^\top) \approx 0.3$. Each time we vary one of these parameters while fixing the other two, and the results are plotted in Figure 4. We point out that although the convergence result (Theorem 10) is deterministic, the vanishing optimization error (Proposition 18) is guaranteed under a probabilistic argument. Hence, it is possible that for a specific configuration of parameters, 97% of the signals are exactly recovered but HT-SVRG fails on the remaining, as we have observed in, e.g., Figure 2. Clearly, we are not supposed to average all the results to examine the convergence rate. For our purpose, we set a threshold 95%, that is, we average over the success trials if more than 95% percents of the signals are exactly recovered. Otherwise, we say that the set of parameters cannot ensure convergence and we average over these failure signals which will give an illustration of divergence.

The left panel of Figure 4 verifies the condition that k has to be larger than K, while the second panel shows the update frequency m can be reasonably small in the price of a slow convergence rate. Finally, the empirical study demonstrates that our heuristic choice $\eta = 0.3$ works well, and when $\eta > 3$, the objective value exceeds 10^{120} within 3 stages (which cannot be depicted in the figure). For very small step sizes, we plot the convergence curve by gradually enlarging the update frequency m in Figure 5. The empirical results agree with Theorem 10 that for any $0 < \eta < 1/(4L)$, HT-SVRG converges as soon as m is large enough.

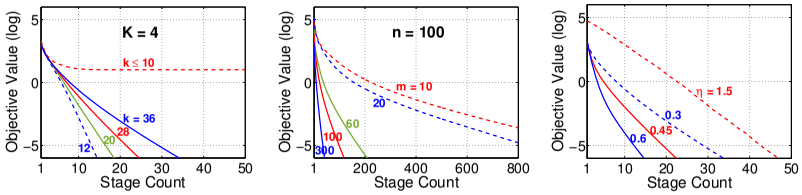

Figure 4: **Convergence of HT-SVRG with different parameters.** We have 100 measurements for the 256-dimensional signal where only 4 elements are non-zero. The standard setting is $k = 36$, $m = 300$ and $\eta = 0.3$. **Left:** If the sparsity parameter k is not large enough, HT-SVRG will not recover the signal. **Middle:** A small m leads to a frequent full gradient evaluation and hence slow convergence. **Right:** We observe divergence when $\eta \geq 3$.

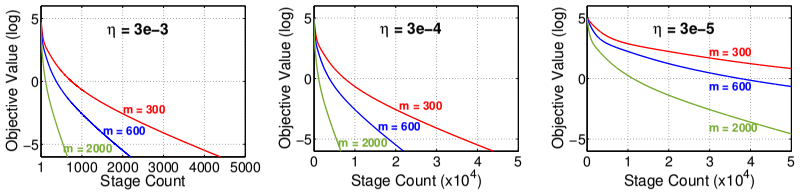

Figure 5: **Convergence behavior under small step size.** We observe that as long as we pick a sufficiently large value for m, HT-SVRG always converges. This is not surprising since our theorem guarantees for any $\eta < 1/(4L)$, HT-SVRG will converge if m is large enough. Also note that the geometric convergence rate is observed after certain iterations, e.g., for $\eta = 3 \times 10^{-5}$, the log(error) decreases linearly after 20 thousands iterations.

5.2 Classification

In addition to the application of sparse recovery, we illustrated that HT-SVRG can deal with binary classification by minimizing the sparse logistic regression problem (4.10). Here, we study the performance on a realistic image dataset MNIST[1], consisting of 60 thousands training samples and 10 thousands samples for testing. There is one digit on each image of size 28-by-28, hence totally 10 classes. Some of the images are shown in Figure 6.

The update frequency m is fixed as $m = 3n$. We compute the heuristic step size η as in the previous section, i.e., $\eta = 2/\mathrm{svds}(\boldsymbol{A}\boldsymbol{A}^\top) \approx 10^{-3}$. Since for the real-world dataset, the true sparsity is actually unknown, we tune the sparsity parameter k and study the performance of the algorithm.

First, we visualize five pair-wise models learned by HT-SVRG in Figure 7, where each row is associated with a binary classification task indicated by the two digits at the leading of the row, and the subsequent red-blue figures are used to illustrate the learned models under different sparsity parameter. For example, the third colorful figure depicted on the second row corresponds to recognizing a digit is "1" or "7" with the sparsity $k = 30$. In particular, for each pair, we label the small digit as positive and the large one as negative, and the blue and red pixels are the weights with positive and negative values respectively. Apparently, the models we learned are discriminative.

1. http://yann.lecun.com/exdb/mnist/

Figure 6: **Sample images in the MNIST database.**

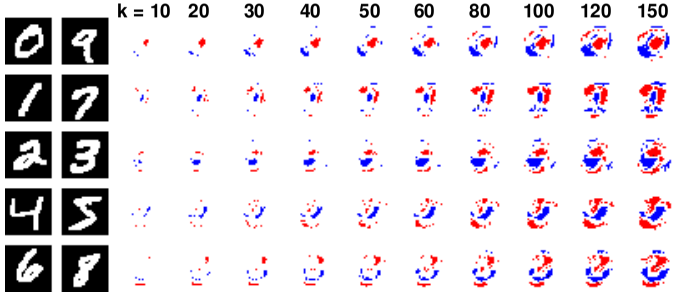

Figure 7: **Visualization of the models.** We visualize 5 models learned by HT-SVRG under different choices of sparsity shown on the top of each column. Note that the feature dimension is 784. From the top row to the bottom row, we illustrate the models of "0 vs 9", "1 vs 7", "2 vs 3", "4 vs 5" and "6 vs 8", where for each pair, we label the small digit as positive and the large one as negative. The red color represents negative weights while the blue pixels correspond with positive weights.

We also quantitatively show the convergence and prediction accuracy curves in Figure 8. Note that here, the y-axis is the objective value $F(\widetilde{\boldsymbol{x}}^s)$ rather than $\log(F(\widetilde{\boldsymbol{x}}^s) - F(\boldsymbol{x}_{\mathrm{opt}}))$, due to the fact that computing the exact optimum of (4.10) is NP-hard. Generally speaking, HT-SVRG converges quite fast and usually attains the minimum of objective value within 20 stages. It is not surprising to see that choosing a large quantity for the sparsity leads to a better (lower) objective value. However,

in practice a small assignment for the sparsity, e.g., $k = 70$ facilitates an efficient computation while still suffices to ensure fast convergence and accurate prediction.

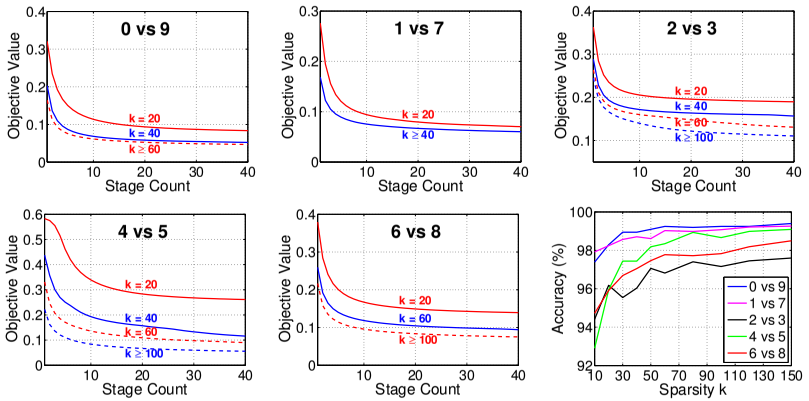

Figure 8: **Quantitative results on convergence and accuracy.** The first 5 figures demonstrate the convergence behavior of HT-SVRG for each binary classification task, where curves with different colors represent the objective value against number of stages under different sparsity k. Generally speaking, HT-SVRG converges within 20 stages which is a very fast rate. The last figure reflects the classification accuracy against the sparsity for all 5 classification tasks, where we find that for a moderate choice, e.g., $k = 70$, it already guarantees an accurate prediction (we recall the dimension is 784).

6. Conclusion and Open Problems

In this paper, we have provided a tight bound on the deviation resulting from the hard thresholding operator, which underlies a vast volume of algorithms developed for sparsity-constrained problems. Our derived bound is universal over all choices of parameters and we have proved that it cannot be improved without further information on the signals. We have discussed the implications of our result to the community of compressed sensing and machine learning, and have demonstrated that the theoretical results of a number of popular algorithms in the literature can be advanced. In addition, we have devised a novel algorithm which tackles the problem of sparse learning in large-scale setting. We have elaborated that our algorithm is guaranteed to produce global optimal solution for prevalent statistical models only when it is equipped with the tight bound, hence justifying that the conventional bound is not applicable in the challenging scenario.

There are several interesting open problems. The first question to ask is whether one can establish sharp RIP condition or sharp phase transition for hard thresholding based algorithms such as IHT and CoSaMP with the tight bound. Moreover, compared to the hard thresholded SGD method (Nguyen et al., 2014), HT-SVRG admits a vanishing optimization error. This poses a

question of whether we are able to provably show the necessity of variance reduction for such a sparsity-constrained problem.

Acknowledgments

We would like to thank Jing Wang for insightful discussion since the early stage of the work. We also thank Martin Slawski for helpful discussion on the statistical precision of the problem, and thank Jian Wang for bringing the paper Nguyen et al. (2014) into our attention. We appreciate Huan Xu's high level comments on the work. Finally, we thank the anonymous reviewers for a careful check on our proof and for the encouraging comments. The work was partially funded by NSF-Bigdata-1419210 and NSF-III-1360971.

Appendix A. Technical Lemmas

We present some useful lemmas that will be invoked by subsequent analysis. The following is a characterization of the co-coercivity of the objective function $F(\boldsymbol{x})$. A similar result was obtained in Nguyen et al. (2014) but we present a refined analysis which is essential for our purpose.

Lemma 19 *For a given support set Ω, assume that the continuous function $F(\boldsymbol{x})$ is $L_{|\Omega|}$-RSS and is α_K-RSC for some sparsity level K. Then, for all vectors $\boldsymbol{x}$ and $\boldsymbol{x}'$ with $|\mathrm{supp}\,(\boldsymbol{x}-\boldsymbol{x}')\cup\Omega| \leq K$,*

$$\left\|\nabla_\Omega F(\boldsymbol{x}') - \nabla_\Omega F(\boldsymbol{x})\right\|_2^2 \leq 2L_{|\Omega|}\big(F(\boldsymbol{x}') - F(\boldsymbol{x}) - \left\langle \nabla F(\boldsymbol{x}), \boldsymbol{x}'-\boldsymbol{x}\right\rangle\big).$$

Proof We define an auxiliary function

$$G(\boldsymbol{w}) := F(\boldsymbol{w}) - \langle \nabla F(\boldsymbol{x}), \boldsymbol{w}\rangle .$$

For all vectors $\boldsymbol{w}$ and $\boldsymbol{w}'$, we have

$$\left\|\nabla G(\boldsymbol{w}) - \nabla G(\boldsymbol{w}')\right\|_2 = \left\|\nabla F(\boldsymbol{w}) - \nabla F(\boldsymbol{w}')\right\|_2 \leq L_{|\mathrm{supp}(\boldsymbol{w}-\boldsymbol{w}')|}\left\|\boldsymbol{w}-\boldsymbol{w}'\right\|_2,$$

which is equivalent to

$$G(\boldsymbol{w}) - G(\boldsymbol{w}') - \left\langle \nabla G(\boldsymbol{w}'), \boldsymbol{w}-\boldsymbol{w}'\right\rangle \leq \frac{L_r}{2}\left\|\boldsymbol{w}-\boldsymbol{w}'\right\|_2^2, \tag{A.1}$$

where $r := |\mathrm{supp}\,(\boldsymbol{w}-\boldsymbol{w}')|$. On the other hand, due to the RSC property of $F(\boldsymbol{x})$, we obtain

$$G(\boldsymbol{w}) - G(\boldsymbol{x}) = F(\boldsymbol{w}) - F(\boldsymbol{x}) - \langle \nabla F(\boldsymbol{x}), \boldsymbol{w}-\boldsymbol{x}\rangle \geq \frac{\alpha_{|\mathrm{supp}(\boldsymbol{w}-\boldsymbol{x})|}}{2}\left\|\boldsymbol{w}-\boldsymbol{x}\right\|_2^2 \geq 0,$$

provided that $|\mathrm{supp}\,(\boldsymbol{w}-\boldsymbol{x})| \leq K$. For the given support set Ω, we pick $\boldsymbol{w} = \boldsymbol{x}' - \frac{1}{L_{|\Omega|}}\nabla_\Omega G(\boldsymbol{x}')$. Clearly, for such a choice of $\boldsymbol{w}$, we have $\mathrm{supp}\,(\boldsymbol{w}-\boldsymbol{x}) = \mathrm{supp}\,(\boldsymbol{x}-\boldsymbol{x}')\cup\Omega$. Hence, by assuming that $|\mathrm{supp}\,(\boldsymbol{x}-\boldsymbol{x}')\cup\Omega|$ is not larger than K, we get

$$\begin{aligned} G(\boldsymbol{x}) &\leq G\left(\boldsymbol{x}' - \frac{1}{L_{|\Omega|}}\nabla_\Omega G(\boldsymbol{x}')\right) \\ &\leq G(\boldsymbol{x}') + \left\langle \nabla G(\boldsymbol{x}'), -\frac{1}{L_{|\Omega|}}\nabla_\Omega G(\boldsymbol{x}')\right\rangle + \frac{1}{2L_{|\Omega|}}\left\|\nabla_\Omega G(\boldsymbol{x}')\right\|_2^2 \\ &= G(\boldsymbol{x}') - \frac{1}{2L_{|\Omega|}}\left\|\nabla_\Omega G(\boldsymbol{x}')\right\|_2^2, \end{aligned}$$

where the second inequality follows from (A.1). Now expanding $\nabla_\Omega G(\boldsymbol{x}')$ and rearranging the terms gives the desired result. ■

Lemma 20 *Consider the HT-SVRG algorithm for a fixed stage s. Let $\widehat{\boldsymbol{x}}$ be the target sparse vector. Let Ω be a support set such that $\operatorname{supp}\left(\boldsymbol{x}^{t-1}\right) \cup \operatorname{supp}\left(\widetilde{\boldsymbol{x}}\right) \cup \operatorname{supp}\left(\widehat{\boldsymbol{x}}\right) \subseteq \Omega$. Put $r = |\Omega|$. Assume (A2). For all $1 \leq t \leq m$, denote $\boldsymbol{v}^t = \nabla f_{i_t}(\boldsymbol{x}^{t-1}) - \nabla f_{i_t}(\widetilde{\boldsymbol{x}}) + \widetilde{\boldsymbol{\mu}}$. Then we have the following:*

$$\begin{aligned}\mathbb{E}_{i_t|\boldsymbol{x}^{t-1}}\left[\left\|\mathcal{P}_\Omega\left(\boldsymbol{v}^t\right)\right\|_2^2\right] \leq\ & 4L_r\left[F(\boldsymbol{x}^{t-1}) - F(\widehat{\boldsymbol{x}})\right] + 4L_r\left[F(\widetilde{\boldsymbol{x}}) - F(\widehat{\boldsymbol{x}})\right] \\ & - 4L_r\left\langle \nabla F(\widehat{\boldsymbol{x}}), \boldsymbol{x}^{t-1} + \widetilde{\boldsymbol{x}} - 2\widehat{\boldsymbol{x}}\right\rangle + 4\left\|\mathcal{P}_\Omega\left(\nabla F(\widehat{\boldsymbol{x}})\right)\right\|_2^2.\end{aligned}$$

Proof We have

$$\begin{aligned}\left\|\mathcal{P}_\Omega\left(\boldsymbol{v}^t\right)\right\|_2^2 =\ & \left\|\mathcal{P}_\Omega\left(\nabla f_{i_t}(\boldsymbol{x}^{t-1}) - \nabla f_{i_t}(\widetilde{\boldsymbol{x}}) + \widetilde{\boldsymbol{\mu}}\right)\right\|_2^2 \\ \leq\ & 2\left\|\mathcal{P}_\Omega\left(\nabla f_{i_t}(\boldsymbol{x}^{t-1}) - \nabla f_{i_t}(\widehat{\boldsymbol{x}})\right)\right\|_2^2 + 2\left\|\mathcal{P}_\Omega\left(\nabla f_{i_t}(\widetilde{\boldsymbol{x}}) - \nabla f_{i_t}(\widehat{\boldsymbol{x}}) - \widetilde{\boldsymbol{\mu}}\right)\right\|_2^2 \\ =\ & 2\left\|\mathcal{P}_\Omega\left(\nabla f_{i_t}(\boldsymbol{x}^{t-1}) - \nabla f_{i_t}(\widehat{\boldsymbol{x}})\right)\right\|_2^2 + 2\left\|\mathcal{P}_\Omega\left(\nabla f_{i_t}(\widetilde{\boldsymbol{x}}) - \nabla f_{i_t}(\widehat{\boldsymbol{x}})\right)\right\|_2^2 \\ & + 2\left\|\mathcal{P}_\Omega\left(\widetilde{\boldsymbol{\mu}}\right)\right\|_2^2 - 4\left\langle \mathcal{P}_\Omega\left(\nabla f_{i_t}(\widetilde{\boldsymbol{x}}) - \nabla f_{i_t}(\widehat{\boldsymbol{x}})\right), \mathcal{P}_\Omega\left(\widetilde{\boldsymbol{\mu}}\right)\right\rangle \\ \overset{\xi_1}{=}\ & 2\left\|\mathcal{P}_\Omega\left(\nabla f_{i_t}(\boldsymbol{x}^{t-1}) - \nabla f_{i_t}(\widehat{\boldsymbol{x}})\right)\right\|_2^2 + 2\left\|\mathcal{P}_\Omega\left(\nabla f_{i_t}(\widetilde{\boldsymbol{x}}) - \nabla f_{i_t}(\widehat{\boldsymbol{x}})\right)\right\|_2^2 \\ & + 2\left\|\mathcal{P}_\Omega\left(\widetilde{\boldsymbol{\mu}}\right)\right\|_2^2 - 4\left\langle \nabla f_{i_t}(\widetilde{\boldsymbol{x}}) - \nabla f_{i_t}(\widehat{\boldsymbol{x}}), \mathcal{P}_\Omega\left(\widetilde{\boldsymbol{\mu}}\right)\right\rangle \\ \overset{\xi_2}{\leq}\ & 4L_r\left[f_{i_t}(\boldsymbol{x}^{t-1}) - f_{i_t}(\widehat{\boldsymbol{x}}) - \left\langle \nabla f_{i_t}(\widehat{\boldsymbol{x}}), \boldsymbol{x}^{t-1} - \widehat{\boldsymbol{x}}\right\rangle\right] \\ & + 4L_r\left[f_{i_t}(\widetilde{\boldsymbol{x}}) - f_{i_t}(\widehat{\boldsymbol{x}}) - \langle \nabla f_{i_t}(\widehat{\boldsymbol{x}}), \widetilde{\boldsymbol{x}} - \widehat{\boldsymbol{x}}\rangle\right] \\ & + 2\left\|\mathcal{P}_\Omega\left(\widetilde{\boldsymbol{\mu}}\right)\right\|_2^2 - 4\left\langle \nabla f_{i_t}(\widetilde{\boldsymbol{x}}) - \nabla f_{i_t}(\widehat{\boldsymbol{x}}), \mathcal{P}_\Omega\left(\widetilde{\boldsymbol{\mu}}\right)\right\rangle,\end{aligned}$$

where ξ_1 is by algebra, ξ_2 applies Lemma 19 and the fact that $|\Omega| = r$.

Taking the conditional expectation, we obtain the following:

$$\begin{aligned}& \mathbb{E}_{i_t|\boldsymbol{x}^{t-1}}\left[\left\|\mathcal{P}_\Omega\left(\boldsymbol{v}^t\right)\right\|_2^2\right] \\ \leq\ & 4L_r\left[F(\boldsymbol{x}^{t-1}) - F(\widehat{\boldsymbol{x}})\right] + 4L_r\left[F(\widetilde{\boldsymbol{x}}) - F(\widehat{\boldsymbol{x}})\right] \\ & - 4L_r\left\langle \nabla F(\widehat{\boldsymbol{x}}), \boldsymbol{x}^{t-1} + \widetilde{\boldsymbol{x}} - 2\widehat{\boldsymbol{x}}\right\rangle + 2\left\langle 2\mathcal{P}_\Omega\left(\nabla F(\widehat{\boldsymbol{x}})\right) - \mathcal{P}_\Omega\left(\widetilde{\boldsymbol{\mu}}\right), \mathcal{P}_\Omega\left(\widetilde{\boldsymbol{\mu}}\right)\right\rangle \\ =\ & 4L_r\left[F(\boldsymbol{x}^{t-1}) - F(\widehat{\boldsymbol{x}})\right] + 4L_r\left[F(\widetilde{\boldsymbol{x}}) - F(\widehat{\boldsymbol{x}})\right] \\ & - 4L_r\left\langle \nabla F(\widehat{\boldsymbol{x}}), \boldsymbol{x}^{t-1} + \widetilde{\boldsymbol{x}} - 2\widehat{\boldsymbol{x}}\right\rangle + \left\|2\mathcal{P}_\Omega\left(\nabla F(\widehat{\boldsymbol{x}})\right)\right\|_2^2 \\ & - \left\|2\mathcal{P}_\Omega\left(\nabla F(\widehat{\boldsymbol{x}})\right) - \mathcal{P}_\Omega\left(\widetilde{\boldsymbol{\mu}}\right)\right\|_2^2 - \left\|\mathcal{P}_\Omega\left(\widetilde{\boldsymbol{\mu}}\right)\right\|_2^2 \\ \leq\ & 4L_r\left[F(\boldsymbol{x}^{t-1}) - F(\widehat{\boldsymbol{x}})\right] + 4L_r\left[F(\widetilde{\boldsymbol{x}}) - F(\widehat{\boldsymbol{x}})\right] \\ & - 4L_r\left\langle \nabla F(\widehat{\boldsymbol{x}}), \boldsymbol{x}^{t-1} + \widetilde{\boldsymbol{x}} - 2\widehat{\boldsymbol{x}}\right\rangle + 4\left\|\mathcal{P}_\Omega\left(\nabla F(\widehat{\boldsymbol{x}})\right)\right\|_2^2.\end{aligned}$$

The proof is complete. ■

Corollary 21 *Assume the same conditions as in Lemma 20. If $\nabla F(\widehat{\boldsymbol{x}}) = 0$, we have*

$$\mathbb{E}_{i_t|\boldsymbol{x}^{t-1}}\left[\left\|\mathcal{P}_\Omega\left(\boldsymbol{v}^t\right)\right\|_2^2\right] \leq 4L_r\left[F(\boldsymbol{x}^{t-1}) + F(\widetilde{\boldsymbol{x}}) - 2F(\widehat{\boldsymbol{x}})\right].$$

Appendix B. Proofs for Section 2

B.1 Proof of Theorem 1

Proof The result is true for the trivial case that $\boldsymbol{b}$ is a zero vector. In the following, we assume that $\boldsymbol{b}$ is not a zero vector. Denote

$$\boldsymbol{w} := \mathcal{H}_k\left(\boldsymbol{b}\right).$$

Let Ω be the support set of $\boldsymbol{w}$ and let $\overline{\Omega}$ be its complement. We immediately have $\mathcal{P}_\Omega\left(\boldsymbol{b}\right) = \boldsymbol{w}$.

Let Ω' be the support set of $\boldsymbol{x}$. For the sake of simplicity, let us split the vector $\boldsymbol{b}$ as follows:

$$\begin{aligned}\boldsymbol{b}_1 = \mathcal{P}_{\Omega\setminus\Omega'}\left(\boldsymbol{b}\right), &\quad \boldsymbol{b}_2 = \mathcal{P}_{\Omega\cap\Omega'}\left(\boldsymbol{b}\right), \\ \boldsymbol{b}_3 = \mathcal{P}_{\overline{\Omega}\setminus\Omega'}\left(\boldsymbol{b}\right), &\quad \boldsymbol{b}_4 = \mathcal{P}_{\overline{\Omega}\cap\Omega'}\left(\boldsymbol{b}\right).\end{aligned}$$

Likewise, we denote

$$\begin{aligned}&\boldsymbol{w}_1 = \mathcal{P}_{\Omega\setminus\Omega'}\left(\boldsymbol{w}\right), \quad \boldsymbol{w}_2 = \mathcal{P}_{\Omega\cap\Omega'}\left(\boldsymbol{w}\right), \quad \boldsymbol{w}_3 = \mathcal{P}_{\overline{\Omega}\setminus\Omega'}(\boldsymbol{w}) = \boldsymbol{0}, \quad \boldsymbol{w}_4 = \mathcal{P}_{\overline{\Omega}\cap\Omega'}\left(\boldsymbol{w}\right) = \boldsymbol{0}, \\ &\boldsymbol{x}_1 = \mathcal{P}_{\Omega\setminus\Omega'}\left(\boldsymbol{x}\right) = \boldsymbol{0}, \quad \boldsymbol{x}_2 = \mathcal{P}_{\Omega\cap\Omega'}\left(\boldsymbol{x}\right), \quad \boldsymbol{x}_3 = \mathcal{P}_{\overline{\Omega}\setminus\Omega'}(\boldsymbol{x}) = \boldsymbol{0}, \quad \boldsymbol{x}_4 = \mathcal{P}_{\overline{\Omega}\cap\Omega'}\left(\boldsymbol{x}\right).\end{aligned}$$

Due to the hard thresholding, we have

$$\boldsymbol{w}_1 = \boldsymbol{b}_1, \quad \boldsymbol{w}_2 = \boldsymbol{b}_2.$$

In this way, by simple algebra we have

$$\begin{aligned}\|\boldsymbol{w} - \boldsymbol{x}\|_2^2 &= \|\boldsymbol{b}_1\|_2^2 + \|\boldsymbol{b}_2 - \boldsymbol{x}_2\|_2^2 + \|\boldsymbol{x}_4\|_2^2, \\ \|\boldsymbol{b} - \boldsymbol{x}\|_2^2 &= \|\boldsymbol{b}_1\|_2^2 + \|\boldsymbol{b}_2 - \boldsymbol{x}_2\|_2^2 + \|\boldsymbol{b}_3\|_2^2 + \|\boldsymbol{b}_4 - \boldsymbol{x}_4\|_2^2.\end{aligned}$$

Our goal is to estimate the maximum of $\|\boldsymbol{w} - \boldsymbol{x}\|_2^2 / \|\boldsymbol{b} - \boldsymbol{x}\|_2^2$. It is easy to show that when attaining the maximum value, $\|\boldsymbol{b}_3\|_2$ must be zero since otherwise one may decrease this term to make the objective larger. Hence, maximizing $\|\boldsymbol{w} - \boldsymbol{x}\|_2^2 / \|\boldsymbol{b} - \boldsymbol{x}\|_2^2$ amounts to estimating the upper bound of the following over all choices of $\boldsymbol{x}$ and $\boldsymbol{b}$:

$$\gamma := \frac{\|\boldsymbol{b}_1\|_2^2 + \|\boldsymbol{b}_2 - \boldsymbol{x}_2\|_2^2 + \|\boldsymbol{x}_4\|_2^2}{\|\boldsymbol{b}_1\|_2^2 + \|\boldsymbol{b}_2 - \boldsymbol{x}_2\|_2^2 + \|\boldsymbol{b}_4 - \boldsymbol{x}_4\|_2^2}. \tag{B.1}$$

Firstly, we consider the case of $\|\boldsymbol{b}_1\|_2 = 0$, which means $\Omega = \Omega'$ implying $\gamma = 1$. In the following, we consider $\|\boldsymbol{b}_1\|_2 \neq 0$. In particular, we consider $\gamma > 1$ since we are interested in the maximum value of γ.

Arranging (B.1) we obtain

$$(\gamma - 1)\|\boldsymbol{b}_2 - \boldsymbol{x}_2\|_2^2 + \gamma\|\boldsymbol{b}_4 - \boldsymbol{x}_4\|_2^2 - \|\boldsymbol{x}_4\|_2^2 + (\gamma - 1)\|\boldsymbol{b}_1\|_2^2 = 0. \tag{B.2}$$

Let us fix $\boldsymbol{b}$ and define the function

$$G(\boldsymbol{x}_2, \boldsymbol{x}_4) = (\gamma - 1)\|\boldsymbol{b}_2 - \boldsymbol{x}_2\|_2^2 + \gamma\|\boldsymbol{b}_4 - \boldsymbol{x}_4\|_2^2 - \|\boldsymbol{x}_4\|_2^2 + (\gamma - 1)\|\boldsymbol{b}_1\|_2^2.$$

Thus, (B.2) indicates that $G(\boldsymbol{x}_2, \boldsymbol{x}_4)$ can attain the objective value of zero. Note that $G(\boldsymbol{x}_2, \boldsymbol{x}_4)$ is a quadratic function and its gradient and Hessian matrix can be computed as follows:

$$\begin{aligned}\frac{\partial}{\partial \boldsymbol{x}_2} G(\boldsymbol{x}_2, \boldsymbol{x}_4) &= 2(\gamma - 1)(\boldsymbol{x}_2 - \boldsymbol{b}_2),\\ \frac{\partial}{\partial \boldsymbol{x}_4} G(\boldsymbol{x}_2, \boldsymbol{x}_4) &= 2\gamma(\boldsymbol{x}_4 - \boldsymbol{b}_4) - 2\boldsymbol{x}_4,\\ \nabla^2 G(\boldsymbol{x}_2, \boldsymbol{x}_4) &= 2(\gamma - 1)\boldsymbol{I},\end{aligned}$$

where $\boldsymbol{I}$ is the identity matrix. Since the Hessian matrix is positive definite, $G(\boldsymbol{x}_2, \boldsymbol{x}_4)$ attains the global minimum at the stationary point, which is given by

$$\boldsymbol{x}_2^* = \boldsymbol{b}_2, \quad \boldsymbol{x}_4^* = \frac{\gamma}{\gamma - 1}\boldsymbol{b}_4,$$

resulting in the minimum objective value

$$G(\boldsymbol{x}_2^*, \boldsymbol{x}_4^*) = \frac{\gamma}{1-\gamma}\left\|\boldsymbol{b}_4\right\|_2^2 + (\gamma - 1)\left\|\boldsymbol{b}_1\right\|_2^2.$$

In order to guarantee the feasible set of (B.2) is non-empty, we require that

$$G(\boldsymbol{x}_2^*, \boldsymbol{x}_4^*) \le 0,$$

implying

$$\left\|\boldsymbol{b}_1\right\|_2^2\gamma^2 - (2\left\|\boldsymbol{b}_1\right\|_2^2 + \left\|\boldsymbol{b}_4\right\|_2^2)\gamma + \left\|\boldsymbol{b}_1\right\|_2^2 \le 0.$$

Solving the above inequality with respect to γ, we obtain

$$\gamma \le 1 + \frac{\left\|\boldsymbol{b}_4\right\|_2^2 + \sqrt{\left(4\left\|\boldsymbol{b}_1\right\|_2^2 + \left\|\boldsymbol{b}_4\right\|_2^2\right)\left\|\boldsymbol{b}_4\right\|_2^2}}{2\left\|\boldsymbol{b}_1\right\|_2^2}. \tag{B.3}$$

To derive an upper bound that is uniform over the choice of $\boldsymbol{b}$, we recall that $\boldsymbol{b}_1$ contains the largest absolute elements of $\boldsymbol{b}$ while $\boldsymbol{b}_4$ has smaller values. In particular, the averaged value of $\boldsymbol{b}_4$ is no greater than that of $\boldsymbol{b}_1$ in magnitude, i.e.,

$$\frac{\left\|\boldsymbol{b}_4\right\|_2^2}{\left\|\boldsymbol{b}_4\right\|_0} \le \frac{\left\|\boldsymbol{b}_1\right\|_2^2}{\left\|\boldsymbol{b}_1\right\|_0}.$$

Note that $\left\|\boldsymbol{b}_1\right\|_0 = k - \left\|\boldsymbol{b}_2\right\|_0 = k - (K - \left\|\boldsymbol{b}_4\right\|_0)$. Hence, combining with the fact that $0 \le \left\|\boldsymbol{b}_4\right\|_0 \le \min\{K, d-k\}$ and optimizing over $\left\|\boldsymbol{b}_4\right\|_0$ gives

$$\left\|\boldsymbol{b}_4\right\|_2^2 \le \frac{\min\{K, d-k\}}{k - K + \min\{K, d-k\}}\left\|\boldsymbol{b}_1\right\|_2^2.$$

Plugging back to (B.3), we finally obtain

$$\gamma \le 1 + \frac{\rho + \sqrt{(4+\rho)\,\rho}}{2}, \quad \rho = \frac{\min\{K, d-k\}}{k - K + \min\{K, d-k\}}.$$

The proof is complete. ■

Appendix C. Proofs for Section 3

C.1 Proof of Theorem 6

We follow the proof pipeline of Blumensath and Davies (2009) and only remark the difference of our proof and theirs, i.e., where Theorem 1 applies. In case of possible confusion due to notation, we follow the symbols in Blumensath and Davies. One may refer to that article for a complete proof.

The first difference occurs in Eq. (22) of Blumensath and Davies (2009), where they reached

$$\text{(Old)} \quad \left\|\boldsymbol{x}^s - \boldsymbol{x}^{[n+1]}\right\|_2 \le 2\left\|\boldsymbol{x}^s_{B^{n+1}} - \boldsymbol{a}^{[n+1]}_{B^{n+1}}\right\|_2,$$

while Theorem 1 gives

$$\text{(New)} \quad \left\|\boldsymbol{x}^s - \boldsymbol{x}^{[n+1]}\right\|_2 \le \sqrt{\nu}\left\|\boldsymbol{x}^s_{B^{n+1}} - \boldsymbol{a}^{[n+1]}_{B^{n+1}}\right\|_2.$$

Combining this new inequality and Eq. (23) therein, we obtain

$$\left\|\boldsymbol{x}^s - \boldsymbol{x}^{[n+1]}\right\|_2 \le \sqrt{\nu}\left\|(\boldsymbol{I} - \boldsymbol{\Phi}^\top_{B^{n+1}}\boldsymbol{\Phi}_{B^{n+1}})\boldsymbol{r}^{[n]}_{B^{n+1}}\right\|_2 + \sqrt{\nu}\left\|(\boldsymbol{\Phi}^\top_{B^{n+1}}\boldsymbol{\Phi}_{B^{n+1}\setminus B^{n+1}})\boldsymbol{r}^{[n]}_{B^{n+1}\setminus B^{n+1}}\right\|_2.$$

By noting the fact that $\left|B^n \cup B^{n+1}\right| \le 2s + s^*$ where s^* denotes the sparsity of the global optimum and following their reasoning of Eq. (24) and (25), we have a new bound for Eq. (26):

$$\text{(New)} \quad \left\|\boldsymbol{r}^{[n+1]}\right\|_2 \le \sqrt{2\nu}\delta_{2s+s^*}\left\|\boldsymbol{r}^{[n]}\right\|_2 + \sqrt{(1+\delta_{s+s^*})\nu}\left\|\boldsymbol{e}\right\|_2.$$

Now our result follows by setting the coefficient of $\left\|\boldsymbol{r}^{[n]}\right\|_2$ to 0.5. Note that specifying $\nu = 4$ gives the result of Blumensath and Davies (2009).

C.2 Proof of Theorem 7

We follow the proof technique of Theorem 6.27 in Foucart and Rauhut (2013) which gives the best known RIP condition for the CoSaMP algorithm to date. Since most of the reasoning is similar, we only point out the difference of our proof and theirs, i.e., where Theorem 1 applies. In case of confusion by notation, we follow the symbols used in Foucart and Rauhut (2013). The reader may refer to that book for a complete proof.

The first difference is in Eq. (6.49) of Foucart and Rauhut (2013). Note that to derive this inequality, Foucart and Rauhut invoked the conventional bound (1.1), which gives

$$\text{(Old)} \quad \left\|\boldsymbol{x}_S - \boldsymbol{x}^{n+1}\right\|_2^2 \le \left\|(\boldsymbol{x}_S - \boldsymbol{u}^{n+1})_{\overline{U^{n+1}}}\right\|_2^2 + 4\left\|(\boldsymbol{x}_S - \boldsymbol{u}^{n+1})_{U^{n+1}}\right\|_2^2,$$

while utilizing Theorem 1 gives

$$\text{(New)} \quad \left\|\boldsymbol{x}_S - \boldsymbol{x}^{n+1}\right\|_2^2 \le \left\|(\boldsymbol{x}_S - \boldsymbol{u}^{n+1})_{\overline{U^{n+1}}}\right\|_2^2 + \nu\left\|(\boldsymbol{x}_S - \boldsymbol{u}^{n+1})_{U^{n+1}}\right\|_2^2.$$

Combining this new inequality with Eq. (6.50) and Eq. (6.51) therein, we obtain

$$\begin{aligned}\left\|\boldsymbol{x}_S - \boldsymbol{x}^{n+1}\right\|_2 \leq \sqrt{2}\delta_{3s+s^*}\sqrt{\frac{1+(\nu-1)\delta_{3s+s^*}^2}{1-\delta_{3s+s^*}^2}}\left\|\boldsymbol{x}^n - \boldsymbol{x}_S\right\|_2 \\ + \sqrt{2}\delta_{3s+s^*}\sqrt{\frac{1+(\nu-1)\delta_{3s+s^*}^2}{1-\delta_{3s+s^*}^2}}\left\|(\boldsymbol{A}^*\boldsymbol{e}')_{(S\cup S^n)\Delta T^{n+1}}\right\|_2 \\ + \frac{2}{1-\delta_{3s+s^*}}\left\|(\boldsymbol{A}^*\boldsymbol{e}')_{U^{n+1}}\right\|_2,\end{aligned}$$

where s^* denotes the sparsity of the optimum. Our new bound follows by setting the coefficient of $\|\boldsymbol{x}^n - \boldsymbol{x}_S\|_2$ to 0.5 and solving the resultant equation. Note that setting $\nu = 4$ gives the old bound of Foucart and Rauhut.

Appendix D. Proofs for Section 4

D.1 Proof of Theorem 10

Proof Fix a stage s. Let us denote

$$\boldsymbol{v}^t = \nabla f_{i_t}(\boldsymbol{x}^{t-1}) - \nabla f_{i_t}(\widetilde{\boldsymbol{x}}) + \widetilde{\boldsymbol{\mu}},$$

so that

$$\boldsymbol{b}^t = \boldsymbol{x}^{t-1} - \eta\boldsymbol{v}^t.$$

By specifying $\Omega = \operatorname{supp}\left(\boldsymbol{x}^{t-1}\right) \cup \operatorname{supp}\left(\boldsymbol{x}^t\right) \cup \operatorname{supp}\left(\widetilde{\boldsymbol{x}}\right) \cup \operatorname{supp}\left(\widehat{\boldsymbol{x}}\right)$, it follows that

$$\boldsymbol{r}^t = \mathcal{H}_k\left(\boldsymbol{b}^t\right) = \mathcal{H}_k\left(\mathcal{P}_\Omega\left(\boldsymbol{b}^t\right)\right).$$

Thus, the Euclidean distance of $\boldsymbol{x}^t$ and $\widehat{\boldsymbol{x}}$ can be bounded as follows:

$$\left\|\boldsymbol{x}^t - \widehat{\boldsymbol{x}}\right\|_2^2 \leq \left\|\boldsymbol{r}^t - \widehat{\boldsymbol{x}}\right\|_2^2 = \left\|\mathcal{H}_k\left(\mathcal{P}_\Omega\left(\boldsymbol{b}^t\right)\right) - \widehat{\boldsymbol{x}}\right\|_2^2 \leq \nu\left\|\mathcal{P}_\Omega\left(\boldsymbol{b}^t\right) - \widehat{\boldsymbol{x}}\right\|_2^2, \tag{D.1}$$

where the first inequality holds because $\boldsymbol{x}^t = \Pi_\omega(\boldsymbol{r}^t)$ and $\|\widehat{\boldsymbol{x}}\|_2 \leq \omega$. We also have

$$\begin{aligned}\left\|\mathcal{P}_\Omega\left(\boldsymbol{b}^t\right) - \widehat{\boldsymbol{x}}\right\|_2^2 &= \left\|\boldsymbol{x}^{t-1} - \widehat{\boldsymbol{x}} - \eta\mathcal{P}_\Omega\left(\boldsymbol{v}^t\right)\right\|_2^2 \\ &= \left\|\boldsymbol{x}^{t-1} - \widehat{\boldsymbol{x}}\right\|_2^2 + \eta^2\left\|\mathcal{P}_\Omega\left(\boldsymbol{v}^t\right)\right\|_2^2 - 2\eta\left\langle\boldsymbol{x}^{t-1} - \widehat{\boldsymbol{x}}, \boldsymbol{v}^t\right\rangle,\end{aligned}$$

where the second equality uses the fact that $\left\langle\boldsymbol{x}^{t-1} - \widehat{\boldsymbol{x}}, \mathcal{P}_\Omega\left(\boldsymbol{v}^t\right)\right\rangle = \left\langle\boldsymbol{x}^{t-1} - \widehat{\boldsymbol{x}}, \boldsymbol{v}^t\right\rangle$. The first term will be preserved for mathematical induction. The third term is easy to manipulate thanks to the unbiasedness of $\boldsymbol{v}^t$. For the second term, we use Lemma 20 to bound it. Put them together,

conditioning on $\boldsymbol{x}^{t-1}$ and taking the expectation over i_t for (D.1), we have

$$\begin{aligned}&\mathbb{E}_{i_t|\boldsymbol{x}^{t-1}}\left[\left\|\boldsymbol{x}^t - \widehat{\boldsymbol{x}}\right\|_2^2\right] \\ \overset{\xi_1}{\leq}\ &\nu\left\|\boldsymbol{x}^{t-1} - \widehat{\boldsymbol{x}}\right\|_2^2 + 4\nu\eta^2 L\left[F(\boldsymbol{x}^{t-1}) - F(\widehat{\boldsymbol{x}}) + F(\widetilde{\boldsymbol{x}}) - F(\widehat{\boldsymbol{x}})\right] - 2\nu\eta\left\langle\boldsymbol{x}^{t-1} - \widehat{\boldsymbol{x}}, \nabla F(\boldsymbol{x}^{t-1})\right\rangle \\ &- 4\nu\eta^2 L\left\langle\nabla F(\widehat{\boldsymbol{x}}), \boldsymbol{x}^{t-1} + \widetilde{\boldsymbol{x}} - 2\widehat{\boldsymbol{x}}\right\rangle + 4\nu\eta^2\left\|\mathcal{P}_\Omega\left(\nabla F(\widehat{\boldsymbol{x}})\right)\right\|_2^2 \\ \overset{\xi_2}{\leq}\ &\nu(1-\eta\alpha)\left\|\boldsymbol{x}^{t-1} - \widehat{\boldsymbol{x}}\right\|_2^2 - 2\nu\eta(1-2\eta L)\left[F(\boldsymbol{x}^{t-1}) - F(\widehat{\boldsymbol{x}})\right] + 4\nu\eta^2 L\left[F(\widetilde{\boldsymbol{x}}) - F(\widehat{\boldsymbol{x}})\right] \\ &+ 4\nu\eta^2 L\left\|\mathcal{P}_\Omega\left(\nabla F(\widehat{\boldsymbol{x}})\right)\right\|_2 \cdot \left\|\boldsymbol{x}^{t-1} + \widetilde{\boldsymbol{x}} - 2\widehat{\boldsymbol{x}}\right\|_2 + 4\nu\eta^2\left\|\mathcal{P}_\Omega\left(\nabla F(\widehat{\boldsymbol{x}})\right)\right\|_2^2 \\ \leq\ &\nu(1-\eta\alpha)\left\|\boldsymbol{x}^{t-1} - \widehat{\boldsymbol{x}}\right\|_2^2 - 2\nu\eta(1-2\eta L)\left[F(\boldsymbol{x}^{t-1}) - F(\widehat{\boldsymbol{x}})\right] \\ &+ 4\nu\eta^2 L\left[F(\widetilde{\boldsymbol{x}}) - F(\widehat{\boldsymbol{x}})\right] + 4\nu\eta^2 Q'(4L\omega + Q')\end{aligned}$$

where ξ_1 applies Lemma 20, ξ_2 applies Assumption $(A1)$ and we write $Q' := \|\nabla_{3k+K}F(\widehat{\boldsymbol{x}})\|_2$ for brevity.

Now summing over the inequalities over $t = 1, 2, \cdots, m$, conditioning on $\widetilde{\boldsymbol{x}}$ and taking the expectation with respect to $\mathcal{I}^s = \{i_1, i_2, \cdots, i_m\}$, we have

$$\begin{aligned}&\mathbb{E}_{\mathcal{I}^s|\widetilde{\boldsymbol{x}}}\left[\left\|\boldsymbol{x}^m - \widehat{\boldsymbol{x}}\right\|_2^2\right] \\ \leq\ &\left[\nu(1-\eta\alpha) - 1\right]\mathbb{E}_{\mathcal{I}^s|\widetilde{\boldsymbol{x}}}\sum_{t=1}^m\left\|\boldsymbol{x}^{t-1} - \widehat{\boldsymbol{x}}\right\|_2^2 + \left\|\boldsymbol{x}^0 - \widehat{\boldsymbol{x}}\right\|_2^2 + 4\nu\eta^2 Q'(4L\omega + Q')m \\ &- 2\nu\eta(1-2\eta L)\mathbb{E}_{\mathcal{I}^s|\widetilde{\boldsymbol{x}}}\sum_{t=1}^m\left[F(\boldsymbol{x}^{t-1}) - F(\widehat{\boldsymbol{x}})\right] + 4\nu\eta^2 Lm\left[F(\widetilde{\boldsymbol{x}}) - F(\widehat{\boldsymbol{x}})\right] \\ =\ &\left[\nu(1-\eta\alpha) - 1\right]m\mathbb{E}_{\mathcal{I}^s,j^s|\widetilde{\boldsymbol{x}}}\left\|\widetilde{\boldsymbol{x}}^s - \widehat{\boldsymbol{x}}\right\|_2^2 + \left\|\widetilde{\boldsymbol{x}} - \widehat{\boldsymbol{x}}\right\|_2^2 + 4\nu\eta^2 Q'(4L\omega + Q')m \\ &- 2\nu\eta(1-2\eta L)m\mathbb{E}_{\mathcal{I}^s,j^s|\widetilde{\boldsymbol{x}}}\left[F(\widetilde{\boldsymbol{x}}^s) - F(\widehat{\boldsymbol{x}})\right] + 4\nu\eta^2 Lm\left[F(\widetilde{\boldsymbol{x}}) - F(\widehat{\boldsymbol{x}})\right] \\ \leq\ &\left[\nu(1-\eta\alpha) - 1\right]m\mathbb{E}_{\mathcal{I}^s,j^s|\widetilde{\boldsymbol{x}}}\left\|\widetilde{\boldsymbol{x}}^s - \widehat{\boldsymbol{x}}\right\|_2^2 + \left(\frac{2}{\alpha} + 4\nu\eta^2 Lm\right)\left[F(\widetilde{\boldsymbol{x}}) - F(\widehat{\boldsymbol{x}})\right] \\ &- 2\nu\eta(1-2\eta L)m\mathbb{E}_{\mathcal{I}^s,j^s|\widetilde{\boldsymbol{x}}}\left[F(\widetilde{\boldsymbol{x}}^s) - F(\widehat{\boldsymbol{x}})\right] + 4\nu\eta^2 Q'(4L\omega + Q')m + 2Q'\omega/\alpha,\end{aligned} \tag{D.2}$$

where we recall that j^s is the randomly chosen index used to determine $\widetilde{\boldsymbol{x}}^s$ (see Algorithm 1). The last inequality holds due to the RSC condition and $\left\|\boldsymbol{x}^t\right\|_2 \leq \omega$. For brevity, we write

$$Q := 4\nu\eta^2 Q'(4L\omega + Q')m + 2Q'\omega/\alpha, \quad Q' = \|\nabla_{3k+K}F(\widehat{\boldsymbol{x}})\|_2.$$

Based on (D.2), we discuss two cases to examine the convergence of the algorithm.

Case 1. $\nu(1-\eta\alpha) \leq 1$. This immediately results in

$$\begin{aligned}&\mathbb{E}_{\mathcal{I}^s|\widetilde{\boldsymbol{x}}}\left[\left\|\boldsymbol{x}^m - \widehat{\boldsymbol{x}}\right\|_2^2\right] \\ \leq\ &\left(\frac{2}{\alpha} + 4\nu\eta^2 Lm\right)\left[F(\widetilde{\boldsymbol{x}}) - F(\widehat{\boldsymbol{x}})\right] - 2\nu\eta(1-2\eta L)m\,\mathbb{E}_{\mathcal{I}^s,j^s|\widetilde{\boldsymbol{x}}}\left[F(\widetilde{\boldsymbol{x}}^s) - F(\widehat{\boldsymbol{x}})\right] + Q,\end{aligned}$$

which implies

$$\nu\eta(1-2\eta L)m\mathbb{E}_{\mathcal{I}^s,j^s|\widetilde{\boldsymbol{x}}}\left[F(\widetilde{\boldsymbol{x}}^s)-F(\widehat{\boldsymbol{x}})\right]\leq\left(\frac{1}{\alpha}+2\nu\eta^2Lm\right)\left[F(\widetilde{\boldsymbol{x}})-F(\widehat{\boldsymbol{x}})\right]+\frac{Q}{2}.$$

Pick η such that

$$1-2\eta L>0, \tag{D.3}$$

we obtain

$$\mathbb{E}_{\mathcal{I}^s,j^s|\widetilde{\boldsymbol{x}}}\left[F(\widetilde{\boldsymbol{x}}^s)-F(\widehat{\boldsymbol{x}})\right]\leq\left(\frac{1}{\nu\eta\alpha(1-2\eta L)m}+\frac{2\eta L}{1-2\eta L}\right)\left[F(\widetilde{\boldsymbol{x}})-F(\widehat{\boldsymbol{x}})\right]+\frac{Q}{2\nu\eta\alpha(1-2\eta L)m}.$$

To guarantee the convergence, we must impose

$$\frac{2\eta L}{1-2\eta L}<1. \tag{D.4}$$

Putting (D.3), (D.4) and $\nu(1-\eta\alpha)\leq 1$ together gives

$$\eta<\frac{1}{4L},\quad \nu\leq\frac{1}{1-\eta\alpha}. \tag{D.5}$$

The convergence coefficient here is

$$\beta=\frac{1}{\nu\eta\alpha(1-2\eta L)m}+\frac{2\eta L}{1-2\eta L}. \tag{D.6}$$

Thus, we have

$$\mathbb{E}\left[F(\widetilde{\boldsymbol{x}}^s)-F(\widehat{\boldsymbol{x}})\right]\leq\beta^s\left[F(\widetilde{\boldsymbol{x}}^0)-F(\widehat{\boldsymbol{x}})\right]+\frac{Q}{2\nu\eta\alpha(1-2\eta L)(1-\beta)m},$$

where the expectation is taken over $\{\mathcal{I}^1,j^1,\mathcal{I}^2,j^2,\cdots,\mathcal{I}^s,j^s\}$.

Case 2. $\nu(1-\eta\alpha)>1$. In this case, (D.2) implies

$$\begin{aligned}\mathbb{E}_{\mathcal{I}^s|\widetilde{\boldsymbol{x}}}\left[\|\boldsymbol{x}^m-\widehat{\boldsymbol{x}}\|_2^2\right]\leq&\left(\frac{2}{\alpha}+4\nu\eta^2Lm\right)\left[F(\widetilde{\boldsymbol{x}})-F(\widehat{\boldsymbol{x}})\right]+Q\\&+\left(\frac{2}{\alpha}\left[\nu(1-\eta\alpha)-1\right]m-2\nu\eta(1-2\eta L)m\right)\mathbb{E}_{\mathcal{I}^s,j^s|\widetilde{\boldsymbol{x}}}\left[F(\widetilde{\boldsymbol{x}}^s)-F(\widehat{\boldsymbol{x}})\right].\end{aligned}$$

Rearranging the terms gives

$$\left(2\nu\eta\alpha-2\nu\eta^2\alpha L-\nu+1\right)m\,\mathbb{E}_{\mathcal{I}^s,j^s|\widetilde{\boldsymbol{x}}}\left[F(\widetilde{\boldsymbol{x}}^s)-F(\widehat{\boldsymbol{x}})\right]\leq\left(1+2\nu\eta^2\alpha Lm\right)\left[F(\widetilde{\boldsymbol{x}})-F(\widehat{\boldsymbol{x}})\right]+\frac{\alpha Q}{2}.$$

To ensure the convergence, the minimum requirements are

$$\begin{aligned}&2\nu\eta\alpha-2\nu\eta^2\alpha L-\nu+1>0,\\&2\nu\eta\alpha-2\nu\eta^2\alpha L-\nu+1>2\nu\eta^2\alpha L.\end{aligned}$$

That is,

$$4\nu\alpha L\eta^2-2\nu\alpha\eta+\nu-1<0.$$

We need to guarantee the feasible set of the above inequality is non-empty for the positive variable η. Thus, we require

$$4\nu^2\alpha^2-4\times 4\nu\alpha L(\nu-1)>0,$$

which is equivalent to

$$\nu<\frac{4L}{4L-\alpha}.$$

Combining it with $\nu(1-\eta\alpha)>1$ gives

$$\frac{1}{1-\eta\alpha}<\nu<\frac{4L}{4L-\alpha}.$$

To ensure the above feasible set is non-empty, we impose

$$\frac{1}{1-\eta\alpha}<\frac{4L}{4L-\alpha},$$

so that

$$0<\eta<\frac{1}{4L},\quad \frac{1}{1-\eta\alpha}<\nu<\frac{4L}{4L-\alpha}. \tag{D.7}$$

The convergence coefficient for this case is

$$\beta=\frac{1}{\left(2\nu\eta\alpha-2\nu\eta^2\alpha L-\nu+1\right)m}+\frac{2\nu\eta^2\alpha L}{2\nu\eta\alpha-2\nu\eta^2\alpha L-\nu+1}. \tag{D.8}$$

Thus,

$$\mathbb{E}\left[F(\widetilde{\boldsymbol{x}}^s)-F(\widehat{\boldsymbol{x}})\right]\leq\beta^s\left[F(\widetilde{\boldsymbol{x}}^0)-F(\widehat{\boldsymbol{x}})\right]+\frac{\alpha Q}{2(2\nu\eta\alpha-2\nu\eta^2\alpha L-\nu+1)(1-\beta)m}.$$

By combining (D.5) and (D.7), the minimum requirement for η and ν is

$$0<\eta<\frac{1}{4L},\quad \nu<\frac{4L}{4L-\alpha}.$$

The proof is complete. ■

D.2 Proof of Corollary 16

Proof By noting the concavity of the square root function, we have

$$\begin{aligned}\mathbb{E}\left[\sqrt{\max\{F(\widetilde{\boldsymbol{x}}^s)-F(\widehat{\boldsymbol{x}}),0\}}\right]&\leq\sqrt{\mathbb{E}\left[\max\{F(\widetilde{\boldsymbol{x}}^s)-F(\widehat{\boldsymbol{x}}),0\}\right]}\\&\leq\sqrt{(2/3)^s\max\{F(\widetilde{\boldsymbol{x}}^0)-F(\widehat{\boldsymbol{x}}),0\}+\tau(\widehat{\boldsymbol{x}})}.\end{aligned}$$

Suppose that $F(\boldsymbol{x})$ satisfies RSS with parameter $L' \in [\alpha, L]$. It follows that

$$F(\widetilde{\boldsymbol{x}}^0) - F(\widehat{\boldsymbol{x}}) \leq \left\langle \nabla F(\widehat{\boldsymbol{x}}), \widetilde{\boldsymbol{x}}^0 - \widehat{\boldsymbol{x}} \right\rangle + \frac{L'}{2} \left\| \widetilde{\boldsymbol{x}}^0 - \widehat{\boldsymbol{x}} \right\|_2^2 \leq \frac{1}{2L'} \left\| \nabla_{k+K} F(\widehat{\boldsymbol{x}}) \right\|_2^2 + L' \left\| \widetilde{\boldsymbol{x}}^0 - \widehat{\boldsymbol{x}} \right\|_2^2.$$

Recall that

$$\tau(\widehat{\boldsymbol{x}}) = \frac{5\omega}{\alpha} \left\| \nabla_{3k+K} F(\widehat{\boldsymbol{x}}) \right\|_2 + \frac{1}{\alpha L} \left\| \nabla_{3k+K} F(\widehat{\boldsymbol{x}}) \right\|_2^2.$$

Hence using $\sqrt{a+b+c+d} \leq \sqrt{a} + \sqrt{b} + \sqrt{c} + \sqrt{d}$ gives

$$\begin{aligned} \mathbb{E}\left[\sqrt{\max\{F(\widetilde{\boldsymbol{x}}^s) - F(\widehat{\boldsymbol{x}}), 0\}} \right] \leq \sqrt{L'} \left(\frac{2}{3} \right)^{\frac{s}{2}} \left\| \widetilde{\boldsymbol{x}}^0 - \widehat{\boldsymbol{x}} \right\|_2 + \sqrt{\frac{5\omega}{\alpha} \left\| \nabla_{3k+K} F(\widehat{\boldsymbol{x}}) \right\|_2} \\ + \left(\frac{1}{\alpha} + \sqrt{\frac{1}{2\alpha}} \right) \left\| \nabla_{3k+K} F(\widehat{\boldsymbol{x}}) \right\|_2. \end{aligned}$$

Finally, the RSC property immediately suggests that (see, e.g., Lemma 20 in Shen and Li (2017b))

$$\begin{aligned} \mathbb{E}\left[\left\| \widetilde{\boldsymbol{x}}^s - \widehat{\boldsymbol{x}} \right\|_2 \right] &\leq \sqrt{\frac{2}{\alpha}} \mathbb{E}\left[\sqrt{\max\{F(\widetilde{\boldsymbol{x}}^s) - F(\widehat{\boldsymbol{x}}), 0\}} \right] + \frac{2 \left\| \nabla_{k+K} F(\widehat{\boldsymbol{x}}) \right\|_2}{\alpha} \\ &\leq \sqrt{\frac{2L'}{\alpha}} \cdot \left(\frac{2}{3} \right)^{\frac{s}{2}} \left\| \widetilde{\boldsymbol{x}}^0 - \widehat{\boldsymbol{x}} \right\|_2 + \sqrt{\frac{10\omega}{\alpha^2} \left\| \nabla_{3k+K} F(\widehat{\boldsymbol{x}}) \right\|_2} \\ &\quad + \left(\sqrt{\frac{2}{\alpha^3}} + \frac{3}{\alpha} \right) \left\| \nabla_{3k+K} F(\widehat{\boldsymbol{x}}) \right\|_2. \end{aligned}$$

The proof is complete. ■

Appendix E. HT-SAGA

We demonstrate that the hard thresholding step can be integrated into SAGA (Defazio et al., 2014) as shown in Algorithm 2. Note that the only difference of Algorithm 2 and the one proposed in Defazio et al. (2014) is that we perform hard thresholding rather than proximal operator. Hence, our algorithm guarantees k-sparse solution.

Theorem 22 *Assume the same conditions as in Defazio et al. (2014). Further assume the optimum of* (4.1) *without the sparsity constraint happens to be k-sparse. Then, the sequence of the solutions produced by Algorithm 2 converges to the optimum with geometric rate for some properly chosen sparsity parameter k.*

Proof Define the Lyapunov function Z as follows:

$$Z^t := Z(\boldsymbol{x}^t, \{\boldsymbol{\phi}_i^t\}) = \frac{1}{n} \sum_{i=1}^n f_i(\boldsymbol{\phi}_i^t) - F(\widehat{\boldsymbol{x}}) - \frac{1}{n} \sum_{i=1}^n \left\langle \nabla f_i(\widehat{\boldsymbol{x}}), \boldsymbol{\phi}_i^t - \widehat{\boldsymbol{x}} \right\rangle + c \left\| \boldsymbol{x}^t - \widehat{\boldsymbol{x}} \right\|_2^2.$$

Algorithm 2 SAGA with Hard Thresholding (HT-SAGA)

Require: The current iterate $\boldsymbol{x}^t$ and of each $\nabla f_i(\boldsymbol{\phi}_i^t)$ at the end of iteration t, the step size η.
Ensure: The new iterate.
1: Pick $j \in \{1, 2, \cdots, n\}$ uniformly at random.
2: Take $\boldsymbol{\phi}_j^{t+1} = \boldsymbol{x}^t$ and store $\nabla f_j(\boldsymbol{\phi}_j^{t+1})$ in the table. All other entries in the table remain unchanged.
3: Update the new iterate $\boldsymbol{x}^{t+1}$ as follows:

$$\begin{aligned} \boldsymbol{b}^{t+1} &= \boldsymbol{x}^t - \eta \left[\nabla f_j(\boldsymbol{\phi}_j^{t+1}) - \nabla f_j(\boldsymbol{\phi}_j^t) + \frac{1}{n} \sum_{i=1}^n \nabla f_i(\boldsymbol{\phi}_i^t) \right], \\ \boldsymbol{x}^{t+1} &= \mathcal{H}_k\left(\boldsymbol{b}^{t+1} \right). \end{aligned}$$

We examine Z^{t+1}. We have

$$\begin{aligned} \mathbb{E}\left[\frac{1}{n} \sum_i f_i(\boldsymbol{\phi}_i^{t+1}) \right] &= \frac{1}{n} F(\boldsymbol{x}^t) + \left(1 - \frac{1}{n} \right) \frac{1}{n} \sum_i f_i(\boldsymbol{\phi}_i^t), \\ \mathbb{E}\left[-\frac{1}{n} \sum_i \left\langle \nabla f_i(\widehat{\boldsymbol{x}}), \boldsymbol{\phi}_i^{t+1} - \widehat{\boldsymbol{x}} \right\rangle \right] &= -\frac{1}{n} \left\langle \nabla F(\widehat{\boldsymbol{x}}), \boldsymbol{x}^t - \widehat{\boldsymbol{x}} \right\rangle \\ &\quad - \left(1 - \frac{1}{n} \right) \frac{1}{n} \sum_i \left\langle \nabla f_i(\widehat{\boldsymbol{x}}), \boldsymbol{\phi}_i^t - \widehat{\boldsymbol{x}} \right\rangle. \end{aligned}$$

Also,

$$c \left\| \boldsymbol{x}^{t+1} - \widehat{\boldsymbol{x}} \right\|_2^2 \leq c\nu \left\| \boldsymbol{b}^{t+1} - \widehat{\boldsymbol{x}} \right\|_2^2 = c\nu \left\| \boldsymbol{b}^{t+1} - \widehat{\boldsymbol{x}} + \eta \nabla F(\widehat{\boldsymbol{x}}) \right\|_2^2.$$

For the first term, we have

$$\begin{aligned} &c\nu \, \mathbb{E} \left\| \boldsymbol{b}^{t+1} - \widehat{\boldsymbol{x}} + \eta \nabla F(\widehat{\boldsymbol{x}}) \right\|_2^2 \\ \leq\ & c\nu(1 - \eta\alpha) \left\| \boldsymbol{x}^t - \widehat{\boldsymbol{x}} \right\|_2^2 + c\nu \left((1+\mu)\eta^2 - \frac{\eta}{L} \right) \mathbb{E} \left\| \nabla f_j(\boldsymbol{x}^t) - \nabla f_j(\widehat{\boldsymbol{x}}) \right\|_2^2 \\ &- \frac{2c\nu\eta(L - \alpha)}{L} \left[F(\boldsymbol{x}^t) - F(\widehat{\boldsymbol{x}}) - \left\langle \nabla F(\widehat{\boldsymbol{x}}), \boldsymbol{x}^t - \widehat{\boldsymbol{x}} \right\rangle \right] - c\nu\eta^2\mu \left\| \nabla F(\boldsymbol{x}^t) - \nabla F(\widehat{\boldsymbol{x}}) \right\|_2^2 \\ &+ 2c\nu(1 + \mu^{-1})\eta^2 L \left[\frac{1}{n} \sum_i f_i(\boldsymbol{\phi}_i^t) - F(\widehat{\boldsymbol{x}}) - \frac{1}{n} \sum_i \left\langle \nabla f_i(\widehat{\boldsymbol{x}}), \boldsymbol{\phi}_i^t - \widehat{\boldsymbol{x}} \right\rangle \right]. \end{aligned}$$

Therefore,

$$\begin{aligned} &\mathbb{E}[Z^{t+1}] - Z^t \\ \leq\ & -\frac{1}{\kappa} Z^t + \left(\frac{1}{n} - \frac{2c\nu\eta(L - \alpha)}{L} - 2c\nu\eta^2\alpha\mu \right) \left[F(\boldsymbol{x}^t) - F(\widehat{\boldsymbol{x}}) - \left\langle \nabla F(\widehat{\boldsymbol{x}}), \boldsymbol{x}^t - \widehat{\boldsymbol{x}} \right\rangle \right] \\ &+ \left(\frac{1}{\kappa} + 2c\nu(1 + \mu^{-1})\eta^2 L - \frac{1}{n} \right) \left[\frac{1}{n} \sum_i f_i(\boldsymbol{\phi}_i^t) - F(\widehat{\boldsymbol{x}}) - \frac{1}{n} \sum_i \left\langle \nabla f_i(\widehat{\boldsymbol{x}}), \boldsymbol{\phi}_i^t - \widehat{\boldsymbol{x}} \right\rangle \right] \\ &+ \left(\frac{c}{\kappa} - c\nu\eta\alpha \right) \left\| \boldsymbol{x}^t - \widehat{\boldsymbol{x}} \right\|_2^2 + \left((1+\mu)\eta - \frac{1}{L} \right) c\nu\eta \, \mathbb{E} \left\| \nabla f_j(\boldsymbol{x}^t) - \nabla f_j(\widehat{\boldsymbol{x}}) \right\|_2^2. \end{aligned}$$

In order to guarantee the convergence, we choose proper values for η, c, κ, μ and ν such that the terms in round brackets are non-positive. That is, we require

$$\begin{aligned}\frac{c}{\kappa} - c\nu\eta\alpha &\leq 0,\\ (1+\mu)\eta - \frac{1}{L} &\leq 0,\\ \frac{1}{n} - \frac{2c\nu\eta(L-\alpha)}{L} - 2c\nu\eta^2\alpha\mu &\leq 0,\\ \frac{1}{\kappa} + 2c\nu(1+\mu^{-1})\eta^2 L - \frac{1}{n} &\leq 0.\end{aligned}$$

Pick

$$\begin{aligned}\eta &= \frac{1}{2(\alpha n + L)},\\ \mu &= \frac{2\alpha n + L}{L},\\ \kappa &= \frac{1}{\nu\eta\alpha},\end{aligned}$$

we fulfill the first two inequalities. Pick

$$c = \frac{1}{2\eta(1-\eta\alpha)n}.$$

Then by the last two equalities, we require

$$1 - \eta\alpha \leq \nu \leq \frac{(1-\eta\alpha)L}{\eta\alpha(1-\eta\alpha)Ln + 1}.$$

On the other hand, by Theorem 1, we have

$$\nu > 1.$$

Thus, we require

$$1 < \nu \leq \frac{(1-\eta\alpha)L}{\eta\alpha(1-\eta\alpha)Ln + 1},$$

By algebra, the above inequalities has non-empty feasible set provided that

$$(6\alpha^2 - 8\alpha^2 L)n^2 + (14\alpha L - \alpha - 16\alpha L^2)n + 8L^2(1-L) < 0.$$

Due to $\alpha \leq L$, we know

$$n \geq \frac{14L + \sqrt{224L^3 + 1}}{2\alpha(8L-6)}$$

suffices where we assume $L > 3/4$. Picking

$$\nu = \frac{(1-\eta\alpha)L}{\eta\alpha(1-\eta\alpha)Ln + 1}$$

completes the proof. ■

Abstract

Estimation of Markov Random Field and covariance models from high-dimensional data represents a canonical problem that has received a lot of attention in the literature. A key assumption, widely employed, is that of *sparsity* of the underlying model. In this paper, we study the problem of estimating such models exhibiting a more intricate structure comprising simultaneously of *sparse, structured sparse* and *dense* components. Such structures naturally arise in several scientific fields, including molecular biology, finance and political science. We introduce a general framework based on a novel structured norm that enables us to estimate such complex structures from high-dimensional data. The resulting optimization problem is convex and we introduce a linearized multi-block alternating direction method of multipliers (ADMM) algorithm to solve it efficiently. We illustrate the superior performance of the proposed framework on a number of synthetic data sets generated from both random and structured networks. Further, we apply the method to a number of real data sets and discuss the results.

Keywords: Markov Random Fields, Gaussian covariance graph model, structured sparse norm, regularization, alternating direction method of multipliers (ADMM), convergence.

1. Introduction

There is a substantial body of literature on methods for estimating network structures from high-dimensional data, motivated by important biomedical and social science applications; see Barabási and Albert (1999); Liljeros et al. (2001); Robins et al. (2007); Guo et al. (2011a); Danaher et al. (2014); Friedman et al. (2008); Tan et al. (2014); Guo et al. (2015). Two powerful formalisms have been employed for this task, the Markov Random Field (MRF) model and the Gaussian covariance graph model (GCGM). The former captures statistical conditional dependence relationships amongst random variables that correspond to the network nodes, while the latter to marginal associations. Since in most applications the number of model parameters to be estimated far exceeds the available sample size, the assumption of sparsity is made and imposed through regularization. An ℓ_1 penalty on the parameters encoding the network edges is the most common choice; see Friedman et al. (2008); Karoui (2008); Cai and Liu (2011); Xue et al. (2012), which can also be interpreted from the Bayesian perspective as using an independent double-exponential prior distribution on each edge parameter. Consequently, this approach encourages sparse uniform network structures that may not be the most suitable choice for many real world applications, which in turn have *hub* nodes or *dense subgraphs*. As argued in Barabási and Albert (1999); Liljeros et al. (2001); Newman (2001); Li et al. (2005); Fortunato (2010); Newman (2012) many networks exhibit different structures at different scales. An example includes a densely connected subgraph, also known as a *community* in the social networks literature. Such structures in social interaction networks may correspond to groups of people sharing common interests or being co-located (Traud et al., 2011; Newman and Girvan, 2004), while in biological systems to groups of proteins responsible for regulating or synthesizing chemical products (Guimera and Amaral, 2005; Lewis et al., 2010; see, Figure 3 for an example). Hence, in many applications, simple sparsity or alternatively, a dense structure fails to capture salient features of the true underlying mechanism that gave rise to the available data.

In this paper, we introduce a framework based on a novel structured sparse norm that allows us to recover such complex structures. Specifically, we consider Markov Random Field and covariance models where the parameter of interest, Θ can be expressed as the superposition of sparse, structured sparse and dense components as follows:

$$\Theta = \underbrace{Z_1 + Z_1^\top}_{\text{sparse part}} + \underbrace{Z_2 + Z_2^\top + \cdots + Z_n + Z_n^\top}_{\text{structured sparse part}} + \underbrace{E}_{\text{dense part}}, \tag{1}$$

where Z_1 is a sparse matrix, $Z_2, \ldots, Z_n$ are the set of $n-1$ structured sparse matrices (see, Figure 3 for an example of such structured matrices), and E is a dense matrix having possibly very many small, non-zero entries. As shown in Figure 3, the elements of Z_1 represent edges between non-structured nodes, and the non-zero parts of structured matrices $Z_2, \ldots, Z_n$ correspond to densely connected subgraphs (communities).

We elaborate more on the decomposition proposed above. We start by discussing on the sparse and structured sparse component and then elaborate on the dense component. Traditional sparse (lasso Tibshirani, 1996; Friedman et al., 2008) and group sparse (group lasso Yuan and Lin, 2007; Jacob et al., 2009; Obozinski et al., 2011) are tailor-made to estimate and recover sparse and structured sparse model structures, respectively. However, these methods can not accommodate different structures, unless users specify a *priori* the structure of interest (e.g. hub nodes and sparse components), thus severely limiting their application scope. On the other hand, the general framework introduced, is capable of estimating from high-dimensional data, *groups with overlaps*, *hubs* and *dense subgraphs*, with the size and location of such structures *not known a priori*.

Next, we discuss the role of the dense component E. In many applications, the data generation mechanism may correspond to a true sparse or structured sparse structure, "corrupted" by a dense component comprising of possible many small entries. A simple example of such a generating mechanism in linear models would have the regression coefficient being sparse with a few large entries and a more dense component having possibly many small, nonzero entries. In such instances, a pure sparse model formulation may not perform particularly well due to the presence of the dense component and may require very careful

tuning to recover the sparse component of interest. This line of reasoning is also adopted in Chernozhukov et al. (2017). Note however, that the model may also be used in settings where there is a significant dense component; however, as discussed in Chernozhukov et al. (2017) recovery of the individual component is not guaranteed. Hence, in this work we adopt the viewpoint that E represents a small "perturbation" of the sparse+structured sparse structure. To achieve these goals, it leverages a new structured norm that is used as the regularization term of the corresponding objective function.

The resulting optimization problem is solved through a multi-block ADMM algorithm. A key technical innovation is the development of a linearized ADMM algorithm that avoids introducing auxiliary variables which is a common strategy in the literature. We establish the global convergence of the proposed algorithm and illustrate its efficiency through numerical experimentation. The algorithm takes advantage of the special structure of the problem formulation and thus is suitable for large instances of the problem. To the best of our knowledge, this is the first work that gives global convergence guarantees for linearized multi-block ADMM with Gauss-Seidel updates, which is of interest in its own accord.

The remainder of the paper is organized as follows: In Section 2, we present the new structured norm used as the regularization term in the objective function of the Markov Random Field, covariance graph, regression and vector auto-regression models. In Section 3, we introduce an efficient multi-block ADMM algorithm to solve the problem, and provide the convergence analysis of the algorithm. In Section 4, we illustrate the proposed framework on a number of synthetic and real data sets, while some concluding remarks are drawn in Section 5.

2. A General Framework for Learning under Structured Sparsity

We start by introducing key definitions and associated notation.

2.1 Symmetric Structured Overlap Norm

Let X be an $m \times p$ data matrix, Θ be a $p \times p$ symmetric matrix containing the parameters of interest of the statistical loss function $\mathcal{G}(X, \Theta)$. The most popular assumption used in the literature is that Θ is *sparse* and can be successfully recovered from high-dimensional data by solving the following optimization problem

$$\underset{\Theta \in \mathcal{S}}{\text{minimize}} \quad \mathcal{G}(X, \Theta) + \lambda \big\|\Theta\big\|_1, \tag{2}$$

where $\mathcal{S}$ is some set depending on the loss function; λ is s a non-negative regularization constant; and $\|.\|_1$ denotes the ℓ_1 norm or the sum of the absolute values of the matrix elements.

To explicitly model different structures in the parameter Θ, we introduce the following *symmetric structured overlap norm (SSON)*:

Definition 1 ***(Symmetric Structured Overlap Norm)****. Let Θ be a $p \times p$ symmetric matrix containing the model parameters of interest. The symmetric structured overlap norm for a set of partitioned matrices $Z_1, \ldots, Z_n$ is given by,*

$$\begin{aligned}
\underset{Z_1,\ldots,Z_n,\ E}{\text{minimize}} \quad \Omega(\Theta, Z_1, \ldots, Z_n, E) \ &:= \ \lambda_1 \|Z_1 - \text{diag}(Z_1)\|_1 \\
&+ \ \sum_{i=2}^{n} \hat{\lambda}_i \|Z_i - \text{diag}(Z_i)\|_1 + \lambda_i \sum_{j=1}^{l_i} \|(Z_i - \text{diag}(Z_i))_j\|_F \\
&+ \ \frac{\lambda_e}{2} \|E\|_F^2, \\
\Theta \ &= \ \sum_{i=1}^{n} \big(Z_i + Z_i^\top\big) + E,
\end{aligned} \tag{3}$$

where $\{\lambda_i\}_{i=1}^n$ and $\{\hat{\lambda}_i\}_{i=2}^n$ are nonnegative regularization constants; l_i is the number of blocks of the partitioned matrix Z_i; $(Z_i - \text{diag}(Z_i))_j$ is the jth block of the partitioned matrix Z_i; E is an unstructured noise matrix; $\|.\|_1$ denotes the ℓ_1 norm or the sum of the absolute values of the matrix elements; and $\|.\|_F$ the Frobenius norm.

We note that the overlap norm defined by Mohan et al. (2012); Tan et al. (2014) encourages the recovery of matrices that can be expressed as a union of few rows and the corresponding columns (i.e. hub nodes). However, SSON represents a new symmetric and significantly more general variant of the overlap norm that promotes matrices that can be expressed as the sum of symmetric structured matrices. Moreover, unlike the previous group sparsity and the latent group lasso discussed in Yuan and Lin (2007); Jacob et al. (2009); Obozinski et al. (2011) that require users to specify structures of interest *a priori*, the SSON achieves a similar objective in an *agnostic manner*, relying only on how well such structures fit the observed data.

In many applications, such as regression models, we are interested in modeling different structures in a parameter vector θ. In these cases, we have the following definition as a special case of SSON:

Definition 2 *Let θ be a $p \times 1$ vector containing the model parameters of interest. The structured overlap norm for a set of partitioned vectors $z_1, \ldots, z_n$ is given by,*

$$\begin{aligned}
\underset{z_1,\ldots,z_n,\ e}{\text{minimize}} \quad \omega(\theta, z_1, \ldots, z_n, e) \ &:= \ \lambda_1 \|z_1\|_1 + \sum_{i=2}^{n} \hat{\lambda}_i \|z_i\|_1 + \lambda_i \sum_{j=1}^{l_i} \|z_{ij}\|_2 + \frac{\lambda_e}{2} \|e\|_2^2, \\
\theta \ &= \ z_1 + z_2 + \cdots + z_n + e,
\end{aligned} \tag{4}$$

where $\{\lambda_i\}_{i=1}^n$ and $\{\hat{\lambda}_i\}_{i=2}^n$ are nonnegative regularization constants; l_i is the number of blocks of the partitioned vector z_i; z_{i_j} is the jth block of the partitioned vector z_i (see, Figure 1); e is an unstructured noise vector; $\|.\|_1$ denotes the ℓ_1 norm or the sum of the absolute values of the vector elements; and $\|.\|_2$ the two norm.

Remark 3 *In the formulation of the problem, λ_1, $\{\hat{\lambda}_2, \ldots, \hat{\lambda}_n, \lambda_2, \ldots, \lambda_n\}$, and λ_e are tuning parameters corresponding to the sparse component Z_1, the structured components $\{Z_2, \ldots Z_n\}$ and the dense (noisy) component E, respectively. While the nonzero components may be clustered into groups, the nonzero groups may also be sparse. The latter can be achieved by (3) when $\{\hat{\lambda}_2, \ldots, \hat{\lambda}_n\}$ are positive constants.*

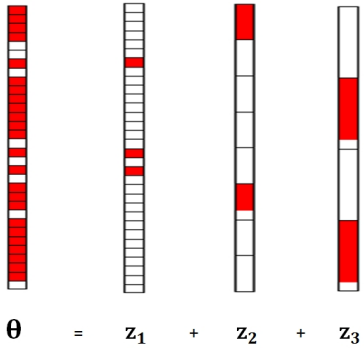

Figure 1: Decomposition of a vector θ into partitioned vectors z_1, z_2 and z_3, where z_1 is sparse, z_2 and z_3 are structured sparse vectors. White and red elements are zero and non-zero in the model parameter vector θ, respectively.

Remark 4 *The SSON admits the lasso (Tibshirani, 1996), the group lasso with overlaps (Jacob et al., 2009; Obozinski et al., 2011) and the ridge shrinkage (Hoerl and Kennard, 1970) methods as three extreme cases, by respectively setting* $\{\hat{\lambda}_2, \ldots, \hat{\lambda}_n, \lambda_2, \ldots, \lambda_n, \lambda_e\} \to \infty$, $\{\lambda_1, \hat{\lambda}_2, \ldots, \hat{\lambda}_n, \lambda_e\} \to \infty$, *and* $\{\lambda_1, \ldots, \lambda_n, \hat{\lambda}_2, \ldots, \hat{\lambda}_n\} \to \infty$[1].

Note that SSON is rather different from the sparse group lasso, which also uses a combination of ℓ_1 and ℓ_G penalization, where $\|.\|_G$ is the group lasso norm. The sparse group lasso penalty is $\bar{\omega}(\theta) = \lambda_1\|\theta\|_1 + \lambda_2\|\theta\|_G$, and thus the includes lasso and group lasso as extreme cases corresponding to $\lambda_2 = 0$ and $\lambda_1 = 0$, respectively. However, $\bar{\omega}(\theta)$ does not split θ into a sparse and a group sparse part and will produce a sparse solution as long as $\lambda_1 > 0$. Hence, the sparse group lasso method can be thought of as a sparsity-based method with additional shrinkage by $\|\theta\|_G$. The group sparsity processes data very differently from SSON and consequently has very different prediction risk behavior. The same argument illustrates the advantages of the proposed SSON penalty over the well-known elastic net penalty. The elastic net is a combination of lasso and ridge penalties (Zou and Hastie, 2005). However, the elastic net does not split θ into a sparse and a dense component. Our results show that SSON tends to perform no worse than, and often performs significantly better than ridge, lasso, group lasso or elastic net with penalty levels chosen by cross-validation.

Remark 5 *In order to encourage different structures in the parameter matrix* Θ*, we consider the Frobenius norm of blocks of partitioned matrices, which leads to recovery of dense subgraphs. Other values for the norm of such blocks are also possible; e.g. the* ℓ_∞ *norm.*

Remark 6 *The matrix* E *is an important component of the SSON framework.*

It enables to develop a convergent multi-block ADMM *to solve the problem of estimating a structured Markov Random Field or covariance model. Note that in general, a direct extension of ADMM to multi-block convex minimization problems is* not *necessarily convergent even without linearization of the corresponding subproblems as shown in Chen et al. (2016).*

From a performance standpoint, our results show that adding a ridge penalty term $\frac{\lambda_e}{2}\|E\|_F^2$ *to the structured norm is provably effective in correctly identifying the underlying structures in the presence of noisy data (Zou and Hastie, 2005; Chernozhukov et al., 2017) (see, Figure 2 for an example of decomposition* (1) *in the presense of noise for covariance matrix estimation.)*

1. For example, with $\lambda_e \to \infty$, we set $\frac{\lambda_e}{2}\|E\|_F^2 = 0$ when $E = 0$, so the problem is well-defined.

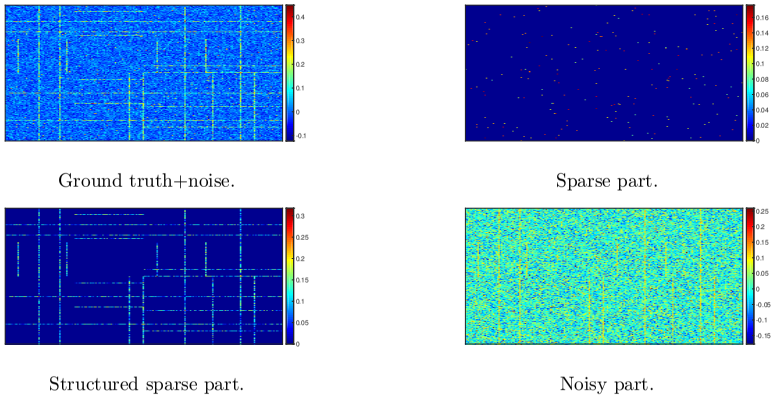

Figure 2: Heat map of the covariance matrix Θ_3 decomposed into sparse and structured sparse parts in the presence of noise, estimated by SSON using problem (11).

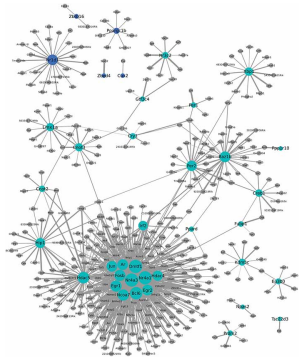
Next, we discuss the use of the SSON as a regularizer for maximum likelihood estimation of the following popular statistical models: (i) members of the Markov Random Field family including the Gaussian graphical model, the Gaussian graphical model with latent variables and the binary Ising model, (ii) the Gaussian covariance graph model and (iii) the classical regression and the vector auto-regression models. For the sake of completeness, we provide a complete, but succinct description of the corresponding models and the proposed regularization.

2.2 Structured Gaussian Graphical Models

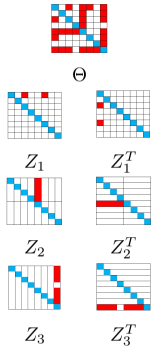
Let X be a data matrix consisting of p-dimensional samples from a zero mean Gaussian distribution,

$$x_1, \ldots, x_m \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0, \Sigma).$$

In order to obtain a sparse and interpretable estimate of the precision matrix Σ^{-1} that captures conditional dependence relationships, many authors have considered the well-known



(a) Postpartum NAC Gene Network (Zhao et al., 2014).



(b) Examples of partitioned matrices for the underlying network in (a).

Figure 3: The figure illustrates that block partitions through structured matrices could be set based on a desire for interpretability of the resulting estimated network structure. Panel (a) shows example of structured gene network, while panel (b) provides decomposition into structured matrices for the network in (a). Blue elements are diagonal ones, white elements are zero and red elements are non-zero in the model parameter matrix Θ. The structured penalty function (3) is then applied to each block for matrices $\{Z_i\}_{i=1}^n$.

graphical lasso problem (Friedman et al., 2008; Rothman et al., 2008) in the form of (2) with loss function

$$\mathcal{G}_1(X, \Theta_1) := \text{trace}(\hat{\Sigma}\Theta_1) - \log\det\Theta_1, \qquad \Theta_1 \in \mathcal{S}, \tag{5}$$

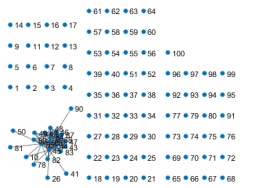
where $\hat{\Sigma}$ is the empirical covariance matrix of X; Θ_1 is the estimate of the precision matrix Σ^{-1}; and $\mathcal{S}$ is the set of $p \times p$ symmetric positive definite matrices.

As is well known, the norm penalty in (2) encourages zeros (sparsity) in the solution. However, as previously argued, many biological and social network applications exhibit more complex structures than mere sparsity. Using the proposed SSON, we define the following objective function for the problem at hand:

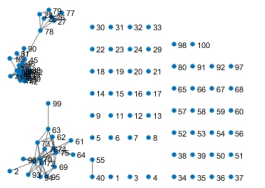
$$\begin{aligned} \underset{\Theta_1, Z_1, \ldots, Z_n \in \mathcal{S},\ E}{\text{minimize}} \quad & \mathcal{G}_1(X, \Theta_1) + \Omega(\Theta_1, Z_1, \ldots, Z_n, E), \\ \Theta_1 \quad = \quad & \sum_{i=1}^{n} \left(Z_i + Z_i^\top\right) + E, \end{aligned} \tag{6}$$

where Θ_1 is the model parameter matrix and $\Omega(\Theta_1, Z_1, \ldots, Z_n, E)$ the corresponding SSON defined in (3).

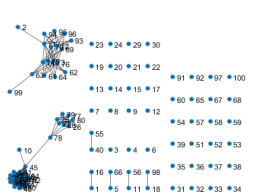
Formulation (6) allows us to obtain more accurate and compact network estimates than conventional methods whenever the network exhibits different structures. Moreover, our formulation does not require *a priori* knowledge of the underlying network structure (i.e. which nodes in the network form densely connected subgraphs (see, Figure 4)).



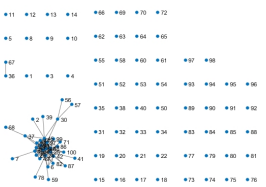
(a) Graphical lasso regularization.



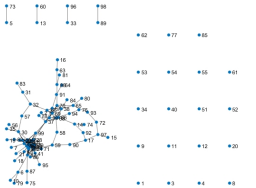
(b) SSON based regularization.



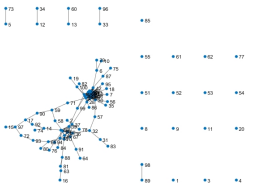
(c) Ground truth.



(d) Graphical lasso regularization.



(e) SSON based regularization.



(f) Ground truth.

Figure 4: Estimates from the SSON based regularization on two examples of Gaussian graphical models comprising of $p = 100$ nodes, using in (4b) three structured matrices and in (4e) four structured matrices.

In Figure 4, the performance of our proposed approach is illustrated on two simulated data sets exhibiting different structures (sub-figures (4c) and (4f)); it can be seen that the proposed SSON based graphical lasso (sub-figures (4b) and (4e)) can recover the network structure much better than the popular graphical lasso based estimator (Friedman et al., 2008) (subfigures (4a) and (4d)).

2.3 Structured Ising Model

Another popular graphical model, suitable for binary or categorical data, is the Ising one (Ising, 1925). It is assumed that observations $x_1, \ldots, x_m$ are independent and identically distributed from

$$f(x, \Theta_2) = \frac{1}{\mathbb{W}(\Theta_2)} \exp\Big(\sum_{j=1}^{p} \theta_{jj} x_j + \sum_{1 \le j < j' \le p} \theta_{jj'} x_j x_{j'}\Big), \tag{7}$$

where $\mathbb{W}(\Theta_2)$ is the partition function, which ensures that the density sums to one. Here, Θ_2 is a $p \times p$ symmetric matrix that specifies the network structure: $\theta_{jj'} = 0$ implies that the jth and j'th variables are conditionally independent given the remaining ones.

Several papers proposing estimation procedures for this model have been published. Lee et al. (2007) considered maximizing an ℓ_1-penalized log-likelihood for this model. Due to the difficulty in computing the log-likelihood with the expensive partition function, several authors have considered alternative approaches. For instance, Ravikumar et al. (2011)

proposed a neighborhood selection approach. The latter proposal involves solving p logistic regressions separately (one for each node in the network), which leads to an estimated parameter matrix that is in general not symmetric. In contrast, several authors considered maximizing an ℓ_1-penalized pseudo-likelihood with a symmetric constraint on Θ_2 (Guo et al., 2011a,b). Under the model (7), the log-pseudo-likelihood for m observations takes the form

$$\mathcal{G}_2(X,\Theta_2) := \sum_{j=1}^{p}\sum_{j'=1}^{p}\theta_{jj'}(X^TX)_{jj'} - \sum_{i=1}^{m}\sum_{j=1}^{p}\log\Big(1+\exp\big(\theta_{jj}+\sum_{j'\neq j}\theta_{jj'}x_{ij'}\big)\Big), \tag{8}$$

We propose instead to impose the SSON on Θ_2 in (8) in order to estimate a binary network with different structures. This leads to the following optimization problem

$$\begin{aligned}\underset{\Theta_2,Z_1,\ldots,Z_n\in\mathcal{S},\ E}{\text{minimize}} \quad & \mathcal{G}_2(X,\Theta_2)+\Omega(\Theta_2,Z_1,\ldots,Z_n,E),\\ \Theta_2 \;&=\; \sum_{i=1}^{n}\big(Z_i+Z_i^\top\big)+E,\end{aligned} \tag{9}$$

where Θ_2 is the model parameter matrix and $\Omega(\Theta_2,Z_1,\ldots,Z_n,E)$ the corresponding SSON defined in (3).

An interesting connection can be drawn between our technique and the Ising block model discussed in Berthet et al. (2016), which is a perturbation of the mean field approximation of the Ising model known as the Curie-Weiss model: the sites are partitioned into two blocks of equal size and the interaction between those within the same block is stronger than across blocks, to account for more order within each block. However, one can easily seen that the Ising block model is a special case of (9).

2.4 Structured Gaussian Covariance Graphical Models

Next, we consider estimation of a covariance matrix under the assumption that

$$x_1,\ldots,x_m \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0,\Sigma).$$

This is of interest because the sparsity pattern of Σ specifies the structure of the marginal independence graph (Drton and Richardson, 2002, 2008).

Let Θ_3 be a $p\times p$ symmetric matrix containing the parameters of interest. Setting the loss function $\mathcal{G}_3(X,\Theta_3) := \frac{1}{2}\|\Theta_3-\hat{\Sigma}\|_F^2$, Xue et al. (2012) proposed to estimate the positive definite covariance matrix, $\hat{\Sigma}$ by solving

$$\underset{\Theta_3\in\mathcal{S}}{\text{minimize}} \quad \mathcal{G}_3(X,\Theta_3)+\lambda\|\Theta_3\|_1, \tag{10}$$

where $\hat{\Sigma}$ is the empirical covariance matrix, $\mathcal{S}=\{\Theta_3:\Theta_3\succeq\varepsilon I \text{ and } \Theta_3=\Theta_3^T\}$, and ε is a small positive constant. We extend (10) to accommodate structures of the covariance graph by imposing the SSON on Θ_3. This results in the following optimization problem

$$\begin{aligned}\underset{\Theta_3,Z_1,\ldots,Z_n\in\mathcal{S},\ E}{\text{minimize}} \quad & \mathcal{G}_3(X,\Theta_3)+\Omega(\Theta_3,Z_1,\ldots,Z_n,E),\\ \Theta_3 \;&=\; \sum_{i=1}^{n}\big(Z_i+Z_i^\top\big)+E.\end{aligned} \tag{11}$$

where Θ_3 is the model parameter matrix and $\Omega(\Theta_3,Z_1,\ldots,Z_n,E)$ the corresponding SSON defined in (3).

2.5 Structured Gaussian Graphical Models with latent variables

In many applications throughout science and engineering, it is often the case that some relevant variables are not observed. For the Gaussian Graphical model, Chandrasekaran et al. (2010) proposed a convex optimization problem to estimate it in the presence of latent variables. Let Θ_4 be a $p\times p$ symmetric matrix containing the parameters of interest. Setting $\mathcal{G}_4(X,\Theta_4) := \langle\Theta_4,\Sigma_O\rangle - \log\det\Theta_4$, their objective function is given by

$$\begin{aligned}\underset{\Theta_4,Z_1,Z_2\in\mathcal{S}}{\text{minimize}} \quad & \mathcal{G}_4(X,\Theta_4)+\alpha\|Z_1\|_1+\beta\,\text{trace}(Z_{n+1})+\mathbb{1}_{Z_{n+1}\succeq 0},\\ \Theta_4 \;&=\; Z_1-Z_{n+1},\end{aligned} \tag{12}$$

where Σ_O is the sample covariance matrix of the observed variables; α and β are positive constants; and the indicator function $\mathbb{1}_{Z_{n+1}\succeq 0}$ is defined as

$$\mathbb{1}_{Z_{n+1}\succeq 0} := \begin{cases}0, & \text{if } Z_{n+1}\succeq 0,\\ +\infty, & \text{otherwise.}\end{cases}$$

This convex optimization problem aims to estimate an inverse covariance matrix that can be decomposed into a sparse matrix Z_1 minus a low-rank matrix Z_{n+1} based on high-dimensional data.

Next, we extend the SSON to solve the latent variable graphical model selection. Problem (12) can be rewritten in the following equivalent form by introducing new variables $\{Z_i\}_{i=1}^n$:

$$\begin{aligned}\underset{\Theta_4,Z_1,\ldots,Z_n\in\mathcal{S},\ E}{\text{minimize}} \quad & \mathcal{G}_4(X,\Theta_4)+\Omega(\Theta_4,Z_1,\ldots,Z_n,E)+\lambda_{n+1}\,\text{trace}(Z_{n+1})+\mathbb{1}_{Z_{n+1}\succeq 0},\\ \Theta_4 \;&=\; \sum_{i=1}^{n}\big(Z_i+Z_i^\top\big)-Z_{n+1}+E,\end{aligned} \tag{13}$$

where Θ_4 is the model parameter matrix and $\Omega(\Theta_4,Z_1,\ldots,Z_n,E)$ the corresponding SSON defined in (3).

2.6 Structured Linear Regression and Vector Auto-Regression

The proposed SSON is also applicable to structured regression problems. Although this is not the main focus on this paper, nevertheless, we include a brief discussion, especially for lag selection in vector autoregressive models that are of prime interest in the analysis of high-dimensional time series data. The canonical formulation of the regularized regression problem is given by:

$$\min_{\theta\in\mathbb{R}^p}\|y-X\theta\|_2+\lambda\Psi(\theta). \tag{14}$$

where $\{(y_i,x_i)\}_{i=1}^m$, $y_i\in\mathbb{R}$, $x_i\in\mathbb{R}^p$, with $y=[y_1,\ldots,y_m]^\top$ being the response variable and $X=[x_1^\top,\ldots x_m^\top]$ a set of p-predictors that are assumed to be independently and identically distributed (i.i.d.); $\lambda>0$ is a regularization parameter and $\Psi(\theta)$ is a suitable norm. Specific

choices of $\Psi(.)$ lead to popular regularizers including the lasso -$\Psi(\theta) = \|\theta\|_1$- and the group lasso.

We propose instead to impose the SSON on θ in (14) in order to solve structured regression problems. Problem (14) can be rewritten in the following form by introducing new variables $\{z_i\}_{i=1}^n$ and e:

$$\begin{aligned} \underset{\theta, z_1, .., z_n, e}{\text{minimize}} \quad & \mathcal{G}(X, \theta) + \omega(\theta, z_1, \ldots, z_n, e), \\ \theta_4 \quad = \quad & z_1 + z_2 + \cdots + z_n + e, \end{aligned} \tag{15}$$

where $\mathcal{G}(X, \theta) = \|y - X\theta\|_2$; θ is the model parameter vector and $\omega(\theta, z_1, \ldots, z_n, e)$ the corresponding structured norm defined in (4).

Problem (15) can equivalently be thought of as a generalization of subspace clustering (Elhamifar and Vidal, 2009). Indeed, in order to segment the data into their respective subspaces, we need to compute an affinity vector θ that encodes the pairwise affinities between data vectors.

An interesting application of the SSON for multivariate regression problems is on structured estimation of *vector autoregression* (VAR) models (Lütkepohl, 2005), a popular model for economic and financial time series data (Tsay, 2005), dynamical systems (Ljung, 1998) and more recently brain function connectivity (Valdés-Sosa et al., 2005). The model captures both temporal and cross-dependencies between stationary time series. Formally, let $\{x_1, \ldots, x_m\}$ be a p-dimensional time series set of observations that evolve over time according to a lag-d model:

$$x_{t+1} = \sum_{k=1}^{d} \Theta_k^\top x_{t-k} + \epsilon_t, \qquad \epsilon_1, \ldots, \epsilon_{m-1} \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0, \Sigma), \qquad t = 1, \ldots, m-1,$$

where $\{\Theta\}_{k=1}^d \in \mathbb{R}^{p \times p}$ are *transition matrices* for different lags, and $\{\epsilon_1, \ldots, \epsilon_{m-1}\}$ independent multivariate Gaussian *white noise* processes. The VAR process is assumed to be stable and stationary (bounded spectral density), while the noise covariance matrix Σ is assumed to be positive definite with bounded largest eigenvalue (Basu and Michailidis, 2015).

Given m observations $\{x_1, x_2, \ldots, x_m\}$ from a stationary VAR process, the lag-m VAR can be written is given by

$$\underbrace{\begin{bmatrix} x_m \\ x_{m-1} \\ \vdots \\ x_2 \end{bmatrix}}_{\mathbf{Y}} = \underbrace{\begin{bmatrix} {x_{m-1}}^\top \\ {x_{m-2}}^\top \\ \vdots \\ {x_1}^\top \end{bmatrix}}_{\mathbf{X}} \Theta + \underbrace{\begin{bmatrix} {\epsilon_{m-1}}^\top \\ {\epsilon_{m-2}}^\top \\ \vdots \\ {\epsilon_1}^\top \end{bmatrix}}_{\varepsilon}. \tag{16}$$

It can be seen that to estimate Θ one can solve the following least squares problem

$$\min_{\Theta \in \mathbb{R}^{p \times p}} \|Y - X\Theta\|_F. \tag{17}$$

However, as the number of component time series increases, the number of parameters to be estimated grows as dp^2 ; hence, structural assumptions are imposed to estimate them from

limited sample size. A popular choice is the lasso (Basu and Michailidis, 2015), that leads to sparse estimates. However, it does not incorporate the notion of lag selection, which could lead to certain spurious coefficients coming from further lags in the past. To address this problem, Basu et al. (2015) proposed a thresholded lasso estimate. However, our SSON can be used for lag selection, that guarantees that more recent lags are favored over further in the past ones.

Let Θ_5 be a $mp \times mp$ symmetric matrix containing the parameters of interest for all m lages of the problem. Setting the loss function $\mathcal{G}_5(X, \Theta_5) := \|Y - X\Theta_5\|$, we propose to estimate the transition matrix, Θ by solving the following optimization problem:

$$\begin{aligned} \min_{\Theta_5, Z_1, .., Z_n, E \in \mathbb{R}^{p \times p}} \quad & \mathcal{G}_5(X, \Theta_5) + \Omega(\Theta_5, Z_1, \ldots, Z_n, E), \\ \Theta_5 \quad = \quad & \sum_{i=1}^{n} \left(Z_i + Z_i^\top\right) + E, \end{aligned} \tag{18}$$

where Θ_5 is the estimate of the covariance matrix and $\Omega(\Theta_5, Z_1, \ldots, Z_n, E)$ the corresponding SSON defined in (3).

3. Multi-Block ADMM for Estimating Structured Network Models

Objective functions (6), (9), (11), (13), (15), and (18) involve separable convex functions, while the constraint is simply linear, and therefore they are suitable for ADMM based algorithms. We next introduce a linearized multi-block ADMM algorithm to solve these problems and establish its global convergence properties.

The alternating direction method of multipliers (ADMM) is widely used in solving structured convex optimization problems due to its superior performance in practice; see Scheinberg et al. (2010); Boyd et al. (2011); Hong and Luo (2017); Lin et al. (2015, 2016); Sun et al. (2015); Davis and Yin (2015); Hajinezhad and Hong (2015); Hajinezhad et al. (2016). On the theoretical side, Chen et al. (2016) provided a counterexample showing that the ADMM may *fail to converge* when the number of blocks exceeds *two*. Hence, many authors reformulate the problem of estimating a Markov Random Field model to a two block ADMM algorithm by grouping the variables and introducing auxiliary variables (Ma et al., 2013; Mohan et al., 2012; Tan et al., 2014). However, in the context of large-scale optimization problems, the grouping ADMM method becomes expensive due to its high memory requirements. Moreover, despite lack of convergence guarantees under standard convexity assumptions, it has been observed by many researchers that the unmodified multi-block ADMMs with Gauss-Seidel updates often outperform all its modified versions in practice (Wang et al., 2013; Sun et al., 2015; Davis and Yin, 2015).

Next, we present a *convergent multi-block* ADMM with Gauss-Seidel updates to solve convex problems (6), (9), (11), (13), and (18). The ADMM is constructed for an augmented Lagrangian function defined by

$$\begin{aligned} \mathcal{L}_\gamma(\Theta, Z_1, \ldots, Z_n, E; \Lambda) \quad = \quad & \mathcal{G}(X, \Theta) + f_1(Z_1) + \cdots + f_n(Z_n) + \frac{\lambda_e}{2}\|E\|_F^2 \\ - \quad & \langle \Lambda, \Theta - \sum_{i=1}^{n} Z_i + Z_i^\top - E \rangle + \frac{\gamma}{2}\|\Theta - \sum_{i=1}^{n} Z_i + Z_i^\top - E\|_F^2, \end{aligned} \tag{19}$$

where Λ is the Lagrange multiplier, γ a penalty parameter, $\mathcal{G}(X,\Theta)$ the loss function of interest and

$$\begin{aligned} f_1(Z_1) &:= \lambda_1\|Z_1 - \mathrm{diag}(Z_1)\|_1, \\ f_i(Z_i) &:= \hat{\lambda}_i\|Z_i - \mathrm{diag}(Z_i)\|_1 + \lambda_i \sum_{j=1}^{l_i} \|(Z_i - \mathrm{diag}(Z_i))_j\|_F, \quad i = 2,\ldots,n. \end{aligned} \tag{20}$$

In a typical iteration of the ADMM for solving (19), the following updates are implemented:

$$\Theta^{k+1} = \underset{\Theta}{\mathrm{argmin}} \quad \mathcal{G}(X,\Theta) + \frac{\gamma}{2}\|\Theta - B_0\|_F^2, \tag{21}$$

$$Z_i^{k+1} = \underset{Z_i}{\mathrm{argmin}} \quad f_i(Z_i) + \frac{\gamma}{2}\|Z_i + Z_i^\top - B_i\|_F^2, \qquad i = 1,\ldots n, \tag{22}$$

$$E^{k+1} = \underset{E}{\mathrm{argmin}} \quad f_e(E) + \frac{\gamma}{2}\|E - B_{n+1}\|_F^2, \tag{23}$$

$$\Lambda^{k+1} = \Lambda^k - \gamma(\Theta^{k+1} - \sum_{i=1}^{n} Z_i^{k+1} + {Z_i^{k+1}}^\top - E^{k+1}). \tag{24}$$

where

$$\begin{aligned} B_0 &= \sum_{i=1}^{n} Z_i^k + {Z_i^k}^\top + E^k + \frac{1}{\gamma}\Lambda^k, \\ B_1 &= \Theta^{k+1} - (\sum_{i=2}^{n} Z_i^k + {Z_i^k}^\top + E^k + \frac{1}{\gamma}\Lambda^k), \\ B_i &= \Theta^{k+1} - (\sum_{j=1}^{i-1} Z_j^{k+1} + {Z_j^{k+1}}^\top \\ &\quad + \sum_{j=i+1}^{n} Z_j^k + {Z_j^k}^\top + E^k + \frac{1}{\gamma}\Lambda^k), \qquad i = 2,\ldots n-1, \\ B_n &= \Theta^{k+1} - (\sum_{i=1}^{n-1} Z_i^{k+1} + {Z_i^{k+1}}^\top + E^k + \frac{1}{\gamma}\Lambda^k), \\ B_{n+1} &= \Theta^{k+1} - (\sum_{i=1}^{n} Z_i^{k+1} + {Z_i^{k+1}}^\top + \frac{1}{\gamma}\Lambda^k). \end{aligned} \tag{25}$$

To avoid introducing auxiliary variables and still solve subproblems (22) efficiently, we propose to approximate the subproblems (22) by linearizing the quadratic term of its objective function (see also Bolte et al., 2014; Lin et al., 2011; Yang and Yuan, 2013). With this linearization, the resulting approximation to (22) is then simple enough to have a closed-form solution. More specifically, letting $H_i(Z_i) = \frac{\gamma}{2}\|Z_i + Z_i^\top - B_i\|_F^2$, we define the following majorant function of $H_i(Z_i)$ at point Z_i^k,

$$H_i(Z_i) \le \gamma\Big(\frac{1}{2}\|Z_i^k + {Z_i^k}^\top - B_i\|_F^2 + \langle \nabla H_i(Z_i^k), Z_i - Z_i^k\rangle + \frac{\varrho}{2}\|Z_i - Z_i^k\|_F^2\Big), \tag{26}$$

where ϱ is a proximal parameter, and

$$\nabla H_i(Z_i^k) := 2(Z_i^k + {Z_i^k}^\top) - (B_i + B_i^\top), \tag{27}$$

Plugging (26) into (22), with simple algebraic manipulations, we obtain:

$$Z_i^{k+1} = \underset{Z_i}{\mathrm{argmin}} \quad f_i(Z_i) + \frac{\varrho\gamma}{2}\|Z_i - C_i\|_F^2, \qquad i = 1,\ldots n, \tag{28}$$

where $C_i = Z_i^k - \frac{1}{\varrho}\nabla H_i(Z_i^k)$.

The next result establishes the sufficient decrease property of the objective function given in (22), after a proximal map step computed in (28).

Lemma 7 *(Sufficient decrease property). Let $\varrho > \frac{L_{H_i}}{\gamma}$, where L_{H_i} is a Lipschitz constant of the gradient $\nabla H_i(Z_i)$ and γ is a penalty parameter defined in* (19)*. Then, we have*

$$f_i(Z_i^{k+1}) + H_i(Z_i^{k+1}) \le f_i(Z_i^k) + H_i(Z_i^k) - \frac{(\varrho\gamma - L_{H_i})}{2}\|Z_i^{k+1} - Z_i^k\|_F^2, \qquad i = 1,\ldots,n,$$

where $Z_i^{k+1} \in \mathbb{R}^{n\times n}$ defined by (28)*.*

Proof. The proof of this Lemma follows along similar lines to the proof of Lemma 3.2 in Bolte et al. (2014).

It is well known that (28) has a closed-form solution that is given by the shrinkage operation (Boyd et al., 2011):

$$\begin{aligned} Z_1^{k+1} &= \mathrm{Shrink}\Big(C_1, \frac{\lambda_1}{\varrho\gamma}\Big), \\ Z_{i_j}^{k+1} &= \max\big(1 - \frac{\lambda_i}{\varrho\gamma\|\mathrm{Shrink}(C_{i_j}, \frac{\hat{\lambda}_i}{\varrho\gamma})\|_F}, 0\big)\cdot \mathrm{Shrink}(C_{i_j}, \frac{\hat{\lambda}_i}{\varrho\gamma}), \quad \substack{i=2,\ldots n,\\ j=1,\ldots,l_i,} \end{aligned} \tag{29}$$

where $\mathrm{Shrink}(\cdot,\cdot)$ in (29) denotes the soft-thresholds operator, applied element-wise to a matrix A (Boyd et al., 2011):

$$\mathrm{Shrink}(A_{ij}, b) := \mathrm{sign}(A_{ij})\max\big(|A_{ij}| - b, 0\big) \qquad \substack{i=1,\ldots p,\\ j=1,\ldots,p,}.$$

Remark 8 *Note that in the case of solving problem* (13)*, one needs to add another block function $f_{n+1}(Z_{n+1}) := \lambda_{n+1}\,\mathrm{trace}(Z_{n+1}) + \mathbb{1}_{Z_{n+1}\succeq 0}$ to the augmented Lagrangian function* (19) *and update $\{C_i\}_{i=1}^n$. In this case, the proximal mapping of f_{n+1} is*

$$prox(f_{n+1}, \gamma, Z_{n+1}) := \underset{Z_{n+1}}{\mathrm{argmin}}\, f_{n+1}(Z_{n+1}) + \frac{\gamma}{2}\|Z_{n+1} - C_{n+1}\|_F^2, \tag{30}$$

where $C_{n+1} = \Theta^{k+1} - (\sum_{i=1}^n Z_i^{k+1} + {Z_i^{k+1}}^\top + E^k + \frac{1}{\gamma}\Lambda^k)$. It is easy to verify that (30) *has a closed-form solution given by*

$$Z_{n+1} = U\ \max(D - \frac{\lambda_{n+1}}{\gamma}, 0)\ U^T,$$

where UDU^T is the eigenvalue decomposition of C_{n+1} (see, Chandrasekaran et al., 2010; Ma et al., 2013 for more details).

The discussions above suggest that the following unmodified ADMM for solving (19) gives rise to an efficient algorithm.

Algorithm 1 Multi-Block ADMM Algorithm for Solving (19).

1: **Initialize** The parameters:

(a) Primal variables Θ, Z_1, ..., Z_n, E, to the $p \times p$ identity matrix.

(b) Dual variable Λ to the $p \times p$ zero matrix.

(c) Constants $\varrho, \lambda_e, \tau > 0$, and $\gamma \geq \sqrt{2}\lambda_e$.

(d) Nonnegative regularization constants $\lambda_1, \ldots, \lambda_n$, $\hat{\lambda}_2, \ldots, \hat{\lambda}_n$.

2: **Iterate** Until the stopping criterion $\|\Theta^k - \Theta^{k-1}\|_F^2 / \|\Theta^{k-1}\|_F \leq \tau$ is met:

(a) Update Θ:

$$\Theta^{k+1} = \underset{\Theta \in \mathcal{S}}{\operatorname{argmin}} \ \mathcal{G}(X, \Theta) + \frac{\gamma}{2}\|\Theta - B_0\|_F^2,$$

where B_0 is defined in (25).

(b) Update Z_i:

i. $Z_1^{k+1} = \mathrm{Shrink}\Big(C_1, \frac{\lambda_1}{\varrho\gamma}\Big)$,

ii. $Z_{ij}^{k+1} = \max\big(1 - \dfrac{\lambda_i}{\varrho\gamma\|\mathrm{Shrink}(C_{ij}, \frac{\hat{\lambda}_i}{\varrho\gamma})\|_F}, 0\big) \cdot \mathrm{Shrink}(C_{ij}, \frac{\hat{\lambda}_i}{\varrho\gamma}), \quad \substack{i=2,\ldots n,\\ j=1,\ldots l_i,}$

where C_i is defined in (28).

(c) Update E:

$$E^{k+1} = \underset{E}{\operatorname{argmin}} \ \tfrac{\lambda_e}{2}\|E\|_F^2 + \tfrac{\gamma}{2}\|E - B_{n+1}\|_F^2$$

where B_{n+1} is defined in (25).

(d) Update Λ:

$$\Lambda^{k+1} = \Lambda^k - \gamma(\Theta^{k+1} - \textstyle\sum_{i=1}^n Z_i^{k+1} + Z_i^{k+1^\top} - E^{k+1})$$

Remark 9 *The complexity of Algorithm 1 is of the same order as the graphical lasso (Friedman et al., 2008), the method in Tan et al. (2014) for hub node discovery and the algorithm used for estimation of sparse covariance matrices introduced by Xue et al. (2012). Indeed, one can easily see that with any set of structured matrices $\{Z_i\}_{i=1}^n$, the complexity of Algorithm 1 is equal to $O(p^3)$, which is the complexity of the eigen-decomposition for updating Θ in step 2(a).*

Since both the objective function and constraints of (19) become separable after using the linearization technique introduced in (26), the problem can be decomposed into $n+2$ smaller subproblems; the latter can be solved in a parallel and distributed manner with a small modification in Algorithm 1. Indeed, we can apply a Jacobian ADMM to solve (19)

with the following updates,

$$\begin{aligned}
\Theta^{k+1} &= \underset{\Theta}{\operatorname{argmin}} \quad \mathcal{G}(X, \Theta) + \frac{\gamma}{2}\|\Theta - B_0\|_F^2, \\
Z_i^{k+1} &= \underset{Z_i}{\operatorname{argmin}} \quad f_i(Z_i) + \frac{\varrho\gamma}{2}\|Z_i - C_i\|_F^2, \qquad i = 1, \ldots n, \\
E^{k+1} &= \underset{E}{\operatorname{argmin}} \quad f_e(E) + \frac{\gamma}{2}\|E - B_{n+1}\|_F^2, \\
\Lambda^{k+1} &= \Lambda^k - \gamma(\Theta^{k+1} - \sum_{i=1}^n Z_i^{k+1} + Z_i^{k+1^\top} - E^{k+1}).
\end{aligned} \tag{31}$$

where C_i is defined in (28) with

$$\begin{aligned}
B_0 &= \sum_{i=1}^n Z_i^k + Z_i^{k^\top} + E^k + \frac{1}{\gamma}\Lambda^k, \\
B_i &= \Theta^k - (\sum_{j=1}^{i-1} Z_j^k + Z_j^{k^\top} \\
&\quad + \sum_{j=i+1}^{n} Z_j^k + Z_j^{k^\top} + E^k + \frac{1}{\gamma}\Lambda^k), \qquad i = 2, \ldots n-1, \\
B_n &= \Theta^k - (\sum_{i=1}^{n-1} Z_i^k + Z_i^{k^\top} + E^k + \frac{1}{\gamma}\Lambda^k), \\
B_{n+1} &= \Theta^k - (\sum_{i=1}^{n} Z_i^k + Z_i^{k^\top} + \frac{1}{\gamma}\Lambda^k).
\end{aligned} \tag{32}$$

Intuitively, the performance of the Jacobian ADMM should be worse than the Gauss-Seidel version, because the latter always uses the latest information of the primal variables in the updates. We refer to Liu et al. (2015); Lin et al. (2015) for a detailed discussion on the convergence analysis of the Jacobian ADMM and its variants. On the positive side, we obtain a parallelizable version of the multi-block ADMM algorithm.

3.1 Convergence analysis

The next result establishes the global convergence of the standard multi-block ADMM for solving SSON based statistical learning problems, by using the Kurdyka- Lojasiewicz (KL) property of the objective function in (19).

Theorem 10 *The sequence $U^k := (\Theta^k, Z_1^k, \ldots, Z_n^k, E^k, \Lambda^k)$ generated by Algorithm 1 from any starting point converges to a stationary point of the problem given in* (19).

Proof. A detailed exposition is given in Appendix B.

4. Experimental Results

In this section, we present numerical results for Algorithm 1 (henceforth called SSONA), on both synthetic and real data sets. The results are organized in the following three sub-sections: in Section 4.1, we present numerical results on synthetic data comparing the performance of SSONA to that of grouping variables ADMM and also for assessing the accuracy in recovering a multi-layered structure in Markov Random Field and covariance graph models that constitute the prime focus in this paper. In Section 4.2 we use the proposed SSONA for feature selection in classification problems involving two real data sets in order to calibrate SSON performance with respect to an independent validation set. Finally, in Section 4.3, we analyze using SSONA on some other interesting real data sets from the social and biological sciences.

4.1 Experimental results for the SSON algorithm on graphical models based on synthetic data

Next, we evaluate the performance of SSONA on ten synthetic graphical model problems, comprising of $p = 100$, 500 and 1000 variables. The underlying network structure corresponds to an Erdős-Rényi model graph, a nearest neighbor graph and a scale-free random graph, respectively. The CONTEST [1] package is used to generate the synthetic graphs, and the UGM [2] package to implement Gibbs sampling for estimating the Ising Model. Based on the generated graph topologies, we consider the following settings for generating synthetic data sets:

I. **Gaussian graphical models**:
For a given number of variables p, we first create a symmetric matrix $E \in \mathbb{R}^{p\times p}$ by using CONTEST in a MATLAB environment. Given matrix E, we set Σ^{-1} equal to $E + (0.1 - \bar{\Lambda}_{\min}(E))\ I$, where $\bar{\Lambda}_{\min}(E)$ is the smallest eigenvalue of E and I denotes the identity matrix. We then draw $N = 5p$ i.i.d. vectors $x_1, \ldots, x_m$ from the gasserian distribution $\mathcal{N}(0, \Sigma)$ by using the *mvnrnd* function in MATLAB, and then compute a sample covariance matrix of the variables.

II. **Gaussian graphical models with latent variables:**
For a given number of variables p, we first create a matrix $\Sigma^{-1} \in \mathbb{R}^{(p+r)\times(p+r)}$ by using CONTEST as described in I. We then choose the sub-matrix $\Theta_O = \Sigma^{-1}(1:p, 1:p)$ as the ground truth matrix of the matrix Θ_4 and chose

$$\begin{aligned}\Theta_U &= \Sigma^{-1}(1:p,\ p+1:p+r)\big(\Sigma^{-1}(p+1:p+r,\ p+r:p+r)\big)^{-1} \\ &\quad \Sigma^{-1}(p+1:p+r,\ 1:p)\end{aligned}$$

as the ground truth matrix of the low rank matrix U. We then draw $N = 5p$ i.i.d. vectors $x_1, \ldots, x_m$ from the Gaussian distribution $\mathcal{N}(0, (\Theta_O - \Theta_U)^{-1})$, and compute the sample covariance matrix of the variables Σ_O.

III. **The Binary Network**:
To generate the parameter matrix Σ, we create an adjacency matrix as in Setup I by using CONTEST. Then, each of $N = 5p$ observations is generated through Gibbs sampling. We take the first 100000 iterations as our burn-in period, and then collect observations, so that they are nearly independent.

1. CONTEST is available at http://www.mathstat.strath.ac.uk/outreach/contest/
2. UGM is available at http://www.di.ens.fr/ mschmidt/Software/UGM.html

We compare SSONA to the following competing methods:

- **CovSel**, designed to estimate a sparse Gaussian graphical model (Friedman et al., 2008);
- **HGL**, focusing on learning a Gaussian graphical model having hub nodes (Tan et al., 2014);
- **PGADM**, designed to learn a Gaussian graphical model with some latent nodes (Ma et al., 2013);
- **Pseudo-Exact**, designed to learn a binary Ising graphical model (Höfling and Tibshirani, 2009);
- **glasso-SF**, Learning Scale Free Networks by reweighted ℓ_1 Regularization (Liu and Ihler, 2011);
- **GADMM**, A two block ADMM method with grouping variables.

All the algorithms have been implemented in the MATLAB R2015b environment on a PC with a 1.8 GHz processor and 6GB RAM memory. Further, all the algorithms are being terminated either when

$$\frac{\|\Theta^k - \Theta^{k-1}\|_F^2}{\|\Theta^{k-1}\|_F^2} \leq \tau, \qquad \tau = 1e-5,$$

or the number of iterations and CPU times exceed 1,000 and 10 minutes, respectively.

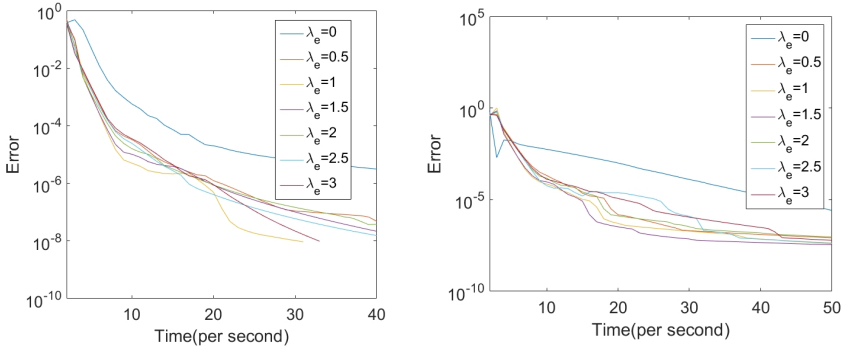
We found that in practice the computation cost for SSONA increases with the size of structured matrices. Therefore, we use a limited memory version of SSONA in our experimental results to obtain good accuracy. Block sizes in Figure 3 could be set based on a desire for interpretability of the resulting estimates. In this section, we choose four structured matrices with blocks of size

$$\begin{aligned}(Z_2)_j &= [1, \frac{p}{2}], \qquad j = 1\ldots, l_2,\\ (Z_3)_j &= [1, \frac{p}{5}], \qquad j = 1\ldots, l_3,\\ (Z_4)_j &= [1, \frac{p}{10}], \qquad j = 1\ldots, l_4,\\ (Z_5)_j &= [1, \frac{p}{20}], \qquad j = 1\ldots, l_5,\end{aligned}$$

where l_i is determined based on size of the adjacency matrix, p (see, Figure 3).

The penalty parameters λ_e and $\{\lambda_i\}_{i=1}^n$ play an important rule for the convex decomposition to be successful. We learn them through numerical experimentation (see Figures 5 and 6) and set them respectively to

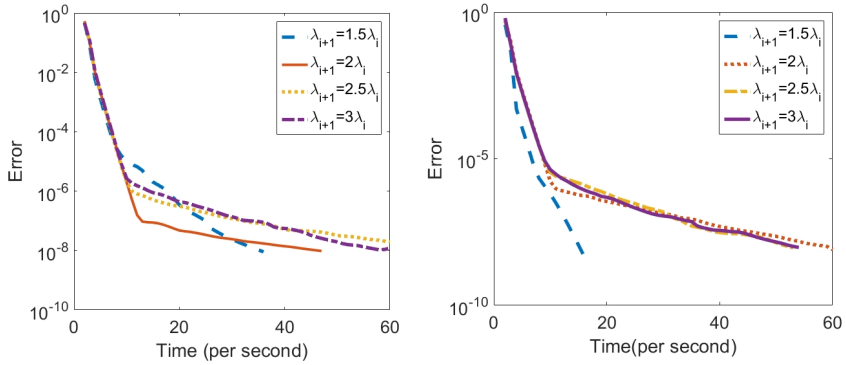
$$\varrho = 4, \quad \lambda_e = 1, \quad \lambda_1, \lambda_2 = 0.5\lambda_e, \quad \hat{\lambda}_i = 0.25\lambda_e, \quad \text{and} \quad \lambda_{i+1} = 2\lambda_i \quad \text{for} \quad i = 2, \ldots, n.$$



(a) (b)

Figure 5: Learning turning parameter λ_e for two covariance estimation problems. Comparison of the absolute errors produced by the algorithms based on CPU time for different choices of λ_e.

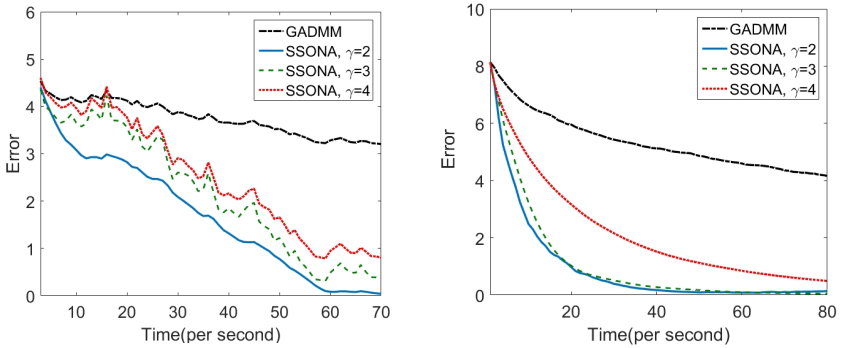
It can be seen from Figure 5 that with the addition of the ridge penalty term $\frac{\lambda_e}{2}\|E\|_F^2$ the algorithm clearly outperforms its unmodified counterpart in terms of CPU time for any fixed number of iterations. Indeed, when the model becomes more dense, SSONA is more effective to recover the network structure.



(a) (b)

Figure 6: Learning turning parameter λ_i for $i = 2, \ldots, n$ for two covariance estimation problems for different choices of λ_i for $i = 2, \ldots, n$.

Next, we conduct experiments to assess the performance of the developed multi-block ADMM algorithm (SSONA) vis-a-vis the GADMM for solving two covariance graph estimation problems of dimension 1000 in the presence of noise. Figure 7 depicts the absolute error of the objective function for different choices of the regularization parameter γ of the augmented Lagrangian and that of the dense noisy component λ_e; note that the latter is key for the convergence of the proposed algorithm.



(a) (b)

Figure 7: Comparison of the absolute errors produced by the algorithms based on CPU time for different choices of γ.

We define the following two performance measures, as proposed in Tan et al. (2014):

- Number of correctly estimated edges, n_e :

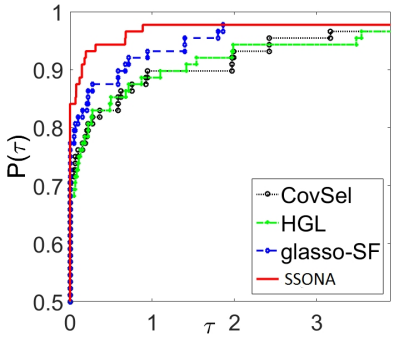
$$\sum_{j<j'} \left(1_{\{|\hat{\Theta}|>1e-4 \text{ and } |\Theta_{jj'}|\neq 0\}}\right).$$

- Sum of squared errors, s_e:

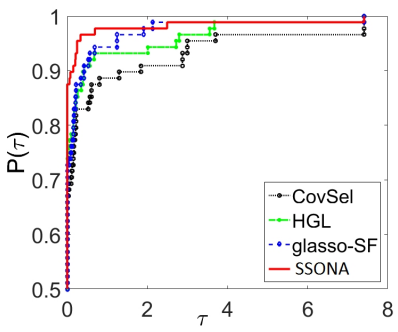
$$\sum_{j<j'} \left(|\hat{\Theta}_{jj'} - \Theta_{jj'}|\right)^2.$$

The experiment is repeated ten times and the average number of correctly estimated edges, n_e and sum of squared errors, s_e are considered for comparison. We have used the *performance profile*, as proposed in Dolan and Moré (2002), to display the efficiency of the algorithms considered, in terms of n_e and s_e. As stated in Dolan and Moré (2002), this profile provides a wealth of information such as solver efficiency, robustness and probability of success in compact form and eliminates the influence of a small number of problems on the evaluating process and the sensitivity of results associated with the ranking of solvers. Indeed, the performance profile plots the fraction of problem instances for which any given method is within a factor of the best solver. The horizontal axis of the figure gives the percentage of the test problems for which a method is efficient, while the vertical axis gives

the percentage of the test problems that were successfully solved by each method (robustness). The performance profiles of the considered algorithms in log2 scale are depicted in Figures 8,9 and 10.

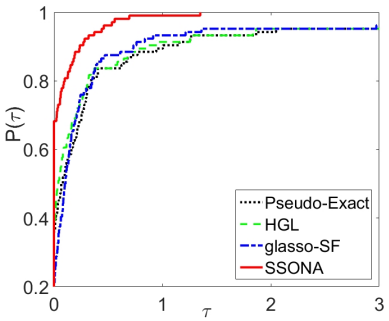


(a) Performance based on n_e.

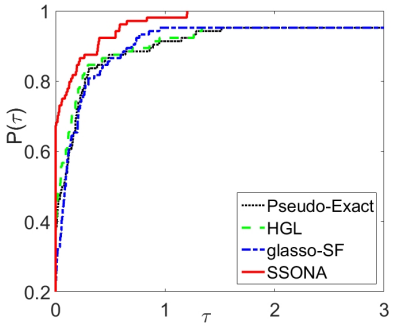


(b) Performance based on s_e.

Figure 8: Performance profiles of CovSel, HGL, glasso-SF and SSONA



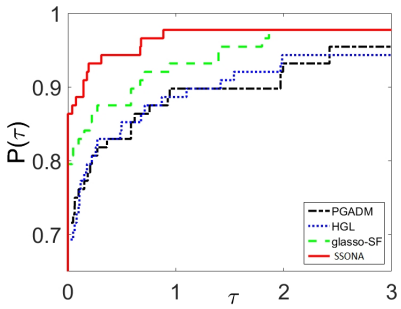
(a) Performance based on n_e.



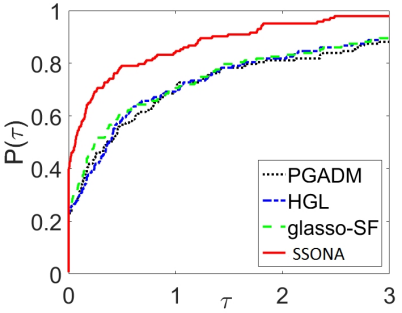
(b) Performance based on s_e.

Figure 9: Performance profiles of Pseudo-Exact, HGL, glasso-SF and SSONA.

Figures 8,9 and 10 show the performance profiles of the considered algorithms for estimation of graphical models in terms of number of correctly estimated edges and sum of squared errors, respectively. The left and right panel are drawn in terms of n_e and s_e, respectively. The results in these figures clearly demonstrate the superior performance of the proposed method, since it solves all test problems without exhibiting any failure. Moreover, the SSONA algorithm is the best algorithm among the considered ones, as it solves more than 80 % of the test problems achieving the maximum number of correctly estimated edge



(a) Performance based on n_e.



(b) Performance based on s_e.

Figure 10: Performance profiles of PGADM, HGL, glasso-SF and SSONA.

n_e and minimum value of estimation loss s_e. Further, the performance index of SSONA grows up rapidly in comparison with the other considered algorithms. The latter implies that whenever SSONA is not the best algorithm, its performance index is close to the index of the best one.

4.1.1 Experiments on structured graphical models

In this section, we present numerical results on structured graphical models to demonstrate the efficiency of SSONA. We compare the behavior of SSONA for a fixed value of $p = 100$ with a lasso version of our algorithm. Results provided in Figures 11, 12, 13 and 14 indicate the efficiency of algorithm 1 on structured graphical models. These results also show how the structure of the network returned by the two algorithms changes with growing m (note that λ_i and $\hat{\lambda}_i$ are kept fixed for each value of m). It can be easily seen from these figures (comparing Row I and II) that SSONA is less sensitive to the number of samples and shows a better approximation of the network structure even for small sample sizes.

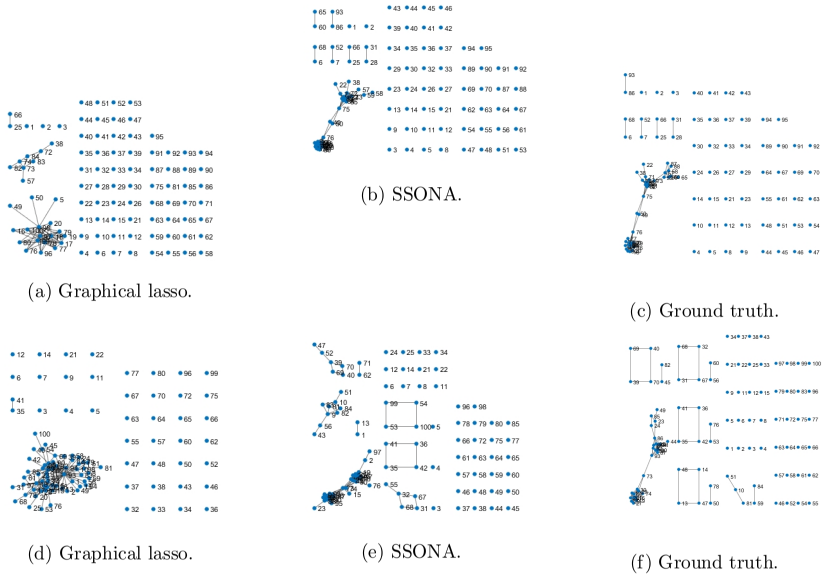
4.2 Classification and clustering accuracy based on SSONA

In this section, we evaluate the efficiency of SSONA on real data sets in recovering complex structured sparsity patterns and subsequently evaluate them on a classification task. The two data sets deal with applications in cancer genomic and document classification.

4.2.1 SSONA for Gene Selection Task

Classification with a sparsity constraint has become a standard tool in applications involving Omics data, due to the large number of available features and the small number of samples. The data set under study considers gene expression profiles of lung cancer tumors. Specifically, the data[2] consist of gene expression profiles of 12,626 genes for 197 lung tissue

2. http://www.broadinstitute.org/cgibin/cancer/publications/view/87.



(a) Graphical lasso. (b) SSONA. (c) Ground truth.

(d) Graphical lasso. (e) SSONA. (f) Ground truth.

Figure 11: Simulation for the Gaussian graphical model. Row I: Results for $p = 100$ and $m = 200$. Row II: Results for $p = 100$ and $m = 100$.

samples, with 139 adenocarcinomas(AD), 21 squamous cell carcinomas(SQ), 20 carcinoids (COID) and 17 normal lung tissue (NL). To distinguish lung adenocarcinomas from the normal lung tissues, we consider the diagnosis of lung cancer as a binary classification problem. Let the 17 normal lung comprise the positive class and the 139 lung adenocarcinomas the negative class. Following the workflow in Monti et al. (2003), we reserve the 1000 most significant genes after a preprocessing step. In the numerical experiment, we compare group lasso (Yuan and Lin, 2007), group lasso with overlap (Obozinski et al., 2011) and SSONA according to the following two criteria: average classification accuracy and gene selection performance. The experiment is repeated ten times and the average accuracy and performance are depicted in Table 1.

(a) Graphical lasso. (b) SSONA. (c) Ground truth.

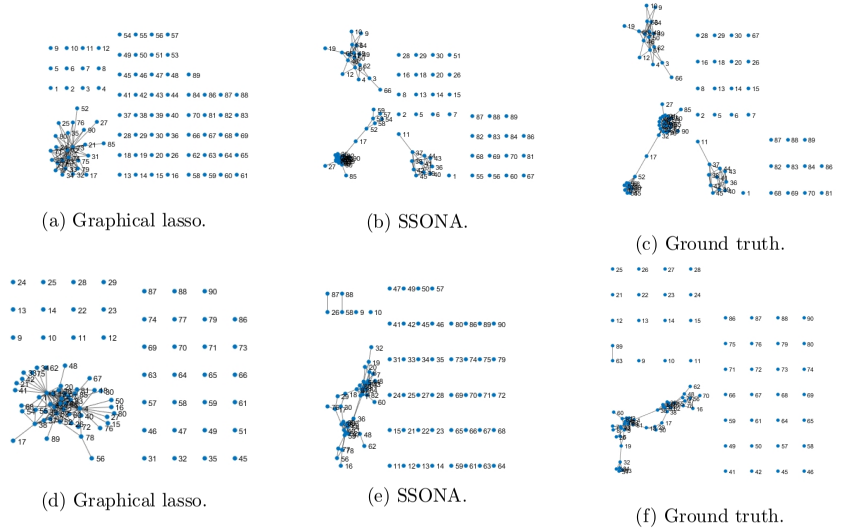
(d) Graphical lasso. (e) SSONA. (f) Ground truth.

Figure 12: Simulation for the Covariance graph model. Row I: Results for $p = 100$ and $m = 200$. Row II: Results for $p = 100$ and $m = 100$.

Method	**Average classification accuracy**	**Average number of genes selected**
Group lasso (Yuan and Lin, 2007)	0.815(0.046)	69.11(3.23)
Group lasso with overlap (Obozinski et al., 2011)	0.834(0.035)	57.30(2.71)
SSONA (4 structured matrices)	0.807(0.028)	61.44(2.80)
SSONA (6 structured matrices)	0.839(0.022)	56.111(2.100)

Table 1: Experimental results on lung cancer data over 10 replications (the standard deviations are reported in parentheses).

As is shown in Table 1, SSONA achieves higher classification accuracy than the group lasso and lower classification accuracy than the latent group lasso, although the performance of all three methods is very similar and within the variability induced by the replicates. However, our SSON based lasso does not require a priori knowledge of group structures, which is a prerequisite for the other two methods. One can easily improve the the classification accuracy and gene selection performance of SSONA by adding more structured matrices.



(a) Graphical lasso. (b) SSONA. (c) Ground truth.

(d) Graphical lasso. (e) SSONA. (f) Ground truth.

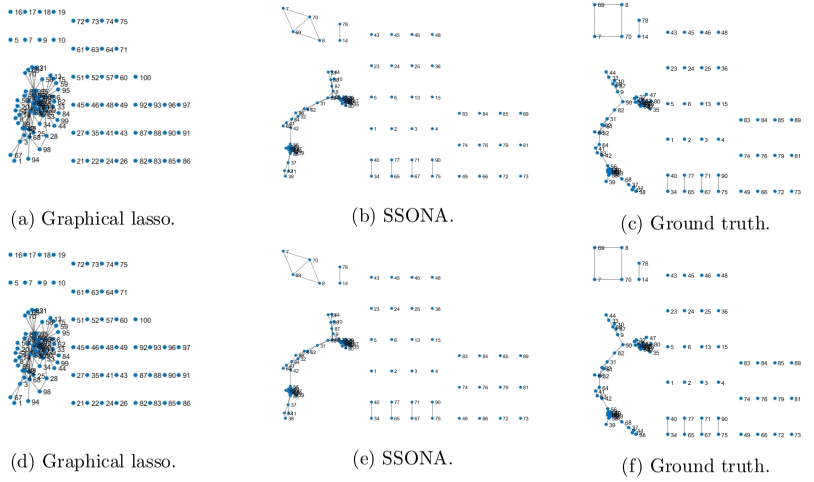
Figure 13: Simulation for the Gaussian graphical model with 10 latent variables. Row I: Results for $p = 100$ and $m = 200$. Row II: Results for $p = 100$ and $m = 100$.

In our experiments, SSONA selects the least number of genes and achieves the smallest standard deviation of average number of genes *without any priori knowledge*. Due to the different number of randomly selected genes, the average number of gene sometimes will be a non-integer.

4.2.2 SSONA for Document Classification Task

The next example involves a data set [3] containing 1427 documents with a corpus of size 17785 words. We randomly partition the data into 999 training, 214 validation and 214 test examples, corresponding to a 70/15/15 split (Rao et al., 2016). We first train a Latent Dirichlet Allocation based topics model (Blei et al., 2003) to assign the words to 100 "topics". These correspond to our groups, and since a single word can be assigned to multiple topics, the groups overlap. We then train a lasso logistic model using as outcome variable indicating whether the document discusses atheism or not , together with an overlapping group lasso and a SSON based lasso model where the tuning parameters are selected based on cross validation. Table 2 shows that the variants of the SSON yield almost the same misclassification rate compared to the other two methods, while it does not require a priori knowledge of group structures.

3. `http://qwone.com/jason/ 20Newsgroups/`



(a) Graphical lasso. (b) SSONA. (c) Ground truth.

(d) Graphical lasso. (e) SSONA. (f) Ground truth.

Method	**Misclassification Rate**
Group lasso (Yuan and Lin, 2007)	0.445
Group lasso with overlap (Obozinski et al., 2011)	0.390
SSONA (5 structured matrices)	0.435
SSONA (6 structured matrices)	0.421
SSONA (7 structured matrices)	0.401

Table 2: Misclassification rate on the test set for document classification.

4.2.3 SSONA for structured subspace clustering

Our last example focuses on data clustering. The data come from multiple low-dimensional linear or affine subspaces embedded in a high-dimensional space. Our method is based on (11), wherein each point in a union of subspaces has a representation with respect to a dictionary formed by all other data points. In general, finding such a representation is NP hard. We apply our subspace clustering algorithm to a structured data in the presence of noise. The segmentation of the data is obtained by applying SSONA to the adjacency matrix built from the data. Our method can handle noise and missing data and is effective to detect the clusters.

Figure 15 shows that our approach significantly outperforms state-of-the-art methods.

Figure 15: Heatmap of different algorithms for detecting clusters in data.

4.3 Application to real data sets

Next, we use the SSON framework to analyze three data sets from molecular and social science domains. Although there is no known ground truth, the proposed framework recovers interesting patterns and highly interpretable structures.

Analysis of connectivity in the financial sector. We applied the SSON methodology to analyze connectivity in the financial sector. We use monthly stock returns data from August, 2001 to July, 2016 for three financial sectors, namely banks (BA), primary broker/dealers (PB), and insurance companies (INS). The data are obtained from the University of Chicago's Center for Research in Security Prices database (CRSP).

Our final sample covers 75 different institutions spanning a 16-year period. Figure 16 shows the mean (in %) of monthly stock returns across different sectors in each 3-year long rolling windows. As expected, the average returns are significantly lower during the financial 2007-2009 crisis period, compared to any other period in our sample. Indeed, looking across the sectors, all three sectors experienced diminished performance during the 2007-2009 crisis. Further, the almost linear ramp-up following 2009 clearly captures the recovery of financial stocks and the broader market.

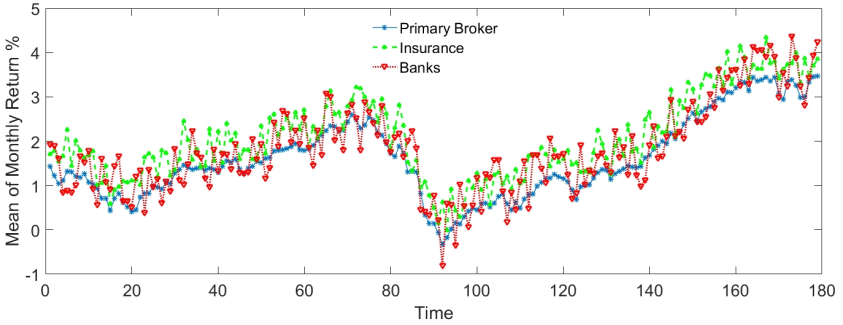

Figure 16: Average monthly return of firms in the three sectors- Bank, primary broker-dealer and insurance firms, in different 3-year rolling windows during 180 months. The figure shows diminished performance during the 2007-2009 crisis (time step : 80-100) and also clearly captures the strong recovery of stock performance starting in 2009.

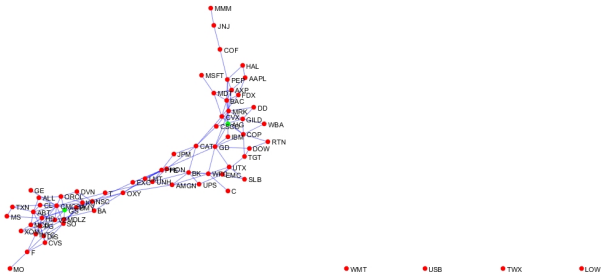
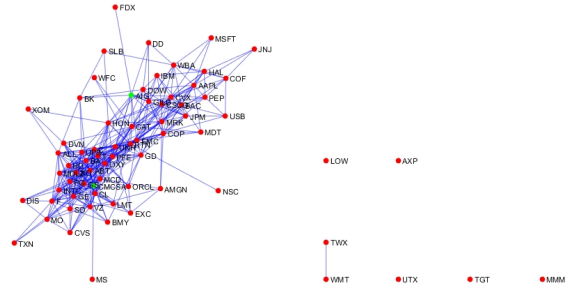
Next, we estimate a measure of network connectivity for a sample of the 71 components of the SP100 index that were present during the entire 2001-16 period under consideration. Figure 17 depicts the network estimates of the transition (lead-lag) matrices using straight lasso VAR and SSONA based VAR for the January 2007 to Oct 2009 period. It can be seen that the lasso VAR estimates produce a more highly connected network, while the SSONA ones identify two more connected components. Both methods highlight the key role played by AIG and GS (Goldman Sachs), but the SSONA based network indicates that one dense connected component is centered around the former, while the other dense connected component around the latter. In summary, both methods capture the main connectivity patterns during the crisis period, but SSONA provides a more nuanced picture.

US House voting data set. We applied SSONA to describe the relationships amongst House Representatives in the U.S. Congress during the 2005-2006 period (109th Congress). The variables correspond to the 435 representatives, and the observations to the 1210 votes that the House deliberated and voted on during that period, which include bills, resolutions, motions, debates and roll call votes. The assumption of our model is that bills are i.i.d. sample from the same underlying Ising model. The votes are recorded as "yes" (encoded as "1") and "no" (encoded as "0"). Missing observations were replaced with the majority vote of the House members party on that particular vote. Following Guo et al. (2015), we used a bootstrap procedure with the proposed SSONA estimator to evaluate the confidence of the estimated edges. Specifically, we estimated the network for multiple bootstrap samples of the same size, and only retained the edges that appeared more that ω percent of the time. The goal of the analysis is to understand the type of relationships that existed among the House members in the 109th Congress. In particular, we wish to identify and interpret the presence of densely connected components, as well of sparse components. The heatmap of



(a) SSONA VAR



(b) Lasso VAR

Figure 17: Networks estimate by SSONA and Lasso VAR during crisis period of Jan 2007 to Oct 2009.

the adjacency matrix of the estimated network by using SSONA is depicted in Figure 18. It can be easily seen that there exist densely connected components in the network, a fact that the glasso algorithm (Friedman et al., 2008) fails to recover (see, Figure 19).

The network representation of subgraphs, with a cut-off value of 0.6, is given in Figures 20, 21 and 22. We only plot the edges associated with the subgraphs to enhance the visual reading of densely correlated areas. An interesting result of applying SSONA on this data set is the clear separation between members of the Democratic and Republican parties, as expected (see, Figures 20, 21 and 22). Moreover, voting relationships within the two parties exhibit a clustering structure, which a closer inspection of the votes and subsequent analysis showed was mainly driven by the position of the House member on the ideological/political spectrum.

Other interesting patterns emerging from the analysis is that SSONA recovers members of opposite parties as a sparse component in each subgraph (see, Figures 20, 21 and 22). For instance, Figure 21 shows that Republican members such as Simpson, Kirk and Hyde are sparsely connected in a clustered group of Democratic members. This is possibly due to

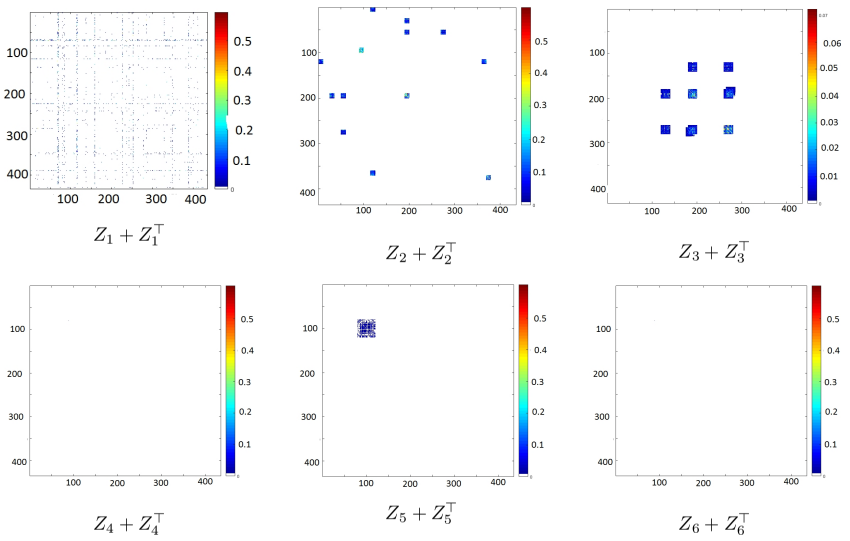


Figure 18: Heatmap of the structured precision matrix Θ decomposed into $Z_1 + Z_1^\top + \cdots + Z_6 + Z_6^\top$ in the House voting data, estimated by SSONA.

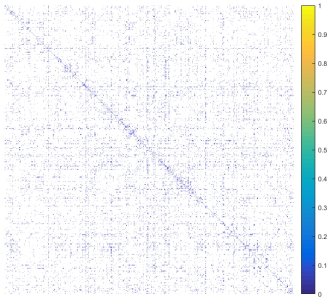

Figure 19: Heatmap of the inverse covariance matrix in the voting record of the U.S. House of Representatives, estimated by the graphical lasso method (Friedman et al., 2008).

the overall centrist record of Kirk and alignment of Hyde and Simpson on selected issues. Similarly, Figure 21 indicates that Democratic members Bishop, Hastings and Meek are approximately sparsely connected to a subgraph of Republican members. Bishop from Georgia has compiled a fairly conservative voting record. The same conclusion can be derived from Figure 21. Indeed, Figures 20, 21 and 22 reveals that there are strong positive

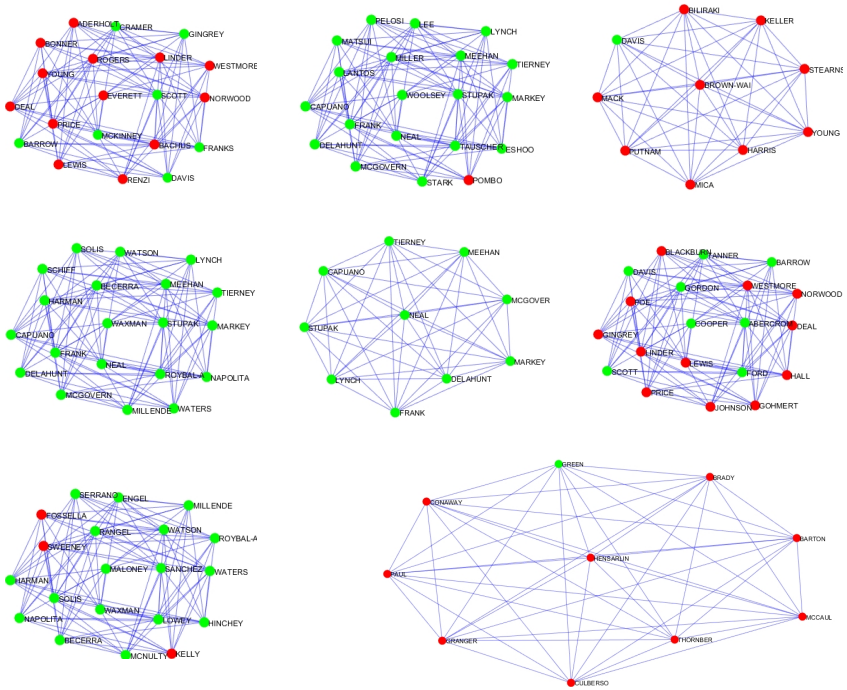

Figure 20: Dense subgraphs identified by SSONA for the House voting data with an inclusion cutoff value of 0.6. Subfigures correspond to a densely connected area in Figure 18 for the symmetric structured matrix $Z_2 + Z_2^\top$. The nodes represent House members, with red and green colored nodes corresponding to Republicans and Democrats, respectively. A blue line corresponds to an edge between two nodes.

associations between members of the same party and negative associations between members of opposite parties. Obviously, at the higher cutoff value the dependence structure between members of opposite parties becomes sparser.

Other patterns of interest include a strong dependence between members of two opposite parties in selected subgraphs when the members come from the same state, as is the case for New York state members Jerrold Nadler (D), Anthony D. Weiner (D), Ed Towns (D), Major Owens (D), Nydia Velzquez (D), Vito Fossella (R), Carolyn B. Maloney (D), Charles B. Rangel (D), Jos Serrano (D), Eliot L. Engel (D), Nita Lowey (D), Sue W. Kelly (R), John E. Sweeney (R), Michael R. McNulty (D), Maurice Hinchey (D), John M. McHugh (R), Sherwood Boehlert (R), Jim Walsh (R), Tom Reynolds (R), Brian Higgins (D) -see

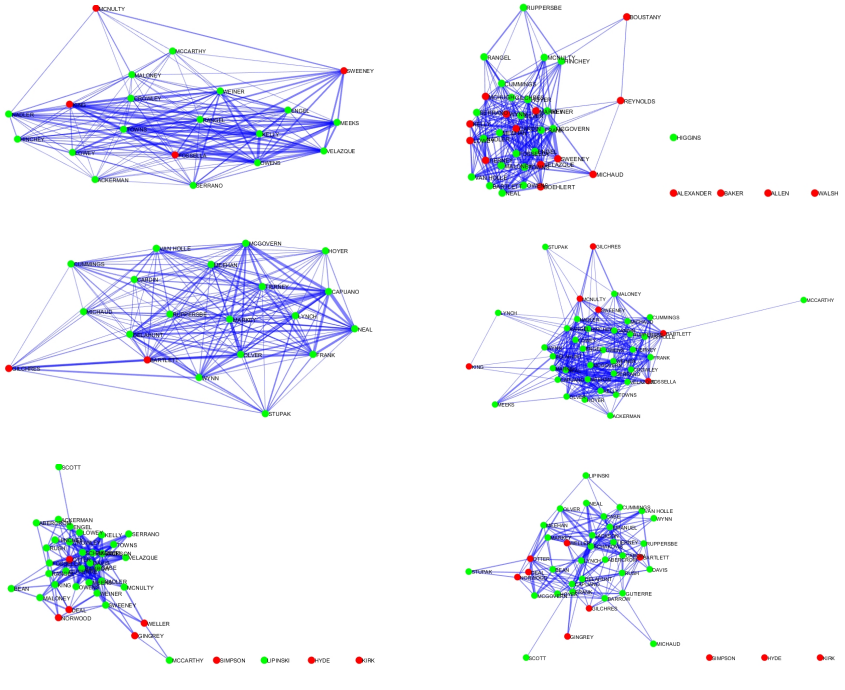

Figure 21: Dense subgraphs identified by SSONA for the House voting data with an inclusion cutoff value of 0.6. Subfigures correspond to a densely connected area in Figure 18 for the symmetric structured matrix $Z_3 + Z_3^\top$. The nodes represent House members, with red and green colored nodes corresponding to Republicans and Democrats, respectively. A blue line corresponds to an edge between two nodes.

Figure 21. However, in this instance, there is also a cluster of positive associations between Democrats.

In summary, SSONA provides deeper insights into relationships between House members, going beyond the obvious separation into two parties, according to their voting record.

Analysis of a breast cancer data set. We applied SSONA to a data set containing 800 gene expression measurements from large epithelial cells obtained from 255 patients with breast cancer. The goal is to capture regulatory interactions amongst the genes, as well as to identify genes that tend to have interactions with other genes in a group and hence act as master regulators, thus providing insights into the molecular circuitry of the disease. Figure 23 depicts the heat map of the estimated adjacency matrix for the breast cancer

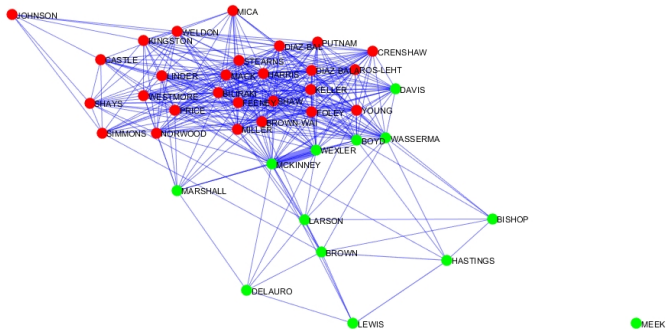

Figure 22: Dense subgraph identified by SSONA for the House voting data with an inclusion cutoff value of 0.6. Subfigures corresponds to a densely connected area in Figure 18 for the symmetric structured matrix $Z_5 + Z_5^\top$. The nodes represent House members, with red and blue node colors corresponding to Republicans and Democrats, respectively. A blue line corresponds to an edge between two nodes.

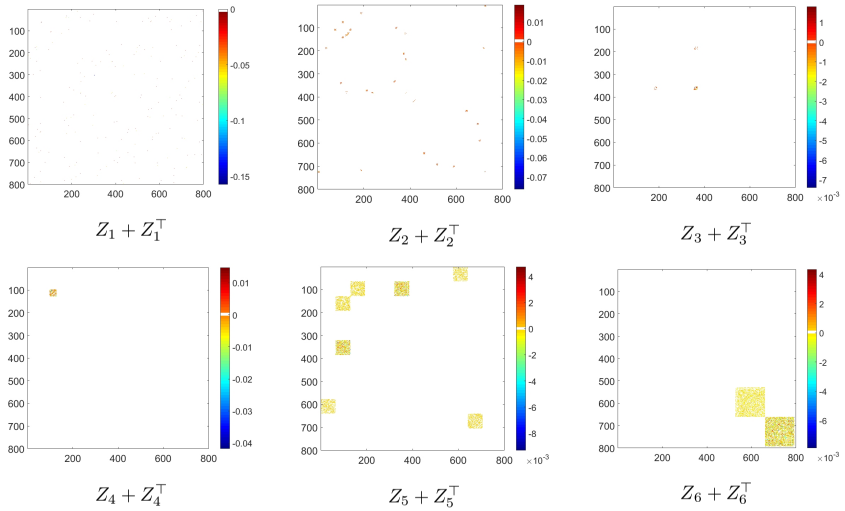

Figure 23: Heat map of the structured precision matrix Θ decomposed into $Z_1 + Z_1^\top + \cdots + Z_6 + Z_6^\top$ in the breast cancer data set, estimated by SSONA.

data set. As it is clear in Figure 23, $Z_2 + Z_2^\top, \ldots, Z_5 + Z_5^\top$ and $Z_6 + Z_6^\top$ show that selected

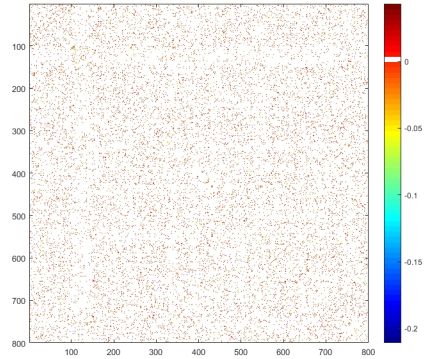

Figure 24: Heatmap of the inverse covariance matrix in the breast cancer data sets, estimated from graphical lasso (Friedman et al., 2008).

genes are densely connected, which is not the case when employing the the graphical lasso algorithm (see, Figure 24). Therefore, SSONA can provide an intuitive explanation of the relationships among the genes in the breast cancer data set (see, Figure 25 and 26 for two examples). These genes connectivity in the tumor samples may indicate a relationship that is common to an important subset of cancers. Many other genes belong to this network, each indicating a potentially interesting interaction in cancer biology. We omit the full list of densely connected genes in our estimated network and provide a complete list in the on-line supplementary materials available in the first author's homepage.

5. Conclusion

In this paper, a new structured norm minimization method for solving multi-structure graphical model selection problems is proposed. Using the proposed SSON, we can efficiently and accurately recover the underlying network structure. Our method utilizes a class of sparse structured norms in order to achieve higher order accuracy in approximating the decomposition of the parameter matrix in Markov Random Field and Gaussian Covariance Graph models. We also provide a brief discussion of its application to regression and classification problems. Further, we introduce a linearized multi-block ADMM algorithm to solve the resulting optimization problem. The global convergence of the algorithm is established without any upper bound on the penalty parameter. We applied the proposed methodology to a number of real and synthetic data sets that establish its overall usefulness and superior performance to competing methods in the literature.

Acknowledgments

The authors would like to thank the Editor and three anonymous referees for many constructive comments and suggestions that improved significantly the structure and readability of the paper. This work was supported in part by NSF grants DMS-1545277, DMS-1632730, NIH grant 1R01-GM1140201A1 and by the UF Informatics Institute.

Appendix A. Update for Θ

In each iteration of Algorithm 1 the update for Θ depends on the form of the loss function $g(\Theta)$. We consider the following cases to update Θ:

1. The update for Θ_1 in Algorithm 1 (step 2(a)) can be obtained by minimizing

$$\text{trace}(\hat{\Sigma}\Theta_1) - \log\det\Theta_1 + \frac{\gamma}{2}\|\Theta_1 - (\sum_{i=1}^{n} Z_i^k + {Z_i^k}^\top + E^k + \frac{1}{\gamma}\Lambda^k)\|_F^2,$$

with respect to Θ_1 (note that the constraint $\Theta_1 \in \mathcal{S}$ in (6) is treated as an implicit constraint, due to the domain of definition of the log det function). This can be shown to have the solution

$$\Theta_1 = \frac{1}{2}U\Big(D + \sqrt{D^2 + \frac{4}{\gamma}I}\Big)U^T,$$

where UDU^T stands for the eigen-decomposition of $\sum_{i=1}^n Z_i^k + {Z_i^k}^\top + E^k + \frac{1}{\gamma}\Lambda^k - \frac{1}{\gamma}\hat{\Sigma}$.

2. Update for Θ_2 in Step 2(a) of Algorithm 1 leads to the following optimization problem

$$\begin{aligned}\underset{\Theta_3\in\mathcal{S}}{\text{minimize}}\ \Phi(\Theta_2) \quad &= \quad \sum_{j=1}^{p}\sum_{j'=1}^{p}\theta_{jj'}(X^TX)_{jj'} - \sum_{i=1}^{m}\sum_{j=1}^{p}\log\Big(1+\exp[\theta_{jj}+\sum_{j'\neq j}\theta_{jj'}x_{ij'}]\Big)\\ &+ \quad \frac{\gamma}{2}\|\Theta_2 - (\sum_{i=1}^{n} Z_i^k + {Z_i^k}^\top + E^k + \frac{1}{\gamma}\Lambda^k)\|_F^2. \qquad (33)\end{aligned}$$

We use a novel non-monotone version of the Barzilai-Borwein method (Barzilai and Borwein, 1988; Raydan, 1997; Fletcher, 2005; Ataee Tarzanagh et al., 2014) to solve (33). The details are given in Algorithm 2.

Algorithm 2 Non-monotone Barzilai Borwein Method for solving (33)

Initialize The parameters:

(a) $\Theta^0 = I$, $\Theta^1 = 2\Theta^0$, $\alpha^1 = 1$ and $t^0 = 10$.

(b) A positive sequence $\{\eta^t\}$ satisfying $\sum_{k=1}^{\infty}\eta^t = \eta < \infty$.

(c) Constants $\sigma > 0$, $\epsilon > 0$, and $\nu \in (0,1)$.

Iterate Until the stopping criterion $\dfrac{\|\Theta^t - \Theta^{t-1}\|_F^2}{\|\Theta^{t-1}\|_F^2} \leq \epsilon$ is met:

1. $\mathbb{G}^t = -\alpha^t\nabla\Phi(\Theta^t)$.
2. Set $\rho = 1$.
3. **If** $t > t^0$, **then**
   While $\|\Phi(\Theta^t + \rho^t\mathbb{G}^t)\|_F \leq \Phi(\Theta^t) + \eta^t - \sigma\rho^2{\alpha^t}^2\|\mathbb{G}^t\|_F^2$, **do**
   Set $\rho = \nu\rho$;
   EndWhile
   EndIf
4. Define $\rho^t = \rho$ and $\Theta^{t+1} = \Theta^t + \rho^t\mathbb{G}^t$.
5. Define $\alpha^{t+1} = \dfrac{\text{trace}\Big((\Theta^t - \Theta^{t+1})^T(\Theta^t - \Theta^{t+1})\Big)}{\text{trace}\Big((\nabla\Phi(\Theta^t) - \nabla\Phi(\Theta^{t+1}))^T(\Theta^t - \Theta^{t+1})\Big)}$

3. To update Θ_3 in step 2(a), using (11), we have that

$$\begin{aligned}\underset{\Theta_3}{\text{minimize}}\ \frac{1}{2}\|\Theta_3-\hat{\Sigma}\|_F^2 \quad &+ \quad \frac{\gamma}{2}\|\Theta_3-\Big(\sum_{i=1}^{n}Z_i^k+Z_i^{k^\top}+E^k+\frac{1}{\gamma}\Lambda^k\Big)\|_F^2\\ &= \quad \Big(\frac{1}{1+\gamma}(\hat{\Sigma}+\gamma(\sum_{i=1}^{n}Z_i^k+Z_i^{k^\top}+E^k)+\Lambda^k)\Big)_+\end{aligned}$$

where $V_+ = U_\dagger D_+ U_\dagger$ such that

$$UDU=\begin{pmatrix}U_\dagger & U_\ddagger\end{pmatrix}\begin{pmatrix}D_+ & 0\\ 0 & D_-\end{pmatrix}\begin{pmatrix}U_\dagger\\ U_\ddagger\end{pmatrix},$$

is the eigen-decomposition of the matrix V , and D_+ and D_- are the nonnegative and negative eigenvalues of V.

Appendix B. Convergence Analysis

Before establishing the main result on global convergence of the proposed ADMM algorithm, we provide the necessary definitions used in the proofs (for more details see Bolte et al. (2014)):

Definition 11 *(Kurdyka- Lojasiewicz property).*
The function f is said to have the Kurdyka- Lojasiewicz (K-L) property at point Z_0, if there exist $c_1>0$, $c_2>0$ and $\phi\in\Gamma_{c_2}$ such that for all

$$Z\in B(Z_0,c_1)\cap\{Z: f(Z_0)<f(Z)<f(Z_0)+c_2\},$$

the following inequality holds

$$\phi'\big(f(Z)-f(Z_0)\big)dist\big(0,\partial f(Z)\big)\geq 1,$$

where Γ_{c_2} stands for the class of functions $\phi:[0,c_2)\to\mathbb{R}^+$ with the properties:

(i) ϕ is continuous on $[0,c_2)$;

(ii) ϕ is smooth concave on $(0,c_2)$;

(iii) $\phi(0)=0$, $\nabla\phi(s)>0$, $\forall\ s\in(0,c_2)$.

Definition 12 *(Semi-algebraic sets and functions).*

(i) A subset $C\in\mathbb{R}^{n\times n}$ is semi-algebraic, if there exists a finite number of real polynomial functions h_{ij}, $s_{ij}:\mathbb{R}^{n\times n}\to\mathbb{R}$ such that

$$C=\cup_{i=1}^{\bar{p}}\cap_{j=1}^{\bar{q}}\{Z\in\mathbb{R}^{n\times n}:\ g_{ij}(Z)=0\quad and\quad s_{ij}(Z)<0\}.$$

(ii) A function $h:\mathbb{R}^{n\times n}\to(-\infty,+\infty]$ is called semi-algebraic, if its graph

$$\mathbb{G}(h):=\{(Z,y)\in\mathbb{R}^{n\times n+1}: h(Z)=y\},$$

is a semi-algebraic set in $R^{n\times n+1}$.

Definition 13 *(Sub-analytic sets and functions).*

(i) A subset $C\in\mathbb{R}^{n\times n}$ is sub-analytic, if there exists a finite number of real analytic functions h_{ij}, $s_{ij}:\mathbb{R}^{n\times n}\to\mathbb{R}$ such that

$$C=\cup_{i=1}^{\bar{p}}\cap_{j=1}^{\bar{q}}\{Z\in\mathbb{R}^{d}: g_{ij}(Z)=0\quad and\quad s_{ij}(Z)<0\}.$$

(ii) A function h: $R^{n\times n}\to(-\infty,+\infty]$ is called sub-analytic, if its graph

$$\mathbb{G}(h):=\{(Z,y)\in\mathbb{R}^{n\times n+1}: h(Z)=y\}$$

is a sub-analytic set in $R^{n\times n+1}$.

It can be easily seen that both real analytic and semi-algebraic functions are sub-analytic. In general, the sum of two sub-analytic functions is not necessarily sub-analytic. However, it is easy to show that for two sub-analytic functions, if at least one function maps bounded sets to bounded sets, then their sum is also sub-analytic (Bolte et al., 2014).

Remark 14 *Each f_i in (19) is a convex semi-algebraic function (see, example 5.3 in (Bolte et al., 2014)), while the loss function $\mathcal{G}$ in (6), (9), (11), (13), and (18) is sub-analytic (even analytic). Since each function f_i maps bounded sets to bounded sets, we can conclude that the augmented Lagrangian function*

$$\begin{aligned}\mathcal{L}_\gamma(\Theta,Z_1,\ldots,Z_n,E;\Lambda) \quad &= \quad \mathcal{G}(X,\Theta)+f_1(Z_1)+\cdots+f_n(Z_n)+f_e(E)\\ &- \quad \langle\Lambda,\Theta-\sum_{i=1}^{n}Z_i+Z_i^\top-E\rangle\\ &+ \quad \frac{\gamma}{2}\|\Theta-\sum_{i=1}^{n}Z_i+Z_i^\top-E\|_F^2,\end{aligned}$$

which is the summation of sub-analytic functions is itself sub-analytic. All sub-analytic functions which are continuous over their domain satisfy a K-L inequality, as well as some, but not all, convex functions (see Bolte et al., 2014 for details and a counterexample). Therefore, the augmented Lagrangian function $\mathcal{L}_\gamma$ satisfies the K-L property.

Next, we establish a series of lemmas used in the proof of Theorem 10.

Lemma 15 *Let $U^k:=(\Theta^k,Z_1^k,\ldots,Z_n^k,E^k;\Lambda^k)$ be a sequence generated by Algorithm 1, then there exists a positive constant ϑ such that*

$$\begin{aligned}\mathcal{L}_\gamma(U^{k+1}) \quad &\leq \quad \mathcal{L}_\gamma(U^k)-\frac{\vartheta}{2}\Big(\|\Theta^k-\Theta^{k+1}\|_F\\ &+ \quad \sum_{i=1}^{n}\|Z_i^k-Z_i^{k+1}\|_F+\|E^k-E^{k+1}\|_F+\|\Lambda^k-\Lambda^{k+1}\|_F\Big).\end{aligned}\tag{34}$$

Proof. Using the first-order optimality conditions for (21) and the convexity of $\mathcal{G}(X,\Theta)$, we obtain

$$\begin{aligned}
0 &= \langle \Theta^k - \Theta^{k+1}, \nabla\mathcal{G}(X,\Theta^{k+1}) - \Lambda^k + \gamma(\Theta^{k+1} - \sum_{i=1}^n Z_i^k + Z_i^{k\top} - E^k)\rangle \\
&\leq \mathcal{G}(X,\Theta^k) - \mathcal{G}(X,\Theta^{k+1}) - \langle \Theta^k - \Theta^{k+1}, \Lambda^k\rangle \\
&+ \gamma\langle \Theta^k - \Theta^{k+1}, \Theta^{k+1} - \sum_{i=1}^n Z_i^k + Z_i^{k\top} - E^k\rangle \\
&= \mathcal{G}(X,\Theta^k) - \langle \Theta^k, \Lambda^k\rangle + \frac{\gamma}{2}\sum_{i=1}^n \|\Theta^k - \sum_{i=1}^n Z_i^k + Z_i^{k\top} - E^k\|_F^2 - \frac{\gamma}{2}\|\Theta^k - \Theta^{k+1}\|_F^2 \\
&- \Big(\mathcal{G}(X,\Theta^{k+1}) - \langle \Theta^{k+1}, \Lambda^k\rangle + \frac{\gamma}{2}\|\Theta^{k+1} - \sum_{i=1}^n Z_i^k + Z_i^{k\top} - E^k\|_F^2\Big) \\
&= \mathcal{L}_\gamma(U^k) - \mathcal{L}_\gamma(\Theta^{k+1}, Z_1^k, \ldots, Z_n^k, E^k; \Lambda^k) - \frac{\gamma}{2}\|\Theta^k - \Theta^{k+1}\|_F^2, \qquad (35)
\end{aligned}$$

where the second equality follows from the fact that

$$(u_1-u_2)^T(u_3-u_1) = \frac{1}{2}\Big(\|u_2-u_3\|_F^2 - \|u_1-u_2\|_F^2 - \|u_1-u_3\|_F^2\Big).$$

Using (22), (23) and Lemma 7, we have that

$$\begin{aligned}
\mathcal{L}_\gamma(\Theta^{k+1}, Z_1^k, Z_2^k, \ldots, E^k; \Lambda^k) &- \mathcal{L}_\gamma(\Theta^{k+1}, Z_1^{k+1}, Z_2^k, \ldots, E^k; \Lambda^k) \\
&- \frac{(\gamma\varrho - L_{H_1})}{2}\|Z_1^k - Z_1^{k+1}\|_F^2 \\
&\geq 0, \\
\mathcal{L}_\gamma(\Theta^{k+1}, \ldots, Z_{i-1}^{k+1}, Z_i^k, \ldots, E^k; \Lambda^k) &- \mathcal{L}_\gamma(\Theta^{k+1}, \ldots, Z_i^{k+1}, Z_{i+1}^k, \ldots, E^k; \Lambda^k) \\
&- \frac{(\gamma\varrho - L_{H_i})}{2}\|Z_i^k - Z_i^{k+1}\|_F^2 \\
&\geq 0, \qquad i = 2, \ldots, n, \qquad (36)
\end{aligned}$$

where L_{H_i} is a Lipschitz constant of the gradient $\nabla H_i(Z_i)$, and $\varrho \geq \frac{L_{H_i}}{\gamma}$, $(i = 1, \ldots, n)$ is a proximal parameter.

Following the same steps as (35), we have that

$$\begin{aligned}
\mathcal{L}_\gamma(\Theta^k, Z_1^{k+1}, \ldots, Z_n^{k+1}, E^k; \Lambda^k) &- \mathcal{L}_\gamma(\Theta^{k+1}, Z_1^{k+1}, \ldots, Z_n^{k+1}, E^{k+1}; \Lambda^k) \\
&- \frac{\gamma}{2}\|E^k - E^{k+1}\|_F^2 \\
&\geq 0, \qquad (37)
\end{aligned}$$

and

$$\begin{aligned}
\mathcal{L}_\gamma(\Theta^{k+1}, Z_1^{k+1}, \ldots, Z_n^{k+1}, E^{k+1}; \Lambda^k) &- \mathcal{L}_\gamma(\Theta^{k+1}, Z_1^{k+1}, \ldots, Z_n^{k+1}, E^{k+1}; \Lambda^{k+1}) \\
&- \frac{\lambda_e^2}{\gamma}\|E^k - E^{k+1}\|_F^2 \\
&\geq 0. \qquad (38)
\end{aligned}$$

Let

$$\hat{\gamma} := \max(\gamma\varrho - L_{H_1}, \ldots, \gamma\varrho - L_{H_n}), \quad \bar{\gamma} := \frac{\gamma^2 - 2\lambda_e^2}{\gamma(1+\lambda_e^2)}, \quad \vartheta := \max(\hat{\gamma}, \bar{\gamma}, \gamma).$$

Then, using (35)– (38), and $\gamma \geq \sqrt{2}\lambda_e$, we have

$$\begin{aligned}
&\mathcal{L}_\gamma(U^k) - \mathcal{L}_\gamma(U^{k+1}) \geq \frac{\gamma}{2}\|\Theta^k - \Theta^{k+1}\|_F^2 \\
&+ \frac{\hat{\gamma}}{2}\sum_{i=1}^n \|Z_i^k - Z_i^{k+1}\|_F^2 + \frac{\gamma^2 - 2\lambda_e^2}{2\gamma}\|E^k - E^{k+1}\|_F^2, \\
&= \frac{\gamma}{2}\|\Theta^k - \Theta^{k+1}\|_F^2 + \frac{\hat{\gamma}}{2}\sum_{i=1}^n \|Z_i^k - Z_i^{k+1}\|_F^2 + \frac{\bar{\gamma}}{2}\|E^k - E^{k+1}\|_F^2 + \frac{\lambda_e^2\bar{\gamma}}{2}\|E^k - E^{k+1}\|_F^2, \\
&= \frac{\gamma}{2}\|\Theta^k - \Theta^{k+1}\|_F^2 + \frac{\hat{\gamma}}{2}\sum_{i=1}^n \|Z_i^k - Z_i^{k+1}\|_F^2 + \frac{\bar{\gamma}}{2}\Big(\|E^k - E^{k+1}\|_F^2 + \|\Lambda^k - \Lambda^{k+1}\|_F^2\Big), \\
&\geq \frac{\vartheta}{2}\Big(\|\Theta^k - \Theta^{k+1}\|_F^2 + \sum_{i=1}^n \|Z_i^k - Z_i^{k+1}\|_F^2 + \|E^k - E^{k+1}\|_F^2 + \|\Lambda^k - \Lambda^{k+1}\|_F^2\Big).
\end{aligned}$$

□

Lemma 16 *Let $U^k = (\Theta^k, Z_1^k, \ldots X_n^k, E^k, \Lambda^k)$ be a sequence generated by Algorithm 1. Then, there exists a subsequence U^{k_s} of $\{U^k\}$, such that*

$$\lim_{s\to\infty} \mathcal{G}(X,\Theta^{k_s}) = g(\Theta^*), \quad \lim_{s\to\infty} f_i(Z_i^{k_s}) = f_i(Z_i^*), \quad \lim_{s\to\infty} f_e(E_i^{k_s}) = f_e(E_i^*),$$

where

$$\lim_{s\to\infty} U^{k_s} = (\Theta^*, Z_1^*, \ldots, Z_n^*, E^*, \Lambda^*).$$

Proof. Let $\Upsilon^{k+1} = \Theta^{k+1} - \sum_{i=1}^n Z_i^{k+1} + Z_i^{k+1\top} - E^{k+1}$. Using the quadratic function $f_e(E) = \frac{\lambda_e}{2}\|E\|_F^2$, we have that

$$\begin{aligned}
f_e(E^{k+1} - \Upsilon^{k+1}) &= \frac{\lambda_e}{2}\|E^{k+1} - \Upsilon^{k+1}\|_F^2 \\
&= \frac{\lambda_e}{2}\|E^{k+1}\|^2 - \lambda_e\langle E^{k+1}, \Upsilon^{k+1}\rangle + \frac{\lambda_e}{2}\|\Upsilon^{k+1}\|_F^2. \qquad (39)
\end{aligned}$$

Using (39) and the fact that each function f_i is lower bounded, there exists $\underline{\mathcal{L}}$, such that

$$\begin{aligned}
\mathcal{L}_\gamma(U^{k+1}) &= \mathcal{G}(X,\Theta^{k+1}) + f_1(Z_1^{k+1}) + \ldots f_n(Z_n^{k+1}) + \frac{\lambda_e}{2}\|E^{k+1} - \Upsilon^{k+1}\|_F^2 \\
&+ \frac{\gamma - \lambda_e}{2}\|\Upsilon^{k+1}\|_F^2 \geq \underline{g} + \underline{f_1} + \cdots + \underline{f_n} \geq \underline{\mathcal{L}}, \qquad (40)
\end{aligned}$$

since $\mathcal{G}(X,\Theta^{k+1})$ and $f_i(Z_i^{k+1})(i = 1, \ldots, n)$ are all lower bounded.

Now, using Lemma 15, we have that

$$\frac{\vartheta}{2}\sum_{k=0}^{K}\Big(\|\Theta^k-\Theta^{k+1}\|_F^2+\sum_{i=1}^{n}\|Z_i^k-Z_i^{k+1}\|_F^2 \;+\; \|E^k-E^{k+1}\|_F^2+\|\Lambda^k-\Lambda^{k+1}\|_F^2\Big) \leq \mathcal{L}_\gamma(U^0)-\underline{\mathcal{L}}. \tag{41}$$

Lemma 15 together with (41) shows that $\mathcal{L}_\gamma(U^k)$ converges to $\mathcal{L}_\gamma(U^*)$. Note that (41) and the coerciveness of $\mathcal{G}(X,\Theta)$ and f_i $(i=1,\ldots,n)$ imply that $\{(\Theta^k,Z_1^k,\ldots,Z_n^k)\}$ is a bounded sequence. This together with the updating formula of Λ^{k+1} and (41) yield the boundedness of E^{k+1}. Moreover, the fact that $\Lambda^k=-\lambda_e E^k$, gives the boundedness of Λ^k, which implies that the entire sequence $\{U^k\}$ is a bounded one. Therefore, there exists a subsequence

$$U^{k_s}=(\Theta^{k_s},Z_1^{k_s},\ldots,Z_n^{k_s},E^{k_s};\Lambda^{k_s}),\qquad s=0,1,\ldots$$

such that $U^{k_s}\to U^*$ as $s\to\infty$.

Now, using the fact that $\mathcal{G}(X,\Theta)$, $f_i(Z_i)$ $(i=1,\ldots,n)$ and $f_e(E)$ are continuous functions, we have that

$$\lim_{s\to\infty}\mathcal{G}(X,\Theta^{k_s})=g(\Theta^*),\quad \lim_{s\to\infty}f_i(Z_i^{k_q})=f_i(Z_i^*),\quad \lim_{s\to\infty}f_e(E_i^{k_q})=f_e(E_i^*).$$

□

Lemma 17 *Algorithm 1 either stops at a stationary point of the problem* (19) *or generates an infinite sequence* $\{U^k\}$*, so that any limit point of* $\{U^k\}$ *is a critical point of* $\mathcal{L}_\gamma(U^k)$ (19)*.*

Proof. From the definition of the augmented Lagrangian function in (19), we have that

$$\begin{aligned}
&\nabla\mathcal{G}(X,\Theta^{k+1})-\Lambda^{k+1}+\gamma\Upsilon^{k+1}=\nabla_\Theta\mathcal{L}_\gamma(U^{k+1}),\\
&\partial f_i(Z_i^{k+1})-\Lambda^{k+1}-{\Lambda^{k+1}}^\top-\gamma(\Upsilon^{k+1}+{\Upsilon^{k+1}}^\top)\in\partial_{Z_i}\mathcal{L}_\gamma(U^{k+1}),\quad i=1,\ldots,n,\\
&\lambda_e E^{k+1}+\Lambda^{k+1}-\gamma\Upsilon^{k+1}=\nabla_E\mathcal{L}_\gamma(U^{k+1}),\\
&\gamma\Upsilon^{k+1}=-\nabla_\Lambda\mathcal{L}_\gamma(U^{k+1}),
\end{aligned}\tag{42}$$

where $\Upsilon^{k+1}=\Theta^{k+1}-\sum_{i=1}^n Z_i^{k+1}+{Z_i^{k+1}}^\top-E^{k+1}$.

Moreover, the updating formula of Λ^{k+1}, (20) and (28) yields that

$$\begin{aligned}
\nabla\mathcal{G}(X,\Theta^{k+1})-\Lambda^{k+1} &= \gamma\Big(\Theta^{k+1}-\Theta^k\\
&+\sum_{i=1}^n Z_i^k-Z_i^{k+1}+(Z_i^k-Z_i^{k+1})^\top+E^k-E^{k+1}\Big)\\
\partial f_1(Z_1^{k+1})-\Lambda^{k+1}-{\Lambda^{k+1}}^\top &= \gamma\varrho(Z_1^k-Z_1^{k+1})+\gamma\Big(\Theta^{k+1}-\Theta^k\\
&+(\Theta^{k+1}-\Theta^k)^\top+\sum_{i=1}^n Z_i^k-Z_i^{k+1}\\
&+(Z_i^k-Z_i^{k+1})^\top+E^k-E^{k+1}+(E^k-E^{k+1})^\top\Big)
\end{aligned}\tag{43}$$

$$\begin{aligned}
\partial f_i(Z_i^{k+1})-\Lambda^{k+1}-{\Lambda^{k+1}}^\top &= \gamma\varrho(Z_i^k-Z_i^{k+1})\\
&+\gamma\Big(\Theta^{k+1}-\Theta^k+(\Theta^{k+1}-\Theta^k)^\top\\
&+\sum_{j=i}^n Z_i^k-Z_i^{k+1}+(Z_i^k-Z_i^{k+1})^\top\\
&+E^k-E^{k+1}+(E^k-E^{k+1})^\top\Big)\qquad i=2,\ldots,n,\\
\lambda_e E^{k+1}+\Lambda^{k+1} &= 0.
\end{aligned}\tag{44}$$

Combining (42), (43), and the updating formula of Λ^{k+1}, we have that

$$(\hbar_\Theta^{k+1},\hbar_1^{k+1},\ldots,\hbar_n^{k+1},\hbar_E^{k+1},\hbar_\Lambda^{k+1})\in\partial\mathcal{L}_\gamma(U^{k+1}),\tag{45}$$

where

$$\begin{aligned}
\hbar_\Theta^{k+1} &:= \Lambda^k-\Lambda^{k+1}+\gamma\Big(\Theta^{k+1}-\Theta^k+\sum_{i=1}^n Z_i^k-Z_i^{k+1}+(Z_i^k-Z_i^{k+1})^\top+E^k-E^{k+1}\Big)\\
\hbar_{Z_1}^{k+1} &:= \Lambda^k-\Lambda^{k+1}+(\Lambda^k-\Lambda^{k+1})^\top+\gamma\varrho(Z_1^k-Z_1^{k+1})\\
&+\gamma\Big(\Theta^{k+1}-\Theta^k+(\Theta^{k+1}-\Theta^k)^\top+\sum_{i=1}^n Z_i^k-Z_i^{k+1}+(Z_i^k-Z_i^{k+1})^\top\\
&+E^k-E^{k+1}+(E^k-E^{k+1})^\top\Big)\\
\hbar_{Z_i}^{k+1} &:= \Lambda^k-\Lambda^{k+1}+(\Lambda^k-\Lambda^{k+1})^\top+\gamma\varrho(Z_i^k-Z_i^{k+1})\\
&+\gamma\Big(\Theta^{k+1}-\Theta^k+(\Theta^{k+1}-\Theta^k)^\top+\sum_{j=i}^n Z_i^k-Z_i^{k+1}+(Z_i^k-Z_i^{k+1})^\top\\
&+E^k-E^{k+1}+(E^k-E^{k+1})^\top\Big),\qquad i=2,\ldots,n,\\
\hbar_E^{k+1} &:= \Lambda^k-\Lambda^{k+1},\\
\hbar_\Lambda^{k+1} &:= \frac{1}{\gamma}(\Lambda^{k+1}-\Lambda^k),
\end{aligned}\tag{46}$$

Now, using (41), we obtain that

$$\lim_{k\to\infty}(\|h_\Theta^{k+1}\|_F, \|h_{Z_1}^{k+1}\|_F, \ldots, \|h_{Z_n}^{k+1}\|_F, \|h_E^{k+1}\|_F; \|R_\Lambda^{k+1}\|_F) = (0, \ldots, 0). \tag{47}$$

Suppose that Algorithm 1 does not stop at a stationary point. Using Lemma 16, there exists a subsequence U^{k_s}, such that $U^{k_s} \to U^*$ as $s \to \infty$. Using (45) and (47), we conclude that $(0, \ldots, 0) \in \partial\mathcal{L}_\gamma(U^*)$. □

Proof of Theorem 10. Lemmas 16 and 17 imply that $\{U^k\}$ is a bounded sequence and the set of limit points of $\{U^k\}$ starting from U^0 is non-empty, respectively. Moreover, Lemma 5 and Remark 5 of (Bolte et al., 2014) imply that the set of limit points of $\{U^k\}$ starting from U^0 is compact. The remainder of the proof of this Theorem follows along similar lines to the proof of Theorem 1 in (Bolte et al., 2014), by utilizing the K-L property of the problem (19) (see, Remark 14). □

Abstract

In a recent paper, Caron and Fox suggest a probabilistic model for sparse graphs which are exchangeable when associating each vertex with a time parameter in $\mathbb{R}_+$. Here we show that by generalizing the classical definition of graphons as functions over probability spaces to functions over σ-finite measure spaces, we can model a large family of exchangeable graphs, including the Caron-Fox graphs and the traditional exchangeable dense graphs as special cases. Explicitly, modelling the underlying space of features by a σ-finite measure space $(S, \mathcal{S}, \mu)$ and the connection probabilities by an integrable function $W\colon S \times S \to [0,1]$, we construct a random family $(G_t)_{t\geq 0}$ of growing graphs such that the vertices of G_t are given by a Poisson point process on S with intensity $t\mu$, with two points x, y of the point process connected with probability $W(x,y)$. We call such a random family a *graphon process*. We prove that a graphon process has convergent subgraph frequencies (with possibly infinite limits) and that, in the natural extension of the cut metric to our setting, the sequence converges to the generating graphon. We also show that the underlying graphon is identifiable only as an equivalence class over graphons with cut distance zero. More generally, we study metric convergence for arbitrary (not necessarily random) sequences of graphs, and show that a sequence of graphs has a convergent subsequence if and only if it has a subsequence satisfying a property we call *uniform regularity of tails*. Finally, we prove that every graphon is equivalent to a graphon on $\mathbb{R}_+$ equipped with Lebesgue measure.

Keywords: graphons, graph convergence, sparse graph convergence, modelling of sparse networks, exchangeable graph models

1. Introduction

The theory of graphons has provided a powerful tool for sampling and studying convergence properties of sequences of dense graphs. Graphons characterize limiting properties of dense graph sequences, such as properties arising in combinatorial optimization and statistical physics. Furthermore, sequences of dense graphs sampled from a (possibly random) graphon are characterized by a natural notion of exchangeability via the Aldous-Hoover theorem. This paper presents an analogous theory for sparse graphs.

In the past few years, graphons have been used as non-parametric extensions of stochastic block models, to model and learn large networks. There have been several rigorous papers on the subject of consistent estimation using graphons (see, for example, papers by Bickel and Chen, 2009, Bickel, Chen, and Levina, 2011, Rohe, Chatterjee, and Yu, 2011, Choi, Wolfe, and Airoldi, 2012, Wolfe and Olhede, 2013, Gao, Lu, and Zhou, 2015, Chatterjee, 2015, Klopp, Tsybakov, and Verzelen, 2017, and Borgs, Chayes, Cohn, and Ganguly, 2015, as well as references therein), and graphons have also been used to estimate real-world networks, such as Facebook and LinkedIn (E. M. Airoldi, private communication, 2015). This makes it especially useful to have graphon models for sparse networks with unbounded degrees, which are the appropriate description of many large real-world networks.

In the classical theory of graphons as studied by, for example, Borgs, Chayes, Lovász, Sós, and Vesztergombi (2006), Lovász and Szegedy (2006), Borgs, Chayes, Lovász, Sós, and Vesztergombi (2008), Bollobás and Riordan (2009), Borgs, Chayes, and Lovász (2010), and Janson (2013), a graphon is a symmetric $[0,1]$-valued function defined on a probability space. In our generalized theory we let the underlying measure space of the graphon be a σ-finite measure space; i.e., we allow the space to have infinite total measure. More precisely, given a σ-finite measure space $\mathscr{S} = (S, \mathcal{S}, \mu)$ we define a graphon to be a pair $\mathcal{W} = (W, \mathscr{S})$, where $W\colon S \times S \to \mathbb{R}$ is a symmetric integrable function, with the special case when W is $[0,1]$-valued being most relevant for the random graphs studied in the current paper. We present a random graph model associated with these generalized graphons which has a number of properties making it appropriate for modelling sparse networks, and we present a new theory for convergence of graphs in which our generalized graphons arise naturally as limits of sparse graphs.

Given a $[0,1]$-valued graphon $\mathcal{W} = (W, \mathscr{S})$ with $\mathscr{S} = (S, \mathcal{S}, \mu)$ a σ-finite measure space, we will now define a random process which generalizes the classical notion of $\mathcal{W}$-random graphs, introduced in the statistics literature (Hoff, Raftery, and Handcock, 2002) under the name latent position graphs, in the context of graph limits (Lovász and Szegedy, 2006) as $\mathcal{W}$-random graphs, and in the context of extensions of the classical random graph theory (Bollobás, Janson, and Riordan, 2007) as inhomogeneous random graphs. Recall that in the classical setting where $\mathcal{W}$ is defined on a probability space, $\mathcal{W}$-random graphs are generated by first choosing n points $x_1, \dots, x_n$ i.i.d. from the probability distribution μ over the feature space S, and then connecting the vertices i and j with probability $W(x_i, x_j)$. Here, inspired by Caron and Fox (2014), we generalize this to arbitrary σ-finite measure spaces by first considering a Poisson point process[1] Γ_t with intensity $t\mu$ on S for any fixed $t > 0$, and

1. We will make this construction more precise in Section 2.4; in particular, we will explain that we may associate Γ_t with a collection of random variables $x_i \in S$. The same result holds for the Poisson point process Γ considered in the next paragraph.

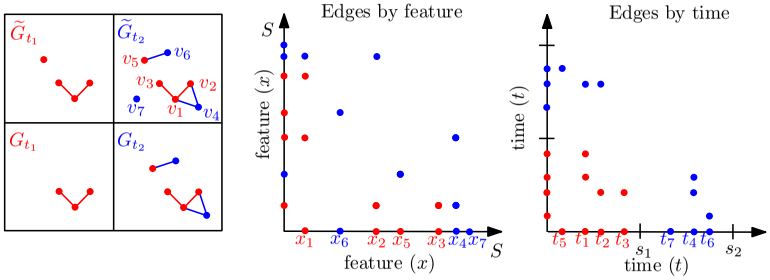

Figure 1: This figure illustrates how we can generate a graphon process $(G_t)_{t\geq 0}$ from a graphon $\mathcal{W} = (W, \mathscr{S})$, where $\mathscr{S} = (S, \mathcal{S}, \mu)$ is a σ-finite measure space. The two coordinate axes on the middle figure represent our feature space S, where the red (resp. blue) dots on the axes represent vertices born during $[0, s_1]$ (resp. $(s_1, s_2]$) for $0 < s_1 < s_2$, and the red (resp. blue) dots in the interior of the first quadrant represent edges in G_t for $t \geq s_1$ (resp. $t \geq s_2$). The graph G_t is an induced subgraph of a graph $\widetilde{G}_t$ with infinitely many vertices in the case $\mu(S) = \infty$, such that G_t is obtained from $\widetilde{G}_t$ by removing isolated vertices. At time $t \geq 0$ the marginal law of the features of $V(\widetilde{G}_t)$ is a Poisson point process on S with intensity $t\mu$. Two distinct vertices with features x and x', respectively, are connected to each other by an undirected edge with probability $W(x, x')$. The coordinate axes on the right figure represent time $\mathbb{R}_+$. We get the graph G_t by considering the edges restricted to $[0, t]^2$. Note that the coordinate axes in the right figure and the graphs $\widetilde{G}_t$ in the left figure are slightly inaccurate if we assume $\mu(S) = \infty$, since in this case there are infinitely many isolated vertices in $\widetilde{G}_t$ for each $t > 0$. We have chosen to label the vertices by the order in which they appear in G_t, where ties are resolved by considering the time the vertices were born, i.e., by considering the time they appeared in $\widetilde{G}_t$.

then connecting two points x_i, x_j in Γ_t with probability $W(x_i, x_j)$. As explained in the next paragraph, this leads to a family of graphs $(\widetilde{G}_t)_{t\geq 0}$ such that the graphs $\widetilde{G}_t$ have almost surely at most countably infinitely many vertices and (assuming appropriate integrability conditions on W, e.g., $W \in L^1$) a finite number of edges. Removing all isolated vertices from $\widetilde{G}_t$, we obtain a family of graphs $(G_t)_{t\geq 0}$ that are almost surely finite. We refer to the families $(\widetilde{G}_t)_{t\geq 0}$ and $(G_t)_{t\geq 0}$ as *graphon processes*; when it is necessary to distinguish the two, we call them graphon processes with or without isolated vertices, respectively.

To interpret the graphon process $(G_t)_{t\geq 0}$ as a family of growing graphs we will need to couple the graphs G_t for different times $t \geq 0$. To this end, we consider a Poisson point process Γ on $\mathbb{R}_+ \times S$ (with $\mathbb{R}_+ := [0, \infty)$ being equipped with the Borel σ-algebra and Lebesgue measure). Each point $v = (t, x)$ of Γ corresponds to a vertex of an infinite graph $\widetilde{G}$, where the coordinate t is interpreted as the time the vertex is born and the coordinate

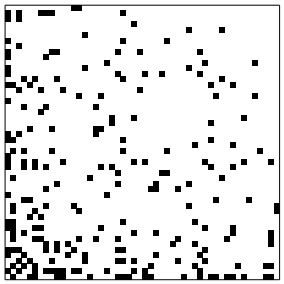
x describes a feature of the vertex. Two distinct vertices $v = (t, x)$ and $v' = (t', x')$ are connected by an undirected edge with probability $W(x, x')$, independently for each possible pair of distinct vertices. For each fixed time $t \geq 0$ define a graph G_t by considering the induced subgraph of $\widetilde{G}$ corresponding to vertices which are born at time t or earlier, where we do not include vertices which would be isolated in G_t. See Figure 1 for an illustration. The family of growing graphs $(G_t)_{t\geq 0}$ just described includes classical dense $\mathcal{W}$-random graphs (up to isolated vertices) and the sparse graphs studied by Caron and Fox (2014) and Herlau, Schmidt, and Mørup (2016) as special cases, and is (except for minor technical differences) identical to the family of random graphs studied by Veitch and Roy (2015), a paper which was written in parallel with our paper; see our remark at the end of this introduction.

The graphon process $(\widetilde{G}_t)_{t\geq 0}$ satisfies a natural notion of exchangeability. Roughly speaking, in our setting this means that the features of newly born vertices are homogeneous in time. More precisely, it can be defined as joint exchangeability of a random measure in $\mathbb{R}^2_+$, where the two coordinates correspond to time, and each edge of the graph corresponds to a point mass. We will prove that graphon processes as defined above, with W integrable and possibly random, are characterized by exchangeability of the random measure in $\mathbb{R}^2_+$ along with a certain regularity condition we call *uniform regularity of tails*. See Proposition 26 in Section 2.4. This result is an analogue in the setting of possibly sparse graphs satisfying the aforementioned regularity condition of the Aldous-Hoover theorem (Aldous, 1981; Hoover, 1979), which characterizes $\mathcal{W}$-random graphs over probability spaces as graphs that are invariant in law under permutation of their vertices.

The graphon processes defined above also have a number of other properties making them particularly natural to model sparse graphs or networks. They are suitable for modelling networks which grow over time since no additional rescaling parameters (like the explicitly given density dependence on the number of vertices specified by Bollobás and Riordan, 2009, and Borgs, Chayes, Cohn, and Zhao, 2014a) are necessary; all information about the random graph model is encoded by the graphon alone. The graphs are *projective* in the sense that if $s < t$ the graph G_s is an induced subgraph of G_t. Finally, a closely related family of weighted graphs is proven by Caron and Fox (2014) to have power law degree distribution for certain $\mathcal{W}$, and our graphon processes are expected to behave similarly. The graphon processes studied in this paper have a different qualitative behavior than the sparse $\mathcal{W}$-random graphs studied by Bollobás and Riordan (2009) and Borgs, Chayes, Cohn, and Zhao (2014a,b) (see Figure 2), with the only overlap of the two theories occurring when the graphs are dense. If the sparsity of the graphs is caused by the degrees of the vertices being scaled down approximately uniformly over time, then the model studied by Bollobás and Riordan (2009) and Borgs, Chayes, Cohn, and Zhao (2014a,b) is most natural. If the sparsity is caused by later vertices typically having lower connectivity probabilities than earlier vertices, then the model presented in this paper is most natural. The sampling method we will use in our forthcoming paper (Borgs, Chayes, Cohn, and Holden, 2017) generalizes both of these methods.

To compare different models, and to discuss notions of convergence, we introduce the following natural generalization of the cut metric for graphons on probability spaces to our setting. For two graphons $\mathcal{W}_1 = (W_1, \mathscr{S}_1)$ and $\mathcal{W}_2 = (W_2, \mathscr{S}_2)$, this metric is easiest to define when the two graphons are defined over the same space. However, for applications we

rescaled graphon on probability space



graphon with non-compact support

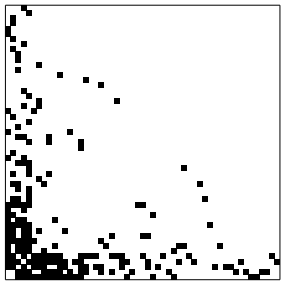


Figure 2: The adjacency matrices of graphs sampled as described by Borgs, Chayes, Cohn, and Zhao (2014a) (left) and in this paper (right), where we used the graphon $\mathcal{W}_1 = (W_1, [0,1])$ (left) and the graphon $\mathcal{W}_2 = (W_2, \mathbb{R}_+)$ (right), with $W_1(x_1, x_2) = x_1^{-1/2} x_2^{-1/2}$ for $x_1, x_2 \in [0,1]$ and $W_2(x_1, x_2) = \min(0.8, 7\min(1, x_1^{-2})\min(1, x_2^{-2}))$ for $x_1, x_2 \in \mathbb{R}_+$. Black (resp. white) indicates that there is (resp. is not) an edge. We rescaled the height of the graphon by $\rho := 1/40$ on the left figure. As described by Borgs, Chayes, Cohn, and Zhao (2014a,b) the type of each vertex is sampled independently and uniformly from $[0,1]$, and each pair of vertices is connected with probability $\min(\rho W_1, 1)$. In the right figure the vertices were sampled by a Poisson point process on $\mathbb{R}_+$ of intensity $t = 4$, and two vertices were connected independently with a probability given by W_2; see Section 2.4 and the main text of this introduction. The two graphs have very different qualitative properties. In the left graph most vertices have a degree close to the average degree, where the average degree depends on our scaling factor ρ. In the right graph the edges are distributed more inhomogeneously: most of the edges are contained in induced subgraphs of constant density, and the sparsity is caused by a large number of vertices with very low degree.

want to compare graphons over different spaces, say two Borel spaces $\mathscr{S}_1$ and $\mathscr{S}_2$. Assuming that both Borel spaces have infinite total measure, the cut distance between $\mathcal{W}_1$ and $\mathcal{W}_2$ can then be defined as

$$\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = \inf_{\psi_1,\psi_2} \sup_{U,V\subseteq\mathbb{R}_+^2} \left| \int_{U\times V} \left(W_1^{\psi_1} - W_2^{\psi_2}\right) d\mu\, d\mu \right|, \tag{1}$$

where we take the infimum over measure-preserving maps $\psi_j \colon \mathbb{R}_+ \to S_j$ for $j = 1, 2$, $W_j^{\psi_j}(x, y) := W_j(\psi_j(x), \psi_j(y))$ for $x, y \in \mathbb{R}_+$, and the supremum is over measurable sets $U, V \subseteq \mathbb{R}_+^2$. (See Definition 5 below for the definition of the cut distance for graphons over general spaces, including the case where one or both spaces have finite total mass.) We call two graphons *equivalent* if they have cut distance zero. As we will see, two graphons are equivalent if and only if the random families $(G_t)_{t\geq 0}$ generated from these graphons have the same distribution; see Theorem 27 below.

To compare graphs and graphons, we embed a graph on n vertices into the set of step functions over $[0,1]^2$ in the usual way by decomposing $[0,1]$ into adjacent intervals $I_1, \ldots, I_n$ of lengths $1/n$, and define a step function W^G as the function which is equal to 1 on $I_i \times I_j$ if i and j are connected in G, and equal to 0 otherwise. Extending W^G to a function on $\mathbb{R}_+^2$ by setting it to zero outside of $[0,1]^2$, we can then compare graphs to graphons on measure spaces of infinite mass, and in particular we get a notion of convergence in metric of a sequence of graphs $(G_n)_{n\in\mathbb{N}}$ to a graphon $\mathcal{W}$.

In the classical theory of graph convergence, such a sequence will converge to the zero graphon whenever the sequence is sparse.[2] We resolve this difficulty by rescaling the input arguments of the step function W^G so as to get a "stretched graphon" $\mathcal{W}^{G,s} = (W^{G,s}, \mathbb{R}_+)$ satisfying $\|W^{G,s}\|_1 = 1$. Equivalently, we may interpret $\mathcal{W}^{G,s}$ as a graphon where the measure of the underlying measure space is rescaled. See Figure 3 for an illustration, which also compares the rescaling in the current paper with the rescaling considered by Borgs, Chayes, Cohn, and Zhao (2014a). We say that $(G_n)_{n\in\mathbb{N}}$ converges to a graphon $\mathcal{W}$ (with L^1 norm equal to 1) for the stretched cut metric if $\lim_{n\to\infty} \delta_\square(\mathcal{W}^{G_n,s}, \mathcal{W}) = 0$. Graphons on σ-finite measure spaces of infinite total measure may therefore be considered as limiting objects for sequences of sparse graphs, similarly as graphons on probability spaces are considered limits of dense graphs. We prove that graphon processes converge to the generating graphon in the stretched cut metric; see Proposition 28 in Section 2.4. We will also consider another family of random sparse graphs associated with a graphon $\mathcal{W}$ over a σ-finite measure space, and prove that these graphs are also converging for the stretched cut metric.

Particular random graph models of special interest arise by considering certain classes of graphons $\mathcal{W}$. Caron and Fox (2014) consider graphons on the form $W(x_1, x_2) = 1 - \exp(-f(x_1)f(x_2))$ (with a slightly different definition on the diagonal, since they also allow for self-edges) for certain decreasing functions $f \colon \mathbb{R}_+ \to \mathbb{R}_+$. In this model x represents a sociability parameter of each vertex. A multi-edge version of this model allows for an alternative sampling procedure to the one we present above (Caron and Fox, 2014, Section 3). Herlau, Schmidt, and Mørup (2016) introduced a generalization of the model of Caron and Fox (2014) to graphs with block structure. In this model each node is associated to a

2. Here, as usual, a sequence of simple graphs is considered sparse if the number of edges divided by the square of the number of vertices goes to zero.

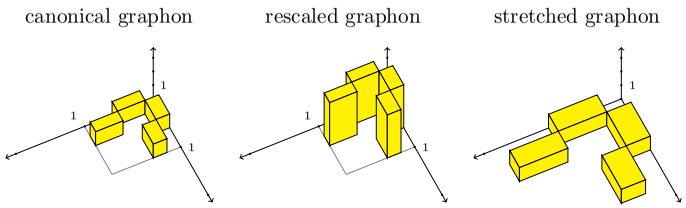

Figure 3: The figure shows three graphons associated with the same simple graph G on five vertices. In the classical theory of graphons all simple sparse graphs converge to the zero graphon. We may prevent this by renormalizing the graphons, either by rescaling the height of the graphon (middle) or by stretching the domain on which it is defined (right). The first approach was chosen by Bollobás and Riordan (2009) and Borgs, Chayes, Cohn, and Zhao (2014a,b), and the second approach is chosen in this paper. In our forthcoming paper (Borgs, Chayes, Cohn, and Holden, 2017) we choose a combined approach, where the renormalization depends on the observed graph.

type from a finite index set $[K] := \{1, \dots, K\}$ for some $K \in \mathbb{N}$, in addition to its sociability parameter, such that the probability of two nodes connecting depends both on their type and their sociability. More generally we can obtain sparse graphs with block structure by considering integrable functions $W_{k_1,k_2} \colon \mathbb{R}_+^2 \to [0,1]$ for $k_1, k_2 \in \{1, \dots, K\}$, and defining $S := [K] \times \mathbb{R}_+$ and $W((k_1, x_1), (k_2, x_2)) := W_{k_1,k_2}(x_1, x_2)$. As compared to the block model of Herlau, Schmidt, and Mørup (2016), this allows for a more complex interaction within and between the blocks. An alternative generalization of the stochastic block model to our setting is to consider infinitely many disjoint intervals $I_k \subset \mathbb{R}_+$ for $k \in \mathbb{N}$, and define $W := \sum_{k_1,k_2 \in \mathbb{N}} p_{k_1,k_2} \mathbf{1}_{I_{k_1} \times I_{k_2}}$ for constants $p_{k_1,k_2} \in [0,1]$. For the block model of Herlau, Schmidt, and Mørup (2016) and our first generalization above (with $S := [K] \times \mathbb{R}_+$), the degree distribution of the vertices within each block will typically be strongly inhomogeneous; by contrast, in our second generalization above (with infinitely many blocks), all vertices within the same block have the same connectivity probabilities, and hence the degree distribution will be more homogeneous.

We can also model sparse graphs with mixed membership structure within our framework. In this case we let $\widetilde{S} \subset [0,1]^K$ be the standard $(K-1)$-simplex, and define $S := \widetilde{S} \times \mathbb{R}_+$. For a vertex with feature $(\widetilde{x}, x) \in \widetilde{S} \times \mathbb{R}_+$ the first coordinate $\widetilde{x} = (\widetilde{x}_1, \dots, \widetilde{x}_K)$ is a vector such that $\widetilde{x}_j$ for $j \in [K]$ describes the proportion of time the vertex is part of community $j \in [K]$, and the second coordinate x describes the role of the vertex within the community; for example, x could be a sociability parameter. For each $k_1, k_2 \in [K]$ let $\mathcal{W}_{k_1,k_2} = (W_{k_1,k_2}, \mathbb{R}_+)$ be a graphon describing the interactions between the communities k_1 and k_2. We define our mixed membership graphon $\mathcal{W} = (W, \mathscr{S})$ by

$$W\big((\widetilde{x}^1, x^1), (\widetilde{x}^2, x^2)\big) := \sum_{k_1,k_2 \in [K]} \widetilde{x}^1_{k_1} \widetilde{x}^2_{k_2} W_{k_1,k_2}(x^1, x^2).$$

Alternatively, we could define $S := \widetilde{S} \times \mathbb{R}_+^K$, which would provide a model where, for example, the sociability of a node varies depending on which community it is part of.

In the classical setting of dense graphs, many papers only consider graphons defined on the unit square, instead of graphons on more general probability spaces. This is justified by the fact that every graphon with a probability space as base space is equivalent to a graphon with base space $[0,1]$. The analogue in our setting would be graphons over $\mathbb{R}_+$ equipped with the Lebesgue measure. As the examples in the preceding paragraphs illustrate, for certain random graph models it is more natural to consider another underlying measure space. For example, each coordinate in some higher-dimensional space may correspond to a particular feature of the vertices, and changing the base space can disrupt certain properties of the graphon, such as smoothness conditions. For this reason we consider graphons defined on general σ-finite measure spaces in this paper. However, we will prove that every graphon is equivalent to a graphon on $\mathbb{R}_+$ equipped with the Borel σ-algebra and Lebesgue measure, in the sense that their cut distance is zero; see Proposition 10 in Section 2.2. As stated before, our results then imply that they correspond to the same random graph model.

The set of $[0,1]$-valued graphons on probability spaces is compact for the cut metric. For the possibly unbounded graphons studied by Borgs, Chayes, Cohn, and Zhao (2014a), which are real-valued and defined on probability spaces, compactness holds if we consider closed subsets of the space of graphons which are *uniformly upper regular* (see Section 2.3 for the definition). In our setting, where we look at graphons over spaces of possibly infinite measure, the analogous regularity condition is *uniform regularity of tails* if we restrict ourselves to, say, $[0,1]$-valued graphons. In particular our results imply that a sequence of simple graphs with uniformly regular tails is subsequentially convergent, and conversely, that every convergent sequence of simple graphs has uniformly regular tails. See Theorem 15 in Section 2.3 and the two corollaries following this theorem.

In the setting of dense graphs, convergence for the cut metric is equivalent to left convergence, meaning that subgraph densities converge. This equivalence does not hold in our setting, or for the unbounded graphons studied by Borgs, Chayes, Cohn, and Zhao (2014a,b); its failure is characteristic of sparse graphs, because deleting even a tiny fraction of the edges in a sparse graph can radically change the densities of larger subgraphs (see the discussion by Borgs, Chayes, Cohn, and Zhao, 2014a, Section 2.9). However, randomly sampled graphs do satisfy a notion of left convergence; see Proposition 30 in Section 2.5.

As previously mentioned, in our forthcoming paper (Borgs, Chayes, Cohn, and Holden, 2017) we will generalize and unify the theories and models presented by Bollobás and Riordan (2009), Borgs, Chayes, Cohn, and Zhao (2014a,b), Caron and Fox (2014), Herlau, Schmidt, and Mørup (2016), and Veitch and Roy (2015). Along with the introduction of a generalized model for sampling graphs and an alternative (and weaker) cut metric, we will prove a number of convergence properties of these graphs. Since the graphs in this paper are obtained as a special case of the graphs in our forthcoming paper, the mentioned convergence results also hold in our setting.

In Section 2 we will state the main results of this paper, which will be proved in the subsequent appendices. In Appendix A we prove that the cut metric $\delta_\square$ is well defined. In Appendix B we prove that any graphon is equivalent to a graphon with underlying measure space $\mathbb{R}_+$. We also prove that under certain conditions on the underlying measure space we may define the cut metric $\delta_\square$ in a number of equivalent ways. In Appendix C, we deal with

some technicalities regarding graph-valued processes. In Appendix D we prove that certain random graph models derived from a graphon $\mathcal{W}$, including the graphon processes defined above, give graphs converging to $\mathcal{W}$ for the cut metric. We also prove that two graphons are equivalent (i.e., they have cut distance zero) iff the corresponding graphon processes are equal in law. In Appendix E we prove that uniform regularity of tails is sufficient to guarantee subsequential metric convergence for a sequence of graphs; conversely, we prove that every convergent sequence of graphs with non-negative edge weights has uniformly regular tails. In Appendix F we prove some basic properties of sequences of graphs which are metric convergent, for example that metric convergence implies unbounded average degree if the number of edges diverge and the graph does not have too many isolated vertices; see Proposition 22 below. We also compare the notion of metric graph convergence in this paper to the one studied by Borgs, Chayes, Cohn, and Zhao (2014a). In Appendix G we prove with reference to the Kallenberg theorem for jointly exchangeable measures that graphon processes for integrable W are uniquely characterized as exchangeable graph processes satisfying uniform tail regularity. We also describe more general families of graphs that may be obtained from the Kallenberg representation theorem if this regularity condition is not imposed. Finally, in Appendix H we prove our results on left convergence of graphon processes.

Remark 1 *After writing a first draft of this work, but a little over a month before completing the paper, we became aware of parallel, independent work by Veitch and Roy (2015), who introduce a closely related model for exchangeable sparse graphs and interpret it with reference to the Kallenberg theorem for exchangeable measures. The random graph model studied by Veitch and Roy (2015) is (up to minor differences) the same as the graphon processes introduced in the current paper. Aside from both introducing this model, the results of the two papers are essentially disjoint. While Veitch and Roy (2015) focus on particular properties of the graphs in a graphon process (in particular, the expected number of edges and vertices, the degree distribution, and the existence of a giant component under certain assumptions on $\mathcal{W}$), our focus is graph convergence, the cut metric, and the question of when two different graphons lead to the same graphon process.*

See also the subsequent paper by Janson (2016) expanding on the results of our paper, characterizing in particular when two graphons are equivalent, and proving additional compactness results for graphons over σ-finite spaces.

2. Definitions and Main Results

We will work mainly with simple graphs, but we will allow the graphs to have weighted vertices and edges for some of our definitions and results. We denote the vertex set of a graph G by $V(G)$ and the edge set of G by $E(G)$. The sets $V(G)$ and $E(G)$ may be infinite, but we require them to be countable. If G is weighted, with edge weights $\beta_{ij}(G)$ and vertex weights $\alpha_i(G)$, we require the vertex weights to be non-negative, and we often (but not always) require that $\|\beta(G)\|_1 := \sum_{i,j\in V(G)} \alpha_i(G)\alpha_j(G)|\beta_{ij}(G)| < \infty$ (note that $\|\beta(G)\|_1$ is defined in such a way that for an unweighted graph, it is equal to $2|E(G)|$, as opposed to the density, which is ill-defined if $|V(G)| = \infty$). We define the edge density of a finite simple graph G to be $\rho(G) := 2|E(G)|/|V(G)|^2$. Letting $\mathbb{N} = \{1, 2, \dots\}$ denote the positive integers, a sequence $(G_n)_{n\in\mathbb{N}}$ of simple, finite graphs will be called sparse if $\rho(G_n) \to 0$ as $n \to \infty$,

and dense if $\liminf_{n\to\infty} \rho(G_n) > 0$. When we consider graph-valued stochastic processes $(G_n)_{n\in\mathbb{N}}$ or $(G_t)_{t\geq 0}$ of simple graphs, we will assume each vertex is labeled by a distinct number in $\mathbb{N}$, so we can view $V(G)$ as a subset of $\mathbb{N}$ and $E(G)$ as a subset of $\mathbb{N}\times\mathbb{N}$. The labels allow us to keep track of individual vertices in the graph over time. In Section 2.4 we define a topology and σ-algebra on the set of such graphs.

2.1 Measure-theoretic Preliminaries

We start by recalling several notions from measure theory.

For two measure spaces $\mathscr{S} = (S, \mathcal{S}, \mu)$ and $\mathscr{S}' = (S', \mathcal{S}', \mu')$, a measurable map $\phi\colon S \to S'$ is called *measure-preserving* if for every $A \in \mathcal{S}'$ we have $\mu(\phi^{-1}(A)) = \mu'(A)$. Two measure spaces $(S, \mathcal{S}, \mu)$ and $(S', \mathcal{S}', \mu')$ are called *isomorphic* if there exists a bimeasurable, bijective, and measure-preserving map $\phi\colon S \to S'$. A *Borel measure space* is defined as a measure space that is isomorphic to a Borel subset of a complete separable metric space equipped with a Borel measure.

Throughout most of this paper, we consider *σ-finite measure spaces*, i.e., spaces $\mathscr{S} = (S, \mathcal{S}, \mu)$ such that S can be written as a countable union of sets $A_i \in \mathcal{S}$ with $\mu(A_i) < \infty$. Recall that a set $A \in \mathcal{S}$ is an *atom* if $\mu(A) > 0$ and if every measurable $B \subseteq A$ satisfies either $\mu(B) = 0$ or $\mu(B) = \mu(A)$. The measure space $\mathscr{S}$ is atomless if it has no atoms. Every atomless σ-finite Borel space of infinite measure is isomorphic to $(\mathbb{R}_+, \mathcal{B}, \lambda)$, where $\mathcal{B}$ is the Borel σ-algebra and λ is Lebesgue measure; for the convenience of the reader, we prove this as Lemma 33 below.

We also need the notion of a coupling, a concept well known for probability spaces: if $(S_i, \mathcal{S}_i, \mu_i)$ is a measure space for $i = 1, 2$ and $\mu_1(S_1) = \mu_2(S_2) \in (0, \infty]$, we say that μ is a *coupling* of μ_1 and μ_2 if μ is a measure on $(S_1 \times S_2, \mathcal{S}_1 \times \mathcal{S}_2)$ with marginals μ_1 and μ_2, i.e., if $\mu(U \times S_2) = \mu_1(U)$ for all $U \in \mathcal{S}_1$ and $\mu(S_1 \times U) = \mu_2(U)$ for all $U \in \mathcal{S}_2$. Note that this definition of coupling is closely related to the definition of coupling of probability measures, which applies when $\mu_1(S_1) = \mu_2(S_2) = 1$. For probability spaces, it is easy to see that every pair of measures has a coupling (for example, the product space of the two probability spaces). We prove the existence of a coupling for σ-finite measure spaces in Appendix A, where this fact is stated as part of a more general lemma, Lemma 34.

Finally, we say that a measure space $\widetilde{\mathscr{S}} = (\widetilde{S}, \widetilde{\mathcal{S}}, \widetilde{\mu})$ *extends* a measure space $\mathscr{S} = (S, \mathcal{S}, \mu)$ if $S \in \widetilde{\mathcal{S}}$, $\mathcal{S} = \{A \cap S : A \in \widetilde{\mathcal{S}}\}$, and $\mu(A) = \widetilde{\mu}(A)$ for all $A \in \mathcal{S}$. We say that $\mathscr{S}$ is a *restriction* of $\widetilde{\mathscr{S}}$, or, if S is specified, *the restriction* of $\widetilde{\mathscr{S}}$ *to* S.

2.2 Graphons and Cut Metric

We will work with the following definition of a graphon.

Definition 2 *A* graphon *is a pair $\mathcal{W} = (W, \mathscr{S})$, where $\mathscr{S} = (S, \mathcal{S}, \mu)$ is a σ-finite measure space satisfying $\mu(S) > 0$ and W is a symmetric real-valued function $W \in L^1(S \times S)$ that is measurable with respect to the product σ-algebra $\mathcal{S} \times \mathcal{S}$ and integrable with respect to $\mu \times \mu$. We say that $\mathcal{W}$ is a* graphon over $\mathscr{S}$.

Remark 3 *Most literature on graphons defines a graphon to be the function W instead of the pair $(W, \mathscr{S})$. We have chosen the above definition since the underlying measure space*

will play an important role. Much literature on graphons requires W to take values in $[0,1]$, and some of our results will also be restricted to this case. The major difference between the above definition and the definition of a graphon in the existing literature, however, is that we allow the graphon to be defined on a measure space of possibly infinite measure, instead of a probability space.[3]

Remark 4 *One may relax the integrability condition for W in the above definition such that the corresponding random graph model (as defined in Definition 25 below) still gives graphs with finitely many vertices and edges for each bounded time. This more general definition is used by Veitch and Roy (2015). We work with the above definition since the majority of the analysis in this paper is related to convergence properties and graph limits, and our definition of the cut metric is most natural for integrable graphons. An exception is the notion of subgraph density convergence in the corresponding random graph model, which we discuss in the more general setting of not necessarily integrable graphons; see Remark 31 below.*

We will mainly study simple graphs in the current paper, in particular, graphs which do not have self-edges. However, the theory can be generalized in a straightforward way to graphs with self-edges, in which case we would also impose an integrability condition for W along its diagonal.

If $\mathcal{W} = (W, (S, \mathcal{B}, \lambda))$, where S is a Borel subset of $\mathbb{R}$, $\mathcal{B}$ is the Borel σ-algebra, and λ is Lebesgue measure, we write $\mathcal{W} = (W, S)$ to simplify notation. For example, we write $\mathcal{W} = (W, \mathbb{R}_+)$ instead of $\mathcal{W} = (W, (\mathbb{R}_+, \mathcal{B}, \lambda))$.

For any measure space $\mathscr{S} = (S, \mathcal{S}, \mu)$ and integrable function $W\colon S \times S \to \mathbb{R}$, define the *cut norm* of W over $\mathscr{S}$ by

$$\|W\|_{\square,S,\mu} := \sup_{U,V\in\mathcal{S}} \left| \int_{U\times V} W(x,y)\, d\mu(x)\, d\mu(y) \right|.$$

If S and/or μ is clear from the context we may write $\|\cdot\|_\square$ or $\|\cdot\|_{\square,\mu}$ to simplify notation.

Given a graphon $\widetilde{\mathcal{W}} = (\widetilde{W}, \widetilde{\mathscr{S}})$ with $\widetilde{\mathscr{S}} = (\widetilde{S}, \widetilde{\mathcal{S}}, \widetilde{\mu})$ and a set $S \in \widetilde{\mathcal{S}}$, we say that $\mathcal{W} = (W, \mathscr{S})$ is *the restriction of $\widetilde{\mathcal{W}}$ to S* if $\mathscr{S}$ is the restriction of $\widetilde{\mathscr{S}}$ to S and $\widetilde{W}|_{S\times S} = W$. We say that $\widetilde{\mathcal{W}} = (\widetilde{W}, \widetilde{\mathscr{S}})$ is *the trivial extension of $\mathcal{W}$ to $\widetilde{\mathscr{S}}$* if $\mathcal{W} = (W, \mathscr{S})$ is the restriction of $\widetilde{\mathcal{W}}$ to S and $\operatorname{supp}(\widetilde{W}) \subseteq S \times S$. For measure spaces $\mathscr{S} = (S, \mathcal{S}, \mu)$ and $\mathscr{S}' = (S', \mathcal{S}', \mu')$, a graphon $\mathcal{W} = (W, \mathscr{S})$, and a measurable map $\phi\colon S' \to S$, we define the graphon $\mathcal{W}^\phi = (W^\phi, \mathscr{S}')$ by $W^\phi(x_1, x_2) := W(\phi(x_1), \phi(x_2))$ for $x_1, x_2 \in S'$. We say that $\mathcal{W}^\phi$ (resp. W^ϕ) is a *pullback* of $\mathcal{W}$ (resp. W) onto $\mathscr{S}'$. Finally, let $\|\cdot\|_1$ denote the L^1 norm.

Definition 5 *For $i = 1, 2$, let $\mathcal{W}_i = (W_i, \mathscr{S}_i)$ with $\mathscr{S}_i = (S_i, \mathcal{S}_i, \mu_i)$ be a graphon.*

3. The term "graphon" was coined by Borgs, Chayes, Lovász, Sós, and Vesztergombi (2008), but the use of this concept in combinatorics goes back to at least Frieze and Kannan (1999), who considered a version of the regularity lemma for functions over $[0,1]^2$. As a limit object for convergent graph sequences it was introduced by Lovász and Szegedy (2006), where it was called a W-function, and graphons over general probability spaces were first studied by Borgs, Chayes, and Lovász (2010) and Janson (2013).

(i) If $\mu_1(S_1) = \mu_2(S_2) \in (0, \infty]$, the cut metric $\delta_\square$ *and* invariant L^1 metric δ_1 *are defined by*

$$\begin{aligned} \delta_\square(\mathcal{W}_1, \mathcal{W}_2) &:= \inf_\mu \|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square, S_1\times S_2, \mu} \quad \text{and} \\ \delta_1(\mathcal{W}_1, \mathcal{W}_2) &:= \inf_\mu \|W_1^{\pi_1} - W_2^{\pi_2}\|_{1, S_1\times S_2, \mu}, \end{aligned} \tag{2}$$

where $\pi_i\colon S_1 \times S_2 \to S_i$ denotes projection for $i = 1, 2$, and we take the infimum over all couplings μ of μ_1 and μ_2.

(ii) If $\mu_1(S_1) \neq \mu_2(S_2)$, let $\widetilde{\mathscr{S}}_i = (\widetilde{S}_i, \widetilde{\mathcal{S}}_i, \widetilde{\mu}_i)$ be a σ-finite measure space extending $\mathscr{S}_i$ for $i = 1, 2$ such that $\widetilde{\mu}_1(\widetilde{S}_1) = \widetilde{\mu}_2(\widetilde{S}_2) \in (0, \infty]$. Let $\widetilde{\mathcal{W}}_i = (\widetilde{W}_i, \widetilde{\mathscr{S}}_i)$ be the trivial extension of $\mathcal{W}_i$ to $\widetilde{\mathscr{S}}_i$, and define

$$\delta_\square(\mathcal{W}_1, \mathcal{W}_2) := \delta_\square(\widetilde{\mathcal{W}}_1, \widetilde{\mathcal{W}}_2) \quad \text{and} \quad \delta_1(\mathcal{W}_1, \mathcal{W}_2) := \delta_1(\widetilde{\mathcal{W}}_1, \widetilde{\mathcal{W}}_2).$$

(iii) We call two graphons $\mathcal{W}_1$ and $\mathcal{W}_2$ equivalent *if $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$.*

The following proposition will be proved in Appendix A. Recall that a pseudometric on a set S is a function from $S \times S$ to $\mathbb{R}_+$ which satisfies all the requirements of a metric, except that the distance between two different points might be zero.

Proposition 6 *The metrics $\delta_\square$ and δ_1 given in Definition 5 are well defined; in other words, under the assumptions of (i) there exists at least one coupling μ, and under the assumptions of (ii) the definitions of $\delta_\square(\mathcal{W}_1, \mathcal{W}_2)$ and $\delta_1(\mathcal{W}_1, \mathcal{W}_2)$ do not depend on the choice of extensions $\widetilde{\mathscr{S}}_1, \widetilde{\mathscr{S}}_2$. Furthermore, $\delta_\square$ and δ_1 are pseudometrics on the space of graphons.*

An important input to the proof of the proposition (Lemma 42 in Appendix A) is that the $\delta_\square$ (resp. δ_1) distance between two graphons over spaces of equal measure, as defined in Definition 5(i), is invariant under trivial extensions. The lemma is proved by first showing that it holds for step functions (where the proof more or less boils down to an explicit calculation) and then using the fact that every graphon can be approximated by a step function.

We will see in Proposition 48 in Appendix B that under additional assumptions on the underlying measure spaces $\mathscr{S}_1$ and $\mathscr{S}_2$ the cut metric can be defined equivalently in a number of other ways, giving, in particular, the equivalence of the definitions (1) and (2) in the case of two Borel spaces of infinite mass. Similar results hold for the metric δ_1; see Remark 49.

While the two metrics $\delta_\square$ and δ_1 are not equivalent, a fact which is already well known from the theory of graph convergence for dense graphs, it turns out that the statement that two graphons have distance zero in the cut metric is equivalent to the same statement in the invariant L^1 metric. This is the content of our next proposition.

Proposition 7 *Let $\mathcal{W}_1$ and $\mathcal{W}_2$ be graphons. Then $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$ if and only if $\delta_1(\mathcal{W}_1, \mathcal{W}_2) = 0$.*

The proposition will be proved in Appendix B. (We will actually prove a generalization of this proposition involving an invariant version of the L^p metric; see Proposition 50.) The proof proceeds by first showing (Proposition 51) that if $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$ for graphons $\mathcal{W}_i = (W_i, \mathscr{S}_i)$ with $\mathscr{S}_i = (S_i, \mathcal{S}_i, \mu_i)$ for $i = 1, 2$, then there exists a particular measure μ on $S_1 \times S_2$ such that $\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu} = 0$. Under certain conditions we may assume that μ is a coupling measure, in which case it follows that the infimum in the definition of $\delta_\square$ is a minimum; see Proposition 8 below.

To state our next proposition we define a coupling between two graphons $\mathcal{W}_i = (W_i, \mathscr{S}_i)$ with $\mathscr{S}_i = (S_i, \mathcal{S}_i, \mu_i)$ for $i = 1, 2$ as a pair of graphons $\widetilde{\mathcal{W}}_i$ over a space of the form $\mathscr{S} = (S_1 \times S_2, \mathcal{S}_1 \times \mathcal{S}_2, \mu)$, where μ is a coupling of μ_1 and μ_2 and $\widetilde{\mathcal{W}}_i = W_i^{\pi_i}$, and where as before, π_i denotes the projection from $S_1 \times S_2$ onto S_i for $i = 1, 2$.

Proposition 8 *Let $\mathcal{W}_i$ be graphons over σ-finite Borel spaces $\mathscr{S}_i = (S_i, \mathcal{S}_i, \mu_i)$, and let $\widetilde{S}_i = \{x \in S_i \colon \int |W_i(x, y)| d\mu_i(y) > 0\}$, for $i = 1, 2$. If $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$, then the restrictions of $\mathcal{W}_1$ and $\mathcal{W}_2$ to $\widetilde{S}_1$ and $\widetilde{S}_2$ can be coupled in such a way that they are equal a.e.*

The proposition will be proved in Appendix B. Note that Janson (2016, Theorem 5.3) independently proved a similar result, building on a previous version of the present paper which did not yet contain Proposition 8. His result states that if the cut distance between two graphons over σ-finite Borel spaces is zero, then there are trivial extensions of these graphons such that the extensions can be coupled so as to be equal almost everywhere. It is easy to see that our result implies his, but we believe that with a little more work, it should be possible to deduce ours from his as well.

Remark 9 *Note that the classical theory of graphons on probability spaces appears as a special case of the above definitions by taking $\mathscr{S}$ to be a probability space. Our definition of the cut metric $\delta_\square$ is equivalent to the standard definition for graphons on probability spaces; see, for example, papers by Borgs, Chayes, Lovász, Sós, and Vesztergombi (2008) and Janson (2013). Note that $\delta_\square$ is not a true metric, only a pseudometric, but we call it a metric to be consistent with existing literature on graphons. However, it is a metric on the set of equivalence classes as derived from the equivalence relation in Definition 5 (iii).*

We work with graphons defined on general σ-finite measure spaces, rather than graphons on $\mathbb{R}_+$, since particular underlying spaces are more natural to consider for certain random graphs or networks. However, the following proposition shows that every graphon is equivalent to a graphon over $\mathbb{R}_+$.

Proposition 10 *For each graphon $\mathcal{W} = (W, \mathscr{S})$ there exists a graphon $\mathcal{W}' = (W', \mathbb{R}_+)$ such that $\delta_\square(\mathcal{W}, \mathcal{W}') = 0$.*

The proof of the proposition follows a similar strategy as the proof of the analogous result for probability spaces by Borgs, Chayes, and Lovász (2010, Theorem 3.2) and Janson (2013, Theorem 7.1), and will be given in Appendix B. The proof uses in particular the result that an atomless σ-finite Borel space is isomorphic to an interval equipped with Lebesgue measure (Lemma 33).

2.3 Graph Convergence

To define graph convergence in the cut metric, one traditionally (Borgs, Chayes, Lovász, Sós, and Vesztergombi, 2006; Lovász and Szegedy, 2006; Borgs, Chayes, Lovász, Sós, and Vesztergombi, 2008) embeds the set of graphs into the set of graphons via the following map. Given any finite weighted graph G we define the *canonical graphon* $\mathcal{W}^G = (W^G, [0, 1])$ as follows. Let $v_1, \dots, v_n$ be an ordering of the vertices of G. For any $v_i \in V(G)$ let $\alpha_i > 0$ denote the weight of v_i, for any $(v_i, v_j) \in E(G)$ let $\beta_{ij} \in \mathbb{R}$ denote the weight of the edge (v_i, v_j), and for $(v_i, v_j) \notin V(G)$ define $\beta_{ij} = 0$. By rescaling the vertex weights if necessary we assume without loss of generality that $\sum_{i=1}^{|V(G)|} \alpha_i = 1$. If G is simple all vertices have weight $|V(G)|^{-1}$, and we define $\beta_{ij} := \mathbf{1}_{(v_i, v_j) \in E(G)}$. Let $I_1, \dots, I_n$ be a partition of $[0, 1]$ into adjacent intervals of lengths $\alpha_1, \dots, \alpha_n$ (say the first one closed, and all others half open), and finally define W^G by

$$W^G(x_1, x_2) = \beta_{ij} \quad \text{if} \quad x_1 \in I_i \text{ and } x_2 \in I_j.$$

Note that W^G depends on the ordering of the vertices, but that different orderings give graphons with cut distance zero. We define a sequence of weighted, finite graphs G_n to be *sparse*[4] if $\|W^{G_n}\|_1 \to 0$ as $n \to \infty$. Note that this generalizes the definition we gave in the very beginning of Section 2 for simple graphs.

A sequence $(G_n)_{n \in \mathbb{N}}$ of graphs is then defined to be *convergent in metric* if $\mathcal{W}^{G_n}$ is a Cauchy sequence in the metric $\delta_\square$, and it is said to be *convergent to a graphon* $\mathcal{W}$ if $\delta_\square(\mathcal{W}^{G_n}, \mathcal{W}) \to 0$. Equivalently, one can define convergence of $(G_n)_{n \in \mathbb{N}}$ by identifying a weighted graph G with the graphon $(\beta(G), \mathscr{S}_G)$, where $\mathscr{S}_G$ consists of the vertex set $V(G)$ equipped with the probability measure given by the weights α_i (or the uniform measure if G has no vertex weights), and $\beta(G)$ is the function that maps $(i, j) \in V(G) \times V(G)$ to $\beta_{ij}(G)$.

In the classical theory of graph convergence a sequence of sparse graphs converges to the trivial graphon with $W \equiv 0$. This follows immediately from the fact that $\delta_\square(\mathcal{W}^{G_n}, 0) \le \|W^{G_n}\|_1 \to 0$ for sparse graphs. To address this problem, Bollobás and Riordan (2009) and Borgs, Chayes, Cohn, and Zhao (2014a) considered the sequence of reweighted graphons $(\mathcal{W}^{G_n, r})_{n \in \mathbb{N}}$, where $\mathcal{W}^{G,r} := (W^{G,r}, [0, 1])$ with $W^{G,r} := \frac{1}{\|W^G\|_1} W^G$ for any graph G, and defined $(G_n)_{n \in \mathbb{N}}$ to be convergent iff $(\mathcal{W}^{G_n, r})_{n \in \mathbb{N}}$ is convergent. The theory developed in the current paper considers a different rescaling, namely a rescaling of the *arguments* of the function W^G, which, as explained after Definition 11 below, is equivalent to *rescaling the measure* of the underlying measurable space.

We define the *stretched canonical graphon* $\mathcal{W}^{G,s}$ to be identical to $\mathcal{W}^G$ except that we "stretch" the function W^G to a function $W^{G,s}$ such that $\|W^{G,s}\|_1 = 1$. More precisely, $\mathcal{W}^{G,s} := (W^{G,s}, \mathbb{R}_+)$, where

$$W^{G,s}(x_1, x_2) := \begin{cases} W^G\left(\|W^G\|_1^{1/2} x_1, \|W^G\|_1^{1/2} x_2\right) & \text{if } 0 \le x_1, x_2 \le \|W^G\|_1^{-1/2}, \text{ and} \\ 0 & \text{otherwise.} \end{cases}$$

4. Note that in the case of weighted graphs there are multiple natural definitions of what it means for a sequence of graphs to be sparse or dense. Instead of considering the L^1 norm as in our definition, one may for example consider the fraction of edges with non-zero weight, either weighted by the vertex weights or not. In the current paper we do not define what it means for a sequence of weighted graphs to be dense, since it is not immediate which definition is most natural, and since the focus of this paper is sparse graphs.

Note that in the case of a simple graph G, each node in $V(G)$ corresponds to an interval of length $1/|V(G)|$ in the canonical graphon $\mathcal{W}^G$, while it corresponds to an interval of length $1/\sqrt{2|E(G)|}$ in the stretched canonical graphon.

It will sometimes be convenient to define stretched canonical graphons for graphs with infinitely many vertices (but finitely[5] many edges). Our definition of W^G makes no sense for simple graphs with infinitely many vertices, because they cannot all be crammed into the unit interval. Instead, given a finite or countably infinite graph G with vertex weights $(\alpha_i)_{i\in V(G)}$ which do not necessarily sum to 1 (and may even sum to ∞), we define a graphon $\widetilde{\mathcal{W}}^G = (\widetilde{W}^G, \mathbb{R}_+)$ by setting $\widetilde{W}^G(x,y) = \beta_{ij}(G)$ if $(x,y) \in I_i \times I_j$, and $\widetilde{W}^G(x,y) = 0$ if there exist no such pair $(i,j) \in V(G)\times V(G)$, with I_i being the interval $[a_{i-1}, a_i)$ where we assume the vertices of G have been labeled $1, 2, \ldots$, and $a_i = \sum_{1\le k\le i} \alpha_k$ for $i = 0, 1, \ldots$. The stretched canonical graphon will then be defined as the graphon $\mathcal{W}^{G,s} := (W^{G,s}, \mathbb{R}_+)$ with

$$W^{G,s}(x_1,x_2) := \widetilde{W}^G\left(\|\widetilde{W}^G\|_1^{1/2} x_1, \|\widetilde{W}^G\|_1^{1/2} x_2\right),$$

a definition which can easily be seen to be equivalent to the previous one if G is a finite graph.

Alternatively, one can define a stretched graphon G^s as a graphon over $V(G)$ equipped with the measure $\widehat{\mu}_G$, where

$$\widehat{\mu}_G(A) = \frac{1}{\sqrt{\|\beta(G)\|_1}} \sum_{i\in A} \alpha_i$$

for any $A \subseteq V(G)$. In the case where $\sum_i \alpha_i < \infty$, this graphon is obtained from the graphon representing G by rescaling the probability measure

$$\mu_G(A) = \frac{1}{\sum_{i\in V(G)} \alpha_i} \sum_{i\in A} \alpha_i$$

to the measure $\widehat{\mu}_G$, while the function $\beta(G)\colon V(G)\times V(G) \to \mathbb{R}$ with $(i,j) \mapsto \beta_{ij}(G)$ is left untouched.

Note that any graphon with underlying measure space $\mathbb{R}_+$ can be "stretched" in the same way as W^G; in other words, given any graphon $\mathcal{W} = (W, \mathbb{R}_+)$ we may define a graphon $(W^\phi, \mathbb{R}_+)$, where $\phi\colon \mathbb{R}_+ \to \mathbb{R}_+$ is defined to be the linear map such that $\|W^\phi\|_1 = 1$, except when $\|W\|_1 = 0$, in which case we define the stretched graphon to be 0. But for graphons over general measure spaces, this rescaling is ill-defined. Instead, we consider a different, but related, notion of rescaling, by rescaling the measure of the underlying space, a notion which is the direct generalization of our definition of the stretched graphon G^s.

Definition 11 *(i) For two graphons $\mathcal{W}_i = (W_i, \mathscr{S}_i)$ with $\mathscr{S}_i = (S_i, \mathcal{S}_i, \mu_i)$ for $i = 1, 2$, define the* stretched cut metric $\delta^s_\square$ *by*

$$\delta^s_\square(\mathcal{W}_1, \mathcal{W}_2) := \delta_\square(\widehat{\mathcal{W}}_1, \widehat{\mathcal{W}}_2),$$

where $\widehat{\mathcal{W}}_i := (W_i, \widehat{\mathscr{S}_i})$ with $\widehat{\mathscr{S}_i} := (S_i, \mathcal{S}_i, \widehat{\mu}_i)$ and $\widehat{\mu}_i := \|W_i\|_1^{-1/2}\mu_i$. (In the particular case where $\|W_i\|_1 = 0$, we define $\widehat{\mathcal{W}}_i := (0, \mathscr{S}_i)$.) Identifying G with the graphon $\widetilde{\mathcal{W}}^G$ introduced above, this also defines the stretched distance between two graphs, or a graph and a graphon.

(ii) A sequence of graphs $(G_n)_{n\in\mathbb{N}}$ or graphons $(\mathcal{W}_n)_{n\in\mathbb{N}}$ is called convergent in the stretched cut metric *if they form a Cauchy sequence for this metric; they are called* convergent to a graphon $\mathcal{W}$ for the stretched cut metric *if $\delta^s_\square(G_n, \mathcal{W}) \to 0$ or $\delta^s_\square(\mathcal{W}_n, \mathcal{W}) \to 0$, respectively.*

5. More generally, in the setting of weighted graphs, we can allow for infinitely many edges as long as $\|\beta(G)\|_1 < \infty$.

Note that for the case of graphons over $\mathbb{R}_+$, the above notion of convergence is equivalent to the one involving the stretched graphons $\mathcal{W}_i^s = (W_i^s, \mathbb{R}_+)$ of $\mathcal{W}_i$ defined by

$$W_i^s(x_1,x_2) := W_i\left(\|W_i\|_1^{1/2} x_1, \|W_i\|_1^{1/2} x_2\right).$$

To see this, just note that by the obvious coupling between λ and $\widehat{\mu}_i$, where in this case $\widehat{\mu}_i$ is a constant multiple of Lebesgue measure, we have $\delta_\square(\mathcal{W}_i^s, \widehat{\mathcal{W}}_i) = 0$, and hence $\delta^s_\square(\mathcal{W}_1, \mathcal{W}_2) = \delta_\square(\mathcal{W}_1^s, \mathcal{W}_2^s)$. As a consequence, we have in particular that $\delta^s_\square(G, G') = \delta_\square(G^s, (G')^s) = \delta_\square(\mathcal{W}^{G,s}, \mathcal{W}^{G',s})$ for any two graphs G and G'. Note also that the stretched cut metric does not distinguish two graphs obtained from each other by deleting isolated vertices, in the sense that

$$\delta^s_\square(G, G') = 0 \tag{3}$$

whenever G is obtained from G' by removing a set of vertices that have degree 0 in G'.

The following basic example illustrates the difference between the notions of convergence in the classical theory of graphons, the approach for sparse graphs taken by Bollobás and Riordan (2009) and Borgs, Chayes, Cohn, and Zhao (2014a), and the approach of the current paper. Proposition 20 below makes this comparison more general.

Example 12 *Let $\alpha \in (0,1)$. For any $n \in \mathbb{N}$ let G_n be an Erdős-Rényi graph on n vertices with parameter $n^{\alpha-1}$; i.e., each two vertices of the graph are connected independently with probability $n^{\alpha-1}$. Let $\widetilde{G}_n$ be a simple graph on n vertices, such that $\lfloor n^{(1+\alpha)/2}\rfloor$ vertices form a complete subgraph, and $n - \lfloor n^{(1+\alpha)/2}\rfloor$ vertices are isolated. Both graph sequences are sparse, and hence their canonical graphons converge to the trivial graphon for which $W \equiv 0$, i.e., $\delta_\square(\mathcal{W}^{G_n}, 0), \delta_\square(\mathcal{W}^{\widetilde{G}_n}, 0) \to 0$, where we let 0 denote the mentioned trivial graphon. The sequence $(G_n)_{n\in\mathbb{N}}$ converges to $\mathcal{W}_1 := (\mathbf{1}_{[0,1]^2}, [0,1])$ with the notion of convergence introduced by Bollobás and Riordan (2009) and Borgs, Chayes, Cohn, and Zhao (2014a), but does not converge for $\delta^s_\square$. The sequence $(\widetilde{G}_n)_{n\in\mathbb{N}}$ converges to $\mathcal{W}_1$ for the stretched cut metric, i.e., $\delta^s_\square(\widetilde{G}_n, \mathcal{W}_1) = \delta_\square(\mathcal{W}^{\widetilde{G}_n,s}, \mathcal{W}_1) \to 0$, but it does not converge with the notion of convergence studied by Bollobás and Riordan (2009) and Borgs, Chayes, Cohn, and Zhao (2014a).*

The sequence $(\widetilde{G}_n)_{n\in\mathbb{N}}$ defined above illustrates one of our motivations to introduce the stretched cut metric. One might argue that this sequence of graphs should converge to the same limit as a sequence of complete graphs; however, earlier theories for graph convergence are too sensitive to isolated vertices or vertices with very low degree to accommodate this.

The space of all $[0,1]$-valued graphons over $[0,1]$ is compact under the cut metric (Lovász and Szegedy, 2007). This implies that every sequence of simple graphs is subsequentially

convergent to some graphon under $\delta_\square$, when we identify a graph G with its canonical graphon $\mathcal{W}^G$. Our generalized definition of a graphon, along with the introduction of the stretched canonical graphon $\mathcal{W}^{G,s}$ and the stretched cut metric $\delta^s_\square$, raises the question of whether a similar result holds in this setting. We will see in Theorem 15 and Corollary 17 below that the answer is yes, provided we restrict ourselves to uniformly bounded graphons and impose a suitable regularity condition; see Definition 13. The sequence $(G_n)_{n\in\mathbb{N}}$ in Example 12 illustrates that we may not have subsequential convergence when this regularity condition is not satisfied.

Definition 13 *Let $\widetilde{\mathscr{W}}$ be a set of uniformly bounded graphons. We say that $\widetilde{\mathscr{W}}$ has* uniformly regular tails *if for every $\varepsilon > 0$ we can find an $M > 0$ such that for every $\mathcal{W} = (W, \mathscr{S}) \in \widetilde{\mathscr{W}}$ with $\mathscr{S} = (S, \mathcal{S}, \mu)$, there exists $U \in \mathcal{S}$ such that $\|W - W\mathbf{1}_{U\times U}\|_1 < \varepsilon$ and $\mu(U) \le M$. A set $\mathcal{G}$ of graphs has* uniformly regular tails *if $\|\beta(G)\|_1 < \infty$ for all $G \in \mathcal{G}$ and the corresponding set of stretched canonical graphons $\{\mathcal{W}^{G,s} : G \in \mathcal{G}\}$ has uniformly regular tails.*

Remark 14 *It is immediate from the definition that a set of simple graphs $\mathcal{G}$ has uniformly regular tails if and only if for each $\varepsilon > 0$ we can find $M > 0$ such that the following holds. For all $G \in \mathcal{G}$, assuming the vertices of G are labeled by degree (from largest to smallest) with ties resolved in an arbitrary way,*

$$\sum_{i\le\lceil M\sqrt{|E(G)|}\rceil} \deg(i; G) \le \varepsilon|E(G)|.$$

In Lemma 59 in Appendix F we will prove that for a set of graphs with uniformly regular tails we may assume the sets U in the above definition correspond to sets of vertices. Note that if a collection $\widetilde{\mathscr{W}}$ of graphons has uniformly regular tails, then every collection of graphons which can be derived from $\widetilde{\mathscr{W}}$ by adding a finite number of the graphons to $\widetilde{\mathscr{W}}$ will still have uniformly regular tails. In other words, if $\widetilde{\mathscr{W}}, M, \varepsilon$ are such that the conditions of Definition 13 are satisfied for all but finitely many graphons in $\widetilde{\mathscr{W}}$, then the collection $\widetilde{\mathscr{W}}$ has uniformly regular tails.

The following theorem shows that a necessary and sufficient condition for subsequential convergence is the existence of a subsequence with uniformly regular tails.

Theorem 15 *Every sequence $(\mathcal{W}_n)_{n\in\mathbb{N}}$ of uniformly bounded graphons with uniformly regular tails converges subsequentially to some graphon $\mathcal{W}$ for the cut metric $\delta_\square$. Moreover, if $\mathcal{W}_n$ is non-negative then every $\delta_\square$-Cauchy sequence of uniformly bounded, non-negative graphons has uniformly regular tails.*

The proof of the theorem will be given in Appendix E. The most challenging part of the proof is to show that uniform regularity of tails implies subsequential convergence. We prove in Lemma 58 that the property of having uniformly regular tails is invariant under certain operations, which allows us to prove subsequential convergence similarly as in the setting of dense graphs, i.e., by approximating the graphons by step functions and using a martingale convergence theorem.

Two immediate corollaries of Theorem 15 are the following results.

Corollary 16 *The set of all $[0,1]$-valued graphons is complete for the cut metric $\delta_\square$, and hence also for $\delta^s_\square$.*

Corollary 17 *Let $(G_n)_{n\in\mathbb{N}}$ be a sequence of finite graphs with non-negative, uniformly bounded edge weights such that $|E(G_n)| < \infty$ for each $n \in \mathbb{N}$. Then the following hold:*

(i) If $(G_n)_{n\in\mathbb{N}}$ has uniformly regular tails, then $(G_n)_{n\in\mathbb{N}}$ has a subsequence that converges to some graphon $\mathcal{W}$ in the stretched cut metric.

(ii) If $(G_n)_{n\in\mathbb{N}}$ is a $\delta^s_\square$-Cauchy sequence, then it has uniformly regular tails.

(iii) If $(G_n)_{n\in\mathbb{N}}$ is a $\delta^s_\square$-Cauchy sequence, then it converges to some graphon $\mathcal{W}$ in the stretched cut metric.

The former of the above corollaries makes two assumptions: (i) the graphons are uniformly bounded, and (ii) the graphons are non-negative. We remark that both of these conditions are necessary.

Remark 18 *The set of all $\mathbb{R}_+$-valued graphons is not complete for the cut metric $\delta_\square$; see for example the argument of Borgs, Chayes, Cohn, and Zhao (2014a, Proposition 2.12(b)) for a counterexample. The set of all $[-1,1]$-valued graphons is also not complete, as the following example suggested to us by Svante Janson illustrates. For each $n \in \mathbb{N}$ let $\mathcal{V}_n = (V_n, \mathbb{R}_+)$ be a $\{-1,1\}$-valued graphon supported in $[n-1,n]^2$ satisfying $\|V_n\|_\square < 2^{-n}$ and $\|V_n\|_1 = 1$, by defining $\mathcal{V}_n$ to be an appropriately rescaled version of a graphon for a sufficiently large Erdős-Rényi random graph with edge density $1/2$. Define $\mathcal{W}_n = (W_n, \mathbb{R}_+)$ by $W_n := \sum_{k=1}^n V_k$, and assume there is a graphon $\mathcal{W} = (W, \mathbb{R}_+)$ such that $\lim_{n\to\infty} \delta_\square(\mathcal{W}, \mathcal{W}_n) = 0$. Then we can find a sequence of measure-preserving transformations $(\phi_n)_{n\in\mathbb{N}}$ with $\phi_n\colon \mathbb{R}_+ \to \mathbb{R}_+$, such that $\lim_{n\to\infty} \|W^{\phi_n} - W_n\|_\square = 0$. This implies that $\lim_{n\to\infty} \|W^{\phi_n}\mathbf{1}_{[k-1,k]^2} - V_k\|_\square = 0$ for each $k \in \mathbb{N}$. Since V_k is a graphon associated with an Erdős-Rényi random graph it is a step graphon. For any intervals $I, J \subseteq \mathbb{R}_+$ such that $V_k|_{I\times J} = 1$ or $V_k|_{I\times J} = -1$ we have $\lim_{n\to\infty} \|(W^{\phi_n}\mathbf{1}_{[k-1,k]^2} - V_k)\mathbf{1}_{I\times J}\|_\square = 0$, so since W takes values in $[-1,1]$ we have $\lim_{n\to\infty} \|W^{\phi_n}\|_{L^1(I\times J)} = \|V_k\|_{L^1(I\times J)}$. Since $\|V_k\|_{L^1([k-1,k]^2)} = 1$ this implies that $\lim_{n\to\infty} \|W^{\phi_n}\|_{L^1([k-1,k]^2)} = 1$. We have obtained a contradiction to the assumption that $\mathcal{W}$ is a graphon, since for each $n \in \mathbb{N}$ we have $\|W\|_1 \ge \sum_{k=1}^\infty \|W^{\phi_n}\|_{L^1([k-1,k]^2)}$.*

Remark 19 *For comparison, Lovász and Szegedy (2007, Theorem 5.1) proved that $[0,1]$-valued graphons on the probability space $[0,1]$ (and hence any probability space) form a compact metric space under $\delta_\square$. Compactness fails in our setting, because convergence requires uniformly regular tails, but completeness still holds.*

Our next result compares the theory of graph convergence developed by Borgs, Chayes, Cohn, and Zhao (2014a,b) with the theory developed in this paper. First we will define the *rescaled cut metric* $\delta^r_\square$. A sequence of graphs is convergent in the sense considered by Borgs, Chayes, Cohn, and Zhao (2014a,b) iff it converges for this metric. For two graphons $\mathcal{W}_1 = (W_1, \mathscr{S}_1)$ and $\mathcal{W}_2 = (W_2, \mathscr{S}_2)$, where $\mathscr{S}_1$ and $\mathscr{S}_2$ are measure spaces of the same total measure, define $\widetilde{W}_1 := \|W_1\|_1^{-1} W_1$, $\widetilde{W}_2 := \|W_2\|_1^{-1} W_2$, and

$$\delta^r_\square(\mathcal{W}_1, \mathcal{W}_2) := \inf_\mu \|\widetilde{W}_1^{\pi_1} - \widetilde{W}_2^{\pi_2}\|_{\square, S_1\times S_2, \mu},$$

where we take the infimum over all measures μ on $S_1 \times S_2$ with marginals μ_1 and μ_2, respectively. For any graphs G and G' we let $\mathcal{W}^G$ and $\mathcal{W}^{G'}$, respectively, denote the canonical graphons associated with G and G', and for any graphon $\mathcal{W}$ we define

$$\delta^r_\square(G,\mathcal{W}) := \delta^r_\square(\mathcal{W}^G,\mathcal{W}), \qquad \delta^r_\square(G,G') := \delta^r_\square(\mathcal{W}^G,\mathcal{W}^{G'}).$$

For the notion of convergence studied by Borgs, Chayes, Cohn, and Zhao (2014a), *uniform upper regularity* plays a similar role to that of regularity of tails in the current paper. More precisely, subsequential uniform upper regularity for a sequence of graphs or graphons defined over a probability space is equivalent to subsequential convergence to a graphon for the metric $\delta^r_\square$ (Borgs, Chayes, Cohn, and Zhao, 2014a, Appendix C). The primary conceptual difference is that the analogue of Corollary 16 does not hold in the theory studied by Borgs, Chayes, Cohn, and Zhao (2014a).

We will now define what it means for a sequence of graphs or graphons to be uniformly upper regular. A *partition* of a measurable space $(S,\mathcal{S})$ is a finite collection $\mathcal{P}$ of disjoint elements of $\mathcal{S}$ with union S. For any graphon $\mathcal{W} = (W,\mathscr{S})$ with $\mathscr{S} = (S,\mathcal{S},\mu)$ and a partition $\mathcal{P}$ of $(S,\mathcal{S})$ into parts of nonzero measure, define $\mathcal{W}_\mathcal{P}$ by averaging W over the partitions. More precisely, if $\mathcal{P} = \{I_i : i = 1,\dots,m\}$ for some $m \in \mathbb{N}$, define $\mathcal{W}_\mathcal{P} := ((W)_\mathcal{P},\mathscr{S})$, where

$$(W_\mathcal{P})(x_1,x_2) := \frac{1}{\mu(I_i)\mu(I_j)} \int_{I_i\times I_j} W(x_1',x_2')\,dx_1'\,dx_2' \qquad \text{if } (x_1,x_2) \in I_i \times I_j.$$

A sequence $(\mathcal{W}_n)_{n\in\mathbb{N}}$ of graphons $\mathcal{W}_n = (W_n,\mathscr{S}_n)$ over probability spaces $\mathscr{S}_n = (S_n,\mathcal{S}_n,\mu_n)$ is *uniformly upper regular* if there exists a function $K\colon (0,\infty) \to (0,\infty)$ and a sequence $\{\eta_n\}_{n\in\mathbb{N}}$ of positive real numbers converging to zero, such that for every $\varepsilon > 0$, $n \in \mathbb{N}$, and partition $\mathcal{P}$ of S_n such that the μ_n-measure of each part is at least η_n, we have

$$\|(W_n)_\mathcal{P}\mathbf{1}_{|(W_n)_\mathcal{P}|\ge K(\varepsilon)}\|_1 \le \varepsilon.$$

For any graph G define the *rescaled canonical graphon* $\mathcal{W}^{G,r} = (W^{G,r},[0,1])$ of G to be equal to the canonical graphon $\mathcal{W}^G$ of G, except that we rescale the graphon such that $\|W^{G,r}\|_1 = 1$. More precisely, we define $\mathcal{W}^{G,r} := (W^{G,r},[0,1])$ with $W^{G,r} := \|W^G\|_1^{-1}W^G$. We say that a sequence of graphs $(G_n)_{n\in\mathbb{N}}$ is uniformly upper regular if $(\mathcal{W}^{G_n,r})_{n\in\mathbb{N}}$ is uniformly upper regular, where we only consider partitions $\mathcal{P}$ corresponding to partitions of $V(G_n)$, and we require every vertex of G_n to have weight less than a fraction η_n of the total weight of $V(G_n)$.

The following proposition, which will be proved in Appendix F, illustrates the very different nature of the sparse graphs studied by Borgs, Chayes, Cohn, and Zhao (2014a,b) and the graphs studied in this paper.

Proposition 20 *Let $(G_n)_{n\in\mathbb{N}}$ be a sequence of simple graphs satisfying $|V(G_n)| < \infty$ for each $n \in \mathbb{N}$.*

(i) If $(G_n)_{n\in\mathbb{N}}$ is sparse it cannot both be uniformly upper regular and have uniformly regular tails; hence it cannot converge for both metrics $\delta^s_\square$ and $\delta^r_\square$ if it is sparse.

(ii) Assume $(G_n)_{n\in\mathbb{N}}$ is dense and has convergent edge density. Then $(G_n)_{n\in\mathbb{N}}$ is a Cauchy sequence for $\delta^s_\square$ iff it is a Cauchy sequence for $\delta^r_\square$. If we do not assume convergence of the edge density, being a Cauchy sequence for $\delta^r_\square$ (resp. $\delta^s_\square$) does not imply being a Cauchy sequence for $\delta^s_\square$ (resp. $\delta^r_\square$).

Many natural properties of graphons are continuous under the cut metric, for example certain properties related to the degrees of the vertices. For graphons defined on probability spaces it was shown by Borgs, Chayes, Cohn, and Ganguly (2015, Section 2.6) that the appropriately normalized degree distribution is continuous under the cut metric. A similar result holds in our setting, but the normalization is slightly different: instead of the proportion of vertices whose degrees are at least λ times the average degree, we will consider a normalization in terms of the square root of the number of edges. Given a graph G and vertex $v \in V(G)$, let $d_G(v)$ denote the degree of v, and given a graphon $\mathcal{W} = (W,(S,\mathcal{S},\mu))$, define the analogous function $D_W\colon S \to \mathbb{R}$ by

$$D_W(x) = \int_S W(x,y)\,d\mu(y).$$

The following proposition is an immediate consequence of Lemma 45 in Appendix A, which compares the functions D_{W_1} and D_{W_2} for graphons that are close in the cut metric.

Proposition 21 *Let $\mathcal{W}_n = (W_n,(S_n,\mathcal{S}_n,\mu_n))$ be a sequence of graphons that converge to a graphon $\mathcal{W} = (W,(S,\mathcal{S},\mu))$ in the cut metric $\delta_\square$, and let $\lambda > 0$ be a point where the function $\lambda \mapsto \mu(\{D_W > \lambda\})$ is continuous. Then $\mu_n(\{D_{W_n} > \lambda\}) \to \mu(\{D_W > \lambda\})$. In particular,*

$$\frac{1}{\sqrt{2|E(G_n)|}}\left|\left\{v \in V(G_n)\colon d_{G_n}(v) > \lambda\sqrt{2|E(G_n)|}\right\}\right| \to \mu(\{D_{W^s} > \lambda\})$$

whenever G_n is a sequence of finite simple graphs that converge to a graphon $\mathcal{W}^s$ in the stretched cut metric and $\mu(\{D_{W^s} > \lambda\})$ is continuous at λ.

Our final result in this section, which will be proved in Appendix F, is that graphs which converge for the stretched cut metric have unbounded average degree under certain assumptions, a result which also holds for graphs that converge under the rescaled cut metric (Borgs, Chayes, Cohn, and Zhao, 2014a, Proposition C.15).

Proposition 22 *Let $(G_n)_{n\in\mathbb{N}}$ be a sequence of finite simple graphs such that the number of isolated vertices in G_n is $o(|E(G_n)|)$ and such that $\lim_{n\to\infty}|E(G_n)| = \infty$. If there is a graphon $\mathcal{W}$ such that $\lim_{n\to\infty}\delta^s_\square(G_n,\mathcal{W}) = 0$, then $(G_n)_{n\in\mathbb{N}}$ has unbounded average degree.*

The proof of the proposition proceeds by showing that graphs with bounded average degree and a divergent number of edges cannot have uniformly regular tails.

2.4 Random Graph Models

In this section we will present two random graph models associated with a given $[0,1]$-valued graphon $\mathcal{W} = (W,\mathscr{S})$ with $\mathscr{S} = (S,\mathcal{S},\mu)$.

Before defining these models, we introduce some notation. In particular, we will introduce the notion of a graph process, defined as a stochastic process taking values in the set of labeled graphs with finitely many edges and countably many vertices, equipped with a suitable σ-algebra. Explicitly, consider a family of graphs $\mathcal{G} = (G_t)_{t\ge 0}$, where the vertices have labels in $\mathbb{N}$. Let $\mathbb{G}$ denote the set of simple graphs with finitely many edges and countably many vertices, such that the vertices have distinct labels in $\mathbb{N}$. Observe that a

graph in this space can be identified with an element of $\{0,1\}^{\mathbb{N}\cup\binom{\mathbb{N}}{2}}$. We equip $\{0,1\}^{\mathbb{N}\cup\binom{\mathbb{N}}{2}}$ with the product topology and $\mathbb{G}$ with the subspace topology $\mathbb{T}$. Recall that a stochastic process is càdlàg if it is right-continuous with a left limit at every point. Observe that the topological space $(\mathbb{G},\mathbb{T})$ is Hausdorff, which implies that a convergent sequence of graphs has a unique limit. The σ-algebra on $\mathbb{G}$ is the Borel σ-algebra induced by $\mathbb{T}$.

Definition 23 *A* graph process *is a càdlàg stochastic process $\mathcal{G} = (G_t)_{t\geq 0}$ taking values in the space of graphs $\mathbb{G}$ equipped with the topology $\mathbb{T}$ defined above. The process is called* projective *if for all $s < t$, G_s is an induced subgraph of G_t.*

We now define the graphon process already described informally in the introduction. Sample a Poisson random measure $\mathcal{V}$ on $\mathbb{R}_+ \times S$ with intensity given by $\lambda \times \mu$ (see the book of Çınlar, 2011, Chapter VI, Theorem 2.15), and identify $\mathcal{V}$ with the collection of points (t,x) at which $\mathcal{V}$ has a point mass.[6] Let $\widetilde{G}$ be a graph with vertex set $\mathcal{V}$, such that for each pair of vertices $v_1 = (t_1, x_1)$ and $v_2 = (t_2, x_2)$ with $v_1 \neq v_2$, there is an edge between v_1 and v_2 with probability $W(x_1, x_2)$, independently for any two v_1, v_2. Note that $\widetilde{G}$ is a graph with countably infinitely many vertices, and that the set of edges is also countably infinite except if W is equal to 0 almost everywhere. For each $t \geq 0$ let $\widetilde{G}_t$ be the induced subgraph of $\widetilde{G}$ consisting only of the vertices (t', x) for which $t' \leq t$. Finally define G_t to be the induced subgraph of $\widetilde{G}_t$ consisting only of the vertices having degree at least one. While $\widetilde{G}_t$ is a graph on infinitely many vertices if $\mu(S) = \infty$, it has finitely many edges almost surely, and thus G_t is a graph with finitely many vertices. We view the graphs G_t and $\widetilde{G}_t$ as elements of $\mathbb{G}$ by enumerating the points of $\mathcal{V}$ in an arbitrary but fixed way.

When $\mu(S) < \infty$ the set of graphs $\{\widetilde{G}_t : t \geq 0\}$ considered above is identical in law to a sequence of $\mathcal{W}$-random graphs as defined by Lovász and Szegedy (2006) for graphons over $[0,1]$ and, for example, by Bollobás, Janson, and Riordan (2007) for graphons over general probability spaces. More precisely, defining a stopping time t_n as the first time when $|V(\widetilde{G}_t)| = n$ and relabeling the vertices in $V(\widetilde{G}_{t_n})$ by labels in $[n]$, we have that the sequence $\{\widetilde{G}_{t_n} : n \in \mathbb{N}\}$ has the same distribution as the sequence of random graphs generated from $\mathcal{W}$, except for the fact that μ should be replaced by the probability measure $\widetilde{\mu} = \frac{1}{\mu(S)}\mu$, a fact which follows immediately from the observation that a Poisson process with intensity $t\mu$ conditioned on having n points is just a distribution of n points chosen i.i.d. from the distribution $\widetilde{\mu}$. In the case when $\mu(S) = \infty$ it is primarily the graphs G_t (rather than $\widetilde{G}_t$) which are of interest for applications, since the graphs $\widetilde{G}_t$ have infinitely many (isolated) vertices. But from a mathematical point of view, both turn out to be useful.

Definition 24 *Two graph processes $(G_t^1)_{t\geq 0}$ and $(G_t^2)_{t\geq 0}$ are said to be* equal up to relabeling of the vertices *if there is a bijection $\phi\colon \bigcup_{t\geq 0} V(G_t^1) \to \bigcup_{t\geq 0} V(G_t^2)$ such that $\phi(G_t^1) = G_t^2$ for all $t \geq 0$, where $\phi(G_t^1)$ is the graph whose vertex and edge sets are $\{\phi(i)\}_{i\in V(G_t)}$ and $\{\phi(i)\phi(j)\}_{ij\in E(G_t)}$, respectively. Two graph processes $(G_t^1)_{t\geq 0}$ and $(G_t^2)_{t\geq 0}$ are said to be* equal in law up to relabeling of the vertices *if they can be coupled in such a way that a.s., the two families are equal up to relabeling of the vertices.*

6. We see that this collection of points exists by observing that for any measurable set $A \subset \mathbb{R}_+ \times S$ of finite measure, we may sample $\{(t,x) \in \mathcal{V} \cap A\}$ by first sampling the total number of points $N_A \in \mathbb{N} \cup \{0\}$ in the set (which is a Poisson random variable with parameter $\mu(A)$), and then sampling N_A points independently at random from A using the measure $\mu|_A$ renormalized to be a probability measure. Note that our Poisson random measure is not necessarily a random counting measure as defined for example by Çınlar (2011), since in general, not all singletons (t,x) are measurable, unless we assume that the singletons $\{x\}$ in S are measurable.

Note that in order for the notion of "equal in law up to relabeling of the vertices" to be well defined, one needs to show that the event that two graph processes $(G_t)_{t\geq 0}$ and $(\widetilde{G}_t)_{t\geq 0}$ are equal up to relabeling is measurable. The proof of this fact is somewhat technical and will be given in Appendix C.

Definition 25 *Let $\mathcal{W} = (W, \mathscr{S})$ be a $[0,1]$-valued graphon. Define $\widetilde{\mathcal{G}}(\mathcal{W}) = (\widetilde{G}_t(\mathcal{W}))_{t\geq 0}$ (resp. $\mathcal{G}(\mathcal{W}) = (G_t(\mathcal{W}))_{t\geq 0}$) to be a random family of graphs with the same law as the graphs $(\widetilde{G}_t)_{t\geq 0}$ (resp. $(G_t)_{t\geq 0}$) defined above.*

(i) A random family of simple graphs is called a graphon process without isolated vertices *generated by $\mathcal{W}$ if it has the same law as $\mathcal{G}(\mathcal{W})$ up to relabeling of the vertices, and it is called a* graphon process with isolated vertices *generated by $\mathcal{W}$ if it has the same law as $\widetilde{\mathcal{G}}(\mathcal{W})$ up to relabeling of the vertices.*

(ii) A random family $\widetilde{\mathcal{G}} = (\widetilde{G}_t)_{t\geq 0}$ of simple graphs is called a graphon process *if there exists a graphon $\mathcal{W}$ such that after removal of all isolated vertices, $\widetilde{\mathcal{G}}$ has the same law as $\mathcal{G}(\mathcal{W})$ up to relabeling of the vertices.*

If $\mathcal{G} = (G_t)_{t\geq 0}$ is a graphon process, then we refer to G_t as the graphon process at time t.

Given a graphon $\mathcal{W} = (W, \mathscr{S})$ one can define multiple other natural random graph models; see below. However, the graph models of Definition 25 have one property which sets them apart from these models: exchangeability. To formulate this, we first recall that a random measure ξ in the first quadrant $\mathbb{R}_+^2$ is jointly exchangeable iff for every $h > 0$, permutation σ of $\mathbb{N}$, and $i, j \in \mathbb{N}$,

$$\xi(I_i \times I_j) \stackrel{d}{=} \xi(I_{\sigma(i)} \times I_{\sigma(j)}), \qquad \text{where } I_k := [h(k-1), hk].$$

Here $\stackrel{d}{=}$ means equality in distribution, and, as usual, a random measure on $\mathbb{R}_+^2$ is a measure drawn from some probability distribution over the set of all Borel measures on $\mathbb{R}_+^2$, equipped with the minimal σ-algebra for which the functions $\mu \mapsto \mu(B)$ are measurable for all Borel sets B.

To relate this notion of exchangeability to a property of a graphon process, we will assign a random measure $\xi(\mathcal{G})$ to an arbitrary projective graph process $\mathcal{G} = (G_t)_{t\geq 0}$. Defining the birth time t_v of a vertex $v \in V(\mathcal{G})$ as the infimum over all times t such that $v \in V(G_t)$, we define a random measure $\xi = \xi(\mathcal{G})$ on $\mathbb{R}_+^2$ by

$$\xi(\mathcal{G}) := \sum_{(u,v)\in E(\mathcal{G})} \delta_{(t_u, t_v)}, \tag{4}$$

where each edge $(u,v) = (v,u)$ is counted twice so that the measure is symmetric. If $\mathcal{G}$ is a graphon process with isolated vertices, i.e., $\mathcal{G} = \widetilde{\mathcal{G}}(\mathcal{W})$ for some graphon $\mathcal{W}$, it is easy to see

that at any given time, at most one vertex is born, and that at time $t = 0$, G_t is empty. In other words,

$$V(G_0) = \emptyset \quad \text{and} \quad |V(G_t)\backslash V(G_{t^-})| \leq 1 \text{ for all } t > 0. \tag{5}$$

It is not that hard to check that the measure ξ is jointly exchangeable if $\mathcal{G}$ is a graphon process with isolated vertices[7] generated from some graphon $\mathcal{W}$. But it turns out that the converse is true as well, provided the sequence has uniformly regular tails. The following theorem will be proved in Appendix G, and as with Caron and Fox (2014) we will rely on the Kallenberg theorem for jointly exchangeable measures (Kallenberg, 2005, Theorem 9.24) for this description. Veitch and Roy (2015) have independently formulated and proved a similar theorem, except that their version does not include integrability of the graphon or uniform tail regularity of the sequence of random graphs.

Before stating our theorem, we note that given a locally finite symmetric measure ξ that is a countable sum of off-diagonal, distinct atoms of weight one in the interior of $\mathbb{R}^2_+$, we can always find a projective family of simple graphs G_t obeying the condition (5) and the other assumptions we make above, and that up to vertices which stay isolated for all times, this family of graphs is uniquely determined by ξ up to relabeling of the vertices. Any projective family of countable simple graphs $\mathcal{G}$ with finitely many edges at any given time can be transformed into one obeying the condition (5) (by letting the vertices appear in the graph G_t exactly at the time they were born and merging vertices born at the same time, and then labeling vertices by their birth time), provided the measure $\xi(\mathcal{G})$ has only point masses of weight one, and has no points on the diagonal and the coordinate axes.

Theorem 26 *Let $\widetilde{\mathcal{G}} = (\widetilde{G}_t)_{t\geq 0}$ be a projective family of random simple graphs which satisfy (5), and define $\xi = \xi(\widetilde{\mathcal{G}})$ by (4). Then the following two conditions are equivalent:*

(i) The measure ξ is a jointly exchangeable random measure and $(\widetilde{G}_t)_{t\geq 0}$ has uniformly regular tails.

(ii) There is a $\mathbb{R}_+$-valued random variable α such that $\mathcal{W}_\alpha = (W_\alpha, \mathbb{R}_+)$ is a $[0,1]$-valued graphon almost surely, and such that conditioned on α, $(\widetilde{G}_t)_{t\geq 0}$ (modulo vertices that are isolated for all $t \geq 0$) has the law of $\widetilde{\mathcal{G}}(\mathcal{W}_\alpha)$ up to relabeling of the vertices.

Recall that we called two graphons equivalent if their distance in the cut metric $\delta_\square$ is zero. The following theorem shows that this notion of equivalence is the same as equivalence of the graphon process generated from two graphons, in the sense that the resulting random graphs have the same distribution. Note that in (ii) we only identify the law of $\widetilde{G}_t$ up to vertices that are isolated for all times; it is clear that if we extend the underlying measure space $\mathscr{S}$ and extend $\mathcal{W}$ trivially to this measure space, the resulting graphon is equivalent to $\mathcal{W}$ and the law of the graphs G_t remains unchanged, while the law of $\widetilde{G}_t$ might change due to additional isolated vertices.

7. This is one of the instances in which the family $\widetilde{\mathcal{G}}(\mathcal{W})$ is more useful that the family $\mathcal{G}(\mathcal{W})$: the latter only contains information about when a vertex first appeared in an edge in $\widetilde{\mathcal{G}}(\mathcal{W})$, and not information about when it was born.

Theorem 27 *For $i = 1, 2$ let $\mathcal{W}_i = (W_i, \mathscr{S}_i)$ be $[0,1]$-valued graphons, and let $(\widetilde{G}^i_t)_{t\geq 0}$ and $(G^i_t)_{t\geq 0}$ be the graphon processes generated from $\mathcal{W}_i$ with and without, respectively, isolated vertices. Then the following statements are equivalent:*

(i) $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$.

(ii) After removing all vertices which are isolated for all times, $(\widetilde{G}^1_t)_{t\geq 0}$ and $(\widetilde{G}^2_t)_{t\geq 0}$ are equal in law up to relabeling of the vertices.

(iii) $(G^1_t)_{t\geq 0}$ and $(G^2_t)_{t\geq 0}$ are equal in law up to relabeling of the vertices.

The theorem will be proved in Appendix D. We show that (i) implies (ii) and (iii) by using Proposition 51, which says that the infimum in the definition of $\delta_\square$ is attained under certain assumptions on the underlying graphons. We show that (ii) or (iii) imply (i) by using Theorem 28(i).

As indicated before, in addition to the graphon processes defined above, there are several other natural random graph models generated from a graphon $\mathcal{W}$. Consider a sequence of probability measures $(\mu_n)_{n\in\mathbb{N}}$ on $(S, \mathcal{S})$, and construct a sequence of random graphs G_n as follows. Start with a single vertex $(1, x_1)$ with x_1 sampled from μ_1. In step n, sample x_n from μ_n, independently from all vertices and edges sampled so far, and for each $i = 1, \dots k$, add an edge between (i, x_i) and (n, x_n) with probability $W(x_i, x_n)$, again independently for each i (and independently of all vertices and edges chosen before). Alternatively, sample an infinite sequence of independent features $x_1, x_2, \dots$ distributed according to $\mu_1, \mu_2, \dots$, and let G be the graph on infinitely many vertices with vertex set identified with $\{(n, x_n) : n \in \mathbb{N}\}$, such that for any two $n_1, n_2 \in \mathbb{N}$ there is an edge between (n_1, x_{n_1}) and (n_2, x_{n_2}) independently with probability $W(x_{n_1}, x_{n_2})$. For each $n \in \mathbb{N}$ let G_n be the induced subgraph of G consisting only of the vertices (k, x_k) for which $k \leq n$.

It was proven by Borgs, Chayes, Lovász, Sós, and Vesztergombi (2008) that dense $\mathcal{W}$-random graphs generated from graphons on probability spaces converge to $\mathcal{W}$. The following theorem generalizes this to graphon processes, as well as for the alternative model defined in terms of a suitable sequence of measures μ_n.

Theorem 28 *Let $\mathcal{W} = (W, \mathscr{S})$ with $\mathscr{S} = (S, \mathcal{S}, \mu)$ be a $[0,1]$-valued graphon. Then the following hold:*

(i) Almost surely $\lim_{t\to\infty} \delta^s_\square(\mathcal{W}, \widetilde{G}_t(\mathcal{W})) = 0$ and $\lim_{t\to\infty} \delta^s_\square(\mathcal{W}, G_t(\mathcal{W})) = 0$.

(ii) Let $(G_n)_{n\in N}$ be the sequence of simple graphs generated from $\mathcal{W}$ with arrival probabilities $\mu_n := \mu(S_n)^{-1}\mu|_{S_n}$ as described above, where we assume $\bigcup_{n\in\mathbb{N}} S_n = S$, $S_n \subseteq S_{n+1}$, and $0 < \mu(S_n) < \infty$ for all $n \in \mathbb{N}$, and W is not equal to 0 almost everywhere. Then a.s.-$\lim_{n\to\infty} \delta^s_\square(\mathcal{W}, G_n) = 0$ if and only if $\sum_{n=1}^\infty \mu(S_n)^{-1} = \infty$.

We will prove the theorem in Appendix D. Part (i) of the theorem is proved by observing that for any set $A \subseteq S$ of finite measure, the induced subgraph of $\widetilde{G}_t$ consisting of the vertices with feature in A has the law of a graph generated from a graphon over a probability space. This implies that we can use convergence results for dense graphs to conclude the proof. In

our proof of part (ii) we first show that the condition on S_n is necessary for convergence, by showing that otherwise $E(G_n)$ is empty for all $n \in \mathbb{N}$ with positive probability. We show that the condition on S_n is sufficient by constructing a coupling of $(G_n)_{n\in\mathbb{N}}$ and a graphon process $(\widetilde{G}_t)_{t\geq 0}$.

2.5 Left Convergence

Left convergence is a notion of convergence where we consider subgraph counts of small test graphs. Existing literature defines left convergence both for dense graphs (Lovász and Szegedy, 2006) and for bounded degree graphs (Borgs, Chayes, Kahn, and Lovász, 2013), with a different renormalization factor to adjust for the difference in edge density. We will operate with a definition of subgraph density with an intermediary renormalization factor, to take into account that our graphon process satisfies $\omega(|V(G_t)|) = |E(G_t)| = O(|V(G_t)|^2)$. For dense graphs our definition of left convergence coincides with the standard definition in the theory of dense graphs.

For a simple graph F and a simple graph G define $\hom(F,G)$ to be the number of adjacency preserving maps $\phi\colon V(F) \to V(G)$, i.e., maps ϕ such that if $(v_1,v_2) \in E(F)$, then $(\phi(v_1),\phi(v_2)) \in E(G)$, and define $\mathrm{inj}(F,G)$ be the number of such maps that are injective.

Define the *rescaled homomorphism density* $h(F,G)$ and the *rescaled injective homomorphism density* $h_{\mathrm{inj}}(F,G)$ of F in G by

$$h(F,G) := \frac{\hom(F,G)}{(2|E(G)|)^{|V(F)|/2}} \quad \text{and} \quad h_{\mathrm{inj}}(F,G) := \frac{\mathrm{inj}(F,G)}{(2|E(G)|)^{|V(F)|/2}}.$$

For any $[0,1]$-valued graphon $\mathcal{W} = (W,\mathscr{S})$ we define the rescaled homomorphism density of F in $\mathcal{W}$ by

$$h(F,\mathcal{W}) := \|W\|_1^{-|V(F)|/2} \int_{S^{|V(F)|}} \prod_{(i,j)\in E(F)} W(x_i,x_j)\, dx_1 \dots dx_{|V(F)|}.$$

Note that in general, $h(F,\mathcal{W})$ need not be finite. Take, for example, $\mathcal{W} = (W,\mathbb{R}_+)$ to be a graphon of the form

$$W(x,y) = \begin{cases} 1 & \text{if } y \leq f(x), \text{ and} \\ 0 & \text{otherwise,} \end{cases}$$

where

$$f(x) = \begin{cases} x^{-1/2} & \text{if } 0 \leq x \leq 1, \text{ and} \\ x^{-2} & \text{if } x \geq 1. \end{cases}$$

Let $D_W(x) = \int_{\mathbb{R}_+} W(x,y)\, dy$. Then D_W is in $L^1(\mathbb{R}_+)$, but not in $L^k(\mathbb{R}_+)$ for any $k \geq 2$. Thus if F is a star with $k \geq 2$ leaves, then $h(F,\mathcal{W}) := \|W\|_1^{-(k+1)/2} \int_{\mathbb{R}_+} D_W^k(x)dx = \infty$. Proposition 30(ii) below, whose proof is based on Lemma 62 in Appendix H, gives one criterion which guarantees that $h(F,\mathcal{W}) < \infty$ for all simple connected graphs F.

Definition 29 *A sequence $(G_n)_{n\in\mathbb{N}}$ is left convergent if its edge density is converging, and if for every simple connected graph F with at least two vertices, the limit $\lim_{n\to\infty} h(F,G_n)$ exists and is finite. Left convergence is defined similarly for a continuous-time family of graphs $(G_t)_{t\geq 0}$.*

For dense graphs left convergence is equivalent to metric convergence (Borgs, Chayes, Lovász, Sós, and Vesztergombi, 2008). This equivalence does not hold for our graphs, but convergence of subgraph densities (possibly with an infinite limit) does hold for graphon processes.

Proposition 30 *(i) If $\mathcal{W} = (W,\mathscr{S})$ is a $[0,1]$-valued graphon and $(G_t)_{t>0}$ is a graphon process, then for every simple connected graph F with at least two vertices,*

$$\lim_{t\to\infty} h_{\mathrm{inj}}(F,G_t) = h(F,\mathcal{W}) \in [0,\infty]$$

almost surely.

(ii) In the setting of (i), if $D_W(x) := \int_S W(x,x')\, d\mu(x')$ is in L^p for all $p \in [1,\infty)$, then $h(F,\mathcal{W}) < \infty$ for every simple connected graph F with at least two vertices and

$$\lim_{t\to\infty} h(F,G_t) = \lim_{t\to\infty} h_{\mathrm{inj}}(F,G_t) = h(F,\mathcal{W})$$

almost surely, so in particular $(G_t)_{t>0}$ is left convergent.

(iii) Assume $(G_n)_{n\in\mathbb{N}}$ is a sequence of simple graphs with bounded degree such that

$$\lim_{n\to\infty} |V(G_n)| = \infty$$

and $E(G_n) \neq \emptyset$ for all sufficiently large n. Then $(G_n)_{n\in\mathbb{N}}$ is trivially left convergent, and $\lim_{n\to\infty} h(F,G_n) = 0$ for every connected F for which $|V(F)| \geq 3$.

(iv) Left convergence does not imply convergence for $\delta^{\mathrm{s}}_{\square}$, and convergence for $\delta^{\mathrm{s}}_{\square}$ does not imply left convergence.

The proposition will be proved in Appendix H. Part (i) is immediate from Proposition 56, which is proved using martingale convergence and that $\mathrm{inj}(F,G_{-t})$ appropriately normalized evolves as a backwards martingale. Part (ii) is proved by using that $h(F,G_t)$ and $h_{\mathrm{inj}}(F,G_t)$ are not too different under certain assumptions on the underlying graphon. Part (iii) is proved by bounding $\hom(F,G_n)$ from above, and part (iv) is proved by constructing explicit counterexamples.

Remark 31 *While we stated the above proposition for graphons, i.e., for the case when $W \in L^1$, the main input used in the proof, Proposition 56 below, does not require an integrable W, but just the measurability of the function $W\colon S \times S \to [0,1]$.*

Acknowledgments

We thank Svante Janson for his careful reading of an earlier version of the paper and for his numerous suggestions, and we thank Edoardo Airoldi for helpful discussions. Holden was supported by an internship at Microsoft Research New England and by a doctoral research fellowship from the Norwegian Research Council.

Appendix A. Cut Metric and Invariant L^p Metric

The main goal of this appendix is to prove Proposition 6, which says that $\delta_\square$ and δ_1 are well defined and pseudometrics. In the course of our proof, we will actually generalize this proposition, and show that it can be extended to the invariant L^p metric δ_p, provided the two graphons are non-negative and in L^p.

We start by defining the distance $\delta_p(\mathcal{W}_1,\mathcal{W}_2)$ for two such graphons $\mathcal{W}_1 = (W_1,\mathscr{S}_1)$ and $\mathcal{W}_2 = (W_1,\mathscr{S}_2)$ over two spaces $\mathscr{S}_1 = (S_1,\mathcal{S}_1,\mu_i)$ and $\mathscr{S}_2 = (S_2,\mathcal{S}_2,\mu_2)$ of equal total measure, in which case we set

$$\delta_p(\mathcal{W}_1,\mathcal{W}_2) := \inf_\mu \|W_1^{\pi_1} - W_2^{\pi_2}\|_{p,S_1\times S_2,\mu},$$

where, as before, π_1 and π_2 are the projections from $S_1\times S_2$ to S_1 and S_2, respectively, and the infimum is over all couplings μ of μ_1 and μ_2. If $\mu_1(S_1)\neq\mu_2(S_2)$ we define $\delta_p(\mathcal{W}_1,\mathcal{W}_2)$ by trivially extending $\mathcal{W}_1$ and $\mathcal{W}_2$ to two graphons $\widetilde{\mathcal{W}}_1$ and $\widetilde{\mathcal{W}}_2$, respectively, over measure spaces of equal measure, and defining $\delta_p(\mathcal{W}_1,\mathcal{W}_2) := \delta_p(\widetilde{\mathcal{W}}_1,\widetilde{\mathcal{W}}_2)$, just as in Definition 5 (ii).

Proposition 32 *For $i=1,2$, let $\mathcal{W}_i=(W_i,\mathscr{S}_i)$ be non-negative graphons over $\mathscr{S}_i = (S_i,\mathcal{S}_i,\mu_i)$ with $W_i\in L^p(S_i\times S_i)$ for some $p\in(1,\infty)$. Then $\delta_p(\mathcal{W}_1,\mathcal{W}_2)$ is well defined. In particular, $\delta_p(\mathcal{W}_1,\mathcal{W}_2)$ does not depend on the choice of extensions $\widetilde{\mathcal{W}}_1$ and $\widetilde{\mathcal{W}}_2$. Furthermore, δ_p is a pseudometric on the space of non-negative graphons in L^p.*

We will prove Proposition 32 at the same time as Proposition 6. We will also establish an estimate (Lemma 44) saying that two graphons are close in the cut metric if we obtain one from the other by slightly modifying the measure of the underlying measure space. Finally we state and prove a lemma, Lemma 45, that immediately implies Proposition 21.

The following lemma will be used in the proof of Propositions 10 and 48. The analogous result for probability spaces can for example be found in a paper by Janson (2013, Theorem A.7), and the extension to σ-finite measure spaces is straightforward.

Lemma 33 *Let $\mathscr{S}=(S,\mathcal{S},\mu)$ be an atomless σ-finite Borel space. Then $\mathscr{S}$ is isomorphic to $([0,\mu(S)),\mathcal{B},\lambda)$, where $\mathcal{B}$ is the Borel σ-algebra and λ is Lebesgue measure.*

Proof For $\mu(S)<\infty$, this holds because every atomless Borel probability space is isomorphic to $[0,1]$ equipped with the Borel σ-algebra and Lebesgue measure (Janson, 2013, Theorem A.7). For $\mu(S)=\infty$ we use that by the hypotheses of σ-finiteness there exist disjoint sets $S_k\in\mathcal{S}$ for $k\in\mathbb{N}$ such that $S=\bigcup_{k=1}^\infty S_k$ and $\mu(S_k)<\infty$ for all $k\in\mathbb{N}$. For each $k\in\mathbb{N}$ we can find isomorphisms $\phi\colon [0,\mu(S_k)]\to[0,\mu(S_k))$ and $\widetilde{\phi}\colon S_k\to[0,\mu(S_k)]$. It follows by considering the composed map $\phi\circ\widetilde{\phi}$ that S_k is isomorphic to $[0,\mu(S_k))$. The lemma follows by constructing an isomorphism from S to $\mathbb{R}_+$ where each set S_k is mapped onto an half-open interval of length $\mu(S_k)$. ∎

The first statement of Proposition 6, i.e., the existence of a coupling, follows directly from the following more general result.

Lemma 34 *For $k=1,2$ let $\mathscr{S}_k=(S_k,\mathcal{S}_k,\mu_k)$ be a σ-finite measure space such that $\mu_1(S_1)=\mu_2(S_2)\in(0,\infty]$. Let $D_k\in\mathcal{S}_k$, and let $\widetilde{\mu}$ be a measure on the product space $D_1\times D_2$, where D_k is equipped with the induced σ-algebra from S_k. Assume the marginals $\widetilde{\mu}_1$ and $\widetilde{\mu}_2$ of $\widetilde{\mu}$ are bounded above by $\mu_1|_{D_1}$ and $\mu_2|_{D_2}$, respectively, and that either $D_1=D_2=\emptyset$ or $\mu_k(S_k\setminus D_k)=\infty$ for $k=1,2$. Then there exists a coupling μ of $\mathscr{S}_1$ and $\mathscr{S}_2$, such that $\mu|_{D_1\times D_2}=\widetilde{\mu}$.*

Proof First we consider the case when $D_1=D_2=\emptyset$. If $\mu_1(S_1)=\mu_2(S_2)<\infty$ we define μ to be proportional to the product measure of μ_1 and μ_2. Explicitly, for $A\in\mathcal{S}_1$ and $B\in\mathcal{S}_2$, we set $\mu(A\times B)=\mu_1(A)\mu_2(B)/\mu_1(S_1)$. This clearly gives $\mu(S_1\times B)=\mu_2(B)$ and $\mu(A\times S_2)=\mu_1(A)$, as required.

If $\mu_1(S_1)=\mu_2(S_2)=\infty$, we consider partitions of S_1 and S_2 into disjoint sets of finite measure, with $S_k=\bigcup_{i\geq1}A_i^k$ for $k=1,2$. Let $I_1,I_2,\dots$ and $J_1,J_2,\dots$ be decompositions of $[0,\infty)$ into adjacent intervals of lengths $\mu_1(A_1^1),\mu_1(A_2^1),\dots$ and $\mu_2(A_1^2),\mu_2(A_2^2),\dots$, respectively. We then define a measure μ on $(S_1\times S_2,\mathcal{S}_1\times\mathcal{S}_2)$ by

$$\mu(A\times B)=\sum_{i,j\geq1}\frac{\lambda(I_i\cap J_j)}{\lambda(I_i)\lambda(J_j)}\mu_1(A\cap A_i^1)\mu_2(B\cap A_j^2),\quad\text{for } A\in\mathcal{S}_1, B\in\mathcal{S}_2.$$

As a weighted sum of product measures, μ is a measure, and inserting $A=S_1$ or $B=S_2$, one easily verifies that μ has marginals μ_1 and μ_2. This completes the proof of the lemma in the case that $D_1=D_2=\emptyset$.

Now we consider the general case. Decomposing D_1 and D_2 into disjoint sets of finite mass with respect to μ_1 and μ_2, $D_k=\bigcup_{i\geq1}D_i^k$ with $\mu_k(D_i^k)<\infty$, we define measures $\widehat{\mu}_k^{(\ell)}$ on S_k for $k,\ell=1,2$ by

$$\begin{aligned}
\widehat{\mu}_1^{(1)}(A)&=\frac{1}{2}\mu_1(A\cap(S_1\setminus D_1))\text{ for all }A\in\mathcal{S}_1,\\
\widehat{\mu}_2^{(1)}(B)&=\frac{1}{2}\mu_2(B\cap(S_2\setminus D_2))+\sum_{i\geq1}\Big[\mu_2(B\cap D_i^2)-\widetilde{\mu}_2(B\cap D_i^2)\Big]\text{ for all }B\in\mathcal{S}_2,\\
\widehat{\mu}_1^{(2)}(A)&=\frac{1}{2}\mu_1(A\cap(S_1\setminus D_1))+\sum_{i\geq1}\Big[\mu_1(A\cap D_i^1)-\widetilde{\mu}_1(A\cap D_i^1)\Big]\text{ for all }A\in\mathcal{S}_1,\text{ and}\\
\widehat{\mu}_2^{(2)}(S_1)&=\frac{1}{2}\mu_2(B\cap(S_2\setminus D_2))\text{ for all }B\in\mathcal{S}_2.
\end{aligned}$$

Note that $\widehat{\mu}_1^{(\ell)}(S_1)=\widehat{\mu}_2^{(\ell)}(S_2)=\infty$ for $\ell=1,2$ by our assumption $\mu_k(S_k\setminus D_k)=\infty$ for $k=1,2$. By the result for the case $D_1=D_2=\emptyset$, for $\ell=1,2$, we can find couplings $\widehat{\mu}^{(\ell)}$ of $\widehat{\mu}_1^{(\ell)}$ and $\widehat{\mu}_2^{(\ell)}$ on $S_1\times S_2$. Extending the measure $\widetilde{\mu}$ to a measure on $S_1\times S_2$ by assigning measure 0 to all sets which have an empty intersection with $D_1\times D_2$, the measure $\mu:=\widehat{\mu}^{(1)}+\widehat{\mu}^{(2)}+\widetilde{\mu}$ has the appropriate marginals. To see that $\mu|_{D_1\times D_2}=\widetilde{\mu}$, we note that $\widehat{\mu}^{(1)}(D_1\times S_2)=\widehat{\mu}_1^{(1)}(D_1)=0$ and $\widehat{\mu}^{(2)}(S_1\times D_2)=\widehat{\mu}_2^{(2)}(D_2)=0$, implying in particular that $\widehat{\mu}^{(1)}(D_1\times D_2)=\widehat{\mu}^{(2)}(D_1\times D_2)=0$. ∎

Corollary 35 *For $k = 1, 2$ let $\mathscr{S}_k = (S_k, \mathcal{S}_k, \mu_k)$ be a σ-finite measure space such that $\mu_1(S_1) = \mu_2(S_2) \in (0, \infty]$, and let μ be a coupling of μ_1 and μ_2. Let $D_k \in \mathcal{S}_k$ be such that $\mu(D_1 \times (S_2 \setminus D_2)) = \mu((S_1 \setminus D_1) \times D_2) \in (0, \infty]$. Then there exists a coupling $\widetilde{\mu}$ of μ_1 and μ_2 such that $\widetilde{\mu}$ is supported on $(D_1 \times D_2) \cup ((S_1 \setminus D_1) \times (S_2 \setminus D_2))$ and $\widetilde{\mu} \geq \mu$ on $(D_1 \times D_2) \cup ((S_1 \setminus D_1) \times (S_2 \setminus D_2))$.*

Proof Let μ' be the restriction of μ to $(D_1 \times D_2) \cup ((S_1 \setminus D_1) \times (S_2 \setminus D_2))$, let μ'_1 and μ'_2 be its marginals, and let $\delta_i = \mu_i - \mu'_i$. Then $\delta_1(D_1) = \mu(D_1 \times (S_2 \setminus D_2))$ and $\delta_2(D_2) = \mu((S_1 \setminus D_1) \times D_2) = \delta_1(D_1)$ by the hypotheses of the corollary. In a similar way, $\delta_1(S_1 \setminus D_1) = \mu((S_1 \setminus D_1) \times D_2) = \delta_2(S_2 \setminus D_2)$. With the help of the previous lemma, and considering the domains $D_1 \times D_2$ and $(S_1 \setminus D_1) \times (S_2 \setminus D_2)$ separately, we then construct a coupling δ of δ_1 and δ_2 that has support on $(D_1 \times D_2) \cup ((S_1 \setminus D_1) \times (S_2 \setminus D_2))$. Setting $\tilde{\mu} = \mu' + \delta$ we obtain the statement of the corollary. ∎

The following basic lemma will be used multiple times throughout this appendix. The analogous result for probability spaces can be found for example in a paper by Janson (2013, Lemma 6.4).

Lemma 36 *Let $p \geq 1$, let $\mathscr{S}_i = (S_i, \mathcal{S}_i, \mu_i)$ for $i = 1, 2$ be such that $\mu_1(S_1) = \mu_2(S_2)$, and let $\mathcal{W}_1 = (W_1, \mathscr{S}_1)$, $\mathcal{W}'_1 = (W'_1, \mathscr{S}_1)$, and $\mathcal{W}_2 = (W_2, \mathscr{S}_2)$ be graphons in L^p. Defining $\delta_\square$ and δ_p as in Definition 5(i), we have*

$$\delta_\square(\mathcal{W}_1, \mathcal{W}_2) \leq \delta_\square(\mathcal{W}'_1, \mathcal{W}_2) + \|W_1 - W'_1\|_\square \leq \delta_\square(\mathcal{W}'_1, \mathcal{W}_2) + \|W_1 - W'_1\|_1$$

and

$$\delta_p(\mathcal{W}_1, \mathcal{W}_2) \leq \delta_p(\mathcal{W}'_1, \mathcal{W}_2) + \|W_1 - W'_1\|_p.$$

Proof The second bound on $\delta_\square(\mathcal{W}_1, \mathcal{W}_2)$ is immediate, so the rest of the proof will consist of proving the first bound on $\delta_\square(\mathcal{W}_1, \mathcal{W}_2)$ as well as the bound on $\delta_p(\mathcal{W}_1, \mathcal{W}_2)$. Let μ be a measure on $(S_1 \times S_2, \mathcal{S}_1 \times \mathcal{S}_2)$ with marginals μ_1 and μ_2, respectively, and let $\pi_i \colon S_1 \times S_2 \to S_i$ denote projections for $i = 1, 2$. Since $\|\cdot\|_\square$ clearly satisfies the triangle inequality,

$$\begin{aligned}\delta_\square(\mathcal{W}_1, \mathcal{W}_2) &\leq \|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square, S_1 \times S_2, \mu} \\ &\leq \|(W'_1)^{\pi_1} - W_2^{\pi_2}\|_{\square, S_1 \times S_2, \mu} + \|(W'_1)^{\pi_1} - W_1^{\pi_1}\|_{\square, S_1 \times S_2, \mu} \\ &= \|(W'_1)^{\pi_1} - W_2^{\pi_2}\|_{\square, S_1 \times S_2, \mu} + \|W'_1 - W_1\|_{\square, S_1, \mu_1}.\end{aligned}$$

The desired result follows by taking an infimum over all couplings. The bound on $\delta_p(\mathcal{W}_1, \mathcal{W}_2)$ follows in the same way from the triangle inequality for $\|\cdot\|_p$. ∎

Remark 37 *We state the above lemma only for the case when $\mu_1(S_1) = \mu_2(S_2)$, since we have not yet proved that $\delta_\square$ and δ_p are well defined otherwise. However, once we have proved this, it is a direct consequence of Definition 5(ii) that the above lemma also holds when $\mu_1(S_1) \neq \mu_2(S_2)$.*

Definition 38 *Let $(S, \mathcal{S})$ be a measurable space, and consider a function $W \colon S \times S \to \mathbb{R}$. Then W is a* step function *if there are some $n \in \mathbb{N}$, disjoint sets $A_i \in \mathcal{S}$ satisfying $\mu(A_i) < \infty$ for $i \in \{1, \dots, n\}$, and constants $a_{i,j} \in \mathbb{R}$ for $i, j \in \{1, \dots, n\}$ such that*

$$W = \sum_{i,j \in \{1,\dots,n\}} a_{i,j} \mathbf{1}_{A_i \times A_j}.$$

Note that in order for W to be a step function it is not sufficient that it is simple, i.e., that it attains a finite number of values; the sets on which the function is constant are required to be product sets. The set of step functions is dense in L^1; hence Lemma 36 implies that every graphon can be approximated arbitrarily closely by a step function for the $\delta_\square$ metric.

Lemma 39 *Let $p \geq 1$, let $\mathcal{W}_1 = (W_1, \mathscr{S}_1)$ and $\mathcal{W}_2 = (W_2, \mathscr{S}_2)$ be graphons, and let $S_1 = \bigcup_{i \in I} A_i$ and $S_2 = \bigcup_{k \in J} B_k$ for finite index sets I and J such that $A_i \cap A_{i'} = \emptyset$ for $i \neq i'$ and $B_j \cap B_{j'} = \emptyset$ for $j \neq j'$. Suppose W_1 and W_2 are step functions of the form*

$$W_1 = \sum_{i,i' \in I} a_{i,i'} \mathbf{1}_{A_i \times A_{i'}} \quad \text{and} \quad W_2 = \sum_{j,j' \in J} b_{j,j'} \mathbf{1}_{B_j \times B_{j'}},$$

where $a_{i,i'}$ and $b_{j,j'}$ are constants in $\mathbb{R}$. Let μ and μ' be two coupling measures on $S_1 \times S_2$, such that $\mu(A_i \times B_k) = \mu'(A_i \times B_k)$ for all $(i, k) \in I \times J$. Then $\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu} = \|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu'}$ and $\|W_1^{\pi_1} - W_2^{\pi_2}\|_{p,\mu} = \|W_1^{\pi_1} - W_2^{\pi_2}\|_{p,\mu'}$.

Proof For all $U, V \subseteq S_1 \times S_2$,

$$\int_{U \times V} \left(W_1^{\pi_1} - W_2^{\pi_2}\right) d\mu \, d\mu = \sum_{i,i',j,j'} \mu(U \cap (A_i \times B_j)) \mu(V \cap (A_{i'} \times B_{j'}))(a_{i,i'} - b_{j,j'}). \quad (6)$$

From the form of this expression and the definition of $\|\cdot\|_\square$ it is clear that we may assume there are sets $U', V' \subseteq S_1 \times S_2$ such that for all i, j,

$$A_i \times B_j \subseteq U' \quad \text{or} \quad (A_i \times B_j) \cap U' = \emptyset$$

and

$$A_i \times B_j \subseteq V' \quad \text{or} \quad (A_i \times B_j) \cap V' = \emptyset,$$

and such that

$$\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu} = \int_{U' \times V'} \left(W_1^{\pi_1} - W_2^{\pi_2}\right) d\mu \, d\mu.$$

Hence it follows from (6) that $\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu} = \|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu'}$ if $\mu(A_i \times B_j) = \mu'(A_i \times B_j)$ for all i, j. The proof for the L^p metric follows from the fact that

$$\|W_1^{\pi_1} - W_2^{\pi_2}\|_{p,\mu}^p = \sum_{i,i',j,j'} |a_{i,i'} - b_{j,j'}|^p \mu(A_i \times B_j) \mu(A_{i'} \times B_{j'}).$$

∎

Corollary 40 *Let $p \geq 1$ and for $k = 1, 2$, let $\mathcal{W}_k = (W_k, \mathscr{S}_k)$ with $\mathscr{S}_k = (S_k, \mathcal{S}_k, \mu_k)$ be graphons in L^p. For $k = 1, 2$, let $\widetilde{\mathscr{S}_k} = (\widetilde{S}_k, \widetilde{\mathcal{S}}_k, \widetilde{\mu}_k)$ and $\widehat{\mathscr{S}_k} = (\widehat{S}_k, \widehat{\mathcal{S}}_k, \widehat{\mu}_k)$ be extensions of $\mathscr{S}_k$ with $\widetilde{\mu}_1(\widetilde{S}_1) = \widetilde{\mu}_2(\widetilde{S}_2) \in (0, \infty]$ and $\widehat{\mu}_1(\widehat{S}_1) = \widehat{\mu}_2(\widehat{S}_2) \in (0, \infty]$, and let $\widetilde{W}_k$ and $\widehat{W}_k$ be the trivial extensions of W_k to $\widetilde{\mathscr{S}_k}$ and $\widehat{\mathscr{S}_k}$. Let $\widetilde{\mu}$ and $\widehat{\mu}$ be couplings of $\widetilde{\mu}_1$ and $\widetilde{\mu}_2$, and $\widehat{\mu}_1$ and $\widehat{\mu}_2$, respectively. If $\widetilde{\mu}$ and $\widehat{\mu}$ agree on $S_1 \times S_2$, then $\|\widetilde{W}_1^{\pi_1} - \widetilde{W}_2^{\pi_2}\|_{\square,\widetilde{\mu}} = \|\widehat{W}_1^{\pi_1} - \widehat{W}_2^{\pi_2}\|_{\square,\widehat{\mu}}$ and $\|\widetilde{W}_1^{\pi_1} - \widetilde{W}_2^{\pi_2}\|_{p,\widetilde{\mu}} = \|\widehat{W}_1^{\pi_1} - \widehat{W}_2^{\pi_2}\|_{p,\widehat{\mu}}$.*

Proof By Lemma 36 and the fact that step functions are dense in L^1 and in L^p, it is sufficient to prove the corollary for step functions. The corollary then follows from Lemma 39 by observing that for two sets $A \in \mathcal{S}_1$ and $B \in \mathcal{S}_2$ with finite measure $\mu_1(A)$ and $\mu_2(B)$, the $\widetilde{\mu}$ measure of sets of the form $A \times (\widetilde{S}_2 \setminus S_2)$ and $(\widetilde{S}_1 \setminus S_1) \times B$ can be expressed as $\mu_1(A) - \widetilde{\mu}(A \times S_2)$ and $\mu_2(B) - \widetilde{\mu}(S_1 \times B)$, respectively, implying that $\|\widetilde{W}_1^{\pi_1} - \widetilde{W}_2^{\pi_2}\|_{\square,\widetilde{\mu}}$ and $\|\widetilde{W}_1^{\pi_1} - \widetilde{W}_2^{\pi_2}\|_{p,\widetilde{\mu}}$ depend only on the restriction of $\widetilde{\mu}$ to $S_1 \times S_2$, and similarly for $\|\widehat{W}_1^{\pi_1} - \widehat{W}_2^{\pi_2}\|_{\square,\widehat{\mu}}$ and $\|\widehat{W}_1^{\pi_1} - \widehat{W}_2^{\pi_2}\|_{p,\widehat{\mu}}$. ■

Lemma 39 is also used in the proof of the triangle inequality in the following lemma. The proof follows the same strategy as the proof by Janson (2013, Lemma 6.5) for the case of probability spaces.

Lemma 41 *Let $p \geq 1$. For $i = 1, 2, 3$ let $\mathcal{W}_i = (W_i, \mathscr{S}_i)$ with $\mathscr{S}_i = (S_i, \mathcal{S}_i, \mu_i)$ be a graphon in L^p, such that $\mu_1(S_1) = \mu_2(S_2) = \mu_3(S_3) \in (0, \infty]$. Defining $\delta_\square$ and δ_p as in Definition 5(i), we have*

$$\delta_\square(\mathcal{W}_1, \mathcal{W}_3) \leq \delta_\square(\mathcal{W}_1, \mathcal{W}_2) + \delta_\square(\mathcal{W}_2, \mathcal{W}_3) \quad \text{and} \quad \delta_p(\mathcal{W}_1, \mathcal{W}_3) \leq \delta_p(\mathcal{W}_1, \mathcal{W}_2) + \delta_p(\mathcal{W}_2, \mathcal{W}_3).$$

Proof By Lemma 36 and since step functions are dense in L^1, we may assume that W_i is a step function for $i = 1, 2, 3$. Let $\mathscr{S}_1 = \bigcup_{j=1}^\infty A_j$ (resp. $\mathscr{S}_2 = \bigcup_{j=1}^\infty B_j$, $\mathscr{S}_3 = \bigcup_{j=1}^\infty C_j$) be such that $W_1|_{A_j \times A_k}$ (resp. $W_2|_{B_j \times B_k}$, $W_3|_{C_j \times C_k}$) is constant for all $j, k \in \mathbb{N}$, and assume without loss of generality that $\mu_1(A_j), \mu_2(B_j), \mu_3(C_j) \in (0, \infty)$ for all $j \in \mathbb{N}$. Throughout the proof we abuse notation slightly and let π_i denote projection onto S_i from any space which is a product of S_i and another space; for example, π_1 denotes projection onto S_1 from $S_1 \times S_2 \times S_3$, $S_1 \times S_2$, and $S_1 \times S_3$.

Let $\varepsilon > 0$, and let μ' (resp. μ'') be a coupling measure on $S_1 \times S_2$ (resp. $S_2 \times S_3$) such that

$$\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu'} < \delta_\square(\mathcal{W}_1, \mathcal{W}_2) + \varepsilon \quad \text{and} \quad \|W_2^{\pi_2} - W_3^{\pi_3}\|_{\square,\mu''} < \delta_\square(\mathcal{W}_2, \mathcal{W}_3) + \varepsilon.$$

We define a measure μ on $S_1 \times S_2 \times S_3$ for any $E \subseteq S_1 \times S_2 \times S_3$ which is measurable for the product σ-algebra by

$$\mu(E) = \sum_{i,j,k} \frac{\mu'(A_i \times B_j)\mu''(B_j \times C_k)}{\mu_2(B_j)} \frac{\mu_1 \times \mu_2 \times \mu_3(E \cap (A_i \times B_j \times C_k))}{\mu_1(A_i)\mu_2(B_j)\mu_3(C_k)}.$$

By a straightforward calculation (see, for example, the paper by Janson, 2013, Lemma 6.5) the three mappings $\pi_l \colon (S_1 \times S_2 \times S_3, \mu) \to (S_l, \mu_l)$ for $l = 1, 2, 3$ are measure-preserving.

Furthermore, if $\widetilde{\mu}'$ is the pushforward measure of μ for the projection $\pi_{12} \colon S_1 \times S_2 \times S_3 \to S_1 \times S_2$, then

$$\widetilde{\mu}'(A_i \times B_j) = \mu'(A_i \times B_j) \quad \text{for all } i, j.$$

By Lemma 39 and since $\pi_{12} \colon (S_1 \times S_2 \times S_3, \mu) \to (S_1 \times S_2, \widetilde{\mu}')$ is measure-preserving,

$$\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,S_1 \times S_2,\mu'} = \|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,S_1 \times S_2,\widetilde{\mu}'} = \|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,S_1 \times S_2 \times S_3,\mu}.$$

Hence,

$$\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,S_1 \times S_2 \times S_3,\mu} < \delta_\square(\mathcal{W}_1, \mathcal{W}_2) + \varepsilon.$$

Similarly,

$$\|W_2^{\pi_2} - W_3^{\pi_3}\|_{\square,S_1 \times S_2 \times S_3,\mu} < \delta_\square(\mathcal{W}_2, \mathcal{W}_3) + \varepsilon.$$

Letting $\widehat{\mu}$ be the pushforward measure on $S_1 \times S_3$ of μ for the projection $\pi_{13} \colon S_1 \times S_2 \times S_3 \to S_1 \times S_3$, we have

$$\|W_1^{\pi_1} - W_3^{\pi_3}\|_{\square,S_1 \times S_3,\widehat{\mu}} = \|W_1^{\pi_1} - W_3^{\pi_3}\|_{\square,S_1 \times S_2 \times S_3,\mu}.$$

Since the cut norm $\|\cdot\|_\square$ clearly satisfies the triangle inequality,

$$\begin{aligned}\delta_\square(\mathcal{W}_1, \mathcal{W}_3) &\leq \|W_1^{\pi_1} - W_3^{\pi_3}\|_{\square,S_1 \times S_3,\widehat{\mu}} = \|W_1^{\pi_1} - W_3^{\pi_3}\|_{\square,S_1 \times S_2 \times S_3,\mu} \\ &\leq \|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,S_1 \times S_2 \times S_3,\mu} + \|W_2^{\pi_2} - W_3^{\pi_3}\|_{\square,S_1 \times S_2 \times S_3,\mu} \\ &< \delta_\square(\mathcal{W}_1, \mathcal{W}_2) + \delta_\square(\mathcal{W}_2, \mathcal{W}_3) + 2\varepsilon.\end{aligned}$$

Since ε was arbitrary this completes our proof for $\delta_\square$. The proof for δ_p is identical. ■

Lemma 42 *Let $\mathcal{W}_i = (W_i, \mathscr{S}_i)$ with $\mathscr{S}_i = (S_i, \mathcal{S}_i, \mu_i)$ be a graphon for $i = 1, 2$, such that $\mu_1(S_1) = \mu_2(S_2) \in (0, \infty]$. For $i = 1, 2$ let $\widetilde{\mathscr{S}_i} = (\widetilde{S}_i, \widetilde{\mathcal{S}}_i, \widetilde{\mu}_i)$ be an extension of $\mathscr{S}_i$, such that $\widetilde{\mu}_1(\widetilde{S}_1) = \widetilde{\mu}_2(\widetilde{S}_2) \in (0, \infty]$, and let $\widetilde{\mathcal{W}}_i$ be the trivial extension of $\mathcal{W}_i$ to $\widetilde{\mathscr{S}_i}$. Then $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = \delta_\square(\widetilde{\mathcal{W}}_1, \widetilde{\mathcal{W}}_2)$ and $\delta_1(\mathcal{W}_1, \mathcal{W}_2) = \delta_1(\widetilde{\mathcal{W}}_1, \widetilde{\mathcal{W}}_2)$, where $\delta_\square$ and δ_1 are as in Definition 5(i). If $p > 1$ and $\mathcal{W}_1$ and $\mathcal{W}_2$ are non-negative graphons in L^p, then the result holds for δ_p as well.*

Remark 43 *We remark that the assumption of non-negativity is necessary for the lemma to hold when $p > 1$. If for example $\mathcal{W}_1 = (\mathbf{1}, [0, 1])$ and $\mathcal{W}_2 = (-\mathbf{1}, [0, 1])$ are graphons over $[0, 1]$, and if $\widetilde{\mathcal{W}}_1$ and $\widetilde{\mathcal{W}}_2$ are the trivial extensions to $[0, 2]$, then $\delta_p(\mathcal{W}_1, \mathcal{W}_2) = 2$ and $\delta_p(\widetilde{\mathcal{W}}_1, \widetilde{\mathcal{W}}_2) = 2^{1/p}$.*

Proof We start with the proof for the cut metric. We will first prove the result for the case when $\widetilde{S}_i = \mathbb{N}$ and $S_i = S := \{1, \ldots, n\}$ for $i = 1, 2$ and some $n \in \mathbb{N}$, $\mathcal{S}_i$ and $\widetilde{\mathcal{S}}_i$ are the associated discrete σ-algebras, and $\widetilde{\mu}_i(x) = c$ for all $x \in \widetilde{S}_i$ and some $c \in (0, 1)$.

First we will argue that

$$\delta_\square(\mathcal{W}_1, \mathcal{W}_2) \geq \delta_\square(\widetilde{\mathcal{W}}_1, \widetilde{\mathcal{W}}_2).$$

By Definition 5(i) it is sufficient to prove that for each coupling measure μ on $S \times S$ we can define a coupling measure $\widetilde{\mu}$ on $\mathbb{N} \times \mathbb{N}$ such that $\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu} = \|\widetilde{W}_1^{\widetilde{\pi}_1} - \widetilde{W}_2^{\widetilde{\pi}_2}\|_{\square,\widetilde{\mu}}$. But

this is immediate, since we can define $\widetilde{\mu}$ such that $\widetilde{\mu}|_{S\times S} = \mu$, and $\widetilde{\mu}(A_1 \times A_2) = c|A_1 \cap A_2|$ for $A_i \subseteq \mathbb{N}\backslash S$.

Next we will prove that

$$\delta_\square(\mathcal{W}_1, \mathcal{W}_2) \leq \delta_\square(\widetilde{\mathcal{W}_1}, \widetilde{\mathcal{W}_2}). \tag{7}$$

Again by Definition 5(i), it will be sufficient to prove that given any coupling measure $\widetilde{\mu}$ on $\mathbb{N}\times\mathbb{N}$ we can find a coupling measure μ on $S \times S$ such that $\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu} \leq \|\widetilde{W}_1^{\pi_1} - \widetilde{W}_2^{\pi_2}\|_{\square,\widetilde{\mu}}$.

By the following argument we may approximate $\|\widetilde{W}_1^{\pi_1} - \widetilde{W}_2^{\pi_2}\|_{\square,\widetilde{\mu}}$ arbitrarily well by replacing $\widetilde{\mu}$ with a coupling measure which is supported on $(\widehat{S}\times\widehat{S}) \cup ((\mathbb{N}\backslash\widehat{S}) \times (\mathbb{N}\backslash\widehat{S}))$, where $\widehat{S} := \{1,\dots,K\}$ for some sufficiently large $K \in \mathbb{N}$. Indeed, by Corollary 35, given a coupling measure $\widetilde{\mu}$ on $\mathbb{N}\times\mathbb{N}$ and $K \in \mathbb{N}$, we can define a measure $\widehat{\mu}$ supported on $(\widehat{S}\times\widehat{S}) \cup ((\mathbb{N}\backslash\widehat{S}) \times (\mathbb{N}\backslash\widehat{S}))$ such that $\widehat{\mu} \geq \widetilde{\mu}$ on $(\widehat{S}\times\widehat{S}) \cup ((\mathbb{N}\backslash\widehat{S}) \times (\mathbb{N}\backslash\widehat{S}))$. It is easy to see from the construction of this measure in the proof of Corollary 35 that when K converges to infinity, the measure $\widehat{\mu}$ converges to $\widetilde{\mu}$ when restricted to $(S\times\mathbb{N}) \cup (\mathbb{N}\times S)$ (for example for the topology where we look at the maximum difference of the measure assigned to any set in $(S\times\mathbb{N}) \cup (\mathbb{N}\times S)$). Therefore the corresponding cut norms also converge. This shows that we may assume that $\widetilde{\mu}$ is supported on $(\widehat{S}\times\widehat{S}) \cup ((\mathbb{N}\backslash\widehat{S}) \times (\mathbb{N}\backslash\widehat{S}))$ for some $K \in \mathbb{N}$ when proving (7).

Let $\widetilde{\mu}'$ be the restriction of $\widetilde{\mu}$ to $\widehat{S}\times\widehat{S}$. Then $\|\widetilde{W}_1 - \widetilde{W}_2\|_{\square,\mathbb{N}\times\mathbb{N},\widetilde{\mu}} = \|\widehat{W}_1 - \widehat{W}_2\|_{\square,\widehat{S}\times\widehat{S},\widetilde{\mu}'}$ where $\widehat{\mathcal{W}_i} = (\widehat{W_i}, \widehat{\mathscr{S}_i})$ is the trivial extensions of $\mathcal{W}_i$ to the measure space $\widehat{\mathscr{S}_i}$ associated with $\widehat{S}_i$. We will prove that we may assume without loss of generality that $\widetilde{\mu}'$ corresponds to a permutation of $\widehat{S}$. By choosing $M \in \mathbb{N}$ sufficiently large we can approximate $\|\widehat{W}_1 - \widehat{W}_2\|_{\square,\widetilde{\mu}'}$ arbitrarily well by replacing $\widetilde{\mu}'$ with a measure such that each element $(i,j) \in \widehat{S}\times\widehat{S}$ has a measure which is an integer multiple of c/M; hence we may assume $\widetilde{\mu}'$ is on this form. Each such $\widetilde{\mu}'$ can be described in terms of a permutation σ' of $[KM]$ via $\widetilde{\mu}'((i,j)) = \sum_{\ell=1}^{KM} c/M\delta_{i,\lceil \ell/M\rceil}\delta_{j,\lceil\sigma'(\ell)/M\rceil}$. Let $\widehat{\mathcal{W}_i'} = (\widehat{W_i'}, [KM])$ be the graphon such that each $j \in [KM]$ has measure c/M, and such that $\widehat{W_i'} = (\widehat{W_i})^\phi$ for the measure-preserving map $\phi\colon [KM] \to [K]$ defined by $\phi(j) := \lceil j/M\rceil$. Using Proposition 39 and the above observation on describing $\widetilde{\mu}'((i,j))$ in terms of a permutation σ' of $[KM]$ we see that $\|\widehat{W}_1 - \widehat{W}_2\|_{\square,\widetilde{\mu}'} = \|\widehat{W}_1' - (\widehat{W}_2')^{\sigma'}\|_\square$. Upon replacing $\widehat{W}_i$ by $\widehat{W}_i'$ throughout the proof, we may assume that the measure $\widetilde{\mu}'$ is a permutation.

To complete the proof it is therefore sufficient to consider some permutation $\widehat{\sigma}$ of $\widehat{S}$ and prove that we can find a permutation σ of $\widehat{S}$ mapping S to S such that

$$\|\widehat{W}_1 - \widehat{W}_2^{\widehat{\sigma}}\|_\square \geq \|\widehat{W}_1 - \widehat{W}_2^{\sigma}\|_\square. \tag{8}$$

We modify the permutation $\widehat{\sigma}$ step by step to obtain a permutation mapping S to S. Abusing notation slightly we let $\widehat{\sigma}$ and σ denote the old and new, respectively, permutations in a single step. In each step choose $i_1, i_2 \leq n$ and $j_1, j_2 > n$ such that $\widehat{\sigma}(i_1) = j_1$ and $\widehat{\sigma}(j_2) = i_2$; if such i_1, i_2, j_1, j_2 do not exist we know that $\widehat{\sigma}$ maps S to S. Then define $\sigma(i_1) := i_2$ and $\sigma(j_2) := j_1$, and for $k \notin \{i_1, j_2\}$ define $\sigma(k) := \widehat{\sigma}(k)$. We have $\|\widehat{W}_1 - \widehat{W}_2^{\sigma}\|_\square \leq \|\widehat{W}_1 - \widehat{W}_2^{\widehat{\sigma}}\|_\square$ by the following argument. Let $U, V \subseteq \mathbb{N}$ be such that $\|\widehat{W}_1 - \widehat{W}_2^{\sigma}\|_\square = |\int_{U\times V} \left(\widehat{W}_1 - \widehat{W}_2^{\sigma}\right) dx\, dy|$. Since $\sigma(j_2) > n$ (implying that both $\widehat{W}_1$ and $\widehat{W}_2^{\sigma}$ are trivial on $(j_2\times\mathbb{N})$ and $(\mathbb{N}\times j_2)$)

the following identity holds if we define $U' := U\backslash\{j_2\}$ or $U' := U \cup \{j_2\}$, and if we define $V' := V\backslash\{j_2\}$ or $V' := V \cup \{j_2\}$:

$$\int_{U\times V} \left(\widehat{W}_1 - \widehat{W}_2^{\sigma}\right) dx\, dy = \int_{U'\times V'} \left(\widehat{W}_1 - \widehat{W}_2^{\sigma}\right) dx\, dy.$$

In other words, $\int_{U\times V}(\widehat{W}_1 - \widehat{W}_2^{\sigma})\, dx\, dy$ is invariant under adding or removing j_2 from U and/or V. Therefore we may assume without loss of generality that

$$j_2 \in U \text{ iff } i_1 \in U, \qquad j_2 \in V \text{ iff } i_1 \in V, \tag{9}$$

since if (9) is not satisfied we may redefine U and V such that (9) holds, and we still have $\|\widehat{W}_1 - \widehat{W}_2^{\sigma}\|_\square = |\int_{U\times V}(\widehat{W}_1 - \widehat{W}_2^{\sigma})\, dx\, dy|$. The assumption (9) implies that $\int_{U\times V}(\widehat{W}_1 - \widehat{W}_2^{\sigma})\, dx\, dy = \int_{U\times V}(\widehat{W}_1 - \widehat{W}_2^{\widehat{\sigma}})\, dx\, dy$, which implies (8) since we can obtain a permutation σ mapping S to S in finitely many steps as described above.

Now we will prove the lemma for general graphons. We will reduce the problem step by step to a problem with additional conditions on the measure spaces involved, until we have reduced the problem to the special case considered above.

First we show that we may assume $\mathscr{S}_i$ and $\widetilde{\mathscr{S}_i}$ are non-atomic. Define $S_i' := S_i \times [0,1]$ and $\widetilde{S}_i' := \widetilde{S}_i \times [0,1]$, let $\mathscr{S}_i'$ and $\widetilde{\mathscr{S}_i'}$ be the corresponding atomless product measure spaces when $[0,1]$ is equipped with Lebesgue measure, and let $\mathcal{W}_i' = (W_i', \mathscr{S}_i')$ and $\widetilde{\mathcal{W}}_i' = (\widetilde{W}_i', \widetilde{\mathscr{S}_i'})$ be graphons such that $W_i' = (W_i)^{\pi_i^1}$ and $\widetilde{W}_i' = (\widetilde{W}_i)^{\widetilde{\pi}_i^1}$, where $\pi_i^1\colon \mathscr{S}_i' \to \mathscr{S}_i$ and $\widetilde{\pi}_i^1\colon \widetilde{\mathscr{S}_i'} \to \widetilde{\mathscr{S}_i}$ are the projection maps on the first coordinates. By considering the natural coupling of $\widetilde{S}_i'$ and $\widetilde{S}_i$ it is clear that $\delta_\square(\widetilde{W}_i', \widetilde{W}_i) = 0$. It therefore follows from the triangle inequality that $\delta_\square(\widetilde{W}_1, \widetilde{W}_2) = \delta_\square(\widetilde{W}_1', \widetilde{W}_2')$. Similarly, $\delta_\square(W_1, W_2) = \delta_\square(W_1', W_2')$. In order to prove that $\delta_\square(\widetilde{W}_1, \widetilde{W}_2) = \delta_\square(W_1, W_2)$ it is therefore sufficient to prove that $\delta_\square(\widetilde{W}_1', \widetilde{W}_2') = \delta_\square(W_1', W_2')$. Since $\mathscr{S}_i'$ and $\widetilde{\mathscr{S}_i'}$ are atomless and $\widetilde{W}_i'$ is a trivial extension of W_i' it is therefore sufficient to prove the lemma for atomless measure spaces.

Next we will reduce the general case to the case when $\widetilde{\mu}_i(\widetilde{S}_i) = \infty$. If $\widetilde{\mu}_i(\widetilde{S}_i) < \infty$ we extend $\widetilde{\mathscr{S}_i}$ to a space $\widehat{\mathscr{S}_i}$ of infinite measure, and let $\widehat{\mathcal{W}_i}$ be the trivial extension of $\widetilde{\mathcal{W}_i}$ to $\widehat{\mathscr{S}_i}$. Assuming we have proved the lemma for the case when the extended measure spaces have infinite measure, it follows that

$$\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = \delta_\square(\widehat{\mathcal{W}_1}, \widehat{\mathcal{W}_2}) = \delta_\square(\widetilde{\mathcal{W}_1}, \widetilde{\mathcal{W}_2});$$

hence the lemma also holds for the case when $\widetilde{\mu}_i(\widetilde{S}_i) < \infty$.

Next we prove that we may assume $\mu_i(S_i) < \infty$. We proceed similarly as in the previous paragraph, and assume $\mu_i(S_i) = \infty$. By Lemma 36 we may assume W_i are supported on sets of finite measure, and we let $\widehat{\mathscr{S}_i} = (\widehat{S}_i, \widehat{\mathcal{S}}_i, \widehat{\mu}_i)$ be a restriction of $\mathscr{S}_i$ such that $\mathrm{supp}(W_i) \subseteq \widehat{S}_i \times \widehat{S}_i$ and $\widehat{\mu}_i(\widehat{S}_i) < \infty$. Since $\mathscr{S}_i$ is non-atomic we may assume $\widehat{\mu}_1(\widehat{S}_1) = \widehat{\mu}_2(\widehat{S}_2)$. Define the graphon $\widehat{\mathcal{W}_i} = (\widehat{W}_i, \widehat{\mathscr{S}_i})$ to be such that $\mathcal{W}_i$ is the trivial extension of $\widehat{\mathcal{W}_i}$ to $\mathscr{S}_i$. Assuming we have proved the lemma for the case when $\mu_i(S_i) < \infty$, it follows that

$$\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = \delta_\square(\widehat{\mathcal{W}_1}, \widehat{\mathcal{W}_2}) = \delta_\square(\widetilde{\mathcal{W}_1}, \widetilde{\mathcal{W}_2});$$

hence the lemma also holds for the case when $\mu_i(S_i) < \infty$.

Next we will prove that we may assume W_i is a step function for $i = 1, 2$, such that each step has the same measure $c > 0$. Step functions are dense in L^1, and hence it is immediate from Lemma 36 that we may assume W_i is a step function. We may assume that the measure of each step is a rational multiple of $\mu_i(S_i)$; if this is not the case we may adjust the steps slightly (because $\mathscr{S}_i$ is non-atomic, we can choose subsets of the steps of any desired measures, by Exercise 2 from §41 in the book of Halmos, 1974) to obtain this. Assuming each step has a measure which is a rational multiple of $\mu_i(S_i)$ we may subdivide each step such that each step obtains the same measure $c > 0$, again using the exercise in the book by Halmos (1974).

Assume W_i are step functions consisting of $k \in \mathbb{N}$ steps each having measure $c > 0$, and that $\mu_i(S_i) < \infty$ and $\widetilde{\mu}_i(\widetilde{S}_i) = \infty$. Let $\mathcal{W}_i' = (W_i', [n])$ (resp. $\widetilde{\mathcal{W}}_i' = (\widetilde{W}_i', \mathbb{N})$) be a graphon over $[n] := \{1, \dots, n\}$ (resp. $\mathbb{N}$) equipped with the discrete σ-algebra, such that each $j \in [n]$ (resp. $j \in \mathbb{N}$) has measure c, and such that $W_i = (W_i')^{\phi_i}$ (resp. $\widetilde{W}_i = (\widetilde{W}_i')^{\widetilde{\phi}_i}$) for a measure-preserving map $\phi_i \colon S_i \to [k]$ (resp. $\widetilde{\phi}_i \colon \widetilde{S}_i \to \mathbb{N}$). Then $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = \delta_\square(\mathcal{W}_1', \mathcal{W}_2')$ and $\delta_\square(\widetilde{\mathcal{W}}_1, \widetilde{\mathcal{W}}_2) = \delta_\square(\widetilde{\mathcal{W}}_1', \widetilde{\mathcal{W}}_2')$. By the special case we considered in the first paragraphs of the proof, $\delta_\square(\mathcal{W}_1', \mathcal{W}_2') = \delta_\square(\widetilde{\mathcal{W}}_1', \widetilde{\mathcal{W}}_2')$. Combining the above identities, our desired result $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = \delta_\square(\widetilde{\mathcal{W}}_1, \widetilde{\mathcal{W}}_2)$ follows.

To prove the result for the metric δ_p, we follow the steps above. The only place where the proof differs is in the proof of (8). Let σ, $\widehat{\sigma}$, and i_1, i_2, j_1, j_2 be as in the proof of (8). We would like to show that

$$\|\widehat{W}_1 - \widehat{W}_2^{\sigma}\|_p^p \le \|\widehat{W}_1 - \widehat{W}_2^{\widehat{\sigma}}\|_p^p.$$

Writing both sides as a sum over $(i, j) \in \widehat{S}^2$ we consider the following three cases separately: (i) $(i, j) \in (\widehat{S} \setminus \{i_1, j_2\})^2$, (ii) $(i, j) \in \{i_1, j_2\} \times (\widehat{S} \setminus \{i_1, j_2\})$ or $(i, j) \in (\widehat{S} \setminus \{i_1, j_2\}) \times \{i_1, j_2\}$, and (iii) $(i, j) \in \{i_1, j_2\} \times \{i_1, j_2\}$. In case (i) the terms are identical on the left side and on the right side. For dealing with case (ii) it is sufficient to prove that for an arbitrary $i \in (\widehat{S} \setminus \{i_1, j_2\})$,

$$\begin{aligned}|\widehat{W}_1(i_1, i) - \widehat{W}_2^{\sigma}(i_1, i)|^p + |\widehat{W}_1(j_2, i) - \widehat{W}_2^{\sigma}(j_2, i)|^p \\ \le |\widehat{W}_1(i_1, i) - \widehat{W}_2^{\widehat{\sigma}}(i_1, i)|^p + |\widehat{W}_1(j_2, i) - \widehat{W}_2^{\widehat{\sigma}}(j_2, i)|^p.\end{aligned}$$

This is equivalent to

$$|\widehat{W}_1(i_1, i) - \widehat{W}_2(i_2, \widehat{\sigma}(i))|^p \le |\widehat{W}_1(i_1, i)|^p + |\widehat{W}_2(i_2, \widehat{\sigma}(i))|^p.$$

This inequality is obviously true if either $p = 1$ or both $\widehat{W}_1$ and $\widehat{W}_2$ are non-negative. For case (iii) we need to show that

$$\sum_{i,j \in \{i_1, j_2\}} |\widehat{W}_1(i, j) - \widehat{W}_2^{\sigma}(i, j)|^p \le \sum_{i,j \in \{i_1, j_2\}} |\widehat{W}_1(i, j) - \widehat{W}_2^{\widehat{\sigma}}(i, j)|^p.$$

Writing out both sides we see that this is equivalent to

$$|\widehat{W}_1(i_1, i_1) - \widehat{W}_2(i_2, i_2)|^p \le |\widehat{W}_1(i_1, i_1)|^p + |\widehat{W}_2(i_2, i_2)|^p,$$

which is again true if either $p = 1$ or both $\widehat{W}_1$ and $\widehat{W}_2$ are non-negative. ■

Proof of Proposition 6 and Proposition 32 The existence of a coupling follows from Lemma 34 with $D_1 = D_2 = \emptyset$.

To prove the next statement of the proposition, i.e., that the value of $\delta_\square(\mathcal{W}_1, \mathcal{W}_2)$ is independent of the extensions $\widetilde{\mathscr{S}}_i$, we consider alternative extensions $\widehat{\mathscr{S}}_i = (\widehat{S}_i, \widehat{\mathcal{S}}_i, \widehat{\mu}_i)$ of $\mathscr{S}_i$ for $i = 1, 2$, and let $\widehat{\mathcal{W}}_i$ denote the trivial extension of $\mathcal{W}_i$ to $\widehat{\mathscr{S}}_i$. By Lemma 42 it is sufficient to consider the case when $\widetilde{\mu}_i(\widetilde{S}_i \setminus S_i) = \widehat{\mu}_i(\widehat{S}_i \setminus S_i) = \infty$, since if the extensions do not satisfy this property we can extend them to a space of infinite measure, and Lemma 42 shows that the cut norm is unchanged. It is sufficient to prove that, given any coupling measure $\widetilde{\mu}$ on $\widetilde{S}_1 \times \widetilde{S}_2$, we can find a coupling measure $\widehat{\mu}$ on $\widehat{S}_1 \times \widehat{S}_2$, such that

$$\|\widetilde{W}_1^{\pi_1} - \widetilde{W}_2^{\pi_2}\|_{\square, \widetilde{S}_1 \times \widetilde{S}_2, \widetilde{\mu}} = \|\widehat{W}_1^{\pi_1} - \widehat{W}_2^{\pi_2}\|_{\square, \widehat{S}_1 \times \widehat{S}_2, \widehat{\mu}}. \tag{10}$$

By Corollary 40, the left side of (10) only depends on $\widetilde{\mu}$ restricted to $S_1 \times S_2$; in a similar way, the right side only depends on $\widehat{\mu}$ restricted to $S_1 \times S_2$. We therefore can define an appropriate measure $\widehat{\mu}$ on $\widehat{S}_1 \times \widehat{S}_2$ by defining $\widehat{\mu}|_{S_1 \times S_2} = \widetilde{\mu}|_{S_1 \times S_2}$, and extending it to a coupling measure on $\widehat{S}_1 \times \widehat{S}_2$ by Lemma 34; this yields (10).

The function $\delta_\square$ is clearly symmetric and non-negative. To prove that it is a pseudometric it is therefore sufficient to prove that it satisfies the triangle inequality. This is immediate by Lemma 41 and the definition of $\delta_\square$ as given in Definition 5(ii).

The proof for the metric δ_1 follows exactly the same steps.

Using the statements of Lemma 42, Corollary 40, and Lemma 41 for $p > 1$, the above proof of Proposition 6 immediately generalizes to the invariant L^p metric δ_p as long as the graphons in question are non-negative graphons in L^p (in addition to being in L^1, as required by the definition of a graphon). This proves Proposition 32. ■

For two graphons $\mathcal{W} = (W, \mathscr{S})$ and $\widetilde{\mathcal{W}} = (\widetilde{W}, \widetilde{\mathscr{S}})$ for which $\mathscr{S} = \widetilde{\mathscr{S}}$, it is immediate that $\delta_\square(\mathcal{W}, \widetilde{\mathcal{W}}) \le \|W - \widetilde{W}\|_1$. The following lemma gives an analogous bound when W and $\widetilde{W}$ are defined on the same measurable space and $W = \widetilde{W}$, but the measures are not identical. If μ and $\widetilde{\mu}$ are two measures on the same measurable space $(S, \mathcal{S})$ and $a \ge 0$ we write $\mu \le a\widetilde{\mu}$ to mean that $\mu(A) \le a\widetilde{\mu}(A)$ for every $A \in \mathcal{S}$.

Lemma 44 *Let $\mathcal{W} = (W, \mathscr{S})$ with $\mathscr{S} = (S, \mathcal{S}, \mu)$ and $\widetilde{\mathcal{W}} = (W, \widetilde{\mathscr{S}})$ with $\widetilde{\mathscr{S}} = (S, \mathcal{S}, \widetilde{\mu})$ be graphons, and assume there is an $\varepsilon \in (0, 1)$ such that $\mu \le \widetilde{\mu} \le (1 + \varepsilon)\mu$. Then $\delta_\square(\mathcal{W}, \widetilde{\mathcal{W}}) \le 3\varepsilon\|W\|_{1,\mu}$.*

Proof To distinguish between the graphons $\mathcal{W}$ and $\widetilde{\mathcal{W}}$ we will write $\widetilde{\mathcal{W}} = (\widetilde{W}, \widetilde{\mathscr{S}})$ and $\widetilde{\mathscr{S}} = (\widetilde{S}, \widetilde{\mathcal{S}}, \widetilde{\mu})$, but recall throughout the proof that $\widetilde{W} = W$ and $(\widetilde{S}, \widetilde{\mathcal{S}}) = (S, \mathcal{S})$. Define $(S', \mathcal{S}') := (S, \mathcal{S})$, $\mu' := \widetilde{\mu} - \mu$, and $\mathscr{S}' := (S', \mathcal{S}', \mu')$, and let $\mathscr{S}''$ be the disjoint union of $\mathscr{S}$ and $\mathscr{S}'$. Let $\mathcal{W}'' = (W'', \mathscr{S}'')$ be the trivial extension of $\mathcal{W}$ to $\mathscr{S}''$, and note that $\mathcal{W}''$ and $\widetilde{\mathcal{W}}$ are graphons over spaces of equal total measure. Since $\delta_\square(\mathcal{W}'', \mathcal{W}) = 0$ it is sufficient to prove that $\delta_\square(\widetilde{\mathcal{W}}, \mathcal{W}'') \le 3\varepsilon\|W\|_{1,\mu}$. Let $\widehat{\mu}$ be the coupling measure on $\widetilde{S} \times S''$ such that if $\widetilde{A} \in \widetilde{\mathcal{S}}$, $A \in \mathcal{S}$, and $A' \in \mathcal{S}'$, then

$$\widehat{\mu}(\widetilde{A} \times (A \cup A')) = \mu(\widetilde{A} \cap A) + \mu'(\widetilde{A} \cap A'). \tag{11}$$

To complete the proof of the lemma it is sufficient to show that for all measurable sets $U'', V'' \subseteq \widetilde{S} \times S''$,

$$\left| \int_{U'' \times V''} (\widetilde{W}^{\pi_1} - (W'')^{\pi_2}) \, d\widehat{\mu} \, d\widehat{\mu} \right| \leq 3\varepsilon \|W\|_{1,\mu}, \tag{12}$$

where $\pi_1 \colon \widetilde{S} \times S'' \to \widetilde{S}$ (resp. $\pi_2 \colon \widetilde{S} \times S'' \to S''$) is the projection onto the first (resp. second) coordinate of $\widetilde{S} \times S''$. Let $U, V \subseteq \widetilde{S} \times S$ and $U', V' \subseteq \widetilde{S} \times S'$ be such that $U'' = U \cup U'$ and $V'' = V \cup V'$. Recall that since $S' = S$ we may also view U', V' as sets in $\widetilde{S} \times S$, and we denote these sets by U'_S, V'_S, respectively. By first using $W''|_{(S'' \times S'') \setminus (S \times S)} = 0$ while $\widehat{\mu}$-almost surely $\widetilde{W}^{\pi_1} = (W'')^{\pi_2}$ on $(\tilde{S} \times S)^2$, then using $\mu' \leq \varepsilon\mu$, and then using $\widetilde{W} = W$ and (11), we obtain the estimate (12):

$$\begin{aligned}
&\left| \int_{U'' \times V''} \left(\widetilde{W}^{\pi_1} - (W'')^{\pi_2}\right) d\widehat{\mu} \, d\widehat{\mu} \right| \\
&\quad = \left| \int_{U \times V'} \widetilde{W}^{\pi_1} \, d\widehat{\mu} \, d\widehat{\mu} + \int_{U' \times V} \widetilde{W}^{\pi_1} \, d\widehat{\mu} \, d\widehat{\mu} + \int_{U' \times V'} \widetilde{W}^{\pi_1} \, d\widehat{\mu} \, d\widehat{\mu} \right| \\
&\quad \leq \varepsilon \int_{U \times V'_S} |\widetilde{W}|^{\pi_1} \, d\widehat{\mu} \, d\widehat{\mu} + \varepsilon \int_{U'_S \times V} |\widetilde{W}|^{\pi_1} \, d\widehat{\mu} \, d\widehat{\mu} + \varepsilon^2 \int_{U'_S \times V'_S} |\widetilde{W}|^{\pi_1} \, d\widehat{\mu} \, d\widehat{\mu} \\
&\quad \leq 3\varepsilon \|W\|_1.
\end{aligned}$$

■

We close this appendix with a lemma that immediately implies Proposition 21.

Lemma 45 *Let $\varepsilon \geq 0$ and let $\mathcal{W} = (W, (S, \mathcal{S}, \mu))$ and $\mathcal{W}' = (W', (S', \mathcal{S}', \mu'))$ be two graphons with $\delta_\square(\mathcal{W}, \mathcal{W}') \leq \varepsilon^2/2$. Then*

$$\mu(\{D_W > \lambda + 2\varepsilon\}) - \varepsilon \leq \mu'(\{D_{W'} > \lambda + \varepsilon\}) \leq \mu(\{D_W > \lambda\}) + \varepsilon$$

for all $\lambda \geq 0$.

Proof Since the trivial extension of a graphon $\mathcal{W}$ only changes the measure of the set $\{D_W = 0\}$, we may assume without loss of generality that $\mu(S) = \mu'(S')$. Let π_1 and π_2 be the projections from $S \times S'$ onto the two coordinates, let $\varepsilon' > \varepsilon$, and let $\widehat{\mu}$ be a coupling of μ and μ' such that

$$\|W^{\pi_1} - (W')^{\pi_2}\|_{\square,\widehat{\mu}} \leq \frac{(\varepsilon')^2}{2}.$$

By definition of the cut metric, this implies that

$$\left| \int_U (D_W(x) - D_{W'}(x')) \, d\widehat{\mu}(x, x') \right| \leq \frac{(\varepsilon')^2}{2}$$

for all $U \subseteq S \times S'$. Applying this bound for $U = \{(x, x') \in S \times S' \colon D_W(x) - D_{W'}(x') \geq 0\}$ and $U = \{(x, x') \in S \times S' \colon D_W(x) - D_{W'}(x') \leq 0\}$, this implies that

$$\int_{S \times S'} \left| D_W(x) - D_{W'}(x') \right| d\widehat{\mu}(x, x') \leq (\varepsilon')^2,$$

which in turn implies that

$$\widehat{\mu}\left(\{(x, x') \in S \times S' \colon \left|D_W(x) - D_{W'}(x')\right| \geq \varepsilon'\}\right) \leq \varepsilon'.$$

As a consequence

$$\begin{aligned}
\mu(\{D_W > \lambda + 2\varepsilon'\}) - \varepsilon' &\leq \widehat{\mu}(\{(x, x') \colon D_W(x) > \lambda + 2\varepsilon' \text{ and } \left|D_W(x) - D_{W'}(x')\right| < \varepsilon'\}) \\
&\leq \widehat{\mu}(\{(x, x') \colon D_{W'}(x') > \lambda + \varepsilon' \text{ and } \left|D_W(x) - D_{W'}(x')\right| < \varepsilon'\}) \\
&\leq \mu'(\{D_{W'} > \lambda + \varepsilon'\}).
\end{aligned}$$

Taking $\varepsilon' \downarrow \varepsilon$ and using monotone convergence we obtain the first inequality in the statement of the lemma. The second is proved in the same way. ■

Proof of Proposition 21 Let $\varepsilon_n = \delta_\square(\mathcal{W}_n, \mathcal{W})$, and choose n large enough so that $\varepsilon_n < \lambda$. By Lemma 45,

$$\mu_n(\{D_{W_n} > \lambda\}) \leq \mu(\{D_W > \lambda - \varepsilon_n\}) + \varepsilon_n.$$

Since $\mu(\{D_W > \lambda\})$ is assumed to be continuous at λ, this gives

$$\limsup_{n \to \infty} \mu_n(\{D_{W_n} > \lambda\}) \leq \mu(\{D_W > \lambda\}).$$

The matching lower bound on the lim inf is proved in the same way. ■

Appendix B. Representation of Graphons Over $\mathbb{R}_+$

In this appendix we will prove that every graphon is equivalent to a graphon over $\mathbb{R}_+$ (Proposition 10), and prove that under certain assumptions on the underlying measure space of a graphon the cut metric can be defined in a number of equivalent ways (Proposition 48).

The first statement of the following lemma is a generalization of the analogous result for probability spaces, which was considered by Borgs, Chayes, and Lovász (2010, Corollary 3.3) and Janson (2013, Lemma 7.3). It will be used to prove Theorem 15 and Proposition 10. We proceed similarly to the proof by Janson (2013, Lemma 7.3), but in this case we also need to argue that underlying measure space of the constructed graphon is σ-finite, and we include an additional result on atomless measure spaces.

Lemma 46 *Every graphon $\mathcal{W} = (W, \mathscr{S})$ with $\mathscr{S} = (S, \mathcal{S}, \mu)$ is a pullback by a measure-preserving map of a graphon on some σ-finite Borel measure space. If $\mathscr{S}$ is atomless, the σ-finite Borel space can be taken to be atomless as well.*

Proof Let $S_0 := \emptyset$, and let $(S_k)_{k \in \mathbb{N}}$ be such that for each $k \in \mathbb{N}$, we have $S_k \in \mathcal{S}$, $S_k \subseteq S_{k+1}$, $\mu(S_k) < \infty$, and $\bigcup_{k \in \mathbb{N}} S_k = S$. We claim that we can find a sequence of sets $(A_i)_{i \in \mathbb{N}}$ satisfying the following properties: (i) if $\mathcal{A} := \{A_i : i \in \mathbb{N}\}$ and $\mathcal{S}_0 := \sigma(\mathcal{A})$, then W is $\mathcal{S}_0 \times \mathcal{S}_0$-measurable, (ii) for all $k \in \mathbb{N}$ there exists $i \in \mathbb{N}$ such that $A_i = S_k \setminus S_{k-1}$, (iii) for each $i \in \mathbb{N}$ there exists a $k \in \mathbb{N}$ such that $A_i \subseteq S_k \setminus S_{k-1}$, and (iv) $\bigcup_{i \in \mathbb{N}} A_i = S$. A set $\mathcal{A}$ satisfying (i) can be constructed by noting that each level set $\{(x_1, x_2) \in S \times S : W(x_1, x_2) < q\}$

for $q \in \mathbb{Q}$ is measurable with respect to $\sigma(\sigma(\mathcal{A}_q) \times \sigma(\mathcal{A}_q))$ for some countable set $\mathcal{A}_q$ (this follows, for example, by Lemma 3.4 in the paper of Borgs, Chayes, and Lovász, 2010). By adding the sets $S_k \setminus S_{k-1}$ to $\mathcal{A}$ we obtain a collection of sets satisfying (i) and (ii). Given a set $\widetilde{\mathcal{A}}$ satisfying (i) and (ii), we can easily obtain an $\mathcal{A}$ satisfying (i)–(iii) by replacing each $A \in \widetilde{\mathcal{A}}$ with the countable collection of sets $\{A \cap (S_k \setminus S_{k-1}) : k \in \mathbb{N}\}$. Finally, (ii) implies (iv).

Let $\mathcal{C} = \{0,1\}^\infty$ be the Cantor cube equipped with the product topology, and define $\phi\colon S \to \mathcal{C}$ by $\phi(x) := (\mathbf{1}_{x \in A_i})_{i \in \mathbb{N}}$. Let ν be the pushforward measure of μ onto $\mathcal{C}$ equipped with the Borel σ-algebra. We claim that ν is a σ-finite measure on $\mathcal{C}$. For each $k \in \mathbb{N}$ define $\widehat{C}_k := \{(a_i)_{i\in\mathbb{N}} \in \mathcal{C} : a_i = 0 \text{ if } A_i \not\subseteq S_k \setminus S_{k-1}\}$ and $\widetilde{C}_k := (\bigcup_{i \le k} \widehat{C}_i) \cup \widehat{C}_0$, where $\widehat{C}_0 := \mathcal{C} \setminus (\bigcup_{i\in\mathbb{N}} \widehat{C}_i) \subseteq \mathcal{C} \setminus \phi(S)$, and observe that all the subsets of $\mathcal{C}$ just defined are measurable. The claim will follow if we can prove that (a) $\nu(\widetilde{C}_k) < \infty$ for each $k \in \mathbb{N}$, and (b) $\bigcup_{k\in\mathbb{N}} \widetilde{C}_k = \mathcal{C}$. Property (a) is immediate since from the definition of ν, the fact $\nu(\widehat{C}_0) = 0$, and the properties (ii) and (iii) of $\mathcal{A}$, which imply that $\nu(\widehat{C}_k) = \mu(\phi^{-1}(\widehat{C}_k)) = \mu(S_k \setminus S_{k-1}) < \infty$. To prove (b) let $(a_i)_{i\in\mathbb{N}} \in \mathcal{C}$. We want to prove that $(a_i)_{i\in\mathbb{N}} \in \widetilde{C}_k$ for some $k \in \mathbb{N}$. If $(a_i)_{i\in\mathbb{N}} \notin \phi(S)$ we have $x \in \widehat{C}_0$, so $(a_i)_{i\in\mathbb{N}} \in \widetilde{C}_k$ for all $k \in \mathbb{N}$. If $(a_i)_{i\in\mathbb{N}} = \phi(x)$ for some $x \in S$, then $x \in S_k \setminus S_{k-1}$ for exactly one $k \in \mathbb{N}$, so $(a_i)_{i\in\mathbb{N}} = \phi(x) \in \widehat{C}_k \subseteq \widetilde{C}_k$.

The argument in the following paragraph is similar to the proof by Janson (2013, Lemma 7.3), but we repeat it for completeness. Since the σ-field on S generated by ϕ equals $\mathcal{S}_0$, the σ-field on $S \times S$ generated by $(\phi,\phi)\colon S^2 \to \mathcal{C}^2$ equals $\mathcal{S}_0 \times \mathcal{S}_0$. Since W is measurable with respect to $\mathcal{S}_0 \times \mathcal{S}_0$ we may use the Doob-Dynkin Lemma (see, for example, the book of Kallenberg, 2002, Lemma 1.13) to conclude that there exists a measurable function $V\colon \mathcal{C}^2 \to [0,1]$ such that $W = V^\phi$. We may assume V is symmetric upon replacing it by $\frac{1}{2}(V(x,x') + V(x',x))$. This completes the proof of the main assertion, since V is a graphon on a σ-finite Borel measure space.

Finally we will prove the last claim of the lemma, i.e., that if $\mathscr{S}$ is atomless we may take ν to be atomless as well. To prove this claim it is sufficient to establish that the set $\mathcal{A}$ in the above argument can be modified in such a way that $\nu(x) = 0$ for each $x \in \mathcal{C}$. Given a collection of sets $\mathcal{A}$ satisfying (i)–(iv) above we define a new collection of sets $\widetilde{\mathcal{A}}$ as follows. First define $\mathcal{A}_1 := \mathcal{A}$, and then define $\mathcal{A}_k$ for $k > 1$ inductively as follows. For any $k > 1$ and $A \in \mathcal{A}_{k-1}$, let $A^1 \in \mathcal{S}$ and $A^2 \in \mathcal{S}$ be disjoint sets with union A such that $\mu(A^1) = \mu(A^2) = \frac{1}{2}\mu(A)$; note that such sets A^1 and A^2 can be found since $\mathscr{S}$ is atomless. Then define $\mathcal{A}_k := \{A^1 : A \in \mathcal{A}_{k-1}\} \cup \{A^2 : A \in \mathcal{A}_{k-1}\}$, and finally define $\widetilde{\mathcal{A}} = \bigcup_{k\in\mathbb{N}} \mathcal{A}_k$. Then $\widetilde{\mathcal{A}}$ is countable, satisfies (i)–(iv), and by defining the measure ν using $\widetilde{\mathcal{A}}$ instead of $\mathcal{A}$ we have $\nu(x) = 0$ for every $x \in \mathcal{C}$. Proceeding as above with $\widetilde{\mathcal{A}}$ instead of $\mathcal{A}$ we get $W = V^\phi$, where V is a graphon over an atomless σ-finite Borel space. ■

Proposition 10 follows immediately from the following lemma, whose proof in turn follows a similar strategy as a proof by Janson (2013, Theorem 7.1).

Lemma 47 *Let $\mathcal{W} = (W, \mathscr{S})$ be a graphon over an arbitrary σ-finite space $\mathscr{S}$.*

(i) There are two graphons $\mathcal{W}' = (W', \mathbb{R}_+)$ and $\mathcal{W}'' = (W'', \mathscr{S}'')$ and measure-preserving maps $\phi\colon S \to S''$ and $\phi'\colon [0,\mu(S)) \to S''$ such that $W = (W'')^\phi$ and W' is the trivial extension of $(W'')^{\phi'}$ from $[0,\mu(S))$ to $\mathbb{R}_+$.

(ii) If $\mathscr{S}$ is a Borel measure space, then we can find a measure-preserving map

$$\phi'\colon [0,\mu(S)) \to S$$

such that $\mathcal{W}^{\phi'}$ is a graphon over $[0,\mu(S))$ equipped with the Borel σ-algebra and Lebesgue measure.

(iii) If $\mathscr{S}$ is an atomless Borel measure space, we may take ϕ' in (ii) to be an isomorphism between $\mathscr{S}$ and $[0,\mu(S))$.

Proof We start with the proof of (ii) and (iii). If $\mathscr{S}$ is an atomless Borel space the statement is immediate from Lemma 33. If $\mathscr{S}$ has atoms, we define a graphon $\widetilde{\mathcal{W}} = (\widetilde{W}, \widetilde{\mathscr{S}})$ where $\widetilde{\mathscr{S}} = (\widetilde{S}, \widetilde{\mathcal{S}}, \widetilde{\mu}) = (S \times [0,1], \mathcal{S} \times \mathcal{B}, \mu \times \lambda))$ is the product measure space and $\widetilde{W} := (W)^\pi$, with $\pi\colon S \times [0,1] \to S$ being the projection. Since $\widetilde{\mathscr{S}}$ is an atomless Borel space we may again use Lemma 33, giving the existence of an isomorphism $\psi\colon [0,\widetilde{\mu}(\widetilde{S})) \to \widetilde{S}$ such that $\widetilde{W}^\psi$ is a graphon over $[0,\widetilde{\mu}(\widetilde{S}))$ equipped with Lebesgue measure. Observing that $\widetilde{\mu}(\widetilde{S}) = \mu(S)$, we obtain statement (ii) with $\phi' = \pi \circ \psi$.

To prove (i) we use that by Lemma 46, $\mathcal{W}$ can be expressed as $(\mathcal{W}'')^\phi$ for a graphon $\mathcal{W}''$ on some Borel space $\mathscr{S}'' = (S'', \mathcal{S}'', \mu'')$ and some measure-preserving map $\phi\colon S \to S''$. We then apply the just proven statement (ii) to the graphon $\mathcal{W}''$, and define $\mathcal{W}'$ to be the trivial extension of $(\mathcal{W}'')^{\phi'}$ from $[0,\mu(S))$ to $\mathbb{R}_+$. ■

Proof of Proposition 10 The statement of the proposition follows from Lemma 47 by observing that $\delta_\square(\mathcal{W},\mathcal{W}') \le \delta_\square(\mathcal{W},\mathcal{W}'') + \delta_\square(\mathcal{W}'',\mathcal{W}') = \delta_\square((\mathcal{W}'')^\phi,\mathcal{W}'') + \delta_\square(\mathcal{W}'',(\mathcal{W}'')^{\phi'}) = 0$. ■

The following proposition provides equivalent definitions of the cut metric $\delta_\square$ under certain assumption on the underlying measure spaces. See papers by Borgs, Chayes, Lovász, Sós, and Vesztergombi (2008, Lemma 3.5) and Janson (2013, Theorem 6.9) for analogous results for probability spaces.

Proposition 48 *For $j = 1,2$ let $\mathcal{W}_j = (W_j, \mathscr{S}_j)$ with $\mathscr{S}_j = (S_j, \mathcal{S}_j, \mu_j)$ be a graphon satisfying $\mu_j(S_j) = \infty$. Then the following identities hold, and thus (a)–(e) provide alternative definitions of $\delta_\square$ under certain assumptions on the underlying measure spaces:*

(a) If S_j are Borel spaces, then $\delta_\square(\mathcal{W}_1,\mathcal{W}_2) = \inf_{\psi_1,\psi_2} \|W_1^{\psi_1} - W_2^{\psi_2}\|_\square$, where we take the infimum over measure-preserving $\psi_j\colon \mathbb{R}_+ \to S_j$ for $j = 1,2$, where $\mathbb{R}_+$ is equipped with the Borel σ-algebra and Lebesgue measure.

(b) If S_j are atomless Borel spaces, then $\delta_\square(\mathcal{W}_1,\mathcal{W}_2) = \inf_\psi \|W_1 - W_2^\psi\|_\square$, where we take the infimum over measure-preserving $\psi\colon S_1 \to S_2$.

(c) If S_j are atomless Borel spaces, then $\delta_\square(\mathcal{W}_1,\mathcal{W}_2) = \inf_\psi \|W_1 - W_2^\psi\|_\square$, where we take the infimum over isomorphisms $\psi\colon S_1 \to S_2$.

(d) If $S_j = \mathbb{R}_+$, then $\delta_\square(\mathcal{W}_1,\mathcal{W}_2) = \inf_{\widetilde{\sigma}} \|W_1 - W_2^{\widetilde{\sigma}}\|_\square$, where we take the infimum over all interval permutations $\widetilde{\sigma}$ (i.e., $\widetilde{\sigma}$ maps I_i to $I_{\sigma(i)}$ for some permutation σ of the non-negative integers, and $I_i := [ih, (i+1)h]$ for some $h > 0$).

(e) For $j = 1, 2$ let $(S_j^k)_{k\in\mathbb{N}}$ be increasing sets satisfying $\mu_j(S_j^k) < \infty$ and $\bigcup_{k\in\mathbb{N}} S_j^k = S_j$. Then $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = \lim_{k\to\infty} \delta_\square(\mathcal{W}_1|_{S_1^k}, \mathcal{W}_2|_{S_2^k})$, where $\mathcal{W}_j|_{S_j^k} := (W_j \mathbf{1}_{S_j^k\times S_j^k}, \mathscr{S}_j^k)$ and $\mathscr{S}_j^k$ is the restriction of $\mathscr{S}^k$ to S_j^k.

Proof of Proposition 48 Let $\delta_\square^{(a)}$, $\delta_\square^{(b)}$, $\delta_\square^{(c)}$, and $\delta_\square^{(d)}$ denote the right sides of the equalities in (a), (b), (c), and (d), respectively. For $j = 1, 2$ fix some arbitrary sequence $(S_j^k)_{k\in\mathbb{N}}$ satisfying $\mu_j(S_j^k) < \infty$ for all $k \in \mathbb{N}$, $S_j^k \subseteq S_j^{k+1}$, and $\bigcup_{k\in\mathbb{N}} S_j^k = S_j$. Define $\delta_\square^{(e)}$ and $\delta_\square^{(e')}$ by

$$\delta_\square^{(e)}(\mathcal{W}_1, \mathcal{W}_2) := \limsup_{k\to\infty} \delta_\square(\mathcal{W}_1^k, \mathcal{W}_2^k) \quad \text{and} \quad \delta_\square^{(e')}(\mathcal{W}_1, \mathcal{W}_2) := \liminf_{k\to\infty} \delta_\square(\mathcal{W}_1^k, \mathcal{W}_2^k),$$

where $\mathcal{W}_k^j = \mathcal{W}_j|_{S_j^k}$. By Lemma 33 it is sufficient to consider the case $\mathscr{S} = (\mathbb{R}_+, \mathcal{B}, \lambda)$ in (b) and (c), since we can consider graphons $(W_j^{\phi_j}, \mathbb{R}_+)$ on $\mathbb{R}_+$, which satisfy $\delta_\square((W_j^{\phi_j}, \mathbb{R}_+), \mathcal{W}_j) = 0$, by using measure-preserving transformations $\phi_j \colon \mathbb{R}_+ \to S_j$. Under this assumption we have $\delta_\square \le \delta_\square^{(b)} \le \delta_\square^{(c)} \le \delta_\square^{(d)}$, since we take the infimum over smaller and smaller sets of maps. By definition, $\delta_\square^{(e')} \le \delta_\square^{(e)}$. To complete the proof of the proposition it is therefore sufficient to prove the following results: (i) $\delta_\square^{(e)} \le \delta_\square \le \delta_\square^{(e')}$ for general σ-finite measure spaces $\mathscr{S}_1, \mathscr{S}_2$ of infinite measure, (ii) $\delta_\square^{(d)} \le \delta_\square$ for $\mathscr{S}_1 = \mathscr{S}_2 = (\mathbb{R}_+, \mathcal{B}, \lambda)$, and (iii) $\delta_\square^{(a)} = \delta_\square^{(c)}$.

We will start by proving (i). Since $\lim_{k\to\infty} \|W_j - W_j \mathbf{1}_{S_j^k\times S_j^k}\|_1 = 0$, Lemma 36 implies that it is sufficient to prove $\delta_\square^{(e)} \le \delta_\square \le \delta_\square^{(e')}$ for the case when $\operatorname{supp}(W_j) \subseteq S_j^k \times S_j^k$ for some $k \in \mathbb{N}$. Under this assumption $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = \delta_\square(\mathcal{W}_1|_{S_1^{k'}}, \mathcal{W}_2|_{S_2^{k'}})$ for all $k' \ge k$, and (i) follows.

Now we will prove (ii). Since $\lim_{M\to\infty} \|W_j - W_j \mathbf{1}_{|W_j|\le M} \mathbf{1}_{[0,M]^2}\|_1 = 0$ by the dominated convergence theorem, as above we may assume by Lemma 36 that there is an $M > 0$ such that W is bounded and $\operatorname{supp}(W_j) \subseteq [0, M]^2$ for $j = 1, 2$. For $j = 1, 2$ define $\widehat{\mathcal{W}}_j = (\widehat{W}_j, [0, M])$, where $\widehat{W}_j := W_j|_{[0,M]^2}$ is a bounded graphon on $[0, M]^2$. By Lemma 42 in the current paper and Lemma 3.5 of Borgs, Chayes, Lovász, Sós, and Vesztergombi (2008) (or, equivalently, Theorem 6.9 of Janson, 2013),

$$\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = \delta_\square(\widehat{\mathcal{W}}_1, \widehat{\mathcal{W}}_2) = \inf_{\widehat{\sigma}} \|\widehat{W}_1 - \widehat{W}_2^{\widehat{\sigma}}\|_\square \ge \inf_{\widetilde{\sigma}} \|W_1 - W_2^{\widetilde{\sigma}}\|_\square,$$

where $\widehat{\sigma}$ is an interval permutation of $[0, M]$ and $\widetilde{\sigma}$ is an interval permutation of $\mathbb{R}_+$.

Finally we will prove (iii). By Lemma 47 there are measure-preserving maps $\phi_j \colon \mathbb{R}_+ \to S_j$ such that $\delta_\square(\mathcal{W}_j, (\mathcal{W}_j)^{\phi_j}) = 0$. The triangle inequality then implies that $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = \delta_\square((\mathcal{W}_1)^{\phi_1}, (\mathcal{W}_2)^{\phi_2})$. Since $(\mathcal{W}_1)^{\phi_1}$ and $(\mathcal{W}_2)^{\phi_2}$ are graphons over atomless Borel spaces, it follows that $\delta_\square^{(a)} = \delta_\square^{(c)}$. ∎

Remark 49 *The proof of the above proposition clearly generalizes to the metric δ_1, the only additional ingredient being the analogue of a result by Janson (2013, Theorem 6.9) for the metric δ_1 (Janson, 2013, Remark 6.13). Using the results and proof techniques of Borgs, Chayes, Cohn, and Ganguly (2015, Appendix A) instead of Janson (2013, Theorem 6.9), it can also be generalized to the metric δ_p for $p > 1$, again provided both graphons are non-negative and in L^p.*

We close this appendix by proving Proposition 7. In fact, we will prove a generalization of this proposition for the invariant L^p metric δ_p. The second statement of this proposition involves the distance $\delta_p(\mathcal{W}_1, \mathcal{W}_2)$ of graphons $\mathcal{W}_1 = (W_1, \mathbb{R}_+)$ and $\mathcal{W}_2 = (W_2, \mathbb{R}_+)$ that are not necessarily non-negative, which means we do not have Proposition 32 at our disposal to guarantee that δ_p is well defined. We avoid this problem by defining δ_p as in Proposition 48, i.e., by setting

$$\delta_p(\mathcal{W}_1, \mathcal{W}_2) := \inf_{\phi\colon \mathbb{R}_+\to\mathbb{R}_+} \|W_1 - W_2^\phi\|_p$$

with the infimum going over isomorphisms. Note that by Remark 49, for non-negative graphons in L^p, this definition is equivalent to the one given at the beginning of Appendix A.

Proposition 50 *Let $p \ge 1$, and let $\mathcal{W}_1$ and $\mathcal{W}_2$ be graphons in L^p. Then*

(i) $\delta_1(\mathcal{W}_1, \mathcal{W}_2) = 0$ if and only if $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$, and

(ii) if $\mathcal{W}_1$ and $\mathcal{W}_2$ are non-negative or graphons over $\mathbb{R}_+$, then $\delta_p(\mathcal{W}_1, \mathcal{W}_2) = 0$ if and only if $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$.

Proposition 50 (and hence Proposition 7) and Proposition 8 follow from the next proposition.

Proposition 51 *For $i = 1, 2$, let $\mathcal{W}_i = (W_i, \mathscr{S}_i)$ be a graphon over a Borel space $\mathscr{S}_i$ such that $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$ and $\mu_1(S_1) = \mu_2(S_2)$. Then there exists a measure μ on $S_1 \times S_2$ such that*

(i) $\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu} = 0$,

(ii) the first (resp. second) marginal of μ is dominated by μ_1 (resp. μ_2), i.e., for any $A \in \mathcal{S}_1$ (resp. $A \in \mathcal{S}_2$) we have $\mu(A \times S_2) \le \mu_1(A)$ (resp. $\mu(S_1 \times A) \le \mu_2(A)$),

(iii) if $A \in \mathcal{S}_1$ is such that $\mu(A \times S_2) < \mu_1(A)$ then $\mu_1(A \cap E_1) > 0$, where

$$E_i := \left\{ x \in S_i \,:\, \int_{S_i} |W_i(x, x')|\, dx' = 0 \right\} \quad \text{for } i = 1, 2,$$

and the same property holds with the roles of $\mathcal{W}_1$ and $\mathcal{W}_2$ interchanged, and

(iv) in particular, if $\mu_1(E_1) = \mu_2(E_2) = 0$ with E_i as in (iii), then μ is a coupling measure.

Remark 52 *The analogous statement to Proposition 51 for graphons over probability spaces (see, for example, the paper of Janson, 2013, Theorem 6.16) states that when the underlying space is a Borel probability space, the infimum in the definition of the cut distance using couplings is attained. Proposition 51 says that the same result is true in our setting of σ-finite measure spaces if we make two additional assumptions: (a) the cut distance between the graphons is zero, and (b) $\mu_i(E_i) = 0$ for $i = 1, 2$, where E_i is defined in part (iii) of the proposition. We remark that both of these assumptions are necessary; see the examples following this remark.*

Janson (2016, Theorem 5.3) proves a related result, stating that if the cut distance of two graphons over σ-finite Borel spaces is zero, then there are trivial extensions of these graphons such that the extensions can be coupled so as to be equal almost everywhere. Proposition 51 implies a similar result, namely Proposition 8, which states that under this assumption, the restrictions of the two graphons to the sets $S_i \setminus E_i$ can be coupled so that they are equal a.e. To see this, we note that by Proposition 50 two graphons W_1, W_2 with cut distance zero have distance zero in the metric δ_1, which in turn implies that $|W_1|$ and $|W_2|$ have distance zero in δ_1 and hence in $\delta_\square$. By Lemma 45, this in turn implies that $\mu_1(S_1 \setminus E_1) = \mu_2(S_2 \setminus E_2)$, which allows us to use Proposition 51 to deduce the claim.

Example 53 *Assumption (a) in Remark 52 is necessary by the following counterexample, which illustrates that there are graphons $\mathcal{W}_1, \mathcal{W}_2$ over $\mathbb{R}_+$ such that $\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu} > \delta_\square(\mathcal{W}_1, \mathcal{W}_2)$ for all coupling measures μ. Let $\mathcal{W}_1 = (W_1, \mathbb{R}_+)$ be an arbitrary graphon such that W_1 is strictly positive everywhere, and let $\mathcal{W}_2 = (W_2, \mathbb{R}_+)$ be defined by $W_2(x,y) = W_1(x-1, y-1)$ for $x, y \geq 1$, $W_2(x,y) = -1$ for $x, y \in [0,1)$, and $W_2(x,y) = 0$ otherwise. First observe that $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) \leq 1$, since if $\phi_n \colon \mathbb{R}_+ \to \mathbb{R}_+$ is defined by $\phi_n(x) = x + 1$ for $x \in [0, n]$, $\phi_n(x) = x - n$ for $x \in (n, n+1]$, and $\phi_n(x) = x$ for $x > n + 1$, then*

$$\lim_{n\to\infty} \|W_1 - W_2^{\phi_n}\|_\square = 1.$$

Then observe that $\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu} > 1$ for all coupling measures μ, since if $S = \mathbb{R}_+^2$ and $T = \mathbb{R}_+ \times [0,1]$ then

$$\begin{aligned}\|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu} &\geq \left| \int_{S\times T} W_1^{\pi_1} - W_2^{\pi_2} \, d\mu \, d\mu \right| \\ &= \left| \int_{\mathbb{R}_+\times T} W_1(x, \pi_1(y)) \, d\lambda \, d\mu - \int_{\mathbb{R}_+\times[0,1]} W_2 \, d\lambda \, d\lambda \right| > 1.\end{aligned}$$

Assumption (b) is necessary by the following counterexample, which illustrates that there are non-negative graphons $\mathcal{W}_1, \mathcal{W}_2$ over $\mathbb{R}_+$ such that $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$ and $\|W_1 - W_2\|_{\square,\mu} > 0$ for all coupling measures μ. Letting $\mathcal{W}_1$ and $\mathcal{W}_2$ be defined as above, except that $W_2(x,y) = 0$ for all $x, y \in \mathbb{R}_+$ for which either $x < 1$ or $y < 1$, we proceed as in case (a) to conclude that the graphons satisfy the desired property.

Proof of Proposition 51 First we note that for $\mu_1(S_1) = \mu_2(S_2) = 1$, the proposition follows immediately from a result of Janson (2013, Theorem 6.16), which in fact gives μ as a coupling of μ_1 and μ_2. The case $\mu_1(S_1) = \mu_2(S_2) = c < \infty$ with $c \neq 1$ can be reduced to the case $c = 1$ by considering the graphons $\mathcal{W}_i' = (W_i, \mathscr{S}_i')$ where $\mathscr{S}_i'$ is obtained from $\mathscr{S}_i$ by multiplying the measures μ_i by $1/c$, turning them into probability measures. All that is left to consider is therefore the case $\mu_1(S_1) = \mu_2(S_2) = \infty$.

Next we argue that we may assume $\mathscr{S}_i$ is atomless for $i = 1, 2$. Assuming the proposition has been proved for the case of atomless Borel measure spaces, and given graphons $\mathcal{W}_i$ over arbitrary Borel measure spaces, we define graphons $\widetilde{\mathcal{W}}_i$ over the measure space $\widetilde{\mathscr{S}}_i$ defined as the product of $\mathscr{S}_i$ and $[0,1]$, such that $\widetilde{\mathcal{W}}_i = \mathcal{W}_i^{\phi_i}$ for the projection map $\phi_i \colon S_i \times [0,1] \to S_i$. Assume that $\widetilde{\mu}$ is a measure on $\widetilde{S}_1 \times \widetilde{S}_2$ such that the statements of the proposition hold

for $\widetilde{\mu}$ and $\widetilde{\mathcal{W}}_1, \widetilde{\mathcal{W}}_2$. Defining a measure μ for $S_1 \times S_2$ by letting μ be the pushforward of $\widetilde{\mu}$ for the map $\widetilde{S}_1 \times \widetilde{S}_2 \to S_1 \times S_2$ sending $\big((x_1, r_1), (x_2, r_2)\big) \mapsto (x_1, x_2)$, one easily checks that μ is a measure satisfying the conclusions of the proposition for $\mathcal{W}_1$ and $\mathcal{W}_2$. It follows that we may assume the spaces $\mathscr{S}_i$ are atomless Borel measure spaces, and by Lemma 33 we may assume that they are $\mathbb{R}_+$ equipped with the Lebesgue measure; we will make these assumptions in the remainder of the proof. In particular, we will no longer use the notation μ_1 and μ_2 from the proposition statement, since they are now both Lebesgue measure λ; it will be convenient to use the notation μ_n for other purposes.

Consider a sequence of coupling measures $(\mu_n)_{n\in\mathbb{N}}$ such that $\|W_1^{\pi_1} - W_2^{\pi_1}\|_{\square,\mu_n} \to 0$. For any given $M > 0$, let $\mu_n^M = \mu_n|_{[0,M]^2}$. The measures μ_n^M are not necessarily coupling measures, but their marginals are dominated by the Lebesgue measure on $[0, M]$, and they satisfy $\lim_{n\to\infty} \|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu_n^M} = 0$. Furthermore, as a sequence of measures of uniformly bounded total mass over a compact metrizable space, they have a subsequence that converges in the weak topology (Billingsley, 1999, Theorem 5.1), i.e., in the topology in which the integrals over all continuous functions on $[0, M]^2$ converge. Let μ^M be some subsequential limit, and note that as a limit of a sequence of measures having this property, the marginals of μ^M are dominated by the Lebesgue measure on $[0, M]$ as well. Note also that $\mu_n^M \times \mu_n^M$ converges weakly to $\mu^M \times \mu^M$ along any subsequence on which μ_n^M converges weakly to μ^M (Billingsley, 1999, Theorem 2.8). We will argue that

$$\left| \int_{A\times B} \Big(W_1^{\pi_1} - W_2^{\pi_2} \Big) \, d\mu^M \, d\mu^M \right| = 0 \tag{13}$$

for all measurable subsets $A, B \subseteq [0, M]^2$.

Indeed, given two such subsets and $\varepsilon > 0$, let $\widetilde{W}_i$ be continuous functions over $[0, M]^2$ such that $\|W_i - \widetilde{W}_i\|_{1,\lambda|_{[0,M]^2}} \leq \varepsilon$ for $i = 1, 2$, and let $f, g \colon [0, M]^2 \to [0, 1]$ be continuous functions such that $(\|\widetilde{W}_1\|_\infty + \|\widetilde{W}_2\|_\infty)\|\mathbf{1}_A - f\|_{1,\mu^M} \leq \varepsilon$ and $(\|\widetilde{W}_1\|_\infty + \|\widetilde{W}_2\|_\infty)\|\mathbf{1}_B - g\|_{1,\mu^M} \leq \varepsilon$ (existence of appropriate functions $\widetilde{W}_i, f, g$ follows from, for example, Stroock, 2011b, Corollary 3.2.15). Using the fact that $|\int f(x)g(y)(W_1^{\pi_1}(x,y) - W_2^{\pi_2}(x,y)) \, d\mu_n^M \, d\mu_n^M| \leq \|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu_n^M}$ and the fact that the marginals of μ_n^M and μ^M are dominated by the Lebesgue measure on $[0, M]$, this allows us to conclude that for some sufficiently large n chosen from the subsequence along which μ_n^M converges,

$$\begin{aligned}\left| \int_{A\times B} \Big(W_1^{\pi_1} - W_2^{\pi_2} \Big) \, d\mu^M \, d\mu^M \right| &\leq \left| \int_{A\times B} \Big(\widetilde{W}_1^{\pi_1}(x,y) - \widetilde{W}_2^{\pi_2}(x,y) \Big) \, d\mu^M \, d\mu^M \right| + 2\varepsilon \\ &\leq \left| \int f(x)g(y) \Big(\widetilde{W}_1^{\pi_1}(x,y) - \widetilde{W}_2^{\pi_2}(x,y) \Big) \, d\mu^M \, d\mu^M \right| + 4\varepsilon \\ &\leq \left| \int f(x)g(y) \Big(\widetilde{W}_1^{\pi_1}(x,y) - \widetilde{W}_2^{\pi_2}(x,y) \Big) \, d\mu_n^M \, d\mu_n^M \right| + 5\varepsilon \\ &\leq \left| \int f(x)g(y) \Big(W_1^{\pi_1}(x,y) - W_2^{\pi_2}(x,y) \Big) \, d\mu_n^M \, d\mu_n^M \right| + 7\varepsilon \\ &\leq \|W_1^{\pi_1} - W_2^{\pi_2}\|_{\square,\mu_n^M} + 7\varepsilon \leq 8\varepsilon.\end{aligned}$$

Since ε was arbitrary, this proves (13).

For each $M \in \mathbb{N}$ we let μ^M be a measure as in the previous paragraph. We may assume the subsequence along which μ_n^{M+1} converges to μ^{M+1} is a subsequence of the subsequence along which μ_n^M converges to μ^M. This implies that $\mu^{M+1}|_{[0,M]^2} = \mu^M$ for all $M \in \mathbb{N}$, so there is a measure μ on $\mathbb{R}_+^2$ such that $\mu|_{[0,M]^2} = \mu^M$. Furthermore, there is a subsequence of $(\mu_n)_{n\in\mathbb{N}}$ converging weakly to μ, such that for any $M \in \mathbb{N}$ the measures $\mu_n|_{[0,M]^2}$ converge weakly to $\mu|_{[0,M]^2}$ along this subsequence, and as a limit of measures with these properties, the measure μ satisfies (ii), as well as

$$\sup_{A,B\subseteq\mathbb{R}_+^2} \left| \int_{A\times B} W_1^{\pi_1} - W_2^{\pi_2} \, d\mu \, d\mu \right| = 0,$$

where, *a priori*, the supremum is over measurable, bounded subsets $A, B \subset \mathbb{R}_+^2$. But it is easy to see that if the supremum over these sets is zero, then the same holds for the supremum over all measurable subsets $A, B \subseteq \mathbb{R}_+^2$ (use (ii) to conclude that the integrand is in L^1, which means it can be approximated by functions over bounded subsets of $\mathbb{R}_+^4$). The property (i) of μ follows.

It remains to prove that μ satisfies (iii), since (iv) follows immediately from (iii). Recall that the by definition of the measures μ_n,

$$\sup_{A_1,A_2,K} \left| \int_{(A_1\times[K,\infty))\times(A_2\times\mathbb{R}_+)} W_1^{\pi_1} - W_2^{\pi_2} \, d\mu_n \, d\mu_n \right| \to 0,$$

where the supremum is over $A_1, A_2 \subseteq \mathbb{R}_+$ and $K \geq 0$. Fix any $\varepsilon > 0$, and observe that for all $K > 1$ sufficiently large,

$$\sup_{A_1,A_2} \left| \int_{(A_1\times[K,\infty))\times(A_2\times\mathbb{R}_+)} W_2^{\pi_2} \, d\mu_n \, d\mu_n \right| \leq \sup_{A_1,A_2} \int_{[K,\infty)\times\mathbb{R}_+} |W_2| \, d\lambda \, d\lambda < \varepsilon,$$

so

$$\begin{aligned}\limsup_{n\to\infty} \sup_{A_1,A_2} &\left| \int_{(A_1\times[K,\infty))\times A_2} W_1(\pi_1(x), x') \, d\mu_n(x) \, d\lambda(x') \right| \\ &= \limsup_{n\to\infty} \sup_{A_1,A_2} \left| \int_{(A_1\times[K,\infty))\times(A_2\times\mathbb{R}_+)} W_1^{\pi_1} \, d\mu_n \, d\mu_n \right| < \varepsilon.\end{aligned}$$

Fix any $A_1, A_2 \subseteq \mathbb{R}_+$, and observe from the above that for K sufficiently large,

$$\limsup_{n\to\infty} \left| \int_{A_1\times A_2} W_1(x, x') \, d(\lambda - \mu_n^{1,K})(x) \, d\lambda(x') \right| < \varepsilon,$$

where $\mu_n^{1,K}$ is the projection of $\mu_n|_{\mathbb{R}_+\times[0,K]}$ onto the first coordinate. Choose $\widetilde{W}_1 \in C_c(\mathbb{R}_+^2)$ such that $\|\widetilde{W}_1 - W_1\|_1 < \varepsilon$, where $C_c(\mathbb{R}_+^2)$ is the space of continuous and compactly supported functions on $\mathbb{R}_+^2$ (the existence of such a function follows again from, for example, Stroock, 2011b, Corollary 3.2.15). For all $K > 1$ sufficiently large,

$$\left| \int_{A_1\times A_2} \widetilde{W}_1(x, x') \, d(\mu^1 - \mu^{1,K})(x) \, d\lambda(x') \right| < \varepsilon,$$

where $\mu^{1,K}$ (resp. μ^1) is the projection of $\mu|_{\mathbb{R}_+\times[0,K]}$ (resp. μ) onto the first coordinate. Next we claim that $\mu_n^{1,K}|_{[0,K']}$ converges weakly to $\mu^{1,K}|_{[0,K']}$ for any $K, K' > 0$. To see that, we need to show that for any continuous function $f\colon [0, K'] \to \mathbb{R}_+$ the associated integral converges when $n \to \infty$. To this end, we approximate the function $(x, x') \mapsto f(x)\mathbf{1}_{x'\in[0,K]}$ (with $f(x) = 0$ for $x > K'$) by a function $g\colon \mathbb{R}_+^2 \to \mathbb{R}$, where $g(x, x') = \widehat{f}(x)\chi(x')$, $\widehat{f}\colon \mathbb{R}_+ \to \mathbb{R}_+$ is a continuous function with support in $[0, K']$ approximating f and satisfying $\|\widehat{f}\|_\infty \leq \|f\|_\infty$, and $\chi\colon \mathbb{R}_+ \to [0, 1]$ is a continuous function with support in $[0, K]$ approximating the indicator function of the set $[0, K]$. Since $\widehat{f}$ and χ can be chosen to be arbitrarily close approximations in the L^1 norm and the marginals of μ_n are given by Lebesgue measure, this implies the claim. Therefore we can find $n_K \in \mathbb{N}$ depending on K, such that for all $n \geq n_K$

$$\left| \int_{A_1\times A_2} \widetilde{W}_1(x, x') \, d(\mu^{1,K} - \mu_n^{1,K})(x) \, d\lambda(x') \right| < \varepsilon.$$

Combining the above estimates and using the triangle inequality, we get that for sufficiently large K and $n \geq n_K$,

$$\begin{aligned}\left| \int_{A_1\times A_2} W_1(x, x') \, d(\lambda - \mu^1)(x) \, d\lambda(x') \right| \leq{}& \left| \int_{A_1\times A_2} W_1(x, x') - \widetilde{W}_1(x, x') \, d(\lambda - \mu^1)(x) \, d\lambda(x') \right| \\ &+ \left| \int_{A_1\times A_2} \widetilde{W}_1(x, x') \, d(\lambda - \mu_n^{1,K})(x) \, d\lambda(x') \right| \\ &+ \left| \int_{A_1\times A_2} \widetilde{W}_1(x, x') \, d(\mu_n^{1,K} - \mu^{1,K})(x) \, d\lambda(x') \right| \\ &+ \left| \int_{A_1\times A_2} \widetilde{W}_1(x, x') \, d(\mu^{1,K} - \mu^1)(x) \, d\lambda(x') \right| \\ &< 4\varepsilon.\end{aligned}$$

Since $\varepsilon > 0$ was arbitrary this implies that

$$\left| \int_{A_1\times A_2} W_1(x, x') \, d(\lambda - \mu^1)(x) \, d\lambda(x') \right| = 0.$$

Since $\lambda - \mu^1$ is absolutely continuous with respect to λ, we know by the Radon-Nikodym theorem that there is a non-negative function f such that $d(\lambda - \mu^1)(x) = f(x) \, d\lambda(x)$. The Lebesgue differentiation theorem now says that $W_1(x, x')f(x) = 0$ almost everywhere, which implies (iii). ∎

Proof of Proposition 50 Since $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) \leq \delta_1(\mathcal{W}_1, \mathcal{W}_2)$, we only need to prove that $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$ implies $\delta_1(\mathcal{W}_1, \mathcal{W}_2) = 0$ in order to prove (i). Assume first that the graphons are over $\mathbb{R}_+$, and let μ be as in Proposition 51. Then $W_1^{\pi_1} - W_2^{\pi_2} = 0$ μ-almost everywhere. For each $n \in \mathbb{N}$ let μ_n be some arbitrary coupling measure on $S_1 \times S_2$ such that $\mu_n|_{[0,n]^2} = \mu|_{[0,n]^2}$. Then $\lim_{n\to\infty} \|W_1^{\pi_1} - W_2^{\pi_2}\|_{1,\mu_n} = 0$, so $\delta_1(\mathcal{W}_1, \mathcal{W}_2) = 0$. To obtain the result for graphons over general measure spaces we use Proposition 10, the triangle inequality, and the fact that two graphons have distance zero for $\delta_\square$ and δ_1 if one is a pullback of the other.

For (ii) with graphons over $\mathbb{R}_+$ and $\delta_\square$ defined in terms of measure-preserving transformations, we will first prove that $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$ implies $\delta_p(\mathcal{W}_1, \mathcal{W}_2) = 0$. This follows by the exact same argument as in the preceding paragraph, i.e., by using Proposition 51 to construct a measure μ and coupling measures μ_n on $S_1 \times S_2$.

Now we will prove that $\delta_p(\mathcal{W}_1, \mathcal{W}_2) = 0$ implies $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$, still assuming the graphons are over $\mathbb{R}_+$ and that δ_p is defined in terms of measure-preserving transformations. By part (i) it is sufficient to show that $\delta_p(\mathcal{W}_1, \mathcal{W}_2) = 0$ implies $\delta_1(\mathcal{W}_1, \mathcal{W}_2) = 0$. Fix $\varepsilon > 0$ and let $A_1, A_2 \subseteq \mathbb{R}_+$ be such that $\|W_i - W_i \mathbf{1}_{A_i \times A_i}\|_1 < \varepsilon/2$ and $M := \lambda(A_1) + \lambda(A_2) < \infty$. By Hölder's inequality, for any isomorphism $\phi\colon \mathbb{R}_+ \to \mathbb{R}_+$ and $A := A_1 \cup \phi^{-1}(A_2)$,

$$\begin{aligned}\|W_1 - W_2^\phi\|_1 &\leq \|(\mathbf{1} - \mathbf{1}_{A\times A})(W_1 - W_2^\phi)\|_1 + \|(W_1 - W_2^\phi)\mathbf{1}_{A\times A}\|_1 \\ &\leq \varepsilon + \|W_1 - W_2^\phi\|_p \cdot M^{2-2/p}.\end{aligned}$$

Taking the infimum over ϕ we see that $\delta_1(\mathcal{W}_1, \mathcal{W}_2) \leq \varepsilon + M^{2-2/p}\delta_p(\mathcal{W}_1, \mathcal{W}_2) = \varepsilon$. Since ε was arbitrary, this shows that $\delta_1(\mathcal{W}_1, \mathcal{W}_2) = 0$.

We get (ii) for non-negative graphons and δ_p defined in terms of couplings by using Proposition 48 and Remark 49, and to move from graphons over $\mathbb{R}_+$ to graphons over a general σ-finite space we use Lemma 47. ■

Appendix C. Measurability properties of graph processes

Recall the definition of a graph process (Definition 23) and the measurable space of graphs $\mathbb{G}$, as well as what it means for two graph processes to be equal up to relabeling of the vertices (Definition 24). Before stating our main result about the measurability of the relation of being equal up to relabeling, we state and prove the following simple lemma.

Lemma 54 *Let $\mathcal{G} = (G_t)_{t\geq 0}$ be a graph process.*

(i) Let $V \subset V' \subset \mathbb{N}$ and $E \subset E' \subset \binom{\mathbb{N}}{2}$ be finite sets. Then there are increasing sequences $(a_k)_{k\in\mathbb{N}}$ and $(b_k)_{k\in\mathbb{N}}$ of real numbers such that

$$\{t \in \mathbb{R}_+ \colon V' \cap V(G_t) = V \text{ and } E' \cap E(G_t) = E\} = \bigcup_{k\in\mathbb{N}} [a_k, b_k).$$

Furthermore, for any set of the form $T = \bigcup_{k\in\mathbb{N}}[a_k, b_k)$ with a_k, b_k as above, the event that $T = \{t \in \mathbb{R}_+ \colon V' \cap V(G_t) = V \text{ and } E' \cap E(G_t) = E\}$ is measurable.

(ii) For $i = 1, 2$ let $V_i \subset V_i' \subset \mathbb{N}$ and $E_i \subset E_i' \subset \binom{\mathbb{N}}{2}$ be finite sets, let $\mathcal{G}^i = (G_t^i)_{t\geq 0}$ be a graph process, and let $T_i(\mathcal{G}^i)$ be the set of times for which $V_i' \cap V(G_t^i) = V_i$ and $E_i' \cap E(G_t^i) = E_i$. Then the event that $T_1(\mathcal{G}^1) = T_2(\mathcal{G}^2)$ is measurable.

(iii) The event that a specified vertex in $\mathbb{N}$ is isolated for all times is measurable.

(iv) If $\mathcal{G} = (G_t)_{t\geq 0}$ is projective, then the birth time $t_v \in [0, \infty]$ of any vertex $v \in \mathbb{N}$ is measurable, and under the assumptions (5) from Section 2.4, the map defined in (4) is measurable, where the σ-algebra used on the space of measures is defined above (4).

Proof The time set considered in (i) takes the required form since the set of graphs $\{G\colon V' \cap V(G) = V \text{ and } E' \cap E(G) = E\}$ is an open set in $\mathbb{G}$ and since $\mathcal{G} = (G_t)_{t\geq 0}$ is càdlàg. The measurability claim in (i) follows since the event in question occurs if and only if the two time sets have the same intersection with $\mathbb{Q}$. The statement (ii) follows by a similar argument. Both statements (iii) and (iv) immediately follow from (i). ■

Proposition 55 *The event that two graph processes $(G_t)_{t\geq 0}$ and $(\widehat{G}_t)_{t\geq 0}$ are equal up to relabeling is measurable.*

Proof The proposition is immediate in the case where $\bigcup_{t\geq 0} V(G_t)$ or $\bigcup_{t\geq 0} V(\widehat{G}_t)$ is finite, since the set of maps $\phi\colon [n] \to [n]$ is finite, and given any ϕ the event that this map satisfies the requirements of Definition 24 is measurable by Lemma 54. We may therefore assume that both $\bigcup_{t\geq 0} V(G_t)$ and $\bigcup_{t\geq 0} V(\widehat{G}_t)$ are infinite. We may further assume without loss of generality that $\bigcup_{t\geq 0} V(G_t) = \bigcup_{t\geq 0} V(\widehat{G}_t) = \mathbb{N}$; we may do this upon relabeling the vertices of both graph processes.

Next, we reduce the proof of the proposition to the case where no vertices are isolated for all times. For $V \subseteq \mathbb{N}$ let G_t^V denote the induced subgraph of G_t that has vertex set $V \cap V(G_t)$. Let $V_0 \subseteq \mathbb{N}$ (resp. $\widehat{V}_0 \subseteq \mathbb{N}$) denote the set of vertices for $(G_t)_{t\geq 0}$ (resp. $(\widehat{G}_t)_{t\geq 0}$) that are isolated for all times. Then $(G_t)_{t\geq 0}$ and $(\widehat{G}_t)_{t\geq 0}$ are equal up to relabeling of the vertices if and only if this property holds for $(G_t^{V_0})_{t\geq 0}$ and $(\widehat{G}_t^{\widehat{V}_0})_{t\geq 0}$ and for $(G_t^{\mathbb{N}\setminus V_0})_{t\geq 0}$ and $(\widehat{G}_t^{\mathbb{N}\setminus\widehat{V}_0})_{t\geq 0}$. To reduce to the case in which no vertices are isolated for all times, it is sufficient to show measurability of the event that $(G_t^{V_0})_{t\geq 0}$ and $(\widehat{G}_t^{\widehat{V}_0})_{t\geq 0}$ are equal up to relabeling of the vertices. We say that two vertices $i, j \in V_0$ are equivalent if $\{t \geq 0 : i \in V(G_t^{V_0})\} = \{t \geq 0 : j \in V(G_t^{V_0})\}$. Equivalence for two vertices $i, j \in \widehat{V}_0$ and for two vertices $i \in V_0$ and $j \in \widehat{V}_0$ is defined similarly. We observe that $(G_t^{V_0})_{t\geq 0}$ and $(\widehat{G}_t^{\widehat{V}_0})_{t\geq 0}$ are equal up to relabeling of the vertices if and only if each equivalence class has equal cardinality in V_0 and $\widehat{V}_0$. The latter event is measurable, since for any two vertices the event that these two vertices are equivalent is measurable by Lemma 54. Thus, we can assume that no vertices are permanently isolated.

To complete the proof, we must determine whether there exists a bijection $\phi_0\colon \mathbb{N} \to \mathbb{N}$ satisfying the properties of the map ϕ in Definition 24, i.e., whether there is a bijective map $\phi_0\colon \mathbb{N} \to \mathbb{N}$ such that for all times $t \geq 0$, $\phi_0(G_t) = \widehat{G}_t$. We will construct such a map by first constructing a sequence of maps ϕ_n defined on a growing sequence of domains, and then using a subsequence construction to transform them into a map $\phi_0\colon \mathbb{N} \to \mathbb{N}$ with the desired properties. We will show that this construction succeeds if and only if the two graph processes are equal up to relabeling.

To construct the maps ϕ_n, we define A_n^0 to be the set of injective maps $\phi\colon D \to \mathbb{N}$ such that D is finite, $\{1, \ldots, \lceil n/2 \rceil\} \subseteq D$, and $\{1, \ldots, \lfloor n/2 \rfloor\} \subseteq \phi(D)$. Let A_n to be the set of maps $\phi \in A_n^0$ such that $\phi(G_t^D) = \widehat{G}_t^{\phi(D)}$ for all $t \geq 0$. Note that A_n is non-empty for all n if the two graph processes are equal up to relabeling (just choose ϕ to be a restriction of the bijection ϕ_0). Note further that the set A_n^0 is countable, and that for each $\phi \in A_n^0$ the event that $\phi \in A_n$ is measurable by Lemma 54.

After these preparations, we are ready to construct the map ϕ_0. First we define $\phi_0(1)$. For each $j \in \mathbb{N}$ define the event B_j by $B_j = \bigcap_{n\in\mathbb{N}} B_{j,n}$, where $B_{j,n}$ is the event that there exists a map $\phi \in A_n$ for which $\phi(1) = j$. If the graph processes are equal up to relabeling, then B_j must occur for some j. We will prove that conversely, if B_j occurs for some j, then the graph processes are equal up to relabeling. Since B_j is a countable intersection of measurable events, this will finish our proof that the event that the two graph processes are equal up to relabeling is measurable.

To prove that the event B_j implies the existence of a bijection ϕ_0 such that $\phi_0(G_t) = \widehat{G}_t$ for all $t \geq 0$, we first note that the occurrence of B_j implies the existence of a sequence of maps $\phi_n \in A_n$ such that $\phi_n(1) = j$. Accordingly, we set $\phi_0(1) = j$. In the second step of the construction (explained below), we will determine $\phi_0^{-1}(1)$ by passing to a subsequence for which $\phi_n^{-1}(1)$ is constant. More generally, in the kth step of the construction, we will pass to a subsequence to ensure that $\phi_n(i)$ is constant for $1 \leq i \leq \lceil k/2 \rceil$ and $\phi_n^{-1}(i)$ is constant for $1 \leq i \leq \lfloor k/2 \rfloor$.

We will carry out this construction by induction on k. Suppose that we have defined $\phi_0(1), \ldots, \phi_0(\lceil k/2 \rceil)$ and $\phi_0^{-1}(1), \ldots, \phi_0^{-1}(\lfloor k/2 \rfloor)$ so that there exists a sequence $(\phi_n^k)_{n\geq k}$ of maps $\phi_n^k \in A_n$ for which

$$\begin{aligned} \phi_n^k(i) &= \phi_0(i) && \text{for all } n \geq k \text{ and all } i \leq \lceil k/2 \rceil, \text{ and} \\ (\phi_n^k)^{-1}(i) &= \phi_0^{-1}(i) && \text{for all } n \geq k \text{ and all } i \leq \lfloor k/2 \rfloor. \end{aligned}$$

Assume first that k is odd, in which case we need to define $\phi_0^{-1}(\lfloor (k+1)/2 \rfloor)$. Choose t in such a way that $\lfloor (k+1)/2 \rfloor$ is not isolated in $\widehat{G}_t$. Then $(\phi_n^k)^{-1}(\lfloor (k+1)/2 \rfloor)$ cannot be isolated in G_t either, and since G_t contains only a finite number of edges, we know there exists a finite set V such that for all $n \geq k$, $(\phi_n^k)^{-1}(\lfloor (k+1)/2 \rfloor) \in V$. But this implies that we can find a subsequence of $(\phi_n^k)_{n\geq k}$ on which $(\phi_n^k)^{-1}(\lfloor (k+1)/2 \rfloor)$ takes a fixed value, which we use to define $\phi_0^{-1}(\lfloor (k+1)/2 \rfloor)$. To conclude we need to prove the existence of a sequence $\phi_n^{k+1} \in A_n$ satisfying the induction hypothesis. For n in the subsequence obtained above we define $\phi_n^{k+1} = \phi_n^k$. To turn this subsequence into a sequence $\phi_n^{k+1} \in A_n$ defined for all $n \geq k+1$, we can simply reuse elements to fill in any gaps that occur before them, because $A_n \subset A_m$ for $m < n$. This completes the proof when k is odd, and the even case differs only in notation. ■

Appendix D. Random Graph Models

The main goal of this appendix is to establish Theorems 27 and 28. Proposition 56 will be used to prove left convergence of graphon processes in Section 2.5. It will also be applied in the proof of Theorem 28(i) in this appendix, where we need to consider the normalized number of edges in a graphon process.

A result of Lovász and Szegedy (2006, Corollary 2.6) in the setting of graphons over probability spaces is closely related to the following proposition. However, the proofs are different, even if both rely on martingale techniques. Note that in the course of proving the below proposition we give an alternative proof of a result of Veitch and Roy (2015, Theorem 5.3) for the special case of graphs with no self-edges. Recall from Section 2.5 that

for a simple graph F and a simple graph G we let $\mathrm{inj}(F, G)$ denote the number of injective adjacency preserving maps $\phi\colon V(F) \to V(G)$.

Proposition 56 *Let $\mathcal{W} = (W, \mathscr{S})$, where $W\colon S \times S \to [0,1]$ is a symmetric, measurable (but not necessarily integrable) function, and $\mathscr{S} = (S, \mathcal{S}, \mu)$ is a σ-finite measure space. Let F be a simple graph with vertex set $V(F) = \{1, \ldots, k\}$ for $k \geq 2$, such that F has no isolated vertices. Then a.s.*

$$\lim_{t\to\infty} t^{-k}\mathrm{inj}(F, G_t(\mathcal{W})) = \int_{S^k} \prod_{(i,j)\in E(F)} W(x_i, x_j)\, dx_1 \cdots dx_k, \tag{14}$$

where both sides should be read as elements of the extended non-negative reals $[0, \infty]$.

Remark 57 *Note that the proposition makes no integrability assumptions on W. All that is used is that W is measurable. As a consequence, the proposition can deal with situations where, say, the triangle density converges, even though $G_t(\mathcal{W})$ has infinitely many edges. An extreme example of such a behavior can be obtained by taking $\mathcal{W} = (W, \mathbb{R}_+)$ to be the "bipartite" graphon defined by $W(x,y) = \sum_{i,j\in\mathbb{N}} \mathbf{1}_{2i-2<x<2i-1}\mathbf{1}_{2j-1<y<2j} + \sum_{i,j\in\mathbb{N}} \mathbf{1}_{2i-1<x<2i}\mathbf{1}_{2j-2<y<2j-1}$, leading to a sequence of graphs $G_t(\mathcal{W})$ where every vertex has a.s. infinite degree, while all subgraph frequencies for graphs F that are not bipartite converge to zero.*

Proof of Proposition 56 We first prove the proposition under the assumption that the right side of (14) is finite. Throughout the proof we let $G_t := \widetilde{G}_t(\mathcal{W})$ be the graphon process generated by $\mathcal{W}$ with isolated vertices. Note that the left side of (14) is invariant under replacing $G_t(\mathcal{W})$ with $\widetilde{G}_t(\mathcal{W})$, because F has no isolated vertices. For each $t > 0$ define Y_{-t} to be the left side of (14) (with $G_t(\mathcal{W})$ replaced by G_t), i.e.,

$$Y_{-t} := t^{-k}\,\mathrm{inj}(F, G_t) = t^{-k} \sum_{v_1,\ldots,v_k\in V(G_t)} \prod_{(i,j)\in E(F)} \mathbf{1}_{(v_i,v_j)\in E(G_t)}.$$

As a first step, we will prove that for each $t > 0$,

$$\mathbb{E}[Y_{-t}] = \int_{S^k} \prod_{(i,j)\in E(F)} W(x_i, x_j)\, dx_1 \cdots dx_k. \tag{15}$$

We may assume that $\mu(S) < \infty$, since we can write S as a union of increasing sets S_m of finite measure for each $m \in \mathbb{N}$, and by the monotone convergence theorem it is sufficient to establish (15) with W replaced by $W\mathbf{1}_{S_m\times S_m}$, and with Y_{-t} defined in terms of graphs where we only consider vertices $v = (t, x)$ for which $x \in S_m$. If $N := |V(G_t)| < k$, then $Y_{-t} = 0$. If $N \geq k$, then

$$\mathbb{E}[Y_{-t} \,|\, N] = \frac{1}{t^k}\frac{N!}{(N-k)!}\frac{1}{\mu(S)^k}\int_{S^k} \prod_{(i,j)\in E(F)} W(x_i, x_j)\, dx_1 \cdots dx_k,$$

since we can form $\frac{N!}{(N-k)!}$ ordered sets of size k from $V(G_t)$, and the probability that a uniformly chosen injective map from $V(F)$ to $V(G_t)$ is a homomorphism, is given by

$$\frac{1}{\mu(S)^k}\int_{S^k} \prod_{(i,j)\in E(F)} W(x_i, x_j)\, dx_1 \cdots dx_k.$$

Since N has the law of a Poisson random variable with parameter $t\mu(S)$ we can conclude that (15) holds:

$$\begin{aligned}\mathbb{E}[Y_{-t}] &= \sum_{n=0}^{\infty} \mathbb{P}(N=n)\mathbb{E}[Y_{-t} \,|\, N=n] \\ &= \sum_{n=k}^{\infty} \frac{(t\mu(S))^n}{n!} e^{-t\mu(S)} \frac{1}{t^k} \frac{n!}{(n-k)!} \frac{1}{\mu(S)^k} \int_{S^k} \prod_{(i,j)\in E(F)} W(x_i,x_j)\, dx_1 \cdots dx_k \\ &= \int_{S^k} \prod_{(i,j)\in E(F)} W(x_i,x_j)\, dx_1 \cdots dx_k,\end{aligned}$$

implying in particular that Y_t is integrable for all $t < 0$ given that for now we assumed that the right side of (14) is finite. Note that in particular this implies that Y_t is a.s. finite, even though W may be such that the event that G_t has infinitely many edges has non-zero probability.

Let $\widehat{G}_t$ be identical to G_t, except that a vertex $v = (t,x) \in V(G_t)$ is labeled only with x. In order words, conditioning on a realization of $\widehat{G}_t$ is equivalent to conditioning on a realization of G_t, except that the time the different vertices were born (i.e., the time they appeared in the graphon process $(\widetilde{G}_t)_{t\geq 0}$) is unknown. Note that since S may have point masses multiple vertices of $\widehat{G}_t$ may have the same label, but they are still considered to be different. For $t \leq -1$, define $\mathcal{S}_t$ to be the σ-algebra generated by $(\widehat{G}_s)_{s\geq -t}$. Then $\mathcal{S}_s \subseteq \mathcal{S}_t$ for $s \leq t \leq -1$, so $(\mathcal{S}_t)_{t\leq -1}$ is a filtration, and Y_t is measurable with respect to $\widehat{G}_{-t}$ and hence $\mathcal{S}_t$; in other words, $(Y_t)_{t\leq -1}$ is adapted to the filtration.

Let $t > s > 0$. Given any k distinct vertices in $\widehat{G}_t$, the probability (conditioned on $(\widehat{G}_{t'})_{t'\geq t}$) that all k vertices are also in $\widehat{G}_s$ is given by $(s/t)^k$. Since $\widehat{G}_s$ is an induced subgraph of $\widehat{G}_t$, it follows that

$$\begin{aligned}\mathbb{E}[Y_{-s} \,|\, \mathcal{S}_{-t}] &= \mathbb{E}[Y_{-s} \,|\, (\widehat{G}_{t'})_{t'\geq t}] \\ &= \frac{1}{s^k} \sum_{v_1,\ldots,v_k \in V(\widehat{G}_t)} \prod_{(i,j)\in E(F)} \mathbf{1}_{(v_i,v_j)\in E(G_t)} \cdot \\ &\qquad\qquad \mathcal{P}\big(v_1,\ldots,v_k \in V(\widehat{G}_s) \,|\, v_1,\ldots,v_k \in V(\widehat{G}_t)\big) \\ &= Y_{-t},\end{aligned}$$

proving that $(Y_t)_{t<0}$ is a backwards martingale. The limit $Y_{-\infty} = \lim_{t\to\infty, t\in\mathbb{Q}} Y_{-t}$ exists almost surely (Kallenberg, 2002, Theorem 7.18). Since $\mathbb{E}[Y_{-t}] < \infty$ for all $t > 0$ we know that a.s., $Y_{-t} < \infty$ for all $t > 0$, which implies that a.s., $|E(G_t)| < \infty$ for all $t > 0$. Therefore $(Y_t)_{t<0}$ has finitely many discontinuities in any bounded interval, and is left-continuous with limits from the right. It follows that $Y_{-\infty} = \lim_{t\to\infty} Y_{-t}$; i.e., we do not need to take the limit along rationals.

To complete the proof it is sufficient to prove that the limit $Y_{-\infty}$ is equal to the right side of (15) almost surely. To establish this it is sufficient to prove that $Y_{-\infty}$ is equal to a deterministic constant almost surely, since $(Y_t)_{t<0}$ is uniformly integrable (Kallenberg, 2002, Theorem 7.21), which implies that $(Y_t)_{t<0}$ converges to $Y_{-\infty}$ also in L^1.

We will use the Kolmogorov 0-1 law (Stroock, 2011a, Theorem 1.1.2) to deduce this. For any $n \in \mathbb{N}$ define $\mathcal{V}_n := \{(s,x) \in \mathcal{V} : n-1 \leq s < n\}$. Let $\mathcal{F}_n$ be the σ-algebra generated by the set $\mathcal{V}_n$ and the edges between the vertex set $\mathcal{V}_n$ and the vertex set $\bigcup_{1\leq m\leq n} \mathcal{V}_m$. Since the randomness of the edges can be represented as an infinite sequence of independent uniform random variables, the σ-algebras $\mathcal{F}_n$ can be considered independent even if the edges considered in $\mathcal{F}_n$ join vertices in $\mathcal{V}_n$ and $\mathcal{V}_m$ for $m < n$. In order to apply the 0-1 law it is sufficient to prove that $Y_{-\infty}$ is measurable with respect to the σ-algebra generated by $\bigcup_{n\geq n_0} \mathcal{F}_n$ for all $n_0 \in \mathbb{N}$.

Define $Y_{-t,\geq n_0}$ in the same way as Y_{-t}, except that instead of summing over vertices in $V(G_t)$, we sum over vertices in $V(G_t) \cap \mathcal{V}_{\geq n_0}$, where $\mathcal{V}_{\geq n_0} = \bigcup_{n\geq n_0} \mathcal{V}_n$. Since $Y_{-t,\geq n_0}$ is measurable with respect to the σ-algebra generated by $\bigcup_{n\geq n_0} \mathcal{F}_n$, all we need to show is that for all $n \geq n_0$, a.s., $Y_{-t} - Y_{-t,\geq n_0} \to 0$ as $t \to \infty$. The difference between Y_{-t} and $Y_{-t,\geq n_0}$ can then be bounded by

$$t^{-k} \sum_{\substack{v_1,\ldots,v_k \in V(G_t) \\ t_i \leq n_0 \text{ for some } i\in[k]}} \prod_{(i,j)\in E(F)} \mathbf{1}_{(v_i,v_j)\in E(G_t)},$$

where t_i is the time label of v_i. Conditioned on $v_1,\ldots,v_k \in V(G_t)$, the probability that at least one of them has time label $t_i \leq t_0$ is bounded by kt_0/t. Continuing as in the proof of (15), we therefore obtain that

$$0 \leq \mathbb{E}[Y_{-t} - Y_{-t,\geq n_0}] \leq k\Big(\frac{t_0}{t}\Big) \int_{S^k} \prod_{(i,j)\in E(F)} W(x_i,x_j)\, dx_1 \cdots dx_k. \tag{16}$$

Since the limit $Y_{-\infty} = \lim_{t\to\infty} Y_{-t}$ exists, we can calculate $Y_{-\infty}$ along any sequence, say the sequence $(Y_{-n^2})_{n\in\mathbb{N}}$. The bound (16) combined with Markov's inequality and the Borel-Cantelli lemma therefore implies that $Y_{-\infty} = \lim_{n\to\infty} Y_{-n^2,\geq n_0}$, proving that $Y_{-\infty}$ is measurable with respect to the σ-algebra generated by $\bigcup_{n\geq n_0} \mathcal{F}_n$, as required for the application of the 0-1 law.

This completes the proof of the proposition under the assumption that the right side of (14) is finite. If the right side is infinite, we note that for any set A of finite measure (14) holds with $W\mathbf{1}_{A\times A}$ instead of W on both the left side and the right side. We can make the right side arbitrarily large by increasing A. The left side is monotone in A, and therefore the limit inferior of the left side (with W, not $W\mathbf{1}_{A\times A}$) is larger than any fixed constant, and hence is equal ∞. ■

Proof of Theorem 28 (i) Since the result of the theorem is immediate for $\|W\|_1 = 0$, we will assume throughout the proof that $\|W\|_1 > 0$. Since $\delta_\square(\widetilde{G}_t, G_t) = 0$ by (3), it is enough to prove the statement for either $(\widetilde{G}_t)_{t\geq 0}$ or $(G_t)_{t\geq 0}$.

If S has finite total mass, then, a.s., $|V(\widetilde{G}_t)|$ is finite for each fixed $t \geq 0$, and conditioned on the size of $|V(\widetilde{G}_t)|$, the graph $\widetilde{G}_t$ is a $\mathcal{W}$-random graph in the sense of the theory of dense graph convergence. The results of Borgs, Chayes, Lovász, Sós, and Vesztergombi (2008) imply that $\delta_\square(\widetilde{G}_t, \widetilde{\mathcal{W}}) \to 0$ and $\|W^{\widetilde{G}_t}\|_1 \to \|\widetilde{W}\|_1$ where $\widetilde{\mathcal{W}} = (\widetilde{W}, \widetilde{\mathscr{S}})$ is obtained from $\mathcal{W}$ by normalizing the measure to a probability measure (giving, in particular, $\|\widetilde{W}\|_1 = \|W\|_1/\pi(S)^2$.) Combined with Lemma 44, this implies that $\delta^{\mathrm{s}}_\square(\widetilde{G}_t, \mathcal{W}) \to 0$ when $\pi(S) < \infty$.

If $\pi(S) = \infty$, we use Lemma 47, and the observation that two graphons generate graphon processes with the same law if one graphon is a pullback of the other, to reduce the proof to the case $\mathscr{S} = (\mathbb{R}_+, \mathcal{B}, \lambda)$. Given $0 < \varepsilon < 1/2$ choose $M > 0$ such that $\|W - W\mathbf{1}_{[0,M]^2}\|_1 < \varepsilon\|W\|_1$, and define $\mathcal{W}_M$ to be the graphon $W_M = W\mathbf{1}_{[0,M]^2}$ over $[0, M]$, and $\widetilde{G}_t^M$ to be the induced subgraph of $\widetilde{G}_t$ on the set of vertices (s, x) such that $x \le M$. Define $\widetilde{W}^{\widetilde{G}_t^M,s} := W^{\widetilde{G}_t^M}(\lambda_M \cdot, \lambda_M \cdot)$ with $\lambda_M := M^{-1}\|W\|_1^{1/2}$. In the cut metric $\delta_\square$, the stretched graphon $\widetilde{W}^{\widetilde{G}_t^M,s}$ then converges to $\widetilde{W}_M^s := W_M(\|W\|_1^{1/2} \cdot, \|W\|_1^{1/2} \cdot)$, again by the convergence of $\mathcal{W}$-random graphs for $\mathcal{W}$ defined on a probability space.

Furthermore, by Proposition 56 applied to the graph F consisting of a single edge, we have that a.s., the number of edges in $\widetilde{G}_t^M$ divided by t^2 converges to $\frac{1}{2}\|W\mathbf{1}_{[0,M]^2}\|_1$, so in particular the time t_M where $\widetilde{G}_t^M$ has at least one edge is a.s. finite. For the rest of this proof, we will always assume that $t \ge t_M$.

Defining G_t' to be the graph obtained from $\widetilde{G}_t$ by removing all isolated vertices (s, x) from $V(\widetilde{G}_t)$ for which $x > M$, we note that by (3), it is sufficient to prove that $\delta_\square^s(G_t', \mathcal{W}) \to 0$. Recall that each vertex $v = (s, x)$ of G_t' corresponds to an interval when we define the stretched canonical graphon $\mathcal{W}^{G_t',s}$ of G_t'. Assume the intervals are ordered according the value of x; i.e., if the vertices $v = (s, x)$ and $v' = (s', x')$ satisfy $x < x'$, then the interval corresponding to v is to the left on the real line of the interval corresponding to v'. Noting that by our assumption $t \ge t_M$, there exists at last one vertex $v = (s, x)$ in G_t' such that $x \le M$, we define the graphon $\widetilde{\mathcal{W}}^{G_t',s} = (\widetilde{W}^{G_t',s}, \mathbb{R}_+)$ to be a "stretched" version of $\mathcal{W}^{G_t'}$ such that the vertices $v = (s, x)$ for which $x \in [0, M]$ correspond to the interval $[0, \lambda_M^{-1}]$. In other words, $\widetilde{W}^{G_t',s} = W^{G_t',s}(r_t \cdot, r_t \cdot)$ for some appropriately chosen constant $r_t > 0$. To calculate r_t, we note that $W^{G_t',s} = W^{G_t'}(\lambda \cdot, \lambda \cdot)$ with $\lambda = \|W^{G_t'}\|_1^{1/2} = |V(G_t')|^{-1}\sqrt{2|E(G_t')|}$ and $\widetilde{W}^{G_t',s} = W^{G_t'}(\lambda' \cdot, \lambda' \cdot)$ with $\lambda' = \lambda_M|V(\widetilde{G}_t^M)||V(G_t')|^{-1}$, giving $r_t = \lambda'/\lambda = \sqrt{\lambda_M^2|V(\widetilde{G}_t^M)|^2/(2|E(G_t')|)}$. Since $|V(\widetilde{G}_t^M)|$ is an exponential random variable with expectation Mt, and $|E(G_t')|/t^2 = |E(G_t)|/t^2 \to \frac{1}{2}\|W\|_1$ a.s. by Proposition 56, we have that, a.s., $r_t \to 1$ as $t \to \infty$. By the triangle inequality, Lemma 36, and the fact that $\widetilde{W}^{G_t',s}|_{[0,\lambda_M^{-1}]^2} = \widetilde{W}^{\widetilde{G}_t^M,s}$,

$$\begin{aligned}\delta_\square^s(\mathcal{W}, G_t') \le \|W^s - \widetilde{W}_M^s\|_1 + \delta_\square(\widetilde{\mathcal{W}}_M^s, \widetilde{W}^{\widetilde{G}_t^M,s}) \\ + \|\widetilde{W}^{G_t',s}|_{[0,\lambda_M^{-1}]^2} - \widetilde{W}^{G_t',s}\|_1 + \delta_\square(\widetilde{\mathcal{W}}^{G_t',s}, \mathcal{W}^{G_t',s}).\end{aligned} \tag{17}$$

The first term on the right side of (17) is bounded by ε by assumption, and the second converges to zero as already discussed above. The third term on the right side of (17) is the product of r_t^{-2} and the fraction of edges of G_t for which at least one vertex $v = (t, x)$ satisfies $x > M$. By Proposition 56 (applied with the random graphs $\widetilde{G}_t^M$ and $\widetilde{G}_t$ and the same simple graph F as above) and $\lim_{t\to\infty} r_t = 1$ it follows that this term is less than 2ε for all sufficiently large $t > 0$. The fourth term on the right side of (17) converges to zero by $\lim_{t\to\infty} r_t = 1$ and Lemma 44. Since $\varepsilon > 0$ was arbitrary we can conclude that $\lim_{t\to\infty} \delta_\square^s(\mathcal{W}, G_t) = 0$. ∎

Proof of Theorem 28 (ii) First we will show that the condition $\sum_{n=1}^\infty \mu(S_n)^{-1} = \infty$ is necessary. We will use proof by contradiction, and assume $\sum_{n=1}^\infty \mu(S_n)^{-1} < \infty$ and

a.s.-$\lim_{n\to\infty} \delta_\square^s(\mathcal{W}, G_n) = 0$. We will obtain the contradiction by proving that with positive probability $E(G_n) = \emptyset$ for all $n \in \mathbb{N}$ (which clearly contradicts a.s.-$\lim_{n\to\infty} \delta_\square^s(\mathcal{W}, G_n) = 0$). By rescaling the measure of $\mathscr{S}$ we may assume without loss of generality that $\|W\|_1 = 1$. Furthermore, we assume that $\mu(S) = \infty$ by extending $\mathscr{S}$ and W to a space of infinite measure. Note that the condition $\bigcup_i S_i = S$ will not hold after such an extension has been done, but we will not use this property in the proof. (The property $\bigcup_i S_i = S$ is applied only in the second part of the proof, where we show that the condition $\sum_{n=1}^\infty \mu(S_n)^{-1} = \infty$ is sufficient.)

First we will prove that there is a random $N \in \mathbb{N}$ such that $\mathcal{W}^{G_n,s} = \mathcal{W}^{G_N,s}$ (up to interval permutations) for all $n \ge N$. Since $(|E(G_n)|)_{n\in\mathbb{N}}$ is increasing, in order to do this it is sufficient to prove that $(|E(G_n)|)_{n\in\mathbb{N}}$ is bounded almost surely, and by monotone convergence, this in turn follows once we show that $\sup_{n\in\mathbb{N}} \mathbb{E}[|E(G_n)|] < \infty$. Letting $v_i \in V(G_i)$ denote the vertex added in step $i \in \mathbb{N}$, and defining $S_0 = \emptyset$, we obtain the desired result:

$$\begin{aligned}\mathbb{E}[|E(G_n)|] &= \sum_{1\le i<j\le n} \mathbb{P}[(v_i, v_j) \in E(G_n)] \\ &= \sum_{1\le i<j\le n} \frac{1}{\mu(S_i)\mu(S_j)}\|W\mathbf{1}_{S_i\times S_j}\|_1 \\ &\le \sum_{i',j'=1}^n \|W\mathbf{1}_{(S_{i'}\setminus S_{i'-1})\times(S_{j'}\setminus S_{j'-1})}\|_1 \sum_{i\ge i', j\ge j'} \frac{1}{\mu(S_i)\mu(S_j)} \\ &\le \|W\|_1 \left(\sum_{n=1}^\infty \mu(S_n)^{-1}\right)^2 \\ &< \infty.\end{aligned}$$

Since $\lim_{n\to\infty} \delta_\square^s(G_n, \mathcal{W}) = 0$ it follows that $\delta_\square(\mathcal{W}^{G_N,s}, \mathcal{W}) = 0$.

We saw in the above paragraph that $\delta_\square(\mathcal{W}^{G_N,s}, \mathcal{W}) = 0$ a.s. for some random $N \in \mathbb{N}$. Therefore there is a deterministic step graphon $\widehat{\mathcal{W}} = (\widehat{W}, \mathbb{R}_+)$ with values in $\{0, 1\}$ such that $\delta_\square(\widehat{\mathcal{W}}, \mathcal{W}) = 0$. Since the set $\{D_{\widehat{W}} > 0\}$ has finite measure, by Lemma 45, the set $A = \{D_W > 0\}$ has finite measure as well. After changing W on a set of measure 0, we have $\operatorname{supp} W \subseteq A \times A$. Note also that by Proposition 7 we have $\delta_1(\widehat{W}, W) = 0$.

For any $n \in \mathbb{N}$ the probability that a feature sampled from the measure μ_n is contained in A is given by $\mu(A \cap S_n)/\mu(S_n) \le \mu(A)/\mu(S_n)$. Hence the Borel-Cantelli lemma implies that finitely many vertices in $\bigcup_{n\ge1} V(G_n)$ have a feature in A. Therefore we can find a deterministic $n_0 \in \mathbb{N}$ such that $\mathbb{P}(x_n \notin A \text{ for all } n \ge n_0) > 0$. It follows that with uniformly positive probability conditioned on G_{n_0}, no edges are added to G_n after time n_0.

To conclude our proof (i.e., obtain a contradiction by proving that $E(G_n) = \emptyset$ with positive probability) it is therefore sufficient to prove that $E(G_{n_0}) = \emptyset$ with positive probability. We will do this by sampling a sequence of graphs $(\widehat{G}_n)_{n\in\mathbb{N}}$ from $\widehat{\mathcal{W}}$ which is close in law to $(G_n)_{n\in\mathbb{N}}$, and use that $E(\widehat{G}_n) = \emptyset$ with positive probability since $\widehat{W}$ is zero on a certain subdomain since the graphs we consider have no loops. (Note that our approach would not have worked if we allowed for loops; if, for example, $\widehat{W}|_{[0,1]^2} \equiv 1$ and $S_1, S_2 \subset [0, 1]$ we would have had $\mathbb{P}(E(\widehat{G}_n) = \emptyset) = 0$.) Let $\varepsilon > 0$, and recalling that $\delta_1(\widehat{\mathcal{W}}, \mathcal{W}) = 0$, choose a coupling measure $\widetilde{\mu}$ on $S \times \mathbb{R}_+$ such that $\|W^{\pi_1} - \widehat{W}^{\pi_2}\|_{1,\widetilde{\mu}} < \varepsilon$. By using $\widetilde{\mu}$ we can sample

two coupled sequences of graphs $(G_n)_{1\le n\le n_0}$ and $(\widehat{G}_n)_{1\le n\le n_0}$, such that the two sequences have a law which is close in total variation distance, $(G_n)_{1\le n\le n_0}$ has the law of the graphs in the statement of the theorem, and $(\widehat{G}_n)_{1\le n\le n_0}$ is sampled similarly as $(G_n)_{n\in\mathbb{N}}$ but with $\widehat{\mathcal{W}}$ instead of $\mathcal{W}$. More precisely, for each $n\in\{1,\dots,n_0\}$ we sample $(x,\widehat{x})\in S_n\times\mathbb{R}_+$ from the probability measure $\mu(S_n)^{-1}\widetilde{\mu}|_{S_n\times\mathbb{R}_+}$, we let x (resp. $\widehat{x}$) be the feature of the nth vertex of G_n (resp. $\widehat{G}_n$), and by using that $\|W^{\pi_1}-\widehat{W}^{\pi_2}\|_{1,\widetilde{\mu}}<\varepsilon$ we can couple $(G_n)_{1\le n\le n_0}$ and $(\widehat{G}_n)_{1\le n\le n_0}$ such that for each $n_1,n_2\in\{1,\dots,n_0\}$ for which $n_1\neq n_2$ we have

$$\begin{aligned}\mathcal{P}\Big(&\big\{(x_{n_1},x_{n_2})\in E(G_{n_0}),(\widehat{x}_{n_1},\widehat{x}_{n_2})\notin E(\widehat{G}_{n_0})\big\}\cup\\&\qquad\big\{(x_{n_1},x_{n_2})\notin E(G_{n_0}),(\widehat{x}_{n_1},\widehat{x}_{n_2})\in E(\widehat{G}_{n_0})\big\}\Big)\\&\le\mu(S_{n_1})^{-1}\mu(S_{n_2})^{-1}\int_{(S_{n_1}\times\mathbb{R}_+)\times(S_{n_2}\times\mathbb{R}_+)}\left|W^{\pi_1}-\widehat{W}^{\pi_2}\right|\,d\widetilde{\mu}\,d\widetilde{\mu}\\&<\mu(S_{n_1})^{-1}\mu(S_{n_2})^{-1}\varepsilon.\end{aligned}$$

Hence the total variation distance between the laws of $(G_n)_{1\le n\le n_0}$ and $(\widehat{G}_n)_{1\le n\le n_0}$ is bounded by $n_0^2\mu(S_1)^{-2}\varepsilon$. Since we can make this distance arbitrarily small by decreasing ε, in order to complete our proof it is sufficient to prove that $E(\widehat{G}_{n_0})=\emptyset$ with a uniformly positive probability for all coupling measures $\widetilde{\mu}$. Write $\mathbb{R}_+=\bigcup_{n=0}^N A_n$, such that $A_0,\dots,A_N$ correspond to the steps of the step function $\widehat{W}$, with, say, A_0 corresponding to the set of all x such that $\int\widehat{W}(x,y)\,dy=0$. For any choice of $\widetilde{\mu}$ we can find a $k=k_{\widetilde{\mu}}\in\{0,\dots,N\}$ such that $\widetilde{\mu}(S_1\times A_k)\ge\mu(S_1)/(N+1)$. Therefore there is a uniformly positive probability that all the vertices of $\widehat{G}_{n_0}$ have a feature in A_k. On this event we have $E(\widehat{G}_{n_0})=\emptyset$, since $\widehat{W}|_{A_k\times A_k}\equiv 0$ as the graphs we consider are simple (i.e., they do not have loops). This completes our proof that the condition $\sum_{n=1}^\infty\mu(S_n)^{-1}=\infty$ is necessary.

Now we will prove that the condition $\sum_{n=1}^\infty\mu(S_n)^{-1}=\infty$ is sufficient to guarantee that a.s.-$\lim_{n\to\infty}\delta^s_\square(\mathcal{W},G_n)=0$. We will couple $(G_n)_{n\in\mathbb{N}}$ to a graphon process $(\widetilde{G}_t)_{t\ge0}$ with isolated vertices. Fix $\varepsilon>0$, and choose $N\in\mathbb{N}$ sufficiently large such that $\|W-W\mathbf{1}_{S_N\times S_N}\|_\square<\varepsilon$. Sample $(\widetilde{G}_t)_{t\ge0}$, and independently from $(\widetilde{G}_t)_{t\ge0}$, sample $(G_n)_{1\le n\le N}$ as described in the statement of the theorem. Define $(t_n)_{n\ge N}$ inductively as follows

$$t_N=0,\qquad t_n=\inf\{t>t_{n-1}\,:\,\text{there exists } x\in S_n\text{ such that }(t,x)\in V(\widetilde{G}_t)\}.$$

Note that $t_n\to\infty$ a.s. as $n\to\infty$, because the increments t_n-t_{n-1} are independent and exponentially distributed with mean $\mu(S_n)^{-1}$, and $\sum_{n=N+1}^\infty\mu(S_n)^{-1}=\infty$ by assumption. For $n>N$ let $\widehat{G}_n$ be the induced subgraph of $\widetilde{G}_{t_n}$ whose vertex set is

$$V(\widehat{G}_n)=\{(t,x)\in V(\widetilde{G}_{t_n})\,:\,\text{there exists }\widetilde{n}\in\{N+1,\dots,n\}\text{ such that }t=t_{\widetilde{n}}\}.$$

For each $n>N$ let G_n be the union of G_N and $\widehat{G}_n$, such that the edge set of G_n is given by $E(G_N)\cup E(\widehat{G}_n)$ in addition to independently sampled edges between the vertices of G_N and the vertices of $\widehat{G}_n$, such that the probability of connecting vertices with features x and x' is $W(x,x')$, and such that G_{n-1} is an induced subgraph of G_n. It is immediate that $(G_n)_{n\in\mathbb{N}}$ has the same law as the sequence of graphs $(G_n)_{n\in\mathbb{N}}$ described in the statement of the theorem.

We will prove that $|E(G_n)\backslash E(\widetilde{G}_{t_n})|=o(|E(\widetilde{G}_{t_n})|)$ and $|E(\widetilde{G}_{t_n})\backslash E(G_n)|<\varepsilon|E(\widetilde{G}_{t_n})|$ for all large $n\in\mathbb{N}$. This is sufficient to complete the proof of the theorem, since $\varepsilon>0$ was arbitrary, since $\lim_{n\to\infty}\delta^s_\square(\mathcal{W},\widetilde{G}_{t_n})=0$ by part (i) of the theorem, and since $\delta^s_\square(G_n,\widetilde{G}_{t_n})\to0$ as $n\to\infty$ and $\varepsilon\to0$ by the following argument. Define $\widetilde{\mathcal{W}}^{G_n,s}:=(\widetilde{W}^{G_n,s},\mathbb{R}_+)$ and $\widetilde{W}^{G_n,s}:=W^{G_n,s}(r_n^{-1}\cdot,r_n^{-1}\cdot)$ for $r_n=|E(G_n)|^{1/2}|E(\widetilde{G}_{t_n})|^{-1/2}$; i.e., $\widetilde{W}^{G_n,s}$ is a stretched version of $W^{G_n,s}$ defined such that each vertex of G_n corresponds to an interval of length $(2|E(\widetilde{G}_{t_n})|)^{-1/2}$. Then each vertex corresponds to an interval of length $(2|E(\widetilde{G}_{t_n})|)^{-1/2}$ both for $\widetilde{W}^{G_n,s}$ and for $W^{\widetilde{G}_{t_n},s}$, so by ordering the vertices appropriately when defining the graphons we have $\|\widetilde{W}^{G_n,s}-W^{\widetilde{G}_{t_n},s}\|_1\le|E(G_n)\triangle E(\widetilde{G}_{t_n})||E(\widetilde{G}_{t_n})|^{-1}=o_n(1)+\varepsilon$. For sufficiently small $\varepsilon>0$ and large $n\in\mathbb{N}$ we have $|r_n-1|<\big||E(G_n)|^{1/2}-|E(\widetilde{G}_{t_n})|^{1/2}\big||E(\widetilde{G}_{t_n})|^{-1/2}<o_n(1)+\varepsilon$, and hence Lemma 44 implies that $\delta_\square(\mathcal{W}^{G_n,s},\widetilde{\mathcal{W}}^{G_n,s})<4\varepsilon$ for all sufficiently small $\varepsilon>0$ and sufficiently large $n\in\mathbb{N}$. Combining the above estimates we get that for all sufficiently small $\varepsilon>0$ and sufficiently large $n\in\mathbb{N}$,

$$\delta^s_\square(G_n,\widetilde{G}_{t_n})\le\delta_\square(\mathcal{W}^{G_n,s},\widetilde{\mathcal{W}}^{G_n,s})+\delta_\square(\widetilde{\mathcal{W}}^{G_n,s},\mathcal{W}^{\widetilde{G}_{t_n},s})\le4\varepsilon+\|\widetilde{W}^{G_n,s}-W^{\widetilde{G}_{t_n},s}\|_1\le6\varepsilon.$$

First we prove that conditioned on almost any realization of G_N, $|E(G_n)\backslash E(\widetilde{G}_{t_n})|=o(|E(\widetilde{G}_{t_n})|)$ as $n\to\infty$. Note that $E(G_n)\backslash E(\widetilde{G}_{t_n})$ consists of the edges in $E(G_N)$, plus independently sampled edges between $V(G_N)$ and $V(\widehat{G}_n)$. Since $V(\widehat{G}_n)\subset V(\widetilde{G}_{t_n})$, we overcount the latter if we independently sample one edge for each $v\in V(G_N)$ and $v'\in V(\widetilde{G}_{t_n})$, with the probability of an edge between v and v' given by W evaluated at the features of v and v'. Defining $\deg(v;\widetilde{G}_{t_n})$ to be the number of edges between $v\in V(G_N)$ and $V(\widetilde{G}_{t_n})$ obtained in this way, we thus have

$$|E(G_n)\backslash E(\widetilde{G}_{t_n})|\le|E(G_N)|+\sum_{v\in V(G_N)}\deg(v;\widetilde{G}_{t_n}).$$

By Proposition 56 applied with F being the simple connected graph with two vertices, $|E(\widetilde{G}_{t_n})|=\Theta(t_n^2)$. In order to prove that $|E(G_n)\backslash E(\widetilde{G}_{t_n})|=o(|E(\widetilde{G}_{t_n})|)$ it is therefore sufficient to prove that, conditioned on almost any realization of G_N, each vertex $v\in V(G_N)$ satisfies $\deg(v;\widetilde{G}_{t_n})\le Ct_n$ for all sufficiently large n and some $C>0$ depending on the feature of the vertex. Condition on a realization of G_N such that $\int_S W(x,y)\,d\mu(y)<\infty$ for all $x\in S$ such that x is the feature of some vertex in G_N. We will prove that if $x\in S$ is the feature of $v\in V(G_N)$ then a.s.

$$\lim_{t\to\infty}Y_{-t}=\int_S W(x,y)\,d\mu(y),\qquad\text{where }Y_{-t}:=t^{-1}\deg(v;\widetilde{G}_t)\text{ for all }t>0,\tag{18}$$

which is sufficient to imply the existence of an appropriate constant C. The convergence result (18) follows by noting that $(Y_t)_{t<0}$ is a backwards martingale with expectation $\int_S W(x,y)\,d\mu(y)$, which is left-continuous with right limits at each $t<0$; see the proof of Proposition 56 for a very similar argument. Hence the Kolmogorov 0-1 law implies (18). We can conclude that $|E(G_n)\backslash E(\widetilde{G}_{t_n})|=o(|E(\widetilde{G}_{t_n})|)$.

Now we prove $|E(\widetilde{G}_{t_n})\backslash E(G_n)|<\varepsilon|E(\widetilde{G}_{t_n})|$. Let $\overline{G}_{t_n}$ be the induced subgraph of $\widetilde{G}_{t_n}$ corresponding to vertices with feature in S_N. Then

$$|E(\widetilde{G}_{t_n})\backslash E(G_n)|\le|E(\widetilde{G}_{t_n})|-|E(\overline{G}_{t_n})|.$$

By applying Proposition 56 to each of the graphs $\overline{G}_{t_n}$ and $\widehat{G}_{t_n}$, and with F being the simple connected graph on two vertices, it follows that

$$\limsup_{n\to\infty} |E(\widetilde{G}_{t_n})|^{-1}|E(\widetilde{G}_{t_n})\backslash E(G_n)| \leq \lim_{n\to\infty} |E(\widetilde{G}_{t_n})|^{-1}(|E(\widetilde{G}_{t_n})| - |E(\overline{G}_{t_n})|)$$
$$= \|W\|_1 - \|W\mathbf{1}_{S_N\times S_N}\|_1 = \|W - W\mathbf{1}_{S_N\times S_N}\|_1 < \varepsilon.$$

■

Proof of Theorem 27 Assume that (i) holds, i.e., $\delta_\square(\mathcal{W}_1,\mathcal{W}_2) = 0$. We will prove that (ii) and (iii) also hold. It is sufficient to prove that (ii) holds, since (ii) implies (iii).

We first consider the case when $\mu_i(I_i) < \infty$ for $i = 1, 2$, where $I_i := \{x \in S_i : D_{W_i}(x) > 0\}$. Recall that by Proposition 21 we have $\mu_1(I_1) = \mu_2(I_2)$, so by restricting the graphon $\mathcal{W}_i$ to the space I_i for $i = 1, 2$ we obtain two graphons with cut distance zero over spaces of finite and equal measure. By definition of I_i, almost surely no vertices of $(\widetilde{G}_t)_{t\geq 0}$ will be isolated for all times, and it is proved that (ii) holds in, for example, a paper by Janson (2013, Theorem 8.10), who refers to papers by Borgs, Chayes, Lovász, Sós, and Vesztergombi (2008), Borgs, Chayes, and Lovász (2010), and Diaconis and Janson (2008) for the original proofs.

Next we consider the case where $\mu_1(I_1) = \mu_2(I_2) = \infty$. We may assume $\mu_i(S_i \setminus I_i) = 0$, since replacing the graphon $\mathcal{W}_i$ by its restriction to $S_i \setminus I_i$ amounts to removing vertices which are isolated for all times. Part (i) of Proposition 51 now implies that we can find a measure μ such that $W_1^{\pi_1} = W_2^{\pi_2}$ μ-almost everywhere. By the assumption $\mu_i(S_i \setminus I_i) = 0$, part (iv) of the proposition implies that μ is a coupling measure. Sampling a graphon process from $\mathcal{W}_i$ may be done by associating the vertex set with a Poisson point process on $(S_1 \times S_2) \times \mathbb{R}_+$ with intensity $\mu \times \lambda$, such that each $((x_1, x_2), t) \in (S_1 \times S_2) \times \mathbb{R}_+$ is associated with a vertex with feature x_i appearing at time t.

Now we will prove that (ii) or (iii) imply (i). We will only show that (ii) implies (i), since we can prove that (iii) implies (i) by the exact same argument. We assume (ii) holds, and couple $(\widetilde{G}_t^1)_{t\geq 0}$ and $(\widetilde{G}_t^2)_{t\geq 0}$ such that $\widetilde{G}_t^1 = \widetilde{G}_t^2$ for all $t \geq 0$. By Theorem 28(i) we know that $\lim_{t\to\infty} \delta_\square(\mathcal{W}_i, \mathcal{W}^{\widetilde{G}_t^i}) = 0$. Since $\mathcal{W}^{\widetilde{G}_t^1} = \mathcal{W}^{\widetilde{G}_t^2}$ for all $t \geq 0$ it follows by the triangle inequality that $\delta_\square(\mathcal{W}_1, \mathcal{W}_2) = 0$, so (i) holds. ■

Appendix E. Compactness

In this appendix we will establish Theorem 15.

Lemma 58 *Let $(\mathcal{W}_n)_{n\in\mathbb{N}}$ and $(\widetilde{\mathcal{W}}_n)_{n\in\mathbb{N}}$ be two sequences of graphons, with $\mathcal{W}_n = (W_n, \mathscr{S}_n)$, $\mathscr{S}_n = (S_n, \mathcal{S}_n, \mu_n)$, $\widetilde{\mathcal{W}}_n = (\widetilde{W}_n, \widetilde{\mathscr{S}}_n)$, and $\widetilde{\mathscr{S}}_n = (\widetilde{S}_n, \widetilde{\mathcal{S}}_n, \widetilde{\mu}_n)$, such that there are measure-preserving transformations $\phi_n \colon S_n \to \widetilde{S}_n$ for which $\lim_{n\to\infty} \|W_n - \widetilde{W}_n^{\phi_n}\|_1 = 0$. Furthermore, assume that either (i) ϕ_n is a bimeasurable bijection, or (ii) $S_n = \widetilde{S}_n \times [0, 1]$, where $[0, 1]$ is equipped with Lebesgue measure, and $\phi_n \colon S_n \to \widetilde{S}_n$ is the projection map. Then $(\mathcal{W}_n)_{n\in\mathbb{N}}$ has uniformly regular tails iff $(\widetilde{\mathcal{W}}_n)_{n\in\mathbb{N}}$ has uniformly regular tails.*

Proof Let $(\varepsilon_n)_{n\in\mathbb{N}}$ be a sequence of positive real numbers converging to zero, such that $\|W_n - \widetilde{W}_n^{\phi_n}\|_1 < \varepsilon_n$ for all $n \in \mathbb{N}$. First assume $(\widetilde{\mathcal{W}}_n)_{n\in\mathbb{N}}$ has uniformly regular tails. Given any $\varepsilon > 0$ let $M \geq 0$ be such that for all $n \in \mathbb{N}$ we can find $\widetilde{U}_n \in \widetilde{\mathcal{S}}_n$ satisfying $\widetilde{\mu}_n(\widetilde{U}_n) < M$ and $\|\widetilde{W}_n - \widetilde{W}_n\mathbf{1}_{\widetilde{U}_n\times\widetilde{U}_n}\|_1 < \varepsilon/2$. Define $U_n := \phi_n^{-1}(\widetilde{U}_n)$. Since ϕ_n is measure-preserving, $\mu_n(U_n) = \mu_n(\widetilde{U}_n) < M$. By first using $\|W_n - \widetilde{W}_n^{\phi_n}\|_1 < \varepsilon_n$ (which implies that $\|(W_n - \widetilde{W}_n^{\phi_n})\mathbf{1}_{U_n\times U_n}\|_1 < \varepsilon_n$) and then using that ϕ_n is measure-preserving we get

$$\begin{aligned}
&\|W_n - W_n\mathbf{1}_{U_n\times U_n}\|_1 \\
&\quad\leq \|W_n - \widetilde{W}_n^{\phi_n}\|_1 + \|\widetilde{W}_n^{\phi_n} - \widetilde{W}_n^{\phi_n}\mathbf{1}_{U_n\times U_n}\|_1 + \|(\widetilde{W}_n^{\phi_n} - W_n)\mathbf{1}_{U_n\times U_n}\|_1 \\
&\quad\leq \|\widetilde{W}_n^{\phi_n} - \widetilde{W}_n^{\phi_n}\mathbf{1}_{U_n\times U_n}\|_1 + 2\varepsilon_n \\
&\quad= \|\widetilde{W}_n - \widetilde{W}_n\mathbf{1}_{\widetilde{U}_n\times\widetilde{U}_n}\|_1 + 2\varepsilon_n \\
&\quad< \varepsilon/2 + 2\varepsilon_n.
\end{aligned}$$

The right side is less than ε for all sufficiently large $n \in \mathbb{N}$. Therefore $(\mathcal{W}_n)_{n\in\mathbb{N}}$ has uniformly regular tails.

Next assume $(\mathcal{W}_n)_{n\in\mathbb{N}}$ has uniformly regular tails. We consider the two cases (i) and (ii) separately. In case (i) it is immediate from the above result that $(\widetilde{\mathcal{W}}_n)_{n\in\mathbb{N}}$ has uniformly regular tails, since $\|\widetilde{W}_n - W_n^{\phi_n^{-1}}\|_1 < \varepsilon_n$. Now consider case (ii). Given any $\varepsilon > 0$ let $M > 0$ be such that for all $n \in \mathbb{N}$ we can find $U_n \in \mathcal{S}_n$ satisfying $\mu_n(U_n) < M/2$ and $\|W_n - W_n\mathbf{1}_{U_n\times U_n}\|_1 < \varepsilon/5$. Define $\widetilde{U}_n$ by

$$\widetilde{U}_n := \left\{x \in \widetilde{S}_n \,:\, \int_0^1 \mathbf{1}_{(x,s)\in U_n}\, ds > \frac{1}{2}\right\},$$

and define $U_n' := \phi_n^{-1}(\widetilde{U}_n)$. Note that $\widetilde{U}_n$ is a measurable set since $(x, s) \mapsto \mathbf{1}_{(x,s)\in U_n}$ is measurable. Then $\widetilde{\mu}_n(\widetilde{U}_n) < M$, since

$$\mu_n(U_n) = \int_{\widetilde{S}_n}\int_0^1 \mathbf{1}_{(x,s)\in U_n}\, ds\, d\widetilde{\mu}(x) \geq \int_{\widetilde{U}_n}\int_0^1 \mathbf{1}_{(x,s)\in U_n}\, ds\, d\widetilde{\mu}(x) \geq \int_{\widetilde{U}_n} \frac{1}{2}\, d\widetilde{\mu}(x) = \frac{1}{2}\widetilde{\mu}_n(\widetilde{U}_n).$$

Next we will argue that

$$\|\widetilde{W}_n - \widetilde{W}_n\mathbf{1}_{\widetilde{U}_n\times\widetilde{U}_n}\|_1 \leq 2\|\widetilde{W}_n^{\phi_n} - \widetilde{W}_n^{\phi_n}\mathbf{1}_{U_n\times U_n}\|_1. \tag{19}$$

If $(x, x') \in (\widetilde{S}_n \times \widetilde{S}_n)\backslash(\widetilde{U}_n \times \widetilde{U}_n)$ it holds by the definition of $\widetilde{U}_n$ that

$$\int_0^1\int_0^1 \mathbf{1}_{((x,s),(x',s'))\in(S_n\times S_n)\setminus(U_n\times U_n)}\, ds'\, ds = 1 - \int_0^1 \mathbf{1}_{(x,s)\in U_n}\, ds \int_0^1 \mathbf{1}_{(x',s)\in U_n}\, ds \geq \frac{1}{2},$$

which implies (19) by

$$\begin{aligned}
\|\widetilde{W}_n - \widetilde{W}_n \mathbf{1}_{\widetilde{U}_n\times\widetilde{U}_n}\|_1 &= \int_{\widetilde{S}_n\times\widetilde{S}_n} d\mu(x)\,d\mu(x')\left|\widetilde{W}_n(x,x')\right| \mathbf{1}_{(x,x')\in(\widetilde{S}_n\times\widetilde{S}_n)\setminus(\widetilde{U}_n\times\widetilde{U}_n)} \\
&\le 2\int_{\widetilde{S}_n\times\widetilde{S}_n} d\mu(x)\,d\mu(x')\Bigg(\left|\widetilde{W}_n(x,x')\right| \mathbf{1}_{(x,x')\in(\widetilde{S}_n\times\widetilde{S}_n)\setminus(\widetilde{U}_n\times\widetilde{U}_n)} \\
&\qquad \cdot \int_0^1\int_0^1 \mathbf{1}_{((x,s),(x',s'))\in(S_n\times S_n)\setminus(U_n\times U_n)}\,ds'\,ds\Bigg) \\
&\le 2\int_{\widetilde{S}_n\times\widetilde{S}_n} d\mu(x)\,d\mu(x')\left|\widetilde{W}_n(x,x')\right| \int_0^1\int_0^1 \mathbf{1}_{((x,s),(x',s'))\in(S_n\times S_n)\setminus(U_n\times U_n)}\,ds'\,ds \\
&= 2\left\|\widetilde{W}_n^{\phi_n}\mathbf{1}_{(S_n\times S_n)\setminus(U_n\times U_n)}\right\|_1 \\
&= 2\|\widetilde{W}_n^{\phi_n} - \widetilde{W}_n^{\phi_n}\mathbf{1}_{U_n\times U_n}\|_1.
\end{aligned}$$

Using that ϕ_n is measure-preserving, the triangle inequality, that $\|\widetilde{W}_n^{\phi_n} - W_n\|_1 < \varepsilon_n$, and the estimate (19) we get

$$\begin{aligned}
\|\widetilde{W}_n - \widetilde{W}_n\mathbf{1}_{\widetilde{U}_n\times\widetilde{U}_n}\|_1 &\le 2\|\widetilde{W}_n^{\phi_n} - \widetilde{W}_n^{\phi_n}\mathbf{1}_{U_n\times U_n}\|_1 \\
&\le 2\|W_n - W_n\mathbf{1}_{U_n\times U_n}\|_1 + 4\varepsilon_n < 2\varepsilon/5 + 4\varepsilon_n.
\end{aligned}$$

The right side is less than ε for all sufficiently large $n\in\mathbb{N}$, and thus $(\widetilde{\mathcal{W}}_n)_{n\in\mathbb{N}}$ has uniformly regular tails. ∎

Proof of Theorem 15 First we will prove that every $\delta_\square$-Cauchy sequence has uniformly regular tails. Let $(\mathcal{W}_n)_{n\in\mathbb{N}}$ with $\mathcal{W}_n = (W_n, \mathscr{S}_n)$ be a $\delta_\square$-Cauchy sequence of graphons, i.e., $\lim_{n,m\to\infty}\delta_\square(\mathcal{W}_n,\mathcal{W}_m) \to 0$. By Lemma 58 we may assume without loss of generality that $\mathscr{S}_n$ is atomless for all $n\in\mathbb{N}$. By Lemmas 46 and 33 we can find graphons $\widetilde{\mathcal{W}}_n = (\widetilde{W}_n, \mathbb{R}_+)$ and measure-preserving maps $\psi_n\colon S_n\to\mathbb{R}_+$ such that $W_n = (\widetilde{W}_n)^{\psi_n}$. Since $\delta_\square(\widetilde{\mathcal{W}}_n,\mathcal{W}_n) = 0$, $(\widetilde{\mathcal{W}}_n)_{n\in\mathbb{N}}$ is a Cauchy sequence. Given any $\varepsilon>0$ choose $N\in\mathbb{N}$ such that $\delta_\square(\widetilde{\mathcal{W}}_N,\widetilde{\mathcal{W}}_n) < \varepsilon/4$ for all $n\ge N$. For each $n\le N$ let $M_n\in\mathbb{R}_+$ be such that $\|\widetilde{W}_n - \widetilde{W}_n\mathbf{1}_{[0,M_n]^2}\|_1 < \varepsilon/3$, and define $M := \sup_{n\le N} M_n < \infty$. To prove that $(\widetilde{\mathcal{W}}_n)_{n\in\mathbb{N}}$ has uniformly regular tails it is sufficient to prove that for each $n\ge N$ we can find a Borel-measurable set $\widetilde{A}_n\subset\mathbb{R}_+$ such that

$$\lambda(\widetilde{A}_n)\le M, \qquad \|\widetilde{W}_n - \widetilde{W}_n\mathbf{1}_{\widetilde{A}_n\times\widetilde{A}_n}\|_1 < \varepsilon. \tag{20}$$

We can clearly find an appropriate set $\widetilde{A}_n$ for $n=N$; indeed, we can find a set $\widetilde{A}_N\subset\mathbb{R}_+$ such that the second bound holds with $\varepsilon/3$ instead of ε. By Proposition 48(c) we can find isomorphisms $\phi_n\colon\mathbb{R}_+\to\mathbb{R}_+$ such that $\|\widetilde{W}_N - \widetilde{W}_n^{\phi_n}\|_\square < \varepsilon/3$ for all $n\ge N$. Define $\widetilde{A}_n = \phi_n(\widetilde{A}_N)$, and note that

$$\|\widetilde{W}_n - \widetilde{W}_n\mathbf{1}_{\widetilde{A}_n\times\widetilde{A}_n}\|_\square = \|\widetilde{W}_n^{\phi_n} - \widetilde{W}_n^{\phi_n}\mathbf{1}_{\widetilde{A}_N\times\widetilde{A}_N}\|_\square \le \|\widetilde{W}_N - \widetilde{W}_N\mathbf{1}_{\widetilde{A}_N\times\widetilde{A}_N}\|_\square + \frac{2\varepsilon}{3} < \varepsilon.$$

Observing that for non-negative graphons the cut norm is equal to the L^1 norm, this gives that (20) is satisfied and $(\widetilde{\mathcal{W}}_n)_{n\in\mathbb{N}}$ has uniformly regular tails. Defining $A_n := \psi^{-1}(\widetilde{A}_n)$, we

have $\mu(A_n) < M$ and $\|W_n - W_n\mathbf{1}_{A_n\times A_n}\|_1 = \|\widetilde{W}_n - \widetilde{W}_n\mathbf{1}_{\widetilde{A}_n\times\widetilde{A}_n}\|_1 < \varepsilon$. Hence $(\mathcal{W}_n)_{n\in\mathbb{N}}$ has uniformly regular tails.

Now we will prove that uniform regularity of tails implies subsequential convergence for $\delta_\square$. We consider some sequence of graphons $(\mathcal{W}_n)_{n\in\mathbb{N}}$ with uniformly regular tails, and will prove that the sequence is subsequentially convergent for $\delta_\square$ towards some graphon $\mathcal{W}$. By Lemma 58 we may assume without loss of generality that $\mathscr{S}_n$ is atomless for all $n\in\mathbb{N}$, and by trivially extending $\mathcal{W}_n$ to a graphon over a space of infinite total mass if needed, we may assume that $\mu_n(S_n) = \infty$. Recall the definition of a partition of a measurable space, which was given as part of the discussion before the statement of Proposition 20. We will prove that we can find increasing sequences $(m_k)_{k\in\mathbb{N}}$ and $(M_k)_{k\in\mathbb{N}}$ with values in $\mathbb{N}$, such that for each $k,n\in\mathbb{N}$ there is a partition $\mathcal{P}_{n,k}$ of S_n and a graphon $\mathcal{W}_{n,k} = (W_{n,k},\mathbb{R}_+)$ such that the following hold:

(i) We have $\mathcal{P}_{n,k} = \{I^i_{n,k} : i = 0,\dots,m_k\}$, where $\mu_n(S_n\setminus I^0_{n,k}) = M_k$ and $\mu_n(I^i_{n,k}) = M_k/m_k$ for $i\in\{1,\dots,m_k\}$.

(ii) We have $\delta_\square(\mathcal{W}_n,\mathcal{W}_{n,k}) < 1/k$ for all $n\in\mathbb{N}$.

(iii) For each $i_1,i_2\in\{1,\dots,m_k\}$ the value of $W_{n,k}$ on $([i_1-1,i_1)\times[i_2-1,i_2))M_k/m_k$ is constant and equal to the value of $(W_n)_{\mathcal{P}_{n,k}}$ on $I^{i_1}_{n,k}\times I^{i_2}_{n,k}$. On the complement of $[0,M_k]^2$, we have $W_{n,k}=0$.

(iv) The partition $\mathcal{P}_{n,k+1}$ refines the partition $\mathcal{P}_{n,k}$. We number the elements of the partition $\mathcal{P}_{n,k+1}$ to be consistent with the refinement. More precisely, defining $r_k := (M_k/m_k)/(M_{k+1}/m_{k+1})\in\mathbb{N}$ to be the ratio of the partition sizes in the two partitions, we have $I^i_{n,k} = \bigcup_{j=(i-1)r_k+1}^{ir_k} I^j_{n,k+1}$ for every i with $0<i\le m_k$.

Partitions $\mathcal{P}_{n,k}$ and graphons $\mathcal{W}_{n,k}$ satisfying (i)–(iv) exist by the following argument. By the assumption of uniformly regular tails, for each $k\in\mathbb{N}$ we can find an $M_k\in\mathbb{N}$ such that for appropriate sets $I^0_{n,k}$ satisfying $\mu_n(S_n\setminus I^0_{n,k}) = M_k$ we have $\|W_n - W_n\mathbf{1}_{(S_n\setminus I^0_{n,k})\times(S_n\setminus I^0_{n,k})}\|_1 < 1/(3k)$ for all $n\in\mathbb{N}$. By Lemmas 46 and 33, for each $n,k\in\mathbb{N}$ the graphon $(W_n|_{(S_n\setminus I^0_{n,k})\times(S_n\setminus I^0_{n,k})}, S_n\setminus I^0_{n,k})$ is a pullback of a graphon $\widetilde{\mathcal{W}}_{n,k} = (\widetilde{W}_{n,k},[0,M_k])$ by a measure-preserving transformation $\varphi_{n,k}$. By applying Szemerédi regularity for equitable partitions to $\widetilde{W}_{n,k}$ (see, for example, the paper of Borgs, Chayes, Cohn, and Zhao, 2014a, Lemma 3.3) we can find appropriate $m_k\in\mathbb{N}$ and partitions $\widetilde{\mathcal{P}}_{n,k}$ of $[0,M_k]$ such that $\|(\widetilde{W}_{n,k} - (\widetilde{W}_{n,k})_{\widetilde{\mathcal{P}}_{n,k}})\|_\square < 1/(3k)$. Then the pullback of $(\widetilde{W}_{n,k})_{\widetilde{\mathcal{P}}_{n,k}}$ along $\varphi_{n,k}$ equals $(W_n)_{\mathcal{P}_{n,k}}$ for an appropriate partition of S_n satisfying (i), and

$$\begin{aligned}
\|W_n - (W_n)_{\mathcal{P}_{n,k}}\|_\square &\le \|W_n - W_n\mathbf{1}_{(S_n\setminus I^0_{n,k})\times(S_n\setminus I^0_{n,k})}\|_\square \\
&\quad + \|(W_n - (W_n)_{\mathcal{P}_{n,k}})\mathbf{1}_{(S_n\setminus I^0_{n,k})\times(S_n\setminus I^0_{n,k})}\|_\square \\
&\quad + \|(W_n)_{\mathcal{P}_{n,k}}\mathbf{1}_{(S_n\setminus I^0_{n,k})\times(S_n\setminus I^0_{n,k})} - (W_n)_{\mathcal{P}_{n,k}}\|_\square \\
&= \|W_n - W_n\mathbf{1}_{(S_n\setminus I^0_{n,k})\times(S_n\setminus I^0_{n,k})}\|_\square + \|\widetilde{W}_{n,k}^{\varphi_{n,k}} - (\widetilde{W}_{n,k})^{\varphi_{n,k}}_{\widetilde{\mathcal{P}}_{n,k}}\|_\square \\
&\quad + \left\|\left(W_n\mathbf{1}_{(S_n\setminus I^0_{n,k})\times(S_n\setminus I^0_{n,k})} - W_n\right)_{\mathcal{P}_{n,k}}\right\|_\square \\
&< 1/k.
\end{aligned}$$

Define $\mathcal{W}_{n,k}$ as described in (iii), and note that all requirements (i)–(iv) are satisfied since $\delta_\square(((W_n)_{\mathcal{P}_{n,k}},\mathscr{S}_n),\mathcal{W}_{n,k})=0$.

By compactness, for each $k\in\mathbb{N}$ there exists a step function $U_k\colon\mathbb{R}_+^2\to[0,1]$ (with support in $[0,M_k]^2$) such that $(W_{n,k})_{n\in\mathbb{N}}$ converges pointwise and in L^1 along a subsequence towards U_k. We may assume the subsequence along which $(W_{n,k+1})_{n\in\mathbb{N}}$ converges is contained in the subsequence along which $(W_{n,k})_{n\in\mathbb{N}}$ converges. Note that for each $i_1,i_2\in\{1,\dots,m_k\}$ the function U_k is constant on $([i_1-1,i_1]\times[i_2-1,i_2])M_k/m_k$. Furthermore, observe that if $k,k'\in\mathbb{N}$ and $k'\geq k$, the value of U_k at $([i_1-1,i_1]\times[i_2-1,i_2])M_k/m_k$ is equal to the average of $U_{k'}$ over this set. Define the graphon $\mathcal{U}_k$ by $\mathcal{U}_k:=(U_k,\mathbb{R}_+)$.

Choose $M>1$, and then choose k' such that $M_k\geq M_{k'}\geq M$ for all $k\geq k'$. Let (X,Y) be a uniformly random point in $[0,M_{k'}]^2$. By the observations in the preceding paragraph $(U_k(X,Y))_{k\geq k'}$ is a martingale. Hence the martingale convergence theorem implies that the limit $\lim_{k\to\infty}U_k(X,Y)$ exists a.s. Since M was arbitrary it follows that there is a set $E\subset\mathbb{R}_+^2$ of measure zero outside of which $(U_k)_{k\geq k'}$ converges pointwise. Define the graphon $\mathcal{U}:=(U,\mathbb{R}_+)$ as follows. For any $(x_1,x_2)\in\mathbb{R}_+^2\backslash E$ define $U(x_1,x_2):=\lim_{k\to\infty}U_k(x_1,x_2)$, and for any $(x_1,x_2)\in E$ define $U(x_1,x_2):=0$. Since the functions U_k are uniformly bounded, martingale convergence also implies that $U_k|_{[0,M_\ell]^2}$ converges to $U|_{[0,M_\ell]^2}$ in L^1 for each $\ell\in\mathbb{N}$.

Next we will show that $\lim_{k\to\infty}\|U_k-U\|_1=0$. Since $\lim_{k\to\infty}\|(U_k-U)\mathbf{1}_{[0,M_\ell]^2}\|_1=0$ for each $\ell\in\mathbb{N}$ it is sufficient to prove that $\|U_k\mathbf{1}_{\mathbb{R}_+^2\backslash[0,M_\ell]^2}\|_1<1/(3\ell)$ for all $k,\ell\in\mathbb{N}$ for which $k>\ell$. This follows by Fatou's lemma and the inequality

$$\begin{aligned}\int_{\mathbb{R}_+^2\backslash[0,M_\ell]^2}|W_{n,k}|&=\int_{[0,M_k]^2\backslash[0,M_\ell]^2}|W_{n,k}|\leq\int_{(S_n\backslash I^0_{n,k})^2\backslash(S_n\backslash I^0_{n,\ell})^2}|W_n|_{\mathcal{P}_{n,k}}\\&=\int_{(S_n\backslash I^0_{n,k})^2\backslash(S_n\backslash I^0_{n,\ell})^2}|W_n|<1/(3\ell).\end{aligned}$$

By the result of the preceding paragraph

$$\limsup_{k\to\infty}\delta_\square(\mathcal{U}_k,\mathcal{U})\leq\limsup_{k\to\infty}\|U_k-U\|_1=0,$$

and we conclude the proof by applying the triangle inequality to obtain

$$\liminf_{n\to\infty}\delta_\square(\mathcal{U},\mathcal{W}_n)\leq\limsup_{k\to\infty}\liminf_{n\to\infty}\Big(\delta_\square(\mathcal{U},\mathcal{U}_k)+\delta_\square(\mathcal{U}_k,\mathcal{W}_{n,k})+\delta_\square(\mathcal{W}_{n,k},\mathcal{W}_n)\Big)=0.$$

■

Appendix F. Basic Properties of Metric Convergent Sequences of Graphs

In this appendix we will establish Propositions 20 and 22. First we prove a lemma saying that for a set of graphs with uniformly regular tails we may assume the sets U in Definition 13 correspond to sets of vertices.

Lemma 59 *Let $\mathcal{G}$ be a set of graphs with uniformly regular tails. For every $\varepsilon>0$ there is an $M>0$ such that for each $G\in\mathcal{G}$ we can find a set $U\subset\mathbb{R}_+$ corresponding to a set of vertices for G such that $\|W^{G,s}-W^{G,s}\mathbf{1}_{U\times U}\|_1<\varepsilon$ and $\lambda(U)<M$.*

Proof Since $\mathcal{G}$ has uniformly regular tails we can find an $M>0$ such that for each $G\in\mathcal{G}$ there is a set $\widetilde{U}\subset\mathbb{R}_+$ (not necessarily corresponding to a set of vertices for G) such that $\|W^{G,s}-W^{G,s}\mathbf{1}_{\widetilde{U}\times\widetilde{U}}\|_1<\varepsilon/2$ and $\lambda(\widetilde{U})<M/2$. Recall that each vertex $i\in V(G)$ corresponds to an interval $I_i\subset\mathbb{R}_+$ for the stretched canonical graphon $W^{G,s}$, such that $\lambda(I_i)$ is proportional to the weight of the vertex. Given a set $\widetilde{U}\subset\mathbb{R}_+$ as above, define

$$U:=\bigcup_{i\in\mathcal{I}}I_i,\quad\text{where}\quad\mathcal{I}:=\{i\in V(G)\,:\,2\lambda(I_i\cap\widetilde{U})>\lambda(I_i)\}.$$

The lemma now follows by observing that $\lambda(U)\leq2\lambda(\widetilde{U})<M$ and

$$\begin{aligned}\|W^{G,s}-W^{G,s}\mathbf{1}_{U\times U}\|_1&=\sum_{i,j\in V(G)\,:\,(i,j)\notin\mathcal{I}\times\mathcal{I}}\beta_{i,j}\lambda(I_i)\lambda(I_j)\\&\leq2\sum_{i,j\in V(G)\,:\,(i,j)\notin\mathcal{I}\times\mathcal{I}}\beta_{ij}\big(\lambda(I_i)\lambda(I_j)-\lambda(I_i\cap\widetilde{U})\lambda(I_j\cap\widetilde{U})\big)\\&\leq2\|W^{G,s}-W^{G,s}\mathbf{1}_{\widetilde{U}\times\widetilde{U}}\|_1\\&<\varepsilon.\end{aligned}$$

■

Proof of Proposition 20 Define $M_n:=\inf\{M>0\,:\,\operatorname{supp}(W^{G_n,s})\subseteq[0,M]^2\}$. If $(G_n)_{n\in\mathbb{N}}$ is sparse, then $\liminf_{n\to\infty}M_n=\infty$. By Lemma 59, if $(G_n)_{n\in\mathbb{N}}$ has uniformly regular tails there exists an $M'>0$ such that if we order the vertices of G_n appropriately when defining the canonical graphon W^{G_n} of G_n, then $\|W^{G_n,s}\mathbf{1}_{[0,M']^2}\|_1>1/2$ for all $n\in\mathbb{N}$.

The graphons $\mathcal{W}^{G_n,r}$ and $\mathcal{W}^{G_n,s}$ are related by $W^{G_n,r}=\widetilde{M}_n^2W^{G_n,s}(\widetilde{M}_n\,\cdot\,,\widetilde{M}_n\,\cdot\,)$ for some $\widetilde{M}_n\geq M_n$ (with $\widetilde{M}_n=M_n$ if G_n has no isolated vertices; if G_n has isolated vertices corresponding to the end of the interval $[0,1]$ for the canonical graphon W^{G_n} we will have $\widetilde{M}_n>M_n$). If $\lim_{n\to\infty}\widetilde{M}_n=\infty$ and $\|W^{G_n,s}\mathbf{1}_{[0,M']^2}\|_1>1/2$ for all $n\in\mathbb{N}$, then

$$\|W^{G_n,r}\mathbf{1}_{[0,a_n]^2}\|_1>1/2\qquad\text{and}\qquad\lim_{n\to\infty}a_n=0,\qquad\text{where }a_n:=\min\big(M'\widetilde{M}_n^{-1},1\big).\quad(21)$$

The proof of (i) is complete if we can prove that (21) implies that $(G_n)_{n\in\mathbb{N}}$ is not uniformly upper regular. Assume the opposite, and let $K\colon(0,\infty)\to(0,\infty)$ and $(\eta_m)_{n\in\mathbb{N}}$ be as in the definition of uniform upper regularity. Let $\mathcal{P}_n$ be a partition of $\mathbb{R}_+$ such that one of the parts is $[0,a'_n]$, where $a'_n\geq a_n$ is chosen as small as possible such that $[0,a'_n]$ corresponds to an integer number of vertices of G_n for the canonical graphon. Then $\lim_{n\to\infty}a'_n=0$ since $\lim_{n\to\infty}a_n=0$ and $\lim_{n\to\infty}V(G_n)=\infty$. By the first part of (21) it follows that $(W^{G_n,r})_{\mathcal{P}_n}>K(1/2)$ on $[0,a'_n]^2$ for all sufficiently large n; hence for all sufficiently large n,

$$\|(W^{G_n,r})_{\mathcal{P}_n}\mathbf{1}_{|(W^{G_n,r})_{\mathcal{P}_n}|\geq K(1/2)}\|_1\geq\|(W^{G_n,r})_{\mathcal{P}_n}\mathbf{1}_{[0,a'_n]^2}\|_1=\|W^{G_n,r}\mathbf{1}_{[0,a'_n]^2}\|_1>1/2.$$

We have obtained a contradiction to the assumption of uniform upper regularity, and thus the proof of (i) is complete.

Defining $\rho_n:=\rho(G_n)$ (recall the definition of ρ in the beginning of Section 2), we have $W^{G_n,s}=W^{G_n}(\rho_n^{1/2}\,\cdot\,,\rho_n^{1/2}\,\cdot\,)$ and $W^{G_n,r}=\rho_n^{-1}W^{G_n}$. If $(G_n)_{n\in\mathbb{N}}$ is dense and has convergent

edge density the following limit exists and is positive: $\rho := \lim_{n\to\infty} \rho_n > 0$. It follows by Lemma 44 (resp. Lemma 36) that $(G_n)_{n\in\mathbb{N}}$ is a Cauchy sequence for $\delta^s_\square$ (resp. $\delta^r_\square$) iff $(\mathcal{W}^{G_n})_{n\in\mathbb{N}}$ is a Cauchy sequence for $\delta_\square$, since for any $n, m \in \mathbb{N}$,

$$\begin{aligned}\Big|\delta^s_\square(G_n, G_m) - \delta_\square\big((W^{G_n}(\rho^{1/2}\cdot\,,\rho^{1/2}\cdot\,),\mathbb{R}_+),(W^{G_m}(\rho^{1/2}\cdot\,,\rho^{1/2}\cdot\,),\mathbb{R}_+)\big)\Big| \\ \leq \delta_\square\big(W^{G_n,s},(W^{G_n}(\rho^{1/2}\cdot\,,\rho^{1/2}\cdot\,),\mathbb{R}_+)\big) \\ + \delta_\square\big((W^{G_m}(\rho^{1/2}\cdot\,,\rho^{1/2}\cdot\,),\mathbb{R}_+),W^{G_m,s}\big) \\ \to 0\end{aligned}$$

as $n, m \to \infty$, and a similar estimate holds with $\delta^r_\square$ instead of $\delta^s_\square$. This completes the proof of the first assertion of (ii).

To prove the second assertion of (ii) consider the following sequence of dense graphs $(G_n)_{n\in\mathbb{N}}$, which is a Cauchy sequence for $\delta^s_\square$ but not for $\delta^r_\square$. For odd n let G_n be a complete simple graph on n vertices, and for even n let G_n be the union of a complete graph on $n/2$ vertices and $n/2$ isolated vertices. This sequence converges to $\mathcal{W}_1 := (\mathbf{1}_{[0,1]^2}, \mathbb{R}_+)$ for $\delta^s_\square$, but does not converge for $\delta^r_\square$.

Conversely, the following sequence of dense graphs $(G_n)_{n\in\mathbb{N}}$ is a Cauchy sequence for $\delta^r_\square$ but not for $\delta^s_\square$. For odd n let G_n be a complete graph on n vertices, and for even n let G_n be an Erdős-Rényi graph with edge probability $1/2$. This sequence converges to $\mathcal{W}_1$ for $\delta^r_\square$, but does not converge for $\delta^s_\square$. ■

Proof of Proposition 22 We will assume throughout the proof that the graphs have no isolated vertices, since the case of $o|E(G_n)|$ vertices clearly follows from this case. We assume the average degree of $(G_n)_{n\in\mathbb{N}}$ is bounded above by $d \in \mathbb{N}$, and want to obtain a contradiction. When defining the canonical stretched graphon $W^{G_n,s}$ of G_n, each vertex of G_n corresponds to an interval of length $1/\sqrt{2|E(G_n)|}$. Since $|E(G_n)|/|V(G_n)| \leq d/2$ by assumption, the vertices of G_n correspond to an interval of length $|V(G_n)|/\sqrt{2|E(G_n)|} \geq \sqrt{2|E(G_n)|}/d$, which is too stretched out to be compatible with uniformly regular tails. Explicitly, given that G_n has no isolated vertices it follows that for any $M > 0$ and any Borel set $I \subset \mathbb{R}_+$ satisfying $\lambda(I) < M$,

$$\int_{(\mathbb{R}_+\setminus I)\times\mathbb{R}_+} W^{G_n,s} \geq \frac{\sqrt{2|E(G_n)|}/d - M}{\sqrt{2|E(G_n)|}}.$$

By the assumption that $\lim_{n\to\infty}|E(G_n)| = \infty$, the right side of this equation is greater than $1/(2d)$ for all sufficiently large $n \in \mathbb{N}$. Since $M > 0$ was arbitrary, this is not compatible with G_n having uniformly regular tails, which together with Theorem 15 gives a contradiction. ■

Appendix G. Exchangeability of Graphon Processes

The main goal of this appendix is to prove Theorem 26.

Lemma 60 *Let $(\widetilde{G}_n)_{n\in\mathbb{N}}$ be a sequence of simple graphs with uniformly regular tails, such that $|E(\widetilde{G}_n)| < \infty$ for all $n \in \mathbb{N}$ and $\lim_{n\to\infty}|E(\widetilde{G}_n)| = \infty$. Fix $d \in \mathbb{N}$, and for each $n \in \mathbb{N}$ let $\widehat{G}_n$ be an induced subgraph of $\widetilde{G}_n$ where all or some of the vertices of degree at most d are removed. Then $\lim_{n\to\infty}|E(\widehat{G}_n)|/|E(\widetilde{G}_n)| = 1$.*

Proof We wish to prove that $\varepsilon := \limsup_{n\to\infty}\varepsilon_n = 0$, where $\varepsilon_n := 1 - |E(\widehat{G}_n)|/|E(\widetilde{G}_n)|$. By taking a subsequence we may assume $\varepsilon = \lim_{n\to\infty}\varepsilon_n$. We will carry out the proof by contradiction, and assume $\varepsilon > 0$. By definition of $\widehat{G}_n$ there are at least $\varepsilon_n|E(\widetilde{G}_n)|$ edges of $\widetilde{G}_n$ which have at least one endpoint of degree at most d. Hence there are at least $\varepsilon_n|E(\widetilde{G}_n)|/d$ vertices with degree between 1 and d. In the canonical stretched graphon of $\widetilde{G}_n$, each vertex corresponds to an interval of length $(2|E(\widetilde{G}_n)|)^{-1/2}$. Hence the total length of the intervals corresponding to vertices of degree between 1 and d is at least $2^{-1/2}\varepsilon_n|E(\widetilde{G}_n)|^{1/2}d^{-1}$, which tends to infinity as $n \to \infty$. It follows that for each $M > 0$ and any sets $U_n \subset \mathbb{R}_+$ of measure at most M,

$$\|W^{\widetilde{G}_n,s} - W^{\widetilde{G}_n,s}\mathbf{1}_{U_n\times U_n}\|_1 \geq \big(2^{-1/2}\varepsilon_n|E(\widetilde{G}_n)|^{1/2}d^{-1} - M\big)\cdot(2|E(\widetilde{G}_n)|)^{-1/2},$$

which is at least $\varepsilon(2^{3/2}d)^{-1}$ when n is sufficiently large. Thus $(\widetilde{G}_n)_{n\in\mathbb{N}}$ does not have uniformly regular tails, and we have obtained the desired contradiction. ■

We will now prove Theorem 26. Note that we use a result of Kallenberg (2005, Theorem 9.25) for part of the argument, a result which is also used by Veitch and Roy (2015), but that we use it to prove Theorem 26, which characterizes exchangeable random graphs that have uniformly regular tails, while Veitch and Roy (2015) use it to characterize exchangeable random graphs that have finitely many edges for each finite time, but which do not necessarily have uniformly regular tails (a notion not considered by Veitch and Roy, 2015).

Proof of Theorem 26 First assume $(\widetilde{G}_t)_{t\geq 0}$ is a graphon process generated by $\mathcal{W}_\alpha$ with isolated vertices, where α is a random variable. We want to prove that $(\widetilde{G}_t)_{t\geq 0}$ has uniformly regular tails, and that the measure ξ is exchangeable. Regularity of tails is immediate from Theorems 28(i) and 15. Exchangeability is immediate by observing that the Poisson random measure $\mathcal{V}$ on $\mathbb{R}_+ \times S$ defined in the beginning of Section 2.4 is identical in law to $\{(\phi(t), x) : (t, x) \in \mathcal{V}\}$ for any measure-preserving transformation $\phi\colon \mathbb{R}_+ \to \mathbb{R}_+$ (in particular, for the case when ϕ corresponds to a permutation of intervals).

To prove the second part of the theorem assume that ξ is jointly exchangeable and that $(\widetilde{G}_t)_{t\geq 0}$ has uniformly regular tails. By joint exchangeability of ξ it follows from the representation theorem for jointly exchangeable random measures on $\mathbb{R}^2_+$ (Kallenberg, 2005, Theorem 9.24) that a.s.

$$\begin{aligned}\xi = &\sum_{i,j} f(\alpha, x_i, x_j, \zeta_{\{i,j\}})\delta_{t_i,t_j} + \beta\lambda_D + \gamma\lambda^2 \\ &+ \sum_{j,k}\big(g(\alpha, x_j, \chi_{j,k})\delta_{t_j,\sigma_{j,k}} + g'(\alpha, x_j, \chi_{j,k})\delta_{\sigma_{j,k},t_j}\big) \\ &+ \sum_j\big(h(\alpha, x_j)(\delta_{t_j}\otimes\lambda) + h'(\alpha, x_j)(\lambda\otimes\delta_{t_j})\big) \\ &+ \sum_k\Big(l(\alpha,\eta_k)\delta_{\rho_k,\rho'_k} + l'(\alpha,\eta_k)\delta_{\rho'_k,\rho_k}\Big),\end{aligned} \tag{22}$$

for some measurable functions $f \geq 0$ on $\mathbb{R}_+^4$, $g, g' \geq 0$ on $\mathbb{R}_+^3$, and $h, h', l, l' \geq 0$ on $\mathbb{R}_+^2$, a set of independent uniform random variables $(\zeta_{\{i,j\}})_{i,j\in\mathbb{N}}$ with values in $[0,1]$, independent unit rate Poisson processes $(t_j, x_j)_{j\in\mathbb{N}}$ and $(\sigma_{i,j}, \chi_{i,j})_{j\in\mathbb{N}}$ on $\mathbb{R}_+^2$ for $i \in \mathbb{N}$ and $(\rho_j, \rho'_j, \eta_j)_{j\in\mathbb{N}}$ on $\mathbb{R}_+^3$, an independent set of random variables $\alpha, \beta, \gamma \geq 0$, and λ (resp. λ_D) denoting Lebesgue measure on $\mathbb{R}_+$ (resp. the diagonal $x_1 = x_2 \geq 0$).

By the definition (4) in Section 2.4 of ξ as a sum of point masses, all the terms in (22) involving Lebesgue measure must be zero; i.e., except on an event of probability zero, $\beta = \gamma = 0$ and $h(\alpha, x_j) = h'(\alpha, x_j) = 0$ for all $j \in \mathbb{N}$. Recall that by (5) each vertex can be uniquely identified with the time $t \geq 0$ when it appeared in the graph, and that each point mass $\delta_{t,t'}$ with $t, t' \geq 0$ represents an edge between the two vertices associated with t and t'. Almost surely no two of the random variables $\rho_k, \rho'_k, t_i, t_j, \sigma_{j,k}$ for $i, j, k \in \mathbb{N}$ have the same value, and hence the functions f, g, g', l, l' take values in $\{0, 1\}$ almost everywhere. Furthermore, since the graphs $\widetilde{G}_t$ are undirected, we have $g = g'$ and $l = l'$, and f is symmetric in its second and third input argument.

First we will argue that the subgraphs $\widehat{G}_t$ of $\widetilde{G}_t$ corresponding to the terms

$$f(\alpha, x_i, x_j, \zeta_{\{i,j\}})\delta_{t_i,t_j}$$

have the law of a graphon process with isolated vertices generated by some (possibly random) graphon $\mathcal{W}$. Condition on the realization of α, and define the function $W_\alpha \colon \mathbb{R}_+^2 \to [0,1]$ by

$$W_\alpha(x, x') := \mathbb{P}(f(\alpha, x, x', \zeta_{\{i,j\}}) = 1 \,|\, \alpha) \qquad \text{for all } x, x' \in \mathbb{R}_+.$$

It follows that, conditioned on α such that $W_\alpha \in L^1$, $(\widehat{G}_t)_{t\geq 0}$ has the law of a graphon process generated by $\mathcal{W}_\alpha = (W_\alpha, \mathbb{R}_+)$. To conclude we need to prove that $W_\alpha \in L^1$ almost surely, which will be done in the next two paragraphs.

First we will argue that $(\widehat{G}_t)_{t\geq 0}$ has uniformly regular tails. Since no two of the random variables $\rho_k, \rho'_k, t_i, t_j, \sigma_{j,k}$ have the same value for $i, j, k \in \mathbb{N}$, each point mass δ_{ρ_k,ρ'_k} or $\delta_{\rho'_k,\rho_k}$ of ξ corresponds to an isolated edge, i.e., an edge between two vertices each of degree one, and each point mass $\delta_{\sigma_{j,k},t_j}$ or $\delta_{t_j,\sigma_{j,k}}$ of ξ corresponds to an edge between the vertex t_j in $\widehat{G}_t$ and a vertex of degree one; i.e., $\sum_{k\in\mathbb{N}}(\delta_{t_j,\sigma_{j,k}} + \delta_{\sigma_{j,k},t_j})$ corresponds to a star centered at the vertex associated with t_j. Note that $\widehat{G}_t$ and $\widetilde{G}_t$ satisfy the conditions of Lemma 60 with $d = 1$. Hence $\lim_{t\to\infty} |E(\widehat{G}_t)|/|E(\widetilde{G}_t)| = 1$, and since $\widetilde{G}_t$ has uniformly regular tails this implies that $\widehat{G}_t$ must also have uniformly regular tails.

We assume that W_α is not almost surely integrable, and will derive a contradiction. We condition on α such that $W_\alpha \notin L^1$, and to simplify notation we will write W instead of W_α. Let $\widehat{G}_t^+$ (resp. $\widehat{G}_t^-$) be the induced subgraph of $\widehat{G}_t$ consisting of the vertices for which the feature x satisfies $x \in I := \{x' \in \mathbb{R}_+ : \int_{\mathbb{R}_+} W(x, x')\, dx' \geq 1\}$ (resp. $x \notin I$). Let $\mathcal{W}^+ = (W^+, \mathbb{R}_+)$ and $\mathcal{W}^- = (W^-, \mathbb{R}_+)$ denote the corresponding graphons (we will see shortly that they are integrable), i.e., $W^+ = W\mathbf{1}_{I\times I}$ and $W^- = W\mathbf{1}_{I^c\times I^c}$. Since $|E(\widehat{G}_t)| < \infty$ a.s. for each $t \geq 0$ the measure ξ is locally finite a.s. We deduce from this that $\lambda(I) < \infty$ and $\|W^-\|_1 < \infty$ (Kallenberg, 2005, Theorem 9.25, (iii) and (iv)). By applying Proposition 56 this implies further that

$$\lim_{t\to\infty} t^{-2}|E(\widehat{G}_t^+)| = \frac{1}{2}\|W^+\|_1 \leq \frac{1}{2}\lambda(I)^2 < \infty,$$

$$\lim_{t\to\infty} t^{-2}|E(\widehat{G}_t^-)| = \frac{1}{2}\|W^-\|_1 < \infty,$$

and

$$\lim_{t\to\infty} t^{-2}|E(\widehat{G}_t)| = \infty.$$

It follows that if $\widetilde{E}(\widehat{G}_t) := E(\widehat{G}_t)\backslash(E(\widehat{G}_t^+) \cup E(\widehat{G}_t^-))$ is the set of edges having one endpoint in $V(\widehat{G}_t^+)$ and one endpoint in $V(\widehat{G}_t^-)$, we have

$$\lim_{t\to\infty} |\widetilde{E}(\widehat{G}_t)|/|E(\widehat{G}_t)| = 1. \tag{23}$$

For the stretched canonical graphon $\mathcal{W}^{\widehat{G}_t,s}$ the edges $\widetilde{E}(\widehat{G}_t)$ correspond to $A := (J_t \times J_t^c) \cup (J_t^c \times J_t) \subset \mathbb{R}_+^2$, where $J_t \subset \mathbb{R}_+$ corresponds to $V(\widehat{G}_t^+)$. Since $|V(\widehat{G}_t^+)| = \Theta(t)$, we have $\lambda(J_t) = |V(\widehat{G}_t^+)|(2|E(\widehat{G}_t)|)^{-1/2} = o_t(1)$. By (23) and $\|W^{\widehat{G}_t,s}\|_1 = 1$, we have $\lim_{t\to\infty} \|W^{\widehat{G}_t,s}\mathbf{1}_{A^c}\|_1 = 0$. Since $\lambda(J_t) = o_t(1)$ and $W^{\widehat{G}_t,s}$ takes values in $[0,1]$, we have $\lim_{t\to\infty} \|W^{\widehat{G}_t,s}\mathbf{1}_{A\cap U_t^2}\|_1 = 0$ for all sets $U_t \subset \mathbb{R}_+$ of bounded measure. We have obtained a contradiction to the hypothesis of uniform regularity of tails, since

$$\lim_{t\to\infty} \|W^{\widehat{G}_t,s}\mathbf{1}_{U_t^2}\|_1 \leq \lim_{t\to\infty} \|W^{\widehat{G}_t,s}\mathbf{1}_{U_t^2\cap A}\|_1 + \lim_{t\to\infty} \|W^{\widehat{G}_t,s}\mathbf{1}_{A^c}\|_1 = 0.$$

To complete the proof that $(\widetilde{G}_t)_{t\geq 0}$ has the law of a graphon process with isolated vertices, we need to argue that a.s.

$$l(\alpha, \eta_k) = g(\alpha, x_j, \chi_{j,k}) = 0 \qquad \text{for all } k, j \in \mathbb{N}. \tag{24}$$

Let $N_t \in \mathbb{N}_0$ denote the number of edges associated with terms of ξ of the form $\delta_{\rho_k,\rho'_k} + \delta_{\rho'_k,\rho_k}$, and let $\widetilde{N}_t$ denote the number of edges associated with terms of ξ of the form $\delta_{\sigma_{j,k},t_j} + \delta_{t_j,\sigma_{j,k}}$. Since $\widehat{G}_t$ and $\widetilde{G}_t$ satisfy the conditions of Lemma 60 with $d = 1$, and since Lemma 56 implies that a.s.-$\lim_{t\to\infty} |E(\widetilde{G}_t)|/t^2 = \frac{1}{2}\|W\|_1$, it follows that a.s.

$$\lim_{t\to\infty} N_t/t^2 = 0 \quad \text{and} \quad \lim_{t\to\infty} \widetilde{N}_t/t^2 = 0. \tag{25}$$

We will prove (24) by contradiction, and will consider each term separately. First assume $\lambda(\mathrm{supp}(l(\alpha, \cdot))) > 0$ with positive probability. Conditioned on a realization of α such that $p := \lambda(\mathrm{supp}(l(\alpha, \cdot))) > 0$, the random variable N_t is a Poisson random variable with expectation $t^2 p$. Hence $\lim_{t\to\infty} N_t/t^2 = p$, which is a contradiction to (25). It follows that $\lambda(\mathrm{supp}(l(\alpha, \cdot))) = 0$ a.s., and thus $l(\alpha, \eta_k) = 0$ for all $k \in \mathbb{N}$ a.s.

Now assume $\lambda(\mathrm{supp}(g(\alpha, \cdot, \cdot))) > 0$ with positive probability. Then there exists $\varepsilon > 0$ such that with positive probability there is a set $I \subset \mathbb{R}_+$ (depending on α) satisfying $\lambda(I) = \varepsilon$, and such that for all $x \in I$ it holds that $\lambda(I_x) > \varepsilon$, where $I_x := \{x' \in \mathbb{R}_+ : g(\alpha, x, x') = 1\}$. Consider the Poisson point process $(t_j, x_j)_{j\in\mathbb{N}}$ corresponding to the graphon process $\widetilde{G}_t$ with isolated vertices. The number of points $(t_j, x_j) \in [0, t] \times I$ evolves as a function of t as a Poisson process with rate $\varepsilon > 0$; hence the number of such points divided by t converges to ε a.s. For any given pair $(t_j, x_j) \in [0, t] \times I$ the number of points $(\sigma_{i,j}, \chi_{i,j}) \in [0, t] \times I_{x_j}$

for the Poisson point process $(\sigma_{i,j}, \chi_{i,j})_{i\in\mathbb{N}}$ has the law of a Poisson random variable with intensity greater than $t\varepsilon$. Hence,

$$t^{-2}\lim_{t\to\infty}\widetilde{N}_t = t^{-2}\lim_{t\to\infty}\sum_{j,k\,:\,t_j,\sigma_{j,k}\le t} g(\alpha, x_j, \chi_{j,k}) > \varepsilon^2.$$

This contradicts (25), and thus completes our proof that $(\widetilde{G}_t)_{t\ge 0}$ has the law of a graphon process with isolated vertices. ■

Remark 61 *In our proof above we observed that the assumption of exchangeability alone is not sufficient to prove that $(\widetilde{G}_t)_{t\ge 0}$ has the law of a graphon process with isolated vertices. More precisely, without this assumption we might have $W \notin L^1$ and the measure might also consist of the terms containing g, g' and l, l'. We observed in the proof that the terms containing l, l' correspond to isolated edges, and that the terms containing g, g' correspond to "stars" centered at a vertex in the graphon process. It is outside the scope of this paper to do any further analysis of these more general exchangeable graphs.*

Appendix H. Left Convergence of Graphon Processes

In this appendix we will prove Proposition 30. The following lemma will imply part (ii) of the proposition.

Lemma 62 *Let $\mathcal{W}$ be a bounded, non-negative graphon, and assume that $h(F_k, \mathcal{W}) < \infty$ for a star F_k with k leaves. Then $h(F, \mathcal{W}) < \infty$ for all simple, connected graphs F of maximal degree at most k.*

Proof We first note that if $h(F_k, \mathcal{W}) = \int D_W(x)^k \, d\mu(x) < \infty$ for a star with k leaves, then the same holds for all stars with at most k leaves, since we know that $D_W \in L^1(S)$ by our definition of a graphon. Also, using that W is bounded, we assume without loss of generality that F is a tree T of maximal degree $\Delta \le k$.

Designate one of the vertices, r, as the root of the tree, and choose a vertex u_1 such that no other vertex is further from the root. If u_1 has distance 1 from r, then T is a star and there is nothing to prove. Let u be u_1's grandparent, let v be its parent, and let $u_2, \dots, u_s$ for $1 \le s \le \Delta - 1$ be its siblings. Note that by our assumption on u_1, all the siblings $u_1, \dots, u_s$ are leaves. Furthermore, if their grandparent u is the root and the root has no other children, then T is again a star, so we can rule that out as well.

If we remove the edge uv from T, we obtain two disjoint trees T_1 and T_2, and as just argued, the one containing u is a tree with at least 2 vertices and maximal degree at most Δ, while the second one is a star, again of maximal degree at most Δ. Because $h(T, \mathcal{W}) \le \|W\|_\infty h(T_1, \mathcal{W}) h(T_2, \mathcal{W})$, the lemma now follows by induction. ■

Proof of Proposition 30 We will start by proving (i). Fix some simple connected graph F with k vertices. By Proposition 56 applied with F and the simple connected graph on two vertices, respectively,

$$\lim_{t\to\infty} t^{-k}\mathrm{inj}(F, G_t) = \|W\|_1^{k/2} h(F, \mathcal{W}), \qquad 2\lim_{t\to\infty} t^{-2}|E(G_t)| = \|W\|_1,$$

and hence

$$\lim_{t\to\infty} |2E(G_t)|^{-k/2}\mathrm{inj}(F, G_t) = h(F, \mathcal{W}), \tag{26}$$

proving (i).

(ii) Since $h(F, \mathcal{W}) = \int D_w^k$ if F is a star with k leaves, we can use Lemma 62 to conclude that $h(F, \mathcal{W}) < \infty$ for every simple connected graph F with at least two vertices. Express $\hom(F, G_t)$ as $\hom(F, G_t) = \sum_\Phi \mathrm{inj}(F/\Phi, G_t)$, where we sum over all equivalence relations Φ on $V(F)$. By Proposition 56 applied with F/Φ, we have

$$\lim_{t\to\infty} |2E(G_t)|^{-k/2}\mathrm{inj}(F/\Phi, G_t) = 0$$

unless Φ is the equivalence relation for which the number of equivalence classes equals $|V(F)|$. Hence the estimate (26) holds with hom in place of inj, which completes the proof of (ii).

Next we will prove (iii). Let F be a simple connected graph with at least three vertices, and assume $d \in \mathbb{N}$ is such that the degree of the vertices of G_n is bounded by d. We may assume G_n has no isolated vertices, since $h(F, G_n)$ is invariant under adding or deleting isolated vertices. Under the assumption of no isolated vertices, we have $|E(G_n)| \ge |V(G_n)|/2$. By boundedness of degrees, $\hom(F, G_n) \le |V(G_n)| d^{|V(F)|-1}$. Combining these estimates, $h(F, G_n) \le |V(G_n)|^{1-|V(F)|/2} d^{|V(F)|-1}$, from which the desired result follows.

Now we will prove (iv). We first construct an example of a sequence of graphs $(G_n)_{n\in\mathbb{N}}$ which converges for the stretched cut metric $\delta_\square^s$, but which is not left convergent. Let $(\widetilde{G}_n)_{n\in\mathbb{N}}$ be a sequence of simple dense graphs with $|V(\widetilde{G}_n)| \to \infty$ that is convergent in the $\delta_\square$ metric, and hence also in the $\delta_\square^s$ metric.

Define $G_n := \widetilde{G}_n$ for even n, and for odd n let G_n be the union of $\widetilde{G}_n$ and $|E(\widetilde{G}_n)|^{7/8}$ vertices of degree one, which are all connected to the same uniformly random vertex of $\widetilde{G}_n$. Then $(G_n)_{n\in\mathbb{N}}$ converges for $\delta_\square^s$ with the same limit as $(\widetilde{G}_n)_{n\in\mathbb{N}}$, since $\widetilde{G}_n$ is an induced subgraph of G_n and $|E(\widetilde{G}_n)|/|E(G_n)| \to 1$. On the other hand, $(G_n)_{n\in\mathbb{N}}$ is not left convergent, since if F is the simple connected graph with three vertices and two edges, then $\hom(F, G_n) = \Omega(|E(\widetilde{G}_n)|^{14/8})$ for odd n and hence $h(F, G_n) \to \infty$ along sequences of odd n, while $h(F, G_n)$ converges to a finite number by the fact that dense graph sequences which are convergent in the cut metric are left convergent.

Finally we will provide a counterexample in the reverse direction; i.e., we will construct a sequence of graphs $(G_n)_{n\in\mathbb{N}}$ which is left convergent, but does not converge for the stretched cut metric. Let $(\widetilde{G}_n)_{n\in\mathbb{N}}$ be left convergent and satisfy $\lim_{n\to\infty} |E(\widetilde{G}_n)| = \infty$, and let G_n be the union of $\widetilde{G}_n$ and $|E(\widetilde{G}_n)|$ isolated edges. Then $(G_n)_{n\in\mathbb{N}}$ is left convergent, since $\hom(F, G_n) = \hom(F, \widetilde{G}_n) + 2|E(\widetilde{G}_n)|$ when F is the simple connected graph on two vertices, and $\hom(F, G_n) = \hom(F, \widetilde{G}_n)$ when F has at least three vertices. On the other hand, $(G_n)_{n\in\mathbb{N}}$ is not convergent for $\delta_\square^s$, since it does not have uniformly regular tails. ■

Abstract

In recent years, stochastic gradient descent (SGD) methods and randomized linear algebra (RLA) algorithms have been applied to many large-scale problems in machine learning and data analysis. SGD methods are easy to implement and applicable to a wide range of convex optimization problems. In contrast, RLA algorithms provide much stronger performance guarantees but are applicable to a narrower class of problems. We aim to bridge the gap between these two methods in solving *constrained* overdetermined linear regression problems—e.g., ℓ_2 and ℓ_1 regression problems.

- We propose a hybrid algorithm named pwSGD that uses RLA techniques for preconditioning and constructing an importance sampling distribution, and then performs an SGD-like iterative process with weighted sampling on the preconditioned system.
- By rewriting a deterministic ℓ_p regression problem as a stochastic optimization problem, we connect pwSGD to several existing ℓ_p solvers including RLA methods with algorithmic leveraging (RLA for short).
- We prove that pwSGD inherits faster convergence rates that only depend on the lower dimension of the linear system, while maintaining low computation complexity. Such SGD convergence rates are superior to other related SGD algorithm such as the weighted randomized Kaczmarz algorithm.
- Particularly, when solving ℓ_1 regression with size n by d, pwSGD returns an approximate solution with ϵ relative error in the objective value in $\mathcal{O}(\log n \cdot \mathrm{nnz}(A) + \mathrm{poly}(d)/\epsilon^2)$ time. This complexity is *uniformly* better than that of RLA methods in terms of both ϵ and d when the problem is unconstrained. In the presence of constraints, pwSGD only has to solve a sequence of much simpler and smaller optimization problem over the same constraints. In general this is more efficient than solving the constrained subproblem required in RLA.
- For ℓ_2 regression, pwSGD returns an approximate solution with ϵ relative error in the objective value and the solution vector measured in prediction norm in $\mathcal{O}(\log n \cdot \mathrm{nnz}(A) + \mathrm{poly}(d)\log(1/\epsilon)/\epsilon)$ time. We show that for unconstrained ℓ_2 regression, this complexity is comparable to that of RLA and is asymptotically better over several state-of-the-art solvers in the regime where the desired accuracy ϵ, high dimension n and low dimension d satisfy $d \geq 1/\epsilon$ and $n \geq d^2/\epsilon$.

We also provide lower bounds on the coreset complexity for more general regression problems, indicating that still new ideas will be needed to extend similar RLA preconditioning ideas to weighted SGD algorithms for more general regression problems. Finally, the effectiveness of such algorithms is illustrated numerically on both synthetic and real datasets, and the results are consistent with our theoretical findings and demonstrate that pwSGD converges to a medium-precision solution, e.g., $\epsilon = 10^{-3}$, more quickly.

1. Introduction

Many novel algorithms for large-scale data analysis and machine learning problems have emerged in recent years, among which stochastic gradient descent (SGD) methods and randomized linear algebra (RLA) algorithms have received much attention—both for their strong performance in practical applications and for their interesting theoretical properties (Bottou, 2010; Mahoney, 2011). Here, we consider the ubiquitous ℓ_1 and ℓ_2 regression problems, and we describe a novel RLA-SGD algorithm called pwSGD (preconditioned weighted SGD). Our new algorithm combines the advantages of both RLA and SGD methods for solving constrained overdetermined ℓ_1 and ℓ_2 regression problems.

Consider the overdetermined ℓ_p regression problem

$$\min_{x \in \mathcal{Z}} f(x) = \|Ax - b\|_p, \tag{1}$$

where $p \in [1, \infty]$, $A \in \mathbb{R}^{n \times d}$, $b \in \mathbb{R}^n$ and $n \gg d$. When $\mathcal{Z} = \mathbb{R}^d$, i.e., the solution space is unconstrained, the cases $p \in \{1, 2\}$ are respectively known as the Least Absolute Deviations (LAD, or ℓ_1) and Least-squares (LS, or ℓ_2) regression problems. Classically, the unconstrained ℓ_2 regression problem can be solved by eigenvector-based methods with worst-case running time $\mathcal{O}(nd^2)$ (Golub and Van Loan, 1996); or by iterative methods for which the running time depends on the condition number of A (Barrett et al., 1994; Kelley, 1995; Saad, 2003), while the unconstrained ℓ_1 regression problem can be formulated as a linear program (Portnoy and Koenker, 1997; Chen et al., 2001) and solved by an interior-point method (Portnoy and Koenker, 1997; Portnoy, 1997).

For these and other regression problems, SGD algorithms are widely used in practice because of their scalability and efficiency. In contrast, RLA algorithms have better theoretical guarantees but (thus far) have been less flexible, e.g., in the presence of constraints. For example, they may use an interior point method for solving a constrained subproblem, and this may be less efficient than SGD. (Without constraints, RLA methods can be used to construct subproblems to be solved exactly, or they can be used to construct preconditioners for the original problem; see Yang et al. (2016b) for details and implementations of these RLA methods to compute low, medium, and high precision solutions on up to terabyte-sized input data.) In this paper, we combine these two algorithmic approaches to develop a method that takes advantage of the strengths of both of these approaches.

*. A conference version of this paper appears under the same title in *Proceedings of ACM-SIAM Symposium on Discrete Algorithms*, Arlington, VA, 2016 (Yang et al., 2016a).

1.1 Overview of our main algorithm

Our main algorithm pwSGD is a hybrid method for solving constrained overdetermined ℓ_1 and ℓ_2 regression problems. It consists of two main steps. First, apply RLA techniques for preconditioning and construct an importance sampling distribution. Second, apply an SGD-like iterative phase with weighted sampling on the preconditioned system. Such an algorithm preserves the simplicity of SGD and the high quality theoretical guarantees of RLA. In particular, we prove that after preconditioning, the number of iterations required to converge to a target accuracy is fully predictable and only depends on the low dimension d, i.e., it is independent of the high dimension n. We show that, with a proper choice of preconditioner, pwSGD runs in $\mathcal{O}(\log n \cdot \mathrm{nnz}(A) + \mathrm{poly}(d)/\epsilon^2)$ time to return an approximate solution with ϵ relative error in the objective for constrained ℓ_1 regression; and in $\mathcal{O}(\log n \cdot \mathrm{nnz}(A) + \mathrm{poly}(d)\log(1/\epsilon)/\epsilon)$ time to return an approximate solution with ϵ relative error in the solution vector in prediction norm for constrained ℓ_2 regression. Furthermore, for unconstrained ℓ_2 regression, pwSGD runs in $\mathcal{O}(\log n \cdot \mathrm{nnz}(A) + d^3\log(1/\epsilon)/\epsilon)$ time to return an approximate solution with ϵ relative error in the objective.

To provide a quick overview of how pwSGD compares to existing algorithms, in Tables 1 and 2, we summarize the complexity required to compute a solution $\hat{x}$ with relative error, i.e., $(f(\hat{x}) - f(x^*))/f(x^*) = \epsilon$, of several solvers for unconstrained ℓ_1 and ℓ_2 regression. In Table 1, RLA with algorithmic leveraging (RLA for short) (Clarkson et al., 2013; Yang et al., 2014) is a popular method for obtaining a low-precision solution and randomized IPCPM is an iterative method for finding a higher-precision solution (Meng and Mahoney, 2013b) for unconstrained ℓ_1 regression. Clearly, pwSGD has a uniformly better complexity than that of RLA methods in terms of both d and ϵ, no matter which underlying preconditioning method is used. This makes pwSGD a more suitable candidate for getting a medium-precision, e.g., $\epsilon = 10^{-3}$, solution.

In Table 2, all the methods require constructing a sketch first. Among them, "low-precision" solvers refer to "sketching + direct solver" type algorithms; see Drineas et al. (2011); Clarkson and Woodruff (2013) for projection-based examples and Clarkson and Woodruff (2013); Drineas et al. (2012) for sampling-based examples. "High-precision" solvers refer to "sketching + preconditioning + iterative solver" type algorithms; see Avron et al. (2010); Meng et al. (2014) for examples. One can show that, when $d \geq 1/\epsilon$ and $n \geq d^2/\epsilon$, pwSGD is asymptotically better than all the solvers shown in Table 2. Moreover, although high-precision solvers are more efficient when a high-precision solution is desired, usually they are designed for unconstrained problems, whereas pwSGD also works for constrained problems.

We remark that, compared to general SGD algorithms, our RLA-SGD hybrid algorithm pwSGD *works for problems in a narrower range, i.e., ℓ_p regression, but inherits the strong theoretical guarantees of RLA. When solving ℓ_2 regression, for which traditional RLA methods are well designed,* pwSGD *has a comparable complexity. On the other hand, when solving ℓ_1 regression, due to the efficiency of SGD update,* pwSGD *has a strong advantage over traditional RLA methods.* See Sections 4.3 and 4.4 for more detailed discussions.

Finally, in Section 5, empirically we show that pwSGD performs favorably compared to other competing methods, as it converges to a medium-precision solution more quickly.

solver	complexity (general)	complexity (sparse)
RLA with algorithmic leveraging	$time(R) + \mathcal{O}(\mathrm{nnz}(A)\log n + \bar{\kappa}_1^{\frac{5}{4}} d^{\frac{17}{4}}/\epsilon^{\frac{5}{2}})$	$\mathcal{O}(\mathrm{nnz}(A)\log n + d^{\frac{69}{8}}\log^{\frac{25}{8}} d/\epsilon^{\frac{5}{2}})$
randomized IPCPM	$time(R) + nd^2 + \mathcal{O}((nd + \mathrm{poly}(d))\log(\bar{\kappa}_1 d/\epsilon))$	$nd^2 + \mathcal{O}((nd + \mathrm{poly}(d))\log(d/\epsilon))$
pwSGD	$time(R) + \mathcal{O}(\mathrm{nnz}(A)\log n + d^3\bar{\kappa}_1/\epsilon^2)$	$\mathcal{O}(\mathrm{nnz}(A)\log n + d^{\frac{13}{2}}\log^{\frac{5}{2}} d/\epsilon^2)$

Table 1: Summary of complexity of several unconstrained ℓ_1 solvers that use randomized linear algebra. The target is to find a solution $\hat{x}$ with accuracy $(f(\hat{x}) - f(x^*))/f(x^*) \leq \epsilon$, where $f(x) = \|Ax - b\|_1$. In the above, $time(R)$ denotes the time needed to compute a matrix R such that AR^{-1} is well-conditioned with condition number $\bar{\kappa}_1$ (Definition 1). The general complexity bound and the one using sparse reciprocal exponential transform (Woodruff and Zhang, 2013) as the underlying sketching method are presented. Here, we assume $n \gg d$ such that $n > d^3\log d$ and the underlying ℓ_1 regression solver in RLA with algorithmic leveraging algorithm takes $\mathcal{O}(n^{\frac{5}{4}}d^3)$ time to return a solution (Portnoy and Koenker, 1997). The complexity of each algorithm is computed by setting the failure probability to be a constant.

solver	complexity (SRHT)	complexity (CW)
low-precision solvers (projection)	$\mathcal{O}\left(nd\log(d/\epsilon) + d^3\log n(\log d + 1/\epsilon)\right)$	$\mathcal{O}\left(\mathrm{nnz}(A) + d^4/\epsilon^2\right)$
low-precision solvers (sampling)	$\mathcal{O}\left(nd\log n + d^3\log n\log d + d^3\log d/\epsilon\right)$	$\mathcal{O}\left(\mathrm{nnz}(A)\log n + d^4 + d^3\log d/\epsilon\right)$
high-precision solvers	$\mathcal{O}\left(nd\log n + d^3\log n\log d + nd\log(1/\epsilon)\right)$	$\mathcal{O}\left(\mathrm{nnz}(A) + d^4 + nd\log(1/\epsilon)\right)$
pwSGD	$\mathcal{O}\left(nd\log n + d^3\log n\log d + d^3\log(1/\epsilon)/\epsilon\right)$	$\mathcal{O}\left(\mathrm{nnz}(A)\log n + d^4 + d^3\log(1/\epsilon)/\epsilon\right)$

Table 2: Summary of complexity of several unconstrained ℓ_2 solvers that use randomized linear algebra. The target is to find a solution $\hat{x}$ with accuracy $(f(\hat{x}) - f(x^*))/f(x^*) \leq \epsilon$, where $f(x) = \|Ax - b\|_2$. Two sketching methods, namely, SRHT (Drineas et al., 2011; Tropp, 2011) and CW (Clarkson and Woodruff, 2013) are considered. Here, we assume $d \leq n \leq e^d$. The complexity of each algorithm is computed by setting the failure probability to be a constant.

1.2 Connection to related algorithms

As a side point of potentially independent interest, a connection between ℓ_p regression and stochastic optimization will allow us to unify our main algorithm pwSGD and some existing ℓ_p regression solvers under the same framework. In Figure 1, we present the basic structure of this framework, which provides a view of pwSGD from another perspective. To be more specific, we (in Proposition 4 formally) reformulate the deterministic ℓ_p regression problem in (1) as a stochastic optimization problem, i.e.,

$$\min_{y\in\mathcal{Y}} \|Uy - b\|_p^p = \min_{y\in\mathcal{Y}} \mathbb{E}_{\xi\sim P}\left[|U_\xi y - b_\xi|^p/p_\xi\right],$$

where U is a basis for the range space of A and ξ is a random variable over $\{1,\ldots,n\}$ with distribution $P = \{p_i\}_{i=1}^n$. As suggested in Figure 1, to solve this stochastic optimization problem, typically one needs to answer the following three questions.

- *(C1): How to sample: SAA (Sampling Average Approximation, i.e., draw samples in a batch mode and deal with the subproblem) or SA (Stochastic Approximation, i.e., draw a mini-batch of samples in an online fashion and update the weight after extracting useful information)?*
- *(C2): Which probability distribution P (uniform distribution or not) and which basis U (preconditioning or not) to use?*

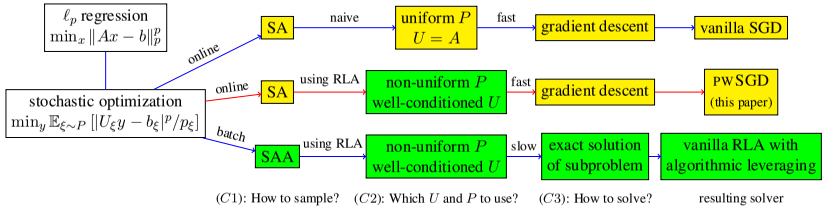

Figure 1: An overview of our framework for solving ℓ_p regression via stochastic optimization. To construct a solver, three choices have to be made. For ($C1$), the answer can be either SAA (Sampling Average Approximation, i.e., sample a batch of points and deal with the subproblem) or SA (Stochastic Approximation, i.e., sample a mini-batch in an online fashion and update the weight vector after extracting useful information). In ($C2$), the answer is determined by P, which denotes the underlying sampling distribution (uniform or nonuniform) and U, which denotes the basis with which to work (original or preconditioned system). Finally, for ($C3$), the answer determines how we solve the subproblem (in SAA) or what information we extract and how we update the weight (in SA).

- *($C3$): Which solver to use (e.g., how to solve the subproblem in SAA or how to update the weight in SA)?*

Some combinations of these choices may lead to existing solvers; see Figure 1 and Section 3 for more details. A natural question arises: is there a combination of these choices that leverages the algorithmic benefits of RLA preconditioning to improve the performance of SGD-type algorithms? Recall that RLA methods (in particular, those that exploit algorithmic averaging; see Appendix B and also Drineas et al. (2012); Yang et al. (2016b)) inherit strong theoretical guarantees because the underlying sampling distribution P captures most of the important information of the original system; moreover, such a carefully constructed leverage-based distribution is defined based on a well-conditioned basis U, e.g., an orthogonal matrix for $p = 2$. One immediate idea is to develop an SGD-like algorithm that uses the same choice of U and P as in RLA methods. This simple idea leads to our main algorithm pwSGD, which is an online algorithm ($C1$) that uses a non-uniform sampling distribution ($C2$) and performs a gradient descent update ($C3$) on a preconditioned system ($C2$), as Figure 1 suggests.

Indeed, for least-squares problems (unconstrained ℓ_2 regression), pwSGD is highly related to the weighted randomized Kaczmarz (RK) algorithm (Strohmer and Vershynin, 2009; Needell et al., 2014) in the way that both algorithms are SGD algorithm with non-uniform P but pwSGD runs on a well-conditioned basis U while randomized RK doesn't involve preconditioning. In Section 4.5 we show that this preconditioning step dramatically reduces the number of iterations required for pwSGD to converge to a (fixed) desired accuracy.

1.3 Main contributions

Now we are ready to state our main contributions.

- We reformulate the deterministic ℓ_p regression problem (1) into a stochastic optimization problem (4) and make connections to existing solvers including RLA methods with algorithmic leveraging and weighted randomized Kaczmarz algorithm (Sections 3 and 4.5).
- We develop a hybrid algorithm for solving *constrained* overdetermined ℓ_1 and ℓ_2 regression called pwSGD, which is an SGD algorithm with preconditioning and a non-uniform sampling distribution constructed using RLA techniques. We present several choices of the preconditioner and their tradeoffs. We show that with a suitable preconditioner, convergence rate of the SGD phase only depends on the low dimension d, and is independent of the high dimension n (Sections 4.1 and 4.2).
- We prove that pwSGD returns an approximate solution with ϵ relative error in the objective value in $\mathcal{O}(\log n \cdot \mathrm{nnz}(A) + \mathrm{poly}(d)/\epsilon^2)$ time for ℓ_1 regression. This complexity is *uniformly* better than that of RLA methods in terms of both ϵ and d when the problem is unconstrained. In the presence of constraints, pwSGD only has to solve a sequence of much simpler and smaller optimization problems over the same constraints, which in general can be more efficient than solving the constrained subproblem required in RLA (Sections 4.3 and 4.4).
- We prove that pwSGD returns a solution with ϵ relative error in the objective value and the solution vector measured in prediction norm in $\mathcal{O}(\log n \cdot \mathrm{nnz}(A) + \mathrm{poly}(d)\log(1/\epsilon)/\epsilon)$ time for ℓ_2 regression. We show that for unconstrained ℓ_2 regression, this complexity is asymptotically better than several state-of-the-art solvers in the regime where $d \geq 1/\epsilon$ and $n \geq d^2/\epsilon$ (Sections 4.3 and 4.4).
- Empirically, we show that when solving ℓ_1 and ℓ_2 regression problems, pwSGD inherits faster convergence rates and performs favorably in the sense that it obtains a medium-precision much faster than other competing SGD-like solvers do. Also, theories regarding several choices of preconditioners are numerically verified (Section 5).
- We show connections between RLA algorithms and coreset methods of empirical optimization problems under the framework of Feldman and Langberg (2011). We show that they are equivalent for ℓ_p regression and provide lower bounds on the coreset complexity for some more general regression problems. We also discuss the difficulties in extending similarly RLA preconditioning ideas to general SGD algorithms (Section 6).

1.4 Other prior related work

Numerous RLA algorithms have been proposed to solve ℓ_p regression problems (Yang et al., 2016b). RLA theories show that to achieve a relative-error bound, the required sampling size only depends on d, independent of n, and the running time also depends on the time to implement the random projection at the first step. Regarding the performance of unconstrained regression problems, in Dasgupta et al. (2009) the authors provide an algorithm that constructs a well-conditioned basis by ellipsoid rounding and a subspace-preserving sampling matrix for ℓ_p regression problems in $\mathcal{O}(nd^5 \log n)$ time; a sampling algorithm based on Lewis weights for ℓ_p regression have been proposed by Cohen and Peng (2015); the algorithms in Sohler and Woodruff (2011) and Clarkson et al. (2013) use the "slow" and "fast" Cauchy Transform to compute the low-distortion ℓ_1 embedding matrix and solve the over-constrained ℓ_1 regression problem in $\mathcal{O}(nd^{1.376+})$ and $\mathcal{O}(nd \log n)$ time, respectively; the algorithms in Drineas et al. (2012) estimate the leverage scores up to a small factor and solve the ℓ_2 regression problem in $\mathcal{O}(nd \log n)$ time respectively; and the algorithms in Clarkson and Woodruff (2013); Meng and Mahoney (2013a); Nelson and Nguyen (2013), solve the problem via sparse random projections in nearly input-sparsity time, i.e., $\mathcal{O}(\log n \cdot \mathrm{nnz}(A))$

time, plus lower-order terms, and a tighter analysis is provided by Cohen (2016). As for iterative algorithms, the algorithms in Avron et al. (2010); Meng et al. (2014) use randomized linear algebra to compute a preconditioner and call iterative solvers such as LSQR to solve the preconditioned problem.

In contrast, SGD algorithms update the solution vector in an iterative fashion and are simple to implement and scalable to large datasets (Bottou and Le Cun, 2004; Shalev-Shwartz and Srebro, 2008; Bottou and Bousquet, 2008). Moreover, these methods can be easily extended for problems with general convex loss functions and constraints, such as Pegasos (Shalev-Shwartz et al., 2007) for regularized SVM and stochastic coordinate descent (SCD) for ℓ_1 regularization (Shalev-Shwartz and Tewari, 2009). Several techniques, such as SAGE (Hu et al., 2009), AdaGrad (Duchi et al., 2011), SVRG (Johnson and Zhang, 2013), have recently been proposed to accelerate the convergence rate of SGD, and Niu et al. (2011) also show that SGD is favorable for parallel/distributed computation. More recently, several works, e.g., Zhao and Zhang (2015); Needell et al. (2014) regarding SGD with weighted sampling are proposed, in which the authors show that the performance of SGD can be improved by using a nonuniform sampling distribution.

In addition, as we point out in Section 4.2, pwSGD has a close relationship to second-order methods. It can be viewed as an algorithm with approximate Hessians obtained by sketching and stochastic gradients. This is related to the iterative Hessian sketching algorithm for solving constrained least squares problems proposed by Pilanci and Wainwright (2014) which is essentially a Newton-type algorithm with iterative sketched Hessians and batch gradients. Moreover, the idea of using approximate Hessians and stochastic gradients have been discussed in several recent papers. For example, (Moritz et al., 2016; Byrd et al., 2016; Curtis, 2016) exploit the idea of approximating Hessian with L-BFGS type updates and (variance-reduced) stochastic updates.

2. Preliminaries

For any matrix $A \in \mathbb{R}^{n\times d}$, we use A_i and A^j to denote the i-th row and j-th column of A, respectively. We assume A has full rank, i.e., $\text{rank}(A) = d$. Also denote by $\kappa(A)$ the usual condition number of A, by $\text{nnz}(A)$ the number of nonzero elements in A, and by $\text{poly}(d)$ a low-degree polynomial in d. We also use $[n]$ to denote the set of indices $1, \ldots, n$.

Throughout this subsection, the definitions are applied to general $p \in [1, \infty)$. We denote by $|\cdot|_p$ the element-wise ℓ_p norm of a matrix: $|A|_p = \left(\sum_{i=1}^n \sum_{j=1}^d |A_{ij}|^p\right)^{1/p}$. In particular, when $p = 2$, $|\cdot|_2$ is equivalent to the Frobenius norm.

The following two notions on well-conditioned bases and leverage scores are crucial to our methods. The first notion is originally introduced by Clarkson (2005) and stated more precisely in Dasgupta et al. (2009), and it is used to justify the well-posedness of a ℓ_p regression problem. These notions were introduced by Dasgupta et al. (2009).

Definition 1 ((α, β, p)-conditioning and well-conditioned basis) *A matrix $A \in \mathbb{R}^{n\times d}$ is (α, β, p)-conditioned if $|A|_p \le \alpha$ and for all $x \in \mathbb{R}^d$, $\beta\|Ax\|_p \ge \|x\|_q$, where $1/p + 1/q = 1$. Define $\bar{\kappa}_p(A)$ as the minimum value of $\alpha\beta$ such that A is (α, β, p)-conditioned. We say that a basis U for* range(A) *is a well-conditioned basis if $\bar{\kappa}_p = \bar{\kappa}_p(U)$ is a low-degree polynomial in d, independent of n.*

The notion of leverage scores captures how important each row in the dataset is, and is used in the construction of the sampling probability.

Definition 2 (ℓ_p leverage scores) *Given $A \in \mathbb{R}^{n\times d}$, suppose U is an (α, β, p) well-conditioned basis for* range(A)*. Then the i-th leverage score λ_i of A is defined as $\lambda_i = \|U_i\|_p^p$ for $i = 1, \ldots, n$.*

2.1 Preconditioning

Here, we briefly review the preconditioning methods that will be used in our main algorithms. A detailed summary of various preconditioning methods can be found in Yang et al. (2014, 2016b). The procedure for computing a preconditioner can be summarized in the following two steps.

- Given a matrix $A \in \mathbb{R}^{n\times d}$ with full rank, we first construct a sketch $SA \in \mathbb{R}^{s\times d}$ for A satisfying
$$\sigma_S \cdot \|Ax\|_p \le \|SAx\|_p \le \kappa_S\sigma_S \cdot \|Ax\|_p, \quad \forall x \in \mathbb{R}^d, \tag{2}$$
where κ_S is the distortion factor independent of n.
- Next, we compute the QR factorization of SA whose size only depends on d. Return R^{-1}.

The following lemma guarantees that the preconditioner satisfies that AR^{-1} is well-conditioned since κ_S and s depend on d only, independent of n.

Lemma 3 *Let R be the matrix returned by the above preconditioning procedure, then we have*
$$\bar{\kappa}_p(AR^{-1}) \le \kappa_S d^{\max\{\frac{1}{2}, \frac{1}{p}\}} s^{|\frac{1}{p} - \frac{1}{2}|}. \tag{3}$$

Various ways of computing a sketching matrix S satisfying (2) are proposed recently. It is worth mentioning that sketching algorithms that run in nearly input-sparsity time, i.e., in time proportional to $\mathcal{O}(\text{nnz}(A))$ to obtain such a sketch matrix for $p = 1$ and $p = 2$ are available via random projections composed of sparse matrices; see Clarkson and Woodruff (2013); Meng and Mahoney (2013a); Woodruff and Zhang (2013); Nelson and Nguyen (2013) for details. In Tables 5 and 6 in Appendix A we provide a short summary of these sketching methods and the resulting running time and condition number.

3. A connection to stochastic optimization

In this section, we describe our framework for viewing deterministic ℓ_p regression problems from the perspective of stochastic optimization. This framework will recover both RLA and SGD methods in a natural manner; and by combining these two approaches in a particular way we will obtain our main algorithm.

We reformulate overdetermined ℓ_p regression problems of the form (1) into a stochastic optimization problem of the form (4) [1], which reformulates a deterministic regression problem into a stochastic optimization problem. Note that the result holds for general $p \in [1, \infty)$.

Proposition 4 *Let $U \in \mathbb{R}^{n\times d}$ be a basis of the range space of A in the form $U = AF$, where $F \in \mathbb{R}^{d\times d}$. The constrained overdetermined ℓ_p regression problem* (1) *is equivalent to*
$$\min_{y\in\mathcal{Y}} \|Uy - b\|_p^p = \min_{y\in\mathcal{Y}} \mathbb{E}_{\xi\sim P}\left[H(y, \xi)\right], \tag{4}$$

1. Technically, this result is straightforward; but this reformulation allows us to introduce randomness—parameterized by a probability distribution P—into the deterministic problem (1) in order to develop randomized algorithms for it.

where ξ is a random variable over $\{1,\dots,n\}$ with distribution $P=\{p_i\}_{i=1}^n$, y is the decision variable in $\mathcal{Y}$, and $H(y,\xi)=|U_\xi y-b_\xi|^p/p_\xi$. The constraint set of y is $\mathcal{Y}=\{y\in\mathbb{R}^d|y=F^{-1}x, x\in\mathcal{Z}\}$.

With Proposition 4, as suggested in Figure 1, one can solve the overdetermined ℓ_p regression problem (1) by applying either SAA or SA, i.e., $(C1)$ on the stochastic optimization problem (4). In addition to the choice of SA versus SAA, one also has to choose U and P, i.e., $(C2)$, and determine the underlying solver, i.e., $(C3)$.

Assume that if SAA is used, then for $(C3)$ we solve the subproblem exactly, i.e., we compute a high-precision solution of the subproblem; this leads to a class of *randomized linear algebra* (RLA) algorithms for solving ℓ_p regression. Alternatively, if we assume that SA is used, then we extract the first-order information, i.e., sub-gradient of the sample, and update the weight in a gradient descent fashion; this leads to a family of *stochastic gradient descent* (SGD) algorithms for solving ℓ_p regression.

For $(C2)$, we need to choose a basis U that converts (1) into an equivalent problem represented by U and choose a distribution P for which the algorithm samples a row at every iteration accordingly. In general, different choices of U and P lead to different algorithms. In the following two subsections, we will discuss their effects on SAA and SA and make connections between existing solvers and our new solution methods. For simplicity, we assume there are no constraints, i.e., $\mathcal{Z}=\mathbb{R}^d$ (although much of this framework generalizes to nontrivial constraints).

3.1 Using RLA (SAA) to solve ℓ_p regression

In this subsection, we briefly discuss the algorithms induced by applying SAA to (4) with different choices of basis U and distribution P in Proposition 4.

We first show that the choice of the basis U has no effect on the resulting sampling algorithm. Let $S\in\mathbb{R}^{s\times n}$ be the equivalent sampling matrix in the sampling algorithm. That is,

$$S_{ij}=\begin{cases}1/p_j & \text{if the } j\text{-th row is sampled in the } i\text{-th iteration}\\ 0 & \text{otherwise.}\end{cases}$$

Then the subproblem can be cast as $\min_{y\in\mathcal{Y}}\|SUy-b\|_p^p$, which is equivalent to $\min_{x\in\mathcal{Z}}\|SAx-b\|_p^p$. Therefore, with a given distribution P, applying SAA to the stochastic optimization problem associated with any basis U is equivalent to applying SAA to the original problem with matrix A.

Next, we discuss the effect of the choice of P, i.e., the sampling distribution in SAA, on the required sampling size.

Naive choice of P One choice of P is a uniform distribution, i.e., $p_i=1/n$ for $i=1,\dots,n$. The resulting SAA algorithm becomes uniformly sampling s rows from the original n rows and solving the subproblem induced by the selected rows. If all the rows are equally "important", such an algorithm can be expected to work. However, consider the following toy example for which uniform sampling gives undesirable answers with high probability. Suppose the first row of the matrix contains the only nonzero element in the first column of the design matrix A. Since the only measurement of x_1 lies in the first row, in order to recover the optimal value, namely x_1^*, the first row in matrix A is crucial. However, when a uniform sampling scheme is used, the sampling size required in order to sample the first row is $\Omega(n)$. This implies that RLA with uniform sampling will fail with high probability unless the sampling size $s=\Omega(n)$.

Smarter choice of P In the above example, it is not hard to show that the leverage score of the first row is 1, i.e., it is much larger than the average value of the leverage scores. This inspires us to put more weights on "important" rows, i.e., rows with higher leverage scores. An immediate solution is to define P based on the leverage scores as follows:

$$p_i=\frac{\lambda_i}{\sum_{j=1}^n\lambda_j},$$

where λ_i is the i-th leverage score of A (which depends on whether one is working with ℓ_1, ℓ_2, or more general ℓ_p regression). Applying SAA with this distribution and solving the subproblem exactly recovers the recently proposed RLA methods with algorithmic leveraging for solving overdetermined ℓ_p regression problems; see Mahoney (2011); Dasgupta et al. (2009); Clarkson et al. (2013); Yang et al. (2014); Clarkson and Woodruff (2013); Meng and Mahoney (2013a); Ma et al. (2014) for details. (In RLA, this is simply solving the subproblem of the original problem, but in statistical learning theory, this has the interpretation of Empirirical Risk Minimization.) This algorithm is formally stated in Algorithm 3 in Appendix B. We also include its approximation-of-quality results from (Dasgupta et al., 2009) in Appendix B, which state that the resulting approximate solution $\hat{x}$ produces a $(1+\epsilon)$-approximation to the objective if the sampling size s is large enough. (Note, in particular, that "large enough" here means that when the desired accuracy and failure probability are fixed, the required sampling size only depends on the lower dimension d, independent of n.)

3.2 Using SGD (SA) to solve ℓ_p regression

Applying SA to (4) and updating the weight vector using first-order information results in a SGD algorithm. It is not hard to show that, given $U=AF$ and $P=\{p_i\}_{i=1}^n$, the update rule is as follows. Suppose the ξ_t-th row is sampled; then the weight vector x_t is updated by

$$x_{t+1}=x_t-\eta c_t H^{-1}A_{\xi_t},$$

where $H=\left(FF^\top\right)^{-1}\in\mathbb{R}^{d\times d}$, η is the step size, and c_t is a constant that depends on x_t and ξ_t.

Next, we discuss how different choices of U and P affect the convergence rates of the resulting SGD algorithms. For simplicity, we restrict our discussions to unconstrained ℓ_1 regressions.

Naive choice of U and P Consider the following choices of U and P that lead to undesirable convergence rates. Let $U=A$. If we apply the SGD with some distribution $P=\{p_i\}_{i=1}^n$, some simple arguments in the SGD convergence rate analysis lead to a relative approximation error of

$$\frac{f(\hat{x})-f(x^*)}{f(\hat{x})}=\mathcal{O}\left(\frac{\|x^*\|_2\max_{1\le i\le n}\|A_i\|_1/p_i}{\|Ax^*-b\|_1}\right), \tag{5}$$

where $f(x)=\|Ax-b\|_1$ and x^* is the optimal solution. When $\{p_i\}_{i=1}^n$ is the uniform distribution, (5) becomes $\mathcal{O}\left(n\frac{\|x^*\|_2\cdot M}{\|Ax^*-b\|_1}\right)$, where $M=\max_{1\le i\le n}\|A_i\|_1$ is the maximum ℓ_1 row norm of A. Alternatively, if one chooses p_i to be proportional to the row norms of A, i.e., $p_i=\frac{\|A_i\|_1}{\|A\|_1}$, then (5) becomes $\mathcal{O}\left(\frac{\|x^*\|_2\cdot\|A\|_1}{\|Ax^*-b\|_1}\right)$. Consider the following scenario. Given A and b, we continue to append samples (z,c) satisfying $z^\top x^*=c$ and $\|z\|_2\le M$ to A and b, respectively. This process will keep

x^*, M and $\|Ax^* - b\|_1$ unchanged. However, the value of n and $\|A\|_1$ will increase. Thus, in this case, the expected time for convergence of SGD with these naive sampling distributions might blow up as the size of the matrix grows.

Smarter choice of U and P To avoid this problem, we need to precondition the linear regression problem. If we work with a well-conditioned basis U for the range space of A and choose the sampling probabilities proportional to the row norms of U, i.e., leverage scores of A, then the resulting convergence rate on the relative error of the objective becomes $\mathcal{O}\left(\frac{\|y^*\|_2 \cdot \|U\|_1}{\|Uy^* - b\|_1}\right)$, where y^* is an optimal solution to the transformed problem. By Definition 1, if U is a well-conditioned basis, then one obtains $\|U\|_1 \leq \alpha$ and $\|y^*\|_\infty \leq \beta \|Uy^*\|_1$. Since the condition number $\alpha\beta$ of a well-conditioned basis depends only on d and since $\|Uy^* - b\|_1 / \|Uy^*\|_1$ is a constant, it implies that the resulting SGD inherits a convergence rate in a relative scale that depends on d and is independent of n.

The idea of using a preconditioner and a sampling distribution according to the leverage scores leads to our main algorithm.

4. Our Main Algorithm

In this section, we will state our main algorithm pwSGD (Algorithm 1) for solving the *constrained* overdetermined ℓ_1 and ℓ_2 regression problems. We now summarize the main steps of our main algorithm as follows.

First, we compute a well-conditioned basis U (Definition 1) for the range space of A implicitly via a conditioning method; see Tables 5 and 6 in Appendix A for a summary of recently proposed randomized conditioning methods. We refer this as the "implicit" method, i.e., it focuses on computing $R \in \mathbb{R}^{d \times d}$ such that $U = AR^{-1}$. A typical way of obtaining R is via the QR decomposition of SA where SA is a sketch of A; see Appendix A for more details.

Second, we either exactly compute or quickly approximate the leverage scores (Definition 2), i.e., the row norms of U as $\{\lambda_i\}_{i=1}^n$. To compute $\{\lambda_i\}_{i=1}^n$ exactly, we have to form the matrix U explicitly, which takes time $\mathcal{O}(nd^2)$. Alternatively, we can estimate the row norms of U without computing the product between A and R^{-1}, in order to further reduce the running time; see Appendix A for more details. We assume that $\{\lambda_i\}_{i=1}^n$ satisfy

$$(1-\gamma)\|U_i\|_p^p \leq \lambda_i \leq (1+\gamma)\|U_i\|_p^p, \tag{6}$$

where γ is the approximation factor of estimation. When the leverage scores are exact, the approximation factor $\gamma = 0$. From that, we can define a distribution P over $\{1, \ldots, n\}$ based on $\{\lambda_i\}_{i=1}^n$ as follows:

$$p_i = \frac{\lambda_i}{\sum_{j=1}^n \lambda_j}. \tag{7}$$

Third, in each iteration a new sample corresponding to a row of A is drawn according to distribution P and we apply an SGD process to solve the following equivalent problem with a specific choice of $F \in \mathbb{R}^{d \times d}$:

$$\min_{y \in \mathcal{Y}} h(y) = \|AFy - b\|_p^p = \mathbb{E}_{\xi \sim P}\left[|A_\xi Fy - b_\xi|^p / p_\xi\right]. \tag{8}$$

Here the matrix F is called the preconditioner for the linear system being solved; see Section 4.2 for several choices of F. Below, we show that with a suitable choice of F, the convergence rate of the

Algorithm 1 pwSGD— preconditioned weighted SGD for over-determined ℓ_1 and ℓ_2 regression

Input: $A \in \mathbb{R}^{n \times d}$, $b \in \mathbb{R}^n$ with $\text{rank}(A) = d$, $x_0 \in \mathcal{Z}$, η and T.
Output: An approximate solution vector to problem $\min_{x \in \mathcal{Z}} \|Ax - b\|_p^p$ for $p = 1$ or 2.
Compute $R \in \mathbb{R}^{d \times d}$ such that $U = AR^{-1}$ is a well-conditioned basis U as described in Section 2.1.
Compute or estimate $\|U_i\|_p^p$ with leverage scores λ_i, for $i \in [n]$, that satisfies (6).
Let $p_i = \frac{\lambda_i}{\sum_{j=1}^n \lambda_j}$, for $i \in [n]$.
Construct the preconditioner $F \in \mathbb{R}^{d \times d}$ based on R; see Section 4.2 for details.
for $t = 0, \ldots, T$ **do**
  Pick ξ_t from $[n]$ based on distribution $\{p_i\}_{i=1}^n$.

$$c_t = \begin{cases} \text{sgn}\left(A_{\xi_t} x_t - b_{\xi_t}\right) / p_{\xi_t} & \text{if } p = 1; \\ 2\left(A_{\xi_t} x_t - b_{\xi_t}\right) / p_{\xi_t} & \text{if } p = 2. \end{cases}$$

  Update x by

$$x_{t+1} = \begin{cases} x_t - \eta c_t H^{-1} A_{\xi_t} & \text{if } \mathcal{Z} = \mathbb{R}^d; \\ \arg\min\limits_{x \in \mathcal{Z}} \ \eta c_t A_{\xi_t} x + \frac{1}{2}\|x_t - x\|_H^2 & \text{otherwise.} \end{cases} \tag{11}$$

  where $H = \left(FF^\top\right)^{-1}$.
end for
Return $\bar{x}$ for $p = 1$ or x_T for $p = 2$.

SGD phase can be improved significantly. Indeed, we can perform the update rule in the original domain (with solution vector x instead of y), i.e., (11). Notice that if $\mathcal{Z} = \mathbb{R}^d$ and $F = I$, then the update rule can be simplified as

$$x_{t+1} = x_t - \eta c_t A_{\xi_t}. \tag{9}$$

If $\mathcal{Z} = \mathbb{R}^d$ and $F = R^{-1}$, then the update rule becomes

$$x_{t+1} = x_t - \eta c_t H^{-1} A_{\xi_t}, \tag{10}$$

where $H = (R^\top R)^{-1}$. In the presence of constraints, (11) only needs to solve an optimization problem with a quadratic objective over the same constraints whose size is independent of n.

Finally, the output is the averaged value over all iterates, i.e., $\bar{x} = \frac{1}{T}\sum_{t=1}^\top x_t$, for ℓ_1 regression, or the last iterate, i.e., x_T, for ℓ_2 regression.

4.1 Main results for ℓ_1 and ℓ_2 regression problems

The quality-of-approximation of Algorithm 1 is presented in Proposition 5 and Proposition 6 for ℓ_1 and ℓ_2 regression, respectively, in which we give the expected number of iterations that pwSGD needs for convergence within small tolerance. We show that pwSGD inherits a convergence rate of $\mathcal{O}\left(1/\sqrt{T}\right)$ for ℓ_1 regression and $\mathcal{O}\left(\log T/T\right)$ for ℓ_2 regression and the constant term only depends on the lower dimension d when $F = R^{-1}$. Worth mentioning is that for ℓ_2 regression, our bound on the solution vector is measured in prediction norm, i.e., $\|Ax\|_2$. For completeness, we

present the non-asymptotic convergence analysis of PWSGD in Proposition 14 and Proposition 15 in Appendix A. All the proofs can be found in Appendix C. The analysis of these results is based on the convergence properties of SGD; see Appendix D for technical details.

In the following results, R is the matrix computed in step 3 in Algorithm 1, $\{\lambda_i\}_{i\in[n]}$, are the leverage scores computed in step 4, F is the preconditioner chosen in step 6 in Algorithm 1 and $H = \left(FF^\top\right)^{-1}$. Denote by $\bar{\kappa}_p(U)$ the condition number of the well-conditioned basis $U = AR^{-1}$ and γ the approximation factor of the leverage scores λ_i, $i \in [n]$, that satisfies (6). For any vector $x \in \mathbb{R}^d$, denote by $\|x\|_H^2 = x^\top Hx$ the ellipsoidal norm of x induced by matrix $H = H^\top \succ 0$. For any non-singular matrix A, denote $\kappa(A) = \|A\|_2\|A^{-1}\|_2$ and $\hat{\kappa}(A) = |A|_1|A^{-1}|_1$. The exact form of the step-sizes used can be found in the proofs [2].

Proposition 5 *For $A \in \mathbb{R}^{n\times d}$ and $b \in \mathbb{R}^n$, define $f(x) = \|Ax-b\|_1$ and suppose $f(x^*) > 0$. Then there exists a step-size η such that after*

$$T = d\bar{\kappa}_1^2(U)\hat{\kappa}^2(RF)\frac{c_1^2c_2c_3^2}{\epsilon^2}$$

iterations, Algorithm 1 with $p = 1$ returns a solution vector estimate $\bar{x}$ that satisfies the expected relative error bound

$$\frac{\mathbb{E}\left[f(\bar{x})\right] - f(x^*)}{f(x^*)} \leq \epsilon.$$

Here, the expectation is taken over all the samples $\xi_1, \ldots, \xi_T$ and x^* is the optimal solution to the problem $\min_{x\in\mathcal{Z}} f(x)$. The constants in T are given by $c_1 = \frac{1+\gamma}{1-\gamma}$, $c_2 = \frac{\|x^*-x_0\|_H^2}{\|x^*\|_H^2}$ and $c_3 = \|Ax^*\|_1/f(x^*)$.

Proposition 6 *For $A \in \mathbb{R}^{n\times d}$ and $b \in \mathbb{R}^n$, define $f(x) = \|Ax-b\|_2$ and suppose $f(x^*) > 0$. Then there exists a step-size η such that after*

$$T = c_1\bar{\kappa}_2^2(U)\kappa^2(RF)\cdot\log\left(\frac{2c_2\kappa^2(U)\kappa^2(RF)}{\epsilon}\right)\cdot\left(1+\frac{\kappa^2(U)\kappa^2(RF)}{c_3\epsilon}\right)$$

iterations, Algorithm 1 with $p = 2$ returns a solution vector estimate x_T that satisfies the expected relative error bound

$$\frac{\mathbb{E}\left[\|A(x_T-x^*)\|_2^2\right]}{\|Ax^*\|_2^2} \leq \epsilon.$$

Furthermore, when $\mathcal{Z} = \mathbb{R}^d$ and $F = R^{-1}$, there exists a step-size η such that after

$$T = c_1\bar{\kappa}_2^2(U)\cdot\log\left(\frac{c_2\kappa^2(U)}{\epsilon}\right)\cdot\left(1+\frac{2\kappa^2(U)}{\epsilon}\right)$$

iterations, Algorithm 1 with $p = 2$ returns a solution vector estimate x_T that satisfies the expected relative error bound

$$\frac{\mathbb{E}\left[f(x_T)\right] - f(x^*)}{f(x^*)} \leq \epsilon.$$

2. The exact expression of the optimal stepsize contains unknown quantities such as x^*. In fact, this is also the case for many SGD-type algorithms. In practice, standard techniques for searching stepsizes can be used. In our experiments, we evaluate our algorithm using theoretically optimal stepsizes as well as stepsizes after grid searching.

Here, the expectation is taken over all the samples $\xi_1, \ldots, \xi_T$, and x^* is the optimal solution to the problem $\min_{x\in\mathcal{Z}} f(x)$. The constants in T are given by $c_1 = \frac{1+\gamma}{1-\gamma}$, $c_2 = \frac{\|x^*-x_0\|_H^2}{\|x^*\|_H^2}$, $c_3 = \|Ax^*\|_2^2/f(x^*)^2$.

The above results indicate two important properties of PWSGD. First recall that the condition number [3] $\bar{\kappa}_p(U)$ of the well-conditioned basis U is a polynomial of d that is independent of n. Thus with a preconditioner $F = R^{-1}$ and an appropriate step-size in PWSGD, the number of iterations T required to achieve an arbitrarily low relative error only depends on the *low dimension* d of the input matrix A. Second, PWSGD is *robust* to leverage score approximations, i.e., the expected convergence rate will only be affected by a small distortion factor even when the approximation has low accuracy, such as $\gamma = 0.5$.

Remark. For constrained ℓ_2 regression, the bound is on the solution vector measured in prediction norm. By the triangular inequality, this directly implies $(\mathbb{E}\left[f(x_T)\right] - f(x^*))/f(x^*) \leq \sqrt{c_3\epsilon}$.

Remark. Our approach can also be applied to other type of linear regression problems such as ridge regressions in which SGD can be invoked in a standard way. In this case, the "condition number" of SGD is lower than κ due to the regularization term. The randomized preconditioning methods discussed in Section 2.1 can be used but it is an "overkill'. More sophisticated preconditioning methods can be devised, e.g., based on ridge leverage scores (Cohen et al., 2015b).

4.2 The choice of the preconditioner F

As we can see, the preconditioner F plays an important role in our algorithm. It converts the original regression problem in (1) to the stochastic optimization problem in (8). From Proposition 5 and Proposition 6, clearly, different choices of F will lead to different convergence rates in the SGD phase (reflected in $\kappa(RF)$[4]) and additional computational costs (reflected in H in (11)).

When $F = R^{-1}$, the effect of $\kappa_2(RF)$ on T vanishes. In this case, H is also a good approximation to the Hessian $A^\top A$. This is because usually R is the R-factor in the QR decomposition of SA, where SA is a "sketch" of A satisfying (2) that shares similar properties with A. Together we have $H = R^\top R = (SA)^\top(SA) \approx A^\top A$. This implies (10) is close to the Newton-type update. However, as a tradeoff, since H^{-1} is a $d \times d$ dense matrix, an additional $\mathcal{O}(d^2)$ cost per iteration is required to perform SGD update (11).

On the other hand, when $F = I$, no matrix-vector multiplication is needed in updating x. However, based on the discussion above, one should expect $\kappa(R) = \kappa(SA)$ to be close to $\kappa(A)$. Then the term $\kappa(RF) = \kappa(R)$ can be large if A is poorly conditioned, which might lead to undesirable performance in SGD phase.

Besides the obvious choices of F such as R^{-1} and I, one can also choose F to be a diagonal preconditioner D that scales R to have unit column norms. According to van der Sluis (1969), the condition number after preconditioning $\kappa(RD)$ is always upper bounded by the original condition number $\kappa(R)$, while the additional cost per iteration to perform SGD updates with diagonal preconditioner is only $\mathcal{O}(d)$. In Section 5 we will illustrate the tradeoffs among these three choices of preconditioners empirically.

3. One can show that $\bar{\kappa}_2$ is a scaled version of the standard condition number κ. $\bar{\kappa}_1$ is also related to κ with $\bar{\kappa}_1 \geq \kappa/\sqrt{nd}$. This implies that in general $\bar{\kappa}_1$ can be large without preconditioning, e.g., the `buzz` dataset used in our experiments.

4. It is also reflected in $\hat{\kappa}(RF)$; however, it depends on $\kappa(RF)$ because one can show $m_1\kappa(RF) \leq \hat{\kappa}(RF) \leq m_2\kappa(RF)$, where m_1, m_2 are constants derived using matrix norm equivalences.

4.3 Complexities

Here, we discuss the complexity of pwSGD with $F = R^{-1}$. The running time of Algorithm 1 consists of three parts. First, for computing a matrix R such that $U = AR^{-1}$ is well-conditioned, Appendix A provides a brief overview of various recently proposed preconditioning methods for computing R for both ℓ_1 and ℓ_2 norms; see also Table 5 and Table 6 for their running time $time(R)$ and preconditioning quality $\bar{\kappa}_p(U)$. Particularly, there are several available sparse preconditioning methods that run in $\mathcal{O}(\mathrm{nnz}(A))$ plus lower order terms in d time (Clarkson and Woodruff, 2013; Meng and Mahoney, 2013a; Nelson and Nguyen, 2013; Yang et al., 2016b; Woodruff and Zhang, 2013). Second, to estimate the leverage scores, i.e., the row norms of AR^{-1}, Drineas et al. (2012); Clarkson et al. (2013) proposed several algorithms for approximating the ℓ_1 and ℓ_2 leverage scores without forming matrix U. For a target constant approximation quality, e.g., $\gamma = 0.5$ and $c_1 = \frac{1+\gamma}{1-\gamma} = 3$, the running time of these algorithms is $\mathcal{O}(\log n \cdot \mathrm{nnz}(A))$. Third, Proposition 5 and Proposition 6 provide upper bounds for the expected algorithmic complexity of our proposed SGD algorithm when a target accuracy is fixed. Combining these, we have the following results.

Proposition 7 *Suppose the preconditioner in step 3 of Algorithm 1, is chosen from Table 5 or Table 6, with constant probability, one of the following events holds for* pwSGD *with* $F = R^{-1}$*. To return a solution* $\tilde{x}$ *with relative error* ϵ *on the objective,*

- *It runs in* $time(R) + \mathcal{O}(\log n \cdot \mathrm{nnz}(A) + d^3\bar{\kappa}_1(U)/\epsilon^2)$ *for unconstrained* ℓ_1 *regression.*
- *It runs in* $time(R)+\mathcal{O}(\log n\cdot\mathrm{nnz}(A)+time_{update}\cdot d\bar{\kappa}_1(U)/\epsilon^2)$ *for constrained* ℓ_1 *regression.*
- *It runs in* $time(R) + \mathcal{O}(\log n \cdot \mathrm{nnz}(A) + d^3\log(1/\epsilon)/\epsilon)$ *for unconstrained* ℓ_2 *regression.*
- *It runs in* $time(R) + \mathcal{O}(\log n \cdot \mathrm{nnz}(A) + time_{update} \cdot d\log(1/\epsilon)/\epsilon^2)$ *for constrained* ℓ_2 *regression.*

In the above, $time(R)$ *denotes the time for computing the matrix* R *and* $time_{update}$ *denotes the time for solving the optimization problem in* (11)*.*

Notice that, since $time_{update}$ only depends on d, an immediate conclusion is that by using sparse preconditioning methods, to find an ϵ-approximate solution, pwSGD runs in $\mathcal{O}(\log n \cdot \mathrm{nnz}(A) + \mathrm{poly}(d)/\epsilon^2)$ time for ℓ_1 regression and in $\mathcal{O}(\log n \cdot \mathrm{nnz}(A) + \mathrm{poly}(d)\log(1/\epsilon)/\epsilon)$ time for ℓ_2 regression (in terms of solution vector in prediction norm for constrained problems or objective value for unconstrained problems).

Also, as can be seen in Proposition 7, for the complexity for ℓ_1 regression, the tradeoffs in choosing preconditioners from Table 5 are reflected here. On the other hand, for ℓ_2 regression, as all the preconditioning methods in Table 5 provide similar preconditioning quality, i.e., $\kappa(U) = \mathcal{O}(1)$, $time(R)$ becomes the key factor for choosing a preconditioning method. In Table 3, we summarize the complexity of pwSGD using various sketching methods for solving unconstrained ℓ_1 and ℓ_2 regression problems. The results are obtained by a direct combination of Tables 2, 5 and 6. We remark that, with decaying step-sizes, it is possible to improve the dependence on ϵ from $\log(1/\epsilon)/\epsilon$ to $1/\epsilon$ (Rakhlin et al., 2012).

Finally, we remind readers that Table 1 and 2 summarize the complexities of several related algorithms for unconstrained ℓ_1 and ℓ_2 regression. As we can see, pwSGD is more suitable for finding a medium-precision, e.g., $\epsilon = 10^{-3}$, solution. In particular, it has a dependency uniformly better than RLA methods for ℓ_1 regression. Moreover, unlike the high-precision solvers, pwSGD also works for constrained problems, in which case each iteration of pwSGD only needs to solve an optimization problem with quadratic objective over the same constraints.

type	sketch	complexity
ℓ_1	Dense Cauchy (Sohler and Woodruff, 2011)	$\mathcal{O}(nd^2\log n + d^3\log d + d^{\frac{11}{2}}\log^{\frac{3}{2}} d/\epsilon^2)$
ℓ_1	Fast Cauchy (Clarkson et al., 2013)	$\mathcal{O}(nd\log n + d^3\log^5 d + d^{\frac{17}{2}}\log^{\frac{9}{2}} d/\epsilon^2)$
ℓ_1	Sparse Cauchy (Meng and Mahoney, 2013a)	$\mathcal{O}(\mathrm{nnz}(A)\log n + d^7\log^5 d + d^{\frac{19}{2}}\log^{\frac{11}{2}} d/\epsilon^2)$
ℓ_1	Reciprocal Exponential (Woodruff and Zhang, 2013)	$\mathcal{O}(\mathrm{nnz}(A)\log n + d^3\log d + d^{\frac{13}{2}}\log^{\frac{5}{2}} d/\epsilon^2)$
ℓ_1	Lewis Weights (Cohen and Peng, 2015)	$\mathcal{O}(\mathrm{nnz}(A)\log n + d^3\log d + d^{\frac{9}{2}}\log^{\frac{1}{2}} d/\epsilon^2)$
ℓ_2	Gaussian Transform	$\mathcal{O}(nd^2 + d^3\log(1/\epsilon)/\epsilon)$
ℓ_2	SRHT (Tropp, 2011)	$\mathcal{O}(nd\log n + d^3\log n\log d + d^3\log(1/\epsilon)/\epsilon)$
ℓ_2	Sparse ℓ_2 embedding (Cohen, 2016)	$\mathcal{O}(\mathrm{nnz}(A)\log n + d^3\log d + d^3\log(1/\epsilon)/\epsilon)$
ℓ_2	Refinement Sampling (Cohen et al., 2015a)	$\mathcal{O}(\mathrm{nnz}(A)\log(n/d)\log d + d^3\log(n/d)\log d + d^3\log(1/\epsilon)/\epsilon)$

Table 3: Summary of complexity of pwSGD with different sketching methods for computing the preconditioner when solving unconstrained ℓ_1 and ℓ_2 regression problems. The target is to return a solution $\tilde{x}$ with relative error ϵ on the objective. Here, the complexity of each algorithm is calculated by setting the failure probability to be a constant.

4.4 Complexity comparison between pwSGD and RLA

As we pointed out in Section 3, pwSGD and RLA methods with algorithmic leveraging (Appendix B) (RLA for short) are closely related as they can be viewed as methods using SA and SAA to solve the stochastic optimization problem (4). Omitting the time for computing basis U and sampling distribution P, the comparison of complexity boils down to comparing $time_{sub}(s, d)$ (for RLA) and $time_{update} \cdot T$ (for pwSGD) where $time_{sub}(s, d)$ is the time needed to solve the same constrained regression problem with size s by d and $time_{update}$ denotes the time needed for to solve the optimization problem in (11). According to the theory, for the same target accuracy, the required s (sampling size) and T (number of iterations) are the same asymptotically, up to logarithmic factors; see Dasgupta et al. (2009); Yang et al. (2014); Drineas et al. (2011) and Section B for expression of s. When the problem is unconstrained, due to the efficiency of SGD, $time_{update} = \mathcal{O}(d^2)$ as indicated in (11). For ℓ_2 regression, due to the efficiency of the direct solver, $time_{sub}(s, d) = \mathcal{O}(sd^2)$. This explains why pwSGD and RLA (low-precision solvers (sampling)) have similar complexities as shown in Table 2. On the other hand, for unconstrained ℓ_1 regression, a typical ℓ_1 regression solver requires time $time_{sub}(s, d) > sd^2$. For example, if an interior point method is used (Portnoy and Koenker, 1997), $time_{sub}(s, d)$ is not even linear in s. This explains the advantage pwSGD has over RLA as shown in Table 1. We also note that in the presence of constraints, pwSGD may still be more efficient for solving ℓ_1 regression because roughly speaking, $time_{sub}(s, d)/s > time_{update}$.

4.5 Connection to weighted randomized Kaczmarz algorithm

As mentioned in Section 1, our algorithm pwSGD for least-squares regression is related to the weighted randomized Kaczmarz (RK) algorithm (Strohmer and Vershynin, 2009; Needell et al., 2014). To be more specific, weighted RK algorithm can be viewed as an SGD algorithm with constant step-size that exploits a sampling distribution based on row norms of A, i.e., $p_i = \|A_i\|_2^2/\|A\|_F^2$. In pwSGD, if the preconditioner $F = R^{-1}$ is used and the leverage scores are computed exactly, the resulting algorithm is equivalent to applying the weighted randomized Karczmarz algorithm on a well-conditioned basis $U = AR^{-1}$ since leverage scores are defined as the row norms of U.

Since the matrix A itself can be a basis for its range space, setting $U = A$ and $F = R = I$ in Proposition 6 indicates that weighted RK algorithm inherits a convergence rate that depends on condition number $\kappa(A)$ times the scaled condition number $\bar{\kappa}_2(A)$. Notice that in pwSGD, the preconditioning step implicitly computes a basis U such that both $\kappa(U)$ and $\bar{\kappa}(U)$ are low. One should expect the SGD phase in pwSGD inherits a faster convergence rate, as verified numerically in Section 5.

5. Experiments

In this section, we provide empirical evaluations of our main algorithm pwSGD. We evaluate its convergence rate and overall running time on both synthetic and real datasets. For pwSGD, we implement it with three different choices of the preconditioner F. Herein, throughout the experiments, by pwSGD-full, pwSGD-diag, pwSGD-noco, we respectively mean pwSGD with preconditioner $F = R^{-1}, D, I$; see Section 4.2 for details. Note that, for pwSGD, we use the methods from Clarkson and Woodruff (2013) for preconditioning. Also, we exactly compute the row norms of AR^{-1} and use them as the leverage scores. In each experiment, the initial solution vector estimate is set as zero. The above algorithms are then run in the following manner. Each epoch contains $\lceil n/10 \rceil$ iterations. At the beginning of each epoch, we sample $\lceil n/10 \rceil$ indices according to the underlying distribution without replacement and update the weight using the $\lceil n/10 \rceil$ row samples from the data matrix. Finally, the plots are generated by averaging the results over 20 independent trials.

5.1 Empirical evaluations on synthetic datasets

Theoretically the major advantage of pwSGD is the fast convergence rate. To evaluate its performance, we compare the convergence rate of relative error, i.e., $|\hat{f} - f^*|/f^*$, with other competing algorithms including vanilla SGD and fully weighted randomized Kaczmarz (weighted-RK) algorithm (Needell et al. (2014); Strohmer and Vershynin (2009)) for solving least-squares problem (unconstrained ℓ_2 regression). For each of these methods, given a target relative error $\epsilon = 0.1$ on the objective, i.e., $(\hat{f} - f^*)/f^* = 0.1$, we use the optimal step-size suggested in the theory. In particular, for pwSGD, we are showing the convergence rate of the SGD phase after preconditioning. We stop the algorithm when the relative error reaches ϵ. In this task, we use synthetic datasets for better control over the properties on input matrices A and b. Each dataset has size 1000 by 10 and is generated in one of the following two ways.

Synthetic 1 The design matrix A has skewed row norms and skewed leverage scores. That is, 5 rows have leverage scores and row norms significantly larger than the rest[5].

Synthetic 2 The design matrix A is of the form $A = U\Sigma V^\top$ where $U \in \mathbb{R}^{1000\times 10}$ and $V \in \mathbb{R}^{10\times 10}$ are random orthonormal matrices and $\Sigma \in \mathbb{R}^{10\times 10}$ is a diagonal matrix that controls $\kappa(A)$.

In both cases, the true solution x^* is a standard Gaussian vector and the response vector b is set to be Ax^* corrupted by some Gaussian noise with standard deviation 0.1.

In Figure 2, we present the results on two `Synthetic 1` datasets with condition number around 1 and 5. From the plots we can clearly see that among the methods we used, pwSGD-full and pwSGD-diag exhibit superior speed in terms of achieving the target accuracy. The relative ordering within pwSGD with three different preconditioners is consistent with the theory according to our discussions in Section 4.2. Since the datasets considered here are well-conditioned, the preconditioning phases in pwSGD-diag and pwSGD-full have similar effects and both methods perform well. However as suggested in Corollary 6, as the condition number increases (in comparison of the results in Figure 2(a) versus Figure 2(b)), other methods show degradations in convergence. Furthermore Figure 2(a) shows that the weighted-RK algorithm outperforms standard SGD. This is due to the fact that A in this dataset is well-conditioned but with non-uniform row norms.

We further investigate the relation between the condition number of A and convergence rate. As suggested in Proposition 6, for weighted SGD algorithm, the number of iterations required to solve an ℓ_2 regression problem is proportional to $\bar{\kappa}_2^2(A)\kappa^2(A) = \|(A^\top A)^{-1}\|_2^2\|A\|_2^2\|A\|_F^2 \leq \bar{\kappa}_2^4(A)$. To verify this hypothesis, we generate a sequence of A matrices using `Synthetic 2` dataset with increasing $\bar{\kappa}_2^4(A)$ values such that U and V in the sequence are constants.[6] This construction ensures that all other properties such as leverage scores and coherence (the largest leverage score) remain unchanged. Similar to Figure 2, we present the experimental results (number of iterations required for different methods versus $\bar{\kappa}_2^4(A)$) for the `Synthetic 2` dataset in Figure 3.

As shown in Figure 3, the required number of iterations of all the methods except for pwSGD-full scales linearly in $\bar{\kappa}_2^4(A)$. This phenomenon matches the result predicted in theory. A significant advantage of pwSGD-full over other methods is its robust convergence rate against variations in $\bar{\kappa}_2^4(A)$. This is mainly because its SGD phase operates on a well-conditioned basis after preconditioning and the preconditioning quality of pwSGD-full depends only on the low-dimension of A; thus increasing $\bar{\kappa}_2^4(A)$ has little effect on changing its convergence rate. Also, while the diagonal preconditioner in pwSGD-diag reduces the condition number, i.e., $\kappa(RD) \leq \kappa(R)$, its convergence rate still suffers from the increase of $\bar{\kappa}_2^4(A)$.

5.2 Time-accuracy tradeoffs

Next, we present the time-accuracy tradeoffs among these methods on the following two datasets described in Table 4.

name	#rows	# columns	$\kappa(A)$
`Year`[7]	5×10^5	90	2×10^3
`Buzz`[8]	5×10^5	77	10^8

Table 4: Summary of the two real datasets we evaluate in the experiments.

Here we test the performance of various methods in solving unconstrained ℓ_1 and ℓ_2 regression problems. Although there are no theoretical results to support the solution vector convergence on ℓ_1 regression problems with pwSGD, we still evaluate relative error in the solution vector. To further examine the performance of pwSGD methods, we also include AdaGrad, SVRG, and RLA methods with algorithmic leveraging (RLA for short) mentioned in Section 3 and Appendix B for comparisons. For AdaGrad, we use diagonal scaling and mirror descent update rule. For SVRG, we compute the full gradient every $\lfloor n/2 \rfloor$ iterations. As for implementation details, in all SGD-like

5. Note that, in general, there is no correlation between row norms and leverage scores unless the matrix has nearly orthonormal columns. For construction details of `Synthetic 1`, see the construction of NG matrices Section 5.3 in Yang et al. (2016b).

6. In `Synthetic 2`, U and V are fixed. Σ is of the form $\mathrm{diag}(\sigma_1, \ldots, \sigma_d)$ where $\sigma_i = 1 + (i-1)q$ for $i \in [d]$. We solve for q such that $\sum_{i=1}^d \sigma_i^2 = \bar{\kappa}_2^2(U)$ for any desired value $\bar{\kappa}_2^2(U)$.

8. `https://archive.ics.uci.edu/ml/datasets/Buzz+in+social+media+`

algorithms, step-size tuning is done by grid-searching where at each trial the algorithm is run with a candidate step-size for enough iterations. Then the step-size that yields the lowest error within 10 seconds is used. The time/accuracy pair at every 2000 iterations is recorded. For RLA, we choose s from a wide range of values and record the corresponding time/accuracy pairs. The results on the two datasets are presented in Figures 4 and 5, respectively.

As we can see in Figures 4 and 5, in our algorithm PWSGD, a faster convergence comes with the additional cost of preconditioning. For example, the preconditioning phase of PWSGD takes approximately 0.5 seconds. Nevertheless, with a faster convergence rate in a well-conditioned basis, PWSGD-full still outperforms other methods in converging to a higher-precision solution at a given time span. As PWSGD-diag balances convergence rate and computational cost, it outperforms PWSGD-full at the early stage and yields comparable results to AdaGrad. As expected, due to the poor conditioning, SGD, weighted-RK, SVRG, and PWSGD-noco suffer from slow convergence rates. As for RLA methods, they have the same first step as in PWSGD, i.e., preconditioning and constructing the sampling distribution. For ℓ_1 regression, to obtain a fairly high-precision solution, the sampling size has to be fairly large, which might drastically increase the computation time for solving the sampled subproblem. This explains the advantage of PWSGD-full over RLA methods in Figure 4. It is worth mentioning that, although for ℓ_2 regression our theory provides relative error bound on the solution vector measured in the prediction norm, here we also see that PWSGD-full and PWSGD-diag display promising performance in approximating the solution vector measured in ℓ_2 norm.

We also notice that on `Buzz` (Figure 5), all the methods except for PWSGD-full and PWSGD-diag have a hard time converging to a solution with low solution error. This is due to the fact that `Buzz` has a high condition number. The advantage of applying a preconditioner is manifested.

Finally, notice that RLA uses a high performance direct solver to solve the mid-size subsampled problem for ℓ_2 regression. In this case PWSGD methods do not show significant advantages over RLA in terms of speed. For this reason we have not included RLA results in Figure 4(a) and 4(b). Nevertheless, PWSGD methods may still be favorable over RLA in terms of speed and feasibility when the size of the dataset becomes increasingly larger, e.g., 10^7 by 500.

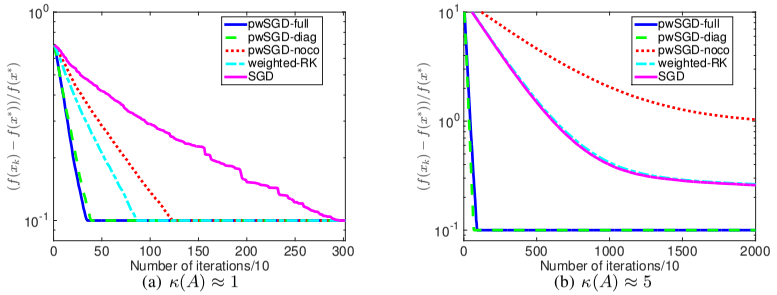

Figure 2: Convergence rate comparison of several SGD-type algorithms including PWSGD with three different choices of preconditioners for solving ℓ_2 regression on `Synthetic 1` datasets with condition number around 1 and 5, respectively. For each method, the optimal step-size is set according to the theory with target accuracy $|f(\hat{x})-f(x^*)|/f(x^*)=0.1$. The y-axis is showing the relative error on the objective, i.e., $|f(\hat{x})-f(x^*)|/f(x^*)$.

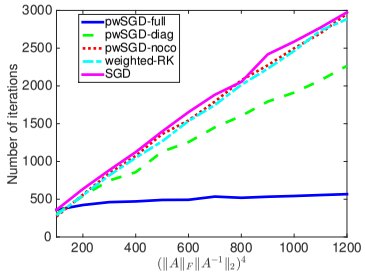

Figure 3: Convergence rate comparison of several SGD-type algorithms including PWSGD with three different choices of preconditioners for solving ℓ_2 regression on `Synthetic 2` datasets with increasing condition number. For each method, the optimal step-size is set according to the theory with target accuracy $|f(\hat{x})-f(x^*)|/f(x^*)=0.1$. The y-axis is showing the minimum number of iterations for each method to find a solution with the target accuracy.

5.3 Empirical evaluations with sparse ℓ_2 regression

Finally, we evaluate our algorithm on a constrained problem — sparse ℓ_2 regression, which is a special case of (1). The problem formulation is as follows. Given a matrix $A\in\mathbb{R}^{n\times d}$ and a vector

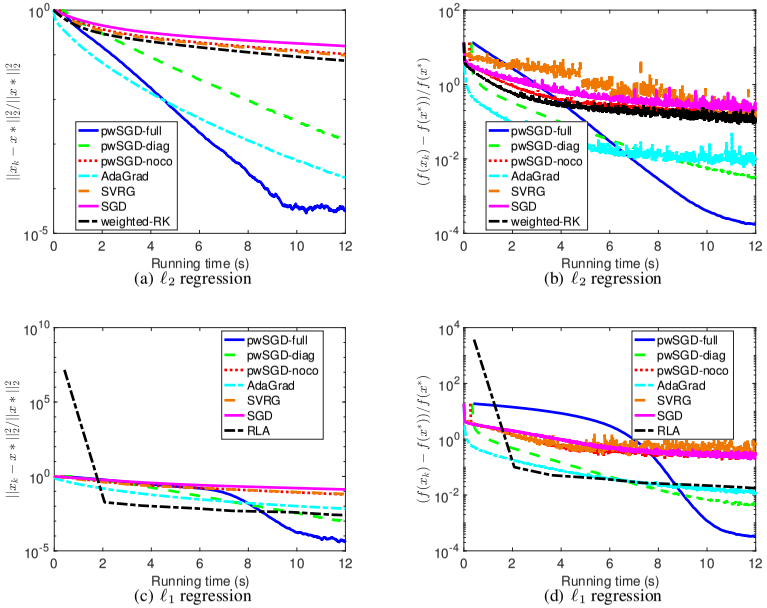

Figure 4: Time-accuracy tradeoffs of several algorithms including pwSGD with three different choices of preconditioners on `year` dataset. Both ℓ_1 and ℓ_2 regressions are tested and the relative error on both the objective value, i.e., $|f(\hat{x}) - f(x^*)|/f(x^*)$, and the solution vector, i.e., $\|\hat{x} - x^*\|_2^2/\|x^*\|_2^2$, are measured.

$b \in \mathbb{R}^n$, we want to solve the following constrained problem

$$\min_{\|x\|_1 \leq R} \|Ax - b\|_2, \tag{12}$$

where R controls the size of the ℓ_1-ball constraint.

When using pwSGD, according to (11) in Algorithm 1, at each iteration, a sparse ℓ_2 regression problem with size d by d needs to be solved. Here, to use the samples more efficiently, we use a mini-batch version of pwSGD. That is, in Step 8-10 of Algorithm 1, rather than picking only one row from A to compute the noisy gradient, we select m rows and average the scaled version of them. Doing this allows us to reduce the variance of the noisy gradient. In our experiments, we set $m = 200$.

In this task, the observation model is generated in the following manner, $b = Ax^* + e$ where $A \in \mathbb{R}^{n \times d}$ has independent standard normal entries, x^* has s nonzero entries and noise vector $e \in \mathbb{R}^n$ has independent standard normal entries. We evaluate both the optimization error $\|\hat{x} -$

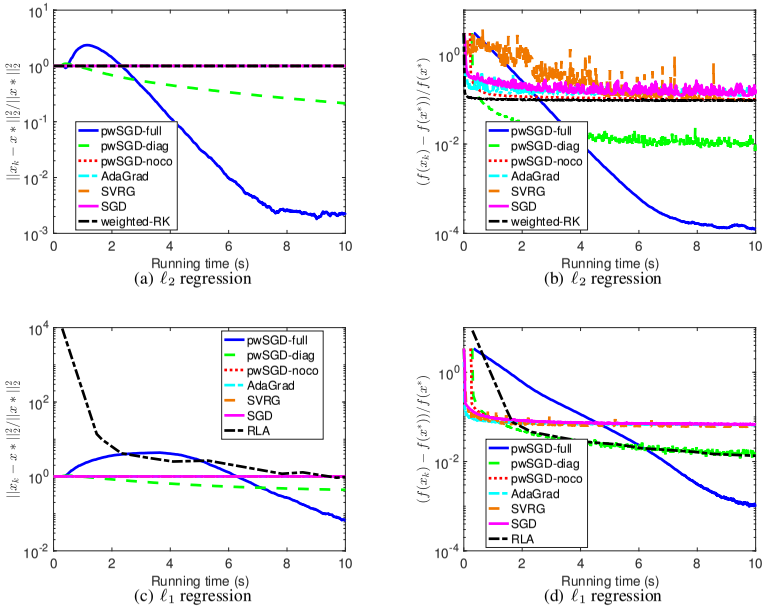

Figure 5: Time-accuracy tradeoffs of several algorithms including pwSGD with three different choices of preconditioners on `buzz` dataset. Both ℓ_1 and ℓ_2 regressions are tested and the relative error on both the objective value, i.e., $|f(\hat{x}) - f(x^*)|/f(x^*)$, and the solution vector, i.e., $\|\hat{x} - x^*\|_2^2/\|x^*\|_2^2$, are measured.

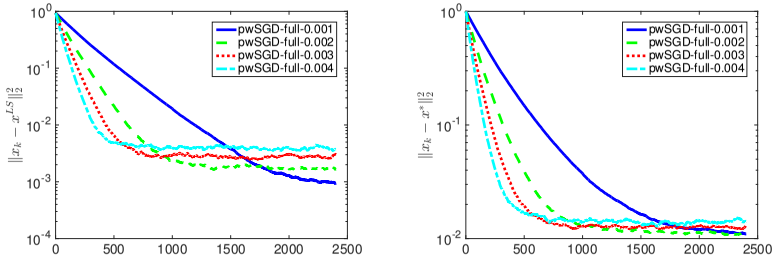
$x^{LS}\|_2$ and statistical error $\|\hat{x} - x^*\|_2$ of pwSGD-full with several choices of stepsize η where x^{LS} the optimal solution of problem (12). It is known that the least squares error of x^{LS} is $\|x^{LS} - x^*\|_2 \approx \sqrt{s\log(ed/s)/n}$ (Hastie et al., 2015). The statistical error can be bounded using the triangle inequality as shown below,

$$\|\hat{x} - x^*\|_2 \leq \|\hat{x} - x^{LS}\|_2 + \|x^{LS} - x^*\|_2.$$

Therefore, the statistical error $\|\hat{x} - x^*\|_2$ is dominated by the least squares error $\|x^{LS} - x^*\|_2$ when the optimization error $\|\hat{x} - x^{LS}\|_2$ is small.

In Figure 6, we show the results on a data instance with $n = 1e4$, $d = 400$ and $s = 30$. Here R is set to be $R = \|x^*\|_1$ for the experimental purpose. First, we briefly describe the effect of stepsize η. When a constant stepsize is used, typically, a smaller η allows the algorithm to converge to a more accurate solution with a slower convergence rate. This is verified by Figure 6(a) in which the performance of pwSGD-full with larger η's saturates earlier at a coarser level while $\eta = 0.001$ allows the algorithm to achieve a finer solution. Nevertheless, as discussed above, the statical error

is typically dominated by the least squares error. For our choice of (n, d, s), one can show that the least squares error $\|x^{LS} - x^*\|_2^2 \approx 0.01$. Therefore, the statistical error shown in Figure 6(b) is around 0.01 when the optimization error is small enough.



(a) Optimization error $\|x_k - x^{LS}\|_2^2$ (b) Statistical error $\|x_k - x^*\|_2^2$

Figure 6: Performance of pwSGD-full on a synthetic sparse ℓ_2 regression problem with difference choices of stepsize η. Both optimization error and statistical error are shown.

6. Connection with Coreset Methods

After viewing RLA and SGD from the stochastic optimization perspective and using that to develop our main algorithm, a natural question arises: can we do this for other types of problems? To do so, we need to define "leverage scores" for them, since they play a crucial role in this stochastic framework. Here, we first describe the coreset framework of Feldman and Langberg (2011). Then we show that—on ℓ_p regression problems—two key notions (leverage scores from RLA and sensitivities from coresets) correspond. Finally we will show what amounts to a negative result (i.e., a lower bound) for other problems. Note here, in this section, we work on constrained ℓ_p regression (1) with $p \in [1, \infty)$ and we use $\bar{A}$ to denote the augmented linear system $\begin{pmatrix} A & b \end{pmatrix}$.

6.1 Short summary of coreset methods

In Feldman and Langberg (2011), the authors propose a framework for computing a coreset of $\mathcal{F}$ to a given optimization problem of the form,

$$\text{cost}(\mathcal{F}, x) = \min_{x \in \mathcal{X}} \sum_{f \in \mathcal{F}} f(x),$$

where $\mathcal{F}$ is a set of functions from a set $\mathcal{X}$ to $[0, \infty)$. By Proposition 4, it is not hard to see, the ℓ_p regression problem (1) can be written as

$$\min_{x \in \mathcal{C}} \sum_{i=1}^{n} f_i(x),$$

Algorithm 2 Compute ϵ-coreset

Input: A class of functions $\mathcal{F}$, sampling size s.
Output: An ϵ-coreset to $\mathcal{F}$.
Initialize $\mathcal{D}$ as an empty set.
Compute the sensitivity $m(f)$ for each function $f \in \mathcal{F}$.
$M(\mathcal{F}) \leftarrow \sum_{f \in \mathcal{F}} m(f)$.
for $f \in \mathcal{F}$ **do**
  Compute probabilities $p(f) = \frac{m(f)}{M(\mathcal{F})}$.
end for
for $i = 1, \ldots, s$ **do**
  Pick f from $\mathcal{F}$ with probability $p(f)$.
  Add $f/(s \cdot p(f))$ to $\mathcal{D}$.
end for
Return $\mathcal{D}$.

where $f_i(x) = |\bar{A}_i x|^p$ and $\mathcal{C} = \{x \in \mathbb{R}^{d+1} | x_{d+1} = -1\}$, in which case one can define a set of functions $\mathcal{F} = \{f_i\}_{i=1}^n$.
Central to the coreset method of Feldman and Langberg (2011) is the following notion of sensitivity, which is used to construct importance sampling probabilities, as shown in Algorithm 2, and the dimension of the given class of function, which is based as Definition 6.1 in Feldman and Langberg (2011). They are defined as below.

Definition 8 *Given a set of function $\mathcal{F} = \{f_i\}_{i=1}^n$, the* sensitivity $m(f)$ *of each function is defined as $m(f) = \lfloor \sup_{x \in \mathcal{X}} n \cdot \frac{f(x)}{\text{cost}(\mathcal{F}, x)} \rfloor + 1$, and the* total sensitivity $M(\mathcal{F})$ *of the set of functions is defined as $M(\mathcal{F}) = \sum_{f \in \mathcal{F}} m(f)$.*

Definition 9 *The dimension of $\mathcal{F}$ is defined as the smallest integer d such that for any $G \subset \mathcal{F}$,*

$$|\{\textbf{Range}(G, x, r) \mid x \in \mathcal{X}, r \geq 0\}| \leq |G|^d,$$

where $\textbf{Range}(G, x, r) = \{g \in G \mid g(x) \leq r\}$.

The algorithm proposed in Feldman and Langberg (2011) is summarized in Algorithm 2 below, and the corresponding result of quality of approximation is presented in Theorem 10.

Theorem 10 *Given a set of functions $\mathcal{F}$ from $\mathcal{X}$ to $[0, \infty]$, if $s \geq \frac{cM(\mathcal{F})}{\epsilon^2}(\dim(\mathcal{F}') + \log\left(\frac{1}{\delta}\right))$, then with probability at least $1 - \delta$, Algorithm 2 returns an ϵ-coreset for $\mathcal{F}$. That is,*

$$(1 - \epsilon) \sum_{f \in \mathcal{F}} f(x) \leq \sum_{f \in \mathcal{D}} f(x) \leq (1 + \epsilon) \sum_{f \in \mathcal{F}} f(x),$$

where $\mathcal{F}' = \{f/s(f) \mid f \in \mathcal{F}\}$ is a rescaled version of $\mathcal{F}$.

6.2 Connections between RLA and coreset methods

In the following, we present two results on the connection between RLA with algorithmic leveraging, i.e., with sampling based on exact or approximate leverage scores, and coreset methods. These results originally appeared in Varadarajan and Xiao (2012). We include them here and give different proofs.

The first result shows that the sensitivities are upper bounded by a constant factor times the ℓ_p leverage scores. With this connection between leverage scores and sensitivities, it is not hard to see that applying Algorithm 2 to ℓ_p regression is exactly the same as applying Algorithm 3 (RLA sampling algorithm described in Appendix B).

Proposition 11 *Given $\bar{A} \in \mathbb{R}^{n\times(d+1)}$, let $f_i(x) = |\bar{A}_i x|^p$, for $i \in [n]$. Let λ_i be the i-th leverage score of $\bar{A}$. Then, the i-th sensitivity*

$$m(f_i) \leq n\beta^p\lambda_i + 1,$$

for $i \in [n]$ and the total sensitivity

$$M(\mathcal{F}) \leq n((\alpha\beta)^p + 1).$$

The second result is that, for the ℓ_p regression problem, the dimension of the class of functions $\dim(\mathcal{F}')$ is the same as the dimension of the subspace being considered, which is $\mathcal{O}(d)$. To be more specific, since all the $f \in \mathcal{F}'$ here are of the form $f(x) = |a^T x|^p$ for some vector $a \in \mathbb{R}^d$, we consider a broader class of functions, namely $\mathcal{A} = \{|a^T x|^p \mid a \in \mathbb{R}^d\}$, and compute its dimension.

Proposition 12 *Let $\mathcal{A} = \{|a^T x|^p \mid a \in \mathbb{R}^d\}$. We have*

$$\dim(\mathcal{A}) \leq d + 1.$$

With these results, in combination with Theorem 10, we can see that to compute a coreset $\mathcal{D}$, which leads to a $\left(\frac{1+\epsilon}{1-\epsilon}\right)$-approximate solution the ℓ_p regression using coreset method of (Feldman and Langberg, 2011), the required sampling complexity is the same (up to constants) as that of RLA sampling algorithm, as indicated by Theorem 16 (assuming $\gamma = 0$) in Appendix B.

6.3 Limitation of our approach

From the above, we see that for ℓ_p regression, a small coreset whose size only depends on d exists, and by solving it we can get a $(1+\epsilon)$-approximation solution. This results in the same sampling algorithm as in RLA. Also, the sensitivities defined in the framework can be used as a distribution when one converts a deterministic problem into a stochastic optimization problem. We want to see whether we can extend this scheme to other problems. Indeed, beyond ℓ_p regression, the coreset methods work for any kind of convex loss function (Feldman and Langberg, 2011). However, since it depends on the total sensitivity, the size of the coreset is not necessarily small. For RLA, this translates into requiring a very large sample size to construct a good subproblem. For example, for hinge loss, we have the following example showing that the size of the coreset has an exponential dependency on d.

Proposition 13 *Define $f_i(x) = f(x, a_i) = (x^T a_i)^+$, where $x, a_i \in \mathbb{R}^d$ for $i \in [n]$. There exists a set of vectors $\{a_i\}_{i=1}^d$ such that the total sensitivity of $\mathcal{F} = \{f_i\}_{i=1}^n$ is approximately 2^d.*

This result indicates that new ideas will be needed to extend similarly RLA preconditioning ideas to weighted SGD algorithms for other types of convex optimization problems. This should not be surprising, since RLA methods have been developed for randomized *linear* algebra problems, but it suggests several directions for follow-up work.

7. Conclusion

In this paper, we propose a novel RLA-SGD hybrid algorithm called pwSGD. We show that after a preconditioning step and constructing a non-uniform sampling distribution using RLA techniques, its SGD phase inherits fast convergence rates that only depend on the lower dimension of the input matrix. For ℓ_1 regression, pwSGD displays strong advantages over RLA methods in terms of the overall complexity. For ℓ_2 regression, it has a complexity comparable to that of several state-of-the-art solvers. Empirically we show that pwSGD is preferable when a medium-precision solution is desired. Finally, we provide lower bounds on the coreset complexity for more general regression problems, which point to specific directions for future work to extend our main results.

Acknowledgments. We would like to acknowledge the Army Research Office, the Defense Advanced Research Projects Agency, and the Department of Energy for providing partial support for this work.

Appendix A. Supplementary Details of Algorithm 1

As we discussed, we need to compute a well-conditioned basis implicitly and estimate its row norms, i.e., AR^{-1} and $\{\lambda_i\}_{i=1}^n$ in Steps 3 and 4 in Algorithm 1.

In Section 2.1 we have summarized the major steps for computing the preconditioner using sketching. Below in Table 5 we provide a short summary of preconditioning methods using various sketches along with the resulting running time and condition number. Note that the running time here denotes the total running for computing the matrix R which is the sketching time plus the time

for QR factorization of the sketch. Again, below $\bar{\kappa}_p(U)$ is the condition number of $U = AR^{-1}$ as defined in Definition 1 and $\kappa(U)$ is the standard condition number of U.

name	running time	$\bar{\kappa}_1(U)$
Dense Cauchy Transform (Sohler and Woodruff, 2011)	$\mathcal{O}(nd^2 \log d + d^3 \log d)$	$\mathcal{O}(d^{5/2} \log^{3/2} d)$
Fast Cauchy Transform (Clarkson et al., 2013)	$\mathcal{O}(nd \log d + d^3 \log d)$	$\mathcal{O}(d^{11/2} \log^{9/2} d)$
Sparse Cauchy Transform (Meng and Mahoney, 2013a)	$\mathcal{O}(\text{nnz}(A) + d^7 \log^5 d)$	$\mathcal{O}(d^{\frac{13}{2}} \log^{\frac{11}{2}} d)$
Reciprocal Exponential Transform (Woodruff and Zhang, 2013)	$\mathcal{O}(\text{nnz}(A) + d^3 \log d)$	$\mathcal{O}(d^{\frac{7}{2}} \log^{\frac{5}{2}} d)$
Lewis Weights (Cohen and Peng, 2015)	$\mathcal{O}(\text{nnz}(A) \log n + d^3 \log d)$	$\mathcal{O}(d^{\frac{3}{2}} \log^{\frac{1}{2}} d)$

Table 5: Summary of running time and condition number, for several different ℓ_1 conditioning methods. The failure probability of each chmethod is set to be a constant.

name	running time	$\kappa_2(U)$	$\bar{\kappa}_2(U)$

Sparse ℓ_2 Embedding (Clarkson and Woodruff, 2013)	$\mathcal{O}(\text{nnz}(A) + d^4)$	$\mathcal{O}(1)$	$\mathcal{O}(\sqrt{d})$
Sparse ℓ_2 Embedding[9] (Cohen, 2016)	$\mathcal{O}(\text{nnz}(A) \log d + d^3 \log d)$	$\mathcal{O}(1)$	$\mathcal{O}(\sqrt{d})$
Refinement Sampling (Cohen et al., 2015a)	$\mathcal{O}(\text{nnz}(A) \log(n/d) \log d + d^3 \log(n/d) \log d)$	$\mathcal{O}(1)$	$\mathcal{O}(\sqrt{d})$

Table 6: Summary of running time and condition number, for several different ℓ_2 conditioning methods. Here, we assume $d \leq n \leq e^d$. The failure probability of each method is set to be a constant.

Next, given the implicit representation of U by R, to compute the leverage scores $\|U_i\|_p^p$ exactly, one has to compute U which takes $\mathcal{O}(nd^2)$ time. Instead of forming U explicitly and "reading off" the row norms for computing the leverage scores, one can estimate the row norms of U up to a small factor by post-multiplying a random projection matrix; see Clarkson et al. (2013); Drineas et al. (2012) for the cases when $p = 1, 2$ respectively. The above process can be done in $\mathcal{O}(\text{nnz}(A) \cdot \log n)$ time.

Finally, we present two additional results regarding the non-asymptotic convergence rate of PWSGD on ℓ_1 and ℓ_2 regression, respectively. Notation is similar to the one used in Proposition 5 and Proposition 6.

Proposition 14 *For $A \in \mathbb{R}^{n \times d}$ and $b \in \mathbb{R}^n$, define $f(x) = \|Ax - b\|_1$. Algorithm 1 with $p = 1$ returns a solution vector estimate $\bar{x}$ that satisfies the following expected error bound*

$$\mathbb{E}\left[f(\bar{x})\right] - f(x^*) \leq \frac{1}{2\eta T}\|x^* - x_1\|_H^2 + \frac{\eta}{2}\left(c_1 \alpha \|RF\|_1\right)^2. \tag{13}$$

Hereby, the expectation is taken over all the samples $\xi_1, \ldots, \xi_T$ and x^* is an optimal solution to the problem $\min_{x \in \mathcal{Z}} f(x)$. The constant in the error bound is given by $c_1 = \frac{1+\gamma}{1-\gamma}$.

9. In Cohen (2016), the author analyzes a more general version of the original count-sketch like sparse ℓ_2 embedding (Clarkson and Woodruff, 2013). By setting the sparsity parameter differently, different running time complexities can be achieved.

Proposition 15 *For $A \in \mathbb{R}^{n\times d}$ and $b \in \mathbb{R}^n$, define $f(x) = \|Ax - b\|_2$. Algorithm 1 with $p = 2$ returns a solution vector estimate x_T that satisfies the following expected error bound*

$$\mathbb{E}\left[\|x_t - x^*\|_H^2\right] \leq \left(\frac{1 - 4\eta\left(1 - 2\eta c_1\alpha^2\|RF\|_2^2\right)}{\beta^2\|(RF)^{-1}\|_2^2}\right)^T \|x_0 - x^*\|_H^2 + \frac{2c_1\eta\bar{\kappa}_2^2(U)\kappa^2(RF)h(y^*)}{1 - 2c_1\eta\alpha^2\|RF\|_2^2}. \tag{14}$$

Hereby, $H = (F^{-1})^\top F^{-1}$ is the weighs of the ellipsoidal norm and the expectation is taken over all the samples $\xi_1, \ldots, \xi_T$ and x^* is an optimal solutions to the problem $\min_{x\in\mathcal{Z}} f(x)$. The constant in the error bound is given by $c_1 = \frac{1+\gamma}{1-\gamma}$.

Appendix B. RLA Methods with Algorithmic Leveraging

In this section, we present the RLA sampling algorithms with algorithmic leveraging for solving ℓ_p regression problems mentioned in Section 3. The main idea in this class of algorithms is to sample rows based on the leverage scores of $\begin{pmatrix} A & b \end{pmatrix}$ and solve the sample average approximation of the ℓ_p regression problem. This method is formally stated in Algorithm 3.

The following theorem (from Dasgupta et al. (2009)) states that if the sampling size s is large enough, the resulting approximation solution $\hat{x}$ produces a $\left(\frac{1+\epsilon}{1-\epsilon}\right)$-approximation to the original solution vector. The following theorem also shows that when the desired accuracy and confidence interval are fixed, the required sampling size only depends on the lower dimension d since α and β are independent of n.

Theorem 16 *Given input matrix $A \in \mathbb{R}^{n\times d}$ and vector $b \in \mathbb{R}^n$, let α, β be the condition numbers of the well-conditioned basis U for the range space of $\begin{pmatrix} A & b \end{pmatrix}$ and γ be the quality of approximation to the leverage scores satisfying* (6)*. Then when $\epsilon < 1/2$ and the sampling size satisfies the following condition*

$$s \geq \frac{1+\gamma}{1-\gamma}\frac{(32\alpha\beta)^p}{p^2\epsilon^2}\left((d+1)\log\left(\frac{12}{\epsilon}\right) + \log\left(\frac{2}{\delta}\right)\right), \tag{15}$$

Algorithm 3 returns a solution vector $\hat{x}$ that satisfies the following inequality with probability at least $1 - \delta$,

$$\|A\hat{x} - b\|_p \leq \left(\frac{1+\varepsilon}{1-\varepsilon}\right)\|Ax^* - b\|_p, \tag{16}$$

where $x^* \in \mathcal{Z}$ is an optimal solution to the original problem $\min_{x\in\mathcal{Z}} \|Ax - b\|_p$.

Remark. Compared to the RLA algorithm described in Section 3, the algorithm described here computes the leverage scored based on a basis for the range space of the augmented linear system $\bar{A} = \begin{pmatrix} A & b \end{pmatrix}$ rather than A. One can show similar results if the basis is computed for the range space of A.

Remark. As can be seen, the sampling size is $s = \mathcal{O}(\text{poly}(d)\log(1/\epsilon)/\epsilon^2)$ for a target accuracy ϵ. For unconstrained ℓ_2 regression, however, it can be shown that a sampling size $s = \mathcal{O}(\text{poly}(d)\log(1/\epsilon)/\epsilon)$ is sufficient to compute an ϵ-approximate solution; see Drineas et al. (2011); Clarkson and Woodruff (2013) for details.

Appendix C. Proofs

Here, we present the proofs of the theoretical results in the main text.

Algorithm 3 RLA methods with algorithmic leveraging for constrained ℓ_p regression

Input: $A \in \mathbb{R}^{n\times d}$, $b \in \mathbb{R}^n$ with $\text{rank}(\bar{A}) = k$ where $\bar{A} = \begin{pmatrix} A & b \end{pmatrix}$, $\mathcal{Z}$ and $s > 0$.
Output: An approximate solution $\hat{x} \in \mathbb{R}^d$ to problem $\text{minimize}_{x\in\mathcal{Z}} \|Ax - b\|_p^p$.
Compute $R \in \mathbb{R}^{k\times(d+1)}$ such that $\bar{A} = UR$ and U is an (α, β) well-conditioned basis U for the range space of $\bar{A}$.
Compute or estimate $\|U_i\|_p^p$ by λ_i satisfying (6) with γ, for $i \in [n]$.
Let $p_i = \frac{\lambda_i}{\sum_{j=1}^n \lambda_j}$, for $i \in [n]$.
Let $S \in \mathbb{R}^{s\times n}$ be a zero matrix.
for $i = 1, \ldots, s$ **do**
  Pick ξ_t from $[n]$ based on distribution $\{p_i\}_{i=1}^n$.
  Set $S_{i,\xi_t} = \left(\frac{1}{p_{\xi_t}}\right)^{\frac{1}{p}}$.
end for
Return $\hat{x} = \arg\min_{x\in\mathcal{Z}} \|SAx - Sb\|_p$.

C.1 Proof of Proposition 7

Consider the following three events:

- $\mathcal{E}_1$: Compute a matrix R such that $U = AR^{-1}$ has condition number $\bar{\kappa}_p$, and then compute $F = R^{-1}$ and $H = \left(FF^\top\right)^{-1}$.
- $\mathcal{E}_2$: Given R^{-1}, compute $\{\lambda_i\}_{i=1}^n$ as an estimation of row norms of AR^{-1} satisfying (6) with $\gamma = 0.5$.
- $\mathcal{E}_3$: For a given basis U with condition number $\bar{\kappa}_p(U)$ and $\{\lambda_i\}_{i=1}^n$ with approximation quality γ, pwSGD returns a solution with the desired accuracy with iterations $10T$ where T is specified in Proposition 5 or Proposition 6.

Since each preconditioning method shown in Table 5 successes with constant probability, $\mathcal{E}_1$ holds with a constant probability. Also, as introduced in Appendix A, $\mathcal{E}_2$ has a constant failure probability. Finally, by Markov inequality, we know that $\mathcal{E}_3$ holds with probability at least 0.9. As setting the failure probability of $\mathcal{E}_1$ and $\mathcal{E}_2$ to be arbitrarily small will not alter the results in big-O notation, we can ensure that, with constant probability, $\mathcal{E}_1 \cap \mathcal{E}_2 \cap \mathcal{E}_3$ holds.

Conditioned on the fact that $\mathcal{E}_1 \cap \mathcal{E}_2 \cap \mathcal{E}_3$ holds, to converge to the desired solution, for ℓ_1 regression, pwSGD runs in $\mathcal{O}(d\bar{\kappa}_1(U)/\epsilon^2)$ iterations. Since all the preconditioning methods in Table 6 provide $\kappa(U) = \mathcal{O}(1)$ and $\bar{\kappa}_2(U) = \mathcal{O}(\sqrt{d})$, for unconstrained ℓ_2 regression, it runs in $\mathcal{O}(d\log(1/\epsilon)/\epsilon)$ iterations. For constrained ℓ_2 regression, since an ϵ-approximate solution in terms of the solution vector measured in the prediction norm implies a $\sqrt{\epsilon}$-approximate solution on the objective, it runs in $\mathcal{O}(d\log(1/\epsilon)/\epsilon^2)$ iterations to return an ϵ-solution in the objective value.

The overall complexity is the sum of the complexity needed in each of the above events. For $\mathcal{E}_1$, it is $time(R)$ since the time for computing F and H is $\mathcal{O}(d^3)$ which can absorbed into $time(R)$ and they only have to be computed once. For $\mathcal{E}_2$, it is $\mathcal{O}(\text{nnz}(A)\cdot\log n)$. Finally, for $\mathcal{E}_3$, when the problem is unconstrained, $time_{update} = \mathcal{O}(d^2)$; when the problem is constrained, $time_{update} = \text{poly}(d)$. Combining these, we get the complexities shown in the statement. This completes the proof.

C.2 Proof of Proposition 14

The proof of this proposition is structured as follows. First we reformulate the problem using Proposition 4. Second we show that the sequence of solution vector estimates $\{x_t\}_{t=1}^T$ in Algorithm 1 is equivalent to the solution vector estimates $\{y_t\}_{t=1}^T$ obtained by running SGD on the equivalent problem. Third, we analyze the convergence rate of $\{y_t\}_{t=1}^T$ and conclude the error bound analysis.

Problem reformulation Suppose U is an ℓ_p well-conditioned basis for the range space of A and $A = UR$ for some nonsingular matrix R. Let P be the distribution defined based on the estimation of the corresponding leverage scores. That is, for $i \in [n]$,

$$p_i = \frac{\lambda_i}{\sum_{j=1}^n \lambda_j}, \tag{17}$$

where λ_i is an estimation of $\|U_i\|_p^p$ satisfying

$$(1-\gamma)\|U_i\|_p^p \le \lambda_i \le (1+\gamma)\|U_i\|_p^p. \tag{18}$$

This implies

$$\frac{1-\gamma}{1+\gamma}\frac{\|U_i\|_p^p}{\|U\|_p^p} \le p_i \le \frac{1+\gamma}{1-\gamma}\frac{\|U_i\|_p^p}{\|U\|_p^p}. \tag{19}$$

From Proposition 4, recall that for any non-singular matrix $F \in \mathbb{R}^{(d+1)\times(d+1)}$, the constrained ℓ_p regression problem

$$\min_{x\in\mathcal{Z}} f(x) := \|Ax-b\|_p^p \tag{20}$$

can be equivalently written as the following stochastic optimization problem,

$$\min_{y\in\mathcal{Y}} h(y) = \|URFy-b\|_p^p = \mathbb{E}_{\xi\sim P}\left[|U_\xi RFy - b_\xi|^p/p_\xi\right]. \tag{21}$$

Notice that by comparing to the objective function defined in (1) where $f(x) = \|Ax-b\|_p$, we rewrite $f(x)$ into the form of the sum of subfunctions, i.e., $f(x) = \|Ax-b\|_p^p$, so that SGD can be applied.

Equivalence of sequences By using the following linear transformation, one notices that the sequence $\{x_t\}_{t=1}^T$ obtained by (11) in Algorithm 1 has a one-to-one correspondence to the sequence $\{y_t\}_{t=1}^T$ obtained by running SGD on problem (21):

$$\begin{aligned} Fy_t &= x_t, \\ F\bar{y} &= \bar{x}, \\ Fy^* &= x^*. \end{aligned} \tag{22}$$

Thus with condition (22), immediately the objective function value has the following equivalence as well:

$$\begin{aligned} h(y_t) &= f(x_t), \\ h(\bar{y}) &= f(\bar{x}), \\ h(y^*) &= f(x^*), \end{aligned} \tag{23}$$

where $\bar{x} = \frac{1}{T}\sum_{i=1}^T x_t$, $\bar{y} = \frac{1}{T}\sum_{i=1}^T y_t$ and x^* and y^* are the optimal point to optimization problem (20) and (21) respectively.

Now we prove (22) by induction. By defining $Fy_0 = x_0$, one immediately shows that the equivalence condition holds at the base case ($t = 0$). Now by induction hypothesis, assume (22) holds for case $t = k$. Now for $t = k+1$, we show that x_{k+1} returned by Algorithm 1 and y_{k+1} returned by the update rule of SGD satisfy (22).

For simplicity, assume that at k-th iteration, the i-th row is picked. For subfunction $h_k(y) = |U_iRFy|^p - b_i/p_i$, its (sub)gradient is

$$g_k(y) = p\cdot \mathrm{sgn}(U_iRFy - b_i)\cdot(U_iRFy-b_i)^{p-1}\cdot U_iRF/p_i, \tag{24}$$

for which the SGD update rule becomes

$$y_{k+1} = \arg\min_{y\in\mathcal{Y}} \eta\langle y - y_k, c_kU_iRF\rangle + \frac{1}{2}\|y_k - y\|_2^2, \tag{25}$$

where $c_k = p\cdot\mathrm{sgn}(U_iRFy-b_i)\cdot(U_iRFy-b_i)^{p-1}/p_i$ is the corresponding (sub)gradient. Recall the linear transformation $Fy_k = x_k$, feasible set $\mathcal{Y} = \{y\in\mathbb{R}^k | y = F^{-1}x, x\in\mathcal{Z}\}$ and input matrix $A_i = U_iR$, the update rule (25) becomes

$$x_{k+1} = \arg\min_{x\in\mathcal{Z}} \eta c_kA_ix + \frac{1}{2}\|F^{-1}(x_k - x)\|_2^2. \tag{26}$$

The equation above is exactly the update performed in (11). In particular, when $\mathcal{Z} = \mathbb{R}^d$, i.e., in the unconstrained case, (26) has a closed-form solution as shown in (11). From the above analysis on the equivalence between (25) and (26), one notices x_{k+1} and y_{k+1} satisfy the relationship defined in (22), i.e., the induction hypothesis holds at $t = k+1$.

Therefore by induction, we just showed that condition (22), and therefore condition (23), hold for any t.

Convergence rate Based on the equivalence condition in (23), it is sufficient to analyze the performance of sequence $\{y_t\}_{t=1}^T$. When $p = 1$, the objective function is non-differentiable. Thus by substituting the subgradient of an ℓ_1 objective function to the update in (25), one notices that the SA method simply reduces to stochastic subgradient descent. We now analyze the convergence rate of running stochastic subgradient descent on problem (21) with $p = 1$.

Suppose the i-th row is picked at the t-th iteration. Recall that the (sub)gradient of the sample objective $|U_iRFy - b_i|/p_i$ in (25) is expressed as

$$g_t(y) = \mathrm{sgn}(U_iRFy - b_i)\cdot U_iRF/p_i. \tag{27}$$

Hence, by inequality (19), the norm of $g_t(y)$ is upper-bounded as follows:

$$\begin{aligned} \|g_t(y)\|_1 &= \|U_iRF\cdot\mathrm{sgn}(U_iRFy-b_i)\|_1/p_i \\ &\le |RF|_1\|U_i\|_1\frac{1+\gamma}{1-\gamma}\cdot\frac{|U|_1}{\|U_i\|_1} \le \alpha|RF|_1\frac{1+\gamma}{1-\gamma}. \end{aligned} \tag{28}$$

In above, we use the property of the well-conditioned basis U. Furthermore by Proposition 17 and the equivalence condition in (23), for $H = \left(FF^\top\right)^{-1}$ we have

$$\begin{aligned}\mathbb{E}\left[f(\bar{x})\right] - f(x^*) &= \mathbb{E}\left[h(\bar{y})\right] - h(y^*) \quad (29)\\ &\leq \frac{1}{2\eta(T+1)}\|y^* - y_0\|_2^2 + \frac{\eta}{2}\left(\alpha|RF|_1\frac{1+\gamma}{1-\gamma}\right)^2\\ &= \frac{1}{2\eta(T+1)}\|x^* - x_0\|_H^2 + \frac{\eta}{2}\left(\alpha|RF|_1\frac{1+\gamma}{1-\gamma}\right)^2, \quad (30)\end{aligned}$$

which completes the proof.

C.3 Proof of Proposition 5

By Proposition 17, when the step-size equals to

$$\eta = \frac{\|y^* - y_0\|_2}{\alpha|RF|_1\sqrt{T+1}}\frac{1-\gamma}{1+\gamma},$$

the expected error bound is given by

$$\mathbb{E}\left[h(\bar{y})\right] - h(y^*) \leq \alpha|RF|_1\frac{\|y^* - y_0\|_2}{\sqrt{T+1}}\frac{1+\gamma}{1-\gamma}. \quad (31)$$

By simple algebraic manipulations, we have that

$$\begin{aligned}\frac{1}{\sqrt{d}}\|y^*\|_2 &\leq \|y^*\|_\infty = \|(RF)^{-1}RFy^*\|_\infty \leq |(RF)^{-1}|_1\|RFy^*\|_\infty\\ &\leq \beta|(RF)^{-1}|_1\|URFy^*\|_1 = c_3\beta|(RF)^{-1}|_1 h(y^*), \quad (32)\end{aligned}$$

where $c_3 = \|URFy^*\|_1/h(y^*)$. In above, we use the property of the well-conditioned basis U.

Furthermore from inequality (31) and the equivalence condition in (23), the expected relative error bound can be upper-bounded by

$$\begin{aligned}\frac{\mathbb{E}\left[f(\bar{x})\right] - f(x^*)}{f(x^*)} &= \frac{\mathbb{E}\left[h(\bar{y})\right] - h(y^*)}{h(y^*)}\\ &\leq \frac{c_3\sqrt{d}\beta|(RF)^{-1}|_1}{\|y^*\|_2}\left(\alpha|RF|_1\frac{\|y^* - y_0\|_2}{\sqrt{T+1}}\frac{1+\gamma}{1-\gamma}\right)\\ &\leq |RF|_1|(RF)^{-1}|_1\frac{\|y^* - y_0\|_2}{\|y^*\|_2}\left(\frac{c_3\sqrt{d}\alpha\beta}{\sqrt{T+1}}\frac{1+\gamma}{1-\gamma}\right). \quad (33)\end{aligned}$$

Since the right hand side of the above inequality is a function of stopping time $T > 0$, for any arbitrarily given error bound threshold $\epsilon > 0$, by setting the right hand side to be ϵ, one obtains the following stopping condition:

$$\frac{\sqrt{d}\alpha\beta}{\sqrt{T+1}} = \frac{\epsilon}{c_1c_3\sqrt{c_2}|RF|_1|(RF)^{-1}|_1}, \quad (34)$$

where the above constants are given by

$$c_1 = \frac{1+\gamma}{1-\gamma},\ c_2 = \frac{\|x_0 - x^*\|_H^2}{\|x^*\|_H^2} = \frac{\|y_0 - y^*\|_2^2}{\|y^*\|_2^2}.$$

Rearranging the above terms we know that after

$$T \geq \frac{d\alpha^2\beta^2c_1^2c_2c_3^2}{\epsilon^2}|RF|_1^2|(RF)^{-1}|_1^2 \quad (35)$$

iterations, the relative expected error is upper-bounded by $\epsilon > 0$, i.e.,

$$\frac{\mathbb{E}\left[f(\bar{x})\right] - f(x^*)}{f(x^*)} \leq \epsilon. \quad (36)$$

This completes the proof.

C.4 Proof of Proposition 15

Similar to the proof of Proposition 14, the proof of this proposition is split into three parts: **Problem reformulation**, **Equivalence of sequences** and **Convergence rates**. From the proof of Proposition 14, one notices that the proofs in **Problem reformulation** and **Equivalence of sequences** hold for general p, and thus the proofs hold for the case when $p = 2$ as well. Now we proceed to the proof of the convergence rate. Again by the equivalence condition, we can show the convergence rate of solution vector estimate $\{x_t\}$ by showing the convergence rate achieved by the sequence $\{y_t\}$, i.e., the convergence rate of SGD of problem (21) for $p = 2$.

Throughout the rest of the proof, we denote

$$f(x) = \|Ax - b\|_2^2, \quad h(y) = \|AFy - b\|_2^2. \quad (37)$$

Denote by $H = \left(FF^\top\right)^{-1}$ the weighs of the ellipsoidal norm. Also recall that when the leverage scores satisfy the error condition in (6), we have the following condition

$$\frac{1-\gamma}{1+\gamma}\frac{\|U_i\|_2^2}{\|U\|_2^2} \leq p_i \leq \frac{1+\gamma}{1-\gamma}\frac{\|U_i\|_2^2}{\|U\|_2^2}. \quad (38)$$

Also, we assume that U is (α, β)-conditioned with $\bar{\kappa}_2(U) = \alpha\beta$. Based on Definition 1, we have

$$\begin{aligned}\alpha^2 &= \|U\|_F^2, \quad (39)\\ \beta^2 &= \|(U^\top U)^{-1}\|_2, \quad (40)\end{aligned}$$

and thus

$$\bar{\kappa}_2^2(U) = \|(U^\top U)^{-1}\|_2 \cdot \|U\|_F^2 = \alpha^2\beta^2. \quad (41)$$

Before deriving the convergence rate, we compute a few constants.

$$\mu = 2\sigma_{\min}^2(AF) = \frac{2}{\left\|((URF)^\top URF)^{-1}\right\|_2^2} \geq \frac{2}{\left\|(U^\top U)^{-1}\right\|_2 \cdot \|(RF)^{-1}\|_2^2} = \frac{2}{\beta^2 \cdot \|(RF)^{-1}\|_2^2}, \quad (42)$$

and

$$\sup_i L_i = \sup_i \frac{2\|A_iF\|_2^2}{p_i} = \sup_i \frac{2\|U_iRF\|_2^2}{p_i} \le 2c_1\|U\|_F^2 \cdot \|RF\|_2^2 = 2c_1\alpha^2 \cdot \|RF\|_2^2, \tag{43}$$

and

$$\begin{aligned}
\sigma^2 = \mathbb{E}_{i\sim\mathcal{D}}\left[\|g_i(y^*)\|^2\right] &= 4\sum_{i=1}^n (A_iFy^* - b_i)^2\|A_iF\|^2/p_i \\
&= 4\sum_{i=1}^n (U_iRFy^* - b_i)^2\|U_iRF\|^2/p_i \\
&\le 4c_1\|RF\|_2^2\|U\|_F^2\left(\sum_{i=1}^n (U_iRFy^* - b_i)^2\right) \\
&= 4c_1\|U\|_F^2 \cdot \|RF\|_2^2 \cdot h(y^*) \\
&= 4c_1\alpha^2 \cdot \|RF\|_2^2 \cdot h(y^*).
\end{aligned} \tag{44}$$

Equipped with these constant and from Proposition 18, we have the following error bound of the solution vector estimate $\{y_t\}_{t=1}^T$ generated by the weighted SGD algorithm

$$\begin{aligned}
&\mathbb{E}\left[\|x_T - x^*\|_H^2\right] \\
&= \mathbb{E}\left[\|y_T - y^*\|_2^2\right] \\
&\le \left(1 - 4\eta\sigma_{\min}^2(AF)\left(1 - \eta\sup_i \frac{2\|A_iF\|_2^2}{p_i}\right)\right)^T \|y_0 - y^*\|_2^2 \\
&\quad + \frac{2\eta\sum_{i=1}^n (A_iFy^* - b_i)^2\|A_iF\|_2^2/p_i}{\sigma_{\min}^2(AF)(1 - \eta\sup_i \frac{2\|A_iF\|_2^2}{p_i})} \\
&= \left(1 - 4\eta\sigma_{\min}^2(AF)\left(1 - \eta\sup_i \frac{2\|A_iF\|_2^2}{p_i}\right)\right)^T \|x_0 - x^*\|_H^2 \\
&\quad + \frac{2\eta\sum_{i=1}^n (A_iFy^* - b_i)^2\|A_iF\|_2^2/p_i}{\sigma_{\min}^2(AF)(1 - \eta\sup_i \frac{2\|A_iF\|_2^2}{p_i})} \\
&\le \left(\frac{1 - 4\eta\left(1 - 2\eta c_1\alpha^2\|RF\|_2^2\right)}{\beta^2\|(RF)^{-1}\|_2^2}\right)^T \|x_0 - x^*\|_H^2 + \frac{2c_1\eta\bar{\kappa}_2^2(U)\kappa^2(RF)h(y^*)}{1 - 2\eta c_1\alpha^2\|RF\|_2^2}.
\end{aligned} \tag{45}$$

Notice that the above equalities follow from the equivalence condition in (23). Combining the results from the above parts completes the proof of this lemma.

C.5 Proof of Proposition 6

Throughout the proof, we denote

$$f(x) = \|Ax - b\|_2^2, \quad h(y) = \|AFy - b\|_2^2. \tag{46}$$

Denote by $H = \left(FF^\top\right)^{-1}$ the weights of the ellipsoidal norm. Also recall the following constants defined in the statement of proposition

$$c_1 = \frac{1+\gamma}{1-\gamma},\ c_2 = \frac{\|y_0 - y^*\|_2^2}{\|y^*\|_2^2} = \frac{\|x_0 - x^*\|_H^2}{\|x^*\|_H^2},\ c_3 = \frac{\|Ax^*\|_2^2}{f(x^*)}. \tag{47}$$

Before diving into the detailed proof, we first show a useful inequality.

$$c_3h(y^*) = c_3f(x^*) = \|Ax^*\|_2^2 = \|URFy^*\|_2^2 \ge \mu\|y^*\|_2^2/2. \tag{48}$$

Now we show the first part. For an arbitrary target error $\epsilon > 0$, using (42), (43), (44) and setting

$$\frac{c_3\epsilon \cdot h(y^*)}{\|AF\|_2^2} \to \epsilon \tag{49}$$

in Corollary 19 we have that when the step-size is set to be

$$\eta = \frac{1}{4}\frac{c_3\epsilon \cdot \sigma_{\min}^2(AF) \cdot h(y^*)/\|AF\|_2^2}{\sum_{i=1}^n (A_iFy^* - b_i)^2\|A_iF\|_2^2/p_i + c_3\left(\epsilon \cdot h(y^*)/\|AF\|_2^2\right)\sigma_{\min}^2(AF)\sup_i \frac{\|A_iF\|_2^2}{p_i}}, \tag{50}$$

then after

$$\begin{aligned}
&\log\left(\frac{2\|y_0 - y^*\|_2^2}{c_3\epsilon \cdot h(y^*)/(\|U\|_2^2\|RF\|_2^2)}\right) \cdot \\
&\quad \left(c_1\alpha^2\beta^2\|RF\|_2^2\|(RF)^{-1}\|_2^2 + \frac{c_1\alpha^2\beta^4\|U\|_2^2\|RF\|_2^4\|(RF)^{-1}\|_2^4}{c_3\epsilon}\right) \\
&\le \log\left(\frac{2\|U\|_2^2\|RF\|_2^2 \cdot \|y_0 - y^*\|_2^2}{c_3\epsilon \cdot h(y^*)}\right)\left(c_1\bar{\kappa}_2^2(U)\kappa^2(RF) + \frac{c_1\bar{\kappa}_2^2(U)\kappa^2(U)\kappa^4(RF)}{c_3\epsilon}\right) \\
&\le \log\left(\frac{2c_2\kappa^2(U)\kappa^2(RF))}{\epsilon}\right)\left(c_1\bar{\kappa}_2^2(U)\kappa^2(RF)\right)\left(1 + \frac{\kappa^2(U)\kappa^2(RF)}{c_3\epsilon}\right)
\end{aligned} \tag{51}$$

iterations, the sequence $\{y_t\}_{k=1}^T$ generated by running weighted SGD algorithm satisfies the error bound

$$\|y_T - y^*\|_2^2 \le \frac{c_3\epsilon \cdot h(y^*)}{\|AF\|_2^2}. \tag{52}$$

Notice that in (51), we used (48). From this, we have

$$\begin{aligned}
\|A(x_T - x^*)\|_2^2 &= \|AFF^{-1}(x_T - x^*)\|_2^2 \\
&\le \|AF\|_2^2 \cdot \|x_T - x^*\|_H^2 \\
&= \|AF\|_2^2 \cdot \|y_T - y^*\|_2^2 \\
&= c_3\epsilon \cdot h(y^*) \\
&= \epsilon\|Ax^*\|_2^2.
\end{aligned} \tag{53}$$

For the second part, we show the result for general choice of F. The proof is basically the same as that of the first part except that we set

$$\frac{2\epsilon h(y^*)}{\|AF\|_2^2} \to \epsilon \tag{54}$$

in Corollary 19. The resulting step-size η and number of iterations required T become

$$\eta = \frac{1}{4}\frac{2\epsilon \cdot \sigma_{\min}^2(AF) \cdot h(y^*)/\|AF\|_2^2}{\sum_{i=1}^n (A_iFy^* - b_i)^2\|A_iF\|_2^2/p_i + \left(2\epsilon \cdot h(y^*)/\|AF\|_2^2\right)\sigma_{\min}^2(AF)\sup_i \frac{\|A_iF\|_2^2}{p_i}} \tag{55}$$

and

$$T = \log\left(\frac{c_2\kappa^2(U)\kappa^2(RF))}{\epsilon}\right)\left(c_1\bar{\kappa}_2^2(U)\kappa^2(RF)\right)\left(1+\frac{\kappa^2(U)\kappa^2(RF)}{2\epsilon}\right). \tag{56}$$

Setting $F = R^{-1}$ recovers the value of T shown in Proposition 6. The sequence $\{y_t\}_{k=1}^T$ generated by running weighted SGD algorithm satisfies the error bound

$$\|y_T - y^*\|_2^2 \le \frac{2\epsilon h(y^*)}{\|AF\|_2^2}. \tag{57}$$

Notice that when the problem is unconstrained, by smoothness of the objective $h(y)$, we have

$$h(y_T) - h(y^*) \le \|AF\|_2^2 \cdot \|y_T - y^*\|_2^2 \le 2\epsilon h(y^*). \tag{58}$$

Then by (23), we have

$$f(x_T) \le (1+2\epsilon)f(x^*) \le (1+2\epsilon+\epsilon^2)f(x^*). \tag{59}$$

This implies

$$\sqrt{f(x_T)} \le (1+\epsilon)\sqrt{f(x^*)}. \tag{60}$$

This completes the proof since $\sqrt{f(x)} = \|Ax-b\|_2$.

C.6 Proof of Theorem 10

Let G_f consist of m_f copies of g_f and $G = \bigcup_{f\in\mathcal{F}} G_f$. We may view the sampling step in Algorithm 2 as follows. Sample s items uniformly from G independently with replacement and denote the corresponding subset of samples by S. Then rescale every function in S by $M(\mathcal{F})/s$ and obtain $\mathcal{D}$.

By Theorem 4.1 in Feldman and Langberg (2011), we know that if the above intermediate set S is an $(\epsilon\cdot n/M(\mathcal{F}))-$approximation of the set G, then the resulting set $\mathcal{D}$ is a desired ϵ-coreset for $\mathcal{F}$. Indeed, S is such a set according to Theorem 6.10 in Feldman and Langberg (2011).

C.7 Proof of Proposition 11

We use A to denote $\bar{A}$ for the sake of simplicity. Also define the sensitivity at row index $i\in[n]$ as

$$s_i = n\cdot\sup_{x\in\mathcal{C}}\frac{|A_ix|^p}{\sum_{j=1}^n|A_jx|^p}. \tag{61}$$

Suppose $U\in\mathbb{R}^{n\times k}$ is an (α,β) well-conditioned basis of the range space of A satisfying $A=UR$, where $k=\text{rank}(A)$ and $R\in\mathbb{R}^{k\times(d+1)}$. Then from (61), we have that

$$\frac{s_i}{n} = \sup_{x\in\mathcal{C}}\frac{|A_ix|^p}{\|Ax\|_p^p} = \sup_{x\in\mathcal{C}}\frac{|U_iRx|^p}{\|URx\|_p^p} = \sup_{y\in\mathcal{C}'}\frac{|U_iy|^p}{\|Uy\|_p^p} \le \sup_{y\in\mathcal{C}'}\frac{\|U_i\|_p^p\|y\|_q^p}{\|y\|_q^p/\beta^p} = \beta^p\|U_i\|_p^p = \beta^p\cdot\lambda_i, \tag{62}$$

where $\mathcal{C}' = \{y\in\mathbb{R}^d | y = Rx, x\in\mathcal{C}\}$ is a one-to-one mapping. The first inequality follows from Hölder's inequality with $\frac{1}{p}+\frac{1}{q}=1$ and the properties of well-conditioned bases. According to the definition of sensitivity $m(f_i) = \lfloor s_i\rfloor + 1$, the above property implies

$$m(f_i) \le n\beta^p\lambda_i + 1. \tag{63}$$

which implies $M(\mathcal{F}) = \sum_{i=1}^n s_i \le (n\beta^p\sum_{i=1}^n\lambda_i) + n = n((\alpha\beta)^p+1)$, and completes the proof.

C.8 Proof of Proposition 12

According to Definition 9, we only have to show that for any arbitrary constant n and set of points $G=\{a_1,\ldots,a_n\}\subseteq\mathbb{R}^d$, the following condition holds:

$$|\{\textbf{Range}(G,x,r)|x\in\mathcal{X}, r\ge 0\}| \le n^{d+1},$$

where $\textbf{Range}(G,x,r) = \{a_i||a_i^\top x|^p\le r\}$ is the region located in the $p-$norm ellipsoid $|a_i^\top x|^p = r$. Since the following condition holds: $\{a_i||a_i^\top x|^p\le r\} = \{a_i||a_i^\top x|\le r^{\frac{1}{p}}\}$ and the constant r is non-negative and arbitrary. Without loss of generality, we assume $p=1$ in the above definition, i.e., $\textbf{Range}(G,x,r) = \{a_i||a_i^\top x|\le r\}$.

Notice that for every x and r, $\textbf{Range}(G,x,r)$ is a subset of G. Hence, we may view it as a binary classifier on G, denoted by $c_{x,r}$. Given $x\in\mathcal{X}$ and $r\ge 0$, for any $a_i\in G$ we have that

$$c_{x,r}(a_i) = \begin{cases}1, & \text{if } |a_i^\top x|\le r;\\ 0, & \text{otherwise.}\end{cases}$$

Therefore, one immediately sees that $|\{\textbf{Range}(G,x,r)|x\in\mathcal{X},r\ge0\}|$ is the shattering coefficient of $C := \{c_{x,r}|x\in\mathcal{X},r\ge0\}$ on n points, denoted by $s(C,n)$. To bound the shattering coefficient of C, we provide an upper bound based on its VC dimension.

We claim that the VC dimension of C is at most $d+1$. By contradiction, suppose there exists $n+2$ points such that any labeling on these $n+2$ points can be shattered by C. By Radon's Theorem (Clarkson et al., 1993), we can partition these points into two disjoint subsets, namely, V and W with size n_1 and n_2 respectively, where the intersection of their convex hulls is nonempty. Let b be a point located in the intersection of the convex hulls of V and W, which in general can be written as

$$b = \sum_{i=1}^{n_1}\lambda_iv_i = \sum_{i=1}^{n_2}\sigma_iw_i, \tag{64}$$

where $\lambda_i\ge0$, $\sigma_i\ge0$ and $\sum_{i=1}^{n_1}\lambda_i = \sum_{i=1}^{n_2}\sigma_i = 1$.

By the above assumption, we can find vector $x\in\mathbb{R}^n$ and nonnegative constant r such that the following conditions hold:

$$-r\le x^\top v_i\le r,\quad i=1,\ldots,n_1; \tag{65}$$

$$x^\top w_i > r \text{ or } x^\top w_i < -r,\quad i=1,\ldots,n_2. \tag{66}$$

By combining the conditions in (64), (65) and (66), we further obtain both inequalities

$$-r\le b^\top x\le r, \tag{67}$$

and

$$b^\top x < -r \text{ or } b^\top x > r, \tag{68}$$

which is clearly paradoxical! This concludes that the VC dimension of C is less than or equal to $d+1$. Furthermore, by Sauer's Lemma (Sauer), for $n\ge2$ the shattering coefficient $s(C,n) = |\{\textbf{Range}(G,x,r)|x\in\mathcal{X},r\ge0\}|$ is less than n^{d+1}, which completes the proof of this proposition.

C.9 Proof of Proposition 13

Without loss of generality, assume the low dimension d is even (because if d is odd, we can always add an extra arbitrary row to input matrix A and upper bound the size of the original total sensitivity set by the same analysis). Let $a_i \in [0,1]^d$ be a vector with exactly $d/2$ elements to be 1. For each $i \in [n]$, let $B_i = \{j | a_{ij} = 1\}$, where a_{ij} denotes the j-th element of vector a_i. For fixed i, define x as follows,

$$x_j = \begin{cases} 2/d, & \text{if } \ j \in B_i, \\ -d, & \text{otherwise.} \end{cases} \tag{69}$$

One immediately notices from the above expression that $x^\top a_i = 1$. Thus for $j \neq i$, $a_j \neq a_i$, there exists an index $k \in [d]$ such that $a_{jk} = 1$ but $a_{ik} = 0$. Furthermore the above condition implies

$$x^\top a_j = \sum_{l=1}^{d} x_l a_{jl} = \sum_{l \in B_j, l \neq k}^{d} x_l a_{jl} + \sum_{l \neq B_j}^{d} x_l a_{jl} + x_k a_{jk} \leq (d/2-1)(2/d) - d < 0, \tag{70}$$

which further implies $f_j(x) = x^\top a_j = 0$; Therefore, the i-th sensitivity becomes

$$s_i = \sup_x \frac{f_i(x)}{\sum_{i=j}^{n} f_j(x)} \geq 1. \tag{71}$$

Since the above condition holds for arbitrary index $i \in [n]$, and we have $\binom{d}{d/2}$ number of vectors a_i, i.e., $n = \binom{d}{d/2}$, this concludes that the size of the total sensitivity set is at least $\binom{d}{d/2} \approx 2^d$.

Appendix D. Stochastic Gradient Descent

Consider minimizing the following objective

$$\text{minimize}_{x \in \mathcal{X}} f(x) = \mathbb{E}_{i \sim P}\left[f_i(x)\right]. \tag{72}$$

Stochastic gradient descent (SGD) exploits the following update rule

$$x_{t+1} = \arg\min_{x \in \mathcal{X}} \eta \langle x - x_t, g_{\xi_t}(x_t) \rangle + \frac{1}{2}\|x - x_t\|_2^2, \tag{73}$$

where $\xi_t \in [n]$ is an index drawn according to P, $g_{\xi_t}(x) = \nabla f_{\xi_t}(x)$ and $\mathbb{E}_{\xi_t \sim P}\left[f_{\xi_t}(x)\right] = f(x)$. When $\mathcal{X} = \mathbb{R}^d$, the update rule (73) boils down to $x_{t+1} = x_t - \eta g_{\xi_t}(x_t)$. Note here, if $f_{\xi_t}(x)$ is not differentiable, we take $g_{\xi_t}(x_t)$ to be one of its sub-gradients, i.e., $g_{\xi_t}(x_t) \in \partial f_{\xi_t}(x_t)$. In this case, SGD boils down to stochastic sub-gradient method. For simplicity, we still refer to the algorithms as SGD.

In the following, we present two results regarding the convergence rate of SGD on problem with non-strongly convex objective and strongly convex objective, respectively.

D.1 Non-strongly convex case

Here we analyze the case where the objective function $f(x)$ is not strongly convex. Also, each sub-function is not necessary differentiable. That is, $g_i(x)$ can be a sub-gradient of function f_i at x.

Proposition 17 *Assume that $\frac{1}{2}\|\cdot\|_2^2 \geq \frac{\lambda}{2}\|\cdot\|^2$ for some norm $\|\cdot\|^2$. Also assume that $\|g_t(x_t)\|_* \leq M$ for any $t > 0$ where $\|\cdot\|_*$ is the dual norm of $\|\cdot\|$. The output $\bar{x} = \frac{1}{T+1}\sum_{t=1}^{T} x_t$ of SGD satisfies, for any $y \in \mathcal{X}$,*

$$\mathbb{E}\left[f(\bar{x})\right] - f(y) \leq \frac{\|y - x_0\|_2^2}{2\eta(T+1)} + \frac{\eta}{2\lambda}M^2. \tag{74}$$

In particular, when $\eta = \frac{\|y-x_0\|_2}{M}\sqrt{\frac{\lambda}{T+1}}$, we have

$$\mathbb{E}\left[f(\bar{x})\right] - f(y) \leq M\|y - x_0\|_2\sqrt{\frac{1}{(T+1)\lambda}}. \tag{75}$$

Proof From Lemma 1 in Duchi et al. (2010), at step t, we have that

$$\eta(f_t(x_t) - f_t(y)) \leq \frac{1}{2}\|y - x_t\|_2^2 - \frac{1}{2}\|y - x_{t+1}\|_2^2 + \frac{\eta^2}{2\lambda}\|g_t(x_t)\|_*^2. \tag{76}$$

Conditioned on x_t, taking the conditional expectation with respect to ξ_t on both sides, we have

$$\mathbb{E}\left[\eta(f_t(x_t) - f_t(y))|x_t\right] \leq \mathbb{E}\left[\frac{1}{2}\|y - x_t\|_2^2 - \frac{1}{2}\|y - x_{t+1}\|_2^2 + \frac{\eta^2}{2\lambda}\|g_t(x_t)\|_*^2|x_t\right]. \tag{77}$$

Noticing that $\mathbb{E}_{\xi_t \sim P}\left[f_t(x)\right] = f(x)$, we have

$$\eta f(x_t) - \eta f(y) \leq \frac{1}{2}\|y - x_t\|_2^2 + \mathbb{E}\left[-\frac{1}{2}\|y - x_{t+1}\|_2^2 + \frac{\eta^2}{2\lambda}\|g_t(x_t)\|_*^2|x_t\right]. \tag{78}$$

Then by taking the expectation over x_t and using the fact that $\|g_t(x_t)\|_* \leq M$, we have

$$\mathbb{E}\left[\eta f(x_t)\right] - \eta f(y) \leq \mathbb{E}\left[\frac{1}{2}\|y - x_t\|_2^2\right] - \mathbb{E}\left[\frac{1}{2}\|y - x_{t+1}\|_2^2\right] + \frac{\eta^2}{2\lambda}M^2. \tag{79}$$

Summing up the above equation with $t = 0, \ldots, T$ and noticing $\|y - x_{t+1}\|_2^2 \geq 0$, we have

$$\eta\sum_{t=0}^{T}\mathbb{E}\left[f(x_t)\right] - \eta(T+1)f(y) \leq \frac{1}{2}\|y - x_0\|_2^2 + \frac{\eta^2(T+1)}{2\lambda}M^2. \tag{80}$$

Finally by convexity of f, we have that

$$\mathbb{E}\left[f(\bar{x})\right] - f(y) \leq \frac{\|y - x_0\|_2^2}{2\eta(T+1)} + \frac{\eta}{2\lambda}M^2. \tag{81}$$

In particular with $\eta = \frac{\|y-y_1\|_2}{M}\sqrt{\frac{\lambda}{T+1}}$, we have

$$\mathbb{E}\left[f(\bar{x})\right] - f(y) \leq M\|y - x_0\|_2\sqrt{\frac{1}{(T+1)\lambda}}, \tag{82}$$

which completes the proof. ■

D.2 Strongly convex case

Here we analyze the case where the objective function $f(x)$ is strongly convex. We make the following two assumptions:

(A1) Function $f(x)$ is strongly convex with modulus μ. That is, for any $x, y \in \mathcal{X}$,

$$f(y) \geq f(x) + \langle \nabla f(x), y - x \rangle + \frac{\mu}{2}\|y - x\|_2^2. \tag{83}$$

(A2) For each $i \in [n]$, the gradient of each sub-function $\nabla f_i(x)$ is Lipschitz continuous with constant L_i. That is, for any $x, y \in \mathcal{X}$,

$$\|\nabla f_i(y) - \nabla f_i(x)\|_2 \leq L_i \|y - x\|_2. \tag{84}$$

The following results also appeared in Needell et al. (2014).

Proposition 18 *Under assumption (A1), (A2), the sequence $\{x_t\}$ generated by SGD satisfies*

$$\mathbb{E}\left[\|x_T - x^*\|_2^2\right] \leq (1 - 2\eta\mu(1 - \eta \sup L_i))^T \|x_0 - x^*\|_2^2 + \frac{\eta\sigma^2}{\mu(1 - \eta \sup L_i)}, \tag{85}$$

where $\sigma^2 = \mathbb{E}_{i\sim\mathcal{D}}\left[\|\nabla f_i(x^*)\|_2^2\right]$ and x^* is the optimal solution to (72).

Proof The proof essentially follows the same lines of arguments as in Needell et al. (2014). The only difference is that, here we are working on the constrained problem where update rule (73) is equivalent to

$$x_{t+1} = \Pi_{\mathcal{X}}(x_t - \eta g_t(x_t)). \tag{86}$$

Notice that $\Pi_{\mathcal{X}}(x)$ is a projection operator to the feasible set $\mathcal{X}$ and it is non-expansive. This further implies

$$\|x_{t+1} - x^*\|_2^2 = \|\Pi_{\mathcal{X}}(x_t - \eta g_t(x_t)) - x^*\|_2^2 \leq \|x_t - \eta g_t(x_t) - x^*\|_2^2. \tag{87}$$

The rest of the proof follows analogous arguments in Needell et al. (2014). ■

Corollary 19 *Given a target accuracy $\epsilon > 0$, and let the step-size be $\eta = \frac{\epsilon\mu}{2\sigma^2 + 2\epsilon\mu \sup L_i}$. Then after*

$$T \geq \log\left(\frac{2\|x_0 - x^*\|^2}{\epsilon}\right)\left(\frac{\sigma^2}{\epsilon\mu^2} + \frac{\sup L_i}{\mu}\right) \tag{88}$$

iterations, we have that

$$\mathbb{E}\left[\|x_T - x^*\|_2^2\right] \leq \epsilon. \tag{89}$$

Proof The proof can be found in Needell et al. (2014). ■

Abstract

We introduce a generic scheme for accelerating gradient-based optimization methods in the sense of Nesterov. The approach, called Catalyst, builds upon the inexact accelerated proximal point algorithm for minimizing a convex objective function, and consists of approximately solving a sequence of well-chosen auxiliary problems, leading to faster convergence. One of the keys to achieve acceleration in theory and in practice is to solve these sub-problems with appropriate accuracy by using the right stopping criterion and the right warm-start strategy. We give practical guidelines to use Catalyst and present a comprehensive analysis of its global complexity. We show that Catalyst applies to a large class of algorithms, including gradient descent, block coordinate descent, incremental algorithms such as SAG, SAGA, SDCA, SVRG, MISO/Finito, and their proximal variants. For all of these methods, we establish faster rates using the Catalyst acceleration, for strongly convex and non-strongly convex objectives. We conclude with extensive experiments showing that acceleration is useful in practice, especially for ill-conditioned problems.

Keywords: convex optimization, first-order methods, large-scale machine learning

1. Introduction

A large number of machine learning and signal processing problems are formulated as the minimization of a convex objective function:

$$\min_{x\in\mathbb{R}^p} \left\{ f(x) \triangleq f_0(x) + \psi(x) \right\}, \tag{1}$$

where f_0 is convex and L-smooth, and ψ is convex but may not be differentiable. We call a function L-smooth when it is differentiable and its gradient is L-Lipschitz continuous.

∗. Institute of Engineering Univ. Grenoble Alpes

In statistics or machine learning, the variable x may represent model parameters, and the role of f_0 is to ensure that the estimated parameters fit some observed data. Specifically, f_0 is often a large sum of functions and (1) is a regularized empirical risk which writes as

$$\min_{x\in\mathbb{R}^p} \left\{ f(x) \triangleq \frac{1}{n}\sum_{i=1}^n f_i(x) + \psi(x) \right\}. \tag{2}$$

Each term $f_i(x)$ measures the fit between x and a data point indexed by i, whereas the function ψ acts as a regularizer; it is typically chosen to be the squared ℓ_2-norm, which is smooth, or to be a non-differentiable penalty such as the ℓ_1-norm or another sparsity-inducing norm (Bach et al., 2012).

We present a unified framework allowing one to accelerate gradient-based or first-order methods, with a particular focus on problems involving large sums of functions. By "accelerating", we mean generalizing a mechanism invented by Nesterov (1983) that improves the convergence rate of the gradient descent algorithm. When $\psi = 0$, gradient descent steps produce iterates $(x_k)_{k\geq 0}$ such that $f(x_k) - f^* \leq \varepsilon$ in $O(1/\varepsilon)$ iterations, where f^* denotes the minimum value of f. Furthermore, when the objective f is μ-strongly convex, the previous iteration-complexity becomes $O((L/\mu)\log(1/\varepsilon))$, which is proportional to the condition number L/μ. However, these rates were shown to be suboptimal for the class of first-order methods, and a simple strategy of taking the gradient step at a well-chosen point different from x_k yields the optimal complexity—$O(1/\sqrt{\varepsilon})$ for the convex case and $O(\sqrt{L/\mu}\log(1/\varepsilon))$ for the μ-strongly convex one (Nesterov, 1983). Later, this acceleration technique was extended to deal with non-differentiable penalties ψ for which the proximal operator defined below is easy to compute (Beck and Teboulle, 2009; Nesterov, 2013).

$$\mathrm{prox}_{\psi}(x) \triangleq \arg\min_{z\in\mathbb{R}^p} \left\{ \psi(z) + \frac{1}{2}\|x - z\|^2 \right\}, \tag{3}$$

where $\|.\|$ denotes the Euclidean norm.

For machine learning problems involving a large sum of n functions, a recent effort has been devoted to developing fast incremental algorithms such as SAG (Schmidt et al., 2017), SAGA (Defazio et al., 2014a), SDCA (Shalev-Shwartz and Zhang, 2012), SVRG (Johnson and Zhang, 2013; Xiao and Zhang, 2014), or MISO/Finito (Mairal, 2015; Defazio et al., 2014b), which can exploit the particular structure (2). Unlike full gradient approaches, which require computing and averaging n gradients $(1/n)\sum_{i=1}^n \nabla f_i(x)$ at every iteration, incremental techniques have a cost per-iteration that is independent of n. The price to pay is the need to store a moderate amount of information regarding past iterates, but the benefits may be significant in terms of computational complexity. In order to achieve an ε-accurate solution for a μ-strongly convex objective, the number of gradient evaluations required by the methods mentioned above is bounded by $O\left(\left(n + \frac{\bar{L}}{\mu}\right)\log(\frac{1}{\varepsilon})\right)$, where $\bar{L}$ is either the maximum Lipschitz constant across the gradients ∇f_i, or the average value, depending on the algorithm variant considered. Unless there is a big mismatch between $\bar{L}$ and L (global Lipschitz constant for the sum of gradients), incremental approaches significantly outperform the full gradient method, whose complexity in terms of gradient evaluations is bounded by $O\left(n\frac{L}{\mu}\log(\frac{1}{\varepsilon})\right)$.

Yet, these incremental approaches do not use Nesterov's extrapolation steps and whether or not they could be accelerated was an important open question when these methods were introduced. It was indeed only known to be the case for SDCA (Shalev-Shwartz and Zhang, 2016) for strongly convex objectives. Later, other accelerated incremental algorithms were proposed such as Katyusha (Allen-Zhu, 2017), or the method of Lan and Zhou (2017).

We give here a positive answer to this open question. By analogy with substances that increase chemical reaction rates, we call our approach "Catalyst". Given an optimization method $\mathcal{M}$ as input, Catalyst outputs an accelerated version of it, eventually the same algorithm if the method $\mathcal{M}$ is already optimal. The sole requirement on the method in order to achieve acceleration is that it should have linear convergence rate for strongly convex problems. This is the case for full gradient methods (Beck and Teboulle, 2009; Nesterov, 2013) and block coordinate descent methods (Nesterov, 2012; Richtárik and Takáč, 2014), which already have well-known accelerated variants. More importantly, it also applies to the previou incremental methods, whose complexity is then bounded by $\tilde{O}\left(\left(n+\sqrt{n\bar{L}/\mu}\right)\log(\frac{1}{\varepsilon})\right)$ after Catalyst acceleration, where $\tilde{O}$ hides some logarithmic dependencies on the condition number $\bar{L}/\mu$. This improves upon the non-accelerated variants, when the condition number is larger than n. Besides, acceleration occurs regardless of the strong convexity of the objective—that is, even if $\mu = 0$—which brings us to our second achievement.

Some approaches such as MISO, SDCA, or SVRG are only defined for strongly convex objectives. A classical trick to apply them to general convex functions is to add a small regularization term $\varepsilon\|x\|^2$ in the objective (Shalev-Shwartz and Zhang, 2012). The drawback of this strategy is that it requires choosing in advance the parameter ε, which is related to the target accuracy. The approach we present here provides a *direct support for non-strongly convex objectives*, thus removing the need of selecting ε beforehand. Moreover, we can immediately establish a faster rate for the resulting algorithm. Finally, some methods such as MISO are numerically unstable when they are applied to strongly convex objective functions with small strong convexity constant. By defining better conditioned auxiliary subproblems, Catalyst also provides better numerical stability to these methods.

A short version of this paper has been published at the NIPS conference in 2015 (Lin et al., 2015a); in addition to simpler convergence proofs and more extensive numerical evaluation, we extend the conference paper with a new Moreau-Yosida smoothing interpretation with significant theoretical and practical consequences as well as new practical stopping criteria and warm-start strategies.

The paper is structured as follows. We complete this introductory section with some related work in Section 1.1, and give a short description of the two-loop Catalyst algorithm in Section 1.2. Then, Section 2 introduces the Moreau-Yosida smoothing and its inexact variant. In Section 3, we introduce formally the main algorithm, and its convergence analysis is presented in Section 4. Section 5 is devoted to numerical experiments and Section 6 concludes the paper.

1.1 Related Work

Catalyst can be interpreted as a variant of the proximal point algorithm (Rockafellar, 1976; Güler, 1991), which is a central concept in convex optimization, underlying augmented Lagrangian approaches, and composite minimization schemes (Bertsekas, 2015; Parikh and

Boyd, 2014). The proximal point algorithm consists of solving (1) by minimizing a sequence of auxiliary problems involving a quadratic regularization term. In general, these auxiliary problems cannot be solved with perfect accuracy, and several notions of inexactness were proposed by Güler (1992); He and Yuan (2012) and Salzo and Villa (2012). The Catalyst approach hinges upon (i) an acceleration technique for the proximal point algorithm originally introduced in the pioneer work of Güler (1992); (ii) a more practical inexactness criterion than those proposed in the past.[1] As a result, we are able to control the rate of convergence for approximately solving the auxiliary problems with an optimization method $\mathcal{M}$. In turn, we are also able to obtain the computational complexity of the global procedure, which was not possible with previous analysis (Güler, 1992; He and Yuan, 2012; Salzo and Villa, 2012). When instantiated in different first-order optimization settings, our analysis yields systematic acceleration.

Beyond Güler (1992), several works have inspired this work. In particular, accelerated SDCA (Shalev-Shwartz and Zhang, 2016) is an instance of an inexact accelerated proximal point algorithm, even though this was not explicitly stated in the original paper. Catalyst can be seen as a generalization of their algorithm, originally designed for stochastic dual coordinate ascent approaches. Yet their proof of convergence relies on different tools than ours. Specifically, we introduce an approximate sufficient descent condition, which, when satisfied, grants acceleration to any optimization method, whereas the direct proof of Shalev-Shwartz and Zhang (2016), in the context of SDCA, does not extend to non-strongly convex objectives. Another useful methodological contribution was the convergence analysis of inexact proximal gradient methods of Schmidt et al. (2011) and Devolder et al. (2014). Finally, similar ideas appeared in the independent work (Frostig et al., 2015). Their results partially overlap with ours, but the two papers adopt rather different directions. Our analysis is more general, covering both strongly-convex and non-strongly convex objectives, and comprises several variants including an almost parameter-free variant.

Then, beyond accelerated SDCA (Shalev-Shwartz and Zhang, 2016), other accelerated incremental methods have been proposed, such as APCG (Lin et al., 2015b), SDPC (Zhang and Xiao, 2015), RPDG (Lan and Zhou, 2017), Point-SAGA (Defazio, 2016) and Katyusha (Allen-Zhu, 2017). Their techniques are algorithm-specific and cannot be directly generalized into a unified scheme. However, we should mention that the complexity obtained by applying Catalyst acceleration to incremental methods matches the optimal bound up to a logarithmic factor, which may be the price to pay for a generic acceleration scheme.

A related recent line of work has also combined smoothing techniques with outer-loop algorithms such as Quasi-Newton methods (Themelis et al., 2016; Giselsson and Fält, 2016). Their purpose was not to accelerate existing techniques, but rather to derive new algorithms for nonsmooth optimization.

To conclude this survey, we mention the broad family of extrapolation methods (Sidi, 2017), which allow one to extrapolate to the limit sequences generated by iterative algorithms for various numerical analysis problems. Scieur et al. (2016) proposed such an approach for convex optimization problems with smooth and strongly convex objectives. The approach we present here allows us to obtain global complexity bounds for strongly

1. Note that our inexact criterion was also studied, among others, by Salzo and Villa (2012), but their analysis led to the conjecture that this criterion was too weak to warrant acceleration. Our analysis refutes this conjecture.

convex and non strongly convex objectives, which can be decomposed into a smooth part and a non-smooth proximal-friendly part.

1.2 Overview of Catalyst

Before introducing Catalyst precisely in Section 3, we give a quick overview of the algorithm and its main ideas. Catalyst is a generic approach that wraps an algorithm $\mathcal{M}$ into an accelerated one $\mathcal{A}$, in order to achieve the same accuracy as $\mathcal{M}$ with reduced computational complexity. The resulting method $\mathcal{A}$ is an inner-outer loop construct, presented in Algorithm 1, where in the *inner loop* the method $\mathcal{M}$ is called to solve an auxiliary strongly-convex optimization problem, and where in the *outer loop* the sequence of iterates produced by $\mathcal{M}$ are *extrapolated* for faster convergence. There are therefore three main ingredients in Catalyst: a) a smoothing technique that produces strongly-convex sub-problems; b) an extrapolation technique to accelerate the convergence; c) a balancing principle to optimally tune the inner and outer computations.

Smoothing by infimal convolution Catalyst can be used on any algorithm $\mathcal{M}$ that enjoys a linear-convergence guarantee when minimizing strongly-convex objectives. However the objective at hand may be poorly conditioned or even might not be strongly convex. In Catalyst, we use $\mathcal{M}$ to *approximately minimize* an auxiliary objective h_k at iteration k, defined in (4), which is strongly convex and better conditioned than f. Smoothing by infimal convolution allows one to build a well-conditioned convex function F from a poorly-conditioned convex function f (see Section 3 for a refresher on Moreau envelopes). We shall show in Section 3 that a notion of *approximate Moreau envelope* allows us to define precisely the information collected when approximately minimizing the auxiliary objective.

Extrapolation by Nesterov acceleration Catalyst uses an extrapolation scheme " à la Nesterov " to build a sequence $(y_k)_{k\geq 0}$ updated as

$$y_k = x_k + \beta_k(x_k - x_{k-1}) \ ,$$

where $(\beta_k)_{k\geq 0}$ is a positive decreasing sequence, which we shall define in Section 3.

	Without Catalyst		With Catalyst	
	$\mu > 0$	$\mu = 0$	$\mu > 0$	$\mu = 0$
FG	$O\left(n\frac{L}{\mu}\log\left(\frac{1}{\varepsilon}\right)\right)$	$O\left(n\frac{L}{\varepsilon}\right)$	$\tilde{O}\left(n\sqrt{\frac{L}{\mu}}\log\left(\frac{1}{\varepsilon}\right)\right)$	$\tilde{O}\left(n\sqrt{\frac{L}{\varepsilon}}\right)$
SAG/SAGA	$O\left(\left(n+\frac{\bar{L}}{\mu}\right)\log\left(\frac{1}{\varepsilon}\right)\right)$	$O\left(n\frac{\bar{L}}{\varepsilon}\right)$	$\tilde{O}\left(\left(n+\sqrt{\frac{n\bar{L}}{\mu}}\right)\log\left(\frac{1}{\varepsilon}\right)\right)$	$\tilde{O}\left(\sqrt{\frac{n\bar{L}}{\varepsilon}}\right)$
MISO		not avail.		
SDCA				
SVRG				
Acc-FG	$O\left(n\sqrt{\frac{L}{\mu}}\log\left(\frac{1}{\varepsilon}\right)\right)$	$O\left(n\frac{L}{\sqrt{\varepsilon}}\right)$	no acceleration	
Acc-SDCA	$\tilde{O}\left(\left(n+\sqrt{\frac{n\bar{L}}{\mu}}\right)\log\left(\frac{1}{\varepsilon}\right)\right)$	not avail.		

Table 1: Comparison of rates of convergence, before and after the Catalyst acceleration, in the strongly-convex and non strongly-convex cases, respectively. The notation $\tilde{O}$ hides logarithmic factors. The constant L is the global Lipschitz constant of the gradient's objective, while $\bar{L}$ is the average Lipschitz constants of the gradients ∇f_i, or the maximum value, depending on the algorithm's variants considered.

We shall show in Section 4 that we can get faster rates of convergence thanks to this extrapolation step when the smoothing parameter κ, the inner-loop stopping criterion, and the sequence $(\beta_k)_{k\geq 0}$ are carefully built.

Balancing inner and outer complexities The optimal balance between inner loop and outer loop complexity derives from the complexity bounds established in Section 4. Given an estimate about the condition number of f, our bounds dictate a choice of κ that gives the optimal setting for the inner-loop stopping criterion and all technical quantities involved in the algorithm. We shall demonstrate in particular the power of an appropriate warm-start strategy to achieve near-optimal complexity.

Overview of the complexity results Finally, we provide in Table 1 a brief overview of the complexity results obtained from the Catalyst acceleration, when applied to various optimization methods $\mathcal{M}$ for minimizing a large finite sum of n functions. Note that the complexity results obtained with Catalyst are optimal, up to some logarithmic factors (see Agarwal and Bottou, 2015; Arjevani and Shamir, 2016; Woodworth and Srebro, 2016).

2. The Moreau Envelope and its Approximate Variant

In this section, we recall a classical tool from convex analysis called the Moreau envelope or Moreau-Yosida smoothing (Moreau, 1962; Yosida, 1980), which plays a key role for understanding the Catalyst acceleration. This tool can be seen as a smoothing technique,

which can turn any convex lower semicontinuous function f into a smooth function, and an ill-conditioned smooth convex function into a well-conditioned smooth convex function.

The Moreau envelope results from the infimal convolution of f with a quadratic penalty:

$$F(x) \triangleq \min_{z\in\mathbb{R}^p} \left\{ f(z) + \frac{\kappa}{2}\|z-x\|^2 \right\}, \tag{5}$$

where κ is a positive regularization parameter. The proximal operator is then the unique minimizer of the problem—that is,

$$p(x) \triangleq \operatorname{prox}_{f/\kappa}(x) = \operatorname*{arg\,min}_{z\in\mathbb{R}^p} \left\{ f(z) + \frac{\kappa}{2}\|z-x\|^2 \right\}.$$

Note that $p(x)$ does not admit a closed form in general. Therefore, computing it requires to solve the sub-problem to high accuracy with some iterative algorithm.

2.1 Basic Properties of the Moreau Envelope

The smoothing effect of the Moreau regularization can be characterized by the next proposition (see Lemaréchal and Sagastizábal, 1997, for elementary proofs).

Proposition 1 (Regularization properties of the Moreau Envelope) *Given a convex continuous function f and a regularization parameter $\kappa > 0$, consider the Moreau envelope F defined in (5). Then,*

1. *F is convex and minimizing f and F are equivalent in the sense that*

$$\min_{x\in\mathbb{R}^p} F(x) = \min_{x\in\mathbb{R}^p} f(x)\ .$$

   Moreover the solution set of the two above problems coincide with each other.

2. *F is continuously differentiable even when f is not and*

$$\nabla F(x) = \kappa(x - p(x))\ . \tag{6}$$

   Moreover the gradient ∇F is Lipschitz continuous with constant $L_F = \kappa$.

3. *If f is μ-strongly convex, then F is μ_F-strongly convex with $\mu_F = \frac{\mu\kappa}{\mu+\kappa}$.*

Interestingly, F is friendly from an optimization point of view as it is convex and differentiable. Besides, F is κ-smooth with condition number $\frac{\mu+\kappa}{\mu}$ when f is μ-strongly convex. Thus F can be made arbitrarily well conditioned by choosing a small κ. Since both functions f and F admit the same solutions, a naive approach to minimize a non-smooth function f is to first construct its Moreau envelope F and then apply a smooth optimization method on it. As we will see next, Catalyst can be seen as an accelerated gradient descent technique applied to F with inexact gradients.

2.2 A Fresh Look at Catalyst

First-order methods applied to F provide us several well-known algorithms.

The proximal point algorithm. Consider gradient descent steps on F:

$$x_{k+1} = x_k - \frac{1}{L_F}\nabla F(x_k).$$

By noticing that $\nabla F(x_k) = \kappa(x_k - p(x_k))$ and $L_f = \kappa$, we obtain in fact

$$x_{k+1} = p(x_k) = \operatorname*{arg\,min}_{z\in\mathbb{R}^p} \left\{ f(z) + \frac{\kappa}{2}\|z-x_k\|^2 \right\},$$

which is exactly the proximal point algorithm (Martinet, 1970; Rockafellar, 1976).

Accelerated proximal point algorithm. If gradient descent steps on F yields the proximal point algorithm, it is then natural to consider the following sequence

$$x_{k+1} = y_k - \frac{1}{L_F}\nabla F(y_k) \quad \text{and} \quad y_{k+1} = x_{k+1} + \beta_{k+1}(x_{k+1} - x_k),$$

where β_{k+1} is Nesterov's extrapolation parameter (Nesterov, 2004). Again, by using the closed form of the gradient, this is equivalent to the update

$$x_{k+1} = p(y_k) \quad \text{and} \quad y_{k+1} = x_{k+1} + \beta_{k+1}(x_{k+1} - x_k),$$

which is known as the accelerated proximal point algorithm of Güler (1992).

While these algorithms are conceptually elegant, they suffer from a major drawback in practice: each update requires to evaluate the proximal operator $p(x)$. Unless a closed form is available, which is almost never the case, we are not able to evaluate $p(x)$ exactly. Hence an iterative algorithm is required for each evaluation of the proximal operator which leads to the inner-outer construction (see Algorithm 1). Catalyst can then be interpreted as an accelerated proximal point algorithm that calls an optimization method $\mathcal{M}$ to compute inexact solutions to the sub-problems. The fact that such a strategy could be used to solve non-smooth optimization problems was well-known, but the fact that it could be used for acceleration is more surprising. The main challenge that will be addressed in Section 3 is how to control the complexity of the inner-loop minimization.

2.3 The Approximate Moreau Envelope

Since Catalyst uses inexact gradients of the Moreau envelope, we start with specifying the inexactness criteria.

Inexactness through absolute accuracy. Given a proximal center x, a smoothing parameter κ, and an accuracy $\varepsilon > 0$, we denote the set of ε-approximations of the proximal operator $p(x)$ by

$$p^\varepsilon(x) \triangleq \{z \in \mathbb{R}^p \quad \text{s.t.} \quad h(z) - h^* \le \varepsilon\} \quad \text{where} \quad h(z) = f(z) + \frac{\kappa}{2}\|x-z\|^2, \tag{C1}$$

and h^* is the minimum function value of h.

Checking whether $h(z) - h^* \le \varepsilon$ may be impactical since h^* is unknown in many situations. We may then replace h^* by a lower bound that can be computed more easily. We may use the Fenchel conjugate for instance. Then, given a point z and a lower-bound

$d(z) \leq h^*$, we can guarantee $z \in p^\varepsilon(x)$ if $h(z) - d(z) \leq \varepsilon$. There are other choices for the lower bounding function d which result from the specific construction of the optimization algorithm. For instance, dual type algorithms such as SDCA (Shalev-Shwartz and Zhang, 2012) or MISO (Mairal, 2015) maintain a lower bound along the iterations, allowing one to compute $h(z) - d(z) \leq \varepsilon$.

When none of the options mentioned above are available, we can use the following fact, based on the notion of gradient mapping; see Section 2.3.2 of (Nesterov, 2004). The intuition comes from the smooth case: when h is smooth, the strong convexity yields

$$h(z) - \frac{1}{2\kappa}\|\nabla h(z)\|^2 \leq h^*.$$

In other words, the norm of the gradient provides enough information to assess how far we are from the optimum. From this perspective, the gradient mapping can be seen as an extension of the gradient for the composite case where the objective decomposes as a sum of a smooth part and a non-smooth part (Nesterov, 2004).

Lemma 2 (Checking the absolute accuracy criterion) *Consider a proximal center x, a smoothing parameter κ and an accuracy $\varepsilon > 0$. Consider an objective with the composite form (1) and we set function h as*

$$h(z) = f(z) + \frac{\kappa}{2}\|x - z\|^2 = \underbrace{f_0(z) + \frac{\kappa}{2}\|x - z\|^2}_{\triangleq\, h_0} + \psi(x).$$

For any $z \in \mathbb{R}^p$, we define

$$[z]_\eta = \operatorname{prox}_{\eta\psi}\left(z - \eta\nabla h_0\left(z\right)\right), \quad \textit{with} \quad \eta = \frac{1}{\kappa + L}. \tag{7}$$

Then, the gradient mapping of h at z is defined by $\frac{1}{\eta}(z - [z]_\eta)$ and

$$\frac{1}{\eta}\left\|z - [z]_\eta\right\| \leq \sqrt{2\kappa\varepsilon} \quad \textit{implies} \quad [z]_\eta \in p^\varepsilon(x).$$

The proof is given in Appendix B. The lemma shows that it is sufficient to check the norm of the gradient mapping to ensure condition (C1). However, this requires an additional full gradient step and proximal step at each iteration.

As soon as we have an approximate proximal operator z in $p^\varepsilon(x)$ in hand, we can define an approximate gradient of the Moreau envelope,

$$g(z) \triangleq \kappa(x - z), \tag{8}$$

by mimicking the exact gradient formula $\nabla F(x) = \kappa(x - p(x))$. As a consequence, we may immediately draw a link

$$z \in p^\varepsilon(x) \quad \Longrightarrow \quad \|z - p(x)\| \leq \sqrt{\frac{2\varepsilon}{\kappa}} \quad \Longleftrightarrow \quad \|g(z) - \nabla F(x)\| \leq \sqrt{2\kappa\varepsilon}, \tag{9}$$

where the first implication is a consequence of the strong convexity of h at its minimum $p(x)$. We will then apply the approximate gradient g instead of ∇F to build the inexact proximal point algorithm. Since the inexactness of the approximate gradient can be bounded by an absolute value $\sqrt{2\kappa\varepsilon}$, we call (C1) the absolute accuracy criterion.

Relative error criterion. Another natural way to bound the gradient approximation is by using a relative error, namely in the form $\|g(z) - \nabla F(x)\| \leq \delta'\|\nabla F(x)\|$ for some $\delta' > 0$. This leads us to the following inexactness criterion.

Given a proximal center x, a smoothing parameter κ and a relative accuracy δ in $[0, 1)$, we denote the set of δ-relative approximations by

$$g^\delta(x) \triangleq \left\{ z \in \mathbb{R}^p \quad \text{s.t.} \quad h(z) - h^* \leq \frac{\delta\kappa}{2}\|x - z\|^2 \right\}, \tag{C2}$$

At a first glance, we may interpret the criterion (C2) as (C1) by setting $\varepsilon = \frac{\delta\kappa}{2}\|x - z\|^2$. But we should then notice that the accuracy depends on the point z, which is is no longer an absolute constant. In other words, the accuracy varies from point to point, which is proportional to the squared distance between z and x. First one may wonder whether $g^\delta(x)$ is an empty set. Indeed, it is easy to see that $p(x) \in g^\delta(x)$ since $h(p(x)) - h^* = 0 \leq \frac{\delta\kappa}{2}\|x - p(x)\|^2$. Moreover, by continuity, $g^\delta(x)$ is closed set around $p(x)$. Then, by following similar steps as in (9), we have

$$z \in g^\delta(x) \quad \Longrightarrow \quad \|z - p(x)\| \leq \sqrt{\delta}\|x - z\| \leq \sqrt{\delta}(\|x - p(x)\| + \|p(x) - z\|).$$

By defining the approximate gradient in the same way $g(z) = \kappa(x - z)$ yields,

$$z \in g^\delta(x) \quad \Longrightarrow \quad \|g(z) - \nabla F(x)\| \leq \delta'\|\nabla F(x)\| \quad \text{with} \quad \delta' = \frac{\sqrt{\delta}}{1 - \sqrt{\delta}},$$

which is the desired relative gradient approximation.

Finally, the discussion about bounding $h(z) - h^*$ still holds here. In particular, Lemma 2 may be used by setting the value $\varepsilon = \frac{\delta\kappa}{2}\|x - z\|^2$. The price to pay is as an additional gradient step and an additional proximal step per iteration.

A few remarks on related works. Inexactness criteria with respect to subgradient norms have been investigated in the past, starting from the pioneer work of Rockafellar (1976) in the context of the inexact proximal point algorithm. Later, different works have been dedicated to more practical inexactness criteria (Auslender, 1987; Correa and Lemaréchal, 1993; Solodov and Svaiter, 2001; Fuentes et al., 2012). These criteria include duality gap, ε-subdifferential, or decrease in terms of function value. Here, we present a more intuitive point of view using the Moreau envelope.

While the proximal point algorithm has caught a lot of attention, very few works have focused on its accelerated variant. The first accelerated proximal point algorithm with inexact gradients was proposed by Güler (1992). Then, Salzo and Villa (2012) proposed a more rigorous convergence analysis, and more inexactness criteria, which are typically stronger than ours. In the same way, a more general inexact oracle framework has been proposed later by Devolder et al. (2014). To achieve the Catalyst acceleration, our main effort was to propose and analyze criteria that allow us to control the complexity for finding approximate solutions of the sub-problems.

3. Catalyst Acceleration

Catalyst is presented in Algorithm 2. As discussed in Section 2, this scheme can be interpreted as an inexact accelerated proximal point algorithm, or equivalently as an accelerated

gradient descent method applied to the Moreau envelope of the objective with inexact gradients. Since an overview has already been presented in Section 1.2, we now present important details to obtain acceleration in theory and in practice.

Algorithm 2 Catalyst

input Initial estimate x_0 in $\mathbb{R}^p$, smoothing parameter κ, strong convexity parameter μ, optimization method $\mathcal{M}$ and a stopping criterion based on a sequence of accuracies $(\varepsilon_k)_{k\geq 0}$, or $(\delta_k)_{k\geq 0}$, or a fixed budget T.

1: Initialize $y_0 = x_0$, $q = \frac{\mu}{\mu+\kappa}$. If $\mu > 0$, set $\alpha_0 = \sqrt{q}$, otherwise $\alpha_0 = 1$.

2: **while** the desired accuracy is not achieved **do**

3: Compute an approximate solution of the following problem with $\mathcal{M}$

$$x_k \approx \arg\min_{x\in\mathbb{R}^p} \left\{ h_k(x) \triangleq f(x) + \frac{\kappa}{2}\|x - y_{k-1}\|^2 \right\},$$

using the warm-start strategy of Section 3 and one of the following stopping criteria:

(a) *absolute accuracy:* find x_k in $p^{\varepsilon_k}(y_{k-1})$ by using criterion (C1);

(b) *relative accuracy:* find x_k in $g^{\delta_k}(y_{k-1})$ by using criterion (C2);

(c) *fixed budget:* run $\mathcal{M}$ for T iterations and output x_k.

4: Update α_k in $(0,1)$ by solving the equation

$$\alpha_k^2 = (1-\alpha_k)\alpha_{k-1}^2 + q\alpha_k. \tag{10}$$

5: Compute y_k with Nesterov's extrapolation step

$$y_k = x_k + \beta_k(x_k - x_{k-1}) \quad \text{with} \quad \beta_k = \frac{\alpha_{k-1}(1-\alpha_{k-1})}{\alpha_{k-1}^2 + \alpha_k}. \tag{11}$$

6: **end while**

output x_k (final estimate).

Requirement: linear convergence of the method $\mathcal{M}$. One of the main characteristic of Catalyst is to apply the method $\mathcal{M}$ to strongly-convex sub-problems, without requiring strong convexity of the objective f. As a consequence, Catalyst provides direct support for convex but non-strongly convex objectives to $\mathcal{M}$, which may be useful to extend the scope of application of techniques that need strong convexity to operate. Yet, Catalyst requires solving these sub-problems efficiently enough in order to control the complexity of the inner-loop computations. When applying $\mathcal{M}$ to minimize a strongly-convex function h, we assume that $\mathcal{M}$ is able to produce a sequence of iterates $(z_t)_{t\geq 0}$ such that

$$h(z_t) - h^* \leq C_{\mathcal{M}}(1-\tau_{\mathcal{M}})^t(h(z_0) - h^*), \tag{12}$$

where z_0 is the initial point given to $\mathcal{M}$, and $\tau_{\mathcal{M}}$ in $(0,1)$, $C_{\mathcal{M}} > 0$ are two constants. In such a case, we say that $\mathcal{M}$ admits a linear convergence rate. The quantity $\tau_{\mathcal{M}}$ controls the speed

of convergence for solving the sub-problems: the larger is $\tau_{\mathcal{M}}$, the faster is the convergence. For a given algorithm $\mathcal{M}$, the quantity $\tau_{\mathcal{M}}$ depends usually on the condition number of h. For instance, for the proximal gradient method and many first-order algorithms, we simply have $\tau_{\mathcal{M}} = O((\mu+\kappa)/(L+\kappa))$, as h is $(\mu+\kappa)$-strongly convex and $(L+\kappa)$-smooth. Catalyst can also be applied to randomized methods $\mathcal{M}$ that satisfy (12) in expectation:

$$\mathbb{E}[h(z_t) - h^*] \leq C_{\mathcal{M}}(1-\tau_{\mathcal{M}})^t(h(z_0) - h^*), \tag{13}$$

Then, the complexity results of Section 4 also hold in expectation. This allows us to apply Catalyst to randomized block coordinate descent algorithms (see Richtárik and Takáč, 2014, and references therein), and some incremental algorithms such as SAG, SAGA, or SVRG. For other methods that admit a linear convergence rates in terms of duality gap, such as SDCA, MISO/Finito, Catalyst can also be applied as explained in Appendix C.

Stopping criteria. Catalyst may be used with three types of stopping criteria for solving the inner-loop problems. We now detail them below.

(a) *absolute accuracy*: we predefine a sequence $(\varepsilon_k)_{k\geq 0}$ of accuracies, and stop the method $\mathcal{M}$ by using the absolute stopping criterion (C1). Our analysis suggests

- if f is μ-strongly convex,

$$\varepsilon_k = \frac{1}{2}(1-\rho)^k(f(x_0) - f^*) \quad \text{with} \quad \rho < \sqrt{q}\,.$$

- if f is convex but not strongly convex,

$$\varepsilon_k = \frac{f(x_0) - f^*}{2(k+2)^{4+\gamma}} \quad \text{with} \quad \gamma > 0\,.$$

Typically, $\gamma = 0.1$ and $\rho = 0.9\sqrt{q}$ are reasonable choices, both in theory and in practice. Of course, the quantity $f(x_0) - f^*$ is unknown and we need to upper bound it by a duality gap or by Lemma 2 as discussed in Section 2.3.

(b) *relative accuracy*: To use the relative stopping criterion (C2), our analysis suggests the following choice for the sequence $(\delta_k)_{k\geq 0}$:

- if f is μ-strongly convex,

$$\delta_k = \frac{\sqrt{q}}{2-\sqrt{q}}\,.$$

- if f is convex but not strongly convex,

$$\delta_k = \frac{1}{(k+1)^2}\,.$$

(c) *fixed budget*: Finally, the simplest way of using Catalyst is to fix in advance the number T of iterations of the method $\mathcal{M}$ for solving the sub-problems without

checking any optimality criterion. Whereas our analysis provides theoretical budgets that are compatible with this strategy, we found them to be pessimistic and impractical. Instead, we propose an aggressive strategy for incremental methods that simply consists of setting $T = n$. This setting was called the "one-pass" strategy in the original Catalyst paper (Lin et al., 2015a).

Warm-starts in inner loops. Besides linear convergence rate, an adequate warm-start strategy needs to be used to guarantee that the sub-problems will be solved in reasonable computational time. The intuition is that the previous solution may still be a good approximation of the current subproblem. Specifically, the following choices arise from the convergence analysis that will be detailed in Section 4.

Consider the minimization of the $(k+1)$-th subproblem $h_{k+1}(z) = f(z) + \frac{\kappa}{2}\|z - y_k\|^2$, we warm start the optimization method $\mathcal{M}$ at z_0 as following:

(a) when using criterion (C1) to find x_{k+1} in $p^{\varepsilon_k}(y_k)$,

- if f is smooth ($\psi = 0$), then choose $z_0 = x_k + \frac{\kappa}{\kappa+\mu}(y_k - y_{k-1})$.
- if f is composite as in (1), then define $w_0 = x_k + \frac{\kappa}{\kappa+\mu}(y_k - y_{k-1})$ and

$$z_0 = [w_0]_\eta = \text{prox}_{\eta\psi}\left(w_0 - \eta g\right) \text{ with } \eta = \frac{1}{L+\kappa} \text{ and } g = \nabla f_0(w_0) + \kappa(w_0 - y_k).$$

(b) when using criteria (C2) to find x_{k+1} in $g^{\delta_k}(y_k)$,

- if f is smooth ($\psi = 0$), then choose $z_0 = y_k$.
- if f is composite as in (1), then choose

$$z_0 = [y_k]_\eta = \text{prox}_{\eta\psi}(y_k - \eta\nabla f_0(y_k)) \quad \text{with} \quad \eta = \frac{1}{L+\kappa}.$$

(c) when using a fixed budget T, choose the same warm start strategy as in (b).

Note that the earlier conference paper (Lin et al., 2015a) considered the the warm start rule $z_0 = x_{k-1}$. That variant is also theoretically validated but it does not perform as well as the ones proposed here in practice.

Optimal balance: choice of parameter κ. Finally, the last ingredient is to find an optimal balance between the inner-loop (for solving each sub-problem) and outer-loop computations. To do so, we minimize our global complexity bounds with respect to the value of κ. As we shall see in Section 5, this strategy turns out to be reasonable in practice. Then, as shown in the theoretical section, the resulting rule of thumb is

We select κ by maximizing the ratio $\tau_{\mathcal{M}}/\sqrt{\mu+\kappa}$.

We recall that $\tau_{\mathcal{M}}$ characterizes how fast $\mathcal{M}$ solves the sub-problems, according to (12); typically, $\tau_{\mathcal{M}}$ depends on the condition number $\frac{L+\kappa}{\mu+\kappa}$ and is a function of κ.[2] In Table 2, we illustrate the choice of κ for different methods. Note that the resulting rule for incremental methods is very simple for the pracitioner: select κ such that the condition number $\frac{\bar{L}+\kappa}{\mu+\kappa}$ is of the order of n; then, the inner-complexity becomes $O(n\log(1/\varepsilon))$.

Method $\mathcal{M}$	Inner-complexity	$\tau_{\mathcal{M}}$	Choice for κ
FG	$O\left(n\frac{L+\kappa}{\mu+\kappa}\log\left(\frac{1}{\varepsilon}\right)\right)$	$\propto \frac{\mu+\kappa}{L+\kappa}$	$L - 2\mu$
SAG/SAGA/SVRG	$O\left(\left(n + \frac{\bar{L}+\kappa}{\mu+\kappa}\right)\log\left(\frac{1}{\varepsilon}\right)\right)$	$\propto \frac{\mu+\kappa}{n(\mu+\kappa)+\bar{L}+\kappa}$	$\frac{\bar{L}-\mu}{n+1} - \mu$

Table 2: Example of choices of the parameter κ for the full gradient (FG) and incremental methods SAG/SAGA/SVRG. See Table 1 for details about the complexity.

4. Convergence and Complexity Analysis

We now present the complexity analysis of Catalyst. In Section 4.1, we analyze the convergence rate of the outer loop, regardless of the complexity for solving the sub-problems. Then, we analyze the complexity of the inner-loop computations for our various stopping criteria and warm-start strategies in Section 4.2. Section 4.3 combines the outer- and inner-loop analysis to provide the global complexity of Catalyst applied to a given optimization method $\mathcal{M}$.

4.1 Complexity Analysis for the Outer-Loop

The complexity analysis of the first variant of Catalyst we presented in (Lin et al., 2015a) used a tool called "estimate sequence", which was introduced by Nesterov (2004). Here, we provide a simpler proof. We start with criterion (C1), before extending the result to (C2).

4.1.1 Analysis for Criterion (C1)

The next theorem describes how the errors $(\varepsilon_k)_{k\geq 0}$ accumulate in Catalyst.

Theorem 3 (Convergence of outer-loop for criterion (C1)) *Consider the sequences $(x_k)_{k\geq 0}$ and $(y_k)_{k\geq 0}$ produced by Algorithm 2, assuming that x_k is in $p^{\varepsilon_k}(y_{k-1})$ for all $k \geq 1$, Then,*

$$f(x_k) - f^* \leq A_{k-1}\left(\sqrt{(1-\alpha_0)(f(x_0) - f^*) + \frac{\gamma_0}{2}\|x^* - x_0\|^2} + 3\sum_{j=1}^{k}\sqrt{\frac{\varepsilon_j}{A_{j-1}}}\right)^2,$$

2. Note that the rule for the non strongly convex case, denoted here by $\mu = 0$, slightly differs from Lin et al. (2015a) and results from a tighter complexity analysis.

where

$$\gamma_0 = (\kappa+\mu)\alpha_0(\alpha_0 - q) \quad \textit{and} \quad A_k = \prod_{j=1}^{k}(1-\alpha_j) \quad \textit{with } A_0 = 1\,. \tag{14}$$

Before we prove this theorem, we note that by setting $\varepsilon_k = 0$ for all k, the speed of convergence of $f(x_k) - f^*$ is driven by the sequence $(A_k)_{k\geq 0}$. Thus we first show the speed of A_k by recalling the Lemma 2.2.4 of Nesterov (2004).

Lemma 4 (Lemma 2.2.4 of Nesterov 2004) *Consider the quantities γ_0, A_k defined in (14) and the α_k's defined in Algorithm 2. Then, if $\gamma_0 \geq \mu$,*

$$A_k \leq \min\left\{(1-\sqrt{q})^k, \frac{4}{\left(2+k\sqrt{\frac{\gamma_0}{\kappa}}\right)^2}\right\}.$$

For non-strongly convex objectives, A_k follows the classical accelerated $O(1/k^2)$ rate of convergence, whereas it achieves a linear convergence rate for the strongly convex case. Intuitively, we are applying an inexact Nesterov method on the Moreau envelope F, thus the convergence rate naturally depends on the inverse of its condition number, which is $q = \frac{\mu}{\mu+\kappa}$. We now provide the proof of the theorem below.

Proof We start by defining an approximate sufficient descent condition inspired by a remark of Chambolle and Pock (2015) regarding accelerated gradient descent methods. A related condition was also used by Paquette et al. (2018) in the context of non-convex optimization.

Approximate sufficient descent condition. Let us define the function

$$h_k(x) = f(x) + \frac{\kappa}{2}\|x - y_{k-1}\|^2.$$

Since $p(y_{k-1})$ is the unique minimizer of h_k, the strong convexity of h_k yields: for any $k \geq 1$, for all x in $\mathbb{R}^p$ and any $\theta_k > 0$,

$$\begin{aligned}
h_k(x) &\geq h_k^* + \frac{\kappa+\mu}{2}\|x - p(y_{k-1})\|^2 \\
&\geq h_k^* + \frac{\kappa+\mu}{2}(1-\theta_k)\|x - x_k\|^2 + \frac{\kappa+\mu}{2}\left(1-\frac{1}{\theta_k}\right)\|x_k - p(y_{k-1})\|^2 \\
&\geq h_k(x_k) - \varepsilon_k + \frac{\kappa+\mu}{2}(1-\theta_k)\|x - x_k\|^2 + \frac{\kappa+\mu}{2}\left(1-\frac{1}{\theta_k}\right)\|x_k - p(y_{k-1})\|^2,
\end{aligned}$$

where the $(\mu+\kappa)$-strong convexity of h_k is used in the first inequality; Lemma 19 is used in the second inequality, and the last one uses the relation $h_k(x_k) - h_k^* \leq \varepsilon_k$. Moreover, when $\theta_k \geq 1$, the last term is positive and we have

$$h_k(x) \geq h_k(x_k) - \varepsilon_k + \frac{\kappa+\mu}{2}(1-\theta_k)\|x - x_k\|^2.$$

If instead $\theta_k \leq 1$, the coefficient $\frac{1}{\theta_k} - 1$ is non-negative and we have

$$-\frac{\kappa+\mu}{2}\left(\frac{1}{\theta_k}-1\right)\|x_k - p(y_{k-1})\|^2 \geq -\left(\frac{1}{\theta_k}-1\right)(h_k(x_k) - h_k^*) \geq -\left(\frac{1}{\theta_k}-1\right)\varepsilon_k.$$

In this case, we have

$$h_k(x) \geq h_k(x_k) - \frac{\varepsilon_k}{\theta_k} + \frac{\kappa+\mu}{2}(1-\theta_k)\|x - x_k\|^2.$$

As a result, we have for all value of $\theta_k > 0$,

$$h_k(x) \geq h_k(x_k) + \frac{\kappa+\mu}{2}(1-\theta_k)\|x - x_k\|^2 - \frac{\varepsilon_k}{\min\{1,\theta_k\}}.$$

After expanding the expression of h_k, we then obtain the approximate descent condition

$$f(x_k) + \frac{\kappa}{2}\|x_k - y_{k-1}\|^2 + \frac{\kappa+\mu}{2}(1-\theta_k)\|x - x_k\|^2 \leq f(x) + \frac{\kappa}{2}\|x - y_{k-1}\|^2 + \frac{\varepsilon_k}{\min\{1,\theta_k\}}. \tag{15}$$

Definition of the Lyapunov function. We introduce a sequence $(S_k)_{k\geq 0}$ that will act as a Lyapunov function, with

$$S_k = (1-\alpha_k)(f(x_k) - f^*) + \alpha_k\frac{\kappa\eta_k}{2}\|x^* - v_k\|^2. \tag{16}$$

where x^* is a minimizer of f, $(v_k)_{k\geq 0}$ is a sequence defined by $v_0 = x_0$ and

$$v_k = x_k + \frac{1-\alpha_{k-1}}{\alpha_{k-1}}(x_k - x_{k-1}) \quad \text{for } k \geq 1,$$

and $(\eta_k)_{k\geq 0}$ is an auxiliary quantity defined by

$$\eta_k = \frac{\alpha_k - q}{1-q}.$$

The way we introduce these variables allow us to write the following relationship,

$$y_k = \eta_k v_k + (1-\eta_k)x_k, \quad \text{for all } k \geq 0,$$

which follows from a simple calculation. Then by setting $z_k = \alpha_{k-1}x^* + (1-\alpha_{k-1})x_{k-1}$ the following relations hold for all $k \geq 1$.

$$\begin{aligned}
f(z_k) &\leq \alpha_{k-1}f^* + (1-\alpha_{k-1})f(x_{k-1}) - \frac{\mu\alpha_{k-1}(1-\alpha_{k-1})}{2}\|x^* - x_{k-1}\|^2, \\
z_k - x_k &= \alpha_{k-1}(x^* - v_k),
\end{aligned}$$

and also the following one

$$\begin{aligned}
\|z_k - y_{k-1}\|^2 &= \|(\alpha_{k-1} - \eta_{k-1})(x^* - x_{k-1}) + \eta_{k-1}(x^* - v_{k-1})\|^2 \\
&= \alpha_{k-1}^2\left\|\left(1 - \frac{\eta_{k-1}}{\alpha_{k-1}}\right)(x^* - x_{k-1}) + \frac{\eta_{k-1}}{\alpha_{k-1}}(x^* - v_{k-1})\right\|^2 \\
&\leq \alpha_{k-1}^2\left(1 - \frac{\eta_{k-1}}{\alpha_{k-1}}\right)\|x^* - x_{k-1}\|^2 + \alpha_{k-1}^2\frac{\eta_{k-1}}{\alpha_{k-1}}\|x^* - v_{k-1}\|^2 \\
&= \alpha_{k-1}(\alpha_{k-1} - \eta_{k-1})\|x^* - x_{k-1}\|^2 + \alpha_{k-1}\eta_{k-1}\|x^* - v_{k-1}\|^2,
\end{aligned}$$

where we used the convexity of the norm and the fact that $\eta_k \leq \alpha_k$. Using the previous relations in (15) with $x = z_k = \alpha_{k-1}x^* + (1-\alpha_{k-1})x_{k-1}$, gives for all $k \geq 1$,

$$\begin{aligned} f(x_k) + \frac{\kappa}{2}\|x_k - y_{k-1}\|^2 + \frac{\kappa+\mu}{2}(1-\theta_k)\alpha_{k-1}^2\|x^* - v_k\|^2 \\ \leq \alpha_{k-1}f^* + (1-\alpha_{k-1})f(x_{k-1}) - \frac{\mu}{2}\alpha_{k-1}(1-\alpha_{k-1})\|x^* - x_{k-1}\|^2 \\ + \frac{\kappa\alpha_{k-1}(\alpha_{k-1}-\eta_{k-1})}{2}\|x^* - x_{k-1}\|^2 + \frac{\kappa\alpha_{k-1}\eta_{k-1}}{2}\|x^* - v_{k-1}\|^2 + \frac{\varepsilon_k}{\min\{1,\theta_k\}}. \end{aligned}$$

Remark that for all $k \geq 1$,

$$\alpha_{k-1} - \eta_{k-1} = \alpha_{k-1} - \frac{\alpha_{k-1}-q}{1-q} = \frac{q(1-\alpha_{k-1})}{1-q} = \frac{\mu}{\kappa}(1-\alpha_{k-1}),$$

and the quadratic terms involving $x^* - x_{k-1}$ cancel each other. Then, after noticing that for all $k \geq 1$,

$$\eta_k\alpha_k = \frac{\alpha_k^2 - q\alpha_k}{1-q} = \frac{(\kappa+\mu)(1-\alpha_k)\alpha_{k-1}^2}{\kappa},$$

which allows us to write

$$f(x_k) - f^* + \frac{\kappa+\mu}{2}\alpha_{k-1}^2\|x^* - v_k\|^2 = \frac{S_k}{1-\alpha_k}. \tag{17}$$

We are left, for all $k \geq 1$, with

$$\frac{1}{1-\alpha_k}S_k \leq S_{k-1} + \frac{\varepsilon_k}{\min\{1,\theta_k\}} - \frac{\kappa}{2}\|x_k - y_{k-1}\|^2 + \frac{(\kappa+\mu)\alpha_{k-1}^2\theta_k}{2}\|x^* - v_k\|^2. \tag{18}$$

Control of the approximation errors for criterion (C1). Using the fact that

$$\frac{1}{\min\{1,\theta_k\}} \leq 1 + \frac{1}{\theta_k},$$

we immediately derive from equation (18) that

$$\frac{1}{1-\alpha_k}S_k \leq S_{k-1} + \varepsilon_k + \frac{\varepsilon_k}{\theta_k} - \frac{\kappa}{2}\|x_k - y_{k-1}\|^2 + \frac{(\kappa+\mu)\alpha_{k-1}^2\theta_k}{2}\|x^* - v_k\|^2. \tag{19}$$

By minimizing the right-hand side of (19) with respect to θ_k, we obtain the following inequality

$$\frac{1}{1-\alpha_k}S_k \leq S_{k-1} + \varepsilon_k + \sqrt{2\varepsilon_k(\mu+\kappa)}\alpha_{k-1}\|x^* - v_k\|,$$

and after unrolling the recursion,

$$\frac{S_k}{A_k} \leq S_0 + \sum_{j=1}^k \frac{\varepsilon_j}{A_{j-1}} + \sum_{j=1}^k \frac{\sqrt{2\varepsilon_j(\mu+\kappa)}\alpha_{j-1}\|x^* - v_j\|}{A_{j-1}}.$$

From Equation (17), the lefthand side is larger than $\frac{(\mu+\kappa)\alpha_{k-1}^2\|x^* - v_k\|^2}{2A_{k-1}}$. We may now define $u_j = \frac{\sqrt{(\mu+\kappa)}\alpha_{j-1}\|x^* - v_j\|}{\sqrt{2A_{j-1}}}$ and $a_j = 2\frac{\sqrt{\varepsilon_j}}{\sqrt{A_{j-1}}}$, and we have

$$u_k^2 \leq S_0 + \sum_{j=1}^k \frac{\varepsilon_j}{A_{j-1}} + \sum_{j=1}^k a_j u_j \quad \text{for all } k \geq 1.$$

This allows us to apply Lemma 20, which yields

$$\begin{aligned} \frac{S_k}{A_k} &\leq \left(\sqrt{S_0 + \sum_{j=1}^k \frac{\varepsilon_j}{A_{j-1}}} + 2\sum_{j=1}^k \sqrt{\frac{\varepsilon_j}{A_{j-1}}}\right)^2, \\ &\leq \left(\sqrt{S_0} + 3\sum_{j=1}^k \sqrt{\frac{\varepsilon_j}{A_{j-1}}}\right)^2 \end{aligned}$$

which provides us the desired result given that $f(x_k) - f^* \leq \frac{S_k}{1-\alpha_k}$ and that $v_0 = x_0$. ■

We are now in shape to state the convergence rate of the Catalyst algorithm with criterion (C1), without taking into account yet the cost of solving the sub-problems. The next two propositions specialize Theorem 3 to the strongly convex case and non strongly convex cases, respectively. Their proofs are provided in Appendix B.

Proposition 5 (μ-strongly convex case, criterion (C1))
In Algorithm 2, choose $\alpha_0 = \sqrt{q}$ and

$$\varepsilon_k = \frac{2}{9}(f(x_0) - f^*)(1-\rho)^k \quad \text{with} \quad \rho < \sqrt{q}.$$

Then, the sequence of iterates $(x_k)_{k\geq 0}$ satisfies

$$f(x_k) - f^* \leq \frac{8}{(\sqrt{q}-\rho)^2}(1-\rho)^{k+1}(f(x_0) - f^*).$$

Proposition 6 (Convex case, criterion (C1))
When $\mu = 0$, choose $\alpha_0 = 1$ and

$$\varepsilon_k = \frac{2(f(x_0) - f^*)}{9(k+1)^{4+\gamma}} \quad \text{with} \quad \gamma > 0.$$

Then, Algorithm 2 generates iterates $(x_k)_{k\geq 0}$ such that

$$f(x_k) - f^* \leq \frac{8}{(k+1)^2}\left(\frac{\kappa}{2}\|x_0 - x^*\|^2 + \frac{4}{\gamma^2}(f(x_0) - f^*)\right).$$

4.1.2 Analysis for Criterion (C2)

Then, we may now analyze the convergence of Catalyst under criterion (C2), which offers similar guarantees as (C1), as far as the outer loop is concerned.

Theorem 7 (Convergence of outer-loop for criterion (C2)) *Consider the sequences $(x_k)_{k\geq 0}$ and $(y_k)_{k\geq 0}$ produced by Algorithm 2, assuming that x_k is in $g^{\delta_k}(y_{k-1})$ for all $k \geq 1$ and δ_k in $(0,1)$. Then,*

$$f(x_k) - f^* \leq \frac{A_{k-1}}{\prod_{j=1}^k (1-\delta_j)} \left((1-\alpha_0)(f(x_0) - f^*) + \frac{\gamma_0}{2}\|x_0 - x^*\|^2 \right),$$

where γ_0 and $(A_k)_{k\geq 0}$ are defined in (14) in Theorem 3.

Proof Remark that x_k in $g^{\delta_k}(y_{k-1})$ is equivalent to x_k in $p^{\varepsilon_k}(y_{k-1})$ with an adaptive error $\varepsilon_k = \frac{\delta_k \kappa}{2}\|x_k - y_{k-1}\|^2$. All steps of the proof of Theorem 3 hold for such values of ε_k and from (18), we may deduce

$$\frac{S_k}{1-\alpha_k} - \frac{(\kappa+\mu)\alpha_{k-1}^2\theta_k}{2}\|x^* - v_k\|^2 \leq S_{k-1} + \left(\frac{\delta_k \kappa}{2\min\{1,\theta_k\}} - \frac{\kappa}{2} \right) \|x_k - y_{k-1}\|^2.$$

Then, by choosing $\theta_k = \delta_k < 1$, the quadratic term on the right disappears and the left-hand side is greater than $\frac{1-\delta_k}{1-\alpha_k} S_k$. Thus,

$$S_k \leq \frac{1-\alpha_k}{1-\delta_k} S_{k-1} \leq \frac{A_k}{\prod_{j=1}^k (1-\delta_j)} S_0,$$

which is sufficient to conclude since $(1-\alpha_k)(f(x_k) - f^*) \leq S_k$. ■

The next propositions specialize Theorem 7 for specific choices of sequence $(\delta_k)_{k\geq 0}$ in the strongly and non strongly convex cases.

Proposition 8 (μ-strongly convex case, criterion (C2))
In Algorithm 2, choose $\alpha_0 = \sqrt{q}$ and

$$\delta_k = \frac{\sqrt{q}}{2-\sqrt{q}}.$$

Then, the sequence of iterates $(x_k)_{k\geq 0}$ satisfies

$$f(x_k) - f^* \leq 2\left(1 - \frac{\sqrt{q}}{2}\right)^k (f(x_0) - f^*).$$

Proof This is a direct application of Theorem 7 by remarking that $\gamma_0 = (1-\sqrt{q})\mu$ and

$$S_0 = (1-\sqrt{q})\left(f(x_0) - f^* + \frac{\mu}{2}\|x^* - x_0\|^2 \right) \leq 2(1-\sqrt{q})(f(x_0) - f^*).$$

And $\alpha_k = \sqrt{q}$ for all $k \geq 0$ leading to

$$\frac{1-\alpha_k}{1-\delta_k} = 1 - \frac{\sqrt{q}}{2}$$

■

Proposition 9 (Convex case, criterion (C2))
When $\mu = 0$, choose $\alpha_0 = 1$ and

$$\delta_k = \frac{1}{(k+1)^2}.$$

Then, Algorithm 2 generates iterates $(x_k)_{k\geq 0}$ such that

$$f(x_k) - f^* \leq \frac{4\kappa\|x_0 - x^*\|^2}{(k+1)^2}. \tag{20}$$

Proof This is a direct application of Theorem 7 by remarking that $\gamma_0 = \kappa$, $A_k \leq \frac{4}{(k+2)^2}$ (Lemma 4) and

$$\prod_{i=1}^k \left(1 - \frac{1}{(i+1)^2}\right) = \prod_{i=1}^k \frac{i(i+2)}{(i+1)^2} = \frac{k+2}{2(k+1)} \geq \frac{1}{2}.$$

■

Remark 10 *In fact, the choice of δ_k can be improved by taking $\delta_k = \frac{1}{(k+1)^{1+\gamma}}$ for any $\gamma > 0$, which comes at the price of a larger constant in (20).*

4.2 Analysis of Warm-start Strategies for the Inner Loop

In this section, we study the complexity of solving the subproblems with the proposed warm start strategies. The only assumption we make on the optimization method $\mathcal{M}$ is that it enjoys linear convergence when solving a strongly convex problem—meaning, it satisfies either (12) or its randomized variant (13). Then, the following lemma gives us a relation between the accuracy required to solve the sub-problems and the corresponding complexity.

Lemma 11 (Accuracy vs. complexity) *Let us consider a strongly convex objective h and a linearly convergent method $\mathcal{M}$ generating a sequence of iterates $(z_t)_{t\geq 0}$ for minimizing h. Consider the complexity $T(\varepsilon) = \inf\{t \geq 0, h(z_t) - h^* \leq \varepsilon\}$, where $\varepsilon > 0$ is the target accuracy and h^* is the minimum value of h. Then,*

1. *If $\mathcal{M}$ is deterministic and satisfies (12), we have*

$$T(\varepsilon) \leq \frac{1}{\tau_{\mathcal{M}}} \log\left(\frac{C_{\mathcal{M}}(h(z_0) - h^*)}{\varepsilon} \right).$$

2. *If $\mathcal{M}$ is randomized and satisfies (13), we have*

$$\mathbb{E}[T(\varepsilon)] \leq \frac{1}{\tau_{\mathcal{M}}} \log\left(\frac{2C_{\mathcal{M}}(h(z_0) - h^*)}{\tau_{\mathcal{M}}\varepsilon} \right) + 1$$

The proof of the deterministic case is straightforward and the proof of the randomized case is provided in Appendix B.4. From the previous result, a good initialization is essential for fast convergence. More precisely, it suffices to control the initialization $\frac{h(z_0)-h^*}{\varepsilon}$ in order to bound the number of iterations $T(\varepsilon)$. For that purpose, we analyze the quality of various warm-start strategies.

4.2.1 Warm Start Strategies for Criterion (C1)

The next proposition characterizes the quality of initialization for (C1).

Proposition 12 (Warm start for criterion (C1)) *Assume that $\mathcal{M}$ is linearly convergent for strongly convex problems with parameter $\tau_{\mathcal{M}}$ according to (12), or according to (13) in the randomized case. At iteration $k+1$ of Algorithm 2, given the previous iterate x_k in $p^{\varepsilon_k}(y_{k-1})$, we consider the following function*

$$h_{k+1}(z) = f(z) + \frac{\kappa}{2}\|z - y_k\|^2,$$

which we minimize with $\mathcal{M}$, producing a sequence $(z_t)_{t\geq 0}$. Then,

- *when f is smooth, choose $z_0 = x_k + \frac{\kappa}{\kappa+\mu}(y_k - y_{k-1})$;*
- *when $f = f_0 + \psi$ is composite, choose $z_0 = [w_0]_\eta = \operatorname{prox}_{\eta\psi}(w_0 - \eta\nabla h_0(w_0))$ with $w_0 = x_k + \frac{\kappa}{\kappa+\mu}(y_k - y_{k-1})$, $\eta = \frac{1}{L+\kappa}$ and $h_0 = f_0 + \frac{\kappa}{2}\|\cdot - y_k\|^2$.*

We also assume that we choose α_0 and $(\varepsilon_k)_{k\geq 0}$ according to Proposition 5 for $\mu > 0$, or Proposition 6 for $\mu = 0$. Then,

1. *if f is μ-strongly convex, $h_{k+1}(z_0) - h_{k+1}^* \leq C\varepsilon_{k+1}$ where,*

$$C = \frac{L+\kappa}{\kappa+\mu}\left(\frac{2}{1-\rho} + \frac{2592(\kappa+\mu)}{(1-\rho)^2(\sqrt{q}-\rho)^2\mu}\right) \quad \text{if } f \text{ is smooth,} \tag{21}$$

   or

$$C = \frac{L+\kappa}{\kappa+\mu}\left(\frac{2}{1-\rho} + \frac{23328(L+\kappa)}{(1-\rho)^2(\sqrt{q}-\rho)^2\mu}\right) \quad \text{if } f \text{ is composite.} \tag{22}$$

2. *if f is convex with bounded level sets, there exists a constant $B > 0$ that only depends on f, x_0 and κ such that*

$$h_{k+1}(z_0) - h_{k+1}^* \leq B. \tag{23}$$

Proof We treat the smooth and composite cases separately.

Smooth and strongly-convex case. When f is smooth, by the gradient Lipschitz assumption,

$$h_{k+1}(z_0) - h_{k+1}^* \leq \frac{(L+\kappa)}{2}\|z_0 - p(y_k)\|^2.$$

Moreover,

$$\begin{aligned}
\|z_0 - p(y_k)\|^2 &= \left\|x_k + \frac{\kappa}{\kappa+\mu}(y_k - y_{k-1}) - p(y_k)\right\|^2 \\
&= \left\|x_k - p(y_{k-1}) + \frac{\kappa}{\kappa+\mu}(y_k - y_{k-1}) - (p(y_k) - p(y_{k-1}))\right\|^2 \\
&\leq 2\|x_k - p(y_{k-1})\|^2 + 2\left\|\frac{\kappa}{\kappa+\mu}(y_k - y_{k-1}) - (p(y_k) - p(y_{k-1}))\right\|^2.
\end{aligned}$$

Since x_k is in $p^{\varepsilon_k}(y_{k-1})$, we may control the first quadratic term on the right by noting that

$$\|x_k - p(y_{k-1})\|^2 \leq \frac{2}{\kappa+\mu}(h_k(x_k) - h_k^*) \leq \frac{2\varepsilon_k}{\kappa+\mu}.$$

Moreover, by the coerciveness property of the proximal operator,

$$\left\|\frac{\kappa}{\kappa+\mu}(y_k - y_{k-1}) - (p(y_k) - p(y_{k-1}))\right\|^2 \leq \|y_k - y_{k-1}\|^2,$$

see Appendix B.5 for the proof. As a consequence,

$$\begin{aligned}
h_{k+1}(z_0) - h_{k+1}^* &\leq \frac{(L+\kappa)}{2}\|z_0 - p(y_k)\|^2 \\
&\leq 2\frac{L+\kappa}{\mu+\kappa}\varepsilon_k + (L+\kappa)\|y_k - y_{k-1}\|^2,
\end{aligned} \tag{24}$$

Then, we need to control the term $\|y_k - y_{k-1}\|^2$. Inspired by the proof of accelerated SDCA of Shalev-Shwartz and Zhang (2016),

$$\begin{aligned}
\|y_k - y_{k-1}\| &= \|x_k + \beta_k(x_k - x_{k-1}) - x_{k-1} - \beta_{k-1}(x_{k-1} - x_{k-2})\| \\
&\leq (1+\beta_k)\|x_k - x_{k-1}\| + \beta_{k-1}\|x_{k-1} - x_{k-2}\| \\
&\leq 3\max\{\|x_k - x_{k-1}\|, \|x_{k-1} - x_{k-2}\|\},
\end{aligned}$$

The last inequality was due to the fact that $\beta_k \leq 1$. In fact,

$$\beta_k^2 = \frac{\left(\alpha_{k-1} - \alpha_{k-1}^2\right)^2}{\left(\alpha_{k-1}^2 + \alpha_k\right)^2} = \frac{\alpha_{k-1}^2 + \alpha_{k-1}^4 - 2\alpha_{k-1}^3}{\alpha_k^2 + 2\alpha_k\alpha_{k-1}^2 + \alpha_{k-1}^4} = \frac{\alpha_{k-1}^2 + \alpha_{k-1}^4 - 2\alpha_{k-1}^3}{\alpha_{k-1}^2 + \alpha_{k-1}^4 + q\alpha_k + \alpha_k\alpha_{k-1}^2} \leq 1,$$

where the last equality uses the relation $\alpha_k^2 + \alpha_k\alpha_{k-1}^2 = \alpha_{k-1}^2 + q\alpha_k$ from (10). Then,

$$\|x_k - x_{k-1}\| \leq \|x_k - x^*\| + \|x_{k-1} - x^*\|,$$

and by strong convexity of f

$$\frac{\mu}{2}\|x_k - x^*\|^2 \leq f(x_k) - f^* \leq \frac{36}{(\sqrt{q}-\rho)^2}\varepsilon_{k+1},$$

where the last inequality is obtained from Proposition 5. As a result,

$$\begin{aligned}
\|y_k - y_{k-1}\|^2 &\leq 9\max\left\{\|x_k - x_{k-1}\|^2, \|x_{k-1} - x_{k-2}\|^2\right\} \\
&\leq 36\max\left\{\|x_k - x^*\|^2, \|x_{k-1} - x^*\|^2, \|x_{k-2} - x^*\|^2\right\} \\
&\leq \frac{2592\,\varepsilon_{k-1}}{(\sqrt{q}-\rho)^2\mu}.
\end{aligned}$$

Since $\varepsilon_{k+1} = (1-\rho)^2\varepsilon_{k-1}$, we may now obtain (21) from (24) and the previous bound.

Smooth and convex case. When $\mu = 0$, Eq. (24) is still valid but we need to control $\|y_k - y_{k-1}\|^2$ in a different way. From Proposition 6, the sequence $(f(x_k))_{k\geq 0}$ is bounded by a constant that only depends on f and x_0; therefore, by the bounded level set assumption, there exists $R > 0$ such that

$$\|x_k - x^*\| \leq R, \quad \text{for all } k \geq 0.$$

Thus, following the same argument as the strongly convex case, we have

$$\|y_k - y_{k-1}\| \leq 36R^2 \quad \text{for all } k \geq 1,$$

and we obtain (23) by combining the previous inequality with (24).

Composite case. By using the notation of gradient mapping introduced in (7), we have $z_0 = [w_0]_\eta$. By following similar steps as in the proof of Lemma 2, the gradient mapping satisfies the following relation

$$h_{k+1}(z_0) - h^*_{k+1} \leq \frac{1}{2(\kappa+\mu)} \left\| \frac{1}{\eta}(w_0 - z_0) \right\|^2,$$

and it is sufficient to bound $\|w_0 - z_0\| = \|w_0 - [w_0]_\eta\|$. For that, we introduce

$$[x_k]_\eta = \text{prox}_{\eta\psi}(x_k - \eta(\nabla f_0(x_k) + \kappa(x_k - y_{k-1}))).$$

Then,

$$\|w_0 - [w_0]_\eta\| \leq \|w_0 - x_k\| + \|x_k - [x_k]_\eta\| + \|[x_k]_\eta - [w_0]_\eta\|, \tag{25}$$

and we will bound each term on the right. By construction

$$\|w_0 - x_k\| = \frac{\kappa}{\kappa+\mu}\|y_k - y_{k-1}\| \leq \|y_k - y_{k-1}\|.$$

Next, it is possible to show that the gradient mapping satisfies the following relation (see Nesterov, 2013),

$$\frac{1}{2\eta}\|x_k - [x_k]_\eta\|^2 \leq h_k(x_k) - h^*_k \leq \varepsilon_k.$$

And then since $[x_k]_\eta = \text{prox}_{\eta\psi}(x_k - \eta(\nabla f_0(x_k) + \kappa(x_k - y_{k-1})))$ and $[w_0]_\eta = \text{prox}_{\eta\psi}(w_0 - \eta(\nabla f_0(w_0) + \kappa(w_0 - y_k)))$. From the non expansiveness of the proximal operator, we have

$$\begin{aligned}
\|[x_k]_\eta - [w_0]_\eta\| &\leq \|x_k - \eta(\nabla f_0(x_k) + \kappa(x_k - y_{k-1})) - (w_0 - \eta(\nabla f_0(w_0) + \kappa(w_0 - y_k)))\| \\
&\leq \|x_k - \eta(\nabla f_0(x_k) + \kappa(x_k - y_{k-1})) - (w_0 - \eta(\nabla f_0(w_0) + \kappa(w_0 - y_{k-1})))\| \\
&\quad + \eta\kappa\|y_k - y_{k-1}\| \\
&\leq \|x_k - w_0\| + \eta\kappa\|y_k - y_{k-1}\| \\
&\leq 2\|y_k - y_{k-1}\|.
\end{aligned}$$

We have used the fact that $\|x - \eta\nabla h(x) - (y - \eta\nabla h(y))\| \leq \|x - y\|$. By combining the previous inequalities with (25), we finally have

$$\|w_0 - [w_0]_\eta\| \leq \sqrt{2\eta\varepsilon_k} + 3\|y_k - y_{k-1}\|.$$

Thus, by using the fact that $(a+b)^2 \leq 2a^2 + 2b^2$ for all a, b,

$$h_{k+1}(z_0) - h^*_{k+1} \leq \frac{L+\kappa}{\kappa+\mu}\left(2\varepsilon_k + 9(L+\kappa)\|y_k - y_{k-1}\|^2\right),$$

and we can obtain (22) and (23) by upper-bounding $\|y_k - y_{k-1}\|^2$ in a similar way as in the smooth case, both when $\mu > 0$ and $\mu = 0$.

■

Finally, the complexity of the inner loop can be obtained directly by combining the previous proposition with Lemma 11.

Corollary 13 (Inner-loop Complexity for Criterion (C1)) *Consider the setting of Proposition 12; then, the sequence $(z_t)_{t\geq 0}$ minimizing h_{k+1} is such that the complexity $T_{k+1} = \inf\{t \geq 0, h_{k+1}(z_t) - h^*_{k+1} \leq \varepsilon_{k+1}\}$ satisfies*

$$T_{k+1} \leq \frac{1}{\tau_{\mathcal{M}}}\log(C_{\mathcal{M}}C) \quad \text{if } \mu > 0 \quad \Longrightarrow \quad T_{k+1} = \tilde{O}\left(\frac{1}{\tau_{\mathcal{M}}}\right),$$

where C is the constant defined in (21) or in (22) for the composite case; and

$$T_{k+1} \leq \frac{1}{\tau_{\mathcal{M}}}\log\left(\frac{9C_{\mathcal{M}}(k+2)^{4+\eta}B}{2(f(x_0) - f^*)}\right) \quad \text{if } \mu = 0 \quad \Longrightarrow \quad T_{k+1} = \tilde{O}\left(\frac{\log(k+2)}{\tau_{\mathcal{M}}}\right),$$

where B is the uniform upper bound in (23). Furthermore, when $\mathcal{M}$ is randomized, the expected complexity $\mathbb{E}[T_{k+1}]$ is similar, up to a factor $2/\tau_{\mathcal{M}}$ in the logarithm—see Lemma 11, and we have $\mathbb{E}[T_{k+1}] = \tilde{O}(1/\tau_{\mathcal{M}})$ when $\mu > 0$ and $\mathbb{E}[T_{k+1}] = \tilde{O}(\log(k+2)/\tau_{\mathcal{M}})$. Here, $\tilde{O}(.)$ hides logarithmic dependencies in parameters $\mu, L, \kappa, C_{\mathcal{M}}$, $\tau_{\mathcal{M}}$ and $f(x_0) - f^*$.

4.2.2 Warm Start Strategies for Criterion (C2)

We may now analyze the inner-loop complexity for criterion (C2) leading to upper bounds with smaller constants and simpler proofs. Note also that in the convex case, the bounded level set condition will not be needed, unlike for criterion (C1). To proceed, we start with a simple lemma that gives us a sufficient condition for (C2) to be satisfied.

Lemma 14 (Sufficient condition for criterion (C2)) *If a point z satisfies*

$$h_{k+1}(z) - h^*_{k+1} \leq \frac{\delta_{k+1}\kappa}{8}\|p(y_k) - y_k\|^2,$$

then z is in $g^{\delta_{k+1}}(y_k)$.

Proof

$$\begin{aligned} h_{k+1}(z) - h_{k+1}^* &\leq \frac{\delta_{k+1}\kappa}{8}\|p(y_k) - y_k\|^2 \\ &\leq \frac{\delta_{k+1}\kappa}{4}\left(\|p(y_k) - z\|^2 + \|z - y_k\|^2\right) \\ &\leq \frac{\delta_{k+1}\kappa}{4}\left(\frac{2}{\mu+\kappa}(h_{k+1}(z) - h_{k+1}^*) + \|z - y_k\|^2\right) \\ &\leq \frac{1}{2}\left(h_{k+1}(z) - h_{k+1}^*\right) + \frac{\delta_{k+1}\kappa}{4}\|z - y_k\|^2. \end{aligned}$$

Rearranging the terms gives the desired result. ■

With the previous result, we can control the complexity of the inner-loop minimization with Lemma 11 by choosing $\varepsilon = \frac{\delta_{k+1}\kappa}{8}\|p(y_k) - y_k\|^2$. However, to obtain a meaningful upper bound, we need to control the ratio

$$\frac{h_{k+1}(z_0) - h_{k+1}^*}{\varepsilon} = \frac{8(h_{k+1}(z_0) - h_{k+1}^*)}{\delta_{k+1}\kappa\|p(y_k) - y_k\|^2}.$$

Proposition 15 (Warm start for criterion (C2)) *Assume that $\mathcal{M}$ is linearly convergent for strongly convex problems with parameter $\tau_{\mathcal{M}}$ according to (12), or according to (13) in the randomized case. At iteration $k+1$ of Algorithm 2, given the previous iterate x_k in $g^{\delta_k}(y_{k-1})$, we consider the following function*

$$h_{k+1}(z) = f(z) + \frac{\kappa}{2}\|z - y_k\|^2,$$

which we minimize with $\mathcal{M}$, producing a sequence $(z_t)_{t\geq 0}$. Then,

- *when f is smooth, set $z_0 = y_k$;*
- *when $f = f_0 + \psi$ is composite, set $z_0 = [y_k]_\eta = \operatorname{prox}_{\eta\psi}(y_k - \eta\nabla f_0(y_k))$ with $\eta = \frac{1}{L+\kappa}$.*

Then,

$$h_{k+1}(z_0) - h_{k+1}^* \leq \frac{L+\kappa}{2}\|p(y_k) - y_k\|^2. \tag{26}$$

Proof When f is smooth, the optimality conditions of $p(y_k)$ yield $\nabla h_{k+1}(p(y_k)) = \nabla f(p(y_k)) + \kappa(p(y_k) - y_k) = 0$. As a result,

$$\begin{aligned} h_{k+1}(z_0) - h_{k+1}^* &= f(y_k) - \left(f(p(y_k)) + \frac{\kappa}{2}\|p(y_k) - y_k\|^2\right) \\ &\leq f(p(y_k)) + \langle\nabla f(p(y_k)), y_k - p(y_k)\rangle + \frac{L}{2}\|y_k - p(y_k)\|^2 \\ &\quad - \left(f(p(y_k)) + \frac{\kappa}{2}\|p(y_k) - y_k\|^2\right) \\ &= \frac{L+\kappa}{2}\|p(y_k) - y_k\|^2. \end{aligned}$$

When f is composite, we use the inequality in Lemma 2.3 of Beck and Teboulle (2009): for any z,

$$h_{k+1}(z) - h_{k+1}(z_0) \geq \frac{L+\kappa}{2}\|z_0 - y_k\|^2 + (L+\kappa)\langle z_0 - y_k, y_k - z\rangle,$$

Then, we apply this inequality with $z = p(y_k)$, and thus,

$$\begin{aligned} h_{k+1}(z_0) - h_{k+1}^* &\leq -\frac{L+\kappa}{2}\|z_0 - y_k\|^2 - (L+\kappa)\langle z_0 - y_k, y_k - p(y_k)\rangle \\ &\leq \frac{L+\kappa}{2}\|p(y_k) - y_k\|^2. \end{aligned}$$

■

We are now in shape to derive a complexity bound for criterion (C2), which is obtained by combining directly Lemma 11 with the value $\varepsilon = \frac{\delta_{k+1}\kappa}{8}\|p(y_k) - y_k\|^2$, Lemma 14, and the previous proposition.

Corollary 16 (Inner-loop Complexity for Criterion (C2)) *Consider the setting of Proposition 15 when $\mathcal{M}$ is deterministic; assume further that α_0 and $(\delta_k)_{k\geq 0}$ are chosen according to Proposition 8 for $\mu > 0$, or Proposition 9 for $\mu = 0$.*

Then, the sequence $(z_t)_{t\geq 0}$ is such that the complexity $T_{k+1} = \inf\{t \geq 0, z_t \in g^{\delta_{k+1}}(y_k)\}$ satisfies

$$T_{k+1} \leq \frac{1}{\tau_{\mathcal{M}}}\log\left(4C_{\mathcal{M}}\frac{(L+\kappa)}{\kappa}\frac{2-\sqrt{q}}{\sqrt{q}}\right) \quad \text{when } \mu > 0,$$

and

$$T_{k+1} \leq \frac{1}{\tau_{\mathcal{M}}}\log\left(4C_{\mathcal{M}}\frac{(L+\kappa)}{\kappa}(k+2)^2\right) \quad \text{when } \mu = 0.$$

When $\mathcal{M}$ is randomized, the expected complexity is similar, up to a factor $2/\tau_{\mathcal{M}}$ in the logarithm—see Lemma 11, and we have $\mathbb{E}[T_{k+1}] = \tilde{O}(1/\tau_{\mathcal{M}})$ when $\mu > 0$ and $\mathbb{E}[T_{k+1}] = \tilde{O}(\log(k+2)/\tau_{\mathcal{M}})$.

The inner-loop complexity is asymptotically similar with criterion (C2) as with criterion (C1), but the constants are significantly better.

4.3 Global Complexity Analysis

In this section, we combine the previous outer-loop and inner-loop convergence results to derive a global complexity bound. We treat here the strongly convex ($\mu > 0$) and convex ($\mu = 0$) cases separately.

4.3.1 Strongly Convex Case

When the problem is strongly convex, we remark that the subproblems are solved in a constant number of iterations $T_k = T = \tilde{O}\left(\frac{1}{\tau_{\mathcal{M}}}\right)$ for both criteria (C1) and (C2). This means that the iterate x_k in Algorithm 2 is obtained after $s = kT$ iterations of the method $\mathcal{M}$. Thus, the true convergence rate of Catalyst applied to $\mathcal{M}$ is of the form

$$f_s - f^* = f\left(x_{\frac{s}{T}}\right) - f^* \leq C'(1-\rho)^{\frac{s}{T}}(f(x_0) - f^*) \leq C'\left(1 - \frac{\rho}{T}\right)^s(f(x_0) - f^*), \tag{27}$$

where $f_s = f(x_k)$ is the function value after s iterations of $\mathcal{M}$. Then, choosing κ consists of maximizing the rate of convergence (27). In other words, we want to maximize $\sqrt{q}/T = \tilde{O}(\sqrt{q}\tau_{\mathcal{M}})$. Since $q = \frac{\mu}{\mu+\kappa}$, this naturally lead to the maximization of $\tau_{\mathcal{M}}/\sqrt{\mu+\kappa}$. We now state more formally the global convergence result in terms of complexity.

Proposition 17 (Global Complexity for strongly convex objectives) *When f is μ-strongly convex and all parameters are chosen according to Propositions 5 and 12 when using criterion (C1), or Propositions 8 and 15 for (C2), then Algorithm 2 finds a solution $\hat{x}$ such that $f(\hat{x}) - f^* \leq \varepsilon$ in at most $N_{\mathcal{M}}$ iterations of a deterministic method $\mathcal{M}$ with*

1. *when criterion (C1) is used,*

$$N_{\mathcal{M}} \leq \frac{1}{\tau_{\mathcal{M}}\rho} \log\left(C_{\mathcal{M}} C\right) \cdot \log\left(\frac{8(f(x_0) - f^*)}{(\sqrt{q}-\rho)^2\varepsilon}\right) = \tilde{O}\left(\frac{1}{\tau_{\mathcal{M}}\sqrt{q}} \log\left(\frac{1}{\varepsilon}\right)\right),$$

   where $\rho = 0.9\sqrt{q}$ and C is the constant defined in (21) or (22) for the composite case;

2. *when criterion (C2) is used,*

$$N_{\mathcal{M}} \leq \frac{2}{\tau_{\mathcal{M}}\sqrt{q}} \log\left(4C_{\mathcal{M}}\frac{L+\kappa}{\kappa}\frac{2-\sqrt{q}}{\sqrt{q}}\right) \cdot \log\left(\frac{2(f(x_0) - f^*)}{\varepsilon}\right) = \tilde{O}\left(\frac{1}{\tau_{\mathcal{M}}\sqrt{q}} \log\left(\frac{1}{\varepsilon}\right)\right).$$

Note that similar results hold in terms of expected number of iterations when the method $\mathcal{M}$ is randomized (see the end of Proposition 12).

Proof Let K be the number of iterations of the outer-loop algorithm required to obtain an ε-accurate solution. From Proposition 5, using (C1) criterion yields

$$K \leq \frac{1}{\rho} \log\left(\frac{8(f(x_0) - f^*)}{(\sqrt{q}-\rho)^2\varepsilon}\right).$$

From Proposition 8, using (C2) criterion yields

$$K \leq \frac{2}{\sqrt{q}} \log\left(\frac{2(f(x_0) - f^*)}{\varepsilon}\right).$$

Then since the number of runs of $\mathcal{M}$ is constant for any inner loop, the total number $N_{\mathcal{M}}$ is given by KT where T is respectively given by Corollaries 13 and 16. ■

4.3.2 Convex, but not Strongly Convex Case

When $\mu = 0$, the number of iterations for solving each subproblems grows logarithmically, which means that the iterate x_k in Algorithm 2 is obtained after $s =\leq kT\log(k+2)$ iterations of the method $\mathcal{M}$, where T is a constant. By using the global iteration counter $s = kT\log(k+2)$, we finally have

$$f_s - f^* \leq C' \frac{\log^2(s)}{s^2}\left(f(x_0) - f^* + \frac{\kappa}{2}\|x_0 - x^*\|^2\right). \tag{28}$$

This rate is *near-optimal*, up to a logarithmic factor, when compared to the optimal rate $O(1/s^2)$. This may be the price to pay for using a generic acceleration scheme. As before, we detail the global complexity bound for convex objectives in the next proposition.

Proposition 18 (Global complexity for convex objectives) *When f is convex and all parameters are chosen according to Propositions 6 and 12 when using criterion (C1), or Propositions 9 and 15 for criterion (C2), then Algorithm 2 finds a solution $\hat{x}$ such that $f(\hat{x}) - f^* \leq \varepsilon$ in at most $N_{\mathcal{M}}$ iterations of a deterministic method $\mathcal{M}$ with*

1. *when criterion (C1) is applied*

$$N_{\mathcal{M}} \leq \frac{1}{\tau_{\mathcal{M}}} K \log\left(\frac{9C_{\mathcal{M}}BK^{4+\gamma}}{2(f(x_0) - f^*)}\right) = \tilde{O}\left(\frac{1}{\tau_{\mathcal{M}}}\sqrt{\frac{\kappa}{\varepsilon}} \log\left(\frac{1}{\varepsilon}\right)\right),$$

   where,

$$K_\varepsilon = \sqrt{\frac{8\left(\frac{\kappa}{2}\|x_0 - x^*\|^2 + \frac{4}{\gamma^2}(f(x_0) - f^*)\right)}{\varepsilon}};$$

2. *when criterion (C2) is applied,*

$$\begin{aligned} N_{\mathcal{M}} &\leq \frac{1}{\tau_{\mathcal{M}}}\sqrt{\frac{4\kappa\|x_0 - x^*\|^2}{\varepsilon}} \log\left(\frac{16C_{\mathcal{M}}(L+\kappa)\|x_0 - x^*\|^2}{\varepsilon}\right) \\ &= \tilde{O}\left(\frac{1}{\tau_{\mathcal{M}}}\sqrt{\frac{\kappa}{\varepsilon}} \log\left(\frac{1}{\varepsilon}\right)\right). \end{aligned}$$

Note that similar results hold in terms of expected number of iterations when the method $\mathcal{M}$ is randomized (see the end of Proposition 15).

Proof Let K denote the number of outer-loop iterations required to achieve an ε-accurate solution. From Proposition 6, when (C1) is applied, we have

$$K \leq \sqrt{\frac{8\left(\frac{\kappa}{2}\|x_0 - x^*\|^2 + \frac{4}{\gamma^2}(f(x_0) - f^*)\right)}{\varepsilon}}.$$

From Proposition 9, when (C2) is applied, we have

$$K \leq \sqrt{\frac{4\kappa\|x_0 - x^*\|^2}{\varepsilon}}.$$

Since the number of runs in the inner loop is increasing, we have

$$N_{\mathcal{M}} = \sum_{i=1}^{K} T_i \leq KT_K.$$

Respectively apply T_K obtained from Corollary 13 and Corollary 16 gives the result. ■

Theoretical foundations of the choice of κ. The parameter κ plays an important rule in the global complexity result. The linear convergence parameter $\tau_{\mathcal{M}}$ depends typically on κ since it controls the strong convexity parameter of the subproblems. The natural way to choose κ is to minimize the global complexity given by Proposition 17 and Proposition 18, which leads to the following rule

Choose κ to maximize $\frac{\tau_{\mathcal{M}}}{\sqrt{\mu+\kappa}}$,

where $\mu = 0$ when the problem is convex but not strongly convex. We now illustrate two examples when applying Catalyst to the classical gradient descent method and to the incremental approach SVRG.

Gradient descent. When $\mathcal{M}$ is the gradient descent method, we have

$$\tau_{\mathcal{M}} = \frac{\mu+\kappa}{L+\kappa}.$$

Maximizing the ratio $\frac{\tau_{\mathcal{M}}}{\sqrt{\mu+\kappa}}$ gives

$$\kappa = L - 2\mu, \quad \text{when } L > 2\mu.$$

Consequently, the complexity in terms of gradient evaluations for minimizing the finite sum (2), where each iteration of $\mathcal{M}$ cost n gradients, is given by

$$N_{\mathcal{M}} = \begin{cases} \tilde{O}\left(n\sqrt{\frac{L}{\mu}}\log\left(\frac{1}{\varepsilon}\right)\right) & \text{when } \mu > 0; \\ \tilde{O}\left(n\sqrt{\frac{L}{\varepsilon}}\log\left(\frac{1}{\varepsilon}\right)\right) & \text{when } \mu = 0. \end{cases}$$

These rates are near-optimal up to logarithmic constants according to the first-order lower bound (Nemirovskii and Yudin, 1983; Nesterov, 2004).

SVRG. For SVRG (Xiao and Zhang, 2014) applied to the same finite-sum objective,

$$\tau_{\mathcal{M}} = \frac{1}{n + \frac{\bar{L}+\kappa}{\mu+\kappa}}.$$

Thus, maximizing the corresponding ratio gives

$$\kappa = \frac{\bar{L}-\mu}{n+1} - \mu, \quad \text{when } \bar{L} > (n+2)\mu.$$

Consequently, the resulting global complexity, here in terms of expected number of gradient evaluations, is given by

$$\mathbb{E}[N_{\mathcal{M}}] = \begin{cases} \tilde{O}\left(\sqrt{n\frac{\bar{L}}{\mu}}\log\left(\frac{1}{\varepsilon}\right)\right) & \text{when } \mu > 0; \\ \tilde{O}\left(\sqrt{\frac{n\bar{L}}{\varepsilon}}\log\left(\frac{1}{\varepsilon}\right)\right) & \text{when } \mu = 0. \end{cases}$$

Note that we treat here only the case $\bar{L} > (n+2)\mu$ to simplify, see Table 1 for a general results. We also remark that Catalyst can be applied to similar incremental algorithms such as SAG/SAGA (Schmidt et al., 2017; Defazio et al., 2014a) or dual-type algorithm MISO/Finito (Mairal, 2015; Defazio et al., 2014b) or SDCA Shalev-Shwartz and Zhang (2012). Moreover, the resulting convergence rates are near-optimal up to logarithmic constants according to the first-order lower bound (Woodworth and Srebro, 2016; Arjevani and Shamir, 2016).

4.3.3 Practical Aspects of the Theoretical Analysis

So far, we have not discussed the fixed budget criterion mentioned in Section 3. The idea is quite natural and simple to implement: we predefine the number of iterations to run for solving each subproblems and stop worrying about the stopping condition. For example, when $\mu > 0$ and $\mathcal{M}$ is deterministic, we can simply run $T_{\mathcal{M}}$ iterations of $\mathcal{M}$ for each subproblem where $T_{\mathcal{M}}$ is greater than the value given by Corollaries 13 or 16, then the criterions (C1) and (C2) are guaranteed to be satisfied. Unfortunately, the theoretical bound of $T_{\mathcal{M}}$ is relatively poor and does not lead to a practical strategy. On the other hand, using a more aggressive strategy such as $T_{\mathcal{M}} = n$ for incremental algorithms, meaning one pass over the data, seems to provide outstanding results, as shown in the experimental part of this paper.

Finally, one could argue that choosing κ according to a worst-case convergence analysis is not necessarily a good choice. In particular, the convergence rate of the method $\mathcal{M}$, driven by the parameter $\tau_{\mathcal{M}}$ is probably often under estimated in the first place. This suggests that using a smaller value for κ than the one we have advocated earlier is a good thing. In practice, we have observed that indeed Catalyst is often robust to smaller values of κ than the theoretical one, but we have also observed that the theoretical value performs reasonably well, as we shall see in the next section.

5. Experimental Study

In this section, we conduct various experiments to study the effect of the Catalyst acceleration and its different variants, showing in particular how to accelerate SVRG, SAGA, and MISO. In Section 5.1, we describe the data sets and formulations considered for our evaluation, and in Section 5.2, we present the different variants of Catalyst. Then, we study different questions: which variant of Catalyst should we use for incremental approaches? (Section 5.3); how do various incremental methods compare when accelerated with Catalyst? (Section 5.4); what is the effect of Catalyst on the test error when Catalyst is used to minimize a regularized empirical risk? (Section 5.5); is the theoretical value for κ appropriate? (Section 5.6). The code used for all our experiments is available at `https://github.com/hongzhoulin89/Catalyst-QNing/`.

5.1 Data sets, Formulations, and Metric

Data sets. We consider six machine learning data sets with different characteristics in terms of size and dimension to cover a variety of situations.

name	covtype	alpha	real-sim	rcv1	MNIST-CKN	CIFAR-CKN
n	581 012	250 000	72 309	781 265	60 000	50 000
d	54	500	20 958	47 152	2 304	9 216

While the first four data sets are standard ones that were used in previous work about optimization methods for machine learning, the last two are coming from a computer vision application. MNIST and CIFAR-10 are two image classification data sets involving 10 classes. The feature representation of each image was computed using an unsupervised

convolutional kernel network Mairal (2016). We focus here on the the task of classifying class #1 vs. the rest of the data set.

Formulations. We consider three common optimization problems in machine learning and signal processing, which admit a particular structure (large finite sum, composite, strong convexity). For each formulation, we also consider a training set $(b_i, a_i)_{i=1}^n$ of n data points, where the b_i's are scalars in $\{-1, +1\}$ and the a_i are feature vectors in $\mathbb{R}^p$. Then, the goal is to fit a linear model x in $\mathbb{R}^p$ such that the scalar b_i can be well predicted by the inner-product $\approx a_i^\top x$, or by its sign. Specifically, the three formulations we consider are listed below.

- **ℓ_2^2-regularized Logistic Regression**:

$$\min_{x\in\mathbb{R}^p} \quad \frac{1}{n}\sum_{i=1}^n \log\left(1+\exp(-b_i\, a_i^T x)\right) + \frac{\mu}{2}\|x\|^2,$$

  which leads to a μ-strongly convex smooth optimization problem.

- **ℓ_1-regularized Linear Regression (LASSO)**:

$$\min_{x\in\mathbb{R}^p} \quad \frac{1}{2n}\sum_{i=1}^n (b_i - a_i^T x)^2 + \lambda\|x\|_1,$$

  which is non smooth and convex but not strongly convex.

- **$\ell_1 - \ell_2^2$-regularized Linear Regression (Elastic-Net)**:

$$\min_{x\in\mathbb{R}^p} \quad \frac{1}{2n}\sum_{i=1}^n (b_i - a_i^T x)^2 + \lambda\|x\|_1 + \frac{\mu}{2}\|x\|^2,$$

  which is based on the Elastic-Net regularization (Zou and Hastie, 2005) and leading to a strongly-convex optimization problem.

Each feature vector a_i is normalized, and a natural upper-bound on the Lipschitz constant L of the un-regularized objective can be easily obtained with $L_{\text{logistic}} = 1/4$ and $L_{\text{lasso}} = 1$. The regularization parameter μ and λ are choosing in the following way:

- For **Logistic Regression**, we find an optimal regularization parameter μ^* by 10-fold cross validation for each data set on a logarithmic grid $2^i/n$, with $i \in [-12, 3]$. Then, we set $\mu = \mu^*/2^3$ which corresponds to a small value of the regularization parameter and a relatively ill-conditioned problem.

- For **Elastic-Net**, we set $\mu = 0.01/n$ to simulate the ill-conditioned situation and add a small l_1-regularization penalty with $\lambda = 1/n$ that produces sparse solutions.

- For the **Lasso problem**, we consider a logarithmic grid $10^i/n$, with $i = -3, -2, \ldots, 3$, and we select the parameter λ that provides a sparse optimal solution closest to 10% non-zero coefficients, which leads to $\lambda = 10/n$ or $100/n$.

Note that for the strongly convex problems, the regularization parameter μ yields a lower bound on the strong convexity parameter of the problem.

Metric used. In this chapter, and following previous work about incremental methods (Schmidt et al., 2017), we plot objective values as a function of the number of gradients evaluated during optimization, which appears to be the computational bottleneck of all previously mentioned algorithms. Since no metric is perfect for comparing algorithms' speed, we shall make the two following remarks, such that the reader can interpret our results and the limitations of our study with no difficulty.

- Ideally, CPU-time is the gold standard but CPU time is implementation-dependent and hardware-dependent.

- We have chosen to count only gradients computed with random data access. Thus, computing n times a gradient f_i by picking each time one function at random counts as "n gradients", whereas we ignore the cost of computing a full gradient $(1/n)\sum_{i=1}^n \nabla f_i$ at once, where the f_i's can be accessed in sequential order. Similarly, we ignore the cost of computing the function value $f(x) = (1/n)\sum_{i=1}^n f_i(x)$, which is typically performed every pass on the data when computing a duality gap. While this assumption may be inappropriate in some contexts, the cost of random gradient computations was significantly dominating the cost of sequential access in our experiments, where (i) data sets fit into memory; (ii) computing full gradients was done in C++ by calling BLAS2 functions exploiting multiple cores.

5.2 Choice of Hyper-parameters and Variants

Before presenting the numerical results, we discuss the choice of default parameters used in the experiments as well as different variants.

Choice of method $\mathcal{M}$. We consider the acceleration of incremental algorithms which are able to adapt to the problem structure we consider: large sum of functions and possibly non-smooth regularization penalty.

- The proximal SVRG algorithm of Xiao and Zhang (2014) with stepsize $\eta = 1/L$.

- The SAGA algorithm Defazio et al. (2014a) with stepsize $\eta = 1/3L$.

- The proximal MISO algorithm of Lin et al. (2015a).

Choice of regularization parameter κ. As suggested by the theoretical analysis, we take κ to minimize the global complexity, leading to the choice

$$\kappa = \frac{L-\mu}{n+1} - \mu.$$

Stopping criteria for the inner loop. The choice of the accuracies are driven from the theoretical analysis described in paragraph 3. Here, we specify it again for the clarity of presentation:

- **Stopping criterion (C1).** Stop when $h_k(z_t) - h_k^* \leq \varepsilon_k$, where

$$\varepsilon_k = {}^5 \begin{cases} \frac{1}{2}(1-\rho)^k f(x_0) \;\text{ with }\; \rho = 0.9\sqrt{\frac{\mu}{\mu+\kappa}} & \text{when } \mu > 0; \\ \frac{f(x_0)}{2(k+1)^{4.1}} & \text{when } \mu = 0. \end{cases}$$

The duality gap $h(w_t) - h^*$ can be estimated either by evaluating the Fenchel conjugate function or by computing the squared norm of the gradient.

- **Stopping criterion (C2).** Stop when $h_k(z_t) - h_k^* \leq \delta_k \cdot \frac{\kappa}{2}\|z_t - y_{k-1}\|^2$, where

$$\delta_k = \begin{cases} \frac{\sqrt{q}}{2-\sqrt{q}} \text{ with } q = \frac{\mu}{\mu+\kappa} & \text{when } \mu > 0; \\ \frac{1}{(k+1)^2} & \text{when } \mu = 0. \end{cases}$$

- **Stopping criterion (C3) .** Perform exactly one pass over the data in the inner loop without checking any stopping criteria.[4]

Warm start for the inner loop. This is an important point to achieve acceleration which was not highlighted in the conference paper (Lin et al., 2015a). At iteration $k+1$, we consider the minimization of

$$h_{k+1}(z) = f_0(z) + \frac{\kappa}{2}\|z - y_k\|^2 + \psi(z).$$

We warm start according to the strategy defined in Section 3. Let x_k be the approximate minimizer of h_k, obtained from the last iteration.

- **Initialization for (C1).** Let us define $\eta = \frac{1}{L+\kappa}$, then initialize at

$$z_0^{C1} = \begin{cases} w_0 \triangleq x_k + \frac{\kappa}{\kappa+\mu}(y_k - y_{k-1}) & \text{if } \psi = 0; \\ [w_0]_\eta & \text{otherwise.} \end{cases}$$

  where $[w_0]_\eta = \text{prox}_{\eta\psi}(w_0 - \eta g)$ with $g = \nabla f_0(w_0) + \kappa(w_0 - y_k)$.

- **Initialization for (C2).** Intialize at

$$z_0^{C2} = \begin{cases} y_k & \text{if } \psi = 0; \\ [y_k]_\eta = \text{prox}_{\eta\psi}(y_k - \eta\nabla f_0(y_k)) & \text{otherwise.} \end{cases}$$

- **Initialization for (C3).** Take the best initial point among x_k and z_0^{C1}

$$z_0^{C3} \text{ such that } h_k(z_0^{C3}) = \min\{h_k(x_{k-1}), h_k(z_0^{C1})\}.$$

- **Initialization for (C1*).** Use the strategy (C1) with z_0^{C3}.

The warm start at z_0^{C3} requires to choose the best point between the last iterate x_k and the point z_0^{C1}. The motivation is that since the one-pass strategy is an aggressive heuristic, the solution of the subproblems may not be as accurate as the ones obtained with other criterions. Allowing using the iterate x_k turned out to be significantly more stable in practice. Then, it is also natural to use a similar strategy for criterion (C1), which we call (C1*). Using a similar strategy for (C2) turned out not to provide any benefit in practice and is thus omitted from the list here.

5. Here we upper bound $f(x_0) - f^*$ by $f(x_0)$ since f is always positive in our models.
4. This stopping criterion is heuristic since one pass may not be enough to achieve the required accuracy. What we have shown is that with a large enough $T_{\mathcal{M}}$, then the convergence will be guaranteed. Here we take heuristically $T_{\mathcal{M}}$ as one pass.

5.3 Comparison of Stopping Criteria and Warm-start Strategies

First, we evaluate the performance of the previous strategies when applying Catalyst to SVRG, SAGA and MISO. The results are presented in Figures 1, 2, and 3, respectively.

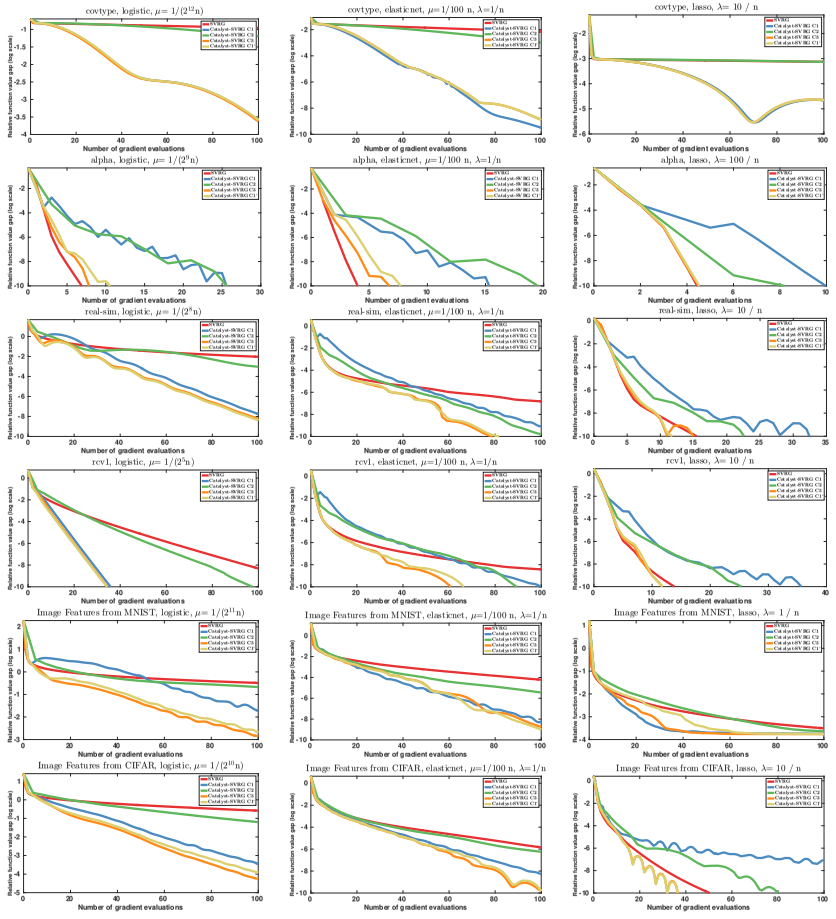

Figure 1: Experimental study of different stopping criterions for Catalyst-SVRG. We plot the value $f(x_k)/f^* - 1$ as a function of the number of gradient evaluations, on a logarithmic scale; the optimal value f^* is estimated with a duality gap.

Observations for Catalyst-SVRG. We remark that in most of the cases, the curve of (C3) and (C1*)are superimposed, meaning that one pass through the data is enough for solving the subproblem up to the required accuracy. Moreover, they give the best performance among all criterions. Regarding the logistic regression problem, the acceleration is significant (even huge for the covtype data set) except for alpha, where only (C3) and (C1*)do not degrade significantly the performance. For sparse problems, the effect of acceleration is more mitigated, with 7 cases out of 12 exhibiting important acceleration and 5 cases no acceleration. As before, (C3) and (C1*)are the only strategies that never degrade performance.

One reason explaining why acceleration is not systematic may be the ability of incremental methods to adapt to the unknown strong convexity parameter $\mu' \geq \mu$ hidden in the objective's loss, or local strong convexity near the solution. When $\mu'/L \geq 1/n$, we indeed obtain a well-conditioned regime where acceleration should not occur theoretically. In fact the complexity $O(n \log(1/\varepsilon))$ is already optimal in this regime, see Arjevani and Shamir (2016); Woodworth and Srebro (2016). For sparse problems, conditioning of the problem with respect to the linear subspace where the solution lies might also play a role, even though our analysis does not study this aspect. Therefore, this experiment suggests that adaptivity to unknown strong convexity is of high interest for incremental optimization.

Observations for Catalyst-SAGA. Our conclusions with SAGA are almost the same as with SVRG. However, in a few cases, we also notice that criterion C1 lacks stability, or at least exhibits some oscillations, which may suggest that SAGA has a larger variance compared to SVRG. The difference in the performance of (C1) and (C1*)can be huge, while they differ from each other only by the warm start strategy. Thus, *choosing a good initial point for solving the sub-problems is a key for obtaining acceleration in practice.*

Observations for Catalyst-MISO. The warm-start strategy of MISO is different from primal algorithms because parameters for the dual function need to be specified. The most natural way for warm starting the dual functions is to set

$$d_{k+1}(x) = d_k(x) + \frac{\kappa}{2}\|x - y_k\|^2 - \frac{\kappa}{2}\|x - y_{k-1}\|^2,$$

where d_k is the last dual function of the previous subproblem h_k. This gives the warm start

$$z_0 = \text{prox}\left(x_k + \frac{\kappa}{\kappa + \mu}(y_k - y_{k-1})\right).$$

For other choices of z_0, the dual function needs to be recomputed from scratch, which is computationally expensive and unstable for ill-conditioned problems. Thus, we only present the experimental results with respect to criterion (C1) and the one-pass heuristic (C3) . As we observe, a huge acceleration is obtained in logistic regression and Elastic-net formulations. For Lasso problem, the original Prox-MISO is not defined since the problem is not strongly convex. Thus, in order to make a comparison, we compare with Catalyst-SVRG which shows that the acceleration achieves a similar performance. This aligns with the theoretical result stating that Catalyst applied to incremental algorithms yields a similar convergence rate. Notice also that the original MISO algorithm suffers from numerical stability in this ill-conditioned regime chosen for our experiments. Catalyst not only accelerates MISO, but it also stabilizes it.

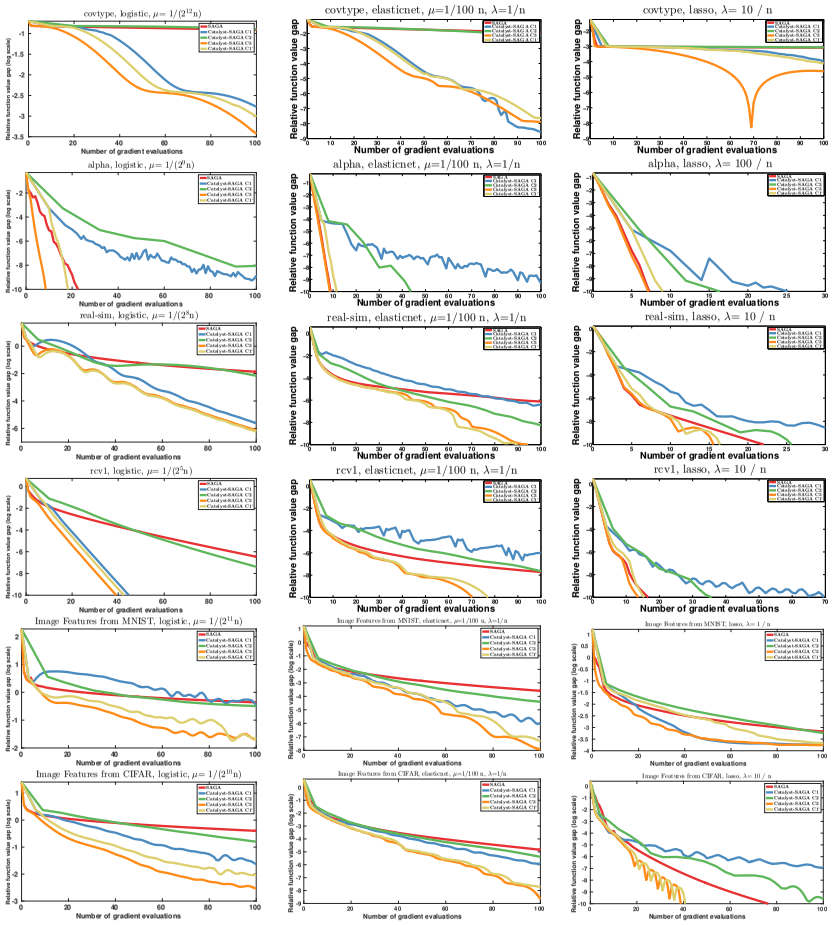

Figure 2: Experimental study of different stopping criterions for Catalyst-SAGA, with a similar setting as in Figure 1.

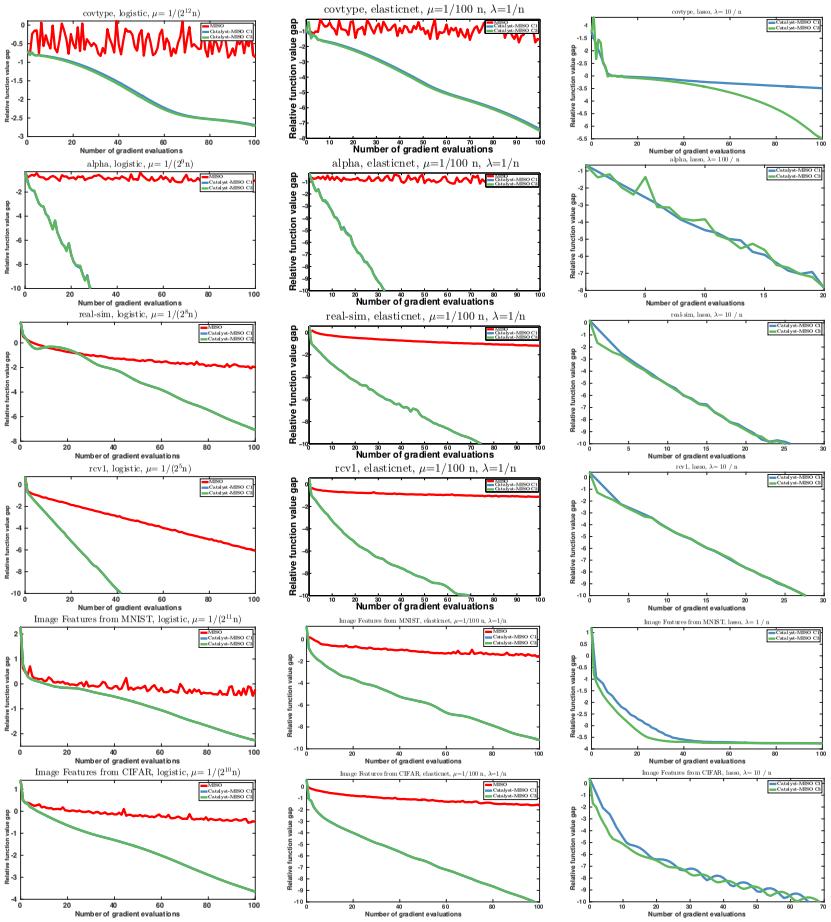

Figure 3: Experimental study of different stopping criterions for Catalyst-MISO, with a similar setting as in Figure 1

5.4 Acceleration of Existing Methods

Then, we put the previous curves into perspective and make a comparison of the performance before and after applying Catalyst across methods. We show the best performance among the three developed stopping criteria, which corresponds to be (C3) .

Observations. In Figure 4, we observe that by applying Catalyst, we accelerate the original algorithms up to the limitations discussed above (comparing the dashed line and the solid line of the same color). In three data sets (covtype, real-sim and rcv1), significant improvements are achieved as expected by the theory for the ill-conditioned problems in logistic regression and Elastic-net. For data set alpha, we remark that an relative accuracy in the order 10^{-10} is attained in less than 10 iterations. This suggests that the problems is in fact well-conditioned and there is some hidden strong convexity for this data set. Thus, the incremental algorithms like SVRG or SAGA are already optimal under this situation and no further improvement can be obtained by applying Catalyst.

5.5 Empirical Effect on the Generalization Error

A natural question that applies to all incremental methods is whether or not the acceleration that we may see for minimizing an empirical risk on *training* data affects the objective function and the test accuracy on new unseen *test* data. To answer this question, we consider the logistic regression formulation with the regularization parameter μ^* obtained by cross-validation. Then, we cut each data set into 80% of training data and set aside 20% of the data point as test data.

Observations on the test loss and test accuracy. The left column of Figure 5 shows the loss function on the training set, where acceleration is significant in 5 cases out of 6. The middle column shows the loss function evaluated on the test set, but on a non-logarithmic scale since the optimal value of the test loss is unknown. Acceleration appears in 4 cases out of 6. Regarding the test accuracy, an important acceleration is obtained in 2 cases, whereas it is less significant or negligible in the other cases.

5.6 Study of the Parameter κ

Finally, we evaluate the performance for different values of κ.

Observations for different choices of κ. We consider a logarithmic grid $\kappa = 10^i \kappa_0$ with $i = -2, -1, \cdots, 2$ and κ_0 is the optimal κ given by the theory. We observe that for ill-conditioned problems, using optimal choice κ_0 provides much better performance than other choices, which confirms the theoretical result. For the data set of alpha or Lasso problems, we observe that the best choice is given by the smallest $\kappa = 0.01\kappa_0$. This suggests that, as discussed before, there is a certain degree of strong convexity present in the objective even without any regularization.

6. Conclusion

We have introduced a generic algorithm called Catalyst that allows us to extend Nesterov's acceleration to a large class of first-order methods. We have shown that it can be effective

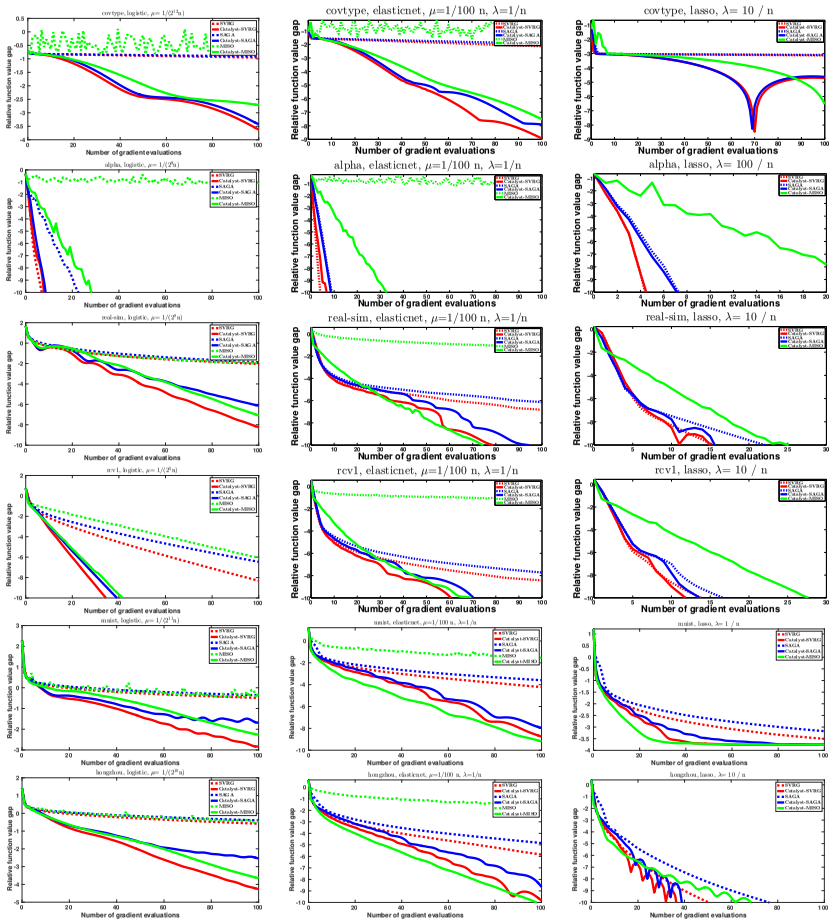

Figure 4: Experimental study of the performance of Catalyst applying to SVRG, SAGA and MISO. The dashed lines correspond to the original algorithms and the solid lines correspond to accelerated algorithms by applying Catalyst. We plot the relative function value gap $(f(x_k) - f^*)/f^*$ in the number of gradient evaluations, on a logarithmic scale.

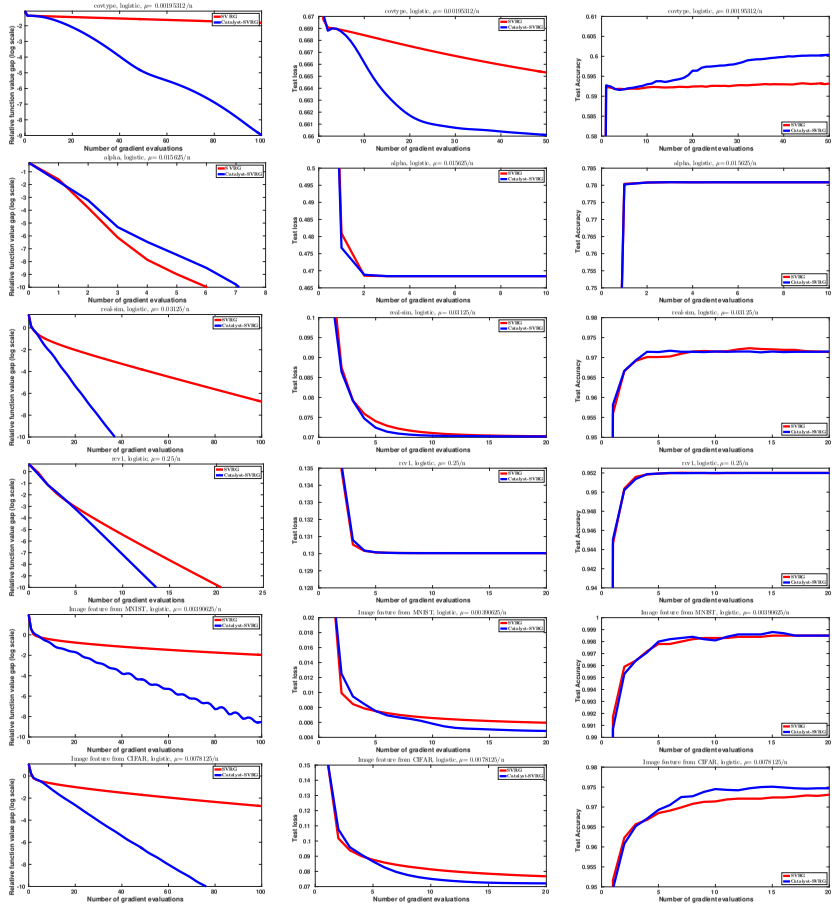

Figure 5: Empirical effect on the generalization error. For a logistic regression experiment, we report the value of the objective function evaluated on the training data on the left column, the value of the loss evaluated on a test set on the middle column, and the classification error evaluated on the test set on the right.

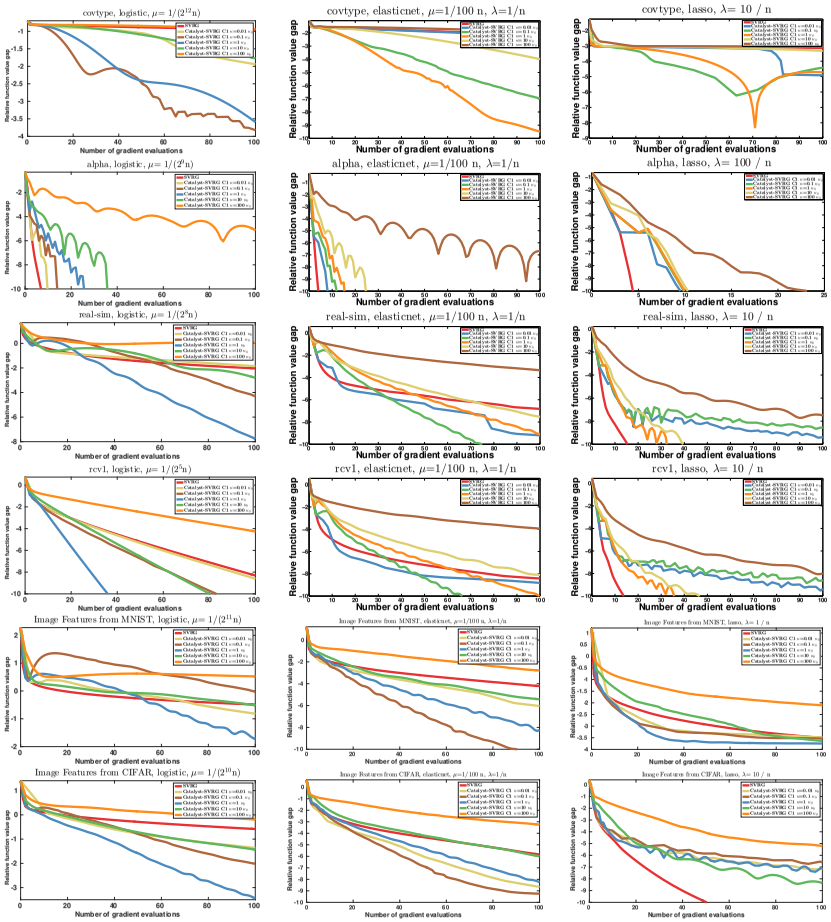

Figure 6: Evaluations of Catalyst-SVRG for different κ using stopping criterion C1, where κ_0 is the theoretical choice given by the complexity analysis.

in practice for ill-conditioned problems. Besides acceleration, Catalyst also improves the numerical stability of a given algorithm, by applying it to auxiliary problems that are better conditioned than the original objective. For this reason, it also provides support to convex, but not strongly convex objectives, to algorithms that originally require strong convexity. We have also studied experimentally many variants to identify the ones that are the most effective and the simplest to use in practice. For incremental methods, we showed that the "almost-parameter-free" variant, consisting in performing a single pass over the data at every outer-loop iteration, was the most effective one in practice.

Even though we have illustrated Catalyst in the context of finite-sum optimization problems, the main feature of our approach is its versatility. Catalyst could also be applied to other algorithms that have not been considered so far and give rise to new accelerated algorithms.

Appendix A. Useful Lemmas

Lemma 19 (Simple lemma on quadratic functions) *For all vectors x, y, z in $\mathbb{R}^p$ and $\theta > 0$,*

$$\|x - y\|^2 \geq (1-\theta)\|x - z\|^2 + \left(1 - \frac{1}{\theta}\right)\|z - y\|^2.$$

Proof

$$\begin{aligned}
\|x - y\|^2 &= \|x - z + z - y\|^2 \\
&= \|x - z\|^2 + \|z - y\|^2 + 2\langle x - z, z - y\rangle \\
&= \|x - z\|^2 + \|z - y\|^2 + \left\|\sqrt{\theta}(x - z) + \frac{1}{\sqrt{\theta}}(z - y)\right\|^2 - \theta\|x - z\|^2 - \frac{1}{\theta}\|z - y\|^2 \\
&\geq (1-\theta)\|x - z\|^2 + \left(1 - \frac{1}{\theta}\right)\|z - y\|^2.
\end{aligned}$$

■

Lemma 20 (Simple lemma on non-negative sequences) *Consider a increasing sequence $(S_k)_{k\geq 0}$ and two non-negative sequences $(a_k)_{k\geq 0}$ and $(u_k)_{k\geq 0}$ such that for all k,*

$$u_k^2 \leq S_k + \sum_{i=1}^{k} a_i u_i. \tag{29}$$

Then,

$$S_k + \sum_{i=1}^{k} a_i u_i \leq \left(\sqrt{S_k} + \sum_{i=1}^{k} a_i \right)^2. \tag{30}$$

Proof This lemma is identical to the Lemma A.10 in the original Catalyst paper (Lin et al., 2015a), inspired by a lemma of Schmidt et al. (2011) for controlling errors of inexact proximal gradient methods.

We give here an elementary proof for completeness based on induction. The relation (30) is obviously true for $k = 0$. Then, we assume it is true for $k-1$ and prove the relation for k. We remark that from (29),

$$\left(u_k - \frac{a_k}{2}\right)^2 \leq S_k + \sum_{i=1}^{k-1} a_i u_i + \frac{a_k^2}{4},$$

and then

$$u_k \leq \sqrt{S_k + \sum_{i=1}^{k-1} a_i u_i + \frac{a_k^2}{4}} + \frac{a_k}{2}.$$

We may now prove the relation (30) by induction,

$$\begin{aligned}
S_k + \sum_{i=1}^{k} a_i u_i &\leq S_k + \sum_{i=1}^{k-1} a_i u_i + a_k \left(\frac{a_k}{2} + \sqrt{S_k + \sum_{i=1}^{k-1} a_i u_i + \frac{a_k^2}{4}} \right) \\
&\leq S_k + \sum_{i=1}^{k-1} a_i u_i + a_k \left(a_k + \sqrt{S_k + \sum_{i=1}^{k-1} a_i u_i} \right) \\
&\leq \left(\sqrt{S_k + \sum_{i=1}^{k-1} a_i u_i} + a_k \right)^2 \\
&= \left(\sqrt{(S_k - S_{k-1}) + (S_{k-1} + \sum_{i=1}^{k-1} a_i u_i)} + a_k \right)^2 \\
&\leq \left(\sqrt{(S_k - S_{k-1}) + \left(\sqrt{S_{k-1}} + \sum_{i=1}^{k-1} a_i \right)^2} + a_k \right)^2 \quad \text{(by induction)} \\
&\leq \left(\sqrt{S_k} + \sum_{i=1}^{k} a_i \right)^2.
\end{aligned}$$

The last inequality is obtained by developing the square $\left(\sqrt{S_{k-1} + \sum_{i=1}^{k-1} a_i} \right)^2$ and use the increasing assumption $S_{k-1} \leq S_k$. ■

Lemma 21 (Growth of the sequence $(A_k)_{k\geq 0}$)
Let $(A_k)_{k\geq 0}$ be the sequence defined in (14) where $(\alpha_k)_{k\geq 0}$ is produced by (10) with $\alpha_0 = 1$ and $\mu = 0$. Then, we have the following bounds for all $k \geq 0$,

$$\frac{2}{(k+2)^2} \leq A_k \leq \frac{4}{(k+2)^2}.$$

Proof The righthand side is directly obtained from Lemma 4 by noticing that $\gamma_0 = \kappa$ with the choice of α_0. Using the recurrence of α_k, we have for all $k \geq 1$,

$$\alpha_k^2 = (1 - \alpha_k)\alpha_{k-1}^2 = \prod_{i=1}^{k} (1 - \alpha_i)\alpha_0^2 = A_k \leq \frac{4}{(k+2)^2}.$$

Thus, $\alpha_k \leq \frac{2}{k+2}$ for all $k \geq 1$ (it is also true for $k = 0$). We now have all we need to conclude the lemma:

$$A_k = \prod_{i=1}^{k} (1 - \alpha_i) \geq \prod_{i=1}^{k} \left(1 - \frac{2}{i+2}\right) = \frac{2}{(k+2)(k+1)} \geq \frac{2}{(k+2)^2}.$$

■

Appendix B. Proofs of Auxiliary Results

B.1 Proof of Lemma 2

Proof Let us introduce the notation $h'(z) \triangleq \frac{1}{\eta}(z - [z]_\eta)$ for the gradient mapping at z. The first order conditions of the convex problem defining $[z]_\eta$ give

$$h'(z) - \nabla h_0(z) \in \partial\psi([z]_\eta).$$

Then, we may define

$$\begin{aligned}
u &\triangleq \frac{1}{\eta}(z - [z]_\eta) - (\nabla h_0(z) - \nabla h_0([z]_\eta)), \\
&= h'(z) - \nabla h_0(z) + \nabla h_0([z]_\eta) \in \partial h([z]_\eta).
\end{aligned}$$

Then, by strong convexity,

$$\begin{aligned}
h^* &\geq h([z]_\eta) + u^\top (p(x) - [z]_\eta) + \frac{\kappa + \mu}{2} \|p(x) - [z]_\eta\|^2 \\
&\geq h([z]_\eta) - \frac{1}{2(\kappa + \mu)} \|u\|^2.
\end{aligned}$$

Moreover,

$$\begin{aligned}
\|u\|^2 &= \left\| \frac{1}{\eta}(z - [z]_\eta) \right\|^2 - \frac{2}{\eta} \langle z - [z]_\eta, \nabla h_0(z) - \nabla h_0([z]_\eta) \rangle + \|\nabla h_0(z) - \nabla h_0([z]_\eta)\|^2 \\
&\leq \|h'(z)\|^2 - \|\nabla h_0(z) - \nabla h_0([z]_\eta)\|^2 \\
&\leq \|h'(z)\|^2,
\end{aligned}$$

where the first inequality comes from the relation (Nesterov, 2004, Theorem 2.1.5) using the fact h_0 is $(1/\eta)$-smooth

$$\|\nabla h_0(z) - \nabla h_0([z]_\eta)\|^2 \leq \frac{1}{\eta}\langle z - [z]_\eta, \nabla h_0(z) - \nabla h_0([z]_\eta)\rangle.$$

Thus,

$$h([z]_\eta) - h^* \leq \frac{1}{2(\kappa+\mu)}\|u\|^2 \leq \frac{1}{2(\kappa+\mu)}\|h'(z)\|^2.$$

As a result,

$$\|h'(z)\| \leq \sqrt{2\kappa\varepsilon} \quad \Rightarrow \quad h([z]_\eta) - h^* \leq \varepsilon.$$

■

B.2 Proof of Proposition 5

Proof We simply use Theorem 3 and specialize it to the choice of parameters. The initialization $\alpha_0 = \sqrt{q}$ leads to a particularly simple form of the algorithm, where $\alpha_k = \sqrt{q}$ for all $k \geq 0$. Therefore, the sequence $(A_k)_{k\geq 0}$ from Theorem 3 is also simple since we indeed have $A_k = (1-\sqrt{q})^k$. Then, we remark that $\gamma_0 = \mu(1-\sqrt{q})$ and thus, by strong convexity of f,

$$S_0 = (1-\sqrt{q})\left(f(x_0) - f^* + \frac{\mu}{2}\|x_0 - x^*\|^2\right) \leq 2(1-\sqrt{q})(f(x_0) - f^*).$$

Therefore,

$$\begin{aligned}
\sqrt{S_0} + 3\sum_{j=1}^k \sqrt{\frac{\varepsilon_j}{A_{j-1}}} &\leq \sqrt{2(1-\sqrt{q})(f(x_0)-f^*)} + 3\sum_{j=1}^k \sqrt{\frac{\varepsilon_j}{A_{j-1}}} \\
&= \sqrt{2(1-\sqrt{q})(f(x_0)-f^*)}\left[1 + \sum_{j=1}^k \underbrace{\left(\sqrt{\frac{1-\rho}{1-\sqrt{q}}}\right)^j}_{\eta}\right] \\
&= \sqrt{2(1-\sqrt{q})(f(x_0)-f^*)}\,\frac{\eta^{k+1}-1}{\eta-1} \\
&\leq \sqrt{2(1-\sqrt{q})(f(x_0)-f^*)}\,\frac{\eta^{k+1}}{\eta-1}.
\end{aligned}$$

Therefore, Theorem 3 combined with the previous inequality gives us

$$\begin{aligned}
f(x_k) - f^* &\leq 2A_{k-1}(1-\sqrt{q})(f(x_0)-f^*)\left(\frac{\eta^{k+1}}{\eta-1}\right)^2 \\
&= 2\left(\frac{\eta}{\eta-1}\right)^2(1-\rho)^k(f(x_0)-f^*) \\
&= 2\left(\frac{\sqrt{1-\rho}}{\sqrt{1-\rho}-\sqrt{1-\sqrt{q}}}\right)^2(1-\rho)^k(f(x_0)-f^*) \\
&= 2\left(\frac{1}{\sqrt{1-\rho}-\sqrt{1-\sqrt{q}}}\right)^2(1-\rho)^{k+1}(f(x_0)-f^*).
\end{aligned}$$

Since $\sqrt{1-x}+\frac{x}{2}$ is decreasing in $[0,1]$, we have $\sqrt{1-\rho}+\frac{\rho}{2} \geq \sqrt{1-\sqrt{q}}+\frac{\sqrt{q}}{2}$. Consequently,

$$f(x_k) - f^* \leq \frac{8}{(\sqrt{q}-\rho)^2}(1-\rho)^{k+1}(f(x_0)-f^*).$$

■

B.3 Proof of Proposition 6

Proof The initialization $\alpha_0 = 1$ leads to $\gamma_0 = \kappa$ and $S_0 = \frac{\kappa}{2}\|x^* - x_0\|^2$. Then,

$$\begin{aligned}
\sqrt{\frac{\gamma_0}{2}\|x_0 - x^*\|^2} + 3\sum_{j=1}^k \sqrt{\frac{\varepsilon_j}{A_{j-1}}} &\leq \sqrt{\frac{\kappa}{2}\|x_0 - x^*\|^2} + 3\sum_{j=1}^k \sqrt{\frac{(j+1)^2\varepsilon_j}{2}} \quad \text{(from Lemma 21)} \\
&\leq \sqrt{\frac{\kappa}{2}\|x_0 - x^*\|^2} + \sqrt{f(x_0)-f^*}\left(\sum_{j=1}^k \frac{1}{(j+1)^{1+\gamma/2}}\right),
\end{aligned}$$

where the last inequality uses Lemma 21 to upper-bound the ratio ε_j/A_j. Moreover,

$$\sum_{j=1}^k \frac{1}{(j+1)^{1+\gamma/2}} \leq \sum_{j=2}^\infty \frac{1}{j^{1+\gamma/2}} \leq \int_1^\infty \frac{1}{x^{1+\gamma/2}}\,\mathrm{d}x = \frac{2}{\gamma}.$$

Then applying Theorem 3 yields

$$\begin{aligned}
f(x_k) - f^* &\leq A_{k-1}\left(\sqrt{\frac{\kappa}{2}\|x_0 - x^*\|^2} + \frac{2}{\gamma}\sqrt{f(x_0)-f^*}\right)^2 \\
&\leq \frac{8}{(k+1)^2}\left(\frac{\kappa}{2}\|x_0 - x^*\|^2 + \frac{4}{\gamma^2}(f(x_0)-f^*)\right).
\end{aligned}$$

The last inequality uses $(a+b)^2 \leq 2(a^2+b^2)$. ■

B.4 Proof of Lemma 11

Proof We abbreviate $\tau_{\mathcal{M}}$ by τ and $C = C_{\mathcal{M}}(h(z_0) - h^*)$ to simplify the notation. Set

$$T_0 = \frac{1}{\tau} \log\left(\frac{1}{1-e^{-\tau}}\frac{C}{\varepsilon}\right).$$

For any $t \geq 0$, we have

$$\mathbb{E}[h(z_t) - h^*] \leq C(1-\tau)^t \leq C\, e^{-t\tau}.$$

By Markov's inequality,

$$\mathbb{P}[h(z_t) - h^* > \varepsilon] = \mathbb{P}[T(\varepsilon) > t] \leq \frac{\mathbb{E}[h(z_t) - h^*]}{\varepsilon} \leq \frac{C\, e^{-t\tau}}{\varepsilon}.$$

Together with the fact $\mathbb{P} \leq 1$ and $t \geq 0$. We have

$$\mathbb{P}[T(\varepsilon) \geq t+1] \leq \min\left\{\frac{C}{\varepsilon}e^{-t\tau}, 1\right\}.$$

Therefore,

$$\begin{aligned}
\mathbb{E}[T(\varepsilon)] &= \sum_{t=1}^{\infty} \mathbb{P}[T(\varepsilon) \geq t] = \sum_{t=1}^{T_0} \mathbb{P}[T(\varepsilon) \geq t] + \sum_{t=T_0+1}^{\infty} \mathbb{P}[T(\varepsilon) \geq t] \\
&\leq T_0 + \sum_{t=T_0}^{\infty} \frac{C}{\varepsilon} e^{-t\tau} = T_0 + \frac{C}{\varepsilon} e^{-T_0\tau} \sum_{t=0}^{\infty} e^{-t\tau} \\
&= T_0 + \frac{C}{\varepsilon}\frac{e^{-\tau T_0}}{1-e^{-\tau}} = T_0 + 1.
\end{aligned}$$

A simple calculation shows that for any $\tau \in (0,1)$, $\frac{\tau}{2} \leq 1 - e^{-\tau}$ and then

$$\mathbb{E}[T(\varepsilon)] \leq T_0 + 1 = \frac{1}{\tau}\log\left(\frac{1}{1-e^{-\tau}}\frac{C}{\varepsilon}\right) + 1 \leq \frac{1}{\tau}\log\left(\frac{2C}{\tau\varepsilon}\right) + 1.$$

■

B.5 Proof of coerciveness property of the proximal operator

Lemma 22 *Given a μ-strongly convex function $f : \mathbb{R}^p \to \mathbb{R}$ and a positive parameter $\kappa > 0$. For any x, $y \in \mathbb{R}^p$, the following inequality holds,*

$$\frac{\kappa}{\kappa+\mu}\langle y - x, p(y) - p(x)\rangle \geq \|p(y) - p(x)\|^2,$$

where $p(x) = \arg\min_{z \in \mathbb{R}^p} \left\{ f(z) + \frac{\kappa}{2}\|z - x\|^2 \right\}$.

Proof By the definition of $p(x)$, we have $0 \in \partial f(p(x)) + \kappa(p(x) - x)$, meaning that $\kappa(x - p(x)) \in \partial f(p(x))$. By strong convexity of f,

$$\langle \kappa(y - p(y)) - \kappa(x - p(x)), p(y) - p(x)\rangle \geq \mu\|p(y) - p(x)\|^2.$$

Rearranging the terms yields the desired inequality. ■

As a consequence,

$$\begin{aligned}
&\left\|\frac{\kappa}{\kappa+\mu}(y_k - y_{k-1}) - (p(y_k) - p(y_{k-1}))\right\|^2 \\
&\quad= \left\|\frac{\kappa}{\kappa+\mu}(y_k - y_{k-1})\right\|^2 - 2\frac{\kappa}{\kappa+\mu}\langle y_k - y_{k-1}, p(y_k) - p(y_{k-1})\rangle + \|p(y_k) - p(y_{k-1})\|^2 \\
&\quad\leq \left\|\frac{\kappa}{\kappa+\mu}(y_k - y_{k-1})\right\|^2 \\
&\quad\leq \|y_k - y_{k-1}\|^2.
\end{aligned}$$

Appendix C. Catalyst for MISO/Finito/SDCA

In this section, we present the application of Catalyst to MISO/Finito (Mairal, 2015; Defazio et al., 2014b), which may be seen as a variant of SDCA (Shalev-Shwartz and Zhang, 2016). The reason why these algorithms require a specific treatment is due to the fact that their linear convergence rates are given in a different form than (12); specifically, Theorem 4.1 of Lin et al. (2015a) tells us that MISO produces a sequence of iterates $(z_t)_{t\geq 0}$ for minimizing the auxiliary objective $h(z) = f(z) + \frac{\kappa}{2}\|z - y\|^2$ such that

$$\mathbb{E}[h(z_t)] - h^* \leq C_{\mathcal{M}}(1 - \tau_{\mathcal{M}})^{t+1}(h^* - d_0(z_0)),$$

where d_0 is a lower-bound of h defined as the sum of a simple quadratic function and the composite regularization ψ. More precisely, these algorithms produce a sequence $(d_t)_{t\geq 0}$ of such lower-bounds, and the iterate z_t is obtained by minimizing d_t in closed form. In particular, z_t is obtained from taking a proximal step at a well chosen point w_t, providing the following expression,

$$z_t = \mathrm{prox}_{\psi/(\kappa+\mu)}(w_t).$$

Then, linear convergence is achieved for the duality gap

$$\mathbb{E}[h(z_t) - h^*] \leq \mathbb{E}[h(z_t) - d_t(z_t)] \leq C_{\mathcal{M}}(1 - \tau_{\mathcal{M}})^t(h^* - d_0(z_0)).$$

Indeed, the quantity $h(z_t) - d_t(z_t)$ is a natural upper-bound on $h(z_t) - h^*$, which is simple to compute, and which can be naturally used for checking the criterions (C1) and (C2). Consequently, the expected complexity of solving a given problem is slightly different compared to Lemma 11.

Lemma 23 (Accuracy vs. complexity) *Let us consider a strongly convex objective h and denote $(z_t)_{t\geq 0}$ the sequence of iterates generated by MISO/Finito/SDCA. Consider the*

complexity $T(\varepsilon) = \inf\{t \geq 0, h(z_t) - d_t(z_t) \leq \varepsilon\}$*, where* $\varepsilon > 0$ *is the target accuracy and* h^* *is the minimum value of* h*. Then,*

$$\mathbb{E}[T(\varepsilon)] \leq \frac{1}{\tau_{\mathcal{M}}} \log\left(\frac{2C_{\mathcal{M}}(h^* - d_0(z_0))}{\tau_{\mathcal{M}}\varepsilon}\right) + 1,$$

where d_0 *is a lower bound of* f *built by the algorithm.*

For the convergence analysis, the outer-loop complexity does not change as long as the algorithm finds approximate proximal points satisfying criterions (C1) and (C2). It is then sufficient to control the inner loop complexity. As we can see, we now need to bound the dual gap $h^* - d_0(z_0)$ instead of the primal gap $h(z_0) - h^*$, leading to slightly different warm start strategies. Here, we show how to restart MISO/Finito.

Proposition 24 (Warm start for criterion (C1)) *Consider applying Catalyst with the same parameter choices as in Proposition 12 to MISO/Finito. At iteration* $k+1$ *of Algorithm 2, assume that we are given the previous iterate* x_k *in* $p^{\varepsilon_k}(y_{k-1})$*, the corresponding dual function* $d(x)$ *and its prox-center* w_k *satisfying* $x_k = \mathrm{prox}_{\psi/(\kappa+\mu)}(w_k)$*. Then, initialize the sequence* $(z_t)_{t\geq 0}$ *for minimizing* $h_{k+1} = f + \frac{\kappa}{2}\|\cdot - y_k\|^2$ *with,*

$$z_0 = \mathrm{prox}_{\psi/(\kappa+\mu)}\left(w_k + \frac{\kappa}{\kappa+\mu}(y_k - y_{k-1})\right),$$

and initialize the dual function as

$$d_0(x) = d(x) + \frac{\kappa}{2}\|x - y_k\|^2 - \frac{\kappa}{2}\|x - y_{k-1}\|^2.$$

Then,

1. *when* f *is* μ*-strongly convex, we have* $h^*_{k+1} - d_0(z_0) \leq C\varepsilon_{k+1}$ *with the same constant as in (21) and (22), where* d_0 *is the dual function corresponding to* z_0*;*
2. *when* f *is convex with bounded level sets, there exists a constant* $B > 0$ *identical to the one of (23) such that*
$$h^*_{k+1} - d_0(z_0) \leq B.$$

Proof The proof is given in Lemma D.5 of Lin et al. (2015a), which gives

$$h^*_{k+1} - d_0(z_0) \leq \varepsilon_k + \frac{\kappa^2}{2(\kappa+\mu)}\|y_k - y_{k-1}\|^2.$$

This term is smaller than the quantity derived from (24), leading to the same upper bound. ■

Proposition 25 (Warm start for criterion (C2)) *Consider applying Catalyst with the same parameter choices as in Proposition 15 to MISO/Finito. At iteration* $k+1$ *of Algorithm 2, we assume that we are given the previous iterate* x_k *in* $g^{\delta_k}(y_{k-1})$ *and the*

corresponding dual function $d(x)$*. Then, initialize the sequence* $(z_t)_{t\geq 0}$ *for minimizing* $h_{k+1} = f + \frac{\kappa}{2}\|\cdot - y_k\|^2$ *by*

$$z_0 = \mathrm{prox}_{\psi/(\kappa+\mu)}\left(y_k - \frac{1}{\kappa+\mu}\nabla f_0(y_k)\right),$$

where $f = f_0 + \psi$ *and* f_0 *is the smooth part of* f*, and set the dual function* d_0 *by*

$$d_0(x) = f_0(y_k) + \langle \nabla f_0(y_k), x - y_k\rangle + \frac{\kappa+\mu}{2}\|x - y_k\|^2 + \psi(x).$$

Then,

$$h^*_{k+1} - d_0(z_0) \leq \frac{(L+\kappa)^2}{2(\mu+\kappa)}\|p(y_k) - y_k\|^2. \tag{31}$$

Proof Since $p(y_k)$ is the minimum of h_{k+1}, the optimality condition provides

$$-\nabla f_0(p(y_k)) - \kappa(p(y_k) - y_k) \in \partial\psi(p(y_k)).$$

Thus, by convexity,

$$\begin{aligned}
&\psi(p(y_k)) + \langle -\nabla f_0(p(y_k)) - \kappa(p(y_k) - y_k), z_0 - p(y_k)\rangle \leq \psi(z_0),\\
&f_0(p(y_k)) + \frac{\kappa}{2}\|p(y_k) - y_k\|^2 + \langle \nabla f_0(p(y_k)) + \kappa(p(y_k) - y_k), y_k - p(y_k)\rangle \leq f_0(y_k).
\end{aligned}$$

Summing up gives

$$h^*_{k+1} \leq f_0(y_k) + \psi(z_0) + \langle \nabla f_0(p(y_k)) + \kappa(p(y_k) - y_k), z_0 - y_k\rangle.$$

As a result,

$$\begin{aligned}
h^*_{k+1} - d_0(z_0) &\leq f_0(y_k) + \psi(z_0) + \langle \nabla f_0(p(y_k)) + \kappa(p(y_k) - y_k), z_0 - y_k\rangle - d_0(z_0)\\
&= \langle \nabla f_0(p(y_k)) + \kappa(p(y_k) - y_k) - \nabla f_0(y_k), z_0 - y_k\rangle - \frac{\kappa+\mu}{2}\|z_0 - y_k\|^2\\
&\leq \frac{1}{2(\kappa+\mu)}\|\nabla \underbrace{f_0(p(y_k)) - \nabla f_0(y_k)}_{\|\cdot\|\leq L\|p(y_k)-y_k\|} + \kappa(p(y_k) - y_k)\|^2\\
&\leq \frac{(L+\kappa)^2}{2(\mu+\kappa)}\|p(y_k) - y_k\|^2.
\end{aligned}$$

■

The bound obtained from (31) is similar to the one form Proposition 15, and differs only in the constant factor. Thus, the inner loop complexity in Section 4.2.2 still holds for MISO/Finito up to a constant factor. As a consequence, the global complexity of MISO/Finito applied to Catalyst is similar to one obtained by SVRG, yielding an acceleration for ill-conditioned problems.

Abstract

The Information Bottleneck (IB) is a conceptual method for extracting the most compact, yet informative, representation of a set of variables, with respect to the target. It generalizes the notion of minimal sufficient statistics from classical parametric statistics to a broader information-theoretic sense. The IB curve defines the optimal trade-off between representation complexity and its predictive power. Specifically, it is achieved by minimizing the level of mutual information (MI) between the representation and the original variables, subject to a minimal level of MI between the representation and the target. This problem is shown to be in general NP hard. One important exception is the multivariate Gaussian case, for which the Gaussian IB (GIB) is known to obtain an analytical closed form solution, similar to Canonical Correlation Analysis (CCA). In this work we introduce a Gaussian lower bound to the IB curve; we find an embedding of the data which maximizes its "Gaussian part", on which we apply the GIB. This embedding provides an efficient (and practical) representation of any arbitrary data-set (in the IB sense), which in addition holds the favorable properties of a Gaussian distribution. Importantly, we show that the optimal Gaussian embedding is bounded from above by non-linear CCA. This allows a fundamental limit for our ability to Gaussianize arbitrary data-sets and solve complex problems by linear methods.

Keywords: Information Bottleneck, Canonical Correlations, ACE, Gaussianization, Mutual Information Maximization, Infomax

1. Introduction

The problem of extracting the relevant aspects of complex data is a long standing staple in statistics and machine learning. The Information Bottleneck (IB) method, presented by Tishby et al. (1999), approaches this problem by extending its classical notion to a broader information-theoretic setup. Specifically, given the joint distribution of a set of explanatory variables $\underline{X}$ and a target variable $\underline{Y}$ (which may also be of a higher dimension), the IB method strives to find the most compressed representation of $\underline{X}$, while preserving information about $\underline{Y}$. Thus, $\underline{Y}$ implicitly regulates the compression of $\underline{X}$, so that its compressed representation maintains a level of relevance as explanatory variables with respect to $\underline{Y}$.

The IB problem is formally defined as follows:

$$\begin{aligned} \min_{P(\underline{T}|\underline{X})} \quad & I(\underline{X};\underline{T}) \\ \text{subject to} \quad & I(\underline{T};\underline{Y}) \geq I_Y \end{aligned} \tag{1}$$

where $\underline{T}$ is the compressed representation of $\underline{X}$ and the minimization is over the mapping of $\underline{X}$ to $\underline{T}$, defined by the conditional probability $P(\underline{T}|\underline{X})$. Here, I_Y is a constant parameter that sets the level of information to be preserved between the compressed representation and the target. Solving this problem for a range of I_Y values defines the *IB curve* – a continuous concave curve which provides the optimal trade-off between representation complexity (regarded as $I(\underline{X};\underline{T})$) and predictive power ($I(\underline{T};\underline{Y})$).

The IB method showed to be a powerful tool in a variety of machine learning domains and related areas (Slonim and Tishby, 2000; Friedman et al., 2001; Sinkkonen and Kaski, 2002; Slonim et al., 2005; Hecht et al., 2009). It is also applicable to other fields such as neuroscience (Schneidman et al., 2001) and optimal control (Tishby and Polani, 2011). Recently, Tishby and Zaslavsky (2015) and Shwartz-Ziv and Tishby (2017) demonstrated its abilities in analyzing and optimizing the performance of deep neural networks.

Generally speaking, solving the IB problem (1) for an arbitrary joint distribution is not a simple task. In the introduction of the IB method, Tishby et al. (1999) defined a set of self-consistent equations which formulate the necessary conditions for the optimal solution of (1). Further, they provided an iterative Arimoto– Blahut like algorithm which shows to converge to local optimum. In general, these equations do not hold a tractable solution and are usually approximated by different means (Slonim, 2002). An extensive attention was given to the simpler categorical setup, where the IB curve is somewhat easier to approximate. Here, $\underline{X}$ and $\underline{Y}$ take values on a finite set and $\underline{T}$ represents (soft and informative) clusters of $\underline{X}$ (Slonim, 2002). Naturally, the IB problem also applies for continuous variables. In this case, approximating the solution to the self-consistent equations is even more involved. A special exception is the Gaussian case, where $\underline{X}$ and $\underline{Y}$ are assumed to follow a jointly normal distribution and the *Gaussian IB* problem (GIB) is analytically solved by linear projections to the canonical correlation vector space (Chechik et al., 2005). However, evaluating the IB curve for arbitrary continuous random variables is still considered a highly complicated task where most attempts focus on approximating or bounding it (Rey and Roth, 2012; Chalk et al., 2016). A detailed discussion regarding currently known methods is provided in the following section.

In this work we present a novel Gaussian lower bound to the IB curve, which applies to all types of random variables (continuous, nominal and categorical). Our bound strives to maximize the "jointly Gaussian part" of the data and apply the analytical GIB to it. Specifically, we seek for two transformations, $\underline{U} = \phi(\underline{X})$ and $\underline{V} = \psi(\underline{Y})$ so that $\underline{U}$ and $\underline{V}$ are highly correlated and "as jointly Gaussian as possible". In addition, we ask that the transformations preserve as much information as possible between $\underline{X}$ and $\underline{Y}$. This way, we maximize the portion of the data that can be explained by linear means, $I(\underline{U};\underline{V}) \leq I(\underline{X};\underline{Y})$, specifically using the GIB.

In fact, our results go beyond the specific context of the information bottleneck. In this work we tackle the fundamental question of linearizing non-linear problems. In other words, we ask ourselves whether it is possible to "push" all the information in the data

to its second moments. This problem has received a great amount of attention over the years. For example, Schneidman et al. (2006) discuss this problem in the context of neural networks; they provide preliminary evidence that in the vertebrate retina, weak pairwise correlations may describe the collective (non-linear) behavior of neurons. In this work, we provide both fundamental limits and constructive algorithms for maximizing the part of the data that can be optimally analyzed by linear means. This basic property holds both theoretical and practical implications, as it defines the maximal portion which allows favorable analytical properties in many applications. Interestingly, we show that even if we allow the transformations $\underline{U} = \phi(\underline{X})$ and $\underline{V} = \psi(\underline{Y})$ to increase the dimensions of $\underline{X}$ and $\underline{Y}$, our ability to linearize the problem is still limited, and governed by the non-linear canonical correlations (Breiman and Friedman, 1985) of the original variables.

Our suggested approach may also be viewed as an extension of the *Shannon lower bound* (Cover and Thomas, 2012), for evaluating the mutual information. In his seminal work, Shannon provided an analytical Gaussian lower bound for the generally involved rate distortion function. He showed that the rate distortion function $R(D)$ can be bounded from below by $h(X) - \frac{1}{2}\log(2\pi eD)$ where X is the compressed source, $h(X)$ is its corresponding deferential entropy and $\frac{1}{2}\log(2\pi eD)$ is the differential entropy of an independent Gaussian noise with a maximal distortion level D. This bound holds some favorable theoretical properties (Cover and Thomas, 2012) and serves as one of the most basic tools for approximating the rate distortion function to this very day. In this work, we use a similar rationale and derive a Gaussian lower bound for the mutual information of two random variables, which holds an analytical expression just like the Shannon's bound. We then extend our result to the entire IB curve and discuss its theoretical properties and practical considerations. A matlab implementation of our suggested approach is publicly available at the first author's web-page[1].

The rest of this manuscript is organized as follows: In Section 2 we review previous work on the IB method for continuous random variables. Section 3 defines our suggested lower bound and formulates it as an optimization problem. We then propose a set of solutions and bounds to this problem, as we distinguish between the easier univariate case (Section 4) and the more involved multivariate case (Section 5). Finally, in Section 6 we extend our results to the entire IB curve.

2. Related work

As discussed in the previous section, solving the IB problem for continuous variables is in general a difficult task. A special exception is where $\underline{X}$ and $\underline{Y}$ follow a jointly normal distribution. Chechik et al. (2005) show that in this case, the Gaussian IB problem (GIB) is solved by a noisy linear projection, $T = A\underline{X} + \underline{\zeta}$. Specifically, assume that $\underline{X}$ and $\underline{Y}$ are of dimensions n_X and n_Y respectively and denote the covariance matrix of $\underline{X}$ as $C_{\underline{X}}$ while the conditional covariance matrix of $\underline{X}|\underline{Y}$ is $C_{\underline{X}|\underline{Y}}$. Then, $\underline{\zeta}$ is a Gaussian random vector with a zero mean and a unit covariance matrix, independent of $\underline{X}$. The matrix A is defined as follows:

$$A = \begin{Bmatrix} [0^T;\ldots;0^T] & 0 \le \beta \le \beta_1^C \\ [a_1 v_1^T; 0^T; \ldots; 0^T] & \beta_1^C \le \beta \le \beta_2^C \\ [a_1 v_1^T; a_2 v_2^T; 0^T; \ldots; 0^T] & \beta_2^C \le \beta \le \beta_3^C \\ \vdots & \vdots \end{Bmatrix}. \quad (2)$$

where $\{v_1^T, v_2^T, \ldots, v_{n_x}^T\}$ are the left eigenvectors of $C_{\underline{X}|\underline{Y}} C_{\underline{X}}^{-1}$, sorted by their corresponding ascending eigenvalues $\lambda_1, \ldots, \lambda_{n_X}$, $\beta_I^C = \frac{1}{\lambda_i}$ are the critical β values, a_i are defined by $a_i = \sqrt{\frac{\beta(1-\lambda_i)-1}{\lambda_i r_i}}$. $r_i = v_i^T C_{\underline{X}} v_i$ and 0^T is an n_X row vector of zeros. Notice that the critical values β correspond to the slope of the IB curve, as they represent the Lagrange multipliers of the IB problem.

Unfortunately, this solution is limited to jointly Gaussian random variables. In fact, it can be shown that a closed form analytical solution (for continuous random variables) may only exist under quite restrictive assumptions on the underlaying distribution. Moreover, as the IB curve is so challenging to evaluate in the general case, most known attempts either focus on extending the GIB to other distributions under varying assumptions, or approximate the IB curve by different means.

Rey and Roth (2012) reformulate the IB problem in terms of probabilistic copulas. They show that under a Gaussian copula assumption, an analytical solution (which extends the GIB) applies to joint distributions with arbitrary marginals. This formulation provides several interesting insights on the IB problem. However, its practical implications are quite limited as the Gaussian copula assumption is very restrictive. In fact, it implicitly requires that the joint distribution would maintain a Gaussian structure. As we show in the following sections, this assumption makes the problem significantly easier and does not hold in general.

Chalk et al. (2016) provide a lower bound to the IB curve by using an approximate variational scheme, analogous to variational expectation maximization. Their method relaxes the IB problem by restricting the class of distributions, $P(\underline{Y}|\underline{T})$ and $P(\underline{T})$ to a set of parametric models. This way, the relaxed IB problem may be solved in EM-like steps; their suggested algorithm iteratively maximizes the objective over the mappings (for fixed parameters) and then maximize the set of parameters, for fixed mappings. Chalk et al. (2016) show that this method can be effectively applied to "sparse" data in which $\underline{X}$ and $\underline{Y}$ are generated by sparsely occurring latent features. However, in the general case, their suggested bound strongly depends on the assumption that the chosen parametric models provide reasonable approximations for the optimal distributions. This assumption is obviously quite restrictive. Moreover, it is usually difficult to validate, as the optimal distributions are unknown. Kolchinsky et al. (2017) take a somewhat similar approach, as they suggest a variational upper bound to the IB curve. The main difference between the two methods relies on the variational approximation of objective, $I(\underline{X};\underline{Y})$. However, they are both prone to the same difficulties stated above.

Alemi et al. (2016) propose an additional variational inference method to construct a lower bound to the IB curve. Here, they re-parameterize the IB problem followed by Monte Carlo sampling, to get an unbiased estimate of the IB objective gradient. This allows them to apply deep neural networks in order to parameterize any given distribution. However,

1. https://sites.google.com/site/amichaipainsky/software

this method fails to provide guarantees on the obtained bound, as a result of the suggested stochastic gradient descent optimization approach.

Achille and Soatto (2018) relax the bottleneck problem by introducing an additional *total correlation* (TC) regularization term that strives to maximize the independence among the components of the representation T. They show that under the assumption that the Lagrange multipliers of the TC and MI constraints are identical, the relaxed problem may be solved by adding auxiliary variables. However, this assumption is usually invalid, and the suggested method fails to provide guarantees on the difference between the obtained objective and original IB formulation.

In this work we suggest a novel lower bound to the IB curve which provides both theoretical and practical guarantees. In addition, we introduce upper and lower bounds to our suggested solution that are very easy to attain. This way we allow immediate benchmarks to the IB curve using common off-the-shelf methods.

3. Problem formulation

Throughout this manuscript we use the following standard notation: underlines denote vector quantities, where their respective components are written without underlines but with index. For example, the components of the n-dimensional vector $\underline{X}$ are $X_1, X_2, \ldots X_n$. Random variables are denoted with capital letters while their realizations are denoted with the respective lower-case letters. The mutual information of two random variables is defined as $I(\underline{X};\underline{Y}) = h(\underline{X}) + h(\underline{Y}) - h(\underline{X},\underline{X})$ where $h(\underline{X}) = -\int_{\underline{X}} f_{\underline{X}}(\underline{x}) \log f_{\underline{X}}(\underline{x}) d\underline{x}$ is the differential entropy of $\underline{X}$ and $f_{\underline{X}}(\underline{x})$ is its probability density function.

We begin by introducing a Gaussian lower bound to the mutual information $I(\underline{X};\underline{Y})$. We then extend our result to the entire IB curve.

3.1 Problem statement

Let $\underline{X} \in \mathbb{R}^{d_x}, \underline{Y} \in \mathbb{R}^{d_y}$ be two multivariate random vectors with a joint cumulative distribution function (CDF) $F_{XY}(x,y)$ and mutual information $I(\underline{X},\underline{Y})$. In the following sections we focus on bounding $I(\underline{X},\underline{Y})$ from below with an analytical expression. Let $\underline{U} = \phi(\underline{X})$ and $\underline{V} = \psi(\underline{Y})$ be two transformations of $\underline{X}$ and $\underline{Y}$, respectively. Assume that $\underline{U} \in \mathbb{R}^{d_u}$ and $\underline{V} \in \mathbb{R}^{d_v}$ are *separately normally distributed*. This means that $\underline{U} \sim N\left(\mu_{\underline{U}}, C_{\underline{U}}\right)$ and $\underline{V} \sim N\left(\mu_{\underline{V}}, C_{\underline{V}}\right)$ but the vector $[\underline{U},\underline{V}]^T$ is not necessarily normally distributed. This allows us to derive the following basic inequality

$$\begin{aligned} I(\underline{X},\underline{Y}) \geq & I(\underline{U},\underline{V}) = h(\underline{U}) + h(\underline{V}) - h(\underline{U},\underline{V}) \geq \\ & h(\underline{U}) + h(\underline{V}) - h(\underline{U}_{jg},\underline{V}_{jg}) = \frac{1}{2}\log\left(\frac{\left|C_{[\underline{U},\underline{V}]}\right|}{|C_{\underline{U}}||C_{\underline{V}}|}\right) \end{aligned} \tag{3}$$

where the first inequality follows from the Data Processing lemma (Cover and Thomas, 2012) and the second inequality follows from $\left[\underline{U}_{jg},\underline{V}_{jg}\right]^T$ being jointly Gaussian (jg) distributed with the same covariance matrix as $[\underline{U},\underline{V}]^T$, $C_{[\underline{U}_{jg},\underline{V}_{jg}]} = C_{[\underline{U},\underline{V}]}$, so that $h(\underline{U}_{jg},\underline{V}_{jg}) \geq h(\underline{U},\underline{V})$ (Cover and Thomas, 2012). Notice that (3) can also be derived from an *information geometry* (IG) view point, as shown by Cardoso (2003).

Equality is attained in (3) iff $I(\underline{X},\underline{Y}) = I(\underline{U},\underline{V})$ (no information is lost in the transformation) and $\underline{U} = \phi(\underline{X})$, $\underline{V} = \psi(\underline{Y})$ are jointly normally distributed. In other words, in order to preserve all the information we must find ϕ and ψ that capture all the mutual information, and at the same time make $\underline{X}$ and $\underline{Y}$ jointly normal. This is obviously a complicated task as ϕ and ψ only operate on $\underline{X}$ and $\underline{Y}$ separately. Therefore, we are interested in maximizing this lower bound as much as possible:

$$\begin{aligned} \max_{\phi,\psi} \quad & \log\left(\frac{\left|C_{[\underline{U},\underline{V}]}\right|}{|C_{\underline{U}}||C_{\underline{V}}|}\right) \\ \text{subject to} \quad & \underline{U} = \phi(\underline{X}) \sim N\left(0, C_{\underline{U}}\right) \\ & \underline{V} = \psi(\underline{Y}) \sim N\left(0, C_{\underline{V}}\right) \end{aligned} \tag{4}$$

where the constraints imply that $\underline{U}$ and $\underline{V}$ are separately normally distributed random vectors with zero means and covariance matrices $C_{\underline{U}}$ and $C_{\underline{V}}$, respectively. In other words, we would like to maximize Cardoso (2003) IG bound by applying two transformations, ϕ and ψ, to the original variables. This would allow us to achieve a tighter result.

Notice that our objective is invariant to the means of $\underline{U},\underline{V}$ so they are chosen to be zero. In addition, it is easy to show that our objective is invariant to linear transformations of $\underline{U},\underline{V}$. This means we can equivalently assume that $C_{\underline{U}}, C_{\underline{V}}$ are identity covariance matrices. As shown by Kay (1992) and others (Klami and Kaski, 2005; Chechik et al., 2005), maximizing the objective of (4) is equivalent to maximizing the canonical correlations, $\text{cov}(U_i, V_i)$. Therefore, our problem may be written as

$$\begin{aligned} \max_{\phi,\psi} \quad & \sum_{i=1}^{k} E\left(U_i V_i\right) \\ \text{subject to} \quad & \underline{U} = \phi(\underline{X}) \sim N\left(0, I\right) \\ & \underline{V} = \psi(\underline{Y}) \sim N\left(0, I\right) \end{aligned} \tag{5}$$

where $k = \min\{d_u, d_v\}$. This problem may also be viewed as a variant of the well-known CCA problem (Hotelling, 1936), where we optimize over nonlinear transformations ϕ and ψ, and impose additional normality constraints. As in CCA, this problem can be solved iteratively by gradually finding the the optimal canonical components in each step (subject to the normality constraint), while maintaining orthogonality with the components that were previously found. For simplicity of the presentation we begin by solving (5) in the univariate (1-D) case. Then, we generalize to the multivariate case. In each of these setups we present a solution to the problem, followed by simpler upper and lower bounds.

4. The univariate case

In the univariate case we assume that $d_x = d_y = k = 1$. We seek ϕ, ψ such that

$$\begin{aligned} \max_{\phi,\psi} \quad & \rho = E(UV) \\ \text{subject to} \quad & U = \phi(X) \sim N(0,1) \\ & V = \psi(Y) \sim N(0,1). \end{aligned} \tag{6}$$

As a first step towards this goal, let us relax our problem by replacing the normality constraint with simpler second order statistics constraints,

$$\begin{aligned} \max_{\phi,\psi} \quad & \rho = E(UV) \\ \text{subject to} \quad & U = \phi(X),\ E(U) = 0,\ E(U^2) = 1 \\ & V = \psi(Y),\ E(V) = 0,\ E(V^2) = 1. \end{aligned} \tag{7}$$

As mentioned above, this problem is a non-linear extension of CCA, which traces back to early work by Lancaster (1963). As this problem is also a relaxed version of our original task (6), it may serve us as an upper bound. This means that the optimum of (7), denoted as ρ_{ub}, necessarily bound from above ρ_*, the optimum of (6).

4.1 Alternation Conditional Expectation (ACE)

Breiman and Friedman (1985) show that the optimal solution to (7) is achieved by a simple alternating conditional expectation procedure, named ACE. Assume that $\psi(Y)$ is fixed, known and satistfies the constraints. Then, we optimize (7) only over ϕ and by Cauchy-Schwarz inequality, we have that

$$E(\phi(X)\psi(Y)) = E_x\left(\phi(X)E(\psi(Y)|X)\right) \leq \sqrt{\text{var}(\phi(X))}\sqrt{\text{var}(E(\psi(Y)|X))}$$

with equality iff $\phi(X) = c \cdot E(\psi(Y)|X)$. Therefore, choosing the constant c to satisfy the unit variance constraint we achieve $\phi(X) = \frac{E(\psi(Y)|X)}{\sqrt{var(E(\psi(Y)|X))}}$. In the same manner we may fix $\phi(X)$ and attain $\psi(Y) = \frac{E(\phi(X)|Y)}{\sqrt{var(E(\phi(X)|Y))}}$. These coupled equations are in fact necessary conditions for the optimality of ϕ and ψ, leading to an alternating procedure in which at each step we fix one transformation and optimize the other. Breiman and Friedman (1985) prove that this procedure convergences to the global optimum using Hilbert space algebra. They show that the transformations ϕ and ψ may be represented in a zero-mean and finite variance Hilbert space, while the conditional expectation projection is linear, closed, and shown to be self-adjoint and compact under mild assumptions. Then, the coupled equations may be formulate as an eigen problem in the Hilbert space, for which there exists a unique and optimal solution.

The following lemma defines a strict connection between the non-linear canonical correlations and the Gaussinized IB problem.

Lemma 1 *Let ρ_{ub} be the solution to (7). If $I(X;Y) > -\log\left(1-\rho_{ub}^2\right)$, then there are no transformations ϕ, ψ such that $U = \phi(X)$ and $V = \psi(Y)$ are jointly normally distributed and preserve all of the mutual information, $I(X;Y)$.*

Proof Let ρ_* be the solution to (6). As mentioned above, $\rho_{ub} \geq \rho_*$. Therefore, $I(X;Y) > -\log\left(1-\rho_{ub}^2\right) > -\log\left(1-\rho_*^2\right)$. This means that the inequality (3) cannot be achieved with equality. Hence, there are no transformations $U = \phi(X)$ and $V = \psi(Y)$ so that U and V are jointly normal and preserve all of the mutual information, $I(X;Y)$. ■

Lemma 1 suggests that if the optimal transformations of the relaxed problem (which can be obtained by ACE) fails to capture all the mutual information between X and Y, then there

are no transformations that can project X and Y onto jointly normal variables without losing information. Moreover, notice that the maximal level of correlation ρ_{ub} cannot be further increased, even if we allow $\underline{U} = \phi(X)$ and $\underline{V} = \phi(Y)$ to reside in greater dimensions. This means that Lemma 1 holds for any $\phi : R^{d_x} \to R^{d_u}$ and $\psi : R^{d_y} \to R^{d_v}$, such that $d_u, d_v \geq 0$.

4.2 Alternating Gaussinized Conditional Expectations (AGCE)

Let us go back to our original problem, which strives to maximize the correlation between U and V, subject to marginal normality constraints (6). Here we follow Breiman and Friedman (1985), and suggest an alternating optimization procedure.

Let us fix $\psi(Y)$ and optimize (6) with respect to $\phi(X)$. As before, we can write the correlation objective as $E(\phi(X)\psi(Y)) = E_x\left(\phi(X)E(\psi(Y)|X)\right)$. Since $E(\phi(X)^2)$ is constrained to be equal to 1 while $E\left(E(\psi(Y)|X)^2\right)$ is fixed, maximizing $E_x\left(\phi(X)E(\psi(Y)|X)\right)$ is equivalent to minimizing $E_x\left(\phi(X) - E(\psi(Y)|X)\right)^2$. For simplicity, denote $\bar{X} \equiv E(\psi(Y)|X)$. Then, our optimization problem can be reformulated as

$$\begin{aligned} \min_{\phi} \quad & E\left(\phi(\bar{X}) - \bar{X}\right)^2 \\ \text{subject to} \quad & \bar{X} \sim F_{\bar{X}} \\ & \phi(\bar{X}) \sim N(0,1) \end{aligned} \tag{8}$$

where $F_{\bar{X}}$ is the (fixed) CDF of $\bar{X} \equiv E(\psi(Y)|X)$. Notice that ϕ is necessarily a function of $\bar{X}$ alone (as opposed to X), for simple optimization considerations. Assuming that $\bar{X}$ and $U = \phi(\bar{X})$ are two separable metric spaces such that any probability measure on $\bar{X}$ (or U) is a Radon measure (i.e. they are Radon spaces), then (8) is simply an optimal transportation problem (Monge, 1781) with a strictly convex cost function (mean square error). We refer to $\phi^*(\bar{X})$ that minimizes (8) as the optimal map.

The optimal transportation problem was presented by Monge (1781) and has generated an important branch of mathematics. The problem originally studied by Monge was the following: assume we are given a pile of sand (in $\mathbb{R}^3$) and a hole that we have to completely fill up with that sand. Clearly the pile and the hole must have the same volume and different ways of moving the sand will give different costs of the operation. Monge wanted to minimize the cost of this operation. Formally, the optimal transportation problem is defined as

$$\inf\left\{\int_{\bar{X}} c(\bar{X}, \phi(\bar{X}))d\mu(\bar{X}) \middle| \phi_*(\mu) = \nu\right\}$$

where μ and ν are the probability measures of $\bar{X}$ and U respectively, $c(\cdot,\cdot)$ is some cost function and $\phi_*(\mu)$ denotes the push forward of μ by the map ϕ. Clearly, (8) is a special case of the optimal transportation problem where the $\mu = F_{\bar{X}}$, ν is a standard normal distribution and the cost function is the euclidean distance between the two.

Assume that $\bar{X} \in \mathbb{R}$ has finite p^{th} moments for $1 \leq p < \infty$ and a strictly continuous CDF, $F_{\bar{X}}$ (that is $\bar{X}$ is a strictly continuous random variable). Then, Rachev and Rüschendorf (1998) show that the optimal map (which minimizes (8)) is exactly $\phi^*(\bar{X}) = \Phi_N^{-1} \circ F_{\bar{X}}(\bar{X})$ where Φ_N^{-1} is the inverse CDF of a standard normal distribution. As shown by Rachev and

Rüschendorf (1998), the optimal map is unique and achieves

$$E\left(\left(\phi^*(\bar{X})-\bar{X}\right)^2\right)=\int_0^1\left(F_{\bar{X}}(s)-\Phi_N(s)\right)^2 ds. \tag{9}$$

Notice that the optimal map may be generalized to the multivariate case, as discussed in the next Section. The solution to the optimal transportation problem is in fact the "optimal projection" of our problem (8). Further, it allows us to quantify how much we lose from imposing the marginal normality constraint, compared with ACE's optimal projection.

Notice that the optimal map, $\phi^*(\bar{X})=\Phi_N^{-1}\circ F_{\bar{X}}(\bar{X})$, is simply marginal Gaussianization of $\bar{X}$: applying $\bar{X}$'s CDF to itself results in a uniformly distributed random variable, while Φ_N^{-1} shapes this uniform distribution into a standard normal. In other words, while the optimal projection of $\psi(Y)$ on X is its conditional expectation, the optimal projection under a normality constraint is simply a Gaussianization of the conditional expectation. The uniqueness of the optimal map leads to the following necessary conditions for an optimal solution to (6),

$$\begin{aligned}\phi(X)&=\Phi_N^{-1}\circ F_{E(\psi(Y)|X)}(E(\psi(Y)|X))\\ \psi(Y)&=\Phi_N^{-1}\circ F_{E(\phi(X)|Y)}(E(\phi(X)|Y)).\end{aligned} \tag{10}$$

As in ACE, these necessary conditions imply an alternating projection algorithm, namely, the Alternating Gaussinized Conditional Expectation (AGCE). Here, we begin by randomly choosing a transformation that only satisfies the normality constraint $\psi(Y)\sim N(0,1)$. Then, we iterate by fixing one of the transformation while optimizing the other, according to (10). We terminate once $E(\phi(X)\psi(Y))$ fails to increase, which means that we converged to a set of transformations that satisfy the necessary conditions for optimal solution. Algorithm 1 summarizes our suggested approach. Notice that in every step of our procedure, we may either:

1. Increase our objective value, as a result of the optimal map for (8).
2. Maintain with the same objective value and with the same transformation that was found in of the previous iteration, as we converged to (10).

This means that our alternating method generates a monotonically increasing sequence of objective values. Moreover, as written in Section 4, this sequence is bounded from above by the optimal correlation given by ACE. Therefore, according to the monotone convergence theorem, our suggested method converges to a local optimum.

Unfortunately, as opposed to ACE, our projection operator is not linear and we cannot claim for global optimality. We see that for different random initializations we converge to (a limited number) of local optima. Yet, AGCE provides an effective tool for finding local maximizers of (4), which together with MCMC (Gilks, 2005) initializations (or any other random search mechanisms) is capable of finding the global optimum.

4.3 Off-the-shelf lower bound

Although the AGCE method provides a (locally) optimal solution to (4), we would still like to consider a simpler "off-the-shelf" mechanism that is easier to implement and gives a lower

Algorithm 1 Alternating Gaussinized Conditional Expectations (AGCE) for the univariate case

Require: F_{XY}, the joint distribution function of X and Y.
Require: $g:\mathbb{R}\to\mathbb{R}$, a random mapping.
Set $\psi(Y)=\Phi_N^{-1}\circ F_{g(Y)}(g(Y))$.
Set $\phi(X)=\Phi_N^{-1}\circ F_{E(\psi(Y)|X)}(E(\psi(Y)|X))$.
Set $\rho=E(\phi(X)\psi(Y))$.
Set $T=0$
while $T\neq 1$ **do**
  Set $\psi(Y)=\Phi_N^{-1}\circ F_{E(\phi(X)|Y)}(E(\phi(X)|Y))$.
  Set $\phi(X)=\Phi_N^{-1}\circ F_{E(\psi(Y)|X)}(E(\psi(Y)|X))$.
  if $E(\phi(X)\psi(Y))\not>\rho$ **then**
    $T=1$
  else
    $\rho=E(\phi(X)\psi(Y))$
  end if
end while
return $\phi(X),\psi(Y),\rho$

bound to the best we can hope for. Here, we tackle (4) in two phases. In the first phase we would like to maximize the correlation objective, $E(UV)$, subject to the relaxed second order statistics constraints (as defined in (7)). Then, we enforce the marginal normality constraints by simply applying *separate Gaussianization* to the outcome of the first phase. In other words, we first apply ACE to increase our objective as much as possible, and then separately Gaussianize the results to meet the normality constraints, hoping this process does not reduce our objective "too much". Notice that in this univariate case, separate Gaussianization is achieved according to Theorem 2:

Theorem 2 *Let X be any random variable $X\sim F_X(x)$ and $\theta\sim Unif[0,1]$ be statistically independent of it. In order to shape X to a normal distribution the following applies:*

1. *Assume X is a non-atomic distribution ($F_X(x)$ is strictly increasing) then*

$$\Phi_N^{-1}\circ F_X(X)\sim N(0,1)$$

2. *Assume X is discrete or a mixture probability distribution then*

$$\Phi_N^{-1}\circ\left(F_X(X)-\theta P_X(x)\right)\sim N(0,1)$$

The proof of this theorem can be located in Appendix 1 of (Shayevitz and Feder, 2011). Theorem 2 implies that if X is strictly continuous then we may achieve a normal distribution by applying $\Phi_N^{-1}\circ F_X(X)$ to it, as discussed in the previous section. Otherwise, we shall handle its CDF's singularity points by randomly scattering them in a uniform manner, followed by applying Φ_N^{-1} to the random variable we achieved. Notice that this process do not allow any flexibility in the Gaussianization process. However, we show that in the

multivariate case (Section (5.3)) the equivalent process is quite flexible and allows us to control the correlation objective.

Further, notice that this lower bound is by no means a candidate for an optimal solution to (6), as it does not meet the necessary conditions described in (10). Yet, by finding both an upper and lower bounds (through ACE, and then separately Gaussianizing the result of ACE) we may immediately achieve the range in which the optimal solution necessarily resides. Assuming this range is not too large, one may settle for a sub-optimal solution without a need to apply AGCE at all.

4.4 Illustrative example

We now demonstrate our suggested methodology with a simple illustrative example. Let $X \sim N(0,1)$, $W \sim N(0,\epsilon^2)$ and $Z \sim N(\mu_z,1)$ be three normally distributed random variables, all independent of each other. Let P be a Bernoulli distributed random variable with a parameter $\frac{1}{2}$, independent of X, W and Z. Define Y as:

$$Y = \left\{ \begin{array}{ll} \text{X+W} & \text{P=0} \\ \text{Z} & \text{P=1} \end{array} \right\}.$$

Then, Y is a balanced Gaussian mixture with parameters

$$\theta_y = \left\{\mu_1 = 0, \sigma_1^2 = 1+\epsilon^2, \mu_2 = \mu_z, \sigma_2^2 = 1\right\}.$$

The joint probability density function of X and Y is also a balanced two-dimensional Gaussian mixture with parameters

$$\theta_{xy} = \left\{\mu_1 = \left[\begin{array}{c} 0 \\ 0 \end{array}\right], C_1 = \left[\begin{array}{cc} 1 & 1 \\ 1 & 1+\epsilon^2 \end{array}\right], \mu_2 = \left[\begin{array}{c} 0 \\ \mu_z \end{array}\right], C_2 = I\right\}.$$

Let us further assume that μ_z is large enough, and ϵ^2 is small enough, so that the overlap between the two Gaussian is negligible. For example, we set $\mu_z = 10$ and $\epsilon = 0.1$. The correlation between X and Y is easily shown to be $\rho_{xy} = \frac{1/2}{\sqrt{1+1/2\epsilon^2+1/4\mu_z}} = 0.098$. The mutual information between X and Y is defined as

$$I(X;Y) = h(X) + h(Y) - h(X;Y).$$

Since we assume that the Gaussians in the mixture practically do not overlap, we have that

$$h(Y) = -\int f_Y(y)\log f_Y(y)dy \approx \frac{1}{4}\log\left(2\pi e(1+\epsilon^2)\right) + \frac{1}{4}\log\left(2\pi e\right) + 1. \tag{11}$$

In the same manner,

$$h(X,Y) = -\int f_{X,Y}(x,y)\log f_{X,Y}(x,y)dxdy \approx \tag{12}$$
$$\frac{1}{4}\log\left((2\pi e)^2|C_1|\right) + \frac{1}{4}\log\left((2\pi e)^2|C_2|\right) + 1.$$

Plugging $\mu_z = 10$ and $\epsilon = 0.1$ we have that

$$I(X;Y) = h(X) + h(Y) - h(X;Y) \approx 1.66\text{bits}. \tag{13}$$

The scatter plot on the left of Figure 1 illustrates 10,000 independent draws of X and Y, where the blue circles corresponds to the "correlated samples" ($P = 0$) while the blue crosses are the "noise" ($P = 1$).

Before we proceed to apply our suggested methods, let us first examine two benchmark options for separate Gaussianization. As an immediate option, we may always apply separate Gaussianization, directly to X and Y, denoted as U_a and V_a respectively. This corresponds to Cardoso (2003) information geometry bound. Since X is already normally distributed we may set $U_a = X$ and only apply Gaussinization to Y. Let $V_a = \psi(Y)$ be the Gaussianization of Y. This means that

$$V_a = \Phi_N^{-1}\left(F_Y\left(Y\right)\right) = \Phi_N^{-1}\left(\Phi_{GM(\theta_y)}(Y)\right)$$

where $\Phi_{GM(\theta_y)}$ is the cumulative distribution function a Gaussian Mixture with the parameters θ_y described above. Therefore,

$$\rho_{u_a,v_a} = E(XV) = \frac{1}{2}E\left(X\Phi_N^{-1}\left(\Phi_{GM(\theta_y)}(X+W)\right)\right).$$

Although it is not possible to obtain a closed form solution to this expectation, it may be numerically evaluated quite easily, as X and W are independent. Assuming $\mu_z = 10$ and $\epsilon = 0.1$ we get that $\rho_{u_a,v_a} \approx 0.288$ and our lower bound on the mutual information, as appears in (3), is $I_g \equiv -\frac{1}{2}\log\left(1-\rho_{u_a,v_a}^2\right) \approx 0.0628$bits. The middle scatter plot of Figure 1 presents this separate marginal Gaussianization of the previously drawn 10,000 samples of X and Y. Notice that the marginal Gaussianization is a monotonic transformation, so that the Y samples are not being shuffled and maintain the separation between the two parts of the mixture. While the red circles are now "half Gaussian", the blue crosses are shaped in a curvy manner, so that their marginal distribution (projected on the y axis) is also a "half Gaussian", leading to a normal marginal distribution of Y. We notice that while the mutual information between X and Y is 1.66 bits, the lower bound attained by this naive Gaussianization approach is close to zero. This is obviously an unsatisfactory result.

A second benchmark alternative for separate Gaussianization is to take advantage of the Gaussian mixture properties. Since we assume that the two Gaussians of Y are practically separable, we may distinguish between observations from the two Gaussians. Therefore, we can simply reduce μ_z from the Z samples (the red circles), and normalize the observations of $X + W$. This way the transformed Y becomes a Gaussian mixture of two co-centered standard Gaussians, and no further Gaussianization is necessary. For $\mu_z = 10$ and $\epsilon = 0.1$, this leads to a correlation of

$$\rho_{u_b,v_b} = \frac{1}{2}E\left(\frac{1}{\sqrt{1+\epsilon^2}}(X+W)X\right) = \frac{1}{2}\frac{1}{\sqrt{1+\epsilon^2}} = 0.497 \tag{14}$$

and a corresponding mutual information lower bound of $I_g = 0.204$ bits. However, notice that the suggested transformation is not invertible and may cause a reduction in mutual information. Specifically, we now have that the joint distribution of $U_b = X$ and V_b follows a Gaussian mixture model with parameters:

$$\theta_{u_b,v_b} = \left\{\mu_1 = \left[\begin{array}{c} 0 \\ 0 \end{array}\right], C_1 = \left[\begin{array}{cc} 1 & \frac{1}{\sqrt{1+\epsilon^2}} \\ \frac{1}{\sqrt{1+\epsilon^2}} & 1 \end{array}\right], \mu_2 = \left[\begin{array}{c} 0 \\ 0 \end{array}\right], C_2 = I\right\}.$$

Therefore,

$$h(U_b, V_b) = -\int f_{U_b,V_b}(u,v)\log\left(f_{U_b,V_b}(u,v)\right)dudv = \tag{15}$$
$$-\int \phi_{GN(\theta_{u_b,v_b})}(u,v)\log\phi_{GN(\theta_{u_b,v_b})}(u,v)dudv \approx 3.1384\text{bits}$$

where $\phi_{GN(\theta_{u_b,v_b})}(u,v)$ is the probability density function of a Gaussian mixture with the parameters θ_{u_b,v_b} described above, and the last approximation step is due to numerical integration. This leads to $I(U_b;V_b) = 0.95$ bits.

To conclude, although the mutual information is reduced from 1.66 bits to 0.95 bits, the suggested bound increased quite dramatically, from 0.0628 bits to 0.204 bits. The right plot of Figure 1 demonstrates this customized separate Gaussianization (as it only applies for this specific setup) to the previously sampled X and Y. Again, we emphasis that this solution is not applicable in general, and is only feasible due to the specific nature of this Gaussian mixture model.

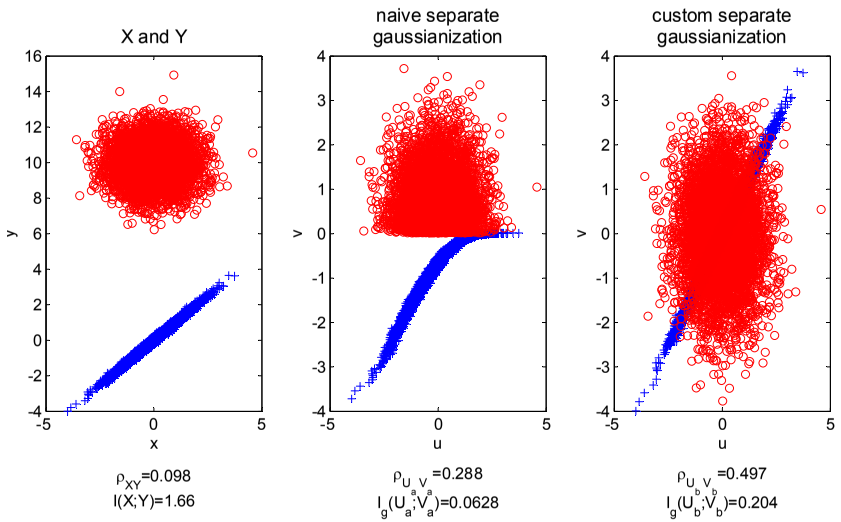

Figure 1: Univariate Gaussianization: Left: scatter of X and Y. Middle: naive separate Gaussianization to X and Y. Right: separate Gaussianization which considers the Gaussian Mixture model of X and Y, as described in the text.

Let us now turn to our suggested methods, as described in detail in the previous sections. We begin by applying the ACE procedure (Section 4.1), to attain an upper bound on our problem (6). Not surprisingly, ACE converges to a solution in which the samples of Y that are independent of X (the ones that come from Z) are set to zero,

while the rest are normalized to achieve an unit variance. Therefore, the resulting correlation is $\rho_{ub} = \frac{1/2}{\sqrt{1/2(1+\epsilon^2)}} = 0.703$. This results further implies that we can never find a Gaussianization procedure that will capture all the information between X and Y, as $I(X;Y) > -\log\left(1-\rho_{ub}^2\right) = 0.4917$ bits, according to Lemma 1. The left scatter plot of Figure 2 demonstrates the outcome of the ACE procedure, applied to the drawn $10,000$ samples of X and Y.

Next, we apply our suggested AGCE routine, described in Section 4.2. As discussed above, the AGCE only converges to a local optimum. Therefore, we initialize it with several random transformation (including the ACE solution that we just found). We notice that the number of convergence points is very limited and results in almost similar maxima. The middle scatter plot of Figure 4.2 shows the best result we achieve, leading to a correlation coefficient of 0.66 and a lower bound on a corresponding Gaussian lower bound (3) of 0.411 bits. This result demonstrates the power of our suggested approach, as it significantly improves the benchmarks, even compared with the U_b, V_b that considers the separable Gaussian mixture nature of our samples.

Finally, we evaluate a lower bound for (6), as described in Section 4.3. Here, we simply apply separate Gaussianization to the outcome of the ACE procedure. This results in $\rho_{lb} = 0.646$ and a corresponding $I_g = 0.389$. The right scatter plot of Figure 2 shows the Gaussianized samples the we achieve. We notice that this lower bound is not significantly lower than AGCE, suggesting that in some cases we may settle for this less involved method.

To conclude, our suggested solution surpasses the benchmarks quite easily, as we increase the lower bound from 0.204 bits using the custom Gaussianization procedure to 0.411 bits using our suggested solution. We notice that all of the discussed procedures result in joint distributions that are quite far from normal. This is not surprising, since X and Y were highly "non-normal" to begin with. Specifically, all of the suggested procedures lose information, compared with the original $I(X;Y) = 1.66$. However, our suggested solution minimizes this loss, and may be considered "more jointly normal" than others, in this regards.

5. The multivariate case

Let us now consider the multivariate case where both $\underline{X} \in \mathbb{R}^{d_x}$ and $\underline{Y} \in \mathbb{R}^{d_y}$ are random vectors with a joint CDF $F_{\underline{X},\underline{Y}}$. One of the fundamental differences from the univariate case is that Gaussianizing each of these vectors (even separately) is not a simple task. In other words, finding a transformation $\phi : \mathbb{R}^{d_x} \to \mathbb{R}^{d_u}$ such that $\underline{U} = \phi(\underline{X})$ is normally distributed may be theoretically straight-forward but practically involved.

For the simplicity of the presentation, assume that $\underline{X} = [X_1, X_2]^T$ is a two dimensional, strictly continuous, random vector. Then, Gaussianization may be achieved in two steps: first, apply marginal Gaussianization to X_1, so that $U_1 = \Phi_N^{-1} \circ F_{X_1}(X_1)$. Then, apply marginal Gaussianization on X_2, conditioned on each possible realization of the previous component, $U_2|u_1 = \Phi_N^{-1} \circ F_{X_2|U_1}(X_2|U_1 = u_1)$. This results in a jointly normally distributed vector $\underline{U} = [U_1, U_2]^T$. While this procedure is theoretically simple, it is quite problematic to apply in practice, as it requires Gaussianizing each and every conditional CDF. This is obviously impossible, given a finite number of samples. Yet, it gives us a constructive

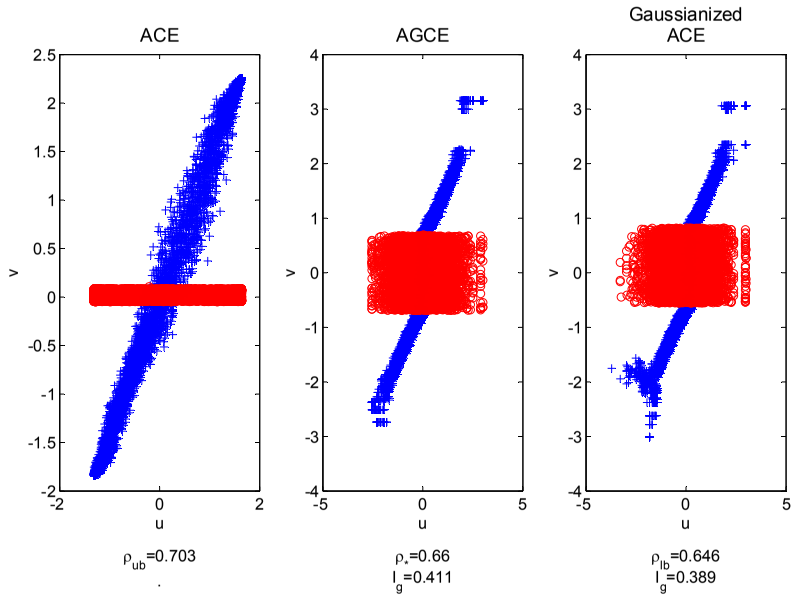

Figure 2: Our Suggested Univariate Gaussianization Schemes: Left: upper bound by ACE. Middle: (local) optimal solution by AGCE. Right: lower bound by separate Guassianization to ACE.

method, assuming that all the CDF's are known. In the following sections we shall present several alternatives for Gaussianization in a finite sample size setup.

5.1 Upper bound by ACE

As in the univariate case, we begin our analysis by relaxing the normality constraints with softer second order statistics constraints. This leads to an immediate multivariate generalization of the ACE procedure:

We begin by extracting the first canonical pair, which satisfies $U_1 = c \cdot E(V_1|\underline{X})$ and $V_1 = c \cdot E(U_1|\underline{Y})$. As in the univariate case, c is a normalization coefficient (the square root of the variance of the conditional expectation), and the optimization is done by alternating projections. Then, we shall extract the second pair of canonical components, subject to an orthogonality constraint with the first pair. It is easy to show that if V_2 is orthogonal to V_1, then $U_2 = c \cdot E(V_2|\underline{X})$ is orthogonal to U_1, and obviously maximizes the correlation with V_2. Therefore, we may extract the second canonical pair by first randomly assigning a zero-mean and unit variance V_2 that is also orthogonal to V_1 (by the Gram-Schmidt procedure, for example), followed by alternating conditional expectations with respect to V_2 and U_2, in the same manner as we did with the first pair. We continue this way for the rest of the

canonical pairs. As in the univariate case, convergence to a global maximum is guaranteed from the same Hilbert space arguments. As before, the multivariate ACE sets an upper bound to (5) as it maximizes a relaxed version of this problem.

Lemma 3 *Let $\underline{U}_*, \underline{V}_*$ be the outcome of multivariate ACE procedure (the canonical vectors). Assuming that $I(\underline{X};\underline{Y}) > \log\left|C_{[\underline{U}_*,\underline{V}_*]}\right|$, then there are no transformations such that $\underline{U} = \phi(\underline{X})$ and $\underline{V} = \psi(\underline{Y})$ follow a jointly normal distribution and preserve all of the mutual information, $I(X;Y)$.*

The proof of Lemma 3 follows exactly from the proof of Lemma 1. Here again, the multivariate ACE objective, $\log\left|C_{[\underline{U}_*,\underline{V}_*]}\right|$, cannot be further increased by artificially inflating the dimension of the problem. Therefore, Lemma 3 holds for any $\phi : \mathbb{R}^{d_x} \to \mathbb{R}^{d_u}$ and $\psi : \mathbb{R}^{d_y} \to \mathbb{R}^{d_v}$, such that $d_u, d_v \geq 0$.

5.2 multivariate AGCE

As with the multivariate ACE, we propose a generalized multivariate procedure for AGCE. We begin by extracting the first pair, in the same manner as we did in the univariate case. That is, we find a pair U_1 and V_1 that satisfies

$$\begin{aligned} U_1 &= \Phi_N^{-1} \circ F_{E(U_1|\underline{X})}(E(U_1|\underline{X})) \\ V_1 &= \Phi_N^{-1} \circ F_{E(V_1|\underline{Y})}(E(V_1|\underline{Y})) \end{aligned} \tag{16}$$

by applying the alternating optimization scheme. As we proceed to the second pair, we require that U_2 is both orthogonal and jointly normally distributed with U_1 (same goes for V_2 with respect to V_1). This means that the second pair needs not only to be orthogonal, but also statistically independent with the first pair. In other words, assuming V_2 is fixed, our basic projection step is

$$\begin{aligned} \max_{\phi_2} \quad & E\left(\phi_2(\underline{X})V_2\right) \\ \text{subject to} \quad & \phi_2(\underline{X}) \sim N(0,1) \\ & \phi_2(\underline{X}) \perp\!\!\!\perp \phi_1(\underline{X}). \end{aligned} \tag{17}$$

Let us denote a subspace $\tilde{\underline{X}} \subset \underline{X}$ that is statistically independent of $U_1 = \phi_1(\underline{X})$. Then, the problem of maximizing $E\left(\phi_2(\tilde{\underline{X}})V_2\right)$ subject to $\phi_2(\tilde{\underline{X}}) \sim N(0,1)$ is again solved by the optimal map, $\phi_2(\tilde{\underline{X}}) = \Phi_N^{-1} \circ F_{E(V_2|\tilde{\underline{X}})}(E(V_2|\tilde{\underline{X}}))$. Therefore, the remaining task is to find the "best" subspace $\tilde{\underline{X}} \subset \underline{X}$, so that $E\left(\phi_2(\tilde{\underline{X}})V_2\right)$ is maximal, when plugging the optimal map.

Proposition 4 *Let $U_1 = u_1$ be the value (realization) of U_1. Let $\tilde{\underline{X}} = g(\underline{X}, u_1)$ be a subspace of $\underline{X}$, independent of U_1. If $g(\underline{X}, u_1)$ is an invertible function with respect to $\underline{X}$ given u_1, then $\tilde{\underline{X}}$ is an optimal subspace for maximizing $E\left(\phi_2(\tilde{\underline{X}})V_2\right)$ subject to $\phi_2(\tilde{\underline{X}}) \sim N(0,1)$.*

Proof Assume there exists a different subspace $\underline{\tilde{X}}' = g'(\underline{X}, u_1)$ so that

$$\max_{\phi_2'} E\left(\phi_2'(\underline{\tilde{X}}')V_2\right) > \max_{\phi_2} E\left(\phi_2(\underline{\tilde{X}})V_2\right)$$

subject to the normality constraint. Since g is invertible we have that $\underline{X} = g^{-1}(\underline{\tilde{X}}, u_1)$. Therefore, $\underline{\tilde{X}}' = g'\left(g^{-1}(\underline{\tilde{X}}, u_1)\right) \equiv f(\underline{\tilde{X}}, u_1)$. Plugging this to the inequality above leads to

$$\max_{\phi_2'} E\left(\phi_2'(f(\underline{\tilde{X}}, u_1))V_2\right) > \max_{\phi_2} E\left(\phi_2(\underline{\tilde{X}})V_2\right)$$

which obviously contradicts the optimality of maximization over ϕ_2. ■

Therefore, we are left with finding $\underline{\tilde{X}} = g(\underline{X}, u_1)$ that is a subspace of $\underline{X}$, independent of U_1 and invertible with respect to $\underline{X}$ given u_1. For simplicity of the presentation, let us first assume that X is univariate. Then, the function $g(X, u_1) = F_{X|U_1}(X|U_1 = u1)$ is independent of U_1 (as it holds the same (uniform) distribution, regardless to the value of U_1), and invertible given u_1 (assuming that the conditional CDF's $F_{X|U_1}(X|U_1 = u1)$ are continuous for every u_1). Going back to the multivariate $\underline{X} \in \mathbb{R}^{d_x}$, we may follow the same rationale by choosing a single d_x-dimensional distribution that all the conditional CDF's, $F_{\underline{X}|U_1}$ will be shaped to. For simplicity we choose a d_x-dimensional uniform distribution, denoted by its CDF as F_{unif}. Then, $g_*\left(F_{\underline{X}|U_1}, u_1\right) = F_{unif}$, where $g_*(P, x) = Q$ refers to a mapping that pushes forward the distribution P into Q, given x. Specifically, if $p(w)$ and $q(w)$ are the corresponding density functions of the (absolutely continuous) CDF's P and Q respectively, then we know from basic probability theory that the push forward transformation S satisfies

$$p(w) = q\left(S(w)\right)\left|J_S\left(S(w)\right)\right|$$

where J_S is the Jacobian operator of the map S.

To conclude, in order to construct $\underline{\tilde{X}}$ that is independent of U_1 and invertible given u_1, we need to push forward all the conditional CDF's $F_{\underline{X}|U_1}(\underline{X}|U_1 = u_1)$ into a predefined distribution (say, uniform). Then, the optimal map $\phi_2(\underline{\tilde{X}})$ that maximizes $E\left(\phi_2(\underline{\tilde{X}})V_2\right)$ subject to $\phi_2(\underline{\tilde{X}}) \sim N(0,1)$ is given by $\phi_2(\underline{\tilde{X}}) = \Phi_N^{-1} \circ F_{E(V_2|\underline{\tilde{X}})}(E(V_2|\underline{\tilde{X}}))$. In the same manner, we may find $\underline{\tilde{Y}}$ that is independent of V_1 and invertible given v_1, and carry on with the alternating projections. This process continues for all the Gaussinized canonical components and converges to a local optimum, from the same considerations described in the univariate case.

It is important to notice that while this procedure may be considered practically infeasible (as it requires estimating the conditional CDF's), it is equivalently impractical as the multivariate Gaussianization considered in the beginning of this section. Yet, it gives us a local optimum for our problem, assuming that the joint probability distribution is known.

5.3 Off-the-shelf lower bound in the multivariate case

In the same manner as with the univariate case, we may apply a simple off-the-shelf lower bound to (4) by first maximizing the objective as much as we can (using multivariate ACE) followed by Gaussianizing the outcome vectors, hoping we do not reduce the objective

"too much". However, as mentioned in the beginning of Section 5, applying multivariate Gaussianization may be practically infeasible. Therefore, we begin this section by reviewing practical multivariate Gaussianization methodologies. Then, we use these ideas to suggest a practical lower bound, which unlike the univariate case, is not oblivious to our objective.

5.3.1 Practical multivariate Gaussianization

The Gaussianization procedure strives to find a transformation $\underline{Z} = \mathcal{G}(\underline{X})$ so that $\underline{Z} \sim N(0, I)$. A reasonable a cost function for describing "how Gaussian" $\underline{Z}$ really is, may be the Kullback Leibler divergence (KLD) between $\underline{Z}$'s PDF, $f_{\underline{Z}}(\underline{z})$, and a standard normal distribution,

$$J(\underline{Z}) = D_{KL}\left(f_{\underline{Z}}(\underline{z})||f_N(\underline{Z})\right) = \int_{\underline{Z}} f_{\underline{Z}}(\underline{z}) \log\left(\frac{f_{\underline{Z}}(\underline{z})}{f_N(\underline{Z})}\right) dz$$

where $f_N(\underline{Z})$ is the PDF of a standard normal distribution. As shown by Chen and Gopinath (2001), $J(\underline{Z})$ may be decomposed into

$$J(\underline{Z}) = D_{KL}\left(f_{\underline{Z}}(\underline{z})||\prod_{i=1}^{d_z} f_{Z_i}(z_i)\right) + \sum_{i=1}^{d_z} D_{KL}\left(f_{Z_i}(z_i)||f_N(z_i)\right) \tag{18}$$

where the first term quantifies how independent are the components of $\underline{Z}$, and the second term indicates how normally distributed they are. This decomposition led Chen and Gopinath (2001) to an iterative algorithm. In each iteration, their suggested approach applies Independent Component Analysis (Hyvärinen et al., 2004), to minimize the first term, followed by marginal Gaussianization of each component (as we describe for the univariate case), to minimize the second term. Chen and Gopinath show that minimizing one term does not effect the other, which leads to a monotonically decreasing procedure that converges once $\underline{Z}$ is normally distributed.

Notice that the Independent Component Analysis (ICA) is a linear operator. Therefore, if $\underline{Z}$ can be linearly decomposed into independent components, then Chen and Gopinath's Gaussianizion process converges in a single step. Moreover, notice that this Gaussianization process does not require estimating the multivariate distribution. However, it does require estimating the marginals, f_{Z_i} which is considered a much easier task, in general.

A similar yet different multivariate Gaussianization approach was suggested by Laparra et al. (2011). Here, the authors propose to replace the computationally costly ICA with a simple random rotation matrix. This way, they abandon the effort of minimizing the first term of (18), and only shuffle the components so that consequent marginal Gaussianization would further decrease $J(\underline{Z})$. Although this approach takes more iterations to converge to a normal distribution (as in each iteration, only the second term of (18) is being minimized), it holds several favorable properties. First, the overall run-time is dramatically shorter, since applying random rotations is much faster then applying linear ICA. Second, it implies a degree of freedom in choosing the rotation matrix, as the suggested random matrix is just one example of linear shuffling of the components.

5.3.2 Bi-terminal multivariate Gaussianization

Going back to our problem, we would like to Gaussinize $\underline{U}_*$ and $\underline{V}_*$, the outcomes of the multivariate ACE procedure described above. Ideally, we would like to do so while refraining

(as much as we can) from reducing our objective,

$$\log\left(\frac{\left|C_{[\underline{U}_*,\underline{V}_*]}\right|}{|C_{\underline{U}_*}||C_{\underline{V}_*}|}\right). \tag{19}$$

Following the Gaussianization procedures described in the previous section, we suggest an iterative process, where in each iteration we apply a rotation matrix to both vectors, followed by marginal Gaussianization to each of the components of the two vectors. It is easy to show that (19) is invariant to full rank linear transformations. However, it may be effected by the (non-linear) marginal Gaussianization of the components (as described in Theorem 2). Therefore, we would like to find rotation matrices that minimize the effect of the consequent marginal Gaussianization step. This problem is far from trivial. In fact, due to the complicated nature of the marginal Gaussianization procedure, it is quite impossible to minimize the effect of the marginal Gaussianization a-priori, without actually applying it and see how it effects (19). Therefore, we suggest a stochastic search mechanism, which allows us to construct a "reasonable" rotation matrix.

Our suggested mechanism works as follow: At each iteration we begin by drawing two random rotation matrices R_1 and R_2 for the two vectors we are to Gaussianize, just like Laparra et al. (2011). We apply marginal Gaussianization to all the components and evaluate our objective (19). Then, we randomly choose two dimensions and an angle, θ, and construct a corresponding rotation matrix $\tilde{R}$ that rotates the space spanned by the two dimensions in θ degrees. We apply $\tilde{R}\cdot R_1$ to our vector, followed by marginal Gaussianization, and again evaluate (19). If the objective increases we assign $R_1 = \tilde{R}\cdot R_1$. We repeat this process a configurable number of times, for the two vectors we are to Gaussianize.

Notice that our suggested procedure applies a stochastic hill climbing (SHC) search in each step: it randomly searches for the best rotation matrix by gradually composing "small" rotation steps (of two dimensions and an angle), as the complete search space is practically infinite. This procedure guarantees to converge to two multivariate normal vectors, as shown by Laparra et al. (2011), under the reasonable assumption that R_1 and R_2 do not repeatedly converge to identity matrices. Our suggested approach is described in detail in Algorithm 2.

As we see in our experiments, the Bi-terminal Gaussianization process is superior to naively applying a Gaussianization procedure to each of the vectors separately (as suggested by Chen and Gopinath (2001) or Laparra et al. (2011)), in all the cases we examine.

5.4 Illustrative examples

We now examine our suggests multivariate approach in different setups. As in the univariate case, we draw samples from a given model and bound from below the mutual information $I(\underline{X},\underline{Y})$ according to (3). First, we apply the multivariate ACE procedure (Section 5.1) to achieve an upper bound to our objective. Then, we apply separate Gaussianization to ACE's outcome, to attain an immediate lower bound (Section 5.3.1). Further, we tighten this lower bound by replacing the separate Gaussianization with bi-terminal Gaussianization to ACE's outcome (Section 5.3.2). Since our multivariate AGCE procedure (Section 5.2) is practically infeasible, we refrain from using it. This would be further justified later in our results, as we see that the gap between the lower and upper bounds is relatively small. In

Algorithm 2 Bi-terminal multivariate Gaussianization

Require: $\underline{X} \in \mathbb{R}^{d_x}$, $\underline{Y} \in \mathbb{R}^{d_y}$.
Require: Th, a Gaussianization convergence threshold and N, the SHC parameter.
Set $\underline{U} = \underline{X}$ and $\underline{V} = \underline{Y}$.
Set $J_U = J(\underline{U})$ and $J_V = J(\underline{V})$ according to (18).
while $J_U \geq Th$ OR $J_V \geq Th$ **do**
  Draw a rotation martix R_1 of dimensions $d_x \times d_x$ and set $\underline{U}^* = R_1\underline{U}$.
  Draw a rotation matrix R_2 of dimensions $d_y \times d_y$ and set $\underline{V}^* = R_2\underline{V}$.
  Apply marginal Gaussianization to $\underline{U}^*$ and $\underline{V}^*$.
  Set $\rho^* = \log\left(\frac{\left|C_{[\underline{U}^*,\underline{V}^*]}\right|}{|C_{\underline{U}^*}||C_{\underline{V}^*}|}\right)$.
  for all $n = 1$ to N **do**
    Draw an angle θ.
    Draw (without replacement) two dimensions d_a, d_b from the set $\{1,\ldots,d_x\}$.
    Construct a rotation matrix $\tilde{R}$ from θ, d_a, d_b and set $\tilde{\underline{U}} = \tilde{R}R_1\underline{U}$.
    Apply marginal Gaussianization to $\tilde{\underline{U}}$.
    Set $\tilde{\rho} = \log\left(\frac{\left|C_{[\tilde{\underline{U}},\underline{V}^*]}\right|}{|C_{\tilde{\underline{U}}}||C_{\underline{V}^*}|}\right)$.
    if $\tilde{\rho} > \rho^*$ **then**
      Set $R_1 = \tilde{R}R_1$, $\underline{U}^* = \tilde{\underline{U}}$ and $\rho^* = \tilde{\rho}$.
    end if
    Draw an angle θ.
    Draw (without replacement) two dimensions d_a, d_b from the set $\{1,\ldots,d_y\}$.
    Construct a rotation matrix $\tilde{R}$ from θ, d_a, d_b and set $\tilde{\underline{V}} = \tilde{R}R_2\underline{U}$.
    Apply marginal Gaussianization to $\tilde{\underline{V}}$.
    Set $\tilde{\rho} = \log\left(\frac{\left|C_{[\underline{U}^*,\tilde{\underline{V}}]}\right|}{|C_{\underline{U}^*}||C_{\tilde{\underline{V}}}|}\right)$.
    if $\tilde{\rho} > \rho$ **then**
      Set $R_2 = \tilde{R}R_2$, $\underline{V}^* = \tilde{\underline{V}}$ and $\rho^* = \tilde{\rho}$.
    end if
  end for
  Set $\underline{U} = \underline{U}^*$ and $\underline{V} = \underline{V}^*$.
  Set $J_U = J(\underline{U})$ and $J_V = J(\underline{V})$ according to (18).
end while
return $\underline{U}, \underline{V}, \rho^*$.

all of our experiments, our benchmark would be a direct separate Gaussianization of $\underline{X}$ and $\underline{Y}$, as an immediate alternative.

We begin with a simple toy example. Let $\underline{X} \sim N(0, I)$ and $\underline{W} \sim N(0, I)$ be independent random vectors. Define $\underline{Y} = \underline{X} + \underline{W}$, so that $\underline{X}$ and $\underline{Y}$ are jointly normally distributed. Further, we "scramble" $\underline{X}$ and $\underline{Y}$ by applying invertible, yet non-monotonic, transformations to each of them separately. We ask that the transformations are invertible to guarantee that the (analytically derived) mutual information is preserved. We further require non-monotonic transformations since marginal Gaussianization is invariant to monotonic functions (see Proposition 5), which would make this experiment too easy. In this experiment, we multiply all the observations in the range $[-1, 1]$ by -1. This operation simply mirrors these observations with respect to the origin.

Proposition 5 *Let $\tilde{X} = g(X)$ be a monotonic transformation on $X \in \mathbb{R}$. Then Gaussinizing $\tilde{X}$ is equivalent to Gaussinizing X.*

Proof Let $\tilde{V} = \Phi_N^{-1}\left(F_{\tilde{X}}\left(\tilde{X}\right)\right)$ be the Gaussianization $\tilde{X}$ and $V = \Phi_N^{-1}\left(F_X\left(X\right)\right)$ is the Gaussianization of X. Assume that g is monotonically increasing. Then,

$$F_{\tilde{X}}(a) = P(\tilde{X} \leq a) = P(g(X) \leq a) = P(X \leq g^{-1}(a)).$$

Therefore, $F_{\tilde{X}}\left(\tilde{X}\right) = F_X\left(g^{-1}(\tilde{X})\right) = F_X(X)$ and $\tilde{V} = V$. An equivalent derivation holds for the monotonically decreasing case. ■

Before we proceed, it is important to briefly comment on the implications of the finite sample size in our multivariate experiments. The ACE procedure estimates conditional expectations at each of its iterations. This estimation task is known to be quite challenging in a finite sample size regime. Breiman and Friedman (1985) suggest a *k nearest neighbor* estimator which guarantees favorable consistency properties. Unfortunately, this solution suffers from the curse of dimensionality (Hastie et al., 2005). Therefore, as the dimension of our problem increases, we cannot turn to ACE and have to settle for suboptimal solutions. In our experiments, we use the kernel CCA (Lai and Fyfe, 2000) as an alternative to ACE when the dimension size is greater than $d = 5$. The kernel CCA (KCCA) is a non-linear generalization to the classical CCA which embeds the data in a high-dimensional Hilbert space and applies CCA in that space. It is known to significantly improve the flexibility of CCA while avoiding over-fitting of the data. Notice that other non-linear CCA extensions, such as *Deep CCA* (Andrew et al., 2013) or *nonparametric CCA* (Michaeli et al., 2016), may also apply as a finite sample size alternative to ACE.

We now demonstrate our suggested approach to the jointly Gaussian model discussed above. The left plot of Figure 3 demonstrates the results we achieve for different dimension sizes d. The black line on the top is $I(\underline{X}, \underline{Y})$, which can be analytically derived. The red curve with the squares at the bottom is separate Gaussianization of $\underline{X}$ and $\underline{Y}$, which results in a very poor lower bound to the mutual information due to the non-monotonic nature of the transformation that we apply. The green curve with the circles is ACE, while the dashed blue curve is separate Gaussianization of ACE. Finally, the blue line between them is bi-terminal Gaussianization of ACE. As we can see, ACE succeeds in recovering the jointly Gaussian

representation of $\underline{X}$ and $\underline{Y}$, which makes further Gaussianization redundant. Unfortunately, for $d > 5$ we can no longer apply ACE and turn to KCCA instead. We use a Gaussian kernel with varying parameters to achieve the reported results. Since the KCCA attains a suboptimal representation it is followed by Gaussianization, which further decreases our objective. Here, we notice the improved effect of the bi-terminal Gaussianization, compared with separate Gaussianization.

Next, we turn to a more challenging exponential model. In this model, each component of $\underline{X}$ and $\underline{W}$ is exponentially distributed with a unit parameter, while all the components are independent of each other. Again, we define $\underline{Y} = \underline{X} + \underline{W}$ so that $\underline{Y}$ is Gamma distributed. This allows us to analytically derive $I(\underline{X}, \underline{Y})$. As before, we apply an invertible non-monotonic transformation to each of the components of $\underline{X}$ and $\underline{Y}$. Notice that this time we mirror the observations in the range $[0, 2]$ with respect to 1. We then apply a linear rotation, so that the components are no longer independent. The plot in the middle of Figure 3 demonstrates the results we achieve. As before, we notice that separate Gaussianzation of $\underline{X}$ and $\underline{Y}$ preforms very poorly. On the other hand, ACE as well does not succeed in maintaining the MI. This means that no Gaussianzation procedure would allow jointly normal representation of $\underline{X}$ and $\underline{Y}$ without losing information (Lemma 3). Still, by applying bi-terminal Gaussianization to ACE's results we are able to capture more than half of the information in the worst case (for $d = 5$, where ACE still applies). As before, we witness a reduction of performance when turning from ACE to KCCA.

Finally, we go back to the multivariate extension of the Gaussian mixture model described in Section 4.4 and apply our suggested procedures. Again, we witness the same behavior described in the previous experiments. In addition, our results indicate that in this model, the Gaussian part of the MI is significantly smaller, compared with the exponential model. This further demonstrates the ability of our method to quantify how well an arbitrary distribution may be represented as jointly normal.

6. Gaussian lower bound for the Information Bottleneck Curve

We now extended our derivation to the Information Bottleneck (IB) curve. We show that by maximizing the Gaussian lower bound of the mutual information (3), we allow a maximization of a Gaussian lower bound to the entire IB curve. We prove this in two steps. First, we show that the IB curve of $\phi(\underline{X}), \psi(\underline{Y})$ bounds from below the IB curve of X and Y, for any choice of ϕ, ψ (specifically, $\phi(\underline{X}) \sim N$ and $\psi(\underline{Y}) \sim N$, in our case). This property is referred to as the *data processing lemma for the IB curve*. Then, we show that the IB curve of jointly normal random variables bounds from below the IB curve of separately normal random variable. Finally, by applying the GIB (Chechik et al., 2005) to the maximally correlated jointly normal random variables that satisfy (3), we attain the desired Gaussian lower bound for the IB of $\underline{X}$ and $\underline{Y}$.

Lemma 6 *(data processing lemma for the IB Curve): Let (20) be the equivalent maximization problem of the IB problem (1):*

$$\begin{aligned} \max_{T} \quad & I(T(\underline{X}); \underline{Y}) \\ \textit{subject to} \quad & I(T(\underline{X}); \underline{X}) \leq I_X. \end{aligned} \tag{20}$$

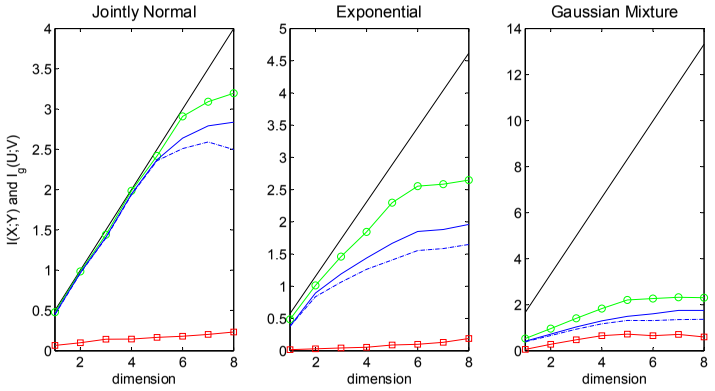

Figure 3: Multivariate Gaussianization experiments: The black line on the top of each plot is $I(\underline{X},\underline{Y})$. The red curve with the squares at the bottom is separate Gaussianization of $\underline{X}$ and $\underline{Y}$. The green curve with the circles is ACE, while the dashed blue curve is separate Gaussianization of ACE. The blue line in between is bi-terminal Gaussianization of ACE.

Denote its solution as $I_*^\beta(\underline{X};\underline{Y})$. *Then,* $I_*^\beta(\underline{X};\underline{Y}) \geq I_*^\beta(\phi(\underline{X});\psi(\underline{Y}))$ *for any* ϕ,ψ, *and with equality iff* $I(\underline{X};\underline{Y}) = I(\phi(\underline{X});\psi(\underline{Y}))$.

Proof We prove this lemma by showing that $I_*^\beta(\underline{X};\underline{Y}) \geq I_*^\beta(\underline{X};\psi(\underline{Y})) \geq I_*^\beta(\psi(\underline{X});\psi(\underline{Y}))$. We start with the first inequality. According to the data processing lemma, we have that $I(T(\underline{X});\underline{Y}) \geq I(T(\underline{X});\psi(\underline{Y}))$. Notice that for convenience, we emphasize that T is indeed a mapping of X alone. In addition, since our constraint (1) is independent of Y, we have that $I_*^\beta(\underline{X};\underline{Y}) \geq I_*^\beta(\underline{X};\psi(\underline{Y}))$, as desired. Second, denote the minimizer of (1) as $I_*(\underline{X};\underline{Y})$. Assume that there exists such ϕ that

$$I_*(\underline{X};\underline{Y}) > I_*(\phi(\underline{X});\underline{Y}). \tag{21}$$

This means that for $I(T(\underline{X});\underline{Y}) \geq I_Y$ and $I(T'(\phi(\underline{X}));\underline{Y}) \geq I_Y$ we have that $I(T(\underline{X});\underline{X}) > I(T'(\phi(\underline{X}));\phi(\underline{X}))$ where T and T' are the optimizers of (1) with respect to $(\underline{X},\underline{Y})$ and $(\phi(\underline{X}),\underline{Y})$, for a given I_Y, respectively. Let us set $\bar{T} \equiv T' \circ \phi$ and apply this transformation to $\underline{X}$. Then, we have that the constraint of (1) is met, as $I(\bar{T}(\underline{X});\underline{Y}) \equiv I(T'(\phi(\underline{X}));\underline{Y}) \geq I_Y$. In addition, we have that

$$I(\bar{T}(\underline{X});\underline{X}) \equiv I(T'(\phi(\underline{X}));\underline{X}) = I(T'(\phi(\underline{X}));\phi(\underline{X}))$$

where the second equality follows from T' being independent of $\underline{X}$, given $\phi(\underline{X})$. Therefore, $\bar{T} = T' \circ \phi$ is a better optimizer to (1) with respect to $\underline{X}$ and $\underline{Y}$, then T. This contradicts the optimality of T as a minimizer of (1), which means that the assumption in (21) is false. Therefore, $I_*(\underline{X};\underline{Y}) \leq I_*(\phi(\underline{X});\underline{Y})$ which means that $I_*^\beta(\underline{X};\underline{Y}) \geq I_*^\beta(\phi(\underline{X});\underline{Y})$ for any $\underline{Y}$ (specifically, $\phi(\underline{Y})$) and our proof is concluded. ■

Lemma 7 *Let* $\underline{U}$ *and* $\underline{V}$ *be separately Gaussian random vectors with a joint covariance matrix* $C_{[\underline{U},\underline{V}]}$ *(that is,* $\underline{U} \sim N$ *and* $\underline{V} \sim N$ *but* $[\underline{U},\underline{V}]^T$ *is not normally distributed). Let* $\underline{U}_{jg},\underline{V}_{jg}$ *be two jointly normally distributed random vectors with the same covariance matrix,* $C_{[\underline{U}_{jg},\underline{V}_{jg}]} = C_{[\underline{U},\underline{V}]}$. *Then, the IB curve of* $\underline{U}_{jg}$ *and* $\underline{V}_{jg}$ *bounds from below the IB curve of* $\underline{U}$ *and* $\underline{V}$.

Proof Let $\big(I(\underline{U}_{jg};\underline{T}), I(\underline{T};\underline{V}_{jg})\big)$ be a point of the IB curve of $\underline{U}_{jg}$ and $\underline{V}_{jg}$. Since $\underline{U}_{jg}$ and $\underline{V}_{jg}$ are jointly normally distributed, T is necessarily a linear transformation of $\underline{U}_{jg}$, with additive independent Gaussian noise (Chechik et al., 2005). Specifically, $T = A\underline{U}_{jg} + \underline{\zeta}$, where $\underline{\zeta} \sim N(0,I)$, independent of $\underline{U}_{jg}$ and $\underline{V}_{jg}$.

Further, let $\underline{T}' = A\underline{U} + \underline{\zeta}$ be the same transformation, applied of $\underline{U}$. Since $\underline{U}$ and $\underline{V}$ are not jointly normal, the point $(I(\underline{U};\underline{T}'), I(\underline{T}';\underline{V}))$ is below the IB curve of $\underline{U}$ and $\underline{V}$. First, notice that

$$I(\underline{U};\underline{T}') \equiv I(\underline{U};A\underline{U}+\underline{\zeta}) = I(\underline{U}_{jg};A\underline{U}_{jg}+\underline{\zeta}) \equiv I(\underline{U}_{jg},\underline{T})$$

where the second equality follows from $\underline{U}$ and $\underline{U}_{jg}$ having the same distribution. In addition, since $C_{[\underline{U}_{jg},\underline{V}_{jg}]} = C_{[\underline{U},\underline{V}]}$ we have that $C_{[A\underline{U}_{jg}+\underline{\zeta},\underline{V}_{jg}]} = C_{[A\underline{U}+\underline{\zeta},\underline{V}]}$. Therefore, $I(A\underline{U}+\underline{\zeta};\underline{V}) \geq I(A\underline{U}_{jg}+\underline{\zeta};\underline{V}_{jg})$, in the same manner as the in (3). This means that $I(\underline{T}';\underline{V}) \geq I(\underline{T};\underline{V}_{jg})$. To conclude, we showed that for the two pairs, $\big(I(\underline{U}_{jg};\underline{T}), I(\underline{T};\underline{V}_{jg})\big)$ and $(I(\underline{U};\underline{T}'), I(\underline{T}';\underline{V}))$, we have that $I(\underline{U};\underline{T}') = I(\underline{U}_{jg},\underline{T})$ while $I(\underline{T}';\underline{V}) \geq I(\underline{T};\underline{V}_{jg})$, as desired. ■

The two theorems above guarantee that the IB curve of $\underline{X}$ and $\underline{Y}$ is bounded from below by the IB curve of $\underline{U}_{jg}$ and $\underline{V}_{jg}$, where $C_{[\underline{U}_{jg},\underline{V}_{jg}]} = C_{[\underline{U},\underline{V}]}$, and $\underline{U} = \phi(\underline{X}) \sim N$, $\underline{V} = \psi(\underline{Y}) \sim N$. Therefore, in order to maximize this lower bound, one needs to maximize the correlation between $\underline{U}$ and $\underline{V}$, subject to a normality constraint, as discussed throughout this manuscript. Moreover, once we have found a pair of $(\underline{U}_{jg},\underline{V}_{jg})$ with a maximal correlation, we may directly apply the GIB to it, as shown by Chechik et al. (2005), to achieve the optimal Gaussian lower bound oIB curve for $\underline{X}$ and $\underline{Y}$.

6.1 Examples

We now demonstrate our suggested Gaussian lower bound for the IB curve in two different setups. Here, we would like to compare our bound with the "true" IB curve, and with an additional benchmark off-the-shelf lower bound. As discussed in Section 1, computing the exact IB curve (for a general joint distribution) is not a simple task. This task becomes even more complicated when dealing with continuous random variables. In fact, to the best of our knowledge, all currently known methods provide approximated curves, which do not claim to converge to the exact IB curve. Moreover, these methods fail to provide any guarantees on the extent of their divergence from the true IB curve. Therefore, in our experiments, we apply the commonly used reverse annealing technique (Slonim, 2002) in order to approximate the "true" IB curve. The reverse annealing algorithm is initiated by computing the mutual information between $\underline{X}$ and $\underline{Y}$, which corresponds to extreme point where $I_Y \to \infty$ on the IB curve. Then, I_Y is gradually decreased and the solution of the IB problem (1) with the previous value of I_Y serves as a starting point to the currently solved I_Y. This results in a greedy "no-regret" optimization method, which in general, fails to

converge to the exact IB curve. However, in some special cases (such as the GIB), it can be shown that the optimal solution for a given value of I_Y is, in fact, the optimal starting point for a smaller value of I_Y. In the general case, it is implicitly assumed to be a reasonable local optimization domain. Since the reverse annealing was originally designed for discrete random variables, we apply discretization (via Gaussian quadratures) to our probability distributions is all of our experiments.

We begin by revisiting the exponential model, described in Section 5.4. In this model, X and W are independent exponentially distributed random variables with a unit parameter. We define $Y = X + W$ so that Y is Gamma distributed. As in Section 5.4 we apply an invertible non-monotonic transformation to X and Y, to make this problem more challenging. Since approximating the IB curve is involved enough for continuous random variables, we limit our attention to the simplest univariate case.

The plot on the left of Figure 4 demonstrates the results we achieve. The black curve on top is the approximated IB curve, using the reverse annealing procedure. The red curve on the bottom is a benchmark lower bound, achieved by simply applying the GIB to X and Y, as if they were jointly Gaussian. The blue curve in the middle is our suggested Gaussian lower bound (Section 4.2). As we can see, our suggested bound surpasses the GIB quite remarkably. This is mainly due to the non-monotonic transformation we apply, which makes the joint distribution highly non-Gaussian. We further notice that our bound is quite tight for smaller I_Y's (closer to the origin) but increasingly diverges as I_Y increases. The reason is that more compressed representations are more "degenerate" and are easier to Gaussianize while maintaining reasonably high correlations.

Next, we revisit the more challenging Gaussian mixture model, described in Section 4.4. The right plot in Figure 4 demonstrates the results we achieve. As before, we notice that our suggested lower bound surpasses the naive benchmark, while demonstrating favorable performance closer to the origin. Comparing the two models, we notice that the Gaussian mixture is more difficult to bound from below using our suggested method. This result is not surprising, given the gap in our ability to bound from below the mutual information in these two models, as discussed in Section 5.4.

7. Discussion and conclusion

In this work we address the fundamental problem of normalizing non-Gaussian data, while trying to avoid loss of information. This allows us to solve complex problems by linear means, as we push information to the data's second moments. We show that our ability to do so is strongly governed by the non-linear canonical correlations of the data. In other words, if the non-linear canonical coefficients of the data fail to maintain its mutual information, then it is impossible to describe its high order dependencies just by second order statistics. This result is of high interest to a broad variety of applications, as solving non-linear problems by linear means is a common alternative in many scientific and engineering fields. Further, we provide a variety of methods to quantify the minimal amount of information that may be lost when normalizing the data. We show that in many cases, our suggested approach is able to preserve a significant portion of the information, even for highly non-Gaussian joint distributions. Our results improve upon Cardoso (2003) information geometry bound, as we show that a tighter bound may be obtained by the AGCE method.

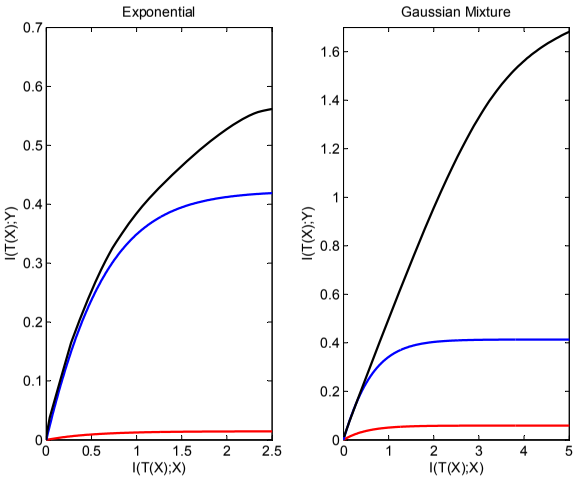

Figure 4: Bounding the Information Bottleneck curve for Exponential and Gaussian Mixture distributions: The black line is the approximated IB curve and the blue line is our suggested Gaussian lower bound. The red curve is achieved by applying the GIB directly to X, Y.

It is important to mention that while our suggested approach is theoretically found, it exhibits several practical limitation in a finite sample-size setup. This is a direct result of our use of the ACE algorithm, which suffers from the curse of dimensionality when applied to high-dimensional data. Therefore, we further examine different non-linear CCA methods, which are less vulnerable to this problem. However, these methods fail to converge to the optimal canonical coefficients.

Finally, we show that our results may be generalized to bound from below the entire information bottleneck curve. This allows a practical alternative for different approximation methods and restrictive solutions to the involved IB problem in the continuous case. Our experiments show that the suggested Gaussian lower bound provides a meaningful benchmark to the IB curve, even in highly non-Gaussian setups.

Abstract

This paper introduces `tick`, is a statistical learning library for Python 3, with a particular emphasis on time-dependent models, such as point processes, tools for generalized linear models and survival analysis. The core of the library provides model computational classes, solvers and proximal operators for regularization. It relies on a C++ implementation and state-of-the-art optimization algorithms to provide very fast computations in a single node multi-core setting. Source code and documentation can be downloaded from `https://github.com/X-DataInitiative/tick`.

Keywords: Statistical Learning; Python; Hawkes processes; Optimization; Generalized linear models; Point Process; Survival Analysis

1. Introduction

The aim of the `tick` library is to provide for the Python community a large set of tools for statistical learning, previously not available in any framework. Though `tick` focuses on time-dependent modeling, it actually introduces a set of tools that go way beyond this particular set of models, thanks to a highly modular optimization toolbox. It benefits from thorough documentation (including tutorials with many examples), and a strongly tested Python API that brings to the scientific community cutting-edge algorithms with a high level of customization. Optimization algorithms such as SVRG (Johnson and Zhang, 2013) or SDCA (Shalev-Shwartz and Zhang, 2013) are among the several optimization algorithms available in `tick` that can be applied (in a modular way) to a large variety of models. An emphasis is placed on time-dependent models: from the Cox regression model (Andersen et al., 2012), a very popular model in survival analysis, to Hawkes processes, used in a wide range of applications such as geophysics (Ogata, 1988), finance (Bacry et al., 2015) and more recently social networks (Zhou et al., 2013; Xu et al., 2016). To the best of our knowledge, `tick` is the most comprehensive library that deals with Hawkes processes, since it brings parametric and nonparametric estimators of these models to a new accessibility level.

2. Existing Libraries

The `tick` library follows, whenever possible, `scikit-learn`'s API (Pedregosa et al., 2011; Buitinck et al., 2013) which is well-known for its completeness and ease of use. However, while `scikit-learn` targets a wide spectrum, `tick` has a more specific objective: implementing highly-optimized algorithms with a particular emphasis on time-dependent modeling (not proposed in `scikit-learn`). The `tick` optimization toolbox relies on state-of-the-art optimization algorithms, and is implemented in a very modular way. It allows more possibilities than other `scikit-learn` API based optimization libraries such as `lightning`[1].

A wide variety of time-dependent models are taken care of by `tick`, which makes it the most comprehensive library that deals with Hawkes processes for instance, by including the main inference algorithms from the literature. Despite the growing interest in Hawkes models, very few open source packages are available. There are mainly three of them. The library `pyhawkes`[2] proposes a small set of Bayesian inference algorithms for Hawkes process. `hawkes` R[3] is an R-based library that provides a single estimation algorithm, and is hardly optimized. Finally, `PtPack`[4] a C++ library which proposes parametric maximum likelihood estimators, with sparsity-inducing regularizations. However, since `tick` is a Python library, it addresses a different community to PtPack. Moreover, as illustrated below, `tick` provides better performance than `PtPack`.

3. Package Architecture

The `tick` library has four main modules: `tick.hawkes` for Hawkes processes (see Section 4 for a detailed review), `tick.linear_model` with linear, logistic and Poisson regression, `tick.robust` for robust linear models and `tick.survival` for survival analysis. Each of these modules provide simulation tools and learners to easily learn from data. The core of `tick` is made of easy to combine penalization techniques (`tick.prox` module) and several convex solvers (`tick.solver`), to train almost any available model in the library, see Table 1 for a non-exhaustive list of possible combinations. An exhaustive list is available on the documentation web page[5], and is given in Figure 7 of the supplementary material.

4. Hawkes

Distributing a comprehensive open source library for Hawkes processes is one of the primary aims of the `tick` library: it provides many non-parametric and parametric estimation algorithms that are listed in Table 2 as well as simulation tools for many kernel types as shown in Figure 5 of the supplementary material. This diversity of algorithms is illustrated in Figure 1 in which we show how two kernels of different shapes are estimated by four different algorithms. A first use case for modeling high-frequency financial data is given in Figure 2 (with the associated Python code), while a second use-case about propagation analysis of earthquake aftershocks can be found in Figure 3.

Wiener-Hopf (Bacry and Muzy, 2014)	Sum of gaussians kernels (Xu et al., 2016)
NPHC (Achab et al., 2017)	ADM4 (Zhou et al., 2013)

Table 2: Models and estimation techniques for Hawkes processes available in `tick`

5. Benchmarks

In Figure 4, we benchmark computational times for both simulation and estimation of Hawkes processes (with exponential kernels) using `hawkes` R (where only simulation is available), `PtPack` and `tick` on respectively 2, 4 and 16 cores. The model fits in plots "Fit" and "Multicore fit" are compared on simulated 16-dimensional Hawkes processes, with an increasing number of events: small=5×10^4, medium=2×10^5, large=10^6, xlarge= 5×10^7, while 200, 400 and 750 dimensional Hawkes processes are fitted in plot "High-dimensional fitting". We observe that `tick` outperforms by several orders of magnitudes both `hawkes` R and `PtPack`, in particular for large datasets. Benchmarks against `scikit-learn` for logistic regression are also provided in Figure 6 from the supplementary material.

Editor: Geoff Holmes

Abstract

We consider the problem of finding the minimizer of a function $f : \mathbb{R}^d \to \mathbb{R}$ of the finite-sum form $\min f(w) = 1/n \sum_i^n f_i(w)$. This problem has been studied intensively in recent years in the field of machine learning (ML). One promising approach for large-scale data is to use a stochastic optimization algorithm to solve the problem. SGDLibrary is a readable, flexible and extensible pure-MATLAB library of a collection of stochastic optimization algorithms. The purpose of the library is to provide researchers and implementers a comprehensive evaluation environment for the use of these algorithms on various ML problems.

Keywords: Stochastic optimization, stochastic gradient, finite-sum minimization problem, large-scale optimization problem

1. Introduction

This work aims to facilitate research on stochastic optimization for large-scale data. We particularly address a regularized finite-sum minimization problem defined as

$$\min_{w \in \mathbb{R}^d} f(w) := \frac{1}{n} \sum_{i=1}^{n} f_i(w) = \frac{1}{n} \sum_{i=1}^{n} L(w, x_i, y_i) + \lambda R(w), \tag{1}$$

where $w \in \mathbb{R}^d$ represents the model parameter and n denotes the number of samples (x_i, y_i). $L(w, x_i, y_i)$ is the loss function and $R(w)$ is the regularizer with the regularization parameter $\lambda \geq 0$. Widely diverse machine learning (ML) models fall into this problem. Considering $L(w, x_i, y_i) = (w^T x_i - y_i)^2$, $x_i \in \mathbb{R}^d$, $y_i \in \mathbb{R}$ and $R(w) = \|w\|_2^2$, this results in an ℓ_2-norm regularized linear regression problem (a.k.a. ridge regression) for n training samples $(x_1, y_1), \cdots, (x_n, y_n)$. In the case of binary classification with the desired class label $y_i \in \{+1, -1\}$ and $R(w) = \|w\|_1$, an ℓ_1-norm regularized logistic regression (LR) problem is obtained as $f_i(w) = \log(1 + \exp(-y_i w^T x_i)) + \lambda \|w\|_1$, which encourages the sparsity of the solution of w. Other problems covered are matrix completion, support vector machines (SVM), and sparse principal components analysis, to name but a few.

Full gradient descent (a.k.a. steepest descent) with a step-size η is the most straightforward approach for (1), which updates as $w_{k+1} \leftarrow w_k - \eta \nabla f(w_k)$ at the k-th iteration. However, this is expensive when n is extremely large. In fact, one needs a sum of n calculations of the inner product $w^T x_i$ in the regression problems above, leading to $\mathcal{O}(nd)$ cost overall per iteration. For this issue, a popular and effective alternative is *stochastic gradient descent* (SGD), which updates as $w_{k+1} \leftarrow w_k - \eta \nabla f_i(w_k)$ for the i-th sample uniformly at random (Robbins and Monro, 1951; Bottou, 1998). SGD assumes an *unbiased estimator* of the full gradient as $\mathbb{E}_i[\nabla f_i(w^k)] = \nabla f(w^k)$. As the update rule represents, the calculation cost is independent of n, resulting in $\mathcal{O}(d)$ per iteration. Furthermore, *mini-batch* SGD (Bottou, 1998) calculates $1/|\mathcal{S}_k| \sum_{i \in \mathcal{S}_k} \nabla f_i(w_k)$, where $\mathcal{S}_k$ is the set of samples of size $|\mathcal{S}_k|$. SGD needs a *diminishing* step-size algorithm to guarantee convergence, which causes a severe slow convergence rate (Bottou, 1998). To accelerate this rate, we have two active research directions in ML; *Variance reduction* (VR) techniques (Johnson and Zhang, 2013; Roux et al., 2012; Shalev-Shwartz and Zhang, 2013; Defazio et al., 2014; Nguyen et al., 2017) that explicitly or implicitly exploit a full gradient estimation to reduce the variance of the noisy stochastic gradient, leading to superior convergence properties. Another promising direction is to modify deterministic *second-order* algorithms into stochastic settings, and solve the potential problem of *first-order* algorithms for *ill-conditioned* problems. A direct extension of *quasi-Newton* (QN) is known as online BFGS (Schraudolph et al., 2007). Its variants include a regularized version (RES) (Mokhtari and Ribeiro, 2014), a limited memory version (oLBFGS) (Schraudolph et al., 2007; Mokhtari and Ribeiro, 2015), a stochastic QN (SQN) (Byrd et al., 2016), an incremental QN (Mokhtari et al., 2017), and a non-convex version. Lastly, hybrid algorithms of the SQN with VR are proposed (Moritz et al., 2016; Kolte et al., 2015). Others include (Duchi et al., 2011; Bordes et al., 2009).

The performance of stochastic optimization algorithms is strongly influenced not only by the distribution of data but also by the step-size algorithm (Bottou, 1998). Therefore, we often encounter results that are completely different from those in papers in every experiment. Consequently, an evaluation framework to test and compare the algorithms at hand is crucially important for fair and comprehensive experiments. One existing tool is *Lightning* (Blondel and Pedregosa, 2016), which is a Python library for large-scale ML problems. However, its supported algorithms are limited, and the solvers and the problems such as classifiers are mutually connected. Moreover, the implementations utilize Cython, which is a C-extension for Python, for efficiency. Subsequently, they decrease users' readability of code, and also make users' evaluations and extensions more complicated. SGDLibrary is a readable, flexible and extensible pure-MATLAB library of a collection of stochastic optimization algorithms. The library is also operable on GNU Octave. The purpose of the library is to provide researchers and implementers a collection of state-of-the-art stochastic optimization algorithms that solve a variety of large-scale optimization problems such as linear/non-linear regression problems and classification problems. This also allows researchers and implementers to easily extend or add solvers and problems for further evaluation. To the best of my knowledge, no report in the literature and no library describe a comprehensive experimental environment specialized for stochastic optimization algorithms. The code is available at `https://github.com/hiroyuki-kasai/SGDLibrary`.

2. Software architecture

The software architecture of SGDLibrary follows a typical *module-based* architecture, which separates *problem descriptor* and *optimization solver*. To use the library, the user selects one problem descriptor of interest and no less than one optimization solvers to be compared.

Problem descriptor: The problem descriptor, denoted as `problem`, specifies the problem of interest with respect to w, noted as `w` in the library. This is implemented by MATLAB `classdef`. The user does nothing other than calling a problem definition function, for instance, `logistic_regression()` for the ℓ_2-norm regularized LR problem. Each problem definition includes the functions necessary for solvers; (i) (full) cost function $f(w)$, (ii) mini-batch stochastic derivative `v`$=1/|\mathcal{S}|\nabla f_{i\in\mathcal{S}}(w)$ for the set of samples $\mathcal{S}$. (iii) stochastic Hessian (Bordes et al., 2009), and (iv) stochastic Hessian-vector product for a vector `v`. The built-in problems include, for example, ℓ_2-norm regularized multidimensional linear regression, ℓ_2-norm regularized linear SVM, ℓ_2-norm regularized LR, ℓ_2-norm regularized softmax classification (multinomial LR), ℓ_1-norm multidimensional linear regression, and ℓ_1-norm LR. The problem descriptor provides additional specific functions. For example, the LR problem includes the prediction and the classification accuracy calculation functions.

Optimization solver: The optimization solver implements the main routine of the stochastic optimization algorithm. Once a solver function is called with one selected problem descriptor `problem` as the first argument, it solves the optimization problem by calling some corresponding functions via `problem` such as the cost function and the stochastic gradient calculation function. Examples of the supported optimization solvers in the library are listed in categorized groups as; (i) **SGD methods:** Vanila SGD (Robbins and Monro, 1951), SGD with classical momentum, SGD with classical momentum with Nesterov's accelerated gradient (Sutskever et al., 2013), AdaGrad (Duchi et al., 2011), RMSProp, AdaDelta, Adam, and AdaMax, (ii) **Variance reduction (VR) methods:** SVRG (Johnson and Zhang, 2013), SAG (Roux et al., 2012), SAGA (Defazio et al., 2014), and SARAH (Nguyen et al., 2017), (iii) **Second-order methods**: SQN (Bordes et al., 2009), oBFGS-Inf (Schraudolph et al., 2007; Mokhtari and Ribeiro, 2015), oBFGS-Lim (oLBFGS) (Schraudolph et al., 2007; Mokhtari and Ribeiro, 2015), Reg-oBFGS-Inf (RES) (Mokhtari and Ribeiro, 2014), and Damp-oBFGS-Inf, (iv) **Second-order methods with VR**: SVRG-LBFGS (Kolte et al., 2015), SS-SVRG (Kolte et al., 2015), and SVRG-SQN (Moritz et al., 2016), and (v) **Else**: BB-SGD and SVRG-BB. The solver function also receives optional parameters as the second argument, which forms a *struct*, designated as `options` in the library. It contains elements such as the maximum number of epochs, the batch size, and the step-size algorithm with an initial step-size. Finally, the solver function returns to the caller the final solution `w` and rich statistical information, such as a record of the cost function values, the optimality gap, the processing time, and the number of gradient calculations.

Others: SGDLibrary accommodates a *user-defined* step-size algorithm. This accommodation is achieved by setting as `options.stepsizefun=@my_stepsize_alg`, which is delivered to solvers. Additionally, when the regularizer $R(w)$ in the minimization problem (1) is a non-smooth regularizer such as the ℓ_1-norm regularizer $\|w\|_1$, the solver calls the *proximal operator* as `problem.prox(w,stepsize)`, which is the wrapper function defined in each problem. The ℓ_1-norm regularized LR problem, for example, calls the *soft-threshold* function as `w = prox(w,stepsize)=soft_thresh(w,stepsize*lambda)`, where `stepsize` is the step-size η and `lambda` is the regularization parameter $\lambda > 0$ in (1).

3. Tour of the SGDLibrary

We embark on a tour of SGDLibrary exemplifying the ℓ_2-norm regularized LR problem. The LR model generates n pairs of (x_i, y_i) for an unknown model parameter w, where x_i is an input d-dimensional vector and $y_i \in \{-1, 1\}$ is the binary class label, as $P(y_i|x_i, w) = 1/(1 + \exp(-y_i w^T x_i))$. The problem seeks w that fits the regularized LR model to the generated data (x_i, y_i). This problem is cast as a minimization problem as $\min f(w) := 1/n \sum_{i=1}^{n} \log[1 + \exp(-y_i w^T x_i)] + \lambda/2\|w\|^2$. The code for this problem is in Listing 1.

```
% generate synthetic 300 samples of dimension 3 for logistic regression
d = logistic_regression_data_generator(300,3);
% define logistic regression problem
problem = logistic_regression(d.x_train,d.y_train,d.x_test,d.y_test);

options.w_init = d.w_init;                          % set initial value
options.step_init = 0.01;                           % set initial stepsize
options.verbose = 1;                                % set verbose mode
[w_sgd, info_sgd] = sgd(problem, options);          % perform SGD solver
[w_svrg, info_svrg] = svrg(problem, options);       % perform SVRG solver
[w_svrg, info_svrg] = sqn(problem, options);      % perform SQN solver
% display cost vs. number of gradient evaluations
display_graph('grad_calc_count','cost',{'SGD','SVRG'},...
                {w_sgd,w_svrg},{info_sgd,info_svrg});
```

Listing 1: Demonstration code for logistic regression problem.

First, we generate train/test datasets `d` using `logistic_regression_data_generator()`, where the input feature vector is with $n = 300$ and $d = 3$. $y_i \in \{-1, 1\}$ is its class label. The LR problem is defined by calling `logistic_regression()`, which internally contains the functions for cost value, the gradient and the Hessian. This is stored in `problem`. Then, we execute solvers, i.e., SGD and SVRG, by calling solver functions, i.e., `sgd()` and `svrg()` with `problem` and `options` after setting some options into the `options` struct. They return the final solutions of `{w_sgd,w_svrg}` and the statistical information `{info_sgd,info_svrg}`. Finally, `display_graph()` visualizes the behavior of the cost function values in terms of the number of gradient evaluations. It is noteworthy that each algorithm requires a different number of evaluations of samples in each epoch. Therefore, it is common to use this value to evaluate the algorithms instead of the number of iterations. Illustrative results additionally including SQN and SVRG-LBFGS are presented in Figure 1, which are generated by `display_graph()`, and `display_classification_result()` specialized for classification problems. Thus, SGDLibrary provides rich visualization tools as well.

Abstract

We study the stochastic multi-armed bandit (MAB) problem in the presence of side-observations across actions that occur as a result of an underlying network structure. In our model, a bipartite graph captures the relationship between actions and a common set of unknowns such that choosing an action reveals observations for the unknowns that it is connected to. This models a common scenario in online social networks where users respond to their friends' activity, thus providing side information about each other's preferences. Our contributions are as follows: 1) We derive an asymptotic lower bound (with respect to time) as a function of the bi-partite network structure on the regret of any *uniformly good policy* that achieves the maximum long-term average reward. 2) We propose two policies - a randomized policy; and a policy based on the well-known upper confidence bound (UCB) policies - both of which explore each action at a rate that is a function of its network position. We show, under mild assumptions, that these policies achieve the asymptotic lower bound on the regret up to a multiplicative factor, independent of the network structure. Finally, we use numerical examples on a real-world social network and a routing example network to demonstrate the benefits obtained by our policies over other existing policies.

Keywords: Multi-armed Bandits, Side Observations, Bipartite Graph, Regret Bounds

1. Introduction

Multi-armed bandit (MAB) problems are well-known models of sequential decision-making under uncertainty (Lai and Robbins, 1985) and have lately been used to model new and exciting decision problems in content recommendation systems, online advertising platforms, and social networks, among others. In the classical MAB setting, at each time, a bandit policy must choose an action from a set of actions with unknown probability distributions. Choosing an action gives a random reward drawn from the distribution of the action. The regret of any policy is defined as the difference between the total reward obtained from the action with the highest average reward and the given policy's total reward. The goal is to find policies that minimize the expected regret over time.

In this work, we consider an important extension to the classical MAB problem, where choosing an action not only generates a reward from that action, but also reveals important information for a subset of the remaining actions. We model this relationship between different actions using a bipartite graph between the set of actions and a common set of unknowns (see Figure 2). The reward from each action is a known function of a subset of the unknowns (called its parents) and choosing an action reveals observations from each of its parents. Our main objective in this work is to leverage such a structure to improve scalability of bandit policies in terms of the action/decision space.

Such an information structure between actions becomes available in a variety of applications. For example, consider the problem of *routing* in communication networks, where packets are to be sent over a set of links from source to destination (called a path or a route) in order to minimize the delay. Here, the total delay on each path is the sum of individual link delays, which are unknown. In addition, traveling along a path reveals observations for delays on each of constituent links. Hence, each path provides additional information for all other paths that share some of their links with it. In this example, actions correspond to a set of feasible paths and the set of unknowns corresponds to random delays on all the links in the network.

Another example occurs in advertising in online social networks through promotional offers. Suppose a user is offered a promotion/discounted price for a product in return for advertising it to his friends/neighbors in an online social network. The influence of the user is then measured by the friends that respond to his message through comments/likes, etc. Each user has an intrinsic unknown probability of responding to such messages on social media. Here, the set of actions correspond to the set of users (to whom promotions are given) and the set of unknowns are the users' intrinsic responsiveness to such promotions.

In this work, we aim to characterize the asymptotic lower bound on the regret for a general stochastic multi-armed bandit problem in the presence of such an information structure and investigate policies that achieve this lower bound by taking the network structure into account. Our main contributions are as follows:

- We model the MAB problem in the presence of additional structure and derive an asymptotic (with respect to time) lower bound (as a function of the network structure) on the regret of any uniformly good policy which achieves the maximum long term average reward. This lower bound is presented in terms of the optimal value of a linear program (LP).
- Motivated by the LP lower bound, we propose and investigate the performance of a randomized policy, we call ϵ_t-greedy-LP policy, as well as an upper confidence bound based policy, we call UCB-LP policy. Both of these policies *explore each action at a rate that is a function of its location in the network.* We show under some mild assumptions that these policies are optimal in the sense that they achieve the asymptotic lower bound on the regret up to a multiplicative constant that is independent of the network structure.

The model considered in this work is an important first step in the direction of more general models of interdependence across actions. For this model, we show that as the

number of actions becomes large, significant benefits can be obtained from policies that explicitly take network structure into account. While ϵ_t-greedy-LP policy explores actions at a rate proportional to their network position, its exploration is oblivious to the average rewards of the sub-optimal actions. On the other hand, UCB-LP policy takes into account both the upper confidence bounds on the mean rewards as well as network position of different actions at each time.

2. Related Work

The seminal work of Lai and Robbins (1985) showed that the asymptotic lower bound on the regret of any uniformly good policy scales logarithmically with time with a multiplicative constant that is a function of the distributions of actions. Further, Lai and Robbins (1985) provide constructive policies called Upper Confidence Bound (UCB) policies based on the concept of optimism in the face of uncertainty that asymptotically achieve the lower bound. More recently, Auer et al. (2002) considered the case of bounded rewards and propose simpler sample-mean-based UCB policies and a decreasing-ϵ_t-greedy policy that achieve logarithmic regret uniformly over time, rather than only asymptotically as in the previous works.

The traditional multi-armed bandit policies incur a regret that is linear in the number of suboptimal arms. This makes them unsuitable in settings such as content recommendation, advertising, etc, where the action space is typically very large. To overcome this difficulty, richer models specifying additional information across reward distributions of different actions have been studied, such as dependent bandits by Pandey et al. (2007), $\mathcal{X}$-armed bandits by Bubeck et al. (2011), linear bandits by Rusmevichientong and Tsitsiklis (2010), contextual side information in bandit problems by Li et al. (2010), combinatorial bandits by Chen et al. (2013) etc..

The works of Mannor and Shamir (2011), Caron et al. (2012), and Buccapatnam et al. (2014) proposed to handle the large number of actions by assuming that choosing an action reveals observations from a larger set of actions. In this setting, actions are embeded in a network and choosing an action provides observations for all the immediate neighbors in the network. The policies proposed in Mannor and Shamir (2011) achieve the best possible regret in the adversarial setting (see Bubeck and Cesa-Bianchi (2012) for a survey of adversarial MABs) with side-observations, and the regret bounds of these policies are in terms of the independence number of the network. The stochastic version of this problem is introduced in Caron et al. (2012) and Buccapatnam et al. (2014), which improves upon the results in Caron et al. (2012). In Buccapatnam et al. (2014), the authors derive a lower bound on regret in stochastic network setting for any uniformly good policy and propose two policies that achieve this lower bound in these settings up to a multiplicative constant. Our current work extends the setting in Caron et al. (2012); Buccapatnam et al. (2014) to a more general and important graph feedback structure between the set of actions and a set of common unknowns, which may or may not coincide with the set of actions available to the decision maker. The setting of Mannor and Shamir (2011), Caron et al. (2012), and Buccapatnam et al. (2014) is a special case of this general feedback structure, where the set of unknowns and the set of actions coincide.

More recently, Cohen et al. (2016), have studied the multi-armed bandit problem with a graph based feedback structure similar to Mannor and Shamir (2011), and Buccapatnam et al. (2014). However, they assume that the graph structure is never fully revealed. In contrast, in many cases such as the problem of routing in communication networks and the problem of influence maximization in social networks, the graph structure is revealed or learnt apriori and is known. When the graph structure is known, the authors in Buccapatnam et al. (2014) propose algorithms for the stochastic setting whose regret performance is bounded by the domination number of the graph. In contrast, the algorithms proposed in Cohen et al. (2016) assume that the graph is unknown and achieve a regret that is upper bounded by the independence number of the graph. (Note that the independence number of a graph is larger than or equal to the domination number). Our current work proposes a general feedback structure of which Buccapatnam et al. (2014) and Cohen et al. (2016) can be viewed as a special case. Moreover, we present algorithms that benefit significantly from the knowledge of the graph feedback structure.

The setting of combinatorial bandits (CMAB) by Chen et al. (2013) is also closely related to our work. In CMAB, a subset of base actions with unknown distributions form super actions and in each round, choosing a super action reveals outcomes of its constituent actions. The reward obtained is a function of these outcomes. The number of super actions and their composition in terms of base actions is assumed to be arbitrary and the policies do not utilize the underlying network structure between base actions and super actions. In contrast, in our work, we derive a regret lower bound in terms of the underlying network structure and propose policies that achieve this bound. This results in markedly improved performance when the number of super actions is not substantially larger than the number of base actions.

3. Problem Formulation

In this section, we formally define the general bandit problem in the presence of side observations across actions. Let $\mathcal{N} = \{1, \ldots, N\}$ denote the collection of *base-arms* with unknown distributions. Subsets of base-arms form *actions*, and are indexed by $\mathcal{K} = \{1, \ldots, K\}$. A decision maker must choose an action $j \in \mathcal{K}$ at each time t and observes the rewards of related base-arms. Let $X_i(t)$ be the reward of base-arm i observed by the decision maker (on choosing some action) at time t. We assume that $\{X_i(t), t \geq 0\}$ are independent and identically distributed (i.i.d.) for each i and $\{X_i(t), \forall i \in \mathcal{N}\}$ are independent for each time t. Let $V_j \subseteq \mathcal{N}$ be the subset of base-arms that are observed when playing action j. Then, we define $S_i = \{j : i \in V_j\}$ as the support of base-arm i, i.e., the decision maker gets observations for base-arm i on playing action $j \in S_i$. When the decision maker chooses action j at time t, he or she observes one realization for each of the random variables $X_i(t)$, $i \in V_j$. The reward of the played action j depends on the outcomes of its related base-arms subset, denoted by $\mathcal{K}_j \subseteq \mathcal{N}$, and some known function $f_j(\cdot)$. Note that $\mathcal{K}_j \subseteq V_j$ because there may be some base-arms that can be observed by action j but not counted as reward in general (see Figure 2 for a concrete example). Let the vector $\vec{X}_j(t) = [X_i(t)]_{i \in \mathcal{K}_j}$ denote the collection of random variables associated with the reward of action j. Then the reward from playing action j at time t is given by $f_j(\vec{X}_j(t))$. We assume that the reward is bounded in $[0, 1]$ for each action. Note that we only assume that the reward function $f_j(\cdot)$ is bounded

and the specific form of $f_j(\cdot)$ and $\mathcal{K}_j$ are determined by the decision maker or the specific problem. Let μ_j be the mean of reward on playing action j.

Side-observation model : The actions $\mathcal{K}$ and base-arms $\mathcal{N}$ form nodes in a network G, represented by a bipartite graph $(\mathcal{K},\mathcal{N},E)$ and the collection $\{\mathcal{K}_j\}_{j\in\mathcal{K}}$. The $N \times K$ adjacency matrix $E = [e_{ij}]$ is defined by $e_{ij} = 1$ if $i \in V_j$ and $e_{ij} = 0$ otherwise. If there is an edge between action j and base-arm i, i.e., $e_{ij} = 1$, then we can observe a realization of base-arm i when choosing action j. Intuitively, the bipartite graph determined by $\{V_j\}_{j\in\mathcal{K}}$ describes the side-observation relationships while the collection $\{\mathcal{K}_j\}_{j\in\mathcal{K}}$ captures the reward structure. Without loss of generality, we assume that $\cup_{i\in\mathcal{K}}\mathcal{K}_i = \mathcal{N}$, which means that there are no useless (dummy) unknown base-arms in the network.

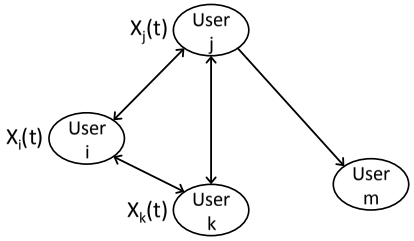

Figure 1: At time t, suppose that the decision maker chooses user i to offer a promotion. He then receives a response $X_i(t)$ from user i. Using the social interconnections, he also observes responses $X_j(t)$ and $X_k(t)$ of i's neighbors j and k.

Figure 1 illustrates the side-observation model for the example of targeting users in an online social network. Such side observations are made possible in settings of online social networks like Facebook by surveying or tracking a user's neighbors' reactions (likes, dislikes, no opinion, etc.) to the user's activity. This is possible when the online social network has a survey or a like/dislike indicator that generates side observations. For example, when user i is offered a promotion, her neighbors may be queried as follows: "User i was recently offered a promotion. Would you also be interested in the offer?[1]"

Figure 2 shows the bipartite graph generated from the example shown in Figure 1. The set of base-arms is the set of users since they act independently according to their own preferences in the promotion, which are unknown to the decision maker. The set of actions is also the set of users because the decision maker wants to target the users with the maximum expected reward. When action j (user j) is chosen, the decision maker observes $X_i(t)$, $X_j(t)$, $X_k(t)$ and $X_m(t)$ from user i, j, k and m since $V_j = \{i,j,k,m\}$. The reward of playing action j depends on $\mathcal{K}_j$ and $f_j(\cdot)$. Suppose $f_j(\vec{X}_j(t)) = \sum_{i\in\mathcal{K}_j} X_i(t)$. Then $\mathcal{K}_j = \{i,j,k,m\}$ means that the reward is the sum of all positive feedbacks. It is also

1. Since, the neighbors do not have any information on whether the user i accepted the promotion, they act independently according to their own preferences in answering this survey. The network itself provides a better way for surveying and obtaining side observations.

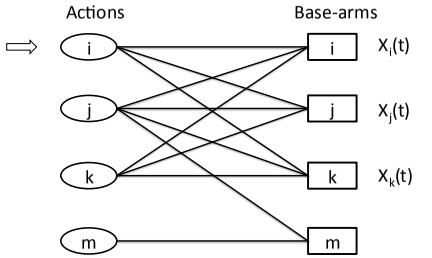

Figure 2: Bipartite graph for the example of targeting users in online social network.

possible that the decision maker set $\mathcal{K}_j = \{j\}$, which means that the reward of playing action j is only the observation from the user j.

The reward function can be quite general (but bounded) to accommodate different settings. Also, the bipartite graph can be more general than social networks in two key ways: 1) Connecting two users in two-hop neighborhood means that the reaction of the friend of my friend is also observable, which is true in Facebook. 2) Connecting two users, say i and j, with similar preference profiles means that the network actively recommends the promotion received by user i to user j even though they are not friends. This has been widely applied in recommender systems such as Yelp.

Objective: An allocation strategy or policy $\boldsymbol{\phi}$ chooses the action to be played at each time. Formally, $\boldsymbol{\phi}$ is a sequence of random variables $\{\phi(t), t \geq 0\}$, where $\phi(t) \in \mathcal{K}$ is the action chosen by policy $\boldsymbol{\phi}$ at time t. Let $T_j^{\phi}(t)$ be the total number of times action j is chosen up to time t by policy $\boldsymbol{\phi}$. For each action, rewards are only obtained when the action is chosen by the policy (side-observations do not contribute to the total reward). Then, the regret of policy $\boldsymbol{\phi}$ at time t for a fixed $\boldsymbol{\mu} = (\mu_1,\ldots,\mu_K)$ is defined by

$$R_{\boldsymbol{\mu}}^{\phi}(t) = \mu^* t - \sum_{j=1}^{K} \mu_j \mathbb{E}[T_j^{\phi}(t)] = \sum_{j=1}^{K} \Delta_j \mathbb{E}[T_j^{\phi}(t)],$$

where $\Delta_j \triangleq \mu^* - \mu_j$ and $\mu^* \triangleq \max_{j\in\mathcal{K}} \mu_j$. Henceforth, we drop the superscript ϕ unless it is required. The objective is to find policies that minimize the rate at which the regret grows as a function of time for every fixed network G. We focus our investigation on the class of uniformly good policies (Lai and Robbins, 1985) defined below:

Uniformly good policies: An allocation rule $\boldsymbol{\phi}$ is said to be uniformly good if for every fixed $\boldsymbol{\mu}$, the following condition is satisfied as $t \to \infty$:

$$R_{\boldsymbol{\mu}}(t) = o(t^b), \text{ for every } b > 0.$$

The above condition implies that uniformly good policies achieve the optimal long term average reward of μ^*. Next, we define two structures that will be useful later to bound the performance of allocation strategies in terms of the network structure G.

Definition 1 *A hitting set D is a subset of $\mathcal{K}$ such that $S_i \cap D \neq \emptyset$, $\forall i \in \mathcal{N}$. Then the hitting set number is $\gamma(G) = \inf_{D \subseteq \mathcal{K}}\{|D| : S_i \cap D \neq \emptyset,\ \forall i \in \mathcal{N}\}$. For example, the set $\{i, m\}$ is a hitting set in Figure 2.*

Definition 2 *A clique C is a subset of $\mathcal{K}$ such that $\mathcal{K}_j \subseteq V_i$, $\forall i, j \in C$. This means that for every action i in C, we can observe the reward of playing any action j in C. A clique cover $\mathcal{C}$ of a network G is a partition of all its nodes into sets $C \in \mathcal{C}$ such that the sub-network formed by each C is a clique. Let $\bar{\chi}(G)$ be the smallest number of cliques into which the nodes of the network G can be partitioned, also called the clique partition number.*

Proposition 3 *For any network G with bipartite graph $(\mathcal{K}, \mathcal{N}, E)$ and $\{\mathcal{K}_j\}_{j\in\mathcal{K}}$, if $\cup_{j\in\mathcal{K}}\mathcal{K}_j = \mathcal{N}$, then $\gamma(G) \leq \bar{\chi}(G)$.*

Proof Let $\mathcal{C} = \{C_1, C_2, ..., C_m\}$ be a clique cover with cardinality m, i.e., $|\mathcal{C}| = m$ and each C_k is a clique for $k = 1, ..., m$. Pick arbitrarily an element a_k from C_k for each k. Define $\mathcal{H} = \{a_k : k = 1, ..., m\}$. Now it remains to show that $\mathcal{H}$ is a hitting set, which implies $\gamma(G) \leq \bar{\chi}(G)$. We prove this by contradiction.

Suppose $\mathcal{H}$ is not a hitting set, then $\exists i \in \mathcal{N}$ s.t. $S_i \cap \mathcal{H} = \emptyset$. Since $\cup_{j\in\mathcal{K}}\mathcal{K}_j = \mathcal{N}$, $\exists j \in \mathcal{K}$ s.t. $i \in \mathcal{K}_j$. $\mathcal{C}$ is a clique cover, then $\exists k(j) \in \{1, 2, ..., m\}$ such that $j \in C_{k(j)}$. By the construction of $\mathcal{H}$, there exists $a_{k(j)} \in \mathcal{H} \cap C_{k(j)}$. By the definition of clique, we have $\mathcal{K}_j \subseteq V_{a_{k(j)}}$. Thus, we have $a_{k(j)} \in S_i$ since $i \in \mathcal{K}_j$. It follows that $S_i \cap \mathcal{H} \neq \emptyset$, which contradicts to $S_i \cap \mathcal{H} = \emptyset$. Hence, $\mathcal{H}$ is a hitting set. ■

In the next section, we obtain an asymptotic lower bound on the regret of uniformly good policies for the setting of MABs with side-observations. This lower bound is expressed as the optimal value of a linear program (LP), where the constraints of the LP capture the connectivity of each action in the network.

4. Regret Lower Bound in the Presence of Side Observations

In order to derive a lower bound on the regret, we need some mild regularity assumptions (Assumptions 1, 2, and 3) on the distributions F_i (associated with base-arm i) that are similar to the ones in Lai and Robbins (1985). Let the probability distribution F_i have a univariate density function $g(x; \theta_i)$ with unknown parameters θ_i, for each $i \in \mathcal{N}$. Let $D(\theta||\sigma)$ denote the Kullback Leibler (KL) distance between distributions with density functions $g(x; \theta)$ and $g(x; \sigma)$ and with means $u(\theta)$ and $u(\sigma)$ respectively.

Assumption 1 *(Finiteness) We assume that $g(\cdot;\cdot)$ is such that $0 < D(\theta||\sigma) < \infty$ whenever $u(\sigma) > u(\theta)$.*

Assumption 2 *(Continuity) For any $\epsilon > 0$ and θ, σ such that $u(\sigma) > u(\theta)$, there exists $\eta > 0$ for which $|D(\theta||\sigma) - D(\theta||\rho)| < \epsilon$ whenever $u(\sigma) < u(\rho) < u(\sigma) + \eta$.*

Assumption 3 *(Denseness) For each $i \in \mathcal{N}$, $\theta_i \in \Theta$ where the set Θ satisfies: for all $\theta \in \Theta$ and for all $\eta > 0$, there exists $\theta' \in \Theta$ such that $u(\theta) < u(\theta') < u(\theta) + \eta$.*

Let $\vec{\theta}$ be the vector $[\theta_1, \ldots, \theta_N]$. Define $\Theta_i = \{\vec{\theta} : \exists k \in S_i$ such that $\mu_k(\vec{\theta}) < \mu^*(\vec{\theta})\}$. So, not all actions that support base-arm i are optimal. Suppose $\vec{\theta} \in \Theta_i$. For base arm i, define the set

$$\mathcal{B}_i(\theta_i) = \{\theta_i' : \exists k \in S_i \text{ such that } \mu_k(\vec{\theta}_i') > \mu^*(\vec{\theta})\},$$

where $\vec{\theta}_i' = [\theta_1, \ldots, \theta_i', \ldots \theta_N]$. $\vec{\theta}_i'$ differs from $\vec{\theta}$ only in the i^{th} parameter. In this set $\mathcal{B}_i(\theta_i)$, base-arm i contributes towards a unique optimal action. Define constant $J_i(\theta_i) = \inf\{D(\theta_i||\theta_i') : \theta_i' \in \mathcal{B}_i(\theta_i)\}$. This is well-defined when $\mathcal{B}_i(\theta_i) \neq \emptyset$.

The following proposition is obtained using Theorem 2 in Lai and Robbins (1985). It provides an asymptotic lower bound on the regret of any uniformly good policy under the model described in Section 3:

Proposition 4 *Suppose Assumptions 1, 2, and 3 hold. Let $\mathcal{U} = \{j : \mu_j < \mu^*\}$ be the set of suboptimal actions. Also, let $\Delta_j = \mu^* - \mu_j$. Then, under any uniformly good policy $\boldsymbol{\phi}$, the expected regret is asymptotically bounded below as follows:*

$$\liminf_{t\to\infty} \frac{R_{\boldsymbol{\mu}}(t)}{\log(t)} \geq c_{\boldsymbol{\mu}}, \tag{1}$$

where $c_{\boldsymbol{\mu}}$ is the optimal value of the following linear program (LP) P_1:

$$\begin{aligned} P_1 :\ & \min \sum_{j\in\mathcal{U}} \Delta_j w_j, \\ \textit{subject to:}\ & \sum_{j\in S_i} w_j \geq \frac{1}{J_i(\theta_i)},\ \forall i \in \mathcal{N}, \\ & w_j \geq 0,\ \forall j \in \mathcal{K}. \end{aligned}$$

Proof *(Sketch)* Let $M_i(t)$ be the total number of observations corresponding to base-arm i available at time t. Then, by modifying the proof of Theorem 2 of Lai and Robbins (1985), we have that, for $i \in \mathcal{N}$,

$$\liminf_{t\to\infty} \frac{\mathbb{E}[M_i(t)]}{\log(t)} \geq \frac{1}{J_i(\theta_i)}.$$

An observation is received for base-arm i whenever any action in S_i is chosen. Hence, $M_i(t) = \sum_{j\in S_i} T_j(t)$. These two facts give us the constraints in LP P_1. See Appendix A for the full proof. ■

The linear program given in P_1 contains the graphical information that governs the lower bound. However, it requires the knowledge of $\vec{\theta}$, which is unknown. This motivates the construction of the following linear program, LP P_2, which preserves the graphical structure while eliminating the distributional dependence on $\vec{\theta}$.

$$\begin{aligned} P_2 : \min & \sum_{j\in\mathcal{K}} z_j \\ \text{subject to:}\ & \sum_{j\in S_i} z_j \geq 1,\ \forall i \in \mathcal{N}, \\ \text{and}\ & z_j \geq 0,\ \forall j \in \mathcal{K}. \end{aligned}$$

Let $\mathbf{z}^* = (z_j^*)_{j\in\mathcal{K}}$ be the optimal solution of LP P_2. In Sections 5 and 6, we use the above LP P_2 to modify the ϵ-greedy policy in Auer et al. (2002) and UCB policy in Auer and Ortner (2010) for the setting of side-observations. We provide regret guarantees of these modified policies in terms of the optimal value $\sum_{j\in\mathcal{K}} z_j^*$ of LP P_2. We note that the linear program P_2 is, in fact, the LP relaxation of the minimum hitting set problem on network G. Since, any hitting set of network G is a feasible solution to the LP P_2, we have that the optimal value of the LP $\sum_{j\in\mathcal{K}} z_j^* \leq \gamma(G) \leq \bar{\chi}(G)$.

Proposition 5 *Consider an Erdos-Renyi random bipartite graph $(\mathcal{K}, \mathcal{N}, E)$ such that each entry of the matrix E equals 1 with probability p, where $0 < p < 1$. Suppose $\cup_{j\in\mathcal{K}}\mathcal{K}_j = \mathcal{N}$, i.e., there are no useless base-arms in the network, then $\sum_{j\in\mathcal{K}} z_j^*$ is upper-bounded by $\log_{\frac{1}{1-p}} N$ as $N \to \infty$ in probability.*

Proof *(sketch)* Since $\sum_{j\in\mathcal{K}} z_j^* \leq \gamma(G)$, it remains to be shown that $\gamma(G)$ is upper bounded by the above result. Suppose there are no useless base-arms in the network. Then the set of all actions is a hitting set. Based on this observation, we construct a repeated experiment to generate actions sequentially. Then we define a stopping time τ as the first time that all the generated actions form a hitting set. Hence, we show the asymptotic result of τ as the upper bound of $\gamma(G)$. See full proof in Appendix B. ■

In the next proposition, we provide a lower bound on $c_{\boldsymbol{\mu}}$ in Equation (1) using the optimal solution $\mathbf{z}^* = (z_j^*)_{j\in\mathcal{K}}$ of LP P_2.

Proposition 6 *Let $\mathcal{U} = \{j : \mu_j < \mu^*\}$ be the set of suboptimal actions. Let $\mathcal{O} = \{j : \mu_j = \mu^*\}$ be the set of optimal actions. Then,*

$$\frac{\max_{i\in\mathcal{N}} J_i(\theta_i)}{\min_{j\in\mathcal{U}} \Delta_j} c_{\boldsymbol{\mu}} + |\mathcal{O}| \geq \sum_{j\in\mathcal{K}} z_j^* \geq \frac{\min_{i\in\mathcal{N}} J_i(\theta_i)}{\max_{j\in\mathcal{U}} \Delta_j} c_{\boldsymbol{\mu}}. \tag{2}$$

Proof *(Sketch)* Using the optimal solution of LP P_1, we construct a feasible solution satisfying constraints in LP P_2 for base-arms in $\mathcal{N}$. The feasible solution constructed in this way gives an upper bound on the optimal value of LP P_2 in terms of the optimal value of LP P_1. For the lower bound, we use the fact that any feasible solution of P_2, in particular $\mathbf{z}^*$, can be used to construct a feasible solution of P_1. See Appendix C for the full proof. ■

We note that $\sum_{j\in\mathcal{K}} z_j^* = \Theta(c_\mu)$ completely captures the time dependence of the regret on network structure under the following assumption:

Assumption 4 *The quantities $|\mathcal{O}|$, $\min_{j\in\mathcal{U}} \Delta_j$, and $\min_{i\in\mathcal{N}} J_i(\theta_i)$ are constants that are independent of network size K and N.*

Note that the constants in the above assumption are unknown to the decision maker. In the next section, we propose the ϵ_t-greedy-LP policy which achieves the regret lower bound of $c_{\boldsymbol{\mu}} \log(t)$ up to a multiplicative constant factor that is independent of the network structure and time.

5. Epsilon-greedy-LP policy

Motivated by the LPs P_1 and P_2, we propose a *network-aware* randomized policy called the ϵ_t-greedy-LP policy. We provide an upper bound on the regret of this policy and show that it achieves the asymptotic lower bound, up to a constant multiplier, independent of the network structure. Let $\bar{f}_j(t)$ be the empirical average of observations (rewards and side-observations combined) available for action j up to time t. The ϵ_t-greedy-LP policy is described in Algorithm 1. The policy consists of two iterations - exploitation and exploration, where the exploration probability decreases as $1/t$, similarly to that of the ϵ_t-greedy policy proposed by Auer et al. (2002). However, in our policy, we choose the exploration probability for action j to be proportional to z_j^*/t, where $\mathbf{z}^*$ is the optimal solution of LP P_2, while in the original policy in Auer et al. (2002), the exploration probability is uniform over all actions.

Algorithm 1 : ϵ_t-greedy-LP

Input: $c > 0$, $0 < d < 1$, optimal solution $\mathbf{z}^*$ of LP P_2.

for each time t **do**

Update $\bar{f}_j(t)$ for each $j \in \mathcal{K}$, where $\bar{f}_j(t)$ is the empirically average over all the observations of action j.

Let $\epsilon(t) = \min\left(1, \frac{c\sum_{j\in\mathcal{K}} z_j^*}{d^2 t}\right)$ and $a^* = \arg\max_{j\in\mathcal{K}} \bar{f}_j(t)$.

Sample a from the distribution such that $\mathbb{P}\{a = j\} = \frac{z_j^*}{\sum_{i\in\mathcal{K}} z_i^*}$ for all $j \in \mathcal{K}$.

Play action $\phi(t)$ such that

$$\phi(t) = \begin{cases} a, & \text{with probability } \epsilon(t) \\ a^*, & \text{with probability } 1-\epsilon(t) \end{cases} \tag{3}$$

end for

The following proposition provides performance guarantees on the ϵ_t-greedy-LP policy:

Proposition 7 *For $0 < d < \min_{j\in\mathcal{U}} \Delta_j$, any $c > 0$, and $\alpha > 1$, the probability with which a suboptimal action j is selected by the ϵ_t-greedy-LP policy, described in Algorithm 1, for all $t > t' = \frac{c\sum_{i\in\mathcal{K}} z_i^*}{d^2}$ is at most*

$$\left(\frac{c}{d^2 t} z_j^*\right) + \frac{2\lambda c\delta}{\alpha d^2}\left(\frac{et'}{t}\right)^{cr/\alpha d^2} \log\left(\frac{e^2 t}{t'}\right) + \frac{4}{\Delta_j^2}\left(\frac{et'}{t}\right)^{\frac{c\Delta_j^2}{2\alpha d^2}}, \tag{4}$$

where $r = \frac{3(\alpha-1)^2}{8\alpha-2}$, $\lambda = \max_{j\in\mathcal{K}} |\mathcal{K}_j|$, and $\delta = \max_{i\in\mathcal{N}} |S_i|$ is the maximum degree of the supports in the network. Note that α is a parameter we introduce in the proof, which is used to determine a range for the choice of parameter c as shown in Corollary 8.

Proof *(Sketch)* Since $\mathbf{z}^*$ satisfies the constraints in LP P_2, there is sufficient exploration within each suboptimal action's neighborhood. The proof is then a combination of this fact

and the proof of Theorem 3 in Auer et al. (2002). In particular, we derive an upper bound for the probability that suboptimal action j is played at each time and then sum over the time. See Appendix D for the full proof. ■

In the above proposition, for large enough c, we see that the second and third terms are $O(1/t^{1+\epsilon})$ for some $\epsilon > 0$ (Auer et al., 2002). Using this fact, the following corollary bounds the expected regret of the ϵ_t-greedy-LP policy:

Corollary 8 *Choose parameters c and d such that,*

$$0 < d < \min_{j \in \mathcal{U}} \Delta_j, \quad \text{and} \quad c > \max(2\alpha d^2/r, 4\alpha),$$

for any $\alpha > 1$. Then, the expected regret at time T of the ϵ_t-greedy-LP policy described in Algorithm 1 is at most

$$\left(\frac{c}{d^2} \sum_{j \in \mathcal{U}} \Delta_j z_j^* \right) \log(T) + O(K), \tag{5}$$

where the $O(K)$ term captures constants independent of time but dependent on the network structure. In particular, the $O(K)$ term is at most

$$\sum_{j \in \mathcal{U}} \left[\frac{\pi^2 \lambda c \delta \Delta_j}{3\alpha d^2} \left(et'\right)^{cr/\alpha d^2} + \frac{2\pi^2}{3\Delta_j} \left(et'\right)^{\frac{c\Delta_j^2}{2\alpha d^2}} \right],$$

where t', r, λ and δ are defined in Proposition 7.

Remark 9 *Under Assumption 4, we can see from Proposition 6 and Corollary 8 that, ϵ_t-greedy-LP algorithm is* order optimal *achieving the lower bound $\Omega\left(\sum_{j \in \mathcal{K}} z_j^* \log(T)\right) = \Omega\left(c_{\boldsymbol{\mu}} \log(T)\right)$ as the network and time scale.*

While the ϵ_t-greedy-LP policy is network aware, its exploration is oblivious to the observed average rewards of the sub-optimal actions. Further, its performance guarantees depend on the knowledge of $\min_{j \in \mathcal{U}} \Delta_j$, which is the difference between the best and the second best optimal actions. On the other hand, the UCB-LP policy proposed in the next section is network-aware taking into account the average rewards of suboptimal actions. This could lead to better performance compared to ϵ_t-greedy-LP policy in certain situations, for example, when the action with greater z_j^* is also highly suboptimal.

6. UCB-LP policy

In this section we develop the UCB-LP policy defined in Algorithm 2 and obtain upper bounds on its regret. The UCB-LP policy is based on the improved UCB policy proposed in Auer and Ortner (2010), which can be summarized as follows: the policy estimates the values of Δ_i in each round by a value $\tilde{\Delta}_m$ which is initialized to 1 and halved in each round m. By each round m, the policy draws $n(m)$ observations for each action in the set of

actions not eliminated by round m, where $n(m)$ is determined by $\tilde{\Delta}_m$. Then, it eliminates those actions whose UCB indices perform poorly. Our policy differs from the one in Auer and Ortner (2010) by accounting for the presence of side-observations - this is achieved by choosing each action according to the optimal solution of LP P_2, while ensuring that $n(m)$ observations are available for each action not eliminated by round m.

Algorithm 2 : UCB-LP policy

Input: Set of actions $\mathcal{K}$, time horizon T, and optimal solution $\mathbf{z}^*$ of LP P_2.

Initialization: Let $\tilde{\Delta}_0 := 1$, $A_0 := \mathcal{K}$, and $B_0 := \mathcal{K}$

for round $m = 0, 1, 2, \ldots, \lfloor \frac{1}{2} \log_2 \frac{T}{e} \rfloor$ **do**

Action Selection: Let $n(m) := \left\lceil \frac{2 \log(T \tilde{\Delta}_m^2)}{\tilde{\Delta}_m^2} \right\rceil$

If $|B_m| = 1$: choose the single action in B_m until time T.

Else If $\sum_{i \in \mathcal{K}} z_i^* \leq 2|B_m|\tilde{\Delta}_m : \forall j \in A_m$, choose action j $\left[z_j^*(n(m) - n(m-1)) \right]$ times.

Else For each action j in B_m, choose j for $[n(m) - n(m-1)]$ times.

Update $\bar{f}_j(m)$ and $T_j(m)$ for each $j \in \mathcal{K}$, where $\bar{f}_j(m)$ is the empirical average reward of action j, and $T_j(m)$ is the total number of observations for action j up to round m.

Action Elimination:
To get B_{m+1}, delete all actions j in B_m for which

$$\bar{f}_j(m) + \sqrt{\frac{\log(T\tilde{\Delta}_m^2)}{2T_j(m)}} < \max_{a \in B_m} \left\{ \bar{f}_a(m) - \sqrt{\frac{\log(T\tilde{\Delta}_m^2)}{2T_a(m)}} \right\},$$

Reset:
The set A_{m+1} is given as $A_{m+1} = \bigcup_{i \in D_{m+1}} S_i$, where $D_{m+1} = \bigcup_{j \in B_{m+1}} \mathcal{K}_j$.
Let $\tilde{\Delta}_{m+1} = \frac{\tilde{\Delta}_m}{2}$.

end for

The following proposition provides performance guarantees on the expected regret due to UCB-LP policy:

Proposition 10 *For action j, define round m_j as follows:*

$$m_j := \min \left\{ m : \tilde{\Delta}_m < \frac{\Delta_j}{2} \right\}.$$

Define $\bar{m} = \min\left\{m : \sum_{j\in\mathcal{K}} z_j^* > \sum_{j:m_j>m} 2^{-m+1}\right\}$ *and the set* $B = \{j \in \mathcal{U} : m_j > \bar{m}\}$. *Then, the expected regret due to the UCB-LP policy described in Algorithm 2 is at most*

$$\sum_{j\in\mathcal{U}\setminus B} \Delta_j z_j^* \frac{32\log(T\hat{\Delta}_j^2)}{\hat{\Delta}_j^2} + \sum_{j\in B} \frac{32\log(T\Delta_j^2)}{\Delta_j} + O(K^2), \tag{6}$$

where $\hat{\Delta}_j = \max\{2^{-\bar{m}+2}, \min_{a:j\in G_a}\{\Delta_a\}\}$, $G_a = \cup_{i\in\mathcal{K}_a} S_i$, *and* (z_j^*) *is the solution of LP* P_2. *The* $O(K^2)$ *term captures constants independent of time. Further, under Assumption 4, the regret is also at most*

$$O\left(\sum_{j\in\mathcal{K}} z_j^* \log(T)\right) + O(K^2), \tag{7}$$

where (z_j^*) *entirely captures the time dependence on network structure.*

Proof *(Sketch)* The $\log(T)$ term in the regret follows from the fact that, with high probability, each suboptimal action j is eliminated (from the set B_m) on or before the first round m such that $\tilde{\Delta}_m < \Delta_j/2$. See Appendix E for the full proof. ■

Remark 11 *While* ϵ_t*-greedy-LP does not require knowledge of the time horizon* T, *UCB-LP policy requires the knowledge of* T. *UCB-LP policy can be extended to the case of an unknown time horizon similar to the suggestion in Auer and Ortner (2010). Start with* $T_0 = 2$ *and at end of each* T_l, *set* $T_{l+1} = T_l^2$. *The regret bound for this case is shown in Proposition 19 in Appendix F.*

Next, we briefly describe the policies UCB-N and UCB-MaxN proposed in Caron et al. (2012). In the UCB-N policy, at each time, the action with the highest UCB index is chosen similar to UCB1 policy in Auer et al. (2002). In UCB-MaxN policy, at each time t, the action i with the highest UCB index is identified and its neighboring action j with the highest empirical average reward at time t is chosen.

Remark 12 *The regret upper bound of UCB-N policy is*

$$\inf_{\mathcal{C}} \sum_{C\in\mathcal{C}} \frac{8\max_{j\in C}\Delta_j}{\min_{j\in C}\Delta_j^2}\log(T) + O(K),$$

where $\mathcal{C}$ *is a clique covering of the sub-network of suboptimal actions. The regret upper bound for UCB-MaxN is the same as that for UCB-N with an* $O(|\mathcal{C}|)$ *term instead of the time-invariant* $O(K)$ *term. We show a better regret performance for UCB-LP policy and* ϵ_t*-greedy-LP policies with respect to the* $\log(T)$ *term because* $\sum_{i\in\mathcal{K}} z_i^* \le \gamma(G) \le \bar{\chi}(G)$. *However, the time-invariant term in our policies is* $O(K)$ *and* $O(K^2)$, *can be worse than the time-invariant term* $O(|\mathcal{C}|)$ *in UCB-MaxN.*

Remark 13 *All uniformly good policies that ignore side-observations incur a regret that is at least* $\Omega(|\mathcal{U}|\log(t))$ *Lai and Robbins (1985), where* $|\mathcal{U}|$ *is the number of suboptimal actions. This could be significantly higher than the guarantees on the regret of both* ϵ_t*-greedy-LP policy and UCB-LP policy for a rich network structure as discussed in Remark 12.*

Remark 14 *In our model, we assumed that the side observations are always available. However, in reality, side observations may only be obtained sporadically. Suppose that when action* j *is chosen, side-observations of base-arms* $i \in \mathcal{K}_j$ *are obtained almost surely and that of base-arms* $i \in V_j \setminus \mathcal{K}_j$ *are obtained with a known probability* p_j. *In this case, Proposition 4 holds with the replacement of LP* P_1 *with LP* P_1' *as follows:*

$$\begin{aligned} P_1':\ & \min \sum_{j\in\mathcal{U}} \Delta_j w_j, \\ \textit{subject to:}\ & \sum_{j\in S_i} (w_j \mathbb{1}_{\{i\in\mathcal{K}_j\}} + p_j w_j \mathbb{1}_{\{i\notin\mathcal{K}_j\}}) \ge \frac{1}{J_i(\theta_i)},\ \forall i \in \mathcal{N}, \\ & w_j \ge 0,\ \forall j \in \mathcal{K}. \end{aligned}$$

Both of our policies work for this setting by changing the LP P_2 *to* P_2' *as follows:*

$$\begin{aligned} P_2':\ & \min \sum_{j\in\mathcal{K}} z_j \\ \textit{subject to:}\ & \sum_{j\in S_i} (z_j \mathbb{1}_{\{i\in\mathcal{K}_j\}} + p_j z_j \mathbb{1}_{\{i\notin\mathcal{K}_j\}}) \ge 1,\ \forall i \in \mathcal{N}, \\ & \textit{and } z_j \ge 0,\ \forall j \in \mathcal{K}. \end{aligned}$$

The regret bounds of our policies will now depend on the optimal solution of LP P_2'.

7. Numerical Results

7.1 Algorithm Performance on Data Trace

We consider the Flixster network dataset for the numerical evaluation of our algorithms. The authors in Jamali and Ester (2010) collected this social network data, which contains about 1 million users and 14 million links. We use graph clustering by Dhillon et al. (2007) to identify two strongly clustered sub-networks of sizes 1000 and 2000 nodes. Both these sub-networks have a degree distribution that is a straight line on a log-log plot indicating a power law distribution commonly observed in social networks. [2]

Our empirical setup is as follows. Let $\mathcal{N}$ be the set of users and $\mathcal{K} = \mathcal{N}$. To be specific, each user in the network is offered a promotion at each time, and accepts the promotion with probability $\mu_i \in [0.3, 0.9]$. Let S_i be the set of one-hop neighbors in the social network of user i (including user i). This is the setting when the Flixster has a

2. We note that the social network of interest may or may not display a power law behavior. We find that the subgraphs of the Flixster network have a degree distribution that is a straight line on a log-log plot indicating a power law distribution display while the authors in Ugander et al. (2011) show that the degree distribution of the global Facebook network is not a straight line on log-log plot.

survey or a like/dislike indicator that generates side observations of user's neighborhood. Let $\mathcal{K}_j = \{j\}$ and $f_j(X_j) = X_j$, which means that the decision maker receives a random reward of 1 if the chosen user j accepts the promotion or 0 reward otherwise. μ_j is chosen uniformly at random from $[0.3, 0.8]$ and there are 50 randomly chosen users with optimal $\mu_j = 0.9$.

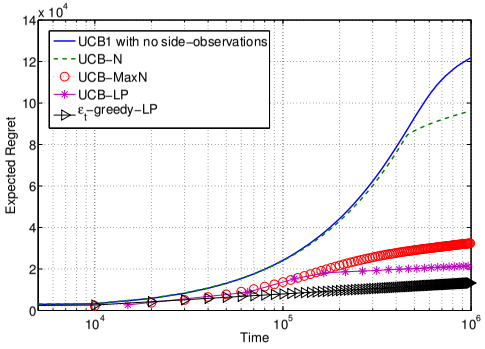

Figure 3: Regret comparison of all the policies for a network of size 1000.

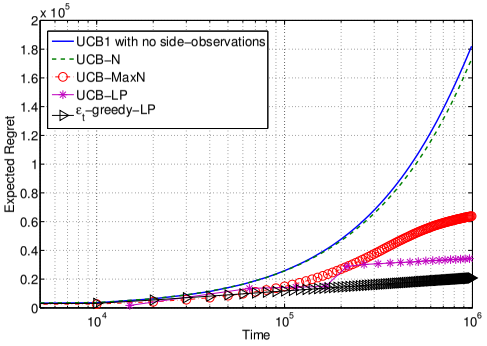

Figure 4: Regret comparison of all the policies for a network of size 2000.

Figures 3 and 4 show the regret performance as a function of time for the two sub-networks of sizes 1000 and 2000 respectively. Note that the average regret is taken over 1000 experiments. For the ϵ_t-greedy-LP policy, we let $c = 5$ and $d = 0.2$ (we choose $d = 0.2$ to show that our algorithm seems to have good performance in more general settings, even when the bounds in the Proposition 7 are not known or used). For both networks, we see that our policies outperform the UCB-N and UCB-MaxN policies Caron et al. (2012)

(UCB-N and UCB-MaxN policies can also be viewed as special cases of those proposed in Chen et al. (2013) for this specific combinatorial structure). We also observe that the improvement obtained by UCB-N policy over the baseline UCB1 policy is marginal. It has been shown (Cooper et al., 2005) that for power law graphs, both $\gamma(G)$ and $\bar{\chi}(G)$ scale linearly with N, although $\gamma(G)$ has a lower slope. Our numerical results show that our policies outperform existing policies even for the Flixster network.

As we show in Corollary 8 and Proposition 10, ϵ_t-greedy-LP and UCB-LP have the same upper bound $O(\sum_{j \in \mathcal{U}} z_j^* \log T)$. It is hard to say which algorithm outperforms the other one. In the Flixster network, we see that the ϵ_t-greedy-LP policy performs better than the UCB-LP policy. As we show in Section 7.2, UCB-LP performs better than ϵ_t-greedy-LP. In addition, the regret gap between the ϵ_t-greedy-LP and UCB-LP is not large compared to their gain to UCB-N and UCB-maxN.

7.2 Algorithm Performance on Synthetic Data

We consider a routing problem defined on a communication network, which is demonstrated as an undirected graph consisting of 6 nodes in Figure 5. We assume that node 1 is the source node and node 6 is the destination node. The decision maker repeatedly sends packets from the source node to the destination node. There exist 13 simple paths from the source node to the destination node. The delay of each path is the sum of delays over all the constituent links. The goal of the decision maker is to identify the path with the smallest expected delay and minimize the regret as much as possible.

Solving the routing problem is a direct application of this work once we let the set of paths be the set of actions and the set of links be the set of base-arms. We assume that the delay of each link i, denoted by $X_i(t)$, is an independent and identically distributed sequence of random variables (drawn from the steady-state distribution) over discrete time t. Then, this is a stochastic bandit problem with side-observations since playing one action (path) reveals some observations of some base-arms (links) that contribute to other actions (paths). For example, choosing path $(1, 2, 4, 6)$ reveals the delay performance of link $(1, 2)$ and $(2, 4)$, which are included in the path $(1, 2, 4, 5, 6)$.

In the routing problem, there are 13 paths and 12 directed links (note that some links are never used in all the paths). Thus, we set $K = 13$ and $N = 12$ in the simulation. Then, we construct the set V_j for each action j such that $i \in V_j$ if path j traverses the link i. And, we set $\mathcal{K}_j = V_j$ for each $j \in \mathcal{K}$ since the delay of a path is the total delay of the traversed links. Let B be the upper bound of all the action delays. Then, we choose the function $f_j(\vec{X}_j(t)) = 1 - \sum_{i \in \mathcal{K}_j} X_i(t)/B$ as the reward of playing action j at time t. In the simulation, we assume that the delay of link i is sampled from a Bernoulli distribution with mean u_i. Each u_i is independently sampled from a uniform distribution from 0 to 1, which realizes the problem instance in Figure 5[3]. One can check that the optimal action (shortest path) is the path $(1, 3, 5, 6)$ given the ground truth $\{u_i\}_{i \in \mathcal{N}}$. We let $B = 5$ in the simulation.

We apply the UCB1, UCB-N, Cohen (Cohen et al., 2016) and our policies to the problem instance in Figure 5 and the regret performance, averaged over 1000 experiments, is shown in Figure 6. We do not represent the result of the UCB-MaxN because it degenerates to

3. The number indicates the mean delay and the arrow indicates the direction of the link

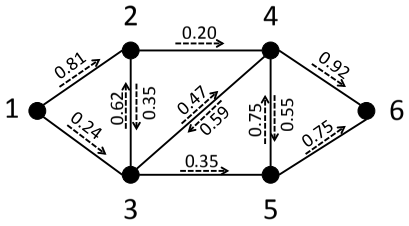

Figure 5: Routing problem on a communication network

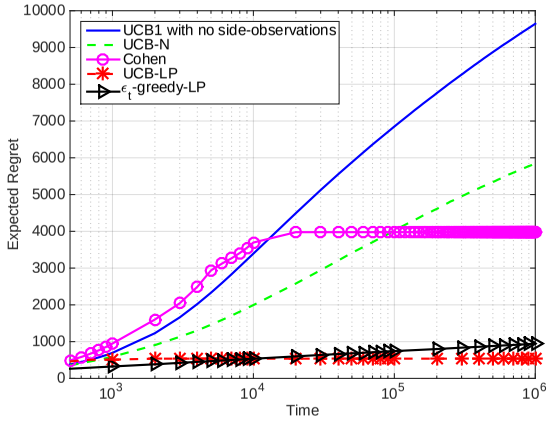

Figure 6: Regret comparison of all the policies for the routing problem

the UCB-N policy. The reason is that there is no non-trivial clique (clique with more than one element) in this problem due to the setting $\mathcal{K}_j = V_j$ and $\mathcal{K}_j \neq \mathcal{K}_a$ for any $j, a \in \mathcal{K}$. Intuitively, there does not exist two paths that can observe the outcome of each other. For the ϵ_t-greedy-LP policy, we let $c = 4$ and $d = 0.05$. From the regret performance, we observe that the improvement obtained by the UCB-N policy against the UCB1 policy is considerably greater than the results in Figure 3 and Figure 4. The reason behind this is that the bipartite graph in the routing problem is more dense and network size is small in the routing problem, which enables the UCB-N policy to take the advantage of side-observations. Overall, we see that our policies outperform the UCB-N policy and Cohen policy because our policies take the network structure into consideration, which enables us to trade off the exploration with exploitation more efficiently.

7.3 Asymptotic Behavior

We run a simulation to verify the result provided in Proposition 5. For each base-arm size N, we sequentially generate action j such that $e_{ij} = 1$ with probability p for any $i \in \mathcal{N}$ independently. Stopping time τ is the number of actions we have generated so that there are no useless base-arms in the network. Note that τ is an upper bound of $\gamma(G)$ and $\sum_{j\in\mathcal{K}} z_j^*$ as shown in Appendix B. Then, we solve the linear program P2 to obtain $\sum_{j\in\mathcal{K}} z_j^*$ and find a hitting set by a greedy algorithm.[4]

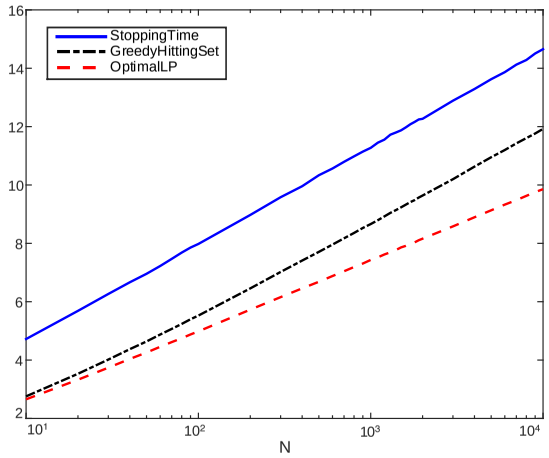

Figure 7: Erdos-Renyi random graph with p=0.5

Figure 7 shows the average result over 1000 samples for each N when $p = 0.5$. The numerical result verifies our theoretical result that $\sum_{j\in\mathcal{K}} z_j^*$ is upper-bounded by a logarithmic function of N asymptotically in Erdos-Renyi random graph. The reason why we are interested in the scaling order of $\sum_{j\in\mathcal{K}} z_j^*$ is that the traditional UCB1 policy suffers from the curse of dimensionality when applied in the real world, such as recommendation systems with thousands of items. However, our policies show a regret of $O(\sum_{j\in\mathcal{K}} z_j^* \log T)$, and $\sum_{j\in\mathcal{K}} z_j^*$ is upper-bounded by a logarithmic function of the number of unknowns, which makes our policies scalable in some large networks.

8. Summary

In this work, we introduce an important structural form of feedback available in many multiarmed bandits using the bipartite network structure. We obtained an asymptotic (with respect to time) lower bound as a function of the network structure on the regret of

4. It is well known that hitting set problem is NP-complete. So we employ the greedy algorithm which brings in the node with the largest degree in the network during each iteration.

any uniformly good policy. Further, we proposed two policies: 1) the ϵ_t-greedy-LP policy, and 2) the UCB-LP policy, both of which are optimal in the sense that they achieve the asymptotic lower bound on the regret, up to a multiplicative constant that is independent of the network structure. These policies can have a better regret performance than existing policies for some important network structures. The ϵ_t-greedy-LP policy is a network-aware any-time policy, but its exploration is oblivious to the average rewards of the suboptimal actions. On the other hand, UCB-LP considers both the network structure and the average rewards of actions.

Important avenues of future work include the case of dynamic graphs – what would be the lower bound and corresponding algorithms if the graph structure remains known but changes with time? Recently Tossou et al. (2017) presented a novel extension of Thompson sampling algorithm for the setting of immediate neighbor feedback studied in Mannor and Shamir (2011); Caron et al. (2012); Buccapatnam et al. (2014). It would be interesting to see how to adapt Thompson sampling algorithm for the bipartite graph feedback structure introduced in our current work.

In what follows, we give the proofs of all propositions stated in the earlier sections. These proofs make use of Lemmas 15, 16, and 17, and Proposition 18 given in Section F.

Appendix A. Proof of Proposition 4

Let $\mathcal{U} = \{j : \mu_j < \mu^*\}$ be the set of suboptimal actions. Also, let $\Delta_j = \mu^* - \mu_j$. Also, $T_j(t)$ is the total number of times action j is chosen up to time t by policy $\boldsymbol{\phi}$. Let $M_i(t)$ be the total number of observations corresponding to base-arm i available at time t. From Proposition 18 given in the Appendix, we have,

$$\liminf_{t\to\infty} \frac{\mathbb{E}[M_i(t)]}{\log(t)} \geq \frac{1}{J_i(\theta_i)}, \ \forall i \in \mathcal{N}. \tag{8}$$

An observation is received for base-arm i whenever any action in S_i is chosen. Hence,

$$M_i(t) = \sum_{j\in S_i} T_j(t). \tag{9}$$

Now, from Equations (8) and (9), for each $i \in \mathcal{N}$,

$$\liminf_{t\to\infty} \frac{\sum_{j\in S_i} \mathbb{E}[T_j(t)]}{\log(t)} \geq \frac{1}{J_i(\theta_i)}. \tag{10}$$

Using (10), we get the constraints of LP P_1. Further, we have from definition of regret that,

$$\liminf_{t\to\infty} \frac{R_\mu(t)}{\log(t)} = \liminf_{t\to\infty} \sum_{j\in\mathcal{U}} \Delta_j \frac{\mathbb{E}[T_j(t)]}{\log(t)}.$$

The above equation along with the constraints of the LP P_1 obtained from (10) gives us the required lower bound on regret.

Appendix B. Proof of Proposition 5

Here we consider a E-R random graph with each entry of the matrix E equals 1 with probability p, where $0 < p < 1$. Consider the following discrete stochastic process. χ_n are i.i.d., such that $\chi_n \subseteq [N]$ is sampled by the following steps: for each $i = 1, 2, .., N$, $i \in \chi_n$ with probability p. Let $q = 1 - p$. Then let τ be a stopping time defined as

$$\tau = \min\{n \geq 1, \cup_{j=1}^{n} \chi_j = [N]\} \tag{11}$$

The complement cdf of τ is the following.

$$P(\tau > n) = 1 - (1 - q^n)^N \tag{12}$$

1. Fix N. Given $0 < p < 1$, then $0 < q < 1$. Thus, $P(\tau = \infty) = 0$
2. What is the upper bound of $E(\tau)$?

$$(1 - q^n)^N > \exp(-\frac{q^n N}{1 - q^n}) \ \ (since \ \ln(1 - x) > -\frac{x}{1 - x} \ \ for \ \ 0 < x < 1) \tag{13}$$

Thus, we have

$$P(\tau > n) < 1 - \exp(-\frac{q^n N}{1-q^n}) \leq \frac{q^n N}{1-q^n} \quad (since\ 1 - e^x \leq -x) \tag{14}$$

Then we can bound the expectation of τ.

$$E(\tau) = \sum_{n=1}^{\infty} P(\tau > n) < \sum_{n=1}^{\infty} q^n \frac{N}{1-q} = \frac{qN}{(1-q)^2} \tag{15}$$

3. What is the upper bound of $P(\tau \leq n)$?

$$P(\tau \leq n) = (1-q^n)^N \leq \exp(-q^n N) \tag{16}$$

4. Does τ converge as N goes to infinity?
Given $\epsilon > 0$, as N goes to ∞,

$$P(\tau \leq (1-\epsilon)\log_{1/q} N) \leq \exp(-q^{(1-\epsilon)\log_{1/q} N} N) = \exp(-N^{\epsilon}) \to 0 \tag{17}$$

$$P(\tau > (1+\epsilon)\log_{1/q} N) \leq \frac{q^{(1+\epsilon)\log_{1/q} N} N}{1-q} = \frac{1}{(1-q)N^{\epsilon}} \to 0 \tag{18}$$

Since ϵ is arbitrary, we can have

$$P(\tau = \log_{1/q} N) \to 1 \ \ as\ N \to \infty. \tag{19}$$

That is to say τ converges to $\log_{1/q} N$ in probability.

Suppose there are no useless base-arms in the network, i.e. $[K]$ is a hitting set. Then τ is less than K with probability 1. Given this information, $\gamma(G)$ should be upper bounded by $\log_{1/q} N$ as N goes to infinity.

Appendix C. Proof of Proposition 6

Let $(z_j^*)_{j\in\mathcal{K}}$ be the optimal solution of LP P_2. We will first prove the upper bound in Equation 2. Using the optimal solution $(w_j^*)_{j\in\mathcal{K}}$ of LP P_1, we construct a feasible solution satisfying constraints in LP P_2 in the following way: For actions $j \in \mathcal{K}$, let $z_j = \left(\max_{i\in\mathcal{N}} J_i(\theta_i)\right) w_j^*$. Then $(z_j)_{j\in\mathcal{K}}$ satisfy constraints for all base-arms $i \in \mathcal{N}$ because w_j^* satisfy constraints of LP P_1.
The feasible solution constructed in this way gives an upper bound on the optimal value of LP P_2. Hence,

$$\begin{aligned}
\sum_{j\in\mathcal{K}} z_j^* &\leq \sum_{j\in\mathcal{U}} z_j + |\mathcal{O}| \\
&\leq \sum_{j\in\mathcal{U}} \left(\max_{i\in\mathcal{N}} J_i(\theta_i)\right) w_j^* + |\mathcal{O}| \\
&\leq \frac{\max_{i\in\mathcal{N}} J_i(\theta_i)}{\min_{j\in\mathcal{U}} \Delta_j} \sum_{j\in\mathcal{U}} \Delta_j w_j^* + |\mathcal{O}| \\
&\leq \frac{\max_{i\in\mathcal{N}} J_i(\theta_i)}{\min_{j\in\mathcal{U}} \Delta_j} c_{\boldsymbol{\mu}} + |\mathcal{O}|
\end{aligned}$$

For the lower bound, any feasible solution of P_2, in particular $\mathbf{z}^*$, can be used to construct a feasible solution of P_1. For actions $j \in \mathcal{K}$, let $w_j = \frac{z_j^*}{\min_{i\in\mathcal{N}} J_i(\theta_i)}$. Then $(w_j)_{j\in\mathcal{K}}$ satisfies the constraints of LP P_1 and hence gives an upper bound on its optimal value. Therefore, we have

$$\begin{aligned}
c_{\boldsymbol{\mu}} &= \sum_{j\in\mathcal{U}} \Delta_j w_j^*, \\
&\leq \sum_{j\in\mathcal{K}} \frac{\Delta_j z_j^*}{\min_{i\in\mathcal{N}} J_i(\theta_i)} \\
&\leq \sum_{j\in\mathcal{K}} \frac{\max_{a\in\mathcal{U}} \Delta_a z_j^*}{\min_{i\in\mathcal{N}} J_i(\theta_i)}
\end{aligned}$$

which gives us the required lower bound.

Appendix D. Proof of Proposition 7

Since $\mathbf{z}^*$ satisfies the constraints in LP P_2, there is sufficient exploration within each suboptimal action's neighborhood. The proof is then a combination of this fact and the proof of Theorem 3 in Auer et al. (2002). Let $\bar{f}_j(t)$ be the random variable denoting the sample mean of all observations available for action j at time t. Let $\bar{f}^*(t)$ be the random variable denoting the sample mean of all observations available for an optimal action at time t. Fix a suboptimal action j. For some $\alpha > 1$, define m_i for each base-arm i as follows,

$$m_i = \frac{1}{\alpha} \frac{\sum_{j\in S_i} z_j^*}{\sum_{j\in\mathcal{K}} z_j^*} \sum_{m=1}^{t} \epsilon(m)$$

Let $\phi(t)$ be the action chosen by ϵ_t-greedy-LP policy at time t. The event $\{\phi(t) = j\}$ implies that either sampling a random action j for exploration or playing the best observed action j for exploitation. Then,

$$\mathbb{P}[\phi(t) = j] \leq \frac{\epsilon(t) z_j^*}{\sum_{a\in\mathcal{K}} z_a^*} + (1 - \epsilon(t))\mathbb{P}[\bar{f}_j(t) \geq \bar{f}^*(t)]$$

The event $\{\bar{f}_j(t) \geq \bar{f}^*(t)\}$ implies that either $\{\bar{f}_j(t) \geq \mu_j + \frac{\Delta_j}{2}\}$ or $\{\bar{f}^*(t) \leq \mu^* - \frac{\Delta_j}{2}\}$ since $\mu_j + \frac{\Delta_j}{2} = \mu^* - \frac{\Delta_j}{2}$. We also have that,

$$\mathbb{P}[\bar{f}_j(t) \geq \bar{f}^*(t)] \leq \mathbb{P}\left[\bar{f}_j(t) \geq \mu_j + \frac{\Delta_j}{2}\right] + \mathbb{P}\left[\bar{f}^*(t) \leq \mu^* - \frac{\Delta_j}{2}\right].$$

The analysis of both the terms in the right hand side of the above expression is similar. Let $O_i^R(t)$ be the total number of observations available for base-arm i from the exploration iterations of the policy up to time t. Let $O_i(t)$ be the total number of observations available for base-arm i up to time t. By concentration inequalities, the probability that the empirical mean deviate from the expectation can be bounded given the number of observations. The

number of observations for action j is lower-bounded by the number of observations from the exploration iterations. Hence, we have,

$$\begin{aligned}
\mathbb{P}\left[\bar{f}_j(t) \geq \mu_j + \frac{\Delta_j}{2}\right] &= \sum_{m=1}^{t} \mathbb{P}\left[\min_{i\in\mathcal{K}_j} O_i(t) = m; \bar{f}_j(t) \geq \mu_j + \frac{\Delta_j}{2}\right] \\
&= \sum_{m=1}^{t} \mathbb{P}\left[\bar{f}_j(t) \geq \mu_j + \frac{\Delta_j}{2} | \min_{i\in\mathcal{K}_j} O_i(t) = m\right] \mathbb{P}\left[\min_{i\in\mathcal{K}_j} O_i(t) = m\right] \\
&\leq \sum_{m=1}^{t} \mathbb{P}\left[\min_{i\in\mathcal{K}_j} O_i(t) = m\right] e^{\frac{-\Delta_j^2 m}{2}} \\
&\text{(follows from Chernoff-Hoeffding bound in Lemma 15)} \\
&\leq \sum_{m=1}^{t} \mathbb{P}\left[\min_{i\in\mathcal{K}_j} O_i^R(t) \leq m\right] e^{\frac{-\Delta_j^2 m}{2}} \\
&\leq \sum_{m=1}^{\lfloor m_0 \rfloor} \mathbb{P}\left[\min_{i\in\mathcal{K}_j} O_i^R(t) \leq m\right] + \sum_{m=\lfloor m_0 \rfloor+1}^{t} e^{\frac{-\Delta_j^2 m}{2}} \\
&\leq m_0 \mathbb{P}\left[\min_{i\in\mathcal{K}_j} O_i^R(t) \leq m_0\right] + \frac{2}{\Delta_j^2} e^{\frac{-\Delta_j^2 m_0}{2}} \\
&\qquad \left(\text{since } \sum_{m+1}^{\infty} e^{-ku} \leq \frac{1}{k} e^{-km}\right) \\
&\leq \sum_{i\in\mathcal{K}_j} m_0 \mathbb{P}\left[O_i^R(t) \leq m_0\right] + \frac{2}{\Delta_j^2} e^{\frac{-\Delta_j^2 m_0}{2}},
\end{aligned}$$

where $m_0 = \min_{i\in\mathcal{N}} m_i$.

Recall that $O_i^R(t)$ is the total number of observations for base-arm i from exploration. Now, we derive the bounds for the expectation and variance of $O_i^R(t)$ in order to use Bernstein's inequality.

$$\begin{aligned}
\mathbb{E}\left[O_i^R(t)\right] &= \sum_{m=1}^{t} \epsilon(m) \sum_{j\in S_i} \frac{z_j^*}{\sum_{j\in\mathcal{K}} z_j^*} \\
&= \frac{\sum_{j\in S_i} z_j^*}{\sum_{j\in\mathcal{K}} z_j^*} \sum_{m=1}^{t} \epsilon(m) = \alpha m_i \\
&\geq \alpha m_0
\end{aligned}$$

$$\begin{aligned}
var\left[O_i^R(t)\right] &= \sum_{m=1}^{t} \left(\epsilon(m) \sum_{j\in S_i} \frac{z_j^*}{\sum_{j\in\mathcal{K}} z_j^*}\right) \left(1 - \epsilon(m) \sum_{j\in S_i} \frac{z_j^*}{\sum_{j\in\mathcal{K}} z_j^*}\right) \\
&\leq \sum_{m=1}^{t} \epsilon(m) \sum_{j\in S_i} \frac{z_j^*}{\sum_{j\in\mathcal{K}} z_j^*} \\
&= \mathbb{E}[O_i^R(t)] = \alpha m_i
\end{aligned}$$

Now, using Bernstein's inequality given in Lemma 16, we have

$$\begin{aligned}
\mathbb{P}\left[O_i^R(t) \leq m_0\right] &= \mathbb{P}\left[O_i^R(t) \leq \mathbb{E}[O_i^R(t)] + m_0 - \alpha m_i\right] \\
&\leq \mathbb{P}\left[O_i^R(t) \leq \mathbb{E}[O_i^R(t)] + m_i - \alpha m_i\right] \\
&\leq \exp\left(-\frac{(\alpha-1)^2 m_i^2}{2\alpha m_i + \frac{2}{3}(\alpha-1)m_i}\right) \\
&= \exp\left(-\frac{3(\alpha-1)^2}{8\alpha-2} m_i\right) = \exp(-r m_i)
\end{aligned}$$

where $r = \frac{3(\alpha-1)^2}{8\alpha-2}$. Now, we will obtain upper and lower bounds on m_i by plugging in the definition of $\epsilon(m)$. For the upper bound, for any $t > t' = \frac{c\sum_{i\in\mathcal{K}} z_i^*}{d^2}$,

$$\begin{aligned}
m_i &= \frac{\sum_{j\in S_i} z_j^*}{\alpha \sum_{j\in\mathcal{K}} z_j^*} \sum_{m=1}^{t} \epsilon(m) \\
&= \frac{\sum_{j\in S_i} z_j^*}{\alpha \sum_{j\in\mathcal{K}} z_j^*} t' + \frac{\sum_{j\in S_i} z_j^*}{\alpha \sum_{j\in\mathcal{K}} z_j^*} \sum_{m=t'+1}^{t} \frac{c\sum_{i\in\mathcal{K}} z_i^*}{d^2 m} \\
&\leq \frac{c\delta}{\alpha d^2} \left(1 + \sum_{m=t'+1}^{t} \frac{1}{m}\right) \\
&\leq \frac{c\delta}{\alpha d^2} \log\left(\frac{e^2 t}{t'}\right).
\end{aligned}$$

where $\delta = \max_{i\in\mathcal{N}} |S_i|$, denoting the maximum degree of the supports in the network. In the above, $\sum_{j\in S_i} z_j^* \leq \delta$ because $z_j^* \leq 1$, which is due to the fact that $\left(z_j^*\right)_{j\in\mathcal{K}}$ is the optimal solution of LP P_2. Next, for the lower bound, we use the fact that $\sum_{j\in S_i} z_j^* \geq 1$ for all i because $\left(z_j^*\right)_{j\in\mathcal{K}}$ satisfies the constraints of LP P_2. Thus

$$\begin{aligned}
m_i &\geq \frac{\sum_{j\in S_i} z_j^*}{\alpha \sum_{j\in\mathcal{K}} z_j^*} \sum_{m=t'+1}^{t} \frac{c\sum_{i\in\mathcal{K}} z_i^*}{d^2 m} \\
&\geq \frac{c}{\alpha d^2} \sum_{m=t'+1}^{t} \frac{1}{m} \\
&\geq \frac{c}{\alpha d^2} \log\left(\frac{t}{et'}\right).
\end{aligned}$$

Let $\lambda = \max_{j\in\mathcal{K}} |\mathcal{K}_j|$. Hence, combining the inequalities above,

$$\begin{aligned}
\mathbb{P}\left[\bar{f}_j(t) \geq \mu_j + \frac{\Delta_j}{2}\right] &\leq \sum_{i\in\mathcal{K}_j} m_0 \mathbb{P}\left[O_i^R(t) \leq m_0\right] + \frac{2}{\Delta_j^2} e^{-\frac{\Delta_j^2 m_0}{2}} \\
&\leq \sum_{i\in\mathcal{K}_j} m_0 \left(\frac{et'}{t}\right)^{cr/\alpha d^2} + \frac{2}{\Delta_j^2} e^{-\frac{\Delta_j^2 m_0}{2}} \\
&\leq \lambda \frac{c\delta}{\alpha d^2}\left(\log\left(\frac{e^2 t}{t'}\right)\right)\left(\frac{et'}{t}\right)^{cr/\alpha d^2} + \frac{2}{\Delta_j^2}\left(\frac{et'}{t}\right)^{\frac{c\Delta_j^2}{2\alpha d^2}}
\end{aligned}$$

Now, similarly for the optimal action, we have, for all $t > t'$

$$\mathbb{P}\left[\bar{f}^*(t) \leq \mu^* - \frac{\Delta_j}{2}\right] \leq \frac{\lambda c\delta}{\alpha d^2}\left(\frac{et'}{t}\right)^{cr/\alpha d^2} \log\left(\frac{e^2 t}{t'}\right) + \frac{2}{\Delta_j^2}\left(\frac{et'}{t}\right)^{\frac{c\Delta_j^2}{2\alpha d^2}}.$$

Combining everything, we have for any suboptimal action j, for all $t > t'$

$$\begin{aligned}
\mathbb{P}[\phi(t) = j] &\leq \frac{\epsilon(t) z_j^*}{\sum_{a\in\mathcal{K}} z_a^*} + (1-\epsilon(t))\, P[\bar{f}_j(t) \geq \bar{f}^*(t)] \\
&\leq \frac{c z_j^*}{d^2 t} + P[\bar{f}_j(t) \geq \bar{f}^*(t)] \\
&\leq \frac{c z_j^*}{d^2 t} + \frac{2\lambda c\delta}{\alpha d^2}\left(\frac{et'}{t}\right)^{cr/\alpha d^2} \log\left(\frac{e^2 t}{t'}\right) + \frac{4}{\Delta_j^2}\left(\frac{et'}{t}\right)^{\frac{c\Delta_j^2}{2\alpha d^2}}
\end{aligned}$$

Appendix E. Proof of Proposition 10

The proof technique is similar to that in Auer and Ortner (2010). We will analyze the regret by conditioning on two disjoint events. The first event is that each suboptimal action a is eliminated by an optimal action on or before the first round m such that $\tilde{\Delta}_m < \Delta_a/2$. This happens with high probability and leads to logarithmic regret. The compliment of the first event yields linear regret in time but occurs with probability proportional to $1/T$. The main difference from the proof in Auer and Ortner (2010) is that on the first event, the number of times we choose each action j is proportional to $z_j^* \log(T)$ in the exploration iterations (i.e., when $|B_m| > 1$) of the policy. This gives us the required upper bound in terms of optimal solution $\mathbf{z}^*$ of LP P_2.

Let $*$ denote any optimal action. Let m^* denote the round in which the last optimal action $*$ is eliminated. For each suboptimal action j, define round $m_j := \min\{m : \tilde{\Delta}_m < \frac{\Delta_j}{2}\}$. For an optimal action j, $m_j = \infty$ by convention. Then, by the definition of m_j, for all rounds $m < m_j$, $\Delta_j \leq 2\tilde{\Delta}_m$, and

$$\frac{2}{\Delta_j} < 2^{m_j} = \frac{1}{\tilde{\Delta}_{m_j}} \leq \frac{4}{\Delta_j} < \frac{1}{\tilde{\Delta}_{m_j+1}} = 2^{m_j+1}. \tag{20}$$

From Lemma 17 in the Appendix, the probability that action j is not eliminated in round m_j by $*$ is at most $\frac{2}{T\tilde{\Delta}_{m_j}^2}$.

Let $I(t)$ be the action chosen at time t by the UCB-LP policy.
Let E_{m^*} be the event that all suboptimal actions with $m_j \leq m^*$ are eliminated by $*$ on or before their respective m_j. Then, the complement of E_{m^*}, denoted as $E_{m^*}^c$, is the event that there exists some suboptimal action j with $m_j \leq m^*$, which is not eliminated by round m_j. Let E_j^c be the event that action j is not eliminated by round m_j by $*$. Let $m_f = \lfloor \frac{1}{2}\log_2 \frac{T}{e} \rfloor$ and $I(t)$ denote the action chosen at time t by the policy. Recall that regret is denoted by $R_{\boldsymbol{\mu}}(T)$. Let $\mathbb{P}[m^* = m]$ be denoted by p_m. Hence, $\sum_{m=0}^{m_f} p_m = 1$.

$$\begin{aligned}
\mathbb{E}\left[R_{\boldsymbol{\mu}}(T)\right] &= \sum_{m=0}^{m_f} \mathbb{E}\left[R_{\boldsymbol{\mu}}(T) | \{m^* = m\}\right] \mathbb{P}[m^* = m] \\
&= \sum_{m=0}^{m_f}\sum_{t=1}^{T}\sum_{j\in\mathcal{U}} \Delta_j \mathbb{P}\left[I(t) = j | \{m^* = m\}\right] p_m \\
&= \sum_{m=0}^{m_f}\sum_{t=1}^{T}\sum_{j\in\mathcal{U}} \Delta_j \mathbb{P}\left[\{I(t) = j\} \cap E_{m^*} | \{m^* = m\}\right] p_m \\
&\quad + \sum_{m=0}^{m_f}\sum_{t=1}^{T}\sum_{j\in\mathcal{U}} \Delta_j \mathbb{P}\left[\{I(t) = j\} \cap E_{m^*}^c | \{m^* = m\}\right] p_m \\
&= (i) + (ii)
\end{aligned}$$

Next we will show that term (i) leads to logarithmic regret while term (ii) leads to a constant regret with time.
First, consider the term (ii) of the regret expression. For each $j \in \mathcal{U}$, we have,

$$\begin{aligned}
&\sum_{m=0}^{m_f}\sum_{t=1}^{T} \mathbb{P}\left[\{I(t) = j\} \cap E_{m^*}^c | \{m^* = m\}\right] \mathbb{P}[m^* = m] \\
&\leq \sum_{m=0}^{m_f}\sum_{t=1}^{T} \mathbb{P}\left[\{I(t) = j\} \cap \left(\cup_{a\in\mathcal{U}: m_a \leq m^*} E_a^c\right) | \{m^* = m\}\right] p_m \\
&\leq \sum_{m=0}^{m_f}\sum_{t=1}^{T} \Big(\mathbb{P}\left[\{I(t) = j\} | \left(\cup_{a\in\mathcal{U}: m_a \leq m^*} E_a^c\right), \{m^* = m\}\right] \\
&\qquad\qquad \mathbb{P}\left[\cup_{a\in\mathcal{U}: m_a \leq m^*} E_a^c | \{m^* = m\}\right] p_m\Big) \\
&\leq T\mathbb{P}\left[\cup_{a\in\mathcal{U}} E_a^c | \{m^* = m_f\}\right] \sum_{m=0}^{m_f} p_m \\
&\leq T \sum_{a\in\mathcal{U}} \frac{2}{T\tilde{\Delta}_{m_a}^2}, \\
&\left(\text{using Lemma 17, } \mathbb{P}\left[E_a^c | \{m^* = m_f\}\right] \leq \frac{2}{T\tilde{\Delta}_{m_a}^2}\right) \\
&\leq \sum_{a\in\mathcal{U}} \frac{32}{\Delta_a^2},
\end{aligned}$$

where the last inequality follows from Equation (20). Hence, the term (ii) of regret is

$$\sum_{m=0}^{m_f}\sum_{t=1}^{T}\sum_{j\in\mathcal{U}}\Delta_j\mathbb{P}\left[\{I(t)=j\}\cap E^c_{m^*}|\{m^*=m\}\right]p_m \leq \sum_{j\in\mathcal{U}}\Delta_j\sum_{a\in\mathcal{U}}\frac{32}{\Delta_a^2}=O(K^2). \tag{21}$$

Next, we consider the term (i). Recall that, in this term, we consider the case that all suboptimal actions j with $m_j \leq m^*$ are eliminated by $*$ on or before m_j.

$$\begin{aligned}
(i) &= \sum_{m=0}^{m_f}\sum_{t=1}^{T}\sum_{j\in\mathcal{U}}\Delta_j\mathbb{P}\left[\{I(t)=j\}\cap E_{m^*}|\{m^*=m\}\right]p_m\\
&= \sum_{m=0}^{m_f}\mathbb{E}\left[R_{\boldsymbol{\mu}}(T)|\{m^*=m\},E_{m^*}\right]\mathbb{P}[E_{m^*}|\{m^*=m\}]p_m\\
&\leq \sum_{m=0}^{m_f}\Big(\mathbb{E}\left[\text{Regret from }\{j:m_j\leq m^*\}|\{m^*=m\},E_{m^*}\right]\\
&\quad+\mathbb{E}\left[\text{Regret from }\{j:m_j>m^*\}|\{m^*=m\},E_{m^*}\right]\Big)p_m\\
&\leq \sum_{m=0}^{m_f}\Big(\mathbb{E}\left[\text{Regret from }\{j:m_j\leq m_f\}|\{m^*=m_f\},E_{m_f}\right]\\
&\quad+\mathbb{E}\left[\text{Regret from }\{j:m_j>m^*\}|\{m^*=m\},E_{m^*}\right]\Big)p_m\\
&\leq \mathbb{E}\left[R_{\boldsymbol{\mu}}(T)|\{m^*=m_f\},E_{m_f}\right]\sum_{m=0}^{m_f}p_m\\
&+\sum_{m=0}^{m_f}\mathbb{E}\left[\text{Regret from }\{j:m_j>m^*\}|\{m^*=m\},E_{m^*}\right]p_m\\
&= (ia)+(ib)
\end{aligned}$$

Once again, we will consider the above two terms separately. For the term (ia), under the event E_{m_f}, each suboptimal action j is eliminated by $*$ by round m_j. Define round $\bar{m}$ and the set B as follows:

$$\begin{aligned}
\bar{m} &= \min\{m:\sum_{j\in\mathcal{K}}z_j^*>\sum_{a:m_a>m}2^{-m+1}\},\\
B &= \{j\in\mathcal{U}:m_j>\bar{m}\}.
\end{aligned}$$

After round $\bar{m}$, Algorithm 2 chooses only those actions with $m_j>\bar{m}$. Also, by the definition of the **Reset** phase of Algorithm 2, we have that any suboptimal action $j\notin B$ is chosen (i.e. appears in the set A_m at round m) only until it is not in A_m or until $\bar{m}$, whichever happens

first. Define $n_j=\min\{\bar{m},\max_{a:j\in G_a}\{m_a\}\}$ for each suboptimal action j, where $G_a=\bigcup_{i\in\mathcal{K}_a}S_i$ for action a. Then any suboptimal action $j\notin B$ is chosen for at most n_j rounds.

$$\begin{aligned}
(ia) &= \mathbb{E}\left[R_{\boldsymbol{\mu}}(T)|\{m^*=m_f\},E_{m_f}\right]\\
&\leq \sum_{j\in\mathcal{U}\setminus B}\Delta_j z_j^*\frac{2\log(T\tilde{\Delta}^2_{n_j})}{\tilde{\Delta}^2_{n_j}}+\sum_{j\in B}\Delta_j\frac{2\log(T\tilde{\Delta}^2_{m_j})}{\tilde{\Delta}^2_{m_j}}\\
&\leq \sum_{j\in\mathcal{U}\setminus B}\Delta_j z_j^*\frac{32\log(T\hat{\Delta}^2_j)}{\hat{\Delta}^2_j}+\sum_{j\in B}\Delta_j\frac{32\log(T\Delta^2_j)}{\Delta^2_j},
\end{aligned} \tag{22}$$

where $\hat{\Delta}_j=\max\{2^{-\bar{m}+2},\min_{a:j\in G_a}\{\Delta_a\}\}$ and (z_j^*) is the solution of LP P_2.
Finally, we consider the term (ib). Note that $T_j(m)\geq n(m),\forall j\in B_m,\forall m$. An optimal action $*$ is not eliminated in round m^* if (25) holds for $m=m^*$. Hence, using (26) and (27), the probability p_m that $*$ is eliminated by a suboptimal action in any round m^* is at most $\frac{2}{T\tilde{\Delta}^2_{m^*}}$. Hence, term (ib) is given as:

$$\begin{aligned}
&\sum_{m=0}^{m_f}\mathbb{E}\left[\text{Regret from }\{j:m_j>m^*\}|\{m^*=m\},E_{m^*}\right]p_m\\
&\leq \sum_{m=0}^{m_f}\sum_{j\in\mathcal{U}:m_j\geq m}\frac{2}{T\tilde{\Delta}^2_m}.T\max_{a\in\mathcal{U}}\Delta_a\\
&\leq \max_{a\in\mathcal{U}}\Delta_a\sum_{m=0}^{m_f}\sum_{j\in\mathcal{U}:m_j\geq m}\frac{2}{\tilde{\Delta}^2_m}\\
&\leq \sum_{j\in\mathcal{U}}\sum_{m=0}^{m_j}\frac{2}{\tilde{\Delta}^2_m}\\
&\leq \sum_{j\in\mathcal{U}}2^{2m_j+2}\leq\sum_{j\in\mathcal{U}}\frac{64}{\Delta^2_j}=O(K).
\end{aligned} \tag{23}$$

Now we get the result (6) by combining the bounds in (21), (22), and (23).
Further, the definition of set B ensures that we have

$$\sum_{j\in B}\Delta_j\leq\sum_{j\in\mathcal{K}}z_j^*.$$

Also, using the Assumption 4, $\frac{32\Delta_j\log(T\hat{\Delta}^2_j)}{\hat{\Delta}^2_j},\frac{32\log(T\Delta^2_j)}{\Delta^2_j}$ are bounded by $C\log(T)$, where $C=\frac{32}{\min_{j\in\mathcal{U}}\Delta^2_j}$, is a constant independent of network structure. When one checks the feasibility of C, note that $\hat{\Delta}_j\geq\min_{a:j\in G_a}\Delta_a$ by definition and $\Delta_j\leq 1$ for any j since the

rewards are bounded by 1. Hence, (22) can be bounded as:

$$\begin{aligned}\sum_{j\in\mathcal{U}\setminus B}\Delta_j z_j^*\frac{32\log(T\hat{\Delta}_j^2)}{\hat{\Delta}_j^2}+\sum_{j\in B}\Delta_j\frac{32\log(T\Delta_j^2)}{\Delta_j^2}&\\ \leq\sum_{j\in\mathcal{U}\setminus B}z_j^*C\log(T)+\sum_{j\in B}\Delta_j C\log(T)&\\ \leq\sum_{j\in\mathcal{U}\setminus B}z_j^*C\log(T)+\sum_{j\in B}2^{-\bar{m}+1}C\log(T)&\\ \leq 2\sum_{j\in\mathcal{K}}z_j^*C\log(T).&\end{aligned}\tag{24}$$

Hence, we get (7) from (24), (21), and (23).

Appendix F. Supplementary Material

$S_n=\frac{1}{n}\sum_{j=1}^n X_j$ denotes the sample mean of the random variables $X_1,\ldots,X_n$. The first two lemmas below state the Chernoff-Hoeffding inequality and Bernstein's inequality.

Lemma 15 *Let $X_1,\ldots,X_n$ be a sequence of random variables with support $[0,1]$ and $\mathbb{E}[X_t]=\mu$ for all $t\leq n$. Let $S_n=\frac{1}{n}\sum_{j=1}^n X_j$. Then, for all $\epsilon>0$, we have,*

$$\begin{aligned}\mathbb{P}[S_n\geq\mu+\epsilon]&\leq e^{-2n\epsilon^2}\\ \mathbb{P}[S_n\leq\mu-\epsilon]&\leq e^{-2n\epsilon^2}.\end{aligned}$$

Lemma 16 *Let $X_1,\ldots,X_n$ be a sequence of random variables with support $[0,1]$ and $\sum_{k=1}^t var[X_k|X_1,\ldots,X_{k-1}]\leq\sigma^2$ for all $t\leq n$. Let $S_n=\sum_{j=1}^n X_j$. Then, for all $\epsilon>0$, we have,*

$$\begin{aligned}\mathbb{P}[S_n\geq\mathbb{E}[S_n]+\epsilon]&\leq\exp\left\{-\frac{\epsilon^2}{2\sigma^2+\frac{2}{3}\epsilon}\right\}\\ \mathbb{P}[S_n\leq\mathbb{E}[S_n]-\epsilon]&\leq\exp\left\{-\frac{\epsilon^2}{2\sigma^2+\frac{2}{3}\epsilon}\right\}.\end{aligned}$$

The next lemma is used in the proof of Proposition 10.

Lemma 17 *The probability that action j is not eliminated in round m_j by $*$ is at most $\frac{2}{T\tilde{\Delta}_{m_j}^2}$.*

Proof Let $\bar{f}_j(m)$ be the sample mean of all observations for action j available in round m. Let $\bar{f}^*(m)$ be the sample mean of the optimal action. The constraints of LP P_2 ensure that at the end of each round m, for all actions in B_m, we have at least $n(m):=\left\lceil\frac{2\log(T\tilde{\Delta}_m^2)}{\tilde{\Delta}_m^2}\right\rceil$ observations. The reason is as follows. The set A_m contains set B_m. In particular, $A_m=\cup_{i\in D_m}S_i$ and $D_m=\cup_{j\in B_m}\mathcal{K}_j$. If each action j in A_m is played z_j^* times, then all the base-arms in D_m have at least 1 observations according the constraints of LP P_2. Thus,

the actions in B_m have at least 1 observations. In sum, for all actions in B_m, we have at least $n(m)-n(m-1)$ observations at round m. Thus, we have at least $n(m)$ observations for all actions in B_m.

Now, for $m=m_j$, if we have,

$$\bar{f}_j(m)\leq\mu_j+\sqrt{\frac{\log(T\tilde{\Delta}_m^2)}{2n(m)}}\quad\text{and}\quad\bar{f}^*(m)\geq\mu^*-\sqrt{\frac{\log(T\tilde{\Delta}_m^2)}{2n(m)}},\tag{25}$$

then, action j is eliminated by $*$ in round m_j. In fact, in round m_j, we have

$$\sqrt{\frac{\log(T\tilde{\Delta}_{m_j}^2)}{2n(m_j)}}\leq\frac{\tilde{\Delta}_{m_j}}{2}<\frac{\Delta_j}{4}.$$

Hence, in the elimination phase of the UCB-LP policy, if (25) holds for action j in round m_j, we have,

$$\begin{aligned}\bar{f}_j(m_j)+\sqrt{\frac{\log(T\tilde{\Delta}_{m_j}^2)}{2n(m_j)}}&\leq\mu_j+2\sqrt{\frac{\log(T\tilde{\Delta}_{m_j}^2)}{2n(m_j)}}\\ &<\mu_j+\Delta_j-2\sqrt{\frac{\log(T\tilde{\Delta}_{m_j}^2)}{2n(m_j)}}\\ &=\mu^*-2\sqrt{\frac{\log(T\tilde{\Delta}_{m_j}^2)}{2n(m_j)}}\\ &\leq\bar{f}^*(m_j)-\sqrt{\frac{\log(T\tilde{\Delta}_{m_j}^2)}{2n(m_j)}},\end{aligned}$$

and action j is eliminated. Hence, the probability that action j is not eliminated in round m_j is the probability that either one of the inequalities in (25) do not hold. Using Chernoff-Hoeffding bound (Lemma 15), we can bound this as follows,

$$\mathbb{P}\left[\bar{f}_j(m)>\mu_j+\sqrt{\frac{\log(T\tilde{\Delta}_m^2)}{2n(m)}}\right]\leq\frac{1}{T\tilde{\Delta}_m^2}\tag{26}$$

$$\mathbb{P}\left[\bar{f}^*(m)<\mu^*-\sqrt{\frac{\log(T\tilde{\Delta}_m^2)}{2n(m)}}\right]\leq\frac{1}{T\tilde{\Delta}_m^2}.\tag{27}$$

Summing the above two inequalities for $m=m_j$ gives us that the probability that action j is not eliminated in round m_j by $*$ is at most $\frac{2}{T\tilde{\Delta}_{m_j}^2}$. ■

The next proposition is a modified version of Theorem 2 in Lai and Robbins (1985). We use it to obtain the regret lower bound in Proposition 4.

Proposition 18 *Suppose Assumptions 1, 2, and 3 hold. Let $M_i(t)$ be the total number of observations for such a base-arm i, for which $\vec{\theta}\in\Theta_i$. Then, under any uniformly good policy $\boldsymbol{\phi}$, we have that*

$$\liminf_{t\to\infty}\frac{\mathbb{E}[M_i(t)]}{\log(t)}\geq\frac{1}{J_i(\theta_i)}.$$

Proof By definition of $J_i(\theta_i)$, for every $\epsilon > 0$, there exists a $\theta_i' \in \mathcal{B}_i(\theta_i)$ such that $J_i(\theta_i) < D(\theta_i||\theta_i') < (1+\epsilon)J_i(\theta_i)$.

Now, under $\vec{\theta}_i' = [\theta_1, \ldots, \theta_i', \ldots \theta_N]$, there exists an action $k \in \mathcal{S}_i$ such that k is the unique optimal action. Then, for any uniformly good policy, for $0 < b < \delta$,

$$\mathbb{E}_{\vec{\theta}_i'}[t - T_k(t)] = o(t^b)$$

and therefore,

$$\mathbb{P}_{\vec{\theta}_i'}\left[T_k(t) < (1-\delta)\log(t)/D(\theta_i||\theta_i')\right] = o(t^{b-1}),$$

similar to the asymptotic lower bound proof in Lai and Robbins (1985).

Let $M_i(t)$ be the total number of observations for base-arm i. Then $M_i(t) \geq T_k(t)$, since choosing any action in $\mathcal{S}_i$ gives observations for i. Hence,

$$\mathbb{P}_{\vec{\theta}_i'}\left[M_i(t) < (1-\delta)\log(t)/D(\theta_i||\theta_i')\right] = o(t^{b-1}),$$

Now the rest of the proof of Theorem 2 in Lai and Robbins (1985) applies directly to $M_i(t)$. We will repeat it below for completeness. Let $(Y_i(r))_{r\geq 1}$ be the observations drawn from distribution F_i and define

$$L_m = \sum_{r=1}^{m} \log\left(\frac{g(Y_i(r);\theta_i)}{g(Y_i(r);\theta_i')}\right).$$

Now, we have that $\mathbb{P}_{\vec{\theta}_i'}[C_t] = o(t^{b-1})$ where $C_t = \{M_i(t) < (1-\delta)\log(t)/D(\theta_i||\theta_i')$ and $L_{M_i(t)} \leq (1-b)\log(t)\}$.

Now, we use the change of measure arguments.

$$\mathbb{P}_{\vec{\theta}_i'}[M_1(t) = m_1, \ldots, M_N(t) = m_N, L_{m_i} \leq (1-b)\log(t)] \tag{28}$$

$$= \int_{\{M_1(t)=m_1,\ldots,M_N(t)=m_N, L_{m_i}\leq(1-b)\log(t)\}} \Pi_{r=1}^{m_i} \frac{g(Y_i(r);\theta_i')}{g(Y_i(r);\theta_i)} dP_{\vec{\theta}_i} \tag{29}$$

$$\geq \exp(-(1-b)\log(t))\mathbb{P}_{\vec{\theta}_i}[M_1(t) = m_1, \ldots, M_N(t) = m_N, L_{m_i} \leq (1-b)\log(t)] \tag{30}$$

Since C_t is a disjoint union of events of the form $\{M_1(t) = m_1, \ldots, M_N(t) = m_N, L_{m_i} \leq (1-b)\log(t)\}$ with $m_i < (1-\delta)\log(t)/D(\theta_i||\theta_i')$, it follows that

$$\mathbb{P}_{\vec{\theta}}[C_t] \leq t^{1-b}\mathbb{P}_{\vec{\theta}_i'}[C_t] \to 0.$$

So far, we show that the probability of the event C_t goes to 0 as t goes to infinity. If we show the event $\{L_{M_i(t)} \leq (1-b)\log(t)|M_i(t) < (1-\delta)\log(t)/D(\theta_i||\theta_i')\}$ occurs almost surely, then we show the probability of $\{M_i(t) < (1-\delta)\log(t)/D(\theta_i||\theta_i')\}$ goes to 0 as t goes to infinity, which is the desired result. By strong law of large numbers $L_m/m \to D(\theta_i||\theta_i')$ as $m \to \infty$ and $\max_{r\leq m} L_r/m \to D(\theta_i||\theta_i')$ almost surely. Now, since $1-b > 1-\delta$, it follows that as $t \to \infty$,

$$\mathbb{P}_{\vec{\theta}}\left[L_r > (1-b)\log(t) \text{ for some } r < (1-\delta)\log(t)/D(\theta_i||\theta_i')\right] \to 0. \tag{31}$$

Hence, we have that as $t \to \infty$,

$$\mathbb{P}_{\vec{\theta}}\left[M_i(t) < (1-\delta)\log(t)/D(\theta_i||\theta_i')\right] \to 0.$$

By choosing ϵ, δ appropriately, this translates to

$$\liminf_{t\to\infty} \frac{\mathbb{E}[M_i(t)]}{\log(t)} \geq \frac{1}{J_i(\theta_i)}.$$

■

Proposition 19 *When the horizon is unknown, start the UCB-LP algorithm with $\tilde{T}_0 = 2$ and increase $\tilde{T}$ after reaching $\tilde{T}$ steps by setting $\tilde{T}_{l+1} = \tilde{T}_l^2$. The regret of unknown horizon UCB-LP is bounded by*

$$\sum_{j\in\mathcal{U}\setminus B} \frac{64\Delta_j z_j^*}{\hat{\Delta}_j^2}\log(T\hat{\Delta}_j^2) + \sum_{j\in B}\frac{64\log(T\Delta_j^2)}{\Delta_j} + O(K^2\log_2\log_2 T). \tag{32}$$

Proof When the horizon is unknown, start the UCB-LP algorithm with $\tilde{T}_0 = 2$ and increase $\tilde{T}$ after reaching $\tilde{T}$ steps by setting $\tilde{T}_{l+1} = \tilde{T}_l^2$. Thus, $\tilde{T}_l = 2^{2^l}$ until reaching horizon T. Also, the period in which horizon is reached is denoted by L. Note that $2 \leq L \leq \log_2\log_2 T$.

In any period $l, (0 \leq l \leq L)$, UCB-LP uses $\tilde{T}_l$ as input. Note that $\bar{m}, m_j, B$ and $\hat{\Delta}_j$ are independent of $\tilde{T}_l$, thus l. Recall that regret of UCB-LP is bounded by (6). The regret of UCB-LP with unknown horizon is upper bounded by the summation over all the periods.

$$\sum_{l=0}^{L}\left[\sum_{j\in\mathcal{U}\setminus B}\Delta_j z_j^*\frac{32\log(\tilde{T}_l\hat{\Delta}_j^2)}{\hat{\Delta}_j^2} + \sum_{j\in B}\frac{32\log(\tilde{T}_l\Delta_j^2)}{\Delta_j} + O(K^2)\right] = (i) + (ii) + (iii).$$

First, we consider the term (i). We can plug in the definition of $\tilde{T}_l$ into (i).

$$\begin{aligned}
(i) &= \sum_{l=0}^{L}\sum_{j\in\mathcal{U}\setminus B}\Delta_j z_j^*\frac{32\log(\tilde{T}_l\hat{\Delta}_j^2)}{\hat{\Delta}_j^2} \\
&= \sum_{j\in\mathcal{U}\setminus B}\frac{32\Delta_j z_j^*}{\hat{\Delta}_j^2}\sum_{l=0}^{L}\log(2^{2^l}\hat{\Delta}_j^2) \\
&= \sum_{j\in\mathcal{U}\setminus B}\frac{32\Delta_j z_j^*}{\hat{\Delta}_j^2}\left((\log 2)\sum_{l=0}^{L}2^l + (L+1)\log\hat{\Delta}_j^2\right) \\
&\leq \sum_{j\in\mathcal{U}\setminus B}\frac{32\Delta_j z_j^*}{\hat{\Delta}_j^2}\left(2^{L+1}(\log 2) + (L+1)\log\hat{\Delta}_j^2\right) \\
&\leq \sum_{j\in\mathcal{U}\setminus B}\frac{32\Delta_j z_j^*}{\hat{\Delta}_j^2}\left(2\log T + (L+1)\log\hat{\Delta}_j^2\right) \quad (since\ L \leq \log_2\log_2 T) \\
&\leq \sum_{j\in\mathcal{U}\setminus B}\frac{64\Delta_j z_j^*}{\hat{\Delta}_j^2}\log(T\hat{\Delta}_j^2) \quad (since\ (L+1)\log\hat{\Delta}_j^2 \leq 2\log\hat{\Delta}_j^2)
\end{aligned}$$

Similarly, we have that $(ii) \leq \sum_{j \in B} \frac{64 \log(T\Delta_j^2)}{\Delta_j}$. Now, we directly sum up the bound for term (iii).

$$(iii) \leq \sum_{l=0}^{L} O(K^2) \leq (L+1)O(K^2) = O(K^2 \log_2 \log_2 T).$$

Hence, by combining the results above, the regret of unknown horizon is bounded by

$$\sum_{j \in \mathcal{U} \setminus B} \frac{64 \Delta_j z_j^*}{\hat{\Delta}_j^2} \log(T\hat{\Delta}_j^2) + \sum_{j \in B} \frac{64 \log(T\Delta_j^2)}{\Delta_j} + O(K^2 \log_2 \log_2 T).$$

Abstract

We consider joint estimation of multiple graphical models arising from heterogeneous and high-dimensional observations. Unlike most previous approaches which assume that the cluster structure is given in advance, an appealing feature of our method is to learn cluster structure while estimating heterogeneous graphical models. This is achieved via a high dimensional version of Expectation Conditional Maximization (ECM) algorithm (Meng and Rubin, 1993). A joint graphical lasso penalty is imposed on the conditional maximization step to extract both homogeneity and heterogeneity components across all clusters. Our algorithm is computationally efficient due to fast sparse learning routines and can be implemented without unsupervised learning knowledge. The superior performance of our method is demonstrated by extensive experiments and its application to a Glioblastoma cancer dataset reveals some new insights in understanding the Glioblastoma cancer. In theory, a non-asymptotic error bound is established for the output directly from our high dimensional ECM algorithm, and it consists of two quantities: *statistical error* (statistical accuracy) and *optimization error* (computational complexity). Such a result gives a theoretical guideline in terminating our ECM iterations.

Keywords: Clustering, finite-sample analysis, graphical models, high-dimensional statistics, non-convex optimization.

1. Introduction

Graphical models have been widely employed to represent conditional dependence relationships among a set of variables. The structure recovery of an undirected Gaussian graph is known to be equivalent to recovering the support of its corresponding precision matrix (Lauritzen, 1996). In the situation where data dimension is comparable to or much larger than the sample size, the penalized likelihood method is proven to be an effective way to learn the structure of graphical models (Yuan and Lin, 2007; Friedman et al., 2008; Shojaie and Michailidis, 2010a,b). When observations come from several distinct subpopulations, a naive way is to estimate each graphical model separately. However, separate estimation ignores the information of common structure shared across different subpopulations, and thus can be inefficient in some real applications. For instance, in the glioblastoma multiforme (GBM) cancer dataset from The Cancer Genome Atlas Research Network (TCGA, 2008), Verhaak et al. (2010) showed that GBM cancer could be classified into four subtypes. Based on this cluster structure, it has been suggested that although the graphs across four subtypes differ in some edges, they share many common structures. In this case, the naive procedure can be suboptimal (Danaher et al., 2014; Lee and Liu, 2015). Such applications have motivated recent studies on joint estimation methods (Guo et al., 2011; Danaher et al., 2014; Lee and Liu, 2015; Qiu et al., 2016; Wang, 2015; Cai et al., 2016a; Peterson et al., 2015) that encourage common structure in estimating heterogeneous graphical models. However, all aforementioned approaches crucially rely on an assumption that the class label of each sample is known in advance.

For certain problems, prior knowledge of the class membership may be available. But this may not be the case for the massive data with complex and unknown population structures. For instance, in online advertising, an important task is to find the most suitable advertisement (ad) for a given user in a specific online context. This could increase the chance of users' favorable actions (e.g., click the ad, inquire about or purchase a product). In recent years, user clustering has gained increasing attention due to its superior performance of ad targeting. This is because users with similar attributes, such as gender, age, income, geographic information, and online behaviors, tend to behave similarly to the same ad (Yan et al., 2009). Moreover, it is very important to understand conditional dependence relationships among user attributes in order to improve ad targeting accuracy (Wang et al., 2015a). Such conditional dependence relationships are expected to share commonality across different groups (user homogeneity) while maintaining some levels of uniqueness within each group (user heterogeneity) (Jeziorski and Segal, 2015). In this online advertising application, previously mentioned joint estimation methods are no longer applicable as they need to know the user cluster structure in advance. Furthermore, with the data being continuously collected, the number of underlying user clusters grows with the sample size (Chen et al., 2009). This provides another reason for simultaneously conducting user clustering and joint graphical model estimation, which is much needed in the era of big data.

Our contributions in this paper are two-fold. On the methodological side, we propose a general framework of **S**imultaneous **C**lustering **A**nd estimatio**N** of heterogeneous graphical models (SCAN). SCAN is a likelihood based method which treats the underlying class label as a latent variable. Based on a high-dimensional version of Expectation Conditional

Maximization (ECM) algorithm (Meng and Rubin, 1993), we are able to conduct clustering and sparse graphical model learning at the same time. In each iteration of the ECM algorithm, the expectation step performs cluster analysis by estimating missing labels and the conditional maximization step conducts feature selection and joint estimation of heterogeneous graphical models via a penalization procedure. With an iteratively updating process, the estimation for both cluster structure and sparse precision matrices becomes more and more refined. Our algorithm is computationally efficient by taking advantage of the fast sparse learning in the conditional maximization step. Moreover, it can be implemented in a user-friendly fashion, without the need of additional unsupervising learning knowledge.

As a promising application, we apply the SCAN method on the GBM cancer dataset to simultaneously cluster the GBM patients and construct the gene regulatory network of each subtype. Our method greatly outperforms the competitors in clustering accuracy and delivers new insights in understanding the GBM disease. Figure 1 reports four gene networks estimated from the SCAN method. The black lines are links shared in all four subtypes, and the color lines are uniquely presented in some subtypes. Our findings generally agree with the GBM disease literature (Verhaak et al., 2010). Besides common edges of all subtypes, we have discovered some unique gene connections that were not found through separate estimation (Danaher et al., 2014; Lee and Liu, 2015). This new finding suggests further investigation on their possible impact on the GBM disease. See Section 4.5 for more discussions.

On the theoretical side, we develop non-asymptotic statistical analysis for the output directly from the high dimensional ECM algorithm. This is nontrivial due to the non-convexity of the likelihood function. In this case, there is no guarantee that the sample-based estimator is close to the maximum likelihood estimator. Hence, we need to directly evaluate the estimation error in each iteration. Let $\mathbf{\Theta}$ represent vectorized cluster means $\boldsymbol{\mu}_k$ and precision matrices $\mathbf{\Omega}_k$, see (3) for a formal definition. Given an appropriate initialization $\mathbf{\Theta}^{(0)}$, the finite sample error bound of the t-th step solution $\mathbf{\Theta}^{(t)}$ consists of two parts:

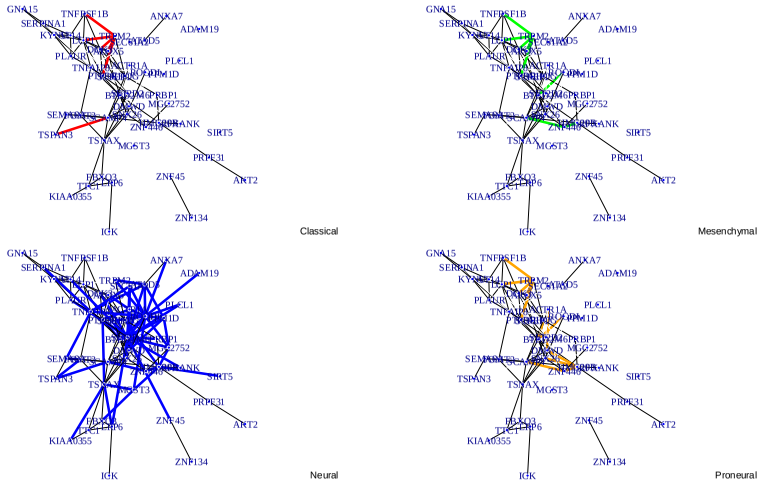
$$\left\|\mathbf{\Theta}^{(t)}-\mathbf{\Theta}^{*}\right\|_2 \leq \underbrace{C\cdot\varepsilon\left(n,p,K,\Psi(\mathcal{M})\right)}_{\text{Statistical Error(SE)}}+\underbrace{\kappa^t\left\|\mathbf{\Theta}^{(0)}-\mathbf{\Theta}^{*}\right\|_2}_{\text{Optimization Error(OE)}}, \tag{1}$$

with high probability. Here, K is the number of clusters, $\Psi(\mathcal{M})$ measures the sparsity of cluster means and precision matrices, and $\kappa\in(0,1)$ is a contraction coefficient. The above theoretical analysis is applicable to any decomposable penalty used in the conditional maximization step.

The error bound (1) enables us to monitor the dynamics of estimation error in each iteration. Specifically, the optimization error decays geometrically with the iteration number t, while the statistical error remains the same when t grows. Therefore, the maximal number of iterations T is implied, beyond which the optimization error is dominated by the statistical error such that consequently the whole error bound is in the same order as the statistical error. In particular,

$$\sum_{k=1}^{K}\left(\left\|\boldsymbol{\mu}_k^{(T)}-\boldsymbol{\mu}_k^{*}\right\|_2+\left\|\mathbf{\Omega}_k^{(T)}-\mathbf{\Omega}_k^{*}\right\|_F\right)=O_P\left(\underbrace{\sqrt{\frac{K^5 d\log p}{n}}}_{\text{Cluster means error}}+\underbrace{\sqrt{\frac{K^3(Ks+p)\log p}{n}}}_{\text{Precision matrices error}}\right),$$

Figure 1: Estimated gene networks corresponding to the Classical, Mesenchymal, Neural and Proneural clusters from our SCAN method applying to the Glioblastoma Cancer Data. In each network, the black lines are the links shared in all four groups. The color lines are the edges shared by some subtypes.



where d and s are the sparsity for a single cluster mean and precision matrix. This result indicates that, after T steps, the SCAN estimator will fall within statistical precision of the true parameter $\{\boldsymbol{\mu}_k^{*},\mathbf{\Omega}_k^{*}\}$. It is worth mentioning that our theory allows the number of clusters K to diverge polynomially with the sample size, reflecting a typical big data scenario. When K is fixed, our statistical rate for the precision matrix estimation under the Frobenius norm, i.e., $O_P(\sqrt{(s+p)\log p/n})$, achieves the optimal rate established in Theorem 7 of Cai et al. (2016b), which is the best rate we could obtain even when the true cluster structure is given.

In the literature, a related line of research focuses on methodological developments of high-dimensional clustering. Pan and Shen (2007) and Sun et al. (2012) introduced regularized model-based clustering and regularized K-means clustering, and Zhou et al. (2009) proposed a network-based clustering approach by imposing a graphical lasso to each individual precision matrix estimation. However, the regularized model-based clustering assumes an identical covariance matrix in each cluster, while the network-based clustering treats each graphical model estimation separately. As pointed out in Danaher et al. (2014) and Lee and Liu (2015), ignoring the network information of other clusters may lead to suboptimal graphical model estimation. During the submission of our paper, we became aware of an independent work by Gao et al. (2016) who also considered the multiple precision ma-

trices estimation via a Gaussian mixture model. Different from ours, Gao et al. (2016) did not enforce the sparsity in the cluster means, which would inevitably lead to sub-optimal estimators in high-dimensional clustering (Yi and Caramanis, 2015; Wang et al., 2015b). Most importantly, no theoretical guarantee was provided in Zhou et al. (2009) and Gao et al. (2016). On the other hand, our SCAN method is more general than these existing methods since we allow the sparsity in both cluster means and precision matrices, and our theoretical analysis of the general SCAN framework sheds some lights on the behavior of these existing method, See Remark 1 for more discussions. In addition, in terms of the heterogeneous graphical model estimation, Saegusa and Shojaie (2016) proposed an interesting two-stage method which used hierarchical clustering to obtain cluster memberships and then estimated the multiple graphical models based on the attained cluster assignments. Despite its simplicity, it is unclear how the performance of clustering in the first stage could affect the performance of precision matrix estimation in the second stage. In comparison, our approach unifies clustering and parameter estimation into one optimization framework, which allows us to quantify both estimation errors in each iteration.

Another line of related work is the theoretical analysis of EM algorithm (Balakrishnan et al., 2016; Yi and Caramanis, 2015; Wang et al., 2015b). Specifically, Balakrishnan et al. (2016) studied the low-dimensional Gaussian mixture model, while Wang et al. (2015b) and Yi and Caramanis (2015) considered its high dimensional extensions. However, their methods are not applicable for the estimation of heterogeneous graphical models due to the assumed identity covariance matrix. In fact, our consideration of the general covariance matrix demands more challenging technical analysis since simultaneous estimation of cluster means and covariance matrices induces a bi-convex optimization beyond the non-convexity of the EM algorithm itself. This also explains why ECM is needed instead of EM. To address these technical issues, key ingredients of our theoretical analysis are to bound the dual norm of the gradient of an auxiliary Q-function and employ nice properties of bi-convex optimization (Boyd et al., 2011) in the regularized M-estimation framework (Negahban et al., 2012). See Section 3 for more details.

In terms of notation, we use $[K]$ to denote the set $\{1, 2, \ldots, K\}$. For a vector $\boldsymbol{\mu} \in \mathbb{R}^p$, $\|\boldsymbol{\mu}\|_2$ is its Euclidean norm. For a matrix $\boldsymbol{X} \in \mathbb{R}^{p_1 \times p_2}$, we denote $\|\boldsymbol{X}\|_F$ and $\|\boldsymbol{X}\|_2$ as its Frobenius norm and spectral norm, respectively, and define its matrix max norm as $\|\boldsymbol{X}\|_{\max} = \max_{i,j} |X_{ij}|$ and its max induced norm as $\|\boldsymbol{X}\|_\infty = \max_{i=1,\ldots,p_1} \sum_{j=1}^{p_2} |X_{ij}|$, which is simply the maximum absolute row sum of the matrix. For a square matrix $\boldsymbol{A} \in \mathbb{R}^{p \times p}$, let $\sigma_{\min}(\boldsymbol{A})$ and $\sigma_{\max}(\boldsymbol{A})$ be its smallest and largest eigenvalue respectively and $|\boldsymbol{A}|$ be its determinant. For a sub-Gaussian random variable Z, we use $\|Z\|_{\psi_2}$ and $\|Z\|_{\psi_1}$ to denote its Orlicz norm. Specifically, $\|Z\|_{\psi_2} = \sup_{p \geq 1} p^{-1/2} (\mathbb{E}|Z|^p)^{1/p}$ and $\|Z\|_{\psi_1} = \sup_{p \geq 1} p^{-1} (\mathbb{E}|Z|^p)^{1/p}$. For two sequences $\{a_n\}$ and $\{b_n\}$ of positive numbers, $a_n \lesssim b_n$ refers to the case that $a_n \leq C b_n$ for some uniform constant C. We write $1(\cdot)$ as an indicator function. Throughout this paper, we use $C, C_1, C_2, \ldots D, D_1, D_2, \ldots$ to denote generic absolute constants, whose values may vary at different places.

The rest of this article is organized as follows. Section 2 introduces heterogeneous graphical models and the SCAN method. Section 3 provides some statistical guarantees for the output directly from the SCAN method. Section 4 shows some simulation results as well as a real data analysis on the Glioblastoma cancer data. Section 5 gives some discussions

for future works. The appendix is devoted to the technical details of the main theorems, and the online supplementary material contains all the supporting lemmas and their proofs.

2. Methodology

In this section, we introduce the SCAN method that simultaneously conducts high-dimensional clustering and estimation of heterogeneous graphical models.

2.1 Heterogeneous Graphical Models

We start our discussions from heterogeneous graphical models with known labels. Assume we are given K groups of data sets $\mathcal{A}_1, \ldots, \mathcal{A}_K$ and the samples in the k-th group are generated i.i.d. from the following Gaussian distribution:

$$f_k(\boldsymbol{x}; \boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k) = (2\pi)^{-p/2} |\boldsymbol{\Sigma}_k|^{-1/2} \exp\left\{ -\frac{1}{2} (\boldsymbol{x} - \boldsymbol{\mu}_k)^\top \boldsymbol{\Sigma}_k^{-1} (\boldsymbol{x} - \boldsymbol{\mu}_k) \right\}, k = 1, \ldots, K. \quad (2)$$

Let $\boldsymbol{\Omega}_k = \boldsymbol{\Sigma}_k^{-1}$ be the k-th precision matrix with the ij-th entry ω_{kij}. For the k-th pair of parameters $(\boldsymbol{\mu}_k, \boldsymbol{\Omega}_k)$, i.e.,

$$\boldsymbol{\mu}_k = \begin{pmatrix} \mu_{k1} \\ \vdots \\ \mu_{kp} \end{pmatrix}, \boldsymbol{\Omega}_k = \begin{pmatrix} \omega_{k11} & \cdots & \omega_{k1p} \\ \vdots & \ddots & \vdots \\ \omega_{kp1} & \cdots & \omega_{kpp} \end{pmatrix},$$

we write $\boldsymbol{\Theta}_k := \mathrm{vec}(\boldsymbol{\mu}_k, \boldsymbol{\Omega}_k) = (\mu_{k1}, \ldots, \mu_{kp}, \omega_{k11}, \ldots, \omega_{kp1}, \ldots, \omega_{k1p}, \ldots, \omega_{kpp}) \in \mathbb{R}^{p^2+p}$ as its vectorized representation, and write the parameter of interest $\boldsymbol{\Theta}$ as

$$\boldsymbol{\Theta} = \left(\boldsymbol{\Theta}_1, \ldots, \boldsymbol{\Theta}_K\right)^\top \in \mathbb{R}^{K(p^2+p)}. \quad (3)$$

Note that the degrees of freedom of $\boldsymbol{\Theta}$ are $K(0.5p^2 + 1.5p)$, including K sets of p means, p variances, as well as $p(p-1)/2$ covariances.

In some cases, there may also exist some common structure across K precision matrices. Danaher et al. (2014) formulated the joint estimation of heterogeneous graphical models as

$$\underset{\boldsymbol{\Omega}_1, \ldots, \boldsymbol{\Omega}_K \succ 0}{\operatorname{argmax}} \sum_{k=1}^{K} \sum_{\boldsymbol{x} \in \mathcal{A}_k} \log f_k(\boldsymbol{x}; \boldsymbol{\Theta}_k) - \mathcal{P}(\boldsymbol{\Omega}_1, \ldots, \boldsymbol{\Omega}_K), \quad (4)$$

where $\mathcal{P}(\boldsymbol{\Omega}_1, \ldots, \boldsymbol{\Omega}_K)$ is an entry-wise penalty which encourages both sparsity of each individual precision matrix and similarity among all precision matrices.

In practice, the cluster label is not always available. A probabilistic model is thus needed to accommodate the latent structure in the data. Assume the observation $\boldsymbol{x}_i; i = 1, \ldots, n$, from unlabeled heterogeneous population has the underlying density

$$f(\boldsymbol{x}, \boldsymbol{\Theta}) = \sum_{k=1}^{K} \pi_k f_k(\boldsymbol{x}; \boldsymbol{\Theta}_k), \quad (5)$$

where π_k is the probability that an observation $\boldsymbol{x}_i$ belongs to the k-th subpopulation. Here, for simplicity we assume the number of cluster K is identifiable. In order to ensure the

identifiability of fixed-dimensional Gaussian graphical models, some sufficient conditions such as the strong identifiability condition was imposed on the density functions. However these conditions are hard to verify in practice. In fact, the identifiability issue for high dimensional mixture model is still an open problem (Ho and Nguyen, 2015) and is beyond the scope of this paper.

Consider the penalized log-likelihood function for the *observed data*

$$\log \mathcal{L}(\boldsymbol{\Theta}|\boldsymbol{X}) := \frac{1}{n}\sum_{i=1}^{n}\log\left(\sum_{k=1}^{K}\pi_k f_k\Big(\boldsymbol{x}_i;\boldsymbol{\mu}_k,(\boldsymbol{\Omega}_k)^{-1}\Big)\right) - \mathcal{R}(\boldsymbol{\Theta}).$$

Our **S**imultaneous **C**lustering **A**nd estimatio**N** (SCAN) method aims to solve

$$\max_{\pi_k,\boldsymbol{\mu}_k,\boldsymbol{\Omega}_k} \log \mathcal{L}(\boldsymbol{\Theta}|\boldsymbol{X}). \tag{6}$$

For an illustration, we take

$$\mathcal{R}(\boldsymbol{\Theta}) = \lambda_1 \underbrace{\sum_{k=1}^{K}\sum_{j=1}^{p}|\mu_{kj}|}_{\mathcal{P}_1(\boldsymbol{\Theta})} + \lambda_2 \underbrace{\sum_{k=1}^{K}\sum_{i\neq j}|\omega_{kij}|}_{\mathcal{P}_2(\boldsymbol{\Theta})} + \lambda_3 \underbrace{\sum_{i\neq j}(\sum_{k=1}^{K}\omega_{kij}^2)^{1/2}}_{\mathcal{P}_3(\boldsymbol{\Theta})}, \tag{7}$$

where $\mathcal{P}_1(\boldsymbol{\Theta})$ and $\mathcal{P}_2(\boldsymbol{\Theta})$ impose sparsity of the estimated cluster mean and precision matrix, and $\mathcal{P}_3(\boldsymbol{\Theta})$ encourages similarity among all estimated precision matrices. The above three tuning parameters can be tuned efficiently via adaptive BIC. More details can be found in Section 4.1.

Remark 1 *It is worth mentioning that our SCAN method is applicable to penalty functions other than* (7)*. For instance, the cluster mean penalty can be replaced by the group lasso penalty in Sun et al. (2012) or the ℓ_0-norm penalty in Shen et al. (2012). The group graphical lasso penalty for the precision matrix estimation can be substituted by the structural pursuit penalty in Zhu et al. (2014) or the weighted bridge penalty in Rothman and Forzani (2014). As shown in Section 2.2, only a slight modification of our algorithm is needed to accommodate other penalty functions. We also note that SCAN reduces to the regularized model-based clustering (Pan and Shen, 2007) when $\lambda_2 = \lambda_3 = 0$, reduces to the method by Zhou et al. (2009) when $\lambda_3 = 0$, and reduces to the method by Gao et al. (2016) when $\lambda_1 = 0$. Consequently, the technical tools developed for the SCAN estimator in Section 3 are also applicable to these special cases.*

2.2 ECM Algorithm

In this subsection, we introduce an efficient ECM algorithm to solve the general non-convex optimization problem in (6). The ECM replaces each M-step with an conditional maximization (CM) step in which each parameter $\pi_k, \boldsymbol{\mu}_k, \boldsymbol{\Omega}_k$ is maximized separately, by fixing other parameters.

Denote the latent cluster assignment matrix as $\boldsymbol{L}$, where $L_{ik} = 1(\boldsymbol{x}_i \in \mathcal{A}_k)$; $i = 1,\ldots,n$, $k = 1,\ldots,K$. If the cluster label L_{ik} is available, the penalized log-likelihood function for the *complete data* can be formulated as

$$\log \mathcal{L}(\boldsymbol{\Theta}|\boldsymbol{X},\boldsymbol{L}) := \frac{1}{n}\sum_{i=1}^{n}\sum_{k=1}^{K} L_{ik}\Big[\log\pi_k + \log f_k(\boldsymbol{x}_i;\boldsymbol{\Theta}_k)\Big] - \mathcal{R}(\boldsymbol{\Theta}).$$

In the expectation step, the conditional expectation of the penalized log-likelihood function is computed as

$$\mathbb{E}_{\boldsymbol{L}|\boldsymbol{X},\boldsymbol{\Theta}^{(t-1)}}\Big[\log\mathcal{L}(\boldsymbol{\Theta}|\boldsymbol{X},\boldsymbol{L})\Big] = Q_n(\boldsymbol{\Theta}|\boldsymbol{\Theta}^{(t-1)}) - \mathcal{R}(\boldsymbol{\Theta}), \tag{8}$$

where $\mathcal{R}(\boldsymbol{\Theta})$ is the penalty in (7) and

$$Q_n(\boldsymbol{\Theta}|\boldsymbol{\Theta}^{(t-1)}) := \frac{1}{n}\sum_{i=1}^{n}\sum_{k=1}^{K} L_{\boldsymbol{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)\Big[\log\pi_k + \log f_k(\boldsymbol{x}_i;\boldsymbol{\Theta}_k)\Big], \tag{9}$$

with the class label being computed based on the parameter $\boldsymbol{\Theta}^{(t-1)}$ and $\pi_k^{(t-1)}$ obtained at the previous iteration, that is,

$$L_{\boldsymbol{\Theta}^{(t-1)},k}(\boldsymbol{x}_i) = \frac{\pi_k^{(t-1)} f_k(\boldsymbol{x}_i;\boldsymbol{\Theta}_k^{(t-1)})}{\sum_{k=1}^{K}\pi_k^{(t-1)} f_k(\boldsymbol{x}_i;\boldsymbol{\Theta}_k^{(t-1)})}. \tag{10}$$

In the conditional maximization step, maximizing (8) with respect to π_k, $\boldsymbol{\mu}_k$, $\boldsymbol{\Omega}_k$ yields the update of parameters. In particular, the update of π_k is given as

$$\pi_k^{(t)} = \sum_{i=1}^{n}\frac{L_{\boldsymbol{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)}{n}, \tag{11}$$

and the update of $\boldsymbol{\mu}_k$ is given in the following Lemma.

Lemma 2 *Let $\boldsymbol{\mu}_k^{(t)} := \arg\max_{\boldsymbol{\mu}_k} Q_n(\boldsymbol{\Theta}|\boldsymbol{\Theta}^{(t-1)}) - \mathcal{R}(\boldsymbol{\Theta})$ and denote $n_k := \sum_{i=1}^{n} L_{\boldsymbol{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)$. We have, for $j = 1,\ldots,p$,*

$$\mu_{kj}^{(t)} = \begin{cases} g_{1,j}(\boldsymbol{x};\boldsymbol{\Theta}_k^{(t-1)}) - \frac{n\lambda_1}{n_k\omega_{kjj}^{(t-1)}}\, sign(\mu_{kj}^{(t-1)}) & \text{if } \Big|\sum_{i=1}^{n} g_{2,j}(\boldsymbol{x}_i;\boldsymbol{\Theta}_k^{(t-1)})\Big| > \lambda_1; \\ 0 & \text{otherwise,} \end{cases}$$

where

$$g_{1,j}(\boldsymbol{x};\boldsymbol{\Theta}_k^{(t-1)}) = \frac{\sum_{i=1}^{n} L_{\boldsymbol{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)\big(\sum_{l=1}^{p} x_{il}\omega_{klj}^{(t-1)}\big)}{\omega_{kjj}^{(t-1)} n_k} - \frac{\sum_{l=1}^{p}\mu_{kl}^{(t-1)}\omega_{klj}^{(t-1)}}{\omega_{kjj}^{(t-1)}} + \mu_{kj}^{(t-1)},$$

$$g_{2,j}(\boldsymbol{x}_i;\boldsymbol{\Theta}_k^{(t-1)}) = L_{\boldsymbol{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)\Big(\sum_{l=1,l\neq j}^{p}(x_{il}-\mu_{kl}^{(t-1)})\omega_{klj}^{(t-1)} + x_{ij}\omega_{kjj}^{(t-1)}\Big).$$

Note that if the lasso penalty is replaced with other penalty functions, then the update formula of $\boldsymbol{\mu}_k^{(t)}$ in Lemma 2 can be modified accordingly. Given the pseudo sample covariance matrix $\widetilde{S}_k$, we are able to develop an update formula for $\boldsymbol{\Omega}_k$ by establishing its connection with joint estimation of heterogeneous graphical models (4).

Lemma 3 *The solution of maximizing (8) with respect to $(\mathbf{\Omega}_1, \ldots, \mathbf{\Omega}_K)$ is equivalent to*

$$(\mathbf{\Omega}_1^{(t)}, \ldots, \mathbf{\Omega}_K^{(t)}) := \arg \max_{\mathbf{\Omega}_1, \ldots, \mathbf{\Omega}_K \succ 0} \sum_{k=1}^{K} n_k \Big[\log\det(\mathbf{\Omega}_k) - trace(\widetilde{S}_k \mathbf{\Omega}_k) \Big] - \mathcal{R}(\mathbf{\Theta}), \tag{12}$$

where $\widetilde{S}_k$ is a pseudo sample covariance matrix defined as

$$\widetilde{S}_k := \frac{\sum_{i=1}^{n} L_{\mathbf{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)(\boldsymbol{x}_i - \boldsymbol{\mu}_k^{(t-1)})^\top (\boldsymbol{x}_i - \boldsymbol{\mu}_k^{(t-1)})}{\sum_{i=1}^{n} L_{\mathbf{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)}.$$

The solution for (12) can be solved efficiently via the ADMM algorithm by slightly modifying the joint graphical lasso algorithm in Danaher et al. (2014). Since Danaher et al. (2014) do not impose the symmetry condition for precision matrix update, $\{\mathbf{\Omega}_k^{(T)}\}_{k=1}^K$ in general is not necessarily symmetric. Following the symmetrization strategy in Cai et al. (2011) and Cai et al. (2016a), we symmetrize $\mathbf{\Omega}_k^{(t)}$ by

$$\omega_{kij}^{(t)} = \omega_{kij}^{(t)} I(|\omega_{kij}^{(t)} \leq \omega_{kij}^{(t)}|) + \omega_{kji}^{(t)} I(|\omega_{kij}^{(t)} > \omega_{kij}^{(t)}|), \tag{13}$$

where $\omega_{kij}^{(t)}$ is the ij-th entry of $\mathbf{\Omega}_k^{(t)}$ and $I(\cdot)$ is the indicator function. This step will not affect the convergence rate of the final estimator, which is illustrated in Cai et al. (2011) and Cai et al. (2016a). We summarize the high-dimensional ECM algorithm for solving the SCAN method in Table 1. Our algorithm is computationally efficient due to fast sparse learning routines shown in Lemmas 2 and 3.

Table 1: The SCAN Algorithm

Input: $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$, number of clusters K, tuning parameters $\lambda_1, \lambda_2, \lambda_3$.
Output: Cluster label $\boldsymbol{L}$, cluster mean $\boldsymbol{\mu}_k$ and precision matrix $\mathbf{\Omega}_k$.
Step 1: Initialize cluster mean $\boldsymbol{\mu}_k^{(0)}$, positive definite precision matrix $\mathbf{\Omega}_k^{(0)}$, and set $\pi_k^{(0)} = 1/K$, for each $k \in [K]$.
Step 2: Until some termination conditions are met, for iteration $t = 1, 2, \ldots$
(a) E-step. Find the cluster assignment $L_{\mathbf{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)$ as in (10).
(b) CM-step. Given $L_{\mathbf{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)$, update $\pi_k^{(t)}$, $\boldsymbol{\mu}_k^{(t)}$, and $\mathbf{\Omega}_k^{(t)}$ in (11), Lemma 2, Lemma 3, respectively. Symmetrize $\mathbf{\Omega}_k^{(t)}$ by (13).

In all of our experiments, we obtain $(\boldsymbol{\mu}_k^{(0)}, \mathbf{\Omega}_k^{(0)})$ by random initialization, which is computationally efficient and practically reliable. In the theoretical study, we require the initialization to be of a constant distance to the truth. See Remark 14 for more discussions. Moreover, in the implementation, ECM step in Step 2 is terminated when the updated parameters are close to their previous values:

$$\sum_{k=1}^{K} \left\{ \frac{\|\boldsymbol{\mu}_k^{(t)} - \boldsymbol{\mu}_k^{(t-1)}\|_2}{\|\boldsymbol{\mu}_k^{(t)}\|_2} + \frac{\|\mathbf{\Omega}_k^{(t)} - \mathbf{\Omega}_k^{(t-1)}\|_F}{\|\mathbf{\Omega}_k^{(t)}\|_F} \right\} \leq 0.01.$$

Remark 4 *In the existing high-dimensional EM algorithms where the covariance matrix is assumed to be an identity matrix (Wang et al., 2015b; Yi and Caramanis, 2015), sample-splitting procedures have been routinely used in the M-step in order to facilitate the theoretical analysis. Although it simplifies theoretical developments, such a sample-splitting procedure does not take advantage of full samples in the M-step and is hard to implement in practice. Our Algorithm 1 is able to avoid this sample-splitting step but still enjoys nice theoretical properties. See Corollary 18 for more discussions on its statistical guarantee.*

3. Statistical Guarantee

In this section, we establish statistical guarantee for the SCAN estimator based on sample-based analysis of (9) and population-based analysis of (16). Here, we consider the high-dimensional setting where $p \gg n$ and K is allowed to diverge with n.

We start by introducing some useful notation. Denote the index set of diagonal components of K precision matrices by

$$\mathcal{G} = \bigcup_{k=1}^{K} \mathcal{G}_k, \text{with } \mathcal{G}_k = \big(k(p+1), k(2p+2), \ldots, k(p^2+p)\big), \tag{14}$$

that is, $\mathbf{\Theta}_{\mathcal{G}} = (\omega_{111}, \ldots, \omega_{1pp}, \ldots, \omega_{K11}, \ldots, \omega_{Kpp}) \in \mathbb{R}^{Kp}$. Let $\mathcal{O}$ be the complete index set of $\mathbf{\Theta}$ and $\mathcal{G}^c = \mathcal{O} \setminus \mathcal{G}$ be the complement set of $\mathcal{G}$. Denote $\mathcal{U}_k := \{i : \mu_{ki}^* \neq 0\}$ where $\boldsymbol{\mu}_k^*$ is the true mean parameter, $\mathcal{V}_k := \{(i,j) : i \neq j, \omega_{kij}^* \neq 0\}$ where $\mathbf{\Omega}_k^*$ is the true precision matrix and $\mathcal{S}_1 = \bigcup_{k=1}^K \mathcal{U}_k$, $\mathcal{S}_2 = \bigcup_{k=1}^K \mathcal{V}_k$. Define $\Xi \subseteq \mathbb{R}^{K(p^2+p)}$ as some non-empty convex set of parameters. Denote the support space $\mathcal{M}$ as

$$\begin{aligned} \mathcal{M} \;:=\; \Big\{ \boldsymbol{V} \in \Xi \;\Big|\; & \mu_{ki} = 0 \text{ for all } i \notin \mathcal{S}_1, \\ & \omega_{kij} = 0 \text{ for all pairs } (i,j) \notin \mathcal{S}_2, k = 1 \ldots, K \Big\}, \end{aligned} \tag{15}$$

where $\boldsymbol{V}$ follows the same definition style used for $\mathbf{\Theta}$ in (3). Denote the sparsity parameters:

$$\begin{aligned} s &:= \#\{(i,j) : \omega_{kij}^* \neq 0, i, j = 1 \ldots p, i \neq j, k = 1, \ldots, K\}, \\ d &:= \#\{i : \mu_{ik}^* \neq 0, i = 1, \ldots, p, k = 1, \ldots, K\}. \end{aligned}$$

3.1 Population-Based Analysis

We define a corresponding population version of Q_n in (9) as

$$Q(\mathbf{\Theta}' | \mathbf{\Theta}) := \mathbb{E}\left[\sum_{k=1}^{K} L_{\mathbf{\Theta},k}(\boldsymbol{X}) [\log \pi_k' + \log f_k(\boldsymbol{X}; \mathbf{\Theta}_k')] \right]. \tag{16}$$

Without loss of generality, we assume the true prior probability $\pi_k^* = 1/K$ for each $k = 1, \ldots, K$. Recall that the update of weights in (11) is independent of the updates of other parameters. Consequently, according to (2), maximizing $Q(\mathbf{\Theta}' | \mathbf{\Theta})$ over $(\boldsymbol{\mu}_k', \mathbf{\Omega}_k')$ is equivalent to maximizing

$$\sum_{k=1}^{K} \mathbb{E}\left[L_{\mathbf{\Theta},k}(\boldsymbol{X}) \left\{ \frac{1}{2} \log\det(\mathbf{\Omega}_k') - \frac{1}{2} (\boldsymbol{X} - \boldsymbol{\mu}_k')^\top \mathbf{\Omega}_k' (\boldsymbol{X} - \boldsymbol{\mu}_k') \right\} \right]. \tag{17}$$

Clearly, the update of $(\boldsymbol{\mu}_l^{'}, \boldsymbol{\Omega}_l^{'})$ is independent of the update of $(\boldsymbol{\mu}_t^{'}, \boldsymbol{\Omega}_t^{'})$ for any $t \neq l$. This enables us to characterize the update of each pair of parameters separately. For any $k = 1, \ldots, K$, define

$$M_{\boldsymbol{\mu}_k^{'}}(\boldsymbol{\Omega}_k^{'}) := \arg\max_{\boldsymbol{\mu}_k^{'}} Q(\boldsymbol{\Theta}^{'}|\boldsymbol{\Theta}) \text{ and } M_{\boldsymbol{\Omega}_k^{'}}(\boldsymbol{\mu}_k^{'}) := \arg\max_{\boldsymbol{\Omega}_k^{'}} Q(\boldsymbol{\Theta}^{'}|\boldsymbol{\Theta}).$$

We show in Lemma 5 that the population update of $\boldsymbol{\mu}_k^{'}$ is independent of $\boldsymbol{\Omega}_k^{'}$, while the population update of $\boldsymbol{\Omega}_k^{'}$ is a function of $\boldsymbol{\mu}_k^{'}$.

Lemma 5 *For any $k = 1, \ldots, K$, we have*

$$M_{\boldsymbol{\mu}_k^{'}}(\boldsymbol{\Omega}_k^{'}) = \big[\mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})]\big]^{-1}\mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\boldsymbol{X}], \tag{18}$$

$$M_{\boldsymbol{\Omega}_k^{'}}(\boldsymbol{\mu}_k^{'}) = \mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})]\left[\mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})(\boldsymbol{X}-\boldsymbol{\mu}_k^{'})(\boldsymbol{X}-\boldsymbol{\mu}_k^{'})^{\top}]\right]^{-1}. \tag{19}$$

The difficulty of simultaneous clustering and estimation can be characterized by the following *sufficiently separable condition*. Define $\mathcal{B}_\alpha(\boldsymbol{\Theta}^*) := \big\{\boldsymbol{\Theta} \in \Xi : \big\|\boldsymbol{\Theta} - \boldsymbol{\Theta}^*\big\|_2 \leq \alpha\big\}$.

Condition 6 (*Sufficiently Separable Condition*) *Denote $W = \max_j W_j$, $W^{'} = \max_j W_j^{'}$, $W^{''} = \max_j W_j^{''}$ with $W_j, W_j^{'}, W_j^{''}$ defined in* (S.4), (S.7) *and* (S.8), *respectively. We assume K clusters are sufficiently separable such that given an appropriately small parameter $\gamma > 0$, it holds a.s.*

$$L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) \cdot L_{\boldsymbol{\Theta},j}(\boldsymbol{X}) \leq \frac{\gamma}{24(K-1)\sqrt{\max\{W, W^{'}, W^{''}\}}}, \tag{20}$$

for each pair $\{(j,k), j,k \in [K], j \neq k\}$ and any $\boldsymbol{\Theta} \in \mathcal{B}_\alpha(\boldsymbol{\Theta}^*)$.

Condition 6 requires that K clusters are sufficiently separable in the sense that $\boldsymbol{X}$ belongs to the k-th cluster with probability either close to zero or close to one such that $L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) \cdot L_{\boldsymbol{\Theta},j}(\boldsymbol{X})$ is close to zero. In the special case that $K = 2$ and $\boldsymbol{\Omega}_1^* = \boldsymbol{\Omega}_2^* = 1_p$, Balakrishnan et al. (2016) requires $\|\boldsymbol{\mu}_1^* - \boldsymbol{\mu}_2^*\|_2$ is sufficiently large. Our Condition 6 extends it to general K and general precision matrices. Note that the condition (20) is related with the number of clusters K. As K grows, the clustering problem gets harder and hence a stronger sufficiently separable condition is needed.

The next lemma guarantees that the curvature of $Q(\cdot|\boldsymbol{\Theta})$ is similar to that of $Q(\cdot|\boldsymbol{\Theta}^*)$ when $\boldsymbol{\Theta}$ is close to $\boldsymbol{\Theta}^*$, which is a key ingredient in our population-based analysis.

Lemma 7 (*Gradient Stability*) *Under Condition 6, the function $\{Q(\cdot|\boldsymbol{\Theta}), \boldsymbol{\Theta} \in \Xi\}$ satisfies,*

$$\big\|\nabla Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}^*)\big\|_2 \leq \tau \cdot \big\|\boldsymbol{\Theta} - \boldsymbol{\Theta}^*\big\|_2, \tag{21}$$

with parameter $\tau \leq \gamma/12$ for any $\boldsymbol{\Theta} \in \mathcal{B}_\alpha(\boldsymbol{\Theta}^*)$. The gradient $\nabla Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})$ is taken with respect to the first variable of $Q(\cdot|\cdot)$.

3.2 Sample-Based Analysis

In this section, we analyze the sample-base function Q_n, defined as the objective function in (9). The statistical error comes from the approximation by using sample-base function Q_n to population-base function Q. We need one regularity condition to ensure that Q_n is strongly concave in a specific Euclidean ball.

Condition 8 *There exist some positive constants β_1, β_2 such that $0 < \beta_1 < \min_{k\in[K]} \sigma_{\min}(\boldsymbol{\Omega}_k^*) < \max_{k\in[K]} \sigma_{\max}(\boldsymbol{\Omega}_k^*) < \beta_2$.*

Lemma 9 verifies the restricted strong concavity condition of Q_n. Note that (22) corresponds to the restricted eigenvalue condition in sparse linear regression (Negahban et al., 2012).

Lemma 9 (*Restricted Strong Concavity*) *Suppose that Condition 8 holds. Then for any $\boldsymbol{\Theta} \in \mathcal{B}_\alpha(\boldsymbol{\Theta}^*)$, with probability at least $1-\delta$, each $\boldsymbol{\Theta}' \in \mathbb{C} := \{\boldsymbol{\Theta}' \mid \|\boldsymbol{\Theta}' - \boldsymbol{\Theta}^*\|_2 \leq 2\alpha\}$ satisfies*

$$Q_n(\boldsymbol{\Theta}'|\boldsymbol{\Theta}) - Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \Big\langle \nabla Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}), \boldsymbol{\Theta}' - \boldsymbol{\Theta}^* \Big\rangle \leq -\frac{\gamma}{2}\Big\|\boldsymbol{\Theta}' - \boldsymbol{\Theta}^*\Big\|_2^2, \tag{22}$$

with sufficiently large n, where $\gamma = c \cdot \min\{\beta_1, 0.5(\beta_2 + 2\alpha)^{-2}\}$ is the strong concavity parameter for some constant c.

Define $\mathcal{P}(\boldsymbol{\Theta}) = M_1\mathcal{P}_1(\boldsymbol{\Theta}) + M_2\mathcal{P}_2(\boldsymbol{\Theta}) + M_3\mathcal{P}_3(\boldsymbol{\Theta})$ for some positive constants M_1, M_2, M_3. Let $\mathcal{P}^*$ be the dual norm of $\mathcal{P}$, which is defined as $\mathcal{P}^*(\boldsymbol{\Theta}) = \sup_{\mathcal{P}(\boldsymbol{\Theta}')\leq 1}\langle \boldsymbol{\Theta}', \boldsymbol{\Theta}\rangle$. For simplicity, write $\|\cdot\|_{\mathcal{P}^*} = \mathcal{P}^*(\cdot)$.

Condition 10 *For any fixed $\boldsymbol{\Theta} \in \mathcal{B}_\alpha(\boldsymbol{\Theta}^*)$, with probability at least $1-\delta_1$,*

$$\Big\|\nabla Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\Big\|_{\mathcal{P}^*} \leq \varepsilon_1, \tag{23}$$

and with probability at least $1-\delta_2$, we have

$$\Big\|\Big[\nabla Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\Big]_{\mathcal{G}}\Big\|_2 \leq \varepsilon_2, \tag{24}$$

where $\mathcal{G}$ is the diagonal index set defined in (14). Here ε_1 and ε_2 are functions of $n, p, K, \delta_1, \delta_2$.

Intuitively, ε_1 and ε_2 quantify the difference between the population-based and sample-based conditional maximization step. Note that $\mathcal{P}$ does not penalize diagonal elements of each precision matrix, thus

$$\Big\|\nabla Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\Big\|_{\mathcal{P}^*} = \Big\|\Big[\nabla Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\Big]_{\mathcal{G}^c}\Big\|_{\mathcal{P}^*}.$$

Our analysis makes use of the property of dual norm to bridge the SCAN penalty term and the targeted error term in L_2 norm. Note that our SCAN penalty does not penalize diagonal terms of precision matrices, and hence it can be treated as a norm only if it is applied to the parameter $\boldsymbol{\Theta}$ without diagonal terms of precision matrices. Otherwise, it is a semi-norm. For this purpose, we separate all the diagonal terms from $\boldsymbol{\Theta}$. Therefore, our statistical error is split by two parts: one from the sparse estimate of cluster means and non-diagonal terms

in precision matrices, and another from the estimate of diagonal terms of precision matrices. In Lemma S.1, ε_1 and ε_2 will be specifically calculated for our proposed SCAN penalty. In the high dimensional ECM algorithm, there is no explicit form for the CM-step update due to the existence of the penalty term. This is a crucial difference from the low-dimensional EM algorithm in Balakrishnan et al. (2016). Fortunately, the decomposability of SCAN penalty enables us to quantify statistical errors by evaluating the gradient of Q-function.

3.3 Statistical Error versus Optimization Error

In this section, we provide the final theoretical guarantee for the high-dimensional ECM algorithm by combining the population and sample-based analysis.

Definition 11 (*Support Space Compatibility Constant*) *For the support subspace $\mathcal{M} \subseteq \mathbb{R}^{K(p^2+p)}$ defined in (15), we define*

$$\nu(\mathcal{M}) = \sup_{\mathbf{\Theta} \in \mathcal{M} \setminus \{0\}} \frac{\mathcal{P}(\mathbf{\Theta})}{\|\mathbf{\Theta}\|_2}. \tag{25}$$

Remark 12 *The support space compatibility constant $\nu(M)$ is a variant of subspace compatibility constant originally proposed by Negahban et al. (2012) and Wainwright (2014). Actually, $\nu(M)$ can be interpreted as a notion of intrinsic dimensionality of M. In order to bound the statistical error, we need some measures for the complexity of parameter $\mathbf{\Theta}$ reflected by the penalty term. One possible way is to specify a model subspace $\mathcal{M}$ and require $\mathbf{\Theta}$ lie in the space. By choosing the support space $\mathcal{M}$ of parameter of interest $\mathbf{\Theta}$, the support space compatibility constant $\nu(\mathcal{M})$ can measure the complexity of $\mathbf{\Theta}$ relative to the penalty term $\mathcal{P}$ and square norm. The larger $\nu(\mathcal{M})$ is, the more samples are needed to guarantee statistical consistency. For examples, if the penalty $\mathcal{P}$ is L_1 penalty with s-sparse coordinate support space $\mathcal{M}'$, then we have $\nu(\mathcal{M}') = \sqrt{s}$. In the context of group lasso penalty, we have $\nu(\mathcal{M}') = \sqrt{|S|}$, where S is the index set of active groups. For our SCAN penalty, $\nu(\mathcal{M})$ is specifically calculated by $M_1\sqrt{Kd} + (M_2\sqrt{K} + M_3)\sqrt{s}$, where d, s are the common sparsity parameters for single cluster means and precision matrices accordingly and M_1, M_2, M_3 are some absolute constants.*

We first provide a general theory that applies to any decomposable penalty, such as the group lasso penalty in Sun et al. (2012) and fused graphical lasso penalty in Danaher et al. (2014). The theoretical result of our SCAN penalty will be discussed in Corollary 18.

Theorem 13 *Suppose Conditions 6, 8, 10 hold and $\mathbf{\Theta}^*$ lies in the interior of Ξ. Let $\kappa = 6\tau/\gamma$, where τ, γ are calculated in Lemma 7 and Lemma 9. Consider our SCAN algorithm in Table 1 with initialization $\mathbf{\Theta}^{(0)}$ falling into a ball $\mathcal{B}_\alpha(\mathbf{\Theta}^*)$ for some constant radius $\alpha > 0$ and assume the tuning parameters satisfy $\lambda_1 = M_1\lambda_n^{(t)}$, $\lambda_2 = M_2\lambda_n^{(t)}$, $\lambda_3 = M_3\lambda_n^{(t)}$, and*

$$\lambda_n^{(t)} = \varepsilon + \kappa\frac{\gamma}{\nu(\mathcal{M})}\left\|\mathbf{\Theta}^{(t-1)} - \mathbf{\Theta}^*\right\|_2. \tag{26}$$

If the sample size n is large enough such that $\varepsilon \le (1-\kappa)\gamma\alpha/(6\nu(\mathcal{M}))$, then $\mathbf{\Theta}^{(t)}$ satisfies, with probability at least $1 - t\delta'$,

$$\left\|\mathbf{\Theta}^{(t)} - \mathbf{\Theta}^*\right\|_2 \le \underbrace{\frac{6\nu(\mathcal{M})}{(1-\kappa)\gamma}\varepsilon}_{\text{Statistical Error(SE)}} + \underbrace{\kappa^t\left\|\mathbf{\Theta}^{(0)} - \mathbf{\Theta}^*\right\|_2}_{\text{Optimiation Error(OE)}}, \tag{27}$$

where $\delta' = \delta + \delta_1 + \delta_2$ with δ, δ_1, δ_2 defined in Lemma 9 and Condition 10 and $\varepsilon = \varepsilon_1 + \varepsilon_2/\nu(\mathcal{M})$.

The above theoretical result suggests that the estimation error in each iteration consists *statistical error* and *optimization error*. From the definition of τ in Lemma 7, κ is less than 0.5 so that it is a contractive parameter. With a relatively good initialization, even though ECM algorithm may be trapped into a local optima after enough iterations, it can be guaranteed to be within a small neighborhood of the truth, in the sense of statistical accuracy. In addition, with a proper choice of δ', the final probability $1 - t\delta'$ will converge to 1; see Corollary 18 for details.

Remark 14 *To our limited knowledge, there is no existing literature to guarantee the global convergence of ECM algorithm in a general case. Compromisingly, we have to require some constraints on the initial value. In our framework, the only requirement for the initial value is to fall into a ball with constant radius to the truth. Such a condition has also been imposed in EM algorithms (Balakrishnan et al., 2016; Wang et al., 2015b; Yi and Caramanis, 2015) and can be fulfilled by some spectral-based initializations (Zhang et al., 2014).*

Remark 15 *In Theorem 13, we introduce an iterative turning procedure (26) which appeared in high dimensional regularized M-estimation (Negahban et al., 2012), and was also applied in Yi and Caramanis (2015) to facilitate their theoretical analysis.*

The error bound in (27) measures the estimation error in each iteration. Here, optimization error decays geometrically with the iteration number t, while the statistical error remains the same when t grows. Therefore, this enables us to provide a meaningful choice of the maximal number of iterations T beyond which the optimization error is dominated by the statistical error such that the whole error bound is in the same order of the statistical error.

In the following corollary, taking the SCAN penalty as an example, we provide a closed form of the maximal number of iterations T and also an explicit form of the estimation error.

Condition 16 *The largest element of cluster means and precision matrices are both bounded, that is, for some positive constants c_1 and c_2,*

$$\|\boldsymbol{\mu}^*\|_\infty := \max_{k\in[K]}\|\boldsymbol{\mu}_k^*\|_\infty < c_1 \text{ and } \|\mathbf{\Omega}^*\|_{\max} := \max_{k\in[K]}\|\mathbf{\Omega}_k^*\|_{\max} < c_2.$$

Condition 17 *Suppose that the number of clusters K satisfies $K^2 = o(p(\log n)^{-1})$.*

Corollary 18 *Suppose Conditions 6, 8, 16 and 17 hold. If sample size n is sufficiently large such that*

$$n \geq \left(\frac{6(CK\|\mathbf{\Omega}^*\|_\infty + C'K^{1.5})(\sqrt{Kd} + \sqrt{Ks} + \sqrt{K}) + C''K^{1.5}\sqrt{p}}{(1-\kappa)\gamma\alpha} \right)^2 \log p,$$

and the iteration step t is large enough such that

$$t \geq T = \log_{1/\kappa} \frac{\left\|\mathbf{\Theta}^{(0)} - \mathbf{\Theta}^*\right\|_2}{\varphi(n,p,K)},$$

where $\varphi(n,p,K) = 6\widetilde{C}((1-\kappa)\gamma)^{-1}\|\mathbf{\Omega}^*\|_\infty(\sqrt{Kd}+\sqrt{Ks+p})\sqrt{K^3\log p/n}$ for some positive constant $\widetilde{C}$, the optimization error in (27) is dominated by the statistical error, and

$$\sum_{k=1}^{K}\left(\left\|\boldsymbol{\mu}_k^{(T)} - \boldsymbol{\mu}_k^*\right\|_2 + \left\|\mathbf{\Omega}_k^{(T)} - \mathbf{\Omega}_k^*\right\|_F\right) \leq \frac{12\widetilde{C}}{(1-\kappa)\gamma}\left(\underbrace{\|\mathbf{\Omega}^*\|_\infty\sqrt{\frac{K^5 d\log p}{n}}}_{\text{Cluster means error}} + \underbrace{\|\mathbf{\Omega}^*\|_\infty\sqrt{\frac{K^3(Ks+p)\log p}{n}}}_{\text{Precision matrices error}}\right),$$

with probability converging to 1.

Remark 19 *If K is fixed, the above upper bound reduces to*

$$\sum_{k=1}^{K}\left(\left\|\boldsymbol{\mu}_k^{(T)} - \boldsymbol{\mu}_k^*\right\|_2 + \left\|\mathbf{\Omega}_k^{(T)} - \mathbf{\Omega}_k^*\right\|_F\right) \lesssim \left(\underbrace{\|\mathbf{\Omega}^*\|_\infty\sqrt{\frac{d\log p}{n}}}_{\text{Cluster means error}} + \underbrace{\|\mathbf{\Omega}^*\|_\infty\sqrt{\frac{(s+p)\log p}{n}}}_{\text{Precision matrices error}}\right). \tag{28}$$

Consider the class of precision matrix $\mathcal{Q} := \{\mathbf{\Omega} : \mathbf{\Omega} \succ 0, \|\mathbf{\Omega}\|_\infty \leq C_\mathcal{Q}\}$ as in Cai et al. (2016b). When $C_\mathcal{Q}$ does not depend on n, p, our rate $\sqrt{(s+p)\log p/n}$ in (28) is minimax optimal for estimating s-sparse precision matrix under Frobenius norm (see Theorem 7 in Cai et al. (2016b)). The same rate has also been obtained in Saegusa and Shojaie (2016) for multiple precision matrix estimation when the true cluster structure is assumed to be given in advance. Moreover, our cluster mean error rate $\sqrt{d\log p/n}$ is minimax optimal for estimating d-sparse cluster means; see Wang et al. (2015b). In short, Corollary 18 indicates that our procedure is able to achieve optimal statistical rates for both cluster means and multiple precision matrices even when the true cluster structure is unknown.

Remark 20 *As a by-product, we establish the variable selection consistency of $\mathbf{\Omega}_k^{(T)}$, which ensures that our precision matrix estimator can asymptotically identify true connected links. Assume $\|\mathbf{\Omega}_k^*\|_\infty$ is bounded and the minimal signal in the true precision matrix satisfies $\omega_{\min} := \min_{(i,j)\in\mathcal{V}_k, k=1,\ldots,K} w_{kij}^* > 2r_n$, where $r_n = (\sqrt{K^5 d} + \sqrt{K^3(Ks+p)})\sqrt{\log p/n}$. The latter condition is weaker than that assumed in Guo et al. (2011), where they require a constant lower bound of $\omega_{\min}$. To ensure the model selection consistency, we threshold the precision matrix estimator $\mathbf{\Omega}_k^{(T)}$ such that $\widetilde{\omega}_{kij} = \omega_{kij}^{(T)} 1\{|\omega_{kij}^{(T)}| > r_n\}$ as in Bickel and Levina (2008) and Lee and Liu (2015). See Theorem S.2 in the online supplementary for some results on the selection consistency result.*

4. Numerical Study

In this section, we discuss an efficient tuning parameter selection procedure and demonstrate the superior numerical performance of our method. We compare our algorithm with three clustering and graphical model estimation methods:

- Standard K-means clustering (MacQueen, 1967).
- Algorithm in Zhou et al. (2009) which applies graphical lasso for each precision matrix estimation.
- A two-stage approach which first uses K-means clustering to obtain the clusters and then applies joint graphical lasso (Danaher et al., 2014) to estimate precision matrices.

For a fair comparison, we assume the number of clusters K is given in all methods.

4.1 Selection of Tuning Parameters

In our simultaneous clustering and graph estimation formulation, three tuning parameters $\Lambda := \{\lambda_1, \lambda_2, \lambda_3\}$ need to be appropriately determined so that both the clustering and network estimation performance can be optimized. In our framework, the tuning parameters are selected through the following adaptive BIC-type selection criterion. For a set of tuning parameters $\Lambda := \{\lambda_1, \lambda_2, \lambda_3\}$, the adaptive BIC criterion is defined as

$$\mathrm{BIC}(\Lambda) = -2\log\widehat{L}(\Lambda) + \log(n)\mathrm{df}_\Lambda(\boldsymbol{\mu}) + 2\mathrm{df}_\Lambda(\mathbf{\Omega}), \tag{29}$$

where $\widehat{L}(\Lambda)$ is the sample likelihood function and $\{\mathrm{df}_\Lambda(\boldsymbol{\mu}), \mathrm{df}_\Lambda(\mathbf{\Omega})\}$ is the degrees of freedom of the model. Here, $\{\mathrm{df}_\Lambda(\boldsymbol{\mu}), \mathrm{df}_\Lambda(\mathbf{\Omega})\}$ can be approximated by the size of selected variables in the final estimator. Therefore, according to the Gaussian mixture model assumption, the adaptive BIC criterion in (29) can be computed as

$$-2\sum_{i=1}^{n}\log\left(\sum_{k=1}^{K}\widehat{\pi}_k f_k\left(\boldsymbol{x}_i; \widehat{\boldsymbol{\mu}}_k, (\widehat{\mathbf{\Omega}}_k)^{-1}\right)\right) + \sum_{k=1}^{K}\{\log n \cdot s_{1k} + 2s_{2k}\},$$

where $s_{1k} = \mathrm{Card}\{i : \widehat{\mu}_{ki} \neq 0\}$, $s_{2k} = \mathrm{Card}\{(i,j) : \widehat{\Omega}_{kij} \neq 0, 1 \leq i < j \leq p\}$ and $\widehat{\pi}_k, \widehat{\boldsymbol{\mu}}_k, \widehat{\mathbf{\Omega}}_k$ are final updates from Algorithm 1. We choose a smaller weight for the degrees of freedom of precision matrices as suggested in Danaher et al. (2014). The mixing weight π is not counted into the degrees of freedom since it only contributes a constant factor.

In our experiment, we choose the optimal set of parameters minimizing the BIC value in (29). In the high-dimensional scenario where p is very large, calculation of BIC over a

grid search for all $\lambda_1, \lambda_2, \lambda_3$ may be computationally expensive. Following Danaher et al. (2014), we suggest a line search over λ_1, λ_2 and λ_3. In detail, we fix λ_2 and λ_3 at their median value of the given range and conduct a grid search over λ_1. Then with tuned λ_1 and median value of λ_3, we conduct a grid search over λ_2. The line search for λ_3 is the same. In our simulations, we choose the tuning range $10^{-2+2t/15}$ with $t = 0, 1, \ldots, 15$ for all $\lambda_1, \lambda_2, \lambda_3$.

4.2 Illustration

In this subsection, we demonstrate the importance of simultaneous clustering and estimation in improving both the clustering performance and the estimation accuracy of multiple precision matrices.

The simulated data consists of $n = 1000$ observations from 2 clusters, and among them 500 observations are from $\mathcal{N}(\boldsymbol{\mu}_1, \boldsymbol{\Sigma})$ and the rest 500 observations are from $\mathcal{N}(\boldsymbol{\mu}_2, \boldsymbol{\Sigma})$ with $\boldsymbol{\mu}_1 = (0, 1)^\top$, $\boldsymbol{\mu}_2 = (0, -1)^\top$, and

$$\boldsymbol{\Sigma} = \begin{pmatrix} 1 & 0.8 \\ 0.8 & 1 \end{pmatrix}.$$

The standard K-means algorithm treats the data space as isotropic (distances unchanged by translations and rotations) (Raykov et al., 2016). This means that data points in each cluster are modeled as lying within a sphere around the cluster centroid. A sphere has the same radius in each dimension. However, the non-diagonal covariance matrix in the mixture model makes the cluster structure highly non-spherical. Thus, the K-means algorithm is expected to produce an unsatisfactory clustering result. This is illustrated in Figure 2 where K-means clustering clearly obtains wrong clusters. On the other hand, by incorporating the precision matrix estimation into clustering, our method is able to identify two correct clusters.

Figure 2: The first plot represents the true clusters shown in red and black in the example of Section 4.2. The middle and right plots show the clusters obtained from the standard K-means clustering (Kmeans) and our SCAN method.

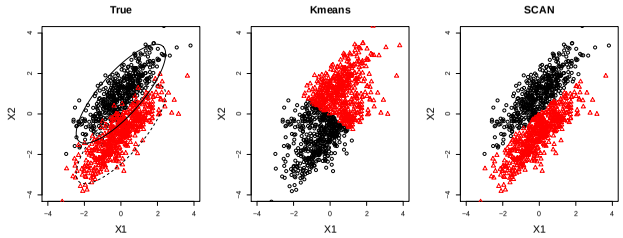


Figure 3 illustrates the estimation performance of precision matrices based on the clusters estimated from the K-means clustering and our method. Clearly, our SCAN method

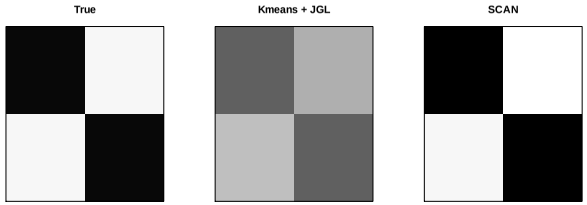
delivers an estimator with improved accuracy when compared to the two stage method which applies joint graphical lasso (JGL) to the clusters obtained from the K-means clustering. This suggests that an accurate clustering is critical for the estimation performance of heterogeneous graphical models.

Figure 3: The true precision matrix and the estimated precision matrices from the two stage method (Kmeans + JGL) and our SCAN method in the example of Section 4.2.



4.3 Effect of Sample Size and Dimension

We investigate the effect of sample size and dimension in terms of the estimation error and computational time. First, we empirically demonstrate the derived upper bound (28) for the estimation error by drawing the error pattern of our precision matrix estimator against sample size and dimension. The setting is the same as Section 4.2 except that we consider a tri-diagonal convariance structure. The results are summarized in Figure 4. In the first plot, we fix the dimension to be 10 and vary the sample size from 400 to 2000. In the second plot, we fix the sample size to be 5000 and vary the dimension from 5 to 50. The box plot refers to the the actual numerical values of precision matrix estimation errors, and the red dot is the theoretical error rate in each scenario. These results demonstrate that the empirical errors match very well with the theoretical error bound.

Second, we compare the average running time of our SCAN algorithm with varying sample sizes and dimensions. Figure 5 shows that our algorithm scales linearly with the sample size and roughly linearly with the dimension. This illustrates the efficiency and scalability of our proposed algorithm.

4.4 Simulations

In this subsection, we conduct extensive simulation studies to evaluate the performance of our algorithm. To assess the clustering performance of various methods, we compute the following clustering error (CE) which calculates the distance between an estimated clustering assignment $\widehat{\psi}$ and the true assignment ψ of the sample data $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_n$ (Wang, 2010; Sun et al., 2012),

$$\mathrm{CE}(\widehat{\psi}, \psi) := \binom{n}{2}^{-1} \Big| \{(i, j) : 1(\widehat{\psi}(\boldsymbol{X}_i) = \widehat{\psi}(\boldsymbol{X}_j)) \neq 1(\psi(\boldsymbol{X}_i) = \psi(\boldsymbol{X}_j)); i < j\} \Big|,$$

Figure 4: Comparison of the numerical error and the theoretical error rates of our SCAN method. The left panel displays the precision matrix estimation error with varying sample sizes. The right panel displays the precision matrix estimation error with varying dimensions.

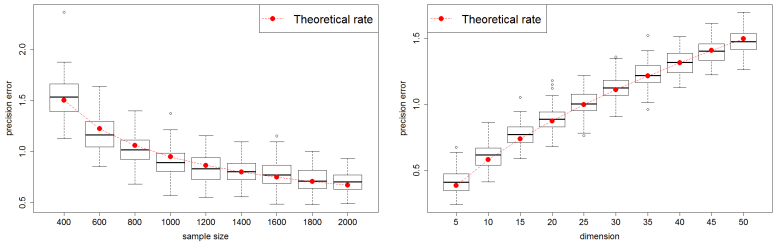


Figure 5: Running time of our algorithm. The left panel is the running time with varying sample sizes and fixed dimension $p = 10$. The right panel is the running time with varying dimensions and fixed sample size $n = 5000$.

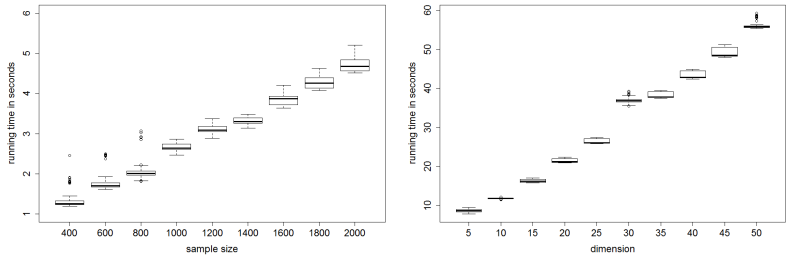

where $|\mathcal{A}|$ is the cardinality of set $\mathcal{A}$. To measure the estimation quality, we calculate the precision matrix error (PME) and cluster mean error (CME)

$$\text{PME} := \frac{1}{K}\sum_{k=1}^{K}\left\|\widehat{\boldsymbol{\Omega}}^{(k)} - \boldsymbol{\Omega}^{(k)}\right\|_F; \ \text{CME} := \frac{1}{K}\sum_{k=1}^{K}\left\|\widehat{\boldsymbol{\mu}}^{(k)} - \boldsymbol{\mu}^{(k)}\right\|_2.$$

Finally, to compare the variable selection performance, we compute the true positive rate (TPR, percentage of true edges selected) and the false positive rate (FPR, percentage of false edges selected)

$$\text{TPR} := \frac{1}{K}\sum_{k=1}^{K}\frac{\sum_{i<j}1(\omega_{kij}\neq 0, \widehat{\omega}_{kij}\neq 0)}{\sum_{i<j}1(\omega_{kij}\neq 0)},$$
$$\text{FPR} := \frac{1}{K}\sum_{k=1}^{K}\frac{\sum_{i<j}1(\omega_{kij}= 0, \widehat{\omega}_{kij}\neq 0)}{\sum_{i<j}1(\omega_{kij}= 0)}.$$

In the simulation, a three-class problem is considered. We illustrate three different types of network structures. In the first scenario, the network is assumed to have some regular structures. We generate a 5-block tridiagonal precision matrix with p features for the precision matrix. To allow the similarity of precision matrices across clusters, we set the off-diagonal entry of $\Omega_1, \Omega_2, \Omega_3$ as η, 0.99η, and 1.01η, respectively. The diagonal entries of Ω_1, Ω_2, and Ω_3 are all 1.

In the second and third scenarios, followed by Danaher et al. (2014), we simulate each network consisting of disjointed modules since many large networks in the real life exhibit a modular structure comprised of many disjointed or loosely connected components of relatively small size (Peng et al., 2009). Thus, each of three networks is generated with p features, which has ten equally sized unconnected subnetworks. Among the ten subnetworks, eight have the same structure and edge values across all the three classes, one remains the same only for the first two classes and the last one appears only for the first class. For the cluster structure of subnetwork, we consider two scenarios: power-law network and chain network, which are generated using the algorithm in Peng et al. (2009) and Fan et al. (2009). The detail construction is described as below.

Power-law network. Given an undirected network structure above, the initial ten-block precision matrix $(w^1_{ij})_{p\times p}$ is generated by

$$w^1_{ij} = \begin{cases} 1 & i \neq j; \\ 0 & i \neq j, \text{ no edge}; \\ \text{Unif}([-0.4,-0.1]\cup[0.1,0.4]) & i \neq j, \text{ edge exits}; \end{cases}$$

To ensure positive definiteness and symmetry, we divide each off-diagonal entry by 0.9 times the sum of the absolute values of off-diagonal entries in its row and average this rescaled matrix with its transpose. Denote the final transformed matrix by $\boldsymbol{A}$. The covariance matrix corresponding to the first class is created by

$$\boldsymbol{\Sigma}_{1ij} = d_{ij}\frac{\boldsymbol{A}^{-1}_{ij}}{\sqrt{\boldsymbol{A}^{-1}_{ii}\boldsymbol{A}^{-1}_{jj}}} \tag{30}$$

where $d_{ij} = 0.9$ for non-diagonal entry and $d_{ij} = 1$ for diagonal entry. For the covariance matrix corresponding to the second class, we create $\boldsymbol{\Sigma}_2$ be identical to $\boldsymbol{\Sigma}_1$ but reset one of ten block matrix to the identity matrix. Similarly, we reset one additional block matrix for $\boldsymbol{\Sigma}_3$.

Chain network. In the scenario, each of ten blocks of the first covariance matrix $\boldsymbol{\Sigma}_1$ is constructed in the following way. The ij-th element of each block has the form

$\sigma_{ij} = \exp(-a|s_i - s_j|)$, where $s_1 < s_2 < \cdots < s_{p/10}$ for some $a > 0$. This is related to the autoregressive process of order one. In our case, we choose $a = 1$ and $s_i - s_{i-1} \sim \text{Unif}(0.5, 1)$ for $i = 2, \ldots, p/10$. Similarly, we create $\mathbf{\Sigma}_2$ be identical to $\mathbf{\Sigma}_1$ but reset one of ten block matrix to the identity matrix and reset one additional block matrix for $\mathbf{\Sigma}_3$.

After the networks are constructed, the samples are generated as follows. First, the cluster membership Y_i's are uniformly sampled from $\{1, 2, 3\}$. Given the cluster label, we generate each sample $\boldsymbol{X}_i \sim \mathcal{N}(\boldsymbol{\mu}(Y_i), \mathbf{\Sigma}(Y_i))$. Here, the cluster mean $\boldsymbol{\mu}(Y_i)$ is sparse, where its first 10 variables are of the form

$$(\mu \mathbf{1}_5^\top, -\mu \mathbf{1}_5^\top)^\top 1(Y_i = 1) + \mu \mathbf{1}_{10} 1(Y_i = 2) + (-\mu \mathbf{1}_5^\top, -\mu \mathbf{1}_5^\top)^\top 1(Y_i = 3),$$

with $\mathbf{1}_5$ being a 5-dimensional vector of all ones, and its last $p - 10$ variables are zeros. For the first scenario, we consider 3 simulation models with varying choices of μ and η:

- Model 1: $\mu = 0.8$ and $\eta = 0.3$,
- Model 2: $\mu = 1$ and $\eta = 0.3$,
- Model 3: $\mu = 1$ and $\eta = 0.4$.

Here μ controls the separability of the three clusters with larger μ corresponding to an easier clustering problem, and η represents the similarity level of precision matrices across clusters. For the second and third scenarios, we considered three simulation models with sequential choices of μ:

- Models 4,7: $\mu = 0.7$,
- Models 5,8: $\mu = 0.8$,
- Models 6,9: $\mu = 0.9$.

The number of features p is equal to 100 and sample size is equal to 300. The results are averaged over 50 experiments. The code is written in R and implemented on an Intel Xeon-E5 processor with 64 GB of RAM. The average computation time for SCAN of a single run took one and half minute.

In the experiment, our method selected the tuning parameters via the BIC criterion in Section 4.1. For a fair comparison, we also used the same tuning parameters λ_1, λ_2 in Zhou et al. (2009), and the same λ_2, λ_3 in the joint graphical lasso penalty of the two-stage approach. We repeated the procedure 50 times and reported the averaged clustering errors, estimation errors, and variable selection errors for each method as well as their standard errors. Table 2 is for regular network, Table 3 is for power-law networks and Table 4 is for chain networks. As shown in Table 3 and Table 4, the standard K-means clustering method has the largest clustering error due to a violation of its diagonal covariance matrix assumption. This will result in poor estimation for multiple precision matrices. The method of Zhou et al. (2009) improves the clustering performance of the standard K-means by using a graphical lasso in the precision matrix estimation. However, it obtains a relatively large precision matrix estimation error and very bad false positive rate since it

ignores the similarity across different precision matrices. In contrast, our SCAN algorithm achieves the best clustering accuracy and best precision matrix estimation accuracy for both scenarios. This is due to our simultaneous clustering and estimation strategy as well as the consideration of similarity of precision matrices across clusters. This experiment shows that a satisfactory clustering algorithm is critical to achieve accurate estimations of heterogeneous graphical models, and alternatively good estimation of the graphical model can also improve the clustering performance. This explains the success of our simultaneous method in terms of both clustering and graphical model estimation.

4.5 Glioblastoma Cancer Data Analysis

In this section, we apply our simultaneous clustering and graphical model estimation method to a Glioblastoma cancer dataset. We aim to cluster the glioblastoma multiforme (GBM) patients and construct the gene regulatory network of each subtype in order to improve our understanding of the GBM disease.

The raw gene expression dataset measures 17814 levels of mRNA expression of 482 GBM patients. Each patient belongs to one of four subgroups of GBM: Classical, Mesenchymal, Neural, and Proneural (Verhaak et al., 2010). Although they are biologically different, these four subtypes share many similarities since they are all GBM diseases. For our analysis, we considered the 840 signature genes established by Verhaak et al. (2010). Following the preprocess procedures in Lee and Liu (2015), we excluded the genes with no subtype information or the genes with missing values. We then applied the sure independence screening analysis (Fan and Lv, 2008) to finally include 50 genes in our analysis. These 50 signature genes are highly distinctive for these four subtypes. In the analysis, we pretended that the subtype information of each patient was unknown and evaluated the clustering accuracy of various clustering methods by comparing the estimated groups with the true subtypes. In all methods, we fixed $K = 4$. Moreover, we set the tuning parameters $\lambda_1 = 0.065, \lambda_2 = 0.238$, and $\lambda_3 = 0.138$ in our SCAN algorithm. For a fair comparison, we also used the same λ_1, λ_2 in Zhou et al. (2009), and the same λ_2, λ_3 in the joint graphical lasso of the two-stage method.

Table 5 reported the clustering errors of all methods as well as the number of informative variables in the corresponding estimated means and precision matrices. The standard K-means clustering has the large clustering error due to its ignorance of the network structure in the precision matrices. Therefore, the consequent joint graphical lasso method of the network reconstruction is less reliable. The method in Zhou et al. (2009) performed even worse. This is because their method estimates each precision matrix individually without borrowing information from each other. In this gene network example, all of the four graphical models share many edges due to the commonality in the GBM diseases. Zhou et al. (2009)'s method may suffer from the small sample size. Our method is able to achieve the best clustering performance due to the procedure of simultaneous clustering and heterogeneous graphical model estimation.

Table 5: The clustering errors and the number of selected features in cluster mean and precision matrix of various methods in the Glioblastoma Cancer Data.

Methods	Clustering Error	$\sum_k \|\widehat{\boldsymbol{\mu}}^{(k)}\|_0$	$\sum_k \|\widehat{\boldsymbol{\Omega}}^{(k)}\|_0$
K-means	0.262	200	NA
Zhou et al. (2009)	0.336	106	1820
K-means + JGL	0.262	200	1360
SCAN	**0.222**	128	1452

To evaluate the ability of reconstructing gene regulatory network of each subtype, we report the four gene networks estimated from our SCAN method in Figure 1. The black lines are links shared in all subtypes, and the color lines are uniquely presented in some subtypes. Clearly, most edges are black lines, which indicates the common structure of all subtypes. For instance, the link between ZNF45 and ZNF134 is significant across all the four subtypes. Those two genes belong to ZNF gene family. They are known to play roles in making

zinc finger proteins, which are regulatory proteins that are functional important to many cellulars. As they play roles in the same biological process, it is reasonable to expect this link is shared by all GBM subtypes. There are two links that shared by three subtypes except neural subtype: TNFRSF1B↔TRPM2, PTPRC↔ TRPM2. One link uniquely appears in Proneural subtype: ACTR1A ↔DWED and one link FBXO3↔HMG20B is uniquely shown in neural subtype. These findings agree with the existing results in Verhaak et al. (2010). It has been shown that the PTPRC is a well-described microglia marker and is highly exposed in the set of murine astrocytic samples which are strongly associated with the Mesenchymal group. In addition, TRPM2 and TNFRSF1B are shown frequently in the GOTERM category of Mesenchymal group but less likely to appear in Neural group. And FBXO3 is only significant in the cell part of neural subtype. Furthermore, ACTR1A is only found in the intracellular non-membrane-bound organelle and protein binding of Proneural subtype in the supplemental material of Verhaak et al. (2010). It would also be of interest to investigate unique gene links that were not discovered in existing literatures for better understanding of GBM diseases.

5. Discussion

In this paper, we propose a new SCAN method for simultaneous clustering and estimation of heterogeneous graphical models with common structures. We describe the theoretical properties of SCAN and we show that the estimation error bound of our SCAN algorithm consists of statistical error and optimization error, which explicitly addresses the trade-off between statistical accuracy and computational complexity. In our experiments, the tuning parameters can be chosen via an efficient BIC-type criterion. For future work, it is of interest to investigate the model selection consistency of these tuning parameters and study the distributed implementation of ECM algorithm based on the work in Wolfe et al. (2008).

APPENDIX

In this section, we provide detailed proofs of key results: Theorem 13 and Corollary 18. The proofs of other lemmas and theorems are deferred to the online supplementary.

Appendix A. Proof of Theorem 13

First we introduce some notation. Recall the definition of support space $\mathcal{M}$ in (15). The orthogonal complement of support space $\mathcal{M}$, namely, is defined as the set

$$\mathcal{M}^{\perp} := \left\{ \boldsymbol{\Theta}' \in \Xi \mid \langle \boldsymbol{V}, \boldsymbol{\Theta}' \rangle = 0 \text{ for all } \boldsymbol{V} \in \mathcal{M} \right\}.$$

The projection operator $\Pi_{\mathcal{M}}(\boldsymbol{\Theta}) : \Xi \to \Xi$ is defined as

$$\Pi_{\mathcal{M}}(\boldsymbol{\Theta}) := \arg\min_{\boldsymbol{V} \in \mathcal{M}} \|\boldsymbol{V} - \boldsymbol{\Theta}\|_2 .$$

To simplify the notation, we frequently use the shorthand $\boldsymbol{\Theta}_{\mathcal{M}} = \Pi_{\mathcal{M}}(\boldsymbol{\Theta})$ and $\boldsymbol{\Theta}_{\mathcal{M}^{\perp}} = \Pi_{\mathcal{M}^{\perp}}(\boldsymbol{\Theta})$.

In order to efficiently solve the high-dimensional regularized problem, we explore some good properties enjoyed by SCAN penalty in Lemma 21 and Lemma 22. Similar properties can be derived by any decomposable penalty.

Lemma 21 *The SCAN penalty $\mathcal{P}$ is convex and decomposable with respect to $(\mathcal{M}, \mathcal{M}^{\perp})$. In detail,*

$$\mathcal{P}(\boldsymbol{\Theta}_1 + \boldsymbol{\Theta}_2) = \mathcal{P}(\boldsymbol{\Theta}_1) + \mathcal{P}(\boldsymbol{\Theta}_2), \text{ for any } \boldsymbol{\Theta}_1 \in \mathcal{M}, \boldsymbol{\Theta}_2 \in \mathcal{M}^{\perp}.$$

The dual norm of SCAN penalty $\mathcal{P}$ is given by

$$\mathcal{P}^*(\boldsymbol{\Theta}) := \max_{i,j,k,i \neq j} \left(M_1 \sqrt{\mu_{kj}^2}, M_2 \sqrt{\omega_{kij}^2}, M_3 \left(\sum_{k=1}^{K} \omega_{kij}^2 \right)^{1/2} \right). \tag{31}$$

Proof of Lemma 21: The convexity of SCAN comes from the convexity of lasso penalty for cluster means and the convexity of group graphical lasso penalty for precision matrices. The decomposability and derivation of dual norm is obvious from the definition. Also see Wainwright (2014). ■

Lemma 22 *For all vectors $\boldsymbol{\Theta}$ belonging to support space $\mathcal{M}$, $\mathcal{P}(\boldsymbol{\Theta}_{\mathcal{M}})$ satisfies the following inequality:*

$$\mathcal{P}(\boldsymbol{\Theta}_{\mathcal{M}}) \leq \nu(\mathcal{M}) \|\boldsymbol{\Theta}_{\mathcal{M}}\|_2 , \tag{32}$$

where $\nu(\mathcal{M}) = M_1\sqrt{Kd} + (M_2\sqrt{K} + M_3)\sqrt{s}$ is the support space compatibility constant *defined in (25) .*

Proof of Lemma 22: The detailed proof of Lemma 22 is discussed in S.V. ■

Next lemma is a key step to establish our main theorem. It quantifies the estimation error in one iteration step. According to this lemma, one can precisely understand how the statistical error and optimization error accumulate with more and more iterations.

Lemma 23 *Suppose $\boldsymbol{\Theta}^*$ lies in the interior of Ξ. If $\boldsymbol{\Theta}^{(t-1)} \in \mathcal{B}_{\alpha}(\boldsymbol{\Theta}^*)$, with choice of $\lambda_n^{(t)} = \varepsilon + \tau\|\boldsymbol{\Theta}^{(t-1)} - \boldsymbol{\Theta}^*\|_2/\nu(\mathcal{M})$, final estimation error satisfies $\|\boldsymbol{\Theta}^{(t)} - \boldsymbol{\Theta}^*\|_2 \leq 6\nu(\mathcal{M})\lambda_n^{(t)}/\gamma$ with probability at least $1-\delta'$ for all $t = 1, 2, \ldots$. Here τ, λ and $\nu(\mathcal{M})$ are defined in Lemma 7, Lemma 9 and Lemma 22 accordingly.*

Proof of Lemma 23: Proof is postponed to section B.1. ■

Equipped with Lemmas 23, we are able to precisely quantify the final estimation error after t iteration steps. This can be achieved by mathematical induction. For simplicity, define $\kappa := 6\tau/\gamma$. When $t = 1$, we have $\boldsymbol{\Theta}^{(0)} \in \mathcal{B}_{\alpha}(\boldsymbol{\Theta}^*)$. Applying Lemma 23 yields that

$$\begin{aligned} \left\| \boldsymbol{\Theta}^{(1)} - \boldsymbol{\Theta}^* \right\|_2 &\leq \frac{6\lambda_n^{(1)}\nu(\mathcal{M})}{\gamma} \\ &= \frac{6\nu(\mathcal{M})}{\gamma}\varepsilon + \kappa \left\| \boldsymbol{\Theta}^{(0)} - \boldsymbol{\Theta}^* \right\|_2 . \end{aligned}$$

Suppose the following inequality is true for some $t \geq 1$,

$$\left\| \boldsymbol{\Theta}^{(t)} - \boldsymbol{\Theta}^* \right\|_2 \leq \frac{1-\kappa^t}{1-\kappa} \frac{6\nu(\mathcal{M})}{\gamma}\varepsilon + \kappa^t \left\| \boldsymbol{\Theta}^{(0)} - \boldsymbol{\Theta}^* \right\|_2 ,$$

with probability at least $1-t\delta'$. We need to verify when $t=t+1$, the above inequality still holds. First, we show that $\mathbf{\Theta}^{(t)}$ is within a ball of $\mathbf{\Theta}^*$ with radius α. Under the assumption that $\varepsilon \leq (1-\kappa)\alpha\gamma/(6\nu(\mathcal{M}))$ for sufficient large n, we have

$$\begin{aligned}\left\|\mathbf{\Theta}^{(t)}-\mathbf{\Theta}^*\right\|_2 &\leq \frac{1-\kappa^t}{1-\kappa}\frac{6\nu(\mathcal{M})}{\gamma}\frac{(1-\kappa)\alpha\gamma}{6\nu(\mathcal{M})}+\kappa^t\left\|\mathbf{\Theta}^{(0)}-\mathbf{\Theta}^*\right\|_2\\ &\leq (1-\kappa^t)\alpha+\kappa^t\alpha=\alpha.\end{aligned}$$

Consequently, we have $\mathbf{\Theta}^{(t)}\in\mathcal{B}_\alpha(\mathbf{\Theta}^*)$. Applying Lemma 23 with $t+1$ implies that

$$\begin{aligned}\left\|\mathbf{\Theta}^{(t+1)}-\mathbf{\Theta}^*\right\|_2 &\leq \frac{6\nu(\mathcal{M})\varepsilon}{\gamma}+\kappa\left\|\mathbf{\Theta}^{(t)}-\mathbf{\Theta}^*\right\|_2\\ &\leq \frac{6\nu(\mathcal{M})\varepsilon}{\gamma}+\kappa\left(\frac{1-\kappa^t}{1-\kappa}\frac{6\nu(\mathcal{M})\varepsilon}{\gamma}+\kappa^t\left\|\mathbf{\Theta}^{(0)}-\mathbf{\Theta}^*\right\|_2\right)\\ &= \frac{1-\kappa^{t+1}}{1-\kappa}\frac{6\nu(\mathcal{M})\varepsilon}{\gamma}+\kappa^{t+1}\left\|\mathbf{\Theta}^{(0)}-\mathbf{\Theta}^*\right\|_2,\end{aligned}$$

with probability at least $1-(t+1)\delta'$. Therefore, we reach the conclusion that

$$\begin{aligned}\left\|\mathbf{\Theta}^{(t)}-\mathbf{\Theta}^*\right\|_2 &\leq \frac{1-\kappa^t}{1-\kappa}\frac{6\nu(\mathcal{M})}{\gamma}\varepsilon+\kappa^t\left\|\mathbf{\Theta}^{(0)}-\mathbf{\Theta}^*\right\|_2\\ &\leq \frac{6\nu(\mathcal{M})\varepsilon}{(1-\kappa)\gamma}+\kappa^t\left\|\mathbf{\Theta}^{(0)}-\mathbf{\Theta}^*\right\|_2,\end{aligned}$$

with probability at least $1-t\delta'$. This concludes the proof of Theorem 13. ■

A.1 Proof of Corollary 18

It is worth to notice that sufficiently large iterations ensure that the optimization error will be dominated by statistical error finally as $\kappa<1/2$. First we provide a stopping rule T. Plugging $\varepsilon_1,\varepsilon_2$ from (S.14) & (S.15) into statistical error part and letting $\delta=1/p$, we have:

$$\begin{aligned}SE=&\frac{1}{1-\kappa}\frac{6}{\gamma}\left[\left(\sqrt{Kd}+(\sqrt{K}+1)\sqrt{s}\right)\left(CK\|\mathbf{\Omega}^*\|_\infty+C'K^{1.5}\right)\sqrt{\frac{\log p}{n}}\right]\\ &+\frac{1}{1-\kappa}\frac{6}{\gamma}\left[C''\sqrt{p}\sqrt{\frac{K^3\log p}{n}}\right].\end{aligned}$$

Note that under Condition 17, $K=o(p)$. Then SE is simplified by

$$SE\leq\frac{6\widetilde{C}}{(1-\kappa)\gamma}\|\mathbf{\Omega}^*\|_\infty\left(\sqrt{Kd}+\sqrt{Ks+p}\right)\sqrt{\frac{K^3\log p}{n}},$$

for some constant $\widetilde{C}$. For simplicity, let's denote

$$\varphi(n,p,K)=\frac{6\widetilde{C}}{(1-\kappa)\gamma}\|\mathbf{\Omega}^*\|_\infty\left(\sqrt{Kd}+\sqrt{Ks+p}\right)\sqrt{\frac{K^3\log p}{n}}.$$

Therefore, the bound (27) suggests a reasonable choice of the number of iterations. In particular, when

$$t\geq T=\log_{1/\kappa}\left(\frac{\left\|\mathbf{\Theta}^{(0)}-\mathbf{\Theta}^*\right\|_2}{\varphi(n,p,K)}\right), \tag{33}$$

the optimization error is dominated by statistical error. Final estimation error will be upper bounded by

$$\left\|\mathbf{\Theta}^{(T)}-\mathbf{\Theta}^*\right\|_2\leq\frac{12\widetilde{C}}{(1-\kappa)\gamma}\left(\|\mathbf{\Omega}^*\|_\infty\sqrt{\frac{K^5d\log p}{n}}+\|\mathbf{\Omega}^*\|_\infty\sqrt{\frac{K^3(Ks+p)\log p}{n}}\right),$$

with probability at least $1-T(26K^2+8K+1)/p$. Plugging in the expression of T in (33), the probability term is bounded by:

$$\begin{aligned}\frac{T(26K^2+8K+1)}{p} &\lesssim \frac{\log_{1/\kappa}\left(n/\left(\left(\sqrt{Kd}+\sqrt{Ks+p}\right)\sqrt{K^3\log p}\right)\right)K^2}{p}\\ &\lesssim \frac{K^2\log_{1/\kappa}n}{p}.\end{aligned}$$

Under Condition 17, $T(26K^2+8K+1)/p$ goes to zero as K and p diverging. Putting pieces together, we have

$$\left\|\mathbf{\Theta}^{(T)}-\mathbf{\Theta}^*\right\|_2\leq\frac{12\widetilde{C}}{(1-\kappa)\gamma}\left(\|\mathbf{\Omega}^*\|_\infty\sqrt{\frac{K^5d\log p}{n}}+\|\mathbf{\Omega}^*\|_\infty\sqrt{\frac{K^3(Ks+p)\log p}{n}}\right),$$

which implies

$$\begin{aligned}&\sum_{k=1}^K\left(\left\|\boldsymbol{\mu}_k^{(T)}-\boldsymbol{\mu}_k^*\right\|_2+\left\|\mathbf{\Omega}_k^{(T)}-\mathbf{\Omega}_k^*\right\|_F\right)\\ &\leq\frac{12\widetilde{C}}{(1-\kappa)\gamma}\left(\|\mathbf{\Omega}^*\|_\infty\sqrt{\frac{K^5d\log p}{n}}+\|\mathbf{\Omega}^*\|_\infty\sqrt{\frac{K^3(Ks+p)\log p}{n}}\right),\end{aligned}$$

with probability converging to 1. It ends the proof of Corollary 18. ■

Appendix B. Proof of Key Lemmas

B.1 Proof of Lemma 23

We first consider an unsymmetrized version of $\mathbf{\Theta}^{(t)}$. Our proof makes use of the function $f:\Xi\to\mathbb{R}$ given by:

$$f(\Delta):=Q_n(\mathbf{\Theta}^*+\Delta|\mathbf{\Theta}^{(t-1)})-Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)})-\lambda_n^{(t)}\left(\mathcal{P}(\mathbf{\Theta}^*+\Delta)-\mathcal{P}(\mathbf{\Theta}^*)\right).$$

This function helps us evaluate the error between the iterative estimator $\mathbf{\Theta}^{(t)}$ and the true parameter $\mathbf{\Theta}^*$. In addition, we exploit the following fact:

$$\begin{cases} f(0) = 0 \\ f(\widehat{\Delta}) \geq 0 \text{ when } \widehat{\Delta} = \mathbf{\Theta}^{(t)} - \mathbf{\Theta}^*. \end{cases} \tag{34}$$

The second property is from the optimality of $\mathbf{\Theta}^{(t)}$ in terms of the sample version objective function. In detail,

$$\mathbf{\Theta}^{(t)} = \arg\max_{\mathbf{\Theta}'} Q_n(\mathbf{\Theta}'|\mathbf{\Theta}^{(t-1)}) - \lambda_n^{(t)}\mathcal{P}(\mathbf{\Theta}'). \tag{35}$$

Correspondingly, there is a classical result named self-consistency property for population version objective function in McLachlan and Krishnan (2007), which in detail is

$$\mathbf{\Theta}^* = \arg\max_{\mathbf{\Theta}'} Q(\mathbf{\Theta}'|\mathbf{\Theta}^*). \tag{36}$$

The whole proof follows two steps. In Step I, we show that $f(\Delta) < 0$ if $\|\Delta\|_2 = \xi$. Next in Step II, we show that the error term $\widehat{\Delta}$ must satisfy $\|\widehat{\Delta}\|_2 < \xi$ under the result in Step I.

Step I: we begin to establish an upper bound on $f(\Delta)$ over the set $\mathbb{C}(\xi) := \{\Delta : \|\Delta\|_2 = \xi\}$ for the chosen radius $\xi = 6\lambda_n^{(t)}\nu(\mathcal{M})/\gamma$. From the assumption on n, when n is large enough,

$$\varepsilon \leq \frac{(1-\kappa)\alpha\gamma}{6\nu(\mathcal{M})} \leq \frac{(2-\kappa)\alpha\gamma}{6\nu(\mathcal{M})},$$
$$\frac{6\nu(\mathcal{M})\varepsilon}{\gamma} \leq (2-\kappa)\alpha.$$

On the other hand, as $\|\mathbf{\Theta}^{(t-1)} - \mathbf{\Theta}^*\|_2 \leq \alpha$, ξ satisfies,

$$\xi = \frac{6\nu(\mathcal{M})\varepsilon}{\gamma} + \kappa \left\|\mathbf{\Theta}^{(t-1)} - \mathbf{\Theta}^*\right\|_2 \leq 2\alpha.$$

It is sufficient to show that $\mathbb{C}(\xi) \subseteq \mathbb{C} = \{\Delta | \|\Delta\|_2 \leq 2\alpha\}$. According to Lemma 9, replacing $\mathbf{\Theta}' - \mathbf{\Theta}^*$ by Δ, then any $\Delta \in \mathbb{C}(\xi)$ enjoys restricted strong concavity property, which implies:

$$Q_n(\mathbf{\Theta}^* + \Delta|\mathbf{\Theta}^{(t-1)}) - Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) \leq \left\langle \nabla Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}), \Delta \right\rangle - \frac{\gamma}{2}\|\Delta\|_2^2,$$

with probability at least $1-\delta$. Subtracting $\lambda_n^{(t)}(\mathcal{P}(\mathbf{\Theta}^* + \Delta) - \mathcal{P}(\mathbf{\Theta}^*))$ from both sides, we construct an upper bound of $f(\Delta)$ in the right side,

$$f(\Delta) \leq \underbrace{\left\langle \nabla Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}), \Delta \right\rangle}_{(i)} - \lambda_n^{(t)} \underbrace{\left(\mathcal{P}(\mathbf{\Theta}^* + \Delta) - \mathcal{P}(\mathbf{\Theta}^*)\right)}_{(ii)} - \frac{\gamma}{2}\|\Delta\|_2^2.$$

Bounding (i)**:** Note that Q_n is a sample version Q-function but $\mathbf{\Theta}^*$ comes from population version Q-function (36). So we use $\nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)})$ as a bridge to connect the sample-based

analysis and population-based analysis together.

$$\begin{aligned}(i) \leq\ & |\big\langle \nabla Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) - \nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) \\ & \qquad + \nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) - \nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta}^*), \Delta \big\rangle| \\ \leq\ & \underbrace{|\big\langle \nabla Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) - \nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}), \Delta \big\rangle|}_{\text{Statistical Error(SE)}} \\ & \qquad + \underbrace{|\big\langle \nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) - \nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta}^*), \Delta \big\rangle|}_{\text{Optimization Error(OE)}}.\end{aligned}$$

Note that $\mathbf{\Theta}^*$ lies in the interior of Ξ. According to the self-consistency property (36), $\nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta}^*) = 0$ which implies the first inequality holds. This decomposition for (i) leads to the optimization error part and statistical error part.

For simplicity, we write $h(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) = \nabla Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) - \nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)})$. Since the group graphical lasso penalty does not penalize the diagonal element, it is a semi-norm. Recall that both Δ and $h(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)})$ are $K(p^2+p)$ dimensional vectors. Then by the definition of $\mathcal{G}$ and $\mathcal{G}^c$ in (14), statistical error can be decomposed further by:

$$\begin{aligned}\text{SE} \leq\ & \left|\langle h(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)})_{\mathcal{G}^c}, \Delta_{\mathcal{G}^c}\rangle\right| + \left|\langle h(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)})_{\mathcal{G}}, \Delta_{\mathcal{G}}\rangle\right| \\ \leq\ & \left\|h(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)})_{\mathcal{G}^c}\right\|_{\mathcal{P}^*} \cdot \mathcal{P}(\Delta_{\mathcal{G}^c}) + \|h(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)})_{\mathcal{G}}\|_2 \cdot \|\Delta_{\mathcal{G}}\|_2 \\ \leq\ & \|h(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)})\|_{\mathcal{P}^*} \cdot \mathcal{P}(\Delta) + \|h(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)})_{\mathcal{G}}\|_2 \cdot \|\Delta\|_2.\end{aligned}$$

The second inequality comes from the generalized Cauchy-Schwarz inequality. After excluding the diagonal terms from precision matrices, $\mathcal{P}(\Delta_{\mathcal{G}^c})$ can be treated as a norm. The last inequality is because both the penalties $\mathcal{P}$ and $\mathcal{P}^*$ do not penalize the diagonal term of precision matrices. Under statistical error Condition 10,

$$\text{SE} \leq \varepsilon_1\mathcal{P}(\Delta) + \varepsilon_2\|\Delta\|_2, \tag{37}$$

with probability at least $1 - (\delta_1 + \delta_2)$.

On the other hand, from the assumption that $\mathbf{\Theta}^{(t-1)}$ is in the $\mathcal{B}_\alpha(\mathbf{\Theta}^*)$, we are able to apply the Gradient Stability condition in Lemma 7 to bound OE.

$$\begin{aligned}\text{OE} \leq\ & \|\nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) - \nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta}^*)\|_2 \cdot \|\Delta\|_2 \\ \leq\ & \tau\|\mathbf{\Theta}^{(t-1)} - \mathbf{\Theta}^*\|_2 \cdot \|\Delta\|_2.\end{aligned} \tag{38}$$

Therefore, putting (37) and (38) together, (i) is upper bounded by

$$(i) \leq \varepsilon_1\mathcal{P}(\Delta) + \varepsilon_2\|\Delta\|_2 + \tau\|\mathbf{\Theta}^{(t-1)} - \mathbf{\Theta}^*\|_2 \cdot \|\Delta\|_2, \tag{39}$$

with probability at least $1 - (\delta_1 + \delta_2)$.

Bounding (ii)**:** The decomposability of SCAN penalty in Lemma 21 implies $\mathcal{P}(\mathbf{\Theta}^* + \Delta) = \mathcal{P}(\mathbf{\Theta}^* + \Delta_{\mathcal{M}}) + \mathcal{P}(\Delta_{\mathcal{M}^\perp})$. By triangle inequality, it is sufficient to bound (ii),

$$\begin{aligned}(ii) =\ & \mathcal{P}(\mathbf{\Theta}^* + \Delta_{\mathcal{M}}) + \mathcal{P}(\Delta_{\mathcal{M}^\perp}) - \mathcal{P}(\mathbf{\Theta}^*) \\ \geq\ & \mathcal{P}(\mathbf{\Theta}^*) - \mathcal{P}(\Delta_{\mathcal{M}}) + \mathcal{P}(\Delta_{\mathcal{M}^\perp}) - \mathcal{P}(\mathbf{\Theta}^*) \\ =\ & \mathcal{P}(\Delta_{\mathcal{M}^\perp}) - \mathcal{P}(\Delta_{\mathcal{M}}).\end{aligned} \tag{40}$$

Combining (39) and (40), $f(\Delta)$ is upper bounded by:

$$f(\Delta) \leq \varepsilon_1 \mathcal{P}(\Delta) + \varepsilon_2 \|\Delta\|_2 + \tau \|\mathbf{\Theta}^{(t-1)} - \mathbf{\Theta}^*\|_2 \cdot \|\Delta\|_2 - \lambda_n^{(t)} \left(\mathcal{P}(\Delta_{\mathcal{M}^\perp}) - \mathcal{P}(\Delta_{\mathcal{M}})\right) - \frac{\gamma}{2}\|\Delta\|_2^2.$$

Triangle inequality implies $\mathcal{P}(\Delta) \leq \mathcal{P}(\Delta_{\mathcal{M}}) + \mathcal{P}(\Delta_{\mathcal{M}^\perp})$. After combining some terms, the right hand side above could be further bounded by:

$$f(\Delta) \leq -\frac{\gamma}{2}\|\Delta\|_2^2 + (\lambda_n^{(t)} + \varepsilon_1)\mathcal{P}(\Delta_{\mathcal{M}}) + (\varepsilon_1 - \lambda_n^{(t)})\mathcal{P}(\Delta_{\mathcal{M}^\perp}) + \varepsilon_2\|\Delta\|_2 + \tau\|\mathbf{\Theta}^{(t-1)} - \mathbf{\Theta}^*\|_2 \cdot \|\Delta\|_2, \tag{41}$$

with probability at least $1 - (\delta + \delta_1 + \delta_2)$. Let $\delta' = \delta + \delta_1 + \delta_2$. According to Lemma 22, we have the inequality $\mathcal{P}(\Delta_{\mathcal{M}}) \leq \nu(\mathcal{M})\|\Delta_{\mathcal{M}}\|_2$. By the definition of $\Pi_{\mathcal{M}}(\Delta)$, we have

$$\|\Delta_{\mathcal{M}}\|_2 = \|\Pi_{\mathcal{M}}(\Delta) - \Pi_{\mathcal{M}}(0)\|_2 \leq \|\Delta - 0\|_2 = \|\Delta\|_2.$$

Then $\mathcal{P}(\Delta_{\mathcal{M}})$ is further bounded by

$$\mathcal{P}(\Delta_{\mathcal{M}}) \leq \nu(\mathcal{M})\|\Delta\|_2. \tag{42}$$

Substituting (42) into (41), we obtain:

$$f(\Delta) \leq \left(\varepsilon_1 + \frac{\varepsilon_2 + \tau\|\mathbf{\Theta}^{(t-1)} - \mathbf{\Theta}^*\|_2}{\nu(\mathcal{M})}\right)\nu(\mathcal{M})\|\Delta\|_2 - \frac{\gamma}{2}\|\Delta\|_2^2 + \lambda_n^{(t)}\nu(\mathcal{M})\|\Delta\|_2 + (\varepsilon_1 - \lambda_n^{(t)})\mathcal{P}(\Delta_{\mathcal{M}^\perp}),$$

with at least probability $1 - \delta'$. Recall that we choose

$$\lambda_n^{(t)} = \varepsilon + \frac{\tau\|\mathbf{\Theta}^{(t-1)} - \mathbf{\Theta}^*\|_2}{\nu(\mathcal{M})}, \epsilon = \epsilon_1 + \frac{\epsilon_2}{\nu(\mathcal{M})}.$$

From the construction of $\lambda_n^{(t)}$, the inequality $\varepsilon_1 - \lambda_n^{(t)} < 0$ always holds. Therefore, the upper bound for $f(\Delta)$ can be simplified by

$$\begin{aligned} f(\Delta) &\leq -\frac{\gamma}{2}\|\Delta\|_2^2 + 2\lambda_n^{(t)}\nu(\mathcal{M})\|\Delta\|_2 \\ &= -\frac{6(\lambda_n^{(t)}\nu(\mathcal{M}))^2}{\gamma} < 0. \end{aligned}$$

where the above equality is due to $\Delta \in \mathbb{C}(\xi)$. Now we reach the conclusion that $f(\Delta) < 0$ for all vectors $\Delta \in \mathbb{C}(\xi)$.

Step II: Now we start to prove the following statement: if for some optimal solution $\mathbf{\Theta}^{(t)}$ in (35), the corresponding error term $\widehat{\Delta} = \mathbf{\Theta}^{(t)} - \mathbf{\Theta}^*$ satisfies the inequality $\|\widehat{\Delta}\|_2 > \xi$, there must exist some vectors $\widetilde{\Delta}$ which belong to $\mathbb{C}(\xi)$ such that $f(\widetilde{\Delta}) \geq 0$. Before our forward proofs, let's state a lemma which describe the curvature of function $Q_n(\cdot|\mathbf{\Theta}^{(t-1)})$.

Lemma 24 *$Q_n(\cdot|\mathbf{\Theta}^{(t-1)})$ satisfies the following inequality a.s.:*

$$Q_n(\mathbf{\Theta}^{(1)}|\mathbf{\Theta}^{(t-1)}) - Q_n\left(\mathbf{\Theta}^{(2)}|\mathbf{\Theta}^{(t-1)}\right) \leq \left\langle \nabla Q_n\left(\mathbf{\Theta}^{(2)}|\mathbf{\Theta}^{(t-1)}\right), \mathbf{\Theta}^{(1)} - \mathbf{\Theta}^{(2)}\right\rangle.$$

when $(\mathbf{\Theta}^{(1)}, \mathbf{\Theta}^{(2)}) = (\mathbf{\Theta}^{(t)}, t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*)$ *or* $(\mathbf{\Theta}^*, t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*)$.

Proof of Lemma 24: The detailed proof of Lemma 24 is discussed in S.VI. ■

The lemma tells us that we only require sample-based Q-function to be point-wise concave rather than global concave. If $\|\widehat{\Delta}\|_2 > \xi$, then the line joining $\widehat{\Delta}$ to 0 must intersect the set $\mathbb{C}(\xi)$ at some intermediate points $t^*\widehat{\Delta}$, for some $t^* \in (0,1)$. According to Lemma 24,

$$\begin{aligned} &Q_n(\mathbf{\Theta}^{(t)}|\mathbf{\Theta}^{(t-1)}) - Q_n(t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) \\ &\quad \leq \left\langle \nabla Q_n(t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}), (1-t^*)(\mathbf{\Theta}^{(t)} - \mathbf{\Theta}^*)\right\rangle \\ &Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) - Q_n\left(t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}\right) \\ &\quad \leq \left\langle \nabla Q_n\left(t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}\right), -t^*(\mathbf{\Theta}^{(t)} - \mathbf{\Theta}^*)\right\rangle. \end{aligned}$$

Adding the above two inequalities together with proper scaling, we can get

$$t^*Q_n(\mathbf{\Theta}^{(t)}|\mathbf{\Theta}^{(t-1)}) + (1-t^*)Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) \leq Q_n(t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}).$$

According to the convexity of $\mathcal{P}(\mathbf{\Theta})$,

$$\begin{aligned} &\mathcal{P}\left(\mathbf{\Theta}^* + t^*\widehat{\Delta}\right) - \mathcal{P}\left(\mathbf{\Theta}^*\right) = \mathcal{P}\left(t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*\right) - \mathcal{P}(\mathbf{\Theta}^*) \\ &\leq t^*\mathcal{P}(\mathbf{\Theta}^{(t)}) + (1-t^*)\mathcal{P}(\mathbf{\Theta}^*) - \mathcal{P}(\mathbf{\Theta}^*) = t^*\left(\mathcal{P}(\mathbf{\Theta}^{(t)}) - \mathcal{P}(\mathbf{\Theta}^*)\right). \end{aligned}$$

Putting the above pieces together, it is shown that

$$\begin{aligned} f(t^*\widehat{\Delta}) &= Q_n\left(t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}\right) - Q_n\left(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}\right) \\ &\qquad - \lambda_n^{(t)}\left(\mathcal{P}(\mathbf{\Theta}^* + \Delta) - \mathcal{P}(\mathbf{\Theta}^*)\right) \\ &\geq t^*\left(Q_n(\mathbf{\Theta}^{(t)}|\mathbf{\Theta}^{(t-1)}) - Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}^{(t-1)}) - \lambda_n^{(t)}\left(\mathcal{P}(\mathbf{\Theta}^{(t)}) - \mathcal{P}(\mathbf{\Theta}^*)\right)\right) \\ &= t^*f(\widehat{\Delta}). \end{aligned}$$

On the other hand, the optimality property (34) guarantees $f(\widehat{\Delta}) \geq 0$, and hence $f(t^*\widehat{\Delta}) \geq 0$ as well. Thus, we have constructed a vector $\widetilde{\Delta} = t^*\widehat{\Delta}$ with the claimed properties. This proves the statement in the beginning of Step II. Therefore, combining with the result in Step I, the contradiction of the statement in Step II implies that

$$\left\|\mathbf{\Theta}^{(t)} - \mathbf{\Theta}^*\right\|_2 \leq \xi = \frac{6\lambda_n^{(t)}\nu(\mathcal{M})}{\gamma}, \tag{43}$$

with probability at least $1 - \delta'$. This concludes the proof of Lemma 23. ■

Online Supplementary

This supplementary contains supporting lemmas and their proofs for the theoretical developments in the main paper.

Appendix A. Proof of Several Lemmas and Selection Consistency

S.I Proof of Lemma 5

The result follows by setting the derivative of $Q(\boldsymbol{\Theta}^{'}|\boldsymbol{\Theta})$ with respect to $\boldsymbol{\mu}_k^{'}$ or $\boldsymbol{\Omega}_k^{'}$ as zero. In particular, solving

$$\frac{\partial Q(\boldsymbol{\Theta}^{'}|\boldsymbol{\Theta})}{\partial \boldsymbol{\mu}_k^{'}} = \mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\boldsymbol{\Omega}_k^{'}(\boldsymbol{X}-\boldsymbol{\mu}_k^{'})] = 0,$$

implies that

$$\arg\max_{\boldsymbol{\mu}_k^{'}} Q(\boldsymbol{\Theta}^{'}|\boldsymbol{\Theta}) = \frac{[\boldsymbol{\Omega}_k^{'}]^{-1}\mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\boldsymbol{\Omega}_k^{'}\boldsymbol{X}]}{\mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})]} = \frac{\mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\boldsymbol{X}]}{\mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})]}.$$

Similarly, solving

$$\frac{\partial Q(\boldsymbol{\Theta}^{'}|\boldsymbol{\Theta})}{\partial \boldsymbol{\Omega}_k^{'}} = \frac{1}{2}\mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})][\boldsymbol{\Omega}_k^{'}]^{-1} - \frac{1}{2}\mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})(\boldsymbol{X}-\boldsymbol{\mu}_k^{'})(\boldsymbol{X}-\boldsymbol{\mu}_k^{'})^{\top}] = 0,$$

implies (19). This ends the proof of Lemma 5. ■

S.II Proof of Lemma 7

We consider k-th group first

$$\left\|\nabla_{\boldsymbol{\Theta}_k^{'}} Q(\boldsymbol{\mu}_k^*,\boldsymbol{\Omega}_k^*|\boldsymbol{\Theta}^*) - \nabla_{\boldsymbol{\Theta}_k^{'}} Q(\boldsymbol{\mu}_k^*,\boldsymbol{\Omega}_k^*|\boldsymbol{\Theta})\right\|_2 \leq \tau\left\|\boldsymbol{\Theta}-\boldsymbol{\Theta}^*\right\|_2, \tag{S.1}$$

for any $\boldsymbol{\Theta} \in \mathbb{B}_\alpha(\boldsymbol{\Theta}^*)$. Remind that $\boldsymbol{\Theta}_k^{'} = \mathrm{vec}(\boldsymbol{\mu}_k, \boldsymbol{\Omega}_k) \in \mathbb{R}^{p^2+p}$. According to the derivation in the proof of Lemma 5, we have

$$\nabla_{\boldsymbol{\Theta}_k^{'}} Q(\boldsymbol{\Theta}_k^{'}|\boldsymbol{\Theta}) = \begin{pmatrix} \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\boldsymbol{\Omega}_k^{'}(\boldsymbol{X}-\boldsymbol{\mu}_k^{'})\right] \\ \mathrm{vec}\left\{\frac{1}{2}\mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})]\boldsymbol{\Omega}_k^{'-1} - \frac{1}{2}\mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})(\boldsymbol{X}-\boldsymbol{\mu}_k^{'})(\boldsymbol{X}-\boldsymbol{\mu}_k^{'})^{\top}]\right\}^{\top} \end{pmatrix}.$$

Define $D_L(\boldsymbol{\Theta}^*,\boldsymbol{\Theta}) = L_{\boldsymbol{\Theta}^*,k}(\boldsymbol{X}) - L_{\boldsymbol{\Theta},k}(\boldsymbol{X})$. Therefore, the square of the left hand side of $(S.1)$ can be simplified to

$$\begin{aligned} & \left\|\nabla_{\boldsymbol{\Theta}_k^{'}} Q(\boldsymbol{\mu}_k^*,\boldsymbol{\Omega}_k^*|\boldsymbol{\Theta}^*) - \nabla_{\boldsymbol{\Theta}_k^{'}} Q(\boldsymbol{\mu}_k^*,\boldsymbol{\Omega}_k^*|\boldsymbol{\Theta})\right\|_2^2 \\ = & \underbrace{\left\|\mathbb{E}\left[D_L(\boldsymbol{\Theta}^*,\boldsymbol{\Theta})\boldsymbol{\Omega}_k^*(\boldsymbol{X}-\boldsymbol{\mu}_k^*)\right]\right\|_2^2}_{I} \\ & + \underbrace{\left\|\frac{1}{2}\mathbb{E}[D_L(\boldsymbol{\Theta}^*,\boldsymbol{\Theta})\boldsymbol{\Omega}_k^{*-1} - \frac{1}{2}\mathbb{E}[D_L(\boldsymbol{\Theta}^*,\boldsymbol{\Theta})(\boldsymbol{X}-\boldsymbol{\mu}_k^*)(\boldsymbol{X}-\boldsymbol{\mu}_k^*)^{\top}]\right\|_F^2}_{II}. \end{aligned}$$

If we can show $I \leq \tau_1\|\boldsymbol{\Theta}-\boldsymbol{\Theta}^*\|_2^2$ and $II \leq \tau_2\|\boldsymbol{\Theta}-\boldsymbol{\Theta}^*\|_2^2$, then we have $\tau = \sqrt{\tau_1+\tau_2}$ since

$$\left\|\nabla_{\boldsymbol{\Theta}_k^{'}} Q(\boldsymbol{\mu}_k^*,\boldsymbol{\Omega}_k^*|\boldsymbol{\Theta}^*) - \nabla_{\boldsymbol{\Theta}_k^{'}} Q(\boldsymbol{\mu}_k^*,\boldsymbol{\Omega}_k^*|\boldsymbol{\Theta})\right\|_2 \leq \sqrt{\tau_1+\tau_2}\|\boldsymbol{\Theta}-\boldsymbol{\Theta}^*\|_2.$$

Bounding I: We apply Taylor expansion to simplify $D_L(\boldsymbol{\Theta}^*,\boldsymbol{\Theta})$. Remind that, by assumption, $\pi_k = 1/K$, and hence we have

$$L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) = \frac{\pi_k f_k(\boldsymbol{X};\boldsymbol{\Theta}_k)}{\sum_{k=1}^K \pi_k f_k(\boldsymbol{X};\boldsymbol{\Theta}_k)} = \frac{|\boldsymbol{\Omega}_k|^{1/2}\exp\left\{-\frac{1}{2}(\boldsymbol{X}-\boldsymbol{\mu}_k)^{\top}\boldsymbol{\Omega}_k(\boldsymbol{X}-\boldsymbol{\mu}_k)\right\}}{\sum_{k=1}^K |\boldsymbol{\Omega}_k|^{1/2}\exp\left\{-\frac{1}{2}(\boldsymbol{X}-\boldsymbol{\mu}_k)^{\top}\boldsymbol{\Omega}_k(\boldsymbol{X}-\boldsymbol{\mu}_k)\right\}}.$$

Then, Taylor expansion of $L_{\boldsymbol{\Theta},k}(\boldsymbol{X})$ around $\boldsymbol{\Theta}_k^*$ leads to

$$L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) = L_{\boldsymbol{\Theta}^*,k}(\boldsymbol{X}) + [\nabla_{\boldsymbol{\Theta}} L_{\boldsymbol{\Theta}_t,k}(\boldsymbol{X})]^{\top}(\boldsymbol{\Theta}-\boldsymbol{\Theta}^*), \tag{S.2}$$

where $\boldsymbol{\Theta}_t = \boldsymbol{\Theta}^* + t\Delta$ with $t \in [0,1]$ and $\Delta = \boldsymbol{\Theta}-\boldsymbol{\Theta}^*$. Here the derivative of $L_{\boldsymbol{\Theta},k}(\boldsymbol{X})$ with respect to $\boldsymbol{\Theta} = (\boldsymbol{\Theta}_1,\ldots,\boldsymbol{\Theta}_K)$ can be written as

$$\nabla_{\boldsymbol{\Theta}} L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) = \left([\nabla_{\boldsymbol{\Theta}_1} L_{\boldsymbol{\Theta},k}(\boldsymbol{X})]^{\top},\ldots,[\nabla_{\boldsymbol{\Theta}_K} L_{\boldsymbol{\Theta},k}(\boldsymbol{X})]^{\top}\right)^{\top}, \tag{S.3}$$

where

$$\nabla_{\boldsymbol{\Theta}_j} L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) = \begin{cases} -L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\cdot L_{\boldsymbol{\Theta},j}(\boldsymbol{X})\cdot\delta_{\boldsymbol{\Theta}_j}(\boldsymbol{X}) \text{ when } j \neq k; \\ L_{\boldsymbol{\Theta},k}(\boldsymbol{X})[1-L_{\boldsymbol{\Theta},k}(\boldsymbol{X})]\cdot\delta_{\boldsymbol{\Theta}_k}(\boldsymbol{X}) \text{ when } j = k, \end{cases}$$

and, for $j = 1\ldots,K$, and $\boldsymbol{\Theta}_j = \mathrm{vec}(\mu_j,\boldsymbol{\Omega}_j)$,

$$\delta_{\boldsymbol{\Theta}_j}(\boldsymbol{X}) = \begin{pmatrix} \boldsymbol{\Omega}_j(\boldsymbol{X}-\boldsymbol{\mu}_j) \\ \frac{1}{2}\mathrm{vec}\left\{\boldsymbol{\Omega}_j^{-1} - (\boldsymbol{X}-\boldsymbol{\mu}_j)(\boldsymbol{X}-\boldsymbol{\mu}_j)^{\top}\right\} \end{pmatrix}.$$

Next we apply this Taylor expansion to bound I. According to $(S.2)$, we have

$$\begin{aligned} I &= \left\|\mathbb{E}\left[\boldsymbol{\Omega}_k^*(\boldsymbol{X}-\boldsymbol{\mu}_k^*)[\nabla_{\boldsymbol{\Theta}} L_{\boldsymbol{\Theta}_t,k}(\boldsymbol{X})]^{\top}(\boldsymbol{\Theta}-\boldsymbol{\Theta}^*)\right]\right\|_2^2 \\ &= \left\|\mathbb{E}\left[\boldsymbol{\Omega}_k^*(\boldsymbol{X}-\boldsymbol{\mu}_k^*)[\nabla_{\boldsymbol{\Theta}} L_{\boldsymbol{\Theta}_t,k}(\boldsymbol{X})]^{\top}\right]\right\|_2^2 \cdot \|\boldsymbol{\Theta}-\boldsymbol{\Theta}^*\|_2^2 \\ &\leq \underbrace{\sup_{t\in[0,1]} \mathbb{E}\left[\|\boldsymbol{\Omega}_k^*(\boldsymbol{X}-\boldsymbol{\mu}_k^*)\|_2^2 \cdot \|\nabla_{\boldsymbol{\Theta}} L_{\boldsymbol{\Theta}_t,k}(\boldsymbol{X})\|_2^2\right]}_{\tau_1} \cdot \|\boldsymbol{\Theta}-\boldsymbol{\Theta}^*\|_2^2. \end{aligned}$$

By the definition of $\nabla_{\boldsymbol{\Theta}} L_{\boldsymbol{\Theta}_t,k}(\boldsymbol{X})$, which equals to (S.3) with $\boldsymbol{\Theta} = \boldsymbol{\Theta}_t$, we have

$$\begin{aligned} \|\nabla_{\boldsymbol{\Theta}} L_{\boldsymbol{\Theta}_t,k}(\boldsymbol{X})\|_2^2 &= \underbrace{\sum_{j\neq k}[L_{\boldsymbol{\Theta}_t,k}(\boldsymbol{X})L_{\boldsymbol{\Theta}_t,j}(\boldsymbol{X})]^2\cdot[\delta_{\boldsymbol{\Theta}_{tj}}(\boldsymbol{X})]^{\top}\delta_{\boldsymbol{\Theta}_{tj}}(\boldsymbol{X})}_{A_1} \\ &\quad + \underbrace{\left[L_{\boldsymbol{\Theta}_t,k}(\boldsymbol{X})\big(1-L_{\boldsymbol{\Theta}_t,k}(\boldsymbol{X})\big)\right]^2\cdot[\delta_{\boldsymbol{\Theta}_{tk}}(\boldsymbol{X})]^{\top}\delta_{\boldsymbol{\Theta}_{tk}}(\boldsymbol{X})}_{A_2}. \end{aligned}$$

For each $j = 1, \ldots, K$, we define

$$W_j := \sup_{t\in[0,1]} \mathbb{E}\left\{[\delta_{\mathbf{\Theta}_{tj}}(\boldsymbol{X})]^\top \delta_{\mathbf{\Theta}_{tj}}(\boldsymbol{X}) \cdot \|\mathbf{\Omega}_k^*(\boldsymbol{X}-\boldsymbol{\mu}_k^*)\|_2^2\right\}, \tag{S.4}$$

Then

$$\tau_1 \le \sup_{t\in[0,1]} \mathbb{E}\left[\|\mathbf{\Omega}_k^*(\boldsymbol{X}-\boldsymbol{\mu}_k^*)\|_2^2 (A_1+A_2)\right]. \tag{S.5}$$

Under Condition 6, it is sufficient to get an upper bound for τ_1,

$$\begin{aligned}\tau_1 &\le \sup_{t\in[0,1]} \mathbb{E}\left[\|\mathbf{\Omega}_k^*(\boldsymbol{X}-\boldsymbol{\mu}_k^*)\|_2^2 A_1\right] + \sup_{t\in[0,1]} \mathbb{E}\left[\|\mathbf{\Omega}_k^*(\boldsymbol{X}-\boldsymbol{\mu}_k^*)\|_2^2 A_2\right] \\ &\le \sum_{j\neq k} \frac{\gamma^2}{24^2(K-1)^2 M_j}\cdot W_j + \left(\frac{\gamma}{24(K-1)\sqrt{M_k}}(K-1)\right)^2 \cdot W_k.\end{aligned}$$

It implies that

$$\tau_1 \le \frac{\gamma^2}{288}. \tag{S.6}$$

Bounding II: We can apply similar trick above to bound II. By triangle inequality, we have

$$\begin{aligned}II &\le \underbrace{\left\|\frac{1}{2}\mathbb{E}\big[D_L(\mathbf{\Theta}^*,\mathbf{\Theta})\mathbf{\Omega}_k^{*-1}\big]\right\|_F^2}_{II_1} \\ &\quad + \underbrace{\left\|\frac{1}{2}\mathbb{E}\big[D_L(\mathbf{\Theta}^*,\mathbf{\Theta})(\boldsymbol{X}-\boldsymbol{\mu}_k^*)(\boldsymbol{X}-\boldsymbol{\mu}_k^*)^\top\big]\right\|_F^2}_{II_2}.\end{aligned}$$

Apply Taylor expansion in $(S.2)$, we obtain

$$\begin{aligned}II_1 &\le \underbrace{\frac{1}{2}\mathbb{E}\left[\|\nabla_{\mathbf{\Theta}} L_{\mathbf{\Theta}_t,k}(\boldsymbol{X})\|_2^2 \|\mathbf{\Omega}_k^{*-1}\|_F^2\right]}_{\gamma_{21}} \cdot \|\mathbf{\Theta}-\mathbf{\Theta}^*\|_2^2 \\ II_2 &\le \underbrace{\frac{1}{2}\mathbb{E}\left[\|\nabla_{\mathbf{\Theta}} L_{\mathbf{\Theta}_t,k}(\boldsymbol{X})\|_2^2 \left\|(\boldsymbol{X}-\boldsymbol{\mu}_k^*)(\boldsymbol{X}-\boldsymbol{\mu}_k^*)^\top\right\|_F^2\right]}_{\gamma_{22}} \cdot \|\mathbf{\Theta}-\mathbf{\Theta}^*\|_2^2.\end{aligned}$$

Analogously to (S.4), we define

$$W_j' := \sup_{t\in[0,1]} \mathbb{E}\left\{[\delta_{\mathbf{\Theta}_{tj}}(\boldsymbol{X})]^\top \delta_{\mathbf{\Theta}_{tj}}(\boldsymbol{X}) \left\|\mathbf{\Omega}_k^{*-1}\right\|_F^2\right\}, \tag{S.7}$$

$$W_j'' := \sup_{t\in[0,1]} \mathbb{E}\left\{[\delta_{\mathbf{\Theta}_{tj}}(\boldsymbol{X})]^\top \delta_{\mathbf{\Theta}_{tj}}(\boldsymbol{X}) \left\|(\boldsymbol{X}-\boldsymbol{\mu}_k^*)(\boldsymbol{X}-\boldsymbol{\mu}_k^*)^\top\right\|_F^2\right\}. \tag{S.8}$$

for each $j = 1, \ldots, K$. Under Condition 6, we have that,

$$\tau_{21} < \frac{\gamma^2}{576}, \quad \tau_{22} < \frac{\gamma^2}{576}, \text{ and hence } \tau_2 < \frac{\gamma^2}{288}.$$

This together with (S.6) implies that $\tau = \sqrt{\tau_1+\tau_2} < \gamma/12$, namely

$$\left\|\nabla_{\mathbf{\Theta}_k'} Q(\boldsymbol{\mu}_k^*, \mathbf{\Omega}_k^*|\mathbf{\Theta}^*) - \nabla_{\mathbf{\Theta}_k'} Q(\boldsymbol{\mu}_k^*, \mathbf{\Omega}_k^*|\mathbf{\Theta})\right\|_2 \le \frac{\gamma}{12}.$$

Now we take the summation

$$\sum_{k=1}^K \left\|\nabla_{\mathbf{\Theta}_k'} Q(\boldsymbol{\mu}_k^*, \mathbf{\Omega}_k^*|\mathbf{\Theta}^*) - \nabla_{\mathbf{\Theta}_k'} Q(\boldsymbol{\mu}_k^*, \mathbf{\Omega}_k^*|\mathbf{\Theta})\right\|_2^2 \le \frac{\gamma}{12}\|\mathbf{\Theta}-\mathbf{\Theta}^*\|_2, \tag{S.9}$$

for any $\mathbf{\Theta} \in \mathbb{B}_\alpha(\mathbf{\Theta}^*)$. This ends the proof of Lemma 7. ■

S.III Proof of Lemma 9

In order to compute γ, we consider each $\mathbf{\Theta}_k = \{\mu_k, \mathbf{\Omega}_k\}$ individually. That means we prove the following part first:

$$Q_n(\mathbf{\Theta}_k'|\mathbf{\Theta}) - Q_n(\mathbf{\Theta}_k^*|\mathbf{\Theta}) - \left\langle \nabla Q_n(\mathbf{\Theta}_k^*|\mathbf{\Theta}), \mathbf{\Theta}_k' - \mathbf{\Theta}_k^*\right\rangle \le -\frac{\gamma}{2}\left\|\mathbf{\Theta}_k' - \mathbf{\Theta}_k^*\right\|_2^2,$$

where $Q_n(\mathbf{\Theta}_k|\mathbf{\Theta})$ means we set $\mathbf{\Theta}_i$ $i \neq k$ to zero.

It is sufficient to compute γ_k in (22). Remind that $\mathbf{\Theta}_k' = \mathrm{vec}(\boldsymbol{\mu}_k, \mathbf{\Omega}_k) \in \mathbb{R}^{p^2+p}$. Therefore,

$$\nabla_{\mathbf{\Theta}_k'} Q_n(\mathbf{\Theta}_k'|\mathbf{\Theta}) = ([\nabla_{\boldsymbol{\mu}_k'} Q_n(\mathbf{\Theta}_k'|\mathbf{\Theta})]^\top, [\mathrm{vec}(\nabla_{\mathbf{\Omega}_k'} Q_n(\mathbf{\Theta}_k'|\mathbf{\Theta}))]^\top)^\top, \tag{S.10}$$

with

$$\begin{aligned}\nabla_{\boldsymbol{\mu}_k'} Q_n(\mathbf{\Theta}_k'|\mathbf{\Theta}) &= \frac{1}{n}\sum_{i=1}^n \left[L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\mathbf{\Omega}_k'(\boldsymbol{x}_i - \boldsymbol{\mu}_k')\right] \\ \nabla_{\mathbf{\Omega}_k'} Q_n(\mathbf{\Theta}_k'|\mathbf{\Theta}) &= \frac{1}{2n}\sum_{i=1}^n [L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)]\mathbf{\Omega}_k'^{-1} \\ &\quad - \frac{1}{2n}\sum_{i=1}^n [L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)(\boldsymbol{x}_i - \boldsymbol{\mu}_k')(\boldsymbol{x}_i - \boldsymbol{\mu}_k')^\top].\end{aligned}$$

Denote $h(\boldsymbol{\mu}, \mathbf{\Omega}) := \frac{1}{2}(\boldsymbol{x}_i - \boldsymbol{\mu})^\top \mathbf{\Omega}(\boldsymbol{x}_i - \boldsymbol{\mu})$. According to the definition in (9), we have

$$\begin{aligned}Q_n(\mathbf{\Theta}_k'|\mathbf{\Theta}) - Q_n(\mathbf{\Theta}_k^*|\mathbf{\Theta}) &= \frac{1}{n}\sum_{i=1}^n \Big[L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\big\{\frac{1}{2}\log\det(\mathbf{\Omega}_k') \\ &\quad -\frac{1}{2}\log\det(\mathbf{\Omega}_k^*) + h(\boldsymbol{\mu}_k^*, \mathbf{\Omega}_k^*) - h(\boldsymbol{\mu}_k', \mathbf{\Omega}_k')\big\}\Big].\end{aligned}$$

This together with $(S.10)$ implies that

$$Q_n(\mathbf{\Theta}_k'|\mathbf{\Theta}) - Q_n(\mathbf{\Theta}_k^*|\mathbf{\Theta}) - \left\langle \nabla_{\mathbf{\Theta}_k'} Q_n(\mathbf{\Theta}_k^*|\mathbf{\Theta}), \mathbf{\Theta}_k' - \mathbf{\Theta}_k^*\right\rangle = I + II,$$

where

$$I = \frac{1}{n}\sum_{i=1}^{n}\left[L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\left\{h(\boldsymbol{\mu}_k^*,\mathbf{\Omega}_k^*) - h(\boldsymbol{\mu}_k',\mathbf{\Omega}_k^*)\right\}\right]$$
$$-(\boldsymbol{\mu}_k' - \boldsymbol{\mu}_k^*)^\top \nabla_{\boldsymbol{\mu}_k'} Q_n(\mathbf{\Theta}_k^*|\mathbf{\Theta}^{(t)}),$$
$$II = \frac{1}{n}\sum_{i=1}^{n}\Big[L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\Big\{\frac{1}{2}\log\det(\mathbf{\Omega}_k') - \frac{1}{2}\log\det(\mathbf{\Omega}_k^*)$$
$$+h(\boldsymbol{\mu}_k',\mathbf{\Omega}_k^*) - h(\boldsymbol{\mu}_k',\mathbf{\Omega}_k')\Big\}\Big] - [\mathrm{vec}(\mathbf{\Omega}_k' - \mathbf{\Omega}_k^*)]^\top \nabla_{\mathbf{\Omega}_k'} Q_n(\mathbf{\Theta}_k^*|\mathbf{\Theta}^{(t)}).$$

By a little algebra, we can show that

$$I = -\frac{1}{2n}\sum_{i=1}^{n} L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)(\boldsymbol{\mu}_k' - \boldsymbol{\mu}_k^*)^\top \mathbf{\Omega}_k^*(\boldsymbol{\mu}_k' - \boldsymbol{\mu}_k^*).$$

Due to the positive definiteness of $\mathbf{\Omega}_k^*$, it is shown the following inequality

$$(\boldsymbol{\mu}_k' - \boldsymbol{\mu}_k^*)^\top(\mathbf{\Omega}_k^* - \sigma_{\min}(\mathbf{\Omega}_k^*)I_p)(\boldsymbol{\mu}_k' - \boldsymbol{\mu}_k^*) \geq 0$$

$$(\boldsymbol{\mu}_k' - \boldsymbol{\mu}_k^*)^\top \mathbf{\Omega}_k^*(\boldsymbol{\mu}_k' - \boldsymbol{\mu}_k^*) \geq (\boldsymbol{\mu}_k' - \boldsymbol{\mu}_k^*)^\top \sigma_{\min}(\mathbf{\Omega}_k^*) I_p(\boldsymbol{\mu}_k' - \boldsymbol{\mu}_k^*) \geq \beta_1 \left\|\boldsymbol{\mu}_k' - \boldsymbol{\mu}_k^*\right\|_2^2.$$

Substituting the above bound, it is shown that

$$I \leq -\frac{\beta_1}{2n}\sum_{i=1}^{n} L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\|\boldsymbol{\mu}_k' - \boldsymbol{\mu}_k^*\|_2^2. \tag{S.11}$$

Therefore, it remains to show that

$$II \leq -\frac{1}{2n}\sum_{i=1}^{n}\frac{L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)}{2(\beta_2+2\alpha)^2}\|\mathrm{vec}(\mathbf{\Omega}_k' - \mathbf{\Omega}_k^*)\|_2^2. \tag{S.12}$$

Note that, in order to show ($S.12$), it is equivalent to deriving the strong concavity parameter of $g(\mathbf{\Omega}_k)$, where

$$g(\mathbf{\Omega}_k) \coloneqq \frac{1}{n}\sum_{i=1}^{n}\left[L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\left\{\frac{1}{2}\log\det(\mathbf{\Omega}_k) - h(\boldsymbol{\mu}_k',\mathbf{\Omega}_k)\right\}\right].$$

To see it, finding the strong concavity parameter of $g(\mathbf{\Omega}_k)$ aims to compute ρ_k such that, for any $\mathbf{\Omega}_k', \mathbf{\Omega}_k^* \in \mathcal{B}_\alpha(\mathbf{\Omega}_k^*)$,

$$g(\mathbf{\Omega}_k') - g(\mathbf{\Omega}_k^*) - \left\langle \mathrm{vec}\left(\nabla g(\mathbf{\Omega}_k^*)\right), \mathrm{vec}(\mathbf{\Omega}_k' - \mathbf{\Omega}_k^*)\right\rangle \leq -\rho_k/2 \cdot \|\mathbf{\Omega}_k' - \mathbf{\Omega}_k^*\|_F^2,$$

where the left hand side is exactly II. According to Taylor expansion, we can expand $g(\mathbf{\Omega}_k')$ around $\mathbf{\Omega}_k^*$ and obtain

$$\begin{aligned} g(\mathbf{\Omega}_k') &= g(\mathbf{\Omega}_k^*) + \left\langle \mathrm{vec}(\nabla g(\mathbf{\Omega}_k^*), \mathrm{vec}(\mathbf{\Omega}_k' - \mathbf{\Omega}_k^*)\right\rangle \\ &\quad + \frac{1}{2}\left[\mathrm{vec}(\mathbf{\Omega}_k' - \mathbf{\Omega}_k^*)\right]^\top \nabla^2 g(\mathbf{Z})\left[\mathrm{vec}(\mathbf{\Omega}_k' - \mathbf{\Omega}_k^*)\right], \end{aligned}$$

where $\mathbf{Z} = t\mathbf{\Omega}_k' + (1-t)\mathbf{\Omega}_k^*$ with $t \in [0,1]$. For any two matrices $\mathbf{A}, \mathbf{B}$, we write $\mathbf{A} \succeq \mathbf{B}$ if $\mathbf{A} - \mathbf{B}$ is positive semi-definite. We denote 1_p as the identity matrix with dimension $p \times p$. And $\sigma_i(A)$ is the i-th eigenvalue of matrix A. Therefore, if we can show that $-\nabla^2 g(\mathbf{Z}) \succeq m\, 1_p$, i.e., the minimal eigenvalue value $\sigma_{\min}(-\nabla^2 g(\mathbf{Z})) \geq m$, for some positive $m \in \mathbb{R}$, then we have the strongly concavity parameter $\rho_k = m$. By the definition, we have $\nabla^2 g(\mathbf{\Omega}_k^*) = -\frac{1}{2n}\sum_{i=1}^n L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)[\mathbf{\Omega}_k^*]^{-1} \otimes [\mathbf{\Omega}_k^*]^{-1}$. Denote $\widetilde{\Delta} = \mathbf{\Omega}_k' - \mathbf{\Omega}_k^*$. We obtain

$$-\nabla^2 g(\mathbf{Z}) = \frac{1}{2n}\sum_{i=1}^{n} L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\left(\mathbf{\Omega}_k^* + t\widetilde{\Delta}\right)^{-1} \otimes \left(\mathbf{\Omega}_k^* + t\widetilde{\Delta}\right)^{-1}.$$

According to Theorem 4.2.1 2 in Horn and Johnson (1988), for any two matrices $\mathbf{A}, \mathbf{B}$, the minimal eigenvalue value of $\mathbf{A} \otimes \mathbf{B}$ equals the products of the minimal eigenvalue values of $\mathbf{A}$ and $\mathbf{B}$. Therefore, we have $\sigma_{\min}\left(\mathbf{A}^{-1} \otimes \mathbf{A}^{-1}\right) = \left[\sigma_{\min}(\mathbf{A}^{-1})\right]^2 = [\sigma_{\max}(\mathbf{A})]^{-2} = \|\mathbf{A}\|_2^{-2}$, where $\|\mathbf{A}\|_2$ refers to the spectral norm of matrix $\mathbf{A}$. Hence,

$$\begin{aligned} \sigma_{\min}(-\nabla^2 g(\mathbf{Z})) &= \frac{1}{2n}\sum_{i=1}^{n} L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\|\mathbf{\Omega}_k^* + t\widetilde{\Delta}\|_2^{-2} \\ &\geq \frac{1}{2n}\sum_{i=1}^{n} L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\left[\|\mathbf{\Omega}_k^*\|_2 + \|t\widetilde{\Delta}\|_2\right]^{-2}. \end{aligned}$$

As $\|\mathbf{\Theta}' - \mathbf{\Theta}^*\| \leq 2\alpha$, $\|\mathbf{\Omega}_k' - \mathbf{\Omega}_k^*\|_2 \leq \|\mathbf{\Theta}' - \mathbf{\Theta}^*\|_2 \leq 2\alpha$. Therefore,

$$\begin{aligned} \sigma_{\min}(-\nabla^2 g(\mathbf{Z})) &\geq \frac{1}{2n}\sum_{i=1}^{n} L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\left[\|\mathbf{\Omega}_k^*\|_2 + 2\alpha\right]^{-2} \\ &\geq \frac{1}{2n}\sum_{i=1}^{n} L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\left(\beta_2 + 2\alpha\right)^{-2}, \end{aligned}$$

which implies ($S.12$). Putting the upper bound of I and II together,

$$I + II \leq \underbrace{-\frac{1}{2n}\sum_{i=1}^{n} L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)}_{(a)} \cdot \min\left\{\beta_1, \frac{1}{2(\beta_2+2\alpha)^2}\right\}\|\mathbf{\Theta}_k' - \mathbf{\Theta}_k^*\|_2^2. \tag{S.13}$$

However, (a) is a random term but we require a non-random strong concavity parameter. Thus a concentration bound will be applied on it. $\{L_{\mathbf{\Theta},k}(\boldsymbol{x}_i), i = 1, \ldots, n\}$ are independent random variables with $0 \leq L_{\mathbf{\Theta},k}(\boldsymbol{x}_i) \leq 1$. After applying a basic Hoeffding's inequality, we have

$$\mathbb{P}\left(\left|\frac{1}{n}\sum_{i=1}^{n} L_{\mathbf{\Theta},k}(\boldsymbol{x}_i) - \mathbb{E}[L_{\mathbf{\Theta},k}(\boldsymbol{X})]\right| \leq t\right) \geq 1 - 2e^{-2nt^2},$$

which implies

$$\left|\frac{1}{n}\sum_{i=1}^{n} L_{\mathbf{\Theta},k}(\boldsymbol{x}_i) - \mathbb{E}[L_{\mathbf{\Theta},k}(\boldsymbol{X})]\right| \leq \sqrt{\frac{1}{2}\log\frac{2K}{\delta}}\sqrt{\frac{1}{n}},$$

with probability at least $1-\delta/K$. As $\sqrt{\log(2K/\delta)/2n} = o(1)$, there exists some constant c such that

$$\sqrt{\frac{\log 2K}{2\delta n}} - \mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})] \leq -c,$$

when n is large enough. Then plugging it into (S.13),

$$I + II \leq -\frac{1}{2}c \cdot \min\left\{\beta_1, \frac{1}{2(\beta_2+2\alpha)^2}\right\} \|\boldsymbol{\Theta}_k' - \boldsymbol{\Theta}_k^*\|_2^2,$$

with probability at least $1-\delta/K$, where

$$\gamma = c\min\left\{\beta_1, \frac{1}{2(\beta_2+2\alpha)^2}\right\}.$$

Once the individual strong concavity parameter is computed, we can simply take the summation from 1 to K:

$$\sum_{k=1}^{K} Q_n(\boldsymbol{\Theta}_k'|\boldsymbol{\Theta}) - Q_n(\boldsymbol{\Theta}_k^*|\boldsymbol{\Theta}) - \left\langle \nabla Q_n(\boldsymbol{\Theta}_k^*|\boldsymbol{\Theta}), \boldsymbol{\Theta}_k' - \boldsymbol{\Theta}_k^* \right\rangle \leq -\frac{1}{2}\sum_{k=1}^{K}\gamma \left\|\boldsymbol{\Theta}_k' - \boldsymbol{\Theta}_k^*\right\|_2^2$$

which implies

$$Q_n(\boldsymbol{\Theta}'|\boldsymbol{\Theta}) - Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \left\langle \nabla Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}), \boldsymbol{\Theta}' - \boldsymbol{\Theta}^* \right\rangle \leq -\frac{1}{2}\gamma \left\|\boldsymbol{\Theta}' - \boldsymbol{\Theta}^*\right\|_2^2$$

with probability at least $1-\delta$. This ends the proof of Lemma 9. ■

S.IV A Key Lemma for Proving Corollary 18

The next lemma computes the statistical errors in Condition 10 for our SCAN penalty and provides explicit forms of the corresponding $\varepsilon_1, \varepsilon_2$ and δ_1, δ_2.

Lemma S.1 *Suppose that Condition 16, 17 hold, then Condition 10 is satisfied for SCAN penalty with*

$$\varepsilon_1 = (CK\|\boldsymbol{\Omega}^*\|_\infty + C'K^{1.5})\sqrt{\frac{\log p + \log(e/\delta)}{n}}, \delta_1 = (18K^2+6K)\delta, \tag{S.14}$$

$$\varepsilon_2 = C''\sqrt{p}\sqrt{\frac{K^3\left(\log p + \log(e/\delta)\right)}{n}}, \delta_2 = (8K^2+2K)\delta, \tag{S.15}$$

for some absolute constant $C, C', C'' > 0$. Here $\|\boldsymbol{\Omega}^*\|_\infty$ is the overall max induced norm defined as $\|\boldsymbol{\Omega}^*\|_\infty = \max_{k\in[K]}\|\boldsymbol{\Omega}_k^*\|_\infty$.

In Lemma S.1, the number of clusters K is allowed to grow with the sample size n and the dimension p. The diverging rate of K controls the convergence probability at each iteration and is upper bounded to ensure that the statistical errors hold with a high probability tending to 1 with a proper choice of δ, e.g., $\delta = 1/p$.

Proof of Lemma S.1: For the first part of this proof, we focus on the upper bound of $\|\nabla Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\|_{\mathcal{P}^*}$. Recall that

$$\begin{aligned}\nabla Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) &= \begin{pmatrix} \nabla_{\boldsymbol{\Theta}_1^*} Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\Theta}_1^*} Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) \\ \vdots \\ \nabla_{\boldsymbol{\Theta}_K^*} Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\Theta}_K^*} Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) \end{pmatrix} \\ &= \begin{pmatrix} \nabla_{\boldsymbol{\mu}_1^*} Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\mu}_1^*} Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) \\ \mathrm{vec}\left\{\nabla_{\boldsymbol{\Omega}_1^*} Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\Omega}_1^*} Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\right\}^\top \\ \vdots \\ \nabla_{\boldsymbol{\mu}_K^*} Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\mu}_K^*} Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) \\ \mathrm{vec}\left\{\nabla_{\boldsymbol{\Omega}_K^*} Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\Omega}_K^*} Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\right\}^\top \end{pmatrix}. \end{aligned} \tag{S.16}$$

For simplicity, we define $h_{\mu_k}(\boldsymbol{\Theta}^*) = \nabla_{\boldsymbol{\mu}_k^*} Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\mu}_k^*} Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})$ and $h_{\boldsymbol{\Omega}_k^*}(\boldsymbol{\Theta}^*) = \nabla_{\boldsymbol{\Omega}_k^*} Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\Omega}_k^*} Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})$. Then from the definition of dual norm $\mathcal{P}^*$ (31), we can have

$$\begin{aligned}\|\nabla Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\|_{\mathcal{P}^*} &\leq M_1 \max_{k\in[K]} \underbrace{\|h_{\mu_k}(\boldsymbol{\Theta}^*)\|_\infty}_{I} \\ +M_2 \max_{k\in[K]} \underbrace{\left\|h_{\boldsymbol{\Omega}_k^*}(\boldsymbol{\Theta}^*)\right\|_{\max}}_{II} &+ M_3 \max_{i,j} \underbrace{\left\|\left[h_{\boldsymbol{\Omega}_k^*}(\boldsymbol{\Theta}^*)\right]_{ij}, \ldots, \left[h_{\boldsymbol{\Omega}_k^*}(\boldsymbol{\Theta}^*)\right]_{ij}\right\|_2}_{III},\end{aligned}$$

which are corresponding to the penalty on element-wise cluster means, element-wise precision matrices and group structures of multiple precision matrices, respectively.

Bounding Statistical Error for k-th Cluster Mean: Referring to the proof in Lemma 5,

$$h_{\mu_k^*}(\boldsymbol{\Theta}^*) = \frac{1}{n}\sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)\boldsymbol{\Omega}_k^*(\boldsymbol{x}_i - \boldsymbol{\mu}_k^*) - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\boldsymbol{\Omega}_k^*(\boldsymbol{X} - \boldsymbol{\mu}_k^*)\right].$$

Note that $\|\boldsymbol{\Omega}_k^*\|_\infty$ is a scalar. By using triangle inequality, we simplify I by two parts:

$$\begin{aligned} I &\leq \|\boldsymbol{\Omega}_k^*\|_\infty \left\|\frac{1}{n}\sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)(\boldsymbol{x}_i - \boldsymbol{\mu}_k^*) - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})(\boldsymbol{X} - \boldsymbol{\mu}_k^*)\right]\right\|_\infty \\ &\leq \|\boldsymbol{\Omega}_k^*\|_\infty \underbrace{\left\|\frac{1}{n}\sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)\boldsymbol{x}_i - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\boldsymbol{X}\right]\right\|_\infty}_{I_1} \\ &\quad + \|\boldsymbol{\Omega}_k^*\|_\infty \underbrace{\left\|\left(\frac{1}{n}\sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\right]\right)\boldsymbol{\mu}_k^*\right\|_\infty}_{I_2}. \end{aligned}$$

Bounding I_1: Denote

$$\zeta = \frac{1}{n}\sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)\boldsymbol{x}_i - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\boldsymbol{X}\right]$$

For $\zeta \in \mathbb{R}^p$, we consider the j-th coordinate ζ_j of ζ

$$\zeta_j = \frac{1}{n}\sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)x_{ij} - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})X_j\right]. \tag{S.17}$$

We introduce a set of missing data $\{c_i, i = 1, \ldots, n\}$, which are independent copies of random variable c. The pair $(\boldsymbol{x}_i, c_i)$ are the independent copy of $(\boldsymbol{X}, c)$. Here c takes a value from the set $\{1, \ldots, K\}$, where $c = k'$ indicates that $\boldsymbol{X}$ was generated by the k'-th mixture component. In another word, the conditional distribution of $\boldsymbol{X}$ is defined below:

$$\boldsymbol{X}|c = k' \sim \mathcal{N}(\boldsymbol{\mu}^*_{k'}, \boldsymbol{\Sigma}^*_{k'})$$

$$\mathbb{P}(c = k') = \pi_{k'},\ \sum_{k'}^{K} \pi_{k'} = 1.$$

This is the usual choice of missing data in EM approaches to mixture modeling. The quantity $(\boldsymbol{x}_i, c_i)$ is referred to as the completed data. Now by the assumption, the j-th coordinate x_{ij} of $\boldsymbol{x}_i$ can be rewritten as the form below:

$$x_{ij} = \sum_{k'=1}^{K} I\{c_i = k'\}(\mu^*_{k'j} + V_{k'j}),\ j \in [p] \tag{S.18}$$

where $\mu^*_{k'j}$ is the j-th coordinate of the true cluster mean $\boldsymbol{\mu}^*_{k'}$ and $V_{k'j} \sim \mathcal{N}(0, \boldsymbol{\Sigma}^*_{k'jj})$. Plugging (S.18) into (S.17), it suffices to bound ζ_j.

$$\begin{aligned}
|\zeta_j| &\leq \left|\frac{1}{n}\sum_{i=1}^{n}\sum_{k'=1}^{K} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\}\mu^*_{k'j} - \mathbb{E}\left[\sum_{k'=1}^{K} L_{\boldsymbol{\Theta},k}(\boldsymbol{X})I\{c = k'\}\mu^*_{k'j}\right]\right| \\
&+ \left|\frac{1}{n}\sum_{i=1}^{n}\sum_{k'=1}^{K} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\}V^*_{k'j} - \mathbb{E}\left[\sum_{k'=1}^{K} L_{\boldsymbol{\Theta},k}(\boldsymbol{X})I\{c = k'\}V^*_{k'j}\right]\right| \\
&\leq \sum_{k'=1}^{K} \underbrace{\left|\frac{1}{n}\sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\}\mu^*_{k'j} - \mathbb{E}\Big[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})I\{c = k'\}\mu^*_{k'j}\Big]\right|}_{\zeta_{j_1}} \\
&+ \sum_{k'=1}^{K} \underbrace{\left|\frac{1}{n}\sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\}V^*_{k'j} - \mathbb{E}\Big[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})I\{c = k'\}V^*_{k'j}\Big]\right|}_{\zeta_{j_2}}.
\end{aligned}$$

We bound ζ_{j_1} first. Based on the fact that $|L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\}\mu^*_{k'j}| \leq |\mu^*_{k'j}| \leq \|\boldsymbol{\mu}^*_{k'}\|_\infty$ almost surely it can show that $L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\}\mu^*_{k'j}$ is a sub-gaussian random variable with norm $\|\boldsymbol{\mu}^*_{k'}\|_\infty$. Following the Example 5.8 in Vershynin (2012), $\|L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\}\mu^*_{k'j}\|_{\psi_2} \leq \|\boldsymbol{\mu}^*_{k'}\|_\infty$ where $\|\cdot\|_{\psi_2}$ is defined as sub-Gaussian norm. According to supporting Lemma S.5

$$\left\|L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\}\mu^*_{k'j} - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})I\{c = k'\}\mu^*_{k'j}\right]\right\|_{\psi_2} \leq 2\left\|\boldsymbol{\mu}^*_{k'}\right\|_\infty.$$

The standard concentration result in supporting Lemma S.6 yields that for every $t \geq 0$ and some constant D_1,

$$\mathbb{P}\left(|\zeta_{j_1}| \geq t\right) \leq e\exp\left(-\frac{D_1 n t^2}{4\|\boldsymbol{\mu}^*_{k'}\|^2_\infty}\right),$$

which implies that, with probability at least $1 - \delta$,

$$|\zeta_{j_1}| \leq \sqrt{\frac{4}{D_1}}\|\boldsymbol{\mu}^*_{k'}\|_\infty\sqrt{\frac{\log(e/\delta)}{n}}. \tag{S.19}$$

Now we start to bound ζ_{j_2}. The fact that $L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\} \leq 1$ shows that it is a sub-gaussian random variable with norm $\|L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\}\|_{\psi_2} \leq 1$. $V^*_{k'j}$ is a Gaussian random variable so that it is also a sub-gaussian random variable with norm $\|V^*_{k'j}\|_{\psi_2} \leq (\|\boldsymbol{\Sigma}^*_{k'}\|_{\max})^{1/2}$. Then using the result in supporting Lemma S.4, $L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\}V^*_{k'j}$ is sub-exponential random variable. Moreover, there exists constant D_2 such that

$$\left\|L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\}V^*_{k'j}\right\|_{\psi_1} \leq D_2\Big(\|\boldsymbol{\Sigma}^*_{k'}\|_{\max}\Big)^{1/2}.$$

Supporting lemma S.5 implies

$$\left\|L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i = k'\}V^*_{k'j} - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})I\{c = k'\}V^*_{k'j}\right]\right\|_{\psi_1} \leq 2D_2\Big(\|\boldsymbol{\Sigma}^*_{k'}\|_{\max}\Big)^{1/2}.$$

Following the concentration inequality of sub-exponential random variables in supporting Lemma S.7, there exists some constant D_3 such that the following inequality

$$\mathbb{P}\Big(|\zeta_{j_2}| \geq t\Big) \leq 2\exp\left(-D_3\min\left\{\frac{t^2}{4D_2^2\|\boldsymbol{\Sigma}^*_{k'}\|_{\max}}, \frac{t}{2D_2(\|\boldsymbol{\Sigma}^*_{k'}\|_{\max})^{1/2}}\right\}n\right),$$

holds every $t \geq 0$. For sufficient small t, it reduces to

$$\mathbb{P}\Big(|\zeta_{j_2}| \geq t\Big) \leq 2\exp\left(-D_3\frac{nt^2}{4D_2\|\boldsymbol{\Sigma}^*_{k'}\|_{\max}}\right),$$

which implies that

$$|\zeta_{j_2}| \leq \sqrt{\frac{4D_2}{D_3}}(\|\boldsymbol{\Sigma}^*_{k'}\|_{\max})^{1/2}\sqrt{\frac{\log(2/\delta)}{n}}, \tag{S.20}$$

with probability at least $1 - \delta$.

Adding (S.19) and (S.20) together, we have

$$\begin{aligned}
|\zeta_{j_1}| + |\zeta_{j_2}| &\leq \sqrt{\frac{4}{D_1}}\|\boldsymbol{\mu}^*_{k'}\|_\infty\sqrt{\frac{\log(e/\delta)}{n}} + \sqrt{\frac{4D_2}{D_3}}(\|\boldsymbol{\Sigma}^*_{k'}\|_{\max})^{1/2}\sqrt{\frac{\log(2/\delta)}{n}} \\
&\leq \sqrt{\frac{4}{D}}\left(\|\boldsymbol{\mu}^*_{k'}\|_\infty + (\|\boldsymbol{\Sigma}^*_{k'}\|_{\max})^{1/2}\right)\sqrt{\frac{\log(e/\delta)}{n}},
\end{aligned}$$

by taking $D = \min\{D_1, D_3/D_2\}$, with at least probability $1 - 2\delta$. Therefore, it's sufficient to bound $|\zeta_j|$ by

$$|\zeta_j| \leq \sqrt{\frac{4}{D}}\sum_{k'=1}^{K}\left(\|\boldsymbol{\mu}^*_{k'}\|_\infty + (\|\boldsymbol{\Sigma}^*_{k'}\|_{\max})^{1/2}\right)\sqrt{\frac{\log(e/\delta)}{n}},$$

with at least probability $1-2K\delta$. Taking the union bound over p coordinates, we obtain

$$I_1 \leq \sqrt{\frac{4}{D}} \sum_{k'=1}^{K} \left(\|\boldsymbol{\mu}^*_{k'}\|_\infty + (\|\boldsymbol{\Sigma}^*_{k'}\|_{\max})^{1/2} \right) \sqrt{\frac{\log(e/\delta) + \log p}{n}}, \tag{S.21}$$

with at least probability $1-2K\delta$.

Bounding I_2: Recall that

$$I_2 = \left\| \left(\frac{1}{n} \sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) \right] \right) \boldsymbol{\mu}^*_k \right\|_\infty \leq \left| \frac{1}{n} \sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) \right] \right| \|\boldsymbol{\mu}^*_k\|_\infty .$$

$\{L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) | i = 1, \dots n\}$ are bounded independent random variables within interval between 0 and 1. Then it follows Hoeffding's inequality in supporting Lemma S.8 that

$$\mathbb{P}\left(\left| \frac{1}{n} \sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) - \mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})] \right| \leq t \right) \geq 1 - 2e^{-2nt^2},$$

which implies

$$\left| \frac{1}{n} \sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) - \mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})] \right| \leq \sqrt{\frac{1}{2} \log \frac{2}{\delta}} \cdot \sqrt{\frac{1}{n}}, \tag{S.22}$$

with probability at least $1-\delta$. Combining with the reminder term $\|\boldsymbol{\mu}^*_k\|$,

$$I_2 \leq \sqrt{\frac{1}{2} \log \frac{2}{\delta}} \cdot \sqrt{\frac{1}{n}} \|\boldsymbol{\mu}^*_k\|_\infty. \tag{S.23}$$

Note that the bound in (S.21) is $O_P((\log p/n)^{1/2})$ while the bound in (S.23) is $O_P((1/n)^{1/2})$, there exists some constant D_4 such that $I_2 \leq D_4 I_1$. Consequently, we conclude that I is upper bounded by

$$I \leq (1+D_4)\|\boldsymbol{\Omega}^*_k\|_\infty \sqrt{\frac{4}{D}} \sum_{k'=1}^{K} \left(\|\boldsymbol{\mu}^*_{k'}\|_\infty + (\|\boldsymbol{\Sigma}^*_{k'}\|_{\max})^{1/2} \right) \sqrt{\frac{\log(e/\delta) + \log p}{n}},$$

with probability at least $1-(2K+1)\delta$. For simplicity, let

$$\varphi_K = \sum_{k'=1}^{K} \left(\|\boldsymbol{\mu}^*_{k'}\|_\infty + (\|\boldsymbol{\Sigma}^*_{k'}\|_{\max})^{1/2} \right), \; C_1 = \sqrt{\frac{4(1+D_4)^2}{D}}. \tag{S.24}$$

Applying union bound,

$$\max_{k \in [K]} I \leq C_1 \|\boldsymbol{\Omega}^*\|_\infty \varphi_K \sqrt{\frac{\log p + \log(e/\delta)}{n}}, \tag{S.25}$$

with probability at least $1-K(2K+1)\delta$.

Bounding Statistical Error for k-th Precision Matrix: Referring to the proof in Lemma 5,

$$\begin{aligned} h_{\boldsymbol{\Omega}^*_k}(\boldsymbol{\Theta}^*) &= \frac{1}{2n} \sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) \boldsymbol{\Sigma}^*_k - \frac{1}{2n} \sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)(\boldsymbol{x}_i - \boldsymbol{\mu}^*_k)(\boldsymbol{x}_i - \boldsymbol{\mu}^*_k)^\top \\ &- \frac{1}{2}\mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) \right] \boldsymbol{\Sigma}^*_k + \frac{1}{2}\mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})(\boldsymbol{X} - \boldsymbol{\mu}^*_k)(\boldsymbol{X} - \boldsymbol{\mu}^*_k)^\top \right]. \end{aligned}$$

Now we get an explicit from for $h_{\boldsymbol{\Omega}^*_k}(\boldsymbol{\Theta}^*)$. Then II is decomposed as below:

$$\begin{aligned} II \leq & \underbrace{\left\| \frac{1}{2} \left(\frac{1}{n} \sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) \boldsymbol{\Sigma}^*_k - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) \boldsymbol{\Sigma}^*_k \right] \right) \right\|_{\max}}_{II_1} \\ + & \underbrace{\left\| \frac{1}{2} \left(\frac{1}{n} \sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)(\boldsymbol{x}_i - \boldsymbol{\mu}^*_k)(\boldsymbol{x}_i - \boldsymbol{\mu}^*_k)^\top - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})(\boldsymbol{X} - \boldsymbol{\mu}^*_k)(\boldsymbol{X} - \boldsymbol{\mu}^*_k)^\top \right] \right) \right\|_{\max}}_{II_2}. \end{aligned}$$

The first term is easy to deal with: since $\frac{1}{n}\sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) \right]$ is scalar by the definition of $L_{\boldsymbol{\Theta},k}(\boldsymbol{X})$ we can pull it out of the norm. Combining with the result in (S.22), the first term is upper bounded by

$$II_1 \leq \|\boldsymbol{\Sigma}^*_k\|_{\max} \sqrt{\frac{1}{2} \log \frac{2}{\delta}} \cdot \sqrt{\frac{1}{n}}, \tag{S.26}$$

with probability at least $1-\delta$.

For the second term II_2, it can be decomposed as four following terms:

$$\begin{aligned} II_2 \leq & \underbrace{\left\| \frac{1}{2} \left(\frac{1}{n} \sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) \boldsymbol{x}_i \boldsymbol{x}_i^\top - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) \boldsymbol{X} \boldsymbol{X}^\top \right] \right) \right\|_{\max}}_{II_{21}} \\ + & \underbrace{\left\| \frac{1}{2} \left(\frac{1}{n} \sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) \boldsymbol{x}_i \boldsymbol{\mu}^{*T}_k - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) \boldsymbol{X} \boldsymbol{\mu}^{*\top}_k \right] \right) \right\|_{\max}}_{II_{22}} \\ + & \underbrace{\left\| \frac{1}{2} \left(\frac{1}{n} \sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) \boldsymbol{\mu}^*_k \boldsymbol{x}_i^\top - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) \boldsymbol{\mu}^*_k \boldsymbol{X}^\top \right] \right) \right\|_{\max}}_{II_{23}} \\ + & \underbrace{\left\| \frac{1}{2} \left(\frac{1}{n} \sum_{i=1}^{n} L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) \boldsymbol{\mu}^*_k \boldsymbol{\mu}^{*\top}_k - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X}) \boldsymbol{\mu}^*_k \boldsymbol{\mu}^{*\top}_k \right] \right) \right\|_{\max}}_{II_{24}}. \end{aligned}$$

For the bound of II_{22} and II_{23}, we can just simply pull the $\boldsymbol{\mu}_k^*$ out, which implies

$$\begin{aligned} II_{22} &= \left\| \frac{1}{2}\left(\frac{1}{n}\sum_{i=1}^n L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)\boldsymbol{x}_i - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\boldsymbol{X}\right]\right)\boldsymbol{\mu}_k^{*\top} \right\|_{\max} \\ &\leq \left\| \frac{1}{2}\left(\frac{1}{n}\sum_{i=1}^n L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)\boldsymbol{x}_i - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\boldsymbol{X}\right]\right)\right\|_{\infty} \|\boldsymbol{\mu}_k^*\|_{\infty} \\ &\overset{(a)}{\leq} \sqrt{\frac{4}{D}}\|\boldsymbol{\mu}_k^*\|_{\infty}\varphi_K\sqrt{\frac{\log(e/\delta)+\log p}{n}}, \end{aligned} \tag{S.27}$$

with probability at least $1-2K\delta$, where (a) follows (S.21).

Next we turn to bound II_{21}. Expand $\boldsymbol{x}_i\boldsymbol{x}_i^\top$ to matrix form for convenient use

$$\boldsymbol{x}_i\boldsymbol{x}_i^\top = \begin{pmatrix} x_{i1}x_{i1} & \dots & x_{i1}x_{ip} \\ \vdots & \ddots & \vdots \\ x_{ip}x_{i1} & \dots & x_{ip}x_{ip} \end{pmatrix}.$$

Since we require a matrix max norm here, it suffices to bound II_{21} individually, namely

$$\zeta_{jj'} = \frac{1}{2}\left(\frac{1}{n}\sum_{i=1}^n L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)x_{ij}x_{ij'} - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})X_jX_{j'}\right]\right).$$

Recall in (S.18) the j-th coordinate of $\boldsymbol{x}_i$ could be expressed as

$$x_{ij} = \sum_{k'=1}^K I\{c_i = k'\}(\mu_{k'j}^* + V_{k'j}).$$

By straightforward algebra,

$$\begin{aligned} x_{ij}x_{ij'} &= \sum_{k'=1}^K I\{c_i=k'\}(\mu_{k'j}^*+V_{k'j})\cdot\sum_{k'=1}^K I\{c_i=k'\}(\mu_{k'j'}^*+V_{k'j'}) \\ &\overset{(a)}{=} \sum_{k'=1}^K I\{c_i=k'\}^2(\mu_{k'j}^*+V_{k'j})(\mu_{k'j'}^*+V_{k'j'}) \\ &= \sum_{k'=1}^K I\{c_i=k'\}\left(\mu_{k'j}^*\mu_{k'j'}^* + \mu_{k'j}^*V_{k'j'} + V_{k'j}\mu_{k'j'}^* + V_{k'j}V_{k'j'}\right), \end{aligned}$$

where (a) follows the fact that $I\{c_i=k\}I\{c_i=k'\}=0$ for any $k\neq k'$. Consequently, we divide $\zeta_{jj'}$ into four parts:

$$\zeta_{jj'} = \frac{1}{2}\sum_{k'=1}^K\left(\zeta_{jj'}(\mu_{k'j}^*\mu_{k'j'}^*) + \zeta_{jj'}(\mu_{k'j}^*V_{k'j'}) + \zeta_{jj'}(V_{k'j}\mu_{k'j'}^*) + \zeta_{jj'}(V_{k'j}V_{k'j'})\right),$$

where

$$\begin{aligned} \zeta_{jj'}(\mu_{k'j}^*\mu_{k'j'}^*) &= \frac{1}{n}\sum_{i=1}^n L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i=k'\}\mu_{k'j}^*\mu_{k'j'}^* \\ &\quad -\mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})I\{c=k'\}\mu_{k'j}^*\mu_{k'j'}^*\right]. \end{aligned}$$

Taking the supreme over set $[p]$ in terms of p,p',

$$\begin{aligned} \sup_{j,j'\in[p]}|\zeta_{jj'}| &\leq \sum_{k'=1}^K \underbrace{\left(\sup_{j,j'\in[p]}|\zeta_{jj'}(\mu_{k'j}^*\mu_{k'j'}^*)|\right)}_{(i)} + \sum_{k'=1}^K \underbrace{\left(\sup_{j,j'\in[p]}|\zeta_{jj'}(\mu_{k'j}^*V_{k'j'})|\right)}_{(ii)} \\ &\quad + \sum_{k'=1}^K \underbrace{\left(\sup_{j,j'\in[p]}|\zeta_{jj'}(V_{k'j}\mu_{k'j'}^*)|\right)}_{(iii)} + \sum_{k'=1}^K \underbrace{\left(\sup_{j,j'\in[p]}|\zeta_{jj'}(V_{k'j}V_{k'j'})|\right)}_{(iv)}. \end{aligned}$$

We will bound (i), (ii), (iii) and (iv) sequentially. $L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i=k'\}\mu_{k'j}^*\mu_{k'j'}^*$ is a sub-gaussian random variable with

$$\|L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i=k'\}\mu_{k'j}^*\mu_{k'j'}^*\|_{\psi_2} \leq \|\boldsymbol{\mu}_{k'}^*\|_\infty^2.$$

According to supporting Lemma S.5,

$$\left\|L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i=k'\}\mu_{k'j}^*\mu_{k'j'}^* - \mathbb{E}[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})I\{c=k'\}\mu_{k'j}^*\mu_{k'j'}^*]\right\|_{\psi_2} \leq 2\|\boldsymbol{\mu}_{k'}^*\|_\infty^2.$$

Applying concentration inequality in supporting Lemma S.6 yields that

$$\mathbb{P}\left(|\zeta_{jj'}(\mu_{k'j}^*\mu_{k'j'}^*)| \leq t\right) \geq 1 - e\exp\left(-\frac{D_4nt^2}{4\|\boldsymbol{\mu}_{k'}^*\|_\infty^4}\right), \tag{S.28}$$

for any $t>0$ and some constant D_4. After properly choosing t,

$$(i) \leq \sqrt{\frac{4}{D_4}}\|\boldsymbol{\mu}_{k'}^*\|_\infty^2\sqrt{\frac{\log p+\log(e/\delta)}{n}}, \tag{S.29}$$

with probability at least $1-\delta$. Note that both $L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i=k'\}\mu_{k'j}^*V_{k'j'}$ and $L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i=k'\}V_{k'j'}\mu_{k'j}^*$ are sub-exponential random variables with norm $\|\boldsymbol{\mu}_{k'}^*\|_\infty(\|\boldsymbol{\Sigma}_{k'}^*\|_{\max})^{1/2}$. Similar to the step in (S.20),

$$\left|\zeta_{jj'}(\mu_{k'j}^*V_{k'j'})\right| \leq \sqrt{\frac{4}{D_5}}\left(\|\boldsymbol{\mu}_{k'}^*\|_\infty(\|\boldsymbol{\Sigma}_{k'}^*\|_{\max})^{1/2}\right)\sqrt{\frac{\log(2/\delta)}{n}},$$

with at least probability $1-\delta$. Taking the union bound, it is shown that

$$(ii),(iii) \leq \sqrt{\frac{4}{D_5}}\left(\|\boldsymbol{\mu}_{k'}^*\|_\infty(\|\boldsymbol{\Sigma}_{k'}^*\|_{\max})^{1/2}\right)\sqrt{\frac{\log p+\log(2/\delta)}{n}}, \tag{S.30}$$

with probability at least $1-\delta$ for sufficient large n.

Lastly, the fact that both $L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i=k'\}V_{k'j}$ and $V_{k'j'}$ are sub-gaussian random variables implies $L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)I\{c_i=k'\}V_{k'j}V_{k'j'}$ is sub-exponential random variable with parameter $\|\boldsymbol{\Sigma}_{k'}^*\|_{\max}$. Applying concentration result, there exists some constant D_6 such that the following inequality

$$\mathbb{P}\left(|\zeta_{jj'}(V_{k'j}V_{k'j'})| \geq t\right) \leq 2\exp\left(-\frac{D_6nt^2}{4\|\boldsymbol{\Sigma}_{k'}^*\|_{\max}^2}\right),$$

holds for sufficiently small $t > 0$. Therefore,

$$\mathbb{P}\left(\sup_{j,j'\in[p]}|\zeta_{jj'}(V_{k'j}V_{k'j'})| \geq t\right) \leq 2p^2\exp\left(-\frac{D_6nt^2}{4\|\boldsymbol{\Sigma}^*_{k'}\|^2_{\max}}\right).$$

When n is sufficiently large, with probability at least $1-\delta$

$$(iv) \leq \sqrt{\frac{4}{D_6}}\|\boldsymbol{\Sigma}^*_{k'}\|_{\max}\sqrt{\frac{2\log p+\log(2/\delta)}{n}}. \tag{S.31}$$

Putting (S.29), (S.30) and (S.31) together and after some adjustments, II_{21} is upper bounded by

$$II_{21} \leq \sqrt{\frac{1}{D_7}}\sum_{k'=1}^{K}\left(\|\boldsymbol{\mu}^*_{k'}\|_\infty + (\|\boldsymbol{\Sigma}^*_{k'}\|_{\max})^{1/2}\right)^2\sqrt{\frac{2\log p+\log(e/\delta)}{n}},$$

with probability at least $1-4K\delta$. $D_7 = \min(D_4, D_5, D_6)$. For simplicity, we denote

$$\varphi'_K = \sum_{k'=1}^{K}\left(\|\boldsymbol{\mu}^*_{k'}\|_\infty + (\|\boldsymbol{\Sigma}^*_{k'}\|_{\max})^{1/2}\right)^2.$$

Therefore,

$$II_{21} \leq \sqrt{\frac{2}{D_7}}\varphi'_K\sqrt{\frac{\log p+\log(e/\delta)}{n}}, \tag{S.32}$$

with probability at least $1-4K\delta$.

For the last, it remains to bound II_{24}. Recall that

$$\begin{aligned} II_{24} &= \left\|\frac{1}{2}\left(\frac{1}{n}\sum_{i=1}^{n}L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i)\boldsymbol{\mu}^*_k\boldsymbol{\mu}^{*\top}_k - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\boldsymbol{\mu}^*_k\boldsymbol{\mu}^{*\top}_k\right]\right)\right\|_{\max} \\ &\leq \left|\frac{1}{2}\left(\frac{1}{n}\sum_{i=1}^{n}L_{\boldsymbol{\Theta},k}(\boldsymbol{x}_i) - \mathbb{E}\left[L_{\boldsymbol{\Theta},k}(\boldsymbol{X})\right]\right)\right|\|\boldsymbol{\mu}^*_k\boldsymbol{\mu}^{*\top}_k\|_{\max}. \end{aligned}$$

Applying the result in (S.22), we have

$$II_{24} \leq \|\boldsymbol{\mu}^*_k\boldsymbol{\mu}^{*\top}_k\|_{\max}\sqrt{\frac{1}{2}\log\frac{2}{\delta}}\cdot\sqrt{\frac{1}{n}}, \tag{S.33}$$

with probability at least $1-\delta$.

Putting (S.27), (S.32) and (S.33) together, now we can have a upper bound for II_2.

$$II_2 \leq \sqrt{\frac{1}{D_7}}\left(2\|\boldsymbol{\mu}^*_k\|_\infty\varphi_K + \varphi'_K\right)\sqrt{\frac{\log p+\log(e/\delta)}{n}}, \tag{S.34}$$

for $D_7 < D/2$ with at least probability $1-(8K+1)\delta$. The upper bound in (S.26) is of order $O_P(n^{-1/2})$ while the upper bound in (S.34) is of order $O_P((\log p/n)^{1/2})$. Thus there exists

some constant D_8 such that $II_1 \leq D_8II_2$. Let $C_2 = ((1+D_8)^2/D_7)^{1/2}$. Applying union bound,

$$\max_{k\in[K]}II \leq C_2\left(2\|\boldsymbol{\mu}^*\|_\infty\varphi_K + \varphi'_K\right)\sqrt{\frac{\log p+\log(e/\delta)}{n}}, \tag{S.35}$$

with at least probability $1-K(8K+2)\delta$.

Bound the Group Structure Part of Precision Matrix:

Recall that

$$\begin{aligned} III &= \max_{i,j}\Big\|\left[\nabla_{\boldsymbol{\Omega}^*_1}Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\Omega}^*_1}Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\right]_{ij}, \\ &\qquad \ldots, \left[\nabla_{\boldsymbol{\Omega}^*_K}Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\Omega}^*_K}Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\right]_{ij}\Big\|_2 \\ &\leq \max_{i,j}\sqrt{K}\Big\|\left[\nabla_{\boldsymbol{\Omega}^*_1}Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\Omega}^*_1}Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\right]_{ij}, \\ &\qquad \ldots, \left[\nabla_{\boldsymbol{\Omega}^*_K}Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\Omega}^*_K}Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\right]_{ij}\Big\|_\infty \\ &\leq \sqrt{K}\max_{k\in[K]}\Big\|\Big[\nabla_{\boldsymbol{\Omega}^*_k}Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla_{\boldsymbol{\Omega}^*_k}Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\Big]\Big\|_{\max}. \end{aligned}$$

According to the result in (S.35) and applying union bound over $[K]$,

$$\mathbb{P}\left(III \geq C_2\sqrt{K}\left(2\|\boldsymbol{\mu}^*_k\|_\infty\varphi_K + \varphi'_K\right)\sqrt{\frac{\log p+\log(e/\delta)}{n}}\right) \leq K(8K+2)\delta.$$

Thus, III is upper bounded by

$$III \leq C_2\sqrt{K}\left(2\|\boldsymbol{\mu}^*\|_\infty\varphi_K + \varphi'_K\right)\sqrt{\frac{\log p+\log(e/\delta)}{n}}, \tag{S.36}$$

with at least probability $1-K(8K+2)\delta$.

Finally, putting the upper bound (S.25), (S.35) and (S.36) together, we have a upper bound for the following statistical error

$$\begin{aligned} &\left\|\nabla Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\right\|_{\mathcal{P}^*} \\ \leq\ & C\left((\|\boldsymbol{\Omega}^*\|_\infty + (\sqrt{K}+1)\|\boldsymbol{\mu}^*\|_\infty)\varphi_K + 2(\sqrt{K}+1)\varphi'_K\right)\sqrt{\frac{\log p+\log(e/\delta)}{n}}, \end{aligned}$$

with probability at least $1-(18K+6)\delta$, where $C = \max(M_1C_1, M_2C_2, M_3C_3)$. Under regularity Condition 16, $\varphi_K \leq (c_1+c_2^{1/2})K$, $\varphi'_K \leq (c_1+c_2^{1/2})^2K$. Let $C = C(c_1+c_2^{1/2})$ and $C' = c_1^2 + c_1c_2^{1/2} + 2(c_1+c_2^{1/2})^2$. Consequently, the upper bound for statistical error can be written as:

$$\|\nabla Q_n(\boldsymbol{\Theta}^*|\boldsymbol{\Theta}) - \nabla Q(\boldsymbol{\Theta}^*|\boldsymbol{\Theta})\|_{\mathcal{P}^*} \leq \left(CK\|\boldsymbol{\Omega}^*\|_\infty + C'K^{1.5}\right)\sqrt{\frac{\log p+\log(e/\delta)}{n}},$$

with probability at least $1-(18K+6)\delta$. ■

For the second part of Lemma S.1, we are aiming to bound the statistical error arising from the estimation for diagonal term. The definition of $\mathcal{G}$ in (14) implies that $[\nabla Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}) - \nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta})]_{\mathcal{G}}$ is a Kp-dimensional vector. Following the same derivation before, it suffices to have:

$$\begin{aligned} & \left\|[\nabla Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}) - \nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta})]_{\mathcal{G}}\right\|_2 \\ \leq & \sqrt{Kp}\left\|[\nabla Q_n(\mathbf{\Theta}^*|\mathbf{\Theta}) - \nabla Q(\mathbf{\Theta}^*|\mathbf{\Theta})]_{\mathcal{G}}\right\|_{\max} \\ \overset{(a)}{\leq} & \sqrt{Kp}\cdot C_2\left(2\|\boldsymbol{\mu}^*\|_\infty\varphi_K + \varphi'_K\right)\sqrt{\frac{\log p + \log(e/\delta)}{n}} \\ = & \sqrt{K}\cdot C_2\left(2\|\boldsymbol{\mu}^*\|_\infty\varphi_K + \varphi'_K\right)\sqrt{\frac{p(\log p + \log(e/\delta))}{n}}, \end{aligned}$$

with probability at least $1-(8K^2+2K)\delta$ where (a) comes from (S.36). Now combining two parts together, we end the proof of Lemma S.1. ■

S.V Proof of Lemma 22

For any $\mathbf{\Theta} \in \mathcal{M}$,

$$\begin{aligned} \frac{\mathcal{P}(\mathbf{\Theta})}{\|\mathbf{\Theta}\|_2} &= \frac{\mathcal{P}_1(\mathbf{\Theta})}{\|\mathbf{\Theta}\|_2} + \frac{\mathcal{P}_2(\mathbf{\Theta})}{\|\mathbf{\Theta}\|_2} + \frac{\mathcal{P}_3(\mathbf{\Theta})}{\|\mathbf{\Theta}\|_2} \\ &\leq \frac{M_1\sum_{k=1}^K\sum_{j=1}^p|\mu_{kj}|}{\sqrt{\sum_{k=1}^K\|\boldsymbol{\mu}_k\|_2^2}} + \frac{M_2\sum_{k=1}^K\sum_{i\neq j}|\omega_{kij}|}{\sqrt{\sum_{k=1}^K\|\mathbf{\Omega}_k\|_F^2}} + \frac{\sum_{i\neq j}M_3(\sum_{k=1}^K\omega_{kij}^2)^{1/2}}{\sqrt{\sum_{k=1}^K\|\mathbf{\Omega}_k\|_F^2}}. \end{aligned}$$

By Cauchy's inequality, we can have

$$\frac{\mathcal{P}(\mathbf{\Theta}_{\mathcal{M}})}{\|\mathbf{\Theta}_{\mathcal{M}}\|_2} \leq M_1\sqrt{Kd} + M_2\sqrt{Ks} + M_3\sqrt{s}.$$

Recall that d and s are the sparse parameter for a single cluster mean and precision matrix, respectively. This ends the proof of Lemma 22. ■

S.VI Proof of Lemma 24

First we consider each $\mathbf{\Theta}_k = \{\mu_k, \mathbf{\Omega}_k\}$ individually. That means we prove the following part first:

$$Q_n(\mathbf{\Theta}_k^{(1)}|\mathbf{\Theta}^{(t-1)}) - Q_n(\mathbf{\Theta}_k^{(2)}|\mathbf{\Theta}^{(t-1)}) - \left\langle\nabla_{\mathbf{\Theta}_k}Q_n(\mathbf{\Theta}_k^{(2)}|\mathbf{\Theta}^{(t-1)}), \mathbf{\Theta}_k^{(1)} - \mathbf{\Theta}_k^{(2)}\right\rangle \leq 0,$$

where $Q_n(\mathbf{\Theta}_k|\mathbf{\Theta})$ means we set $\mathbf{\Theta}_i$ $i \neq k$ to zero.

Following the same technique we use in the proof of Lemma (9), the decomposition can be made as below:

$$Q_n(\mathbf{\Theta}_k^{(1)}|\mathbf{\Theta}^{(t-1)}) - Q_n(\mathbf{\Theta}_k^{(2)}|\mathbf{\Theta}^{(t-1)}) - \left\langle\nabla_{\mathbf{\Theta}_k}Q_n(\mathbf{\Theta}_k^{(2)}|\mathbf{\Theta}^{(t-1)}), \mathbf{\Theta}_k^{(1)} - \mathbf{\Theta}_k^{(2)}\right\rangle = I + II,$$

where

$$\begin{aligned} I &= \frac{1}{n}\sum_{i=1}^n\left[L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\left\{h(\boldsymbol{\mu}_k^{(2)}, \mathbf{\Omega}_k^{(2)}) - h(\boldsymbol{\mu}_k^{(1)}, \mathbf{\Omega}_k^{(2)})\right\}\right] \\ &-(\boldsymbol{\mu}_k^{(1)} - \boldsymbol{\mu}_k^{(2)})^\top\nabla_{\boldsymbol{\mu}_k}Q_n(\mathbf{\Theta}_k^{(2)}|\mathbf{\Theta}^{(t-1)}), \\ II &= \frac{1}{n}\sum_{i=1}^n\big[L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\{\frac{1}{2}\log\det(\mathbf{\Omega}_k^{(1)}) - \frac{1}{2}\log\det(\mathbf{\Omega}_k^{(2)}) \\ &+h(\boldsymbol{\mu}_k^{(1)}, \mathbf{\Omega}_k^{(2)}) - h(\boldsymbol{\mu}_k^{(1)}, \mathbf{\Omega}_k^{(1)})\}\big] - [\mathrm{vec}(\mathbf{\Omega}_k^{(1)} - \mathbf{\Omega}_k^{(2)})]^\top\nabla_{\mathbf{\Omega}_k}Q_n(\mathbf{\Theta}_k^{(2)}|\mathbf{\Theta}^{(t-1)}). \end{aligned}$$

Bounding I: By a little algebra, we can show that

$$I = -\frac{1}{2n}\sum_{i=1}^n L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)(\boldsymbol{\mu}_k^{(1)} - \boldsymbol{\mu}_k^{(2)})^\top\mathbf{\Omega}_k^{(2)}(\boldsymbol{\mu}_k^{(1)} - \boldsymbol{\mu}_k^{(2)}).$$

Plugging in $(\mathbf{\Theta}^{(t)}, t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*)$, we have

$$I = -\frac{(1-t^*)^2}{2n}\sum_{i=1}^n L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)(\boldsymbol{\mu}_k^{(t)} - \boldsymbol{\mu}_k^*)^\top\left(t^*\mathbf{\Omega}_k^{(t)} + (1-t^*)\mathbf{\Omega}_k^*\right)(\boldsymbol{\mu}_k^{(t)} - \boldsymbol{\mu}_k^*).$$

Recall that $\mathbf{\Theta}^{(t)}$ is the solution of the optimization problem (35). The algorithm guarantees that $\mathbf{\Omega}_k^{(t)}$ is positive definite. Thus, from the positive definiteness of $\mathbf{\Omega}_k^{(t)}$ and $\mathbf{\Omega}_k^*$, it is sufficient to show that

$$I \leq 0 \quad \text{holds a.s..} \tag{S.37}$$

When plugging in $(\mathbf{\Theta}^*, t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*)$, we have the same conclusion.

Bounding II: Define

$$g(\mathbf{\Omega}_k^{(2)}) := \frac{1}{n}\sum_{i=1}^n\left[L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\left\{\frac{1}{2}\log\det(\mathbf{\Omega}_k^{(2)}) - h\left(\boldsymbol{\mu}_k^{(1)}, \mathbf{\Omega}_k^{(2)}\right)\right\}\right].$$

We rewrite II as

$$g(\mathbf{\Omega}_k^{(1)}) - g(\mathbf{\Omega}_k^{(2)}) - \left\langle\mathrm{vec}\left(\nabla g(\mathbf{\Omega}_k^{(2)})\right), \mathrm{vec}\left(\mathbf{\Omega}_k^{(1)} - \mathbf{\Omega}_k^{(2)}\right)\right\rangle.$$

According to Taylor expansion, we can expand $g(\mathbf{\Omega}_k^{(1)})$ around $\mathbf{\Omega}_k^{(2)}$ and obtain

$$\begin{aligned} g(\mathbf{\Omega}_k^{(1)}) &= g(\mathbf{\Omega}_k^{(2)}) + \left\langle\mathrm{vec}(\nabla g(\mathbf{\Omega}_k^{(2)}), \mathrm{vec}(\mathbf{\Omega}_k^{(1)} - \mathbf{\Omega}_k^{(2)})\right\rangle \\ &+\frac{1}{2}\left[\mathrm{vec}(\mathbf{\Omega}_k^{(1)} - \mathbf{\Omega}_k^{(2)})\right]^\top\nabla^2 g(\mathbf{Z})\left[\mathrm{vec}(\mathbf{\Omega}_k^{(1)} - \mathbf{\Omega}_k^{(2)})\right], \end{aligned}$$

where $\mathbf{Z} = t\mathbf{\Omega}_k^{(1)} + (1-t)\mathbf{\Omega}_k^{(2)}$ with $t \in [0,1]$. So an equivalent expression for II is given below:

$$II = \frac{1}{2}\left[\mathrm{vec}(\mathbf{\Omega}_k^{(1)} - \mathbf{\Omega}_k^{(2)})\right]^\top\nabla^2 g(\mathbf{Z})\left[\mathrm{vec}(\mathbf{\Omega}_k^{(1)} - \mathbf{\Omega}_k^{(2)})\right].$$

By the definition of function g we construct, the negative Hessian matrix of function g is

$$-\nabla^2 g(\mathbf{Z}) = \frac{1}{2n}\sum_{i=1}^{n} L_{\mathbf{\Theta},k}(\boldsymbol{x}_i)\mathbf{Z}^{-1}\otimes\mathbf{Z}^{-1}.$$

According to the analysis in the proof of Lemma 9, $\sigma_{\min}\left(\mathbf{Z}^{-1}\otimes\mathbf{Z}^{-1}\right) = \left[\sigma_{\min}(\mathbf{Z}^{-1})\right]^2 \geq 0$. Therefore, $\nabla^2 g(\mathbf{Z})$ is a negative semi-definite matrix, which implies that $II \leq 0$ holds a.s. for any pair of points $(\mathbf{\Theta}^{(1)}, \mathbf{\Theta}^{(2)})$. Incorporating with the fact that $I < 0$, it implies that

$$Q_n(\mathbf{\Theta}_k^{(1)}|\mathbf{\Theta}^{(t-1)}) - Q_n(\mathbf{\Theta}_k^{(2)}|\mathbf{\Theta}^{(t-1)}) - \langle \nabla_{\mathbf{\Theta}_k} Q_n(\mathbf{\Theta}_k^{(2)}|\mathbf{\Theta}^{(t-1)}), \mathbf{\Theta}_k^{(1)} - \mathbf{\Theta}_k^{(2)}\rangle \leq 0,$$

holds a.s. for pair points $(\mathbf{\Theta}^{(t)}, t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*)$, $(\mathbf{\Theta}^{(t)}, t^*\mathbf{\Theta}^{(t)} + (1-t^*)\mathbf{\Theta}^*)$. After doing the summation from 1 to K, we finish the proof of Lemma 24. ■

S.VII Variable Selection Consistency

Theorem S.2 *Denote the final precision matrix estimator as $\widetilde{\mathbf{\Omega}}_k$ and the set of its nonzero off-diagonal elements as $\widetilde{\mathcal{V}}_k$. Under minimal signal condition, we have, with probability tending to 1, $\widetilde{\mathcal{V}}_k = \mathcal{V}_k$ for any $k = 1, \ldots, K$.*

Proof: We prove it in two steps. In Step 1, we show that $\widetilde{\mathcal{V}_k} \supset \mathcal{V}_k$, and in Step 2, we show that $\widetilde{\mathcal{V}_k} \subset \mathcal{V}_k$, both with high probability.

Step 1: In order to prove $\widetilde{\mathcal{V}_k} \supset \mathcal{V}_k$, it is sufficient to show that for any $(i,j) \in \mathcal{V}_k$ with any $k = 1, \ldots, K$, $\widetilde{\omega}_{kij} \neq 0$. Note that

$$|\omega_{kij}^{(T)}| \geq |\omega_{kij}^*| - |\omega_{kij}^{(T)} - \omega_{kij}^*| \geq |\omega_{kij}^*| - \sqrt{\sum_{i,j}(\omega_{kij}^{(T)} - \omega_{kij}^*)^2},$$

Moreover,

$$\sqrt{\sum_{i,j}(\omega_{kij}^{(T)} - \omega_{kij}^*)^2} \leq \|\mathbf{\Theta}^{(T)} - \mathbf{\Theta}^*\|_2. \tag{S.38}$$

According to Corollary 18 and minimal signal condition we have

$$|\omega_{kij}^{(T)}| > r_n.$$

Therefore, we see that $\widetilde{\omega}_{kij} \neq 0$, which implies $\widetilde{\mathcal{V}_k} \supset \mathcal{V}_k$.

Step 2: In order to show $\widetilde{\mathcal{V}_k} \subset \mathcal{V}_k$, we need to check that, for any $(i,j) \in \mathcal{V}_k^c$, the estimator $\widetilde{\omega}_{kij} = 0$. Note that, the estimator before the thresholding step satisfies,

$$|\omega_{kij}^{(T)}| = |\omega_{kij}^{(T)} - \omega_{kij}^*| \leq \sqrt{\sum_{i,j}(\omega_{kij}^{(T)} - \omega_{kij}^*)^2}.$$

From (S.38), it is known that $|\omega_{kij}^{(T)}| \leq r_n$. Therefore, the thresholding step will set $\widetilde{\omega}_{kij} = \omega_{kij}^{(T)} 1\{|\widehat{\omega}_{kij}| > r_n\} = 0$ with high probability. This ends the proof of Theorem S.2. ■

Appendix B. Updates steps of our SCAN algorithm

S.I Proof of Lemma 2:

The KKT conditions for μ_{kj} to be a maximizer of $Q(\mathbf{\Theta}|\mathbf{\Theta}^{(t-1)}) - \mathcal{R}(\mathbf{\Theta})$ are

$$\frac{1}{n}\sum_{i=1}^{n} L_{\mathbf{\Theta}^{(t-1)},k}\Big(\sum_{l=1}^{p}(x_{il}-\mu_{kl})\omega_{klj}\Big) = \lambda_1 \text{sign}(\mu_{kj}), \text{ when } \mu_{kj} \neq 0,$$
$$\left|\frac{1}{n}\sum_{i=1}^{n} L_{\mathbf{\Theta}^{(t-1)},k}\Big(\sum_{l=1,l\neq j}^{p}(x_{il}-\mu_{kl})\omega_{klj} + x_{ij}\omega_{kjj}\Big)\right| \leq \lambda_1, \text{ when } \mu_{kj} = 0.$$

Therefore, the update of $\mu_{kj}^{(t)}$ is given as:

$$\text{If } \left|\frac{1}{n}\sum_{i=1}^{n} L_{\mathbf{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)\Big(\sum_{l=1,l\neq j}^{p}(x_{il}-\mu_{kl}^{(t-1)})\omega_{klj}^{(t-1)} + x_{ij}\omega_{kjj}^{(t-1)}\Big)\right| \leq \lambda_1,$$

then $\mu_{kj}^{(t)} = 0$; Else

$$\mu_{kj}^{(t)} = \Big(\omega_{kjj}^{(t-1)}\frac{1}{n}\sum_{i=1}^{n} L_{\mathbf{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)\Big)^{-1}\Big\{\frac{1}{n}\sum_{i=1}^{n} L_{\mathbf{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)\big(\sum_{l=1}^{p} x_{il}\omega_{klj}^{(t-1)}\big) -$$
$$\big(\frac{1}{n}\sum_{i=1}^{n} L_{\mathbf{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)\big)\Big(\sum_{l=1}^{p}\mu_{kl}^{(t-1)}\omega_{klj}^{(t-1)} - \mu_{kj}^{(t-1)}\omega_{kjj}^{(t-1)}\Big) - \lambda_1 \text{sign}(\mu_{kj}^{(t-1)})\Big\}$$

Using the definitions of $g_{1,j}(\boldsymbol{x}; \mathbf{\Theta}_k^{(t-1)})$ and $g_{2,j}(\boldsymbol{x}_i; \mathbf{\Theta}_k^{(t-1)})$, we finish the proof of Lemma 2. ■

S.II Proof of Lemma 3:

Recall that in (8)

$$Q_n(\mathbf{\Theta}|\mathbf{\Theta}^{(t-1)}) := \frac{1}{n}\sum_{i=1}^{n}\sum_{k=1}^{K} L_{\mathbf{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)[\log\pi_k + \log f_k(\boldsymbol{x}_i;\mathbf{\Theta}_k)] - \mathcal{R}(\mathbf{\Theta}),$$

Then,

$$\begin{aligned}
&\max_{\boldsymbol{\Omega}_1,\ldots,\boldsymbol{\Omega}_K} \frac{1}{n}\sum_{i=1}^{n}\sum_{k=1}^{K} L_{\boldsymbol{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)[\log \pi_k + \log f_k(\boldsymbol{x}_i;\boldsymbol{\Theta}_k)] - \mathcal{R}(\boldsymbol{\Theta}) \\
= &\max_{\boldsymbol{\Omega}_1,\ldots,\boldsymbol{\Omega}_K} \frac{1}{n}\sum_{i=1}^{n}\sum_{k=1}^{K} L_{\boldsymbol{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)[\log \pi_k - \frac{p}{2}\log(2\pi) + \frac{1}{2}\log\det(\boldsymbol{\Omega}_k) \\
&-\frac{1}{2}(\boldsymbol{x}_i-\boldsymbol{\mu}_k)^\top\boldsymbol{\Omega}_k(\boldsymbol{x}_i-\boldsymbol{\mu}_k)] - \frac{1}{2}\mathcal{R}(\boldsymbol{\Theta}) \\
= &\max_{\boldsymbol{\Omega}_1,\ldots,\boldsymbol{\Omega}_K} \frac{1}{n}\sum_{k=1}^{K}\left\{\frac{1}{n}\sum_{i=1}^{n} L_{\boldsymbol{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)[\log\det(\boldsymbol{\Omega}_k) - (\boldsymbol{x}_i-\boldsymbol{\mu}_k)^\top\boldsymbol{\Omega}_k(\boldsymbol{x}_i-\boldsymbol{\mu}_k)]\right\} - \mathcal{R}(\boldsymbol{\Theta}) \\
= &\max_{\boldsymbol{\Omega}_1,\ldots,\boldsymbol{\Omega}_K} \frac{1}{n}\sum_{k=1}^{K} n_k[\log\det(\boldsymbol{\Omega}_k) - \mathrm{trace}(\widetilde{S}_k\boldsymbol{\Omega}_k)] - \mathcal{R}(\boldsymbol{\Theta}),
\end{aligned}$$

where the last equality is because

$$\begin{aligned}
&\frac{1}{n}\sum_{i=1}^{n} L_{\boldsymbol{\Theta}^{(t-1)},k}(\boldsymbol{x}_i)(\boldsymbol{x}_i-\boldsymbol{\mu}_k)^\top\boldsymbol{\Omega}_k(\boldsymbol{x}_i-\boldsymbol{\mu}_k) \\
= &\frac{1}{n}\sum_{\boldsymbol{x}_i\in\mathcal{A}_k}\mathrm{trace}((\boldsymbol{x}_i-\boldsymbol{\mu}_k)(\boldsymbol{x}_i-\boldsymbol{\mu}_k)^\top\boldsymbol{\Omega}_k) \\
= &\frac{1}{n}\mathrm{trace}\Big(\sum_{\boldsymbol{x}_i\in\mathcal{A}_k}(\boldsymbol{x}_i-\boldsymbol{\mu}_k)(\boldsymbol{x}_i-\boldsymbol{\mu}_k)^\top\boldsymbol{\Omega}_k\Big).
\end{aligned}$$

Then plugging in the last update of $\boldsymbol{\mu}_k$ leads to the desirable result. ■

Appendix C. Supporting Lemma

Lemma S.3 *Consider a finite number of independent centered sub-gaussian random variables X_i. Then $\sum_i X_i$ is also a centered sub-gaussian random variable. Moreover,*

$$\left\|\sum_i X_i\right\|_{\psi_2}^2 \le C\sum_i \|X_i\|_{\psi_2}^2,$$

where C is an absolute constant.

Lemma S.4 *Let X, Y be two sub-Gaussian random variables. Then $Z = X\cdot Y$ is sub-exponential random variable. Moreover, there exits constant C such that*

$$\|Z\|_{\psi_1} \le C\|X\|_{\psi_2}\cdot\|Y\|_{\psi_2}. \tag{S.39}$$

Lemma S.5 *Let X be sub-Gaussian random variable and Y be sub-exponential random variables. Then $X-\mathbb{E}[X]$ is also sub-Gaussian; $Y-\mathbb{E}[Y]$ is also sub-exponential. Moreover, we have*

$$\|X-\mathbb{E}[X]\|_{\psi_2} \le 2\|X\|_{\psi_2},\ \ \|Y-\mathbb{E}[Y]\|_{\psi_1} \le 2\|Y\|_{\psi_1}.$$

Lemma S.6 *Suppose $X_1, X_2, \ldots, X_n$ are n iid centered sub-Gaussian random variables with $\|X_1\|_{\psi_2} \le K$. Then for every $t \ge 0$, we have*

$$\mathbb{P}\left(\left|\frac{1}{n}\sum_{i=1}^{n} X_i\right| \ge t\right) \ge e\cdot\exp\left(-\frac{Cnt^2}{K^2}\right),$$

where C is an absolute constant.

Lemma S.7 *Suppose $X_1, X_2, \ldots, X_n$ are n iid centered sub-expoential random variables with $\|X_1\|_{\psi_1} \le K$. Then for every $t \ge 0$, we have*

$$\mathbb{P}\left(\left|\frac{1}{n}\sum_{i=1}^{n} X_i\right| \ge t\right) \ge 2\cdot\exp\left(-C\min\left\{\frac{t^2}{K^2}, \frac{t}{K}\right\}n\right),$$

where C is an absolute constant.

Lemma S.8 *Hoeffding's inequality Suppose $X_1, X_2 \ldots X_n$ are independent random variable, $a_1 \le X_i \le b_i$, then we can have*

$$\mathbb{P}\left(\left|\frac{1}{n}\sum_{i=1}^{n}(X_i-\mathbb{E}X_i)\right| > \varepsilon\right) \le 2\exp\left\{\frac{-2n\varepsilon^2}{\frac{1}{n}\sum_{i=1}^{n}(b_i-a_i)^2}\right\}.$$

Moreover, if $a_i = 0$ and $b_i = 1$, then we have

$$\mathbb{P}\left(\left|\frac{1}{n}\sum_{i=1}^{n}(X_i-\mathbb{E}X_i)\right| > \varepsilon\right) > 1-2e^{-2n\varepsilon^2}.$$

Abstract

We address the statistical and optimization impacts of the classical sketch and Hessian sketch used to approximately solve the Matrix Ridge Regression (MRR) problem. Prior research has quantified the effects of classical sketch on the strictly simpler least squares regression (LSR) problem. We establish that classical sketch has a similar effect upon the optimization properties of MRR as it does on those of LSR: namely, it recovers nearly optimal solutions. By contrast, Hessian sketch does not have this guarantee; instead, the approximation error is governed by a subtle interplay between the "mass" in the responses and the optimal objective value.

For both types of approximation, the regularization in the sketched MRR problem results in significantly different statistical properties from those of the sketched LSR problem. In particular, there is a bias-variance trade-off in sketched MRR that is not present in sketched LSR. We provide upper and lower bounds on the bias and variance of sketched MRR; these bounds show that classical sketch significantly increases the variance, while Hessian sketch significantly increases the bias. Empirically, sketched MRR solutions can have risks that are higher by an order-of-magnitude than those of the optimal MRR solutions.

We establish theoretically and empirically that model averaging greatly decreases the gap between the risks of the true and sketched solutions to the MRR problem. Thus, in parallel or distributed settings, sketching combined with model averaging is a powerful technique that quickly obtains near-optimal solutions to the MRR problem while greatly mitigating the increased statistical risk incurred by sketching.

Keywords: Randomized Linear Algebra, Matrix Sketching, Ridge Regression

1. Introduction

Regression is one of the most fundamental problems in machine learning. The simplest and most thoroughly studied regression model is least squares regression (LSR). Given features $\mathbf{X} = [\mathbf{x}_1^T; \ldots, \mathbf{x}_n^T] \in \mathbb{R}^{n \times d}$ and responses $\mathbf{y} = [y_1, \ldots, y_n]^T \in \mathbb{R}^n$, the LSR problem $\min_{\mathbf{w}} \|\mathbf{X}\mathbf{w} - \mathbf{y}\|_2^2$ can be solved in $\mathcal{O}(nd^2)$ time using the QR decomposition or in $\mathcal{O}(ndt)$ time using accelerated gradient descent algorithms. Here, t is the number of iterations, which depends on the initialization, the condition number of $\mathbf{X}^T\mathbf{X}$, and the stopping criterion.

This paper considers the $n \gg d$ problem, where there is much redundancy in $\mathbf{X}$. Matrix sketching, as used in the paradigm of Randomized Linear Algebra (RLA) (Mahoney, 2011; Woodruff, 2014; Drineas and Mahoney, 2016), aims to reduce the size of $\mathbf{X}$ while limiting information loss; the sketching operation can consist of sampling a subset of the rows of $\mathbf{X}$, or forming linear combinations of the rows of $\mathbf{X}$. Either operation is modeled mathematically by multiplication with a sketching matrix $\mathbf{S}$ to form the sketch $\mathbf{S}^T\mathbf{X}$. The sketching matrix $\mathbf{S} \in \mathbb{R}^{n \times s}$ satisfies $d < s \ll n$ so that $\mathbf{S}^T\mathbf{X}$ generically has the same rank but much fewer rows as $\mathbf{X}$. Sketching has been used to speed up LSR (Drineas et al., 2006b, 2011; Clarkson and Woodruff, 2013; Meng and Mahoney, 2013; Nelson and Nguyên, 2013) by solving the sketched LSR problem $\min_{\mathbf{w}} \|\mathbf{S}^T\mathbf{X}\mathbf{w} - \mathbf{S}^T\mathbf{y}\|_2^2$ instead of the original LSR problem. Solving sketched LSR costs either $\mathcal{O}(sd^2 + T_s)$ time using the QR decomposition or $\mathcal{O}(sdt + T_s)$ time using accelerated gradient descent algorithms, where t is as defined previously[1] and T_s is the time cost of sketching. For example, $T_s = \mathcal{O}(nd \log s)$ when $\mathbf{S}$ is the subsampled randomized Hadamard transform (Drineas et al., 2011), and $T_s = \mathcal{O}(nd)$ when $\mathbf{S}$ is a CountSketch matrix (Clarkson and Woodruff, 2013).

There has been much work in RLA on analyzing the quality of sketched LSR with different sketching methods and different objectives; see the reviews (Mahoney, 2011; Woodruff, 2014; Drineas and Mahoney, 2016) and the references therein. The concept of sketched LSR originated in the theoretical computer science literature, e.g., Drineas et al. (2006b, 2011), where the behavior of sketched LSR was first studied from an optimization perspective. Let $\mathbf{w}^\star$ be the optimal LSR solution and $\tilde{\mathbf{w}}$ be the solution to sketched LSR. This line of work established that if $s = \mathcal{O}(d/\epsilon + \text{poly}(d))$, then the objective value $\|\mathbf{X}\tilde{\mathbf{w}} - \mathbf{y}\|_2^2$ is at most $(1+\epsilon)$ times greater than $\|\mathbf{X}\mathbf{w}^\star - \mathbf{y}\|_2^2$. These works also bounded $\|\tilde{\mathbf{w}} - \mathbf{w}^\star\|_2^2$ in terms of the difference in the objective function values at $\tilde{\mathbf{w}}$ and $\mathbf{w}^\star$ and the condition number of $\mathbf{X}^T\mathbf{X}$.

A more recent line of work has studied sketched LSR from a statistical perspective: Ma et al. (2015); Raskutti and Mahoney (2016); Pilanci and Wainwright (2015); Wang et al. (2017c) considered statistical properties of sketched LSR such as the bias and variance. In particular, Pilanci and Wainwright (2015) showed that the solutions to sketched LSR have much higher variance than the optimal solutions.

Both of these perspectives are important and of practical interest. The optimization perspective is relevant when the approximate solution is used to initialize an (expensive) iterative optimization algorithm; the statistical perspective is relevant in machine learning and statistics applications where the approximate solution is directly used in lieu of the optimal solution.

1. The condition number of $\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X}$ is very close to that of $\mathbf{X}^T\mathbf{X}$, and thus the number of iterations t is almost unchanged.

In practice, regularized regression, e.g., ridge regression and LASSO, exhibit more attractive bias-variance trade-offs and generalization errors than vanilla LSR. Furthermore, the matrix generalization of LSR, where multiple responses are to be predicted, is often more useful than LSR. However, the properties of sketched regularized matrix regression are largely unknown. Hence, we consider the question: *how does our understanding of the optimization and statistical properties of sketched LSR generalize to sketched regularized regression problems?* We answer this question for the sketched matrix ridge regression (MRR) problem.

Recall that $\mathbf{X}$ is $n \times d$. Let $\mathbf{Y} \in \mathbb{R}^{n \times m}$ denote a matrix of corresponding responses. We study the MRR problem

$$\min_{\mathbf{W}} \Big\{ f(\mathbf{W}) \triangleq \frac{1}{n} \big\| \mathbf{X}\mathbf{W} - \mathbf{Y} \big\|_F^2 + \gamma \|\mathbf{W}\|_F^2 \Big\}, \tag{1}$$

which has optimal solution

$$\mathbf{W}^\star = (\mathbf{X}^T\mathbf{X} + n\gamma \mathbf{I}_d)^\dagger \mathbf{X}^T\mathbf{Y}. \tag{2}$$

Here, $(\cdot)^\dagger$ denotes the Moore-Penrose inversion operation. LSR is a special case of MRR, with $m = 1$ and $\gamma = 0$. The optimal solution $\mathbf{W}^\star$ can be obtained in $\mathcal{O}(nd^2 + nmd)$ time using a QR decomposition of $\mathbf{X}$. Sketching can be applied to MRR in two ways:

$$\mathbf{W}^{\mathrm{c}} = (\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X} + n\gamma \mathbf{I}_d)^\dagger (\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{Y}), \tag{3}$$

$$\mathbf{W}^{\mathrm{h}} = (\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X} + n\gamma \mathbf{I}_d)^\dagger \mathbf{X}^T\mathbf{Y}. \tag{4}$$

Following the convention of Pilanci and Wainwright (2015); Wang et al. (2017a), we call $\mathbf{W}^{\mathrm{c}}$ the **classical sketch** and $\mathbf{W}^{\mathrm{h}}$ the **Hessian sketch**. Table 1 lists the time costs of the three solutions to MRR.

Table 1: The time cost of the solutions to MRR. Here $T_s(\mathbf{X})$ and $T_s(\mathbf{Y})$ denote the time cost of forming the sketches $\mathbf{S}^T\mathbf{X} \in \mathbb{R}^{s \times d}$ and $\mathbf{S}^T\mathbf{Y} \in \mathbb{R}^{s \times m}$.

Solution	Definition	Time Complexity
Optimal Solution	(2)	$\mathcal{O}(nd^2 + nmd)$
Classical Sketch	(3)	$\mathcal{O}(sd^2 + smd) + T_s(\mathbf{X}) + T_s(\mathbf{Y})$
Hessian Sketch	(4)	$\mathcal{O}(sd^2 + nmd) + T_s(\mathbf{X})$

1.1 Main Results and Contributions

We summarize all of our upper bounds in Table 2. Our optimization analysis bounds the gap between the objective function values at the sketched and optimal solutions, while our statistical analysis quantifies the behavior of the bias and variance of the sketched solutions relative to those of the true solutions.

We first study classical and Hessian sketches from the **optimization perspective**. Theorems 1 and 2 show:

Table 2: A summary of our main results. In the table, $\mathbf{W}$ is the solution of classical/Hessian sketch with or without model averaging (mod. avg.); $\mathbf{W}^\star$ is the optimal solution; g is the number of models used in model averaging; and $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2 + n\gamma} \leq 1$, where γ is the regularization parameter. For conciseness, we take the sketching matrix $\mathbf{S} \in \mathbb{R}^{n \times s}$ to correspond to Gaussian projection, SRHT, or shrinkage leverage score sampling. Similar but more complex expressions hold for uniform sampling (with or without model averaging) and CountSketch (only without model averaging.) All the bounds hold with constant probability. The notation $\tilde{\mathcal{O}}$ conceals logarithmic factors.

Theorems	Theorem 5	Theorem 10	Theorem 6	Theorem 11

- Classical sketch achieves relative error in the objective value. With sketch size $s = \tilde{\mathcal{O}}(d/\epsilon)$, the sketched solution satisfies $f(\mathbf{W}^{\mathrm{c}}) \leq (1+\epsilon) f(\mathbf{W}^\star)$.
- Hessian sketch does not achieve relative error in the objective value. In particular, if $\frac{1}{n}\|\mathbf{Y}\|_F^2$ is much larger than $f(\mathbf{W}^\star)$, then $f(\mathbf{W}^{\mathrm{h}})$ can be far larger than $f(\mathbf{W}^\star)$.
- For both classical and Hessian sketch, the relative quality of approximation often improves as the regularization parameter γ increases (because β decreases).

We then study classical and Hessian sketch from the **statistical perspective**, by modeling $\mathbf{Y} = \mathbf{X}\mathbf{W}_0 + \mathbf{\Xi}$ as the sum of a true linear model and random noise, decomposing the risk $R(\mathbf{W}) = \mathbb{E}\|\mathbf{X}\mathbf{W} - \mathbf{X}\mathbf{W}_0\|_F^2$ into bias and variance terms, and bounding these terms. We draw the following conclusions (see Theorems 4, 5, 6 for the details):

- The bias of classical sketch can be nearly as small as that of the optimal solution. The variance is $\Theta\big(\frac{n}{s}\big)$ times that of the optimal solution; this bound is optimal. Therefore over-regularization[2] should be used to supress the variance. (As γ increases, the bias increases, and the variance decreases.)

2. For example, using a larger value of the regularization parameter γ than one would optimally choose for the unsketched problem.

- Since Hessian sketch uses the whole of $\mathbf{Y}$, the variance of Hessian sketch can be close to that of the optimal solution. However, Hessian sketch incurs a high bias, especially when $n\gamma$ is small compared to $\|\mathbf{X}\|_2^2$. This indicates that over-regularization is necessary for Hessian sketch to deliver solutions with low bias.

Our empirical evaluations bear out these theoretical results. In particular, in Section 4, we show in Figure 3 that even when the regularization parameter γ is fine-tuned, the risks of classical and Hessian sketch are worse than that of the optimal solution by an order of magnitude. This is an empirical demonstration of the fact that the near-optimal properties of sketch from the optimization perspective are much less relevant in a statistical setting than its sub-optimal statistical properties.

We propose to use **model averaging**, which averages the solutions of g sketched MRR problems, to attain lower optimization and statistical errors. Without ambiguity, we denote model-averaged classical and Hessian sketches by $\mathbf{W}^{\mathrm{c}}$ and $\mathbf{W}^{\mathrm{h}}$, respectively. Theorems 7, 8, 10, 11 establish the following results:

- Classical Sketch. Model averaging decreases the objective function value and the variance and does not increase the bias. Specifically, with the same sketch size s, model averaging ensures $\frac{f(\mathbf{W}^{\mathrm{c}})-f(\mathbf{W}^\star)}{f(\mathbf{W}^\star)}$ and $\frac{\mathsf{var}(\mathbf{W}^{\mathrm{c}})}{\mathsf{var}(\mathbf{W}^\star)}$ respectively decrease to almost $\frac{1}{g}$ of those of classical sketch without model averaging, provided that $s \gg d$. See Table 2 for the details.

- Hessian Sketch. Model averaging decreases the objective function value and the bias and does not increase the variance.

In the distributed setting, the feature-response pairs $(\mathbf{x}_1, \mathbf{y}_1), \cdots, (\mathbf{x}_n, \mathbf{y}_n) \in \mathbb{R}^d \times \mathbb{R}^m$ are divided among g machines. Assuming that the data have been shuffled randomly, each machine contains a sketch of the MRR constructed by uniformly sampling rows from the data set without replacement. We illustrate this procedure in Figure 1. In this setting, the model averaging procedure communicates the g local models only once to return the final estimate; this process has very low communication and latency costs, and suggests two further applications of classical sketch with model averaging:

- Model Averaging for Machine Learning. When a low-precision solution is acceptable, model averaging can be used in lieu of distributed numerical optimization algorithms requiring multiple rounds of communication. If $\frac{n}{g}$ is large enough compared to d and the row coherence of $\mathbf{X}$ is small, then "one-shot" model averaging has bias and variance comparable to the optimal solution.

- Model Averaging for Optimization. If a high-precision solution to MRR is required, then an iterative numerical optimization algorithm must be used. The cost of such algorithms heavily depends on the quality of the initialization.[3] A good initialization reduces the number of iterations needed to reach convergence. The averaged model is provably close to the optimal solution, so model averaging provides a high-quality initialization for more expensive algorithms.

3. For example, the conjugate gradient method satisfies $\frac{\|\mathbf{W}^{(t)}-\mathbf{W}^\star\|_F^2}{\|\mathbf{W}^{(0)}-\mathbf{W}^\star\|_F^2} \le \theta_1^t$ and stochastic block coordinate descent (Tu et al., 2016) satisfies $\frac{\mathbb{E}f(\mathbf{W}^{(t)})-f(\mathbf{W}^\star)}{f(\mathbf{W}^{(0)})-f(\mathbf{W}^\star)} \le \theta_2^t$. Here $\mathbf{W}^{(t)}$ is the output of the t-th iteration; $\theta_1, \theta_2 \in (0,1)$ depend on the condition number of $\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d$ and some other factors.

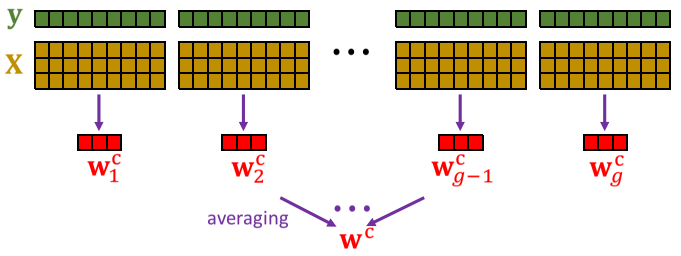

Figure 1: Using model averaging with the classical sketch in the distributed setting to approximately solve LSR.

1.2 Prior Work

The body of work on sketched LSR mentioned earlier (Drineas et al., 2006b, 2011; Clarkson and Woodruff, 2013; Meng and Mahoney, 2013; Nelson and Nguyên, 2013) shares many similarities with our results. However, the theories of sketched LSR developed from the optimization perspective do not obviously extend to MRR, and the statistical analysis of LSR and MRR differ: among other differences, LSR is unbiased while MRR is biased and therefore has a bias-variance tradeoff that must be considered.

Lu et al. (2013) has considered a different application of sketching to ridge regression: they assume $d \gg n$, reduce the number of features in $\mathbf{X}$ using sketching, and conduct statistical analysis. Our setting differs in that we consider $n \gg d$, reduce the number of samples by sketching, and allow for multiple responses.

The model averaging analyzed in this paper is similar in spirit to the AvgM algorithm of (Zhang et al., 2013). When classical sketch is used with uniform row sampling without replacement, our model averaging procedure is a special case of AvgM. However, our results do not follow from those of (Zhang et al., 2013). First, we make no assumption on the data, $\mathbf{X}$ and $\mathbf{Y}$, and the model (parameters), $\mathbf{W}$. Second, we study both the optimization objective, $\|\mathbf{X}\mathbf{W}^{\mathrm{c}} - \mathbf{X}\mathbf{W}^\star\|_F^2$, and the statistical objective, $\mathbb{E}\|\mathbf{X}\mathbf{W}^{\mathrm{c}} - \mathbf{X}\mathbf{W}_0\|_F^2$, where $\mathbf{W}^{\mathrm{c}}$ is the average of the approximate solutions obtained used classical sketch, $\mathbf{W}_0$ is the unknown ground truth, and $\mathbf{W}^\star$ is the optimal solution based on the observed data; they studied solely the optimization objective. Third, our results apply to many other sketching ensembles than uniform sampling without replacement. Our results clearly indicate that the performance critically depends on the row coherence of $\mathbf{X}$; this dependence has not been explicitly captured in (Zhang et al., 2013). Zhang et al. (2015) studied a different statistical objective and their resulting bound has a higher-order of dependence on d and other parameters.

Iterative Hessian sketch has been studied in Pilanci and Wainwright (2015); Wang et al. (2017a,b). By way of comparison, all the algorithms in this paper are "one-shot" rather than iterative. This work has connections to the contemporary works (Avron et al., 2017; Thanei et al., 2017; Derezinski and Warmuth, 2017, 2018). Avron et al. (2017) studied classical sketch from the optimization perspective; Thanei et al. (2017) studied LSR with model averaging; Derezinski and Warmuth (2017, 2018) studied linear regression with volume sampling for experimental design.

1.3 Paper Organization

Section 2 defines our notation and introduces the sketching schemes we consider. Section 3 presents our theoretical results. Sections 4 and 5 conduct experiments to verify our theories and demonstrates the efficacy of model averaging. Section 6 sketches the proofs of our main results. Complete proofs are provided in the appendix.

2. Preliminaries

Throughout, we take $\mathbf{I}_n$ to be the $n \times n$ identity matrix and $\mathbf{0}$ to be a vector or matrix of all zeroes of the appropriate size. Given a matrix $\mathbf{A} = [a_{ij}]$, the i-th row is denoted by $\mathbf{a}_{i:}$, and the j-th column is denoted by $\mathbf{a}_{:j}$. The Frobenius and spectral norms of $\mathbf{A}$ are written as, respectively, $\|\mathbf{A}\|_F$ and $\|\mathbf{A}\|_2$. The set $\{1, 2, \cdots, n\}$ is written $[n]$. Let $\mathcal{O}$, Ω, and Θ be the standard asymptotic notation, and let $\widetilde{\mathcal{O}}$ conceal logarithmic factors.

Throughout, we fix $\mathbf{X} \in \mathbb{R}^{n\times d}$ as our matrix of features. We set $\rho = \text{rank}(\mathbf{X})$ and write the SVD of $\mathbf{X}$ as $\mathbf{X} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$, where $\mathbf{U}$, $\mathbf{\Sigma}$, $\mathbf{V}$ are respectively $n \times \rho$, $\rho \times \rho$, and $d \times \rho$ matrices. We let $\sigma_1 \geq \cdots \geq \sigma_\rho > 0$ be the singular values of $\mathbf{X}$. The Moore-Penrose inverse of $\mathbf{X}$ is defined by $\mathbf{X}^\dagger = \mathbf{V}\mathbf{\Sigma}^{-1}\mathbf{U}^T$. The row leverage scores of $\mathbf{X}$ are $l_i = \|\mathbf{u}_{i:}\|_2^2$ for $i \in [n]$. The row coherence of $\mathbf{X}$ is $\mu(\mathbf{X}) = \frac{n}{\rho}\max_i \|\mathbf{u}_{i:}\|_2^2$. Throughout, we let μ be shorthand for $\mu(\mathbf{X})$. The notation defined in Table 3 is used throughout this paper.

Matrix sketching attempts to reduce the size of large matrices while minimizing the loss of spectral information that is useful in tasks like linear regression. We denote the process of sketching a matrix $\mathbf{X} \in \mathbb{R}^{n\times d}$ by $\mathbf{X}' = \mathbf{S}^T\mathbf{X}$. Here, $\mathbf{S} \in \mathbb{R}^{n\times s}$ is called a sketching matrix and $\mathbf{X}' \in \mathbb{R}^{s\times d}$ is called a sketch of $\mathbf{X}$. In practice, except for Gaussian projection (where the entries of $\mathbf{S}$ are i.i.d. sampled from $\mathcal{N}(0, 1/s)$), the sketching matrix $\mathbf{S}$ is not formed explicitly.

Matrix sketching can be accomplished by random sampling or random projection. **Random sampling** corresponds to sampling rows of $\mathbf{X}$ i.i.d. with replacement according to given row sampling probabilities $p_1, \cdots, p_m \in (0, 1)$. The corresponding (random) sketching matrix $\mathbf{S} \in \mathbb{R}^{n\times s}$ has exactly one non-zero entry, whose position indicates the index of the selected row in each column; in practice, this $\mathbf{S}$ is not explicitly formed. **Uniform sampling** fixes $p_1 = \cdots = p_n = \frac{1}{n}$. **Leverage score sampling** sets p_i proportional to the (exact or approximate (Drineas et al., 2012)) row leverage scores l_i of $\mathbf{X}$. In practice **shrinked leverage score sampling** can be a better choice than leverage score sampling (Ma et al., 2015). The sampling probabilities of shrinked leverage score sampling are defined by $p_i = \frac{1}{2}\left(\frac{l_i}{\sum_{j=1}^n l_j} + \frac{1}{n}\right)$.[4]

Table 3: The commonly used notation.

Notation	Definition
$\mathbf{X} \in \mathbb{R}^{n\times d}$	each row is a data sample (feature vector)
$\mathbf{Y} \in \mathbb{R}^{n\times m}$	each row contains the corresponding responses
$\mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$	the SVD of $\mathbf{X}$
ρ	the rank of $\mathbf{X}$
μ	the row coherence of $\mathbf{X}$
σ_i	the i-th largest singular value of $\mathbf{X}$
γ	the regularization parameter
β	$\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2 + n\gamma} \leq 1$
$\mathbf{S} \in \mathbb{R}^{n\times s}$	the sketching matrix
$\mathbf{W}^\star \in \mathbb{R}^{d\times m}$	the optimal solution (2)
$\mathbf{W}^{\text{c}} \in \mathbb{R}^{d\times m}$	approximate solution obtained using the classical sketch (3)
$\mathbf{W}^{\text{h}} \in \mathbb{R}^{d\times m}$	approximate solution obtained using the Hessian sketch (4)
$\mathbf{W}_0 \in \mathbb{R}^{d\times m}$	the unknown ground truth (in the statistical setting)

The exact leverage scores are unnecessary in practice; constant-factor approximation to the leverage scores is sufficient. Leverage scores can be efficiently approximated by the algorithms of (Drineas et al., 2012). Let $l_1, \cdots, l_n$ be the true leverage scores. We denote the approximate leverages by $\widetilde{l}_1, \cdots, \widetilde{l}_n$ and require that they satisfy

$$\tilde{l}_q \in [l_q, \tau l_q] \quad \text{for all} \quad q \in [n], \tag{5}$$

where $\tau \geq 1$ indicates the quality of approximation. We then use $p_q = \tilde{l}_q / \sum_j \tilde{l}_j$ as the sampling probabilities. One can obtain the same accuracies when using approximate leverage scores in place of the true leverage scores by increasing s by a factor of τ, so as long as τ is a small constant, the orders of the sketch sizes when using exact or approximate leverage score sampling are the same. Thus we do not distinguish between exact and approximate leverage scores in this paper. For shrinked leverage score sampling, we define the sampling probabilities

$$p_i = \frac{1}{2}\left(\frac{\tilde{l}_i}{\sum_{j=1}^n \tilde{l}_j} + \frac{1}{n}\right) \quad \text{for} \quad i = 1, \ldots, n. \tag{6}$$

Gaussian projection is also well-known as the prototypical Johnson-Lindenstrauss transform (Johnson and Lindenstrauss, 1984). Let $\mathbf{G} \in \mathbb{R}^{n\times s}$ be a standard Gaussian matrix, i.e., each entry is sampled independently from $\mathcal{N}(0, 1)$. The matrix $\mathbf{S} = \frac{1}{\sqrt{s}}\mathbf{G}$ is a Gaussian projection matrix. It takes $\mathcal{O}(nds)$ time to apply $\mathbf{S} \in \mathbb{R}^{n\times s}$ to any $n \times d$ dense matrix, which makes Gaussian projection computationally inefficient relative to other forms of sketching.

4. In fact, p_i can be any convex combination of $\frac{l_i}{\sum_{j=1}^n l_j}$ and $\frac{1}{n}$ (Ma et al., 2015). We use the weight $\frac{1}{2}$ for convenience; our conclusions extend in a straightforward manner to other weightings.

The **Subsampled randomized Hadamard transform (SRHT)** (Drineas et al., 2011; Lu et al., 2013; Tropp, 2011) is a more efficient alternative to Gaussian projection. Let $\mathbf{H}_n \in \mathbb{R}^{n\times n}$ be the Walsh-Hadamard matrix with $+1$ and -1 entries, $\mathbf{D} \in \mathbb{R}^{n\times n}$ be a diagonal matrix with diagonal entries sampled uniformly from $\{+1, -1\}$, and $\mathbf{P} \in \mathbb{R}^{n\times s}$ be the uniform row sampling matrix defined above. The matrix $\mathbf{S} = \frac{1}{\sqrt{n}}\mathbf{D}\mathbf{H}_n\mathbf{P} \in \mathbb{R}^{n\times s}$ is an SRHT matrix, and can be applied to any $n \times d$ matrix in $\mathcal{O}(nd \log s)$ time. In practice, the subsampled randomized Fourier transform (SRFT) (Woolfe et al., 2008) is often used in lieu of the SRHT, because the SRFT exists for all values of n, whereas $\mathbf{H}_n$ exists only for some values of n. Their performance and theoretical analyses are very similar.

CountSketch can be applied to any $\mathbf{X} \in \mathbb{R}^{n\times d}$ in $\mathcal{O}(nd)$ time (Charikar et al., 2004; Clarkson and Woodruff, 2013; Meng and Mahoney, 2013; Nelson and Nguyên, 2013; Pham and Pagh, 2013; Weinberger et al., 2009). Though more efficient to apply, CountSketch requires a larger sketch size than Gaussian projections, SRHT, and leverage score sampling to attain the same theoretical guarantees. Interested readers can refer to (Woodruff, 2014) for a detailed description of CountSketch. Unlike the other sketching methods mentioned here, model averaging with CountSketch may not be theoretically sound. See Remark 5 for further discussion.

3. Main Results

Sections 3.1 and 3.2 analyze sketched MRR from, respectively, the optimization and statistical perspectives. Sections 3.3 and 3.4 capture the impacts of model averaging on, respectively, the optimization and statistical properties of sketched MRR.

We described six sketching methods in Section 2. For simplicity, in this section, we refer to leverage score sampling, shrinked leverage score sampling, Gaussian projection, and SRHT as **the four sketching methods** while we refer to uniform sampling and CountSketch by name. Throughout, let μ be the row coherence of $\mathbf{X}$ and $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2+n\gamma} \leq 1$.

3.1 Sketched MRR: Optimization Perspective

Theorem 1 shows that $f(\mathbf{W}^{\mathrm{c}})$, the objective value of classical sketch, is close to the optimal objective value $f(\mathbf{W}^\star)$, and that the approximation quality improves as the regularization parameter γ increases.

Theorem 1 (Classical Sketch) *Let $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2+n\gamma} \leq 1$. For the four sketching methods with $s = \tilde{\mathcal{O}}\big(\frac{d}{\epsilon}\big)$, uniform sampling with $s = \mathcal{O}\big(\frac{\mu d \log d}{\epsilon}\big)$, and CountSketch with $s = \mathcal{O}\big(\frac{d^2}{\epsilon}\big)$, the inequality*

$$f(\mathbf{W}^c) - f(\mathbf{W}^\star) \quad \leq \quad \epsilon\beta\, f(\mathbf{W}^\star)$$

holds with probability at least 0.9. The uncertainty is with respect to the random choice of sketching matrix.

The corresponding guarantee for the performance of Hessian sketch is given in Theorem 2. It is weaker than the guarantee for classical sketch, especially when $\frac{1}{n}\|\mathbf{Y}\|_F^2$ is far larger than $f(\mathbf{W}^\star)$. If $\mathbf{Y}$ is nearly noiseless—$\mathbf{Y}$ is well-explained by a linear combination

of the columns of $\mathbf{X}$—and γ is small, then $f(\mathbf{W}^\star)$ is close to zero, and consequently $f(\mathbf{W}^\star)$ can be far smaller than $\frac{1}{n}\|\mathbf{Y}\|_F^2$. Therefore, in this case which is ideal for MRR, $f(\mathbf{W}^{\mathrm{h}})$ is not close to $f(\mathbf{W}^\star)$ and our theory suggests Hessian sketch does not perform as well as classical sketch. This is verified by our experiments (see Figure 2), which show that unless γ is large or a large portion of $\mathbf{Y}$ is outside the column space of $\mathbf{X}$, the ratio $\frac{f(\mathbf{W}^{\mathrm{h}})}{f(\mathbf{W}^\star)}$ can be large.

Theorem 2 (Hessian Sketch) *Let $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2+n\gamma} \leq 1$. For the four sketching methods with $s = \tilde{\mathcal{O}}\big(\frac{d}{\epsilon}\big)$, uniform sampling with $s = \mathcal{O}\big(\frac{\mu d \log d}{\epsilon}\big)$, and CountSketch with $s = \mathcal{O}\big(\frac{d^2}{\epsilon}\big)$, the inequality*

$$f(\mathbf{W}^h) - f(\mathbf{W}^\star) \quad \leq \quad \epsilon\beta^2 \left(\frac{\|\mathbf{Y}\|_F^2}{n} - f(\mathbf{W}^\star)\right).$$

holds with probability at least 0.9. The uncertainty is with respect to the random choice of sketching matrix.

These two results imply that $f(\mathbf{W}^{\mathrm{c}})$ and $f(\mathbf{W}^{\mathrm{h}})$ can be close to $f(\mathbf{W}^\star)$. When this is the case, curvature of the objective function ensures that the sketched solutions $\mathbf{W}^{\mathrm{c}}$ and $\mathbf{W}^{\mathrm{h}}$ are close to the optimal solution $\mathbf{W}^\star$. Lemma 3 bounds the Mahalanobis distance $\|\mathbf{M}(\mathbf{W} - \mathbf{W}^\star)\|_F^2$. Here $\mathbf{M}$ is any non-singular matrix; in particular, it can be the identity matrix or $(\mathbf{X}^T\mathbf{X})^{1/2}$. Lemma 3 is a consequence of Lemma 25.

Lemma 3 (Mahalanobis Distance) *Let f be the objective function of MRR defined in (1), $\mathbf{W} \in \mathbb{R}^{d\times m}$ be arbitrary, and $\mathbf{W}^\star$ be the optimal solution defined in (2). For any non-singular matrix $\mathbf{M}$, the Mahalanobis distance satisfies*

$$\frac{1}{n}\big\|\mathbf{M}(\mathbf{W} - \mathbf{W}^\star)\big\|_F^2 \;\leq\; \frac{f(\mathbf{W}) - f(\mathbf{W}^\star)}{\sigma_{\min}^2\big[(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{1/2}\mathbf{M}^{-1}\big]}.$$

By choosing $\mathbf{M} = (\mathbf{X}^T\mathbf{X})^{1/2}$, we can bound $\frac{1}{n}\|\mathbf{X}\mathbf{W} - \mathbf{X}\mathbf{W}^\star\|_F^2$ in terms of the difference in the objective values:

$$\tfrac{1}{n}\big\|\mathbf{X}\mathbf{W} - \mathbf{X}\mathbf{W}^\star\big\|_F^2 \quad \leq \quad \beta\big[f(\mathbf{W}) - f(\mathbf{W}^\star)\big],$$

where $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2+n\gamma} \leq 1$. With Lemma 3, we can directly apply Theorems 1 or 2 to bound $\frac{1}{n}\|\mathbf{X}\mathbf{W}^{\mathrm{c}} - \mathbf{X}\mathbf{W}^\star\|_F^2$ or $\frac{1}{n}\|\mathbf{X}\mathbf{W}^{\mathrm{h}} - \mathbf{X}\mathbf{W}^\star\|_F^2$.

3.2 Sketched MRR: Statistical Perspective

We consider the following fixed design model. Let $\mathbf{X} \in \mathbb{R}^{n\times d}$ be the observed feature matrix, $\mathbf{W}_0 \in \mathbb{R}^{d\times m}$ be the true and unknown model, $\mathbf{\Xi} \in \mathbb{R}^{n\times m}$ contain unknown random noise, and

$$\mathbf{Y} \;=\; \mathbf{X}\mathbf{W}_0 + \mathbf{\Xi} \tag{7}$$

be the observed responses. We make the following standard weak assumptions on the noise:

$$\mathbb{E}[\mathbf{\Xi}] = \mathbf{0} \quad \text{and} \quad \mathbb{E}[\mathbf{\Xi}\mathbf{\Xi}^T] = \xi^2\mathbf{I}_n.$$

We observe $\mathbf{X}$ and $\mathbf{Y}$ and seek to estimate $\mathbf{W}_0$.

We can evaluate the quality of the estimate by the risk:

$$R(\mathbf{W}) \;=\; \tfrac{1}{n}\mathbb{E}\big\|\mathbf{X}\mathbf{W}-\mathbf{X}\mathbf{W}_0\big\|_F^2, \tag{8}$$

where the expectation is taken w.r.t. the noise $\boldsymbol{\Xi}$. We study the risk functions $R(\mathbf{W}^\star)$, $R(\mathbf{W}^{\mathrm{c}})$, and $R(\mathbf{W}^{\mathrm{h}})$ in the following.

Theorem 4 (Bias-Variance Decomposition) *We consider the data model described in this subsection. Let* $\mathbf{W}$ *be* $\mathbf{W}^\star$, $\mathbf{W}^c$, *or* $\mathbf{W}^h$, *as defined in* (2), (3), *or* (4), *respectively; then the risk function can be decomposed as*

$$R(\mathbf{W}) \;=\; \mathsf{bias}^2(\mathbf{W})+\mathsf{var}(\mathbf{W}).$$

Recall the SVD of $\mathbf{X}$ *defined in Section 2:* $\mathbf{X}=\mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^T$. *The bias and variance terms can be written as*

$$\begin{aligned}
\mathsf{bias}(\mathbf{W}^\star) &= \gamma\sqrt{n}\Big\|(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\Big\|_F,\\
\mathsf{var}(\mathbf{W}^\star) &= \tfrac{\xi^2}{n}\Big\|\big(\mathbf{I}_\rho+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{-1}\Big\|_F^2,\\
\mathsf{bias}(\mathbf{W}^c) &= \gamma\sqrt{n}\Big\|\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^\dagger\boldsymbol{\Sigma}^{-1}\mathbf{V}^T\mathbf{W}_0\Big\|_F,\\
\mathsf{var}(\mathbf{W}^c) &= \tfrac{\xi^2}{n}\Big\|\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^\dagger\mathbf{U}^T\mathbf{S}\mathbf{S}^T\Big\|_F^2,\\
\mathsf{bias}(\mathbf{W}^h) &= \gamma\sqrt{n}\Big\|\Big(\boldsymbol{\Sigma}^{-2}+\tfrac{\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho}{n\gamma}\Big)\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^\dagger\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\Big\|_F,\\
\mathsf{var}(\mathbf{W}^h) &= \tfrac{\xi^2}{n}\Big\|\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^\dagger\Big\|_F^2.
\end{aligned}$$

The functions $\mathsf{bias}(\mathbf{W}^\star)$ and $\mathsf{var}(\mathbf{W}^\star)$ are deterministic. The randomness in $\mathsf{bias}(\mathbf{W}^{\mathrm{c}})$, $\mathsf{var}(\mathbf{W}^{\mathrm{c}})$, $\mathsf{bias}(\mathbf{W}^{\mathrm{h}})$, and $\mathsf{var}(\mathbf{W}^{\mathrm{h}})$ all arises from the sketching matrix $\mathbf{S}$.

Throughout this paper, we compare the bias and variance of classical sketch and Hessian sketch to those of the optimal solution $\mathbf{W}^\star$. We first study the bias, variance, and risk of $\mathbf{W}^\star$, which will help us understand the subsequent comparisons. We can assume that $\boldsymbol{\Sigma}^2=\mathbf{V}^T\mathbf{X}^T\mathbf{X}\mathbf{V}$ is linear in n; this is reasonable because $\mathbf{X}^T\mathbf{X}=\sum_{i=1}^n\mathbf{x}_i\mathbf{x}_i^T$ and $\mathbf{V}$ is an orthogonal matrix.

- **Bias.** The bias of $\mathbf{W}^\star$ is independent of n and is increasing with γ. The bias is the price paid for using regularization to decrease the variance; for least squares regression, γ is zero, and the bias is zero.
- **Variance.** The variance of $\mathbf{W}^\star$ is inversely proportional to n. As n grows, the variance decreases to zero, and we must also decrease γ to ensure that the sum of the squared bias and variance decreases to zero.
- **Risk.** Note that $\mathbf{W}^\star$ is not the minimizer of $R(\cdot)$; $\mathbf{W}_0$ is the minimizer because $R(\mathbf{W}_0)=0$. Nevertheless, because $\mathbf{W}_0$ is unknown, $\mathbf{W}^\star$ for a carefully chosen γ is a standard proxy for the exact minimizer in practice. It is thus highly interesting to compare the risk of MRR solutions obtained using sketching to to $R(\mathbf{W}^\star)$.

Theorem 5 provides upper and lower bounds on the bias and variance of solutions obtained using classical sketch. In particular, we see that that $\mathsf{bias}(\mathbf{W}^{\mathrm{c}})$ is within a factor of $(1\pm\epsilon)$ of $\mathsf{bias}(\mathbf{W}^\star)$. However, $\mathsf{var}(\mathbf{W}^{\mathrm{c}})$ can be $\Theta(\frac{n}{s})$ times worse than $\mathsf{var}(\mathbf{W}^\star)$. The absolute value of $\mathsf{var}(\mathbf{W}^{\mathrm{c}})$ is inversely proportional to s, whereas the absolute value of $\mathsf{bias}(\mathbf{W}^{\mathrm{c}})$ is almost independent of s.

Theorem 5 (Classical Sketch) *Assume* $s\le n$. *For Gaussian projection and SRHT sketching with* $s=\tilde{\mathcal{O}}(\frac{d}{\epsilon^2})$, *uniform sampling with* $s=\mathcal{O}(\frac{\mu d\log d}{\epsilon^2})$, *or CountSketch with* $s=\mathcal{O}(\frac{d^2}{\epsilon^2})$, *the inequalities*

$$\begin{aligned}
1-\epsilon &\le \tfrac{\mathsf{bias}(\mathbf{W}^c)}{\mathsf{bias}(\mathbf{W}^\star)} \le 1+\epsilon,\\
(1-\epsilon)\tfrac{n}{s} &\le \tfrac{\mathsf{var}(\mathbf{W}^c)}{\mathsf{var}(\mathbf{W}^\star)} \le (1+\epsilon)\tfrac{n}{s}
\end{aligned}$$

hold with probability at least 0.9. For shrinked leverage score sampling with $s=\mathcal{O}(\frac{d\log d}{\epsilon^2})$, *these inequalities, except for the lower bound on the variance, hold with probability at least 0.9. Here the randomness comes from the sketching matrix* $\mathbf{S}$.

Remark 1 *To establish an upper (lower) bound on the variance, we need an upper (lower) bound on* $\|\mathbf{S}\|_2^2$. *There is no nontrivial upper nor lower bound on* $\|\mathbf{S}\|_2^2$ *for leverage score sampling, so the variance of leverage score sampling cannot be bounded. Shrinked leverage score sampling satisfies the upper bound* $\|\mathbf{S}\|_2^2\le\frac{2n}{s}$; *but* $\|\mathbf{S}\|_2^2$ *does not have a nontrivial lower bound, so there is no nontrivial lower bound on the variance of shrinked leverage score. Remark 4 explains the nonexistence of the relevant bounds on* $\|\mathbf{S}\|_2^2$ *for both variants of leverage score sampling.*

Theorem 6 establishes similar upper and lower bounds on the bias and variance of solutions obtained using Hessian sketch. The situation is the reverse of that with classical sketch: the variance of $\mathbf{W}^{\mathrm{h}}$ is close to that of $\mathbf{W}^\star$ if s is large enough, but as the regularization parameter γ goes to zero, $\mathsf{bias}(\mathbf{W}^{\mathrm{h}})$ becomes much larger than $\mathsf{bias}(\mathbf{W}^\star)$. The theory suggest that Hessian sketch should be preferred over classical sketch when $\mathbf{Y}$ is very noisy, because Hessian sketch does not magnify the variance.

Theorem 6 (Hessian Sketch) *For the four sketching methods with* $s=\tilde{\mathcal{O}}(\frac{d}{\epsilon^2})$, *uniform sampling with* $s=\mathcal{O}(\frac{\mu d\log d}{\epsilon^2})$, *and CountSketch with* $s=\mathcal{O}(\frac{d^2}{\epsilon^2})$, *the inequalities*

$$\begin{aligned}
\tfrac{\mathsf{bias}(\mathbf{W}^h)}{\mathsf{bias}(\mathbf{W}^\star)} &\le (1+\epsilon)\big(1+\tfrac{\epsilon\|\mathbf{X}\|_2^2}{n\gamma}\big),\\
1-\epsilon &\le \tfrac{\mathsf{var}(\mathbf{W}^h)}{\mathsf{var}(\mathbf{W}^\star)} \le 1+\epsilon
\end{aligned}$$

hold with probability at least 0.9. Further assume that the ρ*-th singular value of* $\mathbf{X}$ *satisfies* $\sigma_\rho^2\ge\frac{n\gamma}{\epsilon}$, *then*

$$\tfrac{\mathsf{bias}(\mathbf{W}^h)}{\mathsf{bias}(\mathbf{W}^\star)} \;\ge\; \tfrac{1}{1+\epsilon}\big(\tfrac{\epsilon\sigma_\rho^2}{n\gamma}-1\big)$$

with probability at least 0.9. Here the randomness is in the choice of sketching matrix $\mathbf{S}$.

The lower bound on the bias shows that the solution from Hessian sketch can exhibit a much higher bias than the optimal solution. The gap between $\mathsf{bias}(\mathbf{W}^{\mathrm{h}})$ and $\mathsf{bias}(\mathbf{W}^{\star})$ can be lessened by increasing the regularization parameter γ, but such over-regularization increases the baseline $\mathsf{bias}(\mathbf{W}^{\star})$ itself. It is also worth mentioning that unlike $\mathsf{bias}(\mathbf{W}^{\star})$ and $\mathsf{bias}(\mathbf{W}^{\mathrm{c}})$, $\mathsf{bias}(\mathbf{W}^{\mathrm{h}})$ is not monotonically increasing with γ, as is empirically verified in Figure 3.

In sum, our theory shows that the classical and Hessian sketches are not statistically comparable to the optimal solutions: classical sketch has too high a variance, and Hessian sketch has too high a bias for reasonable amounts of regularization. In practice, the regularization parameter γ should be tuned to optimize the prediction accuracy. Our experiments in Figure 3 show that even with carefully chosen γ, the risks of classical and Hessian sketch can be higher than the risk of the optimal solution by an order of magnitude. Formally speaking, $\min_\gamma R(\mathbf{W}^{\mathrm{c}}) \gg \min_\gamma R(\mathbf{W}^{\star})$ and $\min_\gamma R(\mathbf{W}^{\mathrm{h}}) \gg \min_\gamma R(\mathbf{W}^{\star})$ hold in practice.

Our empirical study in Figure 3 suggests classical and Hessian sketch both require over-regularization, i.e., setting γ larger than is best for the optimal solution $\mathbf{W}^{\star}$. Formally speaking, $\operatorname{argmin}_\gamma R(\mathbf{W}^{\mathrm{c}}) > \operatorname{argmin}_\gamma R(\mathbf{W}^{\star})$ and $\operatorname{argmin}_\gamma R(\mathbf{W}^{\mathrm{h}}) > \operatorname{argmin}_\gamma R(\mathbf{W}^{\star})$. Although this is the case for both types of sketching, the underlying explanations are different. Classical sketches have a high variance, so a large γ is required to supress their variance (the variance is non-increasing with γ). Hessian sketches magnify the bias when γ is small, so a reasonably large γ is necessary to lower their bias.

3.3 Model Averaging: Optimization Perspective

We consider model averaging as a method to increase the accuracy of sketched MRR solutions. The model averaging procedure is straightforward: one independently draws g sketching matrices $\mathbf{S}_1, \cdots, \mathbf{S}_g \in \mathbb{R}^{n\times s}$, uses these to form g sketched MRR solutions, denoted by $\{\mathbf{W}_i^{\mathrm{c}}\}_{i=1}^g$ or $\{\mathbf{W}_i^{\mathrm{h}}\}_{i=1}^g$, and averages these solutions to obtain the final estimate $\mathbf{W}^{\mathrm{c}} = \frac{1}{g}\sum_{i=1}^g \mathbf{W}_i^{\mathrm{c}}$ or $\mathbf{W}^{\mathrm{h}} = \frac{1}{g}\sum_{i=1}^g \mathbf{W}_i^{\mathrm{h}}$. Practical applications of model averaging are enumerated in Section 1.1.

Theorems 7 and 8 present guarantees on the optimization accuracy of using model averaging on classical/Hessian sketch solutions. We can contrast these with the guarantees provided for sketched MRR in Theorems 1 and 2. For classical sketch with model averaging, we see that when $\epsilon \le \frac{1}{g}$, the bound on $f(\mathbf{W}^{\mathrm{h}}) - f(\mathbf{W}^{\star})$ is proportional to ϵ/g. From Lemma 3 we see that the distance between $\mathbf{W}^{\mathrm{c}}$ and $\mathbf{W}^{\star}$ also decreases accordingly.

Theorem 7 (Classical Sketch with Model Averaging) *Let $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2+n\gamma} \le 1$. For the four methods, let $s = \tilde{\mathcal{O}}\big(\frac{d}{\epsilon}\big)$, and for uniform sampling, let $s = \mathcal{O}\big(\frac{\mu d\log d}{\epsilon}\big)$, then the inequality*

$$f(\mathbf{W}^{\mathrm{c}}) - f(\mathbf{W}^{\star}) \;\le\; \beta\Big(\frac{\epsilon}{g} + \beta^2\epsilon^2\Big) f(\mathbf{W}^{\star})$$

holds with probability at least 0.8. Here the randomness comes from the choice of sketching matrices.

For Hessian sketch with model averaging, if $\epsilon < \frac{1}{g}$, then the bound on $f(\mathbf{W}^{\mathrm{h}}) - f(\mathbf{W}^{\star})$ is proportional to $\frac{\epsilon}{g}$.

Theorem 8 (Hessian Sketch with Model Averaging) *Let $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2+n\gamma} \le 1$. For the four methods let $s = \tilde{\mathcal{O}}\big(\frac{d}{\epsilon}\big)$, and for uniform sampling let $s = \mathcal{O}\big(\frac{\mu d\log d}{\epsilon}\big)$, then the inequality*

$$f(\mathbf{W}^{h}) - f(\mathbf{W}^{\star}) \;\le\; \beta^2\Big(\frac{\epsilon}{g} + \epsilon^2\Big)\Big(\frac{\|\mathbf{Y}\|_F^2}{n} - f(\mathbf{W}^{\star})\Big)$$

holds with probability at least 0.8. Here the randomness comes from the choice of sketching matrices.

3.4 Model Averaging: Statistical Perspective

Model averaging has the salutatory property of reducing the risks of the classical and Hessian sketches. Our first result conducts a bias-variance decomposition for the averaged solution of the sketched MRR problem.

Theorem 9 (Bias-Variance Decomposition) *We consider the fixed design model* (7). *Decompose the risk function defined in* (8) *as*

$$R(\mathbf{W}) \;=\; \mathsf{bias}^2(\mathbf{W}) + \mathsf{var}(\mathbf{W}).$$

The bias and variance terms are

$$\begin{aligned}
\mathsf{bias}\big(\mathbf{W}^{c}\big) &= \gamma\sqrt{n}\Big\|\frac{1}{g}\sum_{i=1}^g \big(\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U} + n\gamma\mathbf{\Sigma}^{-2}\big)^{\dagger}\mathbf{\Sigma}^{-1}\mathbf{V}^T\mathbf{W}_0\Big\|_F,\\
\mathsf{var}\big(\mathbf{W}^{c}\big) &= \frac{\xi^2}{n}\Big\|\frac{1}{g}\sum_{i=1}^g \big(\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U} + n\gamma\mathbf{\Sigma}^{-2}\big)^{\dagger}\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\Big\|_F^2,\\
\mathsf{bias}\big(\mathbf{W}^{h}\big) &= \gamma\sqrt{n}\Big\|\frac{1}{g}\sum_{i=1}^g \big(\mathbf{\Sigma}^{-2} + \tfrac{\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U}-\mathbf{I}_\rho}{n\gamma}\big)\big(\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U} + n\gamma\mathbf{\Sigma}^{-2}\big)^{\dagger}\mathbf{\Sigma}\mathbf{V}^T\mathbf{W}_0\Big\|_F,\\
\mathsf{var}\big(\mathbf{W}^{h}\big) &= \frac{\xi^2}{n}\Big\|\frac{1}{g}\sum_{i=1}^g \big(\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U} + n\gamma\mathbf{\Sigma}^{-2}\big)^{\dagger}\Big\|_F^2.
\end{aligned}$$

Theorems 10 and 11 provide upper bounds on the bias and variance of averaged sketched MRR solutions for, respectively, classical sketch and Hessian sketch. We can contrast them with Theorems 5 and 6 to see the statistical benefits of model averaging. Theorem 10 shows that when $g \approx \frac{n}{s}$, classical sketch with model averaging yields a solution with comparable bias and variance to the optimal solution.

Theorem 10 (Classical Sketch with Model Averaging) *For the four sketching methods with $s = \tilde{\mathcal{O}}\big(\frac{d}{\epsilon^2}\big)$, or uniform sampling with $s = \mathcal{O}\big(\frac{\mu d\log d}{\epsilon^2}\big)$, the inequalities*

$$\frac{\mathsf{bias}(\mathbf{W}^{c})}{\mathsf{bias}(\mathbf{W}^{\star})} \;\le\; 1+\epsilon \qquad \text{and} \qquad \frac{\mathsf{var}(\mathbf{W}^{c})}{\mathsf{var}(\mathbf{W}^{\star})} \;\le\; \frac{n}{s}\Big(\frac{\sqrt{1+\epsilon}}{\sqrt{h}} + \epsilon\Big)^2,$$

where $h = \min\{g, \Theta(\frac{n}{s})\}$, hold with probability at least 0.8. The randomness comes from the choice of sketching matrices.

Theorem 11 shows that model averaging decreases the bias of Hessian sketch without increasing the variance. For Hessian sketch without model averaging, recall that $\mathsf{bias}(\mathbf{W}^{\mathrm{h}})$ is larger than $\mathsf{bias}(\mathbf{W}^{\star})$ by a factor of $\mathcal{O}(\|\mathbf{X}\|_2^2/(n\gamma))$. Theorem 11 shows that model averaging significantly reduces the bias.

Theorem 11 (Hessian Sketch with Model Averaging) *For the four sketching methods with $s = \tilde{\mathcal{O}}\big(\frac{d}{\epsilon^2}\big)$, or uniform sampling with $s = \mathcal{O}\big(\frac{\mu d \log d}{\epsilon^2}\big)$, the inequalities*

$$\frac{\mathsf{bias}(\mathbf{W}^h)}{\mathsf{bias}(\mathbf{W}^\star)} \leq 1 + \epsilon + \Big(\frac{\epsilon}{\sqrt{g}} + \epsilon^2\Big)\frac{\|\mathbf{X}\|_2^2}{n\gamma} \qquad \textit{and} \qquad \frac{\mathsf{var}(\mathbf{W}^h)}{\mathsf{var}(\mathbf{W}^\star)} \leq 1 + \epsilon$$

hold with probability at least 0.8. Here the randomness comes from the choice of sketching matrices.

4. Experiments on Synthetic Data

We conduct experiments on synthetic data to verify our theory. Section 4.1 describes the data model and experiment settings. Sections 4.2 and 4.3 empirically study classical and Hessian sketch from the optimization and statistical perspectives, respectively, to verify Theorems 1, 2, 5, and 6. Sections 4.4 and 4.5 study model averaging from the optimization and statistical perspectives, respectively, to corroborate Theorems 7, 8, 10, and 11.

4.1 Settings

Following (Ma et al., 2015; Yang et al., 2016), we construct $\mathbf{X} = \mathbf{U}\mathsf{diag}(\boldsymbol{\sigma})\mathbf{V}^T \in \mathbb{R}^{n\times d}$ and $\mathbf{y} = \mathbf{X}\mathbf{w}_0 + \boldsymbol{\varepsilon} \in \mathbb{R}^n$ in the following way.

- We take $\mathbf{U}$ be the matrix of left singular vectors of $\mathbf{A} \in \mathbb{R}^{n\times d}$ which is constructed in the following way. (Note that $\mathbf{A}$ and $\mathbf{X}$ are different.) Let the rows of $\mathbf{A}$ be i.i.d. sampled from a multivariate t-distribution with covariance matrix $\mathbf{C}$ and $v = 2$ degree of freedom, where the (i,j)-th entry of $\mathbf{C} \in \mathbb{R}^{d\times d}$ is $2 \times 0.5^{|i-j|}$. Constructing $\mathbf{A}$ in this manner ensures that it has high row coherence.
- Let the entries of $\mathbf{b} \in \mathbb{R}^d$ be equally spaced between 0 and -6 and take $\sigma_i = 10^{b_i}$ for all $i \in [d]$.
- Let $\mathbf{V} \in \mathbb{R}^{d\times d}$ be an orthonormal basis for the column range of a $d \times d$ standard Gaussian matrix.
- Let $\mathbf{w}_0 = [\mathbf{1}_{0.2d}; 0.1\,\mathbf{1}_{0.6d}; \mathbf{1}_{0.2d}]$.
- Take the entries of $\boldsymbol{\varepsilon} \in \mathbb{R}^n$ to be i.i.d. samples from the $\mathcal{N}(0, \xi^2)$ distribution.

This construction ensures that $\mathbf{X}$ has high row coherence, and its condition number is $\kappa(\mathbf{X}^T\mathbf{X}) = 10^{12}$. Let $\mathbf{S} \in \mathbb{R}^{n\times s}$ be any of the six sketching methods considered in this paper. We fix $n = 10^5$, $d = 500$, and $s = 5,000$. Since the sketching methods are randomized, we repeat each trial 10 times with idependent sketches and report averaged results.

4.2 Sketched MRR: Optimization Perspective

We seek to empirically verify Theorems 1 and 2 which study classical and Hessian sketches, respective, from the optimization perspective. In Figure 2, we plot the objective function value $f(\mathbf{w}) = \frac{1}{n}\|\mathbf{X}\mathbf{w} - \mathbf{y}\|_2^2 + \gamma\|\mathbf{w}\|_2^2$ against γ, under different settings of ξ (the standard deviation of the Gaussian noise added to the response). The black curves correspond to the optimal solution $\mathbf{w}^\star$; the color curves correspond to classical or Hessian sketch with different

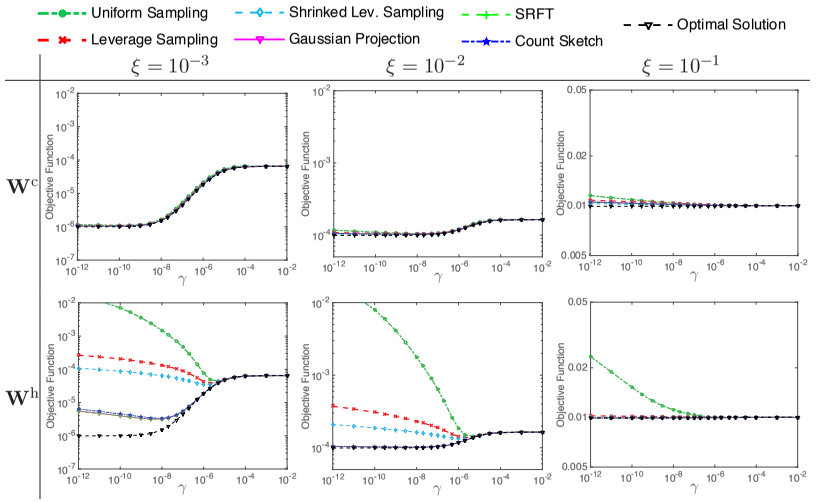

Figure 2: An empirical study of classical and Hessian sketch from the optimization perspective. The x-axis is the regularization parameter γ (log scale); the y-axis is the objective function values (log scale). Here ξ is the standard deviation of the Gaussian noise added to the response.

sketching methods. The results verify our theory: the objective value of the solution from the classical sketch, $\mathbf{w}^c$, is always close to optimal; and the objective value of the solution from the Hessian sketch, $\mathbf{w}^h$, is much worse than the optimal value when γ is small and $\mathbf{y}$ is mostly in the column space of $\mathbf{X}$.

4.3 Sketched MRR: Statistical Perspective

In Figure 3, we plot the analytical expressions for the squared bias, variance, and risk stated in Theorem 4 against the regularization parameter γ. Because these expressions involve the random sketching matrix $\mathbf{S}$, we randomly generate $\mathbf{S}$, repeat this procedure 10 times, and report the average of the computed squared biases, variances, and risks. We fix $\xi = 0.1$ (the standard deviation of the Gaussian noise). The results of this experiment match our theory: classical sketch magnified the variance, and Hessian sketch increased the bias. Even when γ is fine-tuned, the risks of classical and Hessian sketch can be much higher than those of the optimal solution. Our experiment also indicates that classical and Hessian sketch require setting γ larger than the best regularization parameter for the optimal solution $\mathbf{W}^\star$.

Classical and Hessian sketch do not outperform each other in terms of the risk. When variance dominates bias, Hessian sketch is better in terms of the risk; when bias dominates variance, classical sketch is preferable. In the experiment yielding Figure 3, Hessian sketch

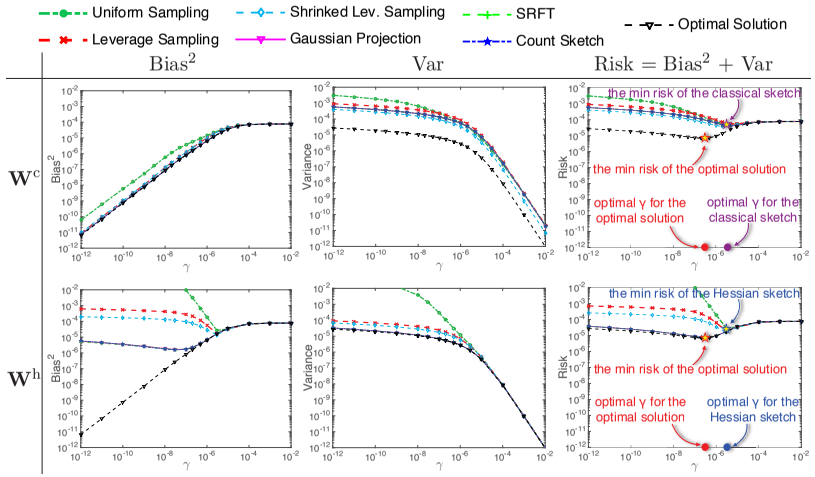

Figure 3: An empirical study of classical sketch and Hessian sketch from the statistical perspective. The x-axis is the regularization parameter γ (log-scale); the y-axes are respectively bias^2, variance, and risk (log-scale). We indicate the minimum risks and optimal choice of γ in the plots.

delivers lower risks than classical sketch. This is not generally true: if we use a smaller ξ (the standard deviation of the Gaussian noise), so that the variance is dominated by bias, then classical sketch results in lower risks than Hessian sketch.

4.4 Model Averaging: Optimization Objective

We consider different noise levels by setting $\xi = 10^{-2}$ or 10^{-1}, where ξ is defined in Section 4.1 as the standard deviation of the Gaussian noise in the response vector $\mathbf{y}$. We calculate the objective function values $f(\mathbf{w}^{\mathrm{c}}_{[g]})$ and $f(\mathbf{w}^{\mathrm{h}}_{[g]})$ for different settings of g, γ. We use different methods of sketching at the fixed sketch size $s = 5,000$.

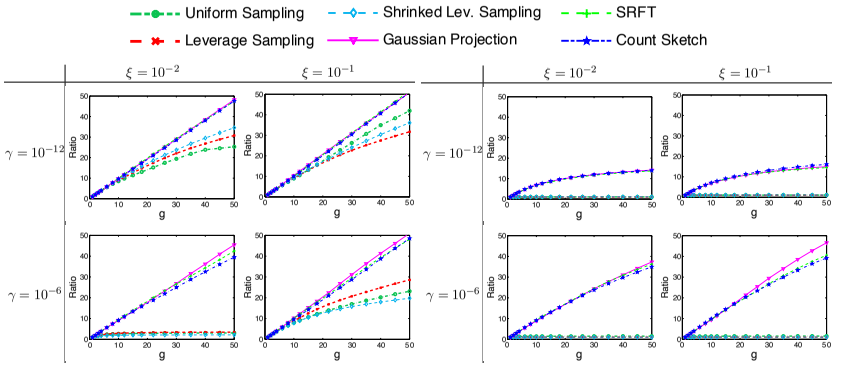
Theorem 7 indicates that for large s, e.g., Gaussian projection with $s = \tilde{\mathcal{O}}(\frac{d}{\epsilon})$,

$$f(\mathbf{w}^{\mathrm{c}}_{[g]}) - f(\mathbf{w}^\star) \quad \leq \quad \beta\left(\tfrac{\epsilon}{g} + \beta^2\epsilon^2\right) f(\mathbf{w}^\star), \tag{9}$$

where $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2 + n\gamma} \leq 1$. In Figure 4(a) we plot the ratio

$$\frac{f(\mathbf{w}^{\mathrm{c}}_{[1]}) - f(\mathbf{w}^\star)}{f(\mathbf{w}^{\mathrm{c}}_{[g]}) - f(\mathbf{w}^\star)} \tag{10}$$

against g. Rapid growth of this ratio indicates that model averaging is highly effective. The results in Figure 4(a) indicate that model averaging significantly improves the accuracy



(a) Classical sketch with model averaging. (b) Hessian sketch with model averaging.

Figure 4: An empirical study of model averaging from the optimization perspective. The x-axis is g, i.e., the number of models that are averaged. In 4(a), the y-axis is the ratio (log-scale) defined in (10). In 4(b), the y-axis is the ratio (log-scale) defined in (11). Here γ is the regularization parameter and ξ is the standard deviation of the Gaussian noise.

as measured by the objective function value. For the three random projection methods, the growth rate of this ratio is almost linear in g. In Figure 4(a), we observe that the regularization parameter γ affects the ratio (10). The ratio grows faster when $\gamma = 10^{-12}$ than when $\gamma = 10^{-6}$. This phenomenon is not explained by our theory.

Theorem 8 shows that for large sketch size s, e.g., Gaussian projection with $s = \tilde{\mathcal{O}}(\frac{d}{\epsilon})$,

$$f(\mathbf{w}^{\mathrm{h}}) - f(\mathbf{w}^\star) \quad \leq \quad \beta^2\left(\tfrac{\epsilon}{g} + \epsilon^2\right)\left(\tfrac{\|\mathbf{y}\|_2^2}{n} - f(\mathbf{w}^\star)\right),$$

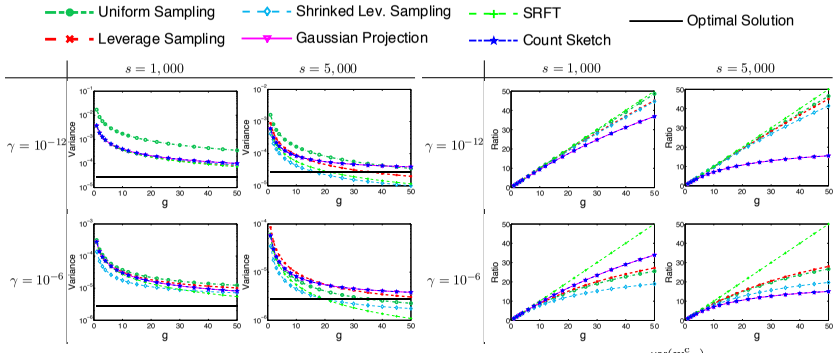
where $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2 + n\gamma} \leq 1$. In Figure 4(b), we plot the ratio

$$\frac{f(\mathbf{w}^{\mathrm{h}}_{[1]}) - f(\mathbf{w}^\star)}{f(\mathbf{w}^{\mathrm{h}}_{[g]}) - f(\mathbf{w}^\star)} \tag{11}$$

against g. Rapid growth of this ratio indicates that model averaging is highly effective. Our empirical results indicate that the growth rate of this ratio is moderately rapid for very small g and very slow for large g.

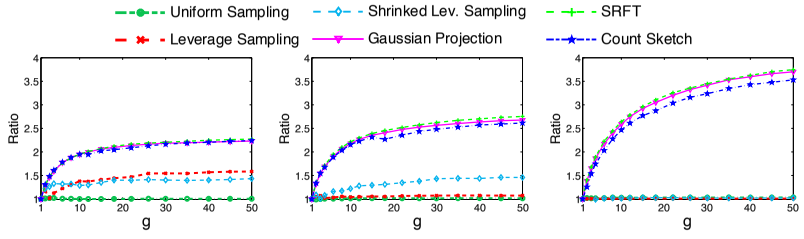
4.5 Model Averaging: Statistical Perspective

We empirically study model averaging from the statistical perspective. We calculate the bias and variance $\mathsf{bias}(\mathbf{w}^\star)$, $\mathsf{var}(\mathbf{w}^\star)$ of the optimal MRR solution according to Theorem 4



(a) The variance $\mathsf{var}(\mathbf{w}^{\mathrm{c}}_{[g]})$. (b) The ratio $\frac{\mathsf{var}(\mathbf{w}^{\mathrm{c}}_{[1]})}{\mathsf{var}(\mathbf{w}^{\mathrm{c}}_{[g]})}$.

Figure 5: An empirical study of the variance of classical sketch with model averaging. The x-axis is g, i.e., the number of models that are averaged. In 5(a), the y-axis is the variance $\mathsf{var}(\mathbf{w}^{\mathrm{c}}_{[g]})$ (log scale) defined in Theorem 9. In 5(b), the y-axis is the ratio $\frac{\mathsf{var}(\mathbf{w}^{\mathrm{c}}_{[1]})}{\mathsf{var}(\mathbf{w}^{\mathrm{c}}_{[g]})}$. Here γ is the regularization parameter and s is the sketch size.



(a) $s = 1,000$ (b) $s = 2,000$ (c) $s = 5,000$

Figure 6: An empirical study of the bias of Hessian sketch with model averaging. The x-axis is g, the number of models being averaged; the y-axis is the ratio (12).

and the bias and variance $\mathsf{bias}(\mathbf{w}^{\mathrm{c}}_{[g]})$, $\mathsf{var}(\mathbf{w}^{\mathrm{c}}_{[g]})$ and $\mathsf{bias}(\mathbf{w}^{\mathrm{h}}_{[g]})$, $\mathsf{var}(\mathbf{w}^{\mathrm{h}}_{[g]})$ of, respectively, the model averaged classical sketch solution and the model averaged Hessian sketch solution according to Theorem 9.

4.5.1 Classical Sketch

Theorem 10 indicates that for large enough s, e.g., Gaussian projection with $s = \tilde{\mathcal{O}}(\frac{d}{\epsilon^2})$, with high probability

$$\frac{\mathsf{bias}(\mathbf{w}^{\mathrm{c}}_{[g]})}{\mathsf{bias}(\mathbf{w}^\star)} \leq 1+\epsilon \qquad \text{and} \qquad \frac{\mathsf{var}(\mathbf{w}^{\mathrm{c}}_{[g]})}{\mathsf{var}(\mathbf{w}^\star)} \leq \frac{n}{s}\left(\sqrt{\frac{1+\epsilon}{h}}+\epsilon\right)^2,$$

where $h = \min\{g, \Theta(\frac{n}{s})\}$. This result implies that model averaging decreases the variance of classical sketch without significantly changing the bias. We conduct experiments to verify this point.

In Figure 5(a) we plot the variance $\mathsf{var}(\mathbf{w}^{\mathrm{c}}_{[g]})$ against g; the variance of the optimal solution $\mathbf{w}^\star$ is depicted for comparison. Clearly, the variance drops as g grows. In particular, when s is big ($s = 5,000$) and g exceeds $\frac{n}{s}$ ($= \frac{100,000}{5,000} = 20$), $\mathsf{var}(\mathbf{w}^{\mathrm{c}}_{[g]})$ can be even lower than $\mathsf{var}(\mathbf{w}^\star)$.

To more clearly decrease the impact of model averaging on the variance, in Figure 5(b) we plot the ratio $\frac{\mathsf{var}(\mathbf{w}^{\mathrm{c}}_{[1]})}{\mathsf{var}(\mathbf{w}^{\mathrm{c}}_{[g]})}$ against g. According to Theorem 10, this ratio grows linearly in g when s is at least $\tilde{\mathcal{O}}(dg)$, and otherwise is sublinear in g. This claim is verified by the empirical results in Figure 5(b).

When $\mathsf{bias}(\mathbf{w}^{\mathrm{c}}_{[g]})$ is plotted as a function of g, the curves are almost horizontal, indicating that, as expected, *the bias is insensitive to the number of models g*. We do not show such plots because these nearly horizontal curves are not interesting.

4.5.2 Hessian Sketch

Theorem 11 indicates that for large enough s, e.g., Gaussian projection with $s = \tilde{\mathcal{O}}(\frac{d}{\epsilon^2})$, the inequalities

$$\frac{\mathsf{bias}(\mathbf{w}^{\mathrm{h}}_{[g]})}{\mathsf{bias}(\mathbf{w}^\star)} \leq 1+\epsilon+\left(\frac{\epsilon}{\sqrt{g}}+\epsilon^2\right)\frac{\|\mathbf{X}\|_2^2}{n\gamma} \qquad \text{and} \qquad \frac{\mathsf{var}(\mathbf{w}^{\mathrm{h}}_{[g]})}{\mathsf{var}(\mathbf{w}^\star)} \leq 1+\epsilon$$

hold with high probability. That is, model averaging improves the bias without affecting the variance. The bound

$$\frac{\mathsf{bias}(\mathbf{w}^{\mathrm{h}}_{[g]})-\mathsf{bias}(\mathbf{w}^\star)}{\mathsf{bias}(\mathbf{w}^\star)} \leq \epsilon+\left(\frac{\epsilon}{\sqrt{g}}+\epsilon^2\right)\frac{\|\mathbf{X}\|_2^2}{n\gamma}$$

indicates that if $n\gamma$ is much smaller than $\|\mathbf{X}\|_2^2$ and $\epsilon \leq \frac{1}{\sqrt{g}}$, or equivalently, s is at least $\tilde{\mathcal{O}}(dg)$, then the ratio is proportional to $\frac{\epsilon}{\sqrt{g}}$.

To verify Theorem 11, we set γ very small—$\gamma = 10^{-12}$—and vary s and g. In Figure 6 we plot the ratio

$$\frac{\mathsf{bias}(\mathbf{w}^{\mathrm{h}}_{[1]})-\mathsf{bias}(\mathbf{w}^\star)}{\mathsf{bias}(\mathbf{w}^{\mathrm{h}}_{[g]})-\mathsf{bias}(\mathbf{w}^\star)}, \tag{12}$$

by fixing $\gamma = 10^{-12}$ and varying s and g. The theory indicates that for large sketch size $s = \tilde{\mathcal{O}}(dg^2)$, this ratio should grow nearly linearly in g. Figure 6 shows that only for large s and very small g, the growth is near linear in g; this verifies our theory.

When we similarly plot $\mathsf{var}\big(\mathbf{w}^{\mathrm{h}}_{[g]}\big)$ against g, we observe that $\mathsf{var}\big(\mathbf{w}^{\mathrm{h}}_{[g]}\big)$ remains nearly unaffected as g grows from 1 to 50. Since the curves of the variance against g are almost horizontal lines, we do not show this plot in the paper.

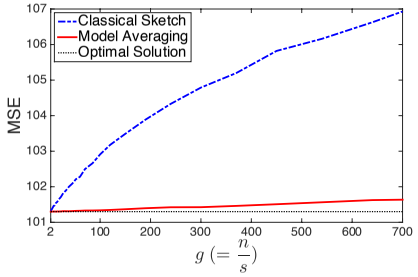


Figure 7: Prediction performance of classical sketch with and without model averaging on the Year Prediction data set. The x-axis is g, the number of data partitions, and the y-axis is the mean squared error (MSE) on the test set.

5. Model Averaging Experiments on Real-World Data

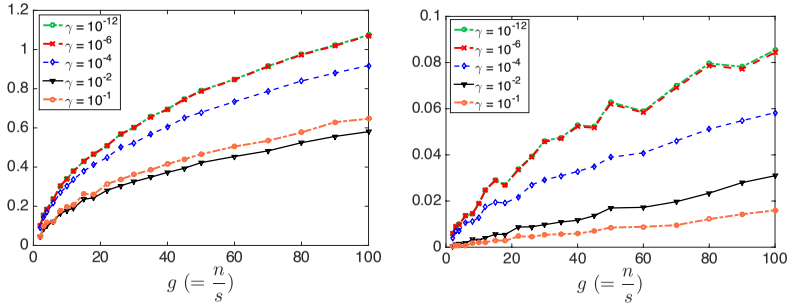
In Section 1 we mentioned that in the distributed setting where the feature-response pairs $(\mathbf{x}_1, \mathbf{y}_1), \cdots, (\mathbf{x}_n, \mathbf{y}_n) \in \mathbb{R}^{d \times m}$ are randomly and uniformly partitioned across g machines,[5] classical sketch with model averaging requires only one round of communication, and is therefore a communication-efficient algorithm that can be used to: (1) obtain an approximate solution of the MRR problem with risk comparable to a batch solution, and (2) obtain a low-precision solution of the MRR optimization problem that can be used as an initializer for more communication-intensive optimization algorithms. In this section, we demonstrate both applications.

We use the Million Song Year Prediction data set, which has $463,715$ training samples and $51,630$ test samples with 90 features and one response. We normalize the data by shifting the responses to have zero mean and scaling the range of each feature to $[-1, 1]$. We randomly partition the training data into g parts, which amounts to uniform row selection with sketch size $s = \frac{n}{g}$.

5.1 Prediction Error

We tested the prediction performance of sketched ridge regression by implementing classical sketch with model averaging in PySpark (Zaharia et al., 2010).[6] We ran our experiments using PySpark in local mode; the experiments proceeded in three steps: (1) use five-fold cross-validation to determine the regularization parameter γ; (2) learn the model $\mathbf{w}$ using the selected γ; and (3) use $\mathbf{w}$ to predict on the test set and record the mean squared errors (MSEs). These steps map cleanly onto the Map-Reduce programming model used by PySpark.

5. If the samples are i.i.d., then any deterministic partition is essentially a uniformly randomly distributed partition. Otherwise, we can invoke a Shuffle operation, which is supported by systems such as Apache Spark (Zaharia et al., 2010), to make the partitioning uniformly randomly distributed.
6. The code is available at https://github.com/wangshusen/SketchedRidgeRegression.git



(a) Classical sketch (b) Classical sketch with model averaging

Figure 8: Optimization performance of classical sketch with and without model averaging. The x-axis is g, the number of data partitions, and the y-axis is the ratio $\frac{\|\mathbf{w}-\mathbf{w}^\star\|_2}{\|\mathbf{w}^\star\|_2}$.

In Figure 7, we plot the test MSE against $g = \frac{n}{s}$. As g grows, the sketch size $s = \frac{n}{g}$ decreases, so the performance of classical sketch deteriorates. However classical sketch with model averaging always has test MSE comparable to the optimal solution.

5.2 Optimization Error

We mentioned earlier that classical sketch with or without model averaging can be used to initialize optimization algorithms for solving MRR problems. If $\mathbf{w}$ is initialized with zero-mean random variables or deterministically with zeros, then $\mathbb{E}\big[\|\mathbf{w}-\mathbf{w}^\star\|_2 / \|\mathbf{w}^\star\|_2\big] \geq 1$. Any $\mathbf{w}$ with the above ratio substantially smaller than 1 provides a better initialization. We implemented classical sketch with and without model averaging in Python and calculated the above ratio on the training set of the Year Prediction data set; to estimate the expectation, we repeated the procedure 100 times and report the average of the ratios.

In Figure 8, we plot the average of the ratio $\frac{\|\mathbf{w}-\mathbf{w}^\star\|_2}{\|\mathbf{w}^\star\|_2}$ against g for different settings of the regularization parameter γ. Clearly, classical sketch does not give a good initialization unless g is small (equivalently, the sketch size $s = \frac{n}{g}$ is large). In contrast, the averaged solution is always close to $\mathbf{w}^\star$.

6. Sketch of Proof

In this section, we outline the proofs of our main results. The complete details are provided in the appendix. Section 6.1 recaps several relevant properties of matrix sketching. Section 6.2 establishes certain properties of averages of sketches; these results are used to analyze the application of model averaging to the MRR problem. Sections 6.3 to 6.6 provide key structural results on sketched solutions to the MRR problem constructed with or without model averaging.

Our main results in Section 3 (Theorems 1, 2, 5, 6, 7, 8, 10, and 11) follow directly from the relevant properties of matrix sketching and the structural results for solutions to the

sketched MRR problem. Table 4 summarizes the dependency relationships among these theorems. For example, Theorem 1, which studies classical sketching from the optimization perspective, is one of our main theorems and is proven using Theorems 12 and 15.

Table 4: An overview of our results and their dependency relationships.

6.1 Properties of Matrix Sketching

Our analysis of the performance of solutions to the sketched MRR problem draws heavily on the three key properties defined in Assumption 1. Theorem 12 establishes that the six sketching methods considered in this paper indeed enjoy the three key properties under certain conditions. Finally, Theorem 13 establishes the lower bounds of $\|\mathbf{S}\|_2^2$ that are used to prove the lower bounds on the variance of sketched MRR solutions in Theorem 5.

Assumption 1 *Let $\eta, \epsilon \in (0,1)$ be fixed parameters. Let $\mathbf{B}$ be any fixed matrix of conformal shape, $\rho = \text{rank}(\mathbf{X})$, and $\mathbf{U} \in \mathbb{R}^{n\times\rho}$ be an orthonormal basis for the column span of $\mathbf{X}$. Let $\mathbf{S} \in \mathbb{R}^{n\times s}$ be a sketching matrix, where s depends on η and/or ϵ. Throughout this paper, we assume that $\mathbf{S}$ satisfies the following properties with a probability that depends on s:*

1.1 $\left\|\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U} - \mathbf{I}_\rho\right\|_2 \le \eta$ *(Subspace Embedding Property);*

1.2 $\left\|\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{B} - \mathbf{U}^T\mathbf{B}\right\|_F^2 \le \epsilon\|\mathbf{B}\|_F^2$ *(Matrix Multiplication Property);*

1.3 When $s < n$, $\|\mathbf{S}\|_2^2 \le \frac{\theta n}{s}$ for some constant θ (Bounded Spectral Norm Property).

The subspace embedding property requires that sketching preserves the inner products between the columns of a matrix with orthonormal columns. Equivalently, it ensures that the singular values of any sketched column-orthonormal matrix are all close to one. The subspace embedding property implies that, in particular, the squared norm of $\mathbf{Sx}$ is close to that of $\mathbf{x}$ for any n-dimensional vector in a fixed ρ-dimensional subspace. A dimension counting argument suggests that since $\mathbf{Sx}$ is an s-dimensional vector, its length must be scaled by a factor of $\sqrt{\frac{n}{s}}$ to ensure that this consequence of the subspace embedding property holds. The bounded spectral norm property requires that the spectral norm of $\mathbf{S}$ is not much larger than this rescaling factor of $\sqrt{\frac{n}{s}}$.

Remark 2 *The first two assumptions were identified in (Mahoney, 2011) and are the relevant structural conditions that allow strong results from the optimization perspective.*

Table 5: The two middle columns provide an upper bound on the sketch size s needed to satisfy the subspace embedding property and the matrix multiplication property, respectively, under the different sketching modalities considered; the right column lists the parameter θ with which the bounded spectral norm property holds. These properties hold with constant probability for the indicated values of s. Here τ is defined in (5) and reflects the quality of the approximation of the leverage scores of $\mathbf{U}$; μ is the row coherence of $\mathbf{U}$. For Gaussian projection and CountSketch, the small-o notation is a consequence of $s = o(n)$.

Sketching	Subspace Embedding	Matrix Multiplication	Spectral Norm
Leverage	$s = \mathcal{O}\left(\frac{\tau\rho}{\eta^2}\log\frac{\rho}{\delta_1}\right)$	$s = \mathcal{O}\left(\frac{\tau\rho}{\epsilon\delta_2}\right)$	$\theta = \infty$
Uniform	$s = \mathcal{O}\left(\frac{\mu\rho}{\eta^2}\log\frac{\rho}{\delta_1}\right)$	$s = \mathcal{O}\left(\frac{\mu\rho}{\epsilon\delta_2}\right)$	$\theta = 1$
Shrinked Leverage	$s = \mathcal{O}\left(\frac{\tau\rho}{\eta^2}\log\frac{\rho}{\delta_1}\right)$	$s = \mathcal{O}\left(\frac{\tau\rho}{\epsilon\delta_2}\right)$	$\theta = 2$
SRHT	$s = \mathcal{O}\left(\frac{\rho+\log n}{\eta^2}\log\frac{\rho}{\delta_1}\right)$	$s = \mathcal{O}\left(\frac{\rho+\log n}{\epsilon\delta_2}\right)$	$\theta = 1$
Gaussian Projection	$s = \mathcal{O}\left(\frac{\rho+\log(1/\delta_1)}{\eta^2}\right)$	$s = \mathcal{O}\left(\frac{\rho}{\epsilon\delta_2}\right)$	$\theta = 1 + o(1)$ w.h.p.
CountSketch	$s = \mathcal{O}\left(\frac{\rho^2}{\delta_1\eta^2}\right)$	$s = \mathcal{O}\left(\frac{\rho}{\epsilon\delta_2}\right)$	$\theta = 1 + o(1)$ w.h.p.

The third assumption is new, but Ma et al. (2015); Raskutti and Mahoney (2016) demonstrated that some sort of additional condition is necessary to obtain strong results from the statistical perspective.

Remark 3 *We note that $\mathbf{U}^T\mathbf{U} = \mathbf{I}_\rho$, and thus Assumption 1.1 can be expressed in the form of an approximate matrix multiplication bound (Drineas et al., 2006a). We call it the Subspace Embedding Property since, as first highlighted in Drineas et al. (2006b), this subspace embedding property is the key result necessary to obtain high-quality sketching algorithms for regression and related problems.*

Theorem 12 shows that the six sketching methods satisfy the three properties when s is sufficiently large. In particular, Theorem 12 shows that for all the sketching methods except leverage score sampling,[7] $\|\mathbf{S}\|_2^2$ has nontrivial upper bound. This is why Theorems 5 and 10 do not apply to leverage score sampling. This fact can also be viewed as a motivation to use shrinked leverage score sampling. We prove Theorem 12 in Appendix A.

Theorem 12 *Fix failure probability δ and error parameters η and ϵ; set the sketch size s as Table 5. Assumption 1.1 is satisfied with probability at least $1 - \delta_1$. Assumption 1.2 is satisfied with probability at least $1 - \delta_2$. Assumption 1.3 is satisfied either surely or with high probability (w.h.p.); the parameter θ is indicated in Table 5.*

Theorem 13 establishes lower bounds on $\|\mathbf{S}\|_2^2$, and will be applied to prove the lower bound on the variance of the classical sketch. From Table 6 we see that the lower bound for

7. If one leverage score approaches zero, then the corresponding sampling probability p_i goes to zero. By the definition of $\mathbf{S}$, the scale factor $\frac{1}{\sqrt{sp_i}}$ goes to infinity, which makes $\|\mathbf{S}\|_2^2$ unbounded. The shinked leverage score sampling avoids this problem and is thus a better choice than the leverage score sampling.

(shrinked) leverage score sampling is not interesting, because μ can be very large. This is why Theorem 5 does not provide a lower bound for shrinked leverage score sampling. We prove Theorem 13 in Appendix A.

Table 6: Lower bounds on ϑ for the sketching modalities (ϑ is defined in Theorem 13). The shrinked leverage score sampling is performed using the row leverage scores of a matrix $\mathbf{X} \in \mathbb{R}^{n\times d}$, and μ is the row coherence of $\mathbf{X}$.

Uniform	$\vartheta = 1$
Leverage	$\vartheta \geq \frac{1}{\mu}$
Shrinked Leverage	$\vartheta \geq \frac{2}{1+\mu}$
SRHT	$\vartheta = 1$
Gaussian Projection	$\vartheta \geq 1 - o(1)$ w.h.p.
CountSketch	$\vartheta \geq 1 - o(1)$ w.h.p.

Theorem 13 (Semidefinite Lower Bound on the Sketching Matrix) *When $s < n$, $\mathbf{S}^T\mathbf{S} \succeq \frac{\vartheta n}{s}\mathbf{I}_s$ holds either surely or with high probability (w.h.p.), where Table 6 provides the applicable ϑ for each sketching method.*

Remark 4 *Let $p_1, \cdots, p_n$ be an arbitrary set of sampling probabilities. By the definition of the associated sampling matrix $\mathbf{S} \in \mathbb{R}^{n\times s}$, the non-zero entries of $\mathbf{S}$ can be any of $\frac{1}{\sqrt{sp_i}}$, for $i \in [n]$.*

For leverage score sampling, since the smallest sampling probability can be zero or close, and the largest sampling probability can be close to one, $\|\mathbf{S}\|_2^2$ has no nontrivial upper or lower bound.[8] *It is because $\min_i p_i$ can be close to zero and $\max_i p_i$ can be large (close to one).*

For shrinked leverage score sampling, because $\min_i p_i$ is at least $\frac{1}{2n}$, $\|\mathbf{S}\|_2^2$ has a nontrivial upper bound; but as in the case of leverage score sampling, since $\max_i p_i$ can be large, there is no nontrivial lower bound on $\|\mathbf{S}\|_2^2$.

6.2 Matrix Sketching with Averaging

Assumptions 1.1 and 1.2 imply that sketching can be used to approximate certain matrix products, but what happens if we independently draw g sketches, use them to approximate the same matrix product, and then average the g results? Intuitively, averaging should lower the variance of the approximation without affecting its bias, and thus provide a better approximation of the true product.

To justify this intuition formally, let $\mathbf{S}_1, \cdots, \mathbf{S}_g \in \mathbb{R}^{n\times s}$ be sketching matrices and $\mathbf{A}$ and $\mathbf{B}$ be fixed conformal matrices. Then evidently

$$\frac{1}{g}\sum_{i=1}^{g} \mathbf{A}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{B} \;=\; \mathbf{A}^T\mathbf{S}\mathbf{S}^T\mathbf{B},$$

8. In our application, nontrivial bound means $\|\mathbf{S}\|_2^2$ is of order $\frac{n}{s}$.

where $\mathbf{S} = \frac{1}{\sqrt{g}}[\mathbf{S}_1, \cdots, \mathbf{S}_g] \in \mathbb{R}^{n\times gs}$ can be thought of as a sketching matrix formed by concatenating the g smaller sketching matrices. If $\mathbf{S}_1, \cdots, \mathbf{S}_g$ are all instance of column selection, SRHT, or Gaussian projection sketching matrices, then $\mathbf{S}$ is a larger instance of the same type of sketching matrix.[9]

To analyze the effect of model averaging on the solution to the sketched MRR problem, we make the following assumptions on the concatenated sketch matrix. Assumption 2.1 is the subspace embedding property, Assumption 2.2 is the matrix multiplication property, and Assumption 2.3 is the bounded spectral norm property.

Assumption 2 *Let $\eta, \epsilon \in (0,1)$ be fixed parameters. Let $\mathbf{B}$ be any fixed matrix of proper size, $\rho = \mathrm{rank}(\mathbf{X})$, and $\mathbf{U} \in \mathbb{R}^{n\times\rho}$ be an orthonormal basis for the column span of $\mathbf{X}$. Let $\mathbf{S}_1, \cdots, \mathbf{S}_g \in \mathbb{R}^{n\times s}$ be sketching matrices and $\mathbf{S} = \frac{1}{\sqrt{g}}[\mathbf{S}_1, \cdots, \mathbf{S}_g] \in \mathbb{R}^{n\times gs}$; here s depends on η and/or ϵ. Throughout this paper we assume that $\mathbf{S}$ and the $\mathbf{S}_i$ satisfy the following properties with a probability that depends on g and s:*

2.1 $\left\|\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U} - \mathbf{I}_\rho\right\|_2 \leq \eta$ *for all* $i \in [g]$ *and* $\left\|\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U} - \mathbf{I}_\rho\right\|_2 \leq \frac{\eta}{\sqrt{g}}$;

2.2 $\left(\frac{1}{g}\sum_{i=1}^{g}\left\|\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{B} - \mathbf{U}^T\mathbf{B}\right\|_F\right)^2 \leq \epsilon\|\mathbf{B}\|_F^2$ *and* $\left\|\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{B} - \mathbf{U}^T\mathbf{B}\right\|_F^2 \leq \frac{\epsilon}{g}\|\mathbf{B}\|_F^2$;

2.3 For some constant θ, $\|\mathbf{S}_i\|_2^2 \leq \frac{\theta n}{s}$ *for all* $i \in [g]$, *and* $\|\mathbf{S}\|_2^2 \leq \frac{\theta n}{gs}$ *for* $gs < n$.

Except in the case of leverage score sampling, when gs is comparable to or larger than n, $\|\mathbf{S}\|_2^2 = \Theta(1)$.

Theorem 14 establishes that random column selection, SRHT, and Gaussian projection matrices satisfy Assumptions 2.1, 2.2, and 2.3. We prove Theorem 14 in Appendix A.

Theorem 14 *Let $\mathbf{S}_1, \cdots, \mathbf{S}_g \in \mathbb{R}^{n\times s}$ be independent and identically distributed random sketching matrices that are either column selection, SRHT, or Gaussian projection matrices. Fix a failure probability δ and error parameters η and ϵ, then set the sketch size s as Table 5.*

Assumption 2.1 holds with probability at least $1 - (g+1)\delta_1$. Assumption 2.2 holds with probability at least $1 - 2\delta_2$. Assumption 2.3 is satisfied either surely or with high probability, with the parameter θ specified in Table 5.

In Theorem 12, Assumption 1.1 fails with probability at most δ_1. In contrast, in Theorem 14, the counterpart assumption fails with probability at most $(g+1)\delta_1$. However, this makes little difference in practice, because the dependence of s on δ_1 is logarithmic, so δ_1 can be set very small (recall Table 5) without increasing s significantly.

Remark 5 *We do not know whether CountSketch enjoys the properties in Assumption 2. There are two difficulties in establishing this using the same route as is employed in our proof of Theorem 12 for other sketching methods. First, the concatenation of multiple CountSketch matrices is not a CountSketch matrix. Second, the probability that a CountSketch matrix does not have the subspace embedding property is constant, rather than exponentially small.*

9. CountSketch sketching matrices does not have this property. If $\mathbf{S}_i \in \mathbb{R}^{n\times s}$ is a CountSketch matrix, then it has only one non-zero entry in each row. In contrast, $\mathbf{S} \in \mathbb{R}^{n\times gs}$ has g non-zero entries in each row.

6.3 Sketched MRR: Optimization Perspective

The randomness in the performance of the classical and Hessian sketch is entirely due to the choice of random sketching matrix. We now assume that the randomly sampled sketching matrices are "nice" in that they satisfy the assumptions just introduced, and state deterministic results on the optimization performance of the classical and Hessian sketches.

Theorem 15 holds under the subspace embedding property and the matrix multiplication property (Assumptions 1.1 and 1.2), and quantifies the suboptimality of the classical sketch. We prove this result in Appendix B.

Theorem 15 (Classical Sketch) *Let Assumptions 1.1 and 1.2 hold for the sketching matrix* $\mathbf{S} \in \mathbb{R}^{n\times s}$. *Let* η *and* ϵ *be defined in Assumption 1, and let* $\alpha = \frac{2\max\{\epsilon,\eta^2\}}{1-\eta}$ *and* $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2+n\gamma}$, *then*

$$f(\mathbf{W}^c) - f(\mathbf{W}^\star) \;\; \leq \;\; \alpha\beta f(\mathbf{W}^\star).$$

Theorem 16 holds under the subspace embedding property (Assumption 1.1), and quantifies the suboptimality of the Hessian sketch. We prove this result in Appendix B.

Theorem 16 (Hessian Sketch) *Let Assumption 1.1 hold for the sketching matrix* $\mathbf{S} \in \mathbb{R}^{n\times s}$. *Let* η *be defined in Assumption 1 and* $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2+n\gamma}$, *then*

$$f(\mathbf{W}^h) - f(\mathbf{W}^\star) \;\; \leq \;\; \frac{\eta^2\beta^2}{(1-\eta)^2}\Big(\frac{\|\mathbf{Y}\|_F^2}{n} - f(\mathbf{W}^\star)\Big).$$

6.4 Sketched MRR: Statistical Perspective

Similarly, we assume that the randomly sampled sketching matrices are nice, and state deterministic results on the bias and variance of the classical and Hessian sketches.

Theorem 17 holds under the subspace embedding property (Assumption 1.1) and the bounded spectral norm property (Assumption 1.3), and bounds the bias and variance of the classical sketch. Specifically, it shows that the bias of the classical sketch is close to that of the optimal solution, but that the variance may be much larger. We prove this result in Appendix C.

Theorem 17 (Classical Sketch) *Let* η *and* θ *be defined in Assumption 1. Under Assumption 1.1, it holds that*

$$\tfrac{1}{1+\eta} \;\leq\; \tfrac{\mathsf{bias}(\mathbf{W}^c)}{\mathsf{bias}(\mathbf{W}^\star)} \;\leq\; \tfrac{1}{1-\eta}.$$

Further assume $s \leq n$; *under Assumptions 1.1 and 1.3, it holds that*

$$\tfrac{\mathsf{var}(\mathbf{W}^c)}{\mathsf{var}(\mathbf{W}^\star)} \;\leq\; \tfrac{(1+\eta)}{(1-\eta)^2}\tfrac{\theta n}{s}.$$

Theorem 18 establishes a lower bound on the variance of the classical sketch. We prove this result in Appendix C.

Theorem 18 (Lower Bound on the Variance) *Under Assumption 1.1 and the additional assumption that* $\mathbf{S}^T\mathbf{S} \succeq \frac{\vartheta n}{s}\mathbf{I}_s$, *it holds that*

$$\tfrac{\mathsf{var}(\mathbf{W}^c)}{\mathsf{var}(\mathbf{W}^\star)} \;\; \geq \;\; \tfrac{1-\eta}{(1+\eta)^2}\tfrac{\vartheta n}{s}.$$

Theorem 19 holds under the subspace embedding property (Assumption 1.1), and quantifies the bias and variance of the Hessian sketch. We prove this result in Appendix C.

Theorem 19 (Hessian Sketch) *Let* η *be defined in Assumption 1, take* $\rho = \mathrm{rank}(\mathbf{X})$, *and let* $\sigma_1 \geq \cdots \geq \sigma_\rho$ *be the singular values of* $\mathbf{X}$. *Under Assumption 1.1, it holds that*

$$\tfrac{\mathsf{bias}(\mathbf{W}^h)}{\mathsf{bias}(\mathbf{W}^\star)} \;\leq\; \tfrac{1}{1-\eta}\Big(1 + \tfrac{\eta\sigma_1^2}{n\gamma}\Big),$$
$$\tfrac{1}{1+\eta} \;\leq\; \tfrac{\mathsf{var}(\mathbf{W}^h)}{\mathsf{var}(\mathbf{W}^\star)} \;\leq\; \tfrac{1}{1-\eta}.$$

Further assume that $\sigma_\rho^2 \geq \frac{n\gamma}{\eta}$. *Then*

$$\tfrac{\mathsf{bias}(\mathbf{W}^h)}{\mathsf{bias}(\mathbf{W}^\star)} \;\geq\; \tfrac{1}{1+\eta}\Big(\tfrac{\eta\sigma_\rho^2}{n\gamma} - 1\Big).$$

6.5 Model Averaging: Optimization Perspective

Theorem 20 holds under the subspace embedding property (Assumption 2.1) and the matrix multiplication property (Assumption 2.2). We prove this result in Appendix D.

Theorem 20 (Classical Sketch with Model Averaging) *Let* η *and* ϵ *be defined in Assumption 2, and let* $\alpha = 2\big(\frac{1}{\sqrt{g}} + 2\beta\eta\big)^2\max\{\epsilon,\eta^2\}$ *and* $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2+n\gamma} \leq 1$. *Under Assumption 2.1 and 2.2, we have that*

$$f(\mathbf{W}^c) - f(\mathbf{W}^\star) \;\; \leq \;\; \alpha\beta f(\mathbf{W}^\star).$$

Theorem 21 holds under the subspace embedding property (Assumption 2.1), and is proven in Appendix D.

Theorem 21 (Hessian Sketch with Model Averaging) *Let* η *be defined in Assumption 2, and let* $\alpha = \big(\frac{\eta}{\sqrt{g}} + \frac{\eta^2}{1-\eta}\big)$ *and* $\beta = \frac{\|\mathbf{X}\|_2^2}{\|\mathbf{X}\|_2^2+n\gamma} \leq 1$. *Under Assumption 2.1, we have that*

$$f(\mathbf{W}^h) - f(\mathbf{W}^\star) \;\; \leq \;\; \alpha^2\beta^2\Big(\tfrac{1}{n}\|\mathbf{Y}\|_F^2 - f(\mathbf{W}^\star)\Big).$$

6.6 Model Averaging: Statistical Perspective

Theorem 22 requires the subspace embedding property (Assumption 2.1). In addition, to bound the variance, the spectral norms of $\mathbf{S}_1, \cdots, \mathbf{S}_g$ and $\mathbf{S} = \frac{1}{\sqrt{g}}[\mathbf{S}_1, \cdots, \mathbf{S}_g]$ must be bounded (Assumption 2.3). This result shows that model averaging decreases the variance of the classical sketch without increasing its bias. We prove this result in Appendix E.

Theorem 22 (Classical Sketch with Model Averaging) *Under Assumption 2.1, it holds that*

$$\frac{\mathsf{bias}(\mathbf{W}^c)}{\mathsf{bias}(\mathbf{W}^\star)} \;\leq\; \frac{1}{1-\eta}.$$

Under Assumptions 2.1 and 2.3, it holds that

$$\frac{\mathsf{var}(\mathbf{W}^c)}{\mathsf{var}(\mathbf{W}^\star)} \;\leq\; \frac{\theta n}{s}\left(\frac{\sqrt{1+\eta/\sqrt{g}}}{\sqrt{h}} + \frac{\eta\sqrt{1+\eta}}{1-\eta}\right)^2.$$

Here η and θ are defined in Assumption 2 and $h = \min\{g, \frac{n}{s}(1-o(1))\}$,

Theorem 23 requires the subspace embedding property (Assumption 2.1), and shows that model averaging decreases the bias of the Hessian sketch without increasing its variance. We prove this result in Appendix E.

Theorem 23 (Hessian Sketch with Model Averaging) *Under Assumption 2.1, it holds that:*

$$\frac{\mathsf{bias}(\mathbf{W}^h)}{\mathsf{bias}(\mathbf{W}^\star)} \;\leq\; \frac{1}{1-\eta} + \Big(\frac{\eta}{\sqrt{g}} + \frac{\eta^2}{1-\eta}\Big)\frac{\|\mathbf{X}\|_2^2}{n\gamma},$$
$$\frac{\mathsf{var}(\mathbf{W}^h)}{\mathsf{var}(\mathbf{W}^\star)} \;\leq\; \frac{1}{1-\eta}.$$

Here η is defined in Assumption 2.

7. Conclusions

We studied sketched matrix ridge regression (MRR) from the optimization and statistical perspectives. Using classical sketch, by taking a large enough sketch, one can obtain an ϵ-accurate approximate solution. Counterintuitively and in contrast to classical sketch, the relative error of Hessian sketch increases as the responses $\mathbf{Y}$ are better approximated by linear combinations of the columns of $\mathbf{X}$. Both classical and Hessian sketches can have statistical risks that are worse than the risk of the optimal solution by an order of magnitude.

We proposed the use of model averaging to attain better optimization and statistical properties. We have shown that model averaging leads to substantial improvements in the theoretical error bounds, suggesting applications in distributed optimization and machine learning. We also empirically verified its practical benefits.

Our fixed-design statistical analysis has limitations. We have shown that the classical sketch and Hessian sketch can significantly increase the in-sample statistical risk, which implies large training error, and that model averaging can alleviate such problems. However, our statistical results are not directly applicable to an unseen test sample. We conjecture that the generalization error can be bounded by following the random design analysis of Hsu et al. (2014), which is left as future work.

Appendix A. Properties of Matrix Sketching: Proofs

In Section A.1 we prove Theorem 12. In Section A.2, we prove Theorem 13. In Section A.3 we prove Theorem 14.

A.1 Proof of Theorem 12

We prove that the six sketching methods considered in this paper satisfy the three key properties. In Section A.1.1 we show the six sketching methods satisfy Assumptions 1.1 and 1.2. In section A.1.2 we show the six sketching methods satisfy Assumption 1.3.

A.1.1 Proof of Assumptions 1.1 and 1.2

For uniform sampling, leverage score sampling, Gaussian projection, SRHT, and CountSketch, the subspace embedding property and matrix multiplication property have been established by the previous works (Drineas et al., 2008, 2011; Meng and Mahoney, 2013; Nelson and Nguyên, 2013; Tropp, 2011; Woodruff, 2014). See also (Wang et al., 2016b) for a summary.

In the following we prove only that **shrinked leverage score sampling** satisfies assumptions 1.1 and 1.2. We cite the following lemma from (Wang et al., 2016a); this lemma was first established in the works (Drineas et al., 2008; Gittens, 2011; Woodruff, 2014).

Lemma 24 (Wang et al. (2016a)) *Let $\mathbf{U} \in \mathbb{R}^{n\times\rho}$ be a fixed matrix with orthonormal columns. Let the column selection matrix $\mathbf{S} \in \mathbb{R}^{n\times s}$ sample s columns according to probabilities $p_1, p_2, \cdots, p_n$. Assume $\alpha \geq \rho$ and*

$$\max_{i\in[n]} \frac{\|\mathbf{u}_{i:}\|_2^2}{p_i} \;\leq\; \alpha.$$

When $s \geq \alpha\frac{6+2\eta}{3\eta^2}\log(\rho/\delta_1)$, it holds that

$$\mathbb{P}\Big\{\big\|\mathbf{I}_\rho - \mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}\big\|_2 \;\geq\; \eta\Big\} \;\leq\; \delta_1.$$

When $s \geq \frac{\alpha}{\epsilon\delta_2}$, it holds that

$$\mathbb{E}\big\|\mathbf{U}\mathbf{B} - \mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{B}\big\|_F^2 \;\leq\; \delta_2\epsilon\|\mathbf{B}\|_F^2;$$

as a consequence of Markov's inequality, it holds that

$$\mathbb{P}\Big\{\big\|\mathbf{U}\mathbf{B} - \mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{B}\big\|_F^2 \;\geq\; \epsilon\|\mathbf{B}\|_F^2\Big\} \;\leq\; \delta_2.$$

Here the expectation and probability are with respect to the randomness in $\mathbf{S}$.

Now we apply the above lemma to analyze **shrinked leverage score sampling**. Given the approximate shrinked leverage scores defined in (5), the sampling probabilities satisfy

$$p_i \;=\; \tfrac{1}{2}\big(\tfrac{1}{n} + \tfrac{\tilde{l}_i}{\sum_{q=1}^n \tilde{l}_q}\big) \;\geq\; \tfrac{\|\mathbf{u}_{i:}\|_2^2}{2\tau\rho}.$$

Here $\tilde{l}_i$ and τ are defined in (5). Thus for all $i \in [n]$, $\frac{\|\mathbf{u}_{i:}\|_2^2}{p_i} \leq 2\tau\rho$. We can then apply Lemma 24 to show that Assumption 1.1 holds with probability at least $1-\delta_1$ when $s \geq 2\tau\rho\frac{6+2\eta}{3\eta^2}\log\frac{\rho}{\delta_1}$ and that Assumption 1.2 holds with probability at least $1-\delta_2$ when $s \geq \frac{2\tau\rho}{\epsilon\delta_2}$.

A.1.2 Proof of Assumption 1.3

For uniform sampling (without replacement) and SRHT, when $s < n$, it is easy to show that $\mathbf{S}^T\mathbf{S} = \frac{n}{s}\mathbf{I}_s$, and thus $\|\mathbf{S}\|_2^2 = \frac{n}{s}$. Let $\{p_i^{\mathrm{s}}\}$ and $\{p_i^{\mathrm{u}}\}$ be the sampling probabilites of shrinked leverage score sampling and uniform sampling, respectively. Obviously $p_i^{\mathrm{s}} \geq \frac{1}{2}p_i^{\mathrm{u}}$. Thus for shrinked leverage score sampling, $\|\mathbf{S}\|_2^2 \leq \frac{2n}{s}$.

The greatest singular value of a standard Gaussian matrix $\mathbf{G} \in \mathbb{R}^{n\times s}$ is at most $\sqrt{n}+\sqrt{s}+t$ with probability at least $1-2e^{-t^2/2}$ (Vershynin, 2012). Thus a Gaussian projection matrix $\mathbf{S}$ satisfies

$$\|\mathbf{S}\|_2^2 \;=\; \frac{1}{s}\|\mathbf{G}\|_2^2 \;\leq\; \frac{(\sqrt{n}+\sqrt{s}+t)^2}{s}$$

with probability at least $1-2e^{-t^2/2}$.

If $\mathbf{S}$ is the CountSketch matrix, then each row of $\mathbf{S}$ has exactly one nonzero entry, either 1 or -1. Because the columns of $\mathbf{S}$ are orthogonal to each other, it holds that

$$\|\mathbf{S}\|_2^2 \;=\; \max_{i\in[s]}\|\mathbf{s}_{:i}\|_2^2 \;=\; \max_{i\in[s]}\mathrm{nnz}(\mathbf{s}_{:i}).$$

The problem of bounding $\mathrm{nnz}(\mathbf{s}_{:i})$ is equivalent to assigning n balls into s bins uniformly at random and bounding the number of balls in the bins. Patrascu and Thorup (2012) showed that for $s \ll n$, the maximal number of balls in any bin is at most $n/s + \mathcal{O}\big(\sqrt{n/s}\log^c n\big)$ with probability at least $1-\frac{1}{n}$, where $c = \mathcal{O}(1)$. Thus

$$\|\mathbf{S}\|_2^2 \;=\; \max_{i\in[s]}\mathrm{nnz}(\mathbf{s}_{:i}) \;\leq\; \frac{n}{s} + \mathcal{O}\bigg(\frac{\sqrt{n}\log^c n}{\sqrt{s}}\bigg) \;=\; \frac{n}{s}\big(1+o(1)\big)$$

holds with probability at least $1-\frac{1}{n}$.

A.2 Proof of Theorem 13

For uniform sampling (without replacement) and SRHT, it holds that $\mathbf{S}^T\mathbf{S} = \frac{n}{s}\mathbf{I}_s$.

For non-uniform sampling with probabilities $p_1, \cdots, p_n$, (with $\sum_i p_i = 1$), let $p_{\max} = \max_i p_i$. The smallest entry in $\mathbf{S}$ is $\frac{1}{\sqrt{sp_{\max}}}$, and thus $\mathbf{S}^T\mathbf{S} \succeq \frac{1}{sp_{\max}}\mathbf{I}_s$. For leverage score sampling, $p_{\max} = \frac{\mu}{n}$. For shrinked leverage score sampling, $p_{\max} = \frac{1+\mu}{2n}$. The lower bound on $\|\mathbf{S}\|_2^2$ is thus established.

The smallest singular value of any $n \times s$ standard Gaussian matrix $\mathbf{G}$ is at least $\sqrt{n}-\sqrt{s}-t$ with probability at least $1-2e^{-t^2/2}$ (Vershynin, 2012). Thus if $\mathbf{S} = \frac{1}{\sqrt{s}}\mathbf{G}$ is the

Gaussian projection matrix, the smallest eigenvalue of $\mathbf{S}^T\mathbf{S}$ is $(1-o(1))\frac{n}{s}$ with probability very close to one.

If $\mathbf{S}$ is the CountSketch matrix, then each row of $\mathbf{S}$ has exactly one nonzero entry, either 1 or -1. Because the columns of $\mathbf{S}$ are orthogonal to each other, it holds that

$$\sigma_{\min}^2(\mathbf{S}) \;=\; \min_{i\in[s]}\|\mathbf{s}_{:i}\|_2^2 \;=\; \min_{i\in[s]}\mathrm{nnz}(\mathbf{s}_{:i}).$$

The problem of bounding $\mathrm{nnz}(\mathbf{s}_{:i})$ is equivalent to assigning n balls into s bins uniformly at random and bounding the number of balls in the bins. Standard concentration arguments imply that each bin has at least $\frac{n}{s}(1-o(1))$ balls w.h.p., and hence $\sigma_{\min}^2(\mathbf{S}) \geq \frac{n}{s}(1-o(1))$ w.h.p.

A.3 Proof of Theorem 14

Assumption 2.1. By Theorem 12 and the union bound, we have that $\big\|\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T - \mathbf{I}_\rho\big\|_2 \leq \eta$ hold simultaneously for all $i \in [g]$ with probability at least $1-g\delta_1$. Because $\mathbf{S} \in \mathbb{R}^{n\times gs}$ is the same type of sketching matrix, it follows from Theorem 12 that $\big\|\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U} - \mathbf{I}_\rho\big\|_2 \leq \frac{\eta}{\sqrt{g}}$ holds with probability at least $1-\delta_1$.

Assumption 2.2. By the same proof of Theorem 12, we can easily show that

$$\mathbb{E}\big\|\mathbf{U}^T\mathbf{B} - \mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{B}\big\|_F^2 \;\leq\; \delta_2\epsilon\,\|\mathbf{B}\|_F^2,$$

where $\mathbf{B}$ is any fixed matrix and the expectation is taken w.r.t. $\mathbf{S}$. It follows from Jensen's inequality that

$$\Big(\mathbb{E}\big\|\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{B} - \mathbf{U}^T\mathbf{B}\big\|_F\Big)^2 \;\leq\; \mathbb{E}\big\|\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{B} - \mathbf{U}^T\mathbf{B}\big\|_F^2 \;\leq\; \delta_2\epsilon\big\|\mathbf{B}\big\|_F^2.$$

It follows that

$$\frac{1}{g}\sum_{i=1}^g \mathbb{E}\big\|\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{B} - \mathbf{U}^T\mathbf{B}\big\|_F \;\leq\; \sqrt{\delta_2\epsilon}\big\|\mathbf{B}\big\|_F,$$

and thus

$$\Big(\frac{1}{g}\sum_{i=1}^g \mathbb{E}\big\|\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{B} - \mathbf{U}^T\mathbf{B}\big\|_F\Big)^2 \;\leq\; \delta_2\epsilon\big\|\mathbf{B}\big\|_F^2.$$

It follows from Markov's bound that

$$\mathbb{P}\bigg\{\Big(\frac{1}{g}\sum_{i=1}^g \big\|\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{B} - \mathbf{U}^T\mathbf{B}\big\|_F\Big)^2 \;\leq\; \epsilon\big\|\mathbf{B}\big\|_F^2\bigg\} \;\geq\; 1-\delta_2.$$

Because $\mathbf{S} \in \mathbb{R}^{n\times gs}$ is the same type of sketching matrix, it follows from Theorem 12 that $\big\|\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{B} - \mathbf{U}^T\mathbf{B}\big\|_F^2 \leq \frac{\epsilon}{g}\|\mathbf{B}\|_F^2$ holds with probability at least $1-\delta_2$.

Assumption 2.3. Theorem 12 shows that $\|\mathbf{S}_i\|_2^2$ can be bounded either surely or w.h.p. (assuming n is large enough). Because $g \ll n$, $\|\mathbf{S}_i\|_2^2$ can be bounded simultaneously for all $i \in [g]$ either surely or w.h.p.

Suppose $sg < n$. Because $\mathbf{S} \in \mathbb{R}^{n \times gs}$ is the same type of sketching matrix, it follows from Theorem 12 that $\|\mathbf{S}\|_2^2 \leq \frac{\theta n}{gs}$ holds either surely or w.h.p.

Suppose $sg \geq n$. It is not hard to show that uniform sampling, shrinked leverage score sampling, and SRHT satisfy $\|\mathbf{S}\|_2 = \Theta(1)$ w.h.p. Previously we have shown that a random Gaussian projection matrix $\mathbf{S} \in \mathbb{R}^{n \times sg}$ satisfies

$$\|\mathbf{S}\|_2^2 \;\leq\; \big(1 + o(1)\big)\, \frac{(\sqrt{n} + \sqrt{gs})^2}{gs}$$

w.h.p. Hence for $sg \geq n$, $\|\mathbf{S}\|_2^2 \leq 4 + o(1)$ w.h.p.

Appendix B. Sketched MRR from the Optimization Perspective: Proofs

In Section B.1 we establish a key lemma. In Section B.2 we prove Theorem 15. In Section B.3 we prove Theorem 16.

B.1 Key Lemma

Recall that the objective function of the matrix ridge regression (MRR) problem is

$$f(\mathbf{W}) \;\triangleq\; \frac{1}{n}\big\|\mathbf{X}\mathbf{W} - \mathbf{Y}\big\|_F^2 + \gamma \|\mathbf{W}\|_F^2.$$

The optimal solution is $\mathbf{W}^\star = \operatorname{argmin}_{\mathbf{W}} f(\mathbf{W})$. The following is the key lemma for understanding the difference between the objective value at $\mathbf{W}^\star$ and any arbitrary $\mathbf{W}$.

Lemma 25 *For any matrix $\mathbf{W}$ and any nonsingular matrix $\mathbf{M}$ of proper size, it holds that*

$$\begin{aligned}
f(\mathbf{W}) &= \frac{1}{n}\mathrm{tr}\Big[\mathbf{Y}^T\mathbf{Y} - (2\mathbf{W}^\star - \mathbf{W})^T(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_n)\mathbf{W}\Big],\\
f(\mathbf{W}^\star) &= \frac{1}{n}\Big[\big\|\mathbf{Y}^\perp\big\|_F^2 + n\gamma\big\|\big(\mathbf{\Sigma}^2 + n\gamma\mathbf{I}_\rho\big)^{-1/2}\mathbf{U}^T\mathbf{Y}\big\|_F^2\Big],\\
f(\mathbf{W}) - f(\mathbf{W}^\star) &= \frac{1}{n}\Big\|(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{1/2}(\mathbf{W} - \mathbf{W}^\star)\Big\|_F^2,\\
\Big\|\mathbf{M}^{-1}(\mathbf{W} - \mathbf{W}^\star)\Big\|_F^2 &\leq \sigma_{\min}^{-2}\Big[(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{1/2}\mathbf{M}\Big]\,\Big\|(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{1/2}(\mathbf{W} - \mathbf{W}^\star)\Big\|_F^2.
\end{aligned}$$

Here $\mathbf{X} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$ is the SVD and $\mathbf{Y}^\perp = \mathbf{Y} - \mathbf{X}\mathbf{X}^\dagger\mathbf{Y}$.

Proof Let $\mathbf{U}$ be the left singular vectors of $\mathbf{X}$. The objective value $f(\mathbf{W})$ can be written as

$$\begin{aligned}
f(\mathbf{W}) &= \frac{1}{n}\big\|\mathbf{X}\mathbf{W} - \mathbf{Y}\big\|_F^2 + \gamma\big\|\mathbf{W}\big\|_F^2\\
&= \frac{1}{n}\mathrm{tr}\Big[\mathbf{Y}^T\mathbf{Y} - (2\mathbf{W}^\star - \mathbf{W})^T(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_n)\mathbf{W}\Big],
\end{aligned}$$

so

$$\begin{aligned}
f(\mathbf{W}^\star) &= \frac{1}{n}\mathrm{tr}\Big[\mathbf{Y}^T\Big(\mathbf{I}_n - \mathbf{X}(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{-1}\mathbf{X}^T\Big)\mathbf{Y}\Big]\\
&= \frac{1}{n}\mathrm{tr}\Big[\mathbf{Y}^T\Big(\mathbf{I}_n - \mathbf{U}(\mathbf{I}_\rho + n\gamma\mathbf{\Sigma}^{-2})^{-1}\mathbf{U}^T\Big)\mathbf{Y}\Big]\\
&= \frac{1}{n}\mathrm{tr}\Big[\mathbf{Y}^T\mathbf{Y} - \mathbf{Y}^T\mathbf{U}\mathbf{U}^T\mathbf{Y} + \mathbf{Y}^T\mathbf{U}\mathbf{U}^T\mathbf{Y} - \mathbf{Y}^T\mathbf{U}(\mathbf{I}_\rho + n\gamma\mathbf{\Sigma}^{-2})^{-1}\mathbf{U}^T\mathbf{Y}\Big]\\
&= \frac{1}{n}\Big\{\mathrm{tr}\Big[\mathbf{Y}^T(\mathbf{I}_n - \mathbf{U}\mathbf{U}^T)\mathbf{Y}\Big] + n\gamma\cdot\mathrm{tr}\Big[\mathbf{Y}^T\mathbf{U}\big(\mathbf{\Sigma}^2 + n\gamma\mathbf{I}_\rho\big)^{-1}\mathbf{U}^T\mathbf{Y}\Big]\Big\}\\
&= \frac{1}{n}\Big[\big\|\mathbf{Y}^\perp\big\|_F^2 + n\gamma\big\|\big(\mathbf{\Sigma}^2 + n\gamma\mathbf{I}_\rho\big)^{-1/2}\mathbf{U}^T\mathbf{Y}\big\|_F^2\Big].
\end{aligned}$$

The difference in the objective values is therefore

$$\begin{aligned}
f(\mathbf{W}) - f(\mathbf{W}^\star) &= \frac{1}{n}\mathrm{tr}\Big[(\mathbf{W} - \mathbf{W}^\star)^T(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)(\mathbf{W} - \mathbf{W}^\star)\Big]\\
&= \frac{1}{n}\Big\|(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{1/2}(\mathbf{W} - \mathbf{W}^\star)\Big\|_F^2.
\end{aligned}$$

Because $\sigma_{\min}(\mathbf{A})\|\mathbf{B}\|_F \leq \|\mathbf{A}\mathbf{B}\|_F$ holds for any nonsingular $\mathbf{A}$ and any $\mathbf{B}$, it holds for any nonsingular matrix $\mathbf{M}$ that

$$\begin{aligned}
\sigma_{\min}^2\Big[(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{1/2}\mathbf{M}\Big]\Big\|\mathbf{M}^{-1}(\mathbf{W} - \mathbf{W}^\star)\Big\|_F^2 &\leq \Big\|(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{1/2}\mathbf{M}\mathbf{M}^{-1}(\mathbf{W} - \mathbf{W}^\star)\Big\|_F^2\\
&= \Big\|(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{1/2}(\mathbf{W} - \mathbf{W}^\star)\Big\|_F^2.
\end{aligned}$$

The last claim in the lemma follows from the above inequality. ■

B.2 Proof of Theorem 15

Proof Let $\rho = \mathrm{rank}(\mathbf{X})$, $\mathbf{U} \in \mathbb{R}^{n\times\rho}$ be the left singular vectors of $\mathbf{X}$, and $\mathbf{Y}^\perp = \mathbf{Y} - \mathbf{X}\mathbf{X}^\dagger\mathbf{Y} = \mathbf{Y} - \mathbf{U}\mathbf{U}^T\mathbf{Y}$. It follows from the definition of $\mathbf{W}^\star$ and $\mathbf{W}^\mathrm{c}$ that

$$\mathbf{W}^\mathrm{c} - \mathbf{W}^\star \;=\; (\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{-1}\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{Y} - (\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{-1}\mathbf{X}^T\mathbf{Y}.$$

It follows that

$$\begin{aligned}
&(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X} + n\gamma\mathbf{I}_d)(\mathbf{W}^\mathrm{c} - \mathbf{W}^\star)\\
&= \mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{Y}^\perp + \mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X}\mathbf{X}^\dagger\mathbf{Y} - (\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X} + n\gamma\mathbf{I}_d)(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{-1}\mathbf{X}^T\mathbf{Y}\\
&= \mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{Y}^\perp - n\gamma\mathbf{X}^\dagger\mathbf{Y} + (\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X} + n\gamma\mathbf{I}_d)\big[\mathbf{X}^\dagger - (\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{-1}\mathbf{X}^T\big]\mathbf{Y}\\
&= \mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{Y}^\perp - n\gamma\mathbf{X}^\dagger\mathbf{Y} + n\gamma(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X} + n\gamma\mathbf{I}_d)(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{-1}\mathbf{X}^\dagger\mathbf{Y}\\
&= \mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{Y}^\perp + n\gamma(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X} - \mathbf{X}^T\mathbf{X})(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{-1}\mathbf{X}^\dagger\mathbf{Y}.
\end{aligned}$$

It follows that

$$(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{-1/2}(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X} + n\gamma\mathbf{I}_d)(\mathbf{W}^\mathrm{c} - \mathbf{W}^\star) \;=\; \mathbf{A} + \mathbf{B}, \tag{13}$$

where

$$\begin{aligned}\mathbf{A} &= \big[(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big]^\dagger\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{Y}^\perp \;=\; \mathbf{V}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{\Sigma}\mathbf{U}\mathbf{S}\mathbf{S}^T\mathbf{Y}^\perp,\\ \mathbf{B} &= n\gamma\big[(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big]^\dagger(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X}-\mathbf{X}^T\mathbf{X})(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^\dagger\mathbf{X}^\dagger\mathbf{Y}\\ &= n\gamma\mathbf{V}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{\Sigma}(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho)\mathbf{\Sigma}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\mathbf{\Sigma}^{-1}\mathbf{U}^T\mathbf{Y}\\ &= n\gamma\mathbf{V}\mathbf{\Sigma}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho)(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\mathbf{U}^T\mathbf{Y}.\end{aligned}$$

It follows from (13) that

$$\begin{aligned}&(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}^{\mathrm{c}}-\mathbf{W}^\star\big)\\ &= \big[(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{-1/2}(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X}+n\gamma\mathbf{I}_d)(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{-1/2}\big]^\dagger(\mathbf{A}+\mathbf{B}).\end{aligned}$$

By Assumption 1.1, we have that

$$(1-\eta)(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d) \;\preceq\; (\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X}+n\gamma\mathbf{I}_d) \;\preceq\; (1+\eta)(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d).$$

It follows that

$$\Big\|\big[(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{-1/2}(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X}+n\gamma\mathbf{I}_d)(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{-1/2}\big]^\dagger\Big\|_2 \;\le\; \frac{1}{1-\eta}.$$

Thus

$$\Big\|(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}^{\mathrm{c}}-\mathbf{W}^\star\big)\Big\|_F^2 \;\le\; \frac{1}{1-\eta}\Big\|\mathbf{A}+\mathbf{B}\Big\|_F^2 \;\le\; \frac{2}{1-\eta}\Big(\|\mathbf{A}\|_F^2+\|\mathbf{B}\|_F^2\Big).$$

Lemma 25 shows

$$f\big(\mathbf{W}^{\mathrm{c}}\big)-f\big(\mathbf{W}^\star\big)=\frac{1}{n}\Big\|(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}(\mathbf{W}^{\mathrm{c}}-\mathbf{W}^\star)\Big\|_F^2\le\frac{2}{n(1-\eta)}\Big(\|\mathbf{A}\|_F^2+\|\mathbf{B}\|_F^2\Big). \quad (14)$$

We respectively bound $\|\mathbf{A}\|_F^2$ and $\|\mathbf{B}\|_F^2$ in the following. It follows from Assumption 1.2 and $\mathbf{U}^T\mathbf{Y}^\perp=\mathbf{0}$ that

$$\begin{aligned}\|\mathbf{A}\|_F^2 &= \Big\|\mathbf{V}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{\Sigma}\mathbf{U}\mathbf{S}\mathbf{S}^T\mathbf{Y}^\perp\Big\|_F^2\\ &\le \big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{\Sigma}\big\|_2^2\,\big\|\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{Y}^\perp-\mathbf{U}^T\mathbf{Y}^\perp\big\|_F^2\\ &\le \epsilon\big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{\Sigma}\big\|_2^2\,\big\|\mathbf{Y}^\perp\big\|_F^2.\end{aligned}$$

By the definition of $\mathbf{B}$, we have

$$\begin{aligned}&\|\mathbf{B}\|_F^2 \;\le\; n^2\gamma^2\big\|\mathbf{\Sigma}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho)(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\mathbf{U}^T\mathbf{Y}\big\|_F^2\\ &\le\; n^2\gamma^2\big\|\mathbf{\Sigma}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho)(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\big\|_2^2\big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{U}^T\mathbf{Y}\big\|_F^2\\ &=\; n^2\gamma^2\big\|\mathbf{\Sigma}\mathbf{N}\big\|_2^2\big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{U}^T\mathbf{Y}\big\|_F^2,\end{aligned}$$

where we define $\mathbf{N}=(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho)(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}$. By Assumption 1.1, we have

$$-\eta(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1} \;\preceq\; \mathbf{N} \;\preceq\; \eta(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}.$$

It follows that

$$\begin{aligned}\|\mathbf{B}\|_F^2 &\le\; n^2\gamma^2\big\|\mathbf{\Sigma}\mathbf{N}^2\mathbf{\Sigma}\big\|_2\big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{U}^T\mathbf{Y}\big\|_F^2\\ &\le\; \eta^2n^2\gamma^2\big\|\mathbf{\Sigma}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-2}\mathbf{\Sigma}\big\|_2\big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{U}^T\mathbf{Y}\big\|_F^2\\ &=\; \eta^2n^2\gamma^2\big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\mathbf{\Sigma}\big\|_2^2\big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{U}^T\mathbf{Y}\big\|_F^2\\ &=\; \eta^2n\gamma\big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{\Sigma}\big\|_2^2\big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{U}^T\mathbf{Y}\big\|_F^2.\end{aligned}$$

The last equality follows from the fact that $\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\|_2\le(n\gamma)^{-1/2}$. It follows that

$$\begin{aligned}\|\mathbf{A}\|_F^2+\|\mathbf{B}\|_F^2 &\le \max\big\{\epsilon,\eta^2\big\}\Big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_d)^{-1}\mathbf{\Sigma}\Big\|_2\Big[\big\|\mathbf{Y}^\perp\big\|_F^2+n\gamma\big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_d)^{-1/2}\mathbf{U}^T\mathbf{Y}\big\|_F^2\Big]\\ &\le \max\big\{\epsilon,\eta^2\big\}\frac{\sigma_{\max}^2}{\sigma_{\max}^2+n\gamma}\Big[\big\|\mathbf{Y}^\perp\big\|_F^2+n\gamma\big\|(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_d)^{-1/2}\mathbf{U}^T\mathbf{Y}\big\|_F^2\Big]\\ &\le \max\big\{\epsilon,\eta^2\big\}\beta nf(\mathbf{W}^\star). \quad (15)\end{aligned}$$

The last inequality follows from Lemma 25. The claimed result now follows from (15) and (14). ■

B.3 Proof of Theorem 16

Proof By the definition of $\mathbf{W}^{\mathrm{h}}$ and $\mathbf{W}^\star$, we have

$$\begin{aligned}&(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}^{\mathrm{h}}-\mathbf{W}^\star\big)\\ &= (\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\Big[(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X}+n\gamma\mathbf{I}_d)^\dagger-(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^\dagger\Big]\mathbf{X}^T\mathbf{Y}\\ &= \mathbf{V}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{1/2}\Big[(\mathbf{\Sigma}\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}\mathbf{\Sigma}+n\gamma\mathbf{I}_\rho)^\dagger-(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\Big]\mathbf{\Sigma}\mathbf{U}^T\mathbf{Y}.\end{aligned}$$

It follows from Assumption 1.1 that $\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}$ has full rank, and thus

$$\begin{aligned}&(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}^{\mathrm{h}}-\mathbf{W}^\star\big)\\ &= \mathbf{V}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{1/2}\Big[(\mathbf{\Sigma}\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}\mathbf{\Sigma}+n\gamma\mathbf{I}_\rho)^{-1}-(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\Big]\mathbf{\Sigma}\mathbf{U}^T\mathbf{Y}\\ &= \mathbf{V}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{1/2}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}(\mathbf{\Sigma}^2-\mathbf{\Sigma}\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}\mathbf{\Sigma})(\mathbf{\Sigma}\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}\mathbf{\Sigma}+n\gamma\mathbf{I}_\rho)^{-1}\mathbf{\Sigma}\mathbf{U}^T\mathbf{Y}\\ &= \mathbf{V}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{\Sigma}(\mathbf{I}_\rho-\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U})\mathbf{\Sigma}(\mathbf{\Sigma}\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}\mathbf{\Sigma}+n\gamma\mathbf{I}_\rho)^{-1}\mathbf{\Sigma}\mathbf{U}^T\mathbf{Y},\end{aligned}$$

where the second equality follow from $\mathbf{M}^{-1}-\mathbf{N}^{-1}=\mathbf{N}^{-1}(\mathbf{N}-\mathbf{M})\mathbf{M}^{-1}$. We define

$$(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}^{\mathrm{h}}-\mathbf{W}^\star\big) \;=\; \mathbf{V}\mathbf{A}\mathbf{B}\mathbf{C},$$

where

$$\begin{aligned}\mathbf{A} &= (\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{\Sigma}(\mathbf{I}_\rho-\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U})\mathbf{\Sigma}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2},\\ \mathbf{B} &= (\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{1/2}(\mathbf{\Sigma}\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}\mathbf{\Sigma}+n\gamma\mathbf{I}_\rho)^{-1}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{1/2},\\ \mathbf{C} &= (\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{\Sigma}\mathbf{U}^T\mathbf{Y}.\end{aligned}$$

It follows from Assumption 1.1 that

$$\begin{aligned}\|\mathbf{A}\|_2 &\leq \eta\Big\|(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\boldsymbol{\Sigma}^2(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\Big\|_2 \leq \eta\beta,\\ \|\mathbf{B}\|_2 &\leq (1-\eta)^{-1}.\end{aligned}$$

It holds that

$$\begin{aligned}\big\|\mathbf{C}\big\|_F^2 &\leq \Big\|(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\boldsymbol{\Sigma}\mathbf{U}^T\mathbf{Y}\Big\|_F^2\\ &= \Big[\operatorname{tr}\Big(\mathbf{Y}^T\mathbf{U}\mathbf{U}^T\mathbf{Y}\Big)-n\gamma\operatorname{tr}\Big(\mathbf{Y}^T\mathbf{U}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_d)^{-1}\mathbf{U}^T\mathbf{Y}\Big)\Big]\\ &= \Big[-\operatorname{tr}\Big(\mathbf{Y}^T(\mathbf{I}_d-\mathbf{U}\mathbf{U}^T)\mathbf{Y}\Big)-n\gamma\operatorname{tr}\Big(\mathbf{Y}^T\mathbf{U}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_d)^{\dagger}\mathbf{U}^T\mathbf{Y}\Big)+\operatorname{tr}\big(\mathbf{Y}^T\mathbf{Y}\big)\Big]\\ &= \Big(-nf(\mathbf{W}^\star)+\big\|\mathbf{Y}\big\|_F^2\Big),\end{aligned}$$

where the last equality follows from Lemma 25. It follows from Lemma 25 that

$$\begin{aligned}f(\mathbf{W}^{\mathrm{h}})-f(\mathbf{W}^\star) &= \frac{1}{n}\big\|(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}^{\mathrm{h}}-\mathbf{W}^\star\big)\big\|_F^2\\ &= \frac{1}{n}\big\|\mathbf{A}\mathbf{B}\mathbf{C}\big\|_F^2 \leq \frac{\eta^2\beta^2}{(1-\eta)^2}\Big(\frac{1}{n}\big\|\mathbf{Y}\big\|_F^2-f(\mathbf{W}^\star)\Big).\end{aligned}$$

■

Appendix C. Sketched MRR from the Statistical Perspective: Proofs

In Section C.1 we prove Theorem 4. In Section C.2 we prove Theorem 17. In Section C.3 we prove Theorem 18. In Section A.2 we prove Theorem 13. In Section C.4 we prove Theorem 19. Recall that the fixed design model is $\mathbf{Y}=\mathbf{X}\mathbf{W}_0+\boldsymbol{\Xi}$ where $\boldsymbol{\Xi}$ is random, $\mathbb{E}\boldsymbol{\Xi}=0$, and $\mathbb{E}[\boldsymbol{\Xi}\boldsymbol{\Xi}^T]=\xi^2\mathbf{I}_n$.

C.1 Proofs of Theorem 4

We prove Theorem 4 in the following. In the proof we exploit several identities. The Frobenius norm and matrix trace satisfy

$$\|\mathbf{A}-\mathbf{B}\|_F^2 \;=\; \operatorname{tr}\big[(\mathbf{A}-\mathbf{B})(\mathbf{A}-\mathbf{B})^T)\big] \;=\; \operatorname{tr}(\mathbf{A}\mathbf{A}^T)+\operatorname{tr}(\mathbf{B}\mathbf{B}^T)-2\operatorname{tr}(\mathbf{A}\mathbf{B}^T)$$

for any conformal matrices $\mathbf{A}$ and $\mathbf{B}$. The trace is linear, and thus for any fixed $\mathbf{A}$ and $\mathbf{B}$ and conformal random matrix $\boldsymbol{\Psi}$,

$$\mathbb{E}\big[\operatorname{tr}(\mathbf{A}\boldsymbol{\Psi}\mathbf{B})\big] \;=\; \operatorname{tr}\big[\mathbf{A}(\mathbb{E}\boldsymbol{\Psi})\mathbf{B}\big],$$

where the expectation is taken with respect to $\boldsymbol{\Psi}$.

Proof It follows from the definition of the optimal solution $\mathbf{W}^\star$ in (2) that

$$\begin{aligned}\mathbf{X}\mathbf{W}^\star &= \mathbf{X}(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{\dagger}\mathbf{X}^T(\mathbf{X}\mathbf{W}_0+\boldsymbol{\Xi})\\ &= \mathbf{U}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\boldsymbol{\Sigma}^3\mathbf{V}^T\mathbf{W}_0+\mathbf{U}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\boldsymbol{\Sigma}^2\mathbf{U}^T\boldsymbol{\Xi}\\ &= \mathbf{U}\Big[\mathbf{I}_\rho-n\gamma(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\Big]\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0+\mathbf{U}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\boldsymbol{\Sigma}^2\mathbf{U}^T\boldsymbol{\Xi}\\ &= \mathbf{X}\mathbf{W}_0-n\gamma\mathbf{U}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0+\mathbf{U}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\boldsymbol{\Sigma}^2\mathbf{U}^T\boldsymbol{\Xi}.\end{aligned}$$

Since $\mathbb{E}[\boldsymbol{\Xi}]=\mathbf{0}$ and $\mathbb{E}[\boldsymbol{\Xi}\boldsymbol{\Xi}^T]=\xi^2\mathbf{I}_n$, it holds that

$$\begin{aligned}R(\mathbf{W}^\star) &= \frac{1}{n}\mathbb{E}\big\|\mathbf{X}\mathbf{W}^\star-\mathbf{X}\mathbf{W}_0\big\|_F^2\\ &= \frac{1}{n}\Big\|-n\gamma(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0+(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\boldsymbol{\Sigma}^2\mathbf{U}^T\boldsymbol{\Xi}\Big\|_F^2\\ &= n\gamma^2\Big\|(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\Big\|_F^2+\frac{\xi^2}{n}\Big\|(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\boldsymbol{\Sigma}^2\Big\|_F^2.\end{aligned}$$

This exposes expressions for the bias and variance of the optimal solution $\mathbf{W}^\star$.

We now decompose the risk function $R\big(\mathbf{W}^{\mathrm{c}}\big)$. It follows from the definition of $\mathbf{W}^{\mathrm{c}}$ in (3) that

$$\begin{aligned}\mathbf{X}\mathbf{W}^{\mathrm{c}} &= \mathbf{X}(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{\dagger}\mathbf{X}^T\mathbf{S}\mathbf{S}^T(\mathbf{X}\mathbf{W}_0+\boldsymbol{\Xi})\\ &= \mathbf{U}\boldsymbol{\Sigma}\big(\boldsymbol{\Sigma}\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}\boldsymbol{\Sigma}+n\gamma\mathbf{I}_d\big)^{\dagger}\boldsymbol{\Sigma}\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0+\mathbf{U}^T\mathbf{S}\mathbf{S}^T\boldsymbol{\Xi}\big)\\ &= \mathbf{U}(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2})^{-1}\Big[(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2})\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0-n\gamma\boldsymbol{\Sigma}^{-1}\mathbf{V}^T\mathbf{W}_0+\mathbf{U}^T\mathbf{S}\mathbf{S}^T\boldsymbol{\Xi}\Big]\\ &= \mathbf{X}\mathbf{W}_0+\mathbf{U}(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2})^{-1}\big(-n\gamma\boldsymbol{\Sigma}^{-1}\mathbf{V}^T\mathbf{W}_0+\mathbf{U}^T\mathbf{S}\mathbf{S}^T\boldsymbol{\Xi}\big).\end{aligned}$$

Since $\mathbb{E}[\boldsymbol{\Xi}]=\mathbf{0}$ and $\mathbb{E}[\boldsymbol{\Xi}\boldsymbol{\Xi}^T]=\xi^2\mathbf{I}_n$, it follows that

$$\begin{aligned}R\big(\mathbf{W}^{\mathrm{c}}\big) &= \frac{1}{n}\mathbb{E}\big\|\mathbf{X}\mathbf{W}^{\mathrm{c}}-\mathbf{X}\mathbf{W}_0\big\|_F^2\\ &= \frac{1}{n}\Big\|-n\gamma(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2})^{-1}\boldsymbol{\Sigma}^{-1}\mathbf{V}^T\mathbf{W}_0+(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2})^{-1}\mathbf{U}^T\mathbf{S}\mathbf{S}^T\boldsymbol{\Xi}\Big\|_F^2\\ &= n\gamma^2\Big\|(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2})^{-1}\boldsymbol{\Sigma}^{-1}\mathbf{V}^T\mathbf{W}_0\Big\|_F^2+\frac{\xi^2}{n}\Big\|(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2})^{-1}\mathbf{U}^T\mathbf{S}\mathbf{S}^T\Big\|_F^2.\end{aligned}$$

This exposes expressions for the bias and variance of the approximate solution $\mathbf{W}^{\mathrm{c}}$.

We now decompose the risk function $R\big(\mathbf{W}^{\mathrm{h}}\big)$. It follows from the definition of $\mathbf{W}^{\mathrm{h}}$ in (4) that

$$\begin{aligned}\mathbf{X}\mathbf{W}^{\mathrm{h}}-\mathbf{X}\mathbf{W}_0 &= \mathbf{X}(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X}+n\gamma\mathbf{I}_n)^{\dagger}\mathbf{X}^T(\mathbf{X}\mathbf{W}_0+\boldsymbol{\Xi})-\mathbf{X}\mathbf{W}_0\\ &= \mathbf{X}(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{\dagger}\mathbf{X}^T\mathbf{X}\mathbf{W}_0-\mathbf{X}\mathbf{W}_0+\mathbf{X}(\mathbf{X}^T\mathbf{S}\mathbf{S}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{\dagger}\mathbf{X}^T\boldsymbol{\Xi}\\ &= \mathbf{U}\big[(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2})^{-1}-\mathbf{I}_\rho^{-1}\big]\mathbf{U}^T\mathbf{X}\mathbf{W}_0+\mathbf{U}(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}^T+n\gamma\boldsymbol{\Sigma}^{-2})^{\dagger}\mathbf{U}^T\boldsymbol{\Xi}\\ &= \mathbf{U}\big(\mathbf{I}_\rho-\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-n\gamma\boldsymbol{\Sigma}^{-2}\big)\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\\ &\quad+\mathbf{U}(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}^T+n\gamma\boldsymbol{\Sigma}^{-2})^{\dagger}\mathbf{U}^T\boldsymbol{\Xi},\end{aligned}$$

where the last equality follows from the fact that $\mathbf{A}^{-1}-\mathbf{B}^{-1}=\mathbf{B}^{-1}(\mathbf{B}-\mathbf{A})\mathbf{A}^{-1}$ for any conformal nonsingular matrices $\mathbf{A}$ and $\mathbf{B}$. Since $\mathbb{E}[\boldsymbol{\Xi}]=\mathbf{0}$ and $\mathbb{E}[\boldsymbol{\Xi}\boldsymbol{\Xi}^T]=\xi^2\mathbf{I}_n$, it follows that

$$R\big(\mathbf{W}^{\mathrm{h}}\big) \;=\; \mathsf{bias}^2\big(\mathbf{W}^{\mathrm{h}}\big)+\mathsf{var}\big(\mathbf{W}^{\mathrm{h}}\big),$$

where

$$\begin{aligned}\mathsf{bias}^2\big(\mathbf{W}^{\mathrm{h}}\big) &= \frac{1}{n}\Big\|\big(n\gamma\boldsymbol{\Sigma}^{-2}+\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho\big)\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\Big\|_F^2,\\ \mathsf{var}\big(\mathbf{W}^{\mathrm{h}}\big) &= \frac{\xi^2}{n}\Big\|\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{-1}\Big\|_F^2.\end{aligned}$$

This exposes expressions for the bias and variance of $\mathbf{W}^{\mathrm{h}}$. ■

C.2 Proof of Theorem 17

Proof Assumption 1.1 ensures that $(1-\eta)\mathbf{I}_\rho\preceq\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}\preceq(1+\eta)\mathbf{I}_\rho$. It follows that

$$(1-\eta)\big(\mathbf{I}_\rho+n\gamma\boldsymbol{\Sigma}^{-2}\big) \;\preceq\; \mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2} \;\preceq\; (1+\eta)\big(\mathbf{I}_\rho+n\gamma\boldsymbol{\Sigma}^{-2}\big).$$

The bias term can be written as

$$\begin{aligned}\mathsf{bias}^2\big(\mathbf{W}^{\mathrm{c}}\big) &= n\gamma^2\big\|\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{\dagger}\boldsymbol{\Sigma}^{-1}\mathbf{V}^T\mathbf{W}_0\big\|_F^2\\ &= n\gamma^2\,\mathrm{tr}\Big(\mathbf{W}_0^T\mathbf{V}\boldsymbol{\Sigma}^{-1}\big[(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2})^{\dagger}\big]^2\boldsymbol{\Sigma}^{-1}\mathbf{V}^T\mathbf{W}_0\Big)\\ &\le \tfrac{n\gamma^2}{(1-\eta)^2}\big\|\big(\mathbf{I}_\rho+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{-1}\boldsymbol{\Sigma}^{-1}\mathbf{V}^T\mathbf{W}_0\big\|_F^2\\ &= \tfrac{n\gamma^2}{(1-\eta)^2}\big\|\big(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho\big)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\big\|_F^2\\ &= \tfrac{1}{(1-\eta)^2}\,\mathsf{bias}^2(\mathbf{W}^\star).\end{aligned}$$

We can analogously show $\mathsf{bias}^2(\mathbf{W}^{\mathrm{c}})\ge\frac{1}{(1+\eta)^2}\mathsf{bias}^2(\mathbf{W}^\star)$.

Let $\mathbf{B}=\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{\dagger}\mathbf{U}^T\mathbf{S}\in\mathbb{R}^{\rho\times s}$. By Assumption 1.1, it holds that

$$(1-\eta)\big[\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^2\big]^{\dagger} \;\preceq\; \mathbf{B}\mathbf{B}^T \;\preceq\; (1+\eta)\big[\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^2\big]^{\dagger}.$$

Applying Assumption 1.1 again, we obtain

$$(1-\eta)^2\big(\mathbf{I}_\rho+n\gamma\boldsymbol{\Sigma}^{-2}\big)^2 \;\preceq\; \big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^2 \;\preceq\; (1+\eta)^2\big(\mathbf{I}_\rho+n\gamma\boldsymbol{\Sigma}^{-2}\big)^2.$$

Note that both sides are nonsingular. Combining the above two equations, we have

$$\tfrac{1-\eta}{(1+\eta)^2}\big(\mathbf{I}_\rho+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{-2} \;\preceq\; \mathbf{B}\mathbf{B}^T \;\preceq\; \tfrac{1+\eta}{(1-\eta)^2}\big(\mathbf{I}_\rho+n\eta\boldsymbol{\Sigma}^{-2}\big)^{-2}.$$

Taking the trace of all the terms, we obtain

$$\tfrac{1-\eta}{(1+\eta)^2} \;\le\; \tfrac{\|\mathbf{B}\|_F^2}{\|(\mathbf{I}_\rho+n\gamma\boldsymbol{\Sigma}^{-2})^{-1}\|_F^2} \;\le\; \tfrac{1+\eta}{(1-\eta)^2}.$$

The variance term can be written as

$$\begin{aligned}\mathsf{var}\big(\mathbf{W}^{\mathrm{c}}\big) &= \tfrac{\xi^2}{n}\big\|\mathbf{B}\mathbf{S}^T\big\|_F^2 \;\le\; \tfrac{\xi^2}{n}\big\|\mathbf{B}\big\|_F^2\big\|\mathbf{S}\big\|_2^2\\ &\le \tfrac{\xi^2(1+\eta)}{n(1-\eta)^2}\big\|\big(\mathbf{I}_\rho+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{-1}\big\|_F^2\big\|\mathbf{S}\big\|_2^2\\ &= \tfrac{(1+\eta)\|\mathbf{S}\|_2^2}{(1-\eta)^2}\mathsf{var}(\mathbf{W}^\star).\end{aligned}$$

The upper bound on the variance follows from Assumption 1.3. ■

C.3 Proof of Theorem 18

Proof Let $\mathbf{B}=\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{\dagger}\mathbf{U}^T\mathbf{S}\in\mathbb{R}^{\rho\times s}$. In the proof of Theorem 5 we show that

$$\mathsf{var}\big(\mathbf{W}^{\mathrm{c}}\big) \;=\; \tfrac{\xi^2}{n}\big\|\mathbf{B}\mathbf{S}^T\big\|_F^2.$$

If $\mathbf{S}^T\mathbf{S}\succeq\frac{\vartheta n}{s}\mathbf{I}_s$, then it holds that

$$\mathsf{var}\big(\mathbf{W}^{\mathrm{c}}\big) \;=\; \tfrac{\xi^2}{n}\big\|\mathbf{B}\mathbf{S}^T\big\|_F^2 \;\ge\; \tfrac{\vartheta n}{s}\tfrac{\xi^2}{n}\big\|\mathbf{B}\big\|_F^2 \;\ge\; \tfrac{\vartheta n}{s}\tfrac{1-\eta}{(1+\eta)^2}\mathsf{var}(\mathbf{W}^\star).$$

This establishes the lower bounds on the variance. ■

C.4 Proof of Theorem 19

Proof Theorem 4 shows that

$$\begin{aligned}\mathsf{bias}\big(\mathbf{W}^{\mathrm{h}}\big) &= \gamma\sqrt{n}\Big\|\Big(\boldsymbol{\Sigma}^{-2}+\tfrac{\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho}{n\gamma}\Big)\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{\dagger}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\Big\|_F\\ &= \gamma\sqrt{n}\big\|\mathbf{A}\boldsymbol{\Sigma}^2\mathbf{B}\big\|_F \;\le\; \gamma\sqrt{n}\big\|\mathbf{A}\boldsymbol{\Sigma}^2\big\|_2\big\|\mathbf{B}\big\|_F,\\ \mathsf{var}\big(\mathbf{W}^{\mathrm{h}}\big) &= \frac{\xi^2}{n}\Big\|\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{\dagger}\Big\|_F^2,\end{aligned}$$

where we define

$$\begin{aligned}\mathbf{A} &= \boldsymbol{\Sigma}^{-2}+\tfrac{\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho}{n\gamma},\\ \mathbf{B} &= \boldsymbol{\Sigma}^{-2}\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\boldsymbol{\Sigma}^{-2}\big)^{\dagger}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0.\end{aligned}$$

We first analyze the bias. It follows from Assumption 1.1 that

$$\boldsymbol{\Sigma}^{-2}\big(\mathbf{I}_\rho-\tfrac{\eta}{n\gamma}\boldsymbol{\Sigma}^2\big) \;\preceq\; \mathbf{A} \;\preceq\; \boldsymbol{\Sigma}^{-2}\big(\mathbf{I}_\rho+\tfrac{\eta}{n\gamma}\boldsymbol{\Sigma}^2\big). \tag{16}$$

Since $\big(\mathbf{I}_\rho-\frac{\eta}{n\gamma}\boldsymbol{\Sigma}^2\big)^2\preceq\big(\mathbf{I}_\rho+\frac{\eta}{n\gamma}\boldsymbol{\Sigma}^2\big)^2\preceq\big(1+\frac{\eta\sigma_1^2}{n\gamma}\big)^2\mathbf{I}_\rho$, it follows that

$$\mathbf{A}^2 \;\preceq\; \boldsymbol{\Sigma}^{-4}\big(\mathbf{I}_\rho+\tfrac{\eta}{n\gamma}\boldsymbol{\Sigma}^2\big)^2 \;\preceq\; \big(1+\tfrac{\eta\sigma_1^2}{n\gamma}\big)^2\boldsymbol{\Sigma}^{-4}.$$

Thus

$$\left\|\mathbf{A}\mathbf{\Sigma}^2\right\|_2^2 \;=\; \left\|\mathbf{\Sigma}^2\mathbf{A}^2\mathbf{\Sigma}^2\right\|_2 \;\leq\; \left(1+\tfrac{\eta\sigma_1^2}{n\gamma}\right)^2.$$

It follows from Assumption 1.1 that

$$\begin{aligned}&(1+\eta)^{-1}\big(\mathbf{I}_\rho+n\gamma\mathbf{\Sigma}^{-2}\big)^{-1} \;\preceq\; \big((1+\eta)\mathbf{I}_\rho+n\gamma\mathbf{\Sigma}^{-2}\big)^{-1}\\ &\preceq\; \big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\mathbf{\Sigma}^{-2}\big)^{\dagger} \;\preceq\; \big((1-\eta)\mathbf{I}_\rho+n\gamma\mathbf{\Sigma}^{-2}\big)^{-1} \;\preceq\; (1-\eta)^{-1}\big(\mathbf{I}_\rho+n\gamma\mathbf{\Sigma}^{-2}\big)^{-1}.\end{aligned}$$

Thus

$$\begin{aligned}\mathbf{B}^T\mathbf{B} \;&=\; \mathbf{W}_0^T\mathbf{V}\mathbf{\Sigma}^3\big(\mathbf{\Sigma}^{-2}(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\mathbf{\Sigma}^{-2})^{\dagger}\mathbf{\Sigma}^{-2}\big)^2\mathbf{\Sigma}^3\mathbf{V}^T\mathbf{W}_0\\ &\preceq\; (1-\eta)^{-2}\mathbf{W}_0^T\mathbf{V}\mathbf{\Sigma}^3\big(\mathbf{\Sigma}^{-2}(\mathbf{I}_\rho+n\gamma\mathbf{\Sigma}^{-2})^{-1}\mathbf{\Sigma}^{-2}\big)^2\mathbf{\Sigma}^3\mathbf{V}^T\mathbf{W}_0\\ &=\; (1-\eta)^{-2}\mathbf{W}_0^T\mathbf{V}\mathbf{\Sigma}\big(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho\big)^{-2}\mathbf{\Sigma}\mathbf{V}^T\mathbf{W}_0. \qquad (17)\end{aligned}$$

It follows that

$$\|\mathbf{B}\|_F^2 \;=\; \mathrm{tr}\big(\mathbf{B}^T\mathbf{B}\big) \;\leq\; (1-\eta)^{-2}\big\|\big(\mathbf{\Sigma}^{-2}+n\gamma\mathbf{I}_\rho\big)^{-1}\mathbf{\Sigma}\mathbf{V}^T\mathbf{W}_0\big\|_F^2 \;=\; \tfrac{\mathsf{bias}^2(\mathbf{W}^\star)}{n\gamma^2(1-\eta)^2},$$

where the last equality follows from the definition of $\mathsf{bias}(\mathbf{W}^\star)$. By the definition of $\mathbf{A}$ and $\mathbf{B}$, we have

$$\mathsf{bias}^2\big(\mathbf{W}^{\mathrm{h}}\big) \;\leq\; \gamma^2 n\left\|\mathbf{A}\mathbf{\Sigma}^2\right\|_2^2\|\mathbf{B}\|_F^2 \;=\; \tfrac{1}{(1-\eta)^2}\left(1+\tfrac{\eta\sigma_1^2}{n\gamma}\right)^2\mathsf{bias}^2\big(\mathbf{W}^\star\big).$$

Thus, the upper bound on $\mathsf{bias}\big(\mathbf{W}^{\mathrm{h}}\big)$ is established.

Using the same $\mathbf{A}$ and $\mathbf{B}$, we can also show that

$$\mathsf{bias}\big(\mathbf{W}^{\mathrm{h}}\big) \;=\; \gamma\sqrt{n}\left\|\mathbf{A}\mathbf{\Sigma}^2\mathbf{B}\right\|_F \;\geq\; \gamma\sqrt{n}\;\sigma_{\min}\big(\mathbf{A}\mathbf{\Sigma}^2\big)\left\|\mathbf{B}\right\|_F.$$

Assume that $\sigma_\rho^2 \geq \frac{n\gamma}{\eta}$. It follows from (16) that

$$\mathbf{A}^2 \;\succeq\; \big(\tfrac{\eta\sigma_\rho^2}{n\gamma}-1\big)^2\mathbf{\Sigma}^{-4}.$$

Thus

$$\sigma_{\min}^2\big(\mathbf{A}\mathbf{\Sigma}^2\big) \;=\; \sigma_{\min}\big(\mathbf{\Sigma}^2\mathbf{A}^2\mathbf{\Sigma}^2\big) \;\geq\; \big(\tfrac{\eta\sigma_\rho^2}{n\gamma}-1\big)^2.$$

It follows from (17) that

$$\mathbf{B}^T\mathbf{B} \;\succeq\; (1+\eta)^{-2}\mathbf{W}_0^T\mathbf{V}\mathbf{\Sigma}\big(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho\big)^{-2}\mathbf{\Sigma}\mathbf{V}^T\mathbf{W}_0.$$

Thus

$$\|\mathbf{B}\|_F^2 \;=\; \mathrm{tr}\big(\mathbf{B}^T\mathbf{B}\big) \;\geq\; (1+\eta)^{-2}\big\|\big(\mathbf{\Sigma}^{-2}+n\gamma\mathbf{I}_\rho\big)^{-1}\mathbf{\Sigma}\mathbf{V}^T\mathbf{W}_0\big\|_F^2 \;=\; \tfrac{1}{n\gamma^2(1+\eta)^2}\,\mathsf{bias}^2\big(\mathbf{W}^\star\big).$$

In sum, we obtain

$$\mathsf{bias}^2\big(\mathbf{W}^{\mathrm{h}}\big) \;\geq\; \gamma^2 n\;\sigma_{\min}^2\big(\mathbf{A}\mathbf{\Sigma}^2\big)\left\|\mathbf{B}\right\|_F^2 \;=\; (1+\eta)^{-2}\left(\tfrac{\eta\sigma_\rho^2}{n\gamma}-1\right)^2\mathsf{bias}^2\big(\mathbf{W}^\star\big).$$

Thus, the lower bound on $\mathsf{bias}\big(\mathbf{W}^{\mathrm{h}}\big)$ is established.

It follows from Assumption 1.1 that

$$(1+\eta)^{-1}\big(\mathbf{I}_\rho+n\gamma\mathbf{\Sigma}^{-2}\big)^{-1} \;\preceq\; \big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\mathbf{\Sigma}^{-2}\big)^{-1} \;\preceq\; (1-\eta)^{-1}\big(\mathbf{I}_\rho+n\gamma\mathbf{\Sigma}^{-2}\big)^{-1}.$$

It follows from Theorem 4 that

$$\begin{aligned}\mathsf{var}\big(\mathbf{W}^{\mathrm{h}}\big) \;&=\; \tfrac{\xi^2}{n}\big\|\big(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}+n\gamma\mathbf{\Sigma}^{-2}\big)^{-1}\big\|_F^2\\ &\in\; \tfrac{1}{1\mp\eta}\tfrac{\xi^2}{n}\big\|\big(\mathbf{I}_\rho+n\gamma\mathbf{\Sigma}^{-2}\big)^{-1}\big\|_F^2\\ &=\; \tfrac{1}{1\mp\eta}\mathsf{var}\big(\mathbf{W}^\star\big).\end{aligned}$$

This concludes the proof. ■

Appendix D. Model Averaging from the Optimization Perspective: Proofs

In Section D.1 we prove Theorem 20. In Section D.2 we prove Theorem 21.

D.1 Proof of Theorem 20

Proof By Lemma 25, we only need to show that $\|(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}(\mathbf{W}^{\mathrm{c}}-\mathbf{W}^\star)\|_F^2 \leq n\alpha\beta f(\mathbf{W}^\star)$. In the proof, we define $\rho=\mathrm{rank}(\mathbf{X})$ and let $\sigma_1\geq\cdots\geq\sigma_\rho$ be the singular values of $\mathbf{X}$.

In the proof of Theorem 15 we show that

$$\begin{aligned}&(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}_i^{\mathrm{c}}-\mathbf{W}^\star\big)\\ &=\; \big[(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{-1/2}(\mathbf{X}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{X}+n\gamma\mathbf{I}_d)(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{-1/2}\big]^{\dagger}\big(\mathbf{A}_i+\mathbf{B}_i\big)\\ &=\; \mathbf{C}_i^{\dagger}\big(\mathbf{A}_i+\mathbf{B}_i\big),\end{aligned}$$

where

$$\begin{aligned}\mathbf{A}_i \;&=\; \mathbf{V}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\mathbf{\Sigma}\mathbf{U}\mathbf{S}_i\mathbf{S}_i^T\mathbf{Y}^\perp,\\ \mathbf{B}_i \;&=\; n\gamma\mathbf{V}\mathbf{\Sigma}(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}(\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U}-\mathbf{I}_\rho)(\mathbf{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}\mathbf{U}^T\mathbf{Y}\\ \mathbf{C}_i \;&=\; \big[(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big]^{\dagger}\big(\mathbf{X}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{X}+n\gamma\mathbf{I}_d\big)\big[(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big]^{\dagger}\\ &=\; \mathbf{V}(\mathbf{I}_\rho+n\gamma\mathbf{\Sigma}^{-2})^{-1/2}(\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U}+n\gamma\mathbf{\Sigma}^{-2})(\mathbf{I}_\rho+n\gamma\mathbf{\Sigma}^{-2})^{-1/2}\mathbf{V}^T\\ &=\; \mathbf{V}\mathbf{V}^T+\mathbf{V}(\mathbf{I}_\rho+n\gamma\mathbf{\Sigma}^{-2})^{-1/2}(\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U}-\mathbf{I}_\rho)(\mathbf{I}_\rho+n\gamma\mathbf{\Sigma}^{-2})^{-1/2}\mathbf{V}^T.\end{aligned}$$

By Assumption 2.1, we have that $\mathbf{C}_i \succeq \big(1-\frac{\eta\,\sigma_{\max}^2}{\sigma_{\max}^2+n\gamma}\big)\mathbf{V}\mathbf{V}^T$. Since $\eta\leq 1/2$, it follows that $\mathbf{C}_i^{\dagger} \preceq \big(1+\frac{2\eta\,\sigma_{\max}^2}{\sigma_{\max}^2+n\gamma}\big)\mathbf{V}\mathbf{V}^T$. Let $\mathbf{C}_i^{\dagger}=\mathbf{V}\mathbf{V}^T+\mathbf{V}\mathbf{\Delta}_i\mathbf{V}^T$. It holds that $\mathbf{\Delta}_i \preceq \frac{2\eta\,\sigma_{\max}^2}{\sigma_{\max}^2+n\gamma}\mathbf{V}\mathbf{V}^T \preceq$

$2\eta\beta\mathbf{V}\mathbf{V}^T$. By definition, $\mathbf{W}^{\mathrm{c}} = \frac{1}{g}\sum_{i=1}^g \mathbf{W}_i^{\mathrm{c}}$. It follows that

$$\begin{aligned}
\Big\|(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}(\mathbf{W}_i^{\mathrm{c}}-\mathbf{W}^\star)\Big\|_F &= \Big\|\frac{1}{g}\sum_{i=1}^g \mathbf{C}_i^\dagger(\mathbf{A}_i+\mathbf{B}_i)\Big\|_F \\
&\le \Big\|\frac{1}{g}\sum_{i=1}^g(\mathbf{A}_i+\mathbf{B}_i)\Big\|_F + \Big\|\frac{1}{g}\sum_{i=1}^g \mathbf{V}\boldsymbol{\Delta}_i\mathbf{V}^T(\mathbf{A}_i+\mathbf{B}_i)\Big\|_F \\
&\le \Big\|\frac{1}{g}\sum_{i=1}^g \mathbf{A}_i\Big\|_F + \Big\|\frac{1}{g}\sum_{i=1}^g \mathbf{B}_i\Big\|_F + \frac{1}{g}\sum_{i=1}^g \|\boldsymbol{\Delta}_i\|_2\Big(\|\mathbf{A}_i\|_F+\|\mathbf{B}_i\|_F\Big) \\
&\le \Big\|\frac{1}{g}\sum_{i=1}^g \mathbf{A}_i\Big\|_F + \Big\|\frac{1}{g}\sum_{i=1}^g \mathbf{B}_i\Big\|_F + 2\eta\beta\frac{1}{g}\sum_{i=1}^g\Big(\|\mathbf{A}_i\|_F+\|\mathbf{B}_i\|_F\Big). \qquad (18)
\end{aligned}$$

By Assumption 2.3, we have that

$$\frac{1}{g}\sum_{i=1}^g \|\mathbf{A}_i\|_F = \|(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_d)^{-1/2}\boldsymbol{\Sigma}\|_2\cdot\frac{1}{g}\sum_{i=1}^g\|\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{Y}^\perp\|_F \le \sqrt{\tfrac{\epsilon\,\sigma_{\max}^2}{\sigma_{\max}^2+n\gamma}}\|\mathbf{Y}^\perp\|_F.$$

We apply Assumption 2.1 and follow the proof of Theorem 15 to show that

$$\|\mathbf{B}_i\|_F^2 \le \eta^2 n\gamma\tfrac{\sigma_{\max}^2}{\sigma_{\max}^2+n\gamma}\Big\|(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_d)^{-1/2}\mathbf{U}^T\mathbf{Y}\Big\|_F^2.$$

It follows that

$$\begin{aligned}
&\frac{1}{g}\sum_{i=1}^g\Big(\|\mathbf{A}_i\|_F+\|\mathbf{B}_i\|_F\Big) \\
&\le \max\Big\{\sqrt{\epsilon},\eta\Big\}\sqrt{\tfrac{\sigma_{\max}^2}{\sigma_{\max}^2+n\gamma}}\Big(\|\mathbf{Y}^\perp\|_F+\sqrt{n\gamma}\|(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_d)^{-1/2}\mathbf{U}^T\mathbf{Y}\|_F\Big) \\
&\le \max\Big\{\sqrt{\epsilon},\eta\Big\}\sqrt{\beta}\sqrt{2\|\mathbf{Y}^\perp\|_F^2+2n\gamma\|(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_d)^{-1/2}\mathbf{U}^T\mathbf{Y}\|_F^2} \\
&= \max\big\{\sqrt{\epsilon},\eta\big\}\sqrt{\beta}\,\sqrt{2n\,f(\mathbf{W}^\star)}. \qquad (19)
\end{aligned}$$

Here the equality follows from Lemma 25. Let $\mathbf{S} = \frac{1}{g}[\mathbf{S}_1,\cdots,\mathbf{S}_g]\in\mathbb{R}^{n\times sg}$. We have that

$$\begin{aligned}
\frac{1}{g}\sum_{i=1}^g\mathbf{A}_i &= \mathbf{V}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_d)^{-1/2}\boldsymbol{\Sigma}\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{Y}^\perp, \\
\frac{1}{g}\sum_{i=1}^g\mathbf{B}_i &= n\gamma\mathbf{V}\boldsymbol{\Sigma}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_d)^{-1/2}(\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho)(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_d)^{-1}\mathbf{U}^T\mathbf{Y}.
\end{aligned}$$

Applying Assumptions 2.1 and 2.2, we use the same techniques as in the above to obtain

$$\begin{aligned}
&\Big\|\frac{1}{g}\sum_{i=1}^g\mathbf{A}_i\Big\|_F+\Big\|\frac{1}{g}\sum_{i=1}^g\mathbf{B}_i\Big\|_F \le \sqrt{2\Big\|\frac{1}{g}\sum_{i=1}^g\mathbf{A}_i\Big\|_F^2+2\Big\|\frac{1}{g}\sum_{i=1}^g\mathbf{B}_i\Big\|_F^2} \\
&\le \max\Big\{\tfrac{\sqrt{\epsilon}}{\sqrt{g}},\tfrac{\eta}{\sqrt{g}}\Big\}\sqrt{\tfrac{\sigma_{\max}^2}{\sigma_{\max}^2+n\gamma}}\sqrt{2n\,f(\mathbf{W}^\star)} = \max\big\{\sqrt{\epsilon},\eta\big\}\tfrac{\sqrt{\beta}}{\sqrt{g}}\sqrt{2n\,f(\mathbf{W}^\star)}. \qquad (20)
\end{aligned}$$

It follows from (18), (19), and (20) that

$$\begin{aligned}
&\Big\|(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}(\mathbf{W}_i^{\mathrm{c}}-\mathbf{W}^\star)\Big\|_F \\
&\le \Big\|\frac{1}{g}\sum_{i=1}^g\mathbf{A}_i\Big\|_F+\Big\|\frac{1}{g}\sum_{i=1}^g\mathbf{B}_i\Big\|_F+2\eta\beta\frac{1}{g}\sum_{i=1}^g\Big(\|\mathbf{A}_i\|_F+\|\mathbf{B}_i\|_F\Big) \\
&\le \Big[\tfrac{1}{\sqrt{g}}\max\big\{\sqrt{\epsilon},\eta\big\}+2\beta\eta\cdot\max\big\{\sqrt{\epsilon},\eta\big\}\Big]\sqrt{\beta}\sqrt{2n\,f(\mathbf{W}^\star)} \\
&= \max\big\{\sqrt{\epsilon},\eta\big\}\cdot\big(\tfrac{1}{\sqrt{g}}+2\beta\eta\big)\sqrt{\beta}\sqrt{2n\,f(\mathbf{W}^\star)} \\
&= \sqrt{\alpha\beta n\,f(\mathbf{W}^\star)}.
\end{aligned}$$

This concludes our proof. ■

D.2 Proof of Theorem 21

Proof By Lemma 25, we only need to show that $\big\|(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}^{\mathrm{h}}-\mathbf{W}^\star\big)\big\|_F^2 \le \alpha^2\beta^2\big(-nf(\mathbf{W}^\star)+\|\mathbf{Y}\|_F^2\big)$.

In the proof of Theorem 2 we show that

$$(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}_i^{\mathrm{h}}-\mathbf{W}^\star\big) = \mathbf{V}\mathbf{A}_i\mathbf{B}_i\mathbf{C},$$

where

$$\begin{aligned}
\mathbf{A}_i &= (\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\boldsymbol{\Sigma}(\mathbf{I}_\rho-\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U})\boldsymbol{\Sigma}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}, \\
\mathbf{B}_i &= (\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{1/2}(\boldsymbol{\Sigma}\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U}\boldsymbol{\Sigma}+n\gamma\mathbf{I}_\rho)^{-1}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{1/2}, \\
\mathbf{C} &= (\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1/2}\boldsymbol{\Sigma}\mathbf{U}^T\mathbf{Y}.
\end{aligned}$$

It follows from Assumption 2.1 that for all $i\in[g]$,

$$\tfrac{1}{1+\eta}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1} \preceq (\boldsymbol{\Sigma}\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U}\boldsymbol{\Sigma}+n\gamma\mathbf{I}_\rho)^{-1} \preceq \tfrac{1}{1-\eta}(\boldsymbol{\Sigma}^2+n\gamma\mathbf{I}_\rho)^{-1}.$$

We let $\mathbf{B}_i = \mathbf{I}_\rho+\boldsymbol{\Delta}_i$. Thus $-\frac{\eta}{1+\eta}\mathbf{I}_\rho\preceq\boldsymbol{\Delta}_i\preceq\frac{\eta}{1-\eta}\mathbf{I}_\rho$. It follows that

$$\begin{aligned}
(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}^{\mathrm{h}}-\mathbf{W}^\star\big) &= \frac{1}{g}\sum_{i=1}^g(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}_i^{\mathrm{h}}-\mathbf{W}^\star\big) \\
&= \frac{1}{g}\sum_{i=1}^g\mathbf{V}\mathbf{A}_i(\mathbf{I}_\rho+\boldsymbol{\Delta}_i)\mathbf{C} = \frac{1}{g}\sum_{i=1}^g\mathbf{V}\mathbf{A}_i\mathbf{C}+\frac{1}{g}\sum_{i=1}^g\mathbf{V}\mathbf{A}_i\boldsymbol{\Delta}_i\mathbf{C}.
\end{aligned}$$

It follows that

$$\begin{aligned}
&\Big\|(\mathbf{X}^T\mathbf{X}+n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}^{\mathrm{h}}-\mathbf{W}^\star\big)\Big\|_F \le \Big\|\frac{1}{g}\sum_{i=1}^g\mathbf{A}_i\Big\|_2\Big\|\mathbf{C}\Big\|_F+\frac{1}{g}\sum_{i=1}^g\|\mathbf{A}_i\|_2\|\boldsymbol{\Delta}_i\|_2\|\mathbf{C}\|_F \\
&\le \Big\|\frac{1}{g}\sum_{i=1}^g\mathbf{A}_i\Big\|_2\Big\|\mathbf{C}\Big\|_F+\frac{\eta}{1-\eta}\Big(\frac{1}{g}\sum_{i=1}^g\|\mathbf{A}_i\|_2\Big)\|\mathbf{C}\|_F. \qquad (21)
\end{aligned}$$

Let $\mathbf{S} = \frac{1}{g}[\mathbf{S}_1, \cdots, \mathbf{S}_g] \in \mathbb{R}^{n \times gs}$. It follows from the definition of $\mathbf{A}_i$ that

$$\begin{aligned}
\big\|\mathbf{A}_i\big\|_2 &= \Big\|(\boldsymbol{\Sigma}^2 + n\gamma\mathbf{I}_\rho)^{-1/2}\boldsymbol{\Sigma}(\mathbf{I}_\rho - \mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U})\boldsymbol{\Sigma}(\boldsymbol{\Sigma}^2 + n\gamma\mathbf{I}_\rho)^{-1/2}\Big\|_2 \\
&\leq \eta\Big\|(\boldsymbol{\Sigma}^2 + n\gamma\mathbf{I}_\rho)^{-1/2}\boldsymbol{\Sigma}\boldsymbol{\Sigma}(\boldsymbol{\Sigma}^2 + n\gamma\mathbf{I}_\rho)^{-1/2}\Big\|_2 = \eta\tfrac{\sigma_{\max}^2}{\sigma_{\max}^2 + n\gamma} = \eta\beta, \\
\Big\|\frac{1}{g}\sum_{i=1}^g \mathbf{A}_i\Big\|_2 &= \Big\|(\boldsymbol{\Sigma}^2 + n\gamma\mathbf{I}_\rho)^{-1/2}\boldsymbol{\Sigma}(\mathbf{I}_\rho - \mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U})\boldsymbol{\Sigma}(\boldsymbol{\Sigma}^2 + n\gamma\mathbf{I}_\rho)^{-1/2}\Big\|_2 \\
&\leq \tfrac{\eta}{\sqrt{g}}\big\|(\boldsymbol{\Sigma}^2 + n\gamma\mathbf{I}_\rho)^{-1/2}\boldsymbol{\Sigma}\boldsymbol{\Sigma}(\boldsymbol{\Sigma}^2 + n\gamma\mathbf{I}_\rho)^{-1/2}\big\|_2 = \tfrac{\eta}{\sqrt{g}}\tfrac{\sigma_{\max}^2}{\sigma_{\max}^2 + n\gamma} = \tfrac{\eta\beta}{\sqrt{g}}.
\end{aligned}$$

It follows from (21) that

$$\begin{aligned}
&\Big\|(\mathbf{X}^T\mathbf{X} + n\gamma\mathbf{I}_d)^{1/2}\big(\mathbf{W}^{\mathrm{h}} - \mathbf{W}^\star\big)\Big\|_F \\
&\leq \Big(\tfrac{\eta}{\sqrt{g}} + \tfrac{\eta^2}{1-\eta}\Big)\beta\big\|\mathbf{C}\big\|_F \\
&\leq \Big(\tfrac{\eta}{\sqrt{g}} + \tfrac{\eta^2}{1-\eta}\Big)\beta\sqrt{-nf(\mathbf{W}^\star) + \|\mathbf{Y}\|_F^2},
\end{aligned}$$

where the latter inequality follows from the proof of Theorem 16. This concludes the proof. ■

Appendix E. Model Averaging from the Statistical Perspective: Proofs

In Section E.1 we prove Theorem 22. In Section E.2 we prove Theorem 23.

E.1 Proof of Theorem 22

Proof The bound on $\mathsf{bias}\big(\mathbf{W}^{\mathrm{c}}\big)$ can be shown in the same way as the proof of Theorem 17.

We prove the bound on $\mathsf{var}\big(\mathbf{W}^{\mathrm{c}}\big)$ in the following. It follows from Assumption 2.1 that

$$(1+\eta)^{-1}(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1} \preceq (\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U} + n\gamma\boldsymbol{\Sigma}^{-2})^\dagger \preceq (1-\eta)^{-1}(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1}.$$

Let

$$(\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U} + n\gamma\boldsymbol{\Sigma}^{-2})^\dagger = (\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1/2}(\mathbf{I}_\rho + \boldsymbol{\Delta}_i)(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1/2}.$$

It holds that

$$-\frac{\eta}{1+\eta}\mathbf{I}_\rho \preceq \boldsymbol{\Delta}_i \preceq \frac{\eta}{1-\eta}\mathbf{I}_\rho.$$

By the definition of $\mathsf{var}(\mathbf{W}^{\mathrm{c}})$ in Theorem 9, we have that

$$\begin{aligned}
&\sqrt{\mathsf{var}\big(\mathbf{W}^{\mathrm{c}}\big)} \\
&= \tfrac{\xi}{\sqrt{n}}\Big\|\frac{1}{g}\sum_{i=1}^g(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1}\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T + \frac{1}{g}\sum_{i=1}^g(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1/2}\boldsymbol{\Delta}_i(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1/2}\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\Big\|_F \\
&\leq \tfrac{\xi}{\sqrt{n}}\Big(\Big\|(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1}\mathbf{U}^T\mathbf{S}\mathbf{S}^T\Big\|_F + \frac{1}{g}\sum_{i=1}^g\Big\|(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1/2}\boldsymbol{\Delta}_i(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1/2}\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\Big\|_F\Big) \\
&\leq \tfrac{\xi}{\sqrt{n}}\big\|(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1}\big\|_F\Big(\big\|\mathbf{U}^T\mathbf{S}\big\|_2\big\|\mathbf{S}\big\|_2 + \frac{\eta}{1-\eta}\frac{1}{g}\sum_{i=1}^g\big\|\mathbf{U}^T\mathbf{S}_i\big\|_2\big\|\mathbf{S}_i\big\|_2\Big) \\
&= \sqrt{\mathsf{var}\big(\mathbf{W}^\star\big)}\Big(\big\|\mathbf{U}^T\mathbf{S}\big\|_2\big\|\mathbf{S}\big\|_2 + \frac{\eta}{1-\eta}\frac{1}{g}\sum_{i=1}^g\big\|\mathbf{U}^T\mathbf{S}_i\big\|_2\big\|\mathbf{S}_i\big\|_2\Big).
\end{aligned}$$

Under Assumption 2.1, we have that $\|\mathbf{S}_i^T\mathbf{U}\|_2^2 \leq 1+\eta$ and $\|\mathbf{S}^T\mathbf{U}\|_2^2 \leq 1 + \frac{\eta}{\sqrt{g}}$. It follows that

$$\sqrt{\frac{\mathsf{var}\big(\mathbf{W}^{\mathrm{c}}\big)}{\mathsf{var}\big(\mathbf{W}^\star\big)}} \leq \sqrt{1 + \frac{\eta}{\sqrt{g}}}\big\|\mathbf{S}\big\|_2 + \frac{\eta\sqrt{1+\eta}}{1-\eta}\frac{1}{g}\sum_{i=1}^g\big\|\mathbf{S}_i\big\|_2.$$

Now the desired result follows from Assumption 2.3. ■

E.2 Proof of Theorem 23

Proof The bound on $\mathsf{var}\big(\mathbf{W}^{\mathrm{h}}\big)$ can be established in the same way as Theorem 19.

We prove the bound on $\mathsf{bias}\big(\mathbf{W}^{\mathrm{h}}\big)$ in the following. Let

$$(\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U} + n\gamma\boldsymbol{\Sigma}^{-2})^\dagger = (\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1/2}(\mathbf{I}_\rho + \boldsymbol{\Delta}_i)(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1/2}.$$

Under Assumption 2.1, we have that $\boldsymbol{\Delta}_i \preceq \frac{\eta}{1-\eta}\mathbf{I}_\rho$. It follows from Theorem 9 that

$$\begin{aligned}
\mathsf{bias}\big(\mathbf{W}^{\mathrm{h}}\big) &= \gamma\sqrt{n}\Big\|\frac{1}{g}\sum_{i=1}^g\Big(\boldsymbol{\Sigma}^{-2} + \tfrac{\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U} - \mathbf{I}_\rho}{n\gamma}\Big)(\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U} + n\gamma\boldsymbol{\Sigma}^{-2})^\dagger\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\Big\|_F \\
&\leq \gamma\sqrt{n}\Big\|\frac{1}{g}\sum_{i=1}^g\Big(\boldsymbol{\Sigma}^{-2} + \tfrac{\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U} - \mathbf{I}_\rho}{n\gamma}\Big)(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\Big\|_F \\
&\quad + \gamma\sqrt{n}\Big\|\frac{1}{g}\sum_{i=1}^g\Big(\boldsymbol{\Sigma}^{-2} + \tfrac{\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U} - \mathbf{I}_\rho}{n\gamma}\Big)(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1/2}\boldsymbol{\Delta}_i(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2})^{-1/2}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\Big\|_F \\
&\triangleq \gamma\sqrt{n}(A+B),
\end{aligned}$$

where

$$\begin{aligned} A &= \left\| \frac{1}{g}\sum_{i=1}^{g} \left(\boldsymbol{\Sigma}^{-2} + \tfrac{\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U}-\mathbf{I}_\rho}{n\gamma}\right)\left(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2}\right)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0 \right\|_F \\ &= \left\| \left(\boldsymbol{\Sigma}^{-2} + \tfrac{\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho}{n\gamma}\right)\left(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2}\right)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0 \right\|_F, \\ B &= \left\| \frac{1}{g}\sum_{i=1}^{g} \left(\boldsymbol{\Sigma}^{-2} + \tfrac{\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U}-\mathbf{I}_\rho}{n\gamma}\right)\left(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2}\right)^{-1/2}\boldsymbol{\Delta}_i\left(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2}\right)^{-1/2}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0 \right\|_F \\ &\leq \frac{1}{g}\sum_{i=1}^{g} \left\| \left(\boldsymbol{\Sigma}^{-2} + \tfrac{\mathbf{U}^T\mathbf{S}_i\mathbf{S}_i^T\mathbf{U}-\mathbf{I}_\rho}{n\gamma}\right)\left(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2}\right)^{-1/2}\boldsymbol{\Delta}_i\left(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2}\right)^{-1/2}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0 \right\|_F. \end{aligned}$$

It follows from Assumption 2.1 that $\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho$ is semidefinitely bounded between $\pm\frac{\eta}{\sqrt{g}}\mathbf{I}_\rho$. Thus

$$\left(1 - \tfrac{\eta\sigma_{\max}^2}{n\gamma\sqrt{g}}\right)\boldsymbol{\Sigma}^{-2} \preceq \boldsymbol{\Sigma}^{-2} + \tfrac{\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho}{n\gamma} \preceq \left(1 + \tfrac{\eta\sigma_{\max}^2}{n\gamma\sqrt{g}}\right)\boldsymbol{\Sigma}^{-2}.$$

It follows that

$$\begin{aligned} A &= \left\| \left(\boldsymbol{\Sigma}^{-2} + \tfrac{\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}-\mathbf{I}_\rho}{n\gamma}\right)\left(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2}\right)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0 \right\|_F \\ &\leq \left(1 + \tfrac{\eta\sigma_{\max}^2}{n\gamma\sqrt{g}}\right)\left\| \left(\boldsymbol{\Sigma}^2 + n\gamma\mathbf{I}_\rho\right)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0 \right\|_F. \end{aligned}$$

Similar to the proof of Theorem 19, we can show that

$$\begin{aligned} B &\leq \left(1 + \frac{\eta\sigma_{\max}^2}{n\gamma}\right)\cdot\frac{1}{g}\sum_{i=1}^{g}\left\|\boldsymbol{\Sigma}^{-2}\left(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2}\right)^{-1/2}\boldsymbol{\Delta}_i\left(\mathbf{I}_\rho + n\gamma\boldsymbol{\Sigma}^{-2}\right)^{-1/2}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\right\|_F \\ &\leq \frac{\eta}{1-\eta}\left(1 + \frac{\eta\sigma_{\max}^2}{n\gamma}\right)\cdot\left\|\left(\boldsymbol{\Sigma}^2 + n\gamma\mathbf{I}_\rho\right)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\right\|_F. \end{aligned}$$

Hence

$$\begin{aligned} \mathsf{bias}\left(\mathbf{W}^{\mathrm{h}}\right) &\leq \gamma\sqrt{n}(A+B) \\ &\leq \left[\tfrac{1}{1-\eta} + \left(\tfrac{\eta}{\sqrt{g}} + \tfrac{\eta^2}{1-\eta}\right)\tfrac{\sigma_{\max}^2}{n\gamma}\right]\gamma\sqrt{n}\left\|\left(\boldsymbol{\Sigma}^2 + n\gamma\mathbf{I}_\rho\right)^{-1}\boldsymbol{\Sigma}\mathbf{V}^T\mathbf{W}_0\right\|_F \\ &= \left[\tfrac{1}{1-\eta} + \left(\tfrac{\eta}{\sqrt{g}} + \tfrac{\eta^2}{1-\eta}\right)\tfrac{\sigma_{\max}^2}{n\gamma}\right]\mathsf{bias}\left(\mathbf{W}^\star\right). \end{aligned}$$

Here the equality follows from Theorem 4. ■

Abstract

We study the usefulness of conditional gradient like methods for determining projections onto convex sets, in particular, projections onto naturally arising convex sets in reproducing kernel Hilbert spaces. Our work is motivated by the recently introduced kernel herding algorithm which is closely related to the Conditional Gradient Method (CGM). It is known that the herding algorithm converges with a rate of $1/t$, where t counts the number of iterations, when a point in the interior of a convex set is approximated. We generalize this result and we provide a necessary and sufficient condition for the algorithm to approximate projections with a rate of $1/t$. The CGM, which is in general vastly superior to the herding algorithm, achieves only an inferior rate of $1/\sqrt{t}$ in this setting. We study the usefulness of such projection algorithms further by exploring ways to use these for solving concrete machine learning problems. In particular, we derive non-parametric regression algorithms which use at their core a slightly modified kernel herding algorithm to determine projections. We derive bounds to control approximation errors of these methods and we demonstrate via experiments that the developed regressors are en-par with state-of-the-art regression algorithms for large scale problems.

1. Introduction

Convex sets and projections onto convex sets are omnipresent in Machine Learning and Statistics. Projections appear already in the most basic approaches like in ordinary least squares regression where the the estimate can be interpreted as the projection of some target vector onto a linear subspace. By adding constraints one arrives naturally at a convex projection problem. Similarly, the ridge regressor and Gaussian process regressor are closely related to projections onto balls and the lasso estimator (Tibshirani, 1996) corresponds to a projection onto a simplex (again a convex set). Regularization approaches with convex constraints are, in general, closely related to the problem of determining a projection. For example, sparsity constraints are often enforced by optimizing over the standard simplex and algorithms that determine projections onto the simplex have been studied extensively (Duchi, Shalev-Shwartz, Singer, and Chandra, 2008).

This paper is about exploring the usefulness of some closely related algorithms for determining projections onto convex sets in the large data context. Our inspiration for this line of research dates back to the paper by Welling (2009) in which an algorithm, called the herding algorithm, has been introduced which computes compact representations of probability measures. By a compact representation we mean here a representation that is supported on few points of the sample space and that can be used to calculate efficiently expectations of functions. The algorithm has garnered attention in recent years and various generalizations of the method have been explored. In one of these works it has been studied how the algorithm behaves in a non-parametric setting where a kernel function is defined on the sample space (Chen, Welling, and Smola, 2010). The authors analyzed the interplay between the algorithm and the reproducing kernel Hilbert space (RKHS, Aronszajn (1950)) associated with the kernel function. Their main finding has been that the algorithm has a guaranteed rate of convergence towards the given probability measure (or, more accurately, towards its representer in the RKHS) of $1/t$, where t is the number of iterations for which the algorithm is run. The rate of $1/t$ is an improvement over randomly selected support points, which would guarantee a rate of $1/\sqrt{t}$, but the rate is slow compared to what many other numerical algorithms yield. It is worth pointing out that we consider here convergence in $\|\cdot\|$, while in the literature results are often reported for quadratic objectives like $\|\cdot\|^2$. The virtue of this algorithm is that the computational costs per iteration are linear in the sample size. These low costs in dependence of the sample size make this algorithm, and related algorithms, attractive in the large data context where algorithms with faster rates of convergence are often prohibitively expensive to compute.

The herding algorithm is iterative and uses at its core an inner product between the approximation error $y - p_t$ at iteration t and a set of candidates S that can be chosen to reduce the error. Here, y lies inside a convex set C, p_t is the approximation of y at iteration t and S is a subset of C. The algorithm selects elements which maximize this inner product $\langle y - p_t, x\rangle$ over $x \in S$. We asked ourselves somewhat naïvely what would happen if y lies outside of C. One would hope that the algorithm converges in this case to the point in C that is closest to y, or in other words, that it would converge to the projection Py of y onto C. The first observation we had was that this will, in fact, be true if $y - Py$ stands orthogonal on the (affine) subspace spanned by C and if Py lies in the (affine) interior of C, because in this case the algorithm is completely unaffected by $y - Py$ and it behaves equivalently to the case where we would apply it directly to $Py \in C$. In this setting, the standard guarantees tell us that the algorithm converges with a rate of $1/t$ to the projection. Our initial observation was in a way naïve since the literature on herding provides a way to show that the algorithm with an added line search converges to the projection. The argument to verify the convergence is based on the observation from Bach, Lacoste-Julien, and Obozinski (2012) that the herding algorithm with an added line search is equivalent to a well known method called the conditional gradient method (CGM, Frank and Wolfe (1956)). Basic guarantees on the convergence of the CGM imply directly that the method converges with a rate of $1/\sqrt{t}$ to the projection (see our Literature Section below for more details). This convergence result is reaffirming, however, the rate of convergence the result guarantees is a slow rate of $1/\sqrt{t}$ and not $1/t$.

The rate of $1/\sqrt{t}$ is, in fact, the actual rate with which CGM converges in non-trivial projection problems. The reason for this is that, in interesting cases, projections lie in the boundary of the convex set and CGM itself achieves only in exceptional cases a rate that is better than $1/\sqrt{t}$ if the solution of an optimization problem lies in the boundary (Cannon and Cullum, 1968). In recent years extensions of the basic CGM algorithm have become popular and it was shown that a linear rate of convergence (a rate significantly better than $1/t$) is achieved by a particular extension, the CGM with away steps algorithm, even if the solution lies in the boundary (Lacoste-Julien and Jaggi, 2015). This is a significant result, but it comes with a caveat: we gain strong guarantees only if the convex set has a large pyramidal width. For instance, the d dimensional cube has a large pyramidal width and the authors provide an upper bound on the reduction of the approximation error in the order of $1/d^2$ per step. The convex sets we are mainly interested in are of the form $C = \{k(x,\cdot) : x \in X\} \subset \mathcal{H}$, where k is the reproducing kernel of the RKHS $\mathcal{H}$. Here, the dimension of the spanned subspace is often equal to the sample size (when using a Gaussian kernel,

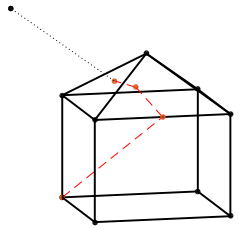

Figure 1: An illustration of the application of the herding algorithm to a projection problem. The aim is to find the projection of a ray starting at the black dot onto the house. The house is compact and convex. The herding algorithm finds for such sets approximations of the projection with an accuracy in the order of $1/t$, where t is the number of iterations. The red dots show the approximation after 0, 2, 5 and 100 steps with an initial estimate that equals the North-West corner on the bottom of the house.

for example). Furthermore, C is significantly more complicated than a cube and we expect that the upper bound gives us guarantees on the reduction that are significantly worse than $1/n^2$ per iteration, where n is the size of the sample. In the large data context, where $n \geq 10^5$, these reductions per step are tiny. Another recent approach to improve the convergence behavior of the CGM has been developed in Garber and Hazan (2013). Standard CGM is in this approach combined with what the authors call a Local Linear Optimization Oracle (LLOO) and it is shown that a linear rate of convergence is achieved by their method. Like in the away step approach the geometry of the convex set factors into the performance. For the method from Garber and Hazan (2013) the geometry affects the run-time of the LLOO and, hence, the run-time of the CGM with the added LLOO. The approach works well for simple shaped convex sets like the simplex but becomes difficult when C has no particular structure as in our RKHS setting. Understanding better the relevant geometric properties of C with respect to the reproducing kernel is an intriguing problem, but it is beyond the aims of this paper. We aim here for a deeper understanding of the core algorithms and their interplay with the projection problem in Hilbert space. The following figure visualizes the relation between the different CGM like methods. We focus in this paper on the methods in the shaded area.

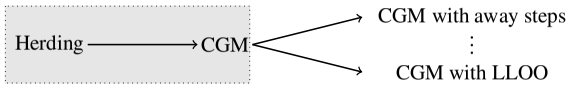

Figure 2: The relation between various CGM like methods.

CGM is known to converge with a linear rate if there exists a ball around the solution inside the convex set (this is also known as Slater's condition, Beck and Teboulle (2004)). Similarly, for the herding algorithm it has been shown that this very same condition guarantees a rate of $1/t$ (Chen et al., 2010). To the best of our knowledge, both convergence results have been derived

independently of each other and it is telling that in both approaches the same assumption plays a fundamental role (the existence of a ball around the optimum). The assumption appears naturally in the analyses since it allows a strong reduction of estimation errors per iteration independently of the direction in which the errors point. If this assumption does not hold then there are directions which pose problems, i.e. if an error builds up in such a direction then these errors will only decay slowly over time. This is why solutions that lie in the boundary pose problems: errors that point away from the convex set can not be easily reduced. We refine the convergence argument to be able to deal with such errors. On a high level our approach can be described in the following way: consider a convex set with finitely many extremes then each point in the boundary is in the relative interior of a face of the original convex set. For example, in Figure 1 our convex set is the house and we want to compute the projection of the black dot onto the house. The dotted line visualizes the process of projecting onto the house and the red dot at the end of the line is the projection that we want to determine algorithmically. The projection does not lie in the interior of the house but it lies inside a face of the convex set (the triangle that contains the projection). A face of a convex set is in turn a convex set and if we would apply the algorithm directly to this face then we could show fast convergence. In general, we can not identify the face that contains the projection without using significant computational resources. However, we can treat elements outside of this face, which are chosen by the algorithm, as perturbations that disturb the behavior of the algorithm. For instance, we applied the herding algorithm to the problem in Figure 1 and we used an initial approximation of the projection which corresponds to the North-West corner on the bottom of the house. The dashed line in red shows how the approximation evolves over multiple steps and how the error that is introduced by the initialization shrinks over time. Our line of attack in the theoretical part of this paper is to control such perturbations and to show that the rate of convergence of the herding algorithm is not negatively affected by these.

We were also interested in understanding how CGM like algorithms to determine projections in Hilbert spaces can be exploited in statistical problems. A blueprint is given in the paper by Chen et al. (2010) where the herding algorithm is applied in an RKHS $\mathcal{H}$ to approximate elements inside a compact and convex set $C \subset \mathcal{H}$. It is natural to consider extensions in which C is modified in a suitable way to represent a space of solutions of certain statistical problems. We showcase this approach in the regression problem. In this case, C is the space of regression functions. The projection approach itself is generic and one can gain with relative ease algorithms that infer kernel regressors from data. We call these CCP-regressors where the acronym CCP stands for compact convex projection. The advantage of this approach is that the corresponding algorithms are cheap to compute and they are applicable in the large data context. We find in experiments that the algorithms we derive are en-par with established kernel regression algorithms like the Gaussian process or the fast kernel ridge regressor (FastKRR, Zhang, Duchi, and Wainwright (2013)).

1.1 Literature

We aim in this section for a short overview summarizing key results that put our work in perspective. We start by stating the herding algorithm for approximating a point x^* inside a convex set C that is induced by the finite set of points S, i.e. $C = \operatorname{cch} S$, where cch denotes the closed convex hull operator. C is typically a subset of $\mathbb{R}^d$ equipped with the Euclidean inner product or some other Hilbert space. Given the starting value $w_0 = x^*$ and the initialization $t = 1$ the herding algorithm iterates

1. choose $x_t \in \arg\max_{x \in S} \langle w_{t-1}, x \rangle$,
2. set $w_t = w_{t-1} - (x_t - x^*)$,
3. set $t \leftarrow t + 1$.

This basic routine is combined with some termination criterion like running the algorithm for T iterations. The approximation of x^* is then $(x_1 + \ldots + x_T)/T$ where T denotes here the number of iterations the algorithm was run for.

The herding algorithm is a special case of what is called the *conditional gradient method (CGM)* or the *Frank-Wolfe algorithm* (Frank and Wolfe, 1956; Bach et al., 2012). The conditional gradient method is known since the fifties and various results about its convergence behavior have been derived throughout the years. The CGM method tries to approximate the minimal value of a differentiable function $f : \mathbb{R}^d \to \mathbb{R}$ on a set C by iterating two steps after an initialization with some value $x_0 \in C$:

1. Choose an $x^\star \in \arg\min_{x \in C} \langle x - x_{t-1}, \nabla f(x_{t-1}) \rangle$,
2. perform a line search over $\lambda \in [0, 1]$, i.e. choose a

$$\lambda^\star \in \arg\min_{\lambda \in [0,1]} f(x_{t-1} + \lambda(x^\star - x_{t-1}))$$

and update $x_t = x_{t-1} + \lambda^\star(x^\star - x_{t-1})$.

Standard results for the CGM method hold for continuously differentiable functions on convex compact subsets C of $\mathbb{R}^d$ (Beck and Teboulle, 2004). Let $f^* = \min_{x \in C} f(x)$ then it is known that a sequence $\{x_t\}_{t \geq 0}$ produced by the CGM attains the minimum eventually, i.e. $\lim_{t \to \infty} f(x_t) = f^*$ and there exists a constant b such that $f(x_t) - f^* \leq b/t$. A differentiable function on a compact set is Lipschitz continuous and the constant b depends on the Lipschitz constant and on the diameter of the set C, $\operatorname{diam}(C) = \sup_{x,y \in C} \|x - y\|$. We can use the CGM to find the projection of z onto C. Letting $f(x) = \|x - z\|^2$, with $\|\cdot\|$ the Euclidean norm, we can observe that f is continuously differentiable with derivative $2\langle x - z, \cdot \rangle$ and we are assured that $\|x_t - z\|^2 - \min_{x \in C} \|x - z\|^2 \leq b/t$ for some constant b and all $t \geq 0$. Observe that this rate is slower then what we aim for since we gain here a rate of about $t^{-1/2}$ for the convergence of $\|x_t - z\|$. The norm itself is not differentiable and we can not derive the faster rate of $1/t$ through these results.

It is also known that the rate of convergence can not be improved in general (Cannon and Cullum, 1968)[Thm. 2]. Hence, stronger assumptions are needed to gain faster rates of convergence. One typical assumption is that *Slater's condition* holds. Slater's condition is in our context the assumption that $z \in \operatorname{int} C$, where $\operatorname{int} C$ denotes the interior of C. Proposition 3.2 in Beck and Teboulle (2004) demonstrates that if Slater's condition is fulfilled then the CGM produces a sequence $\{x_t\}_{t \geq 0}$ which satisfies

$$\|x_t - z\| \leq be^{-tq/2}$$

for some positive constants b and q. The rate is significantly faster than what is known for the herding algorithm but the result is not applicable to the problem of computing projections since (non-trivial) projections lie in the boundary of C and not in the interior. These convergence results are nevertheless fundamental and they are a corner stone for various studies. For instance, in Jaggi (2013) these convergence results for the CGM are combined with a duality argument to give bounds

on the duality gap between the primal and dual solution of the optimization problem. Another line of research considers extensions of the CGM which are build to circumvent the sub-linear rate of convergence. We discussed already the most prominent approaches: the classical approach from Wolfe (1970) in which away steps are added to the CGM and the approach from Garber and Hazan (2013) which both guarantee a linear rate of convergence.

Much of the research on the CGM has been done in the general context where an arbitrary continuously differentiable function on a convex set is optimized. However, the more specialized problem of determining projections onto convex sets has also garnered attention. Especially, in the context of sparsity. The convex set C that is typically considered in this context is the standard simplex in $\mathbb{R}^d$ which is $\Delta^{d-1} = \operatorname{cch}\{e_n : 1 \leq n \leq d\}$, where $e_1, \ldots, e_d$ is the standard basis in $\mathbb{R}^d$. The simplex Δ^{d-1} is of particular importance because ℓ_1-constraints can be naturally expressed through it: $w \in \mathbb{R}^d_+$ with $\|w\|_{\ell_1} = 1$ implies that $w = \sum_{i=1}^d \langle w, e_i \rangle e_i \in \operatorname{cch}\{e_n : 1 \leq n \leq d\} = \Delta^{d-1}$ (and vice versa). The CGM acting on the simplex can be used to find sparse solutions for a variety of problems. Most notably the *lasso estimator* (Tibshirani, 1996) can be found through an application of the CGM to a simplex (Clarkson, 2010). In Duchi et al. (2008) a similar problem is studied. The motivation are there algorithms which require projections onto a simplex. The authors develop a projection algorithm that can be computed in the order of d operations on average (the algorithm is stochastic) where d is the dimension of the simplex. This resembles the order of run time of the CGM.

Another set of important results for the CGM rely on strong convexity assumptions about the function f and the set C, see for exampleGarber and Hazan (2015) and references therein. Under such assumptions one can obtain a rate of $1/t$ for finding the projection on C, i.e. the rate of convergence applies independently of where in C the solution lies. The boundary of a strongly convex set C bends significantly. In our paper we assume very different properties of C. We are interested in the convex hull C of a finite set S and faces of such sets C are flat, i.e. they do not bend.

Closely related to the closed convex hull of a set S is the minimum enclosing ball of S (MEB, Clarkson (2010)). The difference between the two is that an Euclidean ball bends (the Euclidean norm is uniformly convex) while the closed convex hull interpolates the boundaries through hyperplanes. For example, the MEB of $S = \{\pm e_1, \ldots, \pm e_d\}$ is the Euclidean unit ball while $\operatorname{cch} S$ is an ℓ_1-ball (a diamond). There exist efficient algorithms for determining the MEB under different conditions. Furthermore, a variety of machine learning problems can be rephrased as the problem of finding an MEB (support vector algorithms are approached in this way in Tsang et al. (2005a,b)).

1.2 Contributions

In this paper we study the usefulness of conditional gradient methods to determine projections onto compact convex sets in Hilbert spaces. The contributions split naturally into theoretical and applied contributions through which we explore this theme. The theoretical contributions are *two theorems*. Our *first theorem* shows that the herding algorithm retains its rate of convergence of $1/t$ if, and only if, the perturbations introduced through points outside the minimal face are coupled in a certain way. The approach we use (considering the minimal face to which well-known results can be easily adapted and controlling perturbations which are introduced by elements outside of the minimal face) is to the best of our knowledge new and we expect that this line of reasoning can be extended in the future to study more advanced methods like the CGM with away steps.

Our *second theorem* analyses why the standard CGM fares worse in this setting than the herding algorithm. On the applied side we show how projections onto compact convex sets in kernel space can be exploited to develop novel machine learning algorithms. We demonstrate this by developing a *new and fast kernel regressor* that is en-par with state-of-the-art non-parametric regressors. We provide *approximation error bounds* for the method by means of a dual approach and we study its performance in experiments. The approximation error bound is a novel modification of an approach from Wolfe (1976) which sacrifices tightness in favor of a significantly reduced computation time.

2. Compact Convex Projections

We use the following algorithm to find the projection of $y \in \mathcal{H}$ onto the compact convex set $C \subset \mathcal{H}$ in terms of a set of support points from the compact set $S \subseteq C$ which contains the extremes of C. In the following we denote the extremes of C with $\operatorname{ex} C$, i.e. $\operatorname{ex} C = \{x : x \in C,$ there exists no $y, z \in C, \alpha \in (0,1)$ such that $x = \alpha y + (1-\alpha)z\}$.

Algorithm 1. Input: $y \in \mathcal{H}$, $T \in \mathbb{N}$, and $S \subset \mathcal{H}$.

1. [Initialize] Set $w_0 = y, t = 1$.
2. [Optimization oracle] Choose $x_t \in \arg\max_{x \in S} \langle w_{t-1}, x \rangle$.
3. [Update weight] Set $w_t = w_{t-1} - (x_t - y)$.
4. [Iterate] If $t < T$ then increment t by 1 and go back to **2**.
5. [Terminate] Return the approximation $(x_1 + \ldots + x_T)/T$.

A maximizer exists in Step 2 because we search for a maximum of a continuous function on a compact set. If there are multiple maximizer then we can choose an arbitrary one, for instance, we can enumerate S and choose the maximizer with the lowest index. This is the herding algorithm as stated in Section 1.1 with the only modification being that it is applied to y which can lie outside of C. The weight at step t is essentially the approximation error scaled up by t because $w_t = (t+1)y - (x_1 + \ldots + x_t) \approx t(y - p_t)$, where $p_t = (x_1 + \ldots + x_t)/t$ is the approximation. We can also add a line search to the optimization:

Algorithm 1 (ls). Input: $y \in \mathcal{H}$, $T \in \mathbb{N}$, and $S \subset \mathcal{H}$.

1. [Initialize] Set $w_0 = y, t = 1$.
2. [Optimization oracle] Choose $x_t \in \arg\max_{x \in S} \langle w_{t-1}, x \rangle$.
3. [Line search] Calculate $\tilde{\alpha}_t = \langle w_{t-1}, w_{t-1} + (x_t - y) \rangle \,/\, \|w_{t-1} + (x_t - y)\|^2$.
4. [Line search] If $t = 1$ set $\alpha_t = 1$, otherwise set $\alpha_t = 1 \wedge \tilde{\alpha}_t$.
5. [Update weight] Set $w_t = (1 - \alpha_t) w_{t-1} - \alpha_t (x_t - y)$.
6. [Iterate] If $t < T$ then increment t by 1 and go back to **2**.
7. [Terminate] Set $\beta_i = \alpha_i \prod_{j=i+1}^{T} (1 - \alpha_j)$ for all $i \leq T$ and return the approximation $\beta_1 x_1 + \ldots + \beta_T x_T$.

We use here the convention that $0/0 = 1$ which implies that $\alpha_t = 1$ if $x_t = p_t$. The weight in the line search algorithm is similar to the weight of the herding algorithm scaled down by $1/t$, i.e. the weight in the line search algorithm is $w_t = y - (\beta_1^t x_1 + \ldots + \beta_t^t x_t)$ where $\beta_i^t = \alpha_i \prod_{j=i+1}^{t} (1 - \alpha_j)$. The choice $\tilde{\alpha}_t = \langle w_{t-1}, w_{t-1} + (x_t - y) \rangle \,/\, \|w_{t-1} + (x_t - y)\|^2$ minimizes $\|w_t\|$ over all choices of $\tilde{\alpha}_t \in \mathbb{R}$. We need to be assured that the scaling α_t lies in the interval $[0, 1]$ to guarantee that we have a convex combination of points of S as the approximation. $\tilde{\alpha}_t$ is always non-negative since for $t \geq 1$

$$\langle w_{t-1}, w_{t-1} + (x_t - y) \rangle = \langle w_{t-1}, x_t \rangle - \sum_{i=1}^{t-1} \beta_i^{t-1} \langle w_{t-1}, x_i \rangle \geq \langle w_{t-1}, x_t \rangle - \max_{x \in S} \langle w_{t-1}, x \rangle = 0,$$

where we define a sum from $i = 1$ to 0 to be 0. The inequality above holds because the β's are non-negative and they sum to 1. $\tilde{\alpha}_t$ can, however, be strictly larger than 1. Hence, to guarantee that our approximation is a convex combination of points from S we need to force the scaling factor back into the interval $[0, 1]$. We do this in the algorithm by assigning the value 1 to the scaling factor in this case. This choice minimizes $\|w_t\|$ because the derivative of $\|w_t\|^2$ with respect to α is non-positive for all $\alpha \leq \tilde{\alpha}$, that is

$$2(\alpha \|w_{t-1} + (x_t - y)\|^2 - \langle w_{t-1}, w_{t-1} + (x_t - y) \rangle) \leq 0, \quad \text{for all } \alpha \in (-\infty, \tilde{\alpha}_t].$$

Note that Algorithm 1 is the herding algorithm applied to a point outside the convex set. This corresponds to the CGM where the optimization over the step size is replaced by a step size of $1/t$. Algorithm 1 (ls) is the CGM algorithm applied to the problem of finding the projection of y on the convex set spanned by S.

2.1 Rate of Convergence

We take a closer look at the convergence behavior of the herding algorithm and the standard CGM when applied to a projection problem. It is known that the herding algorithm converges with a rate of $1/t$ to elements in the interior of compact convex sets in Hilbert space (this is shown in Chen et al. (2010) for what is called the marginal polytope. The same proof works for arbitrary compact convex sets in a Hilbert space). Hence, if we want to approximate the projection of an element y onto the convex set C and y is already in the interior of C (in essence a trivial projection problem) then standard proofs guarantee a rate of $1/t$. Obviously, the interesting case is one where the projection lies in the boundary. We provide a theorem below (with the proof being postponed to Section 6.1, p. 26) which extends current results to the case where y lies in the boundary or outside the convex set if an assumption on the perturbations is fulfilled. We also show that this assumption is both necessary and sufficient for the algorithm to converge with a rate of $1/t$. We conclude this section by presenting a number of settings in which this assumption is fulfilled.

It is instructive to go through the main ideas of our approach. Consider again Figure 1. We can observe that there is a minimal face of the convex set which contains the projection Py of y onto the convex set, i.e. there exists a face that contains Py and is a subset of any other face that contains Py. In the figure, the minimal face is the convex set which contains the projection, i.e. the red dot. The vector $y - Py$, with $Py \in C$ being the projection, stands orthogonal on this minimal face. Furthermore, this minimal face is either an extreme point or Py lies in the relative interior of it. In the latter case we have a ball around Py (relative to the affine subspace spanned by the minimal face) which is contained in the minimal face. This property of the existence of a ball

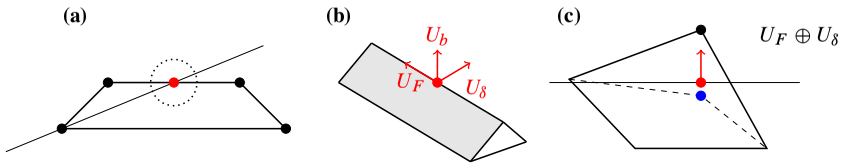

Figure 3: (a) A visualization of Lemma 1. (b) The figure depicts a triangular prism. The point of projection Py is marked by the red dot. The minimal face that contains Py is the top edge of the prism. The red arrows visualize the three subspaces U_F, U_b and U_δ. (c) The figure shows the projection of a set C_c onto the subspace $U_F \oplus U_\delta$ (the polytope enclosed by the thick line). The red dot marks the projection of Py onto the subspace and the red arrow visualizes the error at some stage t, i.e. w_t. The horizontal line represents $\{x : \langle w_t, x\rangle = 0\}$. The inner product between the black dot and w_t might be very different if evaluated over the whole space, i.e. if the component $P_b w_t$ is considered too. In particular, the polytope might appear to the algorithm like the modified polytope in which the black dot is replaced by the blue dot. In this modified polytope the best aligned element is the leftmost point.

around the element that we want to approximate is of crucial importance in all current approaches that demonstrate a fast reduction of error. We can therefore hope for a fast reduction of error in the affine subspace spanned by F. In fact, since $y - Py$ stands orthogonal on the minimal face, we can also observe that the algorithm applied to the minimal face behaves in exactly the same way as if we run it with Py instead of y and we can conclude that the algorithm converges with a rate of $1/t$ if it chooses only elements of F. The obvious problem is that we do not know the minimal face beforehand and we can not force the algorithm to choose only elements from it. At this point, a difficult task is to measure how much harm elements outside the minimal face can do when they are chosen by the algorithm. One important observation here is that for any element x outside the minimal face there exists no ball B around Py such that $\operatorname{aff}\{x, Py\} \cap B$ is contained in C (aff refers to the affine hull operator). Figure 3 (a) is a visualization of this property. The red dot marks Py. The line going through the bottom left corner and Py leaves the polytope at Py and there exists no ball in C such that the line segment in this ball lies fully in C. This property is also not difficult to prove formally. We summarize the result in the following simple lemma.

Lemma 1 *Given a compact convex set $C \subset \mathcal{H}$ and a $y \in \mathcal{H}$ there exists a minimal face F that contains Py and for every $x \in C \setminus F$ and any ball B centered at Py with radius greater than zero we have that* $\operatorname{aff}\{x, Py\} \cap B \not\subset C$.

The existence of the minimal face is shown in Step (ii) of the proof of Theorem 2. If the second part of the lemma would be false then we would have a point in $\operatorname{aff}\{x, Py\} \cap C$ such that Py is a convex combination of x and this point. This would imply $x \in F$ (see eq. 3 on p. 28) with a contradiction to the assumptions of the lemma.

The lemma implies that any element outside the minimal face which is chosen by the algorithm will introduce perturbations into the estimate that can not be easily removed: the line from x through

Py leaves the convex set at Py and there is no element $z \in C$ that is well aligned with $-(x - Py)$, i.e. a component of $-(x - Py)$ points outward of the convex set and there exists no z in C such that $z - Py$ has a positive inner product with this component. These perturbations get only smaller over time because of the down-scaling of the old approximation at steps t by $t/(t+1)$ and not because of future choices of the algorithm which are well aligned with the error. We are able to show that despite this property the herding algorithm converges with the same rate of $1/t$ that it would achieve if Py would lie inside C under an assumption on these perturbations.

Three subspaces. To state our assumption, it is convenient to introduce the centered versions $C_c = \{x - Py : x \in C\}$ of C and $F_c = \{x - Py : x \in F\}$ of F. We denote the linear subspace spanned by C_c with $\operatorname{span} C_c$. We can write $\operatorname{span} C_c$ as a direct sum $U_F \oplus U_\delta \oplus U_b$ of three orthogonal subspaces $U_F, U_\delta, U_b \subseteq \operatorname{span} C_c$ and we denote the orthogonal projections onto these subspaces and onto $\operatorname{span} C_c$ by P_F, P_δ, P_b and P_C. Here,

- $U_F = \operatorname{span} F_c$ ($U_F = \{0\}$ if $F_c = \{0\}$) is the (unique) subspace spanned by the minimal face,
- U_δ and U_b are any two orthogonal subspaces of $\operatorname{span} C_c$ that are also orthogonal to U_F and which fulfill
  1. $\operatorname{span} C_c = U_F \oplus U_\delta \oplus U_b$,
  2. there exists a ball (relative to the subspace U_δ) around 0 in $\{P_\delta x : x \in C_c\}$,
  3. there exists an orthonormal basis of U_b, say $e_1, \ldots, e_k$, $k = \dim U_b$, such that for all $i \leq k$, $\{0\} \neq \{\langle e_i, x\rangle : x \in C_c\} \subset (-\infty, 0]$,
  4. $P_C(y - Py) \in U_b$.

  $U_b = \{0\}$ and $U_\delta = \{0\}$ are possible.

Observe that this representation is not invariant under rotations. In particular, U_δ and U_b can change dimensions when C is rotated (see Figure 4 (a) for an example). The split into these three subspaces is helpful since it allows us to separate the errors that can be minimized by choosing particular elements $x \in S$ from the errors that cannot be reduced by choosing elements in S. Recall that the errors of our algorithms at step t are w_t. The perturbations at step t that cannot be minimized by suitable choices of elements in S are $P_b w_t$ and the remainder $P_\delta w_t + P_F w_t$ consists of the error that can be reduced by choosing appropriate elements in S. The split into these subspaces is shown in Figure 3 (b). U_F is here the subspace spanned by the line on top of the triangular prism, U_δ is the subspace orthogonal to it and aligned with the base of the prism. U_b is orthogonal to these two subspaces and the whole prism lies below Py (the red dot) in U_b.

A perturbed optimization problem. Apart from adding to the overall error, these perturbations introduce a subtle and more serious problem as follows. For any $(P_F + P_\delta)w_t$ we have an element s^* that maximizes $\langle s^*, (P_F + P_\delta)w_t\rangle$ and by choosing s^* we reduce the overall error (the reduction will be significant if $\|(P_F + P_\delta)w_t\|$ is large). Imagine there is a second element s which has a very small positive inner product with $(P_F + P_\delta)w_t$, i.e. $0 < \epsilon_t = \langle s, (P_F + P_\delta)w_t\rangle \ll \langle s^*, (P_F + P_\delta)w_t\rangle$. s will not be chosen if the algorithm optimizes over $U_F \oplus U_\delta$, however, since we optimize over all of $\operatorname{span} C_c$, it is possible that $\langle s, w_t\rangle > \langle s^*, w_t\rangle$. In particular, this may happen if $\langle P_b w_t, s^*\rangle / \langle P_b w_t, s\rangle$ is large and the perturbations $P_b w_t$ are effectively changing the geometry

of the optimization problem in $U_F \oplus U_\delta$ (see Figure 3 (c) for a visualization of this effect). The rate of convergence can be significantly reduced by this effect. In particular this happens if the perturbations make the algorithm choose a sequence of elements with inner products ϵ_t converging to 0 since the error in $U_F \oplus U_\delta$ will then not decrease over time. This problem can only occur if the $P_b w_t$ values affect the different elements in S in a very unbalanced way, i.e. there must be some elements $x, x' \in S$ such that $\langle P_b w_t, x\rangle \gg \langle P_b w_t, x'\rangle$. Our theorem below shows that this is the central problem that can hinder the rate of convergence. We demonstrate that Algorithm 1 converges with a rate of $1/t$ if, and only if, the perturbations affect the different elements in S in a sufficiently balanced way.

The main assumption and the theorems. Assumption 1 below formalizes the concept of a balanced influence of the perturbations on the elements of S. We need the following set of *critical points* for a given sequence of elements x_t chosen by the algorithm to state this assumption,

$$D(\{x_t\}) = \{x : x \in S \backslash F, x_t = x \text{ for infinitely many } t\}.$$

We use here $\{x_t\}$ to abbreviate $\{x_t\}_{t\geq 1}$. Only elements in $D(\{x_t\})$ can lead to a reduction in convergence rates and it suffices to check that none of the elements in $D(\{x_t\})$ lead to the above described effect to demonstrate fast convergence. Our main assumption is now the following:

Assumption 1: *Given sequences $\{x_t\}_{t\geq 1}, \{w_t\}_{t\geq 0}$ we assume that there exists a representation $U_F \oplus U_\delta \oplus U_b = \operatorname{span} C_c$ as described above, where for all $x, x' \in D(\{x_t\})$ there exists a $\Delta < \infty$ and a $t' < \infty$ such that $\langle -P_b w_t, x - Py\rangle \leq \Delta \langle -P_b w_t, x' - Py\rangle$ for all $t \geq t'$.*

We restrict our analysis to the case where there are only finitely many extremes of C. We thus assume that C is compact, convex and has only finitely many extremes. A set C with these properties is called a *convex polytope*. The following theorem demonstrates that for a convex polytope the above assumption is both necessary and sufficient for the fast rate of convergence of Algorithm 1.

Theorem 2 *Given a compact convex set $C \subset \mathcal{H}$ and a finite subset S of C with $\operatorname{ex} C \subseteq S$ there exists for $y \in \mathcal{H}$ a constant $b > 0$ such that Algorithm 1 has a worst-case approximation error of b/t for all $t \geq 1$ if, and only if, Assumption 1 is fulfilled for the sequences $\{x_t\}_{t\geq 1}$ and $\{w_t\}_{t\geq 0}$ generated by the algorithm.*

The reason why the herding algorithm retains its rate of convergence is that elements outside the minimal face will not be chosen anymore after some time $t_0 \in \mathbb{N}$ and the decay $t/(t+1)$ is high enough to remove the perturbations introduced in these first t_0 many steps fast enough so that they do not harm the overall rate of convergence, i.e. if we assume $Py = 0$ then

$$\|(I - P_F)w_t\| = \frac{t-1}{t}\|(I - P_F)w_{t-1}\| = \frac{t-2}{t}\|(I - P_F)w_{t-2}\| = \frac{t_0}{t}\|(I - P_F)w_{t_0}\|$$

and the error orthogonal to the minimal face decays with a rate of $1/t$. The situation is different for the CGM. While we can show that no elements outside the minimal face is chosen after some $t_0 \in \mathbb{N}$ the perturbations introduced in these initial steps dominate the rate of convergence of the algorithm even for steps $t \gg t_0$ (in the case of applying the CGM with away-steps it is known that the minimal face is identified after finite many steps under certain conditions and the algorithms optimizes after

this step over the minimal face (Wolfe, 1970; Guélat and Marcotte, 1986)). We decompose the error in the theorem below into two parts, the error in the affine subspace spanned by minimal face F and the error in the orthogonal complement of that space. This decomposition is natural in the way that we have a strong reduction of the error in the minimal face per step and only a weak reduction in the orthogonal complement of the minimal face. The first part of the theorem is standard and follows from Beck and Teboulle (2004). In the following, p_t denotes the approximation at time t. We use again Assumption 1, but be aware the the weight w_t is defined slightly differently for the CGM, i.e. the weight is scaled down by a factor of $1/t$ at step t.

Theorem 3 *Given a compact convex set $C \subset \mathcal{H}$, a finite subset S of C with $\operatorname{ex} C \subseteq S$ and an element $y \in \mathcal{H}$ the following holds:*

- *If only elements in $F \cap S$, where $F \subset C$ is the minimal face that contains Py, are chosen then the method converges linearly to the projection and there exist constants $b, \beta > 0$ with*

$$\|Py - p_t\| \leq be^{-\beta t}.$$

- *Under Assumption 1 if $\min_{x\in S}\|Py - x\| > 0$ and the approximation does not equal Py in finite many steps then the sequence $\{\|(I - P_F)(Py - p_t)\|\}_{t\geq 0}$ converges sub-linearly and there exists a constant $d > 0$ such that*

$$\|P_F(Py - p_t)\|^2 \leq (1 - \delta_F^2/\operatorname{diam}^2(F))\,\|P_F(Py - p_{t-1})\|^2 + d\,\|(I - P_F)(Py - p_{t-1})\|^2.$$

  Furthermore, there exists a time t_0 after which only elements in $F \cap S$ are chosen.

It is worth noting that the term $(1 - \delta_F^2/\operatorname{diam}^2(F))\,\|P_F(Py - p_{t-1})\|^2$ would guarantee a linear rate of convergence if the extra perturbation part would not be present.

The constant. It is of obvious interest to get insight into the size of the involved constants, in particular into the size of the constant b in Theorem 2 and its relation to quantities like δ_F and the dimension of $\operatorname{span} C_c$. The baseline is here the constant that we gain in the *trivial* case where $F = C$. Here, b can be taken to be $3r + 2r^2/\delta_F$, with $r = \sup_{x\in C}\|x\|$, and the constant does not depend on the affine dimension of C (see the proof of Theorem 2, part (ii.f)). In the case where $F \neq C$ we can first observe that b depends both on δ_m, the radius of the largest ball inside the projection of C_c onto $U_F \oplus U_\delta$, and on $\Delta' = \sup_{x,x'\in D(\{x_t\})} \Delta_{x,x'}$, where $\Delta_{x,x'}$ are the constants in Assumption 1, i.e. b depends on δ_m/Δ' (see the proof of Theorem 2, part (iv.b)). So the larger the ball around Py in $U_F \oplus U_\delta$ and the closer coupled the perturbations are the smaller the constant b. Referring these quantities back to geometric properties of C is non-trivial and in all likelihood providing a general characterization is at least as difficult as providing a general characterization of when Assumption 1 is fulfilled. However, in concrete settings it is often actually rather easy to provide bounds on b depending, for instance, on the affine dimension of C. We provide a number of examples in the next section. In particular, Corollary 6 - 8 contain concrete values for the constant. The dependence on d is here linear or sub-linear if we ignore the dependence of the dimension on the size of the set C, i.e. $r = \sup_{x\in C}\|x\|$ might also depend on the dimension. For instance, for the standard hypercube in d-dimensions $r = \sqrt{d}$.

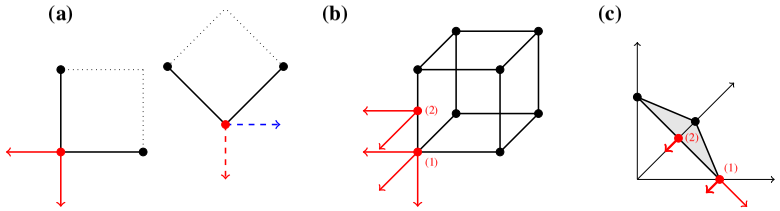

Figure 4: (a) The figure shows two possible splits into $U_b \oplus U_\delta$ depending on how the square is rotated. The first one is visualized by solid red arrows. Here $U_b = \mathbb{R}^2$ and $U_\delta = \{0\}$. The second split is visualized through the dashed arrows. The red dashed arrow is a basis vector of U_b and the blue dashed arrow is a basis vector of U_δ. (b) The figure shows two projection problems. The locations of Py are marked with the red dots and are annotated with (1) and (2). The red arrows visualize the space U_b for the two problems. For problem (1) this is a three dimensional space since U_F is here 0-dimensional and for (2) it is a 2 dimensional space. In both cases $U_\delta = \{0\}$. (c) The figure resambles (b). Instead of the hypercube it shows the simplex in three dimensions. The red arrows depict basis vectors for U_b. $U_\delta = \{0\}$ as for the hypercube.

2.1.1 EXAMPLES

We now take a look at a number of concrete projection problems to demonstrate how Assumption 1 can be used to prove fast convergence of Algorithm 1 in various situations. Our first result does not rely on assumptions about the shape of the convex polytope, but assumes that its span is a $d < \infty$ dimensional subspace of a Hilbert space and the projection Py lies in a $d-1$ dimensional face of the convex set (Corollary 4 and 5). In the applications we have in mind the point of projection is related to an estimator and the convex polytope enforces some form of sparsity. Typically, in such settings, the projection lies in some low dimensional face of the convex polytope.

We provide a rather general condition for this case in Corollary 6 and we use this corollary to demonstrate that Algorithm 1 converges with the fast rate independent of the location of Py if we are working, for instance, with the hypercube or the simplex (Corollary 7 and 8). In particular, Py can lie in a low dimensional face of the simplex or can be an extreme of it. There is certainly more to be understood here, but these cases demonstrate that the performance of Algorithm 1 is robust across a variety of settings and they demonstrate the uses of Assumption 1.

The proofs of the corollaries that follow are contained in the appendix on page 39 and onward. It seems also worth pointing out that we can rotate our coordinate system in an arbitrary way and translate the convex polytope and y without it affecting the algorithms or the rate of convergence. This holds because the algorithm uses only inner products and orthogonal operators (rotations) do not change these. Similarly, a translation does not affect the maximization step or the update. This allows us, for instance, to prove the fast rate of convergence for the standard hypercube $[0,1]^d$ and to generalize this result to arbitrary hypercubes in $\mathbb{R}^d$.

One-Dimensional U_b. If the space U_b is one-dimensional then the perturbations affect all elements in $S \backslash F$ equally (up to a finite multiplier) and Assumption 1 is always fulfilled. This is in particular the case if the minimal face is $(d-1)$-dimensional, but can also be fulfilled for lower dimensional faces if U_δ is not 0-dimensional.

Corollary 4 *Given a compact convex set $C \subset \mathcal{H}$ and a finite subset S of C with $\operatorname{ex} C \subseteq S$. If for $y \in \mathcal{H}$ there exists a decomposition $U_F \oplus U_\delta \oplus U_b$ of $\operatorname{span} C_c$ such that U_b is one dimensional then Assumption 1 is fulfilled. In particular, in this case there exists a constant $b > 0$ such that Algorithm 1 has a worst-case approximation error of b/t for all $t \geq 1$.*

One can relate the assumption that U_b is one-dimensional to a uniqueness assumption about the projection Py. If $P_C\, y \notin C$ and only elements in $A = \{z \in \mathcal{H} : z = \alpha P_C(y - Py) + P_C\, Py, \alpha \in [0,\infty)\}$ are projected onto Py then U_b is 1-dimensional and Assumption 1 is fulfilled. We summarize this result in another corollary.

Corollary 5 *Given a compact convex set $C \subset \mathcal{H}$ and a finite subset S of C with $\operatorname{ex} C \subseteq S$. Assumption 1 is fulfilled if $P_C\, y \in \mathcal{H} \backslash C$ and whenever $Pz = Py$ for some $z \in \mathcal{H}$ then $P_C z \in A$ holds. In particular, in this case there exists a constant $b > 0$ such that Algorithm 1 has a worst-case approximation error of b/t for all $t \geq 1$.*

This last assumption is not fulfilled in Figure 1 if the projection lies in the corners or edges, but it is fulfilled in all other cases. A quite different application of our theorem allows us to exploit the geometry of the convex set to derive the fast rate of convergence independent of the location of Py.

Zero-Dimensional U_δ. If we can rotate the convex set such that we get a split $U_F \oplus U_\delta \oplus U_b$ for which $U_\delta = \{0\}$ then our Assumption 1 is also fulfilled. The next corollary states this result. We use here, and in the following two corollaries, $d = \dim U_b$ and we let $e_1, \ldots, e_d$ be any basis of U_b. Furthermore, $\alpha = \min_{i \leq d} \min\{|\langle e_i, x - Py\rangle| : x \in S \backslash F, \langle e_i, x - Py\rangle \neq 0\} > 0$ and $r = \sup_{x \in C} \|x\|$.

Corollary 6 *Let C be a compact convex set in some Hilbert space $\mathcal{H}$, S a finite set with $\operatorname{cch} S = C$, and $y \in \mathcal{H}$ such that there exists a split into $U_F \oplus U_\delta \oplus U_b$ of $\operatorname{span} C_c$ with $U_\delta = \{0\}$. Assumption 1 is fulfilled and there exists a constant $b > 0$ such that Algorithm 1 has a worst-case approximation error of b/t for all $t \geq 1$. The constant b can be chosen as $\sqrt{d}\, 4r^3/(\alpha\delta_F) + 6r^2(1/\delta_F + 1/\alpha) + 5r$.*

This condition is somewhat abstract but leads, for example, to results that prove that the algorithm converges with the fast rate in classical sparsity settings independent of the location of Py (Corollary 7 and 8 below). Also, observe that Corollary 6 together with Corollary 4 imply that if Py lies in a face of dimension $(d-2)$ then Algorithm 1 will converge with the fast rate: if U_δ is 0-dimensional then this follows from Cor. 6 and if U_δ is 1-dimensional then U_F is also 1-dimensional and the result follows from Cor. 4 (U_δ cannot be 2-dimensional due to Lemma 1).

Hypercubes. Here, we consider the compact convex set $[0,1]^d = \operatorname{cch}\{0,1\}^d \subset \mathbb{R}^d$ and transformations of it (rotations, translations and changes of its size). The set of extremes of the standard hypercube is $\{0,1\}^d$ and the d-dimensional hypercube has $2^{d-m}\binom{d}{m}$ many m-dimensional faces, where $m \leq d$. We formulate the following corollary in terms of a rotation matrix Q, a translation by a vector z and a scaling by a scalar c. In the proof of the corollary we transform the hypercube to the standard hypercube and we show that $U_\delta = \{0\}$ independent of the location of y. This is visualized

in Figure 4 (b) for a 3-dimensional hypercube. (1) and (2) are here two projection problems and the red arrows depict two bases of U_b. Constructing such bases for which $U_\delta = \{0\}$ is always possible for the standard hypercube.

Corollary 7 *Let $y \in \mathbb{R}^d$, Q any orthogonal matrix, $c > 0$ any scaling, $z \in \mathbb{R}^d$, $S = \{0,1\}^d$ and $C = [0,1]^d$, $d \geq 1$. Assumption 1 is fulfilled for the set $\tilde{S} = cQ[S + z]$ and $\tilde{C} = cQ[C + z]$ (independently of the dimensionality of the face Py lies in). In particular, there exists a constant $b > 0$ such that Algorithm 1 has a worst-case approximation error of b/t for all $t \geq 1$. The constant b can be chosen as $\sqrt{d}4r^3/(c\delta_F) + 6r^2(1/\delta_F + 1/c) + 5r$.*

Standard Simplex. Algorithm 1 also attains a fast rate of convergence if the convex set we use is the standard simplex in $\mathbb{R}^d$ independently of the location of y. The standard simplex has $\binom{d}{m}$ many faces of dimension $m-1$, i.e. $1 \leq m \leq d$ and the dimension of the corresponding span of the centered face is $m-1$. The faces of such a simplex are again simplices. In particular, if we denote the standard simplex with $\Delta^{d-1} = \operatorname{cch}\{e_1, \ldots, e_d\}$, then the set of $m-1$ dimensional faces of Δ^{d-1} are $\{\operatorname{cch}\{e_{i_1}, \ldots, e_{i_m}\} : i_1 < i_2 \ldots < i_m, i_j \leq d\ \forall j \leq m\}$. As for the hypercube we can show that $U_\delta = \{0\}$. This is visualized in Figure 4 (c) for the standard simplex in $\mathbb{R}^3$. The figure shows two projection problems (1) and (2) and corresponding bases of U_b.

Corollary 8 *Let $y \in \mathbb{R}^d$, $S = \{e_i : i \leq d\}$ and $C = \Delta^{d-1} = \operatorname{cch} S$, $d \geq 1$. Assumption 1 is fulfilled and there exists a constant $b > 0$ such that Algorithm 1 has a worst-case approximation error of b/t for all $t \geq 1$. The constant b can be chosen as $4dr^3/\delta_F + 6r^2(1/\delta_F + \sqrt{d}) + 5r$.*

2.2 The Algorithm for Finite S

We are particularly interested in the case where $S = \{x_1, \ldots, x_n\}$ is finite. If S is finite we can change the algorithm to keep track of $\langle w_t, x_i\rangle =: a_{ti}$ instead of $w_t \in \mathcal{H}$. This reflects a change of representation from a basis representation of w_t to one based on S. The weight vector can, after this change of representation, be replaced by $a_t = (a_{t1}, \ldots, a_{tn})$ in the algorithm.

Algorithm 2. Input: $y \in \mathcal{H}$, $T \in \mathbb{N}$, and $S \subset \mathcal{H}$.

1. [Initialize] Set $a_0 = (\langle y, x_1\rangle, \ldots, \langle y, x_n\rangle)$ and $t = 1$.
2. [Optimization oracle] Choose $i_t \in \arg\max_{j \leq n} a_{(t-1)j}$.
3. [Update weight] Set $a_t = a_{t-1} - (\langle x_{i_t}, x_1\rangle, \ldots, \langle x_{i_t}, x_n\rangle) + a_0$.
4. [Iterate] If $t < T$ then increment t by 1 and go back to **2**.
5. [Terminate] Return the approximation $(x_{i_1} + \ldots + x_{i_T})/T$.

The computational costs per iteration are then determined by the number of samples n and the computational costs of calculating inner products in $\mathcal{H}$ (n inner products per iteration).

2.3 Line Search for Finite S

The line search in Algorithm 1 (ls) contains terms of the form $\|w_{t-1}\|^2$. The philosophy in Algorithm 2 is to avoid measuring objects in their norm and to work solely with relations between objects in the form of inner products $\langle y, x_i\rangle$ to reduce computational costs. To follow this philosophy we need a version of the line search that does not need access to $\|w_{t-1}\|$ or $\|y\|$. Achieving this goal is

easy enough: the line search aims for finding an α_t such that $p_t = (1-\alpha_t)p_{t-1} + \alpha_t x_{i_t}$, with p_t being our approximation at step t, achieves minimal distance to y. So we want that

$$\alpha_t \in \operatorname*{arg\,min}_{\alpha \in [0,1]} \|(1-\alpha)p_{t-1} + \alpha x_{i_t} - y\|^2 .$$

Setting the derivative of the squared norm to zero with respect to α we gain

$$\tilde{\alpha}_t = \frac{\langle y - p_{t-1}, x_{i_t} - p_{t-1}\rangle}{\|p_{t-1} - x_{i_t}\|^2}.$$

The norm in the denominator can be calculated recursively and calculating its value needs no significant computational resources. Because $\|w_t\| = \|p_t - y\|$ we gain the same $\tilde{\alpha}_t \in [0, \infty)$ as in Algorithm 1 (ls). Also, the minimizer over the interval $[0,1]$ is again $\alpha_t = 1 \wedge \tilde{\alpha}_t$.

2.4 Approximation Error Bounds through Duality

There exists a well established test for the approximation error (Wolfe, 1976). Let $S = \{x_1, \ldots, x_n\}$ still be finite. For any $p \in C$, $p \neq y$, we can write $\langle p, Py\rangle = \langle p, \alpha_1 x_1 + \ldots \alpha_n x_n\rangle \geq \min_{i \leq n}\langle p, x_i\rangle$ and

$$\|p - y\| \geq \|Py - y\| \geq \sum_{i=1}^n \alpha_i \langle x_i - y, \frac{p-y}{\|p-y\|}\rangle \geq \min_{x \in S}\langle x - y, \frac{p-y}{\|p-y\|}\rangle.$$

So

$$\|p - y\| - \|Py - y\| \leq \|p - y\| - \min_{x \in S}\langle x - y, \frac{p-y}{\|p-y\|}\rangle.$$

The last term tells us how far we are away from the optimum and it can be used to guarantee a specific approximation error at termination. In the settings we are interested in $\|p - y\|$ is, in fact, too expensive to compute and we need to modify the approach from Wolfe (1976). Observe that

$$\max_{x \in S}\langle p - x, \frac{p-y}{\|p-y\|}\rangle = \|p - y\| - \min_{x \in S}\langle x - y, \frac{p-y}{\|p-y\|}\rangle$$

gives us the easier to compute

$$\max_{x \in S}\langle p - x, p - y\rangle \geq \|p - y\|\,(\|p - y\| - \|Py - y\|)$$

The right side is directly an upper bound on $(\|p - y\| - \|Py - y\|)^2$, because $\|p - y\| \geq \|p - y\| - \|Py - y\| \geq 0$. However, this bound is overly conservative and we loose an order of magnitude since we lower bound $\|p - y\| \geq \|Py - y\|$ with a quantity that goes to 0. A better way seems to be to use linear functionals to approximate $p - y$. Natural choices are here $\langle x, \cdot\rangle$ for $x \in S$ or $\langle p, \cdot\rangle$ because we can often compute these functionals efficiently. The former choice can be exploited in the following way

$$\|y - p\| \geq \max_{x \in S}\left|\langle y - p, \frac{x}{\|x\|}\rangle\right|$$

and we can calculate a lower bound on $\|y - p\|$ in about $O(n)$ operations (depending on the representation of p) by calculating the right hand side inner product for every $x \in S$. Using this bound we get the following upper bound on the approximation error

$$\frac{\max_{x \in S}\langle p - x, p - y\rangle}{\max_{x \in S}|\langle y - p, x/\|x\|\rangle|} \geq \|p - y\| - \|Py - y\| .$$

The latter choice leads to

$$\|y-p\| \geq \langle y-p, \frac{p}{\|p\|}\rangle = \langle y, \frac{p}{\|p\|}\rangle - \|p\|\,.$$

The inequality also holds when taking the absolute value of the right side and

$$\max_{x\in S} \frac{\langle p-x, p-y\rangle}{|\|p\| - \langle y, p/\|p\|\rangle|} \geq \|p-y\| - \|Py-y\|\,.$$

If our convex set is a norm ball then as $p \to Py$ we also have that $y-p$ gets more and more aligned with $p/\|p\|$ and we expect this bound to be good.

2.5 Parallelization

Algorithm 2 is easy to parallelize since the bottleneck per iteration is the calculation of n inner products in the update equation of a_t. These inner products can be calculated independently of each other and by having c processes available we can distribute the computation such that each process has to calculate at most $\lceil n/c \rceil$ many inner products per iteration. Determining the arg max can then be achieved by a loop over the n entries of a_t. This operation is typically fast and no parallelization is needed. Though, it is easy to distribute this operation too to reduce the computation time to $\lceil n/c \rceil + c$ by first calculating c maxima over sets of size at most $\lceil n/c \rceil$ and by then calculating the maximum of these c maxima. Finally, the summation of the vector of inner products with $a_{t-1} - a_0$ can also be split such that each process has to perform at most $\lceil n/c \rceil$ many of these summations. This gives us in total a computation time in the order of $\lceil n/c \rceil$.

3. CCP-Kernel Regression

We now want to apply the algorithm to a challenging statistical problem. That is the problem of non-parametric regression. For this we use a reproducing kernel Hilbert space (RKHS, Aronszajn (1950)) which is in a certain sense natural given past herding applications, but it is also computationally efficient thanks to the reproducing property.

An RKHS $\mathcal{H}$ is implicitly defined through a kernel function $k(x, x')$. $\mathcal{H}$ is the completion of

$$L := \Big\{\sum_{i=1}^{n} \alpha_i k(x_i, \cdot) : n \in \mathbb{N}, x_i \in X, \alpha_i \in \mathbb{R}\Big\},$$

where X is the domain of the covariates (or inputs). In statistical applications we like to approximate $\mathcal{H}$ with a nested family of sets of functions that are restricted in a certain way in their size. One nested family is, for instance, the family of closed balls B_r of radius r centered at zero. For these we know that $\bigcup_{r\geq 0} B_r = \mathcal{H}$. The balls B_r are, however, not compact if $\mathcal{H}$ is infinite dimensional. Also, controlling the extremes of B_r is not necessarily easy since we usually only have access to the kernel function k and not a basis $\{e_n\}_{n\geq 1}$ of $\mathcal{H}$. So ideally we would like a family of sets that can approximate $\mathcal{H}$ like the balls B_r, but in contrast to B_r the different sets would be compact, convex and controllable through the kernel. There is a family of sets with these properties which arises naturally from the kernel function (cl denotes the closure operator):

$$C(r) = \operatorname{cch}\{k(x,\cdot) : x \in X\} = \operatorname{cl}\Big\{\sum_{i=1}^{n} \alpha_i k(x_i, \cdot) : n \in \mathbb{N}, x \in X^n, \alpha \in \mathbb{R}^n_+, \|\alpha\|_{\ell_1} \leq r\Big\} \subset \mathcal{H}.$$

$C(r)$ is compact and convex and the extremes of $C(r)$ are contained in the set $S = \{k(x,\cdot) : x \in X\}$. There is an obvious similarity to the definition of L and by suitably symmetrizing $C(r)$ we gain a family of sets which covers all of L and can approximate any element in $\mathcal{H}$ up to arbitrary precision.

3.1 Symmetric Closed-Convex Hull

The sets $C(r)$ might not contain 0 or any elements on the negative axes. This is obviously not ideal for representing functions. We overcome this shortcoming by symmetrising $C(r)$ by including the elements $-k(x,\cdot)$. In this way we get the family of sets

$$C_s(r) = \operatorname{cl}\Big\{\sum_{i=1}^{n} \alpha_i k(x_i, \cdot) : n \in \mathbb{N}, x \in X^n, \alpha \in \mathbb{R}^n, \|\alpha\|_{\ell_1} \leq r\Big\}.$$

This family of sets has some similarity to the closed balls in $\mathcal{H}$. In particular, if the kernel function is bounded then $C_s(r)$ is a subset of the closed ball of radius $\tilde{r} = r \sup_{x\in X} k(x,x)$ in $\mathcal{H}$ since

$$\Big\|\sum_{i=1}^{n} \alpha_i k(x_i,\cdot)\Big\| \leq \|\alpha\|_{\ell_1} \sup_{x\in X} k(x,x) \leq \tilde{r}$$

and the smallest closed set containing the elements $\sum_i \alpha_i k(x_i,\cdot)$ can not be larger than a closed ball of radius $\tilde{r}$.

Denseness and Universal Approximation. More important for us is the following property: the set $\bigcup_{r\geq 0} C_s(r)$ is *dense* in $\mathcal{H}$, since for any $f \in \mathcal{H}$ and $\epsilon > 0$ there exists an $n \in \mathbb{N}$, elements $x_1, \ldots, x_n \in X$ and coefficients $\alpha_1, \ldots, \alpha_n \in \mathbb{R}$ such that $\big\|f - \sum_{i=1}^n \alpha_i k(x_i,\cdot)\big\| \leq \epsilon$. But $\sum_{i=1}^n \alpha_i k(x_i,\cdot)$ is an element of $C_s(r)$ if $r \geq \sum_{i=1}^n |\alpha_i|$. In other words, we can approximate any function in $\mathcal{H}$ arbitrary well by making r large enough. Furthermore, if our kernel function is a universal kernel then we can approximate any continuous function on X arbitrary well in the supremums norm. This property is sometimes called the universal approximation property.

3.2 Simplifying the Sets

Optimizing over $C_s(r)$ itself is difficult and from a practical point of view it makes sense to reduce the sets further to save computation time. In regression we have a number of covariates $x_1, \ldots, x_n$ given and we know that we can represent any RKHS function h exactly on these points $x_i, i \leq n$, by functions of the form $\sum_{i=1}^n \alpha_i k(x_i,\cdot)$, where $\alpha \in \mathbb{R}^n$ are suitable weights, if the kernel matrix $K = (k(x_i,x_j))_{i,j\leq n}$ is of full rank because

$$K\alpha = \begin{pmatrix} h(x_1) \\ \vdots \\ h(x_n) \end{pmatrix}$$

has then a (unique) solution. From this point of view it makes sense to use the family of sets

$$\mathcal{C}(r) := \Big\{\sum_{i=1}^{n} \alpha_i k(x_i,\cdot) : \alpha \in \mathbb{R}^n, \|\alpha\|_{\ell_1} \leq r\Big\}.$$

instead of $C_s(r)$. $\mathcal{C}(r)$ is fully characterized by $S = \{\pm rk(x_1,\cdot),\ldots,\pm rk(x_n,\cdot)\}$ in the sense that $\mathcal{C}(r) = \operatorname{cch} S$ and S contains the extremes of $\mathcal{C}(r)$. S itself is of size $2n$ and we can optimize efficiently over it.

3.3 Interpolation in $\mathcal{H}$

Before approaching the regression problem we start with a closely related interpolation problem. We aim for interpolating a function $g \in \mathcal{H}$ at n support points $x_1,\ldots,x_n$. Let $y_1 = g(x_1),\ldots,y_n = g(x_n)$. The interpolation algorithm is essentially an efficient version of Algorithm 2 applied to the elements $\pm rk(x_1,\cdot),\ldots,\pm rk(x_n,\cdot)$, where r is the scaling factor of $\mathcal{C}(r)$. So at the heart of the algorithm we have a vector $a \in \mathbb{R}^n$ which keeps track of the approximation error and the entries a_i are just $\langle w_t, k(x_i,\cdot)\rangle$, where w_t is the weight vector used in Algorithm 1. We formulate the algorithm in terms of "$\leftarrow$" assignments which denote the operation of overwriting the left hand side with the value on the right hand side.

Algorithm 3. Input: $y \in \mathbb{R}^n$, $T \in \mathbb{N}$, $r > 0$, a kernel function k and $x_1,\ldots,x_n \in X$.

1. [Initialize] Set $a = ry$ and $t = 1$.
2. [Optimization oracle] Choose $j' \in \arg\min_{i\le n} a_i$, $j'' \in \arg\max_{i\le n} a_i$.
3. If $-\min_{i\le n} a_i \ge \max_{i\le n} a_i$ then let $j = j', z_t = x_j$ and $s_t = 1$
4. else let $j = j'', z_t = x_j$ and $s_t = -1$.
5. [Update weight] Set $a_i \leftarrow a_i + ry_i - r^2 s_t k(x_i, z_t)$ for all $i \le n$.
6. [Iterate] If $t < T$ then increment t by 1 and go back to **2**.
7. [Terminate] Return the regressor $f(x) = r(s_1 k(z_1,x) + \ldots + s_T k(z_T,x))/T$.

The complexity of the algorithm is $O(Tn)$ since we have T iterations and we need to update in each iteration $a \in \mathbb{R}^n$. The bottleneck in this algorithm is the evaluation of the $k(z_i,x)$.

Line search. The line search version of this algorithm is based on Section 2.3. We update recursively the elements η,γ,π, where at step t we have that $\eta = \|p_{t-1}\|^2$, $\gamma = \langle p_{t-1}, y\rangle$ and $\pi = (\langle p_{t-1}, k(x_1,\cdot)\rangle,\ldots,\langle p_{t-1}, k(x_n,\cdot)\rangle)$, to keep the complexity of the algorithm at $O(Tn)$.

Algorithm 3 (ls). Input: $y \in \mathbb{R}^n$, $T \in \mathbb{N}$, $r > 0$, a kernel function k and $x_1,\ldots,x_n \in X$.

1. [Initialize] Set $a = ry, t = 1, \eta = 0, \gamma = 0$ and $\pi = (0,\ldots,0)$.
2. [Optimization oracle] Choose $j' \in \arg\min_{i\le n} a_i$, $j'' \in \arg\max_{i\le n} a_i$.
3. If $-\min_{i\le n} a_i \ge \max_{i\le n} a_i$ then let $j = j', z_t = x_j$ and $s_t = 1$
4. else let $j = j'', z_t = x_j$ and $s_t = -1$.

5. [Calculate step size] Let $v = r^2(k(x_1,z_t),\ldots,k(x_n,z_t))$ and
$$\tilde{\alpha}_t = \frac{rs_t y_j - rs_t\pi_j - \gamma + \eta}{\eta - 2rs_t\pi_j + v_j}, \quad \text{if } t = 1 \text{ let } \alpha_t = 1 \text{ and otherwise let } \alpha_t = 1 \wedge \tilde{\alpha}_t.$$
6. [Update weight] $a \leftarrow (1-\alpha_t)a + \alpha_t(ry - s_t v)$.
7. [Update line search variables] $\eta \leftarrow (1-\alpha_t)^2\eta + 2\alpha_t(1-\alpha_t)rs_t\pi_j + \alpha_t^2 v_j$, $\pi \leftarrow (1-\alpha_t)\pi + \alpha_t(s_t/r)v$ and $\gamma \leftarrow (1-\alpha_t)\gamma + \alpha_t s_t r y_j$.
8. [Iterate] If $t < T$ then increment t by 1 and go back to **2**.
9. [Terminate] Return the regressor $f(x) = r(s_1\beta_1 k(z_1,x) + \ldots + s_T\beta_T k(z_T,x))/T$, with $\beta_i = \alpha_i \prod_{n=i+1}^{T}(1-\alpha_n)$.

The expensive calculation is here the calculation of $v = (k(x_1,z_t),\ldots,k(x_n,z_t))$.

Approximation error stopping rule. We can also use an approximation error of below ϵ as the stopping criterion by using bounds from Section 2.4. The algorithm below achieves this in $O(Tn)$ for the bound that uses our approximation p_t to gauge the approximation error. The algorithm is very similar to the line search algorithm because we need to store similar quantities for calculating the bound as for the line search. We update recursively the elements η,γ,π, where at step t (before the update) we have that $\eta = \|p_{t-1}\|^2, \gamma = \langle p_{t-1}, y\rangle, \pi = (\langle p_{t-1}, k(x_1,\cdot)\rangle,\ldots,\langle p_{t-1}, k(x_n,\cdot)\rangle)$. The complexity of the algorithm is again $O(Tn)$. The version shown below is for the line search. By replacing α_t with $1/t$ one can gain a version for the standard algorithm. We state only the changes to Algorithm 3 (ls).

Algorithm 3 (ls, ae). *(replace 8. and 9. in Algorithm 3 (ls)).* Input: $y \in \mathbb{R}^n$, $\epsilon > 0$, $r > 0$, a kernel function k and $x_1,\ldots,x_n \in X$.

8. [Upper bound] Calculate the upper bound
$$b = \max_{i\le n} \frac{\eta - r\pi_i - \gamma + ry_i}{\left|\sqrt{\eta} - \gamma/\sqrt{\eta}\right|} \vee \max_{i\le n} \frac{\eta + r\pi_i - \gamma - ry_i}{\left|\sqrt{\eta} - \gamma/\sqrt{\eta}\right|}.$$
9. [Terminate] If $b \le \epsilon$ return the regressor $f(x) = r(s_1\beta_1 k(z_1,x) + \ldots + s_t\beta_t k(z_m,x))$ where $\beta_i = \alpha_i \prod_{n=i+1}^{t}(1-\alpha_n)$. Otherwise, go back to **2**.

As for the other two algorithms above the computationally most demanding operation in this algorithm is the calculation of $(k(x_1,z_t),\ldots,k(x_n,z_t))$.

3.4 Norm Minimizing Regressor

The interpolation algorithms can also be applied to the regression problem. Let the observations be $(x_1,y_1),\ldots,(x_n,y_n)$ and let K be the kernel matrix. If the kernel matrix is of full rank then with $\alpha = K^{-1}y$, where $y = (y_1,\ldots,y_n)^\top$, the function $h(x) = \sum_{i=1}^n \alpha_i k(x_i,\cdot) \in \mathcal{H}$ fulfills $(h(x_1),\ldots,h(x_n)) = K\alpha = y^\top$ and the interpolation algorithm applied to h will converge under

the usual conditions with a rate of $1/t$, that is $\|h - g_t\|^2 \leq b^2/t^2$ with $g_t = (1/t)\sum_{i=1}^{t} k(z_i, \cdot)$. There are two interesting observations here: first, the algorithm minimizes the distance to h implicitly without knowledge of h itself. In fact, determining h numerically is usually impossible due to ill-conditioning. Second, the algorithm minimizes the distance in the RKHS norm and not in a least-squares sense. Both, the RKHS norm and the least-squares criterion can be seen as distance measures that are in certain ways related. For instance, a norm-distance of zero between two functions implies that they have the same least-square error and, furthermore, the least-squares error of our approximation is bounded by

$$\frac{1}{n}\sum_{i=1}^{n}(y_i - g_t(x_i))^2 = \frac{1}{n}\sum_{i=1}^{n}|\langle h - g_t, k(x_i, \cdot)\rangle|^2 \leq \left(\frac{1}{n}\sum_{i=1}^{n}k(x_i, x_i)\right)(\|h - Ph\|^2 + c/t^2)$$

where Ph denotes the projection of h onto $\mathcal{C}(r)$ the constant c is $(b^2/n)\sum_{i=1}^{n}k(x_i, x_i)$.

One can also formulate the norm minimization problem as a convex optimization problem

$$\min_{\alpha \in \mathbb{R}^n} \alpha^\top (K\alpha - 2y) \quad \text{s.t.} \sum_{j=1}^{n} |\alpha_j| = r.$$

and use convex programs to find the projection. This representation has the drawback that it makes explicit use of the $n \times n$ kernel matrix K and for large scale problems this formulation needs significant amounts of memory.

4. Experiments

We conducted a set of experiments to gauge the performance of the approach. The first set of experiments was constructed to demonstrate the behavior of the error bounds and to compare the optimization routine with some standard optimization procedures. The second set of experiments compared the regressor with well established regressors in a small scale setting. The advantage of the small scale setting is that we can compare to methods like the GP regressor. The final set of experiments focused on a large scale benchmark data set and compared our method to the Fast-KRR, which is the state-of-the-art regressor for large scale problems.

4.1 Experiment 1: Empirical Rate of Convergence

The first set of experiments were conducted to explore basic properties of the optimization approach: 'how does a typical regression curve look like in comparison to a GP regression curve?' 'How do the error bounds relate?' 'How does the optimization routine behave in comparison to a general purpose optimizer?' In our first experiment we generated 1000 data points from a Gaussian process (Gaussian covariance function) with normal distributed noise (the right plot in Figure 5). We fitted the maximum a posteriori estimator (MAP, known hyper-parameters) to it (red curve) and then did split the data into an 800 and 200 batch to run a cross validation loop over the hyper parameters (we also used a Gaussian covariance but with an unknown width parameter). We ran the CCP algorithm for 20 (yellow) and 100 (purple) iterations (without line search). The red bars show the points and weights of the solution when the algorithm is run for 100 iterations. The black bars show the solution found by the cvx Matlab toolbox for a precision of about 10^{-16}. The next experiment was about the bounds. We used again 1000 data points generated as above and a fixed hyper-parameter (no cv loop) to see how the bounds behave as the number of iterations increases. There

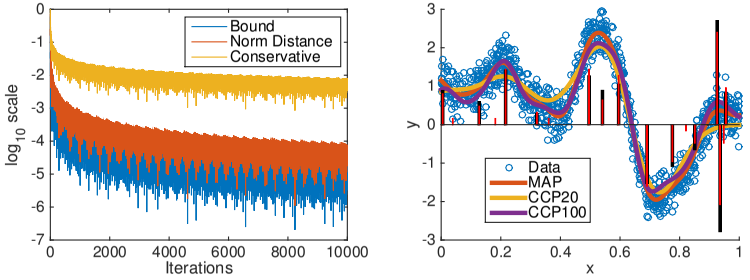

Figure 5: **Left:** The plot shows three different bounds on the approximation error. **Right:** The figure shows data from a Gaussian process with Gaussian likelihood function. The data is overlaid with three regression curves. MAP is here the optimal regressor. The vertical bars show the weight that is assigned by the CCP-regressors with 100 iterations (red) and the cvx matlab optimization toolbox (black) to observations at various locations x.

n	100	500	1000	2000	3000	4000	5000
CCP	0.03(0.03)	0.1(0.08)	0.2(0.09)	0.25(0.29)	0.3(0.26)	0.47(0.26)	0.57(0.61)
cvx	0.64(0.13)	1.3(0.08)	2.7(0.13)	8.16(0.12)	17.2(0.39)	31.3(1.68)	49.8(0.88)

Figure 6: Run time comparison between the CCP projection algorithm and a general purpose solver.

is one difficulty here, which is that we do not have the best fitting function $h \in \mathcal{H}$ and we can not calculate the exact distance to h. The three curves on the left side of the figure are our two bounds of the difference $\|h - g_t\| - \|h - Ph\|$, g_t is the regressor after t iterations and Ph the solution of the optimization problem which we try to find. *Conservative* refers to the bound where we use $\|g_t - h\| \geq (\|g_t - h\| - \|Ph - h\|)$ and *Bound* refers to our second bound) and the distance to Ph (*Norm Distance*), that is $\|g_t - Ph\|$ which is also an upper bound of $\|h - g_t\| - \|h - Ph\|$ (we determined Ph by using cvx with a precision of about 10^{-16}). The results are shown on the left in Figure 5. One can observe that all three bounds show similar behavior, however, the conservative bound is, as expected, very loose.

We were also interested in a run time comparison between the projection algorithm and a general purpose solver (the cvx toolbox) to see how much can be gained by using the specialized projection method. The cvx toolbox uses the SDPT3 package to solve semidefinite-quadratic-linear programming problems. The details of the SDPT3 package are described in Toh, Todd, and Tutuncu (1999); Tutuncu, Toh, and Todd (2003). We used as a stopping rule for both methods an error below 10^{-4}, that is CCP stopped when our bound guaranteed us that the error is below 10^{-4} and cvx stopped when its own error bound signaled an error below this threshold (details about how the precision is calculated in the SDPT3 package can be found in Toh et al. (1999)[Section 3]). The results of the run time comparison are shown in Figure 6 (mean(standard deviation) in seconds averaged over 10 runs; same experimental setup as for the bounds plot; n is the number of data points).

4.2 Experiment 2: Run time vs. Least-Squares Error on a Small Scale Sample

The second set of experiments tested on a small scale how the run time of the CCP-regressor measures against the statistical performance. We were interested in seeing how the method fares in comparison to standard Gaussian process/ridge regression and Fast-KRR. We reproduced the experiment from Zhang et al. (2013) which uses the million songs data set (about 450000 data points and a covariate dimension of 90). We normalized the data as in Zhang et al. (2013) by letting each covariate dimension have standard deviation 1. We also used the same kernel (Gaussian with $\sigma = 6$). Finally, we normalized the response variable (year when a song appeared) to lie in [0, 1] by subtracting the minimal year and dividing by (maximum - minimum). 450000 data points are too much to run the standard GP regressor/ridge regressor and we downsampled the data set to a small subset of 5000 training points and 1000 test points. We were interested in how the radius affects the performance of CCP and how different it is from how λ affects the GP. We were also interested in seeing how the error threshold translates into least-squares performance and run time. The results are shown in the table in Figure 7. The notation is (run time - least-squares error), r is the radius for CCP (with line-search), p the number of elements in each partition of Fast-KRR (we used for Fast-KRR the same regularization schedule as in Zhang et al. (2013)) and ϵ, in CCP-ϵ, refers to the stopping criterion. We used our upper bound to gauge the current error and we stopped when the error bound passed ϵr. The table below shows the results. We also ran the CCP-0.1 setting with $r = 5000$ to see how close we can get to the performance of the GP regressor. The estimator took 30.6 seconds to produce an estimate with an error of 0.124.

$r(p)/\lambda$	50/0.02	100/0.01	250/0.004	500/0.002	1000/0.001
GP	56 - 0.121	55 - 0.121	55 - 0.121	55 - 0.121	65 - 0.121
CCP-0.1	1.03 - 0.53	1.63 - 0.46	2.97 - 0.36	4.77 - 0.22	8.89 - 0.17
CCP-0.01	3.66 - 0.47	6.21 - 0.33	12.8 - 0.19	30.67 - 0.16	93.13 - 0.13
Fast-KRR		9.3 - 0.236	10.6 - 0.203	12.5 - 0.179	16.5 - 0.158

Figure 7: The table shows a comparison between the GP/ridge regressor, the Fast-KRR and the CCP-regressor. Each entry consists of the run time (seconds) and the least-squares error.

As one expects the GP run time is essentially independent of λ. A bit surprising is here that the regularization parameter seems to have hardly any effect on the least-squares error of the GP regressor. The run time of the CCP algorithm, however, is strongly affected by r which is consistent with our bound in which r influences the constant of the convergence rate. For both thresholds the computation time increases slightly non-linearly in r. The least-squares error depends on both ϵ and r. Increasing r results in this experiment in a higher reduction in least-squares error in dependence of the added computation time.

The lowest error is achieved by the GP-regressor (which corresponds to the Fast-KRR with one partition). A slightly suboptimal solution with a least-squares error of 0.124 is achieved by the CCP-regressor in about 25 seconds less than what the GP-regressor needs. One can also observe that Fast-KRR is fast in computing an estimate with a low least-squares errors which is en par with

the CCP-regressor in this experiment (in 10 seconds the Fast-KRR reaches, for instance, about 0.2 and the CCP-regressor 0.17). The interesting question is here how the performance of Fast-KRR and the CCP-regressor scale with the amount of data.

4.3 Experiment 3: Run time vs. Least-Squares Error on a Large Scale Sample

In the last experiment we compared Fast-KRR with the CCP-regressor (line search) on the full million songs data set. We used similar partition sizes as in Zhang et al. (2013) for Fast-KRR and we ran the CCP-regressor with $r = 100000$. The bottleneck in the CCP-regressor is the number of kernel evaluations that need to be performed which are tn for t iterations and n samples. The Fast-KRR regressor needs for m partitions (for simplicity let m be such that $0 \equiv n \mod m$) in the order of n^2/m many kernel evaluations and it needs to calculate m many inverses of matrices of size $(n/m) \times (n/m)$. So if $t = n/m$ then the CCP-regressor needs to perform exactly as many kernel evaluations as the Fast-KRR algorithm. Especially for large m this will leave us with few iterations for the CCP-regressor and one expects that if the kernel evaluation is expensive in comparison to the computational cost of an inverse then Fast-KRR will perform better. On the other hand if we have either small partitions or cheap to evaluate kernels then the CCP-regressor will excel compared to Fast-KRR. In terms of memory: the CCP-regressor needs a small multiple of the original data size while the Fast-KRR needs to store another $n/m \times n/m$ matrix. We made 25 GB of memory available to the Fast-KRR method, which allowed us to go down to 26 partitions on our cluster. The results of the comparison are shown in Figure 8 (mean over 10 runs with randomly chosen training and test sets).

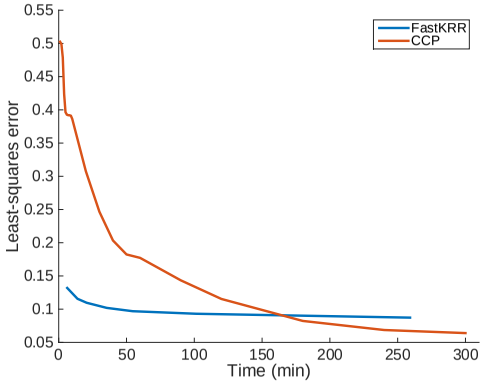

Figure 8: The plot shows the performance of the Fast-KRR and cpp-regressor in dependence of the run-time. We used partition sizes 26, 32, 38, 48, 64, 96, 128 and 256 for Fast-KRR. 26 was the limit we could achieve with 25 GB of memory.

We also determined the standard deviations. These were for both regressors marginal and we did not plot error-bars (maximal standard deviation for Fast-KRR: 0.16×10^{-4}; CCP: 0.02).

The plot shows us that the Fast-KRR achieves already a very good performance if the number of samples per partition is small. The CCP-regressor is significantly outperformed at that stage. With more run-time the CCP-regressor catches up and approaches the minimizer in the set $\mathcal{C}(100000)$. After about three hours of run-time the CCP-regressor overtakes the Fast-KRR and achieves the lowest least-squares error. Another difference one can observe is that there is, in principle, no limit of how long we can let the CCP-regressor optimize while we are limited with the Fast-KRR by the memory that we have available (the memory requirement increases linearly in the number of elements per partition and quadratically in the sample size).

5. Discussion and Open Problems

Motivated by the recent work on kernel herding we explored the uses of herding and the CGM algorithm for calculating projections onto convex sets. We derived a theorem that extends current convergence results for herding to the boundary if the perturbations introduced by our lack of knowledge of the minimal face that contains the projection are in a certain way well behaved. We also showed that our condition on the perturbations is both necessary and sufficient for the algorithm to converge with the fast rate. An important open question is if there exist convex sets for which this assumption can fail to hold. Furthermore, we demonstrated that the herding algorithm and the CGM will chose no elements outside of the minimal face after some finite time t_0 if this condition is fulfilled. Providing tight bounds on the size of t_0 and the number of elements outside the minimal face that are chosen in these first iterations in future research would help with improving the understanding of herding and the CGM further. Such bounds should also be useful to provide a better understanding of algorithms like the CGM with away steps: away steps are essentially trying to remove the perturbations introduced through elements outside of the minimal face. It is known that the CGM with away-steps successfully removes perturbations after finite many steps under certain conditions (e.g. Wolfe (1970); Guélat and Marcotte (1986)), though, as we discussed in the introduction, there is still much to be gained by refined analyses. Another interesting direction for future research concerns the geometry of the convex set in Hilbert space. The geometry factors into the rates of convergence of CGM like algorithms in various ways (Slater's condition, pyramidal width etc.). One might also aim for results that hold for convex sets with countably infinite or uncountable many extremes. We believe that one of the main difficulties will be here that there does not need to exist a gap between the minimal face and extremes that lie outside of the minimal face. We made use of such a gap to show that after some finite time only extremes of the minimal face will be chosen. Without such a gap one expects that there does not exist such a finite window of steps and perturbations will be continuously injected into the approximation.

On the practical side one can wonder how widely applicable the projection in kernel space approach, which we used to derive a novel kernel regressor, is. Projections onto the standard simplex have proven to be very valuable for a variety of statistical problems and the projection onto the set $\{\sum_{i=1}^{n} \alpha_i k(x_i, \cdot) : n \in \mathbb{N}, \|\alpha\|_{\ell_1} \leq 1, x_i \in X \text{ for } i \leq n\}$ is in a way the natural analogue of the standard simplex. There are some obvious differences. The set is, for example, from a geometrical point of view far more complicated since in kernel space the natural way to describe objects is through the kernel function and not through an orthonormal basis. Nevertheless, our results suggest that this approach has merit and it is worth to explore its uses for other non-parametric problems.

6. The Proofs of the Two Theorems and the Corollaries

This section contains the proof details of our two theorems and the various corollaries. We start with a technical lemma that is needed in the proof of the first theorem. Using this we prove that the basic algorithm without line-search achieves a convergence rate of $1/t$.

6.1 The First Theorem

We need a technical lemma that guarantees us that if we have two operators A, B that pull elements x towards the origin if x gets large (in a certain sense) then compositions of these operators (for instance $C = A^2BA^4B^3$) applied to x will be bounded, i.e. $\|Cx\| \leq b$ for some constant b. In fact, we need slightly more. We need a result which holds simultaneously for a family of operators $\mathfrak{A}$. We formulate the lemma in the way that some initial value x_0 and a particular infinite composition C of operators in $\mathfrak{A}$ and B is given. This is necessary since our operators in $\mathfrak{A}$ are not necessarily a contraction for arbitrary elements but only for the elements they are applied to. In the following, we denote with C_t the composition operator that consists of the first t operators in C (in the above example $C_3 = A^2B$) and we use the notation $C_{s,t}$ for the operator that fulfills $C_t = C_{s,t} \circ C_{s-1}$. We split the proof of the lemma and the following theorems into a number of separate claims and we use ❡ (proof) and ❑ (q.e.d.) brackets for the proofs of the claims.

Lemma 9 *Let $\mathcal{H}$ be a Hilbert space, K a closed subspace of $\mathcal{H}$, P the projection onto K, $B : \mathcal{H} \to \mathcal{H}$, $Bx = (I - P)x + PBPx$ an operator, $\mathfrak{A}$ a family of operators $A : \mathcal{H} \to \mathcal{H}$, C a finite composition of operators of $\mathfrak{A}$ and B, and $x_0 \in \mathcal{H}$ such that there exist constants $a, b, \xi > 0$ with*

(i) $\|Ax\|, \|Bx\| \leq \|x\| + b$ *for every* $A \in \mathfrak{A}$, $x \in \mathcal{H}$.

(ii) For any element $x \in \{C_t x_0\}_{t \geq 1}$ and for any $t \geq 1$ for which $C_{t,t} \in \mathfrak{A}$, i.e. an operator in $\mathfrak{A}$ is chosen at time t, we have with $A = C_{t,t} \in \mathfrak{A}$ that

$$\|Ax\|^2 \leq \|x\| (\|x\| - \xi) + b.$$

(iii) If $\|Px\| \geq a$ for an element $x \in \mathcal{H}$ then $\|Bx\| \leq \|x\|$.

Then for all $t \geq 1$

$$\|C_t x_0\|^2 \leq \|x\|^2 \vee (c + b)^2 + (a + b)^2 \quad \text{and} \quad \|C_t x_0\| \leq \|x\| \vee (c + b) + a + b,$$

with the constant $c := ((a + b)^2 + b)/\xi$.

Proof **(a)** For any $n \geq 0$, $x \in \mathcal{H}$, it holds that $\|B^n x\|^2 \leq \|x\|^2 + (a + b)^2$.

❡ Observe that $Bx = (I - P)x + BPx$. $\|Px\| < a$ implies $\|BPx\| \leq a + b$ and if $\|Px\| \geq a$ then

$$\|BPx\|^2 = \|Bx\|^2 - \|(I - P)x\|^2 \leq \|x\|^2 - \|(I - P)x\|^2 = \|Px\|^2$$

and $\|BPx\| \leq \|Px\| \vee (a + b)$. Hence,

$$\|B^n Px\| \leq \left\|PB^{n-1}x\right\| \vee (a + b) = \left\|B^{n-1}Px\right\| \vee (a + b) \leq \|Px\| \vee (a + b).$$

So for any $n \geq 0$ and $x \in \mathcal{H}$ we know that

$$\|B^n x\|^2 = \|(I - P)x\|^2 + \|B^n Px\|^2 \leq \|(I - P)x\|^2 + \|Px\|^2 \vee (a+b)^2 \leq \|x\|^2 + (a+b)^2. \quad ❑$$

(b) For any $n \geq 0$, $A \in \mathfrak{A}$, if $\|x\| \geq c + b$, $x = C_t x_0$ and $C_{t+1,t+n+1} = AB^n$ for some $t \geq 0$ then $\|AB^n x\| \leq \|x\|$ and $\|AB^n x\| \leq \|x\| \vee (c + b)$.

P If $\|x'\| \geq c$ then (ii) tells us that

$$\|Ax'\|^2 \leq \|x'\|^2 - \xi \|x'\| + b \leq \|x'\|^2 - (a + b)^2.$$

So, if $\|B^n x\| \geq c$ then (a) tells us that $\|AB^n x\|^2 \leq \|B^n x\|^2 - (a+b)^2 \leq \|x\|^2$. And, if $\|B^n x\| < c$ then $\|AB^n x\| \leq c + b$. Also, $\|AB^n x\| \leq \|x\|$ if $\|x\| \geq c + b$. **Q**

(c) For any $n \geq 0, m \geq 1$, $A_1, \ldots, A_m \in \mathfrak{A}$, if $\|x\| \geq c + b$, $x = C_t x_0$, $C_{t+1,t+n+m} = A_1 \ldots A_m B^n$ for some $t \geq 1$ then $\|A_1 \ldots A_m B^n x\| \leq \|x\|$ and it holds that $\|A_1 \ldots A_m B^n x\| \leq \|x\| \vee (c + b)$.

P If $\|z\| \geq b/\xi$ for a $z \in \mathcal{H}$ then $\|Az\| \leq \|z\|$ for all $A \in \mathfrak{A}$. If $\|x\| \geq c + b$ then (b) tells us that $\|AB^n x\| \leq \|x\|$ for all $A \in \mathfrak{A}$. Hence, for any $2 \leq l \leq m - 1$, $\|A_{m-l-1} \ldots A_m B^n x\| > \|A_{m-l} \ldots A_m B^n x\|$ implies $\|A_{m-l} \ldots A_m B^n x\| < b/\xi \leq c$. The maximal increase of operators $A \in \mathfrak{A}$ is bounded by b due to (i). Since we can only see an increase if $\|A_{m-l} \ldots A_m B^n x\| \leq c$ we gain $\|A_{m-l-1} \ldots A_m B^n x\| \leq (c + b) \vee \|x\| = \|x\|$. A slight modification of the argument yields the second case. **Q**

(d) It follows that compositions of such sequences, say $A_1 \ldots A_{m_1} B^{n_1} A_{m_1+1} \ldots A_{m_1+m_2} B^{n_2}$, $m_1, m_2 > 0$, $A_1, \ldots, A_{m_1+m_2} \in \mathfrak{A}$ do not increase the bound since with $x' = A_{m_1+1} \ldots A_{m_2} B^{n_2} x$,

$$\|x'\| = \|A_{m_1+1} \ldots A_{m_2} B^{n_2} x\| \leq \|x\| \vee (c + b)$$

we have

$$\|A_1 \ldots A_{m_1} B^{n_1} x'\| \leq \|x'\| \vee (c + b) \leq \|x\| \vee (c + b).$$

These cases cover all possible compositions with the only exception of sequences that start with some B^n, $n \geq 1$. But, if $\|x'\| \leq \|x\| \vee (c + b)$ then from (a) we know that

$$\|Cx\|^2 = \|B^n x'\|^2 \leq \|x'\|^2 + (a + b)^2 \leq \|x\|^2 \vee (c + b)^2 + (a + b)^2.$$

■

We need the definitions of the affine hull and the affine dimension. The *affine hull* of a set $A \subseteq \mathcal{H}$ is

$$\operatorname{aff} A = \left\{ \sum_{i=1}^{n} \alpha_i x_i : n \geq 1, x_i \in A, \sum_{i=1}^{n} \alpha_i = 1 \right\}.$$

The affine hull can be identified with a vector space by centering it around an arbitrary element $x_0 \in \operatorname{aff} A$, i.e. $V = \{x - x_0 : x \in \operatorname{aff} A\}$ is a vector space. The dimension of this vector space is called the *affine dimension* of A. If $A = \{x\}$ for some element $x \in \mathcal{H}$ then $\operatorname{aff} A$ is also just $\{x\}$ and we define its affine dimension to be 0.

We recall some basic properties of the projection Py of y onto a compact convex set C. The projection Py is characterized by $\|y - Py\| = \min_{x \in C} \|y - x\|$ and the geometric property $\langle y - Py, x - Py \rangle \leq 0$ for every $x \in C$. The latter property translates into a sort of orthogonal decomposition for convex sets, that is

$$\|y - x\|^2 = \|y - Py\|^2 - 2\langle y - Py, x - Py \rangle + \|Py - x\|^2 \geq \|y - Py\|^2 + \|Py - x\|^2. \quad (1)$$

We also need the definition of a face of a convex set C. A *face* F is a set which fulfills that whenever there are two points $a, b \in C$ and $\theta \in (0, 1)$ with $\theta a + (1 - \theta) b \in F$ then $a, b \in F$.

Theorem 2 *Given a compact convex set $C \subset \mathcal{H}$ and a finite subset S of C with $\operatorname{ex} C \subseteq S$ there exists for $y \in \mathcal{H}$ a constant $b > 0$ such that Algorithm 1 has a worst-case approximation error of b/t for all $t \geq 1$ if, and only if, Assumption 1 is fulfilled for the sequences $\{x_t\}_{t \geq 1}$ and $\{w_t\}_{t \geq 0}$ generated by the algorithm.*

Proof We start with some general observations before proving that the assumption is sufficient for the fast rate of convergence. That the condition is necessary is shown at the end (see (v)).

(i) The algorithm converges with the right rate to Py if the sequence $\{w_t - y - t(y - Py)\}_{t \geq 1}$ stays in a bounded norm ball of radius b since then

$$b \geq \|w_t - y - t(y - Py)\| = \left\| (t + 1)y - \sum_{i=1}^{t} x_i - y - t(y - Py) \right\| = \left\| tPy - \sum_{i=1}^{t} x_i \right\| \quad (2)$$

because $w_t = (t + 1)y - (x_1 + \ldots + x_t)$ and hence $\|Py - (x_1 + \ldots + x_t)/t\| \leq b/t$. Also observe that we can replace for any $z \in \mathcal{H}$

$$\arg\max_{x \in S} \langle z, x \rangle \quad \text{with} \quad \arg\max_{x \in S} \langle z, x - Py \rangle$$

in the maximization step.

(ii) (a) There exists a minimal face F that contains Py which is

$$F = \{Py\} \cup \{x \in C : \exists z \in C, \theta \in (0, 1) \text{ such that } \theta x + (1 - \theta) z = Py\}. \quad (3)$$

(b) F is a compact and convex set and the extremes of F are $\operatorname{ex} F = \operatorname{ex} C \cap F$.

Let $F_c = \{z - Py : z \in F\}$ be the face F centered around $Py \in F$. The set $\operatorname{aff} F_c = \operatorname{span} F_c$ is a closed subspace of $\mathcal{H}$ with orthogonal complement $(\operatorname{aff} F_c)^\perp = F_c^\perp$. So to any element $z \in \mathcal{H}$ we have a unique $z^{||} \in \operatorname{aff} F_c$ and $z^\perp \in (\operatorname{aff} F_c)^\perp$ with $z = z^{||} + z^\perp$. In the following, denote the projection onto $\operatorname{aff} F_c$ with P_F.

(c) $y - Py$ stands orthogonal on the centered face F_c, i.e. $y - Py \in F_c^\perp$. So the term $t(y - Py)$ contained in w_t does not influence the maximization over F.

(d) Either $F_c = \{0\}$ or there exists a $\delta_F > 0$ such that $B(0, \delta_F) \cap \operatorname{span} F_c = B(0, \delta_F) \cap F_c$, where $B(0, \delta_F)$ is a the closed ball of radius δ_F centered at the origin.

(e) For any w_t, $t \geq 0$, there exists an $x \in C$ such that $\langle x - Py, w_t \rangle \geq 0$. Furthermore, if $F_c \neq \{0\}$ and whenever $\|P_F w_t\| \geq 2r^2/\delta_F$, $r := \sup_{x \in C} \|x\| < \infty$, and an element in $S \cap F$ is chosen by the algorithm then $\|P_F w_{t+1}\| \leq \|P_F w_t\|$. So, if $\|P_F w_t\| \geq 2r^2/\delta_F$ and an element in $S \cap F$ is chosen then $\|w_{t+1} - y - (t + 1)(y - Py)\| \leq \|w_t - y - t(y - Py)\|$.

(f) If $F = C$ then $b = 2r^2/\delta_F + 3r$ satisfies eq. 2 and the error of the algorithm is bounded by $(2r^2/\delta_F + 3r)/t$ for any $t \geq 1$.

P (a) *F is the minimal face.* F is certainly a subset of any face that contains Py by the very definition of a face. It is also a face itself since if for any $x \in F$, $x \neq Py$, there exist two points $a, b \in C$ and a $\lambda \in (0, 1)$ such that $x = \lambda a + (1 - \lambda) b$ then there exists a $\theta \in (0, 1)$ and a $z \in C$ such that $Py = \theta x + (1 - \theta) z = \theta(\lambda a + (1 - \lambda) b) + (1 - \theta) z = \theta\lambda a + \theta(1 - \lambda) b + (1 - \theta) z = \theta\lambda a + (1 - \theta\lambda) \left(\frac{\theta(1-\lambda)}{1-\theta\lambda} b + \frac{1-\theta}{1-\theta\lambda} z \right)$. $c := \theta(1 - \lambda)/(1 - \theta\lambda) b + (1 - \theta)/(1 - \theta\lambda) z$ is an element of C since it is a convex combination of b and z and hence with $\xi := \theta\lambda \in (0, 1)$ we see that $Py = \xi a + (1 - \xi) c$ and $a \in F$. Applying the same argument to b shows us also that $b \in F$ and F is a face.

(b) *F is compact and convex and* $\operatorname{ex} F = \operatorname{ex} C \cap F$. F is a face and as such also convex. Furthermore, $F = C \cap \operatorname{aff} F$ where $\operatorname{aff} F$ is the affine hull of F. The affine hull has finite affine dimension since C has finite affine dimension. Affine hulls with finite affine dimension are closed. Hence, F is closed as the intersection of two closed sets. And since closed subsets of compact sets are compact we see that F is compact. Finally, $\operatorname{ex} F = F \cap \operatorname{ex} C$, that is the extremes of F are just the extremes of C which lie in F. The last property can be verified in the following way: the extremes of C are by definition not convex combinations of any two points $a, b \in C$, $a \neq b$, and hence of no two points in F. So $F \cap \operatorname{ex} C \subseteq \operatorname{ex} F$. On the other hand, if $c \in \operatorname{ex} F$ then there is no point $a \in C \setminus F$ for which a corresponding point $b \in C$ and $\theta \in]0,1[$ exists such that $c = \theta a + (1-\theta)b$ (a would otherwise be in the face F). However, since $c \in \operatorname{ex} F$ there exists also no point $a \in F$ with this property and $c \in \operatorname{ex} C$.

(c) *$y - Py$ is orthogonal to F_c.* If there would be an element $u \in \operatorname{aff} F_c$, $u = \sum_{i=1}^n \alpha_i v_i$ for some $n \geq 1$, $v_i \in F_c$, $\sum_{i=1}^n \alpha_i = 1$, such that $\langle u, y - Py\rangle \neq 0$ there would also be an element $v \in F_c$ with $\langle v, y - Py\rangle \neq 0$ (otherwise $\langle u, y - Py\rangle = \sum_{i=1}^n \alpha_i \langle v_i, y - Py\rangle = 0$). Furthermore, by the characterization of the minimal face in (3) and because $v + Py \in F$ there exists an element $z \in F_c$ such that $Py = \theta(v + Py) + (1-\theta)(z + Py)$ and $0 = \theta v + (1-\theta)z$. Hence, $0 = \langle y - Py, \theta v\rangle + \langle y - Py, (1-\theta)z\rangle$. Because $\langle y - Py, v\rangle \neq 0$ we know that $\langle y - Py, z\rangle \neq 0$ and both have opposing signs. So one of them, say without loss of generality $\langle y - Py, v\rangle$, is strictly greater zero. But this can not be since then $\tilde{v} = v + Py \in C$ would fulfill, in contradiction to the properties of Py, $\langle y - Py, \tilde{v} - Py\rangle > 0$.

(d) *$F_c = \{0\}$ or there exists a $B(0,\delta), \delta > 0$.* If the minimal face consists of a single element x then this element must be Py, since $Py \in F$, so in this case $F_c = \{0\}$. In the other case it suffices to consider a set of basis vectors which span the space $\operatorname{span} F_c$, say $e_1, \ldots, e_d$, where $d < \infty$ is the affine dimension of F. There exist $\alpha_1, \ldots, \alpha_d > 0$ such that $\pm\alpha_i e_i \in F_c$ for all $i \leq d$ if, and only if, $B(0,\delta) \cap \operatorname{span} F_c = B(0,\delta) \cap F_c$ for some $\delta > 0$.

Since, $e_i \in \operatorname{aff} F_c$ there exists a $n \geq 1$, $u_1, \ldots, u_n \in F_c$ and $\sum_{j=1}^n \beta_j = 1$ with $e_i = \sum_{j=1}^n \beta_j u_j$. We can also represent e_i as a sum with only non-negative coefficients, i.e. there exists $\tilde{\beta}_j \geq 0, \tilde{u}_j \in F_c$, $j \leq n$, such that $e_i = \sum_{j=1}^n \tilde{\beta}_j \tilde{u}_j$. This can be achieved by doing the following for each $j \leq n$: if $\beta_j \geq 0$, then let $\tilde{\beta}_j = \beta_j$ and $\tilde{u}_j = u_j$. If $\beta_j < 0$ and $u_j = 0$ then let $\tilde{\beta}_j = -\beta_j$ and $\tilde{u}_j = u_j$. Finally, if neither case applies ($\beta_j < 0$, $u_j \neq 0$) take a $\theta \in]0,1[$ and a $\tilde{u}_j \in F_c$ such that $0 = \theta u_j + (1-\theta)\tilde{u}_j$. Such a θ and $\tilde{u}_j$ exist due to the definition of F. With this choice $\beta_j u_j = -\tilde{u}_j \beta_j (1-\theta)/\theta = \tilde{\beta}_j \tilde{u}_j$, where $\tilde{\beta}_j = -\beta_j(1-\theta)/\theta > 0$.

So $e_i = \sum_{j=1}^n \tilde{\beta}_j \tilde{u}_j$ and $\tilde{\beta}_j \geq 0$. By normalizing the sum with $\xi = \sum_{j=1}^n \tilde{\beta}_j > 0$ (some β_j must be greater 0) we see that $\xi e_i \in F_c$. Furthermore, there exists a $\theta \in]0,1[$ and a $v \in F_c$ such that $-e_i \xi(1-\theta)/\theta = v$. And our claim is shown to be true by letting $\alpha_i = \min\{\xi(1-\theta)/\theta, \xi\}$.

(e) *Shrinking weight vector.* If F consists of more than one element then for any weight vector w_t there exists an element x in F with $\langle x - Py, P_F w_t\rangle = \delta_F \|P_F w_t\|$, since $\delta_F P_F w_t / \|P_F w_t\|$ is in $B(0,\delta_F)$ and $\langle(\delta_F P_F w_t/\|P_F w_t\| + Py) - Py, P_F w_t\rangle = \delta_F \|P_F w_t\|$. This implies directly that we have an element $z \in \operatorname{ex} F \subseteq S \cap F$ with $\langle z - Py, P_F w_t\rangle \geq \delta_F \|P_F w_t\|$, because $x = \sum_{j=1}^n \beta_j u_j$, for suitable n, $\beta_1, \ldots, \beta_n > 0$, $\sum_{j=1}^n \beta_j = 1$ and elements $u_j \in \operatorname{ex} F$ ($\operatorname{ex} C$ is finite and the convex hull C of $\operatorname{ex} C$ is in this case closed. That means any element in C can be represented exactly by a convex combination of finite many extremes), i.e. $\sum_{j=1}^n \beta_j \langle u_j - Py, P_F w_t\rangle = \delta \|P_F w_t\|$ and at least one term $\langle u_j - Py, P_F w_t\rangle$ must be as large as $\delta_F \|P_F w_t\|$.

Now, whenever $\|P_F w_t\| \geq 2r^2/\delta_F$ and an element in $S \cap F$ is chosen, then $\|P_F w_{t+1}\| \leq \|P_F w_t\|$. This can be verified in the following way: there exists an element $x' \in F \cap S$ such that $\langle x' - Py, P_F w_t\rangle \geq \delta_F \|P_F w_t\|$ and, hence, the algorithm will choose an element x with $\langle x - Py, P_F w_t\rangle \geq \langle x' - Py, P_F w_t\rangle \geq \delta_F \|P_F w_t\|$ (as said in (i) the maximization is unaffected by the translation $-Py$). So, since $x - Py \in F_c$ and P_F is linear we have that

$$\begin{aligned}\|P_F w_{t+1}\|^2 &= \|P_F(w_t - (x - Py))\|^2 = \|P_F w_t - (x - Py)\|^2 \\ &= \|P_F w_t\|^2 - 2\langle x - Py, P_F w_t\rangle + \|x - Py\|^2 .\end{aligned}$$

Furthermore, $\|x - Py\| \leq \|x\| + \|Py\|$ is bounded by $2r$ and

$$\|x - Py\|^2 - 2\langle x - Py, P_F w_t\rangle \leq 4r^2 - 2\delta_F \|P_F w_t\| \leq 0$$

by our assumption on $\|P_F w_t\|$.

For $x \in F \cap S$ we can also observe that for any w_t

$$\langle x - Py, w_t\rangle = \langle P_F(x - Py), w_t\rangle = \langle x - Py, P_F w_t\rangle$$

since $x - Py \in \operatorname{aff} F_c$ and P_F is self-adjoint. So there always exists an $x \in C$ such that $\langle x - Py, w_t\rangle \geq 0$. If $F_c = \{0\}$, that is $F = \{Py\}$, then $x = Py$ gives us $\langle x - Py, w_t\rangle = 0$.

(f) If $F = \{Py\}$ then $w_t - y - t(y - Py) = (x_1 - Py) + \ldots + (x_t - Py) = 0$ since all $x_i = Py$. If F contains more than one element and $C = F$ then (e) tells us that if $\|P_F w_t\| \geq 2r^2/\delta_F$ then

$$\|w_{t+1} - y - (t+1)(y - Py)\| \leq \|w_t - y - t(y - Py)\| .$$

Observe that if $F = C$ then the projection P_F is closely related to the projection $\tilde{P}$ onto the affine hull of C, that is $\tilde{P}x = P_F(x - \tilde{P}0) + \tilde{P}0$. Also, $\tilde{P}y = Py$ because $y - Py$ is orthogonal to $\operatorname{span} F_c$. We need to show that $\|P_F w_t\| \geq 2r^2/\delta_F$ under the stated condition. We have that

$$\|P_F w_t\| = \Big\|(t+1)P_F y - \sum_{i=1}^t P_F x_i\Big\| = \Big\|P_F y - \sum_{i=1}^t P_F(x_i - y)\Big\| = \Big\|P_F y - \sum_{i=1}^t (x_i - Py)\Big\|$$

because $x_i - Py$ lies in $\operatorname{span} F_c$ and $P_F y = P_F Py$. On the other hand

$$\|w_t - y - t(y - Py)\| = \Big\|\sum_{i=1}^t (x_i - Py)\Big\| \leq \|P_F w_t\| + \|P_F Py\| \leq \|P_F w_t\| + r.$$

Hence, if $\|w_t - y - t(y - Py)\| \geq r + 2r^2/\delta_F$ then $\|w_{t+1} - y - (t+1)(y - Py)\|$ is smaller than $\|w_t - y - t(y - Py)\|$. So we can only see an increase of the sequence $\{w_t - y - t(y - Py)\}_{t \geq 1}$ if at any given t it holds that $\|w_t - y - t(y - Py)\| < 2r^2/\delta_F + r$ and since the change between t and $t+1$ is just $Py - x$ we gain for any $t \geq 1$ the bound

$$\|w_t - y - t(y - Py)\| < 2r^2/\delta_F + r + \|Py - x\| \leq 3r + 2r^2/\delta_F . \qquad \blacksquare$$

(iii) The case $F = C$ is dealt with in (ii.f) so we may assume in the following that $C \setminus F \neq \emptyset$.

We assign to the three subspaces U_F, U_b and U_δ defined in Section 2.1 orthonormal bases. Take an arbitrary orthonormal basis of U_F and let E_F be the set of these basis elements. Similarly, chose

a basis of U_δ and let E_δ be the set of these basis elements. Finally, group the basis elements of U_b, guaranteed to us in our assumption, in E_b. Furthermore, let δ_m be the largest radius of an open ball around 0 in $U_F \oplus U_\delta$. δ_m is always strictly larger than 0. For any $e \in E_b$ and $t \geq 0$

$$\langle w_t, e\rangle = \langle Py, e\rangle + \langle (t+1)(y-Py), e\rangle - \sum_{n=1}^{t} \langle x_n - Py, e\rangle \geq \langle (t+1)(y-Py), e\rangle + \langle Py, e\rangle$$

and for any $e \in E_b$ and any $t \geq 0$ it holds that

$$\langle w_{t+1} - (y-Py), e\rangle - \langle w_t, e\rangle = -\langle x_{t+1} - Py, e\rangle \geq 0.$$

Hence $\langle w_{t+1} - (y-Py), e\rangle \geq \langle w_t, e\rangle$ for all $e \in E_b$.

Clearly, F_c lies in $U_F \oplus U_\delta$. More importantly, any element that is not in F_c lies at least partly in U_b, or in other words, if $x \in C\backslash F$ then $P_b(x-Py) \neq 0$.

P For any element $x \in C$ that is not in F there exists an $e \in E_b$ such that $\langle x - Py, e\rangle \neq 0$. Otherwise, $x - Py$ would lie in a subspace A for which there is a $\delta' > 0$ and $B(0,\delta') \cap A = B(0,\delta') \cap A \cap C_c$. The element $-(x-Py)$ would then also lie in A and $z = -(\delta'/2)(x - Py)/\|x - Py\| \in B(0,\delta') \cap A = B(0,\delta') \cap A \cap C_c$ ($x \neq Py$, since $Py \in F$ and the norm $\|x - Py\|$ is strictly positive). So with $\zeta = \delta'/(2\|x-Py\|)$ and $\xi = \zeta/(1+\zeta) \in]0,1[$ we would have that

$$\xi(x-Py) + (1-\xi)z = (x-Py)\zeta/(1+\zeta) - (x-Py)\zeta(1-\zeta/(1+\zeta)) = 0$$

and $\xi x + (1-\xi)(z+Py) = Py$. But, because x and $z + Py \in C$ this implies that $x \in F$ by the definition of the minimal face. The conclusion $x \in F$ is a contradiction to our original assumption and our claim holds. **Q**

(iv) (a) If the sequence $\{\|(P_F + P_\delta)(w_t - y - t(y-Py))\|\}_{t\geq 1}$ is bounded then the sequence $\{\|P_b(w_t - y - t(y-Py))\|\}_{t\geq 1}$ is also bounded and elements in $S\backslash F$ are chosen only finitely often.

(b) Under Assumption 1 the sequence $\{\|(P_F + P_\delta)(w_t - y - t(y-Py))\|\}_{t\geq 1}$ is bounded. Furthermore, under this assumption the sequence $\{\|w_t - y - t(y-Py)\|\}_{t\geq 1}$ is bounded and there exists a constant b such that the approximation error is bounded by b/t.

P (a) Let us assume that $\{\|P_b(w_t - y - t(y-Py)\|\}_{t\geq 1}$ is unbounded. If elements in F are chosen at any stage t then $P_b(w_t - y - t(y-Py)) = P_b(w_{t+1} - y - (t+1)(y-Py))$ and there is no increase of the normed sequence. Hence, there must exist an element $x^* \in S\backslash F$ which is selected infinitely often. Let $e = -P_b(x^* - Py)/\|P_b(x^* - Py)\|$ and observe that $\langle e, x - Py\rangle \leq 0$ for all $x \in C$ because $\langle P_b(x^* - Py), x - Py\rangle = \sum_{e' \in E_b} \langle e', x^* - Py\rangle \langle e', x - Py\rangle \geq 0$. If x^* is selected at any step t then from $\langle x^* - Py, w_t\rangle \geq 0$ it follows that

$$\langle x^* - Py, (P_F + P_\delta)w_t\rangle \geq -\langle x^* - Py, P_b w_t\rangle = \|P_b(x^* - Py)\| \langle e, w_t\rangle$$

and $\langle x^* - Py, y - Py\rangle \leq 0$ implies $\langle x^* - Py, (P_F + P_\delta)(y - Py)\rangle \leq -\langle x^* - Py, P_b(y - Py)\rangle$ which in turn implies

$$\begin{aligned}\langle x^* - Py, (P_F + P_\delta)(-y - t(y-Py))\rangle &\geq -\langle x^* - Py, P_b(-y - t(y-Py))\rangle - \langle x^* - Py, Py\rangle \\ &\geq -\langle P_b(x^* - Py), P_b(-y - t(y-Py))\rangle - 2r.\end{aligned}$$

Together, these inequalities give us

$$\langle x^* - Py, (P_F + P_\delta)(w_t - y - t(y-Py))\rangle \geq \|P_b(x^* - Py)\| \langle e, P_b(w_t - y - t(y-Py))\rangle - 2r.$$

Applying the Cauchy-Schwarz inequality yields then

$$\begin{aligned}&\frac{\|x^* - Py\|}{\|P_b(x^* - Py)\|} \|(P_F + P_\delta)(w_t - y - t(y-Py))\| + \frac{2r}{\|P_b(x^* - Py)\|} \geq \langle e, w_t - y - t(y-Py)\rangle \\ &\geq -\sum_{s=1}^{t} \langle e, x_s - Py\rangle \times \chi\{x_s = x^*\} = \sum_{s=1}^{t} \|P_b(x^* - Py)\| \times \chi\{x_s = x^*\}\end{aligned}$$

where χ is the characteristic function. Since $\|P_b(x^* - Py)\| > 0$ and x^* is selected infinitely often we conclude that $\|(P_F + P_\delta)(w_t - y - t(y-Py))\|$ diverges in t and the corresponding sequence $\{\|(P_F + P_\delta)(w_t - y - t(y-Py)\|\}_{t\geq 1}$ is unbounded.

(b) If $U_F = U_\delta = \{0\}$ then $(P_F + P_\delta)x = 0$ for all $x \in \mathcal{H}$ and (a) gives us

$$\|w_t - y - t(y-Py)\| = \Big\|\sum_{i=1}^{t}(x_i - Py)\Big\| = \Big\|\sum_{i=1}^{t} P_b(x_i - Py)\Big\| = \|P_b(w_t - y - t(y-Py)\|$$

and the sequence is bounded due to (a). Hence, the result follows.

Now let us assume that $U_F \oplus U_\delta \neq \{0\}$. We want to apply Lemma 9. Let $\tilde{\mathcal{H}} := U_F \oplus U_\delta$. $\tilde{\mathcal{H}}$ together with the inner product inherited from $\mathcal{H}$ is a Hilbert space. Let A be the operator defined for all $w \in \mathcal{H}$ through

$$x' \in \operatorname*{arg\,max}_{x \in S\backslash F} \langle x - Py, w\rangle \quad \text{and} \quad Aw = w + y - x'.$$

For any w for which there exist multiple maximizer assign to Aw one of these maximizer. Let B be defined in the same way with the only difference that $S\backslash F$ is replaced by $S \cap F$. We like to study the interaction between A and B on the subspace $U_F \oplus U_\delta$. The operator B optimizes over elements in $S \cap F$. For such elements $x \in S \cap F$ we know that $x - Py$ is orthogonal to $P_b w$ for all possible weights w and $P_b w$ does not influence the behavior of the operator B. Let $\tilde{B}$ be $(P_F + P_\delta)B$ restricted to $\tilde{\mathcal{H}}$ and let $K := U_F \subseteq \tilde{H}$. The operator $\tilde{B}$ fulfills the assumptions of the lemma:

- $\tilde{B}$ leaves the space orthogonal to K in $\tilde{H}$ unchanged and the maximization over $S \cap F$ does only depend on $P_F w$ for any $w \in \tilde{\mathcal{H}}$ so $\tilde{B}w = (I - P_F)w + P_F \tilde{B} P_F w$. This also holds (trivially) if $F_c = \{0\}$.
- Let $b := 2r$ then for $w \in \tilde{\mathcal{H}}$, $\|\tilde{B}w\| = \|(P_F + P_\delta)(w + (y - Py) - (x - Py))\| \leq \|w\| + \|x - Py\| \leq \|w\| + b$ where $x \in S \cap F$ and $(P_F + P_\delta)(y - Py) = 0$ by our choice of U_δ.
- If $F_c = \{0\}$ then point (iii) in Lemma 9 holds trivially. In all other cases let $a := 2r^2/\delta_F$, $\delta_F > 0$, then an argument as in (ii.e) tells us that if $\|P_F w\| \geq a$ for some $w \in \tilde{\mathcal{H}}$ then $\|\tilde{B}w\| \leq \|w\|$.

The operator A depends on $P_b w$ and we need to account for this error when studying the behavior of A acting on $U_F \oplus U_\delta$. We do so by working with a family of operators A which are parameterized by $P_b w$. Let

$$\mathfrak{A} = \{\tilde{A}_v : \tilde{\mathcal{H}} \to \tilde{\mathcal{H}} : \tilde{A}_v(w) = (P_F + P_\delta)A(w+v) \text{ for all } w \in \tilde{\mathcal{H}}, v \in U_b, \langle v, e\rangle \geq 0, \forall e \in E_b\}.$$

Observe that there is some time $t'' < \infty$ such that for all $t \geq t''$ no element in $S\backslash(F \cup D(\{x_t\}))$ is chosen and each element in $D(\{x_t\})$ has been chosen at least once. Write $U_b = U \oplus U'$ with $U' = \text{span } D(\{x_t\})$ and a suitable subspace U. Then $P_U w_t = P_U w_{\tilde{t}}$ for all $t \geq \tilde{t}$. Since each element in $D(\{x_t\})$ is chosen infinitely often and $\langle -P_b w_t, x - Py\rangle$ is non-decreasing for $x \in C$ there exists some element $t''' \geq t''$ such that for all $t \geq t'''$, $\langle P_U(x-Py), -P_b w_t\rangle \leq \langle x' - Py, -P_b w_t\rangle$ for all $x \in S\backslash D(\{x_t\})$ and $x' \in D(\{x_t\})$. Let $\tilde{t} < \infty$ be the maximum over all t' in Assumption 1 and t'''. The family of operators $\mathfrak{A}$ fulfills the assumptions of the lemma if Assumption 1 holds and if we use $x_{\tilde{t}}$ as the initial value.

- Given any $w \in \tilde{\mathcal{H}}$, $\tilde{A} \in \mathfrak{A}$ (with corresponding $v \in U_b$, $\langle v, e\rangle \geq 0$ for all $e \in E_b$), there exists a $x \in S\backslash F$ such that

$$\begin{aligned}\left\|\tilde{A}w\right\| &= \|(P_F + P_\delta)A(w+v)\| = \|(P_F + P_\delta)(w + v + (y - Py) - (x - Py))\| \\ &= \|w - (x - Py)\| \leq \|w\| + b.\end{aligned}$$

- If $D(\{x_t\}) = \emptyset$ then only elements in F are chosen after $\tilde{t}$ and the claim of the theorem follows by the arguments in (ii.e).

  In case that $D(\{x_t\}) \neq \emptyset$ consider the maximum over all Δ in Assumption 1 and call this maximum $\tilde{\Delta} < \infty$. We claim that there exists a constant $\Delta' < \infty$ such that with $\xi := 2\delta_m/\Delta'$ for all w_t, $t \geq \tilde{t}$, whenever $x_t \in S\backslash F$, then

$$\langle x_t - Py, (P_F + P_\delta)w_t\rangle \geq \|(P_F + P_\delta)w_t\|\, \delta_m/\Delta'$$

  where x_t is the element selected in the argmax step of A_v, $w_t = u + v, u \in U_F \oplus U_\delta, v \in U_b$. **P** ($\alpha$) Whenever $x_t \in S\backslash F, x_t \in D(\{x_t\})$, for some $t \geq \tilde{t}$ we know that $\langle P_b w_t, x_t - Py\rangle \neq 0$ because each element $x \in D(\{x_t\})$ has been chosen at least once and each element outside the minimal face lies partly in U_b. For any $x \in D(\{x_t\})$ we also have $\langle P_b w_t, x - Py\rangle \neq 0$ and at step $t \geq \tilde{t}$

$$\begin{aligned}&\langle x_t - Py, (P_\delta + P_F)w_t\rangle \geq \langle x - Py, (P_\delta + P_F)w_t\rangle - \langle (x-Py) - (x_t - Py), -P_b w_t\rangle \\ &\geq \langle x - Py, (P_F + P_\delta)w_t\rangle - \left(\frac{\langle x - Py, -P_b w_t\rangle}{\langle x_t - Py, -P_b w_t\rangle} - 1\right)\langle x_t - Py, -P_b w_t\rangle \\ &\geq \langle x - Py, (P_F + P_\delta)w_t\rangle - \left(\frac{\langle x - Py, -P_b w_t\rangle}{\langle x_t - Py, -P_b w_t\rangle} - 1\right)\langle x_t - Py, (P_F + P_\delta)w_t\rangle \\ &\geq \langle x - Py, (P_F + P_\delta)w_t\rangle - (\tilde{\Delta} - 1)\langle x_t - Py, (P_F + P_\delta)w_t\rangle\end{aligned}$$

  and

$$\langle x_t - Py, (P_\delta + P_F)w_t\rangle \geq \langle x - Py, (P_\delta + P_F)w_t\rangle / \tilde{\Delta}.$$

  (β) Consider a set of elements $z_1, \ldots, z_{\tilde{d}} \in D(\{x_t\})$ such that $z_1 - Py, \ldots z_{\tilde{d}} - Py$ are linearly independent and with $\dim U' = \tilde{d} \geq 1$. Apply the Gram-Schmidt method to transform these into an orthonormal basis $\tilde{z}_1, \ldots, \tilde{z}_{\tilde{d}}$ such that $\tilde{z}_i = \sum_{j=1}^{i} \beta_{ij}(z_j - Py)$ for some

scalars β_{ij}. Since the vectors are linearly independent we know that $\max_{i,j\leq d} \left|\beta_{ij}\right| < \infty$. For any $x \in S\backslash(F \cup D(\{x_t\}))$ if $P_b x \in U$ then, by the choice of $\tilde{t}$, for all $t \geq \tilde{t}$

$$\langle -P_b w_t, x - Py\rangle \leq \min_{x' \in D(\{x_t\})} \langle -P_b w_t, x' - Py\rangle.$$

If $P_b x \notin U$ then we can write $P_{U'}(x - Py) = \alpha_1 \tilde{z}_1, \ldots, \alpha_{\tilde{d}} \tilde{z}_{\tilde{d}}$ for suitable scalars $\alpha_1, \ldots, \alpha_{\tilde{d}}$. We claim that there exists a $\Delta_x < \infty$ such that

$$\langle -P_b w_t, P_{U'}(x - Py)\rangle \leq \Delta_x \max_{i \leq d} \langle -P_b w_t, z_i - Py\rangle$$

for all $t \geq \tilde{t}$. This holds since

$$\begin{aligned}\langle -P_b w_t, P_{U'}(x - Py)\rangle &\leq d \max_{i\leq d} |\alpha_i| \max_{i \leq d} \langle -P_b w_t, \tilde{z}_i\rangle \\ &\leq d^2 \max_{i\leq d} |\alpha_i| \max_{i,j\leq d} \left|\beta_{ij}\right| \max_{i\leq d} \langle -P_b w_t, z_i - Py\rangle\end{aligned}$$

and, using Parseval's identity, $|\alpha_i| \leq \|P_{U'}(x - Py)\| \leq 2r$. Hence, the claim follows with $\Delta_x = 2rd^2 \max_{i,j\leq d} \left|\beta_{ij}\right| < \infty$.

Furthermore, because for all $t \geq \tilde{t}$, $x \in S\backslash(F \cup D(\{x_t\}))$, $\langle P_U(x - Py), -P_b w_t\rangle \leq \min_{i\leq d}\langle z_i - Py, -P_b w_t\rangle$ by our choice of $\tilde{t}$ we can observe that for any $x \in S\backslash(F \cup D(\{x_t\}) =: M$

$$\begin{aligned}\langle -P_b w_t, x - Py\rangle &= \langle -P_b w_t, P_U(x - Py)\rangle + \langle -P_b w_t, P_{U'}(x - Py)\rangle \\ &\leq (\sup_{x\in M} \Delta_x + 1) \max_{i\leq d} \langle -P_b w_t, z_i - Py\rangle \\ &\leq \tilde{\Delta}(\sup_{x\in M} \Delta_x + 1)\langle -P_b w_t, x_t - Py\rangle.\end{aligned}$$

Repeating the argument in (α) this tells us that

$$\langle x_t - Py, (P_\delta + P_F)w_t\rangle \geq \langle x - Py, (P_\delta + P_F)w_t\rangle / (\tilde{\Delta}(\sup_{x\in M} \Delta_x + 1)).$$

(γ) The above argument also works for $x \in F$ without the need to adapt the multiplier $\Delta' := \tilde{\Delta}(\sup_{x\in M} \Delta_x + 1)$. Now, we know that there exists an element $x^* \in S$ such that

$$\langle x^* - Py, (P_F + P_\delta)w_t\rangle \geq \|(P_F + P_\delta)w_t\|\, \delta_m$$

and, hence,

$$\langle x_t - Py, (P_F + P_\delta)w_t\rangle \geq \langle x^* - Py, (P_F + P_\delta)w_t\rangle/\Delta' \geq \|(P_F + P_\delta)w_t\|\, \delta_m/\Delta'$$

which proves the claim. **Q**

Writing $u = w + v$, $w \in U_b \oplus U_\delta$, $v \in U_b$, this becomes $\langle x_t - Py, w\rangle \geq \|w\|\, \delta_m/\Delta'$ for all $t \geq \tilde{t}$. The usual argument gives us for the operator $\tilde{A}$ being used at time t that

$$\begin{aligned}\left\|\tilde{A}w\right\|^2 &= \left\|(P_F + P_\delta)(w + v + (y - Py) - (x' - Py))\right\|^2 \\ &= \|w\|^2 - 2\left\langle x' - Py, w\right\rangle + \left\|x' - Py\right\|^2 \\ &\leq \|w\|^2 - 2\|w\|\, \delta_m/\Delta' + b = \|w\|\,(\|w\| - 2\xi) + b.\end{aligned}$$

Hence, the lemma can be applied and the sequence of weights projected onto $U_F \oplus U_\delta$, i.e. $\{(P_F + P_\delta)w_t\}_{t\geq 0}$ is bounded in norm. Together with (a) this implies that the weight sequence stays bounded and the result follows. ◻

(v) The condition is also necessary for the fast rate of convergence. Observe that there always exists a decomposition $U_F \oplus U_\delta \oplus U_b$ of span C_c: let $U_F = \operatorname{span} F_c$. Let $\tilde{U}$ be the orthogonal complement of U_F in span C_c. If this is empty then we are done. Otherwise, chose an orthonormal basis $e_1, \ldots, e_k$ of $\tilde{U}, k = \dim \tilde{U}$ such that $e_1 = P_C(y - Py)/\|P_C(y - Py)\|$ if $P_C(y - Py) \neq 0$. Consider the set $E_b = \{e_i : i \leq k, P_{e_i}[C_c] \subset (-\infty, 0]$ or $P_{e_i}[C_c] \subset [0, \infty)\}$ and let $E_\delta = \{e_1, \ldots e_k\} \backslash E_b$. Then $U_b = \operatorname{span} E_b, U_\delta = \operatorname{span} E_\delta$ fulfill the assumptions. Since $P_\delta[C_c]$ is convex and we have an open interval around 0 in each direction $e \in E_\delta$ we have a ball around 0 in U_δ. Similarly, the assumption for U_b is fulfilled if we exchange $e \in E_b$ with $-e$ whenever $P_e[C_c] \subset [0, \infty)$.

If Assumption 1 is not fulfilled for this decomposition then there exists an element $x \in S \backslash F$ which is selected infinitely often by the algorithm. But, since $\|P_b(w_t - y - t(y - Py))\|$ is non-decreasing in t and because $x \in S \backslash F$ fulfills $\|P_b(x - Py)\| > 0$, we have $\|w_t - y - t(y - Py)\| \geq \|P_b(x - Py)\| \sum_{s=1}^{t} \chi\{x_s = x\}$ and the right side diverges in t. Therefore, we have an unbounded sequence $\{\|w_t - y - t(y - Py)\|\}_{t\geq 1}$. Observe that the algorithm does not converge with the rate $1/t$ if $\{\|w_t - y - t(y - Py)\|\}_{t\geq 1}$ is unbounded. ■

6.2 The Second Theorem

Theorem 3 *Given a compact convex set $C \subset \mathcal{H}$, a finite subset S of C with $\operatorname{ex} C \subseteq S$ and an element $y \in \mathcal{H}$ the following holds:*

- *If only elements in $F \cap S$, where $F \subset C$ is the minimal face that contains Py, are chosen then the method converges linearly to the projection and there exist constants $b, \beta > 0$ with*

$$\|Py - p_t\| \leq be^{-\beta t}.$$

- *Under Assumption 1 if $\min_{x\in S} \|Py - x\| > 0$ and the approximation does not equal Py in finite many steps then the sequence $\{\|(I - P_F)(Py - p_t)\|\}_{t\geq 0}$ converges sub-linearly and there exists a constant $d > 0$ such that*

$$\|P_F(Py - p_t)\|^2 \leq (1 - \delta_F^2/\operatorname{diam}^2(F))\, \|P_F(Py - p_{t-1})\|^2 + d\, \|(I - P_F)(Py - p_{t-1})\|^2 .$$

Furthermore, there exists a time t_0 after which only elements in $F \cap S$ are chosen.

Proof We aim for a similar argument as in the proof of the first theorem: (1) optimizing the approximation of Py by using y instead of Py does not hurt the rate of convergence. (2) This guarantees us that the rate of convergence is what we aim for if we work solely with the minimal face F that contains Py. Since, we do not know this minimal face we need to deal with perturbations that are introduced by elements in $S \backslash F$. These perturbations do slow down the rate of convergence. We adapt the proof from Beck and Teboulle (2004) to address (1). We make use of parts of the proof of Theorem 2 and we use Theorem 2 (ii.a) etc. to refer to it. In the following we will use p_t to denote the approximation at step t (with $p_0 = 0$), x_t as the element that is chosen by the algorithm and $w_t = y - p_t$.

(i) Let F be the minimal face which contains Py (Thm. 2 (ii.a)) and assume that either $C = F$ or only elements in F are chosen by the algorithm. (a) We claim that in this case $\tilde{\alpha}_t \in [0, 1]$ for all $t \geq 1$. ▶ In step 1 we have by definition that $\tilde{\alpha}_t = 1$. If C consists of a single element then $\tilde{\alpha}_t = 0/0$, which we define to be 0, for all $t \geq 2$. For the case that C consists of more than a single element and for any step $t \geq 2$ we have that

$$\tilde{\alpha}_t = \frac{\langle w_{t-1}, w_{t-1} + (x_t - y)\rangle}{\|w_{t-1} + x_t - y\|^2} = \frac{\langle y - p_{t-1}, x_t - p_{t-1}\rangle}{\|x_t - p_{t-1}\|^2} = \frac{\langle Py - p_{t-1}, x_t - p_{t-1}\rangle}{\|x_t - p_{t-1}\|^2}$$

where the last step holds because $x_t - p_{t-1}$ lies in the span of C_c and $y - Py$ stands orthogonal on span C_c (Thm. 2 (ii.c)), i.e. $\langle y - Py, x_t - p_{t-1}\rangle = 0$. We can also observe that

$$\langle Py - p_{t-1}, x_t - Py\rangle = \max_{x\in C} \langle Py - p_{t-1}, x - Py\rangle \geq \delta_F \|Py - p_{t-1}\| \geq 0 \tag{4}$$

holds: $y - Py$ stands orthogonal on span C_c and, hence,

$$\arg\max_{x\in S} \langle w_{t-1}, x\rangle = \arg\max_{x\in S} \langle Py - p_{t-1}, x\rangle \subseteq \arg\max_{x\in C} \langle Py - p_{t-1}, x\rangle .$$

Furthermore, $Py - p_{t-1}$ lies in the span of the centered minimal face, i.e. $Py - p_{t-1} \in F_c$, and Thm. 2 (ii.d) tells us that there exists a constant $\delta_F > 0$ which makes the above true. Following Beck and Teboulle (2004) we complete the square

$$\begin{aligned}\langle Py - p_{t-1}, Py - p_{t-1} - (Py - x_t)\rangle &\leq \|Py - p_{t-1}\|^2 - 2\langle Py - p_{t-1}, Py - x_t\rangle + \|Py - x_t\|^2 \\ &= \|p_{t-1} - x_t\|^2\end{aligned}$$

and observe that $\tilde{\alpha}_t \leq 1$. Hence, $\alpha_t = \tilde{\alpha}_t$. ◻

(b) If $F = C$ or only elements in F are chosen by the algorithm then for any $t \geq 2$ either $Py = p_t$ and for all $s \geq t$ we have $Py = p_s$ or $\|Py - p_t\|^2 \leq (1 - \delta_F^2/\operatorname{diam}^2(C))\, \|\tilde{w}_{t-1}\|^2$. Furthermore, there exist constants $b, \beta > 0$ such that $\|Py - p_t\| \leq be^{-\beta t}$. ▶ We aim at reproducing the argument from Beck and Teboulle (2004) by exploiting the orthogonality between $y - Py$ and span C_c. Let $\tilde{w}_t = Py - p_t = \tilde{w}_{t-1} - \alpha_t(x_t - Py + \tilde{w}_{t-1})$ and assume that $\tilde{w}_{t-1} \neq 0$. In short, if C consists of a single element then there is nothing to show and, otherwise, we have for $t \geq 2$ that $\alpha_t = \tilde{\alpha}_t$ and

$$\|\tilde{w}_t\|^2 = \|\tilde{w}_{t-1}\|^2 - 2\alpha_t \langle \tilde{w}_{t-1}, \tilde{w}_{t-1} + (x_t - Py)\rangle + \alpha_t^2 \|x_t - p_{t-1}\|^2 .$$

Observe that $\langle w_t, \tilde{w}_t\rangle = \langle y - p_t, Py - p_t\rangle = \|\tilde{w}_t\|^2$ because of the orthogonality and because $Py - p_t \in \operatorname{span} C_c$. This, together with the orthogonality between $y - Py$ and $x_t - Py$ yields

$$\langle w_{t-1}, w_{t-1} + (x_t - y)\rangle = \langle w_{t-1}, Py - p_{t-1} + x_t - Py\rangle = \langle \tilde{w}_{t-1}, \tilde{w}_{t-1} + x_t - Py\rangle .$$

Furthermore, $\|w_{t-1} + x_t - y\| = \|x_t - p_{t-1}\|$ and, hence,

$$\alpha_t = \frac{\langle \tilde{w}_{t-1}, \tilde{w}_{t-1} + (x_t - Py)\rangle}{\|x_t - p_{t-1}\|^2}.$$

By filling in this value of α_t we gain

$$\|\tilde{w}_t\|^2 = \|\tilde{w}_{t-1}\|^2 - 2\frac{|\langle \tilde{w}_{t-1}, \tilde{w}_{t-1} + x_t - Py\rangle|^2}{\|x_t - p_{t-1}\|^2} + \frac{|\langle \tilde{w}_{t-1}, \tilde{w}_{t-1} + x_t - Py\rangle|^2}{\|x_t - p_{t-1}\|^2}$$
$$= \frac{\|\tilde{w}_{t-1}\|^2 \|Py - x_t\|^2 - |\langle \tilde{w}_{t-1}, Py - x_t\rangle|^2}{\|x_t - p_{t-1}\|^2}.$$

Since $\arg\max_{x\in S} \langle w_{t-1}, x\rangle = \arg\max_{x\in S} \langle \tilde{w}_{t-1}, x\rangle$ we have that

$$\langle \tilde{w}_{t-1}, x_t - Py\rangle = \max_{x\in C} \langle \tilde{w}_{t-1}, x - Py\rangle \geq \delta_F \|\tilde{w}_{t-1}\|$$

and

$$\|\tilde{w}_{t-1}\|^2 \|Py - x_t\|^2 - |\langle \tilde{w}_{t-1}, Py - x_t\rangle|^2 \leq \|\tilde{w}_{t-1}\|^2 (\|Py - x_t\|^2 - \delta_F^2).$$

Eq. 4 tells us now that $\|x_t - Py + (Py - p_{t-1})\|^2 \geq \|x_t - Py\|^2$ and

$$\|\tilde{w}_t\|^2 \leq \frac{\|\tilde{w}_{t-1}\|^2 (\|x_t - Py\|^2 - \delta_F^2)}{\|x_t - Py\|^2} \leq (1 - \delta_F^2/\mathrm{diam}^2(C)) \|\tilde{w}_{t-1}\|^2.$$

This is the second part of our claim. The first part follows directly from the particular form that α_t attains. With $\tilde{w}_{t-1} = 0$ we have

$$\alpha_t = \frac{\langle \tilde{w}_{t-1}, \tilde{w}_{t-1} + (x_t - Py)\rangle}{\|x_t - p_{t-1}\|^2} = 0$$

and $\tilde{w}_t = \tilde{w}_{t-1} = 0$. Finally, both cases imply the fast rate of convergence: Let $\gamma = \delta_F^2/\mathrm{diam}^2(C) \in (0, 1)$ then in both cases $\|\tilde{w}_t\|^2 \leq (1 - \gamma)\|\tilde{w}_{t-1}\|^2$ for all $t \geq 2$ and Lemma A.1(ii) from Beck and Teboulle (2004) tells us that $\|\tilde{w}_t\|^2 \leq e^{-\gamma t}\|\tilde{w}_1\|^2$. But then with $\beta = \gamma/2$ we have $\|Py - p_t\| \leq e^{-\beta t}\|\tilde{w}_1\|$ and the result follows. ❶

(ii) We address now $F \neq C$. First, we can observe that in the general case either $\tilde{\alpha}_t \leq 1$ holds after at most finite many steps or there is one final step where $\tilde{\alpha}_t > 1$ and the approximation error becomes zero afterwards, i.e. there exists a time $t_0 < \infty$ such that $\tilde{\alpha}_t \leq 1$ for all $t \geq t_0$ or, if $\tilde{\alpha}_t > 1$ for some $t \geq t_0$, then for all $s > t$ we have that $p_s = Py$ and $\tilde{\alpha}_s \in [0, 1]$. t_0 depends here on y and S. ❶ We expand the argument of (i.a). In the case that S does not contain the element Py we can argue in the following way: If $\|y - Py\| > 0$ and $\|p_{t-1} - Py\| \leq (\|x_t - Py\|^2 - \langle p_{t-1} - Py, x_t - Py\rangle)/\|y - Py\|$ then

$$\langle y - p_{t-1}, x_t - p_{t-1}\rangle = \|y - p_{t-1}\|^2 + \langle y - p_{t-1}, x_t - y\rangle$$
$$= \|y - p_{t-1}\|^2 + \langle y - Py, x_t - y\rangle + \langle Py - p_{t-1}, Py - y\rangle + \langle Py - p_{t-1}, x_t - Py\rangle$$
$$= \|Py - p_{t-1}\|^2 - \langle p_{t-1} - Py, x_t - Py\rangle + \langle y - Py, Py - p_{t-1}\rangle + \langle y - Py, x_t - Py\rangle$$
$$\leq \|Py - p_{t-1}\|^2 - \langle p_{t-1} - Py, x_t - Py\rangle + \|y - Py\| \|p_{t-1} - Py\|$$
$$\leq \|x_t - p_{t-1}\|^2$$

and $\tilde{\alpha}_t \leq 1$. S consists of finite many elements and $\eta := \mathrm{dist}(S, Py) = \min_{x\in S} \|x - Py\| > 0$. Since $x_t \in S$ we know that $\|x_t - Py\| \geq \eta$. Furthermore,

$$\langle Py - p_{t-1}, x_t - Py\rangle = -\langle y - Py, x_t - Py\rangle + \langle y - p_{t-1}, x_t - Py\rangle \geq 0$$

because the first inner product is non-positive and the second term is non-negative (the same argument as in Theorem 2 (ii.e)). Hence,

$$\|x_t - Py\|^2 - \langle p_{t-1} - Py, x_t - Py\rangle \geq \eta^2 > 0.$$

Standard results for the CGM tell us that we have a constant $c > 0$ such that $\|p_t - y\|^2 - \|Py - y\|^2 \leq c/t$ and hence

$$\|p_t - Py\|^2 = \|p_t - y\|^2 + 2\langle p_t - y, y - Py\rangle + \|y - Py\|^2 \leq \|p_t - y\|^2 - \|y - Py\|^2 \leq c/t$$

where we used that

$$\langle p_t - y, y - Py\rangle = \langle p_t - Py, y - Py\rangle - \|y - Py\|^2 \leq -\|y - Py\|^2.$$

Hence, for all $t \in \mathbb{N}$ with $t \geq t_0$, where $t_0 = c\|y - Py\|^2/\eta^4$, we know that $\tilde{\alpha}_t \leq 1$. If $y = Py$ then the argument simplifies to

$$\langle y - p_{t-1}, x_t - p_{t-1}\rangle \leq \|Py - p_{t-1}\|^2 - \langle p_{t-1} - Py, x_t - Py\rangle \leq \|x_t - p_{t-1}\|^2.$$

The remaining case is the case where $Py \in S$. In fact, the only critical case is where $x_t = Py$. We can argue in the following way:

$$\tilde{\alpha}_t = \frac{\langle y - Py, Py - p_{t-1}\rangle + \langle Py - p_{t-1}, Py - p_{t-1}\rangle}{\|Py - p_{t-1}\|^2} \geq 1$$

and $\alpha_t = 1$. Hence, $p_t = Py$ and $x_{t+1} = \arg\max_{x\in S} \langle y - p_t, x\rangle = \arg\max_{x\in S} \langle y - Py, x - Py\rangle$. If $x_{t+1} = Py$ then $p_{t+1} = Py$ and $\tilde{\alpha}_{t+1} = 1$. Otherwise, x_{t+1} is an element of the minimal face. Hence, if $p_t = Py$ and $x_{t+1} \neq Py$ then

$$\tilde{\alpha}_{t+1} = \frac{\langle y - Py, x_{t+1} - p_t\rangle + \langle Py - p_t, x_{t+1} - p_t\rangle}{\|x_{t+1} - p_t\|^2} = 0 = \alpha_{t+1}$$

and $p_{t+1} = Py$. The same argument yields that $p_s = Py$ for all $s \geq t$ and $\tilde{\alpha}_s \in [0, 1]$. ❶

(iii) Consider now the split span $C_c = U_F \oplus U_\delta \oplus U_b$. We will use here the same notation δ_m, δ_F etc. as in Theorem 2.

(a) If Assumption 1 holds then there exists a $s_0 < \infty$ such that for all $t \geq s_0$ the algorithm chooses elements $x_t \in F$. ❶ Assumption 1 provides us with a time s_0 after which only elements in $D(\{x_t\}) \cup F$ are chosen. As in Theorem 2 (iv) we can observe that there exists a constant $c > 0$ such that for all $t \geq s_0$

$$\langle x_t - Py, (P_F + P_\delta)w_t\rangle \geq c\|(P_F + P_\delta)w_t\|.$$

$x_t \in S$ is here the element chosen at step t. Hence, the sequence $\{\|t(P_F + P_\delta)w_t\|\}_{t\geq 0}$ is bounded. Furthermore, because $0 \leq \langle x_t - Py, tw_t\rangle = \langle x_t - Py, t(P_F + P_\delta)w_t\rangle + \langle x_t - Py, tP_b w_t\rangle$ we can infer that

$$-\langle x_t - Py, tP_b w_t\rangle \leq \langle x_t - Py, t(P_F + P_\delta)w_t\rangle \leq \|x_t - Py\| \|t(P_F + P_\delta)w_t\|$$

and the sequence $\{-\langle x_t - Py, tP_b w_t\rangle\}_{t\geq 0}$ is bounded. But this implies that $x = x_t$ is either an element of F or it is selected only finitely often (and, hence, $x \notin D(\{x_t\})$). Therefore, $D(\{x_t\})$ is empty and the result follows. ❶

(b) There exists a constant $d > 0$ and a time u_0 after which for all $t \geq u_0$

$$\|P_F \tilde{w}_t\|^2 \leq \left(1 - \frac{\delta_F^2}{\operatorname{diam}^2(F)}\right) \|P_F \tilde{w}_{t-1}\|^2 + d \, \|(I - P_F)\tilde{w}_{t-1}\|^2 .$$

P Let us consider $t > t_0 \vee s_0$ with s_0 from (a) and t_0 from (ii). We know that only elements in F are chosen at t and hence

$$\begin{aligned}\|x_t - p_{t-1}\|^2 \tilde{\alpha}_t &= \langle w_{t-1}, \tilde{w}_{t-1} + x_t - Py\rangle = \langle \tilde{w}_{t-1}, \tilde{w}_{t-1} + x_t - Py\rangle + \langle y - Py, \tilde{w}_{t-1}\rangle \\ &= \langle P_F \tilde{w}_{t-1}, P_F \tilde{w}_{t-1} + x_t - Py\rangle + \|(I - P_F)\tilde{w}_{t-1}\|^2 + \langle y - Py, \tilde{w}_{t-1}\rangle .\end{aligned}$$

Also, $\tilde{\alpha}_t = \alpha_t$ and

$$\begin{aligned}\|P_F \tilde{w}_t\|^2 &= \|P_F \tilde{w}_{t-1}\|^2 - 2\alpha_t \langle P_F \tilde{w}_{t-1}, P_F \tilde{w}_{t-1} + x_t - Py\rangle + \alpha_t^2 \|x_t - P_F p_{t-1}\|^2 \\ &\leq \left(1 - \frac{\delta_F^2}{\operatorname{diam}^2(F)}\right) \|P_F \tilde{w}_{t-1}\|^2 + \frac{(\|(I - P_F)\tilde{w}_{t-1}\|^2 + \langle y - Py, \tilde{w}_{t-1}\rangle)^2}{\|x_t - p_{t-1}\|^2}.\end{aligned}$$

Now, since p_t converges to Py there exists a time $u_0 > t_0 \vee s_0$ after which $\|x_t - p_{t-1}\| \geq \|x_t - Py\|/2 \geq \min_{x \in S} \|x - Py\|/2$ and $\|(I - P_F)\tilde{w}_{t-1}\|^2 \leq \|(I - P_F)\tilde{w}_{t-1}\| \leq 1$. Hence, for all $t \geq u_0$ we have that

$$\|P_F \tilde{w}_t\|^2 \leq \left(1 - \frac{\delta_F^2}{\operatorname{diam}^2(F)}\right) \|P_F \tilde{w}_{t-1}\|^2 + \frac{4(1 + \|y - Py\|)}{\min_{x \in S} \|x - Py\|^2} \|(I - P_F)\tilde{w}_{t-1}\|^2 .$$

Choosing $d = 4(1 + \|y - Py\|)/(\min_{x \in S} \|x - Py\|^2)$ yields the result. **Q**

(c) If $\min_{x \in S} \|x - Py\| > 0$ and if $\|(I - P_F)\tilde{w}_{t_0 \vee s_0}\| > 0$ with s_0 from (a) and t_0 from (ii) then the sequence $\{\|(I - P_F)\tilde{w}_t\|\}_{t \geq 1}$ converges sub-linearly. **P** Let us consider $t \geq t_0 \vee s_0$. We know that only elements in F are chosen at t and that $\alpha_t = \tilde{\alpha}_t$. Therefore $\|(I - P_F)\tilde{w}_{t+1}\| = (1 - \alpha_{t+1}) \|(I - P_F)\tilde{w}_t\|$ and

$$\begin{aligned}\frac{\|(I - P_F)\tilde{w}_{t+1}\|}{\|(I - P_F)\tilde{w}_t\|} = 1 - \alpha_{t+1} &= \frac{\|x_{t+1} - Py + \tilde{w}_t\|^2 - \langle w_t, \tilde{w}_t + x_{t+1} - Py\rangle}{\|x_{t+1} - p_t\|^2} \\ &= \frac{\|x_{t+1} - Py\|^2 + \langle P_F \tilde{w}_t, x_{t+1} - Py\rangle - \langle y - Py, P_b \tilde{w}_t\rangle}{\|x_{t+1} - Py\|^2 + 2\langle x_{t+1} - Py, \tilde{w}_t\rangle + \|\tilde{w}_t\|^2}\end{aligned}$$

which converges to 1 since $\lim_{t \to \infty} \|\tilde{w}_t\| = 0$. This means that the sequence converges sub-linearly. **Q** ■

6.3 Corollaries

Corollary 4 *Given a compact convex set $C \subset \mathcal{H}$ and a finite subset S of C with $\operatorname{ex} C \subseteq S$. If for $y \in \mathcal{H}$ there exists a decomposition $U_F \oplus U_\delta \oplus U_b$ of $\operatorname{span} C_c$ such that U_b is one dimensional then Assumption 1 is fulfilled. In particular, in this case there exists a constant $b > 0$ such that Algorithm 1 has a worst-case approximation error of b/t for all $t \geq 1$.*

Proof Consider elements $x, x' \in S \backslash F$. Since $\|P_b(x - Py)\|, \|P_b(x' - Py)\| > 0$ we know that $\Delta = \|P_b(x - Py)\| / \|P_b(x' - Py)\| < \infty$ and since U_b is one-dimensional we have for any t

$$\langle -P_b w_t, x - Py\rangle = \|P_b w_t\| \, \|P_b(x - Py)\| \leq \Delta \, \|P_b w_t\| \, \|P_b(x' - Py)\| = \Delta \langle -P_b w_t, x' - Py\rangle$$

and Assumption 1 is fulfilled. ■

Let for the following corollary $A = \{z \in \mathcal{H} : z = \alpha P_C(y - Py) + P_C Py, \alpha \in [0, \infty)\}$.

Corollary 5 *Given a compact convex set $C \subset \mathcal{H}$ and a finite subset S of C with $\operatorname{ex} C \subseteq S$. Assumption 1 is fulfilled if $P_C y \in \mathcal{H} \backslash C$ and whenever $Pz = Py$ for some $z \in \mathcal{H}$ then $P_C z \in A$ holds. In particular, in this case there exists a constant $b > 0$ such that Algorithm 1 has a worst-case approximation error of b/t for all $t \geq 1$.*

Proof The assumption guarantees us that U_b is one-dimensional. Assume otherwise. By assumption $\|P_C(y - Py)\| > 0$ and we can chose E_b such that there exist two elements e_1, e_2 in E_b with $e_1 = P_C(y - Py)/\|P_C(y - Py)\|$ and $\langle e_1, e_2\rangle = 0, \|e_1\| = \|e_2\| = 1$. We claim that $z_1 = Py + e_1$ and $z_2 = Py + e_2$ are both projected onto Py, i.e. $Pz_1 = Py = Pz_2$: We know that $P_{e_1}[C_c] \subset (-\infty, 0]$ and $\langle e_1, x - Py\rangle \leq 0$ for all $x \in C$. Hence, for all $x \in C$ we know that $\langle z_1 - Py, x - Py\rangle = \langle e_1, x - Py\rangle \leq 0$. But, this means that $Pz_1 = Py$. The same argument applies to z_2 and Py is the projection of two elements for which $\langle z_1 - Py, z_2 - Py\rangle = 0$. Furthermore, $P_C z_1 = P_C Py + e_1$ and $P_C z_2 = P_C Py + e_2$. If $P_C z_2 \in A$ then there exist $\alpha, \tilde{\alpha} > 0$,

$$e_2 + P_C Py = P_C z_2 = \alpha P_C(y - Py) + P_C Py = \tilde{\alpha} e_1 + P_C Py$$

and $e_2 = \tilde{\alpha} e_1$ with a contradiction to orthogonality. ■

For the next corollaries let $d = \dim U_b$, let $e_1, \ldots, e_d$ be any basis of U_b and let $r = \sup_{x \in C} \|x\|$. Also introduce $\alpha = \min_{i \leq d} \min\{|\langle e_i, x - Py\rangle| : x \in S \backslash F, \langle e_i, x - Py\rangle \neq 0\} > 0$.

Corollary 6 *Let C be a compact convex set in some Hilbert space $\mathcal{H}$, S a finite set with $\operatorname{cch} S = C$, and $y \in \mathcal{H}$ such that there exists a split into $U_F \oplus U_\delta \oplus U_b$ of $\operatorname{span} C_c$ with $U_\delta = \{0\}$. Assumption 1 is fulfilled and there exists a constant $b > 0$ such that Algorithm 1 has a worst-case approximation error of b/t for all $t \geq 1$. The constant b can be chosen as $\sqrt{d}\, 4r^3/(\alpha\delta_F) + 6r^2(1/\delta_F + 1/\alpha) + 5r$.*

Proof If $F_c = \{0\}$ then each element $x \in S \backslash F$ can only be chosen once since $0 > \langle w_t, x - Py\rangle = \langle P_b w_t, x - Py\rangle$ if x has been chosen at least once. This implies that $D(\{x_t\})$ is, in fact, the empty set and Assumption 1 is fulfilled. It is also easy to see that $\langle w_t, e_i\rangle \leq \|x - Py\| \leq 2r$ for all $i \leq d$. This implies that the constant b can in this case be chosen as $2r\sqrt{d}$. Also, since δ_F and α are upper bounded by r this implies that $b \leq 2r^3\sqrt{d}/(\alpha\delta_F)$.

Assume now that $F_c \neq \{0\}$ and that there exists a $x \in D(\{x_t\})$. By definition $x \in S \backslash F$ and x is chosen infinitely often. Hence, $\{\langle P_b w_t, x - Py\rangle\}_{t \geq 1}$ is a non-increasing sequence that diverges to $-\infty$. There exists a $\delta_F > 0$ such that for any w_t, $\max_{x' \in S \cap F} \langle w_t, x' - Py\rangle \geq \delta_F \|P_F w_t\|$. Also, for any $x' \in S$, we have that $\langle w_t, x' - Py\rangle = \langle P_F w_t, x' - Py\rangle + \langle P_b w_t, x' - Py\rangle$ and, since the term $\langle P_b w_t, x' - Py\rangle$ is always non-positive, we know that if $P_F w_t \neq 0$ elements will be chosen such that $\langle P_F w_t, x' - Py\rangle \geq \delta_F \|P_F w_t\|$. Hence, whenever $\|P_F w_t\| \geq 2r^2/\delta_F$ for some t then $\|P_F w_{t+1}\| \leq \|P_F w_t\|$. This implies that $\|P_F w_t\| \leq 2r^2/\delta_F + 3r$ for all $t \geq 1$. Hence, for x to be chosen infinitely often we need for all time steps t where x is chosen that

$$0 \leq \langle w_t, x - Py\rangle \leq \langle P_F w_t, x - Py\rangle + \langle P_b w_t, x - Py\rangle \leq 2r(2r^2/\delta_F + 3r) + \langle P_b w_t, x - Py\rangle$$

since $\|x - Py\| \leq 2r$. Therefore, $-\langle P_b w_t, x - Py\rangle \leq r(4r^2/\delta_F + 6r)$ and $\{\langle P_b w_t, x - Py\rangle\}_{t\geq 1}$ cannot diverge to $-\infty$. In other words, x cannot be chosen infinitely often with a contradiction to the initial assumption. We can also control the constant in this case: $\|P_b w_t\|$ can only grow if either $P_F w_t = 0$ or there is an $x' \in S\backslash F$ such that $-\langle P_b w_t, x' - Py\rangle \leq r(4r^2/\delta_F + 6r)$. Then for w_t if for any $i \leq d$

$$\alpha \langle w_t, e_i\rangle > r(4r^2/\delta_F + 6r)$$

then no $x \in S\backslash F$ with $\langle e_i, x - Py\rangle \neq 0$ can be played since for such a x

$$-\langle P_b w_t, x - Py\rangle \geq \langle e_i, x - Py\rangle \langle e_i, w_t\rangle > r(4r^2/\delta_F + 6r).$$

Hence, $\langle e_i, w_t\rangle \leq r(4r^2/\delta_F + 6r)/\alpha + 2r$ since the increment of w_t in one step is bounded by $2r$. Since this holds for each $i \leq d$ we gain the bound $\|P_b w_t\| \leq \sqrt{d}4r^3/(\delta_F\alpha) + 6r^2/\alpha + 2r$ and

$$\|w_t\| \leq \|P_F w_t\| + \|P_b w_t\| \leq \sqrt{d}4r^3/(\delta_F\alpha) + 6r^2(1/\delta_F + 1/\alpha) + 5r.$$

■

Corollary 7 *Let $y \in \mathbb{R}^d$, Q any orthogonal matrix, $c > 0$ any scaling, $z \in \mathbb{R}^d$, $S = \{0,1\}^d$ and $C = [0,1]^d$, $d \geq 1$. Assumption 1 is fulfilled for the set $\tilde{S} = cQ[S + z]$ and $\tilde{C} = cQ[C + z]$ (independently of the dimensionality of the face Py lies in). In particular, there exists a constant $b > 0$ such that Algorithm 1 has a worst-case approximation error of b/t for all $t \geq 1$. The constant b can be chosen as $\sqrt{d}4r^3/(c\delta_F) + 6r^2(1/\delta_F + 1/c) + 5r$.*

Proof Because the algorithm does not change by translating and rotating S and C we can consider a hypercube anchored at the origin and aligned with the standard basis of $\mathbb{R}^d$. We therefore assume without loss of generality that we have to deal with a scaled standard hypercube in $\mathbb{R}^d$. Let us assume in the following that $\dim U_F = k \leq d$.

Observe that either $U_F = \{0\}$ or we can write $U_F = \text{span}\{e_{i_1}, \ldots, e_{i_k}\}$, where $e_1, \ldots, e_d$ is the standard basis in $\mathbb{R}^d$, $i_j \leq d$ for all $j \leq k$, and $k = \dim U_F$. This holds because a k-dimensional face of the hypercube is a translated k-dimensional hypercube in a subspace spanned by some basis vectors $e_{i_1}, \ldots, e_{i_k}$. Define the following index sets $\mathcal{I} = \{i_1, \ldots, i_k\}$, $\mathcal{I} = \emptyset$ if $U_F = \{0\}$, and $\mathcal{J} = \{1, \ldots, d\}\backslash\mathcal{I}$.

There are signs $s_j \in \{-1, 1\}$, $j \in \mathcal{J}$, such that $E_b = \{s_j e_j : j \in \mathcal{J}\}$ is a basis for U_b, and the split into $U_F \oplus U_\delta \oplus U_b$ is satisfying the conditions of Assumption 1. In particular, $U_\delta = \{0\}$, $P_C(y - Py) \in U_b$ and for all $e \in E_b$ we have $\{\langle x, e\rangle : x \in C_c\} \subset (-\infty, 0]$. ▶ $U_\delta = \{0\}$ because the minimal faces which are orthogonally projected onto a face that contains a ball around Py (relative to the projection) are translated versions of the minimal face and they induce the same subspace as the minimal face. That also implies directly that E_b can be chosen to fulfill Assumption 1. $P_C(y - Py)$ stands orthogonal on U_F and, hence, lies fully in U_b. Therefore, Corollary 6 applies. Observe that α can here be chosen as the scaling factor c and the corollary provides the stated result since $\dim U_b \leq d$. ■

Corollary 8 *Let $y \in \mathbb{R}^d$, $S = \{e_i : i \leq d\}$ and $C = \Delta^{d-1} = \text{cch}\, S$, $d \geq 1$. Assumption 1 is fulfilled and there exists a constant $b > 0$ such that Algorithm 1 has a worst-case approximation error of b/t for all $t \geq 1$. The constant b can be chosen as $4dr^3/\delta_F + 6r^2(1/\delta_F + \sqrt{d}) + 5r$.*

Proof Due to the rotation invariance it suffices to consider the case where $F = \text{cch}\{e_1, \ldots, e_k\}$ for some $k \leq d$. Let us consider first the case where $F = \{e_1\}$ and, hence, $F_c = \{0\}$. In this case, $C_c = \text{cch}\{0, e_2 - e_1, \ldots, e_d - e_1\}$. Observe that $\langle x + e_1, e_j\rangle \geq 0$ for any $x \in C_c$ and all $j \leq d$ since $x + e_1 \in C$ and, hence, $x + e_1 = \sum_{i\leq d} \alpha_i e_i$ for some non-negative α_i. In particular, for $j \geq 2$, $\langle x, e_j\rangle \geq 0$ for all $x \in C_c$. Furthermore, $\langle x, e_1\rangle \leq 0$ for all $x \in C_c$ because $x + e_1 = \sum_{i\leq d} \alpha_i e_i$ with non-negative scalars that fulfill $\sum_{i\leq d} \alpha_i = 1$. I.e. $\langle x, e_1\rangle = \langle x + e_1, e_1\rangle - 1 \leq \|e_1\|^2 - 1 = 0$. Therefore, we have an orthonormal basis $\{-e_1, e_2, \ldots, e_d\}$, of $\mathbb{R}^d$ such that $\langle x, e\rangle \geq 0$ for all basis elements e and all $x \in C_c$. This implies that there exists no basis element $\tilde{e} \in \mathbb{R}^d$ such that there exists elements $x, x' \in C_c$ with $\langle x, \tilde{e}\rangle > 0 > \langle x', \tilde{e}\rangle$ and, hence, $\{-e_1, e_2, \ldots, e_d\}$ spans the d-dimensional space U_b and $U_\delta = \{0\}$. The rate of convergence follows now from Corollary 6.

Let us consider the case $F = \text{cch}\{e_1, \ldots, e_k\}$ and $k \geq 2$. For any e_j, $j > k$, and any $x \in C_c$, $\langle x + Py, e_j\rangle \geq 0$ since $x + Py = \sum_{i\leq d} \alpha_i e_i$ for some non-negative α_i. But this implies $\langle x, e_j\rangle = \langle x + Py, e_j\rangle \geq 0$ because Py is a convex combination of $e_1, \ldots, e_k$. Also $e_{k+1}, \ldots, e_d \in F_c^\perp$ because span $F_c = \text{span}\{e_2 - e_1, \ldots, e_k - e_1\}$ and $\langle e_i - e_1, e_j\rangle = 0$ for any $i \leq k, j > k$. Finally, consider $e = \sum_{j=1}^k e_j/\sqrt{k}$, $\|e\| = 1$, and observe that $\langle e, e_i\rangle = 0$ for all $i > k$. Also, $\langle e, e_i - e_1\rangle = 0$ for $i \leq k$. This implies that e stands orthogonal on F_c because for $v \in \text{span}\, F_c$, $v = \sum_{i=2}^k \alpha_i(e_i - e_1), \alpha_i \in \mathbb{R}$, we have that $\langle e, v\rangle = \sum_{i=2}^k \alpha_i\langle e_i - e_1, e_i + e_1\rangle = 0$. Furthermore, for any $x \in C_c$, $x = \sum_{i=1}^d \alpha_i e_i - Py$, $\sum_{i=1}^d \alpha_i = 1$,

$$\langle e, x\rangle = \sum_{i=1}^d \alpha_i \langle e, e_i - Py\rangle = \sum_{i=1}^d \alpha_i \langle e, e_i - e_1\rangle - \langle e, Py - e_1\rangle = 0.$$

Hence, we have $d + 1 - k$ orthonormal vectors $e_{k+1}, \ldots, e_d, e$ that lie in the orthogonal complement of F_c and for any $x \in C_c$, $\langle x, e_i\rangle \geq 0$, $\langle x, e\rangle \geq 0$, for all $k + 1 \leq i \leq d$. Hence, $U_\delta = \{0\}$ and the result on the rate of convergence follows from Corollary 6.

The constant also follows directly from the corollary: in case that $F_c = \{0\}$ we have that $S\backslash F = \{e_2, \ldots, e_d\}$, the basis of U_b is $\{-e_1, e_2, \ldots, e_d\}$ and $Py = e_1$. α can be lower bounded by $1 : \langle -e_1, x - Py\rangle = 1$ for any $x \in S\backslash F$; $\langle e_i, e_j - Py\rangle$ attains value 1 if $i = j \geq 2$ and value 0 if $i \neq j, i, j \geq 2$.

Otherwise, $S\backslash F = \{e_{k+1}, \ldots, e_d\}$, the basis of U_b is $\{e_{k+1}, \ldots, e_d, \sum_{i=1}^k e_i/\sqrt{k}\}$ and $Py = \sum_{i=1}^k \alpha_i e_i$ for some $\alpha_i \geq 0, \sum_{i=1}^k \alpha_i = 1$. Hence, $\langle e_i, e_j - Py\rangle = 0$ if $i \neq j, i, j > k$; $\langle e_i, e_i - Py\rangle = 1$ if $i > k$; $\langle \sum_{i=1}^k e_i/\sqrt{k}, e_j - Py\rangle = 1/\sqrt{k}$, where $j \geq k$. Hence, $\alpha \geq 1/\sqrt{d}$ and the result follows. ■

Abstract

We present a graphical criterion for covariate adjustment that is sound and complete for four different classes of causal graphical models: directed acyclic graphs (DAGs), maximal ancestral graphs (MAGs), completed partially directed acyclic graphs (CPDAGs), and partial ancestral graphs (PAGs). Our criterion unifies covariate adjustment for a large set of graph classes. Moreover, we define an explicit set that satisfies our criterion, if there is any set that satisfies our criterion. We also give efficient algorithms for constructing all sets that fulfill our criterion, implemented in the `R` package `dagitty`. Finally, we discuss the relationship between our criterion and other criteria for adjustment, and we provide new soundness and completeness proofs for the adjustment criterion for DAGs.

Keywords: causal effects, graphical models, covariate adjustment, latent variables, confounding

1. Introduction

Covariate adjustment is a well-known method to estimate causal effects from observational data. There are, however, still common misconceptions about what variables one should or should not adjust for. For example, it is sometimes thought that adjusting for more variables will lead to a more precise estimate, as long as the added variables are not affected by the exposure variable. While this is true for a randomized exposure, in observational data even adjustment for pre-exposure variables may lead to so-called collider bias as described in the "M-bias graph" (Shrier, 2008; Rubin, 2008). Another example is the "Table 2 fallacy" (Westreich and Greenland, 2013). In observational research papers, Table 1 often describes the data, and Table 2 shows a multiple regression analysis. By presenting all estimated coefficients in one table, it is implicitly suggested that all estimates can be interpreted similarly. This is usually not the case: some coefficients may be interpreted as a total causal effect, some may be interpreted as a direct causal effect, and some do not have any causal interpretation at all.

Table 1: Graphical criteria for covariate adjustment: $\Rightarrow$ - sound, $\Leftrightarrow$ - sound and complete.

The practical importance of covariate adjustment has inspired a growing body of theoretical work on graphical criteria for adjustment. Pearl's back-door criterion (Pearl, 1993) is probably the most well-known, and is sound but not complete for adjustment in DAGs. Shpitser et al. (2010) and Shpitser (2012) refined the back-door criterion to a sound and complete graphical criterion for adjustment in DAGs. Others considered more general graph classes, which can represent structural uncertainty. Van der Zander et al. (2014, 2018) gave sound and complete graphical criteria for MAGs that allow for unobserved variables (latent confounding). Maathuis and Colombo (2015) presented a generalized back-door criterion for DAGs, CPDAGs, MAGs and PAGs, where CPDAGs and PAGs represent Markov equivalence classes of DAGs or MAGs, respectively, and can be inferred directly from data (see, for example, Spirtes et al., 2000; Chickering, 2002; Colombo et al., 2012; Claassen et al., 2013; Colombo and Maathuis, 2014; Nandy et al., 2018; Frot et al., 2018; Heinze-Deml et al., 2017). The generalized back-door criterion is sound but not complete for adjustment. Another line of work explores data driven covariate adjustment that does not require knowing the graph (VanderWeele and Shpitser, 2011; De Luna et al., 2011; Entner et al., 2013). Some of these data driven results are sound and complete for adjustment, but they all rely on some additional assumptions. We will not explore this direction in our paper.

In Perković et al. (2015), the preliminary conference version of the present paper, we extended the results of Shpitser et al. (2010); Shpitser (2012), van der Zander et al. (2014) and Maathuis and Colombo (2015) to derive a single sound and complete adjustment criterion for DAGs, CPDAGs, MAGs and PAGs. The different adjustment criteria are summarized in Table 1. Additionally, we note that van der Zander and Liśkiewicz (2016) showed that the generalized adjustment criterion can also be applied to the more general class of restricted chain graphs (representing a subset of a Markov equivalence class of DAGs). Furthermore, in Perković et al. (2017), we extend the generalized adjustment criterion to maximally oriented partially directed acyclic graphs (PDAGs), which represent CPDAGs with added background knowledge.

To illustrate the use of our generalized adjustment criterion, suppose we are given the CPDAG in Figure 1a and we want to estimate the total causal effect of X on Y. Our

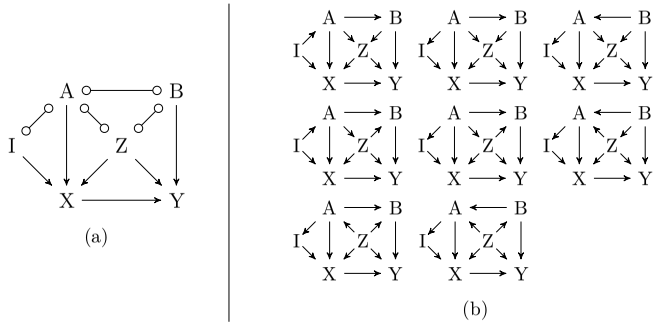

Figure 1: (a) A CPDAG in which, according to our criterion, $\{A, Z\}$ is an adjustment set for the total causal effect of X on Y. (b) The Markov equivalence class of DAGs represented by the CPDAG. An adjustment set for a CPDAG (PAG) is one that is valid for all DAGs (MAGs) in the Markov equivalence class.

criterion will inform us that the set $\{A, Z\}$ is an adjustment set for this CPDAG, meaning that it is an adjustment set in every DAG that the CPDAG represents (Figure 1b). Hence, we can estimate the causal effect without knowledge of the full causal structure. In a similar manner, by applying our criterion to a MAG or a PAG, we find adjustment sets that are valid for all DAGs represented by this MAG or PAG. Our criterion finds such adjustment sets whenever they exist; else, the causal effect is not identifiable by covariate adjustment. We hope that this ability to allow for incomplete structural knowledge, latent confounding, or both will help address concerns that graphical causal modelling "assumes that all [...] DAGs have been properly specified" (West and Koch, 2014). Moreover, our criterion for CPDAGs and PAGs can be combined with causal structure learning algorithms.

In the current paper, we give full proofs of the results in Perković et al. (2015). In addition, we provide several new results that allow us to construct sets $\mathbf{Z}$ that fulfill the generalized adjustment criterion for given sets $\mathbf{X}$ of exposures and $\mathbf{Y}$ of response variables in a DAG, CPDAG, MAG or PAG $\mathcal{G}$. In Corollary 15 we define a specific set that satisfies our criterion, if any set does. We refer to this set as a "constructive set". In Theorem 7, we show how one can express adjustment sets in terms of m-separating sets in a certain subgraph of $\mathcal{G}$. This theorem reduces the problem of finding adjustment sets to the problem of finding m-separating sets, which has been studied in detail by van der Zander et al. (2014). In Lemma 10, we prove that all adjustment sets for a CPDAG (PAG) $\mathcal{G}$ can be found in an arbitrary orientation of $\mathcal{G}$ into a valid DAG (MAG). This allows us to leverage existing implementations (van der Zander et al., 2014). We implemented the criterion itself and the construction of all adjustment sets in the software `dagitty` (Textor et al., 2016), available as a web-based GUI and an R package, and in the R package `pcalg` (Kalisch et al., 2012).

Furthermore, we explore the relationships between our generalized adjustment criterion and the previously suggested generalized back-door criterion and Pearl's back-door criterion. For both Pearl's back-door criterion and the generalized back-door criterion, a constructive

set was given only in the case when the number of exposures is limited to one ($|\mathbf{X}| = 1$). We give constructive sets for each of these criteria for general $\mathbf{X}$ in Corollary 22 and Corollary 24. Moreover, in Theorem 26 we identify cases in which there exist sets satisfying two, or all three of these criteria, as well as cases in which there are only sets satisfying the generalized adjustment criterion.

Another important contribution, included in the appendix, are new soundness and completeness proofs of the adjustment criterion for DAGs as defined in Shpitser et al. (2010) and in the unpublished addendum Shpitser (2012), where the adjustment criterion in Shpitser (2012) is a revised version of the criterion in Shpitser et al. (2010) (see Definition 55 in Appendix E). Since there are no published soundness and completeness proofs for the revised criterion and since we build on this work, we felt it was important to provide these proofs. The proofs are non-trivial, but rely only on elementary concepts.

We note that, although we can find all causal effects that are identifiable by covariate adjustment, we generally do not find all identifiable causal effects, since some effects may be identifiable only by other means, using for example IDA approaches (Maathuis et al., 2009, 2010; Nandy et al., 2017; Malinsky and Spirtes, 2017), Pearl's front-door criterion (Pearl, 2009, Section 3.3.2) or the ID algorithm (Tian and Pearl, 2002; Shpitser and Pearl, 2006).

We also point out that MAGs and PAGs are in principle not only able to represent unobserved confounding, but can also account for unobserved selection variables. In this paper, however, we assume that there are no unobserved selection variables, since selection bias often rules out causal effect identification using just covariate adjustment. Bareinboim et al. (2014) discuss these problems and present creative approaches to work around them, for example by combining data from different sources. The question whether our adjustment criterion could be combined with such auxiliary methods is left for future research.

2. Preliminaries

Throughout the paper we denote sets in bold (for example $\mathbf{X}$), graphs in calligraphic font (for example $\mathcal{G}$) and nodes in a graph in uppercase letters (for example X). All omitted proofs are given in the appendix.

Nodes and edges. A graph $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ consists of a set of nodes (variables) $\mathbf{V} = \{X_1, \ldots, X_p\}$ and a set of edges $\mathbf{E}$. We consider simple graphs, meaning that there is at most one edge between any pair of nodes. Two nodes are called *adjacent* if they are connected by an edge. Every edge has two edge marks that can be arrowheads, tails or circles. Edges can be *directed* $\rightarrow$, *bi-directed* $\leftrightarrow$, *non-directed* $\circ\!\!-\!\!\circ$, or *partially directed* $\circ\!\!\rightarrow$. We use $\bullet$ as a stand in for any of the allowed edge marks. An edge is *into* (*out of*) a node X if the edge has an arrowhead (tail) at X. A *directed graph* contains only directed edges. A *mixed graph* may contain directed and bi-directed edges. A *partial mixed graph* may contain any of the described edges. Unless stated otherwise, definitions apply to partial mixed graphs.

Paths. A *path* p from X to Y in $\mathcal{G}$ is a sequence of distinct nodes $\langle X, \ldots, Y \rangle$ in which every pair of successive nodes is adjacent in $\mathcal{G}$. If $p = \langle X_1, X_2, \ldots, X_k, \rangle, k \geq 2$, then with $-p$ we denote the path $\langle X_k, \ldots, X_2, X_1 \rangle$. A node V *lies on a path* p if V occurs in the sequence of nodes. If $p = \langle X_1, X_2, \ldots, X_k, \rangle, k \geq 2$, then X_1 and X_k are *endpoints* of p, and any other node $X_i, 1 < i < k$, is a *non-endpoint* node on p. The *length* of a path equals the number of edges on the path. A *directed path* from X to Y is a path from X to Y in which

all edges are directed towards Y, that is, $X \to \cdots \to Y$. We also refer to this as a *causal path*. A *possibly directed path* or *possibly causal path* from X to Y is a path from X to Y that does not contain an arrowhead pointing in the direction of X. A path from X to Y that is not possibly causal is called a *non-causal path* from X to Y. A directed path from X to Y together with $Y \to X$ forms a *directed cycle*. A directed path from X to Y together with $Y \leftrightarrow X$ forms an *almost directed cycle*. For two disjoint subsets $\mathbf{X}$ and $\mathbf{Y}$ of $\mathbf{V}$, a path from $\mathbf{X}$ to $\mathbf{Y}$ is a path from some $X \in \mathbf{X}$ to some $Y \in \mathbf{Y}$. A path from $\mathbf{X}$ to $\mathbf{Y}$ is *proper* (wrt $\mathbf{X}$) if only its first node is in $\mathbf{X}$. If $\mathcal{G}$ and $\mathcal{G}^*$ are two graphs with identical adjacencies and p is a path in $\mathcal{G}$, then the *corresponding path* p^* is the path in $\mathcal{G}^*$ constituted by the same sequence of nodes as p.

Subsequences, subpaths and concatenation. A *subsequence* of a path p is a sequence of nodes obtained by deleting some nodes from p without changing the order of the remaining nodes. A subsequence of a path is not necessarily a path. For a path $p = \langle X_1, X_2, \ldots, X_m \rangle$, the *subpath* from X_i to X_k $(1 \leq i \leq k \leq m)$ is the path $p(X_i, X_k) = \langle X_i, X_{i+1}, \ldots, X_k \rangle$. We denote the concatenation of paths by $\oplus$, so that for example $p = p(X_1, X_k) \oplus p(X_k, X_m)$. In this paper, we only concatenate paths if the result of the concatenation is again a path.

Ancestral relationships. If $X \to Y$, then X is a *parent* of Y. If there is a directed (possibly directed) path from X to Y, then X is a *ancestor* (*possible ancestor*) of Y, and Y is a *descendant* (*possible descendant*) of X. We also use the convention that every node is a descendant, possible descendant, ancestor and possible ancestor of itself. The sets of parents, descendants and ancestors of X in $\mathcal{G}$ are denoted by $\mathrm{Pa}(X, \mathcal{G})$, $\mathrm{De}(X, \mathcal{G})$ and $\mathrm{An}(X, \mathcal{G})$ respectively. The sets of possible descendants and possible ancestors of X in $\mathcal{G}$ are denoted by $\mathrm{PossDe}(X, \mathcal{G})$ and $\mathrm{PossAn}(X, \mathcal{G})$ respectively. For a set of nodes $\mathbf{X} \subseteq \mathbf{V}$, we let $\mathrm{Pa}(\mathbf{X}, \mathcal{G}) = \cup_{X \in \mathbf{X}} \mathrm{Pa}(X, \mathcal{G})$, with analogous definitions for $\mathrm{De}(\mathbf{X}, \mathcal{G})$, $\mathrm{An}(\mathbf{X}, \mathcal{G})$, $\mathrm{PossDe}(\mathbf{X}, \mathcal{G})$ and $\mathrm{PossAn}(\mathbf{X}, \mathcal{G})$.

Colliders, shields and definite status paths. If a path p contains $X_i \bullet\!\!\to X_j \leftarrow\!\!\bullet X_k$ as a subpath, then X_j is a *collider* on p. A *collider path* is a path on which every non-endpoint node is a collider. A path of length one is a trivial collider path. A path $\langle X_i, X_j, X_k \rangle$ is an *(un)shielded triple* if X_i and X_k are (not) adjacent. A path is *unshielded* if all successive triples on the path are unshielded. A node X_j is a *definite non-collider* (Zhang, 2008a) on a path p if there is at least one edge out of X_j on p, or if $X_i \bullet\!\!-\!\!\circ X_j \circ\!\!-\!\!\bullet X_k$ is a subpath of p and $\langle X_i, X_j, X_k \rangle$ is an unshielded triple. Any collider on a path is always of definite status and hence, a *definite collider*. In a DAG (MAG) we refer to definite non-colliders as *non-colliders*. A node is of *definite status* on a path if it is a collider or a definite non-collider on the path. A path p is of definite status if every non-endpoint node on p is of definite status.

m-separation and m-connection. A definite status path p between nodes X and Y is *m-connecting* given a set of nodes $\mathbf{Z}$ $(X, Y \notin \mathbf{Z})$ if every definite non-collider on p is not in $\mathbf{Z}$, and every collider on p has a descendant in $\mathbf{Z}$ (Richardson, 2003). Otherwise $\mathbf{Z}$ blocks p. If $\mathcal{G}$ is a DAG or MAG (defined later) and if $\mathbf{Z}$ blocks all paths between X and Y, we say that X and Y are m-separated given $\mathbf{Z}$ in $\mathcal{G}$. Otherwise, X and Y are m-connected given $\mathbf{Z}$ in $\mathcal{G}$. For pairwise disjoint subsets $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ of $\mathbf{V}$ in $\mathcal{G}$, we say that $\mathbf{X}$ and $\mathbf{Y}$ are m-separated given $\mathbf{Z}$ in $\mathcal{G}$ if X and Y are m-separated given $\mathbf{Z}$ in $\mathcal{G}$ for any $X \in \mathbf{X}$ and

$Y \in \mathbf{Y}$. Otherwise, $\mathbf{X}$ and $\mathbf{Y}$ are m-connected given $\mathbf{Z}$ in $\mathcal{G}$. In a DAG, m-separation and m-connection simplify to d-separation and d-connection (Pearl, 2009).

Causal Bayesian networks. A directed graph without directed cycles is a *directed acyclic graph* (DAG). A Bayesian network for a set of variables $\mathbf{V} = \{X_1, \ldots, X_p\}$ is a pair $(\mathcal{G}, f)$, where $\mathcal{G}$ is a DAG, and f is a joint density for $\mathbf{V}$ that factorizes as $f(\mathbf{V}) = \prod_{i=1}^{p} f(X_i | \mathrm{Pa}(X_i, \mathcal{G}))$ (Pearl, 2009). We call a DAG *causal* if every edge $X_i \to X_j$ in $\mathcal{G}$ represents a direct causal effect of X_i on X_j. A Bayesian network $(\mathcal{G}, f)$ is a *causal Bayesian network* if $\mathcal{G}$ is a causal DAG. If a causal Bayesian network is given and all variables are observed, one can easily derive post-intervention densities. In particular, we consider interventions $do(\mathbf{X} = \mathbf{x})$, or shorthand $do(\mathbf{x})$, $(\mathbf{X} \subseteq \mathbf{V})$, which represent outside interventions that set $\mathbf{X}$ to $\mathbf{x}$, uniformly in the population (see Pearl, 2009):

$$f(\mathbf{v} \mid do(\mathbf{x})) = \begin{cases} \prod_{\{i | X_i \in \mathbf{V} \setminus \mathbf{X}\}} f(x_i \mid \mathrm{Pa}(x_i, \mathcal{G})), & \text{if } \mathbf{v} \text{ is consistent with } \mathbf{x}, \\ 0, & \text{otherwise.} \end{cases} \quad (1)$$

Equation (1) is known as the truncated factorization formula (Pearl, 2009), the g-formula (Robins, 1986) or the manipulated density (Spirtes et al., 2000).

Maximal ancestral graphs. A mixed graph $\mathcal{G}$ without directed cycles and almost directed cycles is called *ancestral*. A *maximal ancestral graph* (MAG) is an ancestral graph $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ where every pair of non-adjacent nodes X and Y in $\mathcal{G}$ can be m-separated by a set $\mathbf{Z} \subseteq \mathbf{V} \setminus \{X, Y\}$. A DAG with unobserved variables can be uniquely represented by a MAG on the observed variables that preserves the ancestral and m-separation relationships among the observed variables (page 981 in Richardson and Spirtes, 2002). Since we consider MAGs that do not encode selection bias, the MAGs in this paper can only contain directed $(\to)$ and bi-directed $(\leftrightarrow)$ edges. The MAG of a causal DAG is a *causal* MAG.

Markov equivalence. Several DAGs can encode the same conditional independencies via d-separation. Such DAGs form a *Markov equivalence class* which can be described uniquely by a *completed partially directed acyclic graph* (CPDAG) (Meek, 1995). A CPDAG $\mathcal{C}$ has the same adjacencies as any DAG in the Markov equivalence class described by $\mathcal{C}$. A directed edge $X \to Y$ in a CPDAG $\mathcal{C}$ corresponds to a directed edge $X \to Y$ in every DAG in the Markov equivalence class described by $\mathcal{C}$. For any non-directed edge $X \circ\!\!-\!\!\circ Y$ in a CPDAG $\mathcal{C}$, the Markov equivalence class described by $\mathcal{C}$ contains a DAG with $X \to Y$ and a DAG with $X \leftarrow Y$[1]. Thus, CPDAGs only contain directed $(\to)$ and non-directed $(\circ\!\!-\!\!\circ)$ edges.

Several MAGs can also encode the same conditional independencies via m-separation. Such MAGs form a Markov equivalence class which can be described uniquely by a *partial ancestral graph* (PAG) (Richardson and Spirtes, 2002; Ali et al., 2009). A PAG $\mathcal{P}$ has the same adjacencies as any MAG in the Markov equivalence class described by $\mathcal{P}$. Any non-circle edge-mark in a PAG $\mathcal{P}$ corresponds to that same non-circle edge-mark in every MAG in the Markov equivalence class described by $\mathcal{P}$. We only consider maximally informative PAGs (Zhang, 2008b), that is, for any circle mark $X \circ\!\!\bullet$ in a PAG $\mathcal{P}$, the Markov equivalence class described by $\mathcal{P}$ contains a MAG with $X \leftarrow\!\!\bullet Y$ and a MAG with $X \bullet\!\!-\!\!\bullet Y$. We denote all

1. The non-directed edges in a CPDAG, which we denote as $\circ\!\!-\!\!\circ$, are often denoted as $-$ in the relevant literature, see for example (Meek, 1995). We use $\circ\!\!-\!\!\circ$ instead of $-$ for the sake of consistency among different graph classes.

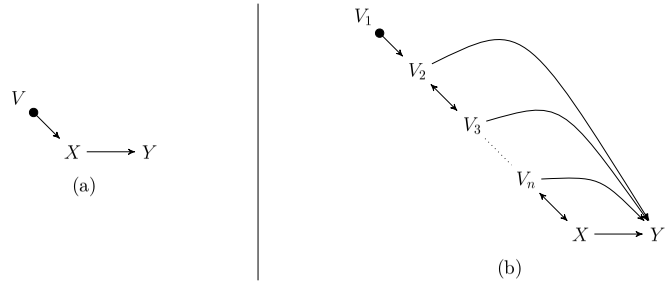

Figure 2: Two configurations where the edge $X \to Y$ is visible. Nodes V and Y must be nonadjacent in 2a, and V_1 and Y must be nonadjacent in 2b.

DAGs (MAGs) in the Markov equivalence class described by a CPDAG (PAG) $\mathcal{G}$ by $[\mathcal{G}]$. The CPDAG (PAG) of a causal DAG (MAG) is a *causal* CPDAG (PAG).

Consistent densities. A density f is *consistent* with a causal DAG $\mathcal{D}$ if the pair $(\mathcal{D}, f)$ forms a causal Bayesian network. A density f is consistent with a causal MAG $\mathcal{M}$ if there exists a causal Bayesian network $(\mathcal{D}', f')$ such that $\mathcal{M}$ represents $\mathcal{D}'$ and f is the observed marginal of f'. A density f is consistent with a causal CPDAG (PAG) $\mathcal{G}$ if it is consistent with a causal DAG (MAG) in $[\mathcal{G}]$.

Visible and invisible edges. All directed edges in DAGs and CPDAGs are said to be visible. Given a MAG $\mathcal{M}$ or a PAG $\mathcal{G}$, a directed edge $X \to Y$ is *visible* if there is a node V not adjacent to Y such that there is an edge $V \bullet\!\!\to X$, or if there is a collider path between V and X that is into X and every non-endpoint node on the path is a parent of Y, see Figure 2 (Zhang, 2006). A visible edge $X \to Y$ means that there are no latent confounders between X and Y. A directed edge $X \to Y$ that is not visible in a MAG $\mathcal{M}$ or a PAG $\mathcal{G}$ is said to be *invisible*. In the FCI algorithm, invisible edges can occur due to orientation rules **R5** - **R10** of Zhang (2008b). When considering MAGs and PAGs that do not encode selection bias, invisible edges occur as a consequence of the orientation rules **R8** - **R10** of Zhang (2008b).

3. The Generalized Adjustment Criterion

Throughout, let $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ represent a DAG, CPDAG, MAG or PAG, and let $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint subsets of $\mathbf{V}$, with $\mathbf{X} \neq \emptyset$ and $\mathbf{Y} \neq \emptyset$. Here, $\mathbf{X}$ represents the set of exposures and $\mathbf{Y}$ represents the set of response variables.

We will define sound and complete graphical conditions for adjustment sets relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. Thus, if a set $\mathbf{Z}$ satisfies our conditions relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$ (see Definition 4), then it is a valid adjustment set for calculating the causal effect of $\mathbf{X}$ on $\mathbf{Y}$ (see Definition 1), and every existing valid adjustment set satisfies our conditions (see Theorem 5). First, we define what we mean by an adjustment set.

Definition 1 ***(Adjustment set;*** *Maathuis and Colombo, 2015) Let* $\mathbf{X}, \mathbf{Y}$ *and* $\mathbf{Z}$ *be pairwise disjoint node sets in a causal* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$. *Then* $\mathbf{Z}$ *is an adjustment set relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$ *if for any density*[2] f *consistent with* $\mathcal{G}$ *we have*

$$f(\mathbf{y} \mid do(\mathbf{x})) = \begin{cases} f(\mathbf{y} \mid \mathbf{x}) & \text{if } \mathbf{Z} = \emptyset, \\ \int_{\mathbf{z}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z}) f(\mathbf{z}) d\mathbf{z} & \text{otherwise.} \end{cases} \tag{2}$$

Thus, adjustment sets allow post-intervention densities involving the do-operator (left-hand side of Equation 2) to be identified as specific functions of conditional densities (right-hand side of Equation 2). The latter can be estimated from observational data. As a result, adjustment sets are important for the computation of causal effects. This is illustrated in Example 1 for the special case of multivariate Gaussian densities.

Example 1 *Suppose* f *is a multivariate Gaussian density that is consistent with a causal* DAG $\mathcal{D}$. *Let* $\mathbf{Z} \neq \emptyset$ *be an adjustment set relative to two distinct variables* X *and* Y *in* $\mathcal{D}$ *such that* $\mathbf{Z} \cap \{X \cup Y\} = \emptyset$. *Then*

$$\begin{aligned} E(Y \mid do(x)) &= \int_y y f(y \mid do(x)) dy = \int_y y \int_{\mathbf{z}} f(y \mid x, \mathbf{z}) f(\mathbf{z}) d\mathbf{z} dy \\ &= \int_{\mathbf{z}} \int_y y f(y \mid x, \mathbf{z}) dy f(\mathbf{z}) d\mathbf{z} = \int_{\mathbf{z}} E(Y \mid x, \mathbf{z}) f(\mathbf{z}) d\mathbf{z} \\ &= \int_{\mathbf{z}} (\alpha + \gamma x + \beta^T \mathbf{z}) f(\mathbf{z}) d\mathbf{z} = \alpha + \gamma x + \beta^T E(\mathbf{Z}), \end{aligned}$$

where we use the fact that all conditional expectations in a multivariate Gaussian distribution are linear, so that $E(Y \mid x, \mathbf{z}) = \alpha + \gamma x + \beta^T \mathbf{z}$, *for some* $\alpha, \gamma \in \mathbb{R}$ *and* $\beta \in \mathbb{R}^{|\mathbf{z}|}$. *Defining the total causal effect of* X *on* Y *as* $\frac{\partial}{\partial x} E(Y \mid do(x))$, *we obtain that the total causal effect of* X *on* Y *is* γ, *that is, the regression coefficient of* X *in the regression of* Y *on* X *and* $\mathbf{Z}$.

Our first goal in this paper is to give a graphical criterion (see Definition 4) that is equivalent to Definition 1. To this end, we introduce some additional terminology.

Definition 2 ***(Amenability)*** *Let* $\mathbf{X}$ *and* $\mathbf{Y}$ *be disjoint node sets in a* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$. *Then* $\mathcal{G}$ *is said to be amenable relative to* $(\mathbf{X}, \mathbf{Y})$ *if every proper possibly directed path from* $\mathbf{X}$ *to* $\mathbf{Y}$ *in* $\mathcal{G}$ *starts with a visible edge out of* $\mathbf{X}$.

If $\mathcal{G}$ is a MAG, then Definition 2 reduces to the notion of amenability as introduced in van der Zander et al. (2014). The intuition behind the concept of amenability is the following: In MAGs and PAGs, directed edges $X \to Y$ can represent causal effects, but also mixtures of causal effects and latent confounding. For instance, when the graph $X \to Y$ is interpreted as a DAG, the empty set is a valid adjustment set with respect to (X, Y). When the same graph is interpreted as a MAG, it can still represent the DAG $X \to Y$, but also the DAG $X \to Y$ with an additional non-causal path $X \leftarrow L \to Y$ where L is latent.

2. We use the notation for continuous random variables throughout. The discrete analogues should be obvious.

In CPDAGs and PAGs, there are edges with unknown direction. This complicates adjustment because paths containing such edges can correspond to causal paths in some represented DAGs and to non-causal paths in others. For example, the CPDAG $X \circ\!\!-\!\!\circ Y$ represents the DAGs $X \to Y$ and $X \leftarrow Y$. Amenable graphs are graphs where these problems do not occur.

Definition 3 *(**Forbidden set;** $\mathrm{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$) Let $\mathbf{X}$ and $\mathbf{Y}$ be disjoint node sets in a* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$. *Then the forbidden set relative to $(\mathbf{X},\mathbf{Y})$ is defined as*

$$\mathrm{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G}) = \{W' \in \mathbf{V} : W' \in \mathrm{PossDe}(W,\mathcal{G}), \text{ for some } W \notin \mathbf{X} \text{ which lies on a proper possibly directed path from } \mathbf{X} \text{ to } \mathbf{Y} \text{ in } \mathcal{G}\}.$$

Definition 4 *(**Generalized adjustment criterion**) Let $\mathbf{X},\mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$. *Then $\mathbf{Z}$ satisfies the generalized adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$ if the following three conditions hold:*

*(**Amenability**) $\mathcal{G}$ is adjustment amenable relative to $(\mathbf{X},\mathbf{Y})$, and*

*(**Forbidden set**) $\mathbf{Z} \cap \mathrm{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G}) = \emptyset$, and*

*(**Blocking**) all proper definite status non-causal paths from $\mathbf{X}$ to $\mathbf{Y}$ are blocked by $\mathbf{Z}$ in $\mathcal{G}$.*

If $\mathcal{G}$ is a DAG (MAG), our criterion reduces to the adjustment criterion of Shpitser (2012), (van der Zander et al., 2014) (see Definition 55 in Appendix E). For consistency, however, we will refer to the generalized adjustment criterion for all graph types.

We note that the amenability condition does not depend on $\mathbf{Z}$. In other words, if the amenability condition is violated, then no set satisfies the generalized adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$. The forbidden set contains nodes that cannot be used for adjustment. We will try to give some intuition. For simplicity, we consider $\mathbf{X} = \{X\}$ and $\mathbf{Y} = \{Y\}$ in a DAG $\mathcal{D}$, and we are interested in estimating the total causal effect of X on Y in $\mathcal{D}$. It is clear that nodes on any causal path from X to Y in $\mathcal{D}$ should not be included in the set used for adjustment, since including such nodes would block the causal path.

To understand why we cannot include descendants of nodes on a causal path from X to Y in $\mathcal{D}$ (except for descendants of X), it is useful to consider *walks* from X to Y in $\mathcal{D}$, that is, sequences of nodes $\langle X,\dots,Y\rangle$ in which every pair of successive nodes is adjacent in $\mathcal{D}$ (but the nodes are not necessarily distinct). A walk $r = \langle X = V_0, V_1, \dots, V_k = Y\rangle$ is non-causal if $V_i \leftarrow\!\!\circ V_{i+1}$ for at least one $i \in \{0,\dots,k-1\}$. A walk r from X to Y in $\mathcal{D}$ is *connecting* given a set of nodes $\mathbf{Z}$ if $\mathbf{Z}$ contains all colliders on r and no non-collider on r is in $\mathbf{Z}$. If a walk r is not connecting given $\mathbf{Z}$, then r is *blocked* by $\mathbf{Z}$. Koster (2002) proved that there is a walk from X to Y that is connecting given $\mathbf{Z}$ in $\mathcal{D}$ if and only if there is path from X to Y that is d-connecting given $\mathbf{Z}$ in $\mathcal{D}$.

Intuitively, all non-causal walks from X to Y should be blocked in order to estimate the total causal effect of X on Y. Now, consider a path p of the form $X \to V_1 \to \cdots \to V_k \to Y$ in $\mathcal{G}$. Assume $V_i \notin \mathbf{Z}$, for all $i \in \{1,\dots,k\}$. Including a descendant A of V_i in the set $\mathbf{Z}$ leads to walk of the form $X \to \cdots \to V_i \to \cdots \to A \leftarrow \cdots \leftarrow V_i \to \cdots \to V_k \to Y$ being connecting given $\mathbf{Z}$ in $\mathcal{G}$. Hence, including A in the adjustment set opens a non-causal walk from X to Y in $\mathcal{G}$.

We now give the main theorem of this section. Corresponding examples can be found in Section 3.1 and the proof of the theorem is given in Section 3.2.

Theorem 5 *Let $\mathbf{X},\mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a causal* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$. *Then $\mathbf{Z}$ is an adjustment set relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$ (see Definition 1) if and only if $\mathbf{Z}$ satisfies the generalized adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$ (see Definition 4).*

Verifying the blocking condition by checking all paths requires keeping track of which paths are non-causal and hence, scales poorly to larger graphs. We therefore give an alternative definition of this condition which relies on m-separation in a so-called proper back-door graph.

Definition 6 *(**Proper back-door graph**; $\mathcal{G}^{pbd}_{\mathbf{XY}}$) Let $\mathbf{X}$ and $\mathbf{Y}$ be disjoint node sets in a* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$. *The proper back-door graph $\mathcal{G}^{pbd}_{\mathbf{XY}}$ is obtained from $\mathcal{G}$ by removing all visible edges out of $\mathbf{X}$ that are on proper possibly directed paths from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$.*

If $\mathcal{G}$ is a DAG or MAG, then Definition 6 reduces to the definition of proper back-door graphs as introduced in van der Zander et al. (2014).

Theorem 7 *Replacing the Blocking condition in Definition 4 with:*

*(**Separation**) $\mathbf{Z}$ m-separates $\mathbf{X}$ and $\mathbf{Y}$ in $\mathcal{G}^{pbd}_{\mathbf{XY}}$,*

results in a criterion that is equivalent to the generalized adjustment criterion.

If $\mathcal{G}$ is a DAG or MAG, then Theorem 7 reduces to Theorem 4.6 in van der Zander et al. (2014).

3.1 Examples

We now provide some examples that illustrate how the generalized adjustment criterion can be applied.

Example 2 *We return to the* CPDAG $\mathcal{C}$ *in Figure 1(a). $\mathcal{C}$ is amenable relative to (X,Y) and $\mathrm{Forb}(X,Y,\mathcal{C}) = \{Y\}$. One can easily verify that any superset of $\{Z,A\}$ or of $\{Z,B\}$ that does not contain X or Y satisfies the generalized adjustment criterion relative to (X,Y) in $\mathcal{C}$.*

Example 3 *To illustrate the concept of amenability, consider Figure 3 with a* PAG $\mathcal{P}$ *in (a), and two* MAGs $\mathcal{M}_1$ *and* $\mathcal{M}_2$ *in $[\mathcal{P}]$ in (b) and (c). The graphs $\mathcal{P}$ and $\mathcal{M}_1$ are not amenable relative to (X,Y). For $\mathcal{P}$ this is due to the path $X \circ\!\!-\!\!\circ Y$, and for $\mathcal{M}_1$ this is due*

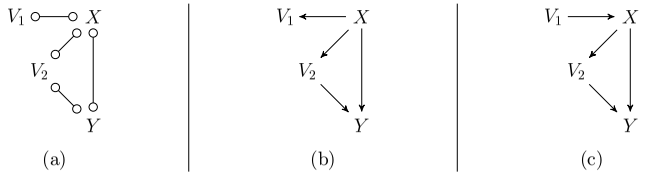

Figure 3: (a) PAG $\mathcal{P}$, (b) MAG $\mathcal{M}_1$, (c) MAG $\mathcal{M}_2$ used in Example 3.

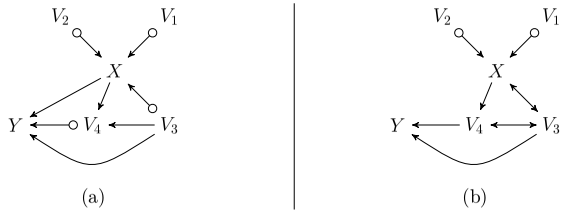

Figure 4: (a) PAG $\mathcal{P}_1$, (b) PAG $\mathcal{P}_2$ used in Example 4 and Example 6.

to the invisible edge $X \to Y$ (which implies that $\mathcal{M}_1$ also represents a DAG that contains a hidden confounder that is an ancestor of both X and Y). On the other hand, $\mathcal{M}_2$ is amenable relative to (X, Y), since the edges $X \to Y$ and $X \to V_2$ are visible due to the edge $V_1 \to X$, with V_1 not adjacent to Y or V_2. Since there are no proper definite status non-causal paths from X to Y in $\mathcal{M}_2$, it follows that the empty set satisfies the generalized adjustment criterion relative to (X, Y) in $\mathcal{M}_2$. Finally, note that $\mathcal{M}_1$ could also be interpreted as a DAG*. In that case, it would be amenable relative to (X, Y). This shows that amenability depends crucially on the interpretation of the graph.*

Example 4 *Let $\mathcal{P}_1$ and $\mathcal{P}_2$ be the* PAG*s in Figure 4(a) and Figure 4(b), respectively. Both* PAG*s are amenable relative to (X, Y). We will show that there is an adjustment set relative to (X, Y) in $\mathcal{P}_1$ but not in $\mathcal{P}_2$. This illustrates that amenability is not a sufficient criterion for the existence of an adjustment set.*

We first consider $\mathcal{P}_1$. Note that $\mathrm{Forb}(X, Y, \mathcal{P}_1) = \{V_4, Y\}$ *and that there are two proper definite status non-causal paths from X to Y: $X \leftrightarrow\circ V_3 \to Y$ and $X \to V_4 \leftarrow V_3 \to Y$. Path $X \leftrightarrow\circ V_3 \to V_4 \circ\!\!\to Y$ is not of definite status, as node V_4 is not of definite status on this path. Both proper definite status non-causal paths from X to Y are blocked by any set containing V_3. Hence, all sets satisfying the generalized adjustment criterion relative to (X, Y) in $\mathcal{P}_1$ are: $\{V_3\}$, $\{V_1, V_3\}$, $\{V_2, V_3\}$ and $\{V_1, V_2, V_3\}$.*

In $\mathcal{P}_2$, we have $\mathrm{Forb}(X, Y, \mathcal{P}_2) = \mathrm{Forb}(X, Y, \mathcal{P}_1) = \{V_4, Y\}$*, and there are three proper definite status non-causal paths from X to Y in $\mathcal{P}_2$: p_1 of the form $X \leftrightarrow V_3 \to Y$, p_2 of the form $X \leftrightarrow V_3 \leftrightarrow V_4 \to Y$ and p_3 of the form $X \to V_4 \leftrightarrow V_3 \to Y$. To block p_1, we must use V_3, and this implies that we must use V_4 to block p_2. But $V_4 \in \mathrm{Forb}(X, Y, \mathcal{P}_2)$. Hence, no set satisfies the generalized adjustment criterion $\mathbf{Z}$ relative to (X, Y) in $\mathcal{P}_2$.*

3.2 Proof of Theorem 5

To prove that the generalized adjustment criterion is sound and complete for adjustment (Theorem 5), we build on the fact that the adjustment criterion for DAGs and MAGs is sound and complete for adjustment. The adjustment criterion for DAGs was first presented in Shpitser et al. (2010) and was modified in the unpublished addendum (Shpitser, 2012). In Appendix E we give the revised version of the criterion, as well as new soundness and completeness proofs, relying only on basic probability calculus, linear algebra and the do-calculus rules. The adjustment criterion for MAGs was presented and proved to be sound and complete for adjustment in van der Zander et al. (2014, see Theorem 5.8). However, van der Zander et al. (2014)'s proof assumed the soundness and completeness of the adjustment criterion for DAGs given in Shpitser (2012). This latter claim is proved here in Theorem 56 in Appendix E.

Lastly, our proof of Theorem 5 heavily relies on the three lemmas given below. Their proofs can be found in Appendix B.

Lemma 8 *Let $\mathbf{X}$ and $\mathbf{Y}$ be disjoint node sets in a* CPDAG (PAG) *$\mathcal{G}$. If $\mathcal{G}$ is amenable (see Definition 4) relative to $(\mathbf{X}, \mathbf{Y})$, then every* DAG (MAG) *in $[\mathcal{G}]$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$. On the other hand, if $\mathcal{G}$ violates the amenability condition relative to $(\mathbf{X}, \mathbf{Y})$, then there is no adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$ (see Definition 1).*

Lemma 9 *Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a* CPDAG (PAG) *$\mathcal{G}$. If $\mathcal{G}$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$, then the following statements are equivalent:*

(i) $\mathbf{Z}$ *satisfies the forbidden set condition (see Definition 4) relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$.*

(ii) $\mathbf{Z}$ *satisfies the forbidden set condition relative to $(\mathbf{X}, \mathbf{Y})$ in every* DAG (MAG) *in $[\mathcal{G}]$.*

Lemma 10 *Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a* CPDAG (PAG) *$\mathcal{G}$. If $\mathcal{G}$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$, and $\mathbf{Z}$ satisfies the forbidden set condition relative to $(\mathbf{X}, \mathbf{Y})$, then the following statements are equivalent:*

(i) $\mathbf{Z}$ *satisfies the blocking condition (see Definition 4) relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$.*

(ii) $\mathbf{Z}$ *satisfies the blocking condition relative to $(\mathbf{X}, \mathbf{Y})$ in every* DAG (MAG) *in $[\mathcal{G}]$.*

(iii) $\mathbf{Z}$ *satisfies the blocking condition relative to $(\mathbf{X}, \mathbf{Y})$ in a* DAG *$\mathcal{D}$ (*MAG *$\mathcal{M}$) in $[\mathcal{G}]$.*

Proof of Theorem 5. If $\mathcal{G}$ is a DAG (MAG), then our criterion reduces to the adjustment criterion from Shpitser (2012) (van der Zander et al., 2014) which is sound and complete for adjustment (Theorem 56 in Appendix E, Theorem 5.8 in van der Zander et al., 2014). Hence, we only consider the case that $\mathcal{G}$ is a CPDAG (PAG).

Suppose first that $\mathbf{Z}$ satisfies the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in the CPDAG (PAG) $\mathcal{G}$. We need to show that $\mathbf{Z}$ is an adjustment set (see Definition 1) relative to $(\mathbf{X}, \mathbf{Y})$ in every DAG $\mathcal{D}$ (MAG $\mathcal{M}$) in $[\mathcal{G}]$. By applying Lemmas 8, 9 and 10 in turn, it directly follows that $\mathbf{Z}$ satisfies the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in every DAG $\mathcal{D}$ (MAG $\mathcal{M}$) in $[\mathcal{G}]$. Since the generalized adjustment criterion is

sound for adjustment in DAGs (MAGs) (see Theorem 58 in Appendix E and Theorem 5.8 in van der Zander et al., 2014), $\mathbf{Z}$ is an adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in every $\mathcal{D}$ ($\mathcal{M}$) in $[\mathcal{G}]$.

To prove the other direction, suppose that $\mathbf{Z}$ does not satisfy the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. First, suppose that $\mathcal{G}$ violates the amenability condition relative to $(\mathbf{X}, \mathbf{Y})$. Then by Lemma 8, there is no adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. Otherwise, $\mathcal{G}$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$, but $\mathbf{Z}$ violates the forbidden set condition or the blocking condition. We need to show $\mathbf{Z}$ is not an adjustment set in at least one DAG $\mathcal{D}$ (MAG $\mathcal{M}$) in $[\mathcal{G}]$. Suppose $\mathbf{Z}$ violates the forbidden set condition. Then by Lemma 9, it follows that there exists a DAG $\mathcal{D}$ (MAG $\mathcal{M}$) in $[\mathcal{G}]$ such that $\mathbf{Z}$ does not satisfy the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ ($\mathcal{M}$). Since the generalized adjustment criterion is complete for adjustment in DAGs (MAGs) (see Theorem 57 in Appendix E and Theorem 5.8 in van der Zander et al., 2014), it follows that $\mathbf{Z}$ is not an adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ ($\mathcal{M}$). Otherwise, suppose $\mathbf{Z}$ satisfies the forbidden set condition, but violates the blocking condition. Then by Lemma 10, it follows that there is a DAG $\mathcal{D}$ (MAG $\mathcal{M}$) in $[\mathcal{G}]$ such that $\mathbf{Z}$ does not satisfy the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ ($\mathcal{M}$). Since the generalized adjustment criterion is complete for adjustment in DAGs (MAGs), it follows that $\mathbf{Z}$ is not an adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ ($\mathcal{M}$). ■

4. Constructing Adjustment Sets

We now present approaches to construct adjustment sets. First, in Theorem 11, we discuss a pre-processing of the node set $\mathbf{X}$ that in conjunction with our generalized adjustment criterion can help identify $f(\mathbf{y}|do(\mathbf{x}))$ in DAG, CPDAG, MAG or PAG $\mathcal{G}$ via adjustment.

As mentioned before, if $f(\mathbf{y}|do(\mathbf{x}))$ is not identifiable via adjustment in $\mathcal{G}$, it may be identifiable through other means. In particular, if $f(\mathbf{y}|do(\mathbf{x}))$ is not identifiable via adjustment in $\mathcal{G}$, there may be a set $\mathbf{X}' \subseteq \mathbf{X}$ such that $f(\mathbf{y}|do(\mathbf{x})) = f(\mathbf{y}|do(\mathbf{x}'))$, and $f(\mathbf{y}|do(\mathbf{x}'))$ is identifiable via adjustment in $\mathcal{G}$. One such example is given in Theorem 11.

Next, we introduce Theorem 14 that will allow us to easily construct adjustment sets that do not contain certain nodes, if any such adjustment set exists. We illustrate the results of Theorem 14 with examples in Section 4.1 and give the proof of this theorem in Section 4.2. In Section 4.3 we explain how to leverage previous results of van der Zander et al. (2014) to enumerate all (minimal) adjustment sets, and discuss how to implement this procedure efficiently.

Theorem 11 *Let $\mathbf{X}$ and $\mathbf{Y}$ be disjoint node sets in a causal DAG, CPDAG, MAG or PAG $\mathcal{G}$. Let $\mathbf{X}' \subseteq \mathbf{X}$ such that there is no possibly directed path from $\mathbf{X} \setminus \mathbf{X}'$ to $\mathbf{Y}$ that is proper with respect to $\mathbf{X}$. Then*

$$f(\mathbf{y}|do(\mathbf{x})) = \begin{cases} f(\mathbf{y}) & \text{if } \mathbf{X}' = \emptyset, \\ f(\mathbf{y}|do(\mathbf{x}')) & \text{otherwise.} \end{cases}$$

Furthermore, if $\mathbf{X}' \neq \emptyset$ and if $\mathbf{Z}$ is an adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$, then $\mathbf{Z}$ is an adjustment set relative to $(\mathbf{X}', \mathbf{Y})$ in $\mathcal{G}$.

Following Theorem 11, we recommend pre-processing the set $\mathbf{X}$ as follows: remove all nodes $X \in \mathbf{X}$ that do not have a possibly directed path to $\mathbf{Y}$ which is proper with respect to $\mathbf{X}$

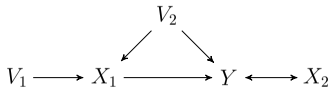

Figure 5: MAG $\mathcal{M}$.

in $\mathcal{G}$. In other words, if $\mathbf{W}$ is the set of all nodes that have a possibly directed path to $\mathbf{Y}$ which is proper with respect to $\mathbf{X}$ in $\mathcal{G}$, then $\mathbf{X}' = \mathbf{X} \cap \mathbf{W}$. Then by choice of $\mathbf{W}$ and the proof of Theorem 11, all nodes in $\mathbf{X}'$ have a possibly directed path to $\mathbf{Y}$ that is proper with respect to $\mathbf{X}'$.

By Theorem 11, this pre-processing of $\mathbf{X}$ cannot hurt in identifying $f(\mathbf{y}|do(\mathbf{x}))$ via adjustment. Moreover, there are cases when this pre-processing helps to identify $f(\mathbf{y}|do(\mathbf{x}))$ via adjustment. For example, in the MAG $\mathcal{M}$ in Figure 5, there is no adjustment set relative to $(\{X_1, X_2\}, Y)$. However, there is no possibly directed path from X_2 to Y that is proper with respect to $\{X_1, X_2\}$. Furthermore, $\{V_2\}$ is an adjustment set relative to (X_1, Y). Hence, by Theorem 11 and Theorem 5, $f(y|do(x_1, x_2)) = f(y|do(x_1)) = \int_{v_2} f(y|x_1, v_2) f(v_2) dv_2$.

We now introduce two definitions that will be used in Theorem 14. First, we define the set $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ relative to disjoint node sets $\mathbf{X}$ and $\mathbf{Y}$ in a DAG, CPDAG, MAG or PAG $\mathcal{G}$.

Definition 12 *(Adjust$(\mathbf{X}, \mathbf{Y}, \mathcal{G})$) Let $\mathbf{X}$ and $\mathbf{Y}$ be disjoint node sets in a* DAG, CPDAG, MAG *or* PAG *$\mathcal{G}$. We define*

$$\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) = \text{PossAn}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G}) \setminus (\mathbf{X} \cup \mathbf{Y} \cup \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})). \tag{3}$$

If $\mathcal{G}$ is a DAG or MAG, then Definition 12 reduces to the definition of $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ in van der Zander et al. (2014), that is, $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) = \text{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G}) \setminus (\mathbf{X} \cup \mathbf{Y} \cup \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G}))$.

Definition 13 ***(Descendral set)*** *Let $\mathbf{I}$ be a node set in a* DAG, CPDAG, MAG *or* PAG *$\mathcal{G}$. Then $\mathbf{I}$ is called descendral in $\mathcal{G}$ if $\mathbf{I} = \text{PossDe}(\mathbf{I}, \mathcal{G})$.*

A descendral set is in a sense analogous to an ancestral set, which is a set containing all ancestors of itself. Note that $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ and $\text{PossDe}(\mathbf{X}, \mathcal{G})$ are both descendral sets. This property will be used throughout the proofs. Note that if $\mathbf{A}$ is an ancestral set and $\mathbf{B}$ is a descendral set, then $\mathbf{A} \setminus \mathbf{B}$ is an ancestral set and $\mathbf{B} \setminus \mathbf{A}$ is a descendral set.

Theorem 14 ***(Constructive set)*** *Let $\mathbf{X}$ and $\mathbf{Y}$ be disjoint node sets in a* DAG, CPDAG, MAG *or* PAG *$\mathcal{G}$. Let $\mathbf{I} \supseteq \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ be a descendral set in $\mathcal{G}$. Then there exists a set $\mathbf{Z}$ that satisfies the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$ such that $\mathbf{Z} \cap \mathbf{I} = \emptyset$ if and only if $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$ satisfies the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$.*

The smallest set we can take for $\mathbf{I}$ in Theorem 14 is $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$. This leads to Corollary 15. Pearl's back-door criterion does not allow using descendants of $\mathbf{X}$ in a DAG $\mathcal{D}$. Moreover, the generalized back-door criterion does not allow using possible descendants of $\mathbf{X}$ in a DAG, CPDAG, MAG or PAG $\mathcal{G}$. Thus, another natural set to consider for $\mathbf{I}$ is $\text{PossDe}(\mathbf{X}, \mathcal{G})$. We will use $\mathbf{I} = \text{PossDe}(\mathbf{X}, \mathcal{G})$ and Theorem 14 in Section 5 to define sets that satisfy generalized back-door criterion and Pearl's back-door criterion.

Corollary 15 *Let $\mathbf{X}$ and $\mathbf{Y}$ be disjoint node sets in a* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$. *The following statements are equivalent:*

(i) There exists an adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$.

(ii) $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ *satisfies the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$.*

(iii) $\mathcal{G}$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$ and $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ *satisfies the blocking condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$.*

4.1 Examples

We now provide some examples that illustrate the construction of adjustment sets.

Example 5 *Consider again the* CPDAG $\mathcal{C}$ *in Figure 1(a). As previously discussed in Example 2, $\mathcal{C}$ is amenable relative to (X, Y). The set* $\text{Adjust}(X, Y, \mathcal{C}) = \{X, Y, I, A, Z, B\} \setminus \{X, Y\} = \{I, A, Z, B\}$ *satisfies the blocking condition relative to (X, Y) in $\mathcal{C}$. Hence, by Corollary 15, $\{I, A, Z, B\}$ satisfies the generalized adjustment criterion relative to (X, Y) in $\mathcal{C}$.*

Example 6 *Consider again the* PAG*s $\mathcal{P}_1$ and $\mathcal{P}_2$ in Figure 4(a) and Figure 4(b), respectively. As previously discussed in Example 4, both $\mathcal{P}_1$ and $\mathcal{P}_2$ are amenable relative to (X, Y).*

In $\mathcal{P}_1$, $\text{Forb}(X, Y, \mathcal{P}_1) = \{V_4, Y\}$, *so* $\text{Adjust}(X, Y, \mathcal{P}_1) = \{X, Y, V_1, V_2, V_3, V_4\} \setminus \{X, Y, V_4\} = \{V_1, V_2, V_3\}$. *Since $\{V_1, V_2, V_3\}$ satisfies the blocking condition relative to (X, Y) in $\mathcal{G}$, it follows that $\{V_1, V_2, V_3\}$ satisfies the generalized adjustment criterion relative to (X, Y) in $\mathcal{G}$.*

In $\mathcal{P}_2$, again $\text{Forb}(X, Y, \mathcal{P}_2) = \{V_4, Y\}$, *so* $\text{Adjust}(X, Y, \mathcal{P}_2) = \{X, Y, V_1, V_2, V_3, V_4\} \setminus \{X, Y, V_4\} = \{V_1, V_2, V_3\}$. *Since $\{V_1, V_2, V_3\}$ does not block the path $X \leftrightarrow V_3 \leftrightarrow V_4 \rightarrow Y$ it does not satisfy the blocking condition relative to (X, Y) in $\mathcal{G}$. Hence, Corollary 15 implies that there is no adjustment set relative to (X, Y) in $\mathcal{P}_2$.*

4.2 Proof of Theorem 14

To prove Theorem 14 we heavily rely on Lemma 16 and Lemma 17 given below. Their proofs are given in Appendix C. Lemma 17 is related to Lemma 1 from Richardson (2003) (see Lemma 37 in Appendix A).

Lemma 16 *Let $\mathbf{X}$ and $\mathbf{Y}$ be disjoint node sets in a* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$. *Let $\mathbf{I} \supseteq \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ be a descendral set in $\mathcal{G}$ (see Definition 13). If there is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$ that is m-connecting given* $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$, *then there is a path p from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$ such that:*

(i) p is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$, and

(ii) all colliders on p are in $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$, *and*

(iii) all definite non-colliders on p are in $\mathbf{I}$, and

(iv) for any collider C on p, there is an unshielded possibly directed path from C to $\mathbf{X} \cup \mathbf{Y}$, that starts with $\circ\!\!\rightarrow$ or $\rightarrow$.

Lemma 17 *Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$. *Let $\mathbf{I} \supseteq \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ be a node set in $\mathcal{G}$ such that $\mathbf{Z} \cap \mathbf{I} = \emptyset$. Let p be a path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$ such that:*

(i) p is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$, and

(ii) all colliders on p are in $\text{An}(\mathbf{X} \cup \mathbf{Y} \cup \mathbf{Z}, \mathcal{G}) \setminus \mathbf{I}$, *and*

(iii) no definite non-collider on p is in $\mathbf{Z}$.

Then there is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\mathbf{Z}$ in $\mathcal{G}$.

Proof of Theorem 14. We only prove the non-trivial direction. Thus, assume there is a set $\mathbf{Z}$ satisfying the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$ such that $\mathbf{Z} \cap \mathbf{I} = \emptyset$. We will prove that $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$ satisfies the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$.

Since $\mathbf{Z}$ satisfies the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$, $\mathcal{G}$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$. Additionally, since $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \subseteq \mathbf{I}$, $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$ satisfies the forbidden set condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. It is only left to prove that $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$ satisfies the blocking condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$.

Suppose for a contradiction that there is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$. Then we can choose a path p^* in $\mathcal{G}$ that satisfies (i)−(iv) in Lemma 16. Then p^* also satisfies (i) in Lemma 17. By (iii) in Lemma 16, every definite non-collider on p^* is in $\mathbf{I}$. Since $\mathbf{Z} \cap \mathbf{I} = \emptyset$, no definite non-collider on p^* is in $\mathbf{Z}$. So p^* satisfies (iii) in Lemma 17. Also, since by (iv) in Lemma 16 there is a possibly directed unshielded path q^* from every collider C on p^* to $\mathbf{X} \cup \mathbf{Y}$ that starts with $C \circ\!\!\rightarrow$, Lemma 42 implies that any other edge on q^* (if there is any) is directed in $\mathcal{G}$.

Then if $\mathcal{G}$ is a DAG, CPDAG or MAG, it follows from (iv) in Lemma 16 that all colliders on p^* are in $\text{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G})$. Combining this with (ii) in Lemma 16 implies that all colliders on p^* are in $\text{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$, so that p^* satisfies (ii) in Lemma 17. Hence, if $\mathcal{G}$ is a DAG, CPDAG or MAG, all conditions of Lemma 17 are satisfied, which implies that $\mathbf{Z}$ does not satisfy the blocking condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$.

Thus, assume $\mathcal{G}$ is a PAG. Let $\mathcal{M} \in [\mathcal{G}]$ be a MAG obtained from $\mathcal{G}$ by first replacing all partially directed edges $\circ\!\!\rightarrow$ by directed edges $\rightarrow$, and then orienting all non-directed edges $\circ\!\!-\!\!\circ$ as a DAG without unshielded colliders (see Lemma 43 in Appendix A). Let p be the path in $\mathcal{M}$ corresponding to p^* in $\mathcal{G}$. Then p satisfies (i) and (iii) in Lemma 17. By the choice of $\mathcal{M}$ and Lemma 42, any possibly directed unshielded path q^* in $\mathcal{G}$ that starts with a partially

directed edge $\circ\!\!\rightarrow$, corresponds to a directed path q in $\mathcal{M}$. Hence, by (iv) in Lemma 16, every collider on p is in $\mathrm{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{M})$. Since p^* satisfies (ii) in Lemma 16 in $\mathcal{G}$, no collider on p^* is in $\mathbf{I}$. Hence, also no collider on p is in $\mathbf{I}$. Then all colliders on p are in $\mathrm{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{M}) \setminus \mathbf{I}$. Additionally, since $\mathbf{I} \supseteq \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$, and $\mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \supseteq \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{M})$, it follows that p satisfies (ii) in Lemma 17. Thus, all conditions of Lemma 17 are satisfied, which implies that $\mathbf{Z}$ does not satisfy the blocking condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{M}$. This contradicts Lemma 10. ■

4.3 Implementation

We now discuss how one can implement the generalized adjustment criterion in an algorithmically efficient manner, and describe our implementation in the software `dagitty` and the R package `pcalg`.

Verification of the criterion. Given a DAG, CPDAG, MAG or PAG $\mathcal{G}$ and three disjoint node sets $\mathbf{X}, \mathbf{Y}$, and $\mathbf{Z}$, we wish to test whether $\mathbf{Z}$ fulfills the generalized adjustment criterion with respect to $(\mathbf{X}, \mathbf{Y})$. Of course, we could do this simply by verifying the three conditions of the generalized adjustment criterion (see Definition 4). However, the blocking condition is a statement about individual paths, which can pose problems for large graphs.

As a worst-case example, consider a DAG with X, Y and p remaining variables. Let every pair of variables be connected by an edge. Then the DAG contains $\sum_{i=0}^{p} p!/i! \approx p!\, e$ paths from X to Y. Thus, a direct implementation of the generalized adjustment criterion has an exponential runtime in p. Still, a verbatim implementation of the criterion can be useful for verification and didactic purposes, as well as for sparse graphs with few paths, and we therefore provide one in the function `gac` of the R package `pcalg`.

The key result for implementing the criterion in an efficient manner is Theorem 7, which replaces the path blocking condition by an m-separation condition in a subgraph of $\mathcal{G}$, the proper back-door graph $\mathcal{G}_{\mathbf{XY}}^{pbd}$. This condition can be checked efficiently by a simple depth-first or breadth-first graph traversal, known as the "Bayes-Ball algorithm" (Shachter, 1998). Specifically, for graphs represented as adjacency lists, the runtime is $O(|p| + |\mathbf{E}|)$ where $|\mathbf{E}|$ is the number of edges. Our implementation of this method can be accessed via the function `isAdjustmentSet` of the R package `dagitty`.

Constructing adjustment sets. Given a DAG, CPDAG, MAG or PAG $\mathcal{G}$ and two disjoint variable sets $\mathbf{X}, \mathbf{Y}$, we wish to find one or several sets $\mathbf{Z}$ that fulfill the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$. If a single set is sufficient, we can directly apply the main result of Section 4 and construct $\mathrm{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ (see Definition 12) and verify whether it satisfies the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$. Since this set is defined in terms of (possible) ancestors of $\mathbf{X}$ and $\mathbf{Y}$, it can be constructed by graph traversal in linear time. However, $\mathrm{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ can be a large set, since it contains all (possible) ancestors of $\mathbf{X}$ and $\mathbf{Y}$ except the forbidden nodes. This may result in a loss of statistical precision.

To avoid this, it is of interest to construct all possible adjustment sets. Again, Theorem 7 is key to achieving this: it allows us to use the algorithmic framework developed by van der Zander et al. (2014) for constructing and enumerating m-separating sets in DAGs and MAGs. For DAGs and MAGs, this can be directly applied. We propose the following procedure for CPDAGs and PAGs:

For a given CPDAG or PAG $\mathcal{G}$ and disjoint node sets $\mathbf{X}$ and $\mathbf{Y}$,

(1) Check if $\mathcal{G}$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$. If not, stop because there is no adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. Otherwise, continue.

(2) Find $\mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$.

(3) If $\mathcal{G}$ is a CPDAG, orient $\mathcal{G}$ into a DAG $\mathcal{D}$ in $[\mathcal{G}]$. If $\mathcal{G}$ is a PAG, orient $\mathcal{G}$ into a MAG $\mathcal{M}$ in $[\mathcal{G}]$ according to Theorem 2 from Zhang (2008b) (see Lemma 43 in Appendix A).

(4) By Lemma 10, finding all sets satisfying the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$ is equivalent to finding all sets $\mathbf{Z}$ satisfying the separation condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ ($\mathcal{M}$) such that $\mathbf{Z} \cap (\mathbf{X} \cup \mathbf{Y} \cup \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})) = \emptyset$. Thus, we can apply the algorithms from van der Zander et al. (2014) on $\mathcal{D}$ ($\mathcal{M}$). These algorithms are able to deal with the additional restriction that the resulting set must not contain nodes in $\mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$.

Thus, through this simple procedure we gain complete access to all functions in the algorithmic framework by van der Zander et al. (2014). These include listing all adjustment sets and all minimal adjustment sets (in polynomial time per set that is listed). We have implemented these features in the function `adjustmentSets` of the R package `dagitty`.

5. Relationship to (Generalized) Back-door Criteria

We now discuss the relationship between our generalized adjustment criterion and some other existing graphical criteria for covariate adjustment. In particular, we discuss Pearl's back-door criterion (see Definition 18) and the generalized back-door criterion (see Definition 20) and give constructive sets for both in Section 5.1. We use the results from Section 5.1 to precisely characterize the differences between our generalized adjustment criterion, Pearl's back-door criterion and the generalized back-door criterion in Theorem 26 of Section 5.2. We illustrate the results of Sections 5.1 and 5.2 with examples in Section 5.3.

Definition 18 *(**Back-door criterion**; Pearl, 1993) Let X and Y be distinct nodes in a* DAG *$\mathcal{D}$. A set of nodes $\mathbf{Z}$ not containing X or Y satisfies the back-door criterion relative to (X, Y) in $\mathcal{D}$ if:*

(i) no node in $\mathbf{Z}$ is a descendant of X, and

(ii) $\mathbf{Z}$ blocks every path between X and Y that contains an arrow into X.

If $\mathbf{X}$ and $\mathbf{Y}$ are two disjoint sets of nodes in $\mathcal{D}$, then $\mathbf{Z}$ is said to satisfy the back-door criterion relative to $(\mathbf{X}, \mathbf{Y})$ if it satisfies the criterion relative to any pair (X, Y) such that $X \in \mathbf{X}$, and $Y \in \mathbf{Y}$. A set $\mathbf{Z}$ that satisfies the back-door criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ is called a back-door set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$.

Definition 19 *(**Back-door path**; Maathuis and Colombo, 2015) Let X and Y be distinct nodes in a* DAG*,* CPDAG*,* MAG *or* PAG *$\mathcal{G}$. A path from X to Y in $\mathcal{G}$ is a back-door path if it does not start with a visible edge out of X.*

Definition 20 *(**Generalized back-door criterion**; Maathuis and Colombo, 2015) Let* $\mathbf{X}, \mathbf{Y}$ *and* $\mathbf{Z}$ *be pairwise disjoint node sets in a* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$. *Then* $\mathbf{Z}$ *satisfies the generalized back-door criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$ *if:*

(i) $\mathbf{Z}$ *does not contain possible descendants of* $\mathbf{X}$ *in* $\mathcal{G}$, *and*

(ii) for every $X \in \mathbf{X}$, *the set* $\mathbf{Z} \cup \mathbf{X} \setminus \{X\}$ *blocks every definite status back-door path from* X *to any member of* $\mathbf{Y}$, *if any, in* $\mathcal{G}$.

A set $\mathbf{Z}$ *that satisfies the generalized back-door criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$ *is called a generalized back-door set relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$.

5.1 Constructing (Generalized) Back-door Sets

We first focus on Pearl's back-door criterion. If $|\mathbf{X}| = 1$, the existence and construction of a back-door set in a causal DAG $\mathcal{D}$ is well understood. If $Y \in \mathrm{Pa}(X, \mathcal{D})$, then there is no back-door set relative to (X, Y) in $\mathcal{D}$, but it is obvious that $f(y \mid \mathrm{do}(x)) = f(y)$. If $Y \notin \mathrm{Pa}(X, \mathcal{D})$, then $\mathrm{Pa}(X, \mathcal{D})$ is a back-door set relative to (X, Y) in $\mathcal{D}$.

If $|\mathbf{X}| \geq 1$, the construction of a back-door set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ is less obvious. One could perhaps think that any set $\mathbf{Z}$ that satisfies our generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ such that $\mathbf{Z} \cap \mathrm{De}(\mathbf{X}, \mathcal{D}) = \emptyset$ satisfies Pearl's back-door criterion. This is not true, as shown in Lemma 21 that describes the graphical pattern that appears when there is an adjustment set but no back-door set. An example of a DAG that satisfies (i)-(iv) in Lemma 21 is given in Figure 8. Using this result and Theorem 14 we are able to define a specific set that satisfies Pearl's back-door criterion, when such a set exists. This result is given in Corollary 22.

Lemma 21 *Let* $\mathbf{X}$ *and* $\mathbf{Y}$ *be disjoint node sets in a* DAG $\mathcal{D}$. *Assume there is a set satisfying the generalized adjustment criterion* $\mathbf{Z}$ *relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}$ *such that* $\mathbf{Z} \cap \mathrm{De}(\mathbf{X}, \mathcal{D}) = \emptyset$. *Then there is no back-door set relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}$ *if and only if there is a path* p *from* $\mathbf{X}$ *to* $\mathbf{Y}$ *such that:*

(i) p *is a back-door path, and*

(ii) a proper subpath of p *is a causal path, and*

(iii) there are no colliders on p, *and*

(iv) all nodes on p *are in* $\mathrm{De}(\mathbf{X}, \mathcal{D})$.

Corollary 22 *(**Constructive back-door set**) Let* $\mathbf{X}$ *and* $\mathbf{Y}$ *be disjoint node sets in a* DAG $\mathcal{D}$. *The following statements are equivalent:*

(i) There exists a set that satisfies Pearl's back-door criterion relative to $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}$.

(ii) $\mathrm{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) \setminus \mathrm{De}(\mathbf{X}, \mathcal{D})$ *satisfies Pearl's back-door criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}$.

(iii) For all $X \in \mathbf{X}$, $Y \in \mathbf{Y}$, $\mathrm{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) \setminus \mathrm{De}(\mathbf{X}, \mathcal{D})$ *satisfies condition (ii) of Pearl's back-door criterion.*

Maathuis and Colombo (2015) presented a constructive generalized back-door set for a DAG, CPDAG, MAG or PAG $\mathcal{G}$ when $|\mathbf{X}| = 1$. In Lemma 23, we show that any set $\mathbf{Z}$ that satisfies our generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$ such that $\mathbf{Z} \cap \mathrm{PossDe}(\mathbf{X}, \mathcal{G}) = \emptyset$ is a generalized back-door set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. Using this result and Theorem 14, we give a constructive set that satisfies the generalized back-door criterion, when such a set exists. This set is given in Corollary 24. If $|\mathbf{X}| = 1$, our constructive set for the generalized back-door criterion is a superset of the set presented in Maathuis and Colombo (2015) (Corollary 53 in Appendix D).

Lemma 23 *Let* $\mathbf{X}, \mathbf{Y}$ *and* $\mathbf{Z}$ *be pairwise disjoint node sets in a* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$. *If* $\mathcal{G}$ *is amenable relative to* $(\mathbf{X}, \mathbf{Y})$ *and* $\mathbf{Z}$ *satisfies the blocking condition relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$, *then* $\mathbf{Z}$ *satisfies condition (ii) of the generalized back-door criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$.

Corollary 24 *(**Constructive generalized back-door set**) Let* $\mathbf{X}$ *and* $\mathbf{Y}$ *be disjoint node sets in a* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$. *The following statements are equivalent:*

(i) There exists a set that satisfies the generalized back-door criterion relative to $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$.

(ii) $\mathrm{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathrm{PossDe}(\mathbf{X}, \mathcal{G})$ *satisfies the generalized back-door criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$.

(iii) $\mathcal{G}$ *is amenable and* $\mathrm{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathrm{PossDe}(\mathbf{X}, \mathcal{G})$ *satisfies condition (ii) of the generalized back-door criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$.

5.2 Graphs for Which the Criteria Differ

We now define graphical conditions for the existence of a set satisfying one, two, or all three of the mentioned criteria. The main result of this section is given in Theorem 26, which describes the 4 graphical patterns that can appear when there is no set satisfying at least one of the criteria.

Previously, in Lemma 8 and Lemma 16, we described such patterns for our generalized adjustment criterion. In Section 5.1, we showed that any set $\mathbf{Z}$ that satisfies our generalized adjustment criterion such that $\mathbf{Z} \cap \mathrm{PossDe}(\mathbf{X}, \mathcal{G}) = \emptyset$ satisfies the generalized back-door criterion. Thus, to describe an additional pattern that appears when there is no set that satisfies the generalized back-door criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$ we give Lemma 25. Lastly, to complete Theorem 26 we add the pattern described in Lemma 21 that additionally appears when there is no set that satisfies Pearl's back-door criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. Thus, Theorem 26 summarizes and subsumes the results of Lemmas 8, 16, 21 and 25.

Lemma 25 *Let* $\mathbf{X}$ *and* $\mathbf{Y}$ *be disjoint node sets in a* DAG, CPDAG, MAG *or* PAG $\mathcal{G}$ *such that there exists an adjustment set relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$. *There is no set that satisfies the generalized back-door criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$ *if and only if there is a path* p *from* $X \in \mathbf{X}$ *to* $Y \in \mathbf{Y}$ *in* $\mathcal{G}$ *and a node* V *on* p *such that:*

(i) p *is a proper definite status non-causal path from* $\mathbf{X}$ *to* $\mathbf{Y}$ *in* $\mathcal{G}$, *and*

(ii) $V \in \text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \cap \text{PossDe}(\mathbf{X}, \mathcal{G})$ *and is a definite non-collider on* p*, and*

(iii) any collider on p *is in* $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \text{PossDe}(\mathbf{X}, \mathcal{G})$ *and any definite non-collider on* $p(V, Y)$ *is in* $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$*, and*

(iv) path p *is of the form* $X \leftarrow \cdots \leftarrow V \leftarrow\!\bullet W \ldots Y$*, where* $W = Y$ *is possible and if* $W \neq Y$ *then* $V \leftrightarrow W$ *is on* p*.*

Theorem 26 *Let* $\mathbf{X}$ *and* $\mathbf{Y}$ *be disjoint node sets in a* DAG*,* CPDAG*,* MAG *or* PAG $\mathcal{G}$*. Consider the following criteria:*

(1) $\mathcal{G}$ *violates the amenability condition relative to* $(\mathbf{X}, \mathbf{Y})$*.*

(2) There is a proper definite status non-causal path p *from* $\mathbf{X}$ *to* $\mathbf{Y}$ *in* $\mathcal{G}$ *such that every collider on* p *is in* $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ *and every definite non-collider on* p *is in* $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$*.*

(3) There is a path p *from* $\mathbf{X}$ *to* $\mathbf{Y}$ *in* $\mathcal{G}$ *that satisfies (i)–(iv) in Lemma 25.*

(4) There is a back-door path p *from* $\mathbf{X}$ *to* $\mathbf{Y}$ *in* $\mathcal{G}$ *that satisfies (i)–(iv) in Lemma 21.*

The following hold:

(i) There is no set that satisfies the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$ *if and only if (1) or (2) are satisfied.*

(ii) There is no generalized back-door set relative to $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$ *if and only if (1), (2) or (3) are satisfied.*

(iii) If $\mathcal{G}$ *is a* DAG*, then there is no back-door set relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$ *if and only if (1), (2), (3) or (4) are satisfied.*

We now further explore condition (2) in Theorem 26 under the assumption that the DAG, CPDAG, MAG or PAG $\mathcal{G}$ is amenable relative to disjoint node sets $(\mathbf{X}, \mathbf{Y})$ (that is, (1) in Theorem 26 is violated). Condition (2) in Theorem 26 is satisfied relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$ if and only if there is no adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$ (Theorem 5). Corollary 27 provides a simple sufficient condition for condition (2) in Theorem 26 to be satisfied in DAGs, CPDAGs, MAGs and PAGs, as well as a necessary and sufficient condition for condition (2) in Theorem 26 in certain DAGs and CPDAGs.

Corollary 27 *Let* $\mathbf{X}$ *and* $\mathbf{Y}$ *be disjoint node sets in a DAG, CPDAG, MAG or PAG* $\mathcal{G}$ *such that* $\mathcal{G}$ *is amenable relative to* $(\mathbf{X}, \mathbf{Y})$*. The following statements hold:*

(i) If $\mathbf{X} \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \neq \emptyset$*, then there is no adjustment set relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$*.*

(ii) Let $\mathcal{G}$ *be a DAG or CPDAG and* $\mathbf{Y} \subseteq \text{PossDe}(\mathbf{X}, \mathcal{G})$*. Then* $\mathbf{X} \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \neq \emptyset$ *if and only if there is no adjustment set relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{G}$*.*

A necessary condition for both (3) and (4) in Theorem 26 is that $\mathcal{G}$ contains a (possibly) directed path from one node in $\mathbf{X}$ to another node in $\mathbf{X}$. Thus, if $|\mathbf{X}| = 1$, both (3) and (4) in Theorem 26 are violated. Hence, if $|\mathbf{X}| = 1$ there is a (generalized) back-door set relative to $(\mathbf{X}, \mathbf{Y})$ in a DAG (or a CPDAG, MAG or PAG) $\mathcal{G}$, if and only if there is a set satisfying the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$.

We finish this section by giving two corollaries that describe some additional simple conditions under which there exists a set satisfying two or all three of the discussed adjustment criteria. The intuition behind these results is as follows. A necessary condition for the existence of a path p from $\mathbf{X}$ to $\mathbf{Y}$ in a DAG $\mathcal{D}$ that satisfies Lemma 21 is the existence of a causal path from one node in $\mathbf{X}$ to another node in $\mathbf{X}$ in $\mathcal{D}$. This gives us Corollary 28. Similarly, a necessary condition for the existence of a path p from $\mathbf{X}$ to $\mathbf{Y}$ in a DAG, CPDAG, MAG or PAG $\mathcal{G}$ that satisfies Lemma 25 is the existence of a causal path from one node in $\mathbf{X}$ to another node in $\mathbf{X}$ that contains at least one node not in $\mathbf{X}$ in $\mathcal{G}$. Or, in the case when $\mathcal{G}$ is a DAG or CPDAG, another necessary condition for the existence of a path p from $\mathbf{X}$ to $\mathbf{Y}$ that satisfies Lemma 25 in $\mathcal{G}$ is that $\mathbf{Y} \not\subseteq \text{PossDe}(\mathbf{X}, \mathcal{G})$. This gives us Corollary 29.

Corollary 28 *Let* $\mathbf{X}$ *and* $\mathbf{Y}$ *be disjoint node sets in a* DAG $\mathcal{D}$*. If there is no directed path from one node in* $\mathbf{X}$ *to another node in* $\mathbf{X}$ *in* $\mathcal{D}$*, then the following statements are equivalent:*

(i) There exists a set that satisfies the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}$*.*

(ii) There exists a back-door set relative to $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}$*.*

Corollary 29 *Let* $\mathbf{X}$ *and* $\mathbf{Y}$ *be disjoint node sets in a* DAG*,* CPDAG*,* MAG *or* PAG $\mathcal{G}$*. 5.3 Examples

Figure 3 (see Example 3) in Section 3.1 shows a non-amenable graph (that is, condition (1) in Theorem 26 is satisfied). Figure 4(b) (see Example 4) in Section 3.1 shows an amenable graph for which there is no set that satisfies the generalized adjustment criterion (that is, condition (1) in Theorem 26 is violated, but condition (2) is satisfied).

We now give three additional examples. Figure 6(b) (see Example 7) shows an amenable graph for which there is no set that satisfies the generalized adjustment criterion (that is, (2) in Theorem 26 is satisfied). This example illustrates the result of Corollary 27. Figure 6(a) (see Example 7) and Figure 7 (see Example 8) show cases where there is a set that satisfies the generalized adjustment criterion, but there is no generalized back-door set (that is, conditions (1) and (2) in Theorem 26 are violated, but condition (3) is satisfied).

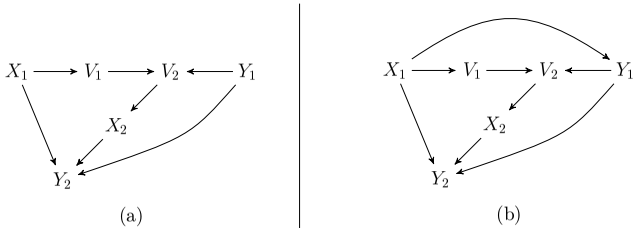

Figure 6: (a) DAG $\mathcal{D}_1$, (b) DAG $\mathcal{D}_2$ used in Example 7.

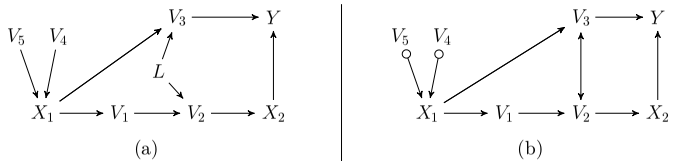

Figure 7: (a) DAG $\mathcal{D}$, (b) PAG $\mathcal{P}$ used in Example 8.

Figure 8 (see Example 9) shows an example of a DAG in which there are sets that satisfy the generalized adjustment criterion and the generalized back-door criterion, but no set satisfies Pearl's back-door criterion (that is, conditions (1), (2) and (3) in Theorem 26 are violated, but condition (4) is satisfied).

Example 7 *Let* $\mathbf{X} = \{X_1, X_2\}$ *and* $\mathbf{Y} = \{Y_1, Y_2\}$ *and consider the* DAG*s* $\mathcal{D}_1$ *and* $\mathcal{D}_2$ *in Figure 6(a) and 6(b) respectively. We first consider* DAG $\mathcal{D}_1$*. The proper non-causal path* $X_2 \leftarrow V_2 \leftarrow Y_1$ *satisfies (i)–(iv) in Lemma 25. Hence, there is no generalized back-door set relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}_1$*. However,* $\{V_1, V_2\}$ *satisfies the generalized adjustment criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}_1$*.*

We now consider DAG $\mathcal{D}_2$*. Note that the only difference between* $\mathcal{D}_1$ *and* $\mathcal{D}_2$ *is the additional edge* $X_1 \to Y_1$ *in* $\mathcal{D}_2$*. This edge implies that* $Y_1 \in \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}_2)$*. Hence, the proper non-causal path* $X_2 \leftarrow V_2 \leftarrow Y_1$ *satisfies (2) in Theorem 26 and thus, there is no set that satisfies the generalized adjustment criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}_2$*. Then by Theorem 5 there is no adjustment set relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}_2$*. Since* $\mathcal{D}_2$ *is a DAG such that* $\mathbf{Y} \subseteq \text{De}(\mathbf{X}, \mathcal{D}_2)$*, (ii) in Corollary 27 implies that* $\mathbf{X} \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}_2) \neq \emptyset$*. This is indeed true, since* $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}_2) = \{X_2, V_2, Y_1, Y_2\}$*.*

Example 8 *Let* $\mathbf{X} = \{X_1, X_2\}$ *and* $\mathbf{Y} = \{Y\}$ *and consider* DAG $\mathcal{D}$ *and* PAG $\mathcal{P}$ *in Figures 7(a) and 7(b). We first consider* DAG $\mathcal{D}$*. Any generalized back-door set relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}$ *must contain* L*. However, the same is not true for the generalized adjustment criterion. For example,* $\{V_1, V_2\}$ *satisfies the generalized adjustment criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}$*.*

We now consider $\mathcal{P}$*. Note that* $\mathcal{P}$ *is the PAG of* $\mathcal{D}$ *when* L *is unobserved. The proper non-causal path* $X_2 \leftarrow V_2 \leftrightarrow V_3 \to Y$ *satisfies (i)–(iv) in Lemma 25. Hence, there is no*

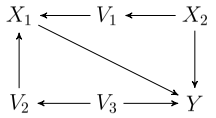

Figure 8: DAG $\mathcal{D}$ used in Example 9.

generalized back-door set relative to $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{P}$*. However, the sets* $\{V_1, V_2\}$*,* $\{V_1, V_2, V_4\}$*,* $\{V_1, V_2, V_5\}$*,* $\{V_1, V_2, V_4, V_5\}$ *all satisfy the generalized adjustment criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{P}$*.*

Example 9 *Let* $\mathbf{X} = \{X_1, X_2\}$ *and* $\mathbf{Y} = \{Y\}$ *and consider* DAG $\mathcal{D}$ *in Figure 8. The non-causal path* $X_1 \leftarrow V_1 \to X_2 \to Y$ *satisfies (i)–(iv) in Lemma 21. Hence, no set can satisfy the back-door criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}$*. However,* $\{V_2\}$*,* $\{V_3\}$*,* $\{V_2, V_3\}$*,* $\{V_1, V_2\}$*,* $\{V_1, V_3\}$*, and* $\{V_1, V_2, V_3\}$ *all satisfy the generalized adjustment criterion and* $\{V_2\}$*,* $\{V_3\}$ *and* $\{V_2, V_3\}$ *all satisfy the generalized back-door criterion relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}$*.*

6. Discussion

We have derived a generalized adjustment criterion that is sound and complete for adjustment in DAGs, MAGs, CPDAGs and PAGs (see Definition 4, Theorem 5). This is relevant in practice, in particular in combination with algorithms that can learn CPDAGs or PAGs from observational data.

In addition to the criterion itself, we have also given all necessary ingredients for implementing efficient algorithms to test the criterion for a given set and to construct all sets that fulfill it, or to learn that no set fulfilling the criterion exists. Thus, we obtain a complete generalization of the algorithmic framework for DAGs and MAGs by van der Zander et al. (2014) to CPDAGs or PAGs. In this sense, our work presented in this paper is a theoretical contribution that closes the chapter on covariate adjustment for DAGs, CPDAGs, MAGs and PAGs without selection variables.

Correa and Bareinboim (2017) define necessary and sufficient graphical conditions for covariate adjustment in latent projection graphs in the presence of selection variables. Future work may explore how to extend their results to MAGs and PAGs with selection variables. Other future work may study the estimation accuracy of estimators based on different adjustment sets. Any valid adjustment set can be used to produce an unbiased estimator of the total causal effect. However, the efficiency of the estimators induced by distinct adjustment sets varies (Greenland et al., 1999; Kuroki and Miyakawa, 2003; Kuroki and Cai, 2004; Hahn, 2004, 1998; Guo and Dawid, 2010; De Luna et al., 2011). Moreover, Kuroki and Miyakawa (2003) and Kuroki and Cai (2004) indicate that a minimal adjustment set does not necessarily lead to the most efficient estimator. Defining a best adjustment set in terms of efficiency is still an open question.

Appendix A. Preliminaries

We first state various existing results and definitions.

Adjacencies, discriminating paths and d-separations. The set of all nodes adjacent to X in a graph $\mathcal{G}$ is denoted by $\mathrm{Adj}(X, \mathcal{G})$. A path $p = \langle X, \dots, Z, V, Y \rangle$ is a *discriminating path* from X to Y for V in graph $\mathcal{G}$, if it consists of at least four nodes, X is not adjacent to Y in $\mathcal{G}$ and every non-endpoint node on $p(X, V)$ is a collider on p and a parent of Y. If $\mathbf{X}$ and $\mathbf{Y}$ are d-separated given $\mathbf{Z}$ in a DAG $\mathcal{D}$, we write $\mathbf{X} \perp_d \mathbf{Y} \mid \mathbf{Z}$.

Definition 30 ***(Distance-from-*$\mathbf{Z}$*)*** *Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a* DAG*,* CPDAG*,* MAG *or* PAG *$\mathcal{G}$. Let p be a path between $\mathbf{X}$ and $\mathbf{Y}$ in $\mathcal{G}$ such that every collider C on p has a possibly directed path (possibly of length 0) to $\mathbf{Z}$. Define the* distance-from-$\mathbf{Z}$ *of C to be the length of a shortest possibly directed path (possibly of length 0) from C to $\mathbf{Z}$, and define the* distance-from-$\mathbf{Z}$ *of p to be the sum of the distances from $\mathbf{Z}$ of the colliders on p.*

If $\mathcal{G}$ is a MAG and p is a path from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\mathbf{Z}$ in $\mathcal{G}$, then Definition 30 reduces to the notion of *distance-from-*$\mathbf{Z}$ in Zhang (2006, p213).

Theorem 31 ***(Wright's rule** cf. Wright, 1921) Let $\mathbf{X} = \mathbf{A}\mathbf{X} + \epsilon$, where $\mathbf{A} \in \mathbb{R}^{k \times k}$, $\mathbf{X} = (X_1, \dots, X_k)^T$ and $\epsilon = (\epsilon_1, \dots, \epsilon_k)^T$ is a vector of mutually independent errors with means zero. Moreover, let $\mathrm{Var}(\mathbf{X}) = \mathbf{I}$. Let $\mathcal{D} = (\mathbf{X}, \mathbf{E})$, be the corresponding* DAG *such that $X_i \to X_j$ in $\mathcal{D}$ if and only if $A_{ji} \neq 0$. A nonzero entry A_{ji} is called the edge coefficient of $X_i \to X_j$. For two distinct nodes $X_i, X_j \in \mathbf{X}$, let $p_1, \dots, p_r$ be all paths between X_i and X_j in $\mathcal{D}$ that do not contain a collider. Then $\mathrm{Cov}(X_i, X_j) = \sum_{s=1}^{r} \pi_s$, where π_s is the product of all edge coefficients along path p_s, $s \in \{1, \dots, r\}$.*

Theorem 32 *(cf. Theorem 3.2.4 Mardia et al., 1980, p63) Let $\mathbf{X} = (\mathbf{X_1}^T, \mathbf{X_2}^T)^T$ be a p-dimensional multivariate Gaussian random vector with mean vector $\mu = (\mu_\mathbf{1}^T, \mu_\mathbf{2}^T)^T$ and covariance matrix $\mathbf{\Sigma} = \begin{bmatrix} \mathbf{\Sigma_{11}} & \mathbf{\Sigma}_{12} \\ \mathbf{\Sigma_{21}} & \mathbf{\Sigma}_{22} \end{bmatrix}$, so that $\mathbf{X_1}$ is a q-dimensional multivariate Gaussian random vector with mean vector $\mu_\mathbf{1}$ and covariance matrix $\mathbf{\Sigma}_{11}$ and $\mathbf{X_2}$ is a $(p-q)$-dimensional multivariate Gaussian random vector with mean vector $\mu_\mathbf{2}$ and covariance matrix $\mathbf{\Sigma}_{22}$. Then $E[\mathbf{X_2} \mid \mathbf{X_1} = \mathbf{x_1}] = \mu_\mathbf{2} + \mathbf{\Sigma}_{21}\mathbf{\Sigma}_{11}^{-1}(\mathbf{x_1} - \mu_\mathbf{1})$.*

Definition 33 ***(Moralization**; Lauritzen and Spiegelhalter, 1988) Let $\mathcal{D}$ be a* DAG*. The moral graph $\mathcal{D}^m$ is formed by adding the edge $A - B$ to any structure of the form $A \to C \leftarrow B$ with $A \notin \mathrm{Adj}(B, \mathcal{D})$ (marrying unmarried parents) and subsequently making all edges in the resulting graph undirected.*

Definition 34 ***(Induced subgraph)*** *Let $\mathbf{X} \subseteq \mathbf{V}$ be a node set in a* DAG *$\mathcal{D} = (\mathbf{V}, \mathbf{E})$. Then $\mathcal{D}_\mathbf{X} = (\mathbf{X}, \mathbf{E_X})$, where $\mathbf{E_X}$ consists of all edges in $\mathbf{E}$ for which both endpoints are in $\mathbf{X}$, is the induced subgraph of $\mathcal{D}$ on $\mathbf{X}$.*

Theorem 35 ***(Reduction of d-separation to node cuts**; cf. Proposition 3 in Lauritzen et al., 1990, cf. Corollary 2 in Richardson, 2003) Let $\mathcal{D}$ be a* DAG *and let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in $\mathcal{D}$. Then $\mathbf{Z}$ d-separates $\mathbf{X}$ and $\mathbf{Y}$ in $\mathcal{D}$ if and only if all paths between $\mathbf{X}$ and $\mathbf{Y}$ in $(\mathcal{D}_{\mathrm{An}(\mathbf{X} \cup \mathbf{Y} \cup \mathbf{Z}, \mathcal{D})})^m$ contain at least one node in $\mathbf{Z}$.*

Lemma 36 ***(Basic property of** CPDAG**s and** PAG**s**; cf. Lemma 1 in Meek, 1995, cf. Lemma 3.3.1 in Zhang, 2006) Let X, Y and Z be distinct nodes in a* CPDAG *or* PAG *$\mathcal{G}$. If $X \bullet\!\!\to Y \circ\!\!-\!\!\bullet Z$, then there is an edge between X and Z with an arrowhead at Z. Furthermore, if the edge between X and Y is $X \to Y$, then the edge between X and Z is either $X \circ\!\!\to Z$ or $X \to Z$ (that is, not $X \leftrightarrow Z$).*

Lemma 37 *(cf. Lemma 1 in Richardson, 2003) Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a* DAG *or* MAG *$\mathcal{G}$. If there is a path p from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$, on which no non-collider is in $\mathbf{Z}$ and every collider on p is in $\mathrm{An}(\mathbf{X} \cup \mathbf{Y} \cup \mathbf{Z}, \mathcal{G})$, then there exists a path q from $X' \in \mathbf{X}$ to $Y' \in \mathbf{Y}$ that is m-connecting given $\mathbf{Z}$ in $\mathcal{G}$.*

Lemma 38 *(Lemma 0 in Zhang, 2006, p208) Let X and Y be distinct nodes in a* MAG *$\mathcal{M}$. If $p = \langle X, \dots, Z, V, Y \rangle$ is a discriminating path from X to Y for V in a* MAG *$\mathcal{M}$, and the corresponding path to $p(X, V)$ in the* PAG *$\mathcal{P}$ of $\mathcal{M}$ is (also) a collider path, then the corresponding path to p in $\mathcal{P}$ is also a discriminating path from X to Y for V.*

Lemma 39 *(cf. Lemma 1 in Zhang, 2006, p208) Let X and Y be distinct nodes and let $\mathbf{Z}$ be a node set that does not contain X and Y in a* MAG *$\mathcal{M}$ (*DAG *$\mathcal{D}$). Let p be a shortest path from X to Y that is m-connecting given $\mathbf{Z}$ in $\mathcal{M}$ ($\mathcal{D}$). Let $\mathcal{P}$ be the* PAG *of $\mathcal{M}$ (*CPDAG *of $\mathcal{D}$) and let p^* in $\mathcal{P}$ be the corresponding path to p in $\mathcal{M}$ ($\mathcal{D}$). Then p^* is a definite status path in $\mathcal{P}$.*

Lemma 40 *(cf. Lemma 2 in Zhang, 2006, p213) Let X and Y be distinct nodes and let $\mathbf{Z}$ be a node set that does not contain X and Y in a* MAG *$\mathcal{M}$ (*DAG *$\mathcal{D}$). Let p be a shortest path from X to Y that is m-connecting given $\mathbf{Z}$ in $\mathcal{M}$ ($\mathcal{D}$) such that no equally short m-connecting path has a shorter distance-from-$\mathbf{Z}$ (see Definition 30) than p does. Let $\mathcal{P}$ be the* PAG *of $\mathcal{M}$ (*CPDAG *of $\mathcal{D}$) and let p^* in $\mathcal{P}$ be the corresponding path to p in $\mathcal{M}$ ($\mathcal{D}$). Then p^* is a definite status path from X to Y that is m-connecting given $\mathbf{Z}$ in $\mathcal{P}$.*

Lemma 41 *(cf. Lemma B.1 in Zhang, 2008b) Let X and Y be distinct nodes in a* CPDAG *or* PAG *$\mathcal{G}$. If $p = \langle X, \dots, Y \rangle$ is a possibly directed path from X to Y in $\mathcal{G}$, then some subsequence of p forms an unshielded possibly directed path from X to Y in $\mathcal{G}$.*

Lemma 42 *(cf. Lemma B.2 in Zhang, 2008b, Lemma 7.2 in Maathuis and Colombo, 2015) Let X and Y be distinct nodes in a* CPDAG *or* PAG *$\mathcal{G}$. If $p = \langle X = V_0, \dots, V_k = Y \rangle$, $k \geq 2$ is an unshielded possibly directed path from X to Y in $\mathcal{G}$, and $V_{i-1} \bullet\!\!\to V_i$ for some $i \in \{1, \dots, k\}$, then $V_{j-1} \to V_j$ for all $j \in \{i+1, \dots, k\}$.*

Lemma 43 *(cf. Theorem 2 in Zhang, 2008b, Lemma 7.6 in Maathuis and Colombo, 2015) Let $\mathcal{G}$ be a* PAG (CPDAG)*. Let $\mathcal{M}$ ($\mathcal{D}$) be the graph resulting from the following procedure applied to a $\mathcal{G}$:*

(1) replace all partially directed edges $\circ\!\!\rightarrow$ in $\mathcal{G}$ with directed edges $\rightarrow$, and

(2) orient the subgraph of $\mathcal{G}$ consisting of all non-directed edges $\circ\!\!-\!\!\circ$ into a DAG *with no unshielded colliders.*

Then $\mathcal{M}$ ($\mathcal{D}$) is in $[\mathcal{G}]$. Moreover, if X is a node in $\mathcal{G}$, then one can always find an orientation of (2) that does not create any new edges into X.

Lemma 44 *(Lemma 7.5 in Maathuis and Colombo, 2015) Let X and Y be two distinct nodes in a* DAG, CPDAG, MAG *or* PAG *$\mathcal{G}$. Then $\mathcal{G}$ cannot have both a possibly directed path from X to Y and an edge of the form $Y \bullet\!\!\rightarrow X$.*

Definition 45 *($DSEP(X,Y,\mathcal{G})$; Spirtes et al., 2000, p136) Let X and Y be two distinct nodes in a* DAG *or* MAG *$\mathcal{G}$. We say that $V \in DSEP(X,Y,\mathcal{G})$ if $V \neq X$ and there is a collider path between X and V in $\mathcal{G}$ such that every node on this path is an ancestor of X or Y in $\mathcal{G}$.*

Definition 46 *($\mathcal{R}$ and $\mathcal{R}_{\underline{X}}$; Maathuis and Colombo, 2015) Let X be a node in a* DAG, CPDAG, MAG *or* PAG *$\mathcal{G}$. Let $\mathcal{R}$ be a* DAG *or* MAG *represented by $\mathcal{G}$, in the following sense. If $\mathcal{G}$ is a* DAG *or* MAG*, let $\mathcal{R} = \mathcal{G}$. If $\mathcal{G}$ is a* CPDAG (PAG)*, let $\mathcal{R}$ be a* DAG (MAG) *in $[\mathcal{G}]$ as defined in Lemma 43, so that $\mathcal{R}$ has the same number of edges into X as $\mathcal{G}$. Let $\mathcal{R}_{\underline{X}}$ be the graph obtained from $\mathcal{R}$ by removing all directed edges out of X that are visible in $\mathcal{G}$.*

Theorem 47 *(Theorem 4.1 in Maathuis and Colombo, 2015) Let X and Y be distinct nodes in a* DAG, CPDAG, MAG *or* PAG *$\mathcal{G}$. Let $\mathcal{R}$ and $\mathcal{R}_{\underline{X}}$ be defined as in Definition 46. Then there exists a generalized back-door set relative to (X,Y) in $\mathcal{G}$ if and only if $Y \notin \mathrm{Adj}(X, \mathcal{R}_{\underline{X}})$ and $DSEP(X,Y,\mathcal{R}_{\underline{X}}) \cap \mathrm{PossDe}(X,\mathcal{G}) = \emptyset$. Moreover, if such a set exists, then $DSEP(X,Y,\mathcal{R}_{\underline{X}})$ is a generalized back-door set relative to (X,Y) in $\mathcal{G}$.*

A.1 Rules of the Do-calculus (Pearl, 2009, Chapter 3.4)

Let $\mathbf{X}', \mathbf{Y}', \mathbf{Z}', \mathbf{W}'$ be pairwise disjoint (possibly empty) sets of nodes in a causal DAG $\mathcal{D}$. Let $\mathcal{D}_{\overline{\mathbf{X}'}}$ denote the graph obtained by deleting all edges into $\mathbf{X}'$ from $\mathcal{D}$. Similarly, let $\mathcal{D}_{\underline{\mathbf{X}'}}$ denote the graph obtained by deleting all edges out of $\mathbf{X}'$ in $\mathcal{D}$ and let $\mathcal{D}_{\overline{\mathbf{X}'}\underline{\mathbf{Z}'}}$ denote the graph obtained by deleting all edges into $\mathbf{X}'$ and all edges out of $\mathbf{Z}'$ in $\mathcal{D}$. Then the following three rules are valid for every density function consistent with $\mathcal{D}$.

Rule 1 (Insertion/deletion of observations) If $\mathbf{Y}' \perp_d \mathbf{Z}' \mid \mathbf{X}' \cup \mathbf{W}'$ in $\mathcal{D}_{\overline{\mathbf{X}'}}$, then

$$f(\mathbf{y}' \mid \mathrm{do}(\mathbf{x}'), \mathbf{w}') = f(\mathbf{y}' \mid \mathrm{do}(\mathbf{x}'), \mathbf{z}', \mathbf{w}'). \tag{4}$$

Rule 2 (Action/observation exchange) If $\mathbf{Y}' \perp_d \mathbf{Z}' \mid \mathbf{X}' \cup \mathbf{W}'$ in $\mathcal{D}_{\overline{\mathbf{X}'}\underline{\mathbf{Z}'}}$, then

$$f(\mathbf{y}' \mid \mathrm{do}(\mathbf{x}'), \mathrm{do}(\mathbf{z}'), \mathbf{w}') = f(\mathbf{y}' \mid \mathrm{do}(\mathbf{x}'), \mathbf{z}', \mathbf{w}'). \tag{5}$$

Rule 3 (Insertion/deletion of actions)If $\mathbf{Y}' \perp_d \mathbf{Z}' \mid \mathbf{X}' \cup \mathbf{W}'$ in $\mathcal{D}_{\overline{\mathbf{X}' \cup \mathbf{Z}'(\mathbf{W}')}}$, then

$$f(\mathbf{y}' \mid \mathrm{do}(\mathbf{x}'), \mathbf{w}') = f(\mathbf{y}' \mid \mathrm{do}(\mathbf{x}'), \mathrm{do}(\mathbf{z}'), \mathbf{w}'), \tag{6}$$

where $\mathbf{Z}'(\mathbf{W}')$ denotes the set of $\mathbf{Z}'$-nodes that are not ancestors of any $\mathbf{W}'$ node in $\mathcal{D}_{\overline{\mathbf{X}'}}$. If $\mathbf{W}' = \emptyset$, then $\mathbf{Z}'(\mathbf{W}') = \mathbf{Z}'$.

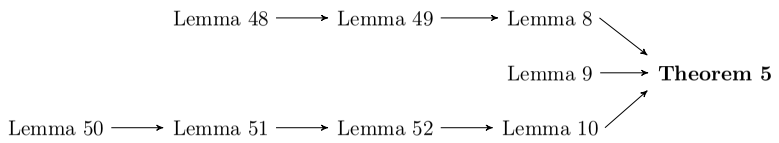

Figure 9: Proof structure of Theorem 5.

A.2 FCI Orientation Rules (Spirtes et al., 2000, p183)

Let A, B, C and D be distinct nodes in a PAG $\mathcal{P}$. Below, we give the first 4 orientation rules of the FCI algorithm defined in Spirtes et al. (2000).
R1 If $A \bullet\!\!\rightarrow B \circ\!\!-\!\!\bullet C$, and A and C are not adjacent, then orient the triple $\langle A, B, C\rangle$ as $A \bullet\!\!\rightarrow B \rightarrow C$.
R2 If $A \rightarrow B \bullet\!\!\rightarrow C$ or $A \bullet\!\!\rightarrow B \rightarrow C$ and $A \bullet\!\!-\!\!\circ C$, then orient $A \bullet\!\!-\!\!\circ C$ as $A \bullet\!\!\rightarrow C$.
R3 If $A \bullet\!\!\rightarrow B \leftarrow\!\!\bullet C$, $A \bullet\!\!-\!\!\circ D \circ\!\!-\!\!\bullet C$, A and C are not adjacent, and $D \bullet\!\!-\!\!\circ B$, then orient $D \bullet\!\!-\!\!\circ B$ as $D \bullet\!\!\rightarrow B$.
R4 If $\langle D, \ldots, A, B, C\rangle$ is a discriminating path from D to C for B and $B \circ\!\!-\!\!\bullet C$, then orient $B \circ\!\!-\!\!\bullet C$ as $B \rightarrow C$ if B is in the separation set of D and C; otherwise orient the triple $\langle A, B, C\rangle$ as $A \leftrightarrow B \leftrightarrow C$.
These four rules were proven to be sound in Spirtes et al. (2000), meaning that edge marks oriented by these rules correspond to invariant edge marks in the maximally informative PAG for the true causal MAG. Six additional orientation rules for the FCI algorithm were defined in Zhang (2008b). The augmented FCI algorithm, including all ten orientation rules was proven to be sound and complete in Zhang (2008b).

Appendix B. Proofs for Section 3

Figure 9 shows how all lemmas in this section fit together to prove Theorem 5.

Lemma 48 *Let X be a node in a* PAG *$\mathcal{P}$. Let $\mathcal{M}$ be a* MAG *$\mathcal{M}$ in $[\mathcal{P}]$ that satisfies Lemma 43. Then any edge that is either $X \circ\!\!-\!\!\circ Y$, $X \circ\!\!\rightarrow Y$ or invisible $X \rightarrow Y$ in $\mathcal{P}$ is invisible $X \rightarrow Y$ in $\mathcal{M}$.*

Proof of Lemma 48. Let $\mathcal{M}$ be a MAG in $[\mathcal{P}]$ that satisfies Lemma 43. Then the edge $X \circ\!\!-\!\!\circ Y$, $X \circ\!\!\rightarrow Y$, or invisible $X \rightarrow Y$ in $\mathcal{P}$ corresponds to edge $X \rightarrow Y$ in $\mathcal{M}$. It is left to prove that $X \rightarrow Y$ is invisible in $\mathcal{M}$ in all these cases.

Suppose for a contradiction that $X \rightarrow Y$ is visible in $\mathcal{M}$. Then there is a node $D \notin \mathrm{Adj}(Y, \mathcal{M})$ such that (1) $D \bullet\!\!\rightarrow X$ is in $\mathcal{M}$, or (2) there is a collider path $\langle D, D_1, \ldots, D_k, X\rangle$, $k \geq 1$, into X such that every $D_i, 1 \leq i \leq k$ is a parent of X in $\mathcal{M}$. We consider these cases separately and show that we arrive at a contradiction.

(1) Since $D \bullet\!\!\rightarrow X$ is in $\mathcal{M}$, the choice of $\mathcal{M}$ implies that $D \bullet\!\!\rightarrow X$ is in $\mathcal{P}$. Since $D \notin \mathrm{Adj}(Y, \mathcal{P})$, $X \rightarrow Y$ must be in $\mathcal{P}$, since otherwise rule **R1** of the FCI algorithm from Spirtes et al. (2000) (see Appendix A) would have been applied in $\mathcal{P}$. But then $X \rightarrow Y$ is visible in $\mathcal{P}$, which is a contradiction.

(2) Path $p = \langle D, D_1, \dots D_k, X, Y\rangle$ is a discriminating path from D to Y for X, that is into X in $\mathcal{M}$. Let p^* be the path in $\mathcal{P}$ corresponding to p in $\mathcal{M}$. Then since $p(D_1, X)$ contains only bi-directed edges in $\mathcal{M}$, the choice of $\mathcal{M}$ implies that $p^*(D_1, X)$ also contains only bi-directed edges in $\mathcal{P}$. Since $D{\bullet\!\!\rightarrow}D_1$ is in $\mathcal{M}$, $D{\circ\!\!-\!\!\circ}D_1$ or $D{\bullet\!\!\rightarrow}D_1$ is in $\mathcal{P}$.

Suppose first that $D{\bullet\!\!\rightarrow}D_1$ is in $\mathcal{P}$, then by Lemma 0 from Zhang (2006) (see Lemma 38), p^* is a discriminating path from D to Y for X, that is into X in $\mathcal{P}$. Hence, $X \to Y$ is in $\mathcal{P}$, since otherwise rule **R4** in Appendix A would have been applied. But then $X \to Y$ is a visible edge in $\mathcal{P}$, which is a contradiction.

Next, suppose that $D{\circ\!\!-\!\!\circ}D_1$ is in $\mathcal{P}$. Since $D_1 \leftrightarrow D_2$ is in $\mathcal{P}$, by Lemma 36 $D{\leftarrow\!\!\bullet}D_2$ is in $\mathcal{P}$. This edge cannot be $D{\leftarrow\!\!\circ}D_2$ or $D \leftarrow D_2$, otherwise $D{\leftarrow\!\!\circ}D_1$ would be in $\mathcal{P}$ (Lemma 36, or **R2** of the FCI orientation rules in Appendix A), contrary to our assumption. Hence, the edge $D \leftrightarrow D_2$ is in $\mathcal{P}$. Then $D \leftrightarrow D_2$ is also in $\mathcal{M}$ and $p_1 = \langle D, D_2, \dots D_k, X, Y\rangle$ is a discriminating path from D to Y for X, that is into X in $\mathcal{M}$. Additionally, since $D \leftrightarrow D_2 \leftrightarrow \cdots \leftrightarrow D_k \leftrightarrow X$ is in $\mathcal{P}$, by Lemma 38 the path ${p_1}^* = \langle D, D_2, \dots D_k, X, Y\rangle$ is a discriminating path from D to Y for X, that is into X. But then $X \to Y$ is a visible edge in $\mathcal{P}$, which is a contradiction. ■

Lemma 49 *Let X and Y be distinct nodes in a* PAG $\mathcal{P}$ *such that there is a possibly directed path p^* from X to Y in $\mathcal{P}$ that does not start with a visible edge out of X. Then there is a* MAG $\mathcal{M}$ *in $[\mathcal{P}]$ such that the path p in $\mathcal{M}$, consisting of the same sequence of nodes as p^* in $\mathcal{P}$, contains a subsequence p' that is a directed path from X to Y starting with an invisible edge in $\mathcal{M}$. In other words, $\mathcal{M}$ violates the amenability condition relative to (X, Y).*

Proof of Lemma 49. If $\mathcal{P}$ violates the amenability condition relative to (X, Y), then there is a possibly directed path p^* from X to Y in $\mathcal{P}$ that does not start with a visible edge out of X. Let $\mathcal{M}$ be a MAG in $[\mathcal{P}]$ that satisfies Lemma 43. We will show that $\mathcal{M}$ violates the amenability condition relative to (X, Y).

Let ${p'}^*$ be a shortest subsequence of p^* such that ${p'}^*$ is also a possibly directed path from X to Y in $\mathcal{P}$ that does not start with a visible edge out of X. We write ${p'}^* = \langle X = V_0, V_1, \dots, V_r = Y\rangle, r \geq 1$. Let p' in $\mathcal{M}$ be the path corresponding to ${p'}^*$ in $\mathcal{P}$. Then by Lemma 48, $X \to V_1$ is an invisible edge in $\mathcal{M}$. It is left to show that p' is a directed path from X to Y in $\mathcal{M}$.

Suppose first that ${p'}^*$ is a definite status path in $\mathcal{P}$. Then all non-endpoint nodes on ${p'}^*$ are definite non-colliders. Hence, $X \to V_1$ in $\mathcal{M}$ implies that all the remaining edges on p' are oriented towards Y.

Else, ${p'}^*$ is not of definite status in $\mathcal{P}$ and $r \geq 2$. Since $X \to V_1$ is in $\mathcal{M}$, it is sufficient to show that $p'(V_1, Y)$ is a directed path from V_1 to Y. Note that by the choice of ${p'}^*$, ${p'}^*(V_1, Y)$ is a shortest possibly directed path from V_1 to Y in $\mathcal{P}$. Hence, it is unshielded (Lemma B.1 from Zhang (2008b), see Lemma 41 in Appendix A). If $V_1{\circ\!\!\rightarrow}V_2$ or $V_1 \to V_2$ is in $\mathcal{P}$, then by the choice of $\mathcal{M}$ (Lemma 43), $V_1 \to V_2$ is in $\mathcal{M}$. Additionally, since $p'(V_1, Y)$ is a possibly directed definite status path, $V_1 \to V_2$ in $\mathcal{M}$ implies that all the remaining edges on $p'(V_1, Y)$ are oriented towards Y.

Otherwise, $V_1{\circ\!\!-\!\!\circ}V_2$ is in $\mathcal{P}$. Path ${p'}^*$ is not of definite status, whereas ${p'}^*(V_1, Y)$ is of definite status, as it is unshielded. Thus, node V_1 is not of definite status on ${p'}^*$ and $X \in \mathrm{Adj}(V_2, \mathcal{P})$. The edge $X{\leftarrow\!\!\bullet}V_2$ is not in $\mathcal{P}$ since ${p'}^*(X, V_2)$ is a possibly directed path from X to V_2 in $\mathcal{P}$ (Lemma 7.5 from Maathuis and Colombo (2015), see Lemma 44 in

Appendix A). Since ${p'}^*$ is a shortest possibly directed path from X to Y in $\mathcal{P}$ that does not start with a visible edge out of X, and $X{\leftarrow\!\!\bullet}V_2$ is not in $\mathcal{P}$, it follows that $X \to V_2$ is visible in $\mathcal{P}$. Since $X \to V_2$ is visible, there is a node $D \notin \mathrm{Adj}(V_2, \mathcal{P})$ such that (1) $D{\bullet\!\!\rightarrow}X$ is in $\mathcal{P}$, or (2) there is a collider path $\langle D, D_1, \dots, D_k, X\rangle, k \geq 1$, that is into X in $\mathcal{P}$ such that every $D_i, 1 \leq i \leq k$ is a parent of V_2 in $\mathcal{P}$. We consider these cases separately and show that we arrive at a contradiction, implying that ${p'}^*(V_1, Y)$ cannot start with $V_1{\circ\!\!-\!\!\circ}V_2$.

(1) A node $D \notin \mathrm{Adj}(V_2, \mathcal{P})$ such that $D{\bullet\!\!\rightarrow}X$ is in $\mathcal{P}$. Since $D{\bullet\!\!\rightarrow}X$ and $X{\circ\!\!-\!\!\circ}V_1$, $X{\circ\!\!\rightarrow}V_1$ or $X \to V_1$ is invisible in $\mathcal{P}$, by Lemma 36 and the definition of visibility, an edge between D and V_1 is in $\mathcal{P}$. This edge is of type $D{\bullet\!\!\rightarrow}V_1$, since otherwise both a possibly directed path $\langle X, V_1, D\rangle$ and $D{\bullet\!\!\rightarrow}X$ are in $\mathcal{P}$ (contrary to Lemma 44). Then $D{\bullet\!\!\rightarrow}V_1{\circ\!\!-\!\!\circ}V_2$ is in $\mathcal{P}$ and Lemma 36 implies that $D \in \mathrm{Adj}(V_2, \mathcal{P})$, a contradiction.

(2) There is a node $D \notin \mathrm{Adj}(V_2, \mathcal{P})$ and a collider path $\langle D, D_1, \dots, D_k, X\rangle, k \geq 1$, into X such that every $D_i, 1 \leq i \leq k$ is a parent of V_2 in $\mathcal{P}$. Paths $D_i \to V_2{\circ\!\!-\!\!\circ}V_1$, $i = 1, \dots, k$ are in $\mathcal{P}$, so by Lemma 36 either $D_i{\circ\!\!\rightarrow}V_1$ or $D_i \to V_1$ is in $\mathcal{P}$, for $i = 1, \dots, k$. If $D_1{\circ\!\!\rightarrow}V_1$ is in $\mathcal{P}$, then $D{\bullet\!\!\rightarrow}D_1{\circ\!\!\rightarrow}V_1$ implies $D{\bullet\!\!\rightarrow}V_1$ is also in $\mathcal{P}$ (Lemma 36). But, then $D{\bullet\!\!\rightarrow}V_1{\circ\!\!-\!\!\circ}V_2$ implies $D \in \mathrm{Adj}(V_2, \mathcal{P})$ (Lemma 36), a contradiction. Hence, $D_1 \to V_1$ is in $\mathcal{P}$.

This allows us to deduce that $D \notin \mathrm{Adj}(V_1, \mathcal{P})$, otherwise $D{\bullet\!\!\rightarrow}D_1 \to V_1$ would imply $D{\bullet\!\!\rightarrow}V_1$ (Lemma 44) and we arrive at the contradiction $D \in \mathrm{Adj}(V_2, \mathcal{P})$, as above. Hence, $\langle D, D_1, D_2, V_1\rangle$ is a discriminating path from D to V_1 for D_2, implying that D_2 is of definite status on this path (**R4** of the FCI orientation rules in Appendix A). Thus, $D_2{\circ\!\!\rightarrow}V_1$ is not possible, and since $D_2 \leftrightarrow V_1$ is already ruled out by Lemma 36, $D_2 \to V_1$ is in $\mathcal{P}$. By the same reasoning, $D_i \to V_1$ is in $\mathcal{P}$, for $i = 3, \dots k$. It then follows that $\langle D, D_1, \dots, D_k, X, V_1\rangle$ is a discriminating path from D to V_1 for X in $\mathcal{P}$, so $X \to V_1$ is in $\mathcal{P}$ (**R4** in Appendix A and the fact that $X{\circ\!\!-\!\!\circ}V_1$, $X{\circ\!\!\rightarrow}V_1$ or invisible $X \to V_1$ is in $\mathcal{P}$) and $X \to V_1$ is visible. This contradicts the fact $X{\circ\!\!-\!\!\circ}V_1$, $X{\circ\!\!\rightarrow}V_1$ or invisible $X \to V_1$ is in $\mathcal{P}$. ■

Proof of Lemma 8. First suppose that $\mathcal{G}$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$, meaning that every proper possibly directed path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$ starts with a visible edge out of $\mathbf{X}$. Any visible edge in $\mathcal{G}$ is visible in all DAGs (MAGs) in $[\mathcal{G}]$, and any proper directed path in a DAG (MAG) in $[\mathcal{G}]$ corresponds to a proper possibly directed path in $\mathcal{G}$. Hence, any proper directed path from $\mathbf{X}$ to $\mathbf{Y}$ in any DAG (MAG) in $[\mathcal{G}]$ starts with a visible edge out of $\mathbf{X}$.

Next, suppose that $\mathcal{G}$ violates the amenability condition relative to $(\mathbf{X}, \mathbf{Y})$. We will show that this implies that there is no adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. Since every directed edge in a CPDAG is visible and since the same does not hold true in a PAG, we give separate proofs for CPDAGs and PAGs.

Suppose that $\mathcal{G}$ is a PAG. Since $\mathcal{G}$ violates the amenability condition relative to $(\mathbf{X}, \mathbf{Y})$, there exists a proper possibly directed path p^* from some $X \in \mathbf{X}$ to some $Y \in \mathbf{Y}$ in $\mathcal{G}$ that does not start with visible edge out of X in $\mathcal{G}$. Then by Lemma 49 there is a MAG $\mathcal{M}$ in $[\mathcal{G}]$ such that the path p in $\mathcal{M}$, consisting of the same sequence of nodes as p^* in $\mathcal{P}$, contains a subsequence p' that is a proper directed path from X to Y starting with an invisible edge in $\mathcal{M}$. Hence, $\mathcal{M}$ violates the amenability condition relative to $(\mathbf{X}, \mathbf{Y})$. Since the generalized adjustment criterion is complete for MAGs (Theorem 5.8 in van der Zander et al., 2014) this means that there is no adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{M}$. Hence, there is no adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$.

Next, suppose $\mathcal{G}$ is a CPDAG. We now show how to find DAGs $\mathcal{D}_1$ and $\mathcal{D}_2$ in $[\mathcal{G}]$, such that a proper causal path q'_1 from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{D}_1$ corresponds to a proper non-causal path q'_2 from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{D}_2$ that does not contain colliders. Since $\mathcal{G}$ is not amenable relative to $(\mathbf{X}, \mathbf{Y})$, there is a proper possibly directed path q^* from a node $X \in \mathbf{X}$ to a node $Y \in \mathbf{Y}$ that starts with a non-directed edge ($\circ\!\!-\!\!\circ$).

Let $q'^* = \langle X = V_0, V_1, \ldots, V_k = Y \rangle, k \geq 1$, be a shortest subsequence of q^* such that q'^* is also a proper possibly directed path from X to Y starting with a non-directed edge in $\mathcal{G}$. Since we chose q'^* using the additional constraint that it must start with a non-directed edge in $\mathcal{G}$, we cannot use Lemma 41 to guarantee that q'^* is of definite status. Hence, we first show that q'^* is a definite status path, by contradiction. Thus, suppose that q'^* is not a definite status path. Then $k \geq 2$. Since the subpath $q'^*(V_1, Y)$ is a definite status path (otherwise, by Lemma 41 we can choose a shorter path), this means that V_1 is not of definite status on q'^*. This implies $X \in \mathrm{Adj}(V_2, \mathcal{G})$. Moreover, we must have $X \to V_2$, since $X \circ\!\!-\!\!\circ V_2$ contradicts the choice of q'^*, and $X \leftarrow V_2$ together with the possibly directed path $q'^*(X, V_2)$ contradicts Lemma 44. Then $X \to V_2$ implies $V_1 \to V_2$, otherwise $X \to V_2$ and a possibly directed path $-q'^*(V_2, X)$ are in $\mathcal{G}$, which contradicts Lemma 44. But then V_1 is a definite non-collider on q'^*, which contradicts that V_1 is not of definite status.

Hence, q'^* is a proper definite status possibly directed path from X to Y. By Lemma 43, there is a DAG $\mathcal{D}_1$ in $[\mathcal{G}]$ such that there are no additional arrowheads into X, as well as a DAG $\mathcal{D}_2$ in $[\mathcal{G}]$ such that there are no additional arrowheads into V_1. Let q'_1 in $\mathcal{D}_1$ (q'_2 in $\mathcal{D}_2$) be the path corresponding to q'^* in $\mathcal{G}$. Then q'_1 is of the form $= X \to V_1 \to \cdots \to Y$ and q'_2 is of the form $X \leftarrow V_1 \to \cdots \to Y$. Since q'_1 is a proper causal path from X to Y and q'_2 is a proper non-causal path from X to Y, $f(\mathbf{y} \mid do(\mathbf{x}))$ generally differs in $\mathcal{D}_1$ and $\mathcal{D}_2$. Since $\mathcal{D}_1$ and $\mathcal{D}_2$ are both represented by $\mathcal{C}$, this implies that $f(\mathbf{y} \mid do(\mathbf{x}))$ is not identifiable in $\mathcal{C}$. ■

Proof of Lemma 9. We first prove (i)⇒(ii). Suppose that $\mathbf{Z} \cap \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) = \emptyset$. Since $\mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) \subseteq \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ ($\mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{M}) \subseteq \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$) for any DAG $\mathcal{D}$ (MAG $\mathcal{M}$) in $[\mathcal{G}]$, it follows directly that $\mathbf{Z}$ satisfies the forbidden set condition relative to $(\mathbf{X}, \mathbf{Y})$ in all DAGs (MAGs) in $[\mathcal{G}]$.

Next, we prove ¬ (i)⇒ ¬ (ii). Suppose that $\mathcal{G}$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$, but there is a node $V \in (\mathbf{Z} \cap \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G}))$. Then $V \in \mathrm{PossDe}(W, \mathcal{G})$ for some $W = V_i, 1 \leq i \leq k$ on a proper possibly directed path $p = \langle X = V_0, V_1, \ldots, V_k = Y \rangle, k \geq 1$. Then $q = p(X, W)$ is proper and $r = p(W, Y)$, where r is allowed to be of zero length (if $W = Y$), does not contain a node in $\mathbf{X}$. Moreover, there is a possibly directed path s from W to V, where this path is allowed to be of zero length. We will show that this implies that there is a DAG $\mathcal{D}$ (MAG $\mathcal{M}$) in $[\mathcal{G}]$ such that $\mathbf{Z} \cap \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) \neq \emptyset$ ($\mathbf{Z} \cap \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{M}) \neq \emptyset$).

By Lemma 41, there are subsequences q', r' and s' of q, r and s that are unshielded possibly directed paths (again r' and s' are allowed to be paths of zero length). Moreover, q' is proper and must start with a directed (visible) edge, since otherwise the concatenated path $q' \oplus r'$, which is a proper possibly directed path from X to Y, would violate the amenability condition. Lemma 42 then implies that q' is a directed path from X to W in $\mathcal{G}$.

By Lemma 43, there is at least one DAG $\mathcal{D}$ (MAG $\mathcal{M}$) in $[\mathcal{G}]$ that has no additional arrowheads into W. In this graph $\mathcal{D}$ ($\mathcal{M}$), the first edge on the path corresponding to r' is oriented out of W and since r' is an unshielded possibly directed path in $\mathcal{P}$, by Lemma 42 the path in $\mathcal{D}$ ($\mathcal{M}$) corresponding to r' is a directed path from W to Y. By the same

reasoning, the path corresponding to s' in $\mathcal{D}$ ($\mathcal{M}$) is a directed path from W to V. Hence, $V \in \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$ ($V \in \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{M})$), so that $\mathbf{Z}$ does not satisfy the forbidden set condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ ($\mathcal{M}$). ■

We now start the path of proving Lemma 10. The most involved part is proving the implication ¬ (ii)⇒ ¬ (i), that is, if there is a proper non-causal path p from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\mathbf{Z}$ in a DAG $\mathcal{D}$ (MAG $\mathcal{M}$) in $[\mathcal{G}]$, then there must be a proper non-causal definite status path p^* from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\mathbf{Z}$ in $\mathcal{G}$ as well. We proceed in three steps. First, we show that proper non-causal paths from $\mathbf{X}$ to $\mathbf{Y}$ that are m-connecting given $\mathbf{Z}$ in $\mathcal{D}$ ($\mathcal{M}$) correspond to proper non-causal paths in $\mathcal{G}$ (Lemma 50). Second, we show that a certain shortest proper non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\mathbf{Z}$ in $\mathcal{D}$ ($\mathcal{M}$) corresponds to a proper definite status non-causal path p^* from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$ (Lemma 51). Lastly, we show that p^* is also m-connecting given $\mathbf{Z}$ in $\mathcal{G}$ (Lemma 52).

Lemma 50 *Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a* PAG (CPDAG) *$\mathcal{P}$. Let $\mathcal{P}$ be amenable relative to $(\mathbf{X}, \mathbf{Y})$ and let $\mathbf{Z}$ satisfy the forbidden set condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{P}$. Let $\mathcal{M}$ be a* MAG (DAG) *in $[\mathcal{P}]$ and let $p = \langle X = V_0, V_1, \ldots, V_n = Y \rangle, n \geq 2$, be a proper non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\mathbf{Z}$ in $\mathcal{M}$. Let p^* in $\mathcal{P}$ denote the path corresponding to p in $\mathcal{M}$. Then:*

(i) Let $i, j \in \mathbb{N}, 0 < i < j \leq n$ such that there is an edge $\langle V_i, V_j \rangle$ in $\mathcal{P}$. The path $p^*(X, V_i) \oplus \langle V_i, V_j \rangle \oplus p^*(V_j, Y)$ ($p^*(V_j, Y)$ is possibly of zero length) is a proper non-causal path in $\mathcal{P}$. For $j = i + 1$, this implies that p^* is a proper non-causal path.

(ii) If V_1 is not of definite status on p^*, then $\langle X, V_2 \rangle \oplus p^*(V_2, Y)$, ($p^*(V_2, Y)$ is possibly of zero length) exists and is a proper non-causal path in $\mathcal{P}$.

(iii) If $n \geq 3$ and $V_k, 2 \leq k < n$ is not of definite status on p^*, and every non-endpoint node on $p^*(X, V_k)$ is a collider on p^* and a parent of V_{k+1} in $\mathcal{M}$, then $\langle X, V_{k+1} \rangle \oplus p^*(V_{k+1}, Y)$, ($p^*(V_{k+1}, Y)$ is possibly of zero length) exists and is a proper non-causal path in $\mathcal{P}$.

.

Proof of Lemma 50. All paths considered are proper as they are subsequences of p^*, which consists of the same sequence of nodes as the proper path p.

(i) Suppose for a contradiction that $q^* = p^*(X, V_i) \oplus \langle V_i, V_j \rangle \oplus p^*(V_j, Y)$ is possibly directed in $\mathcal{P}$. All nodes on q^* except X are in $\mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{P})$. Since $\mathcal{P}$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$, q^* starts with a visible edge $X \to V_1$ in $\mathcal{P}$. Edge $X \to V_1$ is then also in $\mathcal{M}$ and since p is a non-causal path in $\mathcal{M}$, there is at least one collider on p. Let $V_r, r \geq 1$, be the collider closest to X on p. Then $V_r \in \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{P})$. Since p is m-connecting given $\mathbf{Z}$, a descendant of V_r is in $\mathbf{Z}$. This contradicts $\mathbf{Z} \cap \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{P}) = \emptyset$.

(ii) Since V_1 is not of definite status on p^* there is an edge between X and V_2 in $\mathcal{P}$, so path $q^* = \langle X, V_2 \rangle \oplus p^*(V_2, Y)$ exists in $\mathcal{P}$. Suppose for a contradiction that q^* is a possibly directed path from X to Y in $\mathcal{P}$. Then $X \to V_2$ is in $\mathcal{P}$, since $\mathcal{P}$ is amenable relative to

$(\mathbf{X}, \mathbf{Y})$ and every node on q^* except X is in $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{P})$. From (i) above we know that p^* is non-causal, so since q^* is possibly directed, there is an arrowhead towards X on $p^*(X, V_2)$.

First, suppose $X \bullet\!\!\bullet V_1 \leftarrow\!\bullet V_2$. Then $X \rightarrow V_2 \bullet\!\!\rightarrow V_1$ implies $X \bullet\!\!\rightarrow V_1$ is in $\mathcal{P}$, since $\mathcal{P}$ is ancestral. This contradicts that V_1 is not of definite status on p^*.

Next, suppose $X \leftarrow\!\bullet V_1 \bullet\!\!\bullet V_2$ is in $\mathcal{P}$. If $\mathcal{P}$ is a CPDAG then V_1 is a definite non-collider on p^*, which contradicts that V_1 is not of definite status. If $\mathcal{P}$ is a PAG, then since $X \rightarrow V_2$ is a visible edge in $\mathcal{P}$ there is a node $D \notin \text{Adj}(V_2, \mathcal{P})$ such that $D \bullet\!\!\rightarrow X$ in $\mathcal{P}$ (there is a collider path $D \bullet\!\!\rightarrow D_1 \leftrightarrow \cdots \leftrightarrow D_s \leftrightarrow X, s \geq 1$, where every node $D_1, \ldots, D_s$ is a parent of V_2 in $\mathcal{P}$). The path $\langle D, X, V_1, V_2\rangle$ ($\langle D, D_1, \ldots, D_s, X, V_1, V_2\rangle$) is a discriminating path from D to V_2 for V_1 in $\mathcal{P}$ so V_1 is of definite status on p^*, contrary to the assumption.

(iii) If $\mathcal{P}$ is a CPDAG and $p(X, V_k), k \geq 2$ is a collider path, then it must be that $k = 2$ and V_k is of definite status on p. Hence, let $\mathcal{P}$ be a PAG. There is an edge between X and V_{k+1} in $\mathcal{P}$, otherwise by Lemma 38 the subpath $p^*(X, V_{k+1})$ is a discriminating path for V_k in $\mathcal{P}$, so V_k would be of definite status on p^*. Then path $q^* = \langle X, V_{k+1}\rangle \oplus p^*(V_{k+1}, Y)$ exists in $\mathcal{P}$. Suppose for a contradiction that q^* is a possibly directed path from X to Y in $\mathcal{P}$. Because $\mathcal{P}$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$ the edge $X \rightarrow V_{k+1}$ is visible in $\mathcal{P}$. Also, since $V_1 \rightarrow V_{k+1}$ is in $\mathcal{M}$, edge $\langle V_1, V_{k+1}\rangle$ is possibly directed towards V_{k+1} in $\mathcal{P}$.

Consider the edge $X \bullet\!\!\rightarrow V_1$ in $\mathcal{P}$. If $X \bullet\!\!\rightarrow V_1$ is not into X in $\mathcal{P}$ then $p^*(X, V_1) \oplus \langle V_1, V_{k+1}\rangle \oplus p^*(V_{k+1}, Y)$ is a proper possibly directed path from X to Y in $\mathcal{P}$ so $V_1 \in \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{P})$. By assumption V_1 is a collider on p^* in $\mathcal{P}$ and hence also on p in $\mathcal{M}$. Since p is m-connecting given $\mathbf{Z}$, there is a node $Z \in \mathbf{Z}$ such that $Z \in \text{De}(V_1, \mathcal{M})$. Since $\text{De}(V_1, \mathcal{M}) \subseteq \text{PossDe}(V_1, \mathcal{P}) \subseteq \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{P})$, node $Z \in \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{P})$. This contradicts the forbidden set condition.

So $X \leftrightarrow V_1$ must be in $\mathcal{P}$. Since $X \rightarrow V_{k+1}$ is a visible edge in $\mathcal{P}$ there is a node $D \notin \text{Adj}(V_{k+1}, \mathcal{P})$ such that the edge $D \bullet\!\!\rightarrow X$ is in $\mathcal{P}$ (there is a collider path $D \bullet\!\!\rightarrow D_1 \leftrightarrow \cdots \leftrightarrow D_s \leftrightarrow X, s \geq 1$, and every node $D_1, \ldots, D_s$ is a parent of V_{k+1} in $\mathcal{P}$). By Lemma 38, path $\langle D, X, V_1, \ldots, V_k, V_{k+1}\rangle$ ($\langle D, D_1, \ldots, D_s, X, V_1, \ldots, V_k, V_{k+1}\rangle$) is then a discriminating path from D to V_{k+1} for V_k in $\mathcal{P}$. Hence, V_k is of definite status on p^*, contrary to the original assumption. ■

Lemma 51 *Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a* PAG (CPDAG) *$\mathcal{P}$. Let $\mathcal{P}$ be amenable relative to $(\mathbf{X}, \mathbf{Y})$ and let $\mathbf{Z}$ satisfy the forbidden set condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{P}$. Let $\mathcal{M}$ be a* MAG (DAG) *in $[\mathcal{P}]$ and let p be a shortest proper non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\mathbf{Z}$ in $\mathcal{M}$. Let p^* in $\mathcal{P}$ be the corresponding path to p in $\mathcal{M}$. Then p^* is a proper definite status non-causal path in $\mathcal{P}$.*

Proof of Lemma 51. Let $p = \langle X = V_0, V_1, \ldots, V_k = Y\rangle, k \geq 1$, such that $X \in \mathbf{X}, Y \in \mathbf{Y}$. It follows directly that p^* is proper and by (i) in Lemma 50, it is also non-causal in $\mathcal{P}$.

It is left to prove that p^* is of definite status in $\mathcal{P}$. For this we rely on the proof of Lemma 1 from Zhang (2006) (see Lemma 39 in Appendix A) and prove the following claims for p^*.

Claim 1 *If $V_r, 1 \leq r \leq k-1$ is not of definite status on p^*, then V_{r+1} is a parent of V_{r-1} in $\mathcal{M}$.*

Claim 2 *If $V_r, 1 \leq r \leq k-1$ is not of definite status on p^*, then V_{r-1} is a parent of V_{r+1} in $\mathcal{M}$.*

These claims contradict each other, so every node on p^* must be of definite status. Zhang (2006) proved these claims for a path q^* in $\mathcal{P}$, which is the path corresponding to a shortest path q from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\mathbf{Z}$ in $\mathcal{M}$. These claims are proven using the following argument:

If a node on q^* is not of definite status, then a subsequence q'^* that is formed by "jumping" over one, or a sequence of nodes on q^* one of which is not of definite status, constitutes a path in $\mathcal{P}$. Let q' in $\mathcal{M}$ be the path corresponding to q'^* in $\mathcal{P}$. Then q' is a path from $\mathbf{X}$ to $\mathbf{Y}$ that is shorter than q, so it is blocked by $\mathbf{Z}$ in $\mathcal{M}$. By the choice of q', the collider/definite non-collider status of all nodes on q', except two, is the same as on q. Therefore, one of these two nodes must block q' in $\mathcal{M}$. All possible cases for the status of these two nodes are considered in Zhang (2006) and a contradiction is reached in every case that does not support the claim being proven.

Almost exactly the same argument as in Zhang (2006) can be carried out to prove that Claim 1 and 2 hold for p^*. The only difference is in considering the paths that are subsequences of p. Since these paths are shorter than p and proper they are either blocked by $\mathbf{Z}$ or causal in $\mathcal{M}$. However, the subsequences of p considered in the proof of Lemma 39 are either immediately non-causal or they are constructed as in (i)-(iii) in Lemma 50 and thus non-causal by Lemma 50. The argument from Zhang (2006) then still holds for Claims 1 and 2 for p^*. ■

Lemma 52 *Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a* PAG (CPDAG) *$\mathcal{P}$. Let $\mathcal{P}$ be amenable relative to $(\mathbf{X}, \mathbf{Y})$ and let $\mathbf{Z}$ satisfy the forbidden set condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{P}$. Let $\mathcal{M}$ be a* MAG (DAG) *in $[\mathcal{P}]$ and let p be a path with minimal* distance-from-$\mathbf{Z}$ *among the shortest proper non-causal paths from $\mathbf{X}$ to $\mathbf{Y}$ that are m-connecting given $\mathbf{Z}$ in $\mathcal{M}$. Let p^* in $\mathcal{P}$ be the corresponding path to p in $\mathcal{M}$. Then p^* is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\mathbf{Z}$ in $\mathcal{P}$.*

Proof of Lemma 52. By Lemma 51, p^* is a proper definite status non-causal path in $\mathcal{P}$. It is only left to prove that p^* is m-connecting given $\mathbf{Z}$ in $\mathcal{P}$.

Every definite non-collider on p^* in $\mathcal{P}$ corresponds to a non-collider on p in $\mathcal{M}$, and every collider on p^* is also a collider on p. Since p is m-connecting given $\mathbf{Z}$, no non-collider is in $\mathbf{Z}$ and every collider has a descendant in $\mathbf{Z}$. Let Q be an arbitrary collider (if there is one) on p. Then there is a directed path (possibly of zero length) from Q to a node in $\mathbf{Z}$ in $\mathcal{M}$. Let d be a shortest such path from Q to a node in $\mathbf{Z}$. Let d^* in $\mathcal{P}$ denote the corresponding path to p in $\mathcal{M}$. Then d^* is a possibly directed path from Q to Z in $\mathcal{P}$. It is only left to prove that d^* is a directed path. If d^* is of zero length, this is trivially true. Otherwise, suppose for a contradiction that there is a circle mark on d^*. Then d^* must start with a circle mark at Q (Lemma 7.2 from Maathuis and Colombo (2015) and Lemma 42, see Appendix A).

We first prove that d^* is unshielded in $\mathcal{P}$. Suppose for a contradiction that d^* is shielded. Then there exists a subpath $\langle A, B, C\rangle$ of d^* such that the edge $\langle A, C\rangle$ is in $\mathcal{P}$. The path corresponding to $d^*(Q, A) \oplus \langle A, C\rangle \oplus d^*(C, Z)$ must be a non-causal path from Q to Z in $\mathcal{M}$, otherwise we could have chosen a shorter path d. Hence, the edge $A \leftarrow\!\bullet C$ is in $\mathcal{M}$. But path d is directed from Q to Z in $\mathcal{M}$ so $A \rightarrow B \rightarrow C$ is also in $\mathcal{M}$. This contradicts that $\mathcal{M}$ is ancestral.

Let S be the first node on d after Q. If S is not a node on p, then following the proof of Lemma 2 from Zhang (2006) (Lemma 40 in Appendix 2) there exist nodes W on $p(X, Q)$ and

V on $p(Q,Y)$, distinct from Q, such that the path $W \bullet\!\!\rightarrow S \leftarrow\!\!\bullet V$ is in $\mathcal{M}$ and both W and V have the same colliders/non-collider status of both p and $p' = p(X,W) \oplus \langle W,S,V\rangle \oplus p(V,Y)$. Then p' is m-connecting given $\mathbf{Z}$. Since p' is non-causal and shorter than p, or as long as p but with a shorter distance-from-$\mathbf{Z}$ than p, p' must be non-proper, that is, $S \in \mathbf{X}$. But then $\langle S,V\rangle \oplus p(V,Y)$ is a proper non-causal m-connecting path from $\mathbf{X}$ to $\mathbf{Y}$ given $\mathbf{Z}$ that is shorter than p in $\mathcal{M}$. This contradicts our assumption about p.

If S is a node on p, then it lies either on $p(X,Q)$ or $p(Q,Y)$. Assume without loss of generality that S is on $p(Q,Y)$. Following the proof of Lemma 2 from Zhang (2006), there exists a node $W, W \neq Q$, on $p(X,Q)$ such that $W \bullet\!\!\rightarrow S$ is in $\mathcal{M}$ and W has the same collider/non-collider status on both p and $p' = p(X,W) \oplus \langle W,S\rangle \oplus p(S,Y)$. Then p' is m-connecting given $\mathbf{Z}$. Since p' is proper, and shorter than p, or as long as p but with a shorter distance-from-$\mathbf{Z}$ than p, p' must be causal in $\mathcal{M}$. Let p'^* in $\mathcal{P}$ denote the corresponding path to p in $\mathcal{M}$. Then p'^* is a possibly directed path from $\mathbf{X}$ to $\mathbf{Y}$, S is on p'^* and $Z \in \text{PossDe}(S,\mathcal{P})$, so $Z \in \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{P}) \cap \mathbf{Z}$. This is a contradiction with $\mathbf{Z} \cap \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{P}) = \emptyset$. ■

Proof of Lemma 10. Let the CPDAG (PAG) $\mathcal{G}$ be amenable relative to $(\mathbf{X},\mathbf{Y})$, and let $\mathbf{Z} \cap \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G}) = \emptyset$.

We first prove ¬ (i)⇒ ¬ (iii). Assume $\mathbf{Z}$ does not satisfy the blocking condition relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$. Thus, there is a proper definite status non-causal path p from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$ that is m-connecting given $\mathbf{Z}$ in $\mathcal{G}$. Consider any DAG $\mathcal{D}$ (MAG $\mathcal{M}$) in $[\mathcal{G}]$. The path corresponding to p in $\mathcal{D}$ ($\mathcal{M}$) is a proper non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\mathbf{Z}$. Hence, $\mathbf{Z}$ does not satisfy the blocking condition relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{D}$ ($\mathcal{M}$) for all $\mathcal{D}$ ($\mathcal{M}$) in $[\mathcal{G}]$.

The implication ¬ (iii)⇒ ¬ (ii) trivially holds, so it is only left to prove that ¬ (ii)⇒ ¬ (i). Thus, assume that there is a DAG $\mathcal{D}$ (MAG $\mathcal{M}$) in $[\mathcal{G}]$ such that there is a proper non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{D}$ ($\mathcal{M}$) that is m-connecting given $\mathbf{Z}$. We choose a path p with minimal distance-from-$\mathbf{Z}$ among the shortest proper non-causal paths from $\mathbf{X}$ to $\mathbf{Y}$ that are m-connecting given $\mathbf{Z}$ in $\mathcal{D}$ ($\mathcal{M}$). By Lemma 52, the corresponding path p^* in $\mathcal{G}$ is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\mathbf{Z}$. ■

Proof of Theorem 7. Assume that $\mathcal{G}$ is amenable relative to $(\mathbf{X},\mathbf{Y})$ and $\mathbf{Z}$ satisfies the blocking condition relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$. Then it is left to prove that $\mathbf{Z}$ satisfies the blocking condition relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$ if and only if it satisfies the separation condition relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}^{pbd}_{\mathbf{XY}}$.

We first prove that if $\mathbf{Z}$ satisfies the blocking condition, then $\mathbf{Z}$ m-separates $\mathbf{X}$ and $\mathbf{Y}$ in $\mathcal{G}^{pbd}_{\mathbf{XY}}$, that is, $\mathbf{Z}$ blocks all definite status paths from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}^{pbd}_{\mathbf{XY}}$. Since every definite status path from $\mathbf{X}$ to $\mathbf{Y}$ has a proper definite status path as a subpath, it is enough to show that $\mathbf{Z}$ blocks all proper definite status paths from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}^{pbd}_{\mathbf{XY}}$. Let p be a proper definite status path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}^{pbd}_{\mathbf{XY}}$. Then p must be non-causal, since otherwise $\mathcal{G}$ is not amenable. Let p^* in $\mathcal{G}$ be the path corresponding to p in $\mathcal{G}^{pbd}_{\mathbf{XY}}$, consisting of the same sequence of nodes as p. Then p^* is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$. Thus, p^* is blocked by $\mathbf{Z}$. Since removing edges cannot m-connect a previously blocked path, p is blocked by $\mathbf{Z}$ in $\mathcal{G}^{pbd}_{\mathbf{XY}}$.

Next, we prove that if $\mathbf{Z}$ m-separates $\mathbf{X}$ and $\mathbf{Y}$ in $\mathcal{G}^{pbd}_{\mathbf{XY}}$, then $\mathbf{Z}$ satisfies the blocking condition. Suppose for a contradiction that there exists a proper definite status non-causal path p^* from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$ that is m-connecting given $\mathbf{Z}$. Let $\tilde{p}^*$ in $\mathcal{G}^{pbd}_{\mathbf{XY}}$ be the path corresponding to p^* in $\mathcal{G}$, constituted by the same sequence of nodes as p^*, if such a path exists in $\mathcal{G}^{pbd}_{\mathbf{XY}}$.

First, suppose $\tilde{p}^*$ does not exist in $\mathcal{G}^{pbd}_{\mathbf{XY}}$. Then since p^* is proper, it must start with a visible edge $X \rightarrow D$ in $\mathcal{G}$ such that D lies on a proper causal path from X to $\mathbf{Y}$, that is, $D \in \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$. Since p^* is non-causal and of definite status it must contain a collider $C \in \text{PossDe}(D,\mathcal{G})$. Since $\text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$ is descendral (see Definition 13), $C \in \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$ and similarly all descendants of C are in $\text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$. Considering that p^* is m-connecting given $\mathbf{Z}$ and C is a collider on p^*, it follows that $C \in \text{An}(\mathbf{Z},\mathcal{G})$. This contradicts $\mathbf{Z} \cap \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G}) = \emptyset$.

Otherwise, $\tilde{p}^*$ is a path in $\mathcal{G}^{pbd}_{\mathbf{XY}}$. Then $\tilde{p}^*$ is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}^{pbd}_{\mathbf{XY}}$ that is blocked by $\mathbf{Z}$. Since p^* is m-connecting given $\mathbf{Z}$ in $\mathcal{G}$, all colliders on p^* are in $\text{An}(\mathbf{Z},\mathcal{G})$. Since no definite non-collider on p^* is in $\mathbf{Z}$, no definite non-collider on $\tilde{p}^*$ is in $\mathbf{Z}$. However, $\tilde{p}^*$ is blocked by $\mathbf{Z}$ in $\mathcal{G}^{pbd}_{\mathbf{XY}}$, so at least one collider C on $\tilde{p}^*$ (and therefore p^* as well) is not in $\text{An}(\mathbf{Z},\mathcal{G}^{pbd}_{\mathbf{XY}})$. Thus, any directed path from C to $\mathbf{Z}$ must contain a visible edge $X \rightarrow D$, where $D \in \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$. This implies $D \in \text{An}(\mathbf{Z},\mathcal{G})$, which contradicts $\mathbf{Z} \cap \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G}) = \emptyset$. ■

Appendix C. Proofs for Section 4

Proof of Theorem 11. The first part of the theorem follows from from Rule 3 of the do-calculus for DAGs from Pearl (2009), Rule 3 of the do-calculus for MAGs and PAGs from Zhang (2006) and the properties of the CPDAG.

Since the generalized adjustment criterion is sound and complete with respect to adjustment in DAGs, CPDAGs, MAGs and PAGs (Theorem 5), we will prove the second part of this theorem by proving that if $\mathbf{Z}$ satisfies the generalized adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$, then $\mathbf{Z}$ satisfies the generalized adjustment criterion relative to $(\mathbf{X}',\mathbf{Y})$ in $\mathcal{G}$. We prove this by showing that $\mathbf{Z}$ satisfies the three conditions of Definition 4 relative to $(\mathbf{X}',\mathbf{Y})$ in $\mathcal{G}$.

We first show that a possibly directed path from $\mathbf{X}'$ to $\mathbf{Y}$ is proper with respect to $\mathbf{X}'$ if and only if it is proper with respect to $\mathbf{X}$. Since $\mathbf{X}' \subseteq \mathbf{X}$ any path that is proper with respect to $\mathbf{X}$ will also be proper with respect to $\mathbf{X}'$. Hence, we only need to show that if p is a possibly directed path from $X' \in \mathbf{X}'$ to $Y \in \mathbf{Y}$ that is proper with respect to $\mathbf{X}'$, then p is also proper with respect to $\mathbf{X}$. Suppose for a contradiction that p is not proper with respect to $\mathbf{X}$. Let $p(X,Y)$ be the subpath of p that is proper with respect to $\mathbf{X}$. Since $X \notin \mathbf{X}'$, X must be in $\mathbf{X} \setminus \mathbf{X}'$, which contradicts the assumption that there are no possibly directed paths from $\mathbf{X} \setminus \mathbf{X}'$ to $\mathbf{Y}$ that are proper with respect to $\mathbf{X}$.

Then $\text{Forb}(\mathbf{X}',\mathbf{Y},\mathcal{G}) \subseteq \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$, so $\mathbf{Z}$ must satisfy the forbidden set condition relative to $(\mathbf{X}',\mathbf{Y})$ in $\mathcal{G}$. Additionally, since $\mathbf{Z}$ satisfies the generalized adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$, $\mathcal{G}$ must be amenable relative to $(\mathbf{X},\mathbf{Y})$. This means that every possibly directed path from $\mathbf{X}$ to $\mathbf{Y}$ that is proper with respect to $\mathbf{X}$ starts with a visible edge out of $\mathbf{X}$. Since $\mathbf{X}' \subseteq \mathbf{X}$ and since possibly directed paths from $\mathbf{X}'$ to $\mathbf{Y}$ that are proper with respect to $\mathbf{X}'$ are proper with respect to $\mathbf{X}$, it follows that the amenability condition is satisfied relative to $(\mathbf{X}',\mathbf{Y})$ and $\mathcal{G}$.

It is only left to show that $\mathbf{Z}$ satisfies the blocking condition relative to $(\mathbf{X}', \mathbf{Y})$ in $\mathcal{G}$. Since $\mathbf{Z}$ satisfies the blocking condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$ and since $\mathbf{X}' \subseteq \mathbf{X}$, $\mathbf{Z}$ blocks every definite status non-causal path from $\mathbf{X}'$ to $\mathbf{Y}$ that is proper with respect to $\mathbf{X}$. Hence, we only need to show that $\mathbf{Z}$ also blocks every definite status non-causal path from $\mathbf{X}'$ to $\mathbf{Y}$ that is proper with respect to $\mathbf{X}'$, but not proper with respect to $\mathbf{X}$. Let p be one such path from $X' \in \mathbf{X}'$ to $Y \in \mathbf{Y}$. Since p is proper with respect to $\mathbf{X}'$, but not with respect to $\mathbf{X}$, let $X \in \mathbf{X} \setminus \mathbf{X}'$ be the node on p such that $p(X, Y)$ is proper with respect to $\mathbf{X}$. Since there is no possibly directed path from $\mathbf{X} \setminus \mathbf{X}'$ to $\mathbf{Y}$ that is proper with respect to $\mathbf{X}$, $p(X, Y)$ must be a non-causal path from X to Y. Additionally, since $p(X, Y)$ is a subpath of p, $p(X, Y)$ is of definite status. Then $p(X, Y)$ is a non-causal definite status path from $\mathbf{X}$ to $\mathbf{Y}$ that is proper with respect to $\mathbf{X}$, so $p(X, Y)$ is blocked by $\mathbf{Z}$. Thus, p is also blocked by $\mathbf{Z}$. ■

Proof of Lemma 16. There is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$. Among all such paths consider the ones with minimal length and among those let $p = \langle X, \dots, Y \rangle, X \in \mathbf{X}, Y \in \mathbf{Y}$ be the path with a shortest distance-from-$(\mathbf{X} \cup \mathbf{Y})$ in $\mathcal{G}$. By the choice of p, (i) holds. It is left to prove that (ii)−(iv) also hold for p.

(ii) Since p is m-connecting given $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$ and since $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I} = \text{PossAn}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G}) \setminus (\mathbf{X} \cup \mathbf{Y} \cup \mathbf{I})$, any collider on p is in $\text{PossAn}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G})$. Since p is proper, no collider on p is in $\mathbf{X}$. Additionally, no collider C on p is in $\mathbf{Y} \setminus \mathbf{I}$, otherwise $p(X, C)$ is a non-causal path and we could have chosen a shorter p. It is only left to show that no collider on p is in $\mathbf{I}$. Suppose for a contradiction that a collider on p is in $\mathbf{I}$. Since $\mathbf{I}$ is a descendral set, all (possible) descendants of this collider are also in $\mathbf{I}$. But then p is not m-connecting given $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$, a contradiction.

(iii) Any definite non-collider on p is a possible ancestor of an endpoint node of p or of a collider on p. Then it follows from (ii) that any definite non-collider on p is in $\text{PossAn}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G})$. Furthermore, p is m-connecting given $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$, so no definite non-collider on p is in $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$. Since $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I} = \text{PossAn}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G}) \setminus (\mathbf{X} \cup \mathbf{Y} \cup \mathbf{I})$, it follows that all definite non-colliders on p are in $\text{PossAn}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G}) \cap (\mathbf{X} \cup \mathbf{Y} \cup \mathbf{I})$. Since p is proper, no definite non-collider on p is in $\mathbf{X}$. Additionally, no definite non-collider C on p is in $\mathbf{Y} \setminus \mathbf{I}$, otherwise we could have chosen path $p(X, C)$ instead of p. Thus, all definite non-colliders on p are in $\text{PossAn}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G}) \cap \mathbf{I} \subseteq \mathbf{I}$.

(iv) Let C be a collider on p. From (ii), it follows that $C \notin \mathbf{X} \cup \mathbf{Y}$ and that there is an unshielded possibly directed path from C to a node $V \in \mathbf{X} \cup \mathbf{Y}$. Suppose that this path starts with an edge of type $C \circ\!\!-\!\!\circ Q$ (possibly $Q = V$). We derive a contradiction by constructing a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$ and shorter than p, or of the same length as p, but with a shorter distance-from-$(\mathbf{X} \cup \mathbf{Y})$.

Let A and B be nodes on p such that $A \bullet\!\!\rightarrow C \leftarrow\!\!\bullet B$ is a subpath of p (possibly $A = X$, $B = Y$). Then paths $A \bullet\!\!\rightarrow C \circ\!\!-\!\!\circ Q$ and $B \bullet\!\!\rightarrow C \circ\!\!-\!\!\circ Q$ together with Lemma 36 imply that $A \bullet\!\!\rightarrow Q \leftarrow\!\!\bullet B$ is in $\mathcal{G}$.

Since all colliders on p are not in $\mathbf{I}$, and all definite non-colliders on p are in $\mathbf{I}$, and since $\mathbf{I}$ is a descendral set, it follows that no collider on p is a possible descendant of a definite non-collider on p. Thus, if $A \neq X$ $(B \neq Y)$, then $A \leftrightarrow C$ $(C \leftrightarrow B)$ is in $\mathcal{G}$. Moreover, if $A \leftrightarrow C$ $(C \leftrightarrow B)$ is in $\mathcal{G}$, then $A \leftrightarrow Q$ $(Q \leftrightarrow B)$ is in $\mathcal{G}$, otherwise a possibly directed path

$\langle A, Q, C \rangle$ $(\langle B, Q, C \rangle)$ and $C \leftrightarrow A$ $(C \leftrightarrow B)$ are in $\mathcal{G}$, which contradicts Lemma 44. Hence, if $A \neq X$ $(B \neq Y)$, the collider/definite non-collider status of A (B) is the same on p and on $p(X, A) \oplus \langle A, Q \rangle$ $(\langle Q, B \rangle \oplus p(B, Y))$.

Suppose first that $Q \in \mathbf{X} \cup \mathbf{Y}$. If $Q \in \mathbf{X}$, then $\langle Q, B \rangle \oplus p(B, Y)$ is a proper definite status non-causal path that is m-connecting given $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$ in $\mathcal{G}$ and shorter than p. Otherwise, $Q \in \mathbf{Y}$. If $Q \in \mathbf{Y} \cap \mathbf{I}$, this would imply that $C \in \mathbf{I}$, which contradicts (ii). So Q must be in $\mathbf{Y} \setminus \mathbf{I}$. Then $p(X, A) \oplus \langle A, Q \rangle$ is a non-causal path. Hence, we found a proper definite status non-causal path that is m-connecting given $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$ in $\mathcal{G}$ and shorter than p, which is a contradiction.

Next, suppose that $Q \notin \mathbf{X} \cup \mathbf{Y}$. Then if Q is not on p, $p(X, A) \oplus \langle A, Q, B \rangle \oplus p(B, Y)$ is a proper definite status non-causal path that is m-connecting given $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$ in $\mathcal{G}$ and of the same length as p, but with a shorter distance-from-$(\mathbf{X} \cup \mathbf{Y})$. Otherwise, Q is on p. Then Q is a collider on p, otherwise $Q \in \mathbf{I}$ and $C \in \mathbf{I}$. Suppose first that Q is on $p(C, Y)$. Then $p(X, A) \oplus \langle A, Q \rangle \oplus p(Q, Y)$ is a non-causal path because $p(Q, Y)$ is into Q. Hence, there is a proper definite status non-causal path that is m-connecting given $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$ in $\mathcal{G}$ and shorter than p, which is a contradiction. Next, suppose that Q is on $p(X, C)$. Then $p(X, Q) \oplus \langle Q, B \rangle \oplus p(B, Y)$ is a non-causal path since it contains $Q \leftarrow B$. This path is a proper definite status non-causal path that is m-connecting given $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \setminus \mathbf{I}$ in $\mathcal{G}$ and shorter than p, which is a contradiction. ■

The following proof is similar to the proof of Lemma 1 from Richardson (2003) (see Lemma 37 in Appendix A). The difference lies in the fact that Lemma 17 additionally considers CPDAGs and PAGs $\mathcal{G}$ in which we define m-separation (m-connection) only for paths of definite status, as well as the fact that we require the resulting path p to be proper and non-causal from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$.

Proof of Lemma 17. Let p be a path in $\mathcal{G}$ satisfying (i)−(ii). If there is no collider on p, or all colliders on p are in $\text{An}(\mathbf{Z}, \mathcal{G})$, then p is a proper definite status non-causal path that is m-connecting given $\mathbf{Z}$ in $\mathcal{G}$ and the lemma holds.

Hence, assume there is at least one collider C on p that is not in $\text{An}(\mathbf{Z}, \mathcal{G})$. By (ii), $C \in \text{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G}) \setminus \text{An}(\mathbf{Z}, \mathcal{G})$. We now construct a path q from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$ that is m-connecting given $\mathbf{Z}$ and prove it is proper, of definite status and non-causal.

Let D be the node closest to Y on p such that $D \in \text{An}(\mathbf{X}, \mathcal{G}) \setminus \text{An}(\mathbf{Z}, \mathcal{G})$ if such a node exists, otherwise let $D = X$. Let E be the node closest to D on $p(D, Y)$ such that $E \in \text{An}(\mathbf{Y}, \mathcal{G}) \setminus \text{An}(\mathbf{Z}, \mathcal{G})$ if such a node exists, otherwise let $E = Y$. Since at least one collider on p is in $\text{An}(\mathbf{X} \cup \mathbf{Y}) \setminus \text{An}(\mathbf{Z}, \mathcal{G})$, either $D \neq X$ or $E \neq Y$ must hold. Moreover, if $D = X$, then since there is at least one collider C on p that is in $\text{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G}) \setminus \text{An}(\mathbf{Z}, \mathcal{G})$, it follows that $E \neq D$. However, if $D \neq X$, then $D = E$ is possible.

Since $D \in \text{An}(\mathbf{X}, \mathcal{G}) \setminus \text{An}(\mathbf{Z}, \mathcal{G})$, let v_D be a shortest directed path from D to a node in $\mathbf{X}$ (possibly of length zero). Since $E \in \text{An}(\mathbf{Y}, \mathcal{G}) \setminus \text{An}(\mathbf{Z}, \mathcal{G})$, let v_E be a shortest directed path from E to a node in $\mathbf{Y}$ (possibly of length zero). Thus, all non-endpoint nodes on v_D and v_E are in $\text{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G}) \setminus \text{An}(\mathbf{Z}, \mathcal{G})$. Also, by the choice of D and E, no non-endpoint node on $p(D, E)$ is in $\text{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{G}) \setminus \text{An}(\mathbf{Z}, \mathcal{G})$. Hence, no non-endpoint node on either v_D or v_E is also on $p(D, E)$.

Let $q = (-v_D) \oplus p(D, E) \oplus v_E$. We prove that q is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$ that is m-connecting given $\mathbf{Z}$. Path q is of definite status by construction.

To prove that q is proper we must show that no non-endpoint node on v_D or v_E is in $\mathbf{X}$. No non-endpoint node on v_D is in $\mathbf{X}$, otherwise we could have chosen a shorter v_D. Similarly, no non-endpoint node on v_E is in $\mathbf{X}$, as this would contradict the choice of D. It is left to show that q is non-causal from $\mathbf{X}$ to $\mathbf{Y}$ and m-connecting given $\mathbf{Z}$.

We first show that q is m-connecting given $\mathbf{Z}$. By assumption, no definite non-collider on p is in $\mathbf{Z}$. Additionally, if D and E are non-endpoints on p, then all nodes on v_D and v_E are in $\mathrm{An}(\mathbf{X}\cup\mathbf{Y},\mathcal{G})\setminus\mathrm{An}(\mathbf{Z},\mathcal{G})$, that is, no node on either v_D or v_E is in $\mathbf{Z}$. Hence, no definite non-collider on q is in $\mathbf{Z}$. For q to be m-connecting given $\mathbf{Z}$ we still have to show that all colliders on q are in $\mathrm{An}(\mathbf{Z},\mathcal{G})$. Any collider on q is a non-endpoint node on $p(D,E)$. Since no non-endpoint node on $p(D,E)$ is in $\mathrm{An}(\mathbf{X}\cup\mathbf{Y},\mathcal{G})\setminus\mathrm{An}(\mathbf{Z},\mathcal{G})$, by choice of D and E, and all colliders on p are in $\mathrm{An}(\mathbf{X}\cup\mathbf{Y}\cup\mathbf{Z},\mathcal{G})$, by assumption, it follows that any collider on $p(D,E)$ must be in $\mathrm{An}(\mathbf{Z},\mathcal{G})$.

It is only left to show that q is a non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$. If v_D is not of zero length, this is obviously true. If v_D is of zero length, then $q=p(X,E)\oplus v_E$. Since v_E is a directed path from E to Y, we need to show that $p(X,E)$ is non-causal from X to E. Suppose for a contradiction that $p(X,E)$ is possibly directed from X to E. Then q is a proper possibly directed path from $\mathbf{X}$ to $\mathbf{Y}$, so $E\in\mathrm{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})\subseteq\mathbf{I}$. By assumption, there is at least one collider on p, and in particular on $p(E,Y)$. Let C be the collider on $p(E,Y)$ closest to E. Then $C\in\mathrm{De}(E,\mathcal{G})$. Since $\mathrm{De}(E,\mathcal{G})\subseteq\mathrm{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$, it follows that $C\in\mathrm{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$. Since $\mathrm{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})\subseteq\mathbf{I}$, this is in contradiction with (ii). ■

Appendix D. Proofs for Section 5

Proof of Lemma 21. If there is a path p from $\mathbf{X}$ to $\mathbf{Y}$ for which the listed statements hold, then no set $\mathbf{Z}$ such that $\mathbf{Z}\cap\mathrm{De}(\mathbf{X},\mathcal{D})=\emptyset$ can block p.

Conversely, since $\mathbf{Z}\cap\mathrm{De}(\mathbf{X},\mathcal{D})=\emptyset$ and $\mathbf{Z}$ satisfies the generalized adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{D}$, then $\mathbf{Z}'=\mathrm{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{D})\setminus\mathrm{De}(\mathbf{X},\mathcal{D})$ satisfies the generalized adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{D}$ (Theorem 14). Suppose there is no back-door set relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{D}$. Then $\mathbf{Z}'$ violates condition (ii) of Pearl's back-door criterion relative to at least one $X\in\mathbf{X}$ and $Y\in\mathbf{Y}$ in $\mathcal{D}$. Hence, we can choose p to be a shortest back-door path from a node $X\in\mathbf{X}$ to a node $Y\in\mathbf{Y}$ that is d-connecting given $\mathbf{Z}'$ in $\mathcal{D}$. Then the statement in (i) holds for p. We prove that the statements (ii)−(iv) also hold for p.

(ii) Since $\mathbf{Z}'$ satisfies the generalized adjustment criterion and $\mathbf{Z}'$ does not block the back-door path p, it follows that p is not proper. Since p is not proper, a subpath of p forms a proper path q from $\mathbf{X}$ to $\mathbf{Y}$. If q is non-causal, then it is blocked by $\mathbf{Z}'$. But in this case $\mathbf{Z}'$ would block p as well. Hence, q is causal.

(iii) Any non-collider on p is an ancestor of an endpoint or a collider on p. Since p is d-connecting given $\mathbf{Z}'$, all colliders on p are in $\mathrm{An}(\mathbf{Z}',\mathcal{D})$. By our choice of $\mathbf{Z}'$, $\mathrm{An}(\mathbf{Z}',\mathcal{D})\subseteq\mathrm{An}(\mathbf{X}\cup\mathbf{Y},\mathcal{D})$, so all colliders on p are in $\mathrm{An}(\mathbf{X}\cup\mathbf{Y},\mathcal{D})$. Since any non-collider on p is an ancestor of an endpoint or a collider on p, it follows that all non-colliders on p are also in $\mathrm{An}(\mathbf{X}\cup\mathbf{Y},\mathcal{D})$. Moreover, since p is d-connecting given $\mathbf{Z}'$, no non-collider on p is in $\mathbf{Z}'$. Thus, since $\mathbf{Z}'=\mathrm{An}(\mathbf{X}\cup\mathbf{Y},\mathcal{D})\setminus(\mathrm{De}(\mathbf{X},\mathcal{D})\cup\mathbf{Y})$, any non-collider on p must be in $\mathrm{An}(\mathbf{X}\cup\mathbf{Y},\mathcal{D})\cap(\mathrm{De}(\mathbf{X},\mathcal{D})\cup\mathbf{Y})$. Path p is a shortest back-door path from $\mathbf{X}$ to $\mathbf{Y}$, so no non-collider on p is in $\mathbf{Y}$. Hence, all non-colliders on p are in $\mathrm{De}(\mathbf{X},\mathcal{D})$.

Now, assume that there is a collider C on p. This collider is a descendant of X or a non-collider on p, so $C\in\mathrm{De}(\mathbf{X},\mathcal{D})$ as well. However, since $\mathrm{De}(\mathbf{X},\mathcal{D})\cap\mathbf{Z}=\emptyset$ and $\mathrm{De}(C,\mathcal{D})\subseteq\mathrm{De}(\mathbf{X},\mathcal{D})$ it follows that p is blocked by $\mathbf{Z}'$. This contradicts that p is d-connecting given $\mathbf{Z}'$.

(iv) From (ii), it follows that $Y\in\mathrm{De}(\mathbf{X},\mathcal{D})$. Additionally, we've shown in (iii) that there is no collider on p and that all non-collider on p are in $\mathrm{De}(\mathbf{X},\mathcal{D})$. Thus, all nodes on p are in $\mathrm{De}(\mathbf{X},\mathcal{D})$. ■

Proof of Lemma 23. Let p be a definite status back-door path from a node $X\in\mathbf{X}$ to a node $Y\in\mathbf{Y}$ in $\mathcal{G}$. Then there exists a node $X'\in\mathbf{X}$ (possibly $X'=X$) on p such that the subpath $p(X',Y)$ is a proper path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$. Since $p(X',Y)$ is a subpath of p, $p(X',Y)$ is of definite status.

If $X'\neq X$ and X' is a definite non-collider on p, then since $X'\in\mathbf{Z}\cup\mathbf{X}\setminus\{X\}$, p is blocked by $\mathbf{Z}\cup\mathbf{X}\setminus\{X\}$. Else, $X'\neq X$ and X' is a definite collider on p, or $X'=X$ and p is a proper back-door path in $\mathcal{G}$. Since $\mathcal{G}$ is amenable, all proper back-door paths from $\mathbf{X}$ to $\mathbf{Y}$ are also proper non-causal paths from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$. We prove that $\mathbf{Z}\cup\mathbf{X}\setminus\{X\}$ blocks p, by proving that it blocks $p(X',Y)$.

Suppose for a contradiction that $p(X',Y)$ is m-connecting given $\mathbf{Z}\cup\mathbf{X}\setminus\{X\}$ in $\mathcal{G}$. We show that it is then possible to construct a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$, that is m-connecting given $\mathbf{Z}$, which contradicts that $\mathbf{Z}$ satisfies the blocking condition relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$. Since $p(X',Y)$ is a proper back-door path and since $\mathcal{G}$ is amenable relative to $(\mathbf{X},\mathbf{Y})$, $p(X',Y)$ is a non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$. Then since $p(X',Y)$ also of definite status, it must be blocked by $\mathbf{Z}$ in $\mathcal{G}$. Since $p(X',Y)$ is m-connecting given $\mathbf{Z}\cup\mathbf{X}\setminus\{X\}$ and blocked by $\mathbf{Z}$, it follows that no definite non-collider on $p(X',Y)$ is in $\mathbf{Z}$ and there is at least one collider on $p(X',Y)$ that is in $\mathrm{An}(\mathbf{X}\setminus\{X\},\mathcal{G})\setminus\mathrm{An}(\mathbf{Z},\mathcal{G})$. Let C be the collider closest to Y on $p(X',Y)$ such that $C\in\mathrm{An}(\mathbf{X},\mathcal{G})\setminus\mathrm{An}(\mathbf{Z},\mathcal{G})$. Let q be of the form $C\to\cdots\to X''$, $X''\in\mathbf{X}$ be the shortest causal path from C to $\mathbf{X}$. Since $p(X',Y)$ is proper, it follows that $C\neq X''$.

Let D be the node closest to X'' on $-q$ such that D is also on $p(C,Y)$ (possibly $D=C$) and $r=-q(X'',D)\oplus p(D,Y)$. It is left to show that r is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that is m-connecting given $\mathbf{Z}$ in $\mathcal{G}$. Since $p(C,Y)$ does not contain a node in $\mathbf{X}$, it follows that $-q(X'',D)$ is of non-zero length. So r is a definite status non-causal path. Additionally, since q was chosen as the shortest path from C to $\mathbf{X}$, it follows that r is proper. Lastly, since both q and $p(C,Y)$ are m-connecting given $\mathbf{Z}$ and $D\notin\mathbf{Z}$ and D is a definite non-collider on r, it follows that r is m-connecting given Z. ■

Corollary 53 *Let X and Y be distinct nodes in a* DAG, CPDAG, MAG *or* PAG *$\mathcal{G}$ and let $\mathcal{R}_{\underline{X}}$ be a graph as defined in Definition 46. If there exists a generalized back-door set relative to (X,Y) in $\mathcal{G}$, then $DSEP(X,Y,\mathcal{R}_{\underline{X}})\subseteq\mathrm{Adjust}(X,Y,\mathcal{G})\setminus\mathrm{PossDe}(X,\mathcal{G})$.*

Proof of Corollary 53. Since there exists a generalized back-door set relative to (X,Y) in $\mathcal{G}$, by Theorem 47 $DSEP(X,Y,\mathcal{R}_{\underline{X}})\subseteq\mathrm{PossAn}(X\cup Y,\mathcal{G})\setminus(\mathrm{PossDe}(X,\mathcal{G})\cup Y)$ is a generalized back-door set relative to (X,Y) in $\mathcal{G}$. Additionally, by Corollary 24 $\mathrm{Adjust}(X,Y,\mathcal{G})\setminus\mathrm{PossDe}(X,\mathcal{G})$ is also generalized back-door set relative to (X,Y) in $\mathcal{G}$ and $\mathrm{Adjust}(X,Y,\mathcal{G})\setminus\mathrm{PossDe}(X,\mathcal{G})=\mathrm{PossAn}(X\cup Y,\mathcal{G})\setminus(\mathrm{PossDe}(X,\mathcal{G})\cup Y)$. ■

Proof of Lemma 25. Let there be a p from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$ for which (i)−(iv) hold. Then p is a proper definite status non-causal path that is m-connecting given $\text{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{G}) \setminus \text{PossDe}(\mathbf{X},\mathcal{G})$. Thus, $\text{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{G}) \setminus \text{PossDe}(\mathbf{X},\mathcal{G})$ violates the blocking condition relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$ and Theorem 14 implies that there is no adjustment set $\mathbf{Z}$ relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$ such that $\mathbf{Z} \cap \text{PossDe}(\mathbf{X},\mathcal{G}) = \emptyset$.

Conversely, assume there is no adjustment set $\mathbf{Z}$ relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$ such that $\mathbf{Z} \cap \text{PossDe}(\mathbf{X},\mathcal{G}) = \emptyset$. Since there exists an adjustment set relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$, $\mathcal{G}$ is amenable relative to $(\mathbf{X},\mathbf{Y})$. Then Theorem 14 implies that $\text{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{G}) \setminus \text{PossDe}(\mathbf{X},\mathcal{G})$ violates the blocking condition relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$. Hence, there is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$ that is m-connecting given $\text{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{G}) \setminus \text{PossDe}(\mathbf{X},\mathcal{G})$. Then we can use Lemma 16 with $\mathbf{I} = \text{PossDe}(\mathbf{X},\mathcal{G})$ to choose a shortest path p from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$ for which (i)−(iv) in Lemma 16 hold.

We now show that (i)−(iv) in Lemma 25 hold for p.

(i) Follows immediately from (i) in Lemma 16.

(ii) Any definite non-collider on p is in $\text{PossDe}(\mathbf{X},\mathcal{G})$ ((iii) in Lemma 16). Since there is an adjustment set relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$, it follows from Corollary 15 that $\text{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{G})$ satisfies the generalized adjustment criterion. Thus, p is blocked by $\text{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{G})$ and m-connecting given $\text{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{G}) \setminus \text{PossDe}(\mathbf{X},\mathcal{G})$. This implies that at least one definite non-collider on p must be in $\text{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{G}) \cap \text{PossDe}(\mathbf{X},\mathcal{G})$.

For the remainder of the proof let V be the definite non-collider that is closest to Y on p, among all definite non-colliders on p in $\text{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{G}) \cap \text{PossDe}(\mathbf{X},\mathcal{G})$.

(iii) By (ii) in Lemma 16, all colliders on p are in $\text{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{G}) \setminus \text{PossDe}(\mathbf{X},\mathcal{G})$. It is left to show that all definite non-colliders on $p(V,Y)$ are in $\text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$.

All definite non-colliders on p are possible ancestors of an endpoint node of p or a collider on p. Hence, all definite non-colliders on p are in $\text{PossAn}(\mathbf{X}\cup\mathbf{Y},\mathcal{G})$. By (iii) in Lemma 16, all definite non-colliders are also in $\text{PossDe}(\mathbf{X},\mathcal{G})$. Hence, all definite non-colliders on p are in $\text{PossAn}(\mathbf{X}\cup\mathbf{Y},\mathcal{G}) \cap \text{PossDe}(\mathbf{X},\mathcal{G})$. Additionally, by the choice of V, no definite non-collider on $p(V,Y)$ is in $\text{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{G}) \cap \text{PossDe}(\mathbf{X},\mathcal{G})$. Since $\text{Adjust}(\mathbf{X},\mathbf{Y},\mathcal{G}) \cap \text{PossDe}(\mathbf{X},\mathcal{G}) = (\text{PossAn}(\mathbf{X}\cup\mathbf{Y},\mathcal{G}) \cap \text{PossDe}(\mathbf{X},\mathcal{G})) \setminus (\mathbf{X}\cup\mathbf{Y}\cup\text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G}))$, it follows that all definite non-colliders on $p(V,Y)$ are in $\mathbf{X}\cup\mathbf{Y}\cup\text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$. It is only left to show that no definite non-collider on $p(V,Y)$ is in $\mathbf{X}$ or $\mathbf{Y} \setminus \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$. Since p is proper, no definite non-collider on p is in $\mathbf{X}$. Also, no non-endpoint node C on p is in $\mathbf{Y} \setminus \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$, otherwise $p(X,C)$ is a non-causal path and we could have chosen a shorter p. Hence, any definite non-collider on $p(V,Y)$ is in $\text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$.

(iv) Let V_2 be the node closest to Y on p such that $p(V,V_2)$ is a possibly directed path from V to V_2 (possibly of zero length). We will show that $V_2 = V$. Note that V_2 is either Y, V or a collider on p. Since $V_2 \in \text{PossDe}(V,\mathcal{G})$ and $\text{PossDe}(V,\mathcal{G}) \subseteq \text{PossDe}(\mathbf{X},\mathcal{G})$, by (iii) V_2 cannot be a collider on p. Hence, V_2 is either Y or V.

Let V_1 be the node closest to X on p such that $-p(V,V_1)$ is an possibly directed path from V to V_1 (possibly of zero length). We will show that $V_1 = X$. Note that V_1 is either X, V or a collider on p. Using the same reasoning as for V_2, V_1 cannot be a collider on p. So V_1 is either X or V. As V is a definite non-collider on p, either $V_1 \neq V$ or $V_2 \neq V$.

Suppose that $V_2 \neq V$. Then $V_2 = Y$ and $p(V,Y)$ is a possibly directed path from V to Y. Since $V \in \text{PossDe}(\mathbf{X},\mathcal{G})$, let q be a proper possibly directed path from $X' \in \mathbf{X}$ (possibly $X = X'$) to V in $\mathcal{G}$. Let W' (possibly $W' = V$) be the node closest to X' on q that is also on

$p(V,Y)$. Then $q(X',W') \oplus p(W',Y)$ is a proper possibly directed path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$, so $W' \in \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$. Since $V \in \text{PossDe}(W',\mathcal{G})$, it follows that $V \in \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$. This contradicts (ii).

Hence, $V_2 = V$. Then $V_1 = X$ and p is of the form $X \cdots \leftarrow V \leftarrow\!\bullet W \ldots Y$, possibly $W = Y$ is in $\mathcal{G}$. Since p is of definite status, $p(X,V)$ must be of the form $X \leftarrow \cdots \leftarrow V$. If $W \neq Y$, then if W is a definite non-collider on $p(V,Y)$, (iii) implies that $W \in \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$. Hence, $V \leftrightarrow W$ is in $\mathcal{G}$, otherwise $V \in \text{PossDe}(W,\mathcal{G}) \subseteq \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$, which contradicts (ii). Else, W is a collider on $p(V,Y)$, so $V \leftrightarrow W$ must be on p. ■

Proof of Corollary 27. (i) Let $\mathbf{X}' = \mathbf{X} \cap \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$. Since $\mathbf{X}' \neq \emptyset$, there exists a proper possibly directed path $p = \langle X = V_1, \ldots, V_k = Y\rangle, k > 1$, from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$ in $\mathcal{G}$ such that for some V_i, $i \in \{2,\ldots,k\}$, $\text{PossDe}(V_i,\mathcal{G}) \cap \mathbf{X}' \neq \emptyset$. Let $V_j, j \in \{2,\ldots,k\}$, be the node closest to Y on p such that $\text{PossDe}(V_j,\mathcal{G}) \cap \mathbf{X}' \neq \emptyset$. Let q be a shortest possibly directed path from V_j to a node X' in $\mathbf{X}'$. Since p was chosen to be proper with respect to $\mathbf{X}$, we know that $V_j \neq X'$.

By the choice of V_j on p, no other node from $p(V_j,Y)$ is on q. By Lemma 41, let $\overline{p(V_j,Y)}$ be a subsequence of $p(V_j,Y)$ that forms a possibly directed definite status path from V_j to Y. Now, we can concatenate $-q$ and $\overline{p(V_j,Y)}$ to form the path $r = (-q) \oplus \overline{p(V_j,Y)}$. We will show that r is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that does not contain a collider and consists of nodes in $\text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$. This means that r satisfies condition (2) in Theorem 26, so there is no set that satisfies the generalized adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$. By completeness of the generalized adjustment criterion (Theorem 5), there is no adjustment set relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{G}$.

We first show that r is proper with respect to $\mathbf{X}$. Since p is proper with respect to $\mathbf{X}$ and since $V_j \neq X$, $\overline{p(V_j,Y)}$ does not contain a node in $\mathbf{X}$. Additionally, by choice of q, X' is the only node from $\mathbf{X}$ on q. Hence, r is proper with respect to $\mathbf{X}$.

Since q and $\overline{p(V_j,Y)}$ are possibly directed paths from V_j to X' and from V_j to Y, there is no collider on r. Additionally, since $V_j \in \text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$ and since $\text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$ is a descendral set in $\mathcal{G}$, all nodes on r are in $\text{Forb}(\mathbf{X},\mathbf{Y},\mathcal{G})$.

Next, we show that r is of definite status. First, $\overline{p(V_j,Y)}$ is of definite status. Since q is a shortest possibly directed path from V_j to X', it is of definite status by Lemma 41. Hence, if $V_j = Y$, then $r = (-q)$ is of definite status. If $V_j \neq Y$, it is left to show that V_j is of definite status on r.

We prove this by contradiction. Thus, suppose that V_j is not of definite status on r. Let $\langle A,V_j,B\rangle$ be a subpath of r, so that A is the node adjacent to V_j on q and B is the node adjacent to V_j on $\overline{p(V_j,Y)}$. Then $A\bullet\!\!\rightarrow V_j \circ\!\!-\!\!\bullet B$, $A\bullet\!\!-\!\!\circ V_j \leftarrow\!\!\bullet B$, or $A\bullet\!\!-\!\!\circ V_j \circ\!\!-\!\!\bullet B$ is in $\mathcal{G}$ and there is an edge $\langle A,B\rangle$ in $\mathcal{G}$. Since q and $\overline{p(V_j,Y)}$ are possibly directed paths from V_j to X' and from V_j to Y, $A\bullet\!\!\rightarrow V_j \circ\!\!-\!\!\bullet B$ and $A\bullet\!\!-\!\!\circ V_j \leftarrow\!\!\bullet B$ cannot be in $\mathcal{G}$. Hence, $A\bullet\!\!-\!\!\circ V_j \circ\!\!-\!\!\bullet B$ is a subpath of r.

Since $A\bullet\!\!-\!\!\circ V_j \circ\!\!-\!\!\bullet B$ is in $\mathcal{G}$, neither $A\bullet\!\!\rightarrow B$ nor $A \leftarrow\!\!\bullet B$ can be in $\mathcal{G}$ (Lemma 36). This implies that $A \circ\!\!-\!\!\circ B$ is in $\mathcal{G}$ and so, $\langle B,A\rangle \oplus q(A,X')$ is a possibly directed path from B to X', which contradicts the choice of V_j (since B is closer to Y on p).

It is only left to show that r is a non-causal path from X' to Y. We again use a proof by contradiction. Thus, suppose that r is a possibly directed path from X' to Y. Then, since $r(X',V_j) = (-q)$ and q are both possibly directed paths in $\mathcal{G}$, r must start with a

non-directed edge. Hence, r is a proper possibly directed path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$ that starts with a non-directed edge, which contradicts that $\mathcal{G}$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$.

(ii) Let $\mathcal{G}$ be a DAG or CPDAG that is amenable relative to $(\mathbf{X}, \mathbf{Y})$ and let $\mathbf{Y} \subseteq \text{PossDe}(\mathbf{X}, \mathcal{G})$. By (i), it follows that if $\mathbf{X} \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G}) \neq \emptyset$, then there is no adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. Hence, we only prove the converse statement.

If there is no adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$, then by the soundness of the generalized adjustment criterion (Theorem 5) there is no set that satisfies the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. Since $\mathcal{G}$ is amenable relative to $(\mathbf{X}, \mathbf{Y})$, this means that there is a path p from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$ in $\mathcal{G}$ that satisfies condition (2) in Theorem 26 i.e., p is a proper definite status non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{G}$ such that every collider on p is in $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ and every definite non-collider on p is in $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$.

We first note that, since $\mathbf{Y} \subseteq \text{PossDe}(\mathbf{X}, \mathcal{G})$, $\mathbf{Y} \subseteq \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$. We now show, by contradiction, that there is no collider on p. Thus, suppose that there is a collider C on p. Then C must be either a descendant of a non-collider on p or a descendant of both X and Y. Since $C \in \text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$, $C \notin \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$. Moreover, every non-collider on p is in $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ and since $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ is a descendral set, C cannot be a descendant of a non-collider on p. Then p must be of the form $X \to C \leftarrow Y$. Since $Y \in \text{PossDe}(\mathbf{X}, \mathcal{G})$ and $C \in \text{De}(Y, \mathcal{G})$, this contradicts that $C \notin \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$.

Hence, p does not contain a collider. Additionally, p is a non-causal path from X to Y. This implies that there is a node A on p, $A \neq X$, such that $-p(A, X)$ is a directed path from A to X. Since A is either a non-collider on p, or $A = Y$, $A \in \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$. Hence, $X \in \mathbf{X} \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$. ■

Proof of Corollary 28. Since there is no directed path from one node in $\mathbf{X}$ to another node in $\mathbf{X}$ in $\mathcal{D}$, it is easy to see that a path of the form $X \leftarrow V \dots Y$, where $X \in \mathbf{X}, Y \in \mathbf{Y}$ and $V \in \text{De}(\mathbf{X}, \mathcal{D})$ cannot occur in $\mathcal{D}$. Then there can be no path p from $\mathbf{X}$ to $\mathbf{Y}$ that satisfies condition (i) in Lemma 21 (condition (iv) in Lemma 25) in $\mathcal{D}$. Hence, conditions (3) and (4) in Theorem 26 are violated relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$. Then by (i) and (iii) in Theorem 26 it follows that there exists a set that satisfies the generalized adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ if and only if there exists a back-door set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$. ■

Proof of Corollary 29. It is enough to prove that if there exists an adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$ and the assumptions of the corollary hold, then there is no proper definite status non-causal path p_1 that satisfies (i)−(iv) in Lemma 25.

If $\mathcal{G}$ contains no possibly directed path $p = \langle V_1, \dots, V_k \rangle$, with $k \geq 3, \{V_1, V_k\} \subseteq \mathbf{X}$ and $\{V_2, \dots, V_{k-1}\} \cap \mathbf{X} = \emptyset$, it follows that there cannot be a node $V \in \text{PossDe}(\mathbf{X}, \mathcal{G})$ and the path $X \leftarrow \cdots \leftarrow V$ in $\mathcal{G}$. So there cannot be a proper definite status non-causal path p_1 that satisfies (i)−(iv) in Lemma 25.

Next, suppose that $\mathcal{G}$ is a DAG or CPDAG and that $\mathbf{Y} \subseteq \text{PossDe}(\mathbf{X}, \mathcal{G})$ and that there exists an adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. By Corollary 15, it follows that $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ then satisfies the blocking condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. Suppose for a contradiction that there is a proper definite status non-causal path p_1 that satisfies (i)−(iv) in Lemma 25. Then p_1 is of the form $X \leftarrow \cdots \leftarrow V \leftarrow Y$. By assumption $Y \in \text{PossDe}(\mathbf{X}, \mathcal{G})$, so it follows that $Y \in \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$. By the definition of the forbidden set, every other node on p is also in $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$. But then $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ does cannot block p. This is

in contradiction with $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$ satisfying the blocking condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{G}$. ■

Appendix E. Adjustment Criterion for DAGs

In this section we provide the soundness and completeness proof for the adjustment criterion from Shpitser (2012); van der Zander et al. (2014) (see Definition 55). The main result is given in Theorem 56.

This section can be read independently from the rest of the paper. Since we restrict our proof to DAGs, we first define adjustment sets (see Definition 54) and the adjustment criterion (see Definition 55) in DAGs. Thus, Definition 54 and Definition 55 are special cases of Definition 1 and Definition 4 for DAGs.

Definition 54 *(**Adjustment set**; Pearl, 2009, Chapter 3.3.1) Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a causal* DAG *$\mathcal{D}$. Then $\mathbf{Z}$ is an adjustment set relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ if for any density f consistent with $\mathcal{D}$:*

$$f(\mathbf{y} \mid do(\mathbf{x})) = \begin{cases} f(\mathbf{y} \mid \mathbf{x}) & \text{if } \mathbf{Z} = \emptyset, \\ \int_{\mathbf{z}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z}) f(\mathbf{z}) d\mathbf{z} & \text{otherwise.} \end{cases}$$

Definition 55 *(**Adjustment criterion**; cf. Shpitser, 2012, van der Zander et al., 2014) Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a* DAG *$\mathcal{D}$. Let $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$ denote the set of all descendants in $\mathcal{D}$ of any $W \notin \mathbf{X}$ which lies on a proper causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{D}$. Then $\mathbf{Z}$ satisfies the adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ if the following two conditions hold:*

*(**Forbidden set**) $\mathbf{Z} \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) = \emptyset$, and*

*(**Blocking**) all proper non-causal paths from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{D}$ are blocked by $\mathbf{Z}$.*

Definition 55 was introduced in van der Zander et al. (2014) and differs from the definition of the adjustment criterion in Shpitser (2012) in that it uses $\mathcal{D}$ in the forbidden set condition, as opposed to $\mathcal{D}_{\overline{\mathbf{X}}}$, where $\mathcal{D}_{\overline{\mathbf{X}}}$ is the graph obtained by removing all edges into $\mathbf{X}$ from $\mathcal{D}$. These two formulations of the adjustment criterion are equivalent (Remark 4.3 in van der Zander et al., 2014). We now give the main result in Theorem 56, which follows directly from Theorem 57 and Theorem 58. To prove Theorem 58 we rely on Lemma 59 and Lemma 60, which are given later in this section.

Theorem 56 *Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a causal* DAG *$\mathcal{D} = (\mathbf{V}, \mathbf{E})$. Then $\mathbf{Z}$ satisfies the adjustment criterion (see Definition 55) if and only if $\mathbf{Z}$ is an adjustment set (see Definition 54).*

Theorem 57 *(**Completeness of the adjustment criterion for** DAG**s**) Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ be pairwise disjoint node sets in a causal* DAG *$\mathcal{D}$. If $\mathbf{Z}$ does not satisfy the adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$, then there exists a density f consistent with $\mathcal{D}$ such that $f(\mathbf{y} \mid do(\mathbf{x})) \neq \int_{\mathbf{z}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z}) f(\mathbf{z}) d\mathbf{z}$.*

Proof of Theorem 57. Suppose that $\mathbf{Z}$ does not satisfy the adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D} = (\mathbf{V}, \mathbf{E})$. It suffices to show that there is a density consistent with $\mathcal{D}$ such that $E[Y \mid do(\mathbf{X} = \mathbf{1})] \neq \int_z E[Y \mid \mathbf{X} = \mathbf{1}, \mathbf{z}] f(\mathbf{z}) d\mathbf{z}$ for at least one node $Y \in \mathbf{Y}$.

We consider multivariate Gaussian densities with mean vector zero, constructed using linear structural equation models (SEMs) with Gaussian noise. In particular, we let each random variable $A \in \mathbf{V}$ be a linear combination of its parents in $\mathcal{D}$ and a designated Gaussian noise variable ϵ_A with zero mean and a fixed variance. We also assume that the Gaussian noise variables $\{\epsilon_A : A \in \mathbf{V}\}$, are mutually independent. Thus, this model can be parameterized using one number per node (the residual variance) and one number per edge (the edge coefficient).

Since $\mathbf{Z}$ does not satisfy the adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$, $\mathbf{Z}$ violates the forbidden set condition or the blocking condition.

1 If $\mathbf{Z}$ violates the forbidden set condition, then there is a proper causal path $\langle X, V_1, \ldots, V_k = Y \rangle$, $k \geq 1$, from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$ in $\mathcal{D}$ and a node $Z \in \mathbf{Z}$ such that

   (a) $Z = V_i$, for some $i \in \{1, \ldots k-1\}$, or

   (b) $Z \in \mathrm{De}(\mathbf{Y}, \mathcal{D})$, or

   (c) $Z \in \mathrm{De}(V_i, \mathcal{D}) \setminus \{V_1, \ldots, V_{k-1}\}$ for some $i \in \{1, \ldots k-1\}$.

2 If $\mathbf{Z}$ violates the blocking condition, then there exists a proper non-causal path from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$ that is d-connecting given $\mathbf{Z}$ in $\mathcal{D}$ such that:

   (a) the path does not contain any colliders, or

   (b) the path contains at least one collider.

We now discuss these cases systematically.

(i) Suppose there is a path p from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$ that satisfies 2(a) in $\mathcal{D}$. Since p is a proper non-causal path that does not contain colliders, p starts with an edge into X, that is, p is of the form $X \leftarrow \ldots Y$.

We define our SEM so that all edge coefficients except for the ones on p are 0, and all edge coefficients on p are in $(0, 1)$ and small enough so that we can choose the residual variances so that the variance of every random variable in $\mathbf{V}$ is 1. Then the density f generated by this SEM is consistent with the causal DAG $\mathcal{D}$. Moreover, f is also consistent with the causal DAG $\mathcal{D}'$ that is obtained from $\mathcal{D}$ by removing all edges except for the ones on p.

Since $Y \perp_d \mathbf{X}$ in $\mathcal{D}'_{\underline{\mathbf{X}}}$, we use Rule 3 of the do-calculus (see Equation 6 in Appendix A), with $\mathbf{X}' = \emptyset, \mathbf{W}' = \emptyset$, $\mathbf{Z}' = \mathbf{X}$ and $\mathbf{Y}' = \{Y\}$, so that $E[Y \mid do(\mathbf{X} = \mathbf{1})] = E[Y] = 0$.

Since p is proper, no node in $\mathbf{X} \setminus \{X\}$ is on p. Additionally, since p is d-connecting given $\mathbf{Z}$ and p does not contain colliders, no node in $\mathbf{Z}$ is on p. This implies $Y \perp_d \mathbf{Z} \cup \mathbf{X} \setminus \{X\}$ in $\mathcal{D}'$. Furthermore, $Y \perp_d \mathbf{Z} \cup \mathbf{X} \mid \mathbf{S}$ in $\mathcal{D}'$ for any subset $\mathbf{S}$ of the remaining nodes. In particular, we have $Y \perp_d \mathbf{Z} \cup \mathbf{X} \setminus \{X\} \mid X$ in $\mathcal{D}'$, so that $\int_{\mathbf{z}} E[Y \mid \mathbf{X} = \mathbf{1}, \mathbf{z}] f(\mathbf{z}) d\mathbf{z} = E[Y \mid X = 1]$. By Theorem 32, $E[Y \mid X = 1] = \mathrm{Cov}(X, Y)$. By Wright's rule (Theorem 31), $\mathrm{Cov}(X, Y) = a$, where a is the product of all edge coefficients on p. Since $\int_{\mathbf{z}} E[Y \mid \mathbf{X} = \mathbf{1}, \mathbf{z}] f(\mathbf{z}) d\mathbf{z} = a \neq 0$, this case is completed.

Figure 10: An example of path $p \oplus q$ in $\mathcal{D}$ corresponding to (iii), where $Z \in \mathbf{Z}$.

(ii) Suppose no path satisfies 2(a) in $\mathcal{D}$, but there is a path p from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$ that satisfies 1(a) in $\mathcal{D}$. Let $\tilde{\mathbf{Z}}$ be the set of all nodes in $\mathbf{Z}$ that are on p and let $Z \in \tilde{\mathbf{Z}}$.

We define our SEM so that all edge coefficients except the ones on p are 0, and all edge coefficients on p are in $(0, 1)$ and small enough so that we can choose the residual variances such that the variance of every random variable in $\mathbf{V}$ is 1. Then the density f generated by this SEM is consistent with the causal DAG $\mathcal{D}$, and also with the causal DAG $\mathcal{D}'$ that is obtained from $\mathcal{D}$ by removing all edges except for the ones on p.

Since no node from $\mathbf{X} \setminus \{X\}$ is on p, it follows that $Y \perp_d \mathbf{X} \setminus \{X\}$ in $\mathcal{D}'$. Furthermore, $Y \perp_d \mathbf{X} \setminus \{X\} \mid X$ in $\mathcal{D}'_{\underline{X}}$. We use Rule 3 of the do-calculus, with $\mathbf{X}' = \{X\}, \mathbf{W}' = \emptyset$, $\mathbf{Z}' = \mathbf{X} \setminus \{X\}$ and $\mathbf{Y}' = \{Y\}$, so that $E[Y \mid do(\mathbf{X} = \mathbf{1})] = E[Y \mid do(X = 1)]$. This means that we have reduced a joint intervention to a single intervention.

Additionally, since $Y \perp_d X$ in $\mathcal{D}'_{\underline{X}}$, we use Rule 2 of the do-calculus, with $\mathbf{X}' = \emptyset, \mathbf{W}' = \emptyset$, $\mathbf{Z}' = X$ and $\mathbf{Y}' = \{Y\}$, so that $E[Y \mid do(X = 1)] = E[Y \mid X = 1]$. By Theorem 32, $E[Y \mid X = 1] = \mathrm{Cov}(X, Y)$. Let a be the product of all edge coefficients on p. By Wright's rule (Theorem 31), we have that $\mathrm{Cov}(X, Y) = a \neq 0$.

We complete this case by showing that $\int_{\mathbf{z}} E[Y \mid \mathbf{X} = \mathbf{1}, \mathbf{z}] f(\mathbf{z}) d\mathbf{z} = 0$. Since p is proper, no node in $\mathbf{X} \setminus \{X\}$ is on p. Additionally, by our choice of $\tilde{\mathbf{Z}}$, no node in $\mathbf{Z} \setminus \tilde{\mathbf{Z}}$ is on p. Thus, $Y \perp_d \mathbf{X} \cup (\mathbf{Z} \setminus \tilde{\mathbf{Z}}) \mid \tilde{\mathbf{Z}}$ in $\mathcal{D}'$. Then $\int_{\mathbf{z}} E[Y \mid \mathbf{X} = \mathbf{1}, \mathbf{z}] f(\mathbf{z}) d\mathbf{z} = \int_{\tilde{\mathbf{z}}} E[Y \mid \tilde{\mathbf{z}}] f(\tilde{\mathbf{z}}) d\tilde{\mathbf{z}} = E[Y] = 0$.

(iii) Suppose no path satisfies 2(a) or 1(a), but there is a path p from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$ that satisfies 1(b) in $\mathcal{D}$. Choose $Z \in \mathbf{Z}$ such that the causal path q from Y to Z is a shortest causal path from Y to a node in $\mathbf{Z}$. Then Y is the only node that is on both p and q, otherwise there is a cycle in $\mathcal{D}$. Hence, $p \oplus q$ is a causal path from X to Z that contains Y (see Figure 10).

We define our SEM so that all edge coefficients except the ones on $p \oplus q$ are 0, and all edge coefficients on $p \oplus q$ are in $(0, 1)$ and small enough so that we can choose the residual variances such that the variance of every random variable in $\mathbf{V}$ is 1. Then the density f generated by this SEM is consistent with the causal DAG $\mathcal{D}$, as well as with the causal DAG $\mathcal{D}'$ that is obtained from $\mathcal{D}$ by removing all edges except the ones on $p \oplus q$.

Since there is no path that satisfies 2(a) in $\mathcal{D}$, no node from $\mathbf{X}$ is on q. Additionally, since p is proper, no node in $\mathbf{X} \setminus \{X\}$ is on $p \oplus q$. Thus, $Y \perp_d \mathbf{X} \setminus \{X\} \mid X$ in $\mathcal{D}'$. Furthermore, $Y \perp_d \mathbf{X} \setminus \{X\} \mid X$ in $\mathcal{D}'_{\underline{X}}$. Hence, we use Rule 3 of the do-calculus, with $\mathbf{X}' = \{X\}, \mathbf{W}' = \emptyset$, $\mathbf{Z}' = \mathbf{X} \setminus \{X\}$ and $\mathbf{Y}' = \{Y\}$, so that $E[Y \mid do(\mathbf{X} = \mathbf{1})] = E[Y \mid do(X = 1)]$.

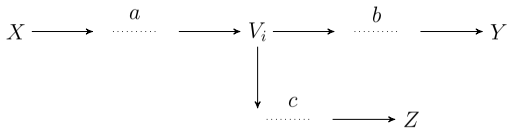

Figure 11: An example of paths p and q_i in $\mathcal{D}$ corresponding to (iv), where $Z \in \mathbf{Z}$.

Moreover, $Y \perp_d X$ in $\mathcal{D}'_{\underline{X}}$. Hence, we use Rule 2 of the do-calculus, with $\mathbf{X}' = \emptyset, \mathbf{W}' = \emptyset$, $\mathbf{Z}' = X$ and $\mathbf{Y}' = \{Y\}$, so that $E[Y \mid do(X = 1)] = E[Y \mid X = 1]$. Lastly, using Theorem 32 and Wright's rule (Theorem 31), we have that $E[Y \mid X = 1] = \mathrm{Cov}(X, Y) = a$, where a is the product of all edge coefficients on p .

Next, we show that $\int_{\mathbf{z}} E[Y \mid \mathbf{X} = \mathbf{1}, \mathbf{z}] f(\mathbf{z}) d\mathbf{z} \neq a$. Since no path satisfies 1(a), no node from $\mathbf{Z}$ is on p. Furthermore, by the choice of q, no node from $\mathbf{Z} \setminus \{Z\}$ is on q. Hence, Z is the only node from $\mathbf{Z}$ that is on $p \oplus q$. From the above, we also know that X is the only node from $\mathbf{X}$ that is on $p \oplus q$. Hence, $Y \perp_d (\mathbf{X} \cup \mathbf{Z}) \setminus \{X, Z\} \mid \{X, Z\}$ in $\mathcal{D}'$ and we have that $\int_{\mathbf{z}} E[Y \mid \mathbf{X} = \mathbf{1}, \mathbf{z}] f(\mathbf{z}) d\mathbf{z} = \int_z E[Y \mid X = 1, z] f(z) dz$.

Let b be the product of all edge coefficients on q. By Wright's rule (Theorem 31), we have that $\mathrm{Cov}(X, Y) = a, \mathrm{Cov}(Y, Z) = b$ and $\mathrm{Cov}(X, Z) = ab$. Now, we use Theorem 32 to calculate $E[Y \mid X = 1, z]$:

$$E[Y \mid X = 1, z] = \begin{bmatrix} a & b \end{bmatrix} \begin{bmatrix} 1 & ab \\ ab & 1 \end{bmatrix}^{-1} \begin{bmatrix} 1 \\ z \end{bmatrix} = \frac{a(1-b^2)}{1-(ab)^2} + \frac{b(1-a^2)}{1-(ab)^2} z.$$

$$\int_z E[Y \mid X = 1, z] f(z) dz = a \frac{1-b^2}{1-(ab)^2} + \frac{b(1-a^2)}{1-(ab)^2} E[Z] = a \frac{1-b^2}{1-(ab)^2}. \tag{7}$$

Since $0 < a < 1$ and $0 < b < 1$, right-hand side of Equation (7) is strictly smaller than $a = E[Y \mid do(\mathbf{X} = \mathbf{1})]$.

(iv) Suppose no path satisfies 1(a), 1(b), or 2(a), but there is a path p from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$ that satisfies 1(c) in $\mathcal{D}$. Let V_i, $i \in \{1, \ldots, k-1\}$, be a node on p that has a shortest causal path to a node in $\mathbf{Z}$. Let q_i be such a shortest causal path from V_i to $\mathbf{Z}$. Then no node except V_i is on both p and q_i, otherwise we would have chosen a different V_i (see Figure 11).

We define our SEM so that all edge coefficients which are not on p or q_i are 0, and all edge coefficients on p and q_i are in $(0, 1)$ and small enough so that we can choose the residual variances so that the variance of every random variable in $\mathbf{V}$ is 1. Then the density f generated by this SEM is consistent with the causal DAG $\mathcal{D}$, as well as with the causal DAG $\mathcal{D}'$ that is obtained from $\mathcal{D}$ by removing all edges except for the ones on p and q_i.

Since there is no path that satisfies 2(a), no node from $\mathbf{X}$ is on q_i. Additionally, since p is proper, no node from $\mathbf{X} \setminus \{X\}$ is on p. Thus, $Y \perp_d \mathbf{X} \setminus \{X\} \mid X$ in $\mathcal{D}'_{\underline{X}}$ and we

use Rule 3 of the do-calculus, with $\mathbf{X}' = \{X\}, \mathbf{W}' = \emptyset$, $\mathbf{Z}' = \mathbf{X} \setminus \{X\}$ and $\mathbf{Y}' = \{Y\}$, so that $E[Y \mid do(\mathbf{X} = \mathbf{1})] = E[Y \mid do(X = 1)]$.

Additionally, $Y \perp_d X$ in $\mathcal{D}'_{\underline{X}}$. Hence, we use Rule 2 of the do-calculus with $\mathbf{X}' = \emptyset, \mathbf{W}' = \emptyset$, $\mathbf{Z}' = \{X\}$ and $\mathbf{Y}' = \{Y\}$, so that $E[Y \mid do(X = 1)] = E[Y \mid X = 1]$. Let a be the product of all edge coefficients on $p(X, V_i)$ and let b be the product of all edge coefficients on $p(V_i, Y)$. Then, using Theorem 32 and Wright's rule (Theorem 31), we have that $E[Y \mid X = 1] = \mathrm{Cov}(X, Y) = ab$.

Since there is no path that satisfies 1(a), no node from $\mathbf{Z}$ is on p. By the choice of q_i, no node from $\mathbf{Z} \setminus \{Z\}$ is on q_i. Hence, no node from $(\mathbf{X} \cup \mathbf{Z}) \setminus \{X, Z\}$ is on p nor q_i. Then $Y \perp_d (\mathbf{X} \cup \mathbf{Z}) \setminus \{X, Z\} \mid \{X, Z\}$ in $\mathcal{D}'$ and it follows that $\int_{\mathbf{z}} E[Y \mid \mathbf{X} = \mathbf{1}, \mathbf{z}] f(\mathbf{z}) d\mathbf{z} = \int_z E[Y \mid X = 1, z] f(z) dz$.

Let c be the product of all edge coefficients on q_i. By Wright's rule (Theorem 31), we have that $\mathrm{Cov}(X, Y) = ab, \mathrm{Cov}(Y, Z) = bc$ and $\mathrm{Cov}(X, Z) = ac$. We can now use Theorem 32 to calculate $E[Y \mid X = 1, z]$:

$$E[Y \mid X = 1, z] = \begin{bmatrix} ab & bc \end{bmatrix} \begin{bmatrix} 1 & ac \\ ac & 1 \end{bmatrix}^{-1} \begin{bmatrix} 1 \\ z \end{bmatrix} = \frac{ab(1-c^2)}{1-(ac)^2} + \frac{bc(1-a^2)}{1-(ac)^2} z.$$

Hence,

$$\int_z E[Y \mid X = 1, z] f(z) dz = \frac{ab(1-c^2)}{1-(ac)^2} + \frac{bc(1-a^2)}{1-(ac)^2} E[Z] = ab \frac{1-c^2}{1-(ac)^2}. \tag{8}$$

Since $0 < a < 1$, $0 < b < 1$ and $0 < c < 1$, right-hand side of Equation (8) is strictly smaller than $ab = E[Y \mid do(\mathbf{X} = \mathbf{1})]$.

(v) Suppose there is no path that satisfies 1(a), 1(b), 1(c), or 2(a), but there is a path that satisfies 2(b) in $\mathcal{D}$. Let p be such a path from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$ in $\mathcal{D}$ that contains the smallest number of colliders among all such paths. Since no path satisfies 2(a), there is at least one collider on p. Let $C_1, \ldots, C_r$, $r \geq 1$, be all colliders on p ordered from the collider closest to X on p, which is C_1, to the collider closest to Y on p, which is C_r. Since p is d-connecting given $\mathbf{Z}$, we have $C_i \in \mathrm{An}(\mathbf{Z}, \mathcal{D})$ for all $i = 1, \ldots, r$. . For each $i = 1, \ldots, r$, let q_i be a shortest path (possibly of length zero) from C_i to $\mathbf{Z}$. Let $\tilde{\mathbf{Z}}$ be the collection of all nodes in $\mathbf{Z}$ that are enpoints of $q_1, \ldots, q_r$.

We define our SEM so that all edge coefficients which are not on $p, q_1, \ldots, q_r$ are 0, and all edge coefficients which are on $p, q_1, \ldots, q_r$ are in $(0, 1)$ and are small enough so that we can choose the residual variances such that the variance of every random variable in $\mathbf{V}$ is 1. Then the density f generated by this SEM is consistent with the causal DAG $\mathcal{D}$, as well as with the causal DAG $\mathcal{D}'$ which is obtained from $\mathcal{D}$ by removing all edges except the ones on p, $q_1, \ldots, q_r$. Moreover, f is a non-degenerate multivariate Gaussian density on $\mathbf{V}$.

Since there is no path that satisfies 2(a) in $\mathcal{D}$, no node from $\mathbf{X}$ is on q_r. Additionally, no node from $\mathbf{X}$ is on q_i, for any $i \in \{1, \ldots, r-1\}$, when $r > 1$, since otherwise there is a proper non-causal path p' from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{D}$ that is d-connecting given $\mathbf{Z}$ and

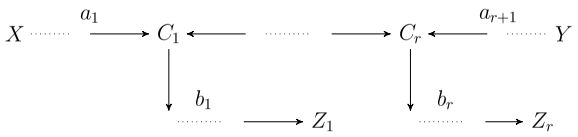

Figure 12: An example of paths p and $q_1, \ldots, q_r$ in $\mathcal{D}$ corresponding to (v).

that contains a smaller number of colliders than p. Hence, X is the only node from $\mathbf{X}$ that is on $p, q_1, \ldots, q_r$.

Since X is the only node from $\mathbf{X}$ that is on $p, q_1, \ldots, q_r$, $Y \perp_d \mathbf{X} \setminus \{X\}$ in $\mathcal{D}'$. By assumption there is at least one collider on p. Since there is no path that satisfies 1(b) in $\mathcal{D}$, Y is not on q_1. Additionally, Y is not on q_i, for any $i \in \{2, \ldots, r\}$, when $r > 1$, otherwise there is a proper non-causal path p' from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{D}$ that is d-connecting given $\mathbf{Z}$ and that contains a smaller number of colliders than p. Hence, $Y \perp_d \mathbf{X}$ in $\mathcal{D}'$. Furthermore, $Y \perp_d \mathbf{X}$ in $\mathcal{D}'_{\overline{X}}$, so we use Rule 3 of the do-calculus, with $\mathbf{X}' = \emptyset, \mathbf{W}' = \emptyset$, $\mathbf{Z}' = \mathbf{X}$ and $\mathbf{Y}' = \{Y\}$, so that $E[Y \mid do(\mathbf{X} = \mathbf{1})] = E[Y] = 0$.

By the choice of $p, q_1, \ldots, q_r$, $\tilde{\mathbf{Z}}$ are the only nodes from $\mathbf{Z}$ that are on $p, q_1, \ldots, q_r$. Then $\{X\} \cup \tilde{\mathbf{Z}}$ are the only nodes from $\mathbf{X} \cup \mathbf{Z}$ that are on $p, q_1, \ldots, q_r$. Hence, $Y \perp_d (\mathbf{X} \cup \mathbf{Z}) \setminus (\{X\} \cup \tilde{\mathbf{Z}})$ in $\mathcal{D}'$. Furthermore, $Y \perp_d (\mathbf{X} \cup \mathbf{Z}) \setminus (\{X\} \cup \tilde{\mathbf{Z}}) \mid \{X\} \cup \tilde{\mathbf{Z}}$ in $\mathcal{D}'$. Hence, $\int_{\mathbf{z}} E[Y \mid \mathbf{X} = \mathbf{1}, \mathbf{z}] f(\mathbf{z}) d\mathbf{z} = \int_{\tilde{\mathbf{z}}} E[Y \mid X = 1, \tilde{\mathbf{z}}] f(\tilde{\mathbf{z}}) d\tilde{\mathbf{z}}$.

We now show $\int_{\tilde{\mathbf{z}}} E[Y \mid X = 1, \tilde{\mathbf{z}}] f(\tilde{\mathbf{z}}) d\tilde{\mathbf{z}} \neq 0$. For this we need the covariance matrix of $(X, \tilde{\mathbf{Z}}, Y)^T$, which we will compute by applying Wright's rule to $\mathcal{D}'$ (see Figure 12). In order to do this, we first need to show that no node on q_i is on q_j, for all $i, j \in \{1, \ldots, r\}$ with $i \neq j$ and that no node on q_i except C_i is on p, for all $i \in \{1, \ldots, r\}$. From this it will follow that each path q_i ends in a different node in $\tilde{\mathbf{Z}}$. We label these nodes as $\tilde{\mathbf{Z}} = (Z_1, \ldots, Z_r)^T$ (see Figure 12).

We start by showing that no node on q_i, except C_i, is on p, for any $i \in \{1, \ldots, r\}$. Suppose for a contradiction that for some $i \in \{1, \ldots, r\}$ a node on q_i, other than C_i, is on p. Then q_i is at least of length 1, that is, $C_i \notin \mathbf{Z}$. Let D be the node closest to C_i on q_i that is also on p. Then D is either on $p(X, C_i)$ or on $p(C_i, Y)$.

Suppose first that D is on $p(X, C_i)$. Let $p' = p(X, D) \oplus (-q_i)(D, C_i) \oplus p(C_i, Y)$. From the above, we know that p' is a proper path from $\mathbf{X}$ to $\mathbf{Y}$. Since $(-q_i)(D, C_i)$ is of the form $D \leftarrow \cdots \leftarrow C_i$, p' is a non-causal path from X to Y. By construction p' will have fewer colliders than p. Hence, p' is a proper non-causal path from X to Y with fewer colliders than p, since C_i is a non-collider on p'. Hence, in order to reach a contradiction, we only need to show that p' is d-connecting given $\mathbf{Z}$.

Since $p, q_1, \ldots, q_r$ are d-connecting given $\mathbf{Z}$, we only need to discuss the collider/non-collider status of D and C_i on p'. Since $C_i \notin \mathbf{Z}$ and since C_i is a non-collider on p', we have that $p'(D, Y) = (-q_i)(D, C_i) \oplus p(C_i, Y)$ is d-connecting given $\mathbf{Z}$. Since D is on q_i, $D \in \mathrm{An}(\mathbf{Z}, \mathcal{D})$. So if D is a collider on p', p' is d-connecting given $\mathbf{Z}$. If D is a non-collider on p', then $(-p)(D, X)$ is out of D, so D is also a non-collider on p. Thus, in this case $D \notin \mathbf{Z}$ and hence, p' is d-connecting given $\mathbf{Z}$.

Next, suppose that D is on $p(C_i, Y)$. Let $p' = p(X, C_i) \oplus q_i(C_i, D) \oplus p(D, Y)$. From the above, we know that p' is a proper path from $\mathbf{X}$ to $\mathbf{Y}$. Since $D \in \mathrm{An}(\mathbf{Z}, \mathcal{D})$ and since there is no path that satisfies 1(a), 1(b), or 1(c), p' cannot be a causal path. Thus, p' is a proper non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that by construction has fewer colliders than p, since C_i is a non-collider on p'. Hence, in order to reach a contradiction, we only need to show that p' is d-connecting given $\mathbf{Z}$.

Since $p, q_1, \ldots, q_r$ are d-connecting given $\mathbf{Z}$, we only need to discuss the collider/non-collider status of D and C_i on p'. Since $C_i \notin \mathbf{Z}$ and since C_i is a non-collider on p', we have that $p'(X, D) = p(X, C_i) \oplus q_i(C_i, D)$ is d-connecting given $\mathbf{Z}$. Similarly as above, $D \in \mathrm{An}(\mathbf{Z}, \mathcal{D})$, so if D is a collider on p', p' is d-connecting given $\mathbf{Z}$. If D is a non-collider on p', then $p(D, Y)$ starts with an edge out of D, so D is also a non-collider on p. Thus, in this case $D \notin \mathbf{Z}$ and hence, p' is d-connecting given $\mathbf{Z}$.

Thus, we have shown that no node on q_i, other than C_i, is on p, for all $i \in \{1, \ldots, r\}$. Next, we consider the case $r > 1$ and show, by contradiction, that no node on q_i is on q_j, for any $i, j \in \{1, \ldots, r\}$ with $i \neq j$. Hence, suppose that there are q_i and q_j such that a node on q_i is also on q_j, for some $i < j$. Let D be the node closest to C_i on q_i, that is also on q_j. Note that from the above, $D \neq C_j$ and $D \neq C_i$, so that q_i and q_j are at least of length 1. Then let $p' = p(X, C_i) \oplus q_i(C_i, D) \oplus (-q_j)(D, C_j) \oplus p(C_j, Y)$. As discussed above, no node on q_i (or q_j) is in $\mathbf{X}$. Hence, p' is a proper path from $\mathbf{X}$ to $\mathbf{Y}$. Since $(-q_j)(D, C_j)$ is of the form $D \leftarrow \cdots \leftarrow C_j$, p' is also a non-causal path from X to Y. Thus p' is a proper non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that by construction has fewer colliders than p, since C_i and C_j are non-colliders on p'. Hence, in order to reach a contradiction we only need to show that it is d-connecting given $\mathbf{Z}$.

Since $p, q_1, \ldots, q_r$ are d-connecting given $\mathbf{Z}$, we only need to discuss the collider/non-collider status of D, C_i and C_j on p'. Since C_i and C_j are non-colliders on p', we have that $p'(X, D)$ and $p'(D, Y)$ are both d-connecting given $\mathbf{Z}$. Since D is on q_i, $D \in \mathrm{An}(\mathbf{Z}, \mathcal{D})$. Since D is a collider on p', p' is d-connecting given $\mathbf{Z}$.

We have now established that $\mathcal{D}'$ looks like Figure 12, where none of the paths intersect, and we can compute the covariance matrix of $(X, \tilde{\mathbf{Z}}^T, Y)^T$ using Wright's rule (Theorem 31) on $\mathcal{D}'$. For this purpose, let a_1 and a_{r+1} be the products of all edge coefficients on $p(X, C_1)$ and $p(C_r, Y)$, respectively. Let b_i, $i \in \{1, \ldots, r\}$ be product of all edge coefficients on q_i. If $r > 1$, let a_j, $j \in \{2, \ldots, r\}$ be the product of all edge coefficients on $p(C_{j-1}, C_j)$. Let $\mathbf{\Sigma}$ be the covariance matrix of $(X, \tilde{\mathbf{Z}}^T, Y)^T$. Then using Wright's rule (Theorem 31) on $\mathcal{D}'$ yields:

$$\mathbf{\Sigma} = \begin{array}{c} \begin{matrix} 1 & 2 & 3 & \cdots & r+1 & r+2 \end{matrix} \\ \begin{bmatrix} 1 & a_1 b_1 & & & & \\ a_1 b_1 & 1 & b_1 a_2 b_2 & & & \\ & b_1 a_2 b_2 & 1 & \ddots & & 0 \\ & & \ddots & \ddots & \ddots & \\ & 0 & & 1 & b_{r-1} a_r b_r & \\ & & & b_{r-1} a_r b_r & 1 & b_r a_{r+1} \\ & & & & b_r a_{r+1} & 1 \end{bmatrix} \end{array} = \begin{bmatrix} \mathbf{\Sigma}_{11} & \mathbf{\Sigma}_{12} \\ \mathbf{\Sigma}_{21} & \mathbf{\Sigma}_{22} \end{bmatrix},$$

where $\mathbf{\Sigma}_{11}$ is the covariance matrix of $(X, \tilde{\mathbf{Z}}^T)^T$, $\mathbf{\Sigma}_{22} = 1$, $\mathbf{\Sigma}_{21} = \mathbf{\Sigma}_{12}^T$ and $\mathbf{\Sigma}_{21} = \begin{bmatrix} 0 & \cdots & 0 & b_r a_{r+1} \end{bmatrix}$, $\mathbf{\Sigma}_{21} \in \mathbb{R}^{1\times(r+1)}$. Then using Theorem 32 we have that

$$E[Y \mid X = 1, \tilde{\mathbf{z}}] = \begin{bmatrix} 0 & \dots & 0 & b_r a_{r+1} \end{bmatrix} \mathbf{\Sigma}_{11}^{-1} \begin{bmatrix} 1 \\ \tilde{\mathbf{z}} \end{bmatrix}.$$

Since our multivariate Gaussian distribution is non-degenerate, $\mathrm{Det}(\mathbf{\Sigma}_{11}) > 0$. Let $t_{i,j}$ denote $(i,j)^{th}$ element of $\mathbf{\Sigma}_{11}^{-1}$, $\mathbf{\Sigma}_{11}^{-1} \in \mathbb{R}^{(r+1)\times(r+1)}$. Putting everything together, we have that

$$\begin{aligned}
\int_{\mathbf{z}} E[Y|\mathbf{X} = \mathbf{1}, \mathbf{z}] f(\mathbf{z}) d\mathbf{z} &= \int_{\tilde{\mathbf{z}}} E[Y|X = 1, \tilde{\mathbf{z}}] f(\tilde{\mathbf{z}}) d\tilde{\mathbf{z}} \\
&= \int_{\tilde{\mathbf{z}}} \begin{bmatrix} 0 & \dots & 0 & b_r a_{r+1} \end{bmatrix} \begin{bmatrix} t_{1,1} & \dots & t_{1,r+1} \\ \vdots & \ddots & \vdots \\ t_{r+1,1} & \dots & t_{r+1,r+1} \end{bmatrix} \begin{bmatrix} 1 \\ \tilde{\mathbf{z}} \end{bmatrix} f(\tilde{\mathbf{z}}) d\tilde{\mathbf{z}} \\
&= b_r a_{r+1} t_{r+1,1} + \sum_{i=1}^{r} b_r a_{r+1} t_{r+1,i+1} E[Z_i] = b_r a_{r+1} t_{r+1,1}.
\end{aligned}$$

Since $b_r \neq 0$ and $a_{r+1} \neq 0$, it is only left to show that $t_{r+1,1} \neq 0$. Using standard linear algebra, we find

$$\begin{aligned}
t_{r+1,1} &= \frac{(-1)^r}{\mathrm{Det}(\mathbf{\Sigma}_{11})} \begin{vmatrix} a_1 b_1 & 1 & b_1 a_2 b_2 & & & \\ & b_1 a_2 b_2 & 1 & b_2 a_3 b_3 & & 0 \\ & & \ddots & \ddots & \ddots & \\ & 0 & & b_{r-3} a_{r-2} b_{r-2} & 1 & b_{r-2} a_{r-1} b_{r-1} \\ & & & & b_{r-2} a_{r-1} b_{r-1} & 1 \\ & & & & & b_{r-1} a_r b_r \end{vmatrix} \\
&= \frac{(-1)^r a_r b_r}{\mathrm{Det}(\mathbf{\Sigma}_{11})} \prod_{i=1}^{r-1} a_i b_i^2.
\end{aligned}$$

Since $a_i \neq 0$ and $b_i \neq 0$ for all $i \in \{1, \dots, r\}$, the proof is completed.

■

Theorem 58 ***(Soundness of the adjustment criterion for*** DAG***s)*** *Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z_0}$ be pairwise disjoint node sets in a causal* DAG *$\mathcal{D}$. If $\mathbf{Z_0}$ satisfies the adjustment criterion (see Definition 55), then $\mathbf{Z_0}$ is an adjustment set (see Definition 54).*

Proof of Theorem 58. Assume that $\mathbf{Z_0}$ satisfies the adjustment criterion (see Definition 55) relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ and let f be a density consistent with $\mathcal{D}$. We need to show that

$$f(\mathbf{y} \mid \mathrm{do}(\mathbf{x})) = \int_{\mathbf{z_0}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_0}) f(\mathbf{z_0}) d\mathbf{z_0}. \tag{9}$$

Let $\mathbf{Y_D} = \mathbf{Y} \cap \mathrm{De}(\mathbf{X}, \mathcal{D})$ and $\mathbf{Y_N} = \mathbf{Y} \setminus \mathrm{De}(\mathbf{X}, \mathcal{D})$. Then $\mathbf{Y_N} \perp_d \mathbf{X}$ in $\mathcal{D}_{\overline{\mathbf{X}}}$, since $\mathcal{D}_{\overline{\mathbf{X}}}$ does not contain paths into $\mathbf{X}$ and all paths from $\mathbf{X}$ to $\mathbf{Y_N}$ that are out of $\mathbf{X}$ in $\mathcal{D}_{\overline{\mathbf{X}}}$ must contain a collider by definition of $\mathbf{Y_N}$. Hence, using Rule 3 of the do-calculus (see Equation 6 in Appendix A), with $\mathbf{X}' = \emptyset, \mathbf{W}' = \emptyset$, $\mathbf{Z}' = \mathbf{X}$ and $\mathbf{Y}' = \mathbf{Y_N}$ we have

$$f(\mathbf{y_N}) = f(\mathbf{y_N} \mid \mathrm{do}(\mathbf{x})). \tag{10}$$

Now, assume that $\mathbf{Y_D} = \emptyset$, so that $\mathbf{Y} = \mathbf{Y_N}$. Then all paths from $\mathbf{X}$ to $\mathbf{Y}$ are non-causal in $\mathcal{D}$. Since $\mathbf{Z_0}$ satisfies the adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ it blocks all proper non-causal paths from $\mathbf{X}$ to $\mathbf{Y}$. Thus, $\mathbf{Z_0}$ also blocks all non-causal paths from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{D}$, so $\mathbf{X} \perp_d \mathbf{Y} \mid \mathbf{Z_0}$ in $\mathcal{D}$. Combining the probabilistic implications of d-separation and Equation (10) with the right-hand side of Equation (9) we obtain

$$\begin{aligned}
\int_{\mathbf{z_0}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_0}) f(\mathbf{z_0}) d\mathbf{z_0} &= \int_{\mathbf{z_0}} f(\mathbf{y} \mid \mathbf{z_0}) f(\mathbf{z_0}) d\mathbf{z_0} \\
&= f(\mathbf{y}) = f(\mathbf{y} \mid \mathrm{do}(\mathbf{x})).
\end{aligned} \tag{11}$$

For the remainder of the proof we assume $\mathbf{Y_D} \neq \emptyset$. We enlarge the set $\mathbf{Z_0}$ to $\mathbf{Z} = \mathbf{Z_0} \cup \mathrm{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{D}) \setminus (\mathrm{De}(\mathbf{X}, \mathcal{D}) \cup \mathbf{Y})$. Then applying (iii) in Lemma 59 to the right-hand side of Equation (9) we get

$$\int_{\mathbf{z_0}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_0}) f(\mathbf{z_0}) d\mathbf{z_0} = \int_{\mathbf{z}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z}) f(\mathbf{z}) d\mathbf{z}. \tag{12}$$

Let $\mathbf{Z_D} = \mathbf{Z} \cap \mathrm{De}(\mathbf{X}, \mathcal{D})$ and $\mathbf{Z_N} = \mathbf{Z} \setminus \mathrm{De}(\mathbf{X}, \mathcal{D})$. Now suppose that $\mathbf{Y} = \mathbf{Y_D}$, so that $\mathbf{Y_N} = \emptyset$. From (iii) in Lemma 60, we have $\mathbf{Y_D} \perp_d \mathbf{Z_D} \mid \mathbf{X} \cup \mathbf{Z_N}$. Using the probabilistic implications of d-separation, the right-hand side of Equation (12) equals

$$\begin{aligned}
\int_{\mathbf{z_D}, \mathbf{z_N}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_D}, \mathbf{z_N}) f(\mathbf{z_D}, \mathbf{z_N}) d\mathbf{z_D} d\mathbf{z_N} &= \int_{\mathbf{z_D}, \mathbf{z_N}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_N}) f(\mathbf{z_D}, \mathbf{z_N}) d\mathbf{z_D} d\mathbf{z_N} \\
&= \int_{\mathbf{z_N}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_N}) f(\mathbf{z_N}) d\mathbf{z_N}.
\end{aligned} \tag{13}$$

Since $\mathbf{Z_N}$ satisfies the generalized back-door criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$ (see (iv) in Lemma 60) and since the generalized back-door criterion is sound by Theorem 3.1 in Maathuis and Colombo (2015), we have

$$\int_{\mathbf{z_N}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_N}) f(\mathbf{z_N}) d\mathbf{z_N} = f(\mathbf{y} \mid \mathrm{do}(\mathbf{x})). \tag{14}$$

Combining Equations (12), (13) and (14) completes the proof when $\mathbf{Y_N} = \emptyset$. In the remainder of the proof we assume $\mathbf{Y_D} \neq \emptyset$ and $\mathbf{Y_N} \neq \emptyset$. From (iii) in Lemma 60,

$\mathbf{Y_D} \perp_d \mathbf{Z_D} \mid \mathbf{Y_N} \cup \mathbf{X} \cup \mathbf{Z_N}$. Using the probabilistic implications of d-separation, the right-hand side of Equation (12) equals

$$\begin{aligned}
&\int_{\mathbf{z_D},\mathbf{z_N}} f(\mathbf{y_D},\mathbf{y_N} \mid \mathbf{x},\mathbf{z_D},\mathbf{z_N}) f(\mathbf{z_D},\mathbf{z_N}) d\mathbf{z_D} d\mathbf{z_N} \\
&= \int_{\mathbf{z_D},\mathbf{z_N}} f(\mathbf{y_D} \mid \mathbf{y_N},\mathbf{x},\mathbf{z_D},\mathbf{z_N}) f(\mathbf{y_N} \mid \mathbf{x},\mathbf{z_D},\mathbf{z_N}) f(\mathbf{z_D},\mathbf{z_N}) d\mathbf{z_D} d\mathbf{z_N} \\
&= \int_{\mathbf{z_N}} f(\mathbf{y_D} \mid \mathbf{y_N},\mathbf{x},\mathbf{z_N}) \int_{\mathbf{z_D}} f(\mathbf{y_N} \mid \mathbf{x},\mathbf{z_D},\mathbf{z_N}) f(\mathbf{z_D},\mathbf{z_N}) d\mathbf{z_D} d\mathbf{z_N}. \qquad (15)
\end{aligned}$$

Since $\mathbf{Z}$ satisfies the adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{D}$ ((ii) in Lemma 59), $\mathbf{Z}$ blocks all proper non-causal paths from $\mathbf{X}$ to $\mathbf{Y}$. Hence, $\mathbf{Z}$ blocks all proper paths from $\mathbf{X}$ to $\mathbf{Y_N}$ in $\mathcal{D}$, so $\mathbf{X} \perp_d \mathbf{Y_N} \mid \mathbf{Z}$ in $\mathcal{D}$. Additionally, the empty set satisfies the generalized back-door criterion relative to $((\mathbf{Y_N} \cup \mathbf{X} \cup \mathbf{Z_N}), \mathbf{Y_D})$ ((v) in Lemma 60). Since the generalized back-door criterion is sound by Theorem 3.1 in Maathuis and Colombo (2015), we apply this to the right-hand side of Equation (15)

$$\begin{aligned}
&\int_{\mathbf{z_N}} f(\mathbf{y_D} \mid \mathbf{y_N},\mathbf{x},\mathbf{z_N}) \int_{\mathbf{z_D}} f(\mathbf{y_N} \mid \mathbf{x},\mathbf{z_D},\mathbf{z_N}) f(\mathbf{z_D},\mathbf{z_N}) d\mathbf{z_D} d\mathbf{z_N} \\
&= \int_{\mathbf{z_N}} f(\mathbf{y_D} \mid \mathrm{do}(\mathbf{x},\mathbf{y_N},\mathbf{z_N})) \int_{\mathbf{z_D}} f(\mathbf{y_N} \mid \mathbf{z_N},\mathbf{z_D}) f(\mathbf{z_D},\mathbf{z_N}) d\mathbf{z_D} d\mathbf{z_N} \\
&= \int_{\mathbf{z_N}} f(\mathbf{y_D} \mid \mathrm{do}(\mathbf{x},\mathbf{y_N},\mathbf{z_N})) f(\mathbf{z_N} \mid \mathbf{y_N}) f(\mathbf{y_N}) d\mathbf{z_N}. \qquad (16)
\end{aligned}$$

To finish the proof we rely on the do-calculus rules. By (vi) in Lemma 60, it follows that $\mathbf{Y_N} \cup \mathbf{Z_N} \perp_d \mathbf{Y_D} \mid \mathbf{X}$ in $\mathcal{D}_{\overline{\mathbf{X}\mathbf{Y_N}\cup\mathbf{Z_N}}}$. Using Rule 2 of the do-calculus (see Equation 5 in Appendix A) with $\mathbf{X'} = \mathbf{X}, \mathbf{W'} = \emptyset, \mathbf{Z'} = \mathbf{Y_N} \cup \mathbf{Z_N}$ and $\mathbf{Y'} = \mathbf{Y_D}$:

$$f(\mathbf{y_D} \mid \mathrm{do}(\mathbf{x},\mathbf{y_N},\mathbf{z_N})) = f(\mathbf{y_D} \mid \mathrm{do}(\mathbf{x}),\mathbf{z_N},\mathbf{y_N}). \qquad (17)$$

Additionally, by (vii) in Lemma 60, $\mathbf{Z_N} \perp_d \mathbf{X} \mid \mathbf{Y_N}$ in $\mathcal{D}_{\overline{\mathbf{X}}}$. Using Rule 3 of the do-calculus (see Equation 6 in Appendix A) with $\mathbf{X'} = \emptyset, \mathbf{W'} = \mathbf{Y_N}, \mathbf{Z'} = \mathbf{X}$ and $\mathbf{Y'} = \mathbf{Z_N}$:

$$f(\mathbf{z_N} \mid \mathbf{y_N}) = f(\mathbf{z_N} \mid \mathrm{do}(\mathbf{x}),\mathbf{y_N}). \qquad (18)$$

Finally, we combine Equations (17),(18) and (10) with the right-hand side of Equation (16):

$$\begin{aligned}
&\int_{\mathbf{z_N}} f(\mathbf{y_D} \mid \mathrm{do}(\mathbf{y_N},\mathbf{x},\mathbf{z_N})) f(\mathbf{z_N} \mid \mathbf{y_N}) f(\mathbf{y_N}) d\mathbf{z_N} \\
&= \int_{\mathbf{z_N}} f(\mathbf{y_D} \mid \mathbf{z_N},\mathbf{y_N},\mathrm{do}(\mathbf{x})) f(\mathbf{z_N} \mid \mathbf{y_N},\mathrm{do}(\mathbf{x})) f(\mathbf{y_N} \mid \mathrm{do}(\mathbf{x})) d\mathbf{z_N} \\
&= \int_{\mathbf{z_N}} f(\mathbf{y_D},\mathbf{z_N} \mid \mathbf{y_N},\mathrm{do}(\mathbf{x})) f(\mathbf{y_N} \mid \mathrm{do}(\mathbf{x})) d\mathbf{z_N} \\
&= f(\mathbf{y_D} \mid \mathbf{y_N},\mathrm{do}(\mathbf{x})) f(\mathbf{y_N} \mid \mathrm{do}(\mathbf{x})) = f(\mathbf{y_D},\mathbf{y_N} \mid \mathrm{do}(\mathbf{x})) = f(\mathbf{y} \mid \mathrm{do}(\mathbf{x})).
\end{aligned}$$

■

Lemma 59 *Let $\mathbf{X},\mathbf{Y}$ and $\mathbf{Z_0}$ be pairwise disjoint node sets in a* DAG *$\mathcal{D}$ such that $\mathbf{Z_0}$ satisfies the adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{D}$. Let $\mathbf{Z_1} \subseteq \mathrm{An}(\mathbf{X}\cup\mathbf{Y},\mathcal{D})\backslash(\mathrm{De}(\mathbf{X},\mathcal{D})\cup\mathbf{Y})$ and $\mathbf{Z} = \mathbf{Z_0} \cup \mathbf{Z_1}$. Then:*

(i) $\mathbf{X},\mathbf{Y}$ and $\mathbf{Z}$ are pairwise disjoint, and

(ii) $\mathbf{Z}$ satisfies the adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{D}$, and

(iii) $\int_{\mathbf{z_0}} f(\mathbf{y} \mid \mathbf{x},\mathbf{z_0}) f(\mathbf{z_0}) d\mathbf{z_0} = \int_{\mathbf{z_0},\mathbf{z_1}} f(\mathbf{y} \mid \mathbf{x},\mathbf{z_0},\mathbf{z_1}) f(\mathbf{z_0},\mathbf{z_1}) d\mathbf{z_0} d\mathbf{z_1}$, for any density f consistent with $\mathcal{D}$.

Proof of Lemma 59. (i) Since $\mathbf{X},\mathbf{Y}$ and $\mathbf{Z_0}$ are pairwise disjoint, and $\mathbf{Z} = \mathbf{Z_0} \cup \mathbf{Z_1}$, where $\mathbf{Z_1} \cap (\mathbf{X} \cup \mathbf{Y}) = \emptyset$, it follows that $\mathbf{X},\mathbf{Y}$ and $\mathbf{Z}$ are also pairwise disjoint.

(ii) A set that satisfies the forbidden set condition of the adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{D}$ satisfies the blocking condition if and only if it d-separates $\mathbf{X}$ and $\mathbf{Y}$ in the proper back-door graph $\mathcal{D}^{pbd}_{\mathbf{XY}}$ (van der Zander et al. (2014, Theorem 4.6); see Theorem 7 in Section 3). Thus, $\mathbf{Z_0}$ d-separates $\mathbf{X}$ and $\mathbf{Y}$ in $\mathcal{D}^{pbd}_{\mathbf{XY}}$. Then by Theorem 35, any path between $\mathbf{X}$ and $\mathbf{Y}$ in $((\mathcal{D}^{pbd}_{\mathbf{XY}})_{\mathrm{An}(\mathbf{X}\cup\mathbf{Y}\cup\mathbf{Z_0},\mathcal{D}^{pbd}_{\mathbf{XY}})})^m$ contains a node in $\mathbf{Z_0}$.

Since $\mathbf{Z_1} \cap \mathrm{De}(\mathbf{X},\mathcal{D}) = \emptyset$, $\mathrm{Forb}(\mathbf{X},\mathbf{Y},\mathcal{D}) \subseteq \mathrm{De}(\mathbf{X},\mathcal{D})$ and $\mathbf{Z_0} \cap \mathrm{Forb}(\mathbf{X},\mathbf{Y},\mathcal{D}) = \emptyset$, $\mathbf{Z} \cap \mathrm{Forb}(\mathbf{X},\mathbf{Y},\mathcal{D}) = \emptyset$. Additionally, since $\mathbf{Z} \supseteq \mathbf{Z_0}$, all paths between $\mathbf{X}$ and $\mathbf{Y}$ in $((\mathcal{D}^{pbd}_{\mathbf{XY}})_{\mathrm{An}(\mathbf{X}\cup\mathbf{Y}\cup\mathbf{Z_0},\mathcal{D}^{pbd}_{\mathbf{XY}})})^m$ contain a node in $\mathbf{Z}$. Furthermore, $\mathbf{Z_1} \subseteq \mathrm{An}(\mathbf{X}\cup\mathbf{Y},\mathcal{D})$ implies that $\mathrm{An}(\mathbf{X}\cup\mathbf{Y}\cup\mathbf{Z},\mathcal{D}) = \mathrm{An}(\mathbf{X}\cup\mathbf{Y}\cup\mathbf{Z_0},\mathcal{D})$. Thus, all paths between $\mathbf{X}$ and $\mathbf{Y}$ in $((\mathcal{D}^{pbd}_{\mathbf{XY}})_{\mathrm{An}(\mathbf{X}\cup\mathbf{Y}\cup\mathbf{Z},\mathcal{D}^{pbd}_{\mathbf{XY}})})^m$ contain a node in $\mathbf{Z}$. Hence, $\mathbf{Z}$ satisfies the blocking condition relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{D}$ (Theorem 35, Theorem 7).

(iii) We prove this statement by induction on the number of nodes in $\mathbf{Z_1}$. Below, we prove the base case: $|\mathbf{Z_1}| = 1$. We then assume that the result holds for $|\mathbf{Z_1}| = k$, and show that it holds for $|\mathbf{Z_1}| = k+1$. Thus, let $|\mathbf{Z_1}| = k+1$ and take an arbitrary $Z_1 \in \mathbf{Z_1}$. Let $\mathbf{Z_0'} = \mathbf{Z_0} \cup \{Z_1\}$ and $\mathbf{Z_1'} = \mathbf{Z_1} \setminus \{Z_1\}$. The base case then implies

$$\begin{aligned}
\int_{\mathbf{z_0}} f(\mathbf{y} \mid \mathbf{x},\mathbf{z_0}) f(\mathbf{z_0}) d\mathbf{z_0} &= \int_{\mathbf{z_0}} f(\mathbf{y} \mid \mathbf{x},\mathbf{z_0}) \int_{z_1} f(\mathbf{z_0},z_1) dz_1 d\mathbf{z_0} \\
&= \int_{\mathbf{z_0},z_1} f(\mathbf{y} \mid \mathbf{x},\mathbf{z_0},z_1) f(\mathbf{z_0},z_1) d\mathbf{z_0} dz_1 \\
&= \int_{\mathbf{z_0'}} f(\mathbf{y} \mid \mathbf{x},\mathbf{z_0'}) f(\mathbf{z_0'}) d\mathbf{z_0'}. \qquad (19)
\end{aligned}$$

By (ii) above $\mathbf{Z_0'}$ satisfies the adjustment criterion relative to $(\mathbf{X},\mathbf{Y})$ in $\mathcal{D}$ and $\mathbf{Z_1'} \subseteq \mathrm{An}(\mathbf{X}\cup\mathbf{Y},\mathcal{D})$. Then since $|\mathbf{Z_1'}| = k$, by the induction hypothesis

$$\int_{\mathbf{z_0'}} f(\mathbf{y} \mid \mathbf{x},\mathbf{z_0'}) f(\mathbf{z_0'}) d\mathbf{z_0'} = \int_{\mathbf{z_0'},\mathbf{z_1'}} f(\mathbf{y} \mid \mathbf{x},\mathbf{z_0'},\mathbf{z_1'}) f(\mathbf{z_0'},\mathbf{z_1'}) d\mathbf{z_0'} d\mathbf{z_1'}. \qquad (20)$$

Combining 19 and 20 yields

$$\int_{\mathbf{z_0}} f(\mathbf{y} \mid \mathbf{x},\mathbf{z_0}) f(\mathbf{z_0}) d\mathbf{z_0} = \int_{\mathbf{z_0},\mathbf{z_1}} f(\mathbf{y} \mid \mathbf{x},\mathbf{z_0},\mathbf{z_1}) f(\mathbf{z_0},\mathbf{z_1}) d\mathbf{z_0} d\mathbf{z_1}.$$

It is left to prove the base case of the induction. Hence, suppose $\mathbf{Z_1} = \{Z_1\}$. We show below that either (a) $\mathbf{Y} \perp_d Z_1 \mid \mathbf{X} \cup \mathbf{Z_0}$ or (b) $\mathbf{X} \perp_d Z_1 \mid \mathbf{Z_0}$ are satisfied in $\mathcal{D}$. (Note that (a) and (b) are very similar to the conditions U1 and U2, as well as U1* and U2*, from Greenland et al., 1999. These conditions are also used in Theorem 5 from Kuroki and Miyakawa, 2003, Lemma 3 from Kuroki and Cai, 2004 and are the foundation for the results in De Luna et al., 2011. Additionally, Pearl and Paz, 2014 give a discussion of these conditions, which they refer to as c-equivalence conditions, in their Theorem 1.)

If (a) $\mathbf{Y} \perp_d Z_1 \mid \mathbf{X} \cup \mathbf{Z_0}$ in $\mathcal{D}$, then by the probabilistic implications of d-separation we have that for any density f consistent with $\mathcal{D}$

$$\begin{aligned}\int_{\mathbf{z_0}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_0}) f(\mathbf{z_0}) d\mathbf{z_0} &= \int_{\mathbf{z_0}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_0}) \int_{z_1} f(\mathbf{z_0}, z_1) dz_1 d\mathbf{z_0} \\ &= \int_{\mathbf{z_0}, z_1} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_0}) f(\mathbf{z_0}, z_1) d\mathbf{z_0} dz_1 \\ &= \int_{\mathbf{z_0}, z_1} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_0}, z_1) f(\mathbf{z_0}, z_1) d\mathbf{z_0} dz_1.\end{aligned}$$

If (b) $\mathbf{X} \perp_d Z_1 \mid \mathbf{Z_0}$ in $\mathcal{D}$, then similarly

$$\begin{aligned}\int_{\mathbf{z_0}} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_0}) f(\mathbf{z_0}) d\mathbf{z_0} &= \int_{\mathbf{z_0}} f(\mathbf{z_0}) \int_{z_1} f(\mathbf{y}, z_1 \mid \mathbf{x}, \mathbf{z_0}) dz_1 d\mathbf{z_0} \\ &= \int_{\mathbf{z_0}, z_1} f(\mathbf{y}, z_1 \mid \mathbf{x}, \mathbf{z_0}) f(\mathbf{z_0}) d\mathbf{z_0} dz_1 \\ &= \int_{\mathbf{z_0}, z_1} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_0}, z_1) f(z_1 \mid \mathbf{x}, \mathbf{z_0}) f(\mathbf{z_0}) d\mathbf{z_0} dz_1 \\ &= \int_{\mathbf{z_0}, z_1} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_0}, z_1) f(z_1 \mid \mathbf{z_0}) f(\mathbf{z_0}) d\mathbf{z_0} dz_1 \\ &= \int_{\mathbf{z_0}, z_1} f(\mathbf{y} \mid \mathbf{x}, \mathbf{z_0}, z_1) f(z_1, \mathbf{z_0}) d\mathbf{z_0} dz_1.\end{aligned}$$

We complete the proof by showing that (a) or (b) must hold. Suppose for a contradiction that both (a) and (b) are violated. Then there is a path from $\mathbf{X}$ to Z_1 that is d-connecting given $\mathbf{Z_0}$ and a path from $\mathbf{Y}$ to Z_1 that is d-connecting given $\mathbf{X} \cup \mathbf{Z_0}$. Let p be a proper path from $X \in \mathbf{X}$ to Z_1 that is d-connecting given $\mathbf{Z_0}$ in $\mathcal{D}$ and let q be a path from Z_1 to $Y \in \mathbf{Y}$ that is d-connecting given $\mathbf{X} \cup \mathbf{Z_0}$ in $\mathcal{D}$. We will show that this contradicts that $\mathbf{Z_0}$ satisfies the adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$.

We first show, by contradiction, that q also is d-connecting given $\mathbf{Z_0}$. Thus, assume that $q = \langle Z_1, \dots, Y \rangle$ is blocked by $\mathbf{Z_0}$. Since q is d-connecting given $\mathbf{X} \cup \mathbf{Z_0}$ and blocked by $\mathbf{Z_0}$, it must contain at least one collider in $\mathrm{An}(\mathbf{X}, \mathcal{D}) \setminus \mathrm{An}(\mathbf{Z_0}, \mathcal{D})$. Let C be the collider closest to Y on q such that $C \in \mathrm{An}(\mathbf{X}, \mathcal{D}) \setminus \mathrm{An}(\mathbf{Z_0}, \mathcal{D})$. Let $r = \langle C, \dots, X' \rangle, X' \in \mathbf{X}$ be a shortest directed path from C to $\mathbf{X}$ (possibly of zero length). Then no node on $q(C, Y)$ or r, except possibly C, is in $\mathbf{X}$. We now concatenate the paths $-r(X', C)$ and $q(C, Y)$, while taking out possible loops. Hence, let V be the node closest to X' on r that is also on $q(C, Y)$. Then $-r(X', V) \oplus q(V, Y)$ is non-causal since either $-r(X', V)$ is of non-zero length, or $X' = V = C$ and $q(C, Y)$ is a path into C, because C is a collider on q. By the

choice of C and r, $-r(X', V) \oplus q(V, Y)$ is a proper path that is d-connecting given $\mathbf{Z_0}$. This contradicts that $\mathbf{Z_0}$ satisfies the adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$. Thus, q is also d-connecting given $\mathbf{Z_0}$.

Let $\tilde{p}$ and $\tilde{q}$ be paths in the proper back-door graph $\mathcal{D}^{pbd}_{\mathbf{XY}}$ constituted by the same sequences of nodes as p and q in $\mathcal{D}$ respectively. We first prove that the paths $\tilde{p}$ and $\tilde{q}$ exist in $\mathcal{D}^{pbd}_{\mathbf{XY}}$. Path q is d-connecting given $\mathbf{X} \cup \mathbf{Z_0}$, so any node in $\mathbf{X}$ on q must be a collider on q. Since $\mathcal{D}^{pbd}_{\mathbf{XY}}$ is obtained from $\mathcal{D}$ by removing certain edges out of $\mathbf{X}$, no edges from q are removed and $\tilde{q}$ exists in $\mathcal{D}^{pbd}_{\mathbf{XY}}$.

Since p is proper, for $\tilde{p}$ to exist in $\mathcal{D}^{pbd}_{\mathbf{XY}}$, it is enough to show that p does not start with an edge of type $X \to W$ in $\mathcal{D}$ where W lies on a proper causal path from X to $\mathbf{Y}$ in $\mathcal{D}$. Suppose for a contradiction that p does start with $X \to W$. Then $W \in \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$. Then either p is a directed path from X to Z_1 so that $Z_1 \in \mathrm{De}(W, \mathcal{D})$, or p is non-causal and there is a collider C' on p such that $C' \in \mathrm{De}(W, \mathcal{D})$. In the former case, since $\mathrm{De}(W, \mathcal{D}) \subseteq \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$, it follows that $Z_1 \in \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$, which contradicts the choice of Z_1 because $Z_1 \notin \mathrm{De}(\mathbf{X}, \mathcal{D})$. In the latter case, since p is d-connecting given $\mathbf{Z_0}$, we have $\mathrm{De}(C', \mathcal{D}) \cap \mathbf{Z_0} \neq \emptyset$. Combining this with $\mathrm{De}(C', \mathcal{D}) \subseteq \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$, it follows that $\mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) \cap \mathbf{Z_0} \neq \emptyset$ which contradicts that $\mathbf{Z_0}$ satisfies the forbidden set condition relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$. Thus, $\tilde{p}$ exists in $\mathcal{D}^{pbd}_{\mathbf{XY}}$.

We now show that $\tilde{p}$ and $\tilde{q}$ are d-connecting given $\mathbf{Z_0}$ in $\mathcal{D}^{pbd}_{\mathbf{XY}}$. The collider/non-collider status of any node on $\tilde{p}$ and $\tilde{q}$ in $\mathcal{D}^{pbd}_{\mathbf{XY}}$ is the same as the collider/non-collider status of that same node on p and q in $\mathcal{D}$ respectively. So $\tilde{p}$ and $\tilde{q}$ are both d-connecting given $\mathbf{Z_0}$, unless every causal path from a collider on either p or q to $\mathbf{Z_0}$ contains a first edge on a proper causal path from $\mathbf{X}$ to $\mathbf{Y}$ in $\mathcal{D}$. Any such causal path also contains a node in $\mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$, so a node in $\mathbf{Z_0}$ would be a descendant of $\mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$ in $\mathcal{D}$. Since $\mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$ is descendral, it follows that $\mathbf{Z_0} \cap \mathrm{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) \neq \emptyset$. This contradicts that $\mathbf{Z_0}$ satisfies the adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$, specifically the forbidden set condition.

Since $\tilde{p}$ is d-connecting given $\mathbf{Z_0}$ in $\mathcal{D}^{pbd}_{\mathbf{XY}}$, by Theorem 35 it follows that there is a path a from X to Z_1 that does not contain a node in $\mathbf{Z_0}$ in the moral induced subgraph of $\mathcal{D}^{pbd}_{\mathbf{XY}}$ on nodes $\mathrm{An}(\mathbf{X} \cup \mathbf{Y} \cup \mathbf{Z_0} \cup \{Z_1\}, \mathcal{D}^{pbd}_{\mathbf{XY}})$. Similarly, $\tilde{q}$ is a d-connecting path from Z_1 to Y given $\mathbf{Z_0}$ in $\mathcal{D}^{pbd}_{\mathbf{XY}}$, so there is a path b from Z_1 to Y that does not contain a node in $\mathbf{Z_0}$ in the moral induced subgraph of $\mathcal{D}^{pbd}_{\mathbf{XY}}$ on nodes $\mathrm{An}(\mathbf{X} \cup \mathbf{Y} \cup \mathbf{Z_0} \cup \{Z_1\}, \mathcal{D}^{pbd}_{\mathbf{XY}})$. By combining paths a and b we get a path c from $\mathbf{X}$ to $\mathbf{Y}$ that does not contain a node in $\mathbf{Z_0}$ in the moral induced subgraph of $\mathcal{D}^{pbd}_{\mathbf{XY}}$ on nodes $\mathrm{An}(\mathbf{X} \cup \mathbf{Y} \cup \mathbf{Z_0} \cup \{Z_1\}, \mathcal{D}^{pbd}_{\mathbf{XY}})$. Since $Z_1 \in \mathrm{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{D})$ and $\mathcal{D}^{pbd}_{\mathbf{XY}}$ is obtained from $\mathcal{D}$ by removing certain edges out of $\mathbf{X}$, it follows that $Z_1 \in \mathrm{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{D}^{pbd}_{\mathbf{XY}})$. Then $\mathrm{An}(\mathbf{X} \cup \mathbf{Y} \cup \mathbf{Z_0} \cup \{Z_1\}, \mathcal{D}^{pbd}_{\mathbf{XY}}) = \mathrm{An}(\mathbf{X} \cup \mathbf{Y} \cup \mathbf{Z_0}, \mathcal{D}^{pbd}_{\mathbf{XY}})$. Hence, c is a path from $\mathbf{X}$ to $\mathbf{Y}$ that does not contain a node in $\mathbf{Z_0}$ in the moral induced subgraph of $\mathcal{D}^{pbd}_{\mathbf{XY}}$ on nodes $\mathrm{An}(\mathbf{X} \cup \mathbf{Y} \cup \mathbf{Z_0}, \mathcal{D}^{pbd}_{\mathbf{XY}})$. Thus, by Theorem 35, $\mathbf{X}$ and $\mathbf{Y}$ are d-connected given $\mathbf{Z_0}$ in $\mathcal{D}^{pbd}_{\mathbf{XY}}$. By Theorem 7, this contradicts that $\mathbf{Z_0}$ satisfies the adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$. ■

Lemma 60 *Let $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z_0}$ be pairwise disjoint node sets in a* DAG *$\mathcal{D}$ such that $\mathbf{Z_0}$ satisfies the adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$. Let $\mathbf{Z} = \mathbf{Z_0} \cup \mathrm{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{D}) \setminus (\mathrm{De}(\mathbf{X}, \mathcal{D}) \cup \mathbf{Y})$. Additionally, let $\mathbf{Z_D} = \mathbf{Z} \cap \mathrm{De}(\mathbf{X}, \mathcal{D})$, $\mathbf{Z_N} = \mathbf{Z} \setminus \mathrm{De}(\mathbf{X}, \mathcal{D})$, $\mathbf{Y_D} = \mathbf{Y} \cap \mathrm{De}(\mathbf{X}, \mathcal{D})$ and $\mathbf{Y_N} = \mathbf{Y} \setminus \mathrm{De}(\mathbf{X}, \mathcal{D})$. Then the following statements hold:*

(i) $(\mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z}) \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) = \emptyset$, *and*

(ii) *if* $p = \langle A, \dots, Y_d \rangle$ *is a non-causal path from a node* $A \in \mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z}$ *to a node* $Y_d \in \mathbf{Y_D}$, *then* p *is blocked by* $(\mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z_N}) \setminus \{A\}$ *in* $\mathcal{D}$, *and*

(iii) $\mathbf{Y_D} \perp_d \mathbf{Z_D} \mid \mathbf{Y_N} \cup \mathbf{X} \cup \mathbf{Z_N}$ *in* $\mathcal{D}$, *where* $\mathbf{Y_N} = \emptyset$ *is allowed, and*

(iv) *if* $\mathbf{Y_N} = \emptyset$ *then* $\mathbf{Z_N}$ *is a generalized back-door set relative to* $(\mathbf{X}, \mathbf{Y})$ *in* $\mathcal{D}$, *and*

(v) *the empty set is a generalized back-door set relative to* $((\mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z_N}), \mathbf{Y_D})$ *in* $\mathcal{D}$, *and*

(vi) $\mathbf{Y_N} \cup \mathbf{Z_N} \perp_d \mathbf{Y_D} \mid \mathbf{X}$ *in* $\mathcal{D}_{\overline{\mathbf{X}}\underline{\mathbf{Y_N} \cup \mathbf{Z_N}}}$, *and*

(vii) $\mathbf{X} \perp_d \mathbf{Z_N} \mid \mathbf{Y_N}$ *in* $\mathcal{D}_{\overline{\mathbf{X}}}$.

Proof of Lemma 60. (i) By Lemma 59, $\mathbf{Z}$ satisfies the adjustment criterion relative to $(\mathbf{X}, \mathbf{Y})$ in $\mathcal{D}$, implying that $\mathbf{Z} \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) = \emptyset$. By definition $\mathbf{Y_N} \cap \text{De}(\mathbf{X}, \mathcal{D}) = \emptyset$ and $\text{De}(\mathbf{X}, \mathcal{D}) \supseteq \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{G})$. Hence, $\mathbf{Y_N} \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) = \emptyset$. It is only left to show that $\mathbf{X} \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) = \emptyset$.

Suppose for a contradiction that $\mathbf{X} \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) \neq \emptyset$. Let $V \notin \mathbf{X}$ be a node on a proper causal path p from $\mathbf{X}$ to $\mathbf{Y}$ (possibly $V \in \mathbf{Y}$) such that $V \in \text{An}(\mathbf{X}, \mathcal{D})$. Let $q = \langle V, \dots, X \rangle$, $X \in \mathbf{X}$, be a shortest causal path from V to $\mathbf{X}$. All nodes on $p(V, Y)$ and q are in $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$. We now concatenate $-q$ and $p(V, Y)$, while taking out loops. Hence, let W be the node closest to X on q that is also on $p(V, Y)$. Then $r = -q(X, W) \oplus p(W, Y)$ is a proper non-causal path from $\mathbf{X}$ to $\mathbf{Y}$ that cannot be blocked by $\mathbf{Z}$ since $\mathbf{Z} \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) = \emptyset$, which contradicts Lemma 59.

(ii) We distinguish the cases that p is (a) out of, or (b) into Y_d.

(a) Let p be out of Y_d. Since $Y_d \in \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$ and since by (i) node $A \notin \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$, there is at least one collider on p. The collider closest to Y_d on p and all of its descendants are also in $\text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$. It then follows from (i) that p is blocked by $(\mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z_N}) \setminus \{A\}$.

(b) Let p be into Y_d. Since p is a non-causal path from A to Y_d, there is at least one node on p that has two edges out of it. Let B be the closest such node to Y_d on p. Then $B \in \text{An}(Y_d, \mathcal{D})$. If any node on $p(B, Y_d)$ is in $\mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z_N}$, then (ii) holds.

Hence, assume no node on $p(B, Y_d)$ is in $\mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z_N}$. Then $B \notin \mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z_N}$. Since $B \notin \mathbf{Z_N}$, $\mathbf{Z_N} \supseteq \text{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{D}) \setminus (\text{De}(\mathbf{X}, \mathcal{D}) \cup \mathbf{Y})$, it follows that $B \notin \text{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{D}) \setminus (\text{De}(\mathbf{X}, \mathcal{D}) \cup \mathbf{Y})$. Additionally, since $B \in \text{An}(Y_d, \mathcal{D})$, $B \in \text{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{D})$. Combining $B \notin \text{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{D}) \setminus (\text{De}(\mathbf{X}, \mathcal{D}) \cup \mathbf{Y})$ and $B \in \text{An}(\mathbf{X} \cup \mathbf{Y}, \mathcal{D})$ implies $B \in \text{De}(\mathbf{X}, \mathcal{D}) \cup \mathbf{Y}$. Furthermore, $B \notin \mathbf{X} \cup \mathbf{Y_N}$ and $\mathbf{Y_D} \subseteq \text{De}(\mathbf{X}, \mathcal{D}) \setminus \mathbf{X}$, so $B \in \text{De}(\mathbf{X}, \mathcal{D}) \setminus \mathbf{X}$. But $B \in \text{An}(Y_d, \mathcal{D})$ through $p(B, Y_d)$ on which no other node is in $\mathbf{X}$, so $B \in \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$. Now, $-p(B, A)$ is a path out of B, where $B \in \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$ and $A \notin \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D})$ by (i). Using the same reasoning as in (a), $p(A, B)$ is blocked by $(\mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z_N}) \setminus \{A\}$. Hence, p is also blocked by $(\mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z_N}) \setminus \{A\}$.

(iii) By (ii) every non-causal path from $\mathbf{Z_D}$ to $\mathbf{Y_D}$ is blocked by $\mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z_N}$. Additionally, $\mathbf{Z_D} \cap \text{Forb}(\mathbf{X}, \mathbf{Y}, \mathcal{D}) = \emptyset$ and $\mathbf{Z_D} \subseteq \text{De}(\mathbf{X}, \mathcal{D})$, so no node in $\mathbf{Z_D}$ can have a proper causal path to $\mathbf{Y_D}$ in $\mathcal{D}$. Hence, any causal path p from $\mathbf{Z_D}$ to $\mathbf{Y_D}$ in $\mathcal{D}$, must be non-proper with respect to $\mathbf{X}$, that is, p has to contain a node in $\mathbf{X}$ as a non-collider. Hence, every causal path from $\mathbf{Z_D}$ to $\mathbf{Y_D}$ is also blocked by $\mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z_N}$ in $\mathcal{D}$.

(iv) Follows directly from $\mathbf{Z_N} \cap \text{De}(\mathbf{X}, \mathcal{D}) = \emptyset$ and (ii) for $\mathbf{Y_N} = \emptyset$.

(v) Follows directly from (ii).

(vi) Since $\mathcal{D}_{\overline{\mathbf{X}}\underline{\mathbf{Y_N} \cup \mathbf{Z_N}}}$ does not contain edges into $\mathbf{X}$, all paths from $\mathbf{Y_N} \cup \mathbf{Z_N}$ to $\mathbf{Y_D}$ in $\mathcal{D}_{\overline{\mathbf{X}}\underline{\mathbf{Y_N} \cup \mathbf{Z_N}}}$ that contain a collider are blocked by $\mathbf{X}$. Hence, it is enough to prove that $\mathbf{X}$ blocks any path from $\mathbf{Y_N} \cup \mathbf{Z_N}$ to $\mathbf{Y_D}$ in $\mathcal{D}_{\overline{\mathbf{X}}\underline{\mathbf{Y_N} \cup \mathbf{Z_N}}}$ that does not contain a collider. Let $r = \langle A, \dots, Y_d \rangle$, $A \in \mathbf{Y_N} \cup \mathbf{Z_N}$, $Y_d \in \mathbf{Y_D}$ be an arbitrary path from $\mathbf{Y_N} \cup \mathbf{Z_N}$ to $\mathbf{Y_D}$ in $\mathcal{D}_{\overline{\mathbf{X}}\underline{\mathbf{Y_N} \cup \mathbf{Z_N}}}$ that does not contain a collider. Since there are no edges out of $\mathbf{Y_N} \cup \mathbf{Z_N}$ in $\mathcal{D}_{\overline{\mathbf{X}}\underline{\mathbf{Y_N} \cup \mathbf{Z_N}}}$, it follows that r is into A and that r does not contain non-colliders that are in $\mathbf{Y_N} \cup \mathbf{Z_N}$. Let r' in $\mathcal{D}$ be the path constituted by the same sequence of nodes as r in $\mathcal{D}_{\overline{\mathbf{X}}\underline{\mathbf{Y_N} \cup \mathbf{Z_N}}}$. Since removing edges cannot d-connect blocked paths, it is enough to prove that r' is blocked by $\mathbf{X}$ in $\mathcal{D}$. Since r' is into A, r' is a non-causal path from $\mathbf{Y_N} \cup \mathbf{Z_N}$ to $\mathbf{Y_D}$, so by (ii), r' is blocked by $(\mathbf{X} \cup \mathbf{Y_N} \cup \mathbf{Z_N}) \setminus \{A\}$ in $\mathcal{D}$. Since $A \in \mathbf{Y_N} \cup \mathbf{Z_N}$ and $(\mathbf{Y_N} \cup \mathbf{Z_N}) \cap \mathbf{X} = \emptyset$, it follows that $A \notin \mathbf{X}$. Then r' is blocked by $\mathbf{X} \cup ((\mathbf{Y_N} \cup \mathbf{Z_N}) \setminus \{A\})$. Furthermore, since r does not contain non-colliders in $\mathbf{Y_N} \cup \mathbf{Z_N}$, the same is true for r', so r' is blocked by $\mathbf{X}$.

(vii) Since $\mathcal{D}_{\overline{\mathbf{X}}}$ does not contain edges into $\mathbf{X}$, all paths from $\mathbf{X}$ to $\mathbf{Z_N}$ in $\mathcal{D}_{\overline{\mathbf{X}}}$ are out of $\mathbf{X}$. Since $\mathbf{Z_N} \cap \text{De}(\mathbf{X}, \mathcal{D}) = \emptyset$ and $\text{De}(\mathbf{X}, \mathcal{D}) \supseteq \text{De}(\mathbf{X}, \mathcal{D}_{\overline{\mathbf{X}}})$, all paths from $\mathbf{X}$ to $\mathbf{Z_N}$ in $\mathcal{D}_{\overline{\mathbf{X}}}$ contain at least one collider. The closest collider to $\mathbf{X}$ on any such path is then in $\text{De}(\mathbf{X}, \mathcal{D}_{\overline{\mathbf{X}}})$. Since $\mathbf{Y_N} \cap \text{De}(\mathbf{X}, \mathcal{D}) = \emptyset$ and $\text{De}(\mathbf{X}, \mathcal{D}) \supseteq \text{De}(\mathbf{X}, \mathcal{D}_{\overline{\mathbf{X}}})$, this path is blocked by $\mathbf{Y_N}$ in $\mathcal{D}_{\overline{\mathbf{X}}}$. ■

Katyusha: The First Direct Acceleration of Stochastic Gradient Methods

Zeyuan Allen-Zhu* zeyuan@csail.mit.edu

Editor: Leon Bottou

Abstract

Nesterov's momentum trick is famously known for accelerating gradient descent, and has been proven useful in building fast iterative algorithms. However, in the stochastic setting, counterexamples exist and prevent Nesterov's momentum from providing similar acceleration, even if the underlying problem is convex and finite-sum.

We introduce `Katyusha`, a direct, primal-only stochastic gradient method to fix this issue. In convex finite-sum stochastic optimization, `Katyusha` has an optimal accelerated convergence rate, and enjoys an optimal parallel linear speedup in the mini-batch setting.

The main ingredient is *Katyusha momentum*, a novel "negative momentum" on top of Nesterov's momentum. It can be incorporated into a variance-reduction based algorithm and speed it up, both in terms of *sequential and parallel* performance. Since variance reduction has been successfully applied to a growing list of practical problems, our paper suggests that in each of such cases, one could potentially try to give Katyusha a hug.

1. Introduction

In large-scale machine learning, the number of data examples is usually very large. To search for the optimal solution, one often uses *stochastic gradient methods* which only require one (or a small batch of) random example(s) per iteration in order to form an *estimator* of the full gradient.

While full-gradient based methods can enjoy an *accelerated* (and optimal) convergence rate if Nesterov's momentum trick is used (Nesterov, 1983, 2004, 2005), theory for stochastic gradient methods are generally lagging behind and less is known for their acceleration.

At a high level, momentum is *dangerous* if stochastic gradients are present. If some gradient estimator is very inaccurate, then adding it to the momentum and moving further in this direction (for every future iteration) may hurt the convergence performance. In other words, when naively equipped with momentum, stochastic gradient methods are "very prune to error accumulation" (Konečnỳ et al., 2016) and do *not* yield accelerated convergence rates in general.[1]

In this paper, we show that at least for convex optimization purposes, such an issue can be solved with a novel "negative momentum" that can be added on top of momentum. We obtain accelerated and the first optimal convergence rates for stochastic gradient methods. As one of our side results, under this "negative momenmtum," our new method enjoys a linear speedup in the parallel (i.e., mini-match) setting. We hope our new insight could potentially deepen our understanding to the theory of accelerated methods.

Problem Definition. Consider the following composite convex minimization problem

$$\min_{x\in\mathbb{R}^d}\left\{F(x)\stackrel{\text{def}}{=}f(x)+\psi(x)\stackrel{\text{def}}{=}\frac{1}{n}\sum_{i=1}^n f_i(x)+\psi(x)\right\}\ . \tag{1.1}$$

Here, $f(x)=\frac{1}{n}\sum_{i=1}^n f_i(x)$ is a convex function that is a finite average of n convex, smooth functions $f_i(x)$, and $\psi(x)$ is convex, lower semicontinuous (but possibly non-differentiable) function, sometimes referred to as the *proximal* function. We mostly focus on the case when $\psi(x)$ is σ-strongly convex and each $f_i(x)$ is L-smooth. (Both these assumptions can be removed and we shall discuss that later.) We look for approximate minimizers $x\in\mathbb{R}^d$ satisfying $F(x)\le F(x^*)+\varepsilon$, where $x^*\in\arg\min_x\{F(x)\}$.

Problem (1.1) arises in many places in machine learning, statistics, and operations research. All convex *regularized empirical risk minimization (ERM)* problems such as Lasso, SVM, Logistic Regression, fall into this category (see Section 1.3). Efficient stochastic methods for Problem (1.1) have also inspired stochastic algorithms for neural nets (Johnson and Zhang, 2013; Allen-Zhu and Hazan, 2016a; Lei et al., 2017) as well as SVD, PCA, and CCA (Garber et al., 2016; Allen-Zhu and Li, 2016, 2017b).

We summarize the history of stochastic gradient methods for Problem (1.1) in three eras.

The First Era: Stochastic Gradient Descent (SGD).

Recall that stochastic gradient methods iteratively perform the following update

$$\text{stochastic gradient iteration:}\qquad x_{k+1}\leftarrow\arg\min_{y\in\mathbb{R}^d}\left\{\frac{1}{2\eta}\|y-x_k\|_2^2+\langle\widetilde{\nabla}_k,y\rangle+\psi(y)\right\}\ ,$$

where η is the step length and $\widetilde{\nabla}_k$ is a random vector satisfying $\mathbb{E}[\widetilde{\nabla}_k]=\nabla f(x_k)$ and is referred to as the *gradient estimator*. If the proximal function $\psi(y)$ equals zero, the update reduces to $x_{k+1}\leftarrow x_k-\eta\widetilde{\nabla}_k$. A popular choice for the gradient estimator is to set $\widetilde{\nabla}_k=\nabla f_i(x_k)$ for some random index $i\in[n]$ per iteration, and methods based on this choice are known as *stochastic gradient descent (SGD)* (Zhang, 2004; Bottou). Since computing $\nabla f_i(x)$ is usually n times faster than that of $\nabla f(x)$, SGD enjoys a low per-iteration cost as compared to full-gradient methods; however, SGD cannot converge at a rate faster than $1/\varepsilon$ even if $F(\cdot)$ is strongly convex and smooth.

∗. The arXiv version of this paper can be found at `http://arxiv.org/abs/1603.05953`, and may include future revisions.

1. In practice, experimentalists have observed that momentums could sometimes help if stochastic gradient iterations are used. However, the so-obtained methods (1) sometimes fail to converge in an accelerated rate, (2) become unstable and hard to tune, and (3) have no support theory behind them. See Section 7.1 for an experiment illustrating that, even for convex stochastic optimization.

The Second Era: Variance Reduction Gives Faster Convergence.

The convergence rate of SGD can be further improved with the so-called *variance-reduction* technique, first proposed by Schmidt et al. (2013) (solving a sub-case of Problem (1.1)) and then followed by many others (Zhang et al., 2013; Mahdavi et al., 2013; Johnson and Zhang, 2013; Shalev-Shwartz and Zhang, 2013; Shalev-Shwartz, 2016; Shalev-Shwartz and Zhang, 2012; Xiao and Zhang, 2014; Defazio et al., 2014; Mairal, 2015; Allen-Zhu and Yuan, 2016). In these cited results, the authors have shown that SGD converges much faster if one makes a better choice of the gradient estimator $\widetilde{\nabla}_k$ so that its variance reduces as k increases. One way to choose this estimator can be described as follows (Johnson and Zhang, 2013; Zhang et al., 2013). Keep a *snapshot* vector $\widetilde{x} = x_k$ that is updated once every m iterations (where m is some parameter usually around $2n$), and compute the full gradient $\nabla f(\widetilde{x})$ only for such snapshots. Then, set

$$\widetilde{\nabla}_k = \nabla f_i(x_k) - \nabla f_i(\widetilde{x}) + \nabla f(\widetilde{x}) \ . \tag{1.2}$$

This choice of gradient estimator ensures that its variance approaches to zero as k grows. Furthermore, the number of stochastic gradients (i.e., the number of computations of $\nabla f_i(x)$ for some i) required to reach an ε-approximate minimizer of Problem (1.1) is only $O\big(\big(n+\frac{L}{\sigma}\big)\log\frac{1}{\varepsilon}\big)$. Since it is often denoted by $\kappa \stackrel{\text{def}}{=} L/\sigma$ the condition number of the problem, we rewrite the above iteration complexity as $O\big((n+\kappa)\log\frac{1}{\varepsilon}\big)$.

Unfortunately, the iteration complexities of all known variance-reduction based methods have a linear dependence on κ. It was an open question regarding how to obtain an *accelerated* stochastic gradient method with an optimal $\sqrt{\kappa}$ dependency.

The Third Era: Acceleration Gives Fastest Convergence.

This open question was partially solved recently by the APPA (Frostig et al., 2015) and Catalyst (Lin et al., 2015) reductions, both based on an outer-inner loop structure first proposed by Shalev-Shwartz and Zhang (2014). We refer to both of them as Catalyst in this paper. Catalyst solves Problem (1.1) using $O\big(\big(n+\sqrt{n\kappa}\big)\log\kappa\log\frac{1}{\varepsilon}\big)$ stochastic gradient iterations, through a logarithmic number of calls to a variance-reduction method.[2] However, Catalyst is still imperfect for the following reasons:

- Optimality. Catalyst does not match the optimal $\sqrt{\kappa}$ dependence (Woodworth and Srebro, 2016) and has an extra $\log\kappa$ factor. It yields suboptimal rate $\frac{\log^4 T}{T^2}$ if the objective is not strongly convex or is non-smooth; and it yields suboptimal rate $\frac{\log^4 T}{T}$ if the objective is both non-strongly convex and non-smooth.[3]
- Practicality. To the best of our knowledge, Catalyst is not very practical since each of its inner iterations needs to be very accurately executed. This makes the stopping criterion hard to be tuned, and makes Catalyst sometimes run slower than non-accelerated variance-reduction methods. We have also confirmed this in our experiments.
- Parallelism. To the best of our knowledge, Catalyst does not give competent parallel performance (see Section 1.2). If $b \in \{1,\dots,n\}$ stochastic gradients (instead of one) are computed in each iteration, the number of iterations of Catalyst reduces by $O(\sqrt{b})$. In contrast, the best parallel speedup one can hope for is "linear speedup": that is, to reduce the number of iterations by a factor of $O(b)$ for $b \le \sqrt{n}$.
- Generality. To the best of our knowledge, being a reduction-based method, Catalyst does not seem to support non-Euclidean norm smoothness (see Section 1.2).

Another acceleration method by Lan and Zhou (2015) is based on a primal-dual analysis that also has suboptimal convergence rates like Catalyst. Their method requires n times more storage compared with Catalyst for solving Problem (1.1).

In sum, it is desirable and also an open question to develop a *direct*, *primal-only*, and *optimal* accelerated stochastic gradient method without using reductions. This could have both theoretical and practical impacts to the problems that fall into the general framework of (1.1), and potentially deepen our understanding to acceleration in stochastic settings.

1.1 Our Main Results and High-Level Ideas

We develop a direct, accelerated stochastic gradient method `Katyusha` for Problem (1.1) in

$$\boxed{O\big(\big(n+\sqrt{n\kappa}\big)\log(1/\varepsilon)\big) \text{ stochastic gradient iterations (see Theorem 2.1).}}$$

This gives both optimal dependency on κ and on ε which was not obtained before for stochastic gradient methods. In addition, if $F(\cdot)$ is non-strongly convex (non-SC), `Katyusha` converges to an ε-minimizer in

$$\boxed{O\big(n\log(1/\varepsilon)+\sqrt{nL/\varepsilon}\,\big) \text{ stochastic gradient iterations (see Corollary 3.7).}}$$

This gives an optimal $\varepsilon \propto \frac{n}{T^2}$ rate where in contrast Catalyst has rate $\varepsilon \propto \frac{n\log^4 T}{T^2}$. The lower bound from Woodworth and Srebro (2016) is $\Omega\big(n+\sqrt{nL/\varepsilon}\big)$.

Our Algorithm. If ignoring the proximal term $\psi(\cdot)$ and viewing it as zero, our `Katyusha` method iteratively perform the following updates for $k = 0, 1, \dots$:

- $x_{k+1} \leftarrow \tau_1 z_k + \tau_2 \widetilde{x} + (1-\tau_1-\tau_2) y_k$; (so $x_{k+1} = y_k + \tau_1(z_k - y_k) + \tau_2(\widetilde{x} - y_k)$)
- $\widetilde{\nabla}_{k+1} \leftarrow \nabla f(\widetilde{x}) + \nabla f_i(x_{k+1}) - \nabla f_i(\widetilde{x})$ where i is a random index in $[n]$;
- $y_{k+1} \leftarrow x_{k+1} - \frac{1}{3L}\widetilde{\nabla}_{k+1}$, and
- $z_{k+1} \leftarrow z_k - \alpha\widetilde{\nabla}_{k+1}$.

Above, $\widetilde{x}$ is a snapshot point which is updated every m iterations, $\widetilde{\nabla}_{k+1}$ is the gradient estimator defined in the same way as (1.2), $\tau_1, \tau_2 \in [0,1]$ are two momentum parameters, and α is a parameter that is equal to $\frac{1}{3\tau_1 L}$. The reason for keeping three vector sequences (x_k, y_k, z_k) is a common ingredient that can be found in all existing accelerated methods.[4]

Our New Technique – Katyusha Momentum. The most interesting ingredient of `Katyusha` is the novel choice of x_{k+1} which is a convex combination of y_k, z_k, and $\widetilde{x}$. Our theory suggests the parameter choices $\tau_2 = 0.5$ and $\tau_1 = \min\{\sqrt{n\sigma/L}, 0.5\}$ and they work well in practice too. To explain this novel combination, let us recall the classical "momentum" view of accelerated methods.

2. Note that $n+\sqrt{n\kappa}$ is always less than $O(n+\kappa)$.
3. Obtaining *optimal* rates is one of the main goals in optimization and machine learning. For instance, obtaining the optimal $1/T$ rate for online learning was a very meaningful result, even though the $\log T/T$ rate was known (Hazan and Kale, 2014; Rakhlin et al., 2012).
4. One can of course rewrite the algorithm and keep track of only two vectors per iteration during implementation. This will make the algorithm statement less clean so we refrain from doing so in this paper.

In a classical accelerated gradient method, x_{k+1} is only a convex combination of y_k and z_k (or equivalently, $\tau_2 = 0$ in our formulation). At a high level, z_k plays the role of "momentum" which adds a weighted sum of the gradient history into y_{k+1}. As an illustrative example, suppose $\tau_2 = 0$, $\tau_1 = \tau$, and $x_0 = y_0 = z_0$. Then, one can compute that

$$y_k = \begin{cases} x_0 - \frac{1}{3L}\widetilde{\nabla}_1, & k=1; \\ x_0 - \frac{1}{3L}\widetilde{\nabla}_2 - \big((1-\tau)\frac{1}{3L}+\tau\alpha\big)\widetilde{\nabla}_1, & k=2; \\ x_0 - \frac{1}{3L}\widetilde{\nabla}_3 - \big((1-\tau)\frac{1}{3L}+\tau\alpha\big)\widetilde{\nabla}_2 - \big((1-\tau)^2\frac{1}{3L}+(1-(1-\tau)^2)\alpha\big)\widetilde{\nabla}_1, & k=3. \end{cases}$$

Since α is usually much larger than $1/3L$, the above recursion suggests that the contribution of a fixed gradient $\widetilde{\nabla}_t$ gradually increases as time goes. For instance, the weight on $\widetilde{\nabla}_1$ is increasing because $\frac{1}{3L} < \big((1-\tau)\frac{1}{3L}+\tau\alpha\big) < \big((1-\tau)^2\frac{1}{3L}+(1-(1-\tau)^2)\alpha\big)$. This is known as "momentum" which is at the heart of all accelerated first-order methods.

In `Katyusha`, we put a "magnet" around $\widetilde{x}$, where we choose $\widetilde{x}$ to be essentially "the average x_t of the most recent n iterations". Whenever we compute the next x_{k+1}, it will be attracted by the magnet $\widetilde{x}$ with weight $\tau_2 = 0.5$. This is a strong magnet: it ensures that x_{k+1} is not too far away from $\widetilde{x}$ so the gradient estimator remains "accurate enough". This can be viewed as a "negative momentum" component, because the magnet retracts x_{k+1} back to $\widetilde{x}$ and this can be understood as "counteracting a fraction of the positive momentum incurred from earlier iterations."

We call it the Katyusha momentum.

This summarizes the high-level idea behind our `Katyusha` method. We remark here if $\tau_1 = \tau_2 = 0$, `Katyusha` becomes almost identical to SVRG (Johnson and Zhang, 2013; Zhang et al., 2013) which is a variance-reduction based method.

1.2 Our Side Results

Parallelism / Mini-batch. Instead of using a single $\nabla f_i(\cdot)$ per iteration, for any stochastic gradient method, one can replace it with the average of b stochastic gradients $\frac{1}{b}\sum_{i\in S}\nabla f_i(\cdot)$, where S is a random subset of $[n]$ with cardinality b. This is known as the *mini-batch* technique and it allows the stochastic gradients to be computed in a distributed manner, using up to b processors.

Our `Katyusha` method trivially extends to this mini-batch setting. For instance, at least for $b \in \{1, 2, \ldots, \lceil\sqrt{n}\rceil\}$, `Katyusha` enjoys a *linear speed-up* in the parallel running time. In other words, if ignoring communication overhead,

> `Katyusha` can be distributed to $b \le \sqrt{n}$ machines with a parallel speed-up factor b.

In contrast, to the best of our knowledge, without any additional assumption, (1) non-accelerated methods such as SVRG or SAGA are not known to enjoy any parallel speed-up; (2) Catalyst enjoys a parallel speed-up factor of only $\sqrt{b}$. Details are in Section 5.

Non-Uniform Smoothness. If each $f_i(\cdot)$ has a possibly different smooth parameter L_i and $\overline{L} = \frac{1}{n}\sum_{i=1}^n L_i$, then an naive implementation of `Katyusha` only gives a complexity that depends on $\max_i L_i$ but not $\overline{L}$. In such a case, we can select the random index $i \in [n]$ with probability proportional to L_i per iteration to slightly improve the total running time.

Furthermore, suppose $f(x) = \frac{1}{n}\sum_{i=1}^n f_i(x)$ is smooth with parameter L, it satisfies $\overline{L} \in [L, nL]$. One can ask whether or not L influences the performance of `Katyusha`. We show that, in the mini-batch setting when b is large, the total complexity becomes a function on L as opposed to $\overline{L}$. The details are in Section 5.

A Precise Statement. Taking into account both the mini-batch parameter b and the non-uniform smoothness parameters L and $\overline{L}$, we show `Katyusha` solves Problem (1.1) in

$$\boxed{O\Big(\big(n + b\sqrt{L/\sigma} + \sqrt{n\overline{L}/\sigma}\big)\cdot\log\frac{1}{\varepsilon}\Big) \text{ stochastic gradient computations (see Theorem 5.2)}}$$

Non-Euclidean Norms. If the smoothness of each $f_i(x)$ is with respect to a non-Euclidean norm (such as the well known ℓ_1 norm case over the simplex), our main result still holds. Our update on the y_{k+1} side becomes the non-Euclidean norm gradient descent, and our update on the z_{k+1} side becomes the non-Euclidean norm mirror descent. We include such details in Section 6. To the best of our knowledge, most known accelerated methods (including Catalyst, AccSDCA and APCG) do not work with non-Euclidean norms. SPDC can be revised to work with non-Euclidean norms, see (Allen-Zhu et al., 2016b).

Remark on Katyusha Momentum Weight τ_2. To provide the simplest proof, we choose $\tau_2 = 1/2$ which also works well in practice. Our proof trivially generalizes to all constant values $\tau_2 \in (0, 1)$, and it could be beneficial to tune τ_2 for different datasets. However, for a stronger comparison, in our experiments we refrain from tuning τ_2: by fixing $\tau_2 = 1/2$ and without increasing parameter tuning difficulties, `Katyusha` already outperforms most of the state-of-the-arts.

In the mini-batch setting, it turns out the best theoretical choice is essentially $\tau_2 = \frac{1}{2b}$, where b is the size of the mini-batch. In other words, the larger the mini-batch size, the smaller weight we want to give to Katyusha momentum. This should be intuitive, because when $b = n$ we are almost in the full-gradient setting and do not need Katyusha momentum.

1.3 Applications: Optimal Rates for Empirical Risk Minimization

Suppose we are given n feature vectors $a_1, \ldots, a_n \in \mathbb{R}^d$ corresponding to n data samples. Then, the *empirical risk minimization (ERM)* problem is to study Problem (1.1) when each $f_i(x)$ is "rank-one" structured: $f_i(x) \stackrel{\text{def}}{=} g_i(\langle a_i, x\rangle)$ for some loss function $g_i : \mathbb{R} \to \mathbb{R}$. Slightly abusing notation, we write $f_i(x) = f_i(\langle a_i, x\rangle)$.[5] In such a case, Problem (1.1) becomes

$$\text{ERM:} \quad \min_{x\in\mathbb{R}^d}\Big\{F(x) \stackrel{\text{def}}{=} f(x) + \psi(x) \stackrel{\text{def}}{=} \tfrac{1}{n}\textstyle\sum_{i=1}^n f_i(\langle a_i, x\rangle) + \psi(x)\Big\} \ . \tag{1.3}$$

Without loss of generality, we assume each a_i has norm 1 because otherwise one can scale $f_i(\cdot)$ accordingly. As summarized for instance in Allen-Zhu and Hazan (2016b), there are four interesting cases of ERM problems, all can be written in the form of (1.3):

Case 1: $\psi(x)$ is σ-SC and $f_i(x)$ is L-smooth. Examples: ridge regression, elastic net;

Case 2: $\psi(x)$ is non-SC and $f_i(x)$ is L-smooth. Examples: Lasso, logistic regression;

Case 3: $\psi(x)$ is σ-SC and $f_i(x)$ is non-smooth. Examples: support vector machine;

5. Assuming "rank-one" simplifies the notations; all of the results stated in this subsection generalize to constant-rank structured functions $f_i(x)$.

Case 4: $\psi(x)$ is non-SC and $f_i(x)$ is non-smooth. Examples: ℓ_1-SVM.

Known Results. For all of the four ERM cases above, accelerated stochastic methods were introduced in the literature, most notably AccSDCA (Shalev-Shwartz and Zhang, 2014), APCG (Lin et al., 2014), SPDC (Zhang and Xiao, 2015). These methods have suboptimal convergence rates for Cases 2, 3 and 4. (In fact, they also have the suboptimal dependence on the condition number L/σ for Case 1.) The best known rate was $\frac{\log(1/\varepsilon)}{\sqrt{\varepsilon}}$, $\frac{\log(1/\varepsilon)}{\sqrt{\varepsilon}}$, or $\frac{\log(1/\varepsilon)}{\varepsilon}$ respectively for Cases 2, 3, or 4, and is a factor $\log(1/\varepsilon)$ worse than optimal (Woodworth and Srebro, 2016).

It is an open question to design a stochastic gradient method with optimal convergence for such problems. In particular, Dang and Lan (2014) provided an interesting attempt to remove such log factors but using a non-classical notion of convergence.[6]

Besides the log factor loss in the running time,[7] the aforementioned methods suffer from several other issues that most dual-based methods also suffer. First, they only apply to ERM problems but not to the more general Problem (1.1). Second, they require proximal updates with respect to the Fenchel conjugate $f_i^*(\cdot)$ which is sometimes unpleasant to work with. Third, their performances cannot benefit from the implicit strong convexity in $f(\cdot)$. All of these issues together make these methods sometimes even outperformed by primal-only non-accelerated ones, such as SAGA (Defazio et al., 2014) or SVRG (Johnson and Zhang, 2013; Zhang et al., 2013).

Our Results. `Katyusha` simultaneously closes the gap for all of the three classes of problems with the help from the optimal reductions developed in Allen-Zhu and Hazan (2016b). We obtain an ε-approximate minimizer for Case 2 in $O\big(n\log\frac{1}{\varepsilon}+\frac{\sqrt{nL}}{\sqrt{\varepsilon}}\big)$ iterations, for Case 3 in $O\big(n\log\frac{1}{\varepsilon}+\frac{\sqrt{n}}{\sqrt{\sigma\varepsilon}}\big)$ iterations, and for Case 4 in $O\big(n\log\frac{1}{\varepsilon}+\frac{\sqrt{n}}{\varepsilon}\big)$ iterations. None of the existing accelerated methods can lead to such optimal rates even if the optimal reductions are used.

Woodworth and Srebro (2016) proved the tightness of our results. They showed lower bounds $\Omega\big(n+\frac{\sqrt{nL}}{\sqrt{\varepsilon}}\big)$, $\Omega\big(n+\frac{\sqrt{n}}{\sqrt{\sigma\varepsilon}}\big)$, and $\Omega\big(n+\frac{\sqrt{n}}{\varepsilon}\big)$ for Cases 2, 3, and 4 respectively.[8]

1.4 Roadmap

- In Section 2, we state and prove our theorem on `Katyusha` for the strongly convex case.
- In Section 3, we apply `Katyusha` to non-strongly convex or non-smooth cases by reductions.
- In Section 4, we provide a *direct* algorithm `Katyusha`$^{\mathtt{ns}}$ for the non-strongly case.
- In Section 5, we generalize `Katyusha` to mini-batch and non-uniform smoothness.
- In Section 6, we generalize `Katyusha` to the non-Euclidean norm setting.
- In Section 7, we provide an empirical evaluation to illustrate the necessity of Katyusha momentum, and the practical performance of `Katyusha`.

1.5 Notations

Throughout this paper (except Section 6), we denote by $\|\cdot\|$ the Euclidean norm. We denote by $\nabla f(x)$ the full gradient of function f if it is differentiable, or any of its subgradients if f is only Lipschitz continuous. Recall some classical definitions on strong convexity (SC) and smoothness.

Definition 1.1 *For a convex function $f\colon \mathbb{R}^n \to \mathbb{R}$,*

- *f is σ-strongly convex if $\forall x,y\in\mathbb{R}^n$, it satisfies $f(y)\geq f(x)+\langle\nabla f(x),y-x\rangle+\frac{\sigma}{2}\|x-y\|^2$.*
- *f is L-smooth if $\forall x,y\in\mathbb{R}^n$, it satisfies $\|\nabla f(x)-\nabla f(y)\|\leq L\|x-y\|$.*

2. Katyusha in the Strongly Convex Setting

We formally introduce our `Katyusha` algorithm in Algorithm 1. It follows from our high-level description in Section 1.1, and we make several remarks here behind our specific design.

- `Katyusha` *is divided into epochs each consisting of m iterations. In theory, m can be anything linear in n. We let snapshot $\widetilde{x}$ be a weighted average of y_k in the most recent epoch.*

  $\widetilde{x}$ and $\widetilde{\nabla}_k$ correspond to a standard design on variance-reduced gradient estimators, called SVRG (Johnson and Zhang, 2013; Zhang et al., 2013). The practical recommendation is $m=2n$ (Johnson and Zhang, 2013). Our choice $\widetilde{\nabla}_k$ is independent from our acceleration techniques, and we expect our result continues to apply to other choices of gradient estimators. We choose $\widetilde{x}$ to be a weighted average, rather than the last or the uniform average, because it yields the tightest possible result.[9]

- *τ_1 and α are standard parameters already present in Nesterov's full-gradient method (Allen-Zhu and Orecchia, 2017).*

  We choose $\alpha=1/3\tau_1 L$ to present the simplest proof, and recall it was $\alpha=1/\tau_1 L$ in the original Nesterov's full-gradient method. (Any α that is constant factor smaller than $1/\tau_1 L$ works in theory, and we use $1/3$ to provide the simplest proof.) In practice, like other accelerated methods, it suffices to fix $\alpha=1/3\tau_1 L$ and only tune τ_1 and thus τ_1 is viewed as the learning rate.

6. Dang and Lan (2014) work in a primal-dual $\phi(x,y)$ formulation of Problem (1.1), and produce a primal-dual pair (x,y) so that for every fixed (u,v), the expectation $\mathbb{E}[\phi(x,v)-\phi(u,y)]\leq\varepsilon$. Unfortunately, to ensure x is an ε-approximate minimizer of Problem (1.1), one needs the stronger $\mathbb{E}[\max_{(u,v)}\phi(x,v)-\phi(u,y)]\leq\varepsilon$ to hold.
7. In fact, dual-based methods have to suffer from a log factor loss in the convergence rate. This is so because even for Case 1 of Problem (1.3), converting an ε-maximizer for the dual objective to the primal, one only obtains an $n\kappa\varepsilon$-minimizer on the primal objective. As a result, algorithms like APCG who directly work on the dual, algorithms like SPDC who maintain both primal and dual variables, and algorithms like RPDG (Lan and Zhou, 2015) that are primal-like but still use dual analysis, have to suffer from a log loss in the convergence rates.
8. More precisely, their lower bounds for Cases 3 and 4 are $\Omega\big(\min\big\{\frac{1}{\sigma\varepsilon},n+\frac{\sqrt{n}}{\sqrt{\sigma\varepsilon}}\big\}\big)$ and $\Omega\big(\min\big\{\frac{1}{\varepsilon^2},n+\frac{\sqrt{n}}{\varepsilon}\big\}\big)$. However, since the vanilla SGD requires $O(\frac{1}{\sigma\varepsilon})$ and $O(\frac{1}{\varepsilon^2})$ iterations for Cases 3 and 4, such lower bounds are matched by combining the best between `Katyusha` and SGD.
9. If one uses the uniform average, in theory, the algorithm needs to restart every a number of epochs (that is, by resetting $k=0$, $s=0$, and $x_0=y_0=z_0$); we refrain from doing so because we wish to provide a simple and direct algorithm. We can also use the last iterate, then the total complexity loses a factor $\log(L/\sigma)$. In practice, it was reported that even for SVRG, choosing average works better than choosing the last iterate (Allen-Zhu and Yuan, 2016).

Algorithm 1 `Katyusha`(x_0, S, σ, L)

$m \leftarrow 2n$; ◇ *epoch length*
$\tau_2 \leftarrow \frac{1}{2}$, $\tau_1 \leftarrow \min\{\frac{\sqrt{m\sigma}}{\sqrt{3L}}, \frac{1}{2}\}$, $\alpha \leftarrow \frac{1}{3\tau_1 L}$; ◇ *parameters*
$y_0 = z_0 = \widetilde{x}^0 \leftarrow x_0$; ◇ *initial vectors*
for $s \leftarrow 0$ **to** $S-1$ **do**
  $\mu^s \leftarrow \nabla f(\widetilde{x}^s)$; ◇ *compute the full gradient once every m iterations*
  for $j \leftarrow 0$ **to** $m-1$ **do**
    $k \leftarrow (sm)+j$;
    $x_{k+1} \leftarrow \tau_1 z_k + \tau_2 \widetilde{x}^s + (1-\tau_1-\tau_2) y_k$;
    $\widetilde{\nabla}_{k+1} \leftarrow \mu^s + \nabla f_i(x_{k+1}) - \nabla f_i(\widetilde{x}^s)$ where i is random from $\{1, 2, \ldots, n\}$;
    $z_{k+1} = \arg\min_z \{\frac{1}{2\alpha}\|z - z_k\|^2 + \langle \widetilde{\nabla}_{k+1}, z\rangle + \psi(z)\}$;
    Option I: $y_{k+1} \leftarrow \arg\min_y \{\frac{3L}{2}\|y - x_{k+1}\|^2 + \langle \widetilde{\nabla}_{k+1}, y\rangle + \psi(y)\}$;
    Option II: $y_{k+1} \leftarrow x_{k+1} + \tau_1(z_{k+1} - z_k)$ ◇ *we analyze only I but II also works*
  end for
  $\widetilde{x}^{s+1} \leftarrow \big(\sum_{j=0}^{m-1}(1+\alpha\sigma)^j\big)^{-1} \cdot \big(\sum_{j=0}^{m-1}(1+\alpha\sigma)^j \cdot y_{sm+j+1}\big)$; ◇ *compute snapshot $\widetilde{x}$*
end for
return $\widetilde{x}^S$.

- *The parameter τ_2 is our novel weight for the Katyusha momentum. Any constant in $(0,1)$ works for τ_2, and we simply choose $\tau_2 = 1/2$ for our theoretical and experimental results.*

We state our main theorem for `Katyusha` as follows:

Theorem 2.1 *If each $f_i(x)$ is convex, L-smooth, and $\psi(x)$ is σ-strongly convex in the above Problem (1.1), then* `Katyusha`(x_0, S, σ, L) *satisfies*

$$\mathbb{E}\big[F(\widetilde{x}^S)\big] - F(x^*) \le \begin{cases} O\Big(\big(1+\sqrt{\sigma/(3Lm)}\big)^{-Sm}\Big) \cdot \big(F(x_0) - F(x^*)\big), & \text{if } \frac{m\sigma}{L} \le \frac{3}{4}; \\ O\big(1.5^{-S}\big) \cdot \big(F(x_0) - F(x^*)\big), & \text{if } \frac{m\sigma}{L} > \frac{3}{4}. \end{cases}$$

In other words, choosing $m = \Theta(n)$, `Katyusha` *achieves an ε-additive error (i.e., $\mathbb{E}\big[F(\widetilde{x}^S)\big] - F(x^*) \le \varepsilon$) using at most $O\big(\big(n+\sqrt{nL/\sigma}\big) \cdot \log\frac{F(x_0)-F(x^*)}{\varepsilon}\big)$ iterations.*[10]

The proof of Theorem 2.1 is included in Section 2.1 and 2.2. As discussed in Section 1.1, the main idea behind our theorem is the negative momentum that helps reduce the error occurred from the stochastic gradient estimator.

Remark 2.2 *Because $m = 2n$, each iteration of* `Katyusha` *computes only 1.5 stochastic gradients $\nabla f_i(\cdot)$ in the amortized sense, the same as non-accelerated methods such as SVRG (Johnson and Zhang, 2013).*[11] *Therefore, the per-iteration cost of* `Katyusha` *is dominated by the computation of $\nabla f_i(\cdot)$, the proximal update in Line 10 of Algorithm 1, plus an overhead $O(d)$. If $\nabla f_i(\cdot)$ has at most $d' \le d$ non-zero entries, this overhead $O(d)$ is improvable to $O(d')$ using a sparse implementation of* `Katyusha`.[12]

For ERM problems defined in Problem (1.3), the amortized per-iteration complexity of `Katyusha` *is $O(d')$ where d' is the sparsity of feature vectors, the same as the per-iteration complexity of SGD.*

11. The claim "SVRG or `Katyusha` computes 1.5 stochastic gradients" requires one to store $\nabla_i f(\widetilde{x})$ in the memory for each $i \in [n]$, and this costs $O(dn)$ space in the most general setting. If one does not store $\nabla_i f(\widetilde{x})$ in the memory, then each iteration of SVRG or `Katyusha` computes 2.5 stochastic gradients for the choice $m = 2n$.

2.1 One-Iteration Analysis

In this subsection, we first analyze the behavior of `Katyusha` in a single iteration (i.e., for a fixed k). We view y_k, z_k and x_{k+1} as fixed in this section so the only randomness comes from the choice of i in iteration k. We abbreviate in this subsection by $\widetilde{x} = \widetilde{x}^s$ where s is the epoch that iteration k belongs to, and denote by $\sigma_{k+1}^2 \stackrel{\text{def}}{=} \|\nabla f(x_{k+1}) - \widetilde{\nabla}_{k+1}\|^2$ so $\mathbb{E}[\sigma_{k+1}^2]$ is the variance of the gradient estimator $\widetilde{\nabla}_{k+1}$ in this iteration.

Our first lemma lower bounds the expected objective decrease $F(x_{k+1}) - \mathbb{E}[F(y_{k+1})]$. Our $\mathsf{Prog}(x_{k+1})$ defined below is a non-negative, classical quantity that would be a lower bound on the amount of objective decrease if $\widetilde{\nabla}_{k+1}$ were equal to $\nabla f(x_{k+1})$ (Allen-Zhu and Orecchia, 2017). However, since the variance σ_{k+1}^2 is non-zero, this lower bound must be compensated by a negative term that depends on $\mathbb{E}[\sigma_{k+1}^2]$.

Lemma 2.3 (proximal gradient descent) *If*

$$y_{k+1} = \arg\min_y \Big\{\frac{3L}{2}\|y - x_{k+1}\|^2 + \langle \widetilde{\nabla}_{k+1}, y - x_{k+1}\rangle + \psi(y) - \psi(x_{k+1})\Big\} \ , \qquad \text{and}$$

$$\mathsf{Prog}(x_{k+1}) \stackrel{\text{def}}{=} -\min_y \Big\{\frac{3L}{2}\|y - x_{k+1}\|^2 + \langle \widetilde{\nabla}_{k+1}, y - x_{k+1}\rangle + \psi(y) - \psi(x_{k+1})\Big\} \ge 0 \ ,$$

we have (where the expectation is only over the randomness of $\widetilde{\nabla}_{k+1}$)

$$F(x_{k+1}) - \mathbb{E}\big[F(y_{k+1})\big] \ge \mathbb{E}\big[\mathsf{Prog}(x_{k+1})\big] - \frac{1}{4L}\mathbb{E}[\sigma_{k+1}^2] \ .$$

Proof

$$\begin{aligned} \mathsf{Prog}(x_{k+1}) &= -\min_y \Big\{\frac{3L}{2}\|y - x_{k+1}\|^2 + \langle \widetilde{\nabla}_{k+1}, y - x_{k+1}\rangle + \psi(y) - \psi(x_{k+1})\Big\} \\ &\stackrel{①}{=} -\Big(\frac{3L}{2}\|y_{k+1} - x_{k+1}\|^2 + \langle \widetilde{\nabla}_{k+1}, y_{k+1} - x_{k+1}\rangle + \psi(y_{k+1}) - \psi(x_{k+1})\Big) \\ &= -\Big(\frac{L}{2}\|y_{k+1} - x_{k+1}\|^2 + \langle \nabla f(x_{k+1}), y_{k+1} - x_{k+1}\rangle + \psi(y_{k+1}) - \psi(x_{k+1})\Big) \\ &\quad + \Big(\langle \nabla f(x_{k+1}) - \widetilde{\nabla}_{k+1}, y_{k+1} - x_{k+1}\rangle - L\|y_{k+1} - x_{k+1}\|^2\Big) \\ &\stackrel{②}{\le} -\Big(f(y_{k+1}) - f(x_{k+1}) + \psi(y_{k+1}) - \psi(x_{k+1})\Big) + \frac{1}{4L}\|\nabla f(x_{k+1}) - \widetilde{\nabla}_{k+1}\|^2 \ . \end{aligned}$$

Above, ① is by the definition of y_{k+1}, and ② uses the smoothness of function $f(\cdot)$, as well as Young's inequality $\langle a, b\rangle - \frac{1}{2}\|b\|^2 \le \frac{1}{2}\|a\|^2$. Taking expectation on both sides we arrive at the desired result. ■

12. This requires to defer a coordinate update to the moment it is accessed. Update deferral is a standard technique used in sparse implementations of all stochastic gradient methods, including SVRG, SAGA, APCG (Johnson and Zhang, 2013; Defazio et al., 2014; Lin et al., 2014).

The following lemma provides a novel upper bound on the expected variance of the gradient estimator. Note that all known variance reduction analysis for convex optimization, in one way or another, upper bounds this variance essentially by $4L\cdot(f(\widetilde{x})-f(x^*))$, the objective distance to the minimizer (c.f. Johnson and Zhang (2013); Defazio et al. (2014)). The recent result of Allen-Zhu and Hazan (2016b) upper bounds it by the point distance $\|x_{k+1}-\widetilde{x}\|^2$ for non-convex objectives, which is tighter if $\widetilde{x}$ is close to x_{k+1} but unfortunately not enough for the purpose of this paper.

In this paper, we upper bound it by the tightest possible quantity which is essentially $2L\cdot\big(f(\widetilde{x})-f(x_{k+1})\big)\ll 4L\cdot\big(f(\widetilde{x})-f(x^*)\big)$. Unfortunately, this upper bound needs to be compensated by an additional term $\langle\nabla f(x_{k+1}),\widetilde{x}-x_{k+1}\rangle$, which could be positive but we shall cancel it using the introduced Katyusha momentum.

Lemma 2.4 (variance upper bound)

$$\mathbb{E}\big[\|\widetilde{\nabla}_{k+1}-\nabla f(x_{k+1})\|^2\big]\le 2L\cdot\big(f(\widetilde{x})-f(x_{k+1})-\langle\nabla f(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\big)\ .$$

Proof Each $f_i(x)$, being convex and L-smooth, implies the following inequality which is classical in convex optimization and can be found for instance in Theorem 2.1.5 of the textbook of Nesterov (2004).

$$\|\nabla f_i(x_{k+1})-\nabla f_i(\widetilde{x})\|^2\le 2L\cdot\big(f_i(\widetilde{x})-f_i(x_{k+1})-\langle\nabla f_i(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\big)$$

Therefore, taking expectation over the random choice of i, we have

$$\begin{aligned}\mathbb{E}\big[\|\widetilde{\nabla}_{k+1}-\nabla f(x_{k+1})\|^2\big]&=\mathbb{E}\big[\big\|\big(\nabla f_i(x_{k+1})-\nabla f_i(\widetilde{x})\big)-\big(\nabla f(x_{k+1})-\nabla f(\widetilde{x})\big)\big\|^2\big]\\&\overset{①}{\le}\mathbb{E}\big[\big\|\nabla f_i(x_{k+1})-\nabla f_i(\widetilde{x})\big\|^2\big]\\&\overset{②}{\le}2L\cdot\mathbb{E}\big[f_i(\widetilde{x})-f_i(x_{k+1})-\langle\nabla f_i(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\big]\\&=2L\cdot\big(f(\widetilde{x})-f(x_{k+1})-\langle\nabla f(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\big)\ .\end{aligned}$$

Above, ① is because for any random vector $\zeta\in\mathbb{R}^d$, it holds that $\mathbb{E}\|\zeta-\mathbb{E}\zeta\|^2=\mathbb{E}\|\zeta\|^2-\|\mathbb{E}\zeta\|^2$; ② follows from the first inequality in this proof. ■

The next lemma is a classical one for proximal mirror descent.

Lemma 2.5 (proximal mirror descent) *Suppose $\psi(\cdot)$ is σ-SC. Then, fixing $\widetilde{\nabla}_{k+1}$ and letting*

$$z_{k+1}=\arg\min_z\big\{\frac{1}{2}\|z-z_k\|^2+\alpha\langle\widetilde{\nabla}_{k+1},z-z_k\rangle+\alpha\psi(z)-\alpha\psi(z_k)\big\}\ ,$$

it satisfies for all $u\in\mathbb{R}^d$,

$$\alpha\langle\widetilde{\nabla}_{k+1},z_{k+1}-u\rangle+\alpha\psi(z_{k+1})-\alpha\psi(u)\le-\frac{1}{2}\|z_k-z_{k+1}\|^2+\frac{1}{2}\|z_k-u\|^2-\frac{1+\alpha\sigma}{2}\|z_{k+1}-u\|^2\ .$$

Proof By the minimality definition of z_{k+1}, we have that

$$z_{k+1}-z_k+\alpha\widetilde{\nabla}_{k+1}+\alpha g=0$$

where g is *some* subgradient of $\psi(z)$ at point $z=z_{k+1}$. This implies that for every u it satisfies

$$0=\big\langle z_{k+1}-z_k+\alpha\widetilde{\nabla}_{k+1}+\alpha g,z_{k+1}-u\big\rangle\ .$$

At this point, using the equality $\langle z_{k+1}-z_k,z_{k+1}-u\rangle=\frac{1}{2}\|z_k-z_{k+1}\|^2-\frac{1}{2}\|z_k-u\|^2+\frac{1}{2}\|z_{k+1}-u\|^2$, as well as the inequality $\langle g,z_{k+1}-u\rangle\ge\psi(z_{k+1})-\psi(u)+\frac{\sigma}{2}\|z_{k+1}-u\|^2$ which comes from the strong convexity of $\psi(\cdot)$, we can write

$$\begin{aligned}&\alpha\langle\widetilde{\nabla}_{k+1},z_{k+1}-u\rangle+\alpha\psi(z_{k+1})-\alpha\psi(u)\\&=-\langle z_{k+1}-z_k,z_{k+1}-u\rangle-\langle\alpha g,z_{k+1}-u\rangle+\alpha\psi(z_{k+1})-\alpha\psi(u)\\&\le-\frac{1}{2}\|z_k-z_{k+1}\|^2+\frac{1}{2}\|z_k-u\|^2-\frac{1+\alpha\sigma}{2}\|z_{k+1}-u\|^2\ .\end{aligned}$$

■

The following lemma combines Lemma 2.3, Lemma 2.4 and Lemma 2.5 all together, using the special choice of x_{k+1} which is a convex combination of y_k, z_k and $\widetilde{x}$:

Lemma 2.6 (coupling step 1) *If $x_{k+1}=\tau_1z_k+\tau_2\widetilde{x}+(1-\tau_1-\tau_2)y_k$, where $\tau_1\le\frac{1}{3\alpha L}$ and $\tau_2=\frac{1}{2}$,*

$$\begin{aligned}&\alpha\langle\nabla f(x_{k+1}),z_k-u\rangle-\alpha\psi(u)\\&\le\frac{\alpha}{\tau_1}\Big(F(x_{k+1})-\mathbb{E}\big[F(y_{k+1})\big]+\tau_2F(\widetilde{x})-\tau_2f(x_{k+1})-\tau_2\langle\nabla f(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\Big)\\&\quad+\frac{1}{2}\|z_k-u\|^2-\frac{1+\alpha\sigma}{2}\mathbb{E}\big[\|z_{k+1}-u\|^2\big]+\frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}\psi(y_k)-\frac{\alpha}{\tau_1}\psi(x_{k+1})\ .\end{aligned}$$

Proof We first apply Lemma 2.5 and get

$$\begin{aligned}&\alpha\langle\widetilde{\nabla}_{k+1},z_k-u\rangle+\alpha\psi(z_{k+1})-\alpha\psi(u)\\&=\alpha\langle\widetilde{\nabla}_{k+1},z_k-z_{k+1}\rangle+\alpha\langle\widetilde{\nabla}_{k+1},z_{k+1}-u\rangle+\alpha\psi(z_{k+1})-\alpha\psi(u)\\&\le\alpha\langle\widetilde{\nabla}_{k+1},z_k-z_{k+1}\rangle-\frac{1}{2}\|z_k-z_{k+1}\|^2+\frac{1}{2}\|z_k-u\|^2-\frac{1+\alpha\sigma}{2}\|z_{k+1}-u\|^2\ .\end{aligned}\tag{2.1}$$

By defining $v\overset{\text{def}}{=}\tau_1z_{k+1}+\tau_2\widetilde{x}+(1-\tau_1-\tau_2)y_k$, we have $x_{k+1}-v=\tau_1(z_k-z_{k+1})$ and therefore

$$\begin{aligned}&\mathbb{E}\Big[\alpha\langle\widetilde{\nabla}_{k+1},z_k-z_{k+1}\rangle-\frac{1}{2}\|z_k-z_{k+1}\|^2\Big]=\mathbb{E}\Big[\frac{\alpha}{\tau_1}\langle\widetilde{\nabla}_{k+1},x_{k+1}-v\rangle-\frac{1}{2\tau_1^2}\|x_{k+1}-v\|^2\Big]\\&=\mathbb{E}\Big[\frac{\alpha}{\tau_1}\Big(\langle\widetilde{\nabla}_{k+1},x_{k+1}-v\rangle-\frac{1}{2\alpha\tau_1}\|x_{k+1}-v\|^2-\psi(v)+\psi(x_{k+1})\Big)+\frac{\alpha}{\tau_1}\Big(\psi(v)-\psi(x_{k+1})\Big)\Big]\\&\overset{①}{\le}\mathbb{E}\Big[\frac{\alpha}{\tau_1}\Big(\langle\widetilde{\nabla}_{k+1},x_{k+1}-v\rangle-\frac{3L}{2}\|x_{k+1}-v\|^2-\psi(v)+\psi(x_{k+1})\Big)+\frac{\alpha}{\tau_1}\Big(\psi(v)-\psi(x_{k+1})\Big)\Big]\\&\overset{②}{\le}\mathbb{E}\Big[\frac{\alpha}{\tau_1}\Big(F(x_{k+1})-F(y_{k+1})+\frac{1}{4L}\sigma_{k+1}^2\Big)+\frac{\alpha}{\tau_1}\Big(\psi(v)-\psi(x_{k+1})\Big)\Big]\\&\overset{③}{\le}\mathbb{E}\Big[\frac{\alpha}{\tau_1}\Big(F(x_{k+1})-F(y_{k+1})+\frac{1}{2}\big(f(\widetilde{x})-f(x_{k+1})-\langle\nabla f(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\big)\Big)\\&\quad+\frac{\alpha}{\tau_1}\Big(\tau_1\psi(z_{k+1})+\tau_2\psi(\widetilde{x})+(1-\tau_1-\tau_2)\psi(y_k)-\psi(x_{k+1})\Big)\Big]\ .\end{aligned}\tag{2.2}$$

Above, ① uses our choice $\tau_1 \le \frac{1}{3\alpha L}$, ② uses Lemma 2.3, ③ uses Lemma 2.4 together with the convexity of $\psi(\cdot)$ and the definition of v. Finally, noticing that $\mathbb{E}[\langle \widetilde{\nabla}_{k+1}, z_k - u\rangle] = \langle \nabla f(x_{k+1}), z_k - u\rangle$ and $\tau_2 = \frac{1}{2}$, we obtain the desired inequality by combining (2.1) and (2.2). ■

The next lemma simplifies the left hand side of Lemma 2.6 using the convexity of $f(\cdot)$, and gives an inequality that relates the objective-distance-to-minimizer quantities $F(y_k) - F(x^*)$, $F(y_{k+1}) - F(x^*)$, and $F(\widetilde{x}) - F(x^*)$ to the point-distance-to-minimizer quantities $\|z_k - x^*\|^2$ and $\|z_{k+1} - x^*\|^2$.

Lemma 2.7 (coupling step 2) *Under the same choices of τ_1, τ_2 as in Lemma 2.6, we have*

$$0 \le \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}\big(F(y_k) - F(x^*)\big) - \frac{\alpha}{\tau_1}\big(\mathbb{E}\big[F(y_{k+1})\big] - F(x^*)\big) + \frac{\alpha\tau_2}{\tau_1}\big(F(\widetilde{x}) - F(x^*)\big) + \frac{1}{2}\|z_k - x^*\|^2 - \frac{1+\alpha\sigma}{2}\mathbb{E}\big[\|z_{k+1} - x^*\|^2\big] \ .$$

Proof We first compute that

$$\begin{aligned}
&\alpha\big(f(x_{k+1}) - f(u)\big) \overset{①}{\le} \alpha\langle \nabla f(x_{k+1}), x_{k+1} - u\rangle \\
&= \alpha\langle \nabla f(x_{k+1}), x_{k+1} - z_k\rangle + \alpha\langle \nabla f(x_{k+1}), z_k - u\rangle \\
&\overset{②}{=} \frac{\alpha\tau_2}{\tau_1}\langle \nabla f(x_{k+1}), \widetilde{x} - x_{k+1}\rangle + \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}\langle \nabla f(x_{k+1}), y_k - x_{k+1}\rangle + \alpha\langle \nabla f(x_{k+1}), z_k - u\rangle \\
&\overset{③}{\le} \frac{\alpha\tau_2}{\tau_1}\langle \nabla f(x_{k+1}), \widetilde{x} - x_{k+1}\rangle + \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}(f(y_k) - f(x_{k+1})) + \alpha\langle \nabla f(x_{k+1}), z_k - u\rangle \ .
\end{aligned}$$

Above, ① uses the convexity of $f(\cdot)$, ② uses the choice that $x_{k+1} = \tau_1 z_k + \tau_2 \widetilde{x} + (1-\tau_1-\tau_2)y_k$, and ③ uses the convexity of $f(\cdot)$ again. By applying Lemma 2.6 to the above inequality, we have

$$\begin{aligned}
&\alpha\big(f(x_{k+1}) - F(u)\big) \le \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}(F(y_k) - f(x_{k+1})) \\
&+\frac{\alpha}{\tau_1}\Big(F(x_{k+1}) - \mathbb{E}\big[F(y_{k+1})\big] + \tau_2 F(\widetilde{x}) - \tau_2 f(x_{k+1})\Big) + \frac{1}{2}\|z_k - u\|^2 - \frac{1+\alpha\sigma}{2}\mathbb{E}\big[\|z_{k+1} - u\|^2\big] - \frac{\alpha}{\tau_1}\psi(x_{k+1})
\end{aligned}$$

which implies

$$\begin{aligned}
&\alpha\big(F(x_{k+1}) - F(u)\big) \le \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}(F(y_k) - F(x_{k+1})) \\
&+\frac{\alpha}{\tau_1}\Big(F(x_{k+1}) - \mathbb{E}\big[F(y_{k+1})\big] + \tau_2 F(\widetilde{x}) - \tau_2 F(x_{k+1})\Big) + \frac{1}{2}\|z_k - u\|^2 - \frac{1+\alpha\sigma}{2}\mathbb{E}\big[\|z_{k+1} - u\|^2\big] \ .
\end{aligned}$$

After rearranging and setting $u = x^*$, the above inequality yields

$$0 \le \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}\big(F(y_k) - F(x^*)\big) - \frac{\alpha}{\tau_1}\big(\mathbb{E}\big[F(y_{k+1}) - F(x^*)\big]\big) + \frac{\alpha\tau_2}{\tau_1}\big(F(\widetilde{x}) - F(x^*)\big) + \frac{1}{2}\|z_k - x^*\|^2 - \frac{1+\alpha\sigma}{2}\mathbb{E}\big[\|z_{k+1} - x^*\|^2\big] \ .$$

■

2.2 Proof of Theorem 2.1

We are now ready to combine the analyses across iterations, and derive our final Theorem 2.1. Our proof next requires a careful telescoping of Lemma 2.7 together with our specific parameter choices.

Proof [Proof of Theorem 2.1] Define $D_k \overset{\text{def}}{=} F(y_k) - F(x^*)$, $\widetilde{D}^s \overset{\text{def}}{=} F(\widetilde{x}^s) - F(x^*)$, and rewrite Lemma 2.7:

$$0 \le \frac{(1-\tau_1-\tau_2)}{\tau_1}D_k - \frac{1}{\tau_1}D_{k+1} + \frac{\tau_2}{\tau_1}\mathbb{E}\big[\widetilde{D}^s\big] + \frac{1}{2\alpha}\|z_k - x^*\|^2 - \frac{1+\alpha\sigma}{2\alpha}\mathbb{E}\big[\|z_{k+1} - x^*\|^2\big] \ .$$

At this point, let us define $\theta = 1 + \alpha\sigma$ and multiply the above inequality by θ^j for each $k = sm + j$. Then, we sum up the resulting m inequalities for all $j = 0, 1, \ldots, m-1$:

$$\begin{aligned}
0 \le \mathbb{E}\Big[\frac{(1-\tau_1-\tau_2)}{\tau_1}\sum_{j=0}^{m-1} D_{sm+j}\cdot\theta^j - \frac{1}{\tau_1}\sum_{j=0}^{m-1} D_{sm+j+1}\cdot\theta^j\Big] + \frac{\tau_2}{\tau_1}\widetilde{D}^s\cdot\sum_{j=0}^{m-1}\theta^j \\
+ \frac{1}{2\alpha}\|z_{sm} - x^*\|^2 - \frac{\theta^m}{2\alpha}\big[\|z_{(s+1)m} - x^*\|^2\big] \ .
\end{aligned}$$

Note that in the above inequality we have assumed all the randomness in the first $s-1$ epochs are fixed and the only source of randomness comes from epoch s. We can rearrange the terms in the above inequality and get

$$\begin{aligned}
\mathbb{E}\Big[\frac{\tau_1+\tau_2-(1-1/\theta)}{\tau_1}\sum_{j=1}^{m} D_{sm+j}\cdot\theta^j\Big] \le \frac{(1-\tau_1-\tau_2)}{\tau_1}\Big(D_{sm} - \theta^m\mathbb{E}\big[D_{(s+1)m}\big]\Big) \\
+ \frac{\tau_2}{\tau_1}\widetilde{D}^s\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1}{2\alpha}\|z_{sm} - x^*\|^2 - \frac{\theta^m}{2\alpha}\mathbb{E}\big[\|z_{(s+1)m} - x^*\|^2\big] \ .
\end{aligned}$$

Using the special choice that $\widetilde{x}^{s+1} = \big(\sum_{j=0}^{m-1}\theta^j\big)^{-1}\cdot\sum_{j=0}^{m-1} y_{sm+j+1}\cdot\theta^j$ and the convexity of $F(\cdot)$, we derive that $\widetilde{D}^{s+1} \le \big(\sum_{j=0}^{m-1}\theta^j\big)^{-1}\cdot\sum_{j=0}^{m-1} D_{sm+j+1}\cdot\theta^j$. Substituting this into the above inequality, we get

$$\begin{aligned}
\frac{\tau_1+\tau_2-(1-1/\theta)}{\tau_1}\theta\mathbb{E}\big[\widetilde{D}^{s+1}\big]\cdot\sum_{j=0}^{m-1}\theta^j \le \frac{(1-\tau_1-\tau_2)}{\tau_1}\Big(D_{sm} - \theta^m\mathbb{E}\big[D_{(s+1)m}\big]\Big) \\
+ \frac{\tau_2}{\tau_1}\widetilde{D}^s\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1}{2\alpha}\|z_{sm} - x^*\|^2 - \frac{\theta^m}{2\alpha}\mathbb{E}\big[\|z_{(s+1)m} - x^*\|^2\big] \ . \quad (2.3)
\end{aligned}$$

We consider two cases next.

Case 1. Suppose $\frac{m\sigma}{L} \le \frac{3}{4}$. In this case, we choose $\alpha = \frac{1}{\sqrt{3m\sigma L}}$ and $\tau_1 = \frac{1}{3\alpha L} = m\alpha\sigma = \frac{\sqrt{m\sigma}}{\sqrt{3L}} \in [0, \frac{1}{2}]$ for `Katyusha`. It implies $\alpha\sigma \le 1/2m$ and therefore the following inequality holds:

$$\tau_2(\theta^{m-1} - 1) + (1 - 1/\theta) = \frac{1}{2}((1+\alpha\sigma)^{m-1} - 1) + (1 - \frac{1}{1+\alpha\sigma}) \le (m-1)\alpha\sigma + \alpha\sigma = m\alpha\sigma = \tau_1 \ .$$

In other words, we have $\tau_1+\tau_2-(1-1/\theta)\geq\tau_2\theta^{m-1}$ and thus (2.3) implies that

$$\mathbb{E}\Big[\frac{\tau_2}{\tau_1}\widetilde{D}^{s+1}\cdot\sum_{j=0}^{m-1}\theta^j+\frac{1-\tau_1-\tau_2}{\tau_1}D_{(s+1)m}+\frac{1}{2\alpha}\|z_{(s+1)m}-x^*\|^2\Big]$$
$$\leq\theta^{-m}\cdot\Big(\frac{\tau_2}{\tau_1}\widetilde{D}^{s}\cdot\sum_{j=0}^{m-1}\theta^j+\frac{1-\tau_1-\tau_2}{\tau_1}D_{sm}+\frac{1}{2\alpha}\|z_{sm}-x^*\|^2\Big)\ .$$

If we telescope the above inequality over all epochs $s=0,1,\ldots,S-1$, we obtain

$$\mathbb{E}\big[F(\widetilde{x}^S)-F(x^*)\big]=\mathbb{E}\big[\widetilde{D}^S\big]\overset{①}{\leq}\theta^{-Sm}\cdot O\Big(\widetilde{D}^0+D_0+\frac{\tau_1}{\alpha m}\|x_0-x^*\|^2\Big)$$
$$\overset{②}{\leq}\theta^{-Sm}\cdot O\Big(1+\frac{\tau_1}{\alpha m\sigma}\Big)\cdot\big(F(x_0)-F(x^*)\big)$$
$$\overset{③}{=}O((1+\alpha\sigma)^{-Sm})\cdot\big(F(x_0)-F(x^*)\big)\ . \qquad (2.4)$$

Above, ① uses the fact that $\sum_{j=0}^{m-1}\theta^j\geq m$ and $\tau_2=\frac{1}{2}$; ② uses the strong convexity of $F(\cdot)$ which implies $F(x_0)-F(x^*)\geq\frac{\sigma}{2}\|x_0-x^*\|^2$; and ③ uses our choice of τ_1.

Case 2. Suppose $\frac{m\sigma}{L}>\frac{3}{4}$. In this case, we choose $\tau_1=\frac{1}{2}$ and $\alpha=\frac{1}{3\tau_1 L}=\frac{2}{3L}$ as in `Katyusha`. Our parameter choices help us simplify (2.3) as (noting $(\tau_1+\tau_2-(1-1/\theta))\theta=1$)

$$2\mathbb{E}\big[\widetilde{D}^{s+1}\big]\cdot\sum_{j=0}^{m-1}\theta^j\leq\widetilde{D}^s\cdot\sum_{j=0}^{m-1}\theta^j+\frac{1}{2\alpha}\|z_{sm}-x^*\|^2-\frac{\theta^m}{2\alpha}\mathbb{E}\big[\|z_{(s+1)m}-x^*\|^2\big]\ .$$

Since $\theta^m=(1+\alpha\sigma)^m\geq1+\alpha\sigma m=1+\frac{2\sigma m}{3L}\geq\frac{3}{2}$, the above inequality implies

$$\frac{3}{2}\mathbb{E}\big[\widetilde{D}^{s+1}\big]\cdot\sum_{j=0}^{m-1}\theta^j+\frac{9L}{8}\mathbb{E}\big[\|z_{(s+1)m}-x^*\|^2\big]\leq\widetilde{D}^s\cdot\sum_{j=0}^{m-1}\theta^j+\frac{3L}{4}\|z_{sm}-x^*\|^2\ .$$

If we telescope this inequality over all the epochs $s=0,1,\ldots,S-1$, we immediately have

$$\mathbb{E}\Big[\widetilde{D}^S\cdot\sum_{j=0}^{m-1}\theta^j+\frac{3L}{4}\|z_{Sm}-x^*\|^2\Big]\leq\big(\frac{2}{3}\big)^S\cdot\Big(\widetilde{D}^0\cdot\sum_{j=0}^{m-1}\theta^j+\frac{3L}{4}\|z_0-x^*\|^2\Big)\ .$$

Finally, since $\sum_{j=0}^{m-1}\theta^j\geq m$ and $\frac{\sigma}{2}\|z_0-x^*\|^2\leq F(x_0)-F(x^*)$ owing to the strong convexity of $F(\cdot)$, we conclude that

$$\mathbb{E}\big[F(\widetilde{x}^S)-F(x^*)\big]\leq O\big(1.5^{-S}\big)\cdot\big(F(x_0)-F(x^*)\big)\ . \qquad (2.5)$$

Combining (2.4) and (2.5) we finish the proof of Theorem 2.1. ■

3. Corollaries on Non-Smooth or Non-SC Problems

In this section we apply reductions to translate our Theorem 2.1 into optimal algorithms also for non-strongly convex objectives and/or non-smooth objectives.

To begin with, recall the following definition of the HOOD property:

Definition 3.1 (Allen-Zhu and Hazan (2016b)) *An algorithm solving the strongly convex case of Problem (1.1) satisfies the* homogenous objective decrease (HOOD) *property with $T(L,\sigma)$, if for every starting point x_0, it produces an output x' satisfying $\mathbb{E}\big[F(x')\big]-F(x^*)\leq\frac{F(x_0)-F(x^*)}{4}$ in at most $T(L,\sigma)$ stochastic gradient iterations.*

Theorem 2.1 shows that `Katyusha` satisfies the HOOD property:

Corollary 3.2 `Katyusha` *satisfies the HOOD property with $T(L,\sigma)=O\big(n+\frac{\sqrt{nL}}{\sqrt{\sigma}}\big)$.*

Remark 3.3 *Existing accelerated stochastic methods before this work (even for simpler Problem (1.3)) either do not satisfy HOOD or satisfy HOOD with an additional factor $\log(L/\sigma)$ in the number of iterations.*

Allen-Zhu and Hazan (2016b) designed three reductions algorithms to convert an algorithm satisfying the HOOD property to solve the following three cases:

Theorem 3.4 *Given algorithm $\mathcal{A}$ satisfying HOOD with $T(L,\sigma)$ and a starting vector x_0.*

- NonSC+Smooth. *For Problem (1.1) where $f(\cdot)$ is L-smooth,* AdaptReg($\mathcal{A}$) *outputs x satisfying $\mathbb{E}\big[F(x)\big]-F(x^*)\leq O(\varepsilon)$ in T stochastic gradient iterations where*

$$T=\sum_{s=0}^{S-1}T\Big(L,\frac{\sigma_0}{2^s}\Big)\ \text{where}\ \sigma_0=\frac{F(x_0)-F(x^*)}{\|x_0-x^*\|^2}\ \text{and}\ S=\log_2\frac{F(x_0)-F(x^*)}{\varepsilon}.$$

- SC+NonSmooth. *For Problem (1.3) where $\psi(\cdot)$ is σ-SC and each $f_i(\cdot)$ is $\sqrt{G}$-Lipschitz continuous,* AdaptSmooth($\mathcal{A}$) *outputs x satisfying $\mathbb{E}\big[F(x)\big]-F(x^*)\leq O(\varepsilon)$ in*

$$T=\sum_{s=0}^{S-1}T\Big(\frac{2^s}{\lambda_0},\sigma\Big)\ \text{where}\ \lambda_0=\frac{F(x_0)-F(x^*)}{G}\ \text{and}\ S=\log_2\frac{F(x_0)-F(x^*)}{\varepsilon}.$$

- NonSC+NonSmooth. *For Problem (1.3) where each $f_i(\cdot)$ is $\sqrt{G}$-Lipschitz continuous, then* JointAdaptRegSmooth($\mathcal{A}$) *outputs x satisfying $\mathbb{E}\big[F(x)\big]-F(x^*)\leq O(\varepsilon)$ in*

$$T=\sum_{s=0}^{S-1}T\Big(\frac{2^s}{\lambda_0},\frac{\sigma_0}{2^s}\Big)$$
$$\text{where}\ \lambda_0=\frac{F(x_0)-F(x^*)}{G},\ \sigma_0=\frac{F(x_0)-F(x^*)}{\|x_0-x^*\|^2}\ \text{and}\ S=\log_2\frac{F(x_0)-F(x^*)}{\|x_0-x^*\|^2}.$$

Combining Corollary 3.2 with Theorem 3.4, we have the following corollaries:

Corollary 3.5 *If each $f_i(x)$ is convex, L-smooth and $\psi(\cdot)$ is not necessarily strongly convex in Problem (1.1), then by applying* AdaptReg *on* `Katyusha` *with a starting vector x_0, we obtain an output x satisfying $\mathbb{E}[F(x)]-F(x^*)\leq\varepsilon$ in*

$$T=O\Big(n\log\tfrac{F(x_0)-F(x^*)}{\varepsilon}+\tfrac{\sqrt{nL}\cdot\|x_0-x^*\|}{\sqrt{\varepsilon}}\Big)\propto\tfrac{1}{\sqrt{\varepsilon}}\ \textit{iterations. (Or equivalently}\ \varepsilon\propto\tfrac{1}{T^2}.\textit{)}$$

In contrast, the best known convergence rate was $\varepsilon\propto\frac{\log^4 T}{T^2}$ or more precisely

Catalyst: $T=O\Big(\Big(n+\frac{\sqrt{nL}\cdot\|x_0-x^*\|}{\sqrt{\varepsilon}}\Big)\log\frac{F(x_0)-F(x^*)}{\varepsilon}\log\frac{L\|x_0-x^*\|^2}{\varepsilon}\Big)\propto\frac{\log^2(1/\varepsilon)}{\sqrt{\varepsilon}}$ iterations.

Algorithm 2 $\texttt{Katyusha}^{\texttt{ns}}(x_0, S, \sigma, L)$

$m \leftarrow 2n$; ◇ *epoch length*
$\tau_2 \leftarrow \frac{1}{2}$;
$y_0 = z_0 = \widetilde{x}^0 \leftarrow x_0$; ◇ *initial vectors*
for $s \leftarrow 0$ **to** $S-1$ **do**
  $\tau_{1,s} \leftarrow \frac{2}{s+4}$, $\alpha_s \leftarrow \frac{1}{3\tau_{1,s}L}$ ◇ *different parameter choices comparing to* Katyusha
  $\mu^s \leftarrow \nabla f(\widetilde{x}^s)$; ◇ *compute the full gradient only once every m iterations*
  for $j \leftarrow 0$ **to** $m-1$ **do**
    $k \leftarrow (sm)+j$;
    $x_{k+1} \leftarrow \tau_{1,s} z_k + \tau_2 \widetilde{x}^s + (1-\tau_{1,s}-\tau_2) y_k$;
    $\widetilde{\nabla}_{k+1} \leftarrow \mu^s + \nabla f_i(x_{k+1}) - \nabla f_i(\widetilde{x}^s)$ where i is randomly chosen from $\{1,2,\dots,n\}$;
    $z_{k+1} = \arg\min_z \left\{ \frac{1}{2\alpha_s}\|z - z_k\|^2 + \langle \widetilde{\nabla}_{k+1}, z\rangle + \psi(z) \right\}$;
    Option I: $y_{k+1} \leftarrow \arg\min_y \left\{ \frac{3L}{2}\|y - x_{k+1}\|^2 + \langle \widetilde{\nabla}_{k+1}, y\rangle + \psi(y) \right\}$;
    Option II: $y_{k+1} \leftarrow x_{k+1} + \tau_{1,s}(z_{k+1} - z_k)$ ◇ *we analyze only I but II also works*
  end for
  $\widetilde{x}^{s+1} \leftarrow \frac{1}{m}\sum_{j=1}^m y_{sm+j}$; ◇ *compute snapshot $\widetilde{x}$*
end for
return $\widetilde{x}^S$.

Corollary 3.6 *If each $f_i(x)$ is $\sqrt{G}$-Lipschitz continuous and $\psi(x)$ is σ-SC in Problem (1.3), then by applying* AdaptSmooth *on* Katyusha *with a starting vector x_0, we obtain an output x satisfying $\mathbb{E}[F(x)] - F(x^*) \le \varepsilon$ in*

$$T = O\Big(n \log \tfrac{F(x_0)-F(x^*)}{\varepsilon} + \tfrac{\sqrt{nG}}{\sqrt{\sigma\varepsilon}}\Big) \propto \tfrac{1}{\sqrt{\varepsilon}} \text{ iterations. } (\text{Or equivalently } \varepsilon \propto \tfrac{1}{T^2}.)$$

In contrast, the best known convergence rate was $\varepsilon \propto \frac{\log^2 T}{T^2}$, or more precisely

$$\text{APCG/SPDC:} \quad T = O\Big(\Big(n + \tfrac{\sqrt{nG}}{\sqrt{\sigma\varepsilon}}\Big) \log \tfrac{nG(F(x_0)-F(x^*))}{\sigma\varepsilon}\Big) \propto \tfrac{\log(1/\varepsilon)}{\sqrt{\varepsilon}} \text{ iterations.}$$

Corollary 3.7 *If each $f_i(x)$ is $\sqrt{G}$-Lipschitz continuous and $\psi(x)$ is not necessarily strongly convex in Problem (1.3), then by applying* JointAdaptRegSmooth *on* Katyusha *with a starting vector x_0, we obtain an output x satisfying $\mathbb{E}[F(x)] - F(x^*) \le \varepsilon$ in*

$$T = O\Big(n \log \tfrac{F(x_0)-F(x^*)}{\varepsilon} + \tfrac{\sqrt{nG}\|x_0 - x^*\|}{\varepsilon}\Big) \propto \tfrac{1}{\varepsilon} \text{ iterations. } (\text{Or equivalently } \varepsilon \propto \tfrac{1}{T}.)$$

In contrast, the best known convergence rate was $\varepsilon \propto \frac{\log T}{T}$, or more precisely

$$\text{APCG/SPDC:} \quad T = O\Big(\Big(n + \tfrac{\sqrt{nG}\|x_0 - x^*\|}{\varepsilon}\Big) \log \tfrac{nG\|x_0 - x^*\|^2 (F(x_0)-F(x^*))}{\varepsilon^2}\Big) \propto \tfrac{\log(1/\varepsilon)}{\varepsilon} \text{ iterations.}$$

4. Katyusha in the Non-Strongly Convex Setting

Due to the increasing popularity of *non-strongly convex* minimization tasks (most notably ℓ_1-regularized problems), researchers often make additional efforts to design separate methods for minimizing the non-strongly convex variant of Problem (1.1) that are *direct*, meaning without restarting and in particular without using any reductions such as Theorem 3.4 (Defazio et al., 2014; Allen-Zhu and Yuan, 2016).

In this section, we also develop our *direct and accelerated* method for the non-strongly convex variant of Problem (1.1). We call it $\texttt{Katyusha}^{\texttt{ns}}$ and state it in Algorithm 2.

The only difference between $\texttt{Katyusha}^{\texttt{ns}}$ and Katyusha is that we choose $\tau_1 = \tau_{1,s} = \frac{2}{s+4}$ to be a parameter that depends on the epoch index s, and accordingly $\alpha = \alpha_s = \frac{1}{3L\tau_{1,s}}$. This should not be a big surprise because in accelerated full-gradient methods, the values τ_1 and α also decrease (although with respect to k rather than s) when there is no strong convexity (Allen-Zhu and Orecchia, 2017). We note that τ_1 and τ_2 remain constant throughout an epoch, and this could simplify the implementations.

We state the following convergence theorem for $\texttt{Katyusha}^{\texttt{ns}}$ and defer its proof to Appendix C.1. The proof also relies on the one-iteration inequality in Lemma 2.7, but requires telescoping such inequalities in a different manner as compared with Theorem 2.1.

Theorem 4.1 *If each $f_i(x)$ is convex, L-smooth in Problem (1.1) and $\psi(\cdot)$ is not necessarily strongly convex, then $\texttt{Katyusha}^{\texttt{ns}}(x_0, S, L)$ satisfies*

$$\mathbb{E}\big[F(\widetilde{x}^S)\big] - F(x^*) \le O\Big(\frac{F(x_0)-F(x^*)}{S^2} + \frac{L\|x_0 - x^*\|^2}{mS^2}\Big)$$

In other words, choosing $m = \Theta(n)$, $\texttt{Katyusha}^{\texttt{ns}}$ achieves an ε-additive error (i.e., $\mathbb{E}\big[F(\widetilde{x}^S)\big] - F(x^*) \le \varepsilon$) using at most $O\Big(\frac{n\sqrt{F(x_0)-F(x^*)}}{\sqrt{\varepsilon}} + \frac{\sqrt{nL}\|x_0-x^*\|}{\sqrt{\varepsilon}}\Big)$ iterations.

Remark 4.2 $\texttt{Katyusha}^{\texttt{ns}}$ *is a* direct, accelerated *solver for the non-SC case of Problem (1.1). It is illustrative to compare it with the convergence theorem of a* direct, non-accelerated *solver of the same setting. Below is the convergence theorem of SAGA after translating to our notations:*

$$\textit{SAGA:} \quad \mathbb{E}\big[F(x)\big] - F(x^*) \le O\Big(\frac{F(x_0)-F(x^*)}{S} + \frac{L\|x_0 - x^*\|^2}{nS}\Big) \ .$$

It is clear from this comparison that $\texttt{Katyusha}^{\texttt{ns}}$ is a factor S faster than non-accelerated methods such as SAGA, where $S = T/n$ if T is the total number of stochastic iterations. This convergence can also be written in terms of the number of iterations which is $O\big(\frac{n(F(x_0)-F(x^*))}{\varepsilon} + \frac{L\|x_0-x^*\|^2}{\varepsilon}\big)$.

Remark 4.3 *Theorem 4.1 appears worse than the reduction-based complexity in Corollary 3.7. This can be fixed by setting either the parameters τ_1 or the epoch length m in a more sophisticated way. Since it complicates the proofs and the notations we refrain from doing so in this version of the paper.*[13] *In practice, being a direct method, $\texttt{Katyusha}^{\texttt{ns}}$ enjoys satisfactory performance.*

5. Katyusha in the Mini-Batch Setting

We mentioned in earlier versions of this paper that our Katyusha method naturally generalizes to mini-batch (parallel) settings and non-uniform smoothness settings, but did not include a full proof. In this section, we carefully deal with both generalizations together.

13. Recall that a similar issue has also happened in the non-accelerated world: the iteration complexity $O(\frac{n+L}{\varepsilon})$ in SAGA can be improved to $O(n \log \frac{1}{\varepsilon} + \frac{L}{\varepsilon})$ by doubling the epoch length across epochs (Allen-Zhu and Yuan, 2016). Similar techniques can also be used to improve our result above.

Mini-batch. In each iteration k, instead of using a single $\nabla f_i(x_{k+1})$, one can

$$\text{use the average of } b \text{ stochastic gradients } \frac{1}{b}\sum_{i\in S_k}\nabla f_i(x_{k+1})$$

where S_k is a random subset of $[n]$ with cardinality b. This average can be computed in a distributed manner using up to b processors. This idea is known as *mini-batch* for stochastic gradient methods.

Non-Uniform Smoothness. Suppose in Problem (1.1),

$$\text{each } f_i(x) \text{ is } L_i\text{-smooth and } f(x)=\frac{1}{n}\sum_{i=1}^n f_i(x) \text{ is } L\text{-smooth.}$$

We denote by $\overline{L}=\frac{1}{n}\sum_{i=1}^n L_i$, and assume without loss of generality $L\le\overline{L}\le nL$. [14] We note that $\overline{L}$ can sometimes be indeed much greater than L, see Remark 5.3.

Remark 5.1 *L_i and L only need to be upper bounds to the minimum smoothness parameters of $f_i(\cdot)$ and $f(\cdot)$ respectively. In practice, sometimes the minimum smoothness parameters for $f_i(x)$ is efficiently computable (such as for ERM problems).*

5.1 Algorithmic Changes and Theorem Restatement

To simultaneously deal with mini-batch and non-uniform smoothness, we propose the following changes to `Katyusha`:

- *Change the epoch length from $m=\Theta(n)$ to $m=\lceil\frac{n}{b}\rceil$.*

  This is standard. In each iteration we need to compute $O(b)$ stochastic gradients; therefore every $\lceil\frac{n}{b}\rceil$ iterations, we can compute the full gradient once without hurting the total performance.

- *Define distribution $\mathcal{D}$ over $[n]$ to be choosing $i\in[n]$ with probability $p_i\stackrel{\text{def}}{=}L_i/n\overline{L}$, and define gradient estimator $\widetilde{\nabla}_{k+1}\stackrel{\text{def}}{=}\nabla f(\widetilde{x})+\frac{1}{b}\sum_{i\in S_k}\frac{1}{np_i}\big(\nabla f_i(x_{k+1})-\nabla f_i(\widetilde{x})\big)$, where $S_k\subseteq[n]$ is a multiset with b elements each i.i.d. generated from $\mathcal{D}$.*

  This is standard, see for instance Prox-SVRG (Xiao and Zhang, 2014), and it is easy to verify $\mathbb{E}[\widetilde{\nabla}_{k+1}]=\nabla f(x_{k+1})$.

- *Change τ_2 from $\frac{1}{2}$ to $\min\{\frac{\overline{L}}{2Lb},\frac{1}{2}\}$.*

  Note that if $\overline{L}=L$ then we have $\tau_2=\frac{1}{2b}$. In other words, the larger the mini-batch size, the smaller weight we want to give to Katyusha momentum. This should be intuitive. The reason τ_2 has a more involved form when $L\neq\overline{L}$ is explained in Remark 5.4 later.

- *Change L in gradient descent step (Line 19) to some other $L_\diamond\ge L$, and define $\alpha=\frac{1}{3\tau_1 L_\diamond}$ instead.*

  In most cases (e.g., when $\overline{L}=L$ or $L\ge\overline{L}m/b$) we choose $L_\diamond=L$. Otherwise, we let $L_\diamond=\frac{\overline{L}}{2b\tau_2}\ge L$. The reason $L_\diamond$ has a more involved form is explained in Remark 5.4 later.

14. It is easy to verify (using triangle inequality) that $f(x)=\frac{1}{n}\sum_{i\in[n]}f_i(x)$ must be $\overline{L}$ smooth. Also, if $f(x)$ is L-smooth then each $f_i(x)$ must be nL smooth (this can be checked via Hessian $\nabla^2 f_i(x)\preceq n\nabla^2 f(x)$ or similarly if f is not twice-differentiable).

Algorithm 3 `Katyusha1`$(x_0,S,\sigma,L,(L_1,\dots,L_n),b)$

1: $m\leftarrow\lceil n/b\rceil$ and $\overline{L}\leftarrow\frac{1}{n}(L_1+\cdots+L_n)$; ◇ *$m$ is epoch length*
2: $\tau_2\leftarrow\min\{\frac{\overline{L}}{2Lb},\frac{1}{2}\}$; ◇ *if $\overline{L}=L$ then $\tau_2=\frac{1}{2b}$ and $L_\diamond=L$*
3: **if** $L\le\frac{\overline{L}m}{b}$ **then**
4: $\quad\tau_1\leftarrow\min\{\frac{\sqrt{8bm\sigma}}{\sqrt{3\overline{L}}}\tau_2,\tau_2\}$ and $L_\diamond\leftarrow\frac{\overline{L}}{2b\tau_2}$;
5: **else**
6: $\quad\tau_1\leftarrow\min\{\frac{\sqrt{2\sigma}}{\sqrt{3L}},\frac{1}{2m}\}$ and $L_\diamond\leftarrow L$;
7: **end if**
8: $\alpha\leftarrow\frac{1}{3\tau_1 L_\diamond}$; ◇ *parameters*
9: Let distribution $\mathcal{D}$ be to output $i\in[n]$ with probability $p_i\stackrel{\text{def}}{=}L_i/(n\overline{L})$.
10: $y_0=z_0=\widetilde{x}^0\leftarrow x_0$; ◇ *initial vectors*
11: **for** $s\leftarrow0$ **to** $S-1$ **do**
12: $\quad\mu^s\leftarrow\nabla f(\widetilde{x}^s)$; ◇ *compute the full gradient once every m iterations*
13: $\quad$**for** $j\leftarrow0$ **to** $m-1$ **do**
14: $\quad\quad k\leftarrow(sm)+j$;
15: $\quad\quad x_{k+1}\leftarrow\tau_1 z_k+\tau_2\widetilde{x}^s+(1-\tau_1-\tau_2)y_k$;
16: $\quad\quad S_k\leftarrow b$ independent copies of i from $\mathcal{D}$ with replacement.
17: $\quad\quad\widetilde{\nabla}_{k+1}\leftarrow\mu^s+\frac{1}{b}\sum_{i\in S_k}\frac{1}{np_i}\big(\nabla f_i(x_{k+1})-\nabla f_i(\widetilde{x}^s)\big)$;
18: $\quad\quad z_{k+1}=\arg\min_z\{\frac{1}{2\alpha}\|z-z_k\|^2+\langle\widetilde{\nabla}_{k+1},z\rangle+\psi(z)\}$;
19: $\quad\quad$Option I: $y_{k+1}\leftarrow\arg\min_y\{\frac{3L_\diamond}{2}\|y-x_{k+1}\|^2+\langle\widetilde{\nabla}_{k+1},y\rangle+\psi(y)\}$;
20: $\quad\quad$Option II: $y_{k+1}\leftarrow x_{k+1}+\tau_1(z_{k+1}-z_k)$ ◇ *we analyze only I but II also works*
21: $\quad$**end for**
22: $\quad\widetilde{x}^{s+1}\leftarrow\big(\sum_{j=0}^{m-1}\theta^j\big)^{-1}\cdot\big(\sum_{j=0}^{m-1}\theta^j\cdot y_{sm+j+1}\big)$; ◇ *where $\theta=1+\min\{\alpha\sigma,\frac{1}{4m}\}$*
23: **end for**
24: **return** $x^{\mathsf{out}}\leftarrow\frac{\tau_2 m\widetilde{x}^S+(1-\tau_1-\tau_2)y_{Sm}}{\tau_2 m+(1-\tau_1-\tau_2)}$.

- *Change τ_1 to be $\tau_1=\min\{\frac{\sqrt{8bm\sigma}}{\sqrt{3\overline{L}}}\tau_2,\tau_2\}$ if $L\le\overline{L}m/b$ or $\tau_1=\min\{\frac{\sqrt{2\sigma}}{\sqrt{3L}},\frac{1}{2m}\}$ if $L>\overline{L}m/b$.*

  This corresponds to a phase-transition behavior of `Katyusha1` (see Remark 5.5 later). Intuitively, when $L\le\overline{L}m/b$ then we are in a mini-batch phase; when $L>\overline{L}m/b$ we are in a full-batch phase.

- *Due to technical reasons, we define $\widetilde{x}^s$ as a slightly different weighted average (Line 22) and output x^{out} which is a weighted combination of $\widetilde{x}^S$ and y_{Sm} as opposed to simply $\widetilde{x}^S$ (Line 24).*

We emphasize here that some of these changes are not necessary for instance in the special case of $\overline{L}=L$, but to state the strongest theorem, we have to include all such changes. It is a simple exercise to verify that, if $\overline{L}=L$ and $b=1$, then up to only constant factors in the parameters, `Katyusha1` is exactly identical to `Katyusha`. We have the following main theorem for `Katyusha1`:

Theorem 5.2 *If each $f_i(x)$ is convex and L_i-smooth, $f(x)$ is L-smooth, $\psi(x)$ is σ-strongly convex in Problem (1.1), then for any $b \in [n]$,*

$$x^{\mathsf{out}} = \texttt{Katyusha1}(x_0, S, \sigma, L, (L_1, \dots, L_n), b)$$

satisfies $\mathbb{E}\big[F(x^{\mathsf{out}})\big] - F(x^*)$

$$\leq \begin{cases} O\Big(\Big(1+\sqrt{b\sigma/(6\overline{L}m)}\Big)^{-Sm}\Big) \cdot \big(F(x_0)-F(x^*)\big), & \text{if } \frac{m\alpha b}{\overline{L}} \leq \frac{3}{8} \text{ and } L \leq \frac{\overline{L}m}{b}; \\ O\Big(\big(1+\sqrt{\sigma/(6L)}\big)^{-Sm}\Big) \cdot \big(F(x_0)-F(x^*)\big), & \text{if } \frac{m^2\sigma}{L} \leq \frac{3}{8} \text{ and } L > \frac{\overline{L}m}{b}; \\ O\big(1.25^{-S}\big) \cdot \big(F(x_0)-F(x^*)\big), & \text{otherwise.} \end{cases}$$

In other words, choosing $m = \lceil n/b \rceil$, Katyusha achieves an ε-additive error (that is, $\mathbb{E}\big[F(x^{\mathsf{out}})\big] - F(x^*) \leq \varepsilon$) using at most

$$S \cdot n = O\Big(\big(n + b\sqrt{L/\sigma} + \sqrt{n\overline{L}/\sigma}\big) \cdot \log \frac{F(x_0)-F(x^*)}{\varepsilon}\Big)$$

stochastic gradient computations.

5.2 Observations and Remarks

We explain the significance of Theorem 5.2 below. We use *total work* to refer to the total number of stochastic gradient computations, and *iteration complexity* (also known as parallel depth) to refer to the total number of iterations.

Parallel Performance. The total work of Katyusha1 stays the same when $b \leq (n\overline{L}/L)^{1/2} \in \big[\sqrt{n}, n\big]$. This means, at least for all values $b \in \{1, 2, \dots, \lceil\sqrt{n}\rceil\}$, our Katyusha1 achieves the same total work and thus

Katyusha1 can be distributed to $b \leq \sqrt{n}$ machines with a parallel speed-up factor b
(known as linear speed-up if ignoring communication overhead.)

In contrast, even in the special case of $\overline{L} = L$ and if no additional assumption is made, to the best of our knowledge:

- Mini-batch SVRG requires $\widetilde{O}\big(n + \frac{bL}{\sigma}\big)$ total work.

  Therefore, if SVRG is distributed to b machines, the total work is increased by a factor of b, and the parallel speed-up factor is 1 (i.e., no speed up).

- Catalyst on top of mini-batch SVRG requires $\widetilde{O}\big(n + \frac{\sqrt{bLn}}{\sqrt{\sigma}}\big)$ total work.

  Therefore, if Catalyst is distributed to b machines, the total work is increased by a factor $\sqrt{b}$, and the parallel speed-up factor is $\sqrt{b}$ only.

When preparing the journal revision (i.e., version 5), we found out at least in the case $\overline{L} = L$, some other groups of researchers very recently obtained similar results for the ERM Problem (1.3) using SPDC (Shibagaki and Takeuchi, 2017), and for the general Problem (1.1) (Murata and Suzuki, 2017).[15] These results together with Theorem 5.2 confirm the power of acceleration in the parallel regime for stochastic gradient methods.

15. These two papers claimed that Katyusha does not enjoy linear speed-up for $b \leq \sqrt{n}$, based on an earlier version of the paper (where we did not include the mini-batch theorem). As evidenced by Theorem 5.2, such claims are false.

Outperforming Full-Gradient Method. If $b = n$, the total work of Katyusha1 becomes $\widetilde{O}\big((L/\sigma)^{1/2}n\big)$. This matches the total work of Nesterov's accelerated gradient method (Nesterov, 1983, 2004; Allen-Zhu and Orecchia, 2017), and does not depend on the possibly larger parameter $\overline{L}$.

More interestingly, to achieve the *same* iteration complexity $\widetilde{O}\big((L/\sigma)^{1/2}\big)$ as Nesterov's method, our Katyusha1 only needs to compute $b = (n\overline{L}/L)^{1/2}$ stochastic gradients $\nabla f_i(\cdot)$ per iteration (in the amortized sense). This can be much faster than computing $\nabla f(\cdot)$.

Remark 5.3 *Recall $\overline{L}$ is in the range $[L, nL]$ so indeed $\overline{L}$ can be much larger than L. For instance in linear regression we have $f_i(x) = \frac{1}{2}(\langle a_i, x\rangle - b_i)^2$. Denoting by $A = [a_1, \dots, a_n] \in \mathbb{R}^{d\times n}$, we have $L = \frac{1}{n}\lambda_{\max}(A^\top A)$ and $\overline{L} = \frac{1}{n}\|A\|_F^2$. If each entry of each a_i is a random Gaussian $N(0,1)$, then $\overline{L}$ is around d and $\overline{L}$ is around only $\Theta(1+\frac{d}{n})$ (using the Wishart random matrix theory).*

Remark 5.4 *The parameter specifications in* Katyusha1 *look intimidating partially because we have tried to obtain the strongest statement and match the full-gradient descent performance when $b = n$. If $\overline{L}$ is equal to L, then one can simply set $\tau_2 = \frac{1}{2b}$ and $L_\diamond = L$ in* Katyusha1.

Phase Transition between Mini-Batch and Full-Batch. Theorem 5.2 indicates a phase transition of Katyusha1 at the point $b_0 = (n\overline{L}/L)^{1/2}$.

- If $b \leq b_0$, we say Katyusha1 is in the *mini-batch phase* and the total work is $\widetilde{O}\big(n + \sqrt{n\overline{L}/\sigma}\big)$, independent of b.
- If $b > b_0$, we say Katyusha1 is in the *full-batch phase*, and the total work is $\widetilde{O}\big(n+b\sqrt{L/\sigma}\big)$, so essentially linearly-scales with b and matches that of Nesterov's method when $b = n$.

Remark 5.5 *We set different values for τ_1 and $L_\diamond$ in the mini-batch phase and full-batch phase respectively (see Line 3). From the final complexities above, it should not be surprising that τ_1 depends on $\overline{L}$ but not L in the mini-batch phase, and depends on L but not $\overline{L}$ in the full-batch phase. In addition, one can even tune the parameters so that it suffices for* Katyusha *to output $\widetilde{x}^S$ in the mini-batch phase and y_{Sm} in the full-batch phase; we did not do so and simply choose to output x^{out} which is a convex combination of $\widetilde{x}^S$ and y_{Sm}.*

Remark 5.6 *In the simple case $\overline{L} = L$, Nitanda (2014) obtained a total work $\widetilde{O}\big(n+\frac{n-b}{n-1}\frac{L}{\sigma} + b\sqrt{L/\sigma}\big)$, which also implies a phase transition for b. However, this result is no better than ours for all b, and in addition, in terms of total work, it is no faster than SVRG when $b \leq n/2$, and no faster than accelerated full-gradient descent when $b > n/2$.*

5.3 Corollaries on Non-Smooth or Non-SC Problems

In the same way as Section 3, we can apply the reductions from Allen-Zhu and Hazan (2016b) to convert the performance of Theorem 5.2 to non-smooth or non-strongly convex settings. We state the corollaries below:

Corollary 5.7 *If each $f_i(x)$ is convex and L_i-smooth, $f(x)$ is L-smooth, $\psi(\cdot)$ is not necessarily strongly convex in Problem (1.1), then for any $b \in [n]$, by applying* AdaptReg *on* `Katyusha1` *with a starting vector x_0, we obtain an output x satisfying $\mathbb{E}[F(x)] - F(x^*) \le \varepsilon$ in at most*

$$O\Big(n \log \tfrac{F(x_0)-F(x^*)}{\varepsilon} + \tfrac{b\sqrt{L}\cdot\|x_0-x^*\|}{\sqrt{\varepsilon}} + \tfrac{\sqrt{nL}\cdot\|x_0-x^*\|}{\sqrt{\varepsilon}}\Big) \text{ stochastic gradient computations.}$$

Corollary 5.8 *If each $f_i(x)$ is $\sqrt{G_i}$-Lipschitz continuous and $\psi(x)$ is σ-SC in Problem (1.3), then for any $b \in [n]$, by applying* AdaptSmooth *on* `Katyusha1` *with a starting vector x_0, we obtain an output x satisfying $\mathbb{E}[F(x)] - F(x^*) \le \varepsilon$ in at most*

$$O\Big(n \log \tfrac{F(x_0)-F(x^*)}{\varepsilon} + \tfrac{b\sqrt{\overline{G}}}{\sqrt{\sigma\varepsilon}} + \tfrac{\sqrt{n\overline{G}}}{\sqrt{\sigma\varepsilon}}\Big) \text{ stochastic gradient computations.}$$

Corollary 5.9 *If each $f_i(x)$ is $\sqrt{G_i}$-Lipschitz continuous and $\psi(x)$ is not necessarily strongly convex in Problem (1.3), then for any $b \in [n]$, by applying* JointAdaptRegSmooth *on* `Katyusha1` *with a starting vector x_0, we obtain an output x satisfying $\mathbb{E}[F(x)] - F(x^*) \le \varepsilon$ in at most*

$$O\Big(n \log \tfrac{F(x_0)-F(x^*)}{\varepsilon} + \tfrac{b\overline{G}\|x_0-x^*\|}{\varepsilon} + \tfrac{\sqrt{n\,\overline{G}}\|x_0-x^*\|}{\varepsilon}\Big) \text{ stochastic gradient computations.}$$

6. Katyusha in the Non-Euclidean Norm Setting

In this section, we show that `Katyusha` and `Katyusha`$^{\mathsf{ns}}$ naturally extend to settings where the smoothness definition is with respect to a non-Euclidean norm.

Non-Euclidean Norm Smoothness. We consider smoothness (and strongly convexity) with respect to an arbitrary norm $\|\cdot\|$ in domain $Q \stackrel{\text{def}}{=} \{x \in \mathbb{R}^d : \psi(x) < +\infty\}$. Symbolically, we say

- f is σ-strongly convex w.r.t. $\|\cdot\|$ if $\forall x, y \in Q$, it satisfies $f(y) \ge f(x) + \langle \nabla f(x), y - x\rangle + \frac{\sigma}{2}\|x-y\|^2$;
- f is L-smooth w.r.t. $\|\cdot\|$ if $\forall x, y \in Q$, it satisfies $\|\nabla f(x) - \nabla f(y)\|_* \le L\|x-y\|$.[16]

Above, $\|\cdot\|_* \stackrel{\text{def}}{=} \max\{\langle \xi, x\rangle : \|x\| \le 1\}$ is the dual norm of $\|\cdot\|$. For instance, ℓ_p norm is dual to ℓ_q norm if $\frac{1}{p} + \frac{1}{q} = 1$. Some famous problems have better smoothness parameters when non-Euclidean norms are adopted, see the discussions in Allen-Zhu and Orecchia (2017).

Bregman Divergence. Following the traditions in the non-Euclidean norm setting (Allen-Zhu and Orecchia, 2017), we

- select a *distance generating function* $w(\cdot)$ that is 1-strongly convex w.r.t. $\|\cdot\|$, and[17]
- define the *Bregman divergence function* $V_x(y) \stackrel{\text{def}}{=} w(y) - w(x) - \langle \nabla w(x), y - x\rangle$.

The final algorithms and proofs will be described using $V_x(y)$ and $w(x)$.

16. This definition has another equivalent form: $\forall x, y \in Q$, it satisfies $f(y) \le f(x) + \langle \nabla f(x), y-x\rangle + \frac{L}{2}\|y-x\|^2$.
17. For instance, if $Q = \mathbb{R}^d$ and $\|\cdot\|_p$ is the ℓ_p norm for some $p \in (1, 2]$, one can choose $w(x) = \frac{1}{2(p-1)}\|x\|_p^2$; if $Q = \{x \in \mathbb{R}^d : \sum_i x_i = 1\}$ is the probability space and $\|\cdot\|_1$ is the ℓ_1 norm, one can choose $w(x) = \sum_i x_i \log x_i$.

Generalized Strong Convexity of $\psi(\cdot)$. We require $\psi(\cdot)$ to be σ-strongly convexity with respect to function $V_x(y)$ rather than the $\|\cdot\|$ norm; or symbolically,

$$\psi(y) \ge \psi(x) + \langle \nabla\psi(x), y - x\rangle + \sigma V_x(y) \ .$$

(For instance, this is satisfied if $\omega(y) \stackrel{\text{def}}{=} \frac{1}{\sigma}\psi(y)$.) This is known as the "generalized strong convexity" (Shalev-Shwartz, 2007) and is necessary for any linear-convergence result in the SC setting. Of course, in the non-SC setting, we do not require any (general or not) strong convexity for $\psi(\cdot)$.

6.1 Algorithm Changes and Theorem Restatements

Suppose each $f_i(x)$ is L_i-smooth with respect to norm $\|\cdot\|$, and a Bregman divergence function $V_x(y)$ is given. We perform the following changes to the algorithms:

- In Line 9 of `Katyusha` (resp. Line 10 of `Katyusha`$^{\mathsf{ns}}$), we choose i with probability proportional to L_i instead of uniformly at random.
- In Line 10 of `Katyusha` (resp. Line 11 of `Katyusha`$^{\mathsf{ns}}$), we change the arg min to be its non-Euclidean norm variant (Allen-Zhu and Orecchia, 2017): $z_{k+1} = \arg\min_z \big\{\frac{1}{\alpha}V_{z_k}(z) + \langle \widetilde{\nabla}_{k+1}, z\rangle + \psi(z)\big\}$
- We forbidden Option II and use Option I only (but *without* replacing $\|y - x_{k+1}\|^2$ with $V_{x_{k+1}}(y)$).
