$$\begin{aligned}&\mathbb{E}_{\gamma^T}\left(\mathcal{E}_{\mathbb{P}^T}(\beta^{CS})\right) \geq \mathbb{E}_{\gamma^T}\left(\mathcal{E}_{\mathbb{P}^T}(\beta^{S^*})\right) \\ &\Leftrightarrow (\beta_X^{CS})^t\mathrm{diag}(\sigma_X^2)(\beta_X^{CS}) + (\beta_Z^{CS})^2\left(V_Y\Sigma^2 + \sigma_\eta^2\right) + V_Y - 2\alpha^t\mathrm{diag}(\sigma_X^2)\beta_X^{CS} \geq \sigma^2 \\ &\Leftrightarrow (\beta_Z^{CS})^2\left(V_Y\Sigma^2 + \sigma_\eta^2\right) \geq 2\alpha^t\mathrm{diag}(\sigma_X^2)\beta_X^{CS} - (\beta_X^{CS})^t\mathrm{diag}(\sigma_X^2)\beta_X^{CS} - \alpha^t\mathrm{diag}(\sigma_X^2)\alpha \\ &\Leftrightarrow (\beta_Z^{CS})^2\left(V_Y\Sigma^2 + \sigma_\eta^2\right) \geq -\frac{\bar\gamma^2}{D^2}(\beta_Z^{CS})^2\alpha^t\mathrm{diag}(\sigma_X^2)\alpha, \end{aligned} \tag{14}$$

by replacing $\beta_X^{CS} = \alpha - \alpha\frac{\bar\gamma}{D}\beta_Z^{CS}$. This inequality holds true for any value of the variance Σ^2, and the pooled coefficient leads to larger error in expectation.

Consider now that the coefficients γ^k are fixed and centered around a non-zero value μ. Then the expectation with respect to γ^T of the loss in the test task is the following:

$$\begin{aligned}\mathbb{E}_{\gamma^T}\left(\mathcal{E}_{\mathbb{P}^T}(\beta^{CS})\right) = (\beta_X^{CS})^t\mathrm{diag}(\sigma_X^2)\beta_X^{CS} + (\beta_Z^{CS})^2\left(V_Y(\Sigma^2 + \mu^2) + \sigma_\eta^2\right) \\ + 2\beta_Z^{CS}\alpha^t\mathrm{diag}(\sigma_X^2)\beta_X^{CS}\mu + V_Y - 2\alpha^t\mathrm{diag}(\sigma_X^2)\beta_X^{CS} - 2\beta_Z^{CS}V_Y\mu. \end{aligned} \tag{15}$$

Then, if $\bar\gamma \neq 0$ (if $\bar\gamma = 0$, both estimators coincide):

$$\mathbb{E}_{\gamma^T}\left(\mathcal{E}_{\mathbb{P}^T}(\beta^{CS})\right) \geq \mathbb{E}_{\gamma^T}\left(\mathcal{E}_{\mathbb{P}^T}(\beta^{S^*})\right) \Leftrightarrow \Sigma^2 \geq P(\mu), \tag{16}$$

where $P(\mu) = -\mu^2 - \frac{2}{\beta_Z^{CS}}\left(\left(1 - \frac{\bar\gamma}{D}\beta_Z^{CS}\right)\frac{\alpha^t\mathrm{diag}(\sigma_X^2)\alpha}{V_Y} - 1\right)\mu - \frac{\bar\gamma^2}{V_Y D^2}\alpha^t\mathrm{diag}(\sigma_X^2)\alpha + \frac{\sigma_\eta}{V_Y}$.

A.3 Proof of Proposition 3

Proof For $k \in \{1, \dots, D, T\}$, let $\mathbb{Q}^k$ be the probability distribution with density:

$$q^k(\mathbf{x}_{S^*}, \mathbf{x}_N, y) := p^k(\mathbf{x}_{S^*}, y)p^T(\mathbf{x}_N \,|\, \mathbf{x}_{S^*}, y). \tag{17}$$

In the test task T, we trivially have $q^T = p^T$. First, it is easy to see that q^k and p^k have the same marginal distribution over $\mathbf{x}_{S^*}$ and y. Indeed:

$$\begin{aligned}q^k(\mathbf{x}_{S^*}, y) &= \int_{\mathbb{R}^{|N|}} q^k(\mathbf{x}_{S^*}, \mathbf{x}_N, y)d\mathbf{x}_N \\ &= \int_{\mathbb{R}^{|N|}} p^k(\mathbf{x}_{S^*}, y)p^T(\mathbf{x}_N \,|\, \mathbf{x}_{S^*}, y)d\mathbf{x}_N \\ &= p^k(\mathbf{x}_{S^*}, y)\int_{\mathbb{R}^{|N|}} p^T(\mathbf{x}_N \,|\, \mathbf{x}_{S^*}, y)d\mathbf{x}_N = p^k(\mathbf{x}_{S^*}, y). \end{aligned} \tag{18}$$

Second, we prove that the conditional $q^k(y \,|\, \mathbf{x}_{S^*}, \mathbf{x}_N)$ is the same in all tasks. Indeed, by applying Bayes' rule:

$$\begin{aligned}q^k(y \,|\, \mathbf{x}_{S^*}, \mathbf{x}_N) &= q^k(\mathbf{x}_N \,|\, y, \mathbf{x}_{S^*})\frac{q^k(y, \mathbf{x}_{S^*})}{q^k(\mathbf{x}_{S^*}, \mathbf{x}_N)} \\ &= p^T(\mathbf{x}_N \,|\, y, \mathbf{x}_{S^*})\frac{q^k(y \,|\, \mathbf{x}_{S^*})}{q^k(\mathbf{x}_N \,|\, \mathbf{x}_{S^*})} \\ &= p^T(\mathbf{x}_N \,|\, y, \mathbf{x}_{S^*})\frac{p^k(y \,|\, \mathbf{x}_{S^*})}{\int_{\mathbb{R}} q^k(y, \mathbf{x}_N \,|\, \mathbf{x}_{S^*})dy} \\ &= p^T(\mathbf{x}_N \,|\, y, \mathbf{x}_{S^*})\frac{p^k(y \,|\, \mathbf{x}_{S^*})}{\int_{\mathbb{R}} q^k(\mathbf{x}_N \,|\, y, \mathbf{x}_{S^*})q^k(y \,|\, \mathbf{x}_{S^*})dy} \\ &= p^T(\mathbf{x}_N \,|\, y, \mathbf{x}_{S^*})\frac{p^k(y \,|\, \mathbf{x}_{S^*})}{\int_{\mathbb{R}} p^T(\mathbf{x}_N \,|\, y, \mathbf{x}_{S^*})p^k(y \,|\, \mathbf{x}_{S^*})dy}. \end{aligned}$$

We have used the fact that $q^k(\mathbf{x}_N \,|\, y, \mathbf{x}_{S^*}) = p^T(\mathbf{x}_N \,|\, y, \mathbf{x}_{S^*})$, which follows from (18). Since the last equality leads to a term which is equal in all tasks (indeed, Assumption (A1) ensures that $p^k(y \,|\, \mathbf{x}_{S^*})$ is the same for all $k \in \{1, \dots, D, T\}$), we have the desired result. ■

A.4 Statement and proof of Proposition 5

In this Section, we provide an analytic expression for β^{opt} from (3) in terms of α and ϵ.

Proposition 5 *Assume that $\mathbf{X}_{S^*}$ follows an arbitrary distribution and that Assumptions (A1) and (A2) hold. Let $\gamma \in \mathbb{R}^{|N|}$ be the solution of an L^2 regression from $\mathbf{X}_N^T$ on Y^T. Therefore, we can write $\mathbf{X}_N^T = \gamma Y^T + \eta$, with η uncorrelated to Y^T, and the components of η can be correlated. Then the regression coefficients $\beta^{opt} = (\beta_{S^*}^{opt}, \beta_N^{opt})$ minimizing the expected squared loss in the test task satisfy*

$$\beta_N^{opt} = \mathbb{E}(\epsilon^2) M^{-1} \gamma \,, \tag{19}$$

$$\beta_{S^*}^{opt} = \alpha \left(1 - (\gamma^T)^t \beta_N^T\right) - \Sigma_{X,S^*}^{-1} \Sigma_{X,N} \beta_N \,, \tag{20}$$

where $M = \mathbb{E}(\epsilon^2)\gamma\gamma^t + \Sigma_N - \Sigma_{X,N}^t \Sigma_{X,S^*}^{-1} \Sigma_{X,N}$, and $\Sigma_N := \mathbb{E}(\eta\eta^t)$, $\Sigma_{X,S^*} := \mathbb{E}(\mathbf{X}_{S^*}\mathbf{X}_{S^*}^t)$, $\Sigma_{X,N} := \mathbb{E}(\mathbf{X}_{S^*}\eta^t)$ are the corresponding Gram matrices.[4]

Proof To simplify notation, we write Y^T, $\mathbf{X}_{S^*}^T$ and $\mathbf{X}_N^T$ as Y, $\mathbf{X}_{S^*}$ and $\mathbf{X}_N$. We compute the gradients of the expected squared loss after replacing the expression for Y and $\mathbf{X}_{S^*}$:

$$\begin{aligned} L &= \mathbb{E}(Y - \beta_{S^*}^t \mathbf{X}_{S^*} - \beta_N^t \mathbf{X}_N)^2 \\ &= (\alpha(1 - \gamma^t\beta_N) - \beta_{S^*})^t \Sigma_{X,S^*} (\alpha(1 - \gamma^t\beta_N) - \beta_{S^*}) \\ &\quad + (1 - \beta_N^t\gamma)^2 \mathbb{E}(\epsilon^2) + \beta_N^t \Sigma_N \beta_N - 2(\alpha(1 - \gamma^t\beta_N) - \beta_{S^*})^t \Sigma_{X,N} \beta_N \end{aligned}$$

The gradients satisfy

$$\begin{aligned} \frac{\partial L}{\partial \beta_{S^*}} &= -2\Sigma_{X,S^*}(\alpha(1 - \gamma^t\beta_N) - \beta_{S^*}) + 2\Sigma_{X,N}\beta_N \\ \frac{1}{2}\frac{\partial L}{\partial \beta_N} &= \Sigma_N \beta_N - (1 - \gamma^t\beta_N)\mathbb{E}(\epsilon^2)\gamma + \gamma\alpha^t \Sigma_{X,N}\beta_N \\ &\quad - \gamma\alpha^t \Sigma_{X,S^*}(\alpha(1 - \gamma^t\beta_N) - \beta_{S^*}) - \Sigma_{X,N}^t(\alpha(1 - \gamma^t\beta_N) - \beta_{S^*}) \end{aligned}$$

By setting these to zero, we find the stated values for $\beta_{S^*}^{opt}$ and β_N^{opt}. ■

Appendix B.

The code to reproduce the experiments in the paper can be found in `https://github.com/mrojascarulla/causal_transfer_learning`.

4. We dropped the superscript T to lighten the notation.

Abstract

When performing regression on a data set with p variables, it is often of interest to go beyond using main linear effects and include interactions as products between individual variables. For small-scale problems, these interactions can be computed explicitly but this leads to a computational complexity of at least $\mathcal{O}(p^2)$ if done naively. This cost can be prohibitive if p is very large.

We introduce a new randomised algorithm that is able to discover interactions with high probability and under mild conditions has a runtime that is subquadratic in p. We show that strong interactions can be discovered in almost linear time, whilst finding weaker interactions requires $\mathcal{O}(p^\alpha)$ operations for $1 < \alpha < 2$ depending on their strength. The underlying idea is to transform interaction search into a closest pair problem which can be solved efficiently in subquadratic time. The algorithm is called *xyz* and is implemented in the language `R`. We demonstrate its efficiency for application to genome-wide association studies, where more than 10^{11} interactions can be screened in under 280 seconds with a single-core 1.2 GHz CPU.

Keywords: interactions, high-dimensional data, regression, computational tradeoffs, close pairs

1. Introduction

Given a response vector $\mathbf{Y} \in \mathbb{R}^n$ and matrix of associated predictors $\mathbf{X} = (\mathbf{X}_1, \ldots, \mathbf{X}_p) \in \mathbb{R}^{n \times p}$, finding interactions is often of great interest as they may reveal important relationships and improve predictive power. When the number of variables p is large, fitting a model involving interactions can involve serious computational challenges. The simplest form of interaction search consists of screening for pairs (j, k) with high inner product between the outcome of interest $\mathbf{Y}$ and the point-wise product $\mathbf{X}_j \circ \mathbf{X}_k$:

$$\text{Keep all pairs } (j,k) \text{ for which } \mathbf{Y}^T(\mathbf{X}_j \circ \mathbf{X}_k)/n > \kappa. \tag{1}$$

This search is of complexity $\mathcal{O}(np^2)$ in a naive implementation and quickly becomes infeasible for large p. Of course one would typically be interested in maximising (absolute values of) correlations rather than dot products in (1), an optimisation problem that would be at least as computationally intensive.

Even more challenging is the task of fitting a linear regression model involving pairwise interactions:

$$Y_i = \mu + \sum_{j=1}^{p} X_{ij}\beta_j + \sum_{k=1}^{p}\sum_{j=1}^{k-1} X_{ij}X_{ik}\theta_{jk} + \varepsilon_i. \tag{2}$$

Here $\mu \in \mathbb{R}$ is the intercept and β_j and θ_{jk} contain coefficients for main effects and interactions respectively, and ε_i is random noise.

In this paper, we make several contributions to the problem of searching for interactions in high-dimensional settings.

(a) We first establish a form of equivalence between (1) and closest-pair problems (Shamos and Hoey, 1975; Agarwal et al., 1991). Assume for now that all predictors and outcomes are binary, so $X_{ij}, Y_i \in \{-1, 1\}$ (we will later relax this assumption) and define $\mathbf{Z} \in \{-1,1\}^{n \times p}$ as $Z_{ij} = Y_i X_{ij}$. Then it is straightforward to show that (1) is equivalent to

$$\text{Keep all pairs } (j,k) \text{ for which } \|\mathbf{X}_j - \mathbf{Z}_k\|_2 < \kappa' \tag{3}$$

for some κ'. This connects the search for interactions to literature in computational geometry on problems of finding closest pairs of points.

(b) We introduce the *xyz* algorithm to solve (3) based on randomly projecting each of the columns in $\mathbf{X}$ and $\mathbf{Z}$ to a one-dimensional space. By exploiting the ability to sort the resulting $2p$ points with $\mathcal{O}(p\log(p))$ computational cost, we achieve a run time that is always subquadratic in p and can even reach a linear complexity $\mathcal{O}(np)$ when κ is much larger than the quantity $|\mathbf{Y}^T(\mathbf{X}_j \circ \mathbf{X}_k)|/n$ of the bulk of the pairs (j, k). We show that our approach can be viewed as an example of locality sensitive hashing (Leskovec et al., 2014) optimised for our specific problem.

(c) We show how any method for solving (1) can be used to fit regression models with interactions (15) by building it into an algorithm for the Lasso (Tibshirani, 1996). The use of *xyz* thus leads to a procedure for applying the Lasso to all main effects and interactions with computational cost that scales subquadratically in p.

(d) We provide implementations of both the core *xyz* algorithm and its extension to the Lasso in the R package `xyz`, which is available on github (Thanei, 2016) and CRAN.

Our work here is thus related to "closest pairs of points" algorithms in computational geometry as well as an extensive literature on modelling interactions in statistics, both of which we now review.

1.1 Related work

A common approach to avoid the quadratic cost in p of searching over all pairs of variables (1) is to restrict the search space: one can first seek a small number of important main effects, and then only consider interactions involving these discovered main effects. More specifically, one could fit a main effects Lasso (Tibshirani, 1996) to the data first, add interactions between selected main effects to the matrix of predictors, and then run the Lasso once more on the augmented design matrix in order to produce the final model (see Wu et al. (2010) for example). Tree-based methods such as CART (Breiman et al., 1984) work in a similar fashion by aiming to identify an important main effect and then only considering interactions involving this discovered effect.

However it is quite possible for the signal to be such that main effects corresponding to important interactions are hard to detect. As a concrete example of this phenomenon, consider the setting where $\mathbf{X}$ is generated randomly with all entries independent and having the uniform distribution on $\{-1, 1\}$. Suppose the response is given by $Y_i = X_{i1}X_{i2}$, so there is no noise. Since the distribution $Y_i|X_{ij}$ is the same for all k, main effects regressions would find it challenging to select variables 1 and 2. Note that by reparametrising the model by adding one to each entry of $\mathbf{X}$ for example, we obtain $Y_i = (X_{i1} - 1)(X_{i2} - 1) = 1 - X_{i1} - X_{i2} + X_{i1}X_{i2}$. The model now respects the so-called strong hierarchical principle (Bien et al., 2013) that interactions are only present when their main effects are. The hierarchical principle is useful to impose on any fitted model. However, imposing the principle on the model does not imply that the interactions will easily be found by searching for main effects first. The difficulty of the example problem is due to interaction effects masking main effects: this is a property of the signal $\mathbb{E}(Y_i)$ and of course no reparametrisation can make the main effects any easier to find. Approaches that increase the set of interactions to be considered iteratively can help to tackle this sort of issue in practice (Bickel et al., 2010; Hao and Zhang, 2014; Friedman, 1991; Shah, 2016) as can those that randomise the search procedure (Breiman, 2001). However they cannot eliminate the problem of missing interactions, nor do these approaches offer guarantees of how likely it is that they discover an interaction.

As alluded to earlier, the pure interaction search problem (3) is related to close pairs of points problems, and more specifically the close bichromatic pairs problem in computational geometry (Agarwal et al., 1991). Most research in this area has focused on algorithms that lead to computationally optimal results in the number of points p whilst considering the dimension n to be constant. This has resulted in algorithms where the scaling of the computational complexity with n is at least of order 2^n (Shamos and Hoey, 1975). Since for meaningful statistical results one would typically require $n \gg \log(p)$, these approaches would not lead to subquadratic complexity. An exception is the so-called lightbulb algorithm (Paturi et al., 1989) which employs a similar strategy for binary data; our work here shows that this is optimal among random projection-based methods and also that it may be modified to handle continuous data and also detect interactions in high-dimensional regression settings.

In the special case where $n = p$ and $Z_{ij}, X_{ij} \in \{-1, 1\}$, (3) may be seen to be equivalent to searching for large magnitude entries in the product of square matrices $\mathbf{X}$ and $\mathbf{Z}^T$. This latter problem is amenable to fast matrix multiplication algorithms, which in theory can

deliver a subquadratic complexity of roughly $\mathcal{O}(p^{2.4}) = \mathcal{O}(np^{1.4})$ (Williams, 2012; Davie and Stothers, 2013; Le Gall, 2012). However the constants hidden in the order notation are typically very large, and practical implementations are unavailable. The Strassen algorithm (Strassen, 1969) is the only fast matrix multiplication algorithm used regularly in practice to the best of our knowledge. With a complexity of roughly $\mathcal{O}(p^{2.8}) = \mathcal{O}(np^{1.8})$, the improvement over a brute force close pairs search is only slight.

The strategy we use is most closely related to locality sensitive hashing (LSH) (Indyk and Motwani, 1998) which encompasses a family of hashing procedures such that similar points are mapped to the same bucket with high probability. A close pair search can then be conducted by searching among pairs mapped to the same bucket. In fact, our approach for solving (3) can be thought of as an example of LSH optimised for our particular problem setting. This connection is detailed in Appendix B.

A seemingly attractive alternative to the subsampling-based LSH-strategy we employ is the method of random projections which is motivated by the theoretical guarantees offered by the Johnson–Lindenstrauss Lemma (Achlioptas, 2003). Perhaps surprisingly, we can show that using random projections instead of our subsampling-based scheme leads to a quadratic run time for interaction search (see Theorem 1 and section 5.1).

An approach that bears some similarity with our procedure is that of *epiq* (Arkin et al., 2014). This works by projecting the data and then searches through a lower dimensional representation for close pairs. This appears to improve upon a naive brute force empirically but there are no proven guarantees that the run time improves on the $\mathcal{O}(np^2)$ complexity of a naive search.

The *Random Intersection Trees* algorithm of Shah and Meinshausen (2014) searches for potentially deeper interactions in data with both $\mathbf{X}$ and $\mathbf{Y}$ binary. In certain cases with strong interactions a complexity close to linear in p is achieved; however it is not clear how to generalise the approach to continuous data or embed it within a regression procedure.

The idea of Kong et al. (2016) is to first transform the data by forming $\tilde{\mathbf{Y}} = \mathbf{Y} \circ \mathbf{Y}$ and $\tilde{\mathbf{X}}_j = \mathbf{X}_j \circ \mathbf{X}_j$ for each predictor. Next $\tilde{\mathbf{X}}_j$ and $\tilde{\mathbf{Y}}$ are tested for independence using the distance correlation test. In certain settings, this can reveal important interactions with a computational cost linear in p. However, the powers of these tests depend on the distributions of the transformed variables $\tilde{\mathbf{X}}_j$. For example in the binary case when $\mathbf{X} \in \{-1, 1\}^{n \times p}$, each transformed variable will be a vector of 1's and the independence tests will be unhelpful. We will see that our proposed approach works particularly well in this setting.

1.2 Organisation of the paper

In Section 2 we consider the case where both the response $\mathbf{Y}$ and the predictors $\mathbf{X}$ are binary. We first demonstrate how (15) may be converted to a form of closest pair of points problem. We then introduce a general version of the *xyz* algorithm which solves this based on random projections. As we show in Section 2.1 there is a particular random projection distribution that is optimal for our purposes. This leads to our final version of the *xyz* algorithm which we present in Section 2.3 along with an analysis of its run time and probabilistic guarantees that it recovers important interactions. In Section 3 we extend the *xyz* algorithm to continuous data. These ideas are then used in Section 4 to

demonstrate how the *xyz* algorithm can be embedded within common algorithms for high-dimensional regression (Friedman et al., 2010) allowing high-dimensional regression models with interactions to be fitted with subquadratic complexity in p. Section 5 contains a variety of numerical experiments on real and simulated data that complement our theoretical results and demonstrate the effectiveness of our proposal in practice. We conclude with a brief discussion in Section 6 and all proofs are collected in the Appendix.

2. The *xyz* algorithm for binary data

In this section, we present a version of the *xyz* algorithm applicable in the special case where both $\mathbf{X}$ and $\mathbf{Y}$ are binary, so $X_{ij} \in \{-1, 1\}$ and $Y_i \in \{-1, 1\}$. We build up to the algorithm in stages, giving the final version in Section 2.2.

Define $\mathbf{Z} \in \{-1, 1\}^{n \times p}$ by $Z_{ij} = Y_i X_{ij}$ and

$$\gamma_{jk} = \frac{1}{n} \sum_{i=1}^{n} \mathbb{1}_{\{Y_i = X_{ij} X_{ik}\}}. \tag{4}$$

We call γ_{jk} the interaction strength of the pair (j, k). It is easy to see that the interaction search problem (1) can be expressed in terms of either the γ_{jk} or the normalised squared distances. Indeed

$$2\gamma_{jk} - 1 = \mathbf{Y}^T(\mathbf{X}_j \circ \mathbf{X}_k)/n = \mathbf{Z}_j^T \mathbf{X}_k / n = 1 - \|\mathbf{Z}_j - \mathbf{X}_k\|_2^2/(2n). \tag{5}$$

Thus those pairs (j, k) with $\mathbf{Y}^T(\mathbf{X}_j \circ \mathbf{X}_k)/n$ large will have γ_{jk} large, and $\|\mathbf{Z}_j - \mathbf{X}_k\|_2^2$ small. This equivalence suggests that to solve (1), we can search for pairs (j, k) of columns $\mathbf{Z}_j, \mathbf{X}_k$ that are close in ℓ_2 distance. At first sight, this new problem would also appear to involve a search across all pairs, and would thus incur an $\mathcal{O}(np^2)$ cost. As mentioned in the introduction, close pair searches that avoid a quadratic cost in p incur typically an exponential cost in n. Since n would typically be much larger than $\log(p)$, such searches would be computationally infeasible.

We can however project each of the n-dimensional columns of $\mathbf{X}$ and $\mathbf{Z}$ to a lower dimensional space and then perform a close pairs search. The Johnson–Lindenstrauss Lemma, which states roughly that one can project p points into a space of dimension $\mathcal{O}(\log(p))$ and faithfully preserve distances, may appear particularly relevant here. The issue is that the projected dimension suggested by the Johnson–Lindenstrauss Lemma is still too large to allow for an efficient close pairs search. The following observation however gives some encouragement: if we had $\mathbf{Y} = \mathbf{X}_j \circ \mathbf{X}_k$ so $\mathbf{X}_j = \mathbf{Z}_k$, even a one-dimensional projection $\mathbf{R} \in \mathbb{R}^n$ will have $|\mathbf{R}^T(\mathbf{X}_j - \mathbf{Z}_k)| = 0 = \|\mathbf{X}_j - \mathbf{Z}_k\|_2$, which implies that a perfect interaction will have zero distance in the projected space. We will later see that our approach leads to a linear run time in such a case. Importantly, we are only interested in using a projection that preserves the distances between the close pairs rather than all pairs, which makes our problem very different to the setting considered in the Johnson–Lindenstrauss Lemma.

With this in mind, consider the following general strategy. First project the columns of $\mathbf{X}$ and $\mathbf{Z}$ to one-dimensional vectors x and z using a random projection $\mathbf{R}$: $\mathbf{x} = \mathbf{X}^T\mathbf{R}$, $\mathbf{z} = \mathbf{Z}^T\mathbf{R}$. Next for some threshold τ, collect all pairs (j, k) such that $|x_j - z_k| \leq \tau$ in the set E. By first sorting $\mathbf{x}$ and $\mathbf{z}$, a step requiring only $\mathcal{O}(p \log(p))$ computations (see

for example Sedgewick (1998)), this close pairs search can be shown to be very efficient. Given this set of candidate interactions, we can check for each $(j, k) \in E$ whether we have $\gamma_{jk} \geq \gamma$. The process can be repeated L times with different random projections, and one would hope that given enough repetitions, any given strong interaction would be present in one of the candidate sets $E_1, \ldots, E_L$ with high probability. This approach is summarised in Algorithm 1 which we term the general form of the *xyz* algorithm. A schematic overview is given in Figure 1.

Algorithm 1 A general form of the *xyz* algorithm.

Input: $\mathbf{X} \in \{-1, 1\}^{n \times p}$, $\mathbf{Y} \in \{-1, 1\}^n$
Parameters: $\xi = (G, L, \tau, \gamma)$. Here G is the joint distribution for the projection vector $\mathbf{R}$, L is the number of projections, and τ and γ are the thresholds for close pairs and interactions strength respectively.
Output: I set of strong interactions.

Form $\mathbf{Z}$ via $Z_{ij} = Y_i X_{ij}$ and set $I := \emptyset$.
for $l \in \{1, \ldots, L\}$ **do**
  Draw random vector $\mathbf{R} \in \mathbb{R}^n$ with distribution G and project the data using $\mathbf{R}$, to form

$$\mathbf{x} = \mathbf{X}^T\mathbf{R} \text{ and } \mathbf{z} = \mathbf{Z}^T\mathbf{R}.$$

  Collect in E_l all pairs (j, k) such that $|x_j - z_k| \leq \tau$.
  Add to I those $(j, k) \in E_l$ for which $\gamma_{jk} \geq \gamma$.
end for

There are several parameters that must be selected, and a key choice to be made is the form of the random projection $\mathbf{R}$. For the joint distribution G of $\mathbf{R}$ we consider the following general class of distributions, which includes both dense and sparse projections. We sample a random or deterministic number M of indices from the set $\{1, \ldots, n\}$, $i_1, \ldots, i_M$, either with or without replacement. Then, given a distribution $F \in \mathcal{F}$ where $\mathcal{F}$ is a class of distributions to be specified later, we form a vector $\mathbf{D} \in \mathbb{R}^M$ with independent components each distributed according to F. We then define the random projection vector $\mathbf{R}$ by

$$R_i = \sum_{m=1}^{M} D_m \mathbb{1}_{\{i_m = i\}}, \qquad i = 1, \ldots, n. \tag{6}$$

Each configuration of the *xyz* algorithm is characterised by fixing the following parameters:

(i) G, a distribution for the projection vector R which is determined through (6) by $F \in \mathcal{F}$, a distribution for the subsample size M and whether sampling is with replacement or not;

(ii) $L \in \mathbb{N}$, the number of projection steps;

(iii) $\tau \geq 0$, the close pairs threshold;

(iv) $\gamma \in (0, 1)$, the interaction strength threshold.

We will denote the collection of all possible parameter levels by Ξ. This includes the following subclasses of interest. Fix $F \in \mathcal{F}$.

(a) **Dense projections**. Let $\mathbf{R} \in \mathbb{R}^n$ have independent components distributed according to F and denote the distribution of $\mathbf{R}$ by G. This falls within our general framework above with M set to n and sampling without replacement. Let

$$\Xi_{\text{dense}} := \{\xi \in \Xi \text{ with joint distribution equal to G}\}.$$

(b) **Subsampling**. Let $\mathcal{G}_{\text{subsample}}$ be the set of distributions for R obtained through (6) when subsampling with replacement. Let

$$\Xi_{\text{subsample}} := \{\xi \in \Xi : \text{joint distribution } G \in \mathcal{G}_{\text{subsample}}\}.$$

(c) **Minimal subsampling**. Let Ξ_{minimal} be the set of all parameters in $\Xi_{\text{subsample}}$ such that the close pairs threshold is $\tau = 0$ and M takes randomly values in the set $\{m, m+1\}$ for some positive integer m.

$$\Xi_{\text{minimal}} := \{\xi \in \Xi_{\text{subsample}} \text{ with } \tau = 0 \text{ and } M \in \{m, m+1\} \text{ for some } m \in \mathbb{N}\}.$$

Note that we have suppressed the dependence of the classes above on the fixed distribution $F \in \mathcal{F}$ for notational simplicity. We define $\mathcal{F}$ to be the set of all univariate absolutely continuous and symmetric distributions with bounded density and finite third moment. The restriction to continuous distributions in $\mathcal{F}$ ensures that Ξ_{minimal} is invariant to the choice of F: when $\tau \equiv 0$, every $F \in \mathcal{F}$ with $L \in \mathbb{N}$ and the distribution for M fixed yields the same algorithm. Moreover the set of close pairs in C_l is simply the set of pairs (j,k) that have $X_{i_m j} = Z_{i_m k}$ for all $m = 1, \ldots, M$, that is the set of pairs that are equal on the subsampled rows. We note that the symmetry and boundedness of the densities in $\mathcal{F}$ and finiteness of the third moment are mainly technical conditions necessary for the theoretical developments in the following section. We will assume without loss of generality that the second moment is equal to 1. This condition places no additional restriction on Ξ since a different second moment may be absorbed into the choice of τ.

Minimal subsampling represents a very small subset of the much larger class of randomised algorithms outlined above. However, Theorem 1 below shows that minimal subsampling is essentially always at least as good as any algorithm from the wider class, which is perhaps surprising. A beneficial consequence of this result is that we only need to search for the optimal ways of selecting M and L; the threshold τ is fixed at $\tau = 0$ and the choice of the continuous distribution F is inconsequential for minimal subsampling. The choices we give in Section 2.2 yield a subquadratic run time that approaches linear in p when the interactions to be discovered are much stronger than the bulk of the remaining interactions.

2.1 Optimality of minimal subsampling

In this section, we compare the run time of the algorithms in $\xi \in \Xi_{\text{dense}}, \Xi_{\text{subsample}}$ and Ξ_{minimal} that return strong interactions with high probability. Let (j^*, k^*) be the indices of

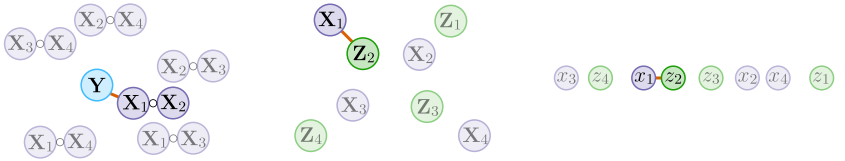

Figure 1: Illustration of the general *xyz* algorithm. The strongest interaction is the pair $(1,2)$ and $p = 4$. Panel a) illustrates the interaction search among $\mathbf{Y}$ and $\mathbf{X}_j \circ \mathbf{X}_k$, panel b) shows the closest pair problem after the transformation $Z_{ij} = X_{ij} Y_i$ and panel c) depicts the closest pair problem after the data has been projected. These are the three main steps in the *xyz* algorithm.

a strongest interaction pair, that is $\gamma_{j^*k^*} = \max_{j,k \in \{1,\ldots,p\}} \gamma_{jk}$. We will consider algorithms ξ with γ set to $\gamma_{j^*k^*}$. Define the power of $\xi \in \Xi$ as

$$\text{Power}(\xi) := \mathbb{P}_\xi((j^*, k^*) \in I).$$

For $\eta \in (0,1)$, let

$$\Xi_{\text{dense}}(\eta) = \{\xi \in \Xi_{\text{dense}} : \text{Power}(\xi) \geq \eta\},$$

and define $\Xi_{\text{subsample}}(\eta)$ and $\Xi_{\text{minimal}}(\eta)$ analogously. Note that these classes depend on the underlying $F \in \mathcal{F}$, which is considered to be fixed, and moreover that we are fixing $\gamma = \gamma_{j^*k^*}$. We consider an asymptotic regime where we have a sequence of response–predictor matrix pairs $(\mathbf{Y}^{(n)}, \mathbf{X}^{(n)}) \in \mathbb{R}^n \times \mathbb{R}^{n \times p_n}$. Write $\gamma_{jk}^{(n)}$ for the corresponding interaction strengths, and let $\gamma_1^{(n)} = \max_{j,k} \gamma_{jk}^{(n)}$. Let $f_{\boldsymbol{\gamma}^{(n)}}$ be the probability mass function corresponding to drawing an element of $\boldsymbol{\gamma}^{(n)}$ uniformly at random. Note that $f_{\boldsymbol{\gamma}^{(n)}}$ has domain $\{0, 1/n, 2/n, \ldots, 1\}$. We make the following assumptions about the sequence of interaction strength matrices $\boldsymbol{\gamma}^{(n)}$.

(A1) There exists c_0 such that $|\{(j,k) : \gamma_{jk}^{(n)} = \gamma_1^{(n)}\}| \leq c_0 p_n$.

(A2) There exists $\gamma_l > 0$, $\gamma_u < 1$ such that $\gamma_u \geq \gamma_1^{(n)} \geq \gamma_l$ for all n.

(A3) There exists $\rho < 1$ such that $f_{\boldsymbol{\gamma}^{(n)}}$ is non-increasing on $[\rho\gamma_1^{(n)}, \gamma_1^{(n)}) \cap \{0, 1/n, \ldots, 1\}$.

Assumption (A1) is rather weak: typically one would expect the maximal strength interaction to be essentially unique, while (A1) requires that at most of order p_n interactions have maximal strength. (A2) requires the maximal interaction strength to be bounded away from 0 and 1, which is the region where complexity results for the search of interactions are of interest. As mentioned earlier, if the maximal interaction strength is 1, it will always be retained in the close-pair sets C_l, whilst if its strength is too close to 0, then it is near impossible to distinguish it from the remaining interactions. (A3) ensures a certain form of separation between maximal strength interactions and the bulk of the interactions.

To aid readability, in the following we suppress the dependence of quantities on n in the notation. Given $\mathbf{X}$ and $\mathbf{Y}$, we may define $T(\xi)$ as the expected number of computational operations performed by the algorithm corresponding to ξ. We have the following result.

Theorem 1 *Given $F \in \mathcal{F}$ and $\eta \in (0,1)$, there exists n_0 such that for all $n \geq n_0$ we have*

$$\inf_{\xi \in \Xi_{minimal}(\eta)} T(\xi) = \inf_{\xi \in \Xi_{subsample}(\eta)} T(\xi), \tag{7}$$

$$\inf_{\xi \in \Xi_{minimal}(\eta)} \frac{T(\xi)}{np^2} \to 0, \tag{8}$$

and there exists $c > 0$ such that

$$\inf_{\xi \in \Xi_{dense}(\eta)} \frac{T(\xi)}{np^2} > c. \tag{9}$$

The theorem shows that the optimal run time is achieved when using minimal subsampling. The last point is surprising: setting $\mathbf{R} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$, for example, will not improve the computational complexity over the brute-force approach and dense Gaussian projections hence do not reduce the complexity of the search. This is not caused by the larger computational effort involved in computing the dense projections: indeed even if these could be computed for free this result would remain. Rather the cost stems from the fact that dense projections have a much lower power for detecting true close pairs in the projected one-dimensional space.

2.2 The final version of xyz

The optimality properties of minimal subsampling presented in the previous section suggest the approach set out in Algorithm 2, which we will refer to as the *xyz* algorithm. Here we

Algorithm 2 Final version of the *xyz* algorithm.

Input: $\mathbf{X} \in \{-1,1\}^{n \times p}$, $\mathbf{Y} \in \{-1,1\}^n$, subsample size M, number of projections L, threshold for interaction strength γ.
Output: I set of strong interactions.
1: Form $\mathbf{Z}$ via $Z_{ij} = Y_i X_{ij}$.
2: **for** $l \in \{1, \ldots, L\}$ **do**
3: Form $\mathbf{R} \in \mathbb{R}^n$ as in (6) with distribution $F = U[0,1]$ and set $\mathbf{x} = \mathbf{X}^T\mathbf{R}$, $\mathbf{z} = \mathbf{Z}^T\mathbf{R}$.
4: Find all pairs (j,k) such that $x_j = z_k$ and store these in E_l.
5: Add to I those pairs in E_l for which $\gamma_{jk} \geq \gamma$.
6: **end for**

are using a simplified version of the minimal subsampling proposal given in the previous section where we keep M fixed rather than allowing it to be random. The reason is that the potential additional gain from allowing M to be any one of two consecutive numbers with certain probabilities is minimal but necessary for Theorem 1 and so the simpler approach is preferable. We note that the uniform distribution in line 3 may be replaced with any continuous distribution to yield identical results.

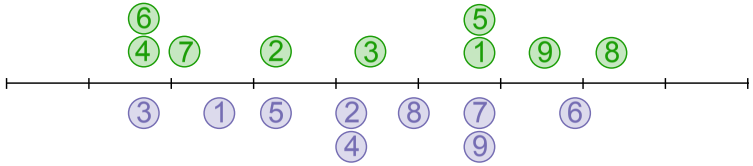

Figure 2: Illustration of an equal pairs search among components of $\mathbf{x}, \mathbf{z} \in \mathbb{R}^p$ when $p = 9$. The horizontal locations of blue and green circles numbered j give x_j and z_j respectively. Sorting of $(\mathbf{x}, \mathbf{z})$ allows traversal of the unique locations. At each of these it is checked whether points of both colours are present, and if so, the indices are recorded. Here the set of equal pairs $(\{3\} \times \{4,6\}) \cup (\{5\} \times \{2\}) \cup (\{7,9\} \times \{1,5\})$ would be returned.

To perform the equal pairs search in line 4, we sort the concatenation $(\mathbf{x}, \mathbf{z}) \in \mathbb{R}^{2p}$ to determine the unique elements of $\{x_1, \ldots, x_p, z_1, \ldots, z_p\}$. At each of these locations, we can check if there are components from both x and z lying there, and if so record their indices. This procedure, which is illustrated in Figure 2, gives us the set of equal pairs E in the form of a union of Cartesian products. The computational cost is $\mathcal{O}(p \log(p))$. This complexity is driven by the cost of sorting whilst the recording of indices is linear in p. We note, however, that looping through the set of equal pairs in order to output a list of close pairs of the form $(j_1, k_1), \ldots, (j_{|E|}, k_{|E|})$ would incur an additional cost of the size of E, though in typical usage we would have $|E| = o(p)$. Readers familiar with locality sensitive hashing (LSH) can find a short interpretation of equal pairs search as an LSH-family in the appendix. In the next section, we discuss in detail the impact of minimal subsampling on the complexity of the *xyz* algorithm and the discovery probability it attains.

2.3 Computational and statistical properties of xyz

We have the following upper bound on the expected number of computational operations performed by *xyz* (Algorithm 2) when the subsample size and number of repetitions are M and L:

$$C(M,L) := \underset{\text{(i)}}{np} + L\{\underset{\text{(ii)}}{Mp} + \underset{\text{(iii)}}{p\log(p)} + \underset{\text{(iv)}}{n\mathbb{E}_\xi(|E_1|)}\}. \tag{10}$$

The terms may be explained as follows: (i) construction of $\mathbf{Z}$; (ii) multiplying M subsampled rows of $\mathbf{X}$ and $\mathbf{Z}$ by $\mathbf{R} \in \mathbb{R}^n$; (iii) finding the equal pairs; (iv) checking whether the interactions exceed the interaction strength threshold γ. Note we have omitted a constant factor from the upper bound $C(M,L)$. There is a lower bound only differing from (10) in the equal pairs search term (iii), which is p instead of $p\log(p)$. It will be shown that (iv) is the dominating term and therefore the upper and lower bound are asymptotically equivalent, implying the bounds are tight.

An interaction with strength γ is retained in E_1 with probability γ^M. Hence it is present in the final set of interactions I with probability

$$\eta(M,L) = 1 - (1 - \gamma^M)^L. \tag{11}$$

The following result demonstrates how the *xyz* algorithm can be used to find interactions whilst incurring only a subquadratic computational cost.

Theorem 2 *Let F_Γ be the distribution function corresponding to a random draw from the set of interaction strengths $\{\gamma_{jk}\}_{j,k\in\{1,\dots,p\}}$. Given an interaction strength threshold γ, let $1-F_\Gamma(\gamma) = c_1/p$. Define $\gamma_0 = p^{-1/M}$ and let c_2 be defined by $1-F_\Gamma(\gamma_0) = c_2 p^{\log(\gamma)/\log(\gamma_0)-1}$. We assume that $\gamma_0 < \gamma$. Finally given a discovery threshold $\eta' \in [1/2, 1)$ let L be the minimal L' such that $\eta(M, L') \geq \eta'$. Ignoring constant factors we have*

$$C(M, L) \leq \log\{1/(1-\eta')\}(1 + c_1 + c_2)[\{1 + 1/\log(\gamma_0^{-1})\}\log(p) + n]p^{1+\log(\gamma)/\log(\gamma_0)}.$$

If $n \gg \log(p)$ and γ_0 is bounded away from 1 we see that the dominant term in the above is

$$cnp^{1+\log(\gamma)/\log(\gamma_0)}, \tag{12}$$

where $c = \log\{1/(1-\eta')\}(1 + c_1 + c_2)$. Typically we would expect γ to be such that $|\{\gamma_{jk} : \gamma_{jk} > \gamma\}| \sim p$ as only the largest interactions would be of interest: thus we may think of c_1 as relatively small. If M is such that γ_0 is also larger than the bulk of the interactions, we would also expect c_2 to be small. Indeed, suppose that the proportion of interactions whose strengths are larger than γ_0 is $1 - F_\Gamma(\gamma_0) = c_1'/p$. Then $c_2 = c_1'/p^{\log(\gamma)/\log(\gamma_0)} < c_1'$. As a concrete example, if $\gamma = 0.9$ and M is such that $\gamma_0 = 0.55$, the exponent in (12) is around 1.17, which is significantly smaller than the exponent of 2 that a brute-force approach would incur; see also the examples in Section 5. Note also that when $\gamma = 1$, the exponent is 1 for all $\gamma_0 < 1$: if we are only interested in interactions whose strength is as large as possible, we have a run time that is linear in p.

It is interesting to compare our results here with the run times of approaches based on fast matrix multiplication. By computing $\mathbf{X}^T\mathbf{Z}$ we may solve the interaction search problem (1). Naive matrix multiplication would require $\mathcal{O}(np^2)$ operations, but there are faster alternatives when $n = p$. The fastest known algorithm (Williams, 2012) gives a theoretical run time of $\mathcal{O}(np^{1.37})$ when $n = p$. For *xyz* to achieve such a run time when $\gamma_0 = 0.55$ for example, the target interaction strength would have to be $\gamma \geq 0.81$: a somewhat moderate interaction strength. For $\gamma > 0.81$, *xyz* is strictly better; we also note that fast matrix multiplication algorithms tend to be unstable or lack a known implementation and are therefore rarely used in practice. A further advantage is that the *xyz* algorithm has an optimal memory usage of $\mathcal{O}(np)$.

We also note that whilst Theorem 2 concerns the the discovery of any single interaction with strength at least γ, the run time required to discover a fixed number interactions with strength at least γ would only differ by a multiplicative constant. If we however want a guarantee of discovering the p strongest pairs the bound in Theorem 2 would no longer hold.

To minimise the run time in (12), we would like γ_0 to be larger than most of the interactions in order that c_2 and hence c be small, yet a smaller γ_0 yields a more favourable exponent. Thus a careful choice of M, on which γ_0 depends, is required for *xyz* to enjoy good performance. In the following we show that an optimal choice of M exists, and we discuss how this M may be estimated based on the data.

Clearly if for some pair (M, L), we find another pair (M', L') with $\eta(M', L') > \eta(M, L)$ but $C(M', L') \leq C(M, L)$, we should always use (M', L') rather than (M, L). It turns out

that there is in fact an optimal choice of M such that the parameter choice is not dominated by any others in this fashion. Define

$$M^* = \operatorname*{arg\,min}_{M\in\mathbb{N}} \left\{ -\frac{1}{\log(1-\gamma^M)}\left(Mp + p\log(p) + n\sum_{j,k}\gamma_{jk}^M\right)\right\}, \tag{13}$$

where it is implicitly assumed that the minimiser is unique. This will always be the case except for peculiar values of γ.

Proposition 3 *Let $L \in \mathbb{N}$. If $(M', L') \in \mathbb{N}^2$ has $\eta(M', L') \geq \eta(M^*, L)$, then also $C(M', L') \geq C(M^*, L)$ with the final inequality being strict if $M' \neq M^*$ and M^* is a unique minimiser.*

Thus there is a unique Pareto optimal M. Although the definition of M^* involves the moments of F_Γ, this can be estimated by sampling from $\{\gamma_{jk}\}$. We can then numerically optimise a plugin version of the objective to arrive at an approximately optimal M.

3. Interaction search on continuous data

In the previous section we demonstrated how the *xyz* algorithm can be used to efficiently solve the simplest form of interaction search (1) when both $\mathbf{X}$ and $\mathbf{Y}$ are binary. In this section we show how small modifications to the basic algorithm can allow it to do the same when $\mathbf{Y}$ is continuous, and also when $\mathbf{X}$ is continuous. We discuss the regression setting in Section 4.

3.1 Continuous Y and binary $\mathbf{X}$

We begin by considering the setting where $\mathbf{X} \in \{-1, 1\}^{n\times p}$, but where we now allow real-valued $\mathbf{Y} \in \mathbb{R}^n$. Without loss of generality, we will assume $\|\mathbf{Y}\|_1 = 1$. The approach we take is motivated by the observation that the inner product $\mathbf{Y}^T(\mathbf{X}_j \circ \mathbf{X}_k)$ can be interpreted as a weighted inner product of $\mathbf{X}_j \circ \mathbf{X}_k$ with the sign pattern of $\mathbf{Y}$, using weights $w_i = |Y_i|$.

With this in mind, we modify *xyz* in the following way. We set $\mathbf{Z}$ to be $Z_{ij} = \operatorname{sgn}(Y_i)X_{ij}$. Let $i_1, \dots, i_M \in \{1, \dots, n\}$ be i.i.d. such that $\mathbb{P}(i_s = i) = w_i$. Forming the projection vector $\mathbf{R}$ using (6), we then find the probability of (j, k) being in the equal pairs set may be computed as follows.

$$\begin{aligned}
\{\mathbb{P}(\mathbf{R}^T\mathbf{X}_j = \mathbf{R}^T\mathbf{Z}_k)\}^{1/M} &= \mathbb{P}\left(X_{i_s j} = \operatorname{sgn}(Y_{i_s})X_{i_s k} \text{ for all } s = 1, \dots, M\right) \\
&= \mathbb{P}(X_{i_1 j} = \operatorname{sgn}(Y_{i_1})X_{i_1 k}) \qquad \text{as the } i_s \text{ are i.i.d.} \\
&= \sum_{i=1}^n \mathbb{P}(X_{i_1 j} = \operatorname{sgn}(Y_{i_1})X_{i_1 k} | i_1 = i)\mathbb{P}(i_1 = i) \\
&= \sum_{i=1}^n |Y_i| \mathbb{1}_{\{X_{ij} = \operatorname{sgn}(Y_i)X_{ik}\}} \\
&= \sum_{i:\operatorname{sgn}(Y_i) = X_{ij}X_{ik}} Y_i X_{ij} X_{ik} =: \tilde{\gamma}_{jk},
\end{aligned}$$

where $\mathbb{P}$ here is with respect to the randomness of $\mathbf{R}$ (and, equivalently, the random indices $i_1, \dots, i_M$) with $\mathbf{Y}$ and $\mathbf{X}$ considered fixed. The calculation above shows that the run time

bound of Theorem 2 continues to hold in the setting with continuous $\mathbf{Y}$ provided we replace the interaction strengths γ_{jk} with their continuous analogues $\tilde{\gamma}_{jk}$.

As a simple example, consider the model

$$Y_i = X_{i1}X_{i2} + \varepsilon_i,$$

with $\varepsilon_i \sim \mathcal{N}(0, \sigma^2)$ and $\mathbf{X}$ generated randomly having each entry drawn independently from $\{-1, 1\}$ each with probability $1/2$. Then for a non-interacting pair $j \neq 1, 2$ or $k \neq 1, 2$, we have $\tilde{\gamma}_{jk} \approx 0.5$. For the pair $(1, 2)$ we calculate an interaction strength of

$$\begin{aligned}\tilde{\gamma}_{12} &= \mathbb{P}(\operatorname{sgn}(Y_{i_1}) = X_{i_1 1}X_{i_1 2}) = \mathbb{P}(\operatorname{sgn}(X_{i_1 1}X_{i_1 2} + \varepsilon_i) = X_{i_1 1}X_{i_1 2}) \\ &= \mathbb{P}(|\varepsilon_i| < 1) + \frac{1}{2}\mathbb{P}(|\varepsilon_i| > 1) = \frac{1}{2}(1 + \mathbb{P}(|\varepsilon_i| < 1)).\end{aligned}$$

Note that here that probability is over the randomness in the noise ε_i. A quick simulation gives the following table:

σ^2	0.1	0.25	0.5	1	2	5
$\tilde{\gamma}_{12}$	0.99	0.98	0.92	0.84	0.76	0.67

Using Theorem 2 and the above table we can estimate the computational complexity needed to discover the pair $(1, 2)$ given a value of σ^2.

3.2 Continuous Y and continuous X

The previous section demonstrated how resampling with non-uniform weights transforms a setup with continuous $\mathbf{Y}$ into one with binary response. If both $\mathbf{X}$ and $\mathbf{Y}$ are continuous, we continue to use the previous strategy to deal with the continuous response. For the matrix $\mathbf{X}$ with continuous predictor values we cannot use weighted resampling as the weights would depend on the interaction pair of interest. In the following we examine the effects of transformations of $\mathbf{X}$ to a binary data matrix $\tilde{\mathbf{X}}$. To allow for randomized mappings, we define the transformations via a function $g : \mathbb{R} \mapsto [0, 1]$ as

$$\mathbb{P}(\tilde{X}_{ij} = 1) = g(X_{ij}) \text{ and } 1 - \mathbb{P}(\tilde{X}_{ij} = -1) = 1 - g(X_{ij}),$$

where the transformation is always applied independently for each entry of the predictor matrix and for each subsample.

The following gives the probability of Y_i agreeing in sign with $\tilde{X}_{ij}\tilde{X}_{ik}$ when i is sampled with probability proportional to $|Y_i|$.

Proposition 4 *Given the transform $\mathbb{P}(\tilde{X}_{ij} = 1) = g(X_{ij})$ and sampling an index i_s according to $\mathbb{P}(i_s = i) = Y_i/\|\mathbf{Y}\|_1$, then the probability of a match is*

$$\mathbb{P}(\operatorname{sgn}(Y_{i_s}) = \tilde{X}_{i_s j}\tilde{X}_{i_s k}) = \frac{1}{2} + \frac{1}{2\|\mathbf{Y}\|_1}\sum_{i=1}^{n} Y_i(1 - 2g(X_{ij}))(1 - 2g(X_{ik})). \tag{14}$$

Thus we may define a continuous analogue of the interaction strength γ_{jk} based on the transform given by g as

$$\gamma^g_{jk} = \frac{1}{2} + \frac{1}{2\|\mathbf{Y}\|_1}\sum_{i=1}^{n} Y_i(1 - 2g(X_{ij}))(1 - 2g(X_{ik})).$$

These quantities may be substituted into Theorem 2 to yield the following upper bound on expected run time when using *xyz* on transformed data.

Corollary 5 *Let F_{Γ^g} be the distribution function corresponding to a random draw from the set of interaction strengths $\{\gamma^g_{jk}\}_{j,k\in\{1,\dots,p\}}$. Given an interaction strength threshold γ, let $1-F_{\Gamma^g}(\gamma) = c_1/p$. Define $\gamma_0 = p^{-1/M}$ and let c_2 be defined by $1-F_\Gamma(\gamma_0) = c_2 p^{\log(\gamma)/\log(\gamma_0)-1}$. We assume that $\gamma_0 < \gamma$. Finally given a discovery threshold $\eta' \in [1/2, 1)$ let L be the minimal L' such that $\eta(M, L') \geq \eta'$. Ignoring constant factors we have*

$$C(M, L) \leq \log\{1/(1-\eta')\}(1 + c_1 + c_2)[\{1 + 1/\log(\gamma_0^{-1})\}\log(p) + n]p^{1+\log(\gamma)/\log(\gamma_0)}.$$

The expected computational costs depends critically on the distribution of the interaction strengths F_{Γ^g}. To gain a better understanding of what impact different transformations have on this distribution and subsequently on run time we will study the following simple model for $(\mathbf{Y}, \mathbf{X}) \in \mathbb{R}^n \times \mathbb{R}^{n\times p}$:

$$Y_i = X_{ij^*}X_{ik^*} + \varepsilon_i, \qquad i = 1, \dots, n, \tag{15}$$

where the ε_i are independent and have identical sub-exponential distributions symmetric about 0 and the rows of $\mathbf{X}$ are i.i.d. We now introduce two practically useful choices of g and study their properties in the context of model (15).

The unbiased transform

A natural choice for the transform g is one that satisfies the unbiasedness requirement:

$$\mathbb{E}(\tilde{X}_{ij}) = X_{ij}. \tag{16}$$

It turns out that this requirement uniquely defines the transform, which we refer to as the *unbiased transform*.

Proposition 6 *Let $X_{ij} \in [-1, 1]$. If its transformed version $\tilde{X}_{ij}$ satisfies* (16)*, then g takes the form*

$$\mathbb{P}(\tilde{X}_{ij} = 1) = g(X_{ij}) = \frac{X_{ij} + 1}{2}.$$

Furthermore the interaction strength in (14) *is given by*

$$\mathbb{P}(\operatorname{sgn}(Y_{i_s}) = \tilde{X}_{i_s j}\tilde{X}_{i_s k}) = \gamma^g_{jk} = \frac{1}{2} + \frac{1}{2\|\mathbf{Y}\|_1}\sum_{i=1}^{n} Y_i X_{ij} X_{ik}.$$

Proposition 6 shows that γ^g_{jk} is a monotone function of the inner product $\sum_{i=1}^n Y_i X_{ij} X_{ik}$.

We remark that if the entries of $\mathbf{X}$ do not lie in $[-1, 1]$, we may divide each entry in the ith row by $\nu_i := \max_j |X_{ij}|$, and multiply Y_i by ν_i^2, for each i. Proposition 6 will then hold for the scaled versions of $\mathbf{Y}$ and $\mathbf{X}$. In order to describe the performance of the unbiased transform when applied to data generated by the model (15), we define the following quantities:

$$\mathbb{E}(|X_{ij^*}X_{ik^*}|) = m_1, \;\; \mathbb{E}(X^2_{ij^*}X^2_{ik^*}) = m_2 \text{ and } \mathbb{E}(|\varepsilon_i|) = m_\varepsilon.$$

We consider an asymptotic regime where $p = p_n$ may diverge as n tends to infinity, though we suppress this in the notation. We introduce the following assumptions.

(B1) $m_2(r_u-1) \leq \mathbb{E}(X_{ij^*}X_{ik*}X_{ij}X_{ik}) \leq m_2(1-r_u)$, for $r_u \in (0,1)$ and $\forall\, j,k \in \{1,\ldots,p\}^2$.

(B2) The noise level satisfies the bound

$$\frac{1}{1-r_u} > 1 + \frac{m_\epsilon}{m_1}.$$

(B3) Let p be such that be such that

$$\frac{\log(n)\log(p)}{n} \overset{n\to\infty}{\to} 0.$$

(B1) ensures non-interactions are not too strongly correlated to the actual interaction pair (j^*, k^*). Note that (B3) allows for high-dimensional settings with $p \gg n$.

Theorem 7 *Assume all entries of* $\mathbf{X}$ *have mean zero and lie in* $[-1,1]$ *almost surely. Further assume (B1)–(B3) hold. When* M *and* L *are as in Corollary 5 and the unbiased transform is used, we have*

$$C(M,L) = o_{\mathbb{P}}\Big(np^{1+\delta+\frac{\log(1/2+m_2/2(m_1+m_\varepsilon))}{\log(1/2+m_2(1-r_u)/2m_1)}}\Big)$$

for any $\delta > 0$. *Here* $\mathbb{P}$ *is with respect to the randomness in* $\mathbf{X}$ *and* $\boldsymbol{\varepsilon}$.

Though the run time above can often improve significantly on the worst-case quadratic run time, observe that unlike in the binary case, if there is no noise and $Y_i = X_{ij^*}X_{ik^*}$, we do not necessarily have a run time close to linear in p. For example, when $X_{ij} \overset{iid}{\sim} \text{Uniform}(-1,1)$, the interaction strength of the true interaction can be shown to equal to

$$\gamma^g_{j^*k^*} = \frac{1}{2} + \frac{\sum_{i=1}^n Y_i X_{ij^*} X_{ik^*}}{2\|\mathbf{Y}\|_1} = \frac{1}{2} + \frac{\|\mathbf{Y}\|_2^2}{2\|\mathbf{Y}\|_1} \overset{n\to\infty}{=} \frac{13}{18}.$$

Substituting this into the run time given by Theorem 2, this would result in an expected complexity of roughly $\mathcal{O}(np^{1.47})$; this is still substantially smaller than a quadratic run time, but raises the question as to whether such a loss in speed is avoidable.

Additionally, if $\mathbf{X}$ has several outlying entries, normalising the design matrix by scaling by the row-wise maximums can shrink $\gamma^g_{j^*k^*}$ towards $1/2$. To limit the impact of this normalisation, we can first cap the entries of $\mathbf{X}$ so their absolute value is bounded by some $c > 0$. Though the resulting interaction strength will not have the form given in Proposition 6, it may better discriminate between interactions of interest and noise.

Capping with $c = 1$ is closely related to applying the sign transform, which we study next.

The sign transform

We now consider the *sign transform* given by $\tilde{X}_{ij} = \text{sgn}(X_{ij})$; if there are zero cases we use a coin toss to map them to $\{-1,1\}$. For the sign transform we have $g(X_{ij}) = 2\,\text{sgn}(X_{ij}) - 1$ and so the interaction strength is given as:

$$\mathbb{P}(\text{sgn}(Y_{i_s}) = \tilde{X}_{i_s j}\tilde{X}_{i_s k}) = \gamma^g_{jk} = \frac{1}{2} + \frac{1}{2\|\mathbf{Y}\|_1}\sum_{i=1}^n Y_i \text{sgn}(X_{ij})\text{sgn}(X_{ik}).$$

The sign transform recovers the close to linear run time achieved in the binary case when a interaction is perfect as now if $Y_i = X_{ij^*}X_{ik^*}$, we have $\gamma^g_{j^*k^*} = 1$. Also the sign transform is not adversely affected by the presence of outlying entries in $\mathbf{X}$, and for our theory we can relax the assumption that the entries of $\mathbf{X}$ are in $[-1,1]$ to here only requiring that they have a subexponential distribution. To facilitate comparison with the unbiased transform, we impose assumptions analogous to (B1)–(B3):

(C1) $r_s/2 \leq \mathbb{P}(X_{ij} < 0 | X_{ik}, X_{ij^*}, X_{ik^*}) \leq 1 - r_s/2$, for $r_s \in (0,1)$ and $\forall\, j,k \in \{1,...,p\}^2$.

(C2) The noise level satisfies

$$\frac{1}{1-r_s} > 1 + \frac{m_\epsilon}{m_1}.$$

(C3) Let p be such that

$$\frac{\log(p)^5}{n} \overset{n\to\infty}{\to} 0.$$

Theorem 8 *Suppose that each entry of* $\mathbf{X}$ *has a mean-zero subexponential distribution. Further assume (C1)–(C3). When* M *and* L *are as in Corollary 5 and the sign transform is used, we have*

$$C(M,L) = o_{\mathbb{P}}\Big(np^{1+\delta+\frac{\log(1/2+m_1/2(m_1+m_\varepsilon))}{\log(1-r_s)}}\Big)$$

for any $\delta > 0$. *Here* $\mathbb{P}$ *is with respect to the randomness in* $\mathbf{X}$ *and* ε.

Both transforms yield a run time of the form $o_{\mathbb{P}}(np^\alpha)$. Comparing the exponents α we have:

unbiased transform:

$$\alpha_u = 1 + \frac{\log(1/2 + m_2/2(m_1+m_\varepsilon))}{\log(1/2 + m_2(1-r_u)/2m_1)}$$

sign transform:

$$\alpha_s = 1 + \frac{\log(1/2 + m_1/2(m_1+m_\varepsilon))}{\log(1/2 + (1-r_s)/2)}.$$

For bounded data $\mathbf{X} \in [-1,1]^{n\times p}$ and when $m_\varepsilon \ll m_1$, we have $m_1/2(m_1+m_\varepsilon) \approx 1/2$ so that $\alpha_s = 1$ whereas $\alpha_u > 1$. Hence in case of a strong signal the sign transform can give a smaller run time than the unbiased transform.

4. Application to Lasso regression

Thus far we have only considered the simple version of the interaction search problem (1) involving finding pairs of variables whose interaction has a large dot product with $\mathbf{Y}$. In this section we show how any solution to this, and in particular the *xyz* algorithm, may be used to fit the Lasso (Tibshirani, 1996) to all main effects and pairwise interactions in an efficient fashion.

Given a response $\mathbf{Y} \in \mathbb{R}^n$ and a matrix of predictors $\mathbf{X} \in \mathbb{R}^{n\times p}$, let $\mathbf{W} \in \mathbb{R}^{n\times p(p+1)/2}$ be the matrix of interactions defined by

$$\mathbf{W} = (\mathbf{X}_1 \circ \mathbf{X}_1, \mathbf{X}_1 \circ \mathbf{X}_2, \cdots, \mathbf{X}_1 \circ \mathbf{X}_p, \mathbf{X}_2 \circ \mathbf{X}_2, \mathbf{X}_2 \circ \mathbf{X}_3, \cdots, \mathbf{X}_p \circ \mathbf{X}_p).$$

We will assume that $\mathbf{Y}$ and the columns of $\mathbf{X}$ have been centred. Note that the centring of $\mathbf{X}$ means the $\mathbf{W}$ implicitly contains main effects terms. Let $\tilde{\mathbf{W}}$ be a version of $\mathbf{W}$ with centred columns. Consider the Lasso objective function

$$(\hat{\boldsymbol{\beta}}, \hat{\boldsymbol{\theta}}) = \underset{\boldsymbol{\beta}\in\mathbb{R}^p, \boldsymbol{\theta}\in\mathbb{R}^{p(p+1)/2}}{\operatorname{argmin}} \left\{ \frac{1}{2n} \|\mathbf{Y} - \mathbf{X}\boldsymbol{\beta} - \tilde{\mathbf{W}}\boldsymbol{\theta}\|_2^2 + \lambda(\|\boldsymbol{\beta}\|_1 + \|\boldsymbol{\theta}\|_1) \right\}. \tag{17}$$

Note that since the entire design matrix in the above is column-centred, any intercept term would always be zero.

In order to avoid a cost of $\mathcal{O}(np^2)$ it is necessary to avoid explicitly computing $\mathbf{W}$. To describe our approach, we first review in Algorithm 3 the active set strategy employed by several of the fastest Lasso solvers such as `glmnet` (Friedman et al., 2010). We use the notation that for a matrix $\mathbf{M}$ and a set of column indices H, $\mathbf{M}_H$ is the submatrix of $\mathbf{M}$ formed from those columns indexed by H. Similarly for a vector $\mathbf{v}$ and component indices H, $\mathbf{v}_H$ is the subvector of $\mathbf{v}$ formed from the components of $\mathbf{v}$ indexed by H.

Algorithm 3 Active set strategy for Lasso computation

Input: $\mathbf{X}$, $\mathbf{Y}$ and grid of λ values $\lambda_1 > \cdots > \lambda_L$.
Output: Lasso solutions $\hat{\boldsymbol{\beta}}_{\lambda_l}$ and $\hat{\boldsymbol{\theta}}_{\lambda_l}$ at each λ on the grid.

1: **for** $l \in \{1, \ldots, L\}$ **do**
2: If $l = 1$ set $A, B = \emptyset$; otherwise set $A = \{k : \hat{\beta}_{\lambda_{l-1},k} \neq 0\}$ and $B = \{k : \hat{\theta}_{\lambda_{l-1},k} \neq 0\}$.
3: Compute the Lasso solution $(\hat{\boldsymbol{\beta}}, \hat{\boldsymbol{\theta}})$ when $\lambda = \lambda_l$ under the additional constraint that $\hat{\boldsymbol{\beta}}_{A^c} = 0$ and $\hat{\boldsymbol{\theta}}_{B^c} = 0$.
4: Let $U = \{k : |\mathbf{X}_k^T(\mathbf{Y} - \mathbf{X}_A\hat{\boldsymbol{\beta}}_A - \tilde{\mathbf{W}}_B\hat{\boldsymbol{\theta}}_B)|/n > \lambda_l\}$ and $V = \{k : |\tilde{\mathbf{W}}_k^T(\mathbf{Y} - \mathbf{X}_A\hat{\boldsymbol{\beta}}_A - \tilde{\mathbf{W}}_B\hat{\boldsymbol{\theta}}_B)|/n > \lambda_l\}$ be the set of coordinates that violate the KKT conditions when $(\hat{\boldsymbol{\beta}}, \hat{\boldsymbol{\theta}})$ is taken as a candidate solution.
5: If U and V are empty, we set $\hat{\boldsymbol{\beta}}_{\lambda_l} = \hat{\boldsymbol{\beta}}$, $\hat{\boldsymbol{\theta}}_{\lambda_l} = \hat{\boldsymbol{\theta}}$. Else we update $A = A \cup U$ and $B = B \cup V$ and return to line 3.
6: **end for**

As the sets A and B would be small, computation of the Lasso solution in line 3 is not too expensive. Instead line 4, which performs a check of the Karush–Kuhn–Tucker (KKT) conditions involving dot products of all interaction terms and the residuals, is the computational bottleneck: a naive approach would incur a cost of $\mathcal{O}(np^2)$ at this stage.

There is however a clear similarity between the KKT conditions check for the interactions and the simple interaction search problem (1). Indeed the computation of V, the set containing all interactions that violate the KKT conditions, may be expressed in the following way:

$$\text{Keep all pairs } (j,k) \text{ for which } |(\mathbf{Y} - \mathbf{X}_A\hat{\boldsymbol{\beta}}_A - \tilde{\mathbf{W}}_B\hat{\boldsymbol{\theta}}_B)^T(\mathbf{X}_j \circ \mathbf{X}_k)/n| > \lambda_l. \tag{18}$$

Note that since $\mathbf{Y} - \mathbf{X}_A\hat{\boldsymbol{\beta}}_A - \tilde{\mathbf{W}}_B\hat{\boldsymbol{\theta}}_B$ is necessarily centered, there is no need to center the interactions in (18). In order to solve (18) we can use the *xyz* algorithm, setting γ in Algorithm 2 to λ_l and $\mathbf{Y}$ to each of $\pm(\mathbf{Y} - \mathbf{X}_A\hat{\boldsymbol{\beta}}_A - \tilde{\mathbf{W}}_B\hat{\boldsymbol{\theta}}_B)$ in turn.

Precisely the same strategy of performing KKT condition checks using *xyz* can be used to accelerate computation for interaction modeling for a variety of variants of the Lasso such

as the elastic net (Zou and Hastie, 2005) and ℓ_1-penalised generalised linear models. Note also that it is straightforward to use a different scaling for the penalty on the interaction coefficients in (17), which may be helpful in practice.

5. Experiments

To test the algorithm and theory developed in the previous sections, we run a sequence of experiments on real and simulated data.

5.1 Comparison of minimal subsampling and dense projections

One of the surprising outcomes of our theoretical analysis is extent of the suboptimality of Gaussian random projections, which whilst they suffice for the conclusion of the Johnson–Lindenstrauss Lemma, are not well-suited for our purposes here (see Theorem 1). We can explicitly compute the probability of retaining an interaction of strength γ in E_1 for both dense Gaussian projections ξ_{Gauss} and minimal subsampling $\xi_{minimal}$ given an equal computational budget. We consider various values of p ranging from 10 up to 10^6 and we fix $n = 1000$. We set $L = 1$ and select other parameters of the algorithms to ensure the average size of E_1 is equal to p in the setting when all interaction strengths are equal to 0.5. Specifically we make the following choices.

- ξ_{Gauss}: the close pairs threshold $\tau \geq 0$ is the $1/p$–quantile of the distribution of $|W|$ when $W \sim N(0, 0.5n)$.
- $\xi_{minimal}$: the subsample size $M = \lceil \log(1/p)/\log(0.5) \rceil$.

We then plot the probability η of discovering an interaction of strength γ, as a function of γ for different values of p (Figure 3). For $\xi_{minimal}$, η is given in equation (11). For ξ_{Gauss}, η is the $1/p$–quantile of the distribution of $|W|$ when $W \sim N(0, n(1-\gamma))$.

5.2 Scaling

In this experiment we test how the *xyz* algorithm scales on a simple test example as we increase the dimension p. We generate data $\mathbf{X} \in \mathbb{R}^{n\times p}$ with each entry sampled independently uniformly from $\{-1, 1\}$. We do this for different values of p, ranging from 1000 to 30 000: this way for the largest p considered there are more than 400 million possible interactions. Then for each $\mathbf{X}$ we construct response vectors $\mathbf{Y}$ such that only the pair $(1, 2)$ is a strong interaction with an interaction strength taking values in $\{0.7, 0.8, 0.9\}$. Through this construction, if n is large enough, all the pairs except $(1, 2)$ will have an interaction strength around 0.5, and very few will have one above 0.55. We thus set M so that $\gamma_0 = p^{-1/M} \approx 0.55$. Since the only strong interaction is $(1, 2)$, we set $\gamma = \gamma_{12}$ Each data set configuration determined by p and γ_{12} is simulated 300 times and we measure the time it takes *xyz* to find the pair $(1, 2)$. In Figure 3 we plot the average run time against the dimension p with the different choices for γ_{12} highlighted in different colours.

Theorem 2 indicates that the run time should be of the order $np^{1+\log(\gamma)/\log(\gamma_0)}$. We see that the experimental results here are in close agreement with this prediction.

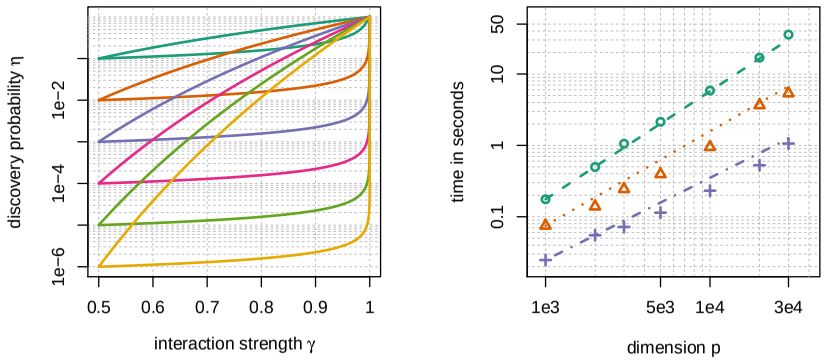

Figure 3: Left panel: Discovery probability as a function of γ for different values of $p \in \{10^1, \ldots, 10^6\}$ (colours decreasing in p from yellow $p = 10^6$ to green $p = 10$). The lower lines correspond to the dense Gaussian projections, the upper lines to minimal subsampling. It can be seen that the discovery probability for minimal subsampling is much higher (up to factor 10^4) than for Gaussian projections. Right panel: Time to discover the interaction pair as a function of the data set dimension p. Lines correspond to the theoretical prediction (with the intercept chosen based on the data points) and symbols give the actual measured run time. Colour coding: green $\gamma = 0.7$, orange $\gamma = 0.8$ and purple $\gamma = 0.9$.

5.3 Run on SNP data

In the next experiment we compare the performance of *xyz* to its closest competitors on a real data set. For each method we measure the time it takes to discover strong interactions. We consider the LURIC data set (Winkelmann et al., 2001), which contains data of patients that were hospitalised for coronary angiography. We use a preprocessed version of the data set that is made up of $n = 859$ observations and 687 253 predictors. The data set is binary. The response $\mathbf{Y}$ indicates coronary disease (1 corresponding to affected and -1 healthy) and $\mathbf{X}$ contains Single Nucleotide Polymorphisms (SNPs) which are variations of base-pairs on DNA. The response vector $\mathbf{Y}$ is strongly unbalanced: there are 681 affected cases ($Y_i = 1$) and 178 unaffected ($Y_i = -1$).

To get a contrast of the performance of *xyz* we compare it to *epiq* (Arkin et al., 2014), another method for fast high-dimensional interaction search. In order for *epiq* to detect interactions it needs to assume the model

$$Y_i = \alpha_{j^*k^*} X_{ij^*} X_{ik^*} + \varepsilon_i, \tag{19}$$

where $\varepsilon_i \sim \mathcal{N}(0, \sigma^2)$. It then searches for interactions by considering the test statistics

$$T_{jk} = (\mathbf{R}^T(\mathbf{Y} \circ \mathbf{X}_j))(\mathbf{R}^T\mathbf{X}_k)$$

where $\mathbf{R} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$. These are used to try to find the pair (j^*, k^*), which is assumed to be the pair for which the inner product $\mathbf{Y}^T(\mathbf{X}_j \circ \mathbf{X}_k)$ is maximal. It is an easy calculation to show

that $\mathbb{E}(T_{jk}) = \mathbf{Y}^T(\mathbf{X}_j \circ \mathbf{X}_k)$. To maximise the inner product on the right, *epiq* considers pairs where T_{jk}^2 is large by looking at pairs where both $(\mathbf{R}^T(\mathbf{Y} \circ \mathbf{X}_j))^2$ and $(\mathbf{R}^T\mathbf{X}_k)^2$ are large. While the approach of *epiq* is somewhat related to *xyz*, there are no bounds available for the time it takes to find strong interactions.

We also compare both methods to a naive approach where we subsample a fixed number of interactions uniformly at random, and retain the strongest one. We refer to this as *naive search*.

At fixed time intervals we check for the strongest interaction found so far with all three methods. We plot the interaction strength as a function of the computational time (Figure 4). All three methods eventually discover interactions of very similar strength and it would be a hasty judgement to say whether one significantly outperforms the others. *xyz* nevertheless discovers the strongest interactions on average for a fixed run time compared to the other two approaches. To get a clearer picture we run two additional experiments on a slight modification of the LURIC data set. We implant artificial interactions where we set the strength to $\gamma_{12} = 0.8$ and another example with $\gamma_{12} = 0.9$. In these two experiments *xyz* clearly outperforms all other methods considered (Figure 4; panels 3 and 4). Besides *xyz* being the fastest at interaction search, it also offers a probabilistic guarantee that there are no strong interactions left in the data. This guarantee comes out of Theorem 2. To run *xyz* we have to calculate the optimal subsample size (13) for use of minimal subsampling:

$$M^* = \operatorname*{arg\,min}_{M \in \mathbb{N}} \left\{ -\frac{1}{\log(1 - \gamma^M)} \left(Mp + p\log(p) + n \sum_{j,k} \gamma_{jk}^M \right) \right\} = 21.$$

The sum in this optimisation can be approximated by uniformly sampling over pairs. Assume we have an interaction pair (j^*, k^*) with interaction strength $\gamma_{j^*k^*} = 0.85$ and say the rest of the pairs (j, k) have an interaction strength of no more than $\gamma_{jk} \leq 0.55$. The probability that we discover this pair in one run ($L = 1$) of the *xyz* algorithm is $\gamma_{j^*k^*}^{21}$. Therefore the probability of missing this pair after $L = 100$ runs is given by

$$(1 - \gamma_{j^*k^*}^{21})^L \approx 0.03.$$

Note that the number of possible interactions is $p(p-1)/2 \approx 10^{11}$. The whole search took 280 seconds. Naive search offers a similar guarantee, however it is extremely weak. The probability of not discovering the pair after drawing pL samples (with $L = 100$) is bounded by $[1 - 2/\{p(p-1)\}]^{Lp} \approx 0.999$. If we consider the run time guarantee from Theorem 2, the dominating term in the complexity of *xyz* in terms of p is

$$p^{1 + \frac{\log(0.85)}{\log(0.55)}} \approx p^{1.27}.$$

This may be compared to the expected run time of order p^2 for naive search, which means that *xyz* is about 30 000 times faster than naive search (when $p = 687\,253$). In the empirical comparison this factor is around 20 000.

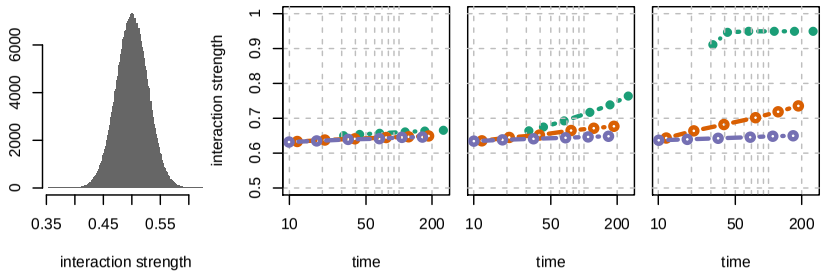

Figure 4: Left: Histogram of interaction strength of 10^6 interaction pairs, sampled at random from the more than 10^{11} existing pairs from the LURIC data set. The right three panels show the interaction strength of the discovered pairs as a function of the computation time for *xyz* (green), *epiq* (orange) and naive search (purple). The first panel gives results on the the original LURIC data set, and the second and third (rightmost) panels show results with an implanted interaction with strengths $\gamma_{12} = 0.8$ and $\gamma_{12} = 0.95$ respectively. It can be clearly seen that *xyz* outperforms its competitors by a large margin.

5.4 Regression on artificial data

In this section we demonstrate the capabilities of *xyz* in interaction search for continuous data as explained in Section 3. We simulate two different models of the form (15):

$$Y_i = \mu + \sum_{j=1}^{p} X_{ij}\beta_j + \sum_{k=1}^{p}\sum_{j=1}^{k-1} X_{ij}X_{ik}\theta_{jk} + \varepsilon_i.$$

We consider three settings. For all three settings we have $n = 1000$. We let $p \in \{250, 500, 750, 1000\}$. Each row of $\mathbf{X}$ is generated i.i.d. as $\mathcal{N}(\mathbf{0}, \mathbf{\Sigma})$. The magnitudes of both the main and interaction effects are chosen uniformly from the interval $[2, 6]$ (20 main effects and 10 interaction effects) and we set $\varepsilon_i \sim \mathcal{N}(0, 1)$. The three settings we consider are as follows.

1. $\mathbf{\Sigma} = \mathbf{I} \in \mathbb{R}^{p\times p}$, we generate a hierarchical model: $\theta_{jk} \neq 0 \Rightarrow \beta_j \neq 0$ and $\beta_k \neq 0$. We first sample the main effects and then pick interaction effects uniformly from the pairs of main effects.

2. $\mathbf{\Sigma} = \mathbf{I} \in \mathbb{R}^{p\times p}$, we generate a strictly non-hierarchical model: $\theta_{jk} \neq 0 \Rightarrow \beta_j = 0$ and $\beta_k = 0$. We first sample the main effects and then pick interaction effects uniformly from all pairs excluding main effects as coordinates.

3. We repeat the setting 2 with a data set that contains strong correlations. We create a dependence structure in $\mathbf{X}$, by first generating a DAG with on average 10 edges per node. Each node is sampled so that it is a linear function of its parents plus some independent centred Gaussian noise, with a variance of 10% the variance coming from the direct parents. The resulting correlation matrix then unveils for each variable $\mathbf{X}_j$ a substantial number of variables strongly correlated to $\mathbf{X}_j$ (There is usually around 10 variables with a correlation of above 0.9). Such a correlation structure will make it easier to detect pairs of variables whose product can serve as strong predictor of $\mathbf{Y}$, even though it has not been included in the construction of $\mathbf{Y}$.

We run three different procedures to estimate the main and interaction effects.

- **Two-stage Lasso:** We fit the Lasso to the data, and then run the Lasso once more on an augmented design matrix containing interactions between all selected main effects. Complexity analysis of the Least Angle Regression (LARS) algorithm (Efron et al., 2004) suggests the computational cost would be $\mathcal{O}(np\min(n, p))$, making the procedure very efficient. However, as the results show, it struggles in situations such as that given by model 2, where a main effects regression will fail to select variables involved in strong interactions.

- **Lasso with all interactions:** Building the full interaction matrix and computing the standard Lasso on this augmented data matrix. Analysis of the LARS algorithm would suggest the computational complexity would be in the order $\mathcal{O}(np^2\min(n, p^2))$. Nevertheless, for small p, this approach is feasible.

- **xyz:** This is Algorithm 3; we set the parameter L to be $\sqrt{p}$ in order to target the strong interactions.

The experiment (seen in Figure 5) shows that *xyz* enjoys the favourable properties of both its competitors: it is as fast as the two-stage Lasso that gives an almost linear run time in p, and it is about as accurate as the estimator calculated from screening all pairs (brute-force).

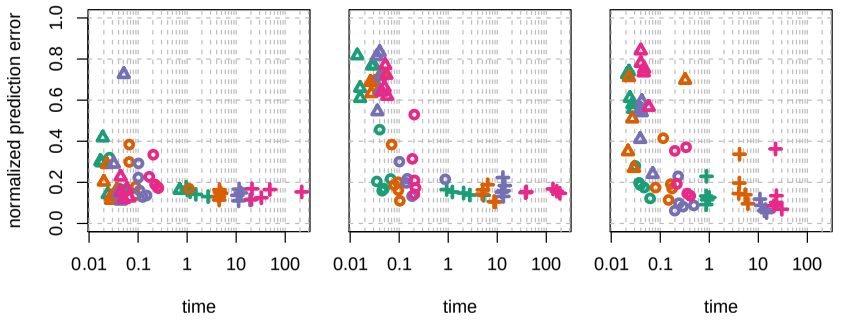

Figure 5: Normalised ℓ_2^2 prediction error as a function of time in seconds. Triangle: Two-stage Lasso. Circle: *xyz*-regression. Cross: Brute-force. The different colours correspond to different values of p: green $p = 250$, orange $p = 500$, purple $p = 750$ and pink $p = 1000$. The left panel shows the results on setting 1, center panel shows setting 2 and right panel setting 3.

5.5 Regression on real data

Here we run *xyz* regression on continuous real data sets where the ground truth is unknown. On each data set we pick at random $p = 2000$ variables and run *xyz* and the Lasso implemented in `glmnet` with all interactions included. We subsample an increasing number of variables to vary the difficulty of the regression problem. For each sample we measure the run time and the normalized out of sample squared ℓ_2^2 error:

$$\frac{\|\mathbf{Y}_{\text{test}} - \mathbf{X}_{\text{test}}\hat{\boldsymbol{\beta}} - \tilde{\mathbf{W}}_{\text{test}}\hat{\boldsymbol{\theta}}\|_2^2}{\|\mathbf{Y}_{\text{test}}\|_2^2}.$$

Experiments are run on the following three different data sets:

- **Riboflavin:** The Riboflavin production data set (Bühlmann et al., 2014) contains $n = 71$ samples and $p = 4088$ predictors (gene-expressions). The response $\mathbf{Y}$ and the design $\mathbf{X}$ are both continuous.
- **Kemmeren:** The Kemmeren (Kemmeren and et al., 2014) data set records knock-outs of $p = 6170$ genes. The data $\mathbf{X}$ is continuous. We sample $\mathbf{Y}$ randomly from the genes not present in the subsample taken from $\mathbf{X}$.
- **Climate:** The climate data set from the CNRM model from the CMIP5 model ensemble (Knutti et al., 2013) simulates the temperature of points on the northern hemisphere which is recorded in $\mathbf{X}$. The response $\mathbf{Y}$ simulates the temperature on a random position on the southern hemisphere. The data contains $n = 231$ observations.

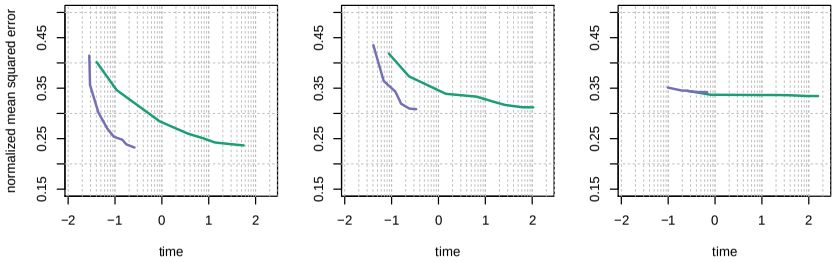

Figure 6: From left to right column the experiments correspond to Riboflavin, Kemmeren and Climate. The y-axis depicts the normalized squared error and the x-axis records the run time in seconds on the $\log_{10}$ scale. It can be seen that *xyz* (purple) offers clear computational advantages while giving similar level of prediction error to the Lasso fitted to all interactions as implemented in `glmnet` (green).

For each experiment we fix the number of runs L to $\sqrt{p}$ so the run time of *xyz* is $\mathcal{O}(np^{1.5})$. The experiments show that the *xyz* algorithm has a similar prediction performance to the Lasso applied to all interactions as implemented in `glmnet`. However *xyz* is around 100 times faster for $p = 2000$. The results of all 6 experiments can be seen in Figure 6.

6. Discussion

In this work we exploited a relationship between closest pairs of point problems and interaction search. By solving the former problem using random projections to project points down to a one-dimensional space and then sorting the resulting projected points, we were able to produce an algorithm for interaction search that enjoys a run time that is sub quadratic under mild assumptions and when used to search for very strong interactions can be almost linear. Though we have looked at interaction search in this paper, the basic engine for computing the large inner products between collections of vectors may have other interesting applications, for example in large-scale clustering problems. We hope to study such applications in future work.

Table of frequently used notation

n, p	number of observations and number of variables
$\mathbf{X}, \mathbf{Y}$	predictor matrix and response vector
$\mathbf{X}_j$	jth variable / column of $\mathbf{X}$
$\boldsymbol{\beta}, \boldsymbol{\theta}$	coefficients of main effects and interaction effects
γ_{jk}	interaction strength of the pair (j, k)
G	distribution of projection
M	subsample size
$\mathbf{R}$	projection vector
L	number of projections
τ, γ	close pairs threshold and interaction strength threshold
Ξ	set of all configurations of the *xyz* algorithm, the elements of this set are denoted by ξ
η	probability that a given interaction is present in the output of the *xyz* algorithm
$\tilde{\mathbf{X}}$	binarized version of $\mathbf{X}$
$\mathbf{W}$	predictor matrix containing all possible interaction pairs

Appendix A

Here we include proofs that were omitted earlier.

Proof of Theorem 1

In the following, we fix the following notation for convenience:

$$\Psi = \Xi_{\text{minimal}}, \qquad \Psi(\eta) = \Xi_{\text{minimal}}(\eta),$$
$$\Xi = \Xi_{\text{subsample}}, \qquad \Xi(\eta) = \Xi_{\text{subsample}}(\eta).$$

Note that both $\Psi(\eta)$ and $\Xi(\eta)$ depend on F though this is suppressed in the notation. Also define $\Xi_{\text{all}} = \Xi \cup \Xi_{\text{dense}}$ and $\Xi_{\text{all}}(\eta) = \Xi(\eta) \cup \Xi_{\text{dense}}(\eta)$. We will reference the parameters levels contained in $\xi \in \Xi_{\text{all}}$ as ξ_L and ξ_τ. If $\xi \in \Xi$ then we will write ξ_M for the distribution of the subsample size M.

If we let V denote the complexity of the search for τ-close pairs, similarly to (10) we have that

$$T(\xi) = c_1 np + L(c_2 \mathbb{E}_\xi M p + \mathbb{E}_\xi V + c_3 n \mathbb{E}_\xi |E_1|), \tag{20}$$

where c_1, c_2, c_3 are constants. Suppose $\psi \in \Psi$ and $\xi \in \Xi$ have $\mathbb{E}_\xi |E_1| = \mathbb{E}_\psi |E_1|$. Then since searching for τ-close pairs is at least as computationally difficult as finding equal pairs we know that $\mathbb{E}_\xi V \geq \mathbb{E}_\psi V$.

Similarly for $\xi \in \Xi_{\text{dense}}$ we have

$$T(\xi) = c_1 np + L(c_2 np + \mathbb{E}_\xi V + c_3 n \mathbb{E}_\xi |E_1|). \tag{21}$$

For $\xi \in \Xi_{\text{all}}$, define

$$\alpha(\xi) = \mathbb{E}_\xi |E_1| / p^2, \qquad \beta(\xi) = \mathbb{P}_\xi((j^*, k^*) \in I_1)$$

where I_1 is the set of candidate interactions I when $L = 1$. Note that

$$\mathbb{P}_\xi((j^*, k^*) \in I) = 1 - \{1 - \beta(\xi)\}^{\xi_L}.$$

Thus any $\xi \in \Xi_{\text{all}}(\eta)$ with $T(\xi)$ minimal must have ξ_L as the smallest L such that $1 - \{1 - \beta(\xi)\}^{\xi_L} \geq \eta$, whence

$$\xi_L = \lceil \log(1 - \eta) / \log\{1 - \beta(\xi)\} \rceil. \tag{22}$$

Note that $\beta(\xi)$ does not depend on ξ_L, so the above equation completely determines the optimal choice of L once other parameters have been fixed. We will therefore henceforth assume that L has been chosen this way so that the discovery probability of all the algorithms is at least η.

The proofs of (8) and (9) are contained in Lemmas 12 and 13 respectively. The proof of (7) is more involved and proceeds by establishing a Neyman–Pearson type lemma (Lemmas 10 and 11) showing that given a constraint on the 'size' α that is sufficiently small, minimal subsampling enjoys maximal 'power' β. To complete the argument, we show that any sequence of algorithms with size α remaining constant as $p \to \infty$ cannot have a subquadratic complexity, whilst Lemma 12 attests that in contrast minimal subsampling does have subquadratic complexity under the assumptions of the theorem. Several auxiliary technical lemmas are collected in Section 6

Our proofs Lemmas 10 and 11 make use of the following bound on a quantity related to the ratio of the size to the power of minimal subsampling.

Lemma 9 *Suppose $\psi \in \Psi$ has distribution for M placing mass on M and $M + 1$. Under the assumptions of Theorem 1,*

$$\frac{\alpha(\psi)}{\gamma_1^M} \leq \frac{2}{1 - \rho} \frac{1}{M + 1}.$$

Proof We have

$$\frac{\alpha(\psi)}{\gamma_1^M} \leq \frac{1}{p^2} \sum_{j,k} (\gamma_{jk}/\gamma_1)^M \leq \frac{c_0}{p} + \sum_{i=0}^{n\gamma_1 - 1} \left(\frac{i}{n\gamma_1}\right)^M f_n(i/n).$$

Now the sum on the RHS is maximised over f_n obeying constraints (A1) and (A2) in the following way. If $\rho\gamma_1 n > \gamma_1 n - 1$ then f_n places all available mass on $\gamma_1 - 1/n$. Otherwise f_n should be as close to constant as possible on $\lceil \rho\gamma_1 n \rceil / n, \ldots, (\gamma_1 n - 1)/n$, and zero below $\lceil \rho\gamma_1 n \rceil / n$. In both cases it can be seen that

$$\sum_{i=0}^{n\gamma_1 - 1} \left(\frac{i}{n\gamma_1}\right)^M f_n(i/n) \leq \frac{2}{1 - \rho} \int_{(1+\rho)/2}^1 x^M dx \leq \frac{2}{1 - \rho} \frac{1}{M + 1}.$$

■

The following Neyman–Pearson-type lemma considers only non-randomised algorithms in Ξ. In Lemma 11 we extend this result to randomised algorithms.

Lemma 10 *Let Ξ_0 be the set of $\xi \in \Xi$ such that ξ_M places mass only on a single M, so the subsample size is not randomised. There exists an α_0 independent of n such that for all $\alpha' \leq \alpha_0$, we have*

$$\sup_{\psi \in \Psi : \alpha(\psi) \leq \alpha'} \beta(\psi) = \sup_{\xi \in \Xi_0 : \alpha(\xi) \leq \alpha'} \beta(\xi).$$

Moreover the suprema are achieved.

Proof Each $\xi \in \Xi_0$ is parametrised by its close pairs threshold τ and subsample size M. Given a $\xi \in \Xi_0$ with parameter values τ and M we compute $\alpha(\xi)$ as follows. Note that by replacing the threshold τ by $\tau/2$, we may assume that $\mathbf{X}$ and $\mathbf{Z}$ have entries in $\{-1/2, 1/2\}$. Thus $\mathbf{X}_j - \mathbf{Z}_k$ has components in $\{-1, 0, 1\}$. Let J_{jk} be the number of non-zero components of $(X_{i_m j} - Z_{i_m k})_{m=1}^M$. Then $J_{jk} \sim \mathrm{Binom}(M, 1 - \gamma_{jk})$. Thus

$$\mathbb{P}\Big(\Big| \sum_{m=1}^M D_m (X_{i_m j} - Z_{i_m k}) \Big| \leq \tau \Big) = \mathbb{P}(J_{jk} = 0) + \sum_{r=1}^M \mathbb{P}\Big(\Big| \sum_{m=1}^r D_m \Big| \leq \tau \Big) \mathbb{P}(J_{jk} = r),$$

noting that $D_m \stackrel{d}{=} -D_m$. By Lemma 14 we know there exists an $a > 0$ such that for all $\tau \leq a\sqrt{M}$ the RHS is bounded below by

$$\gamma_{jk}^M + \sum_{r=r_0}^M \frac{c_1 \tau}{\sqrt{r}} \binom{M}{r} \gamma_{jk}^{M-r} (1 - \gamma_{jk})^r \tag{23}$$

for M sufficiently large. Here the constants $a, c_1 > 0$ and $r_0 \in \mathbb{N}$ depend only on F.

Consider $\tau > a\sqrt{M}$. In this case, for $r \leq M$ sufficiently large we have by Lemma 14

$$\mathbb{P}\Big(\Big| \sum_{m=1}^r D_m \Big| \leq \tau \Big) \geq \mathbb{P}\Big(\Big| \sum_{m=1}^r D_m \Big| \leq a\sqrt{r} \Big) \geq c_1 a.$$

However then for M sufficiently large,

$$\mathbb{P}(J_{jk} = 0) + \sum_{r=1}^M \mathbb{P}\Big(\Big| \sum_{m=1}^r D_m \Big| \leq \tau \Big) \mathbb{P}(J_{jk} = r) \geq c_1 a/2,$$

so $\alpha(\xi) \geq c_1 a/2$. Note also that we must have $\alpha_0 \geq \alpha(\xi) \geq \gamma_l^M$, so $M \geq \log(\alpha_0)/\log(\gamma_l)$. Thus by choosing $0 < \alpha_0 < c_1 a/2$ sufficiently small, we can rule out $\tau > a\sqrt{M}$ and so we henceforth assume that $\tau \leq a\sqrt{M}$, and that M is sufficiently large such that (23) holds for all (j, k).

We have

$$\alpha(\xi) \geq \frac{1}{p^2} \sum_{j,k} \Big\{ \gamma_{jk}^M + \tau \sum_{r=r_0}^M \frac{c_1}{\sqrt{r}} \binom{M}{r} \gamma_{jk}^{M-r} (1 - \gamma_{jk})^r \Big\}. \tag{24}$$

Similarly we have

$$\beta(\xi) \leq \gamma_1^M + \tau \sum_{r=1}^M \frac{c_2}{\sqrt{r}} \binom{M}{r} \gamma_1^{M-r} (1 - \gamma_1)^r. \tag{25}$$

Now substituting the upper bound on τ implied by (24) into (25), we get

$$\beta(\xi) \leq \gamma_1^M + Q_M \Big(\alpha(\xi) - \frac{1}{p^2} \sum_{j,k} \gamma_{jk}^M \Big)$$

where

$$Q_M = \frac{c_2 \sum_{r=1}^M r^{-1/2} \binom{M}{r} \gamma_1^{M-r} (1 - \gamma_1)^r}{c_1 p^{-2} \sum_{j,k} \sum_{r=r_0} r^{-1/2} \binom{M}{r} \gamma_{jk}^{M-r} (1 - \gamma_{jk})^r}.$$

Now by Lemma 15, for M sufficiently large and some constant Q we have

$$Q_M \leq Q \frac{\sqrt{1 - \gamma_1}}{\sum_{j,k} \sqrt{1 - \gamma_{jk}}/p^2} \leq Q.$$

Thus

$$\beta(\xi) \leq \gamma_1^M + Q \Big(\alpha(\xi) - \frac{1}{p^2} \sum_{j,k} \gamma_{jk}^M \Big) \tag{26}$$

for all M sufficiently large. Now given α_0, let M_0 be such that

$$\frac{1}{p^2} \sum_{j,k} \gamma_{jk}^{M_0} \geq \alpha_0 \geq \frac{1}{p^2} \sum_{j,k} \gamma_{jk}^{M_0+1}.$$

Consider the minimal subsampling algorithm ψ that chooses subsample size as either M_0 or $M_0 + 1$ with probabilities b and $1 - b$ such that

$$\alpha(\psi) = \frac{1}{p^2} \sum_{j,k} \{ b\gamma_{jk}^{M_0} + (1 - b)\gamma_{jk}^{M_0+1} \} = \alpha_0.$$

Then we have $\beta(\psi) = b\gamma_1^{M_0} + (1 - b)\gamma_1^{M_0+1}$. Now suppose $\xi \in \Xi_0$ has $\alpha(\xi) \leq \alpha_0$. Then in particular $M \geq M_0 + 1$. We first examine the case where $M = M_0 + 1$. Then

$$\begin{aligned}
\frac{1}{\gamma_1^{M_0}} \{ \beta(\psi) - \beta(\xi) \} &\geq b + (1 - b)\gamma_1 - \gamma_1 - \frac{Q}{\gamma_1^{M_0}} \Big(\alpha_0 - \frac{1}{p^2} \sum_{j,k} \gamma_{j,k}^{M_0+1} \Big) \\
&= b + (1 - b)\gamma_1 - \gamma_1 - \frac{aQ}{\gamma_1^{M_0}} \frac{1}{p^2} \sum_{j,k} (\gamma_{j,k}^{M_0} - \gamma_{j,k}^{M_0+1}) \\
&\geq b \Big((1 - \gamma_u) - \frac{2Q}{1 - \rho} \frac{1}{M_0 + 1} \Big),
\end{aligned}$$

using Lemma 9 in the final line. Note this is non-negative for M_0 sufficiently large. When $M \geq M_0 + 2$ we instead have

$$\frac{\beta(\xi)}{\beta(\psi)} \leq \frac{\beta(\xi)}{\gamma_1^{M_0+1}} \leq \gamma_1 + \frac{2Q}{\gamma_1(1 - \rho)} \frac{1}{M_0 + 1} \leq \gamma_u + \frac{2Q}{\gamma_l(1 - \rho)} \frac{1}{M_0 + 1} < 1$$

for M_0 sufficiently large. Recall that by making α_0 sufficiently small, we can force M_0 to be arbitrarily large. Thus the result is proved. ■

Lemma 11 *There exists an α_0 independent of n such that for all $\alpha' \leq \alpha_0$, we have*

$$\sup_{\psi\in\Psi:\alpha(\psi)\leq\alpha'} \beta(\psi) = \sup_{\xi\in\Xi:\alpha(\xi)\leq\alpha'} \beta(\xi).$$

Moreover the suprema are achieved.

Proof With a slight abuse of notation, write $\xi(M', \tau')$ for the element of $\xi \in \Xi$ that fixes $M = M'$ and $\tau = \tau'$. Using the notation of Lemma 10, define function $f : [0, 1] \to [0, 1]$ by

$$f(\alpha') = \sup_{\xi\in\Xi_0:\,\alpha(\xi)\leq\alpha'} \beta(\xi).$$

Note that for $\xi \in \Xi$ we have

$$\beta(\xi) \leq \mathbb{E}_{M\sim\xi_M} f[\alpha\{\xi(M, \xi_\tau)\}]. \tag{27}$$

Now by Lemma 10 we know there exists α_0 (depending on F) such that on $[0, \alpha_0]$, f is the linear interpolation of points

$$\left(\frac{1}{p^2}\sum_{j,k} \gamma_{j,k}^M,\, \gamma_1^M\right)_{M=1}^{\infty}.$$

We claim that f is concave on $[0, \alpha_0]$. Indeed, it suffices to show that the slopes of the successive linear interpolants are decreasing in this region, or equivalently that their reciprocals are increasing. We have

$$\frac{1}{p^2}\sum_{j,k} \frac{\gamma_{jk}^{M+1} - \gamma_{jk}^M}{\gamma_1^{M+1} - \gamma_1^M} = \frac{1}{p^2}\sum_{j,k} \left(\frac{\gamma_{j,k}}{\gamma_1}\right)^M \frac{\gamma_{jk} - 1}{\gamma_1 - 1} \tag{28}$$

which increases as M decreases, thus proving the claim.

Note also that the RHS of (28) is at most $\alpha(\psi)/\{(1 - \gamma_u)\gamma_1^M\}$ when ψ has subsample size fixed at M. Thus by Lemma 9 we see the derivatives of the linear interpolants approach infinity as they get closer to the origin. This implies the existence of an $0 < \alpha_1 < \alpha_0$ such that $-\sup\big(\partial(-f)(\alpha_1)\big) \geq \{1 - f(\alpha_1)\}/(\alpha_0 - \alpha_1)$, where $\partial(-f)(\alpha_1)$ denotes the subdifferential of the function $-f$ at α_1. We may therefore invoke Lemma 16 to conclude that for ξ with $\alpha(\xi) \leq \alpha_1$

$$\mathbb{E}_{M\sim\xi_M} f[\alpha\{\xi(M, \xi_\tau)\}] \leq f[\mathbb{E}_{M\sim\xi_M}\alpha\{\xi(M, \xi_\tau)\}] = f(\alpha(\xi)) \leq f(\alpha_1) = \max_{\psi\in\Psi:\alpha(\psi)\leq\alpha_1} \beta(\psi).$$

Combining with (27) gives the result. ■

The next lemma establishes subquadratic complexity of minimal subsampling.

Lemma 12 *Under the assumptions of Theorem 1, we have* $\inf_{\psi\in\Psi(\eta)} T(\psi)/(np^2) \to 0$.

Proof Let $\psi \in \Psi$ be such that ψ_M places all mass on M. We have that $\beta(\psi) = \gamma_1^M$. Thus using the inequality $-x \leq \log(1 - x)$ for $x \in (0, 1)$, we have

$$\psi_L \leq -\gamma_1^{-M}\log(1 - \eta).$$

Lemma 9 gives an upper bound on $\psi_L\mathbb{E}_\psi E_1$. Note that $\mathbb{E}_\psi V = \mathcal{O}(p\log(p))$. Thus ignoring constant factors, we have

$$T(\psi)/(np^2) \leq \frac{M + \log(p)}{\gamma_1^M np} + \frac{1}{M + 1}.$$

Taking $M = \big\lfloor \log(1/\sqrt{p})/\log(\gamma_1)\big\rfloor$ then ensures $T(\psi)/(np^2) \to 0$. ■

Lemma 13 *Let $\xi \in \Xi_{dense}$. There exists $c > 0$ and $n_0 \in \mathbb{N}$ such that for all $n \geq n_0$,*

$$\inf_{\xi\in\Xi_{dense}} T(\xi)/(np^2) > c.$$

Proof Each $\xi \in \Xi_{\text{dense}}$ is parametrised by its close pairs threshold τ. Given a $\xi \in \Xi_{\text{dense}}(F)$ with close pairs threshold τ we compute $\alpha(\xi)$ as follows. Similarly to Lemma 10 we may assume without loss of generality that $\mathbf{X}$ and $\mathbf{Z}$ have entries in $\{-1/2, 1/2\}$ so $\mathbf{X}_j - \mathbf{Z}_k$ has components in $\{-1, 0, 1\}$. Since $R_i \overset{d}{=} -R_i$ as $F \in \mathcal{F}$, we have

$$\mathbb{P}\bigg(\bigg|\sum_{i=1}^n R_i(X_{ij} - Z_{ik})\bigg| \leq \tau\bigg) = \mathbb{P}\bigg(\bigg|\sum_{i=1}^{n(1-\gamma_{jk})} R_i\bigg| \leq \tau\bigg).$$

We now use Lemma 14. For $n(1-\gamma_u)$ sufficiently large, when $\tau \leq a\sqrt{n}$ the RHS is bounded below by

$$\frac{c_1\tau}{\sqrt{n(1 - \gamma_{jk})}}.$$

Here constant $a, c_1 > 0$ also depend only on F. Thus

$$\alpha(\xi) \geq \frac{1}{p^2}\sum_{j,k} \frac{c_1\tau}{\sqrt{n(1 - \gamma_{jk})}} \geq c_1\tau/\sqrt{n}. \tag{29}$$

Similarly we have

$$\beta(\xi) \leq \frac{c_2\tau}{\sqrt{n(1 - \gamma_1)}}. \tag{30}$$

Note that from (29), when $\tau > a\sqrt{n}$ we have $\alpha(\xi) \geq c_1 a$. Thus from (21) we know there exists n_0 such that for all $n \geq n_0$, we have

$$\inf_{\xi\in\Xi_{\text{dense}}(\eta):\xi_\tau>a\sqrt{n}} T(\xi)/(np^2) \geq \inf_{\xi\in\Xi_{\text{dense}}(\eta):\xi_\tau>a\sqrt{n}} \xi_L\alpha(\xi) \geq \xi_L c_1 a > 0. \tag{31}$$

We therefore need only consider the case where $\tau \leq a\sqrt{n}$ and where $\alpha(\xi) \to 0$.

Substituting the upper bound on τ implied by (29) into (30), we get

$$\beta(\xi) \leq \alpha(\xi)\frac{c_2}{c_1\sqrt{1 - \gamma_u}}.$$

Note that then

$$\xi_L \geq \frac{\log(1-\eta)}{\log\{1-\alpha(\xi)c_2/(c_1\sqrt{1-\gamma_u})\}} \geq c_3\frac{\log\big(1/1-\eta\big)}{\alpha(\xi)}$$

for some $c_3 > 0$ provided $\alpha(\xi) < 1/2$ say. However this gives us

$$\inf_{\xi\in\Xi_{\text{dense}}(\eta):\xi_\tau\leq a\sqrt{n}} T(\xi)/(np^2) \geq \inf_{\xi\in\Xi_{\text{dense}}(\eta):\xi_\tau\leq a\sqrt{n}} \xi_L\alpha(\xi) \geq \min\{1/2, c_3\log\big(1/1-\eta\big)\} > 0.$$

Combined with (31) this give the result. ■

With the previous lemmas in place, we are in a position to prove (7) of Theorem 1.

Proof of Theorem 1

The proofs of (8) and (9) are contained in Lemmas 12 and 13 respectively. To show (7) we argue as follows. Given F and η, suppose for contradiction that there exists a sequence $\xi^{(1)}, \xi^{(2)}, \ldots$ and $n_1 < n_2 < \cdots$ such that (making the dependence on n of the computational time explicit)

$$\inf_{\psi\in\Psi(\eta)} T^{(n_k)}(\psi) > T^{(n_k)}(\xi^{(k)})$$

for all k. By Lemma 12, we must have $T^{(n_k)}(\xi^{(k)})/(np^2) \to 0$. This implies that $\alpha(\xi^{(k)}) \to 0$. By Lemma 11, we know that for k sufficiently large

$$\sup_{\psi\in\Psi:\alpha(\psi)=\alpha(\xi^{(k)})} \beta(\psi) \geq \beta(\xi^{(k)}).$$

Let $\psi^{(k)}$ be the maximiser of the LHS. In order for $T^{(n_k)}(\psi^{(k)}) > T^{(n_k)}(\xi^{(k)})$, it must be the case that $\mathbb{E}_{M\sim\psi^{(k)}_M} M > \mathbb{E}_{M\sim\xi^{(k)}_M} M$. However we claim that $\xi = \psi^{(k)}$ minimises $\mathbb{E}_{M\sim\xi_M} M$ among all $\xi \in \Xi$ with $\alpha(\xi) \leq \alpha(\xi^{(k)}) =: \alpha_0$, which gives a contradiction and completes the proof. Let f be the function that linearly interpolates the points

$$\Big(\frac{1}{p^2}\sum_{j,k}\gamma_{j,k}^M,\, M\Big)_{M=1}^{\infty}.$$

Note that f is decreasing. By considering the inverse of f it is clear that f is convex. With a slight abuse of notation, write $\xi(M,\tau)$ for the element of $\xi \in \Xi$ such that ξ_M places all mass on M and $\xi_\tau = \tau$. Note that

$$\mathbb{E}_{M\sim\xi_M} M = \mathbb{E}_{M\sim\xi_M} f[\alpha\{\xi(M,0)\}] \geq \mathbb{E}_{M\sim\xi_M} f[\alpha\{\xi(M,\xi_\tau)\}].$$

Now suppose ξ has $\alpha(\xi) \leq \alpha_0$. Then from the above and Jensen's inequality,

$$\mathbb{E}_{M\sim\xi_M} M \geq f\big(\mathbb{E}_{M\sim\xi_M}\alpha(\xi(M,\xi_\tau))\big) \geq f(\alpha_0) = \mathbb{E}_{M\sim\psi^{(k)}_M} M. ■$$

Proof of Theorem 2

First note that from (11) we have $L \leq \log(1-\eta')/\log(1-\gamma^M)+1$. Then using the inequality $\log(1-x) \leq -x$ for $x \in (0,1)$, we have

$$L \leq \frac{\log\{1/(1-\eta')\}+1}{\gamma^M}.$$

Note that from the definition of γ_0 we have $\gamma^{-M} = p^{\log(\gamma)/\log(\gamma_0)}$. We then see that

$$\begin{aligned}
\gamma^{-M}\mathbb{E}(E_1) &= \gamma^{-M}\sum_{j,k}\gamma_{jk}^M \\
&\leq \gamma^{-M}\Big(\sum_{j,k:\gamma_{jk}>\gamma}\gamma_{jk}^M + \sum_{j,k:\gamma_0<\gamma_{jk}\leq\gamma}\gamma_{jk}^M + \sum_{j,k:\gamma_{jk}\leq\gamma_0}\gamma_{jk}^M\Big) \\
&\leq c_1 p\gamma^{-M} + c_2 p^{1+\log(\gamma)/\log(\gamma_0)} + p^2\gamma_0^M\gamma^{-M} \\
&\leq (c_1+c_2+1)p^{1+\log(\gamma)/\log(\gamma_0)}.
\end{aligned}$$

Collecting together the terms in (10) we have

$$C(M,L) \leq np + [\log\{1/(1-\eta')\}+1][\log(p)\{1+1/\log(\gamma_0^{-1})\} + n(c_1+c_2+1)]p^{1+\log(\gamma)/\log(\gamma_0)}$$

from which the result easily follows.

Proof of Proposition 3

Let $\eta^* = \eta(M^*, L)$. Note that in order for $\eta(M', L') \geq \eta^*$ it must be the case that $L' \geq \log(1-\eta^*)/\log(1-\gamma^{M'})$. Therefore

$$\begin{aligned}
C(M',L') - np &\geq \frac{\log(1-\eta^*)}{\log(1-\gamma^{M'})}\Big(M'p + p\log(p) + n\sum_{j,k}\gamma_{jk}^{M'}\Big) \\
&\geq \min_{M\in\mathbb{N}}\frac{\log(1-\eta^*)}{\log(1-\gamma^M)}\Big(Mp + p\log(p) + n\sum_{j,k}\gamma_{jk}^M\Big) \qquad (32) \\
&= \frac{\log(1-\eta^*)}{\log(1-\gamma^{M^*})}\Big(M^*p + p\log(p) + n\sum_{j,k}\gamma_{jk}^{M^*}\Big) = C(M^*,L).
\end{aligned}$$

Moreover, the inequality leading to (32) is strict if M^* is the unique minimiser and $M' \neq M^*$.

Technical lemmas

Lemma 14 *Let $F \in \mathcal{F}$ and suppose $(R_i)_{i=1}^\infty$ is an i.i.d. sequence with $R_i \sim F$.*

Then for all $a > 0$, there exists $c_1, c_2 > 0$ and $l_0 \in \mathbb{N}$ such that for all $l \geq l_0$ and $0 \leq \tau \leq a\sqrt{l}$ we have

$$\frac{c_1\tau}{\sqrt{l}} \leq \mathbb{P}\Big(\Big|\sum_{i=1}^l R_i\Big| \leq \tau\Big) \leq \frac{c_2\tau}{\sqrt{l}}.$$

Proof Let f_l be the density of $\sum_{i=1}^l R_i/\sqrt{l}$. Note that as $\mathbb{E}(|R_1|^3) < \infty$, we must have $\mathbb{E}(R_1^2) < \infty$, so we may assume without loss of generality that $\mathbb{E}(R_1^2) = 1$. Then by Theorem 3 of Petrov (1964) we have that for sufficiently large l,

$$|f_l(t) - \phi(t)| \leq \frac{c}{\sqrt{l}(1+|t|^3)}. \tag{33}$$

Here c is a constant and $\phi(t) = e^{-t^2/2}/\sqrt{2\pi}$ is the standard normal density. Now by the mean value theorem, we have

$$2 \inf_{0\leq t\leq \tau/\sqrt{l}} \{f_l(t)\}\frac{\tau}{\sqrt{l}} \leq \mathbb{P}\Big(\big|\sum_{i=1}^l R_i\big|/\sqrt{l} \leq \tau/\sqrt{l}\Big) \leq 2 \sup_{0\leq t\leq \tau/\sqrt{l}} \{f_l(t)\}\frac{\tau}{\sqrt{l}}.$$

Thus from (33), for l sufficiently large we have

$$\mathbb{P}\Big(\big|\sum_{i=1}^l R_i\big| \leq \tau\Big) \geq \frac{\tau}{\sqrt{l}}\Big(\frac{\sqrt{2}}{\sqrt{\pi}}\exp\{-\tau^2/(2l)\} - \frac{2c}{\sqrt{l}}\Big).$$

Note that for $a > 0$ and l sufficiently large we have $\sqrt{2/\pi}e^{-a^2/2} > 2c/\sqrt{l}$, whence

$$\mathbb{P}\Big(\big|\sum_{i=1}^l R_i\big| \leq \tau\Big) \geq \frac{c_1\tau}{\sqrt{l}}$$

for $0 \leq \tau \leq a\sqrt{l}$, some $c_1 > 0$. A similar argument yields the upper bound in the final result. ■

Lemma 15 *Suppose $\gamma \in [0,1)$. For all $M \in \mathbb{N}$ we have*

$$\sum_{r=1}^M \frac{1}{\sqrt{r}}\binom{M}{r}(1-\gamma)^r\gamma^{M-r} \leq \frac{\sqrt{2}}{\sqrt{(1-\gamma)M}}. \tag{34}$$

Given $r_0 \in \mathbb{N}$ and $\gamma \in [0,1)$, there exists $c > 0$ and $M_0 \in \mathbb{N}$ such that for all $M \geq M_0$ we have

$$\sum_{r=r_0}^M \frac{1}{\sqrt{r}}\binom{M}{r}(1-\gamma)^r\gamma^{M-r} \geq \frac{c}{\sqrt{(1-\gamma)M}}. \tag{35}$$

Proof First we show the upper bound (34). Let $J \sim \text{Binomial}(M, 1-\gamma)$.

$$\begin{aligned}\sum_{r=1}^M \frac{1}{\sqrt{r}}\binom{M}{r}(1-\gamma)^r\gamma^{M-r} &\leq \sqrt{2}\sum_{r=1}^M \frac{1}{\sqrt{r+1}}\binom{M}{r}(1-\gamma)^r\gamma^{M-r} \\ &\leq \sqrt{2}\mathbb{E}(1/\sqrt{J+1}).\end{aligned}$$

Next, by Jensen's inequality we have $\mathbb{E}(1/\sqrt{J+1}) \leq \sqrt{\mathbb{E}\{1/(J+1)\}}$. We now compute $\mathbb{E}\{1/(J+1)\}$ as follows.

$$\begin{aligned}\mathbb{E}\Big(\frac{1}{J+1}\Big) &= \sum_{r=0}^M \frac{1}{r+1}\binom{M}{r}(1-\gamma)^r\gamma^{M-r} \\ &= \frac{1}{M+1}\sum_{r=0}^M \binom{M+1}{r+1}(1-\gamma)^r\gamma^{M-r} \\ &= \frac{1}{(1-\gamma)(M+1)}\sum_{r=0}^M \binom{M+1}{r+1}(1-\gamma)^{r+1}\gamma^{M-r} \\ &= \frac{1-\gamma^{M+1}}{(1-\gamma)(M+1)} \leq \frac{1}{(1-\gamma)(M+1)}.\end{aligned}$$

Putting things together gives (34).

Turning now to (35), we see that the LHS equals

$$\mathbb{E}(1/\sqrt{J}\mathbb{1}_{\{J\geq r_0\}}) = \mathbb{E}(1/\sqrt{J}|J \geq r_0)\mathbb{P}(J \geq r_0).$$

By Jensen's inequality we have

$$\mathbb{E}(1/\sqrt{J}|J \geq r_0) \geq \frac{1}{\sqrt{\mathbb{E}(J|J\geq r_0)}} = \frac{\sqrt{\mathbb{P}(J\geq r_0)}}{\sqrt{\mathbb{E}(J\mathbb{1}_{\{J\geq r_0\}})}} \geq \frac{\sqrt{\mathbb{P}(J\geq r_0)}}{\sqrt{(1-\gamma)M}}.$$

But as $M \to \infty$, $\mathbb{P}(J \geq r_0) \to 1$, which easily gives the result. ■

Lemma 16 *Let $f : [0,\infty) \to [0,1]$ be non-decreasing. Suppose there exists $0 < \alpha_1 < \alpha_0$ such that:*

(i) f is concave on $[0, \alpha_0]$;

(ii) $-\sup\big(\partial(-f)(\alpha_1)\big) \geq \{1 - f(\alpha_1)\}/(\alpha_0 - \alpha_1)$, where $\partial(-f)(\alpha_1)$ denotes the subdifferential of the function $-f$ at α_1.

Then if random variable X has $\mathbb{E}(X) \leq \alpha_0$, then $f(\mathbb{E}X) \geq \mathbb{E}f(X)$.

Proof Write $m = -\sup\big(\partial(-f)(\alpha_1)\big)$ Let function $g : [0,\infty) \to [0,\infty)$ be defined as follows.

$$g(x) = \begin{cases} f(x) & \text{if } 0 \leq x \leq \alpha_1 \\ f(\alpha_1) + m(x-\alpha_1) & \text{if } x > \alpha_1. \end{cases}$$

Note that g thus defined has $g(\alpha_0) \geq 1$. We see that g is convex and $g \geq f$. Thus if $\mathbb{E}(X) \leq \alpha_1$, by Jensen's inequality we have

$$f(\mathbb{E}X) = g(\mathbb{E}X) \geq \mathbb{E}g(X) \geq \mathbb{E}f(X).$$

■

Appendix B

Connection to LSH

Minimal subsampling as considered in Algorithm 2 is closely related to the locality-sensitive hashing (LSH) framework: Define $h(j) = \mathbf{R}^T\mathbf{X}_j$ ($\mathbf{R}$ corresponds to the minimal subsampling projection) to be the hashing function and $\mathcal{H}$ to be the family of such functions, from which we sample uniformly. Then $\mathcal{H}$ is $(\gamma, c\gamma, p_1, p_2)$-sensitive, that is:

- if $\gamma_{jk} \geq \gamma$ then $\mathbb{P}(h(j) = h(k)) \geq p_1$
- if $\gamma_{jk} \leq c\gamma$ then $\mathbb{P}(h(j) = h(k)) \leq p_2$,

where $0 < c < 1$. In the case of the minimal subsampling we have $p_1 = \gamma^M$ and $p_2 = \gamma^M c^M$. However, the typical LSH machinery cannot be applied directly to the equal pairs problem above. In our setting, we are not interested in preserving close pairs but rather the closest pairs. Theorem 1 establishes that the family $\mathcal{H}$ leads to the maximal ratio p_1/p_2 among all linear hashing families.

Appendix C

Proof of Proposition 4

Proof

$$\begin{aligned}\mathbb{P}(\mathrm{sgn}(Y_i) = \tilde{X}_{ij}\tilde{X}_{ik}) &= \frac{\mathrm{sgn}(Y_i)+1}{2}(g(X_{ij})g(X_{ik}) + (1-g(X_{ij}))(1-g(X_{ik})))\\ &+ \frac{1-\mathrm{sgn}(Y_i)}{2}(g(X_{ij})(1-g(X_{ik})) + (1-g(X_{ij}))g(X_{ik}))\\ &= \frac{1}{2} + \frac{\mathrm{sgn}(Y_i)}{2}(1-2g(X_{ij}))(1-2g(X_{ik})).\end{aligned}$$

■

Appendix D

The unbiased transform and the sign transform

Proposition 6
Proof The equation

$$\mathbb{E}[\tilde{X}_{ij}] = \mathbb{P}(\tilde{X}_{ij} = 1) - \mathbb{P}(\tilde{X}_{ij} = -1) = X_{ij},$$

implies

$$\mathbb{P}(\tilde{X}_{ij} = 1) = \frac{X_{ij}+1}{2}$$

This uniquely determines the unbiased transform. ■

Next we show two Lemmas that will be useful when proving Theorems 7 and 8.

Lemma 17 *Consider the setup of Theorem 7. Then there exists constants $C_1^\varepsilon, C_2^\varepsilon > 0$ such that defining*

$$\alpha_{n,p}^u = \alpha_{n,p}^u(t) = \left(1 + \frac{t + \log(nC_1^\varepsilon)}{C_2^\varepsilon}\right)\sqrt{2\{t + \log(4p)\}/n},$$

with probability at least $1 - 2\exp(-t)$ we have:

$$\begin{aligned}\frac{\sum_i Y_i X_{ij^*} X_{ik^*}}{\|\mathbf{Y}\|_1} &\notin \Big[-\frac{m_2 - \alpha_{n,p}^u}{m_1 + m_\varepsilon + \alpha_{n,p}^u}, \frac{m_2 - \alpha_{n,p}^u}{m_1 + m_\varepsilon + \alpha_{n,p}^u}\Big]\\ \frac{\sum_{i=1}^n Y_i X_{ij} X_{ik}}{\|\mathbf{Y}\|_1} &\in \Big[-\frac{m_2(1-r_u) + \alpha_{n,p}^u}{m_1 - \alpha_{n,p}^u}, \frac{m_2(1-r_u) + \alpha_{n,p}^u}{m_1 - \alpha_{n,p}^u}\Big] \ \forall (j,k) \neq (j^*, k^*).\end{aligned}$$

Proof First we consider a capped version of ε:

$$\varepsilon_i' = \begin{cases}\varepsilon_i \text{ if } |\varepsilon_i| \leq \sigma\\ \sigma\mathrm{sgn}(\varepsilon_i) \text{ otherwise,}\end{cases}$$

where σ is to be chosen later. We may apply Hoeffding's inequality to these bounded variables. We have to bound two terms:

$\frac{\sum_{i=1}^n Y_i X_{ij^*} X_{ik^*}}{\|\mathbf{Y}\|_1}$ from below and $\frac{\sum_{i=1}^n Y_i X_{ij} X_{ik}}{\|\mathbf{Y}\|_1}$ from above, for $(j,k) \neq (j^*, k^*)$.

Schematically the first term can be dealt with in the following way:

$$\mathbb{P}\Big(\frac{A+B}{C+D} \geq \frac{a+b}{c+d}\Big) \geq 1 - \mathbb{P}(A \leq a) - \mathbb{P}(B \leq b) - \mathbb{P}(C \geq c) - \mathbb{P}(D \geq d) \tag{36}$$

where

$$A + B = \sum_{i=1}^n (X_{ij^*}X_{ik^*})^2 + \varepsilon_i' X_{ij^*}X_{ik^*} \ \text{ and } \ C + D = \sum_{i=1}^n |X_{ij^*}X_{ik^*} + \varepsilon_i'|.$$

We deal with each term individually. Using Hoeffding's inequality we get:

$$A: \ \mathbb{P}\Big(\textstyle\sum_{i=1}^p (X_{ij^*}X_{ik^*})^2 \leq nm_2 - \delta\Big) \leq \exp(-\delta^2/2n))$$

$$B: \ \mathbb{P}\Big(\textstyle\sum_{i=1}^n \varepsilon_i' X_{ij^*}X_{ik^*} \leq -\kappa\Big) \leq \exp(-\kappa^2/2n\sigma^2)$$

$$C: \ \mathbb{P}\Big(\textstyle\sum_{i=1}^n |X_{ij^*}X_{ik^*}| \geq nm_1 + \delta\Big) \leq \exp(-\delta^2/2n)$$

$$D: \ \mathbb{P}\Big(\textstyle\sum_{i=1}^n |\varepsilon_i'| \geq nm_\varepsilon + \kappa\Big) \leq \exp(-2\kappa^2/n\sigma^2).$$

This gives us a bound of the interaction strength of the true interaction pair:

$$\begin{aligned}\mathbb{P}\Big(\frac{\sum_i Y_i X_{ij^*} X_{ik^*}}{\|\mathbf{Y}\|_1} &\geq \frac{nm_2 - \delta - \kappa}{nm_1 + nm_\varepsilon + \delta + \kappa}\Big)\\ &\geq 1 - \exp(-\delta^2/2n) - \exp(-\delta^2/2n)\\ &\quad - \exp(-\kappa^2/2n\sigma^2) - \exp(-\kappa^2/2n\sigma^2)\end{aligned}$$

Similarly we can treat the interaction strength of the non interacting pairs:

$A:$ Here we use assumption $(B1)$:

$$m_2(r_u - 1) \leq \mathbb{E}[X_{ij^*}X_{ik^*}X_{im}X_{io}] \leq m_2(1 - r_u).$$

Hence, $\mathbb{P}\Big(\sum_{i=1}^n X_{ij^*}X_{ik^*}X_{ij}X_{ik} \geq nm_2(1-r_u) + \delta\Big) \geq \exp(-\delta/2n)$.

For the rest we run the same bounds as before (using $|X_{ij^*}X_{ik^*} + \varepsilon_i'| \geq |X_{ij^*}X_{ik^*}| + \varepsilon_i'$). This yields the bound

$$\begin{aligned}\mathbb{P}\Big(\frac{\sum_{i=1}^n Y_i X_{ij}X_{ik}}{\|\mathbf{Y}\|_1} \leq \frac{nm_2(1-r_u)+\delta+\kappa}{nm_1 - \delta - \kappa}\Big) &\geq 1 - \exp(-\delta^2/2n) - \exp(-\delta^2/2n) \\ &\quad - \exp(-\kappa^2/2n\sigma^2) - \exp(-\kappa^2/2n\sigma^2)\end{aligned}$$

The above inequality needs to hold for all at most p^2 pairs that are not interactions, so that we effectively multiply the exponential terms with p^2. Another factor of 2 is multiplied in for the negative sign, as the fraction also has to be bounded away from -1. In total we thus have:

$$\begin{aligned}\frac{\sum_{i=1}^n Y_i X_{ij^*}X_{ik^*}}{\|\mathbf{Y}\|_1} &\notin \Big[-\frac{nm_2 - \delta - \kappa}{nm_1 + nm_\varepsilon + \delta + \kappa}, \frac{nm_2 - \delta - \kappa}{nm_1 + nm_\varepsilon + \delta + \kappa}\Big] \\ \frac{\sum_{i=1}^n Y_i X_{ij}X_{ik}}{\|\mathbf{Y}\|_1} &\in \Big[-\frac{nm_2(1-r_u)+\delta+\kappa}{nm_1 - \delta - \kappa}, \frac{nm_2(1-r_u)+\delta+\kappa}{nm_1 - \delta - \kappa}\Big] \ \forall (m,o) \neq (j,l)\end{aligned}$$

with probability at least $1 - \exp(-\delta^2/2n) - \exp(-\delta^2/2n) - \exp(-\kappa^2/2n\sigma^2) - \exp(-\kappa^2/2n\sigma^2)$.

Finally, let $\sigma \geq 1$, then we have to set δ and κ so that the probability is bigger than $1 - \exp(-t)$. This gives:

$$\exp(-t) = 4p\exp(-\delta^2/2n) \text{ and } \exp(-t) = 4p\exp(-\kappa^2/2n\sigma^2).$$

This gives

$$\delta = \sqrt{2n(t + \log(4p))} \text{ and } \kappa = \sqrt{2n\sigma^2(t + \log(4p))}.$$

Thus for $\alpha_{n,p}^u = \frac{\sqrt{2(t+\log(4p))(1+\sigma^2)}}{\sqrt{n}}$,

$$\begin{aligned}\frac{\sum_i Y_i X_{ij^*}X_{ik^*}}{\|\mathbf{Y}\|_1} &\notin \Big[-\frac{m_2 - \alpha_{n,p}^u}{m_1 + m_\varepsilon + \alpha_{n,p}^u}, \frac{m_2 - \alpha_{n,p}^u}{m_1 + m_\varepsilon + \alpha_{n,p}^u}\Big] \\ \frac{\sum_{i=1}^n Y_i X_{ij}X_{ik}}{\|\mathbf{Y}\|_1} &\in \Big[-\frac{m_2(1-r_u)+\alpha_{n,p}^u}{m_1 - \alpha_{n,p}^u}, \frac{m_2(1-r_u)+\alpha_{n,p}^u}{m_1 - \alpha_{n,p}^u}\Big] \ \forall (j,k) \neq (j^*,k^*)\end{aligned}$$

with probability at least $1 - \exp(-t)$.

Now we extend this result to the case of unbounded errors, that is we now assume that with high probability ε_i are bounded:

$$\mathbb{P}(\varepsilon_i = \varepsilon_i', \ \forall\, i) = 1 - \exp(-t).$$

Here we used the sub-exponential tail behavior of ε. We have $\mathbb{P}(|\varepsilon_i| \geq t) \leq C_1^\varepsilon \exp(-C_2^\varepsilon t)$. Hence we set

$$t = C_2^\varepsilon \sigma - \log(nC_1^\varepsilon) \ \Rightarrow \sigma = \frac{t + \log(nC_1^\varepsilon)}{C_2^\varepsilon}$$

Thus,

$$\alpha_{n,p}^u = \frac{\sqrt{2\{t + \log(4p)\}\{1 + (\frac{t+\log(nC_1^\varepsilon)}{C_2^\varepsilon})\}^2\}}}{\sqrt{n}}$$

with probability at least $1 - 2\exp(-t)$ we have:

$$\begin{aligned}\frac{\sum_i Y_i X_{ij^*}X_{ik^*}}{\|\mathbf{Y}\|_1} &\notin \Big[-\frac{m_2 - \alpha_{n,p}^u}{m_1 + m_\varepsilon + \alpha_{n,p}^u}, \frac{m_2 - \alpha_{n,p}^u}{m_1 + m_\varepsilon + \alpha_{n,p}^u}\Big] \\ \frac{\sum_{i=1}^n Y_i X_{ij}X_{ik}}{\|\mathbf{Y}\|_1} &\in \Big[-\frac{m_2(1-r_u)+\alpha_{n,p}^u}{m_1 - \alpha_{n,p}^u}, \frac{m_2(1-r_u)+\alpha_{n,p}^u}{m_1 - \alpha_{n,p}^u}\Big] \ \forall (j,k) \neq (j^*,k^*).\end{aligned}$$

■

Next we prove the equivalent result for the sign transform. The proof is very similar to the unbiased case:

Lemma 18 *Consider the setup of Theorem 8. Then there exists constants $C_1^X, C_2^X, C_1^\varepsilon, C_2^\varepsilon > 0$ such that defining*

$$\alpha_{n,p}^s = \alpha_{n,p}^s(t) = \frac{\sqrt{2(t + \log(4p))\Big(\Big(\frac{t+\log(pmC_1^X)}{C_2^X}\Big)^4 + \Big(\frac{t+\log(nC_1^\varepsilon)}{C_2^\varepsilon}\Big)^2\Big)}}{\sqrt{n}},$$

with probability at least $1 - 3\exp(-t)$ we have:

$$\begin{aligned}\frac{\sum_{i=1}^n Y_i \mathrm{sgn}(X_{ij^*}X_{ik^*})}{\|\mathbf{Y}\|_1} &\notin \Big[-\frac{m_1 - \alpha_{n,p}^s}{m_1 + m_\varepsilon + \alpha_{n,p}^s}, \frac{m_1 - \alpha_{n,p}^s}{m_1 + m_\varepsilon + \alpha_{n,p}^s}\Big] \\ \frac{\sum_{i=1}^n Y_i \mathrm{sgn}(X_{ij}X_{ik})}{\|\mathbf{Y}\|_1} &\in \Big[-\frac{m_1(1-r_s)+\alpha_{n,p}^s}{m_1 - \alpha_{n,p}^s}, \frac{m_1(1-r_s)+\alpha_{n,p}^s}{m_1 - \alpha_{n,p}^s}\Big] \ \forall\, (m,o) \neq (j^*,k^*).\end{aligned}$$

Proof First consider capped versions of the random variables of interest:

$$X_{ij}' = \begin{cases} X_{ij} \text{ if } |X_{ij}| \leq M \\ M\mathrm{sgn}(X_{ij}) \text{ otherwise}\end{cases} \quad \text{and} \quad \varepsilon_i' = \begin{cases} \varepsilon_i \text{ if } |\varepsilon_i| \leq \sigma \\ \sigma\mathrm{sgn}(\varepsilon_i) \text{ otherwise}\end{cases}$$

where M and σ are to be chosen later. Given these capped variables we can use Hoeffding's inequality as we now deal with bounded variables. We have to bound two terms:

$\frac{\sum_{i=1}^n Y_i \mathrm{sgn}(X_{ij^*}'X_{ik^*}')}{\|\mathbf{Y}\|_1}$ from below and $\frac{\sum_{i=1}^n Y_i \mathrm{sgn}(X_{ij}'X_{ik}')}{\|\mathbf{Y}\|_1}$ from above, for $(j,k) \neq (j^*,k^*)$

As in Lemma 17 equation (36):

$$A + B = \sum_{i=1}^n |X_{ij^*}'X_{ik^*}'| + \varepsilon_i' \mathrm{sgn}(X_{ij^*}'X_{ik^*}') \ \text{ and } \ C + D = \sum_{i=1}^n |X_{ij^*}'X_{ik^*}' + \varepsilon_i'|.$$

We deal with each term individually. Using Hoeffding's inequality we get:

$A:\ \mathbb{P}\Big(\sum_{i=1}^{p}|X'_{ij^*}X'_{ik^*}|\le nm_1-\delta\Big)\le\exp(-\delta^2/2nM^4))$

$B:\ \mathbb{P}\Big(\sum_{i=1}^{n}\varepsilon'_i\le-\kappa\Big)\le\exp(-\kappa^2/2n\sigma^2)$

$C:\ \mathbb{P}\Big(\sum_{i=1}^{n}|X'_{ij^*}X'_{ik^*}|\ge nm_1+\delta\Big)\le\exp(-\delta^2/2nM^4)$

$D:\ \mathbb{P}\Big(\sum_{i=1}^{n}|\varepsilon'|\ge nm'_\varepsilon+\kappa\Big)\le\exp(-2\kappa^2/n\sigma^2)$

This gives us a bound of the interaction strength of the true interaction pair:

$$\mathbb{P}\Big(\frac{\sum_i Y_i\mathrm{sgn}(X'_{ij^*}X'_{ik^*})}{\|\mathbf{Y}\|_1}\ge\frac{nm_1-\delta-\kappa}{nm_1+nm_\varepsilon+\delta+\kappa}\Big)\ge1-2\exp(-\delta^2/2nM^4)-2\exp(-\kappa^2/2n\sigma^2)$$

Similarly we can treat the interaction strength of the non interacting pairs:

$A:$ Here we use assumption $(C1)$. It implies

$$r_s/2\le\mathbb{P}(\mathrm{sgn}(X'_{ij^*}X'_{ik^*})=\mathrm{sgn}(X'_{ij}X'_{ik})|\mathbf{X})\le1-r_s/2.$$

This we use for computing the expectation:

$$\begin{aligned}\mathbb{E}[X'_{ij^*}X'_{ik^*}\mathrm{sgn}(X'_{ij}X'_{ik})]&=\mathbb{E}[\mathbb{E}[|X'_{ij^*}X'_{ik^*}|\mathrm{sgn}(X'_{ij}X'_{ik}X'_{ij^*}X'_{ik^*})]\\&=\mathbb{E}[\mathbb{E}[2|X'_{ij^*}X'_{ik^*}|\mathbf{1}_{\{\mathrm{sgn}(X'_{ij}X'_{ik}X'_{ij^*}X'_{ik^*})=1\}}|\mathbf{X}]]-\mathbb{E}[|X'_{ij^*}X'_{ik^*}|]\\&=\mathbb{E}[\mathbb{E}[2|X'_{ij^*}X'_{ik^*}||\mathbf{X}]]\mathbb{P}(\mathrm{sgn}(X'_{ij}X'_{ik}X'_{ij^*}X'_{ik^*})=1|\mathbf{X})-\mathbb{E}[|X'_{ij^*}X'_{ik^*}|]\\&=\mathbb{E}[|X'_{ij^*}X'_{ik^*}|](2\mathbb{P}(\mathrm{sgn}(X'_{ij}X'_{ik}X'_{ij^*}X'_{ik^*})=1|\mathbf{X})-1).\end{aligned}$$

Thus the expectation is given as:

$$m_1(r_s-1)\le E[X'_{ij^*}X'_{ik^*}\mathrm{sgn}(X'_{ij}X'_{ik})]\le m_1(1-r_s).$$

Hence, $\mathbb{P}\Big(\sum_{i=1}^{n}X'_{ij^*}X'_{ik^*}\mathrm{sgn}(X'_{ij}X'_{ik})\ge nm_1(1-r_s)+\delta\Big)\ge\exp(-2\delta/nM^4)$.

For the rest we use the same bounds as before (using $|X'_{ij^*}X'_{ik^*}+\varepsilon'_i|\ge|X'_{ij^*}X'_{ik^*}|+\varepsilon'_i$). This yields the bound

$$\mathbb{P}\Big(\frac{\sum_{i=1}^{n}Y_i\mathrm{sgn}(X'_{ij}X'_{ik})}{\|\mathbf{Y}\|_1}\le\frac{nm_1(1-r_s)+\delta+\kappa}{nm_1-\delta-\kappa}\Big)\ge1-\exp(-2\delta^2/nM^4)-\exp(-2\kappa^2/n\sigma^2).$$

The above inequality needs to hold for the at most p^2 pairs that are not interactions, so that we effectively multiply the exponential terms with p^2. Another factor of 2 is multiplied in for the negative sign, as the fraction also has to be bounded away from -1. In total we thus have:

$$\begin{aligned}&\frac{\sum_i Y_i\mathrm{sgn}(X'_{ij^*}X'_{ik^*})}{\|\mathbf{Y}\|_1}\notin\Big[-\frac{nm_1-\delta-\kappa}{nm_1+nm_\varepsilon+\delta+\kappa},\frac{nm_1-\delta-\kappa}{nm_1+nm_\varepsilon+\delta+\kappa}\Big]\\&\frac{\sum_{i=1}^{n}Y_i\mathrm{sgn}(X'_{ij}X'_{ik})}{\|\mathbf{Y}\|_1}\in\Big[-\frac{nm_1(1-r_s)+\delta+\kappa}{nm_1-\delta-\kappa},\frac{nm_1(1-r_s)+\delta+\kappa}{nm_1-\delta-\kappa}\Big]\ \forall(j,k)\neq(j^*,k^*)\end{aligned}$$

with probability at least $1-2p\exp(-\delta^2/2nM^4)-2p\exp(-\kappa^2/2n\sigma^2)$.

Finally we have to set δ and κ so that the probability is bigger than $1-\exp(-t)$. This gives:

$$\exp(-t)=4p\exp(-\delta^2/2nM^4)\ \text{ and }\ \exp(-t)=4p\exp(-\kappa^2/2n\sigma^2)$$

This gives

$$\delta=\sqrt{2nM^4(t+\log(4p))}\ \text{ and }\ \kappa=\sqrt{2n\sigma^2(t+\log(4p))}$$

Thus for $\alpha^s_{n,p}=\frac{\sqrt{2(t+\log(4p))(M^4+\sigma^2)}}{\sqrt{n}}$

$$\begin{aligned}&\frac{\sum_i Y_i\mathrm{sgn}(X'_{ij^*}X'_{ik^*})}{\|\mathbf{Y}\|_1}\notin\Big[-\frac{m_1-\alpha^s_{n,p}}{m_1+m_\varepsilon+\alpha^s_{n,p}},\frac{m_1-\alpha^s_{n,p}}{m_1+m_\varepsilon+\alpha^s_{n,p}}\Big]\\&\frac{\sum_{i=1}^{n}Y_i\mathrm{sgn}(X'_{ij}X'_{ik})}{\|\mathbf{Y}\|_1}\in\Big[-\frac{m_1(1-r_s)+\alpha^s_{n,p}}{m_1-\alpha^s_{n,p}},\frac{m_1(1-r_s)+\alpha^s_{n,p}}{m_1-\alpha^s_{n,p}}\Big]\ \forall(j,k)\neq(j^*,k^*)\end{aligned}$$

with probability at least $1-\exp(-t)$.

We now extend this result to the case of unbounded variables, that is we now assume that with high probability the variables X_{ij} and ε_i are bounded:

$$\mathbb{P}(\,X_{ij}=X'_{ij},\ \forall\,i,j)=1-\exp(-t)\ \text{ and }\ \mathbb{P}(\varepsilon_i=\varepsilon'_{ij},\ \forall\,i)=1-\exp(-t).$$

Here we used the sub-exponential tail behaviour of the X_{ij} and ε_i. There exists constants C_1^X, C_2^X such that $\mathbb{P}(|X_{ij}|\ge t)\le C_1^X\exp(-C_2^Xt)$ and similarly for ε. Hence we set

$$t=C_2^XM-\log(pnC_1^X)\ \Rightarrow M=\frac{t+\log(pnC_1^X)}{C_2^X}$$

$$t=C_2^\varepsilon\sigma-\log(nC_1^\varepsilon)\ \Rightarrow\sigma=\frac{t+\log(nC_1^\varepsilon)}{C_2^\varepsilon}$$

Thus we have

$$\alpha^s_{n,p}=\frac{\sqrt{2(t+\log(4p))\Big(\Big(\frac{t+\log(pnC_1^X)}{C_2^X}\Big)^4+\Big(\frac{t+\log(nC_1^\varepsilon)}{C_2^\varepsilon}\Big)^2\Big)}}{\sqrt{n}}$$

■

Next we prove **Theorem** 7:

Proof Given $\delta,\epsilon>0$, choose t such that $3\exp(-t)<\epsilon$. From (B3) we have that $\alpha^u_{n,p}(t)$ defined in Lemma 17 satisfies $\alpha^u_{n,p}(t)\to0$ as $n\to\infty$. Thus from Lemma 17 we know that there exists N such that for all $n\ge N$, with probability $1-\epsilon$ we have

$$\frac{\log(\gamma^g_{j^*k^*})}{\log(\gamma^g_{jk})}<\frac{\log\{(1+\frac{m_2}{m_1+m_\varepsilon})/2\}}{\log\{(1+\frac{m_1}{m_2(1-r_s)})/2\}}+\delta/2.$$

Thus for $n\ge N$, applying Corollary 5 we have that with probability $1-\epsilon$,

$$C(M,L)\le cnp^{1+\delta/2+\frac{\log(1/2+m_2/2((m_1+m_\varepsilon)))}{\log(1/2+m_2(1-r_u)/(2m_1))}},$$

for some constant c. ■

The proof of **Theorem** 8 is very similar and is thus omitted.

Abstract

We show a Talagrand-type concentration inequality for Multi-Task Learning (MTL), with which we establish sharp excess risk bounds for MTL in terms of the Local Rademacher Complexity (LRC). We also give a new bound on the LRC for any norm regularized hypothesis classes, which applies not only to MTL, but also to the standard Single-Task Learning (STL) setting. By combining both results, one can easily derive fast-rate bounds on the excess risk for many prominent MTL methods, including—as we demonstrate—Schatten norm, group norm, and graph regularized MTL. The derived bounds reflect a relationship akin to a conservation law of asymptotic convergence rates. When compared to the rates obtained via a traditional, global Rademacher analysis, this very relationship allows for trading off slower rates with respect to the number of tasks for faster rates with respect to the number of available samples per task.

Keywords: Excess Risk Bounds, Local Rademacher Complexity, Multi-task Learning

1. Introduction

A commonly occurring problem, when applying machine learning in the sciences, is the lack of a sufficient amount of training data to attain acceptable performance results; either obtaining such data may be very costly or they may be unavailable due to technological limitations. For example, in cancer genomics, tumor bioptic samples may be relatively scarce due to the limited number of cancer patients, when compared to samples of healthy individuals. Also, in neuroscience, electroencephalogram experiments are carried out on human subjects to record training data and typically involve only a few dozen subjects.

In such settings, when considering any type of prediction task per individual subject (for example, whether the subject is indeed suffering from a specific medical affliction or not), relying solely on the scarce data per individual most often leads to inadequate predictive performance. Such a direct approach completely ignores the advantages that might be gained, when considering intrinsic, strong similarities between subjects and, hence, tasks. For instance, in the area of genomics, different living organisms can be related to each other in terms of their evolutionary relationships as given by the tree of life. Taking into account such relationships may be instrumental in detecting genes of recently developed organisms, for which only a limited number of training data is available. While our discussion here has focused on the realm of biomedicine, similar limitations and opportunities to overcome them exist in other fields as well.

Transfer learning (Pan and Yang, 2010) and, in particular, Multi-Task Learning (MTL) (Caruana, 1997) leverage such underlying common links among a group of tasks, while respecting the tasks' individual idiosyncrasies to the extent warranted. This is achieved by phrasing the learning process as a joint, mutually dependent learning problem. An early example of such a learning paradigm is the neural network-based approach introduced by Caruana (1997), while more recent works consider convex MTL problems (Ando and Zhang, 2005; Evgeniou and Pontil, 2004; Argyriou et al., 2008a). At the core of each such MTL formulation lies a mechanism that encodes task relatedness into the learning problem (Evgeniou et al., 2005). Such relatedness mechanism can always be thought of as jointly constraining the tasks' hypothesis spaces, so that their geometry is mutually coupled, *e.g.*, via a block norm constraint (Yousefi et al., 2015). Thus, from a regularization perspective, the tasks mutually regularize their learning based on their inter-task relatedness. This process of information exchange during co-learning is often referred to as *information sharing*. With respect to learning theory results, the analysis of MTL goes back to the seminal work of Baxter (2000), which was followed up by the works of Ando and Zhang (2005); Maurer (2006a). Nowadays, MTL frameworks are routinely employed in a variety of settings. Some recent applications include computational genetics (Widmer et al., 2013), image segmentation (An et al., 2008), HIV therapy screening (Bickel et al., 2008), collaborative filtering (Cao et al., 2010), age estimation from facial images (Zhang and Yeung, 2010), and sub-cellular location prediction (Xu et al., 2011), just to name a few prominent ones.

MTL learning guarantees are centered around notions of (global) Rademacher complexities, which were introduced to machine learning by Bartlett et al. (2002); Bartlett and Mendelson (2002); Koltchinskii and Panchenko (2000); Koltchinskii (2001); Koltchinskii and Panchenko (2002), and employed in the context of MTL by Maurer (2006a,b); Kakade et al. (2012); Maurer and Pontil (2013); Maurer (2016); Maurer et al. (2016). All these works are briefly surveyed in Sect. 1.3. It is worth noting that, if T denotes the number of tasks being co-learned and n denotes the number of

available observations per task, then the fastest-converging error or excess risk bounds derived in these works are of the order $O(1/\sqrt{nT})$.

More recently, Koltchinskii (2006) and Bartlett et al. (2005) introduced a more nuanced variant of these complexities, termed Local Rademacher Complexity (LRC), as opposed to the original Global Rademacher Complexity (GRC). This new, modified function class complexity measure is attention-worthy, since, as shown by Bartlett et al. (2005), an LRC-based analysis is capable of producing more rapidly-converging excess risk bounds ("fast rates"), when compared to the ones obtained via a GRC analysis. This can be attributed to the fact that, unlike LRCs, GRCs ignore the fact that learning algorithms typically choose well-performing hypotheses that belong only to a subset of the entire hypothesis space under consideration. The end result of this distinction empowers a local analysis to provide less conservative and, hence, sharper bounds than the standard global analysis. To date, there have been only a few additional works attempting to reap the benefits of such local analysis in various contexts: active learning for binary classification tasks (Koltchinskii, 2010), multiple kernel learning (Kloft and Blanchard, 2011; Cortes et al., 2013), transductive learning (Tolstikhin et al., 2014), semi-supervised learning (Oneto et al., 2015) and bounds on the LRCs via covering numbers (Lei et al., 2015).

1.1 Our Contributions

Through a Talagrand-type concentration inequality adapted to the MTL case, this paper's main contribution is the derivation of sharp bounds on the MTL excess risk in terms of the distribution- and data-dependent LRC. For a given number of tasks T, these bounds admit faster (asymptotic) convergence characteristics in the number of observations per task n, when compared to corresponding bounds hinging on the GRC. Hence, these faster rates ensure us that the MTL hypothesis selected by a learning algorithm approaches the best-in-class solution as n increases beyond a certain threshold. We also prove a new bound on the LRC, which generally holds for hypothesis classes with any norm regularizers. This bound readily facilitates the bounding of the LRC for a range of such regularizers not only for MTL, but also for the standard Single-Task Learning (STL) setting. As a matter of fact, we demonstrate such results, in Sect. 4, for classes induced by graph-based, Schatten and group norm regularizers. Moreover, we prove matching lower bounds and, thus, show that, aside from constants, the LRC-based bounds are tight for the considered applications.

Our derived bounds reflect that one can trade off a slow convergence speed w.r.t. T for an improved convergence rate w.r.t. n. The latter one ranges from the typical GRC-based $O(1/\sqrt{n})$ bounds, all the way up to the fastest rate of order $O(1/n)$ by allowing the bound to depend less on T. Nevertheless, the premium in question becomes less relevant to MTL, since T is typically considered fixed is such setting.

Fixing all other parameters when the number of samples per task n approaches infinity, our local bounds yield faster rates compared to their global counterparts. Also, it is observed that, if the number of tasks T and the radius R of the ball-norms can grow with n, there are cases wherein local analysis always improves over the global one. When our local bounds are compared to the ones in(Maurer and Pontil, 2013; Maurer, 2006b), which stem from a global analysis, one observes that our bounds yield faster, $O(1/T)$ and $O(1/n)$ convergence rates.

1.2 Organization

The paper is organized as follows: Sect. 2 lays the foundations for our analysis by considering a Talagrand-type concentration inequality suitable for deriving our bounds. Next, in Sect. 3, after suitably defining LRCs for MTL hypothesis spaces, we provide our LRC-based MTL excess risk bounds. Based on these bounds, we follow up this section with a local analysis of linear MTL frameworks, in which task-relatedness is presumed and enforced by imposing a norm constraint. More specifically, leveraging off Hölder's inequality, Sect. 4 presents generic upper bounds for the relevant LRC of any norm regularized hypothesis class. These results are subsequently specialized to the case of group norm, Schatten norm and graph regularized linear MTL. Sect. 5 supplies the corresponding excess risk bounds based on the LRC of the aforementioned hypothesis classes. The paper concludes with Sect. 6, which investigates the convergence rate of our LRC-based excess risk bounds for the previously mentioned hypothesis spaces. We also compare our local bounds with those obtained from a GRC-based analysis provided in Maurer and Pontil (2013); Maurer (2006b).

1.3 Previous Related Works

An earlier work by Maurer (2006a), which considers linear MTL frameworks for binary classification, investigates the generalization guarantees based on Rademacher averages. In this framework, all tasks are pre-processed by a common bounded linear operator and operator norm constraints are used to control the complexity of the associated hypothesis spaces. The GRC-based error bounds derived are of order $O(1/\sqrt{nT})$. Another contemporary study (Maurer, 2006b) provides bounds for the empirical and expected Rademacher complexities of linear transformation classes. Based on Hölder's inequality, GRC-based risk bounds of order $O(1/\sqrt{nT})$ are established for MTL hypothesis spaces with graph-based and L_{S_q}-Schatten norm regularizers, where $q \in \{2\} \cup [4, \infty]$.

The subject of MTL generalization guarantees benefited from renewed attention in recent years. Kakade et al. (2012) take advantage of the strongly-convex nature of certain matrix-norm regularizers to easily obtain generalization bounds for a variety of machine learning problems. Part of their work is devoted to the realm of online and off-line MTL. In the latter case, which pertains to the focus of our work, the paper provides a GRC-based excess risk bound of order $O(1/\sqrt{nT})$. Moreover, Maurer and Pontil (2013) present a global Rademacher complexity analysis leading to excess risk bounds of order $O(\sqrt{\log(nT)/nT}$ for a trace norm regularized MTL model. Also, Maurer (2016) examines the bounding of (global) Gaussian complexities of function classes that result from considering composite maps, as is typical in several settings, including MTL. An application of the paper's results yields MTL risk bounds of order $O(1/\sqrt{nT})$. More recently, Maurer et al. (2016) presents excess risk bounds of order $O(1/\sqrt{nT})$ for both MTL and Learning-to-Learn (LTL) and reveals conditions, under which MTL is more beneficial over learning tasks independently.

Finally, although loosely related to our focus, we mention in passing a few works that pertain to generalization guarantees in the realm of life-long learning and domain adaptation. Generalization performance analysis in life-long learning has been investigated by Thrun and Pratt (2012); Ben-David and Schuller (2003); Ben-David and Borbely (2008); Pentina and Lampert (2015) and Pentina and Ben-David (2015). Also, in the context of domain adaptation, similar considerations are examined by Mansour et al. (2009a,b,c); Cortes and Mohri (2011); Zhang et al. (2012); Mansour and Schain (2013) and Cortes and Mohri (2014).

1.4 Basic Assumptions & Notations

Consider T supervised learning tasks sampled from the same input-output space $\mathcal{X} \times \mathcal{Y}$. Each task t is represented by an independent random variable (X_t, Y_t) governed by a probability distribution μ_t. Also, the *i.i.d.* samples related to each task t are described by the sequence $(X_t^i, Y_t^i)_{i=1}^n$, drawn from μ_t.

In what follows, we use the following notational conventions: vectors and matrices are depicted in bold face. The superscript T, when applied to a vector/matrix, denotes the transpose of that quantity. We define $\mathbb{N}_T := \{1, \ldots, T\}$. For any random variables X, Y and function f we use $\mathbb{E}f(X,Y)$ and $\mathbb{E}_X f(X,Y)$ to denote the expectation with w.r.t. all the involved random variables and the conditional expectation w.r.t. the random variable X respectively. For any vector-valued function $\boldsymbol{f} = (f_1, \ldots, f_T)$, we introduce the following two notations:

$$P\boldsymbol{f} := \frac{1}{T}\sum_{t=1}^{T} Pf_t, \qquad P_n\boldsymbol{f} := \frac{1}{T}\sum_{t=1}^{T} P_n f_t.$$

where $Pf_t := \mathbb{E}[f_t(X_t)]$ and $P_n f_t := \frac{1}{n}\sum_{i=1}^n f_t(X_t^i)$. When well-defined, we denote the component-wise exponentiation of a vector $\boldsymbol{f}$ as $\boldsymbol{f}^\alpha = (f_1^\alpha, \ldots, f_T^\alpha), \forall \alpha \in \mathbb{R}$. For any loss function $\ell : \mathbb{R} \times \mathbb{R} \to \mathbb{R}_+$ and any $\boldsymbol{f} = (f_1, \ldots, f_T)$ we define $\ell_{\boldsymbol{f}} = (\ell_{f_1}, \ldots, \ell_{f_T})$ where ℓ_{f_t} is the function defined by $\ell_{f_t}((X_t, Y_t)) = \ell(f_t(X_t), Y_t)$.

Finally, in the subsequent material, we always assume the measurability of functions and suprema whenever necessary. Furthermore, operators on separable Hilbert spaces are assumed to be of trace class.

2. Talagrand-Type Inequality for Multi-Task Learning

Our derivation of LRC-based error bounds for MTL is founded on a Talagrand-type concentration inequality, which was adapted to the context of MTL and is presented next. It shows that the uniform deviation between the true and empirical means for a vector-valued function class $\mathcal{F}$ can be dominated by the associated *multi-task Rademacher complexity* plus a term involving the variance of functions in $\mathcal{F}$. A notable property of Theorem 1 is that the correlation among different components of $\boldsymbol{f}$, encoded by either the constraint on variances or the constraint imposed in the hypothesis space, is preserved. This last observation is congruent with the spirit of MTL. The proof of Theorem 1, which is deferred to Appendix A, is based on a so-called *Logarithmic Sobolev inequality* on log-moment generating functions.

Theorem 1 (TALAGRAND-TYPE INEQUALITY FOR MTL) *Let $\mathcal{F} = \{\boldsymbol{f} := (f_1, \ldots, f_T)\}$ be a class of vector-valued functions satisfying $\max_{t\in N_T} \sup_{x\in\mathcal{X}} |f_t(x)| \leq b$. Also, assume that $X := (X_t^i)_{(t,i)=(1,1)}^{(T,N_t)}$ is a vector of $\sum_{t=1}^T N_t$ independent random variables where $X_t^1, \ldots, X_t^n, \forall t$ are identically distributed. Let $\{\sigma_t^i\}_{t,i}$ be a sequence of independent Rademacher variables. If $\frac{1}{T}\sup_{\boldsymbol{f}\in\mathcal{F}} \sum_{t=1}^T \mathbb{E}\left[f_t(X_t^1)\right]^2 \leq r$, then, for every $x > 0$, with probability at least $1 - e^{-x}$,*

$$\sup_{\boldsymbol{f}\in\mathcal{F}}(P\boldsymbol{f} - P_n\boldsymbol{f}) \leq 4\mathfrak{R}(\mathcal{F}) + \sqrt{\frac{8xr}{nT}} + \frac{12bx}{nT}, \tag{1}$$

where $n := \min_{t\in\mathbb{N}_T} N_t$, and the multi-task Rademacher complexity *of function class $\mathcal{F}$ is defined as*

$$\mathfrak{R}(\mathcal{F}) := \mathbb{E}_{X,\sigma}\left\{\sup_{\boldsymbol{f}=(f_1,\ldots,f_T)\in\mathcal{F}} \frac{1}{T}\sum_{t=1}^{T}\frac{1}{N_t}\sum_{i=1}^{N_t}\sigma_t^i f_t(X_t^i)\right\}.$$

Note that the same bound also holds for $\sup_{\boldsymbol{f}\in\mathcal{F}}(P_n\boldsymbol{f} - P\boldsymbol{f})$.

In Theorem 1, the data from different tasks are assumed to be mutually independent, which is typically presumed in MTL (Maurer, 2006a). To present the results in a clear way we always assume in the following that the available data for each task is the same, namely n.

Remark 2 *Note that Theorem 1 pertains to classes of uniformly bounded functions and is used in the sequel to bound the excess risk of multi-task learning function classes. However, using a new argument by Mendelson (2014), Theorem 1 can be extended beyond the case of classes of uniformly bounded loss functions. In particular, rather than adopting a concentration-based inequality, which is crucial to our approach here to bound the suprema of the resulting empirical processes, the approach in Mendelson (2014) relies on a "small ball" assumption. Such an assumption holds for functions with "well-behaved high-order moments" (e.g. heavy-tailed functions).*

Remark 3 *At this point, we present the result of the previous theorem for the special case of single task learning. It is very straightforward to verify that, for $T = 1$, the bound in* (1) *can be written as*

$$\sup_{f\in\mathcal{F}}(Pf - P_n f) \leq 4\mathfrak{R}(\mathcal{F}) + \sqrt{\frac{8xr}{n}} + \frac{12bx}{n}, \tag{2}$$

where the function f is chosen from a scalar-valued function class $\mathcal{F}$. This bound can be compared to the result of Theorem 2.1 of Bartlett et al. (2005), which for $\alpha = 1$ reads as

$$\sup_{f\in\mathcal{F}}(Pf - P_n f) \leq 4\mathfrak{R}(\mathcal{F}) + \sqrt{\frac{2xr}{n}} + \frac{8bx}{3n}. \tag{3}$$

Note that the difference between the constants in (2) *and* (3) *is due to the fact that we were unable to directly apply Bousquet's version of Talagrand's inequality (like it was done in Bartlett et al. (2005) for scalar-valued functions) to the class of vector-valued functions. To be more clear, let Z be defined as in* (A.2) *with the jackknife replication $Z_{s,j}$. We find a lower bound $Z''_{s,j}$ such that $Z''_{s,j} \leq Z - Z_{s,j}$. Then, in order to apply Theorem 2.5 of Bousquet (2002), one needs to show that the quantity $\frac{1}{nT}\sum_{s=1}^T\sum_{j=1}^n \mathbb{E}_{s,j}[(Z''_{s,j})^2]$ is bounded. This goal, ideally, can be achieved by including a constraint similar to $\frac{1}{T}\sup_{\boldsymbol{f}\in\mathcal{F}}\sum_{t=1}^T \mathbb{E}\left[f_t(X_t^1)\right]^2 \leq r$ in Theorem 1. However, we found that—when dealing with MTL class of functions—it is not very straightforward to define such a constraint that satisfies the boundedness condition $\frac{1}{nT}\sum_{s=1}^T\sum_{j=1}^n \mathbb{E}_{s,j}[(Z''_{s,j})^2]$ in terms of r. With that being said, the key ingredient to Theorem 1's proof is the so-called* Logarithmic Sobolev *inequality—Theorem A.1—which can be considered as the exponential version of* Efron-Stein*'s inequality.*

3. MTL Excess Risk Bounds based on Local Rademacher Complexities

At the heart of Theorem 1 lies a variance bound, which motivates us to consider Rademacher averages associated with a function sub-class enjoying small variances. As pointed out in Bartlett et al. (2005), these (local) averages are always smaller than the corresponding global Rademacher averages and allow for eventually deriving sharper generalization bounds. Herein, we exploit this very fact for MTL generalization guarantees.

Definition 4 (MULTI-TASK LOCAL RADEMACHER COMPLEXITY) *For a vector-valued function class $\mathcal{F} = \{\boldsymbol{f} = (f_1, \dots, f_T)\}$, the* Multi-Task Local Rademacher Complexity (MT-LRC) *$\mathfrak{R}(\mathcal{F}, r)$ is defined as*

$$\mathfrak{R}(\mathcal{F}, r) := \mathbb{E}_{X,\sigma}\Big[\sup_{\substack{\boldsymbol{f}=(f_1,\dots,f_T)\in\mathcal{F}\\ V(\boldsymbol{f})\le r}} \frac{1}{nT}\sum_{t=1}^{T}\sum_{i=1}^{n}\sigma_t^i f_t(X_t^i)\Big], \tag{4}$$

where $V(\boldsymbol{f})$ is an upper bound on the variance of the functions in $\mathcal{F}$.

For the case $T = 1$, it is clear that the MT-LRC reduces to the standard LRC for scalar-valued function classes. Analogous to single task learning, a challenge in using the MT-LRC to refine existing learning rates is to find an optimal radius trading-off the variance and the associated complexity, which, as we show later, reduces to the calculation of the fixed-point of a sub-root function.

Definition 5 (SUB-ROOT FUNCTION) *A function $\psi : [0, \infty] \to [0, \infty]$ is sub-root if and only if it is non-decreasing and the function $r \mapsto \psi(r)/\sqrt{r}$ is non-increasing for $r > 0$.*

Lemma 6 (Lemma 3.2 Bartlett et al. (2005)) *If ψ is a sub-root function, then it is continuous on $[0, \infty]$, and the equation $\psi(r) = r$ has a unique (non-zero) solution r^*, which is known as the fixed point of ψ. Moreover, for any $r > 0$, it holds that $r > \psi(r)$ if and only if $r^* \le r$.*

Intuitively, the model sought for by learning algorithms would hopefully attain a small generalization error and enjoy a small variance, when there is a relationship between risks and variances. The concept of local Rademacher complexity allows us to focus on identifying such models.

Definition 7 (VECTOR-VALUED BERNSTEIN CLASS) *Let $0 < \beta \le 1$ and $B > 0$. A vector-valued function class $\mathcal{F}$ is said to be a (β, B)-Bernstein class with respect to the probability measure P if there exists a function $V : \mathcal{F} \to \mathbb{R}^+$ such that*

$$P\boldsymbol{f}^2 \le V(\boldsymbol{f}) \le B(P\boldsymbol{f})^\beta, \quad \forall \boldsymbol{f} \in \mathcal{F}. \tag{5}$$

It can be shown that the Bernstein condition (5) is not too restrictive and it holds, for example, for non-negative bounded functions with respect to any probability distribution as shown in (Bartlett et al., 2004). Other examples include the class of excess risk functions $\mathcal{L}_\mathcal{F} := \{\ell_f - \ell_{f^*} : f \in \mathcal{F}\}$—with $f^* \in \mathcal{F}$ being the minimizer of $P\ell_f$— when the function class $\mathcal{F}$ is convex and the loss function ℓ is strictly convex.

In this section, we show that under some mild assumptions on a vector-valued Bernstein class, LRC-based excess risk bounds can be established for MTL. We will assume that the loss function ℓ and the vector-valued hypothesis space $\mathcal{F}$ satisfy the following conditions:

Assumption 8

1. *There is a function $\boldsymbol{f}^* = (f_1^*, \dots, f_T^*) \in \mathcal{F}$ satisfying $P\ell_{\boldsymbol{f}^*} = \inf_{\boldsymbol{f}\in\mathcal{F}} P\ell_{\boldsymbol{f}}$.*
2. *There is a constant $B' \ge 1$ and $0 < \beta \le 1$, such that for every $\boldsymbol{f} \in \mathcal{F}$ we have $P(\boldsymbol{f} - \boldsymbol{f}^*)^2 \le B'\big(P(\ell_{\boldsymbol{f}} - \ell_{\boldsymbol{f}^*})\big)^\beta$.*
3. *There is a constant L, such that the loss function ℓ is L-Lipschitz in its first argument.*

As pointed out in Bartlett et al. (2005), many regularized algorithms satisfy these conditions. More specifically, a uniform convexity condition on the loss function ℓ is usually sufficient to satisfy Assumption 8.2. A typical example is the quadratic loss function $\ell(f(X), Y) = (f(X) - Y)^2$. More specifically, if $|f(X) - Y| \le 1$ for any $f \in \mathcal{F}, x \in \mathcal{X}$ and $Y \in \mathcal{Y}$, then it can be shown that the conditions of Assumption 8 are met with $L = 1$ and $B = 1$.

We now present the main result of this section showing that the excess risk of MTL can be bounded by the fixed-point of a sub-root function dominating the MT-LRC. The proof of the results is provided in Appendix B.

Theorem 9 (Excess risk bound for MTL) *Let $\mathcal{F} := \{\boldsymbol{f} := (f_1, \dots, f_T)\}$ be a class of vector-valued functions $\boldsymbol{f}$ satisfying $\max_{t\in\mathbb{N}_T}\sup_{x\in\mathcal{X}}|f_t(x)| \le b$. Assume that $X := (X_t^i, Y_t^i)_{(t,i)=(1,1)}^{(T,n)}$ is a vector of nT independent random variables, where for each task t, the samples $(X_t^1, Y_t^1)\dots,(X_t^n, Y_t^n)$ are identically distributed. Suppose that Assumption 8 holds. Define $\mathcal{F}^* := \{\boldsymbol{f} - \boldsymbol{f}^*\}$, where $\boldsymbol{f}^*$ is the function satisfying $P\ell_{\boldsymbol{f}^*} = \inf_{\boldsymbol{f}\in\mathcal{F}} P\ell_{\boldsymbol{f}}$. Let $B := \max(B'L^2, 1)$ and ψ be a sub-root function with fixed point r^* such that $BL\mathfrak{R}(\mathcal{F}^*, r) \le \psi(r), \forall r \ge r^*$, where $\mathfrak{R}(\mathcal{F}^*, r)$ is the LRC of the functions class $\mathcal{F}^*$:*

$$\mathfrak{R}(\mathcal{F}^*, r) := \mathbb{E}_{X,\sigma}\Big[\sup_{\substack{\boldsymbol{f}\in\mathcal{F},\\ L^2P(\boldsymbol{f}-\boldsymbol{f}^*)^2\le r}} \frac{1}{nT}\sum_{t=1}^{T}\sum_{i=1}^{n}\sigma_t^i f_t(X_t^i)\Big]. \tag{6}$$

Then, for any $\boldsymbol{f} \in \mathcal{F}$, $K > 1$ and $x > 0$, with probability at least $1 - e^{-x}$,

$$P(\ell_{\boldsymbol{f}} - \ell_{\boldsymbol{f}^*}) \le \frac{K}{K-\beta}P_n(\ell_{\boldsymbol{f}} - \ell_{\boldsymbol{f}^*}) + (2K)^{\frac{\beta}{2-\beta}}20^{\frac{2}{2-\beta}}\max\Big((r^*)^{\frac{1}{2-\beta}}, (r^*)^{\frac{1}{\beta}}\Big) + \Big(\frac{2^{\beta+3}B^2K^\beta x}{nT}\Big)^{\frac{1}{2-\beta}} + \frac{48LBbx}{(2-\beta)nT}. \tag{7}$$

The following corollary is direct by noting that $P_n(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) \le 0$.

Corollary 10 *Let $\hat{\boldsymbol{f}}$ be any element of function class $\mathcal{F}$ satisfying $P_n\ell_{\hat{\boldsymbol{f}}} = \inf_{\boldsymbol{f}\in\mathcal{F}} P_n\ell_{\boldsymbol{f}}$. Assume that the conditions of Theorem 9 hold. Then for any $x > 0$ and $r > \psi(r)$, with probability at least $1 - e^{-x}$,*

$$P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) \le (2K)^{\frac{\beta}{2-\beta}}20^{\frac{2}{2-\beta}}\max\Big((r^*)^{\frac{1}{2-\beta}}, (r^*)^{\frac{1}{\beta}}\Big) + \Big(\frac{2^{\beta+3}B^2K^\beta x}{nT}\Big)^{\frac{1}{2-\beta}} + \frac{48LBbx}{(2-\beta)nT}. \tag{8}$$

An immediate consequence of this section's results is that one can derive excess risk bounds for given regularized MTL hypothesis spaces. In the sequel, we will derive excess risk bounds for several commonly used norm regularized MTL hypothesis spaces by further bounding the fixed point r^* appearing in Corollary 10.

4. Local Rademacher Complexity Bounds for Norm Regularized MTL Models

This section presents very general MT-LRC bounds for hypothesis spaces defined by norm regularizers, which allows us to immediately derive, as specific application cases, LRC bounds for group norm, Schatten norm, and graph regularized MTL models.

4.1 Preliminaries

We consider linear MTL models, where we associate to each task a functional $f_t(X) := \langle \boldsymbol{w}_t, \phi(X)\rangle$. Here, $\boldsymbol{w}_t$ belongs to a *Reproducing Kernel Hilbert Space (RKHS)* $\mathcal{H}$, equipped with an inner product $\langle .,.\rangle$ and an induced norm $\|.\| := \sqrt{\langle .,.\rangle}$. Also, $\phi : \mathcal{X} \to \mathcal{H}$ is a feature map associated to $\mathcal{H}$'s reproducing kernel k satisfying $k(X, \tilde{X}) = \langle \phi(X), \phi(\tilde{X})\rangle, \forall X, \tilde{X} \in \mathcal{X}$. We assume that the multi-task model $\boldsymbol{W} = (\boldsymbol{w}_1, \ldots, \boldsymbol{w}_T) \in \mathcal{H} \times \ldots \times \mathcal{H}$ is learned using the regularized cost function:

$$\min_{\boldsymbol{W}} \Omega\left(\boldsymbol{D}^{1/2}\boldsymbol{W}\right) + C\sum_{t=1}^{T}\sum_{i=1}^{n} \ell(\langle \boldsymbol{w}_t, \phi(X_t^i)\rangle, Y_t^i), \tag{9}$$

where the regularizer $\Omega(\cdot)$ may be used to reflect a priori information. This regularization scheme amounts to performing *Empirical Risk Minimization (ERM)* using the hypothesis space

$$\mathcal{F} := \left\{X \mapsto [\langle \boldsymbol{w}_1, \phi(X_1)\rangle, \ldots, \langle \boldsymbol{w}_T, \phi(X_T)\rangle]^T : \Omega(\boldsymbol{D}^{1/2}\boldsymbol{W}) \leq R^2\right\}, \tag{10}$$

where $\boldsymbol{D}$ is a given positive operator defined on $\mathcal{H}$. Note that the hypothesis spaces corresponding to the group and Schatten norms can be recovered by setting $\boldsymbol{D} = \boldsymbol{I}$ and by using their corresponding norms. More specifically, by choosing $\Omega(\boldsymbol{W}) = \frac{1}{2}\|\boldsymbol{W}\|_{2,q}^2$, one obtains an $L_{2,q}$-group norm hypothesis space in (10). Similarly, the choice $\Omega(\boldsymbol{W}) = \frac{1}{2}\|\boldsymbol{W}\|_{S_q}^2$ gives an L_{S_q}-Schatten norm hypothesis space in (10). Furthermore, the graph regularized MTL (Micchelli and Pontil, 2004; Evgeniou et al., 2005; Maurer, 2006b) can be obtained by taking $\Omega(\boldsymbol{W}) = \frac{1}{2}\|\boldsymbol{D}^{1/2}\boldsymbol{W}\|_F^2$, where $\|.\|_F$ is a Frobenius norm, $\boldsymbol{D} := \boldsymbol{L} + \eta\boldsymbol{I}$, $\boldsymbol{L}$ is the relevant graph Laplacian, and $\eta > 0$ is a regularization constant. On balance, all these MTL models can be considered as norm regularized models. Note that in the sequel, we let q^* be the Hölder conjugate exponent of q, *i.e.* $1/q + 1/q^* = 1$.

4.2 General Bound on the LRC

Now, we can provide the main results on general LRC bounds for any MTL hypothesis space of the form $\Omega(\boldsymbol{W}) = \frac{1}{2}\|\boldsymbol{W}\|^2$ for a norm $\|.\|$. In what follows, the Hilbert-Schmidt operator $\phi(X) \otimes \phi(X) : \mathcal{H} \to \mathcal{H}$ is defined as $\phi(X) \otimes \phi(X)(\boldsymbol{u}) = \langle \phi(X), \boldsymbol{u}\rangle\phi(X)$.

Theorem 11 (LRC bounds for MTL models with norm regularizers) *Let the regularizer $\Omega(\boldsymbol{W})$ in* (9) *be given as an appropriate norm $\|.\|$, whose dual is denoted by $\|.\|_*$. Let the kernels be uniformly bounded, that is, $\|k\|_\infty \leq \mathcal{K} < \infty$, and $X_t^1, \ldots, X_t^n$ be an i.i.d. sample drawn from P_t. Also, assume that for each task t, the eigen-decomposition of the Hilbert-Schmidt covariance operator J_t is given by $J_t := \mathbb{E}(\phi(X_t) \otimes \phi(X_t)) = \sum_{j=1}^{\infty} \lambda_t^j \boldsymbol{u}_t^j \otimes \boldsymbol{u}_t^j$, where $(\boldsymbol{u}_t^j)_{j=1}^{\infty}$ forms an orthonormal basis of $\mathcal{H}$ and $(\lambda_t^j)_{j=1}^{\infty}$ are the corresponding eigenvalues in non-increasing order. Then, for any given positive operator $\boldsymbol{D}$ on $\mathbb{R}^T$, any $r > 0$ and any non-negative integers $h_1, \ldots, h_T$:*

$$\mathfrak{R}(\mathcal{F}, r) \leq \min_{0 \leq h_t \leq \infty} \left\{ \sqrt{\frac{r\sum_{t=1}^{T} h_t}{nT}} + \frac{\sqrt{2}R}{T}\mathbb{E}_{X,\sigma}\left\|\boldsymbol{D}^{-1/2}\boldsymbol{V}\right\|_* \right\}, \tag{11}$$

where $\boldsymbol{V} := \left(\sum_{j>h_t}\left\langle \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle \boldsymbol{u}_t^j\right)_{t=1}^{T}$

Proof Using the LRC's definition, we have

$$\begin{aligned}
\mathfrak{R}(\mathcal{F}, r) &= \frac{1}{nT}\mathbb{E}_{X,\sigma}\left\{\sup_{\substack{\boldsymbol{f}=(f_1,\ldots,f_T)\in\mathcal{F},\\ P\boldsymbol{f}^2\leq r}} \sum_{i=1}^{n}\left\langle (\boldsymbol{w}_t)_{t=1}^{T}, \left(\sigma_t^i\phi(X_t^i)\right)_{t=1}^{T}\right\rangle\right\} \\
&= \frac{1}{T}\mathbb{E}_{X,\sigma}\left\{\sup_{\substack{\boldsymbol{f}\in\mathcal{F},\\ P\boldsymbol{f}^2\leq r}} \left\langle (\boldsymbol{w}_t)_{t=1}^{T}, \left(\sum_{j=1}^{\infty}\left\langle \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle \boldsymbol{u}_t^j\right)_{t=1}^{T}\right\rangle\right\} \\
&\leq \frac{1}{T}\mathbb{E}_{X,\sigma}\left\{\sup_{P\boldsymbol{f}^2\leq r}\left\langle \left(\sum_{j=1}^{h_t}\sqrt{\lambda_t^j}\left\langle \boldsymbol{w}_t, \boldsymbol{u}_t^j\right\rangle \boldsymbol{u}_t^j\right)_{t=1}^{T}, \right.\right. \\
&\qquad\qquad \left.\left.\left(\sum_{j=1}^{h_t}\sqrt{\lambda_t^j}^{-1}\left\langle \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle \boldsymbol{u}_t^j\right)_{t=1}^{T}\right\rangle\right\} \qquad (12) \\
&\quad + \frac{1}{T}\mathbb{E}_{X,\sigma}\left\{\sup_{\boldsymbol{f}\in\mathcal{F}}\left\langle (\boldsymbol{w}_t)_{t=1}^{T}, \left(\sum_{j>h_t}\left\langle \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle \boldsymbol{u}_t^j\right)_{t=1}^{T}\right\rangle\right\} \qquad (13) \\
&= A_1 + A_2,
\end{aligned}$$

where A_1 and A_2 stand respectively for the first (12) and second (13) term of the previous bound.

Step 1. Controlling A_1: By applying the Cauchy-Schwartz (C.S.) inequality on A_1, one gets

$$\begin{aligned}
A_1 &\leq \frac{1}{T}\mathbb{E}_{X,\sigma}\left\{\sup_{P\boldsymbol{f}^2\leq r}\left[\left(\sum_{t=1}^{T}\left\|\sum_{j=1}^{h_t}\sqrt{\lambda_t^j}\left\langle \boldsymbol{w}_t, \boldsymbol{u}_t^j\right\rangle \boldsymbol{u}_t^j\right\|^2\right)^{\frac{1}{2}}\right.\right. \\
&\qquad\qquad \left.\left.\left(\sum_{t=1}^{T}\left\|\sum_{j=1}^{h_t}\left(\sqrt{\lambda_t^j}\right)^{-1}\left\langle \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle \boldsymbol{u}_t^j\right\|^2\right)^{\frac{1}{2}}\right]\right\} \\
&= \frac{1}{T}\mathbb{E}_{X,\sigma}\left\{\sup_{P\boldsymbol{f}^2\leq r}\left[\left(\sum_{t=1}^{T}\sum_{j=1}^{h_t}\lambda_t^j\left\langle \boldsymbol{w}_t, \boldsymbol{u}_t^j\right\rangle^2\right)^{\frac{1}{2}}\right.\right.
\end{aligned}$$

$$\left(\sum_{t=1}^{T}\sum_{j=1}^{h_t}\left(\lambda_t^j\right)^{-1}\left\langle\frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i),\boldsymbol{u}_t^j\right\rangle^2\right)^{\frac{1}{2}}\Bigg]\Bigg\}.$$

With the help of Jensen's inequality and taking advantage of the fact that $\mathbb{E}_{X,\sigma}\left\langle\frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i),\boldsymbol{u}_t^j\right\rangle^2=\frac{\lambda_t^j}{n}$ and $P\boldsymbol{f}^2\leq r$ together imply that $\frac{1}{T}\sum_{t=1}^{T}\sum_{j=1}^{\infty}\lambda_t^j\left\langle\boldsymbol{w}_t,\boldsymbol{u}_t^j\right\rangle^2\leq r$ (see Lemma C.1 in the Appendix for the proof), we can further bound A_1 as

$$A_1\leq\sqrt{\frac{r\sum_{t=1}^{T}h_t}{nT}}. \tag{14}$$

Step 2. Controlling A_2: We now use Hölder's inequality to bound the second term A_2 as follows:

$$\begin{aligned}A_2&=\frac{1}{T}\mathbb{E}_{X,\sigma}\left\{\sup_{\boldsymbol{f}\in\mathcal{F}}\left\langle(\boldsymbol{w}_t)_{t=1}^{T},\left(\sum_{j>h_t}\left\langle\frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i),\boldsymbol{u}_t^j\right\rangle\boldsymbol{u}_t^j\right)_{t=1}^{T}\right\rangle\right\}\\&=\frac{1}{T}\mathbb{E}_{X,\sigma}\left\{\sup_{\boldsymbol{f}\in\mathcal{F}}\left\langle\boldsymbol{D}^{1/2}\boldsymbol{W},\boldsymbol{D}^{-1/2}\boldsymbol{V}\right\rangle\right\}\\&\overset{\text{Hölder}}{\leq}\frac{1}{T}\mathbb{E}_{X,\sigma}\left\{\sup_{\boldsymbol{f}\in\mathcal{F}}\left\|\boldsymbol{D}^{1/2}\boldsymbol{W}\right\|.\left\|\boldsymbol{D}^{-1/2}\boldsymbol{V}\right\|_*\right\}\\&\leq\frac{\sqrt{2}R}{T}\mathbb{E}_{X,\sigma}\left\|\boldsymbol{D}^{-1/2}\boldsymbol{V}\right\|_*.\end{aligned} \tag{15}$$

Combining (15) and (14) completes the proof. ■

In what follows, we demonstrate the power of Theorem 11 by applying it to derive the LRC bounds for some popular MTL models, including group norm, Schatten norm and graph regularized models, which have been extensively studied in the MTL literature; for example, see (Maurer, 2006b; Argyriou et al., 2007a,b, 2008a; Li et al., 2015; Argyriou et al., 2014).

4.3 Group Norm Regularized MTL

We first consider the MTL scheme, which captures the inter-task relationships by the group norm regularizer $\frac{1}{2}\|\boldsymbol{W}\|_{2,q}^2:=\frac{1}{2}\left(\sum_{t=1}^{T}\|\boldsymbol{w}_t\|_2^q\right)^{2/q}$ (Argyriou et al., 2007a, 2008a; Lounici et al., 2009; Romera-Paredes et al., 2012). Its associated hypothesis space takes the form

$$\mathcal{F}_q:=\left\{X\mapsto[\langle\boldsymbol{w}_1,\phi(X_1)\rangle,\ldots,\langle\boldsymbol{w}_T,\phi(X_T)\rangle]^T:\frac{1}{2}\|\boldsymbol{W}\|_{2,q}^2\leq R_{max}^2\right\}. \tag{16}$$

Before presenting the result for this case, we point out that A_1 does not depend on the hypothesis space's $\boldsymbol{W}$-constraint. Therefore, the bound for A_1 is independent of the the choice of regularizers we consider in this study. However, A_2 can be further bounded in a manner that depends on the regularization function.

We start off with a useful lemma which helps with bounding A_2 for the group norm hypothesis space (16). The proof of this lemma, which is based on the application of the Khintchine (C.1) and Rosenthal (C.2) inequalities, is presented in Appendix C.

Lemma 12 *Assume that the kernels in* (9) *are uniformly bounded, that is,* $\|k\|_\infty\leq\mathcal{K}<\infty$. *Then, for the group norm regularizer* $\frac{1}{2}\|\boldsymbol{W}\|_{2,q}^2$ *in* (16) *and for any* $1\leq q\leq 2$, *the expectation* $\mathbb{E}_{X,\sigma}\left\|\boldsymbol{D}^{-1/2}\boldsymbol{V}\right\|_{2,q^*}$ *(for* $\boldsymbol{D}=\boldsymbol{I}$*) can be upper-bounded as*

$$\mathbb{E}_{X,\sigma}\left\|\left(\sum_{j>h_t}\left\langle\frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i),\boldsymbol{u}_t^j\right\rangle\boldsymbol{u}_t^j\right)_{t=1}^{T}\right\|_{2,q^*}\leq\frac{\sqrt{\mathcal{K}}eq^*T^{\frac{1}{q^*}}}{n}+\sqrt{\frac{eq^{*2}}{n}\left\|\left(\sum_{j>h_t}\lambda_t^j\right)_{t=1}^{T}\right\|_{\frac{q^*}{2}}}.$$

Corollary 13 *Using Theorem 11, for any* $1<q\leq 2$, *the LRC of function class* $\mathcal{F}_q$ *in* (16) *can be bounded as*

$$\mathfrak{R}(\mathcal{F}_q,r)\leq\sqrt{\frac{4}{nT}\left\|\left(\sum_{j=1}^{\infty}\min\left(rT^{1-\frac{2}{q^*}},\frac{2eq^{*2}R_{max}^2}{T}\lambda_t^j\right)\right)_{t=1}^{T}\right\|_{\frac{q^*}{2}}}+\frac{\sqrt{2\mathcal{K}e}R_{max}q^*T^{\frac{1}{q^*}}}{nT}. \tag{17}$$

Proof Sketch: We use Lemma 12 to upper-bound A_2 for the group norm hypothesis space (16) as

$$A_2(\mathcal{F}_q)\leq\sqrt{\frac{2eq^{*2}R_{max}^2}{nT^2}\left\|\left(\sum_{j>h_t}\lambda_t^j\right)_{t=1}^{T}\right\|_{\frac{q^*}{2}}}+\frac{\sqrt{2\mathcal{K}e}R_{max}q^*T^{\frac{1}{q^*}}}{nT}. \tag{18}$$

Now, combining (14) and (18) provides the following bound on $\mathfrak{R}(\mathcal{F}_q,r)$

$$\mathfrak{R}(\mathcal{F}_q,r)\leq\sqrt{\frac{r\sum_{t=1}^{T}h_t}{nT}}+\sqrt{\frac{2eq^{*2}R_{max}^2}{nT^2}\left\|\left(\sum_{j>h_t}\lambda_t^j\right)_{t=1}^{T}\right\|_{\frac{q^*}{2}}}+\frac{\sqrt{2\mathcal{K}e}R_{max}q^*T^{\frac{1}{q^*}}}{nT}. \tag{19}$$

Then, using the inequalities shown below, which hold for any $\alpha_1,\alpha_2>0$, any vectors $\boldsymbol{a}_1,\boldsymbol{a}_2\in\mathbb{R}^T$ with non-negative elements, any $0\leq q\leq p\leq\infty$ and any $s\geq 1$,

$$(\star)\ \sqrt{\alpha_1}+\sqrt{\alpha_2}\leq\sqrt{2(\alpha_1+\alpha_2)} \tag{20}$$

$$(\star\star)\quad l_q-to-l_p:\quad\|\boldsymbol{a}_1\|_q=\langle\boldsymbol{1},\boldsymbol{a}_1^q\rangle^{\frac{1}{q}}\overset{\text{Hölder's}}{\leq}\left(\|\boldsymbol{1}\|_{(p/q)^*}\|\boldsymbol{a}_1^q\|_{(p/q)}\right)^{\frac{1}{q}}=T^{\frac{1}{q}-\frac{1}{p}}\|\boldsymbol{a}_1\|_p \tag{21}$$

$$(\star\star\star)\quad\|\boldsymbol{a}_1\|_s+\|\boldsymbol{a}_2\|_s\leq 2^{1-\frac{1}{s}}\|\boldsymbol{a}_1+\boldsymbol{a}_2\|_s\leq 2\|\boldsymbol{a}_1+\boldsymbol{a}_2\|_s, \tag{22}$$

one obtains the desired result. See Appendix C for the detailed proof.

Remark 14 *Since the LRC bound above is non-monotonic in q, it is more practical to state the above bound in terms of* $\kappa\geq q$; *note that choosing* $\kappa=q$ *is not always the optimal choice. Trivially,*

for the group norm regularizer with any $\kappa \geq q$, it holds that $\|\boldsymbol{W}\|_{2,\kappa} \leq \|\boldsymbol{W}\|_{2,q}$ and, therefore, $\mathfrak{R}(\mathcal{F}_q, r) \leq \mathfrak{R}(\mathcal{F}_\kappa, r)$. Thus, we have the following bound on $\mathfrak{R}(\mathcal{F}_q, r)$ for any $\kappa \in [q, 2]$,

$$\mathfrak{R}(\mathcal{F}_q, r) \leq \sqrt{\frac{4}{nT}\left\|\left(\sum_{j=1}^{\infty}\min\left(rT^{1-\frac{2}{\kappa^*}}, \frac{2e\kappa^{*2}R_{max}^2}{T}\lambda_t^j\right)\right)_{t=1}^{T}\right\|_{\frac{\kappa^*}{2}}} + \frac{\sqrt{2Ke}R_{max}\kappa^* T^{\frac{1}{\kappa^*}}}{nT}. \tag{23}$$

Remark 15 (Sparsity-inducing group norm) *The use of the group norm regularizer $\frac{1}{2}\|\boldsymbol{W}\|_{2,1}^2$ encourages a sparse representation that is shared across multiple tasks (Argyriou et al., 2007b, 2008a). Notice that for any $\kappa \geq 1$, it holds that $\mathfrak{R}(\mathcal{F}_1, r) \leq \mathfrak{R}(\mathcal{F}_\kappa, r)$. Also, assuming an identical tail sum $\sum_{j\geq h}\lambda^j$ for all tasks, the bound gets minimized for $\kappa^* = \log T$. For this particular choice of κ^*, it is easy to show that*

$$\begin{aligned}\mathfrak{R}(\mathcal{F}_1, r) &\leq \sqrt{\frac{4}{nT}\left\|\left(\sum_{j=1}^{\infty}\min\left(rT^{1-\frac{2}{\kappa^*}}, \frac{2e\kappa^{*2}R_{max}^2}{T}\lambda_t^j\right)\right)_{t=1}^{T}\right\|_{\frac{\kappa^*}{2}}} + \frac{\sqrt{2Ke}R_{max}\kappa^* T^{\frac{1}{\kappa^*}}}{nT} \\ &\overset{(l_{\frac{\kappa^*}{2}}-to-l_\infty)}{\leq} \sqrt{\frac{4}{nT}\left\|\left(\sum_{j=1}^{\infty}\min\left(rT, \frac{2e^3(\log T)^2R_{max}^2}{T}\lambda_t^j\right)\right)_{t=1}^{T}\right\|_{\infty}} + \frac{\sqrt{2K}R_{max}e^{\frac{3}{2}}\log T}{nT}.\end{aligned}$$

Remark 16 ($L_{2,q}$ Group norm regularizer with $q \geq 2$) *For any $q \geq 2$, Theorem 11 provides an LRC bound for the function class $\mathcal{F}_q$ in* (16) *given as*

$$\mathfrak{R}(\mathcal{F}_q, r) \leq \sqrt{\frac{4}{nT}\left\|\left(\sum_{j=1}^{\infty}\min\left(rT^{1-\frac{2}{q^*}}, \frac{2R_{max}^2}{T}\lambda_t^j\right)\right)_{t=1}^{T}\right\|_{\frac{q^*}{2}}}, \tag{24}$$

where $q^* := \frac{q}{q-1}$.

Proof Using $\boldsymbol{D} = \boldsymbol{I}$, and $\|.\| = \|.\|_{2,q}$ in (15) gives

$$\begin{aligned}A_2(\mathcal{F}_q) &\overset{\text{Hölder's}}{\leq} \frac{1}{T}\mathbb{E}_{X,\sigma}\left\{\sup_{\boldsymbol{f}\in\mathcal{F}_q}\|\boldsymbol{W}\|_{2,q}\|\boldsymbol{V}\|_{2,q^*}\right\} \\ &\leq \frac{\sqrt{2}R_{max}}{T}\mathbb{E}_{X,\sigma}\left(\sum_{t=1}^{T}\left\|\sum_{j>h_t}\left\langle\frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle\boldsymbol{u}_t^j\right\|^{q^*}\right)^{\frac{1}{q^*}} \\ &\overset{\text{Jensen's}}{\leq} \frac{\sqrt{2}R_{max}}{T}\left(\sum_{t=1}^{T}\left(\mathbb{E}_{X,\sigma}\left\|\sum_{j>h_t}\left\langle\frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle\boldsymbol{u}_t^j\right\|^2\right)^{\frac{q^*}{2}}\right)^{\frac{1}{q^*}} \\ &= \frac{\sqrt{2}R_{max}}{T}\left(\sum_{t=1}^{T}\left(\sum_{j>h_t}\mathbb{E}_{X,\sigma}\left\langle\frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle^2\right)^{\frac{q^*}{2}}\right)^{\frac{1}{q^*}}\end{aligned}$$

$$= \frac{\sqrt{2}R_{max}}{T}\left(\sum_{t=1}^{T}\left(\sum_{j>h_t}\frac{\lambda_t^j}{n}\right)^{\frac{q^*}{2}}\right)^{\frac{1}{q^*}} = \sqrt{\frac{2R_{max}^2}{nT^2}\left\|\left(\sum_{j>h_t}\lambda_t^j\right)_{t=1}^{T}\right\|_{\frac{q^*}{2}}}.$$

By applying (20), (21) and (22), this last result together with the bound for A_1 in (14) yields the result. ■

To investigate the tightness of the bound in (17), we derive the corresponding lower bound, which holds for the LRC of $\mathcal{F}_q$ with $q \geq 1$. The proof of this result can be found in Appendix C.

Theorem 17 (Lower bound) *Consider the hypothesis space shown in* (16)*. The following lower bound holds for the local Rademacher complexity of $\mathcal{F}_q$ for any $q \geq 1$. There is an absolute constant c such that, if $\lambda_t^1 \geq 1/(nR_{max}^2)$ $\forall t$, then, for all $r \geq \frac{1}{n}$ and $q \geq 1$,*

$$\mathfrak{R}(\mathcal{F}_{q,R_{max},T}, r) \geq \sqrt{\frac{c}{nT^{1-\frac{2}{q^*}}}\sum_{j=1}^{\infty}\min\left(rT^{1-\frac{2}{q^*}}, \frac{R_{max}^2}{T}\lambda_1^j\right)}. \tag{25}$$

To make a clear comparison between the lower bound in (25) and the upper bound in (17), we assume identical eigenvalue tail sums $\sum_{j\geq\infty}\lambda_t^j$ for all tasks. In this case, the upper bound translates to

$$\mathfrak{R}(\mathcal{F}_{q,R_{max},T}, r) \leq \sqrt{\frac{4}{nT^{1-\frac{2}{q^*}}}\sum_{j=1}^{\infty}\min\left(rT^{1-\frac{2}{q^*}}, \frac{2eq^{*2}R_{max}^2}{T}\lambda_t^j\right)} + \frac{\sqrt{2Ke}R_{max}q^*T^{\frac{1}{q^*}}}{nT}.$$

By comparing this to (25), we see that the lower bound matches the upper bound up to constants. The same analysis for MTL models with Schatten norm and graph regularizers yields similar results and confirms that the LRC upper bounds that we have obtained are reasonably tight.

Remark 18 *It is worth pointing out that a matching lower bound on the local Rademacher complexity does not necessarily imply a tight bound on the expectation of an empirical minimizer $\hat{f}$. As shown in Section 4 of Bartlett et al. (2004), a direct analysis of the empirical minimizer can lead to sharper bounds compared to the LRC-based bounds. Consequently, based on Theorem 8 in Bartlett et al. (2004), there might be cases in which the local Rademacher complexity bounds are constants, while $P\hat{f}$ is a decreasing function of the number of samples n. Moreover, it is shown in the same paper that, under some mild conditions on the loss function ℓ, a similar argument also holds for the class of loss functions $\{\ell_f - \ell_{f^*} : f \in \mathcal{F}\}$.*

4.4 Schatten Norm Regularized MTL

Argyriou et al. (2007b) developed a spectral regularization framework for MTL, wherein the L_{S_q}-Schatten norm $\frac{1}{2}\|\boldsymbol{W}\|_{S_q}^2 := \frac{1}{2}\left[\mathrm{tr}\left(\boldsymbol{W}^T\boldsymbol{W}\right)^{\frac{q}{2}}\right]^{\frac{2}{q}}$ is studied as a concrete example that corresponds to performing ERM in the following hypothesis space:

$$\mathcal{F}_{S_q} := \left\{X \mapsto \left[\langle\boldsymbol{w}_1, \phi(X_1)\rangle, \ldots, \langle\boldsymbol{w}_T, \phi(X_T)\rangle\right]^T : \frac{1}{2}\|\boldsymbol{W}\|_{S_q}^2 \leq R'^2_{max}\right\}. \tag{26}$$

Corollary 19 *For any $1 < q \leq 2$ in (26), the LRC of function class $\mathcal{F}_{S_q}$ is bounded as*

$$\mathfrak{R}(\mathcal{F}_{S_q}, r) \leq \sqrt{\frac{4}{nT}\left\|\left(\sum_{j=1}^{\infty}\min\left(r, \frac{2q^* R_{max}'^2}{T}\lambda_t^j\right)\right)_{t=1}^{T}\right\|_1}.$$

The proof is provided in Appendix C.

Remark 20 (Sparsity-inducing Schatten norm (trace norm)) *Trace norm regularized MTL, corresponding to Schatten norm regularization with $q = 1$ (Maurer and Pontil, 2013; Pong et al., 2010), imposes a low-rank structure on the spectrum of $\boldsymbol{W}$. It can also be interpreted as low dimensional subspace learning (Argyriou et al., 2008b; Kumar and Daume III, 2012; Kang et al., 2011). Note that for any $q \geq 1$, it holds that $\mathfrak{R}(\mathcal{F}_{S_1}, r) \leq \mathfrak{R}(\mathcal{F}_{S_q}, r)$. Therefore, choosing the optimal $q^* = 2$, we get*

$$\mathfrak{R}(\mathcal{F}_{S_1}, r) \leq \sqrt{\frac{4}{nT}\left\|\left(\sum_{j=1}^{\infty}\min\left(r, \frac{4R_{max}'^2}{T}\lambda_t^j\right)\right)_{t=1}^{T}\right\|_1}.$$

Remark 21 (L_{S_q} Schatten norm regularizer with $q \geq 2$) *For any $q \geq 2$, Theorem 11 provides an LRC bound for the function class $\mathcal{F}_{S_q}$ in (26) as*

$$\mathfrak{R}(\mathcal{F}_{S_q}, r) \leq \sqrt{\frac{4}{nT}\left\|\left(\sum_{j=1}^{\infty}\min\left(rT^{1-\frac{2}{q^*}}, \frac{2R_{max}'^2}{T}\lambda_t^j\right)\right)_{t=1}^{T}\right\|_{\frac{q^*}{2}}}, \tag{27}$$

where $q^* := \frac{q}{q-1}$.

Proof We first bound the expectation $\mathbb{E}_{X,\sigma}\|\boldsymbol{V}\|_{S_{q^*}}$. Take $\boldsymbol{U}_t^i$ as a matrix with T columns where the only non-zero column t of $\boldsymbol{U}_t^i$ is defined as $\sum_{j>h_t}\left\langle \frac{1}{n}\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle \boldsymbol{u}_t^j$. Based on the definition of $\boldsymbol{V} = \left(\sum_{j>h_t}\left\langle \frac{1}{n}\sum_{i=1}^n \sigma_t^i \phi(X_t^i), \boldsymbol{u}_t^j\right\rangle \boldsymbol{u}_t^j\right)_{t=1}^T$, we can then provide a bound for this expectation as follows

$$\begin{aligned}
\mathbb{E}_{X,\sigma}\|\boldsymbol{V}\|_{S_{q^*}} &= \mathbb{E}_{X,\sigma}\left\|\sum_{t=1}^{T}\sum_{i=1}^{n}\sigma_t^i \boldsymbol{U}_t^i\right\|_{S_{q^*}} \\
&\overset{\text{Jensen}}{\leq} \left[\text{tr}\left(\left(\sum_{t,s=1}^{T}\sum_{i,j=1}^{n}\mathbb{E}_{X,\sigma}\left(\sigma_t^i\sigma_s^j \boldsymbol{U}_t^{i\,T}\boldsymbol{U}_s^j\right)\right)^{\frac{q^*}{2}}\right)\right]^{\frac{1}{q^*}} \\
&= \left[\text{tr}\left(\left(\sum_{t=1}^{T}\sum_{i=1}^{n}\mathbb{E}_X\left(\boldsymbol{U}_t^{i\,T}\boldsymbol{U}_t^i\right)\right)^{\frac{q^*}{2}}\right)\right]^{\frac{1}{q^*}} \\
&= \left[\text{tr}\left(\left(\text{diag}\left(\mathbb{E}_X\sum_{i=1}^{n}\sum_{j>h_1}\langle\frac{1}{n}\phi(X_1^i), \boldsymbol{u}_1^j\rangle^2, \ldots, \mathbb{E}_X\sum_{i=1}^{n}\sum_{j>h_T}\langle\frac{1}{n}\phi(X_T^i), \boldsymbol{u}_T^j\rangle^2\right)\right)^{\frac{q^*}{2}}\right)\right]^{\frac{1}{q^*}} \\
&= \left[\text{tr}\left(\left(\frac{1}{n}\text{diag}\left(\sum_{j>h_1}\lambda_1^j, \ldots, \sum_{j>h_T}\lambda_T^j\right)\right)^{\frac{q^*}{2}}\right)\right]^{\frac{1}{q^*}} \\
&= \sqrt{\frac{1}{n}}\left(\sum_{t=1}^{T}\left(\sum_{j>h_t}\lambda_t^j\right)^{\frac{q^*}{2}}\right)^{\frac{1}{q^*}} = \sqrt{\frac{1}{n}\left\|\left(\sum_{j>h_t}\lambda_t^j\right)_{t=1}^{T}\right\|_{\frac{q^*}{2}}}.
\end{aligned}$$

One can derive the final result by replacing this last expression into (11) and by utilizing (20), (21) and (22). ■

4.5 Graph Regularized MTL

The idea underlying graph regularized MTL is to force the models of related tasks to be close to each other, by penalizing the squared distance $\|\boldsymbol{w}_t - \boldsymbol{w}_s\|^2$ with different weights ω_{ts}. Here we consider the following MTL graph regularizer (Maurer, 2006b)

$$\Omega(\boldsymbol{W}) = \frac{1}{2}\sum_{t=1}^{T}\sum_{s=1}^{T}\omega_{ts}\|\boldsymbol{w}_t - \boldsymbol{w}_s\|^2 + \eta\sum_{t=1}^{T}\|\boldsymbol{w}_t\|^2 = \sum_{t=1}^{T}\sum_{s=1}^{T}(\boldsymbol{L} + \eta\boldsymbol{I})_{ts}\langle\boldsymbol{w}_t, \boldsymbol{w}_s\rangle,$$

where $\boldsymbol{L}$ is the graph-Laplacian associated to a matrix of edge weights ω_{ts}, $\boldsymbol{I}$ is the identity operator, and $\eta > 0$ is a regularization parameter. According to the identity $\sum_{t=1}^T\sum_{s=1}^T(\boldsymbol{L} + \eta\boldsymbol{I})_{ts}\langle\boldsymbol{w}_t, \boldsymbol{w}_s\rangle = \|(\boldsymbol{L} + \eta\boldsymbol{I})^{1/2}\boldsymbol{W}\|_F^2$, the corresponding hypothesis space is:

$$\mathcal{F}_G := \left\{X \mapsto [\left\langle \boldsymbol{w}_1, \phi(X_1)\right\rangle, \ldots, \left\langle \boldsymbol{w}_T, \phi(X_T)\right\rangle]^T : \frac{1}{2}\|\boldsymbol{D}^{1/2}\boldsymbol{W}\|_F^2 \leq R_{max}''^2\right\}. \tag{28}$$

where we define $\boldsymbol{D} := \boldsymbol{L} + \eta\boldsymbol{I}$.

Corollary 22 *For any given positive operator $\boldsymbol{D}$ in (28), the LRC of $\mathcal{F}_G$ is bounded by*

$$\mathfrak{R}(\mathcal{F}_G, r) \leq \sqrt{\frac{4}{nT}\left\|\left(\sum_{j=1}^{\infty}\min\left(r, \frac{2\boldsymbol{D}_{tt}^{-1}R_{max}''^2}{T}\lambda_t^j\right)\right)_{t=1}^{T}\right\|_1}. \tag{29}$$

where $\left(\boldsymbol{D}_{tt}^{-1}\right)_{t=1}^T$ are the diagonal elements of $\boldsymbol{D}^{-1}$.

See Appendix C for the proof.

Remark 23 *Note that if one considers a strongly convex norm of $\boldsymbol{W}$, an alternative proof strategy can be used to bound the A_2 term in* (13)*. This strategy is based on the duality of strong convexity and strong smoothness (Theorem 3 in Kakade et al. (2012)) along with the application of the Fenchel-Young inequality. This approach results in $A_2 \leq \mathcal{A}_{ub} := \sqrt{\frac{2}{\mu}\mathbb{E}_{X,\sigma}\left\|\boldsymbol{D}^{-1/2}\boldsymbol{V}\right\|_*^2}$, where μ is the strong convexity parameter. For the strongly convex cases considered in our study (e.g. $\frac{1}{2}\|\boldsymbol{W}\|_{2,q}^2$ or $\frac{1}{2}\|\boldsymbol{W}\|_{S_q}^2$ for any $q \in (1,2]$), it holds that $\mu \leq 1$ (see Theorem 16 and Corollary 19 in Kakade et al. (2009)). Now, comparing $\sqrt{2}\mathbb{E}_{X,\sigma}\left\|\boldsymbol{D}^{-1/2}\boldsymbol{V}\right\|_*$ in* (15) *with $\mathcal{A}_{ub}$, one can easily verify that $\sqrt{2}\mathbb{E}_{X,\sigma}\left\|\boldsymbol{D}^{-1/2}\boldsymbol{V}\right\|_* \overset{Jensen's}{\leq} \sqrt{\frac{2}{\mu}\mathbb{E}_{X,\sigma}\left\|\boldsymbol{D}^{-1/2}\boldsymbol{V}\right\|_*^2}$ for any $\mu \leq 1$. Therefore, for the strongly convex norms we considered here, Hölder's inequality yields slightly tighter bounds for the MT-LRC.*

5. Excess Risk Bounds for Norm Regularized MTL Models

In this section we will provide excess risk bounds for the hypothesis spaces considered earlier. Note that, due to space limitations, the proofs are provided only for the hypothesis space $\mathcal{F}_q$ with $q \in (1,2]$. However, for the cases involving the $L_{2,q}$-group norm with $q = 1$ or $q \geq 2$, as well as the L_{S_q}-Schatten and graph norms, the proofs can be obtained in a very similar fashion. More specifically, by using the LRC bounds of Remark 16, Corollary 19, Remark 21 and Corollary 22, one can follow the same proof steps shown in this section to arrive at the results pertaining to these cases.

Theorem 24 (Excess risk bound for an $L_{2,q}$ group norm regularized MTL) *Assume that $\mathcal{F}_q$ in* (16) *is a convex class of functions with ranges in $[-b,b]$ and let the loss function ℓ of Problem* (9) *satisfy Assumption 8. Let $\hat{\boldsymbol{f}}$ be any element of $\mathcal{F}_q$ for $1 < q \leq 2$ satisfying $P_n\ell_{\hat{\boldsymbol{f}}} = \inf_{\boldsymbol{f}\in\mathcal{F}_q} P_n\ell_{\boldsymbol{f}}$. Assume, moreover, that k is a positive definite kernel on $\mathcal{X}$ such that $\|k\|_\infty \leq \mathcal{K} < \infty$. Denote by r^* the fixed point of $2BL\mathfrak{R}(\mathcal{F}_q, \frac{r}{4L^2})$. Then, for any $K > 1$ and $x > 0$, with probability at least $1 - e^{-x}$, the excess loss of function class $\mathcal{F}_q$ is bounded as*

$$P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) \leq (2K)^{\frac{\beta}{2-\beta}} 20^{\frac{2}{2-\beta}} \max\left((r^*)^{\frac{1}{2-\beta}}, (r^*)^{\frac{1}{\beta}}\right) + \left(\frac{2^{\beta+3}B^2K^\beta x}{nT}\right)^{\frac{1}{2-\beta}} + \frac{48LBbx}{(2-\beta)nT},$$

where the fixed point r^* of the local Rademacher complexity $2BL\mathfrak{R}(\mathcal{F}_q, \frac{r}{4L^2})$ satisfies

$$r^* \leq \min_{0\leq h_t\leq\infty} \frac{B^2\sum_{t=1}^T h_t}{nT} + 4BL\sqrt{\frac{2eq^{*2}R_{max}^2}{nT^2}\left\|\left(\sum_{j>h_t}\lambda_t^j\right)_{t=1}^T\right\|_{\frac{q^*}{2}}} + \frac{4\sqrt{2\mathcal{K}e}R_{max}BLq^*T^{\frac{1}{q^*}}}{nT}, \tag{30}$$

and where $h_1, \ldots, h_T$ are arbitrary non-negative integers.

Proof First, notice that $\mathcal{F}_q$ is convex and, therefore, it is star-shaped around any of its elements. Hence, according to Lemma 3.4 in Bartlett et al. (2005)—which indicates that the local Rademacher complexity of the star-hull of any function class $\mathcal{F}$ is a sub-root function—$\mathfrak{R}(\mathcal{F}_q, r)$ is a sub-root function. Moreover, because of the symmetry of the σ_t^i's distribution and because $\mathcal{F}_q$ is convex and symmetric, it can be shown that $\mathfrak{R}(\mathcal{F}_q^*, r) \leq 2\mathfrak{R}(\mathcal{F}_q, \frac{r}{4L^2})$, where $\mathfrak{R}(\mathcal{F}_q^*, r)$ is defined in (6) for the

class of functions $\mathcal{F}_q$. Therefore, it suffices to find the fixed point of $2BL\mathfrak{R}(\mathcal{F}_q, \frac{r}{4L^2})$ by solving $\phi(r) = r$. For this purpose, we will use (19) as a bound for $\mathfrak{R}(\mathcal{F}_q, r)$, and solve $\sqrt{\alpha r} + \gamma = r$ (or equivalently $r^2 - (\alpha + 2\gamma)r + \gamma^2 = 0$) for r, where we define

$$\alpha := \frac{B^2\sum_{t=1}^T h_t}{nT}, \text{ and } \gamma := 2BL\sqrt{\frac{2eq^{*2}R_{max}^2}{nT^2}\left\|\left(\sum_{j>h_t}\lambda_t^j\right)_{t=1}^T\right\|_{\frac{q^*}{2}}} + \frac{2\sqrt{2\mathcal{K}e}R_{max}BLq^*T^{\frac{1}{q^*}}}{nT}. \tag{31}$$

It is not hard to verify that $r^* \leq \alpha + 2\gamma$. Substituting the definition of α and γ in $r^* \leq \alpha + 2\gamma$ gives the result. ■

Now, regarding the fact that the λ_t^js are non-increasing with respect to j, we can assume $\exists d_t : \lambda_t^j \leq d_t j^{-\alpha_t}$ for some $\alpha_t > 1$. For example, this assumption holds for finite rank kernels, as well as for convolution kernels. Thus, it can be shown that

$$\sum_{j>h_t}\lambda_t^j \leq d_t\sum_{j>h_t} j^{-\alpha_t} \leq d_t\int_{h_t}^\infty x^{-\alpha_t}dx = d_t\left[\frac{1}{1-\alpha_t}x^{1-\alpha_t}\right]_{h_t}^\infty = -\frac{d_t}{1-\alpha_t}h_t^{1-\alpha_t}. \tag{32}$$

Note that via the $l_q - to - l_p$ conversion inequality (21), for $p = 1$ and $q = \frac{q^*}{2}$, we have

$$\frac{B^2\sum_{t=1}^T h_t}{Tn} \leq B\sqrt{\frac{B^2T\sum_{t=1}^T h_t^2}{n^2T^2}} \overset{(\star\star)}{\leq} B\sqrt{\frac{B^2T^{2-\frac{2}{q^*}}\left\|\left(h_t^2\right)_{t=1}^T\right\|_{\frac{q^*}{2}}}{n^2T^2}}.$$

which with the help of $\sqrt{\alpha_1} + \sqrt{\alpha_2} \leq \sqrt{2(\alpha_1+\alpha_2)}$ for any $\alpha_1, \alpha_2 > 0$, and $\|\boldsymbol{a}_1\|_s + \|\boldsymbol{a}_2\|_s \leq 2\|\boldsymbol{a}_1 + \boldsymbol{a}_2\|_s$ for any non-negative vectors $\boldsymbol{a}_1, \boldsymbol{a}_2 \in \mathbb{R}^T$ and $s = \frac{q^*}{2}$ gives

$$r^* \leq \min_{0\leq h_t\leq\infty} 2B\sqrt{\left\|\left(\frac{B^2T^{2-\frac{2}{q^*}}h_t^2}{n^2T^2} - \frac{32d_teq^{*2}R_{max}^2L^2}{nT^2(1-\alpha_t)}h_t^{1-\alpha_t}\right)_{t=1}^T\right\|_{\frac{q^*}{2}}} + \frac{4\sqrt{2\mathcal{K}e}R_{max}BLq^*T^{\frac{1}{q^*}}}{nT}. \tag{33}$$

Taking the partial derivative of the above bound with respect to h_t and setting it to zero yields the optimal h_t as

$$h_t = \left(16d_teq^{*2}R_{max}^2B^{-2}L^2T^{\frac{2}{q^*}-2}n\right)^{\frac{1}{1+\alpha_t}}.$$

Note that substituting the previous expression for $\alpha := \min_{t\in\mathbb{N}_T}\alpha_t$ and $d = \max_{t\in\mathbb{N}_T} d_t$ into (33), we can upper-bound the fixed point of r^* as

$$r^* \leq \frac{14B^2}{n}\sqrt{\frac{\alpha+1}{\alpha-1}}\left(dq^{*2}R_{max}^2B^{-2}L^2T^{\frac{2}{q^*}-2}n\right)^{\frac{1}{1+\alpha}} + \frac{10\sqrt{\mathcal{K}}R_{max}BLq^*T^{\frac{1}{q^*}}}{nT},$$

which implies that

$$r^* = O\left(d^{\frac{1}{1+\alpha}}\left(\frac{T^{1-\frac{1}{q^*}}}{q^*}\right)^{\frac{-2}{1+\alpha}} n^{\frac{-\alpha}{1+\alpha}}\right).$$

It can be seen that the convergence rate can be as slow as $O\left(\frac{q^* T^{1/q^*}\sqrt{d}}{T\sqrt{n}}\right)$ (for small α, where at least one $\alpha_t \approx 1$), and as fast as $O(\frac{1}{n})$ (when $\alpha_t \to \infty$, for all t). The bound obtained for the fixed point together with Theorem 24 provides a bound for the excess risk, which leads to the following remark. Note that in the sequel, we assume that the data distribution of each task is concentrated and uniform on the same M-dimensional unit sphere. This implies that (by symmetry) the eigenvalues must all be equal and they sum up to 1. Thus, for each task t, $\lambda_t^j = \frac{1}{M}$. On the other hand, we assumed earlier that $\lambda_t^j \le d_t j^{-\alpha}$ for all $1 \le j \le M$. Therefore, choosing $j = M$, we are forced to set $d = M^{\alpha-1}$.

Remark 25 (Excess risk bounds for selected norm regularized MTL problems) *Assume that $\mathcal{F}$ is a class of functions with ranges in $[-b, b]$. Let the loss function ℓ of Problem* (9) *satisfy Assumption 8. Additionally, assume that k is a positive definite kernel on $\mathcal{X}$, such that $\|k\|_\infty \le \mathcal{K} < \infty$. Also, denote $\alpha := \min_{t\in\mathbb{N}_T} \alpha_t$ and $d := max_{t\in\mathbb{N}_T} d_t$. Then, for any $\boldsymbol{f} \in \mathcal{F}$, $K > 1$ and $x > 0$, with probability at least $1 - e^{-x}$,*

$$P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) \le (2K)^{\frac{\beta}{2-\beta}} 20^{\frac{2}{2-\beta}} \max\left((r^*)^{\frac{1}{2-\beta}}, (r^*)^{\frac{1}{\beta}}\right) + \left(\frac{2^{\beta+3} B^2 K^\beta x}{nT}\right)^{\frac{1}{2-\beta}} + \frac{48LBbx}{(2-\beta)nT}, \tag{34}$$

where, for $\mathcal{F} \in \{\mathcal{F}_q, \mathcal{F}_{S_q}, \mathcal{F}_G\}$, $\hat{\boldsymbol{f}}$ is such that $P_n \ell_{\hat{\boldsymbol{f}}} = \inf_{\boldsymbol{f}\in\mathcal{F}} P_n \ell_{\boldsymbol{f}}$ and r^* is the fixed point of the local Rademacher complexity $2BL\mathfrak{R}(\mathcal{F}, \frac{r}{4L^2})$. Furthermore, r^* can be bounded for each of the three hypothesis spaces as follows:

- *Group norm: For any $1 < q \le 2$,*

$$r^* \le \min_{\kappa\in[q,2]} 14\sqrt{\frac{\alpha+1}{\alpha-1}}\left(\kappa^{*2} R_{max}^2 L^2\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} B^{\frac{2\alpha}{\alpha+1}} \left(T^{\frac{2}{\kappa}}\right)^{\frac{-1}{1+\alpha}} n^{\frac{-\alpha}{1+\alpha}} + \frac{10\sqrt{\mathcal{K}} R_{max} BL\kappa^* T^{\frac{1}{\kappa^*}}}{nT}. \tag{35}$$

  Also, for any $q \ge 2$, we have

$$r^* \le 8\sqrt{\frac{\alpha+1}{\alpha-1}}\left(R_{max}^2 L^2\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} B^{\frac{2\alpha}{\alpha+1}} \left(T^{\frac{2}{q}}\right)^{\frac{-1}{1+\alpha}} n^{\frac{-\alpha}{1+\alpha}}. \tag{36}$$

- *Schatten norm: For any $1 < q \le 2$,*

$$r^* \le 8\sqrt{\frac{\alpha+1}{\alpha-1}}\left(q^* R_{max}'^2 L^2\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} B^{\frac{2\alpha}{\alpha+1}} T^{\frac{-1}{1+\alpha}} n^{\frac{-\alpha}{1+\alpha}}. \tag{37}$$

  Note that for the trace norm, we would have $q^* = 2$ in the previous bound (see Remark 20). Additionally, for any $q \ge 2$, it holds

$$r^* \le 8\sqrt{\frac{\alpha+1}{\alpha-1}}\left(R_{max}'^2 L^2\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} B^{\frac{2\alpha}{\alpha+1}} \left(T^{\frac{2}{q}}\right)^{\frac{-1}{1+\alpha}} n^{\frac{-\alpha}{1+\alpha}}. \tag{38}$$

- *Graph regularizer: For any positive operator $\boldsymbol{D}$,*

$$r^* \le 8\sqrt{\frac{\alpha+1}{\alpha-1}}\left(R_{max}''^2 L^2 \boldsymbol{D}_{max}^{-1}\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} B^{\frac{2\alpha}{\alpha+1}} T^{\frac{-1}{1+\alpha}} n^{\frac{-\alpha}{1+\alpha}}. \tag{39}$$

  where $\boldsymbol{D}_{max}^{-1} := \max_{t\in\mathbb{N}_T} \boldsymbol{D}_{tt}^{-1}$.

6. Discussion

In this section, we investigate the convergence rate of our LRC-based excess risk bounds, which were established in the previous section. We also discuss related works and provide a new excess risk bound by employing a rather different approach, which exhibits the benefit of a MTL regularizer at the expense of a slower convergence rate in terms of the number of examples per task n. Note that, for the purpose of this section, we will assume that $\beta = 1$, which hold for many loss function classes, see Bartlett et al. (2004) for a discussion.

6.1 Convergence Rates

In order to facilitate a more concrete comparison of convergence rates, we will assume the same spherical M-dimensional data distribution for each task t; this assumption leads to $\lambda_t^j = \frac{1}{M}$, or equivalently $d = M^{\alpha-1}$. Furthermore, we will concentrate only on the parameters R, n, T, q^*, M and α and we will assume that all the other parameters are fixed and, hence, hidden in the big-O notation. Thus, for our LRC-based bounds we have

$$\begin{aligned}
\text{Group norm:}\quad & \text{(a) } \forall \kappa \in [q,2], \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left(\left(R_{max}^2 \kappa^{*2}\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} \left(T^{\frac{2}{\kappa}}\right)^{-\frac{1}{1+\alpha}} n^{\frac{-\alpha}{1+\alpha}}\right).\\
& \text{(b) } \forall q \in [2,\infty], \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left(\left(R_{max}^2\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} \left(T^{\frac{2}{q}}\right)^{-\frac{1}{1+\alpha}} n^{\frac{-\alpha}{1+\alpha}}\right).\\
\text{Schatten norm:}\quad & \text{(c) } \forall q \in (1,2], \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left(\left(R_{max}'^2\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} T^{\frac{-1}{1+\alpha}} n^{\frac{-\alpha}{1+\alpha}}\right).\\
& \text{(d) } \forall q \in [2,\infty], \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left(\left(R_{max}'^2\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} \left(T^{\frac{2}{q}}\right)^{-\frac{1}{1+\alpha}} n^{\frac{-\alpha}{1+\alpha}}\right).\\
\text{Graph:}\quad & \text{(e)} \qquad\qquad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left(\left(R_{max}''^2\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} T^{\frac{-1}{1+\alpha}} n^{\frac{-\alpha}{1+\alpha}}\right).
\end{aligned} \tag{40}$$

A close appraisal of the results in (40) points to a conservation of asymptotic rates between n and T, when all other remaining quantities are held fixed. This phenomenon is more apparent for the Schatten norm and graph-based regularization cases, where the rates (exponents) of n and T sum up to -1. Note that the trade-off is determined by the value of α, which can facilitate faster n-rates and, simultaneously, compromise with slower T-rates. A similar trade-off is witnessed in the case of group norm regularization, but this time between n and $T^{2/\kappa}$, instead of T, due to the specific characteristics of the group norm. Now, consider the following two cases:

- M is large (high-dimensional data distribution): Note that in the case of very large M, $\alpha > 1$; Also, large M implies small α, that is, $\alpha \to 1$. In this case we get dimension-independent bounds, which should be considered as an advantage for the case of high-dimensional data distribution.

$$\text{Group norm:}\quad \text{(a) } \forall \kappa \in [q,2], \qquad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left(\left(R_{max}^2 \kappa^{*2}\right)^{\frac{1}{2}} \left(T^{\frac{2}{\kappa}}\right)^{-\frac{1}{2}} n^{-\frac{1}{2}}\right).$$

$$\text{(b) } \forall q \in [2,\infty], \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left((R_{max}^2)^{\frac{1}{2}} \left(T^{\frac{2}{q}}\right)^{-\frac{1}{2}} n^{-\frac{1}{2}}\right).$$

Schatten-norm:

$$\text{(c) } \forall q \in (1,2], \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left((R_{max}'^2 q^*)^{\frac{1}{2}} T^{\frac{-1}{2}} n^{-\frac{1}{2}}\right).$$

$$\text{(d) } \forall q \in [2,\infty], \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left((R_{max}'^2)^{\frac{1}{2}} \left(T^{\frac{2}{q}}\right)^{-\frac{1}{2}} n^{-\frac{1}{2}}\right).$$

Graph:

$$\text{(e)} \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left((R_{max}''^2)^{\frac{1}{2}} T^{\frac{-1}{2}} n^{-\frac{1}{2}}\right).$$

- M is small (low-dimensional data distribution): This case happens when the decay rate α is fast ($\alpha \to \infty$), which gives the following rates

Group norm:

$$\text{(a) } \forall \kappa \in [q,2], \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left(Mn^{-1}\right).$$

$$\text{(b) } \forall q \in [2,\infty], \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left(Mn^{-1}\right).$$

Schatten-norm:

$$\text{(c) } \forall q \in (1,2], \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left(Mn^{-1}\right).$$

$$\text{(d) } \forall q \in [2,\infty], \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left(Mn^{-1}\right).$$

Graph:

$$\text{(e)} \quad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) = O\left(Mn^{-1}\right).$$

Note that, most likely, a more realistic case lies somewhere in between these two extreme cases, which can be interpreted as follows: when the data is relatively low-dimensional (small M and fast decay of eigenvalues), we will have bounds with fast rates in n. However, MTL may offer little advantage in this case due to the corresponding slow rates in T. This analysis confirms the general belief that MTL proffers a potential advantage if there are many tasks with little data per task and are sampled from high-dimensional data distributions.

6.2 Comparisons to Related Works

It is interesting to compare our local bound for the trace norm regularized MTL with the GRC-based excess risk bound provided in Maurer and Pontil (2013), wherein they apply a trace norm regularizer to capture the tasks' relatedness. It is worth mentioning that they consider a slightly different hypothesis space for $\boldsymbol{W}$ than the one we mentioned earlier; in our notation, this space reads as

$$\mathcal{F}'_{S_1} := \left\{ \boldsymbol{W} : \frac{1}{2} \|\boldsymbol{W}\|_{S_1}^2 \leq T R_{max}'^2 \right\}. \tag{41}$$

The form of this space is based on the premise that, assuming a common vector $\boldsymbol{w}$ for all tasks, the regularizer should not be a function of the number of tasks (Maurer and Pontil, 2013). Given the task-averaged covariance operator $C := 1/T \sum_{t=1}^T J_t = 1/T \sum_{t=1}^T \mathbb{E}\left(\phi(X_t) \otimes \phi(X_t)\right)$, the excess risk bound in Maurer and Pontil (2013) reads as

$$P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) \leq 2\sqrt{2} L R'_{max} \left(\sqrt{\frac{\|C\|_\infty}{n}} + 5 \sqrt{\frac{\ln(nT)+1}{nT}} \right) + \sqrt{\frac{bLx}{nT}}.$$

Under the aforementioned M-dimensional data distributions and by using the hypothesis space of (41), our local bound for the trace norm for any $\alpha > 1$ is given as

$$P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) \leq 6400K \sqrt{\frac{\alpha+1}{\alpha-1}} \left(R_{max}'^2 L^2\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} B^{\frac{2\alpha}{\alpha+1}} n^{\frac{-\alpha}{1+\alpha}} + \frac{(48Lb + 16BK)Bx}{nT}. \tag{42}$$

Now, let λ_t^{max} be the maximum eigenvalue of the trace operator J_t. Also, let $\lambda_{max} := \max_{t \in \mathbb{N}_T} \{\lambda_t^{max}\}$. It is easy to verify that $\mathbf{tr}(J_t) \leq M \lambda_t^{max}$ and $\|C\|_\infty \leq \lambda_{max} = 1/M$, which renders the GRC-based bound in Maurer and Pontil (2013) into the form

$$P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) \leq 2\sqrt{2} L R'_{max} \left(\sqrt{\frac{\lambda_{max}}{n}} + 5 \sqrt{\frac{\ln(nT)+1}{nT}} \right) + \sqrt{\frac{bLx}{nT}}. \tag{43}$$

One observes that, in both cases, the bound vanishes as $n \to \infty$. However, it does so at a rate of $n^{-\alpha/1+\alpha}$ for our local bound in (42) and at a slower rate of $\sqrt{\ln n / n}$ for the one in (43). Also, we remark that, as $T \to \infty$, both bounds converge to a non-zero limit: our local bound in (42) at a fast rate of $1/T$ and at a the slower rate of $\sqrt{\ln T / T}$ for the bound in (43). More specifically, making the benevolent choices $B = 1$ and $R'_{max} L = 1$ and ignoring the factor of $6400K\sqrt{\frac{\alpha+1}{\alpha-1}}$, the limit of our local bound in (42) as $T \to \infty$ becomes $g(\alpha) := M^{\frac{\alpha-1}{1+\alpha}} n^{\frac{-\alpha}{1+\alpha}}$. One can very easily verify that $g(\alpha)$ is increasing in α (*i.e.* $g'(\alpha) > 0$), if and only if $\ln(Mn^{-\frac{1}{2}}) > 0$, or, equivalently, $M > \sqrt{n}$. In this case the optimal choice of $\alpha \in (1,\infty)$ (*i.e.* $\alpha \approx 1$) makes our local bound of the order $O(\frac{1}{\sqrt{n}})$. In other words, when the data distribution is sufficiently high-dimensional relative to n, the LRC bound fails in competing with the $O(\frac{1}{\sqrt{Mn}})$ GRC bound in Maurer and Pontil (2013). On the other hand, for lower dimensional distributions or sufficiently large n, we obtain a rate of $1/n$ for the LRC bound at the expense of explicit dependence on the dimension. In particular, the local bound remains larger than the GRC bound in (43) until $n = M^3$ and improves only for larger sample sizes per task.

Another interesting comparison can be performed between our bounds and the one introduced in Maurer (2006b) for a graph regularized MTL. Similar to Maurer (2006b), we consider the following hypothesis space

$$\mathcal{F}'_G = \left\{ \boldsymbol{W} : \frac{1}{2} \left\| \boldsymbol{D}^{1/2} \boldsymbol{W} \right\|_F^2 \leq T R_{max}''^2 \right\}. \tag{44}$$

Maurer (2006b) provides a bound on the empirical GRC of the aforementioned hypothesis space that can be easily converted to a distribution dependent GRC bound of the form

$$\mathfrak{R}\left(\mathcal{F}'_G\right) \leq \sqrt{\frac{2R_{max}''^2}{nT} \left\| \left(\boldsymbol{D}_{tt}^{-1} \mathbf{tr}(J_t)\right)_{t=1}^T \right\|_1}.$$

Now, with $\boldsymbol{D} := \boldsymbol{L} + \eta \boldsymbol{I}$ (where $\boldsymbol{L}$ is the graph-Laplacian, $\boldsymbol{I}$ is the identity operator, and $\eta > 0$ is a regularization parameter) and the same M-dimensional distributional assumptions, it can be shown that

$$\left\| \left(\boldsymbol{D}_{tt}^{-1} \mathbf{tr}(J_t)\right)_{t=1}^T \right\|_1 = \sum_{t=1}^T \boldsymbol{D}_{tt}^{-1} \mathbf{tr}(J_t) \leq M \lambda_{max} \sum_{t=1}^T \boldsymbol{D}_{tt}^{-1} = M \lambda_{max} \mathbf{tr}\left(\boldsymbol{D}^{-1}\right) =$$

$$= M \lambda_{max} \mathbf{tr}\left(\boldsymbol{L} + \eta \boldsymbol{I}\right)^{-1} = M \lambda_{max} \left(\sum_{t=1}^T \frac{1}{\delta_t + \eta} + \frac{1}{\eta} \right) \leq M \lambda_{max} \left(\frac{T}{\delta_{min} + \eta} + \frac{1}{\eta} \right).$$

where $\lambda_{max} = \frac{1}{M}$ as argued earlier. Furthermore, let $\{\delta_2, \ldots, \delta_T\}$ be the nonzero eigenvalues of $\boldsymbol{L}$ with $\delta_{min} := \min\{\delta_2, \ldots, \delta_T\}$. Then, the GRC-based excess risk bound is obtained as

$$\text{Maurer (2006b) :} \qquad P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) \leq \frac{2LR''_{max}}{\sqrt{n}} \sqrt{2M\lambda_{max} \left(\frac{1}{\delta_{min}} + \frac{1}{T\eta} \right)} + \sqrt{\frac{bLx}{nT}}$$

(45)

Also, based on Remark 25, the LRC-based bound is given as

$$P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) \leq 6400K\sqrt{\frac{\alpha+1}{\alpha-1}}\left(R''^2_{max}L^2\boldsymbol{D}^{-1}_{max}\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} B^{\frac{2\alpha}{\alpha+1}} n^{\frac{-\alpha}{1+\alpha}} + \frac{(48Lb+16BK)Bx}{nT}. \tag{46}$$

The above results show that, when $n \to \infty$, both GRC and LRC bounds approach zero, albeit at different rates: the global bound at a rate of $\sqrt{1/n}$ and the local one at a faster rate of $n^{-\alpha/\alpha+1}$, since $\alpha > 1$. Additionally, both bounds approach non-zero limits as $T \to \infty$. Nevertheless, the global bound does so at a rate of $\sqrt{1/T}$ and the local one at a faster rate of $1/T$. Furthermore, similar to the previous case, it can be shown that at the limit $T \to \infty$, for high-dimensional data distribution (large M, small $\alpha \approx 1$), both local and global bounds yield the same convergence rate of $O(\frac{1}{\sqrt{n}})$. However, for low number of dimensions relative to n (in specific, for $M < n^{\frac{1}{3}}$), our bound improves over the GRC bound.

6.3 A Different Technique for The Trace Norm Regularized Space $\mathcal{F}'_{S_1}$

In what follows, we show that, by applying a rather different proof technique (departing from Theorem 11), we can obtain an excess risk bound for the MTL space $\mathcal{F}'_{S_1}$ in (41), which aims at slower rates in n and T, but exhibits the benefits of a multi-task regularizer. Recall that $\mathcal{F}'_{S_1}$ is given as

$$\mathcal{F}'_{S_1} := \left\{ X \mapsto [\langle \boldsymbol{w}_1, \phi(X_1)\rangle, \ldots, \langle \boldsymbol{w}_T, \phi(X_T)\rangle]^T : \frac{1}{2}\|\boldsymbol{W}\|^2_{S_1} \leq TR'^2_{max} \right\}. \tag{47}$$

Also recall that, from Theorem 11, it can be shown that the LRC of $\mathcal{F}'_{S_1}$ can be bounded as

$$\mathfrak{R}(\mathcal{F}'_{S_1}, r) \leq \min_{0\leq h_t \leq \infty} \left\{ \sqrt{\frac{r\sum_{t=1}^T h_t}{nT}} + \sqrt{\frac{2R'^2_{max}}{n^2T}}\mathbb{E}_{X,\sigma}\left\|\boldsymbol{V}'\right\|_{S_\infty} \right\}, \tag{48}$$

where

$$\boldsymbol{V}' := \left(\sum_{j>h_t} \left\langle \sum_{i=1}^n \sigma_t^i \phi(X_t^i), \boldsymbol{u}_t^j \right\rangle \boldsymbol{u}_t^j \right)_{t=1}^T. \tag{49}$$

Now, following an approach similar to the one applied in Maurer and Pontil (2013), we will bound $\mathbb{E}_{X,\sigma}\|\boldsymbol{V}'\|_{S_\infty}$ to yield the next theorem. Note that $\|.\|_{S_\infty}$ stands for the operator norm on the separable Hilbert space $\mathcal{H}$.

Theorem 26 *Assume that the conditions of Theorem 24 hold for the hypothesis space $\mathcal{F}'_{S_1}$ in* (47)*. Also, denote by r^* the fixed point of $2BL\mathfrak{R}(\mathcal{F}'_{S_1}, \frac{r}{4L^2})$. Then, for any $K > 1$ and $x > 0$, with probability at least $1 - e^{-x}$, the excess loss of function class $\mathcal{F}'_{S_1}$ is bounded as*

$$P(\ell_{\hat{\boldsymbol{f}}} - \ell_{\boldsymbol{f}^*}) \leq (2K)^{\frac{\beta}{2-\beta}} 20^{\frac{2}{2-\beta}} \max\left((r^*)^{\frac{1}{2-\beta}}, (r^*)^{\frac{1}{\beta}}\right) + \left(\frac{2^{\beta+3}B^2K^\beta x}{nT}\right)^{\frac{1}{2-\beta}} + \frac{48LBbx}{(2-\beta)nT},$$

for

$$r^* \leq \min_{0\leq h_t\leq\infty} \left\{ \frac{B^2\sum_{t=1}^T h_t}{nT} + 4BL\sqrt{\frac{2R'^2_{max}\lambda_h}{n}} + 24BL\sqrt{\frac{2R'^2_{max}\mathcal{K}\left(\ln(nT)+1\right)}{nT}} \right\}, \tag{50}$$

where $\lambda_h := \max_{t\in\mathbb{N}_T}\{\lambda_t^{h_t}\}$ and where $h_1, \ldots, h_T$ are arbitrary non-negative integers.

The proof of the results is provided in Appendix D.

By considering the same M-dimensional data distribution, the bound in (50) becomes

$$r^* \leq 6BLR'_{max}\left(\sqrt{\frac{1}{Mn}} + 6\sqrt{\frac{\mathcal{K}\left(\ln(nT)+1\right)}{nT}}\right). \tag{51}$$

It can be seen that, when the number of tasks T approaches ∞, the above bound simplifies to

$$r^* \leq \frac{6BLR'_{max}}{\sqrt{Mn}}.$$

In the sequel, we compare the two bounds (37) and (51) for the trace norm regularized MTL models in terms of their convergence rates.

Remark 27 *Using two different techniques, we proved the two following bounds on the fixed point r^* of the local Rademacher complexity $2BL\mathfrak{R}(\mathcal{F}'_{S_1}, \frac{r}{4L^2})$:*

- *Our approach*

$$r^* \leq 12\sqrt{\frac{\alpha+1}{\alpha-1}}\left(R'^2_{max}L^2\right)^{\frac{1}{1+\alpha}} M^{\frac{\alpha-1}{1+\alpha}} B^{\frac{2\alpha}{\alpha+1}} n^{\frac{-\alpha}{1+\alpha}}. \tag{52}$$

- *MP approach (Maurer and Pontil, 2013)*

$$r^* \leq 6BLR'_{max}\left(\sqrt{\frac{1}{Mn}} + 6\sqrt{\frac{\mathcal{K}\left(\ln(nT)+1\right)}{nT}}\right). \tag{53}$$

As a reminder, the proof of Theorem 11 refers to two terms: A_1, which embodies a variance constraint, and A_2, which constitutes a MTL regularization constraint. The aforementioned bounds were derived by using two different approaches to bound the A_2 term, namely the LRC-based approach for (52) *and the MP technique for* (53)*. In the case of* (52)*, due to the LRC-based approach, the variance constraint (A_1 term) plays a dominant role in the overall bound and, thus, yields faster rates in n for any $\alpha > 1$. However, it offers no improvements in the limit $T \to \infty$, since this bound does not decrease with increasing T. In contrast, using the MP technique, the MTL regularization constraint (A_2 term) is dominant in* (53)*. While this prevents obtaining faster rates in terms of the number of samples, it potentially offers the advantages of MTL for large T and high-dimensional data distributions.*

Appendices

Appendix A. Proof of Theorem 1

This section presents the proof of Theorem 1. We first provide some useful foundations used in the derivation of our result in Theorem 1.

Theorem A.1 (Theorem 2 in Boucheron et al. (2003)) *Let $X_1, \dots, X_n$ be n independent random variables taking values in a measurable space $\mathcal{X}$. Assume that $g : \mathcal{X}^n \to \mathbb{R}$ is a measurable function and $Z := g(X_1, \dots, X_n)$. Let $X'_1, \dots, X'_n$ denote an independent copy of $X_1, \dots, X_n$, and $Z'_i := g(X_1, \dots, X_{i-1}, X'_i, X_{i+1}, \dots, X_n)$, which is obtained by replacing the variable X_i with X'_i. Define the random variable $V^+ := \sum_{i=1}^n \mathbb{E}'\big[(Z - Z'_i)_+^2\big]$, where $(u)_+ := \max\{u, 0\}$, and $\mathbb{E}'[\cdot] := \mathbb{E}[\cdot|X]$ denotes the expectation only w.r.t. the variables $X'_1, \dots, X'_n$. Let $\theta > 0$ and $\lambda \in (0, 1/\theta)$. Then,*

$$\log \mathbb{E}\big[e^{\lambda(Z - \mathbb{E}Z)}\big] \leq \frac{\lambda\theta}{1 - \lambda\theta} \log \mathbb{E}\big[\exp\big(\frac{\lambda V^+}{\theta}\big)\big].$$

Definition A.2 (Section 3.3 in Boucheron et al. (2013)) *A function $g : \mathcal{X}^n \to [0, \infty)$ is said to be b-self bounding ($b > 0$), if there exist functions $g_i : \mathcal{X}^{n-1} \to \mathbb{R}$, such that for all $X_1, \dots, X_n \in \mathcal{X}$ and all $i \in \mathbb{N}_n$,*

$$0 \leq g(X_1, \dots, X_n) - g_i(X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_n) \leq b,$$

and

$$\sum_{i=1}^n \big[g(X_1, \dots, X_n) - g_i(X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_n)\big] \leq g(X_1, \dots, X_n).$$

Theorem A.3 (Theorem 6.12 in Boucheron et al. (2013)) *Assume that $Z = g(X_1, \dots, X_n)$ is a b-self bounding function ($b > 0$). Then, for any $\lambda \in \mathbb{R}$ we have*

$$\log \mathbb{E}e^{\lambda Z} \leq \frac{\big(e^{\lambda b} - 1\big)}{b} \mathbb{E}Z.$$

Lemma A.4 (Lemma 2.11 in Bousquet (2002)) *Let Z be a random variable, $A, B > 0$ be some constants. If for any $\lambda \in (0, 1/B)$ it holds*

$$\log \mathbb{E}\big(e^{\lambda(Z - \mathbb{E}Z)}\big) \leq \frac{A\lambda^2}{2\big(1 - B\lambda\big)},$$

then, for all $x \geq 0$,

$$\Pr\big[Z \geq \mathbb{E}Z + \sqrt{2Ax} + Bx\big] \leq e^{-x}.$$

Lemma A.5 (Contraction property in Bartlett et al. (2005)) *Let ϕ be a Lipschitz function with Lipschitz constant $L \geq 0$, that is, $|\phi(a) - \phi(b)| \leq L|a - b|$, $\forall a, b \in \mathbb{R}$. Let $X_1, \dots, X_n$ be n independent random variables. Then, for every real-valued function class $\mathcal{F}$, it holds*

$$\mathbb{E}_\sigma \sup_{f \in \mathcal{F}} \sum_{i=1}^n \sigma_i \phi(f(X_i)) \leq L \mathbb{E}_\sigma \sup_{f \in \mathcal{F}} \sum_{i=1}^n \sigma_i f(X_i). \tag{A.1}$$

Note that, in Theorem 17 of Maurer (2006a), it has been shown that the result of this lemma also holds for classes of vector-valued functions.

Proof of Theorem 1

Before laying out the details, we first provide a sketch of the proof. By defining

$$Z := \sup_{\boldsymbol{f}\in\mathcal{F}} \Big[\frac{1}{T}\sum_{t=1}^{T}\frac{1}{N_t}\sum_{i=1}^{N_t}[\mathbb{E}f_t(X_t^i) - f_t(X_t^i)]\Big], \tag{A.2}$$

we first apply Theorem A.1 to control the log-moment generating function $\log\mathbb{E}\big(e^{\lambda(Z-\mathbb{E}Z)}\big)$. From Theorem A.1, we know that the main component to control $\log\mathbb{E}\big(e^{\lambda(Z-\mathbb{E}Z)}\big)$ is the variance-type quantity $V^+ = \sum_{s=1}^{T}\sum_{j=1}^{N_s}\mathbb{E}'\big[\big(Z - Z'_{s,j}\big)_+^2\big]$. In the next step, we show that V^+ can also be bounded in terms of two other quantities denoted by W and Υ. Applying Theorem A.1 for a specific value of θ, then gives a bound for $\log\mathbb{E}\big(e^{\lambda(Z-\mathbb{E}Z)}\big)$ in terms of $\log\mathbb{E}[e^{\frac{\lambda}{b'}(W+\Upsilon)}]$. We then turn to controlling W and Υ respectively. Our approach to tackle W is to show that it is a self-bounding function and then apply Theorem A.3 to control $\log\mathbb{E}[e^{\frac{\lambda W}{b'}}]$. The Υ term is closely related to the constraint imposed on the variance of functions in $\mathcal{F}$ and can be easily upper-bounded in terms of r. We finally apply Lemma A.4 to transfer the upper bound on the log-moment generating function $\log\mathbb{E}\big(e^{\lambda(Z-\mathbb{E}Z)}\big)$ to the tail probability on Z. For clarify, we divide the proof into four main steps.

Step 1. Controlling the log-moment generating function of Z with the random variable W and variance Υ. Let $X' := (X_t'^i)_{(t,i)=(1,1)}^{(T,N_t)}$ be an independent copy of $X := (X_t^i)_{(t,i)=(1,1)}^{(T,N_t)}$. Define the quantity $Z'_{s,j}$ by replacing the variable X_s^j in Z with $X_s'^j$. Then,

$$Z'_{s,j} := \sup_{\boldsymbol{f}\in\mathcal{F}} \Big[\frac{1}{TN_s}\big[\mathbb{E}'f_s(X_s'^j) - f_s(X_s'^j)\big] - \frac{1}{TN_s}\big[\mathbb{E}f_s(X_s^j) - f_s(X_s^j)\big] + \frac{1}{T}\sum_{t=1}^{T}\frac{1}{N_t}\sum_{i=1}^{N_t}[\mathbb{E}f_t(X_t^i) - f_t(X_t^i)]\Big]. \tag{A.3}$$

Let $\hat{\boldsymbol{f}} := (\hat{f}_1, \dots \hat{f}_T)$ be such that $Z = \frac{1}{T}\sum_{t=1}^{T}\frac{1}{N_t}\sum_{i=1}^{N_t}\big[\mathbb{E}\hat{f}_t(X_t^i) - \hat{f}_t(X_t^i)\big]$ and introduce

$$W := \sup_{\boldsymbol{f}\in\mathcal{F}} \Big[\frac{1}{T^2}\sum_{t=1}^{T}\frac{1}{N_t^2}\sum_{i=1}^{N_t}[\mathbb{E}f_t(X_t^i) - f_t(X_t^i)]^2\Big],$$

$$\Upsilon := \sup_{\boldsymbol{f}\in\mathcal{F}} \Big[\frac{1}{T^2}\sum_{t=1}^{T}\frac{1}{N_t^2}\sum_{i=1}^{N_t}\mathbb{E}[\mathbb{E}f_t(X_t^i) - f_t(X_t^i)]^2\Big].$$

It can be shown that, for any $j \in \mathbb{N}_n$ and any $s \in \mathbb{N}_T$,

$$Z - Z'_{s,j} \le \frac{1}{TN_s}\big[\mathbb{E}\hat{f}_s(X_s^j) - \hat{f}_s(X_s^j)\big] - \frac{1}{TN_s}\big[\mathbb{E}'\hat{f}_s(X_s'^j) - \hat{f}_s(X_s'^j)\big]$$

and, therefore,

$$(Z - Z'_{s,j})_+^2 \le \frac{1}{T^2N_s^2}\big([\mathbb{E}\hat{f}_s(X_s^j) - \hat{f}_s(X_s^j)] - [\mathbb{E}'\hat{f}_s(X_s'^j) - \hat{f}_s(X_s'^j)]\big)^2.$$

Then, from the identity $\mathbb{E}'[\mathbb{E}'\hat{f}_s(X_s'^j) - \hat{f}_s(X_s'^j)] = 0$, it follows that

$$\sum_{s=1}^{T}\sum_{j=1}^{N_s}\mathbb{E}'\big[\big(Z - Z'_{s,j}\big)_+^2\big] \le \sum_{s=1}^{T}\sum_{j=1}^{N_s}\frac{1}{T^2N_s^2}\mathbb{E}'\Big[\Big([\mathbb{E}\hat{f}_s(X_s^j) - \hat{f}_s(X_s^j)] - [\mathbb{E}'\hat{f}_s(X_s'^j) - \hat{f}_s(X_s'^j)]\Big)^2\Big]$$

$$\begin{aligned}
&= \sum_{s=1}^{T}\sum_{j=1}^{N_s}\frac{1}{T^2N_s^2}[\mathbb{E}\hat{f}_s(X_s^j) - \hat{f}_s(X_s^j)]^2 + \sum_{s=1}^{T}\sum_{j=1}^{N_s}\frac{1}{T^2N_s^2}\mathbb{E}'[\mathbb{E}'\hat{f}_s(X_s'^j) - \hat{f}_s(X_s'^j)]^2\\
&\le \sup_{\boldsymbol{f}\in\mathcal{F}}\sum_{s=1}^{T}\sum_{j=1}^{N_s}\frac{1}{T^2N_s^2}[\mathbb{E}f_s(X_s^j) - f_s(X_s^j)]^2 + \sup_{\boldsymbol{f}\in\mathcal{F}}\sum_{s=1}^{T}\sum_{j=1}^{N_s}\frac{1}{T^2N_s^2}\mathbb{E}[\mathbb{E}f_s(X_s^j) - f_s(X_s^j)]^2\\
&= W + \Upsilon.
\end{aligned}$$

Introduce $b' := \frac{2b}{nT}$. Applying Theorem A.1 and the above bound to $\sum_{s=1}^{T}\sum_{j=1}^{N_s}\mathbb{E}'\big[\big(Z - Z'_{s,j}\big)_+^2\big]$ yields the following bound on the log-moment generating function of Z

$$\log\mathbb{E}\big[e^{\lambda(Z-\mathbb{E}Z)}\big] \le \frac{\lambda b'}{1-\lambda b'}\log\mathbb{E}\big[e^{\frac{\lambda}{b'}(W+\Upsilon)}\big], \quad \forall\lambda \in (0, 1/b'). \tag{A.4}$$

Step 2. Controlling the log-moment generating function of W. We now upper-bound the log-moment generating function of W by showing that it is a self-bounding function. For any $s \in \mathbb{N}_T, j \in \mathbb{N}_{N_s}$, introduce

$$W_{s,j} := \sup_{\boldsymbol{f}\in\mathcal{F}} \Big[\frac{1}{T^2}\sum_{t=1}^{T}\frac{1}{N_t^2}\sum_{i=1}^{N_t}[\mathbb{E}f_t(X_t^i) - f_t(X_t^i)]^2 - \frac{1}{T^2N_s^2}[\mathbb{E}f_s(X_s^j) - f_s(X_s^j)]^2\Big].$$

Note that $W_{s,j}$ is a function of $\{X_t^i, t \in \mathbb{N}_T, i \in \mathbb{N}_{N_t}\}\backslash\{X_s^j\}$. Letting $\tilde{\boldsymbol{f}} := (\tilde{f}_1, \dots, \tilde{f}_T)$ be the function achieving the supremum in the definition of W, one can verify that (note that $b' = \frac{2b}{nT}$)

$$T^2[W - W_{s,j}] \le \frac{1}{N_s^2}[\mathbb{E}\tilde{f}_s(X_s^j) - \tilde{f}_s(X_s^j)]^2 \le \frac{4b^2}{n^2} = T^2b'^2. \tag{A.5}$$

Similarly, if $\tilde{\boldsymbol{f}}^{s,j} := (\tilde{f}_1^{s,j} \dots, \tilde{f}_T^{s,j})$ is the function achieving the supremum in the definition of $W_{s,j}$, then one can derive the following inequality

$$T^2[W - W_{s,j}] \ge \frac{1}{N_s^2}[\mathbb{E}\tilde{f}_s^{s,j}(X_s^j) - \tilde{f}_s^{s,j}(X_s^j)]^2 \ge 0.$$

Also, it can be shown that

$$\begin{aligned}
\sum_{s=1}^{T}\sum_{i=1}^{N_s}[W - W_{s,j}] &\le \frac{1}{T^2}\sum_{s=1}^{T}\frac{1}{N_s^2}\sum_{i=1}^{N_s}[\mathbb{E}\tilde{f}_s(X_s^j) - \tilde{f}_s(X_s^j)]^2\\
&= \sup_{\boldsymbol{f}\in\mathcal{F}}\Big[\frac{1}{T^2}\sum_{t=1}^{T}\frac{1}{N_t^2}\sum_{i=1}^{N_t}[\mathbb{E}f_t(X_t^i) - f_t(X_t^i)]^2\Big] = W.
\end{aligned} \tag{A.6}$$

Therefore, according to Definition A.2, W/b' is a b'-self bounding function. Applying Theorem A.3 then gives the following inequality for any $\lambda \in (0, 1/b')$:

$$\log\mathbb{E}e^{\lambda(W/b')} \le \frac{(e^{\lambda b'} - 1)}{b'^2}\mathbb{E}W = \frac{(e^{\lambda b'} - 1)}{b'^2}\Sigma^2 \le \frac{\lambda\Sigma^2}{b'(1-\lambda b')}, \tag{A.7}$$

where we introduced $\Sigma^2 := \mathbb{E}W$ and where the last step uses the inequality $(e^x - 1)(1 - x) \leq x, \forall x \in [0, 1]$. By further noting that (σ_t^i) is a sequence of independent Rademacher variables independent of X_t^i, the Σ^2 term can be controlled as follows

$$\begin{aligned}
\Sigma^2 &\leq \frac{1}{T^2}\mathbb{E}_X \sup_{\boldsymbol{f}\in\mathcal{F}}\Big[\sum_{t=1}^{T}\frac{1}{N_t^2}\sum_{i=1}^{N_t}\big[\mathbb{E}f_t(X_t^i) - f_t(X_t^i)\big]^2 - \sum_{t=1}^{T}\frac{1}{N_t^2}\sum_{i=1}^{N_t}\mathbb{E}\big[\mathbb{E}f_t(X_t^i) - f_t(X_t^i)\big]^2\Big] + \Upsilon \\
&\leq 2\mathbb{E}_{X,\sigma}\Big[\sup_{\boldsymbol{f}\in\mathcal{F}}\frac{1}{T^2}\sum_{t=1}^{T}\frac{1}{N_t^2}\sum_{i=1}^{N_t}\sigma_t^i\big[\mathbb{E}f_t(X_t^i) - f_t(X_t^i)\big]^2\Big] + \Upsilon \\
&\leq 8b\mathbb{E}_{X,\sigma}\Big[\sup_{\boldsymbol{f}\in\mathcal{F}}\frac{1}{T^2}\sum_{t=1}^{T}\frac{1}{N_t^2}\sum_{i=1}^{N_t}\sigma_t^i\big[\mathbb{E}f_t(X_t^i) - f_t(X_t^i)\big]\Big] + \Upsilon \\
&\leq \frac{16b\mathfrak{R}(\mathcal{F})}{nT} + \Upsilon,
\end{aligned}$$

where the first inequality follows from the definition of W and Υ and the second inequality follows from the standard symmetrization technique used to relate the Rademacher complexity to the uniform deviation of empirical averages from their expectation; see Bartlett et al. (2005). The third inequality comes from a direct application of Lemma A.5 with $\phi(x) = x^2$ (with Lipschitz constant $4b$ on $[-2b, 2b]$), and the last inequality uses Jensen's inequality together with the definition of $\mathfrak{R}(\mathcal{F})$ and the fact that $\frac{1}{N_t^2} \leq \frac{1}{nN_t}$. Substituting the previous inequality on Σ^2 back into (A.7) gives

$$\log \mathbb{E}e^{\lambda(W/b')} \leq \frac{\lambda}{b'(1-\lambda b')}\Big[\frac{16b\mathfrak{R}(\mathcal{F})}{nT} + \Upsilon\Big], \quad \forall \lambda \in (0, 1/b'). \tag{A.8}$$

Step 3. Controlling the term Υ. Note that Υ can be upper-bounded as

$$\begin{aligned}
\Upsilon :&= \sup_{\boldsymbol{f}\in\mathcal{F}}\Big[\frac{1}{T^2}\sum_{s=1}^{T}\frac{1}{N_s^2}\sum_{j=1}^{N_s}\mathbb{E}[\mathbb{E}f_s(X_s^j) - f_s(X_s^j)]^2\Big] \\
&\leq \frac{1}{nT^2}\sup_{\boldsymbol{f}\in\mathcal{F}}\Big[\sum_{s=1}^{T}\mathbb{E}[\mathbb{E}f_s(X_s^1) - f_s(X_s^1)]^2\Big] \\
&\leq \frac{1}{nT^2}\sup_{\boldsymbol{f}\in\mathcal{F}}\Big[\sum_{s=1}^{T}\mathbb{E}[f_s(X_s^1)]^2\Big] \\
&\leq \frac{r}{nT},
\end{aligned} \tag{A.9}$$

where the last inequality follows from the assumption $\frac{1}{T}\sup_{\boldsymbol{f}\in\mathcal{F}}\Big[\sum_{s=1}^{T}\mathbb{E}[f_s(X_s^1)]^2\Big] \leq r$ of the theorem.

Step 4. Transferring the bound on log-moment generating function of Z into tail probabilities. Substituting the bound on $\log \mathbb{E}e^{\lambda W/b'}$ in (A.8) and the bound on Υ in (A.9) back into (A.4) immediately yields the following inequality on the log-moment generating function of Z for any

$\lambda \in (0, 1/2b')$

$$\begin{aligned}
\log \mathbb{E}[e^{\lambda(Z-\mathbb{E}Z)}] &\leq \frac{\lambda b'}{1-\lambda b'}\Big[\frac{\lambda}{b'(1-\lambda b')}\big[16(nT)^{-1}b\mathfrak{R}(\mathcal{F}) + \Upsilon\big] + \frac{\lambda\Upsilon}{b'}\Big] \\
&\leq \frac{\lambda b'}{1-\lambda b'}\frac{\lambda}{b'(1-\lambda b')}\Big[\frac{16b\mathfrak{R}(\mathcal{F})}{nT} + 2\Upsilon\Big] \\
&\leq \frac{2\lambda^2}{2(1-2\lambda b')}\Big[\frac{16b\mathfrak{R}(\mathcal{F})}{nT} + \frac{2r}{nT}\Big],
\end{aligned} \tag{A.10}$$

where the last inequality uses $(1 - \lambda b')^2 \geq 1 - 2\lambda b' > 0$ since $\lambda \in (0, 1/2b')$. That is, the conditions of Lemma A.4 hold and we can apply it (with $A = 2\big[\frac{16b\mathfrak{R}(\mathcal{F})}{nT} + \frac{2r}{nT}\big]$ and $B = 2b'$) to get the following inequality with probability at least $1 - e^{-x}$ (note that $b' = \frac{2b}{nT}$)

$$\begin{aligned}
Z &\leq \mathbb{E}[Z] + \sqrt{4x\Big[\frac{16b\mathfrak{R}(\mathcal{F})}{nT} + \frac{2r}{nT}\Big]} + 2b'x \\
&\leq \mathbb{E}[Z] + 8\sqrt{\frac{bx\mathfrak{R}(\mathcal{F})}{nT}} + \sqrt{\frac{8xr}{nT}} + \frac{4bx}{nT} \\
&\leq \mathbb{E}[Z] + 2\mathfrak{R}(\mathcal{F}) + \frac{8bx}{nT} + \sqrt{\frac{8xr}{nT}} + \frac{4bx}{nT} \\
&\leq 4\mathfrak{R}(\mathcal{F}) + \sqrt{\frac{8xr}{nT}} + \frac{12bx}{nT},
\end{aligned}$$

where the third inequality follows from $2\sqrt{uv} \leq u + v$, and the last step uses the following inequality due to the symmetrization technique (here, the "ghost" sample X' is an *i.i.d.* copy of the initial sample X)

$$\begin{aligned}
\mathbb{E}Z &= \mathbb{E}_X\Big[\sup_{\boldsymbol{f}\in\mathcal{F}}\frac{1}{T}\mathbb{E}_{X'}\Big[\sum_{t=1}^{T}\frac{1}{N_t}\sum_{i=1}^{N_t}\big(f_t(X_t'^i) - f_t(X_t^i)\big)\Big]\Big] \\
&\leq \mathbb{E}_{X,X'}\Big[\sup_{\boldsymbol{f}\in\mathcal{F}}\frac{1}{T}\sum_{t=1}^{T}\frac{1}{N_t}\sum_{i=1}^{N_t}\big(f_t(X_t'^i) - f_t(X_t^i)\big)\Big] \\
&= \mathbb{E}_{X,X',\sigma}\Big[\sup_{\boldsymbol{f}\in\mathcal{F}}\frac{1}{T}\sum_{t=1}^{T}\frac{1}{N_t}\sum_{i=1}^{N_t}\sigma_t^i\big(f_t(X_t'^i) - f_t(X_t^i)\big)\Big] \\
&\leq 2\mathfrak{R}(\mathcal{F}).
\end{aligned}$$

Note that the second identity holds since for any σ_t^i, the random variable $f_t(X_t'^i) - f_t(X_t^i)$ has the same distribution as $\sigma_t^i(f_t(X_t'^i) - f_t(X_t^i))$.

Appendix B. Proofs of the results in Sect. 3

Theorem B.3 is at the core of proving Theorem 9 in Sect. 3. We first present some useful lemmata.

Lemma B.1 *Let $c_1, c_2 > 0$ and $s > q > 0$. Then the equation $x^s - c_1x^q - c_2 = 0$ has a unique positive solution x_0 satisfying*

$$x_0 \leq \Big[c_1^{\frac{s}{s-q}} + \frac{sc_2}{s-q}\Big]^{\frac{1}{s}}.$$

Furthermore, for any $x \geq x_0$, we have $x^s \geq c_1 x^q + c_2$.

Proof Denote $p(x) := x^s - c_1 x^q - c_2$. The uniqueness of a positive solution for the equation $p(x) = 0$ is shown in Lemma 7.2 in Cucker and Zhou (2007). Let x_0 be this unique positive solution. Then, it follows from Young's inequality

$$xy \leq p^{-1}x^p + q^{-1}y^q, \quad \forall x, y \geq 0, p, q > 0, p^{-1} + q^{-1} = 1, \tag{B.1}$$

that

$$x_0^s = c_1 x_0^q + c_2 \leq \frac{x_0^{q \cdot \frac{s}{q}}}{\frac{s}{q}} + \frac{c_1^{\frac{s}{s-q}}}{\frac{s}{s-q}} + c_2 = \frac{q}{s} x_0^s + \frac{s-q}{s} c_1^{\frac{s}{s-q}} + c_2,$$

from which we have $x_0^s \leq c_1^{\frac{s}{s-q}} + \frac{sc_2}{s-q}$. The inequality $p(x) \geq 0$ for any $x \geq x_0$ then follows immediately from the facts that $p(x_0) = 0$, $\lim_{x\to\infty} p(x) = \infty$ and the uniqueness of roots for the equation $p(x) = 0$. ■

Also, we will need the following lemma for the second step of the proof of Theorem B.3.

Lemma B.2 *Let $K > 1, r > 0, 0 < \beta \leq 1$ and $B \geq 1$. Assume that $\mathcal{F} = \{\boldsymbol{f} := (f_1, \ldots, f_T)\}$ is a vector-valued (β, B)-Bernstein class of functions. Define the re-scaled version of $\mathcal{F}$ as*

$$\mathcal{F}_r := \left\{ \boldsymbol{f}' = (f_1', \ldots, f_T') : f_t' := \frac{r f_t}{\max(r, V(\boldsymbol{f}))}, \boldsymbol{f} = (f_t, \ldots, f_T) \in \mathcal{F} \right\}. \tag{B.2}$$

If $V_r^+ := \sup_{\boldsymbol{f}' \in \mathcal{F}_r} [P\boldsymbol{f}' - P_n \boldsymbol{f}'] \leq \frac{r^{\frac{1}{\beta}}}{BK}$, then

$$\forall \boldsymbol{f} \in \mathcal{F} \qquad P\boldsymbol{f} \leq \frac{K}{K-\beta} P_n \boldsymbol{f} + \frac{r^{\frac{1}{\beta}}}{K}. \tag{B.3}$$

Proof We prove (B.3) by considering two cases. Let $\boldsymbol{f}$ be any element in $\mathcal{F}$. If $V(\boldsymbol{f}) \leq r$, then $\boldsymbol{f}' = \boldsymbol{f}$ and the inequality $V_r^+ \leq \frac{r^{\frac{1}{\beta}}}{BK}$ leads to

$$P\boldsymbol{f} \leq P_n \boldsymbol{f} + \frac{r^{\frac{1}{\beta}}}{BK} \leq \frac{K}{K-\beta} P_n \boldsymbol{f} + \frac{r^{\frac{1}{\beta}}}{K}. \tag{B.4}$$

If $V(\boldsymbol{f}) \geq r$, then $\boldsymbol{f}' = r\boldsymbol{f}/V(\boldsymbol{f})$ and the inequality $V_r^+ \leq \frac{r^{\frac{1}{\beta}}}{BK}$ yields

$$\begin{aligned} P\boldsymbol{f} &\leq P_n \boldsymbol{f} + \frac{r^{\frac{1}{\beta}-1} V(\boldsymbol{f})}{BK} \leq P_n \boldsymbol{f} + \frac{r^{\frac{1}{\beta}-1} (P\boldsymbol{f})^\beta}{K} \\ &\overset{\text{(B.1)}}{\leq} P_n \boldsymbol{f} + \frac{1}{K} \frac{[(P\boldsymbol{f})^\beta]^{\frac{1}{\beta}}}{\frac{1}{\beta}} + \frac{1}{K} \frac{(r^{\frac{1}{\beta}-1})^{\frac{1}{1-\beta}}}{\frac{1}{1-\beta}} \\ &= P_n \boldsymbol{f} + \frac{\beta}{K} P\boldsymbol{f} + \frac{(1-\beta) r^{\frac{1}{\beta}}}{K}, \end{aligned}$$

where we have used Bernstein's condition $V(\boldsymbol{f}) \leq BP(\boldsymbol{f})^\beta$. The previous inequality can be equivalently written as

$$P\boldsymbol{f} \leq \frac{K}{K-\beta} P_n \boldsymbol{f} + \frac{1-\beta}{K-\beta} r^{\frac{1}{\beta}} \leq \frac{K}{K-\beta} P_n \boldsymbol{f} + \frac{r^{\frac{1}{\beta}}}{K}. \tag{B.5}$$

Eq. (B.3) follows by combining (B.4) and (B.5). ■

Theorem B.3 (LRC-based bounds for MTL) *Let $\mathcal{F} = \{\boldsymbol{f} := (f_1, \ldots, f_T) : \forall t, f_t \in \mathbb{R}^{\mathcal{X}}\}$ be a class of vector-valued functions satisfying $\max_{t\in\mathbb{N}_T} \sup_{x\in\mathcal{X}} |f_t(x)| \leq b$. Let $X := (X_t^i, Y_t^i)_{(t,i)=(1,1)}^{(T,n)}$ be a vector of nT independent random variables where $(X_t^1, Y_t^1), \ldots, (X_t^n, Y_t^n), \forall t \in \mathbb{N}_T$ are identically distributed. Assume that $\mathcal{F}$ is a (β, B)-Bernstein class of vector-valued functions with $0 < \beta \leq 1$ and $B \geq 1$. Let ψ be a sub-root function with fixed point r^*. If $B\mathfrak{R}(\mathcal{F}, r) \leq \psi(r), \forall r \geq r^*$, then, for any $K > 1$, and $x > 0$, with probability at least $1 - e^{-x}$, every $\boldsymbol{f} \in \mathcal{F}$ satisfies*

$$P\boldsymbol{f} \leq \frac{K}{K-\beta} P_n \boldsymbol{f} + (2K)^{\frac{\beta}{2-\beta}} 20^{\frac{2}{2-\beta}} \max\left((r^*)^{\frac{1}{2-\beta}}, (r^*)^{\frac{1}{\beta}}\right) + \left(\frac{2^{\beta+3} B^2 K^\beta x}{nT}\right)^{\frac{1}{2-\beta}} + \frac{24Bbx}{(2-\beta)nT}. \tag{B.6}$$

Proof Let $r \geq r^*$ be a fixed real number. Here, we use the vector-valued function class $\mathcal{F}_r$ as defined in (B.2). The proof is broken down into two major steps. The first step applies Theorem 1 and the "peeling" technique (Van De Geer, 1987; Van Der Vaart and Wellner, 1996) to establish an inequality on the uniform deviation over the function class $\mathcal{F}_r$. The second step then uses the Bernstein assumption $V(\boldsymbol{f}) \leq B(P\boldsymbol{f})^\beta$ to convert this inequality stated for $\mathcal{F}_r$ to a uniform deviation inequality for $\mathcal{F}$.

Step 1. Controlling uniform deviations for $\mathcal{F}_r$. To apply Theorem 1 to $\mathcal{F}_r$, we need to control the variances and uniform bounds for elements in $\mathcal{F}_r$. We first show that $P\boldsymbol{f}'^2 \leq r, \forall \boldsymbol{f}' \in \mathcal{F}_r$. Indeed, for any $\boldsymbol{f} \in \mathcal{F}$ with $V(\boldsymbol{f}) \leq r$, the definition of $\mathcal{F}_r$ implies $f_t' = f_t$ and, hence, $P\boldsymbol{f}'^2 = P\boldsymbol{f}^2 \leq V(\boldsymbol{f}) \leq r$. Otherwise, if $V(\boldsymbol{f}) \geq r$, then $f_t' = r f_t / V(\boldsymbol{f})$ and we get

$$P\boldsymbol{f}'^2 = \frac{1}{T} \sum_{t=1}^T P f_t'^2 = \frac{r^2}{\left[V(\boldsymbol{f})\right]^2} \left(\frac{1}{T} \sum_{t=1}^T P f_t^2\right) \leq \frac{r^2}{\left[V(\boldsymbol{f})\right]^2} V(\boldsymbol{f}) \leq r.$$

Therefore, $\frac{1}{T} \sup_{\boldsymbol{f}' \in \mathcal{F}_r} \sum_{t=1}^T \mathbb{E}[f_t'(X_t)]^2 \leq r$. Also, since functions in $\mathcal{F}$ admit a range of $[-b, b]$ and since $0 \leq r / \max(r, V(\boldsymbol{f})) \leq 1$, it holds that $\max_{t\in\mathbb{N}_T} \sup_{x\in\mathcal{X}} |f_t'(x)| \leq b$ for any $\boldsymbol{f}' \in \mathcal{F}_r$. Applying Theorem 1 to the function class $\mathcal{F}_r$ then yields the following inequality with probability at least $1 - e^{-x}, \forall x > 0$

$$\sup_{\boldsymbol{f}' \in \mathcal{F}_r} [P\boldsymbol{f}' - P_n \boldsymbol{f}'] \leq 4\mathfrak{R}(\mathcal{F}_r) + \sqrt{\frac{8xr}{nT}} + \frac{12bx}{nT}. \tag{B.7}$$

It remains to control the Rademacher complexity of $\mathcal{F}_r$. Denote $\mathcal{F}(u, v) := \left\{\boldsymbol{f} \in \mathcal{F} : u \leq V(\boldsymbol{f}) \leq v\right\}, \forall 0 \leq u \leq v$, and introduce

$$\mathfrak{R}_n \boldsymbol{f}' := \frac{1}{nT} \sum_{t=1}^T \sum_{i=1}^n \sigma_t^i f_t'(X_t^i), \qquad \mathfrak{R}_n(\mathcal{F}_r) := \sup_{\boldsymbol{f}' \in \mathcal{F}_r} \left[\mathfrak{R}_n \boldsymbol{f}'\right].$$

Note that $\mathfrak{R}(\mathcal{F}_r) = \mathbb{E}\mathfrak{R}_n(\mathcal{F}_r)$. Our assumption implies that $V(\boldsymbol{f}) \leq B(P\boldsymbol{f})^\beta \leq Bb^\beta, \forall \boldsymbol{f} \in \mathcal{F}$. Fix $\lambda > 1$ and define k as the smallest integer such that $r\lambda^{k+1} \geq Bb^\beta$. Then, according to the union bound inequality

$$\mathfrak{R}(\mathcal{G}_1 \cup \mathcal{G}_2) \leq \mathfrak{R}(\mathcal{G}_1) + \mathfrak{R}(\mathcal{G}_2), \tag{B.8}$$

we obtain

$$\begin{aligned}
\mathfrak{R}(\mathcal{F}_r) &= \mathbb{E}\Big[\sup_{\boldsymbol{f}' \in \mathcal{F}_r} \mathfrak{R}_n \boldsymbol{f}'\Big] = \mathbb{E}\Big[\sup_{\boldsymbol{f} \in \mathcal{F}} \frac{1}{nT}\sum_{t=1}^{T}\sum_{i=1}^{n} \frac{r}{\max(r, V(\boldsymbol{f}))}\sigma_t^i f_t(X_t^i)\Big] \\
&\overset{\text{(B.8)}}{\leq} \mathbb{E}\Big[\sup_{\boldsymbol{f} \in \mathcal{F}(0,r)} \frac{1}{nT}\sum_{t=1}^{T}\sum_{i=1}^{n} \sigma_t^i f_t(X_t^i)\Big] + \mathbb{E}\Big[\sup_{\boldsymbol{f} \in \mathcal{F}(r, Bb^\beta)} \frac{1}{nT}\sum_{t=1}^{T}\sum_{i=1}^{n} \frac{r}{V(\boldsymbol{f})}\sigma_t^i f_t(X_t^i)\Big] \\
&\overset{\text{(B.8)}}{\leq} \mathbb{E}\Big[\sup_{\boldsymbol{f} \in \mathcal{F}(0,r)} \frac{1}{nT}\sum_{t=1}^{T}\sum_{i=1}^{n} \sigma_t^i f_t(X_t^i)\Big] + \sum_{j=0}^{k} \lambda^{-j}\mathbb{E}\Big[\sup_{\boldsymbol{f} \in \mathcal{F}(r\lambda^j, r\lambda^{j+1})} \mathfrak{R}_n \boldsymbol{f}\Big] \\
&\leq \mathfrak{R}(\mathcal{F}, r) + \sum_{j=0}^{k} \lambda^{-j}\mathfrak{R}\big(\mathcal{F}, r\lambda^{j+1}\big) \\
&\leq \frac{\psi(r)}{B} + \frac{1}{B}\sum_{j=0}^{k} \lambda^{-j}\psi(r\lambda^{j+1}).
\end{aligned}$$

The sub-root property of ψ implies that $\psi(\xi r) \leq \xi^{\frac{1}{2}}\psi(r)$ for any $\xi \geq 1$ and, hence,

$$\mathfrak{R}(\mathcal{F}_r) \leq \frac{\psi(r)}{B}\Big(1 + \sqrt{\lambda}\sum_{j=0}^{k} \lambda^{-\frac{j}{2}}\Big) \leq \frac{\psi(r)}{B}\Big(1 + \frac{\lambda}{\sqrt{\lambda} - 1}\Big).$$

Choosing $\lambda = 4$ in the above inequality implies that $\mathfrak{R}(\mathcal{F}_r) \leq 5\psi(r)/B$, which, together with the inequality $\psi(r) \leq \sqrt{r/r^*}\psi(r^*) = \sqrt{rr^*}, \forall r \geq r^*$, gives

$$\mathfrak{R}(\mathcal{F}_r) \leq \frac{5}{B}\sqrt{rr^*}, \quad \forall r \geq r^*.$$

Combining (B.7) and the above inequality, for any $r \geq r^*$ and $x > 0$, we derive the following inequality with probability at least $1 - e^{-x}$,

$$\sup_{\boldsymbol{f}' \in \mathcal{F}_r} [P\boldsymbol{f}' - P_n\boldsymbol{f}'] \leq \frac{20}{B}\sqrt{rr^*} + \sqrt{\frac{8xr}{nT}} + \frac{12bx}{nT}. \tag{B.9}$$

Step 2. Transferring uniform deviations for $\mathcal{F}_r$ to uniform deviations for $\mathcal{F}$. letting $A := 20\sqrt{r^*}/B + \sqrt{8x/nT}$ and $C := 12bx/nT$, the upper bound of (B.9) can be written as $A\sqrt{r} + C$, that is, $\sup_{\boldsymbol{f}' \in \mathcal{F}_r}[P\boldsymbol{f}' - P_n\boldsymbol{f}'] \leq A\sqrt{r} + C$. Now, according to Lemma B.2, if $\sup_{\boldsymbol{f}' \in \mathcal{F}_r}[P\boldsymbol{f}' - P_n\boldsymbol{f}'] \leq \frac{r^{\frac{1}{\beta}}}{BK}$, then for any $\boldsymbol{f} \in \mathcal{F}$,

$$P\boldsymbol{f} \leq \frac{K}{K - \beta}P_n\boldsymbol{f} + \frac{r^{\frac{1}{\beta}}}{K}.$$

To apply Lemma B.2, we let $A\sqrt{r} + C = r^{\frac{1}{\beta}}/(BK)$. Assume r_0 is the unique positive solution of the equation $A\sqrt{r} + C = r^{\frac{1}{\beta}}/(BK)$, which can be written as

$$r^{\frac{1}{\beta}} - ABKr^{\frac{1}{2}} - BKC = 0.$$

Lemma B.1 then implies

$$\begin{aligned}
r_0^{\frac{1}{\beta}} &\leq (ABK)^{\frac{2}{2-\beta}} + \frac{2BKC}{2 - \beta} \\
&\leq (BK)^{\frac{2}{2-\beta}} 2^{\frac{\beta}{2-\beta}}\Big[(20B^{-1})^{\frac{2}{2-\beta}}(r^*)^{\frac{1}{2-\beta}} + \Big(\frac{8x}{nT}\Big)^{\frac{1}{2-\beta}}\Big] + \frac{24BKbx}{(2-\beta)nT},
\end{aligned} \tag{B.10}$$

where we have used the inequality $(x+y)^p \leq 2^{p-1}(x^p + y^p)$ for any $x, y \geq 0, p \geq 1$. If $r^* \leq r_0$, we can take $r = r_0$ in (B.9) to show that $V_{r_0}^+ \leq A\sqrt{r_0} + C = r_0^{\frac{1}{\beta}}/(BK)$, which, coupled with (B.10) and Lemma B.2, gives

$$P\boldsymbol{f} \leq \frac{K}{K - \beta}P_n\boldsymbol{f} + (2K)^{\frac{\beta}{2-\beta}}20^{\frac{2}{2-\beta}}(r^*)^{\frac{1}{2-\beta}} + \Big(\frac{2^{\beta+3}B^2K^\beta x}{nT}\Big)^{\frac{1}{2-\beta}} + \frac{24Bbx}{(2-\beta)nT}. \tag{B.11}$$

If $r^* > r_0$, Lemma B.1 implies that $A\sqrt{r^*} + C \leq (r^*)^{\frac{1}{\beta}}/(BK)$. We now take $r = r^*$ in (B.9) to get $V_{r^*}^+ \leq A\sqrt{r^*} + C \leq (r^*)^{\frac{1}{\beta}}/(BK)$, from which—via Lemma B.2—we obtain that

$$P\boldsymbol{f} \leq \frac{K}{K - \beta}P_n\boldsymbol{f} + \frac{r_*^{\frac{1}{\beta}}}{K}. \tag{B.12}$$

Note that inequality (B.6) follows immediately by combining (B.11) and (B.12). ■

Proof of Theorem 9

Note that the proof of this theorem relies on the results of Theorem B.3. Introduce the following class of excess loss functions

$$\mathcal{H}_{\mathcal{F}}^* := \{h_{\boldsymbol{f}} = (h_{f_1}, \ldots, h_{f_T}), h_{f_t} : (X_t, Y_t) \mapsto \ell(f_t(X_t), Y_t) - \ell(f_t^*(X_t), Y_t), \boldsymbol{f} \in \mathcal{F}\}. \tag{B.13}$$

It can be shown that

$$\max_{t \in \mathbb{N}_T}\sup_{x \in \mathcal{X}}|h_{f_t}(x, y)| = \max_{t \in \mathbb{N}_T}\sup_{x \in \mathcal{X}}|\ell(f_t(x), y) - \ell(f_t^*(x), y)| \leq L\max_{t \in \mathbb{N}_T}\sup_{x \in \mathcal{X}}|f_t(x) - f_t^*(x)| \leq 2Lb.$$

Also, Assumption 8 implies that

$$P(\ell_{\boldsymbol{f}} - \ell_{\boldsymbol{f}^*})^2 \leq L^2P(\boldsymbol{f} - \boldsymbol{f}^*)^2 \leq B'L^2\big(P(\ell_{\boldsymbol{f}} - \ell_{\boldsymbol{f}^*})\big)^\beta, \quad \forall h_{\boldsymbol{f}} \in \mathcal{H}_{\mathcal{F}}^*,$$

By letting $B := \max(B'L^2, 1)$, we have for all $h_{\boldsymbol{f}} \in \mathcal{H}_{\mathcal{F}}^*$,

$$Ph_{\boldsymbol{f}}^2 \leq V(h_{\boldsymbol{f}}) := L^2P(\boldsymbol{f} - \boldsymbol{f}^*)^2 \leq B\big(P(\ell_{\boldsymbol{f}} - \ell_{\boldsymbol{f}^*})\big)^\beta = B(Ph_{\boldsymbol{f}})^\beta.$$

which implies that $\mathcal{H}^*_{\mathcal{F}}$ is a (β, B)-Bernstein class of vector-valued functions. In addition, for any $r \geq r^*$, one can verify that

$$\begin{aligned} B\mathfrak{R}(\mathcal{H}^*_{\mathcal{F}}, r) &= B\mathbb{E}_{X,\sigma}\left[\sup_{V(h_{\boldsymbol{f}})\leq r, \boldsymbol{f}\in\mathcal{F}} \frac{1}{nT}\sum_{t=1}^{T}\sum_{i=1}^{n}\sigma_t^i h_{f_t}(X_t^i, Y_t^i)\right] \\ &= B\mathbb{E}_{X,\sigma}\left[\sup_{V(h_{\boldsymbol{f}})\leq r, \boldsymbol{f}\in\mathcal{F}} \frac{1}{nT}\sum_{t=1}^{T}\sum_{i=1}^{n}\sigma_t^i \ell_{f_t}(X_t^i, Y_t^i)\right] \\ &\leq BL\mathfrak{R}(\mathcal{F}^*, r) \leq \psi(r), \end{aligned}$$

where the second to last inequality is due to Lemma A.5. Applying Theorem B.3 to the function class $\mathcal{H}^*_{\mathcal{F}}$ completes the proof.

Appendix C. Proofs of the results in Sect. 4: "Local Rademacher Complexity Bounds for Norm Regularized MTL Models"

Lemma C.1 *Assume that the conditions of Theorem 11 hold. Then, for ever $\boldsymbol{f} \in \mathcal{F}$,*

*(**a**) $P\boldsymbol{f}^2 \leq r$ implies $1/T\sum_{t=1}^{T}\sum_{j=1}^{\infty}\lambda_t^j\left\langle \boldsymbol{w}_t, \boldsymbol{u}_t^j\right\rangle^2 \leq r$.*
*(**b**) $\mathbb{E}_{X,\sigma}\left\langle \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle^2 = \frac{\lambda_t^j}{n}$.*

Proof We first prove part (**a**). Given the eigen-decomposition $\mathbb{E}(\phi(X_t)\otimes\phi(X_t)) = \sum_{j=1}^{\infty}\lambda_t^j \boldsymbol{u}_t\otimes\boldsymbol{u}_t^j$ for each task $t \in \mathbb{N}_T$, we obtain

$$\begin{aligned} P\boldsymbol{f}^2 =& \frac{1}{T}\sum_{t=1}^{T}\mathbb{E}\left(\langle \boldsymbol{w}_t, \phi(X_t)\rangle\right)^2 = \frac{1}{T}\sum_{t=1}^{T}\mathbb{E}\left(\langle \boldsymbol{w}_t\otimes\boldsymbol{w}_t, \phi(X_t)\otimes\phi(X_t)\rangle\right) \\ =& \frac{1}{T}\sum_{t=1}^{T}\langle \boldsymbol{w}_t\otimes\boldsymbol{w}_t, \mathbb{E}_X\left(\phi(X_t)\otimes\phi(X_t)\right)\rangle = \frac{1}{T}\sum_{t=1}^{T}\sum_{j=1}^{\infty}\lambda_t^j\left\langle \boldsymbol{w}_t\otimes\boldsymbol{w}_t, \boldsymbol{u}_t^j\otimes\boldsymbol{u}_t^j\right\rangle \\ =& \frac{1}{T}\sum_{t=1}^{T}\sum_{j=1}^{\infty}\lambda_t^j\left\langle \boldsymbol{w}_t, \boldsymbol{u}_t^j\right\rangle\left\langle \boldsymbol{w}_t, \boldsymbol{u}_t^j\right\rangle = \frac{1}{T}\sum_{t=1}^{T}\sum_{j=1}^{\infty}\lambda_t^j\left\langle \boldsymbol{w}_t, \boldsymbol{u}_t^j\right\rangle^2 \leq r. \end{aligned}$$

Now, we turn to part (**b**). From the independence among the elements of the sequence $\left\{\sigma_t^i\right\}_{\substack{i\in\mathbb{N}_n \\ t\in\mathbb{N}_T}}$, it follows that

$$\begin{aligned} &\mathbb{E}_{X,\sigma}\left\langle \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle^2 = \frac{1}{n^2}\mathbb{E}_{X,\sigma}\sum_{i,k=1}^{n}\sigma_t^i\sigma_t^k\left\langle \phi(X_t^i), \boldsymbol{u}_t^j\right\rangle\left\langle \phi(X_t^k), \boldsymbol{u}_t^j\right\rangle \\ &\overset{\sigma_t^{i.i.d.}}{=} \frac{1}{n^2}\mathbb{E}_X\left(\sum_{i=1}^{n}\left\langle \phi(X_t^i), \boldsymbol{u}_t^j\right\rangle^2\right) = \frac{1}{n}\left\langle \frac{1}{n}\sum_{i=1}^{n}\mathbb{E}_X\left(\phi(X_t^i)\otimes\phi(X_t^i)\right), \boldsymbol{u}_t^j\otimes\boldsymbol{u}_t^j\right\rangle \\ &= \frac{1}{n}\sum_{l=1}^{\infty}\lambda_t^l\left\langle \boldsymbol{u}_t^l\otimes\boldsymbol{u}_t^l, \boldsymbol{u}_t^j\otimes\boldsymbol{u}_t^j\right\rangle = \frac{\lambda_t^j}{n}. \end{aligned}$$

■

The next lemmata are used in the proof of the LRC bound for the $L_{2,q}$-group norm regularized MTL in Corollary 13.

Lemma C.2 (Khintchine-Kahane Inequality in (Peshkir and Shiryaev, 1995)) *Let $\mathcal{H}$ be an inner-product space with induced norm $\|\cdot\|_{\mathcal{H}}$, $v_1, \ldots, v_M \in \mathcal{H}$ and $\sigma_1, \ldots, \sigma_n$ i.i.d. Rademacher random variables. Then, for any $p \geq 1$, we have that*

$$\mathbb{E}_{\boldsymbol{\sigma}}\left\|\sum_{i=1}^{n}\sigma_i v_i\right\|_{\mathcal{H}}^p \leq \left(c\sum_{i=1}^{n}\|v_i\|_{\mathcal{H}}^2\right)^{\frac{p}{2}}. \tag{C.1}$$

where $c := \max\{1, p-1\}$. The inequality also holds for p in place of c.

Lemma C.3 (Rosenthal-Young Inequality; Lemma 3 of (Kloft and Blanchard, 2012)) *Let the independent non-negative random variables $X_1, \ldots, X_n$ satisfy $X_i \leq B < +\infty$ almost surely for all $i = 1, \ldots, n$. If $q \geq \frac{1}{2}$, $c_q := (2qe)^q$, then it holds*

$$\mathbb{E}\left(\frac{1}{n}\sum_{i=1}^{n}X_i\right)^q \leq c_q\left[\left(\frac{B}{n}\right)^q + \left(\frac{1}{n}\sum_{i=1}^{n}\mathbb{E}X_i\right)^q\right]. \tag{C.2}$$

Proof of Lemma 12

For the group norm regularizer $\|\boldsymbol{W}\|_{2,q}$, we can further bound the expectation term in (15) for $\boldsymbol{D} = \boldsymbol{I}$ as follows

$$\begin{aligned} \mathbb{E} :=& \mathbb{E}_{X,\sigma}\left\|\left(\sum_{j>h_t}\left\langle \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle\boldsymbol{u}_t^j\right)_{t=1}^{T}\right\|_{2,q^*} \\ =& \mathbb{E}_{X,\sigma}\left(\sum_{t=1}^{T}\left\|\sum_{j>h_t}\left\langle \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle\boldsymbol{u}_t^j\right\|^{q^*}\right)^{\frac{1}{q^*}} \\ \overset{\text{Jensen}}{\leq}& \mathbb{E}_X\left(\sum_{t=1}^{T}\mathbb{E}_\sigma\left\|\sum_{j>h_t}\left\langle \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle\boldsymbol{u}_t^j\right\|^{q^*}\right)^{\frac{1}{q^*}} \\ \overset{\text{(C.1)}}{\leq}& \mathbb{E}_X\left(\sum_{t=1}^{T}\left(q^*\sum_{i=1}^{n}\left\|\sum_{j>h_t}\left\langle \frac{1}{n}\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle\boldsymbol{u}_t^j\right\|^2\right)^{\frac{q^*}{2}}\right)^{\frac{1}{q^*}} \\ =& \sqrt{\frac{q^*}{n}}\mathbb{E}_X\left(\sum_{t=1}^{T}\left(\sum_{j>h_t}\frac{1}{n}\sum_{i=1}^{n}\left\langle \phi(X_t^i), \boldsymbol{u}_t^j\right\rangle^2\right)^{\frac{q^*}{2}}\right)^{\frac{1}{q^*}} \end{aligned}$$

$$\overset{\text{Jensen}}{\leq} \sqrt{\frac{q^*}{n}} \left(\sum_{t=1}^{T} \mathbb{E}_X \left(\sum_{j>h_t} \frac{1}{n} \sum_{i=1}^{n} \left\langle \phi(X_t^i), \boldsymbol{u}_t^j \right\rangle^2 \right)^{\frac{q^*}{2}} \right)^{\frac{1}{q^*}}. \tag{C.3}$$

Note that, for $q \leq 2$, it holds that $q^*/2 \geq 1$. Therefore, we cannot employ Jensen's inequality to move the expectation operator inside the inner term and, instead, we need to apply the Rosenthal-Young (R+Y) inequality (see Lemma C.3), which yields

$$\begin{aligned}
\mathbb{E} &\overset{\text{R+Y}}{\leq} \sqrt{\frac{q^*}{n}} \left(\sum_{t=1}^{T} (eq^*)^{\frac{q^*}{2}} \left(\left(\frac{\mathcal{K}}{n} \right)^{\frac{q^*}{2}} + \left(\sum_{j>h_t} \frac{1}{n} \sum_{i=1}^{n} \mathbb{E}_X \left\langle \phi(X_t^i), \boldsymbol{u}_t^j \right\rangle^2 \right)^{\frac{q^*}{2}} \right) \right)^{\frac{1}{q^*}} \\
&= \sqrt{\frac{q^*}{n}} \left(\sum_{t=1}^{T} (eq^*)^{\frac{q^*}{2}} \left(\left(\frac{\mathcal{K}}{n} \right)^{\frac{q^*}{2}} + \left(\sum_{j>h_t} \lambda_t^j \right)^{\frac{q^*}{2}} \right) \right)^{\frac{1}{q^*}}.
\end{aligned} \tag{C.4}$$

The last quantity can be further bounded using the sub-additivity of $\sqrt[q^*]{\cdot}$ as shown next

$$\begin{aligned}
\mathbb{E} &\leq q^* \sqrt{\frac{e}{n}} \left[\left(T \left(\frac{\mathcal{K}}{n} \right)^{\frac{q^*}{2}} \right)^{\frac{1}{q^*}} + \left(\sum_{t=1}^{T} \left(\sum_{j>h_t} \lambda_t^j \right)^{\frac{q^*}{2}} \right)^{\frac{1}{q^*}} \right] \\
&= q^* \sqrt{\frac{e}{n}} \left[T^{\frac{1}{q^*}} \sqrt{\frac{\mathcal{K}}{n}} + \left\| \left(\sum_{j>h_t} \lambda_t^j \right)_{t=1}^{T} \right\|_{\frac{q^*}{2}}^{\frac{1}{2}} \right] \\
&= \frac{\sqrt{\mathcal{K}e} q^* T^{\frac{1}{q^*}}}{n} + \sqrt{\frac{eq^{*2}}{n} \left\| \left(\sum_{j>h_t} \lambda_t^j \right)_{t=1}^{T} \right\|_{\frac{q^*}{2}}}.
\end{aligned} \tag{C.5}$$

Proof of Corollary 13

Combining (14), (15) and Lemma 12 provides the next bound on $\mathfrak{R}(\mathcal{F}_q, r)$

$$\begin{aligned}
\mathfrak{R}(\mathcal{F}_q, r) &\leq \sqrt{\frac{r \sum_{t=1}^{T} h_t}{nT}} + \sqrt{\frac{2eq^{*2} R_{max}^2}{nT^2} \left\| \left(\sum_{j>h_t} \lambda_t^j \right)_{t=1}^{T} \right\|_{\frac{q^*}{2}}} + \frac{\sqrt{2\mathcal{K}e} R_{max} q^* T^{\frac{1}{q^*}}}{nT} \\
&\overset{(\star)}{\leq} \sqrt{\frac{2}{nT} \left(r \sum_{t=1}^{T} h_t + \frac{2eq^{*2} R_{max}^2}{T} \left\| \left(\sum_{j>h_t} \lambda_t^j \right)_{t=1}^{T} \right\|_{\frac{q^*}{2}} \right)} + \frac{\sqrt{2\mathcal{K}e} R_{max} q^* T^{\frac{1}{q^*}}}{nT}
\end{aligned} \tag{C.6}$$

$$\begin{aligned}
&\overset{(\star\star)}{\leq} \sqrt{\frac{2}{nT} \left(rT^{1-\frac{2}{q^*}} \left\| (h_t)_{t=1}^{T} \right\|_{\frac{q^*}{2}} + \frac{2eq^{*2} R_{max}^2}{T} \left\| \left(\sum_{j>h_t} \lambda_t^j \right)_{t=1}^{T} \right\|_{\frac{q^*}{2}} \right)} + \frac{\sqrt{2\mathcal{K}e} R_{max} q^* T^{\frac{1}{q^*}}}{nT} \\
&\overset{(\star\star\star)}{\leq} \sqrt{\frac{4}{nT} \left\| \left(rT^{1-\frac{2}{q^*}} h_t + \frac{2eq^{*2} R_{max}^2}{T} \sum_{j>h_t} \lambda_t^j \right)_{t=1}^{T} \right\|_{\frac{q^*}{2}}} + \frac{\sqrt{2\mathcal{K}e} R_{max} q^* T^{\frac{1}{q^*}}}{nT},
\end{aligned}$$

where in steps $(\star)$, $(\star\star)$ and $(\star\star\star)$ we applied the corresponding inequalities shown next, which hold for all non-negative numbers α_1 and α_2, any non-negative vectors $\boldsymbol{a}_1, \boldsymbol{a}_2 \in \mathbb{R}^T$, any p, q such that $0 \leq q \leq p \leq \infty$ and any $s \geq 1$.

$(\star) \sqrt{\alpha_1} + \sqrt{\alpha_2} \leq \sqrt{2(\alpha_1 + \alpha_2)}$

$(\star\star) \quad l_p - to - l_q: \quad \|\boldsymbol{a}_1\|_q = \langle \mathbf{1}, \boldsymbol{a}_1^q \rangle^{\frac{1}{q}} \overset{\text{Hölder}}{\leq} \left(\|\mathbf{1}\|_{(p/q)^*} \|\boldsymbol{a}_1^q\|_{(p/q)} \right)^{\frac{1}{q}} = T^{\frac{1}{q}-\frac{1}{p}} \|\boldsymbol{a}_1\|_p$

$(\star\star\star) \quad \|\boldsymbol{a}_1\|_s + \|\boldsymbol{a}_2\|_s \leq 2^{1-\frac{1}{s}} \|\boldsymbol{a}_1 + \boldsymbol{a}_2\|_s \leq 2 \|\boldsymbol{a}_1 + \boldsymbol{a}_2\|_s.$

Since inequality $(\star\star\star)$ holds for any non-negative h_t, it follows that

$$\begin{aligned}
\mathfrak{R}(\mathcal{F}_q, r) &\leq \sqrt{\frac{4}{nT} \left\| \left(\min_{h_t \geq 0} rT^{1-\frac{2}{q^*}} h_t + \frac{2eq^{*2} R_{max}^2}{T} \sum_{j>h_t} \lambda_t^j \right)_{t=1}^{T} \right\|_{\frac{q^*}{2}}} + \frac{\sqrt{2\mathcal{K}e} R_{max} q^* T^{\frac{1}{q^*}}}{nT} \\
&\leq \sqrt{\frac{4}{nT} \left\| \left(\sum_{j=1}^{\infty} \min \left(rT^{1-\frac{2}{q^*}}, \frac{2eq^{*2} R_{max}^2}{T} \lambda_t^j \right) \right)_{t=1}^{T} \right\|_{\frac{q^*}{2}}} + \frac{\sqrt{2\mathcal{K}e} R_{max} q^* T^{\frac{1}{q^*}}}{nT}.
\end{aligned}$$

Proof of Theorem 17

By considering the hypothesis space in (16) and the MT-LRC's definition, we have

$$\begin{aligned}
\mathfrak{R}(\mathcal{F}_{q,R_{max},T}, r) &= \frac{1}{T} \mathbb{E}_{X,\sigma} \left\{ \sup_{\substack{Pf^2 \leq r, \\ \|\boldsymbol{W}\|_{2,q}^2 \leq 2R_{max}^2}} \sum_{t=1}^{T} \left\langle \boldsymbol{w}_t, \frac{1}{n} \sum_{i=1}^{n} \sigma_t^i \phi(X_t^i) \right\rangle \right\} \\
&= \frac{1}{T} \mathbb{E}_{X,\sigma} \left\{ \sup_{\substack{1/T \sum_{t=1}^{T} \mathbb{E}\langle \boldsymbol{w}_t, \phi(X_t) \rangle^2 \leq r, \\ \|\boldsymbol{W}\|_{2,q}^2 \leq 2R_{max}^2}} \sum_{t=1}^{T} \left\langle \boldsymbol{w}_t, \frac{1}{n} \sum_{i=1}^{n} \sigma_t^i \phi(X_t^i) \right\rangle \right\} \\
&\geq \frac{1}{T} \mathbb{E}_{X,\sigma} \left\{ \sup_{\substack{\forall t\, \mathbb{E}_X \langle \boldsymbol{w}_t, \phi(X_t) \rangle^2 \leq r, \\ \|\boldsymbol{W}\|_{2,q}^2 \leq 2R_{max}^2, \\ \|\boldsymbol{w}_1\|_2 = \ldots = \|\boldsymbol{w}_t\|_2}} \sum_{t=1}^{T} \left\langle \boldsymbol{w}_t, \frac{1}{n} \sum_{i=1}^{n} \sigma_t^i \phi(X_t^i) \right\rangle \right\}
\end{aligned}$$

$$= \frac{1}{T}\mathbb{E}_{X,\sigma}\left\{\sup_{\substack{\forall t\, \mathbb{E}_X\langle \boldsymbol{w}_t,\phi(X_t)\rangle^2\le r,\\ \forall t\, \|\boldsymbol{w}_t\|_2^2\le 2R_{max}^2 T^{-\frac{2}{q}}}} \sum_{t=1}^{T}\left\langle \boldsymbol{w}_t, \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i)\right\rangle\right\}$$

$$= \frac{1}{T}\sum_{t=1}^{T}\mathbb{E}_{X,\sigma}\left\{\sup_{\substack{\forall t\, \mathbb{E}_X\langle \boldsymbol{w}_t,\phi(X_t)\rangle^2\le r,\\ \forall t\, \|\boldsymbol{w}_t\|_2^2\le 2R_{max}^2 T^{-\frac{2}{q}}}} \left\langle \boldsymbol{w}_t, \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i)\right\rangle\right\}$$

$$= \mathbb{E}_{X,\sigma}\left\{\sup_{\substack{\mathbb{E}_X\langle \boldsymbol{w}_1,\phi(X_1)\rangle^2\le r,\\ \|\boldsymbol{w}_1\|_2^2\le 2R_{max}^2 T^{-\frac{2}{q}}}} \left\langle \boldsymbol{w}_1, \frac{1}{n}\sum_{i=1}^{n}\sigma_1^i\phi(X_1^i)\right\rangle\right\}$$

$$= \mathfrak{R}(\mathcal{F}_{1,R_{max}T^{-\frac{1}{q}},1}, r).$$

According to Mendelson (2003), it can be shown that there is a constant c such that if $\lambda_t^1 \ge \frac{1}{nR_{max}^2}$, then, for all $r \ge \frac{1}{n}$, it holds that $\mathfrak{R}(\mathcal{F}_{1,R_{max}T^{-\frac{1}{q}},1}, r) \ge \sqrt{\frac{c}{n}\sum_{j=1}^{\infty}\min\left(r, R_{max}^2 T^{-\frac{2}{q}}\lambda_1^j\right)}$, which provides the desired result after some algebraic manipulations. The following lemma is used in the proof of the LRC bounds for the L_{S_q}-Schatten norm regularized MTL in Corollary 19.

Lemma C.4 (Khintchine's inequality for arbitrary matrices in Tomczak-Jaegermann (1974)) *Let $\boldsymbol{Q}_1, \ldots, \boldsymbol{Q}_n$ be a set of arbitrary $m \times n$ matrices and let $\sigma_1, \ldots, \sigma_n$ be a sequence of independent Bernoulli random variables. Then for all $p \ge 2$,*

$$\mathbb{E}_\sigma\left[\left\|\sum_{i=1}^{n}\sigma_i\boldsymbol{Q}_i\right\|_{S_p}^{p}\right] \le p^{p/2}\left(\sum_{i=1}^{n}\|\boldsymbol{Q}_i\|_{S_p}^2\right)^{p/2}. \tag{C.7}$$

Proof of Corollary 19

In order to find an LRC bound for an L_{S_q}-Schatten norm regularized hypothesis space of (26), one just needs to bound the expectation term in (11). Define $\boldsymbol{U}_t^i$ as the matrix with T columns, whose only non-zero t^{th} column equals $\sum_{j>h_t}\left\langle \frac{1}{n}\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle \boldsymbol{u}_t^j$. Recall that, for the Schatten norm regularized hypothesis space of (26), it holds that $\boldsymbol{D} = \boldsymbol{I}$. Therefore, we will have that

$$\mathbb{E}_{X,\sigma}\left\|\boldsymbol{D}^{-1/2}\boldsymbol{V}\right\|_* = \mathbb{E}_{X,\sigma}\left\|\left(\sum_{j>h_t}\left\langle \frac{1}{n}\sum_{i=1}^{n}\sigma_t^i\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle \boldsymbol{u}_t^j\right)_{t=1}^{T}\right\|_{S_{q^*}}$$

$$= \mathbb{E}_{X,\sigma}\left\|\sum_{t=1}^{T}\sum_{i=1}^{n}\sigma_t^i\boldsymbol{U}_t^i\right\|_{S_{q^*}} \overset{\text{Jensen}}{\le} \mathbb{E}_X\left\{\mathbb{E}_\sigma\left\|\sum_{t=1}^{T}\sum_{i=1}^{n}\sigma_t^i\boldsymbol{U}_t^i\right\|_{S_{q^*}}^{q^*}\right\}^{\frac{1}{q^*}}$$

$$\overset{\text{(C.7)}}{\le} \mathbb{E}_X\left\{(q^*)^{q^*/2}\left(\sum_{t=1}^{T}\sum_{i=1}^{n}\|\boldsymbol{U}_t^i\|_{S_{q^*}}^2\right)^{q^*/2}\right\}^{\frac{1}{q^*}}$$

$$= \sqrt{q^*}\mathbb{E}_X\left(\sum_{t=1}^{T}\sum_{i=1}^{n}\left\|\sum_{j>h_t}\left\langle \frac{1}{n}\phi(X_t^i), \boldsymbol{u}_t^j\right\rangle \boldsymbol{u}_t^j\right\|^2\right)^{1/2}$$

$$= \sqrt{q^*}\mathbb{E}_X\left(\sum_{t=1}^{T}\sum_{i=1}^{n}\sum_{j>h_t}\frac{1}{n^2}\left\langle \phi(X_t^i), \boldsymbol{u}_t^j\right\rangle^2\right)^{1/2}$$

$$\overset{\text{Jensen}}{\le} \frac{\sqrt{q^*}}{n}\left(\sum_{t=1}^{T}\sum_{i=1}^{n}\sum_{j>h_t}\lambda_t^j\right)^{\frac{1}{2}} = \sqrt{\frac{q^*}{n}\left\|\left(\sum_{j>h_t}\lambda_t^j\right)_{t=1}^{T}\right\|_1}. \tag{C.8}$$

Proof of Corollary 22

Similar to the proof of Corollary 19, for the graph regularized hypothesis space depicted in (28), one can bound the expectation term in (11) in this manner

$$\mathbb{E}_{X,\sigma}\left\|\boldsymbol{D}^{-1/2}\boldsymbol{V}\right\|_* = \mathbb{E}_{X,\sigma}\left[\mathrm{tr}\left(\boldsymbol{V}^T\boldsymbol{D}^{-1}\boldsymbol{V}\right)\right]^{\frac{1}{2}}$$

$$\overset{\text{Jensen}}{\le} \mathbb{E}_X\left(\frac{1}{n^2}\sum_{t,s=1}^{T,T}\sum_{i,l=1}^{n,n}\sum_{j>h_t}\sum_{k>h_s}\boldsymbol{D}_{st}^{-1}\mathbb{E}_\sigma\left(\sigma_t^i\sigma_s^l\right)\left\langle \phi(X_t^i), \boldsymbol{u}_t^j\right\rangle\left\langle \phi(X_s^l), \boldsymbol{u}_s^k\right\rangle\left\langle \boldsymbol{u}_t^j, \boldsymbol{u}_s^k\right\rangle\right)^{\frac{1}{2}}$$

$$= \mathbb{E}_X\left(\frac{1}{n}\sum_{t=1}^{T}\boldsymbol{D}_{tt}^{-1}\sum_{j>h_t}\frac{1}{n}\sum_{i=1}^{n}\left\langle \phi(X_t^i), \boldsymbol{u}_t^j\right\rangle^2\right)^{\frac{1}{2}}$$

$$\overset{\text{Jensen}}{\le} \left(\frac{1}{n}\sum_{t=1}^{T}\boldsymbol{D}_{tt}^{-1}\sum_{j>h_t}\frac{1}{n}\sum_{i=1}^{n}\mathbb{E}_X\left\langle \phi(X_t^i), \boldsymbol{u}_t^j\right\rangle^2\right)^{\frac{1}{2}}$$

$$= \frac{1}{\sqrt{n}}\left(\sum_{t=1}^{T}\sum_{j>h_t}\boldsymbol{D}_{tt}^{-1}\lambda_t^j\right)^{\frac{1}{2}} = \sqrt{\frac{1}{n}\left\|\left(\boldsymbol{D}_{tt}^{-1}\sum_{j>h_t}\lambda_t^j\right)_{t=1}^{T}\right\|_1}. \tag{C.9}$$

The remainder of the derivation is similar to that of Corollary 13 and is omitted for brevity.

Appendix D. Proof of the results in Sect. 6: "Discussion"

In what follows, we provide some general results that imply Theorem 26. More specifically, we restate two concentration results for sums of non-negative operators with finite-dimensional ranges. Towards this end, we will say that two operators A and B are related as $A \preceq B$, if $B - A$ is a positive semi-definite operator.

Theorem D.1 (Theorem A.3 in Maurer and Pontil (2016)) *Consider the separable Hilbert space $\mathcal{H}$. Let $\mathcal{M} \subseteq \mathcal{H}$ be a subspace of finite dimension d. Also, consider the finite sequence A_k of random, independent, self-adjoint operators on $\mathcal{H}$. Assume that, for all $m \in \mathbb{N}$, $k \in \mathbb{N}_N$ and some $R \geq 0$, it holds that $A_k \succeq 0$, Ran$(A_k) \subseteq M$ almost surely and*

$$\mathbb{E}A_k^m \preceq m! R^{m-1} \mathbb{E}A_k.$$

Then,

$$\sqrt{\mathbb{E}\|\sum_k A_k\|_{S_\infty}} \leq \sqrt{\|\mathbb{E}\sum_k A_k\|_{S_\infty}} + \sqrt{R\left(\ln \dim(M) + 1\right)}. \tag{D.1}$$

Lemma D.2 (Lemma A.4 in Maurer and Pontil (2016)) *Let $a_1, \ldots, a_n \in \mathbb{R}^d$. Let*

$$\alpha := \sum_{i=1}^n \|a_i\|^2,$$

and define a rank-one operator Q_x on H, such that $Q_x v = \langle v, x\rangle x$. Also, let $D := \sum_{i=1}^n \sigma_i a_i$. Then, for any $p \geq 1$, it holds that

$$\mathbb{E}[(Q_D)^p] \preceq (2p-1)!! \alpha^{p-1} \mathbb{E}[Q_D],$$

where $(2p-1)!! := \prod_{i=1}^p (2i-1) = (2p-1)(2(p-1)-1) \times \ldots \times 5 \times 3 \times 1$.

Theorem D.3 (Theorem 7 in Maurer and Pontil (2013)) *Consider the independent random operators $A_1, \ldots, A_N$, which satisfy $0 \preceq A_k \preceq I$, $\forall k$. Also, assume that, for some $d \in \mathbb{N}$, it holds that*

$$\text{dimSpan}(\text{Ran}(A_1), \ldots, \text{Ran}(A_N)) \leq d,$$

almost surely. Then

$$\sqrt{\mathbb{E}\|\sum_{k=1}^N A_k\|_{S_\infty}} \leq \sqrt{\|\mathbb{E}\sum_{k=1}^N A_k\|_{S_\infty}} + \sqrt{6\left(\ln\left(4d^2\right) + 1\right)}. \tag{D.2}$$

Proof of Theorem 26

We first proceed to bound $\mathbb{E}_\sigma \|\boldsymbol{V}'\|_{S_\infty}$. Let $\boldsymbol{D}_t$ be the random vector $\sum_{j>h_t} \left\langle \sum_{i=1}^n \sigma_t^i \phi(X_t^i), \boldsymbol{u}_t^j \right\rangle \boldsymbol{u}_t^j$, and recall that the rank-one operator $Q_{\boldsymbol{D}_t}$ is such that $Q_{\boldsymbol{D}_t} v := \langle v, \boldsymbol{D}_t\rangle \boldsymbol{D}_t$. Then, it is clear that $\boldsymbol{V}'^* \boldsymbol{V}' = \sum_{t=1}^T Q_{\boldsymbol{D}_t}$ and, by using Jensen's inequality, we have

$$\mathbb{E}_\sigma \|\boldsymbol{V}'\|_{S_\infty} \leq \sqrt{\mathbb{E}_\sigma \|\sum_{t=1}^T Q_{\boldsymbol{D}_t}\|_\infty}.$$

Note that $\boldsymbol{D}_t$ is the projection of $\sum_{i=1}^n \sigma_t^i \phi(X_t^i)$ onto the space spanned by $\left(\boldsymbol{u}_t^j\right)_{j>h_t}$. Since $\sum_{i=1}^n \sigma_t^i \phi(X_t^i)$ belongs to the space spanned by $\left(\phi(X_t^i)\right)_{i=1}^n$, we know that $\boldsymbol{D}_t$ belongs to a subspace of dimension at most n. It then follows that Ran$(Q_{\boldsymbol{D}_1}), \ldots,$ Ran$(Q_{\boldsymbol{D}_T})$ lie in a subspace of dimension at most nT. Thus, Lemma D.2 for $\alpha_t := \sum_{i=1}^n \|\phi(X_t^i)\|^2$ yields

$$\mathbb{E}_\sigma[(Q_{\boldsymbol{D}_t})^m] \preceq (2m-1)!! \alpha_t^{m-1} \mathbb{E}_\sigma[Q_{\boldsymbol{D}_t}] \preceq m! \left(2 \max_t \alpha_t\right)^{m-1} \mathbb{E}_\sigma[Q_{\boldsymbol{D}_t}],$$

Therefore, applying Theorem D.1 with $R = 2\max_t \alpha_t$ and dimension less than nT gives

$$\sqrt{\mathbb{E}_\sigma \|\sum_{t=1}^T Q_{\boldsymbol{D}_t}\|_{S_\infty}} \leq \sqrt{\|\mathbb{E}_\sigma \sum_{t=1}^T Q_{\boldsymbol{D}_t}\|_{S_\infty}} + \sqrt{2\max_t \alpha_t \left(\ln(nT) + 1\right)}.$$

Since $\alpha_t = \sum_{i=1}^n \|\phi(X_t^i)\|^2 \leq n\mathcal{K}$, we get

$$\sqrt{\mathbb{E}_\sigma \|\sum_{t=1}^T Q_{\boldsymbol{D}_t}\|_{S_\infty}} \leq \sqrt{\|\mathbb{E}_\sigma \sum_{t=1}^T Q_{\boldsymbol{D}_t}\|_{S_\infty}} + \sqrt{2n\mathcal{K}\left(\ln(nT) + 1\right)}.$$

Now, we define

$$\begin{aligned} B_t := \mathbb{E}_\sigma Q_{\boldsymbol{D}_t} &= \sum_{i=1}^n \sum_{j,j'>h_t} \left\langle \phi(X_t^i), \boldsymbol{u}_t^j \right\rangle \left\langle \phi(X_t^i), \boldsymbol{u}_t^{j'} \right\rangle \boldsymbol{u}_t^i \otimes \boldsymbol{u}_t^{j'} \\ &= \sum_{i=1}^n \left\langle \sum_{j>h_t} \left\langle \phi(X_t^i), \boldsymbol{u}_t^j \right\rangle \boldsymbol{u}_t^j \right\rangle \otimes \left\langle \sum_{j'>h_t} \left\langle \phi(X_t^i), \boldsymbol{u}_t^{j'} \right\rangle \boldsymbol{u}_t^{j'} \right\rangle = \sum_{i=1}^n Q_{\boldsymbol{D}_{t,i}}, \end{aligned}$$

where we introduce $\boldsymbol{D}_{t,i} := \sum_{j>h_t} \left\langle \phi(X_t^i), \boldsymbol{u}_t^j \right\rangle \boldsymbol{u}_t^j$. Note that, in taking the expectation with respect to the random variables X_t^i's, Theorem D.1 cannot be utilized, since the covariance may have infinite rank, that is, we might not be able to find a finite-dimensional subspace, which contains the range of all the $Q_{\boldsymbol{D}_{t,i}}$'s. However, since for all $t \in \mathbb{N}_T$ and $i \in \mathbb{N}_n$, it holds that $\|\boldsymbol{D}_{t,i}\| \leq \sqrt{\mathcal{K}}$, all the $Q_{\boldsymbol{D}_{t,i}}$'s satisfy $0 \preceq Q_{\boldsymbol{D}_{t,i}} \preceq \mathcal{K} I$ and they all are rank-one operators. It then follows that

$$\text{dimSpan}\Big((\text{Ran}(\boldsymbol{B}_1), \ldots, \text{Ran}(\boldsymbol{B}_T))\Big) \leq nT.$$

Therefore, we can apply Theorem D.3 with $d = nT$, which, in conjunction with the Jensen's inequality, yields

$$\begin{aligned} \mathbb{E}_X \mathbb{E}_\sigma \|\boldsymbol{V}'\|_{S_\infty} &\leq \mathbb{E}_X \sqrt{\mathbb{E}_\sigma \|\sum_{t=1}^T Q_{\boldsymbol{D}_t}\|_{S_\infty}} \\ &\leq \mathbb{E}_X \sqrt{\|\mathbb{E}_\sigma \sum_{t=1}^T Q_{\boldsymbol{D}_t}\|_{S_\infty}} + \sqrt{2n\mathcal{K}\left(\ln(nT) + 1\right)} \\ &\leq \sqrt{\mathbb{E}_X \|\sum_{t=1}^T \boldsymbol{B}_t\|_{S_\infty}} + \sqrt{2n\mathcal{K}\left(\ln(nT) + 1\right)} \\ &\leq \sqrt{\|\mathbb{E}_X \sum_{t=1}^T \boldsymbol{B}_t\|_{S_\infty}} + \sqrt{6\mathcal{K}\left(\ln(4n^2T^2) + 1\right)} + \sqrt{2n\mathcal{K}\left(\ln(nT) + 1\right)}. \end{aligned} \tag{D.3}$$

After some simplifications, we arrive at

$$\mathbb{E}_{X,\sigma} \|\boldsymbol{V}'\|_{S_\infty} \leq \sqrt{\|\mathbb{E}_X \sum_{t=1}^T \boldsymbol{B}_t\|_{S_\infty}} + 6\sqrt{n\mathcal{K}\left(\ln(nT) + 1\right)}. \tag{D.4}$$

Furthermore, it can be shown that

$$\mathbb{E}_X \boldsymbol{B}_t = n \sum_{j>h_t} \lambda_t^j \boldsymbol{u}_t^j \otimes \boldsymbol{u}_t^j.$$

By considering the task-averaged operator $C = 1/T \sum_{t=1}^T J_t = 1/T \sum_{t=1}^T \sum_{j=1}^\infty \lambda_t^j \boldsymbol{u}_t^j \otimes \boldsymbol{u}_t^j$ and choosing $\lambda_h := \max_{t \in \mathbb{N}_T} \{\lambda_t^{h_t}\}$, we get

$$\begin{aligned} \mathbb{E}_{X,\sigma} \|\boldsymbol{V}'\|_{S_\infty} &\leq \sqrt{n \| \sum_{t=1}^T \sum_{j>h_t} \lambda_t^j \boldsymbol{u}_t^j \otimes \boldsymbol{u}_t^j \|_{S_\infty}} + 6\sqrt{n\mathcal{K}\left(\ln(nT)+1\right)} \\ &= \sqrt{nT\lambda_h} + 6\sqrt{n\mathcal{K}\left(\ln(nT)+1\right)}. \end{aligned} \tag{D.5}$$

This last result, combined with (48), provides the LRC bound for the trace norm regularized class $\mathcal{F}'_{S_1}$

$$\mathfrak{R}(\mathcal{F}'_{S_1}, r) \leq \sqrt{\frac{r\sum_{t=1}^T h_t}{nT}} + \sqrt{\frac{2R'^2_{max}\lambda_h}{n}} + 6\sqrt{\frac{2R'^2_{max}\mathcal{K}\left(\ln(nT)+1\right)}{nT}}. \tag{D.6}$$

Finally, using a similar argument as the one in Theorem 24, we get

$$r^* \leq \min_{0 \leq h_t \leq \infty} \left\{ \frac{B^2 \sum_{t=1}^T h_t}{nT} + 4BL\sqrt{\frac{2R'^2_{max}\lambda_h}{n}} + 24BL\sqrt{\frac{2R'^2_{max}\mathcal{K}\left(\ln(nT)+1\right)}{nT}} \right\}. \tag{D.7}$$

Abstract

In this paper, we introduce a new estimator for the emission densities of a nonparametric hidden Markov model. It is adaptive and minimax with respect to each state's regularity–as opposed to globally minimax estimators, which adapt to the worst regularity among the emission densities. Our method is based on Goldenshluger and Lepski's methodology. It is computationally efficient and only requires a family of preliminary estimators, without any restriction on the type of estimators considered. We present two such estimators that allow to reach minimax rates up to a logarithmic term: a spectral estimator and a least squares estimator. We show how to calibrate it in practice and assess its performance on simulations and on real data.

Keywords: hidden Markov model, model selection, nonparametric density estimation, oracle inequality, adaptive minimax estimation, spectral method, least squares method

1. Introduction

Finite state space hidden Markov models, or HMMs in short, are powerful tools for studying discrete time series and have been used in a variety of applications such as economics, signal processing and image analysis, genomics, ecology, speech recognition and ecology among others. The core idea is that the behaviour of the observations depends on a hidden variable that evolves like a Markov chain.

Formally, a hidden Markov model is a process $(X_j, Y_j)_{j\geq 1}$ in which $(X_j)_j$ is a Markov chain on $\mathcal{X}$, the Y_i's are independent conditionally on $(X_j)_j$ and the conditional distribution of Y_i given $(X_j)_j$ depends only on X_i. The parameters of the HMM are the parameters of the Markov chain, that is its initial distribution and transition matrix, and the parameters of the observations, that is the *emission distributions* $(\nu_k^*)_{k\in\mathcal{X}}$ where ν_k^* is the distribution of Y_j conditionally to $X_j = k$. Only the observations $(Y_j)_j$ are available.

In this article, we focus on estimating the emission distributions in a nonparametric setting. More specifically, assume that the emission distributions have a density with respect to some known dominating measure μ, and write f_k^* their densities–which we call the *emission densities*. The goal of this paper is to estimate all f_k^*'s with their minimax rate of convergence when the emission densities are not restricted to belong to a set of densities described by finitely many parameters.

1.1 Nonparametric State-by-state Adaptivity

Theoretical results in the nonparametric setting have only been developed recently. De Castro et al. (2017) and Bonhomme et al. (2016b) introduce spectral methods, and the latter is proved to be minimax but not adaptive–which means one needs to know the regularity of the densities beforehand to reach the minimax rate of convergence. De Castro et al. (2016) introduce a least squares estimator which is shown to be minimax adaptive up to a logarithmic term. However, all these papers have a common drawback: they study the emission densities as a whole and can not handle them separately. This comes from their error criterion, which is the supremum of the errors on all densities: what they actually prove is that $\max_{k\in\mathcal{X}} \|\hat{f}_k - f_k^*\|_2$ converges with minimax rate when $(\hat{f}_k)_k$ are their density estimators. In general, the regularity of each emission density could be different, leading to different rates of convergence. This means that having just one emission density that is very hard to estimate is enough to deteriorate the rate of convergence of all emission densities.

In this paper, we construct an estimator that is adaptive and estimates each emission density with its own minimax rate of convergence. We call this property state-by-state adaptivity. Our method does so by handling each emission density individually in a way that is theoretically justified–reaching minimax and adaptive rates of convergence with respect to the regularity of the emission densities–and computationally efficient thanks to its low computational and sample complexity.

Our approach for estimating the densities nonparametrically is model selection. The core idea is to approximate the target density using a family of parametric models that is dense within the nonparametric class of densities. For a square integrable density f^*, we consider its projection f_M^* on a finite-dimensional space $\mathfrak{P}_M$ (the parametric model), where M is a model index. This projection introduces an error, the *bias*, which is the distance $\|f^* - f_M^*\|_2$ between the target quantity and the model. The larger the model, the smaller the bias. On the other hand, larger models will make the estimation harder, resulting in a larger *variance* $\|\hat{f}_M - f_M^*\|_2^2$. The key step of model selection is to select a model with a small total error–or alternatively, a good *bias-variance tradeoff*.

In many situations, it is possible to reach the minimax rate of convergence with a good bias-variance tradeoff. Previous estimators of the emission densities of a HMM perform such a tradeoff based on an error that takes the transition matrix and all emission densities into account. Such an error leads to a rate of convergence that corresponds to the slowest minimax rate among the different parameters. In contrast, our method performs a bias-variance tradeoff for each emission density using an error term that depends only on the density in question, which makes it possible to reach the minimax rates for each density.

1.2 Plug-in Procedure

The method we propose is based on the method developed in the seminal papers of Goldenshluger and Lepski (2011, 2014) for density estimation, extended by Goldenshluger and Lepski (2013) to the white noise and regression models. It takes a family of estimators as input and chooses the estimator that performs a good bias-variance tradeoff separately for each hidden state. We recommend the article of Lacour et al. (2017) for an insightful presentation of this method in the case of conditional density estimation.

Our method and assumptions are detailed in Section 2. Let us give a quick overview of the method. Assume the densities belong to a Hilbert space $\mathcal{H}$. Given a family of subsets of finite-dimensional subspaces of $\mathcal{H}$ (the models) indexed by M and estimators $\hat{f}_k^{(M)}$ of the emission densities for each hidden state k and each model M, one computes a substitute for the bias of the estimators by

$$A_k(M) = \sup_{M'} \left\{ \left\| \hat{f}_k^{(M')} - \hat{f}_k^{(M \wedge M')} \right\|_2 - \sigma(M') \right\}.$$

for some penalty σ. Then, for each state k, one selects the estimator $\hat{M}_k$ from the model M minimizing the quantity $A_k(M) + 2\sigma(M)$. The penalty σ can also be interpreted as a variance bound, so that this penalization procedure can be seen as performing a bias-variance tradeoff. The novelty of this method is that it selects a different $\hat{M}_k$, that is a different model, for each hidden state: this is where the state-by-state adaptivity comes from. Also note that contrary to Goldenshluger and Lepski (2013), we do not make any assumption on how the estimators are computed, provided a variance bound holds.

The main theoretical result is an oracle inequality on the selected estimators $\hat{f}_k^{(\hat{M}_k)}$, see Theorem 2. As a consequence, we are able to get a rate of convergence that is different for each state. These rates of convergence will even be adaptive minimax up to a logarithmic factor when the method is applied to our two families of estimators: spectral estimators and least squares estimators. To the best of our knowledge, this is the first state-by-state adaptive algorithm for hidden Markov models.

Note that finding the right penalty term σ is essential in order to obtain minimax rates of convergence. This requires a fine theoretical control of the variance of the auxiliary estimators, in the form of assumption $[\mathbf{H}(\epsilon)]$ (see Section 2.1). To the best of our knowledge, there is no suitable result in the literature. This is the second theoretical contribution of this paper: we control two families of estimators in a way that makes it possible to reach adaptive minimax rate with our state-by-state selection method, up to a logarithmic term.

On the practical side, we run this method and several variants on data simulated from a HMM with three hidden states and one irregular density, as illustrated in Section 4. The simulations confirm that it converges with a different rate for each emission density, and that the irregular density does not alter the rate of convergence of the other ones, which is exactly what we wanted to achieve.

Better still, the added computation time is negligible compared to the computation time of the estimators: even for the spectral estimators of Section 3.2 (which can be computed much faster than the least squares estimators and the maximum likelihood estimators using EM), computing the estimators on 200 models for 50,000 observations (the lower bound of our sample sizes) of a 3-states HMM requires a few minutes, compared to a couple of seconds for the state-by-state selection step. The difference becomes even larger for more observations, since the complexity of the state-by-state selection step is independent of the sample size: for instance, computing the spectral estimators on 300 models for 2,200,000 observations requires a bit less than two hours, and a bit more than ten hours for 10,000,000 observations, compared to less than ten seconds for the selection step in both cases. We refer to Section 4.6 for a more detailled discussion about the algorithmic complexity of the algorithms.

1.3 Families of Estimators

We use two methods to construct families of estimators and apply the selection algorithm. The motivation and key result of this part of the paper is to control the variances of the estimators by the right penalty σ. This part is crucial if one wants to get adaptive minimax rates, and has not been adressed in previous papers. For both methods, we develop new theoretical results that allow to obtain a penalty σ that leads to adaptive minimax rates of convergence up to a logarithmic term. We present the algorithms and theoretical guarantees in Section 3.

The first method is a spectral method and is detailed in Section 3.2. Several spectral algorithms were developed, see for instance Anandkumar et al. (2012) and Hsu et al. (2012) in the parametric setting, and Bonhomme et al. (2016b) and De Castro et al. (2017) in a nonparametric framework. The main advantages of spectral methods are their computational efficiency and the fact that they do not resort to optimization procedure such as the EM and more generally nonconvex optimization algorithm, thus avoiding the well-documented issue of getting stuck into local sub-optimal minima.

Our spectral algorithm is based on the one studied in De Castro et al. (2017). However, their estimator cannot reach the minimax rate of convergence: the variance bound $\sigma(M)$ deduced from their results is proportional to M^3, while reaching the minimax rate requires $\sigma(M)$ to be proportional to M. To solve this issue, we introduce a modified version of their algorithm and show that it has the right variance bound, so that it is able to reach the adaptive minimax rate after our state-by-state selection procedure, up to a logarithmic term. Our algorithm also has an improved complexity: it is at most quasi-linear in the number of observations and in the model dimension, instead of cubic in the model dimension for the original algorithm.

The second method is a least squares method and is detailed in Section 3.3. Nonparametric least squares methods were first introduced by De Castro et al. (2016) to estimate the emission densities and extended by Lehéricy (to appear) to estimate all parameters at once. They rely on estimating the density of three consecutive observations of the HMM using a least squares criterion. Since the model is identifiable from the distribution of three consecutive observations when the emission distributions are linearly independent, it is possible to recover the parameters from this density. In practice, these methods are more accurate than the spectral methods and are more stable when the models are close to not satisfying the identifiability condition, see for instance De Castro et al. (2016) for the accuracy and Lehéricy (to appear) for the stability. However, since they rely on the minimization of a nonconvex criterion, the computation times of the corresponding algorithms are often longer than the ones from spectral methods.

A key step in proving theoretical guarantees for least squares methods is to relate the error on the density of three consecutive observations to the error on the HMM parameters in order to obtain an oracle inequality on the parameters from the oracle inequality on the density of three observations. More precisely, the difficult part is to lower bound the error on the density by the error on the parameters. Let us write g and g' the densities of the first three observations of a HMM with parameters θ and θ' respectively (these parameters actually correspond to the transition matrix and the emission densities of the HMM). Then

one would like to get

$$\|g - g'\|_2 \geq \mathcal{C}(\theta)\, d(\theta, \theta')$$

where d is the natural $\mathbf{L}^2$ distance on the parameters and $\mathcal{C}(\theta)$ is a positive constant which does not depend on θ'. Such inequalities are then used to lower bound the variance of the estimator of the density of three observations g^* by the variance of the parameter estimators: let g be the projection of g^* and g' be the estimator of g^* on the current approximation space (with index M). Denote θ^*_M and $\hat{\theta}_M$ the corresponding parameters and assume that the error $\|g - g'\|_2$ is bounded by some constant $\sigma'(M)$, then the result will be that

$$d(\hat{\theta}_M, \theta^*_M) \leq \frac{\sigma'(M)}{\mathcal{C}(\theta^*_M)}.$$

Such a result is crucial to control the variance of the estimators by a penalty term σ, which is the result we need for the state-by-state selection method. In the case where only the emission densities vary, De Castro et al. (2016) proved that such an inequality always holds for HMMs with 2 hidden states using brute-force computations, but it is still unknown whether it is always true for larger number of states. When the number of states is larger than 2, they show that this inequality holds under a generic assumption. Lehéricy (to appear) extended this result to the case where all parameters may vary. However, the constants deduced from both articles are not explicit, and their regularity (when seen as a function of θ) is unknown, which makes it impossible to use in our setting: one needs the constants $\mathcal{C}(\theta^*_M)$ to be lower bounded by the same positive constant, which requires some sort of regularity on the function $\theta \longmapsto \mathcal{C}(\theta)$ in the neighborhood of the true parameters.

To solve this problem, we develop a finer control of the behaviour of the difference $\|g - g'\|_2$, which is summarized in Theorem 10. We show that it is possible to assume $\mathcal{C}$ to be lower semicontinuous and positive without any additional assumption. In addition, we give an explicit formula for the constant when θ' and θ are close, which gives an explicit bound for the asymptotical rate of convergence. This result allows us to control the variance of the least squares estimators by a penalty σ which ensures that the state-by-state method reaches the adaptive minimax rate up to a logarithmic term.

1.4 Numerical Validation and Application to Real Data Sets

Section 4 shows how to apply the state-by-state selection method in practice and shows its performance on simulated data and a comparison with a method based on cross validation that does note estimate state by state.

Note that the theoretical results give a penalty term σ known only up to a multiplicative constant which is unknown in practice. This problem, the *penalty calibration* issue, is usual in model selection methods. It can be solved using algorithms such as the dimension jump heuristics, see for instance Birgé and Massart (2007), who introduce this heuristics and prove that it leads to an optimal penalization in the special case of Gaussian model selection framework. This method has been shown to behave well in practice in a variety of domains, see for instance Baudry et al. (2012). We describe the method and show how to use this heuristics to calibrate the penalties in Section 4.2.

We propose and compare several variants of our algorithm. Section 4.2 shows some variants in the calibration of the penalties and Section 4.3 shows other ways to select the final estimator. We discuss the result of the simulations and the convergence of the selected estimators in Section 4.4.

In Section 4.5, we compare our method with a non state-by-state adaptive method based on cross validation. Finally, we discuss the complexities of the auxiliary estimation methods and of our selection procedures in Section 4.6.

In Section 5, we apply our algorithm to two sets of GPS tracks. The first data set contains trajectories of artisanal fishers from Madagascar, recorded using a regular sampling with 30 seconds time steps. The second data set contains GPS positions of Peruvian seabird, recorded with 1 second time steps. We convert these tracks into the average velocity during each time step and apply our method using spectral estimators as input. The observed behaviour confirms the ability of our method to adapt to the different regularities by selecting different dimensions for each emission density.

Section 6 contains a conclusion and perspectives for this work.

Finally, Appendix A contains the details of our spectral algorithm and Appendix B is dedicated to the proofs.

1.5 Notations

We will use the following notations throughout the paper.

- $[K] = \{1, \dots, K\}$ is the set of integers between 1 and K.
- $\mathfrak{S}(K)$ is the set of permutations of $[K]$.
- $\|\cdot\|_F$ is the Frobenius norm. We implicitely extend the definition of the Frobenius norm to tensors with more than 2 dimensions.
- $\mathrm{Span}(A)$ is the linear space spanned by the family A.
- $\sigma_1(A) \geq \cdots \geq \sigma_{p\wedge n}(A)$ are the singular values of the matrix $A \in \mathbb{R}^{n\times p}$.
- $\mathbf{L}^2(\mathcal{Y}, \mu)$ is the set of real square integrable measurable functions on $\mathcal{Y}$ with respect to the measure μ.
- For $\mathbf{f} = (f_1, \dots, f_K) \in \mathbf{L}^2(\mathcal{Y}, \mu)^K$, $G(\mathbf{f})$ is the Gram matrix of $\mathbf{f}$, defined by $G(\mathbf{f})_{i,j} = \langle f_i, f_j \rangle$ for all $i, j \in [K]$.

2. The State-by-state Selection Procedure

In this section, we introduce the framework and our state-by-state selection method.

In Section 2.1, we introduce the notations and assumptions. In Section 2.2, we present our selection method and prove that it satisfies an oracle inequality.

2.1 Framework and Assumptions

Let $(X_j)_{j\geq 1}$ be a Markov chain with finite state space $\mathcal{X}$ of size K. Let $\mathbf{Q}^*$ be its transition matrix and π^* be its initial distribution. Let $(Y_j)_{j\geq 1}$ be random variables on a measured space $(\mathcal{Y}, \mu)$ with μ σ-finite such that conditionally on $(X_j)_{j\geq 1}$ the Y_j's are independent with a distribution depending only on X_j. Let ν^*_k be the distribution of Y_j conditionally to $\{X_j = k\}$. Assume that ν^*_k has density f^*_k with respect to μ. We call $(\nu^*_k)_{k\in\mathcal{X}}$ the *emission distributions* and $\mathbf{f}^* = (f^*_k)_{k\in\mathcal{X}}$ the *emission densities*. Then $(X_j, Y_j)_{j\geq 1}$ is a hidden Markov

model with parameters $(\pi^*, \mathbf{Q}^*, \mathbf{f}^*)$. The hidden chain $(X_j)_{j\geq 1}$ is assumed to be unobserved, so that the estimators are based only on the observations $(Y_j)_{j\geq 1}$.

Let $(\mathfrak{P}_M)_{M\in\mathbb{N}}$ be a nested family of finite-dimensional subspaces such that their union is dense in $\mathbf{L}^2(\mathcal{Y}, \mu)$. The spaces $(\mathfrak{P}_M)_{M\in\mathbb{N}}$ are our models; in the following we abusively call M the model instead of $\mathfrak{P}_M$. For each index $M \in \mathbb{N}$, we write $\mathbf{f}^{*,(M)} = (f_k^{*,(M)})_{k\in\mathcal{X}}$ the projection of $\mathbf{f}^*$ on $(\mathfrak{P}_M)^K$. It is the best approximation of the true densities within the model M.

In order to estimate the emission densities, we do not need to use every models. Typically there is no point in taking models with more dimensions than the sample size, since they will likely be overfitting. Let $\mathcal{M}_n \subset \mathbb{N}$ be the set of indices which will be used for the estimation from n observations. For each $M \in \mathcal{M}_n$, we assume we are given an estimator $\hat{\mathbf{f}}_n^{(M)} = (\hat{f}_{n,k}^{(M)})_{k\in\mathcal{X}} \in (\mathfrak{P}_M)^K$. We will need to assume that for all models, the variance–that is the distance between $\hat{\mathbf{f}}_n^{(M)}$ and $\mathbf{f}^{*,(M)}$–is small with high probability. In the following, we drop the dependency in n and simply write $\mathcal{M}$ and $\hat{\mathbf{f}}^{(M)}$.

The following result is what one usually obtains in model selection. It bounds the distance between the estimators $\hat{\mathbf{f}}^{(M)}$ and the projections $\mathbf{f}^{*,(M)}$ by some penalty function σ. Thus, $\sigma/2$ can be seen as a bound of the variance term.

[H(ϵ)] With probability $1-\epsilon$,

$$\forall M \in \mathcal{M}, \qquad \inf_{\tau_{n,M}\in\mathfrak{S}(K)} \max_{k\in\mathcal{X}} \left\| \hat{f}_k^{(M)} - f^{*,(M)}_{\tau_{n,M}(k)} \right\|_2 \leq \frac{\sigma(M,\epsilon,n)}{2}$$

where the upper bound $\sigma : (M, \epsilon, n) \in \mathcal{M} \times [0,1] \times \mathbb{N}^* \longmapsto \sigma(M,\epsilon,n) \in \mathbb{R}_+$ is nondecreasing in M. We show in Sections 3.2 and 3.3 how to obtain such a result for a spectral method and for a least squares method (using an algorithm from Lehéricy (to appear)). In the following, we omit the parameters ϵ and n in the notations and only write $\sigma(M)$.

What is important for the selection step is that the permutation $\tau_{n,M}$ does not depend on the model M: one needs all estimators $(\hat{f}_k^{(M)})_{M\in\mathcal{M}}$ to correspond to the same emission density, namely $f^*_{\tau_n(k)}$ when $\tau_{n,M} = \tau_n$ is the same for all models M. This can be done in the following way: let $M_0 \in \mathcal{M}$ and let

$$\hat{\tau}^{(M)} \in \arg\min_{\tau\in\mathfrak{S}(K)} \left\{ \max_{k\in\mathcal{X}} \left\| \hat{f}^{(M)}_{\tau(k)} - \hat{f}^{(M_0)}_k \right\|_2 \right\}$$

for all $M \in \mathcal{M}$. Then, consider the estimators obtained by swapping the hidden states by these permutations. In other words, for all $k \in \mathcal{X}$, consider

$$\hat{f}^{(M)}_{k,\text{new}} = \hat{f}^{(M)}_{\hat{\tau}^{(M)}(k)}.$$

Now, assume that the error on the estimators is small enough. More precisely, write $B_{M,M_0} = \max_{k\in\mathcal{X}} \left\| f_k^{*,(M)} - f_k^{*,(M_0)} \right\|_2$ the distance between the projections of $\mathbf{f}^*$ on the models M and M_0 and assume that $2\left[\sigma(M)/2 + \sigma(M_0)/2 + B_{M,M_0}\right]$ (that is twice the upper bound of the distance between two estimated emission densities corresponding to the same hidden states in models M and M_0) is smaller than $m(\mathbf{f}^*, M_0) := \min_{k'\neq k} \left\| f_k^{*,(M_0)} - f_{k'}^{*,(M_0)} \right\|_2$, which is the smallest distance between two different densities of the vector $\mathbf{f}^{*,(M_0)}$.

Then **[H(ϵ)]** ensures that with probability as least $1-\epsilon$, for all k, there exists a single component of $\hat{\mathbf{f}}^{(M)}$ that is closer than $\sigma(M)/2 + \sigma(M_0)/2$ of $f_k^{*,(M_0)}$, and this component will be $\hat{f}^{(M)}_{\hat{\tau}^{(M)}(k)}$ by definition. This is summarized in the following lemma.

Lemma 1 *Assume [**H**(ϵ)] holds. Then with probability $1-\epsilon$, there exists a permutation $\tau_n \in \mathfrak{S}(K)$ such that for all $k \in \mathcal{X}$ and for all $M \in \mathcal{M}$ such that*

$$\sigma(M) + \sigma(M_0) + 2B_{M,M_0} < m(\mathbf{f}^*, M_0),$$

one has

$$\max_{k\in\mathcal{X}} \left\| \hat{f}^{(M)}_{k,new} - f^{*,(M)}_{\tau_n(k)} \right\|_2 \leq \frac{\sigma(M)}{2}. \tag{1}$$

Proof Proof in Section B.1 ■

Thus, this property holds asymptotically as soon as $\inf \mathcal{M}$ tends to infinity and $\sup_{M\in\mathcal{M}} \sigma(M)$ tends to zero.

2.2 Estimator and Oracle Inequality

Let us now introduce our selection procedure. This method and the following theorem are based on the approach of Goldenshluger and Lepski (2011), but do not require any assumption on the structure of the estimators, provided a variance bound such as Equation (1) holds.

For each $k \in \mathcal{X}$ and $M \in \mathcal{M}$, let

$$A_k(M) = \sup_{M'\in\mathcal{M}} \left\{ \left\| \hat{f}_k^{(M')} - \hat{f}_k^{(M\wedge M')} \right\|_2 - \sigma(M') \right\}.$$

$A_k(M)$ serves as a replacement for the bias of the estimator $\hat{f}_k^{(M)}$, as can be seen in Equation (2). This comes from the fact that for large M', the quantity $\|\hat{f}_k^{(M')} - \hat{f}_k^{(M)}\|_2$ is upper bounded by the variances $\|\hat{f}_k^{(M')} - f_k^{*,(M')}\|_2$ and $\|\hat{f}_k^{(M)} - f_k^{*,(M)}\|_2$ (which are bounded by $\sigma(M')/2$) plus the bias $\|f_k^{*,(M)} - f_k^*\|_2$. Thus, only the bias term remains after substracting the variance bound $\sigma(M')$.

Then, for all $k \in \mathcal{X}$, select a model through the bias-variance tradeoff

$$\hat{M}_k \in \arg\min_{M\in\mathcal{M}} \{A_k(M) + 2\sigma(M)\}$$

and finally take

$$\hat{f}_k = \hat{f}_k^{(\hat{M}_k)}.$$

The following theorem shows an oracle inequality on this estimator.

Theorem 2 *Let $\epsilon \geq 0$ and assume equation (1) holds for all $k \in \mathcal{X}$ with probability $1-\epsilon$. Then with probability $1-\epsilon$,*

$$\forall k \in \mathcal{X}, \quad \|\hat{f}_k - f^*_{\tau_n(k)}\|_2 \leq 4 \inf_{M\in\mathcal{M}} \left\{ \|f^{*,(M)}_{\tau_n(k)} - f^*_{\tau_n(k)}\|_2 + \sigma(M,\epsilon) \right\}.$$

Proof We restrict ourselves to the event of probability at least $1-\epsilon$ where equation (1) holds for all $k \in \mathcal{X}$.

The first step consists in decomposing the total error: for all $M \in \mathcal{M}$ and $k \in \mathcal{X}$,

$$\left\|\hat{f}_k^{(\hat{M}_k)} - f^*_{\tau_n(k)}\right\|_2 \leq \left\|\hat{f}_k^{(\hat{M}_k)} - \hat{f}_k^{(\hat{M}_k \wedge M)}\right\|_2 + \left\|\hat{f}_k^{(\hat{M}_k \wedge M)} - \hat{f}_k^{(M)}\right\|_2 + \left\|\hat{f}_k^{(M)} - f^{*,(M)}_{\tau_n(k)}\right\|_2 + \left\|f^{*,(M)}_{\tau_n(k)} - f^*_{\tau_n(k)}\right\|_2.$$

From now on, we will omit the subscripts k and $\tau_n(k)$. Using equation (1) and the definition of $A(M)$ and $\hat{M}$, one gets

$$\begin{aligned}\left\|\hat{f}^{(\hat{M})} - f^*\right\|_2 \leq & (A(M) + \sigma(\hat{M})) + (A(\hat{M}) + \sigma(M)) \\ & + \sigma(M) + \left\|f^{*,(M)} - f^*\right\|_2 \\ \leq & 2A(M) + 4\sigma(M) + \left\|f^{*,(M)} - f^*\right\|_2.\end{aligned}$$

Then, notice that $A(M)$ can be bounded by

$$\begin{aligned}A(M) \leq & \sup_{M'} \left\{\left\|\hat{f}^{(M')} - f^{*,(M')}\right\|_2 + \left\|\hat{f}^{(M\wedge M')} - f^{*,(M\wedge M')}\right\|_2 - \sigma(M')\right\} \\ & + \sup_{M'} \left\|f^{*,(M')} - f^{*,(M\wedge M')}\right\|_2.\end{aligned}$$

Since σ is nondecreasing, $\sigma(M \wedge M') \leq \sigma(M')$, so that the first term is upper bounded by zero thanks to equation (1). The second term can be controlled since the orthogonal projection is a contraction. This leads to

$$A(M) \leq \left\|f^* - f^{*,(M)}\right\|_2, \tag{2}$$

which is enough to conclude. ■

Remark 3 *The oracle inequality also holds when taking*

$$A_k(M) = \sup_{M' \geq M} \left\{\left\|\hat{f}_k^{(M')} - \hat{f}_k^{(M)}\right\|_2 - \sigma(M')\right\}_+.$$

Remark 4 *Note that the selected $\hat{M}_k$ implicitely depends on the probability of error ϵ through the penalty σ.*

In the asymptotic setting, we take ϵ as a function of n, so that $\hat{M}_k$ is a function of n only. This will be used to get rid of ϵ when proving that the estimators reach the minimax rates of convergence.

3. Plug-in Estimators and Theoretical Guarantees

In this section, we introduce two methods to construct families of estimators of the emission densities. We show that they satisfy assumption [$\mathbf{H}(\epsilon)$] for a given variance bound σ.

In Section 3.1, we introduce the assumptions we will need for both methods. Section 3.2 is dedicated to the spectral estimator and Section 3.3 to the least squares estimator.

3.1 Framework and Assumptions

Recall that we approximate $\mathbf{L}^2(\mathcal{Y}, \mu)$ by a nested family of finite-dimensional subspaces $(\mathfrak{P}_M)_{M\in\mathcal{M}}$ such that their union is dense in $\mathbf{L}^2(\mathcal{Y}, \mu)$ and write $f_k^{*,(M)}$ the orthogonal projection of f_k^* on $\mathfrak{P}_M$ for all $k \in \mathcal{X}$ and $M \in \mathcal{M}$. We assume that $\mathcal{M} \subset \mathbb{N}$ and that the space $\mathfrak{P}_M$ has dimension M. A typical way to construct such spaces is to take $\mathfrak{P}_M$ spanned by the first M vectors of an orthonormal basis.

Both methods will construct an estimator of the emission densities for each model of this family. These estimators will then be plugged in the state-by-state selection method of Section 2.2, which will select one model for each state of the HMM.

We will need the following assumptions.

[**HX**] $(X_j)_{j\geq 1}$ is a stationary ergodic Markov chain with parameters $(\pi^*, \mathbf{Q}^*)$;

[**Hid**] $\mathbf{Q}^*$ is invertible and the family $\mathbf{f}^*$ is linearly independent.

The ergodicity assumption in [**HX**] is standard in order to obtain convergence results. In this case, the initial distribution is forgotten exponentially fast, so that the HMM will essentially behave like a stationary process after a short period of time. For the sake of simplicity, we assume the Markov chain to be stationary.

[**Hid**] appears in identifiability results, see for instance Gassiat et al. (2015) and Theorem 8. It is sufficient to ensure identifiability of the HMM from the law of three consecutive observations. Note that it is in general not possible to recover the law of a HMM from two observations (see for instance Appendix G of Anandkumar et al. (2012)), so that three is actually the minimum to obtain general identifiability.

3.2 The Spectral Method

Algorithm 1 is a variant of the spectral algorithm introduced in De Castro et al. (2017). Unlike the original one, it is able to reach the minimax rate of convergence thanks to two improvements. The first one consists in decomposing the joint density on different models, hence the use of two dimensions m and M. The second one consists in trying several randomized joint diagonalizations instead of just one, and selecting the best one, hence the parameter r. These additional parameters do not actually add much to the complexity of the algorithm: in theory, the choice $m, r \approx \log(n)$ is fine (see Corollary 6), and in practice, any large enough constant works, see Section 4 for more details.

For all $M \in \mathcal{M}$, let $(\varphi_1^M, \dots, \varphi_M^M)$ be an orthonormal basis of $\mathfrak{P}_M$. Let

$$\eta_3(m, M)^2 := \sup_{y,y' \in \mathcal{Y}^3} \sum_{a,c=1}^{m} \sum_{b=1}^{M} (\varphi_a^m(y_1)\varphi_b^M(y_2)\varphi_c^m(y_3) - \varphi_a^m(y_1')\varphi_b^M(y_2')\varphi_c^m(y_3'))^2.$$

The following theorem follows the proof of Theorem 3.1 of De Castro et al. (2017), with modifications that allow to control the error of the spectral estimators in expectation and are essential to obtain the right rates of convergence in Corollary 6.

Theorem 5 *Assume **[HX]** and **[Hid]** hold. Then there exists a constant M_0 depending on $\mathbf{f}^*$ and constants C_σ and n_1 depending on $\mathbf{f}^*$ and $\mathbf{Q}^*$ such that for all $\epsilon \in (0,1)$, for all*

Algorithm 1: Spectral estimation of the emission densities of a HMM (short version)

Data: A sequence of observations $(Y_1, \dots, Y_{n+2})$, two dimensions $m \leq M$, an orthonormal basis $(\varphi_1, \dots, \varphi_M)$ and number of retries r.

Result: Spectral estimators $(\hat{f}_k^{(M,r)})_{k\in\mathcal{X}}$.

[Step 1] Consider the following empirical estimators: for any $a, c \in [m]$ and $b \in [M]$,

- $\hat{\mathbf{M}}_{m,M,m}(a,b,c) := \frac{1}{n}\sum_{s=1}^{n} \varphi_a(Y_s)\varphi_b(Y_{s+1})\varphi_c(Y_{s+2})$
- $\hat{\mathbf{P}}_{m,m}(a,c) := \frac{1}{n}\sum_{s=1}^{n} \varphi_a(Y_s)\varphi_c(Y_{s+2})$.

[Step 2] Let $\hat{\mathbf{U}}_m$ be the $m \times K$ matrix of orthonormal left singular vectors of $\hat{\mathbf{P}}_{m,m}$ corresponding to its top K singular values. $\hat{\mathbf{U}}_m$ can be seen as a projection. Denote by $\mathbf{P}'$ and $\mathbf{M}'(\cdot,b,\cdot)$ the projected tensors, defined by $\mathbf{P}' = \hat{\mathbf{U}}_m^\top \hat{\mathbf{P}}_{m,m}\hat{\mathbf{U}}_m$ and likewise for $\mathbf{M}'$.

[Step 3] Form the matrices $\mathbf{B}(b) := (\mathbf{P}')^{-1}\mathbf{M}'$ for all $b \in [M]$.

[Step 4] Construct a matrix $\hat{\mathbf{O}}$ by taking the best approximate simultaneous diagonalization of all $\mathbf{B}(b)$ among r attempts: for all $b \in [M]$, $\mathbf{B}(b) \approx \mathbf{R}\mathrm{Diag}[\hat{\mathbf{O}}(b,\cdot)]\mathbf{R}^{-1}$ for some matrix $\mathbf{R}$ (see details in Algorithm 3, in Appendix A).

[Step 5] Define the emission densities estimators $\hat{\mathbf{f}}^{(M,r)} := (\hat{f}_k^{(M,r)})_{k\in\mathcal{X}}$ by: for all $k \in \mathcal{X}$, $\hat{f}_k^{(M,r)} := \sum_{b=1}^{M} \hat{\mathbf{O}}(b,k)\varphi_b$.

$m, M \in \mathcal{M}$ such that $M \geq m \geq M_0$ and for all $n \geq n_1\eta_3^2(m,M)(-\log\epsilon)^2$, with probability greater than $1-6\epsilon$,

$$\inf_{\tau\in\mathfrak{S}(K)} \max_{k\in\mathcal{X}} \|\hat{f}_k^{(M,\lceil t\rceil)} - f_{\tau(k)}^{*,(M)}\|_2^2 \leq C_\sigma \eta_3^2(m,M)\frac{(-\log\epsilon)^2}{n}$$

Proof Proof in Section B.2. ■

Note that the constants n_1 and C_σ depend on $\mathbf{Q}^*$ and $\mathbf{f}^*$. This dependency will not affect the rates of convergence of the estimators (with respect to the sample size n), but it can change the constants of the bounds and the minimum sample size needed to reach the asymptotic regime.

Let us now apply the state-by-state selection method to these estimators. The following corollary shows that it is possible to reach the minimax rate of convergence up to a logarithmic term separately for each state under standard assumptions. Note that we need to bound the resulting estimators by some power of n, but this assumption is not very restrictive since α can be arbitrarily large.

Corollary 6 *Assume **[HX]** and **[Hid]** hold. Also assume that $\eta_3^2(m,M) \leq C_\eta m^2 M$ for a constant $C_\eta > 0$ and that for all $k \in \mathcal{X}$, there exists s_k such that $\|f_k^{*,(M)} - f_k^*\|_2 = O(M^{-s_k})$. Then there exists a constant C_σ depending on $\mathbf{f}^*$ and $\mathbf{Q}^*$ such that the following holds.*

Let $\alpha > 0$ and $C \geq 2(1+2\alpha)\sqrt{C_\eta C_\sigma}$. Let $\hat{\mathbf{f}}^{sbs}$ be the estimators selected from the family $(\hat{\mathbf{f}}^{(M,\lceil(1+2\alpha)\log(n)\rceil)})_{M\leq M_{\max}(n)}$ with $M_{\max}(n) = n/\log(n)^5$, $m_M = \log(n)$ and $\sigma(M) = C\sqrt{\frac{M\log(n)^4}{n}}$ for all M. Then there exists a sequence of random permutations $(\tau_n)_{n\geq 1}$ such that

$$\forall k \in \mathcal{X}, \qquad \mathbb{E}\left[\left\|(-n^\alpha)\vee(\hat{f}^{sbs}_{\tau_n(k)}\wedge n^\alpha) - f_k^*\right\|_2^2\right] = O\left(\left(\frac{n}{\log(n)^4}\right)^{\frac{-2s_k}{2s_k+1}}\right).$$

The novelty of this result is that each emission density is estimated with its own rate of convergence: the rate $\frac{-s_k}{2s_k+1}$ is different for each emission density, even though the original spectral estimators did not handle them separately. This is due to our state-by-state selection method.

Moreover, it is able to reach the minimax rate for each density in an adaptive way. For instance, in the case of a β-Hölder density on $\mathcal{Y} = [0,1]^D$ (equipped with a trigonometric basis), one can easily check the control of η_3, and the control $\|f_k^{*,(M)} - f_k^*\|_2 = O(M^{-\beta/D})$ follows from standard approximation results, see for instance DeVore and Lorentz (1993). Thus, our estimators converge with the rate $(n/\log(n)^4)^{-2\beta/(2\beta+D)}$ to this density: this is the minimax rate up to a logarithmic factor.

Remark 7 *By aligning the estimators like in Section 2.1, one can replace the sequence of permutations in Corollary 6 by a single permutation, in other words there exists a random permutation τ which does not depend on n such that*

$$\forall k \in \mathcal{X}, \qquad \mathbb{E}\left[\left\|(-n^\alpha)\vee(\hat{f}^{sbs}_{\tau(k)}\wedge n^\alpha) - f_k^*\right\|_2^2\right] = O\left(\left(\frac{n}{\log(n)^4}\right)^{\frac{-2s_k}{2s_k+1}}\right).$$

This means that the sequence $(\hat{f}_k^{sbs})_{n\geq 1}$ is an adaptive rate-minimax estimator of f_k^*–or more precisely of one of the emission densities $(f_{k'}^*)_{k'\in\mathcal{X}}$, but since the distribution of the HMM is invariant under relabelling of the hidden states, one can assume the limit to be f_k^* without loss of generality–up to a logarithmic term.

At this point, it is important to note that the choice of the constant $C \geq 2(1+2\alpha)\sqrt{C_\eta C_\sigma}$ depends on the hidden parameters of the HMM and as such is unknown. This penalty calibration problem is very common in the model selection framework and can be solved in practice using methods such as the slope heuristics or the dimension jump method which have been proved to be theoretically valid in several cases, see for instance Baudry et al. (2012) and references therein. We use the dimension jump method and explain its principle and implementation in Section 4.2.

Proof Using Theorem 5, one gets that for all n and for all $M \in \mathcal{M}$ such that $n \geq n_1\eta_3^2(m_M,M)(1+2\alpha)^2\log(n)^2$, with probability $1-6n^{-1-2\alpha}$,

$$\begin{aligned}\inf_{\tau\in\mathfrak{S}(K)} \max_{k\in\mathcal{X}} \|\hat{f}_k^{(M,\lceil t\rceil)} - f_{\tau(k)}^{*,(M)}\|_2^2 &\leq C_\sigma\eta_3^2(m_M,M)\frac{(1+2\alpha)^2\log(n)^2}{n}\\ &\leq (1+\alpha)^2 C_\sigma C_\eta M\frac{\log(n)^4}{n}\\ &\leq \frac{\sigma(M)^2}{4}\end{aligned}$$

where $\sigma(M) = C\sqrt{\frac{M\log(n)^4}{n}}$ with C such that $C^2 \geq 4(1+2\alpha)^2 C_\sigma C_\eta$.

The condition on M becomes

$$n \geq n_1 \log(n)^4 M(1+2\alpha)^2$$

and is asymptotically true for all $M \leq M_{\max}(n)$ as soon as $M_{\max}(n) = o(n/\log(n)^4)$.

Thus, $[\mathbf{H}(6n^{-(1+2\alpha)})]$ is true for the family $(\hat{\mathbf{f}}^{(M,\lceil(1+2\alpha)\log(n)\rceil)})_{M\leq M_{\max}(n)}$. Note that the assumption $M_{\max}(n) = o(n/\log(n)^4)$ also implies that there exists M_1 such that for n large enough, Lemma 1 holds for all $M \geq M_1$, so that Theorem 2 implies that for n large enough, there exists a permutation τ_n such that with probability $1 - 6n^{-(1+2\alpha)}$, for all $k \in \mathcal{X}$,

$$\begin{aligned}
\|\hat{f}^{\mathrm{sbs}}_{\tau_n(k)} - f^*_k\|_2 &\leq 4 \inf_{M_1\leq M\leq M_{\max}} \{\|f^{*,(M)}_k - f^*_k\|_2 + \sigma(M)\} \\
&= O\left(\inf_{M_1\leq M\leq M_{\max}} \left\{M^{-s_k} + \sqrt{\frac{M\log(n)^4}{n}}\right\}\right) \\
&= O\left(\left(\frac{n}{\log(n)^4}\right)^{-s_k/(1+2s_k)}\right),
\end{aligned}$$

where the tradeoff is reached for $M = (\frac{n}{\log(n)^4})^{1/(1+2s_k)}$, which is in $[M_1, M_{\max}(n)]$ for n large enough.

Finally, write A the event of probability smaller than $6n^{-(1+2\alpha)}$ where $[\mathbf{H}(6n^{-(1+\alpha)})]$ doesn't hold, then for n large enough and for all $k \in \mathcal{X}$,

$$\begin{aligned}
\mathbb{E}\left[\left\|(-n^\alpha)\vee(\hat{f}^{\mathrm{sbs}}_{\tau_n(k)}\wedge n^\alpha) - f^*_k\right\|_2^2\right] &\leq \mathbb{E}\left[\mathbf{1}_A\left\|\hat{f}^{\mathrm{sbs}}_{\tau_n(k)} - f^*_k\right\|_2^2\right] + \mathbb{E}\left[\mathbf{1}_{A^c}(n^{2\alpha} + \|f^*_k\|_2^2)\right] \\
&= O\left(\left(\frac{n}{\log(n)^4}\right)^{-2s_k/(1+2s_k)}\right) + O\left(\frac{n^{2\alpha} + \|f^*_k\|_2^2}{n^{1+2\alpha}}\right) \\
&= O\left(\left(\frac{n}{\log(n)^4}\right)^{-2s_k/(1+2s_k)}\right).
\end{aligned}$$

■

3.3 The Penalized Least Squares Method

Let $\mathcal{F}$ be a subset of $\mathbf{L}^2(\mathcal{Y},\mu)$. We will need the following assumption on $\mathcal{F}$ in order to control the deviations of the estimators:

[HF] $\mathbf{f}^* \in \mathcal{F}^{K^*}$, $\mathcal{F}$ is closed under projection on $\mathfrak{P}_M$ for all $M \in \mathcal{M}$ and

$$\forall f \in \mathcal{F}, \quad \begin{cases} \|f\|_\infty \leq C_{\mathcal{F},\infty} \\ \|f\|_2 \leq C_{\mathcal{F},2} \end{cases}$$

with $C_{\mathcal{F},\infty}$ and $C_{\mathcal{F},2}$ larger than 1.

A simple way to construct such a set $\mathcal{F}$ when μ is a finite measure is to take the sets $(\mathfrak{P}_M)_M$ spanned by the first M vectors of an orthonormal basis $(\varphi_i)_{i\geq 0}$ whose first vector φ_0 is proportional to $\mathbf{1}$. Then any set $\mathcal{F}$ of densities such that $\int f d\mu = 1$, $\sum_i \langle f,\varphi_i\rangle^2 \leq C_{\mathcal{F},2}$ and $\sum_i |\langle f,\varphi_i\rangle| \|\varphi_i\|_\infty \leq C_{\mathcal{F},\infty}$ for given constants $C_{\mathcal{F},2}$ and $C_{\mathcal{F},\infty}$ and for all $f \in \mathcal{F}$ satisfies **[HF]**.

When $\mathbf{Q} \in \mathbb{R}^{K\times K}$, $\pi \in \mathbb{R}^K$ and $\mathbf{f} \in (\mathbf{L}^2(\mathcal{Y},\mu))^K$, let

$$g^{\pi,\mathbf{Q},\mathbf{f}}(y_1,y_2,y_3) = \sum_{k_1,k_2,k_3=1}^K \pi(k_1)\mathbf{Q}(k_1,k_2)\mathbf{Q}(k_2,k_3) f_{k_1}(y_1) f_{k_2}(y_2) f_{k_3}(y_3).$$

When π is a probability distribution, $\mathbf{Q}$ a transition matrix and $\mathbf{f}$ a K-tuple of probability densities, then $g^{\pi,\mathbf{Q},\mathbf{f}}$ is the density of the first three observations of a HMM with parameters $(\pi,\mathbf{Q},\mathbf{f})$. The motivation behind estimating $g^{\pi,\mathbf{Q},\mathbf{f}}$ is that it allows to recover the true parameters under the identifiability assumption **[Hid]**, as shown in the following theorem.

Let $\mathcal{Q}$ be the set of transition matrices on $\mathcal{X}$ and Δ the set of probability distributions on $\mathcal{X}$. For a permutation $\tau \in \mathfrak{S}(K)$, write $\mathbb{P}_\tau$ its matrix (that is the matrix defined by $\mathbb{P}_\tau(i,j) = \mathbf{1}_{\{j=\tau(i)\}}$). Finally, define the distance on the HMM parameters

$$\begin{aligned}
&d_{\mathrm{perm}}((\pi_1,\mathbf{Q}_1,\mathbf{f}_1),(\pi_2,\mathbf{Q}_2,\mathbf{f}_2))^2 \\
&\qquad = \inf_{\tau\in\mathfrak{S}(K)} \left\{\|\pi_1 - \mathbb{P}_\tau\pi_2\|_2^2 + \|\mathbf{Q}_1 - \mathbb{P}_\tau\mathbf{Q}_2\mathbb{P}_\tau^\top\|_F^2 + \sum_{k\in\mathcal{X}} \|f_{1,k} - f_{2,\tau(k)}\|_2^2\right\}.
\end{aligned}$$

This distance is invariant under permutation of the hidden states. This corresponds to the fact that a HMM is only identifiable up to relabelling of its hidden states.

Theorem 8 (Identifiability) *Let $(\pi^*,\mathbf{Q}^*,\mathbf{f}^*) \in \Delta\times\mathcal{Q}\times(\mathbf{L}^2(\mathcal{Y},\mu))^K$ such that $\pi^*_x > 0$ for all $x \in \mathcal{X}$ and **[Hid]** holds. Then for all $(\pi,\mathbf{Q},\mathbf{f}) \in \Delta\times\mathcal{Q}\times(\mathbf{L}^2(\mathcal{Y},\mu))^K$,*

$$(g^{\pi,\mathbf{Q},\mathbf{f}} = g^{\pi^*,\mathbf{Q}^*,\mathbf{f}^*}) \;\Rightarrow\; d_{perm}((\pi,\mathbf{Q},\mathbf{f}),(\pi^*,\mathbf{Q}^*,\mathbf{f}^*)) = 0.$$

Proof The spectral algorithm of De Castro et al. (2017) applied on the finite dimensional space spanned by the components of $\mathbf{f}$ and $\mathbf{f}^*$ allows to recover all the parameters even when the emission densities are not probability densities and when the Markov chain is not stationary. ■

Define the empirical contrast

$$\gamma_n(t) = \|t\|_2^2 - \frac{2}{n}\sum_{j=1}^n t(Z_j)$$

where $Z_j := (Y_j, Y_{j+1}, Y_{j+2})$ and $(Y_j)_{1\leq j\leq n+2}$ are the observations. It is a biased estimator of the $\mathbf{L}^2$ loss: for all $t \in (\mathbf{L}^2(\mathcal{Y},\mu))^3$,

$$\mathbb{E}[\gamma_n(t)] = \|t - g^*\|_2^2 - \|g^*\|_2^2$$

Algorithm 2: Least squares estimation of the emission densities of a HMM

Data: A sequence of observations $(Y_1, \dots, Y_{n+2})$, a dimension M and an orthonormal basis $\Phi = (\varphi_1, \dots, \varphi_M)$.

Result: Least squares estimators $\hat{\pi}^{(M)}$, $\hat{\mathbf{Q}}^{(M)}$ and $(\hat{f}_k^{(M)})_{k\in\mathcal{X}}$.

[Step 1] Compute the tensor $\hat{\mathbf{M}}_M$ defined by $\hat{\mathbf{M}}_M(a,b,c) := \frac{1}{n}\sum_{s=1}^{n} \varphi_a(Y_s)\varphi_b(Y_{s+1})\varphi_c(Y_{s+2})$ for all $a, b, c \in [M]$.

[Step 2] Find a minimizer $(\hat{\pi}^{(M)}, \hat{\mathbf{Q}}^{(M)}, \hat{\mathbf{O}})$ of $(\pi, \mathbf{Q}, \mathbf{O}) \longmapsto \|\mathbf{M}_{(\pi,\mathbf{Q},\mathbf{O})} - \hat{\mathbf{M}}_M\|_F^2$ where

- $\pi \in \mathbb{R}^K$ is a probability distribution on $\mathcal{X}$, i.e. $\sum_{k\in\mathcal{X}} \pi_k = 1$;
- $\mathbf{Q} \in \mathbb{R}^{K\times K}$ is a transition matrix on $\mathcal{X}$, i.e. $\sum_{k'\in\mathcal{X}} Q(k,k') = 1$ for all $k \in \mathcal{X}$;
- $\mathbf{O}$ is a $M \times K$ matrix such that for all $k \in \mathcal{X}$, $\sum_{b=1}^{M} \mathbf{O}(b,k)\varphi_b \in \mathcal{F}$;
- $\mathbf{M}_{(\pi,\mathbf{Q},\mathbf{O})} \in \mathbb{R}^{M\times M\times M}$ is defined by $\mathbf{M}_{(\pi,\mathbf{Q},\mathbf{O})}(\cdot,b,\cdot) = \mathbf{O}\mathrm{Diag}[\pi]\mathbf{Q}\mathrm{Diag}[\mathbf{O}(b,\cdot)]\mathbf{Q}\mathbf{O}^\top$ for all $b \in [M]$.

[Step 3] Consider the emission densities estimators $\hat{\mathbf{f}}^{(M)} := (\hat{f}_k^{(M)})_{k\in\mathcal{X}}$ defined by for all $k \in \mathcal{X}$, $\hat{f}_k^{(M)} := \sum_{b=1}^{M} \hat{\mathbf{O}}(b,k)\varphi_b$.

where $g^* = g^{\pi^*,\mathbf{Q}^*,\mathbf{f}^*}$. Since the bias does not depend on the function t, one can hope that the minimizers of γ_n are close to minimizers of $\|t - g^*\|_2$. We will show that this is indeed the case.

The least squares estimators of all HMM parameters are defined for each model $\mathfrak{P}_M$ by

$$(\hat{\pi}^{(M)}, \hat{\mathbf{Q}}^{(M)}, \hat{\mathbf{f}}^{(M)}) \in \underset{\pi\in\Delta,\, \mathbf{Q}\in\mathcal{Q},\, \mathbf{f}\in(\mathfrak{P}_M\cap\mathcal{F})^K}{\arg\min} \gamma_n(g^{\pi,\mathbf{Q},\mathbf{f}}).$$

The procedure is summarized in Algorithm 2. Note that with the notations of the algorithm,

$$\gamma_n(g^{\pi,\mathbf{Q},\mathbf{O}^\top\Phi}) = \|\mathbf{M}_{(\pi,\mathbf{Q},\mathbf{O})} - \hat{\mathbf{M}}_M\|_F^2 - \|\hat{\mathbf{M}}_M\|_F^2.$$

Then, the proof of the oracle inequality of Lehéricy (to appear) allows to get the following result.

Theorem 9 *Assume **[HF]**, **[HX]** and **[Hid]** hold.*

Then there exists constants C and n_0 depending on $C_{\mathcal{F},2}$, $C_{\mathcal{F},\infty}$ and $\mathbf{Q}^*$ such that for all $n \geq n_0$, for all $t > 0$, with probability greater than $1 - e^{-t}$, one has for all $M \in \mathcal{M}$ such that $M \leq n$:

$$\|\hat{g}^{\hat{\pi}^{(M)},\hat{\mathbf{Q}}^{(M)},\hat{\mathbf{f}}^{(M)}} - g^{\pi^*,\mathbf{Q}^*,\mathbf{f}^{*,(M)}}\|_2^2 \leq C\Big(\frac{t}{n} + M\frac{\log(n)}{n}\Big).$$

In order to deduce a control of the error on the parameters–and in particular on the emission densities–from the previous result, we will need to assume that the quadratic form derived from the second-order expansion of $(\pi, \mathbf{Q}, \mathbf{f}) \in \Delta \times \mathcal{Q} \times \mathcal{F}^K \longmapsto \|g^{\pi,\mathbf{Q},\mathbf{f}} - g^*\|_2^2$ around $(\pi^*, \mathbf{Q}^*, \mathbf{f}^*)$ is nondegenerate.

It is still unknown whether this nondegeneracy property is true for all parameters $(\pi^*, \mathbf{Q}^*, \mathbf{f}^*)$ such that **[Hid]** and **[HX]** hold. De Castro et al. (2016) prove it for $K = 2$ hidden states when only the emission densities are allowed to vary by using brute-force computations. To do so, they introduce an (explicit) polynomial in the coefficients of π^*, $\mathbf{Q}^*$ and of the Gram matrix of $\mathbf{f}^*$ and prove that its value is nonzero if and only if the quadratic form is nondegenerate for the corresponding parameters. The difficult part of the proof is to show that this polynomial is always nonzero.

For the expression of this polynomial–which we will write H–in our setting, we refer to Section B.3. Note that Lehéricy (to appear) proves that this polynomial H is non identically zero: it is shown that there exists parameters $(\pi, \mathbf{Q}, \mathbf{f})$ satisfying **[HX]** and **[Hid]** such that $H(\pi, \mathbf{Q}, \mathbf{f}) \neq 0$, which means that the following assumption is generically satisfied:

[Hdet] $H(\pi^*, \mathbf{Q}^*, \mathbf{f}^*) \neq 0$.

The following result allows to lower bound the $\mathbf{L}^2$ error on the density of three consecutive observations by the error on the parameters of the HMM using this condition. It is an improvement of Theorem 6 of De Castro et al. (2016) and Theorem 9 of Lehéricy (to appear). The main difference is that the constant $c^*(\pi^*, \mathbf{Q}^*, \mathbf{f}^*, \mathcal{F})$ does not depend on the $\mathbf{f}$ around which the parameters are taken. This is crucial to obtain Corollary 11, from which we will deduce **[H0]**. Note that we do not need $\mathbf{f}$ to be in a compact neighborhood of $\mathbf{f}^*$. Another improvement is that the constant in the minoration only depends on the true parameters and on the set $\mathcal{F}$.

Theorem 10 *1. Assume that **[HF]** holds and that for all $f \in \mathcal{F}$, $\int f d\mu = 1$.*

*Then there exist a lower semicontinuous function $(\pi^*, \mathbf{Q}^*, \mathbf{f}^*) \longmapsto c^*(\pi^*, \mathbf{Q}^*, \mathbf{f}^*, \mathcal{F})$ that is positive when **[Hid]** and **[Hdet]** hold and a neighborhood $\mathcal{V}$ of $\mathbf{f}^*$ in $\mathcal{F}^K$ depending only on π^*, $\mathbf{Q}^*$, $\mathbf{f}^*$ and $\mathcal{F}$ such that for all $\mathbf{f} \in \mathcal{V}$ and for all $\pi \in \Delta$, $\mathbf{Q} \in \mathcal{Q}$ and $\mathbf{h} \in \mathcal{F}^K$,*

$$\|g^{\pi,\mathbf{Q},\mathbf{h}} - g^{\pi^*,\mathbf{Q}^*,\mathbf{f}}\|_2^2 \geq c^*(\pi^*, \mathbf{Q}^*, \mathbf{f}^*, \mathcal{F}) d_{perm}((\pi, \mathbf{Q}, \mathbf{h}), (\pi^*, \mathbf{Q}^*, \mathbf{f}))^2.$$

*2. There exists a continuous function $\epsilon : (\pi^*, \mathbf{Q}^*, \mathbf{f}^*) \mapsto \epsilon(\pi^*, \mathbf{Q}^*, \mathbf{f}^*)$ that is positive when **[Hid]** and **[Hdet]** hold and such that for all $\pi \in \Delta$, $\mathbf{Q} \in \mathcal{Q}$ and $\mathbf{h} \in (\mathbf{L}^2(\mathcal{Y}, \mu))^K$ a K-tuple of probability densities such that $d_{perm}((\pi, \mathbf{Q}, \mathbf{h}), (\pi^*, \mathbf{Q}^*, \mathbf{f}^*)) \leq \epsilon(\pi^*, \mathbf{Q}^*, \mathbf{f}^*)$, one has*

$$\|g^{\pi,\mathbf{Q},\mathbf{h}} - g^{\pi^*,\mathbf{Q}^*,\mathbf{f}^*}\|_2^2 \geq c_0(\pi^*, \mathbf{Q}^*, \mathbf{f}^*) d_{perm}((\pi, \mathbf{Q}, \mathbf{h}), (\pi^*, \mathbf{Q}^*, \mathbf{f}^*))^2.$$

where

$$c_0(\pi^*, \mathbf{Q}^*, \mathbf{f}^*) = \frac{(\inf_{k\in\mathcal{X}} \pi^*(k))\, \sigma_K(\mathbf{Q}^*)^4 \sigma_K(G(\mathbf{f}^*))^2}{4} \wedge \frac{H(\pi^*, \mathbf{Q}^*, \mathbf{f}^*)}{2(1 \wedge K\|G(\mathbf{f}^*)\|_\infty)(3K^3(1 \vee \|G(\mathbf{f}^*)\|_\infty^4))^{K^2-K/2}}.$$

Proof Proof in Section B.4. ∎

Corollary 11 *Assume **[HX]**, **[HF]**, **[Hid]** and **[Hdet]** hold. Also assume that for all $f \in \mathcal{F}$, $\int f d\mu = 1$.*

Then there exists a constant n_0 depending on $C_{\mathcal{F},2}$, $C_{\mathcal{F},\infty}$ and $\mathbf{Q}^*$ and constants M_0 and C' depending on $\mathcal{F}$, $\mathbf{Q}^*$ and $\mathbf{f}^*$ such that for all $n \geq n_0$ and $t > 0$, with probability greater than $1 - e^{-t}$, one has for all $M \in \mathcal{M}$ such that $M_0 \leq M \leq n$:

$$\inf_{\tau \in \mathfrak{S}(K)} \max_{k \in \mathcal{X}} \|\hat{f}_k^{(M)} - f_{\tau(k)}^{*,(M)}\|_2^2 \leq C' \left(M \frac{\log(n)}{n} + \frac{t}{n} \right).$$

Remark 12 *Using the second point of Theorem 10, one can alternatively take n_0 and M_0 depending on $\mathcal{F}$, $\mathbf{Q}^*$ and $\mathbf{f}^*$, and C' depending on $C_{\mathcal{F},2}$, $C_{\mathcal{F},\infty}$, $\mathbf{Q}^*$ and $\mathbf{f}^*$ only. For instance, one can take $C' = C/c_0(\pi^*, \mathbf{Q}^*, \mathbf{f}^*)$ with the notations of Theorems 9 and 10.*

In particular, this means that the asymptotic variance bound of the least squares estimators (and therefore the rate of convergence of the estimators selected by our state-by-state selection method) does not depend on the set $\mathcal{F}$, but only on the HMM parameters and on the bounds $C_{\mathcal{F},2}$ and $C_{\mathcal{F},\infty}$ on the square and supremum norms of the emission densities. Note that this universality result is essentially an asymptotic one since it requires n_0 to depend on $\mathcal{F}$ in a non-explicit way.

Proof Let $\mathcal{V}$ be the neighborhood given by Theorem 10, then there exists M_0 such that for all $M \geq M_0$, $\mathbf{f}^{*,(M)} \in \mathcal{V}$. Then Theorem 9 and Theorem 10 applied to $\pi = \hat{\pi}^{(M)}$, $\mathbf{Q} = \hat{\mathbf{Q}}^{(M)}$, $\mathbf{h} = \hat{\mathbf{f}}^{(M)}$ and $\mathbf{f} = \mathbf{f}^{*,(M)}$ for all M allow to conclude. ■

We may now state the following result which shows that the state-by-state selection method applied to these estimators reaches the minimax rate of convergence (up to a logarithmic factor) in an adaptive manner under generic assumptions. Its proof is the same as the one of Corollary 6.

Corollary 13 *Assume **[HX]**, **[HF]**, **[Hid]** and **[Hdet]** hold. Also assume that for all $f \in \mathcal{F}$, $\int f d\mu = 1$ and that for all k, there exists s_k such that $\|f_k^{*,(M)} - f_k^*\|_2 = O(M^{-s_k})$. Then there exists a constant C_σ depending on $C_{\mathcal{F},2}$, $C_{\mathcal{F},\infty}$, $\mathbf{Q}^*$ and $\mathbf{f}^*$ such that the following holds.*

Let $C \geq C_\sigma$ and let $\hat{\mathbf{f}}^{sbs}$ be the estimators selected from the family $(\hat{\mathbf{f}}^{(M)})_{M \leq n}$ with $\sigma(M) = C\sqrt{\frac{M \log(n)}{n}}$ for all M, aligned like in Remark 7. Then there exists a random permutation τ which does not depend on n such that

$$\forall k \in \mathcal{X}, \qquad \mathbb{E}\left[\left\| \hat{f}_{\tau(k)}^{sbs} - f_k^* \right\|_2 \right] = O\left(\left(\frac{n}{\log(n)} \right)^{\frac{-s_k}{2s_k+1}} \right).$$

4. Numerical Experiments

This section is dedicated to the discussion of the practical implementation of our method. We run the spectral estimators on simulated data for different number of observations and study the rate of convergence of the selected estimators for several variants of our method.

Finally, we discuss the algorithmic complexity of the different estimators and selection methods.

In Section 4.1, we introduce the parameters with which we generate the observations. In Section 4.2, we discuss how to calibrate the constant of the penalty in practice. In Section 4.3, we introduce two other ways to select the final estimators, the POS and MAX variants. Section 4.4 contains the results of the simulations for each variant and calibration method. In Section 4.5, we present a cross validation procedure and compare its results with the one obtained using our method. Finally, we discuss the algorithmic complexity of the different algorithms and estimators in Section 4.6.

4.1 Setting and Parameters

We take $\mathcal{Y} = [0, 1]$ equipped with the Lebesgue measure. We choose the approximation spaces spanned by a trigonometric basis: $\mathfrak{P}_M := \mathrm{Span}(\varphi_1, \dots, \varphi_M)$ with

$$\begin{cases} \varphi_1(x) & = 1 \\ \varphi_{2m}(x) & = \sqrt{2}\cos(2\pi m x) \\ \varphi_{2m+1}(x) & = \sqrt{2}\sin(2\pi m x) \end{cases}$$

for all $x \in [0, 1]$ and $m \in \mathbb{N}^*$. We will consider a hidden Markov model with $K = 3$ hidden states and the following parameters:

- Transition matrix

$$\mathbf{Q}^* = \begin{pmatrix} 0.7 & 0.1 & 0.2 \\ 0.08 & 0.8 & 0.12 \\ 0.15 & 0.15 & 0.7 \end{pmatrix};$$

- Emission densities (see Figure 1)
  - Uniform distribution on $[0; 1]$;
  - Symmetrized Beta distribution, that is a mixture with the same weight of $\frac{2}{3}X$ and $1 - \frac{1}{3}X'$ with X, X' iid following a Beta distribution with parameters $(3, 1.6)$;
  - Beta distribution with parameters $(3, 7)$.

We generate n observations and run the spectral algorithm in order to obtain estimators for the models $\mathfrak{P}_M$ with $\texttt{M\_min} \leq M \leq \texttt{M\_max}$, $m = 20$ and $r = \lceil 2\log(n) + 2\log(M) \rceil$, where $\texttt{M\_min} = 3$ and $\texttt{M\_max} = 300$. Finally, we use the state-by-state selection method to choose the final estimator for each emission density. The main reason for using spectral estimators instead of maximum likelihood estimation or least squares estimation is its computational speed: it is much faster for large n than the least squares algorithm or the EM algorithm, which makes studying asymptotic behaviours possible.

We made 300 simulations, 20 per value of n, with n taking values in $\{5 \times 10^4, 7 \times 10^4, 1 \times 10^5, 1.5 \times 10^5, 2.2 \times 10^5, 3.5 \times 10^5, 5 \times 10^5, 7 \times 10^5, 1 \times 10^6, 1.5 \times 10^6, 2.2 \times 10^6, 3.5 \times 10^6, 5 \times 10^6, 7 \times 10^6, 1 \times 10^7\}$.

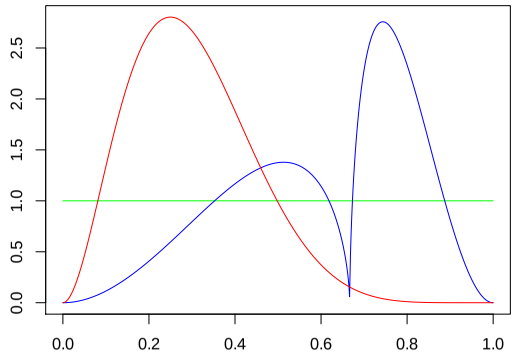

Figure 1: Emission densities. In all following figures, the uniform distribution corresponds to the green lines, the Beta distribution to the red lines and the symmetrized Beta distribution to the blue lines.

4.2 Penalty Calibration

It is important to note that when considering spectral and least squares methods, the penalty σ in the state-by-state selection procedure depends on the hidden parameters of the HMM and as such is unknown in practice. This penalty calibration problem is well known and several procedures exist that allow to solve it, for instance the slope heuristics and the dimension jump method (see for instance Baudry et al. (2012) and references therein). In the following, we will use the dimension jump method to calibrate the penalty in the state-by-state selection procedure.

Consider a penalty shape $\mathrm{pen}_{\mathrm{shape}}$ and define $\hat{M}_k(\rho)$ the model selected for the hidden state k by the state-by-state selection estimator using the penalty $\rho\,\mathrm{pen}_{\mathrm{shape}}$:

$$\hat{M}_k(\rho) \in \operatorname*{arg\,min}_{M\in\mathcal{M}}\{A_k(M) + 2\rho\,\mathrm{pen}_{\mathrm{shape}}(M)\}.$$

where

$$A_k(M) = \sup_{M'\in\mathcal{M}} \left\{ \left\| \hat{f}_k^{(M')} - \hat{f}_k^{(M\wedge M')} \right\|_2 - \rho\,\mathrm{pen}_{\mathrm{shape}}(M') \right\}.$$

The dimension jump method relies on the heuristics that there exists a constant C such that $C\,\mathrm{pen}_{\mathrm{shape}}$ is a *minimal penalty*. This means that for all $\rho < C$, the selected models $\hat{M}_k(\rho)$ will be very large, while for $\rho > C$, the models will remain small. This translates into a sharp jump located around a value $\rho_{\mathrm{jump},k} = C$ in the plot of $\rho \longmapsto \hat{M}_k(\rho)$. The final step consists in taking twice this value to calibrate the constant of the penalty, thus

selecting the model $\hat{M}(2\rho_{\mathrm{jump},k})$. In practice, we take $\rho_{\mathrm{jump},k}$ as the position of the largest jump of the function $\rho \longmapsto \hat{M}_k(\rho)$.

Figure 2 shows the resulting dimension jumps for $n = 220,000$ observations. Each curve corresponds to one of the $\hat{M}_k(\rho)$ and has a clear dimension jump, which confirms the relevance of the heuristics. Several methods may be used to calibrate the constant of the penalty:

eachjump. Calibrate the constant independently for each state. This method has the advantage of being easy to calibrate since there is usually a single sharp jump in each state's complexity. However, our theoretical results do not suggest that the penalty constant is different for each state;

jumpmax. Calibrate the constant for all states together using only the latest jump. This consists in taking the maximum of the $\rho_{\mathrm{jump},k}$ to select the final models. Since the penalty is known up to a multiplicative constant and taking a constant larger than needed does not affect the rates of convergence–contrary to smaller constants–this is the "safe" option;

jumpmean. Calibrate the constant for all states together using the mean of the positions of the different jumps.

We try and compare these calibration methods in Section 4.4.

4.3 Alternative Selection Procedures

4.3.1 Variant POS.

As mentionned in Section 2.2, it is also possible to select the estimators using the criterion

$$A_k(M) = \sup_{M'\geq M} \left\{ \left\| \hat{f}_k^{(M')} - \hat{f}_k^{(M)} \right\|_2 - \sigma(M') \right\}_+$$

followed by

$$\hat{M}_k \in \operatorname*{arg\,min}_{M\in\mathcal{M}}\{A_k(M) + 2\sigma(M)\}.$$

This positivity condition was in the original Goldenshluger-Lepski method. The theoretical guarantees remain the same as the previous method and both behave almost identically in practice, as shown in Section 4.4.

4.3.2 Variant MAX.

In the context of kernel density estimation, Lacour et al. (2017) show that the Goldenshluger-Lepski method still works when the biais estimate $A_k(M)$ of the model M is replaced by the distance between the estimator of the model M and the estimator with the smallest bandwidth (the analog of the largest model in our setting). They also prove an oracle inequality for this method after adding a corrective term to the penalty.

The following variant is based on the same idea. It consists in selecting the model

$$\hat{M}_k \in \operatorname*{arg\,min}_{M\in\mathcal{M}}\{\| \hat{f}_k^{(M_{\max})} - \hat{f}_k^{(M)} \|_2 + \sigma(M)\}$$

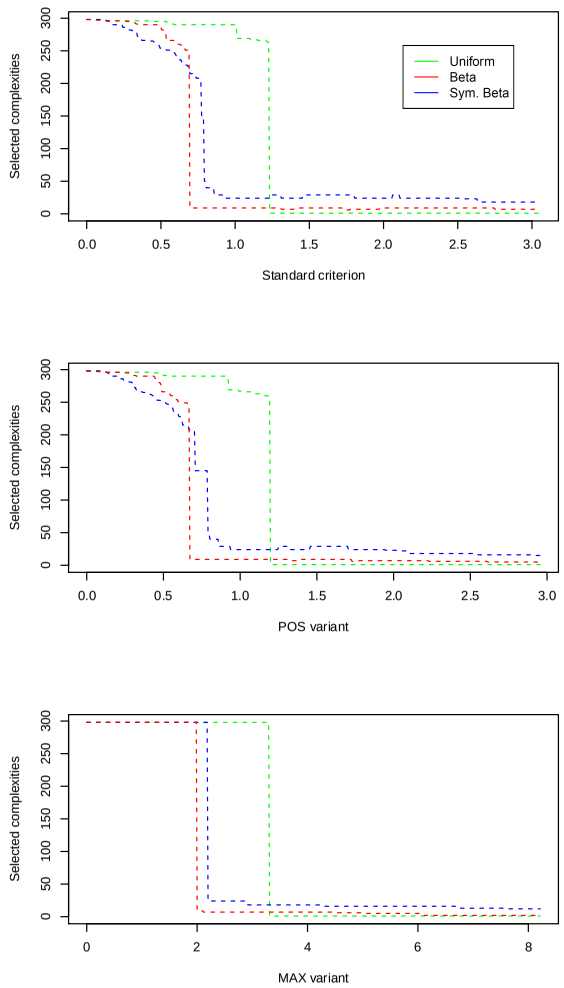

Figure 2: Selected complexities with respect to the penalty constant ρ for the same simulation of $n = 500,000$ observations. The colored dashed lines correspond to the single-state complexities $M_k(\rho)$.

for each $k \in \mathcal{X}$ and takes

$$\hat{f}_k = \hat{f}_k^{(\hat{M}_k)},$$

where σ is the same penalty as the one in the usual state-by-state selection method.

An advantage of this algorithm is its lower complexity, since it requires $O(M_{\max})$ computations of $\mathbf{L}^2$ norms instead of $O(M_{\max}^2)$. We do not study this method theoretically in our setting. However, the simulations (and in particular Figure 4) show that it behaves similarly to the standard state-by-state selection method in the asymptotic regime and even has a smaller error for small number of observations. In addition, the dimension jumps are much sharper for this method than for the usual state-by-state selection method (see Figure 2), which makes the calibration heuristics easier to use.

4.4 Results

Figure 3 shows the evolution of the error $\|\hat{f}_k - f_k^*\|_2$ for each state k with respect to the number of observations n, for all penalty calibration methods and all variants of the model selection procedure. Figure 4 compares the evolution of the median error for the different calibration methods and for the different selection variants, and Figure 5 compares two estimators with the oracle estimators.

When the number of observations n is large enough, the logarithm of the error decreases linearly with respect to $\log(n)$. This corresponds to the asymptotic convergence regime: the error is expected to decrease as a power of the number of observations n when n tends to infinity. The corresponding slopes are listed in Table 1.

For each state, the confidence intervals of the rates of all estimators–including the oracle estimators–have a common intersection (except for the symmetrized Beta distribution in the jumpmax MAX variant, whose estimators seem to converge faster than the others). This tends to confirm that the calibration and selection variants are asymptotically equivalent. This phenomenon is also visible in Figures 3 and 4: in the asymptotic regime, the errors decrease in a similar way for all methods.

Furthermore, the rates of convergence are clearly distinct. The uniform distribution is estimated with a rate of convergence of approximately $n^{-1/2}$, which is also the best possible rate (it corresponds to a parametric estimation rate). In comparison, the rate of convergence for the symmetrized Beta distribution is much slower (around $n^{-0.36}$). This shows that the algorithm effectively adapts to the regularity of each state and that one irregular emission density does not deteriorate the rates of convergence of the other densities.

Note that the above rates are in accordance with the minimax rates as far as the Hölder regularity is concerned. The minimax Hölder rate for the symmetrized Beta (which is 0.6-Hölder) is $n^{-3/11}$, or approximately $n^{-0.27}$, which means our estimator converges faster than the minimax rate would suggest. The minimax Hölder rate for the Beta distribution (which is 3-Hölder) is $n^{-3/7}$, or approximately $n^{-0.43}$, which is around the observed value.

4.5 Comparison with Cross Validation

In this section, we use a cross validation procedure based on our spectral estimators to check whether our method actually improves estimation accuracy.œ

When estimating a density by taking an estimator within some class (the model), two sources of error appear: the bias, that is the (deterministic) distance between the true

In Subfigures (a)-(c), the full lines correspond to the basic selection method, the dashed ones to the POS method and the dotted ones to the MAX method. In Subfigures (d)-(f), the full lines correspond to the eachjump method, the dashed ones to the jumpmax method and the dotted ones to the jumpmean method.

density and the model, and the variance, that is the (random) error of the estimation within the model. Small models will have a large bias but a small variance, while large models will have a small bias and a large variance. The core issue of model selection is to select a model that minimizes the total error, that is large enough to accurately describe the true densities and small enough to prevent overfitting: in other words, perform a bias-variance tradeoff.

Cross validation seeks to achieve such a tradeoff by computing an estimate of the total error. This is done by splitting the sample into two sets, the training sample being used for the calibration of the estimator and the validation sample for measuring the error.

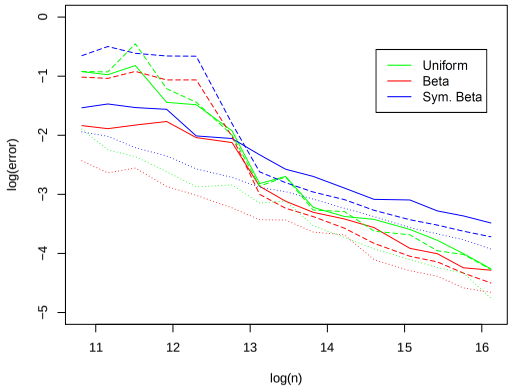

Figure 5: Comparison of the errors for the eachjump MAX method (full lines), for the eachjump method (dashed lines) and for the oracle estimators (dotted lines). For each k, the oracle estimator is defined as $\hat{f}_k^{(M_k^{\text{oracle}})}$ where M_k^{oracle} minimizes $M \longmapsto \|\hat{f}_k^{(M)} - f_k^*\|_2$. The oracle corresponds to the best estimator one could possibly select among the preliminary estimator if the true densities were known.

Taking the mean of these errors for different splits between training and validation samples provides an estimator of the total error. This method has become popular for its simplicity of use. We refer to the survey of Arlot et al. (2010) for an overview on this method and its guarantees.

4.5.1 Risk

We use the least squares criterion of Algorithm 2 to quantify the error of the estimators. Since the guarantees on spectral estimators rely on the $\mathbf{L}^2$ norm, a least squares criterion is more natural than the likelihood. In addition, the spectral estimators might take negative values depending on the orthonormal basis, which is not a problem as far as $\mathbf{L}^2$ error is concerned but can be an issue for the likelihood.

Let us first recall this criterion. Given an orthonormal basis $(\varphi_i)_{i\in\mathbb{N}}$ of $\mathbf{L}^2(\mathcal{Y},\mu)$, define the coordinate tensor of the empirical distribution of the triplet (Y_1,Y_2,Y_3) on this basis by

$$\hat{\mathbf{M}}(a,b,c) := \frac{1}{n}\sum_{s=1}^{n} \varphi_a(Y_s)\varphi_b(Y_{s+1})\varphi_c(Y_{s+2}) \quad \text{for all } a,b,c \in \mathbb{N}.$$

Given a transition matrix $\mathbf{Q}$ of size K, a stationary distribution π of $\mathbf{Q}$ and a vector of densities $\mathbf{f} = (f_1,\dots,f_K)$, define the coordinate matrix $\mathbf{O}$ of $\mathbf{f}$ by $\mathbf{O}(b,k) = \langle \varphi_b, f_k\rangle$. Let $\mathbf{M}_{(\pi,\mathbf{Q},\mathbf{f})}$ be the coordinate tensor of the distribution of (Y_1,Y_2,Y_3) under the parameters $(\pi,\mathbf{Q},\mathbf{f})$, that is

$$\mathbf{M}_{(\pi,\mathbf{Q},\mathbf{f})}(\cdot,b,\cdot) = \mathbf{O}\text{Diag}[\pi]\mathbf{Q}\text{Diag}[\mathbf{O}(b,\cdot)]\mathbf{Q}\mathbf{O}^\top \quad \text{for all } b \in \mathbb{N}.$$

Minimax (Hölder)	-0.5	$-3/11 \approx -0.273$	$-3/7 \approx -0.429$

Table 1: Exponents of the rates of convergence for the different algorithms. The rates are obtained from a linear regression with the relation $\log(\|\hat{f}_k - f_k^*\|_2) \sim \log(n)$ for the estimators $\hat{f}_k$ computed with $n \geq 700,000$ observations ($n \geq 1,000,000$ for the cross validation estimators from Section 4.5). The smaller the exponent, the faster the estimators converge. The line "hidden states known" is obtained by density estimation when the hidden states are observed.

The empirical least squares criterion is $\|\mathbf{M}_{(\pi,\mathbf{Q},\mathbf{f})} - \hat{\mathbf{M}}\|_F^2$. It corresponds to the $\mathbf{L}^2$ error between the empirical distribution of three consecutive observations and the theoretical distribution under the parameters $(\pi,\mathbf{Q},\mathbf{f})$.

4.5.2 Implementation

We use 10-fold cross validation, that is we split the sequence into 10 segments of same size $I_1,\dots,I_{10}$. In order to avoid interferences between samples, we prune the ends of each segment, so that the observations in each segment can be considered independent. In practice, we take a gap of 30 observations between two segments.

We ran 150 simulations, 10 per value of n, with the same parameters as in Section 4.1. Each simulation is as follows.

For each segment I_j, we run the spectral algorithm on all models $\mathfrak{P}_M$ for `M_min` $\leq M \leq$ `M_max` using only the observations from the other segments. The transition matrix is estimated using an additional step of the spectral method which is adapted from Steps 8 and 9 of Algorithm 1 of De Castro et al. (2017). Then, we compute the least squares

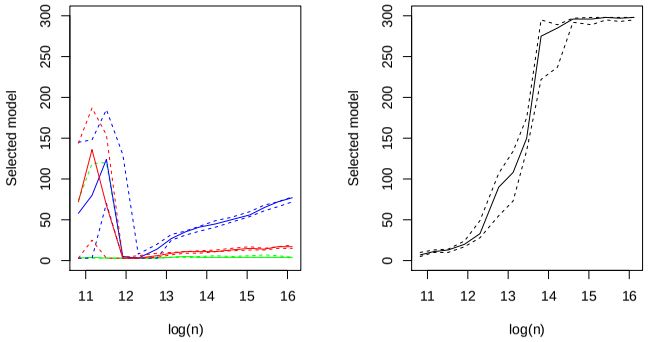

Figure 6: Selected model dimensions for each n using our state-by-state selection method (left) and 10-fold cross validation (right). The full lines are the median model dimensions and the dashed lines are the 25 and 75 percentiles.

criterion for the estimated parameters using the segment I_j as observed sample. Finally, for each M, we average this error on all segments I_j, which gives the least squares cross validation error $E_{\mathrm{VC}}(M)$.

This cross validation criterion is used to select one model $\hat{M}_{\mathrm{VC}} \in \arg\min_M E_{\mathrm{VC}}(M)$, from which we construct the final estimators of the emission densities $\hat{f}_k = \hat{f}_k^{(\hat{M}_{\mathrm{VC}})}$ for all k. Note that the selected model is the same for all emission densities.

4.5.3 Results

Figure 6 compares the selected model dimensions for each n using our state-by-state selection method and using the cross validation method. When the number of observations n becomes larger than 10^6, the cross validation tends to always pick the largest model, which means that it does not prevent overfitting as well as our method.

The $\mathbf{L}^2$ errors on the emission densities are shown in Figure 7. It appears that the cross validation has a lower error for small n ($n \leq 350,000$) than our method. However, for larger values of n, the errors becomes larger than the ones of our method (see Figure 5) by up to one order of magnitude, and only start decreasing once the selected model is set to the maximum dimension.

Finally, the estimated rates of convergence are shown in Table 1. Our state-by-state method outperforms the cross validation method for all emission densities. The cross validation estimators only reach the minimax rate of convergence for the less regular density: the symmetrized Beta, and even then they converge slower than the state-by-state estimator. All other emission densities are estimated slower than their minimax rate.

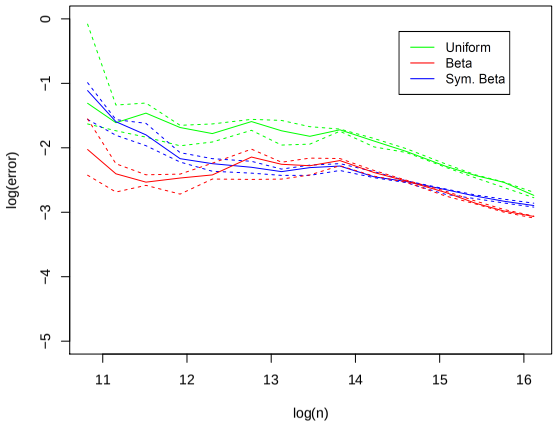

Figure 7: Error of the cross validation estimators for each n using 10-fold cross validation. The full lines are the median errors for each density and the dashed lines are the 25 and 75 percentiles.

4.6 Algorithmic Complexity

In the following, we treat K as a constant as far as the algorithmic complexity is concerned. The different complexities are summarized in Table 2.

4.6.1 Spectral Algorithm (see Section 3.2)

We consider the algorithmic complexity of estimating the emission densities for all models M such that $M_{\min} \leq M \leq M_{\max}$ with n observations and auxiliary parameters r and m depending on n and M (upper bounded by $m_{\max}$ and $r_{\max}$).

Step 1 can be computed for all models with $O(nM_{\max}m_{\max}^2)$ operations. It is the only step whose complexity depends on n. Steps 2 and 3 require $O(m^3M)$ operations for each model and Steps 4 to 7 require $O(Mr)$ operations for each model, for a total of $O(nM_{\max}m_{\max}^2 + M_{\max}^2 m_{\max}^3 + M_{\max}^2 r_{\max})$ operations.

In practice, one takes $m \propto \log(n)$, $r \propto \log(n) + \log(M)$ and $M_{\max} \leq n$, so that the total complexity of the spectral algorithm is $O(n \log(n)^2 M_{\max})$.

In comparison, the complexity of the spectral algorithm of De Castro et al. (2017) is $O(nM_{\max}^3)$ because of Step 1. This becomes much larger than our complexity when $M_{\max}$ grows as a power of n (which is necessary in order to reach minimax rates).

4.6.2 Least Squares Algorithm (see Section 3.3)

We consider the algorithmic complexity of estimating the emission densities for all models M such that $M_{\min} \leq M \leq M_{\max}$ with n observations.

Step 1 is similar to the one of the spectral algorithm, but with $O(nM_{\max}^3)$ operations. The complexity of Step 2 is more difficult to evaluate. Since the criterion is nonconvex, finding the minimizer requires to run an approximate minimization algorithm whose complexity C_n will depend on the desired precision–which will in turn depend on the number of observations n–and on the initial points. As discussed in Lehéricy (to appear), this is usually the longest step when computing least squares estimators. Thus, the total complexity of the least squares algorithm is $O(nM_{\max}^3 + C_n)$.

Note that despite the worse sample complexity, the least squares algorithm is tractable and can greatly improve the estimation for small sample size. As shown in Section 4.4, the spectral algorithm is unstable for small samples, which makes the state-by-state selection procedure return abnormal results. This can be explained by the matrix inversions of the spectral method, which sometimes lead to nearly singular matrices when the noise is too large. On the other hand, the least squares method does not involve any matrix inversion, and often gives better results than the spectral estimators, as shown in De Castro et al. (2016), thus making it a relevant choice for small to medium data sets.

4.6.3 Selection Method and POS Variant (see Sections 2.2 and 4.3)

We consider the algorithmic complexity of selecting estimators from a family of estimators $(\hat{\mathbf{f}}^{(M)})_{M_{\min} \leq M \leq M_{\max}}$. The selection algorithms can be decomposed in two parts.

- Compute the distances $\|\hat{f}_k^{(M)} - \hat{f}_k^{(M')}\|_2$ for all M, M' and k. This has complexity $O(M_{\max}^3)$: it requires to compute the $\mathbf{L}^2$ distance of at most $M_{\max}^2$ couples of functions in a Hilbert space of dimension $M_{\max}$.

- Compute $\hat{\rho}_k$ defined as the abscissa of the largest jump of the function $\rho \longmapsto \hat{M}_k(\rho)$ for all k, where $\hat{M}_k$ is defined as in Section 4.2. Note that computing $\hat{M}_k(\rho)$ requires $O(M_{\max}^2)$ operations. An approximate value of $\hat{\rho}_k$ can be computed in $O(\log(\hat{\rho}_k)M_{\max}^2)$ operations, which is usually $O(M_{\max}^2)$.

Once the $\hat{\rho}_k$ are known, it is possible to calibrate the penalty in constant time for the three calibrations methods (eachjump, jumpmax and jumpmean) and to select the final models in $O(M_{\max}^2)$ operations.

Thus, the total complexity of the selection algorithm and of its POS variant is $O(M_{\max}^3)$.

4.6.4 Selection Method, MAX Variant (see Section 4.3)

In the MAX variant, the first step of the standard selection procedure is replaced by computing the distances $\|\hat{f}_k^{(M_{\max})} - \hat{f}_k^{(M)}\|_2$ for all M. This has complexity $O(M_{\max}^2)$. The complexity of the other steps remains unchanged.

Thus, the total complexity of the MAX variant of the selection algorithm is $O(M_{\max}^2)$.

	Algorithm	Complexity
Preliminary estimators	Spectral method	$O(n\log(n)^2 M_{\max})$
	Spectral method (De Castro et al. (2017))	$O(nM_{\max}^3)$
	Least squares method	$O(nM_{\max}^3 + C_n)$
Selection step	Standard and POS variant	$O(M_{\max}^3)$
	MAX variant	$O(M_{\max}^2)$

Table 2: Complexities of the different algorithms. n is the number of observations, $M_{\max}$ is the largest model dimension considered.

5. Application to Real Data

In this section, we present the results of our method on two sets of trajectories. Trajectories are a typical example of dependent data that shows several behaviours depending on the activity of the entity being tracked, which makes hidden Markov models a popular modelling choice. For instance, the movement of a fisher is not the same depending on whether he's travelling to the next fishing zone or actually fishing.

The first data set follows artisanal fishers in Madagascar. The second one contains seabird movements. Studying the movements of fishers and seabirds has many applications, for instance understanding the fishing habits of the tracked entity, controlling the fishing pressure on local ecosystems and monitoring the dynamics of coastal ecosystems, see for instance Boyd et al. (2014); Vermard et al. (2010) and references therein.

5.1 Artisanal Fishery

We use GPS tracks of artisanal fishers with a regular sampling period of 30 seconds. These tracks were produced by Faustinato Behivoke (Institut Halieutiques et des Sciences Marines, Université de Toliara, Madagascar) and Marc Léopold (IRD), who recorded artisanal fishers from Ankilibe, in Madagascar. Their fishing method is a seine netting.

From this data, we compute the velocity of the fisher during each time step. In order to estimate densities on $[0,1]$, we divide this velocity by an upper bound of the maximum observed velocity. We consider the observation space $\mathcal{Y} = [0,1]$ endowed with the dominating measure $\delta_0 + \text{Leb}$, where δ_0 is the dirac measure in zero and Leb is the Lebesgue measure on $[0,1]$. As a proof of concept, we use the orthonormal basis consisting of the trigonometric basis on $[0,1]$ and the indicator function of $\{0\}$, that is the family $(\varphi_m)_{m\in\mathbb{N}}$ defined on $[0,1]$

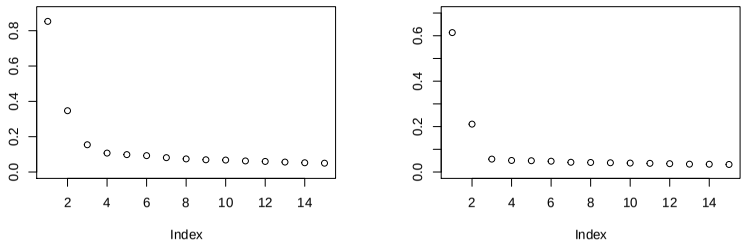

Figure 8: First 15 eigenvalues of the spectrum of the empirical tensor $\hat{\mathbf{N}}_{50,50}$ (see Algorithm 3 in Appendix A). Left: fisher 1, right: fisher 2.

by

$$\text{if } x = 0, \begin{cases} \varphi_0(x) = 1 \\ \varphi_m(x) = 0 \quad \text{for all } m \in \mathbb{N}^* \end{cases}$$

$$\text{if } x \neq 0, \begin{cases} \varphi_0(x) = 0 \\ \varphi_1(x) = 1 \\ \varphi_{2m}(x) = \sqrt{2}\cos(2\pi m x) \quad \text{for all } m \in \mathbb{N}^* \\ \varphi_{2m+1}(x) = \sqrt{2}\sin(2\pi m x) \quad \text{for all } m \in \mathbb{N}^* \end{cases}$$

The number of hidden states is chosen using the spectral thresholding method of Lehéricy (to appear). This methods consists is based on the fact that the rank of the spectral tensor $\mathbb{E}\hat{\mathbf{N}}_{m,m}$ (with the notations of Algorithm 3 in Appendix A) is the number of hidden states. This is visible in the spectrum of $\hat{\mathbf{N}}_{m,m}$ by an elbow, as shown in Figure 8. Based on these spectra, we use two hidden states.

The results using `M_max` $= 1000$ are shown in Figures 9 and 10. We took the normalizing velocity large enough that all observed normalized velocities belong to $[0, 0.8]$, hence the plot betweeen 0 and 0.8 for the densities.

In both cases, the selected model complexities differ greatly depending on the state. This comes from the fact that in both cases, one of the density is spiked, thus requiring more vectors of the orthonormal basis to be approximated. This illustrates that our method is able to estimate the smoother densities with fewer vectors of the basis, thus preventing overfitting.

As a side note, we needed considerably less observations than in the simulations: around 10,000, compared to 500,000 in the simulations. This can be explained by the fact that each state is very stable, with an estimated probability of leaving the states below 0.02–compared to 0.3 in the simulations. This is encouraging, as hidden states in real data are expected to be rather stable, especially when the sampling frequency is high, as long as the conditional independance of the observations can be assumed to hold.

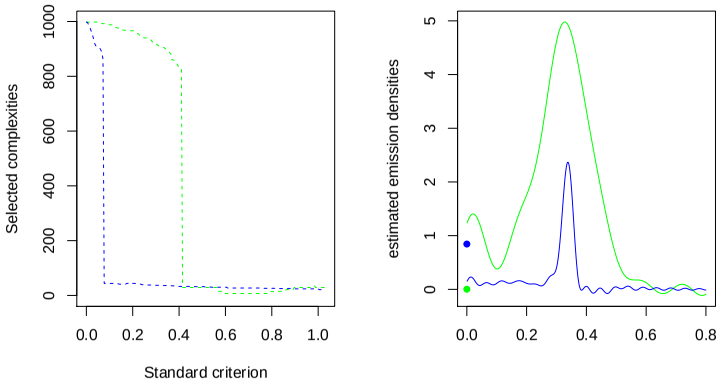

Figure 9: Selected complexities and estimated densities on artisanal fishery data (fisher 1, $n = 17,300$). Green = state 1, blue = state 2. The dirac component is shown as a dot at $y = 0$. The selected dimensions are $(14, 41)$.

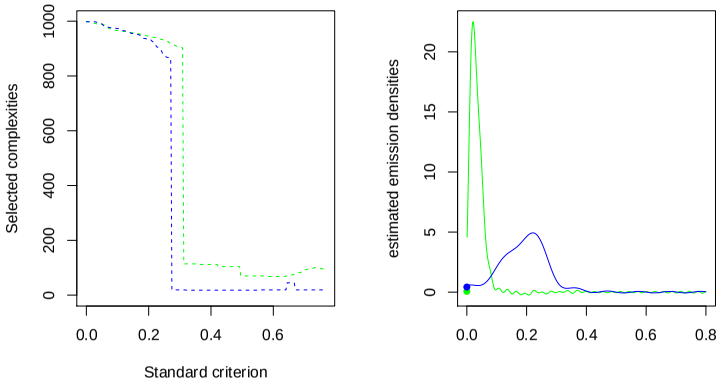

Figure 10: Selected complexities and estimated densities on artisanal fishery data (fisher 2, $n = 11,600$). Green = state 1, blue = state 2. The dirac component is shown as a dot at $y = 0$. The selected dimensions are $(68, 18)$.

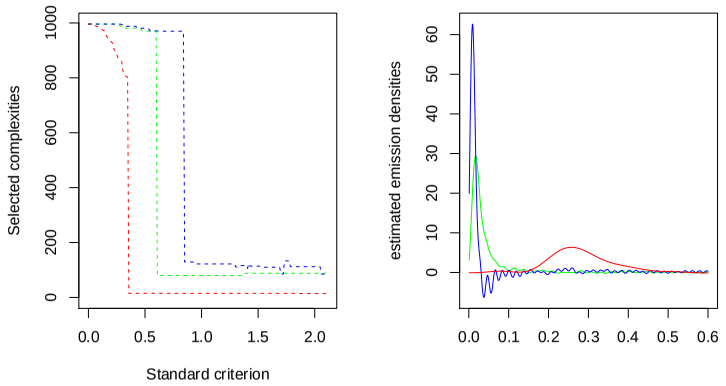

Figure 11: Selected complexities and estimated densities for Cormorant d's trajectory ($n = 2,891$). Green = state 1, blue = state 2, red = state 3. The selected dimensions are $(80, 110, 15)$.

5.2 Seabird Foraging

In this Section, we consider the seabird data from Bertrand et al. (2015) and we focus on the tracks named cormorant d in this paper.

We apply the same transformation as in the previous section to obtain normalized velocities in $[0, 0.8]$ (after removal of anomalous velocities exceeding 150 m/s) and run the spectral algorithm with the trigonometric basis on $[0, 1]$ plus the indicator of $\{0\}$. The spectral thresholding gives a number of hidden states equal to two; we set it to three to account for more complex behaviours of the seabirds. The results are shown in Figure 11.

Note that the use of the trigonometric basis allows the estimated densities to take negative values. This is not a problem as far as minimax rates of convergence (in $\mathbf{L}^2$ norm) are concerned, however this can become an issue if one wants to use these densities in a forward-backward algorithm in order to get an estimator of the hidden states. One way to circumvent this problem is to use simplex projection to compute an approximation of the projection of these estimated density on the simplex of all probability densities. Note that since this is an $\mathbf{L}^2$ projection on a convex set which contains the true densities, the projected densities have an even smaller error, thus keeping the minimax rate of convergence of the original estimators. The resulting densities are shown in Figure 12

The number of observations in this setting is even smaller than for the fishery's data set: our algorithm was able to recover three emission densities from less than 3,000 observations, despite the states being less stable than in the fishery data set: the diagonal terms of the estimated transition matrix using the EM algorithm are $(0.83, 0.93, 0.98)$. In addition, the result of our method is consistent with other estimation methods, as shown in Figure 12:

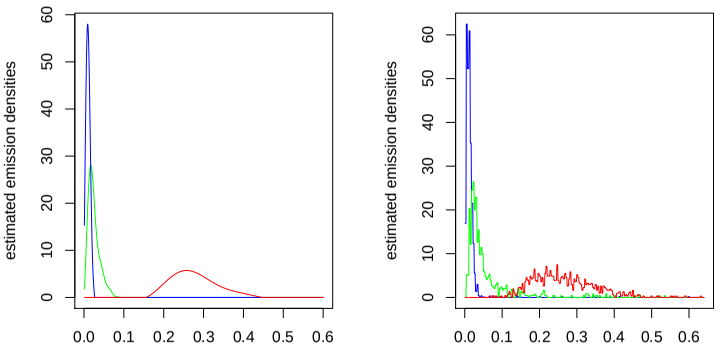

Figure 12: Projection of the estimated densities of Figure 11 for Cormorant d on the set of probability densities (left) and comparison with an estimation with histogram densities on a regular partition of size 300 using the EM algorithm (right).

estimating the parameters with the EM algorithm using piecewise constant densities leads to a very similar result.

6. Conclusion and Perspectives

We propose a state-by-state selection method to infer the emission densities of a HMM. Using a family of estimators, our method selects one estimator for each hidden state in a way that is adaptive with respect to this state's regularity. This method does not depend on the type of preliminary estimator, as long as a suitable variance bound is available. As such, it may be seen as a plug-in that takes a family of estimators and the corresponding variance bound and outputs the selected estimator. Note that its complexity does not depend on the number of observations used to compute the estimators, which makes it applicable to arbitrarily large data sets.

To apply this method, we present two families of estimators: a least squares estimator and a spectral estimator. For both, we prove a bound on their variance and show that this bound allows to recover the minimax rate of convergence separately on each hidden state, up to a logarithmic factor. The variance bounds are similar to a BIC penalty, with an additional logarithmic factor for the spectral estimators.

We carry out a numerical study of the method and some variants on simulated data. We use the spectral estimators, which are both fast and don't suffer from initialization issues, unlike the least squares and maximum likelihood estimators. The simulations show that

our selection method is very fast compared to the computation of the estimators and that indeed, the final estimators reach the minimax rate of convergence on each state.

Then, we compare our method with a cross validation estimator based on a least square risk. This estimator only reaches the minimax rate corresponding to the worst regularity among the emission densities and fails to select models with small dimensions. It is still noteworthy that the cross validation returns relevant results for small sample sizes, whereas our method requires the sample size to be large enough to work properly. An interesting problem would be to investigate whether cross validation or other methods can be combined with our state-by-state selection method to give an algorithm that is both fast, stable for small sample sizes and optimal in the asymptotic setting.

Finally, we apply our algorithm to real trajectory data sets. On this data, our method proves that it is able to match the regularity of the underlying emission densities. In addition, it is able to produce sensible results with far fewer observations than in our simulation study.

Our state-by-state selection method can be easily applied to multiview mixture models (also named mixture models with repeated measurement, see for instance Bonhomme et al. (2016a) and Gassiat et al. (2018)). Let us first describe the model. A multiview mixture model consists of two random variables, a hidden state U and an observation vector $\mathbf{Y} := (Y_i)_{i\in[m]}$ such that conditionally to U, the components Y_i of $\mathbf{Y}$ are independent with a distribution depending only on U and i. Let us assume that U takes its values in a finite set $\mathcal{X}$ of size K and that the Y_i have some density $f^*_{u,i}$ conditionally to $U = u$ with respect to a dominating measure. A question of interest is to estimate the densities $f^*_{u,i}$ from a sequence of observed $(\mathbf{Y}_n)_{n\geq 1}$.

Our state-by-state selection method can be applied directly to such a model as long as estimators with a proper variance bound are available (see assumption $[\mathbf{H}(\epsilon)]$ in Section 2.1). Indeed, we never use the dependency structure of the model. Regarding the development of preliminary estimators, multiview mixture models appear closely related to hidden Markov models: Anandkumar et al. (2012) and Bonhomme et al. (2016b) develop spectral methods that work for both multiview mixtures and HMMs at the same time using the same theoretical arguments. Thus, it seems clear that variance bounds such as the ones we developed can also be written for multiview mixture models.

Acknowledgments

I am grateful to Elisabeth Gassiat and Claire Lacour for their precious advice. I thank Augustin Touron for providing me with a R implementation of the spectral algorithm. I would also like to thank Marie-Pierre Etienne and of course Faustinato Behivoke (Institut Halieutiques et des Sciences Marines, Université de Toliara, Madagascar), Marc Léopold (IRD) and Sophie Bertrand (IRD) for letting me work on their data sets.

Appendix A. Spectral Algorithm, Full Version

Algorithm 3: Spectral estimation of the emission densities of a HMM (full version)

Data: A sequence of observations $(Y_1, \dots, Y_{n+2})$, two dimensions $m \leq M$, an orthonormal basis $(\varphi_1, \dots, \varphi_M)$ and number of retries r.

Result: Spectral estimators $(\hat{f}_k^{(M,r)})_{k\in\mathcal{X}}$, $\hat{\mathbf{Q}}$ and $\hat{\pi}$.

[Step 1] Consider the following empirical estimators: for any $a, c \in [m]$ and $b \in [M]$,

- $\hat{\mathbf{L}}_m(a) := \frac{1}{n}\sum_{s=1}^n \varphi_a(Y_s)$
- $\hat{\mathbf{M}}_{m,M,m}(a,b,c) := \frac{1}{n}\sum_{s=1}^n \varphi_a(Y_s)\varphi_b(Y_{s+1})\varphi_c(Y_{s+2})$
- $\hat{\mathbf{N}}_{m,M}(a,b) := \frac{1}{n}\sum_{s=1}^n \varphi_a(Y_s)\varphi_b(Y_{s+1})$
- $\hat{\mathbf{P}}_{m,m}(a,c) := \frac{1}{n}\sum_{s=1}^n \varphi_a(Y_s)\varphi_c(Y_{s+2})$.

[Step 2] Let $\hat{\mathbf{U}}_m$ be the $m \times K$ matrix of orthonormal left singular vectors and $\hat{\mathbf{V}}_M$ be the $M \times K$ matrix of orthonormal right singular vectors of $\hat{\mathbf{N}}_{m,M}$ corresponding to its top K singular values.

[Step 3] Form the matrices for all $b \in [M]$, $\hat{\mathbf{B}}(b) := (\hat{\mathbf{U}}_m^\top \hat{\mathbf{P}}_{m,m}\hat{\mathbf{U}}_m)^{-1}\hat{\mathbf{U}}_m^\top \hat{\mathbf{M}}_{m,M,m}(.,b,.)\hat{\mathbf{U}}_m$.

[Step 4] Set $(\Theta_i)_{1\leq i\leq r}$ r iid $(K \times K)$ unitary matrix uniformly drawn. Form the matrices for all $k \in \mathcal{X}$ and $i \in [r]$, $\hat{\mathbf{C}}_i(k) := \sum_{b=1}^M (\hat{\mathbf{V}}_M\Theta_i)(b,k)\hat{\mathbf{B}}(b)$.

[Step 5] Compute $\hat{\mathbf{R}}_i$ a $(K \times K)$ unit Euclidean norm columns matrix that diagonalizes the matrix $\hat{\mathbf{C}}_i(1)$: $\hat{\mathbf{R}}_i^{-1}\hat{\mathbf{C}}_i(1)\hat{\mathbf{R}}_i = \mathrm{Diag}(\hat{\Lambda}_i(1,1), \dots, \hat{\Lambda}_i(1,K))$.

[Step 6] Set for all $k, k' \in \mathcal{X}$, $\hat{\Lambda}_i(k,k') := (\hat{\mathbf{R}}_i^{-1}\hat{\mathbf{C}}_i(k)\hat{\mathbf{R}}_i)(k',k')$. Choose i_0 maximizing $\min_k \min_{k_1\neq k_2} |\hat{\Lambda}_i(k,k_1) - \hat{\Lambda}_i(k,k_2)|$ and set $\hat{\mathbf{O}} := \hat{\mathbf{V}}_M\Theta_{i_0}\hat{\Lambda}_{i_0}$.

[Step 7] Consider the emission densities estimators $\hat{\mathbf{f}}^{(M,r)} := (\hat{f}_k^{(M,r)})_{k\in\mathcal{X}}$ defined by for all $k \in \mathcal{X}$, $\hat{f}_k^{(M,r)} := \sum_{b=1}^M \hat{\mathbf{O}}(b,k)\varphi_b$.

[Step 8] Let $\hat{\mathbf{O}}_m$ be the $m \times K$ matrix containing the first m rows of $\hat{\mathbf{O}}$. Set $\hat{\pi} = \Pi_\Delta\left((\hat{\mathbf{U}}_m^\top\hat{\mathbf{O}}_m)^{-1}\hat{\mathbf{U}}_m^\top\hat{\mathbf{L}}_m\right)$ where Π_Δ is the $\mathbf{L}^2$ projection onto the probability simplex.

[Step 9] Let $\hat{\mathbf{Q}}$ be the transition matrix defined by $\hat{\mathbf{Q}} = \Pi_{\mathrm{TM}}\left((\hat{\mathbf{U}}_m^\top\hat{\mathbf{O}}_m\mathrm{Diag}[\hat{\pi}])^{-1}\hat{\mathbf{U}}_m^\top\hat{\mathbf{N}}_{m,M}\hat{\mathbf{V}}_M(\hat{\mathbf{O}}^\top\hat{\mathbf{V}}_M)^{-1}\right)$ where Π_{TM} is the projection onto the set of transition matrices. This projection is obtained by projecting each line of the matrix onto the probability simplex.

Appendix B. Proofs

B.1 Proof of Lemma 1

Let $\tau_{n,M}$ be the permutation that minimizes $\tau \longmapsto \max_{k\in\mathcal{X}} \left\|\hat{f}_k^{(M)} - f^{*,(M)}_{\tau(k)}\right\|_2$. $[\mathbf{H}(\epsilon)]$ means that with probability $1-\epsilon$, one has $\max_{k\in\mathcal{X}} \left\|\hat{f}_k^{(M)} - f^{*,(M)}_{\tau(k)}\right\|_2 \leq \frac{\sigma(M)}{2}$.

Let $M \in \mathcal{M}$. Let us show that $\left\|\hat{f}^{(M)}_{\tau^{-1}_{n,M}(k')} - \hat{f}^{(M_0)}_{\tau^{-1}_{n,M_0}(k)}\right\|_2 > \left\|\hat{f}^{(M)}_{\tau^{-1}_{n,M}(k)} - \hat{f}^{(M_0)}_{\tau^{-1}_{n,M_0}(k)}\right\|_2$ for all $k, k' \in \mathcal{X}$ such that $k' \neq k$. If this holds, then the definition of $\hat{\tau}^{(M)}$ implies that $\hat{\tau}^{(M)} = \tau^{-1}_{n,M} \circ \tau_{n,M_0}$. Thus, one has $\max_{k\in\mathcal{X}} \left\|\hat{f}^{(M)}_{k,\text{new}} - f^{*,(M)}_{\tau_{n,M_0}(k)}\right\|_2 \leq \frac{\sigma(M)}{2}$, which is exactly Equation (1) with $\tau_n = \tau_{n,M_0}$.

Applying the triangular inequality leads to

$$\begin{aligned}\left\|\hat{f}^{(M)}_{\tau^{-1}_{n,M}(k)} - \hat{f}^{(M_0)}_{\tau^{-1}_{n,M_0}(k)}\right\|_2 \leq& \left\|\hat{f}^{(M)}_{\tau^{-1}_{n,M}(k)} - f^{*,(M)}_k\right\|_2 + \left\|f^{*,(M)}_k - f^{*,(M_0)}_k\right\|_2 + \left\|f^{*,(M_0)}_k - \hat{f}^{(M_0)}_{\tau^{-1}_{n,M_0}(k)}\right\|_2\\ \leq& \frac{\sigma(M)}{2} + B_{M,M_0} + \frac{\sigma(M_0)}{2}\end{aligned}$$

and

$$\begin{aligned}\left\|\hat{f}^{(M)}_{\tau^{-1}_{n,M}(k')} - \hat{f}^{(M_0)}_{\tau^{-1}_{n,M_0}(k)}\right\|_2 \geq& \left\|f^{*,(M_0)}_{k'} - f^{*,(M_0)}_k\right\|_2 - \left\|\hat{f}^{(M)}_{\tau^{-1}_{n,M}(k')} - f^{*,(M)}_{k'}\right\|_2\\ &- \left\|f^{*,(M)}_{k'} - f^{*,(M_0)}_{k'}\right\|_2 - \left\|f^{*,(M_0)}_k - \hat{f}^{(M_0)}_{\tau^{-1}_{n,M_0}(k)}\right\|_2\\ \geq& m(\mathbf{f}^*, M_0) - \frac{\sigma(M)}{2} - B_{M,M_0} - \frac{\sigma(M_0)}{2}.\end{aligned}$$

Thus, the result holds as soon as $m(\mathbf{f}^*, M_0) - \frac{\sigma(M)}{2} - B_{M,M_0} - \frac{\sigma(M_0)}{2} > \frac{\sigma(M)}{2} + B_{M,M_0} + \frac{\sigma(M_0)}{2}$, which is the condition of Lemma 1.

B.2 Proof of Theorem 5

The structure of the proof is the same as the one of Theorem 3.1 of De Castro et al. (2017).

The first difference lies in the fact that we consider different models for each component of the tensors $\hat{\mathbf{N}}_{m,M}$ and $\hat{\mathbf{M}}_{m,M,m}$ in Step 1. As a consequence, we use the left *and* right singular vectors of $\hat{\mathbf{N}}_{m,M}$ instead of just the right singular vectors of $\hat{\mathbf{P}}_{m,m}$. A careful reading shows that their proof can be adapted straightforwardly to this situation.

The second difference consists in generating several independant random unitary matrices in Step 4 and keeping the one that separates the eigenvalues of all $\hat{\mathbf{C}}_i(k)$ best. This allows to replace Lemma F.6 of De Castro et al. (2017) by the following one, based on the independence of the unitary matrices:

Lemma 14 *For all $x > 0$ and $r \in \mathbb{N}^*$,*

$$\mathbb{P}\left[\forall k, k_1 \neq k_2, |\hat{\Lambda}_{i_0}(k, k_1) - \hat{\Lambda}_{i_0}(k, k_2)| \geq \frac{2e^{-x/r}(1 - \epsilon^2_{\mathbf{N}_{m,M}})^{1/2}}{\sqrt{e}K^{5/2}(K-1)}\gamma(\mathbf{O}_M)\right] \geq 1 - e^{-x}$$

and

$$\mathbb{P}\left[\|\hat{\Lambda}_{i_0}\|_\infty \geq \frac{1 + \sqrt{2}\sqrt{x + \log(K^2 r)}}{\sqrt{K}}\|\mathbf{O}_M\|_{2,\infty}\right] \leq e^{-x},$$

The notations $\epsilon_{\mathbf{N}_{m,M}}$ (or $\epsilon_{\mathbf{P}_M}$ in the original proof), $\gamma(\mathbf{O}_M)$ et $\|\mathbf{O}_M\|_{2,\infty}$ are introduced in De Castro et al. (2017).

Using this lemma, their proof leads to our result by taking $r = x = t$.

B.3 Definition of the Polynomial H

B.3.1 Definition

We parameterize the application

$$(\pi, \mathbf{Q}, \mathbf{f}) \in \Delta \times \mathcal{Q} \times \text{Span}(\mathbf{f}^*)^K \longmapsto \|g^{\pi,\mathbf{Q},\mathbf{f}} - g^{\pi^*,\mathbf{Q}^*,\mathbf{f}^*}\|_2^2 \tag{3}$$

in the following way. For $p \in \mathbb{R}^{K-1}$, $q \in \mathbb{R}^{K\times(K-1)}$ and $A \in \mathbb{R}^{K\times(K-1)}$, define the extensions

- $\bar{p} \in \mathbb{R}^K$ defined by $\bar{p}(k) = p(k)$ for all $k \in [K-1]$ and $\bar{p}(K) = -\sum_{k\in[K-1]} p(k)$;
- $\bar{q} \in \mathbb{R}^{K\times K}$ by $\bar{q}(k, K) = -\sum_{k'\in[K-1]} q(k, k')$;
- $\bar{A} \in \mathbb{R}^{K\times K}$ by $\bar{A}(k, K) = -\sum_{k'\in[K-1]} A(k, k')$.

$\bar{p}$ corresponds to $\pi - \pi^*$, $\bar{q}$ to $\mathbf{Q} - \mathbf{Q}^*$ and A to the components of $\mathbf{f} - \mathbf{f}^*$ on $\mathbf{f}^*$ (which is a basis as soon as **[Hid]** holds). The condition on the last component of $\bar{p}$ and of each line of $\bar{q}$ and $\bar{A}$ follows from the fact that $\bar{p}$ corresponds to the difference of two probability vectors, $\bar{q}$ corresponds to the difference of two transition matrices and $\bar{A}$ correspond to the difference of two vectors of probability densities on a basis of probability densities.

Then, consider the quadratic form derived from the Taylor expansion of

$$(p, q, A) \in \mathbb{R}^{K-1} \times \mathbb{R}^{K\times(K-1)} \times \mathbb{R}^{(K-1)\times K} \longmapsto \|g^{\pi^*+\bar{p},\mathbf{Q}^*+\bar{q},\mathbf{f}+\bar{A}\mathbf{f}^*} - g^{\pi^*,\mathbf{Q}^*,\mathbf{f}^*}\|_2^2.$$

Let M be the matrix associated to this quadratic form. We define H as the determinant of M. Direct computations show that H is a polynomial in the coefficients of π^*, $\mathbf{Q}^*$ and $G(\mathbf{f}^*)$.

B.3.2 Link between H and the Quadratic Form from Equation (3)

The goal of this section is to show how H can be used to lower bound the quadratic form from Equation (3) by a positive constant times the distance between $(\pi, \mathbf{Q}, \mathbf{f})$ and $(\pi^*, \mathbf{Q}^*, \mathbf{f}^*)$. We will not need the assumptions **[Hid]**, **[HF]** or **[Hdet]** unless specified otherwise.

Let us start by the relation between the norms of (p, q, A) and $(\bar{p}, \bar{q}, \bar{A})$.

Lemma 15 *For all $(p, q, A) \in \mathbb{R}^{K-1} \times \mathbb{R}^{K\times(K-1)} \times \mathbb{R}^{(K-1)\times K}$,*

$$\begin{aligned}\|p\|_2^2 \leq \|\bar{p}\|_2^2 \leq K\|p\|_2^2,\\ \|q\|_F^2 \leq \|\bar{q}\|_F^2 \leq K\|q\|_F^2,\\ \|A\|_F^2 \leq \|\bar{A}\|_F^2 \leq K\|A\|_F^2.\end{aligned}$$

Proof $\|p\|_2^2 \leq \|\bar{p}\|_2^2$ is immediate. Then,

$$\begin{aligned}\|\bar{p}\|_2^2 =& \|p\|_2^2 + \left(\sum_{k\in[K-1]} p(k)\right)^2\\ \leq& \|p\|_2^2 + (K-1)\sum_{k\in[K-1]} p(k)^2\\ =& K\|p\|_2^2.\end{aligned}$$

The proof is the same for q and A. ■

The next lemma will be used to link the norms of A and $A\mathbf{f}$.

Lemma 16 *For all $\bar{A} \in \mathbb{R}^{K\times K}$ and $\mathbf{f}^* \in (\mathbf{L}^2(\mathcal{Y},\mu))^K$,*

$$\sigma_K(G(\mathbf{f}^*))\|\bar{A}\|_F^2 \leq \sum_{k\in\mathcal{X}} \|(\bar{A}\mathbf{f}^*)_k\|_2^2 \leq K\|G(\mathbf{f}^*)\|_\infty \|\bar{A}\|_F^2$$

Proof For the first inequality, we use that for all $k \in \mathcal{X}$,

$$\begin{aligned}\|(\bar{A}\mathbf{f}^*)_k\|_2^2 =& \bar{A}(k,\cdot)G(\mathbf{f}^*)\bar{A}(k,\cdot)^\top \\ \geq& \sigma_K(G(\mathbf{f}^*))\|\bar{A}(k,\cdot)\|_2^2\end{aligned}$$

and the inequality follows by summing over k.

For the second inequality,

$$\begin{aligned}\sum_{k\in\mathcal{X}} \|(\bar{A}\mathbf{f}^*)_k\|_2^2 &= \sum_{k\in[K]} \int (\bar{A}\mathbf{f}^*)_k(x)^2\mu(dx) \\ &= \sum_{k\in[K]} \int \left(\sum_{j\in[K]} \bar{A}(k,j) f_j^*(x)\right)^2 \mu(dx) \\ &\leq \sum_{k\in[K]} \int K \sum_{j\in[K]} \bar{A}(k,j)^2 (f_j^*)^2(x)\mu(dx) \\ &\leq K\left(\sum_{k,j\in[K]} \bar{A}(k,j)^2\right) \sup_{j\in\mathcal{X}} \int (f_j^*)^2(x)\mu(dx) \\ &= K\|\bar{A}\|_F^2 \|G(\mathbf{f}^*)\|_\infty.\end{aligned}$$

■

Finally, we will use the following result of Lehéricy (to appear) (Section B.2) in order to upper bound the spectrum of the matrix M.

Lemma 17 *For all $\pi_1,\pi_2 \in \Delta$, for all $\mathbf{Q}_1,\mathbf{Q}_2 \in \mathcal{Q}$ and for all $\mathbf{f}_1,\mathbf{f}_2 \in (\mathbf{L}^2(\mathcal{Y},\mu))^K$,*

$$\|g^{\pi_1,\mathbf{Q}_1,\mathbf{f}_1} - g^{\pi_2,\mathbf{Q}_2,\mathbf{f}_2}\|_2 \leq \sqrt{3K(\|G(\mathbf{f}_1)\|_\infty^3 \vee \|G(\mathbf{f}_2)\|_\infty^3)}\, d_{perm}((\pi_1,\mathbf{Q}_1,\mathbf{f}_1),(\pi_2,\mathbf{Q}_2,\mathbf{f}_2))$$

Together, these results imply that for all (p,q,A),

$$\begin{aligned}\|g^{\pi^*+\bar{p},\mathbf{Q}^*+\bar{q},\mathbf{f}^*+\bar{A}\mathbf{f}^*} - g^{\pi^*,\mathbf{Q}^*,\mathbf{f}^*}\|_2^2 & \\ \leq& 3K(\|G(\mathbf{f}^*+\bar{A}\mathbf{f}^*)\|_\infty^3 \vee \|G(\mathbf{f}^*)\|_\infty^3)(\|\bar{p}\|_2^2 + \|\bar{q}\|_F^2 + \sum_{k\in\mathcal{X}} \|(\bar{A}\mathbf{f})_k\|_F^2) \\ \leq& 3K\|G(\mathbf{f}^*)\|_\infty^3 (1+K^2\|A\|_F^2)^3 (K\|p\|_2^2 + K\|q\|_F^2 + K^2\|G(\mathbf{f}^*)\|_\infty \|A\|_F^2)\end{aligned}$$

so that $\sigma_1(M) \leq \sqrt{3K^3}(1 \vee \|G(\mathbf{f})\|_\infty^2)$. Since $H = \prod_{i=1}^{(K-1)(2K+1)} \sigma_i(M)$, one has

$$\sigma_{(K-1)(2K+1)}(M) \geq \frac{H}{(3K^3(1\vee\|G(\mathbf{f})\|_\infty^4))^{K^2-K/2}}.$$

Now, assume that **[Hid]** holds, so that $\sigma_K(G(\mathbf{f}^*)) > 0$, then

$$\begin{aligned}\|g^{\pi^*+\bar{p},\mathbf{Q}^*+\bar{q},\mathbf{f}^*+\bar{A}\mathbf{f}^*} - g^{\pi^*,\mathbf{Q}^*,\mathbf{f}^*}\|_2^2 \geq& \sigma_{(K-1)(2K+1)}(M)(\|p\|_2^2 + \|q\|_F^2 + \|A\|_F^2) \\ &+ o(\|p\|_2^2 + \|q\|_F^2 + \|A\|_F^2) \\ \geq& \frac{\sigma_{(K-1)(2K+1)}(M)}{1\wedge K\|G(\mathbf{f}^*)\|_\infty}\left(\|\bar{p}\|_2^2 + \|\bar{q}\|_F^2 + \sum_{k\in\mathcal{X}} \|(\bar{A}\mathbf{f}^*)_k\|_F^2\right) \\ &+ o\left(\frac{1}{1\wedge\sigma_K(G(\mathbf{f}^*))}\left(\|\bar{p}\|_2^2 + \|\bar{q}\|_F^2 + \sum_{k\in\mathcal{X}} \|(\bar{A}\mathbf{f}^*)_k\|_F^2\right)\right)\end{aligned}$$

and finally

$$\begin{aligned}\|g^{\pi^*+\bar{p},\mathbf{Q}^*+\bar{q},\mathbf{f}^*+\bar{A}\mathbf{f}^*} - g^{\pi^*,\mathbf{Q}^*,\mathbf{f}^*}\|_2^2 & \\ \geq& c_2(\pi^*,\mathbf{Q}^*,\mathbf{f}^*)\left(\|\bar{p}\|_2^2 + \|\bar{q}\|_F^2 + \sum_{k\in\mathcal{X}} \|(\bar{A}\mathbf{f}^*)_k\|_F^2\right) \\ &+ o\left(\|\bar{p}\|_2^2 + \|\bar{q}\|_F^2 + \sum_{k\in\mathcal{X}} \|(\bar{A}\mathbf{f}^*)_k\|_F^2\right) \quad (4)\end{aligned}$$

where

$$c_2(\pi^*,\mathbf{Q}^*,\mathbf{f}^*) = \frac{H}{(1\wedge K\|G(\mathbf{f}^*)\|_\infty)(3K^3(1\vee\|G(\mathbf{f}^*)\|_\infty^4))^{K^2-K/2}}$$

is positive as soon as **[Hid]** and **[Hdet]** hold.

B.4 Proof of Theorem 10

Let

$$N_{\mathbf{f}}(p,q,\mathbf{h}) = \|g^{\pi^*+p,\mathbf{Q}^*+q,\mathbf{f}+\mathbf{h}} - g^{\pi^*,\mathbf{Q}^*,\mathbf{f}}\|_2^2$$

and

$$\|(p,q,\mathbf{h})\|_{\mathbf{f}}^2 = d_{\text{perm}}((\pi^*+p,\mathbf{Q}^*+q,\mathbf{f}+\mathbf{h}),(\pi^*,\mathbf{Q}^*,\mathbf{f}))^2.$$

We want to show that there exists a constant $c^* > 0$ such that there exists a neighborhood $\mathcal{V}$ of $\mathbf{f}^*$ such that if one writes

$$c_{\mathbf{f}} := \inf_{p\in(\Delta-\Delta),\, q\in(\mathcal{Q}-\mathcal{Q}),\, \mathbf{h}\in(\mathcal{F}-\mathcal{F})^K} \frac{N_{\mathbf{f}}(p,q,\mathbf{h})}{\|(p,q,\mathbf{h})\|_{\mathbf{f}}^2}$$

then $\inf_{\mathbf{f}\in\mathcal{V}} c_{\mathbf{f}} \geq c^*$.

The proof follows the structure of the proof of Theorem 6 of De Castro et al. (2016). It consists of three steps: the first one controls the component of $\mathbf{h}$ that is orthogonal to $\mathbf{f}$. This makes it possible to restrict $\mathbf{h}$ to the finite-dimensional space spanned by $\mathbf{f}$ in the two other parts. The second step controls the case when $\mathbf{h}$ is small, so that the behaviour of $N_{\mathbf{f}}$ is given by its quadratic form, and the last step controls the case where $\mathbf{h}$ is far from zero.

B.4.1 The Orthogonal Part

Let $\mathbf{u}$ be the orthogonal projection of $\mathbf{h}$ on Span($\mathbf{f}$). Then

$$N_{\mathbf{f}}(p,q,\mathbf{h}) = N_{\mathbf{f}}(p,q,\mathbf{u}) + M_{\mathbf{f}}(p,q,\mathbf{u},\mathbf{h}-\mathbf{u})$$

where

$$\begin{aligned}
M_{\mathbf{f}}(p,q,\mathbf{u},\mathbf{a}) = \sum_{i_1,j_1,k_1}\sum_{i_2,j_2,k_2} &(\pi^*+p)(i_1)(\mathbf{Q}^*+q)(i_1,j_1)(\mathbf{Q}^*+q)(j_1,k_1)\\
&(\pi^*+p)(i_2)(\mathbf{Q}^*+q)(i_2,j_2)(\mathbf{Q}^*+q)(j_2,k_2)\\
&\Big(\langle a_{i_1},a_{i_2}\rangle\langle (f+u)_{j_1},(f+u)_{j_2}\rangle\langle (f+u)_{k_1},(f+u)_{k_2}\rangle\\
&+\langle (f+u)_{i_1},(f+u)_{i_2}\rangle\langle a_{j_1},a_{j_2}\rangle\langle (f+u)_{k_1},(f+u)_{k_2}\rangle\\
&+\langle (f+u)_{i_1},(f+u)_{i_2}\rangle\langle (f+u)_{j_1},(f+u)_{j_2}\rangle\langle a_{k_1},a_{k_2}\rangle\\
&\quad+\langle a_{i_1},a_{i_2}\rangle\langle a_{j_1},a_{j_2}\rangle\langle (f+u)_{k_1},(f+u)_{k_2}\rangle\\
&\quad+\langle a_{i_1},a_{i_2}\rangle\langle (f+u)_{j_1},(f+u)_{j_2}\rangle\langle a_{k_1},a_{k_2}\rangle\\
&\quad+\langle (f+u)_{i_1},(f+u)_{i_2}\rangle\langle a_{j_1},a_{j_2}\rangle\langle a_{k_1},a_{k_2}\rangle\\
&\qquad+\langle a_{i_1},a_{i_2}\rangle\langle a_{j_1},a_{j_2}\rangle\langle a_{k_1},a_{k_2}\rangle\Big).
\end{aligned}$$

Let us write Π' the matrix whose diagonal terms are the elements of π^*+p and $\mathbf{Q}'$ the matrix $\mathbf{Q}^*+q$, then $M_{\mathbf{f}}$ can be written as

$$\begin{aligned}
M_{\mathbf{f}}(p,q,\mathbf{u},\mathbf{a}) = \sum_{i,j}\Big(&((\Pi'\mathbf{Q}')^\top G(\mathbf{a})\Pi'\mathbf{Q}')_{i,j}G(\mathbf{f}+\mathbf{u})_{i,j}(\mathbf{Q}'^\top G(\mathbf{f}+\mathbf{u})\mathbf{Q}')_{i,j}\\
&+((\Pi'\mathbf{Q}')^\top G(\mathbf{f}+\mathbf{u})\Pi'\mathbf{Q}')_{i,j}G(\mathbf{a})_{i,j}(\mathbf{Q}'^\top G(\mathbf{f}+\mathbf{u})\mathbf{Q}')_{i,j}\\
&+((\Pi'\mathbf{Q}')^\top G(\mathbf{f}+\mathbf{u})\Pi'\mathbf{Q}')_{i,j}G(\mathbf{f}+\mathbf{u})_{i,j}(\mathbf{Q}'^\top G(\mathbf{a})\mathbf{Q}')_{i,j}\\
&+((\Pi'\mathbf{Q}')^\top G(\mathbf{a})\Pi'\mathbf{Q}')_{i,j}G(\mathbf{a})_{i,j}(\mathbf{Q}'^\top G(\mathbf{f}+\mathbf{u})\mathbf{Q}')_{i,j}\\
&+((\Pi'\mathbf{Q}')^\top G(\mathbf{a})\Pi'\mathbf{Q}')_{i,j}G(\mathbf{f}+\mathbf{u})_{i,j}(\mathbf{Q}'^\top G(\mathbf{a})\mathbf{Q}')_{i,j}\\
&+((\Pi'\mathbf{Q}')^\top G(\mathbf{f}+\mathbf{u})\Pi'\mathbf{Q}')_{i,j}G(\mathbf{a})_{i,j}(\mathbf{Q}'^\top G(\mathbf{a})\mathbf{Q}')_{i,j}\\
&+((\Pi'\mathbf{Q}')^\top G(\mathbf{a})\Pi'\mathbf{Q}')_{i,j}G(\mathbf{a})_{i,j}(\mathbf{Q}'^\top G(\mathbf{a})\mathbf{Q}')_{i,j}\Big).
\end{aligned}$$

By the Schur product theorem, these terms are nonnegative since they correspond to Hadamard products of three Gram matrices which are nonnegative. Thus, one can lower bound $M_{\mathbf{f}}(p,q,\mathbf{u},\mathbf{a})$ by the second term of the sum, which leads to

$$M_{\mathbf{f}}(p,q,\mathbf{u},\mathbf{a}) \geq \sum_{i,j=1}^{K}((\Pi'\mathbf{Q}')^\top G(\mathbf{f}+\mathbf{u})\Pi'\mathbf{Q}')_{i,j}(\mathbf{Q}'^\top G(\mathbf{f}+\mathbf{u})\mathbf{Q}')_{i,j}\langle a_i,a_j\rangle$$

Assume [**Hid**] holds for the parameters $(\pi^*+p,\mathbf{Q}^*+q,\mathbf{f}+\mathbf{u})$, then the matrices $(\Pi'\mathbf{Q}')^\top G(\mathbf{f}+\mathbf{u})\Pi'\mathbf{Q}'$ and $\mathbf{Q}'^\top G(\mathbf{f}+\mathbf{u})\mathbf{Q}'$ are positive symmetric with respective lowest eigenvalue lower

bounded by $(\inf_k(\pi_k^*+p_k)\sigma_K(\mathbf{Q}^*+q))^2\sigma_K(G(\mathbf{f}+\mathbf{u}))$ and $\sigma_K(\mathbf{Q}^*+q)^2\sigma_K(G(\mathbf{f}+\mathbf{u}))$. Therefore, their Hadamard product is positive, and one has

$$(((\Pi'\mathbf{Q}')^\top G(\mathbf{f}+\mathbf{u})\Pi'\mathbf{Q}')_{i,j}(\mathbf{Q}'^\top G(\mathbf{f}+\mathbf{u})\mathbf{Q}')_{i,j})_{i,j} = (D\mathbf{U})^\top(D\mathbf{U})$$

with $\mathbf{U}$ an orthogonal matrix and D a diagonal matrix with positive diagonal coefficients. Moreover, the Schur product theorem implies that $\sigma_K(D)^2 \geq (\inf_k(\pi_k^*+p_k))^2\sigma_K(\mathbf{Q}^*+q)^4\sigma_K(G(\mathbf{f}+\mathbf{u}))^2$. Then

$$\begin{aligned}
M_{\mathbf{f}}(p,q,\mathbf{u},\mathbf{a}) &\geq \sum_{i,j=1}^{K}((D\mathbf{U})^\top(D\mathbf{U}))_{i,j}\langle a_i,a_j\rangle\\
&= \sum_{j=1}^{K}\|D\mathbf{U}\mathbf{a}\|_2^2\\
&\geq \sigma_K(D)^2\|\mathbf{U}\mathbf{a}\|_2^2\\
&\geq (\inf_k(\pi_k^*+p_k))^2\sigma_K(\mathbf{Q}^*+q)^4\sigma_K(G(\mathbf{f}+\mathbf{u}))^2\|\mathbf{a}\|_2^2.
\end{aligned}$$

Finally, let $c_1(\pi^*+p,\mathbf{Q}^*+q,\mathbf{f}+\mathbf{u}) = (\inf_k(\pi_k^*+p_k))^2\sigma_K(\mathbf{Q}^*+q)^4\sigma_K(G(\mathbf{f}+\mathbf{u}))^2$. The application $(p,\pi^*,q,\mathbf{Q}^*,\mathbf{u},\mathbf{f}) \mapsto c_1(\pi^*+p,\mathbf{Q}^*+q,\mathbf{f}+\mathbf{u})$ is continuous and nonnegative, it is positive when [**Hid**] holds for the parameters $(\pi^*+p,\mathbf{Q}^*+q,\mathbf{f}+\mathbf{u})$, and one has

$$M_{\mathbf{f}}(p,q,\mathbf{u},\mathbf{a}) \geq c_1(\pi^*+p,\mathbf{Q}^*+q,\mathbf{f}+\mathbf{u})\|\mathbf{a}\|_2^2.$$

We will now control the term $N_{\mathbf{f}}(p,q,\mathbf{u})$. Two cases appear: when $(\pi^*+p,\mathbf{Q}^*+q,\mathbf{f}+\mathbf{u})$ is close to $(\pi^*,\mathbf{Q}^*,\mathbf{f}^*)$ in some sense and when it is not. The first case will be solved using the nondegeneracy of the quadratic form ensured by [**Hdet**]. The second case will be solved using the identifiability of the HMM.

B.4.2 In the Neighborhood of $\mathbf{f}^*$.

The Taylor expansion of

$$(p,q,\mathbf{u}) \in (\Delta-\Delta)\times(\mathcal{Q}-\mathcal{Q})\times((\mathcal{F}-\mathcal{F})\cap\text{Span}(\mathbf{f}))^K \mapsto N_{\mathbf{f}}(p,q,\mathbf{u})$$

around $(0,0,0)$ leads to a nonnegative quadratic form and no linear part. [**Hdet**], [**Hid**] and equation (4) ensure that this form is positive for $\mathbf{f}=\mathbf{f}^*$. Let $c_2(\mathbf{Q}^*,\pi^*,\mathbf{f})$ be as defined in Section B.3.2, then $\mathbf{f} \mapsto c_2(\mathbf{Q}^*,\pi^*,\mathbf{f})$ is continuous and it is positive in the neighborhood of $\mathbf{f}^*$. Moreover, there exists a positive constant η depending on $\|G(\mathbf{f})\|_\infty$ such that for all $(p,q,\mathbf{u})$ such that $\|(p,q,\mathbf{u})\|_{\mathbf{f}} \leq 1$, one has

$$N_{\mathbf{f}}(p,q,\mathbf{u}) \geq c_2(\mathbf{Q}^*,\pi^*,\mathbf{f})\|(p,q,\mathbf{u})\|_{\mathbf{f}}^2 - \eta\|(p,q,\mathbf{u})\|_{\mathbf{f}}^3.$$

For instance, $\eta = 4000K^6\|G(\mathbf{f})\|_\infty^3$ works: the terms of order 2 or more in the Taylor expansion of $N_{\mathbf{f}}$ are the scalar product of sums of terms of the form $\sum_{i,j,k\in\mathcal{X}}\pi^*(i)\mathbf{Q}^*(i,j)\mathbf{Q}^*(j,k)f_i\otimes f_j\otimes f_k$ where zero to three of the f may be replaced by u, zero to two of the $\mathbf{Q}^*$ by q and π^* may be replaced by p and at least one of them is replaced. There are 63 possibilities, which leads to a sum of $(63K^3)^2$ terms, each of which can be bounded by

$\|G(\mathbf{f})\|_\infty^3(\max\{p(i),q(i,j),\|u_i\|_2 \mid i,j\in\mathcal{X}\})^r$ where r is the number of replaced terms. By taking the right permutation of states, the max can be bounded by $\|(p,q,\mathbf{u})\|_{\mathbf{f}}$, hence the result.

Then, using $\|(p,q,\mathbf{h})\|_{\tilde{\mathbf{f}}}^2 = \|(p,q,\mathbf{u})\|_{\mathbf{f}}^2 + \|\mathbf{a}\|_2^2$ leads to

$$\begin{aligned}\frac{N_{\mathbf{f}}(p,q,\mathbf{h})}{\|(p,q,\mathbf{h})\|_{\tilde{\mathbf{f}}}^2} \geq& c_1(\mathbf{Q}^*+q,\pi^*+p,\mathbf{f}+\mathbf{u})\frac{\|\mathbf{a}\|_2^2}{\|(p,q,\mathbf{u})\|_{\mathbf{f}}^2+\|\mathbf{a}\|_2^2}\\ &+c_2(\mathbf{Q}^*,\pi^*,\mathbf{f})\frac{\|(p,q,\mathbf{u})\|_{\mathbf{f}}^2}{\|(p,q,\mathbf{u})\|_{\mathbf{f}}^2+\|\mathbf{a}\|_2^2}-\eta\frac{\|(p,q,\mathbf{u})\|_{\mathbf{f}}^2}{(\|(p,q,\mathbf{u})\|_{\mathbf{f}}^2+\|\mathbf{a}\|_2^2)^{1/2}}\\ \geq& c_1(\mathbf{Q}^*+q,\pi^*+p,\mathbf{f}+\mathbf{u})\frac{\|\mathbf{a}\|_2^2}{\|(p,q,\mathbf{u})\|_{\mathbf{f}}^2+\|\mathbf{a}\|_2^2}\\ &+c_2(\mathbf{Q}^*,\pi^*,\mathbf{f})\frac{\|(p,q,\mathbf{u})\|_{\mathbf{f}}^2}{\|(p,q,\mathbf{u})\|_{\mathbf{f}}^2+\|\mathbf{a}\|_2^2}-\eta\sqrt{\|(p,q,\mathbf{u})\|_{\mathbf{f}}^2}\end{aligned}$$

Let $c_0 = \min(c_1/2,c_2)/2$, then c_0 is continuous and there exists a continuous function $(\pi^*,\mathbf{Q}^*,\mathbf{f})\mapsto\epsilon(\pi^*,\mathbf{Q}^*,\mathbf{f})$ which is positive as soon as **[Hid]** and **[Hdet]** hold for $(\pi^*,\mathbf{Q}^*,\mathbf{f})$ and such that

$$\|(p,q,\mathbf{u})\|_{\mathbf{f}}\leq\epsilon(\pi^*,\mathbf{Q}^*,\mathbf{f}) \;\Rightarrow\; \frac{N_{\mathbf{f}}(p,q,\mathbf{h})}{\|(p,q,\mathbf{h})\|_{\mathbf{f}}^2}\geq c_0(\mathbf{Q}^*,\pi^*,\mathbf{f}).$$

Thus, there exists positive constants ϵ_0 and c_{near} depending on $\mathbf{Q}^*$, π^* and $\mathbf{f}^*$ such that

$$\begin{aligned}&\forall(p,q,\mathbf{h},\mathbf{f})\in(\Delta-\Delta)\times(\mathcal{Q}-\mathcal{Q})\times(\mathcal{F}-\mathcal{F})^K\times\mathcal{F}^K\\ &\qquad\text{s.t. }\|(p,q,\mathbf{u})\|_{\mathbf{f}}\leq\epsilon_0 \text{ and } \sum_{k\in\mathcal{X}}\|f_k-f_k^*\|_2^2\leq\epsilon_0^2, \qquad \frac{N_{\mathbf{f}}(p,q,\mathbf{h})}{\|(p,q,\mathbf{h})\|_{\mathbf{f}}^2}\geq c_{\text{near}}.\end{aligned}$$

B.4.3 Far from $\mathbf{f}^*$.

Lemma 18 *The application*

$$(p,q,\mathbf{u},\mathbf{f})\in(\Delta-\Delta)\times(\mathcal{Q}-\mathcal{Q})\times(\mathcal{F}-\mathcal{F})^K\times\mathcal{F}^K\longmapsto N_{\mathbf{f}}(p,q,\mathbf{u})$$

restricted to the set of $(p,q,\mathbf{u},\mathbf{f})$ such that $\mathbf{u}\in Span(\mathbf{f})^K$ is uniformly continuous for the norm $\|\cdot\|_{tot}$ defined by

$$\|(p,q,\mathbf{u},\mathbf{f})\|_{tot}^2 := \|p\|_2^2+\|q\|_F^2+\sum_{k\in\mathcal{X}}\left(\|u_k\|_2^2+\|f_k\|_2^2\right).$$

Thus, by compactness of $(\Delta-\Delta)\times(\mathcal{Q}-\mathcal{Q})\times((\mathcal{F}-\mathcal{F})\cap\text{Span}(\mathbf{f}))^K$, the application

$$c_{\text{far}}:\mathbf{f}\longmapsto\inf_{(p,q,\mathbf{u})\in(\Delta-\Delta)\times(\mathcal{Q}-\mathcal{Q})\times((\mathcal{F}-\mathcal{F})\cap\text{Span}(\mathbf{f}))^K\text{ s.t. }\|(p,q,\mathbf{u})\|_{\mathbf{f}}>\epsilon_0}N_{\mathbf{f}}(p,q,\mathbf{u})$$

is continuous. Let us now prove that $c_{\text{far}}(\mathbf{f}^*)>0$.

Let $(p_n,q_n,\mathbf{u}_n)_n\in((\Delta-\Delta)\times(\mathcal{Q}-\mathcal{Q})\times((\mathcal{F}-\mathcal{F})\cap\text{Span}(\mathbf{f}^*))^K)^{\mathbb{N}}$ be a sequence such that $\|(p_n,q_n,\mathbf{u}_n)\|_{\mathbf{f}^*}>\epsilon_0$ for all n and

$$c_{\text{far}}(\mathbf{f}^*)=\lim_n N_{\mathbf{f}^*}(p_n,q_n,\mathbf{u}_n).$$

By compactness, this sequences converges towards a limit $(p,q,\mathbf{u})$ up to taking a subsequence. Necessarily $\|(p,q,\mathbf{u})\|_{\mathbf{f}^*}\geq\epsilon_0$. Since **[Hid]** holds, Theorem 8 shows that $N_{\mathbf{f}^*}(p,q,\mathbf{u})>0$, which implies $c_{\text{far}}(\mathbf{f}^*)>0$ by continuity of $N_{\mathbf{f}^*}$. Note that $c_{\text{far}}(\mathbf{f}^*)$ may depend on $\mathcal{F}$ in addition to the parameters π^*, $\mathbf{Q}^*$ and $\mathbf{f}^*$.

Thus, by continuity, there exists $\epsilon_1>0$ such that for all $\mathbf{f}\in\mathcal{F}^K$ such that $\sum_{k\in\mathcal{X}}\|f_k-f_k^*\|_2^2\leq\epsilon_1^2$, $c_{\text{far}}(\mathbf{f})\geq c_{\text{far}}(\mathbf{f}^*)/2$.

Finally, **[HF]** implies that there exists a constant $\mathcal{C}$ depending only on $C_{\mathcal{F},2}$ such that $\|(p,q,\mathbf{u})\|_{\mathbf{f}}^2\leq\|(p,q,\mathbf{h})\|_{\mathbf{f}}^2\leq\mathcal{C}$ for all $(p,q,\mathbf{h})\in(\Delta-\Delta)\times(\mathcal{Q}-\mathcal{Q})\times(\mathcal{F}-\mathcal{F})^K$. Therefore,

$$\begin{aligned}&\forall(p,q,\mathbf{h},\mathbf{f})\in(\Delta-\Delta)\times(\mathcal{Q}-\mathcal{Q})\times(\mathcal{F}-\mathcal{F})^K\times\mathcal{F}^K\\ &\text{s.t. }\|(p,q,\mathbf{u})\|_{\mathbf{f}}\geq\epsilon_0 \text{ and } \sum_{k\in\mathcal{X}}\|f_k-f_k^*\|_2^2\leq\epsilon_1^2, \qquad \frac{N_{\mathbf{f}}(p,q,\mathbf{h})}{\|(p,q,\mathbf{h})\|_{\mathbf{f}}^2}\geq\frac{N_{\mathbf{f}}(p,q,\mathbf{u})}{\mathcal{C}}\\ &\qquad\qquad\geq\frac{c_{\text{far}}(\mathbf{f}^*)}{2\mathcal{C}}.\end{aligned}$$

The theorem follows by taking $c^*(\pi^*,\mathbf{Q}^*,\mathbf{f}^*,\mathcal{F})=\min\left(\frac{c_{\text{far}}(\mathbf{f}^*)}{2\mathcal{C}},c_{\text{near}}\right)$ and the neighborhood containing all $\mathbf{f}\in\mathcal{F}^K$ such that $\sum_{k\in\mathcal{X}}\|f_k-f_k^*\|_2^2\leq\min(\epsilon_0,\epsilon_1)^2$. Moreover, $(\pi,\mathbf{Q},\mathbf{f})\longmapsto c^*(\pi,\mathbf{Q},\mathbf{f},\mathcal{F})$ is lower bounded by this value in a neighborhood of $(\pi^*,\mathbf{Q}^*,\mathbf{f}^*)$, so that it can be assumed to be lower semicontinuous.

Note that the dependency of c^* on $\mathcal{F}$ appears during this last step and is made non explicit because of the compactness assumption.

B.4.4 Proof of Lemma 18

$$\begin{aligned}&\left|N_{\mathbf{f}}(p,q,\mathbf{u})-N_{\mathbf{f}'}(p',q',\mathbf{u}')\right|\\ &\quad=\left|\|g^{\pi^*+p,\mathbf{Q}^*+q,\mathbf{f}+\mathbf{u}}-g^{\pi^*,\mathbf{Q}^*,\mathbf{f}}\|_2^2-\|g^{\pi^*+p',\mathbf{Q}^*+q',\mathbf{f}'+\mathbf{u}'}-g^{\pi^*,\mathbf{Q}^*,\mathbf{f}'}\|_2^2\right|\\ &\quad\leq 2\|g^{\pi^*+p,\mathbf{Q}^*+q,\mathbf{f}+\mathbf{u}}-g^{\pi^*+p',\mathbf{Q}^*+q',\mathbf{f}'+\mathbf{u}'}\|_2^2+2\|g^{\pi^*,\mathbf{Q}^*,\mathbf{f}}-g^{\pi^*,\mathbf{Q}^*,\mathbf{f}'}\|_2^2\\ &\qquad+2\left|\left\langle g^{\pi^*+p',\mathbf{Q}^*+q',\mathbf{f}'+\mathbf{u}'}-g^{\pi^*,\mathbf{Q}^*,\mathbf{f}'},g^{\pi^*+p,\mathbf{Q}^*+q,\mathbf{f}+\mathbf{u}}-g^{\pi^*+p',\mathbf{Q}^*+q',\mathbf{f}'+\mathbf{u}'}\right\rangle\right|\\ &\qquad+2\left|\left\langle g^{\pi^*+p',\mathbf{Q}^*+q',\mathbf{f}'+\mathbf{u}'}-g^{\pi^*,\mathbf{Q}^*,\mathbf{f}'},g^{\pi^*,\mathbf{Q}^*,\mathbf{f}}-g^{\pi^*,\mathbf{Q}^*,\mathbf{f}'}\right\rangle\right|\end{aligned}$$

Then, using the fact that $\|g^{\pi,\mathbf{Q},\mathbf{f}}-g^{\pi',\mathbf{Q}',\mathbf{f}'}\|_2\leq\sqrt{3K}C_{\mathcal{F},2}^3\|(\pi-\pi',\mathbf{Q}-\mathbf{Q}',\mathbf{f}-\mathbf{f}',0)\|_{\text{tot}}$ (see Lemma 17), that $\|g^{\pi,\mathbf{Q},\mathbf{f}}\|_2\leq C_{\mathcal{F},2}^3$ (see for instance Lemma 29 of Lehéricy (to appear)) and the Cauchy-Schwarz inequality,

$$\begin{aligned}\left|N_{\mathbf{f}}(p,q,\mathbf{u})-N_{\mathbf{f}'}(p',q',\mathbf{u}')\right|\leq&6KC_{\mathcal{F},2}^6\|(p-p',q-q',\mathbf{f}+\mathbf{u}-\mathbf{f}'-\mathbf{u}',0)\|_{\text{tot}}^2\\ &+6KC_{\mathcal{F},2}^6\|(0,0,0,\mathbf{f}-\mathbf{f}')\|_{\text{tot}}^2\\ &+4\sqrt{3K}C_{\mathcal{F},2}^6\|(p-p',q-q',\mathbf{f}+\mathbf{u}-\mathbf{f}'-\mathbf{u}',0)\|_{\text{tot}}\\ &+4\sqrt{3K}C_{\mathcal{F},2}^6\|(0,0,0,\mathbf{f}-\mathbf{f}')\|_{\text{tot}}^2\\ \leq&24KC_{\mathcal{F},2}^6\Big(\|(p-p',q-q',\mathbf{u}-\mathbf{u}',\mathbf{f}-\mathbf{f}')\|_{\text{tot}}^2\\ &+\|(p-p',q-q',\mathbf{u}-\mathbf{u}',\mathbf{f}-\mathbf{f}')\|_{\text{tot}}\Big),\end{aligned}$$

which proves the uniform continuity of the application.

Abstract

When tracking user-specific online activities, each user's preference is revealed in the form of choices and comparisons. For example, a user's purchase history is a record of her choices, i.e. which item was chosen among a subset of offerings. A user's preferences can be observed either explicitly as in movie ratings or implicitly as in viewing times of news articles. Given such individualized ordinal data in the form of comparisons and choices, we address the problem of collaboratively learning representations of the users and the items. The learned features can be used to predict a user's preference of an unseen item to be used in recommendation systems. This also allows one to compute similarities among users and items to be used for categorization and search. Motivated by the empirical successes of the MultiNomial Logit (MNL) model in marketing and transportation, and also more recent successes in word embedding and crowdsourced image embedding, we pose this problem as learning the MNL model parameters that best explain the data. We propose a convex relaxation for learning the MNL model, and show that it is minimax optimal up to a logarithmic factor by comparing its performance to a fundamental lower bound. This characterizes the minimax sample complexity of the problem, and proves that the proposed estimator cannot be improved upon other than by a logarithmic factor. Further, the analysis identifies how the accuracy depends on the topology of sampling via the spectrum of the sampling graph. This provides a guideline for designing surveys when one can choose which items are to be compared. This is accompanied by numerical simulations on synthetic and real data sets, confirming our theoretical predictions.

Keywords: Collaborative Ranking, Nuclear Norm Minimization, Multi-Nomial Logit Model

1. Introduction

Given data on how users compared subsets of items, we address the fundamental problem of learning a representation of users and items. Such data can be observed in the form of choices (e.g. which item was bought) or in the form of comparisons (e.g. which items are rated higher). From such ordinal data on the items, we want to find low dimensional representations, which we call (latent) features, that explain crucial aspects of the users' choices. Once learned, these features can be used to predict each user's preference over items that the user has not seen yet, which can be used in recommendation systems and revenue management. These learned features also provide an embedding of the users and items on the same Euclidean space that allows us to directly quantify similarities via distances, that can be used to categorize and cluster. These embeddings can reveal the underlying structure of data such as images. Such an embedding of a discrete set of objects based on ordinal data has recently gained tremendous attraction mainly due to word embeddings based on co-occurrence data and their successes in numerous downstream natural language processing tasks Mikolov et al. (2013b).

The fundamental question in such a representation learning is: what makes one representation better than the others? Our guiding principle is that a good representation is the one that defines a generative model that best explains the given data in the maximum likelihood sense. To this end, we focus on a parametric generative model known as Multi-Nomial Logit (MNL) model, widely used and studied in revenue management. The MNL model has a natural interpretation of human choices as an outcome of maximizing a utility by agents with noisy perception of the utility, also known as *random utility model* in Walker and Ben-Akiva (2002); Azari Soufiani et al. (2012), defined as follows. Each user and item has a latent low-dimensional feature $u_i \in \mathbb{R}^r$ and $v_j \in \mathbb{R}^r$ respectively. The true utility of an item is the inner product of these two features $\Theta_{ij} \triangleq \langle\!\langle u_i, v_j \rangle\!\rangle = \sum_k u_{ik} v_{jk}$. The inherent low-rank structure of $\Theta = [\Theta_{ij}]$ captures the collaborative nature of the problem, where users with similar preferences in the past are likely to prefer similar items in the future.

When presented with a set of items, a user reveals a noisy ordering of the items sorted according to her perceived utilities of the items, each of which is perturbed by an i.i.d. noise added to the true utility Θ_{ij}. The MNL model is a special case where the noise follows the standard Gumbel distribution, and is one of the most popular models in choice theory for its simplicity and empirical success McFadden (1973); McFadden and Train (2000). The MNL model has several important properties, making this model realistic in various domains, including marketing Guadagni and Little (1983), transportation McFadden (1980); Ben-Akiva and Lerman (1985), biology Sham and Curtis (1995), sports games Tsokos et al. (2018) and natural language processing Mikolov et al. (2013a). The MNL model (*i*) satisfies the 'independence of irrelevant alternatives' in social choice theory Ray (1973); (*ii*) has a maximum likelihood estimator (MLE) which is a convex program in Θ; and (*iii*) has a simple characterization of sequential (random) choices as follows. Let $\mathbb{P}\{a > \{b, c, d\}\}$ denote the probability a was chosen as the best alternative among the set $\{a, b, c, d\}$. Then, the probability that user i reveals a linear order $(a > b > c > d)$ is $\mathbb{P}\{a > \{b, c, d\}\}\mathbb{P}\{b > \{c, d\}\}\mathbb{P}\{c > d\}$, where $\mathbb{P}\{a > \{b, c, d\}\} = e^{\Theta_{ia}}/(e^{\Theta_{ia}} + e^{\Theta_{ib}} + e^{\Theta_{ic}} + e^{\Theta_{id}})$. Essentially the user is modeled as making a sequence of choices, choosing the best alternative first and then making choices on the remaining ones. We give the precise definition of the MNL model in Section 2 for pairwise comparisons and in Section 4 for higher order comparisons and choices. Beyond its success in classical applications such as transportation and marketing, the MNL model and its variants are being rediscovered and successfully applied in more modern applications

such as embedding images using crowdsourcing Tamuz et al. (2011) and word embedding Mikolov et al. (2013b), whose connections we make precise in Section 6.

Motivated by recent advances in learning low-rank models, e.g. Negahban et al. (2009); Davenport et al. (2014), we ask the fundamental question of learning the MNL model from data on comparisons and choices. We provide a general framework using convex relaxations for learning the model. As data is collected in various forms on modern social computing systems, we consider the following four canonical scenarios:

- *Pairwise comparisons.* The most simple and canonical piece of ordinal data one can collect from a user at a time is a pairwise comparison; given two options, we ask the user which one is better. Such data is prevalent in the real world and is the most popular scenario studied in ranking literature, e.g. Shah et al. (2014). However, one significant aspect of the real data that has not been addressed in the literature is irregularities in the sampling. Consider an online seller with various products, say cars and watches. It does not make sense to ask a user to compare a car and a watch; one cannot sample an outcome of a comparison between a watch and a car. However, knowing a user's preference on cars can help in learning her preference on watches. We want to propose a model and design an inference algorithm that can take into account such restrictions in sampling. We further want to quantify the gain in using all such data together in inference, as opposed to running inference in each category separately. To this end, we propose a new model for sampling that we call *graph sampling*. This model explains such irregularities in the real world data. We propose a novel inference algorithm tailored for the given sampling pattern. Our analysis captures precisely how the accuracy depends on the different topologies of the sampling.

- *Higher order comparisons.* Consider an online market that collects each of its user's preference as a ranking over a subset of items that is 'seen' by the user. Such data can be obtained by directly asking to compare some items, or by indirectly tracking online activities on which items are viewed, how much time is spent on the page or how the user rated the items. However, collecting such comparisons over multiple items might come at a cost. We, therefore, want to quantify the gain in the accuracy of the inference when higher order comparison outcomes are collected. We characterize the optimal trade-off between accuracy and the number of items compared, and show that our proposed algorithm seamlessly generalizes to this setting and also achieves the optimal trade-off.

- *Customer choices.* One of the most widely applicable data collection scenarios is customer purchase history. Online and offline service providers can track each customer on which subset of items is offered and which item is chosen. Given historical data on such choices on best-out-of-a-subset, we extract features on the users and items that best explains the collected data.

- *Bundled choices.* Another data collection scenario that is gaining interest recently is bundled choices Chu et al. (2011); Benson et al. (2018). Typical choice models assume that the willingness to buy an item is independent of what else the user bought. In many cases, however, we make 'bundled' purchases: we buy particular ingredients together for one recipe or we buy two connecting flights. One choice (the first flight) has a significant impact on the other (the connecting flight). In order to optimize the assortment (which flight schedules to offer) for maximum expected revenue, it is crucial to accurately predict the willingness of the consumers to purchase bundled items, based on past history. We propose a model that can capture such interacting preferences for bundled items (e.g. jeans and shirts), and use this model to extract the features of the items in each category from historical bundled purchase data. Both our inference algorithm and the analyses extend to this setting, achieving the optimal trade-off between sample size and accuracy.

Contribution. We first study the canonical scenario of pairwise comparisons from the MNL model in Section 3. Our contribution in the modeling is a new sampling scenario we call *graph sampling* that captures how different pairs of items have varying likelihood of being compared together. Our algorithmic contribution is a convex relaxation with a new regularizer using a variation of the standard nuclear norm tailored for the graph sampling topology. Our theoretical contribution is in the analysis of the proposed estimator and a matching fundamental lower bound (up to a poly-logarithmic factor). This (a) characterizes the minimax sample complexity of the problem; (b) proves that the proposed estimator cannot be improved upon; and (c) identifies how the accuracy depends on the topology of sampling. This in turn provides a guideline for designing surveys when one has a choice on which pairs are to be compared. This is accompanied by experiments on synthetic and real data sets confirming our theoretical predictions.

This framework is extended to higher order comparisons in Section 4. We establish minimax optimality (up to a poly-logarithmic factor) of our estimator and identify the fundamental trade-off between accuracy and sample size. When each user provides a total linear ordering among k items, we show that the required sample size effectively is reduced by a factor of k. When the user provides her best choice (as in purchase history) instead of the total linear ordering, we extend our framework and establish minimax optimality in Section 5.2. We also consider a bundled purchase scenario in Section 5, where customers buy pairs of items from each of the two categories. We extend our framework and establish minimax optimality under the bundled purchase setting. We present experimental results on both synthetic and real-world data sets confirming our theoretical predictions and showing the improvement of the proposed approach in predicting users' choices[1].

Technically, we borrow analysis tools from 1-bit matrix completion Davenport et al. (2014), matrix completion Negahban and Wainwright (2012), and restricted strong convexity Negahban et al. (2009), and crucially utilize the Random Utility Model (RUM) Thurstone (1927); Marschak (1960); Luce (1959) interpretation (outlined in Section 2.1) of the MNL model to prove both the upper bound and the fundamental limit. This could be of interest to analyzing more general class of RUMs.

Notations. We use $|||A|||_{\rm F}$ and $|||A|||_{\infty}$to denote the Frobenius norm and the ℓ_∞ norm, $|||A|||_{\rm nuc} = \sum_i \sigma_i(A)$ to denote the nuclear norm where $\sigma_i(A)$ denotes the i-th singular value, and $|||A|||_2 = \sigma_1(A)$ for the spectral norm. We use $\langle\!\langle u, v \rangle\!\rangle = \sum_i u_i v_i$ and $\|u\|$ to

1. Code for our experiments are available at https://github.com/POLane16/Nucnorm-Ranking.

denote the inner product and the Euclidean norm. All ones vector is denoted by $\mathbb{1}$, $\mathbf{I}$ denotes the identity matrix and $\mathbb{I}(A)$ is the indicator function of the event A. The set of the first N integers are denoted by $[N] = \{1, \ldots, N\}$.

1.1 Related Work

Bradley-Terry and Plackett-Luce models. The simplest form of the MNL model is when all users are sharing the same feature vector such that each item is parametrized by a scalar value. This is known as Bradley-Terry (BT) model when pairwise comparisons are concerned and Plackett-Luce (PL) model when higher order comparisons are concerned. This has been proposed and rediscovered several times in the last century Zermelo (1929); Thurstone (1927); Bradley and Terry (1955); Luce (1959); Plackett (1975); McFadden (1973, 1980) in the context of ranking teams in sports games, ranking items based on surveys, and ranking routes in transportation systems. Unlike the general MNL model, maximum likelihood estimator for the BT and PL models are naturally convex programs. However, learning the BT model has first been addressed in Jr. (1957) where the convergence of the iterative algorithm is analyzed, without explicitly relying on the convexity of the problem. A new algorithm based on Majorize-Minimize framework was proposed in Hunter (2004). First sample complexity of learning BT model was provided in Negahban et al. (2012) where a novel estimator, called Rank Centrality, of the BT parameters was proposed. The authors construct a random walk over a graph where the nodes are the items and the transition probability is constructed from the comparisons outcomes. This spectral approach is proven to achieve a minimax optimal sample complexity. This has been a building block for several ranking algorithms, which further process the Rank Centrality to get better accuracy on top of it Chen and Suh (2015); Jang et al. (2016, 2017); Chen et al. (2017). For higher order comparisons, the sample complexity of learning PL model was provided in Hajek et al. (2014); Shah et al. (2014), where the Maximum Likelihood (ML) estimator is shown to achieve the minimax optimality. Later, Maystre and Grossglauser (2015) made the connection between the spectral approach of Rank Centrality and the ML estimator precise by providing a unifying random walk view to the problem. This led to a novel Accelerated Spectral Ranking algorithm introduced in Agarwal et al. (2018), which not only finds the parameters of the PL model more efficiently in computation, but also achieves optimal sample complexity under general sampling graphs. Recently, Borkar et al. (2016) treat the learning problem as solving a noisy linear system, and propose an algorithm that is amenable to on-line, distributed and asynchronous variants. Vojnovic and Yun (2016) analyzes a more general class of random utility models known as Thurstone models, and provide the minimax sample complexity by analyzing the ML estimator. Note that the ML estimators for Thurstone models in general are computationally intractable.

Generalized BT and PL models. As studied in Rajkumar and Agarwal (2014), the BT model covers a subset of probabilistic models over comparisons. There is a hierarchy of models with increasing complexity and descriptive power. One popular extension is the mixture of BT or PL models. It is known that any choice model can be approximated arbitrarily close with a mixed PL model with sufficient number of mixture components McFadden and Train (2000). The sample complexity of learning a mixed PL model was analyzed in Oh and Shah (2014) where a tensor decomposition for learning a mixture model

was proposed and analyzed under some separation conditions between the weights of the mixtures. For a mixture of two PL model, Chierichetti et al. (2018) shows identifiability and uniqueness of the mixture weights, when all marginal probability over all possible rankings among two items and three items are known. In a crowdsourced setting, Chen et al. (2013) models pairwise comparisons using a mixture of PL models consisting of hammer distribution, which reports the true output of a comparison, and spammer distribution, which reports the exact opposite of a comparison. A different approach that tackles the problem by learning to cluster the users based on the pairwise comparisons is proposed in Rui et al. (2015). The MNL model we study in this paper can be thought of as a generalization of the mixed PL models, where each user has her own preference. To make learning feasible, we inherently impose similarities among users via a low-rank condition. Note that a mixed PL model with r mixture is a special case of the MNL model with rank r, where each user's membership is encoded as a r-dimensional feature in standard basis. In the context of collaborative ranking, algorithms for learning the MNL model from pairwise comparisons have been proposed in Park et al. (2015). Instead of nuclear norm regularization as we propose in this paper, Park et al. (2015) proposes solving a convex relaxation of maximizing the likelihood over matrices with bounded nuclear norm. Under the standard assumption of uniformly chosen pairs, it is shown that this approach achieves statistically optimal generalization error rate, instead of Frobenius norm error that we analyze.

Beyond BT and PL models. Modeling choice is an important problem where the ultimate goal is to find the right parametric model to capture human choices. Ragain and Ugander (2016); Blanchet et al. (2013) use Markov chains to model choices with the parameters in the transition matrix defining the probability model. Ideal point model Massimino and Davenport (2018); Kazemi et al. (2018) assumes that the pairwise comparisons of two items by a user depends on their distance from an ideal item (ideal point) for the user in some metric embedding space of the items. Novel nonparametric models have also been proposed to model human choices, for example Shah et al. (2016b); Pananjady et al. (2017); Falahatgar et al. (2018) uses strong stochastic transitivity to model pairwise choices and Farias et al. (2009) uses distribution over all permutations with sparse support to model higher order choices. We also note that in the context of (non-collaborative) ranking, Gleich and Lim (2011) has proposed nuclear norm minimization based algorithm when comparisons between all pairs items are modeled as a low-rank skew-symmetric matrix. Other nonparametric approaches to solving ranking include empirical risk minimization. Clémençon et al. (2005) analyses risk minimization of U-statistics and a more feasible surrogate convex loss minimization to estimate ranking. Katz-Samuels and Scott (2017) assumes that rating of an item by a user is a Lipschitz function of the user-item pair and analyses a nonparametric collaborative ranking algorithm from partial observation of such ratings.

While we are interested in the (parameters of) full ranking over all items, there have been several recent works which aim to only approximately rank the items, such as retrieving only the top-m items Chen and Suh (2015); Jang et al. (2016, 2017) or partitioning the items into ordered buckets of fixed size Katariya et al. (2018); Heckel et al. (2018).

2. Model and Approach for Pairwise Comparisons

The MultiNomial Logit (MNL) model is one of the most popular models that explains how people make choices when given multiple options and is widely used in behavioral psychology and revenue management. For brevity, we focus our discussion on data collected in the form of pairwise comparisons in Sections 2 and 3, and defer the discussion of the MNL model in its full generality to Sections 4 and 5 . We give a precise definition of the model for paired comparisons and provide a novel algorithmic solution to learn this model from samples.

2.1 MultiNomial Logit (MNL) Model for Pairwise Comparisons

Let Θ^* be a $d_1 \times d_2$ dimensional matrix capturing preferences of d_1 users on d_2 items. The probability with which a user, $i \subseteq [d_1]$, when presented with two items $j_1, j_2 \subseteq [d_2]$, prefers item j_1 over item j_2 is,

$$\mathbb{P}\{j_1 > j_2\} = \frac{e^{\Theta^*_{ij_1}}}{e^{\Theta^*_{ij_1}} + e^{\Theta^*_{ij_2}}}\,. \tag{1}$$

This implies that, more preferred items (as per the ordering of Θ^*_{ij}) are more likely to be ranked higher, with the randomness in choices captured by the probabilistic model.

If we do not impose any further constraints on Θ^*, one entry of Θ^* is not related in any way to any other entries. This implies that one user's preference is completely independent of others' and no efficient learning is possible. Each user's preference has to be learned separately. On the other hand, in real applications, it is reasonable to say that preferences of users depend only on a handful of factors for example, quality, price, and aesthetics. We do not know which features affect users' choices, but we assume that there are r-dimensional latent features for each of the users and items that govern such choices, and that $r \ll d_1, d_2$. This assumption mathematically captures the conventional belief that when two people have similar preferences over a subset of items, they tend to have similar tastes on other items as well. Formally, MNL model assumes that Θ^* is a rank r matrix with $r \ll d_1, d_2$. In this paper, we do not impose a hard constraint on the rank and provide general results for matrices of any rank. In this case, we identify how the accuracy depends on the rate of decay of the singular values.

This MNL model has many roots. In revenue management, this has been proposed as a special case of Random Utility Model (RUM). RUM explains choices that a person makes as the result of maximizing perceived random utilities associated with the set of alternatives presented. In the case of MNL, each decision maker and each alternative are associated with an r-dimensional vector, u_i and v_j, resulting in a low-rank Θ^* if $\Theta^*_{ij} = \langle\!\langle u_i, v_j \rangle\!\rangle$. The perceived utility of the item j for decision maker i is,

$$U_{ij} = \langle\!\langle u_i, v_j \rangle\!\rangle + \xi_{ij}\,, \tag{2}$$

where ξ_{ij}'s are i.i.d. random variables following the standard Gumbel distribution. Different choices of distributions give different variants of RUMs. In our analyses, we utilize this RUM interpretation of the MNL model to prove a particular concentration in Section C.4, for example. The model in Equation. (1) has also been re-discoverd several times in the literature Zermelo (1929); Thurstone (1927); Luce (1959); Bradley and Terry (1955) in several domains.

2.2 Low-rank Regularization using Nuclear Norm Minimization

Given the low-rank structure of the model, a natural but inefficient approach is to minimize the negative of the log likelihood, $\mathcal{L}(\cdot)$, regularized by the rank:

$$\widehat{\Theta} \;\in\; \arg\min_{\Theta \in \mathbb{R}^{d_1 \times d_2}} -\mathcal{L}(\Theta) \,+\, \lambda\, \mathrm{rank}(\Theta), \tag{3}$$

for some parameter $\lambda > 0$. As this rank minimization is a notoriously challenging problem, we instead solve a convex relaxation of it. Note that the nuclear norm ball is the convex hull of rank-1 matrices Recht et al. (2010). Analogous to l_1-norm in the case of sparse vectors, nuclear norm is a tight convex surrogate for low-rank solutions. We propose the following nuclear norm regularized optimization problem,

$$\widehat{\Theta} \;\in\; \arg\min_{\Theta \in \Omega} -\mathcal{L}(\Theta) \,+\, \lambda\, |||\Theta|||_{\mathrm{nuc}}, \tag{4}$$

where Ω is a convex constraint which takes care of identifiability and Lipschitz smoothness conditions. Nuclear norm regularization has been widely used Recht et al. (2010) for rank minimization; however, provable guarantees exist only for quadratic loss functions $\mathcal{L}(\Theta)$ Candès and Recht (2009); Negahban and Wainwright (2012). Our analyses extend such results to a convex loss, by first proving that $-\mathcal{L}(\cdot)$ satisfies restricted strong convexity property with high probability. Similar to how (non-collaborative) rank aggregation has been generalized to any strongly log-concave distribution in Shah et al. (2014), our analysis can naturally be extended to a general class of strongly log-concave distributions. We give the expression for the log likelihood in Equation. (8) for pairwise comparisons.

3. Learning MNL Model from Pairwise Comparisons under Graph Sampling

Probabilistic model for sampling. In order to provide performance guarantees on the proposed approach, we need to specify how we sample the pairs that are to be compared. We provide a novel sampling model, which we call *graph sampling* with respect to a weighted graph $\mathcal{G}$. This naturally generalizes Bernoulli sampling typically studied under matrix completion literature Candès and Recht (2009); Keshavan et al. (2010a); Negahban and Wainwright (2012); Jain et al. (2013), and the resulting analysis captures how the performance depends on the topology of the samples. Note that the proposed graph sampling is different from deterministic sampling graphs studied in Hajek et al. (2014); Shah et al. (2016a). This is analytically tractable only in the simpler case of estimating the weight vector of the PL model where there is only one user and the ML estimator is a convex program. However, such deterministic sampling is notoriously hard to handle for matrix estimation, even in the simpler case of matrix completion Bhojanapalli and Jain (2014). Hence, we introduce a probabilistic model that allows enough flexibility to capture the interesting aspects of sampling biases, i.e. grouping.

Precisely, we have a weighted undirected graph $\mathcal{G} = ([d_2], E, \{P_{j_1,j_2}\}_{(j_1,j_2)\in E})$ with d_2 nodes, which represent items, a set of edges E and the edge weight P_{j_1,j_2} between nodes j_1 and j_2. The weights can be written in a symmetric matrix $P \in \mathbb{R}^{d_2 \times d_2}$, and $P_{j_1,j_2} + P_{j_2,j_1} = 2P_{j_1,j_2}$ represent the probability with which the pair (j_1, j_2) is chosen for comparison. Note

that $P_{j,j} = 0$,$\forall j \in [d_2]$, $P_{j_1,j_2} = P_{j_2,j_1}$ and $\sum_{j_1,j_2\in[d_2]} P_{j_1,j_2} = 1$. We assume we get i.i.d. samples from first choosing a random user among $[d_1]$ users, and then choosing a pair (j_1, j_2) of items at random from P, and finally getting a random comparison from the MNL model, i.e. the probability with which user i prefers item j_1 over item j_2 is $\exp\Theta^*_{ij_1}/\left(\exp\Theta^*_{ij_1} + \exp\Theta^*_{ij_2}\right)$.

One of the most important aspects of real-world data that is captured by this graph sampling model is grouping. Consider two groups of items, say, cars and phones. It does not make sense to ask an individual to compare a phone with a brand of a car (i.e. direct comparison is not feasible), but knowing an individual's preference on cars can help in learning her preference on phones. In graph sampling terms, we are sampling from a graph $\mathcal{G}$ consisting of two disjoint cliques: one for cars and another for phones. By analyzing such a sampling scenario, we want to characterize the gain in using the data from both groups of items together, although there are no inter-group comparisons.

In the preference matrix Θ^*, the values in the set of columns corresponding to each connected component in the sampling graph can be arbitrarily shifted together, without changing the pairwise comparisons outcome distributions. This is because adding the same constant to those items that are compared does not change the probability (for those items within the same group), i.e.

$$\mathbb{P}\{j_1 > j_2\} \;=\; \frac{e^{\Theta^*_{ij_1}}}{e^{\Theta^*_{ij_1}} + e^{\Theta^*_{ij_2}}} \;=\; \frac{e^{\Theta^*_{ij_1}+c}}{e^{\Theta^*_{ij_1}+c} + e^{\Theta^*_{ij_2}+c}} \;,$$

and adding different constants to those items that are not in the same group does not change the probability of the outcome as those items are never compared. Hence, to handle this unidentifiability, we let a centered version of Θ^* represent all those shifted versions defining the same probability distribution. Formally, let a zero-one vector $g_k \in \{0,1\}^{d_2}$ denote the group membership such that $g_{i,k} = 1$ if item j is in group k, else $g_{i,k} = 0$. Note that, by definition, no item can be present in more than one group, that is, $\sum_{k=1}^{G} g_k = \mathbb{1}$, where G is the number of groups. We define an equivalence class of Θ^* which represent the same probabilistic model as

$$[\Theta^*] \;=\; \left\{\Theta^* + \sum_{k=1}^{G} u_k g_k^T \;\text{ for all } u_k \in \mathbb{R}^{d_1}\right\}. \tag{5}$$

To overcome the identifiability issue, we represent each equivalence class with the centered matrix satisfying

$$\Theta^* g_k = 0, \quad \forall\, k \in \{1, 2, \ldots, G\} \tag{6}$$

As matrices with large "spikiness" are known to be hard to estimate Negahban and Wainwright (2012), we capture the dependence of the sample complexity on the spikiness as measured by $\alpha := |||\Theta^*|||_\infty$. This captures the dynamic range of the underlying preference matrix. For a related problem of matrix completion, where the loss $\mathcal{L}(\theta)$ is quadratic, either a similar condition on ℓ_∞ norm is required or another condition on incoherence is required.

Graph Laplacian. The performance of our approach depends on the sampling graph P via its graph Laplacian defined as

$$L \;=\; \mathrm{diag}(P\mathbb{1}) - P \tag{7}$$

where $\mathrm{diag}(P\mathbb{1})$ is a diagonal matrix with $\sum_v P_{u,v}$ in the diagonals. Notice that, L is singular and the nullspace is spanned by vectors $\{g_k\}_{k=1}^G$. Let $\sigma_{\max}(L) = \|L\|_2$ and $\sigma_{\min}(L)$ be the smallest eigenvalue of L discounting the G zero-valued eigenvalues. Since the graph has G disconnected maximal components and L is real symmetric, by spectral theorem, $L = U\Sigma U^T$, where U is a matrix of size $d_2 \times (d_2 - G)$ and its $d_2 - G$ columns form an orthonormal set, and Σ is a diagonal matrix such that its diagonal elements are the singular values of L. Let $L^\dagger := U\Sigma^{-1}U^T$ and $L^x := U\Sigma^x U^T$ for all $x \in \mathbb{R}$. We also define the Laplacian induced norms of matrices as,

$$|||\Theta|||_{\mathrm{L}} := \left|\left|\left|\Theta L^{1/2}\right|\right|\right|_{\mathrm{F}}, \text{ and, } |||\Theta|||_{\text{L-nuc}} := \left|\left|\left|\Theta L^{1/2}\right|\right|\right|_{\mathrm{nuc}}.$$

These Laplacian induced norms are more appropriate to analyze and quantify the distance between the estimated matrix $\widehat{\Theta}$ and Θ^*.

When items $k(i)$, $l(i)$ are chosen for comparison by user $j(i)$ as the i-th pair of items, we capture this choice with the matrix $X^{(i)} = e_{j(i)}(e_{k(i)} - e_{l(i)})^T$. The outcome of the comparison is represented by y_i, with $y_i = 1$ when item $k(i)$ wins over item $l(i)$ and $y_i = 0$ if otherwise. The log-likelihood of the comparison outcomes with respect to a parameter matrix Θ is,

$$\mathcal{L}(\Theta) \;=\; \frac{1}{n}\sum_{i=1}^{n}\left[y_i\langle\!\langle\Theta, X^{(i)}\rangle\!\rangle - \log\left(1 + \exp\left(\langle\!\langle\Theta, X^{(i)}\rangle\!\rangle\right)\right)\right]. \tag{8}$$

We propose and analyze the following convex optimization problem,

$$\widehat{\Theta} \;\in\; \underset{\Theta\in\Omega_\alpha}{\mathrm{argmin}} - \mathcal{L}(\Theta) + \lambda|||\Theta|||_{\text{L-nuc}}, \tag{9}$$

where,

$$\Omega_\alpha \;=\; \left\{\Theta \in \mathbb{R}^{d_1\times d_2} \mid |||\Theta|||_\infty \le \alpha, \Theta g_k = 0,\ \forall\, k \in [G]\right\}, \tag{10}$$

with an appropriately chosen $\lambda = 8\sqrt{2}\max\left\{\sqrt{\frac{\sigma\log(2d)}{n}}, \frac{\sigma_{\min}(L)^{-1/2}\log(2d)}{n}\right\}$ with $\sigma = \max\{(d_2 - G)/d_1, 1\}$, where $d = (d_1 + d_2)/2$. In practice, the sampling probability distribution P and the corresponding Laplacian L might not be known. In those cases, we propose using the empirical sampling probability distribution $\hat{P}$ and corresponding empirical Laplacian $\hat{L}$ instead. We describe this version of the algorithm formally in Section 3.4.4, where we empirically demonstrate the robustness of this approach. Further, in experiments with real data sets, we use the empirical Laplacian Section 3.4.5.

3.1 Performance Guarantee

We consider the graph sampling scenario where each sample is i.i.d., the ℓ-th sample consists of user i_ℓ chosen uniformly at random, pair of items $(j_{1,\ell}, j_{2,\ell})$ chosen according to the sampling graph $\mathcal{G} = ([d_2], E, P)$, and the resulting outcome y_ℓ distributed as the MNL model with parameter Θ^*.

Theorem 1 *Under the graph sampling with respect to $\mathcal{G} = ([d_2], E, P)$ with a graph Laplacian L, and under the MNL preference model with preference matrix Θ^*, solving the optimization problem in (9) with n i.i.d. samples achieves, with probability greater than $1 - 1/4d^3$,*

$$\frac{1}{d_1}\left|\left|\left|\left(\Theta^* - \widehat{\Theta}\right) L^{1/2}\right|\right|\right|_{\mathrm{F}}^2 \leq 36\lambda\left(\alpha + \frac{1}{\psi(2\alpha)}\right)\left(\sqrt{2r}\left|\left|\left|\left(\Theta^* - \widehat{\Theta}\right) L^{1/2}\right|\right|\right|_{\mathrm{F}} + \sum_{j=r+1}^{\min\{d_1, d_2 - G\}} \sigma_j(\Theta^* L^{1/2})\right), \tag{11}$$

for any $r \in \{1, 2, \ldots, \min\{d_1, d_2 - G\}\}$, any $\lambda \geq 8\sqrt{2}\max\left\{\sqrt{\frac{\sigma\log(2d)}{n}}, \frac{\sigma_{\min}(L)^{-1/2}\log(2d)}{n}\right\}$ where $\sigma = \max\{(d_2 - G)/d_1, 1\}$ and $d = (d_1 + d_2)/2$, $\psi(x) \triangleq e^x/(1 + e^x)^2$, and for $n \leq \min\{2^6 d_1^2\sigma^2, 2^2\left(d_1\sigma_{\min}(L)^{-1}\right)^{2/3}\}\log(2d)$.

We provide a proof in Appendix A. The above bound holds for any r, where r allows us to trade off the two types of errors: the estimation error and the approximation error. Concretely, the above bound shows a natural splitting of the error into two terms; the first term corresponding to the *estimation error* for the top rank-r component of Θ^* and the second term corresponding to the *approximation error* for how well one can approximate Θ^* with a rank-r matrix. If we know the singular values of Θ^*, we can optimize over r to get the tightest bound. If Θ^* is exactly low-rank then applying a matching rank in the bound gives the following guarantee.

Corollary 2 (Exact rank-r matrix) *Under the same hypothesis as in Theorem 1 with a choice of $\lambda = c_0\max\left\{\sqrt{\frac{\sigma\log(2d)}{n}}, \frac{\sigma_{\min}(L)^{-1/2}\log(2d)}{n}\right\}$ for some $c_0 > 0$, if Θ^* is exactly rank r, there exists a positive constant c_1 such that the proposed estimator achieves,*

$$\frac{1}{\sqrt{d_1}}\left|\left|\left|\left(\Theta^* - \widehat{\Theta}\right) L^{1/2}\right|\right|\right|_{\mathrm{F}} \leq c_1\left(\alpha + \frac{1}{\psi(2\alpha)}\right)\sqrt{r}\max\left\{\sqrt{\frac{\sigma\, d_1\log(2d)}{n}}, \frac{\sqrt{(\sigma_{\min}(L)^{-1}d_1)}\,\log(2d)}{n}\right\}, \tag{12}$$

with probability at least $1 - 2/(d_1 + d_2)^3$ and $\sigma = \max\{(d_2 - G)/d_1, 1\}$.

The second term in the maximization is an artifact of the weakness of current analysis technique and does not reflect the actual error. This is confirmed in our simulation results on graphs with very small spectral gap in Figures 1.(b), (d), and (f), where the error in Laplacian-induced norm error does not decrease with spectral gap of L as the line graph has a much smaller spectral gap compared to a complete graph, for example. In fact, for a special Θ^* in Figure 1.(d) it is the other way, for which we do not have a theoretical explanation.

The number of entries in Θ^* is $d_1 d_2$ and we want to rescale the Frobenius norm error appropriately by $1/\sqrt{d_1 d_2}$. As a typical scaling of $L^{1/2}$ is $1/\sqrt{d_2}$ in spectral norm, we

only need to rescale the Laplacian-induced norm error by $1/\sqrt{d_1}$ in the left-hand side of the above bound. For a rank-r Θ^*, the number of degrees of freedom in describing it is $r(d_1 + d_2) - r^2 = O(r(d_1 + d_2))$. The above theorem shows that the total number of samples n needs to scale as $O(r(d_1 + d_2)\log d)$ in order to achieve an arbitrarily small error. This is only a poly-logarithmic factor larger than the degrees of freedom. In Section 3.2 we make this comparison precise by providing a lower bound that matches the upper bound up to a logarithmic factor.

The upper-bound constraint in Theorem 1 on the number of samples n can be met for large enough d_1 and d_2. For simplicity, assume that $d_1 = d_2 = d$ and r is a constant. Since $\sigma_{\min}(L) = O(1/d_2)$, the upper-bound on n becomes $O(\max\{d^2, d^{4/3}\})$. For large enough d, the upper bound on the RHS of Eq. (12) can be made arbitrarily small with n only scaling as $O(r\,d)$. This is significantly smaller than the upper-bound of $O(d^2)$ on n. Further, in the experiments in Section 3.4, we show that n has no practical upper-bound constraint since the error decreases at the same rate as predicted, for arbitrarily large values of n. This constraint may not be necessary and might be a by-product of the proof techniques.

The dependence on the dynamic range α, however, is sub-optimal. It is expected that the error increases with α, since the Θ^* scales as α, but the exponential dependence in the bound seems to be a weakness of the analysis (for example as seen from numerical experiments in the right panel of Figure 6). Although the error increase with α, numerical experiments suggest that it only increases at most linearly. However, tightening the scaling with respect to α is a challenging problem, and such sub-optimal dependence is also present in existing literature for learning even simpler models, such as the Bradley-Terry model Negahban et al. (2012) or the Plackett-Luce model Hajek et al. (2014), which are special cases of the MNL model studied in this paper.

Another issue is that the underlying matrix might not be exactly low rank. It is more realistic to assume that it is approximately low rank. Following Negahban and Wainwright (2012) we formalize this notion with "ℓ_q-ball" of matrices defined as

$$\mathbb{B}_q(\rho_q) \equiv \{\Theta \in \mathbb{R}^{d_1 \times d_2} \mid \sum_{j \in [\min\{d_1, d_2\}]} |\sigma_j(\Theta^*)|^q \leq \rho_q\}\,. \tag{13}$$

When $q = 0$, this is a set of rank-ρ_0 matrices. For $q \in (0, 1]$, this is set of matrices whose singular values decay relatively fast. By optimizing the choice of r in Theorem 1, we get the following result.

Corollary 3 (Approximately low-rank matrices) *Suppose $\Theta^* \in \mathbb{B}_q(\rho_q)$ for some $q \in (0, 1]$ and $\rho_q > 0$. Under the hypotheses of Theorem 1, with a choice of $\lambda = c_0\max\left\{\sqrt{\frac{\sigma\log(2d)}{n}}, \frac{\sigma_{\min}(L)^{-1/2}\log(2d)}{n}\right\}$ for some constant $c_0 > 0$ there exists a constant $c_1 > 0$ such that solving the optimization (9) achieves with probability at least $1 - 2/(d_1 + d_2)^3$,*

$$\frac{1}{\sqrt{d_1}}\left|\left|\left|\left(\Theta^* - \widehat{\Theta}\right) L^{1/2}\right|\right|\right|_{\mathrm{F}} \leq \frac{c_1\sqrt{\rho_q}}{\sqrt{d_1}}\left(\left(\alpha + \frac{1}{\psi(2\alpha)}\right)\sqrt{\frac{d_1^2\,\sigma\,\log(2d))}{n}}\right)^{\frac{2-q}{2}}, \tag{14}$$

provided $n \geq \sigma\,\log(2d)/\sigma_{\min}(L)$.

This is a strict generalization of Corollary 2. For $q = 0$ and $\rho_0 = r$, this recovers the exact low-rank estimation bound up to a factor of two. For approximate low-rank matrices in an ℓ_q-ball, we lose in the error exponent, which reduces from one to $(2-q)/2$.

3.2 Information-theoretic Lower Bound

For a polynomial-time algorithm of convex relaxation, we gave in the previous section a bound on the achievable error. We next compare this to the fundamental limit of this problem, by giving a lower bound on the achievable error by any algorithm (efficient or not). A simple parameter counting argument indicates that it requires the number of samples to scale as the number of degrees of freedom i.e., $n \propto r(d_1+d_2)$, to estimate a $d_1 \times d_2$ dimensional matrix of rank r. We construct an appropriate packing over the set of low-rank matrices with bounded entries in Ω_α defined as (10), and show that no algorithm can accurately estimate the true matrix with high probability using the generalized Fano's inequality. This provides a constructive argument to lower bound the minimax error rate, which in turn establishes that the bounds in Theorem 1 is sharp up to a logarithmic factor, and proves no other algorithm can significantly improve over the nuclear norm minimization.

Theorem 4 *Suppose Θ^* has a rank r. Under the previously described graph based sampling model, there exists a constant $c > 0$ such that*

$$\inf_{\widehat{\Theta}} \sup_{\Theta^* \in \Omega_\alpha} \mathbb{E}\Big[\frac{1}{\sqrt{d_1}}\Big|\Big|\Big|\Big(\Theta^* - \widehat{\Theta}\Big) L^{1/2}\Big|\Big|\Big|_{\mathrm{F}}\Big] \geq c \min\left\{e^{-\alpha}\sqrt{\frac{r\,d_1}{n}}\,, \alpha \max\left\{\sqrt{\frac{r}{\mathrm{tr}\left(L_r^\dagger\right)}}\,, \frac{d_2}{\sqrt{d_1 \log d}}\right\}\right\}, \quad (15)$$

where the infimum is taken over all measurable functions over the observed comparison results and $L_r^\dagger$ is the pseudo inverse of the rank r approximation of the graph Laplacian.

A proof of this theorem is provided in Appendix B. The term of primary interest in this bound is the first one, which shows the scaling of the (rescaled) minimax rate as $\sqrt{rd_1/n}$ and matches the upper bound in (12) up to a logarithmic factor. It is the dominant term in the bound whenever the number of samples is larger than $n \geq d_1 \max\{\mathrm{tr}\left(L_r^\dagger\right), d_1 \log d/d_2^2\}$. As suggested in numerical simulations on graphs with very small spectral gap in Figures 1.(b), (d), and (f), the dependence in $\mathrm{tr}\left(L_r^\dagger\right)$ is an artifact of the weakness of the current analysis technique. Here we note that, while the lower bound in Theorem 4 is in expectation, the upper bound in Theorem 1 is a high-probability result. The upper bound can immediately be translated into a bound in expected error with an additional term scaling as $\alpha\sigma_{\max}(L)^{1/2}\sqrt{d_2}d^{-3}$, which is smaller than other terms in the bound.

3.3 Performance Guarantee and Lower Bound for Complete Graph

It follows from a simple relation $|||(\Theta^* - \widehat{\Theta})L^{1/2}|||_F \geq \sigma_{min}^{1/2}|||\Theta^* - \widehat{\Theta}|||_F$, which is true since Θ^*, $\widehat{\Theta}$ are in the range space of L, that the above upper bounds automatically give the error bound in the Frobenius norm. When the sampling graph is uniform, i.e. a complete graph

with equal weights $P_{j_1,j_2} = 1/d_2(d_2-1)$, $\forall j_1 \neq j_2$, Frobenius norm is the right metric and we show matching upper and lower bounds.

Corollary 5 (Complete graph upper-bound) *Under the same hypothesis as in Corollary 2, if $\mathcal{G}$ is a complete graph, with a choice of $\lambda = c_0 \max\left\{\sqrt{\frac{\sigma\log(2d)}{n}}, \frac{\sqrt{(d_2-1)}\log(2d)}{n}\right\}$ for some $c_0 > 0$, if Θ^* is exactly rank r, there exists a positive constant c_1 such that the proposed estimator achieves,*

$$\frac{\left|\left|\left|\Theta^* - \widehat{\Theta}\right|\right|\right|_{\mathrm{F}}}{\sqrt{d_1(d_2-1)}} \leq c_1\left(\alpha + \frac{1}{\psi(2\alpha)}\right)\sqrt{r}\max\left\{\sqrt{\frac{\sigma\ d_1\log(2d)}{n}}, \frac{\sqrt{(d_2-1)d_1}\ \log(2d)}{n}\right\}, \quad (16)$$

with probability at least $1 - 2/(d_1+d_2)^3$ and $\sigma = \max\{(d_2-1)/d_1, 1\}$.

Corollary 6 (Complete graph lower-bound) *Suppose Θ^* has rank r. Under the previously described graph based sampling model with graph being a complete graph, there is a universal numerical constant $c > 0$ such that*

$$\inf_{\widehat{\Theta}} \sup_{\Theta^* \in \Omega_\alpha} \mathbb{E}\Big[\frac{1}{\sqrt{d_1\,(d_2-1)}}\Big|\Big|\Big|\widehat{\Theta} - \Theta^*\Big|\Big|\Big|_{\mathrm{F}}\Big] \geq c \min\left\{e^{-\alpha}\sqrt{\frac{r\,d_1}{n}}\,, \alpha\max\left\{\frac{1}{\sqrt{(d_2-1)}}\,, \frac{d_2}{\sqrt{d_1\log d}}\right\}\right\}, \quad (17)$$

where the infimum is taken over all measurable functions over the observed comparison results.

3.4 Experiments

We provide a first-order method to solve the proposed convex optimization, and provide numerical experiments using this algorithm. We present two simulation results followed by an experiment on real data.

For the synthetic experiments, we generate random rank-r matrices of dimension $d \times d$, of the form $\Theta^* = UV^T$ with $U \in \mathbb{R}^{d\times r}$ and $V \in \mathbb{R}^{d\times r}$ entries generated i.i.d from uniform distribution over $[0,1]$. Then the connected-component-mean is subtracted form each connected component, and then the whole matrix is scaled such that the largest entry is $\alpha = 5$. Note that this operation does not increase the rank of the matrix Θ. This is because this de-meaning can be written as $\Theta - \sum_k \Theta g g^T/(g^T\mathbb{1})$ and both terms in the operation are of the same column space as Θ which is of rank r.

3.4.1 Algorithm

Let $\Theta' \triangleq \Theta L^{1/2}$. As the nuclear norm regularizer in (9) is non differentiable, we use the proximal gradient descent Agarwal et al. (2010); Cai et al. (2010). At each iteration, we apply the following two operations on the current estimate, Θ'_t, of $\Theta^* L^{1/2}$,

$$\widetilde{\Theta'}_{t+1} = \Theta'_t - \eta_t \nabla_\Theta \mathcal{L}(\Theta'_t L^{-1/2})L^{-1/2} \quad \text{(gradient descent)} \quad (18)$$

$$\Theta'_{t+1} = M_t(\Gamma_t - \eta_t\lambda\mathbf{I})^+ N_t^T \quad \text{(singular value shrinkage and thresholding)} \quad (19)$$

where $M_t \Gamma_t N_t^T := \widetilde{\Theta'}_t$ is the singular value decomposition of $\widetilde{\Theta'}_t$, such that Γ_t is a diagonal matrix with positive entries, $(\cdot)^+$ is the entry-wise thresholding operation $\max(0, x)$, and η_t is an appropriate step-size. Constraint of zero row sum, is taken care of by initializing the descent algorithm with $\Theta'_0 = 0$, since rows of gradients sum to zero. In practice we do not know the value of α, and hence in experiments we do not enforce the $\|\Theta\|_\infty \leq \alpha$ constraint.

Another issue in the implementation is that the convergence rate can be significantly slower for some graph topologies. We accelerate the proximal gradient descent with the following (modified) Barzilai-Borwein (BB) rule Barzilai and Borwein (1988) for choosing the step-size η_t,

$$\eta_t = \begin{cases} \frac{\|\Theta'_t - \Theta'_{t-1}\|_2^2}{\left\langle\!\left\langle \Theta'_t - \Theta'_{t-1}, \nabla_{\Theta'}\mathcal{L}'(\Theta'_t) - \nabla_{\Theta'}\mathcal{L}'(\Theta'_{t-1}) \right\rangle\!\right\rangle}, & \text{when } t \text{ is odd} \\ \frac{\left\langle\!\left\langle \Theta'_t - \Theta'_{t-1}, \nabla_{\Theta'}\mathcal{L}'(\Theta'_t) - \nabla_{\Theta'}\mathcal{L}'(\Theta'_{t-1}) \right\rangle\!\right\rangle}{\|\nabla_{\Theta'}\mathcal{L}'(\Theta'_t) - \nabla_{\Theta'}\mathcal{L}'(\Theta'_{t-1})\|_2^2}, & \text{when } t \text{ is even} \end{cases}, \tag{20}$$

where $\nabla_{\Theta'}\mathcal{L}'(\Theta') := \nabla_\Theta \mathcal{L}(\Theta' L^{-1/2}) L^{-1/2}$. We stop the descent algorithm whenever an upper bound of the KKT error is smaller than 10^{-5}.

3.4.2 The Role of the Topology of the Sampling Pattern

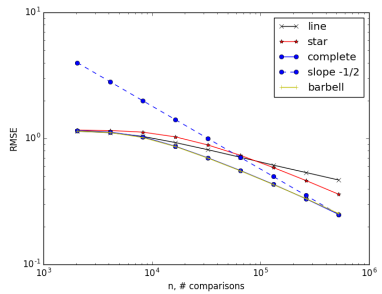
In figure 1, we plot the error of our nuclear norm minimization based algorithm versus number of samples (in log-scale), n for $d_1 = d_2 = 300$, $r = 4$, $\alpha = 5.0$, $G = 1$. We consider two errors here; root mean squared error (RMSE) $= \left|\!\left|\!\left| \Theta - \widehat{\Theta} \right|\!\right|\!\right|_{\mathrm{F}} / \sqrt{d_1 d_2}$ and Laplacian induced RMSE (L-RMSE)$= \left|\!\left|\!\left| (\Theta - \widehat{\Theta}) L^{1/2} \right|\!\right|\!\right|_{\mathrm{F}} / \sqrt{d_1}$. We plot these errors for four topologies of varying spectral gaps. As discussed Section 3.1, we do not expect the L-RMSE error to change much as we change the topology of sampling. However, as seen from the simple relation $|||(\Theta^* - \widehat{\Theta}) L^{1/2}|||_F \geq \sigma_{min}^{1/2} |||\Theta^* - \widehat{\Theta}|||_F$ Frobenius norm error is more sensitive to the topology of the sampling pattern, captured via the spectral gap, i.e. $\sigma_{\min}(L)$. Specifically we use the following graph topologies.

- **Complete graph.** We first consider a uniform sampling over a complete graph where $P_{j_1,j_2} = 1/d_2(d_2-1)$ for all $j_1, j_2 \in [d_2]$. The resulting spectral gap is $1/(d_2-1)$, which is the maximum possible value. Hence, complete graphs are optimal for learning MNL models, compared in the error metric of the Frobenius norm for fairness.

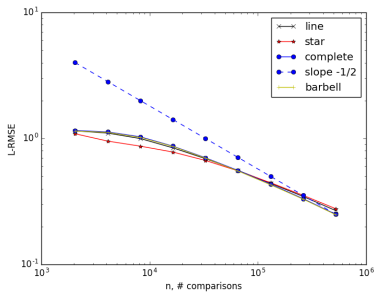
- **Star graph.** Here we choose one item to be the center, and every other items can only be compared to this center item uniformly at random. Let item 1 be the center one, then $P_{j_1,1} = P_{1,j_2} = 1/2(d_2 - 1)$. Standard spectral analysis shows that the spectral gap is $\Theta(1/d_2)$, and thus the graph is near-optimal for learning MNL models.

- **Line graph.** Next, we consider a line graph with $d_2 - 1$ edges where $P_{j,j+1} = P_{j+1,j} = 1/2(d_2 - 1)$. It has a spectral gap of $\Theta(1/d_2^2)$, and is strictly sub-optimal for learning MNL models.

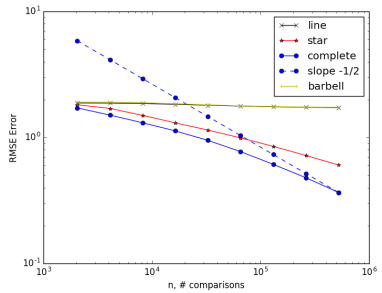
- **Barbell graph.** Consider two equal sized groups of items. Within each group the sub-graph is complete, and between the groups there is a single edge connecting one of the node from group one and one of the node from group two. Each edge is chosen



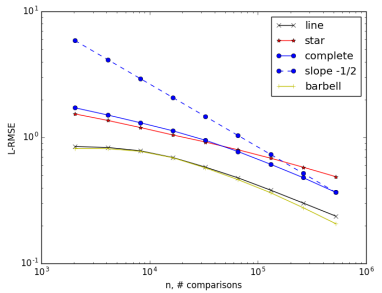
(a) RMSE for i.i.d. Θ^*_{ij}



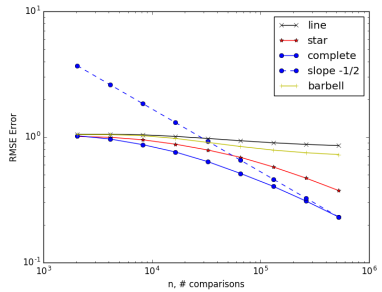
(b) L-RMSE for i.i.d. Θ^*_{ij}



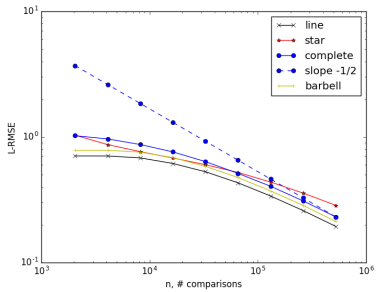
(c) RMSE for barbell bias Θ^*_{ij}



(d) L-RMSE for barbell bias Θ^*_{ij}



(e) RMSE for line bias Θ^*_{ij}



(f) L-RMSE for line bias Θ^*_{ij}

Figure 1: Graphs with small spectral gap achieve significantly larger Frobenius norm error (RMSE) $\left|\!\left|\!\left| \Theta - \widehat{\Theta} \right|\!\right|\!\right|_{\mathrm{F}} / \sqrt{d_1 d_2}$, whereas the Laplacian-induced norm error (L-RMSE) $\left|\!\left|\!\left| (\Theta - \widehat{\Theta}) L^{1/2} \right|\!\right|\!\right|_{\mathrm{F}} / \sqrt{d_1}$ is not sensitive to the spectral gap.

uniformly at random for comparisons. The resulting spectral gap is $\Theta(1/d_2^2)$, and this graph too is strictly sub-optimal for learning MNL models.

First in sub-figures 1a, 1b, we plot RMSE and L-RMSE errors for different graphs using randomly generated Θ^*_{ij}. We see that L-RMSE curves for different graphs are the same (and slopes in log-scale are as expected approaches $-1/2$ with more samples). Further, we do not see any significant difference w.r.t the graph topology even when error is measured in Frobenius norm. The reason is that since Θ^*_{ij}'s are generated i.i.d., the empirical distributions of any large sub-group of items would be similar. Thus, the means of the two cliques of the barbell graph or the means of the items on the two far ends of the line graph are similar. Thus although barbell and line graphs have small spectral gap (high mixing-time), its effect is minimized because these sub-groups can individually be solved without having them to mix since the empirical distributions of the Θ^*_{ij} in the two sub-groups are similar.

To illustrate the role of the topology of the graph, we choose specific Θ^* which depends on the topology of the graph as guided by our analysis on the lower bound (Theorem 4) in sub-figures 1c, 1d. The items are divided into two sets (corresponding to each side of barbell graph), such that corresponding Θ^*_{ij} are i.i.d. inside a set but have similar but shifted means across the sets. We call this type of preference data as *barbell biased*. As expected from theoretical analyses, L-RMSE behave similar to the i.i.d. case. However, we see the Frobenius norm error significantly worse in the case of line and barbell shaped graphs, as expected from the Frobenius error bound. In sub-figures 1e, 1f, we simulate *line biased* preference data Θ^*. Items are ordered (in the order of the line graph), such that Θ^*_{ij}'s have similar distributions but their means get shifted in an arithmetic progression as you go down the ordering. Again, Frobenius norm error is significantly larger for line and barbell graphs as spectral gaps are small.

3.4.3 The Gain in Inference over Multiple Groups of Items

Consider G groups of items such that, within each group, every pair of items is uniformly likely to get compared, but items from different group are never compared with each each other. As a baseline, one can run inference on each group separately. On the other hand, we propose running inference on all the G groups jointly. Let $\widehat{\Theta}$ be the estimate of Θ^* when solving the groups together, and let $\bar{\Theta}$ be the estimate when groups are estimated separately. Let L, $L^{(k)}$ be the graph Laplacians of the whole graph and k-th connected component (group) respectively. suppose, for simplicity, that $d_1 = d_2$ and the groups are equally sized complete sub-graph components,

$$L = \frac{1}{(d_2 - G)} \left(\mathbf{I}_{d_2 \times d_2} - \frac{G}{d_2} \sum_{k=1}^{G} g_k g_k^T \right), \text{ and,} \tag{21}$$

$$L^{(k)} = \frac{1}{(d_2/G - 1)} \left(\mathbf{I}_{\frac{d_2}{G} \times \frac{d_2}{G}} - \frac{G}{d_2} \mathbb{1}\mathbb{1}^T \right). \tag{22}$$

According to Theorems 1 and 4, the L-RMSE error of $\widehat{\Theta}$ satisfies,

$$\frac{1}{\sqrt{d_1}} \left\| \left(\Theta^* - \widehat{\Theta} \right) L^{1/2} \right\|_{\mathrm{F}} = \frac{1}{\sqrt{d_1 (d_2 - G)}} \left\| \Theta^* - \widehat{\Theta} \right\|_{\mathrm{F}} = \tilde{O} \left(\sqrt{\frac{r d_1}{n}} \right). \tag{23}$$

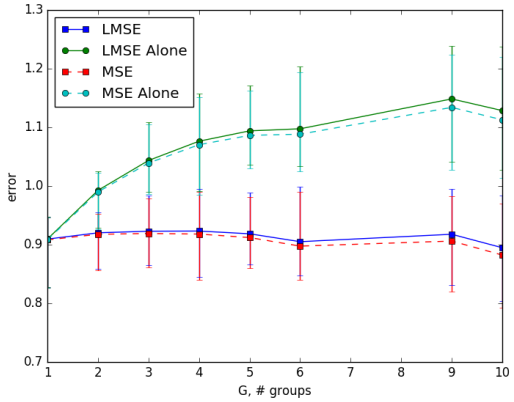


Figure 2: As the number of groups increase, the gain in joint inference increases.

Similarly L-RMSE error (with respect to the full Laplacian L) of $\bar{\Theta}$ satisfies,

$$\frac{1}{d_1} \left\| \left(\Theta^* - \bar{\Theta} \right) L^{1/2} \right\|_{\mathrm{F}}^2 = \frac{1}{d_1 (d_2 - G)} \left\| \Theta^* - \bar{\Theta} \right\|_{\mathrm{F}}^2 \tag{24}$$

$$\overset{(a)}{=} \frac{(d_2/G - 1)}{(d_2 - G)} \sum_{k=1}^{G} \frac{\left\| \left(\Theta^*_k - \bar{\Theta}_k \right) (L^{(k)})^{1/2} \right\|_{\mathrm{F}}^2}{d_2} \tag{25}$$

$$= \frac{1}{G} \sum_{k=1}^{G} \tilde{O} \left(\frac{r d_1}{n/G} \right) \tag{26}$$

$$= \tilde{O} \left(\frac{G r d_1}{n} \right), \tag{27}$$

where (a) follows from Eq. (22) and assuming $\Theta^*_k, \bar{\Theta}_k$ are sub-matrices restricted to the columns in group k. Thus the estimation errors when running joint inference and separate inference for each group are of the order of $O_G(1)$ and $O_G(\sqrt{G})$ respectively. That is, a user's preference in one group of items will be useful in inferring the same user's preference in another group of items. We illustrate this gain of joint inference in Figure 2. Concretely, the sampling graph $\mathcal{G}$ has G groups where each component is a complete graph and $d_1 = d_2 = 360$, $r = 4$, $\alpha = 5.0$, $n = 2^{14}$. Figure 2 plots the L-RMSE (RMSE) $= \left\| (\Theta - \widehat{\Theta}) L^{1/2} \right\|_{\mathrm{F}} / \sqrt{d_1}$ ($\left\| (\Theta - \widehat{\Theta}) \right\|_{\mathrm{F}} / \sqrt{d_1 \, d_2}$) errors vs. G, when all the groups are solved together (labelled as LMSE and MSE) or when the groups are solved separately (labelled as LMSE Alone and MSE Alone) using our algorithm. We see that solving the components together keeps the error relatively similar as the number of groups increase, but if we solve

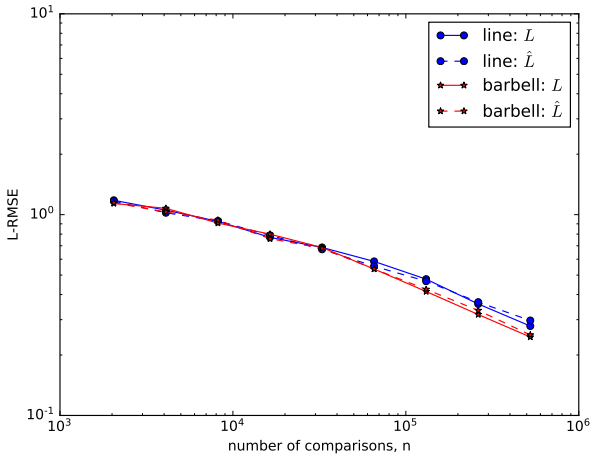

Figure 3: L-RMSE for various sampling graphs when true Laplacian L is known (solid) and when empirical Laplacian $\hat{L}$ is used (dashed)

.

the groups separately the error increases with number of groups, although it is at a lower rate than predicted by the upper bound.

3.4.4 Robustness to the Mismatched L-nuc Norm Regularizer

In practical scenarios, one might not have access to the sampling graph Laplacian L. We propose using empirical Laplacian $\hat{L}$ defined as

$$\hat{L} \triangleq \operatorname{diag}\big(\hat{P}\mathbb{1}\big) - \hat{P}\,, \tag{28}$$

where $\hat{P} \in \mathbb{R}^{d_2 \times d_2}$ is the empirical distribution of sampled pairs in the given data. Under the experimental setting from Figure 1b, we run additional experiments with this empirical Laplacian $\hat{L}$ in the optimization: minimize $-\mathcal{L}(\Theta) + \lambda \|\!|\Theta|\!\|_{\hat{L}\text{-nuc}}$. Figure 3 illustrates that the effect on the performance of not knowing the true L is marginal. Both approaches achieve the same error.

3.4.5 Real data: Food100

To showcase the practicality of our nuclear norm based algorithm (9) we apply our algorithm to the Food100 Data set[2] Wilber et al. (2014). In the data set, $n = 250320$ triplets, denoted by $\{(a_i, b_i, c_i)\}_i$, of 3 distinct food dishes from a selection of $d = 100$ were sampled. Then in

2. Data set is from `https://vision.cornell.edu/se3/projects/cost-effective-hits`.

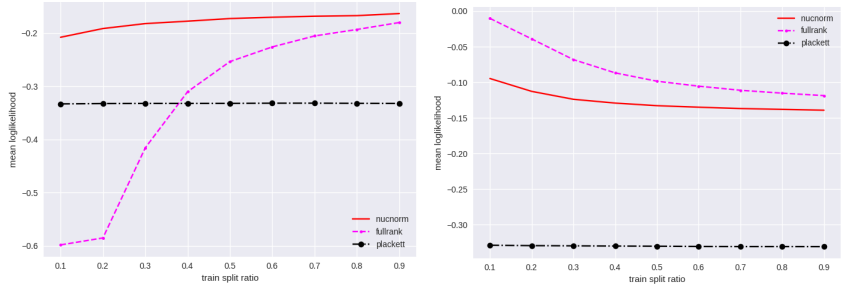
a crowdsourcing setting, users were asked if, a_i is more similar to b_i than to c_i. The goal is to learn an low-dimensional embedding of the 100 food items where the above similarities are captured. We model the problem as learning an MNL model, parameterized by Θ^*, which gives the following probability distribution for i-th user's answer,

$$\mathbb{P}\{a_i \text{ is more similar to } b_i \text{ than to } c_i\} \;=\; \frac{e^{\Theta^*_{a_i,b_i}}}{e^{\Theta^*_{a_i,b_i}} + e^{\Theta^*_{a_i,c_i}}}\,.$$

This is the same model as the pairwise comparisons from Section 2, except for the fact that instead of a user (row) comparing two items (columns), here we compare a food item (row) to two other food items (columns). We implement three different algorithms: our nuclear norm based algorithm ('nucnorm'), unregualrized ($\lambda = 0$) likelihood maximization ('fullrank') and maximum likelihood based algorithm to learn rank-1 Plackett-Luce model Luce (1959); Plackett (1975) ('plackett').

In Figure 4, we plot the mean log-likelihood of the learned model versus fraction x of the data used for training for the various algorithms for testing (a) and training (b) data. If x fraction of the data is used for training, we use the rest $(1-x)$ of the data for testing. For the nuclear norm minimization, we estimate the Laplacian L using the empirical distribution of the triplets and λ is chosen to be $0.1\sqrt{\log(d)/2\,d\,x n}$.

In the Fig. 4(b) (to the left) on the testing data set, we see that our MNL model based nuclear norm regularized algorithm clearly outperforms both unregularized algorithm and the Placket-Luce model estimator, especially when there is less training data. In fact, the mean likelihood ($\log(P_{\text{model}}(\text{test data}))$) on the testing data remains relatively the same when we decrease the size of the training data, which supports our claim that real data has low-rank structure. In the Fig. 4(b) (right) on the training data sets, the non-regularized approach of 'fullrank' achieves higher likelihood on the training data, indicating that it overfits to training data.



(a) Mean log-likelihood on testing data set (b) Mean likelihood on training data set

Figure 4: Mean log-likelihood vs fraction of the total data used for training. Our nuclear norm regularized algorithm ('nucnorm') fits the test data better than both unregularized algorithm ('fullrank') and Plackett-Luce model based estimation, especially when training data is small in size.

Figure 5: Food100: t-SNE embedding of the columns of the learned MNL parameter $\widehat{\Theta}$. Desserts (bottom left) are seperated from other dishes. Meat dishes are also separated from vegetable dishes.

In Fig. 5 we plot the t-SNE embedding Maaten and Hinton (2008) of the columns of the estimated MNL parameter matrix $\widehat{\Theta}$ when all the data is used for training. The desserts (left bottom) are separated from other dishes, and meat dishes and salad dishes form two clusters (top right).

4. Learning the MNL Model under Higher Order Comparisons

Higher order comparisons, where a subset of k items are offered to a user who then provides a complete ranking (total linear ordering) of those item, is a natural generalization of pairwise comparisons, that captures some aspect of heterogeneous and complex modern data sets. We refer to such scenarios as k-wise comparisons or k-wise rankings. The MNL model generalizes to such comparisons. Let Θ^* be the $d_1 \times d_2$ dimensional matrix capturing the preference of d_1 users on d_2 items, where the rows and columns correspond to users and items, respectively. In this k-wise ranking setting, when a user i is presented with a set,

$S_i \subseteq [d_2]$, of k alternatives she reveals her preferences as a ranked list over those items. To simplify the notations, we assume that all the users compare the same number k of items, but the analysis naturally generalizes to the case when the size might differ from a user to a user and when each user provides more than one k-wise ranking. Let $v_{i,\ell} \in S_i$ denote the (random) ℓ-th best choice of user i. Each user gives a ranking, independent of other users' rankings, from

$$\mathbb{P}\left\{v_{i,1}, \ldots, v_{i,k} | S_i \text{ is presented to user } i\right\} = \prod_{\ell=1}^{k} \frac{e^{\Theta^*_{i,v_{i,\ell}}}}{\sum_{j \in S_{i,\ell}} e^{\Theta^*_{i,j}}}\,, \tag{29}$$

where with $S_{i,\ell} \equiv S_i \setminus \{v_{i,1}, \ldots, v_{i,\ell-1}\}$ and $S_{i,1} \equiv S_i$. For a user i, the i-th row of Θ^* represents the underlying preference vector of the user, and the more preferred items are more likely to be ranked higher.

Similar to the pairwise comparisons, the distribution (29) is independent of shifting each row of Θ^* by a constant. Since we can only estimate Θ^* up to this equivalent class, we search for the one whose rows sum to zero, i.e. $\sum_{j \in [d_2]} \Theta^*_{i,j} = 0$ for all $i \in [d_1]$. For capturing the "spikiness" Negahban and Wainwright (2012) of Θ^*, we define $\alpha \equiv \max_{i,j_1,j_2} |\Theta^*_{ij_1} - \Theta^*_{ij_2}|$ to denote the dynamic range of the underlying Θ^*, such that when k items are compared, we always have

$$\frac{1}{k} e^{-\alpha} \;\le\; \frac{1}{1+(k-1)e^{\alpha}} \;\le\; \mathbb{P}\left\{v_{i,1} = j\right\} \;\le\; \frac{1}{1+(k-1)e^{-\alpha}} \;\le\; \frac{1}{k} e^{\alpha}\,, \tag{30}$$

for all $j \in S_i$, all $S_i \subseteq [d_2]$ satisfying $|S_i| = k$ and all $i \in [d_1]$. We do not make any assumptions on α other than that $\alpha = O(1)$ with respect to d_1 and d_2. Given this definition, we solve the following optimization

$$\widehat{\Theta} \in \arg\min_{\Theta \in \Omega_\alpha} -\mathcal{L}(\Theta) + \lambda |||\Theta|||_{\text{nuc}}, \tag{31}$$

where,

$$\mathcal{L}(\Theta) = \frac{1}{k\, d_1} \sum_{i=1}^{d_1} \sum_{\ell=1}^{k} \left(\langle\!\langle \Theta, e_i e_{v_{i,\ell}}^T \rangle\!\rangle - \log \left(\sum_{j \in S_{i,\ell}} \exp\left(\langle\!\langle \Theta, e_i e_j^T \rangle\!\rangle \right) \right) \right)\,, \tag{32}$$

over

$$\Omega_\alpha = \left\{ A \in \mathbb{R}^{d_1 \times d_2} \,\middle|\, |||A|||_\infty \le \alpha, \text{ and } \forall i \in [d_1] \text{ we have } \sum_{j \in [d_2]} A_{ij} = 0 \right\}. \tag{33}$$

Note that unlike graph sampling for pairwise comparisons, we assume that each user is presented a subset of k items and provides a complete ranking over those k items. This choice of sampling scenario, together with independent choices of the items in subset S_i's, is crucial for getting a bound that is tight in its scaling with respect to not only d_1, d_2, and r, but also k, as a certain independence is required to apply the symmetrization technique (in Lemma 29) which gives us the desired tight bound on the error. It trivially follows from our analysis that one can relax the assumptions in the sampling scenario significantly (e.g. sampling without replacement, heterogeneous sampling probabilities for each item-user pair, etc.), and the only change in the upper bound of Eq. (34) will be a weaker dependence k.

4.1 Performance Guarantee

We provide an upper bound on the resulting error of our convex relaxation, when a *multi-set* of items S_i presented to user i is drawn uniformly at random with replacement. Precisely, for a given k, $S_i = \{j_{i,1}, \ldots, j_{i,k}\}$ where $j_{i,\ell}$'s are independently drawn uniformly at random over the d_2 items. Further, if an item is sampled more than once, i.e. if there exists $j_{i,\ell_1} = j_{i,\ell_2}$ for some i and $\ell_1 \neq \ell_2$, then we assume that the user treats these two items as if they are two distinct items with the same MNL weights $\Theta^*_{i,j_{i,\ell_1}} = \Theta^*_{i,j_{i,\ell_2}}$. The resulting preference is therefore always over k items (with possibly multiple copies of the same item), and distributed according to (29). For example, if $k = 3$, it is possible to have $S_i = \{j_{i,1} = 1, j_{i,2} = 1, j_{i,3} = 2\}$, in which case the resulting ranking can be $(v_{i,1} = j_{i,1}, v_{i,2} = j_{i,3}, v_{i,3} = j_{i,2})$ with probability $(e^{\Theta^*_{i,1}})/(2\,e^{\Theta^*_{i,1}} + e^{\Theta^*_{i,2}}) \times (e^{\Theta^*_{i,2}})/(e^{\Theta^*_{i,1}} + e^{\Theta^*_{i,2}})$. Such a sampling with replacement is necessary for the analysis, where we require independence in the choice of the items in S_i in order to apply the symmetrization technique (e.g. Boucheron et al. (2013)) to bound the expectation of the deviation (cf. Appendix C.4). Similar sampling assumptions have been made in existing analyses on learning low-rank models from noisy observations, e.g. Negahban and Wainwright (2012). Let $d \equiv (d_1 + d_2)/2$, and let $\sigma_j(\Theta^*)$ denote the j-th singular value of the matrix Θ^*. Define

$$\lambda_0 \;\equiv\; e^{2\alpha}\sqrt{\frac{d_1 \log d + d_2\,(\log d)^2(\log 2d)^4}{k\,d_1^2\,d_2}}\,. \tag{34}$$

Theorem 7 *Under the described sampling model, assume* $24 \leq k \leq \min\{d_1^2 \log d, (d_1^2 + d_2^2)/(2d_1)\log d,\ (1/e)\,d_2(4\log d_2 + 2\log d_1)\}$*, and* $\lambda \in [480\lambda_0, c_0\lambda_0]$ *with any constant* $c_0 = O(1)$ *larger than 480. Then, solving the optimization* (31) *achieves*

$$\frac{1}{d_1 d_2}\left|\!\left|\!\left|\widehat{\Theta} - \Theta^*\right|\!\right|\!\right|_{\rm F}^2 \;\leq\; 288\sqrt{2}\,e^{4\alpha}c_0\lambda_0\sqrt{r}\left|\!\left|\!\left|\widehat{\Theta} - \Theta^*\right|\!\right|\!\right|_{\rm F} + 288e^{4\alpha}c_0\lambda_0\sum_{j=r+1}^{\min\{d_1,d_2\}}\sigma_j(\Theta^*)\,, \tag{35}$$

for any $r \in \{1, \ldots, \min\{d_1, d_2\}\}$ *with probability at least* $1 - 2d^{-3} - d_2^{-3}$ *where* $d = (d_1 + d_2)/2$.

A proof is provided in Appendix C. This bound holds for all values of r and one could potentially optimize over r. We show such results in the following corollaries.

Corollary 8 (Exact low-rank matrices) *Suppose* Θ^* *has rank at most* r*. Under the hypotheses of Theorem 7, solving the optimization* (31) *with the choice of the regularization parameter* $\lambda \in [480\lambda_0, c_0\lambda_0]$ *achieves with probability at least* $1 - 2d^{-3} - d_2^{-3}$*,*

$$\frac{1}{\sqrt{d_1 d_2}}\left|\!\left|\!\left|\widehat{\Theta} - \Theta^*\right|\!\right|\!\right|_{\rm F} \;\leq\; 288\sqrt{2}e^{6\alpha}c_0\sqrt{\frac{r(d_1 \log d + d_2\,(\log d)^2(\log 2d)^4)}{k\,d_1}}\,. \tag{36}$$

The number of entries is $d_1 d_2$ and we rescale the Frobenius norm error appropriately by $1/\sqrt{d_1 d_2}$. For a rank-r matrix Θ^* with $r(d_1 + d_2) - r^2 = O(r(d_1 + d_2))$ degrees of freedom, the above theorem shows that the total number of samples, which is $(k\,d_1)$, needs to scale

as $O(rd_1(\log d) + rd_2\,(\log d)^2(\log 2d)^4)$ in order to achieve an arbitrarily small error. This is only poly-logarithmic factor larger than the degrees of freedom. In Section 4.2, we provide a lower bound on the error directly, that matches the upper bound up to a logarithmic factor. The dependence on the dynamic range α is sub-optimal. The exponential dependence in the bound seems to be a weakness of the analysis, as seen from numerical experiments in the right panel of Figure 6. Although the error increase with α, numerical experiments suggests that it only increases at most linearly. A practical issue in achieving the above rate is the choice of λ, since the dynamic range α is not known in advance. Figure 6 illustrates that the error is not sensitive to the choice of λ for a wide range.

For approximately low-rank matrices in ℓ_q-ball defined in (13), optimizing the choice of r in Theorem 7, we get the following result. This is a strict generalization of Corollary 8 and a proof of this Corollary is provided in Appendix D.

Corollary 9 (Approximately low-rank matrices) *Suppose* $\Theta^* \in \mathbb{B}_q(\rho_q)$ *for some* $q \in (0, 1]$ *and* $\rho_q > 0$*. Under the hypotheses of Theorem 7, solving the optimization* (31) *with the choice of the regularization parameter* $\lambda \in [480\lambda_0, c_0\lambda_0]$ *achieves with probability at least* $1 - 2d^{-3}$*,*

$$\frac{1}{\sqrt{d_1 d_2}}\left|\!\left|\!\left|\widehat{\Theta} - \Theta^*\right|\!\right|\!\right|_{\rm F} \;\leq\; \frac{2\sqrt{\rho_q}}{\sqrt{d_1 d_2}}\left(288\sqrt{2}c_0 e^{6\alpha}\sqrt{\frac{d_1 d_2(d_1 \log d + d_2\,(\log d)^2(\log 2d)^4)}{k\,d_1}}\right)^{\frac{2-q}{2}}. \tag{37}$$

4.2 Information-theoretic Lower Bound for Low-rank Matrices

A simple parameter counting argument indicates that it requires the number of samples to scale as the degrees of freedom i.e., $kd_1 \propto r(d_1 + d_2)$, to estimate a $d_1 \times d_2$ dimensional matrix of rank r. By applying Fano's inequality with appropriately chosen hypotheses, the following lower bound establishes that the bound in Theorem 7 is sharp up to a logarithmic factor.

Theorem 10 *Suppose* Θ^* *has rank* r*. Under the described sampling model, for large enough* d_1 *and* $d_2 \geq d_1$*, there is a universal numerical constant* $c > 0$ *such that*

$$\inf_{\widehat{\Theta}}\sup_{\Theta^* \in \Omega_\alpha}\mathbb{E}\Big[\frac{1}{\sqrt{d_1 d_2}}\left|\!\left|\!\left|\widehat{\Theta} - \Theta^*\right|\!\right|\!\right|_{\rm F}\Big] \;\geq\; c\,\min\left\{\alpha e^{-\alpha}\sqrt{\frac{r\,d_2}{k\,d_1}}\,,\ \frac{\alpha d_2}{\sqrt{d_1 d_2 \log d}}\right\}, \tag{38}$$

where the infimum is taken over all measurable functions over the observed ranked lists $\{(v_{i,1}, \ldots, v_{i,k})\}_{i \in [d_1]}$.

A proof of this theorem is provided in Appendix E. The term of primary interest in this bound is the first one, which shows the scaling of the (rescaled) minimax rate as $\sqrt{r(d_1 + d_2)/(kd_1)}$ (when $d_2 \geq d_1$), and matches the upper bound in (35). It is the dominant term in the bound whenever the number of samples is larger than the degrees of freedom by a logarithmic factor, i.e., $kd_1 > r(d_1 + d_2)\log d$, ignoring the dependence on α. This is a typical regime of interest, where the sample size is comparable to the latent dimension of the problem. In this regime, Theorem 10 establishes that the upper bound in Theorem 7 is minimax-optimal up to a logarithmic factor in the dimension d.

4.3 Rank Breaking for Higher Order Comparisons

A common approach in practice to handle higher order comparisons is *rank breaking*, which refers to the practice of breaking the higher order comparisons into a set of pairwise comparisons and applying an estimator tailored for pairwise comparisons treating each pair as independent Azari Soufiani et al. (2013, 2014). When the higher order comparison is given as partial rankings (as opposed to total linear ordering as we assume) then rank breaking can be inconsistent, and special algorithms are needed for weighted rank breaking Khetan and Oh (2016a,b). However, when k-wise rankings (also called total linear orderings) are observed as we assume, simple and standard rank breaking achieves a similar performance as the higher order estimator in (31). Assume that $u_{i,m},\ i \in [d_1],\ m \in [k]$, denotes the m-th element observed by the i-th user. Concretely, in rank breaking, we convert the k-wise ranking data into pairwise ranking data and then we solve the following optimization problem:

$$\mathcal{L}(\Theta) = \frac{1}{d_1 \binom{k}{2}} \sum_{i \in [d_1]} \sum_{(m_1,m_2) \in \mathcal{P}_0} \left(\Theta_{i,\, h_i(m_1,m_2)} - \log\left(\exp\left(\Theta_{i,\, u_{i,m_1}} \right) + \exp\left(\Theta_{i,\, u_{i,m_2}} \right) \right) \right) \,, \tag{39}$$

where $\mathcal{P}_0 = \{(i,j) :\ 1 \le i < j \le k\}$, and $h_i\,(m_1,m_2)$ and $l_i\,(m_1,m_2)$ is defined as the higher and lower ranked index among u_{i,m_1} and u_{i,m_2} respectively. Then modified optimization problem becomes,

$$\widehat{\Theta} \ \in \ \arg\min_{\Theta \in \Omega_\alpha} -\mathcal{L}(\Theta) + \lambda |||\Theta|||_{\text{nuc}} \tag{40}$$

Let $d \equiv (d_1+d_2)/2$, and let $\sigma_j(\Theta^*)$ denote the j-th singular value of the matrix Θ^*. Define

$$\lambda_0 \ \equiv \ \sqrt{\frac{d \log d}{k\, d_1^2\, d_2}} \,. \tag{41}$$

With this choice of regularization coefficient, we get the following upper bounds on the rank breaking estimator (40) that are comparable to the upper bounds of k-wise ranking estimator in Theorem 7 and Corollary 8.

Theorem 11 *Under the described sampling model, assume* $2(c+4)\log d \le k \le \max\{d_1, d_2^2/d_1\}\log d$, $d_1 \ge 4$, *and* $\lambda \in [2\sqrt{32(c+4)}\lambda_0, c_p\lambda_0]$ *with any constant* $c = O(1)$ *larger than* $2\sqrt{32(c+4)}$. *Then, solving the optimization* (40) *achieves*

$$\frac{1}{d_1 d_2} \left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\text{F}}^2 \ \le \ 144\sqrt{2}\, e^{2\alpha} c\lambda\sqrt{r} \left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\text{F}} + 144 e^{2\alpha} c\lambda \sum_{j=r+1}^{\min\{d_1,d_2\}} \sigma_j(\Theta^*) \,, \tag{42}$$

for any $r \in \{1, \ldots, \min\{d_1,d_2\}\}$ *with probability at least* $1 - 2d^{-c} - 2d^{-2^{13}}$ *where* $d = (d_1+d_2)/2$.

A proof of this theorem is provided in Appendix F, and the following corollary follows for rank-r matrices.

Corollary 12 (Exact low-rank matrices) *Suppose* Θ^* *has rank at most* r. *Under the hypotheses of Theorem 11, there exists a constant* $c_1 > 0$ *such that solving the optimization* (40) *with the choice of the regularization parameter* $\lambda \in [2\sqrt{32(c+4)}\lambda_0, c\lambda_0]$ *achieves with probability at least* $1 - 2d^{-c} - 2d^{-2^{13}}$,

$$\frac{1}{\sqrt{d_1 d_2}} \left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\text{F}} \ \le \ 144\sqrt{2} e^{2\alpha} c_1 \sqrt{\frac{r d \log d}{k\, d_1}} \,. \tag{43}$$

4.4 Experiments

We provide results from numerical experiments on both synthetic and real data sets.

4.4.1 Algorithm

Similar to the case of pairwise comparisons in Section 3.4.1, we use proximal gradient descent Agarwal et al. (2010); Cai et al. (2010) along with modified Barzilai-Borwein (BB) step-size selection rule Barzilai and Borwein (1988) with the initial point $\Theta_0 = 0$. Each iteration of the algorithm applies the following two operations on the current estimate, Θ_t, of Θ^*,

$$\widetilde{\Theta}_{t+1} = \Theta_t - \eta_t \nabla_\Theta \mathcal{L}(\Theta_t) \qquad \text{(gradient descent)} \tag{44}$$

$$\Theta_{t+1} = M_t(\Gamma_t - \eta_t\lambda \mathbf{I})^+ N_t^T \qquad \text{(singular value shrinkage and thresholding)} \tag{45}$$

where $M_t\Gamma_t N_t^T := \widetilde{\Theta}_t$ is the singular value decomposition of $\widetilde{\Theta}_t$, such that Γ_t is a diagonal matrix with positive entries, $(\cdot)^+$ is the entry-wise thresholding operation $\max(0,x)$, and η_t is an BB step-size calculated as,

$$\eta_t = \begin{cases} |||\Theta_t - \Theta_{t-1}|||_2^2 / \langle\!\langle \Theta_t - \Theta_{t-1}, \nabla_\Theta \mathcal{L}(\Theta_t) - \nabla_\Theta \mathcal{L}(\Theta_{t-1}) \rangle\!\rangle, & \text{when } t \text{ is odd} \\ \langle\!\langle \Theta_t - \Theta_{t-1}, \nabla_\Theta \mathcal{L}(\Theta_t) - \nabla_\Theta \mathcal{L}(\Theta_{t-1}) \rangle\!\rangle / |||\nabla_\Theta \mathcal{L}(\Theta_t) - \nabla_\Theta \mathcal{L}(\Theta_{t-1})|||_2^2, & \text{when } t \text{ is even} \end{cases} . \tag{46}$$

4.4.2 Simulation: Higher Order Comparisons

The left panel of Figure 6 confirms the scaling of the error rate as predicted by Corollary 8. The lines merge to a single line when the sample size is rescaled appropriately (inset). We make a choice of $\lambda = \sqrt{(\log d)/(kd^2)}$. This choice is independent of α and is smaller than proposed in Theorem 7. We generate the random rank-r true MNL parameters matrices of dimension $d \times d$ using the process mentioned in Section 3.4.1. The root mean squared error (RMSE) is plotted where RMSE $= (1/\sqrt{d_1\, d_2})|||\Theta^* - \widehat{\Theta}|||_{\text{F}}$. We implement and solve the convex optimization (31) using proximal gradient descent method as analyzed in Agarwal et al. (2010). The right panel in Figure 6 illustrates that the actual error is insensitive to the choice of λ for a broad range of $\lambda \in [\sqrt{(\log d)/(kd^2)}, 2^8\sqrt{(\log d)/(kd^2)}]$, after which it increases with λ.

4.4.3 Simulation: Rank Breaking

In this section we compare the higher order k-wise comparison algorithm (31) ('kwise') with the pairwise rank breaking algorithm (40) ('kbreak'). We use the same setting as

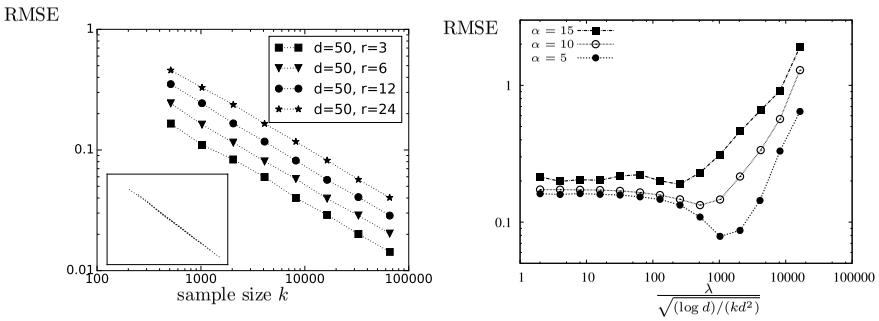


Figure 6: The (rescaled) RMSE scales as $\sqrt{r(\log d)/k}$ as expected from Corollary 8 for fixed $d = 50$ (left). In the inset, the same data is plotted versus rescaled sample size $k/(r \log d)$. The (rescaled) RMSE is stable for a broad range of λ and α for fixed $d = 50$ and $r = 3$ (right).

in Section 4.4.2, where we observe samples from k-wise ranking from an underlying true MNL model and the aim is to recover the true parameter Θ^* of the model. We use $\lambda = 0.45\sqrt{(\log d)/(kd^2)}$ and $\lambda = 0.1\sqrt{(\log d)/(kd^2)}$ for k-wise and pairwise rank breaking algorithms respectively. In Fig. 7 we plot the RMSE for both the algorithm for $d = 50$ and $r = 3, 12$. We note that the even though the RMSE decreases in the rate as predicted by the theorem, we see that pairwise rank breaking is worser than the higher order k-wise algorithm which directly uses the k-wise rankings. This is consistent with the experimental observation made previously in Hajek et al. (2014). Further we note that rank breaking is much slower than the other algorithm, since gradient computation of the former takes $O(k^2)$ time whereas for the latter it can be computed in $O(k)$ time.

4.4.4 Real data: Jester

Jester data set[3] Goldberg et al. (2001) has $24,982$ users, each rating a subset of 100 jokes on continuous scale of $[-10, 10]$. As the scale is continuous, we derive ordinal data from the scores (ties broken uniformly at random). We use only the 7200 users who rated all the jokes for our experiments. For each user, $k = 100x$ jokes were randomly selected uniformly at random for training, rest of the $100 - k = 100(1 - x)$ jokes where used for testing, where x is the fraction of jokes selected for training. We implment four algorithms: nuclear norm minimization ('nucnorm') (31), unregularized ($\lambda = 0$) log-likelihood maximization ('fullrank'), rank-1 Plackett-Luce model estimation ('plackett'), and rank breaking algorithm ('rankbreak') (40). We use $\lambda = 0.7\sqrt{(0.5\log(d_1 d_2))/(kd_1\sqrt{d_1 d_2})}$ and $\lambda = 0.16\sqrt{(0.5\log(d_1 d_2))/(kd_1\sqrt{d_1 d_2})}$ for k-wise and pairwise rank breaking algorithms respectively. In Fig. 8 (a) we plot the multiplicative bias in the mean log-likelihood on the testing data versus the fraction x of training data used. For each model in {'nucnorm',

3. Data set is from `http://eigentaste.berkeley.edu/dataset/`.

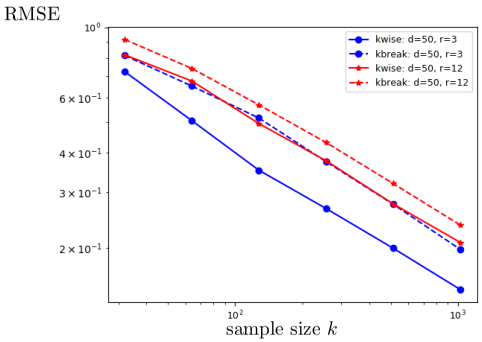

Figure 7: Rank Breaking: RMSE error versus number of samples per user k. k-wise ('kwise') algorithm performs better than the rank breaking ('kbreak') approach.

'fullrank', 'plackett', 'rankbreak'}, we plot in the y-axis

$$\frac{\log(P_{\text{model}}(\text{test data})) - \log(P_{\text{fullrank}}(\text{test data}))}{|\log(P_{\text{fullrank}}(\text{test data}))|},$$

using fullrank model as a baseline as it has the least test likelihood. Plackett-Luce model achieves the best performance when sample size is small, as this simplest model avoids overfitting. However, for most regimes of sample size, both the nuclear norm minimization and rank breaking achieve similar performance improving upon the others.

The same trend holds when we measure the perfomrance in the normalized Spearman's footule distance Diaconis and Graham (1977) $F(\pi_1, \pi_2) \in [0, 1]$ between two rank-lists π_1, π_2 of length k:

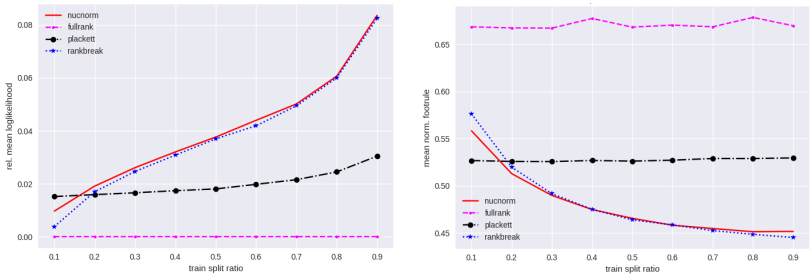
$$F(\pi_1, \pi_2) = \frac{2}{k^2}\sum_{i=1}^{k} |\pi_1(i) - \pi_2(i)|$$

In Fig. 8 (b) we plot the average normalized Spearman's footrule distance between the ground truths and the most likely ranking on the testing data under the estimated model parameters. We see that k-wise nuclear norm minimization and rank breaking algorithms perform the best in recovering the true ranking, except when the fraction of training data used is very small so that the rank-1 Plackett-Luce recovers better ranking.

4.4.5 Real data: Irish Election

The Irish Election data set[4] is an opinion poll conducted among 1083 participants during the 1997 Irish presidential election campaign Gormley and Murphy (2009). Each participant responded with a ranking the of their top 1, 2, 3, 4, or 5 choices from the 5 candidates:

4. Data set is from `https://projecteuclid.org/euclid.aoas/1231424218#supplemental`.



(a) Multiplicative bias in the mean log-likelihood (b) Spearman's footrule distance

Figure 8: Jester data set: Performance on test data vs. fraction of the total data used for training. The proposed nuclear norm regularized algorithm ('nucnorm') and rank breaking ('rankbreak') improves upon both the unregularized algorithm ('fullrank') and the Plackett-Luce model estimation ('plackett') for most regimes of the sample size.

Banotti, McAleese, Nally, Roche, and Scallon. For our experiments we use only the 807 participants who gave their top-5 choices, i.e. full-rankings of all the candidates. Next we divide these participants into 60 (2x3x5x2) group according to a Cartesian product of four categorizations: sex (male/female), marital status (single/married/widowed+divorced), social class (F/AB/C1/C2/DE)[5], location (rural/city+town). We assume that within each group the responses of its member follow the same distriubtion and these distributions of all all the groups are captured by an MNL model with parameter $\Theta^* \in \mathbb{R}^{60\times 5}$. We implement three algorithms: nuclear norm minimization ('nucnorm') (31), unregularized ($\lambda = 0$) log-likelihood maximization ('fullrank'), and rank-1 Plackett-Luce model estimation ('plackett'). We use $\lambda = 0.8\sqrt{(0.5\log(d_1 d_2))/(kd_1\sqrt{d_1 d_2})}$. If x randomly sampled fraction of the data is used for training, then rest of the data is used for testing. In Fig. 9 we plot the mean log-likelihood ($\log(P_{\text{model}}(\text{test data}))$) on the testing data versus the fraction of training data used. We see that nuclear norm minimization and Plackett-Luce model estimation tie for the first place and both improves significantly upon the un-regularized full-rank MNL model estimation. In Fig. 11 we plot the t-SNE Maaten and Hinton (2008) embedding of the rows of the estimated parameter matrix $\widehat{\Theta}$ when all the data is used for training. In Fig. 11a the markers represent the marital status of the group: single/married/divorced+widowed. In Fig. 11b the markers represent the social class of the groups. We see that married (left) and divorced+widowed (right) groups are clearly separated in the embedding, indicating that marital status influences the preference of candidates. However, we see that the social classes are less influential.

In Fig. 10 we represent the voting characteristics of the top 4 right singular vectors $\{\hat{v}_j\}_{j=1}^4$ of $\widehat{\Theta}$, which has a rank of 4 when all the data is used for training. The each stacked bar corresponds to the singular value σ_j marked on the x-axis. Partition of a bar represents the choice model distribution of the corresponding singular vector: $\exp(v_j)/(\mathbb{1}^T\exp(v_j))$,

5. Social classes are F: farmer, AB: middle class. C1: lower middle class, C2: skilled working class, and DE: other working class.

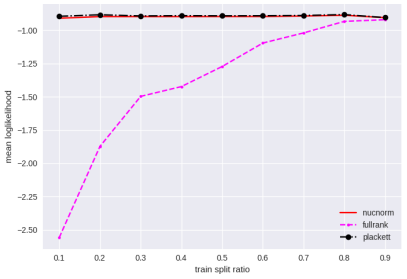


Figure 9: Irish Election: Mean log-likelihood on the test data versus fraction of the data used for training. Nuclear norm minimization and Plackett-Luce model estimator tie for the best performance.

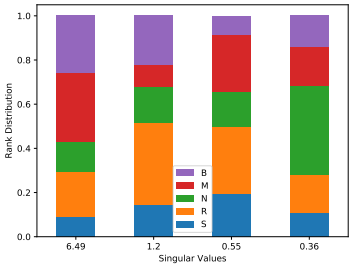

Figure 10: Irish Election: Each bar corresponds to rank distribution of one of the singular 4 values (x-axis) of the $\widehat{\Theta}$. Heights of the partitions represent the probability with which the distribution ranks the corresponding candidate as first (Section 4.4.5).

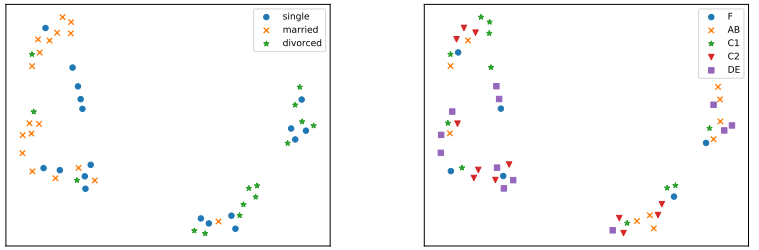
where $\exp(v_j)$ is the element-wise exponentiation operator. We see that there are 2 majors voting "basis" distributions; one favoring McAleese and another favoring Roche. Similar voting blocs have been observed earlier Gormley and Murphy (2009). Even though Placket-Luce model estimator achieves the similar likelihood as our nuclear norm regularized algorithm, the latter helps us in identifying voter "basis", solely from rank data without using the side-information on the voters as in Gormley and Murphy (2009).



(a) Martial status (b) Social class

Figure 11: Irish Election: t-SNE embedding of rows of the estimated parameter matrix $\widehat{\Theta}$. The markers correspond to the marital or social status (F: farmer, AB: middle class. C1: lower middle class, C2: skilled working class, DE: other working class) of the rows.

5. Learning the MNL Model from Choices

Choice modeling has had widespread success in numerous application domains such as transportation and marketing Train (1986); Guadagni and Little (1983). Choice models stem from revenue management to tackle the fundamental problem of maximizing expected revenue where the expectation is taken over a probabilistic choice model that is learned from historical purchase data. Revenue management has focused on designing efficient solvers for the optimization problem with exact or approximation guarantees, and has less to do with *learning* the parameters of probabilistic choice model of interest.

In this section, we tackle this unexplored domain of learning choice models from samples with provable guarantees on the sample complexity. In particular, we study learning the MNL model from choices. We study two types of choices under the MNL model that together include all practical scenarios of interest: *bundled choice* and *consumer choice*.

Bundled choice. We consider a novel scenario of significant practical interest: choice modeling from bundled purchase history. In this setting, we assume that we have bundled purchase history data from n users. Precisely, there are two categories of interest with d_1 and d_2 alternatives in each category respectively. For example, there are d_1 tooth pastes to choose from and d_2 tooth brushes to choose from. For the i-th user, a subset $S_i \subseteq [d_1]$ of alternatives from the first category is presented along with a subset $T_i \subseteq [d_2]$ of alternatives from the second category. We use k_1 and k_2 to denote the number of alternatives presented to a single user, i.e. $k_1 = |S_i|$ and $k_2 = |T_i|$, and we assume that the number of alternatives presented to each user is fixed, to simplify notations. However, the analysis naturally generalizes if the number differs from a user to another user. Given these sets of alternatives, each user makes a 'bundled' purchase, of an item from S_i and another item from T_i together, and we use (u_i, v_i) to denote these bundled pair of alternatives (e.g. a tooth brush and a tooth paste) purchased by the i-th user. Each user makes a choice of the best alternative, independent of other users's choices, according to the MNL model as

$$\mathbb{P}\left\{(u_i, v_i) = (j_1, j_2)\right\} \;=\; \frac{e^{\Theta^*_{j_1,j_2}}}{\sum_{j_1' \in S_i, j_2' \in T_i} e^{\Theta^*_{j_1',j_2'}}}\,, \tag{47}$$

for all $j_1 \in S_i$ and $j_2 \in T_i$. We emphasize here that the preference matrix is indexed by items of type one (in the rows) and items of type two (in the columns). We are taking the existing standard MNL model over user-item pairs to propose a novel choice model for bundled purchases over two types of items. One could go beyond paired bundled choices and include the user identity as another dimension, or add other types of items and consider higher order bundled purchases. This would require MNL model over higher order tensors, which is outside the scope of this paper, but are interesting generalizations. The main challenge in learning such tensor MNL models is that nuclear norm of a higher order tensor is not a computable quantity and hence minimizing the nuclear norm is not algorithmically feasible Yuan and Zhang (2014). Efficient methods exist based on alternating minimizations, but existing analysis tools can handle only quadratic losses Jain and Oh (2014).

The distribution (47) is independent of shifting all the values of Θ^* by a constant. Hence, there is an equivalent class of Θ^* that gives the same distribution for the choices: $[\Theta^*] \equiv \{A \in \mathbb{R}^{d_1 \times d_2} \,|\, A = \Theta^* + c\mathbb{1}\mathbb{1}^T \text{ for some } c \in \mathbb{R}\}$. Since we can only estimate Θ^* up to

this equivalent class, we search for the one that sums to zero, i.e. $\sum_{j1 \in [d_1], j_2 \in [d_2]} \Theta^*_{j_1,j_2} = 0$. Let $\alpha = \max_{j_1,j_1' \in [d_1], j_2, j_2' \in [d_2]} |\Theta^*_{j_1,j_2} - \Theta^*_{j_1',j_2'}|$, denote the dynamic range of the underlying Θ^*, such that when $k_1 \times k_2$ alternatives are presented, we always have

$$\frac{1}{k_1 k_2} e^{-\alpha} \;\le\; \mathbb{P}\left\{(u_i, v_i) = (j_1, j_2)\right\} \;\le\; \frac{1}{k_1 k_2} e^{\alpha}\,, \tag{48}$$

for all $(j_1, j_2) \in S_i \times T_i$ and for all $S_i \subseteq [d_1]$ and $T_i \subseteq [d_2]$ such that $|S_i| = k_1$ and $|T_i| = k_2$. We do not make any assumptions on α other than that $\alpha = O(1)$ with respect to d_1 and d_2. Assuming Θ^* is well approximated by a low-rank matrix, we solve the following convex relaxation, given the observed bundled purchase history $\{(u_i, v_i, S_i, T_i)\}_{i \in [n]}$:

$$\widehat{\Theta} \;\in\; \arg\min_{\Theta \in \Omega_\alpha} \mathcal{L}(\Theta) + \lambda |||\Theta|||_{\text{nuc}}\,, \tag{49}$$

where the negative log likelihood function according to (47) is

$$\mathcal{L}(\Theta) \;=\; -\frac{1}{n} \sum_{i=1}^{n} \left(\langle\!\langle \Theta, e_{u_i} e_{v_i}^T \rangle\!\rangle - \log \left(\sum_{j_1 \in S_i, j_2 \in T_i} \exp\left(\langle\!\langle \Theta, e_{j_1} e_{j_2}^T \rangle\!\rangle \right) \right) \right), \text{ and} \tag{50}$$

$$\Omega_\alpha \;\equiv\; \left\{ A \in \mathbb{R}^{d_1 \times d_2} \,\middle|\, |||A|||_\infty \le \alpha, \text{ and } \sum_{j_1 \in [d_1], j_2 \in [d_2]} A_{j_1,j_2} = 0 \right\}. \tag{51}$$

Compared to collaborative ranking, (a) rows and columns of Θ^* correspond to an alternative from the first and second category, respectively; (b) each sample corresponds to the purchase choice of a user which follow the MNL model with Θ^*; (c) each person is presented subsets S_i and T_i of items from each category; (d) each sampled data represents the most preferred bundled pair of alternatives.

Customer choice. The standard customer choice can be thought of as either a special case of *bundled choice* or as a special case of *higher order comparisons*. We consider the standard customer choice data from purchase history. In this setting, we assume that we have purchase history data from d_1 users over d_2 alternatives. The i-th sample is i.i.d. with user u_i chosen uniformly at random and a subset $S_i \subseteq [d_2]$ of alternatives of size k. We fix k in order to be efficient in the notations and any variable size offerings can be handled seamlessly. We assume S_i is chosen uniformly at random with replacement, in a similar way as bundled choice and higher order comparisons.

Given these sets of alternatives, the user u_i makes a 'choice' and we use v_i to denote the purchased alternative by the i-th (sampled) user. Each user makes a choice of the best alternative, independent of other users's choices, according to the MNL model as

$$\mathbb{P}\left\{v_i = j_2 | u_i = j_1\right\} \;=\; \frac{e^{\Theta^*_{j_1,j_2}}}{\sum_{j_2' \in S_i} e^{\Theta^*_{j_1,j_2'}}}\,, \tag{52}$$

for all $j_2 \in S_i$. Up to the fact that we index rows by users and not items of one category, this is a special case of the *bundled choice* model where we fix $k_1 = 1$. Mathematically, all of our results under consumer choices are derived as corollaries from our results under bundled choices, but given the prevalent interest in customer choice models, we emphasize the implications of our framework under customer choice models in a separate section (see Section 5.2).

5.1 Learning the MNL Model from Bundled Choices

We provide an upper bound on the error achieved by our convex relaxation, when the *multi-set* of alternatives S_i from the first category and T_i from the second category are drawn uniformly at random with replacement from $[d_1]$ and $[d_2]$ respectively. Precisely, for given k_1 and k_2, we let $S_i = \{j_{1,1}^{(i)}, \ldots, j_{1,k_1}^{(i)}\}$ and $T_i = \{j_{2,1}^{(i)}, \ldots, j_{2,k_2}^{(i)}\}$, where $j_{1,\ell}^{(i)}$'s and $j_{2,\ell}^{(i)}$'s are independently drawn uniformly at random over the d_1 and d_2 alternatives, respectively. Similar to the previous section, this sampling with replacement is necessary for the analysis. Define

$$\lambda_0 = \sqrt{\frac{e^{2\alpha} \max\{d_1, d_2\} \log d}{n\, d_1\, d_2}}\,. \tag{53}$$

Theorem 13 *Under the described sampling model, assume* $16e^{2\alpha} \min\{d_1, d_2\} \log d \le n$ *and* $n \le \min\{d^5, k_1 k_2 \max\{d_1^2, d_2^2\}\} \log d$*, and* $\lambda \in [8\lambda_0, c_1\lambda_0]$ *with any constant* $c_1 = O(1)$ *larger than* $\max\{8, 128/\sqrt{\min\{k_1, k_2\}}\}$*. Then, solving the optimization* (49) *achieves*

$$\frac{1}{d_1 d_2} \left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\mathrm{F}}^2 \;\le\; 48\sqrt{2}\, e^{2\alpha} c_1 \lambda \sqrt{r} \left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\mathrm{F}} + 48 e^{2\alpha} c_1 \lambda \sum_{j=r+1}^{\min\{d_1,d_2\}} \sigma_j(\Theta^*)\,, \tag{54}$$

for any $r \in \{1, \ldots, \min\{d_1, d_2\}\}$ *with probability at least* $1 - 2d^{-3}$ *where* $d = (d_1 + d_2)/2$.

A proof is provided in Appendix G. Optimizing over r gives the following corollaries.

Corollary 14 (Exact low-rank matrices) *Suppose* Θ^* *has rank at most* r*. Under the hypotheses of Theorem 13, solving the optimization* (49) *with the choice of the regularization parameter* $\lambda \in [8\lambda_0, c_1\lambda_0]$ *achieves with probability at least* $1 - 2d^{-3}$*,*

$$\frac{1}{\sqrt{d_1 d_2}} \left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\mathrm{F}} \;\le\; 48\sqrt{2} e^{3\alpha} c_1 \sqrt{\frac{r(d_1 + d_2)\log d}{n}}\,. \tag{55}$$

This corollary shows that the number of samples n needs to scale as $O(r(d_1 + d_2)\log d)$ in order to achieve an arbitrarily small error. This is only a logarithmic factor larger than the number of degrees of freedom. For approximately low-rank matrices in an ℓ_1-ball as defined in (13), we show an upper bound on the error, whose error exponent reduces from one to $(2 - q)/2$.

Corollary 15 (Approximately low-rank matrices) *Suppose* $\Theta^* \in \mathbb{B}_q(\rho_q)$ *for some* $q \in (0, 1]$ *and* $\rho_q > 0$*. Under the hypotheses of Theorem 13, solving the optimization* (49) *with the choice of the regularization parameter* $\lambda \in [8\lambda_0, c_1\lambda_0]$ *achieves with probability at least* $1 - 2d^{-3}$*,*

$$\frac{1}{\sqrt{d_1 d_2}} \left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\mathrm{F}} \;\le\; \frac{2\sqrt{\rho_q}}{\sqrt{d_1 d_2}} \left(48\sqrt{2} c_1 e^{3\alpha} \sqrt{\frac{d_1 d_2 (d_1 + d_2)\log d}{n}} \right)^{\frac{2-q}{2}}\,. \tag{56}$$

This follows from the same line of proof as in the proof of Corollary 9 in Appendix D. We next, provide a fundamental lower bound on the error, that matches the upper bound up to a logarithmic factor.

Theorem 16 *Suppose* Θ^* *has rank* r*. Under the described sampling model, there is a universal constant* $c > 0$ *such that that the minimax rate where the infimum is taken over all measurable functions over the observed purchase history* $\{(u_i, v_i, S_i, T_i)\}_{i\in[n]}$ *is lower bounded by*

$$\inf_{\widehat{\Theta}} \sup_{\Theta^* \in \Omega_\alpha} \mathbb{E}\Big[\frac{1}{\sqrt{d_1 d_2}} \left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\mathrm{F}} \Big] \;\ge\; c \min\left\{ \sqrt{\frac{e^{-5\alpha}\, r\,(d_1 + d_2)}{n}}\,,\; \frac{\alpha(d_1 + d_2)}{\sqrt{d_1 d_2 \log d}} \right\}\,. \tag{57}$$

We provide a proof in Appendix H. The first term is dominant, and when the sample size is comparable to the latent dimension of the problem, Theorem 13 is minimax optimal up to a logarithmic factor. We emphasize here that the bound in (55) and the matching lower bound in (57) do not depend on the size of the offerings k_1 and k_2. It is independent of how large k_1 and k_2 are because, we only observe one choice, and intuitively the information we get scales at best by a factor of $\log(k_1 k_2)$. The theorems prove that there is no essential gain in learning from large offerings. One might be tempted to stop at proving an upper bound that scales as $O(\sqrt{k_1 k_2 r(d_1 + d_2)\log d/n})$, which is larger than (55) by a factor of $\sqrt{k_1 k_2}$. Such a loose bound follows if one ignores the tight concentration analysis that we do using the symmetrization technique (e.g. in Lemma 29). Getting the tight dependency in k_1 and k_2 is one of the crucial technical challenges we overcome in this paper.

5.2 Learning the MNL Model from Customer Choices

The results for the *customer choice* model follow immediately from the results in *bundled choice* model by simply setting $k_1 = 1$, and we explicitly write those corollaries in this section for completeness. The proposed estimator is minimax optimal up to a logarithmic factor under the standard customer choice model of sampling.

Corollary 17 *Under the described sampling model, assume* $16e^{2\alpha} \min\{d_1, d_2\} \log d \le n \le \min\{d^5, k \max\{d_1^2, d_2^2\}\} \log d$*, and* $\lambda \in [8\lambda_0, c_1\lambda_0]$ *with any constant* $c_1 = O(1)$ *larger than* 128*. Then, solving the optimization* (49) *achieves*

$$\frac{1}{d_1 d_2} \left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\mathrm{F}}^2 \;\le\; 48\sqrt{2}\, e^{2\alpha} c_1 \lambda \sqrt{r} \left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\mathrm{F}} + 48 e^{2\alpha} c_1 \lambda \sum_{j=r+1}^{\min\{d_1,d_2\}} \sigma_j(\Theta^*)\,, \tag{58}$$

for any $r \in \{1, \ldots, \min\{d_1, d_2\}\}$ *with probability at least* $1 - 2d^{-3}$ *where* $d = (d_1 + d_2)/2$.

Corollary 18 (Exact low-rank matrices) *Suppose* Θ^* *has rank at most* r*. Under the hypotheses of Theorem 17, solving the optimization* (49) *with the choice of the regularization parameter* $\lambda \in [8\lambda_0, c_1\lambda_0]$ *achieves with probability at least* $1 - 2d^{-3}$*,*

$$\frac{1}{\sqrt{d_1 d_2}} \left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\mathrm{F}} \;\le\; 48\sqrt{2} e^{3\alpha} c_1 \sqrt{\frac{r(d_1 + d_2)\log d}{n}}\,. \tag{59}$$

Corollary 19 (Approximately low-rank matrices) *Suppose $\Theta^* \in \mathbb{B}_q(\rho_q)$ for some $q \in (0,1]$ and $\rho_q > 0$. Under the hypotheses of Theorem 17, solving the optimization (49) with the choice of the regularization parameter $\lambda \in [8\lambda, c_1\lambda]$ achieves with probability at least $1 - 2d^{-3}$,*

$$\frac{1}{\sqrt{d_1 d_2}} \left\| \widehat{\Theta} - \Theta^* \right\|_{\mathrm{F}} \leq \frac{2\sqrt{\rho_q}}{\sqrt{d_1 d_2}} \left(48\sqrt{2} c_1 e^{3\alpha} \sqrt{\frac{d_1 d_2 (d_1 + d_2) \log d}{n}} \right)^{\frac{2-q}{2}} . \tag{60}$$

We emphasize again that the bound in (59) does not depend on the size of the offerings k. It is significantly easier to stop at proving an upper bounds that scale as $O(\sqrt{kr(d_1+d_2)\log d/n})$, which are larger than (59) by a factor of $\sqrt{k}$. Such a loose bound follows if one ignores the tight concentration analysis that we do using the symmetrization technique (e.g. in Lemma 29). Getting the tight dependency in k is one of the crucial technical challenges we overcome in this paper.

5.3 Experiments

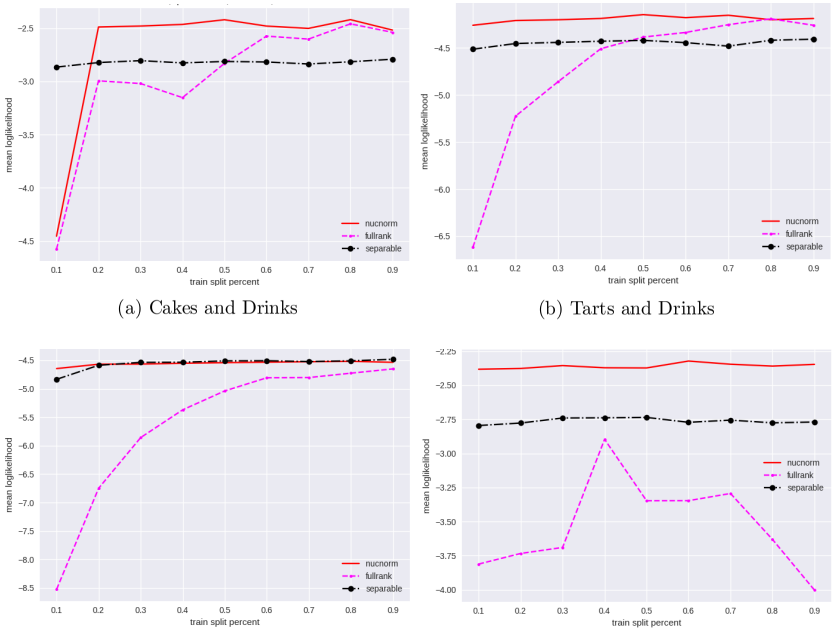
We applied our algorithm to a real world choice data set. The implementation is similar to that of higher order comparisons (see Section 4.4.1).

5.3.1 Real data: Extended Bakery

Extended Bakery data set [6] Benson et al. (2018) consists of details of 75,000 purchases at a bakery from a selection of 50 items, specifically each purchase is recorded by the set of items bought together. We use only the 13,579 purchases where a pair of items where bought. We divide the items into five categories: cakes (1-10), tarts (11-21), cookies (22-30), pastries (31-40) and drinks (41-50). We study four cases of bundled pairs, cakes and drinks, tarts and drinks, cookies and drinks, and pastries and drinks. These cases have 1503, 910, 500 and 1791 purchases in them respectively. We model the data with an MNL model parameterized by a matrix Θ^*, such that rows and columns corresponds to first and second categories respectively. For every purchase we assume that the subset of alternatives presented is the universal choice set, that is $k_1 = d_1$ and $k_2 = d_2$, so that the purchase of item j_1 from category 1 and j_1 from category 2 has a probability of $\exp(\Theta^*_{j_1,j_2}) / \sum_{j_1',j_2'=1}^{d_1,d_2} \exp(\Theta^*_{j_1',j_2'})$, where d_1, d_2 are number of items in category 1 and 2 respectively. We also fit the separable model proposed in Benson et al. (2018), which is a simpler model with $\Theta^*_{j,j_2} = a^*_{j_1} + b^*_{j_2}$, where $a \in \mathbb{R}^{d_1}, b \in \mathbb{R}^{d_2}$.

In Fig. 12 we plot the mean log-likelihood on the test data versus the fraction of the data used for our nuclear norm minimization based algorithm ('nucnorm'), un-regularized log-likelihood maximization algorithm ('fullrank'), and maximum likelihood estimator for the separable model ('separable') over 10 trials. We see that nuclear norm minimization outperforms the 'fullrank' and 'separable' algorithms. This is consistent with the marketing practice, of providing different prices for bundled combinations of products, which uses the rationale that, worth of a bundle of products might be different from the sum of the worths

6. Data set is from `https://github.com/arbenson/discrete-subset-choice/tree/master/data`.



(a) Cakes and Drinks (b) Tarts and Drinks

(c) Cookies and Drinks (d) Pastries and Drinks

Figure 12: Bakery: Mean log-likelihood on test data versus fraction of data used for training. Nuclear norm minimization improves upon the un-regularized likelihood maximization and separable model, for most of the regimes we consider.

of the individual products constituting the bundle. We also note that the un-regularized algorithm ('fullrank') has the worst performance and high variance and separable model fits the samples almost as good as the nuclear norm minimization in the case of cookies and drinks in the large training data regime.

6. Conclusion

The sample complexity of learning one of the most popular choice models known as Multi-Nomial Logit model has not been addressed in the literature. The main challenge is in the inherent low-rank structure of the parameter to be learned, which leads to a non-convex likelihood maximized problem. Thanks to recent advances in learning low-rank matrices, in particular in 1-bit matrix completion Davenport et al. (2014), matrix completion Negahban and Wainwright (2012), and restricted strong convexity Negahban et al. (2009), we have a polynomial time algorithm and the technical tools to characterize the fundamental sample complexity of learning MNL from samples. This provides a novel algorithm to learn a

low-dimensional representation of users and items from users' historical comparisons and choices. We study three types of data, pairwise comparison, higher order comparison, and choices, and take the first principle approach of identifying the fundamental limits and also developing efficient algorithms matching those fundamental trade offs. We provide a unifying framework to learn the latent preferences by solving a convex program. For each of the data types, accompanied by natural sampling scenarios, we show that our framework achieves a minimax optimal performance, and hence cannot be improved upon other than a small logarithmic factor. This opens a new door to learn representations from comparisons and choices, and we propose new research directions and challenges below. Beyond the low-rank model studied in this paper, recent advances in modeling data in a matrix form such as low algebraic dimension by Ongie et al. (2018) and non-parametric approximation by Borgs et al. (2017) can provide new research directions for modeling choice.

Efficient implementations via non-convex optimization. Nuclear norm minimization, while polynomial-time, is still slow. We want first-order methods that are efficient with provable guarantees. Two main challenges are providing a good initialization to start such non-convex approaches and analyzing gradient descent on the likelihood maximization which is non-convex.

Recent advances in non-convex optimization with rank-constraints have developed via a sequence of innovations that can be summarized as follows, in a number of example problems including matrix completion, robust PCA, matrix sensing, phase retrieval. First, a convex relaxation of nuclear norm minimization is analyzed, e.g. Candès and Recht (2009). Then, a more efficient two-step non-convex optimization approach is proposed with provable guarantees where a global initialization step is followed by a first-order method e.g. Keshavan et al. (2010a,b). Next, first-order methods starting at any initialization point is analyzed via understanding the geometry and checking the stationary points of the objective function e.g. Ge et al. (2016). This recipe, spurred by the advances in the matrix completion problem, has been repeated for several interesting problems involving low rank matrices, over the last decade and over numerous publications by collective effort of the machine learning community.

For the problem of learning MNL, we are at the first stage of this progression where we propose a convex relaxation and provide minimax optimal guarantees. We currently do not have the analysis tools to follow up in analyzing an efficient non-convex optimization problem, although writing the algorithm and implementing is straight forward, and also has been proposed in Park et al. (2015). It is a promising research direction to overcome the challenges in analyzing non-convex optimization methods for the MNL likelihood objective function.

Assumption on sampling with replacement. As mentioned earlier, we assume sampling with replacement, where we can ask a user to compare the same pair more than once, and also we can ask a user to compare two copies of the identical item. Although such sampling with replacement does not happen in practice, the number of such collisions is also very low with high probability under the proposed model. Further, such assumption is critical for getting an upper bound that is tight not only in r, d_1 and d_2, but also in k for higher order comparisons and choices. If, instead, one is interested in sampling without

replacement, then one either can resort to proving a loose bound that is weaker in its dependence in k (and follows trivially as a corollary of the proof of our results) or needs to invent new innovative concentration bounds that do not rely on the powerful symmetrization. The first option is trivial, so we do not provide such corollaries in this paper, and the second option provides an interesting but technically challenging question of resolving between sampling with replacement and sampling without replacement. This we believe is outside the scope of this paper.

Modern data analysis applications. As learning representation from ordinal data is of fundamental interest, there are numerous exciting applications that both the algorithmic framework and also the analysis techniques we develop could be naturally extended to. We present two such examples. First is a recent application of embedding objects with crowdsourced similarity measures, first proposed in Tamuz et al. (2011). Consider a crowdsourcing setting where you have d images and want to learn similarities among those images such that one can embed those images in a lower dimensional Euclidean space. One can show to a person a triplet of images (i_1, i_2, i_3) and ask whether the image in the middle is more similar to the one in the left or the right. A natural model proposed in Tamuz et al. (2011) is to assume that there exists a similarity parameter matrix $\Theta \in \mathbb{R}^{d\times d}$ such that

$$\mathbb{P}\left\{i_1 \text{ is more similar to } i_2 \text{ than } i_3 \text{ is to } i_2\right\} \;=\; \frac{e^{\Theta_{i_2,i_1}}}{e^{\Theta_{i_2,i_1}} + e^{\Theta_{i_2,i_3}}}\,.$$

A heuristic algorithm is proposed to learn a low-rank Θ without guarantees. Given the similarity of this model to MNL in (1), both our algorithm and also the analysis will go through to provide a tight characterization of the sample complexity of this problem.

The second application is in word embedding Mikolov et al. (2013b), where the goal is to find embeddings for English words in a lower dimensional Euclidean space. The most successful word embedding has been based on fitting a low-rank matrix $\Theta \in \mathbb{R}^{d\times d}$ where d is the size of the vocabulary, over an MNL-type model:

$$\mathbb{P}\{\text{word } i \text{ and word } j \text{ appear within distance ten}|\text{word } j \text{ appear in a sentence}\} \;=\; \frac{e^{\Theta_{ij}}}{\sum_{i'} e^{\Theta_{i'j}}}\,.$$

As the denominator involves summation over millions of words in the vocabulary, efficient heuristics are proposed to learn such a model from skip-grams; a skip-gram is the count matrix counting how many times words co-appear in the same sentence within a predefined distance. There are several challenges in applying our framework directly to such a setting mainly due to the size of the problem, but nevertheless our analysis can be applied directly to identify the fundamental minimax sample complexity of learning a word embedding from skip-grams.

Appendix A. Proof of the Upper Bound for Graph Sampling Theorem 1

The proof of the theorem relies on the following two lemmas. First lemma shows that the negative of the log-likelihood satisfies Restricted Strong Convexity with high probability.

Lemma 20 ***(Restricted Strong Convexity)*** *Let* $R = \max\left\{\sqrt{\frac{\sigma\log(2d)}{n}}, \frac{\sigma_{\min}(L)^{-1/2}\log(2d)}{n}\right\}$ *and the set* $\mathcal{A}(\alpha) = \left\{\Theta \in \mathbf{R}^{d_1\times d_2}, |||\Theta|||_\infty \le \alpha, |||\Theta|||_{\text{L-nuc}} \le \frac{|||\Theta L^{1/2}|||_{\text{F}}^2}{16\alpha d_1 R}\right\}$. *Then we have,*

$$\frac{1}{n}\sum_{i=1}^{n}(\langle\!\langle\Theta, X_i\rangle\!\rangle)^2 \ge \frac{1}{3d_1}|||\Theta|||_{\text{L}}^2, \quad \forall\ \Theta \in \mathcal{A}(\alpha), \tag{61}$$

with probability at least $1 - 2(2d)^{-4}$, *provided that* $n \le \log(2d)\min\{2^2(d_1\sigma_{\min}(L)^{-1})^{2/3}, 2^6 d_1^2\sigma^2\}$, .

Here the upper bound on n may not be necessary, but it is present due to a technical difficulty in using the peeling argument. The intuition behind the above lemma is that the empirical average uniformly concentrates around its expectation. Proof is in Section A.1. The next lemma says that the gradient of the log-likelihood at the actual parameter matrix, Θ^* is controllably small.

Lemma 21 ***(Bounded Gradient)*** *Let* $R = \max\left\{\sqrt{\frac{\sigma\log(2d)}{n}}, \frac{\sigma_{\min}(L)^{-1/2}\log(2d)}{n}\right\}$. *The spectral norm of gradient of the log-likelihood at the actual parameter matrix,* $\nabla\mathcal{L}(\Theta^*)$, *can be upper-bounded with high probability as follows,*

$$\mathbb{P}\left\{\left\|\nabla\mathcal{L}(\Theta^*)L^{-1/2}\right\|_2 \ge \sqrt{32}R\right\} \le \frac{1}{(d_1+d_2)^3} \tag{62}$$

Proof the above lemma is in Section A.4. Let $\Delta = \hat{\Theta} - \Theta^*$.
Case 1: $\Delta \notin \mathcal{A}(2\alpha)$ Then,

$$|||\Delta|||_{\text{L}}^2 \le 32\alpha d_1 R|||\Delta|||_{\text{L-nuc}}$$

Case 2: $\Delta \in \mathcal{A}(2\alpha)$ We first write down the second order Taylor series expansion of $\mathcal{L}(\hat{\Theta})$ at around $\Theta = \Theta^*$.

$$-\mathcal{L}(\hat{\Theta}) = -\mathcal{L}(\Theta^*) + \langle\!\langle -\nabla\mathcal{L}(\Theta^*), \Delta\rangle\!\rangle + \frac{1}{2n}\sum_{i=1}^{n}\psi\left(\langle\!\langle\Theta^*, X^{(i)}\rangle\!\rangle + s\langle\!\langle\Delta, X^{(i)}\rangle\!\rangle\right)\langle\!\langle\Delta, X^{(i)}\rangle\!\rangle^2, \tag{63}$$

where $\psi(x) = e^x/(1+e^x)^2$, $x \in [-2\alpha, 2\alpha]$ and $s \in [0,1]$. Next using Lemma 20 and the fact that $\psi(x)$ attains minimum at $x = 2\alpha$ we get,

$$-\mathcal{L}(\hat{\Theta}) + \mathcal{L}(\Theta^*) + \langle\!\langle\nabla\mathcal{L}(\Theta^*), \Delta\rangle\!\rangle \ge \frac{1}{2n}\sum_{i=1}^{n}\psi(2\alpha)\langle\!\langle\Delta, X^{(i)}\rangle\!\rangle^2 \ge \frac{\psi(2\alpha)}{6d_1}|||\Delta|||_{\text{L}}^2, \tag{64}$$

with probability at least $1 - 1/(d_1+d_2)^3$. Since $\hat{\Theta}$ is the minimizer for the objective function 9, we have,

$$-\mathcal{L}(\hat{\Theta}) + \lambda\left|||\hat{\Theta}|||_{\text{L-nuc}} \le -\mathcal{L}(\Theta^*) + \lambda|||\Theta^*|||_{\text{L-nuc}},$$

which in turn gives us,

$$\begin{aligned}\frac{\psi(2\alpha)}{6d_1}|||\Delta|||_{\text{L}}^2 &\le -\mathcal{L}(\hat{\Theta}) + \mathcal{L}(\Theta^*) + \langle\!\langle\nabla\mathcal{L}(\Theta^*), \Delta\rangle\!\rangle \qquad (65)\\ &\le \lambda\left(|||\Theta^*|||_{\text{L-nuc}} - \left|||\hat{\Theta}|||_{\text{L-nuc}}\right) + \langle\!\langle\nabla\mathcal{L}(\Theta^*), \Delta\rangle\!\rangle\\ &\le \lambda\left(|||\Delta|||_{\text{L-nuc}}\right) + \langle\!\langle\nabla\mathcal{L}(\Theta^*)L^{-1/2}, \Delta L^{1/2}\rangle\!\rangle\\ &\le \lambda\left(|||\Delta|||_{\text{L-nuc}}\right) + \left\|\nabla\mathcal{L}(\Theta^*)L^{-1/2}\right\|_2|||\Delta|||_{\text{L-nuc}}, \qquad (66)\end{aligned}$$

where last two inequalities follow from the triangle inequality for nuclear norm and generalized Hölder's inequality. Now we put $\lambda = 2\sqrt{32}R$ and use Lemma 21 to get,

$$|||\Delta|||_{\text{L}}^2 \le \frac{6d_1}{\psi(2\alpha)}\left(\lambda + \frac{\lambda}{2}\right)|||\Delta|||_{\text{L-nuc}} \le \frac{9d_1\lambda}{\psi(2\alpha)}|||\Delta|||_{\text{L-nuc}}, \tag{67}$$

with probability at least $1 - 1/(d_1+d_2)^3$. Combining Case 1 and 2 we get,

$$|||\Delta|||_{\text{L}}^2 \le 9\left(\alpha + \frac{1}{\psi(2\alpha)}\right)d_1\lambda|||\Delta|||_{\text{L-nuc}}$$

Lemma 22 *If* $\lambda \ge 2|||\nabla\mathcal{L}(\Theta^*)|||_2$, *then we have*

$$|||\Delta|||_{\text{L-nuc}} \le 4\sqrt{2r}|||\Delta|||_{\text{L}} + 4\sum_{j=r+1}^{\min\{d_1, d_2-G\}}\sigma_j(\Theta^* L^{1/2}), \tag{68}$$

for all $r \in [\min\{d_1, d_2 - G\}]$. *(Proof in Section A.5)*

Finally, utilizing the above lemma, we get,

$$\frac{1}{d_1}|||\Delta|||_{\text{L}}^2 \le 36\lambda\left(\alpha + \frac{1}{\psi(2\alpha)}\right)\left(\sqrt{2r}|||\Delta|||_{\text{L}} + \sum_{j=r+1}^{\min\{d_1, d_2-G\}}\sigma_j(\Theta^* L^{1/2})\right)$$

A.1 Proof of Lemma 20

$$\begin{aligned}&\mathbb{P}\left\{\frac{1}{n}\sum_{i=1}^{n}\left(\langle\!\langle\Theta, X^{(i)}\rangle\!\rangle\right)^2 \ge \frac{1}{3d_1}|||\Theta|||_{\text{L}}^2,\ \forall\ \Theta \in \mathcal{A}\right\}\\ &= 1 - \mathbb{P}\left\{\exists\ \Theta \in \mathcal{A}, \text{ such that } \frac{1}{n}\sum_{i=1}^{n}\left(\langle\!\langle\Theta, X^{(i)}\rangle\!\rangle\right)^2 < \frac{1}{3d_1}|||\Theta|||_{\text{L}}^2\right\} \qquad (69)\end{aligned}$$

When $\Theta \in \mathcal{A}$,

$$\|\|\Theta\|\|_{\mathrm{L}}^2 \geq 16\alpha d_1 R \|\|\Theta\|\|_{\text{L-nuc}} \geq 16\alpha d_1 R \|\|\Theta\|\|_{\mathrm{L}} \implies \|\|\Theta\|\|_{\mathrm{L}} \geq 16\alpha d_1 R := \mu\,, \tag{70}$$

where the second inequality follows from $\|\|\Theta\|\|_{\text{L-nuc}} = \left\|\left|\Theta\, L^{1/2}\right|\right\|_{\text{nuc}} \geq \left\|\left|\Theta\, L^{1/2}\right|\right\|_{\mathrm{F}} = \|\|\Theta\|\|_{\mathrm{L}}$.

Lemma 23 *Let* $\mathcal{B}(D) := \left\{\Theta \in \mathbb{R}^{d_1 \times d_2} | \|\|\Theta\|\|_{\infty} \leq \alpha,\ \|\|\Theta\|\|_{\mathrm{L}} \leq D,\ \|\|\Theta\|\|_{\text{L-nuc}} \leq \frac{D^2}{16\alpha d_1 R}\right\}$, *and,* $Z_D := \sup_{\Theta \in \mathcal{B}(D)} \left(-\frac{1}{n}\sum_{i=1}^n \left(\langle\!\langle \Theta, X^{(i)} \rangle\!\rangle\right)^2 + \frac{2}{d_1}\|\|\Theta\|\|_{\mathrm{L}}^2\right)$, *then,*

$$\mathbb{P}\left\{Z_D \geq \frac{3}{2d_1}D^2\right\} \leq \exp\left(-\frac{nD^4}{32\alpha^4 d_1^2}\right). \tag{71}$$

Above lemma is proved in Section A.2. Let $\beta = \sqrt{\frac{10}{9}}$, then the sets,

$$\mathcal{S}_\ell = \left\{\Theta \in \mathbb{R}^{d_1 \times d_2} | \|\|\Theta\|\|_{\infty} \leq \alpha, \beta^{\ell-1}\mu \leq \|\|\Theta\|\|_{\mathrm{L}} \leq \beta^\ell \mu,\ \|\|\Theta\|\|_{\text{L-nuc}} \leq \frac{(\beta^\ell \mu)^2}{16\alpha d_1 R}\right\},\ \ell = 1, 2, 3, \ldots, \tag{72}$$

cover the set $\mathcal{A}$, that is $\mathcal{A} \subset \cup_{\ell=1}^{\infty} \mathcal{S}_\ell$ and $\mathcal{S}_\ell \subseteq \mathcal{B}(\beta^\ell \mu)$. This gives us,

$$\begin{aligned}
&\mathbb{P}\left\{\exists\, \Theta \in \mathcal{A} \text{ s.t.} \frac{1}{n}\sum_{i=1}^n \left(\langle\!\langle \Theta, X^{(i)} \rangle\!\rangle\right)^2 < \frac{1}{3d_1}\|\|\Theta\|\|_{\mathrm{L}}^2\right\} \\
&\leq \sum_{\ell=1}^{\infty} \mathbb{P}\left\{\exists\, \Theta \in \mathcal{S}_\ell \text{ s.t. } \frac{1}{n}\sum_{i=1}^n \left(\langle\!\langle \Theta, X^{(i)} \rangle\!\rangle\right)^2 < \frac{1}{3d_1}\|\|\Theta\|\|_{\mathrm{L}}^2\right\} \\
&\leq \sum_{\ell=1}^{\infty} \mathbb{P}\left\{\exists\, \Theta \in \mathcal{B}(\beta^\ell \mu) \text{ s.t. } \frac{1}{n}\sum_{i=1}^n \left(\langle\!\langle \Theta, X^{(i)} \rangle\!\rangle\right)^2 < \frac{1}{3d_1}\|\|\Theta\|\|_{\mathrm{L}}^2\right\}
\end{aligned} \tag{73}$$

If there exists a $\Theta \in \mathcal{B}(\beta^\ell \mu)$ such that $\frac{1}{n}\sum_{i=1}^n \left(\langle\!\langle \Theta, X^{(i)} \rangle\!\rangle\right)^2 < \frac{1}{3d_1}\|\|\Theta\|\|_{\mathrm{L}}^2$ then,

$$Z_{\beta^\ell \mu} \geq -\frac{1}{n}\sum_{i=1}^n \left(\langle\!\langle \Theta, X^{(i)} \rangle\!\rangle\right)^2 + \frac{2}{d_1}\|\|\Theta\|\|_{\mathrm{L}}^2 > \frac{5}{3d_1}\|\|\Theta\|\|_{\mathrm{L}}^2 \geq \frac{5}{3d_1}\beta^{2\ell-2}\mu^2 = \frac{3}{2d_1}(\beta^\ell \mu)^2,$$

which gives us,

$$\begin{aligned}
\mathbb{P}\left\{\exists\, \Theta \in \mathcal{A} \ni \frac{1}{n}\sum_{i=1}^n \left(\langle\!\langle \Theta, X^{(i)} \rangle\!\rangle\right)^2 < \frac{1}{3d_1}\|\|\Theta\|\|_{\mathrm{L}}^2\right\} &\leq \sum_{\ell=1}^{\infty} \mathbb{P}\left\{Z_{\beta^\ell \mu} > \frac{3}{2d_1}(\beta^\ell \mu)^2\right\} \\
&\overset{(a)}{\leq} \sum_{\ell=1}^{\infty} \exp\left(-\frac{n(\beta^\ell \mu)^4}{32\alpha^4 d_1^2}\right) \\
&\overset{(b)}{\leq} \sum_{\ell=1}^{\infty} \exp\left(-\frac{4\ell(\beta-1)n\mu^4}{32\alpha^4 d_1^2}\right) \\
&\overset{(c)}{\leq} 2\exp\left(-\frac{4(\beta-1)n\mu^4}{32\alpha^4 d_1^2}\right)
\end{aligned} \tag{74}$$

where (a) is from Lemma 23, (b) is true since $\beta^{4\ell} \geq 4\ell(\beta-1)$ when $\beta \geq 1$ and (c) is obtained by summing the geometric series, with common ratio less than $1/2$, in previous inequality. Finally if we assume that $n \leq 2^6 d_1^2 \sigma^2 \log(2d)$ and $n \leq 2^2 (d_1 \sigma_{\min}(L)^{-1})^{2/3} \log(2d)$, then we have $2^2 \log(2d) \leq 4(\beta-1)n\mu^4/32\alpha^4 d_1^2$ as follows

$$\begin{aligned}
\frac{4(\beta-1)n\mu^4}{32\alpha^4 d_1^2} = \frac{4(\beta-1)n(16\alpha d_1 R)^4}{32\alpha^4 d_1^2} &= 2^{13}(\beta-1)d_1^2 \max\left\{\frac{\sigma^2 \log^2(2d)}{n}, \frac{\sigma_{\min}(L)^{-2}\log^4(2d)}{n^3}\right\} \\
&\geq 2^2 \log(2d)
\end{aligned} \tag{75}$$

A.2 Proof of Lemma 23

Notice that the $\frac{2}{d_1}\|\|\Theta\|\|_{\mathrm{L}}^2$ is the mean of $\frac{1}{n}\sum_{i=1}^n \langle\!\langle \Theta, X^{(i)} \rangle\!\rangle^2$,

$$\begin{aligned}
\mathbb{E}\left[\frac{1}{n}\sum_{i=1}^n \langle\!\langle \Theta, X^{(i)} \rangle\!\rangle^2\right] &= \frac{1}{d_1}\sum_{j \in [d1]}\sum_{k,l \in [d2]} (\Theta_{j,k} - \Theta_{j,l})^2 P_{k,l} \\
&= \frac{2}{d_1}\sum_j \sum_k \Theta_{j,k}^2 \sum_l P_{k,l} - 2\sum_{k,l} \Theta_{j,k}\Theta_{j,l} P_{k,l} \\
&\overset{(a)}{=} \frac{2}{d_1}\sum_j \langle\!\langle \Theta_j \Theta_j^T, \mathrm{diag}(P_k) \rangle\!\rangle - 2\langle\!\langle \Theta_j \Theta_j^T, P \rangle\!\rangle \\
&= \frac{2}{d_1}\sum_j \langle\!\langle \Theta_j \Theta_j^T, L \rangle\!\rangle = \frac{2}{d_1}\left\|\left|\Theta L^{1/2}\right|\right\|_{\mathrm{F}}^2
\end{aligned}$$

where, in (a) $P_k = \sum_{l \in [d2]} P_{k,l}$ and Θ_j is the j-th row of Θ. Therefore we use the following standard technique to get a handle on supremum of deviation from mean.

First, we use bounded differences property to prove that Z_D concentrates around its mean. We write $Z_D(X^{(1)}, \ldots, X^{(n)})$ to represent Z_D as a function of n independent random variables. Now, let $X^{(i)}$ and $\tilde{X}^{(i)}$ be two realization of the i-th ($1 \leq i \leq n$) random parameter of Z_D, then,

$$\begin{aligned}
&\left|Z_D(X^{(1)}, \ldots, X^{(i)}, \ldots, X^{(n)}) - Z_D(X^{(1)}, \ldots, \tilde{X}^{(i)}, \ldots, X^{(n)})\right| \\
&= \left|\sup_{\Theta \in \mathcal{B}(D)} \left(-\frac{1}{n}\sum_{i=1}^n \langle\!\langle \Theta, X^{(i)} \rangle\!\rangle^2 + \frac{2}{d_1}\|\|\Theta\|\|_{\mathrm{L}}^2\right) - \right. \\
&\quad \left. \sup_{\Theta' \in \mathcal{B}(D)} \left(-\frac{1}{n}\left(\sum_{i=1, i \neq i'}^n \langle\!\langle \Theta', X^{(i)} \rangle\!\rangle^2 + \langle\!\langle \Theta', \tilde{X}^{(i')} \rangle\!\rangle^2\right) + \frac{2}{d_1}\|\|\Theta'\|\|_{\mathrm{L}}^2\right)\right|
\end{aligned} \tag{76}$$

Now WLOG assume that $Z_D(X^{(1)},\dots,X^{(i)},\dots,X^{(n)}) \geq Z_D(X^{(1)},\dots,\tilde{X}^{(i)},\dots,X^{(n)})$ and the first supremum is achieved at $\tilde{\Theta}$, which gives us.

$$
\begin{aligned}
&= \sup_{\Theta\in\mathcal{B}(D)} \left(-\frac{1}{n}\sum_{i=1}^{n}\langle\!\langle \Theta, X^{(i)}\rangle\!\rangle^2 + \frac{2}{d_1}|||\Theta|||_{\mathrm{L}}^2\right) - \\
&\sup_{\Theta'\in\mathcal{B}(D)} \left(-\frac{1}{n}\left(\sum_{\substack{i=1\\ i\neq i'}}^{n}\langle\!\langle \Theta', X^{(i)}\rangle\!\rangle^2 + \langle\!\langle \Theta', \tilde{X}^{(i')}\rangle\!\rangle^2\right) + \frac{2}{d_1}|||\Theta'|||_{\mathrm{L}}^2\right) \\
&\leq \left(-\frac{1}{n}\sum_{i=1}^{n}\langle\!\langle \bar{\Theta}, X^{(i)}\rangle\!\rangle^2 + \frac{2}{d_1}|||\bar{\Theta}|||_{\mathrm{L}}^2\right) - \left(-\frac{1}{n}\left(\sum_{\substack{i=1\\ i\neq i'}}^{n}\langle\!\langle \bar{\Theta}, X^{(i)}\rangle\!\rangle^2 + \langle\!\langle \bar{\Theta}, \tilde{X}^{(i')}\rangle\!\rangle^2\right) + \frac{2}{d_1}|||\bar{\Theta}|||_{\mathrm{L}}^2\right) \\
&\leq \sup_{\Theta\in\mathcal{B}(D)} \frac{1}{n}\left|\langle\!\langle \Theta, X^{(i)}\rangle\!\rangle^2 - \langle\!\langle \Theta, \tilde{X}^{(i)}\rangle\!\rangle^2\right| \\
&\leq \frac{4\alpha^2}{n}, \qquad (77)
\end{aligned}
$$

where the last inequality is true since, $|||\Theta|||_\infty \leq \alpha$ for any $\Theta \in \mathcal{B}(D) \subseteq \Omega_\alpha$. Now we upper bound $\mathbb{E}[Z_D]$ as follows,

$$
\begin{aligned}
\mathbb{E}[Z_D] &\overset{(a)}{\leq} 2\mathbb{E}\left[\sup_{\Theta\in\mathcal{B}(D)} \frac{1}{n}\sum_{i=1}^{n}\varepsilon_i\langle\!\langle \Theta, X^{(i)}\rangle\!\rangle^2\right] \\
&\overset{(b)}{\leq} 4\alpha\mathbb{E}\left[\sup_{\Theta\in\mathcal{B}(D)} \frac{1}{n}\sum_{i=1}^{n}\varepsilon_i\langle\!\langle \Theta L^{1/2}, X^{(i)}L^{-1/2}\rangle\!\rangle\right] \\
&\leq 4\alpha\mathbb{E}\left[\sup_{\Theta\in\mathcal{B}(D)} |||\Theta|||_{\text{L-nuc}}\left\|\frac{1}{n}\sum_{i=1}^{n}\varepsilon_i X^{(i)}L^{-1/2}\right\|_2\right] \\
&\leq 4\alpha \sup_{\Theta\in\mathcal{B}(D)} |||\Theta|||_{\text{L-nuc}}\mathbb{E}\left[\left\|\frac{1}{n}\sum_{i=1}^{n}\varepsilon_i X^{(i)}L^{-\text{`}1/2}\right\|_2\right],
\end{aligned}
$$

where (a) is standard symmetrization argument using i.i.d. Rademacher variables $\{\varepsilon_i\}_{i=1}^n$ and since $|\langle\!\langle \Theta, X^{(i)}\rangle\!\rangle| \leq 2\alpha$ we use Ledoux-Talagrand contraction inequality Ledoux and Talagrand (2013) to obtain (b).

Lemma 24 *Let* $R = \max\left\{\sqrt{\frac{\sigma\log(2d)}{n}}, \frac{\sigma_{\min}(L)^{-1/2}\log(2d)}{n}\right\}$. *For* $\{X^{(i)}\}_{i=1}^n$ *as defined in the graph sampling and for a binary random variable* ε_i *such that* $\mathbb{E}\left[\varepsilon_i|X^{(i)}\right] = 0$ *and* $|\varepsilon_i| \leq 1$, *we have,*

$$
\mathbb{P}\left\{\left\|\frac{1}{n}\sum_{i=1}^{n}\varepsilon_i X^{(i)}L^{-1/2}\right\|_2 \geq \sqrt{32}R\right\} \leq \frac{1}{(d_1+d_2)^3}, \quad \textit{and,} \quad \mathbb{E}\left[\left\|\frac{1}{n}\sum_{i=1}^{n}\varepsilon_i X^{(i)}L^{-1/2}\right\|_2\right] \leq 4R. \qquad (78)
$$

Proof of the lemma is in Section A.3. Now using Lemma 24 we have $\mathbb{E}[Z_D]$ $\leq 16R\alpha\sup_{\Theta\in\mathcal{B}(D)}|||\Theta|||_{\text{L-nuc}} \leq \frac{D^2}{d_1}$. Then using the bounded differences property and the upper bound on the mean, we get the McDiarmid's concentration,

$$
\begin{aligned}
\mathbb{P}\left\{Z_D - D^2/d_1 \geq t\right\} &\leq \mathbb{P}\left\{Z_D - \mathbb{E}[Z_D] \geq t\right\} \\
&\leq \exp\left(-\frac{nt^2}{8\alpha^4}\right) \qquad (79)
\end{aligned}
$$

and putting $t = D^2/2d_1$ gives us the theorem.

A.3 Proof of Lemma 24

Let $W_i := \frac{1}{n}\varepsilon_i X^{(i)}L^{-1/2} = \frac{1}{n}\varepsilon_i e_{j(i)}\left(e_{k(i)} - e_{l(i)}\right)^T L^{-1/2}$ and pseudo-inverse of L be $L^\dagger$, then, $\|W_i\|_2 \leq \sigma_{\min}(L)^{-1/2}\sqrt{2}/n$,

$$
\begin{aligned}
\mathbb{E}\left[W_i W_i^T\right] &= \mathbb{E}\left[\frac{1}{n^2}e_{j(i)}\left(e_{k(i)} - e_{l(i)}\right)^T L^{-1/2}L^{-1/2}\left(e_{k(i)} - e_{l(i)}\right)e_{j(i)}^T\right] \\
&= \mathbb{E}\left[\frac{1}{n^2}e_{j(i)}e_{j(i)}^T\right]\mathbb{E}\left[\left(e_{k(i)} - e_{l(i)}\right)^T L^\dagger\left(e_{k(i)} - e_{l(i)}\right)\right] \\
&= \frac{1}{n^2 d_1}\mathbf{I}_{d_1\times d_1} \times 2\left(\mathbb{E}\left[e_{k(i)}^T L^\dagger e_{k(i)}\right] - \mathbb{E}\left[e_{k(i)}^T L^\dagger e_{l(i)}\right]\right) \\
&= \frac{2}{n^2 d_1}\left(\sum_{u\in[d_1]} P_u L^\dagger_{u,u} - \sum_{u,v\in[d_1]} P_{u,v}L^\dagger_{u,v}\right)\mathbf{I}_{d_1\times d_1} \\
&= \frac{2}{n^2 d_1}\langle\!\langle L, L^\dagger\rangle\!\rangle\mathbf{I}_{d_1\times d_1} \\
&= \frac{2(d_2 - G)}{n^2 d_1}\mathbf{I}_{d_1\times d_1}, \qquad (80)
\end{aligned}
$$

$$
\begin{aligned}
\mathbb{E}\left[W_i^T W_i\right] &= L^{-1/2}\mathbb{E}\left[\frac{1}{n^2}\left(e_{k(i)} - e_{l(i)}\right)\left(e_{k(i)} - e_{l(i)}\right)^T\right]L^{-1/2} \\
&= \frac{1}{n^2}L^{-1/2}\left(\sum_{u,v=1}^{d_2}\left(e_u - e_v\right)\left(e_u - e_v\right)^T P_{u,v}\right)L^{-1/2} \\
&= \frac{1}{n^2}L^{-1/2}\left(2L\right)L^{-1/2} \\
&= \frac{2}{n^2}(\mathbf{I}_{d_2\times d_2} - \sum_{k\in[G]} g_k g_k^T/\|g_k\|_2^2), \text{ and,} \qquad (81)
\end{aligned}
$$

$$
\max\left\{\left\|\mathbb{E}\left[\sum_{i=1}^{n}W_i W_i^T\right]\right\|_2, \left\|\mathbb{E}\left[\sum_{i=1}^{n}W_i^T W_i\right]\right\|_2\right\} \leq \sum_{i=1}^{n}\max\left\{\left\|\mathbb{E}\left[W_i W_i^T\right]\right\|_2, \left\|\mathbb{E}\left[W_i^T W_i\right]\right\|_2\right\} \qquad (82)
$$

$$
\leq \frac{2}{n}\sigma\,. \qquad (83)
$$

where $\sigma = \max\left\{\frac{d_2-G}{d_1}, 1\right\}$. Now by Matrix Bernstein concentration theorem Tropp (2015) we have,

$$\mathbb{P}\left\{\left\|\frac{1}{n}\sum_{i=1}^{n}\varepsilon_i X^{(i)}L^{-1/2}\right\|_2 \geq t\right\} \leq \exp\left(\frac{-nt^2/2}{2\sigma + \sqrt{2}\sigma_{\min}(L)^{-1/2}t/3}\right), \text{ and,} \tag{84}$$

$$`\mathbb{E}\left[\left\|\frac{1}{n}\sum_{i=1}^{n}\varepsilon_i X^{(i)}L^{-1/2}\right\|_2\right] \leq \sqrt{\frac{4\sigma\log(d_1+d_2)}{n}} + \frac{\sqrt{2\sigma_{\min}(L)^{-1}}}{3n}\log(d_1+d_2)\,. \tag{85}$$

Choosing $t = \max\left\{\sqrt{\frac{24\sigma\log(d_1+d_2)}{n}}, \frac{16\sqrt{2\sigma_{\min}(L)^{-1}}\log(d_1+d_2)}{n}\right\}$ produces the desired result.

A.4 Proof of Lemma 21

The gradient can be written down as,

$$\nabla\mathcal{L}(\Theta^*) = \frac{1}{n}\sum_{i=1}^{n}\left(y_i - \frac{\exp(\langle\!\langle\Theta^*, X^{(i)}\rangle\!\rangle)}{1+\exp(\langle\!\langle\Theta^*, X^{(i)}\rangle\!\rangle)}\right)X^{(i)}. \tag{86}$$

Then Lemma 24 directly gives the result because,

$$\mathbb{E}\left[y_i - \frac{\exp(\langle\!\langle\Theta^*, X^{(i)}\rangle\!\rangle)}{1+\exp(\langle\!\langle\Theta^*, X^{(i)}\rangle\!\rangle)}\middle| X^{(i)}\right] = 0 \quad \text{and} \quad \left|y_i - \frac{\exp(\langle\!\langle\Theta^*, X^{(i)}\rangle\!\rangle)}{1+\exp(\langle\!\langle\Theta^*, X^{(i)}\rangle\!\rangle)}\right| \leq 1.$$

A.5 Proof of Lemma 22

Denote the singular value decomposition of $\Theta^*L^{1/2}$ by $\Theta^*L^{1/2} = U\Sigma V^T$, where $U \in \mathbb{R}^{d_1\times d_1}$ and $V \in \mathbb{R}^{d_2\times d_2}$ are orthogonal matrices. For a given $r \in [\min\{d_1, d_2 - G\}]$, let $U_r = [u_1, \ldots, u_r]$ and $V_r = [v_1, \ldots, v_r]$, where $u_i \in \mathbb{R}^{d_1\times 1}$ and $v_i \in \mathbb{R}^{d_2\times 1}$ are the left and right singular vectors corresponding to the i-th largest singular value, respectively. Define T to be the subspace spanned by all matrices in $\mathbb{R}^{d_1\times d_2}$ of the form U_rA^T or BV_r^T for any $A \in \mathbb{R}^{d_2\times r}$ or $B \in \mathbb{R}^{d_1\times r}$, respectively. The orthogonal projection of any matrix $M \in \mathbb{R}^{d_1\times d_2}$ onto the space T is given by $\mathcal{P}_T(M) = U_rU_r^TM + MV_rV_r^T - U_rU_r^TMV_rV_r^T$. The projection of M onto the complement space $T^\perp$ is $\mathcal{P}_{T^\perp}(M) = (I - U_rU_r^T)M(I - V_rV_r^T)$. The subspace T and the respective projections onto T and $T^\perp$ play crucial a role in the analysis of nuclear norm minimization, since they define the sub-gradient of the nuclear norm at Θ^*. We refer to Candès and Recht (2009) for more detailed treatment of this topic.

Let $\Delta' = \mathcal{P}_T(\Delta L^{1/2})$ and $\Delta'' = \mathcal{P}_{T^\perp}(\Delta L^{1/2})$. Notice that $\mathcal{P}_T(\Theta^*L^{1/2}) = U_r\Sigma_rV_r^T$, where $\Sigma_r \in \mathbb{R}^{r\times r}$ is the diagonal matrix formed by the top r singular values. Since $\mathcal{P}_T(\Theta^*L^{1/2})$ and Δ'' have row and column spaces that are orthogonal, it follows from Lemma 2.3 in Recht et al. (2010) that

$$\left|\left|\left|\mathcal{P}_T(\Theta^*L^{1/2}) - \Delta''\right|\right|\right|_{\text{nuc}} = \left|\left|\left|\mathcal{P}_T(\Theta^*L^{1/2})\right|\right|\right|_{\text{nuc}} + \left|\left|\left|\Delta''\right|\right|\right|_{\text{nuc}}.$$

Hence, in view of the triangle inequality,

$$\begin{aligned}
\left|\left|\left|\widehat{\Theta}L^{1/2}\right|\right|\right|_{\text{nuc}} &= \left|\left|\left|\mathcal{P}_T(\Theta^*L^{1/2}) + \mathcal{P}_{T^\perp}(\Theta^*L^{1/2}) - \Delta' - \Delta''\right|\right|\right|_{\text{nuc}} \\
&\geq \left|\left|\left|\mathcal{P}_T(\Theta^*L^{1/2}) - \Delta''\right|\right|\right|_{\text{nuc}} - \left|\left|\left|\mathcal{P}_{T^\perp}(\Theta^*L^{1/2}) - \Delta'\right|\right|\right|_{\text{nuc}} \\
&= \left|\left|\left|\mathcal{P}_T(\Theta^*L^{1/2})\right|\right|\right|_{\text{nuc}} + \left|\left|\left|\Delta''\right|\right|\right|_{\text{nuc}} - \left|\left|\left|\mathcal{P}_{T^\perp}(\Theta^*L^{1/2}) - \Delta'\right|\right|\right|_{\text{nuc}} \\
&\geq \left|\left|\left|\mathcal{P}_T(\Theta^*L^{1/2})\right|\right|\right|_{\text{nuc}} + \left|\left|\left|\Delta''\right|\right|\right|_{\text{nuc}} - \left|\left|\left|\mathcal{P}_{T^\perp}(\Theta^*L^{1/2})\right|\right|\right|_{\text{nuc}} - \left|\left|\left|\Delta'\right|\right|\right|_{\text{nuc}} \\
&= \left|\left|\left|\Theta^*L^{1/2}\right|\right|\right|_{\text{nuc}} + \left|\left|\left|\Delta''\right|\right|\right|_{\text{nuc}} - 2\left|\left|\left|\mathcal{P}_{T^\perp}(\Theta^*L^{1/2})\right|\right|\right|_{\text{nuc}} - \left|\left|\left|\Delta'\right|\right|\right|_{\text{nuc}}.
\end{aligned} \tag{87}$$

Because $\widehat{\Theta}$ is an optimal solution, we have

$$\begin{aligned}
\lambda\left(\left|\left|\left|\widehat{\Theta}L^{1/2}\right|\right|\right|_{\text{nuc}} - \left|\left|\left|\Theta^*L^{1/2}\right|\right|\right|_{\text{nuc}}\right) &\leq -\mathcal{L}(\Theta^*) + \mathcal{L}(\widehat{\Theta}) \\
&\overset{(a)}{\leq} \langle\!\langle\Delta L^{1/2}, \nabla\mathcal{L}(\Theta^*)L^{-1/2}\rangle\!\rangle \\
&\overset{(b)}{\leq} \left|\left|\left|\Delta\right|\right|\right|_{\text{L-nuc}}\left\|\nabla\mathcal{L}(\Theta^*)L^{-1/2}\right\|_2 \leq \frac{\lambda}{2}\left|\left|\left|\Delta\right|\right|\right|_{\text{L-nuc}},
\end{aligned} \tag{88}$$

where (a) holds due to the convexity of $-\mathcal{L}$; (b) follows from the Cauchy-Schwarz inequality; the last inequality holds due to the assumption that $\lambda \geq 2\|\nabla\mathcal{L}(\Theta^*)\|_2$. Combining (87) and (88) yields

$$2\left(\left|\left|\left|\Delta''\right|\right|\right|_{\text{nuc}} - 2\left|\left|\left|\mathcal{P}_{T^\perp}(\Theta^*L^{1/2})\right|\right|\right|_{\text{nuc}} - \left|\left|\left|\Delta'\right|\right|\right|_{\text{nuc}}\right) \leq \left|\left|\left|\Delta\right|\right|\right|_{\text{L-nuc}} \leq \left|\left|\left|\Delta'\right|\right|\right|_{\text{nuc}} + \left|\left|\left|\Delta''\right|\right|\right|_{\text{nuc}}.$$

Thus $\left|\left|\left|\Delta''\right|\right|\right|_{\text{nuc}} \leq 3\left|\left|\left|\Delta'\right|\right|\right|_{\text{L-nuc}} + 4\left|\left|\left|\mathcal{P}_{T^\perp}(\Theta^*L^{1/2})\right|\right|\right|_{\text{nuc}}$. By triangle inequality,

$$\left|\left|\left|\Delta\right|\right|\right|_{\text{L-nuc}} \leq 4\left|\left|\left|\Delta'\right|\right|\right|_{\text{nuc}} + 4\left|\left|\left|\mathcal{P}_{T^\perp}(\Theta^*L^{1/2})\right|\right|\right|_{\text{nuc}}.$$

Notice that $\Delta' = U_rU_r^T\Delta L^{1/2} + (I - U_rU_r^T)\Delta L^{1/2}V_rV_r^T$. Both $U_rU_r^T\Delta L^{1/2}$ and $(I - U_rU_r^T)\Delta L^{1/2}V_rV_r^T$ have rank at most r. Thus Δ' has rank at most $2r$. Hence, $\left|\left|\left|\Delta'\right|\right|\right|_{\text{nuc}} \leq \sqrt{2r}\left|\left|\left|\Delta'\right|\right|\right|_{\text{F}} \leq \sqrt{2r}\left|\left|\left|\Delta L^{1/2}\right|\right|\right|_{\text{F}} \leq \sqrt{2r}\left|\left|\left|\Delta\right|\right|\right|_{\text{L}}$. Then the theorem follows because $\left|\left|\left|\mathcal{P}_{T^\perp}(\Theta^*L^{1/2})\right|\right|\right|_{\text{nuc}} = \sum_{j=r+1}^{\min\{d_1,d_2\}}\sigma_j(\Theta^*L^{1/2})$.

Appendix B. Proof of the Information-theoretic Graph Sampling Lower Bound, Theorem 4

The proof uses Fano Inequality based packing set argument to get an lower bound on the error of any (measurable) estimator. We will construct a packing set in Ω_α with a minimum distance of δ between any pair of elements in the packing.

Let $\{\Theta^{(1)}, \Theta^{(2)}, \ldots, \Theta^{(M)}\}$ be a set of M matrices within the set Ω_α, satisfying $\left|\left|\left|\Theta^{(\ell_1)} - \Theta^{(\ell_1)}\right|\right|\right|_{\text{L}} \geq \delta$ for all $\ell_1, \ell_2 \in [M]$. Now, $\Theta^{(N)}$ is uniformly drawn from this set and then the comparison results (according to MNL model) of n randomly chosen pairs of items,

each drawn according to the probability matrix P and each compared by uniformly chosen user. Let $\widehat{N}$ be the best estimator of N from the observations. Then we can show that,

$$\sup_{\Theta^* \in \Omega_\alpha} \mathbb{P}\left\{ \left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\mathrm{L}}^2 \geq \frac{\delta^2}{2} \right\} \quad \geq \quad \mathbb{P}\left\{ \widehat{N} \neq N \right\}, \tag{89}$$

Now we have converted the problem of finding the minimum estimation error, into finding the minimum probability error of a M-ary hypothesis testing problem. If we can prove that the above RHS is lower bounded by $1/2$, we are done.

The generalized Fanos inequality along with data processing inequality gives us,

$$\begin{aligned} \mathbb{P}\left\{ \widehat{N} \neq N \right\} &\geq 1 - \frac{\mathbb{E}[\, I(\widehat{N}; N)\,] + \log 2}{\log M} && (90) \\ &\geq 1 - \frac{\binom{M}{2}^{-1} \sum_{\ell_1, \ell_2 \in [M]} D_{\mathrm{KL}}(\Theta^{(\ell_1)} \| \Theta^{(\ell_2)}) + \log 2}{\log M}, && (91) \end{aligned}$$

where $D_{\mathrm{KL}}(\Theta^{(\ell_1)} \| \Theta^{(\ell_2)})$ denotes the *expected* Kullback-Leibler divergence between the probability distributions of the comparison results of the observed nd_1 pairs, for $N = \ell_1$ and $N = \ell_2$. The expectation is taken over different choices for the selected pairs for comparison.

$$\begin{aligned} D_{\mathrm{KL}}(\Theta^{(\ell_1)} \| \Theta^{(\ell_2)}) = \frac{n}{d_1} \sum_{\substack{i \in [d_1] \\ \{j,j'\} \subset [d_2]}} 2P_{j,j'} \Bigg[& \frac{e^{\Theta_{ij}^{(\ell_1)}}}{e^{\Theta_{ij}^{(\ell_1)}} + e^{\Theta_{ij'}^{(\ell_1)}}} \log \left(\frac{e^{\Theta_{ij}^{(\ell_1)}} \Big/ \left(e^{\Theta_{ij}^{(\ell_1)}} + e^{\Theta_{ij'}^{(\ell_1)}} \right)}{e^{\Theta_{ij}^{(\ell_2)}} \Big/ \left(e^{\Theta_{ij}^{(\ell_2)}} + e^{\Theta_{ij'}^{(\ell_2)}} \right)} \right) && (92) \\ & + \frac{e^{\Theta_{ij'}^{(\ell_1)}}}{e^{\Theta_{ij}^{(\ell_1)}} + e^{\Theta_{ij'}^{(\ell_1)}}} \log \left(\frac{e^{\Theta_{ij'}^{(\ell_1)}} \Big/ \left(e^{\Theta_{ij}^{(\ell_1)}} + e^{\Theta_{ij'}^{(\ell_1)}} \right)}{e^{\Theta_{ij'}^{(\ell_2)}} \Big/ \left(e^{\Theta_{ij}^{(\ell_2)}} + e^{\Theta_{ij'}^{(\ell_2)}} \right)} \right) \Bigg] && (93) \end{aligned}$$

where n is the number of pairs of items selected and compared by one random user each, $P_{j,j'}$ is half the probability with which item pair $\{j, j'\}$ is selected and the observation probabilities come from the standard MNL model. Let $x_{ijj'} \equiv e^{\Theta_{ij'}^{(\ell_1)}} / (e^{\Theta_{ij}^{(\ell_1)}} + e^{\Theta_{ij'}^{(\ell_1)}})$ and $y_{ijj'} \equiv e^{\Theta_{ij'}^{(\ell_2)}} / (e^{\Theta_{ij}^{(\ell_2)}} + e^{\Theta_{ij'}^{(\ell_2)}})$.

$$\begin{aligned} D_{\mathrm{KL}}(\Theta^{(\ell_1)} \| \Theta^{(\ell_2)}) &\overset{(a)}{=} n \sum_{i \in [d_1]} \frac{1}{d_1} \sum_{\{j,j'\} \subset [d_2]} 2P_{j,j'} \left[x_{ijj'} \log \frac{x_{ijj'}}{y_{ijj'}} + (1 - x_{ijj'}) \log \frac{1 - x_{ijj'}}{1 - y_{ijj'}} \right] && (94) \\ &\overset{(a)}{\leq} n \sum_{i \in [d_1]} \frac{1}{d_1} \sum_{\{j,j'\} \subset [d_2]} 2P_{j,j'} \left[x_{ijj'} \frac{x_{ijj'} - y_{ijj'}}{y_{ijj'}} + (1 - x_{ijj'}) \frac{y_{ijj'} - x_{ijj'}}{1 - y_{ijj'}} \right] && (95) \\ &= 2n \sum_{i \in [d_1]} \frac{1}{d_1} \sum_{\{j,j'\} \subset [d_2]} \frac{(x_{ijj'} - y_{ijj'}) P_{j,j'} (x_{ijj'} - y_{ijj'})}{y_{ijj'}(1 - y_{ijj'})} && (96) \\ &\overset{(b)}{\leq} 8ne^{2\alpha} \sum_{i \in [d_1]} \frac{1}{d_1} \sum_{\{j,j'\} \subset [d_2]} (x_{ijj'} - y_{ijj'}) P_{j,j'} (x_{ijj'} - y_{ijj'}), && (97) \end{aligned}$$

where (a) is due to the fact that $\log(x/y) \leq (x - y)/y$ for $x/y \geq 0$ and (b) is true because $|\Theta_{ij}^{(\ell_2)}| \leq \alpha$ implies, $y_{ijj'} = e^{\Theta_{ij}^{(\ell_2)}} / (e^{\Theta_{ij}^{(\ell_2)}} + e^{\Theta_{ij'}^{(\ell_2)}}) \geq e^{-2\alpha}/2$ which in turn implies, $y_{ijj'}(1 - y_{ijj'}) \geq e^{-2\alpha}(2 - e^{-2\alpha})/4 \geq e^{-2\alpha}/4$. Let $f(z) = 1/(1 + e^{-z})$, a 1-Lipschitz function, it can be seen that $(x_{ijj'} - y_{ijj'})^2 = (f(\Theta_{ij}^{(\ell_1)} - \Theta_{ij'}^{(\ell_1)}) - f(\Theta_{ij}^{(\ell_2)} - \Theta_{ij'}^{(\ell_2)}))^2 \leq ((\Theta_{ij}^{(\ell_1)} - \Theta_{ij'}^{(\ell_1)}) - (\Theta_{ij}^{(\ell_2)} - \Theta_{ij'}^{(\ell_2)}))^2$. This gives us,

$$\begin{aligned} D_{\mathrm{KL}}(\Theta^{(\ell_1)} \| \Theta^{(\ell_2)}) &\leq \frac{8ne^{2\alpha}}{d_1} \sum_{i \in [d_1]} \sum_{\{j,j'\} \subset [d_2]} P_{u,v} ((\Theta_{ij}^{(\ell_1)} - \Theta_{ij}^{(\ell_2)}) - (\Theta_{ij'}^{(\ell_1)} - \Theta_{ij'}^{(\ell_2)}))^2, && (98) \\ &\overset{(a)}{\leq} \frac{8ne^{2\alpha}}{d_1} \sum_{i \in [d_1]} (\Theta^{(\ell_1)} - \Theta^{(\ell_2)})_i L (\Theta^{(\ell_1)} - \Theta^{(\ell_2)})_i, && (99) \\ &= \frac{8ne^{2\alpha}}{d_1} \sum_{i \in [d_1]} (\Theta^{(\ell_1)} - \Theta^{(\ell_2)})_i L (\Theta^{(\ell_1)} - \Theta^{(\ell_2)})_i, && (100) \\ &= \frac{8ne^{2\alpha}}{d_1} \left|\!\left|\!\left| (\Theta^{(\ell_1)} - \Theta^{(\ell_2)}) L^{1/2} \right|\!\right|\!\right|_{\mathrm{F}}^2 && (101) \\ &= \frac{8ne^{2\alpha}}{d_1} \left|\!\left|\!\left| \Theta^{(\ell_1)} - \Theta^{(\ell_2)} \right|\!\right|\!\right|_{\mathrm{L}}^2 && (102) \\ & && (103) \end{aligned}$$

where (a) is due to the fact that $L = \mathrm{diag}(P_u) - P$ is the Laplacian of the probability matrix P, and Θ_i denotes the i-th row of matrix Θ. Combining the above with (91), we get,

$$\mathbb{P}\left\{ \widehat{N} \neq N \right\} \geq 1 - \frac{\binom{M}{2}^{-1} \sum_{\ell_1, \ell_2 \in [M]} (8ne^{2\alpha}/d_1) \left|\!\left|\!\left| \Theta^{(\ell_1)} - \Theta^{(\ell_2)} \right|\!\right|\!\right|_{\mathrm{L}}^2 + \log 2}{\log M}. \tag{104}$$

The remainder of the proof relies on the following probabilistic packing.

Lemma 25 *For each $r \in \{1, \dots, d_1\}$, and for any positive $\delta > 0$ there exists a family of $d_1 \times d_2$ dimensional matrices $\{\Theta^{(1)}, \dots, \Theta^{(M(\delta))}\}$ with cardinality $M(\delta) = \lfloor \exp(rd_1/256) \rfloor$ such that each matrix is rank r and the following bounds hold:*

$$\begin{aligned} \left|\!\left|\!\left| \Theta^{(\ell)} \right|\!\right|\!\right|_{\mathrm{L}} &\leq \delta \ , \ \textit{for all } \ell \in [M] && (105) \\ \left|\!\left|\!\left| \Theta^{(\ell_1)} - \Theta^{(\ell_2)} \right|\!\right|\!\right|_{\mathrm{L}} &\geq \delta \ , \ \textit{for all } \ell_1, \ell_2 \in [M] && (106) \\ \Theta^{(\ell)} &\in \Omega_{\tilde{\alpha}} \ , \ \textit{for all } \ell \in [M] \ , && (107) \end{aligned}$$

with $\tilde{\alpha} = (8\delta/d_2)\sqrt{2 \log d}$ for $d = (d_1 + d_2)/2$.

Now if we assume $\delta \leq \alpha d_2 / 8\sqrt{2 \log d}$, we get $\Theta^{(\ell)} \in \Omega_\alpha$ for $\ell \in [M]$. The above lemma also implies that $\left|\!\left|\!\left| \Theta^{(\ell_1)} - \Theta^{(\ell_2)} \right|\!\right|\!\right|_{\mathrm{F}}^2 \leq 4\delta^2$ which implies,

$$\mathbb{P}\left\{ \widehat{N} \neq N \right\} \geq 1 - \frac{32ne^{2\alpha}\delta^2/d_1 + \log 2}{rd_1/256} \geq \frac{1}{2} \ , \tag{108}$$

where the last inequality holds when $\delta \leq (e^{-\alpha}/128)\sqrt{rd_1^2/n}$. Along with (89), this proves that,

$$\inf_{\widehat{\Theta}} \sup_{\Theta^* \in \Omega_\alpha} \mathbb{E}\Big[\left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\mathrm{L}} \Big] \geq \frac{\delta}{2} \ , \tag{109}$$

for all $\delta \leq \min\{\alpha d_2 / 8\sqrt{2 \log d}, (e^{-\alpha}/128)\sqrt{rd_1^2/n}\}$.

Similarly using the following lemma, Lemma 26, we can prove that,

$$\inf_{\widehat{\Theta}} \sup_{\Theta^* \in \Omega_\alpha} \mathbb{E}\Big[\left|\!\left|\!\left| \widehat{\Theta} - \Theta^* \right|\!\right|\!\right|_{\mathrm{L}} \Big] \geq \frac{\delta}{2} \ , \tag{110}$$

for all $\delta \leq \min\{\alpha\sqrt{rd_1}/\mathrm{tr}\left(\sqrt{(L_r)^\dagger}\right), (e^{-\alpha}/128)\sqrt{rd_1^2/n}\}$.

Lemma 26 *For each $r \in \{1, \dots, d_1\}$, and for any positive $\delta > 0$ there exists a family of $d_1 \times d_2$ dimensional matrices $\{\Theta^{(1)}, \dots, \Theta^{(M(\delta))}\}$ with cardinality $M(\delta) = \lfloor \exp(rd_1/256) \rfloor$ such that each matrix is rank r and the following bounds hold:*

$$\begin{aligned} \left|\!\left|\!\left| \Theta^{(\ell)} \right|\!\right|\!\right|_{\mathrm{L}} &\leq \delta \ , \ \textit{for all } \ell \in [M] && (111) \\ \left|\!\left|\!\left| \Theta^{(\ell_1)} - \Theta^{(\ell_2)} \right|\!\right|\!\right|_{\mathrm{L}} &\geq \delta \ , \ \textit{for all } \ell_1, \ell_2 \in [M] && (112) \\ \Theta^{(\ell)} &\in \Omega_{\tilde{\alpha}} \ , \ \textit{for all } \ell \in [M] \ , && (113) \end{aligned}$$

with $\tilde{\alpha} = \delta\sqrt{\mathrm{tr}\left((L_r)^\dagger\right)}/\sqrt{rd_1}$, where L_r is the (best) rank r approximation of L.

Now combining (109) and (110), and maximizing the RHS proves the theorem.

B.1 Proof of Lemma 25

Following the construction in Negahban and Wainwright (2012), we use probabilistic method to prove the existence of the desired family. We will show that the following procedure succeeds in producing the desired family with probability at least half, which proves its existence. Let $d = (d_1 + d_2)/2$, and suppose $d_2 \geq d_1$ without loss of generality. For the choice of $M' = e^{rd_2/576}$, and for each $\ell \in [M']$, generate a rank-r matrix $\Theta^{(\ell)} \in \mathbb{R}^{d_1 \times d_2}$ as follows:

$$\Theta^{(\ell)} \ = \ \frac{\delta}{\sqrt{rd_2}} U (V^{(\ell)})^T \Big(\mathbf{I}_{d_2 \times d_2} - \sum_{i \in [G]} \frac{g_i g_i^T}{g_i^T g_i} \Big) \ , \tag{114}$$

where $U \in \mathbb{R}^{d_1 \times r}$ is a random orthogonal basis such that $U^T U = \mathbf{I}_{r \times r}$ and $V^{(\ell)} \in \mathbb{R}^{d_2 \times r}$ is a random matrix with each entry $V_{ij}^{(\ell)} \in \{-1, +1\}$ chosen independently and uniformly at random. By construction, notice that,

$$\left|\!\left|\!\left| \Theta^{(\ell)} \right|\!\right|\!\right|_{\mathrm{L}}^2 = \frac{\delta^2}{r\, d_2} \left|\!\left|\!\left| (V^{(\ell)})^T L^{1/2} \right|\!\right|\!\right|_{\mathrm{F}}^2 = \frac{\delta^2}{r\, d_2} \sum_{i \in [d_2]} (V_i^{(\ell)})^T L V_i^{(\ell)} \leq \frac{\delta^2}{r\, d_2} |\!|\!| L |\!|\!|_2 \sum_{i \in [d_2]} \left|\!\left|\!\left| V_i^{(\ell)} \right|\!\right|\!\right|_{\mathrm{F}}^2 = \delta^2 \ , \tag{115}$$

where $V_i^{(\ell)}$ is the i-th column of $V^{(\ell)}$, since $g_{i i=1}^G$ span the null space of the Laplacian L, $|\!|\!| L |\!|\!|_2 \leq 1$, and $\left|\!\left|\!\left| V^{(\ell)} \right|\!\right|\!\right|_{\mathrm{F}} = \sqrt{rd_2}$. Now, consider $\left|\!\left|\!\left| \Theta^{(\ell_1)} - \Theta^{(\ell_2)} \right|\!\right|\!\right|_{\mathrm{F}}^2 = (\delta^2/(rd_2)) \left|\!\left|\!\left| (V^{(\ell_1)} - V^{(\ell_2)})^T \right|\!\right|\!\right|_{\mathrm{L}}^2 \equiv f(V^{(\ell_1)}, V^{(\ell_2)})$ which is a function over $2rd_2$ i.i.d. random Rademacher variables $V^{(\ell_1)}$ and $V^{(\ell_2)}$ which define $\Theta^{(\ell_1)}$ and $\Theta^{(\ell_2)}$ respectively. Since f is Lipschitz in the following sense, we can apply McDiarmid's concentration inequality. For all $(V^{(\ell_1)}, V^{(\ell_2)})$ and $(\widetilde{V}^{(\ell_1)}, \widetilde{V}^{(\ell_2)})$ that differ in only one variable, say $\widetilde{V}^{(\ell_1)} = V^{(\ell_1)} + 2e_{ij}$, for some standard basis matrix e_{ij}, we have

$$\begin{aligned} & \left| f(V^{(\ell_1)}, V^{(\ell_2)}) - f(\widetilde{V}^{(\ell_1)}, \widetilde{V}^{(\ell_2)}) \right| \ = \\ & \left| \ \frac{\delta^2}{r\, d_2} \left|\!\left|\!\left| (V^{(\ell_1)} - V^{(\ell_2)})^T \right|\!\right|\!\right|_{\mathrm{L}}^2 - \frac{\delta^2}{r\, d_2} \left|\!\left|\!\left| (V^{(\ell_1)} - V^{(\ell_2)} + 2e_{ij})^T \right|\!\right|\!\right|_{\mathrm{L}}^2 \ \right| && (116) \\ & = \ \frac{\delta^2}{r\, d_2} \left| \ 2e_i^T L (V_j^{(\ell_1)} - V_j^{(\ell_2)}) + 4 e_i^T L e_i \ \right| && (117) \\ & = \ \frac{\delta^2}{r\, d_2} (2 |\!|\!| L_i |\!|\!|_1 \left|\!\left|\!\left| V_j^{(\ell_1)} - V_j^{(\ell_2)} \right|\!\right|\!\right|_\infty + 4P_i) && (118) \\ & \leq \ \frac{12\, \delta^2}{r\, d_2} \ , && (119) \end{aligned}$$

where we used the fact that $|\!|\!| L_i |\!|\!|_1 = 2P_i \leq 2$ and $V^{(\ell_1)} - V^{(\ell_2)}$ is entry-wise bounded by 2. The expectation $\mathbb{E}[f(V^{(\ell_1)}, V^{(\ell_2)})]$ is

$$\frac{\delta^2}{r\, d_2} \mathbb{E}\left[\left|\!\left|\!\left| (V^{(\ell_1)} - V^{(\ell_2)})^T \right|\!\right|\!\right|_{\mathrm{L}}^2 \right] = \frac{2\delta^2}{r\, d_2} \mathbb{E}\left[\left|\!\left|\!\left| (V^{(\ell_1)})^T \right|\!\right|\!\right|_{\mathrm{L}}^2 \right] \leq 2\delta^2 \ , \tag{120}$$

where we use equation (115). Applying McDiarmid's inequality with bounded difference $12\delta^2/(rd_2)$, we get that

$$\mathbb{P}\Big\{ \ f(V^{(\ell_1)}, V^{(\ell_2)}) \leq 2\delta^2 - t \ \Big\} \ \leq \ \exp\Big\{ -\frac{t^2\, r\, d_2}{144\, \delta^4} \Big\} \ , \tag{121}$$

Since there are less than $(M')^2$ pairs of (ℓ_1, ℓ_2), setting $t = \delta^2$ and applying the union bound gives

$$\mathbb{P}\left\{ \min_{\ell_1,\ell_2 \in [M']} \left|\left|\left| \Theta^{(\ell_1)} - \Theta^{(\ell_2)} \right|\right|\right|_{\mathrm{F}}^2 \geq \delta^2 \right\} \;\geq\; 1 - \exp\left\{ -\frac{r\, d_2}{144} + 2\log M' \right\} \geq \frac{7}{8}\,, \quad (122)$$

where we used $M' = \exp\{r d_2/576\}$ and $d_2 \geq 607$.

We are left to prove that $\Theta^{(\ell)}$'s are in $\Omega_{(8\delta/d_2)\sqrt{2\log d_2}}$ as defined in (10). Since we removed the mean for each connected component, such that $\Theta^{(\ell)} g_i = 0$, $\forall i \in [G]$ by construction, we only need to show that the maximum entry is bounded by $(8\delta/d_2)\sqrt{2\log d_2}$. We first prove an upper bound in (124) for a fixed $\ell \in [M']$, and use this to show that there exists a large enough subset of matrices satisfying this bound. From (114), consider $(UV^T)_{ij} = \langle\!\langle u_i, v_j \rangle\!\rangle$, where $u_i \in \mathbb{R}^r$ is the first r entries of a random vector drawn uniformly from the d_2-dimensional sphere, and $v_j \in \mathbb{R}^r$ is drawn uniformly at random from $\{-1,+1\}^r$ with $\|v_j\| = \sqrt{r}$. Using Levy's theorem for concentration on the sphere Ledoux (2005), we have

$$\mathbb{P}\left\{ |\langle\!\langle u_i, v_j \rangle\!\rangle| \geq t \right\} \;\leq\; 2\exp\left\{ -\frac{d_2\, t^2}{8\, r} \right\}. \quad (123)$$

Notice that by the definition (114), $\max_{i,j} |\Theta^{(\ell)}_{ij}| \leq (2\delta/\sqrt{r d_2}) \max_{i,j} |\langle\!\langle u_i, v_j \rangle\!\rangle|$. Setting $t = \sqrt{(32r/d_2)\log d_2}$ and taking the union bound over all $d_1 d_2$ indices, we get

$$\mathbb{P}\left\{ \max_{i,j} |\Theta^{(\ell)}_{ij}| \leq \frac{2\delta\sqrt{32\log d_2}}{d_2} \right\} \;\geq\; 1 - 2 d_1 d_2 \exp\left\{ -4\log d_2 \right\} \;\geq\; \frac{1}{2}\,, \quad (124)$$

for a fixed $\ell \in [M']$. Consider the event that there exists a subset $S \subset [M']$ of cardinality $M = (1/4)M'$ with the same bound on maximum entry, then from (124) we get

$$\mathbb{P}\left\{ \exists S \subset [M'] \text{ such that } \left|\left|\left| \Theta^{(\ell)} \right|\right|\right|_\infty \leq \frac{2\delta\sqrt{32\log d_2}}{d_2} \text{ for all } \ell \in S \right\} \geq \sum_{m=M}^{M'} \binom{M'}{m} \left(\frac{1}{2}\right)^m, \quad (125)$$

which is larger than half for our choice of $M < M'/2$.

B.2 Proof of Lemma 26

Inspired from the construction in Negahban and Wainwright (2012), we furnish the following probabilistic argument for the existence of the desired family. For the choice of $M = \lfloor e^{r d_1/256} \rfloor$, and for each $\ell \in [M]$, generate a rank-r matrix $\Theta^{(\ell)} \in \mathbb{R}^{d_1 \times d_2}$ as follows:

$$\Theta^{(\ell)} \;=\; \frac{\delta}{\sqrt{r d_1}} V^{(\ell)} \sqrt{\Lambda_r^\dagger}\, U_r^T\,, \quad (126)$$

where the columns of $U_r \in \mathbb{R}^{d_2 \times r}$ are the top r singular vectors of $L = U\Lambda U^T$, Λ_r is a diagonal matrix in $\mathbb{R}^{r\times r}$ and its diagonal elements are the top r singular values of L corresponding to columns of U_r, $\dagger$ represents the Moore-Penrose pseudo inverse, and $V^{(\ell)}$ is a random matrix with each entry $V^{(\ell)}_{ij} \in \{-1,+1\}$ chosen independently and uniformly at random. First by definition, $\left|\left|\left| \Theta^{(\ell)} \right|\right|\right|_{\mathrm{L}} = (\delta/\sqrt{r d_1}) \left|\left|\left| V^{(\ell)} \right|\right|\right|_{\mathrm{F}} \leq \delta$, since $\left|\left|\left| V^{(\ell)} \right|\right|\right|_{\mathrm{F}} = \sqrt{r d_1}$.

Define f as $f(V^{(\ell_1)}, V^{(\ell_2)}) \equiv \left|\left|\left| \Theta^{(\ell_1)} - \Theta^{(\ell_2)} \right|\right|\right|_{\mathrm{L}}^2 = (\delta^2/(r d_1)) \left|\left|\left| V^{(\ell_1)} - V^{(\ell_2)} \right|\right|\right|_{\mathrm{F}}^2$ which is a function of $2rd_1$ i.i.d. random Rademacher variables. Now we can apply McDiarmid's concentration inequality since f is Lipschitz as folows. For all $(V^{(\ell_1)}, V^{(\ell_2)})$ and $(\widetilde{V}^{(\ell_1)}, \widetilde{V}^{(\ell_2)})$ that differ in only one variable, say $\widetilde{V}^{(\ell_1)} = V^{(\ell_1)} + 2e_{ij}$, for some standard basis matrix e_{ij}, we have

$$\begin{aligned}
&\left| f(V^{(\ell_1)}, V^{(\ell_2)}) - f(\widetilde{V}^{(\ell_1)}, \widetilde{V}^{(\ell_2)}) \right| \\
&= \left| \frac{\delta^2}{r\, d_2} \left|\left|\left| V^{(\ell_1)} - V^{(\ell_2)} \right|\right|\right|_{\mathrm{F}}^2 - \frac{\delta^2}{r\, d_2} \left|\left|\left| V^{(\ell_1)} - V^{(\ell_2)} + 2e_{ij} \right|\right|\right|_{\mathrm{F}}^2 \right| \\
&= \left| \frac{\delta^2}{r\, d_2} \|2e_{ij}\|_{\mathrm{F}}^2 + \frac{\delta^2}{r\, d_2} \langle\!\langle (V^{(\ell_1)} - V^{(\ell_2)}), 2e_{ij} \rangle\!\rangle \right| \\
&\leq \frac{4\,\delta^2}{r\, d_1} + \frac{\delta^2}{r\, d_1} \left|\left|\left| V^{(\ell_1)} - V^{(\ell_2)} \right|\right|\right|_\infty \|2e_{ij}\|_1 \\
&\leq \frac{8\,\delta^2}{r\, d_1}\,, \qquad (127)
\end{aligned}$$

where the penultimate step is true since $(V^{(\ell_1)} - V^{(\ell_2)})$ is entry-wise bounded by 2. The expectation $\mathbb{E}[f(V^{(\ell_1)}, V^{(\ell_2)})]$ is

$$\begin{aligned}
\frac{\delta^2}{r\, d_1} \mathbb{E}\left[\left|\left|\left| (V^{(\ell_1)} - V^{(\ell_2)}) \right|\right|\right|_{\mathrm{F}}^2 \right] &= \frac{2\delta^2}{r\, d_1} \mathbb{E}\left[\left|\left|\left| V^{(\ell_1)} \right|\right|\right|_{\mathrm{F}}^2 \right] \\
&= 2\,\delta^2\,. \qquad (128)
\end{aligned}$$

Now applying McDiarmid's inequality on the function f, we get that

$$\mathbb{P}\left\{ f(V^{(\ell_1)}, V^{(\ell_2)}) \leq 2\delta^2 - t \right\} \;\leq\; \exp\left\{ -\frac{t^2\, r\, d_1}{64\, \delta^4} \right\}, \quad (129)$$

Setting $t = \delta^2$ and applying the union bound gives us,

$$\mathbb{P}\left\{ \min_{\ell_1,\ell_2 \in [M]} \left|\left|\left| \Theta^{(\ell_1)} - \Theta^{(\ell_2)} \right|\right|\right|_{\mathrm{F}}^2 \geq \delta^2 \right\} \;\geq\; 1 - \exp\left\{ -\frac{r\, d_1}{64} + 2\log M \right\} > 0\,. \quad (130)$$

In the last step, we used $M = \lfloor \exp\{r d_1/\ 256\} \rfloor$. At last we prove that $\Theta^{(\ell)}$'s are in $\Omega_{\delta\sqrt{\mathrm{tr}\left((L_r)^\dagger\right)/r d_1}}$ as defined in (10). Since we know that g_i belongs to the kernel of L for all $i \in [G]$, $\Theta^{(\ell)} g = 0$ by construction (6). From (126), consider $(V\sqrt{\Lambda_r^\dagger} U_r^T)_{ij} = \langle\!\langle v_i, \sqrt{\Lambda_r^\dagger}(u_r)_j \rangle\!\rangle$, where $(u_r)_j \in \mathbb{R}^r$ is the vector of i-th entries of the top r singular vectors of L, and $v_i \in \mathbb{R}^r$ is drawn uniformly at random from $\{-1,+1\}^r$.

$$\left| \langle\!\langle v_i, \sqrt{\Lambda_r^\dagger}(u_r)_j \rangle\!\rangle \right| \leq \|v_i\|_\infty \left\| \sqrt{\Lambda_r^\dagger}(u_r)_j \right\|_1 \leq \sqrt{\mathrm{tr}\left(\Lambda_r^\dagger\right)} = \sqrt{\mathrm{tr}\left((L_r)^\dagger\right)}\,. \quad (131)$$

The above inequality proves that $\left|\left|\left| \Theta^{(\ell)} \right|\right|\right|_\infty$ is upper bounded as desired.

Appendix C. Proof of Theorem 7

We first introduce some additional notations used in the proof. Recall that $\mathcal{L}(\Theta)$ is the log likelihood function. Let $\nabla\mathcal{L}(\Theta) \in \mathbb{R}^{d_1\times d_2}$ denote its gradient such that $\nabla_{ij}\mathcal{L}(\Theta) = \frac{\partial\mathcal{L}(\Theta)}{\partial\Theta_{ij}}$. Let $\nabla^2\mathcal{L}(\Theta) \in \mathbb{R}^{d_1d_2\times d_1d_2}$ denote its Hessian matrix such that $\nabla^2_{ij,i'j'}\mathcal{L}(\Theta) = \frac{\partial^2\mathcal{L}(\Theta)}{\partial\Theta_{ij}\partial\Theta_{i'j'}}$. By the definition of $\mathcal{L}(\Theta)$ in (32), we have

$$\nabla\mathcal{L}(\Theta^*) \;=\; -\frac{1}{k\,d_1}\sum_{i=1}^{d_1}\sum_{\ell=1}^{k} e_i(e_{v_{i,\ell}} - p_{i,\ell})^T\,, \tag{132}$$

where $p_{i,\ell}$ denotes the conditional choice probability at ℓ-th position. Precisely, $p_{i,\ell} = \sum_{j\in S_{i,\ell}} p_{j|(i,\ell)}e_j$ where $p_{j|(i,\ell)}$ is the probability that item j is chosen at ℓ-th position from the top by the user i conditioned on the top $\ell-1$ choices such that $p_{j|(i,\ell)} \equiv \mathbb{P}\{v_{i,\ell} = j|v_{i,1},\ldots,v_{i,\ell-1},S_i\} = e^{\Theta^*_{ij}}/(\sum_{j'\in S_{i,\ell}} e^{\Theta_{ij'}})$ and $S_{i,\ell} \equiv S_i\setminus\{v_{i,1},\ldots,v_{i,\ell-1}\}$, where S_i is the set of alternatives presented to the i-th user and $v_{i,\ell}$ is the item ranked at the ℓ-th position by the user i. Notice that for $i\neq i'$, $\frac{\partial^2\mathcal{L}(\Theta)}{\partial\Theta_{ij}\partial\Theta_{i'j'}} = 0$ and the Hessian is

$$\begin{aligned}\frac{\partial^2\mathcal{L}(\Theta)}{\partial\Theta_{ij}\partial\Theta_{ij'}} &= \frac{1}{k\,d_1}\sum_{\ell=1}^{k}\mathbb{I}\big(j\in S_{i,\ell}\big)\frac{\partial p_{j|(i,\ell)}}{\partial\Theta_{ij'}}\\ &= \frac{1}{k\,d_1}\sum_{\ell=1}^{k}\mathbb{I}\big(j,j'\in S_{i,\ell}\big)\left(p_{j|(i,\ell)}\mathbb{I}(j=j') - p_{j|(i,\ell)}p_{j'|(i,\ell)}\right).\end{aligned} \tag{133}$$

This Hessian matrix is a block-diagonal matrix $\nabla^2\mathcal{L}(\Theta) = \mathrm{diag}(H^{(1)}(\Theta),\ldots,H^{(d_1)}(\Theta))$ with

$$H^{(i)}(\Theta) = \frac{1}{k\,d_1}\sum_{\ell=1}^{k}\left(\mathrm{diag}(p_{i,\ell}) - p_{i,\ell}p_{i,\ell}^T\right). \tag{134}$$

Let $\Delta = \Theta^* - \widehat{\Theta}$ where $\widehat{\Theta}$ is the optimal solution of the convex program in (31). We first introduce three key technical lemmas. The first lemma follows from Lemma 1 of Negahban and Wainwright (2012), and shows that Δ is approximately low-rank.

Lemma 27 *If $\lambda \geq 2|||\nabla\mathcal{L}(\Theta^*)|||_2$, then we have*

$$|||\Delta|||_{\mathrm{nuc}} \;\leq\; 4\sqrt{2r}|||\Delta|||_{\mathrm{F}} + 4\sum_{j=r+1}^{\min\{d_1,d_2\}}\sigma_j(\Theta^*)\,, \tag{135}$$

for all $r\in[\min\{d_1,d_2\}]$.

Proof of the above lemma is omitted because of its similarity to that of Lemma 22. The following lemma provides a bound on the gradient using the concentration in measure of sum of independent random matrices Tropp (2011).

Lemma 28 *For any positive constant $c\geq 1$ and $k\leq(1/e)\;d_2(4\log d_2+\log d_1)$, with probability at least $1-2d^{-c}-d_2^{-3}$,*

$$\begin{aligned}&|||\nabla\mathcal{L}(\Theta^*)|||_2\\ &\leq\sqrt{\frac{4(1+c)\,\log d}{k\,d_1^2}}\max\Big\{\sqrt{d_1/d_2},\;e^{2\alpha}\sqrt{4(1+c)\log(d)}(8\log d_2+2\log d_1)\log k\Big\}\,.\end{aligned} \tag{136}$$

Since we are typically interested in the regime where the number of samples is much smaller than the dimension $d_1\times d_2$ of the problem, the Hessian is typically not positive definite. However, when we restrict our attention to the vectorized Δ with relatively small nuclear norm, then we can prove restricted strong convexity, which gives the following bound.

Lemma 29 (Restricted Strong Convexity for collaborative ranking) *Fix any $\Theta\in\Omega_\alpha$ and assume $24\leq k\leq\min\{d_1^2,(d_1^2+d_2^2)/(2d_1)\}\log d$. Under the random sampling model of the alternatives $\{j_{i\ell}\}_{i\in[d_1],\ell\in[k]}$ and the random outcome of the comparisons described in section 1, with probability larger than $1-2d^{-2^{18}}$,*

$$\mathrm{Vec}(\Delta)^T\,\nabla^2\mathcal{L}(\Theta)\,\mathrm{Vec}(\Delta) \;\geq\; \frac{e^{-4\alpha}}{24\,d_1d_2}|||\Delta|||_{\mathrm{F}}^2\,, \tag{137}$$

for all Δ in $\mathcal{A}$ where

$$\mathcal{A} = \Big\{\Delta\in\mathbb{R}^{d_1\times d_2}\;\Big|\;|||\Delta|||_\infty\leq 2\alpha\,,\;\sum_{j\in[d_2]}\Delta_{ij} = 0\;\textit{for all}\;i\in[d_1]\;\textit{and}\;|||\Delta|||_{\mathrm{F}}^2\geq\mu|||\Delta|||_{\mathrm{nuc}}\Big\}\,. \tag{138}$$

with

$$\mu \;\equiv\; 2^{10}\,e^{2\alpha}\,\alpha\,d_2\sqrt{\frac{d_1\,\log d}{k\,\min\{d_1,d_2\}}}\,. \tag{139}$$

Building on these lemmas, the proof of Theorem 7 is divided into the following two cases. In both cases, we will show that

$$|||\Delta|||_{\mathrm{F}}^2 \;\leq\; 72\,e^{4\alpha}c_0\lambda_0\,d_1d_2\,|||\Delta|||_{\mathrm{nuc}}\,, \tag{140}$$

with high probability. Applying Lemma 27 proves the desired theorem. We are left to show Eq. (140) holds.

Case 1: Suppose $|||\Delta|||_{\mathrm{F}}^2\geq\mu|||\Delta|||_{\mathrm{nuc}}$. With $\Delta = \Theta^* - \widehat{\Theta}$, the Taylor expansion yields

$$\mathcal{L}(\widehat{\Theta}) = \mathcal{L}(\Theta^*) - \langle\!\langle\nabla\mathcal{L}(\Theta^*),\Delta\rangle\!\rangle + \frac{1}{2}\mathrm{Vec}(\Delta)\nabla^2\mathcal{L}(\Theta)\mathrm{Vec}^T(\Delta), \tag{141}$$

where $\Theta = a\widehat{\Theta}+(1-a)\Theta^*$ for some $a\in[0,1]$. It follows from Lemma 29 that with probability at least $1-2d^{-2^{18}}$,

$$\begin{aligned}\mathcal{L}(\widehat{\Theta})-\mathcal{L}(\Theta^*) &\geq -\langle\!\langle\nabla\mathcal{L}(\Theta^*),\Delta\rangle\!\rangle + \frac{e^{-4\alpha}}{48\,d_1\,d_2}|||\Delta|||_{\mathrm{F}}^2\\ &\geq -|||\nabla\mathcal{L}(\Theta^*)|||_2|||\Delta|||_{\mathrm{nuc}} + \frac{e^{-4\alpha}}{48\,d_1\,d_2}|||\Delta|||_{\mathrm{F}}^2\,.\end{aligned}$$

From the definition of $\widehat{\Theta}$ as an optimal solution of the minimization, we have

$$\mathcal{L}(\widehat{\Theta}) - \mathcal{L}(\Theta^*) \;\le\; \lambda\left(|||\Theta^*|||_{\rm nuc} - \left|\left|\left|\widehat{\Theta}\right|\right|\right|_{\rm nuc}\right) \;\le\; \lambda|||\Delta|||_{\rm nuc}\,.$$

By the assumption, we choose $\lambda \ge 480\lambda_0$. In view of Lemma 28, this implies that $\lambda \ge 2|||\nabla\mathcal{L}(\Theta^*)|||_2$ with probability at least $1-2d^{-3}$. It follows that with probability at least $1-2d^{-3}-2d^{-2^{18}}$,

$$\frac{e^{-4\alpha}}{48d_1d_2}|||\Delta|||_{\rm F}^2 \;\le\; \left(\lambda + |||\nabla\mathcal{L}(\Theta^*)|||_2\right)|||\Delta|||_{\rm nuc} \;\le\; \frac{3\lambda}{2}|||\Delta|||_{\rm nuc}\,.$$

By our assumption on $\lambda \le c_0\lambda_0$, this proves the desired bound in Eq. (140)
Case 2: Suppose $|||\Delta|||_{\rm F}^2 \le \mu|||\Delta|||_{\rm nuc}$. By the definition of μ and the fact that $c_0 \ge 480$, it follows that $\mu \le 72\,e^{4\alpha}c_0\lambda_0\,d_1d_2$, and we get the same bound as in Eq. (140).

C.1 Proof of Lemma 28

Define $X_i = -e_i\sum_{\ell=1}^k(e_{v_{i,\ell}} - p_{i,\ell})^T$ such that $\nabla\mathcal{L}(\Theta^*) = \frac{1}{k\,d_1}\sum_{i=1}^{d_1}X_i$, which is a sum of d_1 independent random matrices. Although $|||X_i|||_2$ can be as large as $O(k)$, this occurs with very low probability. We make this precise in the following lemma and focus on the case where $|||X_i|||_2 = O(\sqrt{k})$ for all $i \in [d_1]$.

Lemma 30 *For a fixed $i \in [d_1]$ and $j \in [d_2]$, if $k \le (1/e)\,d_2\,(4\log d_2 + \log d_1)$, then the number of times the item j is observed by the user i is at most $8(\log d_2) + 2(\log d_1)$ with probability larger than $1 - 1/(d_2^4d_1)$.*

Proof is given in the end of this Section. Applying union bound over the d_1 items and d_2 users, we have the multiplicity in sampling for any item for all users is bounded by $8(\log d_2) + 2(\log d_1)$ with probability at least $1 - d_2^{-3}$. We denote this event by $\mathcal{A}$ and let $\mathbb{I}(\mathcal{A})$ be the indicator function that all the multiplicities in sampling are bounded. We first upper bound $|||(\sum_i X_i)\,\mathbb{I}(\mathcal{A})|||_2$ using the Matrix Bernstein inequality Tropp (2011).

$$\begin{aligned}
|||X_i\mathbb{I}(\mathcal{A})|||_2 &= \left\|\mathbb{I}(\mathcal{A})\sum_{\ell=1}^k\left(e_{v_{i,\ell}} - p_{i,\ell}\right)\right\| \\
&\overset{(a)}{\le} \left\|\mathbb{I}(\mathcal{A})\sum_{\ell=1}^k e_{v_{i,l}}\right\| + \left\|\mathbb{I}(\mathcal{A})\sum_{\ell=1}^k p_{i,\ell}\right\| \\
&\overset{(b)}{\le} (8(\log d_2) + 2(\log d_1))\sqrt{\min\{k,d_2\}}\left(1 + \left(\sum_{\ell=1}^k\frac{e^{2\alpha}}{\ell}\right)\right) \\
&\overset{(c)}{\le} \sqrt{k}(8(\log d_2) + 2(\log d_1))\left(1 + 2e^{2\alpha}\;\log k\right) \\
&\le 3\sqrt{k}(8(\log d_2) + 2(\log d_1))e^{2\alpha}\;\log k\,, \qquad (142)
\end{aligned}$$

where (a) is by triangle inequality, (b) is because under the given event $\mathcal{A}$ each term in $\sum_\ell e_{v_{i,\ell}}$ and $\sum_l p_{i,\ell}$ are upper bounded by $\log d_2$ and $\left(\sum_{\ell=1}^k\frac{e^{2\alpha}}{\ell}\right)\log d_2$ respectively and because there can be at most $\min\{d_2,k\}$ non-zero entries in the two vectors $\sum_\ell e_{v_{i,\ell}}$ and

$\sum_\ell p_{i,\ell}$ and, (c) is due to the fact that k-th harmonic number $\sum_{\ell=1}^k\frac{1}{\ell}$ is upper bounded by $\log k$. We also have,

$$\begin{aligned}
\left\|\sum_i\mathbb{E}\left[X_iX_i^T\mathbb{I}(\mathcal{A})\right]\right\|_2 &\le \left\|\sum_i\mathbb{E}\left[X_iX_i^T\right]\right\|_2 \\
&\le \left\|\sum_{i=1}^{d_1}e_ie_i^T\mathbb{E}\left[\sum_{\ell,\ell'=1}^k\left(e_{v_{i,\ell}} - p_{i,\ell}\right)^T\left(e_{v_{i,\ell'}} - p_{i,\ell'}\right)\right]\right\|_2 \\
&= \left\|\sum_{i=1}^{d_1}e_ie_i^T\mathbb{E}\left[\sum_{\ell=1}^k\left(e_{v_{i,\ell}} - p_{i,\ell}\right)^T\left(e_{v_{i,\ell}} - p_{i,\ell}\right)\right]\right\|_2 \\
&= \left\|\sum_{i=1}^{d_1}e_ie_i^T\mathbb{E}\left[\sum_{\ell=1}^k e_{v_{i,\ell}}^Te_{v_{i,\ell}} - p_{i,\ell}^Tp_{i,\ell}\right]\right\|_2 \\
&\le \left\|\sum_{i=1}^{d_1}e_ie_i^T\mathbb{E}\left[\sum_{\ell=1}^k e_{v_{i,\ell}}^Te_{v_{i,\ell}}\right]\right\|_2 \\
&= k|||\mathbf{I}_{d_1\times d_1}|||_2 = k, \qquad (143)
\end{aligned}$$

and

$$\begin{aligned}
\left\|\sum_{i=1}^{d_1}\mathbb{E}\left[X_i^TX_i\mathbb{I}(\mathcal{A})\right]\right\|_2 &\le \left\|\sum_{i=1}^{d_1}\mathbb{E}\left[X_i^TX_i\right]\right\|_2 \\
&\le \left\|\sum_{i=1}^{d_1}\mathbb{E}\left[\sum_{\ell,\ell'=1}^k(e_{v_{i,\ell}} - p_{i,\ell})(e_{v_{i,\ell'}} - p_{i,\ell'})^T\right]\right\|_2 \\
&= \left\|\sum_{i=1}^{d_1}\mathbb{E}\left[\sum_{\ell=1}^k(e_{v_{i,\ell}} - p_{i,\ell})(e_{v_{i,\ell}} - p_{i,\ell})^T\right]\right\|_2 \qquad (144) \\
&= \left\|\sum_{i=1}^{d_1}\mathbb{E}\left[\sum_{\ell=1}^k e_{v_{i,\ell}}e_{v_{i,\ell}}^T - p_{i,\ell}p_{i,\ell}^T\right]\right\|_2 \\
&\le \left\|\sum_{i=1}^{d_1}\mathbb{E}\left[\sum_{\ell=1}^k e_{v_{i,\ell}}e_{v_{i,\ell}}^T\right]\right\|_2 \\
&= \left\|\sum_{i=1}^{d_1}\frac{k}{d_2}\mathbf{I}_{d_2\times d_2}\right\|_2 = \frac{kd_1}{d_2}\,. \qquad (145)
\end{aligned}$$

By matrix Bernstein inequality Tropp (2011),

$$\begin{aligned}
&\mathbb{P}\Big(|||\nabla\mathcal{L}(\Theta^*)\mathbb{I}(\mathcal{A})|||_2 > t\Big) \\
&\le (d_1+d_2)\exp\Big(\frac{-k^2\,d_1^2t^2/2}{(d_1k/\min\{d_2,d_1\}) + (3e^{2\alpha}k^{3/2}d_1(8(\log d_2) + 2(\log d_1))\log k\;t/3)}\Big)\,,
\end{aligned}$$

which gives the tail probability of $2d^{-c}$ for the choice of

$$t = \max\left\{\sqrt{\frac{4(1+c)\,\log d}{k\,d_1\,\min\{d_2,d_1\}}},\ \frac{4(1+c)e^{2\alpha}\log(d)\,(8(\log d_2)+2(\log d_1))\log k}{k^{1/2}\,d_1}\right\}$$
$$= \frac{\sqrt{4(1+c)\,\log d}}{k^{1/2}\,d_1}\max\left\{\sqrt{d_1/d_2}\,,\ e^{2\alpha}\sqrt{4(1+c)\log(d)}\,(8(\log d_2)+2(\log d_1))\log k\right\}.$$

Now with a high probability of $1-\frac{2}{d^c}-\frac{1}{d_2^3}$ the desired bound is true.

C.2 Proof of Lemma 30

In a classical balls-in-bins setting, we consider k as the number of balls and d_2 as the number of bins. We can consider the number of balls in a particular bin as the number of times the user i observes item j. Let the event that this number is at least δ be denoted by the event A_δ^j. Then, $\mathbb{P}\left\{A_\delta^j\right\} \le \binom{k}{\delta}\frac{1}{d_2^\delta} \le \left(\frac{ke}{d_2\delta}\right)^\delta$. Using the fact that $(1/x)^x \le a$ for any $x \ge (2\log(1/a))/(\log\log(1/a))$, we let $x = d_2\delta/(ke)$ to get

$$\left(\frac{ke}{d_2\delta}\right)^\delta \le a^{\frac{ke}{d_2}}\,,$$

for $\delta \ge (ke/d_2)(2\log(1/a))/(\log\log(1/a))$. Choosing $a = (1/d_2^4 d_1)^{d_2/ke}$, we have $\mathbb{P}\left\{A_\delta^j\right\} \le 1/(d_1 d_2^4)$, for a choice of $\delta = 2\ \log(d_2^4 d_1) \ge 2\log(d_2^4 d_1)/(\log((d_2/ke)\log(d_2^4 d_1)))$.

C.3 Proof of Lemma 29

Recall that the Hessian matrix is a block-diagonal matrix with the i-th block $H^{(i)}(\Theta)$ given by (134). We use the following remark from Hajek et al. (2014) to bound the Hessian.

Remark 31 *(Hajek et al., 2014, Claim 1) Given $\theta \in \mathbb{R}^r$, let p be the column probability vector with $p_i = e^{\theta_i}/(e^{\theta_1}+\cdots+e^{\theta_\rho})$ for each $i \in [\rho]$ and for any positive integer ρ. If $|\theta_i| \le \alpha$, for all $i \in [\rho]$, then*

$$e^{2\alpha}\Big(\mathrm{diag}(p) - pp^T\Big) \ \succeq\ \frac{1}{\rho}\mathrm{diag}(\mathbb{1}) - \frac{1}{\rho^2}\mathbb{1}\mathbb{1}^T\,.$$

By letting $\mathbb{1}_{S_{i,\ell}} = \sum_{j\in S_{i,\ell}} e_j$ and applying the above claim, we have

$$e^{2\alpha}H^{(i)}(\Theta) \succeq \frac{1}{k\,d_1}\sum_{\ell=1}^{k}\left(\frac{1}{k-\ell+1}\mathrm{diag}(\mathbb{1}_{S_{i,\ell}}) - \frac{1}{(k-\ell+1)^2}\mathbb{1}_{S_{i,\ell}}\mathbb{1}_{S_{i,\ell}}^T\right)$$
$$= \frac{1}{2\,k\,d_1}\sum_{\ell=1}^{k}\frac{1}{(k-\ell+1)^2}\sum_{j,j'\in S_{i,\ell}}(e_j-e_{j'})(e_j-e_{j'})^T$$
$$\succeq \frac{1}{2\,k^3\,d_1}\sum_{\ell=1}^{k}\sum_{j,j'\in S_{i,\ell}}(e_j-e_{j'})(e_j-e_{j'})^T.$$

Hence,

$$\mathrm{Vec}(\Delta)\nabla^2\mathcal{L}(\Theta)\mathrm{Vec}^T(\Delta) = \sum_{i=1}^{d_1}(\Delta^T e_i)^T H^{(i)}(\Theta)(\Delta^T e_i)$$
$$\ge \frac{e^{-2\alpha}}{2\,k^3\,d_1}\sum_{i=1}^{d_1}\sum_{\ell=1}^{k}\sum_{j,j'\in S_{i,\ell}}\left|\left|\left|e_i^T\Delta(e_j-e_{j'})\right|\right|\right|_2^2.$$

By changing the order of the summation, we get that

$$\sum_{\ell=1}^{k}\sum_{j,j'\in S_{i,\ell}}\left|\left|\left|e_i^T\Delta(e_j-e_{j'})\right|\right|\right|_2^2 = \sum_{\ell,\ell'=1}^{k}\langle\!\langle\Delta, e_{i,j_{i,\ell}}-e_{i,j_{i,\ell'}}\rangle\!\rangle^2\sum_{\ell''=1}^{k}\mathbb{I}\big(\,\sigma_i(j_{i,\ell''})$$
$$\le \min\{\sigma_i(j_{i,\ell}),\sigma_i(j_{i,\ell'})\}\big).$$

Define

$$\chi_{i,\ell,\ell',\ell''} \ \equiv\ \mathbb{I}\big(\,\sigma_i(j_{i,\ell''}) \le \min\{\sigma_i(j_{i,\ell}),\sigma_i(j_{i,\ell'})\}\,\big)\,, \tag{146}$$

and let

$$H(\Delta)\ \equiv\ \frac{e^{-2\alpha}}{2\,k^3\,d_1}\sum_{i=1}^{d_1}\sum_{\ell,\ell'=1}^{k}\langle\!\langle\Delta, e_{i,j_{i,\ell}}-e_{i,j_{i,\ell'}}\rangle\!\rangle^2\sum_{\ell''=1}^{k}\chi_{i,\ell,\ell',\ell''}.$$

Then we have $\mathrm{Vec}^T(\Delta)\nabla^2\mathcal{L}(\Theta)\mathrm{Vec}(\Delta) \ge H(\Delta)$. To prove the theorem, it suffices to bound $H(\Delta)$ from the below. First, we prove a lower bound on the expectation $\mathbb{E}[H(\Delta)]$. Notice that for $\ell \ne \ell'$, the conditional expectation of $\chi_{i,\ell,\ell',\ell''}$'s, given the set of alternatives presented to user i is

$$\mathbb{E}\Big[\sum_{\ell''=1}^{k}\chi_{i,\ell,\ell',\ell''}\,\Big|\,j_{i,1},\ldots,j_{i,k}\Big] = 1+\sum_{\ell''\ne\ell,\ell'}\frac{\exp(\theta_{i,j_{i,\ell''}})}{\exp(\theta_{i,j_{i,\ell''}})+\exp(\theta_{i,j_{i,\ell'}})+\exp(\theta_{i,j_{i,\ell}})}$$
$$\ge 1+\frac{k-2}{1+2e^{2\alpha}} \ge \frac{k}{3e^{2\alpha}}.$$

Then,

$$\mathbb{E}[H(\Delta)] = \frac{e^{-2\alpha}}{2\,k^3\,d_1}\sum_{i,\ell,\ell'}\mathbb{E}\Big[\langle\!\langle\Delta, e_{i,j_{i,\ell}}-e_{i,j_{i,\ell'}}\rangle\!\rangle^2\mathbb{E}\big[\sum_{\ell''=1}^{k}\chi_{i,\ell,\ell',\ell''}\,\big|\,j_{i,1},\ldots,j_{i,k}\big]\Big]$$
$$\ge \frac{e^{-4\alpha}}{6\,k^2\,d_1}\sum_{i=1}^{d_1}\sum_{\ell,\ell'\in[k]}\mathbb{E}\left[\langle\!\langle\Delta, e_{i,j_{i,\ell}}-e_{i,j_{i,\ell'}}\rangle\!\rangle^2\right]$$
$$= \frac{e^{-4\alpha}}{6\,k^2\,d_1}\sum_{i=1}^{d_1}\sum_{\ell\ne\ell'\in[k]}\left(\frac{2}{d_2}\sum_{j=1}^{d_2}\Delta_{ij}^2 - \frac{2}{d_2^2}\sum_{j,j'=1}^{d_2}\Delta_{ij}\Delta_{ij'}\right)$$
$$= \frac{e^{-4\alpha}(k-1)}{3\,k\,d_1\,d_2}|||\Delta|||_{\mathrm{F}}^2\,, \tag{147}$$

where the last equality holds because $\sum_{j\in[d_2]}\Delta_{ij}=0$ for $\Delta\in\Omega_{2\alpha}$ and for all $i\in[d_1]$.

We are left to prove that $H(\Delta)$ cannot deviate from its mean too much. Suppose there exists a $\Delta\in\mathcal{A}$ such that Eq. (137) is violated, i.e. $H(\Delta)<(e^{-4\alpha}/(24\,d_1d_2))|||\Delta|||_{\rm F}^2$. We will show this happens with a small probability. From Eq. (147), we get that for $k\geq 24$,

$$\begin{aligned}\mathbb{E}[H(\Delta)]-H(\Delta) &\geq \frac{(7k-8)}{24k}\frac{e^{-4\alpha}}{d_1\,d_2}|||\Delta|||_{\rm F}^2\\ &\geq \frac{(20/3)\,e^{-4\alpha}}{24\,d_1d_2}|||\Delta|||_{\rm F}^2\,. \end{aligned}\tag{148}$$

We use a peeling argument as in (Negahban and Wainwright, 2012, Lemma 3), Van De Geer (2000) to upper bound the probability that Eq. (148) is true. We first construct the following family of subsets to cover $\mathcal{A}$ such that $\mathcal{A}\subseteq\bigcup_{\ell=1}^{\infty}\mathcal{S}_\ell$. Recall $\mu=2^{10}e^{2\alpha}\alpha d_2\sqrt{(d_1\log d)/(k\min\{d_1,d_2\})}$, define in (139). Notice that since for any $\Delta\in\mathcal{A}$, $|||\Delta|||_{\rm F}^2\geq\mu|||\Delta|||_{\rm nuc}\geq\mu|||\Delta|||_{\rm F}$, it follows that $|||\Delta|||_{\rm F}\geq\mu$. Then, we can cover $\mathcal{A}$ with the family of sets

$$\mathcal{S}_\ell=\Big\{\Delta\in\mathbb{R}^{d_1\times d_2}\,\Big|\,|||\Delta|||_\infty\leq 2\alpha\,,\,\beta^{\ell-1}\mu\leq|||\Delta|||_{\rm F}\leq\beta^\ell\mu\,,\\ \sum_{j\in[d_2]}\Delta_{ij}=0\text{ for all }i\in[d_1],\text{ and }|||\Delta|||_{\rm nuc}\leq\beta^{2\ell}\mu\Big\}\,,$$

where $\beta=\sqrt{10/9}$ and for $\ell\in\{1,2,3,\ldots\}$. This implies that when there exists a $\Delta\in\mathcal{A}$ such that (148) holds, then there exists an $\ell\in\mathbb{Z}_+$ such that $\Delta\in\mathcal{S}_\ell$ and

$$\begin{aligned}\mathbb{E}[H(\Delta)]-H(\Delta) &\geq \frac{(20/3)\,e^{-4\alpha}}{24\,d_1d_2}\beta^{2(\ell-1)}\mu^2\\ &\geq \frac{e^{-4\alpha}}{4\,d_1d_2}\beta^{2\ell}\mu^2\,.\end{aligned}\tag{149}$$

Applying the union bound over $\ell\in\mathbb{Z}_+$, we get from (148) and (149) that

$$\begin{aligned}&\mathbb{P}\Big\{\exists\Delta\in\mathcal{A}\,,\;H(\Delta)<\frac{e^{-4\alpha}}{24\,d_1d_2}|||\Delta|||_{\rm F}^2\Big\}\\ &\leq\sum_{\ell=1}^{\infty}\mathbb{P}\Big\{\sup_{\Delta\in\mathcal{S}_\ell}\big(\,\mathbb{E}[H(\Delta)]-H(\Delta)\,\big)>\frac{e^{-4\alpha}}{4\,d_1d_2}(\beta^\ell\mu)^2\Big\}\\ &\leq\sum_{\ell=1}^{\infty}\mathbb{P}\Big\{\sup_{\Delta\in\mathcal{B}(\beta^\ell\mu)}\big(\,\mathbb{E}[H(\Delta)]-H(\Delta)\,\big)>\frac{e^{-4\alpha}}{4\,d_1d_2}(\beta^\ell\mu)^2\Big\}\,,\end{aligned}\tag{150}$$

where we define a new set $\mathcal{B}(D)$ such that $\mathcal{S}_\ell\subseteq\mathcal{B}(\beta^\ell\mu)$:

$$\mathcal{B}(D)=\big\{\,\Delta\in\mathbb{R}^{d_1\times d_2}\,\big|\,|||\Delta|||_\infty\leq 2\alpha,|||\Delta|||_{\rm F}\leq D,\\ \sum_{j\in[d_2]}\Delta_{ij}=0\text{ for all }i\in[d_1],\mu|||\Delta|||_{\rm nuc}\leq D^2\,\big\}\,.\tag{151}$$

The following key lemma provides the upper bound on this probability.

Lemma 32 *For* $(16\min\{d_1,d_2\}\log d)/(3d_1)\leq k\leq d_1^2\log d$,

$$\mathbb{P}\Big\{\sup_{\Delta\in\mathcal{B}(D)}\big(\,\mathbb{E}[H(\Delta)]-H(\Delta)\,\big)\geq\frac{e^{-4\alpha}}{4d_1d_2}D^2\Big\}\;\leq\;\exp\Big\{-\frac{e^{-4\alpha}\,k\,D^4}{2^{19}\alpha^4d_1d_2^2}\Big\}\,.\tag{152}$$

Let $\eta=\exp\Big(-\frac{e^{-4\alpha}4k(\beta-1.002)\mu^4}{2^{19}\alpha^4d_1d_2^2}\Big)$. Applying the tail bound to (150), we get

$$\begin{aligned}\mathbb{P}\Big\{\exists\Delta\in\mathcal{A}\,,\;H(\Delta)<\frac{e^{-4\alpha}}{24\,d_1d_2}|||\Delta|||_{\rm F}^2\Big\} &\leq \sum_{\ell=1}^{\infty}\exp\Big\{-\frac{e^{-4\alpha}k(\beta^\ell\mu)^4}{2^{19}\alpha^4d_1d_2^2}\Big\}\\ &\overset{(a)}{\leq}\sum_{\ell=1}^{\infty}\exp\Big\{-\frac{e^{-4\alpha}4k\ell(\beta-1.002)\mu^4}{2^{19}\alpha^4d_1d_2^2}\Big\}\\ &\leq\frac{\eta}{1-\eta},\end{aligned}$$

where (a) holds because $\beta^x\geq x\log\beta\geq x(\beta-1.002)$ for the choice of $\beta=\sqrt{10/9}$. By the definition of μ,

$$\eta\;=\;\exp\Big\{-\frac{2^{23}\,e^{4\alpha}d_2^2d_1(\log d)^2(\beta-1.002)}{k(\min\{d_1,d_2\})^2}\Big\}\;\leq\;\exp\{-2^{18}\,\log d\}\,,$$

where the last inequality follows from the assumption that $k\leq\max\{d_1,d_2^2/d_1\}\log d=(d_2^2d_1\log d)/(\min\{d_1,d_2\})^2$, and $\beta-1.002\geq 2^{-5}$. Since for $d\geq 2$, $\exp\{-2^{18}\log d\}\leq 1/2$ and thus $\eta\leq 1/2$, the lemma follows by assembling the last two displayed inequalities.

C.4 Proof of Lemma 32

Recall that

$$H(\Delta)=\frac{e^{-2\alpha}}{2\,k^3\,d_1}\sum_{i=1}^{d_1}\sum_{\ell,\ell'=1}^{k}\langle\!\langle\Delta,e_{i,j_{i,\ell}}-e_{i,j_{i,\ell'}}\rangle\!\rangle^2\sum_{\ell''=1}^{k}\chi_{i,\ell,\ell',\ell''}\,,$$

with $\chi_{i,\ell,\ell',\ell''}=\mathbb{I}\Big(\sigma_i(j_{i,\ell''})\leq\min\{\sigma_i(j_{i,\ell}),\sigma_i(j_{i,\ell'})\}\Big)$. Let $Z=\sup_{\Delta\in\mathcal{B}(D)}\mathbb{E}[H(\Delta)]-H(\Delta)$ be the worst-case random deviation of $H(\Delta)$ form its mean. We prove an upper bound on Z by showing that $Z-\mathbb{E}[Z]\leq e^{-4\alpha}D^2/(64d_1d_2)$ with high probability, and $\mathbb{E}[Z]\leq 9e^{-4\alpha}D^2/(40d_1d_2)$. This proves the desired claim in Lemma 32.

To prove the concentration of Z, we utilize the random utility model (RUM) theoretic interpretation of the MNL model. The random variable Z depends on the random choice of alternatives $\{j_{i,\ell}\}_{i\in[d_1],\ell\in[k]}$ and the random k-wise ranking outcomes $\{\sigma_i\}_{i\in[d_1]}$. The random utility theory, pioneered by Thurstone (1927); Marschak (1960); Luce (1959), tells us that the k-wise ranking from the MNL model has the same distribution as first drawing independent (unobserved) utilities $u_{i,\ell}$'s of the item $j_{i,\ell}$ for user i according to the standard Gumbel Cumulative Distribution Function (CDF) $F(c-\Theta_{i,j_{i,\ell}})$ with $F(c)=e^{-e^{-c}}$, and then ranking the k items for user i according to their respective utilities. Given this definition of the MNL model, we have $\chi_{i,\ell,\ell',\ell''}=\mathbb{I}\Big(u_{i,\ell''}\geq\max\{u_{i,\ell},u_{i,\ell'}\}\Big)$. Thus Z is a function of independent

choices of the items and their (unobserved) utilities, i.e. $Z = f(\{(j_{i,\ell}, u_{i,\ell})\}_{i\in[d_1],\ell\in[k]})$. Let $x_{i,\ell} = (j_{i,\ell}, u_{i,\ell})$ and write $H(\Delta)$ as $H(\Delta, \{x_{i,\ell}\}_{i\in[d_1],\ell\in[k]})$. This allows us to bound the difference and apply McDiarmid's tail bound. Note that for any $i \in [d_1]$, $\ell \in [k]$, $x_{1,1}, \ldots, x_{d_1,k}$, and $x'_{i,\ell}$,

$$
\begin{aligned}
&\left| f\big(x_{1,1}, \ldots, x_{i,\ell}, \ldots, x_{d_1,k}\big) - f\big(x_{1,1}, \ldots, x'_{i,\ell}, \ldots, x_{d_1,k}\big) \right| \\
&= \Big| \sup_{\Delta\in\mathcal{B}(D)} \big(\mathbb{E}\left[H(\Delta)\right] - H(\Delta, x_{1,1}, \ldots, x_{i,\ell}, \ldots, x_{d_1,k})\big) - \\
&\sup_{\Delta\in\mathcal{B}(D)} \big(\mathbb{E}\left[H(\Delta)\right] - H(\Delta, x_{1,1}, \ldots, x'_{i,\ell}, \ldots, x_{d_1,k})\big) \Big| \\
&\le \sup_{\Delta\in\mathcal{B}(D)} \left|H(\Delta, x_{1,1}, \ldots, x_{i,\ell}, \ldots, x_{d_1,k}) - H(\Delta, x_{1,1}, \ldots, x'_{i,\ell}, \ldots, x_{d_1,k})\right| \\
&\overset{(a)}{\le} \frac{e^{-2\alpha}}{2\,k^3\,d_1} \sup_{\Delta\in\mathcal{B}(D)} \Big\{ 2 \sum_{\ell'\in[k]} \langle\!\langle \Delta, e_{i,j_{i,\ell}} - e_{i,j_{i,\ell'}} \rangle\!\rangle^2 \sum_{\ell''=1}^{k} \chi_{i,\ell,\ell',\ell''} + \\
&\sum_{\ell',\ell''\in[k]} \langle\!\langle \Delta, e_{i,j_{i,\ell'}} - e_{i,j_{i,\ell''}} \rangle\!\rangle^2 \chi_{i,\ell',\ell'',\ell} \Big\} \\
&\overset{(b)}{\le} \frac{8\alpha^2 e^{-2\alpha}}{k^3\,d_1} \Big\{ 2 \sum_{\ell'\in[k]\setminus\{\ell\}} \sum_{\ell''=1}^{k} \chi_{i,\ell,\ell',\ell''} + \sum_{\ell',\ell''\in[k],\ell'\neq\ell''} \chi_{i,\ell',\ell'',\ell} \Big\} \\
&\le \frac{16\alpha^2 e^{-2\alpha}}{k\,d_1} \,,
\end{aligned}
$$

where (a) follows because for a fixed i and ℓ, the random variable $x_{i,\ell} = (j_{i,\ell}, u_{i,\ell})$ can appear in three terms, i.e. $\sum_{\ell',\ell''} \langle\!\langle \Delta, e_{i,j_{i,\ell}} - e_{i,j_{i,\ell'}} \rangle\!\rangle^2 \chi_{i,\ell,\ell',\ell''} + \sum_{\ell',\ell''} \langle\!\langle \Delta, e_{i,j_{i,\ell'}} - e_{i,j_{i,\ell}} \rangle\!\rangle^2 \chi_{i,\ell',\ell,\ell''} + \sum_{\ell',\ell''} \langle\!\langle \Delta, e_{i,j_{i,\ell'}} - e_{i,j_{i,\ell''}} \rangle\!\rangle^2 \chi_{i,\ell',\ell'',\ell}$, and (b) follows because $|\Delta_{ij}| \le 2\alpha$ for all i, j since $\Delta \in \mathcal{B}(D)$. The last inequality follows because in the worst case, $\sum_{\ell'\in[k]\setminus\{\ell\}} \sum_{\ell''=1}^{k} \chi_{i,\ell,\ell',\ell''} \le k(k-1)/2$ and $\sum_{\ell',\ell''\in[k],\ell'\neq\ell''} \chi_{i,\ell',\ell'',\ell} \le k(k-1)$. This holds with equality if $\sigma_i(j_{i,\ell}) = k$ and $\sigma_i(j_{i,\ell}) = 1$, respectively. By bounded differences inequality, we have

$$
\mathbb{P}\left\{Z - \mathbb{E}\left[Z\right] \ge t\right\} \le \exp\left(-\frac{k^2\,d_1^2\,t^2}{2^7\,\alpha^4 e^{-4\alpha} d_1 k}\right),
$$

It follows that for the choice of $t = e^{-4\alpha} D^2/(64 d_1 d_2)$,

$$
\mathbb{P}\left\{Z - \mathbb{E}\left[Z\right] \ge \frac{e^{-4\alpha} D^2}{64 d_1 d_2}\right\} \le \exp\Big(-\frac{e^{-4\alpha} k D^4}{2^{19}\alpha^4 d_1 d_2^2}\Big)\,.
$$

We are left to prove the upper bound on $\mathbb{E}[Z]$ using symmetrization and contraction. Define random variables

$$
Y_{i,\ell,\ell',\ell''}(\Delta) \;\equiv\; (\Delta_{i,j_{i,\ell}} - \Delta_{i,j_{i,\ell'}})^2 \chi_{i,\ell,\ell',\ell''}\,, \tag{153}
$$

where the randomness is in the choice of alternatives $j_{i,\ell}, j_{i,\ell'}$, and $j_{i,\ell''}$, and the outcome of the comparisons of those three alternatives.

The main challenge in applying the symmetrization to $\sum_{\ell,\ell',\ell''\in[k]} Y_{i,\ell,\ell',\ell''}(\Delta)$ is that we need to partition the summation over the set $[k] \times [k] \times [k]$ into subsets of independent random variables, such that we can apply the standard symmetrization argument. To this end, we prove in the following lemma a generalization of the well-known problem of scheduling a round robin tournament to a tournament of matches involving three teams each. No teams are present in more than one triple in a single round, and we want to minimize the number of rounds to cover all combination of triples are matched. For example, when there are $k = 6$ teams, there is a simple construction of such a tournament: $T_1 = \{(1,2,3),(4,5,6)\}$, $T_2 = \{1,2,4),(3,5,6)\}$, $T_3 = \{(1,2,5),(3,4,6)\}$, $T_4 = \{(1,2,6),(3,4,5)\}$, $T_5 = \{(1,3,4),(2,5,6)\}$, $T_6 = \{(1,3,5),(2,4,6)\}$, $T_7 = \{(1,3,6),(2,4,5)\}$, $T_8 = \{(1,4,5),(2,3,6)\}$, $T_9 = \{(1,4,6),(2,3,5)\}$, $T_{10} = \{(1,5,6),(2,3,4)\}$. This is a perfect scheduling of a tournament with three teams in each match. For a general k, the following lemma provides a construction with $O(k^2)$ rounds.

Lemma 33 *There exists a partition $(T_1, \ldots, T_N)$ of $[k] \times [k] \times [k]$ for some $N \le 24k^2$ such that T_a's are disjoint subsets of $[k] \times [k] \times [k]$, $\bigcup_{a\in[N]} T_a = [k] \times [k] \times [k]$, $|T_a| \le \lfloor k/3 \rfloor$ and for any $a \in [N]$ the set of random variables in T_a satisfy*

$$
\{Y_{i,\ell,\ell',\ell''}\}_{i\in[d_1],(\ell,\ell',\ell'')\in T_a} \text{ are mutually independent } .
$$

Now, we are ready to partition the summation.

$$
\begin{aligned}
\mathbb{E}\big[Z\big] &= \frac{e^{-2\alpha}}{2\,k^3\,d_1} \mathbb{E}\Big[\sup_{\Delta\in\mathcal{B}(D)} \sum_{i\in[d_1]} \sum_{\ell,\ell',\ell''\in[k]} \big\{\mathbb{E}[Y_{i,\ell,\ell',\ell''}(\Delta)] - Y_{i,\ell,\ell',\ell''}(\Delta)\big\}\Big] \\
&= \frac{e^{-2\alpha}}{2\,k^3\,d_1} \mathbb{E}\Big[\sup_{\Delta\in\mathcal{B}(D)} \sum_{i\in[d_1]} \sum_{a\in[N]} \sum_{(\ell,\ell',\ell'')\in T_a} \big\{\mathbb{E}[Y_{i,\ell,\ell',\ell''}(\Delta)] - Y_{i,\ell,\ell',\ell''}(\Delta)\big\}\Big] \\
&\le \frac{e^{-2\alpha}}{2\,k^3\,d_1} \sum_{a\in[N]} \mathbb{E}\Big[\sup_{\Delta\in\mathcal{B}(D)} \sum_{i\in[d_1]} \sum_{(\ell,\ell',\ell'')\in T_a} \big\{\mathbb{E}[Y_{i,\ell,\ell',\ell''}(\Delta)] - Y_{i,\ell,\ell',\ell''}(\Delta)\big\}\Big] \\
&\le \frac{e^{-2\alpha}}{k^3\,d_1} \sum_{a\in[N]} \mathbb{E}\Big[\sup_{\Delta\in\mathcal{B}(D)} \sum_{i\in[d_1]} \sum_{(\ell,\ell',\ell'')\in T_a} \xi_{i,\ell,\ell',\ell''} Y_{i,\ell,\ell',\ell''}(\Delta)\Big] \\
&= \frac{e^{-2\alpha}}{k^3\,d_1} \sum_{a\in[N]} \mathbb{E}\Big[\sup_{\Delta\in\mathcal{B}(D)} \sum_{i\in[d_1]} \sum_{(\ell,\ell',\ell'')\in T_a} \xi_{i,\ell,\ell',\ell''} (\Delta_{i,j_{i,\ell}} - \Delta_{i,j_{i,\ell'}})^2 \chi_{i,\ell,\ell',\ell''}\Big]\,, \qquad (154)
\end{aligned}
$$

where the first inequality follows from the fact that sum of the supremum is no less than the supremum of the sum, and the second inequality follows from standard symmetrization argument applied to independent random variables $\{Y_{i,\ell,\ell',\ell''}(\Delta)\}_{i\in[d_1],(\ell,\ell',\ell'')\in T_a}$ with i.i.d. Rademacher random variables $\xi_{i,\ell,\ell',\ell''}$'s. Since $(\Delta_{i,j_{i,\ell}} - \Delta_{i,j_{i,\ell'}})^2 \chi_{i,\ell,\ell',\ell''} \le 4\alpha |\Delta_{i,j_{i,\ell}} - \Delta_{i,j_{i,\ell'}}| \chi_{i,\ell,\ell',\ell''}$, we have by the Ledoux-Talagrand contraction inequality Ledoux and Tala-

grand (2013) that

$$\mathbb{E}\Big[\sup_{\Delta\in\mathcal{B}(D)}\sum_{i\in[d_1]}\sum_{(\ell,\ell',\ell'')\in T_a}\xi_{i,\ell,\ell',\ell''}(\Delta_{i,j_{i,\ell}}-\Delta_{i,j_{i,\ell'}})^2\chi_{i,\ell,\ell',\ell''}\Big]$$
$$\le\ 8\alpha\mathbb{E}\Big[\sup_{\Delta\in\mathcal{B}(D)}\sum_{i\in[d_1]}\sum_{(\ell,\ell',\ell'')\in T_a}\xi_{i,\ell,\ell',\ell''}\,\chi_{i,\ell,\ell',\ell''}\,\langle\!\langle\Delta,e_i(e_{j_{i,\ell}}-e_{j_{i,\ell'}})^T\rangle\!\rangle\Big] \tag{155}$$

Applying Hölder's inequality, we get that

$$\Big|\sum_{i\in[d_1]}\sum_{(\ell,\ell',\ell'')\in T_a}\xi_{i,\ell,\ell',\ell''}\,\chi_{i,\ell,\ell',\ell''}\,\langle\!\langle\Delta,e_i(e_{j_{i,\ell}}-e_{j_{i,\ell'}})^T\rangle\!\rangle\Big|$$
$$\le\ |||\Delta|||_{\rm nuc}\left|\left|\left|\sum_{i\in[d_1]}\sum_{(\ell,\ell',\ell'')\in T_a}\xi_{i,\ell,\ell',\ell''}\,\chi_{i,\ell,\ell',\ell''}\left(e_i(e_{j_{i,\ell}}-e_{j_{i,\ell'}})^T\right)\right|\right|\right|_2. \tag{156}$$

We are left to prove that the expected value of the right-hand side of the above inequality is bounded by $C|||\Delta|||_{\rm nuc}\sqrt{kd_1\log d/\min\{d_1,d_2\}}$ for some numerical constant C. For $i\in[d_1]$ and $(\ell,\ell',\ell'')\in T_a$, let $W_{i,\ell,\ell',\ell''}=\xi_{i,\ell,\ell',\ell''}\,\chi_{i,\ell,\ell',\ell''}\left(e_i(e_{j_{i,\ell}}-e_{j_{i,\ell'}})^T\right)$ be independent zero-mean random matrices, such that

$$|||W_{i,\ell,\ell',\ell''}|||_2=\left|\left|\left|\xi_{i,\ell,\ell',\ell''}\,\chi_{i,\ell,\ell',\ell''}\left(e_i(e_{j_{i,\ell}}-e_{j_{i,\ell'}})^T\right)\right|\right|\right|_2\le\sqrt{2}\,,$$

almost surely, and

$$\begin{aligned}\mathbb{E}[W_{i,\ell,\ell',\ell''}W_{i,\ell,\ell',\ell''}^T]&=\mathbb{E}[\big(e_i(e_{j_{i,\ell}}-e_{j_{i,\ell'}})^T(e_{j_{i,\ell}}-e_{j_{i,\ell'}})e_i^T\big)\chi_{i,\ell,\ell',\ell''}]\\&=2\mathbb{E}\left[\chi_{i,\ell,\ell',\ell''}\right]e_ie_i^T\\&\preceq 2e_ie_i^T\,,\end{aligned}$$

and

$$\begin{aligned}\mathbb{E}[W_{i,\ell,\ell',\ell''}^TW_{i,\ell,\ell',\ell''}]&=\mathbb{E}[\big((e_{j_{i,\ell}}-e_{j_{i,\ell'}})e_i^Te_i(e_{j_{i,\ell}}-e_{j_{i,\ell'}})^T\big)\chi_{i,\ell,\ell',\ell''}]\\&\preceq\mathbb{E}[(e_{j_{i,\ell}}-e_{j_{i,\ell'}})e_i^Te_i(e_{j_{i,\ell}}-e_{j_{i,\ell'}})^T]\\&=\frac{2}{d_2}\mathbf{I}_{d_2\times d_2}-\frac{2}{d_2^2}\mathbb{1}\mathbb{1}^T\,.\end{aligned}$$

This gives

$$\begin{aligned}\sigma^2&=\max\left\{\left|\left|\left|\sum_{\substack{i\in[d_1]\\(\ell,\ell',\ell'')\in T_a}}\mathbb{E}[W_{i,\ell,\ell',\ell''}W_{i,\ell,\ell',\ell''}^T]\right|\right|\right|_2,\left|\left|\left|\sum_{\substack{i\in[d_1]\\(\ell,\ell',\ell'')\in T_a}}\mathbb{E}[W_{i,\ell,\ell',\ell''}^TW_{i,\ell,\ell',\ell''}]\right|\right|\right|_2\right\}\\&\le\max\left\{2|T_a|\,,\frac{2d_1|T_a|}{d_2}\right\}=\frac{2d_1|T_a|}{\min\{d_1,d_2\}}\le\frac{2d_1k}{3\min\{d_1,d_2\}}\,,\end{aligned}$$

since we have designed T_a's such that $|T_a|\le k/3$. Applying matrix Bernstein inequality Tropp (2011) yields the tail bound

$$\mathbb{P}\left\{\left|\left|\left|\sum_{i\in[d_1]}\sum_{(\ell,\ell',\ell'')\in T_a}W_{i,\ell,\ell',\ell''}\right|\right|\right|_2\ge t\right\}\ \le\ (d_1+d_2)\exp\Big(\frac{-t^2/2}{\sigma^2+\sqrt{2}t/3}\Big)\,.$$

Choosing $t=\max\big\{\sqrt{32kd_1\log d/(3\min\{d_1,d_2\})},(16\sqrt{2}/3)\log d\big\}$, we obtain with probability at least $1-2d^{-3}$,

$$\left|\left|\left|\sum_{i\in[d_1]}\sum_{(\ell,\ell',\ell'')\in T_a}W_{i,\ell,\ell',\ell''}\right|\right|\right|_2\ \le\ \max\left\{\sqrt{\frac{32kd_1\log d}{3\min\{d_1,d_2\}}},\frac{16\sqrt{2}\log d}{3}\right\}\,.$$

It follows from the fact $\left|\left|\left|\sum_{i\in[d_1]}\sum_{(\ell,\ell',\ell'')\in T_a}W_{i,\ell,\ell',\ell''}\right|\right|\right|_2\le\sum_{i,(\ell,\ell',\ell'')}|||W_{i,\ell,\ell',\ell''}|||_2\le\frac{\sqrt{2}d_1k}{3}$ that

$$\begin{aligned}\mathbb{E}\left[\left|\left|\left|\sum_{i\in[d_1]}\sum_{(\ell,\ell',\ell'')\in T_a}W_{i,\ell,\ell',\ell''}\right|\right|\right|_2\right]&\le\max\left\{\sqrt{\frac{32kd_1\log d}{3\min\{d_1,d_2\}}},\frac{16\sqrt{2}\log d}{3}\right\}+\frac{2\sqrt{2}d_1k}{3d^3}\\&\le 2\sqrt{\frac{32kd_1\log d}{3\min\{d_1,d_2\}}}\,,\end{aligned}$$

where the last inequality follows from the assumption that $(16\min\{d_1,d_2\}\log d)/(3d_1)\le k\le d_1^2\log d$. Substituting this in the RHS of Eq. (156), and then together with Eqs. (155) and (154), this gives the following desired bound:

$$\begin{aligned}\mathbb{E}[Z]&\le\sum_{a\in[N]}\sup_{\Delta\in\mathcal{B}(D)}\frac{16\alpha e^{-2\alpha}}{k^3\,d_1}\sqrt{\frac{32kd_1\log d}{3\min\{d_1,d_2\}}}|||\Delta|||_{\rm nuc}\\&\le\sum_{a\in[N]}\frac{e^{-4\alpha}\sqrt{2}}{16\sqrt{3}k^2\,d_1\,d_2}\underbrace{\left(2^{10}e^{2\alpha}\alpha d_2\sqrt{\frac{d_1\log d}{k\min\{d_1,d_2\}}}\right)}_{=\mu}|||\Delta|||_{\rm nuc}\\&\le\frac{9e^{-4\alpha}D^2}{40d_1d_2}\,,\end{aligned}$$

where the last inequality holds because $N\le 4k^2$ and $\mu|||\Delta|||_{\rm nuc}\le D^2$.

C.5 Proof of Lemma 33

Recall that $Y_{i,\ell,\ell',\ell''}(\Delta)=(\Delta_{i,j_{i,\ell}}-\Delta_{i,j_{i,\ell'}})^2\chi_{i,\ell,\ell',\ell''}$, as defined in (153). From the random utility model (RUM) interpretation of the MNL model presented in Section 1, it is not difficult to show that $Y_{i,\ell,\ell',\ell''}$ and $Y_{i,\tilde{\ell},\tilde{\ell}',\tilde{\ell}''}$ are mutually independent if the two triples (ℓ,ℓ',ℓ'') and $(\tilde{\ell},\tilde{\ell}',\tilde{\ell}'')$ do not overlap, i.e., no index is present in both triples.

Now, borrowing the terminologies from round robin tournaments, we construct a schedule for a tournament with k teams where each match involve three teams. Let $T_{a,b}$ denote

a set of triples playing at the same round, indexed by two integers $a \in \{3, \ldots, 2k-3\}$ and $b \in \{5, \ldots, 2k-1\}$. Hence, there are total $N = (2k-5)^2$ rounds.

Each round (a, b) consists of disjoint triples and is defined as

$$T_{a,b} \equiv \left\{(\ell, \ell', \ell'') \in [k] \times [k] \times [k] \,|\, \ell < \ell' < \ell'', \ell + \ell' = a, \text{ and } \ell' + \ell'' = b\right\}.$$

We need to prove that (a) there is no missing triple; and (b) no team plays twice in a single round. First, for any ordered triple (ℓ, ℓ', ℓ''), there exists $a \in \{3, \ldots, 2k-3\}$ and $b \in \{5, \ldots, 2k-1\}$ such that $\ell + \ell' = a$ and $\ell' + \ell'' = b$. This proves that all ordered triples are covered by the above construction. Next, given a pair (a, b), no two triples in $T_{a,b}$ can share the same team. Suppose there exists two distinct ordered triples (ℓ, ℓ', ℓ'') and $(\tilde{\ell}, \tilde{\ell}', \tilde{\ell}'')$ both in $T_{a,b}$, and one of the triples are shared. Then, from the two equations $\ell + \ell' = \tilde{\ell} + \tilde{\ell}' = a$ and $\ell' + \ell'' = \tilde{\ell}' + \tilde{\ell}'' = b$, it follows that all three indices must be the same, which is a contradiction. This proves the desired claim for ordered triples.

One caveat is that we wanted to cover the whole $[k] \times [k] \times [k]$, and not just the ordered triples. In the above construction, for example, a triple $(3, 2, 1)$ does not appear. This can be resolved by simply taking all $T_{a,b}$'s from the above construction, and make 6 copies of each round, and permuting all the triples in each copy according to the same permutation over $\{1, 2, 3\}$. This increases the total rounds to $N = 6(2k-5)^2 \le 24k^2$. Note that $|T_{a,b}| \le \lfloor k/3 \rfloor$ since no item can be in more than one triple.

Appendix D. Proof of Estimating Approximate Low-rank Matrices in Corollary 9

We follow closely the proof of a similar corollary in Negahban and Wainwright (2012). First fix a threshold $\tau > 0$, and set $r = \max\{j | \sigma_j(\Theta^*) > \tau\}$. With this choice of r, we have

$$\sum_{j=r+1}^{\min\{d_1,d_2\}} \sigma_j(\Theta^*) \;=\; \tau \sum_{j=r+1}^{\min\{d_1,d_2\}} \frac{\sigma_j(\Theta^*)}{\tau} \;\le\; \tau \sum_{j=r+1}^{\min\{d_1,d_2\}} \Big(\frac{\sigma_j(\Theta^*)}{\tau}\Big)^q \;\le\; \tau^{1-q}\rho_q \,.$$

Also, since $r\tau^q \le \sum_{j=1}^r \sigma_j(\Theta^*)^q \le \rho_q$, it follows that $\sqrt{r} \le \sqrt{\rho_q}\tau^{-q/2}$. Using these bounds, Eq. (35) is now

$$\Big|\Big|\Big|\widehat{\Theta} - \Theta\Big|\Big|\Big|_{\mathrm{F}}^2 \;\le\; \underbrace{288\sqrt{2}c_0 e^{4\alpha} d_1 d_2 \lambda_0}_{=A} \left(\sqrt{\rho_q}\tau^{-q/2}\Big|\Big|\Big|\widehat{\Theta} - \Theta\Big|\Big|\Big|_{\mathrm{F}} + \tau^{1-q}\rho_q\right).$$

With the choice of $\tau = A$ and due to the fact that $x^2 \le bx + c$ implies $x \le (b + \sqrt{b^2 + 4c})/2$ we have,

$$\Big|\Big|\Big|\widehat{\Theta} - \Theta\Big|\Big|\Big|_{\mathrm{F}} \;\le\; 2\sqrt{\rho_q} A^{(2-q)/2} \,.$$

Appendix E. Proof of the Information-theoretic Lower Bound in Theorem 10

The proof uses information-theoretic methods which reduces the estimation problem to a multiway hypothesis testing problem. To prove a lower bound on the expected error, it

suffices to prove that,

$$\sup_{\Theta^* \in \Omega_\alpha} \mathbb{P}\left\{\Big|\Big|\Big|\widehat{\Theta} - \Theta^*\Big|\Big|\Big|_{\mathrm{F}}^2 \ge \frac{\delta^2}{4}\right\} \;\ge\; \frac{1}{2}\,. \tag{157}$$

To prove the above claim, we follow the standard recipe of constructing a packing in Ω_α. Consider a family $\{\Theta^{(1)}, \ldots, \Theta^{(M(\delta))}\}$ of $d_1 \times d_2$ dimensional matrices contained in Ω_α satisfying $\big|\big|\big|\Theta^{(\ell_1)} - \Theta^{(\ell_2)}\big|\big|\big|_{\mathrm{F}} \ge \delta$ for all $\ell_1, \ell_2, \in [M(\delta)]$. We will use M to refer to $M(\delta)$ for simplify the notation. Suppose we draw an index $L \in [M(\delta)]$ uniformly at random, and we are given direct observations σ_i as per MNL model with $\Theta^* = \Theta^{(L)}$ on a randomly chosen set of k items S_i for each user $i \in [d_1]$. It follows from triangular inequality that

$$\sup_{\Theta^* \in \Omega_\alpha} \mathbb{P}\left\{\Big|\Big|\Big|\widehat{\Theta} - \Theta^*\Big|\Big|\Big|_{\mathrm{F}}^2 \ge \frac{\delta^2}{4}\right\} \;\ge\; \mathbb{P}\left\{\widehat{L} \ne L\right\}, \tag{158}$$

where $\widehat{L}$ is the resulting best estimate of the multiway hypothesis testing on L. The generalized Fano's inequality gives

$$\begin{aligned}
\mathbb{P}\left\{\widehat{L} \ne L | S(1), \ldots, S(d_1)\right\} &\ge 1 - \frac{I(\widehat{L}; L) + \log 2}{\log M} &(159)\\
&\ge 1 - \frac{\binom{M}{2}^{-1} \sum_{\ell_1, \ell_2 \in [M]} D_{\mathrm{KL}}(\Theta^{(\ell_1)} \| \Theta^{(\ell_2)}) + \log 2}{\log M}\,, &(160)
\end{aligned}$$

where $D_{\mathrm{KL}}(\Theta^{(\ell_1)} \| \Theta^{(\ell_2)})$ denotes the Kullback-Leibler divergence between the distributions of the partial rankings $\mathbb{P}\left\{\sigma_1, \ldots, \sigma_{d_1} | \Theta^{(\ell_1)}, S(1), \ldots, S(d_1)\right\}$ and $\mathbb{P}\left\{\sigma_1, \ldots, \sigma_{d_1} | \Theta^{(\ell_2)}, S(1), \ldots, S(d_1)\right\}$. The second inequality follows from a standard technique, which we repeat here for completeness. Let $\Sigma = \{\sigma_1, \ldots, \sigma_{d_1}\}$ denote the observed outcome of comparisons. Since L–$\Theta^{(L)}$–Σ–$\widehat{L}$ form a Markov chain, the data processing inequality gives $I(\widehat{L}; L) \le I(\Sigma; L)$. For simplicity, we drop the conditioning on the set of alternatives $\{S(1), \ldots, S(d_1)\}$, and and let $p(\cdot)$ denotes joint, marginal, and conditional distribution of respective random variables. It follows that

$$\begin{aligned}
I(\Sigma; L) &= \sum_{\ell \in [M], \Sigma} p(\Sigma|\ell) \frac{1}{M} \log \frac{p(\ell, \Sigma)}{p(\ell)p(\Sigma)}\\
&= \frac{1}{M} \sum_{\ell \in [M]} \sum_{\Sigma} p(\Sigma|\ell) \log \frac{p(\Sigma|\ell)}{\frac{1}{M}\sum_{\ell'} p(\Sigma|\ell')}\\
&\le \frac{1}{M^2} \sum_{\ell, \ell' \in [M]} \sum_{\Sigma} p(\Sigma|\ell) \log \frac{p(\Sigma|\ell)}{p(\Sigma|\ell')}\\
&= \frac{1}{M^2} \sum_{\ell, \ell' \in [M]} D_{\mathrm{KL}}(\Theta^{(\ell_1)} \| \Theta^{(\ell_2)})\,, &(161)
\end{aligned}$$

where the first inequality follows from Jensen's inequality. To compute the KL-divergence, recall that from the RUM interpretation of the MNL model (see Section 1), one can generate sample rankings Σ by drawing random variables with exponential distributions with mean

$e^{\Theta^*_{ij}}$'s. Precisely, let $X^{(\ell)} = [X^{(\ell)}_{ij}]_{i\in[d_1], j\in S_i}$ denote the set of random variables, where $X^{(\ell)}_{ij}$ is drawn from the exponential distribution with mean $e^{-\Theta^{(\ell)}_{ij}}$. The MNL ranking follows by ordering the alternatives in each S_i according to this $\{X^{(\ell)}_{ij}\}_{j\in S_i}$ by ranking the smaller ones on the top. This forms a Markov chain L–$X^{(L)}$–Σ, and the standard data processing inequality gives

$$\begin{aligned} D_{\mathrm{KL}}(\Theta^{(\ell_1)}\|\Theta^{(\ell_2)}) &\leq D_{\mathrm{KL}}(X^{(\ell_1)}\|X^{(\ell_2)}) && (162)\\ &= \sum_{i\in[d_1]}\sum_{j\in S_i}\Big\{e^{\Theta^{(\ell_1)}_{ij}-\Theta^{(\ell_2)}_{ij}} - (\Theta^{(\ell_1)}_{ij}-\Theta^{(\ell_2)}_{ij}) - 1\Big\} && (163)\\ &\leq \frac{e^{2\alpha}}{4\alpha^2}\sum_{i\in[d_1]}\sum_{j\in S_i}(\Theta^{(\ell_1)}_{ij}-\Theta^{(\ell_2)}_{ij})^2\,, && (164)\end{aligned}$$

where the last inequality follows from the fact that $e^x - x - 1 \leq (e^{2\alpha}/(4\alpha^2))x^2$ for any $x \in [-2\alpha, 2\alpha]$. Taking expectation over the randomly chosen set of alternatives,

$$\mathbb{E}_{S(1),\ldots,S(d_1)}[D_{\mathrm{KL}}(\Theta^{(\ell_1)}\|\Theta^{(\ell_2)})] \;\leq\; \frac{e^{2\alpha}\,k}{4\,\alpha^2\,d_2}\Big|\Big|\Big|\Theta^{(\ell_1)}-\Theta^{(\ell_2)}\Big|\Big|\Big|^2_{\mathrm{F}}\,. \tag{165}$$

Combined with (160), we get that

$$\begin{aligned}\mathbb{P}\Big\{\widehat{L}\neq L\Big\} &= \mathbb{E}_{S(1),\ldots,S(d_1)}[\mathbb{P}\Big\{\widehat{L}\neq L|S(1),\ldots,S(d_1)\Big\}] && (166)\\ &\geq 1 - \frac{\binom{M}{2}^{-1}\sum_{\ell_1,\ell_2\in[M]}(e^{2\alpha}k/(4\alpha^2 d_2))\Big|\Big|\Big|\Theta^{(\ell_1)}-\Theta^{(\ell_2)}\Big|\Big|\Big|^2_{\mathrm{F}} + \log 2}{\log M}\,, && (167)\end{aligned}$$

The remainder of the proof relies on the following probabilistic packing.

Lemma 34 *Let $d_2 \geq d_1 \geq 607$ be positive integers. Then for each $r \in \{1,\ldots,d_1\}$, and for any positive $\delta > 0$ there exists a family of $d_1 \times d_2$ dimensional matrices $\{\Theta^{(1)},\ldots,\Theta^{(M(\delta))}\}$ with cardinality $M(\delta) = \lfloor(1/4)\exp(rd_2/576)\rfloor$ such that each matrix is rank r and the following bounds hold:*

$$\begin{aligned}\Big|\Big|\Big|\Theta^{(\ell)}\Big|\Big|\Big|_{\mathrm{F}} &\leq \delta\,,\ \textit{for all } \ell\in[M] && (168)\\ \Big|\Big|\Big|\Theta^{(\ell_1)}-\Theta^{(\ell_2)}\Big|\Big|\Big|_{\mathrm{F}} &\geq \delta\,,\ \textit{for all } \ell_1,\ell_2\in[M] && (169)\\ \Theta^{(\ell)} &\in \Omega_{\tilde{\alpha}}\,,\ \textit{for all } \ell\in[M]\,, && (170)\end{aligned}$$

with $\tilde{\alpha} = (8\delta/d_2)\sqrt{2\log d}$ for $d = (d_1+d_2)/2$.

We omit the proof of the above lemma since it is similar to that of Lemma 25. Suppose $\delta \leq \alpha d_2/(8\sqrt{2\log d})$ such that the matrices in the packing set are entry-wise bounded by α, then the above lemma implies that $\big|\big|\big|\Theta^{(\ell_1)}-\Theta^{(\ell_2)}\big|\big|\big|^2_{\mathrm{F}} \leq 4\delta^2$, which gives

$$\mathbb{P}\Big\{\widehat{L}\neq L\Big\} \;\geq\; 1 - \frac{\frac{e^{2\alpha}k\delta^2}{\alpha^2 d_2} + \log 2}{\frac{rd}{576} - 2\log 2} \;\geq\; \frac{1}{2}\,,$$

where the last inequality holds for $\delta^2 \leq (\alpha^2 d_2/(e^{2\alpha}k))((rd/1152) - 2\log 2)$. If we assume $rd \geq 3195$ for simplicity, this bound on δ can be simplified to $\delta \leq \alpha e^{-\alpha}\sqrt{r\,d_2\,d/(2304\,k)}$. Together with (157) and (158), this proves that for all $\delta \leq \min\{\alpha d_2/(8\sqrt{2\log d}),$ $\alpha e^{-\alpha}\sqrt{r\,d_2\,d/(2304\,k)}\}$,

$$\inf_{\widehat{\Theta}}\sup_{\Theta^*\in\Omega_\alpha}\mathbb{E}\Big[\Big|\Big|\Big|\widehat{\Theta}-\Theta^*\Big|\Big|\Big|_{\mathrm{F}}\Big] \;\geq\; \frac{\delta}{4}\,.$$

Choosing δ appropriately to maximize the right-hand side finishes the proof of the desired claim.

Appendix F. Proof of Pairwise Rank Breaking in Theorem 11

Analogous to Section C, we define the gradient $\nabla\mathcal{L}(\Theta)$ as $\nabla_{ij}\mathcal{L} = \frac{\partial\mathcal{L}(\Theta)}{\partial\Theta_{ij}}$ and $\Delta \equiv \hat{\Theta} - \Theta^*$, and provide two main technical lemmas.

Lemma 35 *If $\lambda \geq 2|||\nabla\mathcal{L}(\Theta^*)|||_2$, then we have,*

$$|||\Delta|||_{\mathrm{nuc}} \leq 4\sqrt{2r}|||\Delta|||_{\mathrm{F}} + 4\sum_{j=\rho+1}^{\min\{d_1,d_2\}}\sigma_j(\Theta^*)\,, \tag{171}$$

for all $\rho \in [\min\{d_1,d_2\}]$.

Proof This follows from the proof of Lemma 27, which only depends on the convexity of $\mathcal{L}(\Theta)$. ∎

Lemma 36 *For any positive constant $c \geq 1$, if $k \leq \max\{d_1, d_2^2/d_1\}\log d$ and $d_1 \geq 4$ then with probability at least $1 - 2d^{-c}$,*

$$|||\nabla\mathcal{L}(\Theta^*)|||_2 \;\leq\; \sqrt{\frac{16(c+4)\log d}{k\,d_1^2}}\max\left\{\sqrt{\max\left\{\frac{1}{4},\frac{d_1}{d_2}\right\}}\,,\ \frac{2}{3}\sqrt{\frac{2(c+4)\log d}{k}}\right\}\,. \tag{172}$$

The proof of this lemma is provided in Section F.1. We will simplify the above lemma by assuming, $2(c+4)\log d \leq k$ which implies the last term in RHS is less than equal to first term,

$$\frac{2}{3}\sqrt{\frac{2(4+c)\log d}{k}} \leq \sqrt{\frac{1}{4}}\,. \tag{173}$$

(173) simplifies (172) as,

$$\begin{aligned}|||\nabla\mathcal{L}(\Theta^*)|||_2 &\leq \sqrt{\frac{16(c+4)\log d}{k\,d_1^2}\max\left\{\frac{1}{4},\frac{d_1}{d_2}\right\}}\\ &\leq \sqrt{\frac{32d\,(c+4)\log d}{k\,d_1^2\,d_2}}\\ &\overset{(a)}{\leq} \sqrt{32(c+4)}\lambda\,, && (174)\end{aligned}$$

where (a) is due to (41) .

For Lemma 35 and further proof of Theorem11 we want $\lambda \geq 2|||\nabla \mathcal{L}(\Theta)|||_2$, therefore we assume that,

$$\lambda \in [2\sqrt{32(c+4)}\lambda, c_p\lambda], \text{ for some } c_p \geq 2\sqrt{32(c+4)} \tag{175}$$

Similar to the k-wise ranking,we will divide the proof into two cases and each part we will prove that $\|\Delta\|_{\mathrm{F}}^2 \leq 36e^{2\alpha}\, c\, \lambda\, d_1 d_2\, |||\Delta|||_{\text{nuc}}$ with probability at least $1 - 2/d^c - 2/d^{2^{13}}$. We define a new constant μ as,

$$\mu = 16\alpha\sqrt{\frac{48\, d_1 d_2^2 \log d}{k\, \min\{d_1, d_2\}}}\,. \tag{176}$$

Case 1: Assume $\mu|||\Delta|||_{\text{nuc}} \leq \|\Delta\|_{\mathrm{F}}^2$.
Since $\mathcal{L}$ is a sum of a linear function of Θ and log-sum-exponential functions, which are convex, we know that $\mathcal{L}$ is a convex function of Θ. Therefore, by convexity and Taylor expansion we get,

$$\begin{aligned}\mathcal{L}(\hat{\Theta}) = \mathcal{L}(\Theta^*) - \langle\!\langle \nabla\mathcal{L}(\Theta^*), \Delta\rangle\!\rangle \; + \\ \frac{1}{2!\; d_1\binom{k}{2}} \sum_{i=1}^{d_1} \sum_{(m_1,m_2)\in\mathcal{P}_0} \frac{e^{\Theta_{i,u_{i,m_1}}} e^{\Theta_{i,u_{i,m_2}}}}{\left(e^{\Theta_{i,u_{i,m_1}}} + e^{\Theta_{i,u_{i,m_2}}}\right)^2} \left(\Delta_{i,u_{i,m_1}} - \Delta_{i,u_{i,m_2}}\right)^2 ,\end{aligned} \tag{177}$$

where $\Theta = a\Theta^* + (1-a)\hat{\Theta}$ for some $a \in [0,1]$ and $\mathcal{P}_0 = \{(i,j)|\;\; 1 \leq i < j \leq k\}$. We lower bound the final term in (177) as,

$$\begin{aligned}&\frac{1}{2!\; d_1\binom{k}{2}} \sum_{i=1}^{d_1} \sum_{(m_1,m_2)\in\mathcal{P}_0} \frac{e^{\Theta_{i,u_{i,m_1}}} e^{\Theta_{i,u_{i,m_2}}}}{\left(e^{\Theta_{i,u_{i,m_1}}} + e^{\Theta_{i,u_{i,m_2}}}\right)^2} \left(\Delta_{i,u_{i,m_1}} - \Delta_{i,u_{i,m_2}}\right)^2 \\ &\overset{(a)}{\geq} \frac{1}{2\; d_1\binom{k}{2}} \sum_{i=1}^{d_1} \sum_{(m_1,m_2)\in\mathcal{P}_0} \frac{e^{-\alpha}e^{\alpha}}{(e^{-\alpha}+e^{\alpha})^2} \left(\Delta_{i,u_{i,m_1}} - \Delta_{i,u_{i,m_2}}\right)^2 \\ &\geq \frac{1}{2\; d_1\binom{k}{2}} \sum_{i=1}^{d_1} \sum_{(m_1,m_2)\in\mathcal{P}_0} \frac{e^{-2\alpha}}{4} \left(\Delta_{i,u_{i,m_1}} - \Delta_{i,u_{i,m_2}}\right)^2 ,\end{aligned} \tag{178}$$

where (a) is due to the fact that Δ_{ij}'s are upper and lower bounded by α and $-\alpha$ respectively. We can bound this term further according to the following Lemma.

Lemma 37 *For $(4\log d)/9 \leq k \leq \max\{d_1, d_2^2/d_1\}\log d$, with probability at least $1 - 2d^{-2^{13}}$,*

$$\frac{1}{d_1\binom{k}{2}} \sum_{i=1}^{d_1} \sum_{(m_1,m_2)\in\mathcal{P}_0} \left(\Delta_{i,u_{i,m_1}} - \Delta_{i,u_{i,m_2}}\right)^2 \geq \frac{1}{3d_1d_2}|||\Delta|||_{\mathrm{F}}^2 \,, \tag{179}$$

for all $\Delta \in \mathcal{A}_p$ where,

$$\mathcal{A} = \left\{ \Delta \in \mathbb{R}^{d_1\times d_2} \;\middle|\; |||\Delta|||_\infty \leq 2\alpha,\; \sum_{j\in[d_2]} \Delta_{ij} = 0 \text{ , for all } i \in [d_2],\; \text{and } \mu|||\Delta|||_{\text{nuc}} \leq \|\Delta\|_{\mathrm{F}}^2 \right\}. \tag{180}$$

The proof is given in Section F.2. Now using Lemma 37 and (178) with high probability we get,

$$\frac{1}{2!\; d_1\binom{k}{2}} \sum_{i=1}^{d_1} \sum_{(m_1,m_2)\in\mathcal{P}_0} \frac{e^{\Theta_{i,u_{i,m_1}}} e^{\Theta_{i,u_{i,m_2}}}}{\left(e^{\Theta_{i,u_{i,m_1}}} + e^{\Theta_{i,u_{i,m_2}}}\right)^2} \left(\Delta_{i,u_{i,m_1}} - \Delta_{i,u_{i,m_1}}\right)^2 \geq \frac{e^{-2\alpha}}{24\; d_1\; d_2}|||\Delta|||_{\mathrm{F}}^2 \,. \tag{181}$$

Incorporating the above inequality in (177) we obtain,

$$\frac{e^{-2\alpha}}{24\; d_1\; d_2}|||\Delta|||_{\mathrm{F}}^2 \leq \mathcal{L}(\hat{\Theta}) - \mathcal{L}(\Theta^*) + \langle\!\langle \nabla\mathcal{L}(\Theta^*), \Delta\rangle\!\rangle \,. \tag{182}$$

From the definition of $\hat{\Theta}$ we have $\mathcal{L}(\hat{\Theta}) - \mathcal{L}(\Theta^*) \leq \lambda\left(|||\Theta^*|||_{\text{nuc}} - \left|||\hat{\Theta}\right|||_{\text{nuc}}\right) \leq \lambda|||\Delta|||_{\text{nuc}}$, and we assume that $\lambda \geq 2\sqrt{32(c+1)}\;\lambda$, so that $\lambda \geq 2|||\nabla\mathcal{L}\,(\Theta^*)|||_2$ is true with a probability of at least $1 - 2d^{-c}$ from Lemma 36 . These give us the following with at least probability $1 - 2d^{-c} - 2d^{-2^{13}}$.

$$\begin{aligned}\frac{e^{-2\alpha}}{24\; d_1\; d_2}|||\Delta|||_{\mathrm{F}}^2 &\leq \lambda|||\Delta|||_{\text{nuc}} + |||\nabla\mathcal{L}(\Theta^*)|||_2|||\Delta|||_{\text{nuc}} \\ &\leq \frac{3\lambda}{2}|||\Delta|||_{\text{nuc}}\end{aligned} \tag{183}$$

which gives us,

$$\begin{aligned}|||\Delta|||_{\mathrm{F}}^2 &\leq 36e^{2\alpha}\;\lambda\; d_1d_2\;|||\Delta|||_{\text{nuc}} \\ &\overset{(a)}{\leq} 36e^{2\alpha}\; c_p\;\lambda\; d_1d_2\;|||\Delta|||_{\text{nuc}} \,,\end{aligned} \tag{184}$$

where (a) is due to the fact that $\lambda \leq c_p\lambda$.

Case 2: Assume $|||\Delta|||_{\mathrm{F}}^2 \leq \mu|||\Delta|||_{\text{nuc}}$.
Here we prove that $\mu \leq 36\; e^{2\alpha}\; c_p\lambda\; d_1d_2$.

$$\begin{aligned}\frac{\mu}{36\; e^{2\alpha}\; c_p\lambda\; d_1d_2} &\overset{(a)}{\leq} \frac{\alpha}{e^{2\alpha}} \times \frac{16\sqrt{48}}{72\sqrt{32(c+4)}} \times \sqrt{\frac{d_1d_2}{min\{d_1,d_2\}d}} \\ &\overset{(b)}{\leq} 1 \times \frac{16\sqrt{48}}{72\sqrt{32\times 4}} \times \sqrt{\frac{\max\{d_1,d_2\}}{d}} \\ &\overset{(c)}{\leq} \sqrt{\frac{\max\{d_1,d_2\}}{2d}} \\ &\overset{(d)}{\leq} 1 \,,\end{aligned} \tag{185}$$

where (a) is by substituting μ, λ and c_p from (176), (41) and (175) respectively, (b) is because $x \leq e^x$ (c) is because $d = (\max\{d_1,d_2\} + \min\{d_1,d_2\})/2$.

Now combining the above result with (171) we get with probability at least $1 - 2d^{-c} - 2d^{-2^{13}}$,

$$\frac{1}{d_1d_2}|||\Delta|||_{\mathrm{F}}^2 \leq 144\sqrt{2}e^{2\alpha}c_p\lambda\sqrt{r}|||\Delta|||_{\mathrm{F}} + 144e^{2\alpha}c_p\lambda \sum_{j=\rho+1}^{\min\{d_1,d_2\}} \sigma_j(\Theta^*) \,. \tag{186}$$

F.1 Proof of Lemma 36

From definition of $\mathcal{L}(\Theta)$ in (39) we get,

$$\nabla \mathcal{L}_p(\Theta^*) = \frac{1}{d_1\binom{k}{2}} \sum_{i=1}^{d_1} \sum_{(m_1,m_2)\in\mathcal{P}_0} \frac{e_i \left(e_{l_i(m_1,m_2)} - e_{h_i(m_1,m_2)}\right)^T}{\exp\left(\Theta^*_{i,h_i(m_1,m_2)} - \Theta^*_{i,l_i(m_1,m_2)}\right) + 1} , \tag{187}$$

where $\mathcal{P}_0 = \{(i,j)|\ \ 1 \le i < j \le k\}$. We use the matrix Bernstein inequality Tropp (2011) for the sum of independent matrices. Similar to Lemma 42, we can partition the set of all pairs $\mathcal{P}_0$ into $(k-1)$ sets $\{\mathcal{P}_a\}_{a\in[k-1]}$ of $k/2$ disjoint pairs each. Define $Y_a \equiv \sum_{i=1}^{d_1}\sum_{(m_1,m_2)\in\mathcal{P}_a} \tilde{X}_{i,m_1,m_2}$, and

$$\tilde{X}_{i,m_1,m_2} \ \equiv \ \frac{\exp\left(\Theta^*_{i,l_i(m_1,m_2)}\right)}{\exp\left(\Theta^*_{i,h_i(m_1,m_2)}\right) + \exp\left(\Theta^*_{i,l_i(m_1,m_2)}\right)} e_i \left(e_{l_i(m_1,m_2)} - e_{h_i(m_1,m_2)}\right)^T ,$$

such that

$$\nabla \mathcal{L}_p(\Theta^*) = \frac{1}{d_1\binom{k}{2}} \sum_{a=1}^{k-1} \tilde{Y}_a . \tag{188}$$

For a fixed value of a, it is easy to see that $\tilde{X}_{i,m_1,m_2}$'s are independent. Further, we can easily show that $\mathbb{E}\left[\tilde{X}_{i,m_1,m_2}\right] = 0$, and $\|\tilde{X}_{i,m_1,m_2}\|_2 \le \sqrt{2}$. We also have,

$$\begin{aligned}
&\mathbb{E}\left[\tilde{X}_{i,m_1,m_2}\tilde{X}^T_{i,m_1,m_2}\right] \\
&\preceq 2\, e_i e_i^T\, \mathbb{E}\left[\mathbb{E}\left[\frac{\exp\left(\Theta^*_{i,l_i(m_1,m_2)}\right)^2}{\left(\exp\left(\Theta^*_{i,u_{i,m_1}}\right) + \exp\left(\Theta^*_{i,u_{i,m_2}}\right)\right)^2}\,\middle|\, u_{i,m_1}, u_{i,m_1}\right]\right] \\
&\overset{(a)}{=} 2\, e_i e_i^T\, \mathbb{E}\left[\frac{\exp\left(\Theta^*_{iu_{i,m_1}}\right)\exp\left(\Theta^*_{iu_{i,m_2}}\right)}{\left(\exp\left(\Theta^*_{i,u_{i,m_1}}\right) + \exp\left(\Theta^*_{i,u_{i,m_2}}\right)\right)^2}\right] \\
&\overset{(b)}{\preceq} \frac{1}{2} e_i e_i^T ,
\end{aligned} \tag{189}$$

where we get (a) from the MNL model for the random choice of $l_i(m_1,m_2)$, (b) is due to the fact that $xy/(x+y)^2 \le 1/4$ for all $x, y > 0$.

Let $p_{i,m_1,m_2} \equiv \frac{\left(\exp(\Theta^*_{i,u_{i,m_1}})e_{u_{i,m_1}} + \exp(\Theta^*_{i,u_{i,m_2}})e_{u_{i,m_2}}\right)}{\left(\exp(\Theta^*_{i,u_{i,m_1}}) + \exp(\Theta^*_{i,u_{i,m_2}})\right)}$, then we have,

$$\begin{aligned}
\mathbb{E}\left[\tilde{X}^T_{i,m_1,m_2}\tilde{X}_{i,m_1,m_2}\right] &= \mathbb{E}\left[(e_{h_i(m_1,m_2)} - p_{i,m_1,m_2})(e_{h_i(m_1,m_2)} - p_{i,m_1,m_2})^T\right] \\
&= \mathbb{E}\left[e_{h_i(m_1,m_2)}e^T_{h_i(m_1,m_2)}\right] - \mathbb{E}\left[p_{i,m_1,m_2}p^T_{i,m_1,m_2}\right] \\
&\overset{(a)}{\preceq} \mathbb{E}\left[e_{u_{i,m_1}}e^T_{u_{i,m_1}} + e_{u_{i,m_2}}e^T_{u_{i,m_2}}\right] \\
&= \frac{2}{d_2}\mathbf{I}_{d_2\times d_2} ,
\end{aligned} \tag{190}$$

where (a) comes from the fact that $p_{i,m_1,m_2}p^T_{i,m_1,m_2}$ is a positive semi-definite matrix. Therefore using (189) and (190), we get

$$\begin{aligned}
\sigma^2 &\equiv \left\{ \left\| \sum_{\substack{i\in[d_1]\\(m_1,m_2)\in\mathcal{P}_a}} \mathbb{E}\left[\tilde{X}_{i,m_1,m_2}\tilde{X}^T_{i,m_1,m_2}\right] \right\|_2 , \left\| \sum_{\substack{i\in[d_1]\\(m_1,m_2)\in\mathcal{P}_a}} \mathbb{E}\left[\tilde{X}^T_{i,m_1,m_2}\tilde{X}_{i,m_1,m_2}\right] \right\|_2 \right\} \\
&\le k \max\left\{\frac{1}{4}, \frac{d_1}{d_2}\right\} .
\end{aligned} \tag{191}$$

Define $\rho \equiv \max\{1/4, d_1/d_2\}$, then by the matrix Bernstein inequality Tropp (2011), $\forall\ a \in [k-1]$,

$$\mathbb{P}\Big(\left\|\tilde{Y}_a\right\|_2 > t\Big) \le (d_1+d_2)\exp\left(\frac{-t^2/2}{k\rho + \sqrt{2}t/3}\right) ,$$

which gives a tail probability of $2d^{-c}/(k-1)$ for the choice of

$$t = \max\left\{\sqrt{4k\rho\left((1+c)\log d + \log(k-1)\right)}\,,\ \frac{4\sqrt{2}((1+c)\log d + \log(k-1))}{3}\right\} . \tag{192}$$

For this choice of t, using union bound we can get the probabilistic bound on the derivative of log likelihood as,

$$\begin{aligned}
\mathbb{P}\left(\|\nabla\mathcal{L}_p(\Theta^*)\|_2 \ge \frac{k-1}{d_1\binom{k}{2}}t\right) &\le \mathbb{P}\left(\sum_{a=1}^{k-1}\left\|\tilde{Y}_a\right\|_2 \ge (k-1)t\right) \\
&\overset{(a)}{\le} \mathbb{P}\left(\max_{a\in[k-1]}\left\|\tilde{Y}_a\right\|_2 \ge t\right) \\
&\overset{(b)}{\le} \sum_{a=1}^{k-1}\mathbb{P}\Big(\left\|\tilde{Y}_a\right\|_2 \ge t\Big) \\
&= 2\,d^{-c} ,
\end{aligned} \tag{193}$$

where we obtain (a) by pigeon-hole principle which implies that among a set of numbers, there should be, at the very least one number greater or equal to the average of the set of numbers and (b) by union-bound. Assuming $k \le \max\{d_1, d_2^2/d_1\}\log d$ and $d_1 \ge 4$, we have,

$$(c+1)\log d + \log(k-1) \le (c+4)\log d\,, \tag{194}$$

from $\log(k-1) \le \log\left(\max\{d_1, d_2^2/d_1\}\log d\right) \le \log(\left((d_1^2+d_2^2)\log d\right)/d_1) \le \log\left((4\,d^2\log d)/d_1\right)$ $\le 3\log d$. This proves the desired lemma.

F.2 Proof of Lemma 37

With a slight abuse of notation, we define $\tilde{H}$ as

$$\tilde{H}(\Delta) \;\equiv\; \frac{1}{d_1\binom{k}{2}}\sum_{i=1}^{d_1}\sum_{(m_1,m_2)\in\mathcal{P}_0}\left(\Delta_{i,u_{i,m_1}} - \Delta_{i,u_{i,m_2}}\right)^2\,, \tag{195}$$

and provide a lower bound. The mean is easily computed as

$$\begin{aligned}\mathbb{E}\left[\tilde{H}(\Delta)\right] &= \frac{1}{d_1\binom{k}{2}}\sum_{i=1}^{d_1}\sum_{(m_1,m_2)\in\mathcal{P}_0}\left[\frac{2}{d_2}\sum_{j\in[d_2]}\Delta_{ij}^2 - \frac{2}{d_2^2}\sum_{j\in[d_2]}\Delta_{ij}\sum_{j'\in[d_2]}\Delta_{ij'}\right]\\ &= \frac{2}{d_1 d_2}|||\Delta|||_{\mathrm{F}}^2\,,\end{aligned} \tag{196}$$

where we used the fact that $\sum_j \Delta_{ij} = 0$. We want to upper bound the probability that $\tilde{H}(\Delta) \le \frac{1}{3d_1d_2}|||\Delta|||_{\mathrm{F}}^2$ for some $\Delta \in \mathcal{A}$. As in the case of k-wise ranking we using the following peeling argument used in (Negahban and Wainwright, 2012, Lemma 3), Van De Geer (2000). The strategy is to split this above event as union of many event events as follows. We construct the following family of subsets $\{\tilde{\mathcal{S}}_\ell\}$ such that $\mathcal{A} \subseteq \cup_{\ell=1}^{\infty}\tilde{\mathcal{S}}_\ell$ and,

$$\begin{aligned}\tilde{\mathcal{S}}_\ell = \Bigg\{\Delta \in \mathbb{R}^{d_1\times d_2} \;\Big|\; |||\Delta|||_\infty \le 2\alpha,\; \beta^{\ell-1}\mu \le |||\Delta|||_{\mathrm{F}} \le \beta^\ell\mu,\\ \sum_{j\in[d_2]}\Delta_{ij} = 0 \text{ for all } i\in[d_2],\text{ and } |||\Delta|||_{\mathrm{nuc}} \le \beta^{2\ell}\mu\Bigg\}\,,\end{aligned} \tag{197}$$

where $\beta = \sqrt{10/9}$ and $\ell \in \{1,2,3,\ldots\}$. This is true since, for any $\Delta \in \mathcal{A}$, $|||\Delta|||_{\mathrm{F}}^2 \ge \mu|||\Delta|||_{\mathrm{nuc}}$ and this implies $|||\Delta|||_{\mathrm{F}}^2 \ge \mu|||\Delta|||_{\mathrm{F}}$ (or, $|||\Delta|||_{\mathrm{F}} \ge \mu$). Also note that,

$$\begin{aligned}\tilde{H}(\Delta) \le \frac{1}{3d_1d_2}|||\Delta|||_{\mathrm{F}}^2 &\implies \frac{2}{d_1d_2}|||\Delta|||_{\mathrm{F}}^2 - \tilde{H}(\Delta) \ge \frac{5}{3d_1d_2}|||\Delta|||_{\mathrm{F}}^2\\ &\implies \left(\mathbb{E}\left[\tilde{H}(\Delta)\right] - \tilde{H}(\Delta)\right) \ge \frac{5}{3d_1d_2}|||\Delta|||_{\mathrm{F}}^2\,.\end{aligned} \tag{198}$$

Therefore using union bound we get,

$$\begin{aligned}&\mathbb{P}\Big(\exists\,\Delta\in\mathcal{A}\ s.t.\ \tilde{H}(\Delta) \le \frac{1}{3d_1d_2}|||\Delta|||_{\mathrm{F}}^2\Big)\\ &\le \sum_{\ell=1}^{\infty}\mathbb{P}\left(\sup_{\Delta\in\tilde{\mathcal{S}}_\ell}\left(\mathbb{E}\left[\tilde{H}(\Delta)\right] - \tilde{H}(\Delta)\right) \ge \frac{5}{3d_1d_2}|||\Delta|||_{\mathrm{F}}^2\right)\\ &\overset{(a)}{\le} \sum_{\ell=1}^{\infty}\mathbb{P}\left(\sup_{\Delta\in\tilde{\mathcal{S}}_\ell}\left(\mathbb{E}\left[\tilde{H}(\Delta)\right] - \tilde{H}(\Delta)\right) \ge \frac{3}{2d_1d_2}(\beta^\ell\mu)^2\right)\\ &\overset{(b)}{\le} \sum_{\ell=1}^{\infty}\mathbb{P}\left(\sup_{\Delta\in\tilde{\mathcal{B}}(\beta^\ell\mu)}\left(\mathbb{E}\left[\tilde{H}(\Delta)\right] - \tilde{H}(\Delta)\right) \ge \frac{3}{2d_1d_2}(\beta^\ell\mu)^2\right)\,,\end{aligned} \tag{199}$$

where $\tilde{\mathcal{B}}(\mathcal{D})$ is defined as,

$$\begin{aligned}\tilde{\mathcal{B}}(D) = \Bigg\{\Delta\in\mathbb{R}^{d_1\times d_2} \;\Big|\; |||\Delta|||_\infty \le 2\alpha,\ |||\Delta|||_{\mathrm{F}} \le D,\\ \sum_{j\in[d_2]}\Delta_{ij} = 0 \text{ for all } i\in[d_2],\text{ and } \mu|||\Delta|||_{\mathrm{nuc}} \le D^2\Bigg\}\,,\end{aligned} \tag{200}$$

and $(a)$is true because for $\Delta \in \tilde{\mathcal{S}}_l$,

$$\frac{5}{3d_1d_2}|||\Delta|||_{\mathrm{F}}^2 \ge \frac{5}{3d_1d_2}(\beta^{\ell-1}\mu)^2 = \frac{3}{2d_1d_2}(\beta^\ell\mu)^2\,, \tag{201}$$

and (b) is true because $\tilde{\mathcal{S}}_\ell \subset \tilde{\mathcal{B}}(\beta^\ell\mu)$. Now we use following lemma to upper bound (199).

Lemma 38 *For* $4(\log d)/3 \le k \le d^2\log d$,

$$\mathbb{P}\left(\sup_{\Delta\in\tilde{\mathcal{B}}(D)}\left(\mathbb{E}\left[\tilde{H}(\Delta)\right] - \tilde{H}(\Delta)\right) \ge \frac{3}{2d_1d_2}D^2\right) \le \exp\left(\frac{-kD^4}{2048\ \alpha^4\ d_1d_2^2}\right) \tag{202}$$

Proof has been relegated to Section F.3. Now by (199) and Lemma 38 we get,

$$\begin{aligned}
\mathbb{P}\Big(\exists\, \Delta \in \mathcal{A} \text{ s.t. } \tilde{H}(\Delta) \le \frac{1}{3d_1d_2}\|\Delta\|_{\mathrm{F}}^2\Big) &\le \sum_{\ell=1}^{\infty} \exp\left(\frac{-k\left(\beta^\ell\,\mu\right)^4}{2048\;\alpha^4\;d_1d_2^2}\right)\\
&\overset{(a)}{\le} \sum_{\ell=1}^{\infty} \exp\left(\frac{-2^{13}\;9\;\beta^{4\ell}\,d_1d_2^2\log^2 d}{k\;\min^2\{d_1,d_2\}}\right)\\
&\overset{(b)}{\le} \sum_{\ell=1}^{\infty} \exp\left(\frac{-2^{13}\;9\;4\ell\times\frac{1}{36}\,d_1d_2^2\log^2 d}{k\;\min^2\{d_1,d_2\}}\right)\\
&\overset{(c)}{\le} \sum_{\ell=1}^{\infty} \exp\left(-2^{13}\;\ell\;\log d\right)\\
&= \sum_{\ell=1}^{\infty}\left(\frac{1}{d^{2^{13}}}\right)^{\ell}\\
&\overset{(d)}{=} \frac{1/d^{2^{13}}}{1-1/d^{2^{13}}}\\
&\overset{(e)}{\le} \frac{2}{d^{2^{13}}}\,,
\end{aligned} \tag{203}$$

where we get (a) by substituting μ from (176), (b) by the fact that for $\beta=\sqrt{10/9}$ and $x\ge 1$, $\beta^x \ge x\log\beta \ge x(\beta-1)\ge x/32$, (c) is obtained by assuming $k\le \max\{d_1,d_2^2/d_1\}\log d$, we get (d) because we are summing an infinite geometric sequence with common ratio of $1/d^{2^{13}}$ and (e) is because for $d\ge 2$, $1/d^{2^{13}}$ is less than $1/2$.

F.3 Proof of Lemma 38

With a slight abuse of notations, let $\tilde{Z} \equiv \sup_{\Delta\in\tilde{\mathcal{B}}(D)}\Big(\mathbb{E}\left[\tilde{H}(\Delta)\right]-\tilde{H}(\Delta)\Big)$. Notice that $\tilde{Z}$ is a function of d_1k random variables, $\{u_{i,\ell}\}_{i\in[d_1],\ell\in[k]}$. We apply the McDiarmid's bounded differences inequality. Let $\tilde{Z}_1$ and $\tilde{Z}_2$ be two realizations of $\tilde{Z}$ where value of only one random variable $u_{i',\ell'}$ is changed to $u'_{i',\ell'}$. Also with a little more abuse of notation the two realizations of $\tilde{H}(\Delta)$ are written as $\tilde{H}(\Delta', u_{1,1},\ldots,u_{i',\ell'},\ldots,u_{d_1,k})$ and $\tilde{H}(\Delta', u_{1,1},\ldots,u'_{i',\ell'},\ldots,u_{d_1,k})$. We let Δ^* be the maximizer of $\max\{\tilde{Z}_1,\tilde{Z}_2\}$. Maximum

absolute difference between them is upper bounded as follows,

$$\begin{aligned}
&|\tilde{Z}_1-\tilde{Z}_2|\\
&=\Bigg|\max_{\Delta\in\tilde{\mathcal{B}}(D)}\Big(\mathbb{E}\left[\tilde{H}(\Delta)\right]-\tilde{H}(\Delta,u_{1,1},\ldots,u_{i',\ell'},\ldots,u_{d_1,k})\Big)-\\
&\qquad\max_{\Delta'\in\tilde{\mathcal{B}}(D)}\Big(\mathbb{E}\left[\tilde{H}(\Delta')\right]-\tilde{H}(\Delta',u_{1,1},\ldots,u'_{i',\ell'},\ldots,u_{d_1,k})\Big)\Bigg|\\
&\overset{(a)}{\le}\Bigg|\Big(\mathbb{E}\left[\tilde{H}(\Delta^*)\right]-\tilde{H}(\Delta^*,u_{1,1},\ldots,u_{i',\ell'},\ldots,u_{d_1,k})\Big)-\\
&\qquad\Big(\mathbb{E}\left[\tilde{H}(\Delta^*)\right]-\tilde{H}(\Delta^*,u_{1,1},\ldots,u'_{i',\ell'},\ldots,u_{d_1,k})\Big)\Bigg|\\
&\le \sup_{\Delta\in\tilde{\mathcal{B}}(D)}\Big|\tilde{H}(\Delta,u_{1,1},\ldots,u_{i',\ell'},\ldots,u_{d_1,k})-\tilde{H}(\Delta,u_{1,1},\ldots,u'_{i',\ell'},\ldots,u_{d_1,k})\Big|\\
&\overset{(b)}{\le}\sup_{\Delta\in\tilde{\mathcal{B}}(D)}\Bigg|\frac{1}{d_1\binom{k}{2}}\sum_{\ell\neq\ell'}\Big(\Delta_{i',u_{i',\ell}}-\Delta_{i',u_{i',\ell'}}\Big)^2-\Big(\Delta_{i',u_{i',\ell}}-\Delta_{i',u'_{i',\ell'}}\Big)^2\Bigg|\\
&\overset{(c)}{\le}\frac{1}{d_1\binom{k}{2}}(k-1)\,(4\alpha)^2=\frac{32\alpha^2}{d_1k}.
\end{aligned} \tag{204}$$

where (a) follows from the fact that Δ^* is maximizer of $\max\{\tilde{Z}_1,\tilde{Z}_2\}$, (b) is due to the fact that the terms which change because of $u'_{i',\ell'}$ are the $k-1$ difference square terms between $\Delta_{iu_{i',\ell\neq\ell'}}$ and $\Delta_{i,\,u_{i',\ell'}}$ and (c) is because maximum and minimum value of difference square terms are $(4\alpha)^2$ and 0 respectively. Using McDiarmid's bounded differences inequality we get,

$$\mathbb{P}\{\tilde{Z}-\mathbb{E}\left[\tilde{Z}\right]\ge\epsilon\}\le\exp\left(-\frac{2\epsilon^2}{d_1k\left(\frac{32\alpha^2}{d_1k}\right)^2}\right)\,, \tag{205}$$

because of (204) and the fact that there are $d_1 k$ random variables. We upper bound $\mathbb{E}\left[\tilde{Z}\right]$ as follows.

$$\begin{aligned}
\mathbb{E}\left[\tilde{Z}\right] &= \mathbb{E}\sup_{\Delta\in\tilde{\mathcal{B}}(D)} \frac{1}{d_1\binom{k}{2}}\sum_{i=1}^{d_1}\sum_{(m_1,m_2)\in\mathcal{P}_0}\mathbb{E}\left[\left(\Delta_{i,\,u_{i,m_1}}-\Delta_{i,\,u_{i,m_2}}\right)^2\right]-\left(\Delta_{i,\,u_{i,m_1}}-\Delta_{i,\,u_{i,m_2}}\right)^2\\
&\overset{(a)}{\le} \mathbb{E}\sup_{\Delta\in\tilde{\mathcal{B}}(D)} \frac{1}{d_1\binom{k}{2}}\sum_{i=1}^{d_1}\sum_{(m_1,m_2)\in\mathcal{P}_0} 2\tilde{\xi}_{i,m_1,m_2}\left(\Delta_{i,\,u_{i,m_1}}-\Delta_{i,\,u_{i,m_2}}\right)^2\\
&\overset{(b)}{\le} \mathbb{E}\sup_{\Delta\in\tilde{\mathcal{B}}(D)} \frac{1}{d_1\binom{k}{2}}\sum_{i=1}^{d_1}\sum_{a=1}^{k-1}\sum_{(m_1,m_2)\in\mathcal{P}_a} 2\tilde{\xi}_{i,m_1,m_2}\left(\Delta_{i,\,u_{i,m_1}}-\Delta_{i,\,u_{i,m_2}}\right)^2\\
&\overset{(c)}{\le} \sum_{a=1}^{k-1}\mathbb{E}\sup_{\Delta\in\tilde{\mathcal{B}}(D)} \frac{1}{d_1\binom{k}{2}}\sum_{i=1}^{d_1}\sum_{(m_1,m_2)\in\mathcal{P}_a} 2\tilde{\xi}_{i,m_1,m_2}\left(\Delta_{i,\,u_{i,m_1}}-\Delta_{i,\,u_{i,m_2}}\right)^2 ,
\end{aligned} \tag{206}$$

where (a) is by standard symmetrization technique as used in k-wise ranking and $\{\xi_{i,m_1,m_2}\}_{i\in[d_1],\, m_1,m_2\in[k]}$ are i.i.d. Rademacher variables, (b) is due to the fact that we can partition set of all pairs into $k-1$ independent sets as in (188) and (c) is because of fact that supremum of sum is less than or equal to sum of supremum and the linearity of expectation. Since $|\Delta_{i,\,u_{i,m_1}}-\Delta_{i,\,u_{i,m_2}}|\le 4\alpha$, we can use Ledoux-Talagrand contraction inequality Ledoux and Talagrand (2013) on (206) to get,

$$\begin{aligned}
E[\tilde{Z}] &\le \sum_{a=1}^{k-1}\mathbb{E}\sup_{\Delta\in\tilde{\mathcal{B}}(D)} \frac{1}{d_1\binom{k}{2}}\sum_{i=1}^{d_1}\sum_{(m_1,m_2)\in\mathcal{P}_a} 2\tilde{\xi}_{i,m_1,m_2}\left(\Delta_{i,\,u_{i,m_1}}-\Delta_{i,\,u_{i,m_2}}\right)^2\\
&\le \sum_{a=1}^{k-1}\mathbb{E}\sup_{\Delta\in\tilde{\mathcal{B}}(D)} \frac{1}{d_1\binom{k}{2}}\sum_{i=1}^{d_1}\sum_{(m_1,m_2)\in\mathcal{P}_a} 4\alpha\, 2\tilde{\xi}_{i,m_1,m_2}\left(\Delta_{i,\,u_{i,m_1}}-\Delta_{i,\,u_{i,m_2}}\right)\\
&\overset{(a)}{\le} \sum_{a=1}^{k-1}\frac{8\alpha}{d_1\binom{k}{2}}\mathbb{E}\sup_{\Delta\in\tilde{\mathcal{B}}(D)}\langle\!\langle\sum_{i=1}^{d_1}\sum_{(m_1,m_2)\in\mathcal{P}_a}\tilde{W}_{i,m_1,m_2},\Delta\rangle\!\rangle\\
&\overset{(b)}{\le} \sum_{a=1}^{k-1}\frac{8\alpha}{d_1\binom{k}{2}}\mathbb{E}\left[\left|\!\left|\!\left|\sum_{i=1}^{d_1}\sum_{(m_1,m_2)\in\mathcal{P}_a}\tilde{W}_{i,m_1,m_2}\right|\!\right|\!\right|_2\right]\sup_{\Delta\in\tilde{\mathcal{B}}(D)}|\!|\!|\Delta|\!|\!|_{\text{nuc}} ,
\end{aligned} \tag{207}$$

where we get (a) by putting $\tilde{W}_{i,m_1,m_2}=\tilde{\xi}_{i,m_1,m_2}e_i(e_{u_{i,m_1}}-e_{u_{i,m_2}})^T$ and (b) is due to Hölder's inequality ($\langle\!\langle x,y\rangle\!\rangle\le|\!|\!|x|\!|\!|_2|\!|\!|y|\!|\!|_{\text{nuc}}$). Now we use Bernstein's inequality Tropp (2011) to upperbound the above expectation terms. First fix a to value in $[k-1]$. We can easily show that $\tilde{W}_{i,m_1,m_2}$ is zero mean and,

$$\left|\!\left|\!\left|\tilde{W}_{i,m_1,m_2}\right|\!\right|\!\right|_2\le\sqrt{2}\,. \tag{208}$$

We also get,

$$\begin{aligned}
\mathbb{E}\left[\tilde{W}_{i,m_1,m_2}\tilde{W}_{i,m_1,m_2}^T\right] &= 2e_ie_i^T\mathbb{E}\left[1-e_{u_{i,m_1}}^Te_{u_{i,m_2}}\right]\\
&\preceq e_ie_i^T\left(2-\frac{2}{d_2}\right)\\
&\preceq 2e_ie_i^T ,
\end{aligned} \tag{209}$$

and,

$$\begin{aligned}
\mathbb{E}\left[\tilde{W}_{i,m_1,m_2}^T\tilde{W}_{i,m_1,m_2}\right] &= \mathbb{E}\left[2e_{u_{i,m_1}}e_{u_{i,m_1}}^T-2e_{u_{i,m_1}}e_{u_{i,m_2}}^T\right]\\
&\preceq \frac{2}{d_2}\mathbf{I}_{d_2\times d_2}-\frac{2}{d_2^2}\mathbf{1}\mathbf{1}_{d_2\times d_2}\\
&\preceq \frac{2}{d_2}\mathbf{I}_{d_2\times d_2}\,.
\end{aligned} \tag{210}$$

Therefore, using (209) and (210), the standard deviation of $\sum_{(i,m_1,m_2)}Z_{i,m_2,m_2}$ is,

$$\begin{aligned}
\sigma^2 &= \max\left\{\left|\!\left|\!\left|\sum_{\substack{i\in[d_1]\\(m_1,m_2)\in\mathcal{P}_a}}\mathbb{E}\left[\tilde{W}_{i,m_2,m_2}\tilde{W}_{i,m_2,m_2}^T\right]\right|\!\right|\!\right|_2,\left|\!\left|\!\left|\sum_{\substack{i\in[d_1]\\(m_1,m_2)\in\mathcal{P}_a}}\mathbb{E}\left[\tilde{W}_{i,m_2,m_2}^T\tilde{W}_{i,m_2,m_2}\right]\right|\!\right|\!\right|_2\right\}\\
&\le \max\left\{\frac{d_1k}{2}\frac{2}{d_1}|\!|\!|\mathbf{I}|\!|\!|_2,\frac{d_1k}{2}\frac{2}{d_2}|\!|\!|\mathbf{I}|\!|\!|_2\right\}\\
&= \frac{kd_1}{\min\{d_1,d_2\}}\,.
\end{aligned} \tag{211}$$

By matrix Bernstein inequality Tropp (2011), $\forall\ a\in[k-1]$,

$$\mathbb{P}\left(\left|\!\left|\!\left|\sum_{i\in[d_1]}\sum_{(m_1,m_2)\in\mathcal{P}_a}\tilde{W}_{i,m_2,m_2}\right|\!\right|\!\right|_2>t\right)\le(d_1+d_2)\exp\left(\frac{-t^2/2}{2kd_1/\min\{d_1,d_2\}+\sqrt{2}t/3}\right),$$

which gives a tail probability of $2d^{-c_1}$ for the choice of

$$\begin{aligned}
t &= \max\left\{\sqrt{\frac{8kd_1\left((1+c_1)\log d\right)}{\min\{d_1,d_2\}}},\frac{4\sqrt{2}\left((1+c_1)\log d\right)}{3}\right\}\\
&= \sqrt{\frac{8kd_1\left((1+c_1)\log d\right)}{\min\{d_1,d_2\}}},\text{when } k\ge 4(c_1+1)\log d/9\,.
\end{aligned} \tag{212}$$

Therefore $\forall\ a\in[k-1]$,

$$\mathbb{E}\left[\left|\!\left|\!\left|\sum_{i=1}^{d_1}\sum_{(m_1,m_2)\in\mathcal{P}_a}\tilde{W}_{i,m_2,m_2}\right|\!\right|\!\right|_2\right]\le\sqrt{\frac{8kd_1\left((1+c_1)\log d\right)}{\min\{d_1,d_2\}}}+\frac{2}{d^{c_1}}\frac{\sqrt{2}d_1k}{2}\,, \tag{213}$$

because from (208) we get $\left\|\left\|\sum_{\substack{i\in[d_1]\\(m_1,m_2)\in\mathcal{P}_a}}\tilde{W}_{i,m_2,m_2}\right\|\right\|_2 \le \sum_{\substack{i\in[d_1]\\(m_1,m_2)\in\mathcal{P}_a}}\left\|\left\|\tilde{W}_{i,m_2,m_2}\right\|\right\|_2 \le \frac{d_1 k}{2(\sqrt{2})}$. From (207) and (213), putting $c_1 = 2$, we get,

$$\begin{aligned}\mathbb{E}\left[\tilde{Z}\right] &\le \sum_{a=1}^{k-1}\frac{8\alpha}{d_1\binom{k}{2}}\left(\sqrt{\frac{24\,k d_1\log d}{\min\{d_1,d_2\}}} \;+\; \frac{\sqrt{2}d_1 k}{d^2}\right)\sup_{\Delta\in\tilde{\mathcal{B}}(D)}|||\Delta|||_{\rm nuc}\\ &\overset{(a)}{\le} 8\alpha\left(2\sqrt{\frac{24\,\log d}{k\,d_1\min\{d_1,d_2\}}} \;+\; \frac{2\sqrt{2}}{d^2}\right)\frac{D^2}{\mu}\\ &\overset{(b)}{\le} 16\alpha\sqrt{\frac{48\log d}{k\,d_1\min\{d_1,d_2\}}}D^2\frac{1}{16\alpha}\sqrt{\frac{k\,\min\{d_1,d_2\}}{48 d_1 d_2^2\log d}}\\ &= \frac{D^2}{d_1 d_2}\,,\end{aligned} \tag{214}$$

where (a) is obtained because of (200) which gives $\sup_{D\in\mathcal{B}(D)}|||\Delta|||_{\rm nuc} \le D^2/\mu$ and (b) can be got by assuming $k \le d^2\log d$. Using the above bound in (205) we get,

$$\mathbb{P}\{\tilde{Z} - D^2/(d_1 d_2) \ge \epsilon\} \le \mathbb{P}\{\tilde{Z} - \mathbb{E}\left[\tilde{Z}\right] \ge \epsilon\} \le \exp\left(-\frac{2\epsilon^2}{d_1 k\left(\frac{32\alpha^2}{d_1 k}\right)^2}\right)\,, \tag{215}$$

and using $\epsilon = D^2/(2d_1 d_2)$ will get us the required bound.

Appendix G. Proof of Bundled Choices Theorem 13

We use similar notations and techniques as the proof of Theorem 7 in Appendix C. From the definition of $\mathcal{L}(\Theta)$ in Eq. (51), we have for the true parameter Θ^*, the gradient evaluated at the true parameter is

$$\nabla\mathcal{L}(\Theta^*) \;=\; -\frac{1}{n}\sum_{i=1}^{n}(e_{u_i}e_{v_i}^T - p_i)\,, \tag{216}$$

where p_i denotes the conditional probability of the MNL choice for the i-th sample. Precisely, $p_i = \sum_{j_1\in S_i}\sum_{j_2\in T_i} p_{j_1,j_2|S_i,T_i}e_{j_1}e_{j_2}^T$ where $p_{j_1,j_2|S_i,T_i}$ is the probability that the pair of items (j_1,j_2) is chosen at the i-th sample such that $p_{j_1,j_2|S_i,T_i} \equiv \mathbb{P}\{(u_i,v_i) = (j_1,j_2)|S_i,T_i\} = e^{\Theta^*_{j_1,j_2}}/(\sum_{j_1'\in S_i,j_2'\in T_i}e^{\Theta^*_{j_1',j_2'}})$, where (u_i,v_i) is the pair of items selected by the i-th user among the set of pairs of alternatives $S_i\times T_i$. The Hessian can be computed as

$$\frac{\partial^2\mathcal{L}(\Theta)}{\partial\Theta_{j_1,j_2}\,\partial\Theta_{j_1'j_2'}} \;=\; \frac{1}{n}\sum_{i=1}^{n}\mathbb{I}\big((j_1,j_2)\in S_i\times T_i\big)\frac{\partial p_{j_1,j_2|S_i,T_i}}{\partial\Theta_{j_1',j_2'}} \tag{217}$$

$$= \frac{1}{n}\sum_{i=1}^{n}\mathbb{I}\big((j_1,j_2),(j_1',j_2')\in S_i\times T_i\big)\left(p_{j_1,j_2|S_i,T_i}\mathbb{I}((j_1,j_2)=(j_1',j_2')) - p_{j_1,j_2|S_i,T_i}p_{j_1',j_2'|S_i,T_i}\right)\,, \tag{218}$$

We use $\nabla^2\mathcal{L}(\Theta)\in\mathbb{R}^{d_1d_2\times d_1d_2}$ to denote this Hessian. Let $\Delta = \Theta^* - \widehat{\Theta}$ where $\widehat{\Theta}$ is an optimal solution to the convex optimization in (49). We introduce the following key technical lemmas. The following lemma provides a bound on the gradient using the concentration of measure for sum of independent random matrices Tropp (2011).

Lemma 39 *For any positive constant $c \ge 1$ and $n \ge (4(1+c)e^{2\alpha}d_1d_2\log d)/\max\{d_1,d_2\}$, with probability at least $1-2d^{-c}$,*

$$|||\nabla\mathcal{L}(\Theta^*)|||_2 \;\le\; \sqrt{\frac{4(1+c)e^{2\alpha}\max\{d_1,d_2\}\,\log d}{d_1\,d_2\,n}}\,. \tag{219}$$

Since we are typically interested in the regime where the number of samples is much smaller than the dimension $d_1\times d_2$ of the problem, the Hessian is typically not positive definite. However, when we restrict our attention to the vectorized Δ with relatively small nuclear norm, then we can prove restricted strong convexity, which gives the following bound.

Lemma 40 (Restricted Strong Convexity for bundled choice modeling) *Fix any $\Theta\in\Omega_\alpha$ and assume $(\min\{d_1,d_2\}/\min\{k_1,k_2\})\log d \le n \le \min\{d^5\log d, k_1k_2\max\{d_1^2,d_2^2\}\log d\}$. Under the random sampling model of the alternatives $\{j_{ia}\}_{i\in[n],a\in[k_1]}$ from the first set of items $[d_1]$, $\{j_{ib}\}_{i\in[n],b\in[k_1]}$ from the second set of items $[d_2]$ and the random outcome of the comparisons described in section 1, with probability larger than $1-2d^{-2^{25}}$,*

$$\mathrm{Vec}(\Delta)^T\,\nabla^2\mathcal{L}(\Theta)\,\mathrm{Vec}(\Delta) \;\ge\; \frac{e^{-2\alpha}}{8\,d_1\,d_2}|||\Delta|||_{\rm F}^2\,, \tag{220}$$

for all Δ in $\mathcal{A}$ where

$$\mathcal{A} = \left\{\Delta\in\mathbb{R}^{d_1\times d_2}\;\middle|\;|||\Delta|||_\infty \le 2\alpha\,,\ \sum_{j_1\in[d_1],j_2\in[d_2]}\Delta_{j_1j_2} = 0\ \ \textit{and}\ |||\Delta|||_{\rm F}^2 \ge \mu'|||\Delta|||_{\rm nuc}\right\}\,. \tag{221}$$

with

$$\mu' \;\equiv\; 2^{10}\,\alpha\,d_1d_2\sqrt{\frac{\log d}{n\,\min\{d_1,d_2\}\,\min\{k_1,k_2\}}}\,. \tag{222}$$

Building on these lemmas, the proof of Theorem 13 is divided into the following two cases. In both cases, we will show that

$$|||\Delta|||_{\rm F}^2 \;\le\; 12\,e^{2\alpha}c_1\lambda\,d_1d_2\,|||\Delta|||_{\rm nuc}\,, \tag{223}$$

with high probability. Finally, applying an omitted result similar to Lemma 27 proves the desired theorem. We are left to show Eq. (223) holds.

Case 1: Suppose $|||\Delta|||_{\rm F}^2 \ge \mu'|||\Delta|||_{\rm nuc}$. With $\Delta = \Theta^* - \widehat{\Theta}$, the Taylor expansion yields

$$\mathcal{L}(\widehat{\Theta}) = \mathcal{L}(\Theta^*) - \langle\!\langle\nabla\mathcal{L}(\Theta^*),\Delta\rangle\!\rangle + \frac{1}{2}\mathrm{Vec}(\Delta)\nabla^2\mathcal{L}(\Theta)\mathrm{Vec}^T(\Delta), \tag{224}$$

where $\Theta = a\widehat{\Theta}+(1-a)\Theta^*$ for some $a \in [0,1]$. It follows from Lemma 40 that with probability at least $1-2d^{-2^{25}}$,

$$\mathcal{L}(\widehat{\Theta}) - \mathcal{L}(\Theta^*) \;\geq\; -|||\nabla\mathcal{L}(\Theta^*)|||_2 |||\Delta|||_{\rm nuc} + \frac{e^{-2\alpha}}{8\,d_1\,d_2}|||\Delta|||_{\rm F}^2 \,.$$

From the definition of $\widehat{\Theta}$ as an optimal solution of the minimization, we have

$$\mathcal{L}(\widehat{\Theta}) - \mathcal{L}(\Theta^*) \;\leq\; \lambda\left(|||\Theta^*|||_{\rm nuc} - \left|||\widehat{\Theta}\right|||_{\rm nuc}\right) \;\leq\; \lambda|||\Delta|||_{\rm nuc}\,.$$

By the assumption, we choose $\lambda \geq 8\lambda_0$. In view of Lemma 39, this implies that $\lambda \geq 2|||\nabla\mathcal{L}(\Theta^*)|||_2$ with probability at least $1-2d^{-3}$. It follows that with probability at least $1-2d^{-3}-2d^{-2^{25}}$,

$$\frac{e^{-2\alpha}}{8d_1d_2}|||\Delta|||_{\rm F}^2 \;\leq\; \left(\lambda + |||\nabla\mathcal{L}(\Theta^*)|||_2\right)|||\Delta|||_{\rm nuc} \;\leq\; \frac{3\lambda}{2}|||\Delta|||_{\rm nuc}\,.$$

By our assumption on $\lambda \leq c_1\lambda_0$, this proves the desired bound in Eq. (223)

Case 2: Suppose $|||\Delta|||_{\rm F}^2 \leq \mu'|||\Delta|||_{\rm nuc}$**.** By the definition of μ and the fact that $c_1 \geq 128/\sqrt{\min\{k_1,k_2\}}$, it follows that $\mu' \leq 12\,e^{2\alpha}c_1\lambda\,d_1d_2$, and we get the same bound as in Eq. (223).

G.1 Proof of Lemma 39

Define $X_i = -(e_{u_i}e_{v_i}^T - p_i)$ such that $\nabla\mathcal{L}(\Theta^*) = (1/n)\sum_{i=1}^n X_i$, which is a sum of n independent random matrices. Note that since p_i is entry-wise bounded by $e^{2\alpha}/(k_1k_2)$,

$$|||X_i|||_2 \;\leq\; 1 + \frac{e^{2\alpha}}{\sqrt{k_1k_2}}\,,$$

and

$$\sum_{i=1}^n \mathbb{E}[X_iX_i^T] \;=\; \sum_{i=1}^n(\mathbb{E}[e_{u_i}e_{u_i}^T] - p_ip_i^T) \tag{225}$$

$$\preceq\; \sum_{i=1}^n \mathbb{E}[e_{u_i}e_{u_i}^T] \tag{226}$$

$$\preceq\; \frac{e^{2\alpha}n}{d_1}\mathbf{I}_{d_1\times d_1}\,, \tag{227}$$

where the last inequality follows from the fact that for any given S_i, u_i will be chosen with probability at most $e^{2\alpha}/k_1$, if it is in the set S_i which happens with probability k_1/d_1. Therefore,

$$\left|\left|\left|\sum_{i=1}^n \mathbb{E}[X_iX_i^T]\right|\right|\right|_2 \;\leq\; \frac{e^{2\alpha}n}{d_1}\,. \tag{228}$$

Similarly,

$$\left|\left|\left|\sum_{i=1}^n \mathbb{E}[X_i^TX_i]\right|\right|\right|_2 \;\leq\; \frac{e^{2\alpha}n}{d_2}\,. \tag{229}$$

Applying matrix Bernstein inequality Tropp (2011), we get

$$\begin{aligned}&\mathbb{P}\{|||\nabla\mathcal{L}(\Theta^*)|||_2 > t\}\\ &\leq (d_1+d_2)\exp\left\{\frac{-n^2t^2/2}{(e^{2\alpha}n\max\{d_1,d_2\}/(d_1d_2)) \;+\; ((1+(e^{2\alpha}/\sqrt{k_1k_2}))nt/3)}\right\},\end{aligned} \tag{230}$$

which gives the desired tail probability of $2d^{-c}$ for the choice of

$$\begin{aligned}t \;&=\; \max\left\{\sqrt{\frac{4(1+c)e^{2\alpha}\max\{d_1,d_2\}\log d}{d_1d_2n}}\,,\; \frac{4(1+c)(1+\frac{e^{2\alpha}}{\sqrt{k_1k_2}})\log d}{3n}\right\}\\ &=\; \sqrt{\frac{4(1+c)e^{2\alpha}\max\{d_1,d_2\}\log d}{d_1d_2n}}\,,\end{aligned}$$

where the last equality follows from the assumption, $n \geq (4(1+c)e^{2\alpha}d_1d_2\log d)/\max\{d_1,d_2\}$.

G.2 Proof of Lemma 40

Thee quadratic form of the Hessian defined in (218) can be lower bounded by

$$\mathrm{Vec}(\Delta)^T\,\nabla^2\mathcal{L}(\Theta)\,\mathrm{Vec}(\Delta) \;\geq\; \underbrace{\frac{e^{-2\alpha}}{2\,k_1^2\,k_2^2\,n}\sum_{i=1}^n\sum_{j_1,j_1'\in S_i}\sum_{j_2,j_2'\in T_i}\left(\Delta_{j_1,j_2}-\Delta_{j_1',j_2'}\right)^2}_{\equiv H(\Delta)}\,, \tag{231}$$

which follows from Remark 31. To lower bound $H(\Delta)$, we first compute the mean:

$$\mathbb{E}[H(\Delta)] \;=\; \frac{e^{-2\alpha}}{2\,k_1^2\,k_2^2\,n}\sum_{i=1}^n\mathbb{E}\Big[\sum_{j_1,j_1'\in S_i}\sum_{j_2,j_2'\in T_i}\left(\Delta_{j_1,j_2}-\Delta_{j_1',j_2'}\right)^2\Big] \tag{232}$$

$$=\; \frac{e^{-2\alpha}}{d_1\,d_2}|||\Delta|||_{\rm F}^2\,, \tag{233}$$

where we used the fact that $\mathbb{E}[\sum_{j_1\in S_i,j_2\in T_i}\Delta_{j_1,j_2}] = (k_1k_2/(d_1d_2))\sum_{j_1'\in[d_1],j_2'\in[d_2]}\Delta_{j_1',j_2'} = 0$ for $\Delta\in\Omega_{2\alpha}$ in (51).

We now prove that $H(\Delta)$ does not deviate from its mean too much. Suppose there exists a $\Delta\in\mathcal{A}$ defined in (221) such that Eq. (220) is violated, i.e. $H(\Delta) < (e^{-2\alpha}/(8d_1d_2))|||\Delta|||_{\rm F}^2$. In this case,

$$\mathbb{E}[H(\Delta)] - H(\Delta) \;\geq\; \frac{7\,e^{-2\alpha}}{8d_1d_2}|||\Delta|||_{\rm F}^2\,. \tag{234}$$

We will show that this happens with a small probability. We use the same peeling argument as in Appendix C with

$$\begin{aligned}\mathcal{S}_\ell = \Big\{\Delta\in\mathbb{R}^{d_1\times d_2}\,|\,&|||\Delta|||_\infty \leq 2\alpha, \beta^{\ell-1}\mu' \leq |||\Delta|||_{\rm F} \leq \beta^\ell\mu',\\ &\sum_{j_1\in[d_1],j_2\in[d_2]}\Delta_{j_1,j_2} = 0,\ \text{and}\ |||\Delta|||_{\rm nuc} \leq \beta^{2\ell}\mu'\Big\}\,,\end{aligned}$$

where $\beta = \sqrt{10/9}$ and for $\ell \in \{1, 2, 3, \ldots\}$, and μ' is defined in (222). By the peeling argument, there exists an $\ell \in \mathbb{Z}_+$ such that $\Delta \in \mathcal{S}_\ell$ and

$$\mathbb{E}[H(\Delta)] - H(\Delta) \;\; \geq \;\; \frac{7\, e^{-2\alpha}}{8 d_1 d_2} \beta^{2\ell-2} (\mu')^2 \;\; \geq \;\; \frac{7\, e^{-2\alpha}}{9\, d_1 d_2} \beta^{2\ell} (\mu')^2 \, . \tag{235}$$

Applying the union bound over $\ell \in \mathbb{Z}_+$,

$$\begin{aligned}
&\mathbb{P}\left\{ \exists \Delta \in \mathcal{A} \, , \; H(\Delta) < \frac{e^{-2\alpha}}{8\, d_1\, d_2} |\!|\!| \Delta |\!|\!|_{\mathrm{F}}^2 \right\} \\
&\leq \sum_{\ell=1}^{\infty} \mathbb{P}\left\{ \sup_{\Delta \in \mathcal{S}_\ell} \big(\, \mathbb{E}[H(\Delta)] - H(\Delta) \, \big) > \frac{7\, e^{-2\alpha}}{9 d_1 d_2} (\beta^\ell \mu')^2 \right\} \\
&\qquad\qquad \leq \sum_{\ell=1}^{\infty} \mathbb{P}\left\{ \sup_{\Delta \in \mathcal{B}'(\beta^\ell \mu')} \big(\, \mathbb{E}[H(\Delta)] - H(\Delta) \, \big) > \frac{7 e^{-2\alpha}}{9 d_1 d_2} (\beta^\ell \mu')^2 \right\} ,
\end{aligned} \tag{236}$$

where we define the set $\mathcal{B}'(D)$ such that $\mathcal{S}_\ell \subseteq \mathcal{B}'(\beta^\ell \mu')$:

$$\mathcal{B}'(D) = \Big\{ \, \Delta \in \mathbb{R}^{d_1 \times d_2} \, \Big| \, \|\Delta\|_\infty \leq 2\alpha, |\!|\!| \Delta |\!|\!|_{\mathrm{F}} \leq D, \sum_{j_1 \in [d_1], j_2 \in [d_2]} \Delta_{j_1 j_2} = 0, \mu' |\!|\!| \Delta |\!|\!|_{\mathrm{nuc}} \leq D^2 \, \Big\} \, . \tag{237}$$

The following key lemma provides the upper bound on this probability.

Lemma 41 *For* $(\min\{d_1, d_2\}/\min\{k_1, k_2\}) \log d \leq n \leq d^5 \log d$,

$$\mathbb{P}\left\{ \sup_{\Delta \in \mathcal{B}'(D)} \Big(\, \mathbb{E}[H(\Delta)] - H(\Delta) \, \Big) \geq \frac{e^{-2\alpha} D^2}{2 d_1 d_2} \right\} \leq \quad \exp\Big\{ - \frac{n \, \min\{k_1^2, k_2^2\} \, k_1 k_2 \, D^4}{2^{10} \alpha^4 d_1^2 d_2^2} \Big\} \, . \tag{238}$$

Let $\eta = \exp\Big(- \frac{n k_1 k_2 \min\{k_1^2, k_2^2\} (\beta - 1.002) (\mu')^4}{2^{10} \alpha^4 d_1^2 d_2^2} \Big)$. Applying the tail bound to (236), we get

$$\begin{aligned}
\mathbb{P}\left\{ \exists \Delta \in \mathcal{A} \, , \; H(\Delta) < \frac{e^{-2\alpha}}{8\, d_1 d_2} |\!|\!| \Delta |\!|\!|_{\mathrm{F}}^2 \right\} \;\; &\leq \;\; \sum_{\ell=1}^{\infty} \exp\Big\{ - \frac{n \, k_1 k_2 \, \min\{k_1^2, k_2^2\} \, (\beta^\ell \mu')^4}{2^{10} \alpha^4 d_1^2 d_2^2} \Big\} \\
&\overset{(a)}{\leq} \;\; \sum_{\ell=1}^{\infty} \exp\Big\{ - \frac{n k_1 k_2 \min\{k_1^2, k_2^2\} \ell (\beta - 1.002) (\mu')^4}{2^{10} \alpha^4 d_1^2 d_2^2} \Big\} \\
&\leq \;\; \frac{\eta}{1 - \eta},
\end{aligned}$$

where (a) holds because $\beta^x \geq x \log \beta \geq x(\beta - 1.002)$ for the choice of $\beta = \sqrt{10/9}$. By the definition of μ',

$$\eta \;\; = \;\; \exp\Big\{ - \frac{2^{30} \, k_1 k_2 \max\{d_2^2, d_1^2\} (\log d)^2 (\beta - 1.002)}{n} \Big\} \;\; \leq \;\; \exp\{ - 2^{25} \, \log d \} \, ,$$

where the last inequality follows from the assumption that $n \leq k_1 k_2 \max\{d_1^2, d_2^2\} \log d$, and $\beta - 1.002 \geq 2^{-5}$. Since for $d \geq 2$, $\exp\{-2^{25} \log d\} \leq 1/2$ and thus $\eta \leq 1/2$, the lemma follows by assembling the last two displayed inequalities.

G.3 Proof of Lemma 41

Let $Z \equiv \sup_{\Delta \in \mathcal{B}'(D)} \mathbb{E}[H(\Delta)] - H(\Delta)$ and consider the tail bound using McDiarmid's inequality. Note that Z has a bounded difference of $(8\alpha^2 e^{-2\alpha} \max\{k_1, k_2\})/(k_1^2 k_2^2 n)$ when one of the $k_1 k_2 n$ independent random variables are changed, which gives

$$\mathbb{P}\left\{ Z - \mathbb{E}[Z] \geq t \right\} \;\; \leq \;\; \exp\Big(- \frac{k_1^4 k_2^4 n^2 t^2}{64 \alpha^4 e^{-4\alpha} \max\{k_1^2, k_2^2\} k_1 k_2 n} \Big) \, . \tag{239}$$

With the choice of $t = D^2/(4 e^{2\alpha} d_1 d_2)$, this gives

$$\mathbb{P}\left\{ Z - \mathbb{E}[Z] \geq \frac{e^{-2\alpha}}{4 d_1 d_2} D^2 \right\} \;\; \leq \;\; \exp\Big(- \frac{k_1^3 k_2^3 n D^4}{2^{10} \alpha^4 d_1^2 d_2^2 \max\{k_1^2, k_2^2\}} \Big) \, . \tag{240}$$

We first construct a partition of the space similar to Lemma 33. Let

$$\tilde{k} \;\; \equiv \;\; \min\{k_1, k_2\} \, . \tag{241}$$

Lemma 42 *There exists a partition* $(\mathcal{T}_1, \ldots, \mathcal{T}_N)$ *of* $\{[k_1] \times [k_2]\} \times \{[k_1] \times [k_2]\}$ *for some* $N \leq 2 k_1^2 k_2^2 / \tilde{k}$ *such that* $\mathcal{T}_\ell$*'s are disjoint subsets,* $\bigcup_{\ell \in [N]} \mathcal{T}_\ell = \{[k_1] \times [k_2]\} \times \{[k_1] \times [k_2]\}$, $|\mathcal{T}_\ell| \leq \tilde{k}$ *and for any* $\ell \in [N]$ *the set of random variables in* $\mathcal{T}_\ell$ *satisfy*

$$\{ (\Delta_{j_{i,a}, j_{i,b}} - \Delta_{j_{i,a'}, j_{i,b'}})^2 \}_{i \in [n], ((a,b),(a',b')) \in \mathcal{T}_\ell} \text{ are mutually independent } .$$

where $j_{i,a}$ *for* $i \in [n]$ *and* $a \in [k_1]$ *denote the* a*-th chosen item to be included in the set* S_i*.*

Now we prove an upper bound on $\mathbb{E}[Z]$ using the symmetrization technique. Recall that $j_{i,a}$ is independently and uniformly chosen from $[d_1]$ for $i \in [n]$ and $a \in [k_1]$. Similarly, $j_{i,b}$ is independently and uniformly chosen from $[d_1]$ for $i \in [n]$ and $b \in [k_2]$.

$$\begin{aligned}
&\mathbb{E}[Z] \\
&= \frac{e^{-2\alpha}}{2\, k_1^2 k_2^2 \, n} \mathbb{E}\left[\sup_{\Delta \in \mathcal{B}'(D)} \sum_{i=1}^{n} \sum_{\substack{a, a' \in [k_1] \\ b, b' \in [k_2]}} \mathbb{E}\big[\big(\Delta_{j_{i,a}, j_{i,b}} - \Delta_{j_{i,a'}, j_{i,b'}} \big)^2 \big] - \big(\Delta_{j_{i,a}, j_{i,b}} - \Delta_{j_{i,a'}, j_{i,b'}} \big)^2 \right] \\
&\leq \frac{e^{-2\alpha}}{2\, k_1^2 k_2^2 \, n} \sum_{\ell \in [N]} \mathbb{E}\left[\sup_{\Delta \in \mathcal{B}'(D)} \sum_{i=1}^{n} \sum_{(j_1, j_2, j_1', j_2') \in \mathcal{T}_\ell} \mathbb{E}\big[\big(\Delta_{j_1, j_2} - \Delta_{j_1', j_2'} \big)^2 \big] - \big(\Delta_{j_1, j_2} - \Delta_{j_1', j_2'} \big)^2 \right] \\
&\leq \frac{e^{-2\alpha}}{k_1^2 k_2^2 \, n} \sum_{\ell \in [N]} \mathbb{E}\left[\sup_{\Delta \in \mathcal{B}'(D)} \sum_{i=1}^{n} \sum_{(j_1, j_2, j_1', j_2') \in \mathcal{T}_\ell} \xi_{i, j_1, j_2, j_1', j_2'} \big(\Delta_{j_1, j_2} - \Delta_{j_1', j_2'} \big)^2 \right] ,
\end{aligned} \tag{242}$$

where the first inequality follows for the fact that the supremum of the sum is smaller than the sum of supremum, and the second inequality follows from standard symmetrization

with i.i.d. Rademacher random variables $\xi_{i,j_1,j_2,j_1',j_2'}$'s. It follows from Ledoux-Talagrand contraction inequality Ledoux and Talagrand (2013) that

$$\mathbb{E}\left[\sup_{\Delta\in\mathcal{B}'(D)}\sum_{i=1}^{n}\sum_{(j_1,j_2,j_1',j_2')\in\mathcal{T}_\ell}\xi_{i,j_1,j_2,j_1',j_2'}\big(\Delta_{j_1,j_2}-\Delta_{j_1',j_2'}\big)^2\right] \tag{243}$$

$$\leq\ 8\alpha\,\mathbb{E}\left[\sup_{\Delta\in\mathcal{B}'(D)}\sum_{i=1}^{n}\sum_{(j_1,j_2,j_1',j_2')\in\mathcal{T}_\ell}\xi_{i,j_1,j_2,j_1',j_2'}\big(\Delta_{j_1,j_2}-\Delta_{j_1',j_2'}\big)\right] \tag{244}$$

$$\leq\ 8\alpha\,\mathbb{E}\left[\sup_{\Delta\in\mathcal{B}'(D)}|||\Delta|||_{\mathrm{nuc}}\left|\left|\left|\sum_{i=1}^{n}\sum_{(j_1,j_2,j_1',j_2')\in\mathcal{T}_\ell}\xi_{i,j_1,j_2,j_1',j_2'}\big(e_{j_1,j_2}-e_{j_1',j_2'}\big)\right|\right|\right|_2\right] \tag{245}$$

$$\leq\ \frac{8\alpha D^2}{\mu'}\mathbb{E}\left[\left|\left|\left|\sum_{i=1}^{n}\sum_{(j_1,j_2,j_1',j_2')\in\mathcal{T}_\ell}\xi_{i,j_1,j_2,j_1',j_2'}\big(e_{j_1,j_2}-e_{j_1',j_2'}\big)\right|\right|\right|_2\right]\ , \tag{246}$$

where the second inequality follows for the Hölder's inequality and the last inequality follows from $\mu'|||\Delta|||_{\mathrm{nuc}}\leq D^2$ for all $\Delta\in\mathcal{B}'(D)$. To bound the expected spectral norm of the random matrix, we use matrix Bernstein's inequality. Note that $\left|\left|\left|\xi_{i,j_1,j_2,j_1',j_2'}c\right|\right|\right|_2\leq\sqrt{2}$ almost surely, $\mathbb{E}[(e_{j_1,j_2}-e_{j_1',j_2'})(e_{j_1,j_2}-e_{j_1',j_2'})^T]\preceq(2/d_1)\mathbf{I}_{d_1\times d_1}$, and $\mathbb{E}[(e_{j_1,j_2}-e_{j_1',j_2'})^T(e_{j_1,j_2}-e_{j_1',j_2'})]\preceq(2/d_2)\mathbf{I}_{d_2\times d_2}$. It follows that $\sigma^2=2n|\mathcal{T}_\ell|/\min\{d_1,d_2\}$, where $|\mathcal{T}_\ell|\leq\min\{k_1,k_2\}$. It follows that

$$\mathbb{P}\left\{\left|\left|\left|\sum_{i=1}^{n}\sum_{(j_1,j_2,j_1',j_2')\in\mathcal{T}_\ell}\xi_{i,j_1,j_2,j_1',j_2'}\big(e_{j_1,j_2}-e_{j_1',j_2'}\big)\right|\right|\right|_2>t\right\}$$
$$\leq(d_1+d_2)\exp\left\{\frac{-t^2/2}{2n\min\{k_1,k_2\}/\min\{d_1,d_2\}+\sqrt{2}t/3}\right\},$$

Choosing $t=\max\{\sqrt{64n(\min\{k_1,k_2\}/\min\{d_1,d_2\})\log d},(16\sqrt{2}/3)\log d\}$, we obtain a bound on the spectral norm of t with probability at least $1-2d^{-7}$. From the fact that $\left|\left|\left|\sum_{i=1}^{n}\sum_{(j_1,j_2,j_1',j_2')\in\mathcal{T}_\ell}\xi_{i,j_1,j_2,j_1',j_2'}\big(e_{j_1,j_2}-e_{j_1',j_2'}\big)\right|\right|\right|_2\leq(n/\sqrt{2})\min\{k_1,k_2\}$, it follows that

$$\mathbb{E}\left[\left|\left|\left|\sum_{i=1}^{n}\sum_{(j_1,j_2,j_1',j_2')\in\mathcal{T}_\ell}\xi_{i,j_1,j_2,j_1',j_2'}\big(e_{j_1,j_2}-e_{j_1',j_2'}\big)\right|\right|\right|_2\right] \tag{247}$$

$$\leq\ \max\left\{\sqrt{\frac{64\,n\ \min\{k_1,k_2\}\log d}{\min\{d_1,d_2\}}},(16\sqrt{2}/3)\log d\right\}+\frac{2n\min\{k_1,k_2\}}{\sqrt{2}d^7} \tag{248}$$

$$\leq\ \sqrt{\frac{66\,n\ \min\{k_1,k_2\}\log d}{\min\{d_1,d_2\}}} \tag{249}$$

which follows form the assumption that $n\min\{k_1,k_2\}\geq\min\{d_1,d_2\}\log d$ and $n\leq d^5\log d$. Substituting this bound in (242), and (246), we get that

$$\mathbb{E}[Z]\ \leq\ \frac{16e^{-2\alpha}\alpha D^2}{\mu'}\sqrt{\frac{66\log d}{n\min\{k_1,k_2\}\min\{d_1,d_2\}}} \tag{250}$$

$$\leq\ \frac{e^{-2\alpha}D^2}{4\,d_1d_2}\,. \tag{251}$$

Appendix H. Proof of the Information-theoretic Lower Bound in Theorem 16

This proof follow closely the proof of Theorem 10 in Appendix E. We apply the generalized Fano's inequality in the same way to get Eq. (160)

$$\mathbb{P}\left\{\widehat{L}\neq L\right\}\ \geq\ 1-\frac{\binom{M}{2}^{-1}\sum_{\ell_1,\ell_2\in[M]}D_{\mathrm{KL}}(\Theta^{(\ell_1)}\|\Theta^{(\ell_2)})+\log 2}{\log M}\,, \tag{252}$$

The main challenge in this case is that we can no longer directly apply the RUM interpretation to compete $D_{\mathrm{KL}}(\Theta^{(\ell_1)}\|\Theta^{(\ell_2)})$. This will result in over estimating the KL-divergence, because this approach does not take into account that we only take the top winner, out of those k_1k_2 alternatives. Instead, we compute the divergence directly, and provide an appropriate bound. Let the set of k_1 rows and k_2 columns chosen in one of the n samples

be $S \subset [d_1]$ and $T \subset [d_2]$ respectively. Then,

$$
\begin{aligned}
& D_{\mathrm{KL}}(\Theta^{(\ell_1)} \| \Theta^{(\ell_2)}) \\
\overset{(a)}{=} & \frac{n}{\binom{d_1}{k_1}\binom{d_2}{k_2}} \sum_{S,T} \sum_{\substack{i\in S \\ j\in T}} \frac{e^{\Theta_{ij}^{(\ell_1)}}}{\sum_{\substack{i'\in S \\ j'\in T}} e^{\Theta_{i'j'}^{(\ell_1)}}} \log \left(\frac{e^{\Theta_{ij}^{(\ell_1)}} \sum_{\substack{i'\in S \\ j'\in T}} e^{\Theta_{i'j'}^{(\ell_2)}}}{e^{\Theta_{ij}^{(\ell_2)}} \sum_{\substack{i'\in S \\ j'\in T}} e^{\Theta_{i'j'}^{(\ell_1)}}} \right) \\
\overset{(b)}{\le} & \frac{n}{\binom{d_1}{k_1}\binom{d_2}{k_2}} \sum_{S,T} \left(\sum_{i,j} \frac{e^{2\Theta_{ij}^{(\ell_1)}} \sum_{i',j'} e^{\Theta_{i'j'}^{(\ell_2)}} - e^{\Theta_{ij}^{(\ell_1)}+\Theta_{ij}^{(\ell_2)}} \sum_{i',j'} e^{\Theta_{i'j'}^{(\ell_1)}}}{e^{\Theta_{ij}^{(\ell_2)}} \left(\sum_{i',j'} e^{\Theta_{i'j'}^{(\ell_1)}} \right)^2} \right) \\
\overset{(c)}{\le} & \frac{ne^{2\alpha}}{k_1^2 k_2^2 \binom{d_1}{k_1}\binom{d_2}{k_2}} \sum_{S,T} \sum_{i,j} \left(e^{2\Theta_{ij}^{(\ell_1)}-\Theta_{ij}^{(\ell_2)}} \sum_{i',j'} e^{\Theta_{i'j'}^{(\ell_2)}} - e^{\Theta_{ij}^{(\ell_1)}} \sum_{i',j'} e^{\Theta_{i'j'}^{(\ell_1)}} \right) \\
= & \frac{ne^{2\alpha}}{k_1^2 k_2^2 \binom{d_1}{k_1}\binom{d_2}{k_2}} \sum_{S,T} \left(\sum_{i',j'} e^{\Theta_{i'j'}^{(\ell_2)}} \sum_{i,j} \frac{\left(e^{\Theta_{ij}^{(\ell_1)}} - e^{\Theta_{ij}^{(\ell_2)}} \right)^2}{e^{\Theta_{ij}^{(\ell_2)}}} - \Big(\sum_{i,j} (e^{\Theta_{ij}^{(\ell_1)}} - e^{\Theta_{ij}^{(\ell_2)}}) \Big)^2 \right) \\
\overset{(d)}{\le} & \frac{ne^{4\alpha}}{k_1 k_2 \binom{d_1}{k_1}\binom{d_2}{k_2}} \sum_{S,T} \sum_{i,j} \left(e^{\Theta_{ij}^{(\ell_1)}} - e^{\Theta_{ij}^{(\ell_2)}} \right)^2 \\
\overset{(e)}{\le} & \frac{ne^{5\alpha}}{k_1 k_2 \binom{d_1}{k_1}\binom{d_2}{k_2}} \sum_{S,T} \sum_{i,j} \left(\Theta_{ij}^{(\ell_1)} - \Theta_{ij}^{(\ell_2)} \right)^2 \\
\overset{(f)}{=} & \frac{ne^{5\alpha}}{d_1 d_2} \left\| \Theta_{ij}^{(\ell_1)} - \Theta_{ij}^{(\ell_2)} \right\|_{\mathrm{F}}^2
\end{aligned}
$$

Here (a) is by definition of KL-distance and the fact that S, T are chosen uniformly from all possible such sets and (b) is due to the fact that $\log(x) \le x - 1$ with $x = (e^{\Theta_{ij}^{(\ell_1)}} \sum_{i'\in S, j'\in T} e^{\Theta_{i'j'}^{(\ell_2)}})/(e^{\Theta_{ij}^{(\ell_2)}} \sum_{i'\in S, j'\in T} e^{\Theta_{i'j'}^{(\ell_1)}})$. The constants at (c) is due to the fact that each element of $\Theta^{(\ell_1)}$ is upper bounded by α and lower bounded by $-\alpha$. We can get (d) by removing the second term which is always negative, and using the bond of α. (e) is obtained because e^x where $-\alpha \le x \le \alpha$ is Lipschitz continuous with Lipschitz constant e^α. At last (f) is obtained by simple counting of the occurrences of each ij. Thus we have,

$$
\mathbb{P}\left\{ \widehat{L} \neq L \right\} \;\ge\; 1 - \frac{\binom{M}{2}^{-1} \sum_{\ell_1,\ell_2\in[M]} \frac{ne^{5\alpha}}{d_1 d_2} \left\| \Theta_{ij}^{(\ell_2)} - \Theta_{ij}^{(\ell_2)} \right\|_{\mathrm{F}}^2 + \log 2}{\log M}, \tag{253}
$$

The remainder of the proof relies on the following probabilistic packing.

Lemma 43 *Let $d_2 \ge d_1$ be sufficiently large positive integers. Then for each $r \in \{1, \dots, d_1\}$, and for any positive $\delta > 0$ there exists a family of $d_1 \times d_2$ dimensional matrices $\{\Theta^{(1)}, \dots, \Theta^{(M(\delta))}\}$ with cardinality $M(\delta) = \lfloor (1/4)\exp(rd_2/576) \rfloor$ such that each matrix is rank r and the following bounds hold:*

$$
\begin{aligned}
\left\| \Theta^{(\ell)} \right\|_{\mathrm{F}} &\le \delta \;, \text{ for all } \ell \in [M] && (254)\\
\left\| \Theta^{(\ell_1)} - \Theta^{(\ell_2)} \right\|_{\mathrm{F}} &\ge \frac{1}{2}\delta \;, \text{ for all } \ell_1, \ell_2 \in [M] && (255)\\
\Theta^{(\ell)} &\in \Omega_{\tilde{\alpha}} \;, \text{ for all } \ell \in [M] \,, && (256)
\end{aligned}
$$

with $\tilde{\alpha} = (8\delta/d_2)\sqrt{2\log d}$ for $d = (d_1 + d_2)/2$.

Suppose $\delta \le \alpha d_2/(8\sqrt{2\log d})$ such that the matrices in the packing set are entry-wise bounded by α, then the above lemma 43 implies that $\left\| \Theta^{(\ell_1)} - \Theta^{(\ell_2)} \right\|_{\mathrm{F}}^2 \le 4\delta^2$, which gives

$$
\mathbb{P}\left\{ \widehat{L} \neq L \right\} \;\ge\; 1 - \frac{\frac{e^{5\alpha} n 4\delta^2}{d_1 d_2} + \log 2}{\frac{rd_2}{576} - 2\log 2} \;\ge\; \frac{1}{2} \,, \tag{257}
$$

where the last inequality holds for $\delta^2 \le (rd_1 d_2^2/(1152 e^{5\alpha} n))$ and assuming $rd_2 \ge 1600$. Together with (257) and (255), this proves that for all $\delta \le \min\{\alpha d_2/(8\sqrt{2\log d}), \sqrt{rd_1 d_2^2/(9216\, e^{5\alpha} n)}\}$,

$$
\inf_{\widehat{\Theta}} \sup_{\Theta^* \in \Omega_\alpha} \mathbb{E}\Big[\left\| \widehat{\Theta} - \Theta^* \right\|_{\mathrm{F}} \Big] \;\ge\; \delta/4 \,.
$$

Choosing δ appropriately to maximize the right-hand side finishes the proof of the desired claim. Also by symmetry, we can apply the same argument to get similar bound with d_1 and d_2 interchanged.

H.1 Proof of Lemma 43

We show that the following procedure succeeds in producing the desired family with probability at least half, which proves its existence. Let $d = (d_1 + d_2)/2$, and suppose $d_2 \ge d_1$ without loss of generality. For the choice of $M' = e^{rd_2/576}$, and for each $\ell \in [M']$, generate a rank-r matrix $\Theta^{(\ell)} \in \mathbb{R}^{d_1 \times d_2}$ as follows:

$$
\Theta^{(\ell)} \;=\; \frac{\delta}{\sqrt{rd_2}} U (V^{(\ell)})^T - \frac{\delta}{\sqrt{rd_2}} \frac{\mathbb{1}^T U (V^{(\ell)})^T \mathbb{1}}{d_1 d_2} \mathbb{1}\mathbb{1}^T \,, \tag{258}
$$

where $U \in \mathbb{R}^{d_1 \times r}$ is a random orthogonal basis such that $U^T U = \mathbf{I}_{r\times r}$ and $V^{(\ell)} \in \mathbb{R}^{d_2 \times r}$ is a random matrix with each entry $V_{ij}^{(\ell)} \in \{-1, +1\}$ chosen independently and uniformly at random. By construction, notice that $\left\| \Theta^{(\ell)} \right\|_{\mathrm{F}} \le (\delta/\sqrt{rd_2}) \left\| U (V^{(\ell)})^T \right\|_{\mathrm{F}} = \delta$.

Now, by triangular inequality, we have

$$
\begin{aligned}
& \left\| \Theta^{(\ell_1)} - \Theta^{(\ell_2)} \right\|_{\mathrm{F}} \\
\ge\; & \frac{\delta}{\sqrt{rd_2}} \left\| U (V^{(\ell_1)} - V^{(\ell_2)})^T \right\|_{\mathrm{F}} - \frac{\delta \left| \mathbb{1}^T U (V^{(\ell_1)} - V^{(\ell_2)})^T \mathbb{1} \right|}{d_1 d_2 \sqrt{rd_2}} \left\| \mathbb{1}\mathbb{1}^T \right\|_{\mathrm{F}} \\
\ge\; & \frac{\delta}{\sqrt{rd_2}} \underbrace{\left\| V^{(\ell_1)} - V^{(\ell_2)} \right\|_{\mathrm{F}}}_{A} - \frac{\delta}{\sqrt{r\, d_1\, d_2^2}} \big(\underbrace{\left| \mathbb{1}^T U (V^{(\ell_1)})^T \mathbb{1} \right|}_{B} + \left| \mathbb{1}^T U (V^{(\ell_2)})^T \mathbb{1} \right| \big) \,.
\end{aligned}
$$

We will prove that the first term is bounded by $A \geq \sqrt{rd_2}$ with probability at least 7/8 for all M' matrices, and we will show that we can find M matrices such that the second term is bounded by $B \leq 8\sqrt{2rd_2 \log(32r)\log(32d)}$ with probability at least 7/8. Together, this proves that with probability at least 3/4, there exists M matrices such that

$$\left|\left|\left|\Theta^{(\ell_1)} - \Theta^{(\ell_2)}\right|\right|\right|_{\mathrm{F}} \;\geq\; \delta\Big(1 - \sqrt{\frac{2^7 \log(32r)\, \log(32d)}{d_1 d_2}}\Big) \;\geq\; \frac{1}{2}\delta\,,$$

for all ℓ_1, $\ell_2 \in [M]$ and for sufficiently large d_1 and d_2.

Applying similar McDiarmid's inequality as Eq. (122) in Appendix E, it follows that $A^2 \geq rd_2$ with probability at least 7/8 for $M' = e^{rd_2/576}$ and a sufficiently large d_2.

To prove a bound on B, we will show that for a given ℓ,

$$\mathbb{P}\Big\{|\mathbb{1}^T U (V^{(\ell)})^T \mathbb{1}| \leq 8\sqrt{2rd_2 \log(32r)\log(32d)}\Big\} \;\geq\; \frac{7}{8}\,. \tag{259}$$

Then using the similar technique as in (125), it follows that we can find $M = (1/4)M'$ matrices all satisfying this bound and also the bound on the max-entry in (260). We are left to prove (259). We apply a series of concentration inequalities. Let H_1 be the event that $\{|\langle\!\langle V_i^{(\ell)}, \mathbb{1}\rangle\!\rangle| \leq \sqrt{2d_2 \log(32r)}$ for all $i \in [r]\}$. Then, applying the standard Hoeffding's inequality, we get that $\mathbb{P}\{H_1\} \geq 15/16$, where $V_i^{(\ell)}$ is the i-th column of $V^{(\ell)}$. We next change the variables and represent $\mathbb{1}^T U$ as $\sqrt{d_1} u^T \tilde{U}$, where u is drawn uniformly at random from the unit sphere and $\tilde{U}$ is a r dimensional subspace drawn uniformly at random. By symmetry, $\sqrt{d_1} u^T \tilde{U}$ have the same distribution as $\mathbb{1}^T U$. Let H_2 be the event that $\{|\langle\!\langle \tilde{U}_i, (V^{(\ell)})^T \mathbb{1}\rangle\!\rangle| \leq \sqrt{16r(d_2/d_1)\log(32r)\log(32d)}$ for all $i \in [d_1]\}$, where $\tilde{U}_i$ is the i-th row of $\tilde{U}$. Then, applying Levy's theorem for concentration on the sphere Ledoux (2005), we have $\mathbb{P}\{H_2|H_1\} \geq 15/16$. Finally, let H_3 be the event that $\{|\sqrt{d_1}\langle\!\langle u, \tilde{U}(V^{(\ell)})^T\rangle\!\rangle \mathbb{1}| \leq 8\sqrt{2rd_2 \log(32r)\log(32d)}\}$. Then, again applying Levy's concentration, we get $\mathbb{P}\{H_3|H_1, H_2\} \geq 15/16$. Collecting all three concentration inequalities, we get that with probability at least 13/16, $|\mathbb{1}^T U (V^{(\ell)})^T \mathbb{1}| \leq 8\sqrt{2rd_2 \log(32r)\log(32d)}$, which proves Eq. (259).

We are left to prove that $\Theta^{(\ell)}$'s are in $\Omega_{(8\delta/d_2)\sqrt{2\log d_2}}$ as defined in (51). Similar to Eq. (124), applying Levy's concentration gives

$$\mathbb{P}\Big\{\max_{i,j} |\Theta_{ij}^{(\ell)}| \leq \frac{2\delta\sqrt{32\log d_2}}{d_2}\Big\} \;\geq\; 1 - 2\exp\Big\{-2\log d_2\Big\} \;\geq\; \frac{1}{2}\,, \tag{260}$$

for a fixed $\ell \in [M']$. Then using the similar technique as in (125), it follows that there exists $M = (1/4)M'$ matrices all satisfying this bound and also the bound on B in Eq. (259).

Abstract

Variational autoencoders (VAE) represent a popular, flexible form of deep generative model that can be stochastically fit to samples from a given random process using an information-theoretic variational bound on the true underlying distribution. Once so-obtained, the model can be putatively used to generate new samples from this distribution, or to provide a low-dimensional latent representation of existing samples. While quite effective in numerous application domains, certain important mechanisms which govern the behavior of the VAE are obfuscated by the intractable integrals and resulting stochastic approximations involved. Moreover, as a highly non-convex model, it remains unclear exactly how minima of the underlying energy relate to original design purposes. We attempt to better quantify these issues by analyzing a series of tractable special cases of increasing complexity. In doing so, we unveil interesting connections with more traditional dimensionality reduction models, as well as an intrinsic yet underappreciated propensity for robustly dismissing sparse outliers when estimating latent manifolds. With respect to the latter, we demonstrate that the VAE can be viewed as the natural evolution of recent robust PCA models, capable of learning nonlinear manifolds of unknown dimension obscured by gross corruptions.

Keywords: Variational Autoencoder, Deep Generative Model, Robust PCA

1. Introduction

We begin with a data set $\boldsymbol{X} = \{\boldsymbol{x}^{(i)}\}_{i=1}^n$ composed of n i.i.d. samples of some random variable $\boldsymbol{x} \in \mathbb{R}^d$ of interest, with the goal of estimating a tractable approximation for $p_{\boldsymbol{\theta}}(\boldsymbol{x})$, knowledge of which would allow us to generate new samples of $\boldsymbol{x}$. Moreover we assume that each sample is governed by unobserved latent variables $\boldsymbol{z} \in \mathbb{R}^\kappa$, such that $p_{\boldsymbol{\theta}}(\boldsymbol{x}) = \int p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})p(\boldsymbol{z})d\boldsymbol{z}$, where $\boldsymbol{\theta}$ are the parameters defining the distribution we would like to estimate.

Given that this integral is intractable in all but the simplest cases, variational autoencoders (VAE) represent a powerful means of optimizing with respect to $\boldsymbol{\theta}$ a tractable upper bound on $-\log p_{\boldsymbol{\theta}}(\boldsymbol{x})$ (Kingma and Welling, 2014; Rezende et al., 2014). Once these parameters are obtained, we can then generate new samples from $p_{\boldsymbol{\theta}}(\boldsymbol{x})$ by first drawing some $\boldsymbol{z}^{(i)}$ from $p(\boldsymbol{z})$, and then a new $\boldsymbol{x}^{(i)}$ from $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}^{(i)})$. The VAE upper bound itself is constructed as

$$\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}) \;=\; \sum_i \left\{ \mathbb{KL}\left[q_{\boldsymbol{\phi}}\left(\boldsymbol{z}|\boldsymbol{x}^{(i)}\right) || p_{\boldsymbol{\theta}}\left(\boldsymbol{z}|\boldsymbol{x}^{(i)}\right)\right] - \log p_{\boldsymbol{\theta}}(\boldsymbol{x}^{(i)}) \right\} \;\geq\; -\sum_i \log p_{\boldsymbol{\theta}}(\boldsymbol{x}^{(i)}), \tag{1}$$

where $q_{\boldsymbol{\phi}}\left(\boldsymbol{z}|\boldsymbol{x}^{(i)}\right)$ defines an arbitrary approximating distribution, parameterized by $\boldsymbol{\phi}$, and $\mathbb{KL}\left[\cdot||\cdot\right]$ denotes the KL divergence between two distributions, which is always a non-negative quantity. For optimization purposes, it is often convenient to re-express this bound as

$$\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}) \;\equiv\; \sum_i \left(\mathbb{KL}\left[q_{\boldsymbol{\phi}}\left(\boldsymbol{z}|\boldsymbol{x}^{(i)}\right) || p(\boldsymbol{z})\right] - \mathbb{E}_{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}^{(i)})}\left[\log p_{\boldsymbol{\theta}}\left(\boldsymbol{x}^{(i)}|\boldsymbol{z}\right)\right]\right). \tag{2}$$

In these expressions, $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ can be viewed as an *encoder* model that defines a conditional distribution over the latent 'code' $\boldsymbol{z}$, while $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})$ can be interpreted as a *decoder* model since, given a code $\boldsymbol{z}$ it quantifies the distribution over $\boldsymbol{x}$.

By far the most common distributional assumptions are that $p(\boldsymbol{z}) = \mathcal{N}(\boldsymbol{z}; \boldsymbol{0}, \boldsymbol{I})$ and the encoder model satisfies $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) = \mathcal{N}(\boldsymbol{z}; \boldsymbol{\mu}_z, \boldsymbol{\Sigma}_z)$, where the mean $\boldsymbol{\mu}_z$ and covariance $\boldsymbol{\Sigma}_z$ are some function of model parameters $\boldsymbol{\phi}$ and the random variable $\boldsymbol{x}$. Likewise, for the decoder model we assume $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) = \mathcal{N}(\boldsymbol{x}; \boldsymbol{\mu}_x, \boldsymbol{\Sigma}_x)$ for continuous data, with means and covariances defined analogously.[1]

For arbitrarily parameterized moments $\boldsymbol{\mu}_z$, $\boldsymbol{\Sigma}_z$, $\boldsymbol{\mu}_x$, and $\boldsymbol{\Sigma}_x$, the KL divergence in (2) computes to

$$2\mathbb{KL}\left[q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})||p(\boldsymbol{z})\right] \;\equiv\; \mathrm{tr}\left[\boldsymbol{\Sigma}_z\right] + \|\boldsymbol{\mu}_z\|_2^2 - \log|\boldsymbol{\Sigma}_z|, \tag{3}$$

excluding irrelevant constants. However, the remaining integral from the expectation term admits no closed-form solution, making direct optimization over $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ intractable. Likewise, any detailed analysis of the underlying objective function becomes problematic as well.

At least for practical purposes, one way around this is to replace the troublesome expectation with a Monte Carlo stochastic approximation (Kingma and Welling, 2014; Rezende et al., 2014). More specifically we utilize

$$\mathbb{E}_{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}^{(i)})}\left[\log p_{\boldsymbol{\theta}}\left(\boldsymbol{x}^{(i)}|\boldsymbol{z}\right)\right] \;\approx\; \tfrac{1}{\tau}\sum_{t=1}^{\tau} \log p_{\boldsymbol{\theta}}\left(\boldsymbol{x}^{(i)}|\boldsymbol{z}^{(i,t)}\right), \tag{4}$$

where $\boldsymbol{z}^{(i,t)}$ are samples drawn from $q_{\boldsymbol{\phi}}\left(\boldsymbol{z}|\boldsymbol{x}^{(i)}\right)$. Using a simple reparameterization trick, these samples can be constructed such that gradients with respect to $\boldsymbol{\mu}_z$ and $\boldsymbol{\Sigma}_z$ can be

1. For discrete data, a Bernoulli distribution is sometimes adopted instead.

propagated through the righthand side of (4). Therefore, assuming all the required moments $\boldsymbol{\mu}_z$, $\boldsymbol{\Sigma}_z$, $\boldsymbol{\mu}_x$, and $\boldsymbol{\Sigma}_x$ are differentiable with respect to $\boldsymbol{\phi}$ and $\boldsymbol{\theta}$, the entire model can be updated using SGD (Bottou, 2010).

While quite effective in numerous application domains that can apply generative models, e.g., semi-supervised learning (Kingma et al., 2014; Maaløe et al., 2016; Mansimov et al., 2016), certain important mechanisms which dictate the behavior of the VAE are obfuscated by the required stochastic approximation and the opaque underlying objective with high-dimensional integrals. Moreover, it remains unclear to what extent minima remain anchored at desirable locations in the non-convex energy landscape.

We take a step towards better quantifying such issues by probing the basic VAE model under a few simplifying assumptions of increasing complexity whereby closed-form integrations are (partially) possible. This process unveils a number of interesting connections with more transparent, established generative models, each of which shed light on how the VAE may perform under more challenging conditions. This mirrors the rich tradition of analyzing deep networks under various simplifications such as linear layers or i.i.d. random activation patterns (Choromanska et al., 2015a,b; Goodfellow et al., 2016; Kawaguchi, 2016; Saxe et al., 2014), and results in the following key contributions:

1. We demonstrate that the canonical form of the VAE, including the Gaussian distributional assumptions described above, harbors an innate agency for robust outlier removal in the context of learning inlier points constrained to a manifold of unknown dimension. In fact, when the decoder mean $\boldsymbol{\mu}_x$ is restricted to an affine function of $\boldsymbol{z}$, we prove that the VAE model collapses to a form of robust PCA (RPCA) (Candès et al., 2011; Chandrasekaran et al., 2011), a recently celebrated technique for separating data into low-rank (low-dimensional) inlier and sparse outlier components.[2]

2. We elucidate two central, albeit underappreciated roles of the VAE encoder covariance $\boldsymbol{\Sigma}_z$. First, through subtle multi-tasking efforts in both terms of (2), it facilitates learning the correct inlier manifold dimension. Secondly, $\boldsymbol{\Sigma}_z$ can help to smooth out undesirable minima in the energy landscape of what would otherwise resemble a more traditional deterministic autoencoder (AE) (Bengio, 2009). This is true even in certain situations where it provably does not actually alter the globally optimal solution itself. Note that prior to this work the AE could ostensibly be viewed as the most natural candidate for instantiating extensions of RPCA to handle outlier-robust nonlinear manifold learning. However, our results suggest that the VAE maintains pivotal advantages in mitigating the effects of bad local solutions and over-parameterized latent representations, even in completely deterministic settings that require no generative model per se.

As we will soon see, these points can have profound practical repercussions in terms of how VAE models are interpreted and deployed. For example, one immediate consequence is that even if the decoder capacity is not sufficient to capture the generative distribution *within* some fixed, unknown manifold, the VAE can nonetheless still often find the correct manifold itself, which is sufficient for deterministic recovery of uncorrupted inlier points.

2. RPCA represents a rather dramatic departure from vanilla PCA and is characterized by a challenging, combinatorial optimization problem. A formal definition will be provided in Section 3.

This is exactly analogous to RPCA recovery results, whereby it is possible to correctly estimate an unknown low-dimensional linear subspace heavily corrupted with outliers even if in doing so we do not obtain an actual generative model for the inliers within this subspace. We emphasize that this is *not* a job description for which the VAE was originally motivated, but a useful hidden talent nonetheless.

The remainder of this paper is organized as follows. In Section 2 we consider two affine decoder models and connections with past probabilistic PCA-like approaches. Note that the seminal work from (Rezende et al., 2014) mentions in passing that a special case of their VAE decoder model reduces to factor analysis (Bartholomew and Knott, 1999), a cousin of probabilistic PCA; however, no rigorous, complementary analysis is provided, such as how latent-space sparsity can emerge as we will introduce shortly. Next we examine various partially affine decoder models in Section 3, whereby only the mean $\boldsymbol{\mu}_x$ is affine while $\boldsymbol{\Sigma}_x$ has potentially unlimited complexity; all encoder quantities are likewise unconstrained. We precisely characterize how minimizers of the VAE cost, although not available in closed form, nonetheless are capable of optimally decomposing data into low-rank and sparse factors akin to RPCA while avoiding bad local optima. This section also discusses extensions as well as interesting behavioral properties of the VAE.

Section 4 then considers degeneracies in the full VAE model that can arise even with a trivially simple encoder and corresponding latent representation. Section 5 concludes with experiments that directly corroborate a number of interesting, practically-relevant hypotheses generated by our theoretical analyses, suggesting novel usages (unrelated to generating samples) as a tool for deterministic manifold learning in the presence of outliers. We provide final conclusions in Section 6. Note that our prior conference paper has presented the basic demonstration that VAE models can be applied to tackling generalized robust PCA problems (Wang et al., 2017). However this work primarily considers empirical demonstrations and high-level motivations, with minimal analytical support.

Notation: We use a superscript $^{(i)}$ to denote quantities associated with the i-th sample, which at times may correspond with the columns of a matrix, such as the data $\boldsymbol{X}$ or related. For a general matrix $\boldsymbol{M}$, we refer to the i-th row as $\boldsymbol{m}_{i\cdot}$ and the j-th column as $\boldsymbol{m}_{\cdot j}$. Although technically speaking posterior moments are functions of the parameters $\{\boldsymbol{\theta}, \boldsymbol{\phi}\}$, the random variables $\boldsymbol{x}$, and the latent $\boldsymbol{z}$, i.e., $\boldsymbol{\mu}_x \equiv \boldsymbol{\mu}_x(\boldsymbol{z};\boldsymbol{\theta})$, $\boldsymbol{\Sigma}_x \equiv \boldsymbol{\Sigma}_x(\boldsymbol{z};\boldsymbol{\theta})$, $\boldsymbol{\mu}_z \equiv \boldsymbol{\mu}_z(\boldsymbol{x};\boldsymbol{\phi})$, and $\boldsymbol{\Sigma}_z \equiv \boldsymbol{\Sigma}_z(\boldsymbol{x};\boldsymbol{\phi})$, except in cases where some ambiguity exists regarding the arguments, these dependencies are omitted to avoid undue clutter; likewise for $\boldsymbol{\mu}_z^{(i)} \triangleq \boldsymbol{\mu}_z(\boldsymbol{x}^{(i)};\boldsymbol{\phi})$ and $\boldsymbol{\Sigma}_z^{(i)} \triangleq \boldsymbol{\Sigma}_z(\boldsymbol{x}^{(i)};\boldsymbol{\phi})$. Also, with some abuse of notation, we will use $\mathcal{L}$ to denote a number of different VAE-related objective functions and bounds, with varying arguments and context serving as differentiating factors. Finally, the diag[$\cdot$] operator converts vectors to a diagonal matrix, and vice versa as in the Matlab computing environment.

2. Affine Decoder and Probabilistic PCA

If we assume that $\boldsymbol{\Sigma}_x$ is fixed at some $\lambda \boldsymbol{I}$, and force $\boldsymbol{\Sigma}_z = \boldsymbol{0}$ (while removing the now undefined $\log|\boldsymbol{\Sigma}_z|$ term), then it is readily apparent that the resultant VAE model reduces to a traditional AE with squared-error loss function (Bengio, 2009), a common practical assumption. To see this, note that if $\boldsymbol{\Sigma}_z = \boldsymbol{0}$, then $q_{\boldsymbol{\phi}}\left(\boldsymbol{z}|\boldsymbol{x}^{(i)}\right)$ collapses to $\delta(\boldsymbol{\mu}_z)$, i.e., a

delta function at the posterior mean, and $\mathbb{E}_{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}^{(i)})}\left[\log p_{\boldsymbol{\theta}}\left(\boldsymbol{x}^{(i)}|\boldsymbol{z}\right)\right] = \log p_{\boldsymbol{\theta}}\left(\boldsymbol{x}^{(i)}|\boldsymbol{\mu}_z^{(i)}\right)$, which is just a standard AE with quadratic loss and representation $\boldsymbol{\mu}_x\left(\boldsymbol{\mu}_z\left[\boldsymbol{x}\right]\right)$. Moreover, the only remaining (non-constant) regularization from the KL term is $\sum_i \|\boldsymbol{\mu}_z^{(i)}\|_2^2$. However, given scaling ambiguities that may arise in the decoder when $\boldsymbol{\Sigma}_z = \mathbf{0}$, $\boldsymbol{\mu}_z^{(i)}$ can often be made arbitrarily small, and therefore the effect of this quadratic penalty is infinitesimal. With affine encoder and decoder models, the resulting deterministic network will simply learn principal components like vanilla PCA, a well-known special case of the AE (Bourlard and Kamp, 1988).

Therefore to understand the VAE, it is crucial to explore the role of non-trivial selections for the encoder and decoder covariances, that serve as both enlightening and differentiating factors. As a step in this direction, we will explore several VAE reductions that lead to more manageable (yet still representative) objective functions and strong connections to existing probabilistic models. In this section we begin with the following simplification:

Lemma 1 *Suppose that the decoder moments satisfy $\boldsymbol{\mu}_x = \boldsymbol{W}\boldsymbol{z} + \boldsymbol{b}$ and $\boldsymbol{\Sigma}_x = \lambda \boldsymbol{I}$ for some parameters $\boldsymbol{\theta} = \{\boldsymbol{W}, \boldsymbol{b}, \lambda\}$ of appropriate dimensions. Furthermore, we assume for the encoder we have $\boldsymbol{\mu}_z = f(\boldsymbol{x};\boldsymbol{\phi})$, $\boldsymbol{\Sigma}_z = \boldsymbol{S}_z\boldsymbol{S}_z^\top$, and $\boldsymbol{S}_z = g(\boldsymbol{x};\boldsymbol{\phi})$, where f and g are any parameterized functional forms that include arbitrary affine transformations for some arrangement of parameters. Under these assumptions, the objective from (2) admits optimal, closed-form solutions for $\boldsymbol{\mu}_z$ and $\boldsymbol{\Sigma}_z$ in terms of $\boldsymbol{W}$, $\boldsymbol{b}$, and λ such that the resulting VAE cost collapses to*

$$\mathcal{L}(\boldsymbol{W}, \boldsymbol{b}, \lambda) \;=\; \sum_i \boldsymbol{\Omega}^{(i)}(\boldsymbol{W}, \boldsymbol{b}, \lambda \boldsymbol{I}) + n \log \left| \lambda \boldsymbol{I} + \boldsymbol{W}\boldsymbol{W}^\top \right|, \tag{5}$$

where

$$\boldsymbol{\Omega}^{(i)}(\boldsymbol{W}, \boldsymbol{b}, \boldsymbol{\Psi}) \;\triangleq\; \left(\boldsymbol{x}^{(i)} - \boldsymbol{b}\right)^\top \left(\boldsymbol{\Psi} + \boldsymbol{W}\boldsymbol{W}^\top\right)^{-1} \left(\boldsymbol{x}^{(i)} - \boldsymbol{b}\right). \tag{6}$$

Additionally, if we enforce that off-diagonal elements of $\boldsymbol{\Sigma}_z$ must be equal to zero (i.e., $[\boldsymbol{\Sigma}_z]_{ij} = 0$ for $i \neq j$), then (5) further decouples/separates to

$$\mathcal{L}_{sep}(\boldsymbol{W}, \boldsymbol{b}, \lambda) \;=\; \sum_i \boldsymbol{\Omega}^{(i)}(\boldsymbol{W}, \boldsymbol{b}, \lambda \boldsymbol{I}) + n \left[\sum_j \log\left(\lambda + \|\boldsymbol{w}_{\cdot j}\|_2^2\right) + (d - \kappa) \log \lambda \right]. \tag{7}$$

All proofs are deferred to the appendices. The objective (5) is the same as that used by certain probabilistic PCA models (Tipping and Bishop, 1999), even though the latter is originally derived in a completely different manner. Moreover, it can be shown that any minimum of this objective represents a globally optimal solution (i.e, no minima with suboptimal objective function value exist). And with $\boldsymbol{b}$ and λ fixed, the optimal $\boldsymbol{W}$ will be such that span$[\boldsymbol{W}]$ equals the span of the singular vectors of $\boldsymbol{X} - \boldsymbol{b}\mathbf{1}^\top$ associated with singular values greater than $\sqrt{\lambda}$. So the global optimum produces a principal subspace formed by soft-thresholding the singular values of $\boldsymbol{X} - \boldsymbol{b}\mathbf{1}^\top$, with the rank one offset often used to normalize samples to have zero mean.[3]

3. While the details are omitted here, optimal solutions for both $\boldsymbol{b}$ and λ can be analyzed as well.

In contrast, the alternative cost (7), which arises from the oft-used practical assumption that $\boldsymbol{\Sigma}_z$ is diagonal, represents a rigorous upper bound to (5), since

$$\sum_j \log\left(\lambda + \|\boldsymbol{w}_{\cdot j}\|_2^2\right) + (d - \kappa)\log\lambda \;\geq\; \log\left|\lambda \boldsymbol{I} + \boldsymbol{W}\boldsymbol{W}^\top\right| \tag{8}$$

by virtue of Hadamard's inequality (see proof of Theorem 2 below), with equality iff $\boldsymbol{W}^\top\boldsymbol{W}$ is diagonal. Interestingly, all minima of the modified cost nonetheless retain global optimality of the original; however, it can be shown that there will be a combinatorial increase in the actual number of distinct (disconnected) minima:[4]

Theorem 2 *Let $\boldsymbol{R} \in \mathbb{R}^{\kappa\times\kappa}$ denote an arbitrary rotation matrix and $\boldsymbol{P} \in \mathbb{R}^{\kappa\times\kappa}$ an arbitrary permutation matrix. Furthermore let $\boldsymbol{W}^*$ be a minimum of (5) and $\boldsymbol{W}^{**}$ any minimum of (7) with $\boldsymbol{b}$ and λ fixed. Then the following three properties hold:*

1. $\mathcal{L}(\boldsymbol{W}^*, \boldsymbol{b}, \lambda) = \mathcal{L}(\boldsymbol{W}^*\boldsymbol{R}, \boldsymbol{b}, \lambda) = \mathcal{L}_{sep}(\boldsymbol{W}^{**}, \boldsymbol{b}, \lambda)$
$$= \;\; \mathcal{L}(\boldsymbol{W}^{**}\boldsymbol{P}, \boldsymbol{b}, \lambda) = \mathcal{L}_{sep}(\boldsymbol{W}^{**}\boldsymbol{P}, \boldsymbol{b}, \lambda). \tag{9}$$
2. *For any $\boldsymbol{W}^{**}\left(\boldsymbol{W}^{**}\right)^\top$ with distinct nonzero eigenvalues, there will exist at least $\frac{\kappa!}{(\kappa-r)!}$ distinct (disconnected) minima of (7) located at some $\boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{P}$, where $\boldsymbol{U}\boldsymbol{\Lambda}^2\boldsymbol{U}^\top$ represents the SVD of $\boldsymbol{W}^{**}\left(\boldsymbol{W}^{**}\right)^\top$ and $r = rank[\boldsymbol{W}^{**}]$.*
3. *$\boldsymbol{W}^{**}$ will have at most r nonzero columns, while $\boldsymbol{W}^*$ can have any number in $\{r, \ldots, \kappa\}$.*

Although this result applies to relatively simplistic affine decoders (the encoder need not be so constrained however), it nonetheless highlights a couple interesting principles. First, the diagonalization of $\boldsymbol{\Sigma}_z$ collapses the space of globally minimizing solutions to a subset of the original. While the consequences of this may be minor in the fully affine decoder model where all the solutions are still equally good, we surmise that with more sophisticated parameterizations this partitioning of the energy landscape into distinct basins-of-attraction could potentially introduce suboptimal local extrema. And from a broader perspective, Theorem 2 provides tangible validation of prior conjectures that variational Bayesian factorizations of this sort can fragment the space of local minima (Hoffman, 2014).

But there is a second, potentially-advantageous counter-affect elucidated by Theorem 2 as well. Specifically, even if $\boldsymbol{W}$ is overparameterized, meaning that κ is unnecessarily large, there exists an inherent mechanism to prune superfluous columns to exactly zero, i.e., column-wise sparsity. And once columns of $\boldsymbol{W}$ become sparse, the corresponding elements of $\boldsymbol{\mu}_z$ can no longer influence the data fit. Consequently, the $\|\boldsymbol{\mu}_z\|_2^2$ factor from (3) serves as the only relevant influence, pushing these values to be exactly zero even though ℓ_2 norms in most regularization contexts tend to favor diverse, *non-sparse* representations (Rao et al., 2003).

So ultimately, sparsity of $\boldsymbol{\mu}_z$ is an artifact of the diagonal $\boldsymbol{\Sigma}_z$ assumption and the interaction of multiple VAE terms, a subtle influence we empirically demonstrate translates to more complex regimes in Section 5. In any event, we have shown that both variants of the affine decoder model lead to reasonable probabilistic PCA-like objectives regardless of how overparameterized $\boldsymbol{\mu}_z$ and $\boldsymbol{\Sigma}_z$ happen to be.

4. By disconnected we mean that, to traverse from one minimum to another, we must ascend the objective function at some point along the way.

3. Partially Affine Decoder and Robust PCA

Thus far we have considered tight limitations on the complexity allowable in the functional forms of both $\boldsymbol{\mu}_x$ and $\boldsymbol{\Sigma}_x$, while $\boldsymbol{\mu}_z$ and $\boldsymbol{\Sigma}_z$ were free-range variables granted arbitrary flexibility. We now turn our gaze to the case where $\boldsymbol{\Sigma}_x$ can also be any parameterized, diagonal matrix[5] while $\boldsymbol{\mu}_x$ remains restricted. Although this administers considerable capacity to the model at the potential risk of overfitting, we will soon see that the VAE is nonetheless able to self-regularize in a very precise sense: Global minimizers of the VAE objective will ultimately correspond with optimal solutions to

$$\min_{\boldsymbol{L},\boldsymbol{S}} \quad n \cdot \text{rank}\,[\boldsymbol{L}] + \|\boldsymbol{S}\|_0, \qquad \text{s.t. } \boldsymbol{X} = \boldsymbol{L} + \boldsymbol{S}, \tag{10}$$

where $\|\cdot\|_0$ denotes the ℓ_0 norm, or a count of the number of nonzero elements in a vector or matrix. This problem represents the canonical form of robust principal component analysis (RPCA) (Candès et al., 2011; Chandrasekaran et al., 2011), decomposing a data matrix $\boldsymbol{X}$ into low-rank principal factors $\boldsymbol{L} = \boldsymbol{U}\boldsymbol{V}$, with $\boldsymbol{U}$ and $\boldsymbol{V}$ low-rank matrices of appropriate dimension, and a sparse outlier component $\boldsymbol{S}$. However, we must emphasize that (10), unlike traditional PCA, represents an NP-hard, discontinuous optimization problem with a combinatorial number of potentially bad local minima. Still, it is seemingly quite remarkable that the probabilistic VAE model shares any kinship with (10), even more so given that some of the distracting *local* minimizers can be smoothed away, a key VAE advantage as we will later argue.

Before elucidating this relationship, we require one additional technical caveat. Specifically, since $\log 0$ and $\frac{1}{0}$ are both undefined, and yet we will soon require an alliance with degenerate (or nearly so) covariance matrices that mimic the behavior of sparse and low-rank factors through log-det and inverse terms, we must place the mildest of restrictions on the minimal allowable singular values of $\boldsymbol{\Sigma}_x$ and $\boldsymbol{\Sigma}_z$. For this purpose we define $\mathcal{S}_\alpha^m$ as the set of $m \times m$ covariance matrices with singular values all greater than or equal to α, and likewise $\bar{\mathcal{S}}_\alpha^m$ as the subset of $\mathcal{S}_\alpha^m$ containing only diagonal matrices. We also define $\text{supp}_\alpha(\boldsymbol{x}) = \{i : |x_i| > \alpha\}$, noting that per this definition, $\text{supp}_0(\boldsymbol{x}) = \text{supp}(\boldsymbol{x})$, meaning we recover the standard definition of support: the set of indices associated with nonzero elements.

3.1 Main Result and Interpretation

Given the affine assumption from above, and the mild restriction $\boldsymbol{\Sigma}_x \in \bar{\mathcal{S}}_\alpha^d$ and $\boldsymbol{\Sigma}_z \in \mathcal{S}_\alpha^\kappa$ for some small $\alpha > 0$, the resulting constrained VAE minimization problem can be expressed as

$$\min_{\boldsymbol{\theta},\boldsymbol{\phi}} \quad \mathcal{L}\left(\boldsymbol{W}, \boldsymbol{b} = \boldsymbol{0}, \boldsymbol{\Sigma}_x \in \bar{\mathcal{S}}_\alpha^d, \boldsymbol{\mu}_z, \boldsymbol{\Sigma}_z \in \mathcal{S}_\alpha^\kappa\right), \tag{11}$$

where now $\boldsymbol{\theta}$ includes $\boldsymbol{W}$ as well as all the parameters embedded in $\boldsymbol{\Sigma}_x$, while $\boldsymbol{\mu}_z$ and $\boldsymbol{\Sigma}_z$ are parameterized as in Lemma 1. We have also set $\boldsymbol{b} = \boldsymbol{0}$ merely for ease of presentation as its role is minor. We then have the following:

5. A full covariance over $\boldsymbol{x}$ is infeasible given the high dimension, and can lead to undesirable degeneracies anyway. Therefore a diagonal covariance is typically, if not always, used in practice.

Theorem 3 *Suppose that $\boldsymbol{X} = \{\boldsymbol{x}^{(i)}\}_{i=1}^n$ admits a feasible decomposition $\boldsymbol{X} = \boldsymbol{U}\boldsymbol{V} + \boldsymbol{S}$ that uniquely[6] optimizes (10). Then for some $\bar{\alpha}$ sufficiently small, and all $\alpha \in (0, \bar{\alpha}]$, any global minimum $\{\hat{\boldsymbol{W}}, \hat{\boldsymbol{\Sigma}}_x, \hat{\boldsymbol{\mu}}_z, \hat{\boldsymbol{\Sigma}}_z\}$ of (11) will be such that*[7]

$$\textit{span}[\hat{\boldsymbol{W}}] = \textit{span}[\boldsymbol{U}] \qquad \textit{and} \qquad \textit{supp}_\alpha\left(\textit{diag}\left[\hat{\boldsymbol{\Sigma}}_x\left(\hat{\boldsymbol{\mu}}_z\left[\boldsymbol{x}^{(i)}\right]\right)\right]\right) = \textit{supp}[\boldsymbol{s}^{(i)}] \tag{12}$$

for all i provided that the latent representation satisfies $\kappa \geq \textit{rank}\,[\boldsymbol{U}]$.

Several important remarks are warranted here regarding the consequences and interpretation of this result:

- The $\hat{\boldsymbol{W}}$ satisfying (12) forms a linear basis for each inlier component $\boldsymbol{l}^{(i)}$, and likewise, a sample-dependent basis denoted $\boldsymbol{E}^{(i)}$ can be trivially constructed for each outlier component $\boldsymbol{s}^{(i)}$ using $\hat{\boldsymbol{\Sigma}}_x$, and $\hat{\boldsymbol{\mu}}_z$. Specifically, each unique column of $\boldsymbol{E}^{(i)}$ is a vector of zeros with a one in the j-th position, with $j \in \text{supp}_\alpha\left(\text{diag}\left[\hat{\boldsymbol{\Sigma}}_x\left(\hat{\boldsymbol{\mu}}_z\left[\boldsymbol{x}^{(i)}\right]\right)\right]\right)$. It follows that

  $$\boldsymbol{x}^{(i)} = \boldsymbol{l}^{(i)} + \boldsymbol{s}^{(i)} = \left[\hat{\boldsymbol{W}} \;\; \boldsymbol{E}^{(i)}\right]\left[\hat{\boldsymbol{W}} \;\; \boldsymbol{E}^{(i)}\right]^\dagger \boldsymbol{x}^{(i)}, \quad \forall i = 1, \ldots, n. \tag{13}$$

  Therefore if we can globally optimize the VAE objective, we can recover the correct latent representation, or equivalently, the optimal solution to (10).

- The requirements $\boldsymbol{\Sigma}_x \in \bar{\mathcal{S}}_\alpha^d$ and $\boldsymbol{\Sigma}_z \in \mathcal{S}_\alpha^\kappa$ do not portend the need for specialized tuning or brittleness of the result; these are merely technical conditions for dealing with degenerate covariances that occur near optimal solutions. While it might seem natural that $\boldsymbol{\Sigma}_x$ has diagonal elements pushed to zero in regions where near perfect data fit is possible, less intuitively, global optima of (11) can be achieved with an arbitrarily small $\boldsymbol{\Sigma}_z$, e.g., $\boldsymbol{\Sigma}_z = \alpha\boldsymbol{I}$, at least along latent dimensions needed to represent $\boldsymbol{L}$ (see proof construction). And interestingly, this implies that in areas surrounding a global optimum, the VAE objective can *resemble that of a regular AE*. As we will discuss more below, desirable smoothing effects of integration over $\boldsymbol{\Sigma}_z$ occur *elsewhere* in the energy landscape while preserving extrema anchored at the correct latent representation.

- Even if κ is large, meaning $\boldsymbol{W}$ is possibly overcomplete, the VAE will not overfit in the sense that there exists an inherent regulatory effect pushing $\text{span}[\boldsymbol{W}]$ towards $\text{span}[\boldsymbol{U}]$.

- If the globally optimal solution to (10) is not unique (this is different from uniqueness regarding the VAE objective), then a low-rank-plus-sparse model may not be the most reasonable, parsimonious representation of the data to begin with, and exact recovery of $\boldsymbol{L}$ and $\boldsymbol{S}$ will not be possible by *any* algorithm without further assumptions. More concretely, an arbitrary data point $\boldsymbol{x}^{(i)} \in \mathbb{R}^d$ requires d degrees of freedom to represent; however, if the data succinctly adheres to the RPCA model, then for properly chosen $\boldsymbol{U}$, $\boldsymbol{V}$, and $\boldsymbol{S}$, we can have $\boldsymbol{x}^{(i)} = \boldsymbol{U}\boldsymbol{v}^{(i)} + \boldsymbol{s}^{(i)}$, where $\|\boldsymbol{v}^{(i)}\|_0 + \|\boldsymbol{s}^{(i)}\|_0 < d$. Arbitrary

6. Obviously only $\boldsymbol{L}$ and $\boldsymbol{S}$ will be unique; the actual decomposition of $\boldsymbol{L}$ into $\boldsymbol{U}$ and $\boldsymbol{V}$ is indeterminate up to an inconsequential invertible transform.

7. Although somewhat cumbersome in print, the expression $\hat{\boldsymbol{\Sigma}}_x\left(\hat{\boldsymbol{\mu}}_z\left[\boldsymbol{x}^{(i)}\right]\right)$ refers to $\hat{\boldsymbol{\Sigma}}_x$ evaluated at $\hat{\boldsymbol{\mu}}_z$, where the latter is evaluated at $\boldsymbol{x}^{(i)}$, the i-th sample.

data in general position will never admit such a unique decomposition, and we should only expect such structure in data well-represented by our VAE model, or the original RPCA predecessor from (10).

- A number of celebrated results have stipulated conditions (Candès et al., 2011; Chandrasekaran et al., 2011) whereby global solutions of the convex relaxation into nuclear and ℓ_1 norm components given by

$$\min_{\boldsymbol{L},\boldsymbol{S}} \quad \sqrt{n} \cdot \text{rank}\, \|\boldsymbol{L}\|_* + \|\boldsymbol{S}\|_1, \quad \text{s.t. } \boldsymbol{X} = \boldsymbol{L} + \boldsymbol{S}, \tag{14}$$

will equal global solutions of (10). While elegant in theory, and practically relevant given that (10) is discontinuous, non-convex, and difficult to optimize, the required conditions for this equivalence to hold place strong restrictions on the allowable structure in $\boldsymbol{L}$ and support pattern in $\boldsymbol{S}$. In practice these conditions can never be verified and are unlikely to hold, so an alternative modeling approach such as the VAE, which can be viewed as a smoothed version of (10) when an affine decoder mean is used (more on this later), remains attractive. Additionally, there is no clear way to modify (14) to handle nonlinear manifolds, which is obviously the bread and butter of the VAE.

We emphasize that these conclusions are not the product of an overly contrived situation, given that a significant restriction is only placed on $\boldsymbol{\mu}_x$; *all* other posterior quantities are essentially unconstrained provided a sufficient lower complexity bound is exceeded, implying that the result will hold whenever a sufficiently complex deep network is used. Moreover, although we will defer to a formal treatment to future work for purposes of brevity here, with some mild additional conditions, Theorem 3 can naturally be extended to the case where the decoder mean function is generalized to subsume non-linear, union-of-subspace models as commonly assumed in subspace clustering problems (Elhamifar and Vidal, 2013; Rao et al., 2010). This then deviates substantially from any direct PCA-kinship, and buttresses the argument that the analysis presented here transitions to broader scenarios. The experiments from Section 5 will also provide complementary empirical confirmation.

Moving forward, as a point of further comparison it is also interesting to examine how a traditional AE, which emerges when $\boldsymbol{\Sigma}_z$ is forced to zero, behaves under analogous conditions to Theorem 3.

Corollary 4 *Under the same conditions as Theorem 3, if we remove the* $\log|\boldsymbol{\Sigma}_z|$ *term and assume* $\boldsymbol{\Sigma}_z = \boldsymbol{0}$ *elsewhere, then (11) admits a closed-form solution for* $\boldsymbol{\Sigma}_x$ *in terms of* $\boldsymbol{W}$ *and* $\boldsymbol{\mu}_z$ *such that minimizers of the VAE cost are minimizers of*

$$\mathcal{L}\left(\boldsymbol{W}, \boldsymbol{\mu}_z\right) = \sum_i \left\| \boldsymbol{x}^{(i)} - \boldsymbol{W}\boldsymbol{\mu}_z\left(\boldsymbol{x}^{(i)}\right) \right\|_0 \quad \textit{in the limit } \alpha \to 0. \tag{15}$$

From this result we immediately observe that, provided $\boldsymbol{\mu}_z$ enjoys a sufficiently rich parameterization, minimization of (15) is just a constrained version of (10), exactly equivalent to solving

$$\min_{\boldsymbol{L},\boldsymbol{S}} \quad \|\boldsymbol{S}\|_0, \quad \text{s.t. } \boldsymbol{X} = \boldsymbol{L} + \boldsymbol{S}, \;\; \text{rank}\,[\boldsymbol{L}] \leq \kappa. \tag{16}$$

This expression immediately exposes one weakness of the AE; namely, if κ is too large, there is no longer any operation in place to prune away unnecessary dimensions, and the trivial solution $\boldsymbol{L} = \boldsymbol{X}$ will be produced. In the large-κ regime then, global VAE and global AE solutions do in fact deviate, ultimately because of the removal of the $-\log|\boldsymbol{\Sigma}_z|$ term in the latter. So $\boldsymbol{\Sigma}_z$ plays a critical role in determining the correct, low-dimensional inlier structure, and ultimately it is this covariance that chaperons $\boldsymbol{W}$ during the learning process.

3.2 Additional Local Minima Smoothing Effects

There is also a more important, yet subtle, advantage of the VAE over both (16) and the original unconstrained RPCA model from (10). For both RPCA constructions, any feasible support pattern, even the trivial ones associated with non-interesting decompositions satisfying $\|\boldsymbol{v}^{(i)}\|_0 + \|\boldsymbol{s}^{(i)}\|_0 \geq d$ for some i, will necessarily represent a local minimum, since there is an infinite gradient to overcome to move from a zero-valued element of $\boldsymbol{S}$ to a nonzero one.

Unlike these deterministic approaches, the behavior of the VAE reflects a form of differential smoothing that rids the model of many of these pitfalls while retaining desirable minima that satisfy (12).[8] Based on details of the proof of Theorem 3, it can be shown that, excluding small-order terms dependent on other variables and a constant scale factor of $-\log\alpha$, then a representative bound on the VAE objective associated with each sample index i behaves like

$$\text{rank}[\boldsymbol{W}] + \text{supp}_\alpha\left(\text{diag}\left[\boldsymbol{\Sigma}_x\left(\boldsymbol{\mu}_z\left[\boldsymbol{x}^{(i)}\right]\right)\right]\right). \tag{17}$$

But crucially, *this behavior lasts only as long as (17) is strictly less than* d and $\boldsymbol{\Sigma}_z$ is forced to be small or degenerate. In contrast, when the value is at or above d, (17) no longer reflects the energy function, which becomes relatively flat because of smoothing via $\boldsymbol{\Sigma}_z$, avoiding the pitfalls described above. This phenomena then has the potential to smooth out a large constellation of bad locally optimal solutions.

To situate things in the narrative of (10), which is useful for illustration purposes, the VAE can be viewed (at least to first order approximation) as minimizing the alternative lower-bounding objective function

$$\begin{aligned} \sum_i \text{rank}\left[\boldsymbol{L}\boldsymbol{L}^\top + \text{diag}\left(\boldsymbol{s}^{(i)}\right)^2\right] &\leq \sum_i \text{rank}\left[\boldsymbol{L}\boldsymbol{L}^\top\right] + \sum_i \text{rank}\left[\text{diag}\left(\boldsymbol{s}^{(i)}\right)^2\right] \\ &= n \cdot \text{rank}\,[\boldsymbol{L}] + \|\boldsymbol{S}\|_0, \end{aligned} \tag{18}$$

or a smooth surrogate thereof, over the constraint set $\boldsymbol{X} = \boldsymbol{L} + \boldsymbol{S}$. The advantages of this lower bound are substantial: As long as a unique solution exists to the RPCA problem, the globally optimal solution with $\|\boldsymbol{v}^{(i)}\|_0 + \|\boldsymbol{s}^{(i)}\|_0 < d$ for all i will be unchanged; however, *any* feasible solution with $\|\boldsymbol{v}^{(i)}\|_0 + \|\boldsymbol{s}^{(i)}\|_0 \geq d$ will have a constant cost via the expression on the left of the inequality, truncating the many erratic peaks that will necessarily occur with the energy on the righthand side.

8. A more rudimentary form of this smoothing has been observed in much simpler empirical Bayesian models derived using Fenchel duality (Wipf, 2012).

In fact, away from the strongly attractive basins of optimal VAE solutions, the KL term from (2) is likely to push $\mathbf{\Sigma}_z$ more towards

$$\arg\min_{\mathbf{\Sigma}_z \succ \mathbf{0}} \mathbb{KL}\left[q_{\boldsymbol{\phi}}\left(\boldsymbol{z}|\boldsymbol{x}\right)||p(\boldsymbol{z})\right] \quad \equiv \quad \arg\min_{\mathbf{\Sigma}_z \succ \mathbf{0}} \operatorname{tr}\left[\mathbf{\Sigma}_z\right] - \log|\mathbf{\Sigma}_z| \quad = \quad \boldsymbol{I}. \tag{19}$$

Experiments presented in Section 5 confirm that this is indeed the case. And once $\mathbf{\Sigma}_z$ moves away from zero, it will generally contribute a strong smoothing effect via the expectation in (2). However, there exists an important previously unobserved caveat here: If the decoder mean function is excessively complex, it can potentially outwit all regulatory persuasions from $\mathbf{\Sigma}_z$, leading to undesirable degenerate solutions with no representational value as described next.

4. Degeneracies Arising from a Flexible Decoder Mean

In this section we consider the case where $\boldsymbol{\mu}_x$ is finally released from its affine captivity to join with posterior colleagues in the wild. That simultaneously granting $\boldsymbol{\mu}_x$, $\mathbf{\Sigma}_x$, $\boldsymbol{\mu}_z$, and $\mathbf{\Sigma}_z$ unlimited freedom leads to overfitting may not come as a surprise; however, it turns out that even if the latter three are severely constrained, overfitting will not be avoided when $\boldsymbol{\mu}_x$ is over-parameterized in a certain sense extending beyond a single affine layer. This is because, at least at a high level, the once-proud regulatory effects of $\mathbf{\Sigma}_z$ can be completely squashed in these situations leading to the following:

Theorem 5 *Suppose $\kappa = 1$ (i.e., a latent dimension of only one), $\mathbf{\Sigma}_z \equiv \sigma_z^2 = \lambda_z$ (a scalar), $\mu_z = \boldsymbol{a}^\top \boldsymbol{x}$ for some fixed vector $\boldsymbol{a}$, $\mathbf{\Sigma}_x = \lambda_x \boldsymbol{I}$, and $\boldsymbol{\mu}_x$ is an arbitrary piecewise linear function with n segments. Then the VAE objective is unbounded from below at a trivial solution $\{\hat{\lambda}_z, \hat{\boldsymbol{a}}, \hat{\lambda}_x, \hat{\boldsymbol{\mu}}_x\}$ such that the resulting posterior mean $\hat{\boldsymbol{\mu}}_x(z;\boldsymbol{\theta})$ will satisfy $\hat{\boldsymbol{\mu}}_x(z;\boldsymbol{\theta}) \in \{\boldsymbol{x}^{(i)}\}_{i=1}^n$ with probability one for any z.*

In this special case, $\mathbf{\Sigma}_x$, σ_z^2, and μ_z are all simple affine functions and the latent dimension is minimal, and yet an essentially useless, degenerate solution can arbitrarily optimize the VAE objective. This occurs because the VAE has limited power to corral certain types of heavily over-parameterized decoder mean functions, even when all other degrees of freedom are constrained, and in this regime the VAE essentially has no advantage over a traditional autoencoder (its natural self-regulatory agency may sometimes break down). In contrast, as we saw in a previous section, there is no problem taming the influences of an unlimited latent representation (meaning κ is large, e.g., even $\kappa > n$) and its huge, attendant parameterized mean function, provided the latter is affine, as in $\boldsymbol{\mu}_x = \boldsymbol{W}\boldsymbol{z} + \boldsymbol{b}$.

Indeed then, the issue is clearly not the *degree* of over-parameterization in $\boldsymbol{\mu}_x$ per se, but the actual structures in place. And the key problem is that, at least in some situations, the model can circumvent the entire regulatory mechanism of the KL term, pushing the latent variances towards zero even around *undesirable* solutions. For example, in the context of Theorem 5, the piecewise linear structure of $\boldsymbol{\mu}_x$ allows the decoder to act much like a vector quantization process, encouraging z towards a scalar code that selects for piecewise linear segments matched to training samples $\boldsymbol{x}^{(i)}$. And because this will lead to perfect reconstruction error if an optimal segment is found for a particular $z^{(i)}$, $\mathbf{\Sigma}_x = \lambda_x \boldsymbol{I} \approx \mathbf{0}$ serves as a reasonable characterization of posterior uncertainty, pushing $p(\boldsymbol{x}^{(i)}|z^{(i)}) \rightarrow \delta\left(\boldsymbol{x}^{(i)}\right)$ provided that $z^{(i)} \approx \mu_z\left(\boldsymbol{x}^{(i)}; \boldsymbol{a}\right) = \boldsymbol{a}^\top \boldsymbol{x}^{(i)}$, meaning that $\sigma_z^2 = \lambda_z$ is not too large.

In this situation, loosely speaking the data term from (2) will behave like $nd\log\lambda_x$, bullying the over-matched KL term that will scale only as $-n\log\lambda_z$. This in turn leads to a useless, degenerate solution as $\lambda_x = \lambda_z \rightarrow 0$, either for the purposes of generating representative samples, or for outlier removal as we have described herein.

One helpful caveat though, is that actually implementing such a complex piecewise linear function $\hat{\boldsymbol{\mu}}_x(z;\boldsymbol{\theta})$ using typical neural network components would require extremely wide and/or deep structure beyond the first decoder mean layer. And the degrees of freedom in such higher-layer structures would need to scale proportionally with the size of the training data, which is not a practical VAE operational regime to begin with. In contrast, the first layer of the decoder mean network more or less self-regularizes, at least in the affine and related cases as described above. And we conjecture that this self-regularization preserves in more complex networks of reasonable practical size as will be empirically demonstrated in Section 5. So really it is *excessive* complexity in higher decoder mean layers, unrelated to the dimensionality of the latent $\boldsymbol{z}$ bottleneck, where overfitting problems are more likely to arise.

Of course an analogous issue exists with generative adversarial networks (GAN) as well, a popular competing deep generative model composed of a generator network analogous to the VAE decoder, and a discriminator network that replaces the VAE encoder in a loose sense (Goodfellow et al., 2014). If the generator network merely learns a segmentation of $\boldsymbol{z}$-space such that all points in the i-th partition map to $\boldsymbol{x}^{(i)}$, the discriminator will be helpless to avert this degenerate situation even in principle. But there is an asymmetry when it comes to the GAN discriminator network and the VAE encoder: Over-parameterization of the former can be problematic (e.g., it can easily out-wit an affine or other proportionally simple generator), but the latter not so, at least in the sense that a highly flexible VAE encoder need not bully a simple decoder into trivial solutions as we have shown in previous sections.

5. Experiments and Analysis

Theoretical examination of simplified cases can be viewed as a powerful vehicle for generating accessible hypotheses that describe likely behavior in more realistic, practical situations. In this section we empirically evaluate and analyze three concrete hypotheses that directly emanate from our previous technical results and the tight connections between RPCA and VAE models. In aggregate, these hypotheses have wide-ranging consequences in terms of how VAEs should be applied and interpreted.

Before stating these hypotheses, we summarize what can be viewed as two, theoretically-accessible boundary cases considered thus far. First, building on Section 2, Section 3 demonstrated that the VAE can self-regularize and produce useful, robust models provided that restrictions are placed on only the decoder mean network. Conversely, Section 4 demonstrated that, regardless of other model components, if the decoder mean network is unreasonably complex beyond the first layer, then overfitting emerges as a potential concern. But between these two extremes, there exists a large operational regime whereby practical VAE behavior is both worth exploring and likely still informed by the original analysis of these boundary cases.

Within this context then, we conjecture that the desirable VAE properties exposed in Sections 2 and 3 are inherited by models involving deeper decoder mean networks, but at least constrained to practically-sized hidden-layer $\boldsymbol{\mu}_x$ complexity such that the concerns from Section 4 are not a significant factor (e.g., no networks where the degrees of freedom in higher decoder mean layers scales as $d \times n$, an absurd VAE structure by any measure). More specifically, in this section will empirically examine the following three hypotheses:

(i) When the decoder mean function is allowed to have multiple hidden layers of sensible size/depth, the VAE should behave like a nonlinear extension of RPCA, but with natural regularization effects in place that help to avoid local minima and/or overfitting to outliers. It is therefore likely to outperform either RPCA algorithms or, more importantly, an AE on diverse manifold recovery/outlier discovery problems unrelated to the probabilistic generative modeling tasks the VAE was originally designed for.

(ii) If the VAE latent representation $\boldsymbol{z}$ is larger than needed (meaning its dimension κ is higher than the true data manifold dimension), we have proven that unnecessary columns of $\boldsymbol{W}$ in a certain affine decoder mean model $\boldsymbol{\mu}_x = \boldsymbol{W}\boldsymbol{z} + \boldsymbol{b}$ will automatically be pruned as desired. Analogously, in the extended nonlinear case we would then expect that columns of the weight matrix from the first layer of the decoder mean network should be pushed to zero, again effectively pruning away the impact of any superfluous elements of $\boldsymbol{z}$.

(iii) When granted sufficient capacity in both $\boldsymbol{\mu}_x\,(\boldsymbol{\mu}_z\,[\boldsymbol{x}])$ and $\boldsymbol{\Sigma}_x$ to model inliers and outliers respectively, the VAE should have a tendency to push elements of the encoder covariance $\boldsymbol{\Sigma}_z$ to arbitrarily near zero along latent dimensions needed for representing inlier points, *selectively* overriding the KL regularizer that would otherwise push these values towards one. This counterintuitive behavior directly facilitates the VAE's utility as a nonlinear outlier removal tool (per Hypothesis (i)) by preserving exact adherence to the manifold in the neighborhood of optimal solutions.

5.1 Hypothesis (i) Evaluation Using Specially-Designed Ground-Truth Manifolds

If our theory is generally applicable, then a VAE with suitable parameterization should be able to significantly outperform an analogous deterministic AE (i.e., an equivalent VAE but with $\boldsymbol{\Sigma}_z = \boldsymbol{0}$) on the task of recovering data points drawn from a low-dimensional nonlinear manifold, but corrupted with gross outliers. In other words, even if both models have equivalent capacity to capture the intrinsic underlying manifold in principle, the VAE is more likely to avoid bad minima and correctly estimate it. We demonstrate this VAE capability here for the first time across an array of manifold dimensions and corruption percentages, recreating a nonlinear version of what are commonly termed *phase transition plots* in the vast RPCA literature (Candès et al., 2011; Ding et al., 2011; Kim et al., 2013; Wipf, 2012). These plots evaluate the reconstruction quality of competing algorithms for every pairing of subspace dimension and outlier ratio, creating a heat map that differentiates success and failure regions.

Of course explicit knowledge of ground-truth low-dimensional manifolds is required to accomplish this. With linear subspaces it is trivial to generate appropriate synthetic data

by simply creating two low-rank random matrices $\boldsymbol{U} \in \mathbb{R}^{d\times\kappa}$ and $\boldsymbol{V} \in \mathbb{R}^{\kappa\times n}$, a sparse outlier matrix $\boldsymbol{S}$, and then computing $\boldsymbol{X} = \boldsymbol{L} + \boldsymbol{S}$ with $\boldsymbol{L} = \boldsymbol{U}\boldsymbol{V}$. Algorithms are presented with only $\boldsymbol{X}$ and attempt to reconstruct $\boldsymbol{L}$. Here we generalize this process to the nonlinear regime using deep networks and the following non-trivial steps. In this revised context, the generated $\boldsymbol{L}$ will now represent a data matrix with columns confined to a ground-truth nonlinear manifold.

Data Generation: First we draw n low-dimensional samples $\boldsymbol{z}^{(i)} \in \mathbb{R}^{\kappa}$ from $\mathcal{N}(\boldsymbol{z}; \boldsymbol{0}, \boldsymbol{I})$ and pass them through a 3-layer network with ReLU activations (Nair and Hinton, 2010). We express this structure as $\boldsymbol{z}(\kappa)$-$\boldsymbol{D}_1(r_1)$-$\boldsymbol{D}_2(r_2)$-$\boldsymbol{l}(d)$, where $\boldsymbol{D}_1$ and $\boldsymbol{D}_2$ are hidden layers, $\boldsymbol{l}$ here serves as the output layer, and the values inside parentheses denote the respective dimensionalities (these experiment-dependent values will be discussed later). Network weights are set using the initialization procedure from (He et al., 2015). The d-dimensional output produced by $\boldsymbol{z}^{(i)}$ is denoted as $\boldsymbol{l}^{(i)}$, the collection of which form a matrix $\boldsymbol{L}$, with columns effectively lying on a κ-dimensional nonlinear manifold. This network can be viewed as a *ground-truth decoder*, projecting $\boldsymbol{z}^{(i)}$ to clean samples $\boldsymbol{l}^{(i)}$.

But we must also verify that there exists a known *ground-truth encoder* that can correctly invert the decoder, otherwise we cannot be sure that any given VAE structure provably maintains an optimal encoder within its capacity (this is very unlike the linear RPCA case where an analogous condition is trivially satisfied). To check this, we learn the requisite inverse mapping by training something like an inverted autoencoder. Basically, the decoder described above now acts as an encoder, to which we append a new 3-layer ReLU network structured as $\boldsymbol{l}(d)$-$\boldsymbol{E}_1(r_2)$-$\boldsymbol{E}_2(r_1)$-$\hat{\boldsymbol{z}}(\kappa)$, where now $\boldsymbol{E}_1$ and $\boldsymbol{E}_2$ denote candidate hidden layers for a potentially optimal encoder. The entire intverted structure then becomes $\boldsymbol{z}(\kappa)$-$\boldsymbol{D}_1(r_1)$-$\boldsymbol{D}_2(r_2)$-$\boldsymbol{l}(d)$-$\boldsymbol{E}_1(r_2)$-$\boldsymbol{E}_2(r_1)$-$\hat{\boldsymbol{z}}(\kappa)$. If any $\boldsymbol{z}^{(i)}$ passes through this network with zero reconstruction error, it implies that the corresponding $\boldsymbol{l}^{(i)}$ can pass through the flipped network with zero reconstruction error, and we have verified our complete ground truth network.

We could train the entire system end-to-end to accomplish this, which should be easy since $\kappa \ll d$; however, we found that although $\boldsymbol{z}^{(i)} = \hat{\boldsymbol{z}}^{(i)}$ is obviously not difficult to achieve, the corresponding learned samples $\boldsymbol{l}^{(i)}$ are pushed to very near a low-rank matrix when assembled into $\boldsymbol{L}$. This would imply that non-linear manifold learning is not actually even required and RPCA would likely be sufficient.

To circumvent this issue, we instead hold the initial $\boldsymbol{z}(\kappa)$-$\boldsymbol{D}_1(r_1)$-$\boldsymbol{D}_2(r_2)$-$\boldsymbol{l}(d)$ structure fixed, which ensures that the rank of $\boldsymbol{L}$ cannot be altered, and only train the second half using a standard ℓ_2 loss. In doing so we are able to obtain an $\boldsymbol{L}$ matrix, extracted from the middle layer, that is both (a) *not* well-represented by a low-rank approximation, and (b) *does* lie on a *known* low-dimensional non-linear manifold. And given that essentially zero reconstruction error is in fact achievable (up to the expected small ripples introduced by stochastic gradient descent or a similar surrogate), the learned decoder from this process implicitly serves as the ground-truth encoder underlying the data structure. Hence any VAE that includes $\boldsymbol{l}(d)$-$\boldsymbol{E}_1(r_2)$-$\boldsymbol{E}_2(r_1)$-$\hat{\boldsymbol{z}}(\kappa)$ within its encoder mean network capacity, as well as $\boldsymbol{z}(\kappa)$-$\boldsymbol{D}_1(r_1)$-$\boldsymbol{D}_2(r_2)$-$\boldsymbol{l}(d)$ within its decoder mean network capacity, will at least in principle have the capability of zero reconstruction error as well.

Finally, once $\boldsymbol{L}$ has been created in this manner, we then generate the noisy data matrix $\boldsymbol{X}$ by randomly corrupting $100 \cdot \nu\%$ of the entries, replacing the original value with samples from a standardized Gaussian distribution. In doing so, the original 'signal' component from $\boldsymbol{L}$ is completely swamped out at these locations.

Experimental Design: Given a data matrix $\boldsymbol{X}$ as generated above, we test the relative performance of four competing models:

1. VAE: We form a VAE architecture with the cascaded encoder/decoder mean networks $\boldsymbol{\mu}_x(\boldsymbol{\mu}_z[\boldsymbol{x}])$ assembled as $\boldsymbol{x}(100)$-$\boldsymbol{E}_1(2000)$-$\boldsymbol{E}_2(1000)$-$\boldsymbol{\mu}_z(50)$-$\boldsymbol{D}_1(1000)$-$\boldsymbol{D}_2(2000)$-$\boldsymbol{\mu}_x(100)$. This mirrors the high-level structure used to generate the outlier-free data, and ultimately will ensure that the ground-truth manifold is included within the network parameterization. Consistent with the design in (Kingma and Welling, 2014), a diagonal encoder covariance $\boldsymbol{\Sigma}_z$ is produced by sharing just the first two mean network layers. An exponential layer is also appended at the output to produce non-negative values. For consistency with AE models, the decoder covariance $\boldsymbol{\Sigma}_x$ is addressed separately via a special process described below.

2. AE-ℓ_2: We begin with the VAE model from above and fix $\boldsymbol{\Sigma}_z = \boldsymbol{0}$. This reduces the KL regularization term from (3) to simply $\|\boldsymbol{\mu}_z\|_2^2$. If no other changes are included, then the scaling ambiguity between $\boldsymbol{\mu}_z$ and decoder layer $\boldsymbol{D}_1$ is such that $\boldsymbol{\mu}_z$ can be made arbitrarily small without any loss of generality, rendering any beneficial regularization effect from $\|\boldsymbol{\mu}_z\|_2^2$ completely moot as discussed at the beginning of Section 2. Therefore we add a standard weight decay term to the AE-ℓ_2 network parameters $\{\boldsymbol{\theta}, \boldsymbol{\phi}\}$ to ameliorate this scaling ambiguity, which is tantamount to including an additional penalty factor $C_1\|\{\boldsymbol{\theta}, \boldsymbol{\phi}\}\|_2^2$. We also balance $\|\boldsymbol{\mu}_z\|_2^2$ with a second tuning parameter C_2, i.e., $C_2\|\boldsymbol{\mu}_z\|_2^2$. For the experiments in this section, we choose $C_1 = 0.0005$, a typical default value for weight decay, and then tune C_2 for optimal performance.[9]

   Note also that once $\boldsymbol{\Sigma}_z = \boldsymbol{0}$, at every sample $\boldsymbol{\Sigma}_x$ can be solved for in closed form as $\left[\boldsymbol{\Sigma}_x^{(i)}\right]_{jj} = \left(x_j^{(i)} - \mu_{x_j}^{(i)}\right)^2$ for $j = 1, \ldots, d$ assuming sufficient capacity per Corollary 4. We then plug this value into the AE-ℓ_2 cost, effectively optimizing $\boldsymbol{\Sigma}_x^{(i)}$ out of the model altogether making it entirely deterministic. For direct comparison, we apply the same procedure to the VAE from above, which can be interpreted as efficiently modeling the infinite capacity limit for $\boldsymbol{\Sigma}_x$ (i.e., even with infinite capacity in $\boldsymbol{\Sigma}_x$, the VAE model could do no better than this).

3. AE-ℓ_1: To explicitly encourage sparse latent representations, which could potentially be helpful in learning the correct manifold dimension, we begin with the AE-ℓ_2 model from above and replace $\|\boldsymbol{\mu}_z\|_2^2$ with the ℓ_1 norm $\|\boldsymbol{\mu}_z\|_1$, a well-known sparsity-promoting penalty function (Donoho and Elad, 2003). The corresponding parameter C_2 is likewise independently tuned for optimal performance.

4. RPCA: As an additional baseline, we also apply the convex RPCA formulation from (14) to the same corrupted data. This model is implemented via an augmented Lagrangian method using code from (Lin et al., 2010).

For the VAE, AE-ℓ_2, and AE-ℓ_1 networks, all model weights were randomly initialized so as not to copy any information from the ground-truth template. Training was conducted over 200 epochs using the Adam optimization technique (Kingma and Ba, 2014) with a learning rate of 0.0001 and a batch size of 100. We chose $n = 10^6$ training samples for each separate experiment, across which we varied the manifold dimension from $\kappa = 2, 4, \ldots, 20$ while the outlier ratio ranged as $\nu = 0.05, 0.10, \ldots, 0.50$. For each pair of experimental conditions, we train/run all four models and measure performance recovering the true $\boldsymbol{L}$ as quantified by the normalized MSE metric

$$\text{NMSE} \triangleq \|\boldsymbol{L} - \hat{\boldsymbol{L}}\|_{\mathcal{F}}^2 / \|\boldsymbol{L}\|_{\mathcal{F}}^2. \tag{20}$$

Note that although in practice we will not generally know the true manifold dimension κ in advance, because we choose $\dim[\boldsymbol{\mu}_z] = 50 > \kappa$ when constructing encoder networks for all experiments, perfect reconstruction is still theoretically possible by any of the VAE or AE models provided that outlier contributions can be successfully mitigated.

Results: Figure 1 displays the results estimating $\boldsymbol{L}$, where the VAE outperforms RPCA and the AE models by a wide margin. Perhaps most notably, the VAE performance dominates both AE-ℓ_1 and AE-ℓ_2, supporting our theory that the smoothing effect of integrating over $\boldsymbol{\Sigma}_z$ has immense practical value in avoiding bad minimizing solutions through its unique form of differential regularization. In fact, the AE-ℓ_2 objective is identical to the VAE once $\boldsymbol{\Sigma}_z = \boldsymbol{0}$, at least up to the constant C_2 applied to $\|\boldsymbol{\mu}_z\|_2^2$ which is only tuned to benefit the former while remaining fixed for the latter.[10] So this smoothing effect is essentially the *only* difference between the VAE and AE-ℓ_2 models, and therefore, Figures 1(a) and 1(b) truly isolate the benefits of the VAE in this regard.

To summarize then, by design all VAE and AE network structures are equivalent in terms of their predictive capacity, but only the VAE is able to capitalize on the regularizing effect of $\boldsymbol{\Sigma}_z$ to actually reach a good solution in challenging conditions. Moreover, this is even possible without the hassle of tuning tedious hyperparameters to balance regularization effects as required by AE-ℓ_1 and AE-ℓ_2 models.[11] This confirms Hypothesis (i) and suggests that VAEs are a viable candidate for replacing existing RPCA algorithms (Candès et al., 2011; Ding et al., 2011; Kim et al., 2013; Wipf, 2012) in regimes where a single linear

9. For direct comparison, we include the same weight decay factor $C_1\|\{\boldsymbol{\theta}, \boldsymbol{\phi}\}\|_2^2$ with the VAE model even though there is no equivalent issue with scaling ambiguity. In fact, this can be viewed as an advantage of the VAE regularization mechanism, in that it directly prevents large decoder weights from compensating for arbitrarily small values of $\boldsymbol{\mu}_z$, killing regularization effects. This is because there exists a key dependence between the weights from $\boldsymbol{D}_1$ and the covariance $\boldsymbol{\Sigma}_z$ such that any large weights that would accommodate pushing $\boldsymbol{\mu}_z$ towards zero would equally *amplify* the random additive noise coming from the stochastic encoder model, nullifying any benefit to the overall cost.

10. If $C_2 = 1$, the default value as produced by the VAE KL term, the AE-ℓ_2 performance is much worse (not shown) than when using the tuned value of $C_2 = 10^3$ as was adopted in producing Figure 1. In contrast, the VAE requires no such tuning at all, with the default $C_2 = 1$ producing the results shown.

11. Of course we admittedly have not exhaustively ruled out the potential existence of some alternative regularizer capable of outperforming the VAE when carefully tuned to appropriate conditions; however, it is still nonetheless impressive that the VAE can naturally perform so well without such tuning on a task that it was not even originally motivated for.

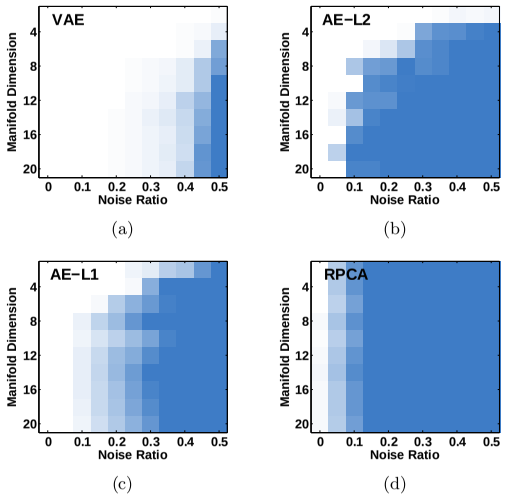

Figure 1: Results recovering synthesized low-dimensional manifolds across different outlier ratios (x-axis) and manifold dimensions (y-axis) for (a) the VAE, (b) the AE-ℓ_2, (c) the AE-ℓ_1, and (d) RPCA. In all cases, white color indicates normalized MSE near 0.0, while dark blue represents 1.0 or failure. The VAE is dramatically superior to each alternative, supporting Hypothesis (i). Additionally, it is crucial to note here that the AE and RPCA solutions perform poorly for quite different reasons. Not surprisingly, convex RPCA fails because it cannot accurately capture the underlying nonlinear manifold using a linear subspace inlier model. In contrast, both AE-ℓ_1 and AE-ℓ_2 have the *exact same* inlier model capacity as the VAE and can in principle represent uncorrupted points perfectly; however, they have inferior agency for pruning superfluous latent dimensions, discarding outliers, or generally avoiding bad locally-optimal solutions.

subspace is an inadequate signal representation. And we stress that, prior to the analysis herein, it was not at all apparent that a VAE could so dramatically outperform comparable AE models on this type of deterministic outlier removal task.

Note also that perfect reconstruction, as consistently exhibited by the VAE in Figure 1(a), does *not* actually require learning the correct generative model *within* the estimated manifold. Rather it only requires that as $\boldsymbol{\Sigma}_z \rightarrow \mathbf{0}$ selectively along appropriate dimensions (consistent with Hypothesis (iii) as will be discussed in Section 5.3), the encoder and decoder mean networks project onto the correct manifold while ignoring outliers. Hence although random samples $\boldsymbol{z}$ will likely lie on the true manifold when passed through the decoder network, they need not be perfectly distributed according to the full generative process

unless sufficient additional capacity exists beyond that needed to represent the manifold itself. We are not aware of this distinction being discussed in previous works, where VAE and related models are typically evaluated by either the overall quality of their generated samples (Dosovitskiy and Brox, 2016; Larsen et al., 2015; Oord et al., 2016), or by the value of the likelihood bound (Kingma and Welling, 2014; Kingma et al., 2016; Burda et al., 2015).[12]

Before proceeding to the next set of experiments, we address a tangential issue related to the RPCA performance as exhibited in Figure 1(d). When the outlier ratio is zero, RPCA can recover the ground-truth by simply defaulting to a full-rank inlier model without actually learning anything about the true manifold itself (the VAE and AE models do not have this luxury since they are forced to represent $\boldsymbol{L}$ using at most $\dim[\boldsymbol{\mu}_z] = 50 < \text{rank}[\boldsymbol{L}] = 100$ dimensions by design). In contrast, as the outlier ratio increases, it becomes increasingly difficult for RPCA to find any linear subspace representation that is both sufficiently high dimensional to include the majority of the inlier variance along the manifold while simultaneously excluding the outlier contributions. This explains the steep drop-off in performance moving from left to right within Figure 1(d). But there is noticeably no change in RPCA performance as we move from top to bottom in the same plot. This is because the clean data $\boldsymbol{L}$ is full-rank regardless of the manifold dimension κ, and so any linear subspace approximation is more or less equally bad across all κ.

5.2 Hypothesis (ii) Evaluation Using Ground-Truth Manifolds and MNIST Data

Synthetic Data Example: To evaluate Hypothesis (ii), we train analogous AE and VAE models as the number of decoder and encoder hidden layers vary, in each case with ground-truth available per the procedure described above. To generate each observed data point $\boldsymbol{x}^{(i)}$, we sample $\boldsymbol{z}^{(i)}$ from a 20-dimensional standard Gaussian distribution and pass it through a neural network structured as $\boldsymbol{z}(20)$-$\boldsymbol{D}_1(200)$-$\boldsymbol{D}_2(200)$-$\boldsymbol{x}(400)$, again with ReLU activations. We then train VAE models of variable depth, with concatenated mean networks $\boldsymbol{\mu}_x(\boldsymbol{\mu}_z[\boldsymbol{x}])$ designed as $\boldsymbol{x}(400)$-$\boldsymbol{E}_1(200)$-...-$\boldsymbol{E}_{N_e}(200)$-$\boldsymbol{\mu}_z(30)$-$\boldsymbol{D}_1(200)$-...-$\boldsymbol{D}_{N_d}(200)$-$\boldsymbol{\mu}_x(400)$, where N_e and N_d represent the number of hidden layers in the encoder and decoder respectively. The corresponding covariances are modeled as in Section 5.1, and likewise, the training protocol is unchanged. Note also that $\dim[\boldsymbol{\mu}_z] = 30$ is considerably larger than the ground-truth dimension of 20.

The first layer of the decoder mean network (before the nonlinearity) can be expressed as

$$\boldsymbol{h}_1 = \boldsymbol{W}_1\boldsymbol{z} + \boldsymbol{b}_1, \tag{21}$$

which in isolation is equivalent to the affine decoder mean model. If the VAE has the ability to find the true underlying manifold dimension, then the number of nonzero columns in $\boldsymbol{W}_1$ should be 20, indicating that $30 - 20 = 10$ dimensions of $\boldsymbol{z}$ are actually useless for

12. Learning the correct distribution within the manifold, as required for full recovery of the entire generative process and the production of realistic samples, is a topic largely orthogonal to the analysis presented herein. Still, to at least partially address these important issues, we have recently derived relatively broad conditions whereby provable recovery within a manifold itself is possible even in situations where $\boldsymbol{\Sigma}_z$ tends towards zero. However, we defer presentation of this topic, which involves many additional subtleties, to a future publication.

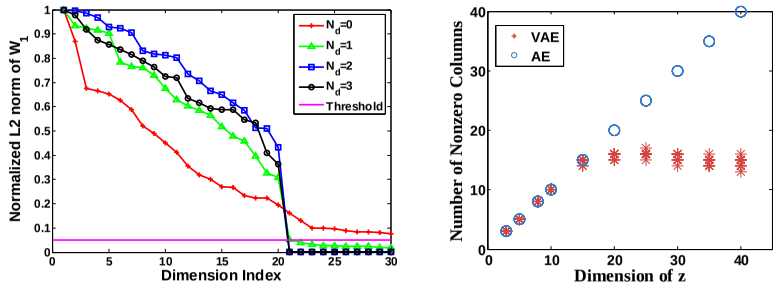
	$N_d = 0$	$N_d = 1$	$N_d = 2$	$N_d = 3$
$N_e = 0$	30.0	21.1	21.0	20.0
$N_e = 1$	30.0	21.0	20.0	20.0
$N_e = 2$	30.0	21.0	20.0	20.0
$N_e = 3$	30.0	20.4	20.0	20.0

Table 1: Number of nonzero columns in the VAE decoder mean first-layer weights $\boldsymbol{W}_1$ learned using different encoder and decoder depths applied to data with a ground-truth latent dimension of 20. Provided that the VAE model is sufficiently complex, the correct estimate is automatically obtained. We have not found an analogous AE model with similar capability.

any subsequent representation, i.e., we can estimate the intrinsic dimension of the latent code by counting the number of nonzero columns in $\boldsymbol{W}_1$, exactly analogous to the affine case. Of course in practice it is unlikely that a column of $\boldsymbol{W}_1$ converges all the way to exactly $\mathbf{0}$ via any stochastic optimization method. Therefore we define a simple threshold as $\text{thr} = 0.05 \times \max_{j=1}^{\kappa} \|\boldsymbol{w}_{\cdot j}\|_2$. If $\|\boldsymbol{w}_{\cdot j}\|_2 < \text{thr}$, we regard it as a zero column. But this heuristic notwithstanding, the partition between zero and non-zero columns is generally quite obvious as will be illustrated later.

Table 1 reports the estimated number of non-zero columns in $\boldsymbol{W}_1$ as N_e and N_d are varied, where we have run 10 trials for every pairing and averaged the results. When there is no hidden layer in the decoder (i.e., $N_d = 0$), which implies that the decoder mean is affine, all the columns are nonzero since the network is overly-simplistic and all degrees of freedom are being utilized to compensate. However, once we increase the depth, especially of the decoder within which $\boldsymbol{W}_1$ actually resides, the number of nonzero columns of $\boldsymbol{W}_1$ tends to exactly 20, which is the correct ground-truth manifold dimension by design, directly supporting Hypothesis (ii). Similar conclusions can be drawn from models of different sizes and configurations as well (not shown). In contrast, we did not find a corresponding AE model with this capability.

Note that prior work has loosely suggested that the KL regularizer indigenous to VAEs could potentially mute the impact of superfluous latent dimensions as part of the model optimization process (Burda et al., 2015; Sønderby et al., 2016). However, there has been no theoretical or empirical demonstration of why this should happen, nor any rigorous explanation of a precise pruning mechanism built into the aggregate VAE cost function itself. And as mentioned previously, the KL term is characterized by an ℓ_2 norm penalty on $\boldsymbol{\mu}_z$ (see (3)), which we would normally expect to promote low-energy latent representations with mostly small, but nonzero values (Chen et al., 1999), the exact *opposite* of any sparsity-promotion or pruning agency. But of course if columns of $\boldsymbol{W}_1$ are set to zero, then no information about $\boldsymbol{z}$ can pass through these dimensions to the hidden layers of the decoder. Therefore the KL term can now be minimized in isolation along these dimensions with the corresponding elements of $\boldsymbol{\mu}_z$ set to exactly zero. Hence it is only the counterintuitive co-mingling of *all* energy terms that leads to this desirable VAE pruning effect as we have meticulously characterized.



(a) (b)

Figure 2: (a) Validation of thresholding heuristic for determining nonzero columns in $\boldsymbol{W}_1$. With $N_e = 3$ and the settings from Table 1, the sorted column norms of $\boldsymbol{W}_1$ are plotted. Clearly for $N_d \in \{2, 3\}$ the gap between zero and nonzero values is extremely clear and any reasonable thresholding heuristic will suffice. (b) Number of nonzero columns in the decoder mean first-layer weights $\boldsymbol{W}_1$ as the latent dimension κ is varied for both AE and VAE models trained on MNIST data. Only the VAE automatically self-regularizes when κ becomes sufficiently large (here at $\kappa \approx 15$), consistent with Hypothesis (ii).

Finally, Figure 2(a) provides validation for our heuristic criterion for classifying columns of $\boldsymbol{W}_1$ as zero or not. Under the same experimental conditions as were used for creating Table 1, we plot the sorted column norms of $\boldsymbol{W}_1$ for the cases where $N_e = 3$ and $N_d \in \{0, 1, 2, 3\}$. Especially when $N_d \in \{2, 3\}$, meaning the model is of (or nearly of) sufficient capacity, zero and nonzero values are easily distinguishable and any reasonable thresholding heuristic would be adequate. Likewise for $N_d = 0$ it is clear that all values are significantly distant from zero. In contrast, when $N_d = 1$ (green curve) it is admittedly more subjective whether or not the smallest 9 or 10 elements should be classified as zero. Regardless, the overall trend is unequivocal, with any heuristic threshold only influencing the $N_d = 1$ boundary case.

MNIST Example: To further verify Hypothesis (ii), we train VAE models on the MNIST data set of handwritten digit images (Lecun et al., 1998) as κ is varied. We use all $n = 70000$ samples, each of size 28×28. We structure 4-layer cascaded VAE mean networks $\boldsymbol{\mu}_x(\boldsymbol{\mu}_z[\boldsymbol{x}])$ as $\boldsymbol{x}(d)$-$\boldsymbol{E}_1(1000)$-$\boldsymbol{E}_2(500)$-$\boldsymbol{E}_3(250)$-$\boldsymbol{\mu}_z(\kappa)$-$\boldsymbol{D}_1(250)$-$\boldsymbol{D}_2(500)$-$\boldsymbol{D}_3(1000)$-$\boldsymbol{\mu}_x(d)$, where $d = 28 \times 28 = 784$ and ReLU activations are used. Covariances and training protocols are handled as before. We draw values of κ from $\{3, 5, 8, 10, 15, 20, 25, 30, 35, 40\}$.

Figure 2(b) displays the number of nonzero columns in $\boldsymbol{W}_1$ produced by each κ-dependent model, again across 10 trials. We observe that when $\kappa > 15$, the number of nonzero columns plateaus for the VAE consistent with Hypothesis (ii). Of course unlike the

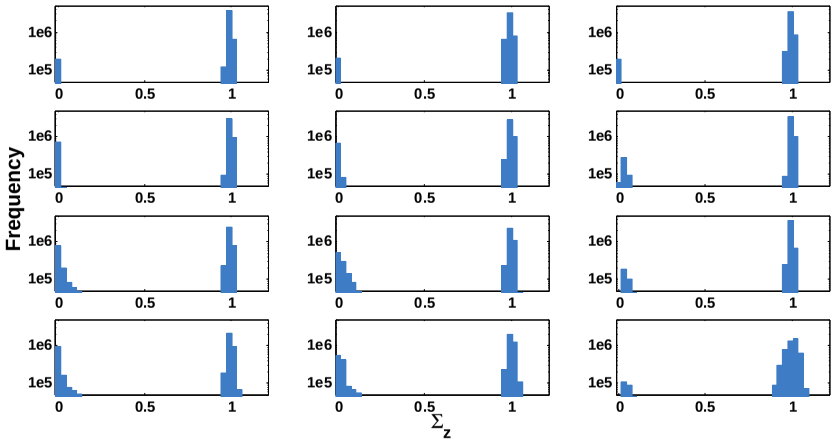


Figure 3: Log-scale histograms of $\left\{\boldsymbol{\Sigma}_z^{(i)}\right\}_{i=1}^n$ diagonal elements as outlier ratios and manifold dimensions are varying for the corrupted manifold recovery experiment corresponding with Figure 1. The three columns represent outlier ratios of $\nu \in \{0.0, 0.25, 0.50\}$ from left to right. The four rows represent manifold dimensions of $\kappa \in \{2, 8, 14, 20\}$ from top to bottom. All plots demonstrate the predicted clustering of variance values around either zero or one. Likewise, the relative sizes of these clusters, including observed changes across experimental conditions, conforms with our theoretical predictions (see detailed description in Section 5.3).

synthetic case, we no longer have access to ground truth for determining what the optimal manifold dimension should be.

We also applied an analogous AE model trained with $C_2 = 0$, i.e., a standard AE with no additional regularization penalty added. Not surprisingly, the number of nonzero columns in $\boldsymbol{W}_1$ is always equal to κ since there is no equivalent agency for column-wise pruning as implicitly instilled by the VAE. Note that tuning C_2 with either ℓ_1- or ℓ_2-norm penalties is of course always possible; however, the optimal value can be κ-dependent making subsequent results less interpretable. Moreover, in general we have not found a setting whereby the penalties lead to correct latent dimensionality estimation in situations where the ground-truth is known.

5.3 Hypothesis (iii) Evaluation Using Covariance Statistics from Corrupted Manifold Recovery Task

If some columns of $\boldsymbol{W}_1$ tend to zero as we have argued both empirically and theoretically, then the corresponding diagonal elements of $\boldsymbol{\Sigma}_z$, like $\boldsymbol{\mu}_z$, can no longer influence the decoder. And with only the lingering KL term to offer guidance, along these coordinates the optimal variance will then equal one by virtue of (19). But for nonzero columns of $\boldsymbol{W}_1$, the behavior of $\boldsymbol{\Sigma}_z$ is much more counter-intuitive. Despite the $-\log|\boldsymbol{\Sigma}_z|$ factor from the KL divergence that contributes an unbounded cost as any $[\boldsymbol{\Sigma}_z]_{jj} \to 0$, we nonetheless have proven for the affine decoder mean case a natural tendency of the VAE to push these variance values arbitrarily close to zero when approaching globally optimal solutions, at least along latent dimensions required for representing inlier points lying on ground-truth manifolds (i.e, dimensions where $\boldsymbol{W}_1$ is nonzero).

We now empirically verify that this same effect is inherited by general VAE models with more sophisticated, nonlinear decoder mean networks. For this purpose, we created histograms of all diagonal elements of $\left\{\boldsymbol{\Sigma}_z^{(i)}\right\}_{i=1}^n$ obtained from the experiments described in Section 5.1 where the outlier ratios and manifold dimensions vary. The results are plotted in Figure 3 for all pairs of outlier ratios $\nu \in \{0.0, 0.25, 0.50\}$ (columns) and ground-truth manifold dimensions $\kappa \in \{2, 8, 14, 20\}$ (rows). These results directly conform with our theoretical predictions per the following explanations.

First, consider the upper-left panel displaying the simplest case from an estimation standpoint, since $\nu = 0.0$ (no outliers) and $\kappa = 2$ (very low-dimensional manifold). Here we observe a clear partitioning between elements of $\left\{\boldsymbol{\Sigma}_z^{(i)}\right\}_{i=1}^n$ going to either zero or one. Moreover, given that $\dim[\boldsymbol{\mu}_z] = 50$ while the ground-truth involves $\kappa = 2$, 48 out of 50 dimensions are actually unnecessary. Hence we should expect that only about 4% of variance values should concentrate around zero, with the remainder forced towards one. In fact, this is precisely the general partitioning we observe (note the log scaling of the y-axis). Additionally, if we examine the other panels in the left-most column of Figure 3, we notice that as the ground-truth κ increases, the percentage of variance values shifts from one to zero roughly proportional to $\kappa/50$. In other words, as more dimensions are required to represent the more challenging, higher-dimensional manifolds, more diagonal elements of each $\boldsymbol{\Sigma}_z^{(i)}$ are pushed towards zero to enforce accurate reconstructions.

Next, we observe that in the top row of Figure 3, each of the three panels are more or less the same, indicating that the inclusion of outliers has not disrupted the VAE's ability to model the ground-truth manifold. In contrast, the bottom row presents a somewhat different story. Given the more challenging conditions with a much higher dimensional ground-truth manifold ($\kappa = 20$), the inclusion of additional outliers (as we move from left to right) shifts more variance elements from zero to one. This implies that the VAE, when confronted with both a higher-dimensional manifold and severe outliers (bottom-right panel), is settling on a relatively lower-dimensional approximation. This behavior is reasonable in the sense that accurately estimating a complex manifold via any method becomes problematic when 50% of the data is corrupted, and a low-dimensional approximation is all that is feasible to avoid simply fitting all the outliers. In this situation some manifold dimensions of lesser

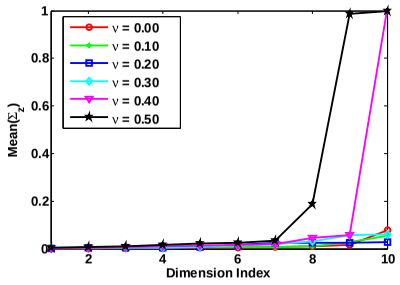

Figure 4: Diagonal values of $\frac{1}{n}\sum_{i=1}^{n}\mathbf{\Sigma}_z^{(i)}$ sorted in ascending order for a VAE model trained with ground-truth $\kappa = \dim[\boldsymbol{\mu}_z] = 10$ on the recovery task from Section 5.1. When the outlier proportion is $\nu \leq 0.30$, the average variance is near zero across all latent dimensions. However, for $\nu > 0.30$, some variance values are pushed towards one, indicating that the VAE is defaulting to a lower-dimensional approximation.

importance can be viewed as expendable, and consequently we will likely have additional elements of $\left\{\mathbf{\Sigma}_z^{(i)}\right\}_{i=1}^{n}$ tending to one.

To further elucidate this phenomena, we include one additional supporting visualization involving the special case where the ground-truth manifold dimension equals 10 while the outlier ratio ν varies. However, we slightly modify the testing conditions from Section 5.1. Instead of choosing $\dim[\boldsymbol{\mu}_z] = 50$, we set this value to the ground-truth value $\kappa = 10$. In this constrained setting, we expect that perfect recovery should require *all* diagonal elements of $\mathbf{\Sigma}_z$ to be pushed towards zero, since there are no longer any superfluous degrees of freedom. Therefore, if any covariance elements tend to one, we have isolated the emergence of a low-dimensional approximation as presumably necessitated by increasing outlier levels.

Figure 4 displays the diagonal values of $\frac{1}{n}\sum_{i=1}^{n}\mathbf{\Sigma}_z^{(i)}$ sorted in ascending order along the x-axis. When $\nu \leq 0.30$, the average variance is near zero across all latent dimensions. However, for $\nu > 0.30$, some variance values are pushed towards one, indicating that the VAE is defaulting to a lower-dimensional approximation.

To summarize then, the results of this section help to confirm a rather curious behavior of the VAE: If $\boldsymbol{\mu}_x(\boldsymbol{\mu}_z[\boldsymbol{x}])$ is suitably parameterized to model inlier samples, and $\mathbf{\Sigma}_x$ is sufficiently complex to model outlier locations, then elements of $\mathbf{\Sigma}_z$ can be selectively pushed towards zero in the neighborhood of global minima. This involves overpowering the $-\log|\mathbf{\Sigma}_z\|$ factor from the KL divergence that would otherwise seemingly prevent this from happening. Moreover, in this degenerate regime, the VAE will exhibit deterministic behavior and can perfectly represent original clean training data samples via a low-dimensional manifold provided that the outlier level is not too high.

6. Discussion

Although originally developed as a viable deep generative model or tractable bound on the data likelihood, in this work we have revealed certain properties and abilities of the VAE that are not obvious from first inspection. For example, in addition to its putative role in driving diversity into the learned generative process, the latent covariance $\mathbf{\Sigma}_z$ also serves as an important smoothing mechanism that aids in the robust recovery of corrupted samples, even if sometimes this requires exhibiting behavior (i.e., selective convergence towards zero) that may seem counterintuitive. And although the VAE only adopts an ℓ_2 norm penalty on $\boldsymbol{\mu}_z$ that in isolation should favor low energy solutions with all or mostly nonzero values, the latent mean estimator nonetheless tends to be highly sparse because of subtle, non-obvious interactions with other factors in the energy function such as the first-layer decoder mean network weights $\boldsymbol{W}_1$. Likewise, outliers can be estimated and completely removed via the action of $\mathbf{\Sigma}_x$ despite no traditional, additive sparsity penalty applied across each data point.

In general, our results speak to many under-appreciated aspects of VAE behavior, have wide ranging practical consequences, and suggest novel usages beyond the original VAE design principles. These include:

- The VAE can be applied to estimating deterministic nonlinear manifolds heavily corrupted with outliers.

- The self-regularization effects of the VAE can largely handle excessive degrees of freedom when it comes to the latent representation $\boldsymbol{z}$ as produced by the full encoder and processed by the first layer of the decoder mean network, as well as an arbitrarily-parameterized decoder covariance $\mathbf{\Sigma}_x$. Conversely, only excessive complexity specifically localized in higher decoder mean network layers can, at least in principle, lead to potential problems with overfitting.

- The latent covariance $\mathbf{\Sigma}_z$ can serve as an approximate bellwether for determining the true dimensionality of a manifold, provided that excessive outliers/corruptions do not lead to an under-estimate. This is because typically near global solutions, we observe $[\mathbf{\Sigma}_z]_{jj} \to 0$ for *useful* dimensions, while for *useless* dimensions we have shown that $[\mathbf{\Sigma}_z]_{jj} \to 1$, a clear bifurcation.

Although the primary purpose of this paper is not to build a better generative model per se, we nevertheless hope that ideas introduced here will help to ensure that VAEs are not under or improperly utilized. Additionally, in closing we should also mention that the focus herein has been almost entirely on the analysis of the VAE energy function itself, independent of the specifics of how this energy function might ultimately be optimized in practice. But we believe the latter to be an equally-important, complementary topic, and further study is undeniably warranted. For example, if an optimization trajectory is somehow lured astray by the Siren's song of a bad local minimum in the VAE energy landscape, then obviously many of our conclusions predicated on global optima will not necessarily still hold.

(a) (b)

Figure 5: (a) Singular value spectrum of MNIST data revealing (approximately) low-rank structure. (b) Normalized MSE recovering MNIST digits from corrupted samples. The VAE is able to reduce the reconstruction error by better modeling more fine-grain details occupying the low end of the singular value spectrum.

Appendix A. Additional MNIST Data Set Experiment

Here we examine practical denoising of MNIST data corrupted with outliers using a VAE model. Outliers are added to MNIST handwritten digit data (Lecun et al., 1998) by randomly replacing from 5% to 50% of the pixels with a value uniformly sampled from $[0, 255]$ to create $\boldsymbol{X}$. We choose $\kappa = 30$ for the dimension of $\boldsymbol{z}$ and apply the same VAE structure as applied to MNIST data in Section 5.2. The model is trained using both $\tau = 1$ and $\tau = 5$ latent samples $\{\boldsymbol{z}^{(i,t)}\}_{t=1}^{\tau}$ for each $\boldsymbol{x}^{(i)}$, observing that the latter, which more closely approximates the posterior, should perform significantly better.

We compare the VAE against convex RPCA on the task of recovering the original, uncorrupted digits. Note that RPCA is commonly used for unsupervised cleaning of this type of data (Elhamifar and Vidal, 2013), and MNIST is known to have significant low-rank structure (Lu et al., 2013) as shown in Figure 5(a). Regardless, we observe in Figure 5(b) that the VAE performs significantly better in terms of normalized MSE by capturing additional manifold details that deviate from a purely low-rank representation. Furthermore, we hypothesize that using extra latent samples (the $\tau = 5$ case) may work better on outlier removal tasks given the strong need for accurate smoothing of the VAE objective as described previously.

Appendix B. Proof of Lemma 1

Proof Under the stated assumptions, the VAE cost can be simplified as

$$\begin{aligned}\mathcal{L}(\boldsymbol{\theta},\boldsymbol{\phi}) &= \sum_i \left\{ \mathbb{E}_{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}^{(i)})}\left[\tfrac{1}{\lambda}\left\|\boldsymbol{x}^{(i)}-\boldsymbol{W}\boldsymbol{z}-\boldsymbol{b}\right\|_2^2\right] + d\log\lambda \right. \\ &+ \left. \operatorname{tr}\left[\boldsymbol{\Sigma}_z^{(i)}\right] - \log\left|\boldsymbol{\Sigma}_z^{(i)}\right| + \|\boldsymbol{\mu}_z^{(i)}\|_2^2 \right\}, \\ &= \sum_i \left\{ \tfrac{1}{\lambda}\left\|\boldsymbol{x}^{(i)}-\boldsymbol{W}\boldsymbol{\mu}_z^{(i)}-\boldsymbol{b}\right\|_2^2 + \tfrac{1}{\lambda}\operatorname{tr}\left[\boldsymbol{\Sigma}_z^{(i)}\boldsymbol{W}^\top\boldsymbol{W}\right] + d\log\lambda \right. \\ &+ \left. \operatorname{tr}\left[\boldsymbol{\Sigma}_z^{(i)}\right] - \log\left|\boldsymbol{\Sigma}_z^{(i)}\right| + \|\boldsymbol{\mu}_z^{(i)}\|_2^2 \right\}, \end{aligned} \tag{22}$$

where $\boldsymbol{\mu}_z^{(i)} \triangleq \boldsymbol{\mu}_z\left(\boldsymbol{x}^{(i)};\boldsymbol{\phi}\right)$ and $\boldsymbol{\Sigma}_z^{(i)} \triangleq \boldsymbol{\Sigma}_z\left(\boldsymbol{x}^{(i)};\boldsymbol{\phi}\right)$. Given that

$$\log\left|\boldsymbol{A}\boldsymbol{A}^\top\right| = \arg\inf_{\boldsymbol{\Gamma}\succ\boldsymbol{0}} \operatorname{tr}\left[\boldsymbol{A}\boldsymbol{A}^\top\boldsymbol{\Gamma}^{-1}\right] + \log|\boldsymbol{\Gamma}|, \tag{23}$$

when optimization is carried out over positive definite matrices $\boldsymbol{\Gamma}$, minimization of (22) with respect to $\boldsymbol{\Sigma}_z^{(i)}$ leads to the revised objective

$$\begin{aligned}\mathcal{L}(\boldsymbol{\theta},\boldsymbol{\phi}) &\equiv \sum_i \left\{ \tfrac{1}{\lambda}\left\|\boldsymbol{x}^{(i)}-\boldsymbol{W}\boldsymbol{\mu}_z^{(i)}-\boldsymbol{b}\right\|_2^2 + \log\left|\tfrac{1}{\lambda}\boldsymbol{W}^\top\boldsymbol{W}+\boldsymbol{I}\right| + d\log\lambda + \|\boldsymbol{\mu}_z^{(i)}\|_2^2 \right\}, \\ &= \sum_i \left\{ \tfrac{1}{\lambda}\left\|\boldsymbol{x}^{(i)}-\boldsymbol{W}\boldsymbol{\mu}_z^{(i)}-\boldsymbol{b}\right\|_2^2 + \log\left|\boldsymbol{W}\boldsymbol{W}^\top+\lambda\boldsymbol{I}\right| + \|\boldsymbol{\mu}_z^{(i)}\|_2^2 \right\}, \end{aligned} \tag{24}$$

ignoring constant terms. This expression only requires that $\boldsymbol{\Sigma}_z^{(i)} = \left[\frac{1}{\lambda}\boldsymbol{W}^\top\boldsymbol{W}+\boldsymbol{I}\right]^{-1}$, or a constant parameterization, independent of $\boldsymbol{x}^{(i)}$. Similarly we can optimize over $\boldsymbol{\mu}_z^{(i)}$ in terms of the other variables. This is just a ridge regression problem, with optimal solution

$$\boldsymbol{\mu}_z^{(i)} = \boldsymbol{W}^\top\left(\lambda\boldsymbol{I}+\boldsymbol{W}\boldsymbol{W}^\top\right)^{-1}\left(\boldsymbol{x}^{(i)}-\boldsymbol{b}\right), \tag{25}$$

or a simple linear function of $\boldsymbol{x}^{(i)}$. Hence as long as the parameterization of both $\boldsymbol{\mu}_z^{(i)}$ and $\boldsymbol{\Sigma}_z^{(i)}$ allows for arbitrary affine functions as stipulated in the lemma statement, these optimal solutions are feasible. Plugging (25) into (24) and applying some basic linear algebra, we arrive at

$$\mathcal{L}(\boldsymbol{\theta},\boldsymbol{\phi}) \equiv \sum_i \left(\boldsymbol{x}^{(i)}-\boldsymbol{b}\right)^\top\left(\boldsymbol{W}\boldsymbol{W}^\top+\lambda\boldsymbol{I}\right)^{-1}\left(\boldsymbol{x}^{(i)}-\boldsymbol{b}\right) + n\log\left|\boldsymbol{W}\boldsymbol{W}^\top+\lambda\boldsymbol{I}\right|. \tag{26}$$

Finally, in the event that we enforce that $\boldsymbol{\Sigma}_z^{(i)}$ be diagonal, (24) must be modified via

$$\boldsymbol{\Sigma}_z^{(i)} = \left[\tfrac{1}{\lambda}\operatorname{diag}\left(\operatorname{diag}\left[\boldsymbol{W}^\top\boldsymbol{W}\right]\right)+\boldsymbol{I}\right]^{-1} = \sum_{j=1}^{\kappa}\log\left(\lambda+\|\boldsymbol{w}_{\cdot j}\|_2^2\right) - \kappa\log\lambda, \tag{27}$$

where the diag[·] operator converts vectors to diagonal matrices, and a matrix to a vector formed from its diagonal (just as in the Matlab computing environment), leading to the stated result. ■

Appendix C. Proof of Theorem 2

Proof First, for part 1 on the theorem, given that $\boldsymbol{W}\boldsymbol{R}\boldsymbol{R}^\top\boldsymbol{W}^\top = \boldsymbol{W}\boldsymbol{P}\boldsymbol{P}^\top\boldsymbol{W}^\top = \boldsymbol{W}\boldsymbol{W}^\top$ for any rotation $\boldsymbol{R}$ and permutation $\boldsymbol{P}$, then obviously if $\boldsymbol{W}^*$ is a minimum of (5), $\boldsymbol{W}^*\boldsymbol{R}$ and $\boldsymbol{W}^*\boldsymbol{P}$ must also be. Likewise, since $\sum_{j=1}^{\kappa}\log\left(\lambda+\|\boldsymbol{w}_{\cdot j}\|_2^2\right)$ is invariant to the order of the summation, then if $\boldsymbol{W}^{**}$ is a minimum of (7), $\boldsymbol{W}^{**}\boldsymbol{P}$ must be as well.

We also have that

$$\begin{aligned}\mathcal{L}_{sep}(\boldsymbol{W}^{**},\boldsymbol{b},\lambda) &= \sum_i \boldsymbol{\Omega}^{(i)}(\boldsymbol{W}^{**},\boldsymbol{b},\lambda\boldsymbol{I}) + n\left[\sum_j \log\left(\lambda+\|\boldsymbol{w}_{\cdot j}^{**}\|_2^2\right) + (d-\kappa)\log\lambda\right] \\ &= \sum_i \boldsymbol{\Omega}^{(i)}(\boldsymbol{W}^{**},\boldsymbol{b},\lambda\boldsymbol{I}) + n\left[\sum_j \log\left(1+\tfrac{1}{\lambda}\|\boldsymbol{w}_{\cdot j}^{**}\|_2^2\right) + d\log\lambda\right] \\ &\geq \sum_i \boldsymbol{\Omega}^{(i)}(\boldsymbol{W}^{**},\boldsymbol{b},\lambda\boldsymbol{I}) + n\left[\log\left|\tfrac{1}{\lambda}\left(\boldsymbol{W}^{**}\right)^\top\boldsymbol{W}^{**}+\boldsymbol{I}\right| + d\log\lambda\right] \\ &= \sum_i \boldsymbol{\Omega}^{(i)}(\boldsymbol{W}^{**},\boldsymbol{b},\lambda\boldsymbol{I}) + n\log\left|\lambda\boldsymbol{I}+\boldsymbol{W}^{**}\boldsymbol{R}\left(\boldsymbol{W}^{**}\boldsymbol{R}\right)^\top\right| \\ &\geq \sum_i \boldsymbol{\Omega}^{(i)}(\boldsymbol{W}^{*},\boldsymbol{b},\lambda\boldsymbol{I}) + n\log\left|\lambda\boldsymbol{I}+\boldsymbol{W}^{*}\boldsymbol{R}\left(\boldsymbol{W}^{*}\boldsymbol{R}\right)^\top\right|, \end{aligned} \tag{28}$$

where the the second inequality follows from the fact that $\boldsymbol{W}^*$ is an optimal solution to (5). The first inequality stems from Hadamard's inequality (Garling, 2007) applied to

$$\tfrac{1}{\lambda}\left(\boldsymbol{W}^{**}\right)^\top\boldsymbol{W}^{**}+\boldsymbol{I} = \boldsymbol{M}^\top\boldsymbol{M} \tag{29}$$

for some square matrix $\boldsymbol{M}$ of appropriate dimension. This results in

$$\log\left|\tfrac{1}{\lambda}\left(\boldsymbol{W}^{**}\right)^\top\boldsymbol{W}^{**}+\boldsymbol{I}\right| = 2\log|\boldsymbol{M}| \leq 2\log\left(\prod_j\|\boldsymbol{m}_{\cdot j}\|_2\right) = \sum_j\log\left(1+\tfrac{1}{\lambda}\|\boldsymbol{w}_{\cdot j}^{**}\|_2^2\right), \tag{30}$$

with equality iff $\boldsymbol{M}^\top\boldsymbol{M}$ is diagonal. We can further manipulate the log-det term in (28) via

$$\begin{aligned} n\log\left|\lambda\boldsymbol{I}+\boldsymbol{W}^*\boldsymbol{R}\left(\boldsymbol{W}^*\boldsymbol{R}\right)^\top\right| &= \log\left|\tfrac{1}{\lambda}\left(\boldsymbol{W}^*\boldsymbol{R}\right)^\top\boldsymbol{W}^*\boldsymbol{R}+\boldsymbol{I}\right| + d\log\lambda \\ &= \log\left|\tfrac{1}{\lambda}\left(\boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{V}^\top\boldsymbol{R}\right)^\top\boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{V}^\top\boldsymbol{R}+\boldsymbol{I}\right| + d\log\lambda \\ &= \log\left|\tfrac{1}{\lambda}\boldsymbol{R}^\top\boldsymbol{V}\boldsymbol{\Lambda}^2\boldsymbol{V}^\top\boldsymbol{R}+\boldsymbol{I}\right| + d\log\lambda, \end{aligned}$$

where $\boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{V}^\top$ is the SVD of $\boldsymbol{W}^*$. Now if we choose $\boldsymbol{R}=\boldsymbol{V}$ and define $\bar{\boldsymbol{W}} \triangleq \boldsymbol{W}\boldsymbol{V}$, then $\Lambda_{jj} = \|\bar{\boldsymbol{w}}_{\cdot j}\|_2^2$ and this expression further reduces via

$$\begin{aligned}\log\left|\tfrac{1}{\lambda}\boldsymbol{R}^\top\boldsymbol{V}\boldsymbol{\Lambda}^2\boldsymbol{V}^\top\boldsymbol{R}+\boldsymbol{I}\right| + d\log\lambda &= \sum_j\log\left(1+\tfrac{1}{\lambda}\Lambda_{jj}\right) + d\log\lambda \\ &= \sum_j\log\left(\lambda+\|\bar{\boldsymbol{w}}_{\cdot j}\|_2^2\right) + (d-\kappa)\log\lambda. \end{aligned} \tag{31}$$

Of course we cannot have

$$\sum_i \boldsymbol{\Omega}^{(i)}(\boldsymbol{W}^{**}, \boldsymbol{b}, \lambda \boldsymbol{I}) + n\left[\sum_j \log\left(\lambda + \|\boldsymbol{w}_{\cdot j}^{**}\|_2^2\right) + (d-\kappa)\log\lambda\right] \tag{32}$$
$$> \sum_i \boldsymbol{\Omega}^{(i)}(\bar{\boldsymbol{W}}, \boldsymbol{b}, \lambda \boldsymbol{I}) + n\left[\sum_j \log\left(\lambda + \|\bar{\boldsymbol{w}}_{\cdot j}\|_2^2\right) + (d-\kappa)\log\lambda\right],$$

otherwise $\boldsymbol{W}^{**}$ would not be a minimum of (7). Therefore, $\bar{\boldsymbol{W}}$ must also be a minimum of (7), from which the remaining parts of (9) immediately follows.

We next confront the arrangement of disconnected minima for part 2 of the theorem. It is not difficult to show that (5), and by virtue of the analysis above (7), will be uniquely minimized by $\boldsymbol{U}$ and $\boldsymbol{\Lambda}$ arising from the SVD of either $\boldsymbol{W}^*$ or equivalently $\boldsymbol{W}^{**}$. Let $\boldsymbol{W}^{**} = \boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{V}^\top$ via such a decomposition. So any partitioning into disconnected minimizers must come at the hands of $\boldsymbol{V}$, which only influences the $\sum_j \log\left(\lambda + \|\boldsymbol{w}_{\cdot j}\|_2^2\right)$ term in (7).

At stated above, if $\boldsymbol{W}^{**}$ is a minimum, then $\boldsymbol{W}^{**}\boldsymbol{P}$ must also be a minimum. Assume for the moment that $\boldsymbol{W}^{**}$ is full column rank. There will obviously be $r!$ unique permutations of its columns, with $r = \text{rank}[\boldsymbol{W}^{**}]$. Moreover, any transition from some permutation $\boldsymbol{P}'$ to another $\boldsymbol{P}''$ will necessarily involve some non-permutation-matrix rotation $\boldsymbol{V}$. Given our assumption of distinct eigenvalues, this will ensure that

$$\tfrac{1}{\lambda}\left(\boldsymbol{W}^{**}\right)^\top \boldsymbol{W}^{**} + \boldsymbol{I} = \tfrac{1}{\lambda}\boldsymbol{V}\boldsymbol{\Lambda}^2\boldsymbol{V}^\top + \boldsymbol{I} \tag{33}$$

is non-diagonal. While this will not increase (5), it *must* increase (7) when diagonalized by Hadamard's inequality. Therefore every permutation will reflect a distinct, disconnected minimizer. If $\boldsymbol{W}^{**}$ also has $\kappa - r$ zero-valued columns, then the resulting number of unique permutations increases to $\frac{\kappa!}{\kappa - r}$ by standard rules of combinatorics.

Finally, part 3 of the theorem follows directly from part 2: Given that any minimizer of (7) must be of the form $\boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{P}$, then there cannot be more than r nonzero columns. In contrast, for (5) we may apply any arbitrary rotation to $\boldsymbol{W}^*$, and hence all columns can be nonzero even if the rank is smaller than κ. ■

Appendix D. Proof of Theorem 3

Proof For convenience we will adopt the notation $f(\alpha) = \mathrm{O}(h(\alpha))$ to indicate that there exists a positive $\bar{\alpha}$ and some constant C independent of α such that $|f(\alpha)| < Ch(\alpha)$ for all $\alpha \in (0, \bar{\alpha}]$. Similarly, we use $f(\alpha) = \Omega(h(\alpha))$ to convey that $|f(\alpha)| > Ch(\alpha)$ under equivalent conditions. We then say $f(\alpha) = \Theta(h(\alpha))$ iff $f(\alpha) = \mathrm{O}(h(\alpha))$ and $f(x) = \Omega(h(\alpha))$. Additionally, if the input argument to one of these expressions is a vector, the result is understood to apply element-wise.

The basic high-level strategy here is as follows: We first present a candidate solution that satisfies (12) and carefully quantify the achievable objective function value for $\alpha \in (0, \bar{\alpha}]$, and $\bar{\alpha}$ small. We then analyze a lower bound on the VAE cost and demonstrate that no solution can do significantly better, namely, any solution that can match the performance

of our original proposal must necessarily also satisfy (12). Given that this is a lower bound, this implies that no other solution can both minimize the VAE objective and not satisfy (12). We now proceed to the details.

Define $\boldsymbol{\mu}_z^{(i)} \triangleq \boldsymbol{\mu}_z\left(\boldsymbol{x}^{(i)}; \boldsymbol{\phi}\right)$ and $\boldsymbol{\Sigma}_z^{(i)} \triangleq \boldsymbol{\Sigma}_z\left(\boldsymbol{x}^{(i)}; \boldsymbol{\phi}\right)$. We first note that if $\boldsymbol{z} = \boldsymbol{\mu}_z^{(i)} + \boldsymbol{S}_z^{(i)}\boldsymbol{\epsilon}$, with $\boldsymbol{S}_z^{(i)}$ satisfying $\boldsymbol{\Sigma}_z^{(i)} = \boldsymbol{S}_z^{(i)}\left(\boldsymbol{S}_z^{(i)}\right)^\top$, and $\boldsymbol{\epsilon} \sim p(\boldsymbol{\epsilon}) = \mathcal{N}(\boldsymbol{\epsilon}; \boldsymbol{0}, \boldsymbol{I})$, then $\boldsymbol{z} \sim q_{\boldsymbol{\phi}}\left(\boldsymbol{z}|\boldsymbol{x}^{(i)}\right)$. With this reparameterization and

$$\begin{aligned}
\boldsymbol{\mu}_x^{(i)} &\triangleq \boldsymbol{W}\boldsymbol{\mu}_z^{(i)} + \boldsymbol{W}\boldsymbol{S}_z^{(i)}\boldsymbol{\epsilon}, \\
\text{diag}[\boldsymbol{\Sigma}_x^{(i)}] &\triangleq \nu\left(\boldsymbol{\mu}_z^{(i)} + \boldsymbol{S}_z^{(i)}\boldsymbol{\epsilon}; \boldsymbol{\theta}\right) \text{ for some function } \nu \\
\boldsymbol{\mu}_z^{(i)} &\triangleq f(\boldsymbol{x}^{(i)}; \boldsymbol{\phi}) \text{ for some function } f \\
\boldsymbol{S}_z^{(i)} &\triangleq g(\boldsymbol{x}^{(i)}; \boldsymbol{\phi}) \text{ for some function } g,
\end{aligned} \tag{34}$$

the equivalent VAE objective becomes

$$\begin{aligned}
\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}) \;=\; & \sum_i \left\{ \mathbb{E}_{p(\boldsymbol{\epsilon})}\left[\left(\boldsymbol{x}^{(i)} - \boldsymbol{W}\boldsymbol{\mu}_z^{(i)} - \boldsymbol{W}\boldsymbol{S}_z^{(i)}\boldsymbol{\epsilon}\right)^\top \left(\boldsymbol{\Sigma}_x^{(i)}\right)^{-1}\left(\boldsymbol{x}^{(i)} - \boldsymbol{W}\boldsymbol{\mu}_z^{(i)} - \boldsymbol{W}\boldsymbol{S}_z^{(i)}\boldsymbol{\epsilon}\right)\right] \right. \\
& \left. + \;\; \mathbb{E}_{p(\boldsymbol{\epsilon})}\left[\log\left|\boldsymbol{\Sigma}_x^{(i)}\right|\right] + \text{tr}\left[\boldsymbol{\Sigma}_z^{(i)}\right] - \log\left|\boldsymbol{\Sigma}_z^{(i)}\right| + \|\boldsymbol{\mu}_z^{(i)}\|_2^2 \right\},
\end{aligned} \tag{35}$$

when $\boldsymbol{b} = \boldsymbol{0}$ as stipulated.[13] For now assume that κ, the dimension of the latent $\boldsymbol{z}$, satisfies $\kappa = \text{rank}[\boldsymbol{U}]$ (later we will relax this assumption).

D.1 A Candidate Solution

Here we consider a candidate solution that, by design, satisfies (12). For the encoder parameters we choose

$$\hat{\boldsymbol{\mu}}_z^{(i)} = \boldsymbol{\pi}^{(i)}, \qquad \hat{\boldsymbol{\Sigma}}_z^{(i)} = \alpha \boldsymbol{I}. \tag{36}$$

where α is a non-negative scalar and $\boldsymbol{\pi}^{(i)}$ is defined in conjunction with a matrix $\boldsymbol{\Psi}$ such that

$$\begin{aligned}
\text{supp}_\alpha\left[\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi}^{(i)}\right] &= \text{supp}\left[\boldsymbol{s}^{(i)}\right] \\
\text{span}\left[\boldsymbol{U}\right] &= \text{span}\left[\boldsymbol{\Psi}\right].
\end{aligned} \tag{37}$$

All quantities in (36) can be readily computed via $\boldsymbol{X}$ applied to an encoder module provided that $\kappa = \dim[\boldsymbol{z}] = \text{rank}\left[\boldsymbol{U}\right]$ as stipulated, and sufficient representational complexity for $\boldsymbol{\mu}_z$ and $\boldsymbol{\Sigma}_z$. Additionally, for the encoder we only need to define the posterior moments at specific points $\boldsymbol{x}^{(i)}$, hence the indexing via i in (36).

In contrast, for the decoder we consider the solution defined over any $\boldsymbol{z}$ given by

$$\begin{aligned}
\hat{\boldsymbol{W}} &= \boldsymbol{\Psi} \\
\hat{\boldsymbol{\mu}}_x &= \hat{\boldsymbol{W}}\boldsymbol{z} \\
\text{diag}\left[\hat{\boldsymbol{\Sigma}}_x\right] &= \boldsymbol{\Lambda}^{(h_\pi(\boldsymbol{z}))},
\end{aligned} \tag{38}$$

13. The extension to arbitrary $\boldsymbol{b}$ is trivial but clutters the presentation.

where $\boldsymbol{\Lambda}^{(i)} \in \mathbb{R}^{d\times d}$ is a diagonal matrix with

$$\left[\boldsymbol{\Lambda}^{(i)}\right]_{jj} = \begin{cases} \alpha, & \text{if } s_j^{(i)} = 0, \\ 1, & \text{otherwise}, \end{cases} \quad \forall j. \tag{39}$$

and $h_\pi : \mathbb{R}^\kappa \rightarrow \{1,\ldots,n\}$ is a function satisfying

$$h_\pi(\boldsymbol{z}) \triangleq \arg\min_{i\in\{1,..,n\}} \|\boldsymbol{z} - \boldsymbol{\pi}^{(i)}\|_2. \tag{40}$$

Again, given sufficient capacity, this function can always be learned by the decoder such that (38) is computable for any $\boldsymbol{z}$. Given these definitions, then the index-specific moments $\hat{\boldsymbol{\mu}}_x^{(i)}$ and $\hat{\boldsymbol{\Sigma}}_x^{(i)}$ are of course reduced to functions of $\boldsymbol{\epsilon}$ given by

$$\begin{aligned} \hat{\boldsymbol{\mu}}_x^{(i)} &= \hat{\boldsymbol{\mu}}_x\left(\hat{\boldsymbol{\mu}}_z^{(i)} + \hat{\boldsymbol{S}}_z^{(i)}\boldsymbol{\epsilon}; \boldsymbol{\theta}\right) \\ \hat{\boldsymbol{\Sigma}}_x^{(i)} &= \hat{\boldsymbol{\Sigma}}_x\left(\hat{\boldsymbol{\mu}}_z^{(i)} + \hat{\boldsymbol{S}}_z^{(i)}\boldsymbol{\epsilon}; \boldsymbol{\theta}\right). \end{aligned} \tag{41}$$

.

We next analyze the behavior of (35) at this specially parameterized solution as $\bar{\alpha}$ becomes small, in which case by design all covariances will be feasible by design. For this purpose, we first consider the integration across all cases where $\hat{\boldsymbol{\Sigma}}_x^{(i)}$ does not reflect the correct support, meaning $\boldsymbol{\epsilon} \notin \mathcal{S}^{(i)}$, where

$$\mathcal{S}^{(i)} \triangleq \left\{\boldsymbol{\epsilon} : \quad \left[\boldsymbol{\Sigma}_x^{(i)}\right]_{jj} = \alpha \;\text{ iff }\; s_j^{(i)} = 0, \;\; \forall j\right\}. \tag{42}$$

With this segmentation in mind, the VAE objection naturally partitions as

$$\mathcal{L}(\boldsymbol{\theta},\boldsymbol{\phi}) = \sum_i \left\{\mathcal{L}^{(i)}(\boldsymbol{\theta},\boldsymbol{\phi}; \epsilon \notin \mathcal{S}^{(i)}) + \mathcal{L}^{(i)}(\boldsymbol{\theta},\boldsymbol{\phi}; \epsilon \in \mathcal{S}^{(i)})\right\}, \tag{43}$$

where $\mathcal{L}^{(i)}(\boldsymbol{\theta},\boldsymbol{\phi}; \epsilon \notin \mathcal{S}^{(i)})$ denotes the cost for the i-th sample when integrated across those samples not in $\mathcal{S}^{(i)}$, and $\mathcal{L}^{(i)}(\boldsymbol{\theta},\boldsymbol{\phi}; \epsilon \in \mathcal{S}^{(i)})$ is the associated complement.

D.2 Evaluation of $\mathcal{L}^{(i)}(\boldsymbol{\theta},\boldsymbol{\phi}; \epsilon \notin \mathcal{S}^{(i)})$

First we define

$$\rho = \min_{i,j\in\{1,..,n\}, i\neq j} \tfrac{1}{2}\|\boldsymbol{\pi}^{(i)} - \boldsymbol{\pi}^{(j)}\|_2, \tag{44}$$

which is just half the minimum distance between any two distinct coefficient expansions. If any $\boldsymbol{z}$ is within this distance of $\boldsymbol{\pi}^{(i)}$, it will necessarily be quantized to this value per our previous definitions. Therefore if $\|\hat{\boldsymbol{S}}_z^{(i)}\boldsymbol{\epsilon}\|_2 < \rho$, we are guaranteed that the correct generating support pattern will be mapped to $\hat{\boldsymbol{\Sigma}}_x^{(i)}$, and so it follows that

$$P\left(\boldsymbol{\epsilon} \notin \mathcal{S}^{(i)}\right)) \leq P\left(\left\|\hat{\boldsymbol{S}}_z^{(i)}\boldsymbol{\epsilon}\right\|_2 > \rho\right) = P(\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2 > \rho) \tag{45}$$

at our candidate solution. We also make use of the quantity

$$\eta \triangleq \max_{i\in\{1,..,n\}} \|\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi}^{(i)}\|_2^2, \tag{46}$$

which represents the maximum data-fitting error. Then for the i-th sample we have

$$\begin{aligned} &\mathcal{L}^{(i)}(\boldsymbol{\theta},\boldsymbol{\phi}; \epsilon \notin \mathcal{S}^{(i)}) \\ &= \int_{\boldsymbol{\epsilon}\notin\mathcal{S}^{(i)}} \left[\left(\boldsymbol{x}^{(i)} - \hat{\boldsymbol{W}}\hat{\boldsymbol{\mu}}_z^{(i)} - \hat{\boldsymbol{W}}\hat{\boldsymbol{S}}_z^{(i)}\boldsymbol{\epsilon}\right)^\top \left(\hat{\boldsymbol{\Sigma}}_x^{(i)}\right)^{-1}\left(\boldsymbol{x}^{(i)} - \hat{\boldsymbol{W}}\hat{\boldsymbol{\mu}}_z^{(i)} - \hat{\boldsymbol{W}}\hat{\boldsymbol{S}}_z^{(i)}\boldsymbol{\epsilon}\right)\right. \\ &\quad + \left.\log\left|\hat{\boldsymbol{\Sigma}}_x^{(i)}\right| + \mathrm{tr}\left[\hat{\boldsymbol{\Sigma}}_z^{(i)}\right] - \log\left|\hat{\boldsymbol{\Sigma}}_z^{(i)}\right| + \|\hat{\boldsymbol{\mu}}_z^{(i)}\|_2^2\right] p(\boldsymbol{\epsilon})d\boldsymbol{\epsilon} \\ &\leq \int_{\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2>\rho} \left[\left(\boldsymbol{x}^{(i)} - \hat{\boldsymbol{W}}\hat{\boldsymbol{\mu}}_z^{(i)} - \hat{\boldsymbol{W}}\hat{\boldsymbol{S}}_z^{(i)}\boldsymbol{\epsilon}\right)^\top \left(\hat{\boldsymbol{\Sigma}}_x^{(i)}\right)^{-1}\left(\boldsymbol{x}^{(i)} - \hat{\boldsymbol{W}}\hat{\boldsymbol{\mu}}_z^{(i)} - \hat{\boldsymbol{W}}\hat{\boldsymbol{S}}_z^{(i)}\boldsymbol{\epsilon}\right)\right. \\ &\quad + \left.\log\left|\hat{\boldsymbol{\Sigma}}_x^{(i)}\right| + \mathrm{tr}\left[\hat{\boldsymbol{\Sigma}}_z^{(i)}\right] - \log\left|\hat{\boldsymbol{\Sigma}}_z^{(i)}\right| + \|\hat{\boldsymbol{\mu}}_z^{(i)}\|_2^2\right] p(\boldsymbol{\epsilon})d\boldsymbol{\epsilon} \\ &\leq \int_{\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2>\rho} \left[\tfrac{1}{\alpha}\left(\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi}^{(i)} - \sqrt{\alpha}\boldsymbol{\Psi}\boldsymbol{\epsilon}\right)^\top \left(\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi}^{(i)} - \sqrt{\alpha}\boldsymbol{\Psi}\boldsymbol{\epsilon}\right)\right. \\ &\quad + \left.\kappa\alpha - \kappa\log\alpha + \|\boldsymbol{\pi}^{(i)}\|_2^2\right] p(\boldsymbol{\epsilon})d\boldsymbol{\epsilon}, \end{aligned} \tag{47}$$

where the second inequality comes from setting $\hat{\boldsymbol{\Sigma}}_x^{(i)} = \alpha\boldsymbol{I}$ (its smallest possible value) in the inverse term and $\hat{\boldsymbol{\Sigma}}_x^{(i)} = \boldsymbol{I}$ (its largest value) in the log-det term. Next, given that

$$\begin{aligned} \|\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi}^{(i)}\|_2^2 &\leq \eta \\ \int_{\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2>\rho} \left(\boldsymbol{\pi}^{(i)}\right)^\top \boldsymbol{\Psi}^\top\boldsymbol{\Psi}\boldsymbol{\epsilon}\cdot p(\boldsymbol{\epsilon})d\boldsymbol{\epsilon} &= 0 \\ \int_{\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2>\rho} \|\boldsymbol{\Psi}\boldsymbol{\epsilon}\|_2^2 p(\boldsymbol{\epsilon})d\boldsymbol{\epsilon} &\leq \mathrm{tr}\left[\boldsymbol{\Psi}^\top\boldsymbol{\Psi}\right], \end{aligned} \tag{48}$$

it follows that the bound from (47) can be further reduced via

$$\begin{aligned} \mathcal{L}^{(i)}(\boldsymbol{\theta},\boldsymbol{\phi}; \epsilon \notin \mathcal{S}^{(i)}) &\leq \mathrm{tr}\left[\boldsymbol{\Psi}^\top\boldsymbol{\Psi}\right] + \int_{\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2>\rho} \left[\tfrac{1}{\alpha}\eta + \kappa\alpha - \kappa\log\alpha + \|\boldsymbol{\pi}^{(i)}\|_2^2\right] p(\boldsymbol{\epsilon})d\boldsymbol{\epsilon} \\ &= \Theta(1) + \left[\tfrac{1}{\alpha}\eta + \kappa\alpha - \kappa\log\alpha + \|\boldsymbol{\pi}^{(i)}\|_2^2\right] \int_{\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2>\rho} p(\boldsymbol{\epsilon})d\boldsymbol{\epsilon} \\ &\leq \Theta(1) + \left[\tfrac{1}{\alpha}\eta + \kappa\alpha - \kappa\log\alpha + \|\boldsymbol{\pi}^{(i)}\|_2^2\right] \tfrac{\alpha}{\rho^2} \\ &= \Theta(1) + \Theta(\alpha^2) - \Theta(\alpha\log\alpha) \\ &= \Theta(1) \quad \text{as } \alpha \rightarrow 0, \end{aligned} \tag{49}$$

where the second inequality holds based on the vector version of Chebyshev's inequality, which ensures that

$$\int_{\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2>\rho} p(\boldsymbol{\epsilon})d\boldsymbol{\epsilon} = P(\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2 > \rho) \leq \tfrac{\alpha}{\rho^2}. \tag{50}$$

Clearly then, as α becomes small, we have established that

$$\mathcal{L}^{(i)}(\boldsymbol{\theta},\boldsymbol{\phi}; \epsilon \notin \mathcal{S}^{(i)}) \rightarrow O\left(1\right). \tag{51}$$

D.3 Evaluation of $\mathcal{L}^{(i)}(\boldsymbol{\theta}, \boldsymbol{\phi}; \epsilon \in \mathcal{S}^{(i)})$

In analyzing $\mathcal{L}^{(i)}(\boldsymbol{\theta}, \boldsymbol{\phi}; \epsilon \in \mathcal{S}^{(i)})$, we note that

$$\begin{aligned}
&\int_{\boldsymbol{\epsilon} \in \mathcal{S}^{(i)}} \left(\boldsymbol{x}^{(i)} - \hat{\boldsymbol{W}}\hat{\boldsymbol{\mu}}_z^{(i)} - \hat{\boldsymbol{W}}\hat{\boldsymbol{S}}_z^{(i)}\boldsymbol{\epsilon}\right)^\top \left(\hat{\boldsymbol{\Sigma}}_x^{(i)}\right)^{-1} \left(\boldsymbol{x}^{(i)} - \hat{\boldsymbol{W}}\hat{\boldsymbol{\mu}}_z^{(i)} - \hat{\boldsymbol{W}}\hat{\boldsymbol{S}}_z^{(i)}\boldsymbol{\epsilon}\right) p(\boldsymbol{\epsilon}) d\boldsymbol{\epsilon} \\
&\quad \leq \int \left(\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi}^{(i)} - \sqrt{\alpha}\boldsymbol{\Psi}\boldsymbol{\epsilon}\right)^\top \left(\boldsymbol{\Lambda}^{(i)}\right)^{-1} \left(\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi}^{(i)} - \sqrt{\alpha}\boldsymbol{\Psi}\boldsymbol{\epsilon}\right) p(\boldsymbol{\epsilon}) d\boldsymbol{\epsilon} \\
&\quad \leq \int \left(\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi}^{(i)}\right)^\top \left(\boldsymbol{\Lambda}^{(i)}\right)^{-1} \left(\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi}^{(i)}\right) p(\boldsymbol{\epsilon}) d\boldsymbol{\epsilon} + \operatorname{tr}\left[\boldsymbol{\Psi}^\top \boldsymbol{\Psi}\right] \\
&\quad \leq \eta + \operatorname{tr}\left[\boldsymbol{\Psi}^\top \boldsymbol{\Psi}\right] \\
&\quad = \Theta(1)
\end{aligned} \tag{52}$$

given the alignment of $\boldsymbol{\Lambda}^{(i)}$ with zero-valued elements in $\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi}^{(i)}$. Furthermore, the remaining terms in $\mathcal{L}^{(i)}(\boldsymbol{\theta}, \boldsymbol{\phi}; \epsilon \in \mathcal{S}^{(i)})$ are independent of $\boldsymbol{\epsilon}$ giving

$$\begin{aligned}
&\int_{\boldsymbol{\epsilon} \in \mathcal{S}^{(i)}} \left[\log \left|\hat{\boldsymbol{\Sigma}}_x^{(i)}\right| + \operatorname{tr}\left[\hat{\boldsymbol{\Sigma}}_z^{(i)}\right] - \log \left|\hat{\boldsymbol{\Sigma}}_z^{(i)}\right| + \|\hat{\boldsymbol{\mu}}_z^{(i)}\|_2^2\right] p(\boldsymbol{\epsilon}) d\boldsymbol{\epsilon} \\
&\quad = \left[\log \left|\boldsymbol{\Lambda}^{(i)}\right| + \kappa\alpha - \kappa \log \alpha + \|\boldsymbol{\pi}^{(i)}\|_2^2\right] \int_{\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2 < \rho} p(\boldsymbol{\epsilon}) d\boldsymbol{\epsilon} \\
&\quad = \left[(r^{(i)} - \kappa)\log \alpha + \kappa\alpha + \|\boldsymbol{\pi}^{(i)}\|_2^2\right] \int_{\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2 < \rho} p(\boldsymbol{\epsilon}) d\boldsymbol{\epsilon} \\
&\quad = \left[(r^{(i)} - \kappa)\log \alpha\right] \int_{\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2 < \rho} p(\boldsymbol{\epsilon}) d\boldsymbol{\epsilon} + O(\alpha) + O(1),
\end{aligned} \tag{53}$$

where

$$r^{(i)} \triangleq \left|\left\{j : \Lambda_{jj}^{(i)} = \alpha\right\}\right| = d - \|\boldsymbol{s}^{(i)}\|_0. \tag{54}$$

Therefore, since $\int_{\|\sqrt{\alpha}\boldsymbol{\epsilon}\|_2 < \rho} p(\boldsymbol{\epsilon}) d\boldsymbol{\epsilon} \to 1$ as α becomes small, we may conclude that

$$\mathcal{L}^{(i)}(\boldsymbol{\theta}, \boldsymbol{\phi}; \epsilon \in \mathcal{S}^{(i)}) \to \left(d - \kappa - \|\boldsymbol{s}^{(i)}\|_0\right) \log \alpha + O(1). \tag{55}$$

D.4 Compilation of Candidate Solution Cost

After combining (51) and (55) across all i we find that

$$\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}) \to \sum_i \left(d - \kappa - \|\boldsymbol{s}^{(i)}\|_0\right) \log \alpha + O(1) \tag{56}$$

for any $\alpha \in (0, \bar{\alpha}]$ as $\bar{\alpha}$ becomes small. If $d > \kappa + \|\boldsymbol{s}^{(i)}\|_0$, then this expression will tend towards minus infinity, indicative of an objective value that is unbounded from below, certainly a fertile region for candidate minimizers. Note that per the theorem statement, $\boldsymbol{L} = \boldsymbol{U}\boldsymbol{V}$ and $\boldsymbol{S}$ must represent a unique feasible solution to

$$\min_{\boldsymbol{L}, \boldsymbol{S}} \; d \cdot \operatorname{rank}[\boldsymbol{L}] + \|\boldsymbol{S}\|_0 \quad \text{s.t.} \quad \boldsymbol{X} = \boldsymbol{L} + \boldsymbol{S}. \tag{57}$$

Given that each column $\boldsymbol{x}^{(i)}$ has d degrees of freedom, then with $\boldsymbol{U}$ fixed there will be an infinite number of feasible solutions $\boldsymbol{x}^{(i)} = \boldsymbol{U}\boldsymbol{v}^{(i)} + \boldsymbol{s}^{(i)}$ such that $\dim[\boldsymbol{v}^{(i)}] + \|\boldsymbol{s}^{(i)}\|_0 = \kappa + \|\boldsymbol{s}^{(i)}\|_0 > d$ and a combinatorial number such that $k + \|\boldsymbol{s}^{(i)}\|_0 = d$. Therefore for uniqueness we require that $k + \|\boldsymbol{s}^{(i)}\|_0 < d$, so it follows that indeed $\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi})$ will be unbounded from below as $\bar{\alpha}$ and therefore α becomes small, with cost given by (56) as a candidate solution satisfying the conditions of the theorem.

Of course it still remains possible that some other candidate solution could exist that violates one of these conditions and yet still achieves (56) or an even lower cost. We tackle this issue next. For this purpose our basic strategy will be to examine a *lower* bound on $\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi})$ and show that essentially any candidate solution violating the theorem conditions will be worse than (56).

D.5 Evaluation of Other Candidate Solutions

To begin, we first observe that if granted the flexibility to optimize $\boldsymbol{\Sigma}_x^{(i)}$ independently over all values of $\boldsymbol{\epsilon}$ inside the integral for computing $\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi})$, we immediately obtain a rigorous lower bound.[14] For this purpose we must effectively solve decoupled problems of the form

$$\inf_{\gamma > \alpha} \tfrac{c}{\gamma} + \log \gamma, \tag{58}$$

to which the optimal solution is just

$$\gamma^* = \xi_\alpha(x) \triangleq [c - \alpha]_+ + \alpha, \tag{59}$$

where the operator $[\cdot]_+$ retains only the positive part of its argument, setting negative values to zero. Plugging this solution back into (58), we find that

$$\inf_{\gamma > \alpha} \tfrac{c}{\gamma} + \log \gamma \quad = \quad \log \xi_\alpha(c) + O(1). \tag{60}$$

In the context of our bound, this leads to

$$\begin{aligned}
\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}) \quad \geq \quad & \sum_i \left\{ \mathbb{E}_{p(\boldsymbol{\epsilon})} \left[\sum_j \log \xi_\alpha \left(\left[x_j^{(i)} - \boldsymbol{w}_{j\cdot} \boldsymbol{\mu}_z^{(i)} - \boldsymbol{w}_{j\cdot} \boldsymbol{S}_z^{(i)} \boldsymbol{\epsilon} \right]^2 \right) \right] \right. \\
& \left. + \; \operatorname{tr}\left[\boldsymbol{\Sigma}_z^{(i)}\right] - \log \left|\boldsymbol{\Sigma}_z^{(i)}\right| + \|\boldsymbol{\mu}_z^{(i)}\|_2^2 \right\} + O(1).
\end{aligned} \tag{61}$$

From this expression, it is clear that the lowest objective value we could ever hope to obtain cannot involve arbitrarily large values of $\boldsymbol{\Sigma}_z^{(i)}$ and $\boldsymbol{\mu}_z^{(i)}$ since the respective trace and quadratic terms grow faster than log-det terms. Likewise $\boldsymbol{\mu}_z^{(i)}$ cannot be unbounded for analogous reasons. Therefore, optimal solutions to (61) that will be unbounded from below must involve the first term becoming small, at least over a range of $\boldsymbol{\epsilon}$ values with significant probability measure. Although the required integral admits no closed-form solution, we can simplify things further using refinements of the above bound.

14. Note that this is never exactly achievable in practice, even with an infinite capacity network for computing $\boldsymbol{\Sigma}_x^{(i)}$, since it would require a unique network for each data sample; however, it nonetheless serves as a useful analysis tool.

For this purpose consider any possible candidate solution $\hat{\boldsymbol{W}} = \boldsymbol{\Psi}$ and $\hat{\boldsymbol{\mu}}_z^{(i)} = \boldsymbol{\pi}^{(i)}$ (not necessarily one that coincides with $\boldsymbol{U}$ and the optimal subspace), and define

$$\Delta_\alpha^{(i)}(\boldsymbol{\Psi}, \boldsymbol{\pi}) \triangleq \text{supp}_\alpha \left[\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi} \right]. \tag{62}$$

Without loss of generality we also specify that

$$\boldsymbol{S}_z^{(i)} \triangleq \boldsymbol{\Xi}^{(i)} \boldsymbol{D}^{(i)}, \tag{63}$$

where $\boldsymbol{\Xi}^{(i)} \in \mathbb{R}^{d \times \kappa}$ has orthonormal columns and $\boldsymbol{D}^{(i)}$ is a diagonal matrix with

$$\left[\boldsymbol{D}^{(i)} \right]_{kk} = \xi_{\sqrt{\alpha}} \left(\sigma_k^{(i)} \right), \tag{64}$$

and $\boldsymbol{\sigma}^{(i)} = [\sigma_1^{(i)}, \ldots, \sigma_\kappa^{(i)}]^\top \in \mathbb{R}_+^\kappa$ is an arbitrary non-negative vector. Any general $\boldsymbol{\Sigma}_z^{(i)} = \boldsymbol{S}_z^{(i)} \left(\boldsymbol{S}_z^{(i)} \right)^\top$, with singular values bounded by α, is expressible via this format. We then reexpress (61) as

$$\begin{aligned}
\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}) \;\geq\; & \sum_i \left\{ \mathbb{E}_{p(\boldsymbol{\epsilon})} \left[\sum_{j \in \Delta_\alpha^{(i)}(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)})} \log \xi_\alpha \left(\left[x_j^{(i)} - \boldsymbol{\psi}_{j\cdot} \boldsymbol{\pi}^{(i)} - \boldsymbol{\psi}_{j\cdot} \boldsymbol{\Xi}^{(i)} \boldsymbol{D}^{(i)} \boldsymbol{\epsilon} \right]^2 \right) \right] \right. \\
& + \mathbb{E}_{p(\boldsymbol{\epsilon})} \left[\sum_{j \notin \Delta_\alpha^{(i)}(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)})} \log \xi_\alpha \left(\left[O(\alpha) + \boldsymbol{\psi}_{j\cdot} \boldsymbol{\Xi}^{(i)} \boldsymbol{D}^{(i)} \boldsymbol{\epsilon} \right]^2 \right) \right] \qquad (65) \\
& \left. + \; \text{tr} \left[\boldsymbol{\Xi}^{(i)} \left(\boldsymbol{D}^{(i)} \right)^2 \left(\boldsymbol{\Xi}^{(i)} \right)^\top \right] - \log \left| \boldsymbol{\Xi}^{(i)} \left(\boldsymbol{D}^{(i)} \right)^2 \left(\boldsymbol{\Xi}^{(i)} \right)^\top \right| + \|\boldsymbol{\pi}^{(i)}\|_2^2 \right\} + O(1), \\
= \; & \sum_i \left\{ \mathbb{E}_{p(\boldsymbol{\epsilon})} \left[\sum_{j \in \Delta_\alpha^{(i)}(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)})} \log \xi_\alpha \left(\left[x_j^{(i)} - \boldsymbol{\psi}_{j\cdot} \boldsymbol{\pi}^{(i)} - \sum_k \bar{\psi}_{jk} \cdot \xi_{\sqrt{\alpha}} \left(\sigma_k^{(i)} \right) \cdot \epsilon_k \right]^2 \right) \right] \right. \\
& + \mathbb{E}_{p(\boldsymbol{\epsilon})} \left[\sum_{j \notin \Delta_\alpha^{(i)}(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)})} \log \xi_\alpha \left(\left[O(\alpha) + \sum_k \bar{\psi}_{jk}^{(i)} \cdot \xi_{\sqrt{\alpha}} \left(\sigma_k^{(i)} \right) \cdot \epsilon_k \right]^2 \right) \right] \qquad (66) \\
& \left. + \; \sum_k \xi_\alpha \left[\left(\sigma_k^{(i)} \right)^2 \right] - \sum_k \log \xi_\alpha \left[\left(\sigma_k^{(i)} \right)^2 \right] + \|\boldsymbol{\pi}^{(i)}\|_2^2 \right\} + O(1),
\end{aligned}$$

where $\bar{\psi}_{jk}^{(i)}$ is the k-th element of the vector $\boldsymbol{\psi}_{j\cdot} \boldsymbol{\Xi}^{(i)}$. We can now analyze any given point $\{\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)}, \boldsymbol{\Xi}^{(i)}, \boldsymbol{\sigma}^{(i)}\}_{i=1}^n$ as α becomes small. The first term can be shown to be $\Theta(1)$ with all

other variables fixed,[15] leading to the revised bound

$$\begin{aligned}
\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}) \;\geq\; & \sum_i \left\{ \mathbb{E}_{p(\boldsymbol{\epsilon})} \left[\sum_{j \notin \Delta_\alpha^{(i)}(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)})} \log \xi_\alpha \left(\left[O(\alpha) + \sum_k \bar{\psi}_{jk}^{(i)} \cdot \xi_{\sqrt{\alpha}} \left(\sigma_k^{(i)} \right) \cdot \epsilon_k \right]^2 \right) \right] \right. \qquad (67) \\
& \left. - \; \sum_k \log \xi_\alpha \left[\left(\sigma_k^{(i)} \right)^2 \right] \right\} + \Theta(1),
\end{aligned}$$

where the terms $\sum_k \xi_\alpha \left[\left(\sigma_k^{(i)} \right)^2 \right]$ and $\|\boldsymbol{\pi}^{(i)}\|_2^2$ have also been absorbed into $\Theta(1)$.

Given that

$$\mathbb{E}_{p(\boldsymbol{\epsilon})} \left[\log \xi_\alpha \left(\left[O(\alpha) + \boldsymbol{a}^\top \boldsymbol{\epsilon} \right]^2 \right) \right] = \log \xi_\alpha \left[\boldsymbol{a}^\top \boldsymbol{a} \right] + O(1) \geq \log \alpha + O(1) \tag{68}$$

for any vector $\boldsymbol{a}$, we have the new bound

$$\begin{aligned}
& \mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}) \qquad (69) \\
\geq \; & \sum_i \left\{ \sum_{j \notin \Delta_\alpha^{(i)}(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)})} \log \xi_\alpha \left(\sum_k \left[\bar{\psi}_{jk}^{(i)} \cdot \xi_{\sqrt{\alpha}} \left(\sigma_k^{(i)} \right) \right]^2 \right) - \sum_k \log \xi_\alpha \left[\left(\sigma_k^{(i)} \right)^2 \right] \right\} + \Theta(1).
\end{aligned}$$

If then we choose $\sigma_k^{(i)} = 0$ for all $i = 1, \ldots n$ and $k = 1, \ldots, \kappa$, then

$$\log \xi_\alpha \left(\sum_k \left[\bar{\psi}_{jk}^{(i)} \cdot \xi_{\sqrt{\alpha}} \left(\sigma_k^{(i)} \right) \right]^2 \right) = \log \alpha + \Theta(1) \tag{70}$$

and we obtain the lower bound

$$\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}) \;\geq\; \sum_i \left(d - \kappa - \left| \Delta_\alpha^{(i)} \left(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)} \right) \right| \right) \log \alpha + \Theta(1). \tag{71}$$

Additionally, if any set $\Delta_\alpha^{(i)} \left(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)} \right)$ exists such that

$$\sum_i \left(d - \kappa - \left| \Delta_\alpha^{(i)} \left(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)} \right) \right| \right) \leq \sum_i \left(d - \kappa - \|\boldsymbol{s}^{(i)}\|_0 \right), \tag{72}$$

then $\boldsymbol{s}^{(i)}$ cannot be part of the unique, feasible solution to (10), i.e., we could use the support pattern from each $\Delta_\alpha^{(i)} \left(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)} \right)$ to find a different feasible solution with equal or lower value of $n \cdot \text{rank}[\boldsymbol{L}] + \|\boldsymbol{S}\|_0$, which would violate either the uniqueness or optimality of the original solution. Therefore, we have established that with $\sigma_k^{(i)} = O(\alpha)$ for all i and k, the resulting bound on $\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi})$ is essentially no better than (56), or the same bound we

15. Note that $x_j^{(i)} - \boldsymbol{\psi}_{j\cdot} \boldsymbol{\pi}^{(i)} = \Theta(1)$ for all $j \in \Delta_\alpha^{(i)} \left(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)} \right)$ and $\int \log \xi_\alpha \left[(\Theta(1) + x)^2 \right] \mathcal{N}(x; 0, \gamma) dx = \Theta(1)$ for any variance $\gamma > 0$.

had before from our feasible trial solution. Moreover, the resulting $\hat{\boldsymbol{W}} = \boldsymbol{\Psi}$ that maximizes this bound, as well as the implicit

$$\hat{\boldsymbol{\Sigma}}_x^{(i)}\left(\hat{\boldsymbol{\mu}}_z\left[\boldsymbol{x}^{(i)}\right]\right) = \text{diag}\left[\left(\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi}^{(i)}\right)^2\right], \tag{73}$$

will necessarily satisfy (12). We then only need consider whether other choices for $\sigma_k^{(i)}$ can do better.

Let $\widetilde{\boldsymbol{\Psi}}^{(i)}$ denote the the rows of $\boldsymbol{\Psi}^{(i)}$ associated with row indeces $j \notin \Delta_\alpha^{(i)}\left(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)}\right)$, meaning the indices at which we assume no sparse corruption term exists. Additionally, define $\boldsymbol{B}^{(i)} \triangleq \widetilde{\boldsymbol{\Psi}}^{(i)}\boldsymbol{\Xi}^{(i)}$. This implies that

$$\begin{aligned}\sum_{j \notin \Delta_\alpha^{(i)}\left(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)}\right)} \log \xi_\alpha\left(\max_k\left[\bar{\psi}_{jk}^{(i)} \cdot \xi_{\sqrt{\alpha}}\left(\sigma_k^{(i)}\right)\right]^2\right) - \sum_k \log \xi_\alpha\left[\left(\sigma_k^{(i)}\right)^2\right] \\ = \sum_j \log \xi_\alpha\left(\max_k\left[B_{jk}^{(i)} \cdot \xi_{\sqrt{\alpha}}\left(\sigma_k^{(i)}\right)\right]^2\right) - \sum_k \log \xi_\alpha\left[\left(\sigma_k^{(i)}\right)^2\right].\end{aligned} \tag{74}$$

Contrary to our prior assumption $\boldsymbol{\sigma}^{(i)} = \boldsymbol{0}$, now consider any solution with $\|\boldsymbol{\sigma}^{(i)}\|_0 = \beta > 0$. For the time being, we also assume that $\boldsymbol{B}^{(i)}$ is full column rank. These conditions imply that

$$\sum_j \log \xi_\alpha\left(\max_k\left[B_{jk}^{(i)} \cdot \xi_{\sqrt{\alpha}}\left(\sigma_k^{(i)}\right)\right]^2\right) \geq \left(d - \beta - \left|\Delta_\alpha^{(i)}\left(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)}\right)\right|\right)\log \alpha + \Theta(1) \tag{75}$$

since at least β elements of the summation over j must now be order $\Theta(1)$. By assumption we also have $\sum_k \log \xi_\alpha\left[\left(\sigma_k^{(i)}\right)^2\right] = (\kappa - \beta)\log\alpha + \Theta(1)$. Combining with (75), we see that such a solution is equivalent or worse than (71). So the former is the best we can do at any value of $\{\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)}, \boldsymbol{\Xi}^{(i)}, \boldsymbol{\sigma}^{(i)}\}_{i=1}^n$, provided that $\boldsymbol{B}^{(i)}$ is full rank, and obtaining the optimal value of $\Delta_\alpha^{(i)}\left(\boldsymbol{\Psi}, \boldsymbol{\pi}^{(i)}\right)$ implies that (12) holds.

However, if $\boldsymbol{B}^{(i)}$ is not full rank it would indeed entail that (74) could be reduced further, since a nonzero element of $\boldsymbol{\sigma}^{(i)}$ would not increase the first summation, while it would reduce the second. But if such a solution were to exist, it would violate the uniqueness assumption of the theorem statement. To see this, note that $\text{rank}[\boldsymbol{B}^{(i)}] = \text{rank}[\widetilde{\boldsymbol{\Psi}}^{(i)}]$ since $\boldsymbol{\Xi}^{(i)}$ is orthogonal, so if the former is not full column rank, neither is the latter. And if $\widetilde{\boldsymbol{\Psi}}^{(i)}$ is not full column rank, there will exist multiple solutions such that $\|\boldsymbol{x}^{(i)} - \boldsymbol{\Psi}\boldsymbol{\pi}^{(i)}\|_0 = \|\boldsymbol{s}^{(i)}\|_0$ or equivalently $\|\boldsymbol{x}^{(i)} - \boldsymbol{U}\boldsymbol{v}^{(i)}\|_0 = \|\boldsymbol{s}^{(i)}\|_0$ in direct violation of the uniqueness clause.

Therefore to conclude, a lower bound on the VAE cost is in fact the same order as that obtainable by our original trial solution. If this lower bound is not achieved, we cannot be at a minimizing solution, and any solution achieving this bound must satisfy (12).

D.6 Generalization to Case where $\kappa > \text{rank}[\boldsymbol{U}]$

Finally, we briefly consider the case where $\kappa > \text{rank}[\boldsymbol{U}] \triangleq \tau$, meaning that $\boldsymbol{W}$ contains redundant columns that are unnecessary in producing an optimal solution to (10). The candidate solution described in Section D.1 can be expanded via $\hat{\boldsymbol{W}} = \left[\boldsymbol{\Psi},\ \boldsymbol{0}_{[d\times(\kappa-\tau)]}\right]$, $\boldsymbol{\mu}_z^{(i)} = \left[(\boldsymbol{\pi}^{(i)})^\top,\ \boldsymbol{0}_{[1\times(\kappa-\tau)]}\right]^\top$, and $\hat{\boldsymbol{\Sigma}}_z^{(i)} = \text{diag}\left[\alpha\boldsymbol{1}_{[\tau\times 1]}^\top,\ \boldsymbol{1}_{[(\kappa-\tau)\times 1]}^\top\right]$ such that the same objective function value is obtained.

Now consider the general case where $\kappa \geq \text{rank}[\hat{\boldsymbol{W}}] > \tau$. If we review the lower bound described in Section D.5, with this general $\hat{\boldsymbol{W}}$ replacing $\boldsymbol{\Psi}$, it can be shown that $\hat{\boldsymbol{\Sigma}}_z^{(i)}$ will be forced to have additional diagonal elements lowered to α, increasing the achievable objective by at least $-\log\alpha$ per sample. The details are not especially enlightening and we omit them here for brevity. Consequently, at any minimizer we must have $\text{rank}[\hat{\boldsymbol{W}}] = \tau$. ■

Appendix E. Proof of Corollary 4

Proof Under the stated conditions, the partially-affine VAE cost simplifies to the function

$$\begin{aligned}\mathcal{L}(\boldsymbol{W}, \boldsymbol{\Sigma}_x, \boldsymbol{\mu}_z) &= \sum_i \left\{\left(\boldsymbol{x}^{(i)} - \boldsymbol{W}\boldsymbol{\mu}_z^{(i)}\right)^\top \left(\boldsymbol{\Sigma}_x^{(i)}\right)^{-1}\left(\boldsymbol{x}^{(i)} - \boldsymbol{W}\boldsymbol{\mu}_z^{(i)}\right) + \log\left|\boldsymbol{\Sigma}_x^{(i)}\right| + \|\boldsymbol{\mu}_z^{(i)}\|_2^2\right\} \\ &= \sum_i \left\{\left(\boldsymbol{x}^{(i)} - \boldsymbol{W}\beta^{-1}\beta\boldsymbol{\mu}_z^{(i)}\right)^\top \left(\boldsymbol{\Sigma}_x^{(i)}\right)^{-1}\left(\boldsymbol{x}^{(i)} - \boldsymbol{W}\beta^{-1}\beta\boldsymbol{\mu}_z^{(i)}\right)\right. \\ &+ \left.\log\left|\boldsymbol{\Sigma}_x^{(i)}\right| + \beta^2\|\boldsymbol{\mu}_z^{(i)}\|_2^2\right\},\end{aligned} \tag{76}$$

where $\beta > 0$ is an arbitrary scaler, $\boldsymbol{\Sigma}_x^{(i)} \triangleq \boldsymbol{\Sigma}_x\left(\boldsymbol{\mu}_z^{(i)}; \boldsymbol{\theta}\right)$, and $\boldsymbol{\mu}_z^{(i)} \triangleq \boldsymbol{\mu}_z(\boldsymbol{x}^{(i)}; \boldsymbol{\phi})$. Taking the limit as $\beta \to 0^+$, we can minimize (76) while ignoring the $\beta^2\|\boldsymbol{\mu}_z^{(i)}\|_2^2$ regularization factor. Consequently, we can without loss of generality consider minimization of

$$\mathcal{L}(\boldsymbol{W}, \boldsymbol{\Sigma}_x, \boldsymbol{\mu}_z) \equiv \sum_i \left\{\left(\boldsymbol{x}^{(i)} - \boldsymbol{W}\boldsymbol{\mu}_z^{(i)}\right)^\top \left(\boldsymbol{\Sigma}_x^{(i)}\right)^{-1}\left(\boldsymbol{x}^{(i)} - \boldsymbol{W}\boldsymbol{\mu}_z^{(i)}\right) + \log\left|\boldsymbol{\Sigma}_x^{(i)}\right|\right\}, \tag{77}$$

ignoring any explicit reparameterization by β for convenience. If we optimize over $\boldsymbol{\Sigma}_x^{(i)}$ in the feasible region $\bar{\mathcal{S}}_\alpha^d$ and plug in the resulting value, then (77) reduces to the new cost

$$\mathcal{L}(\boldsymbol{W}, \boldsymbol{\mu}_z) \equiv \sum_{i,j} \log \xi_\alpha\left(\left[x_j^{(i)} - \boldsymbol{w}_{j\cdot}\boldsymbol{\mu}_z^{(i)}\right]^2\right), \tag{78}$$

an immaterial constant notwithstanding. Given that $\lim_{t\to 0}\frac{1}{t}\left(|x|^t - 1\right) = \log|x|$, and $\lim_{t\to 0}\sum_j |x_j|^p = \|\boldsymbol{x}\|_0$, then up to an irrelevant scaling factor and additive constant, the stated result follows. ■

Appendix F. Proof of Theorem 5

Proof Based on the stated conditions, the VAE objective simplifies to

$$\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}) = \sum_i \left\{\mathbb{E}_{q_{\boldsymbol{\phi}}(z|\boldsymbol{x}^{(i)})}\left[\frac{1}{\lambda_x}\left\|\boldsymbol{x}^{(i)} - \boldsymbol{\mu}_x(z; \boldsymbol{\theta})\right\|^2\right] + d\log\lambda_x + \lambda_z - \log\lambda_z + \left(\boldsymbol{a}^\top\boldsymbol{x}^{(i)}\right)^2\right\}. \tag{79}$$

Now choose some $\hat{\boldsymbol{a}}$ such that $\hat{\mu}_z^{(i)} = \hat{\boldsymbol{a}}^\top \boldsymbol{x}^{(i)}$ has a unique value for every sample $\boldsymbol{x}^{(i)}$ (here we assume that each sample is unique, although this assumption can be relaxed). We then define the function $h : \mathbb{R} \to \{1, \ldots, n\}$ as

$$h(z) \triangleq \arg \min_{i \in \{1,\ldots,n\}} \|z - \mu_z^{(i)}\|_2. \tag{80}$$

and the piecewise linear decoder mean function

$$\boldsymbol{\mu}_x(z; \boldsymbol{\theta}) = \boldsymbol{x}^{(h(z))}. \tag{81}$$

Given these definitions, (79) becomes

$$\begin{aligned}\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}) &= \sum_i \left\{ \mathbb{E}_{q_{\boldsymbol{\phi}}(z|\boldsymbol{x}^{(i)})} \left[\tfrac{1}{\lambda_x} \left\| \boldsymbol{x}^{(i)} - \boldsymbol{x}^{(h(z))} \right\|^2 \right] + d \log \lambda_x + \lambda_z - \log \lambda_z + \left(\hat{\mu}_z^{(i)} \right)^2 \right\} \\ &= \sum_i \left\{ \mathbb{E}_{p(\epsilon)} \left[\tfrac{1}{\lambda_x} \left\| \boldsymbol{x}^{(i)} - \boldsymbol{x}^{(h[\hat{\mu}_z^{(i)} + \sqrt{\lambda_z}\epsilon])} \right\|^2 \right] + d \log \lambda_x + \lambda_z - \log \lambda_z + \left(\hat{\mu}_z^{(i)} \right)^2 \right\}. \end{aligned} \tag{82}$$

Now define the set

$$\mathcal{S}^{(i)} \triangleq \left\{ \epsilon : h\left(\hat{\mu}_z^{(i)} + \sqrt{\lambda_z}\epsilon \right) = i \right\}, \tag{83}$$

which represents the set of ϵ that quantize to the correct index. We then have

$$\begin{aligned} &\mathbb{E}_{p(\epsilon)} \left[\tfrac{1}{\lambda_x} \left\| \boldsymbol{x}^{(i)} - \boldsymbol{x}^{(h[\hat{\mu}_z^{(i)} + \sqrt{\lambda_z}\epsilon])} \right\|^2 \right] \\ &= \int_{\epsilon \in \mathcal{S}^{(i)}} \left[\tfrac{1}{\lambda_x} \left\| \boldsymbol{x}^{(i)} - \boldsymbol{x}^{(h[\hat{\mu}_z^{(i)} + \sqrt{\lambda_z}\epsilon])} \right\|^2 \right] p(\epsilon) d\epsilon + \int_{\epsilon \notin \mathcal{S}^{(i)}} \left[\tfrac{1}{\lambda_x} \left\| \boldsymbol{x}^{(i)} - \boldsymbol{x}^{(h[\hat{\mu}_z^{(i)} + \sqrt{\lambda_z}\epsilon])} \right\|^2 \right] p(\epsilon) d\epsilon \\ &= \int_{\epsilon \notin \mathcal{S}^{(i)}} \left[\tfrac{1}{\lambda_x} \left\| \boldsymbol{x}^{(i)} - \boldsymbol{x}^{(h[\hat{\mu}_z^{(i)} + \sqrt{\lambda_z}\epsilon])} \right\|^2 \right] p(\epsilon) d\epsilon \\ &\leq \int_{\epsilon \notin \mathcal{S}^{(i)}} \tfrac{\eta}{\lambda_x} p(\epsilon) d\epsilon \\ &= \tfrac{\eta}{\lambda_x} P\left(\epsilon \notin \mathcal{S}^{(i)} \right), \end{aligned} \tag{84}$$

where

$$\eta \triangleq \max_{i,j \in \{1,\ldots,n\}, i \neq j} \|\boldsymbol{x}^{(i)} - \boldsymbol{x}^{(j)}\|_2^2, \tag{85}$$

the maximal possible quantization error. Now we also define

$$\rho \triangleq \max_{i,j \in \{1,\ldots,n\}, i \neq j} \frac{1}{2} \|\hat{\mu}_z^{(i)} - \hat{\mu}_z^{(j)}\|_2^2, \tag{86}$$

which is half the minimum distance between any two $\hat{\mu}_z^{(i)}$ and $\hat{\mu}_z^{(j)}$, with $i \neq j$. Then

$$\begin{aligned} P\left(\epsilon \notin \mathcal{S}^{(i)} \right) &\leq P\left(\sqrt{\lambda_z}\epsilon > \rho \right) \\ &\leq \tfrac{\lambda_z}{\rho^2} \end{aligned} \tag{87}$$

by Chebyshev's inequality as was used in proving Theorem 3. This implies that (82) can be bounded via

$$\begin{aligned} \mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}) &\leq \sum_i \left\{ \tfrac{\eta}{\lambda_x} P\left(\epsilon \notin \mathcal{S}^{(i)} \right) + d \log \lambda_x + \lambda_z - \log \lambda_z + \left(\hat{\mu}_z^{(i)} \right)^2 \right\} \\ &= \sum_i \left\{ \tfrac{\eta}{\rho^2} + (d-1) \log \alpha + \alpha + \left(\hat{\mu}_z^{(i)} \right)^2 \right\} \end{aligned} \tag{88}$$

assuming we are at the trial solution $\hat{\lambda}_x = \hat{\lambda}_z = \alpha$. As we allow $\alpha \to 0$, this expression is unbounded from below, and as an upper bound on the VAE objective, the theorem follows. Incidentally, it should also be possible to prove that for α sufficiently small, no other solution can do appreciably better in terms of the dominate $(d-1)\log\alpha$ factor, but we will reserve this for future work. ■

Abstract

We introduce an agglomerative hierarchical clustering (AHC) framework which is generic, efficient and effective. Our approach embeds a sub-family of Lance-Williams (LW) clusterings and relies on inner-products instead of squared Euclidean distances. We carry out a constrained bottom-up merging procedure on a sparsified normalized inner-product matrix. Our method is named SNK-AHC for Sparsified Normalized Kernel matrix based AHC. SNK-AHC is more scalable than the classic dissimilarity matrix based AHC. It can also produce better results when clusters have arbitrary shapes. Artificial and real-world benchmarks are used to exemplify these points. From a theoretical standpoint, SNK-AHC provides another interpretation of the classic techniques which relies on the concept of weighted penalized similarities. The differences between group average, Mcquitty, centroid, median and Ward, can be explained by their distinct averaging strategies for aggregating clusters inter-similarities and intra-similarities. Other features of SNK-AHC are examined. We provide sufficient conditions in order to have monotonic dendrograms, we elaborate a stored data matrix approach for centroid and median, we underline the diagonal translation invariance property of group average, Mcquitty and Ward and we show to what extent SNK-AHC can determine the number of clusters.

Keywords: Agglomerative hierarchical clustering, Lance-Williams formula, Kernel methods, Scalability, Manifold learning.

1. Introduction

Clustering is the process of discovering homogeneous groups among a set of objects. There are many clustering methods and one way to differentiate one approach from another one is by the classification scheme they are based upon. On the one hand, flat clustering provides a partition of the elements. On the other hand, hierarchical clustering outputs a set of nested partitions. The latter classification type is represented by a binary tree named dendrogram.

Hierarchical clustering presents several advantages compared to flat clustering. Firstly, a dendrogram is more informative than a single partition because it provides more insights about the relationships between objects and clusters. Secondly, there is no requirement to set the number of clusters *a priori* unlike most of flat clustering techniques.

In this paper, we focus on hierarchical clustering methods. There are two kinds of procedures: agglomerative and divisive. The former type builds the dendrogram in a bottom-up fashion whereas the latter case uses a top-down approach. We focus on *Agglomerative Hierarchical Clustering (AHC)*. Suppose we are given a pairwise dissimilarity matrix between the elements we want to cluster. The AHC bottom-up procedure initializes a trivial partition composed of singletons then, iteratively merges the two closest clusters until all items are grouped together.

In any AHC method, after each merge, it is required to compute the dissimilarity measure between the newly formed group and other existing clusters. In fact, there are as many AHC methods as dissimilarity measures. Despite the great number of approaches found in the literature, Lance and Williams (1967) proposed a parametric formula (LW formula) that generalizes a lot of them.

The bottom-up strategy described above with the LW formula form the usual stored *Dissimilarities*[1] *based AHC (D-AHC)* framework. Due to its simplicity and flexibility, it has been studied in many research works, implemented in many programming languages and successfully applied in many domains.

However, D-AHC suffers from important scalability issues since, with respect to the number of objects, it has a quadratic memory complexity and a cubic time complexity. These drawbacks severely limit the application of D-AHC to very large data sets.

In this context, our work aims at designing an AHC approach that is equivalent to D-AHC but which can be extended in order to reduce the computational costs. Furthermore, the approach we define is able to take into account the natural geometry of the data. It is thus an unsupervised approach for manifold learning as well.

In a nutshell, the contributions of the paper are the following ones:

- We focus on a sub-part of the LW formula and we establish a more general model which relies on inner-products instead of squared Euclidean distances. In this case, we need two parametric recurrence equations instead of one. Since our model relies on inner-products, it encompasses Reproducing Kernel Hilbert Spaces (RKHS) through the use of kernel functions. This first model called *Kernel matrix based Agglomerative Hierarchical Clustering (K-AHC)* can be viewed as a kind of "dual" of D-AHC when squared Euclidean distances are used as dissimilarities.

- In the usual D-AHC framework, the geometric techniques centroid, median and Ward can be carried out by using data matrices instead of distance matrices. On the contrary, the graph methods group average and Mcquitty do not enjoy such a property. We show that K-AHC enables a stored data[2] matrix approach for the two latter schemes.

- The median and centroid schemes can suffer from pathological behaviors because they can produce reversals in the dendrogram. This phenomenon appears when at an iteration, the dissimilarity value between two clusters becomes lower than the dissimilarity values observed at previous iterations. Median and centroid are said to provide non-monotonic dendrograms. In fact, Ward can be seen as a modification of

1. The terms "stored dissimilarities/similarities" and "stored data" approaches were coined by Anderberg (1973). The former one means that the input is the pairwise proximity matrix whereas the latter one indicates that the input is the data matrix where objects are described by a set of attributes.
2. Defined in the previous footnote.

centroid which enables solving the non-monotonicity issue of the latter scheme. In the same spirit, we introduce a new scheme called w-median which solves the non-monotonicity problem of the median technique.

- We propose to project the data points on an hypersphere and to shift them in order to obtain non-negative inner-products values. As a result, we obtain a *Normalized Kernel (NK) matrix* which can also be interpreted as a similarity matrix satisfying several conditions such as maximal self-similarity. In this case, we can interpret our model in terms of *weighted penalized similarities* and we show that the main differences between classic techniques rely on distinct averaging operations of inter-similarities and of intra-similarities as well.

- Given a NK matrix, we can apply sparsification procedures in order to remove non-relevant similarity relationships between objects. The resulting output is called *Sparsified Normalized Kernel (SNK) matrix* and it can be viewed as the weighted adjacency matrix of a sparse similarity graph. Then, we apply K-AHC on a SNK matrix but with the *constraint* that two clusters can be merged together providing that they have a non-null inter-similarity value. Our approach is called *Sparsified Normalized Kernel matrix based AHC (SNK-AHC)*. SNK-AHC has much lower computational costs compared to K-AHC and D-AHC, both in terms of memory and running time. Moreover, the sparsification enables capturing the intrinsic geometry of the data.

- Unlike a NK matrix, a SNK matrix is not positive semi-definite. Therefore, from a general perspective, SNK-AHC can not be interpreted from a geometrical point of view unlike K-AHC. Nevertheless, we show that in the particular cases of group average, Mcquitty and Ward, SNK-AHC still implicitly acts in an Hilbert space. This is due to the fact that these schemes are invariant with respect to any translation of the diagonal of the SNK matrix.

- By interpreting SNK-AHC in the framework of graph theory, we demonstrate that the bottom-up procedure emulates the same kinds of operations employed in order to determine the connected components of an undirected graph. As a result, we show that SNK-AHC can automatically determine the number of clusters when the latter ones are seen as connected components of a similarity graph.

- We illustrate the aforementioned properties of K-AHC and SNK-AHC on two artificial data sets. In addition, we show the superiority of SNK-AHC over D-AHC on two real-world benchmarks. Our experimental results confirm that SNK-AHC is much more scalable than the classic D-AHC. Last but not least, SNK-AHC can also outperform D-AHC in terms of clustering quality. In fact, in many cases, our approach is both more efficient and more effective than D-AHC.

The remainder of the paper is organized as follows. In section 2, we introduce the notations and some useful definitions. In section 3, we review the basics of D-AHC and of the LW formula. Then, in section 4, we introduce our K-AHC model by establishing an inner-product based expression that embeds the LW sub-equation we are interested in. Several features of K-AHC are examined as well. Afterward, we present SNK-AHC and

study its properties in section 5. Section 6 is dedicated to the experiments which are carried out on both artificial and real-world data sets. After having introduced our approach and exhibited its properties, we present and discuss in section 7 related research works. Finally, in section 8, we conclude the paper and we sketch future work as well.

2. Notations and Definitions

The set of objects (or elements or items or points) to cluster is denoted by $\mathbb{O}$ and $|\mathbb{O}|$ represents its cardinal. We suppose throughout the paper that $|\mathbb{O}|= n$. The usual AHC algorithm takes as input a pairwise dissimilarity matrix.

Definition 1 (Dissimilarity matrix) *A pairwise dissimilarity matrix of elements in $\mathbb{O}$ is denoted $\mathbf{D}$. Given $|\mathbb{O}|= n$, $\mathbf{D}$ is a square matrix of order n satisfying the following conditions:*

$$\begin{cases} \mathbf{D}_{ab} \geq 0, \quad \forall a, b \in \mathbb{O} & \textit{(non-negativity)} \\ \mathbf{D}_{ab} = \mathbf{D}_{ba}, \quad \forall a, b \in \mathbb{O} & \textit{(symmetry)} \end{cases}, \quad \forall a, b \in \mathbb{O}$$

Let $2^{\mathbb{O}}$ denote the set of subsets of $\mathbb{O}$. The AHC procedure builds a set of nested partitions of $\mathbb{O}$. We denote by the letters a, b, c, d, e, f any singletons (or objects) of $\mathbb{O}$, whereas i, j, k, l, m correspond to any item (or clusters) in $2^{\mathbb{O}}$. The cardinal of k is denoted $|k|$. Given k and l, their fusion (or merge or union) is denoted by (kl).

The AHC algorithm is an iterative procedure with $n - 1$ steps. We denote by $\mathbb{T} = \{1, 2, \ldots, n-1\}$ the set of iterations and use t to designate any of its elements.

Let $\mathbb{C}^t$ denote the set of existing clusters at iteration t. It is a partition of $\mathbb{O}$ with $n-t+1$ subsets. We denote by $\mathbf{D}^t$, the dissimilarity matrix of clusters in $\mathbb{C}^t$. It is thus a symmetric square matrix of order $n - t + 1$ satisfying the conditions given in Definition 1.

The AHC bottom-up algorithm produces a set of nested partitions represented by a tree-diagram called dendrogram.

Definition 2 (Dendrogram) *A dendrogram representing a hierarchical clustering of $\mathbb{O}$ is denoted D. Given $|\mathbb{O}|= n$, D is a rooted binary tree with n leaves and $2n-1$ nodes in total. Each node i corresponds to a subset of objects. Any two distinct nodes i and j of D are such that $i \subset j$ or $j \subset i$ or $i \cap j = \emptyset$. Besides, each node i is assigned a non-negative value called the height denoted by $H(i)$.*

Since any node in a dendrogram represents a cluster, we adopt the same notations as precised above: a, b, c, d, e, f are nodes that designate singletons only, while i, j, k, l, m correspond to subsets of $\mathbb{O}$.

As an illustration, we give in Figure 1 an example of a dendrogram of the set $\mathbb{O} = \{a, b, c, d, e, f\}$.

Definition 3 (Monotonic dendrogram) *A dendrogram D is monotonic if and only if $i \subset j \Leftrightarrow H(i) \leq H(j)$, for any two distinct nodes i and j.*

The dendrogram represented in Figure 1 is monotonic. Indeed, the height of larger nodes are higher than smaller ones and any path from a leaf to the root has no reversal.

The following definition is used to compare dendrograms.

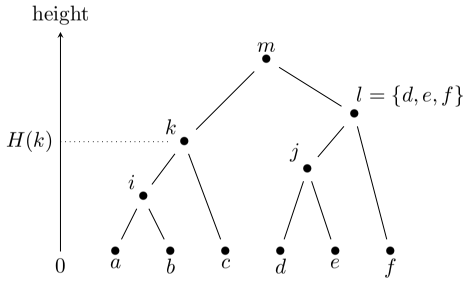

Figure 1: Illustration of a dendrogram.

Definition 4 (Sequence of merges) *A sequence of merges representing a hierarchical clustering of $\mathbb{O}$ is denoted M. Given $|\mathbb{O}|= n$, $M = (m_1, \ldots, m_{n-1})$ is a sequence of $n-1$ couples of disjoint subsets of elements of $\mathbb{O}$. For all $t \in \mathbb{T}$, $m_t = (m_t^1, m_t^2) \in \{(i,j) \in 2^{\mathbb{O}} \times 2^{\mathbb{O}}, i \cap j = \emptyset\}$. Any two elements m_s and m_t of M satisfy the following condition: if $s < t$ then $(m_s^1 \cup m_s^2) \subset (m_t^1 \cup m_t^2)$ or $(m_s^1 \cup m_s^2) \cap (m_t^1 \cup m_t^2) = \emptyset$.*

Whether an AHC technique produces a monotonic dendrogram or not, it always groups two clusters into a larger one at each iteration. If we consider the pairs of clusters that are fused at each step of the AHC bottom-up procedure (regardless the height values) then, it is clear that there is a one-to-one correspondence between dendrograms and sequences of merges.

For example, the sequence of merges in correspondence with the dendrogram provided in Figure 1 is $M = \{(\{a\},\{b\}),(\{d\},\{e\}),(\{a,b\},\{c\}),(\{d,e\},\{f\}),(\{a,b,c\},\{d,e,f\})\}$.

The following definition is used to establish the equivalence between two different AHC algorithms.

Definition 5 (Equivalent dendrograms) *Two dendrograms D and D' of a set of objects $\mathbb{O}$ are equivalent if their respective sequence of merges M and M' are identical.*

Eventually, we introduce the definition of a similarity matrix.

Definition 6 (Similarity matrix) *A pairwise similarity matrix of elements in $\mathbb{O}$ is denoted $\mathbf{S}$. Given $|\mathbb{O}|= n$, $\mathbf{S}$ is a square matrix of order n satisfying the following conditions:*

$$\begin{cases} \mathbf{S}_{ab} \geq 0 \ \textit{(non-negativity)} \\ \mathbf{S}_{ab} = \mathbf{S}_{ba} \ \textit{(symmetry)} \\ \mathbf{S}_{aa} \geq \mathbf{S}_{ab} \ \textit{(maximal self-similarity)} \end{cases}, \quad \forall a, b \in \mathbb{O}$$

The maximal self-similarity condition states that an object a can not be more similar to any other object b but to itself (except if $a = b$).

3. D-AHC : Dissimilarity based AHC

In this section, we review the basic concepts of AHC. Firstly, we introduce the usual LW formula based on dissimilarities. We also provide more detailed explanations about the bottom-up fusion mechanism that builds the dendrogram. Secondly, we review another equivalent way to express the LW formula. This formulation relies on a weighted version of the dissimilarities. In fact, the framework we introduce thereafter, is inspired from this latter expression.

3.1 The LW Formula and the Bottom-up Procedure

For $t = 1$, we initialize $\mathbb{C}^1$ to the set of n singletons with null height values and we set $\mathbf{D}^1 = \mathbf{D}$, the given dissimilarity matrix. Then, at each iteration $t \in \mathbb{T}$, D-AHC merges the[3] couple of clusters (k,l) that satisfies:

$$(k,l) = \underset{(i,j) \in \mathbb{C}^t \times \mathbb{C}^t, i \neq j}{\arg\min} \mathbf{D}_{ij}^t \tag{1}$$

Clusters k and l are fused into (kl) and the dendrogram D is amended with a new node whose height value $H((kl))$ is set to $\mathbf{D}_{kl}^t$. The new partition $\mathbb{C}^{t+1}$ is updated as follows:

$$\mathbb{C}^{t+1} = \mathbb{C}^t \setminus \{k,l\} \cup \{(kl)\} \tag{2}$$

Next, the dissimilarity values between the new cluster (kl) and the other clusters $m \in \mathbb{C}^{t+1}$ have to be computed in order to determine $\mathbf{D}^{t+1}$.

Several schemes were proposed and among the most famous ones we can cite: single linkage, complete linkage, group average (also named UPGMA[4]), Mcquitty (also named WPGMA[5]), centroid (also named UPGMC[6]), median (also named WPGMC[7]) and Ward. The first four techniques are known as graph methods whereas the three latter ones are named geometric methods.

Despite these numerous dissimilarity measures, the LW equation introduced in (Lance and Williams, 1967), is a parametric updating formula that generalizes all aforementioned cases. It is defined as follows:

$$\begin{aligned} \mathbf{D}_{(kl)m}^{t+1} = \alpha'(k,l,m)\mathbf{D}_{km}^t + \alpha'(l,k,m)\mathbf{D}_{lm}^t + \beta'(k,l,m)\mathbf{D}_{kl}^t + \gamma'|\mathbf{D}_{km}^t - \mathbf{D}_{lm}^t|, \\ \forall t \in \mathbb{T}, \forall m \in \mathbb{C}^{t+1}, m \neq (kl) \end{aligned} \tag{3}$$

where γ' is a scalar and α', β' are functions from the set of triples of disjoint subsets of $\mathbb{O}$ to $\mathbb{R}$.

In Table 1, we review the particular definitions of α', β' and γ' for the methods cited above. In this table, observe that:

- For all schemes, β' is symmetric in its two first arguments unlike α'.

3. Note that there might be several couples of clusters as solutions to (1) which could result in different dendrograms.
4. Unweighted Pair Group Method with Arithmetic mean
5. Weighted Pair Group Method with Arithmetic mean
6. Unweighted Pair Group Method Centroid
7. Weighted Pair Group Method Centroid

Method	$\alpha'(k,l,m)$	$\beta'(k,l,m)$	γ'
Single link.	$1/2$	0	$-1/2$
Complete link.	$1/2$	0	$1/2$
Group aver.	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}$	0	0
Mcquitty	$1/2$	0	0
Centroid	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}$	$-\frac{\lvert k\rvert\lvert l\rvert}{(\lvert k\rvert+\lvert l\rvert)^2}$	0
Median	$1/2$	$-1/4$	0
Ward	$\frac{\lvert k\rvert+\lvert m\rvert}{\lvert k\rvert+\lvert l\rvert+\lvert m\rvert}$	$-\frac{\lvert m\rvert}{\lvert k\rvert+\lvert l\rvert+\lvert m\rvert}$	0

Table 1: Particular settings of the LW formula (4).

- Except the Ward method, α' and β' do not depend on a third argument.
- Whatever the triple (k,l,m), α' is constant for single linkage, complete linkage, Mcquitty and median.
- Likewise, β' is constant for single linkage, complete linkage, group average, Mcquitty and median.
- Concerning γ', it is non-null only for single linkage and complete linkage.

In the rest of the paper, we only consider the sub-family of LW clusterings that satisfies $\gamma = 0$. This rules out the single and complete linkage techniques. In fact, these two latter schemes are peculiar since they reduce to the min and max operators respectively. Due to their specific features, single and complete linkages can be addressed using special algorithms (Gower and Ross, 1969; Sibson, 1973; Defays, 1977).

Consequently, we are interested in the following LW sub-formula in what follows:

$$\mathbf{D}^{t+1}_{(kl)m} = \alpha'(k,l,m)\mathbf{D}^t_{km} + \alpha'(l,k,m)\mathbf{D}^t_{lm} + \beta'(k,l,m)\mathbf{D}^t_{kl}, \quad \forall t \in \mathbb{T}, \forall m \in \mathbb{C}^{t+1}, m \neq (kl) \tag{4}$$

To wrap up this sub-section, we provide in Algorithm 1 the pseudo-code of D-AHC using the previous LW sub-formula.

3.2 An Equivalent Dissimilarity Based LW Sub-formula

Henceforth, we suppose that any object $a \in \mathbb{O}$ can be represented as a vector $\mathbf{x}^a$ in an Hilbert space $\mathcal{H}$. Moreover, we assume that dissimilarities are given by squared Euclidean distances. Thus, the general term of $\mathbf{D}$ is:

$$\mathbf{D}_{ab} = \|\mathbf{x}^a - \mathbf{x}^b\|^2, \quad \forall a, b \in \mathbb{O} \tag{5}$$

In this context, we review another dissimilarity based LW sub-formula which is equivalent to (4) and Table 1. Indeed, if objects are vectors in an Hilbert space then, the centroid

Algorithm 1: General procedure of D-AHC.

Input: $\mathbf{D}$ a dissimilarity matrix, an AHC method
Output: D a dendrogram
Initialize D with n leaves;
Set $\mathbf{D}^1 = \mathbf{D}$;
for $t = 1, \ldots, n-1$ **do**
  Find the pair of clusters (k,l) according to (1);
  Merge (k,l) into (kl) and update D;
  Compute $\mathbf{D}^{t+1}$ by applying (4) with the corresponding AHC method parameters values given in Table 1.
end

and Ward update equations can be expressed in terms of cluster representatives (see for e.g. (Murtagh and Contreras, 2012; Müllner, 2011)). Let $\mathbf{g}^i$ be the mean vector of cluster i:

$$\mathbf{g}^i = \frac{1}{|i|}\sum_{a \in i} \mathbf{x}^a, \quad i \in 2^{\mathbb{O}} \tag{6}$$

Then, for two clusters $i, j \in \mathbb{C}^t$, the dissimilarity used by the centroid scheme is:

$$\mathbf{D}^t_{ij} = \|\mathbf{g}^i - \mathbf{g}^j\|^2, \quad \forall t \in \mathbb{T} \tag{7}$$

Regarding the Ward approach, it is in fact, a weighted version of centroid since we have for the former scheme:

$$\mathbf{D}^t_{ij} = \frac{|i||j|}{|i|+|j|}\|\mathbf{g}^i - \mathbf{g}^j\|^2, \quad \forall t \in \mathbb{T}, \forall i, j \in \mathbb{C}^t \tag{8}$$

The following D-AHC iterative procedure is equivalent to Algorithm 1 (see for e.g. (Murtagh and Contreras, 2012)). For $t = 1$, let $\mathbf{D}^1$ be the input dissimilarity matrix $\mathbf{D}$ of squared Euclidean distances between data points. At each iteration, the pair (k,l) which gives the minimum *weighted dissimilarity* is merged:

$$(k,l) = \underset{(i,j) \in \mathbb{C}^t \times \mathbb{C}^t, i \neq j}{\arg\min} p(i,j)\mathbf{D}^t_{ij} \tag{9}$$

where p is a function from $\{(i,j) \in 2^{\mathbb{O}} \times 2^{\mathbb{O}}, i \cap j = \emptyset\}$, the set of pairs of disjoint subsets of $\mathbb{O}$, to $\mathbb{R}$. The definition of p for each dissimilarity scheme is provided in Table 2.

After each merge the dissimilarity matrix is updated as follows:

$$\mathbf{D}^{t+1}_{(kl)m} = \alpha(k,l)\mathbf{D}^t_{km} + \alpha(l,k)\mathbf{D}^t_{lm} + \beta(k,l)\mathbf{D}^t_{kl}, \quad \forall t \in \mathbb{T}, \forall m \in \mathbb{C}^{t+1}, m \neq (kl) \tag{10}$$

where, in this modeling, α and β are set functions whose definitions are also given in Table 2.

It is important to mention that, in the case of Ward, the set functions α and β do not depend on the third argument unlike α' and β'. Consequently, we can globally consider α and β as two-place set functions which only depend on the two clusters being fused at each iteration. More formally, α and β are functions from $\{(i,j) \in 2^{\mathbb{O}} \times 2^{\mathbb{O}}, i \cap j = \emptyset\}$ to $\mathbb{R}$

Method	$\alpha(k,l)$	$\beta(k,l)$	$p(i,j)$
Group aver.	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}$	0	1
Mcquitty	1/2	0	1
Centroid	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}$	$-\frac{\lvert k\rvert\lvert l\rvert}{(\lvert k\rvert+\lvert l\rvert)^2}$	1
Median	1/2	−1/4	1
Ward	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}$	$-\frac{\lvert k\rvert\lvert l\rvert}{(\lvert k\rvert+\lvert l\rvert)^2}$	$\frac{\lvert i\rvert\lvert j\rvert}{\lvert i\rvert+\lvert j\rvert}$
W-Median	1/2	−1/4	$\frac{\lvert i\rvert\lvert j\rvert}{\lvert i\rvert+\lvert j\rvert}$

Table 2: Particular settings of the LW sub-formula (10) in the model defined by (9).

As mentioned previously and by observing (7) and (8), Ward can be interpreted as a weighted version of centroid. Similarly, we introduce a *weighted version of median (w-median)*. The parameters of this new method are defined in the last row of Table 2. W-median set functions α and β are the same as median. It is the set function p which is different: instead of a uniform weight, w-median uses the same weight function as Ward. As we shall demonstrate later on, the w-median method provides monotonic dendrograms unlike the median technique.

4. K-AHC: Kernel Matrix based AHC

We have supposed that the items are represented in an Hilbert space $\mathcal{H}$ and so far, squared Euclidean distances have been used to represent the proximity relationships between points. Henceforth, we also use the underlying inner-product of $\mathcal{H}$.

In this section, we start by introducing a model that generalizes the LW sub-equation (10). Our framework relies on inner-products and it amounts to a *Kernel matrix based AHC (K-AHC)*. Thereafter, we introduce several properties of our model. We provide sufficient conditions for a technique expressed in our modeling to provide monotonic dendrograms. Furthermore, we design a stored data matrix approach that generalizes to group average and Mcquitty schemes.

4.1 Inner-product Based LW Sub-formula

Let $\langle .,. \rangle$ denotes the inner-product of $\mathcal{H}$. The geometrical data representation we assume in this work is formally stated as follows:

$$\left\{ \begin{array}{l} \mathbf{S}_{ab} = \langle \mathbf{x}^a, \mathbf{x}^b \rangle \\ \mathbf{D}_{ab} = \mathbf{S}_{aa} + \mathbf{S}_{bb} - 2\mathbf{S}_{ab} \end{array} \right. , \quad \forall a,b \in \mathbb{O} \tag{C1}$$

This implies that the matrix $\mathbf{S}$ is a *kernel (or Gram) matrix* and satisfies:

$$\left\{ \begin{array}{ll} \mathbf{S}_{ab} = \mathbf{S}_{ba}, \quad \forall a,b \in \mathbb{O} & \text{(symmetry)} \\ \mathbf{S} \succeq 0 & \text{(positive semi-definite)} \end{array} \right. \tag{11}$$

This data representation encompasses Reproducing Kernel Hilbert Spaces (RKHS). Accordingly, our approach is a kernel method (see for e.g. (Scholkopf and Smola, 2001)) which

can benefit from a large spectrum of kernel functions in order to address diverse manifold learning problems, that is K-AHC is able to detect groups of items with arbitrary shapes.

In contrast to the LW sub-formula, our model requires two equations to update the $\mathbf{S}$ matrix: one for the *off-diagonal* elements and one for the *on-diagonal* entries.

Suppose that, for $t=1$, $\mathbf{S}$ is the input matrix of our procedure: $\mathbf{S}^1 = \mathbf{S}$. Assume that, at iteration $t \in \mathbb{T}$, clusters k and l are merged together. In our model, $\mathbf{S}^{t+1}$ is updated according to the two following recurrence equations:

$$\mathbf{S}^{t+1}_{(kl)m} = \mathfrak{a}(k,l)\mathbf{S}^t_{km} + \mathfrak{a}(l,k)\mathbf{S}^t_{lm}, \quad \forall t \in \mathbb{T}, \forall m \in \mathbb{C}^{t+1}, m \neq (kl) \tag{12a}$$

$$\mathbf{S}^{t+1}_{(kl)(kl)} = \mathfrak{b}(k,l)\mathbf{S}^t_{kl} + \mathfrak{c}(k,l)\mathbf{S}^t_{kk} + \mathfrak{c}(l,k)\mathbf{S}^t_{ll}, \quad \forall t \in \mathbb{T} \tag{12b}$$

where $\mathfrak{a}$, $\mathfrak{b}$ and $\mathfrak{c}$ are functions from $\{(i,j) \in 2^{\mathbb{O}} \times 2^{\mathbb{O}}, i \cap j = \emptyset\}$ to $\mathbb{R}$.

Similarly to D-AHC, we assume that the updated matrix is symmetric all along the procedure and thus, $\mathbf{S}^t_{m(kl)} = \mathbf{S}^t_{(kl)m}, \forall t \in \mathbb{T}, \forall m \in \mathbb{C}^{t+1}$.

For all $t \in \mathbb{T}$, let $\mathbf{\Lambda}^t$ be the square matrix of order $n-1+t$ with general term:

$$\mathbf{\Lambda}^t_{ij} = \mathbf{S}^t_{ij} - \frac{1}{2}(\mathbf{S}^t_{ii} + \mathbf{S}^t_{jj}), \quad \forall t \in \mathbb{T}, \forall i,j \in \mathbb{C}^t \tag{13}$$

$\mathbf{\Lambda}^t$ compares each couple of clusters in $\mathbb{C}^t$ and plays a core role in our approach. The following result establishes the connection between the LW sub-equation (10) on the one hand, and our approach (13), (12a), (12b) on the other hand.

Lemma 7 *Let $\{\mathbf{D}^t\}_{t\in\mathbb{T}}$ and $\{\mathbf{\Lambda}^t\}_{t\in\mathbb{T}}$ be the sequences of square matrices with input elements $\mathbf{D}$ and $\mathbf{S}$ and subsequent elements defined by* (10) *and* (13), (12a),(12b), *respectively. Suppose that the related set functions α, β on the one hand and $\mathfrak{a}$, $\mathfrak{b}$, $\mathfrak{c}$ on the other hand, are such that:*

$$\begin{array}{l} \mathfrak{a} = \alpha \\ \mathfrak{b} = -2\beta \\ \mathfrak{c} = \alpha + \beta \end{array}$$

Then, under (C1) *and if $\mathfrak{a}(k,l) + \mathfrak{a}(l,k) = 1, \forall k,l \in 2^{\mathbb{O}}$, it holds:*

$$\mathbf{\Lambda}^t_{ij} = -\frac{1}{2}\mathbf{D}^t_{ij}, \quad \forall t \in \mathbb{T}, \forall i,j \in \mathbb{C}^t, i \neq j$$

Proof Under (C1), it is clear that for $t=1$:

$$\mathbf{\Lambda}^1_{ab} = \mathbf{S}^1_{ab} - \frac{1}{2}(\mathbf{S}^1_{aa} + \mathbf{S}^1_{bb}) = -\frac{1}{2}\mathbf{D}^1_{ab}, \quad \forall a,b \in \mathbb{O}$$

We assume that the property is true for t: $\mathbf{\Lambda}^t_{ij} = \mathbf{S}^t_{ij} - \frac{1}{2}(\mathbf{S}^t_{ii} + \mathbf{S}^t_{jj}) = -\frac{1}{2}\mathbf{D}^t_{ij}, \forall i,j \in \mathbb{C}^t, i \neq j$. Then, let us prove that it is true for $t+1$ as well. Let k and l be the two clusters that are fused at iteration t. We replace in (12a) and (12b) the set functions $\mathfrak{a}$, $\mathfrak{b}$ and $\mathfrak{c}$ with α, -2β and $\alpha+\beta$ respectively. It comes:

$$\mathbf{S}^t_{(kl)m} = \alpha(k,l)\mathbf{S}^t_{km} + \alpha(l,k)\mathbf{S}^t_{lm}$$

$$\mathbf{S}^t_{(kl)(kl)} = -2\beta(k,l)\mathbf{S}^t_{kl} + (\alpha(k,l) + \beta(k,l))\mathbf{S}^t_{kk} + (\alpha(l,k) + \beta(l,k))\mathbf{S}^t_{ll}$$

Method	$\mathfrak{a}(k,l)$	$\mathfrak{b}(k,l)$	$\mathfrak{c}(k,l)$	$\mathfrak{p}(i,j)$
Group average	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}$	0	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}$	1
Mcquitty	1/2	0	1/2	1
Centroid	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}$	$\frac{2\lvert k\rvert\lvert l\rvert}{(\lvert k\rvert+\lvert l\rvert)^2}$	$\frac{\lvert k\rvert^2}{(\lvert k\rvert+\lvert l\rvert)^2}$	1
Median	1/2	1/2	1/4	1
Ward	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}$	$\frac{2\lvert k\rvert\lvert l\rvert}{(\lvert k\rvert+\lvert l\rvert)^2}$	$\frac{\lvert k\rvert^2}{(\lvert k\rvert+\lvert l\rvert)^2}$	$\frac{\lvert i\rvert\lvert j\rvert}{\lvert i\rvert+\lvert j\rvert}$
W-Median	1/2	1/2	1/4	$\frac{\lvert i\rvert\lvert j\rvert}{\lvert i\rvert+\lvert j\rvert}$

Table 3: Particular settings in our model defined by (12a), (12b) and (14).

Next, assuming $\alpha(k,l)+\alpha(l,k)=1$, $\forall k,l\in\mathbb{C}^t$, we have:

$$\mathbf{S}^t_{mm}=(\alpha(k,l)+\alpha(l,k))\mathbf{S}^t_{mm}$$

If we put all these ingredients into (13) for $t+1$, $i=(kl)$ and $j=m$; regroup terms with respect to α and β; replace $\mathbf{S}^t_{ii}+\mathbf{S}^t_{jj}-2\mathbf{S}^t_{ij}$ with $\mathbf{D}^t_{ij}$, for all $i,j\in\{k,l,m\}, i\neq j$; then we have, $\forall m\in\mathbb{C}^{t+1}$:

$$\begin{aligned}\mathbf{\Lambda}^{t+1}_{(kl)m}&=-\frac{1}{2}\left(\alpha(k,l)\mathbf{D}^t_{km}+\alpha(l,k)\mathbf{D}^t_{lm}+\beta(k,l)\mathbf{D}^t_{kl}\right)\\&=-\frac{1}{2}\mathbf{D}^{t+1}_{(kl)m}\end{aligned}$$

■

Next, we introduce our approach which also proceeds in a bottom-up manner. However, unlike D-AHC, K-AHC performs a *maximum search* at each iteration. Indeed, after having initialized a dendrogram D with n leaves, for each $t\in\mathbb{T}$, K-AHC fuses the pair of clusters (k,l) that satisfies:

$$(k,l)=\underset{(i,j)\in\mathbb{C}^t\times\mathbb{C}^t,i\neq j}{\arg\max}\ \mathfrak{p}(i,j)\mathbf{\Lambda}^t_{ij} \tag{14}$$

where $\mathfrak{p}$ is also a real-valued function whose domain is the set of pairs of disjoint subsets of $\mathbb{O}$.

At iteration t, clusters k and l are merged into (kl). The latter subset is represented by a new node in D and its "height" value is $H((kl))=\mathfrak{p}(k,l)\mathbf{\Lambda}^t_{kl}$. $\mathbb{C}^{t+1}$ is updated similarly to (2) and $\mathbf{S}^{t+1}$ is determined from $\mathbf{S}^t$ by applying (12a) and (12b).

In order to clearly state in our model the schemes under study, we provide in Table 3 the definitions of their respective set functions $\mathfrak{a}$, $\mathfrak{b}$, $\mathfrak{c}$ and $\mathfrak{p}$. Furthermore, we summarize in Algorithm 2 the K-AHC procedure.

From Lemma 7 and assuming $\mathfrak{p}=p$, it is clear that Algorithm 1 and Algorithm 2 merge the same[8] couple of clusters at each iteration. Therefore, they have equivalent dendrograms (see Definition 5). The only difference is that the dendrogram provided by K-AHC assigns

8. Assuming that if there are several (but same) solutions to (9) and (14), both algorithms pick the same pair.

Algorithm 2: General procedure of K-AHC.

Input: $\mathbf{S}$ a kernel matrix, an AHC method
Output: D a dendrogram
Initialize D with n leaves;
Set $\mathbf{S}^1=\mathbf{S}$;
for $t=1,\ldots,n-1$ **do**
  Find the pair of clusters (k,l) according to (14) with the corresponding AHC method parameters values given in Table 3 ;
  Merge (k,l) into (kl) and update D;
  Compute $\mathbf{S}^{t+1}$ by applying (12a) and (12b) with the corresponding AHC method parameters values given in Table 3.
end

to each node a "height" value which equals minus one half times the height value assigned to the same node of the dendrogram obtained by D-AHC. As a consequence, we have the following result.

Theorem 8 *Suppose that the conditions in Lemma 7 are satisfied. Suppose in addition, that p in (9) and $\mathfrak{p}$ in (14) are the same. Then, Algorithm 1 and Algorithm 2 provide equivalent dendrograms.*

Note that, since for all techniques listed in Table 3, $\mathfrak{a}(k,l)+\mathfrak{a}(l,k)=1, \forall k,l\in 2^{\mathbb{O}}$ and $p=\mathfrak{p}$ then, for all particular schemes we examine, K-AHC is equivalent to D-AHC.

4.2 Monotonicity

In hierarchical clustering, it is important to know whether a method can provide reversals while building the dendrogram. Indeed, in practice, non-monotonic dendrograms can be difficult to interpret and are thus undesirable.

In the classic AHC framework described by Algorithm 1, a technique provides a monotonic dendrogram if and only if the following condition holds:

$$\mathbf{D}^{t+1}_{(kl)m}\geq\mathbf{D}^t_{kl},\quad\forall t\in\mathbb{T},\forall k,l,m\in\mathbb{C}^t \tag{15}$$

Milligan (1979), provided sufficient conditions for a method expressed in the usual LW equation (4), to output a monotonic dendrogram. It has to satisfy the following relationships:

$$\begin{cases}\alpha'(k,l,m),\alpha'(l,k,m)\geq 0\\ \alpha'(k,l,m)+\alpha'(l,k,m)+\beta'(k,l,m)\geq 1\\ (\gamma'\geq 0)\vee(\gamma'\leq 0\wedge|\gamma'|\geq\alpha'(k,l,m),\alpha'(l,k,m))\end{cases},\quad\forall k,l,m\in 2^{\mathbb{O}} \tag{16}$$

In our approach described in Algorithm 2, the "height" value is rather a *depth value* since it varies in the opposite way than in Algorithm 1. Consequently, the monotonicity definition given previously translates as follows in the K-AHC case:

$$\mathfrak{p}((kl),m)\mathbf{\Lambda}^{t+1}_{(kl)m}\leq\mathfrak{p}(k,l)\mathbf{\Lambda}^t_{kl},\quad\forall t\in\mathbb{T},\forall k,l,m\in\mathbb{C}^t \tag{17}$$

We give below sufficient conditions for a method expressed in our model to give monotonic dendrograms.

Proposition 9 *Let $\{\mathbf{\Lambda}^t\}_{t\in\mathbb{T}}$ be the sequence of square matrices with input element $\mathbf{S}$ and subsequent elements defined by* (13), (12a), (12b). *Suppose that the set functions $\mathfrak{a}, \mathfrak{b}, \mathfrak{c}$ and $\mathfrak{p}$ satisfy:*

$$\begin{cases} \mathfrak{a}(k,l), \mathfrak{b}(k,l), \mathfrak{c}(k,l), \mathfrak{p}(k,l) \geq 0 \\ \mathfrak{a}(k,l) + \mathfrak{a}(l,k) = 1 \\ \mathfrak{b}(k,l) - \mathfrak{b}(l,k) = 0 \\ \mathfrak{c}(k,l) - \mathfrak{a}(k,l) + \frac{1}{2}\mathfrak{b}(k,l) = 0 \\ \frac{\mathfrak{a}(k,l)}{\mathfrak{p}(k,m)} + \frac{\mathfrak{a}(l,k)}{\mathfrak{p}(l,m)} - \frac{\mathfrak{b}(k,l)}{2\mathfrak{p}(k,l)} \geq 0 \\ \mathfrak{p}((kl),m)\left(\frac{\mathfrak{a}(k,l)}{\mathfrak{p}(k,m)} + \frac{\mathfrak{a}(l,k)}{\mathfrak{p}(l,m)} - \frac{\mathfrak{b}(k,l)}{2\mathfrak{p}(k,l)}\right) \geq 1 \end{cases}, \quad \forall k,l,m \in 2^{\mathbb{O}}$$

Then, under (C1), $\{\mathfrak{p}\mathbf{\Lambda}^t\}_{t\in\mathbb{T}}$ *satisfies* (17).

Proof From the definition of $\mathbf{\Lambda}^t$ given in (13), it comes:

$$\mathbf{\Lambda}^{t+1}_{(kl)m} = \mathfrak{a}(k,l)\mathbf{S}^t_{km} + \mathfrak{a}(l,k)\mathbf{S}^t_{lm} - \frac{1}{2}(\mathfrak{b}(k,l)\mathbf{S}^t_{kl} + \mathfrak{c}(k,l)\mathbf{S}^t_{kk} + \mathfrak{c}(l,k)\mathbf{S}^t_{ll} + \mathbf{S}^t_{mm})$$

By using $\mathfrak{c}(k,l) = \mathfrak{a}(k,l) - \frac{1}{2}\mathfrak{b}(k,l)$ and $\mathfrak{a}(k,l) + \mathfrak{a}(l,k) = 1$, we obtain:

$$\mathbf{\Lambda}^{t+1}_{(kl)m} = \mathfrak{a}(k,l)\mathbf{S}^t_{km} + \mathfrak{a}(l,k)\mathbf{S}^t_{lm} - \frac{1}{2}\left(\mathfrak{b}(k,l)\mathbf{S}^t_{kl} + (\mathfrak{a}(k,l) - \frac{1}{2}\mathfrak{b}(k,l))\mathbf{S}^t_{kk} + (\mathfrak{a}(l,k) - \frac{1}{2}\mathfrak{b}(l,k))\mathbf{S}^t_{ll} + (\mathfrak{a}(k,l) + \mathfrak{a}(l,k))\mathbf{S}^t_{mm}\right)$$

Then, by assuming $\mathfrak{b}(k,l) - \mathfrak{b}(l,k) = 0$ and by regrouping terms with respect to $\mathfrak{a}$ and $\mathfrak{b}$, we get:

$$\mathbf{\Lambda}^{t+1}_{(kl)m} = \mathfrak{a}(k,l)\mathbf{\Lambda}^t_{km} + \mathfrak{a}(l,k)\mathbf{\Lambda}^t_{lm} - \frac{1}{2}\mathfrak{b}(k,l)\mathbf{\Lambda}^t_{kl}$$

Next, since k and l are the clusters that have been merged at iteration t, according to (14), we have $\mathfrak{p}(k,l)\mathbf{\Lambda}^t_{kl} \geq \mathfrak{p}(k,m)\mathbf{\Lambda}^t_{km}, \mathfrak{p}(l,m)\mathbf{\Lambda}^t_{lm}$. Therefore, it holds:

$$\begin{aligned} \mathbf{\Lambda}^{t+1}_{(kl)m} &\leq \mathfrak{a}(k,l)\frac{\mathfrak{p}(k,l)}{\mathfrak{p}(k,m)}\mathbf{\Lambda}^t_{kl} + \mathfrak{a}(l,k)\frac{\mathfrak{p}(k,l)}{\mathfrak{p}(l,m)}\mathbf{\Lambda}^t_{kl} - \frac{1}{2}\mathfrak{b}(k,l)\mathbf{\Lambda}^t_{kl} \\ &\leq \left(\frac{\mathfrak{a}(k,l)}{\mathfrak{p}(k,m)} + \frac{\mathfrak{a}(l,k)}{\mathfrak{p}(l,m)} - \frac{\mathfrak{b}(k,l)}{2\mathfrak{p}(k,l)}\right)\mathfrak{p}(k,l)\mathbf{\Lambda}^t_{kl} \end{aligned}$$

Under (C1), it is easy to see that $\mathbf{\Lambda}^1_{ab} \leq 0, \forall a,b \in \mathbb{O}$. Then, by assuming that $\mathfrak{p}(k,l) \geq 0$ and $\frac{\mathfrak{a}(k,l)}{\mathfrak{p}(k,m)} + \frac{\mathfrak{a}(l,k)}{\mathfrak{p}(l,m)} - \frac{\mathfrak{b}(k,l)}{2\mathfrak{p}(k,l)} \geq 0$, $\forall k,l,m \in 2^{\mathbb{O}}$, it is easy to prove by induction that $\mathbf{\Lambda}^t_{ij} \leq 0, \forall t \in \mathbb{T}, \forall i,j \in \mathbb{C}^t$, using the inequality above.

Besides, by multiplying the same previous inequality by $\mathfrak{p}((kl),m)$, we obtain an upper bound for $\mathfrak{p}((kl),m)\mathbf{\Lambda}^{t+1}_{(kl)m}$:

$$\mathfrak{p}((kl),m)\mathbf{\Lambda}^{t+1}_{(kl)m} \leq \mathfrak{p}((kl),m)\left(\frac{\mathfrak{a}(k,l)}{\mathfrak{p}(k,m)} + \frac{\mathfrak{a}(l,k)}{\mathfrak{p}(l,m)} - \frac{\mathfrak{b}(k,l)}{2\mathfrak{p}(k,l)}\right)\mathfrak{p}(k,l)\mathbf{\Lambda}^t_{kl}$$

Finally, since $\mathbf{\Lambda}^t_{kl}, \mathbf{\Lambda}^{t+1}_{(kl)m} \leq 0$ as stated previously, in order to have $\mathfrak{p}((kl),m)\mathbf{\Lambda}^{t+1}_{(kl)m} \leq \mathfrak{p}(k,l)\mathbf{\Lambda}^t_{kl}$, it is sufficient that:

$$\mathfrak{p}((kl),m)\left(\frac{\mathfrak{a}(k,l)}{\mathfrak{p}(k,m)} + \frac{\mathfrak{a}(l,k)}{\mathfrak{p}(l,m)} - \frac{\mathfrak{b}(k,l)}{2\mathfrak{p}(k,l)}\right) \geq 1$$

■

It is easy to check that all six studied techniques described in Table 3 satisfy the first fifth conditions in Proposition 9. However, unlike group average, Mcquitty and Ward, the methods centroid and median do not satisfy the last condition. These three former schemes are known to be monotonic. Regarding w-median, the new technique we introduced at the end of sub-section 3.2, we have the following property.

Proposition 10 *The w-median scheme is monotonic.*

Proof If we apply the w-median parameters values given in Table 3 to the last condition of Proposition 9, the left-hand side of the inequality reads:

$$\frac{(|k|+|l|)|m|}{|k|+|l|+|m|}\left(\frac{|k|+|m|}{2|k||m|} + \frac{|l|+|m|}{2|l||m|} - \frac{|k|+|l|}{4|k||l|}\right)$$

By developing this equation and after some manipulations, we obtain the following equivalent expression:

$$1 + \frac{|m|}{4(|k|+|l|+|m|)}\left(\frac{|l|}{|k|} + \frac{|k|}{|l|} - 2\right)$$

Let $r = \frac{\max(|k|,|l|)}{\min(|k|,|l|)}$ being a non-negative rational number. The term in parenthesis becomes $\left(r + \frac{1}{r} - 2\right)$. It is easy to see that $r + \frac{1}{r} \geq 2$ and thus $\left(\frac{|l|}{|k|} + \frac{|k|}{|l|} - 2\right) \geq 0$, which completes the proof. ■

4.3 Stored Data Matrix Approach Based on K-AHC

Let q be the dimension of the Hilbert space $\mathcal{H}$. Suppose that q is finite and let $\mathbf{X}$ be the data matrix of size $n \times q$ where each row represents a vector.

So far, we have assumed a stored proximity matrix approach where the input of the algorithms is either $\mathbf{D}$ or $\mathbf{S}$ which are both of size $O(n^2)$. However, it can be useful to operate on the data matrix $\mathbf{X}$ instead of $\mathbf{D}$ or $\mathbf{S}$. Indeed, if n is too large, it could be inefficient, or even impossible, to store the whole proximity matrix on a single machine.

If n is very large but q is much lower than n then, the *stored data matrix* approach can be carried out. It takes as input the data matrix $\mathbf{X}$, computes the dissimilarities between vectors on the fly, finds the pair of clusters to merge, represents the new cluster by a representative vector in $\mathcal{H}$ and repeat these latter steps for $t \in \mathbb{T}$. Note that such an approach allows alleviating the storage complexity but not the computational one, since, in the worst case, the proximities between all pairs of objects need to be evaluated.

In order to carry out the stored data approach, any dissimilarity scheme needs to be formulated in terms of representative vectors in $\mathcal{H}$ (see for e.g. (Murtagh and Contreras, 2012)).

We already pointed out, in sub-section 3.2, that the centroid and Ward methods can be performed by using mean vectors. Note that we can determine the latter representative vectors in an iterative fashion. For $t = 1$, we set $\mathbf{g}^a = \mathbf{x}^a, \forall a \in \mathbb{O}$. For $t > 1$, if k and l are the clusters that are fused then, the mean vector $\mathbf{g}^{(kl)}$ can be computed as follows:

$$\mathbf{g}^{(kl)} = \frac{|k|}{|k|+|l|}\mathbf{g}^k + \frac{|l|}{|k|+|l|}\mathbf{g}^l \tag{18}$$

The median and w-median schemes can also be carried out in a similar way. In these cases, clusters are represented by mid-points. Let $\mathbf{g}^i$ denote the representative vector of cluster $i \in 2^{\mathbb{O}}$. For $t = 1$, all objects are considered as singletons and we set again $\mathbf{g}^a = \mathbf{x}^a, \forall a \in \mathbb{O}$. Then, for $t > 1$, the newly formed cluster (kl) is given as follows, for median and w-median:

$$\mathbf{g}^{(kl)} = \frac{1}{2}\mathbf{g}^k + \frac{1}{2}\mathbf{g}^l \tag{19}$$

Then, for the median and w-median methods, the dissimilarity values satisfy:

$$\mathbf{D}^t_{ij} = \|\mathbf{g}^i - \mathbf{g}^j\|^2, \quad \forall t \in \mathbb{T}, \forall i, j \in \mathbb{C}^t, i \neq j \tag{20}$$

For the graph methods group average and Mcquitty, there is no such equivalent way to express their dissimilarity update equation using representative points using the usual LW sub-equation 4. Yet, our approach makes it possible to obtain such a property for these two latter schemes.

In order to introduce this property, let us first discuss the stored data matrix approach for geometric schemes in our inner-product based modeling. We have the following results.

Proposition 11 *Let $\mathbf{g}^i = \frac{1}{|i|}\sum_{a\in i}\mathbf{x}^a, \forall i \in 2^{\mathbb{O}}$. Then, for the centroid and Ward schemes, it holds:*

$$\mathbf{S}^t_{ij} = \langle \mathbf{g}^i, \mathbf{g}^j \rangle, \quad \forall t \in \mathbb{T}, \forall i, j \in \mathbb{C}^t$$

Proof Since $\mathbf{S}$ is a kernel matrix, $\mathbf{S}^1_{ab} = \langle \mathbf{g}^a, \mathbf{g}^b \rangle, \forall a, b \in \mathbb{C}^1$. Assume that $\mathbf{S}^t_{ij} = \langle \mathbf{g}^i, \mathbf{g}^j \rangle, \forall i, j \in \mathbb{C}^t$ holds for t and let us prove that it holds for $t + 1$ as well. The proof simply uses the linear property of the inner-product. Concerning $\mathbf{S}^{t+1}_{(kl)m}$, we have:

$$\begin{aligned}
\mathbf{S}^{t+1}_{(kl)m} &= \mathfrak{a}(k,l)\mathbf{S}^t_{km} + \mathfrak{a}(l,k)\mathbf{S}^t_{lm} \\
&= \frac{|k|}{|k|+|l|}\langle \mathbf{g}^k, \mathbf{g}^m \rangle + \frac{|l|}{|k|+|l|}\langle \mathbf{g}^l, \mathbf{g}^m \rangle \\
&= \frac{|k|}{|k|+|l|}\langle \frac{1}{|k|}\sum_{a\in k}\mathbf{x}^a, \mathbf{g}^m \rangle + \frac{|l|}{|k|+|l|}\langle \frac{1}{|l|}\sum_{b\in l}\mathbf{x}^b, \mathbf{g}^m \rangle \\
&= \langle \frac{1}{|k|+|l|}(\sum_{a\in k}\mathbf{x}^a + \sum_{b\in l}\mathbf{x}^b), \mathbf{g}^m \rangle \\
&= \langle \mathbf{g}^{(kl)}, \mathbf{g}^m \rangle
\end{aligned}$$

Regarding $\mathbf{S}^{t+1}_{(kl)(kl)}$, we have:

$$\begin{aligned}
\mathbf{S}^{t+1}_{(kl)(kl)} &= \mathfrak{b}(k,l)\mathbf{S}^t_{kl} + \mathfrak{c}(k,l)\mathbf{S}^t_{kk} + \mathfrak{c}(l,k)\mathbf{S}^t_{ll} \\
&= \frac{2|k||l|}{(|k|+|l|)^2}\langle \mathbf{g}^k, \mathbf{g}^l \rangle + \frac{|k|^2}{(|k|+|l|)^2}\langle \mathbf{g}^k, \mathbf{g}^k \rangle \\
&+ \frac{|l|^2}{(|k|+|l|)^2}\langle \mathbf{g}^l, \mathbf{g}^l \rangle \\
&= \langle \frac{1}{|k|+|l|}(\sum_{a\in k}\mathbf{x}^a + \sum_{b\in l}\mathbf{x}^b), \frac{1}{|k|+|l|}(\sum_{a\in k}\mathbf{x}^a + \sum_{b\in l}\mathbf{x}^b) \rangle \\
&= \langle \mathbf{g}^{(kl)}, \mathbf{g}^{(kl)} \rangle
\end{aligned}$$

■

Proposition 12 *Let $\mathbf{g}^a = \mathbf{x}^a, \forall a \in \mathbb{O}$ and $\forall t \in \mathbb{T}$, if k and l are merged, let $\mathbf{g}^{(kl)}$ be defined by* (19)*. Then, for the median and w-median schemes, it holds:*

$$\mathbf{S}^t_{ij} = \langle \mathbf{g}^i, \mathbf{g}^j \rangle, \quad \forall t \in \mathbb{T}, \forall i, j \in \mathbb{C}^t$$

Proof The proof is similar than for Proposition 11. ■

Propositions 11 and 12 states that for centroid, Ward, median and w-median, both off-diagonal and on-diagonal entries of $\mathbf{S}^t$ can be determined by inner-products of representative vectors. As far as group average and Mcquitty techniques are concerned, this latter property is only valid for off-diagonal elements of $\mathbf{S}^t$. Indeed, in Table 3, it is clear that group average and Mcquitty respectively have the same weights vectors $\{\mathfrak{a}(k,l), \mathfrak{a}(l,k)\}$ than centroid (or Ward) and median (or w-median). Regarding the on-diagonal entries, we can actually compute these values for group average and Mcquitty efficiently, providing that we initially store, in an extra vector, the squared norm of each element vector. Let $\mathbf{s}$ be the vector of size n with general term:

$$\mathbf{s}_a = \langle \mathbf{x}^a, \mathbf{x}^a \rangle, \quad \forall a \in \mathbb{O} \tag{21}$$

Let $\mathbf{s}^1 = \mathbf{s}$ and for $t = 2, \ldots, n-1$, let $\mathbf{s}^t$ be a vector of size $n - t + 1$ whose component $\mathbf{s}^t_i$ is associated to cluster $i \in \mathbb{C}^t$. At each iteration $t \in \mathbb{T}$, suppose that k and l are the clusters that are merged then, $\mathbf{s}^{t+1}_{(kl)}$ is determined[9] using the following recurrence formula:

$$\mathbf{s}^{t+1}_{(kl)} = \mathfrak{c}(k,l)\mathbf{s}^t_k + \mathfrak{c}(l,k)\mathbf{s}^t_l, \quad \forall t \in \mathbb{T} \tag{22}$$

where $\mathfrak{c}$ is the set function defined for group average and Mcquitty in Table 3.

Then, it is easy to check the following property.

Proposition 13 *Let $\mathbf{s}^1_a = \langle \mathbf{x}^a, \mathbf{x}^a \rangle, \forall a \in \mathbb{O}$ and $\forall t \in \mathbb{T}$, if k and l are merged, let $\mathbf{s}^t_{(kl)}$ be defined by* (22)*. Then, for the group average and Mcquitty schemes, it holds:*

$$\mathbf{S}^t_{ii} = \mathbf{s}^t_i, \quad \forall t \in \mathbb{T}, \forall i \in \mathbb{C}^t$$

All previously discussed results are summarized in Table 4 and Algorithm 3 which provide a K-AHC based stored data matrix approach for all six methods we examine.

9. Note that similarly to $\mathbf{D}^t$ or $\mathbf{S}^t$, $\mathbf{s}^t$ loses one dimension at each iteration.

Method	$\mathbf{S}^t_{ij}, i \neq j$	$\mathbf{S}^t_{ii}$	$\mathfrak{p}(i,j)$	$\mathbf{g}^{(kl)}$	$\mathbf{s}^{t+1}_{(kl)}$
Group average	$\langle \mathbf{g}^i, \mathbf{g}^j \rangle$	$\mathbf{s}^t_i$	1	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}\mathbf{g}^k + \frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}\mathbf{g}^l$	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}\mathbf{s}^t_k + \frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}\mathbf{s}^t_l$
Mcquitty	$\langle \mathbf{g}^i, \mathbf{g}^j \rangle$	$\mathbf{s}^t_i$	1	$\frac{1}{2}\mathbf{g}^k + \frac{1}{2}\mathbf{g}^l$	$\frac{1}{2}\mathbf{s}^t_k + \frac{1}{2}\mathbf{s}^t_l$
Centroid	$\langle \mathbf{g}^i, \mathbf{g}^j \rangle$	$\langle \mathbf{g}^i, \mathbf{g}^i \rangle$	1	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}\mathbf{g}^k + \frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}\mathbf{g}^l$	NA
Median	$\langle \mathbf{g}^i, \mathbf{g}^j \rangle$	$\langle \mathbf{g}^i, \mathbf{g}^i \rangle$	1	$\frac{1}{2}\mathbf{g}^k + \frac{1}{2}\mathbf{g}^l$	NA
Ward	$\langle \mathbf{g}^i, \mathbf{g}^j \rangle$	$\langle \mathbf{g}^i, \mathbf{g}^i \rangle$	$\frac{\lvert i\rvert\lvert j\rvert}{\lvert i\rvert+\lvert j\rvert}$	$\frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}\mathbf{g}^k + \frac{\lvert k\rvert}{\lvert k\rvert+\lvert l\rvert}\mathbf{g}^l$	NA
W-Median	$\langle \mathbf{g}^i, \mathbf{g}^j \rangle$	$\langle \mathbf{g}^i, \mathbf{g}^i \rangle$	$\frac{\lvert i\rvert\lvert j\rvert}{\lvert i\rvert+\lvert j\rvert}$	$\frac{1}{2}\mathbf{g}^k + \frac{1}{2}\mathbf{g}^l$	NA

Table 4: Particular settings in the stored data matrix based on K-AHC and defined by (14), (13) and representative vectors updates.

Algorithm 3: General procedure of the K-AHC based stored data matrix approach.

Input: $\mathbf{X}$ a data matrix, an AHC method
Output: D a dendrogram

Initialize D with n leaves;
Set $\mathbf{g}^a = \mathbf{x}^a, \forall a \in \mathbb{O}$;
Set $\mathbf{s}_a = \langle \mathbf{x}^a, \mathbf{x}^a \rangle, \forall a \in \mathbb{O}$, if appropriate;
for $t = 1, \ldots, n-1$ **do**
  Compute the inner-product matrix of representative vectors;
  Find the pair of clusters (k,l) according to (14) and (13) with the corresponding AHC method definitions given in Table 4 ;
  Merge (k,l) into (kl) and update D;
  Compute the representative vector $\mathbf{g}^{(kl)}$ by applying the corresponding AHC method formula given in Table 4;
  Compute $\mathbf{s}^{t+1}_{(kl)}$ by applying the corresponding AHC method formula given in Table 4, if appropriate.
end

5. SNK-AHC: Sparsified Normalized Kernel Matrix Based AHC

Another important property of K-AHC is that it offers a way to address the scalability issues of stored proximity matrix based AHC procedures. Our main idea can be stated as follows. Given the distance matrix $\mathbf{D}$, it is reasonable to assume that pairs of items whose distance measure is high are unlikely to be grouped together at an early stage. Consequently, in the goal of reducing the storage complexity, these values could be discarded and we may replace them with zero in order to have a sparse $\mathbf{D}$ matrix. However, this is not sound since a zero distance measure would mean that points are identical while they are far away[10]. In order to avoid this drawback, we propose to use the inner-product matrix $\mathbf{S}$ instead, as we shall explain in what follows.

We now introduce our approach called *Sparsified Normalized Kernel matrix based AHC (SNK-AHC)*. Firstly, we introduce the normalization procedure which transform a kernel matrix $\mathbf{S}$ so that it has a constant diagonal and non-negative values. This preliminary step makes it possible to interpret the inner-product matrix $\mathbf{S}$ in terms of similarities (see Definition 6). Next, we present the sparsification procedure which aims at thresholding $\mathbf{S}$ by setting to zero the lowest values. After this, we introduce the SNK-AHC algorithm and its properties. In particular, we study an interesting feature of group average, Mcquitty and Ward methods and we show in what context, SNK-AHC is able to determine the number of clusters.

5.1 Normalized Kernel Matrix

In our perspective, the term *Normalized Kernel (NK) matrix* designates a kernel matrix with a constant diagonal and non-negative terms. In other words, we assume that the points belong to the intersection between an hypersphere and the positive quadrant of $\mathcal{H}$:

$$\mathbf{S}_{aa} = \mathbf{S}_{bb}, \quad \forall a, b \in \mathbb{O} \tag{C2}$$

$$\mathbf{S}_{ab} \geq 0, \quad \forall a, b \in \mathbb{O} \tag{C3}$$

If the kernel matrix $\mathbf{S}$ does not have a constant diagonal then, we can always apply the cosine normalization (or any generalization proposed in (Ah-Pine, 2010)):

$$\mathbf{S}_{ab} \leftarrow \frac{\mathbf{S}_{ab}}{\sqrt{\mathbf{S}_{aa}\mathbf{S}_{bb}}}, \quad \forall a, b \in \mathbb{O} \tag{23}$$

Next, let v be the minimal value in $\mathbf{S}$. If $v < 0$ then we propose to perform a simple translation in order to obtain non-negative values:

$$\mathbf{S}_{ab} \leftarrow \mathbf{S}_{ab} + |v|, \quad \forall a, b \in \mathbb{O} \tag{24}$$

It is worth noting that such a translation does not change the results of Algorithm 2. In fact, the procedure is invariant under any positive linear transformation of the $\mathbf{S}$ matrix for all six schemes we are interested in.

10. Note that we could have replaced these values with a constant which would have been the maximal distance value but in this case, we would have lost the sparsity property.

Proposition 14 *Suppose that the set functions* $\mathfrak{a}, \mathfrak{b}, \mathfrak{c}$ *satisfy:*

$$\begin{cases} \mathfrak{a}(k,l) + \mathfrak{a}(l,k) = 1 \\ \mathfrak{b}(k,l) + \mathfrak{c}(k,l) + \mathfrak{c}(l,k) = 1 \end{cases}, \quad \forall k,l,m \in 2^{\mathbb{O}}$$

Then, Algorithm 2 provides equivalent dendrograms for input similarity matrices $\mathbf{S}$ *and* $\mathbf{T} = u\mathbf{S} + v\mathbf{1}_n$*, with* $u > 0$*,* $v \in \mathbb{R}$ *and* $\mathbf{1}_n$ *being the square matrix of order* n *filled with 1.*

Proof Let $\mathbf{T}$ be a linear transformation of $\mathbf{S}$ with general term $\mathbf{T}_{ab} = u\mathbf{S}_{ab} + v$ where $u > 0$. For $t = 1$, we can write $\mathbf{T}^1_{ab} = u\mathbf{S}^1_{ab} + v$. Assume that $\mathbf{T}^t_{ij} = u\mathbf{S}^t_{ij} + v, \forall i,j \in \mathbb{C}^t$ and let us prove that $\mathbf{T}^{t+1}_{ij} = u\mathbf{S}^{t+1}_{ij} + v, \forall i,j \in \mathbb{C}^{t+1}$. Let k and l be the clusters that are fused at iteration t. First, we need to prove that $\mathbf{T}^{t+1}_{(kl)m} = u\mathbf{S}^{t+1}_{(kl)m} + v, \forall m \in \mathbb{C}^{t+1}, m \neq (kl)$. We have:

$$\begin{aligned} \mathbf{T}^{t+1}_{(kl)m} &= \mathfrak{a}(k,l)\mathbf{T}^t_{km} + \mathfrak{a}(l,k)\mathbf{T}^t_{lm} \\ &= \mathfrak{a}(k,l)(u\mathbf{S}^t_{km} + v) + \mathfrak{a}(l,k)(u\mathbf{S}^t_{lm} + v) \\ &= u(\mathfrak{a}(k,l)\mathbf{S}^t_{km} + \mathfrak{a}(l,k)\mathbf{S}^t_{lm}) + v(\mathfrak{a}(k,l) + \mathfrak{a}(l,k)) \\ &= u\mathbf{S}^{t+1}_{(kl)m} + v, \end{aligned}$$

providing that $\mathfrak{a}(k,l) + \mathfrak{a}(l,k) = 1$.

Next, we prove that $\mathbf{T}^{t+1}_{(kl)(kl)} = u\mathbf{S}^{t+1}_{(kl)(kl)} + v$. Indeed, we have:

$$\begin{aligned} \mathbf{T}^{t+1}_{(kl)(kl)} &= \mathfrak{b}(k,l)\mathbf{T}^t_{kl} + \mathfrak{c}(k,l)\mathbf{T}^t_{kk} + \mathfrak{c}(l,k)\mathbf{T}^t_{ll} \\ &= \mathfrak{b}(k,l)(u\mathbf{S}^t_{kl} + v) + \mathfrak{c}(k,l)(u\mathbf{S}^t_{kk} + v) + \mathfrak{c}(l,k)(u\mathbf{S}^t_{ll} + v) \\ &= u(\mathfrak{b}(k,l)\mathbf{S}^t_{kl} + \mathfrak{c}(k,l)\mathbf{S}^t_{kk} + \mathfrak{c}(l,k)\mathbf{S}^t_{ll}) + v(\mathfrak{b}(k,l) + \mathfrak{c}(k,l) + \mathfrak{c}(l,k)) \\ &= u\mathbf{S}^{t+1}_{(kl)(kl)} + v \end{aligned}$$

providing that $\mathfrak{b}(k,l) + \mathfrak{c}(k,l) + \mathfrak{c}(l,k) = 1$.

Denote respectively $\{\mathbf{\Lambda}^t\}_{t\in\mathbb{T}}$ and $\{\mathbf{\Delta}^t\}_{t\in\mathbb{T}}$, the sequences of square matrices defined by (13), (12a) and (12b), and obtained when $\mathbf{S}$ and $\mathbf{T} = u\mathbf{S} + v\mathbf{1}_n$ are the input kernel matrices respectively. We have, $\forall t \in \mathbb{T}, \forall i,j \in \mathbb{C}^t$:

$$\begin{aligned} \mathbf{\Delta}^t_{ij} &= \mathbf{T}^t_{ij} - \frac{1}{2}(\mathbf{T}^t_{ii} + \mathbf{T}^t_{jj}) \\ &= u\mathbf{S}^t_{ij} + v - \frac{1}{2}(u\mathbf{S}^t_{ii} + v + u\mathbf{S}^t_{jj} + v) \\ &= u(\mathbf{S}^t_{ij} - \frac{1}{2}(\mathbf{S}^t_{ii} + \mathbf{S}^t_{jj})) \\ &= u\mathbf{\Lambda}^t_{ij} \end{aligned}$$

Since $u > 0$ then, $\arg\max_{(i,j)\in\mathbb{C}^t, i\neq j} \mathfrak{p}(i,j)\mathbf{\Delta}^t_{ij} = \arg\max_{(i,j)\in\mathbb{C}^t, i\neq j} \mathfrak{p}(i,j)\mathbf{\Lambda}^t_{ij}, \forall t \in \mathbb{T}$. ■

Moreover, let us remind that a positive linear transformation of the terms of a positive semi-definite matrix provides a positive semi-definite matrix. Therefore, $\mathbf{S}$ remains a kernel matrix after (24) is carried out.

Henceforth, we assume that $\mathbf{S}$ is a NK matrix. In fact, such a matrix enjoys a double interpretation. On the one hand, it gives the inner-products of points represented (on an hypersphere) in an Hilbert space. On the other hand, it can be seen as a similarity matrix satisfying the conditions[11] given in Definition 6.

As a consequence, in the rest of the paper, NK matrix and similarity matrix are terms that we use interchangeably.

5.2 Penalized Similarities: Aggregated Inter-similarities *Versus* Aggregated Intra-similarities

Supposing (C1), (C2) and (C3), we discuss a new interpretation of K-AHC based on similarities. Equation (14) is a maximum search over the set of couples of clusters in $\mathbb{C}^t$. The quality of a pair (i,j) depends on $\mathbf{\Lambda}^t_{ij}$ defined in (13) which is the difference between $\mathbf{S}^t_{ij}$ and the arithmetic mean of $\mathbf{S}^t_{ii}$ and $\mathbf{S}^t_{jj}$. Let us call $\mathbf{S}^t_{ij}$, the *inter-similarity* between clusters i and j, and $\mathbf{S}^t_{ii}$, the *intra-similarity* of cluster i. For the couple of clusters (i,j), $\mathbf{\Lambda}^t_{ij}$ can be seen as their inter-similarity value *penalized* by the arithmetic mean of their respective intra-similarities. According to (13), $\mathbf{\Lambda}^t_{ij}$ is great if the inter-similarity is high *and* the intra-similarities are low. Consequently, i and j are more likely to be merged together if their inter-similarity is high enough with respect to their intra-similarities.

In this context, it is important to formally state the properties of the set functions defining the six schemes we deal with. From Table 3, we can observe that for all methods:

$$\begin{cases} \mathfrak{a}(k,l), \mathfrak{b}(k,l), \mathfrak{c}(k,l) \geq 0 \\ \mathfrak{a}(k,l) + \mathfrak{a}(l,k) = 1 \\ \mathfrak{b}(k,l) + \mathfrak{c}(k,l) + \mathfrak{c}(l,k) = 1 \end{cases}, \quad \forall k,l \in 2^{\mathbb{O}} \tag{25}$$

Therefore, $\{\mathfrak{a}(k,l), \mathfrak{a}(l,k)\}$ and $\{\mathfrak{b}(k,l), \mathfrak{c}(k,l), \mathfrak{c}(l,k)\}$ can be seen as *weight vectors* and we interpret (12a) and (12b) as *averages* of inter-similarities and intra-similarities respectively. From this viewpoint, the differences between the techniques can be understood from their distinct *averaging strategies*.

In order to have a more precise view of the differences between the six methods, let us take an example. Suppose $\mathbb{O} = \{a,b,c,d,e,f,g\}$ and at iteration $t = 4$, $\mathbb{C}^4 = \{k,l,m\}$ with $k = \{a,b,c\}$, $l = \{d,e\}$, $m = \{f,g\}$. Assume that (k,l) is the couple of clusters to be merged. In Figure 2, we illustrate this situation using the input similarity matrix $\mathbf{S}$. The different elements involved in (12a) and (12b) are shown. They correspond to rectangular blocks for inter-similarities $(\mathbf{S}^4_{kl}, \mathbf{S}^4_{lm}, \mathbf{S}^4_{kl})$ and to square blocks for intra-similarities $(\mathbf{S}^4_{kk}, \mathbf{S}^4_{ll}, \mathbf{S}^4_{mm})$.

The inter-similarity $\mathbf{S}^5_{(kl)m}$ is an average of $\mathbf{S}^4_{km}$ and $\mathbf{S}^4_{lm}$ represented by dashed line blocks $k \times m$ and $l \times m$. Mcquitty, median and w-median assign the same weight $1/2$ to both terms whereas group average, centroid and Ward, assign weights which depend on one of the blocks side length.

The intra-similarity $\mathbf{S}^5_{(kl)(kl)}$ is an average of $\mathbf{S}^4_{kl}$, $\mathbf{S}^4_{kk}$ and $\mathbf{S}^4_{ll}$ which are highlighted by a dotted line block and two solid line blocks respectively. Since $\mathbf{S}^4$ is symmetric, it is equivalent to consider that $\mathbf{S}^5_{(kl)(kl)}$ depends on $\mathbf{S}^4_{kl}$, $\mathbf{S}^4_{lk}$, $\mathbf{S}^4_{kk}$ and $\mathbf{S}^4_{ll}$. We can see that these four elements depict a partition of the block $(k\cup l)\times(k\cup l)$. For geometric methods, all four sub-blocks contribute to $\mathbf{S}^5_{(kl)(kl)}$. In the median and w-median schemes, all sub-blocks are assigned a uniform weight of $1/4$ which amounts to an unweighted mean. Regarding centroid

11. Note that in this context, the maximal self-similarity property is due to the Cauchy-Schwartz inequality.

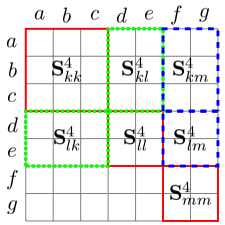

Figure 2: Illustration of inter-similarities and intra-similarities.

and Ward, the weights are distributed with respect to the blocks area. Conversely, for graph methods group average and Mcquitty, $\mathbf{S}^5_{(kl)(kl)}$ only depends on $\mathbf{S}^4_{kk}$ and $\mathbf{S}^4_{ll}$. Consequently, it is not difficult to see that only the on-diagonal terms of $\mathbf{S}$ are involved in the computation of the clusters intra-similarity for these two latter schemes. This observation was already underlined in sub-section 4.3.

5.3 Sparsified Normalized Kernel Matrix

In order to cope with the storage complexity of K-AHC, we sparsify the NK matrix by removing the lowest similarity values. We obtain a *Sparsified Normalized Kernel (SNK) matrix*.

The first sparsification procedure we introduce is a simple thresholding operator[12] based on a real parameter $\theta \geq 0$.

$$\mathbf{S}_{ab} \leftarrow \begin{cases} \mathbf{S}_{ab} & \text{if } \mathbf{S}_{ab} \geq \theta \\ 0 & \text{otherwise} \end{cases}, \quad \forall a, b \in \mathbb{O} \tag{26}$$

Note that under (C2), we have:

$$\begin{aligned} \mathbf{D}_{ab} &= \mathbf{S}_{aa} + \mathbf{S}_{bb} - 2\mathbf{S}_{ab} \\ &= 2(w - \mathbf{S}_{ab}), \quad \forall a, b \in \mathbb{O} \end{aligned}$$

where $\mathbf{S}_{aa} = w, \forall a \in \mathbb{O}$.

Thereby, the entries which correspond to the greatest values in $\mathbf{S}$ are exactly the same entries in $\mathbf{D}$ having the lowest values.

The second sparsification approach is based on the nearest neighbors. Let $\mathbb{NN}_k(a)$ be the set of the k elements closest to a according to $\mathbf{S}$ (or $\mathbf{D}$ equivalently). Then, we define:

$$\mathbf{S}_{ab} \leftarrow \begin{cases} \mathbf{S}_{ab} & \text{if } b \in \mathbb{NN}_k(a) \text{ or } a \in \mathbb{NN}_k(b) \\ 0 & \text{otherwise} \end{cases}, \quad \forall a, b \in \mathbb{O} \tag{27}$$

We point out that for each $a \in \mathbb{O}$, the number of non-null values in the similarity profile $\{\mathbf{S}_{ab}\}_{b \in \mathbb{O}}$ is lower bounded by k. Apart from the k closest items to a in $\mathbb{NN}_k(a)$, an item

12. When using distances, this sparsification procedure is equivalent to the epsilon-neighborhood method.

$c \notin \mathbb{NN}_k(a)$ could have a in its k nearest neighbors in which case $\mathbf{S}_{ca}$ but also $\mathbf{S}_{ac}$ would be non-null. Consequently, if $k = round(n/2)$ for instance, then $\mathbf{S}$ memory usage is not necessarily divided by 2, but by a factor which is lower or equal to 2.

Besides, it should be clear that determining the exact k nearest neighbors graph basically takes $O(n^2)$ time. However, there are different ways to speed-up this procedure (see for e.g. (Franti et al., 2006) and references therein).

Observe that after (26) or (27) is performed, the sparsified similarity matrix $\mathbf{S}$ is no longer positive semi-definite. Thereby, the geometric context we have assumed so far does not hold for a SNK matrix. Nonetheless, as we shall show in sub-section 5.5, three out of the six techniques are not concerned with this issue.

5.4 Performing K-AHC on a SNK Matrix in an Efficient and Effective Manner

We carry out K-AHC on a SNK matrix $\mathbf{S}$. However, owing to the distinct interpretations we can give to $\mathbf{S}$, as exposed in sub-section 5.2, we propose some substantial modifications to Algorithm 2 that lead to interesting properties.

In the stored proximities based AHC algorithms D-AHC or K-AHC, the bottleneck that causes an heavy computational cost is the search for the pair of clusters to fuse. This operation is carried out over the set of all possible pairs in $\mathbb{C}^t \times \mathbb{C}^t$ which has $O(n^2)$ cost. Since there are $n-1$ iterations, the overall time complexity is thus $O(n^3)$.

In our case, $\mathbf{S}$ is a sparse similarity matrix and we introduce the following subset:

$$\mathbb{S} = \{(a, b) \in \mathbb{O} \times \mathbb{O}, \mathbf{S}_{ab} > 0\} \tag{28}$$

Likewise, during the course of the bottom-up merging mechanism, we determine at each iteration, the following subsets:

$$\mathbb{S}^t = \{(i, j) \in \mathbb{C}^t \times \mathbb{C}^t, \mathbf{S}^t_{ij} > 0\}, \quad \forall t \in \mathbb{T} \tag{29}$$

Note that $\mathbb{S}^{t+1}$ can be easily updated from $\mathbb{S}^t$.

In contrast to K-AHC, for each $t \in \mathbb{T}$, SNK-AHC searches for the pair to merge among the elements in $\mathbb{S}^t$ only. Accordingly, we replace (14) with:

$$(k, l) = \underset{(i,j) \in \mathbb{S}^t, i \neq j}{\arg\max} \ \mathfrak{p}(i, j) \mathbf{\Lambda}^t_{ij} \tag{30}$$

Therefore, whatever the value $\mathfrak{p}(i, j)\mathbf{\Lambda}^t_{ij}$, two clusters i and j can not be merged together if they share no similarity at all. SNK-AHC is thus a *constrained AHC procedure*.

The SNK-AHC pseudo-code is given in Algorithm 4. It also describes a bottom-up algorithm but unlike K-AHC, the dendrogram grows as long as $\mathbb{S}^t \neq \emptyset$. As a consequence, the output of Algorithm 4 is not a tree in general but a *forest*. We investigate this point further in sub-section 5.6.

It is clear that restricting the search to $\mathbb{S}^t$ makes it possible to obtain a much more scalable dendrogram building procedure.

Proposition 15 *Let z be the number of non-null entries in $\mathbf{S}$ after the sparsification step in Algorithm 4 has been performed. Then, the bottom-up procedure of Algorithm 4 has $O(z)$ storage complexity and $O(nz)$ processing time complexity.*

Algorithm 4: General procedure of SNK-AHC.

Input: $\mathbf{S}$ a kernel matrix, a sparsification method, an AHC method
Output: D a dendrogram
if *the diagonal of* $\mathbf{S}$ *is not constant* **then**
  Normalize $\mathbf{S}$ using (23);
end
Translate $\mathbf{S}$ using (24);
Sparsify $\mathbf{S}$ using (26) or (27);
Initialize D with n leaves;
Set $\mathbf{S}^1 = \mathbf{S}$;
Determine $\mathbb{S}$ according to (28) and set $\mathbb{S}^1 = \mathbb{S}$;
while $\mathbb{S}^t \neq \emptyset$ **do**
  Find the pair of clusters (k, l) according to (30) with the corresponding AHC method parameters values given in Table 3 ;
  Merge (k, l) into (kl) and update D;
  Update $\mathbb{S}^{t+1}$ from $\mathbb{S}^t$;
  Compute $\mathbf{S}^{t+1}$ by applying (12a) and (12b) with the corresponding AHC method parameters values given in Table 3.
end

Note, however, that if $\mathbf{S}$ is a dense NK matrix which has not been sparsified, and $\mathbf{D}$ is the related distance matrix following (C1), then Algorithm 4 provides the exact same result as Algorithm 2 and thus an output equivalent to the one obtained with Algorithm 1 as well, according to Theorem 8.

As we shall see in section 6 dedicated to the experiments, not only SNK-AHC can be dramatically more efficient than D-AHC from a computational standpoint, but it also enables improving the quality of the clustering results on challenging problems.

5.5 Diagonal Translation Invariance

As highlighted in sub-section 5.3, the SNK matrix $\mathbf{S}$ is not positive semi-definite and we can not assume that the points belong to an Hilbert space any more. However, we can recover this feature quite easily. Indeed, since $\mathbf{S}$ is symmetric and all its diagonal entries are non-negative then, one simple way to make $\mathbf{S}$ positive semi-definite again, is to sufficiently augment the values of the diagonal entries in order to make $\mathbf{S}$ strictly diagonally dominant (see for e.g. (Horn and Johnson, 1986, Theorem 6.1.10)).

While we can always do this, we show, in what follows, that this is not necessary for some techniques.

Let us introduce the following matrix:

$$\mathbf{T} = \mathbf{S} + w\mathbf{I}_n \tag{31}$$

where $\mathbf{I}_n$ is the identity matrix of order n and $w > 0$ is chosen such that $\mathbf{T}$ is positive semi-definite.

Let $M = \{m_1, \ldots, m_{n-1}\}$ be a sequence of merges following Definition 4. By observing that (12a) does not depend on any on-diagonal entry of the SNK matrix then, it is easy to check the following result.

Lemma 16 *Let* $\{\mathbf{S}^t\}_{t\in\mathbb{T}}$ *and* $\{\mathbf{T}^t\}_{t\in\mathbb{T}}$ *be the sequences of square matrices with input elements* $\mathbf{S}$ *and* $\mathbf{T} = \mathbf{S} + w\mathbf{I}_n, w \in \mathbb{R}$ *and subsequent elements defined by* (12a) *and* (12b). *Suppose that* $\{\mathbf{S}^t\}_{t\in\mathbb{T}}$ *and* $\{\mathbf{T}^t\}_{t\in\mathbb{T}}$ *are determined with respect to the same sequence of merges* M. *Then, we have:*

$$\mathbf{T}^t_{ij} = \mathbf{S}^t_{ij}, \quad \forall t \in \mathbb{T}, \forall i, j \in \mathbb{C}^t, i \neq j$$

Lemma 16 indicates that when merging the same sequence of pairs of clusters, the off-diagonal entries of similarity matrices $\{\mathbf{S}^t\}_{t\in\mathbb{T}}$ and $\{\mathbf{T}^t\}_{t\in\mathbb{T}}$ are identical. It is only the intra-similarities that are influenced by the diagonal translation.

For group average, Mcquitty and Ward, we have the following relationships.

Lemma 17 *Let* $\{\mathbf{S}^t\}_{t\in\mathbb{T}}$ *and* $\{\mathbf{T}^t\}_{t\in\mathbb{T}}$ *be the sequences of square matrices with input elements* $\mathbf{S}$ *and* $\mathbf{T} = \mathbf{S} + w\mathbf{I}_n, w \in \mathbb{R}$ *and subsequent elements defined by* (12a) *and* (12b). *Suppose that* $\{\mathbf{S}^t\}_{t\in\mathbb{T}}$ *and* $\{\mathbf{T}^t\}_{t\in\mathbb{T}}$ *are determined with respect to the same sequence of merges* M. *Then, for group average and Mcquitty, we have:*

$$\mathbf{T}^t_{ii} = \mathbf{S}^t_{ii} + w, \quad \forall t \in \mathbb{T}, \forall i \in \mathbb{C}^t$$

Regarding Ward, we have:

$$\mathbf{T}^t_{ii} = \mathbf{S}^t_{ii} + \frac{w}{|i|}, \quad \forall t \in \mathbb{T}, \forall i \in \mathbb{C}^t$$

Proof Let us consider the group average technique and its parameters values given in Table 3. For $t = 1$, it follows from the definition given in (31) that $\mathbf{T}^1_{aa} = \mathbf{S}^1_{aa} + w, \forall a \in \mathbb{C}^1$. Assume that $\mathbf{T}^t_{ii} = \mathbf{S}^t_{ii} + w, \forall i \in \mathbb{C}^t$ for t. Then, let us prove that the latter relation is true for $t + 1$ as well. Suppose that at iteration t, the pair of clusters (k, l) is merged. By applying Lemma 16, it comes:

$$\begin{aligned}
\mathbf{T}^{t+1}_{(kl)(kl)} - \mathbf{S}^{t+1}_{(kl)(kl)} &= \mathfrak{b}(k,l)\mathbf{T}^t_{kl} + \mathfrak{c}(k,l)\mathbf{T}^t_{kk} + \mathfrak{c}(l,k)\mathbf{T}^t_{ll} - (\mathfrak{b}(k,l)\mathbf{S}^t_{kl} + \mathfrak{c}(k,l)\mathbf{S}^t_{kk} + \mathfrak{c}(l,k)\mathbf{S}^t_{ll}) \\
&= \mathfrak{c}(k,l)(\mathbf{T}^t_{kk} - \mathbf{S}^t_{kk}) + \mathfrak{c}(l,k)(\mathbf{T}^t_{ll} - \mathbf{S}^t_{ll}) \\
&= w(\mathfrak{c}(k,l) + \mathfrak{c}(l,k)) \\
&= w
\end{aligned}$$

since $\mathfrak{c}(k,l) + \mathfrak{c}(l,k) = 1$ for group average.
The proofs for Mcquitty and Ward are similar. ■

Theorem 18 *For group average, Mcquitty and Ward methods, Algorithm 4 provides equivalent dendrograms for input similarity matrices* $\mathbf{S}$ *and* $\mathbf{T} = \mathbf{S} + w\mathbf{I}_n$, $w \in \mathbb{R}$.

Proof Denote respectively $\{\mathbf{\Lambda}^t\}_{t\in\mathbb{T}}$ and $\{\mathbf{\Delta}^t\}_{t\in\mathbb{T}}$, the sequences of penalized similarity matrices obtained using $\mathbf{S}$ and $\mathbf{T}$ as input similarity matrices. We prove that for all $t \in \mathbb{T}$, the couple of clusters maximizing $\mathfrak{p}(i,j)\mathbf{\Delta}^t_{ij}$ is the same as the one maximizing $\mathfrak{p}(i,j)\mathbf{\Lambda}^t_{ij}$. To this end, note that a sufficient condition is $\mathfrak{p}(i,j)(\mathbf{\Delta}^t_{ij} - \mathbf{\Lambda}^t_{ij}) = c$, $\forall t \in \mathbb{T}$, where c is a constant. For $t = 1$, we have:

$$\begin{aligned}\mathfrak{p}(a,b)(\mathbf{\Delta}^1_{ab} - \mathbf{\Lambda}^1_{ab}) &= \mathfrak{p}(a,b)(\mathbf{T}^1_{ab} - \frac{1}{2}(\mathbf{T}^1_{aa} + \mathbf{T}^1_{bb}) - \mathbf{S}^1_{ab} + \frac{1}{2}(\mathbf{S}^1_{aa} + \mathbf{S}^1_{bb}))\\ &= -\frac{\mathfrak{p}(a,b)}{2}((\mathbf{T}^1_{aa} - \mathbf{S}^1_{aa}) + (\mathbf{T}^1_{bb} - \mathbf{S}^1_{bb}))\\ &= \underbrace{-\mathfrak{p}(1,1)w}_{c}\end{aligned}$$

where, by abusing the notation, $\mathfrak{p}(1,1)$ denotes $\mathfrak{p}(i,j)$ whenever $|i|=|j|=1$.

For $t = 1$, it is clear that using either $\mathbf{S}$ or $\mathbf{T}$ as input matrices, leads to the same merge. As a consequence, by applying Lemma 16, it is sufficient to prove by induction that:

$$-\frac{\mathfrak{p}(i,j)}{2}((\mathbf{T}^t_{ii} - \mathbf{S}^t_{ii}) + (\mathbf{T}^t_{jj} - \mathbf{S}^t_{jj})) = -\mathfrak{p}(1,1)w, \quad \forall t \in \mathbb{T}, \forall i,j \in \mathbb{C}^t, i \neq j \tag{32}$$

Concerning the group average and the Mcquitty techniques, for both cases $\mathfrak{p}(i,j) = 1, \forall i,j \in 2^{\mathbb{O}}$ and thus $c = -w$. Let assume that at iteration t, the pair of clusters (k,l) is merged. By applying Lemma 17, we have:

$$\begin{aligned}-\frac{1}{2}((\mathbf{T}^{t+1}_{(kl)(kl)} - \mathbf{S}^{t+1}_{(kl)(kl)}) + (\mathbf{T}^{t+1}_{mm} - \mathbf{S}^{t+1}_{mm})) &= -\frac{1}{2}(w + w)\\ &= -w\end{aligned}$$

In the case of Ward, $c = -\mathfrak{p}(1,1)w = -\frac{w}{2}$. By using Lemma 17 again, we have:

$$\begin{aligned}&-\frac{\mathfrak{p}((kl),m)}{2}((\mathbf{T}^{t+1}_{(kl)(kl)} - \mathbf{S}^{t+1}_{(kl)(kl)}) + (\mathbf{T}^{t+1}_{mm} - \mathbf{S}^{t}_{mm}))\\ &= -\frac{|(kl)||m|}{2(|(kl)|+|m|)}(\frac{w}{|(kl)|} + \frac{w}{|m|})\\ &= -\frac{w}{2}\end{aligned}$$

■

Consequently, for these three schemes, the geometrical representation of the objects lying in an Hilbert space is still valid when applying Algorithm 4, even though the SNK matrix $\mathbf{S}$ is not positive semi-definite.

For the other schemes, centroid, median and w-median, some preliminary empirical tests showed that making $\mathbf{S}$ positive semi-definite again is not recommended. Indeed, in these cases, increasing the diagonal provided worst performances in terms of clustering quality. It appears that such a transformation results in a space distortion to which, these latter methods are highly sensitive. Therefore, in Algorithm 4, we do not include a step for diagonal translation by default.

5.6 Clusters as Connected Components

One important issue in clustering is to determine the number of clusters. To some extent, Algorithm 4 is able to address this challenge. In order to detail this property, we place ourselves in the framework of graph theory.

Let G be an undirected graph with $\mathbb{O}$ being the set of nodes and $\mathbb{S}$, defined in (28), being the set of edges. G is connected if for every pair $(a,b) \in \mathbb{O}\times\mathbb{O}$, there is a path joining both nodes. If G is not connected then $\mathbb{O}$ can be separated with respect to its *connected components*. These latter subsets form a partition of $\mathbb{O}$. From a clustering viewpoint, the connected components can be seen as clusters.

One way to determine the connected components of an undirected graph is to use a disjoint sets data structure which typically: (i) puts nodes in a same set if there is a path joining each other and (ii) assigns a representative item to each set (see for e.g. (Cormen et al., 2009, Chapter 21)). In this context, three operations are employed:

- `make_set`(a): creates a set whose only member is a and takes a as its representative.
- `find_set`(a): finds the representative of the set a belongs to.
- `union`(a,b): unites the two disjoint sets that a and b belong to, removes the two latter sets and determine a representative for the new set.

We review in Algorithm 5 the pseudo-code that builds a disjoint sets data structure given a graph $G = (\mathbb{O}, \mathbb{S})$ and outputs the connected components.

Algorithm 5: Connected components determination.

```
Input: G = (𝕆, 𝕊)
Output: The connected components
for a ∈ 𝕆 do
    make_set(a)
end
for (a, b) ∈ 𝕊 do
    if find_set(a) ≠ find_set(b) then
        union(a,b)
    end
end
```

As an illustration, we provide an example in Figure 3. We represent a graph with seven nodes and four edges : $\mathbb{O} = \{a,b,c,d,e,f,g\}$ and $\mathbb{S} = \{(a,b),(a,c),(d,e),(e,f)\}$.

Applying Algorithm 5 to this example, provides the following connected components:

- $a : \{a,b,c\}$,
- $d : \{d,e,f\}$.

In this example, the representative item of a subset is chosen with respect to the lexical order.

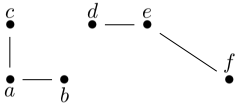

Figure 3: Illustration of a disconnected graph.

In fact, all AHC Algorithms 1-4 we have introduced so far, rely on a bottom-up fusion mechanism that reproduces the same operations than in Algorithm 5. The difference is that instead of scanning all unitary edges $(a, b) \in \mathbb{S}$ in the for loop in Algorithm 5, AHC procedures go through the consolidated edges between the representative items of the disjoint sets (the clusters). Moreover, unlike in Algorithm 5, the edges are not picked randomly in AHC algorithms but they are chosen in the goal of optimizing a criterion which is the weighted dissimilarity value in the case of D-AHC and the weighted penalized similarity value in the cases of K-AHC and SNK-AHC.

Furthermore, in Algorithms 1 and 2, the input proximity matrices are dense and the underlying graphs are thus fully connected. Therefore, these algorithms necessarily produce single trees as outputs. On the contrary, Algorithm 4 uses a sparse similarity matrix and in this case, G might not be connected, especially if $z << n^2$. In such a case, Algorithm 4 outputs a forest and each tree is a connected component which can be considered as a cluster.

This reasoning is summarized in the following statement.

Proposition 19 *Let* $\mathbf{S}$ *be the sparse similarity matrix obtained after the sparsification step of Algorithm 4 and let* $\mathbb{S}$ *be the set of pairs of objects defined by* (28)*. Let* $G = (\mathbb{O}, \mathbb{S})$ *be the associated undirected graph. If* G *is not connected and has* κ *connected components then Algorithm 4 stops at iteration* $n - \kappa - 1$*. Moreover, it outputs a forest where each tree is a connected component.*

Accordingly, note that SNK-AHC output is not a complete dendrogram in general.

6. Experiments

In this section we demonstrate the different properties and advantages of SNK-AHC over D-AHC using different benchmark data sets. We both use artificial and real-world problems which are freely available at (Franti and et al, 2015) and (Lichman, 2013) respectively.

Firstly, we compare the dendrograms obtained by D-AHC and SNK-AHC. Our first purpose is to verify that when no sparsification is performed, SNK-AHC is equivalent to D-AHC. Secondly, we are interested in assessing the proximity between the dendrograms given by D-AHC and SNK-AHC. Thirdly, on medium-size real-world data sets, we demonstrate that Algorithm 4 indeed allows reducing the D-AHC computational costs dramatically. Finally, for all data sets, we show that sparsifying the similarity matrix can also provide better clustering results.

We introduce below the different assessment criteria we used in our experiments, before presenting the benchmarks and the results we obtained.

6.1 Evaluation Measures

In order to measure the proximity between the dendrograms obtained by Algorithms 1 and 4, we use the cophenetic matrices and correlation coefficient (see for e.g. (Everitt et al., 2009, Section 4.4.2)). Given a dendrogram D, the derived cophenetic matrix denoted $\mathbf{C}(D)$, is a pairwise matrix of order n where, for each pair of items $(a, b) \in \mathbb{O} \times \mathbb{O}$, we record the height (D-AHC) or depth value (SNK-AHC) of the node that merges a and b for the first time. Then, let D_{dahc} and D_{snkahc} be the dendrograms obtained by both techniques. The cophenetic correlation is the product moment correlation between the vectorized upper triangular matrices of $\mathbf{C}(D_{dahc})$ and $\mathbf{C}(D_{snkahc})$. We take the opposite value of this measure which is denoted CC. In this case, CC=1 implies that the dendrograms are equivalent.

Next, in order to evaluate the quality of the clustering results we apply an external validation methodology since we are given the correct partition for all data sets. For each obtained dendrogram, we cut the forest so as to obtain the correct number of clusters denoted κ^*. Note that if κ, the number of clusters found by Algorithm 4, is greater than κ^* then, we keep the partition with κ clusters. Afterward, we compare the resulting partition and the ground-truth. The evaluation measure used in this case is the famous adjusted Rand index (Hubert and Arabie, 1985) which is denoted ARI. In this case as well, the greater the better, and ARI=1 means that the ground-truth was recovered perfectly.

Regarding scalability, our baselines are the D-AHC computational costs. Therefore, the memory and running time reductions are reported in comparison to the performances obtained by D-AHC. Relative storage and processing time decreases are thus examined. However, note that these points are mainly analyzed in the case of real-world benchmarks. Indeed, synthetic data sets are small-size and, in these cases it is not worth discussing computational gains in details.

6.2 Artificial Data

Small-size artificial data sets are used in the goal of illustrating the ability of SNK-AHC to address challenging clustering tasks.

In all experiments, before computing the inner-product matrix, we centered and scaled the data matrix with respect to the mean and standard deviation of the variables.

6.2.1 Aggregation Data

The first benchmark is taken from (Gionis et al., 2007). It consists of 788 points in a two-dimensional space. The objects and clusters are represented in Figure 4. There are seven different groups to identify. These clusters have different sizes and shapes. They can be non-convex and connected as well.

In (Gionis et al., 2007), the authors show the shortcomings of classic D-AHC methods such as the single linkage, complete linkage, group average and Ward schemes. The k-means algorithm also fails to recover the seven clusters. In this previous work, Euclidean distances were used.

In Table 5, we report the performance measures obtained by the different schemes used in the framework of SNK-AHC. A Gaussian kernel and the nearest neighbors sparsification operator $\mathbb{NN}_k$ were applied.

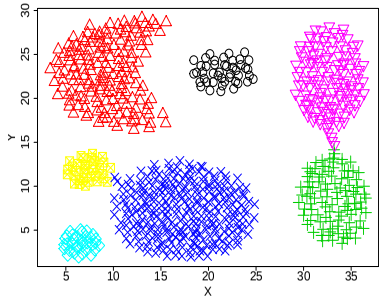

Figure 4: Aggregation data set.

Regarding the Gaussian kernel, we remind its definition below:

$$\mathbf{S}_{ab} = \exp(-\gamma \|\mathbf{x}^a - \mathbf{x}^b\|^2), \quad \forall a, b \in \mathbb{O}$$

We set $\gamma = 1/q$, q being the number of descriptive variables. This default setting is used in popular SVM tools like (Chang and Lin, 2011).

Concerning $\mathbb{NN}_k$, the distinct k values were successively set to (the nearest integer of) $\{100, 90, 75, 50, 25, 10, 1\}$ percent of n, the total number of items. This results in a sequence of sparser and sparser SNK matrices. The two opposite cases are the following ones. $k = n$ corresponds to 100% of the nearest neighbors and in that case, no sparsification is carried out. Applying SNK-AHC without any sparsification is equivalent to K-AHC or D-AHC. This situation corresponds to our baseline. By contrast, setting $k = round(n/100)$ refers to the sparsest similarity matrix that we used.

From Table 5, we observe that:

- For all schemes, when $k = 788$, CC=1. In other words, the obtained dendrograms are equivalent to the ones given by D-AHC. These observations empirically confirm Theorem 8.
- For all methods, a sparse $\mathbf{S}$ matrix that was reduced by up to half of its original memory size, does not alter the quality of SNK-AHC outputs. Therefore, we can improve the scalability without decreasing the ARI values. In addition, we note that the CC values are close to 1. It is likely that the dendrograms we obtain in theses cases are equivalent to the baseline.
- Below fifty percent of nearest neighbors, the performances are not stable and the ARI behavior depends on the method. For median and w-median, the sparsification beyond fifty percent, has a negative effect.
- Conversely, among the interesting cases, group average with only one percent of nearest neighbors was able to recover the correct partition with seven classes (ARI=1).

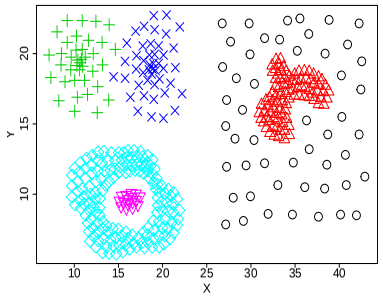

Figure 5: Compound data set.

With the same sparsification level, Ward dramatically improves over its baseline (dense $\mathbf{S}$) since the ARI value increases from 0.688 to 0.965.

- For all methods, κ, the number of clusters found by SNK-AHC, equals one except when $k = 8$. The latter setting corresponds to the sparsest similarity matrix. Only in this case, the underlying graph becomes disconnected and all schemes found five clusters. In Figure 4, the groups that were discovered are the three disconnected clusters (red triangles, black circles and cyan diamonds) and the two pairs of connected clusters which are respectively put together.

6.2.2 Compound Data

The second synthetic data set is a composition of several clustering tasks originally proposed in (Zahn, 1971). It consists of 399 points in a two-dimensional space. The data set is shown in Figure 5. There are six distinct groups of points that are identified with different symbols and colors. This task is particularly challenging since the clusters present very different patterns and are highly non-convex and non-linearly separable.

Similarly to the previous case, we applied a Gaussian kernel using the same default setting. However, the sparsification method we used here is based on a threshold following (26). The different θ values were chosen so that a certain level of sparsity is reached. Precisely, they correspond to the $\{100, 90, 75, 50, 25, 10, 1\}$th percentiles of the similarity values distribution. The 100th percentile does not yield any sparsification. Again, this case is considered as our baseline. On the contrary, the 1th percentile setting means that 99% of the similarity values were thresholded to zero. This latter case is the sparsest $\mathbf{S}$ matrix we experimented with.

The results we obtained are given in Table 6 and we can make the following comments:

- Many observations are actually similar to the ones we made for the previous benchmark. Firstly, when no sparsification is applied, we obtain equivalent dendrograms

Table 6: Results for Compound data set using a Gaussian kernel.

between D-AHC and SNK-AHC. Secondly, an $\mathbf{S}$ matrix that was reduced by half of its original size, provides the same clustering quality than the dense $\mathbf{S}$ matrix. This is true for all techniques. As a consequence, it is possible to divide the computational costs by 2 without degrading the ARI values. Still, when 75% and 90% of similarity values are discarded, we do not obtain consistent improvements. Depending on the scheme, these particular thresholding levels do not always produce better ARI values.

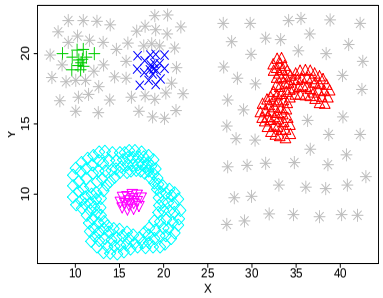

Figure 6: Compound data set results (clusters with size ≤ 3 are all represented by star symbols).

- Considering good performances, we underline the results obtained by the sparsest similarity matrix which only contains the 1% highest similarity values. The ARI value we obtain in this setting reaches 0.906 for all techniques which represents the best overall performance. All methods provided the same partition with 99 clusters. We provide in Figure 6 an illustration of the SNK-AHC outputs. For clarity reasons, we use the same star symbol to represent elements of clusters whose size is lower or equal to three. Note that among the 99 clusters, there are 89 singletons, 3 clusters of size two and 2 clusters of size three. We consider these groups as noise. Consequently, there are 5 "real" clusters that SNK-AHC was able to discover as depicted in Figure 6. Although the high ARI score of 0.906 is partly due to the fact that the SNK-AHC output is a partition with a number of clusters much larger than the ground-truth ($\kappa = 99$ *versus* $\kappa^* = 6$), it is important to precise that this result is a perfect sub-partition of the correct result.

- Finally, we emphasize the fact that SNK-AHC with the sparsest similarity matrix allows us to improve AHC from many viewpoints. Firstly, as we exposed previously, this case gives the best ARI scores and thus shows improvements in comparison with the baselines. The greatest refinement is again observed for the Ward technique whose ARI value increases from 0.501 to 0.906. Secondly, the computational costs of AHC are largely diminished. Last but not least, SNK-AHC was able to detect the core of five correct clusters which have diverse shapes and which were successfully separated from very small groups considered as noise.

6.3 Real-world Data

After having exemplified interesting properties of SNK-AHC on synthetic data sets, we address real-world clustering problems.

In this case, in addition to clustering quality, we discuss in more details the gains that SNK-AHC allow us to achieve in terms of scalability.

Likewise the previous set of experiments, the data matrix was centered and scaled before determining the inner-product matrices.

6.3.1 The Landsat Data Set

The first collection is called the landsat data set[13] which consists of 6,435 items. Each data unit corresponds to a set of 9 contiguous pixels disposed in a 3×3 patch. Each pixel is represented by its four spectral band values which are integer from 0 to 255. Consequently, the objects are described in a vectorial space of 36 dimensions. The task consists in recognizing the nature of an item among six different classes which are: red soil, cotton crop, grey soil, damp grey soil, soil with vegetation stubble, very damp grey soil.

Preliminary experimental results showed that the sparsification based on nearest neighbors provided better clustering results in comparison with the threshold based method. The Gaussian kernel also led to better performances as compared to the linear kernel. Consequently, we report the scores we obtained with these two best performing settings. Concerning $\mathbb{NN}_k$, the sequence of k values used in (27) was set to (the nearest integer of) $\{100, 90, 75, 50, 25, 10\}$ percent of n. As previously, these percentages give an estimation of the density of the $\mathbf{S}$ matrix.

The results we obtained are depicted in Figure 7. Several assessment measures are plotted. ARI and CC curves are represented by dotted lines with triangles and circles respectively. Moreover, the relative memory use and relative running time with respect to the computational costs of the baseline (dense $\mathbf{S}$) are represented. They correspond to solid lines with plus signs and dashed lines with cross signs respectively.

Below are the interesting outcomes we report from this set of experiments:

- On the scalability side, we verify that the sparser the SNK matrix, the lower the memory cost and the processing time since the curves of relative measurements of the two latter criteria clearly decrease. If z is the number of non-null entries in $\mathbf{S}$ then the relative time reduction is linear with respect to this latter variable. In other words, if we reduce $\mathbf{S}$ to 10% of its original memory size then the running time of SNK-AHC will also be reduced to 10% of its initial processing time. This result empirically illustrates Proposition 15.

- On the quality side, we can make the following comments. Firstly, if $k \geq round(n/2)$, the ARI values are not impacted very much whatever the AHC scheme. Likewise the previous benchmarks, we can save nearly half of the initial memory usage and running time without hurting the clustering quality. On the contrary, for the median and w-median approaches, the ARI values are even better. However, when $k < round(n/2)$, the clustering quality is not stable in general. Nevertheless, in the particular cases of group average and Mcquitty, the sparsest similarity matrix given by $k = round(n/10)$ provides the best performances for these techniques. The greatest gain concerns the group average scheme with an ARI score that is more than doubled since it jumped from 0.321 to 0.688.

13. `https://archive.ics.uci.edu/ml/datasets/Statlog+(Landsat+Satellite)`

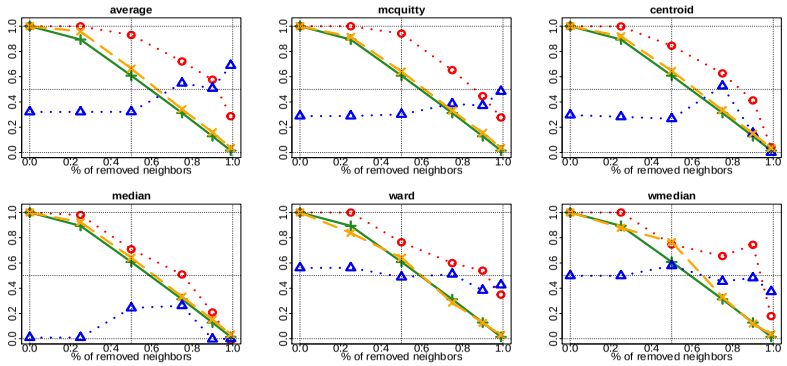

Figure 7: Results for the landsat data set using a Gaussian kernel. The x-axis corresponds to the % of removed neighbors. The y-axis corresponds to the observed values which all belong to $[0, 1]$. Solid lines with plus signs represent the relative memory use, dashed lines with cross signs show the relative running time, dotted lines with circles indicates the CC values, dotted lines with triangles give the ARI values.

- Regarding the new method w-median, it is worth mentioning that it plainly dominates the median scheme. It appears that the non-uniform weight we add to the median technique not only allows obtaining monotonic dendrograms, but it also enables boosting the clustering quality scores.

Note that all similarity graphs are connected even in the case of the sparsest similarity matrix. Thereby, whatever the setting, SNK-AHC always gave a single tree.

6.3.2 The Pendigits Data Set

The second collection we used, is called the pendigits data set[14]. This benchmark consists of handwritten digits that were collected from 44 different writers. Each one of them provided around 250 samples so that the entire collection is composed of 10,992 observations. Each sample is described by 16 numerical features. The 10 digits have equal frequency. Obviously, the task is to recognize groups of elements that correspond to the same digits.

In this case, we report the results we obtained with a linear kernel since they provided similar outcomes than a Gaussian kernel. However, the nearest neighbor sparsification outperformed the one relying on a threshold. Therefore, we report in Figure 8 the scores obtained with this former sparsification technique. We use the same sequence of neighborhood selection as before.

The results we obtain for this benchmark are pretty similar to the landsat case:

14. `https://archive.ics.uci.edu/ml/datasets/Pen-Based+Recognition+of+Handwritten+Digits`

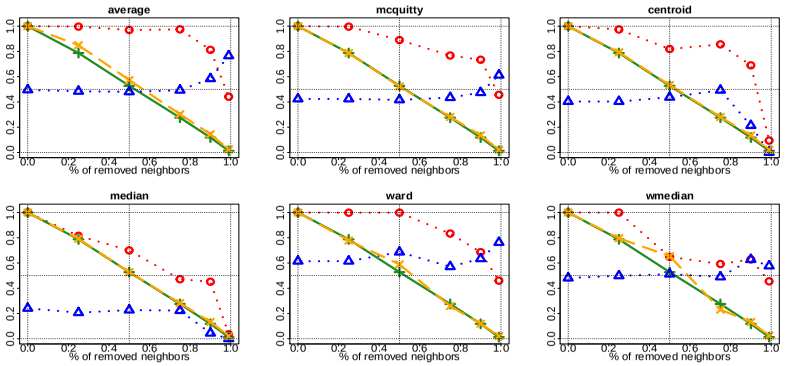

Figure 8: Results for the pendigits data set using a linear kernel. The x-axis corresponds to the % of removed neighbors. The y-axis corresponds to the observed values which all belong to $[0, 1]$. Solid lines with plus signs represent the relative memory use, dashed lines with cross signs show the relative running time, dotted lines with circles indicate the CC values, dotted lines with triangles give the ARI values.

- For all schemes the ARI curves are stable up to 75% of removed neighbors. In regard to scalability, this means that, for any technique, we can save up to ∼70% of memory usage and processing time without degrading the performances. Beyond 75% of removed neighbors, the clustering quality evolution depends on the method. For centroid and median it decreases whereas for the other approaches the ARI curves have a positive slope.

- For group average, Mcquitty and Ward, their respective best ARI scores are achieved with the sparsest $\mathbf{S}$ matrix. Precisely, if we keep only 10% of the nearest neighbors then, the ARI values observed for these techniques clearly outperform their respective baseline. Overall, the best gain and best ARI score is achieved by the group average with a clustering quality going from 0.495 to 0.765 which represents a 54% increase.

- For this data set as well, w-median is superior to median. Moreover, the ARI values we observe for the new method is pretty stable with respect to the level of sparsification.

Similarly to the landsat case, the similarity graph remained connected even with the strongest sparsification we applied.

7. Related Work and Discussion

Our approach is meant to be generic, scalable and effective with respect to challenging clustering tasks where objects belong to non-linear manifolds. Different types of previous

research works are relevant to our framework.

In order to face the inherent scalability issues of hierarchical clustering, several algorithms were introduced in the data mining community. BIRCH (Zhang et al., 1996) and CURE (Guha et al., 1998) are famous examples in that respect. These approaches use random sampling and/or a pre-clustering stage in order to reduce the number of elements to convey to the hierarchical clustering. These methods rely on a vectorial representation of the objects and use classic distances between points.

Carrying out an AHC approach on a sparse graph in the goal of speeding up the hierarchy construction was also studied in (Franti et al., 2006). In this work as well, objects are points in a vectorial space and weighted squared Euclidean distances serve as dissimilarity values. The authors use a directed k nearest neighbors graph. After each merge, the list of the k closest points to each centroid is approximately updated.

These research works provide efficient algorithms. However, they are not generic models of hierarchical clustering. In particular, they assume a feature based description of the items (stored data approach) and in this vectorial representation, the dissimilarities are all related to squared Euclidean distances. In our case, SNK-AHC relies on a generic model that allows designing different kinds of proximity relationships between clusters.

From this standpoint, our approach is in line with the works that were developed during the 1960's in the fields of statistics and data analysis. Overviews of these works can be found in (Gordon, 1987; Everitt et al., 2009; Mirkin, 1996; Murtagh and Contreras, 2012). The LW equation plays a core role in this landscape since it formally represents an infinite family of hierarchical clustering techniques. Furthermore, it makes it possible to algebraically study and define particular sub-families which satisfy different appealing conditions. The guarantee to output a monotonic dendrogram is an example of such conditions. In more general terms, these properties are named admissibility conditions (see for e.g. (Fisher and Van Ness, 1971; Chen and Van Ness, 1994, 1996; Mirkin, 1996)). More recently, Ackerman and Ben-David (2016) introduced other types of properties that characterize a class of linkage-based hierarchical clusterings.

In this context, several research papers have also addressed the scalability problems of D-AHC. We can highlight two research lines in that regard. The first one is essentially a matter of implementation and concerns the whole family of LW clusterings. In fact, by leveraging advanced data structure it is possible to speed-up D-AHC (Anderberg, 1973; Day and Edelsbrunner, 1984). By employing priority queues to efficiently store the nearest neighbors, the running time of the minimum search can be reduced. Maintaining the priority queues can also be done in an efficient fashion and overall, the time complexity of D-AHC can be reduced from cubic to a best-case $O(n^2)$ cost (Day and Edelsbrunner, 1984; Müllner et al., 2013).

In contrast to the previous research avenue, the second research line only involves a subfamily of AHC schemes. It is based on a property called reducibility which was stated by Bruynooghe (1978), and the resulting algorithm is usually named nearest neighbor chains. The reducibility condition is not satisfied by centroid and median for which the latter algorithm is not equivalent to D-AHC. For the other methods, it is an exact procedure that has a worst-case $O(n^2)$ time complexity instead of cubic. The nearest neighbor chains

procedure has been studied and implemented by several authors (de Rham, 1980; Juan, 1982; Benzécri, 1982; Murtagh, 1984; Müllner et al., 2013). More recently, Nguyen et al. (2014) has proposed a memory-efficient online hierarchical clustering called SparseHC which also relies on the reducibility property. However, only single, complete and group average linkages are considered.

These latter research works only focus on the computational efficiency of the usual D-AHC framework. SNK-AHC is able to effectively tackle a more general class of clustering problems.

Complex data such as texts, graphs, images and so on, do not necessarily lie on linear sub-spaces but rather on manifolds. Euclidean distances in the given descriptive space may fail to determine non-convex and arbitrary shapes. In order to better capture the underlying geometry of the data, other different approaches have been proposed in the literature.

In the context of non-parametric hierarchical clustering, one first group of papers, adopts a graph point of view of the clustering task. In particular, the nearest neighbors graph derived from the pairwise proximity values allows a better approximation of the natural geometries of groups of points. It is well-known that the single linkage leads to a chaining effect that is quite effective for arbitrary shapes detection as compared to other schemes. Gower and Ross (1969) pointed out the strong link between single linkage and the minimum spanning tree (MST) problem. Then Zahn (1971) analyzed more in details the application of the MST algorithm to the detection of groups that are non-convex and non-linearly separable. In this context, edge removal appears to be an effective mean to allow the MST to capture a large spectrum of shapes.

Other approaches use non-parametric proximity measures that rely on mutual nearest neighbors and rank-based linkages in order to recover arbitrary clusters shapes (Jarvis and Patrick, 1973; Gowda and Krishna, 1978). More recently, Balcan et al. (2014) uses common nearest neighbors and defines a two-step hierarchical clustering that is robust to outliers and which has interesting properties under some good neighborhood conditions.

Another related work in this context is the CHAMELEON algorithm introduced in (Karypis et al., 1999). It also proceeds in two stages and uses k nearest neighbors graphs. CHAMELEON presents another common point with SNK-AHC since it emphasizes the contrast between inter and intra connectivities of clusters. This so-called dynamic modeling is similar in spirit to our penalized similarities. However, the authors do not propose a generic model unlike our parametric recurrence equations (12a) and (12b).

Yet another research direction for manifold learning is through the use of kernel functions that map the data points from the original description space to a higher dimensional Hilbert space, called the feature space (see for e.g. (Lee and Verleysen, 2007)). It is expected that in the new space, the clusters are easier to detect. To our knowledge, only a few papers have extended D-AHC to kernels (Qin et al., 2003; Endo et al., 2004). In contrast to our model, these papers do not consider the scalability issues. Our previous work (Ah-Pine and Wang, 2016) also studies an inner-product based formulation of the LW equation. In addition, sparse kernel matrices are also employed. Nonetheless, this latter model is different from the framework we present in this paper. In particular, the concept of weighted penalized similarities and the theoretical results we provide are not examined in the framework introduced in (Ah-Pine and Wang, 2016).

Lastly, it is worth emphasizing the relationships between SNK-AHC and spectral clustering (Shi and Malik, 2000; Ng et al., 2001; Von Luxburg, 2007). In the latter family of techniques, kernel functions are employed to construct a similarity graph between objects. Then a sparsification method is applied and the Laplacian of the resulting graph is determined. Theoretical results from spectral graph theory (see for e.g. (Van Mieghem, 2010)) show the links between the eigen-decomposition of the Laplacian and the connected components of the graph. Spectral clustering is a two step procedure which performs a spectral embedding of the objects and subsequently applies a flat clustering method in the new space. The k-means algorithm is usually used in the second step. In this context, roughly speaking, we believe that SNK-AHC is to the classic D-AHC what spectral clustering is to the usual k-means: a significant extension of a conventional clustering method (a sub-family of LW clusterings in our case) which can recover groups of points with non-spherical shapes and which provide an interesting mean to guess the number of clusters. Besides, our approach has all the advantages that hierarchical clustering has over partitional clustering. In addition, since SNK-AHC is much more scalable than D-AHC, it does not have the major drawbacks of hierarchical clustering methods.

8. Conclusion and Future Work

We have introduced K-AHC a generic AHC model which relies on inner-products instead of squared Euclidean distances. Our approach is based on two recurrence formulas which embeds a sub-family of LW clustering techniques. In order to make our model efficient and effective for challenging clustering tasks, we apply K-AHC on a sparsified normalized kernel matrix. In that perspective, the two recurrence formulas highlight aggregation of inter-similarities on the one hand and of intra-similarities on the other hand. Our work can be viewed as a dynamic modeling of weighted penalized similarities of clusters. Moreover, by constraining the bottom-up merging procedure to only fuse pairs of clusters whose inter-similarity value is non-null, our method, SNK-AHC, not only is more scalable than the usual D-AHC, but it is also able to boost the clustering quality and to detect the number of clusters.

However, the performances that SNK-AHC can reach, depend on the way the similarity matrix is sparsified. Note that this is also the case for any method that relies on sparse similarity graphs such as spectral clustering. Therefore, one important future line of research is the study and design of more advanced sparsification techniques. From a clustering quality standpoint, the setting of the sparsification method is an important question to address in practice since it determines the connected components of the SNK matrix and thus the number of clusters our approach will recover. In order to investigate this problem from a theoretical point of view, the cluster tree framework introduced in (Chaudhuri and Dasgupta, 2010) and (Balakrishnan et al., 2013) could be of interest. Regarding the overall complexity of Algorithm 4, techniques that make it possible to exactly or approximately determine nearest neighbors graphs in an efficient manner are important to look at. Indeed, even though the dendrogram building procedure performed by SNK-AHC can be carried out efficiently, the basic computational cost for determining the k nearest neighbors graph remains quadratic and can be a bottleneck in practice.

Still, it is interesting to mention, that, as far as the tree building procedure is concerned, there are already pretty immediate ways to further improve the scalability of our approach. As underlined in the previous section, two directions could be considered. Firstly, we can enhance the complexity of SNK-AHC by using priority queues. Secondly, we can use the nearest neighbor chains approach. In that regard, note that the best performances we observed in our experiments concern schemes that satisfy the reducibility condition.

Finally, our model is generic but we have demonstrated that not all parameters settings are worth considering. From this standpoint, it is interesting to examine how other admissibility conditions are expressed in our framework. In that perspective, a new property which is peculiar to our work is the diagonal translation invariance. We proved that group average, Mcquitty and Ward satisfy this condition. These techniques are among the most effective ones from the experimental results we reported. Accordingly, a characterization of this sub-family of clustering techniques would be beneficial.

Abstract

Markov blanket (Mb) and Markov boundary (MB) are two key concepts in Bayesian networks (BNs). In this paper, we study the problem of Mb and MB for multiple variables. First, we show that Mb possesses the additivity property under the local intersection assumption, that is, an Mb of multiple targets can be constructed by simply taking the union of Mbs of the individual targets and removing the targets themselves. MB is also proven to have additivity under the local intersection assumption. Second, we analyze the cases of violating additivity of Mb and MB and then put forward the notions of Markov blanket supplementary (MbS) and Markov boundary supplementary (MBS). The properties of MbS and MBS are studied in detail. Third, we build two MB discovery algorithms and prove their correctness under the local composition assumption. We also discuss the ways of practically doing conditional independence tests and analyze the complexities of the algorithms. Finally, we make a benchmarking study based on six synthetic BNs and then apply MB discovery to multi-class prediction based on a real data set. The experimental results reveal our algorithms have higher accuracies and lower complexities than existing algorithms.

Keywords: Markov blanket, Markov boundary, Markov blanket supplementary, Markov boundary supplementary, Bayesian network

1. Introduction

Bayesian networks (BNs) are graphical structures used to represent the probabilistic relations among a large number of variables and to make the associated probabilistic inferences (Neapolitan, 2004; Pearl, 1988). In recent years, BNs have become one of the most powerful tools in encoding uncertain expert knowledge in expert systems (Daly et al., 2011; Parviainen and Koivisto, 2013) and also deeply influenced on many other actual domains such as medical diagnosis, financial analysis, bioinformatics, and industrial applications (Zhang and Guo, 2006).

*. Corresponding Author.

As two important concepts in BNs, Markov blanket (Mb) and Markov boundary (MB) play a key role in feature selection (FS; Fu and Desmarais, 2010; Pellet and Elisseeff, 2008; Aliferis et al., 2010a,b). Mathematically, Pearl (1988, pp. 218–221) showed the conditional probability for the target given other variables can be replaced by the MB as the conditional set. Pellet and Elisseeff (2008, pp. 1299, 1302) proved that an MB is the theoretically optimal set of features. Further, under certain assumptions about the learner and the loss function, MB is the solution to the variable selection problem (Tsamardinos and Aliferis, 2003; Statnikov et al., 2013).

So far most authors have focused on the problem of Mb or MB for a single variable. In this paper, we consider the problem of Mb and MB for multiple variables. This occurs if, for example, one wants to compute the joint probability of two or more variables conditioned on all other variables. The basic question for Mb of multiple variables is whether the additivity property holds, that is, can an Mb of multiple variables be constructed by simply taking the union of the Mbs of the individual variables and removing the target variables themselves? The same question is for MB. Further, if the additivity property is violated in some situation, how can we do it?

In the literature, there have been lots of MB discovery algorithms, such as the Koller-Sahami (`KS`) algorithm (Koller and Sahami, 1996), the grow-shrink (`GS`) algorithm (Margaritis and Thrun, 1999, 2000), the incremental association Markov boundary (`IAMB`) algorithm (Tsamardinos et al., 2003) and its several variants, the `HITON` algorithm (Aliferis et al., 2003), the max-min Markov boundary (`MMMB`) algorithm (Tsamardinos et al., 2006), the parents and children based Markov boundary (`PCMB`) algorithm and `KIAMB` algorithms (Peña et al., 2007), the `BFMB` algorithm (Fu and Desmarais, 2007), the algorithmic framework called generalized local learning (`GLL`, Aliferis et al., 2010a), and some others (Fu and Desmarais, 2010; Schlüter, 2014). For a single target variable, most of these algorithms are efficient to seek an approximate MB; for multiple target variables, if simply regarding them as a multivariate variable, these algorithms seem to be feasible. However, this will lead to low accuracies and high computational complexities. Hence, it is necessary to design more efficient MB discovery algorithms for multiple variables.

The remainder of this paper is organized as follows. Section 2 presents necessary preliminaries and the motivations of this paper. Subsection 3.1 shows additivity of Mb and MB under the local intersection assumption. In Subsection 3.2, we first analyze when additivity is violated and then put forward the notions of Markov blanket supplementary (MbS) and Markov boundary supplementary (MBS). The properties of MbS and MBS are studied detailedly. In Section 4, we design two MB discovery algorithms for multiple variables, and prove their correctness under the local composition assumption. In addition, we discuss the ways of practically doing conditional independence (CI) tests and analyze the complexities of the algorithms. Section 5 makes a benchmarking study based on six synthetic BNs, and Section 6 considers a practical application. The experimental results show the superiority of our algorithms with higher accuracies and lower complexities than existing algorithms. Section 7 concludes this paper and presents three remarks.

2. Preliminaries and Motivations

In the paper, we denote a variable and its value by upper-case and lower-case letters in italics (e.g., X, x), a set of variables and its value by upper-case and lower-case bold letters in italics (e.g., $\boldsymbol{X}$, $\boldsymbol{x}$). The difference between $\boldsymbol{X}$ and $\boldsymbol{Y}$ is denoted by $\boldsymbol{X} \setminus \boldsymbol{Y}$. For brevity, we write $(\boldsymbol{X} \setminus \boldsymbol{Y}) \setminus \boldsymbol{Z}$ as $\boldsymbol{X} \setminus \boldsymbol{Y} \setminus \boldsymbol{Z}$. In addition, we use $|\boldsymbol{X}|$ to denote the number of variables involved in $\boldsymbol{X}$.

2.1 Preliminaries

Suppose we have a joint probability distribution $\mathbb{P}$ over $\boldsymbol{V} \triangleq \{X_1, \cdots, X_p\}$ and a directed acyclic graph (DAG) $\mathbb{G}$ with the variables in $\boldsymbol{V}$ as its nodes. We say $(\mathbb{G}, \mathbb{P})$ satisfies the Markov condition if every $X \in \boldsymbol{V}$ is conditionally independent of its nondescendants given its parents; Further, $(\mathbb{G}, \mathbb{P})$ is called a Bayesian network (BN) if it satisfies the Markov condition; Furthermore, $(\mathbb{G}, \mathbb{P})$ satisfies the faithfulness condition if, based on the Markov condition, $\mathbb{G}$ entails all and only conditional independences (CIs) in $\mathbb{P}$ (Pearl, 1988; Neapolitan, 2004).

We write $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$ ($\boldsymbol{X} \not\perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$), if $\boldsymbol{X}$ and $\boldsymbol{Y}$ are conditionally independent (dependent) given $\boldsymbol{Z}$ with respect to $\mathbb{P}$. The following properties describe the relations among CI statements (Pearl, 1988; Peña et al., 2007; Statnikov et al., 2013). For any $\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z}, \boldsymbol{W} \subseteq \boldsymbol{V}$, we have (i) *symmetry*: $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$ is equivalent to $\boldsymbol{Y} \perp\!\!\!\perp \boldsymbol{X} \,|\, \boldsymbol{Z}$; (ii) *decomposition*: $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \cup \boldsymbol{W} \,|\, \boldsymbol{Z}$ implies $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$ and $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{W} \,|\, \boldsymbol{Z}$; (iii) *weak union*: $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \cup \boldsymbol{W} \,|\, \boldsymbol{Z}$ implies $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z} \cup \boldsymbol{W}$; (iv) *contraction*: $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z} \cup \boldsymbol{W}$ and $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{W} \,|\, \boldsymbol{Z}$ imply $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \cup \boldsymbol{W} \,|\, \boldsymbol{Z}$; (v) *self-conditioning*: $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Y} \cup \boldsymbol{Z}$. Further, if $\mathbb{P}$ is strictly positive, then besides (i)∼(v) we also have (vi) *intersection*: $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z} \cup \boldsymbol{W}$ and $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{W} \,|\, \boldsymbol{Z} \cup \boldsymbol{Y}$ imply $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \cup \boldsymbol{W} \,|\, \boldsymbol{Z}$. Furthermore, if $\mathbb{P}$ is faithful to a DAG $\mathbb{G}$, then besides (i)∼(vi) we also have (vii) *composition*: $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$ and $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{W} \,|\, \boldsymbol{Z}$ imply $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \cup \boldsymbol{W} \,|\, \boldsymbol{Z}$.

Among these properties, intersection and composition are two global ones. Statnikov et al. (2013, p. 504) provided a relaxed version for composition called *local composition*: one says $\boldsymbol{T} \subseteq \boldsymbol{V}$ satisfies the local composition property, if $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{X} \,|\, \boldsymbol{Z}$ and $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$ imply $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{X} \cup \boldsymbol{Y} \,|\, \boldsymbol{Z}$ for any $\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \boldsymbol{T}$. We will provide a relaxed version for the intersection property.

Conditional mutual information (CMI) is one of the basic tools for testing CIs. Denote the CMI between $\boldsymbol{X}$ and $\boldsymbol{Y}$ conditioned on $\boldsymbol{Z}$ by $\mathbb{I}(\boldsymbol{X}; \boldsymbol{Y} \mid \boldsymbol{Z})$. Then $\mathbb{I}(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) \geqslant 0$, with equality holding if and only if $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$ (Zhang and Guo, 2006). For a practical problem, we cannot access to the true CMI; instead, we use its empirical estimate, denoted by $\mathbb{I}_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \mid \boldsymbol{Z})$, based on the data $\boldsymbol{D}$ (Cheng et al., 2002). Note that $\mathbb{I}_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \mid \boldsymbol{Z}) \geqslant 0$ also holds for any $\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z} \subseteq \boldsymbol{V}$.

The *chain rule* for CMI (Cover and Thomas, 2006) is useful to prove the main results of this paper: $\mathbb{I}(\boldsymbol{X}; \boldsymbol{Y}_1 \cup \boldsymbol{Y}_2 \,|\, \boldsymbol{Z}) = \mathbb{I}(\boldsymbol{X}; \boldsymbol{Y}_1 \,|\, \boldsymbol{Z}) + \mathbb{I}(\boldsymbol{X}; \boldsymbol{Y}_2 \,|\, \boldsymbol{Z} \cup \boldsymbol{Y}_1)$ holds for any four sets of variables $\boldsymbol{X}$, $\boldsymbol{Y}_1$, $\boldsymbol{Y}_2$, and $\boldsymbol{Z}$ from $\boldsymbol{V}$.

Another notion closely related to CI is d-separation (Pearl, 1988, p. 117). For a DAG $\mathbb{G}$ over $\boldsymbol{V}$, letting $\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z} \subseteq \boldsymbol{V}$ be disjoint, we say $\boldsymbol{Z}$ d-separates $\boldsymbol{X}$ and $\boldsymbol{Y}$ if it blocks every path between $\boldsymbol{X}$ and $\boldsymbol{Y}$, and if this is the case we write $\boldsymbol{X} \perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$. Here, $\boldsymbol{Z}$ blocking a path $\mathbb{c}$ means that $\mathbb{c}$ has a head-to-tail node or a tail-to-tail node belonging to $\boldsymbol{Z}$, or that $\mathbb{c}$ has a head-to-head node C such that C and its all descendants are not in $\boldsymbol{Z}$. As well known, $\boldsymbol{X} \perp \boldsymbol{Y} \,|\, \boldsymbol{Z} \Rightarrow \boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$, if $(\mathbb{G}, \mathbb{P})$ is a BN (Neapolitan, 2004, p. 74). This implication provides a convenient way of identifying CIs.

For example, consider a BN with the graph presented in Figure 1 as its DAG. It follows that: X_2 and X_8 are d-separated by $\{X_4, X_5\}$, meaning $X_2 \perp X_8 \,|\, \{X_4, X_5\}$ and thus $X_2 \perp\!\!\!\perp X_8 \,|\, \{X_4, X_5\}$; X_3 and X_4 are d-separated by $\emptyset$, meaning $X_3 \perp X_4$, so $X_3 \perp\!\!\!\perp X_4$. Note that these two probabilistic CIs can not be directly derived from the Markov condition.

In what follows, the concepts of Mb and MB are presented. They are a direct extension of Mb and MB for a single target variable (Pearl, 1988, p. 97; Neapolitan, 2004, pp. 108–109): an Mb of $\boldsymbol{T}$ is a set of variables shielding $\boldsymbol{T}$ from all other variables, so it carries all information of $\boldsymbol{T}$ that cannot be obtained from other variables, while an MB is a minimal Mb.

Definition 1 *Let $\boldsymbol{T} \subseteq \boldsymbol{V}$ and $\boldsymbol{M} \subseteq \boldsymbol{V} \setminus \boldsymbol{T}$. We call $\boldsymbol{M}$ a Markov blanket (Mb) of $\boldsymbol{T}$ if $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M} \setminus \boldsymbol{T} \,|\, \boldsymbol{M}$. Further, a Markov boundary (MB) of $\boldsymbol{T}$ is any Mb such that none of its proper subsets is an Mb.* ■

When $|\boldsymbol{T}| = 1$, the following results are well known in the literature (Pearl, 1988; Neapolitan, 2004; Statnikov et al., 2013): (a) if $(\mathbb{G}, \mathbb{P})$ is a BN, then for $T \in \boldsymbol{V}$ the set of its all parents, children, and spouses is an Mb of T (denoted by $\boldsymbol{M}_T$); (b) if $\mathbb{P}$ satisfies the intersection property, then T has a unique MB; (c) if $(\mathbb{G}, \mathbb{P})$ satisfies the faithfulness condition, then $\boldsymbol{M}_T$ is the unique MB of T.

Consider again the BN with the graph presented in Figure 1 as its DAG. In this BN, it is seen that $\boldsymbol{M}_{X_4} \triangleq \{X_2, X_6, X_3\}$ is an Mb of X_4; further, $\boldsymbol{M}_{X_4}$ is the unique MB of X_4 if the faithfulness condition is satisfied. Similarly, $\boldsymbol{M}_{X_2} \triangleq \{X_4, X_5\}$ is the unique MB of X_2 under the faithfulness condition.

The above result (b) points out that if the uniqueness of MB is violated, then the intersection property must be violated. Lemeire (2007) provided a case of violating intersection called *information equivalence*: $\boldsymbol{X}$ and $\boldsymbol{Y}$ are called information equivalent with respect to $\boldsymbol{T}$ if $\boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{X}$, $\boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{Y}$, $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{X} \,|\, \boldsymbol{Y}$, and $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{X}$. A related notion is *conditional information equivalence* (Lemeire et al., 2012; Statnikov et al., 2013): $\boldsymbol{X}$ and $\boldsymbol{Y}$ are called to be conditionally information equivalent with respect to $\boldsymbol{T}$ given $\boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \boldsymbol{X} \setminus \boldsymbol{Y} \setminus \boldsymbol{T}$, if $\boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{X} \,|\, \boldsymbol{Z}$, $\boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$, $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{X} \,|\, \boldsymbol{Y} \cup \boldsymbol{Z}$, and $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{X} \cup \boldsymbol{Z}$. Lemeire et al. (2012, pp. 1309–1311) showed that (conditional) information equivalence is one of the two major cases in which *adjacency faithfulness* is violated. Here, the adjacency faithfulness condition (Ramsey et al., 2006; Lemeire et al., 2012) is defined as: if X and Y are adjacent, then $X \not\perp\!\!\!\perp Y \,|\, \boldsymbol{Z}$ for any $\boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \{X, Y\}$. Statnikov et al. (2013, p. 503) provided a local version for adjacency faithfulness by focusing on a specific variable.

Here, we employ the information flow metaphor (Cheng et al., 2002) to intuitively explain information equivalence: we can view a BN as a network of information channels, where each node is a *valve* that is either active or inactive; the valves are connected by *information channels*; information can flow through an active valve but not an inactive one; instantiating a node means this valve becomes inactive. We extend this metaphor by viewing a clique of one or more nodes as a valve. In this sense, a CI relation $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$ means all the channels between $\boldsymbol{X}$ and $\boldsymbol{Y}$ are cut off by $\boldsymbol{Z}$ and thus the information between $\boldsymbol{X}$ and $\boldsymbol{Y}$ can not flow once $\boldsymbol{Z}$ becomes inactive. When information equivalence occurs, we further extend this information flow metaphor as follows: if $\boldsymbol{X}$ and $\boldsymbol{Y}$ are information equivalent with respect to $\boldsymbol{T}$ given $\boldsymbol{Z}$, then there exists an *information equivalent valve*, denoted by $\delta_{\boldsymbol{X},\boldsymbol{Y};\boldsymbol{T}\,|\,\boldsymbol{Z}}$, which connects $\boldsymbol{T}$ and $\boldsymbol{X}$ and connects $\boldsymbol{T}$ and $\boldsymbol{Y}$; *$\delta_{\boldsymbol{X},\boldsymbol{Y};\boldsymbol{T}\,|\,\boldsymbol{Z}}$ is active when and only when both $\boldsymbol{X}$ and $\boldsymbol{Y}$ are active.* Then, the relation "$\boldsymbol{X}$ and $\boldsymbol{Y}$ are information equivalent with respect to $\boldsymbol{T}$ given $\boldsymbol{Z}$" can be presented in Figure 2.

Information equivalence represents all the possible situations leading to the nonuniqueness of MB. In fact, we can show the following result, which indicates that violating the uniqueness of MB implies the presence of information equivalence. The proof is presented in Section B.

Lemma 1 *The intersection property holds if and only if no information equivalence occurs.* ■

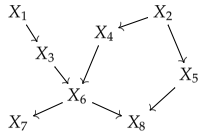

Figure 1: A simple DAG used to illustrate d-separation.

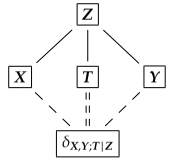

Figure 2: An intuitive illustration for information equivalence.

By analyzing the proof of Lemma 1, we present a relaxed version for the intersection property called *local intersection* as follows.

Definition 2 (Local Intersection) *Letting $\boldsymbol{T} \subseteq \boldsymbol{V}$, we say $\boldsymbol{T}$ satisfies the local intersection property, if the following two types of local conditions hold simultaneously:* (i) *type-I local condition: in the case of $|\boldsymbol{T}| \geqslant 2$, for any disjoint $\boldsymbol{T}_1, \boldsymbol{T}_2 \subseteq \boldsymbol{T}$, there are no disjoint $\boldsymbol{X}, \boldsymbol{Y} \subseteq \boldsymbol{V} \setminus \boldsymbol{T}$ such that $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$ are information equivalent with respect to $\boldsymbol{X}$ conditioned on $\boldsymbol{Y}$; and* (ii) *type-II local condition: there are no disjoint $\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \boldsymbol{T}$ such that $\boldsymbol{X}$ and $\boldsymbol{Y}$ are information equivalent with respect to $\boldsymbol{T}$ conditioned on $\boldsymbol{Z}$.* ■

Clearly, *intersection* implies *local intersection* but not vice versa, because the former requires no any information equivalence while the latter only requires no information equivalence between the targets and the remaining variables. Here, we give a lemma concerning the uniqueness of MB under the local intersection assumption. The proof is presented in Appendix B.

Lemma 2 *For $\boldsymbol{T} \subseteq \boldsymbol{V}$, assume the type-II local condition defined in Definition 2 holds. Then $\boldsymbol{T}$ has a unique MB.* ■

To facilitate the identification of information equivalence, Lemeire (2007) ever introduced the notions of target partition (T-partition) and equivalent partition (E-partition), and then provided a relation among information equivalence, T-partition, and E-partition.

- T-partition: The domain, $\boldsymbol{X}_{\text{dom}}$, of $\boldsymbol{X}$ can be partitioned into disjoint subsets $\boldsymbol{X}_{\text{dom}}^{(k)}$ for which $\mathbb{P}(\boldsymbol{T}\,|\,\boldsymbol{x})$ is the same for all $\boldsymbol{x} \in \boldsymbol{X}_{\text{dom}}^{(k)}$. This is called the T-partition of $\boldsymbol{X}_{\text{dom}}$ with respect to $\boldsymbol{T}$.
- E-partition: A relation $\Re \subset \boldsymbol{X} \otimes \boldsymbol{Y}$ defines an E-partition in $\boldsymbol{Y}_{\text{dom}}$ to a partition of $\boldsymbol{X}_{\text{dom}}$, if: (i) $\neg(\boldsymbol{x}_2 \Re \boldsymbol{y}_1)$ holds for any $\boldsymbol{x}_1, \boldsymbol{x}_2 \in \boldsymbol{X}_{\text{dom}}$ belonging to different partitions and for any $\boldsymbol{y}_1 \in \boldsymbol{Y}_{\text{dom}}$ with $\boldsymbol{x}_1 \Re \boldsymbol{y}_1$; and (ii) for every $\boldsymbol{X}_{\text{dom}}^{(k)}$, there exist $\boldsymbol{x}_1 \in \boldsymbol{X}_{\text{dom}}^{(k)}$ and $y_1 \in \boldsymbol{Y}_{\text{dom}}$ such that $\boldsymbol{x}_1 \Re \boldsymbol{y}_1$.
- Relation among *information equivalence*, *T-partition*, and *E-partition*: If $\boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{X}$ and $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{Y}\,|\,\boldsymbol{X}$, then $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{X}\,|\,\boldsymbol{Y}$ (meaning $\boldsymbol{X}$ and $\boldsymbol{Y}$ are information equivalent with respect to $\boldsymbol{T}$) if and only if the relation $\boldsymbol{x} \Re \boldsymbol{y}$ defined by $\mathbb{P}(\boldsymbol{x}, \boldsymbol{y}) > 0$ with $\boldsymbol{x} \in \boldsymbol{X}_{\text{dom}}$ and $y \in \boldsymbol{Y}_{\text{dom}}$ defines an E-partition in $\boldsymbol{Y}_{\text{dom}}$ to the T-partition of $\boldsymbol{X}_{\text{dom}}$ with respect to $\boldsymbol{T}$.

The graph shown in Figure 3, originally presented by Statnikov and Aliferis (2010), makes an intuitive illustration on T-partition and E-partition. As seen, $\{1, 2\}$ and $\{3\}$ constitute the T-partition of $A_{\text{dom}} \triangleq \{1, 2, 3\}$ with respect to C; $\{1, 2\}$ and $\{3\}$ are the E-partition of $B_{\text{dom}} \triangleq \{1, 2, 3\}$ to the T-partition of A_{dom}, Therefore, A and B are information equivalent with respect to C if $C \not\perp\!\!\!\perp A$, since $C \perp\!\!\!\perp B\,|\,A$ holds inherently because of the Markov condition.

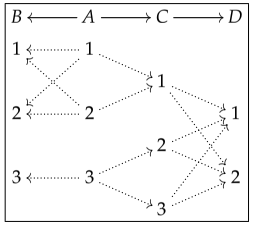

Figure 3: An illustration on T-partition and E-partition: in the DAG "$B \leftarrow A \rightarrow C \rightarrow D$", all variables take $\{1, 2, 3\}$ except for D taking $\{1, 2\}$, and dotted arrows denote all non-zero conditional probabilities of each variable given its parents.

Finally, the notion of *context-independent information equivalence* given by Statnikov et al. (2013) will be used in Example 2. $\boldsymbol{X}$ and $\boldsymbol{Y}$ are called context-independent information equivalent with respect to $\boldsymbol{T}$, if $\boldsymbol{X}$ and $\boldsymbol{Y}$ are information equivalent with respect to $\boldsymbol{T}$ given any $\boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \boldsymbol{X} \setminus \boldsymbol{Y} \setminus \boldsymbol{T}$. For this notion, Statnikov et al. (2013) proved the following conclusion: if $\boldsymbol{M}$ is an Mb of $\boldsymbol{T}$ with $\boldsymbol{X} \subseteq \boldsymbol{M}$, and there is some $\boldsymbol{Y} \subseteq \boldsymbol{V} \setminus \boldsymbol{M} \setminus \boldsymbol{T}$ such that $\boldsymbol{X}$ and $\boldsymbol{Y}$ are context-independent information equivalent with respect to $\boldsymbol{T}$, then $(\boldsymbol{M} \setminus \boldsymbol{X}) \cup \boldsymbol{Y}$ is also an Mb of $\boldsymbol{T}$.

2.2 Two Typical Algorithms: `IAMB` and `KIAMB`

This subsection concisely presents two typical MB discovery algorithms: `IAMB` (Tsamardinos et al., 2003) and `KIAMB` (Peña et al., 2007). We select them because of their high adaptability and time efficiency: (i) correctness of `IAMB` and `KIAMB` requires only the local composition assumption (Statnikov et al., 2013), while the correctness of the parents and children based algorithms, such as `PCMB` and the algorithms in the `GLL` framework, usually requires the faithfulness condition (Peña et al., 2007, Theorem 6; and Aliferis et al., 2010a, Theorem 1); (ii) `IAMB` and `KIAMB` are time efficient and thus suitable for the problem of MB for multiple variables, while the parents and children based algorithms have exponential complexities (Aliferis et al., 2010a, pp. 199–200), so they are hard to work when too many variables are involved, such as the problem of MB discovery for multiple variables.

`IAMB` is an enhanced variant of `GS`. In 2003, Tsamardinos et al. pointed out that `GS` uses a static and potentially inefficient heuristic in the growing phase, and then proposed `IAMB` by employing a dynamic heuristic. Tsamardinos et al. (2003) showed the correctness of `IAMB` under the faithfulness condition; Peña et al. (2007) relaxed the condition to the composition assumption; Statnikov et al. (2013) further relaxed the condition to the local composition assumption. Algorithm 3 describes the pseudo code for `IAMB`. See Appendix A for details.

In the algorithm, there is a function $f_{\boldsymbol{D}}$ (Line 3 of `IAMB` in Algorithm 3) denoting a heuristic used to measure the association between variables (Tsamardinos et al., 2003; Peña et al., 2007). Two widely used selections for $f_{\boldsymbol{D}}$ are CMI (Cheng et al., 2002; Tsamardinos et al., 2003) and the negative p-value (Tsamardinos et al., 2006; Aliferis et al., 2010a,b; Statnikov et al., 2013). Also, Yaramakala (2004, p. 41) suggested an equivalent version of the negative p-value. Subsection 4.3 will make a discussion about the ways of practically doing CI tests and the selections for $f_{\boldsymbol{D}}$.

KIAMB is a stochastic extension of IAMB. It embeds a randomization parameter $K \in [0, 1]$ which specifies the trade-off between greediness and randomness. If taking $K = 1$, KIAMB reduces to IAMB. Peña et al. (2007) proved the correctness of KIAMB under the composition assumption. By the proof, the local composition assumption is sufficient for KIAMB to be correct. Algorithm 3 describes the pseudo code for KIAMB.

For the case of $|\boldsymbol{T}| \geqslant 2$, IAMB and KIAMB can remain correct if strengthening the precondition. We present the correctness of them as follows, without presenting the proof since it is similar to that of the original IAMB and KIAMB (Tsamardinos et al., 2003; Peña et al., 2007; Statnikov et al., 2013). In what follows, we say a CI test for a hypothesis is correct if the statistical decision is correctly made by using a testing method. Subsection 4.3 gives a further discussion on this issue.

Theorem 1 (Correctness of IAMB and KIAMB) *Assume $\boldsymbol{T}$ satisfies the local composition property, and all CI tests are correct. Then* (i) *IAMB outputs an MB of $\boldsymbol{T}$;* (ii) *KIAMB outputs an MB of $\boldsymbol{T}$ for any $K \in [0, 1]$.* ■

2.3 Motivations

This subsection provides three motivations of this paper.

Let $\boldsymbol{M}$ be an MB of T. Then $\mathbb{P}(T \,|\, \boldsymbol{V} \setminus \{T\}) = \mathbb{P}(T \,|\, \boldsymbol{M})$. In other words, all information for predicting T is carried by $\boldsymbol{M}$. Further, $\boldsymbol{M}$ is a solution to the FS problem, if the algorithm that constructs the prediction model can learn any probability distribution, and the performance metric is strictly decreasing with the mean-squared loss with a preference for smaller subsets (Tsamardinos and Aliferis, 2003, Proposition 3). For this reason, MB for a single variable is sufficient.

However, there are the situations where MB for multiple variables is preferred. This occurs if we need the probability distribution of more than one variables given all the others. Let $\boldsymbol{M}_i$ be an MB of T_i for $i = 1, 2$. Denoting $\boldsymbol{T} = \{T_1, T_2\}$, it follows that

$$\mathbb{P}(\boldsymbol{T} \,|\, \boldsymbol{V} \setminus \boldsymbol{T}) = \begin{cases} \mathbb{P}(T_1 \,|\, \boldsymbol{M}_1)\mathbb{P}(T_2 \,|\, \boldsymbol{M}_2) & \text{if } T_1 \notin \boldsymbol{M}_2 \text{ or } T_2 \notin \boldsymbol{M}_1 \\ \mathbb{P}(T_1, T_2, \boldsymbol{V} \setminus \boldsymbol{T}) \,/\, \sum_{t_1, t_2} \mathbb{P}(t_1, t_2, \boldsymbol{V} \setminus \boldsymbol{T}) & \text{if } T_1 \in \boldsymbol{M}_2 \text{ and } T_2 \in \boldsymbol{M}_1 \end{cases}$$

As seen, in the case of $T_1 \in \boldsymbol{M}_2$ and $T_2 \in \boldsymbol{M}_1$, the computation is intractable, especially when the dimension is high. Nevertheless, if we have an MB for $\boldsymbol{T}$, denoted by $\boldsymbol{M}$, then $\mathbb{P}(\boldsymbol{T} \,|\, \boldsymbol{V} \setminus \boldsymbol{T}) = \mathbb{P}(\boldsymbol{T} \,|\, \boldsymbol{M})$ follows immediately, so the problem is simplified greatly. In this sense, it is meaningful to consider the problem of MB for multiple variables.

The second motivation is that we want to know whether the prediction for $\boldsymbol{T}$ will be affected if the observed values of some variables outside $\boldsymbol{T}$ (in a new observation) are missing. Denote these missing variables by $\boldsymbol{V}_{\mathrm{m}}$. This problem can be considered as follows: find an approximate MB (denoted by $\boldsymbol{M}_{\mathrm{m}}$) of $\boldsymbol{T}$ in $\boldsymbol{V} \setminus \boldsymbol{V}_{\mathrm{m}}$ by means of some method, then check if $\boldsymbol{M}_{\mathrm{m}}$ is an Mb in $\boldsymbol{V}$ via some criterion (e.g., a criterion based on Lemma 2 given by Statnikov et al., 2013); and finally assert $\boldsymbol{T}$ will not be affected if the above checking result is "yes". In this sense, it is also preferred to consider MB for multiple variables.

Figure 4 represents the DAG for the ALARM network (Beinlich et al., 1989), which is well known in the literature. Take $T_1 \triangleq X_{22}$ and $T_2 \triangleq X_{23}$. Then, $\boldsymbol{M}_{T_i}$ is the unique MB of T_i for $i = 1, 2$ under the faithfulness condition, with

$$\boldsymbol{M}_{T_1} \triangleq \{X_1, X_4, X_{15}, X_{21}, X_{23}, X_{27}, X_{29}\} \text{ and } \boldsymbol{M}_{T_2} \triangleq \{X_2, X_{22}, X_{24}, X_{25}, X_{27}, X_{29}\}, \tag{1}$$

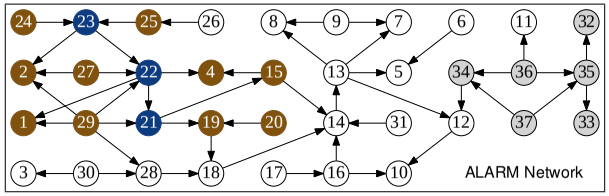

Figure 4: ALARM network (37 nodes and 46 edges): a logical alarm reduction mechanism.

respectively. This leads to intractable computations on the joint probability distribution of T_1 and T_2 given all other variables, consider that $T_1 \in \boldsymbol{M}_{T_2}$ and $T_2 \in \boldsymbol{M}_{T_1}$. Further, if the observed values of some variables (e.g., X_j for $j = 32, 33, \cdots, 37$) in a new observation are missing, can this observation be used any more for predicting T_1 and T_2? Furthermore, we have to face similar problems if three or more target variables are considered.

The third motivation concerns MB discovery algorithms. By Theorem 1, IAMB and KIAMB can be applied to the problem of MB for multiple variables if simply regarding the targets as a multivariate vector, under the strengthened local composition assumption. However, the assumption of local composition imposed on multiple targets may have more occasions to become invalid than imposed on single targets, due to the synergy effect in the sense that neither X nor Y carries information of T but together they contain some information of T (Rauh et al., 2014).

Here is an illustration: considering the BN with the graph in Figure 5 as its DAG, by direct computations using the FullBNT toolbox (Murphy, 2007), we find that

$$\begin{array}{rrll} A \perp\!\!\!\perp C, & A \perp\!\!\!\perp D, & \text{and} & A \perp\!\!\!\perp \{C, D\}; \\ B \perp\!\!\!\perp C, & B \perp\!\!\!\perp D, & \text{and} & B \perp\!\!\!\perp \{C, D\}; \\ \{A, B\} \perp\!\!\!\perp C, & \{A, B\} \perp\!\!\!\perp D, & \text{but} & \{A, B\} \not\perp\!\!\!\perp \{C, D\}. \end{array}$$

By this illustration, the idea of applying the existing MB discovery algorithms to multiple targets seems to be practically improper although it is theoretically feasible, because synergy effects may lead to potential inefficiency and even incorrectness. This motivates us to build some algorithms which are resistant to synergy effects and, further, are time efficient.

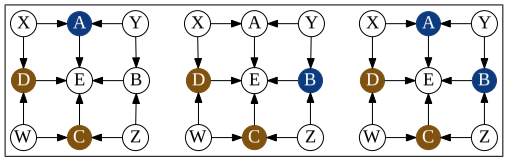

Figure 5: An illustration on synergy effects: each of $\{X, Y, Z, W\}$ takes $\{1, 2\}$ equiprobably; each of $\{A, B, C, D\}$ takes 1 with probabilities p_1, p_2, p_3, p_4 and takes 2 with probabilities $1 - p_1$, $1 - p_2$, $1 - p_3$, $1 - p_4$ given its parents, with $p_4 = p_1 - p_2 + p_3$; E has an arbitrary distribution.

3. Markov Blanket and Markov Boundary for Multiple Variables

This section presents the theoretical results on the problem of Mb and MB for multiple variables when the local intersection property is satisfied and when this property is violated. We study this problem following this way because we are trying to find a suitable approach to transform the problem of Mb and MB from multiple case to single cases, based on which we can build efficient algorithms with high accuracies and low complexities.

3.1 Additivity under Local Intersection

In this subsection, we consider the problem of Mb and MB for multiple variables under the local intersection assumption. We prove Mb and MB possess an ideal property called *additivity*. That is, an Mb of multiple variables can be constructed by simply taking the union of the Mbs of the individual variables and removing the target variables themselves (the same for MB). The results are presented in Theorem 2 and Theorem 3, respectively. Appendix B gives their proofs.

Theorem 2 (Additivity of Mb) *Let $(\mathbb{G}, \mathbb{P})$ be a BN over $\boldsymbol{V}$. The following two statements hold:*

(i) *Let $\boldsymbol{M}_i$ be an Mb of $\boldsymbol{T}_i \subseteq \boldsymbol{V}$ for $i = 1, 2$, and assume $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$ satisfies the local intersection assumption. Then, $(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus (\boldsymbol{T}_1 \cup \boldsymbol{T}_2)$ is an Mb of $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$.*

(ii) *Let $\boldsymbol{M}_i$ be an Mb of $T_i \in \boldsymbol{V}$ for $i = 1, \cdots, k$, and assume $\boldsymbol{T} \triangleq \{T_1, \cdots, T_k\}$ satisfies the local intersection assumption. Then, $\bigcup_{i=1}^{k} \boldsymbol{M}_i \setminus \boldsymbol{T}$ is an Mb of $\boldsymbol{T}$.* ■

The additivity property of Mb can be intuitively described by the information flow metaphor (Cheng et al., 2002) using Figure 6: $(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus (\boldsymbol{T}_1 \cup \boldsymbol{T}_2)$ is enough to cut off all information channels from $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$ to other valves, when no information equivalence associated with $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$ occurs.

Let $\boldsymbol{T} \subseteq \boldsymbol{V}$ be the set of target variables. As we know, in the case of $|\boldsymbol{T}| = 1$ (denoting $\boldsymbol{T} = \{T\}$), the set $\boldsymbol{M}_T$ composed of the parents, children, and spouses of T is an Mb of it (Pearl, 1988), since $\boldsymbol{M}_T$ d-separates T from all other variables. For the case of $|\boldsymbol{T}| \geqslant 2$ (denoting $\boldsymbol{T} = \{T_1, \cdots, T_k\}$), Theorem 2 indicates that the union of all $\boldsymbol{M}_{T_i}$'s with $T_1, \cdots, T_k$ excluded is an Mb of $\boldsymbol{T}$.

Considering the ALARM network presented in Figure 4, we put $T_1 \triangleq X_{22}$ and $T_2 \triangleq X_{23}$. Then $\boldsymbol{M}_{T_i}$ is an Mb of T_i for $i = 1, 2$, where $\boldsymbol{M}_{T_1}$ and $\boldsymbol{M}_{T_2}$ are defined in (1). Assume $\boldsymbol{T}_{1,2} \triangleq \{T_1, T_2\}$ satisfies the local intersection property. It follows from Theorem 2 that

$$(\boldsymbol{M}_{T_1} \cup \boldsymbol{M}_{T_2}) \setminus \boldsymbol{T}_{1,2} = \{X_1, X_2, X_4, X_{15}, X_{21}, X_{24}, X_{25}, X_{27}, X_{29}\} \triangleq \boldsymbol{M}_{1,2} \tag{2}$$

is an Mb of $\boldsymbol{T}_{1,2}$. Those variables outside $\boldsymbol{M}_{1,2}$ contain no information about $\boldsymbol{T}_{1,2}$ conditioned on $\boldsymbol{M}_{1,2}$ and thereby $\mathbb{P}(\boldsymbol{T}_{1,2} \,|\, \boldsymbol{V} \setminus \boldsymbol{T}_{1,2})$ reduces to $\mathbb{P}(\boldsymbol{T}_{1,2} \,|\, \boldsymbol{M}_{1,2})$. Further, if the observed values of

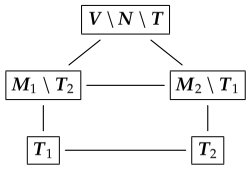

Figure 6: An illustration for additivity of Mb and MB with $\boldsymbol{T} = \boldsymbol{T}_1 \cup \boldsymbol{T}_2$ and $\boldsymbol{N} = (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}$.

X_j for $j = 32, \cdots, 37$ in a new observation are missing, this observation can still be used without affecting the prediction on $\boldsymbol{T}_{1,2}$. Further, $\boldsymbol{M}_{T_3} \triangleq \{X_{15}, X_{19}, X_{20}, X_{22}, X_{29}\}$ is an Mb of $T_3 \triangleq X_{21}$. Assume $\boldsymbol{T}_{1,2,3} \triangleq \{T_1, T_2, T_3\}$ satisfies the local intersection property. Then Theorem 2 shows

$$\boldsymbol{M}_{T_1} \cup \boldsymbol{M}_{T_2} \cup \boldsymbol{M}_{T_3} \setminus \boldsymbol{T}_{1,2,3} = \{X_1, X_2, X_4, X_{15}, X_{19}, X_{20}, X_{24}, X_{25}, X_{27}, X_{29}\} \triangleq \boldsymbol{M}_{1,2,3} \tag{3}$$

is an Mb of $\boldsymbol{T}_{1,2,3}$.

For additivity of Mb shown in (i) of Theorem 2, we have a useful remark (used to simplify our algorithms in Section 4), based on the fact that if $\boldsymbol{M}$ is an Mb of $\boldsymbol{T}$ then $\boldsymbol{M} \cup \boldsymbol{M}_0$ is also an Mb of $\boldsymbol{T}$ for any $\boldsymbol{M}_0 \subseteq \boldsymbol{V} \setminus \boldsymbol{M} \setminus \boldsymbol{T}$. By the remark, the local intersection assumption for additivity of Mb is not required in some special cases. The proof of this remark is given in Appendix B.

Remark 1 *In the case of either $\boldsymbol{T}_1 \subseteq \boldsymbol{V} \setminus \boldsymbol{M}_2$ or $\boldsymbol{T}_2 \subseteq \boldsymbol{V} \setminus \boldsymbol{M}_1$, the conclusion of* (i) *in Theorem 2 holds without requiring the local intersection assumption.* ■

Theorem 2 shows the additivity of Mb. A natural idea is to wonder if additivity is possessed by MB. Theorem 3 affirms this. Appendix B provides the proof. Note that the statements about the uniqueness of MB in this theorem follow from Lemma 2.

Theorem 3 (Additivity of MB) *Let $(\mathbb{G}, \mathbb{P})$ be a BN over $\boldsymbol{V}$. The following two statements hold:*

(i) *Assume $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$ satisfies the local intersection assumption. Let $\boldsymbol{M}_i$ be the unique MB of $\boldsymbol{T}_i$ for $i = 1, 2$. Then, $(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus (\boldsymbol{T}_1 \cup \boldsymbol{T}_2)$ is the unique MB of $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$.*

(ii) *Assume $\boldsymbol{T} \triangleq \{T_1, \cdots, T_k\}$ satisfies the local intersection assumption. Let $\boldsymbol{M}_i$ be the unique MB of T_i for $i = 1, \cdots, k$. Then, $\bigcup_{i=1}^{k} \boldsymbol{M}_i \setminus \boldsymbol{T}$ is the uniqe MB of $\boldsymbol{T}$.* ■

According to Theorem 3, $\boldsymbol{M}_{1,2}$ defined in (2) is not only an Mb but also the unique MB of $\boldsymbol{T}_{1,2}$ in the ALARM network if the faithfulness condition is satisfied. Further, $\boldsymbol{M}_{1,2,3}$ defined in (3) is the unique MB of $\boldsymbol{T}_{1,2,3}$.

3.2 Theoretical Results in the General Case

Let $(\mathbb{G}, \mathbb{P})$ be a BN over $\boldsymbol{V}$, and assume $\boldsymbol{T}_i \subseteq \boldsymbol{V}$ with $|\boldsymbol{T}_i| \geqslant 1$ has an Mb or MB, $\boldsymbol{M}_i$, for $i = 1, 2$. Denote $\boldsymbol{T} = \boldsymbol{T}_1 \cup \boldsymbol{T}_2$ and $\boldsymbol{N} = (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}$. In the case that $\boldsymbol{M}_i$ is an MB of $\boldsymbol{T}_i$, Theorem 3 reveals that $\boldsymbol{N}$ is an MB of $\boldsymbol{T}$ if $\boldsymbol{T}$ satisfies the local intersection assumption. However, when the local intersection assumption does not hold (meaning information equivalence occurs, as Lemma 1 shows), $\boldsymbol{N}$ may be no longer an MB of $\boldsymbol{T}$, due to one of the following reasons: (i) $\boldsymbol{N}$ may be an Mb but it may not possess minimality, as shown by Example 2; (ii) $\boldsymbol{N}$ may be insufficient to shield $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$ from all other variables, so it is no longer an Mb in this case, and some extra variables are required to enter into $\boldsymbol{N}$. Example 1 provides an illustration.

For the first case, we need only to optimize $\boldsymbol{N}$ by simply removing redundant variables from $\boldsymbol{N}$; however, for the second case, the additivity property of MB is thoroughly broken, and the problem of constructing an MB for $\boldsymbol{T}$ based on $\boldsymbol{M}_1$ and $\boldsymbol{M}_2$ becomes complex. On the one hand, there are some variables in $\boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$ needing to enter into $\boldsymbol{N}$; on the other hand, there may be some variables in $\boldsymbol{N}$ becoming redundant once some new members supplement $\boldsymbol{N}$. What we concern are which variables should enter into $\boldsymbol{N}$ and how we find them.

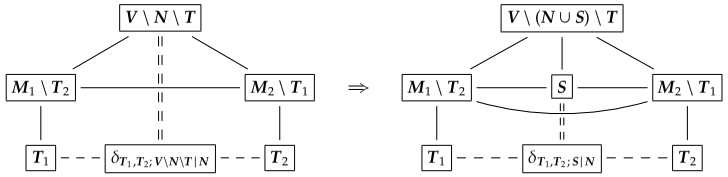

Figure 7: An illustration for the case of violating additivity of Mb and MB, caused by information equivalence.

Assume $\boldsymbol{N}$ is no longer an Mb of $\boldsymbol{T}$. Then, it is easily shown that

$$\boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{T}_1 \,|\, \boldsymbol{N}, \quad \text{but} \quad \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T} \perp\!\!\!\perp \boldsymbol{T}_1 \,|\, \boldsymbol{N} \cup \boldsymbol{T}_2,$$
$$\boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{T}_2 \,|\, \boldsymbol{N}, \quad \text{but} \quad \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T} \perp\!\!\!\perp \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{T}_1.$$

That is, $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$ contain equivalent information about $\boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$ given $\boldsymbol{N}$. See Figure 7 for an illustration: the valves $\boldsymbol{M}_1 \setminus \boldsymbol{T}_2$ and $\boldsymbol{M}_2 \setminus \boldsymbol{T}_1$ can not cut off all information channels between $\boldsymbol{T}$ and $\boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$, because some information can flow through $\delta_{\boldsymbol{T}_1,\boldsymbol{T}_2;\boldsymbol{V}\setminus\boldsymbol{N}\setminus\boldsymbol{T}|\boldsymbol{N}}$, an information equivalent valve of $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$ with respect to $\boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$ given $\boldsymbol{N}$. In other words, $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$ may exchange information directly; besides, they also share the equivalent information about $\boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$. This indicates we should continue to turn off some valves, $\boldsymbol{S} \subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$, besides $\boldsymbol{M}_1 \setminus \boldsymbol{T}_2$ and $\boldsymbol{M}_2 \setminus \boldsymbol{T}_1$ such that $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$ no longer exchange information through external valves and thus such that $\boldsymbol{T}$ has no information exchange with remaining valves.

This analysis motivates us to give the following definition:

Definition 3 *With the notations above, we call $\boldsymbol{S}$ ($\subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$) a Markov blanket supplementary (MbS) (of $\boldsymbol{T}$ to $\boldsymbol{N}$), if $\boldsymbol{N} \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}$. Further, a Markov boundary supplementary (MBS) is any MbS such that none of its proper subsets is an MbS.* ■

In what follows, we give the properties of MbS and MBS.

Theorem 4 *Assume $\boldsymbol{S} \subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$. Then, the following statements are equivalent:*

(i) *$\boldsymbol{S}$ is an MbS;*

(ii) $\mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}) = \min_{\boldsymbol{S}' \subseteq \boldsymbol{V}\setminus\boldsymbol{N}\setminus\boldsymbol{T}} \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}')$;

(iii) $\mathbb{I}(\boldsymbol{T}; \boldsymbol{S} \,|\, \boldsymbol{N}) = \max_{\boldsymbol{S}' \subseteq \boldsymbol{V}\setminus\boldsymbol{N}\setminus\boldsymbol{T}} \mathbb{I}(\boldsymbol{T}; \boldsymbol{S}' \,|\, \boldsymbol{N})$;

(iv) *$\boldsymbol{N} \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}_1$ in $\boldsymbol{V} \setminus \boldsymbol{T}_2$ (or $\boldsymbol{N} \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}_2$ in $\boldsymbol{V} \setminus \boldsymbol{T}_1$).*

In addition, if $\boldsymbol{S}$ is an MbS, then it is also an MBS if and only if $\boldsymbol{T}_1 \not\perp\!\!\!\perp Y \,|\, \boldsymbol{N} \cup (\boldsymbol{S} \setminus \{Y\})$ or $\boldsymbol{T}_2 \not\perp\!\!\!\perp Y \,|\, \boldsymbol{N} \cup (\boldsymbol{S} \setminus \{Y\})$ holds for any $Y \in \boldsymbol{S}$. ■

The proof of this theorem is presented in Appendix B.

As seen, (ii) and (iii) of Theorem 4 explain the implication of MbS that the information flow metaphor illustrates in Figure 7: finding an MbS is equivalent to turning off some valves such that $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$ no longer exchange information through external valves, or equivalent to finding all remaining equivalent information contained by $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$; (iv) and the property of MBS provide a practical way of building MBS discovery algorithms.

Here, we use an example to demonstrate the notions of MbS and MBS and their properties.

Example 1 *Consider the BN $(\mathbb{G}, \mathbb{P})$ over $\boldsymbol{V} = \{A, B, C, D\}$ presented in Figure 8, in which A, B, and C take $\{1, 2, 3\}$ while D takes $\{1, 2\}$. Put $\boldsymbol{T} = \{T_1, T_2\}$, $\boldsymbol{N} = (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T} = \emptyset$, and $\boldsymbol{S} = \{C\}$, $\boldsymbol{S}_0 = \{C, D\}$ with $T_1 = A$, $T_2 = B$, $\boldsymbol{M}_1 = \{B\}$, $\boldsymbol{M}_2 = \{A\}$. Using the theory of information equivalence (Lemeire, 2007), we can show the following results (see Appendix B for the proofs):*

(i) *$\boldsymbol{M}_1$ is an MB of T_1 in $\boldsymbol{V}$: $\mathbb{I}(A; C, D \,|\, B) = 0$ and $\mathbb{I}(A; C, D) > 0$;*

(ii) *$\boldsymbol{M}_2$ is an MB of T_2 in $\boldsymbol{V}$: $\mathbb{I}(B; C, D \,|\, A) = 0$ and $\mathbb{I}(B; C, D) > 0$;*

(iii) *$\boldsymbol{N} \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}$ in $\boldsymbol{V}$, so $\boldsymbol{S}$ is an MbS: $\mathbb{I}(A, B; D \,|\, C) = 0$;*

(iv) *$\mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}) = \min_{\boldsymbol{S}' \subseteq \boldsymbol{V}\setminus\boldsymbol{N}\setminus\boldsymbol{T}} \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}')$, because of $\mathbb{I}(A; B \,|\, C) = \mathbb{I}(A; B \,|\, C, D)$, $\mathbb{I}(A; B \,|\, C) \leqslant \mathbb{I}(A; B \,|\, D)$, and $\mathbb{I}(A; B \,|\, C) \leqslant \mathbb{I}(A; B)$;*

(v) *$\mathbb{I}(\boldsymbol{T}; \boldsymbol{S} \,|\, \boldsymbol{N}) = \max_{\boldsymbol{S}' \subseteq \boldsymbol{V}\setminus\boldsymbol{N}\setminus\boldsymbol{T}} \mathbb{I}(\boldsymbol{T}; \boldsymbol{S}' \,|\, \boldsymbol{N})$;*

(vi) *$\boldsymbol{N} \cup \boldsymbol{S}$ is an MB of T_1 in $\boldsymbol{V} \setminus \{T_2\}$: $\mathbb{I}(A; C, D) > 0$ and $\mathbb{I}(A; D \,|\, C) = 0$;*

(vii) *$\boldsymbol{N} \cup \boldsymbol{S}$ is an MB of T_2 in $\boldsymbol{V} \setminus \{T_1\}$: $\mathbb{I}(B; C, D) > 0$ and $\mathbb{I}(B; D \,|\, C) = 0$;*

(viii) *$\boldsymbol{S}$ is an MBS; $\boldsymbol{S}_0$ is an MbS (not an MBS): $\mathbb{I}(A, B; C, D) > 0$ and $\mathbb{I}(A; B \,|\, C, D) = \mathbb{I}(A; B \,|\, C)$.* ■

By Example 1, A and B share the equivalent information about C, so turning off the valve A (or B) means cutting off all the channels from B (or A) to C. This is why they can screen off each other from C. However, A and B lose the shield if they are integrated into a whole. In this case, we have to turn C off such that A and B no longer exchange information through external valves. This example reveals that an MBS is a minimal set of variables, $\boldsymbol{S} \subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$, such that $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$ contain no equivalent information about the remaining variables given $\boldsymbol{N} \cup \boldsymbol{S}$.

When finding an MBS, $\boldsymbol{S}$, and letting the variables in $\boldsymbol{S}$ supplement $\boldsymbol{N}$, there may be some variables in $\boldsymbol{N}$ becoming redundant. In addition, $\boldsymbol{N}$ may be redundant even before supplementing $\boldsymbol{S}$. Example 2 gives an illustration. For both cases, we need to remove the redundant variables.

Example 2 *Consider the BN presented in Figure 9, in which any one variable from $\{A, B, C\}$ and another from $\{D, E, F\}$ (denoted by X and Y, respectively) contain context-independent equivalent information about G (see Statnikov et al., 2013, Example 3). Then, $\{X, Y\}$ is an MB of G. Put now $\boldsymbol{T}_1 = \{C, F\}$ and $\boldsymbol{T}_2 = \{G\}$, and take $\boldsymbol{M}_1 = \{B, E\}$ and $\boldsymbol{M}_2 = \{B, D\}$. Note that $\boldsymbol{T}_1 \subseteq \boldsymbol{V} \setminus \boldsymbol{M}_2$ (and also $\boldsymbol{T}_2 \subseteq \boldsymbol{V} \setminus \boldsymbol{M}_1$). It concludes that $\boldsymbol{N} = \{B, D, E\}$ is not an MB but only an Mb of $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$, since its proper subset $\{B, E\}$ is also an Mb (and also an MB) of $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$. This shows why the process of refining $\boldsymbol{N}$ is necessary.* ■

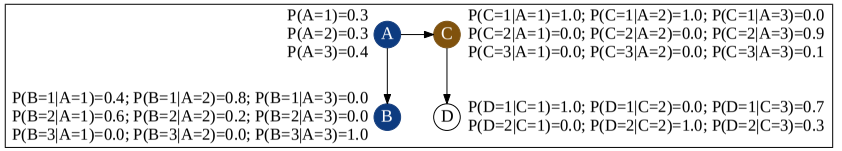

Figure 8: BN $(\mathbb{G}, \mathbb{P})$: $\mathbb{P}$ is a joint probability distribution over $\boldsymbol{V} = \{A, B, C, D\}$ with each variable taking values $\{1, 2, 3\}$ except for D taking $\{1, 2\}$; $\mathbb{G}$ is a DAG over $\boldsymbol{V}$.

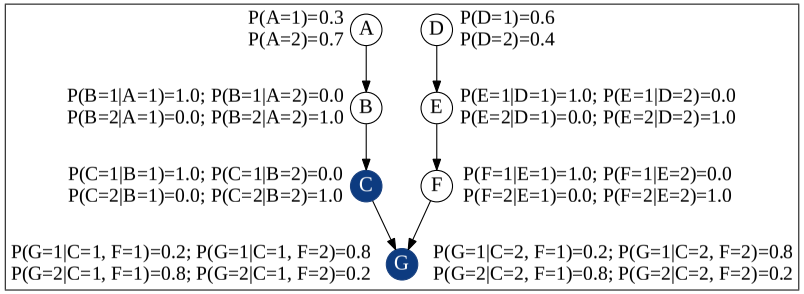

Figure 9: BN $(\mathbb{G},\mathbb{P})$: $\mathbb{P}$ is a joint probability distribution over $\boldsymbol{V}=\{A,B,C,D,E,F,G\}$ with all variables taking values $\{1,2\}$, $\mathbb{G}$ is a DAG with the variables in $\boldsymbol{V}$ as its nodes.

3.3 An Alternative Approach

Before building MB discovery algorithms for multiple targets, this subsection concisely presents an alternative approach to the *additivity based* and *MBS based* methods. In Section 5, we will apply this method as an FS strategy in multi-class prediction problems.

Let $\boldsymbol{T}\triangleq\{T_1,\cdots,T_k\}$ be the targets of interest and T be $\boldsymbol{T}$'s merged version, taking values $\{1,\cdots,t\}$ with $t\geqslant 3$. This procedure transforms the MB discovery for multiple targets $\boldsymbol{T}$ into the MB discovery for single target T, so all the existing MB discovery algorithms can be employed theoretically if the required conditions are satisfied. However, if t is large, selecting features of $\boldsymbol{T}$ or T directly will be difficult. Subsection 3.1 and Subsection 3.2 provide a way of solving this problem in different situations. In this case, an alternative strategy is to further convert T into a set of dummy variables denoted by $\left\{T_j^{(d)}\right\}_{j=1}^{t}$, where $T_j^{(d)}$ is a 0-1 variable defined as

$$T_j^{(d)}=\begin{cases}1, & \text{if } T=j\\ 0, & \text{if } T\neq j\end{cases}$$

This transformation produces a multiple-target $\boldsymbol{T}^{(d)}\triangleq\left(T_1^{(d)},\cdots,T_t^{(d)}\right)$. Clearly, $\boldsymbol{T}$, T, and $\boldsymbol{T}^{(d)}$ have the same MBs. In what follows, we show the MB of $\boldsymbol{T}^{(d)}$ can be derived by simply taking the union of MBs of $T_1^{(d)},\cdots,T_t^{(d)}$ and then removing the redundant variables in an efficient way. The proof will be given in Appendix B.

Theorem 5 *Let $\boldsymbol{M}_j$ be an MB of $T_j^{(d)}$ in $\boldsymbol{V}\setminus\boldsymbol{T}$ for $j=1,\cdots,t$. Then, $\boldsymbol{M}\triangleq\cup_{j=1}^{k}\boldsymbol{M}_j$ is an Mb of $\boldsymbol{T}$. Further, $\boldsymbol{M}$ is an MB of $\boldsymbol{T}$ iff for any $X\in\boldsymbol{M}$ there is some j such that $T_j^{(d)}\not\perp\!\!\!\perp X\mid\boldsymbol{M}\setminus\{X\}$.* ■

For why this transformative method is efficient, the fourth concluding remark in Section 7 will make a brief explanation.

4. Algorithms

This section builds MB discovery algorithms for multiple targets, $\{T_1,\cdots,T_k\}\triangleq\boldsymbol{T}$.

Let $\mathbb{A}$ be an MB discovery algorithm, assumed to perform well when used to discover an MB for a single target. In this paper, we employ `IAMB` and `KIAMB` as $\mathbb{A}$. Clearly, $\mathbb{A}$ can be directly used to find an MB for $\boldsymbol{T}$ if simply regarding $\boldsymbol{T}$ as the input of $\mathbb{A}$. Usually, this will lead to low accuracies and high complexities.

By Theorem 4, the MB discovery problem for multiple targets can be translated equivalently into a number of MB discovery problems for single targets, according to the following way: (i) use $\mathbb{A}$ to find an MB of T_i in $\boldsymbol{V}$ for $i=1,\cdots,k$, denoted by $\boldsymbol{M}_i$; (ii) find an Mb of T_2 in $\boldsymbol{V}\setminus\{T_1\}$ based on $(\boldsymbol{M}_1\cup\boldsymbol{M}_2)\setminus\{T_1,T_2\}$, and then get an MB of $\{T_1,T_2\}$, written as $\boldsymbol{M}_{1,2}$; (iii) find an Mb of T_3 in $\boldsymbol{V}\setminus\{T_1,T_2\}$ based on $(\boldsymbol{M}_{1,2}\cup\boldsymbol{M}_3)\setminus\{T_1,T_2,T_3\}$, and then get an MB of $\{T_1,T_2,T_3\}$, written as $\boldsymbol{M}_{1,2,3}$; (iv) the rest can be done in a similar manner. Following this way, the input of $\mathbb{A}$ for each use is a single variable, so this idea successfully avoids assigning an multivariate input to $\mathbb{A}$. Note that in the above process the equivalent information is extracted in a stepwise manner.

4.1 `IAMBS` and `KIAMBS`

Let $(\mathbb{G},\mathbb{P})$ be a BN over $\boldsymbol{V}$, and assume $\boldsymbol{T}_i\subseteq\boldsymbol{V}$ with $|\boldsymbol{T}_i|\geqslant 1$ has an MB, $\boldsymbol{M}_i$, for $i=1,2$. Denote $\boldsymbol{N}=(\boldsymbol{M}_1\cup\boldsymbol{M}_2)\setminus(\boldsymbol{T}_1\cup\boldsymbol{T}_2)$. This subsection presents the algorithms for discovering an MB of $\boldsymbol{T}_1\cup\boldsymbol{T}_2$. To design one such algorithm, we note that there may be some variables in $\boldsymbol{N}$ becoming redundant once an MBS, $\boldsymbol{S}$, is supplemented. Therefore, we need to first find $\boldsymbol{S}$ by setting $\boldsymbol{N}$ as a whitelist in $\mathbb{A}$ and then refine $\boldsymbol{N}$.

Applying this idea to `IAMB` and `KIAMB`, we obtain two algorithms called `IAMBS` and `KIAMBS`, in which "S" refers to as "supplementary". Their pseudo codes are presented in Algorithm 1. In order to differentiate these two algorithms, we set K in the `KIAMBS` algorithm as $K\in[0,1)$. It is mentioned here that $\boldsymbol{S}_2$ is a random subset of $\boldsymbol{S}_1$ with size $\max\{1,\lfloor|\boldsymbol{S}_1|\cdot K\rfloor\}$ in Line 5 of `KIAMBS`. As seen, these two algorithms first find an MbS, $\boldsymbol{S}$, in the growing phase and then refine $\boldsymbol{S}$ and $\boldsymbol{N}$ in sequence in the shrinking phase.

For example, based on a data set drawn from the BN in Example 1, the unique MB, $\{C\}$, of $\{A,B\}$ can be discovered by calling `IAMBS` or `KIAMBS` only once.

Theorem 1 presents the correctness of `IAMB` and `KIAMB` under the assumption that $\boldsymbol{T}_1\cup\boldsymbol{T}_2$ satisfies the local composition property. The theorem below shows `IAMBS` and `KIAMBS` are correct if $\boldsymbol{T}_2$ (instead of $\boldsymbol{T}_1\cup\boldsymbol{T}_2$) satisfies the local composition property. Appendix B gives the proof.

Theorem 6 (Correctness of `IAMBS` and `KIAMBS`) *Assume that $\boldsymbol{T}_2$ satisfies the local composition property, and that all CI tests are correct. Then* (i) *`IAMBS` outputs an MB of $\boldsymbol{T}_1\cup\boldsymbol{T}_2$;* (ii) *`KIAMBS` outputs an MB of $\boldsymbol{T}_1\cup\boldsymbol{T}_2$ for any $K\in[0,1)$.* ■

The following remark presents a relation among local intersection, local composition, and the adjacency faithfulness condition, under the *orientation faithfulness condition*. The proof is given in Appendix B. Here, the orientation faithfulness condition (Ramsey et al., 2006; Lemeire et al., 2012) is defined as: for any $X,Y,Z\in\boldsymbol{V}$ such that X and Z are adjacent to Y but X is not adjacent to Z, (i) if $X\rightarrow Y\leftarrow Z$, then $X\not\perp\!\!\!\perp Z\,|\,\boldsymbol{W}$ holds for any $\boldsymbol{W}\subseteq\boldsymbol{V}\setminus\{X,Z\}$ with $Y\in\boldsymbol{W}$; (ii) otherwise, $X\not\perp\!\!\!\perp Z\,|\,\boldsymbol{W}$ holds for any $\boldsymbol{W}\subseteq\boldsymbol{V}\setminus\{X,Y,Z\}$.

Remark 2 *The following two statements hold:* (a) *violating local intersection implies violating adjacency faithfulness;* (b) *under the orientation faithfulness condition, violating local composition at the end of the first phase of `IAMB` or `KIAMB` or `IAMBS` or `KIAMBS` means violating adjacency faithfulness.* ■

In addition, the lemma below is useful to explain the succeeding remarks.

Lemma 3 (a) *If there is* $\boldsymbol{P} \subseteq \boldsymbol{M}_1 \setminus \boldsymbol{T}_2$ *such that* $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{P} | (\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_2$, *then* $(\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_2$ *is an Mb of* $\boldsymbol{T}_1$; (b) *If there is* $\boldsymbol{Q} \subseteq \boldsymbol{N} \setminus \boldsymbol{P}$ *such that* $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{Q} | (\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_2$ *and* $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{Q} | (\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_1$, *then* $(\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_2$ *is an Mb of* $\boldsymbol{T}_1$, *and* $(\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_1$ *is an Mb of* $\boldsymbol{T}_2$. ■

For Algorithm 1, we have three remarks below:

(i) In these two algorithms, the two CI tests for adding members to $\boldsymbol{S}$ and for refining $\boldsymbol{S}$ are based on $\boldsymbol{T}_2$ instead of $\boldsymbol{T}$, while the CI test for refining $\boldsymbol{N}$ is based on $\boldsymbol{T}$ instead of $\boldsymbol{T}_2$. (a) For the first two CI tests, $\boldsymbol{T}_2$ can be replaced with $\boldsymbol{T}$ without affecting the correctness of the algorithms, since $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{X} | \boldsymbol{N} \cup \boldsymbol{S}' \Leftrightarrow \boldsymbol{T} \perp\!\!\!\perp \boldsymbol{X} | \boldsymbol{N} \cup \boldsymbol{S}'$ holds for any $\boldsymbol{S}' \subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$ and $\boldsymbol{X} \subseteq \boldsymbol{V} \setminus (\boldsymbol{N} \cup \boldsymbol{S}') \setminus \boldsymbol{T}$. However, if we replace $\boldsymbol{T}_2$ with $\boldsymbol{T}$, the resulting algorithms will need much longer time to run. This is why we use $\boldsymbol{T}_2$ in stead of $\boldsymbol{T}$ in these two places. (b) For the third CI test, $\boldsymbol{T}$ can not be replaced with $\boldsymbol{T}_2$, because of $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{X} | (\boldsymbol{N} \setminus \boldsymbol{X}) \cup \boldsymbol{S} \nRightarrow \boldsymbol{T} \perp\!\!\!\perp \boldsymbol{X} | (\boldsymbol{N} \setminus \boldsymbol{X}) \cup \boldsymbol{S}$.

(ii) According to Remark 2, there may be some situations in which both local intersection and local composition are simultaneously violated. In this case, `IAMBS` and `KIAMBS` may not correctly work. Specifically, the *violation of local intersection* means $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$ contain equivalent information about $\boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$ given $\boldsymbol{N}$; while the *violation of local composition* indicates not all equivalent information are successfully extracted by $\boldsymbol{N}$. Let $\boldsymbol{P}$ and $\boldsymbol{Q}$ be defined as in Lemma 3, and assume $\boldsymbol{P} \cup \boldsymbol{Q} \neq \emptyset$. Then, it can be shown that $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$ contain equivalent information about $\boldsymbol{P} \cup \boldsymbol{Q}$ given $\boldsymbol{N} \setminus (\boldsymbol{P} \cup \boldsymbol{Q})$. This means some equivalent information about $\boldsymbol{P} \cup \boldsymbol{Q}$ shared by $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$ conditioned on $\boldsymbol{N} \setminus (\boldsymbol{P} \cup \boldsymbol{Q})$ may mask some equivalent information about $\boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$ contained by $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$ conditioned on $\boldsymbol{N}$. This may be why not all equivalent information can be extracted by $\boldsymbol{N}$. According to this analysis, a potential remedy is to run `IAMBS` or `KIAMBS` by replacing $\boldsymbol{N}$ with a superset of $\boldsymbol{N} \setminus (\boldsymbol{P} \cup \boldsymbol{Q})$ that is a subset of $\boldsymbol{N}$.

(iii) By Remark 1, if $\boldsymbol{T}_1 \subseteq \boldsymbol{V} \setminus \boldsymbol{M}_2$ or $\boldsymbol{T}_2 \subseteq \boldsymbol{V} \setminus \boldsymbol{M}_1$, $\boldsymbol{N}$ must be an Mb of $\boldsymbol{T}$, so Lines 2∼14 of `IAMBS` and `KIAMBS` can be omitted. In this case, however, it is still necessary to refine $\boldsymbol{N}$, because $\boldsymbol{N}$ may not possess minimality. Example 2 illustrates this necessity.

Algorithm 1: `IAMBS` and `KIAMBS`

Procedure: $\boldsymbol{M} \leftarrow$ `IAMBS`$(\boldsymbol{D}; \boldsymbol{T}_1, \boldsymbol{T}_2; \boldsymbol{M}_1, \boldsymbol{M}_2)$
Input: a data matrix $\boldsymbol{D}$; two sets of targets $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$; an MB $\boldsymbol{M}_i$ of $\boldsymbol{T}_i$ for $i = 1, 2$.
Output: an MB, $\boldsymbol{M}$, of $\boldsymbol{T} \triangleq \boldsymbol{T}_1 \cup \boldsymbol{T}_2$.

```
//Forward: Growing Phase
S ← ∅
while S has changed do
    M ← N ∪ S
    Y ← arg max_{X∈V\M\T} f_D(T_2; X | M)
    if T_2 ⊥⊥ Y | M then
        S ← S ∪ {Y}
    end
end
//Backward: Shrinking Phase
foreach X ∈ S do
    if T_2 ⊥⊥ Y | N ∪ (S \ {Y}) then
        S ← S \ {Y}
    end
end
foreach Y ∈ N do
    if T ⊥⊥ Y | (N \ {Y}) ∪ S then
        N ← N \ {Y}
    end
end
return M ← N ∪ S
```

Procedure: $\boldsymbol{M} \leftarrow$ `KIAMBS`$(\boldsymbol{D}; \boldsymbol{T}_1, \boldsymbol{T}_2; \boldsymbol{M}_1, \boldsymbol{M}_2; K)$
Input: Besides $\{\boldsymbol{D}, \boldsymbol{T}_i, \boldsymbol{M}_i\}$, $K \in [0, 1)$ is a randomization parameter.
Output: an MB, $\boldsymbol{M}$, of $\boldsymbol{T} \triangleq \boldsymbol{T}_1 \cup \boldsymbol{T}_2$.

```
//Forward: Growing Phase
S ← ∅
while S has changed do
    M ← N ∪ S
    if S_1 ← {X∈V\M\T : T_2 ⊥̸⊥ X | M} ≠ ∅ then
        Y ← arg max_{X∈S_2} f_D(T_2; X | M)
        S ← S ∪ {Y}
    end
end
//Backward: Shrinking Phase
foreach X ∈ S do
    if T_2 ⊥⊥ Y | N ∪ (S \ {Y}) then
        S ← S \ {Y}
    end
end
foreach Y ∈ N do
    if T ⊥⊥ Y | (N \ {Y}) ∪ S then
        N ← N \ {Y}
    end
end
return M ← N ∪ S
```

In addition, another problem that we concern is whether we can refine $\boldsymbol{N}$ before seeking $\boldsymbol{S}$ and, if this is the case, which variables in $\boldsymbol{N}$ can be removed directly. We consider this problem because any redundant variable in $\boldsymbol{N}$ can lead to unnecessary inaccuracies when using $\boldsymbol{N}$ as a part of the conditional set in practical computations. Lemma 3 indicates we can do like this. However, to avoid the danger of missing the information about $\boldsymbol{P} \cup \boldsymbol{Q}$ (this occurs if the equivalent information involved in $\boldsymbol{P} \cup \boldsymbol{Q}$ given $\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}$ is different in some sense from any part of the equivalent information involved in $\boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$ given $\boldsymbol{N}$), we recommend to first search the members of $\boldsymbol{S}$ in $\boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$ and then check if some variables in $\boldsymbol{P} \cup \boldsymbol{Q}$ are necessary to enter into $\boldsymbol{S}$ when implementing Lines 2∼8 of `IAMBS` and `KIAMBS`. Note that this will increase the total running time.

4.2 `MIAMB` and `MKIAMB`

In this subsection, we present two multivariate Markov boundary discovery algorithms, called `MIAMB` and `MKIAMB`, respectively.

Let $\{T_1, \cdots, T_k\} \in \boldsymbol{V}$ with $\boldsymbol{M}_i$ as its an MB for $i = 1, \cdots, k$. If the local intersection property is satisfied, Theorem 3 shows $\bigcup_{i=1}^{k} \boldsymbol{M}_i \setminus \boldsymbol{T}$ is an MB of $\boldsymbol{T} \triangleq \{T_1, \cdots, T_k\}$. Otherwise, $\boldsymbol{M}$ may be no longer an MB. In this case, we use `MIAMB` or `MKIAMB` to seek an MB for $\boldsymbol{T}$. Given an ordering of $T_1, \cdots, T_k$, saying $\tau \triangleq \{i_1, \cdots, i_k\}$, which determines the priorities of the variables in $\boldsymbol{T}$ entering into the queue whose an MB will be sought in the current step, we denote an MB of $\{T_{i_1}, \cdots, T_{i_\ell}\} \triangleq \boldsymbol{T}_{i_\ell}^*$ by $\boldsymbol{M}_{i_j}^*$.

With these notations, `MIAMB` and `MKIAMB` are pseudo-coded in Algorithm 2. Their correctness, shown by Theorem 7, is a direct consequence of Theorem 1 and Theorem 6. As seen, `MIAMB` or `MKIAMB` uses the following stepwise idea: it first finds an MB of two targets $\{T_{i_1}, T_{i_2}\} = \{T_{i_1}\} \cup \{T_{i_2}\}$, and then finds an MB of three targets $\{T_{i_1}, T_{i_2}, T_{i_3}\} = \{T_{i_1}, T_{i_2}\} \cup \{T_{i_3}\}$; the rest can be done in a similar manner until all the k target variables are considered.

Theorem 7 (Correctness of `MIAMB` and `MKIAMB`) *Assume that* T_i *satisfies the local composition property for* $i = 1, \cdots, k$, *and that all CI tests are correct. Denote* $\boldsymbol{T} \triangleq \{T_1, \cdots, T_k\}$. *Then* (i) `MIAMB` *outputs an MB of* $\boldsymbol{T}$; (ii) `MKIAMB` *outputs an MB of* $\boldsymbol{T}$ *for any* $K \in [0, 1)$. ■

As we know, for any real data, those preconditions (such as faithfulness or local composition) required by a learning algorithm are hard to hold exactly. However, our algorithms can be seen as an improvement over earlier methods. Specifically, `IAMB`/`KIAMB` algorithms require faithfulness or

local composition for multiple targets when used for MB discovery of multiple targets, while our MIAMB/MKIAMB only need local composition for single targets, which may be more close to real situations than faithfulness or local composition for multiple targets.

For MIAMB or MKIAMB, an ordering τ is set in Algorithm 2 mainly because different orderings may lead to different computational complexities. In Subsection 4.4, we will make a complexity analysis about the algorithms, based on which we present a feasible way of selecting τ, under the expectation that our algorithms should be run as quickly as possible. When $|\boldsymbol{T}| = 2$, however, τ is not necessary.

Besides MIAMB/MKIAMB algorithms (which are *MBS based*), we can consider additivity based (Theorem 3) and dummy variables based (Theorem 5) algorithms: (a) the *additivity based* MIAMB or MKIAMB simply takes the union of outputs of IAMB/KIAMB with respect to all single targets as the output; its correctness requires the conditions in Theorem 7 plus Theorem 3; and (b) the *dummy (variables based)* MIAMB/MKIAMB takes the union of the outputs of IAMB/KIAMB with respect to every dummy variable and removes redundant variables; its correctness requires the same condition as in Theorem 7. Throughout this paper, unless specified, MIAMB/MKIAMB denote the MBS based algorithms.

4.3 A Discussion on CI Test

As argued by Aliferis et al. (2010a, p. 200), the quality of an MB discovery algorithm highly depends on the selected CI testing methods. In this subsection, we discuss the ways of practically doing CI tests. Usually, the Pearson's X^2 test or the log-likelihood ratio G^2 test can be employed for this purpose (Yaramakala, 2004; Bromberg and Margaritis, 2009; Aliferis et al., 2010b; Statnikov et al., 2013). Here, the X^2 statistic and the G^2 statistic have the same asymptotic χ^2 distribution. We can also use some experimental testing methods such as the Akaike information criterion-based test (Cressie and Read, 1989; Scutari, 2010).

Algorithm 2: MIAMB and MKIAMB

Procedure: $\boldsymbol{M} \leftarrow$ MIAMB$(\boldsymbol{D}; \boldsymbol{T}; \tau)$
Input: a data matrix $\boldsymbol{D}$; a target set $\boldsymbol{T} \triangleq \{T_1, \cdots, T_k\}$; and an ordering $\tau \triangleq \{i_1 \cdots, i_k\}$.
Output: an MB, $\boldsymbol{M}$, of $\boldsymbol{T}$.

// MIAMB: $\boldsymbol{M} \leftarrow$ MIAMB$(\boldsymbol{D}; \boldsymbol{T}; \tau)$
for $\ell \leftarrow 1$ **to** k **do**
  $\boldsymbol{M}_{i_\ell} \leftarrow$ IAMB$(\boldsymbol{D}; \{T_{i_\ell}\})$
end
for $\ell \leftarrow 2$ **to** k **do**
  $\boldsymbol{M}^*_{i_\ell} \leftarrow$ IAMBS$(\boldsymbol{D}; \boldsymbol{T}^*_{i_{\ell-1}}, \{T_{i_\ell}\}; \boldsymbol{M}^*_{i_{\ell-1}}, \boldsymbol{M}_{i_\ell})$
end
return $\boldsymbol{M} \leftarrow \boldsymbol{M}^*_{i_k}$

Procedure: $\boldsymbol{M} \leftarrow$ MKIAMB$(\boldsymbol{D}; \boldsymbol{T}; K; \tau)$
Input: a data matrix $\boldsymbol{D}$; a target set $\boldsymbol{T}$; a randomization parameter $K \in [0, 1)$; and an ordering τ.
Output: an MB, $\boldsymbol{M}$, of $\boldsymbol{T}$.

// MKIAMB: $\boldsymbol{M} \leftarrow$ MKIAMB$(\boldsymbol{D}; \boldsymbol{T}; K; \tau)$
for $\ell \leftarrow 1$ **to** k **do**
  $\boldsymbol{M}_{i_\ell} \leftarrow$ KIAMB$(\boldsymbol{D}; \{T_{i_\ell}\}; K)$
end
for $\ell \leftarrow 2$ **to** k **do**
  $\boldsymbol{M}^*_{i_\ell} \leftarrow$ KIAMBS$(\boldsymbol{D}; \boldsymbol{T}^*_{i_{\ell-1}}, \{T_{i_\ell}\}; \boldsymbol{M}^*_{i_{\ell-1}}, \boldsymbol{M}_{i_\ell}; K)$
end
return $\boldsymbol{M} \leftarrow \boldsymbol{M}^*_{i_k}$

Recall that we are dealing with the MB discovery problem for *multiple* target variables. When the target set, namely $\boldsymbol{T}$, contains only a few variables (e.g., 1 or 2), the X^2 test or the G^2 test performs quite well in most situations. Unfortunately, when $\boldsymbol{T}$ contains too many variables (e.g., 5 or 6 or even more), X^2 or G^2 may not work well due to the overmany degrees of freedom. See Appendix C for a detailed discussion. In fact, as Cochran (1954, p. 420) recommended about the working rules for X^2 (also applicable to G^2), these two testing methods are unreliable if more than 20% of the cells in contingency tables have an expected count of less than 5 data points; however, such cases frequently arise in practice (Bromberg and Margaritis, 2009; Yaramakala, 2004).

Many authors have considered improving X^2 and G^2 by adjusting the statistics. Lawley (1956) showed that such tests can be improved by multiplying with a suitable scale factor; Hosmane (1986, 1987, 1990) and the pioneer scholars recommended the following two adjustment procedures (i) replace zero observed counts by a positive constant, leaving nonzero counts intact; and (ii) add a positive constant to all the observed counts. Brin et al. (1997) and Silverstein et al. (1998) used two heuristic "solutions" to the problem of low expected counts as follows: (i) simply ignore these cells when calculating X^2 or G^2; and (ii) use what is called *contingency table support* (CT-support): a set of items S has CT-support s at the t% level if at least t% of the cells in the contingency table for S have value s. Aliferis et al. (2010b) considered a similar heuristic called *heuristic power size*, which denotes the smallest sample size per cell in the contingency table of a reliable CI test.

The above ideas can lead to improvements on X^2 and G^2 to varying degrees if the dimensions are not very high. However, when working on the MB discovery problem for multiple targets, we need more suitable methods to do CI tests. For this reason, we suggest the following *practical operation*: when $|\boldsymbol{T}| \leqslant 2$, we can (i) use X^2 or G^2 or their variants mentioned above to do CI tests; otherwise, we consider the following testing method: (ii) use CMI and an experimental threshold, ε, to make statistical decisions as Cheng et al. (2002) did, in the sense that $\mathbb{I}_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) \geqslant \varepsilon$ asserts $\boldsymbol{X} \not\perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$ while $\mathbb{I}_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) < \varepsilon$ concludes $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$, where $\varepsilon \triangleq |\boldsymbol{T}|^{a_1} \cdot \frac{100\, a_2}{n} \cdot \log_2 v$ is related to the the sample size, the average number of values that each variable takes, and the number of targets (denoted by n, v, and $|\boldsymbol{T}|$, respectively), in which a_1 and a_2 are two adjusting factors ($a_1 = 0.5$ and $a_2 \in (0.1, 0.5)$ are recommended). The association function, $f_{\boldsymbol{D}}$, can be selected as

$$f_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) = \mathbb{I}_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) \triangleq f^{(2)}_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}). \tag{4}$$

Besides this experimental method, we can (iii) improve X^2 or G^2 by adjusting the number of the theoretical degrees of freedom.

For the above (iii), to be clear, we consider the G^2 statistic, $G^2(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) \triangleq 2n \cdot \mathbb{I}_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \mid \boldsymbol{Z})$, which approximates to the chi-square variate with $r \triangleq (r_{\boldsymbol{X}} - 1)(r_{\boldsymbol{Y}} - 1) r_{\boldsymbol{Z}}$ degrees of freedom, namely $\chi^2(r)$, where $r_{\boldsymbol{\xi}}$ represents the number of configurations for $\boldsymbol{\xi}$ (de Campos, 2006, p. 2158). Denote the p-value by

$$p(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) = \mathbb{P}\{\chi^2(r) \geqslant G^2(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z})\}.$$

Then, the G^2 test asserts $\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$ if $p(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) > \alpha$ for a significance level α, and concludes $\boldsymbol{X} \not\perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$ if $p(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) \leqslant \alpha$. In this paper, α is set to be 0.05. Aliferis et al. (2010a, pp. 200–201) provided a further discussion about this. Accordingly, the *negative p-value* is used as the association function, $f_{\boldsymbol{D}}$, as Tsamardinos et al. (2006), Aliferis et al. (2010a,b), and Statnikov et al. (2013) did:

$$f_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) = -p(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) = -\mathbb{P}\{\chi^2(r) \geqslant G^2(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z})\} \triangleq f^{(1)}_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}). \tag{5}$$

Replace the theoretical value of r in $p(\boldsymbol{X};\boldsymbol{Y}\,|\,\boldsymbol{Z})$ with its a damped version of the form

$$g_{n,\kappa}(r) \triangleq r\left(1-\mathrm{e}^{-\frac{n}{\kappa r}}\right), \tag{6}$$

where $\kappa > 0$ is a constant, based on which $\frac{n}{\kappa}$ measures the amount of valid cells that n sample instances can support. For convenience, we will call the resulted p-value, denoted by $p_g(\boldsymbol{X};\boldsymbol{Y}\,|\,\boldsymbol{Z})$ instead of $p(\boldsymbol{X};\boldsymbol{Y}\,|\,\boldsymbol{Z})$, and the resulted testing method to be the *damped p-value* and the *damped log-likelihood ratio test* (or damped G^2 test). Further, we use the the following association function:

$$f_{\boldsymbol{D}}(\boldsymbol{X};\boldsymbol{Y}\,|\,\boldsymbol{Z}) = -p_g(\boldsymbol{X};\boldsymbol{Y}\,|\,\boldsymbol{Z}) = -\mathbb{P}\{\chi^2(g_{n,\kappa}(r)) \geqslant G^2(\boldsymbol{X};\boldsymbol{Y}\,|\,\boldsymbol{Z})\} \triangleq f^{(3)}_{\boldsymbol{D}}(\boldsymbol{X};\boldsymbol{Y}\,|\,\boldsymbol{Z}). \tag{7}$$

In Appendix C, we will provide the details for this damping procedure, and give some numerical illustrations about its reasonability. Clearly, the damped G^2 test approximately degenerates into the ordinary G^2 test when taking κ as a very small positive number.

4.4 Complexity Analysis

In the following, we analyze the computational complexities of the four algorithms: `IAMB`, `KIAMB`, `MIAMB`, and `MKIAMB`. Usually, the number of CI tests can be employed to measure the complexity of a CI-based MB discovery algorithm (Tsamardinos et al., 2003, 2006; Aliferis et al., 2010a), considering there exists efficient implementations of the CMI-based test or the association computation taking time $O(n\log n)$ if the conditional set is small. However, Aliferis et al. (2010a) also mentioned that the running time, denoted by $t_{n,q}$, for computing per CMI-based statistic is linear to the sample size, n, and exponential to the number, q, of variables in the conditional set. This means we should take $t_{n,q}$ into account, not simply using $O(n\log n)$ to measure the complexity.

Assume we are seeking an MB for $\boldsymbol{T} \triangleq \{T_1,\cdots,T_k\}$ according to the ordering τ. Without loss of generality, we assume $\tau = \{1,\cdots,k\}$. Consider the case of $k = 2$. Suppose $\boldsymbol{M}_i$ is an MB of T_i with $|\boldsymbol{M}_i| = m_i \geqslant 1$, and $\boldsymbol{S}$ is an MBS for $\boldsymbol{N} \triangleq \boldsymbol{M}_1 \cup \boldsymbol{M}_2 \setminus \{T_1,T_2\}$ with $|\boldsymbol{S}| = s \geqslant 0$. By Remark 1, we assume $T_1 \in \boldsymbol{M}_2$ and $T_2 \in \boldsymbol{M}_1$. Recall that the number of all variables is p. It follows that:

- In view of $|\boldsymbol{N}\cup\boldsymbol{S}| = m_1+m_2+s-2 \triangleq m$, `IAMB` takes time $O[(mp+m)t_{n,m}]$ to finish an execution. Thus, the complexity of `IAMB` is $O(mpt_{n,m})$. `KIAMB` has almost the same complexity.
- For `MIAMB`, it first takes time $O[(m_1p+m_1)t_{n,m_1}+(m_2p+m_2)t_{n,m_2}]$ to find $\boldsymbol{M}_1$ and $\boldsymbol{M}_2$; then it seeks $\boldsymbol{S}$ and refines $\boldsymbol{N}$ taking time $O\{[s(p-m_1-m_2+2)+m]t_{n,m}\}$. Hence, `MIAMB` needs time $O\{(m_1p+m_1)t_{n,m_1}+(m_2p+m_2)t_{n,m_2}+[s(p-m_1-m_2+2)+m]t_{n,m}\}$ to finish an execution, so its complexity is $O(m_1pt_{n,m_1}+m_2pt_{n,m_2}+spt_{n,m})$. `MKIAMB` has almost the same complexity.

By this analysis, the complexity of `MIAMB` or `MKIAMB` is lower than that of `IAMB` or `KIAMB`. In fact, noting $t_{n,q}$ is exponential to q ($\leqslant m$; meaning $t_{n,q} \ll t_{n,m}$ in most situations) for $q = m_1, m_2$, this implies `MIAMB`/`MKIAMB` are expected to need much less time to run than `IAMB`/`KIAMB`, especially when $\boldsymbol{T}$ contains many variables. The evaluation section (Figure 15) confirms this expectation in the case of moderately large sample size.

For the general case, using the notations in Subsection 4.2 with $|\boldsymbol{M}_i| = m_i$ $(i = 1,\cdots,k)$, we assume $\boldsymbol{S}_i$ be an MBS for $\boldsymbol{M}^*_{i-1}$ and $\boldsymbol{M}_i$, with $|\boldsymbol{S}_i| = s_i$ $(i = 2,\cdots,k)$. Denote $m^*_i \triangleq \sum_{j=1}^{i} m_j + \sum_{j=2}^{i} s_j - i$. Note that, in general, $t_{n,m_a} \ll t_{n,m^*_a} \ll t_{n,m^*_b}$ for $a < b$. Then, the `IAMB` or `KIAMB` algorithm has the complexity $O(m^*_k pt_{n,m^*_k})$, while `MIAMB` or `MKIAMB` has a lower complexity $O(\sum_{i=1}^{k} m_i pt_{n,m_i} + \sum_{i=2}^{k} s_i pt_{n,m^*_i})$.

According to this theoretical result on complexities, we can use the ordering, $\tau \triangleq \{i_1\cdots,i_k\}$, in `MIAMB` or `MKIAMB` such that $m_{i_1} \leqslant \cdots \leqslant m_{i_k}$. This can reduce the complexities to some extent.

Besides, the additivity based `MIAMB`/`MKIAMB` algorithms have almost the same complexity as the MBS based `MIAMB`/`MKIAMB`, while the dummy `MIAMB`/`MKIAMB` have the complexity $O(mr_{\boldsymbol{T}}pt_{n,m})$, where $m = \sum_{j=1}^{k} m_j$, $r_{\boldsymbol{T}} = \prod_{j=1}^{k} r_{T_j}$, r_ξ denotes the number of configurations for ξ. It will be seen from Section 6 that, although the dummy `MIAMB`/`MKIAMB` are of high complexity theoretically, they usually perform well in multi-class prediction problems.

5. Benchmarking Study

This section makes a benchmarking study based on the data sets of six synthetic BNs. These data sets, generated by Tsamardinos et al. (2006) and Aliferis et al. (2010a), and the BNs are briefly described in Table 1. As Tsamardinos et al. (2006) and Aliferis et al. (2010a) stated, these BNs are representatives of a wide range of problem domains. Also, these BNs have different complexities (according to the number of nodes, the number of edges, maximal in-degree, maximal out-degree, and domain range). More details about the BNs and the used data sets are provided by Tsamardinos et al. (2006) and Aliferis et al. (2010a).

The following items are clarified before presenting the experimental results:

- *Measurements*: The primary measurement for the performance of an MB discovery algorithm used in our experiment is the weighted accuracy (WA), which is the average of the rate of true members and that of true nonmembers of an MB with respect to the truth. We also compute what we call the weighted precision (WP) as the average of the rate of true members and that of true nonmembers of an MB with respect to the output. In addition, we record the running time (RT) for every data set of each algorithm and for each BN. Here, RT refers to the single CPU time implemented on an Intel i7-3612QM 2.1 GHz and Windows 7 with 64 bits.

BN	Num. Nodes	Num. Edges	Maximal In-degree	Maximal Out-degree	Domain Range	Selected Targets	Sizes of Data Sets	Total RT (Hours)
Child10	200	257	2	7	2 ~ 6	$X_{131}, X_{132}, X_{98}, X_{194}$,	5×500	3.4297
						$X_{184}, X_{22}, X_{135}, X_{60}$	1×5000	8.2220
ALARM10	370	570	4	7	2 ~ 4	$X_{341}, X_{48}, X_{37}, X_{249}$,	5×500	4.6547
						$X_{209}, X_{188}, X_{192}, X_{161}$	1×5000	6.3721
Pigs	441	592	2	39	3 ~ 3	$X_{390}, X_{357}, X_{180}, X_{400}$,	5×500	11.7651
						$X_{199}, X_{241}, X_{228}, X_{176}$	1×5000	15.8443
Link	724	1125	3	14	2 ~ 4	$X_{369}, X_{293}, X_{303}, X_{457}$,	5×500	9.7932
						$X_{399}, X_{512}, X_{183}, X_{501}$	1×5000	16.1046

						$X_{185}, X_{622}, X_{516}, X_{577}$	1×5000	35.6790

Table 1: BNs and data sets.

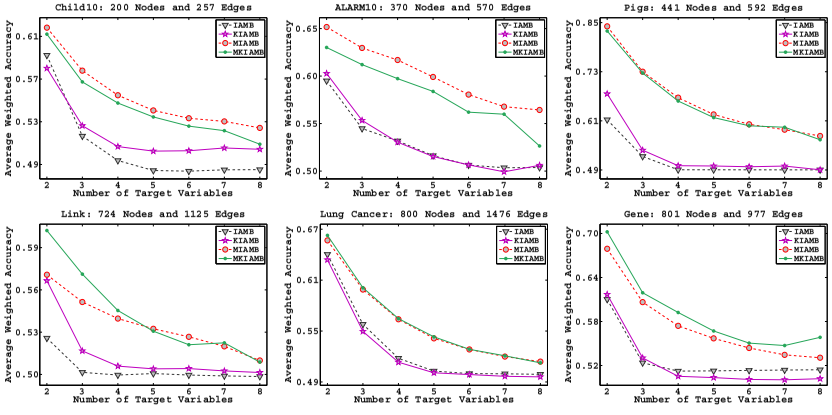

Figure 10: Average WA of the algorithms versus $|\boldsymbol{T}|$ with respect to the data sets of size 500

- *Algorithms*: Four algorithms are used: `IAMB`, `KIAMB`, `MIAMB`, and `MKIAMB`. We take $K = 0.8$ as the randomization parameter in `KIAMB` and `MKIAMB` due to the following two reasons: (i) Peña et al. (2007, p. 227) asserted that $K \in [0.7, 0.9]$ performs best; and (ii) $K = 0.8$ is an appropriate tradeoff between WA (or WP) and RT.
- *Used CI Test*: Following the *practical operation* suggested in Subsection 4.3, we implemented the algorithms via the G^2 test, and found G^2 is suitable for small $|\boldsymbol{T}|$ but is not very suitable and even no longer works for large $|\boldsymbol{T}|$. Then, we used the experimental CMI-based test with a relatively rough $\varepsilon \approx \sqrt{|\boldsymbol{T}|} \cdot \varepsilon_0$, in which $\varepsilon_0 = 0.05$ if $n = 500$ and $\varepsilon_0 = 0.01$ if $n = 5000$; after that, we used the damped G^2 test by setting $\kappa = 5$. The results indicate both alternatives are desirable. Considering the association function, $f_{\boldsymbol{D}}^{(2)}$ defined in (4) corresponding to the CMI-based test, contains no the average number, v, of values that each variable takes, we may need to reselect ε_0 for a BN with a very different v. For these reasons, we eventually decided to use the damped G^2 test for the four algorithms in our experiment.
- *Data*: We use the data sets of sizes 500 and 5000, generated by Tsamardinos et al. (2006) and Aliferis et al. (2010a), which are available at `http://www.nyuinformatics.org/downloads/supplements/JMLR2009/index.html`.
- *Targets*: We employ eight of those variables selected by Aliferis et al. (2010a, p. 226) as the potential targets for each BN. See Table 1 for details. Then, $\boldsymbol{T}$ is any possible combination of k targets for $k = 2, \cdots, 8$.
- *Steps*: For each BN with eight selected targets, the steps of making simulation based on the data set of size 5000 are as follows: (a) for $k = 2, \cdots, 8$, call the four algorithms to obtain four MBs of $\boldsymbol{T} \triangleq \{T_{i_1}, \cdots, T_{i_k}\}$; (b) compute their WAs and WPs, and record the respective RTs; (c) take the average values of these $\binom{8}{k}$ WAs or WPs or RTs for each of the four algorithms. For the five data sets of size 500, each reported WA or WP or RT is the average value of the corresponding five results of an algorithm derived by (a) ~ (c) above.

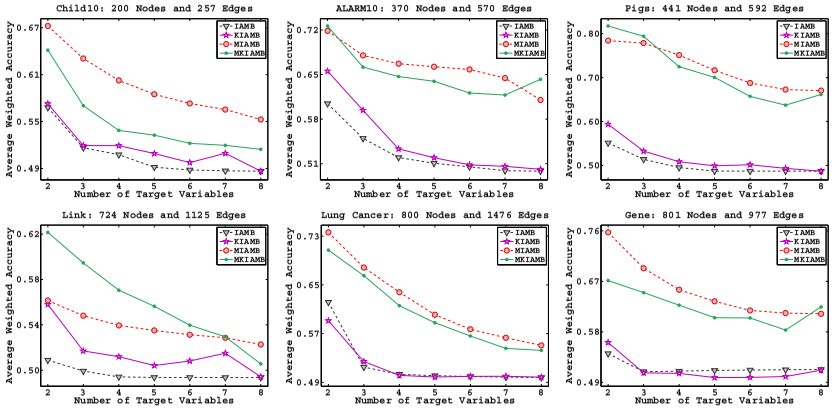

Figure 11: Average WA of the algorithms versus $|\boldsymbol{T}|$ with respect to the data sets of size 5000

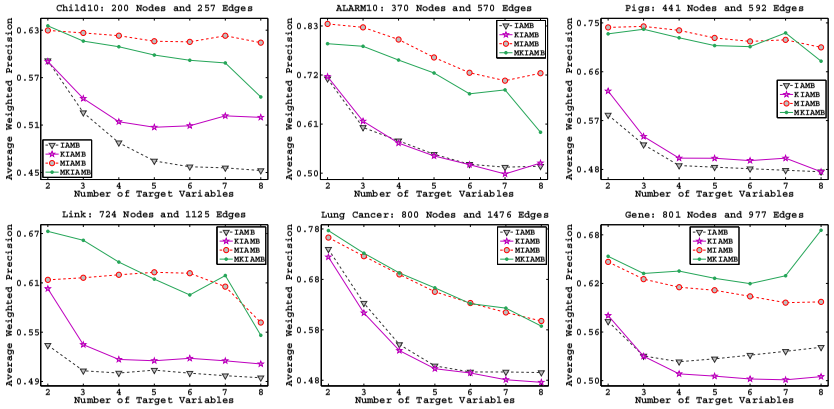

Figure 12: Average WP of the algorithms versus $|\boldsymbol{T}|$ with respect to the data sets of size 500

According to the above description, we make computations with the aid of FullBNT (Murphy, 2007) and MIToolbox (Brown et al., 2012). The results of the WAs are presented in Figure 10 and Figure 11; the results of the WPs are given in Figure 12 and Figure 13; and the results of the RTs are shown in Figure 14, and Figure 15. The total RTs are presented in Table 1. By these figures, it is concluded that, on the whole, our `MIAMB` and `MKIAMB` have higher computational accuracies and lower time complexities than the existing `IAMB` and `KIAMB`.

Specifically, we have:

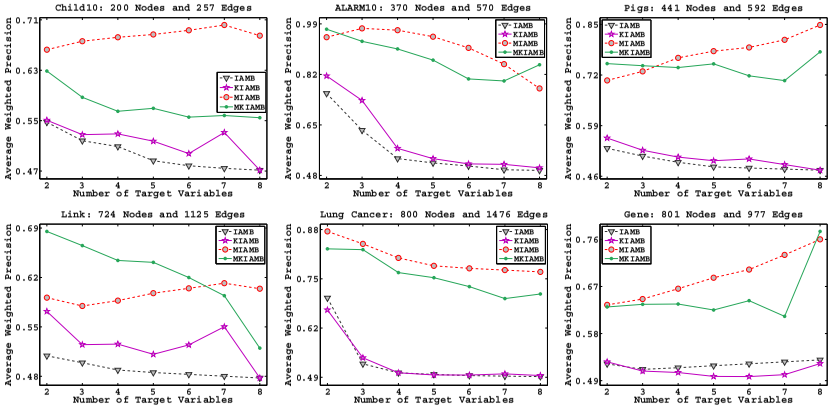

Figure 13: Average WP of the algorithms versus $|\boldsymbol{T}|$ with respect to the data sets of size 5000

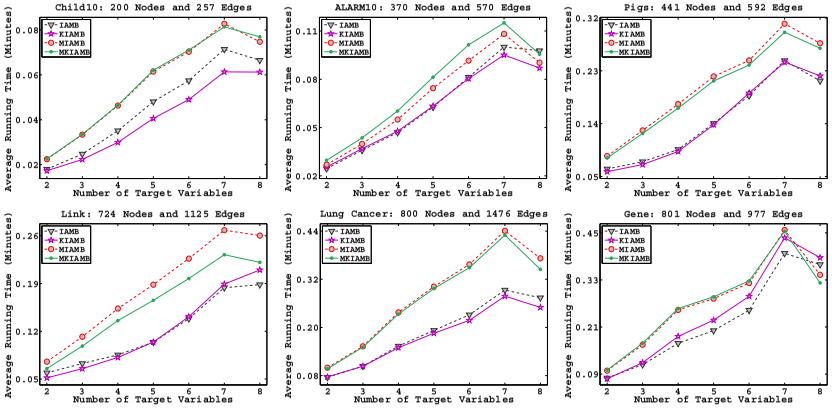

Figure 14: Average RT of the algorithms versus $|\boldsymbol{T}|$ with respect to the data sets of size 500

(i) *Performance on WA*: (a) `MIAMB` and `MKIAMB` have larger WAs than `IAMB` and `KIAMB` for all the six BNs in any case of $|\boldsymbol{T}|$; (b) when $|\boldsymbol{T}|$ increases, WA declines quickly for `IAMB` and `KIAMB`, but it decreases gently for `MIAMB` and `MKIAMB`; and (c) the improvements of `MIAMB` and `MKIAMB` over `IAMB` and `KIAMB` tend to be gradually noticeable and then reduce slightly as $|\boldsymbol{T}|$ increases. The performance degradation along with the increase of $|\boldsymbol{T}|$ can be attributed to two possible aspects: one is that the local composition assumption may be more apt to be violated for a larger $|\boldsymbol{T}|$ because of synergy effects; and the other is that the assumption about

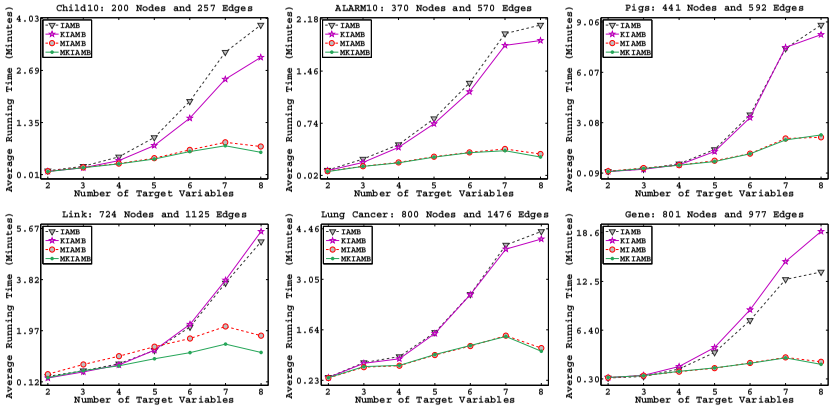

Figure 15: Average RT of the algorithms versus $|\boldsymbol{T}|$ with respect to the data sets of size 5000

the correctness of CI tests may also be more apt to be violated for a larger $|\boldsymbol{T}|$, due to the accumulation and propagation of the cascading errors (Bromberg and Margaritis, 2009). It is mentioned that (a)(b)(c) appear more evidently for the case of $n = 5000$ than for the case of $n = 500$.

(ii) *Performance on WP*: The similar interpretations to (a)(c) of (i) are valid.

(iii) *Performance on RT*: Here, we note that the real RT of an MB discovery algorithm is composed of two parts, in which the *part (I) is for CI tests*, and the *part (II) is for all other computations*. The part (I) is the major part used to measure the complexity of the MB discovery algorithm. Note also that the RT, $t_{n,q}$, of per CI test is linear to the sample size, n, and exponential to the number, q, of variables in the conditional set (see Subsection 4.4 for details).

This means that the part (II) of the real RT may dominate the part (I) if n is not large (for example, $n = 500$).

Let us now observe Figure 14 and Figure 15. First, both figures show the real RT that each algorithm needs is increasing along with the increase of $|\boldsymbol{T}|$. Also, Figure 14 indicates `MIAMB` and `MKIAMB` need slightly longer time to run than `IAMB` and `KIAMB`, because the running for CI tests is dominated by the running for all other computations in the case of a small sample size, while Figure 15 reveals that the real RTs of `IAMB` and `KIAMB` increase sharply as $|\boldsymbol{T}|$ increases and that the real RTs of `MIAMB` and `MKIAMB` increase slowly, just like the theoretical analyses about the complexities of the four algorithms show in Subsection 4.4.

In summary, the existing MB discovery algorithms, `IAMB` and `KIAMB`, can be approximately applied to the problem of MB discovery for multiple target variables when $|\boldsymbol{T}|$ is small, but they will perform poorly if $|\boldsymbol{T}|$ is moderately large. In comparison, our `MIAMB` and `MKIAMB` have higher accuracies and lower complexities for this problem, especially when $|\boldsymbol{T}|$ is large.

6. Application to FS in Multi-Class Prediction Problems

In this section, we apply the MB discovery for multiple targets to FS in multi-class prediction problems based on a real data set, HIVA. This data set is very challenging in WCCI 2006 (`http://www.modelselect.inf.ethz.ch`) and IJCNN 2007 (`http://www.agnostic.inf.ethz.ch`), because it contains many very unbalanced variables.

Let $T \in \boldsymbol{V}$ be a target variable taking values $\{1, \cdots, t\}$, $t \geqslant 3$. The multi-class prediction problem is to select features of T from $\boldsymbol{V} \setminus \{T\}$ such that T can be predicted as accurately as possible based on the chosen features. Let $\boldsymbol{T}^{(d)} \triangleq \left(T_1^{(d)}, \cdots, T_t^{(d)}\right)$ be the dummy version of T. Theoretically, $\boldsymbol{T}^{(d)}$ and T have the same MBs.

With these notations, the experiment is designed as follows:

- *Data*: HIVA contains 4229 data points and 1618 variables.
- *Targets*: In view of the fact that almost all variables in HIVA are binary, we randomly take k 2-class variables ($k = 2, \cdots, 5$) to create a merged 2^k-class target, T. Accordingly, we rearrange the original data to get a data set that is used only for FS of T. Repeat this step $n \triangleq 200$ times. Denote the resulting targets and their dummy versions by $T_1, \cdots, T_n$ and $\boldsymbol{T}_1^{(d)}, \cdots, \boldsymbol{T}_n^{(d)}$, respectively.
- *Algorithms*: We use the following 10 MB discovery algorithms to get the features for each T_j or $\boldsymbol{T}_j^{(d)} \triangleq \left(T_{j1}^{(d)}, \cdots, T_{jt_k}^{(d)}\right)$ with $t_k \triangleq 2^k$, $j = 1, \cdots, n$:
  a) `IAMB/KIAMB`-I: the `IAMB/KIAMB` algorithms working on T_j directly;
  b) `IAMB/KIAMB`-II: the `IAMB/KIAMB` algorithms working on $\boldsymbol{T}_j^{(d)}$ (that is, with $\boldsymbol{T}_j^{(d)}$ as its multiple targets);
  c) `MIAMB/MKIAMB`-I: the additivity based `MIAMB/MKIAMB` algorithms, taking the union of the outputs of `IAMB/KIAMB` with respect to $T_{ji}^{(d)}$ ($i = 1, \cdots, t_k$) as its output;
  d) `MIAMB/MKIAMB`-II: the MBS based `MIAMB/MKIAMB` algorithms, which are pseudo-coded in Algorithm 2;
  e) `MIAMB/MKIAMB`-III: the dummy `MIAMB/MKIAMB` algorithms, which take the union of the outputs of `IAMB/KIAMB` with respect to $T_{ji}^{(d)}$ ($i = 1, \cdots, t_k$) and removing redundant variables.
- *Classifier*: After making a number of preliminary experiments on the six benchmarking BNs, we found that the support vector machines (SVMs; implemented via `LibSVM` v3.22) perform the best in demonstrating the optimality of MBs for FS. This coincides with the assertion of Statnikov et al. (2013). Therefore, we use SVMs for our multi-class prediction problems. All the classifications are performed by 10-fold cross-validation.
- *Measurement* of an algorithm: For each target, the predictive quality of an MB is measured by the *balanced accuracy* defined as $\tau \triangleq \frac{1}{t_k}\sum_{\ell=1}^{t_k}\left(c_{\ell\ell}/\sum_{i=1}^{t_k} c_{i\ell}\right)$, where $\boldsymbol{C} \triangleq \left(c_{i\ell}\right)$ denotes the associated confusion matrix. As seen, τ is equal to one minus the *balanced error rate* used in WCCI 2006 and IJCNN 2007. We choose to use τ (instead of *ordinary accuracy*) because it trades off all values of the target in the sense that any unbalanced value (that the target takes) should not impact on the accuracy too much.[1] On the other hand, when two outputs of algorithms have the same total numbers of "true positives + true negatives", the balanced accuracy can identify the output that prefers to protect the scarce class as the better one, while the ordinary accuracy cannot. Finally, we compute the mean and standard deviation (std) of the n values of balanced accuracy, denoting them in the form of "(mean ± std)".

Problem	IAMB		MIAMB		
	I	II	I	II	III

Table 2: Balanced accuracy of `IAMB/MIAMB` algorithms in the form of "(mean ± std)".

Problem	KIAMB		MKIAMB		
	I	II	I	II	III
4-class	0.9283 ± 0.085	0.8972 ± 0.124	0.9281 ± 0.092	0.9444 ± 0.066	0.9501 ± 0.058
8-class	0.9007 ± 0.105	0.8631 ± 0.144	0.9245 ± 0.089	0.9280 ± 0.082	0.9340 ± 0.078
16-class	0.8886 ± 0.106	0.8494 ± 0.142	0.9159 ± 0.084	0.9168 ± 0.086	0.9263 ± 0.075
32-class	0.8687 ± 0.114	0.8241 ± 0.151	0.9111 ± 0.081	0.9151 ± 0.076	0.9239 ± 0.068

Table 3: Balanced accuracy of `KIAMB/MKIAMB` algorithms in the form of "(mean ± std)".

The experiment is then performed following the above procedures. Its results are summarized in Table 2 and Table 3. In these two tables, the backcolor indicates the performance of algorithms with black corresponding to the best while light blue to the worst. By the results, it can be seen that `MIAMB/MKIAMB` outperform `IAMB/KIAMB` in most situations. Specifically, we have:

- `IAMB/KIAMB` algorithms: `IAMB/KIAMB`-I are much more preferred than `IAMB/KIAMB`-II.
- `MIAMB/MKIAMB` algorithms: `MKIAMB`-I has almost equal performance to `KIAMB`-I in 4-class problems, and they performs slightly better than `IAMB/KIAMB`-I in 16- and 32-class problems;

1. For example, consider an unbalanced target T and its classification with the following two confusion matrices (the left is *extremely bad*, while the right is *very good*):

Test \ Truth	$T = 1$	$T = 2$
$T = 1$	948	49
$T = 2$	2	1

Test \ Truth	$T = 1$	$T = 2$
$T = 1$	899	0
$T = 2$	51	50

Then, we have: (a) for the left *bad* confusion matrix, the ordinary accuracy equals 94.90% (meaning it is impacted deeply by the unbalanced value 1 of T), while its balanced accuracy equals 50.89%; (b) for the right *good* confusion matrix, its ordinary accuracy also equals 94.90%, but its balanced accuracy equals 97.32%. This means balanced accuracy is more reasonable than ordinary accuracy to measure classification performance for a practical problem containing unbalanced variables (note that such problems may frequently occur in practice).

Null hypothesis (H_0)	Problem			
	4-class	8-class	16-class	32-class
MIAMB-I $\preccurlyeq$ IAMB-I	2.0349×10^{-4}	1.3225×10^{-7}	1.3816×10^{-10}	4.0634×10^{-19}
MIAMB-II $\preccurlyeq$ IAMB-I	1.4772×10^{-2}	9.3393×10^{-10}	4.0911×10^{-12}	8.2111×10^{-21}
MIAMB-III $\preccurlyeq$ IAMB-I	2.1276×10^{-10}	9.5876×10^{-16}	1.8800×10^{-20}	9.1061×10^{-30}
MKIAMB-I $\preccurlyeq$ KIAMB-I	0.6221	4.9365×10^{-9}	5.9117×10^{-12}	2.0651×10^{-19}
MKIAMB-I = KIAMB-I	0.7558	——	——	——
MKIAMB-II $\preccurlyeq$ KIAMB-I	2.2839×10^{-6}	5.9538×10^{-11}	5.4564×10^{-12}	2.7021×10^{-22}
MKIAMB-III $\preccurlyeq$ KIAMB-I	4.5857×10^{-10}	1.1261×10^{-15}	4.7802×10^{-20}	6.4206×10^{-30}

Table 4: p-values on paired t-test for comparison between MIAMB/MKIAMB and IAMB/KIAMB. Here, the notations are defined as follows: letting $\mathscr{A}_1$ and $\mathscr{A}_2$ be two algorithms and P be a problem, if $\mathscr{A}_1$ is better (in the sense of possessing higher accuracy) than $\mathscr{A}_2$ when used to solve P, we denote it by $\mathscr{A}_1 \succ \mathscr{A}_2$ (w.r.t. P); otherwise, we write it as $\mathscr{A}_1 \preccurlyeq \mathscr{A}_2$. In addition, we use $\mathscr{A}_1 = \mathscr{A}_2$ to denote $\mathscr{A}_1 \preccurlyeq \mathscr{A}_2$ and $\mathscr{A}_1 \succcurlyeq \mathscr{A}_2$.

MIAMB/MKIAMB-II significantly improve IAMB/KIAMB and even MIAMB/MKIAMB-I in most cases (although MIAMB/MKIAMB-II have larger std values than MIAMB/MKIAMB-I in some cases, the differences are slight). MIAMB/MKIAMB-III perform the best in all situations, with the highest mean values and the smallest std values.

Further, for any two algorithms, denote their balanced accuracy values as n (= 200) paired data points. Then, we can compute the p-values of *paired t-test* of associated hypotheses for one algorithm to be better (in the sense of possessing higher accuracy) than the other. The results are presented in Table 4. This table quantificationally shows the statistical significance of how much MIAMB/MKIAMB improve IAMB/KIAMB: in most cases, the improvement is more and more significant as the classification complex increases.

- The performance of each algorithm degrades with the increase of classification complexity. However, the degenerations of MIAMB/MKIAMB are slower than that of IAMB/KIAMB.

To compare IAMB/KIAMB and MIAMB/MKIAMB detailedly, we take the results of IAMB/KIAMB-I and MIAMB/MKIAMB-III to make a further analysis. For the 4-class prediction problem, denote the results of IAMB-I and MIAMB-III by $\tau_i^{(\mathtt{IAMB})}$ and $\tau_i^{(\mathtt{MIAMB})}$ for $i = 1, \cdots, n$, and draw them in (a) of Figure 16. Put

$$\begin{aligned} \boldsymbol{I}_1 &= \left\{i \in \{1, \cdots, n\} : \tau_i^{(\mathtt{IAMB})} > \tau_i^{(\mathtt{MIAMB})}\right\}, \\ \boldsymbol{I}_2 &= \left\{i \in \{1, \cdots, n\} : \tau_i^{(\mathtt{IAMB})} = \tau_i^{(\mathtt{MIAMB})}\right\}, \\ \boldsymbol{I}_3 &= \left\{i \in \{1, \cdots, n\} : \tau_i^{(\mathtt{IAMB})} < \tau_i^{(\mathtt{MIAMB})}\right\}. \end{aligned}$$

Draw the scatters of $\tau_i^{(\mathtt{IAMB})}$ and $\tau_i^{(\mathtt{MIAMB})}$ for $i \in \boldsymbol{I}_j$ in (a_j) of Figure 16. In addition, the information about (mean ± std) of IAMB-I vs that of MIAMB-III is annotated in each title. For other three K-class prediction problems (K = 8, 16, 32), repeat the above steps to get the scatters drawn in the other subplots of Figure 16. Similarly, Figure 17 draws the results of KIAMB-I versus MKIAMB-III.

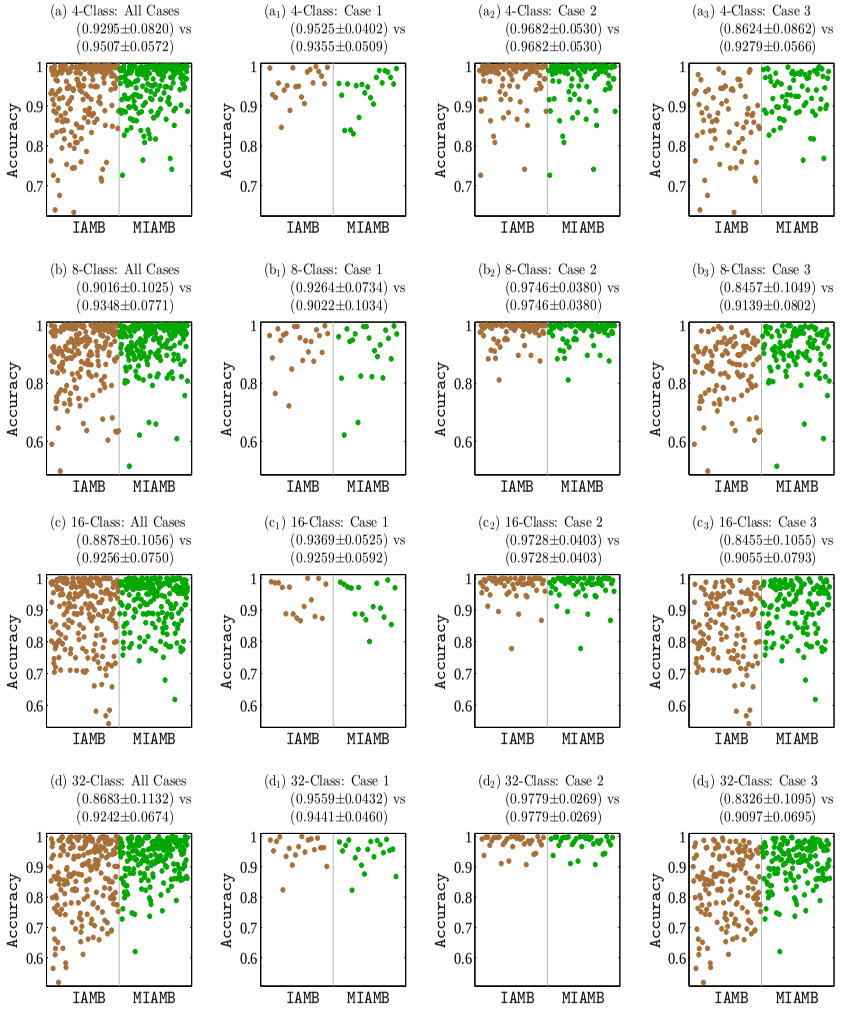

Figure 16: Balanced accuracy results on IAMB/MIAMB algorithms applied to 200 K-class prediction problems (K = 4, 8, 16, 32): the subplots in the first column for all the 200 results; the ones in the second column for the results that IAMB performs better than MIAMB; the ones in the third column for the results that IAMB and MIAMB perform equally well; the ones in the last column for the results that MIAMB performs better than IAMB.

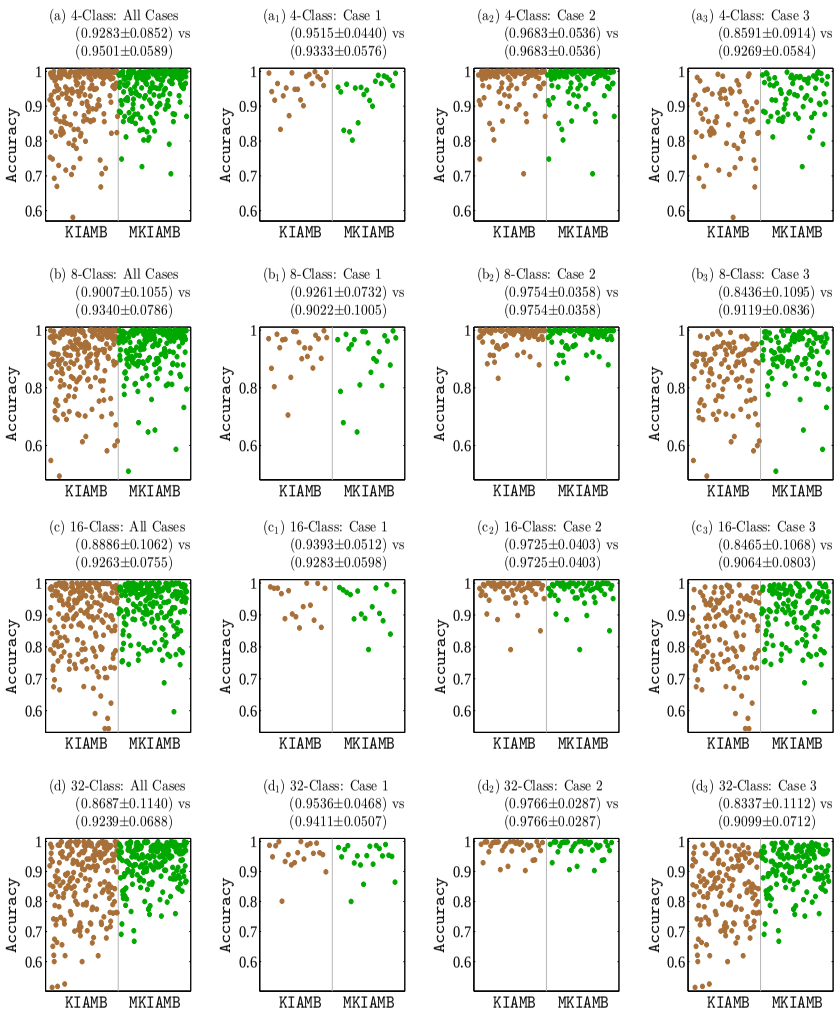

Figure 17: Balanced accuracy results on KIAMB/MKIAMB applied to 200 K-class prediction problems (K = 4, 8, 16, 32): the subplots in the first column for all the 200 results; the ones in the second column for the results that KIAMB performs better than MKIAMB; the ones in the third column for the results that KIAMB and MKIAMB perform equally well; the ones in the last column for the results that MKIAMB performs better than KIAMB.

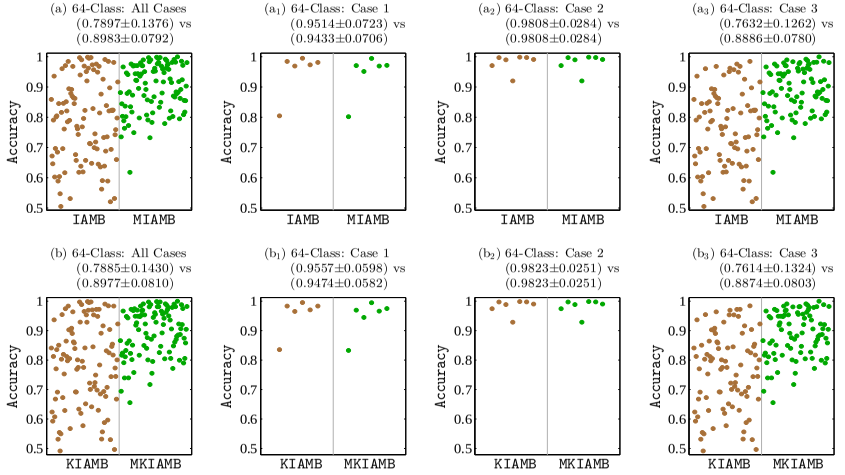

Figure 18: Balanced accuracy results on IAMB/MIAMB and KIAMB/MKIAMB applied to 100 64-class prediction problems: MIAMB/MKIAMB can improve IAMB/KIAMB substantially.

Figure 16 indicates that: (i) In most cases, MIAMB can improve IAMB to various degrees: MIAMB has higher mean values of balanced accuracy and smaller std values as well. Although there are a few of situations in which IAMB performs better than MIAMB, the difference of performance between them is very slight. In addition, there are some situations in which the two algorithms perform equally well (with very high mean and small std). (ii) MIAMB is more resistant to the classification complexity than IAMB: the improvements of MIAMB over IAMB become more and more visible with the increase of K (from 4 to 32). Figure 17 shows similar conclusions.

In brief, an FS problem for multi-class prediction can be transformed into a problem of MB discovery for multiple targets, and then get a more efficient solution. This idea may be particularly useful when the classification complexity is high or very high. To check this imagination, we apply the same procedures to 100 64-class prediction problems (also taken from the HIVA data set). The results are summarized in Figure 18, in which (a) and (a_j) are for IAMB/MIAMB while (b) and (b_j) are for KIAMB/MKIAMB, $j = 1, 2, 3$. By the figure, the improvement (nearly 14% on accuracy) of MIAMB/MKIAMB algorithms over IAMB/KIAMB is really desirable in the case of high classification complexity.

Finally, we apply LibSVM and the random forest (RF) algorithm (Breiman, 2001) to the whole HIVA data without any FS, considering LibSVM is of high classification performance while RF is a state-of-the-art FS algorithm. The results can be served as a baseline to see why FS (or equivalently, MB discovery) is necessary for a complex classification problem. Recall that HIVA contains many unbalanced variables, which enhance the classification complexity. Figure 19 draws the 95% confidence bands of LibSVM and FS, respectively.

By the figure, it follows that:

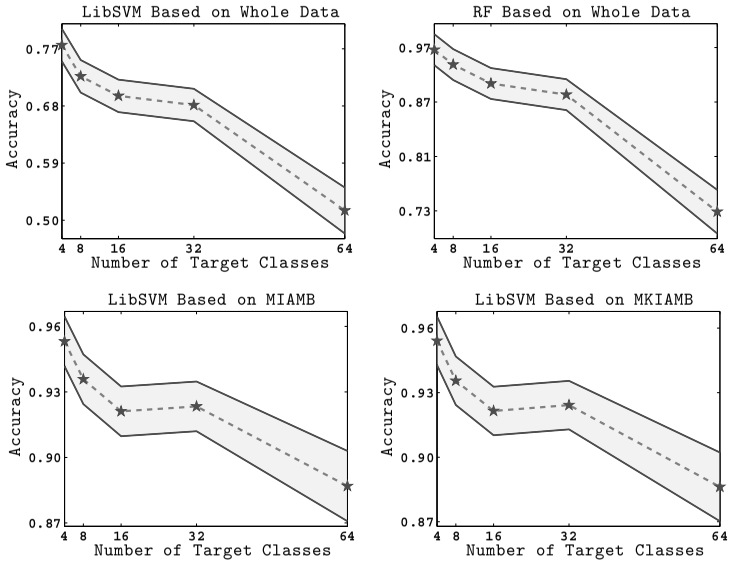

Figure 19: The 95% confidence bands of LibSVM and RF.

- Without any FS, LibSVM performs undesirably in all situations. This may be because too many noisy variables can lead to masking effects upon those unbalanced features such that LibSVM cannot classify targets expectedly. This shows the necessity of FS. In other words, LibSVM may not be suitable for some *high-dimension* problems, especially when there are many unbalanced variables.

- Without any FS, RF performs quite well when the classification complexity is not very high. However, with the increase of classification complexity, the performance of RF decreases gradually and then sharply. In other words, RF may not be suitable for those problems with too *high complexity*, especially when there are many unbalanced variables.

To observe why this happens, we check the results and then randomly take some targets (with extraordinarily low accuracy) to implement LibSVM and RF again by appropriately adjusting the algorithmic setting of LibSVM and increasing the number of trees of RF from 100 to 1000. However, the results change very little.

To make an intuitive comparison, the 95% confidence bands of MIAMB/MKIAMB-based LibSVM are also drawn in Figure 19. As seen, all methods degenerate with the increase of the classification complexity, but our methods degenerate far slower than LibSVM/RF based on the whole data. In a word, MB discovery (or equivalently, FS) is important to make classification, especially when the problem is of *high dimension* and of *high complexity*.

7. Concluding Remarks

In this paper, we considered the problem of Mb and MB of multiple variables. We first addressed their additivity under the local intersection assumption, and then studied this problem in the general case. The two algorithms that we proposed , MIAMB and MKIAMB, were proven to be correct under the local composition assumption with respect to single targets. The benchmarking study based on six synthetic BNs showed that MIAMB and MKIAMB have higher accuracies and lower complexities than the existing IAMB and KIAMB.

Before ending this paper, we present four concluding remarks as follows:

(i) The first remark concerns a method of using MIAMB and MKIAMB to find an MB for a single variable. Such an idea is motivated by the following two aspects: (a) the local composition assumption may be violated in practice, and if this is the case, IAMB and KIAMB may perform not very well in MB discovery even for a single variable; (b) randomness of a data set may result in a violation to the assumption that all the CI tests involved are correct. Naturally, it is useful to take a remedy for these two situations. One remedial strategy is described as follows: letting $T \in \boldsymbol{V}$ be the target variable, and $\boldsymbol{M}_1$ be a potential MB discovered by IAMB or KIAMB, take $T_0 \triangleq \arg\max_{X \in \boldsymbol{M}_1} J_{\boldsymbol{D}}^{(\ell)}(T; X \mid \boldsymbol{M}_1 \setminus \{X\})$ as a co-target of T for $\ell = 1$ or 2 or 3; then, employ MIAMB or MKIAMB to find a potential MB for $\{T, T_0\}$, saying $\boldsymbol{M}_2$. Finally, refine $\{T_0\} \cup \boldsymbol{M}_2$ to obtain $\boldsymbol{M}$, by virtue of the shrinking phase of IAMB or KIAMB, since this phase needs no the local composition precondition.

(ii) Our MIAMB and MKIAMB contain an ordering τ, which may affect the RT and even the WA or WP. A question arises here: is there an optimal selection of τ such that MIAMB or MKIAMB has the highest accuracy and the lowest complexity?

(iii) All the considered algorithms (IAMB, KIAMB, MIAMB, and MKIAMB) need the local composition assumption to theoretically guarantee their correctness. However, this precondition may be violated in practice and in this case only an approximate MB can be obtained by means of one of the above algorithms. Subsection 4.1 provides a potential remedy. We note that MIAMB and MKIAMB transform the problem of MB discovery for multiple targets into the ones for single targets. This idea provides a facilitation to use some stochastic optimization methods such as the particle swarm optimization algorithm (Kennedy and Eberhart, 1995, 1997).

(iv) In Subsection 3.3, we provided a method for MB discovery of a *complex* single variable based on an MB discovery of some *simple* multiple variables. Let us now explain why this transformation method is efficient. With the notations used in Subsection 3.3, let

$$\mathrm{MB}_T = \mathrm{MB}_{\boldsymbol{T}^{(d)}} \triangleq \boldsymbol{M}.$$

Then, a variable X can enter and stay in $\boldsymbol{M}$ (in the sense of MB_T) if $T \not\perp\!\!\!\perp X \mid \boldsymbol{M} \setminus \{X\}$. On the other hand, by Theorem 5, X can enter and stay in $\boldsymbol{M}$ (in the sense of $\mathrm{MB}_{\boldsymbol{T}^{(d)}}$) only if $T_j^{(d)} \not\perp\!\!\!\perp X \mid \boldsymbol{M} \setminus \{X\}$ holds for some j. That is, we need to test the following two pairs of hypotheses:

$$H_0^{(1)}: \quad T \perp\!\!\!\perp X \mid \boldsymbol{M} \setminus \{X\} \quad \leftrightarrow \quad H_1^{(1)}: \quad T \not\perp\!\!\!\perp X \mid \boldsymbol{M} \setminus \{X\};$$
$$H_0^{(2)}: \quad T_j^{(d)} \perp\!\!\!\perp X \mid \boldsymbol{M} \setminus \{X\} \quad \leftrightarrow \quad H_1^{(2)}: \quad T_j^{(d)} \not\perp\!\!\!\perp X \mid \boldsymbol{M} \setminus \{X\}.$$

Clearly, when T is high-dimensional, *the test for* $H_0^{(1)} \leftrightarrow H_1^{(1)}$ requires far more data points than *that for* $H_0^{(2)} \leftrightarrow H_1^{(2)}$, since the test statistic for the first pair of hypotheses contains far more free parameters than that for the second. In addition, the transformation from T to $\boldsymbol{T}^{(d)}$ can be easily made, with almost no running time. This explains why Theorem 5 is useful.

Acknowledgments

The authors are very grateful to the four anonymous reviewers and Prof. Marina Meila and Prof. Joris Mooij for their valuable comments and constructive suggestions which result in the present version. Thanks also to Prof. Kevin Murphy for all of his kind help.

Appendix B. Proofs

In this appendix, we give the proofs of the theoretical results.

Lemma 1 *The intersection property holds if and only if no information equivalence occurs.*

Proof Equivalently, we show that the intersection property is violated if and only if information equivalence occurs. The sufficiency holds clearly. To prove the necessity, we assume the intersection property is violated, that is, there are $\boldsymbol{T}$, $\boldsymbol{X}$, $\boldsymbol{Y}$, and $\boldsymbol{Z}$ such that $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{X} \mid \boldsymbol{Z} \cup \boldsymbol{Y}$, and $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{Y} \mid \boldsymbol{Z} \cup \boldsymbol{X}$, but $\boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{X} \cup \boldsymbol{Y} \mid \boldsymbol{Z}$. Then, we can show $\boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{X} \mid \boldsymbol{Z}$. In fact, if $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{X} \mid \boldsymbol{Z}$, then combined with $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{Y} \mid \boldsymbol{Z} \cup \boldsymbol{X}$ and the contraction property, it concludes $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{X} \cup \boldsymbol{Y} \mid \boldsymbol{Z}$, which contradicts $\boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{X} \cup \boldsymbol{Y} \mid \boldsymbol{Z}$. Similarly, we can show $\boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{Y} \mid \boldsymbol{Z}$. Therefore, $\boldsymbol{X}$ and $\boldsymbol{Y}$ are information equivalent with respect to $\boldsymbol{T}$ given $\boldsymbol{Z}$. That is, information equivalence occurs. ■

Lemma 2 *For $\boldsymbol{T} \subseteq \boldsymbol{V}$, assume the type-II local condition holds. Then $\boldsymbol{T}$ has a unique MB.*

Proof Suppose $\boldsymbol{T}$ has two different MBs, $\boldsymbol{M}_1$ and $\boldsymbol{M}_2$. Putting $\boldsymbol{M}_{12} \triangleq \boldsymbol{M}_1 \setminus \boldsymbol{M}_2$, $\boldsymbol{M}_{21} \triangleq \boldsymbol{M}_2 \setminus \boldsymbol{M}_1$, and $\boldsymbol{M} \triangleq \boldsymbol{M}_1 \cap \boldsymbol{M}_2 \subsetneq \boldsymbol{M}_i$ for $i = 1, 2$, we have

$$\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T} \mid \boldsymbol{M}_1 \;\Rightarrow\; \boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T} \mid \boldsymbol{M} \cup \boldsymbol{M}_{12}, \tag{8}$$

$$\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M}_2 \setminus \boldsymbol{T} \mid \boldsymbol{M}_2 \;\Rightarrow\; \boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M}_2 \setminus \boldsymbol{T} \mid \boldsymbol{M} \cup \boldsymbol{M}_{21}. \tag{9}$$

Now we show $\boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{M}_{12} \mid \boldsymbol{M}$. In fact, suppose we have $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{M}_{12} \mid \boldsymbol{M}$. This combined with (8) implies $\boldsymbol{T} \perp\!\!\!\perp (\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}) \cup \boldsymbol{M}_{12} \mid \boldsymbol{M}$, in view of the contraction property. Equivalently, $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M} \setminus \boldsymbol{T} \mid \boldsymbol{M}$, which contradicts the fact that $\boldsymbol{M}_1$ is an MB of $\boldsymbol{T}$, since $\boldsymbol{M} \subsetneq \boldsymbol{M}_1$. Hence, $\boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{M}_{12} \mid \boldsymbol{M}$. Similarly, we can show $\boldsymbol{T} \not\perp\!\!\!\perp \boldsymbol{M}_{21} \mid \boldsymbol{M}$. On the other hand, by the decomposition property, (9) and (8) indicate $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{M}_{12} \mid \boldsymbol{M} \cup \boldsymbol{M}_{21}$ and $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{M}_{21} \mid \boldsymbol{M} \cup \boldsymbol{M}_{12}$, respectively. Therefore, $\boldsymbol{M}_{12}$ and $\boldsymbol{M}_{21}$ are information equivalent with respect to $\boldsymbol{T}$ conditioned on $\boldsymbol{M}$. This contradicts the precondition. The uniqueness of MB of $\boldsymbol{T}$ is shown under the type-II local condition. ■

Theorem 2 (Additivity of Mb) *Let $(\mathbb{G}, \mathbb{P})$ be a BN over $\boldsymbol{V}$. The following two statements hold:*

(i) *Let $\boldsymbol{M}_i$ be an Mb of $\boldsymbol{T}_i \subseteq \boldsymbol{V}$ for $i = 1, 2$, and assume $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$ satisfies the local intersection assumption. Then, $(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus (\boldsymbol{T}_1 \cup \boldsymbol{T}_2)$ is an Mb of $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$.*

(ii) *Let $\boldsymbol{M}_i$ be an Mb of $T_i \in \boldsymbol{V}$ for $i = 1, \cdots, k$, and assume $\boldsymbol{T} \triangleq \{T_1, \cdots, T_k\}$ satisfies the local intersection assumption. Then, $\bigcup_{i=1}^{k} \boldsymbol{M}_i \setminus \boldsymbol{T}$ is an Mb of $\boldsymbol{T}$.*

Proof It suffices to prove (i), since (ii) is a direct consequence of (i) using induction on the number of variables involved in $\boldsymbol{T}$.

Denote $\boldsymbol{V}_0 = \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$ with $\boldsymbol{N} = \boldsymbol{N}_1 \cup \boldsymbol{N}_2$, in which $\boldsymbol{N}_1 = \boldsymbol{M}_1 \setminus \boldsymbol{T}_2$ and $\boldsymbol{N}_2 = \boldsymbol{M}_2 \setminus \boldsymbol{T}_1$. Note that $\boldsymbol{N}$ can also be expressed as $\boldsymbol{N} = (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}$. First, we prove the following CI relationship, by means of the graphoid properties:

$$\boldsymbol{V}_0 \perp\!\!\!\perp \boldsymbol{T}_1 \mid \boldsymbol{N} \cup \boldsymbol{T}_2. \tag{10}$$

In fact, with the above notations, it is readily justified that $\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1 = \boldsymbol{V}_0 \cup [(\boldsymbol{N}_2 \cup \boldsymbol{T}_2) \setminus \boldsymbol{M}_1]$. On the other hand, $\boldsymbol{M}_1$ is an Mb of $\boldsymbol{T}_1$. Therefore, $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1 \mid \boldsymbol{M}_1$, and thus we obtain $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V}_0 \cup [(\boldsymbol{N}_2 \cup \boldsymbol{T}_2) \setminus \boldsymbol{M}_1] \mid \boldsymbol{M}_1$. By the weak union property, $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V}_0 \mid \boldsymbol{M}_1 \cup [(\boldsymbol{N}_2 \cup \boldsymbol{T}_2) \setminus \boldsymbol{M}_1]$. This means (10) holds, since $\boldsymbol{M}_1 \cup [(\boldsymbol{N}_2 \cup \boldsymbol{T}_2) \setminus \boldsymbol{M}_1] = \boldsymbol{N} \cup \boldsymbol{T}_2$.

Similarly, $\boldsymbol{V}_0 \perp\!\!\!\perp \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{T}_1$, which combined with (10) indicates

$$\boldsymbol{V}_0 \perp\!\!\!\perp \boldsymbol{T} \,|\, \boldsymbol{N}$$

by the local intersection assumption. Or equivalently, $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T} \,|\, \boldsymbol{N}$. That is, $(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T} = \boldsymbol{N}$ is an Mb of $\boldsymbol{T}$. The proof is completed. ■

Remark 1 *In the case of either $\boldsymbol{T}_1 \subseteq \boldsymbol{V} \setminus \boldsymbol{M}_2$ or $\boldsymbol{T}_2 \subseteq \boldsymbol{V} \setminus \boldsymbol{M}_1$, the conclusion of* (i) *in Theorem 2 holds without requiring the local intersection assumption.*

Proof If $\boldsymbol{T}_1 \subseteq \boldsymbol{V} \setminus \boldsymbol{M}_2$ but $\boldsymbol{T}_2 \nsubseteq \boldsymbol{V} \setminus \boldsymbol{M}_1$, $\boldsymbol{M}_1 \cup \boldsymbol{M}_2$ is then an Mb of $\boldsymbol{T}_1$ according to the weak union property whereas $(\boldsymbol{M}_1 \setminus \boldsymbol{T}_2) \cup \boldsymbol{M}_2$ is an Mb of $\boldsymbol{T}_2$. Equivalently, we have

$$\begin{aligned}\boldsymbol{T}_1 &\perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}_1 \,|\, \boldsymbol{M}_1 \cup \boldsymbol{M}_2,\\ \boldsymbol{T}_2 &\perp\!\!\!\perp \boldsymbol{V} \setminus [(\boldsymbol{M}_1 \setminus \boldsymbol{T}_2) \cup \boldsymbol{M}_2] \setminus \boldsymbol{T}_2 \,|\, (\boldsymbol{M}_1 \setminus \boldsymbol{T}_2) \cup \boldsymbol{M}_2.\end{aligned}$$

By means of the contraction property and the decomposition property, it is seen that

$$\begin{aligned}\boldsymbol{V} \setminus [(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}_2] \setminus \boldsymbol{T} &\perp\!\!\!\perp \boldsymbol{T}_1 \,|\, [(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}_2] \cup \boldsymbol{T}_2,\\ \boldsymbol{V} \setminus [(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}_2] \setminus \boldsymbol{T} &\perp\!\!\!\perp \boldsymbol{T}_2 \,|\, (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}_2,\end{aligned}$$

so $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus [(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}_2] \setminus \boldsymbol{T} \,|\, (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}_2$. That is, $(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus (\boldsymbol{T}_1 \cup \boldsymbol{T}_2) = (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}_2$ is an Mb of $\boldsymbol{T}$. If $\boldsymbol{T}_1 \nsubseteq \boldsymbol{V} \setminus \boldsymbol{M}_2$ but $\boldsymbol{T}_2 \subseteq \boldsymbol{V} \setminus \boldsymbol{M}_1$, we can similarly show

$$(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus (\boldsymbol{T}_1 \cup \boldsymbol{T}_2) = (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}_1$$

is an Mb of $\boldsymbol{T}$. Finally, if $\boldsymbol{T}_1 \subseteq \boldsymbol{V} \setminus \boldsymbol{M}_2$ and $\boldsymbol{T}_2 \subseteq \boldsymbol{V} \setminus \boldsymbol{M}_1$, imposing decomposition on

$$\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}_1 \,|\, \boldsymbol{M}_1 \cup \boldsymbol{M}_2$$

and weak union on $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}_2 \,|\, \boldsymbol{M}_1 \cup \boldsymbol{M}_2$, we get

$$\begin{aligned}\boldsymbol{V} \setminus (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T} &\perp\!\!\!\perp \boldsymbol{T}_1 \,|\, \boldsymbol{M}_1 \cup \boldsymbol{M}_2,\\ \boldsymbol{V} \setminus (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T} &\perp\!\!\!\perp \boldsymbol{T}_2 \,|\, (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \cup \boldsymbol{T}_1.\end{aligned}$$

By the contraction property, $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T} \,|\, \boldsymbol{M}_1 \cup \boldsymbol{M}_2$. That is,

$$(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus (\boldsymbol{T}_1 \cup \boldsymbol{T}_2) = \boldsymbol{M}_1 \cup \boldsymbol{M}_2$$

is an Mb of $\boldsymbol{T}$. The conclusion is proved. ■

Theorem 3 (Additivity of MB) *Let $(\mathbb{G}, \mathbb{P})$ be a BN over $\boldsymbol{V}$. The following two statements hold:*

(i) *Assume $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$ satisfies the local intersection assumption. Let $\boldsymbol{M}_i$ be the unique MB of $\boldsymbol{T}_i$ for $i = 1, 2$. Then, $(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus (\boldsymbol{T}_1 \cup \boldsymbol{T}_2)$ is the unique MB of $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$.*

(ii) *Assume $\boldsymbol{T} \triangleq \{T_1, \cdots, T_k\}$ satisfies the local intersection assumption. Let $\boldsymbol{M}_i$ be the unique MB of T_i for $i = 1, \cdots, k$. Then, $\bigcup_{i=1}^{k} \boldsymbol{M}_i \setminus \boldsymbol{T}$ is the uniqe MB of $\boldsymbol{T}$.*

Proof We need only to prove (i), since (ii) is a direct consequence of (i).

Denote $\boldsymbol{N}_1 = \boldsymbol{M}_1 \setminus \boldsymbol{T}_2$ and $\boldsymbol{N}_2 = \boldsymbol{M}_2 \setminus \boldsymbol{T}_1$. By Theorem 2, $(\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T} = \boldsymbol{N}_1 \cup \boldsymbol{N}_2$ is an Mb of $\boldsymbol{T}$. Therefore, it suffices to prove the minimality of $\boldsymbol{N}_1 \cup \boldsymbol{N}_2$, based on Lemma 2. In fact, let $\boldsymbol{N}_0$ be any Mb of $\boldsymbol{T}$ which is a subset of $\boldsymbol{N}_1 \cup \boldsymbol{N}_2$. Note that $\boldsymbol{T}_i \cap \boldsymbol{N}_0 = \emptyset$ for $i = 1, 2$. Denote now $\boldsymbol{M} = \boldsymbol{N}_0 \cup (\boldsymbol{M}_1 \setminus \boldsymbol{N}_1) = \boldsymbol{N}_0 \cup (\boldsymbol{M}_1 \cap \boldsymbol{T}_2)$. It follows that

- $\boldsymbol{M}_1$ is the MB of $\boldsymbol{T}_1$: This implies $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1 \,|\, \boldsymbol{M}_1$, or equivalently, we have

  $$\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1 \,|\, (\boldsymbol{M}_1 \cap \boldsymbol{M}) \cup (\boldsymbol{M}_1 \setminus \boldsymbol{M}), \tag{11}$$

  in view of $\boldsymbol{M}_1 = (\boldsymbol{M}_1 \cap \boldsymbol{M}) \cup (\boldsymbol{M}_1 \setminus \boldsymbol{M})$.
- $\boldsymbol{N}_0$ is an Mb of $\boldsymbol{T}$: Equivalently, we have $\boldsymbol{T}_1 \cup \boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{N}_0 \setminus \boldsymbol{T}_2 \setminus \boldsymbol{T}_1 \,|\, \boldsymbol{N}_0$, which gives

  $$\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{N}_0 \cup \boldsymbol{T}_2) \setminus \boldsymbol{T}_1 \,|\, \boldsymbol{N}_0 \cup \boldsymbol{T}_2,$$

  according to the weak union property, and thus $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{M} \cup \boldsymbol{T}_2) \setminus \boldsymbol{T}_1 \,|\, \boldsymbol{M} \cup \boldsymbol{T}_2$ in view of $\boldsymbol{N}_0 \cup \boldsymbol{T}_2 = \boldsymbol{M} \cup \boldsymbol{T}_2$, or equivalently we have $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M} \setminus \boldsymbol{T}_1 \setminus \boldsymbol{T}_2 \,|\, \boldsymbol{M} \cup \boldsymbol{T}_2$. By the self-conditioning property, this leads to $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{M}_1 \cap \boldsymbol{M}) \setminus \boldsymbol{T}_1 \,|\, \boldsymbol{M} \cup \boldsymbol{T}_2$, Therefore,

  $$\boldsymbol{T}_1 \perp\!\!\!\perp (\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1) \cup (\boldsymbol{M}_1 \setminus \boldsymbol{M}) \,|\, \boldsymbol{M} \cup \boldsymbol{T}_2,$$

  in terms of $\boldsymbol{V} \setminus (\boldsymbol{M}_1 \cap \boldsymbol{M}) \setminus \boldsymbol{T}_1 = (\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1) \cup (\boldsymbol{M}_1 \setminus \boldsymbol{M})$. By the weak union property, this indicates $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{M}_1 \setminus \boldsymbol{M} \,|\, (\boldsymbol{M} \cup \boldsymbol{T}_2) \cup (\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1)$. Consequently,

  $$\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{M}_1 \setminus \boldsymbol{M} \,|\, (\boldsymbol{M}_1 \cap \boldsymbol{M}) \cup (\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1), \tag{12}$$

  due to $(\boldsymbol{M} \cup \boldsymbol{T}_2) \cup (\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1) = (\boldsymbol{M}_1 \cap \boldsymbol{M}) \cup (\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1)$.

By the local intersection property, (11)(12) indicate $\boldsymbol{T}_1 \perp\!\!\!\perp (\boldsymbol{M}_1 \setminus \boldsymbol{M}) \cup (\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1) \,|\, \boldsymbol{M}_1 \cap \boldsymbol{M}$, so

$$\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{M}_1 \cap \boldsymbol{M}) \setminus \boldsymbol{T}_1 \,|\, \boldsymbol{M}_1 \cap \boldsymbol{M},$$

since $(\boldsymbol{M}_1 \setminus \boldsymbol{M}) \cup (\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1) = \boldsymbol{V} \setminus (\boldsymbol{M}_1 \cap \boldsymbol{M}) \setminus \boldsymbol{T}_1$. Hence, $\boldsymbol{M}_1 \cap \boldsymbol{M}$ ($\subseteq \boldsymbol{M}_1$) is an Mb of $\boldsymbol{T}_1$. On the other hand, $\boldsymbol{M}_1$ is the MB of $\boldsymbol{T}_1$ and thereby $\boldsymbol{M}_1 \cap \boldsymbol{M} = \boldsymbol{M}_1$, or equivalently,

$$\boldsymbol{N}_1 \cup (\boldsymbol{M}_1 \cap \boldsymbol{T}_2) = \boldsymbol{M}_1 \subseteq \boldsymbol{M} = \boldsymbol{N}_0 \cup (\boldsymbol{M}_1 \cap \boldsymbol{T}_2),$$

which means $\boldsymbol{N}_1 \subseteq \boldsymbol{N}_0$. In a similar fashion, $\boldsymbol{N}_2 \subseteq \boldsymbol{N}_0$. Combined with $\boldsymbol{N}_0 \subseteq \boldsymbol{N}_1 \cup \boldsymbol{N}_2$, the expected relationship $\boldsymbol{N}_0 = \boldsymbol{N}_1 \cup \boldsymbol{N}_2$ follows. This indicates that $\boldsymbol{N}_1 \cup \boldsymbol{N}_2$ is an MB of $\boldsymbol{T}$. The proof is completed, since Lemma 2 shows the uniqueness of MB under the local intersection assumption. ■

Theorem 4 *Assume $\boldsymbol{S} \subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$. Then, the following statements are equivalent:*

(i) *$\boldsymbol{S}$ is an MbS;*

(ii) *$\mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}) = \min_{\boldsymbol{S}' \subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}} \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}')$;*

(iii) *$\mathbb{I}(\boldsymbol{T}; \boldsymbol{S} \,|\, \boldsymbol{N}) = \max_{\boldsymbol{S}' \subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}} \mathbb{I}(\boldsymbol{T}; \boldsymbol{S}' \,|\, \boldsymbol{N})$;*

(iv) *$\boldsymbol{N} \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}_1$ in $\boldsymbol{V} \setminus \boldsymbol{T}_2$ (or $\boldsymbol{N} \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}_2$ in $\boldsymbol{V} \setminus \boldsymbol{T}_1$).*

In addition, if $\boldsymbol{S}$ is an MbS, then it is also an MBS if and only if $\boldsymbol{T}_1 \not\perp\!\!\!\perp Y \,|\, \boldsymbol{N} \cup (\boldsymbol{S} \setminus \{Y\})$ or $\boldsymbol{T}_2 \not\perp\!\!\!\perp Y \,|\, \boldsymbol{N} \cup (\boldsymbol{S} \setminus \{Y\})$ holds for any $Y \in \boldsymbol{S}$.

Proof We first prove (i) $\Leftrightarrow$ (ii). Put $\boldsymbol{Q} = \boldsymbol{V} \setminus (\boldsymbol{N} \cup \boldsymbol{S}) \setminus \boldsymbol{T}$. First, note that $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1 \,|\, \boldsymbol{M}_1$ since $\boldsymbol{M}_1$ is an Mb of $\boldsymbol{T}_1$. In other words, $a \triangleq \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{Q} \cup (\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1 \setminus \boldsymbol{Q}) \,|\, \boldsymbol{M}_1) = 0$. By the chain rule for CMI (Cover and Thomas, 2006), we have $\mathbb{I}(\boldsymbol{T}_1; \boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1 \setminus \boldsymbol{Q} \,|\, \boldsymbol{M}_1) = 0$. It follows that

$$\begin{aligned} a &= \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1 \setminus \boldsymbol{Q} \,|\, \boldsymbol{M}_1) + \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{Q} \,|\, (\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1 \setminus \boldsymbol{Q}) \cup \boldsymbol{M}_1) \\ &= \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{Q} \,|\, (\boldsymbol{V} \setminus \boldsymbol{M}_1 \setminus \boldsymbol{T}_1 \setminus \boldsymbol{Q}) \cup \boldsymbol{M}_1) \\ &= \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{Q} \,|\, \boldsymbol{N} \cup \boldsymbol{S} \cup \boldsymbol{T}_2) \\ &= \mathbb{I}(\boldsymbol{T}; \boldsymbol{Q} \,|\, \boldsymbol{N} \cup \boldsymbol{S}) - \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{Q} \,|\, \boldsymbol{N} \cup \boldsymbol{S}) \qquad (13) \\ &\triangleq b - c, \end{aligned}$$

which combined with $a = 0$ gives $b = c$. Observing $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M}_2 \setminus \boldsymbol{T}_2 \,|\, \boldsymbol{M}_2$ since $\boldsymbol{M}_2$ is an Mb of $\boldsymbol{T}_2$, we obtain $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{Q} \,|\, (\boldsymbol{V} \setminus \boldsymbol{M}_2 \setminus \boldsymbol{T}_2 \setminus \boldsymbol{Q}) \cup \boldsymbol{M}_2$ by using the weak union property, or equivalently, $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{Q} \,|\, \boldsymbol{N} \cup \boldsymbol{S} \cup \boldsymbol{T}_1$, so $\mathbb{I}(\boldsymbol{T}_2; \boldsymbol{Q} \,|\, \boldsymbol{N} \cup \boldsymbol{S} \cup \boldsymbol{T}_1) = 0$. This means

$$\begin{aligned} 0 \leqslant c &= \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{Q} \,|\, \boldsymbol{N} \cup \boldsymbol{S}) \\ &= \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{T}_1 \cup \boldsymbol{Q} \,|\, \boldsymbol{N} \cup \boldsymbol{S}) - \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{T}_1 \,|\, \boldsymbol{N} \cup \boldsymbol{S} \cup \boldsymbol{Q}) \\ &= \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{T}_1 \,|\, \boldsymbol{N} \cup \boldsymbol{S}) + \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{Q} \,|\, \boldsymbol{N} \cup \boldsymbol{S} \cup \boldsymbol{T}_1) - \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{T}_1 \,|\, \boldsymbol{N} \cup \boldsymbol{S} \cup \boldsymbol{Q}) \\ &= \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{T}_1 \,|\, \boldsymbol{N} \cup \boldsymbol{S}) - \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{T}_1 \,|\, \boldsymbol{N} \cup \boldsymbol{S} \cup \boldsymbol{Q}). \qquad (14) \end{aligned}$$

- (i) $\Leftarrow$ (ii): If $\mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}) \leqslant \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}')$ holds for any $\boldsymbol{S}' \subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$, then (14) indicates $c = 0$ since $0 \leqslant c = \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{T}_1 \,|\, \boldsymbol{N} \cup \boldsymbol{S}) - \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{T}_1 \,|\, \boldsymbol{N} \cup \boldsymbol{S} \cup \boldsymbol{Q}) \leqslant 0$. Therefore,

  $$\mathbb{I}(\boldsymbol{T}; \boldsymbol{V} \setminus (\boldsymbol{N} \cup \boldsymbol{S}) \setminus \boldsymbol{T} \,|\, \boldsymbol{N} \cup \boldsymbol{S}) = \mathbb{I}(\boldsymbol{T}; \boldsymbol{Q} \,|\, \boldsymbol{N} \cup \boldsymbol{S}) = b = 0,$$

  because of $b = c$. That is, $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{N} \cup \boldsymbol{S}) \setminus \boldsymbol{T} \,|\, \boldsymbol{N} \cup \boldsymbol{S}$, which means $\boldsymbol{N} \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}$, or equivalently, $\boldsymbol{S}$ is an MbS.
- (i) $\Rightarrow$ (ii): Observe that $\mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{V} \setminus \boldsymbol{T}) = \min_{\boldsymbol{S}' \subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}} \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}')$ holds according to (14) holding for any $\boldsymbol{S} \subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$ and $\boldsymbol{N} \cup \boldsymbol{S} \cup \boldsymbol{Q} = \boldsymbol{V} \setminus \boldsymbol{T}$. Then,

  $$\mathbb{I}(\boldsymbol{T}; \boldsymbol{Q} \,|\, \boldsymbol{N} \cup \boldsymbol{S}) = \mathbb{I}(\boldsymbol{T}; \boldsymbol{V} \setminus (\boldsymbol{N} \cup \boldsymbol{S}) \setminus \boldsymbol{T} \,|\, \boldsymbol{N} \cup \boldsymbol{S}) = 0$$

  follows immediately if $\boldsymbol{N} \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}$. By (13) and (14), we have

  $$\mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}) = \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{V} \setminus \boldsymbol{T}) = \min_{\boldsymbol{S}' \subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}} \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}'), \qquad (15)$$

  noting again $\boldsymbol{N} \cup \boldsymbol{S} \cup \boldsymbol{Q} = \boldsymbol{V} \setminus \boldsymbol{T}$. This means $\boldsymbol{N} \cup \boldsymbol{S}$ is an MbS.

To prove the equivalence between (ii) and (iii), we need only to show

$$\mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}) = \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{M}_1) + \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{M}_2) - \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2) - \mathbb{I}(\boldsymbol{T}; \boldsymbol{N} \cup \boldsymbol{S}). \qquad (16)$$

In fact, using $\mathbb{I}(\boldsymbol{T}; \boldsymbol{N} \cup \boldsymbol{S}) = \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{N} \cup \boldsymbol{S}) + \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{N} \cup \boldsymbol{S} \,|\, \boldsymbol{T}_1)$, we have

$$\begin{aligned} d &\triangleq \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}) + \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2) + \mathbb{I}(\boldsymbol{T}; \boldsymbol{N} \cup \boldsymbol{S}) \\ &= \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}) + \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{N} \cup \boldsymbol{S}) + \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{T}_1) + \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{N} \cup \boldsymbol{S} \,|\, \boldsymbol{T}_1) \\ &= \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{T}_2 \cup \boldsymbol{N} \cup \boldsymbol{S}) + \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{N} \cup \boldsymbol{S} \cup \boldsymbol{T}_1) \\ &= \mathbb{I}(\boldsymbol{T}_1; \boldsymbol{M}_1) + \mathbb{I}(\boldsymbol{T}_2; \boldsymbol{M}_2), \end{aligned}$$

which is equivalent to (16). This means (ii) $\Leftrightarrow$ (iii).

Now, we show that (i) is equivalent to (iv):

- (i) $\Rightarrow$ (iv): This implication holds clearly due to the decomposition property.
- (i) $\Leftarrow$ (iv): Assume $\boldsymbol{N} \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}_1$ in $\boldsymbol{V} \setminus \boldsymbol{T}_2$, that is, $\boldsymbol{T}_1 \perp\!\!\!\perp (\boldsymbol{V} \setminus \boldsymbol{T}_2) \setminus (\boldsymbol{N} \cup \boldsymbol{S}) \setminus \boldsymbol{T}_1 \,|\, \boldsymbol{N} \cup \boldsymbol{S}$, or equivalently, $\boldsymbol{V} \setminus (\boldsymbol{N} \cup \boldsymbol{S}) \setminus \boldsymbol{T} \perp\!\!\!\perp \boldsymbol{T}_1 \,|\, \boldsymbol{N} \cup \boldsymbol{S}$. On the other hand, $\boldsymbol{M}_2$ is an Mb of $\boldsymbol{T}_2$ in $\boldsymbol{V}$, meaning $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M}_2 \setminus \boldsymbol{T}_2 \,|\, \boldsymbol{M}_2$, which combined with the weak union property gives $\boldsymbol{V} \setminus (\boldsymbol{N} \cup \boldsymbol{S}) \setminus \boldsymbol{T} \perp\!\!\!\perp \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S} \cup \boldsymbol{T}_1$. By the contraction property, $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{N} \cup \boldsymbol{S}) \setminus \boldsymbol{T} \,|\, \boldsymbol{N} \cup \boldsymbol{S}$. This means $\boldsymbol{S}$ is an MbS. Similarly, if $\boldsymbol{N} \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}_2$ in $\boldsymbol{V} \setminus \boldsymbol{T}_1$, we can show $\boldsymbol{S}$ is an MbS.

Finally, we prove that an MbS, $\boldsymbol{S}$, is an MBS if and only if $\boldsymbol{T}_2 \not\perp\!\!\!\perp Y \,|\, \boldsymbol{N} \cup (\boldsymbol{S} \setminus \{Y\})$ holds for any $Y \in \boldsymbol{S}$. We first prove the necessity by reductio ad absurdum. Suppose there is some variable $Y \in \boldsymbol{S}$ such that $\boldsymbol{T}_2 \perp\!\!\!\perp Y \,|\, \boldsymbol{N} \cup \boldsymbol{R}$, in which $\boldsymbol{R} \triangleq \boldsymbol{S} \setminus \{Y\}$. Recall that $\boldsymbol{S}$ is an MbS, we get

$$\boldsymbol{T}_2 \perp\!\!\!\perp (\boldsymbol{V} \setminus \boldsymbol{T}_1) \setminus (\boldsymbol{N} \cup \boldsymbol{S}) \setminus \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{S}.$$

Equivalently, $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{N} \cup \boldsymbol{R}) \setminus \boldsymbol{T} \setminus \{Y\} \,|\, (\boldsymbol{N} \cup \boldsymbol{R}) \cup \{Y\}$, which combined with $\boldsymbol{T}_2 \perp\!\!\!\perp Y \,|\, \boldsymbol{N} \cup \boldsymbol{R}$ gives $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{N} \cup \boldsymbol{R}) \setminus \boldsymbol{T} \,|\, \boldsymbol{N} \cup \boldsymbol{R}$, in view of the contraction property. That is, $\boldsymbol{T}_2 \perp\!\!\!\perp (\boldsymbol{V} \setminus \boldsymbol{T}_1) \setminus (\boldsymbol{N} \cup \boldsymbol{R}) \setminus \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{R}$. Therefore, $\boldsymbol{N} \cup \boldsymbol{R}$ is an Mb of $\boldsymbol{T}_2$ in $\boldsymbol{V} \setminus \boldsymbol{T}_1$, and thus an MbS of $\boldsymbol{T}$ to $\boldsymbol{N}$. This contradicts the condition that $\boldsymbol{S}$ is an MBS of $\boldsymbol{T}$ to $\boldsymbol{N}$, and thus $\boldsymbol{T}_2 \not\perp\!\!\!\perp Y \,|\, \boldsymbol{N} \cup (\boldsymbol{S} \setminus \{Y\})$ holds for any $Y \in \boldsymbol{S}$.

To prove the sufficiency, we suppose $\boldsymbol{S}$ is not a MBS of $\boldsymbol{T}$ to $\boldsymbol{N}$, that is, there is some $\boldsymbol{R} \subsetneq \boldsymbol{S}$ such that $\boldsymbol{R}$ is an MbS of $\boldsymbol{T}$ to $\boldsymbol{N}$. Take any given variable, Y, in $\boldsymbol{S} \setminus \boldsymbol{R}$. Then, $\boldsymbol{N} \cup \boldsymbol{R}$ is an Mb of $\boldsymbol{T}_2$ in $\boldsymbol{V} \setminus \boldsymbol{T}_1$. That is, $\boldsymbol{T}_2 \perp\!\!\!\perp (\boldsymbol{V} \setminus \boldsymbol{T}_1) \setminus (\boldsymbol{N} \cup \boldsymbol{R}) \setminus \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup \boldsymbol{R}$. By the weak union property, we have

$$\boldsymbol{T}_2 \perp\!\!\!\perp (\boldsymbol{V} \setminus \boldsymbol{T}_1) \setminus [\boldsymbol{N} \cup (\boldsymbol{S} \setminus \{Y\})] \setminus \boldsymbol{T}_2 \,|\, \boldsymbol{N} \cup (\boldsymbol{S} \setminus \{Y\}).$$

This combined with the decomposition property means $\boldsymbol{T}_2 \perp\!\!\!\perp Y \,|\, \boldsymbol{N} \cup (\boldsymbol{S} \setminus \{Y\})$, since

$$Y \in (\boldsymbol{V} \setminus \boldsymbol{T}_1) \setminus [\boldsymbol{N} \cup (\boldsymbol{S} \setminus \{Y\})] \setminus \boldsymbol{T}_2,$$

and thus leads to a contradiction to the condition that $\boldsymbol{T}_2 \not\perp\!\!\!\perp Y \,|\, \boldsymbol{N} \cup (\boldsymbol{S} \setminus \{Y\})$ holds for any $Y \in \boldsymbol{S}$.

The proof of Theorem 4 is completed. ■

Example 1 *Consider the BN $(\mathbb{G}, \mathbb{P})$ over $\boldsymbol{V} = \{A, B, C, D\}$ presented in Figure 8, in which A, B, and C take $\{1, 2, 3\}$ while D takes $\{1, 2\}$. Put $\boldsymbol{T} = \{T_1, T_2\}$, $\boldsymbol{N} = (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T} = \emptyset$, and $\boldsymbol{S} = \{C\}$, $\boldsymbol{S}_0 = \{C, D\}$ with $T_1 = A$, $T_2 = B$, $\boldsymbol{M}_1 = \{B\}$, $\boldsymbol{M}_2 = \{A\}$. By Figure 3, we can easily conclude that A and B are information equivalent with respect to C. This means*

$$\mathbb{I}(C; A) > 0, \;\; \mathbb{I}(C; B \,|\, A) = 0; \;\; \textit{and} \;\; \mathbb{I}(C; B) > 0, \;\; \mathbb{I}(C; A \,|\, B) = 0. \qquad (17)$$

It follows from the chain rule for CMI (Cover and Thomas, 2006) that

(i) *$\boldsymbol{M}_1$ is an MB of T_1 in $\boldsymbol{V}$: By (17), we have*

- *$\mathbb{I}(A; C, D \,|\, B) = \mathbb{I}(A; C \,|\, B) + \mathbb{I}(A; D \,|\, B, C) = 0$, since $\{B, C\}$ d-separates $\{A\}$ and $\{D\}$;*
- *$\mathbb{I}(A; C, D) \geqslant \mathbb{I}(A; C) > 0$.*

(ii) $\boldsymbol{M}_2$ *is an MB of* T_2 *in* $\boldsymbol{V}$*: By* (17)*, we have*

- $\mathbb{I}(B;C,D\,|\,A)=\mathbb{I}(B;C\,|\,A)+\mathbb{I}(B;D\,|\,A,C)=0$*, since* $\{A,C\}$ *d-separates* $\{B\}$ *and* $\{D\}$*;*
- $\mathbb{I}(B;C,D)\geqslant\mathbb{I}(B;C)>0$*.*

(iii) $\boldsymbol{N}\cup\boldsymbol{S}$ *is an Mb of* $\boldsymbol{T}$ *in* $\boldsymbol{V}$*, so* $\boldsymbol{S}$ *is an MbS: By* (17)*,*

$$\mathbb{I}(A,B;D\,|\,C)=\mathbb{I}(A;D\,|\,C)+\mathbb{I}(B;D\,|\,A,C)=0,$$

because $\{C\}$ *d-separates* $\{A\}$ *and* $\{D\}$*, while* $\{A,C\}$ *d-separates* $\{B\}$ *and* $\{D\}$*.*

(iv) $\mathbb{I}(\boldsymbol{T}_1;\boldsymbol{T}_2\,|\,\boldsymbol{N}\cup\boldsymbol{S})=\min_{\boldsymbol{S}'\subseteq\boldsymbol{V}\setminus\boldsymbol{N}\setminus\boldsymbol{T}}\mathbb{I}(\boldsymbol{T}_1;\boldsymbol{T}_2\,|\,\boldsymbol{N}\cup\boldsymbol{S}')$*: it suffices to show the following inequalities:*

- $\mathbb{I}(A;B\,|\,C)=\mathbb{I}(A;B\,|\,C,D)$*. In fact,*

$$\begin{aligned}\mathbb{I}(A;B\,|\,C,D)&=\mathbb{I}(A;B,D\,|\,C)-\mathbb{I}(A;D\,|\,C)\\&=\mathbb{I}(A;B\,|\,C)+\mathbb{I}(A;D\,|\,B,C)-\mathbb{I}(A;D\,|\,C)=\mathbb{I}(A;B\,|\,C),\end{aligned}$$

  since both $\{B,C\}$ *and* $\{C\}$ *d-separate* $\{A\}$ *and* $\{D\}$*;*

- $\mathbb{I}(A;B\,|\,C)\leqslant\mathbb{I}(A;B\,|\,D)$*; In fact,*

$$\begin{aligned}\mathbb{I}(A;B\,|\,C)&=\mathbb{I}(A;B\,|\,C,D)=\mathbb{I}(A;B,C\,|\,D)-\mathbb{I}(A;C\,|\,D)\\&=\mathbb{I}(A;B\,|\,D)+\mathbb{I}(A;C\,|\,B,D)-\mathbb{I}(A;C\,|\,D)\\&=\mathbb{I}(A;B\,|\,D)-\mathbb{I}(A;C\,|\,D)\leqslant\mathbb{I}(A;B\,|\,D),\end{aligned}$$

  due to $\mathbb{I}(A;C\,|\,B,D)=0$*, because of*

$$\begin{aligned}0&\leqslant\mathbb{I}(A;C\,|\,B,D)=\mathbb{I}(A;C,D\,|\,B)-\mathbb{I}(A;D\,|\,B)\\&=\mathbb{I}(A;C\,|\,B)+\mathbb{I}(A;D\,|\,B,C)-\mathbb{I}(A;D\,|\,B)\;=\;-\mathbb{I}(A;D\,|\,B)\leqslant 0,\end{aligned}$$

  since $\mathbb{I}(A;C\,|\,B)=0$ *(see Equation 17) and* $\{B,C\}$ *d-separates* $\{A\}$ *and* $\{D\}$*;*

- $\mathbb{I}(A;B\,|\,C)\leqslant\mathbb{I}(A;B)$*. In fact, by* (17)*, we have* $\mathbb{I}(A;C\,|\,B)=0$*. Thus,*

$$\begin{aligned}\mathbb{I}(A;B)&=\mathbb{I}(A;B,C)-\mathbb{I}(A;C\,|\,B)=\mathbb{I}(A;C)+\mathbb{I}(A;B\,|\,C)-\mathbb{I}(A;C\,|\,B)\\&=\mathbb{I}(A;C)+\mathbb{I}(A;B\,|\,C)\geqslant\mathbb{I}(A;B\,|\,C).\end{aligned}$$

(v) $\mathbb{I}(\boldsymbol{T};\boldsymbol{S}\,|\,\boldsymbol{N})=\max_{\boldsymbol{S}'\subseteq\boldsymbol{V}\setminus\boldsymbol{N}\setminus\boldsymbol{T}}\mathbb{I}(\boldsymbol{T};\boldsymbol{S}'\,|\,\boldsymbol{N})$*: the proof is omitted.*

(vi) $\boldsymbol{N}\cup\boldsymbol{S}$ *is an Mb of* T_1 *in* $\boldsymbol{V}\setminus\{T_2\}$*: By* (17)*, we have*

- $\mathbb{I}(A;C,D)\geqslant\mathbb{I}(A;C)>0$*;*
- $\mathbb{I}(A;D\,|\,C)=0$*, since* $\{C\}$ *d-separates* $\{A\}$ *and* $\{D\}$*.*

(vii) $\boldsymbol{N}\cup\boldsymbol{S}$ *is an Mb of* T_2 *in* $\boldsymbol{V}\setminus\{T_1\}$*: By* (17)*, we have*

- $\mathbb{I}(B;C,D)\geqslant\mathbb{I}(B;C)>0$*;*
- $\mathbb{I}(B;D\,|\,C)=0$*, since* $\{C\}$ *d-separates* $\{B\}$ *and* $\{D\}$*.*

(viii) $\boldsymbol{S}$ *is an MBS;* $\boldsymbol{S}_0$ *is an MbS (but not an MBS):* $\mathbb{I}(A;B\,|\,C,D)=\mathbb{I}(A;B\,|\,C)$*. In fact,*

$$\mathbb{I}(A;B\,|\,C,D)=\mathbb{I}(A;B,D\,|\,C)-\mathbb{I}(A;D\,|\,C)=\mathbb{I}(A;B\,|\,C)+\mathbb{I}(A;D\,|\,B,C)-0=\mathbb{I}(A;B\,|\,C),$$

since both $\{B,C\}$ *and* $\{C\}$ *d-separate* $\{A\}$ *and* $\{D\}$*.* ■

Theorem 5 *Let* $\boldsymbol{M}_j$ *be an MB of* $T_j^{(d)}$ *in* $\boldsymbol{V}\setminus\boldsymbol{T}$ *for* $j=1,\cdots,t$*. Then,* $\boldsymbol{M}\triangleq\cup_{j=1}^{k}\boldsymbol{M}_j$ *is an Mb of* $\boldsymbol{T}$*. Further,* $\boldsymbol{M}$ *is an MB of* $\boldsymbol{T}$ *iff for any* $X\in\boldsymbol{M}$ *there is some* j *such that* $T_j^{(d)}\not\perp\!\!\!\perp X\,|\,\boldsymbol{M}\setminus\{X\}$*.*

Proof Recall that T is the merged version of $\boldsymbol{T}$, while $\boldsymbol{T}^{(d)}$ is the dummy version of T; all of them have the same MBs.

First, we have $T_j^{(d)}\perp\!\!\!\perp(\boldsymbol{V}\setminus\boldsymbol{T})\setminus\boldsymbol{M}_j\setminus\{T_j^{(d)}\}\,|\,\boldsymbol{M}_j$ for $j=1,\cdots,t$. Considering $T_j^{(d)}\notin\boldsymbol{V}\setminus\boldsymbol{T}$, it follows that $T_j^{(d)}\perp\!\!\!\perp\boldsymbol{V}\setminus\boldsymbol{T}\setminus\boldsymbol{M}_j\,|\,\boldsymbol{M}_j$, which combined with the weak union property gives

$$T_j^{(d)}\perp\!\!\!\perp\boldsymbol{V}\setminus\boldsymbol{T}\setminus\boldsymbol{M}\,|\,\boldsymbol{M},\quad j=1,\cdots,t,\tag{18}$$

since $\boldsymbol{M}_j\subseteq\boldsymbol{M}$. Putting $\boldsymbol{U}\triangleq\boldsymbol{V}\setminus\boldsymbol{T}\setminus\boldsymbol{M}$, the above independence statements imply

$$\mathbb{P}\big(T_j^{(d)}=1,\,\boldsymbol{U}=\boldsymbol{u}\,\big|\,\boldsymbol{M}\big)=\mathbb{P}\big(T_j^{(d)}=1\,\big|\,\boldsymbol{M}\big)\mathbb{P}\big(\boldsymbol{U}=\boldsymbol{u}\,\big|\,\boldsymbol{M}\big),\quad j=1,\cdots,t,$$

or equivalently, $\mathbb{P}(T=j,\,\boldsymbol{U}=\boldsymbol{u}\,|\,\boldsymbol{M})=\mathbb{P}(T=j\,|\,\boldsymbol{M})\mathbb{P}(\boldsymbol{U}=\boldsymbol{u}\,|\,\boldsymbol{M})$, meaning $T\perp\!\!\!\perp\boldsymbol{V}\setminus\boldsymbol{T}\setminus\boldsymbol{M}\,|\,\boldsymbol{M}$, and thus $\boldsymbol{T}\perp\!\!\!\perp\boldsymbol{V}\setminus\boldsymbol{T}\setminus\boldsymbol{M}\,|\,\boldsymbol{M}$. This shows $\boldsymbol{M}$ is an Mb of $\boldsymbol{T}$.

In what follows, we prove $\boldsymbol{M}$ is an MB of $\boldsymbol{T}$ if and only if, for any $X\in\boldsymbol{M}$, $T_j^{(d)}\not\perp\!\!\!\perp X\,|\,\boldsymbol{M}\setminus\{X\}$ holds for some j:

"⇒" Assume $\boldsymbol{M}$ is an MB of $\boldsymbol{T}$. Suppose there is some variable X such that $T_j^{(d)}\perp\!\!\!\perp X\,|\,\boldsymbol{M}\setminus\{X\}$ holds for any j. Then, by (18) and the contraction property, we get

$$T_j^{(d)}\perp\!\!\!\perp(\boldsymbol{V}\setminus\boldsymbol{T})\setminus(\boldsymbol{M}\setminus\{X\})\,|\,\boldsymbol{M}\setminus\{X\},\quad j=1,\cdots,t.\tag{19}$$

Similar to the proof of the first conclusion, it can be readily proven that (19) implies

$$\boldsymbol{T}\perp\!\!\!\perp(\boldsymbol{V}\setminus\boldsymbol{T})\setminus(\boldsymbol{M}\setminus\{X\})\,|\,\boldsymbol{M}\setminus\{X\},$$

meaning that $\boldsymbol{M}$ has a proper subset, $\boldsymbol{M}\setminus\{X\}$, which is an Mb of $\boldsymbol{T}$. This contradicts the minimality of $\boldsymbol{M}$, and thus proves the necessity.

"⇐" Suppose $\boldsymbol{M}$ is not an MB of $\boldsymbol{T}$ (or T). Then, there is some $X\in\boldsymbol{M}$ such that $T\perp\!\!\!\perp X\,|\,\boldsymbol{M}\setminus\{X\}$. It follows that $\mathbb{P}(T=j,X=x\,|\,\boldsymbol{M}\setminus\{X\})=\mathbb{P}(T=j\,|\,\boldsymbol{M}\setminus\{X\})\mathbb{P}(X=x\,|\,\boldsymbol{M}\setminus\{X\})$ holds for any $j=1,\cdots,t$. Or equivalently, we have

$$\mathbb{P}\big(T_j^{(d)}=1,X=x\,\big|\,\boldsymbol{M}\setminus\{X\}\big)=\mathbb{P}\big(T_j^{(d)}=1\,\big|\,\boldsymbol{M}\setminus\{X\}\big)\mathbb{P}\big(X=x\,\big|\,\boldsymbol{M}\setminus\{X\}\big).\tag{20}$$

Futher, (20) indicates

$$\begin{aligned}\mathbb{P}\big(T_j^{(d)}=0,X=x\,\big|\,\boldsymbol{M}\setminus\{X\}\big)&=\mathbb{P}\big(X=x\,\big|\,\boldsymbol{M}\setminus\{X\}\big)-\mathbb{P}\big(T_j^{(d)}=1,X=x\,\big|\,\boldsymbol{M}\setminus\{X\}\big)\\&=\big[1-\mathbb{P}\big(T_j^{(d)}=1\,\big|\,\boldsymbol{M}\setminus\{X\}\big)\big]\mathbb{P}\big(X=x\,\big|\,\boldsymbol{M}\setminus\{X\}\big)\\&=\mathbb{P}\big(T_j^{(d)}=0\,\big|\,\boldsymbol{M}\setminus\{X\}\big)\mathbb{P}\big(X=x\,\big|\,\boldsymbol{M}\setminus\{X\}\big).\end{aligned}\tag{21}$$

By (20) and (21), we get $T_j^{(d)}\perp\!\!\!\perp X\,|\,\boldsymbol{M}\setminus\{X\}$, which contradicts $T_j^{(d)}\not\perp\!\!\!\perp X\,|\,\boldsymbol{M}\setminus\{X\}$. This proves the sufficiency.

The proof is completed. ■

Theorem 6 (Correctness of IAMBS and KIAMBS) *Assume that $\boldsymbol{T}_2$ satisfies the local composition property, and that all CI tests are correct. Then* (i) *IAMBS outputs an MB of $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$;* (ii) *KIAMBS outputs an MB of $\boldsymbol{T}_1 \cup \boldsymbol{T}_2$ for any $K \in [0, 1)$.*

Proof Clearly, $\boldsymbol{N} \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}_2$ in $\boldsymbol{V} \setminus \boldsymbol{T}_1$ at the end of the growing phase of either IAMBS or KIAMBS under the local composition assumption, as in IAMB and KIAMB. Therefore, $\boldsymbol{S}$ is an MbS at the end of this stage. According to the last conclusion of Theorem 4, $\boldsymbol{S}$ is an MBS after it is refined. Finally, as a direct consequence of Lemma 4 (shown below), $\boldsymbol{N} \cup \boldsymbol{S}$ is an MB at the end of the algorithm, considering the process of refining $\boldsymbol{N}$ is similar to that of refining $\boldsymbol{S}$. ■

Remark 2 *The following two statements hold:* (a) *violating local intersection implies violating adjacency faithfulness;* (b) *under the orientation faithfulness condition, violating local composition at the end of the first phase of IAMB or KIAMB or IAMBS or KIAMBS means violating adjacency faithfulness.*

Proof By Lemma 1, the violation of the local intersection property means information equivalence occurs; further, Lemeire et al. (2012) showed that information equivalence is one of the cases of violating adjacency faithfulness. Hence, the violation of local intersection is one of the violations of adjacency faithfulness.

Now, we show that the violation of local composition, which is present at the end of the first phase of IAMB or KIAMB, is also one of the violations of adjacency faithfulness under the *orientation faithfulness condition*.

In fact, let $\boldsymbol{M}$ be the output of the first phase of IAMB or KIAMB, but not an Mb of $\boldsymbol{T}$. Without loss of generality, we assume $|\boldsymbol{T}| = 1$ and $\boldsymbol{T} = \{T\}$. Then, $T \perp\!\!\!\perp X \,|\, \boldsymbol{M}$ holds for any $X \in \boldsymbol{V} \setminus \boldsymbol{M} \setminus \{T\}$ but $T \not\perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M} \setminus \{T\} \,|\, \boldsymbol{M}$. Considering that the set $\boldsymbol{M}_T$ composed of the parents, children, and spouses of T is an Mb of T, we have $\boldsymbol{M} \not\supseteq \boldsymbol{M}_T$. Thus, there is some $X \in \boldsymbol{M}_T$ such that $X \notin \boldsymbol{M}$. If X is a spouse of T, then all the children of T and X are not in $\boldsymbol{M}$ (if not so, $T \not\perp\!\!\!\perp X \,|\, \boldsymbol{M}$ holds immediately following from the orientation faithfulness condition, and thus contradicts $T \perp\!\!\!\perp X \,|\, \boldsymbol{M}$ since $X \notin \boldsymbol{M}$). In this sense, we conclude that there is some node X adjacent to T such that $T \perp\!\!\!\perp X \,|\, \boldsymbol{M}$. This means the adjacency faithfulness condition is violated.

In short words, both the violation of the local composition property (present at the end of the first phase of IAMB or KIAMB) and the violation of the local intersection property are the violations of adjacency faithfulness, under the orientation faithfulness condition. ■

Lemma 3 (a) *If there is $\boldsymbol{P} \subseteq \boldsymbol{M}_1 \setminus \boldsymbol{T}_2$ such that $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{P} \,|\, (\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_2$, then $(\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_2$ is an Mb of $\boldsymbol{T}_1$;* (b) *If there is $\boldsymbol{Q} \subseteq \boldsymbol{N} \setminus \boldsymbol{P}$ such that $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{Q} \,|\, (\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_2$ and $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{Q} \,|\, (\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_1$, then $(\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_2$ is an Mb of $\boldsymbol{T}_1$, and $(\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_1$ is an Mb of $\boldsymbol{T}_2$.*

Proof Considering that $\boldsymbol{N} \cup \boldsymbol{T}_2$ is an Mb of $\boldsymbol{T}_1$, we have $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{N} \cup \boldsymbol{T}_2) \setminus \boldsymbol{T}_1 \,|\, (\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_2 \cup \boldsymbol{P}$, which combined with $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{P} \,|\, (\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_2$ implies $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus [(\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_2] \setminus \boldsymbol{T}_1 \,|\, (\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_2$, in view of the contraction property. The first conclusion is proved.

For convenience, we denote now $\boldsymbol{N}_1 \triangleq \boldsymbol{M}_1 \setminus \boldsymbol{T}_2$. To show the second conclusion, we note that $\boldsymbol{P} \subseteq \boldsymbol{N}_1$, so $(\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_1$ is an Mb of $\boldsymbol{T}_2$. It follows that: (i) $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus [(\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_2] \setminus \boldsymbol{T}_1 \,|\, (\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_2$, which combined with $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{Q} \,|\, (\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_2$ gives $\boldsymbol{T}_1 \perp\!\!\!\perp \boldsymbol{V} \setminus [(\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_2] \setminus \boldsymbol{T}_1 \,|\, (\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_2$; and (ii) $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{V} \setminus [(\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_1] \setminus \boldsymbol{T}_2 \,|\, (\boldsymbol{N} \setminus \boldsymbol{P}) \cup \boldsymbol{T}_1$, which combined with $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{Q} \,|\, (\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_1$ yields $\boldsymbol{T}_2 \perp\!\!\!\perp \boldsymbol{V} \setminus [(\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_1] \setminus \boldsymbol{T}_2 \,|\, (\boldsymbol{N} \setminus \boldsymbol{P} \setminus \boldsymbol{Q}) \cup \boldsymbol{T}_1$. The second conclusion is also proved. ■

Lemma 4 *Let $\boldsymbol{T}_i$ be a subset of $\boldsymbol{V}$ with an Mb $\boldsymbol{M}_i$ for $i = 1, 2$, and $\boldsymbol{S} \subseteq \boldsymbol{V} \setminus \boldsymbol{N} \setminus \boldsymbol{T}$ be an MBS of $\boldsymbol{T}$ to $\boldsymbol{N}$, with $\boldsymbol{T} = \boldsymbol{T}_1 \cup \boldsymbol{T}_2$ and $\boldsymbol{N} = (\boldsymbol{M}_1 \cup \boldsymbol{M}_2) \setminus \boldsymbol{T}$. Assume $\boldsymbol{N}_0$ be a subset of $\boldsymbol{N}$ such that $\boldsymbol{N}_0 \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}$. Then $\boldsymbol{N}_0 \cup \boldsymbol{S}$ is an MB of $\boldsymbol{T}$ if and only if $\boldsymbol{T} \not\perp\!\!\!\perp Y \,|\, (\boldsymbol{N}_0 \setminus \{Y\}) \cup \boldsymbol{S}$ holds for any $Y \in \boldsymbol{N}_0$.*

Proof By the definition of MBS, $\boldsymbol{N} \cup \boldsymbol{R}$ and thus $\boldsymbol{N}_0 \cup \boldsymbol{R}$ will never be an Mb of $\boldsymbol{T}$ for any $\boldsymbol{N}_0 \subseteq \boldsymbol{N}$ and $\boldsymbol{R} \subsetneq \boldsymbol{S}$, in view of the weak union property.

- Necessity: Suppose there is some $Y \in \boldsymbol{N}_0$ such that $\boldsymbol{T} \perp\!\!\!\perp Y \,|\, (\boldsymbol{N}_0 \setminus \{Y\}) \cup \boldsymbol{S}$. By the precondition that $\boldsymbol{N}_0 \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}$, we have $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus (\boldsymbol{N}_0 \cup \boldsymbol{S}) \setminus \boldsymbol{T} \,|\, [(\boldsymbol{N}_0 \setminus \{Y\}) \cup \boldsymbol{S}] \cup \{Y\}$. These two relationships combined with the contraction property imply
$$\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus [(\boldsymbol{N}_0 \setminus \{Y\}) \cup \boldsymbol{S}] \setminus \boldsymbol{T} \,|\, (\boldsymbol{N}_0 \setminus \{Y\}) \cup \boldsymbol{S},$$
or equivalently, $(\boldsymbol{N}_0 \setminus \{Y\}) \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}$. This contradicts that $\boldsymbol{N}_0 \cup \boldsymbol{S}$ is an MB of $\boldsymbol{T}$.
- Sufficiency: Suppose $\boldsymbol{N}_0 \cup \boldsymbol{S}$ is not an MB of $\boldsymbol{T}$, that is, there is some $\boldsymbol{N}_0' \subsetneq \boldsymbol{N}_0$ such that $\boldsymbol{N}_0' \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}$. Take any given variable, Y, in $\boldsymbol{N}_0 \setminus \boldsymbol{N}_0'$. It can be shown that $\boldsymbol{T} \perp\!\!\!\perp Y \,|\, (\boldsymbol{N}_0 \setminus \{Y\}) \cup \boldsymbol{S}$, which leads to a contradiction. Hence, $\boldsymbol{N}_0 \cup \boldsymbol{S}$ is an MB of $\boldsymbol{T}$.

The proof is completed. ■

Appendix C. Improving the Log-Likelihood Ratio Test

In Subsection 4.3, we mentioned that the X^2 or G^2 test is suitable only for cases of small $|\boldsymbol{T}|$, and then summarized some improving methods proposed in the literature (Lawley, 1956; Hosmane, 1986, 1987, 1990; Brin et al., 1997; Silverstein et al., 1998; Aliferis et al., 2010b). However, we need more suitable CI testing methods when working on the MB discovery problem for multiple targets. In this appendix, we discuss a practical way of improving the G^2 test by damping the number of degrees of freedom for the G^2 statistic.

Consider the G^2 statistic, $G^2(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) \triangleq 2n \cdot \mathbb{I}_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \mid \boldsymbol{Z})$, which approximates to the chi-square variate with $r \triangleq (r_{\boldsymbol{X}} - 1)(r_{\boldsymbol{Y}} - 1) r_{\boldsymbol{Z}}$ degrees of freedom, namely $\chi^2(r)$, where $r_{\boldsymbol{\xi}}$ represents the number of configurations for $\boldsymbol{\xi}$ (de Campos, 2006, p. 2158).

Theoretically, $G^2(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z})$ is a reasonable statistic for testing the hypothesis "$\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$" *when n is large enough.* Unfortunately, this precondition is practically hard to be valid in many situations (Cochran, 1954; Yaramakala, 2004; Bromberg and Margaritis, 2009) due to the following reason: Let $\boldsymbol{X} = \{X_{i_1}, \cdots, X_{i_x}\}$, $\boldsymbol{Y} = \{X_{j_1}, \cdots, X_{j_y}\}$, and $\boldsymbol{Z} = \{X_{k_1}, \cdots, X_{k_z}\}$, in which each variable X_ℓ takes r_ℓ values. Then $r = (\prod_{\ell=1}^{x} r_{i_\ell} - 1)(\prod_{\ell=1}^{y} r_{j_\ell} - 1)(\prod_{\ell=1}^{z} r_{k_\ell})$, which is exponential with respect to x, y, and z. On the one hand, by the Wilson-Hilferty approximation for $\chi^2_\alpha(r)$ (de Campos, 2006; Gao, 2005), we obtain $\chi^2_\alpha(r) \approx c_{\alpha,r}\, r$, in which $c_{\alpha,r} \triangleq \left(1 - 2/(9r) + \sqrt{2/(9r)}\, z_\alpha\right)^3$ is a bit larger than 1, with z_α being the upper α-quantile of the standard normal distribution; on the other hand, we can show $\mathbb{I}_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) \leqslant \log_2 r_{\boldsymbol{X},\boldsymbol{Y}}$ with $r_{\boldsymbol{X},\boldsymbol{Y}} \triangleq \min\{\prod_{\ell=1}^{x} r_{i_\ell}, \prod_{\ell=1}^{y} r_{j_\ell}\}$. It follows that

$$p(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) = \mathbb{P}\left\{\chi^2(r) \geqslant 2n \cdot \mathbb{I}_{\boldsymbol{D}}(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z})\right\} \geqslant \mathbb{P}\left\{\chi^2(r) \geqslant 2n \cdot \log_2 r_{\boldsymbol{X},\boldsymbol{Y}}\right\}.$$

Suppose we are doing a G^2 test for the *false hypothesis* "$\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$" (i.e., the truth is $\boldsymbol{X} \not\perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$). Then, at least $\frac{\chi^2_\alpha(r)}{2\log_2 r_{\boldsymbol{X},\boldsymbol{Y}}} \approx \frac{c_{\alpha,r}\, r}{2\log_2 r_{\boldsymbol{X},\boldsymbol{Y}}} = O\left(\frac{r}{\log_2 r_{\boldsymbol{X},\boldsymbol{Y}}}\right)$ instances are required if we expect the statistical

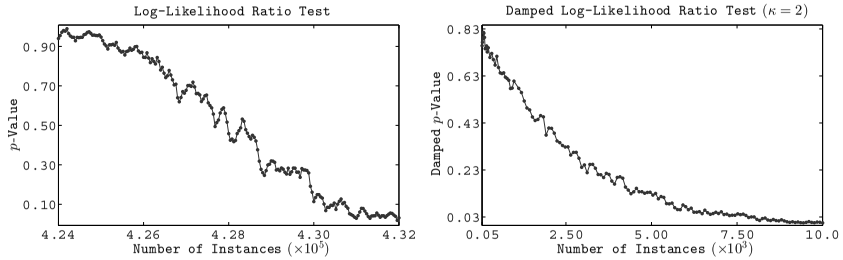

Figure 20: p-value/damped p-value versus the number of instances, n: the left subfigure illustrates why a very large n may still not be "large enough" for making a correct decision about the *false hypothesis* "$\boldsymbol{X}_1 \perp\!\!\!\perp \boldsymbol{Y}_1 \,|\, \boldsymbol{Z}_1$" based on the G^2 test: at least 4.31×10^5 instances are required; while the right illustrates why the damped G^2 test is suitable for testing the same *false hypothesis*: about 8000 instances are sufficient.

decision can be correctly made with the significance level α (or equivalently, $p(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z}) \leqslant \alpha$). In many practical situations, however, n may be far smaller than the required number of sample instances with the magnitude of at least $O(r/\log_2 r_{\boldsymbol{X},\boldsymbol{Y}})$, recalling that r is exponential with respect to x, y, and z, especially when too many variables are involved. In this case, the statistical decision made for the hypothesis will be wrong.

Taking the ALARM network presented in Figure 4 for example, we put

$$\boldsymbol{X}_1 = \{X_{36}\},\ \boldsymbol{Y}_1 = \{X_{11}, X_{34}, X_{35}, X_{37}\},\ \text{and}\ \ \boldsymbol{Z}_1 = \{X_4, X_{14}, X_{15}, X_{16}, X_{18}, X_{21}, X_{22}, X_{31}\};$$

then we compute the p-value versus the number of instances from 1000 to 1,000,000. The results are drawn in Figure 20 (averaged over 10 different samples with the same size). Note that the truth is $\boldsymbol{X}_1 \not\perp\!\!\!\perp \boldsymbol{Y}_1 \,|\, \boldsymbol{Z}_1$ since $\boldsymbol{Y}_1$ is an Mb of $\boldsymbol{X}_1$. By the figure, the CI test for the *false hypothesis* "$\boldsymbol{X}_1 \perp\!\!\!\perp \boldsymbol{Y}_1 \,|\, \boldsymbol{Z}_1$" is not correct unless at least $n_{\min} \approx 4.31 \times 10^5$ sample instances are available. It is mentioned that, in this example, $r/\log_2 r_{\boldsymbol{X}_1,\boldsymbol{Y}_1} \approx 2.42 \times 10^5$.

In short words, the precondition, "*when n is large enough*", for the theoretical assertion that "G^2 is a reasonable statistic for CI testing" may be hard to be guaranteed in practice because the above analysis and the numerical example indicate that a seemingly very large n may still not be "large enough". The problem is then how to improve on the G^2 test.

Observe that, for the G^2 test, the major reason for failing to make a correct statistical decision on CI testing is that the theoretical value of r is far larger than its data-driven value, due to the null cells frequently existing in the multi-contingency tables of $\boldsymbol{X}$ and $\boldsymbol{Y}$ given $\boldsymbol{Z}$ (e.g., Yaramakala, 2004, p. 34). In other words, the linear increase of n is hard to exponentially bring null cells into valid cells. Hence, a feasible way of improving the log-likelihood ratio G^2 test is to damp the increase of r such that the unmatched behaviours of n and r can get alleviated to a certain degree. Mathematically, we replace the theoretical value of r in $p(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z})$ with its a damped version, $g_{n,\kappa}(r)$, defined in (6), where $\kappa > 0$ is a constant, based on which $\frac{n}{\kappa}$ measures the amount of valid cells that n sample

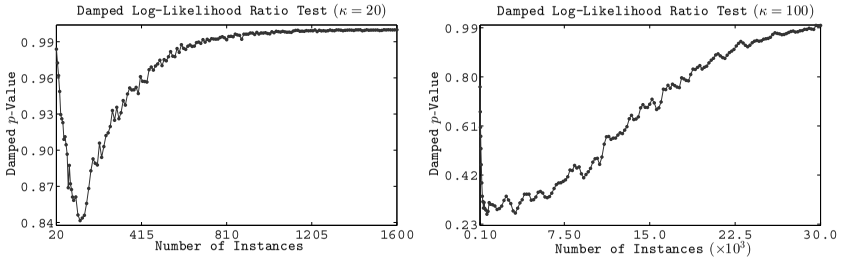

Figure 21: Damped p-value versus the number of instances: κ is taken as 20 and 100, respectively.

instances can support. It is easily seen that $g_{n,\kappa}(\cdot)$ possesses the following properties, which interpret the reasonability of employing such a damping procedure in the G^2 test:

- $g_{n,\kappa}(r)$ is monotonically increasing versus n for given r, and $\lim_{n\to+\infty} g_{n,\kappa}(r) = r$. This means more instances may generate more valid cells in the multi-contingency tables of $\boldsymbol{X}$ and $\boldsymbol{Y}$ given $\boldsymbol{Z}$, and all the theoretical degrees of freedom are valid when n is large enough.
- $g_{n,\kappa}(r)$ is monotonically increasing versus r for given n, and $\lim_{r\to+\infty} g_{n,\kappa}(r) = \frac{n}{\kappa}$. This means a larger r should correspond to a larger $g_{n,\kappa}(r)$, but not exceeding the supporting capacity of the data.
- For sufficient data, the damping function $g_{n,\kappa}(\cdot)$ only plays a little role; while for insufficient data, it trades off the theoretical r and the supporting capacity of the data.

For convenience, we call the resulted p-value, denoted by $p_g(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z})$ instead of $p(\boldsymbol{X}; \boldsymbol{Y} \,|\, \boldsymbol{Z})$, and the resulted testing method to be the *damped p-value* and the *damped log-likelihood ratio test* (or damped G^2 test). Further, we use the negative damped p-value, $f_{\boldsymbol{D}}^{(3)}$ defined in (7), as the association function. It is mentioned here that the damped G^2 test approximately degenerates into the ordinary G^2 test when taking κ as a very small positive number.

The damped G^2 test may be more suitable than the ordinary G^2 test when too many variables are involved in the conditional set. We implement this testing method (by taking κ as $2, 3, \cdots, 10$, respectively) on the *false hypothesis* "$\boldsymbol{X}_1 \perp\!\!\!\perp \boldsymbol{Y}_1 \,|\, \boldsymbol{Z}_1$", and find that the correct decision "$\boldsymbol{X}_1 \not\perp\!\!\!\perp \boldsymbol{Y}_1 \,|\, \boldsymbol{Z}_1$" is always made for $\kappa \geqslant 3$, even when the number of instances is smaller than 1000. For the case of $\kappa = 2$, we present the results in the right subfigure of Figure 20, from which it is seen that, for the damped G^2 test, about 8000 sample instances are sufficient to make the correct decision. Note also that the ordinary G^2 test needs at least 4.31×10^5 instances.

However, the damped G^2 test may also face a potential danger: it may excessively damp the theoretical value of r if a too large κ is inappropriately used. Here, "excessively damping r" means that a too large value of κ will lead to a too small $g_{n,\kappa}(r)$ such that the damped G^2 test incorrectly reject a *true hypothesis* "$\boldsymbol{X} \perp\!\!\!\perp \boldsymbol{Y} \,|\, \boldsymbol{Z}$". To illustrate this explanation, we put

$$\boldsymbol{X}_2 = \{X_{21}\},\ \ \boldsymbol{Y}_2 = \{X_{11}, X_{34}, X_{35}, X_{36}, X_{37}\},\ \ \text{and}\ \ \boldsymbol{Z}_2 = \{X_{15}, X_{19}, X_{20}, X_{22}, X_{29}\}$$

from the ALARM network. The truth is $\boldsymbol{X}_2 \perp\!\!\!\perp \boldsymbol{Y}_2 \,|\, \boldsymbol{Z}_2$ since $\boldsymbol{Z}_2$ is an Mb of $\boldsymbol{X}_2$. Now, use damped G^2 to test the *true hypothesis* "$\boldsymbol{X}_2 \perp\!\!\!\perp \boldsymbol{Y}_2 \,|\, \boldsymbol{Z}_2$" by taking κ as $3, 4, \cdots, 10, 20, 100$, respectively. All

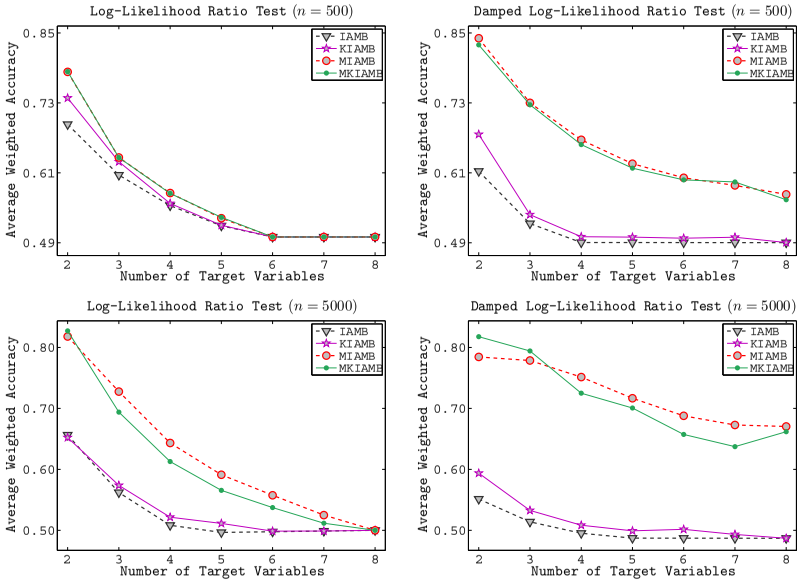

Figure 22: An illustration on why the damped G^2 test is more suitable than the ordinary G^2 test for the problem that involves too many variables, by virtue of the Pigs BN: the G^2 test no longer works when there are too many variables are involved, while the damped G^2 test remains valid in all considered cases.

the decisions are correctly made. However, a too large κ may be more apt to yield a relatively small damped p-value although it is still larger than α, as shown by Figure 21: 0.84 for the case of $\kappa = 20$ and only 0.27 for the case of $\kappa = 100$. Hence, to avoid the potential danger of excessively damping r, we conservatively recommend to take κ from the interval $[3, 10]$ in practice. In our benchmarking study, we employ $\kappa = 5$, which is large enough for testing *false hypotheses* and small enough for testing *true hypotheses*.

To further illustrate why the damped G^2 test is more suitable than the ordinary G^2 when working on a problem that involves too many variables, we make experiments on the six synthetical BNs based on `IAMB`, `KIAMB`, `MIAMB`, and `MKIAMB`.

For each algorithm, the G^2 test and the damped G^2 test are implemented for CI testing. Accordingly, the association functions, $f_{\boldsymbol{D}}^{(1)}$ and $f_{\boldsymbol{D}}^{(3)}$ defined by (5) and (7) are used. Figure 22 presents the results of the Pigs network, in which the left two are based on the ordinary G^2 test while the right two are based on the damped G^2 test. As seen, for the case of $n = 500$ the G^2 test becomes invalid when the target, $\boldsymbol{T}$, contains 6 or more variables, and for the case of $n = 5000$ this method no longer works when $|\boldsymbol{T}| = 8$. In comparison, the damped G^2 test is suitable for all cases. The results of the other five BNs show similar conclusions.

Appendix D. Used Acronyms

BFMB	breadth first search of Markov boundary algorithm (Fu and Desmarais, 2007).
BN	Bayesian network.
CI	conditional independence.
CMI	conditional mutual information.
CT-support	contingency table support: a set of items S has CT-support s at the t% level if at least t% of the cells in the contingency table for S have value s (Silverstein et al., 1998).
DAG	directed acyclic graph.
E-partition	equivalent partition (Lemeire, 2007): a relation $\Re \subset \boldsymbol{X} \otimes \boldsymbol{Y}$ defines an E-partition in $\boldsymbol{Y}_{\text{dom}}$ to a partition of $\boldsymbol{X}_{\text{dom}}$, if: (i) $\neg(\boldsymbol{x}_2 \Re \boldsymbol{y}_1)$ holds for any $\boldsymbol{x}_1, \boldsymbol{x}_2 \in \boldsymbol{X}_{\text{dom}}$ belonging to different partitions and for any $\boldsymbol{y}_1 \in \boldsymbol{Y}_{\text{dom}}$ with $\boldsymbol{x}_1 \Re \boldsymbol{y}_1$; and (ii) for every $\boldsymbol{X}_{\text{dom}}^{(k)}$, there exist $\boldsymbol{x}_1 \in \boldsymbol{X}_{\text{dom}}^{(k)}$ and $y_1 \in \boldsymbol{Y}_{\text{dom}}$ such that $\boldsymbol{x}_1 \Re \boldsymbol{y}_1$.
FS	feature selection.
GLL	generalized local learning: an algorithmic framework for local causal discovery and FS proposed by Aliferis et al. (2010a).
GS	grow-shrink algorithm (Margaritis and Thrun, 1999, 2000).
HITON	an MB discovery algorithm, pronounced hee-tón, from the Greek Χιτών, for "cover", "cloak", or "blanket" (Aliferis et al., 2003).
IAMB	incremental association Markov boundary algorithm (Tsamardinos et al., 2003); see Algorithm 3 for details.
IAMBS	an `IAMB`-based Markov boundary supplementary algorithm, outputting an MB for multiple targets (Algorithm 1).
KIAMB	a stochastic variant of `IAMB` (Peña et al., 2007); see Algorithm 3 for details.
KIAMBS	an `KIAMB`-based Markov boundary supplementary algorithm, outputting an MB for multiple targets (Algorithm 1).
KS	Koller-Sahami algorithm (Koller and Sahami, 1996).
LibSVM	a library for support vector machines contributed by Chang and Lin (2011).
Mb	Markov blanket: we call $\boldsymbol{M}$ an Mb of $\boldsymbol{T}$ if $\boldsymbol{T} \perp\!\!\!\perp \boldsymbol{V} \setminus \boldsymbol{M} \setminus \boldsymbol{T} \mid \boldsymbol{M}$ (Definition 1).
MB	Markov boundary: an MB of $\boldsymbol{T}$ is any Mb such that none of its proper subsets is an Mb of $\boldsymbol{T}$ (Definition 1).
MbS	Markov blanket supplementary: we call $\boldsymbol{S}$ an MbS of $\boldsymbol{T}$ to $\boldsymbol{N}$, if $\boldsymbol{N} \cup \boldsymbol{S}$ is an Mb of $\boldsymbol{T}$ (Definition 3).
MBS	Markov boundary supplementary: an MBS is any MbS such that none of its proper subsets is an MbS (Definition 3).
MIAMB	an `IAMB` and `IAMBS`-based algorithm, outputting an MB for multiple targets (see Algorithm 2 for details).
MKIAMB	an `KIAMB` and `KIAMBS`-based algorithm, outputting an MB for multiple targets (Algorithm 2).
MMMB	max-min Markov boundary algorithm (Tsamardinos et al., 2006).

PCMB	parents and children based Markov boundary algorithm (Peña et al., 2007).
RF	random forest algorithm.
RT	running time: the single CPU time implemented on an Intel i7-3612QM 2.1 GHz and Windows 7 with 64 bits.
SVM	support vector machine (in one-against-one approach).
T-partition	target partition (Lemeire, 2007): the domain, $\boldsymbol{X}_{\text{dom}}$, of $\boldsymbol{X}$ can be partitioned into some disjoint subsets $\boldsymbol{X}_{\text{dom}}^{(k)}$ for which $\mathbb{P}(\boldsymbol{T}\,|\,\boldsymbol{x})$ is the same for all $\boldsymbol{x} \in \boldsymbol{X}_{\text{dom}}^{(k)}$. This is called the T-partition of $\boldsymbol{X}_{\text{dom}}$ with respect to $\boldsymbol{T}$.
WA	weighted accuracy: WA is the average of the rate of true members and that of true nonmembers of an MB with respect to the truth.
WP	weighted precision: WP is the average of the rate of true members and that of true nonmembers of an MB with respect to the test.

Kernel Distribution Embeddings: Universal Kernels, Characteristic Kernels and Kernel Metrics on Distributions

Editor: Ingo Steinwart

Abstract

Kernel mean embeddings have become a popular tool in machine learning. They map probability measures to functions in a reproducing kernel Hilbert space. The distance between two mapped measures defines a semi-distance over the probability measures known as the maximum mean discrepancy (MMD). Its properties depend on the underlying kernel and have been linked to three fundamental concepts of the kernel literature: universal, characteristic and strictly positive definite kernels.

The contributions of this paper are three-fold. First, by slightly extending the usual definitions of universal, characteristic and strictly positive definite kernels, we show that these three concepts are essentially equivalent. Second, we give the first complete characterization of those kernels whose associated MMD-distance metrizes the weak convergence of probability measures. Third, we show that kernel mean embeddings can be extended from probability measures to generalized measures called Schwartz-distributions and analyze a few properties of these distribution embeddings.

Keywords: kernel mean embedding, universal kernel, characteristic kernel, Schwartz-distributions, kernel metrics on distributions, metrisation of the weak topology

1. Introduction

During the past decades, kernel methods have risen to a major tool across various areas of machine learning. They were originally introduced via the "kernel trick" to generalize linear regression and classification tasks by effectively transforming the optimization over a set of linear functions into an optimization over a so-called reproducing kernel Hilbert space (RKHS) $\mathcal{H}_k$, which is entirely defined by the kernel k. This lead to kernel (ridge) regression, kernel SVM and many other now standard algorithms. Besides these regression-type algorithms, another major family of kernel methods rely on kernel mean embeddings (KMEs). A KME is a mapping Φ_k that maps probability measures to functions in an RKHS via $\Phi_k : P \longmapsto \int_{\mathcal{X}} k(.,x)\,\mathrm{d}P(x)$. The RKHS-distance between two mapped measures defines a semi-distance over the set of probability measures, known as the Maximum Mean Discrepancy (MMD). It has numerous applications, ranging from homogeneity (Gretton et al., 2007), distribution comparison (Gretton et al., 2007, 2012) and (conditional) independence tests (Gretton et al., 2005, 2008; Fukumizu et al., 2008; Gretton and Györfi, 2010; Lopez-Paz et al., 2013) to generative adversarial networks (Dziugaite et al., 2015; Li et al., 2015). While KMEs have already been extended to embed not only probability measures, but also signed finite measures, a first contribution of this paper is to show that they can be extended even further to embed generalized measures called *Schwartz-distributions*. For an introduction to Schwartz-distributions—which we will now simply call a distribution, as opposed to a (signed) measure—see Appendix B. Furthermore, we show that for smooth and translation-invariant kernels, if the KME is injective over the set of probability measures, then it remains injective when extended to some Schwartz-distribution sets.

Our second contribution concerns the notions of universal, characteristic and strictly positive definite (s.p.d.) kernels. They are of prime importance to guarantee the consistency of many regression-type or MMD-based algorithms (Steinwart, 2001; Steinwart and Christmann, 2008). While these notions were originally introduced in very different contexts, they were shown to be connected in many ways which were eventually summarized in Figure 1 of Sriperumbudur et al. (2011). But by handling separately all the many variants of universal, characteristic and s.p.d. kernels that had been introduced, this figure—and the general machine learning literature—somehow missed the underlying very general duality principle that connects these notions. By giving a unified definition of these three concepts, we will make their link explicit, easy to remember, and immediate to generalize to Schwartz-distributions and other spaces.

Our third contribution concerns the MMD semi-metric. Through a series of articles, Sriperumbudur et al. (2010b; 2016) gave various sufficient conditions for a kernel to *metrize the weak-convergence of probability measures*, which means that a sequence of probability measures converges in MMD distance if and only if (iff) it converges weakly. Here, we generalize these results and give the first complete characterization of the kernels that metrize weak convergence when the underlying space $\mathcal{X}$ is locally compact.

Finally, we develop a few calculus rules to work with KMEs of Schwartz distributions. In particular, we prove the following formulae:

$$\left\langle f\,,\ \int k(.,x)\,\mathrm{d}D(x)\right\rangle_k = \int \langle f\,,\,k(.,x)\rangle_k\,\mathrm{d}D(x) \qquad \text{(Definition of KME)}$$

$$\left\langle \int k(.,y)\,\mathrm{d}D(y)\,,\ \int k(.,x)\,\mathrm{d}T(x)\right\rangle_k = \int k(x,y)\,\mathrm{d}D(y)\,\mathrm{d}\bar{T}(x) \qquad \text{(Fubini)}$$

$$\int k(.,x)\,\mathrm{d}(\partial^p S)(x) = (-1)^{|p|}\int \partial^{(0,p)}k(.,x)\,\mathrm{d}S(x). \qquad \text{(Differentiation)}$$

The first and second lines are standard calculus rules for KMEs when applied with two probability measures D and T. We extend them to distributions. The third line however is specific to distributions. It uses the distributional derivative ('∂') which extends the usual derivative of functions to signed measures and distributions. For a quick introduction to Schwartz distributions and their derivatives see Appendix B.

The structure of this paper roughly follows this exposition. After fixing our notations, Section 2 introduces KMEs of measures and distributions. In Section 3 we define the concepts of universal, characteristic and s.p.d. kernels and prove their equivalence. Section 4 compares convergence in MMD with other modes of convergence for measures and distributions. Section 5 focuses specifically on KMEs of Schwartz-distributions, and Section 6 gives a brief overview of the related work and concludes.

1.1. Definitions and Notations

Let $\mathbb{N}$, $\mathbb{R}$ and $\mathbb{C}$ be the sets of non-negative integers, of reals and of complex numbers. The input set $\mathcal{X}$ of all considered kernels and functions will be locally compact and Hausdorff. This includes any Euclidian spaces or smooth manifolds, but no infinite-dimensional Banach-space. Whenever referring to differentiable functions or to distributions of order ≥ 1, we will *implicitly* assume that $\mathcal{X}$ is an open subset of $\mathbb{R}^d$ for some $d > 0$.

A *kernel* $k\colon\ \mathcal{X}\times\mathcal{X} \longrightarrow \mathbb{C}$ is a positive definite function, meaning that for all $n \in \mathbb{N}\backslash\{0\}$, all $\lambda_1, \ldots, \lambda_n \in \mathbb{C}$, and all $x_1, x_2, \ldots x_n \in \mathcal{X}$, $\sum_{i,j=1}^n \lambda_i k(x_i, x_j)\overline{\lambda_j} \geq 0$. For $p = (p_1, p_2, \ldots, p_d) \in \mathbb{N}^d$ and $f\colon\ \mathcal{X} \longrightarrow \mathbb{C}$, we define $|p| := \sum_{i=1}^d p_i$ and $\partial^p f := \frac{\partial^{|p|} f}{\partial^{p_1}x_1 \partial^{p_2}x_2 \cdots \partial^{p_d}x_d}$. For $m \in \mathbb{N}\cup\{\infty\}$, we say that f (resp. k) is m-times (resp. (m,m)-times) continuously differentiable and write $f \in \mathcal{C}^m$ (resp. $k \in \mathcal{C}^{(m,m)}$), if for any p with $|p| = m$, $\partial^p f$ (resp. $\partial^{(p,p)}k$) exists and is continuous. $\mathcal{C}_b^m$ (resp. $\mathcal{C}_0^m$, $\mathcal{C}_c^m$) is the subsets of $\mathcal{C}^m$ for which $\partial^p f$ is bounded (resp. converges to 0 at infinity, resp. has compact support) whenever $|p| \leq m$. Whenever $m = 0$, we may drop the superscript m. By default, we equip $\mathcal{C}_*^m$ ($* \in \{\emptyset, b, 0, c\}$) with their natural topologies (see Introduction of Simon-Gabriel and Schölkopf 2016 or Treves 1967). We write $k \in \mathcal{C}_0^{(m,m)}$ whenever k is bounded, (m,m)-times continuously differentiable and for all $|p| \leq m$ and $x \in \mathcal{X}$, $\partial^{(p,p)}k(.,x) \in \mathcal{C}_0$.

We call *space of functions* and denote by $\mathcal{F}$ any locally convex (loc. cv.) topological vector space (TVS) of functions (see Appendix C and Treves 1967). Loc. cv. TVSs include all Banach- or Fréchet-spaces and all function spaces defined in this paper.

The dual $\mathcal{F}'$ of a space of functions $\mathcal{F}$ is the space of *continuous* linear forms over $\mathcal{F}$. We denote $\mathcal{M}_\delta$, $\mathcal{E}^m$, $\mathcal{D}_{L^1}^m$ and $\mathcal{D}^m$ the duals of $\mathbb{C}^\mathcal{X}$, $\mathcal{C}^m$, $\mathcal{C}_0^m$ and $\mathcal{C}_c^m$ respectively. By identifying each signed measure μ with a linear functional of the form $f \longmapsto \int f\,\mathrm{d}\mu$, the Riesz-Markov-Kakutani representation theorem (see Appendix C) identifies $\mathcal{D}^0$ (resp. $\mathcal{D}_{L^1}^0$, $\mathcal{E}^0$ and $\mathcal{M}_\delta$) with the set $\mathcal{M}_r$ (resp. $\mathcal{M}_f$, $\mathcal{M}_c$, $\mathcal{M}_\delta$) of signed regular Borel measures (resp. with finite total variation, with compact support, with finite support). By definition, $\mathcal{D}^\infty$ is the set of all Schwartz-distributions, but all duals defined above can be seen as subsets of $\mathcal{D}^\infty$ and are therefore sets of Schwartz-distributions. Any element μ of $\mathcal{M}_r$ will be called a measure, any element of $\mathcal{D}^\infty$ a distribution. See Appendix B for a brief introduction to distributions and their connection to measures. We extend the usual notation $\mu(f) := \int f(x)\,\mathrm{d}\mu(x)$ for measures μ to distributions D: $D(f) =: \int f(x)\,\mathrm{d}D(x)$. Given a KME Φ_k and two embeddable distributions D, T (see Definition 1), we define

$$\langle D\,,\,T\rangle_k := \langle \Phi_k(D)\,,\,\Phi_k(T)\rangle_k \quad \text{and} \quad \|D\|_k := \|\Phi_k(D)\|_k\ .$$

where $\langle .\,,\,.\rangle_k$ is the inner product of the RKHS $\mathcal{H}_k$ of k. To avoid introducing a new name, we call $\|D\|_k$ the maximum mean discrepancy (MMD) of D, even though the term "discrepancy" usually specifically designates a distance between two distributions rather than the norm of a single one. Given two topological sets $\mathcal{S}_1, \mathcal{S}_2$, we write

$$\mathcal{S}_1 \hookrightarrow \mathcal{S}_2$$

and say that $\mathcal{S}_1$ *is continuously contained in* $\mathcal{S}_2$ if $\mathcal{S}_1 \subset \mathcal{S}_2$ and if the topology of $\mathcal{S}_1$ is stronger than the topology induced by $\mathcal{S}_2$. For a general introduction to topology, TVSs and distributions, we recommend Treves (1967).

2. Kernel Mean Embeddings of Distributions

In this section, we show how to embed general distribution spaces into an RKHS. To do so, we redefine the integral $\int k(.,x)\,\mathrm{d}\mu(x)$ so as to be well-defined even if μ is a distribution. It is often defined as a Bochner-integral; here we instead use the *weak-* (or *Pettis-*) integral:

Definition 1 (Weak Integral and KME) *Let D be a linear form over a space of functions $\mathcal{F}$. Let $\vec{\varphi}\colon\ \mathcal{X} \longrightarrow \mathcal{H}_k$ be an RKHS-valued function such that for any $f \in \mathcal{H}_k$, $x \longmapsto \langle f\,,\,\vec{\varphi}(x)\rangle_k \in \mathcal{F}$. Then $\vec{\varphi}\colon\ \mathcal{X} \longrightarrow \mathcal{H}_k$ is weakly integrable with respect to (w.r.t.) D if there exists a function in $\mathcal{H}_k$, written $\int \vec{\varphi}(x)\,\mathrm{d}D(x)$, such that*

$$\forall f \in \mathcal{H}_k, \quad \left\langle f\,,\,\int \vec{\varphi}(x)\,\mathrm{d}D(x)\right\rangle_k = \int \langle f\,,\,\vec{\varphi}(x)\rangle_k\,\mathrm{d}\bar{D}(x)\,, \tag{1}$$

where the right-hand-side stands for $\bar{D}\,(x \mapsto \langle f\,,\,\vec{\varphi}(x)\rangle_k)$ and $\bar{D}$ denotes the complex-conjugate of D. If $\vec{\varphi}(x) = k(.,x)$, we call $\int k(.,x)\,\mathrm{d}D(x)$ the kernel mean embedding (KME) of D and say that D embeds into $\mathcal{H}_k$. We denote $\Phi_{\vec{\varphi}}$ the map $\Phi_{\vec{\varphi}}\colon\ D \longmapsto \int \vec{\varphi}(x)\,\mathrm{d}D(x)$.

This definition extends the usual Bochner-integral: if $\vec{\varphi}$ is Bochner-integrable w.r.t. a measure $\mu \in \mathcal{M}_r$, then $\vec{\varphi}$ is weakly integrable w.r.t. μ and the integrals coincide (Schwabik, 2005, Prop. 2.3.1). In particular, if $x \longmapsto \|\vec{\varphi}(x)\|_k$ is Lebesgue-integrable, then $\vec{\varphi}$ is Bochner integrable, thus weakly integrable.

The general definition with $\vec{\varphi}$ instead of $k(.,x)$ will be useful in Section 5. But for now, let us concentrate on KMEs where $\vec{\varphi}(x) = k(.,x)$. Kernels satisfy the so-called *reproducing property*: for any $f \in \mathcal{H}_k$, $f(x) = \langle f\,,\,k(.,x)\rangle_k$. Therefore, the condition for all $f \in \mathcal{H}_k$ $x \longmapsto \langle f\,,\,\vec{\varphi}(x)\rangle_k \in \mathcal{F}$ reduces to $\mathcal{H}_k \subset \mathcal{F}$, and Equation (1) reads:

$$\forall f \in \mathcal{H}_k, \qquad \left\langle f\,,\,\int k(.,x)\,\mathrm{d}D(x)\right\rangle_k = \bar{D}(f)\,. \tag{2}$$

Thus, by the Riesz representation theorem (see Appendix C), D embeds into $\mathcal{H}_k$ iff it defines a continuous linear form over $\mathcal{H}_k$. And in that case, its KME $\int k(.,x)\,\mathrm{d}D(x)$ is the Riesz-representer of $\bar{D}$ restricted to $\mathcal{H}_k$. Thus, for an embeddable space of distributions $\mathcal{D}$, the embedding Φ_k can be decomposed as follows:

$$\Phi_k : \left\{\begin{array}{ccccc} \mathcal{D} & \longrightarrow & \mathcal{H}_k' & \longrightarrow & \mathcal{H}_k \\ & \text{Conjugate restriction} & & \text{Riesz representer} & \\ D & \longmapsto & \bar{D}\big|_{\mathcal{H}_k} & \longmapsto & \int k(.,x)\,\mathrm{d}D(x) \end{array}\right. . \tag{3}$$

To know if D is continuous over $\mathcal{H}_k$, we use the following lemma, and its applications.

Lemma 2 *If $\mathcal{H}_k \hookrightarrow \mathcal{F}$, then $\mathcal{F}'$ embeds into $\mathcal{H}_k$.*

Proof Suppose that $\mathcal{H}_k \hookrightarrow \mathcal{F}$. Let $D \in \mathcal{F}'$ and let $f, f_1, f_2, \ldots \in \mathcal{H}_k$. If $f_n \to f$ in $\mathcal{H}_k$ then $f_n \to f$ in $\mathcal{F}$, thus $D(f_n) \to D(f)$. Thus D is a continuous linear form over $\mathcal{H}_k$. ■

In practice we typically use one of the following two corollaries (proofs in Appendices A.1 and A.2). The space $(\mathcal{C}_b)_c$ that they mention will be introduced in the discussions following Theorem 6. It has the same elements as $\mathcal{C}_b$, but carries a weaker topology.

Corollary 3 (Embedding of Measures) *$\mathcal{H}_k \subset \mathcal{C}_0$ (resp. $\mathcal{H}_k \subset \mathcal{C}_b$, resp. $\mathcal{H}_k \subset \mathcal{C}$) iff the two following conditions hold.*

(i) For all $x \in \mathcal{X}$, $k(.,x) \in \mathcal{C}_0$ (resp. $k(.,x) \in \mathcal{C}_b$, resp. $k(.,x) \in \mathcal{C}$).
(ii) $x \longmapsto k(x,x)$ is bounded (resp. bounded, resp. locally *bounded, meaning that, for each $y \in \mathcal{X}$, there exists a (compact) neighborhood of y on which $x \longmapsto k(x,x)$ is bounded.).*

If so, then $\mathcal{H}_k \hookrightarrow \mathcal{C}_0$ (resp. $\mathcal{H}_k \hookrightarrow \mathcal{C}_b$, thus $\mathcal{H}_k \hookrightarrow (\mathcal{C}_b)_c$, resp. $\mathcal{H}_k \hookrightarrow \mathcal{C}$) and $\mathcal{M}_f$ (resp. $\mathcal{M}_f$, resp. $\mathcal{M}_c$) embeds into $\mathcal{H}_k$.

Corollary 4 (Embedding of Distributions)
If $k \in \mathcal{C}^{(m,m)}$, then $\mathcal{H}_k \hookrightarrow \mathcal{C}^m$, thus $\mathcal{E}^m$ embeds into $\mathcal{H}_k$.
If $k \in \mathcal{C}_0^{(m,m)}$, then $\mathcal{H}_k \hookrightarrow \mathcal{C}_0^m$, thus $\mathcal{D}_{L^1}^m$ embeds into $\mathcal{H}_k$.
If $k \in \mathcal{C}_b^{(m,m)}$, then $\mathcal{H}_k \hookrightarrow \mathcal{C}_b^m$, thus $\mathcal{H}_k \hookrightarrow (\mathcal{C}_b^m)_c$, thus $\mathcal{D}_{L^1}^m$ embeds into $\mathcal{H}_k$.

Corollary 3 applied to $\mathcal{C}_b$ shows that $\mathcal{H}_k$ is (continuously) contained in $\mathcal{C}_b$ iff k is bounded and separately continuous. As discovered by Lehtö (1952), there also exist kernels which are not continuous but whose RKHS $\mathcal{H}_k$ is contained in $\mathcal{C}_b$. So the conditions in Corollary 4 are sufficient, but in general not necessary. Concerning Lemma 2, note that it not only requires $\mathcal{H}_k \subset \mathcal{F}$, but also that $\mathcal{H}_k$ carries a stronger topology than $\mathcal{F}$. Otherwise there might exist a continuous form over $\mathcal{F}$ that is defined but non-continuous over $\mathcal{H}_k$. However, Corollary 3 shows that this cannot happen for $\mathcal{C}_*$, because if $\mathcal{H}_k \subset \mathcal{C}_*$ then $\mathcal{H}_k \hookrightarrow \mathcal{C}_*$. Although this also holds for $m = \infty$ (Simon-Gabriel and Schölkopf, 2016, Prop.4 & Comments), we do not know whether it extends to any $m > 0$.

3. Universal, Characteristic and S.P.D. Kernels

The literature distinguishes various variants of universal, characteristic and s.p.d. kernels, such as c-, $cc-$ or c_0-universal kernels, s.p.d. and integrally strictly positive definite ($\int$s.p.d.) kernels. They are all special cases of the following unifying definitions.

Definition 5 *Let k be a kernel, $\mathcal{F}$ be a space of functions such that $\mathcal{H}_k \subset \mathcal{F}$, and $\mathcal{D}$ be an embeddable subset of $\mathcal{F}'$ (e.g. an embeddable set of distributions). We say that k is*

- ▷ universal over $\mathcal{F}$ *if $\mathcal{H}_k$ is dense in $\mathcal{F}$.*
- ▷ characteristic to $\mathcal{D}$ *if the KME Φ_k is injective over $\mathcal{D}$.*
- ▷ strictly positive definite (s.p.d.) over $\mathcal{D}$ *if:* $\forall D \in \mathcal{D},\ \|\Phi_k(D)\|_k^2 = 0 \Rightarrow D = 0$.

A universal kernel over $\mathcal{C}^m$ (resp. $\mathcal{C}_0^m$) will be said c^m- (resp. c_0^m-) universal (without the superscript when $m = 0$). A characteristic kernel to the set $\mathcal{P}$ of probability measures will simply be called characteristic.

In general, instead of writing $\|\Phi_k(D)\|_k$ and $\langle \Phi_k(D), \Phi_k(T)\rangle_k$, we will write $\|D\|_k$ and $\langle D, T\rangle_k$. These definitions encompass the usual s.p.d. definitions. Denoting δ_x the Dirac measure concentrated on x, what is usually called

- ▷ s.p.d. corresponds to $\mathcal{D} = \mathcal{M}_\delta$, i.e.:

$$\forall \mu = \sum_{i=1}^n \lambda_i \delta_{x_i} \in \mathcal{M}_\delta : \quad \|\mu\|_k^2 = \sum_{i,j=1}^n \lambda_i k(x_i, x_j) \bar{\lambda}_j = 0 \quad \Rightarrow \quad \lambda_1 = \ldots = \lambda_n = 0 \ .$$

- ▷ conditionally s.p.d. corresponds to $\mathcal{D} = \mathcal{M}_\delta^0$ where $\mathcal{M}_\delta^0 := \{\mu \in \mathcal{M}_\delta : \mu(\mathcal{X}) = 0\}$, i.e.:

$$\left.\begin{array}{l} \forall \mu = \sum_{i=1}^n \lambda_i \delta_{x_i} \in \mathcal{M}_\delta \\ \text{s.t. } \sum_{i=1}^n \lambda_i = 0 \end{array}\right\} : \ \|\mu\|_k^2 = \sum_{i,j=1}^n \lambda_i k(x_i, x_j) \bar{\lambda}_j = 0 \quad \Rightarrow \quad \lambda_1 = \ldots = \lambda_n = 0 \ .$$

- ▷ $\int$s.p.d. corresponds to $\mathcal{D} = \mathcal{M}_f$, i.e.:

$$\forall \mu \in \mathcal{M}_f : \quad \|\mu\|_k^2 = \iint k(x,y) \, \mathrm{d}\mu(x) \, \mathrm{d}\bar{\mu}(y) = 0 \quad \Rightarrow \quad \mu = 0 \ .$$

Let us now state the general link between universal, characteristic and s.p.d. kernels, which is the key that underlies Figure 1 of Sriperumbudur et al. (2011).

Theorem 6 *If $\mathcal{H}_k \hookrightarrow \mathcal{F}$, then the following statements are equivalent.*

(i) k is universal over $\mathcal{F}$.
(ii) k is characteristic to $\mathcal{F}'$.
(iii) k is strictly positive definite over $\mathcal{F}'$.

Proof Equivalence of (ii) & (iii): Saying that $\|\Phi_k(D)\|_k = 0$ is equivalent to saying $\Phi_k(D) = 0$. Thus Φ_k is s.p.d. over $\mathcal{F}'$ iff the $\mathrm{Ker}(\Phi_k)$ (meaning the vector space that is mapped to 0 via Φ_k) is reduced to $\{0\}$, which happens iff Φ_k is injective over $\mathcal{F}'$.

Equivalence of (i) & (ii): Φ_k is the conjugate restriction operator $|_{\mathcal{H}_k} : D \longmapsto \bar{D}|_{\mathcal{H}_k}$ composed with the Riesz representer mapping (Diagram Eq.3). The Riesz representer map is injective, so Φ_k is injective iff $|_{\mathcal{H}_k}$ is injective. Now, if $\mathcal{H}_k$ is dense in $\mathcal{F}$, then, by continuity, any $D \in \mathcal{F}'$ is uniquely defined by its values taken on $\mathcal{H}_k$. Thus $|_{\mathcal{H}_k}$ is injective. Reciprocally, if $\mathcal{H}_k$ is not dense in $\mathcal{F}$, then, by the Hahn-Banach theorem (Treves, 1967, Thm.18.1, Cor.3), there exists two different elements in $\mathcal{F}'$ that coincide on $\mathcal{H}_k$ but not on the entire space $\mathcal{F}$. So $|_{\mathcal{H}_k}$ is not injective. Thus $|_{\mathcal{H}_k}$ is injective iff $\mathcal{H}_k$ is dense in $\mathcal{F}$. ■

To apply this theorem it suffices to find so-called *duality pairs* $(\mathcal{F}, \mathcal{F}')$ such that $\mathcal{H}_k \hookrightarrow \mathcal{F}$. Table 1 lists several such pairs. It shows in particular the well-known equivalence between c- (resp. c_0-) universal kernels and characteristic kernels to $\mathcal{M}_c$ (resp. $\mathcal{M}_f$) (Sriperumbudur et al., 2008). But we now discover that s.p.d. kernels over $\mathcal{M}_\delta$ can also be characterized in terms of universality over $\mathbb{C}^{\mathcal{X}}$, because $(\mathbb{C}^{\mathcal{X}})' = \mathcal{M}_\delta$ (Duc-Jacquet, 1973, p.II.35). And we directly get the generalization to distributions and c_*^m-universality.

However, Theorem 6 leaves open the important case where k is characteristic (to $\mathcal{P}$). Of course, as $\mathcal{P}$ is contained in $\mathcal{M}_f$, it shows that a c_0-universal kernel must be characteristic. But to really characterize characteristic kernels in terms of universality, we would need to find a predual of $\mathcal{P}$, meaning a space $\mathcal{F}$ such that $\mathcal{F}' = \mathcal{P}$. This is hardly possible, as $\mathcal{P}$ is not even a vector space. However, we will see in Theorem 8 that k is characteristic iff k is

Universal	Characteristic	S.P.D.	Name	Proof
$\mathscr{F}$	$\mathscr{F}'$	$\mathscr{F}'$	/	Thm. 6
$\mathbb{C}^{\mathcal{X}}$	$\mathcal{M}_\delta$	$\mathcal{M}_\delta$	s.p.d.	Thm. 6

Table 1: Equivalence between the notions of universal, characteristic and s.p.d. kernels.

characteristic to the vector space $\mathcal{M}_f^0 := \{\mu \in \mathcal{M}_f : \mu(\mathcal{X}) = 0\}$. So if we find a predual of $\mathcal{M}_f^0$, then we get an analog of Theorem 6 applied to $\mathscr{P}$. Let us do so now.

As $\mathcal{M}_f^0$ is the hyperplane of $\mathcal{M}_f$ that is given by the equation $\int 1 \,\mathrm{d}\mu = 0$, our idea is to take a predual $\mathscr{F}$ of $\mathcal{M}_f$ and consider the quotient $\mathscr{F}/\mathbb{1}$ of $\mathscr{F}$ divided by the constant function $\mathbb{1}$. Proposition 35.5 of Treves (1967) would then show that $(\mathscr{F}/\mathbb{1})' = \mathcal{M}_f^0$. But if we take the usual predual of $\mathcal{M}_f$, $\mathscr{F} = \mathscr{C}_0$, then $\mathbb{1} \notin \mathscr{F}$, so the quotient $\mathscr{F}/\mathbb{1}$ is undefined. However, preduals are not unique, so let us try with another space $\mathscr{F}$ that contains $\mathbb{1}$, for example $\mathscr{F} = \mathscr{C}_b$. This time $\mathbb{1} \in \mathscr{F}$, but now the problem is that $\mathscr{F}'$ is in general strictly bigger than $\mathcal{M}_f$ (Fremlin et al., 1972, Sec. 2, §2) whereas we want $\mathscr{F}' = \mathcal{M}_f$. The trick now is to keep $\mathscr{C}_b$, but equip it with a weaker topology than the usual one, so that $\mathscr{F}'$ becomes smaller. Intuitively, the reason for this decrease of $\mathscr{F}'$ is that, by weakening the topology of $\mathscr{F}$, we let more sequences converge in $\mathscr{F}$. This makes it more difficult for a functional over $\mathscr{F}$ to be continuous, because for any converging sequence in $\mathscr{F}$, its images need to converge. Thus some of the linear functionals that were continuous for the original topology of $\mathscr{F}$ get "kicked out" of $\mathscr{F}'$ when $\mathscr{F}$ carries a weaker topology. Now the only remaining step is to find a topology such that $\mathscr{F}'$ shrinks exactly to $\mathcal{M}_f$. There are at least two such topologies: one defined by Schwartz (1954, p.100-101) and another, called the strict topology, whose definition can be found in Fremlin et al. (1972). Denoting τ_c either of these topologies, and $(\mathscr{C}_b)_c$ the space $\mathscr{C}_b$ equipped with τ_c, we finally get $((\mathscr{C}_b)_c)' = \mathcal{M}_f$, and thus:

Proposition 7 $((\mathscr{C}_b)_c/\mathbb{1})' = \mathcal{M}_f^0$. *Thus, if $\mathcal{H}_k \hookrightarrow (\mathscr{C}_b)_c$, then k is characteristic to $\mathscr{P}$ iff k is universal over the quotient space $((\mathscr{C}_b)_c/\mathbb{1})$.*

Proof That $((\mathscr{C}_b)_c)' = \mathcal{M}_f$ is proven in Fremlin et al. (1972, Thm. 1) or Schwartz (1954, p.100-101). Proposition 35.5 of Treves (1967) then implies $((\mathscr{C}_b)_c/\mathbb{1})' = \mathcal{M}_f^0$ (because $\mathcal{M}_f^0$ is the so-called *polar set* of $\mathbb{1}$; see Treves 1967). Theorem 6 implies the rest. ■

For our purposes, the exact definition of τ_c does not matter. What matters more is that τ_c is weaker than the usual topology of $\mathscr{C}_b$, so that if $\mathcal{H}_k \hookrightarrow \mathscr{C}_b$, then $\mathcal{H}_k \hookrightarrow (\mathscr{C}_b)_c$. Proposition 7 thus applies every time that $\mathcal{H}_k \subset \mathscr{C}_b$ (see Corollaries 3 and 4). However, we do not know of any practical application of Proposition 7, except that it completes our overall picture of the equivalences between universal, characteristic and s.p.d. kernels. Let us also mention that, similarly to Proposition 7, as $(\mathbb{C}^{\mathcal{X}})' = \mathcal{M}_\delta$, we also have $(\mathbb{C}^{\mathcal{X}}/\mathbb{1})' = \mathcal{M}_\delta^0$. So conditionnally s.p.d. kernels (meaning s.p.d. over $\mathcal{M}_\delta^0$) are universal to $\mathbb{C}^{\mathcal{X}}/\mathbb{1}$.

We now prove what we announced and used earlier: a kernel is characteristic to $\mathscr{P}$ iff it is characteristic to $\mathcal{M}_f^0$. We add a few other characterisations which are probably more useful in practice. They rely on the following observation: as $\mathcal{M}_f^0$ is a hyperplane of $\mathcal{M}_f$, saying that k is characteristic to $\mathscr{P}$ is almost the same than saying that it is characteristic to $\mathcal{M}_f$, i.e. $\int$s.p.d. (Thm. 6): after all, there is only one dimension needed to go from $\mathcal{M}_f^0$ to $\mathcal{M}_f$. Thus there should be a way to construct an $\int$s.p.d. kernel out of any characteristic kernel. This is what is described here and proven in Appendix A.3.

Theorem 8 (Characteristic Kernels) *Let k_0 be a kernel. The following is equivalent.*

(i) *k_0 is characteristic to $\mathscr{P}$.*
(ii) *k_0 is characteristic to $\mathcal{M}_f^0$.*
(iii) *There exists $\epsilon \in \mathbb{R}$ such that the kernel $k(x,y) := k_0(x,y) + \epsilon^2$ is $\int$s.p.d..*
(iv) *For all $\epsilon \in \mathbb{R}\backslash\{0\}$, the kernel $k(x,y) := k_0(x,y) + \epsilon^2$ is $\int$s.p.d..*
(v) *There exists an RKHS $\mathcal{H}_k$ with kernel k and a measure $\nu_0 \in \mathcal{M}_f \backslash \mathcal{M}_f^0$ such that k is characteristic to $\mathcal{M}_f$ and $k_0(x,y) = \langle \delta_x - \nu_0 \,,\, \delta_y - \nu_0 \rangle_k$.*

Under these conditions, k_0 and k induce the same MMD semi-metric in $\mathcal{M}_f^0$ and in $\mathscr{P}$.

We will use this theorem to prove Theorem 12. Intuitively, a characteristic kernel guarantees that any two different signed measures μ_1, μ_2 with same total mass get mapped to two different functions in the RKHS. This is captured by (ii) which arbitrarily focuses on the special case where the total mass is 0. When they have different total masses however, they may still get mapped to a same function f, except if, like in (iii) and (iv), we add a positive constant to the kernel. In that case, μ_1 and μ_2 get mapped to the functions $f + \mu_1(\mathcal{X})\mathbb{1}$ and $f + \mu_2(\mathcal{X})\mathbb{1}$ which are now different, because $\mu_1(\mathcal{X}) \neq \mu_2(\mathcal{X})$. Intuively, by adding a positive constant to our kernel, we added one dimension to the RKHS (carried by the function $\mathbb{1}$) that explicitly 'checks' if two measures have the same mass. Finally, (v) tells us that, out of any $\int$s.p.d. kernel k, we can construct a characteristic kernel k_0 that is not $\int$s.p.d. anymore and vice-versa.

4. Topology Induced by k

Remember that for any distribution D of a set of embeddable distributions $\mathcal{D}$ we defined $\|D\|_k := \|\Phi_k(D)\|_k$ and called $\|D\|_k$ the Maximum Mean Discrepancy (MMD) of D. Doing this defines a new topology on $\mathcal{D}$, in which a net D_α converges to D iff $\|D_\alpha - D\|_k$ converges to 0. (A reader unfamiliar with nets may think of them as sequences where the index α

can be continuous; see Berg et al. 1984.) In this section, we investigate how convergence in MMD compares with other types of convergences defined on $\mathcal{D}$ that we now shortly present.

We defined $\mathcal{D}$ as a subset of a dual space $\mathcal{F}'$, so $\mathcal{D}$ will carry the topology induced by $\mathcal{F}'$. Many topologies can be defined on dual spaces, but the two most prominent ones, which we will consider here, are the *weak-** and the *strong* topology, denoted $w(\mathcal{F}', \mathcal{F})$ and $b(\mathcal{F}', \mathcal{F})$ respectively, or simply $w*$ and b. The weak-$*$ topology is the topology of pointwise convergence (where by 'point', we mean a function in $\mathcal{F}$), while the strong topology corresponds to the uniform convergence over the bounded subsets of $\mathcal{F}$ (see Eq. 4). Bounded sets of a TVS are defined in Appendix C (Definition 24). By default, we equip $\mathcal{F}'$ with the strong topology and sometimes write $\mathcal{F}'_b$ to emphasize it. When $\mathcal{F}$ is a Banach space, the strong topology of $\mathcal{F}'$ is the topology of the operator norm $\|D\|_{\mathcal{F}'} := \sup_{\|f\|_{\mathcal{F}} \leq 1} |D(f)|$. In particular, strong convergence in $\mathcal{M}_f = (\mathcal{C}_0)'$ means convergence in total variation (TV) norm and weak-$*$ convergence in $\mathcal{M}_f$ means convergence for any function $f \in \mathcal{C}_0$. On $\mathcal{M}_f$, we will also consider the topology of pointwise convergence over $\mathcal{C}_b$ (instead of $\mathcal{C}_0$). It is widely used in probability theory where it is known as the *weak* (or narrow) convergence topology. We will denote it by σ. Importantly, the weak and weak-$*$ topologies of $\mathcal{M}_f$ coincide on $\mathcal{P}$ (but not on $\mathcal{M}_f$) (Berg et al., 1984, Chap. 2, Cor. 4.3). Finally, we define the weak RKHS convergence of embeddable distributions, denoted by $w-k$, as the pointwise convergence over $\mathcal{H}_k$. Note that D_α converges in $w-k$ to D iff their embeddings converge weakly (or equivalently weakly-$*$) in $\mathcal{H}_k$, in the sense that, for any $f \in \mathcal{H}_k$, $\langle f\,,\, \Phi_k(D_\alpha)\rangle_k$ converges to $\langle f\,,\, \Phi_k(D)\rangle_k$. The following summarizes the different convergence types.

$$
\begin{array}{lrll}
D_\alpha \xrightarrow{b} D := & \sup_{f\in\mathcal{B}} |D_\alpha(f) - D(f)| \longrightarrow 0 & \forall \text{ bounded } \mathcal{B} \subset \mathcal{F} & D_\alpha \in \mathcal{F}' \\
D_\alpha \xrightarrow{w*} D := & |D_\alpha(f) - D(f)| \longrightarrow 0 & \forall f \in \mathcal{F} & D_\alpha \in \mathcal{F}' \\

D_\alpha \xrightarrow{w-k} D := & |D_\alpha(f) - D(f)| \longrightarrow 0 & \forall f \in \mathcal{H}_k & D_\alpha \text{ embeddable} \\
D_\alpha \xrightarrow{\|.\|_k} D := & \|D_\alpha - D\|_k \longrightarrow 0 & & D_\alpha \text{ embeddable}
\end{array}
\tag{4}
$$

4.1. Embeddings of Dual Spaces are Continuous

In this section, we show that the MMD topology is often weaker than other topologies τ defined on $\mathcal{D}$, meaning that if D_α converges to D in τ, then it also converges to D in MMD. Note that this is equivalent to saying that the KME of $\mathcal{D}_\tau$ (read '$\mathcal{D}$ equipped with τ') is continuous. We start with the following pretty coarse, yet very general result.

Proposition 9 *If $\mathcal{H}_k \hookrightarrow \mathcal{F}$, then $D_\alpha \xrightarrow{b} D \;\Rightarrow\; D_\alpha \xrightarrow{\|.\|_k} D$ and $D_\alpha \xrightarrow{w*} D \;\Rightarrow\; D_\alpha \xrightarrow{w-k} D$.*

Proof Proposition 9 states that the KME is continuous when both $\mathcal{F}'$ and $\mathcal{H}_k$ carry their strong or their weak-$*$ topology, which we now show. From Diagram Eq.(3), we know that the KME is the composition of the conjugate restriction operator with the Riesz representer map. The Riesz representer map is a topological (anti-)isomorphism between $\mathcal{H}'_k$ and $\mathcal{H}_k$, thus continuous (see Appendix C). And the restriction map is the adjoint (or transpose) of the canonical embedding map $\begin{array}{rccc} \imath: & \mathcal{H}_k & \longrightarrow & \mathcal{F} \\ & f & \longmapsto & f \end{array}$, thus continuous when both $\mathcal{F}'$ and $\mathcal{H}'_k$ carry their weak-$*$ or strong topologies (Treves, 1967, Prop.19.5 & Corollary). ■

Let us briefly comment on this result. The statement $D_\alpha \xrightarrow{w*} D \;\Rightarrow\; D_\alpha \xrightarrow{w-k} D$ is actually obvious, because $\mathcal{H}_k \subset \mathcal{F}$. Concerning strong convergence, Proposition 9 implies that, if $\mathcal{F}$ is a Banach space, then any net that converges for the dual norm $\|\cdot\|_{\mathcal{F}'}$ converges in MMD. Applying this with $\mathcal{F} = \mathcal{C}_0$ and $\mathcal{F}' = \mathcal{M}_f$ shows that convergence in TV norm implies convergence in MMD, or equivalently, that the TV norm is stronger than the MMD. Similar reasoning can be used to show that the MMD is weaker than the so-called Kantorovich(-Wasserstein) and the Dudley norms (see Example 1 in Simon-Gabriel and Schölkopf 2016). These results can also be found in Sriperumbudur et al. (2010b). However, the authors there directly bounded the MMD semi-norm by the target norm. This has the advantage of giving concrete bounds, but is more difficult to generalize if $\mathcal{F}$ is not a Banach space.

Though very general, Proposition 9 is pretty weak, as it only compares a strong with a strong and a weak-$*$ with a weak(-$*$) topology. But how does the weak-$*$ topology on $\mathcal{F}'$ compare with the strong topology of $\mathcal{H}_k$: does weak-$*$ convergence imply convergence in MMD? This question is discussed in details in Simon-Gabriel and Schölkopf (2016, Sec.7). The short answer is: not always, but sometimes; it depends on the space $\mathcal{F}'$. For example, if $k \in \mathcal{C}^{(m,m)}$, then weak-$*$ convergence in $\mathcal{E}^m$ implies convergence in MMD; but weak-$*$ convergence in $\mathcal{D}^m_{L^1}$ usually does not imply MMD convergence when $\mathcal{X}$ is non-compact. For us, the only thing we will need later is to know what happens on $\mathcal{M}_+$, the set of finite positive measures. The following lemma shows that weak convergence in $\mathcal{M}_+$ usually implies MMD convergence.

Lemma 10 *A bounded kernel k is continuous iff: $\forall\, \mu_\alpha, \mu \in \mathcal{M}_+$, $\mu_\alpha \xrightarrow{\sigma} \mu \implies \mu_\alpha \xrightarrow{\|.\|_k} \mu$.*

Proof We assume k bounded to ensure that any probability measure is embeddable. Now, suppose that weak convergence implies MMD convergence and take $x, y, x_0, y_0 \in \mathcal{X}$ such that $x \to x_0$ and $y \to y_0$. Then $\delta_x \xrightarrow{\sigma} \delta_{x_0}$ and $\delta_y \xrightarrow{\sigma} \delta_{y_0}$, so $\Phi_k(\delta_x) \to \Phi_k(\delta_{x_0})$ and $\Phi_k(\delta_y) \to \Phi_k(\delta_{y_0})$ in $\mathcal{H}_k$. And by continuity of the inner product:

$$k(x,y) = \langle \Phi_k(\delta_y)\,,\, \Phi_k(\delta_x)\rangle_k \to \langle \Phi_k(\delta_{y_0})\,,\, \Phi_k(\delta_{x_0})\rangle_k = k(x_0, y_0)\ ,$$

so k is continuous. Conversely, suppose that k is continuous, and let $\mu_\alpha \xrightarrow{\sigma} \mu$ in $\mathcal{M}_+$. The tensor-product mapping $\begin{array}{ccc} \mathcal{M}_+(\mathcal{X}) & \longrightarrow & \mathcal{M}_+(\mathcal{X}\times\mathcal{X}) \\ \mu & \longmapsto & \mu\otimes\mu \end{array}$ is weakly continuous (Berg et al., 1984, Chap.2, Thm.3.3). So by applying $\bar{\mu}_\alpha \otimes \mu_\alpha$ to a bounded continuous kernel k, we get

$$
\begin{aligned}
\|\Phi_k(\mu_\alpha) - \Phi_k(\mu)\|_k^2 &= \iint k(x,y)\, \mathrm{d}(\mu_\alpha - \mu)(y)\, \mathrm{d}(\bar{\mu}_\alpha - \bar{\mu})(x) \\
&= [\bar{\mu}_\alpha \otimes \mu_\alpha](k) - [\bar{\mu} \otimes \mu_\alpha](k) - [\bar{\mu}_\alpha \otimes \mu](k) + [\bar{\mu}\otimes\mu](k) \longrightarrow 0\ . \quad ■
\end{aligned}
$$

4.2. When Does k Metrize the Topology of $\mathcal{F}'$?

So far we focused on the question: when does convergence in $\mathcal{D}$ imply convergence in MMD. We now seek the opposite: when does MMD-convergence imply convergence in $\mathcal{D}$?

First, the kernel *must* be characteristic to $\mathcal{D}$. Otherwise, the MMD does not define a distance but only a semi-distance, so that the induced topology would not be Hausdorff. Second, we will suppose that $\mathcal{F}$ is barreled. This is a technical, yet very general assumption

that we use in the next theorem. The definition of a barreled space is given in Appendix C for completeness, but all that the reader should remember is that all Banach, Fréchet, Limit-Fréchet and *all function spaces defined in this paper are barreled*,[1] except $(\mathscr{C}_b^m)_c$.

Lemma 11 *Suppose that $\mathcal{F}$ is barreled, k is universal over $\mathcal{F}$, $\mathcal{H}_k \hookrightarrow \mathcal{F}$ and let $(D_\alpha)_\alpha$ be a bounded net in $\mathcal{F}_b'$. Then $D_\alpha \xrightarrow{w-k} D$ iff $D_\alpha \xrightarrow{w*} D$. Hence $D_\alpha \xrightarrow{\|.\|_k} D \;\Rightarrow\; D_\alpha \xrightarrow{w*} D$.*

Proof Proposition 32.5 of Treves (1967) shows that the weak topologies of $\mathcal{F}'$ and of $\mathcal{H}_k'$ coincide on so-called *equicontinuous* sets of $\mathcal{F}'$, and the Banach-Steinhaus theorem (see Appendix C) states that if $\mathcal{F}$ is barreled, then the equicontinuous sets of $\mathcal{F}'$ are exactly its bounded sets. This precisely means that if the net D_α is bounded in $\mathcal{F}'$, then $D_\alpha(f) \to D(f)$ for all $f \in \mathcal{F}$ iff it converges for all $f \in \mathcal{H}_k$. Now, if $\|D_\alpha - D\|_k \to 0$, then, by continuity of the inner product, $D_\alpha(f) - D(f) = \langle f\,,\, D_\alpha - D\rangle_k \to 0$ for any $f \in \mathcal{H}_k$. ■

Lemma 11 says that the weak-$*$ topologies of $\mathcal{F}'$ and of $\mathcal{H}_k$ coincide on subsets of $\mathcal{F}'$ that are bounded in the strong topology. But from the Banach-Steinhaus theorem (see App. C) we know that on barreled spaces it is equivalent to be bounded in strong or in weak topology. Hence the net D_α of Lemma 11 is bounded iff $\sup_\alpha |D_\alpha(f)| < \infty$ for all $f \in \mathcal{F}$. Nevertheless, it is not enough in general to show that $\sup_\alpha \|D_\alpha\|_k < \infty$. A bounded set in $\mathcal{M}_f$ is also a set whose measures have uniformly bounded total variation. The total variation of any probability measure being 1, $\mathcal{P}$ is bounded. So Lemma 11 shows that for continuous c_0-universal kernels, convergence of probability measures in MMD distance implies weak-$*$ convergence, which on $\mathcal{P}$ is the same as weak-convergence. But by Lemma 10 the reverse is true as well. Thus, *for a continuous c_0-universal kernel k, probability measures converge weakly iff they converge in MMD distance.* Such kernels are said to *metrize* the weak convergence on $\mathcal{P}$.

However, the condition that k be c_0-universal seems slightly too restrictive. Indeed, it is needed in Lemma 11 to ensure that the KME be characteristic to $\mathcal{M}_f$ (by Thm. 6 applied to $\mathcal{F} = \mathscr{C}_0$) so that the MMD be a metric over $\mathcal{M}_f$ (not only a semi-metric). But, to be a metric over $\mathcal{P}$, it would suffice that k be characteristic to $\mathcal{P}$, which is a slightly coarser assumption than c_0-universality. Is this condition enough to guarantee the metrization of weak-convergence in $\mathcal{P}$? The following theorem shows that it is.

Theorem 12 *A bounded kernel over a locally compact Hausdorff space $\mathcal{X}$ metrizes the weak convergence of probability measures iff it is continuous and characteristic (to $\mathcal{P}$).*

Proof [Theorem 12] If k metrizes the weak convergence over $\mathcal{P}$, then, by Lemma 10, k is continuous, and, for $\|.\|_k$ to be a norm, k needs to be characteristic. Conversely, if k is continuous, then by Lemma 10 weak convergence implies convergence in MMD. So it remains to show that MMD convergence implies weak convergence. To do so, we use Lemma 20 of the appendix, which states that for an $\int$s.p.d. kernel, MMD convergence of probability measures implies their weak convergence. Now k might not be $\int$s.p.d., but using Theorem 8(iv), we can transform it to a kernel $k_1 := k+1$ which induces the same MMD metric

1. $\mathbb{C}^{\mathcal{X}}$ is barreled, because it is a topological product $\prod_{\mathcal{X}} \mathbb{C}$ of barreled spaces. All other mentioned spaces are either Banach, Fréchet or Limit-Fréchet spaces, thus barreled (Treves, 1967, Prop. 33.2 & Cor.1-3).

over probability measures than k, but which is $\int$s.p.d. This concludes. ■

To the best of our knowledge, this is the first characterization of the class of kernels that metrize the weak-convergence of probability measures. For example Gaussian, Laplace, inverse-multiquadratic or Matérn kernels are continuous and characteristic, so they all metrize the weak convergence over $\mathcal{P}$. In general however, even if a kernel metrizes the weak convergence over $\mathcal{P}$, it usually does not metrize weak convergence over $\mathcal{M}_+$ or $\mathcal{M}_f$ (see Simon-Gabriel and Schölkopf 2016).

5. Kernel Mean Embeddings of Schwartz-Distributions

We extended KMEs of measures to Schwartz-distributions and showed that they are continuous, but we hardly said anything about what to do and how to work with distributions. We will now catch up by focusing on distributions only. In Section 5.1, we discuss and prove the Fubini and the Differentiation formulae featured in the introduction. In Section 5.2 we provide sufficient conditions for a translation-invariant kernel to be c_*^m-universal.

5.1. Distributional Calculus

Proposition 13 (Fubini) *Let D, T be two embeddable distributions into $\mathcal{H}_k$. Then:*

$$\begin{aligned}\langle D\,,\,T\rangle_k &= \iint k(x,y)\,\mathrm{d}D(y)\,\mathrm{d}\bar{T}(x) = \iint k(x,y)\,\mathrm{d}\bar{T}(x)\,\mathrm{d}D(y) \\ \|D\|_k^2 &= \iint k(x,y)\,\mathrm{d}D(y)\,\mathrm{d}\bar{D}(x) = \iint k(x,y)\,\mathrm{d}\bar{D}(x)\,\mathrm{d}D(y)\,,\end{aligned} \tag{5}$$

where $\iint k(x,y)\,\mathrm{d}D(y)\,\mathrm{d}\bar{T}(x)$ is to be understood as $\bar{T}(\mathcal{I})$ with $\mathcal{I}(x) = \int k(x,y)\,\mathrm{d}D(y)$.

Proof Definition 1 of a KME, together with the property that $k(y,x) = \overline{k(x,y)}$ leads to:

$$\begin{aligned}\langle D\,,\,T\rangle_k &= \int_x \left\langle \int_y k(.,y)\,\mathrm{d}D(y)\,,\,k(.,x)\right\rangle_k \mathrm{d}\bar{T}(x) \\ &= \int_x \overline{\left\langle k(.,x)\,,\,\int_y k(.,y)\,\mathrm{d}D(y)\right\rangle_k}\,\mathrm{d}\bar{T}(x) \\ &= \int_x \overline{\int_y \langle k(.,x)\,,\,k(.,y)\rangle_k\,\mathrm{d}\bar{D}(y)}\,\mathrm{d}\bar{T}(x) \\ &= \iint k(x,y)\,\mathrm{d}D(y)\,\mathrm{d}\bar{T}(x).\end{aligned}$$

To prove the right-most part of (5), use $\langle D\,,\,T\rangle_k = \overline{\langle T\,,\,D\rangle}_k$. ■

These formulae are well-known when D and T are probability measures. They show that if you know how to integrate a function (the kernel) w.r.t. a measure or a distribution, then you can compute its MMD norm. However, integrating w.r.t. a distribution that is not a measure can be tedious. But the following proposition gives us a way to convert an integration w.r.t. a distribution into an integration w.r.t. a measure.

Proposition 14 (Differentiation) *Let $k \in \mathscr{C}^{(m,m)}$ and $p \in \mathbb{N}^d$ such that $|p| \leq m$. A distribution D embeds into $\mathcal{H}_k$ via $\partial^{(0,p)}k$ iff $\partial^p D$ embeds into $\mathcal{H}_k$ via k. In that case,*

$$\Phi_k(\partial^p D) = (-1)^{|p|} \int [\partial^{(0,p)}k](.,x)\,\mathrm{d}D(x) = (-1)^{|p|}\,\Phi_{\partial^{(0,p)}k}(D)\,. \tag{6}$$

If moreover k is translation-invariant, then

$$\Phi_k(\partial^p D) = \partial^p[\Phi_k(D)]. \tag{7}$$

Proof The proof holds in the following equalities. For any $f \in \mathcal{H}_k$,

$$\begin{aligned}
\left\langle f\,,\, \int k(.,x)\,\mathrm{d}[\partial^p D](x) \right\rangle_k &= \int \langle f\,,\, k(.,x)\rangle_k\,\mathrm{d}[\partial^p \bar{D}](x) = [\partial^p \bar{D}](f) \\
&= (-1)^{|p|}\bar{D}(\partial^p f) \\
&= (-1)^{|p|}\bar{D}(\left\langle f\,,\, \partial^{(0,p)}k(.,x)\right\rangle_k) \\
&= (-1)^{|p|}\int \left\langle f\,,\, \partial^{(0,p)}k(.,x)\right\rangle_k \mathrm{d}\bar{D}(x) \\
&= \left\langle f\,,\, (-1)^{|p|}\int \partial^{(0,p)}k(.,x)\,\mathrm{d}D(x)\right\rangle_k .
\end{aligned}$$

The first line uses the definition of KMEs (1), the second the definition of distributional derivatives (see App. B), the third Lemma 19, the fourth line rewrites the previous line with our notation convention, and the fifth one uses again the definition of a weak integral (1). ■

Equation (7) describes a commutative diagram pictured in Figure 1: it states that with translation-invariant kernels, it is equivalent to take the (distributional) derivative of a distribution and embed it, or to embed it and take the (usual) derivative of the embedding. See Appendix B for an introduction to distributional derivatives. Note that for a signed measure μ with a $|p|$-times differentiable density q, the distributional derivative $\partial^p\mu$ is the signed measure with density $\partial^p_u q$, where ∂^p_u is the usual partial derivative operator. However, Proposition 14 becomes most useful when μ has no differentiable density, for example when μ is an empirical measure. Then there is no analytical formula for the derivative of μ, but we can still compute its KME analytically by using (6) or (7).

Example 1 *Let us illustrate Proposition 14 on KMEs of Gaussian probability measures μ_σ with density $q_\sigma(x) = \frac{1}{\sqrt{2\pi\sigma^2}}e^{-x^2/\sigma^2}$ using a Gaussian kernel $k(x,y) = e^{-(x-y)^2}$. When σ goes to zero, μ_σ gets more and more peaked around 0 and converges weakly to the Dirac measure $\mu_0 := \delta_0$. The KME of μ_σ is easy to compute and using (7) we get*

$$\begin{aligned}
\Phi_k(\mu_\sigma)(x) &= \frac{1}{\sqrt{1+2\sigma^2}}\,e^{-\frac{x^2}{1+2\sigma^2}} \\
\Phi_k(\partial\mu_\sigma)(x) &= \partial[\Phi_k(\mu_\sigma)] = -\frac{2x}{(1+2\sigma^2)^{3/2}}\,e^{-\frac{x^2}{1+2\sigma^2}}\,,
\end{aligned}$$

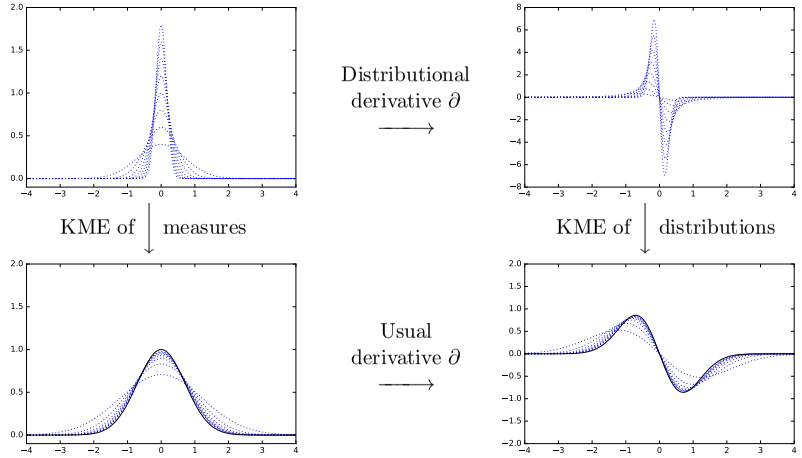

Figure 1: Densities of more and more peaked Gaussian probability measures μ_σ (top left) with their derivatives (top right) and their embeddings (below) using a Gaussian kernel (see Example 1). Equation (7) states that the diagram is commutative. When σ goes to 0, the Gaussians converge (weakly) to a Dirac mass δ_0, which has no density, but who's embedding is the solid black line (bottom left). The derivatives converge (weakly) to the Schwartz-distribution $\partial\delta_0$, which is not even a signed measure, but whose embedding (bottom right, black solid line) can easily be computed using (6) or (7). Moreover, the embeddings of μ_σ and $\partial\mu_\sigma$ converge (weakly) to the embeddings of μ_0 and $\partial\mu_0$, which illustrates Proposition 9.

where the formulae still hold when $\sigma = 0$. Figure 1 plots these embeddings for different σ's. Note that contrary to $\partial\mu_\sigma$ with $\sigma > 0$, $\partial\mu_0$ is not a signed measure (but a Schwartz-distribution) but it has a KME which, moreover, can easily be computed using (7). Notice also that on Figure 1 both the embeddings of μ_σ and $\partial\mu_\sigma$ converge (weakly) to the embeddings of μ_0 and $\partial\mu_0$. This illustrates Proposition 9.

Theoretically, (6) can be used to convert the KME of *any* distribution into a sum of KMEs of measures. In other words, the integral w.r.t. a distribution appearing in (1) can be converted into a sum of integrals w.r.t. signed measures. Here is how. Given a measure $\mu \in \mathcal{M}_f = \mathcal{D}^0_{L^1}(\mathbb{R})$, we may differentiate μ and get a new distribution $\partial\mu$ which may or may not be itself a measure.[2] But in any case, what will follow shows that $\partial\mu$ is in $\mathcal{D}^1_{L^1}(\mathbb{R})$. Thus the space of distributions that can be written as a sum $\mu_0 + \partial\mu_1$ of two finite measures μ_1, μ_2 is a subspace of $\mathcal{D}^1_{L^1}(\mathbb{R})$ and we may wonder how big exactly it is. Schwartz (1954, around p.100) showed that it is exactly the space $\mathcal{D}^1_{L^1}(\mathbb{R})$. More generally, he showed:

Lemma 15 (Schwartz) *For any $m \leq \infty$ and any distribution in $D \in \mathcal{D}^m_{L^1}$ (resp. $D \in \mathscr{C}^m$) there exists a* finite *family of measures $\mu_p \in \mathcal{M}_f$ (resp. $\mu_p \in \mathcal{M}_c$) such that $D = \sum_{|p|\leq m}\partial^p\mu_p$.*

2. Think for example of the Dirac measure: it is a measure, but not its derivative. See App. B.

Using (6), this means that the KME can be computed as $\sum_{|p|\leq m}\int \partial^{(0,p)}k(.,x)\,\mathrm{d}\mu_p(x)$, which gives a way to numerically compute the KME of distributions. As most distributions encountered in practice happen to be defined as measures or derivatives of some measures, this method is highly relevant in practice.

By combining Propositions 13 and 14, we get the following corollary.

Corollary 16 *Let $k \in \mathscr{C}^{(m,m)}$, $p \in \mathbb{N}^d$ with $|p| \leq m$, and let D, T be two distributions such that $\partial^p D$ and $\partial^p T$ embed into $\mathcal{H}_k$. Then*

$$\langle \partial^p D\,,\, \partial^p T\rangle_k = \langle D\,,\, T\rangle_{\partial^{(p,p)}k} \quad \textit{and} \quad \|\partial^p D\|_k = \|D\|_{\partial^{(p,p)}k}\ .$$

Proof The proof reduces to the following equations.

$$\begin{aligned}
\langle \partial^p D\,,\, \partial^p T\rangle_k &\overset{(a)}{=} \left\langle \int \partial^{(0,p)}k(.,x)\,\mathrm{d}D(x)\,,\, \int \partial^{(0,p)}k(.,y)\,\mathrm{d}T(y)\right\rangle_k \\
&\overset{(b)}{=} \int \left\langle \partial^{(0,p)}k(.,y)\,,\, \partial^{(0,p)}k(.,x)\right\rangle_k \mathrm{d}D(y)\,\mathrm{d}\bar{T}(x) \\
&\overset{(c)}{=} \int \partial^{(p,p)}k(x,y)\,\mathrm{d}D(y)\,\mathrm{d}\bar{T}(x) \\
&\overset{(d)}{=} \langle D\,,\, T\rangle_{\partial^{(p,p)}k}\ ,
\end{aligned}$$

Equality (a) uses Proposition 14, (b) uses twice (on the left and on the right of the inner product) the definition of the weak integral (1), (c) uses Equation (9) proven in Appendix A which states that $\left\langle \partial^{(0,p)}k(.,y)\,,\, \partial^{(0,p)}k(.,x)\right\rangle_k = \partial^{(p,p)}k(x,y)$, and (d) uses (5) applied to the kernel $\partial^{(p,p)}k$. ■

Corollary 16 tells us that if we use $\partial^{(p,p)}k$—which is a kernel—to compute the MMD between two probability distributions D, T, then we are actually computing the MMD distance between their derivatives $\partial^p D$ and $\partial^p T$ with the kernel k. One could extend this corollary from (p,p) to (p,q) with $|q| \leq m$, yielding $\langle \partial^p D\,,\, \partial^q T\rangle_k = \int \partial^{(q,p)}k(x,y)\,\mathrm{d}D(y)\,\mathrm{d}\bar{T}(x)$. But in that case, $\partial^{(q,p)}k$ might not be a kernel anymore.

5.2. c^m- and c_0^m-Universal Kernels

Theorem 6 shows the equivalence between c_*^m-universality and characteristicness over $\mathscr{D}_{L^1}^m$ or $\mathscr{E}^m$. But neither the universality, nor the characteristic assumption seems easy to check in general. However, for translation-invariant kernels, meaning kernels that can be written as $k(x,y) = \psi(x-y)$ for some function ψ, we will now show that being characteristic to $\mathscr{P}$ or to $\mathscr{D}_{L^1}^m$ is one and the same thing, provided that $k \in \mathscr{C}_b^{(m,m)}$. Thus, any technique to prove that a kernel is characteristic may also be used to prove that it is characteristic to the much wider space $\mathscr{D}_{L^1}^m$. One of these techniques consists in verifying that the distributional Fourier transform $\mathcal{F}\psi$ has full support. The reader unfamiliar with distributional Fourier transforms may think of them as an extension of the usual Fourier transform—which is usually only defined on L^1, L^2 or $\mathcal{M}_f$—to wider function and distribution spaces. Let us mention that $\mathcal{F}\psi$ is exactly the unique positive, symmetric, finite measure appearing in Bochner's theorem (Wendland, 2004, Thm.6.6), and whose (usual) Fourier transform is ψ. We now successively present the result for $\mathscr{D}_{L^1}^m$, then for $\mathscr{E}^m$.

Theorem 17 *Let $k \in \mathscr{C}^{(m,m)}$ be a translation-invariant kernel $k(x,y) = \psi(x-y)$ with $\mathcal{X} = \mathbb{R}^d$, and $\mathcal{F}\psi$ its distributional Fourier transform. Then $\mathscr{D}_{L^1}^m$ embeds into $\mathcal{H}_k$ and the following are equivalent.*

(i) k is characteristic (to $\mathscr{P}$).
(ii) k is characteristic to $\mathscr{D}_{L^1}^m$.
(iii) $\mathcal{F}\psi$ has full support.

If moreover $\psi \in \mathscr{C}_0^m$, then k is c_0^m-universal iff it is c_0-universal.

Theorem 18 *Let $k \in \mathscr{C}^{(m,m)}$ be a translation-invariant kernel $k(x,y) = \psi(x-y)$ with $\mathcal{X} = \mathbb{R}^d$. If the support of $\mathcal{F}\psi$ has Lebesgue-measure > 0, then k is characteristic to $\mathscr{E}^m$.*

Proof [of Theorem 17] First, note that $\partial^{(p,p)}k(x,y) \leq \partial^{(p,p)}k(x,x)\partial^{(p,p)}k(y,y) = (\partial^{2p}\psi(0))^2$ for any $|p| \leq m$ (see Lemma 19 in Appendix A). Hence $k \in \mathscr{C}_b^{(m,m)}$, which, by Corollary 4, proves that $\mathscr{D}_{L^1}^m$ embeds into $\mathcal{H}_k$. Now suppose that (i) and (ii) are equivalent, then they are also equivalent to k being characteristic to $\mathcal{M}_f$. Using Theorem 6, we thus proved the last sentence. Now, (ii) clearly implies (i) and Theorem 9 of Sriperumbudur et al. (2010b) states that (i) and (iii) are equivalent. So it remains to show that (iii) implies (ii). We now sketch its proof and relegate the details to Appendix A.5. Let Λ be the finite positive measure from Bochner's theorem, such that $\psi = \mathcal{F}\Lambda$ and let $D \in \mathscr{D}_{L^1}^m$. Then

$$\begin{aligned}
\|D\|_k^2 &= \iint \left(\int e^{i(x-y)\cdot\xi}\,\mathrm{d}\Lambda(\xi)\right)\mathrm{d}\bar{D}(x)\,\mathrm{d}D(y) \\
&\overset{(a)}{=} \int \left(\iint (e^{i(x-y)\cdot\xi})\,\mathrm{d}\bar{D}(x)\,\mathrm{d}D(y)\right)\mathrm{d}\Lambda(\xi) \\
&\overset{(b)}{=} \int |[\mathcal{F}D](\xi)|^2\,\mathrm{d}\Lambda(\xi)\,,
\end{aligned}$$

where $\cdot$ denotes the Euclidian inner-product on $\mathbb{R}^d$. Λ being positive, if it has full support, then $[\mathcal{F}D](\xi) = 0$ for almost all $\xi \in \mathcal{X}$. Thus $D = 0$. Assuming that (a) and (b) indeed hold, we just showed that if (iii), then $\|D\|_k = 0$ implies $D = 0$, meaning that k is s.p.d. to $\mathscr{D}_{L^1}^m$, which, with Theorem 6, proves (ii). We relegate the proof of (a) and (b) to Appendix A.5. ■

Proof [of Theorem 18] For any $D \in \mathscr{E}^m$, we can write, like before: $\|D\|_k^2 = \int |[\mathcal{F}D](\xi)|^2\,\mathrm{d}\Lambda(\xi)$. But now, the Paley-Wiener-Schwartz theorem (Treves, 1967, Thm. 29.2) states that $\mathcal{F}D$ is an analytical function, so if its set of zeros has Lebesgue-measure > 0, then $\mathcal{F}D$ is the 0 function, so $D = 0$, showing that Φ_k is injective over $\mathscr{E}^m$. ■

These theorems show for example that Gaussian kernels are c_0^∞-universal and that the sinc kernel, defined on $\mathcal{X} = \mathbb{R}$ by $k(x,y) = \sin(x-y)/(x-y)$ (and 1 on the diagonal), is c^∞- but not c_0^∞-universal. When $\mathcal{X} = \mathbb{R}$, one can refine the conditions on the Fourier transform in Theorem 18 so that they become necessary and sufficient (Simon-Gabriel and Schölkopf, 2016, Theorem 41).

6. Conclusion

We first discuss how this work relates and contributes to the existing machine learning literature and then conclude.

6.1. Related Machine Learning Literature

Universal and characteristic kernels play an essential role in kernel methods and their theory. Universal kernels ensure consistency of many RKHS-based estimators in the context of regression and classification (Steinwart, 2001; Steinwart and Christmann, 2008), whereas characteristic kernels are of prime interest in any MMD-based algorithm, such as kernel two-sample tests (Gretton et al., 2007, 2012), HSIC independence tests (Gretton et al., 2008; Gretton and Györfi, 2010; Fukumizu et al., 2008), kernel density estimators (Sriperumbudur, 2016) and MMD-type GANs (Li et al., 2015; Dziugaite et al., 2015). The machine learning community gradually introduced more and more variants of universal kernels (Steinwart, 2001; Micchelli et al., 2006; Carmeli et al., 2006; Caponnetto et al., 2008), but instead of also introducing variants of characteristic kernels, it stuck to the original definition given by Fukumizu et al. (2004) which considered only characteristicness to $\mathscr{P}$. As a result, the literature started proving various links between the various variants of universal kernels and the only notion of characteristic kernels that it had. Eventually these notions were linked to $\int$s.p.d. and conditionally $\int$s.p.d. kernels (Fukumizu et al., 2004, 2008, 2009b,a; Gretton et al., 2007; Sriperumbudur et al., 2008, 2010a,b) and all known relations got summarized in a superb overview article by Sriperumbudur et al. (2011). However, by not introducing the notion of a characteristic kernel to something else than $\mathscr{P}$, the literature oversaw the fundamental dual link between universal, characteristic and s.p.d. kernels shown in Theorem 6 of this paper, which easily explains all the previously reported links.

Concerning the study of kernels that metrize the weak convergence of probability measures, in mathematics it dates back at least to Guilbart (1978), but it got introduced into the machine learning community only many years later by Sriperumbudur et al. (2010b). They gave new sufficient conditions to metrize the weak convergence, which then got improved by Sriperumbudur (2016)[Thm. 2]. However, by generalizing these sufficient conditions even further, Theorem 12 of this work is the first to provide conditions that are both sufficient *and necessary*, and that holds on any locally compact Hausdorff space $\mathcal{X}$ (which is more general than in the existing literature).

6.2. Future Work and Closing Remarks

This paper grouped various notions of universal, characteristic and s.p.d. kernels into three fundamental definitions—one for each—and showed that they are essentially equivalent: they describe the same family of kernels, but from dual perspectives. Using this duality link, we could systematically recover most of the previously known links, but also discovered new ones, such as the equivalence between characteristicness to $\mathscr{P}$ and universality over $(\mathscr{C}_b)_c/\mathbb{1}$; or between strict positive definiteness (over $\mathcal{M}_\delta$) and universality over $\mathbb{C}^{\mathcal{X}}$. We then compared the convergence in MMD with other convergence types of distributions and measures. Importantly, we showed that a bounded kernel metrizes the weak convergence of probability measures iff it is continuous and characteristic. Incidentally, we also showed that

KMEs over probability measures can be extended to generalized measures called Schwartz-distributions. For translation-invariant kernels, this extension preserves characteristicness, in the sense that a characteristic kernel to $\mathscr{P}$ will also be characteristic to $\mathcal{D}^m_{L^1}$. In all this work, we assumed $\mathcal{X}$ to be locally compact. Although this assumption fits many very general spaces, unfortunately, it does not contain any infinite-dimensional Banach space. So a main open question of this paper is whether our characterization of kernels that metrize the weak convergence of probability measures also applies to more general spaces, such as so-called Polish spaces, which are very standard spaces in probability theory. Finally, we also proved a few results that are specific to KMEs of distributions. Proposition 14 and its Corollary 16 on the embedding of derivatives for example show that these KMEs of distributions naturally appear when considering KMEs w.r.t. derivatives of kernels. We hope that they will in future lead to new insights and applications in machine learning.

Acknowledgments

We are deeply indebted to Alphabet for their support via a Google European Fellowship in Causal Inference accorded to Carl-Johann Simon-Gabriel. We thank Bharath Sriperumbudur for enlightening remarks, Jonas Peters for his kind and helpful advice, Ilya Tolstikhin for useful discussions and encouragements, and the two anonymous reviewers for their extensive, useful and contructive feedback.

Appendix A. Proofs

In this section, we gather all the complements to non fully proved theorems, propositions, corollaries or lemmas appearing in the main text. We start with a lemma that essentially follows from Corollary 4.36 of Steinwart and Christmann (2008), and which we will need a few times for the proofs.

Lemma 19 *Let* $k \in \mathscr{C}_b^{(m,m)}$ *and let* $\Phi : \begin{array}{ccc} \mathcal{X} & \longrightarrow & \mathcal{H}_k \\ x & \longmapsto & k(.,x) \end{array}$ *. Then for any* $p \in \mathbb{N}^d$ *with* $|p| \leq m$*, the partial derivative* $\partial^p\Phi$ *exists, belongs to* $\mathcal{H}_k$*, is continuous and verifies* $\partial^p\Phi(x) = \partial^{(0,p)}k(.,x)$*. Moreover, for any* $f \in \mathcal{H}_k$*,* $\partial^p f$ *exists, belongs to* $\mathcal{H}_k$ *and verifies:*

$$\partial^p f(x) = \Big\langle f\,,\, \partial^{(0,p)}k(.,x)\Big\rangle_k \ . \tag{8}$$

Applied with $f = \partial^{(0,q)}k(.,y)$ *where* $|q| \leq m$ *also proves that*

$$\partial^{(p,q)}k(x,y) = \Big\langle \partial^{(0,q)}k(.,y)\,,\, \partial^{(0,p)}k(.,x)\Big\rangle_k \ . \tag{9}$$

Proof This Lemma is essentially proven in Corollary 4.36 and in its proof of Steinwart and Christmann (2008). We only added Equation (9), which is a straightforward consequence of (8), and the part stating that $\partial^p\Phi(x) = \partial^{(0,p)}k(.,x)$. This can be shown as follows. Steinwart and Christmann (2008) prove that $\partial^p\Phi$ exists and belongs to $\mathcal{H}_k$. Thus

$$[\partial^p\Phi(x)](y) = \langle \partial^p\Phi(x)\,,\, k(.,y)\rangle_k$$

$$= \left\langle \lim_{h\to 0} (\Phi(x+he_i) - \Phi(x))/h \,,\, k(.,y) \right\rangle_k$$
$$= \lim_{h\to 0} (k(y, x+he_i) - k(y,x))/h$$
$$= \partial^{(0,p)} k(y,x) \;,$$

where we used the continuity of the inner product to swap limit and bracket signs. ■

A.1. Proof of Corollary 3

Proof Suppose that $\mathcal{H}_k \subset \mathcal{C}_0$. (i) clearly holds. Suppose (ii) was not met. Then let $x_n \in \mathcal{X}$ such that $k(x_n, x_n) = \|k(.,x_n)\|_k^2 \to \infty$. Thus $k(.,x_n)$ is unbounded. But $\langle f\,,\, k(.,x_n)\rangle_k = f(x_n)$ is bounded for any $f \in \mathcal{H}_k$, thus $k(.,x_n)$ is bounded (Banach-Steinhaus Theorem). Contradiction. Thus (ii) is met.

Conversely, suppose that (i) and (ii) hold. Let $\mathcal{H}_k^{\text{pre}} := \text{span}\{k(.,x)\,|\,x \in \mathcal{X}\}$. Then, $\mathcal{H}_k^{\text{pre}} \subset \mathcal{C}_0$, and for any $f, g \in \mathcal{H}_k$, $\|f-g\|_\infty \leq \|f-g\|_k \, \|k\|_\infty$. Thus $\mathcal{H}_k^{\text{pre}}$ continuously embeds into the *closed* $\mathcal{C}_0$, thus so does its $\|.\|_k$-closure, $\mathcal{H}_k$. The proof of the cases $\mathcal{H}_k \subset \mathcal{C}$ and $\mathcal{H}_k \subset \mathcal{C}_b$ are similar (see also Berlinet and Thomas-Agnan, 2004, Thm. 17). ■

A.2. Proof of Corollary 4

Proof Suppose that $k \in \mathcal{C}_b^{(m,m)}$. Then $\mathcal{H}_k^{\text{pre}} \subset \mathcal{C}_b^m$ (Steinwart and Christmann, 2008, Corollary 4.36) and for any $x \in \mathcal{X}$, $f \in \mathcal{H}_k^{\text{pre}}$, and $|p| \leq m$, we have $\|\partial^p f\|_\infty \leq \|f\|_k \left\| \sqrt{\partial^{(p,p)} k} \right\|_\infty$. Thus $\mathcal{H}_k^{\text{pre}}$ continuously embeds into the *closed* space $\mathcal{C}_b^m$, thus so does its $\|.\|_k$-closure, $\mathcal{H}_k$. But, by definition of $(\mathcal{C}_b^m)_c$ is the space $\mathcal{C}_b$ equipped with a weaker topology (see Section 3), thus $\mathcal{C}_b^m \hookrightarrow (\mathcal{C}_b^m)_c$. Thus $\mathcal{H}_k \hookrightarrow (\mathcal{C}_b^m)_c$, which concludes. The proofs when $k \in \mathcal{C}$ or $k \in \mathcal{C}_0$ are similar. ■

A.3. Proof of Theorem 8

Proof Equivalence between (i) & (ii). As KMEs are linear over $\mathcal{M}_f$, a kernel k is characteristic to $\mathcal{P}$ iff it is characteristic to $\mathcal{P} - P := \{\mu - P : \mu \in \mathcal{P}\}$, where P can be any fixed probability measure. This is equivalent to being characteristic to the linear span of $\mathcal{P} - P$. But the linear span of $\mathcal{P} - P$ is precisely $\mathcal{M}_f^0$, which concludes.

Equivalence of (ii) & (v): First of all, notice that, if (v), then k and k_0 define the same MMD on $\mathcal{M}_f^0$, because, for any $\mu \in \mathcal{M}_f^0$, $\mu(\mathbb{1}) = 0$, thus:

$$\|\mu\|_{k_0}^2 = \iint \langle \delta_x - \nu_0 \,,\, \delta_y - \nu_0 \rangle_k \, \mathrm{d}\bar{\mu}(x) \, \mathrm{d}\mu(y)$$
$$= \iint k(x,y) \, \mathrm{d}\bar{\mu}(x) \, \mathrm{d}\mu(y) - \int \langle \delta_x \,,\, \nu_0 \rangle_k \, \mathrm{d}\bar{\mu}(x) \int \mathrm{d}\mu(y)$$
$$- \int \mathrm{d}\bar{\mu}(x) \int \langle \nu_0 \,,\, \delta_y \rangle_k \, \mathrm{d}\mu(y) - \|\nu_0\|_k^2 \iint \mathrm{d}\bar{\mu}(x) \, \mathrm{d}\mu(y)$$

$$= \|\mu\|_k^2 \;,$$

Thus k_0 is characteristic to $\mathcal{M}_f^0$ iff k is also. Thus (v) implies (ii). Conversely, if k_0 is characteristic to $\mathcal{M}_f^0$, then k_0 is either characteristic to $\mathcal{M}_f$, in which case choosing $k_0 = k$ and $\nu_0 = 0$ fulfills the requirements of (v); or there exists a non zero measure $\nu_0 \in \mathcal{M}_f$ such that $\Phi_{k_0}(\nu_0) = 0$. As Φ_{k_0} is linear, we can choose $\nu_0(\mathbb{1}) = 1$ without loss of generality. Supposing now that we are in the latter case, the proof proceeds as follows.

(a) Show that the constant function $\mathbb{1} \notin \mathcal{H}_{k_0}$.
(b) Construct a new Hilbert space of functions of the form $\mathcal{H}_k = \text{span}\,\mathbb{1} \oplus \mathcal{H}_{k_0}$.
(c) Show that it has a reproducing kernel k.
(d) Show that k_0 and k fulfill the requirements of (v).

(a) Suppose that $\mathbb{1} \in \mathcal{H}_{k_0}$. Then $1 = \bar{\nu}_0(\mathbb{1}) = \int \langle \mathbb{1}\,,\, k_0(.,x)\rangle_{k_0} \, \mathrm{d}\bar{\nu}_0(x) \overset{(*)}{=} \left\langle \mathbb{1}\,,\, \int k_0(.,x) \, \mathrm{d}\nu_0(x) \right\rangle_{k_0} = \langle \mathbb{1}\,,\, \Phi_{k_0}(\nu_0)\rangle_{k_0} = 0$, where in $(*)$ we use the definition of KMEs (1) . Contradiction. Thus $\mathbb{1} \notin \mathcal{H}_{k_0}$.

(b) Define $\mathcal{H} := \text{span}\,\mathbb{1} \oplus \mathcal{H}_{k_0}$ and equip it with the inner product $\langle .\,,\, .\rangle$ that extends the inner product of $\mathcal{H}_{k_0}$ so, that

$$\mathbb{1} \perp \mathcal{H}_{k_0} \quad \text{and} \quad \|\mathbb{1}\| = 1 \,. \tag{10}$$

In other words, for any $f = c_f\mathbb{1} + f^\perp \in \mathcal{H}$ and any $g = c_g\mathbb{1} + g^\perp \in \mathcal{H}$:

$$\langle f\,,\, g\rangle := \left\langle f^\perp \,,\, g^\perp \right\rangle_{k_0} + c_f \bar{c_g}. \tag{11}$$

Obviously $\mathcal{H}$ is a Hilbert space of functions.

(c) We now construct k by first defining an injective embedding Φ and then showing that $k(x,y) := \langle \Phi(\delta_x)\,,\, \Phi(\delta_y)\rangle$ is a reproducing kernel with KME Φ.
As $\mathcal{M}_f^0$ is a hyperplane in $\mathcal{M}_f$ and $\nu_0 \in \mathcal{M}_f \backslash \mathcal{M}_f^0$, each measure $\mu \in \mathcal{M}_f$ can be decomposed uniquely in a sum: $\mu = \mu^\perp + \mu(\mathbb{1})\nu_0$ where $\mu^\perp = \mu - \mu(\mathbb{1})\nu_0 \in \mathcal{M}_f^0$. We may thus define the following linear embedding $\Phi : \mathcal{M}_f \longrightarrow \mathcal{H}$ by

$$\Phi(\mu) := \begin{cases} \Phi_{k_0}(\mu) & \text{if } \mu \in \mathcal{M}_f^0 \\ \mathbb{1} & \text{if } \mu = \nu_0 \end{cases} \quad \text{i.e.} \quad \begin{array}{rcl} \Phi(\mu) & := & \Phi_{k_0}(\mu^\perp) + \mu(\mathbb{1})\mathbb{1} \\ & = & \Phi_{k_0}(\mu) + \mu(\mathbb{1})\mathbb{1} \end{array} . \tag{12}$$

Noting that $\Phi(\mu)^\perp = \Phi(\mu^\perp) = \Phi_{k_0}(\mu^\perp) = \Phi_{k_0}(\mu)$ and using (11), we get

$$\forall f \in \mathcal{H},\ \forall x \in \mathcal{X},\ \ \langle f\,,\, \Phi(\delta_x)\rangle = \left\langle f^\perp \,,\, \Phi(\delta_x)^\perp \right\rangle_{k_0} + c_f = f^\perp(x) + c_f\mathbb{1}(x) = f(x)\,. \tag{13}$$

So by defining $k(x,y) := \langle \Phi(\delta_y)\,,\, \Phi(\delta_x)\rangle$ and applying (13) to $f = \Phi(\delta_y)$, we see that $\Phi(\delta_y) = k(.,y)$. Thus (13) may be rewritten as

$$\forall f \in \mathcal{H}, \forall x \in \mathcal{X}, \qquad \langle f\,,\, k(.,x)\rangle = f(x).$$

Thus $\mathcal{H}$ is an RKHS with reproducing kernel and Φ is its associated KME.

(d) As k_0 is characteristic to $\mathcal{M}_f^0$, Φ is injective over $\mathcal{M}_f^0$. And $\Phi(\nu_0) \in \mathcal{H}\backslash\Phi(\mathcal{M}_f^0)$. Thus Φ is injective over $\mathcal{M}_f$, so k is characteristic to $\mathcal{M}_f$. To conclude, (12) shows that

$$\begin{aligned}\langle \delta_y - \nu_0\,,\, \delta_x - \nu_0\rangle &= \langle \Phi_{k_0}(\delta_y) + (\delta_y - \nu_0)(\mathbb{1})\mathbb{1}\,,\, \Phi_{k_0}(\delta_x) + (\delta_x - \nu_0)(\mathbb{1})\mathbb{1}\rangle \\ &= \langle \Phi_{k_0}(\delta_y) + 0\,,\, \Phi_{k_0}(\delta_x) + 0\rangle \\ &= k_0(x,y)\ .\end{aligned}$$

Equivalence of (v) with (iii) & (iv): First, notice that the kernel k constructed in the proof of (v) $\Rightarrow$ (ii) verifies:

$$\begin{aligned}k(x,y) &= \langle \Phi(\delta_x)\,,\, \Phi(\delta_y)\rangle \\ &= \langle \Phi_{k_0}(\delta_x) + \delta_x(\mathbb{1})\mathbb{1}\,,\, \Phi_{k_0}(\delta_y) + \delta_y(\mathbb{1})\mathbb{1}\rangle \\ &= \langle \Phi_{k_0}(\delta_x)\,,\, \Phi_{k_0}(\delta_y)\rangle + \|\mathbb{1}\|^2 \\ &= k_0(x,y) + 1\ ,\end{aligned}$$

where we used (10), (12) and the fact that by construction $\langle .\,,\,.\rangle$ coincides with $\langle .\,,\,.\rangle_{k_0}$ on $\mathcal{M}_f^0$. Thus the proof of (v) $\Rightarrow$ (ii) shows that, if k_0 characteristic to $\mathcal{M}_f^0$, then the kernel $k_0(x,y)+1$ is characteristic to $\mathcal{M}_f$, thus $\int$s.p.d. (Thm. 6). $k(x,y) := k_0(x,y)+1$ is $\int$s.p.d.. More generally, if instead of fixing $\|\mathbb{1}\|_k = 1$ in (10) we fixed $\|\mathbb{1}\|_k = \epsilon$ for some real $\epsilon > 0$, then we would have ended up with an $\int$s.p.d. kernel k verifying $k(x,y) := k_0(x,y) + \epsilon^2$. Thus (ii) implies (iii) and (iv). Conversely, given any kernel k of the previous form, the inner products defined by k and k_0 coincide on $\mathcal{M}_f^0$. So if k is characteristic to $\mathcal{M}_f^0$, then so is k_0. Thus (iii) or (iv) implies (ii). ■

A.4. Proof of Theorem 12 Continued

The proof of Theorem 12 used the following lemma.

Lemma 20 *Let k be a continuous, $\int$s.p.d. kernel and let $(\mu_\alpha)_\alpha$ be bounded in $\mathcal{M}_+$ (meaning $\sup_\alpha \|\mu_\alpha\|_{TV} < \infty$). Then $\mu_\alpha \xrightarrow{w-k} \mu \;\Rightarrow\; \mu_\alpha \xrightarrow{\sigma} \mu$. Consequently: $\mu_\alpha \xrightarrow{\|.\|_k} \mu \;\Rightarrow\; \mu_\alpha \xrightarrow{\sigma} \mu$.*

Proof We will show that $\mu_\alpha(f) \to \mu(f)$ for any $f \in \mathcal{C}_c$. As $\mathcal{C}_c$ is a dense subset of $\mathcal{C}_0$ and μ_α is bounded, combining Prop. 32.5 and Thm. 33.2 of Treves (1967) then shows that $\mu_\alpha(f) \to \mu(f)$ for any $f \in \mathcal{C}_0$ (weak-$*$ convergence), which implies weak-convergence, $\mu_\alpha \xrightarrow{\sigma} \mu$ (Berg et al., 1984, Chap. 2, Cor. 4.3), and thus concludes.

Let K be a compact subset of $\mathcal{X}$. First, we show that there exists a function $h \in \mathcal{H}_k$ such that $h(x) > 0$ for any $x \in K$. To do so, let $f \in \mathcal{C}_b$ such that $f \geq 1$ on K. k being $\int$s.p.d. and $\mathcal{M}_f$ being the dual of $(\mathcal{C}_b)_c$, $\mathcal{H}_k$ is dense in $(\mathcal{C}_b)_c$ (Thm. 6). So we can find a sequence of functions $f_n \in \mathcal{H}_k$ that converges to f for the topology of $(\mathcal{C}_b)_c$. By definition of the topology of $(\mathcal{C}_b)_c$, this implies in particular that the restrictions of f_n to K converge in infinity norm, meaning: $\sup_{x\in K} |f_n(x) - f(x)| \to 0$. Thus, for a sufficiently large n, $f_n > 0$ on K, so we can take $h = f_n$.

Now, let us define the measures $h.\mu_\alpha$ as $[h.\mu_\alpha](f) = \mu_\alpha(hf)$ for any $f \in \mathcal{C}_b$. Then $\|h.\mu_\alpha\|_{TV} \leq \|h\|_\infty \|\mu_\alpha\|_{TV}$, so the new net $(h.\mu_\alpha)_\alpha$ is bounded. But bounded sets are

relatively compact for the weak-$*$ topology $w(\mathcal{M}_f, \mathcal{C}_0)$. (Treves 1967, Thm. 33.2, or Banach-Alaoglu theorem). So we can extract a subnet $h.\mu_\beta$ of $h.\mu_\alpha$ that converges in weak-$*$ topology. Then $h.\mu_\beta$ is also a Cauchy-net for the weak-$*$ topology, meaning that for any $\epsilon > 0$ and any sufficiently large β, β':

$$|\mu_\beta(hf) - \mu_{\beta'}(hf)| \leq \epsilon, \quad \forall f \in \mathcal{C}_0\ .$$

This inequality holds in particular for functions f whose support is contained in K, which we denote $f \in \mathcal{C}_c(K)$. But the mapping $f \longmapsto g := hf$ is a bijective map from $\mathcal{C}_c(K)$ to itself (because $h > 0$ on K), so we actually have $|\mu_\beta(g) - \mu_{\beta'}(g)| \leq \epsilon$ for any $g \in \mathcal{C}_c(K)$. But this holds for any compact subset K of $\mathcal{X}$. So the inequality also holds for any function $g \in \mathcal{C}_c(\mathcal{X})$, which shows that μ_β is a Cauchy-net for the topology of pointwise convergence in $\mathcal{C}_c(\mathcal{X})$, also known as the *vague* topology. But $\mathcal{M}_+$ is vaguely complete (Bourbaki, 2007, Chap.III, §1, n.9, Prop.14), so μ_β converges to a measure $\mu' \in \mathcal{M}_+$. But for any $f \in \mathcal{C}_c(\mathcal{X})$, $\mu'(f) = \lim_\beta \mu_\beta(f) = \lim_\alpha \mu_\alpha(f) = \mu(f)$, thus μ' and μ coincide on $\mathcal{C}_c(\mathcal{X})$, which is a dense subset of $\mathcal{C}_0$. Thus $\mu' = \mu$, and $\mu_\alpha(f) \to \mu(f)$ for any $f \in \mathcal{C}_c$. ■

Note that if we additionally supposed that $\mathcal{H}_k \hookrightarrow \mathcal{C}_0$ (meaning that k is c_0-universal), then Lemma 20 is a simple consequence of Lemma 11 and the fact that weak-$*$ and weak convergence coincide on $\mathscr{P}$.

A.5. Proof of Theorem 17 Continued

Proof We are left with proving (a) and (b). To do so, we will use the decomposition $D = \sum_{|p|\leq m} \partial^p \mu_p$ of Lemma 15. Indeed, k being in $\mathcal{C}_b^{(m,m)}$, by Corollary 4, $\partial^p \mu_p$ embeds into $\mathcal{H}_k$ for any $|p| \leq m$ and $\mu_p \in \mathcal{M}_f$. Thus

$$\begin{aligned}\langle \partial^p\mu_p\,,\, \partial^q\mu_q\rangle_k &= \langle \Phi_{\partial^{(0,p)}k}(\mu_p)\,,\, \Phi_{\partial^{(0,q)}k}(\mu_q)\rangle_k \\ &= \iint \left\langle \partial^{(0,p)}k(.,y)\,,\, \partial^{(0,q)}k(.,x)\right\rangle_k \mathrm{d}\bar{\mu}_q(x)\,\mathrm{d}\mu_p(y) \\ &= \iint \partial^{(q,p)}k(x,y)\,\mathrm{d}\bar{\mu}_q(x)\,\mathrm{d}\mu_p(y) \\ &= \iiint i^{|p+q|}\xi^{p+q}e^{i(x-y)\cdot\xi}\,\mathrm{d}\Lambda(\xi)\,\mathrm{d}\bar{\mu}_q(x)\,\mathrm{d}\mu_p(x)\ ,\end{aligned}$$

where for $\xi = (\xi_1, \dots \xi_d) \in \mathbb{R}^d$, we defined $\xi^p := \xi_1^{p_1}\xi_2^{p_2}\cdots\xi_d^{p_d}$. The first line uses Proposition 14, the second line uses twice the definition of a weak integral (1), the third uses (9) from Lemma 19 and the fourth line uses the fact that $\partial^{(q,p)}k(x,y) = (-1)^{|p|}\partial^{p+q}\psi(x-y)$ and $\mathcal{F}\partial^{p+q}\,\psi = i^{|p+q|}\xi^{p+q}\,\mathcal{F}\psi = i^{|p+q|}\xi^{p+q}\Lambda$.

Let us denote $\xi^p\Lambda$ the measure defined by $\xi^p\Lambda(A) := \int_A \xi^p\,\mathrm{d}\Lambda(\xi)$. We will now show that $\xi^{p+q}\Lambda$ is finite, so that we can apply the usual Bochner theorem and permute the order of integrations. To do so, notice that $\partial^{(p,p)}k(x,y) = (-1)^{|p|}\partial^{2p}\psi(x-y)$ is a continuous kernel, thus, by Bochner's theorem, its associated measure Λ_∂ is finite and verifies $\mathcal{F}\Lambda_\partial = \partial^{2p}\psi$. But the usual calculus rules with Fourier transforms show that $\partial^{2p}\psi = (-i)^{|2p|}\xi^{2p}\Lambda$. Thus $\Lambda_\partial = i^{|p|}\xi^{2p}\Lambda$, showing that $\tilde{\Lambda}$ is a finite measure. Noting now that $2|\xi^{p+q}| \leq \xi^{2p} + \xi^{2q}$, this also implies that $\xi^{p+q}\Lambda$ is a finite measure. Consequently:

$$\langle \partial^p\mu_p\,,\, \partial^q\mu_q\rangle_k = \iiint i^{|p+q|}e^{i(x-y)}\,\mathrm{d}[\xi^{p+q}\Lambda](\xi)\,\mathrm{d}\bar{\mu}_q(x)\,\mathrm{d}\mu_p(x)$$

$$= \iiint i^{|p+q|} e^{i(x-y)} \,\mathrm{d}\bar{\mu}_q(x)\,\mathrm{d}\mu_p(x)\,\mathrm{d}\tilde{\Lambda}(\xi)$$
$$= \int i^{|p+q|} \xi^{p+q}\, \mathscr{F}\mu_q(\xi)\overline{\mathscr{F}\mu_p(\xi)}\,\mathrm{d}\Lambda(\xi)$$
$$= \int [\mathscr{F}(\,\partial^p \mu_p)](\xi)\overline{[\mathscr{F}(\,\partial^q \mu_q)](\xi)}\,\mathrm{d}\Lambda(\xi).$$

Thus, with the decomposition $D = \sum_{|p|\leq m} \partial^p \mu_p$, we get

$$\|D\|_k^2 = \left\| \sum_{|p|\leq m} \partial^p \mu_p \right\|_k^2 = \int \sum_{|p|,|q|\leq m} [\mathscr{F}(\,\partial^p \mu_p)](\xi)\overline{[\mathscr{F}(\,\partial^q \mu_q)](\xi)}\,\mathrm{d}\Lambda(\xi)$$
$$= \int \Big| \sum_{|p|\leq m} [\mathscr{F}(\,\partial^p \mu_p)](\xi) \Big|^2 \mathrm{d}\Lambda(\xi)$$
$$= \int |\,\mathscr{F}D(\xi)|^2\,\mathrm{d}\Lambda(\xi)\ ,$$

where we used the linearity of the Fourier operator on the last line. ■

Appendix B. Short Introduction to Schwartz-Distributions

To introduce Schwartz-distributions, the first step is to notice that any continuous function f is uniquely characterized by the values taken by $f(\varphi) := \int \varphi(x) f(x)\,\mathrm{d}x$ when φ goes through $\mathscr{C}_c$. Rather than seeing f as a function that acts on points x in $\mathcal{X}$, we could thus equivalently see f as a linear functional that acts on other functions φ in $\mathscr{C}_c$ and takes its values in $\mathbb{C}$. Such functionals are called *linear forms*. We could do the same for measures: a signed measure μ is also characterized by the values of $\mu(\varphi) := \int \varphi(x)\,\mathrm{d}\mu(x)$. So we could also see it as a linear functional that acts on functions φ in $\mathscr{C}_c$. Doing so effectively identifies f with the signed measure μ_f that has density f, because both define the same linear form $\varphi \longmapsto \int \varphi(x) f(x)\,\mathrm{d}x$. So from this perspective, a function f becomes a particular kind of measure, and a measure μ a sort of 'generalized function'. Moreover, seen as linear forms over $\mathscr{C}_c$, f and μ are continuous in the sense that if φ_α converges to φ, then $\mu(\varphi_\alpha)$ converges to $\mu(\varphi)$. Thus, by definition, we just identified f and μ with elements of the dual of $\mathscr{C}_c$.

We may now ask whether there are other continuous linear forms over $\mathscr{C}_c$. The answer is negative and is given by the Riesz-Markov-Kakutani representer theorem (see Appendix C). It states that the dual of $\mathscr{C}_c$ is exactly the set of signed regular Borel measures $\mathcal{M}_r$, meaning that any continuous linear form over $\mathscr{C}_c$ can be written as $\varphi \longmapsto \int \varphi\,\mathrm{d}\mu(x)$ for some $\mu \in \mathcal{M}_r$, and can thus be identified with a measure μ. So it seems that our generalization of functions to measures using continuous linear forms is as general as it can get. But this is forgetting the following detail. To distinguish a measure μ from all the others in $\mathcal{M}_r$, we do not need to know the values $\mu(\varphi)$ for *all* functions φ of $\mathscr{C}_c$. Actually, it suffices to know them for all φ in $\mathscr{C}_c^\infty$. This is because $\mathscr{C}_c^\infty$ is a dense subset of $\mathscr{C}_c$. Thus for any $\varphi \in \mathscr{C}_c$, even if $\varphi \notin \mathscr{C}_c^\infty$, we can reconstruct the value $\mu(\varphi)$ by taking a sequence φ_α in $\mathscr{C}_c^\infty$ that converges to φ and noticing that, by continuity, $\mu(\varphi)$ is the limit of $\mu(\varphi_\alpha)$. So instead of

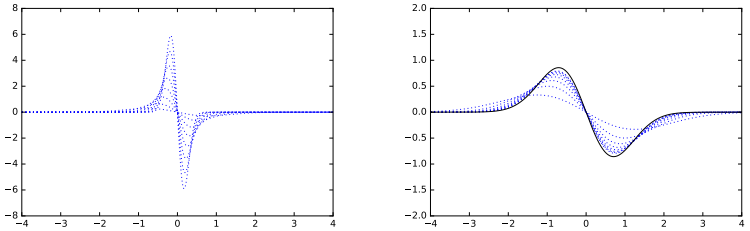

Figure 2: Left: the difference f_σ of two Gaussians that get closer and closer and more and more peaked with decreasing σ. Right: the KMEs of f_σ. Note the difference in the y-axis scale. f_σ converges to a *dipole*, which is not a measure, but a Schwartz-distribution. It cannot be represented as a function, but its KME can (black solid line). Note that the KMEs of f_σ seem to converge to the KME of the dipole.

seeing a function or a measure as an element of $(\mathscr{C}_c)'$, we could also see it as an element of $(\mathscr{C}_c^\infty)'$.

But do we gain anything from it? Yes indeed, because now, we can define linear functionals over $\mathscr{C}_c^\infty$ that we could not define over $\mathscr{C}_c$. For example, suppose that $\mathcal{X} = \mathbb{R}$ and consider the linear form d_x that, to each function φ associates its derivative $\partial\varphi(x)$ evaluated at x. This is a valid (continuous) linear form over $\mathscr{C}_c^\infty$—called a dipole in x—but it cannot be defined over $\mathscr{C}_c$, because not all continuous functions are differentiable. This example shows that, although each measure in $(\mathscr{C}_c)'$ can be seen as an element of $(\mathscr{C}_c^\infty)'$, the latter space contains many more linear forms which do not correspond to a signed measure. This bigger set of linear forms, which we denote $\mathcal{D}^\infty$, is called the set of Schwartz-distributions.

Now, why are distributions useful? First of all, because they can all be seen as limits of functions (Schwartz, 1978)[Theo. XV, Chap. III]. As an example, consider the sequence of functions

$$f_\sigma : \quad x \longmapsto \tfrac{1}{\sigma} g(\tfrac{x+\sigma}{\sigma}) - \tfrac{1}{\sigma} g(\tfrac{x-\sigma}{\sigma})\ ,$$

where g is a Gaussian (see Figure 2). f_σ is the difference of two Gaussians that get closer and closer and more and more peaked with decreasing σ. Now, applying f_σ to a function $\varphi \in \mathscr{C}_c^\infty$, it is not difficult to see that $f_\sigma(\varphi)$ converges to $\partial\varphi(0) = d_0(\varphi)$ when $\sigma \to 0$. The dipole d_0 can thus be seen as a weak limit of the functions f_σ, although it is itself neither a function nor even a signed measure.

Another reason to use distributions is that many common linear operations can be extended to them (or to big subsets of them), such as differentiation, Fourier transformation and convolution. Let us show for example how to extend differentiation. If we want the distributional derivative ∂ to be an extension of the usual derivative, then of course we should require that $\partial\mu_f = \mu_{f'}$ whenever f is a continuously differentiable function over

$\mathcal{X} = \mathbb{R}$ whose usual derivative is f'. Now, by integration by part, we get, for any $\varphi \in \mathscr{C}_c^\infty$:

$$\mu_{f'}(\varphi) = \int f'\varphi = -\int f\varphi' = -\mu_f(\varphi') \ .$$

This suggests to define the derivative of any $D \in \mathscr{D}^\infty$ as $\partial^p D(\varphi) := (-1)^{|p|} D(\partial^p \varphi)$ for any $\varphi \in \mathscr{C}_c^\infty$. Doing so, we just defined a notion of differentiation that is compatible with the usual differentiation and makes *any* distribution infinitely many times differentiable. In particular, any function and any measure is infinitely differentiable in this distributional sense. Moreover, if a sequence of differentiable functions f_n converges to a distribution D (in the sense that $f_n(\varphi)$ converges to $D(\varphi)$ for any φ), then their usual derivatives f_n' converges to ∂D (in the same *distributional* sense). All this makes distributions extremely useful for solving linear differential equations and more generally for physicists. Last but not least, note that, by construction, if Q is a probability measure with smooth density q, then $\partial^p Q$ is the signed measure with density $\partial^p q$.

Appendix C. Other Background Material

Formally, a topological vector space (TVS) $\mathcal{E}$ is a vector space equipped with a topology that is *compatible* with its linear structure, in the sense that the addition $\mathcal{E} \times \mathcal{E} \longrightarrow \mathcal{E}$ and scalar multiplication $\mathbb{C} \times \mathcal{E} \longrightarrow \mathcal{E}$ become continuous for this topology (when their domains are equipped with the product topology). This makes the topology translation-invariant and hence completely defined by the neighborhoods of the origin. A TVS is locally convex (loc. cv.) if there exists a basis of (origin-) neighborhoods consisting of convex sets only. Obviously, the origin-centered balls of any semi-norm are convex. But interestingly, one can show that a TVS is loc. cv. iff its topology can be defined by a family of (continuous) semi-norms. So we can think of loc. cv. TVSs as "multi-normed" spaces, i.e. where convergence is given by a family of possibly multiple semi-norms $(\|.\|_\alpha)_{\alpha \in \mathcal{I}}$ (where the index set $\mathcal{I}$ can be uncountable). If this family contains only a single norm, $\mathcal{E}$ is a normed space. The origin-centered balls of these semi-norms are actually not only convex, they are *barrels*.

Definition 21 (Barrel) *A subset T of a TVS $\mathcal{E}$ is called a* barrel *if it is*

(i) absorbing*: for any $f \in \mathcal{E}$, there exists $c_f > 0$ such that $f \in c_f T$;*
(ii) balanced*: for any $f \in \mathcal{E}$, if $f \in T$ then $\lambda f \in T$ for any $\lambda \in \mathbb{C}$ with $|\lambda| \leq 1$;*
(iii) convex *;*
(iv) closed.

Given that the topology of loc. cv. TVS can be defined by a family of semi-norms, it is not surprising that in loc. cv. spaces there always exists a basis of origin-neighborhoods consisting only of barrels. However, there might be barrels that are not a neighborhood of 0. This leads to

Definition 22 (Barreled spaces) *A TVS is* barreled *if any barrel is a neighborhood of the origin.*

Although many authors include local convexity in the definition, in general, a barreled space need not be loc. cv. Barreled spaces were introduced by Bourbaki, because they were well-suited for the following generalization of the celebrated *Banach-Steinhaus* theorem.

Theorem 23 (Banach-Steinhaus) *Let $\mathcal{E}$ be a barreled TVS, $\mathcal{F}$ be a loc. cv. TVS, and let $L(\mathcal{E},\mathcal{F})$ be the set of continuous linear maps form $\mathcal{E}$ to $\mathcal{F}$. For any $H \subset L(\mathcal{E},\mathcal{F})$ the following properties are equivalent:*

(i) H is equicontinuous.
(ii) H is bounded for the topology of pointwise convergence.
(iii) H is bounded for the topology of bounded convergence.

When $\mathcal{E}$ is a normed space and $\mathcal{F} = \mathbb{C}$, then $L(\mathcal{E},\mathcal{F})$ is by definition $\mathcal{E}'$. With $\|.\|_{\mathcal{E}'}$ being the dual norm in $\mathcal{E}'$, the equivalence of (ii) and (iii) states that

$$\left(\forall f \in \mathcal{E},\ \sup_{h \in H} |h(f)| < \infty\right) \iff \sup_{h \in H} \|h\|_{\mathcal{E}'} < \infty \, .$$

Obviously, to understand the content of the Banach-Steinhaus theorem, one needs the definition of a bounded set. Let us define them now.

When $\mathcal{E}$ is a normed space, then a subset B of $\mathcal{E}$ is called *bounded* if $\sup_{f \in B} \|f\|_{\mathcal{E}} < \infty$. In a more general loc. cv. TVS $\mathcal{E}$, where the topology is given by a family of semi-norms $(\|.\|_\alpha)_{\alpha \in \mathcal{I}}$, a subset B of $\mathcal{E}$ is called *bounded* if, for any $\alpha \in \mathcal{I}$, $\sup_{f \in B} \|f\|_\alpha < \infty$. This can be shown equivalent to the following, more usual definition.

Definition 24 (Bounded Sets in a TVS) *A subset B of a TVS $\mathcal{E}$ is* bounded*, if, for any neighborhood $U \subset \mathcal{E}$ of the origin, there exists a real $c_B > 0$ such that $B \subset c_B U$.*

Note that the notion of boundedness depends on the underlying topology. By default, a bounded set of some dual space $\mathcal{E} = \mathcal{F}'$ designates a set that is bounded for the strong dual topology. We now move on to an unrelated topic: the Riesz Representation theorem for Hilbert spaces. Most of this paper relies on this one theorem.

Theorem 25 (Riesz Representation Theorem for Hilbert Spaces) *A Hilbert space $\mathcal{H}$ and its topological dual $\mathcal{H}'$ are isometrically (anti-) isomorphic via the Riesz representer map*

$$\imath : \begin{array}{ccc} \mathcal{H} & \longrightarrow & \mathcal{H}' \\ f & \longmapsto & D_f := \left\{ \begin{array}{ccc} \mathcal{H} & \longrightarrow & \mathbb{C} \\ g & \longmapsto & \langle g \, , \, f \rangle \end{array} \right. \end{array} \ .$$

In particular, for any continuous linear form $D \in \mathcal{H}'$, there exists a unique element $f \in \mathcal{H}$, called the Riesz representer of D*, such that*

$$\forall g \in \mathcal{H}, \qquad D(g) = \langle g \, , \, f \rangle \ .$$

Note that "anti" in "anti-isomorphic" simply means that, instead of being linear, $\imath$ is anti-linear: for any $\lambda \in \mathbb{C}$ and $f \in \mathcal{H}$, $\imath(\lambda f) = \bar{\lambda}\, \imath(f)$. Often, we prefer to say that $\mathcal{H}$ is isometrically isomorphic to $\overline{\mathcal{H}}'$, where $\overline{\mathcal{H}}'$ denotes the conjugate of $\mathcal{H}$, where the scalar

multiplication is replaced by $(\lambda, f) \longmapsto \bar{\lambda} f$. $\mathcal{H}_k'$ and $\overline{\mathcal{H}_k}'$ are obviously isomorphic via the complex conjugation map $D \longmapsto \bar{D}$.

The Riesz representation theorem for Hilbert spaces is not to be confounded with the following theorem, also known as the Riesz—or Riesz-Markov-Kakutani—representation theorem. In this paper, we always refer to the latter as the Riesz-Markov-Kakutani representation theorem. This theorem has numerous variants, depending on which dual pair $(\mathcal{E}, \mathcal{E}')$ one uses. Here we state it for $\mathcal{E} = \mathscr{C}_0$.

Theorem 26 (Riesz-Markov-Kakutani) *Let $\mathcal{X}$ be a locally compact Hausdorff space. The spaces $\mathcal{M}_f(\mathcal{X})$ and $(\mathscr{C}_0(\mathcal{X}))'$ are isomorphic, both algebraically and topologically via the map*

$$\imath : \begin{array}{ccc} \mathcal{M}_f(\mathcal{X}) & \longrightarrow & (\mathscr{C}_0(\mathcal{X}))' \\ \mu & \longmapsto & D_\mu := \left\{ \begin{array}{ccc} \mathscr{C}_0 & \longrightarrow & \mathbb{C} \\ \varphi & \longmapsto & \int \varphi \, \mathrm{d}\mu \end{array} \right. \end{array} .$$

In other words, for any continuous linear form D over $\mathscr{C}_0(\mathcal{X})$, there exists a unique finite Borel measure $\mu \in \mathcal{M}_f$ such that, for any test function $\varphi \in \mathscr{C}_0(\mathcal{X})$, $D(\varphi) = \int \varphi \, \mathrm{d}\mu$. Moreover, $\sup_{\|\varphi\|_\infty \leq 1} D(\varphi) = |\mu|(\mathcal{X})$, or in short: $\|D\|_{(\mathscr{C}_0)'} = \|\mu\|_{TV}$, where $\|\mu\|_{TV}$ denotes the total variation norm of μ. This is why, in this paper, we identify $\mathcal{M}_f$—a space of σ-additive set functions—with $\mathcal{M}_f$—a space of linear functionals.

In this paper, to embed a space of measures into an RKHS $\mathcal{H}_k$ we successively apply both Riesz representation theorems: If $\mathcal{H}_k$ embeds continuously into $\mathscr{C}_0$, then $(\mathscr{C}_0)'$ embeds continuously into $\overline{\mathcal{H}_k}'$, via the embedding map Φ_k. But $(\mathscr{C}_0)' = \mathcal{M}_f$ (Riesz-Markov-Kakutani Representation) and $\overline{\mathcal{H}_k}' = \mathcal{H}_k$ (Riesz Representation). Thus Φ_k may also be seen as an embedding of $\mathcal{M}_f$ into $\mathcal{H}_k$.

For a further introduction to TVSs and the theorems mentioned here, we suggest Treves (1967).

Random Forests, Decision Trees, and Categorical Predictors: The "Absent Levels" Problem

Timothy C. Au TIMAU@GOOGLE.COM

Mountain View, CA 94043, USA

Editor: Sebastian Nowozin

Abstract

One advantage of decision tree based methods like random forests is their ability to natively handle categorical predictors without having to first transform them (e.g., by using feature engineering techniques). However, in this paper, we show how this capability can lead to an inherent "absent levels" problem for decision tree based methods that has never been thoroughly discussed, and whose consequences have never been carefully explored. This problem occurs whenever there is an indeterminacy over how to handle an observation that has reached a categorical split which was determined when the observation in question's level was absent during training. Although these incidents may appear to be innocuous, by using Leo Breiman and Adele Cutler's random forests `FORTRAN` code and the `randomForest R` package (Liaw and Wiener, 2002) as motivating case studies, we examine how overlooking the absent levels problem can systematically bias a model. Furthermore, by using three real data examples, we illustrate how absent levels can dramatically alter a model's performance in practice, and we empirically demonstrate how some simple heuristics can be used to help mitigate the effects of the absent levels problem until a more robust theoretical solution is found.

Keywords: absent levels, categorical predictors, decision trees, CART, random forests

1. Introduction

Since its introduction in Breiman (2001), random forests have enjoyed much success as one of the most widely used decision tree based methods in machine learning. But despite their popularity and apparent simplicity, random forests have proven to be very difficult to analyze. Indeed, many of the basic mathematical properties of the algorithm are still not completely well understood, and theoretical investigations have often had to rely on either making simplifying assumptions or considering variations of the standard framework in order to make the analysis more tractable—see, for example, Biau et al. (2008), Biau (2012), and Denil et al. (2014).

One advantage of decision tree based methods like random forests is their ability to natively handle categorical predictors without having to first transform them (e.g., by using feature engineering techniques). However, in this paper, we show how this capability can lead to an inherent "absent levels" problem for decision tree based methods that has, to the best of our knowledge, never been thoroughly discussed, and whose consequences have never been carefully explored. This problem occurs whenever there is an indeterminacy over how to handle an observation that has reached a categorical split which was determined when the observation in question's level was absent during training—an issue that can arise in three different ways:

1. The levels are present in the population but, due to sampling variability, are absent in the training set.
2. The levels are present in the training set but, due to bagging, are absent in an individual tree's bootstrapped sample of the training set.
3. The levels are present in an individual tree's training set but, due to a series of earlier node splits, are absent in certain branches of the tree.

These occurrences subsequently result in situations where observations with absent levels are unsure of how to proceed further down the tree—an intrinsic problem for decision tree based methods that has seemingly been overlooked in both the theoretical literature and in much of the software that implements these methods.

Although these incidents may appear to be innocuous, by using Leo Breiman and Adele Cutler's random forests `FORTRAN` code and the `randomForest R` package (Liaw and Wiener, 2002) as motivating case studies,[1] we examine how overlooking the absent levels problem can systematically bias a model. In addition, by using three real data examples, we illustrate how absent levels can dramatically alter a model's performance in practice, and we empirically demonstrate how some simple heuristics can be used to help mitigate their effects.

The rest of this paper is organized as follows. In Section 2, we introduce some notation and provide an overview of the random forests algorithm. Then, in Section 3, we use Breiman and Cutler's random forests `FORTRAN` code and the `randomForest R` package to motivate our investigations into the potential issues that can emerge when the absent levels problem is overlooked. And although a comprehensive theoretical analysis of the absent levels problem is beyond the scope of this paper, in Section 4, we consider some simple heuristics which may be able to help mitigate its effects. Afterwards, in Section 5, we present three real data examples that demonstrate how the treatment of absent levels can significantly influence a model's performance in practice. Finally, we offer some concluding remarks in Section 6.

2. Background

In this section, we introduce some notation and provide an overview of the random forests algorithm. Consequently, the more knowledgeable reader may only need to review Sections 2.1.1 and 2.1.2 which cover how the algorithm's node splits are determined.

2.1 Classification and Regression Trees (CART)

We begin by discussing the Classification and Regression Trees (CART) methodology since the random forests algorithm uses a slightly modified version of CART to construct the

[1] Breiman and Cutler's random forests FORTRAN code is available online at:
`https://www.stat.berkeley.edu/~breiman/RandomForests/`

individual decision trees that are used in its ensemble. For a more complete overview of CART, we refer the reader to Breiman et al. (1984) or Hastie et al. (2009).

Suppose that we have a training set with N independent observations

$$(x_n, y_n), \quad n = 1, 2, \ldots, N,$$

where $x_n = (x_{n1}, x_{n2}, \ldots, x_{nP})$ and y_n denote, respectively, the P-dimensional feature vector and response for observation n. Given this initial training set, CART is a greedy recursive binary partitioning algorithm that repeatedly partitions a larger subset of the training set $\mathcal{N}_\mathcal{M} \subseteq \{1, 2, \ldots, N\}$ (the "mother node") into two smaller subsets $\mathcal{N}_\mathcal{L}$ and $\mathcal{N}_\mathcal{R}$ (the "left" and "right" daughter nodes, respectively). Each iteration of this splitting process, which can be referred to as "growing the tree," is accomplished by determining a decision rule that is characterized by a "splitting variable" $p \in \{1, 2, \ldots, P\}$ and an accompanying "splitting criterion" set $\mathcal{S}_p$ which defines the subset of predictor p's domain that gets sent to the left daughter node $\mathcal{N}_\mathcal{L}$. In particular, any splitting variable and splitting criterion pair $(p, \mathcal{S}_p)$ will partition the mother node $\mathcal{N}_\mathcal{M}$ into the left and right daughter nodes which are defined, respectively, as

$$\mathcal{N}_\mathcal{L}(p, \mathcal{S}_p) = \{n \in \mathcal{N}_\mathcal{M} : x_{np} \in \mathcal{S}_p\} \quad \text{and} \quad \mathcal{N}_\mathcal{R}(p, \mathcal{S}_p) = \left\{n \in \mathcal{N}_\mathcal{M} : x_{np} \in \mathcal{S}'_p\right\}, \tag{1}$$

where $\mathcal{S}'_p$ denotes the complement of the splitting criterion set $\mathcal{S}_p$ with respect to predictor p's domain. A simple model useful for making predictions and inferences is then subsequently fit to the subset of the training data that is in each node.

This recursive binary partitioning procedure is continued until some stopping rule is reached—a tuning parameter that can be controlled, for example, by placing a constraint on the minimum number of training observations that are required in each node. Afterwards, to help guard against overfitting, the tree can then be "pruned"—although we will not discuss this further as pruning has not traditionally been done in the trees that are grown in random forests (Breiman, 2001). Predictions and inferences can then be made on an observation by first sending it down the tree according to the tree's set of decision rules, and then by considering the model that was fit in the furthest node of the tree that the observation is able to reach.

The CART algorithm will grow a tree by selecting, from amongst all possible splitting variable and splitting criterion pairs $(p, \mathcal{S}_p)$, the optimal pair $\left(p^*, \mathcal{S}^*_{p^*}\right)$ which minimizes some measure of "node impurity" in the resulting left and right daughter nodes as defined in (1). However, the specific node impurity measure that is being minimized will depend on whether the tree is being used for regression or classification.

In a regression tree, the responses in a node $\mathcal{N}$ are modeled using a constant which, under a squared error loss, is estimated by the mean of the training responses that are in the node—a quantity which we denote as:

$$\hat{c}(\mathcal{N}) = \text{ave}(y_n \mid n \in \mathcal{N}). \tag{2}$$

Therefore, the CART algorithm will grow a regression tree by partitioning a mother node $\mathcal{N}_\mathcal{M}$ on the splitting variable and splitting criterion pair $\left(p^*, \mathcal{S}^*_{p^*}\right)$ which minimizes the squared error resulting from the two daughter nodes that are created with respect to a

$(p, \mathcal{S}_p)$ pair:

$$\left(p^*, \mathcal{S}^*_{p^*}\right) = \underset{(p, \mathcal{S}_p)}{\arg\min} \left(\sum_{n \in \mathcal{N}_\mathcal{L}(p, \mathcal{S}_p)} [y_n - \hat{c}(\mathcal{N}_\mathcal{L}(p, \mathcal{S}_p))]^2 + \sum_{n \in \mathcal{N}_\mathcal{R}(p, \mathcal{S}_p)} [y_n - \hat{c}(\mathcal{N}_\mathcal{R}(p, \mathcal{S}_p))]^2 \right), \tag{3}$$

where the nodes $\mathcal{N}_\mathcal{L}(p, \mathcal{S}_p)$ and $\mathcal{N}_\mathcal{R}(p, \mathcal{S}_p)$ are as defined in (1).

Meanwhile, in a classification tree where the response is categorical with K possible response classes which are indexed by the set $\mathcal{K} = \{1, 2, \ldots, K\}$, we denote the proportion of training observations that are in a node $\mathcal{N}$ belonging to each response class k as:

$$\hat{\pi}_k(\mathcal{N}) = \frac{1}{|\mathcal{N}|} \sum_{n \in \mathcal{N}} I(y_n = k), \quad k \in \mathcal{K},$$

where $|\cdot|$ is the set cardinality function and $I(\cdot)$ is the indicator function. Node $\mathcal{N}$ will then classify its observations to the majority response class

$$\hat{k}(\mathcal{N}) = \underset{k \in \mathcal{K}}{\arg\max}\ \hat{\pi}_k(\mathcal{N}), \tag{4}$$

with the Gini index

$$G(\mathcal{N}) = \sum_{k=1}^{K} [\hat{\pi}_k(\mathcal{N}) \cdot (1 - \hat{\pi}_k(\mathcal{N}))]$$

providing one popular way of quantifying the node impurity in $\mathcal{N}$. Consequently, the CART algorithm will grow a classification tree by partitioning a mother node $\mathcal{N}_\mathcal{M}$ on the splitting variable and splitting criterion pair $\left(p^*, \mathcal{S}^*_{p^*}\right)$ which minimizes the weighted Gini index resulting from the two daughter nodes that are created with respect to a $(p, \mathcal{S}_p)$ pair:

$$\left(p^*, \mathcal{S}^*_{p^*}\right) = \underset{(p, \mathcal{S}_p)}{\arg\min} \left(\frac{|\mathcal{N}_\mathcal{L}(p, \mathcal{S}_p)| \cdot G(\mathcal{N}_\mathcal{L}(p, \mathcal{S}_p)) + |\mathcal{N}_\mathcal{R}(p, \mathcal{S}_p)| \cdot G(\mathcal{N}_\mathcal{R}(p, \mathcal{S}_p))}{|\mathcal{N}_\mathcal{L}(p, \mathcal{S}_p)| + |\mathcal{N}_\mathcal{R}(p, \mathcal{S}_p)|} \right), \tag{5}$$

where the nodes $\mathcal{N}_\mathcal{L}(p, \mathcal{S}_p)$ and $\mathcal{N}_\mathcal{R}(p, \mathcal{S}_p)$ are as defined in (1).

Therefore, the CART algorithm will grow both regression and classification trees by partitioning a mother node $\mathcal{N}_\mathcal{M}$ on the splitting variable and splitting criterion pair $(p^*, \mathcal{S}^*_{p^*})$ which minimizes the requisite node impurity measure across all possible $(p, \mathcal{S}_p)$ pairs—a task which can be accomplished by first determining the optimal splitting criterion $\mathcal{S}^*_p$ for every predictor $p \in \{1, 2, \ldots, P\}$. However, the specific manner in which any particular predictor p's optimal splitting criterion $\mathcal{S}^*_p$ is determined will depend on whether p is an ordered or categorical predictor.

2.1.1 Splitting on an Ordered Predictor

The splitting criterion $\mathcal{S}_p$ for an ordered predictor p is characterized by a numeric "split point" $s_p \in \mathbb{R}$ that defines the half-line $\mathcal{S}_p = \{x \in \mathbb{R} : x \leq s_p\}$. Thus, as can be observed from (1), a $(p, \mathcal{S}_p)$ pair will partition a mother node $\mathcal{N}_\mathcal{M}$ into the left and right daughter nodes that are defined, respectively, by

$$\mathcal{N}_\mathcal{L}(p, \mathcal{S}_p) = \{n \in \mathcal{N}_\mathcal{M} : x_{np} \leq s_p\} \quad \text{and} \quad \mathcal{N}_\mathcal{R}(p, \mathcal{S}_p) = \{n \in \mathcal{N}_\mathcal{M} : x_{np} > s_p\}.$$

Therefore, determining the optimal splitting criterion $\mathcal{S}_p^* = \{x \in \mathbb{R} : x \leq s_p^*\}$ for an ordered predictor p is straightforward—it can be greedily found by searching through all of the observed training values in the mother node in order to find the optimal numeric split point $s_p^* \in \{x_{np} \in \mathbb{R} : n \in \mathcal{N}_\mathcal{M}\}$ that minimizes the requisite node impurity measure which is given by either (3) or (5).

2.1.2 Splitting on a Categorical Predictor

For a categorical predictor p with Q possible unordered levels which are indexed by the set $\mathcal{Q} = \{1, 2, \ldots, Q\}$, the splitting criterion $\mathcal{S}_p \subset \mathcal{Q}$ is defined by the subset of levels that gets sent to the left daughter node $\mathcal{N}_\mathcal{L}$, while the complement set $\mathcal{S}_p' = \mathcal{Q} \setminus \mathcal{S}_p$ defines the subset of levels that gets sent to the right daughter node $\mathcal{N}_\mathcal{R}$. For notational simplicity and ease of exposition, in the remainder of this section we assume that all Q unordered levels of p are present in the mother node $\mathcal{N}_\mathcal{M}$ during training since it is only these present levels which contribute to the measure of node impurity when determining p's optimal splitting criterion $\mathcal{S}_p^*$. Later, in Section 3, we extend our notation to also account for any unordered levels of a categorical predictor p which are absent from the mother node $\mathcal{N}_\mathcal{M}$ during training.

Consequently, there are are $2^{Q-1}-1$ non-redundant ways of partitioning the Q unordered levels of p into the two daughter nodes, making it computationally expensive to evaluate the resulting measure of node impurity for every possible split when Q is large. However, this computation simplifies in certain situations.

In the case of a regression tree with a squared error node impurity measure, a categorical predictor p's optimal splitting criterion $\mathcal{S}_p^*$ can be determined by using a procedure described in Fisher (1958). Specifically, the training observations in the mother node are first used to calculate the mean response within each of p's unordered levels:

$$\gamma_p(q) = \text{ave}(y_n \mid n \in \mathcal{N}_\mathcal{M} \text{ and } x_{np} = q)\,, \quad q \in \mathcal{Q}. \tag{6}$$

These means are then used to assign numeric "pseudo values" $\tilde{x}_{np} \in \mathbb{R}$ to every training observation that is in the mother node according to its observed level for predictor p:

$$\tilde{x}_{np} = \gamma_p(x_{np}), \quad n \in \mathcal{N}_\mathcal{M}. \tag{7}$$

Finally, the optimal splitting criterion $\mathcal{S}_p^*$ for the categorical predictor p is determined by doing an ordered split on these numeric pseudo values $\tilde{x}_{np}$—that is, a corresponding optimal "pseudo splitting criterion" $\tilde{\mathcal{S}}_p^* = \{\tilde{x} \in \mathbb{R} : \tilde{x} \leq \tilde{s}_p^*\}$ is greedily chosen by scanning through all of the assigned numeric pseudo values in the mother node in order to find the optimal numeric "pseudo split point" $\tilde{s}_p^* \in \{\tilde{x}_{np} \in \mathbb{R} : n \in \mathcal{N}_\mathcal{M}\}$ which minimizes the resulting squared error node impurity measure given in (3) with respect to the left and right daughter nodes that are defined, respectively, by

$$\mathcal{N}_\mathcal{L}(p, \tilde{\mathcal{S}}_p^*) = \{n \in \mathcal{N}_\mathcal{M} : \tilde{x}_{np} \leq \tilde{s}_p^*\} \quad \text{and} \quad \mathcal{N}_\mathcal{R}(p, \tilde{\mathcal{S}}_p^*) = \{n \in \mathcal{N}_\mathcal{M} : \tilde{x}_{np} > \tilde{s}_p^*\}\,. \tag{8}$$

Meanwhile, in the case of a classification tree with a weighted Gini index node impurity measure, whether the computation simplifies or not is dependent on the number of response classes. For the $K > 2$ multiclass classification context, no such simplification is possible, although several approximations have been proposed (Loh and Vanichsetakul, 1988). However, for the $K = 2$ binary classification situation, a similar procedure to the one that was

just described for regression trees can be used. Specifically, the proportion of the training observations in the mother node that belong to the $k = 1$ response class is first calculated within each of categorical predictor p's unordered levels:

$$\gamma_p(q) = \frac{|\{n \in \mathcal{N}_\mathcal{M} : x_{np} = q \text{ and } y_n = 1\}|}{|\{n \in \mathcal{N}_\mathcal{M} : x_{np} = q\}|}, \quad q \in \mathcal{Q}, \tag{9}$$

and where we note here that $\gamma_p(q) \geq 0$ for all q since these proportions are, by definition, nonnegative. Afterwards, and just as in equation (7), these $k = 1$ response class proportions are used to assign numeric pseudo values $\tilde{x}_{np} \in \mathbb{R}$ to every training observation that is in the mother node $\mathcal{N}_\mathcal{M}$ according to its observed level for predictor p. And once again, the optimal splitting criterion $\mathcal{S}_p^*$ for the categorical predictor p is then determined by performing an ordered split on these numeric pseudo values $\tilde{x}_{np}$—that is, a corresponding optimal pseudo splitting criterion $\tilde{\mathcal{S}}_p^* = \{x \in \mathbb{R} : x \leq \tilde{s}_p^*\}$ is greedily found by searching through all of the assigned numeric pseudo values in the mother node in order to find the optimal numeric pseudo split point $\tilde{s}_p^* \in \{\tilde{x}_{np} \in \mathbb{R} : n \in \mathcal{N}_\mathcal{M}\}$ which minimizes the weighted Gini index node impurity measure given by (5) with respect to the resulting two daughter nodes as defined in (8). The proof that this procedure gives the optimal split in a binary classification tree in terms of the weighted Gini index amongst all possible splits can be found in Breiman et al. (1984) and Ripley (1996).

Therefore, in both regression and binary classification trees, we note that the optimal splitting criterion $\mathcal{S}_p^*$ for a categorical predictor p can be expressed in terms of the criterion's associated optimal numeric pseudo split point $\tilde{s}_p^*$ and the requisite means or $k = 1$ response class proportions $\gamma_p(q)$ of the unordered levels $q \in \mathcal{Q}$ of p as follows:

- The unordered levels of p that are being sent *left* have means or $k = 1$ response class proportions $\gamma_p(q)$ that are *less than or equal to* $\tilde{s}_p^*$:

$$\mathcal{S}_p^* = \{q \in \mathcal{Q} : \gamma_p(q) \leq \tilde{s}_p^*\}\,. \tag{10}$$

- The unordered levels of p that are being sent *right* have means or $k = 1$ response class proportions $\gamma_p(q)$ that are *greater than* $\tilde{s}_p^*$:

$$\mathcal{S}_p^{*\prime} = \{q \in \mathcal{Q} : \gamma_p(q) > \tilde{s}_p^*\}\,. \tag{11}$$

As we later discuss in Section 3, equations (10) and (11) lead to inherent differences in the left and right daughter nodes when splitting a mother node on a categorical predictor in CART—differences that can have significant ramifications when making predictions and inferences for observations with absent levels.

2.2 Random Forests

Introduced in Breiman (2001), random forests are an ensemble learning method that corrects for each individual tree's propensity to overfit the training set. This is accomplished through the use of bagging and a CART-like tree learning algorithm in order to build a large collection of "de-correlated" decision trees.

2.2.1 Bagging

Proposed in Breiman (1996a), bagging is an ensembling technique for improving the accuracy and stability of models. Specifically, given a training set

$$Z = \{(x_1, y_1), (x_2, y_2), \ldots, (x_N, y_N)\},$$

this is achieved by repeatedly sampling N' observations with replacement from Z in order to generate B bootstrapped training sets $Z_1, Z_2, \ldots, Z_B$, where usually $N' = N$. A separate model is then trained on each bootstrapped training set Z_b, where we denote model b's prediction on an observation x as $\hat{f}_b(x)$. Here, showing each model a different bootstrapped sample helps to de-correlate them, and the overall bagged estimate $\hat{f}(x)$ for an observation x can then be obtained by averaging over all of the individual predictions in the case of regression

$$\hat{f}(x) = \frac{1}{B}\sum_{b=1}^{B} \hat{f}_b(x),$$

or by taking the majority vote in the case of classification

$$\hat{f}(x) = \underset{k \in \mathcal{K}}{\arg\max} \left(\sum_{b=1}^{B} I\left(\hat{f}_b(x) = k\right) \right).$$

One important aspect of bagging is the fact that each training observation n will only appear "in-bag" in a subset of the bootstrapped training sets Z_b. Therefore, for each training observation n, an "out-of-bag" (OOB) prediction can be constructed by only considering the subset of models in which n did not appear in the bootstrapped training set. Moreover, an OOB error for a bagged model can be obtained by evaluating the OOB predictions for all N training observations—a performance metric which helps to alleviate the need for cross-validation or a separate test set (Breiman, 1996b).

2.2.2 CART-Like Tree Learning Algorithm

In the case of random forests, the model that is being trained on each individual bootstrapped training set Z_b is a decision tree which is grown using the CART methodology, but with two key modifications.

First, as mentioned previously in Section 2, the trees that are grown in random forests are generally not pruned (Breiman, 2001). And second, instead of considering all P predictors at a split, only a randomly selected subset of the P predictors is allowed to be used—a restriction which helps to de-correlate the trees by placing a constraint on how similarly they can be grown. This process, which is known as the random subspace method, was developed in Amit and Geman (1997) and Ho (1998).

3. The Absent Levels Problem

In Section 1, we defined the absent levels problem as the inherent issue for decision tree based methods occurring whenever there is an indeterminacy over how to handle an observation that has reached a categorical split which was determined when the observation in question's

level was absent during training, and we described the three different ways in which the absent levels problem can arise. Then, in Section 2.1.2, we discussed how the levels of a categorical predictor p which were present in the mother node $\mathcal{N}_\mathcal{M}$ during training were used to determine its optimal splitting criterion $\mathcal{S}_p^*$. In this section, we investigate the potential consequences of overlooking the absent levels problem where, for a categorical predictor p with Q unordered levels which are indexed by the set $\mathcal{Q} = \{1, 2, \ldots, Q\}$, we now also further denote the subset of the levels of p that were present or absent in the mother node $\mathcal{N}_\mathcal{M}$ during training, respectively, as follows:

$$\begin{aligned} \mathcal{Q}_\mathcal{P} &= \{q \in \mathcal{Q} : |\{n \in \mathcal{N}_\mathcal{M} : x_{np} = q\}| > 0\}, \\ \mathcal{Q}_\mathcal{A} &= \{q \in \mathcal{Q} : |\{n \in \mathcal{N}_\mathcal{M} : x_{np} = q\}| = 0\}. \end{aligned} \tag{12}$$

Specifically, by documenting how absent levels have been handled by Breiman and Cutler's random forests `FORTRAN` code and the `randomForest R` package, we show how failing to account for the absent levels problem can systematically bias a model in practice. However, although our investigations are motivated by these two particular software implementations of random forests, we emphasize that the absent levels problem is, first and foremost, an intrinsic methodological issue for decision tree based methods.

3.1 Regression

For regression trees using a squared error node impurity measure, recall from our discussions in Section 2.1.2 and equations (6), (10), and (11), that the split of a mother node $\mathcal{N}_\mathcal{M}$ on a categorical predictor p can be characterized in terms of the splitting criterion's associated optimal numeric pseudo split point $\tilde{s}_p^*$ and the means $\gamma_p(q)$ of the unordered levels $q \in \mathcal{Q}$ of p as follows:

- The unordered levels of p being sent *left* have means $\gamma_p(q)$ that are *less than or equal to* $\tilde{s}_p^*$.
- The unordered levels of p being sent *right* have means $\gamma_p(q)$ that are *greater than* $\tilde{s}_p^*$.

Furthermore, recall from (2), that a node's prediction is given by the mean of the training responses that are in the node. Therefore, because the prediction of each daughter node can be expressed as a weighted average over the means $\gamma_p(q)$ of the present levels $q \in \mathcal{Q}_\mathcal{P}$ that are being sent to it, it follows that *the left daughter node $\mathcal{N}_\mathcal{L}$ will always give a prediction that is smaller than the right daughter node $\mathcal{N}_\mathcal{R}$ when splitting on a categorical predictor p in a regression tree that uses a squared error node impurity measure.*

In terms of execution, both the random forests `FORTRAN` code and the `randomForest` R package employ the pseudo value procedure for regression that was described in Section 2.1.2 when determining the optimal splitting criterion $\mathcal{S}_p^*$ for a categorical predictor p. However, the code that is responsible for calculating the mean $\gamma_p(q)$ within each unordered level $q \in \mathcal{Q}$ as in equation (6) behaves as follows:

$$\gamma_p(q) = \begin{cases} \text{ave}(y_n \mid n \in \mathcal{N}_\mathcal{M} \text{ and } x_{np} = q) & \text{if } q \in \mathcal{Q}_\mathcal{P} \\ 0 & \text{if } q \in \mathcal{Q}_\mathcal{A} \end{cases},$$

where $\mathcal{Q}_\mathcal{P}$ and $\mathcal{Q}_\mathcal{A}$ are, respectively, the present and absent levels of p as defined in (12).

Although this "zero imputation" of the means $\gamma_p(q)$ for the absent levels $q \in \mathcal{Q}_{\mathcal{A}}$ is inconsequential when determining the optimal numeric pseudo split point $\tilde{s}_p^*$ during training, it can be highly influential on the subsequent predictions that are made for observations with absent levels. In particular, by (10) and (11), the absent levels $q \in \mathcal{Q}_{\mathcal{A}}$ will be sent left if $\tilde{s}_p^* \geq 0$, and they will be sent right if $\tilde{s}_p^* < 0$. But, due to the systematic differences that exist amongst the two daughter nodes, this arbitrary decision of sending the absent levels left versus right can significantly impact the predictions that are made on observations with absent levels—even though the model's final predictions will also depend on any ensuing splits which take place after the absent levels problem occurs, observations with absent levels will tend to be biased towards smaller predictions when they are sent to the left daughter node, and they will tend to be biased towards larger predictions when they are sent to the right daughter node.

In addition, this behavior also implies that the random forest regression models which are trained using either the random forests `FORTRAN` code or the `randomForest R` package are sensitive to the set of possible values that the training responses can take. To illustrate, consider the following two extreme cases when splitting a mother node $\mathcal{N}_{\mathcal{M}}$ on a categorical predictor p:

- If the training responses $y_n > 0$ for all n, then the pseudo numeric split point $\tilde{s}_p^* > 0$ since the means $\gamma_p(q) > 0$ for all of the present levels $q \in \mathcal{Q}_{\mathcal{P}}$. And because the "imputed" means $\gamma_p(q) = 0 < \tilde{s}_p^*$ for all $q \in \mathcal{Q}_{\mathcal{A}}$, the absent levels will always be sent to the left daughter node $\mathcal{N}_{\mathcal{L}}$ which gives smaller predictions.
- If the training responses $y_n < 0$ for all n, then the pseudo numeric split point $\tilde{s}_p^* < 0$ since the means $\gamma_p(q) < 0$ for all of the present levels $q \in \mathcal{Q}_{\mathcal{P}}$. And because the "imputed" means $\gamma_p(q) = 0 > \tilde{s}_p^*$ for all $q \in \mathcal{Q}_{\mathcal{A}}$, the absent levels will always be sent to the right daughter node $\mathcal{N}_{\mathcal{R}}$ which gives larger predictions.

And although this sensitivity to the training response values was most easily demonstrated through these two extreme situations, the reader should not let this overshadow the fact that the absent levels problem can also heavily influence a model's performance in more general circumstances (e.g., when the training responses are of mixed signs).

3.2 Classification

For binary classification trees using a weighted Gini index node impurity measure, recall from our discussions in Section 2.1.2 and equations (9), (10), and (11), that the split of a mother node $\mathcal{N}_{\mathcal{M}}$ on a categorical predictor p can be characterized in terms of the splitting criterion's associated optimal numeric pseudo split point $\tilde{s}_p^*$ and the $k = 1$ response class proportions $\gamma_p(q)$ of the unordered levels $q \in \mathcal{Q}$ of p as follows:

- The unordered levels of p being sent *left* have $k = 1$ response class proportions $\gamma_p(q)$ that are *less than or equal to* $\tilde{s}_p^*$.
- The unordered levels of p being sent *right* have $k = 1$ response class proportions $\gamma_p(q)$ that are *greater than* $\tilde{s}_p^*$.

In addition, recall from (4), that a node's classification is given by the response class that occurs the most amongst the training observations that are in the node. Therefore, because

the response class proportions of each daughter node can be expressed as a weighted average over the response class proportions of the present levels $q \in \mathcal{Q}_{\mathcal{P}}$ that are being sent to it, it follows that *the left daughter node $\mathcal{N}_{\mathcal{L}}$ is always less likely to classify an observation to the $k = 1$ response class than the right daughter node $\mathcal{N}_{\mathcal{R}}$ when splitting on a categorical predictor p in a binary classification tree that uses a weighted Gini index node impurity measure.*

In terms of implementation, the `randomForest R` package uses the pseudo value procedure for binary classification that was described in Section 2.1.2 when determining the optimal splitting criterion $\mathcal{S}_p^*$ for a categorical predictor p with a "large" number of unordered levels.[2] However, the code that is responsible for computing the $k = 1$ response class proportion $\gamma_p(q)$ within each unordered level $q \in \mathcal{Q}$ as in equation (9) executes as follows:

$$\gamma_p(q) = \begin{cases} \frac{|\{n \in \mathcal{N}_{\mathcal{M}} : x_{np} = q \text{ and } y_n = 1\}|}{|\{n \in \mathcal{N}_{\mathcal{M}} : x_{np} = q\}|} & \text{if } q \in \mathcal{Q}_{\mathcal{P}} \\ 0 & \text{if } q \in \mathcal{Q}_{\mathcal{A}} \end{cases}.$$

Therefore, the issues that arise here are similar to the ones that were described for regression.

Even though this "zero imputation" of the $k = 1$ response class proportions $\gamma_p(q)$ for the absent levels $q \in \mathcal{Q}_{\mathcal{A}}$ is unimportant when determining the optimal numeric pseudo split point $\tilde{s}_p^*$ during training, it can have a large effect on the subsequent classifications that are made for observations with absent levels. In particular, since the proportions $\gamma_p(q) \geq 0$ for all of the present levels $q \in \mathcal{Q}_{\mathcal{P}}$, it follows from our discussions in Section 2.1.2 that the numeric pseudo split point $\tilde{s}_p^* \geq 0$. And because the "imputed" proportions $\gamma_p(q) = 0 \leq \tilde{s}_p^*$ for all $q \in \mathcal{Q}_{\mathcal{A}}$, the absent levels will always be sent to the left daughter node. But, due to the innate differences that exist amongst the two daughter nodes, this arbitrary choice of sending the absent levels left can significantly affect the classifications that are made on observations with absent levels—although the model's final classifications will also depend on any successive splits which take place after the absent levels problem occurs, the classifications for observations with absent levels will tend to be biased towards the $k = 2$ response class. Moreover, this behavior also implies that the random forest binary classification models which are trained using the `randomForest R` package may be sensitive to the actual ordering of the response classes: since observations with absent levels are always sent to the left daughter node $\mathcal{N}_{\mathcal{L}}$ which is more likely to classify them to the $k = 2$ response class than the right daughter node $\mathcal{N}_{\mathcal{R}}$, the classifications for these observations can be influenced by interchanging the indices of the two response classes.

Meanwhile, for cases where the pseudo value procedure is not or cannot be used, the random forests `FORTRAN` code and the `randomForest R` package will instead adopt a more brute force approach that either exhaustively or randomly searches through the space of possible splits. However, to understand the potential problems that absent levels can cause in these situations, we must first briefly digress into a discussion of how categorical splits are internally represented in their code.

Specifically, in their code, a split on a categorical predictor p is both encoded and decoded as an integer whose binary representation identifies which unordered levels go left

[2] The exact condition for using the pseudo value procedure for binary classification in version 4.6-12 of the `randomForest R` package is when a categorical predictor p has $Q > 10$ unordered levels. Meanwhile, although the random forests `FORTRAN` code for binary classification references the pseudo value procedure, it does not appear to be implemented in the code.

(the bits that are "turned on") and which unordered levels go right (the bits that are "turned off"). To illustrate, consider the situation where a categorical predictor p has four unordered levels, and where the integer encoding of the split is 5. In this case, since 0101 is the binary representation of the integer 5 (because $5 = [0] \cdot 2^3 + [1] \cdot 2^2 + [0] \cdot 2^1 + [1] \cdot 2^0$), levels 1 and 3 get sent left while levels 2 and 4 get sent right.

Now, when executing an exhaustive search to find the optimal splitting criterion $\mathcal{S}_p^*$ for a categorical predictor p with Q unordered levels, the random forests `FORTRAN` code and the `randomForest R` package will both follow the same systematic procedure:[3] *all $2^{Q-1} - 1$ possible integer encodings for the non-redundant partitions of the unordered levels of predictor p are evaluated in increasing sequential order starting from 1 and ending at $2^{Q-1} - 1$, with the choice of the optimal splitting criterion $\mathcal{S}_p^*$ being updated if and only if the resulting weighted Gini index node impurity measure strictly improves.*

But since the absent levels $q \in \mathcal{Q}_\mathcal{A}$ are not present in the mother node $\mathcal{N}_\mathcal{M}$ during training, *sending them left or right has no effect on the resulting weighted Gini index.* And because turning on the bit for any particular level q while holding the bits for all of the other levels constant will always result in a larger integer, it follows that *the exhaustive search that is used by these two software implementations will always prefer splits that send all of the absent levels right since they are always checked before any of their analogous Gini index equivalent splits that send some of the absent levels left.*

Furthermore, in their exhaustive search, the leftmost bit corresponding to the Q^{th} indexed unordered level of a categorical predictor p is always turned off since checking the splits where this bit is turned on would be redundant—they would amount to just swapping the "left" and "right" daughter node labels for splits that have already been evaluated. Consequently, the Q^{th} indexed level of p will also always be sent to the right daughter node and, as a result, the classifications for observations with absent levels will tend to be biased towards the response class distribution of the training observations in the mother node $\mathcal{N}_\mathcal{M}$ that belong to this Q^{th} indexed level. Therefore, although it may sound contradictory, this also implies that the random forest multiclass classification models which are trained using either the random forests `FORTRAN` code or the `randomForest R` package may be sensitive to the actual ordering of a categorical predictor's unordered levels—a reordering of these levels could potentially interchange the "left" and "right" daughter node labels, which could then subsequently affect the classifications that are made for observations with absent levels since they will always be sent to whichever node ends up being designated as the "right" daughter node.

Finally, when a categorical predictor p has too many levels for an exhaustive search to be computationally efficient, both the random forests `FORTRAN` code and the `randomForest R` package will resort to approximating the optimal splitting criterion $\mathcal{S}_p^*$ with the best split that was found amongst a large number of randomly generated splits.[4] This is accomplished by randomly setting all of the bits in the binary representations of the splits to either a

[3] The random forests `FORTRAN` code will use an exhaustive search for both binary and multiclass classification whenever $Q < 25$. In version 4.6-12 of the `randomForest R` package, an exhaustive search will be used for both binary and multiclass classification whenever $Q < 10$.

[4] The random forests `FORTRAN` code will use a random search for both binary and multiclass classification whenever $Q \geq 25$. In version 4.6-12 of the `randomForest R` package, a random search will only be used when $Q \geq 10$ in the multiclass classification case.

0 or a 1—a procedure which ultimately results in each absent level being randomly sent to either the left or right daughter node with equal probability. As a result, although the absent levels problem can still occur in these situations, it is difficult to determine whether it results in any systematic bias. However, it is still an open question as to whether or not such a treatment of absent levels is sufficient.

4. Heuristics for Mitigating the Absent Levels Problem

Although a comprehensive theoretical analysis of the absent levels problem is beyond the scope of this paper, in this section we briefly consider several heuristics which may be able to help mitigate the issue. Later, in Section 5, we empirically evaluate and compare how some of these heuristics perform in practice when they are applied to three real data examples.

4.1 Missing Data Heuristics

Even though absent levels are fully observed and known, the missing data literature for decision tree based methods is still perhaps the area of existing research that is most closely related to the absent levels problem.

4.1.1 Stop

One straightforward missing data strategy for dealing with absent levels would be to simply stop an observation from going further down the tree whenever the issue occurs and just use the mother node for prediction—a missing data approach which has been adopted by both the `rpart R` package for CART (Therneau et al., 2015) and the `gbm R` package for generalized boosted regression models (Ridgeway, 2013). Even with this missing data functionality already in place, however, the `gbm R` package has still had its own issues in readily extending it to the case of absent levels—serving as another example of a software implementation of a decision tree based method that has overlooked and suffered from the absent levels problem.[5]

4.1.2 Distribution-Based Imputation (DBI)

Another potential missing data technique would be to send an observation with an absent level down both daughter nodes—perhaps by using the distribution-based imputation (DBI) technique which is employed by the C4.5 algorithm for growing decision trees (Quinlan, 1993). In particular, an observation that encounters an infeasible node split is first split into multiple pseudo-instances, where each instance takes on a different imputed value and weight based on the distribution of observed values for the splitting variable in the mother node's subset of the training data. These pseudo-instances are then sent down their appropriate daughter nodes in order to proceed down the tree as usual, and the final prediction is derived from the weighted predictions of all the terminal nodes that are subsequently reached (Saar-Tsechansky and Provost, 2007).

[5] See, for example, `https://code.google.com/archive/p/gradientboostedmodels/issues/7`

4.1.3 Surrogate Splits

Surrogate splitting, which the `rpart` `R` package also supports, is arguably the most popular method of handling missing data in CART, and it may provide another workable approach for mitigating the effects of absent levels. Specifically, if $(p^*, \mathcal{S}^*_{p^*})$ is found to be the optimal splitting variable and splitting criterion pair for a mother node $\mathcal{N}_\mathcal{M}$, then the first surrogate split is the $(p', \mathcal{S}_{p'})$ pair where $p' \neq p^*$ that yields the split which most closely mimics the optimal split's binary partitioning of $\mathcal{N}_\mathcal{M}$, the second surrogate split is the $(p'', \mathcal{S}_{p''})$ pair where $p'' \notin \{p^*, p'\}$ resulting in the second most similar binary partitioning of $\mathcal{N}_\mathcal{M}$ as the optimal split, and so on. Afterwards, when an observation reaches an indeterminate split, the surrogates are tried in the order of decreasing similarity until one of them becomes feasible (Breiman et al., 1984).

However, despite its extensive use in CART, surrogate splitting may not be entirely appropriate for ensemble tree methods like random forests. As pointed out in Ishwaran et al. (2008):

> Although surrogate splitting works well for trees, the method may not be well suited for forests. Speed is one issue. Finding a surrogate split is computationally intensive and may become infeasible when growing a large number of trees, especially for fully saturated trees used by forests. Further, surrogate splits may not even be meaningful in a forest paradigm. [Random forests] randomly selects variables when splitting a node and, as such, variables within a node may be uncorrelated, and a reasonable surrogate split may not exist. Another concern is that surrogate splitting alters the interpretation of a variable, which affects measures such as [variable importance].

Nevertheless, surrogate splitting is still available as a non-default option for handling missing data in the `partykit` `R` package (Hothorn and Zeileis, 2015), which is an implementation of a bagging ensemble of conditional inference trees that correct for the biased variable selection issues which exist in several tree learning algorithms like CART and C4.5 (Hothorn et al., 2006).

4.1.4 Random/Majority

The `partykit` `R` package also provides some other functionality for dealing with missing data that may be applicable to the absent levels problem. These include the package's default approach of randomly sending the observations to one of the two daughter nodes with the weighting done by the number of training observations in each node or, alternatively, by simply having the observations go to the daughter node with more training observations. Interestingly, the `partykit` `R` package does appear to recognize the possibility of absent levels occurring, and chooses to handle them as if they were missing—its reference manual states that "Factors in test samples whose levels were empty in the learning sample are treated as missing when computing predictions." Whether or not such missing data heuristics adequately address the absent levels problem, however, is still unknown.

4.2 Feature Engineering Heuristics

Apart from missing data methods, feature engineering techniques which transform the categorical predictors may also be viable approaches to mitigating the effects of absent levels.

However, feature engineering techniques are not without their own drawbacks. First, transforming the categorical predictors may not always be feasible in practice since the feature space may become computationally unmanageable. And even when transformations are possible, they may further exacerbate variable selection issues—many popular tree learning algorithms such as CART and C4.5 are known to be biased in favor of splitting on ordered predictors and categorical predictors with many unordered levels since they offer more candidate splitting points to choose from (Hothorn et al., 2006). Moreover, by recoding a categorical predictor's unordered levels into several different predictors, we forfeit a decision tree based method's natural ability to simultaneously consider all of the predictor's levels together at a single split. Thus, it is not clear whether feature engineering techniques are preferable when using decision tree based methods.

Despite these potential shortcomings, transformations of the categorical predictors is currently required by the `scikit-learn` `Python` module's implementation of random forests (Pedregosa et al., 2011). There have, however, been some discussions about extending the module so that it can support the native categorical split capabilities used by the random forests `FORTRAN` code and the `randomForest` `R` package.[6] But, needless to say, such efforts would also have the unfortunate consequence of introducing the indeterminacy of the absent levels problem into another popular software implementation of a decision tree based method.

4.2.1 One-Hot Encoding

Nevertheless, one-hot encoding is perhaps the most straightforward feature engineering technique that could be applied to the absent levels problem—even though some unordered levels may still be absent when determining a categorical split during training, any uncertainty over where to subsequently send these absent levels would be eliminated by recoding the levels of each categorical predictor into separate dummy predictors.

5. Examples

Although the actual severity of the absent levels problem will depend on the specific data set and task at hand, in this section we present three real data examples which illustrate how the absent levels problem can dramatically alter the performance of decision tree based methods in practice. In particular, we empirically evaluate and compare how the seven different heuristics in the set

$$\mathcal{H} = \{\textit{Left}, \textit{Right}, \textit{Stop}, \textit{Majority}, \textit{Random}, \textit{DBI}, \textit{One-Hot}\}$$

perform when confronted with the absent levels problem in random forests.

In particular, the first two heuristics that we consider in our set $\mathcal{H}$ are the systematically biased approaches discussed in Section 3 which have been employed by both the random

[6] See, for example, `https://github.com/scikit-learn/scikit-learn/pull/3346`

forests `FORTRAN` code and the `randomForest R` package due to having overlooked the absent levels problem:

- Left: Sending the observation to the left daughter node.
- Right: Sending the observation to the right daughter node.

Consequently, these two "naive heuristics" have been included in our analysis for comparative purposes only.

In our set of heuristics $\mathcal{H}$, we also consider some of the missing data strategies for decision tree based methods that we discussed in Section 4:

- Stop: Stopping the observation from going further down the tree and using the mother node for prediction.
- Majority: Sending the observation to the daughter node with more training observations, with any ties being broken randomly.
- Random: Randomly sending the observation to one of the two daughter nodes, with the weighting done by the number of training observations in each node.[7]
- Distribution-Based Imputation (DBI): Sending the observation to both daughter nodes using the C4.5 tree learning algorithm's DBI approach.

Unlike the two naive heuristics, these "missing data heuristics" are all less systematic in their preferences amongst the two daughter nodes.

Finally, in our set $\mathcal{H}$, we also consider a "feature engineering heuristic" which transforms all of the categorical predictors in the original data set:

- One-Hot: Recoding every categorical predictor's set of possible unordered levels into separate dummy predictors

Under this heuristic, although unordered levels may still be absent when determining a categorical split during training, there is no longer any uncertainty over where to subsequently send observations with absent levels.

Code for implementing the naive and missing data heuristics was built on top of version 4.6-12 of the `randomForest R` package. Specifically, the `randomForest R` package is used to first train the random forest models as usual. Afterwards, each individual tree's in-bag training data is sent back down the tree according to the tree's set of decision rules in order to record the unordered levels that were absent at each categorical split. Finally, when making predictions or inferences, our code provides some functionality for carrying out each of the naive and missing data heuristics whenever the absent levels problem occurs.

Each of the random forest models that we consider in our analysis is trained "off-the-shelf" by using the `randomForest R` package's default settings for the algorithm's tuning

[7] We also investigated an alternative "unweighted" version of the Random heuristic which randomly sends observations with absent levels to either the left or right daughter node with equal probability (analogous to the random search procedure that was described at the end of Section 3.2). However, because this unweighted version was found to be generally inferior to the "weighted" version described in our analysis, we have omitted it from our discussions for expositional clarity and conciseness.

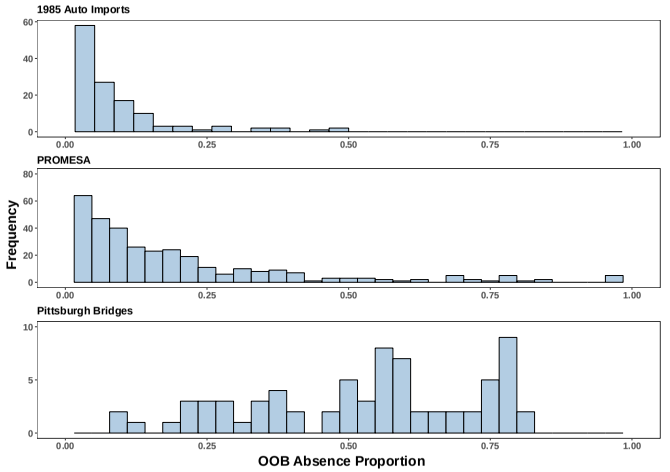

Figure 1: Histograms for each example's distribution of OOB absence proportions.

parameters. Moreover, to account for the inherent randomness in the random forests algorithm, we repeat each of our examples 1000 times with a different random seed used to initialize each experimental replication. However, because of the way in which we have structured our code, we note that our analysis is able to isolate the effects of the naive and missing data heuristics on the absent levels problem since, within each experimental replication, their underlying random forest models are identical with respect to each tree's in-bag training data and differ only in terms of their treatment of the absent levels. As a result, the predictions and inferences obtained from the naive and missing data heuristics will be positively correlated across the 1000 experimental replications that we consider for each example—a fact which we exploit in order to improve the precision of our comparisons.

Recall from Section 4, however, that the random forest models which are trained on feature engineered data sets are intrinsically different from the random forest models which are trained on their original untransformed data set counterparts. Therefore, although we use the same default `randomForest R` package settings and the same random seed to initialize each of the One-Hot heuristic's experimental replications, we note that its predictions and inferences will be essentially uncorrelated with the naive and missing data heuristics across each example's 1000 experimental replications.

5.1 1985 Auto Imports

For a regression example, we consider the 1985 Auto Imports data set from the UCI Machine Learning Repository (Lichman, 2013) which, after discarding observations with missing data, contains 25 predictors that can be used to predict the prices of 159 cars. Categorical predictors for which the absent levels problem can occur include a car's make (18 levels),

Statistic	1985 Auto Imports	PROMESA	Pittsburgh Bridges
Min	0.003	0.001	0.080
1st Quartile	0.021	0.020	0.368
Median	0.043	0.088	0.564
Mean	0.076	0.162	0.526
3rd Quartile	0.093	0.206	0.702
Max	0.498	0.992	0.820

Table 1: Summary statistics for each example's distribution of OOB absence proportions.

body style (5 levels), drive layout (3 levels), engine type (5 levels), and fuel system (6 levels). Furthermore, because all of the car prices are positive, we know from Section 3.1 that the random forests `FORTRAN` code and the `randomForest R` package will both always employ the Left heuristic when faced with absent levels for this particular data set.[8]

The top panel in Figure 1 depicts a histogram of this example's OOB absence proportions, which we define for each training observation as the proportion of its OOB trees across all 1000 experimental replications which had the absent levels problem occur at least once when using the training set with the original untransformed categorical predictors. Meanwhile, Table 1 provides a more detailed summary of this example's distribution of OOB absence proportions. Consequently, although there is a noticeable right skew in the distribution, we see that most of the observations in this example had the absent levels problem occur in less than 5% of their OOB trees.

Let $\hat{y}_{nr}^{(h)}$ denote the OOB prediction that a heuristic h makes for an observation n in an experimental replication r. Then, within each experimental replication r, we can compare the predictions that two different heuristics $h_1, h_2 \in \mathcal{H}$ make for an observation n by considering the difference $\hat{y}_{nr}^{(h_1)} - \hat{y}_{nr}^{(h_2)}$. We summarize these comparisons for all possible pairwise combinations of the seven heuristics in Figure 2, where each panel plots the mean and middle 95% of these differences across all 1000 experimental replications as a function of the OOB absence proportion. From the red intervals in Figure 2, we see that significant differences in the predictions of the heuristics do exist, with the magnitude of the point estimates and the width of the intervals tending to increase with the OOB absence proportion—behavior that agrees with our intuition that the distinctive effects of each heuristic should become more pronounced the more often the absent levels problem occurs.

In addition, we can evaluate the overall performance of each heuristic $h \in \mathcal{H}$ within an experimental replication r in terms of its root mean squared error (RMSE):

$$\text{RMSE}_r^{(h)} = \sqrt{\frac{1}{N}\sum_{n=1}^{N}\left(y_n - \hat{y}_{nr}^{(h)}\right)^2}.$$

[8] This is the case for versions 4.6-7 and earlier of the `randomForest R` package. Beginning in version 4.6-9, however, the `randomForest R` package began to internally mean center the training responses prior to fitting the model, with the mean being subsequently added back to the predictions of each node. Consequently, the Left heuristic isn't always used in these versions of the `randomForest R` package since the training responses that the model actually considers are of mixed sign. Nevertheless, such a strategy still fails to explicitly address the underlying absent levels problem.

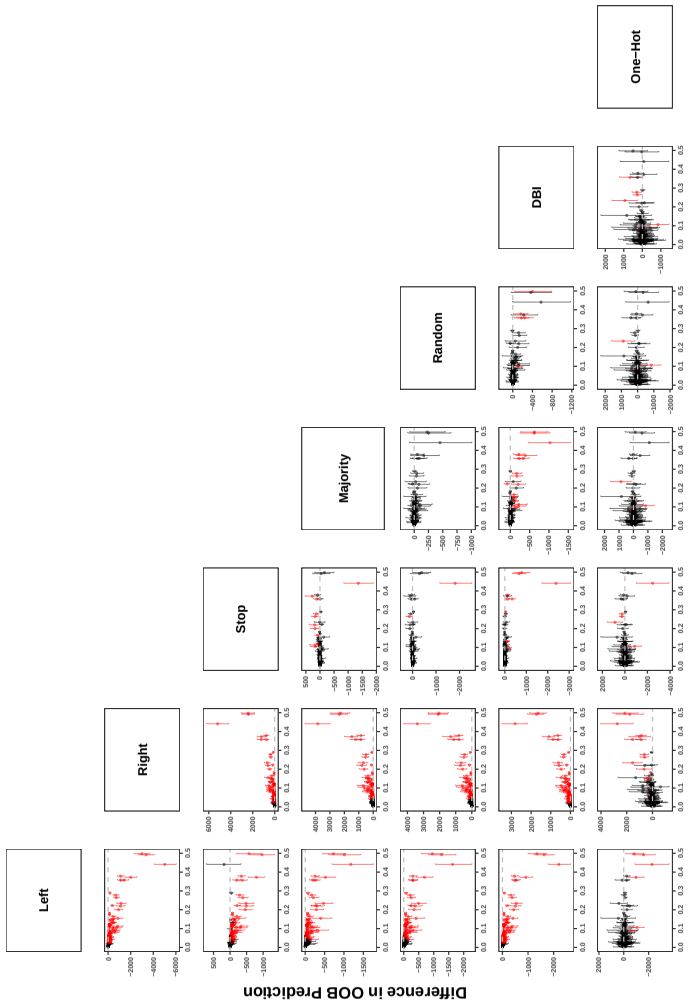

Figure 2: Pairwise differences in the OOB predictions as a function of the OOB absence proportions in the 1985 Auto Imports data set. Each panel plots the mean and middle 95% of the differences across all 1000 experimental replications when the OOB predictions of the heuristic that is labeled at the right of the panel's row is subtracted from the OOB predictions of the heuristic that is labeled at the top of the panel's column. Differences were taken within each experimental replication in order to account for the positive correlation that exists between the naive and missing data heuristics. Intervals containing zero (the horizontal dashed line) are in black, while intervals not containing zero are in red.

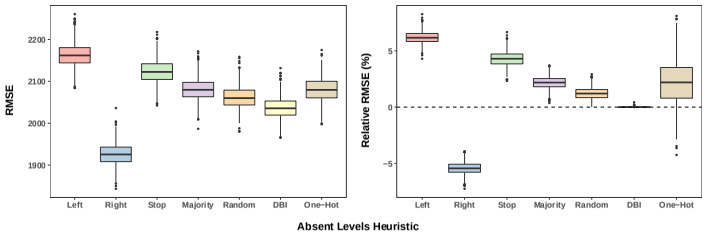

Figure 3: RMSEs for the OOB predictions of the seven heuristics in the 1985 Auto Imports data set. The left panel shows boxplots of each heuristic's marginal distribution of RMSEs across all 1000 experimental replications, which ignores the positive correlation that exists between the naive and missing data heuristics. The right panel accounts for this positive correlation by comparing the RMSEs of the heuristics relative to the best RMSE that was obtained amongst the missing data heuristics within each of the 1000 experimental replications as in (13).

Boxplots displaying each heuristic's marginal distribution of RMSEs across all 1000 experimental replications are shown in the left panel of Figure 3. However, these marginal boxplots ignore the positive correlation that exists between the naive and missing data heuristics. Therefore, within every experimental replication r, we also compare the RMSE for each heuristic $h \in \mathcal{H}$ relative to the best RMSE that was achieved amongst the missing data heuristics $\mathcal{H}_m = \{Stop, Majority, Random, DBI\}$:

$$\text{RMSE}_r^{(h\|\mathcal{H}_m)} = \frac{\text{RMSE}_r^{(h)} - \min_{h\in\mathcal{H}_m} \text{RMSE}_r^{(h)}}{\min_{h\in\mathcal{H}_m} \text{RMSE}_r^{(h)}}. \tag{13}$$

Here we note that the Left and Right heuristics were not considered in the definition of the best RMSE achieved within each experimental replication r due to the issues discussed in Section 3, while the One-Hot heuristic was excluded from this definition since it is essentially uncorrelated with the other six heuristics across all 1000 experimental replications. Boxplots of these relative RMSEs are shown in the right panel of Figure 3.

5.1.1 Naive Heuristics

Relative to all of the other heuristics and consistent with our discussions in Section 3.1, we see from Figure 2 that the Left and Right heuristics have a tendency to severely underpredict and overpredict, respectively. Furthermore, for this particular example, we notice from Figure 3 that the random forests `FORTRAN` code and the `randomForest R` package's behavior of always sending absent levels left in this particular data set substantially underperforms relative to the other heuristics—it gives an RMSE that is, on average, 6.2% worse than the best performing missing data heuristic. And although the Right heuristic appears to

perform exceptionally well, we again stress the misleading nature of this performance—its tendency to overpredict just coincidentally happens to be beneficial in this specific situation.

5.1.2 Missing Data Heuristics

As can be seen from Figure 2, the predictions obtained from the four missing data heuristics are more aligned with one another than they are with the Left, Right, and One-Hot heuristics. Considerable disparities in their predictions do still exist, however, and from Figure 3 we note that amongst the four missing data heuristics, the DBI heuristic clearly performs the best. And although the Majority heuristic fares slightly worse than the Random heuristic, they both perform appreciably better than the Stop heuristic.

5.1.3 Feature Engineering Heuristic

Recall that the One-Hot heuristic is essentially uncorrelated with the other six heuristics across all 1000 experimental replications—a fact which is reflected in its noticeably wider intervals in Figure 2 and in its larger relative RMSE boxplot in Figure 3. Nevertheless, it can still be observed from Figure 3 that although the One-Hot heuristic's predictions are sometimes able to outperform the other heuristics, on average, it yields an RMSE that is 2.2% worse than than the best performing missing data heuristic.

5.2 PROMESA

For a binary classification example, we consider the June 9, 2016 United States House of Representatives vote on the Puerto Rico Oversight, Management, and Economic Stability Act (PROMESA) for addressing the Puerto Rican government's debt crisis. Data for this vote was obtained by using the `Rvoteview R` package to query the Voteview database (Lewis, 2015). After omitting those who did not vote on the bill, the data set contains four predictors that can be used to predict the binary "No" or "Yes" votes of 424 House of Representative members. These predictors include a categorical predictor for a representative's political party (2 levels), a categorical predictor for a representative's state (50 levels), and two ordered predictors which quantify aspects of a representative's political ideological position (McCarty et al., 1997).

The "No" vote was taken to be the $k = 1$ response class in our analysis, while the "Yes" vote was taken to be the $k = 2$ response class. Recall from Section 3.2, that this ordering of the response classes is meaningful in a binary classification context since the `randomForest R` package will always use the Left heuristic which biases predictions for observations with absent levels towards whichever response class is indexed by $k = 2$ (corresponding to the "Yes" vote in our analysis).

From Figure 1 and Table 1, we see that the absent levels problem occurs much more frequently in this example than it did in our 1985 Auto Imports example. In particular, the seven House of Representative members who were the sole representatives from their state had OOB absence proportions that were greater than 0.961 since the absent levels problem occurred for these observations every time they reached an OOB tree node that was split on the state predictor.

For random forest classification models, the predicted probability that an observation belongs to a response class k can be estimated by the proportion of the observation's trees

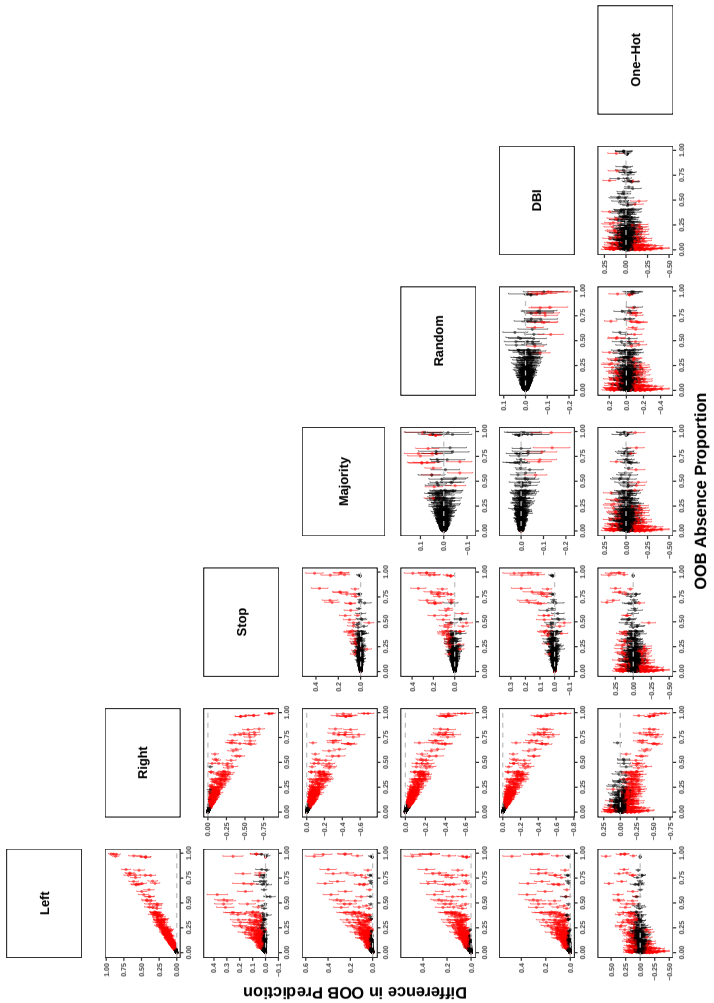

Figure 4: Pairwise differences in the OOB predicted probabilities of voting "Yes" as a function of the OOB absence proportion in the PROMESA data set. Each panel plots the mean and middle 95% of the pairwise differences across all 1000 experimental replications when the OOB predicted probabilities of the heuristic that is labeled at the right of the panel's row is subtracted from the OOB predicted probabilities of the heuristic that is labeled at the top of the panel's column. Differences were taken within each experimental replication to account for the positive correlation that exists between the naive and missing data heuristics. Intervals containing zero (the horizontal dashed line) are in black, while intervals not containing zero are in red.

which classify it to class k.[9] Let $\hat{p}_{nkr}^{(h)}$ denote the OOB predicted probability that a heuristic h assigns to an observation n of belonging to a response class k in an experimental replication r. Then, within each experimental replication r, we can compare the predicted probabilities that two different heuristics $h_1, h_2 \in \mathcal{H}$ assign to an observation n by considering the difference $\hat{p}_{nkr}^{(h_1)} - \hat{p}_{nkr}^{(h_2)}$. We summarize these differences in the predicted probabilities of voting "Yes" for all possible pairwise combinations of the seven heuristics in Figure 4, where each panel plots the mean and middle 95% of these differences across all 1000 experimental replications as a function of the OOB absence proportion.

The large discrepancies in the predicted probabilities that are observed in Figure 4 are particularly concerning since they can lead to different classifications. If we let $\hat{y}_{nr}^{(h)}$ denote the OOB classification that a heuristic h makes for an observation n in an experimental replication r, then Cohen's kappa coefficient (Cohen, 1960) provides one way of measuring the level of agreement between two different heuristics $h_1, h_2 \in \mathcal{H}$:

$$\kappa_r^{(h_1,h_2)} = \frac{o_r^{(h_1,h_2)} - e_r^{(h_1,h_2)}}{1 - e_r^{(h_1,h_2)}}, \tag{14}$$

where

$$o_r^{(h_1,h_2)} = \frac{1}{N}\sum_{n=1}^{N} I\left(\hat{y}_{nr}^{(h_1)} = \hat{y}_{nr}^{(h_2)}\right)$$

is the observed probability of agreement between the two heuristics, and where

$$e_r^{(h_1,h_2)} = \frac{1}{N^2}\sum_{k=1}^{K}\left[\left(\sum_{n=1}^{N} I\left(\hat{y}_{nr}^{(h_1)} = k\right)\right)\cdot\left(\sum_{n=1}^{N} I\left(\hat{y}_{nr}^{(h_2)} = k\right)\right)\right]$$

is the expected probability of the two heuristics agreeing by chance. Therefore, within an experimental replication r, we will observe $\kappa_r^{(h_1,h_2)} = 1$ if the two heuristics are in complete agreement, and we will observe $\kappa_r^{(h_1,h_2)} \approx 0$ if there is no agreement amongst the two heuristics other than what would be expected by chance. In Figure 5, we plot histograms of the Cohen's kappa coefficient for all possible pairwise combinations of the seven heuristics across all 1000 experimental replications when the random forests algorithm's default majority vote discrimination threshold of 0.5 is used.

More generally, the areas underneath the receiver operating characteristic (ROC) and precision-recall (PR) curves can be used to compare the overall performance of binary classifiers as the discrimination threshold is varied between 0 and 1. Specifically, as the discrimination threshold changes, the ROC curve plots the proportion of positive observations that a classifier correctly labels as a function of the proportion of negative observations that a classifier incorrectly labels, while the PR curve plots the proportion of a classifier's positive labels that are truly positive as a function of the proportion of positive observations that a classifier correctly labels (Davis and Goadrich, 2006).

[9] This is the approach that is used by the `randomForest R` package. The `scikit-learn Python` module uses an alternative method of calculating the predicted response class probabilities which takes the average of the predicted class probabilities over the trees in the random forest, where the predicted probability of a response class k in an individual tree is estimated using the proportion of a node's training samples that belong to the response class k.

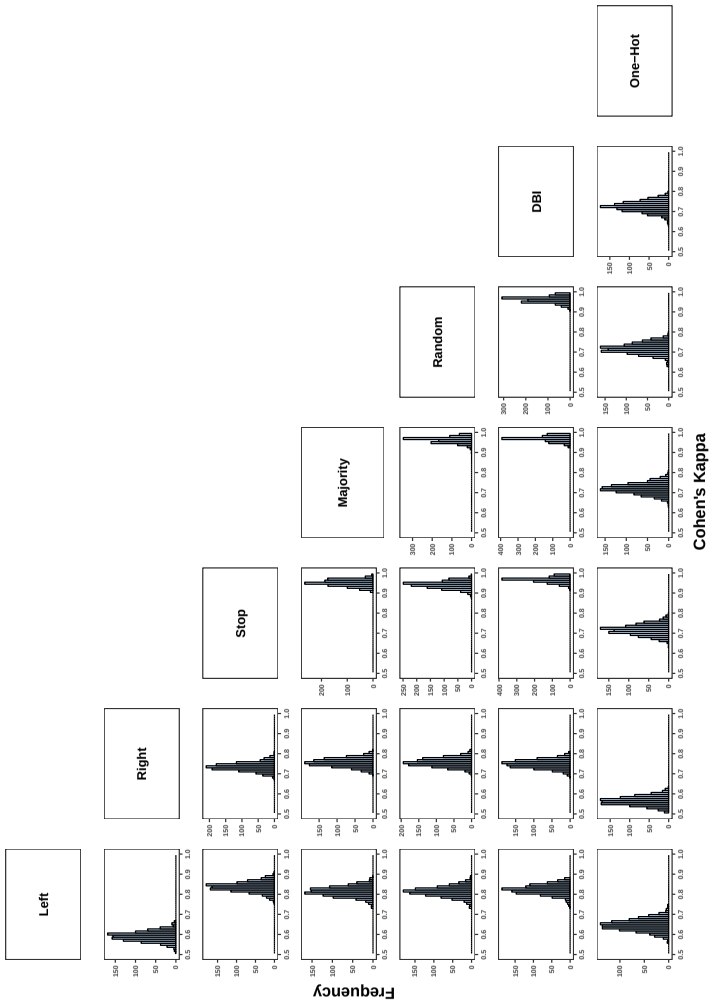

Figure 5: Pairwise Cohen's kappa coefficients for the seven different heuristics as defined in (14) when the random forests algorithm's default majority vote discrimination threshold of 0.5 is used in the PROMESA data set. Each panel plots the histogram of coefficients across all 1000 experimental replications when the OOB classifications of the heuristic that is labeled at the right of the panel's row are compared against the OOB classifications of the heuristic that is labeled at the top of the panel's column. Cohen's kappa coefficients were calculated within each of the 1000 experimental replications to account for the positive correlation between the naive and missing data heuristics.

Taking the "Yes" vote to be the positive response class in our analysis, we calculate the areas underneath the ROC and PR curves for each heuristic $h \in \mathcal{H}$ within each experimental replication r. Boxplots depicting each heuristic's marginal distribution of these two areas across all 1000 experimental replications are shown in the left panels of Figure 6. However, these marginal boxplots ignore the positive correlation that exists between the naive and missing data heuristics. Therefore, within every experimental replication r and similar to what was previously done in our 1985 Auto Imports example, we also compare the areas for each heuristic $h \in \mathcal{H}$ relative to the best area that was achieved amongst the missing data heuristics $\mathcal{H}_m = \{Stop, Majority, Random, DBI\}$:

$$\text{AUC}_r^{(h \| \mathcal{H}_m)} = \frac{\text{AUC}_r^{(h)} - \max_{h \in \mathcal{H}_m} \text{AUC}_r^{(h)}}{\max_{h \in \mathcal{H}_m} \text{AUC}_r^{(h)}}, \tag{15}$$

where, depending on the context, $\text{AUC}_r^{(h)}$ denotes the area that is underneath either the ROC or PR curve for heuristic h in experimental replication r. Boxplots of these relative areas across all 1000 experimental replications are displayed in the right panels of Figure 6.

5.2.1 Naive Heuristics

As expected given our discussions in Section 3.2 and how we have chosen to index the response classes in our analysis, we see from Figure 4 that the Left heuristic results in significantly higher predicted probabilities of voting "Yes" than the other heuristics, while the Right heuristic yields predicted probabilities of voting "Yes" that are substantially lower. The consequences of this behavior in terms of making classifications can be observed in Figure 5, where we note that both the Left and Right heuristics tend to exhibit a high level of disagreement when compared against any other heuristic's classifications. Moreover, Figure 6 illustrates that the `randomForest R` package's practice of always sending absent levels left in binary classification is noticeably detrimental here—relative to the best performing missing data heuristic, it gives areas underneath the ROC and PR curves that are, on average, 1.5% and 3.7% worse, respectively. And although the Right heuristic appears to do well in terms of the area underneath the PR curve, we once again emphasize the spurious nature of this performance and caution against taking it at face value.

5.2.2 Missing Data Heuristics

Similar to what was previously seen in our 1985 Auto Imports example, Figures 4 and 5 show that the four missing data heuristics tend to exhibit a higher level of agreement with one another than they do with the Left, Right, and One-Hot heuristics. However, significant differences do still exist, and we see from Figure 6 that the relative performances of the heuristics will vary depending on the specific task at hand—the Majority heuristic slightly outperforms the three other missing data heuristics in terms of the area underneath the ROC curve, while the Random heuristic does considerably better than all of its missing data counterparts with respect to the area underneath the PR curve.

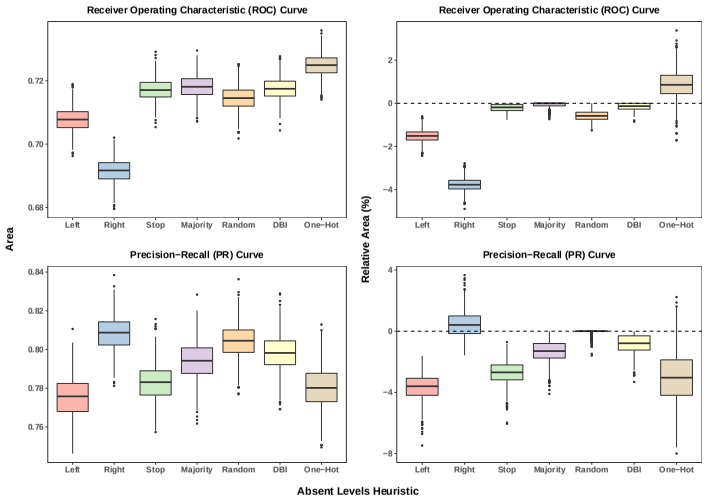

Figure 6: Areas underneath the ROC and PR curves for the seven heuristics in the PROMESA data set. The left panels show boxplots of each heuristic's marginal distribution of areas across all 1000 experimental replications, which ignores the positive correlation that exists between the naive and missing data heuristics. The right panels account for this positive correlation by comparing the areas of the heuristics relative to the best area that was obtained amongst the missing data heuristics within each of the 1000 experimental replications as in (15).

5.2.3 Feature Engineering Heuristic

Although it is essentially uncorrelated with the other six heuristics across all 1000 experimental replications, Figures 4 and 5 still suggest that the One-Hot heuristic's predicted probabilities and classifications can greatly differ from the other six heuristics. Furthermore, Figure 6 shows that even though the One-Hot heuristic may appear to perform well in terms of the area underneath its ROC curve relative to the missing data heuristics, its performance in the PR context is rather lackluster.

5.3 Pittsburgh Bridges

For a multiclass classification example, we consider the Pittsburgh Bridges data set from the UCI Machine Learning Repository which, after removing observations with missing data, contains seven predictors that can be used to classify 72 bridges to one of seven different bridge types. The categorical predictors in this data set for which the absent levels problem can occur include a bridge's river (3 levels), purpose (3 levels), and location (46

levels). Consequently, recall from Section 3.2, that the random forests `FORTRAN` code and `randomForest R` package will both employ an exhaustive search that always sends absent levels right when splitting on either the river or purpose predictors, and that they will both resort to using a random search that sends absent levels either left or right with equal probability when splitting on the location predictor since it has too many levels for an exhaustive search to be computationally efficient. The OOB absence proportions for this example are summarized in the bottom panel of Figure 1 and in Table 1.

Within each experimental replication r, we can use the log loss

$$\text{LogLoss}_r^{(h)} = -\frac{1}{N}\sum_{n=1}^{N}\sum_{k=1}^{K}\left[I(y_n = k)\cdot log\left(\hat{p}_{nkr}^{(h)}\right)\right]$$

to evaluate the overall performance of each heuristic $h \in \mathcal{H}$, where we once again let $\hat{p}_{nkr}^{(h)}$ denote the OOB predicted probability that a heuristic h assigns to an observation n of belonging to a response class k in an experimental replication r. The left panel of Figure 7 displays the marginal distribution of each heuristic's log losses across all 1000 experimental replications. However, to once again account for the positive correlation that exists amongst the naive and missing data heuristics, within every experimental replication r, we also compare the log losses for each heuristic $h \in \mathcal{H}$ relative to the best log loss that was achieved amongst the missing data heuristics $\mathcal{H}_m = \{Stop, Majority, Random, DBI\}$:

$$\text{LogLoss}_r^{(h\|\mathcal{H}_m)} = \frac{\text{LogLoss}_r^{(h)} - \min_{h\in\mathcal{H}_m}\text{LogLoss}_r^{(h)}}{\min_{h\in\mathcal{H}_m}\text{LogLoss}_r^{(h)}}. \tag{16}$$

Boxplots of these relative log losses are depicted in the right panel of Figure 7.

5.3.1 Naive Heuristics

Although we once again stress the systematically biased nature of the Left and Right heuristics, we note from Figure 7 that the two naive heuristics are sometimes able to outperform the missing data heuristics. Nevertheless, on average, the Left and Right heuristics resulted in log losses that are 0.7% and 1.9% worse than the best performing missing data heuristic, respectively.

5.3.2 Missing Data Heuristics

Figure 7 shows that for this particular example, the Majority and Random heuristics perform roughly on par with one another, and that they both also significantly outperform the Stop and DBI heuristics—the smallest log loss amongst all of the missing data heuristics was achieved by either the Majority or the Random heuristic in 999 out of the 1000 experimental replications.

5.3.3 Feature Engineering Heuristic

It can also be observed from Figure 7 that, although the One-Hot heuristic can occasionally outperform the missing data heuristics, on average, it yields a log loss that is 4.5% worse than the best performing missing data heuristic.

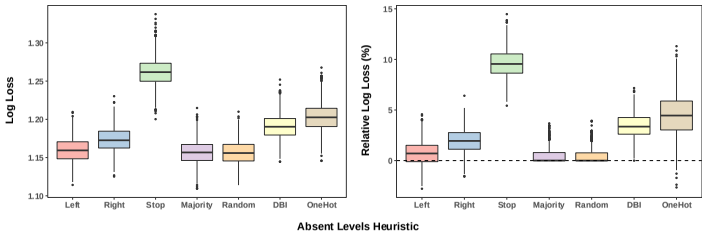

Figure 7: Log losses for the OOB predicted response class probabilities of the seven heuristics in the Pittsburgh Bridges data. The left panel shows boxplots of each heuristic's marginal distribution of log losses set across all 1000 experimental replications, which ignores the positive correlation that exists between the naive and missing data heuristics. The right panel accounts for this positive correlation by comparing the log losses of the heuristics relative to the best log loss that was obtained amongst the missing data heuristics within each of the 1000 experimental replications as in (16).

6. Conclusion

In this paper, we introduced and investigated the absent levels problem for decision tree based methods. In particular, by using Breiman and Cutler's random forests `FORTRAN` code and the `randomForest R` package as motivating case studies, we showed how overlooking the absent levels problem could systematically bias a model. Furthermore, we presented three real data examples which illustrated how absent levels can dramatically alter a model's performance in practice.

Even though a comprehensive theoretical analysis of the absent levels problem was beyond the scope of this paper, we empirically demonstrated how some simple heuristics could be used to help mitigate the effects of absent levels. And although none of the missing data and feature engineering heuristics that we considered performed uniformly better than all of the others, they were all shown to be superior to the biased naive approaches that are currently being employed due to oversights in the software implementations of decision tree based methods.

Consequently, until a more robust theoretical solution is found, we encourage the software implementations which support the native categorical split capabilities of decision trees to incorporate the Random heuristic as a provisional measure given its reliability—in all of our examples, the Random heuristic was always competitive in terms of its performance. Moreover, based on our own personal experiences, we note that the Random heuristic was one of the easier heuristics to implement on top of the `randomForest R` package. In the meantime, while waiting for these mitigations to materialize, we also urge users who rely on decision tree based methods to feature engineer their data sets when possible in order to circumvent the absent levels problem—although our empirical results suggest that this may

sometimes be detrimental to a model's performance, we believe this to still be preferable to the alternative of having to rely on biased approaches which do not adequately address absent levels.

Finally, although this paper primarily focused on the absent levels problem for random forests and a particular subset of the types of analyses in which random forests have been used, it is important to recognize that the issue of absent levels applies much more broadly. For example, decision tree based methods have also been employed for clustering, detecting outliers, imputing missing values, and generating variable importance measures (Breiman, 2003)—tasks which also depend on the terminal node behavior of the observations. In addition, several extensions of decision tree based methods have been built on top of software which currently overlook absent levels—such as the quantile regression forests algorithm (Meinshausen, 2006, 2012) and the infinitesimal jackknife method for estimating the variance of bagged predictors (Wager et al., 2014), which are both implemented on top of the `randomForest R` package. Indeed, given how extensively decision tree based methods have been used, a sizable number of these models have almost surely been significantly and unknowingly affected by the absent levels problem in practice—further emphasizing the need for the development of both theory and software that accounts for this issue.

Acknowledgements

The author is extremely grateful to Art Owen for numerous valuable discussions and insightful comments which substantially improved this paper. The author would also like to thank David Chan, Robert Bell, the action editor, and the anonymous reviewers for their helpful feedback. Finally, the author would like to thank Jim Koehler, Tim Hesterberg, Joseph Kelly, Iván Díaz, Jingang Miao, and Aiyou Chen for many interesting discussions.

On Tight Bounds for the Lasso

Sara van de Geer geer@stat.math.ethz.ch

Editor: Francis Bach

Abstract

We present upper and lower bounds for the prediction error of the Lasso. For the case of random Gaussian design, we show that under mild conditions the prediction error of the Lasso is up to smaller order terms dominated by the prediction error of its noiseless counterpart. We then provide exact expressions for the prediction error of the latter, in terms of compatibility constants. Here, we assume the active components of the underlying regression function satisfy some "betamin" condition. For the case of fixed design, we provide upper and lower bounds, again in terms of compatibility constants. As an example, we give an up to a logarithmic term tight bound for the least squares estimator with total variation penalty.

Keywords: Compatibility, Lasso, Linear Model, Lower Bound

1. Introduction

Let $X \in \mathbb{R}^{n\times p}$ be an input matrix and $\beta^0 \in \mathbb{R}^p$ a vector of unknown coefficients. Consider an n-vector of noisy observations

$$Y = X\beta^0 + \epsilon$$

where the noise $\epsilon \in \mathbb{R}^n$ is a vector of i.i.d. standard Gaussians independent of X. The Lasso estimator $\hat{\beta}$ is

$$\hat{\beta} \in \arg\min_{b\in\mathbb{R}^p}\Big\{\|Y - Xb\|_2^2 + 2\lambda\|b\|_1\Big\} \tag{1}$$

with $\lambda > 0$ a regularization parameter (Tibshirani (1996)). Its prediction error is $\|X(\hat{\beta} - \beta^0)\|_2^2$. Main aim of this paper is to provide lower bounds for this prediction error, bounds which show that compatibility constants necessarily enter into the picture.

The results of this paper can be summarized as follows. Firstly, suppose the design is random and that $\Sigma_0 := \mathbb{E}X^TX/n$ exists. Let β^* be the noiseless Lasso for random design

$$\beta^* \in \arg\min_{b\in\mathbb{R}^p}\Big\{n\|\Sigma_0^{1/2}(b - \beta^0)\|_2^2 + 2\lambda\|b\|_1\Big\}. \tag{2}$$

For the case where the rows of X are i.i.d $\mathcal{N}(0, \Sigma_0)$, we compare $\|X(\hat{\beta} - \beta^0)\|_2$ with $\sqrt{n}\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2$ in Theorem 11. We assume here some mild condition on the growth of the compatibility constants as n increases. The theorem has as an important corollary that $\|X(\hat{\beta} - \beta^0)\|_2$ is up to lower order terms equal to $\sqrt{n}\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2$ whenever (after normalizing the co-variance matrix Σ_0 to having bounded entries) the largest eigenvalue $\Lambda_{\max}^2$ of Σ_0 is of small order $\log n$, see Corollary 12. Secondly, we provide in Theorem 14 exact expressions for the prediction error of the noiseless Lasso in terms of compatibility constants. We require here "betamin" conditions, which roughly say that the non-zero coefficients of β^0 should have the appropriate signs and remain above the noise level in absolute value. Thirdly, for the case of fixed design, we present upper and lower bounds for the prediction error $\|X(\hat{\beta} - \beta^0)\|_2^2$ in terms of weighted compatibility constants. Theorem 17 states the lower bounds, assuming again certain betamin conditions. The upper bounds we present are similar to those obtained the literature and presented for completeness. They are stated as a consequence of Theorem 18 in Corollary 19. Another application of Theorem 18 is given in Corollary 20. It presents an upper bound for $\|X(\hat{\beta} - \beta^*)\|_2$ where β^* is now the counterpart of (2) for the fixed design case. As an illustration we consider least squares estimation with a (one-dimensional) total variation penalty. For this case we arrive in Corollary 22 at lower and upper bounds that are the same up to a logarithmic term.

There are general upper bounds in the literature, in particular *sharp oracle bounds* as in Koltchinskii et al. (2011) (see also Giraud, 2014, Theorem 4.1 or van de Geer, 2016, Theorem 2.2). The oracle bounds involve a compatibility constant, and an improved version of this constant has been developed in Sun and Zhang (2012), Belloni and Wang (2014) and Dalalyan et al. (2017).

Main theme of this paper is to gain further insight into the role of the compatibility constant when applying the Lasso and to see how it occurs in lower bounds. In Zhang et al. (2014) it is shown that for a given sparsity level, there is a design and a lower bound for the mean prediction error in the noisy case, that holds for any polynomial time algorithm. This lower bound is close to the known upper bounds and in particular shows that compatibility conditions or restricted eigenvalue conditions cannot be avoided. This has also been shown by Bellec (2017), where a choice of the particular vector of regression coefficients β^0 leads to a lower bound matching the upper bound. We further elaborate on this issue, and provide lower bounds that hold for a large class of vectors β^0.

To get an idea of the flavour of the type of bounds we are after, we present in Theorem 1 the case of random design. Details of its proof can be found in Subsection 11.9. We provide more explicit statements in Theorem 11.

Throughout the paper, the active set of β^0 is denoted by $S_0 := \{j : \beta_j^0 \neq 0\}$. Its size is denoted by $s_0 := |S_0|$. Our betamin condition is as follows (its meaning should become more clear after looking at Section 3 where compatibility constants are defined).

Betamin condition *Let*

$$b^* \in \arg\min\Big\{\|\Sigma_0^{1/2}b\|_2 : \sum_{j\in S_0}|b_j| - \sum_{j\notin S_0}|b_j| = 1\Big\}$$

and for $j \in S_0$ let z_j^* be the sign of b_j^*. We say that β^0 satisfies the betamin condition for the noiseless case with random design if

$$z_j^* \beta_j^0 > \frac{z_j^* b_j^*}{\|\Sigma_0^{1/2} b^*\|_2^2} \frac{\lambda}{n}, \ \forall j \in S_0. \tag{3}$$

We will make asymptotic statements with the sample size n tending to infinity and apply (stochastic) order symbols. All quantities in the paper are allowed to depend on n unless otherwise stated.

Theorem 1 *Let the rows of X be i.i.d. $\mathcal{N}(0, \Sigma_0)$, let $\|\Sigma_0\|_\infty$ be the maximal entry in the co-variance matrix Σ_0 and $\Lambda_{\max}^2$ be its largest eigenvalue. For $S \subset \{1, \ldots, p\}$, let $\kappa^2(S)$ be the compatibility constant defined in Definition 2. Suppose that*

$$\Lambda_{\max}^2 / \|\Sigma_0\|_\infty = o(\log(2p)),$$

and

$$\max\left\{ \left(\frac{\|\Sigma_0\|_\infty}{\kappa^2(S)} \right) \frac{\log(2p)|S|}{n} : \ S \subset \{1, \ldots, p\}, \ |S| \leq \left(\frac{\Lambda_{\max}^2}{\kappa^2(S_0)} \right) 4 s_0 \right\} = o(1).$$

For some $t > 0$, take the tuning parameter λ to satisfy

$$3\|\Sigma_0\|_\infty^{1/2} \left(\sqrt{2n(\log(2p) + t)} + 2(\log(2p) + t) \right) \leq \lambda = \mathcal{O}\left(\sqrt{\|\Sigma_0\|_\infty^{1/2} \log(2p)} \right).$$

Then, under condition (3) (the betamin condition for the noiseless case with random design), we have

$$\|X(\hat{\beta} - \beta^0)\|_2^2 = \frac{\lambda^2 / n}{\|\Sigma_0^{1/2} b^*\|_2^2} (1 + o_{\mathbf{P}}(1)) + \mathcal{O}_{\mathbf{P}}(1)$$

(where in fact $s_0 \|\Sigma_0^{1/2} b^*\|_2^2 = \kappa^2(S_0)$).

2. Organization of the Paper

In Section 3 the definition of compatibility constants is given and also some of their properties are discussed. Section 4 shows that for the case of random design the squared "bias" of the Lasso dominates its "variance". Section 5 then gives expressions for this "bias", i.e. for the noiseless Lasso. Here, we examine fixed design but the results carry over immediately to random design. In Section 6 the result of Section 5 is illustrated with the total variation penalty (in one dimension). Section 7 presents lower bounds for the noisy case with fixed design, and Section 8 presents some upper bounds. Corollary 19 is essentially as in the papers Sun and Zhang (2012), Belloni and Wang (2014) and Dalalyan et al. (2017), albeit that do not consider the approximately sparse case to avoid digressions. Section 9 has upper and lower bounds for the least squares estimator with total variation penalty in the noisy case. Section 10 concludes. Section 11 contains the proofs.

3. Compatibility Constants

We introduce some notation in order to be able to define the compatibility constants. This notation will also be helpful at other places. For $S \subset \{1, \ldots, p\}$ and a vector $b \in \mathbb{R}^p$ let $b_S \in \mathbb{R}^p$ be the vector with entries $b_{j,S} := b_j 1\{j \in S\}$, $j = 1, \ldots, p$. We apply the same notation for the $|S|$-dimensional vector $\{b_j\}_{j \in S}$. We moreover write $b_{-S} := b_{S^c}$ where S^c is the the complement of the set S.

3.1. Theoretical Compatibility Constants

The population version of the compatibility constant will be used for the case of random design X. We call the population version the theoretical compatibility constant.

Definition 2 *Let $\Sigma_0 := \mathbb{E} X^T X / n$ (assumed to exist). Let $S \subset \{1, \ldots, p\}$ be a set of indices and $u \geq 0$ be a constant. The theoretical compatibility constant is*

$$\kappa^2(u, S) := \min\left\{ |S| \|\Sigma_0^{1/2} b\|_2^2 : \ \|b_S\|_1 - u\|b_{-S}\|_1 = 1 \right\}.$$

For $u = 1$ we write $\kappa(1, S) =: \kappa(S)$.

3.2. Empirical Compatibility Constants

For a vector w we let $W := \mathrm{diag}(w)$ be the diagonal matrix with w on the diagonal.

Definition 3 *(Belloni and Wang, 2014, Dalalyan et al., 2017) Let $S \subset \{1, \ldots, p\}$ be a set of indices and $w \in \mathbb{R}^{p-|S|}$ be a vector of non-negative weights. The (empirical) compatibility constant is is*

$$\hat{\kappa}^2(w, S) := \min\left\{ |S| \|Xb\|_2^2 / n : \ \|b_S\|_1 - \|W b_{-S}\|_1 = 1 \right\}.$$

For the case where $w = \mathbf{1}$ where $\mathbf{1}$ denotes a vector with all entries equal to one, put $\hat{\kappa}^2(S) := \hat{\kappa}^2(\mathbf{1}, S)$.

3.3. Some Properties of Compatibility Constants

One readily sees that the theoretical and empirical compatibility constants differ only in terms of the matrix used in the quadratic form (which is Σ_0 in the theoretical case and the Gram matrix $\hat{\Sigma} := X^T X / n$ in the empirical case). Thus, when discussing their basic properties it suffices to deal with only one of the two. In this section, we therefore restrict attention to the empirical version $\hat{\kappa}(w, S)$. Note that we have generalized the empirical version as compared to the theoretical one, by considering general weight vectors, not just constant vectors. With some abuse of notation, we write $\hat{\kappa}(u, S) = \hat{\kappa}(u\mathbf{1}, S)$ when the weights are the constant vector $u\mathbf{1}$ (it should be clear from the context what is meant).

The empirical compatibility constant as given in Definition 3 is from Belloni and Wang (2014) or Dalalyan et al. (2017). Another version, from for instance van de Geer (2007) or van de Geer (2016) and its references, is presented in the next definition.

Definition 4 *Let $S \subset \{1,\ldots,p\}$ be a set of indices and $u > 0$ be a constant. The (older) compatibility constant is*

$$\hat{\phi}^2(u,S) := \min\Big\{ |S| \|Xb\|_2^2/n : \ \|b_S\|_1 = 1, \ \|b_{-S}\|_1 \leq 1/u \Big\}.$$

Let $\hat{\phi}^2(S) := \hat{\phi}^2(1,S)$ be the compatibility constant for the case $u = 1$.

The constant $\hat{\phi}(u,S)$ compares, for b's satisfying a "cone condition" $\|b_{-S}\|_1 \leq \|b_S\|_1/u$, the ℓ_2-norm $\|Xb\|_2$ with the ℓ_1-norm $\|b_S\|_1$. The constant $\hat{\kappa}(u,S)$ is similar, but takes in the comparison more advantage of a "cone condition" $\|b_S\|_1 - u\|b_{-S}\|_1 > 0$. When $\hat{\kappa}^2(S) > 0$ the null space property holds (Donoho and Tanner, 2005). We will need throughout that the compatibility constant is strictly positive at S_0 (if it is zero our results cease to be of any interest). This means that we implicitly require throughout

Invertibility condition

$$\textit{The matrix } X_{S_0}^T X_{S_0} \textit{ is invertible.} \tag{4}$$

Here, for any $S \subset \{1,\ldots,p\}$ the matrix $X_S = \{X_j\}_{j\in S}$ is the $n \times |S|$ matrix consisting of the columns of X corresponding to the set S.

The newer version $\hat{\kappa}(u,S)$ is an improvement over $\hat{\phi}(u,S)$ in the sense that $\hat{\kappa}(u,S)$ is the larger of the two.

Lemma 5 *For all $u > 0$ it is true that*

$$\hat{\kappa}^2(u,S) \geq \hat{\phi}^2(u,S).$$

Let now for some $v > 0$

$$b^* \in \arg\min\Big\{ \|Xb\|_2^2/n : \ \|b_S\|_1 - v\|b_{-S}\|_1 = 1 \Big\}.$$

Then by definition

$$\hat{\kappa}^2(v,S) = |S| \|Xb^*\|_2^2/n.$$

The restriction $\|b_S\|_1 - v\|b_{-S}\|_1 = 1$ does not put any bound on the ℓ_1-norm of b_S^*. However, if there is a little room to spare, its ℓ_1-norm is bounded. This will be useful to understand the betamin conditions (conditions (3) and (8)). For simplicity we examine only the value $v = 1$.

Lemma 6 *Let*

$$b^* \in \arg\min\Big\{ \|Xb\|_2^2/n : \ \|b_S\|_1 - \|b_{-S}\|_1 = 1 \Big\}.$$

Then for $0 \leq u < 1$

$$\|b_S^*\|_1 \leq \frac{\hat{\kappa}(S) - u\hat{\kappa}(u,S)}{(1-u)\hat{\kappa}(u,S)}.$$

3.4. Comparing Empirical and Theoretical and Compatibility

Having random quadratic forms in mind, the fact that $\|b_S\|_1 - \|b_{-S}\|_1 = 1$ gives no bound on the ℓ_1-norm can be a problem. Again, if there is a little room to spare in the value of u in the compatibility constant, one *does* get a bound on the ℓ_1-norm. We show this in Lemma 7, and with this tool in hand we lower bound the empirical compatibility constant in terms of the theoretical one in Lemma 8.

Lemma 7 *Let $v > u > 0$. Then*

$$\hat{\kappa}^2(v,S) \geq \min\Big\{ |S| \|Xb\|_2^2/n : \ \|b_S\|_1 - u\|b_{-S}\|_1 = 1, \ \|b\|_1 \leq 1 + (1+u)/(v-u) \Big\}.$$

The following lemma will be applied when bounding the prediction error of $\hat{\beta}$ in terms of that of the noiseless Lasso β^*. The lemma may also be of interest in itself with applications elsewhere.

Lemma 8 *Suppose the rows of X are i.i.d. $\mathcal{N}(0,\Sigma_0)$. Let $\|\Sigma_0\|_\infty$ be the largest entry in the matrix Σ_0. For $v > u$, $(1+u)/(v-u) = \mathcal{O}(1)$ and*

$$\left(\frac{\|\Sigma_0\|_\infty}{\kappa^2(u,S)} \right) \frac{s \log(2p)}{n} = o(1),$$

it is true with probability tending to one that

$$\hat{\kappa}^2(v,S) \geq (1-\eta)^2 \kappa^2(u,S).$$

where $\eta = o(1)$.

4. Comparison With the Noiseless Lasso When the Design is Random

In this section we assume that the rows of X are i.i.d. copies of a Gaussian row vector with mean zero and co-variance matrix Σ_0. We denote the largest eigenvalue of Σ_0 by $\Lambda_{\max}^2$ and let $\|\Sigma_0\|_\infty$ be its largest entry. We define a noiseless version β^* of the Lasso where also the random design is replaced by its population counterpart:

$$\beta^* \in \arg\min_{b\in\mathbb{R}^p} \Big\{ n\|\Sigma_0^{1/2}(b - \beta^0)\|_2^2 + 2\lambda\|b\|_1 \Big\}.$$

The normalization with n is to put things on the scale of the empirical version, as $\mathbb{E}X^T X = n\Sigma_0$. One may think of $\|X(\beta^* - \beta^0)\|_2$ as "bias" and $\|X(\hat{\beta} - \beta^*)\|_2^2$ as "variance". We first investigate in some detail the "variance" part in Theorems 9 and 10. Then we apply the triangle inequality as a way to establish that the squared "bias" dominates the "variance", see Theorem 11.

Theorem 9 *Suppose that*

$$\rho^2 := \max\left\{ \left(\frac{\|\Sigma_0\|_\infty}{\kappa^2(S)} \right) \frac{\log(2p)|S|}{n} : \ S \subset \{1,\ldots,p\}, \ |S| \leq \left(\frac{\Lambda_{\max}^2}{\kappa^2(S_0)} \right) 4s_0 \right\} = o(1).$$

Take for some $t > 0$

$$\lambda \geq 3\|\Sigma_0\|_\infty^{1/2}\Big(\sqrt{2n(\log(2p)+t)} + 2(\log(2p)+t)\Big)$$

and define

$$\gamma := (2\Lambda_{\max})\sqrt{n}/\lambda + (2/\|\Sigma_0\|_\infty^{1/2})\rho\lambda/\sqrt{n\log(2p)}.$$

Then we have for all $x > 0$ with probability at least $1 - 4\exp[-t] - \exp[-x] - o(1)$ that

$$\|X(\hat\beta - \beta^*)\|_2 \leq \gamma\sqrt{n}\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2 + \sqrt{2x}.$$

Using concentration of measure, one can remove the dependency of the confidence level on the value of t. This value appears in the choice of the tuning parameter λ. We make some rather arbitrary choices for the constants.

Theorem 10 *With the conditions and notations of Theorem 9, and assuming in addition that $4\exp[-t] < 1/8$ (say), for n large enough and for all $x > 0$, with probability at least $1 - 2\exp[-x]$,*

$$\|X(\hat\beta - \beta^*)\|_2 \leq \gamma\sqrt{n}\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2 + 4\sqrt{\log 2} + \sqrt{2x}.$$

We can now make a type of bias-variance decomposition. The triangle inequality tells us that

$$\Big|\|X(\hat\beta - \beta^0)\|_2 - \|X(\beta^* - \beta^0)\|_2\Big| \leq \|X(\hat\beta - \beta^*)\|_2.$$

We then approximate the empirical "bias" $\|X(\beta^* - \beta^0)\|_2$ by the theoretical "bias" $\sqrt{n}\|\Sigma_0^{1/2}(\beta^* - \beta_0)\|_2$ (which is easy as β^* and β^0 are non-random vectors), and use Theorem 9 or 10 to bound the "variance" $\|X(\hat\beta - \beta^*)\|_2^2$.

Theorem 11 *With the conditions and notations of Theorem 10, we have for n sufficiently large, for all $x > 0$ with probability at least $1 - 2\exp[-x]$*

$$\Big|\|X(\hat\beta - \beta^0)\|_2 - \sqrt{n}\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2\Big|$$

$$\leq (\gamma + o(1))\sqrt{n}\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2 + 4\sqrt{\log 2} + \sqrt{2x}.$$

Corollary 12 *Recall that we defined γ as*

$$\gamma := (2\Lambda_{\max})\sqrt{n}/\lambda + (2/\|\Sigma_0\|_\infty^{1/2})\rho\lambda/\sqrt{n\log(2p)}.$$

Therefore, with the conditions and notations of Theorem 11, and assuming in addition
- $\Lambda_{\max}^2/\|\Sigma_0\|_\infty = o(\log(2p))$,
and
- $\lambda = o(\sqrt{\|\Sigma_0\|_\infty n\log(2p)})/\rho$,
we get with probability at least $1 - 2\exp[-x]$

$$\Big|\|X(\hat\beta - \beta^0)\|_2 - \sqrt{n}\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2\Big| = o(\sqrt{n}\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2) + 4\sqrt{\log 2} + \sqrt{2x}.$$

In words: the squared "bias" dominates the "variance".

Remark 13 *With the help of Lemma 45, one may also prove bounds for $\sqrt{n}\|\Sigma_0(\hat\beta - \beta^0)\|_2$ to complete those for of $\|X(\hat\beta - \beta^0)\|_2$. We refrain from doing this here to avoid digressions.*

5. The Noiseless Case with Fixed Design

In this section we study fixed design X and the noiseless Lasso

$$\beta^* \in \arg\min_{b\in\mathbb{R}^p}\Big\{\|X(b - \beta^0)\|_2^2 + 2\lambda^*\|b\|_1\Big\}. \tag{5}$$

In principle the noiseless Lasso considered here differs from (2), although one can say that for fixed design $\hat\Sigma = \mathbf{E}\hat\Sigma =: \Sigma_0$, with $\hat\Sigma := X^TX/n$ being the Gram matrix. In what follows in this section, we do not use any specific properties of $\hat\Sigma$ and the theory goes through for any positive semi-definite matrix, Σ say. In the upcoming illustration on functions of bounded variation, the fixed design setup is the natural one.

Note that we supplied the tuning parameter λ^* with a supscript $*$. This is because in Theorem 18 we consider a case with different tuning parameters for the noisy and the noiseless case, say λ and λ^*.

The Karush-Kuhn-Tucker (KKT) conditions for the noiseless Lasso read

$$X^TX(\beta^* - \beta^0) + \lambda^*\zeta^* = 0,\ \zeta^* \in \partial\|\beta^*\|_1, \tag{6}$$

where $\partial\|b\|_1$ denotes the sub-differential of $b \mapsto \|b\|_1$:

$$\partial\|b\|_1 = \Big\{z \in \mathbb{R}^p :\ z^Tb = \|b\|_1,\ \|z\|_\infty \leq 1\Big\}.$$

Recall that

$$\hat\kappa^2(S) = |S|/\|Xb^*\|_2^2/n$$

where

$$b^* \in \arg\min_{b\in\mathbb{R}^p}\Big\{\|Xb\|_2 :\ \|b_S\|_1 - \|b_{-S}\|_1 = 1\Big\}. \tag{7}$$

Note that b^* given in (7) is not unique, for example we can flip the signs of b^* (i.e., replace b^* by $-b^*$).

In Theorem 14 below we give a tight result for the noiseless case under the condition that the active coefficients in β^0 are sufficiently large in absolute value: Condition 8. Here sufficiently large depends on the magnitude of the entries of a solution b^* of (7) with $S = S_0$. Therefore, it is of interest to know how large b^* is. Lemma 6 considers its ℓ_1-norm, and in view of this lemma we conclude that if there is a little room to spare, the ℓ_1-norm of $\|b_S^*\|_1$ is bounded, or - in other words - $\{b_j^*|S|\}_{j\in S}$ is bounded "on average".

For the next condition it is useful to know that we show in Lemma 28 that for b^* given in (7), each coefficient b_j^* with $j \in S$ is nonzero (provided $\hat\kappa^2(S) > 0$).

Betamin condition *Suppose $\hat{\kappa}^2(S_0) > 0$. Let b^* satisfy (7) with $S = S_0$. Denote, for $j \in S_0$, the sign of b_j^* as z_j^*. We say that β^0 satisfies the betamin condition for the noiseless case with fixed design if*

$$z_j^* \beta_j^0 > \frac{z_j^* b_j^* s_0}{\hat{\kappa}^2(S_0)} \frac{\lambda^*}{n} \ \forall \ j \in S_0. \tag{8}$$

Here is the main theorem for the noiseless case.

Theorem 14 *Suppose $\hat{\kappa}^2(S_0) > 0$. Let b^* satisfy (7) with $S = S_0$. If β^0 satisfies condition (8) (the betamin condition for the noiseless case with fixed design), then there exists a solution β^* of the KKT conditions (6) such that*

$$\|X(\beta^* - \beta^0)\|_2^2 = \frac{s_0}{\hat{\kappa}^2(S_0)} \frac{\lambda^{*2}}{n}.$$

6. The Total Variation Penalty in the Noiseless Case

In this section Theorem 14 is illustrated with the total variation penalty. For a vector $f \in \mathbb{R}^n$, its total variation is defined as

$$\mathrm{TV}(f) := \sum_{i=2}^n |f_i - f_{i-1}|.$$

Fix a vector $f^0 \in \mathbb{R}^n$ and let $f^* \in \mathbb{R}^n$ is the least squares approximation of f^0 with total variation penalty:

$$f^* \in \arg\min_{f \in \mathbb{R}^n} \Big\{ \|f - f^0\|_2^2 + 2\lambda^* \mathrm{TV}(f) \Big\}. \tag{9}$$

Theorem 15 presents an explicit expression for the compatibility constant $\hat{\kappa}^2(S_0)$ where S_0 is the set consisting of the locations of the jumps of f^0. Invoking Theorem 14 one then arrives at an explicit expression for $\|f^* - f^0\|_2^2$ provided the jumps of f^0 are sufficiently large, see Corollary 16.

First, we need to rewrite problem (9) as a (noiseless) Lasso problem. Indeed, for $j = 1 \ldots, n$,

$$f_j = \sum_{i=1}^n (f_i - f_{i-1}) 1\{j \geq i\} =: (Xb)_j,$$

where $X_{j,i} = 1\{j \geq i\}$ and $b_i = f_i - f_{i-1}$, with $f_0 := 0$. Hence we can say that $f^0 = X\beta^0$ and $f^* = X\beta^*$ with

$$\beta^* := \arg\min_{b \in \mathbb{R}^n} \Big\{ \|X(b - \beta^0)\|_2^2 + 2\lambda^* \sum_{i=2}^n |b_i| \Big\}.$$

Note that the first coefficient b_1 is not penalized. It is therefore typically active, and we consider the active set as the location of the jumps augmented with the index $\{1\}$. We

slightly adjust the definition of the compatibility constant to deal with the a coefficient without penalty: we set for $S \subset \{2, \ldots, n\}$

$$\kappa^2(S) := \min \Big\{ |S \cup \{1\}| \|Xb\|_2^2 : \|b_S\|_1 - \|b_{-(S \cup \{1\})}\|_1 = 1 \Big\}. \tag{10}$$

Let now $S := \{d_1 + 1, d_1 + d_2 + 1, \ldots, d_1 + \cdots + d_s + 1\}$ for some $\{d_j\}_{j=1}^s \subset \{2, \ldots, n\}$ satisfying $\sum_{j=1}^s d_j + 2 < n$. The set S represents locations of jumps, d_1 is the location of the first jump and $\{d_j\}_{j=2}^s$ are the distances between jumps. Let $d_{s+1} := n - \sum_{j=1}^s d_j$ the distance between the last jump and the end point. For simplicity we assume that d_j is even for all $j \in \{2, \ldots, s\}$.

Theorem 15 *The compatibility constant $\hat{\kappa}^2(S)$ is, up the constant 4 and the scaling by $1/n$, the harmonic mean of of the distances between jumps, including the distance between starting point and first jump and last jump and endpoint:*

$$\hat{\kappa}^2(S) = \frac{s+1}{\frac{n}{d_1} + \sum_{j=2}^s \frac{4n}{d_j} + \frac{n}{d_{s+1}}}.$$

In fact

$$\hat{\kappa}^2(S) = (s+1)\|Xb^*\|_2^2/n$$

where $b_j^* = 0$ for all $j \notin S$ and $b^* = \tilde{b}/\|\tilde{b}\|_1$ with

$$\begin{aligned}
\tilde{b}_{d_1+1} &= \frac{n}{d_1} + \frac{2n}{d_2}, \\
\tilde{b}_{d_2+1} &= -\Big(\frac{2n}{d_2} + \frac{2n}{d_3}\Big), \\
&\vdots \\
\tilde{b}_{d_s} &= (-1)^{s+1}\Big(\frac{2n}{d_s} + \frac{n}{d_{s+1}}\Big).
\end{aligned}$$

Corollary 16 *Suppose f^0 jumps at $S_0 := S = \{d_1 + 1, d_1 + d_2 + 1, \ldots, d_1 + \cdots + d_s + 1\}$, with $s = s_0$. Assume f^0 alternates between jumps up and jumps down. Suppose moreover that*

$$\begin{aligned}
|f^0_{d_1+1} - f^0_{d_1}| &\geq \Big(\frac{n}{d_1} + \frac{2n}{d_2}\Big)\frac{\lambda^*}{n}, \\
|f^0_{d_2+1} - f^0_{d_2}| &\geq \Big(\frac{2n}{d_2} + \frac{2n}{d_3}\Big)\frac{\lambda^*}{n}, \\
&\vdots \\
|f^0_{d_{s_0}+1} - f^0_{d_{s_0}}| &\geq \Big(\frac{2n}{d_{s_0}} + \frac{n}{d_{s_0+1}}\Big)\frac{\lambda^*}{n}.
\end{aligned}$$

Then by Theorem 14 combined with Theorem 15

$$\|f^* - f^0\|_2^2 = \Big(\frac{n}{d_1} + \sum_{j=2}^{s_0} \frac{4n}{d_j} + \frac{n}{d_{s_0+1}}\Big)\frac{\lambda^{*2}}{n}.$$

At this point it may be helpful to look how this normalizes. Say we choose $\lambda^* = \sqrt{n \log n}$. *Suppose* $\max_{1 \leq j \leq s_0+1} n/d_j = \mathcal{O}(s_0+1)$. *Then the jumps of* f^0 *are required to be of order at least* $(s_0+1)\sqrt{\log n/n}$. *We then obtain*

$$\|f^* - f^0\|_2^2 = \mathcal{O}\Big((s_0+1)^2 \log n\Big).$$

7. A Lower Bound in the Noisy Case with Fixed Design

We now turn to the Lasso $\hat{\beta}$ in the noisy case, given by

$$\hat{\beta} \in \arg\min_{b \in \mathbb{R}^p} \Big\{ \|Y - Xb\|_2^2 + 2\lambda \|b\|_1 \Big\}$$

where

$$Y = X\beta^0 + \epsilon.$$

We investigate the case of fixed design X. Recall that we assume throughout i.i.d. standard Gaussian noise.

7.1. Towards Betamin Conditions

Consider some vector $\bar{v} \in \mathbb{R}^{p-s_0}$ with $0 < \bar{v}_j < 1$ for all j. This vector represents the "noise" that is to be overruled by the penalty. Define the collection of weights

$$\mathcal{W}(\bar{v}) := \Big\{ w \in \mathbb{R}^{p-s_0} : \ \ 1 - \bar{v}_j \leq w_j \leq 1 + \bar{v}_j \ \forall \ j \Big\}.$$

Let for $\bar{W} := \mathrm{diag}(1 + \bar{v})$

$$b^*(\bar{v}) \in \arg\min \Big\{ \|Xb\|_2^2 : \ \|b_{S_0}\|_1 - \|\bar{W} b_{-S_0}\|_1 = 1 \Big\}, \ z_j^*(\bar{v}) := \mathrm{sign}(b_j^*(\bar{v})), \ j \in S_0.$$

Then by definition $\hat{\kappa}^2(1+\bar{v}, S_0) = s_0 \|Xb^*(\bar{v})\|_2^2/n$. We remark here that by a slight adjustment of Lemma 28, the assumption $\hat{\kappa}(1+\bar{v}, S_0) > 0$ ensures that $b_j^*(\bar{v}) \neq 0$ for all $j \in S_0$.

For $w \in \mathcal{W}(\bar{v})$ we define the convex problem with linear and convex constraints

$$b(w) \in \arg\min \Big\{ \|Xb\|_2^2 : \ z_{S_0}^{*T}(\bar{v}) b_{S_0} - \|W b_{-S_0}\|_1 \geq 1 \Big\}.$$

Finally, define

$$\mathbf{b}_j(\bar{v}) := \max_{w \in \mathcal{W}(\bar{v})} |b_j(w)| / \|Xb(w)\|_2^2, \ j \in S_0.$$

7.2. Projections

We denote the projection of X_{-S_0} on the space spanned by the columns of X_{S_0} by $X_{-S_0} \mathrm{P} X_{S_0}$. The projection is always defined but as it is implicitly assumed that $X_{S_0}^T X_{S_0}$ is invertible (condition (4)), we can clarify what we mean by projection by writing

$$X_{-S_0} \mathrm{P} X_{S_0} := X_{S_0} (X_{S_0}^T X_{S_0})^{-1} X_{S_0}^T X_{-S_0}.$$

The anti-projection is denoted by

$$X_{-S_0} \mathrm{A} X_{S_0} = X_{-S_0} - X_{-S_0} \mathrm{P} X_{S_0}.$$

We define the matrix

$$\begin{aligned} V_{-S_0,-S_0} &:= \Big(X_{-S_0} \mathrm{A} X_{S_0} \Big)^T \Big(X_{-S_0} \mathrm{A} X_{S_0} \Big) \\ &= X_{-S_0}^T \Big(I - X_{S_0} (X_{S_0}^T X_{S_0})^{-1} X_{S_0}^T \Big) X_{-S_0}, \end{aligned}$$

and let $\{v_j^2\}_{j \notin S_0}$ be the diagonal elements of this matrix.

7.3. A Lower Bound

The main result for the noisy case is presented in the next theorem. Here, we use the notations and definitions of the previous two subsections.

Theorem 17 *Take for some* $t > 0$,

$$\lambda > \|v_{-S_0}\|_\infty \sqrt{2(\log(2p) + t)}. \tag{11}$$

Define

$$\bar{v}_j := v_j \sqrt{2(\log(2p) + t)}/\lambda, \ j \notin S_0$$

and

$$\bar{u}_j := u_j \sqrt{2(\log(2p) + t)}/\lambda, \ j \in S_0.$$

where $\{u_j\}_{j \in S_0}$ *are the diagonal elements of the matrix* $(X_{S_0}^T X_{S_0})^{-1}$. *Assume that* $\hat{\kappa}(1 + \bar{v}, S_0) > 0$ *and that the following betamin condition holds:*

$$|\beta_j^0| > \lambda(\mathbf{b}_j(\bar{v}) + \bar{u}_j), \ \mathrm{sign}(\beta_j^0) = z_j^*(\bar{v}) \ \forall j \in S_0.$$

Then for all $x > 0$ *with probability at least* $1 - \exp[-t] - \exp[-x]$ *there is a solution* $\hat{\beta}$ *of the KKT conditions such that*

$$\|X(\hat{\beta} - \beta^0)\|_2 \geq \sqrt{\frac{s_0}{\hat{\kappa}^2(1+\bar{v}, S_0)}} \sqrt{\frac{\lambda^2}{n}} - \sqrt{s_0} - \sqrt{2x}. \tag{12}$$

Note that for $j \in S_0$, the quantity u_j is the variance of the ordinary least squares estimator of β_j^0 for the case S_0 is known. Thus the betamin condition of Theorem 17 needs that the magnitude of the active coefficients should exceed the noise level of the ordinary least squares estimator for known S_0.

8. Comparison with the Noiseless Lasso when the Design is Fixed

This section studies the case of fixed design and compares the noisy Lasso

$$\hat{\beta} := \arg\min_{b \in \mathbb{R}^p} \left\{ \|Y - Xb\|_2^2 + 2\lambda \|b\|_1 \right\}$$

with the noiseless Lasso

$$\beta^* := \arg\min_{b \in \mathbb{R}^p} \left\{ \|X(b - \beta^0)\|_2^2 + 2\lambda^* \|b\|_1 \right\}$$

where $\lambda^* \leq \lambda$. We let S_* be active set of β^* and its cardinality $s_* := |S_*|$. We investigate the error $\|X(\hat{\beta} - \beta^*)\|_2$ in Theorem 18. For $\lambda^* = 0$ we see that $\beta^* = \beta^0$ and then Theorem 18 gives a bound for $\|X(\hat{\beta} - \beta^0)\|_2$. This is elaborated upon in Corollary 19. The case $\lambda^* = \lambda$ is detailed in Corollary 20. The error $\|X(\hat{\beta} - \beta^*)\|_2^2$ can then seen as "variance" and $\|X(\beta^* - \beta^0)\|_2$ as "bias".

8.1. Projections

We now introduce some notations and definitions similar to the ones in Subsections 7.2, now for general S instead of just $S = S_0$. The projection of X_{-S} on the space spanned by the columns of X_S is denoted by $X_{-S}\mathrm{P}X_S$. Recall that such projections are defined, also if X_S does not have full column rank. The anti-projection is

$$X_{-S}\mathrm{A}X_S := X_{-S} - X_{-S}\mathrm{P}X_S.$$

Define the matrix

$$V^S_{-S,-S} := \left(X_{-S}\mathrm{A}X_S \right)^T \left(X_{-S}\mathrm{A}X_S \right)$$

and let $\{(v_j^S)^2\}_{j \notin S}$ be the diagonal elements of this matrix.

8.2. Upper Bound

Recall the KKT conditions for β^* as given in (6), involving the vector ζ^* in the sub-differential $\partial \|\beta^*\|_1$.

Theorem 18 *Fix a set S with cardinality $|S| = s$. Assume that that for some $t > 0$*

$$\lambda > \|v^S_{-S}\|_\infty \sqrt{2(\log(2p) + t)} \tag{13}$$

and write

$$\bar{v}_j^S := v_j^S \sqrt{2(\log(2p) + t)}/\lambda, \ j \notin S. \tag{14}$$

Suppose that

$$\lambda^* |\zeta_j^*|/\lambda < 1 - \bar{v}_j^S \ \forall \ j \notin S.$$

Define

$$\bar{w}_j^S := \frac{1 - \bar{v}_j^S - \lambda^* |\zeta_j^*|/\lambda}{1 - \lambda^*/\lambda}, \ j \notin S.$$

We have for all x with probability at least $1 - \exp[-t] - \exp[-x]$

$$\|X(\hat{\beta} - \beta^*)\|_2 \leq \sqrt{\frac{s}{\hat{\kappa}^2(\bar{w}^S, S)}} \sqrt{\frac{(\lambda - \lambda^*)^2}{n}} + \sqrt{s} + \sqrt{2x}. \tag{15}$$

Corollary 19 *If we take the tuning parameter λ^* of the noiseless Lasso equal to zero, Theorem 18 gives the following: with probability at least $1 - \exp[-t] - \exp[-x]$*

$$\|X(\hat{\beta} - \beta^0)\|_2 \leq \sqrt{s_0/\hat{\kappa}^2(1 - \bar{v}, S_0)} \sqrt{\lambda^2/n} + \sqrt{s_0} + \sqrt{2x}.$$

This result is comparable to results in Sun and Zhang (2012), Belloni and Wang (2014) and Dalalyan et al. (2017), albeit that we do not deal with the extension to the approximately sparse case. One may check that the the combined conclusions of this corollary with that of Theorem 17 also hold with probability at least $1 - \exp[-t] - \exp[-x]$.

Corollary 20 *We can also take $\lambda^* = \lambda$ in Theorem 18. We then formally put $\bar{w}_j^S = \infty$ for all $j \notin S$ and we put $\hat{\kappa}(\bar{w}) = \infty$ as well. Let S with $|S| = s$. Assume that*

$$|\zeta_j^*| < 1 - \bar{v}_j^S \ \forall \ j \notin S \tag{16}$$

(this implies $S \supset S_*$). We have with probability at least $1 - \exp[-t] - \exp[-x]$

$$\|X(\hat{\beta} - \beta^*)\|_2 \leq \sqrt{s} + \sqrt{2x}.$$

This result is as in van de Geer (2016), Problem 2.4.

Corollary 20 is of interest only when $\sqrt{s}$ is small enough This is the case if $\hat{\Sigma} := X^T X/n$ has a well behaved maximal eigenvalue $\hat{\Lambda}^2_{\max}$. Indeed, one can show in the same way as in Lemma 24 (where $\hat{\Sigma}$ is replaced by Σ_0) that

$$s \leq \left(\frac{\hat{\Lambda}^2_{\max}}{(1 - \|\bar{v}^S\|_\infty)^2} \right) \frac{n}{\lambda^2} \|X(\beta^* - \beta^0)\|_2^2.$$

Thus if $\hat{\Lambda}^2_{\max}/(\|\hat{\Sigma}\|_\infty (1 - \|\bar{v}^S\|_\infty)^2) = o(\log(2p))$, then $s = o(\|X(\beta^* - \beta^0)\|_2^2)$. However, for the case of fixed design, one might not want to impose such eigenvalue conditions. Alternatively, one may want to resort to irrepresentable conditions. To this end, fix a set $S \supset S_0$. Let for $j \notin S$, the projection of the j^{th} column X_j on X_S be denoted by

$$X_j \mathrm{P} X_S := X_S \gamma_{S,j}.$$

Then it is not difficult to see that for $j \notin S$ $|\zeta_j^*| \leq \|\gamma_{S,j}\|_1$. In other words, a sufficient condition for (16) to hold is the irrepresentable condition

$$\|\gamma_{S,j}\|_1 \leq 1 - \bar{v}_j^S, \ \forall j \notin S.$$

We conclude that under irrepresentable conditions the squared "bias" $\|X(\beta^* - \beta^0)\|_2^2$ dominates the "variance" $\|X(\hat{\beta} - \beta^*)\|_2^2$.

9. The Total Variation Penalty in the Noisy Case

We continue with the total variation penalty of Section 6, but now in a noisy setting:

$$Y = f^0 + \epsilon,$$

where $f^0 \in \mathbb{R}^n$ is an unknown vector. The least squares estimator with total variation penalty is

$$\hat{f} \in \arg\min_{f \in \mathbb{R}^n} \Big\{ \|Y - f\|_2^2 + 2\lambda \mathrm{TV}(f) \Big\}. \tag{17}$$

As has become clear from the previous sections, to assess the prediction error in the noisy case one needs to evaluate the compatibility constant $\hat{\kappa}(w, S)$ with weights $w_j \neq 1$ for $j \notin S$. For the upper bound on the prediction error, we need lower bounds on $\hat{\kappa}(w, S)$. These are derived in Dalalyan et al. (2017), Proposition 2. We re-derive (and slightly improve) their result using a different proof (the proof in Dalalyan et al., 2017 applies a probabilistic argument).

Suppose as in Section 6 that the locations of the jumps are $S := \{d_1+1, d_1+d_2+1, \ldots, d_1+\cdots+d_s+1\}$ for some $\{d_j\}_{j=1}^s \subset \{2, \ldots, n\}$ satisfying $\sum_{j=1}^s d_j + 2 < n$. Let $d_{s+1} := n - \sum_{j=1}^s d_j$. Assume again for simplicity that d_j is even for all $j \in \{2, \ldots, s\}$.

Lemma 21 *Let $w_1, \ldots, w_n$ be non-negative weights. We have*

$$\frac{\sqrt{s+1}}{\hat{\kappa}(w, S)} \leq \|w\|_\infty \frac{\sqrt{s+1}}{\hat{\kappa}(S)} + \sqrt{n \sum_{i=2}^n (w_i - w_{i-1})^2},$$

where as in Theorem 15

$$\frac{s+1}{\hat{\kappa}^2(S)} = \frac{n}{d_1} + \sum_{j=2}^s \frac{4n}{d_j} + \frac{n}{d_{s+1}}.$$

Corollary 22 *Using the notation of Section 8 suppose that λ satisfies (13) with and let $\bar{v} = \bar{v}^{S_0}$ be given in (14), both with $S := S_0$. Define $\bar{v}_i = 0$ for all $i \in S_0$. We then have with $w_i := 1 - \bar{v}_i$, $j \notin S_0 \cup \{1\}$, $w_1 = w_2$ and $w_i = 1$, $i \in S_0$ that*

$$|w_i - w_{i-1}| \leq |v_i - v_{i-1}| / \|v\|_\infty, \quad i = \{2, \ldots, n\}.$$

In Dalalyan et al. (2017) it is shown in their Proposition 3 that

$$\sum_{i=2}^n (v_i - v_{i-1})^2 / \|v\|_\infty^2 \leq (s_0+1) \log n / n.$$

Hence one obtains from Lemma 21 with $S = S_0$, combined with Corollary 19,

$$\frac{\sqrt{s_0+1}}{\hat{\kappa}(1-\bar{v}, S_0)} \leq \sqrt{\frac{s_0+1}{\hat{\kappa}(S_0)}} + \sqrt{(s_0+1)\log n}$$

where as before

$$\frac{s_0+1}{\hat{\kappa}^2(S_0)} = \frac{n}{d_1} + \sum_{j=2}^{s_0} \frac{4n}{d_j} + \frac{n}{d_{s_0+1}}.$$

Thus, with probability at least $1 - \exp[-t] - \exp[-x]$

$$\|\hat{f} - f^0\|_2 \leq \lambda \Big(\sqrt{\frac{(s_0+1)}{n\hat{\kappa}^2(S_0)}} + \sqrt{\frac{(s_0+1)\log n}{n}} \Big) + \sqrt{s_0} + \sqrt{2x}.$$

Theorem 15 implies that

$$\hat{\kappa}(1+\bar{v}, S_0) \leq \hat{\kappa}(S_0).$$

Recall that for the combined conclusion of Theorem 17 and Corollary 19 we do not have to change the confidence level (which is $1 - \exp[-t] - \exp[-x]$). We therefore obtain that if the jumps of f^0 are sufficiently large in absolute value, as given in Theorem 17, then with probability at least $1 - \exp[-t] - \exp[-x]$

$$\begin{aligned} \lambda \sqrt{\frac{s_0+1}{n\hat{\kappa}^2(S_0)}} - \sqrt{s_0} - \sqrt{2x} \quad &\leq \quad \|\hat{f} - f^0\|_2 \leq \lambda \sqrt{\frac{s_0+1}{n\hat{\kappa}^2(S_0)}} + \sqrt{s_0} + \sqrt{2x} \\ &+ \quad \lambda \sqrt{\frac{(s_0+1)\log n}{n}}. \end{aligned}$$

10. Conclusion

This paper establishes that in a sense the squared "bias" of the Lasso dominates the "variance". Moreover, lower bounds for the prediction error are given. These lower bounds often match up to constants or logarithmic factors the upper bounds, or are in fact tight up to smaller order terms. The bounds show that compatibility constants necessarily enter into the picture. The lower bounds require "betamin" conditions, and - for the case of random design - also certain sparsity conditions. It is as yet unclear what can be said when betamin conditions fail to hold. In combination with this, it would also be of great interest to know what happens when the regression coefficients are not (approximately) sparse. The question to what extent the Lasso will have large prediction error when sparseness assumptions are violated (i.e. when the Lasso is used in a scenario not meant for it) still has some open ends.

11. Proofs

11.1. Proofs of the Lemmas in Section 3

Proof of Lemma 5. We have to show that $\hat{\kappa}^2(u, S) \geq \hat{\phi}^2(u, S)$. Write

$$A := \Big\{ b : \ \|b_{-S}\|_1 \leq \|b_S\|_1 / u, \ \|b_S\|_1 > 0 \Big\}$$

and

$$B := \Big\{ b : \ \|b_S\|_1 - u\|b_{-S}\|_1 > 0 \Big\}.$$

Then

$$B \subset A.$$

Thus

$$\begin{aligned} \hat{\phi}^2(u,S) &= \min\Big\{ \frac{|S|\|Xb\|_2^2/n}{\|b_S\|_1^2} : \ b \in A \Big\} \\ &\leq \min\Big\{ \frac{|S|\|Xb\|_2^2/n}{\|b_S\|_1^2} : \ b \in B \Big\} \\ &= \hat{\kappa}^2(u,S). \end{aligned}$$

□

Proof of Lemma 6. This lemma bounds the ℓ_1-norm of the minimizer b^* if there is a little room to spare. We have

$$\begin{aligned} \|b_S^*\|_1 - u\|b_{-S}^*\|_1 &\leq \sqrt{|S|/n}\|Xb^*\|_2/\hat{\kappa}(u,S) \\ &= \hat{\kappa}(S)/\hat{\kappa}(u,S). \end{aligned}$$

On the other hand

$$\begin{aligned} \|b_S^*\|_1 - u\|b_{-S}^*\|_1 &= \|b_S^*\|_1 - \|b_{-S}^*\|_1 + (1-u)\|b_{-S}^*\|_1 \\ &= 1 + (1-u)\|b_{-S}^*\|_1. \end{aligned}$$

Thus

$$\|b_{-S}^*\|_1 \leq \frac{\hat{\kappa}(S) - \hat{\kappa}(u,S)}{(1-u)\hat{\kappa}(u,S)},$$

yielding

$$\|b_S^*\|_1 = 1 + \|b_{-S}^*\|_1 \leq \frac{\hat{\kappa}(S) - u\hat{\kappa}(u,S)}{(1-u)\hat{\kappa}(u,S)}.$$

□

Proof of Lemma 7. This lemma shows that one has a bound for the ℓ_1-norm in the "cone condition" if there is a little room to spare. Consider a vector $b \in \mathbb{R}^p$ satisfying

$$\|b_S\|_1 - v\|b_{-S}\|_1 = 1.$$

Since

$$\|b_S\|_1 - v\|b_{-S}\|_1 = \|b_S\|_1 - u\|b_{-S}\|_1 - (v-u)\|b_{-S}\|_1$$

we obtain

$$(v-u)\|b_{-S}\|_1 = \|b_S\|_1 - u\|b_{-S}\|_1 - 1 \leq \|b_S\|_1 - u\|b_{-S}\|_1.$$

Moreover, clearly

$$\|b_S\|_1 - u\|b_{-S}\|_1 = (v-u)\|b_{-S}\|_1 + 1 \geq 1.$$

It follows that

$$\min\Big\{ \|Xb\|_2 : \ \|b_S\|_1 - v\|b_{-S}\|_1 = 1 \Big\}$$

$$\geq \min\Big\{ \|Xb\|_2 : \ (v-u)\|b_{-S}\|_1 \leq \|b_S\|_1 - u\|b_{-S}\|_1, \ \|b_S\|_1 - u\|b_{-S}\|_1 \geq 1 \Big\}.$$

Suppose now that for some $c > 1$

$$(v-u)\|b_{-S}\|_1 \leq \|b_S\|_1 - u\|b_{-S}\|_1, \ \|b_S\|_1 - u\|b_{-S}\|_1 = c.$$

Define

$$\tilde{b} := b/c.$$

Then

$$(v-u)\|\tilde{b}_{-S}\|_1 \leq 1, \ \|\tilde{b}_S\|_1 - u\|\tilde{b}_{-S}\|_1 = 1.$$

Moreover

$$\|Xb\|_2 = c\|X\tilde{b}\|_2 > \|X\tilde{b}\|_2.$$

Therefore

$$\begin{aligned} &\min\Big\{ \|Xb\|_2 : \ (v-u)\|b_{-S}\|_1 \leq \|b_S\|_1 - u\|b_{-S}\|_1, \ \|b_S\|_1 - u\|b_{-S}\|_1 \geq 1 \Big\} \\ = \ &\min\Big\{ \|Xb\|_2 : \ (v-u)\|b_{-S}\|_1 \leq 1, \ \|b_S\|_1 - u\|b_{-S}\|_1 = 1 \Big\}. \end{aligned}$$

But if $(v-u)\|b_{-S}\|_1 \leq 1$ and $\|b_S\|_1 - u\|b_{-S}\|_1 = 1$ we see that

$$\begin{aligned} \|b\|_1 &\leq \|b_S\|_1 + \|b_{-S}\|_1 = 1 + (1+u)\|b_{-S}\|_1 \\ &\leq 1 + (1+u)/(v-u). \end{aligned}$$

□

Proof of Lemma 8. This lemma lower bounds the empirical compatibility constant by the theoretical one. Here is a proof. If $\|b_S\|_1 - u\|b_{-S}\|_1 = 1$ we know that

$$1 \leq \|\Sigma_0^{1/2} b\|_2 \sqrt{s}/\kappa(u,S).$$

It therefore follows from Lemma 7 that

$$\hat{\kappa}^2(v,S) \geq \Big\{ |S|\|Xb\|_2^2/n : \ \|b_S\|_1 - u\|b_{-S}\|_1 = 1, \ \|b\|_1 \leq M(u,v)\|\Sigma_0^{1/2} b\|_2 \Big\}$$

where

$$M(u,v) := (1 + (1+u)/(v-u))\sqrt{s}/\kappa(u,S) = o(\sqrt{n/(\|\Sigma_0\|_\infty \log(2p))}).$$

In view of Lemma 45 we know that when $M = o(\sqrt{n/(\|\Sigma_0\|_\infty \log(2p))})$, then with probability tending to one

$$\inf_{\|b\|_1 \leq M\|\Sigma_0^{1/2} b\|_2} \frac{\|Xb\|_2^2/n}{\|\Sigma_0^{1/2} b\|_2^2} \geq (1 - \eta_M)^2$$

for suitable $\eta_M = o(1)$. Hence with probability tending to one

$$\min\Big\{\|Xb\|_2^2/n:\ \|b_S\|_1 - u\|b_{-S}\|_1 = 1,\ \|b\|_1 \le M(u,v)\|\Sigma_0^{1/2}b\|_2\Big\}$$

$$\ge (1-\eta_{M(u,v)})^2 \min\Big\{\|\Sigma_0^{1/2}b\|_2^2:\ \|b_S\|_1 - u\|b_{-S}\|_1 = 1\Big\} = (1-\eta_{M(u,v)})^2\kappa^2(u,S).$$

□

11.2. Proof of Theorem 9

The proof is organized as follows. We first present a bound for $\|\Sigma_0(\beta^* - \beta_0)\|_2$ in Lemma 23. This will be used to bound later the number of active variables s_* of β^*, or rather some extended version of it involving sub-differential calculus, see Lemma 24. We then establish in Lemma 25 a deterministic bound assuming we are on some subset of the underlying probability space. Then in Lemma 26 we show that this subset has large probability.

The noiseless Lasso β^* given in (2) satisfies the KKT conditions

$$n\Sigma_0(\beta^* - \beta^0) + \lambda\zeta^* = 0,\ \zeta^* \in \partial\|\beta^*\|_1, \tag{18}$$

where $\partial\|b\|_1$ is the sub-differential of $b \mapsto \|b\|_1$:

$$\partial\|b\|_1 := \Big\{z:\ \|z\|_\infty \le 1,\ z^T b = \|b\|_1\Big\}.$$

This will be used in Lemma 24 and again in Lemma 25. In the latter we also invoke the KKT conditions for $\hat\beta$

$$X^T X(\hat\beta - \beta^0) + \lambda\hat\zeta = X^T\epsilon,\ \hat\zeta \in \partial\|\hat\beta\|_1. \tag{19}$$

11.2.1. A Bound for the Number of Active Variables of β^*

First we bound the prediction error of β^*.

Lemma 23 *Suppose $\kappa^2(S_0) > 0$. Then*

$$n\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2^2 \le \frac{s_0}{\kappa^2(S_0)}\frac{\lambda^2}{n}.$$

Proof of Lemma 23. This follows from results in the literature and also from a slight adjustment of Theorem 18 in this paper. Let us present a self-contained proof as well. By the KKT conditions (18)

$$-(\beta^* - \beta^0)^T\zeta^* \le \|\beta^0\|_1 - \|\beta^*\|_1 \le \|\beta^*_{S_0} - \beta^0\|_1 - \|\beta^*_{-S_0}\|_1.$$

So if $\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2^2 > 0$ we obtain by the definition of the compatibility constant $\kappa^2(S_0)$ that

$$n\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2^2 \le \lambda\sqrt{s_0}\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2/\kappa(S_0).$$

This yields the result of the lemma. □

Consider the set $S_* := \{\beta_j^* \ne 0\}$ of active coefficients of β^*. We bound the size of this set. In fact we look at bound for the size of a potentially larger set, namely the set $S_*(\nu) := \{j : |\zeta_j^*| \ge 1-\nu\}$ where $0 \le \nu < 1$ is arbitrary. Note that indeed $S_* \subset S_*(\nu)$. We pin down the value of ν to $\nu = 1/2$ but the argument goes through for other values if one adjusts the constants accordingly. We still keep the symbol ν at places to facilitate tracking the constants.

Lemma 24 *We have that*

$$|S_*(\nu)| \le \frac{\Lambda_{\max}^2}{(1-\nu)^2}\frac{n^2}{\lambda^2}\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2^2 \le \frac{\Lambda_{\max}^2}{(1-\nu)^2}\frac{s_0}{\kappa^2(S_0)}.$$

Proof of Lemma 24. Since

$$\|\zeta^*\|_2^2 \ge \|\zeta^*_{S_*(\nu)}\|_2^2 \ge (1-\nu)^2|S_*(\nu)|$$

it follows from the KKT conditions (18) that

$$(1-\nu)^2|S_*(\nu)| \le \|\Sigma_0(\beta^* - \beta^0)\|_2^2\frac{n^2}{\lambda^2} \le \Lambda_{\max}^2\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2^2\frac{n^2}{\lambda^2}.$$

The proof is completed by applying the upper bound of Lemma 23

$$\|\Sigma_0^{1/2}(\beta^* - \beta^0)\|_2^2 \le \frac{s_0}{\kappa^2(S_0)}\frac{\lambda^2}{n^2}.$$

□

11.2.2. Projections

Let $S := S_*(\nu)$, $s := |S|$ (where $\nu = 1/2$). Set

$$\mathbf{U}(S) := \|\epsilon \mathrm{P} X_S\|_2$$

where $\epsilon \mathrm{P} X_S$ is the projection of ϵ on the space spanned by the columns of X_S. Denote the anti-projection of X_{-S} on this space by

$$X_{-S}\mathrm{A}X_S := X_{-S} - X_{-S}\mathrm{P}X_S.$$

11.2.3. Choice of λ

Recall we take for some $t > 0$

$$\lambda \ge 3\|\Sigma_0\|_\infty^{1/2}\Big(\sqrt{2(\log(2p)+t)} + 2(\log(2p)+t)\Big).$$

11.2.4. The Sets $\mathcal{T}_1$, $\mathcal{T}_2$ and $\mathcal{T}_3$

Write

$$v_0 := \|\Sigma_0\|_\infty^{1/2}\Big(\sqrt{2n(\log(2p)+t)}+2(\log(2p)+t)\Big)/\lambda.$$

We now define a suitable subset of the underlying probability space, on which we can derive the searched for inequality. This subset will be the intersection of the following sets:

$$\begin{aligned}
\mathcal{T}_1 &:= \Big\{\|(X_{-S}\mathrm{A}X_S)^T\epsilon\|_\infty \le \lambda v_0,\ \mathbf{U}(S)\le \sqrt{s}+\sqrt{2x}\Big\},\\
\mathcal{T}_2 &:= \Big\{\ \|(X^TX-n\Sigma_0)(\beta^*-\beta^0)\|_\infty \le \lambda\delta\Big\},\\
\mathcal{T}_3 &:= \Big\{\hat\kappa^2((v-v_0-\delta)/\delta,S)\ge(1-\eta)^2\kappa^2(S)\Big\},
\end{aligned}$$

where $x>0$ is arbitrary, $\delta := \|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2$, and where $\eta\in(0,1)$ is arbitrary. We pin down η to $\eta=1/2$ like we did with ν. We require that $\nu-v_0-2\delta>0$. Since $\nu=1/2$ and $v_0\le 1/3$ this is the case for $\delta\le 1/(12)$. In view of Lemma 23, Theorem 9 is about the case $\delta=o(1)$, so $\delta\le 1/(12)$ will be true for n sufficiently large.

11.2.5. Deterministic Part

Lemma 25 *On $\mathcal{T}_1\cap\mathcal{T}_2\cap\mathcal{T}_3$ it holds that*

$$\|X(\hat\beta-\beta^*)\|_2 \le \left(\frac{\Lambda_{\max}}{(1-\nu)}\frac{\sqrt{n}}{\lambda}+\sqrt{\frac{s}{\kappa^2(S)}}\frac{\lambda}{(1-\eta)n}\right)\sqrt{n}\delta+\sqrt{2x}.$$

Proof of Lemma 25. The KKT conditions (18) and (19), for β^* and $\hat\beta$ respectively, are

$$X^TX(\beta^*-\beta^0)+\lambda\zeta^* = Z,$$

with $Z := (X^TX-n\Sigma_0)(\beta^*-\beta^0)$, and

$$X^TX(\hat\beta-\beta^0)+\lambda\hat\zeta = X^T\epsilon.$$

So subtracting the first from the second

$$X^TX(\hat\beta-\beta^*)+\lambda\hat\zeta-\lambda\zeta^* = X^T\epsilon - Z.$$

Multiplying with $\hat\beta-\beta^*$ yields

$$\|X(\hat\beta-\beta^*)\|_2^2+\lambda(\hat\beta-\beta^*)^T(\hat\zeta-\zeta^*) = (\hat\beta-\beta^*)^T(X^T\epsilon-Z). \tag{20}$$

We write (as in the proof of Theorem 18 ahead) with $S:=S_*(\nu)$, $s:=|S|$,

$$X_S\hat b_S := X_S(\hat\beta_S-\beta_S^*)+(X_{-S}\mathrm{P}X_S)\hat\beta_{-S}.$$

Since $|\zeta_j^*|\le 1-\nu<1$ for all $j\notin S$, it must be true that $\beta^*_{-S}=0$. Therefore

$$X(\hat\beta-\beta^*) = X_S\hat b_S+(X_{-S}\mathrm{A}X_S)\hat\beta_{-S}.$$

So

$$(\hat\beta-\beta^*)^TX^T\epsilon = \hat b_S^TX_S^T\epsilon+\hat\beta_{-S}^T(X_{-S}\mathrm{A}X_S)^T\epsilon.$$

We use that (on $\mathcal{T}_1$)

$$\begin{aligned}
\hat b_S^TX_S^T\epsilon &\le \mathbf{U}(S)\|X_S\hat b_S\|_2\\
&\le \mathbf{U}(S)\|X(\hat\beta-\beta^*)\|_2\\
&\le (\sqrt{s}+\sqrt{2x})\|X(\hat\beta-\beta^*)\|_2
\end{aligned}$$

and

$$\hat\beta_{-S}^T(X_{-S}\mathrm{A}X_S)^T\epsilon \le \|\hat\beta_{-S}\|_1\|(X_{-S}\mathrm{A}X_S)^T\epsilon\|_\infty \le \lambda v_0\|\hat\beta_{-S}\|_1.$$

Moreover (on $\mathcal{T}_2$)

$$-(\hat\beta-\beta^*)^TZ \le \|\hat\beta-\beta^*\|_1\|Z\|_\infty \le \lambda\delta\|\hat\beta-\beta^*\|_1.$$

Then

$$\begin{aligned}
(\hat\beta-\beta^*)^T(\zeta^*-\hat\zeta) &= \hat\beta^T\zeta^*-\beta^{*T}\zeta^*+\beta^{*T}\hat\zeta-\hat\beta^T\hat\zeta\\
&= \hat\beta^T\zeta^*-\|\beta^*\|_1+\beta^{*T}\hat\zeta-\|\hat\beta\|_1\\
&\le \|\hat\beta_S\|_1-\|\beta_S^*\|_1+\|\beta_S^*\|_1-\|\hat\beta_S\|_1\\
&+ \hat\beta_{-S}^T\zeta^*_{-S}-\|\hat\beta_S\|_1\\
&= \hat\beta_{-S}^T\zeta^*_{-S}-\|\hat\beta_S\|_1\\
&\le (1-\nu)\|\hat\beta_{-S}\|_1-\|\hat\beta_{-S}\|_1\\
&= -\nu\|\hat\beta_{-S}\|_1.
\end{aligned}$$

Inserting these bounds in (20) gives

$$\|X(\hat\beta-\beta^*)\|_2^2+\lambda(\nu-v_0-\delta)\|\hat\beta_{-S}\|_1 \le (\sqrt{s}+\sqrt{2x})\|X(\hat\beta-\beta^*)\|_2+\lambda\delta\|\hat\beta_S-\beta_S^*\|_1.$$

If

$$\|X(\hat\beta-\beta^*)\|_2 \le (\sqrt{s}+\sqrt{2x})$$

we are done as by Lemma 24, $\sqrt{s}\le\Lambda_{\max}\delta n/((1-\nu)\lambda)$. If

$$\|X(\hat\beta-\beta^*)\|_2 > (\sqrt{s}+\sqrt{2x})$$

we get

$$(\nu-v_0-\delta)\|\hat\beta_{-S}\|_1 < \delta\|\hat\beta_S-\beta_S^*\|_1$$

or

$$\|\hat\beta_S-\beta^*\|_1-((\nu-v_0-\delta)/\delta)\|\hat\beta_{-S}\|_1 > 0.$$

But (on $\mathcal{T}_3$)

$$\begin{aligned} & \|\hat\beta_S-\beta^*_S\|_1-((\nu-v_0-\delta)/\delta)\|\hat\beta_{-S}\|_1 \\ \leq & \frac{\sqrt{s}\|X(\hat\beta-\beta^*)\|_2}{\sqrt{n}\hat\kappa((\nu-v_0-\delta)/\delta),S)} \\ \leq & \frac{\sqrt{s}\|X(\hat\beta-\beta^*)\|_2}{\sqrt{n}\kappa(S)(1-\eta)}. \end{aligned}$$

This gives

$$\|X(\hat\beta-\beta^*)\|_2\leq\sqrt{s}+\sqrt{2x}+\lambda\delta\sqrt{s}/(\sqrt{n}\kappa(S)(1-\eta)).$$

Again, by Lemma 24, $\sqrt{s}\leq\Lambda_{\max}\delta n/((1-\nu)\lambda)$. We see that

$$\|X(\hat\beta-\beta^*)\|_2\leq\left(\frac{\Lambda_{\max}}{(1-\nu)}\frac{\sqrt{n}}{\lambda}+\frac{\sqrt{s}}{\kappa(S)(1-\eta)}\frac{\lambda}{(1-\eta)n}\right)\sqrt{n}\delta+\sqrt{2x}.$$

□

11.2.6. Random Part

We apply the tools of Section 12.

Lemma 26 *It holds that*

$$\mathbb{P}\left(\mathcal{T}_1\cap\mathcal{T}_2\cap\mathcal{T}_3\right)\geq 1-4\exp[-t]-\exp[-x]-o(1).$$

Proof of Lemma 26 . We first show that $\mathbb{P}(\mathcal{T}_1)\geq 1-2\exp[-t]-\exp[-x]$. One component of this is to show that with probability at least $1-2\exp[-t]$

$$\|(X_{-S}\mathrm{A}X_S)^T\epsilon\|_\infty\leq\lambda v_0.$$

For a square matrix B, let $\mathrm{diag}(B)$ be its diagonal. By Lemma 41 we know that with probability at least $1-\exp[-t]$

$$\|(X_{-S}\mathrm{A}X_S)^T\epsilon\|_\infty\leq\|\mathrm{diag}((X_{-S}\mathrm{A}X_S)^T(X_{-S}\mathrm{A}X_S))\|_\infty^{1/2}\sqrt{2(\log(2p)+t)}.$$

But

$$\|\mathrm{diag}((X_{-S}\mathrm{A}X_S)^T(X_{-S}\mathrm{A}X_S))\|_\infty\leq\|\mathrm{diag}(X^TX)\|_\infty.$$

Moreover in view of Lemma 42, and using the union bound, with probability at least $1-\exp[-t]$

$$\left|\|\mathrm{diag}(X^TX)\|_\infty^{1/2}-\sqrt{n}\|\mathrm{diag}(\Sigma_0)\|_\infty^{1/2}\right|\leq\|\Sigma_0\|_\infty^{1/2}\sqrt{2(\log(2p)+t)}.$$

So with probability at least $1-2\exp[-t]$

$$\|(X_{-S}\mathrm{A}X_S)^T\epsilon\|_\infty\leq\|\Sigma_0\|_\infty^{1/2}\left(\sqrt{2n(\log(2p)+t)}+2(\log(2p)+t)\right)\leq\lambda v_0.$$

The second component is to show that

$$\mathbb{P}(\mathbf{U}(S)\leq\sqrt{s}+\sqrt{2x})\leq\exp[-x],$$

but this follows immediately from Lemma 42.

Next we show that $\mathbb{P}(\mathcal{T}_2)\leq 2\exp[-t]$. Set $Z:=(X^TX-n\Sigma_0)(\beta^*-\beta^0)$. Clearly $X(\beta^*-\beta^0)$ is a Gaussian vector with i.i.d. entries with mean zero and variance $\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2^2$. Hence, applying Lemma 43 with $\sigma_u^2\leq\|\Sigma_0\|_\infty$, $\sigma_v^2=\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2^2$ and using the union bound, we obtain that with probability at least $1-2\exp[-t]$

$$\|Z\|_\infty\leq 3\|\Sigma_0\|_\infty^{1/2}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2\left(\sqrt{2n(\log(2p)+t}+\log(2p)+t\right).$$

Finally, the result $\mathbb{P}(\mathcal{T}_3)=1-o(1)$ follows from Lemma 8. □

11.2.7. Collecting the pieces

Combining Lemma 25 with Lemma 26 completes the proof of Theorem 9.

11.3. Proof of Theorems 10 and 11

We use concentration of measure, Lemma 44.

Proof of Theorem 10. Let $m^*:=\mathbb{E}(\|X(\hat\beta-\beta^*)\|_2|X)$. Then we have (by Lemma 44) that with probability at least $1-1/8-3/4-o(1)$

$$\|X(\hat\beta-\beta^*)\|_2\geq m^*-2\sqrt{\log 2}$$

as well as (by Theorem 9),

$$\|X(\hat\beta-\beta^*)\|_2\leq\gamma\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2+2\sqrt{\log 2}.$$

Thus

$$m^*\leq\gamma\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2+4\sqrt{\log 2}.$$

Applying again Lemma 44 we see that

$$\begin{aligned} & \mathbb{P}\left(\|X(\hat\beta-\beta^*)\|\geq\gamma\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2+4\sqrt{\log 2}+\sqrt{2x}\right) \\ & \leq\mathbb{P}\left(\|X(\hat\beta-\beta^*)\|\geq m^*+\sqrt{2x}\right)\leq 2\exp[-x]. \end{aligned}$$

□

Proof of Theorem 11. By the triangle inequality

$$\left|\|X(\hat\beta-\beta^0)\|_2-\|X(\beta^*-\beta^0)\|_2\right|\leq\|X(\hat\beta-\beta^*)\|_2.$$

By Lemma 42, with with probability at least $1-2/n$

$$\left|\|X(\beta^*-\beta^0)\|_2-\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2\right| \leq (\sqrt{2\log n})\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2.$$

So, invoking Theoerem 9, with probability at least $1-4\exp[-t]-\exp[-x]-o(1)-2/n$ (subtracting the term $2/n$ to follow the argument, as of course it can be included in the $o(1)$ term)

$$\left|\|X(\hat\beta-\beta^0)\|_2-\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2\right| \leq (\gamma+\sqrt{2\log n/n})\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2+\sqrt{2x}.$$

Let $m^0:=\mathbb{E}(\|X(\hat\beta-\beta^0)\|_2|X)$. Using the same arguments as in Theorem 10, we arrive at

$$m^0-2\sqrt{\log 2}\leq(1+\gamma+\sqrt{2\log n/n})\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2+2\sqrt{\log 2}$$

and

$$(1-\gamma-\sqrt{2\log n/n})\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2-2\sqrt{\log 2}\leq m^0+2\sqrt{\log 2},$$

or

$$\left|m^0-\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2\right|\leq\left(\gamma+\sqrt{2\log n/n}\right)\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2+4\sqrt{\log 2}.$$

Thus, inserting the triangle inequality,

$$\begin{aligned}&\left|\|X(\hat\beta-\beta^0)\|_2-\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2\right|\\ \leq\ &\left|\|X(\hat\beta-\beta^0)\|_2-m^0\right|+\left|m^0-\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2\right|\\ \leq\ &\left|\|X(\hat\beta-\beta^0)\|_2-m^0\right|+(\gamma+\sqrt{2\log n/n})\sqrt{n}\|\Sigma_0^{1/2}(\beta^*-\beta^0)\|_2+4\sqrt{\log 2}.\end{aligned}$$

Apply Lemma 44 again to finalize the result. □

11.4. Proof of Theorem 14

To establish Theorem 14, we first need to study the minimizer b^* in (7). The minimization

$$\min\left\{\|Xb\|_2^2:\ \|b_S\|_1-\|b_{-S}\|_1=1\right\}$$

has non-convex constraints. If we fix the signs within S of a possible solution b, one can reformulate it as a convex problem with convex constraints. This is done in Lemma 27. We then show that $b_j^*\neq 0$ for all $j\in S$ in Lemma 28. This is important because given the signs within S of a potential solution b, we want the restrictions on these signs to be non-active so that the Lagrangian formulation is of a similar form as the KKT conditions (6) for the noiseless Lasso. This Lagrangian form is then given in Lemma 31 with Lemma 30 serving as a preparation. The Lagrangian form of Lemma 31 with $S=S_0$ in a sense resembles the KKT conditions (6) when the active coefficients in the vector β_S^0 have appropriate signs and $|\beta_j^0|$ is for $j\in S_0$ large enough. This allows one to find a solution β^* of the KKT conditions (6) with the prescribed prediction error.

11.4.1. Non-Sparseness within S

Our first step is to ascertain that a solution

$$b^*\in\arg\min_{b\in\mathbb{R}^p}\left\{\|Xb\|_2:\ \|b_S\|_1-\|b_{-S}\|_1=1\right\}$$

can be found by searching over (at most) $2^{|S|}$ convex problems with convex constraints. This is done in the next lemma, where we also show that the equality constraint $\|b_S\|_1-\|b_{-S}\|_1=1$ can be replaced by an inequality constraint $\|b_S\|_1-\|b_{-S}\|_1\geq 1$.

Lemma 27 *We have*

$$\begin{aligned}&\min\left\{\|Xb\|_2^2:\ \|b_S\|_1-\|b_{-S}\|_1=1\right\}\\ =\ &\min\left\{\|Xb\|_2^2:\ \|b_S\|_1-\|b_{-S}\|_1\geq 1\right\}\\ =\ &\min_{z_S\in\{\pm1\}^{|S|}}\min_b\left\{\|Xb\|_2^2:\ z_S^Tb_S-\|b_{-S}\|_1\geq 1,\ z_jb_j\geq 0\ \forall\ j\in S\right\}.\end{aligned}$$

Proof of Lemma 27. To show that the equality constraint can be turned into an inequality constraint let us consider some $b\in\mathbb{R}^p$ for which it holds that $\|b_S\|_1-\|b_{-S}\|_1=c$, where c is a constant bigger than 1. Let $\tilde b:=b/c$. Then

$$\|\tilde b_S\|_1-\|\tilde b_{-S}\|_1=\left(\|b_S\|_1-\|b_{-S}\|_1\right)/c=1.$$

Moreover

$$\|X\tilde b\|_2=\|Xb\|_2/c<\|Xb\|_2.$$

Thus the first equality of the lemma must be true.

We now show the second equality of the lemma. If for some $z_S\in\{\pm1\}$ it holds that $z_jb_j\geq 0$ for all $j\in S$, we have $z_S^Tb_S=\|b_S\|_1$. Conversely, if we define for $j\in S$ with $b_j\neq 0$, $z_j:=b_j/|b_j|$ as the sign of b_j, and define $z_j\in\{\pm1\}$ arbitrarily for $j\in S$ with $b_j=0$, then we have $z_jb_j\geq 0$ for all $j\in S$. Thus

$$\left\{b:\ \|b_S\|_1-\|b_{-S}\|_1\geq 1\right\}=\cup_{z_S\in\{\pm1\}^{|S|}}\left\{b:\ z_S^Tb_S-\|b_{-S}\|_1\geq 1,\ z_jb_j\geq 0\right\}.$$

□

We establish in the next lemma that sign constraints on b_S^* are not active: b_S^* is so to speak maximally non-sparse. We assume that $\hat\kappa^2(S)>0$, so for $S=S_0$ we implicitly assume Condition 4.

Lemma 28 *Suppose that $\hat\kappa(S)\neq 0$. Then for any minimizer b^* of the problem*

$$\min\left\{\|Xb\|_2:\ \|b_S\|_1-\|b_{-S}\|_1=1\right\}$$

it holds that $b_j^*\neq 0$ for all $j\in S$.

Remark 29 *A (very) special case of Lemma 28 is the minimization problem*

$$\mathrm{b}_S^* \in \arg\min\Big\{\|b_S\|_2^2 :\ \|b_S\|_1 = 1\Big\}.$$

Clearly the solution has $|\mathrm{b}_j^*| = 1/|S| \neq 0$ *for all* $j \in S$*. More generally, for the case without "*b_{-S}*-part" one can apply a geometric argument to show that whenever* $X_S^T X_S$ *is non-singular*

$$\mathrm{b}_S^* \in \arg\min\{\|Xb_S\|_2 :\ \|b_S\|_1 = 1\}$$

must have all its components in S *nonzero.*

Proof of Lemma 28. We use the representation of Lemma 27. Let $z_S^* \in \{\pm 1\}^{|S|}$ satisfy $z_S^{*T} b_S^* = \|b_S^*\|_1$ and $z_j^* b_j^* \geq 0$ for all $j \in S$. Then b^* is a solution of the convex minimization problem with (linear and) convex constraints

$$\min\Big\{\|Xb\|_2^2 :\ z_S^{*T} b_S - \|b_{-S}\|_1 \geq 1, z_j^* b_j \geq 0,\ \forall\, j \in S\Big\}.$$

Note that in the minimization, one may replace the inequality constraint $z_S^{*T} b_S - \|b_{-S}\|_1 \geq 1$ by an inequality constraint $z_S^{*T} b_S - \|b_{-S}\|_1 = 1$. This follows from the same arguments as used in the proof of Lemma 27. A reason to replace the equality constraint by an inequality constraint is that the restrictions become convex.

The solution of the convex problem with convex constraints can be found using Lagrange multipliers $\tilde{\lambda}$ and μ_S, where $\tilde{\lambda} \geq 0$ and where μ_S is an $|S|$-vector with non-negative entries. The Lagrangian formulation is

$$\min\Big\{\|Xb\|_2^2 + 2\tilde{\lambda}\Big(\|b_{-S}\|_1 - z_S^{*T} b_S - 1\Big) - 2\sum_{j\in S} \mu_{j,S} z_j^* b_j\Big\}.$$

Because the inequality constraint can be replaced by an equality constraint, we know that in fact $\tilde{\lambda} > 0$. The Lagrangian formulation has has KKT conditions

$$X^T X b^* = \tilde{\lambda} z^* + \mathrm{diag}(\mu_S) z_S^*,$$

where z_{-S}^* is an element of the sub-differential

$$-\partial\|b_{-S}^*\|_1 = \Big\{z_{-S} :\ \|z_{-S}\|_1 \leq 1,\ z_{-S}^T b_{-s}^* = -\|b_{-S}^*\|_1\Big\}.$$

It follows that for $j \in S$

$$b_j^* \neq 0\ \Rightarrow \mu_{j,S} = 0.$$

Let $\mathcal{N} := \{j \in S :\ b_j^* = 0\}$. Then we have by the above argument

$$(X^T X b^*)_{-\mathcal{N}} = \tilde{\lambda} z_{-\mathcal{N}}^*$$

$$(X^T X b^*)_{\mathcal{N}} = \tilde{\lambda} z_{\mathcal{N}}^* + \mathrm{diag}(\mu_{\mathcal{N}}) z_{\mathcal{N}}^*.$$

The tangent plane of $\{b :\ \|Xb\|_2 = \|Xb^*\|_2\}$ at b^* is

$$\mathcal{U} := \{u = b^* + v :\ v^T X^T X b^* = 0\}.$$

The idea of the proof is now to take an element $u = b^* + tv$ in this tangent plane with $t > 0$ and with $v_j \neq 0$ for at least one $j \in \mathcal{N}$ and such that $v_j \neq 0$ has the same sign as b_j^* for all $j \in S\backslash\mathcal{N}$. For $j \notin S$ we take $v_j = 0$. Then $\tilde{b} := b^* + tv$ has $\|\tilde{b}_S\|_1 - \|\tilde{b}_{-S}\|_1 > 1$ and this leads for a suitable scale t to

$$\frac{\|X\tilde{b}\|_2}{\|\tilde{b}_S\|_1 - \|\tilde{b}_{-S}\|_1} < \|Xb^*\|_2.$$

Let us now work out this idea. It cannot be true that $b_j^* = 0$ for all $j \in S$ as $\|b_S^*\|_1 \geq 1$. Hence $S\backslash\mathcal{N} \neq \emptyset$. Take (for example) $v_j = z_j^*$ for all $j \in S\backslash\mathcal{N}$. Then

$$v_{S\backslash\mathcal{N}}^T z_{S\backslash\mathcal{N}}^* = z_{S\backslash\mathcal{N}}^{*T} z_{S\backslash\mathcal{N}}^* = |S\backslash\mathcal{N}|.$$

Now $\tilde{\lambda} > 0$ and the entries of $\mu_{\mathcal{N}}$ are all positive as well (since $\mu_j = 0$ for some $j \in \mathcal{N}$ would imply $b_j^* = 0$ for this j, which is not possible by the definition of $\mathcal{N}$). Therefore we can choose

$$v_{\mathcal{N}}^T(\tilde{\lambda} z_{\mathcal{N}}^* + \mathrm{diag}(\mu_{\mathcal{N}}) z_{\mathcal{N}}^*) = -\tilde{\lambda}|S\backslash\mathcal{N}|.$$

Then at least one entry of $v_{\mathcal{N}}$ has to be non-zero and moreover

$$\begin{aligned} v^T X^T X b^* &= \tilde{\lambda} v_{S\backslash\mathcal{N}}^T z_{S\backslash\mathcal{N}}^* + v_{\mathcal{N}}^T(\tilde{\lambda} z_{\mathcal{N}}^* + \mathrm{diag}(\mu_{\mathcal{N}}) z_{\mathcal{N}}^*) \\ &= \tilde{\lambda}|S\backslash\mathcal{N}| - \tilde{\lambda}|S\backslash\mathcal{N}| \\ &= 0. \end{aligned}$$

We thus have for all $t > 0$

$$\|X(b^* + tv)\|_2^2 = \|Xb^*\|_2^2 + t^2\|Xv\|_2^2.$$

Moreover

$$\begin{aligned} \|b_S^* + tv_S\|_1 &= \|b_{S\backslash\mathcal{N}}^*\|_1 + t\|v_{S\backslash\mathcal{N}}\|_1 + t\|v_{\mathcal{N}}\|_1 \\ &= \|b_S^*\|_1 + t\|v\|_1. \end{aligned}$$

Therefore

$$\begin{aligned} \|b_S^* + tv_S\|_1 - \|b_{-S}^*\|_1 &= \|b_S^*\|_1 - \|b_{-S}^*\|_1 + t\|v\|_1 \\ &= 1 + t\|v\|_1. \end{aligned}$$

It follows that

$$\begin{aligned} &\frac{\|X(b^* + tv)\|_2^2}{(\|b_S^* + tv_S\|_1 - \|b_{-S}^*\|_1)^2} \\ = \ &\frac{\|Xb^*\|_2^2 + t^2\|Xv\|_2^2}{(1 + t\|v\|_1)^2}. \end{aligned}$$

Define

$$\begin{aligned} \mathrm{A} &:= \|Xb^*\|_2^2 + t^2\|Xv\|_2^2 - \|Xb^*\|_2^2(1+t\|v\|_1)^2 \\ &= t^2\|Xv\|_2^2 - 2t\|Xb^*\|_2^2\|v\|_1 - t^2\|Xb^*\|_2^2\|v\|_1^2 \\ &= t^2(\|Xv\|_2^2 - \|Xb^*\|_2^2\|v\|_1^2) - 2t\|Xb^*\|_2^2\|v\|_1^2. \end{aligned}$$

We will show that for suitable $t > 0$ the constant A is strictly negative. This means

$$\|X(b^* + tv)\|_2^2 < \|Xb^*\|_2^2(\|b^*_S + tv_S\|_1 - \|b^*_{-S}\|_1)^2$$

and so we arrive at a contradiction. To show $\mathrm{A} < 0$ we distinguish two cases. If

$$\|Xv\|_2^2 \leq \|Xb^*\|_2^2\|v\|_1^2$$

then $\mathrm{A} < 0$ for all $t > 0$. If

$$\|Xv\|_2^2 > \|Xb^*\|_2^2\|v\|_1^2$$

then $\mathrm{A} < 0$ for all t satisfying

$$0 < t < \frac{2\|Xb^*\|_2^2\|v\|_1^2}{\|Xv\|_2^2 - \|Xb^*\|_2^2\|v\|_1^2}.$$

Here we used the assumption that $\|Xb^*\|_2^2 > 0$ so that the above right hand side is indeed strictly positive. □

11.4.2. Lagrangian Form

We now present the Lagrangian form given the signs within the set S and given that within the set S the solution has non-zero entries. Let for each $z_S \in \{\pm 1\}^{|S|}$

$$b^*(z_S) \in \arg\min\Big\{ \|Xb\|_2^2 : \ z_S^T b_S - \|b_{-S}\|_1 \geq 1, z_j b_j \geq 0, \ \forall\ j \in S \Big\}.$$

Define

$$\mathcal{Z}_S := \Big\{ z_S \in \{-1,1\}^{|S|} : \ z_j b_j^*(z_S) > 0 \ \forall\ j \in S \Big\}.$$

Lemma 30 *We have for all $z_S \in \mathcal{Z}_S$*

$$X^T X b^*(z_S) = z^*(z_S)\|Xb^*(z_S)\|_2^2$$

where $z_S^*(z_S) = z_S$ and $z^*_{-S}(z_S) \in -\partial\|b^*_{-S}(z_S)\|_1$.

Proof of Lemma 30. To prove this result it is useful to repeat some arguments of the proof of Lemma 28. The convex minimization problem with (linear and) convex constraints

$$\min\Big\{ \|Xb\|_2^2 : \ z_S^T b_S - \|b_{-S}\|_1 \geq 1, z_j b_j \geq 0, \ \forall\ j \in S \Big\}$$

can be solved using Lagrange multipliers $\tilde{\lambda}$ and μ_S, where $\tilde{\lambda} > 0$ and μ_S is an $|S|$-vector with non-negative entries. The Lagrangian formulation is

$$\min\Big\{ \|Xb\|_2^2 + 2\tilde{\lambda}\Big(\|b_{-S}\|_1 - z_S^T b_S - 1 \Big) - 2\sum_{j\in S} \mu_{j,S} z_j b_j \Big\}.$$

This has KKT conditions

$$X^T X b^*(z_S) = \tilde{\lambda} z^* + \mathrm{diag}(\mu_S) z_S,$$

where $z_S^* = z_S$ and $z^*_{-S} = z^*_{-S}(z_S)$ depends on z_S and is an element of the sub-differential

$$-\partial\|b^*_{-S}(z_S)\|_1 = \Big\{ z_{-S} : \ \|z_{-S}\|_\infty \leq 1, \ z_{-S}^T b^*_{-S}(z_S) = -\|b^*_{-S}\|_1 \Big\}.$$

It follows that for $j \in S$

$$b_j^*(z_S) \neq 0 \Rightarrow \mu_{j,S} = 0.$$

The assumption that $z_S \in \mathcal{Z}_S$ thus gives $\mu_S = 0$. The KKT conditions then read

$$X^T X b^*(z_S) = \tilde{\lambda} z^*.$$

One sees that

$$1 = z^{*T} b^*(z_S) = b^{*T}(z_S) X^T X b^*(z_S)/\tilde{\lambda} = \|Xb^*(z_S)\|_2^2/\tilde{\lambda}.$$

This gives

$$\tilde{\lambda} = \|Xb^*(z_S)\|_2^2 \ .$$

□

We apply the above lemma with $z_S := \partial\|b_S^*\|_1$. This gives the following result.

Lemma 31 *Suppose $\hat{\kappa}(S) \neq 0$. Let*

$$b^* \in \arg\min\Big\{ \|Xb\|_2^2 : \ \|b_S\|_1 - \|b_{-S}\|_1 = 1 \Big\}$$

Then

$$X^T X b^* = z^* \|Xb^*\|_2^2.$$

where $z_S^* = \partial\|b_S^*\|_1$ and $z^*_{-S} \in -\partial\|b^*_{-S}\|_1$.

Proof of Lemma 31. By Lemma 28, for each

$$b^* \in \arg\min\Big\{ \|Xb\|_2^2 : \ \|b_S\|_1 - \|b_{-S}\|_1 = 1 \Big\}$$

it holds that $b_j^* \neq 0$ for all $j \in S$. We can therefore define $z_j^* := b_j^*/|b_j^*|$ for all $j \in S$ and then $z_S^* = \partial\|b_S^*\|_1 \in \mathcal{Z}_S$. The result now follows from Lemma 30. □

11.4.3. Finalizing the Proof of Theorem 14

With the help of Lemma 31 we are now in the position to prove Theorem 14.

Proof of Theorem 14. Let b^* and z^* be as in Lemma 31, with $S = S_0$. Define

$$\beta' = \beta^0 - \frac{b^* s_0}{\hat{\kappa}^2(S_0)} \frac{\lambda^*}{n}.$$

Then

$$\begin{aligned} X^T X(\beta' - \beta^0) &= -\frac{\lambda^* X^T X b^* s_0}{n\hat{\kappa}^2(S_0)} \\ &= -\frac{\lambda^* X^T X b^*}{\|Xb^*\|_2^2} \\ &= -\lambda^* z^*. \end{aligned}$$

Let $S_* := \{j : \ b_j^* \neq 0\}$. Then by Lemma 28, $S_0 \subset S_*$. Furthermore

$$z_j^* \beta_j' = \begin{cases} z_j^* \beta_j^0 - \lambda z_j^* b_j^* / \|Xb^*\|_2^2 > 0 & j \in S_0 \\ -\lambda^* z_j^* b_j^* / \|Xb^*\|_2^2 > 0 & j \in S_* \backslash S_0 \\ 0 & j \notin S_* \end{cases}.$$

It follows that $z^* \in \partial \|\beta'\|_1$. Thus, $\beta' =: \beta^*$ is a solution of the KKT conditions (6) with $\zeta^* = z^*$. It holds moreover that

$$\|X(\beta^* - \beta^0)\|_2^2 = \frac{\lambda^{*2} \|Xb^*\|_2^2}{\|Xb^*\|_2^4} = \frac{\lambda^{*2} s_0}{n\hat{\kappa}^2(S_0)}.$$

□

11.5. Proof of Theorem 15

The proof of Theorem 15 consists of several steps. First we note that, given the sizes of its jumps, the total variation of a function is the smallest when this function is decreasing or increasing. This is stated in Lemma 32 as a trivial fact. As a consequence, if one subtracts from an arbitrary function value - or minus this value - the total variation, the result will be at most the average of the absolute values. This is shown in Lemma 33. Lemma 33 is then applied at each jump separately, as $\|b_S\|_1 - \|b_{-S\cup\{1\}}\|_1$ in this example amounts to subtracting at each jump some total variation to the left or to the right of this jump. Lemma 34 shows how this works for one jump. Then Theorem 15 is in part proved by applying this lemma to each jump. This leads to a lower bound for $\hat{\kappa}^2(S)$. The proof is completed by showing that this lower bound is achieved by the vector b^* as given in Theorem 15.

For $f \in \mathbb{R}^n$ we define the ordered vector

$$f_{(1)} \leq \cdots \leq f_{(n)},$$

with arbitrary ordering within ties.

Lemma 32 *It holds that*

$$TV(f) \geq f_{(n)} - f_{(1)}$$

with equality if f is increasing or decreasing.

Proof of Lemma 32. Trivial. □

Lemma 33 *It holds for any $j \in \{1, \ldots, n\}$ that*

$$f_j - \mathrm{TV}(f) \leq f_{(1)} \leq \frac{1}{n} \sum_{i=1}^n |f_i|,$$

and

$$-f_j - \mathrm{TV}(f) \leq -f_{(n)} \leq \frac{1}{n} \sum_{i=1}^n |f_i|.$$

Proof of Lemma 33. We have from Lemma 32 that $\mathrm{TV}(f) \geq f_{(n)} - f_{(1)}$. Moreover, $f_j \leq f_{(n)}$. Thus

$$\begin{aligned} f_j - \mathrm{TV}(f) &\leq f_j - (f_{(n)} - f_{(1)}) \\ &\leq f_{(n)} - (f_{(n)} - f_{(1)}) \\ &= f_{(1)}. \end{aligned}$$

Case 1: if $f_{(1)} < 0$ obviously $f_{(1)} < \frac{1}{n} \sum_{i=1}^n |f_i|$.
Case 2: if $f_{(1)} \geq 0$ then $f_i \geq 0$ for all i and then

$$f_{(1)} \leq \sum_{i=1}^n f_i/n = \sum_{i=1}^n |f_i|/n.$$

In the same way

$$\begin{aligned} -f_j - \mathrm{TV}(f) &\leq -f_j - (f_{(n)} - f_{(1)}) \\ &\leq -f_{(1)} - (f_{(n)} - f_{(1)}) \\ &= -f_{(n)}. \end{aligned}$$

Case 1: if $f_{(n)} > 0$ then $-f_{(n)} < \frac{1}{n} \sum_{i=1}^n |f_i|$.
Case 2: if $f_{(n)} \leq 0$ then $f_i \leq 0$ for all i and then

$$-f_{(n)} \leq -\sum_{i=1}^n f_i/n = \sum_{i=1}^n |f_i|/n.$$

□

Lemma 34 *Let $f \in \mathbb{R}^n$ with total variation $\mathrm{TV}(f) = \sum_{i=2}^n |f_i - f_{i-1}|$ and $g \in \mathbb{R}^m$ with total variation $\mathrm{TV}(g) = \sum_{i=2}^m |g_i - g_{i-1}|$. Then for any $j \in \{1, \ldots, n\}$ and $k \in \{1, \ldots, m\}$*

$$|f_j - g_k| - \mathrm{TV}(f) - \mathrm{TV}(g) \leq \frac{1}{n} \sum_{i=1}^n |f_i| + \frac{1}{m} \sum_{i=1}^m |g_i|.$$

Proof of Lemma 34. Suppose without loss of generality that $f_j \geq g_k$. Then by Lemma 33

$$\begin{aligned} |f_j - g_k| - \mathrm{TV}(f) - \mathrm{TV}(g) &= \underbrace{(f_j - \mathrm{TV}(f))}_{\leq \sum_{i=1}^n |f_i|/n} + \underbrace{(-g_k - \mathrm{TV}(g))}_{\leq \sum_{i=1}^m |g_i|/m} \\ &\leq \frac{1}{n}\sum_{i=1}^n |f_i| + \frac{1}{m}\sum_{i=1}^m |g_i|. \end{aligned}$$

□

Proof of Theorem 15. Let for $j = 2, \ldots, s$, $u_j \in \mathbb{N}$ satisfy $1 \leq u_j \leq d_j - 1$. We may write for $f = Xb$,

$$\begin{aligned} & \|b_S\|_1 - \|b_{-(S\cup\{1\})}\|_1 \\ = \; & |f_{d_1+1} - f_{d_1}| - \sum_{i=2}^{d_1} |f_i - f_{i-1}| - \sum_{i=d_1+2}^{d_1+u_2} |f_i - f_{i-1}| \\ + \; & |f_{d_1+d_2+1} - f_{d_1+d_2}| - \sum_{i=d_1+u_2+1}^{d_1+d_2} |f_i - f_{i-1}| - \sum_{i=d_1+d_2+2}^{d_1+d_2+u_3} |f_i - f_{i-1}| \\ & \ldots \\ + \; & |f_{d_1+\cdots+d_{s-1}+1} - f_{d_1+\cdots+d_{s-1}}| \\ - \; & \sum_{i=d_1+\cdots+d_{s-2}+u_{s-1}+1}^{d_1+\cdots+d_{s-1}} |f_i - f_{i-1}| - \sum_{i=d_1+\cdots+d_{s-1}+2}^{d_1+\cdots+d_{s-1}+u_s} |f_i - f_{i-1}| \\ + \; & |f_{d_1+\cdots+d_s+1} - f_{d_1+\cdots+d_s}| \\ - \; & \sum_{i=d_1+\cdots+d_{s-1}+u_s+1}^{d_1+\cdots+d_s} |f_i - f_{i-1}| - \sum_{i=d_1+\cdots+d_s+2}^{n} |f_i - f_{i-1}| \end{aligned}$$

$$\begin{aligned} \leq \; & \frac{1}{d_1}\sum_{i=1}^{d_1} |f_i| + \frac{1}{u_2}\sum_{i=d_1+1}^{d_1+u_2} |f_i| \\ + \; & \frac{1}{d_2-u_2}\sum_{i=d_1+u_2+1}^{d_1+d_2} |f_i| + \frac{1}{u_3}\sum_{i=d_1+d_2+1}^{d_1+d_2+u_3} |f_i| \\ & \ldots \\ + \; & \frac{1}{d_{s-1}-u_{s-1}}\sum_{i=d_1+\cdots+d_{s-2}+u_{s-1}+1}^{d_1+\cdots+d_{s-1}} |f_i| + \frac{1}{u_s}\sum_{i=d_1+\cdots+d_{s-1}+1}^{d_1+\cdots+d_{s-1}+u_s} |f_i| \\ + \; & \frac{1}{d_s-u_s}\sum_{i=d_1+\cdots+d_{s-1}+u_s+1}^{d_1+\cdots+d_s} |f_i| + \frac{1}{d_{s+1}}\sum_{i=d_1+\cdots+d_s+1}^{n} |f_i| \end{aligned}$$

$$\begin{aligned} \leq \; & \sqrt{\frac{1}{d_1} + \frac{1}{u_2} + \frac{1}{d_2-u_2} + \cdots + \frac{1}{d_{s-1}-u_{s-1}} + \frac{1}{u_s} + \frac{1}{d_s-u_s} + \frac{1}{d_{s+1}}} \\ & \times \sqrt{\sum_{i=1}^n |f_i|^2}, \end{aligned}$$

where in the first inequality we applied Lemma 34 and the second one follows from the Cauchy-Schwarz inequality. The assumption that for all $j \in \{2, \ldots, s\}$ d_j is even allows us to take $u_j = d_j/2$ to arrive at

$$\kappa^2(S) \geq \frac{s+1}{\frac{n}{d_1} + \sum_{j=2}^s \frac{4n}{d_j} + \frac{n}{d_{s+1}}}.$$

Now for the reverse inequality, let $\tilde{b}$ be given as in the theorem and and $\tilde{f} := X\tilde{b}$. Then $\tilde{f}$ is equal to

$$\tilde{f}_i = \begin{cases} -\frac{n}{d_1} & i = 1, \ldots, d_1 \\ \frac{2n}{d_2} & i = d_1+1, \ldots, d_1+d_2 \\ \vdots & \\ (-1)^s \frac{2n}{d_s} & i = \sum_{j=1}^{s-1} d_j + 1, \ldots, \sum_{j=1}^s d_j \\ (-1)^{s+1} \frac{n}{d_{s+1}} & i = \sum_{j=1}^s d_j + 1, \ldots, n \end{cases}.$$

By the definition of $\tilde{f} = X\tilde{b}$,

$$\begin{aligned} \|\tilde{b}_S\|_1 = \sum_{j=1}^s |\tilde{f}_{d_j+1} - \tilde{f}_{d_j}| &= \frac{n}{d_1} + \frac{2n}{d_2} \\ &+ \frac{2n}{d_2} + \frac{2n}{d_3} \\ &\vdots \\ &+ \frac{2n}{d_{s-1}} + \frac{2n}{d_s} \\ &+ \frac{2n}{d_s} + \frac{n}{d_{s+1}} \\ &= \frac{n}{d_1} + \sum_{j=2}^s \frac{4n}{d_j} + \frac{n}{d_{s+1}}, \end{aligned}$$

and also

$$\begin{aligned} \sum_{i=1}^n \tilde{f}_i^2 &= d_1\tilde{f}_{t_1}^2 + \cdots + d_{s+1}\tilde{f}_{d_{s+1}}^2 \\ &= \frac{n^2}{d_1} + 4\sum_{j=2}^s \frac{n^2}{d_j} + \frac{n^2}{d_{s+1}}. \end{aligned}$$

Note also that

$$\begin{aligned} & \|\tilde{b}_{-(S\cup\{1\})}\|_1 \\ = & \sum_{i=2}^{d_1}|\tilde{f}_i-\tilde{f}_{i-1}|+\sum_{i=d_1+2}^{d_2}|\tilde{f}_i-\tilde{f}_{i-1}|+\cdots+\sum_{i=d_1+\cdots+d_s+2}^{n}|\tilde{f}_i-\tilde{f}_{i-1}| \\ = & 0 \end{aligned}$$

It follows that

$$\begin{aligned} \frac{(s+1)\|X\tilde{b}\|_2^2/n}{(\|\tilde{b}_S\|_1-\|\tilde{b}_{-(S\cup\{1\})}\|_1)^2} &= \frac{\sum_{i=1}^n \tilde{f}_i^2/n}{\left(\sum_{j=1}^s|\tilde{f}_{d_j+1}-\tilde{f}_{d_j}|\right)^2} \\ &= \frac{s+1}{\frac{n}{d_1}+\sum_{j=2}^s\frac{4n}{d_j}+\frac{n}{d_{s+1}}}. \end{aligned}$$

□

11.6. Proof of Theorem 17

To prove Theorem 17, we first establish the Lagrangian form of the minimization problem where we have the convex constraint $z_{S_0}^{*T}(\bar{v})b_{S_0}-\|Wb_{-S_0}\|_1\geq 1$. Then we recall the projections and we introduce a subset $\mathcal{T}$ of the underlying probability space where the lower bound of Theorem 17 holds. The latter is shown in Lemma 36. Finally, we show that the subset $\mathcal{T}$ has large probability.

11.6.1. Lagrangian Form

Recall for $w\in\mathcal{W}(\bar{v})$ the convex problem with linear and convex constraints

$$b(w)\in\arg\min\left\{\|Xb\|_2^2:\ z_{S_0}^{*T}(\bar{v})b_{S_0}-\|Wb_{-S_0}\|_1\geq 1\right\}.$$

Note that here we do not require the positivity constraint $z_j^{*T}(\bar{v})b_j\geq 0$ for all $j\in S_0$. The next lemma gives its Lagrangian form. This form plays in the proof of Theorem 17 the same role as in the proof of Theorem 14 for the noiseless version. We also show that for $w\in\mathcal{W}(\bar{v})$ the minimum $\|Xb(w)\|_2^2$ is not larger than $\|Xb^*(\bar{v})\|_2^2$ (recall that by definition $\hat{\kappa}^2(1+\bar{v},S_0)=s_0\|Xb^*(\bar{v})\|_2^2/n$).

Lemma 35 *We have*

$$X^TXb(w)=\|Xb(w)\|_2^2Wz(w),$$

with

$$z_{S_0}(w)=z_{S_0}^*(\bar{v}),\ z_{-S_0}(w)\in-\partial\|b_{-S_0}(w)\|_1.$$

Moreover, for $w\in\mathcal{W}(\bar{v})$

$$s_0\|Xb(w)\|_2^2/n\leq\hat{\kappa}^2(1+\bar{v},S_0).$$

Proof of Lemma 35. The problem

$$\min\left\{\|Xb\|_2^2:\ z_{S_0}^{*T}(\bar{v})b_{S_0}-\|Wb_{-S_0}\|_1\geq 1\right\}$$

has Lagrangian

$$X^TXb(w)=\tilde{\lambda}Wz(w)$$

with $z_{S_0}(w)=z_{S_0}^*(\bar{v})$ and $z_{-S_0}(w)\in-\partial\|b_{-S_0}(w)\|_1$. Moreover

$$\|Xb(w)\|_2^2=\tilde{\lambda}b(w)^TWz(w)=z_{S_0}^{*T}(\bar{v})b_{S_0}-\|Wb_{-S_0}\|_1=1$$

because the minimum is reached at the boundary. So

$$\tilde{\lambda}=\|Xb(w)\|_2^2.$$

To obtain the second statement of the lemma, we use similar arguments as in the proof of Lemma 5. We have

$$\|Xb(w)\|_2=\min_{b\in\mathbb{R}^p}\left\{\frac{\|Xb\|_2}{z_{S_0}^{*T}(\bar{v})b_{S_0}-\|W_{-S_0}b_{-S_0}\|_1}:\ z_{S_0}^{*T}(\bar{v})b_{S_0}-\|W_{-S_0}b_{-S_0}\|_1>0\right\}$$

But for $w\in\mathcal{W}$ and $\bar{w}:=1+\bar{v}$, we know

$$\|Wb_{-S_0}\|_1\leq\|\bar{W}b_{-S_0}\|_1$$

and so

$$z_{S_0}^{*T}(\bar{v})b_{S_0}-\|Wb_{-S_0}\|_1>z_{S_0}^{*T}(\bar{v})b_{S_0}-\|\bar{W}b_{-S_0}\|_1.$$

Let

$$A:=\left\{b:\ z_{S_0}^{*T}(\bar{v})b_{S_0}-\|Wb_{-S_0}\|_1>0\right\}$$

and

$$B:=\left\{b:\ z_{S_0}^{*T}(\bar{v})b_{S_0}-\|\bar{W}b_{-S_0}\|_1>0\right\}.$$

Then $B\subset A$. Hence

$$\begin{aligned} \|Xb(w)\|_2 &= \min_{b\in A}\frac{\|Xb\|_2}{z_{S_0}^{*T}(\bar{v})b_{S_0}-\|Wb_{-S_0}\|_1} \\ &\leq \min_{b\in B}\frac{\|Xb\|_2}{z_{S_0}^{*T}(\bar{v})b_{S_0}-\|Wb_{-S_0}\|_1} \\ &\leq \min_{b\in B}\frac{\|Xb\|_2}{z_{S_0}^{*T}(\bar{v})b_{S_0}-\|\bar{W}b_{-S_0}\|_1} \\ &= \|Xb^*(\bar{v})\|_2 \\ &= \frac{\sqrt{n}\hat{\kappa}(1+\bar{v},S_0)}{\sqrt{s_0}}. \end{aligned}$$

□

11.6.2. Projections

Recall the notation of Subsection 7.2 and that moreover the diagonal elements of the matrix $(X_{S_0}^T X_{S_0})^{-1}$ are denoted by $\{u_j^2\}_{j\in S_0}$. We write

$$\hat{u}_{S_0} := (X_{S_0}^T X_{S_0})^{-1} X_{S_0}^T \epsilon.$$

We denote the projection of ϵ on the space spanned by the columns of X_{S_0} by

$$\epsilon \mathrm{P} X_{S_0} := X_{S_0}(X_{S_0}^T X_{S_0})^{-1} X_{S_0}^T \epsilon = X_{S_0}\hat{u}_{S_0}$$

and write

$$\mathbf{U}(S_0) := \|\epsilon \mathrm{P} X_{S_0}\|_2.$$

11.6.3. Choice of λ

Recall that we require that for some $t > 0$

$$\lambda > \|v_{-S_0}\|_\infty \sqrt{2(\log(2p) + t)}.$$

11.6.4. The Set $\mathcal{T}$

Recall

$$\bar{u}_j := u_j\sqrt{2(\log(2p)+t)}/\lambda,\ j \in S_0,\ \bar{v}_j := v_j\sqrt{2(\log(2p)+t)}/\lambda,\ j \notin S_0. \tag{21}$$

Let $\mathcal{T}$ be the set

$$\begin{aligned}\mathcal{T} &:= \left\{|\hat{u}_j| \le \lambda \bar{u}_j\ \forall j \in S_0\right\} \\ &\cap \left\{|\hat{v}_j| \le \lambda \bar{v}_j\ \forall j \notin S_0\right\} \cap \left\{\mathbf{U}(S_0) \le \sqrt{s_0} + \sqrt{2x}\right\}.\end{aligned}$$

We show in Subsection 11.6.6 that $\mathbb{P}(\mathcal{T}) \ge 1 - \exp[-t] - \exp[-x]$.

11.6.5. Deterministic Part

The idea is now to incorporate the noisy part of the KKT conditions for the noisy Lasso into a weighted sub-differential, creating in that way KKT conditions of the same for as the noiseless KKT conditions (see (22) in the proof). To do so, we first put part of the noise in the vector β^0 without adding additional non-zeros. This makes it possible not to change the sub-differential at S_0. The rewriting of the KKT conditions make them resemble the Lagrangian form of Lemma 35.

We will use the KKT conditions (19) for $\hat{\beta}$:

$$-X^T(Y - X\hat{\beta}) = -\lambda\hat{\zeta},\ \hat{\zeta} \in \partial\|\hat{\beta}\|_1.$$

Lemma 36 *Suppose we are on the set $\mathcal{T}$ defined in Subsection 11.6.4. Then under the conditions of Theorem 17*

$$\|X(\hat{\beta} - \beta^0)\|_n \ge \frac{\lambda\sqrt{s_0}}{\sqrt{n}\hat{\kappa}(1+\bar{v}, S)} + \sqrt{2x}$$

Proof of Lemma 36. Set

$$\hat{\beta}_{S_0}^0 := \beta^0 + \hat{u}_{S_0},\ \hat{\beta}_{-S_0}^0 := 0.$$

Then

$$\begin{aligned}Y &= X\beta^0 + \epsilon \\ &= X_{S_0}\beta_{S_0}^0 + X_{S_0}\hat{u}_{S_0} + \epsilon \mathrm{A} X_{S_0} \\ &= X\hat{\beta}^0 + \epsilon \mathrm{A} X_{S_0}.\end{aligned}$$

The KKT conditions (19) are

$$-X^T(Y - X\hat{\beta}) = -\lambda\hat{\zeta}.$$

We have

$$Y - X\hat{\beta} = -X(\hat{\beta} - \hat{\beta}^0) - \epsilon \mathrm{A} X_{S_0}.$$

Therefore

$$-X^T(Y - X\hat{\beta}) = X^T X(\hat{\beta} - \hat{\beta}^0) - X^T(\epsilon \mathrm{A} X_{S_0}).$$

But

$$X_{S_0}^T(\epsilon \mathrm{A} X_{S_0}) = 0,$$

and

$$\begin{aligned}X_{-S_0}^T(\epsilon \mathrm{A} X_{S_0}) &= X_{-S_0}^T - X_{-S_0}^T X_{S_0}(X_{S_0}^T X_{S_0})^{-1} X_{S_0}^T \epsilon \\ &= (X_{-S_0} \mathrm{A} X_{S_0})^T \epsilon.\end{aligned}$$

Hence the KKT conditions read

$$X^T X(\hat{\beta} - \hat{\beta}^0) = -\lambda\hat{\zeta} + \hat{v},$$

where

$$\hat{v}_{S_0} = 0,\ \hat{v}_{-S_0} = (X_{-S_0} \mathrm{A} X_{S_0})^T \epsilon.$$

Set $\hat{S} := \{j :\ \hat{\beta}_j \ne 0\}$ and define for all $j \in \hat{S}\backslash S_0$

$$\hat{w}_j := 1 + \hat{v}_j/(\lambda\hat{\zeta}_j).$$

By assumption (since we are on $\mathcal{T}$) $|\hat{v}_j| < \lambda\bar{v}_j$. so $\hat{w}_j \ge 1 - \bar{v}_j$ for all $j \in \hat{S}\backslash S_0$. For $j \notin \hat{S} \cup S_0$ we define

$$\hat{w}_j := \max\{|1 + \hat{v}_j/\lambda|, 1 - \bar{v}_j\}.$$

Then for $j \notin \hat{S} \cup S_0$

$$\begin{aligned}\lambda\hat{\zeta}_j + \hat{v}_j &= \lambda|\hat{\zeta}_j + \hat{v}_j/\lambda|\text{sign}(\hat{\zeta}_j + \hat{v}_j/\lambda) \\ &= \begin{cases}\hat{w}_j\text{sign}(\hat{\zeta}_j + \hat{v}_j/\lambda), & |\hat{\zeta}_j + \hat{v}_j/\lambda| \geq 1 - \bar{v}_j \\ \hat{w}_j\frac{|\hat{\zeta}_j+\hat{v}_j/\lambda|}{1-\bar{v}_j}\text{sign}(\hat{\zeta}_j + \hat{v}_j/\lambda) & |\hat{\zeta}_j + \hat{v}_j/\lambda| \leq 1 - \bar{v}_j\end{cases} \\ &= \hat{w}_j\tilde{\zeta}_j,\end{aligned}$$

where

$$\tilde{\zeta}_j := \begin{cases}\text{sign}(\hat{\zeta}_j + \hat{v}_j/\lambda), & |\hat{\zeta}_j + \hat{v}_j/\lambda| \geq 1 - \bar{v}_j \\ \frac{|\hat{\zeta}_j+\hat{v}_j/\lambda|}{1-\bar{v}_j}\text{sign}(\hat{\zeta}_j + \hat{v}_j/\lambda) & |\hat{\zeta}_j + \hat{v}_j/\lambda| \leq 1 - \bar{v}_j\end{cases}.$$

One readily verifies that (on $\mathcal{T}$) $\hat{w}_j \leq 1 + \bar{v}_j$ for all $j \notin S_0$. Taking $\tilde{\zeta}_j = \hat{\zeta}_j$ for $j \in S \cup S_0$ we arrive at the KKT conditions

$$X^T X(\hat{\beta} - \hat{\beta}^0) = -\lambda\hat{W}\tilde{\zeta},\ \tilde{\zeta} \in \partial\|\hat{\beta}\|_1 \tag{22}$$

and where $\hat{W} = \text{diag}(\hat{w})$ with $\hat{w} \in \mathcal{W}(\bar{v})$. Let now $S_0^+ := \{j \in S_0 :\ z_j^*(\bar{v})b_j(\hat{w}) > 0\}$ and $S_0^- := \{j \in S_0 :\ z_j^*(\bar{v})b_j(\hat{w}) \leq 0\}$. Take

$$\beta' = \hat{\beta}^0 - \lambda b_j(\hat{w})/\|Xb(\hat{w})\|_2^2.$$

Case 1 Let $j \in S_0$. By the condition on β^0 we know that $|\beta_j^0| > \lambda|b_j(\hat{w})|/\|Xb(\hat{w})\|_2^2 + |\hat{u}_{S_0}|$, so $|\hat{\beta}_j^0| \geq |\beta_j^0| - |\hat{u}_{S_0}| > \lambda|b_j(\hat{w})|/\|Xb(\hat{w})\|_2^2$. If $z_j^*(\bar{v}) = 1$ and $b_j(\hat{w}) > 0$, then $\hat{\beta}_j^0 > 0$ and

$$\beta_j' = |\hat{\beta}_j^0| - \lambda|b_j(\hat{w})|/\|Xb(\hat{w})\|_2^2 > 0.$$

If $z_j^*(\bar{v}) = 1$ and $b_j(\hat{w}) \leq 0$, then $\hat{\beta}_j^0 > 0$ and we have

$$\beta_j' = |\hat{\beta}_j^0| + \lambda|b_j(\hat{w})|/\|Xb(\hat{w})\|_2^2 > 0.$$

If $z_j^*(\bar{v}) = -1$ and $b_j(\hat{w}) < 0$, then $\hat{\beta}_j^0 < 0$ and

$$\beta_j' = -|\hat{\beta}_j^0| + \lambda|b_j(\hat{w})|/\|Xb(\hat{w})\|_2^2 < 0.$$

If $z_j^*(\bar{v}) = -1$ and $b_j(\hat{w}) \geq 0$, then $\hat{\beta}_j^0 < 0$ and

$$\beta_j' = -|\hat{\beta}_j^0| - \lambda|b_j(\hat{w})|/\|Xb(\hat{w})\|_2^2 < 0.$$

Case 2 Let now $j \notin S_0$. Then

$$\beta_j' = -\lambda b_j(\hat{w})/\|Xb(\hat{w})\|_2^2,$$

so

$$z_j(\hat{w})\beta_j' = -\lambda z_j(\hat{w})b_j(\hat{w})/\|Xb(\hat{w})\|_2^2 > 0.$$

Thus

$$z(\hat{w}) \in \partial\|\beta'\|_1.$$

Furthermore, by the first part of Lemma 35,

$$X^T X(\beta' - \hat{\beta}^0) = -\lambda X^T Xb(\hat{w})/\|Xb(\hat{w})\|_2 = -\lambda\hat{W}z(\hat{w}).$$

So $\beta' =: \hat{\beta}$ satisfies the KKT conditions with $\tilde{\zeta} = z(\hat{w})$. We further have

$$\begin{aligned}\|X(\hat{\beta} - \hat{\beta}^0)\|_2^2 &= \lambda^2 b^T(\hat{w})\hat{W}z(\hat{w})/\|Xb(\hat{w})\|_2^2 \\ &= \lambda^2/\|Xb(\hat{w})\|^2 \\ &\geq \lambda^2 s_0/(n\hat{\kappa}^2(1 + \bar{v}, S_0))\end{aligned}$$

where in the last step we used the second part of Lemma 35. Finally, by the triangle inequality

$$\begin{aligned}\|X(\hat{\beta} - \beta^0)\|_2 &\geq \|X(\hat{\beta} - \hat{\beta}^0)\|_2 - \mathbf{U}(S_0) \\ &\geq \frac{\lambda\sqrt{s_0}}{\sqrt{n}\hat{\kappa}(1 + \bar{v}, S_0)} - \mathbf{U}(S_0) \\ &\geq \frac{\lambda\sqrt{s_0}}{\sqrt{n}\hat{\kappa}(1 + \bar{v}, S_0)} - \sqrt{s_0} - \sqrt{2x}.\end{aligned}$$

□

11.6.6. Random Part

In Lemma 36, we showed that the conclusion (12) of Theorem 17 holds on the set $\mathcal{T}$. This subsection obtains that $\mathbb{P}(\mathcal{T}) \geq 1 - \exp[-t] + \exp[-x]$.

Lemma 37 *It holds that*

$$\mathbb{P}(\mathcal{T}) \geq 1 - \exp[-t] - \exp[-x].$$

Proof of Lemma 37. Apply Lemma 41 with $Z_j = \hat{u}_j/u_j$ for $j \in S_0$ and $Z_j = \hat{v}_j/v_j$ for $j \notin S_0$ to find that with probability at least $1 - \exp[-t]$

$$|\hat{u}_j| \leq \lambda\bar{u}_j\ \forall j \in S_0,\ |\hat{v}_j| \leq \lambda\bar{v}_j\ \forall j \notin S_0.$$

Furthermore, the random variable $\mathbf{U}^2(S_0)$ has a chi-squared distribution with s_0 degrees of freedom. Lemma 42 gives that with probability at least $1 - \exp[-x]$,

$$\mathbf{U}(S_0) \leq \sqrt{s_0} + \sqrt{2x}.$$

□

11.6.7. Collecting the Pieces

Combining Lemma 36 with Lemma 37 completes the proof of Theorem 17.

11.7. Proof of Theorem 18

The proof is along the lines of Theorem 9.

11.7.1. Comparing the KKT Conditions

We compare the KKT conditions for the noisy Lasso with those for the noiseless Lasso.

Lemma 38 *It holds that*

$$\|X(\hat\beta-\beta^*)\|_2^2+\lambda\|\hat\beta\|_1-\lambda^*\hat\beta^T z^*\leq(\hat\beta-\beta^*)^TX^T\epsilon+(\lambda-\lambda^*)\|\beta^*\|_1.$$

Proof of Lemma 38. The KKT conditions (19) for $\hat\beta$ can be written as

$$X^TX(\hat\beta-\beta^0)+\lambda\hat\zeta=X^T\epsilon.$$

where $\hat\zeta\in\partial\|\hat\beta\|_1$. By the KKT conditions (6) for β^*

$$X^TX(\beta^*-\beta^0)+\lambda^*\zeta^*=0.$$

Hence, taking the difference

$$X^TX(\hat\beta-\beta^*)+\lambda\hat\zeta-\lambda^*\zeta^*=X^T\epsilon.$$

Multiply by $(\hat\beta-\beta^*)^T$ to find

$$\|X(\hat\beta-\beta^*)\|_2^2+\lambda(\hat\beta-\beta^*)^T\hat\zeta-\lambda^*(\hat\beta-\beta^*)^T\zeta^*=(\hat\beta-\beta^*)^TX^T\epsilon.$$

But

$$\begin{aligned}&\lambda(\hat\beta-\beta^*)^T\hat\zeta-\lambda^*(\hat\beta-\beta^*)^T\zeta^*\\ =\;&\lambda\|\hat\beta\|_1-\lambda^*\hat\beta^T\zeta^*+\lambda^*\|\beta^*\|_1-\lambda\beta^{*T}\hat\zeta\\ =\;&\lambda\|\hat\beta\|_1-\lambda^*\hat\beta^T\zeta^*+\lambda\|\beta^*\|_1-\lambda\beta^{*T}\hat\zeta-(\lambda-\lambda^*)\|\beta^*\|_1\\ \geq\;&\lambda\|\hat\beta\|_1-\lambda^*\hat\beta^T\zeta^*-(\lambda-\lambda^*)\|\beta^*\|_1\end{aligned}$$

where we used that

$$\|\beta^*\|_1-\beta^{*T}\hat\zeta\geq 0.$$

Therefore

$$\|X(\hat\beta-\beta^*)\|_2^2+\lambda\|\hat\beta\|_1-\lambda^*\hat\beta^T z^*\leq(\hat\beta-\beta^*)^TX^T\epsilon+(\lambda-\lambda^*)\|\beta^*\|_1.$$

□

11.7.2. Projections

Recall the notation of Subsection 8.1. We let moreover $\hat v_{-S_0}$ be the vector

$$\hat v_{-S}^S:=(X_{-S}\mathrm{A}X_S)^T\epsilon.$$

As before, we denote the projection of ϵ on the space spanned by the columns of X_S by $\epsilon\mathrm{P}X_S$ and write

$$\mathbf{U}(S):=\|\epsilon\mathrm{P}X_S\|_2.$$

11.7.3. Choice of λ

Recall that we require that for some $t>0$

$$\lambda>\|v_{-S}^S\|_\infty\sqrt{2(\log(2p)+t)}.$$

11.7.4. The Set $\mathcal{T}^S$

Recall

$$\bar v^S:=v_j^S\sqrt{2(\log(2p)+t)}/\lambda,\ j\notin S.$$

Let

$$\mathcal{T}^S:=\{|\hat v_j|\leq\lambda\bar v_j\ \forall\ j\notin S\}\cap\{\mathbf{U}(S)\leq\sqrt{s}+\sqrt{2x}\}.$$

11.7.5. Deterministic Part

Lemma 39 *On the set $\mathcal{T}^S$ it holds that*

$$\|X(\hat\beta-\beta^*)\|_2\leq\sqrt{s}+\sqrt{2x}+(\lambda-\lambda^*)\sqrt{s/n}/\hat\kappa(\bar w^S,S).$$

Proof of Lemma 39. Since $S_*\subset S$

$$X(\hat\beta-\beta^*)=X_S\hat b_S+X_{-S}\mathrm{A}X_S\hat\beta_{-S}$$

where

$$X_S\hat b_S=X_S(\hat\beta_S-\beta_S^*)+(X_{-S}\mathrm{P}X_S)\hat\beta_{-S}.$$

In view of Lemma 38,

$$\begin{aligned}&\|X(\hat\beta-\beta^*)\|_2^2+\lambda\|\hat\beta\|_1-\lambda^*\beta^Tz^*\\ &\leq\hat b_S^TX_S^T\epsilon+\left[X_{-S}\mathrm{A}X_S\hat\beta_S\right]^T\epsilon+(\lambda-\lambda^*)\|\beta^*\|_1\end{aligned}$$

By the Cauchy-Schwarz inequality and since we are on $\mathcal{T}^S$

$$\hat b_S^TX_S^T\epsilon\leq\mathbf{U}(S)\|X\hat b_S\|_2\leq(\sqrt{s}+\sqrt{2x})\|X\hat b_S\|_2\leq(\sqrt{s}+\sqrt{2x})\|X(\hat\beta-\beta^*)\|_2$$

where in the last inequality we used Pythagoras rule. Moreover, by the definition of $\hat v_{-S}^S$ and since we are on the set $\mathcal{T}^S$

$$\left[X_{-S}\mathrm{A}X_S\hat\beta_{-S}\right]^T\epsilon=\hat\beta_{-S}^T\hat v_{-S}^S\leq\lambda\sum_{j\notin S}\bar v_{-S}^S|\hat\beta_j|.$$

On the other hand,

$$\lambda\|\hat\beta_{-S}\|_1-\lambda^*\zeta_{-S}^{*T}\hat\beta_{-S}\geq\lambda\sum_{j\notin S}(1-\lambda^*|\zeta_j^*|/\lambda)|\hat\beta_j|$$

and

$$(\lambda-\lambda^*)\|\beta^*\|_1-\lambda\|\hat\beta_S\|_1+\lambda^* z^{*T}\hat\beta_S\leq(\lambda-\lambda^*)\|\hat\beta_S-\beta^*_S\|_1.$$

If $\|X(\hat\beta-\beta^*)\|_2\leq\sqrt{s}+\sqrt{2x}$ we are done. Suppose therefore that $\|X(\hat\beta-\beta^*\|_2>\sqrt{s}+\sqrt{2x}$. Then we see that

$$\begin{aligned}&\|X(\hat\beta-\beta^*)\|_2^2-(\sqrt{s}+\sqrt{2x})\|X(\hat\beta-\beta^*)\|_2\\ =\;&\|X(\hat\beta-\beta^*)\|_2\Big(\|X(\hat\beta-\beta^*)\|_2-\sqrt{s}-\sqrt{2x}\Big)\\ >\;&0.\end{aligned}$$

But then

$$\lambda\sum_{j\notin S}(1-\bar v_j^S-\lambda^*|\zeta_j^*|/\lambda)|\hat\beta_j|<(\lambda-\lambda^*)\|\hat\beta_S-\beta^*\|_1.$$

or

$$\|\hat\beta_S-\beta^*_S\|_1-\|\bar W^S\hat\beta_{-S}\|_1>0.$$

Then

$$\|\hat\beta_S-\beta^*_S\|_1-\|\bar W^S\hat\beta_{-S}\|_1\leq(\sqrt{s/n})\|X(\hat\beta-\beta^*)\|_2/\hat\kappa(\bar w^S,S).$$

We thus arrive at

$$\begin{aligned}&\|X(\hat\beta-\beta^*)\|_2^2\\ \leq\;&\Big(\sqrt{s}+\sqrt{2x}+(\lambda-\lambda^*)\sqrt{s/n}/\hat\kappa(\bar w^S,S)\Big)\|X(\hat\beta-\beta^*)\|_2\end{aligned}$$

or

$$\|X(\hat\beta-\beta^*)\|_2\leq\sqrt{s}+\sqrt{2x}+(\lambda-\lambda^*)\sqrt{s/n}/\hat\kappa(\bar w^S,S).$$

□

11.7.6. Random Part

Lemma 40 *We have*

$$\mathbb{P}(\mathcal{T}^S)\geq 1-\exp[-t]-\exp[-x].$$

Proof of Lemma 40. This follows from Lemma 41 and Lemma 42. □

11.7.7. Finalizing the Proof of Theorem 18

Combine Lemma 39 with Lemma 40.

11.8. Proof of the Lemma in Section 9

Proof of Lemma 21. Write $g_i:=w_if_i$, $i=1,\ldots,n$ and $u_j:=d_j/2$, $j=2,\ldots,s$. Then we have

$$\begin{aligned}&\sum_{j=1}^s|g_{d_j+1}-g_{d_j}|-\sum_{i=2}^{d_1}|g_i-g_{i-1}|-\sum_{j=2}^{s-1}\sum_{i=d_j+1}^{d_{j+1}}|g_i-g_{i-1}|-\sum_{i=d_s+1}^{n}|g_i-g_{i-1}|\\ \leq\;&\frac{1}{d_1}\sum_{i=1}^{d_1}|g_i|+\frac{1}{u_2}\sum_{i=d_1+1}^{d_1+u_2}|g_i|\\ +\;&\frac{1}{d_2-u_2}\sum_{i=d_1+u_2+1}^{d_1+d_2}|g_i|+\frac{1}{u_3}\sum_{i=d_1+d_2+1}^{d_1+d_2+u_3}|g_i|\\ &\cdots\\ +\;&\frac{1}{d_{s-1}-u_{s-1}}\sum_{i=d_1+\cdots+d_{s-2}+u_{s-1}+1}^{d_1+\cdots+d_{s-1}}|g_i|+\frac{1}{u_s}\sum_{i=d_1+\cdots+d_{s-1}+1}^{d_1+\cdots+d_{s-1}+u_s}|g_i|\\ +\;&\frac{1}{d_s-u_s}\sum_{i=d_1+\cdots+d_{s-1}+u_s+1}^{d_1+\cdots+d_s}|g_i|+\frac{1}{d_{s+1}}\sum_{i=d_1+\cdots+d_s+1}^{n}|g_i|\\ \leq\;&\Big(\frac{1}{d_1^2}\sum_{i=1}^{d_1}w_i^2+\frac{1}{u_2^2}\sum_{i=d_1+1}^{d_1+u_2}w_i^2\\ +\;&\frac{1}{(d_2-u_2)^2}\sum_{i=d_1+u_2+1}^{d_1+d_2}w_i^2+\frac{1}{u_3^2}\sum_{i=d_1+d_2+1}^{d_1+d_2+u_3}w_i^2\\ &\cdots\\ +\;&\frac{1}{(d_{s-1}-u_{s-1})^2}\sum_{i=d_1+\cdots+d_{s-2}+u_{s-1}+1}^{d_1+\cdots+d_{s-1}}w_i^2+\frac{1}{u_s^2}\sum_{i=d_1+\cdots+d_{s-1}+1}^{d_1+\cdots+d_{s-1}+u_s}w_i^2\\ +\;&\frac{1}{(d_s-u_s)^2}\sum_{i=d_1+\cdots+d_{s-1}+u_s+1}^{d_1+\cdots+d_s}w_i^2+\frac{1}{d_{s+1}^2}\sum_{i=d_1+\cdots+d_s+1}^{n}w_i^2\Big)^{1/2}\\ &\times\Big(\sum_{i=1}^n f_i^2\Big)^{1/2}\\ \leq\;&\sqrt{\frac{n}{d_1}+\frac{n}{u_2}+\frac{n}{d_2-u_2}+\cdots+\frac{n}{d_{s-1}-u_{s-1}}+\frac{n}{u_s}+\frac{n}{d_s-u_s}+\frac{n}{d_{s+1}}}\\ &\times\sqrt{\sum_{i=1}^n|f_i|^2/n}\\ &\times\|w\|_\infty.\end{aligned}$$

Moreover

$$\begin{aligned}
&\sum_{j=1}^{s} w_{d_j+1}|f_{d_j+1}-f_{d_j}| - \sum_{i=2}^{d_1} w_i|f_i - f_{i-1}| \\
- &\sum_{j=2}^{s-1}\sum_{i=d_j+1}^{d_{j+1}} w_i|f_i-f_{i-1}| - \sum_{i=d_s+1}^{n} w_i|f_i-f_{i-1}| \\
\leq &\sum_{j=1}^{s}|g_{d_j+1}-g_{d_j}| - \sum_{i=2}^{d_1}|g_i-g_{i-1}| - \sum_{j=2}^{s-1}\sum_{i=d_j+1}^{d_{j+1}}|g_i-g_{i-1}| - \sum_{i=d_s+1}^{n}|g_i-g_{i-1}| \\
+ &\sum_{i=2}^{n}|w_i-w_{i-1}||f_{i-1}|,
\end{aligned}$$

and

$$\begin{aligned}
\sum_{i=2}^{n}|w_i-w_{i-1}||f_{i-1}| &\leq \sqrt{\sum_{i=2}^{n}(w_i-w_{i-1})^2}\sqrt{\sum_{i=2}^{n} f_{i-1}^2} \\
&\leq \sqrt{\sum_{i=2}^{n}(w_i-w_{i-1})^2}\sqrt{\sum_{i=1}^{n} f_i^2}
\end{aligned}$$

Thus we conclude

$$\begin{aligned}
&\sum_{j=1}^{s} w_{d_j+1}|f_{d_j+1}-f_{d_j}| \\
- &\sum_{i=2}^{d_1} w_i|f_i-f_{i-1}| - \sum_{j=2}^{s-1}\sum_{i=d_j+1}^{d_{j+1}} w_i|f_i-f_{i-1}| - \sum_{i=d_s+1}^{n} w_i|f_i-f_{i-1}| \\
\leq &\left(\|w\|_\infty\sqrt{\frac{n}{d_1}+\sum_{j=2}^{s}\frac{4n}{d_j}+\frac{n}{d_{s+1}}} + \sqrt{n\sum_{i=2}^{n}(w_i-w_{i-1})^2}\right)\sqrt{\sum_{i=1}^{n} f_i^2/n}.
\end{aligned}$$

□

11.9. Proof of Theorem 1

This follows from Corollary 12 combined with Theorem 14, where in the latter we replace $\hat{\Sigma} := X^T X/n$ by the population version Σ_0. This works because we replaced condition (8) by its population counterpart condition (3).

12. Tools from Probability Theory

We first present three standard lemmas for Gaussian random variables, Lemmas 41, 42 and 43. These three lemmas are followed by a concentration of measure result and a result for Gaussian quadratic forms.

Lemma 41 *Let $Z_1, \ldots, Z_p$ be standard normal random variables. Then it holds for all $t > 0$ that*

$$\mathbb{P}\left(\max_{1\leq j\leq p}|Z_j| \geq \sqrt{2(\log(2p)+t)}\right) \leq \exp[-t].$$

Proof of Lemma 41. For each $t > 0$

$$\mathbb{P}(|Z_1| \geq \sqrt{2t}) \leq 2\exp[-t].$$

So by the union bound, for any $t > 0$,

$$\begin{aligned}
\mathbb{P}\left(\max_{1\leq j\leq p}|Z_j| > \sqrt{2(\log(2p)+t)}\right) &\leq p\mathbb{P}(|Z_1| \geq \sqrt{2(\log(2p)+t)}) \\
&\leq 2p\exp[-(\log(2p+t)] = \exp[-t].
\end{aligned}$$

□

Lemma 42 *Let $Z := (Z_1, \ldots, Z_T)^T$ be a vector with i.i.d. standard Gaussian entries. Then it holds for all $x > 0$ that*

$$\mathbb{P}\left(\|Z\|_2 \geq \sqrt{T} + \sqrt{2x}\right) \leq \exp[-x]$$

and

$$\mathbb{P}\left(|\|Z\|_2 - \sqrt{T}| \geq \sqrt{2x}\right) \leq 2\exp[-x].$$

Proof of Lemma 42. This follows from concentration of measure (Borell, 1975, Giné and Nickl, 2015, Theorem 2.5.7) because the map $Z \mapsto \|Z\|_2$ is Lipschitz. Alternatively, one may apply Lemma 1 in Laurent and Massart (2000). □

Lemma 43 *Let $(U, V) \in \mathbb{R}^{n\times 2}$ have i.i.d Gaussian rows with mean zero and covariance matrix*

$$\begin{pmatrix} \sigma_u^2 & \sigma_{uv} \\ \sigma_{uv} & \sigma_v^2 \end{pmatrix}.$$

Then for all $t > 0$, with probability at least $1 - 4\exp[-t]$

$$|U^T V - n\sigma_{uv}| \leq 3\sigma_u\sigma_v\left(\sqrt{2nt} + t\right).$$

Proof of Lemma 43. By standard arguments (see van de Geer (2017) for tracking down some constants) one can derive that with probability at least $1 - 4\exp[-t]$

$$|U^T V - n\sigma_{uv}| \leq (\sigma_u\sigma_v + 2|\sigma_{u,v}|)\sqrt{2nt} + (\sigma_u\sigma_v + 2|\sigma_{u,v}|)t.$$

We simplify this to: with probability at least $1 - 4\exp[-t]$

$$|U^T V - n\sigma_{uv}| \leq 3\sigma_u \sigma_v \Big(\sqrt{2nt} + t\Big).$$

□

This is the concentration of measure lemma that we use in Section 4.

Lemma 44 *For any $b \in \mathbb{R}^p$ and all $x > 0$, we have*

$$\mathbb{P}\Big(\|X(\hat{\beta} - b)\|_2 \geq m_b + \sqrt{2x}\Big) \leq \exp[-x]$$

and

$$\mathbb{P}\Big(\Big|\|X(\hat{\beta} - b)\|_2 - m_b\Big| \geq \sqrt{2x}\Big) \leq 2\exp[-x]$$

where $m_b := \mathbb{E}(\|X(\hat{\beta} - b)\|_2 | X)$.

Proof of Lemma 44. This follows from concentration of measure see e.g. Borell (1975), or Giné and Nickl (2015), Theorem 2.5.7, as the map $\epsilon \mapsto \|X(\hat{\beta} - b)\|^2$ is Lipschitz, see also van de Geer and Wainwright (2017). □

Finally, we give a result for Gaussian quadratic forms.

Lemma 45 *Let X have i.i.d. $\mathcal{N}(0, \Sigma_0)$-distributed rows and let M be a (sequence of) constant(s) such that*

$$M^2 = o\Big(n/(\|\Sigma_0\|_\infty \log(2p))\Big).$$

Then, for a suitable sequence $\eta_M = o(1)$, with probability tending to one

$$\inf_{\|b\|_1 \leq M\|\Sigma_0^{1/2} b\|_2} \frac{\|Xb\|_2^2/n}{\|\Sigma_0^{1/2} b\|_2^2} \geq (1 - \eta_M)^2.$$

Proof of Lemma 45. See for example Chapter 16 in van de Geer (2016) and its references, or van de Geer and Muro (2014). □

Abstract

We propose a new iteratively reweighted least squares (IRLS) algorithm for the recovery of a matrix $X \in \mathbb{C}^{d_1 \times d_2}$ of rank $r \ll \min(d_1, d_2)$ from incomplete linear observations, solving a sequence of low complexity linear problems. The easily implementable algorithm, which we call harmonic mean iteratively reweighted least squares (`HM-IRLS`), optimizes a non-convex Schatten-p quasi-norm penalization to promote low-rankness and carries three major strengths, in particular for the matrix completion setting. First, we observe a remarkable global convergence behavior of the algorithm's iterates to the low-rank matrix for relevant, interesting cases, for which any other state-of-the-art optimization approach fails the recovery. Secondly, `HM-IRLS` exhibits an empirical recovery probability close to 1 even for a number of measurements very close to the theoretical lower bound $r(d_1 + d_2 - r)$, i.e., already for significantly fewer linear observations than any other tractable approach in the literature. Thirdly, `HM-IRLS` exhibits a locally superlinear rate of convergence (of order $2 - p$) if the linear observations fulfill a suitable null space property. While for the first two properties we have so far only strong empirical evidence, we prove the third property as our main theoretical result.

Keywords: Iteratively Reweighted Least Squares, Low-Rank Matrix Recovery, Matrix Completion, Non-Convex Optimization

1. Introduction

The problem of recovering a low-rank matrix from incomplete linear measurements or observations has gained considerable attention in the last few years due to the omnipresence of low-rank models in different areas of science and applied mathematics. Low-rank models arise in a variety of areas such as system identification (Liu et al., 2013; Liu and Vandenberghe, 2010), signal processing (Ahmed and Romberg, 2015), quantum tomography (Gross et al., 2010; Gross, 2011) and phase retrieval (Candès et al., 2013; Candès et al., 2013; Gross et al., 2015). An instance of this problem of particular importance, e.g., in recommender systems (Srebro et al., 2005; Goldberg et al., 1992; Candès and Recht, 2009), is the *matrix completion* problem, where the measurements correspond to entries of the matrix to be recovered.

Although the low-rank matrix recovery problem is NP-hard in general, several tractable algorithms have been proposed that allow for provable recovery in many important cases. The *nuclear norm minimization* (`NNM`) approach (Fazel, 2002; Candès and Recht, 2009), which solves a surrogate semidefinite program, is particularly well-understood. For `NNM`, recovery guarantees have been shown for a number of measurements on the order of the information theoretical lower bound $r(d_1 + d_2 - r)$, if r denotes the rank of a $d_1 \times d_2$-matrix (Recht et al., 2010; Candès and Recht, 2009); i.e., for a number of measurements $m \geqslant \rho r(d_1 + d_2 - r)$ with some oversampling constant $\rho \geqslant 1$. Even though `NNM` is solvable in polynomial time, it can be computationally very demanding if the problem dimensions are large, which is the case in many potential applications. Another issue is that although the number of measurements necessary for successful recovery by nuclear norm minimization is of *optimal order*, it is not *optimal*. More precisely, it turns out that the oversampling factor ρ of nuclear norm minimization *needs to be much larger than the oversampling factor of some other, non-convex algorithmic approaches* (Zheng and Lafferty, 2015; Tanner and Wei, 2013).

These limitations of convex relaxation approaches have led to a rapidly growing line of research discussing the advantages of non-convex optimization for the low-rank matrix recovery problem (Jain et al., 2010; Tanner and Wei, 2013; Haldar and Hernando, 2009; Jain et al., 2013; Wen et al., 2012; Tanner and Wei, 2016; Vandereycken, 2013; Wei et al., 2016; Tu et al., 2016). For several of these non-convex algorithmic approaches, recovery guarantees comparable to those of `NNM` have been derived (Candès et al., 2015; Tu et al., 2016; Zheng and Lafferty, 2015; Sun and Luo, 2016). Their advantage is a higher empirical recovery rate and an often more efficient implementation. While there are some results about global convergence of first-order methods minimizing a non-convex objective (Ge et al., 2016; Bhojanapalli et al., 2016) so that a success of the method might not depend on a particular initialization, the assumptions of these results are not always optimal, e.g., in the scaling of the numbers of measurements m in the rank r (Ge et al., 2016, Theorem 5.3). In general, the success of many non-convex optimization approaches relies on a distinct, possibly expensive initialization step.

1.1 Contribution of this paper

In this spirit, we propose a new iteratively reweighted least squares (IRLS) algorithm for the low-rank matrix recovery problem[1] that strives to minimize a non-convex objective function based on the Schatten-p quasi-norm

$$\min_X \|X\|_{S_p}^p \text{ subject to } \Phi(X) = Y, \tag{1}$$

for $0 < p < 1$, where $\Phi : \mathbb{C}^{d_1 \times d_2} \to \mathbb{C}^m$ is the linear measurement operator and $Y \in \mathbb{C}^m$ is the data vector defining the problem. The overall strategy of the proposed IRLS algorithm is to mimic this minimization by a sequence of weighted least squares problems. This strategy

1. The algorithm and partial results were presented at the 12th International Conference on Sampling Theory and Applications in Tallinn, Estonia, July 3–7, 2017. The corresponding conference paper has been published in its proceedings (Kümmerle and Sigl, 2017).

is shared by the related previous algorithms of (Fornasier et al., 2011; Mohan and Fazel, 2012) which minimize (1) by defining iterates as

$$X^{(n+1)} = \min_X \|W_L^{(n)\frac{1}{2}} X\|_F^2 \text{ subject to } \Phi(X) = Y, \tag{2}$$

where $W_L^{(n)} \approx \left(X^{(n)} X^{(n)*}\right)^{\frac{p-2}{2}}$ is a so-called *weight matrix* which *reweights* the quadratic penalty by operating on the column space of the matrix variable. Thus, we call this column-reweighting type of IRLS algorithms `IRLS-col`. Due to the inherent symmetry, it is evident to conceive, still in the spirit of (Fornasier et al., 2011; Mohan and Fazel, 2012), the algorithm `IRLS-row`

$$X^{(n+1)} = \min_X \|W_R^{(n)\frac{1}{2}} X^*\|_F^2 \text{ subject to } \Phi(X) = Y \tag{3}$$

with $W_R^{(n)} \approx \left(X^{(n)*} X^{(n)}\right)^{\frac{p-2}{2}}$, which reweights the quadratic penalty by acting on the *row space* of the matrix variable. We note that even for square dimensions $d_1 = d_2$, `IRLS-col` and `IRLS-row` do not coincide.

In this paper, as an important innovation, we propose the use of a different type of weight matrices, which can be interpreted as the *harmonic mean* of the matrices $W_L^{(n)}$ and $W_R^{(n)}$ above. This motivates the name *harmonic mean iteratively reweighted least squares* (`HM-IRLS`) for the corresponding algorithm. The harmonic mean of the weight matrices of `IRLS-col` and of `IRLS-row` in `HM-IRLS` is able to use the information in both the column and the row space of the iterates, and it also gives rise to a *qualitatively better* behavior than the use of more obvious symmetrizations as, e.g., the arithmetic mean of weight matrices would allow for both in theory and in practice.

We argue that the choice of harmonic mean weight matrices as in `HM-IRLS` leads to an efficient algorithm for the low-rank matrix recovery problem with fast convergence and superior performance in terms of sample complexity, also compared to algorithms based on strategies different from IRLS.

On the one hand, we show that the accumulation points of the iterates of `HM-IRLS` converge to stationary points of a smoothed Schatten-p functional under the linear constraint, as it is known for, e.g., `IRLS-col`, c.f. (Fornasier et al., 2011; Mohan and Fazel, 2012). On the other hand, we extend the theoretical guarantees which are based on a Schatten-p *null space property* (NSP) of the measurement operator (Oymak et al., 2011; Foucart and Rauhut, 2013) to `HM-IRLS`.

Our main theoretical result is that `HM-IRLS` exhibits a locally superlinear convergence rate of order $2-p$ in the neighborhood of a low-rank matrix for the non-convexity parameter $0 < p < 1$ connected to the Schatten-p quasi-norm, if the measurement operator fulfills the mentioned NSP of sufficient order. For $p \ll 1$, this means that the convergence rate is *almost quadratic*.

Although parts of our theoretical results, as in the case of the IRLS algorithms algorithms of Fornasier et al. (2011) and Mohan and Fazel (2012), do not apply to the matrix completion setting, due to the popularity of the problem and for reasons of comparability with other algorithms, we conduct numerical experiments to explore the empirical performance of `HM-IRLS` also for this setting. Surprisingly enough we observe that the theoretical

results comply with our numerical experiments also for matrix completion. In particular, the theoretically predicted local convergence rate of order $2 - p$ can be observed very precisely for this important measurement model as well (see Figures 3 to 5).

This local superlinear convergence rate of `HM-IRLS` is unprecedented by previous IRLS variants such as `IRLS-col` or those that use the arithmetic mean of the one-sided weight matrices: this means that neither can a superlinear rate be verified numerically, nor is it possible to show such a rate by our proof techniques for any other previsouly considered IRLS variant designed for the low-rank matrix recovery problem.

To the best of our knowledge, `HM-IRLS` is the first algorithm for low-rank matrix recovery which achieves superlinear rate of convergence for low complexity measurements as well as for larger problems.

Additionally, we conduct extensive numerical experiments comparing the efficiency of `HM-IRLS` with previous IRLS algorithms as `IRLS-col`, Riemannian optimization techniques (Vandereycken, 2013), alternating minimization approaches (Haldar and Hernando, 2009; Tanner and Wei, 2016), algorithms based on iterative hard thresholding (Kyrillidis and Cevher, 2014; Blanchard et al., 2015), and others (Park et al., 2016), in terms of sample complexity, again for the important case of *matrix completion*.

The experiments lead to the following observation: `HM-IRLS` recovers low-rank matrices systematically with an optimal number of measurements that is very close to the theoretical lower bound on the number of measurements that is necessary for recovery with high empirical probability. We consider this result to be remarkable, as it means that for problems of moderate dimensionality (matrices of $\approx 10^7$ variables, e.g. $(d_1 \times d_2)$-matrices with $d_1 \approx d_2 \approx 3 \cdot 10^3$) *the proposed algorithm needs fewer measurements for the recovery of a low rank matrix than all the state-of-the-art algorithms we included in our experiments* (see Figure 6).

An important practical observation of `HM-IRLS` is that its performance is very robust to the choice of the initialization and that it can be used as a stand-alone algorithm to recover low-rank matrices also starting from a trivial initialization. This is suggested by our numerical experiments since even for random or adversary initializations, `HM-IRLS` converges to the low-rank matrix, even though it is based on an objective function which is highly non-convex. While a complete theoretical understanding of this behavior is not yet achieved, we regard the empirical evidence in a variety of interesting cases as strong. In this context, we consider a proof of the global convergence of `HM-IRLS` for non-convex penalizations under appropriate assumptions as an interesting open problem.

1.2 Organization of the paper

We proceed in the paper as follows. In Section 2, we introduce some notation to be used and provide some background about different reformulations of the Schatten-p quasi-norm in terms of weighted ℓ_2-norms. This leads to the derivation of the harmonic mean iteratively reweighted least squares (`HM-IRLS`) algorithm in Section 3. We present our main theoretical results, the convergence guarantees and the locally superlinear convergence rate for the algorithm in Section 4. Numerical experiments and comparisons to state-of-the-art methods for low-rank matrix recovery are carried out in Section 5. In Section 6, we interpret the algorithm's different steps as minimizations of an auxililary functional with respect to its

arguments and show theoretical guarantees for `HM-IRLS` extending similar guarantees for `IRLS-col`. After this, we detail the proof of the locally superlinear convergence rate under appropriate assumptions on the null space of the measurement operator.

In Appendix A, we provide a short overview about Kronecker and Hadamard products, and end with some deferred proofs in Appendix B and Appendix C.

2. Notation and background

2.1 General notation, Schatten-p and weighted norms

In this section, we explain some of the notation we use in the course of this paper.

The set of matrices $X \in \mathbb{C}^{d_1 \times d_2}$ is denoted by $M_{d_1 \times d_2}$. Unless stated otherwise, vectors $x \in \mathbb{C}^d$ are considered as column vectors. We also use the vectorized form $X_{\mathrm{vec}} = \begin{bmatrix} X_1^T, \dots, X_j^T, \dots, X_{d_2}^T \end{bmatrix}^T \in \mathbb{C}^{d_1 d_2}$ of a matrix $X \in M_{d_1 \times d_2}$ with columns X_j, $j \in \{1, \dots, d_2\}$. The reverse recast of a vector $x \in \mathbb{C}^{d_1 d_2}$ into a matrix of dimension $d_1 \times d_2$ is denoted by $x_{\mathrm{mat}(d_1,d_2)} = [X_1, \dots, X_j, \dots, X_{d_2}]$, where $X_j = [x_{(d_1-1)\cdot j+1}, \dots, x_{(d_1-1)\cdot j+d_1}]^T$, $j = 1, \dots, d_2$ are column vectors, or X_{mat} if the dimensions are clear from the context. Obviously, it holds that $X = (X_{\mathrm{vec}})_{\mathrm{mat}}$.

The identity matrix in dimension $d \times d$ is denoted by $\mathbf{I}_d$. With $\mathbf{0}_{d_1 \times d_2} \in M_{d_1 \times d_2}$ and $\mathbf{1}_{d_1 \times d_2} \in M_{d_1 \times d_2}$ we denote the matrices with only 0- or 1-entries respectively. The set of Hermitian matrices is denoted by $H_{d \times d} := \{X \in M_{d \times d} \mid X = X^*\}$. We write $X^+ \in M_{d_1 \times d_2}$ for the Moore-Penrose inverse of the matrix $X \in M_{d_1 \times d_2}$.

Let $\mathcal{U}_d = \{U \in \mathbb{C}^{d \times d}; UU^* = \mathbf{I}_d\}$ denote the set of unitary matrices. Then the singular value decomposition of a matrix $X \in M_{d_1 \times d_2}$ can be written as $X = U\Sigma V^*$ with $U \in \mathcal{U}_{d_1}$, $V \in \mathcal{U}_{d_2}$ and $\Sigma \in M_{d_1 \times d_2}$, where Σ is diagonal and contains the singular values of X such that $\Sigma_{ii} = \sigma_i(X) \geqslant 0$ for $i \in \{1, \dots, \min(d_1, d_2)\}$. We define the *Schatten-p (quasi-)norm* of $X \in M_{d_1 \times d_2}$ as

$$\|X\|_{S_p} := \begin{cases} \operatorname{rank}(X), & \text{for } p = 0, \\ \left[\sum_{j=1}^{\min(d_1,d_2)} \sigma_j^p(X)\right]^{1/p}, & \text{for } 0 < p < \infty, \\ \sigma_{\max}(X), & \text{for } p = \infty. \end{cases} \tag{4}$$

Note that for $p = 1$, the Schatten-p norm is also called *nuclear norm*, written as $\|X\|_* := \|X\|_{S_1}$. The *trace* $\operatorname{tr}[X]$ of a matrix $X \in M_{d_1 \times d_2}$ is defined by the sum of its diagonal elements, $\operatorname{tr}[X] = \sum_{j=1}^{\min(d_1,d_2)} X_{jj}$. It can be seen that the p-th power of the Schatten-p norm coincides with $\|X\|_{S_p}^p = \operatorname{tr}\left[(X^*X)^{p/2}\right]$. The Schatten-2 norm is also called *Frobenius norm* and has the property that it is induced by the Frobenius scalar product $\langle X, Y\rangle_F = \operatorname{tr}[X^*Y]$, i.e., $\|X\|_F = \|X\|_{S_2} = \sqrt{\langle X, X\rangle_F}$. We define the *weighted Frobenius scalar product* of two matrices $X, Y \in M_{d_1 \times d_2}$ weighted by the the positive definite weight matrix $W \in H_{d_1 \times d_1}$ as $\langle X, Y\rangle_{F(W)} := \langle WX, Y\rangle_F = \langle X, WY\rangle_F$. This scalar product induces the *weighted Frobenius norm* $\|X\|_{F(W)} = \sqrt{\langle X, X\rangle_{F(W)}} = \sqrt{\operatorname{tr}[(WX)^*X]}$. It is clear that the Frobenius norm of a matrix X coincides with the ℓ_2-norm of its vectorization X_{vec}, i.e., $\|X\|_F = \|X_{\mathrm{vec}}\|_{\ell_2}$.

Similar to weighted Frobenius norms, we define the *weighted ℓ_2-scalar product* of vectors $x, y \in \mathbb{C}^d$ weighted by the positive definite weight matrix $W \in H_{d \times d}$ as $\langle x, y\rangle_{\ell_2(W)} = x^*Wy = \overline{y^*Wx}$ and its induced *weighted ℓ_2-norm* as $\|x\|_{\ell_2(W)} = \sqrt{x^*Wx}$. We use the notation $X \succ 0$ for a positive definite matrix $X \in H_{d \times d}$. Furthermore, we denote the range of a linear map $\Phi : M_{d_1 \times d_2} \to \mathbb{C}^m$ by $\operatorname{Ran}(\Phi) = \left\{Y \in \mathbb{C}^m;\ \text{there is } X \in M_{d_1 \times d_2} \text{ such that } Y = \Phi(X)\right\}$ and its null space by $\mathcal{N}(\Phi) = \left\{X \in M_{d_1 \times d_2}; \Phi(X) = 0\right\}$.

2.2 Problem setting and characterization of S_p- and reweighted Frobenius norm minimizers

Given a linear map $\Phi : M_{d_1 \times d_2} \to \mathbb{C}^m$ such that $m \ll d_1 d_2$, we want to uniquely identify and reconstruct an unknown matrix X_0 from its linear image $Y := \Phi(X_0) \in \mathbb{C}^m$. However, basic linear algebra tells us that this is not possible without further assumptions, since Φ is not injective if $m < d_1 d_2$. Indeed, there is a $(d_1 d_2 - m)$-dimensional affine space $\{X_0\} + \mathcal{N}(\Phi)$ fulfilling the linear constraint

$$\Phi(X) = Y.$$

Nevertheless, under the additional assumption that the matrix $X_0 \in M_{d_1 \times d_2}$ has rank $r < \min(d_1, d_2)$ and under appropriate assumptions on the map Φ, the recovery of X_0 is possible by solving the affine rank minimization problem

$$\min \operatorname{rank}(X) \text{ subject to } \Phi(X) = Y. \tag{5}$$

The unique solvability of (5) is given with high probability if, for example, Φ is a linear map whose matrix representation has i.i.d. Gaussian entries (Eldar et al., 2012) and $m = \Omega(r(d_1 + d_2))$. Unfortunately, solving (5) is intractable in general, but the works (Candès and Recht, 2009; Recht et al., 2010; Candès and Plan, 2011) suggest solving the tractable convex optimization program

$$\min \|X\|_{S_1} \text{ subject to } \Phi(X) = Y, \tag{6}$$

also called *nuclear norm minimization (`NNM`)*, as a proxy.

As discussed in the introduction, there are empirical as well as theoretical results (e.g., in (Daubechies et al., 2010; Chartrand, 2007)) coming from the related *sparse vector recovery* problem that suggest alternative relaxation approaches. These results indicate that it might be even more advantageous to solve the non-convex problem

$$\min F^p(X) := \|X\|_{S_p}^p \text{ subject to } \Phi(X) = Y, \tag{7}$$

for $0 < p < 1$, i.e., minimizing the p-th power of the Schatten-p quasi-norms under the affine constraint. Heuristically, the choice of $p < 1$ relatively small can be motivated by the observation that by the definition (4) of the Schatten-p quasi-norm

$$\|X\|_{S_p}^p \xrightarrow{p \to 0} \operatorname{rank}(X) =: \|X\|_{S_0}.$$

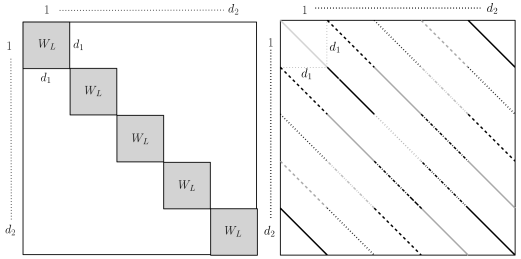
The above consideration suggests that the solution of (7) might be closer to (5) than (6) for small p. On the other hand, again, it is in general computationally intractable to find a global minimum of the non-convex optimization problem (7) if $p < 1$. Therefore it is a

natural and very relevant question to ask which optimization algorithm to use to find global minimizers of (7).

In this paper, we discuss an algorithm striving to solve (7) that is based on the following observations: Assume for the moment that we are given a square matrix $X \in M_{d_1 \times d_2}$ with $d_1 = d_2$ of full rank. Then, we can rewrite the p-th power of its Schatten-p quasi-norm as a squared weighted Frobenius norm, or, using Kronecker product notiation as explained in Appendix A, as a squared weighted ℓ_2-norm (if we use the vectorized notation X_{vec}): It turns out that

(i) $$\|X\|_{S_p}^p = \mathrm{tr}[(XX^*)^{\frac{p}{2}}] = \mathrm{tr}[(XX^*)^{\frac{p-2}{2}}(XX^*)] = \mathrm{tr}(W_L XX^*) = \|W_L^{\frac{1}{2}} X\|_F^2$$
$$= \|X\|_{F(W_L)}^2 = \|(\mathbf{I}_{d_2} \otimes W_L)^{\frac{1}{2}} X_{\mathrm{vec}}\|_{\ell_2}^2 = \|X_{\mathrm{vec}}\|_{\ell_2(\mathbf{I}_{d_2} \otimes W_L)}^2,$$
where W_L is the symmetric weight matrix $(XX^*)^{\frac{p-2}{2}}$ in $M_{d_1 \times d_1}$ and $\mathbf{I}_{d_2} \otimes W_L$ is the block diagonal weight matrix in $M_{d_1 d_2 \times d_1 d_2}$ with d_2 instances of W_L on the diagonal blocks, but also that

(ii) $$\|X\|_{S_p}^p = \mathrm{tr}[(X^*X)^{\frac{p}{2}}] = \mathrm{tr}[(X^*X)(X^*X)^{\frac{p-2}{2}}] = \mathrm{tr}(X^*XW_R) = \|XW_R^{\frac{1}{2}}\|_F^2$$
$$= \|X^*\|_{F(W_R)}^2 = \|(W_R \otimes \mathbf{I}_{d_1})^{\frac{1}{2}} X_{\mathrm{vec}}\|_{\ell_2}^2 = \|X_{\mathrm{vec}}\|_{\ell_2(W_R \otimes \mathbf{I}_{d_1})}^2,$$
where W_R is the symmetric weight matrix $(X^*X)^{\frac{p-2}{2}}$ in $M_{d_2 \times d_2}$. It follows from the definition of the Kronecker product that the weight matrix $W_R \otimes \mathbf{I}_{d_1} \in M_{d_1 d_2 \times d_1 d_2}$ is a block matrix of diagonal blocks of the type $\mathrm{diag}\big((W_R)_{ij}, \ldots, (W_R)_{ij}\big) \in M_{d_1 \times d_1}$, $i, j \in [d_2]$.



(a) $\mathbf{I}_{d_2} \otimes W_L$ (b) $W_R \otimes \mathbf{I}_{d_1}$

Figure 1: Sparsity structure of the weight matrices $\in M_{d_1 d_2 \times d_1 d_2}$

The sparsity structures of $\mathbf{I}_{d_2} \otimes W_L$ and $W_R \otimes \mathbf{I}_{d_1}$ are illustrated in Fig. 1. Note that a representation of $\|X\|_{S_p}^p$ by squares of Frobenius norms can be achieved by multiplying X by $W_L^{\frac{1}{2}}$ from the left in (i), or by $W_R^{\frac{1}{2}}$ from the right in (ii).

The above calculations are not well-defined if X is not of full rank or if $d_1 \neq d_2$, since in these cases at least one of the matrices $XX^* \in M_{d_1 \times d_1}$ or $X^*X \in M_{d_2 \times d_2}$ is singular, prohibiting the definition of the matrices $W_R = (X^*X)^{\frac{p-2}{2}}$ or $W_L = (XX^*)^{\frac{p-2}{2}}$ for $p < 2$. However, these issues can be overcome by introducing a smoothing parameter $\epsilon > 0$ and

smoothed weight matrices $W_L(X, \epsilon) \in M_{d_1 \times d_1}$ and $W_R(X, \epsilon) \in M_{d_2 \times d_2}$ defined by

$$W_L(X, \epsilon) := (XX^* + \epsilon^2 \mathbf{I}_{d_1})^{\frac{p-2}{2}}, \tag{8}$$
$$W_R(X, \epsilon) := (X^*X + \epsilon^2 \mathbf{I}_{d_2})^{\frac{p-2}{2}}. \tag{9}$$

Remark 1 *The weight matrices $W_L(X, \epsilon)$ and $W_R(X, \epsilon)$ are symmetric and positive definite.*

The possibility to rewrite the p-th power of the Schatten-p of a matrix as a squared weighted Frobenius norm gives rise to the general strategy of IRLS algorithms for low-rank matrix recovery: Weighted least squares problems of the type

$$\min_{\substack{X \in M_{d_1 \times d_2} \\ \Phi(X) = Y}} \|X\|_{F(W_L)}^2 \quad \text{or} \quad \min_{\substack{X \in M_{d_1 \times d_2} \\ \Phi(X) = Y}} \|X^*\|_{F(W_R)}^2$$

are solved and weight matrices W_L are updated alternatingly, leading to the algorithms column-reweighting `IRLS-col` and row-reweighting `IRLS-row`, respectively (Mohan and Fazel, 2012; Fornasier et al., 2011).

2.3 Averaging of weight matrices

While the algorithms `IRLS-col` and `IRLS-row` provide a tractable local minimization strategy of smoothed Schatten-p functionals under the linear constraint, we argue that it is suboptimal to follow either one of the two approaches as they do not exploit the symmetry of the problem in an optimal way: They *either* use low-rank information in the column space *or* in the row space.

A first intuitive approach towards a symmetric exploitation of the low-rank structure is inspired by the following identity, by combing the calculations (i) and (ii) carried out in Section 2.2.

Lemma 2 *Let $0 < p \leqslant 2$ and $X \in M_{d_1 \times d_2}$ with $d = d_1 = d_2$ be a matrix of full rank. Then*

$$\|X\|_{S_p}^p = \frac{1}{2}\left(\|W_L^{\frac{1}{2}} X\|_F^2 + \|XW_R^{\frac{1}{2}}\|_F^2\right) = \left\|\left(\frac{W_L \oplus W_R}{2}\right)^{\frac{1}{2}} X_{\mathrm{vec}}\right\|_{\ell_2}^2 = \|X_{\mathrm{vec}}\|_{\ell_2(W_{(arith)})}^2,$$

where

$$\frac{1}{2}\left(\mathbf{I}_{d_2} \otimes W_L + W_R \otimes \mathbf{I}_{d_1}\right) = \frac{W_L \oplus W_R}{2} =: W_{(arith)}$$

is the arithmetic mean matrix of the symmetric and positive definite weight matrices $\mathbf{I}_{d_2} \otimes W_L$ and $W_R \otimes \mathbf{I}_{d_1}$, $W_L := (XX^*)^{\frac{p-2}{2}}$, and $W_R := (X^*X)^{\frac{p-2}{2}}$.

Unfortunately, the introduction of arithmetic mean weight matrices does not prove to be particularly advantageous compared to one-sided reweighting strategies. Convincing improvements could be noted neither in numerical experiments nor in the theoretical investigations for the convergence rate of IRLS for low-rank matrix recovery, cf. also Section 5.2 and Remark 22.

In contrast, we want to promote the usage of the *harmonic mean of the weight matrices* $\mathbf{I}_{d_2} \otimes W_L$ and $W_R \otimes \mathbf{I}_{d_1}$, i.e., weight matrices of the type $2\left(W_R^{-1} \otimes \mathbf{I}_{d_1} + \mathbf{I}_{d_2} \otimes W_L^{-1}\right)^{-1} = 2\left(W_L^{-1} \oplus W_R^{-1}\right)^{-1} =: W_{(\text{harm})}$. In the remaining parts of the paper, we explain why $W_{(\text{harm})}$ is able to significantly outperform other weighting variants both theoretically and practically.

The following lemma verifies that the harmonic mean $W_{(\text{harm})}$ of the weight matrices $\mathbf{I}_{d_2} \otimes W_L$ and $W_R \otimes \mathbf{I}_{d_1}$ leads to a legitimate reformulation of the Schatten-p quasi-norm power, as it we already saw for the arithmetic mean $W_{(\text{arith})}$.

Lemma 3 *Let $0 < p \leqslant 2$ and $X \in \mathbb{C}^{d_1 \times d_2}$ with $d = d_1 = d_2$ be a full rank matrix. Then*

$$\|X\|_{S_p}^p = 2\left\|\left(W_L^{-1} \oplus W_R^{-1}\right)^{-\frac{1}{2}} X_{\text{vec}}\right\|_{\ell_2}^2 = \|X_{\text{vec}}\|_{\ell_2(W_{(harm)})}^2,$$

where

$$2\left(W_R^{-1} \otimes \mathbf{I}_{d_1} + \mathbf{I}_{d_2} \otimes W_L^{-1}\right)^{-1} = 2\left(W_L^{-1} \oplus W_R^{-1}\right)^{-1} =: W_{(harm)}$$

is the harmonic mean matrix of the symmetric and positive definite weight matrices $\mathbf{I}_{d_2} \otimes W_L$ and $W_R \otimes \mathbf{I}_{d_2}$, $W_L := (XX^*)^{\frac{p-2}{2}}$ and $W_R := (X^*X)^{\frac{p-2}{2}}$.

Proof Let $X = U\Sigma V^* = \sum_{i=1}^d \sigma_i u_i v_i^* \in M_{d\times d}$ be the singular value decomposition of X. Therefore for the vectorized version, $X_{\text{vec}} = (V \otimes U)\Sigma_{\text{vec}}$ holds true. By the definitions of W_L and W_R, we can write $W_L^{-1} = \sum_{i=1}^d \sigma_i^{2-p} u_i u_i^*$ and $W_R^{-1} = \sum_{i=1}^d \sigma_i^{2-p} v_i v_i^*$. Using the Kronecker sum inversion formula of Lemma 23 in Appendix A, we obtain

$$\begin{aligned}
\|X_{\text{vec}}\|_{\ell_2(W_{(\text{harm})})}^2 &= \|W_{(\text{harm})}^{\frac{1}{2}} X_{\text{vec}}\|_{\ell_2}^2 = 2\left\|\left(W_L^{-1} \oplus W_R^{-1}\right)^{-\frac{1}{2}} X_{\text{vec}}\right\|_{\ell_2}^2 \\
&= 2\,\text{tr}\left(\left(\left(W_L^{-1} \oplus W_R^{-1}\right)^{-1} X_{\text{vec}}\right)_{\text{mat}}^* X\right) \\
&= \sum_{i=1}^d \sum_{j=1}^d \sum_{k=1}^d \frac{2\sigma_k}{\sigma_i^{2-p} + \sigma_j^{2-p}} v_j v_i^* v_k u_k^* u_i u_i^* \sum_{l=1}^d \sigma_l u_l v_l^* \\
&= 2\left(\sum_{i=1}^d \frac{\sigma_i^2}{2\sigma_i^{2-p}}\right) = \|X\|_{S_p}^p,
\end{aligned}$$

which finishes the proof. ∎

3. Harmonic mean iteratively reweighted least squares algorithm

In this section, we use this idea to formulate a new iteratively reweighted least squares algorithm for low-rank matrix recovery. The so-called *harmonic mean iteratively reweighted least squares* algorithm (`HM-IRLS`) solves a sequence of weighted least squares problems to recover a low-rank matrix $X_0 \in M_{d_1\times d_2}$ from few linear measurements $\Phi(X_0) \in \mathbb{C}^m$. The weight matrices appearing in the least squares problems can be seen as the harmonic mean of the weight matrices in (8) and (9), i.e., the ones used by `IRLS-col` and `IRLS-row`.

More precisely, for $0 < p \leqslant 1$ and $d = \min(d_1, d_2)$, $D = \max(d_1, d_2)$, given a non-increasing sequence of non-negative real numbers $(\epsilon^{(n)})_{n=1}^\infty$ and the sequence of iterates $(X^{(n)})_{n=1}^\infty$ produced by the algorithm, we update our weight matrices such that

$$\widetilde{W}^{(n)} = 2\left[U^{(n)}(\bar{\Sigma}_{d_1}^{(n)})^{2-p}U^{(n)*} \oplus V^{(n)}(\bar{\Sigma}_{d_2}^{(n)})^{2-p}V^{(n)*}\right]^{-1}, \tag{10}$$

with the diagonal matrices $\bar{\Sigma}_{d_t}^{(n)} \in M_{d_t\times d_t}$ for $d_t = \{d_1, d_2\}$ such that

$$(\bar{\Sigma}_{d_t}^{(n)})_{ii} = \begin{cases} (\sigma_i(X^{(n)})^2 + \epsilon^{(n)2})^{\frac{1}{2}} & \text{if } i \leqslant d, \\ 0 & \text{if } d < i \leqslant D, \end{cases} \tag{11}$$

and the matrices $U^{(n)} \in \mathcal{U}_{d_1}$ and $V^{(n)} \in \mathcal{U}_{d_2}$ containing the left and right singular vectors of $X^{(n)}$ in its columns, respectively.

We note that this definition of $\widetilde{W}^{(n)}$ can be seen as a stabilized version of the harmonic mean weight matrix $W_{(\text{harm})}$ of Lemma 3. This stabilization is necessary as $\widetilde{W}^{(n)}$ becomes very ill-conditioned as soon as some of the singular values of $X^{(n)}$ approach zero and, related to that, $(X^{(n)}X^{(n)*})^{\frac{2-p}{2}} \oplus (X^{(n)*}X^{(n)})^{\frac{2-p}{2}}$ would even be singular as soon as $X^{(n)}$ is not of full rank.

Additionally, for the formulation of the algorithm it is convenient to define the linear operator $(\widetilde{\mathcal{W}}^{(n)})^{-1} : M_{d_1\times d_2} \to M_{d_1\times d_2}$ for any $n \in \mathbb{N}$ such that

$$(\widetilde{\mathcal{W}}^{(n)})^{-1}(X) := \frac{1}{2}\left[U^{(n)}(\bar{\Sigma}_{d_1}^{(n)})^{2-p}U^{(n)*}X + XV^{(n)}(\bar{\Sigma}_{d_2}^{(n)})^{2-p}V^{(n)*}\right], \tag{12}$$

describing the operation of the inverse of $\widetilde{W}^{(n)}$ on $M_{d_1\times d_2}$.

Finally, `HM-IRLS` can be formulated in pseudo code as follows.

Algorithm 1 Harmonic Mean IRLS for low-rank matrix recovery (`HM-IRLS`)

Input: A linear map $\Phi : M_{d_1\times d_2} \to \mathbb{C}^m$, image $Y = \Phi(X_0)$ of the ground truth matrix $X_0 \in M_{d_1\times d_2}$, rank estimate $\tilde{r}$, non-convexity parameter $0 < p \leqslant 1$.
Output: Sequence $(X^{(n)})_{n=1}^{n_0} \subset M_{d_1\times d_2}$.
Initialize $n = 0$, $\epsilon^{(0)} = 1$ and $\widetilde{W}^{(0)} = \mathbf{I}_{d_1d_2} \in M_{d_1d_2\times d_1d_2}$.
repeat

$$X^{(n+1)} = \underset{\Phi(X)=Y}{\arg\min} \|X_{\text{vec}}\|_{\ell_2(\widetilde{W}^{(n)})}^2 = ((\widetilde{\mathcal{W}}^{(n)})^{-1}\big(\Phi^*\big((\Phi \circ ((\widetilde{\mathcal{W}}^{(n)})^{-1} \circ \Phi^*)^{-1}(Y)\big)\big), \tag{13}$$

$$\epsilon^{(n+1)} = \min\left(\epsilon^{(n)}, \sigma_{\tilde{r}+1}(X^{(n+1)})\right), \tag{14}$$

$$\widetilde{W}^{(n+1)} = 2\left[U^{(n+1)}(\bar{\Sigma}_{d_1}^{(n+1)})^{2-p}U^{(n+1)*} \oplus V^{(n+1)}(\bar{\Sigma}_{d_2}^{(n+1)})^{2-p}V^{(n+1)*}\right]^{-1}, \tag{15}$$

where $U^{(n+1)} \in \mathcal{U}_{d_1}$ and $V^{(n+1)} \in \mathcal{U}_{d_2}$ are matrices containing the left and right singular vectors of $X^{(n+1)}$ in its columns, and the $\bar{\Sigma}_{d_t}^{(n+1)}$ are defined for $t \in \{1, 2\}$ according to (11).

$$n = n + 1,$$

until *stopping criterion is met.*
Set $n_0 = n$.

From a practical point of view, it is beneficial that the explicit calculation of the very large weight matrices $\widetilde{W}^{(n)} \in H_{d_1 d_2 \times d_1 d_2}$ (cf. (15)) is not necessary in implementations of Algorithm 1. As suggested by formulas (12) and (13), it can be seen that just the operation of its inverse $(\widetilde{W}^{(n)})^{-1}$ is needed, which can be implemented by matrix-matrix multiplications on the space $M_{d_1 \times d_2}$: For matrices $X, \tilde{X} \in M_{d_1 \times d_2}$, we have that $\widetilde{W}^{(n)} X_{\mathrm{vec}} = \tilde{X}_{\mathrm{vec}}$ if and only if $X_{\mathrm{vec}} = (\widetilde{W}^{(n)})^{-1} \tilde{X}_{\mathrm{vec}}$, which can be written in matrix variables as

$$X = \frac{1}{2}\left[U^{(n)} (\bar{\Sigma}_{d_1}^{(n)})^{2-p} U^{(n)*} \tilde{X} + \tilde{X} V^{(n)} (\bar{\Sigma}_{d_2}^{(n)})^{2-p} V^{(n)*}\right].$$

The last equivalence is due to the definitions of $\widetilde{W}^{(n)}$ and the Kronecker sum, cf. (15) and Appendix A.

Note that the smoothing parameters $\epsilon^{(n)}$ are chosen in dependence on a rank estimate $\tilde{r}$ here, which will be an important ingredient for the theoretical analysis of the algorithm. In practice, however, other choices of non-increasing sequences of non-negative real numbers $(\epsilon^{(n)})_{n=1}^{\infty}$ are possible and can as well lead to (a maybe even faster) convergence when tuned appropriately.

We refer to Section 5.4 for a further discussion of implementation details.

Example With a simple example, we illustrate the versatility of `HM-IRLS`: Let $d_1 = d_2 = 4$, and assume that we want to reconstruct the rank-1 matrix

$$X_0 = uv^* = \begin{pmatrix} 1 \\ 10 \\ -2 \\ 0.1 \end{pmatrix} \begin{pmatrix} 1 & 2 & 3 & 4 \end{pmatrix} = \begin{pmatrix} 1 & 2 & 3 & 4 \\ 10 & 20 & 30 & 40 \\ -2 & -4 & -6 & -8 \\ 0.1 & 0.2 & 0.3 & 0.4 \end{pmatrix}$$

from $m = d_f = r(d_1 + d_2 - r) = 7$ sampled entries $\Phi(X_0)$, where Φ is the linear map $\Phi : M_{4\times 4} \to \mathbb{C}^7$, $\Phi(X) = \big(X_{2,1},\ X_{4,1},\ X_{3,2},\ X_{4,2},\ X_{4,3},\ X_{1,4},\ X_{2,4}\big)$. Since the linear map Φ samples some entries of matrices in $M_{4\times 4}$ and does not see the others, this is an instance of the problem that is called *matrix completion*.

In general, reconstructing a $(d_1 \times d_2)$ rank-r matrix from $m = r(d_1 + d_2 - r)$ entries is a hard problem, as it is known that if $m < r(d_1 + d_2 - r)$, there is always more than one matrix X such that $\Phi(X) = \Phi(X_0)$, and even for equality, the property that Φ is invertible on (most) rank-r matrices might be hard to verify (Király et al., 2015).

It can be argued that the specific matrix completion problem we consider is in some sense a hard one, since, e.g., the deterministic sufficient condition for unique completability of (Pimentel-Alarcón et al., 2016, Theorem 2) is not fulfilled (less then 2 observed entries in the third column), and since the classical coherence parameters $\mu(u) = d_1 \max_{1\leqslant i\leqslant 4} \frac{\|uu^* e_i\|_2^2}{\|u\|_2^4} \approx 3.81$ and $\mu(v) = d_2 \max_{1\leqslant i\leqslant 4} \frac{\|vv^* e_i\|_2^2}{\|v\|_2^4} \approx 2.13$ that are used to analyze the behavior of many matrix completion algorithms (Candès and Recht, 2009; Jain et al., 2013) are quite large, with $\mu(u)$ being quite close to the maximal value of 4.

On the other hand, as the problem is small and X_0 has rank $r = 1$, it is possible to impute the missing values of

$$\begin{pmatrix} * & * & * & 4 \\ 10 & * & * & 40 \\ * & -4 & * & * \\ 0.1 & 0.2 & 0.3 & * \end{pmatrix}$$

by solving very simple linear equations, since, for example, $X_{4,4} = u_4 v_4$, $X_{2,1} = u_2 v_1$, $X_{2,4} = u_2 v_4$, and $X_{4,1} = u_4 v_1$, and therefore $X_{4,4} = \frac{X_{4,1} X_{2,4}}{X_{2,1}} = 0.4$. This shows that the only rank-1 matrix compatible with $\Phi(X_0)$ is X_0.

It turns out that—without using the combinatorial simplicity of the problem—the classical `NNM` does not solve the problem, as the nuclear norm minimizer (solution of (6) for $Y = \Phi(X_0)$) produced by the semidefinite program of the convex optimization package `CVX` (Grant and Boyd, 2014) converges to

$$\bar{X}_{\mathrm{nuclear}} \approx \begin{pmatrix} 1 & 0.023 & 0.041 & 4 \\ 10 & 0.232 & 0.411 & 40 \\ -0.056 & -4 & -0.200 & -0.226 \\ 0.1 & 0.2 & 0.3 & 0.400 \end{pmatrix},$$

a matrix with $45.74 \approx \|\bar{X}_{\mathrm{nuclear}}\|_{S_1} < \|X_0\|_{S_1} = \sigma_1(X_0) \approx 56.13$ and a relative Frobenius error of $\frac{\|\bar{X}_{\mathrm{nuclear}} - X_0\|_F}{\|X_0\|_F} = 0.661$.

On the other hand, `HM-IRLS` is able to solve the problem—if p is chosen small enough—with very high precision already after few iterations, for example, up to a relative error of $4.18 \cdot 10^{-13}$ after 24 iterations if $p = 0.1$. This is in contrast to the behavior of `IRLS-col`, `IRLS-row` and also to the behavior of `AM-IRLS`, the IRLS variant that uses weight matrices derived from the *arithmetic mean* of the weights of `IRLS-col` and `IRLS-row`, cf. Lemma 2. The iterates $X^{(n)}$ for iteration $n = 2000$ of these algorithms exhibit relative errors of 0.240, 0.489 and 0.401, respectively, for the choice of $p = 0.1$. Furthermore, there is no choice of p that would lead to a convergence to X_0.

To understand this very different behavior, we note that the n-th iterate of any of the four IRLS variants can be written, using Appendix A, in a concise way as

$$X^{(n+1)} = \operatorname*{arg\,min}_{\Phi(X)=Y} \langle X_{\mathrm{vec}}, W^{(n)} X_{\mathrm{vec}} \rangle, \tag{16}$$

where

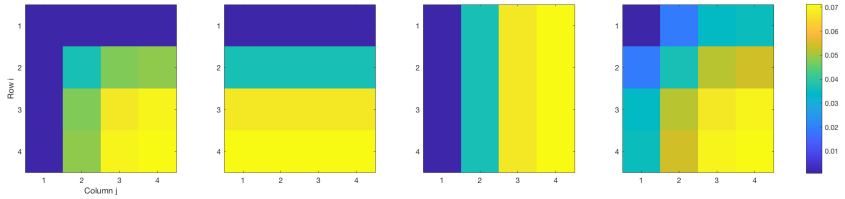
$$\langle X_{\mathrm{vec}}, W^{(n)} X_{\mathrm{vec}} \rangle = \langle X, U^{(n)} \big[H^{(n)} \circ (U^{(n)*} X V^{(n)})\big] V^{(n)*} \rangle_F = \sum_{i,j=1}^{4} H_{ij}^{(n)} |\langle u_i^{(n)}, X v_j^{(n)} \rangle|^2 \tag{17}$$

with $X^{(n)} = U^{(n)} \Sigma^{(n)} V^{(n)*} = \sum_{i=1}^{4} \sigma_i^{(n)} u_i^{(n)} v_i^{(n)}$ being the SVD of $X^{(n)}$, and

$$H_{i,j}^{(n)} = \begin{cases} 2\big[\big((\sigma_i^{(n)})^2 + (\epsilon^{(n)})^2\big)^{\frac{2-p}{2}} + \big((\sigma_j^{(n)})^2 + (\epsilon^{(n)})^2\big)\big)^{\frac{2-p}{2}}\big]^{-1} & \text{for } \texttt{HM-IRLS}, \\ \big((\sigma_i^{(n)})^2 + (\epsilon^{(n)})^2\big)^{\frac{p-2}{2}} & \text{for } \texttt{IRLS-col}, \\ \big((\sigma_j^{(n)})^2 + (\epsilon^{(n)})^2\big)^{\frac{p-2}{2}} & \text{for } \texttt{IRLS-row}, \text{ and} \\ 0.5 \cdot \big[\big((\sigma_i^{(n)})^2 + (\epsilon^{(n)})^2\big)^{\frac{p-2}{2}} + \big((\sigma_i^{(n)})^2 + (\epsilon^{(n)})^2\big)^{\frac{p-2}{2}}\big] & \text{for } \texttt{AM-IRLS}, \end{cases}$$

for $i, j \in \{1, 2, 3, 4\}$ and $\epsilon^{(n)} = \min(\sigma_2^{(n)}, \epsilon^{(n-1)})$.

The values of the matrix $H^{(1)}$ of weight coefficients after the first iteration in the above example are visualized in Figure 2, for each of the four IRLS versions above.



(a) `HM-IRLS` (b) `IRLS-col` (c) `IRLS-row` (d) `AM-IRLS`

Figure 2: Values of the matrix $H^{(1)}$ of "weight coefficients" corresponding to the orthonormal basis $(u_i^{(1)} v_j^{(1)*})_{i,j=1}^4$ after the first iteration in the example

The intuition for the superior behavior of `HM-IRLS` is now the following: Since large entries of $H^{(n)}$ *penalize* the corresponding parts of the space $M_{d_1 \times d_2} = \operatorname{span}\{u_i^{(n)} v_j^{(n)*}, i \in [d_1], j \in [d_2]\}$ in the minimization problem (16), large areas of *blue* and *dark blue* in Figure 2 indicate a benign optimization landscape where the minimizer $X^{(n+1)}$ of (16) *is able to improve considerably* on the previous iterate $X^{(n)}$.

In particular, it can be seen that in the case of `HM-IRLS`, the penalties on the *whole direct sum of column and row space of the best rank-r approximation of $X^{(n)}$*

$$T^{(n)} := \left\{ \begin{pmatrix} u_1^{(n)}, & \dots, & u_r^{(n)} \end{pmatrix} Z_1^* + Z_2 \begin{pmatrix} v_1^{(n)}, & \dots, & v_r^{(n)} \end{pmatrix}^* : Z_1 \in M_{d_1 \times r}, Z_2 \in M_{d_2 \times r} \right\},$$

are small compared to the other penalites, since the coefficients of $H^{(1)}$ corresponding to $T^{(1)}$ are exactly the ones in the first row and first column of the (4×4) matrices in Figure 2—a contrast that becomes more and more pronounced as $X^{(n)}$ approaches the rank-r ground truth X_0 (with $r = 1$ in the example).

On the other hand, `IRLS-col`, `IRLS-row` and `AM-IRLS` only have small coefficients on smaller parts of $T^{(n)}$, which, from a global perspective, explains why their usage might lead to non-global minima of the Schatten-p objective.

We note that the space $T^{(n)}$ plays also an important role in Riemannian optimization approaches for matrix recovery problems (see Vandereycken, 2013), since it is also the tangent space of the smooth manifold of rank-r matrices at the best rank-r approximation of $X^{(n)}$.

4. Convergence results

In the following part, we state our main theoretical results about convergence properties of the algorithm `HM-IRLS`. Furthermore, their relation to existing results for `IRLS-col` and `IRLS-row` is discussed.

It cannot be expected that a low-rank matrix recovery algorithm like `HM-IRLS` succeeds to converge to a low-rank matrix without any assumptions on the measurement operator Φ that defines the recovery problem (5). For the purpose of the convergence analysis of `HM-IRLS`, we introduce the following strong *Schatten-p null space property* (Fornasier et al., 2011; Oymak et al., 2011; Foucart and Rauhut, 2013).

Definition 4 (Strong Schatten-p null space property) *Let $0 < p \leqslant 1$. We say that a linear map $\Phi : M_{d_1 \times d_2} \to \mathbb{C}^m$ fulfills the strong Schatten-p null space property (Schatten-p NSP) of order r with constant $0 < \gamma_r \leqslant 1$ if*

$$\left(\sum_{i=1}^{r} \sigma_i^2(X) \right)^{p/2} < \frac{\gamma_r}{r^{1-\frac{p}{2}}} \left(\sum_{i=r+1}^{d} \sigma_i^p(X) \right) \tag{18}$$

for all $X \in \mathcal{N}(\Phi) \backslash \{0\}$.

Intuitively explained, if a map Φ fulfills the strong Schatten-p null space property of order r, there are no rank-r matrices in the null space and all the elements of the null space must not have a quickly decaying spectrum.

Null space properties have already been used to guarantee the success of nuclear norm minimization (6), or Schatten-1 minimization in our terminology, for solving the low-rank matrix recovery problem (Recht et al., 2011).

We note that the definitions of Schatten-p null space properties are quite analogous to the ℓ_p-null space property in classical compressed sensing (Foucart and Rauhut, 2013, Theorem 4.9), applied to the vector of singular values. In particular, (18) implies that

$$\sum_{i=1}^{r} \sigma_i^p(X) < \sum_{i=r+1}^{d} \sigma_i^p(X) \qquad \text{for all } X \in \mathcal{N}(\Phi) \backslash \{0\}, \tag{19}$$

since $\|X\|_{S_p} \leqslant r^{1/p - 1/2} \|X\|_{S_2}$ for X that is rank-r. This, in turn, ensures the existence of unique solutions to (7) if $Y = \Phi(X_0)$ are the measurements of a low-rank matrix X_0.

Proposition 5 (Foucart (2018)) *Let $\Phi : M_{d_1 \times d_2} \to \mathbb{C}^m$ be a linear map, let $0 < p \leqslant 1$ and $r \in \mathbb{N}$. Then every matrix $X_0 \in M_{d_1 \times d_2}$ such that $\operatorname{rank}(X_0) \leqslant r$ and $\Phi(X_0) = Y \in \mathbb{C}^m$ is the* unique *solution of Schatten-p minimization* (7) *if and only if Φ fulfills* (19).

Remark 6 *The sufficiency of the Schatten-p NSP* (19) *in Proposition 5 has already been pointed out by Oymak et al. (2011). The necessity as stated in the theorem, however, is due to a recent generalization of Mirsky's singular value inequalities to concave functions (Audenaert, 2014; Foucart, 2018).*

It can be seen that the (weak) Schatten-p NSP of (19) is a *stronger* property for larger p in the sense that if $0 < p' \leqslant p \leqslant 1$, the Schatten-$p$ property implies the Schatten-p' property. Very related to this, it can be seen that for any $0 < p \leqslant 1$, the strong Schatten-p null space property is implied by a sufficiently small *rank restricted isometry constant* δ_r, which is a classical tool in the analysis of low-rank matrix recovery algorithms (Recht et al., 2010; Candès and Plan, 2011).

Definition 7 (Restricted isometry property (RIP)) *The* restricted isometry constant $\delta_r > 0$ of order r *of the linear map* $\Phi : M_{d_1\times d_2} \to \mathbb{C}^m$ *is defined as the smallest number such that*

$$(1-\delta_r)\|X\|_F^2 \leqslant \|\Phi(X)\|_{\ell_2}^2 \leqslant (1+\delta_r)\|X\|_F^2$$

for all matrices $X \in M_{d_1\times d_2}$ *of rank at most* r.

Indeed, it follows from the proof of Chavez-Dominguez and Kutzarova (2015, Theorem 4.1) that a restricted isometry constant of order $2r$ such that $\delta_{2r} < \frac{2}{\sqrt{2}+3} \approx 0.4531$ implies the strong Schatten-p NSP of order r with a constant $\gamma_r < 1$ for any $0 < p \leqslant 1$. More precisely, it can be seen that $\delta_{2r} < \frac{2}{\sqrt{2}+3}$ implies that the strong Schatten-p NSP (18) of order r holds with the constant $\gamma_r = \frac{(\sqrt{2}+1)^p}{2^p}\frac{\delta_{2r}^p}{(1-\delta_{2r})^p}$.

Linear maps that are instances drawn from certain random models are known to fulfill the restricted isometry property with high probability if the number of measurements is sufficiently large (Davenport and Romberg, 2016), and, a fortiori, the Schatten-p null space property. In particular, this is true for *(sub-)Gaussian* linear measurement maps $\Phi : M_{d_1\times d_2} \to \mathbb{C}^m$ whose matrix representation is such that

$$\frac{1}{\sqrt{m}}\widetilde{\Phi} \in \mathbb{C}^{m\times d_1 d_2}, \text{ where } \widetilde{\Phi} \text{ has i.i.d. standard (sub-)Gaussian entries,} \tag{20}$$

as it is summarized in the following lemma.

Lemma 8 *For any* $0 < p \leqslant 1$, $0 < \gamma < 1$ *and any (sub-)Gaussian random operator* $\Phi : M_{d_1\times d_2} \to \mathbb{C}^m$ *(e.g. as defined in* (20)*), there exist constants* $C_1 > 1$, $C_2 > 0$ *such that if* $m \geqslant C_1 r(d_1+d_2)$*, the strong Schatten-p null space property* (18) *of order* r *with constant* $\gamma_r < \gamma$ *is fulfilled with probability at least* $1 - e^{-C_2 m}$.

4.1 Local convergence for $p < 1$

In this section, we provide a convergence analysis for `HM-IRLS` covering several aspects. We show that the algorithm converges to stationary points of a smoothed Schatten-p functional g_ϵ^p as in (21) without any additional assumptions on the measurement map Φ. Such guarantees have already been obtained for IRLS algorithms with one-sided reweighting as `IRLS-col` and `IRLS-row`, in particular for $p = 1$ by Fornasier et al. (2011) and for $0 < p \leqslant 1$ by Mohan and Fazel (2012).

Beyond that, assuming the measurement operator fulfills an appropriate Schatten-p null space property as defined in Definition 4, we show the a-posteriori exact recovery statement that `HM-IRLS` converges to the low-rank matrix X_0 if $\lim_{n\to\infty} \epsilon_n = 0$, which only was shown for one-sided `IRLS` for the case $p = 1$ by Fornasier et al. (2011).

Moreover, we provide a local convergence guarantee stating that `HM-IRLS` recovers the low-rank matrix X_0 if we obtain an iterate $X^{(\bar{n})}$ that is close enough to X_0, which is novel for IRLS algorithms.

Let $0 < p \leqslant 1$ and $\epsilon > 0$. To state the theorem, we introduce the *ϵ-perturbed Schatten-p functional* $g_\epsilon^p : M_{d_1\times d_2} \to \mathbb{R}_{\geqslant 0}$ such that

$$g_\epsilon^p(X) = \sum_{i=1}^{d} (\sigma_i(X)^2 + \epsilon^2)^{\frac{p}{2}}, \tag{21}$$

where $\sigma(X) \in \mathbb{R}^d$ denotes the vector of singular values of $X \in M_{d_1\times d_2}$.

Theorem 9 *Let* $\Phi : M_{d_1\times d_2} \to \mathbb{C}^m$ *be a linear operator and* $Y \in \mathrm{Ran}(\Phi)$ *a vector in its range. Let* $(X^{(n)})_{n\geqslant 1}$ *and* $(\epsilon^{(n)})_{n\geqslant 1}$ *be the sequences produced by Algorithm 1 for input parameters* Φ, Y, r *and* $0 < p \leqslant 1$*, let* $\epsilon = \lim_{n\to\infty} \epsilon^{(n)}$.

(i) If $\epsilon = 0$ *and if* Φ *fulfills the strong Schatten-p NSP* (18) *of order* r *with constant* $0 < \gamma_r < 1$*, then the sequence* $(X^{(n)})_{n\geqslant 1}$ *converges to a matrix* $\bar{X} \in M_{d_1\times d_2}$ *of rank at most* r *that is the unique minimizer of the Schatten-p minimization problem* (7)*. Moreover, there exists an absolute constant* $\hat{C} > 0$ *such that for any* X *with* $\Phi(X) = Y$ *and any* $\widetilde{r} \leqslant r$*, it holds that*

$$\|X - \bar{X}\|_F^p \leqslant \frac{\hat{C}}{r^{1-p/2}}\beta_{\widetilde{r}}(X)_{S_p},$$

where $\hat{C} = \frac{2^{p+1}\gamma_r^{1-p/2}}{1-\gamma_r}$ *and* $\beta_{\widetilde{r}}(X)_{S_p}$ *is the best rank-*$\widetilde{r}$ *Schatten-p approximation error of* X*, i.e.,*

$$\beta_{\widetilde{r}}(X)_{S_p} := \inf\left\{\|X - \widetilde{X}\|_{S_p}^p,\ \widetilde{X} \in M_{d_1\times d_2} \text{ has rank } \widetilde{r}\right\}. \tag{22}$$

(ii) If $\epsilon > 0$*, then each accumulation point* $\bar{X}$ *of* $(X^{(n)})_{n\geqslant 1}$ *is a stationary point of the* ϵ*-perturbed Schatten-p functional* g_ϵ^p *of* (21) *under the linear constraint* $\Phi(X) = Y$*. If additionally* $p = 1$*, then* $\bar{X}$ *is the unique global minimizer of* g_ϵ^p.

(iii) Assume that there exists a matrix $X_0 \in M_{d_1\times d_2}$ *with* $\Phi(X_0) = Y$ *such that* $\mathrm{rank}(X_0) = r \leqslant \frac{\min(d_1,d_2)}{2}$*, a constant* $0 < \zeta < 1$ *and an iteration* $\bar{n} \in \mathbb{N}$ *such that*

$$\|X^{(\bar{n})} - X_0\|_{S_\infty} \leqslant \zeta\sigma_{\widetilde{r}}(X_0)$$

and $\epsilon^{\bar{n}} = \sigma_{r+1}(X^{\bar{n}})$*. If* Φ *fulfills the strong Schatten-p NSP of order* $2r$ *with* $\gamma_{2r} < 1$ *and if the condition number* $\kappa = \frac{\sigma_1(X_0)}{\sigma_r(X_0)}$ *of* X_0 *and* ζ *are sufficiently small (see condition* (25) *and formula* (26)*), then*

$$X^{(n)} \to X_0 \quad \text{for } n \to \infty.$$

It is important to note that by using Lemma 8, it follows that the assertions of Theorem 9(i) and (iii) hold for (sub-)Gaussian operators (20) with high probability in the regime of measurements of optimal sample complexity order. In particular, there exist constant oversampling factors $\rho_1, \rho_2 \geqslant 1$ such that the assertions of (i) and (iii) hold with high probability if $m > \rho_k r(d_1+d_2)$, $k \in \{1,2\}$, respectively.

Remark 10 *However, if* $m < d_1 d_2$*, null space property-type assumptions as* (18) *or* (19) *do not hold for the important case of matrix completion-type measurements (Candès and Recht, 2009), where* $\Phi(X)$ *is given as* m *sample entries*

$$\Phi(X)_\ell = X_{i_\ell, j_\ell}, \qquad \ell = 1, \dots, m, \tag{23}$$

and $(i_\ell, j_\ell) \in [d_1]\times[d_2]$ *for all* $\ell \in [m]$*, of the matrix* $X \in M_{d_1\times d_2}$*, which also were considered in the example of Section 3.*

This means that parts (i) and (iii) of Theorem 9 do, unfortunately, not apply for matrix completion measurements, which define a very relevant class of low-rank matrix recovery problems. This problem is shared by any existing theory for IRLS algorithms for low-rank matrix recovery (Fornasier et al., 2011; Mohan and Fazel, 2012). However, in Section 5, we provide strong numerical evidence that `HM-IRLS` *exhibits properties as predicted by (i) and (iii) of Theorem 9 even for the matrix completion setting. We leave the extension of the theory of* `HM-IRLS` *to matrix completion measurements as an open problem to be tackled by techniques different from uniform null space properties (Davenport and Romberg, 2016, Section V).*

4.2 Locally superlinear convergence rate for $p < 1$

Next, we state the second main theoretical result of this paper, Theorem 11. It shows that in a neighborhood of a low-rank matrix X_0 that is compatible with the measurement vector Y, the algorithm `HM-IRLS` converges to X_0 with a *convergence rate* that is *superlinear of the order* $2-p$, if the operator Φ fulfills an appropriate Schatten-p null space property.

Theorem 11 (Locally Superlinear Convergence Rate) *Assume that the linear map* $\Phi : M_{d_1\times d_2} \to \mathbb{C}^m$ *fulfills the strong Schatten-p NSP of order* $2r$ *with constant* $\gamma_{2r} < 1$ *and that there exists a matrix* $X_0 \in M_{d_1\times d_2}$ *with* $\operatorname{rank}(X_0) = r \leqslant \frac{\min(d_1,d_2)}{2}$ *such that* $\Phi(X_0) = Y$*, let* Φ, Y, r *and* $0 < p \leqslant 1$ *be the input parameters of Algorithm 1. Moreover, let* $\kappa = \frac{\sigma_1(X_0)}{\sigma_r(X_0)}$ *be the condition number of* X_0 *and* $\eta^{(n)} := X^{(n)} - X_0$ *be the error matrices of the n-th output of Algorithm 1 for* $n \in \mathbb{N}$*.*
Assume that there exists an iteration $\bar{n} \in \mathbb{N}$ *and a constant* $0 < \zeta < 1$ *such that*

$$\|\eta^{(\bar{n})}\|_{S_\infty} \leqslant \zeta \sigma_r(X_0) \tag{24}$$

and $\epsilon^{(\bar{n})} = \sigma_{r+1}(X^{(\bar{n})})$*. If additionally the condition number* κ *and* ζ *are small enough, or more precisely, if*

$$\mu \|\eta^{(\bar{n})}\|_{S_\infty}^{p(1-p)} < 1 \tag{25}$$

with the constant

$$\mu := 2^{5p}(1+\gamma_{2r})^p \Big(\frac{\gamma_{2r}(3+\gamma_{2r})(1+\gamma_{2r})}{(1-\gamma_{2r})}\Big)^{2-p} \Big(\frac{d-r}{r}\Big)^{2-\frac{p}{2}} r^p \frac{\sigma_r(X_0)^{p(p-1)}}{(1-\zeta)^{2p}} \kappa^p \tag{26}$$

then

$$\|\eta^{(n+1)}\|_{S_\infty} \leqslant \mu^{1/p} \left(\|\eta^{(n)}\|_{S_\infty}\right)^{2-p} \quad \text{and} \quad \|\eta^{(n+1)}\|_{S_p} \leqslant \mu^{1/p} \left(\|\eta^{(n)}\|_{S_p}\right)^{2-p}$$

for all $n \geqslant \bar{n}$*.*

We think that the result of Theorem 11 is remarkable, since there are only few low-rank recovery algorithms which exhibit either theoretically or practically verifiable superlinear convergence rates. In particular, although the algorithms of Mishra et al. (2013) and `NewtonSLRA` of Schost and Spaenlehauer (2016) do show superlinear convergence rates, the first is not competitive to `HM-IRLS` in terms of sample complexity and the second has neither applicable theoretical guarantees for most of the interesting problems nor the ability of solving medium size problems.

Remark 12 *It is interesting to compare Theorem 11 with a related result for an IRLS algorithm for the sparse vector recovery problem in Daubechies et al. (2010, Theorem 7.9). We observe that while the statement describes the observed rates of convergence very accurately (cf. Section 5.2), the assumption* (25) *on the neighborhood that enables convergence of a rate* $2-p$ *is more pessimistic than our numerical experiments suggest. Our experiments confirm that the local convergence rate of order* $2-p$ *also holds for matrix completion measurements, where the assumption of a Schatten-p null space property fails to hold, cf. Section 5.*

4.3 Discussion and comparison with existing IRLS algorithms

Optimally, we would like to have a statement in Theorem 9 about the accumulation points $\bar{X}$ being *global minimizers* of g_ϵ^p, instead of mere stationary points (Fornasier et al., 2011, Theorem 6.11), (Daubechies et al., 2010, Theorem 5.3). A statement that strong is, unfortunately, difficult to achieve due to the non-convexity of the Schatten-p quasi-norm and of the ϵ-perturbed version g_ϵ^p. Nevertheless, our theorems can be seen as analogues of Daubechies et al. (2010, Theorem 7.7), which discusses the convergence properties of an IRLS algorithm for sparse recovery based on ℓ_p-minimization with $p < 1$.

As already mentioned in previous sections, Fornasier et al. (2011) and Mohan and Fazel (2012) proposed IRLS algorithms for low-rank matrix recovery and analysed their convergence properties. The algorithm of Fornasier et al. (2011) corresponds (almost) to `IRLS-col` with $p = 1$ as explained in Section 3. In this context, Theorem 9 recovers the results of Fornasier et al. (2011, Theorem 6.11(i-ii)) for $p = 1$ and generalize them, with weaker conclusions due to the non-convexity, to the cases $0 < p < 1$. The algorithm `IRLS-`p of Mohan and Fazel (2012) is similar to the former, but differs in the choice of the ϵ-smoothing and also covers non-convex choices $0 < p < 1$. However, we note that in the non-convex case, its convergence result (Mohan and Fazel, 2012, Theorem 5.1) corresponds to Theorem 9(ii), but does not provide statements similar to (i) and (iii) of Theorem 9.

Theorem 11 with its analysis of the convergence rate is new in the sense that to the best of our knowledge, there are no convergence rate proofs for IRLS algorithms for the low-rank matrix recovery problem in the literature. Indeed, we refer to Remark 22 in Section 6.3 for an explanation why the variants of Fornasier et al. (2011) and Mohan and Fazel (2012) cannot exhibit superlinear convergence rates, unlike `HM-IRLS`.

We also note that there is a close connection between the statements of Theorems 9 and 11 and results that were obtained for an IRLS algorithm dedicated to the sparse vector recovery problem in Daubechies et al. (2010, Theorems 7.7 and 7.9).

5. Numerical experiments

In this section, we demonstrate first that the superlinear convergence rate that was proven theoretically for Algorithm 1 (`HM-IRLS`) in Theorem 11 can indeed be accurately verified in

numerical experiments, even beyond measurement operators fulfilling the strong null space property, and compare its performance to other variants of `IRLS`.

In Section 5.3, we then examine the recovery performance of `HM-IRLS` for the matrix completion setting with the performance of other state-of-the-art algorithms comparing the measurement complexities that are needed for successful recovery for many random instances.

The numerical experiments are conducted on Linux and Mac systems with MATLAB R2017b. An implementation of `HM-IRLS` for matrix completion including code reproducing many conducted experiments is available at `https://github.com/ckuemmerle/hm_irls`.

5.1 Experimental setup

In the experiments, we sample $(d_1 \times d_2)$ dimensional ground truth matrices X_0 of rank r such that $X_0 = U\Sigma V^*$, where $U \in \mathbb{R}^{d_1 \times r}$ and $V \in \mathbb{R}^{d_2 \times r}$ are independent matrices with i.i.d. standard Gaussian entries and $\Sigma \in \mathbb{R}^{r \times r}$ is a diagonal matrix with i.i.d. standard Gaussian diagonal entries, independent from U and V.

We recall that a rank-r matrix $X \in M_{d_1 \times d_2}$ has $d_f = r(d_1 + d_2 - r)$ degrees of freedom, which is the theoretical lower bound on the number of measurements that are necessary for exact reconstruction (Candès and Plan, 2011). The random measurement setting we use in the experiments can be described as follows: We take measurements of matrix completion type, sampling $m = \lfloor \rho d_f \rfloor$ entries of X_0 uniformly over its $d_1 d_2$ indices to obtain $Y = \Phi(X_0)$. Here, ρ is such that $\frac{d_1 d_2}{d_f} \geqslant \rho \geqslant 1$ and parametrizes the difficulty of the reconstruction problem, from very hard problems for $\rho \approx 1$ to easier problems for larger ρ.

However, this uniform sampling of Φ could yield instances of measurement operators whose information content is not large enough to ensure well-posedness of the corresponding low-rank matrix recovery problem, even if $\rho > 1$. More precisely, it is impossible to recover a matrix exactly if the number of revealed entries in any row or column is smaller than its rank r, which is explained and shown in the context of the proof of Pimentel-Alarcón et al. (2016, Theorem 1).

Thus, in order to provide for a sensible measurement model for small ρ, we exclude operators Φ that sample fewer than r entries in any row or column. Therefore, we adapt the uniform sampling model such that operators Φ are discarded and sampled again until the requirement of at least r entries per column and row is met and recovery can be achieved from a theoretical point of view.

We note that the described phenomenon is very related to the fact that matrix completion recovery guarantees for the uniform sampling model require at least one additional log factor, i.e., they require at least $m \geqslant \log(\max(d_1, d_2))d_f$ sampled entries (Davenport and Romberg, 2016, Section V).

While we detail the experiments for the matrix completion measurement setting just described in the remaining section, we add that Gaussian measurement models also lead to very similar results in experiments.

5.2 Convergence rate comparison with other IRLS algorithms

In this subsection, we vary the Schatten-p parameter between 0 and 1 and compare the corresponding convergence behavior of `HM-IRLS` with the IRLS variant `IRLS-col`, which

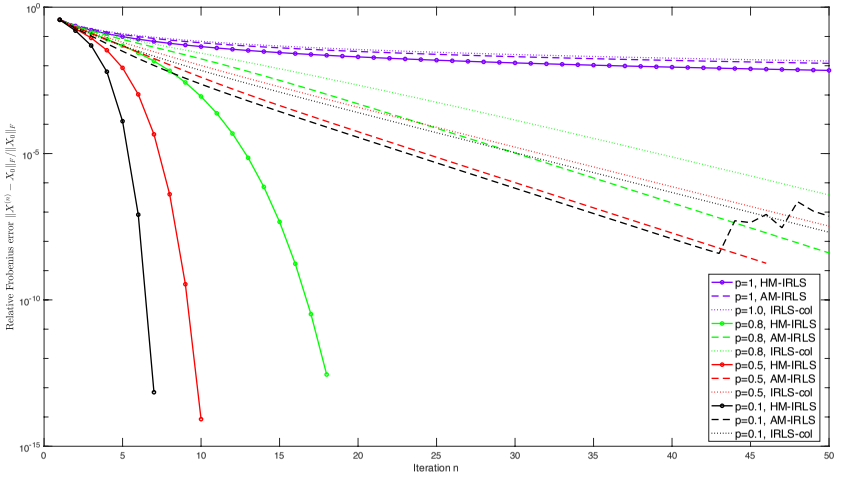


Figure 3: Relative Frobenius errors as a function of the iteration n for oversampling factor $\rho = 2$ (easy problem).

performs the reweighting just in the column space, and with the arithmetic mean variant `AM-IRLS`. The latter two coincide with Algorithm 1 except that the weight matrices are chosen as described in Equation (17) in Section 3.

We note that `IRLS-col` is very similar to the IRLS algorithms of Fornasier et al. (2011) and Mohan and Fazel (2012) and differs from them basically just in the choice of the ϵ-smoothing. We present the experiments with `IRLS-col` to isolate the influence of the weight matrix type, but very similar results can be observed for the algorithms of Fornasier et al. (2011) and Mohan and Fazel (2012).[2]

In the matrix completion setup of Section 5.1, we choose $d_1 = d_2 = 40$, $r = 10$ and distinguish easy, hard and very hard problems corresponding to oversampling factors ρ of 2.0, 1.2 and 1.0, respectively. The algorithms are provided with the ground truth rank r and are stopped whenever the relative change of Frobenius norm $\|X^{(n)} - X^{(n-1)}\|_F / \|X^{(n-1)}\|_F$ drops below the threshold of 10^{-10} or a maximal iteration of iterations $n_{\max}$ is reached.

5.2.1 Convergence rates

First, we study the behavior of the three IRLS algorithms for the easy setting of an oversampling factor of $\rho = 2$, which means that $\frac{2r(d_1+d_2-r)}{d_1 d_2} = 0.875$ of the entries are sampled, and parameters $p \in \{0.1, 0.5, 0.8, 1\}$.

In Figure 3, we observe that for $p = 1$, `HM-IRLS`, `AM-IRLS` and `IRLS-col` have a quite similar behavior, as the relative Frobenius errors $\|X^{(n)} - X_0\|_F / \|X_0\|_F$ decrease only slowly,

2. Implementations of the mentioned authors' algorithms were downloaded from `https://faculty.washington.edu/mfazel/` and `https://github.com/rward314/IRLSM`, respectively.

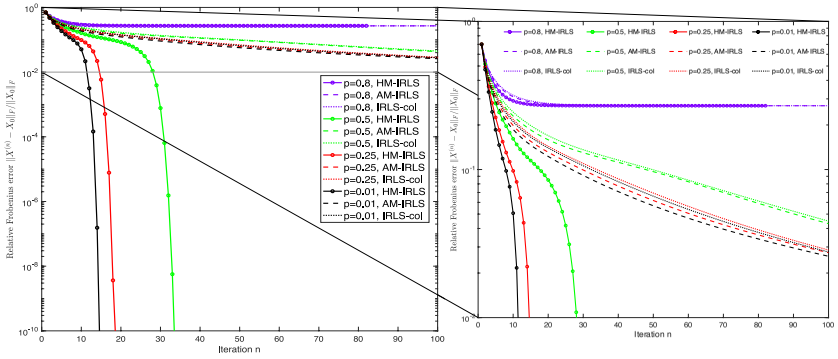

Figure 4: Relative Frobenius errors as a function of the iteration n for oversampling factor $\rho = 1.2$ (hard problem). Left column: y-range $[10^{-10}; 10^{0}]$. Right column: Enlarged section of left column corresponding to y-range of $[10^{-2}; 10^{0}]$.

i.e., even a linear rate is hardly identifiable. For choices $p < 1$ that correspond to non-convex objectives, we observe a very fast, superlinear convergence of `HM-IRLS`, as the iterates $X^{(n)}$ converge up to a relative error of less than 10^{-12} within fewer than 20 iterations for $p \in \{0.8, 0.5, 0.1\}$. Precise calculations verify that the rate of convergences are indeed of order $2 - p$, the order predicted by Theorem 11. We note that this fast convergence rate not only kicks in locally, but starting from the very first iteration.

On the other hand, it is easy to see that `AM-IRLS` and `IRLS-col` converge *linearly, but not superlinearly* to the ground truth X_0 for $p \in \{0.8, 0.5, 0.1\}$. The linear rate of `AM-IRLS` is slightly better than the one of `IRLS-col`, but the numerical stability of `AM-IRLS` deteriorates for $p = 0.1$ close to the ground truth (after iteration 43). This is due to a bad conditioning of the quadratic problems as the $X^{(n)}$ are close to rank-r matrices. In contrast, no numerical instability issues can be observed for `HM-IRLS`.

For the hard matrix completion problems with oversampling factor of $\rho = 1.2$, we observe that for $p = 0.8$, the three algorithms typically do not converge to ground truth. This can be seen in the example that is shown in Figure 4, where `HM-IRLS`, `AM-IRLS` and `IRLS-col` all exhibit a relative error of 0.27 after 100 iterations. We do not visualize the result for $p = 1$, as the iterates of the three algorithms do not converge to the ground truth either, which is to be expected: In some sense, they implement nuclear norm minimization, which is typically not able to recover a low-rank matrix from measurements with an oversampling factor as small as $\rho = 1.2$ (Donoho et al., 2013). The dramatic difference in behavior between `HM-IRLS` and the other approaches becomes very apparent for more non-convex choices of $p \in \{0.01, 0.25, 0.5\}$, where the former converges up to a relative Frobenius error of less than 10^{-10} within 15 to 35 iterations, while the others do not reach a relative error of 10^{-2} even after 100 iterations. For `HM-IRLS`, the convergence of order $2-p$ can be very well locally observed also here, it just takes some iterations until the superlinear convergence begins, which is due to the increased difficulty of the recovery problem.

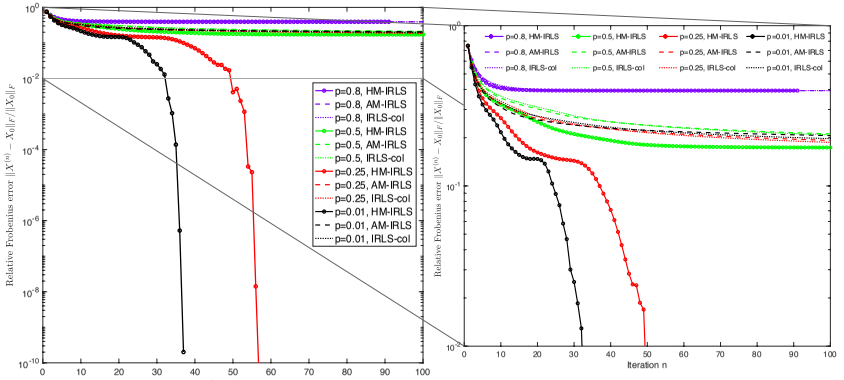

Figure 5: Relative Frobenius errors as a function of the iteration n for oversampling factor $\rho = 1.0$ (very hard problem). Left column: y-range $[10^{-10}; 10^{0}]$. Right column: Enlarged section of left column corresponding to y-range of $[10^{-2}; 10^{0}]$.

Finally, we see in the example shown in Figure 5 that even for the very hard problems where $\rho = 1$, which means that the number of sampled entries corresponds exactly to the degrees of freedom $r(d_1 + d_2 - r)$, `HM-IRLS` can be successful to recover the rank-r matrix if the parameter p is chosen small enough (here: $p \leqslant 0.25$). This is not the case for the algorithms `AM-IRLS` and `IRLS-col`.

5.2.2 `HM-IRLS` as the best extension of IRLS for sparse recovery

We summarize that among the three variants `HM-IRLS`, `AM-IRLS` and `IRLS-col`, only `HM-IRLS` is able to solve the low-rank matrix recovery problem for very low sample complexities corresponding to $\rho \approx 1$. Furthermore, it is the only IRLS algorithm for low-rank matrix recovery that exhibits a superlinear rate of convergence at all.

It is worthwhile to compare the properties of `HM-IRLS` with the behavior of the IRLS algorithm of Daubechies et al. (2010) designed to solve the sparse vector recovery problem by mimicking ℓ_p-minimization for $0 < p \leqslant 1$. While neither `IRLS-col` nor `AM-IRLS` are able to generalize the superlinear convergence behavior of Daubechies et al. (2010) (which is illustrated in Figure 8.3 of the same paper) to the low-rank matrix recovery problem, `HM-IRLS` is, as can be seen in Figures 3 to 5.

Taking the theoretical guarantees as well as the numerical evidence into account, we claim that *`HM-IRLS` is the presently best extension of IRLS for vector recovery in Daubechies et al. (2010) to the low-rank matrix recovery setting*, providing a substantial improvement over the reweighting strategies of Fornasier et al. (2011) and Mohan and Fazel (2012).

Moreover, we mention two observations which suggest that `HM-IRLS` has in some sense even more favorable properties than the algorithm of Daubechies et al. (2010): First, the discussion of Daubechies et al. (2010, Section 8) states that a superlinear convergence can only be observed locally after a considerable amount of iterations with just a linear error

decay. In contrast to that, HM-IRLS exhibits a superlinear error decay quite early (i.e., for example as early as after two iterations), at least if the sample complexity is large enough, cf. Figure 3.

Secondly, it can be observed that the convergence of the algorithm of Daubechies et al. (2010) to a sparse vector often breaks down if p is smaller than 0.5 (Daubechies et al., 2010, Section 8). In contrast to that, we observe that HM-IRLS does not suffer from this loss of global convergence for $p \ll 0.5$. Thus, a choice of very small parameters $p \approx 0.1$ or smaller is suggested as such a choice is accompanied by a very fast convergence.

5.3 Recovery performance compared to state-of-the-art algorithms

After comparing the performance of HM-IRLS with other IRLS variants, we now conduct experiments to compare the empirical performance of HM-IRLS also to that of low-rank matrix recovery algorithms different from IRLS.

To obtain a comprehensive picture, we consider not only the IRLS variants AM-IRLS and IRLS-col, but a variety of state-of-the-art methods in the experiments, as the Riemannian optimization technique Riemann_Opt (Vandereycken, 2013), the alternating minimization approaches AltMin (Haldar and Hernando, 2009), ASD (Tanner and Wei, 2016) and BFGD (Park et al., 2016), and finally the algorithms Matrix ALPS II (Kyrillidis and Cevher, 2014) and CGIHT_Matrix (Blanchard et al., 2015), which are based on iterative hard thresholding. As the IRLS variants we consider, all these algorithms use knowledge about the actual ground truth rank r.

In the experiments, we examine the empirical recovery probabilities of the different algorithms systematically for varying oversampling factors ρ, determining the difficulty of the low-rank recovery problem as the sample complexity fulfills $m = \lfloor \rho d_f \rfloor$. We recall that a large parameter ρ corresponds to an easy reconstruction problem, while a small ρ, e.g., $\rho \approx 1$, defines a very hard problem.

We choose $d_1 = d_2 = 100$ and the $r = 8$ as parameter of the experimental setting, conducting the experiments to recover rank-8 matrices $X_0 \in \mathbb{R}^{100\times 100}$. We remain in the matrix completion measurement setting described in Section 5.1, but sample now 150 random instances of X_0 and Φ for different numbers of measurements varying between $m_{\min} = 1500$ to $m_{\max} = 4000$. This means that the oversampling factor ρ increases from $\rho_{\min} = 0.975$ to $\rho_{\max} = 2.60$. For each algorithm, a successful recovery of X_0 is defined as a relative Frobenius error $\|X^{\text{out}} - X_0\|_F / \|X_0\|_F$ of the matrix X^{out} returned by the algorithm of smaller than 10^{-3}. The algorithms are run until stagnation of the iterates or until the maximal number of iterations $n_{\max} = 3000$ is reached. The number $n_{\max}$ is chosen large enough to ensure that a recovery failure is not due to a lack of iterations.

In the experiments, except for AltMin, for which we used our own implementation, we used implementations provided by the authors of the corresponding papers for the respective algorithms, using default input parameters provided by the authors. The respective code sources can be found in the references.

5.3.1 Beyond the state-of-the-art performance of HM-IRLS

The results of the experiment can be seen in Figure 6. We observe that HM-IRLS exhibits a very high empirical recovery probability for $p = 0.1$ and $p = 0.5$ as soon as the sample

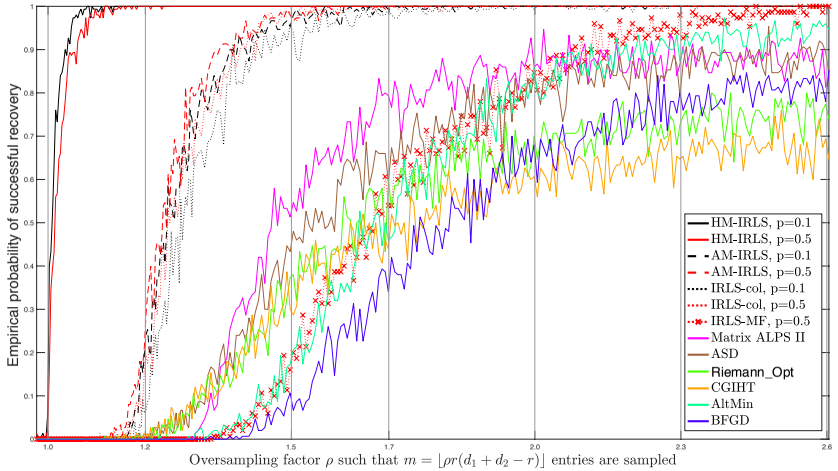

Figure 6: Comparison of empirical success rates of state-of-the-art algorithms, as a function of the oversampling factor ρ

complexity parameter ρ is slightly larger than 1.0, which means that $m = \lfloor \rho r(d_1 + d_2 - r) \rfloor$ measurements suffice to recover $(d_1 \times d_2)$-dimensional rank-r matrices with ρ close to 1. This is very close to the information theoretical lower bound of $d_f = r(d_1 + d_2 - r)$. Very interestingly, it can be observed that the empirical recovery probability reaches almost 1 already for an oversampling factor of $\rho \approx 1.1$, and remains at exactly 1 starting from $\rho \approx 1.2$.

Relatively good success rates can also be observed for the algorithms AM-IRLS and IRLS-col for non-convex parameter choices $p \in \{0.1, 0.5\}$, reaching an empirical success probability of almost 100% at around $\rho = 1.5$. AM-IRLS performs only marginally better than the classical IRLS strategy IRLS-col, which are both outperformed considerably by HM-IRLS. It is important to note that in accordance to what was observed in Section 5.2, in the successful instances, the error threshold that defines successful recovery is achieved already after a few dozen iterations for HM-IRLS, while typically only after several or many hundreds for AM-IRLS and IRLS-col. Furthermore, it is interesting to observe that the algorithm IRLS-MF, which corresponds to the variant studied and implemented by Mohan and Fazel (2012) and differs from IRLS-col mainly only in the choice of the ϵ-smoothing (14), has a considerably worse performance than the other IRLS methods. This is plausible since the smoothing influences severely the optimization landscape of the objective to be minimized.

The strong performance of HM-IRLS is in stark contrast to the behavior of all the algorithms that are based on different approaches than IRLS and that we considered in our experiments. They basically never recover any rank-r matrix if $\rho < 1.2$, and most of the algorithms need a sample complexity parameter of $\rho > 1.7$ to exceed a empirical recovery probability of a mere 0.5. A success rate of close to 0.8 is reached not before raising ρ above

2.0 in our experimental setting, and also only for a subset of the comparison algorithms, in particular for `Matrix ALPS II, ASD, AltMin`. The empirical probability of 1 is only reached for some of the IRLS methods, and not for any competing method in our experimental setting, even for rather large oversampling factors such as $\rho = 2.5$. While we do not rule out that a possible parameter tuning could improve the performance of any of the algorithms slightly, we conclude that for hard matrix completion problems, the experimental evidence for the vast differences in the recovery performance of `HM-IRLS` compared to other methods is very apparent.

Thus, our observation is that the proposed `HM-IRLS` algorithm *recovers low-rank matrices systematically with nearly the optimal number of measurements and needs fewer measurements than all the state-of-the-art algorithms we included in our experiments*, if the non-convexity parameter p is chosen such that $p \ll 1$.

We also note that the very sharp phase transition between failure and success that can be observed in Figure 6 for `HM-IRLS` indicates that the sample complexity parameter ρ is indeed the major variable determining the success of `HM-IRLS`. In contrast, the wider phase transitions for the other algorithms suggest that they might depend more on other factors, as the realizations of the random sampling model and the interplay of measurement operator Φ and ground truth matrix X_0.

Another conclusion that can be drawn from the empirical recovery probability of 1 is that, despite the severe non-convexity of the underlying Schatten-p quasi-norm for, e.g., $p = 0.1$, `HM-IRLS` with the initialization of $X^{(1)}$ as the Frobenius norm minimizer does not get stuck in stationary points if the oversampling factor is large enough. Further experiments conducted with random initializations as well as severely adversary initializations, e.g., with starting points chosen in the orthogonal complement of the spaces spanned by the singular vectors of the ground truth matrix X_0, lead to comparable results. Therefore, we claim that `HM-IRLS` exhibits a global convergence behavior in interesting application cases and for oversampling factor ranges for which competing non-convex low-rank matrix recovery algorithms fail to succeed. We consider a theoretical investigation of such behavior as an interesting open problem to explore.

5.4 Computational complexity

While the harmonic mean weight matrix $\widetilde{W}^{(n)}$, cf. (15), is an inverse of a $(d_1d_2 \times d_1d_2)$-matrix and therefore in general a dense $(d_1d_2 \times d_1d_2)$-matrix, it is important to note that it never has to be computed explicitly in an implementation of `HM-IRLS`; neither is it necessary to compute its inverse $(\widetilde{W}^{(n)})^{-1} = \frac{1}{2}\left(U^{(n)}(\bar{\Sigma}^{(n)})^{2-p}U^{(n)*} \oplus V^{(n)}(\bar{\Sigma}^{(n)})^{2-p}V^{(n)*}\right)$ explicitly.

Indeed, as it can be seen in (13) and by the definition of the Kronecker sum (55), the harmonic mean weight matrix appears just as the linear operator $(\mathcal{W}^{(n)})^{-1}$ on the space of matrices $M_{d_1\times d_2}$, whose action consists of a left- and right-sided matrix multiplication, cf. (12). Therefore, the application of $(\mathcal{W}^{(n)})^{-1}$ is $O(d_1d_2(d_1+d_2))$ by the naive matrix multiplication algorithm, and can be easily parallelized.

While this useful observation is helpful for the implementation of `HM-IRLS`, it is not true for `AM-IRLS`, as the action of $(W^{(n)}_{(\text{arith})})^{-1}$, the inverse of the arithmetic mean weight matrix at iteration n, is not representable as a sum of left- and right-sided matrix multiplication.

This means that even the execution of a fixed number of iterations of `HM-IRLS` is faster than computational advantage over `AM-IRLS`.

The cost to compute $\Phi \circ \widetilde{\mathcal{W}}^{(n)-1} \circ \Phi^* \in M_{m\times m}$ depends on the linear measurement operator Φ. In the matrix completion setting (23), no additional arithmetic operations have to be performed, as Φ is a just a selection operator in this case, and for `HM-IRLS`, this means that $\Phi \circ \widetilde{\mathcal{W}}^{(n)-1} \circ \Phi^*$ is a sparse matrix.

Thus, the algorithm `HM-IRLS` consists of basically of two computational steps per iteration: The computation of the SVD of the $d_1 \times d_2$-matrix $X^{(n)}$ and the solution of the linearly constrained least squares problem in (13). The first is of time complexity $O(d_1d_2\min(d_1,d_2))$. The time complexity of the second depends on Φ, but is dominated by the inversion of a symmetric, $m \times m$ sparse linear system in the matrix completion setting, if m is the number of given entries. This has a worst case time complexity of $O(\max(d_1,d_2)^3r^3)$ if ρ is just a constant oversampling factor.

For the matrix completion case, this allows us to recover low-rank matrices up to, e.g., $d_1 = d_2 = 3000$ on a single machine given very few entries with `HM-IRLS`.

Acceleration possibilities and extensions

To tackle higher dimensionalities in reasonable runtimes, a key strategy could be to address the computational bottleneck of `HM-IRLS`, the solution of the $m \times m$ linear system in (13), by using iterative methods. For IRLS algorithms designed for the related sparse recovery problem, the usage of conjugate gradient (CG) methods is discussed in Fornasier et al. (2016). By coupling the accuracy of the CG solutions to the outer IRLS iteration and using appropriate preconditioning, the authors obtain a competitive solver for the sparse recovery problem, also providing a convergence analysis. Similar ideas could be used for an acceleration of `HM-IRLS`.

It is interesting to see if further computational improvements can be achieved by combining the ideas of `HM-IRLS` with the usage of truncated and randomized SVDs (Halko et al., 2011), replacing the full SVDs of the $X^{(n)}$ that are needed to define the linear operator $(\mathcal{W}^{(n)})^{-1}$ in Algorithm 1.

6. Theoretical analysis

For the theoretical analysis of `HM-IRLS`, we introduce the following auxiliary functional $\mathcal{J}_p$, leading to a variational interpretation of the algorithm. In the whole section, we denote $d = \min(d_1,d_2)$ and $D = \max(d_1,d_2)$.

Definition 13 *Let $0 < p \leqslant 1$. Given a full rank matrix $Z \in M_{d_1\times d_2}$, let*

$$\widetilde{W}(Z) := 2\left[\mathbf{I}_{d_2} \otimes (ZZ^*)^{\frac{1}{2}}\right]\left[(ZZ^*)^{\frac{1}{2}} \oplus (Z^*Z)^{\frac{1}{2}}\right]^{-1}\left[(Z^*Z)^{\frac{1}{2}} \otimes \mathbf{I}_{d_1}\right] \in H_{d_1d_2\times d_1d_2}$$

be the harmonic mean matrix $\widetilde{W}$ associated to Z.

We define the auxiliary functional $\mathcal{J}_p : M_{d_1\times d_2} \times \mathbb{R}_{\geqslant 0} \times M_{d_1\times d_2} \to \mathbb{R}_{\geqslant 0}$ *as*

$$\mathcal{J}_p(X,\epsilon,Z) := \begin{cases} \frac{p}{2}\|X_{\text{vec}}\|^2_{\ell_2(\widetilde{W}(Z))} + \frac{\epsilon^2 p}{2}\sum_{i=1}^{d}\sigma_i(Z) + \frac{2-p}{2}\sum_{i=1}^{d}\sigma_i(Z)^{\frac{p}{(p-2)}} & \text{if } \operatorname{rank}(Z) = d, \\ +\infty & \text{if } \operatorname{rank}(Z) < d. \end{cases}$$

We note that the matrix $\widetilde{W}$ of Definition 13 is just the harmonic mean of the matrices $\widetilde{W}_1 := \mathbf{I}_{d_2} \otimes (ZZ^*)^{\frac{1}{2}}$ and $\widetilde{W}_2 = (Z^*Z)^{\frac{1}{2}} \otimes \mathbf{I}_{d_1}$, as introduced in Section 2.3, if $(ZZ^*)^{\frac{1}{2}}$ *and* $(Z^*Z)^{\frac{1}{2}}$ are positive definite. Indeed, in this case, $(ZZ^*)^{\frac{1}{2}} \oplus (Z^*Z)^{\frac{1}{2}} = \widetilde{W}_1 + \widetilde{W}_2$ is invertible and as $(A^{-1} + B^{-1})^{-1} = A(A+B)^{-1}B$ for any positive definite matrices A and B of the same dimensions,

$$\widetilde{W}(Z) = 2\widetilde{W}_1\big(\widetilde{W}_1 + \widetilde{W}_2\big)^{-1}\widetilde{W}_2 = 2(\widetilde{W}_1^{-1} + \widetilde{W}_2^{-1})^{-1}. \tag{27}$$

We use the more general definition $\widetilde{W}(Z)$ as it is well-defined for any full-rank $Z \in M_{d_1 \times d_2}$ and as it allows to handle the case of non-square matrices, i.e., the case $d_1 \neq d_2$, as in this case $(ZZ^*)^{\frac{1}{2}}$ or $(Z^*Z)^{\frac{1}{2}}$ has to be singular. Using the Moore-Penrose pseudo inverse $\widetilde{W}_1^+$ and $\widetilde{W}_2^+$ of the matrices $\widetilde{W}_1$ and $\widetilde{W}_2$, we can rewrite $\widetilde{W}(Z)$ from Definition 13 as

$$\widetilde{W}(Z) = 2\widetilde{W}_1\big(\widetilde{W}_1 + \widetilde{W}_2\big)^{-1}\widetilde{W}_2 = 2(\widetilde{W}_1^{+} + \widetilde{W}_2^{+})^{-1}.$$

With the auxiliary functional $\mathcal{J}_p$ at hand, we can interpret Algorithm 1 as an alternating minimization of the functional $\mathcal{J}_p(X, \epsilon, Z)$ with respect to its arguments X, ϵ and Z.

In the following, we derive the formula (15) for the weight matrix $\widetilde{W}^{(n+1)}$ as the evaluation $\widetilde{W}^{(n+1)} = \widetilde{W}\big(Z^{(n+1)}\big)$ of $\widetilde{W}$ from Definition 13 at the minimizer

$$Z^{(n+1)} = \operatorname*{arg\,min}_{Z \in M_{d_1 \times d_2}} \mathcal{J}_p(X^{(n+1)}, \epsilon^{(n+1)}, Z), \tag{28}$$

with the minimizer being unique. Similarly, formula (13) can be interpreted as

$$X^{(n+1)} = \operatorname*{arg\,min}_{\substack{X \in M_{d_1 \times d_2} \\ \Phi(X) = Y}} \|X_{\mathrm{vec}}\|^2_{\ell_2(\widetilde{W}(Z^{(n)}))} = \operatorname*{arg\,min}_{\substack{X \in M_{d_1 \times d_2} \\ \Phi(X) = Y}} \mathcal{J}_p(X, \epsilon^{(n)}, Z^{(n)}). \tag{29}$$

These observations constitute the starting point of the convergence analysis of Algorithm 1, which is detailed subsequently after the verification of the optimization steps.

6.1 Optimization of $\mathcal{J}_p$ with respect to Z and X

We fix $X \in M_{d_1 \times d_2}$ with singular value decomposition $X = \sum_{i=1}^{d} \sigma_i u_i v_i^*$, where $u_i \in \mathbb{C}^{d_1}$ $v_i \in \mathbb{C}^{d_2}$ are the left and right singular vectors respectively and $\sigma_i = \sigma_i(X)$ denote its singular values for $i \in [d]$.

Our objective in the following is the justification of formula (15). To yield the building blocks of the weight matrix $\widetilde{W}^{(n+1)}$, we consider the minimization problem

$$\operatorname*{arg\,min}_{Z \in M_{d_1 \times d_2}} \mathcal{J}_p(X, \epsilon, Z) \tag{30}$$

for $\epsilon > 0$.

Lemma 14 *The unique minimizer of* (30) *is given by*

$$Z_{\mathrm{opt}} = \sum_{i=1}^{d} (\sigma_i(X)^2 + \epsilon^2)^{\frac{p-2}{2}} u_i v_i^*.$$

Furthermore, the value of $\mathcal{J}_p$ at the minimizer Z_{opt} is

$$\mathcal{J}_p(X, \epsilon, Z_{\mathrm{opt}}) = \sum_{i=1}^{d} (\sigma_i(X)^2 + \epsilon^2)^{\frac{p}{2}} =: g_\epsilon^p(X) \tag{31}$$

for $p > 0$.

The proof of Lemma 14 is detailed in Appendix B.

Remark 15 *We note that the value of $\mathcal{J}_p(X, \epsilon, Z_{\mathrm{opt}})$ can be interpreted as a smooth ϵ-perturbation of a p-th power of a Schatten-p quasi-norm of the matrix X. In fact, for $\epsilon = 0$ we have*

$$\mathcal{J}_p(X, 0, Z_{\mathrm{opt}}) = \|X\|_{S_p}^p = g_0^p(X).$$

Now, we show that our definition rule (13) of $X^{(n+1)}$ in Algorithm 1 can be interpreted as a minimization of the auxiliary functional $\mathcal{J}_p$ with respect to the variable X. Additionally, this minimization step can be formulated as the solution of a weighted least squares problem with weight matrix $\widetilde{W}^{(n)}$. This is summarized in the following lemma.

Lemma 16 *Let $0 < p \leqslant 1$. Given a full-rank matrix $Z \in M_{d_1 \times d_2}$, let $\widetilde{W}(Z) := 2([[(ZZ^*)^{\frac{1}{2}}]^+ \oplus [(Z^*Z)^{\frac{1}{2}}]^+)^{-1} \in H_{d_1 d_2 \times d_1 d_2}$ be the matrix from Definition 13 and $\mathcal{W}^{-1} : M_{d_1 \times d_2} \to M_{d_1 \times d_2}$ the linear operator of its inverse*

$$\mathcal{W}^{-1}(X) := \frac{1}{2}\left[[(ZZ^*)^{\frac{1}{2}}]^+ X + X[(Z^*Z)^{\frac{1}{2}}]^+\right].$$

Then the matrix

$$X_{\mathrm{opt}} = \big(\mathcal{W}^{-1} \circ \Phi^* \circ (\Phi \circ \mathcal{W}^{-1} \circ \Phi^*)^{-1}\big)\big(Y\big) \in M_{d_1 \times d_2}$$

is the unique minimizer of the optimization problems

$$\operatorname*{arg\,min}_{\Phi(X) = Y} \mathcal{J}_p(X, \epsilon, Z) = \operatorname*{arg\,min}_{\Phi(X) = Y} \|X_{\mathrm{vec}}\|^2_{\ell_2(\widetilde{W})}. \tag{32}$$

Moreover, a matrix $X_{\mathrm{opt}} \in M_{d_1 \times d_2}$ is a minimizer of the minimization problem (32) *if and only if it fulfills the property*

$$\langle \widetilde{W}(Z)(X_{\mathrm{opt}})_{\mathrm{vec}}, H_{\mathrm{vec}} \rangle_{\ell_2} = 0 \quad \text{for all} \quad H \in \mathcal{N}(\Phi) \quad \text{and} \quad \Phi(X_{\mathrm{opt}}) = Y. \tag{33}$$

In Appendix B, the interested reader can find a sketch of the proof of this lemma.

6.2 Basic properties of the algorithm and convergence results

In the following subsection, we will have a closer look at Algorithm 1 and point out some of its properties, in particular, the boundedness of the iterates $(X^{(n)})_{n \in \mathbb{N}}$ and the fact that two consecutive iterates are getting arbitrarily close as $n \to \infty$. These results will be used to show convergence and to determine the rate of convergence of Algorithm 1 under conditions determined along the way.

Lemma 17 *Let $(X^{(n)}, \epsilon^{(n)})_{n\in\mathbb{N}}$ be the sequence of iterates and smoothing parameters of Algorithm 1. Let $X^{(n)} = \sum_{i=1}^{d} \sigma_i^{(n)} u_i^{(n)} v_i^{(n)*}$ be the SVD of the n-th iterate $X^{(n)}$. Let $(Z^{(n)})_{n\in\mathbb{N}}$ be a corresponding sequence such that*

$$Z^{(n)} = \sum_{i=1}^{d} (\sigma_i^{(n)2} + \epsilon^{(n)2})^{\frac{p-2}{2}} u_i^{(n)} v_i^{(n)*}$$

for $n \in \mathbb{N}$. Then the following properties hold:

(a) $\mathcal{J}_p(X^{(n)}, \epsilon^{(n)}, Z^{(n)}) \geqslant \mathcal{J}_p(X^{(n+1)}, \epsilon^{(n+1)}, Z^{(n+1)})$ *for all* $n \geqslant 1$,

(b) $\|X^{(n)}\|_{S_p}^p \leqslant \mathcal{J}_p(X^{(1)}, \epsilon^{(0)}, Z^{(0)}) =: \mathcal{J}_{p,0}$ *for all* $n \geqslant 1$,

(c) The iterates $X^{(n)}, X^{(n+1)}$ come arbitrarily close as $n \to \infty$, i.e., $\lim_{n\to\infty} \|(X^{(n)} - X^{(n+1)})_{\mathrm{vec}}\|_{\ell_2}^2 = 0$.

At this point we notice that, assuming $X^{(n)} \to \bar{X}$ and $\epsilon^{(n)} \to \bar{\epsilon}$ for $n \to \infty$ with the limit point $(\bar{X}, \bar{\epsilon}) \in M_{d_1\times d_2} \times \mathbb{R}_{\geqslant 0}$, it would follow that

$$\mathcal{J}_p(X^{(n)}, \epsilon^{(n)}, Z^{(n)}) \to g_{\bar{\epsilon}}^p(\bar{X})$$

for $n \to \infty$ by equation (31).

Now, let $\epsilon > 0$, a measurement vector $Y \in \mathbb{C}^m$ and the linear operator Φ be given and consider the optimization problem

$$\min_{\substack{X\in M_{d_1\times d_2} \\ \Phi(X)=Y}} g_\epsilon^p(X) \tag{34}$$

with $g_\epsilon^p(X) = \sum_{i=1}^{d} (\sigma_i(X)^2 + \epsilon^2)^{\frac{p}{2}}$ and $\sigma_i(X)$ being the i-th singular value of X, cf. (31). If $g_\epsilon^p(X)$ is non-convex, which is the case for $p < 1$, one might practically only be able to find critical points of the problem.

Lemma 18 *Let $X \in M_{d_1\times d_2}$ be a matrix with the SVD such that $X = \sum_{i=1}^{d} \sigma_i u_i v_i^*$, let $\epsilon > 0$. If we define*

$$\widetilde{W}(X, \epsilon) = 2\left[\Big(\sum_{i=1}^{d} (\sigma_i^2 + \epsilon^2)^{\frac{2-p}{2}} u_i u_i^* \Big) \oplus \Big(\sum_{i=1}^{d} (\sigma_i^2 + \epsilon^2)^{\frac{2-p}{2}} v_i v_i^* \Big) \right]^{-1} \in H_{d_1 d_2 \times d_1 d_2},$$

then $\widetilde{W}(X^{(n)}, \epsilon^{(n)}) = \widetilde{W}^{(n)}$, with $\widetilde{W}^{(n)}$ defined as in Algorithm 1, cf. (10). Furthermore, X is a critical point of the optimization problem (34) if and only if

$$\langle \widetilde{W}(X, \epsilon) X_{\mathrm{vec}}, H_{\mathrm{vec}} \rangle_{\ell_2} = 0 \quad \text{for all} \quad H \in \mathcal{N}(\Phi) \quad \text{and} \quad \Phi(X) = Y. \tag{35}$$

In the case that g_ϵ^p is convex, i.e., if $p = 1$, (35) implies that X is the unique minimizer of (34).

Now, we have some basic properties of the algorithm at hand that allow us, together with the strong nullspace property in Definition 4 to carry out the proof of the convergence result in Theorem 9. The proof is sketched in Appendix C using the results above.

6.3 Locally superlinear convergence

In the proof of Theorem 11 we use the following bound on perturbations of the singular value decomposition, which is originally due to Wedin (1972). It bounds the alignment of the subspaces spanned by the singular vectors of two matrices by their norm distance, given a gap between the first singular values of the one matrix and the last singular values of the other matrix that is sufficiently pronounced.

Lemma 19 (Wedin's bound (Stewart, 2006)) *Let X and $\bar{X}$ be two matrices of the same size and their singular value decompositions*

$$X = \begin{pmatrix} U_1 & U_2 \end{pmatrix} \begin{pmatrix} \Sigma_1 & 0 \\ 0 & \Sigma_2 \end{pmatrix} \begin{pmatrix} V_1^* \\ V_2^* \end{pmatrix} \quad \text{and} \quad \bar{D} = \begin{pmatrix} \bar{U}_1 & \bar{U}_2 \end{pmatrix} \begin{pmatrix} \bar{\Sigma}_1 & 0 \\ 0 & \bar{\Sigma}_2 \end{pmatrix} \begin{pmatrix} \bar{V}_1^* \\ \bar{V}_2^* \end{pmatrix},$$

where the submatrices have the sizes of corresponding dimensions. Suppose that δ, α satisfying $0 < \delta \leqslant \alpha$ are such that $\alpha \leqslant \sigma_{\min}(\Sigma_1)$ and $\sigma_{\max}(\bar{\Sigma}_2) < \alpha - \delta$. Then

$$\|\bar{U}_2^* U_1\|_{S_\infty} \leqslant \sqrt{2} \frac{\|X - \bar{X}\|_{S_\infty}}{\delta} \text{ and } \|\bar{V}_2^* V_1\|_{S_\infty} \leqslant \sqrt{2} \frac{\|X - \bar{X}\|_{S_\infty}}{\delta}. \tag{36}$$

As a first step towards the proof of Theorem 11, we show the following lemma.

Lemma 20 *Let $(X^{(n)})_n$ be the output sequence of Algorithm 1 for parameters Φ, Y, r and $0 < p \leqslant 1$, and $X_0 \in M_{d_1\times d_2}$ be a matrix such that $\Phi(X_0) = Y$.*

(i) Let $\eta_{2r}^{(n+1)}$ be the best rank-$2r$ approximation of $\eta^{(n+1)} = X^{(n+1)} - X_0$. Then

$$\|\eta^{(n+1)} - \eta_{2r}^{(n+1)}\|_{S_p}^{2p} \leqslant 2^{2-p} \Bigg(\sum_{i=r+1}^{d} \big(\sigma_i^2(X^{(n)}) + \epsilon^{(n)2}\big)^{\frac{p}{2}} \Bigg)^{2-p} \|\eta_{\mathrm{vec}}^{(n+1)}\|_{\ell_2(\widetilde{W}^{(n)})}^{2p},$$

where $\widetilde{W}^{(n)}$ denotes the harmonic mean weight matrix from (10).

(ii) Assume that the linear map $\Phi : M_{d_1\times d_2} \to \mathbb{C}^m$ fulfills the strong Schatten-p NSP of order $2r$ with constant $\gamma_{2r} < 1$. Then

$$\|\eta^{(n+1)}\|_{S_2}^{2p} \leqslant 2^p \frac{\gamma_{2r}^{2-p}}{r^{2-p}} \Bigg(\sum_{i=r+1}^{d} \big(\sigma_i^2(X^{(n)}) + \epsilon^{(n)2}\big)^{\frac{p}{2}} \Bigg)^{2-p} \|\eta_{\mathrm{vec}}^{(n+1)}\|_{\ell_2(\widetilde{W}^{(n)})}^{2p}. \tag{37}$$

(iii) Under the same assumption as for (ii), it holds that

$$\|\eta^{(n+1)}\|_{S_p}^{2p} \leqslant (1 + \gamma_{2r})^2 2^{2-p} \Bigg(\sum_{i=r+1}^{d} \big(\sigma_i^2(X^{(n)}) + \epsilon^{(n)2}\big)^{\frac{p}{2}} \Bigg)^{2-p} \|\eta_{\mathrm{vec}}^{(n+1)}\|_{\ell_2(\widetilde{W}^{(n)})}^{2p}.$$

Proof (i) Let the $X^{(n)} = \widetilde{U}^{(n)} \Sigma^{(n)} \widetilde{V}^{(n)*}$ be the (full) singular value decomposition of $X^{(n)}$, i.e., $\widetilde{U}^{(n)} \in \mathcal{U}_{d_1}$ and $\widetilde{V}^{(n)} \in \mathcal{U}_{d_2}$ are unitary matrices and $\Sigma^{(n)} = \mathrm{diag}(\sigma_1(X^{(n)}), \ldots, \sigma_r(X^{(n)})) \in M_{d_1\times d_2}$. We define $U_T^{(n)} \in M_{d_1\times r}$ as the matrix of the first r columns of $\widetilde{U}^{(n)}$ and $U_{T_c}^{(n)} \in$

$M_{d_1\times(d_1-r)}$ as the matrix of its last d_1-r columns, so that $\widetilde{U}^{(n)} = \begin{pmatrix} U_T^{(n)} & U_{T_c}^{(n)} \end{pmatrix}$, and similarly $V_T^{(n)}$ and $V_{T_c}^{(n)}$.

As $\mathbf{I}_{d_1} = U_T^{(n)}U_T^{(n)*} + U_{T_c}^{(n)}U_{T_c}^{(n)*}$ and $\mathbf{I}_{d_2} = V_T^{(n)}V_T^{(n)*} + V_{T_c}^{(n)}V_{T_c}^{(n)*}$, we note that

$$U_{T_c}^{(n)}U_{T_c}^{(n)*}\eta^{(n+1)}V_{T_c}^{(n)}V_{T_c}^{(n)*} = \eta^{(n+1)} - U_T^{(n)}U_T^{(n)*}\eta^{(n+1)} + U_{T_c}^{(n)}U_{T_c}^{(n)*}\eta^{(n+1)}V_T^{(n)}V_T^{(n)*},$$

while $U_T^{(n)}U_T^{(n)*}\eta^{(n+1)} + U_{T_c}^{(n)}U_{T_c}^{(n)*}\eta^{(n+1)}V_T^{(n)}V_T^{(n)*}$ has a rank of at most $2r$. This implies that

$$\|\eta^{(n+1)} - \eta_{2r}^{(n+1)}\|_{S_p} \leqslant \|U_{T_c}^{(n)}U_{T_c}^{(n)*}\eta^{(n+1)}V_{T_c}^{(n)}V_{T_c}^{(n)*}\|_{S_p} = \|U_{T_c}^{(n)*}\eta^{(n+1)}V_{T_c}^{(n)}\|_{S_p}. \tag{38}$$

Using the definitions of $\widetilde{U}^{(n)}$ and $\widetilde{V}^{(n)}$, we write the harmonic mean weight matrices of the n-th iteration (10) as

$$\widetilde{W}^{(n)} = 2(\widetilde{V}^{(n)}\otimes\widetilde{U}^{(n)})\big(\bar{\Sigma}_{d_1}^{(n)2-p}\oplus\bar{\Sigma}_{d_2}^{(n)2-p}\big)^{-1}(\widetilde{V}^{(n)}\otimes\widetilde{U}^{(n)})^*, \tag{39}$$

where $\bar{\Sigma}_{d_1}^{(n)} \in M_{d_1\times d_1}$ and $\bar{\Sigma}_{d_2}^{(n)} \in M_{d_2\times d_2}$ are the diagonal matrices with the smoothed singular values of $X^{(n)}$ from (11), but filled up with zeros if necessary. Using the abbreviation

$$\Omega := (\widetilde{V}^{(n)}\otimes\widetilde{U}^{(n)})^*\widetilde{W}^{(n)\frac{1}{2}}\eta_{\mathrm{vec}}^{(n+1)} \in \mathbb{C}^{d_1d_2}, \tag{40}$$

we rewrite

$$\begin{aligned}\eta_{\mathrm{vec}}^{(n+1)} &= \widetilde{W}^{(n)-\frac{1}{2}}\widetilde{W}^{(n)\frac{1}{2}}\eta_{\mathrm{vec}}^{(n+1)} = 2^{-1/2}(\widetilde{V}^{(n)}\otimes\widetilde{U}^{(n)})\big(\bar{\Sigma}_{d_1}^{(n)2-p}\oplus\bar{\Sigma}_{d_2}^{(n)2-p}\big)^{1/2}\Omega\\ &= 2^{-1/2}(\widetilde{V}^{(n)}\otimes\widetilde{U}^{(n)})\left[(\mathbf{I}_{d_2}\otimes\bar{\Sigma}_{d_1}^{(n)\frac{2-p}{2}})D_L + (\bar{\Sigma}_{d_2}^{(n)\frac{2-p}{2}}\otimes\mathbf{I}_{d_1})D_R\right]\Omega\end{aligned} \tag{41}$$

with the diagonal matrices $D_L, D_R \in M_{d_1d_2\times d_1d_2}$ such that

$$(D_L)_{i+(j-1)d_1,i+(j-1)d_1} = \Big(1+\Big(\frac{\sigma_j^2(X^{(n)})+\epsilon^{(n)2}}{\sigma_i^2(X^{(n)})+\epsilon^{(n)2}}\Big)^{\frac{2-p}{2}}\Big)^{-1/2}$$

and

$$(D_R)_{i+(j-1)d_1,i+(j-1)d_1} = \Big(\Big(\frac{\sigma_i^2(X^{(n)})+\epsilon^{(n)2}}{\sigma_j^2(X^{(n)})+\epsilon^{(n)2}}\Big)^{\frac{2-p}{2}}+1\Big)^{-1/2}$$

for $i\in[d_1]$ and $j\in[d_2]$. This can be seen from the definitions of the Kronecker product $\otimes$ and the Kronecker sum $\oplus$ (cf. Appendix A), as

$$\begin{aligned}&\Big(\big(\bar{\Sigma}_{d_1}^{(n)2-p}\oplus\bar{\Sigma}_{d_2}^{(n)2-p}\big)^{1/2}\Big)_{i+(j-1)d_1,i+(j-1)d_1} = (s_i+s_j)^{1/2}\\ &= s_i(s_i+s_j)^{-1/2} + s_j(s_i+s_j)^{-1/2} = s_i^{1/2}(1+\frac{s_j}{s_i})^{-1/2} + s_j^{1/2}(\frac{s_i}{s_j}+1)^{-1/2}\end{aligned}$$

if s_ℓ denotes the ℓ-th diagonal entry of $\bar{\Sigma}_{d_2}^{(n)2-p}$ and $\bar{\Sigma}_{d_1}^{(n)2-p}$ for $\ell\in[\max(d_1,d_2)]$.

If we write $\bar{\Sigma}_{d_1,T_c}^{(n)\frac{2-p}{2}} \in M_{(d_1-r)\times(d_1-r)}$ for the diagonal matrix containing the d_1-r last diagonal elements of $\bar{\Sigma}_{d_1}^{(n)2-p}$ and $\bar{\Sigma}_{d_2,T_c}^{(n)\frac{2-p}{2}} \in M_{(d_1-r)\times(d_1-r)}$ for the diagonal matrix containing the d_2-r last diagonal elements of $\bar{\Sigma}_{d_2}^{(n)2-p}$, it follows from (41) that

$$\begin{aligned}\big\|U_{T_c}^{(n)*}\eta^{(n+1)}V_{T_c}^{(n)}\big\|_{S_p}^p &= 2^{-\frac{p}{2}}\Big\|U_{T_c}^{(n)*}\widetilde{U}^{(n)}\Big[\bar{\Sigma}_{d_1}^{(n)\frac{2-p}{2}}(D_L\Omega)_{\mathrm{mat}} + (D_R\Omega)_{\mathrm{mat}}\bar{\Sigma}_{d_2}^{(n)\frac{2-p}{2}}\Big]\widetilde{V}^{(n)*}V_{T_c}^{(n)}\Big\|_{S_p}^p\\ &\leqslant 2^{-\frac{p}{2}}\Big\|\bar{\Sigma}_{d_1,T_c}^{(n)\frac{2-p}{2}}\big[(D_L\Omega)_{\mathrm{mat}}\big]_{T_c,T_c}\Big\|_{S_p}^p + \Big\|\big[(D_R\Omega)_{\mathrm{mat}}\big]_{T_c,T_c}\bar{\Sigma}_{d_2,T_c}^{(n)\frac{2-p}{2}}\Big\|_{S_p}^p\end{aligned}$$

with the notation that M_{T_c,T_c} denotes the submatrix of M which contains the intersection of the last d_1-r rows of M with its last d_2-r columns.

Now, Hölder's inequality for Schatten-p quasi-norms (e.g., Gohberg et al. (2000, Theorem 11.2)) can be used to see that

$$\Big\|\bar{\Sigma}_{d_1,T_c}^{(n)\frac{2-p}{2}}\big[(D_L\Omega)_{\mathrm{mat}}\big]_{T_c,T_c}\Big\|_{S_p}^p \leqslant \Big\|\bar{\Sigma}_{T_c}^{(n)\frac{2-p}{2}}\Big\|_{S_{\frac{2p}{2-p}}}^p\Big\|\big[(D_L\Omega)_{\mathrm{mat}}\big]_{T_c,T_c}\Big\|_{S_2}^p. \tag{42}$$

Inserting the definition

$$\Big\|\bar{\Sigma}_{T_c}^{(n)\frac{2-p}{2}}\Big\|_{S_{\frac{2p}{2-p}}}^p = \Big(\sum_{i=r+1}^d\big(\sigma_i^2(X^{(n)})+\epsilon^{(n)2}\big)^{\frac{2p(2-p)}{(2-p)4}}\Big)^{\frac{2-p}{2}} = \Big(\sum_{i=r+1}^d\big(\sigma_i^2(X^{(n)})+\epsilon^{(n)2}\big)^{\frac{p}{2}}\Big)^{\frac{2-p}{2}}$$

allows us to rewrite the first factor, while the second factor can be bounded by

$$\begin{aligned}\big\|\big[(D_L\Omega)_{\mathrm{mat}}\big]_{T_c,T_c}\big\|_{S_2}^p &\leqslant \big\|(D_L\Omega)_{\mathrm{mat}}\big\|_{S_2}^p \leqslant \|\Omega_{\mathrm{mat}}\|_{S_2}^p = \|(\widetilde{V}^{(n)}\otimes\widetilde{U}^{(n)})^*\widetilde{W}^{(n)\frac{1}{2}}\eta_{\mathrm{vec}}^{(n+1)}\|_{\ell_2}^p\\ &= \|\widetilde{W}^{(n)\frac{1}{2}}\eta_{\mathrm{vec}}^{(n+1)}\|_{\ell_2}^p = \|\eta_{\mathrm{vec}}^{(n+1)}\|_{\ell_2(\widetilde{W}^{(n)})}^p,\end{aligned}$$

as the matrix $D_L\in M_{d_1d_2\times d_1d_2}$ from (41) fulfills $\|D_L\|_{S_\infty}\leqslant 1$ since its entries are bounded by 1; we also recall the definition (40) of Ω and that $\widetilde{V}^{(n)}$ and $\widetilde{U}^{(n)}$ are unitary.

The term $\Big\|\big[(D_R\Omega)_{\mathrm{mat}}\big]_{T_c,T_c}\bar{\Sigma}_{d_2,T_c}^{(n)\frac{2-p}{2}}\Big\|_{S_p}^p$ in the bound of $\big\|U_{T_c}^{(n)*}\eta^{(n+1)}V_{T_c}^{(n)}\big\|_{S_p}^p$ can be estimated analogously. Combining this with (38), we obtain

$$\|\eta^{(n+1)} - \eta_{2r}^{(n+1)}\|_{S_p}^{2p} \leqslant 2^{-p}\Big(2\Big(\sum_{i=r+1}^d\big(\sigma_i^2(X^{(n)})+\epsilon^{(n)2}\big)^{\frac{p}{2}}\Big)^{\frac{2-p}{2}}\Big)^2\|\eta_{\mathrm{vec}}^{(n+1)}\|_{\ell_2(\widetilde{W}^{(n)})}^{2p},$$

concluding the proof of statement (i).

(ii) Using the strong Schatten-p null space property (18) of order $2r$ and that $\eta^{(n+1)}\in\mathcal{N}(\Phi)$, we estimate

$$\begin{aligned}\|\eta^{(n+1)}\|_{S_2}^{2p} &= \big(\|\eta_{2r}^{(n+1)}\|_{S_2}^2 + \|\eta^{(n+1)} - \eta_{2r}^{(n+1)}\|_{S_2}^2\big)^p \leqslant \Big(\frac{\gamma_{2r}^{2/p}+\gamma_{2r}^{2/p-1}}{(2r)^{2/p-1}}\|\eta^{(n+1)} - \eta_{2r}^{(n+1)}\|_{S_p}^2\Big)^p\\ &\leqslant \frac{\gamma_{2r}^{2-p}(\gamma_{2r}+1)^p}{(2r)^{2-p}}\|\eta^{(n+1)} - \eta_{2r}^{(n+1)}\|_{S_p}^{2p} \leqslant 2^p\frac{\gamma_{2r}^{2-p}}{2^{2-p}r^{2-p}}\|\eta^{(n+1)} - \eta_{2r}^{(n+1)}\|_{S_p}^{2p},\end{aligned}$$

where we use in the second inequality a version of Stechkin's lemma (Kabanava et al., 2016, Lemma 3.1), which leads to the estimate

$$\|\eta^{(n+1)} - \eta_{2r}^{(n+1)}\|_{S_2}^2 \leqslant \frac{\|\eta_{2r}^{(n+1)}\|_{S_2}^{2-p}}{(2r)^{2-p}}\|\eta^{(n+1)} - \eta_{2r}^{(n+1)}\|_{S_p}^p \leqslant \frac{\gamma_{2r}^{2/p-1}}{(2r)^{2/p-1}}\|\eta^{(n+1)} - \eta_{2r}^{(n+1)}\|_{S_p}^2.$$

Combining the estimate for $\|\eta^{(n+1)}\|_{S_2}^{2p}$ with statement (i), this results in

$$\|\eta^{(n+1)}\|_{S_2}^{2p} \leqslant 2^p \frac{\gamma_{2r}^{2-p}}{r^{2-p}}\Big(\sum_{i=r+1}^{d}\big(\sigma_i^2(X^{(n)}) + \epsilon^{(n)2}\big)^{\frac{p}{2}}\Big)^{2-p}\|\eta_{\mathrm{vec}}^{(n+1)}\|_{\ell_2(\widetilde{W}^{(n)})}^{2p},$$

which shows statement (ii).

(iii) For the third statement, we use the strong Schatten-p NSP (18) to see that

$$\|\eta^{(n+1)}\|_{S_p}^p = \|\eta_{2r}^{(n+1)}\|_{S_p}^p + \|\eta^{(n+1)} - \eta_{2r}^{(n+1)}\|_{S_p}^p \leqslant (1+\gamma_{2r})\|\eta^{(n+1)} - \eta_{2r}^{(n+1)}\|_{S_p}^p,$$

and combine this with statement (i). ∎

Lemma 21 *Let $(X^{(n)})_n$ be the output sequence of Algorithm 1 with parameters Φ, Y, r and $0 < p \leqslant 1$, and $\widetilde{W}^{(n)}$ be the harmonic mean weight matrix matrix (10) for $n \in \mathbb{N}$. Let $X_0 \in M_{d_1\times d_2}$ be a rank-r matrix such that $\Phi(X_0) = Y$ with condition number $\kappa := \frac{\sigma_1(X_0)}{\sigma_r(X_0)}$.*

(i) If (24) is fulfilled for iteration n, then $\eta^{(n+1)} = X^{(n)} - X_0$ fulfills

$$\Big\|\eta_{\mathrm{vec}}^{(n+1)}\Big\|_{\ell_2(\widetilde{W}^{(n)})}^{2p} \leqslant \frac{4^p r^{p/2}\sigma_r(X_0)^{p(p-1)}}{(1-\zeta)^{2p}}\kappa^p\frac{\|\eta^{(n)}\|_{S_\infty}^{2p-p^2}}{(\epsilon^{(n)})^{2p-p^2}}\|\eta^{(n+1)}\|_{S_2}^p.$$

(ii) Under the same assumption as for (i), it holds that

$$\Big\|\eta_{\mathrm{vec}}^{(n+1)}\Big\|_{\ell_2(\widetilde{W}^{(n)})}^{2p} \leqslant \frac{7^p r^{p/2}\max(r,d-r)^{p/2}\sigma_r(X_0)^{p(p-1)}}{(1-\zeta)^{2p}}\kappa^p\frac{\|\eta^{(n)}\|_{S_\infty}^{2p-p^2}}{(\epsilon^{(n)})^{2p-p^2}}\|\eta^{(n+1)}\|_{S_\infty}^p.$$

Proof (i) Recall that $X^{(n+1)} = \operatorname*{arg\,min}_{\Phi(X)=Y}\|X_{\mathrm{vec}}\|_{\ell_2(\widetilde{W}^{(n)})}^2$ is the minimizer of the weighted least squares problem with weight matrix $\widetilde{W}^{(n)}$. As $\eta^{(n+1)} = X^{(n+1)} - X_0$ is in the null space of the measurement map Φ, it follows from Lemma 16 that

$$0 = \langle\widetilde{W}^{(n)}X_{\mathrm{vec}}^{(n+1)}, \eta_{\mathrm{vec}}^{(n+1)}\rangle = \langle\widetilde{W}^{(n)}(\eta^{(n+1)} + X_0)_{\mathrm{vec}}, \eta_{\mathrm{vec}}^{(n+1)}\rangle,$$

which is equivalent to

$$\Big\|\eta_{\mathrm{vec}}^{(n+1)}\Big\|_{\ell_2(\widetilde{W}^{(n)})}^2 = \langle\widetilde{W}^{(n)}\eta_{\mathrm{vec}}^{(n+1)}, \eta_{\mathrm{vec}}^{(n+1)}\rangle = -\langle\widetilde{W}^{(n)}(X_0)_{\mathrm{vec}}, \eta_{\mathrm{vec}}^{(n+1)}\rangle.$$

Using Hölder's inequality, we can therefore estimate

$$\begin{aligned}\Big\|\eta_{\mathrm{vec}}^{(n+1)}\Big\|_{\ell_2(\widetilde{W}^{(n)})}^2 &= -\langle\widetilde{W}^{(n)}(X_0)_{\mathrm{vec}}, \eta_{\mathrm{vec}}^{(n+1)}\rangle_{\ell_2} = -\langle\big[\widetilde{W}^{(n)}(X_0)_{\mathrm{vec}}\big]_{\mathrm{mat}}, \eta^{(n+1)}\rangle_F \\ &\leqslant \big\|\big[\widetilde{W}^{(n)}(X_0)_{\mathrm{vec}}\big]_{\mathrm{mat}}\big\|_{S_2}\|\eta^{(n+1)}\|_{S_2}.\end{aligned} \tag{43}$$

To bound the first factor, we first rewrite the action of $\widetilde{W}^{(n)}$ on X_0 in the matrix space as

$$\begin{aligned}\Big[\widetilde{W}^{(n)}(X_0)_{\mathrm{vec}}\Big]_{\mathrm{mat}} &= 2[(\widetilde{V}^{(n)}\otimes\widetilde{U}^{(n)})\big(\bar{\Sigma}_{d_1}^{(n)2-p}\oplus\bar{\Sigma}_{d_2}^{(n)2-p}\big)^{-1}(\widetilde{V}^{(n)}\otimes\widetilde{U}^{(n)})^*(X_0)_{\mathrm{vec}}]_{\mathrm{mat}} = \\ &= \widetilde{U}^{(n)}\big(H^{(n)}\circ(\widetilde{U}^{(n)*}X_0\widetilde{V}^{(n)})\big)\widetilde{V}^{(n)*},\end{aligned}$$

using (39) and Lemma 20 about the action of inverses of Kronecker sums, with the notation that $H^{(n)} \in M_{d_1\times d_2}$ such that

$$H_{ij}^{(n)} = 2\Big[\mathbb{1}_{\{i\leqslant d\}}(\sigma_i^2(X^{(n)}) + \epsilon^{(n)2})^{\frac{2-p}{2}} + \mathbb{1}_{\{j\leqslant d\}}(\sigma_j^2(X^{(n)}) + \epsilon^{(n)2})^{\frac{2-p}{2}}\Big]^{-1}$$

for $i \in [d_1]$, $j \in [d_2]$, where $\mathbb{1}_{\{i\leqslant d\}} = 1$ if $i \leqslant d$ and $\mathbb{1}_{\{i\leqslant d\}} = 0$ otherwise. This enables us to estimate

$$\begin{aligned}\Big\|\big[\widetilde{W}^{(n)}(X_0)_{\mathrm{vec}}\big]_{\mathrm{mat}}\Big\|_{S_2}^2 &= \Big\|\widetilde{U}^{(n)}\big(H^{(n)}\circ(\widetilde{U}^{(n)*}X_0\widetilde{V}^{(n)})\big)\widetilde{V}^{(n)*}\Big\|_{S_2}^2 = \Big\|H^{(n)}\circ(\widetilde{U}^{(n)*}X_0\widetilde{V}^{(n)})\Big\|_{S_2}^2 \\ &= \left\|H^{(n)}\circ\begin{pmatrix}U_T^{(n)*}X_0V_T^{(n)} & U_T^{(n)*}X_0V_{T_c}^{(n)}\\ U_{T_c}^{(n)*}X_0V_T^{(n)} & U_{T_c}^{(n)*}X_0V_{T_c}^{(n)}\end{pmatrix}\right\|_{S_2}^2 \\ &= \Big\|H_{T,T}^{(n)}\circ(U_T^{(n)*}X_0V_T^{(n)})\Big\|_{S_2}^2 + \Big\|H_{T,T_c}^{(n)}\circ(U_T^{(n)*}X_0V_{T_c}^{(n)})\Big\|_{S_2}^2 \\ &+ \Big\|H_{T_c,T}^{(n)}\circ(U_{T_c}^{(n)*}X_0V_T^{(n)})\Big\|_{S_2}^2 + \Big\|H_{T_c,T_c}^{(n)}\circ(U_{T_c}^{(n)*}X_0V_{T_c}^{(n)})\Big\|_{S_2}^2,\end{aligned} \tag{44}$$

using the notation from the proof of Lemma 20. To bound the first summand, we calculate

$$\begin{aligned}&\Big\|H_{T,T}^{(n)}\circ(U_T^{(n)*}X_0V_T^{(n)})\Big\|_{S_2} \leqslant \Big\|H_{T,T}^{(n)}\circ(U_T^{(n)*}X^{(n)}V_T^{(n)})\Big\|_{S_2} + \Big\|H_{T,T}^{(n)}\circ(-U_T^{(n)*}\eta^{(n)}V_T^{(n)})\Big\|_{S_2} \\ &\leqslant \Big\|H_{T,T}^{(n)}\circ\Sigma_T^{(n)}\Big\|_{S_2} + \Big\|H_{T,T}^{(n)}\circ(U_T^{(n)*}\eta^{(n)}V_T^{(n)})\Big\|_{S_2} \\ &\leqslant \Big(\sum_{i=1}^{r}\frac{\sigma_i^2(X^{(n)})}{\big(\sigma_i^2(X^{(n)}) + \epsilon^{(n)2}\big)^{2-p}}\Big)^{1/2} + \max_{i,j=1}^{r}|H_{i,j}^{(n)}|\|U_T^{(n)*}\eta^{(n)}V_T^{(n)}\|_{S_2} \\ &\leqslant \sqrt{r}\sigma_r^{p-1}(X^{(n)}) + (\sigma_r^2(X^{(n)}) + \epsilon^{(n)2})^{\frac{p-2}{2}}\|U_T^{(n)*}\eta^{(n)}V_T^{(n)}\|_{S_2} \\ &\leqslant \sqrt{r}\sigma_r^{p-1}(X^{(n)}) + \sigma_r^{p-2}(X^{(n)})\sqrt{r}\|\eta^{(n)}\|_{S_\infty} = \sqrt{r}\sigma_r^{p-2}(X^{(n)})\big[\sigma_r(X^{(n)}) + \|\eta^{(n)}\|_{S_\infty}\big],\end{aligned}$$

denoting $\Sigma_T^{(n)} = \mathrm{diag}(\sigma_i(X^{(n)}))_{i=1}^r$ and that the matrices $U_T^{(n)}$ and $V_T^{(n)}$ contain the first r left resp. right singular vectors of $X^{(n)}$ in the second inequality, together with the estimates $\|X\|_{S_1} \leqslant \sqrt{r}\|X\|_{S_2} \leqslant r\|X\|_{S_\infty}$ for $(r\times r)$-matrices X.

With the notations $s_r^0 := \sigma_r(X_0)$ and $s_1^0 := \sigma_1(X_0)$, we note that

$$\sigma_r(X^{(n)}) \geqslant s_r^0(1-\zeta),$$

as the assumption (24) implies that

$$s_r^0 = \sigma_r(X_0) = \sigma_r(X^{(n)} - \eta^{(n)}) \leqslant \sigma_r(X^{(n)}) + \sigma_1(\eta^{(n)}) \leqslant \sigma_r(X^{(n)}) + \zeta s_r^0,$$

using Bernstein (2009, Proposition 9.6.8) in the first inequality.

Therefore, we can bound the first summand of (44) such that

$$\left\| H_{T,T}^{(n)} \circ (U_T^{(n)*} X_0 V_T^{(n)}) \right\|_{S_2} \leqslant \sqrt{r}(s_r^0(1-\zeta))^{p-2}[s_r^0(1-\zeta)+\zeta s_r^0] = \sqrt{r}(s_r^0)^{p-1}(1-\zeta)^{p-2}. \quad (45)$$

For the second summand in the estimate of $\left\| \left[\widetilde{W}^{(n)}(X_0)_{\mathrm{vec}}\right]_{\mathrm{mat}} \right\|_{S_2}^2$, similar arguments and again assumption (24) are used to compute

$$\begin{aligned}
&\left\| H_{T,T_c}^{(n)} \circ (U_T^{(n)*} X_0 V_{T_c}^{(n)}) \right\|_{S_2} \leqslant \left\| H_{T,T_c}^{(n)} \circ \overbrace{(U_T^{(n)*} X^{(n)} V_{T_c}^{(n)})}^{=0} \right\|_{S_2} + \\
&\left\| H_{T,T_c}^{(n)} \circ (U_T^{(n)*} \eta^{(n)} V_{T_c}^{(n)}) \right\|_{S_2} \leqslant \max_{\substack{i\in[r] \\ j\in\{r+1,\dots,d_2\}}} |H_{i,j}^{(n)}| \|U_T^{(n)*} \eta^{(n)} V_{T_c}^{(n)}\|_{S_2} \\
&\leqslant \frac{2\|U_T^{(n)*} \eta^{(n)} V_{T_c}^{(n)}\|_F}{\left[(\sigma_r(X^{(n)})^2 + \epsilon^{(n)2})^{\frac{2-p}{2}}\right]} \leqslant 2\sigma_r(X^{(n)})^{p-2} \|U_T^{(n)*} \eta^{(n)} V_{T_c}^{(n)}\|_{S_2} \\
&\leqslant 2\sqrt{r}(s_r^0(1-\zeta))^{p-2}\|\eta^{(n)}\|_{S_\infty} \leqslant 2\zeta\sqrt{r}(s_r^0)^{p-1}(1-\zeta)^{p-2}.
\end{aligned} \quad (46)$$

From exactly the same arguments it follows that also

$$\left\| H_{T_c,T}^{(n)} \circ (U_{T_c}^{(n)*} X_0 V_T^{(n)}) \right\|_{S_2} \leqslant 2\zeta\sqrt{r}(s_r^0)^{p-1}(1-\zeta)^{p-2}. \quad (47)$$

It remains to bound the last summand $\left\| H_{T_c,T_c}^{(n)} \circ (U_{T_c}^{(n)*} X_0 V_{T_c}^{(n)}) \right\|_{S_2}^2$. We see that

$$\begin{aligned}
&\left\| H_{T_c,T_c}^{(n)} \circ (U_{T_c}^{(n)*} X_0 V_{T_c}^{(n)}) \right\|_{S_2} \leqslant \max_{\substack{i\in\{r+1,\dots,d_1\} \\ j\in\{r+1,\dots,d_2\}}} |H_{i,j}^{(n)}| \|U_{T_c}^{(n)*} X_0 V_{T_c}^{(n)}\|_{S_2} \\
&\leqslant (\epsilon^{(n)})^{p-2} \|U_{T_c}^{(n)*} X_0 V_{T_c}^{(n)}\|_{S_2} \leqslant (\epsilon^{(n)})^{p-2} \|U_{T_c}^{(n)*} U_T^0\|_{S_\infty} \|S^0\|_{S_2} \|V_T^{0*} V_{T_c}^{(n)}\|_{S_\infty} \\
&\leqslant (\epsilon^{(n)})^{p-2} \frac{\sqrt{2}\|\eta^{(n)}\|_{S_\infty}}{(1-\zeta)s_r^0} \sqrt{r} s_1^0 \frac{\sqrt{2}\|\eta^{(n)}\|_{S_\infty}}{(1-\zeta)s_r^0} = 2\sqrt{r}\|\eta^{(n)}\|_{S_\infty}^2 (\epsilon^{(n)})^{p-2}(1-\zeta)^{-2}(s_r^0)^{-1}\frac{s_1^0}{s_r^0},
\end{aligned} \quad (48)$$

where Hölder's inequality for Schatten norms was used in the third inequality. In the fourth inequality, Wedin's singular value perturbation bound of Lemma 19 is used with the choice $Z = X_0$, $\bar{Z} = X^{(n)}$, $\alpha = s_r^0$ and $\delta = (1-\zeta)s_r^0$, and finally $\epsilon^{(n)} \leqslant \zeta s_r^0$ in the last inequality, which is implied by the rule (14) for $\epsilon^{(n)}$ together with assumption (24).

Summarizing the estimates (45)–(48), we conclude that

$$\begin{aligned}
&\left\| \left[\widetilde{W}^{(n)}(X_0)_{\mathrm{vec}}\right]_{\mathrm{mat}} \right\|_{S_2}^2 \leqslant \frac{r(s_r^0)^{2p-2}}{(1-\zeta)^{4-2p}} \left[1 + 8\zeta^2 + 4\frac{\|\eta^{(n)}\|_{S_\infty}^4}{(1-\zeta)^{2p}} (\epsilon^{(n)})^{2p-4} (s_r^0)^{-2p} \left(\frac{s_1^0}{s_r^0}\right)^2 \right] \\
&= \frac{r(s_r^0)^{2p-2}}{(1-\zeta)^4} \left[(1+8\zeta^2)(1-\zeta)^{2p} + 4\frac{\|\eta^{(n)}\|_{S_\infty}^{4-2p}}{(\epsilon^{(n)})^{4-2p}} \frac{\|\eta^{(n)}\|_{S_\infty}^{2p}}{(s_r^0)^{2p}} \left(\frac{s_1^0}{s_r^0}\right)^2 \right] \\
&\leqslant \frac{r(s_r^0)^{2p-2}}{(1-\zeta)^4} \left[9 + 4\frac{\|\eta^{(n)}\|_{S_\infty}^{4-2p}}{(\epsilon^{(n)})^{4-2p}} \zeta^{2p}\kappa^2 \right] \leqslant \frac{13r(s_r^0)^{2p-2}}{(1-\zeta)^4} \left[\frac{\|\eta^{(n)}\|_{S_\infty}^{4-2p}}{(\epsilon^{(n)})^{4-2p}} \kappa^2 \right],
\end{aligned}$$

as $0 < \zeta < 1$, $\epsilon^{(n)} \leqslant \sigma_{r+1}(X^{(n)}) = \|X_{T_c}^{(n)}\|_{S_\infty} \leqslant \|\eta^{(n)}\|_{S_\infty}$ and using the assumption (24) in the second inequality. This concludes the proof of Lemma 21(i) together with inequality (43) as $13^{p/2} \leqslant 16^{p/2} = 4^p$.

(ii) For the second statement of Lemma 21, we proceed similarly as before, but note that by Hölder's inequality, also

$$\left\| \eta_{\mathrm{vec}}^{(n+1)} \right\|_{\ell_2(\widetilde{W}^{(n)})}^2 \leqslant \left\| \left[\widetilde{W}^{(n)}(X_0)_{\mathrm{vec}}\right]_{\mathrm{mat}} \right\|_{S_1} \|\eta^{(n+1)}\|_{S_\infty}, \quad (49)$$

cf. (43). Furthermore

$$\begin{aligned}
\left\| \left[\widetilde{W}^{(n)}(X_0)_{\mathrm{vec}}\right]_{\mathrm{mat}} \right\|_{S_1} &\leqslant \left\| H_{T,T}^{(n)} \circ (U_T^{(n)*} X_0 V_T^{(n)}) \right\|_{S_1} + \left\| H_{T,T_c}^{(n)} \circ (U_T^{(n)*} X_0 V_{T_c}^{(n)}) \right\|_{S_1} \\
&+ \left\| H_{T_c,T}^{(n)} \circ (U_{T_c}^{(n)*} X_0 V_T^{(n)}) \right\|_{S_1} + \left\| H_{T_c,T_c}^{(n)} \circ (U_{T_c}^{(n)*} X_0 V_{T_c}^{(n)}) \right\|_{S_1}.
\end{aligned} \quad (50)$$

The four Schatten-1 norms can then be estimated by $\max(r,(d-r))^{1/2}$ times the corresponding Schatten-2 norms. Using then again inequalities (45)–(48), we conclude the proof of (ii). ∎

We proceed now to the proof of Theorem 11.

Proof First we note that

$$\left(\sum_{i=r+1}^{d} \left(\sigma_i^2(X^{(n)}) + \epsilon^{(n)2}\right)^{\frac{p}{2}} \right)^{2-p} \leqslant 2^{p-\frac{p^2}{2}} (d-r)^{2-p} \sigma_{r+1}(X^{(n)})^{p(2-p)} \quad (51)$$

as $\epsilon^{(n)} \leqslant \sigma_{r+1}(X^{(n+1)})$ due to the choice of $\epsilon^{(n)}$ in (14). We proceed by induction over $n \geqslant \bar{n}$. Theorem 20(ii) and Theorem 21(ii) imply together with (51) that for $n = \bar{n}$,

$$\begin{aligned}
\|\eta^{(n+1)}\|_{S_\infty}^p &\leqslant \frac{\|\eta^{(n+1)}\|_{S_2}^{2p}}{\|\eta^{(n+1)}\|_{S_\infty}^p} \leqslant 2^p \gamma_{2r}^{2-p} 2^{p-\frac{p^2}{2}} \left(\frac{d-r}{r}\right)^{2-p/2} \frac{7^p r^p (s_r^0)^{p(p-1)}}{(1-\zeta)^{2p}} \kappa^p \|\eta^{(n)}\|_{S_\infty}^{2p-p^2} \\
&\leqslant 2^{5p} \gamma_{2r}^{2-p} \left(\frac{d-r}{r}\right)^{2-p/2} \frac{r^p (s_r^0)^{p(p-1)}}{(1-\zeta)^{2p}} \kappa^p \|\eta^{(n)}\|_{S_\infty}^{p(2-p)}
\end{aligned} \quad (52)$$

as $\sigma_{r+1}(X^{(n)}) = \epsilon^{(n)}$ by assumption for $n = \bar{n}$.

Similarly, by Lemma 20(iii), Lemma 21(ii) and (51), the error in the Schatten-p quasi-norm fulfills

$$\|\eta^{(n+1)}\|_{S_p}^{2p} \leqslant (1+\gamma_{2r})^2 2^{2+2p}\big(d-r\big)^{2-p}\frac{r^{p/2}(s_r^0)^{p(p-1)}}{(1-\zeta)^{2p}}\kappa^p\|\eta^{(n)}\|_{S_\infty}^{p(2-p)}\|\eta^{(n+1)}\|_{S_2}^p \tag{53}$$

for $n=\bar{n}$. Using the strong Schatten-p null space property of order $2r$ for the operator Φ, we see with the arguments of the proof of Lemma 20(ii) that

$$\|\eta^{(n)}\|_{S_\infty}^p \leqslant \|\eta^{(n)}\|_{S_2}^p \leqslant \frac{2^{p-1}\gamma_{2r}^{1-p/2}}{r^{1-p/2}}\|\eta^{(n)}\|_{S_p}^p$$

and also $\|\eta^{(n+1)}\|_{S_2}^p \leqslant \frac{2^{p-1}\gamma_{2r}^{1-p/2}}{r^{1-p/2}}\|\eta^{(n+1)}\|_{S_p}^p$. Inserting this in (53) and dividing by $\|\eta^{(n+1)}\|_{S_p}^p$, we obtain

$$\|\eta^{(n+1)}\|_{S_p}^p \leqslant 2^{4p}(1+\gamma_{2r})^2\gamma_{2r}^{2-p}\Big(\frac{d-r}{r}\Big)^{2-p}\frac{r^{p/2}(s_r^0)^{p(p-1)}}{(1-\zeta)^{2p}}\kappa^p\|\eta^{(n)}\|_{S_\infty}^{p(1-p)}\|\eta^{(n)}\|_{S_p}^p.$$

Under the assumption that (25) holds, it follows from this and (52) that

$$\|\eta^{(n+1)}\|_{S_\infty}^p \leqslant \|\eta^{(n)}\|_{S_\infty}^p \text{ and } \|\eta^{(n+1)}\|_{S_p}^p \leqslant \|\eta^{(n)}\|_{S_p}^p \tag{54}$$

for $n=\bar{n}$, which also entails the statement of Theorem 11 for this iteration.

Let now $n'>\bar{n}$ such that (54) is true for all n with $n'>n\geqslant\bar{n}$.

If $\sigma_{r+1}(X^{(n')})\leqslant\epsilon^{(n'-1)}$, then $\epsilon^{(n')}=\sigma_{r+1}(X^{(n')})$ and the arguments from above show (54) also in the case $n=n'$.

Otherwise $\sigma_{r+1}(X^{(n')})>\epsilon^{(n'-1)}$ and there exists $n'>n''\geqslant\bar{n}$ such that $\epsilon^{(n')}=\epsilon^{(n'')}=\sigma_{r+1}(X^{(n'')})$. Then

$$\|\eta^{(n'+1)}\|_{S_\infty}^p \leqslant 14^p\frac{\gamma_{2r}^{2-p}}{r^{2-p}}\Big[\sum_{i=r+1}^d\Big(\frac{\sigma_i^2(X^{(n')})}{\epsilon^{(n'')2}}+1\Big)^{\frac{p}{2}}\Big]^{2-p}\frac{r^{p/2}\max(r,d-r)^{p/2}}{(s_r^0)^{p(1-p)}(1-\zeta)^{2p}}\kappa^p\|\eta^{(n')}\|_{S_\infty}^{p(2-p)}$$

and we compute

$$\begin{aligned}
\Big[\sum_{i=r+1}^d\Big(\frac{\sigma_i^2(X^{(n')})}{\epsilon^{(n'')2}}+1\Big)^{\frac{p}{2}}\Big]^{2-p} &\leqslant \Big[\sum_{i=r+1}^d\frac{\sigma_i^p(X^{(n')})}{\epsilon^{(n'')p}}+(d-r)\Big]^{2-p}\\
&\leqslant \Big[\frac{\|\eta^{(n')}\|_{S_p}^p}{\epsilon^{(n'')p}}+(d-r)\Big]^{2-p} \leqslant \Big[\frac{\|\eta^{(n'')}\|_{S_p}^p}{\epsilon^{(n'')p}}+(d-r)\Big]^{2-p}\\
&\leqslant \Big[\frac{2(1+\gamma_{2r})\|X_{T_c}^{(n'')}\|_{S_p}^p}{(1-\gamma_{2r})\epsilon^{(n'')p}}+(d-r)\Big]^{2-p} \leqslant \Big(\frac{3+\gamma_{2r}}{1-\gamma_{2r}}\Big)^{2-p}(d-r)^{2-p},
\end{aligned}$$

using that X_0 is a matrix of rank at most r in the second inequality, the inductive hypothesis in the third inequality and an analogue of (61) for a Schatten-p quasi-norm on the left hand side (cf. Kabanava et al. (2016, Lemma 3.2) for the corresponding result for $p=1$) in the last inequality. The latter argument uses the assumption on the null space property. This shows that

$$\|\eta^{(n'+1)}\|_{S_\infty}^p \leqslant \mu\|\eta^{(n')}\|_{S_\infty}^{p(2-p)}$$

for

$$\widetilde{\mu} := 2^{4p}\gamma_{2r}^{2-p}\Big(\frac{(3+\gamma_{2r})(d-r)}{(1-\gamma_{2r})r}\Big)^{2-p}\frac{r^{p/2}(s_r^0)^{p(p-1)}}{(1-\zeta)^{2p}}\kappa^p\max\Big(2^p(d-r)^{\frac{p}{2}},(1+\gamma_{2r})^2\Big),$$

and $\|\eta^{(n'+1)}\|_{S_\infty}^p\leqslant\|\eta^{(n')}\|_{S_\infty}^p$ under the assumption (25) of Theorem 11, as $\widetilde{\mu}\leqslant\mu$ with μ as in (26). Indeed, it holds that $\widetilde{\mu}\leqslant\mu$ since

$$\max\Big(2^p(d-r)^{\frac{p}{2}},(1+\gamma_{2r})^2\Big)\Big(\frac{d-r}{r}\Big)^{2-p}r^{p/2} \leqslant 2^p(1+\gamma_{2r})^2\Big(\frac{d-r}{r}\Big)^{2-p/2}r^p.$$

The same argument shows that $\|\eta^{(n'+1)}\|_{S_p}^p\leqslant\|\eta^{(n')}\|_{S_p}^p$, which finishes the proof. ■

Remark 22 *We note that the weight matrices of the previous IRLS approaches* `IRLS-col` *and* `IRLS-row` *Fornasier et al. (2011); Mohan and Fazel (2012) at iteration n could be expressed in our notation as*

$$\mathbf{I}_{d_2}\otimes W_L^{(n)} := \mathbf{I}_{d_2}\otimes U^{(n)}(\bar{\Sigma}_{d_1}^{(n)})^{p-2}U^{(n)*}$$

and

$$W_R^{(n)}\otimes\mathbf{I}_{d_1} := V^{(n)}(\bar{\Sigma}_{d_2}^{(n)})^{p-2}V^{(n)*}\otimes\mathbf{I}_{d_1},$$

respectively, cf. Section 2.2, if $X^{(n)}=U^{(n)}\Sigma^{(n)}V^{(n)*}=U_T^{(n)}\Sigma_T^{(n)}V_T^{(n)*}+U_{T_c}^{(n)}\Sigma_{T_c}^{(n)}V_{T_c}^{(n)*}$ is the SVD of the iterate $X^{(n)}$ with $U_T^{(n)}$ and $V_T^{(n)}$ containing the r first left- and right singular vectors.

Now let

$$T^{(n)} := \big\{U_T^{(n)}Z_1^*+Z_2V_T^{(n)*} : Z_1\in M_{d_1\times r}, Z_2\in M_{d_2\times r}\big\}$$

be the tangent space of the smooth manifold of rank-r matrices at the best rank-r approximation $U_T^{(n)}\Sigma_T^{(n)}V_T^{(n)*}$ of $X^{(n)}$, or, put differently, the direct sum of the row and column spaces of $U_T^{(n)}\Sigma_T^{(n)}V_T^{(n)*}$.

The fact that left- or right-sided weight matrices do not lead to algorithms with superlinear convergence rates for $p<1$ can be explained by noting that there are always parts of the space $T^{(n)}$ that are equipped with too large weights if $X^{(n)}=U^{(n)}\Sigma^{(n)}V^{(n)*}$ is already approximately low-rank. In particular, proceeding as in (44), we obtain for $\mathbf{I}_{d_2}\otimes W_L^{(n)}$

$$\begin{aligned}
\Big\|\big[\mathbf{I}_{d_2}\otimes W_L^{(n)}(X_0)_{\mathrm{vec}}\big]_{\mathrm{mat}}\Big\|_{S_2}^2 &= \Big\|(\bar{\Sigma}_T^{(n)})^{p-2}U_T^{(n)*}X_0V_T^{(n)}\Big\|_{S_2}^2+\Big\|(\bar{\Sigma}_T^{(n)})^{p-2}U_T^{(n)*}X_0V_{T_c}^{(n)}\Big\|_{S_2}^2\\
&\quad+\Big\|\big(\bar{\Sigma}_{T_c}{}^{(n)}\big)^{p-2}U_{T_c}^{(n)*}X_0V_T^{(n)}\Big\|_{S_2}^2+\Big\|(\bar{\Sigma}_{T_c}^{(n)})^{p-2}U_{T_c}^{(n)*}X_0V_{T_c}^{(n)}\Big\|_{S_2}^2
\end{aligned}$$

if $\bar{\Sigma}_T^{(n)}$ denotes the diagonal matrix with the first r non-zero entries of $\bar{\Sigma}_{d_1}^{(n)}$ and $\bar{\Sigma}_{T_c}^{(n)}$ the one of the remaining entries.

Here, the third of the four summands would become too large for $p<1$ to allow for a superlinear convergence when the last $d-r$ singular values of $X^{(n)}$ approach zero. An analogous argument can be used for the right-sided weight matrix $W_R^{(n)}\otimes\mathbf{I}_{d_1}$ and, notably, also for arithmetic mean weight matrices $W_{(arith)}^{(n)}=\mathbf{I}_{d_2}\otimes W_L^{(n)}+W_R^{(n)}\otimes\mathbf{I}_{d_1}$, cf. Section 2.3.

Appendix A. Kronecker and Hadamard products

For two matrices $A = (a_{ij})_{i\in[d_1],j\in[d_3]} \in \mathbb{C}^{d_1\times d_3}$ and $B \in \mathbb{C}^{d_2\times d_4}$, we call the matrix representation of their tensor product with respect to the standard bases the *Kronecker product* $A\otimes B \in \mathbb{C}^{d_1\cdot d_2\times d_3\cdot d_4}$. By its definition, $A\otimes B$ is a block matrix of $d_2 \times d_4$ blocks whose block of index $(i, j) \in [d_1] \times [d_3]$ is the matrix $a_{ij}B \in \mathbb{R}^{d_2\times d_4}$. This implies, e.g., for $A \in \mathbb{C}^{d_1\times d_3}$ with $d_1 = 2$ and $d_3 = 3$ that

$$A \otimes B = \left[\begin{array}{ccc} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \end{array}\right] \otimes B = \left[\begin{array}{c|c|c} a_{11}B & a_{12}B & a_{13}B \\ \hline a_{21}B & a_{22}B & a_{23}B \end{array}\right].$$

The Kronecker product is useful for the elegant formulation of matrix equations involving left and right matrix multiplications with the variable X, as

$$AXB^* = Y \qquad \text{if and only if} \qquad (B\otimes A)X_{\mathrm{vec}} = Y_{\mathrm{vec}}.$$

We define the *Hadamard product* $A \circ B \in \mathbb{C}^{d_1\times d_2}$ of two matrices $A \in \mathbb{C}^{d_1\times d_2}$ and $B \in \mathbb{C}^{d_1\times d_2}$ as their entry-wise product

$$(A \circ B)_{i,j} = A_{i,j}B_{i,j}$$

with $i \in [d_1]$ and $j \in [d_2]$. The Hadamard product is also known as *Schur product* in the literature.

Furthermore, if $d_1 = d_3$ and $d_2 = d_4$, we define the *Kronecker sum* $A \oplus B \in \mathbb{C}^{d_1d_2\times d_1d_2}$ of two matrices $A \in \mathbb{C}^{d_1\times d_1}$ and $B \in \mathbb{C}^{d_2\times d_2}$ as the matrix

$$A \oplus B = (\mathbf{I}_{d_2} \otimes A) + (B \otimes \mathbf{I}_{d_1}). \tag{55}$$

Note that equations of the form $AX + XB^* = Y$ can be rewritten as

$$(A \oplus B)X_{\mathrm{vec}} = Y_{\mathrm{vec}},$$

using again the vectorizations of X and Y. An explicit formula that expresses the inverse $(A \oplus B)^{-1}$ of the Kronecker sum $A \oplus B$ is provided by the following lemma.

Lemma 23 (Jameson (1968)) *Let $A \in H_{d_1\times d_1}$ and $B \in H_{d_2\times d_2}$, where one of the matrices is positive definite and the other positive semidefinite. If we denote the singular vectors of A by $u_i \in \mathbb{C}^{d_1}$, $i \in [d_1]$, its singular values by σ_i, $i \in [d_1]$ and the singular vectors resp. values of B by $v_j \in \mathbb{C}^{d_2}$ resp. μ_j, $j \in [d_2]$, then*

$$(A \oplus B)^{-1} = \sum_{i=1}^{d_1}\sum_{j=1}^{d_2} \frac{v_jv_j^* \otimes u_iu_i^*}{\sigma_i + \mu_j}. \tag{56}$$

Furthermore, the action of $(A \oplus B)^{-1}$ on the matrix space $M_{d_1\times d_2}$ can be written as

$$\big[(A \oplus B)^{-1}Z_{\mathrm{vec}}\big]_{\mathrm{mat}} = U\big(H \circ (U^*ZV)\big)V^*. \tag{57}$$

for $Z \in M_{d_1\times d_2}$, $U = [u_1, \dots, u_{d_1}]$, and $V = [v_1, \dots, v_{d_2}]$ and the matrix $H \in M_{d_1\times d_2}$ with the entries $H_{i,j} = (\sigma_i + \mu_j)^{-1}$, $i \in [d_1]$, $j \in [d_2]$.

Appendix B. Proofs of preliminary statements in Section 6

B.1 Proof of Lemma 14: Main part

First, we define the function

$$f^p_{X,\epsilon}(Z) = \mathcal{J}_p(X, \epsilon, Z) = \begin{cases} \frac{p}{2}\|X_{\mathrm{vec}}\|^2_{\ell_2(\widetilde{W}(Z))} + \frac{\epsilon^2 p}{2}\sum_{i=1}^{d}\sigma_i(Z) + \frac{2-p}{2}\sum_{i=1}^{d}\sigma_i(Z)^{\frac{p}{(p-2)}} & \text{if } \operatorname{rank}(Z) = d, \\ +\infty & \text{if } \operatorname{rank}(Z) < d, \end{cases}$$

for $X \in M_{d_1\times d_2}$, $\epsilon > 0$ fixed and with $Z \in M_{d_1\times d_2}$ as its only argument. We note that the set of minimizers of $f^p_{X,\epsilon}(Z)$ does not contain an instance Z with rank smaller than d as the value of $f^p_{X,\epsilon}(Z)$ is infinite at such points and, therefore, it is sufficient to search for minimizers on the set $\Omega = \{Z \in M_{d_1\times d_2} | \operatorname{rank}(Z) = d\}$ of matrices with rank d. We observe that the set Ω is an open set and that we have that

(a) $f^p_{X,\epsilon}(Z)$ is lower semi-continuous, which means that any sequence $(Z^k)_{k\in\mathbb{N}}$ with $Z^k \overset{k\to\infty}{\longrightarrow} Z$ fulfills $\liminf_{k\to\infty} f^p_{X,\epsilon}(Z^k) \geqslant f^p_{X,\epsilon}(Z)$,

(b) $f^p_{X,\epsilon}(Z) \geqslant \alpha$ for all $Z \in M_{d_1\times d_2}$ for some constant α,

(c) $f^p_{X,\epsilon}(Z)$ is coercive, i.e., for any sequence $(Z^k)_{k\in\mathbb{N}}$ with $\|Z^k\|_F \overset{k\to\infty}{\longrightarrow} \infty$, we have $f^p_{X,\epsilon}(Z^k) \overset{k\to\infty}{\longrightarrow} \infty$.

Property (a) is true as $f^p_{X,\epsilon}(Z))|_\Omega$ is a concatenation of an indicator function of an open set, which is lower semi-continuous and a sum of continuous functions on Ω. Property (b) is obviously true for the choice $\alpha = 0$.

To justify point (c), we note that $f^p_{X,\epsilon}(Z) > \frac{\epsilon^2 p}{2}\sum_{i=1}^{d}\sigma_i(Z) = \frac{\epsilon^2 p}{2}\|Z\|_{S_1} \geqslant \frac{\epsilon^2 p}{2}\|Z\|_F$ and therefore, coercivity is clear from its definition. As a consequence from (a) and (c), it is

also true that the level sets $L_C = \left\{ Z \in M_{d_1 \times d_2} | f^p_{X,\epsilon}(Z) \leqslant C \right\}$ are closed and bounded and, therefore, compact.

Via the direct method of the calculus of variations, we conclude from the properties (a)–(c) that $f^p_{X,\epsilon}(Z)$ has at least one global minimizer belonging to the set of critical points of $f^p_{X,\epsilon}(Z)$ (Dacorogna, 1989, Theorem 1).

To characterize the set of critical points of $f^p_{X,\epsilon}(Z)$, its derivative with respect to Z is calculated explicitly and equated with zero in Subsection B.2. The solution of the resulting equation reveals that $Z_{\text{opt}} = \sum_{i=1}^d (\sigma_i^2(X) + \epsilon^2)^{\frac{p-2}{2}} u_i v_i^* =: \sum_{i=1}^d \tilde{\sigma}_i u_i v_i^*$ is the only critical point and consequently the unique global minimizer of $f^p_{X,\epsilon}(Z)$. We define the matrices $W^L_{\text{opt}} := \sum_{i=1}^d \tilde{\sigma}_i u_i u_i^*$ and $W^R_{\text{opt}} := \sum_{i=1}^d \tilde{\sigma}_i v_i v_i^*$, and note that $\widetilde{W}(Z_{\text{opt}}) = 2\big((W^R_{\text{opt}})^{-1} \oplus (W^L_{\text{opt}})^{-1}\big)^{-1}$ with Definition 13. To verify the second part of the theorem, we simply plug the optimal solution Z_{opt} into the functional $\mathcal{J}_p$ and compute using (56) that

$$\begin{aligned}
\mathcal{J}_p(X, \epsilon, Z_{\text{opt}}) &= \frac{p}{2}\|X_{\text{vec}}\|^2_{\ell_2(\widetilde{W}(Z_{\text{opt}}))} + \frac{\epsilon^2 p}{2}\sum_{i=1}^d \tilde{\sigma}_i + \frac{2-p}{2}\sum_{i=1}^d \tilde{\sigma}_i^{\frac{p}{p-2}} \\
&= \frac{p}{2}\sum_{i=1}^d \left[\sigma_i^2(X)(u_i^* \otimes v_i^*) 2 \left(\sum_{k=1}^{d_2}\sum_{j=1}^{d_1} \frac{u_k u_k^* \otimes v_j v_j^*}{\tilde{\sigma}_k^{-1} + \tilde{\sigma}_j^{-1}} \right)(u_i \otimes v_i) \right]_{ii} + \frac{\epsilon^2 p}{2}\sum_{i=1}^d \tilde{\sigma}_i + \frac{2-p}{2}\sum_{i=1}^d \tilde{\sigma}_i^{\frac{p}{p-2}} \\
&= \frac{p}{2}\sum_{i=1}^d (\sigma_i^2(X) + \epsilon^2)\tilde{\sigma}_i + \frac{2-p}{2}\sum_{i=1}^d \tilde{\sigma}_i^{\frac{p}{p-2}} \\
&= \frac{p}{2}\sum_{i=1}^d (\sigma_i^2(X) + \epsilon^2)(\sigma_i^2(X) + \epsilon^2)^{\frac{p-2}{2}} + \frac{2-p}{2}\sum_{i=1}^d (\sigma_i^2(X) + \epsilon^2)^{\frac{p}{2}} \\
&= \sum_{i=1}^d (\sigma_i^2(X) + \epsilon^2)^{\frac{p}{2}}.
\end{aligned}$$

B.2 Proof of Lemma 14: Critical points of $f^p_{X,\epsilon}$

Let us without loss of generality consider the case $d = d_1 = d_2$ and define

$$\Omega = \{ Z \in M_{d \times d} \text{ s.t. } \operatorname{rank}(Z) = d \}.$$

As already mentioned in (27), the harmonic mean matrix $\widetilde{W}(Z)$ can then be rewritten as

$$\widetilde{W}(Z) = 2\widetilde{W}_1\big(\widetilde{W}_1 + \widetilde{W}_2\big)^{-1}\widetilde{W}_2 = 2(\widetilde{W}_1^{-1} + \widetilde{W}_2^{-1})^{-1}$$

for $Z \in \Omega$ with the definitions $\widetilde{W}_1 := \mathbf{I}_d \otimes (ZZ^*)^{\frac{1}{2}}$ and $\widetilde{W}_2 = (Z^*Z)^{\frac{1}{2}} \otimes \mathbf{I}_d$. For $Z \in \Omega$, we reformulate the auxiliary functional such that

$$\begin{aligned}
f^p_{X,\epsilon}(Z) = \mathcal{J}^p(X, \epsilon, Z) &= \frac{p}{2}\|X_{\text{vec}}\|^2_{\ell_2(\widetilde{W}(Z))} + \frac{\epsilon^2 p}{2}\sum_{i=1}^d \sigma_i(Z) + \frac{2-p}{2}\sum_{i=1}^d \sigma_i(Z)^{\frac{p}{(p-2)}} \\
&= \frac{p}{2}\|X_{\text{vec}}\|^2_{\ell_2(\widetilde{W}(Z))} + \frac{\epsilon^2 p}{2}\|(Z^*Z)^{1/2}\|_F^2 + \frac{2-p}{2}\|(Z^*Z)^{\frac{p}{2(p-2)}}\|_F^2.
\end{aligned}$$

To identify the set of critical points of $f^p_{X,\epsilon}(Z)$ located in Ω, we compute its derivative with respect to Z using the derivative rules (7), (12), (13), (15), (16), (18), (20) in Chapter 8.2

and Theorem 3 in Chapter 8.4 of (Magnus and Neudecker, 1999) in the following. Using the notation of Magnus and Neudecker (1999), we calculate

$$\begin{aligned}
\partial f^p_{X,\epsilon}(Z) = &-\frac{p}{2}\operatorname{tr}\left(X^*_{\text{vec}}\widetilde{W}\partial\widetilde{W}^{-1}\widetilde{W}X_{\text{vec}}\right) + \frac{p\epsilon^2}{4}\left(\operatorname{tr}\left(Z(Z^*Z)^{-\frac{1}{2}}\partial Z^*\right) + \operatorname{tr}((Z^*Z)^{-\frac{1}{2}}Z^*\partial Z)\right) \\
&-\frac{p}{4}\left(\operatorname{tr}\left(Z(Z^*Z)^{\frac{4-p}{2(p-2)}}\partial Z^*\right) + \operatorname{tr}((Z^*Z)^{\frac{4-p}{2(p-2)}}Z^*\partial Z)\right)
\end{aligned}$$

where

$$\begin{aligned}
\partial\widetilde{W}^{-1} = \frac{1}{2}\partial\left[(ZZ^*)^{-\frac{1}{2}} \oplus (Z^*Z)^{-\frac{1}{2}}\right] = &-\frac{1}{4}\left[\left((Z^*Z)^{-\frac{3}{2}}Z^*\partial Z + \partial Z^* Z(Z^*Z)^{-\frac{3}{2}}\right) \otimes \mathbf{I}_{d_1}\right] \\
&-\frac{1}{4}\left[\mathbf{I}_{d_2} \otimes \left(\partial Z(ZZ^*)^{-\frac{3}{2}}Z^* + (ZZ^*)^{-\frac{3}{2}}Z\partial Z^*\right)\right].
\end{aligned} \tag{58}$$

We can reformulate the first term as follows using the cyclicity of the trace,

$$\begin{aligned}
-\frac{p}{2}\operatorname{tr}\left(X^*_{\text{vec}}\widetilde{W}\partial\widetilde{W}^{-1}\widetilde{W}X_{\text{vec}}\right) = \frac{p}{8}\Big[&\operatorname{tr}\left((\widetilde{W}X_{\text{vec}})^*_{\text{mat}}(\widetilde{W}X_{\text{vec}})_{\text{mat}}(Z^*Z)^{-\frac{3}{2}}Z^*\partial Z\right) \\
&+ \operatorname{tr}\left(Z(Z^*Z)^{-\frac{3}{2}}(\widetilde{W}X_{\text{vec}})^*_{\text{mat}}(\widetilde{W}X_{\text{vec}})_{\text{mat}}\partial Z^*\right) \\
&+ \operatorname{tr}\left(Z^*(ZZ^*)^{-\frac{3}{2}}(\widetilde{W}X_{\text{vec}})_{\text{mat}}(\widetilde{W}X_{\text{vec}})^*_{\text{mat}}\partial Z\right) \\
&+ \operatorname{tr}\left((\widetilde{W}X_{\text{vec}})_{\text{mat}}(\widetilde{W}X_{\text{vec}})^*_{\text{mat}}(ZZ^*)^{-\frac{3}{2}}Z\partial Z^*\right)\Big].
\end{aligned}$$

To determine the critical points of $f^p_{X,\epsilon}(Z)$, we summarize the calculations above, rearrange the terms and equate the derivative with zero, such that

$$\begin{aligned}
\partial f^p_{X,\epsilon}(Z) = &\frac{p}{8}\operatorname{tr}\Big(\Big[(\widetilde{W}X_{\text{vec}})^*_{\text{mat}}(\widetilde{W}X_{\text{vec}})_{\text{mat}}(Z^*Z)^{-\frac{3}{2}}Z^* + Z^*(ZZ^*)^{-\frac{3}{2}}(\widetilde{W}X_{\text{vec}})_{\text{mat}}(\widetilde{W}X_{\text{vec}})^*_{\text{mat}} \\
&\quad +2\epsilon^2(Z^*Z)^{-\frac{1}{2}}Z^* - 2(Z^*Z)^{\frac{4-p}{2(p-2)}}Z^*\Big]\partial Z\Big) \\
&+\frac{p}{8}\operatorname{tr}\Big(\Big[Z(Z^*Z)^{-\frac{3}{2}}(\widetilde{W}X_{\text{vec}})^*_{\text{mat}}(\widetilde{W}X_{\text{vec}})_{\text{mat}} + (\widetilde{W}X_{\text{vec}})_{\text{mat}}(\widetilde{W}X_{\text{vec}})^*_{\text{mat}}(ZZ^*)^{-\frac{3}{2}}Z \\
&\quad +2\epsilon^2 Z(Z^*Z)^{-\frac{1}{2}} - 2Z(Z^*Z)^{\frac{4-p}{2(p-2)}}\Big]\partial Z^*\Big) \\
=: &\frac{p}{8}\operatorname{tr}(A\partial Z) + \frac{p}{8}\operatorname{tr}(A^*\partial Z^*) = \frac{p}{8}\operatorname{tr}((A \oplus A)\partial Z) = 0,
\end{aligned}$$

where

$$\begin{aligned}
A = \Big[&(\widetilde{W}X_{\text{vec}})^*_{\text{mat}}(\widetilde{W}X_{\text{vec}})_{\text{mat}}(Z^*Z)^{-\frac{3}{2}}Z^* + Z^*(ZZ^*)^{-\frac{3}{2}}(\widetilde{W}X_{\text{vec}})_{\text{mat}}(\widetilde{W}X_{\text{vec}})^*_{\text{mat}} \\
&+2\epsilon^2(Z^*Z)^{-\frac{1}{2}}Z^* - 2(Z^*Z)^{\frac{4-p}{2(p-2)}}Z^*\Big].
\end{aligned} \tag{59}$$

and hence an easy calculation as in (Duchi) gives

$$\frac{\partial f^p_{X,\epsilon}(Z)}{\partial Z} = \frac{\frac{p}{8}\operatorname{tr}((A \oplus A)\partial Z)}{\partial Z} = \frac{p}{8}(A \oplus A) = 0.$$

Now we have to find Z such that $A \oplus A = 0$. This implies that all eigenvalues of $A \oplus A = A \otimes \mathbf{I}_d + \mathbf{I}_d \otimes A$ are equal to zero. The eigenvalues of the Kronecker sum of two

matrices A_1 and A_2 with eigenvalues λ_s and μ_t with $s,t \in [d]$ are the sum of the eigenvalues $\lambda_s + \mu_t$. As in our case $A = A_1 = A_2$ this means that all eigenvalues of A itself have to be zero. This is only possible if A is the zero matrix.

Let $Z = U\Sigma V^* \in M_{d\times d}$ with $U, V \in \mathcal{U}_d$ and $\Sigma \in M_{d\times d}$, where $\Sigma = \operatorname{diag}(\sigma)$ is a diagonal matrix with *ascending* entries. We define the matrix $H = H_{i,j} = \frac{2}{\sigma_i^{-1}+\sigma_j^{-1}}$ for $i = 1,\dots,d, j = 1,\dots,d$ corresponding to the result of reshaping the diagonal of $2(\Sigma \oplus \Sigma)$ into a $d \times d$-matrix. Using (57), we can express $(\widetilde{W}X_{\mathrm{vec}})_{\mathrm{mat}} = U\big(H \circ (U^*XV)\big)V^*$ and denote $B := H \circ (U^*XV)$.

Plugging the decomposition $Z = U\Sigma V^*$ into (59), we can therefore calculate

$$\begin{aligned}
\mathrm{A} = 0 \Leftrightarrow\ & (UBV^*)^*(UBV^*)(V\Sigma^2V^*)^{-3/2}(U\Sigma V^*)^* + (U\Sigma V^*)^*(U\Sigma^2U^*)^*)^{-3/2}(UBV^*)(UBV^*)^* \\
& + 2\epsilon^2(V\Sigma^2V^*)^{-1/2}(U\Sigma V^*)^* - 2(V\Sigma^2V^*)^{\frac{4-p}{2(p-2)}}(U\Sigma V^*)^* = 0 \\
\Leftrightarrow\ & VB^*B\Sigma^{-2}U^* + V\Sigma^{-2}BB^*U^* + 2\epsilon^2V\mathbf{I}_dU^* - 2V\Sigma^{\frac{2}{p-2}}U^* = 0 \\
\Leftrightarrow\ & B^*B\Sigma^{-2} + \Sigma^{-2}BB^* + 2\epsilon^2\mathbf{I}_d - 2\Sigma^{\frac{2}{p-2}} = 0.
\end{aligned} \tag{60}$$

We now note that $2\epsilon^2\mathbf{I}_d - 2\Sigma^{\frac{2}{p-2}}$ is diagonal and therefore, $B^*B\Sigma^{-2} + \Sigma^{-2}BB^*$ is diagonal as well. Moreover, observe that $B^*B + \Sigma^{-2}BB^*\Sigma^2$ is again a diagonal matrix and has a symmetric first summand B^*B. As the sum or difference of symmetric matrices is again symmetric also the second summand $\Sigma^{-2}BB^*\Sigma^2$ has to be symmetric, i.e., $\Sigma^{-2}BB^*\Sigma^2 = (\Sigma^{-2}BB^*\Sigma^2)^* = \Sigma^2BB^*\Sigma^{-2}$. We conclude that it has to hold that $BB^*\Sigma^4 = \Sigma^4BB^*$ and hence Σ^4 and BB^* commute.

This is only possible if either Σ is a multiple of the identity or if BB^* is diagonal. Assuming the first case, (60) would imply that also BB^* and B^*B have to be a multiple of the identity. Therefore, this first case, where Σ is a multiple of the identity is a special case of the second possible scenario, where BB^* is diagonal. Hence, it suffices to further consider the more general second case. (Considerations for B^*B can be carried out analogously.)

Diagonality of BB^* only occurs if B is either orthonormal or diagonal. Assuming orthonormality would lead to contradictions with the equations in (60). Hence $B = H \circ (U^*XV)$ can only be diagonal.

Let now be $X = \bar{U}\bar{S}\bar{V}^*$ the singular value decomposition of X. As H has no zero entries due to the full rank of W, this implies the diagonality of $U^*\bar{U}\bar{S}\bar{V}^*V$. Consequently, U and V can only be chosen such that $P = [U^*\bar{U}]_{d\times d}$ and $P^* = [\bar{V}^*V]_{d\times d}$ for a permutation matrix $P \in \mathcal{U}_d$. The reshuffled indexing corresponding to P is denoted by $p(i) \in [d]$ for $i \in [d]$. Bearing in mind that $H_{ii} = \sigma_i$ for $i \in [d]$, we obtain

$$\begin{aligned}
& (H \circ (P\bar{S}P^*))^*(H \circ (P\bar{S}P^*))\Sigma^{-2} + \Sigma^{-2}(H \circ (P\bar{S}P^*))(H \circ (P\bar{S}P^*))^* + 2\epsilon^2\mathbf{I}_d - 2\Sigma^{\frac{2}{p-2}} = 0 \\
\Leftrightarrow\ & 2\bar{s}_{p(i)}^2 + 2\epsilon^2 = 2\sigma_i^{\frac{2}{p-2}} \text{ for all } i \in [d] \\
\Leftrightarrow\ & \sigma_i = (\bar{s}_{p(i)}^2 + \epsilon^2)^{\frac{p-2}{2}} \text{ for all } i \in [d].
\end{aligned}$$

As the diagonal of Σ was assumed to have ascending entries and the diagonal of $\bar{S}$ has descending entries, the permutation matrix P has to be equal to the identity matrix. From $P = \mathbf{I}_d$, it follows that $U = \bar{U}$ and $V = \bar{V}$ and hence $\Sigma = (\bar{S}^2 + \epsilon^2\mathbf{I}_d)^{\frac{p-2}{2}}$.

We summarize our calculations by stating that

$$Z_{\mathrm{opt}} = \bar{U}\Sigma\bar{V}^* = \bar{U}(\bar{S}^2 + \epsilon^2\mathbf{I}_d)^{\frac{p-2}{2}}\bar{V}^*$$

is the only critical point of $f^p_{X,\epsilon}$ on the domain Ω.

The results extend for the case $d_1 \neq d_2$, where the definition of $\widetilde{W}(Z)$ is adapted by introducing the Moore-Penrose pseudo inverse of $(ZZ^*)^{1/2}$

$$\widetilde{W}(Z) = 2\widetilde{W}_1\big(\widetilde{W}_1 + \widetilde{W}_2\big)^{-1}\widetilde{W}_2 = 2(\widetilde{W}_1^{+} + \widetilde{W}_2^{-1})^{-1}.$$

The corresponding derivative rule as pointed out in Theorem 5 in Chapter 8.4 of Magnus and Neudecker (1999) can be used for the calculation in (58).

B.3 Proof of Lemma 16

The equality of the optimization problems (32) can easily be seen by the fact that only the first summand of $\mathcal{J}_p(X,\epsilon,Z)$ depends on X. Now, it is important to show first that $\widetilde{W}(Z) = 2([(Z^*Z)^{\frac{1}{2}}]^+ \oplus [(ZZ^*)^{\frac{1}{2}}]^+)^{-1}$ is positive definite as minimizing $\mathcal{J}_p(X,\epsilon,Z)$ then reduces to minimizing a quadratic form. Let $Z = \sum_{i=1}^d \sigma_i u_i v_i^*$, where u_i, v_i for $i \in [d]$ are the left and right singular vector respectively and σ_i for $i \in [d]$ are the singular values of Z. Since $Z^*Z = \sum_{i=1}^d \sigma_i^2 v_i v_i^* \geq 0$, also the generalized inverse root fulfills $[(ZZ^*)^{\frac{1}{2}}]^+ \geq 0$ and for $ZZ^* = \sum_{i=1}^d \sigma_i^2 u_i u_i^* \geq 0$, it follows that $[(ZZ^*)^{\frac{1}{2}}]^+ \geq 0$. We stress that at least one of the matrices $(ZZ^*)^{\frac{1}{2}}$ and $(Z^*Z)^{\frac{1}{2}}$ is positive definite and hence also $\widetilde{W}(Z) \succ 0$. With the fact that $\widetilde{W}(Z) \succ 0$, the statement can be proven analogously to the results in (Fornasier et al., 2011, Lemma 5.1).

B.4 Proof of Lemma 17

(a) With the minimization property that defines $X^{(n+1)}$ in (29), the inequality $\epsilon^{(n+1)} \leqslant \epsilon^{(n)}$, and the minimization property that defines $Z^{(n+1)}$ in (28) and Lemma 14, the monotonicity follows from

$$\begin{aligned}
\mathcal{J}_p(X^{(n)},\epsilon^{(n)},Z^{(n)}) &\geqslant \mathcal{J}_p(X^{(n+1)},\epsilon^{(n)},Z^{(n)}) \geqslant \mathcal{J}_p(X^{(n+1)},\epsilon^{(n+1)},Z^{(n)}) \\
&\geqslant \mathcal{J}_p(X^{(n+1)},\epsilon^{(n+1)},Z^{(n+1)}).
\end{aligned}$$

(b) Using Theorem 14 and the monotonicity property of (a) for all $n \in \mathbb{N}$, we see that

$$\|X^{(n)}\|_{S_p}^p \leqslant g^p_{\epsilon^{(n)}}(X^{(n)}) = \mathcal{J}_p(X^{(n)},\epsilon^{(n)},Z^{(n)}) \leqslant \mathcal{J}_p(X^{(1)},\epsilon^{(0)},Z^{(0)}).$$

(c) The proof follows analogously to (Fornasier et al., 2011, Proposition 6.1) where only the technical calculation to bound $\sigma_1^p((\widetilde{W}^{(n)})^{-1})$ requires to take into account that the spectrum of a Kronecker sum $A \oplus B$ consists of the pairwise sum of the spectra of A and B (Bernstein, 2009, Proposition 7.2.3).

B.5 Proof of Lemma 18

The first statement $\widetilde{W}(X^{(n)},\epsilon^{(n)}) = \widetilde{W}^{(n)}$ is clear from the definition of $\widetilde{W}(X,\epsilon)$ and (10). To show the necessity of (35), let $X \in M_{d_1\times d_2}$ be a critical point of (34). Without loss

of generality, let us assume that $d_1 \leqslant d_2$. In this case, a short calculation shows that $g_\epsilon^p(X) = \operatorname{tr}\left[(XX^* + \epsilon^2 \mathbf{I}_{d_1})^{p/2}\right]$. It follows from the matrix derivative rules of Magnus and Neudecker (1999, (7),(15),(18),(20) of Chapter 8.2) that

$$\nabla g_\epsilon^p(X) = p(XX^* + \epsilon^2 \mathbf{I}_{d_1})^{\frac{p-2}{2}} X = p \sum_{i=1}^{d} (\sigma_i^2 + \epsilon^2)^{\frac{p-2}{2}} \sigma_i u_i v_i^*,$$

using the singular value decomposition $X = \sum_{i=1}^{d} \sigma_i u_i v_i^*$ in the last equality. Using the Kronecker sum inversion formula (56), we see that $\nabla g_\epsilon^p(X) = p\left[\widetilde{W}(X,\epsilon) X_{\mathrm{vec}}\right]_{\mathrm{mat}}$. The proof can be continued analogously to (Daubechies et al., 2010, Lemma 5.2).

Appendix C. Proof of Theorem 9

For statement (i) of the convergence result of Algorithm 1, we use the following *reverse triangle inequalities* implied by the strong Schatten-p NSP: Let $X, X' \in M_{d_1 \times d_2}$ such that $\Phi(X - X') = 0$. Then

$$\|X' - X\|_F^p \leqslant \frac{2^p \gamma_r^{1-p/2}}{r^{1-p/2}} \frac{1}{1-\gamma_r} \left(\|X'\|_{S_p}^p - \|X\|_{S_p}^p + 2\beta_r(X)_{S_p} \right), \tag{61}$$

where $\beta_r(X)_{S_p}$ is defined in (22). This inequality can be proven using an adaptation of the proof of the corresponding result for ℓ_p-minimization in (Gao et al., 2015, Theorem 13) and the generalization of Mirksy's singular value inequality to concave functions (Audenaert, 2014; Foucart, 2018). Furthermore, the proof of the similar statement in (Kabanava et al., 2016, Theorem 12) can be adapted to show (61).

The further part of the proof of (i) as well as (ii) follow analogously to (Fornasier et al., 2011, Theorem 6.11) and (Daubechies et al., 2010, Theorem 5.3) using the preliminary results deduced in Section 6.

Statement (iii) is a direct consequence of Theorem 11, which is proven in Section 6.3.

Abstract

We consider off-policy temporal-difference (TD) learning in discounted Markov decision processes, where the goal is to evaluate a policy in a model-free way by using observations of a state process generated without executing the policy. To curb the high variance issue in off-policy TD learning, we propose a new scheme of setting the λ-parameters of TD, based on generalized Bellman equations. Our scheme is to set λ according to the eligibility trace iterates calculated in TD, thereby easily keeping these traces in a desired bounded range. Compared with prior work, this scheme is more direct and flexible, and allows much larger λ values for off-policy TD learning with bounded traces. As to its soundness, using Markov chain theory, we prove the ergodicity of the joint state-trace process under nonrestrictive conditions, and we show that associated with our scheme is a generalized Bellman equation (for the policy to be evaluated) that depends on both the evolution of λ and the unique invariant probability measure of the state-trace process. These results not only lead immediately to a characterization of the convergence behavior of least-squares based implementation of our scheme, but also prepare the ground for further analysis of gradient-based implementations.

Keywords: Markov decision process, approximate policy evaluation, generalized Bellman equation, reinforcement learning, temporal-difference method, Markov chain, randomized stopping time

1. Introduction

We consider discounted Markov decision processes (MDPs) and off-policy temporal-difference (TD) learning methods for approximate policy evaluation with linear function approximation. The goal is to evaluate a policy in a model-free way by using observations of a state process generated without executing the policy. Off-policy learning is an important part of the reinforcement learning methodology (Sutton and Barto, 1998) and has been studied in the areas of operations research and machine learning. (For an incomplete list of references, see e.g., Glynn and Iglehart, 1989; Precup et al., 2000, 2001; Randhawa and Juneja, 2004; Sutton et al., 2008, 2009; Maei, 2011; Yu, 2012; Dann et al., 2014; Geist and Scherrer, 2014; Mahadevan et al., 2014; Mahmood et al., 2014; Liu et al., 2015; Sutton et al., 2016; Dai et al., 2018.) Available TD algorithms, however, tend to have very high variances due to the use of importance sampling, an issue that limits their applicability in practice. The purpose of this paper is to introduce a new TD learning scheme that can help address this problem.

Our work is motivated by the recently proposed Retrace algorithm (Munos et al., 2016) and ABQ algorithm (Mahmood et al., 2017), and by the Tree-Backup algorithm (Precup et al., 2000) that existed earlier. These algorithms, as explained by Mahmood et al. (2017), all try to use the λ-parameters of TD to curb the high variance issue in off-policy learning. In particular, they all choose the values of λ according to the current state or state-action pair in such a way that guarantees the boundedness of the eligibility traces in TD learning, which can help reduce significantly the variance of the TD iterates. A limitation of these algorithms, however, is that they tend to be over-conservative and restrict λ to small values, whereas small λ can result in large approximation bias in TD solutions.

In this paper, we propose a new scheme of setting the λ-parameters of TD, based on generalized Bellman equations. Our scheme is to set λ according to the eligibility trace iterates calculated in TD, thereby easily keeping those traces in a desired bounded range. Compared with the schemes used in the previous work just mentioned, this is a direct way to bound the traces in TD, and it is also more flexible and allows much larger λ values for off-policy learning.

Regarding generalized Bellman equations, in our context, they will correspond to a family of dynamic programming equations for the policy to be evaluated. These equations all have the true value function as their unique solution, and their associated operators have contraction properties, like the standard Bellman operator. We will refer to the associated operators as generalized Bellman operators or Bellman operators for short. Some authors have considered, at least conceptually, the use of an even broader class of equations for policy evaluation. For example, Ueno et al. (2011) have considered treating the policy evaluation problem as a parameter estimation problem in the statistical framework of estimating equations, and in their framework, any equation that has the true value function as the unique solution can be used to estimate the value function. The family of generalized Bellman equations we consider has a more specific structure. They generalize multistep Bellman equations, and they are associated with randomized stopping times and arise from the strong Markov property (see Section 3.1 for details).

Generalized Bellman equations and operators are powerful tools. In classic MDP theory they have been used in some intricate optimality analyses (e.g., Schäl and Sudderth, 1987). Their computational use, however, seems to emerge primarily in the field of reinforcement learning. Through the λ-parameters and eligibility traces, TD learning is naturally connected with, not a single Bellman operator, but a family of Bellman operators, with different choices of λ or different rules of calculating the eligibility trace iterates corresponding

to different Bellman operators. Early efforts that use this aspect to broaden the scope of TD algorithms and to analyze such algorithms include Sutton's work (1995) on learning at multiple timescales and Tsitsiklis' work on generalized TD algorithms in the tabular case (see the book by Bertsekas and Tsitsiklis, 1996, Chap. 5.3). In the context of off-policy learning, there are more recent approaches that try to utilize this connection of TD with generalized Bellman operators to make TD learning more efficient (Precup et al., 2000; Yu and Bertsekas, 2012; Munos et al., 2016; Mahmood et al., 2017). This is also our aim, in proposing the new scheme of setting the λ-parameters.

Our analyses of the new TD learning scheme will focus on its theoretical side. Using Markov chain theory, we prove the ergodicity of the joint state and trace process under nonrestrictive conditions (see Theorem 2.1), and we show that associated with our scheme is a generalized Bellman equation (for the policy to be evaluated) that depends on both the evolution of λ and the unique invariant probability measure of the state-trace process (see Theorem 3.2 and Corollary 3.1). These results not only lead immediately to a characterization of the convergence behavior of least-squares based implementation of our scheme (see Corollary 2.1 and Remark 3.2), but also prepare the ground for further analysis of gradient-based implementations. (The latter analysis has been carried out recently by Yu (2017); see Remark 3.3.)

In addition to the theoretical study, we also present the results from a preliminary numerical study that compares several ways of setting λ for the least-squares based off-policy algorithm. The results demonstrate the advantages of the proposed new scheme with its greater flexibility.

We remark that although we shall focus exclusively on policy evaluation in this paper, approximate policy evaluation methods are highly pertinent to finding near-optimal policies in MDPs. They can be applied in approximate policy iteration, in policy-gradient algorithms for gradient estimation or in direct policy search (see e.g., Konda, 2002; Mannor et al., 2003). In addition to solving MDPs, they can also be used in artificial intelligence and robotics applications as a means to generate experience-based world models (see e.g., Sutton, 2009). It is, however, beyond the scope of this paper to discuss these applications of our results.

The rest of the paper is organized as follows. In Section 2, after a brief background introduction, we present our scheme of TD learning with bounded traces, and we establish the ergodicity of the joint state-trace process. In Section 3, we first discuss generalized Bellman operators associated with randomized stopping times, and we then derive the generalized Bellman equation associated with our scheme. In Section 4, we present the experimental results on the least-squares based implementation of our scheme. Appendices A-B include a proof for generalized Bellman operators and materials about approximation properties of TD solutions that are too long to include in the main text.

2. Off-Policy TD Learning with Bounded Traces

We describe the off-policy policy evaluation problem and the algorithmic form of TD learning in Section 2.1. We then present our scheme of history-dependent λ in Section 2.2, and analyze the properties of the resulting eligibility trace iterates and the convergence of the corresponding least-squares based algorithm in Section 2.3.

2.1 Preliminaries

The off-policy learning problem we consider in this paper concerns two Markov chains on a finite state space $\mathcal{S} = \{1, \ldots, N\}$. The first chain has transition matrix P, and the second P^o. Whatever physical mechanisms that induce the two chains shall be denoted by π and π^o, and referred to as the target policy and behavior policy, respectively. The second Markov chain we can observe; however, it is the system performance of the first Markov chain that we want to evaluate.

Specifically, we consider a one-stage reward function $r_\pi : \mathcal{S} \to \Re$ and an associated discounted total reward criterion with state-dependent discount factors $\gamma(s) \in [0, 1], s \in \mathcal{S}$. Let Γ denote the $N \times N$ diagonal matrix with diagonal entries $\gamma(s)$. We assume that P and P^o satisfy the following conditions:

Condition 2.1 (Conditions on the target and behavior policies)

(i) *P is such that the inverse $(I - P\Gamma)^{-1}$ exists, and*

(ii) *P^o is such that for all $s, s' \in \mathcal{S}$, $P^o_{ss'} = 0 \Rightarrow P_{ss'} = 0$, and moreover, P^o is irreducible.*

The performance of π is defined as the expected discounted total rewards for each initial state $s \in \mathcal{S}$:

$$v_\pi(s) := \mathbb{E}^\pi_s \left[r_\pi(S_0) + \textstyle\sum_{t=1}^\infty \gamma(S_1)\gamma(S_2) \cdots \gamma(S_t) \cdot r_\pi(S_t) \right], \tag{2.1}$$

where the notation $\mathbb{E}^\pi_s$ means that the expectation is taken with respect to (w.r.t.) the Markov chain $\{S_t\}$ starting from $S_0 = s$ and induced by π (i.e., with transition matrix P). The function v_π is well-defined under Condition 2.1(i). It is called the *value function* of π, and by standard MDP theory (see e.g., Puterman, 1994), we can write it in matrix/vector notation as

$$v_\pi = r_\pi + P\Gamma\, v_\pi, \qquad \text{i.e.,} \quad v_\pi = (I - P\Gamma)^{-1} r_\pi.$$

The first equation above is known as the Bellman equation (or dynamic programming equation) for a stationary policy (cf. Footnote 2).

We compute an approximation of v_π of the form $v(s) = \phi(s)^\top \theta$, $s \in \mathcal{S}$, where $\theta \in \Re^n$ is a parameter vector and $\phi(s)$ is an n-dimensional feature representation for each state s (here $\phi(s), \theta$ are column vectors and the symbol $^\top$ stands for transpose). Data available for this computation are:

(i) a realization of the Markov chain $\{S_t\}$ with transition matrix P^o generated by π^o, and

(ii) rewards $R_t = r(S_t, S_{t+1})$ associated with state transitions, where the function r relates to $r_\pi(s)$ as $r_\pi(s) = \mathbb{E}^\pi_s[r(s, S_1)]$ for all $s \in \mathcal{S}$.[1]

To find a suitable parameter θ for the approximation $\phi(s)^\top\theta$, we use the off-policy TD learning scheme. Define $\rho(s, s') = P_{ss'}/P^o_{ss'}$ (the importance sampling ratio),[2] and write

$$\rho_t = \rho(S_t, S_{t+1}), \qquad \gamma_t = \gamma(S_t).$$

1. One can add to R_t a zero-mean finite-variance noise term. This makes little difference to our analyses, so we have left it out for notational simplicity.
2. Our problem formulation entails both value function and state-action value function estimation for a stationary policy in the standard MDP context. In these applications, it is the state-action space of the MDP that corresponds to the state space $\mathcal{S}$ here. In particular, for value function estimation, S_t here

Given an initial $e_0 \in \Re^n$, for each $t \geq 1$, the eligibility trace vector $e_t \in \Re^n$ and the scalar temporal-difference term $\delta_t(v)$ for any approximate value function $v : \mathcal{S} \to \Re$ are calculated according to

$$e_t = \lambda_t \gamma_t \rho_{t-1} e_{t-1} + \phi(S_t), \tag{2.2}$$

$$\delta_t(v) = \rho_t \big(R_t + \gamma_{t+1} v(S_{t+1}) - v(S_t)\big). \tag{2.3}$$

Here $\lambda_t \in [0, 1], t \geq 1$, are important parameters in TD learning, the choice of which we shall elaborate on shortly.

There exist a number of TD algorithms that use e_t and δ_t to generate a sequence of parameters θ_t for approximate value functions. One such algorithm is LSTD (Boyan, 1999; Yu, 2012), which obtains θ_t by solving the linear equation for $\theta \in \Re^n$,

$$\tfrac{1}{t} \textstyle\sum_{k=0}^{t-1} e_k \delta_k(v) = 0, \quad v = \Phi\theta \tag{2.4}$$

(if it admits a solution), where Φ is a matrix with row vectors $\phi(s)^\top, s \in \mathcal{S}$. LSTD updates the equation (2.4) iteratively by incorporating one by one the observation of (S_t, S_{t+1}, R_t) at each state transition. We will discuss primarily this algorithm in the paper, as its behavior can be characterized directly using our subsequent analyses of the joint state-trace process.

As mentioned earlier, our analyses will also provide bases for analyzing other gradient-based TD algorithms (e.g., Sutton et al., 2008, 2009; Maei, 2011; Mahadevan et al., 2014) by using stochastic approximation theory (Kushner and Yin, 2003; Borkar, 2008; Karmakar and Bhatnagar, 2018). Because of the complexity of this subject, however, we will not delve into it in the present paper, and we refer the reader to the recent work (Yu, 2017) for details.

2.2 Our Scheme of History-dependent λ

We now come to the choices of λ_t in the trace iterates (2.2). For TD with function approximation, one often lets λ_t be a constant or a function of S_t (Sutton, 1988; Tsitsiklis and Van Roy, 1997; Sutton and Barto, 1998). If neither the behavior policy nor the λ_t's are further constrained, $\{e_t\}$ can have unbounded variances and is also unbounded in many natural situations (see e.g., Yu, 2012, Section 3.1), and this makes off-policy TD learning challenging.[3] If we let the behavior policy to be close enough to the target policy so that $P^o \approx P$, then variance can be reduced, but it is not a satisfactory solution, for the applicability of off-policy learning would be seriously limited.

Without restricting the behavior policy, as mentioned earlier, the two recent papers (Munos et al., 2016; Mahmood et al., 2017), as well as the closely related early work by Precup et al. (2000), exploit state-dependent λ's to control variance. Their choices of λ_t are such that $\lambda_t \gamma_t \rho_{t-1} < 1$ for all t, so that the trace iterates e_t are made bounded, which can help reduce the variance of the iterates.

Motivated by this prior work, our proposal is to set λ_t according to e_{t-1} directly, so that we can keep e_t in a desired range straightforwardly and at the same time, allow a much larger range of values for the λ-parameters. As a simple example, if we use λ_t to scale the vector $\gamma_t \rho_{t-1} e_{t-1}$ to be within a ball with some given radius, then we keep e_t always bounded.

In the rest of this paper, we shall focus on analyzing the iteration (2.2) with a particular choice of λ_t of the kind just mentioned. We want to be more general than the preceding simple example. However, since the dependence on the trace e_{t-1} would make λ_t dependent on the entire past history $(S_0, \ldots, S_{t-1})$, we also want to retain certain Markovian properties that are very useful for convergence analysis. This leads us to consider λ_t *being a certain function of the previous trace and past states.* More specifically, we will let λ_t be a function of the previous trace e_{t-1} and a certain memory state that is a summary of the states observed so far. The formulation is as follows.

2.2.1 Formulation and Examples

We denote the memory state at time t by y_t. For simplicity, we assume that y_t can only take values from a finite set $\mathcal{M}$, and its evolution is Markovian: $y_t = g(y_{t-1}, S_t)$ for some given function g. The joint process $\{(S_t, y_t)\}$ is then a simple finite-state Markov chain. Each y_t is a function of the history $(S_0, \ldots, S_t)$ and y_0. We further require, besides the irreducibility of $\{S_t\}$ (cf. Condition 2.1(ii)), that

Condition 2.2 (Evolution of memory states) *Under the behavior policy π^o, the Markov chain $\{(S_t, y_t)\}$ on $\mathcal{S} \times \mathcal{M}$ has a single recurrent class.*

This recurrence condition is nonrestrictive: If the Markov chain has multiple recurrent classes, each recurrent class can be treated separately by using the same arguments we present in this paper. However, we remark that the finiteness assumption on $\mathcal{M}$ is a simplification. We choose to work with finite $\mathcal{M}$ mainly for the reason that with the traces lying in a continuous space, to study the joint state and trace process, we need to resort to properties of Markov chains on infinite spaces. With an infinite $\mathcal{M}$, we would need to introduce more technical conditions that are not essential to our analysis and can obscure our main arguments.

We thus let y_t and λ_t evolve as

$$y_t = g(y_{t-1}, S_t), \qquad \lambda_t = \lambda(y_t, e_{t-1}) \tag{2.5}$$

where $\lambda : \mathcal{M} \times \Re^n \to [0, 1]$. We require the function λ to satisfy two conditions.

Condition 2.3 (Conditions for $\lambda(\cdot)$) *For some norm $\|\cdot\|$ on $\Re^n$, the following hold for each memory state $y \in \mathcal{M}$:*

(i) *For any $e, e' \in \Re^n$, $\|\lambda(y, e)\, e - \lambda(y, e')\, e'\| \leq \|e - e'\|$.*

(ii) *For some constant C_y, $\|\gamma(s')\rho(s, s') \cdot \lambda(y, e)\, e\| \leq C_y$ for all $e \in \Re^n$ and all possible state transitions (s, s') that can lead to the memory state y.*

corresponds to the pair of previous action and current state in the MDP, whereas for state-value function estimation, S_t here corresponds to the current state-action pair in the MDP. The ratio $\rho(s, s') = P_{ss'}/P^o_{ss'}$ then comes out as the ratio of action probabilities under π and π^o, the same as what appears in most of the off-policy learning literature. For the details of these correspondences, see (Yu, 2012, Examples 2.1, 2.2). The third application is in a simulation context where P^o corresponds to a simulated system and both P^o, P are known so that the ratio $\rho(s, s')$ is available. Such simulations are useful, for example, in studying system performance under perturbations, and in speeding up the computation when assessing the impacts of events that are rare under the dynamics P.

3. However, asymptotic convergence can still be ensured for several algorithms (Yu, 2012, 2015, 2016b), thanks partly to a powerful law of large numbers for stationary processes.

In the above, the second condition is to restrict $\{e_t\}$ in a desired range (as it makes $\|e_t\| \leq \max_{y\in\mathcal{M}} C_y + \max_{s\in\mathcal{S}} \|\phi(s)\|$). The first condition is about the continuity of the function $\lambda(y,e)\,e$ in the trace variable e for each memory state y, and it plays a key role in the subsequent analysis, where we will use this condition to ensure that the traces e_t and the states (S_t, y_t) jointly form a Markov chain with appealing properties. We shall defer a further discussion on the technical roles of these conditions to the end of Section 2.3 (cf. Remark 2.2).

Let us give a few simple examples of choosing λ that satisfy Condition 2.3. We will later use these examples in our experimental study (Section 4).

Example 2.1 We consider again the simple scaling example mentioned earlier and describe it using the terminologies just introduced. In this example, we let $y_t = (S_{t-1}, S_t)$. For each $y = (s, s')$, we define the function $\lambda(y,\cdot)$ so that when multiplied with $\lambda(y,e)$, the vector $\gamma(s')\rho(s,s')\,e$ is scaled down whenever its length exceeds a given threshold $C_{ss'}$:

$$\lambda\big(y,e\big) = \begin{cases} 1 & \text{if } \ \gamma(s')\rho(s,s')\|e\|_2 \leq C_{ss'}; \\ \frac{C_{ss'}}{\gamma(s')\rho(s,s')\|e\|_2} & \text{otherwise.} \end{cases} \tag{2.6}$$

Condition 2.3(i) is satisfied because for $y = (s,s')$ with $\gamma(s')\rho(s,s') = 0$, $\lambda\big(y,e\big)e = e$, whereas for $y = (s,s')$ with $\gamma(s')\rho(s,s') \neq 0$, $\lambda\big(y,e\big)e$ is simply the Euclidean projection of e onto the ball (centered at the origin) with radius $C_{ss'}/(\gamma(s')\rho(s,s'))$ and is therefore Lipschitz continuous in e with modulus 1 w.r.t. $\|\cdot\|_2$. Corresponding to (2.6), the update rule (2.2) of e_t becomes

$$e_t = \begin{cases} \gamma_t\,\rho_{t-1}\,e_{t-1} + \phi(S_t) & \text{if } \ \gamma_t\rho_{t-1}\|e_{t-1}\|_2 \leq C_{S_{t-1}S_t}; \\ C_{S_{t-1}S_t}\cdot\frac{e_{t-1}}{\|e_{t-1}\|_2} + \phi(S_t) & \text{otherwise.} \end{cases} \tag{2.7}$$

Note that this scheme of setting λ encourages the use of large λ_t: $\lambda_t = 1$ will be chosen whenever possible. A variation of the scheme is to multiply the right-hand side (r.h.s.) of (2.6) by another factor $\beta_{ss'} \in [0,1]$, so that λ_t can be at most $\beta_{S_{t-1}S_t}$. In particular, one such variation is to simply multiply the r.h.s. of (2.6) by a constant $\beta \in (0,1)$ so that $\lambda_t \leq \beta < 1$ for all t. ■

Example 2.2 The Retrace algorithm (Munos et al., 2016) modifies the trace updates in off-policy TD learning by truncating the importance sampling ratios by 1. In particular, for the off-policy TD(λ) algorithm with a constant $\lambda = \beta \in (0,1]$, Retrace modifies the trace updates to be

$$e_t = \beta\,\gamma_t\cdot\min\{1,\rho_{t-1}\}\cdot e_{t-1} + \phi(S_t). \tag{2.8}$$

As pointed out by Mahmood et al. (2017), to retain the original interpretation of λ as a bootstrapping parameter in TD learning, we can rewrite the above update rule of Retrace equivalently as

$$e_t = \lambda_t\,\gamma_t\,\rho_{t-1}\,e_{t-1} + \phi(S_t) \qquad \text{for } \ \lambda_t = \beta\cdot\tfrac{\min\{1,\rho_{t-1}\}}{\rho_{t-1}} \ \ \text{(with } 0/0 = 0). \tag{2.9}$$

Each λ_t here is a function of (S_{t-1}, S_t) only and does not depend on e_{t-1}, so this choice of λ-parameters automatically satisfies Condition 2.3(i) with the memory states being $y_t = (S_{t-1}, S_t)$. When the discount factors $\gamma(s)$ are all strictly less than 1, $\|e_t\|$ for all t are bounded by a deterministic constant that depends on the initial e_0. Then for each initial e_0, Retrace's choice of λ coincides with a choice in our framework, since the C-parameters in Condition 2.3(ii) can be made vacuously large so that the condition is satisfied by all the traces e_t that could be encountered by Retrace. Thus in this case our framework for choosing λ effectively encompasses the particular choice used by Retrace.

One can make variations on Retrace's trace update rule. For example, instead of truncating each importance sampling ratio $\rho(s,s')$ by 1, one can truncate it by a constant $K_{ss'} \geq 1$, and then use a scaling scheme similar to Example 2.1 to bound the traces. The simplest such variation is to choose two memory-independent positive constants K and C, and replace the definition of λ_t in (2.9) by the following: with $\tilde{\lambda}_t = \frac{\min\{K,\rho_{t-1}\}}{\rho_{t-1}}$ (where we treat $0/0 = 0$),

$$\lambda_t = \begin{cases} \beta\,\tilde{\lambda}_t & \text{if } \ \tilde{\lambda}_t\gamma_t\,\rho_{t-1}\,\|e_{t-1}\|_2 \leq C; \\ \beta\,\tilde{\lambda}_t\cdot\frac{C}{\tilde{\lambda}_t\gamma_t\,\rho_{t-1}\,\|e_{t-1}\|_2} & \text{otherwise.} \end{cases} \tag{2.10}$$

Correspondingly, instead of (2.8), the update rule of e_t becomes

$$e_t = \begin{cases} \beta\,\gamma_t\cdot\min\{K,\rho_{t-1}\}\cdot e_{t-1} + \phi(S_t) & \text{if } \ \gamma_t\cdot\min\{K,\rho_{t-1}\}\cdot\|e_{t-1}\|_2 \leq C; \\ \beta\,C\cdot\frac{e_{t-1}}{\|e_{t-1}\|_2} + \phi(S_t) & \text{otherwise.} \end{cases} \tag{2.11}$$

These variations of Retrace are similar to Example 2.1 and satisfy Condition 2.3.[4] ■

2.2.2 Comparison with Previous Work

For policy evaluation, the Retrace algorithm (Munos et al., 2016) and the ABQ algorithm (Mahmood et al., 2017) are very similar (ABQ was actually developed independently of Retrace before the Munos et al. (2016) paper was published, although the ABQ paper itself was released much later). Both Retrace and ABQ include the Tree-Backup algorithm (Precup et al., 2000) as a special case. They can use additional parameters to select λ from a range of values, whereas Tree-Backup specifies λ, implicitly, in a particular way (which has the advantage of requiring no knowledge of the behavior policy) and does not have the freedom in choosing λ. Because of the relations between these algorithms, when comparing our method to them, we will compare it with Retrace only. In the experimental study given later in Section 4 on the performance of LSTD for various ways of setting λ, we will compare our scheme of choosing λ with that of Retrace for $\beta = 1$, which lets Retrace use the largest λ that it can take.

We see in Example 2.2 that the eligibility trace update rule of Retrace can be written in two equivalent forms, (2.8) and (2.9). The second form (2.9) has the advantage that the λ-parameters involved are shown explicitly. In TD learning, the λ-parameters directly affect the associated Bellman operators and can be meaningfully interpreted as stopping probabilities (see Section 3), whereas the importance sampling ratio terms in the eligibility

4. To see this, let the memory states be $y_t = (S_{t-1}, S_t)$. For each $y = (s,s')$, let $\lambda(y,e)$ be defined according to (2.10), and let C_y in Condition 2.3(ii) be $C_{ss'} = \frac{\rho(s,s')}{\min\{K,\,\rho(s,s')\}}\cdot C$ (treat $0/0 = 0$). Then note that $\|\lambda(y,e)e - \lambda(y,e')e'\|_2 \leq \beta\min\big\{\frac{K}{\rho(s,s')},\,1\big\}\cdot\|e - e'\|_2 \leq \beta\|e - e'\|_2$.

trace iterates are essentially unchanged, for they have to be there in order to correct for the discrepancy between the behavior and target policies. For this reason, we prefer (2.9) to (2.8) and prefer thinking in terms of the selection of λ-parameters to that of what occurs *apparently* to those importance sampling ratio terms in the trace updates.

As mentioned in Example 2.2, the Munos et al. (2016) paper does not make the connection between (2.8) and (2.9). Mahmood et al. (2017) recognized the role of the λ-parameters and made explicit use of it to derive the ABQ algorithm. However, in the ABQ paper, the discussion and the presentation of the algorithm still emphasize the apparent changes in those importance sampling ratio terms in the trace iterates. This is an unsatisfactory point in that paper that we hope we have clarified with our present work.

We mentioned in the introduction that Retrace, ABQ and Tree-Backup are too conservative and tend to use too small λ values. Let us now make this statement more precise and also explain the reason behind.

These algorithms tend to behave effectively like TD(λ) with small constant λ, despite that they can have $\lambda_t = 1$ at some time steps t. This is due to the nature of TD learning with time-varying λ, which is very different from that of TD with constant λ. For time-varying λ, a large λ_t at one time step need not mean that we are using the information of the cumulative rewards over a long time horizon to estimate the value at the state S_t encountered at time t. Because the next λ_{t+1} could be very small or even zero, forcing a TD algorithm to "bootstrap" immediately. When large λ_t's are interleaved with small ones, we are effectively in the situation of TD with small λ. This could occur to our proposed scheme as well if, for example, in Example 2.1 the thresholds $C_{ss'}$ are set too small. When we use larger thresholds, we allow larger λ. By comparison, Retrace, ABQ, and Tree-Backup constrain the state-dependent λ-parameters to be small enough so that all the products $\lambda_t\gamma_t\rho_{t-1} < 1$, and this makes them prone to the small-λ issue just mentioned. (See the experiments in Section 4.2 for demonstrations.)

While we consider Retrace for approximate policy evaluation, the Munos et al. (2016) paper actually focuses primarily on finding an optimal policy for an MDP, in the tabular case, and it has demonstrated good empirical performance of Retrace and Tree-Backup for that purpose. Despite this, its results are not adequate yet to establish asymptotic optimality of these algorithms in the online optimistic policy iteration setting (personal communication with Munos), and it is still an open theoretical question whether online TD algorithms can solve an MDP like the Q-learning algorithm (Watkins, 1989; Tsitsiklis, 1994), when positive λ (small or not) and rapidly changing target policies are involved.

We also mention that for policy evaluation, Munos et al. (2016, Section 3.1) have also conceived the use of generalized Bellman operators, although they did not relate these operators explicitly to history-dependent λ's and did not study corresponding algorithms in this general case.

2.3 Ergodicity Result

The properties of the joint state-trace process $\{(S_t, y_t, e_t)\}$ are important for understanding and characterizing the behavior of our proposed TD learning scheme. We study them in this subsection. Most importantly, we shall establish the ergodicity of the state-trace process. The result will be useful in convergence analysis of several associated TD algorithms (Yu,

2017), although in this paper we discuss only the LSTD algorithm. In the next section we will also use the ergodicity result when we relate the LSTD equation (2.4) to a generalized Bellman equation for the target policy in order to interpret the LSTD solutions.

We note that to obtain the results in this subsection, we will follow similar lines of argument used in (Yu, 2012) for analyzing off-policy LSTD with constant λ. However, because λ is now history-dependent, some proof steps in (Yu, 2012) no longer apply. We shall explain this in more detail after we prove the main result of this subsection.

As another side note, one can introduce nonnegative coefficients $i(y)$ for memory states y to weight the state features (similarly to the use of "interest" weights in the ETD algorithm (Sutton et al., 2016)) and update e_t according to

$$e_t = \lambda_t \gamma_t \rho_{t-1} e_{t-1} + i(y_t)\,\phi(S_t). \tag{2.12}$$

The results given below apply to this update rule as well.

Let us start with two basic properties of $\{(S_t, y_t, e_t)\}$ that follow directly from our choice of the λ function:

(i) By Condition 2.3(i), for each y, $\lambda(y, e)e$ is a continuous function of e, and thus e_t depends continuously on e_{t-1}. This, together with the finiteness of $\mathcal{S} \times \mathcal{M}$, ensures that $\{(S_t, y_t, e_t)\}$ is a weak Feller Markov chain.[5]

(ii) Then, by a property of weak Feller Markov chains (Meyn and Tweedie, 2009, Theorem 12.1.2(ii)), the boundedness of $\{e_t\}$ ensured by Condition 2.3(ii) implies that $\{(S_t, y_t, e_t)\}$ has at least one invariant probability measure.

The third property, given in the lemma below, concerns the behavior of $\{e_t\}$ for different initial e_0. It is an important implication of Condition 2.3(i); actually, it is our purpose of introducing the condition 2.3(i) in the first place. In the lemma, $\overset{a.s.}{\to}$ stands for "converges almost surely to."

Lemma 2.1 *Let $\{e_t\}$ and $\{\hat{e}_t\}$ be generated by the iteration (2.2) and (2.5), using the same trajectory of states $\{S_t\}$ and initial y_0, but with different initial e_0 and $\hat{e}_0$, respectively. Then under Conditions 2.1(i) and 2.3(i), $e_t - \hat{e}_t \overset{a.s.}{\to} 0$.*

Proof The proof is similar to that of (Yu, 2012, Lemma 3.2). Let $\Delta_t = \|e_t - \hat{e}_t\|$, and let $\mathcal{F}_t$ denote the σ-algebra generated by $S_k, k \le t$. Note that under our assumption, in the generation of the two trace sequences $\{e_t\}$ and $\{\hat{e}_t\}$, the states $\{S_t\}$ and the memory states $\{y_t\}$ are the same, but the λ-parameters are different. Let us denote them by $\{\lambda_t\}$ and $\{\hat{\lambda}_t\}$ for the two trace sequences, respectively. Then by (2.2), $e_t - \hat{e}_t = \gamma_t \rho_{t-1}(\lambda_t e_{t-1} - \hat{\lambda}_t \hat{e}_{t-1})$, and by Condition 2.3(i), $\|\lambda_t e_{t-1} - \hat{\lambda}_t \hat{e}_{t-1}\| \le \|e_{t-1} - \hat{e}_{t-1}\|$. Hence $\|e_t - \hat{e}_t\| \le \gamma_t \rho_{t-1} \|e_{t-1} - \hat{e}_{t-1}\|$, so $\mathbb{E}\big[\Delta_t \big| \mathcal{F}_{t-1}\big] \le \mathbb{E}\big[\gamma_t \rho_{t-1} \big| \mathcal{F}_{t-1}\big] \cdot \Delta_{t-1} \le \Delta_{t-1}$. This shows $\{(\Delta_t, \mathcal{F}_t)\}$ is a nonnegative supermartingale. By the supermartingale convergence theorem (Dudley, 2002, Theorem 10.5.7 and Lemma 4.3.3), $\{\Delta_t\}$ converges a.s. to a nonnegative random variable Δ_∞ with $\mathbb{E}[\Delta_\infty] \le \liminf_{t\to\infty} \mathbb{E}[\Delta_t]$. From the inequality $\|e_t - \hat{e}_t\| \le \gamma_t \rho_{t-1} \|e_{t-1} - \hat{e}_{t-1}\|$ for all t, we have $\Delta_t \le \Delta_0 \cdot \prod_{k=1}^{t} \gamma_k \rho_{k-1}$, from which a direct calculation shows $\mathbb{E}\big[\Delta_t\big] \le \Delta_0 \cdot \mathbf{1}^\top (P\Gamma)^t \mathbf{1}$

5. This means that for any bounded continuous function f on $\mathcal{S} \times \mathcal{M} \times \Re^n$ (endowed with the usual topology), with $X_t = (S_t, y_t, e_t)$, $\mathbb{E}\big[f(X_1) \mid X_0 = x\big]$ is a continuous function of x (Meyn and Tweedie, 2009, Prop. 6.1.1).

where $\mathbf{1}$ denotes the n-dimensional vector of all 1's. As $t \to \infty$, $(P\Gamma)^t$ converges to the zero matrix under Condition 2.1(i). Therefore, $\liminf_{t\to\infty} \mathbb{E}[\Delta_t] = 0$ and consequently, we must have $\Delta_\infty = 0$ a.s., i.e., $\Delta_t \overset{a.s.}{\to} 0$. ■

We use Lemma 2.1 and ergodicity properties of weak Feller Markov chains (Meyn, 1989) to prove the ergodicity theorem below. A direct application to LSTD will be discussed immediately after the theorem, before we give its proof.

To state the result, we need some terminology and notation. For $\{(S_t, y_t, e_t)\}$ starting from the initial condition $x = (s, y, e)$, we write $\mathbf{P}_x$ for its probability distribution, and we write "$\mathbf{P}_x$-a.s." for "almost surely with respect to $\mathbf{P}_x$." The *occupation probability measures* are denoted by $\{\mu_{x,t}\}$, and they are random probability measures on $\mathcal{S} \times \mathcal{M} \times \Re^n$ given by

$$\mu_{x,t}(D) := \tfrac{1}{t}\textstyle\sum_{k=0}^{t-1} \mathbb{1}\big((S_k, y_k, e_k) \in D\big) \qquad \forall \text{ Borel sets } D \subset \mathcal{S} \times \mathcal{M} \times \Re^n,$$

where $\mathbb{1}(\cdot)$ is the indicator function. We are interested in the asymptotic convergence of these occupation probability measures in the sense of *weak convergence*: for probability measures $\{\mu_t\}$ and μ on a metric space, $\{\mu_t\}$ converges weakly to μ if $\int f d\mu_t \to \int f d\mu$ as $t \to \infty$, for every bounded continuous function f.

We shall also consider the Markov chain $\{(S_t, S_{t+1}, y_t, e_t)\}$, whose occupation probability measures are defined likewise. This Markov chain is essentially the same as $\{(S_t, y_t, e_t)\}$, but it is more convenient for applying our ergodicity result to TD algorithms because the temporal-difference term $\delta_t(v)$ involves (S_t, S_{t+1}, e_t). Regarding invariant probability measures of the two Markov chains, obviously, if ζ is an invariant probability measure of $\{(S_t, y_t, e_t)\}$, then an invariable probability measure of $\{(S_t, S_{t+1}, y_t, e_t)\}$ is the probability measure ζ_1 composed from the marginal ζ and the conditional distribution of S_1 given (S_0, y_0, e_0) specified by P^o; i.e.,

$$\zeta_1(D) = \int \textstyle\sum_{s' \in \mathcal{S}} P^o_{ss'}\, \mathbb{1}\big((s, s', y, e) \in D\big)\, \zeta\big(d(s, y, e)\big) \qquad \forall \text{ Borel sets } D \subset \mathcal{S}^2 \times \mathcal{M} \times \Re^n. \tag{2.13}$$

(In the above, we used the notation $\int f(x)\, \zeta(dx)$ to write the integral of f w.r.t. ζ, and the notation $\zeta\big(d(s, y, e)\big)$ is the same as $\zeta(dx)$ with $x = (s, y, e)$.)

Theorem 2.1 *Let Conditions 2.1-2.3 hold. Then $\{(S_t, y_t, e_t)\}$ is a weak Feller Markov chain and has a unique invariant probability measure ζ. For each initial condition $x := (s, y, e)$ of (S_0, y_0, e_0), the occupation probability measures $\{\mu_{x,t}\}$ converge weakly to ζ, $\mathbf{P}_x$-a.s.*

Likewise, the same holds for $\{(S_t, S_{t+1}, y_t, e_t)\}$, whose unique invariant probability measure is as given in (2.13).

If the initial distribution of (S_0, y_0, e_0) is ζ, the state-trace process $\{(S_t, y_t, e_t)\}$ is stationary. Let $\mathbb{E}_\zeta$ denote expectation w.r.t. this stationary process. We now state a corollary of the above theorem for LSTD, before we prove the theorem.

Consider the sequence of equations in v, $\frac{1}{t}\sum_{k=0}^{t-1} e_k\, \delta_k(v) = 0$, appeared in (2.4) for LSTD. From the definition (2.3) of $\delta_t(v)$,

$$\delta_t(v) = \rho_t \left(R_t + \gamma_{t+1} v(S_{t+1}) - v(S_t)\right),$$

we see that for fixed v, every $e_k\, \delta_k(v)$ can be expressed as $f(S_k, S_{k+1}, e_k)$ for a continuous function f. Since the traces and hence the entire process lie in a bounded set under Condition 2.3(ii), the weak convergence of the occupation probabilities measures of $\{(S_t, S_{t+1}, y_t, e_t)\}$ shown by Theorem 2.1 implies that this sequence of equations has an asymptotic limit that can be expressed in terms of the stationary state-trace process as follows.

Corollary 2.1 *Let Conditions 2.1-2.3 hold. Then for each initial condition of (S_0, y_0, e_0), almost surely, the sequence of linear equations in v, $\frac{1}{t}\sum_{k=0}^{t-1} e_k\, \delta_k(v) = 0$, tends asymptotically to $\mathbb{E}_\zeta[e_0\, \delta_0(v)] = 0$ (also a linear equation in v), in the sense that the random coefficients in the former equations converge to the corresponding coefficients in the latter equation as $t \to \infty$.*

In the rest of this section we prove Theorem 2.1. Broadly speaking, the line of argument is as follows: We first prove the weak convergence of occupation probability measures to the same invariant probability measure, for each initial condition. This will in turn imply the uniqueness of the invariant probability measure.

After the proof we will first comment in Remark 2.1 on the differences between our proof and that of a similar result in the previous work (Yu, 2012). We will then comment in Remark 2.2 about the technical roles of Condition 2.3 (which concerns the choice of the function $\lambda(\cdot)$) and whether some part of that condition can be relaxed.

Proof of Theorem 2.1 As we discussed before Lemma 2.1, under Conditions 2.3, $\{(S_t, y_t, e_t)\}$ is weak Feller and has at least one invariant probability measure ζ. Then, by (Meyn, 1989, Prop. 4.1), there exists a set $D \subset \mathcal{S} \times \mathcal{M} \times \Re^n$ with ζ-measure 1 such that for each initial condition $x = (s, y, e) \in D$, the occupation probability measures $\{\mu_{x,t}\}$ converge weakly, $\mathbf{P}_x$-a.s., to an invariant probability measure μ_x that depends only on the initial condition x. To prove the theorem using this result, we need to show that (i) all these $\{\mu_x \mid x \in D\}$ are the same invariant probability measure, and (ii) for all $x \notin D$, $\{\mu_{x,t}\}$ has the same weak convergence property.

To this end, we first consider an arbitrary pair (s, y_s) in the recurrent class of $\{(S_t, y_t)\}$ (cf. Condition 2.2). Let us show that for all initial conditions $x \in \{(s, y_s, e) \mid e \in \Re^n\}$, $\{\mu_{x,t}\}$ converges weakly to the same invariant probability measure, almost surely.

Since the finite-state Markov chain $\{(S_t, y_t)\}$ has a single recurrent class (Condition 2.2) and its evolution is not affected by $\{e_t\}$, the marginal of ζ on $\mathcal{S} \times \mathcal{M}$ coincides with the unique invariant probability distribution of $\{(S_t, y_t)\}$. So the fact that $\zeta(D) = 1$ and (s, y_s) is a recurrent state of $\{(S_t, y_t)\}$ implies that there exists some $\hat{e}$ with $(s, y_s, \hat{e}) \in D$. For the initial condition $\hat{x} = (s, y_s, \hat{e})$, by the result of (Meyn, 1989) mentioned earlier, $\{\mu_{\hat{x},t}\}$ converges weakly to $\mu_{\hat{x}}$, almost surely.

Now consider $x = (s, y_s, e)$ for an arbitrary $e \in \Re^n$. Generate iterates $\{\hat{e}_t\}$ and $\{e_t\}$ according to (2.2), using the same trajectory $\{(S_t, y_t)\}$ with $(S_0, y_0) = (s, y_s)$, but with $\hat{e}_0 = \hat{e}$ and $e_0 = e$. By Lemma 2.1, $\hat{e}_t - e_t \overset{a.s.}{\to} 0$. Therefore, except on a null set of sample

paths, it holds for all bounded Lipschitz continuous functions f on $\mathcal{S}\times\mathcal{M}\times\Re^n$ that[6]

$$\left|\int f d\mu_{\hat{x},t} - \int f d\mu_{x,t}\right| = \left|\tfrac{1}{t}\sum_{k=0}^{t-1} f(S_k,y_k,\hat{e}_k) - \tfrac{1}{t}\sum_{k=0}^{t-1} f(S_k,y_k,e_k)\right| \to 0. \tag{2.14}$$

By the a.s. weak convergence of $\mu_{\hat{x},t}$ to $\mu_{\hat{x}}$ proved earlier, except on a null set, $\int f d\mu_{\hat{x},t} \to \int f d\mu_{\hat{x}}$ for all such functions f. Combining this with (2.14) yields that almost surely, $\int f d\mu_{x,t} \to \int f d\mu_{\hat{x}}$ for all such f. By (Dudley, 2002, Theorem 11.3.3), this implies that almost surely, $\mu_{x,t} \to \mu_{\hat{x}}$ weakly.

Thus we have proved that for all initial conditions $x=(s,y_s,e), e\in\Re^n$, $\{\mu_{x,t}\}$ converges weakly, almost surely, to the same invariant probability measure $\mu_{\hat{x}}$. Denote $\mu=\mu_{\hat{x}}$. Let us now show that for any initial condition x, $\{\mu_{x,t}\}$ also converges to μ, $\mathbf{P}_x$-a.s.

Consider $\{(S_t,y_t,e_t)\}$ with an arbitrary initial condition $\bar{x}=(\bar{s},\bar{y},\bar{e})$. Let $\tau=\min\{t \mid (S_t,y_t)=(s,y_s)\}$ (the pair (s,y_s) is as in the proof above). Note that $\tau<\infty$ a.s., because (s,y_s) is a recurrent state of $\{(S_t,y_t)\}$. Define $(\tilde{S}_k,\tilde{y}_k)=(S_{\tau+k},y_{\tau+k})$, $\tilde{e}_k=e_{\tau+k}$ for $k\geq 0$.

By the strong Markov property (see e.g. Nummelin, 1984, Theorem 3.3), $\{(\tilde{S}_k,\tilde{y}_k)\}_{k\geq 0}$ has the same probability distribution as the Markov chain $\{(S_t,y_t)\}$ that starts from $(S_0,y_0)=(s,y_s)$. Therefore, by the preceding proof, $\mathbf{P}_{\bar{x}}$-almost surely, for all bounded continuous functions f on $\mathcal{S}\times\mathcal{M}\times\Re^n$,

$$\lim_{m\to\infty}\tfrac{1}{m}\sum_{k=0}^{m-1} f(\tilde{S}_k,\tilde{y}_k,\tilde{e}_k) = \int f d\mu. \tag{2.15}$$

Denote $a\wedge b=\min\{a,b\}$. Using (2.15) and the fact $\tau<\infty$ a.s., we have that $\mathbf{P}_{\bar{x}}$-almost surely,

$$\begin{aligned}\lim_{t\to\infty}\tfrac{1}{t}\sum_{k=0}^{t-1} f(S_k,y_k,e_k) &= \lim_{t\to\infty}\left(\tfrac{1}{t}\sum_{k=0}^{t\wedge(\tau-1)} f(S_k,y_k,e_k) + \tfrac{1}{t}\sum_{k=\tau}^{t-1} f(S_k,y_k,e_k)\right)\\ &= \lim_{t\to\infty}\tfrac{1}{t}\sum_{k=0}^{t-\tau-1} f(S_{\tau+k},y_{\tau+k},e_{\tau+k})\\ &= \lim_{m\to\infty}\tfrac{1}{m}\sum_{k=0}^{m-1} f(\tilde{S}_k,\tilde{y}_k,\tilde{e}_k) = \int f d\mu.\end{aligned}$$

This proves that $\{\mu_{x,t}\}$ converges weakly to μ almost surely, for each initial condition x.

It now follows that μ must be the unique invariant probability measure of $\{(S_t,y_t,e_t)\}$. To see this, suppose ζ is another invariant probability measure. For any bounded continuous function f, by stationarity, $\mathbb{E}_\zeta[\frac{1}{t}\sum_{k=0}^{t-1} f(S_k,y_k,e_k)] = \int f d\zeta$ for all $t\geq 1$. On the other hand, the preceding proof has established that for all initial conditions x,

$$\tfrac{1}{t}\sum_{k=0}^{t-1} f(S_k,y_k,e_k) = \int f d\mu_{x,t} \to \int f d\mu, \quad \mathbf{P}_x\text{-a.s.},$$

which implies that if ζ is the initial distribution of (S_0,y_0,e_0), then $\frac{1}{t}\sum_{k=0}^{t-1} f(S_k,y_k,e_k)\to\int f d\mu$, $\mathbf{P}_\zeta$-a.s. We thus have

$$\begin{aligned}\int f d\zeta = \mathbb{E}_\zeta\left[\tfrac{1}{t}\sum_{k=0}^{t-1} f(S_k,y_k,e_k)\right] &= \lim_{t\to\infty}\mathbb{E}_\zeta\left[\tfrac{1}{t}\sum_{k=0}^{t-1} f(S_k,y_k,e_k)\right]\\ &= \mathbb{E}_\zeta\left[\lim_{t\to\infty}\tfrac{1}{t}\sum_{k=0}^{t-1} f(S_k,y_k,e_k)\right] = \int f d\mu,\end{aligned}$$

6. Here we are using the same $(S_k,y_k), k\leq t$ in the occupation probability measures $\mu_{\hat{x},t}$ and $\mu_{x,t}$. This is valid because the e_t's do not affect the evolution of $\{(S_t,y_t)\}$ and are functions of these states and the given initial e_0. If we call the $\mu_{x,t}$ here $\tilde{\mu}_{x,t}$ instead and define $\mu_{x,t}$ using another independent copy of $\{(S_t,y_t)\}$, then since the two sequences of occupation probability measures will have the same probability distribution, $\{\mu_{x,t}\}$ will have the same weak convergence property as $\{\tilde{\mu}_{x,t}\}$.

where the third equality follows from the bounded convergence theorem. This shows $\int f d\zeta = \int f d\mu$ for all bounded continuous functions f, and hence $\zeta=\mu$ by (Dudley, 2002, Prop. 11.3.2), proving the uniqueness of the invariant probability measure.

The conclusions for the Markov chain $\{(S_t,S_{t+1},y_t,e_t)\}$ follow from the same arguments given above, if we replace S_t with (S_t,S_{t+1}) and replace the set $\mathcal{S}$ with the set of possible state transitions. (We could have proved the assertions for $\{(S_t,S_{t+1},y_t,e_t)\}$ first and then deduced as their implications the assertions for $\{(S_t,y_t,e_t)\}$. We treated the latter first, as it makes the notation in the proof simpler.) ■

Remark 2.1 (About the proof) Theorem 2.1 is similar to (Yu, 2012, Theorem 3.2) for off-policy LSTD with constant λ (the analysis given in (Yu, 2012) also applies to state-dependent λ). Some of the techniques used to prove the two theorems are also similar. The main difference to (Yu, 2012) is that in the proof here we used an argument based on the strong Markov property to extend the weak convergence property of $\{\mu_{x,t}\}$ for a subset of initial conditions $x\in\{(s,y_s,e)\mid e\in\Re^n\}$ to all initial conditions, whereas in (Yu, 2012) this step was proved using a result on the convergence-in-mean of LSTD iterates established first. The latter approach would not work here due to the dependence of λ_t on the history. Indeed, due to this dependence, the proof of the convergence-in-mean of LSTD given in (Yu, 2012) does not carry over to our case, even though that convergence does hold as a consequence of Theorem 2.1, in view of the boundedness of traces by construction. Compared with the proof of the ergodicity result in (Yu, 2012), the proof we gave here is more direct and therefore better.

Regarding possible alternative proofs of Theorem 2.1, let us also mention that if we prove first the uniqueness of the invariant probability measure, then, since $\{(S_t,y_t,e_t)\}_{t\geq 1}$ lie in a bounded set, the weak convergence of occupation probability measures will follow immediately from (Meyn, 1989, Prop. 4.2). However, because the evolution of the λ_t's depends on both states and traces, it does not seem easy to us to prove directly the uniqueness part first. ■

Remark 2.2 (About the conditions on the function $\lambda(\cdot)$) Our proof of Theorem 2.1 relied on Lemma 2.1 and the two properties discussed preceding that lemma, namely, that $\{(S_t,y_t,e_t)\}$ is a weak Feller Markov chain and has at least one invariant probability measure. As long as these hold when we weaken or change the conditions on the function $\lambda(\cdot)$, the proof and the conclusions of the theorem will remain applicable.

We introduced Condition 2.3(ii) to bound the traces for algorithmic concerns. For the ergodicity of the state-trace process, Condition 2.3(ii) is unimportant—in fact, it can be removed from the conditions of Theorem 2.1. The reason is that we used this condition before Lemma 2.1 to quickly infer that $\{(S_t,y_t,e_t)\}$ has at least one invariant probability measure, but this is still true without Condition 2.3(ii), in view of (Meyn and Tweedie, 2009, Theorem 12.1.2(ii)) and the fact that under Condition 2.1(i), $\{e_t\}$ is bounded in probability (the proof of this fact is straightforward and similar to the proof of (Yu, 2012, Lemma 3.1) or (Yu, 2015, Prop. A.1)).

Condition 2.3(i) is actually two conditions combined into one. The first is the continuity of $\lambda(y,e)e$ in e for each y, which was used to ensure that the state-trace process is a weak

Feller Markov chain. To be more general, instead of letting the evolutions of the traces and memory states be governed by the functions λ and g, one may consider letting them be governed by stochastic kernels. Then by placing a suitable continuity condition on the stochastic kernel λ, one can ensure that the state-trace process has the desired weak Feller Markov property.

The second condition packed into Condition 2.3(i) is that for each y, $\lambda(y,e)e$ is a Lipschitz continuous function of e with modulus 1. This condition is somewhat restrictive, and one may consider instead allowing the function to have Lipschitz modulus greater than 1. However, additional conditions are then needed to ensure that Lemma 2.1 holds. (If this lemma does not hold, then the state-trace process may not be ergodic and one will need a different approach than the one we took to characterize the sample path properties of the state-trace process.)

From an algorithmic perspective, if it is desirable to choose even larger λ_t's or to have greater flexibility in choosing these λ-parameters, some of the generalizations just mentioned can be considered. For example, Condition 2.3(ii) can be replaced and stochastic kernels can be introduced to allow for occasionally large traces e_t, so that instead of having the traces bounded, one only make their variances bounded in a desired range. ■

3. Generalized Bellman Equations

In this section, we continue the analysis started in Section 2.3. Recall that Corollary 2.1 established that the asymptotic limit of the linear equations (2.4) for LSTD is the linear equation (in v):

$$\mathbb{E}_\zeta[\, e_0\, \delta_0(v)] = 0.$$

Our goal now is to relate this equation to a generalized Bellman equation for the target policy π. This will then allow us to interpret solutions of (2.4) computed by LSTD as solutions of approximate versions of that generalized Bellman equation.

To this end, we will first give a general description of randomized stopping times and associated Bellman operators (Section 3.1). We will then use these notions to derive the particular Bellman operators that correspond to our choices of the λ-parameters and appear in the linear equations for LSTD (Section 3.2). We will also discuss a composite scheme of choosing the λ-parameters as a direct application and extension of our results.

To simplify notation in subsequent derivations, we shall use the following shorthand notation: For $k \le m$, denote $S_k^m = (S_k, S_{k+1}, \dots S_m)$,

$$\rho_k^m = \textstyle\prod_{i=k}^m \rho_i, \qquad \lambda_k^m = \prod_{i=k}^m \lambda_i, \qquad \gamma_k^m = \prod_{i=k}^m \gamma_i. \tag{3.1}$$

Also, we shall treat $\rho_k^m = \lambda_k^m = \gamma_k^m = 1$ if $k > m$.

3.1 Randomized Stopping Times and Associated Bellman Operators

Consider the Markov chain $\{S_t\}$ induced by the target policy π. Let Condition 2.1(i) hold. Recall that for the value function v_π, we have that for each state $s \in \mathcal{S}$,

$$v_\pi(s) = \mathbb{E}_s^\pi\big[\textstyle\sum_{t=0}^\infty \gamma_1^t\, r_\pi(S_t)\big] \quad \text{(by definition)}$$

and

$$v_\pi(s) = r_\pi(s) + \mathbb{E}_s^\pi[\gamma_1 v_\pi(S_1)].$$

The second equation is the standard one-step Bellman equation.

To write generalized Bellman equations for π, we shall make use of *randomized stopping times* for $\{S_t\}$, a notion that generalizes naturally stopping times for $\{S_t\}$ in that whether to stop at time t depends not only on the past states S_0^t but also on certain random outcomes. A simple example is to toss a coin at each time and stop as soon as the coin lands on heads, regardless of the history S_0^t. (The corresponding Bellman equation is the one associated with TD(λ) for a constant λ; cf. Example 3.1.) Of interest here is the general case where the stopping decision does depend on the entire history.

To define a randomized stopping time formally, first, the probability space of $\{S_t\}$ is enlarged to take into account whatever randomization scheme that is used to make the stopping decision. (The enlargement will be problem-dependent, as the next subsection will demonstrate.) Then, on the enlarged space, a randomized stopping time τ for $\{S_t\}$ is a stopping time[7] relative to some increasing sequence of σ-algebras $\mathcal{F}_0 \subset \mathcal{F}_1 \subset \cdots$, where the sequence $\{\mathcal{F}_t\}$ is such that

(i) for all $t \ge 0$, $\mathcal{F}_t \supset \sigma(S_0^t)$ (the σ-algebra generated by S_0^t), and

(ii) relative to $\{\mathcal{F}_t\}$, $\{S_t\}$ remains to be a Markov chain with transition probability P, i.e., for all $s \in \mathcal{S}$, $\text{Prob}(S_{t+1} = s \mid \mathcal{F}_t) = P_{S_t s}$.

See (Nummelin, 1984, Chap. 3.3); in particular, see Prop. 3.6 in p. 31-32 therein for several equivalent definitions of randomized stopping times.

Note that if $\mathcal{F}_t = \sigma(S_0^t)$ for all t, then the history of states S_0^t fully determines whether $\tau \le t$ and τ reduces to a stopping time for the Markov chain $\{S_t\}$. The properties (i)-(ii) in the above definition encapsulate our earlier intuitive discussion about making stopping decisions, namely, stopping decisions are made based on the history S_0^t and additional random outcomes that do not affect the evolution of the Markov chain.

Like stopping times, the strong Markov property also holds for randomized stopping times for a Markov chain. This is an important basic property. It says that in the event $\tau < \infty$, conditioned on the σ-algebra $\mathcal{F}_\tau$ associated with the stopping time τ relative to $\{\mathcal{F}_t\}$ (which is the σ-algebra generated by the events that "happen before τ"), the conditional distribution of $(S_\tau, S_{\tau+1}, \dots)$ is the same as the probability distribution of a Markov chain $(S_0, S_1, \dots)$ with initial state $S_0 = S_\tau$ (Nummelin, 1984, Theorem 3.3).

The above abstract definition of a randomized stopping time allows us to write Bellman equations in general forms without worrying about the details of the enlarged space, which are not important at this point. For notational simplicity, when there is no confusion, we shall still write $\mathbf{P}^\pi$ for the probability measure on the enlarged probability space and use $\mathbb{E}^\pi$ and $\mathbb{E}_s^\pi$ to denote the expectation and conditional expectation given $S_0 = s$, respectively, w.r.t. $\mathbf{P}^\pi$.

If τ is a randomized stopping time for $\{S_t\}$, the strong Markov property (Nummelin, 1984, Theorem 3.3) allows us to express v_π in terms of $v_\pi(S_\tau)$ and the total discounted

7. A random time τ is called a stopping time relative to a sequence $\{\mathcal{F}_t\}$ of increasing σ-algebras if the event $\{\tau = t\} \in \mathcal{F}_t$ for every t.

rewards R^τ prior to stopping:

$$\begin{aligned} v_\pi(s) &= \mathbb{E}_s^\pi\left[\sum_{t=0}^{\tau-1}\gamma_1^t\, r_\pi(S_t) + \sum_{t=\tau}^{\infty}\gamma_1^\tau\cdot\gamma_{\tau+1}^t\, r_\pi(S_t)\right] \\ &= \mathbb{E}_s^\pi\big[R^\tau + \gamma_1^\tau\, v_\pi(S_\tau)\big], \end{aligned} \tag{3.2}$$

where $R^\tau = \sum_{t=0}^{\tau-1}\gamma_1^t\, r_\pi(S_t)$ for $\tau \in \{0,1,2,\ldots\}\cup\{+\infty\}$.[8] We can also write the Bellman equation (3.2) in terms of $\{S_t\}$ only, by taking expectation over τ:

$$\begin{aligned} v_\pi(s) &= \mathbb{E}_s^\pi\left[\sum_{t=0}^{\infty}\Big(\mathbb{1}(\tau>t)\cdot\gamma_1^t\, r_\pi(S_t) + \mathbb{1}(\tau=t)\cdot\gamma_1^t\, v_\pi(S_t)\Big)\right], \\ &= \mathbb{E}_s^\pi\left[\sum_{t=0}^{\infty}\Big(q_t^+(S_0^t)\cdot\gamma_1^t\, r_\pi(S_t) + q_t(S_0^t)\cdot\gamma_1^t\, v_\pi(S_t)\Big)\right], \end{aligned} \tag{3.3}$$

where

$$q_t^+(S_0^t) = \mathbf{P}^\pi(\tau > t \mid S_0^t), \qquad q_t(S_0^t) = \mathbf{P}^\pi(\tau = t \mid S_0^t). \tag{3.4}$$

The r.h.s. of (3.2) or (3.3) defines a generalized Bellman operator $T:\Re^N\to\Re^N$ associated with τ, which has several equivalent expressions; e.g.,

$$(Tv)(s) = \mathbb{E}_s^\pi\big[R^\tau + \gamma_1^\tau\, v(S_\tau)\big] = \mathbb{E}_s^\pi\Big[\sum_{t=0}^{\infty}\Big(q_t^+(S_0^t)\cdot\gamma_1^t\, r_\pi(S_t) + q_t(S_0^t)\cdot\gamma_1^t\, v(S_t)\Big)\Big], \quad s\in\mathcal{S}.$$

Depending on the context, one expression can be more convenient to use than the other. For example, the first expression is convenient for defining T through the associated τ and for deducing the contraction property of T, whereas expressions like the second will be of interest when we want to know more explicitly the particular T for our TD learning scheme and its dependence on the λ-parameters.

In common with one-step Bellman operator, the generalized Bellman operator T is affine and involves a substochastic matrix. If $\tau\geq 1$ a.s., then the value function v_π is the unique fixed point of T, i.e., the unique solution of $v = Tv$, and T is a sup-norm contraction. In fact, this can be shown for slightly more general τ:

Theorem 3.1 *Let Condition 2.1(i) hold, and let the randomized stopping time τ be such that $\mathbf{P}^\pi(\tau\geq 1 \mid S_0 = s) > 0$ for all states $s\in\mathcal{S}$. Then v_π is the unique fixed point of the generalized Bellman operator T associated with τ, and T is a contraction w.r.t. a weighted sup-norm on $\Re^N$.*

8. We explain the derivations in this footnote. In the case $\tau = 0$, $R^0 = 0$. In the case $\tau=\infty$, by Condition 2.1(i), $R^\infty = \sum_{t=0}^{\infty}\gamma_1^t\, r_\pi(S_t)$ is almost surely well-defined, while the second term $\gamma_1^\tau\, v_\pi(S_\tau)$ in (3.2) is 0 because $\gamma_1^\infty := \prod_{k=1}^{\infty}\gamma_k = 0$ a.s., under Condition 2.1(i). Equation (3.2) is derived as follows: By the strong Markov property (Nummelin, 1984, Theorem 3.3), on $\{\tau<\infty\}$,

$$\mathbb{E}^\pi\left[\sum_{t=\tau}^{\infty}\gamma_1^\tau\cdot\gamma_{\tau+1}^t\, r_\pi(S_t)\mid\mathcal{F}_\tau\right] = \gamma_1^\tau\cdot\mathbb{E}_{S_\tau}^\pi\left[\sum_{t=0}^{\infty}\gamma_1^t\, r_\pi(S_t)\right] = \gamma_1^\tau v_\pi(S_\tau).$$

Then, since the term $\mathbb{E}_s^\pi\big[\sum_{t=\tau}^{\infty}\gamma_1^\tau\cdot\gamma_{\tau+1}^t\, r_\pi(S_t)\big] = \mathbb{E}_s^\pi\big[\mathbb{1}(\tau<\infty)\cdot\sum_{t=\tau}^{\infty}\gamma_1^\tau\cdot\gamma_{\tau+1}^t\, r_\pi(S_t)\big]$, we use the property of the conditional expectation given $\mathcal{F}_\tau$ and the fact $\mathcal{F}_\tau\supset\sigma(S_0)$ to rewrite this term as

$$\mathbb{E}_s^\pi\big[\mathbb{1}(\tau<\infty)\cdot\mathbb{E}^\pi\big[\textstyle\sum_{t=\tau}^{\infty}\gamma_1^\tau\cdot\gamma_{\tau+1}^t\, r_\pi(S_t)\mid\mathcal{F}_\tau\big]\big] = \mathbb{E}_s^\pi[\mathbb{1}(\tau<\infty)\cdot\gamma_1^\tau v_\pi(S_\tau)] = \mathbb{E}_s^\pi[\gamma_1^\tau v_\pi(S_\tau)],$$

where in the last equality we also used the fact $\gamma_1^\infty = 0$ a.s. This gives (3.2).

We prove this theorem in Appendix A. The proof amounts to showing that if a state process evolves according to the substochastic matrix $\tilde{P}$ involved in the affine operator T, then all the states in $\mathcal{S}$ are transient (equivalently, the spectral radius of $\tilde{P}$ is less than 1 and $I-\tilde{P}$ is invertible (Puterman, 1994, Appendix A.4)). From this the conclusions of the theorem follow as a basic fact from nonnegative matrix theory (Seneta, 2006, Theorem 1.1), and one specific choice of the weights of the sup-norm in the theorem is simply the expected time for the process to leave $\mathcal{S}$ from each initial state (see e.g., the proof of (Bertsekas and Tsitsiklis, 1996, Prop. 2.2)).

For TD algorithms that do not use history-dependent λ, the random times τ and the corresponding Bellman operators T have simple descriptions:

Example 3.1 (TD with constant or state-dependent λ) Depending on the choice of λ, TD(λ) algorithms are associated with different randomized stopping times τ. In the case of constant λ, starting from time 1, we stop the system with probability $1-\lambda$ if it has not stopped yet; i.e.,

$$\tau\geq 1 \quad\text{and}\quad \mathbf{P}^\pi(\tau = t \mid \tau > t-1, S_0^t) = 1-\lambda, \quad \forall\, t\geq 1.$$

In particular, we always stop at $t=1$ if $\lambda = 0$, and we never stop if $\lambda = 1$. Similarly, for state-dependent λ where $\lambda_t = \lambda(S_t)$, a function of the current state, the preceding stopping probability is replaced by $1-\lambda(S_t)$: $\mathbf{P}^\pi(\tau = t \mid \tau > t-1, S_0^t) = 1-\lambda(S_t)$ for $t\geq 1$. In these cases, by taking expectations over τ, the corresponding Bellman operators can be expressed solely in terms of λ and the model parameters for the target policy. ■

3.2 Bellman Equation for the Proposed TD Learning Scheme

With the terminology of randomized stopping times, we are now ready to write down the generalized Bellman equation associated with the TD learning scheme proposed in Section 2.2. It corresponds to a particular randomized stopping time. We shall first describe this random time, from which a generalized Bellman equation follows as seen in the preceding subsection. That this is indeed the Bellman equation for our TD learning scheme will then be proved.

Consider the Markov chain $\{S_t\}$ *under the target policy* π. We define a randomized stopping time τ for $\{S_t\}$:

- Let $y_t, \lambda_t, e_t, t\geq 1$, evolve according to (2.5) and (2.2):

$$y_t = g(y_{t-1}, S_t), \qquad \lambda_t = \lambda(y_t, e_{t-1}), \qquad e_t = \lambda_t\,\gamma_t\,\rho_{t-1}\, e_{t-1} + \phi(S_t), \quad t\geq 1.$$

- Let the initial (S_0, y_0, e_0) be distributed according to ζ, the unique invariant probability measure in Theorem 2.1 for the state-trace process induced by the behavior policy.
- At time $t\geq 1$, we stop the system with probability $1-\lambda_t$ if it has not yet been stopped. Let τ be the time when the system stops ($\tau=\infty$ if the system never stops).

To make the dependence on the initial distribution ζ explicit, we write $\mathbf{P}_\zeta^\pi$ for the probability measure of this process.

Note that by definition λ_t *and* $\lambda_1^t = \prod_{k=1}^t \lambda_k$ *are functions of the initial* (y_0, e_0) *and states* S_0^t. From how the random time τ is defined, we have for all $t \geq 1$,

$$\mathbf{P}_\zeta^\pi(\tau > t \mid S_0^t, y_0, e_0) = \lambda_1^t =: h_t^+(y_0, e_0, S_0^t), \tag{3.5}$$

$$\mathbf{P}_\zeta^\pi(\tau = t \mid S_0^t, y_0, e_0) = \lambda_1^{t-1}(1-\lambda_t) =: h_t(y_0, e_0, S_0^t), \tag{3.6}$$

and hence

$$q_t^+(S_0^t) := \mathbf{P}_\zeta^\pi(\tau > t \mid S_0^t) = \int h_t^+(y, e, S_0^t)\, \zeta\big(d(y,e) \mid S_0\big), \tag{3.7}$$

$$q_t(S_0^t) := \mathbf{P}_\zeta^\pi(\tau = t \mid S_0^t) = \int h_t(y, e, S_0^t)\, \zeta\big(d(y,e) \mid S_0\big), \tag{3.8}$$

where $\zeta(d(y,e) \mid s)$ is the conditional distribution of (y_0, e_0) given $S_0 = s$, w.r.t. the initial distribution ζ. As before, we can write the generalized Bellman operator T associated with τ in several equivalent forms. Let $\mathbb{E}_\zeta^\pi$ denote expectation under $\mathbf{P}_\zeta^\pi$. Similarly to the derivation of (3.3), we can rewrite (3.2) in this case by taking expectation over τ conditioned on (S_0^t, y_0, e_0) to derive that for all $v : \mathcal{S} \to \Re, s \in \mathcal{S}$,

$$(Tv)(s) = \mathbb{E}_\zeta^\pi\Big[\textstyle\sum_{t=0}^\infty \lambda_1^t \gamma_1^t\, r_\pi(S_t) + \sum_{t=1}^\infty \lambda_1^{t-1}(1-\lambda_t)\gamma_1^t\, v(S_t) \mid S_0 = s\Big]. \tag{3.9}$$

Or express T in the form of (3.3) by further integrating over (y_0, e_0) and using (3.7)-(3.8):

$$(Tv)(s) = \mathbb{E}_\zeta^\pi\Big[\textstyle\sum_{t=0}^\infty \Big(q_t^+(S_0^t)\cdot\gamma_1^t\, r_\pi(S_t) + q_t(S_0^t)\cdot\gamma_1^t\, v(S_t)\Big) \,\Big|\, S_0 = s\Big], \tag{3.10}$$

for all $v : \mathcal{S} \to \Re, s \in \mathcal{S}$, where in the case $t = 0$, $q_0^+(S_0) = 1$ and $q_0(S_0) = 0$ since $\tau > 0$ by construction.

It will be useful later to express $TV - V$ in terms of temporal differences. From (3.9), by writing $\lambda_1^{t-1}(1-\lambda_t)\gamma_1^t\, v(S_t) = \lambda_1^{t-1}\gamma_1^t\, v(S_t) - \lambda_1^t\gamma_1^t\, v(S_t)$ and rearranging terms, we have for all $v : \mathcal{S} \to \Re, s \in \mathcal{S}$,

$$\begin{aligned}(Tv)(s) - v(s) &= \mathbb{E}_\zeta^\pi\Big[\textstyle\sum_{t=0}^\infty \lambda_1^t\gamma_1^t\, r_\pi(S_t) + \sum_{t=0}^\infty \lambda_1^t\gamma_1^{t+1}\, v(S_{t+1}) - \sum_{t=0}^\infty \lambda_1^t\gamma_1^t\, v(S_t) \mid S_0 = s\Big] \\ &= \mathbb{E}_\zeta^\pi\Big[\textstyle\sum_{t=0}^\infty \lambda_1^t\gamma_1^t\cdot\Big(r_\pi(S_t) + \gamma_{t+1}\, v(S_{t+1}) - v(S_t)\Big) \,\Big|\, S_0 = s\Big]. \end{aligned} \tag{3.11}$$

In a similar way, from (3.10), we can write[9]

$$(Tv)(s) - v(s) = \mathbb{E}_\zeta^\pi\Big[\textstyle\sum_{t=0}^\infty q_t^+(S_0^t)\cdot\gamma_1^t\cdot\Big(r_\pi(S_t) + \gamma_{t+1}\, v(S_{t+1}) - v(S_t)\Big) \,\Big|\, S_0 = s\Big].$$

Remark 3.1 Comparing the two expressions (3.9) and (3.10) of T, we remark that the expression (3.9) reflects the role of the λ_t's in determining the stopping time, whereas the expression (3.10), which has eliminated the auxiliary variables y_t and e_t, shows more clearly the dependence of the stopping time on the entire history S_0^t. It can also be seen, from the initial distribution ζ, the dependence of λ_t on the traces and the dependence of the traces on the function $\rho(\cdot)$ (which describes importance sampling ratios), that both the behavior policy and the choice of the feature representation assert a significant role in determining the Bellman operator T for the target policy. This is in contrast with off-policy TD learning that uses a constant λ, where the behavior policy and the approximation subspace affect only how one approximates the Bellman equation underlying TD, not the Bellman equation itself, which is solely determined by λ (cf. Example 3.1).

Furthermore, note that as the invariant distribution of the state-trace process, ζ is associated with the dynamic behavior of the states *and traces* under the behavior policy. Generally, there is no explicit expression of ζ in terms of P^o and the parameters in the λ function. As a result, in general we cannot express the operator T in terms of these parameters in the learning scheme. This is different from the case of TD(λ) where λ is a function of the present state only. ■

9. Since τ is a randomized stopping time for the Markov chain $\{S_t\}$, we have $\mathbf{P}_\zeta^\pi(\tau > t \mid S_0^{t+1}) = \mathbf{P}_\zeta^\pi(\tau > t \mid S_0^t)$, so $\mathbf{P}_\zeta^\pi(\tau > t \mid S_0^t) - \mathbf{P}_\zeta^\pi(\tau = t+1 \mid S_0^{t+1}) = \mathbf{P}_\zeta^\pi(\tau > t+1 \mid S_0^{t+1})$, i.e., $q_t^+(S_0^t) - q_{t+1}(S_0^{t+1}) = q_{t+1}^+(S_0^{t+1})$. Thus we can write the term $q_t(S_0^t)$ in (3.10) for $t \geq 1$ as $q_{t-1}^+(S_0^{t-1}) - q_t^+(S_0^t)$, and the expression for $(Tv - v)(s)$ then follows by rearranging terms.

We now proceed to show how the Bellman equation $v = Tv$ given above relates to the off-policy TD learning scheme in Section 2.2. Some notation is needed. Denote by $\zeta_\mathcal{S}$ the invariant probability measure of the Markov chain $\{S_t\}$ *induced by the behavior policy*; note that it coincides with the marginal of ζ on $\mathcal{S}$. For two functions v_1, v_2 on $\mathcal{S}$, we write $v_1 \perp_{\zeta_\mathcal{S}} v_2$ if $\sum_{s\in\mathcal{S}} \zeta_\mathcal{S}(s)\, v_1(s)\, v_2(s) = 0$. If $\mathcal{L}$ is a linear subspace of functions on $\mathcal{S}$ and $v \perp_{\zeta_\mathcal{S}} v'$ for all $v' \in \mathcal{L}$, we write $v \perp_{\zeta_\mathcal{S}} \mathcal{L}$. Recall that ϕ is a function that maps each state s to an n-dimensional feature vector. Denote by $\mathcal{L}_\phi$ the subspace spanned by the n component functions of ϕ, which is the space of approximate value functions for our TD learning scheme. Recall also that $\mathbb{E}_\zeta$ denotes expectation w.r.t. the *stationary* state-trace process $\{(S_t, y_t, e_t)\}$ under the behavior policy (cf. Theorem 2.1).

Theorem 3.2 *Let Conditions 2.1-2.3 hold. Then as a linear equation in* v, $\mathbb{E}_\zeta\big[e_0\, \delta_0(v)\big] = 0$ *is equivalently* $Tv - v \perp_{\zeta_\mathcal{S}} \mathcal{L}_\phi$, *where* T *is the generalized Bellman operator for* π *given in (3.9) or (3.10).*

Remark 3.2 (On LSTD) Note that

$$Tv - v \perp_{\zeta_\mathcal{S}} \mathcal{L}_\phi, \quad v \in \mathcal{L}_\phi$$

is a projected version of the generalized Bellman equation $Tv - v = 0$ (projecting the left-hand side onto the approximation subspace $\mathcal{L}_\phi$ w.r.t. the $\zeta_\mathcal{S}$-weighted Euclidean norm). Theorem 3.2 and Corollary 2.1 together show that this is what LSTD solves in the limit.

Note also that although the generalized Bellman operator T is a contraction (Theorem 3.1), the composition of projection with T is in general not a contraction (cf. Example B.1 in Appendix B). Thus we cannot use contraction-based arguments to analyze approximation properties. For that purpose, we use the oblique projection viewpoint of Scherrer (2010). Specifically, if the preceding projected Bellman equation admits a unique solution $\bar{v}$, then $\bar{v}$ can be viewed as an oblique projection of v_π (Scherrer, 2010) and the approximation error $\bar{v} - v_\pi$ can be characterized as in (Yu and Bertsekas, 2010) by using the oblique projection viewpoint. The details of these are given in Appendix B. ■

Remark 3.3 (On gradient-based TD) While Theorem 3.2 is about the LSTD algorithm, it also helps prepare the ground for analyzing gradient-based algorithms similar to

those discussed in (Maei, 2011; Mahadevan et al., 2014). Like LSTD, these algorithms aim to solve the same projected generalized Bellman equation as characterized by Theorem 3.2 (cf. Remark 3.2). Their average dynamics, which is important for analyzing their convergence using the mean ODE approach from stochastic approximation theory (Kushner and Yin, 2003), can be studied based on the ergodicity result of Theorem 2.1, in essentially the same way as we did in Section 2.3 for the LSTD algorithm. For details of the convergence analysis of these gradient-based TD algorithms, see the recent work (Yu, 2017). ■

In the rest of this subsection, we give a corollary to Theorem 3.2, deferring the proofs of both the theorem and the corollary to the next subsection. The corollary concerns a composite scheme of setting λ, which is slightly more general than what Section 2.2 described. It results in a Bellman operator that is a composition of the components of other Bellman operators, and it can be useful in practice for variance control. Let us describe the scheme first, before explaining our motivation for it.

Partition the state space into m nonempty disjoint sets: $\mathcal{S} = \cup_{i=1}^m \mathcal{S}_i$. Associate each set $\mathcal{S}_i$ with a possibly different scheme of setting λ that is of the type described in Section 2.2, and denote its memory states by $y_t^{(i)}$ and λ-function by $\lambda^{(i)}(\cdot,\cdot)$. Keep m trace vectors $e_t^{(1)},\ldots,e_t^{(m)}$, one for each set, and update them according to

$$e_t^{(i)} = \lambda_t^{(i)}\,\gamma_t\,\rho_{t-1}\,e_{t-1}^{(i)} + \phi(S_t)\,\mathbb{1}(S_t\in\mathcal{S}_i), \qquad 1\le i\le m, \tag{3.12}$$

where $\lambda_t^{(i)} = \lambda^{(i)}\big(y_t^{(i)}, e_{t-1}^{(i)}\big)$. We then have m ergodic state-trace processes that share the same state variables, $\big\{\big(S_t, y_t^{(i)}, e_t^{(i)}\big)\big\}$, $i=1,2,\ldots,m$. Each process has a unique invariant probability measure $\zeta^{(i)}$ (Theorem 2.1) and an associated randomized stopping time $\tau^{(i)}$ and generalized Bellman operator $T^{(i)}$, as discussed in this subsection. Define now an operator T by concatenating the component mappings of $T^{(i)}$ for $\mathcal{S}_i$ as follows: for all $v\in\Re^N$ and $s\in\mathcal{S}$,

$$(Tv)(s) := (T^{(i)}v)(s) \quad \text{if } s\in\mathcal{S}_i. \tag{3.13}$$

Consider an LSTD algorithm that defines the trace e_t to be the sum of the m trace vectors,

$$e_t = \textstyle\sum_{i=1}^m e_t^{(i)}, \tag{3.14}$$

and uses the traces to form the linear equation as before,

$$\tfrac{1}{t}\textstyle\sum_{k=0}^{t-1} e_k\,\delta_k(v) = 0, \quad v=\Phi\theta.$$

Note that $\frac{1}{t}\sum_{k=0}^{t-1} e_k\delta_k(v)=0$ is the same as $\sum_{i=1}^m \frac{1}{t}\sum_{k=0}^{t-1} e_k^{(i)}\delta_k(v)=0$. By Corollary 2.1, as a linear equation in v, it tends asymptotically (as $t\to\infty$) to the linear equation $\sum_{i=1}^m \mathbb{E}_{\zeta^{(i)}}\big[e_0^{(i)}\delta_0(v)\big]=0$.

Corollary 3.1 *Let Condition 2.1 hold. Consider the composite scheme of setting λ discussed above, and let Conditions 2.2-2.3 hold for each of the m schemes involved. Let LSTD calculate traces according to (3.12) and (3.14). Then the limiting linear equation (in v) associated with LSTD, $\sum_{i=1}^m \mathbb{E}_{\zeta^{(i)}}\big[e_0^{(i)}\delta_0(v)\big]=0$, is equivalently $Tv - v \perp_{\zeta_\mathcal{S}} \mathcal{L}_\phi$, where T is the generalized Bellman operator for π given by (3.13) and has the same fixed point and contraction properties as stated in Theorem 3.1.*

The use of composite schemes will be demonstrated by experiments in Section 4.2.2. Here let us explain informally our motivation for such schemes.

Remark 3.4 (About composite schemes of setting λ) Our motivation for using the composite schemes is revealed by the equation (3.13). Typically each $T^{(i)}$ is designed to be simple to implement in TD learning. For example, if we ignore for now the bounding of traces introduced in Section 2.2 and just consider TD(λ) with constant λ, $T^{(i)}$ can be the Bellman operator $T^{(\lambda)}$ for TD(λ) with some constant λ. A simple, extreme example is to partition the state space into two sets, and associate one with $T^{(\lambda)}, \lambda=1$, and the other with $T^{(\lambda)}, \lambda=0$. Using the combination (3.13) of the two operators in TD then means that for the first set of states whose $\lambda=1$, we want to estimate their values by using the information about the total rewards received when starting from those states, whereas for the second set of states whose $\lambda=0$, we only use the information about their one-stage rewards and how these states relate to the "neighboring" states in the transition graph. While this way of using different kinds of information for different states is natural and useful for TD-based policy evaluation, it cannot be realized by keeping a single trace sequence as before and only letting λ_t evolve with states or histories. Indeed, in that case, as discussed in Section 2.2.2, interleaving large and small λ_t's would make the algorithm behave effectively like TD with small λ over the entire state space.

In the context of the more complex scheme of setting λ discussed in this paper, our motivation and reasons for considering composite schemes are the same. Each $T^{(i)}$ can be designed to be simple to implement, such as in the simple scaling example in Section 2.2. The parameters in the ith scheme can be chosen so that they encourage the use of large λ_t's throughout time or dictate the use of only small λ_t's. By combining component mappings of $T^{(i)}$ through (3.13), composite schemes allow us to use cumulative rewards and transition structures at different timescales for different states. This provides additional flexibility in managing the bias-variance trade-off when estimating the value function (see Figure 9 and Figure 11 in Section 4.2.2 for a demonstration).

Finally, we mention that for off-policy LSTD(λ) with constant λ, composite schemes were proposed in (Yu and Bertsekas, 2012) and analyzed in (Yu, 2012, Proposition 4.5, Section 4.3). Our Corollary 3.1 extends that result. The convergence analysis of the gradient-based algorithms for the composite schemes is given in (Yu, 2017). ■

3.3 Proofs of Theorem 3.2 and Corollary 3.1

We divide the proof of Theorem 3.2 into two steps. The first step deals with an expression for the trace vector, given in the following lemma. It is more subtle than the other step in the proof, which involves mostly calculations.

We start by extending the stationary state-trace process $\{(S_t,y_t,e_t)\}_{t\ge0}$ to $t=-1,-2,\ldots$, and work with a double-ended stationary process $\{(S_t,y_t,e_t)\}_{-\infty<t<\infty}$ (by Kolmogorov's existence theorem (Dudley, 2002, Theorem 12.1.2), such a process exists). Note that as before this is a Markov chain whose transition probability is defined by the behavior policy π^o together with the update rules (2.2) and (2.5) for e_t, y_t and λ_t, and the marginal distribution of each (S_t,y_t,e_t) is ζ. We keep using the notation $\mathbf{P}_\zeta$ and $\mathbb{E}_\zeta$ for this double-ended stationary Markov chain.

Recall the shorthand notation (3.1) introduced at the beginning of Section 3: For $k \le m$, $\rho_k^m = \prod_{i=k}^m \rho_i$, $\lambda_k^m = \prod_{i=k}^m \lambda_i$, $\gamma_k^m = \prod_{i=k}^m \gamma_i$, and in addition, $\lambda_1^0 = \gamma_1^0 = \rho_0^{-1} = 1$ by convention.

Lemma 3.1 *$\mathbf{P}_\zeta$-almost surely, $\sum_{t=1}^\infty \lambda_{1-t}^0 \gamma_{1-t}^0 \rho_{-t}^{-1} \phi(S_{-t})$ is well-defined and finite, and*

$$e_0 = \phi(S_0) + \textstyle\sum_{t=1}^\infty \lambda_{1-t}^0 \gamma_{1-t}^0 \rho_{-t}^{-1}\, \phi(S_{-t}). \tag{3.15}$$

Proof First, we show $\mathbb{E}_\zeta\big[\sum_{t=1}^\infty \gamma_{1-t}^0 \rho_{-t}^{-1}\big] < \infty$. Indeed,

$$\mathbb{E}_\zeta\big[\textstyle\sum_{t=1}^\infty \gamma_{1-t}^0 \rho_{-t}^{-1}\big] = \sum_{t=1}^\infty \mathbb{E}_\zeta\big[\gamma_{1-t}^0 \rho_{-t}^{-1}\big] = \sum_{t=1}^\infty \zeta_{\mathcal{S}}^\top (P\Gamma)^t \mathbf{1} < \infty,$$

where the first equality follows from the monotone convergence theorem, the second equality from Condition 2.1(ii) and a direct calculation, and the last inequality follows from Condition 2.1(i) (since $(I - P\Gamma)^{-1} = \sum_{t=0}^\infty (P\Gamma)^t$). This implies $\sum_{t=1}^\infty \gamma_{1-t}^0 \rho_{-t}^{-1} < \infty$, $\mathbf{P}_\zeta$-a.s., so $\gamma_{1-t}^0 \rho_{-t}^{-1} \to 0$ as $t \to \infty$, $\mathbf{P}_\zeta$-a.s. Since $\lambda_{1-t}^0 \le 1$ for all t, it also implies that

$$\mathbb{E}_\zeta\big[\textstyle\sum_{t=1}^\infty \lambda_{1-t}^0 \gamma_{1-t}^0 \rho_{-t}^{-1}\, \|\phi(S_{-t})\|\big] \le \max_{s\in\mathcal{S}} \|\phi(s)\| \cdot \mathbb{E}_\zeta\big[\textstyle\sum_{t=1}^\infty \gamma_{1-t}^0 \rho_{-t}^{-1}\big] < \infty. \tag{3.16}$$

It then follows from a theorem on integration (Rudin, 1966, Theorem 1.38, p. 28-29) that $\mathbf{P}_\zeta$-almost surely, the infinite series $\sum_{t=1}^\infty \lambda_{1-t}^0 \gamma_{1-t}^0 \rho_{-t}^{-1} \phi(S_{-t})$ converges to a finite limit.

We now prove the expression for e_0. By unfolding the iteration (2.2) for e_t backwards in time, we have for all $m \ge 1$,

$$e_0 = \phi(S_0) + \textstyle\sum_{t=1}^{m-1} \lambda_{1-t}^0 \gamma_{1-t}^0 \rho_{-t}^{-1}\, \phi(S_{-t}) + \lambda_{1-m}^0 \gamma_{1-m}^0 \rho_{-m}^{-1}\, e_{-m}. \tag{3.17}$$

Let $m \to \infty$ in the r.h.s. of (3.17). For the last term, the trace e_{-m} lies in a bounded set by Condition 2.3(ii), $\lambda_{1-m}^0 \le 1$, and as we just showed, $\gamma_{1-m}^0 \rho_{-m}^{-1} \to 0$, $\mathbf{P}_\zeta$-a.s. So the last term converges to zero $\mathbf{P}_\zeta$-a.s. Also as we just showed, the second term converges $\mathbf{P}_\zeta$-almost surely to $\sum_{t=1}^\infty \lambda_{1-t}^0 \gamma_{1-t}^0 \rho_{-t}^{-1} \phi(S_{-t})$. The expression (3.15) for e_0 then follows. ■

Proof of Theorem 3.2 Treating $\lambda_1^0 = \gamma_1^0 = \rho_0^{-1} = 1$, we write the expression of e_0 given in Lemma 3.1 as $e_0 = \sum_{t=0}^\infty \lambda_{1-t}^0 \gamma_{1-t}^0 \rho_{-t}^{-1}\, \phi(S_{-t})$, $\mathbf{P}_\zeta$-a.s. We use this expression to calculate first $\mathbb{E}_\zeta\big[e_0 \cdot \rho_0 f(S_0^1)\big]$ for an arbitrary function f on $\mathcal{S} \times \mathcal{S}$. (Note that f is bounded and measurable, since $\mathcal{S}$ is finite.) We have

$$\begin{aligned}
\mathbb{E}_\zeta\big[e_0 \cdot \rho_0 f(S_0^1)\big] &= \textstyle\sum_{t=0}^\infty \mathbb{E}_\zeta\Big[\lambda_{1-t}^0 \gamma_{1-t}^0 \rho_{-t}^{-1}\, \phi(S_{-t}) \cdot \rho_0 f(S_0^1)\Big] \\
&= \textstyle\sum_{t=0}^\infty \mathbb{E}_\zeta\Big[\lambda_1^t \gamma_1^t \rho_0^{t-1} \phi(S_0) \cdot \rho_t f(S_t^{t+1})\Big] \\
&= \textstyle\sum_{t=0}^\infty \mathbb{E}_\zeta\Big[\phi(S_0) \cdot \mathbb{E}_\zeta\left[\lambda_1^t \gamma_1^t \rho_0^t\, f(S_t^{t+1}) \mid S_0, y_0, e_0\right]\Big]
\end{aligned} \tag{3.18}$$

where we used the stationarity of the double-ended state-trace process to derive the second equality, and we changed the order of expectation and summation in the first equality. This change is justified by the dominated convergence theorem (cf. (3.16)), and so are similar interchanges of expectation and summation that will appear in the rest of this proof.

To proceed with the calculation, we relate the expectations in the summation in (3.18) to expectations w.r.t. the process with probability measure $\mathbf{P}_\zeta^\pi$ introduced in Section 3.2

(which we recall is induced by the target policy π and involves the randomized stopping time τ). Let $\tilde{\mathbb{E}}_\zeta^\pi$ denote expectation w.r.t. the marginal of $\mathbf{P}_\zeta^\pi$ on the space of $\{(S_t, y_t, e_t)\}_{t\ge 0}$. From the change of measure performed through ρ_0^t, we have

$$\mathbb{E}_\zeta\left[\lambda_1^t \gamma_1^t \rho_0^t\, f(S_t^{t+1}) \mid S_0, y_0, e_0\right] = \tilde{\mathbb{E}}_\zeta^\pi\left[\lambda_1^t \gamma_1^t\, f(S_t^{t+1}) \mid S_0, y_0, e_0\right], \quad t \ge 0. \tag{3.19}$$

Combining this with (3.18) and using the fact that ζ is the marginal distribution of (S_0, y_0, e_0) in both processes, we obtain

$$\begin{aligned}
\mathbb{E}_\zeta\big[e_0 \cdot \rho_0 f(S_0^1)\big] &= \textstyle\sum_{t=0}^\infty \tilde{\mathbb{E}}_\zeta^\pi\Big[\phi(S_0) \cdot \tilde{\mathbb{E}}_\zeta^\pi\left[\lambda_1^t \gamma_1^t\, f(S_t^{t+1}) \mid S_0, y_0, e_0\right]\Big] \\
&= \tilde{\mathbb{E}}_\zeta^\pi\Big[\phi(S_0) \cdot \textstyle\sum_{t=0}^\infty \tilde{\mathbb{E}}_\zeta^\pi\left[\lambda_1^t \gamma_1^t\, f(S_t^{t+1}) \mid S_0\right]\Big].
\end{aligned} \tag{3.20}$$

We now use (3.20) to calculate $\mathbb{E}_\zeta\big[e_0\, \delta_0(v)\big]$ for a given function v. Recall from (2.3) that $\delta_0(v) = \rho_0 \cdot \big(r(S_0^1) + \gamma_1 v(S_1) - v(S_0)\big)$, so we let $f(S_t^{t+1}) = r(S_t^{t+1}) + \gamma_{t+1} v(S_{t+1}) - v(S_t)$ in (3.20). Since $\mathbb{E}_\zeta^\pi[r(S_t^{t+1}) \mid S_0^t] = r_\pi(S_t)$, we have

$$\begin{aligned}
\textstyle\sum_{t=0}^\infty \tilde{\mathbb{E}}_\zeta^\pi\left[\lambda_1^t \gamma_1^t\, f(S_t^{t+1}) \mid S_0\right] &= \textstyle\sum_{t=0}^\infty \tilde{\mathbb{E}}_\zeta^\pi\Big[\lambda_1^t \gamma_1^t \Big(r_\pi(S_t) + \gamma_{t+1} v(S_{t+1}) - v(S_t)\Big) \,\Big|\, S_0\Big] \\
&= (Tv - v)(S_0),
\end{aligned}$$

where the last equality follows from the expression (3.11) for $TV - V$. Therefore, by (3.20),

$$\mathbb{E}_\zeta\big[e_0\, \delta_0(v)\big] = \textstyle\sum_{s\in\mathcal{S}} \zeta_{\mathcal{S}}(s)\, \phi(s) \cdot (Tv - v)(s), \tag{3.21}$$

and this shows that $\mathbb{E}_\zeta\big[e_0\, \delta_0(v)\big] = 0$ is equivalent to $Tv - v \perp_{\zeta_{\mathcal{S}}} \mathcal{L}_\phi$. ■

We now prove Corollary 3.1.

Proof of Corollary 3.1 We apply Theorem 3.2 to each state-trace process $\big\{\big(S_t, y_t^{(i)}, e_t^{(i)}\big)\big\}$ for $i = 1, 2, \ldots, m$. Specifically, by (3.21) and the definition (3.12) of $e_t^{(i)}$,

$$\mathbb{E}_{\zeta^{(i)}}\big[e_0^{(i)} \delta_0(v)\big] = \textstyle\sum_{s\in\mathcal{S}} \zeta_{\mathcal{S}}(s) \cdot \phi(s) \mathbb{1}(s \in \mathcal{S}_i) \cdot \big(T^{(i)} v - v\big)(s).$$

Hence

$$\begin{aligned}
\textstyle\sum_{i=1}^m \mathbb{E}_{\zeta^{(i)}}\big[e_0^{(i)} \delta_0(v)\big] &= \textstyle\sum_{s\in\mathcal{S}} \zeta_{\mathcal{S}}(s)\, \phi(s) \cdot \Big[\sum_{i=1}^m \mathbb{1}(s \in \mathcal{S}_i) \cdot \big(T^{(i)} v - v\big)(s)\Big] \\
&= \textstyle\sum_{s\in\mathcal{S}} \zeta_{\mathcal{S}}(s)\, \phi(s) \cdot (Tv - v)(s),
\end{aligned}$$

where the last equality follows from the definition (3.13) of the operator T. This shows that the linear equation in v, $\sum_{i=1}^m \mathbb{E}_{\zeta^{(i)}}\big[e_0^{(i)} \delta_0(v)\big] = 0$, is equivalently $Tv - v \perp_{\zeta_{\mathcal{S}}} \mathcal{L}_\phi$.

We now prove that T has v_π as its unique fixed point and is a contraction with respect to a weighted sup-norm—in other words, Theorem 3.1 applies to T. For this, it suffices to show that T satisfies the conditions of Theorem 3.1, namely, T is a generalized Bellman operator associated with a randomized stopping time τ that satisfies $\mathbf{P}^\pi(\tau \ge 1 \mid S_0 = s) > 0$ for all states $s \in \mathcal{S}$. We can define such a random time τ from the randomized stopping times $\tau^{(i)}$ associated with the Bellman operators $T^{(i)}$. In particular, by enlarging

the probability space if necessary, we can regard $\tau^{(i)}$, $i = 1, 2, \ldots, m$, as being defined on the same probability space.[10] We then let $\tau = \tau^{(i)}$ if $S_0 \in \mathcal{S}_i$. With this definition, we have $\mathbf{P}^\pi(\tau \geq 1 \mid S_0 = s) > 0$ for all states $s \in \mathcal{S}$ (since $\tau^{(i)} \geq 1$ a.s. for all i). For each set $\mathcal{S}_i$, by (3.2), the component mappings of the generalized Bellman operator T_τ associated with τ are given by

$$(T_\tau v)(s) = \mathbb{E}_s^\pi\big[R^\tau + \gamma_1^\tau\, v(S_\tau)\big] = \mathbb{E}_s^\pi\big[R^{\tau^{(i)}} + \gamma_1^{\tau^{(i)}}\, v(S_{\tau^{(i)}})\big] = (T^{(i)} v)(s), \quad s \in \mathcal{S}_i.$$

So $T_\tau = T$ by the definition (3.13) of T; i.e., T is the Bellman operator associated with the randomized stopping time τ. ■

4. Numerical Study

In this section, we first use a toy problem to illustrate the behavior of traces calculated by off-policy LSTD(λ) for constant λ and for λ that evolves according to a simple special case of our proposed scheme described in Example 2.1. We then compare the behavior of LSTD for various choices of λ, on the toy problem and on the Mountain Car problem.

4.1 Behavior of Traces

The toy problem we use in this study has 21 states, arranged as shown in Figure 1 (left). One state is located at the centre, and the rest of the states split evenly into four groups, indicated by the four loops in the figure. The topology of the transition graph is the same for the target and behavior policies. We have drawn the transition graph only for the northeast group in Figure 1 (left); the states in each of the other three groups are arranged in the same manner and have the same transition structure. Given this symmetry, to specify the transition matrices P and P^o for the target and behavior policies π and π^o respectively, it suffices to specify the submatrices for the central state and one of the groups. If we label the central state as state 1 and the states in the northeast group clockwise as states 2-6, the submatrices of P and P^o for these states are given, respectively, by

$$\pi: \begin{pmatrix} 0 & 0.25 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0.2 & 0 & 0.8 & 0 & 0 \\ 0 & 0 & 0.2 & 0 & 0.8 & 0 \\ 0 & 0 & 0 & 0.2 & 0 & 0.8 \\ 0.8 & 0 & 0 & 0 & 0.2 & 0 \end{pmatrix}, \quad \pi^o: \begin{pmatrix} 0 & 0.25 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0.5 & 0 & 0.5 & 0 & 0 \\ 0 & 0 & 0.5 & 0 & 0.5 & 0 \\ 0 & 0 & 0 & 0.5 & 0 & 0.5 \\ 0.5 & 0 & 0 & 0 & 0.5 & 0 \end{pmatrix}.$$

Intuitively speaking, from the central state, the system enters one group of states by moving diagonally in one of the four directions with equal probability, and after spending some time in that group, eventually returns to the central state and the process repeats. The behavior policy on average spends more time wandering inside each group than the target policy, while the target policy tends to traverse clockwise through the group more quickly.

10. That we can do so is clear from the definition of each $\tau^{(i)}$ as described at the beginning of Section 3.2 and from the fact that for each i, the initial distribution $\zeta^{(i)}$ on $(S_0, y_0^{(i)}, e_0^{(i)})$ has the same marginal on $\mathcal{S}$, which is $\zeta_{\mathcal{S}}$.

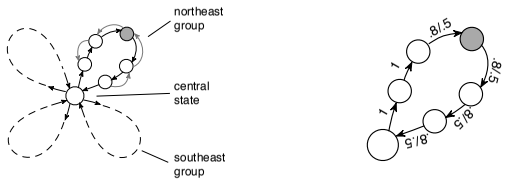

Figure 1: The transition graph of a toy problem (left) and a cycle pattern in it (right). The numbers appearing in the right graph indicate the importance sampling ratios for the state transitions represented by each directed edge. From such cycle patterns one can infer whether the trace sequence is unbounded almost surely.

All the rewards are zero except for the middle state in each group—for the northeast group, this is the shaded state in Figure 1 (left). For the two northern (southern) groups, their middle states have reward 1 (-1). The discount factor is $\gamma = 0.9$ for all states. As to features, we aggregate states into 5 groups: the 4 groups mentioned earlier and the central state forming its own group, and we let each state have 5 binary features indicating its membership.

We now discuss and illustrate the behavior of traces in this toy problem. For comparison, we first do this for the off-policy TD(λ) with a constant λ. It can help explain the challenges in off-policy TD learning and our motivation for proposing the new scheme of setting λ.

4.1.1 Traces for Constant λ

In this experiment we let $\lambda = 1$ and consider the trace iterates $\{e_t\}$ calculated by TD(1). In general, by identifying certain cycle patterns in the transition graph, one can infer whether $\{e_t\}$ will be unbounded over time almost surely (Yu, 2012, Section 3.1). Figure 1 (right) shows such a cycle of states in the transition graph of the toy problem. It consists of the central state and the northeast group of states. Labeled on each edge of the cycle is the importance sampling ratio for that state transition. Traversing through the cycle once from any starting state, and multiplying together the importance sampling ratios of each edge and the discount factors of the destination states, we get $\left(\frac{0.8}{0.5}\right)^4 \cdot \gamma^6 = \left(\frac{0.8}{0.5}\right)^4 \cdot 0.9^6 > 1$. From this one can infer that $\{e_t\}$ calculated by off-policy TD(1) will be unbounded in this problem (cf. Yu, 2012, Prop. 3.1).

We plotted in the upper left graph of Figure 2 the Euclidean norm $\|e_t\|$ of the traces over 8×10^5 iterations for TD(1). One can see the recurring spikes and the exceptionally large values of some of these spikes in the plot. This is consistent with the unboundedness of $\{e_t\}$ just discussed.

The unboundedness of $\{e_t\}$ tells us that the invariant probability measure ζ of the state-trace process $\{(S_t, e_t)\}$ has an unbounded support. Despite this unboundedness, $\{e_t\}$ is bounded in probability (Yu, 2012, Lemma 3.4) and under the invariant distribution ζ, $\mathbb{E}_\zeta\big[\|e_0\|\big] < \infty$ (Yu, 2012, Prop. 3.2). The latter property implies that under the invariant distribution, the probability of $\|e_0\| > x$ decreases as $o(1/x)$ for large x. Since the empirical

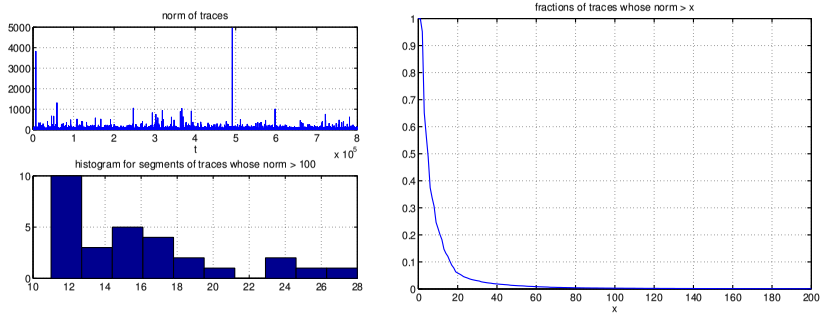

Figure 2: Statistics of traces for TD(1) in a toy problem (see the text in Section 4.1.1 for detailed explanations).

distribution of the state-trace process converges to ζ almost surely (Yu, 2012, Theorem 3.2), during a run of many iterations, we expect to see the fraction of traces with $\|e_t\| > x$ drop in a similar way as x increases.

The simulation result shown in the right part of Figure 2 agrees with the preceding discussion. Plotted in the graph are fractions of traces with $\|e_t\| > x$ during 8×10^5 iterations (the vertical axis indicates the fraction, and the horizontal axis indicates x). It can be seen that despite the recurring spikes in $\|e_t\|$ during the entire run, the fraction of traces with large magnitude x drops sharply with the increase in x.

While only a small fraction of traces have exceptionally large magnitude, they can occur in consecutive iterations. This is illustrated by the histogram in the lower left part of Figure 2. The histogram concerns the excursions of the trajectory $\{e_t\}$ outside of the ball $\{e \in \Re^n \mid \|e\| \leq 100\}$. The horizontal axis indicates the lengths of the excursions (where the length is the number of iterations an excursion contains), and the vertical axis indicates how many excursions of length x occurred during the 8×10^5 iterations of the experimental run. We plotted the histogram for lengths $x > 10$. It can be seen that one can have large traces during many consecutive iterations. Such behavior, although tolerable by LSTD, is especially detrimental to TD algorithms and can disrupt their learning. This is our main motivation for suggesting the use of λ-parameters to bound the traces directly.

4.1.2 Traces with Evolving λ

We now proceed to illustrate the behavior of traces and LSTD for λ that evolves according to our proposed scheme. Specifically, for this demonstration, we will use the simple scaling example given by (2.6)-(2.7) in Example 2.1, with all the thresholds $C_{ss'}$ being the same constant C. That is, the update rule for e_t used in this experiment is

$$e_t = \begin{cases} \gamma_t \rho_{t-1} e_{t-1} + \phi(S_t) & \text{if } \gamma_t \rho_{t-1} \|e_{t-1}\|_2 \leq C; \\ C \cdot \frac{e_{t-1}}{\|e_{t-1}\|_2} + \phi(S_t) & \text{otherwise.} \end{cases} \tag{4.1}$$

We first simulate the state-trace process to illustrate the ergodicity of this process stated by Theorem 2.1. We will shortly study the performance of LSTD for different values of C in Section 4.2.1. The results of these two experiments are shown in Figure 3 and Figures 4-5, respectively, and the details are as follows.

According to the ergodicity result of Theorem 2.1, no matter from which initial state and trace pair (S_0, e_0) we generate a trajectory $\{(S_t, e_t)\}_{0 \leq t \leq \bar{t}}$ according to the behavior policy, the empirical distribution of state and trace pairs in this trajectory should converge, as $\bar{t} \to \infty$, to the same distribution on $\mathcal{S} \times \Re^n$, which is the marginal of the invariant probability measure ζ on that space. Since $\mathcal{S}$ is discrete, we can verify this fact by examining the empirical conditional distribution of the trace given the state. In other words, for each state s, we examine the empirical distribution of the trace for the sub-trajectory (S_{t_k}, e_{t_k}), $k = 1, 2, \ldots$, where $S_{t_k} = s$ and it is the kth visit to state s by the trajectory. We check if this empirical distribution converges to the same one as we increase the length $\bar{t}$ of the trajectory and as we vary the initial condition (S_0, e_0).

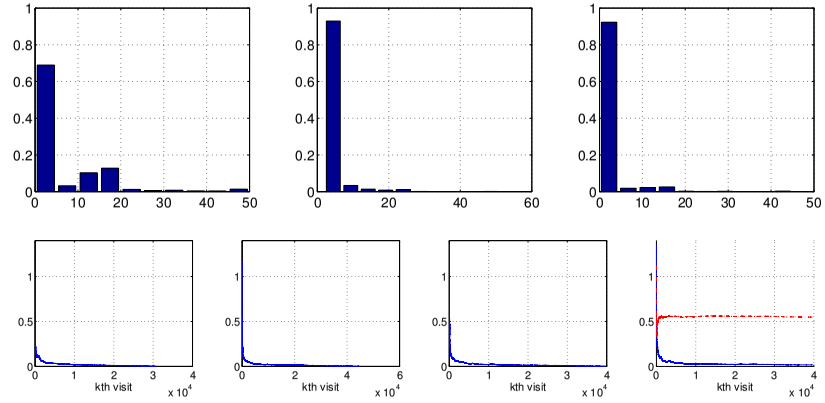

Figure 3: Demonstration of convergence of empirical conditional distributions on the trace space. (See the text in Section 4.1.2 for detailed explanations.)

To give a sense of what these limiting distributions over the trace space look like, we set the parameter $C = 50$ and generated a long trajectory with 8×10^5 iterations. In the top row of Figure 3, we plotted three normalized histograms of the first trace component for the sub-trajectories associated with three states of the toy problem, respectively: the central state (left), the middle state of the northeast group (middle), and the first state of the southeast group (right).

To check whether the empirical conditional distributions on the trace space converge along the sub-trajectory $\{(S_{t_k}, e_{t_k})\}$ for a given state, we compare the characteristic functions f_k of these distributions with the characteristic function f of the empirical conditional distribution obtained at the end of the sub-trajectory during the experimental run. In par-

ticular, we evaluate all these (complex-valued) characteristic functions at 500 points, which are chosen randomly according to the multivariate normal distribution on $\Re^5$ with mean 0 and covariance matrix $200^2 I$. We take the maximal difference between f_k and f at these 500 points as an indicator of the deviation between the two corresponding distributions.[11] In the bottom row of Figure 3, the first three plots show the difference curves obtained in the way just described, for three different states, respectively. These three states are the same ones mentioned earlier in the description of the top row of Figure 3. The horizontal axis of these plots indicates k, the number of visits to the corresponding state. As can be seen, the difference curves all tend to zero as k increases, which is consistent with the predicted convergence of the empirical conditional distributions on the trace space.

So far we compared the empirical distributions along the same trajectory. Next we compare them against the one obtained at the end of another trajectory that starts from a different initial condition. The difference curve for one state (the first state in the southeast group) is plotted in the last graph in the bottom row of Figure 3, and it is the lower curve in that graph. As can be seen, the curve tends to zero, suggesting that the limiting distribution of these empirical distributions does not change if we vary the initial condition, which is consistent with Theorem 2.1.

For comparison, we also plotted the difference curve when these same empirical conditional distributions are compared against the empirical conditional distribution obtained from the same trajectory but for a different state (specifically, the middle state of the northeast group). This is the upper curve in the last graph in the bottom row of Figure 3. It clearly indicates that for the two states, the associated limiting conditional distributions on the trace space are different. It also shows that the characteristic function approach we adopted in this experiment can effectively distinguish between two different distributions (cf. Footnote 11).

4.2 LSTD with Evolving λ

We now present experiments on the LSTD algorithm.

4.2.1 A Toy Problem

Let us first continue with the toy problem of the previous subsection and show how the LSTD algorithm performs in this problem as we vary the parameter C in the λ function for bounding the traces. We ran LSTD for $C = 10, 20, \ldots, 100$, using the same trajectory, for 3×10^5 iterations, and we computed the (Euclidean) distance of these LSTD solutions to the asymptotic TD(1) solution (in the space of the θ-parameters), normalized by the norm of the latter. We then repeat this calculation 10 times, each time with an independently generated trajectory. Plotted in Figure 4 (left) against the values of C are the means and standard deviations of the normalized distances of LSTD solutions thus obtained.

11. Recall that a tight sequence $\{p_k\}$ of probability distributions on $\Re^m$ converges to a probability distribution p if and only if the characteristic functions of p_k converge pointwise to the characteristic function of p (Dudley, 2002, Lemma 9.5.5). Recall also that we are dealing with convergence in distribution here, which is much weaker than convergence in total variation, so we cannot use total variation as a metric on the distribution space in this case.

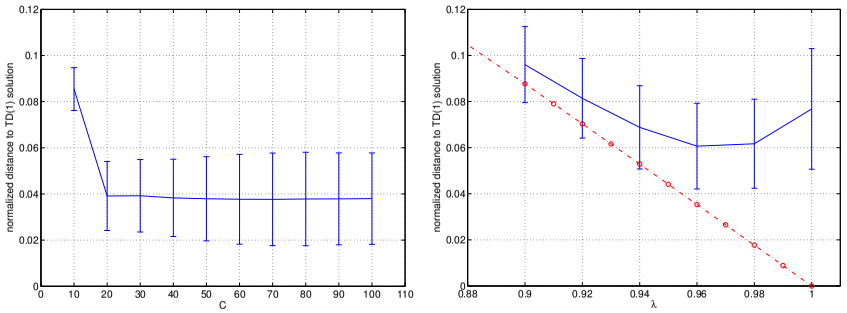

Figure 4: Compare LSTD solutions with evolving λ (left) and with constant λ (right). For constant λ, the red dot-dash curve in the right plot shows the quality of the asymptotic TD(λ) solutions, and LSTD(λ) would approach this curve in the limit, but due to variance issues, it can require an impractically large number of iterations to exhibit this convergent behavior. LSTD with evolving λ outperforms LSTD with constant λ in this case and effectively archives the quality of TD(λ) solutions for large constant λ.

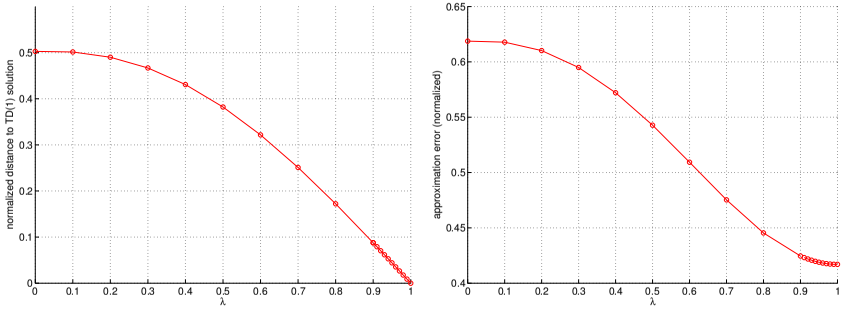

Figure 5: Approximation quality of asymptotic TD(λ) solutions with constant λ for the toy problem. Larger λ yields better approximations.

For comparison, we did the same for LSTD with a large constant λ: $\lambda = 0.9, 0.92, \ldots, 1$. Figure 4 (right) shows the result, where the dash-dot curve indicates the normalized distance of the asymptotic TD(λ) solution—the solution that LSTD(λ) would obtain in the limit. It can be seen that the performance of LSTD deteriorates as λ gets close to 1. We think that this is because due to the high variance issue, the convergence of LSTD with a large constant λ is too slow and requires far more iterations than the 3×10^5 iterations performed. In comparison, LSTD with evolving λ behaves better: it works effectively for $C \geq 20$, and

the approximation quality it achieved with such C is comparable to that of asymptotic TD(λ) solutions for a large constant λ around 0.96.

Figure 5 shows the quality of the asymptotic solutions of TD(λ) with constant λ, for the full range of λ values. Plotted in the left graph is the normalized distance of the TD(λ) solution to the TD(1) solution. Plotted in the right graph is the normalized approximation error of the corresponding approximate value function, where the error is measured by the weighted Euclidean norm with weights specified by $\zeta_{\mathcal{S}}$ (the invariant distribution on $\mathcal{S}$ under the behavior policy), and the normalization is over the weighted norm $\|v_\pi\|_{\zeta_{\mathcal{S}}}$ of the true value function v_π of the target policy. It can be seen that using $\lambda > 0.9$ provides considerably better approximations for this problem than using small λ.

We also found that for this problem, if we set λ according to the Retrace algorithm with $\beta = 1$ (cf. (2.8) in Example 2.2), then the performance of LSTD is comparable to TD(λ) with a small λ around 0.5. (Specifically, for Retrace, the normalized distance to the TD(1) solution is 0.37, and the normalized approximation error is 0.54, which are comparable to the numbers for TD(0.5), as Figure 5 shows.) This is not surprising, because, as we discussed earlier in Section 2.2.2, in keeping $\lambda_t \rho_{t-1} \leq 1$ always, Retrace and ABQ can be too "conservative," resulting in an overall effect that is like using a small λ, even though λ_t may appear to be large at times. Recall also that this can happen to our proposed scheme too. In the present experiment, for instance, this can happen when C is small; in particular, the case $C = 0$ reduces to LSTD(0).

4.2.2 Mountain Car Problem

In this subsection we demonstrate LSTD with evolving λ on a problem adapted from the well-known Mountain Car problem (Sutton and Barto, 1998). The details of this adaptation, including the target and behavior policies involved, can be found in the report (Yu, 2016a, Section 5.1, p. 23-26); most of these details are not crucial for our experiments, so to avoid distraction, we only describe briefly the experimental setup here.

In Mountain Car, the goal is to drive an underpowered car to reach the top of a steep hill, from the bottom of a valley. A state consists of the position and velocity of the car, whose values lie in the intervals $[-1.2, 0.5]$, $[-0.07, 0.07]$, respectively. The position 0.5 corresponds to the desired hill top destination, while the position $-\pi/6$ (≈ -0.52) lies at the bottom of a valley that is between the destination and a second hill peaked at -1.2 in the opposite direction (see the illustration in Figure 6). Except for the destination state, each state has three available actions: $\{\texttt{back}, \texttt{coast}, \texttt{forward}\}$, and the rewards depend only on the action taken and are -1.5, 0 and -1 for the three actions, respectively. The dynamics is as given in (Sutton and Barto, 1998). We consider undiscounted expected total rewards, so the discount factor is 1 except at the destination state, where the discount factor is 0 and from where the car enters a rewardless termination state permanently.

The target policy π is a simple but reasonably well-behaved policy. On either slopes between the two hills, it tries to increase its energy (kinetic plus gravitational potential energy) by accelerating in the direction of its current motion. If this brings it up to the opposite hill (position < -1), it coasts; otherwise, if its velocity drops to near zero, it goes forward or backward with equal probability. Figure 6 visualizes the total costs $-v_\pi$ of the

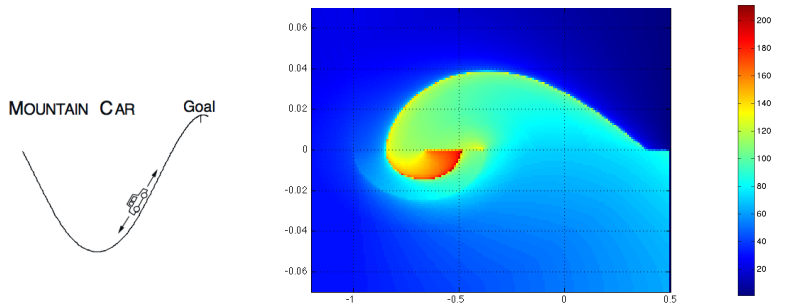

Figure 6: Left: Illustration of the Mountain Car problem. Right: Costs $-v_\pi$ for this problem are estimated and visualized as a color image, with the coloring scheme indicated by the colorbar. (The horizontal and vertical axes of the image correspond to position and velocity, respectively, for the 2-dimensional state space of this problem.)

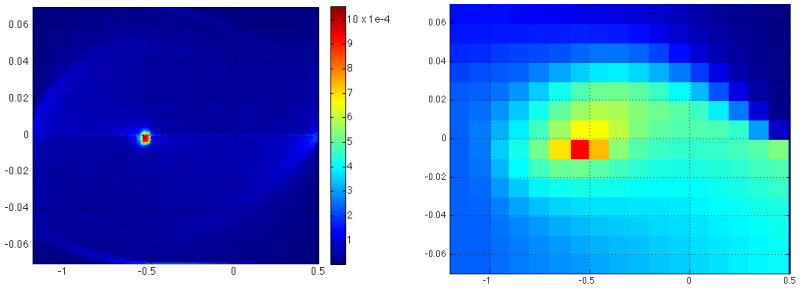

Figure 7: Left: Visualization of weights on states induced by the behavior policy. Right: The color image visualizes the approximation of $-v_\pi$ obtained from a discretized model for the Mountain Car problem, where the coloring scheme is the same as that shown in Figure 6 (right). The quality of this approximation is close to that of TD(0).

target policy,[12] where the horizontal (vertical) axis indicates position (velocity) and the

12. The values of v_π shown in Figure 6 are estimated by simulating the target policy for each starting state in a set of 171 × 141 points evenly spaced in the position-velocity space. In particular, the position (velocity) interval is evenly divided into subintervals of length 0.01 (0.001), and for each stating state, the target policy is simulated 600 times.

colorbar on the right shows the value corresponding to each color. The discontinuity of the function in certain regions can be seen in this figure.

The behavior policy π^o is an artificial policy that takes a random action (chosen with equal probability from the three actions) 90% of the time, and explores the state space by jumping to some random state 10% of the time. It also restarts when it is at the destination: with equal probability, it either restarts near the bottom of the valley or restarts from a random point sampled uniformly from the state space.[13]

We now explain how we will measure approximation qualities. Since the Mountain Car problem has a continuous state space, it is actually not covered by our analysis, which is for finite-state problems. Although we can treat it as essentially a finite-state problem (since the simulation is done with finite precision in computers), the number of states would still be too large to calculate the weights $\zeta_{\mathcal{S}}$. So, to measure weighted approximation errors $\|v - v_\pi\|$ for approximate value functions v produced by various LSTD algorithms in the subsequent experiments, we will compare v and v_π at a grid of points in the state space and calculate a weighted Euclidean distance between the function values at these grid points, using a set of weights precalculated by simulating the behavior policy.[14] The image in Figure 7 (left) visualizes these weights.

We use tile-coding (Sutton and Barto, 1998) to generate 145 binary features for our experiments.[15] The approximate value functions obtained with LSTD algorithms are thus piecewise constant. For comparison, we also build a discrete approximate model by state aggregation. The discretization is done at a resolution comparable to our tile-coding scheme, and the dynamics and rewards of this model are calculated based on data collected under the behavior policy. The solution of the discrete approximate model is shown in Figure 7 (right) (the coloring scheme for this and the subsequent images are the same as shown in Figure 6). It is similar to the approximate value function calculated by LSTD(0), which is shown in Figure 8 (first image, top row). As will be seen shortly, with positive λ, the approximation quality of LSTD improves. Thus the discrete model approximation approach is not as effective as the TD method in this case.

We now report the results of our experiments on the Mountain Car problem.

First Experiment: In this experiment, we compare three ways of setting λ: (i) Retrace with $\beta = 1$ (cf. Example 2.2); (ii) our simple scaling scheme with parameter C used in the previous experiments (cf. (4.1) and Example 2.1); and (iii) a composite scheme of the type discussed at the end of Section 3.2, which partitions the state space into two sets[16]

13. The behavior policy is exactly the same as described in (Yu, 2016a, p. 24-25) except for the possibility of restarting near the bottom of the valley whenever the destination is reached.
14. Specifically, we chose a grid of 171×141 points evenly spaced in the position-velocity space. We ran the behavior policy for 8×10^5 *effective* iterations, where an iteration is considered to be *ineffective* if the behavior policy takes an action, e.g., the restart action, that is impossible for the target policy. A visit to a state at an effective iteration was counted as a visit to the nearest grid point. At the end of the run, visits to a boundary point $(-1.2, 0)$ were disregarded as they were due to boundary effects in the dynamics of this problem, and the final counts were normalized to produce a set of weights on the grid points that sum to 1.
15. Two tilings are used: the first (second) comprises of 64 (81) uneven-sized rectangles that cover the state space. Together they produce a total of 145 binary features. The details of the coding scheme are as described in (Yu, 2016a, p. 28).
16. The first set consists of those states (position, velocity) with either position ≤ -0.9 or velocity ≥ 0.04. The rest of the states belong to the second set.

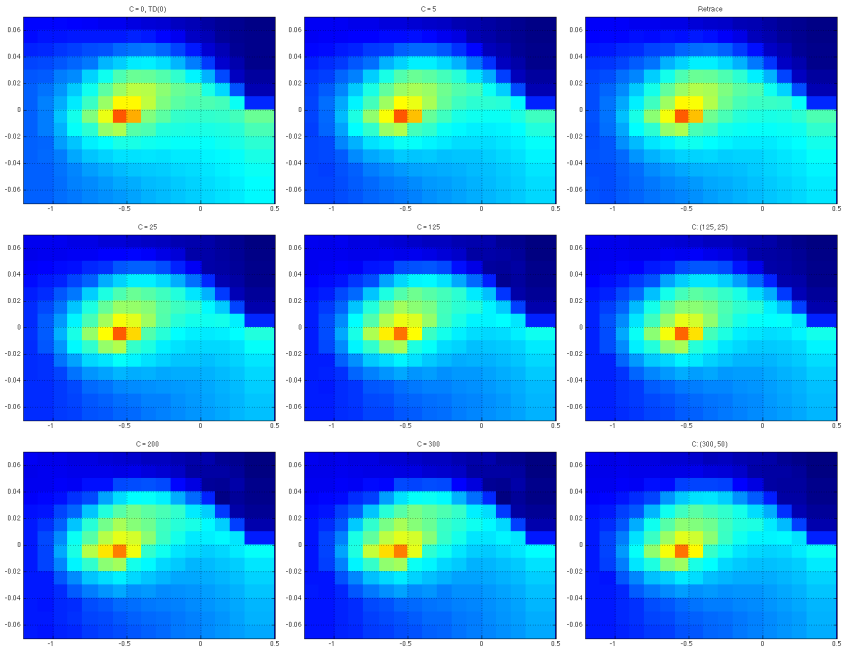

Figure 8: Visualized in the color images are approximations of $-v_\pi$ obtained by LSTD with different schemes of setting λ, where the coloring scheme is as that shown in Figure 6 (right). The choices of λ for each image, from left to right and top to bottom, are as follows. Top row: $C = 0$ (equivalent to LSTD(0)), $C = 5$, Retrace. Middle row: $C = 25$, $C = 125$, C: $(125, 25)$. Bottom row: $C = 200$, $C = 300$, C: $(300, 50)$.

and applies the simple scaling scheme with parameters C_1, C_2 for the first and second set, respectively. When referring to this composite scheme in the figures, we will use the designation C: (C_1, C_2).

We ran LSTD with different ways of setting λ just mentioned, on the same state trajectory generated by the behavior policy, for 6×10^5 effective iterations (cf. Footnote 14). Some of the approximate value functions obtained at the end of the run are visualized as images in Figure 8. It can be seen that the result of Retrace is similar to that of the simple scaling scheme with a small C, and as we increase C, the approximation from the scaling scheme improves.

To compare more precisely the approximation errors and see how they change over time for each algorithm, we did 10 independent runs, each of which consists of 6×10^5 effective

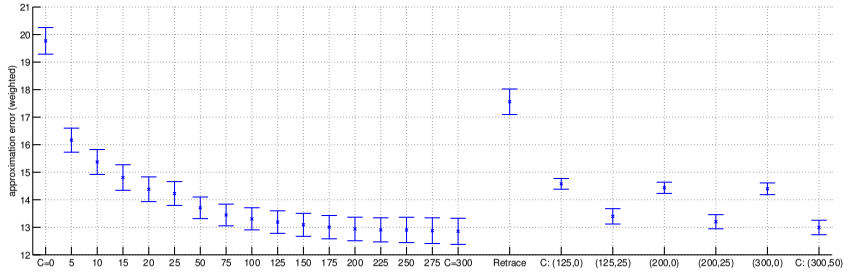

Figure 9: Compare the approximation error of LSTD for different schemes of setting λ.

iterations. The results are shown in Figures 9-11. Plotted in Figure 9 for each algorithm are the mean and standard deviation of the approximation errors for the 10 approximate value functions obtained by that algorithm at the end of the 10 runs. We can see from this figure the improvement in approximation quality as C increases. We can also see that the result of Retrace is in between those of $C = 0$ and $C = 5$, which is consistent with what the images in the top row of Figure 8 tell us.

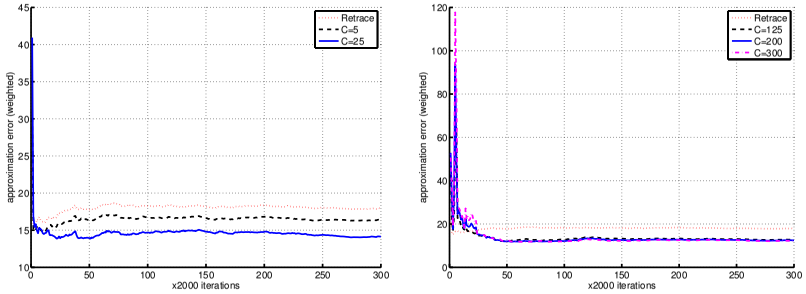

Figure 10: Compare the temporal behavior of LSTD for different schemes of setting λ.

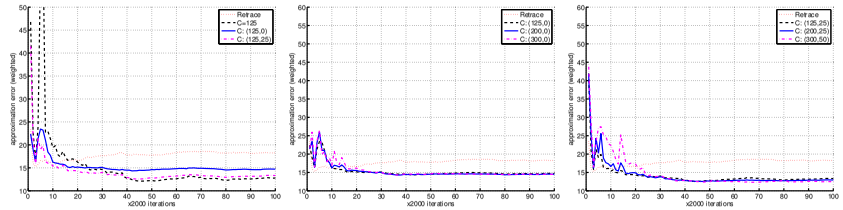

Figure 11: Compare the temporal behavior of LSTD for different schemes of setting λ.

Plotted in Figures 10-11 are the approximation errors calculated per 2000 effective iterations for each algorithm, during one of the 10 experimental runs. Figure 10 (left) shows how Retrace compares with the simple scaling with $C = 5$ and $C = 25$. It can be seen that the latter two achieved better approximation quality than Retrace without increases in variance. Figure 10 (right) shows that for larger values of C, variances also became larger initially; however, after about 5×10^4 iterations, these schemes overtook Retrace, yielding better approximations.

Figure 11 shows how the composite scheme of setting λ performs. Comparing the plots in this figure with the right plot in Figure 10, it can be seen that the composite schemes helped in reducing variances, and in about 2×10^4 iterations the schemes $C\colon (125, 0)$ and $C\colon (125, 25)$ overtook Retrace and yielded better approximations. Together with Figure 9, Figure 11 shows clearly the bias-variance trade-off of using composite schemes in this problem.

Second Experiment: Similarly to the previous experiment, we now compare our proposed method with several other ways of setting λ for the LSTD algorithm as well as with a constrained variant of LSTD: (i) Retrace with $\beta = 1$ as before; (ii) constant λ; (iii) constrained LSTD with constant λ; and (iv) the simple scaling scheme with parameter C. For constant $\lambda \in [0, 1]$, the constrained LSTD(λ) used in this experiment evolves the trace vectors as off-policy LSTD(λ) does, but it forms and solves the linear equation $\frac{1}{t}\sum_{k=0}^{t-1}[e_k]_{50} \cdot \delta_k(v) = 0, v = \Phi\theta$ instead, where the function $[\cdot]_{50}$ truncates each component of the trace vector to be within the interval $[-50, 50]$. (Such an algorithm follows naturally from the ergodicity of the state-trace process and the approximation of an unbounded integrable function by a bounded one. For a detailed discussion, see (Yu, 2016b, Section 3.2) or (Yu, 2017, Section 3.3).)

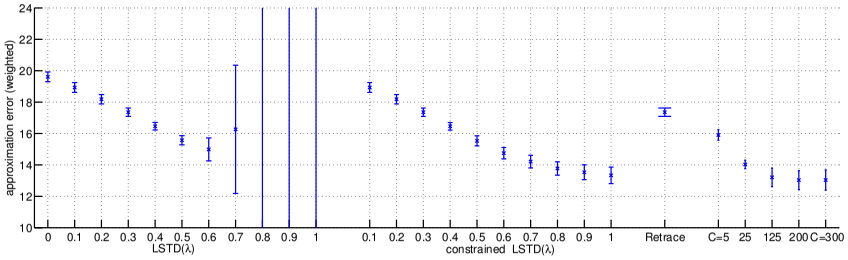

Figure 12: Compare the approximation errors of several LSTD algorithms.

Figure 12 is similar to Figure 9 and shows, for each algorithm, the mean and standard deviation of the approximation errors of 10 approximate value functions obtained at the end of 10 independent experimental runs (each of which consists of 6×10^5 effective iterations). The horizontal axis indicates the algorithms and their parameters. As can be seen from this figure, for constant small λ, LSTD(λ) performed well in this problem, and LSTD(0.3) and Retrace are comparable. For constant $\lambda > 0.7$, LSTD(λ) failed to give sensible results, and LSTD(0.7) started to show this unreliable behavior. This behavior of LSTD(λ) is related to what we observed in Figure 4(right) in the small toy problem, and it is, we think, due to

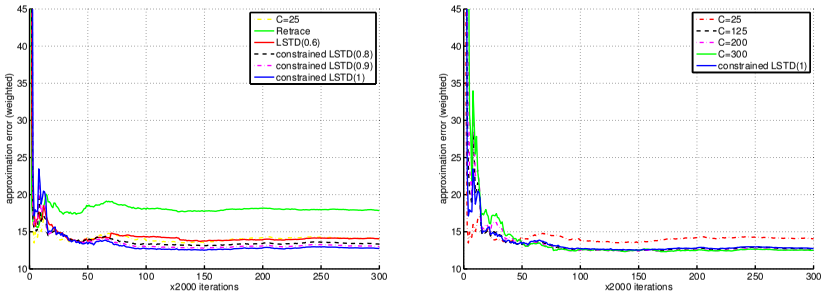

Figure 13: Compare the temporal behavior of several LSTD algorithms.

the high variance issue, which becomes more severe as λ gets larger. Constrained LSTD(λ) is much more reliable, and it did consistently well for all values of λ tested. LSTD with evolving λ also did well, and with $C > 125$, it achieved a slightly better approximation quality than constrained LSTD(1).

Figure 13 compares the temporal behavior of several algorithms during one experimental run. Plotted are the approximation errors calculated per 2000 iterations for each algorithm in the comparison. It can be seen that in this problem constrained LSTD(λ) did not suffer from large variances even with large λ values, and compared with constrained LSTD(1), the behavior of LSTD with evolving λ was also reasonable for large C.

Third Experiment: In this experiment we first compare the simple scaling scheme and Retrace, where both schemes now use an additional parameter $\beta \in [0, 1]$, as discussed in Examples 2.1-2.2. Recall that when $\beta = 1$, they reduce to the schemes that we already compared in the previous experiments. For both schemes, as β becomes smaller, we expect the approximation quality to drop but the variance to get smaller.

Plotted in Figure 14 for $C = 125, C = 200$ and Retrace are the results obtained from a single experimental run consisting of 3×10^5 effective iterations. As before the approximation errors were calculated per 2000 iterations. The results do show the expected bias-variance trade-off effects of the parameter β, during the initial period of the experimental run, although the effects on Retrace turned out to be smaller and hard to discern at the scale of the plot.

Next we test some of the variations on Retrace discussed in Example 2.2. Specifically, we consider (2.10)-(2.11) with parameters $\beta = 0.9$, $K \in \{1.5, 2.0, 2.5, 3.0\}$ and $C \in \{50, 125\}$. Plotted in Figure 15 are the results from one experimental run of 3×10^5 effective iterations. For comparison, the plots also show the behavior of Retrace and the simple scaling scheme with the same values of C during that run (these algorithms used the same $\beta = 0.9$). As expected and can be seen from the figure, the approximation quality improves with K and C. While the variances also tend to increase during the initial part of the run, the variants that truncate the importance sampling ratios by $K = 1.5$ performed comparably to Retrace initially, soon overtook Retrace and achieved better approximation quality.

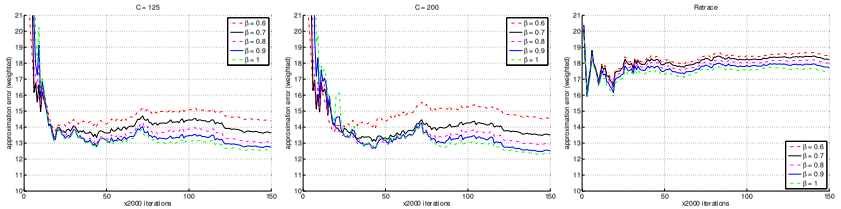

Figure 14: Compare the approximation error and temporal behavior of LSTD for different schemes of setting λ. From left to right: $C = 125$, $C = 200$, Retrace.

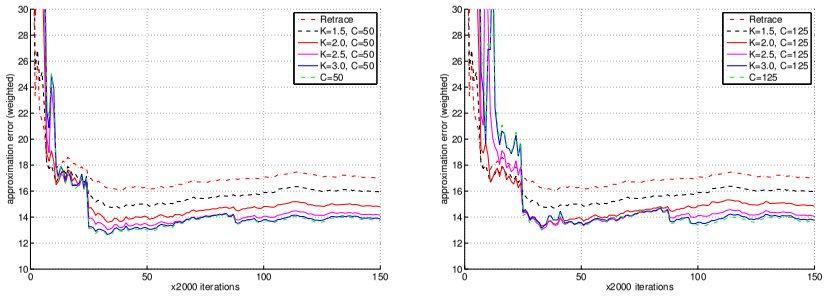

Figure 15: Compare the approximation error and temporal behavior for some variations on Retrace.

5. Conclusion

We developed in this paper a new scheme of setting the λ-parameters for off-policy TD learning, using the ideas of randomized stopping times and generalized Bellman equations for MDPs. Like the two recently proposed algorithms Retrace (Munos et al., 2016) and ABQ (Mahmood et al., 2017), our scheme keeps the traces bounded to reduce variances, but it is much more general and flexible. To study its theoretical properties, we analyzed the resulting state-trace process and established convergence and solution properties for the associated LSTD algorithm, and these results have prepared the ground for convergence analysis of the gradient-based implementation of our proposed scheme (Yu, 2017). In addition we did a preliminary numerical study. It showed that with the proposed scheme LSTD can outperform several existing off-policy LSTD algorithms. It also demonstrated that in order to achieve better bias-variance trade-offs in off-policy learning, it is helpful to have more flexibility in choosing the λ-parameters and to allow for large λ values. Future research is to conduct a more extensive numerical study of both least-squares based and gradient-based algorithms, with more versatile ways of using the memory states and λ-parameters, in off-policy learning applications.

Appendix A. Proof of Theorem 3.1

We prove Theorem 3.1 in this appendix. Recall from Section 3.1 that the generalized Bellman operator T associated with a randomized stopping time τ satisfies that $v_\pi = Tv_\pi$. By (3.2), the substochastic matrix $\tilde{P}$ in this affine operator T is given by

$$\tilde{P}_{ss'} = \mathbb{E}_s^\pi\big[\gamma_1^\tau \, \mathbb{1}(S_\tau = s')\big], \qquad s, s' \in \mathcal{S}. \tag{A.1}$$

We can extend $\tilde{P}$ to a transition matrix $\tilde{P}^e$ by adding an additional absorbing state Δ to the system, so that $\tilde{P}^e_{\Delta\Delta} = 1$ and

$$\tilde{P}^e_{s\Delta} = 1 - \textstyle\sum_{s' \in \mathcal{S}} \tilde{P}_{ss'} = 1 - \mathbb{E}_s^\pi\big[\gamma_1^\tau\big], \qquad s \in \mathcal{S}.$$

Both conclusions of Theorem 3.1 will follow immediately if we show that $I - \tilde{P}$ is invertible. Indeed, if $I - \tilde{P}$ is invertible, then $v = Tv$ has a unique solution, which must be v_π since v_π is always a solution of this equation. In addition, if $I - \tilde{P}$ is invertible, then since $\tilde{P}$ is a substochastic matrix, the spectral radius of $\tilde{P}$ must be less than 1. Consider adding to $\tilde{P}$ a small enough perturbation ϵM, where M is the matrix of all ones and ϵ is a sufficiently small positive number so that the spectral radius of $\tilde{P} + \epsilon M$ is less than 1. Applying (Seneta, 2006, Theorem 1.1) to the nonnegative primitive matrix $\tilde{P} + \epsilon M$, we have that $(\tilde{P} + \epsilon M)w < w$ where w is a positive eigenvector of the matrix $\tilde{P} + \epsilon M$ corresponding to a positive eigenvalue that is strictly less than 1. Consequently $\tilde{P}w \le (\tilde{P} + \epsilon M)w < w$, implying that $\tilde{P}$ is a linear contraction w.r.t. a weighted sup-norm (with weights w), which is the second conclusion of the theorem.

Hence, to prove Theorem 3.1, it suffices to show that the inverse $(I - \tilde{P})^{-1}$ exists, which is equivalent to that for the Markov chain on $\mathcal{S} \cup \{\Delta\}$ with transition matrix $\tilde{P}^e$, all the states in $\mathcal{S}$ are transient (see e.g., Puterman 1994, Appendix A.4).

We prove this by contradiction. Suppose it is not true, and let $\tilde{\mathcal{S}} \subset \mathcal{S}$ be a recurrent class of the Markov chain. Then for all $s \in \tilde{\mathcal{S}}$, $\tilde{P}^e_{ss'} = 0$ for $s' \notin \tilde{\mathcal{S}}$ (i.e., the submatrix of $\tilde{P}$ corresponding to $\tilde{\mathcal{S}}$ is a transition matrix). In particular, $\tilde{P}^e_{s\Delta} = 0$, so

$$\mathbb{E}_s^\pi\big[\gamma_1^\tau\big] = 1 - \tilde{P}^e_{s\Delta} = 1, \qquad \forall\, s \in \tilde{\mathcal{S}}, \tag{A.2}$$

implying that given $S_0 \in \tilde{\mathcal{S}}$, $\gamma_1^\tau = 1$ a.s. (since $\gamma_1^\tau \in [0, 1]$). Then by (A.1),

$$\tilde{P}_{ss'} = \mathbb{E}_s^\pi\big[\mathbb{1}(S_\tau = s')\big], \qquad \forall\, s, s' \in \tilde{\mathcal{S}}. \tag{A.3}$$

Observe from (A.2) that given $S_0 \in \tilde{\mathcal{S}}$, the event $\{\tau = \infty\}$ has zero probability. This is because under Condition 2.1(i), $\gamma_1^t \overset{a.s.}{\to} 0$ (as $t \to \infty$) and consequently $\gamma_1^\infty := \prod_{t=1}^\infty \gamma_t = 0$ a.s. Indeed, the existence of the inverse $(I - P\Gamma)^{-1} = \sum_{t=0}^\infty (P\Gamma)^t$ under Condition 2.1(i) implies $(P\Gamma)^t \to 0$ as $t \to \infty$. Since the sth entry of $(P\Gamma)^t \mathbf{1}$ equals $\mathbb{E}_s^\pi[\gamma_1^t]$, we have $\mathbb{E}_s^\pi[\gamma_1^t] \to 0$ as $t \to \infty$. As the nonnegative sequence $\{\gamma_1^t\}_{t \ge 1}$ is nonincreasing (since each $\gamma_t \in [0, 1]$), this implies, by Fatou's lemma (Dudley, 2002, Lemma 4.3.3), that $\gamma_1^t \overset{a.s.}{\to} 0$. Thus if $S_0 \in \tilde{\mathcal{S}}$, τ is almost surely finite.

We now consider a Markov chain $\{S_t\}$ with transition matrix P and $S_0 \in \tilde{\mathcal{S}}$. We will extract from it a Markov chain $\{\tilde{S}_k\}_{k \ge 0}$ with transition matrix $\tilde{P}^e$ on the recurrent class $\tilde{\mathcal{S}}$, by employing multiple stopping times. We will show $\gamma_1^\infty = 1$ a.s., contrary to the fact $\gamma_1^\infty = 0$ a.s. just discussed.

For ease of explanation, let us imagine that there is a device that if we give it a sequence of states $S_0, S_1, \ldots$ generated according to P, it will output the stopping decision at a random time τ that is exactly the randomized stopping time τ associated with the operator T. (Because τ is a randomized stopping time for $\{S_t\}$, a device that correctly implements τ does not affect the evolution of $\{S_t\}$, so we can give $\{S_t\}$ to the device as inputs.)

Let $\{S_t\}$ start from some state $S_0 = s \in \tilde{\mathcal{S}}$. We use the device just mentioned to generate the first randomized stopping time τ_1. We then reset the device so that it now "sees" the time-shifted process $\{S_{\tau_1 + t'} \mid t' \ge 0\}$ with the initial state being S_{τ_1}. We wait till the device makes another stopping decision, and we designate that time by τ_2. We repeat this procedure as soon as the device makes yet another stopping decision. This gives us a nondecreasing sequence $0 \le \tau_1 \le \tau_2 \le \cdots$.

Since $S_0 = s \in \tilde{\mathcal{S}}$, by what we proved earlier, τ_1 is almost surely finite. Let $\tilde{S}_1 = S_{\tau_1}$ and $\tilde{S}_0 = S_0$. The transition from $\tilde{S}_0$ to $\tilde{S}_1$ is according to the transition matrix $\tilde{P}^e$ by construction (cf. (A.3)). Since $\tilde{\mathcal{S}}$ is a recurrent class for $\tilde{P}^e$, we must have $\tilde{S}_1 \in \tilde{\mathcal{S}}$ almost surely. Then, repeating the same argument and using induction, we have that almost surely, for all $k \ge 1$, τ_k is defined and finite and $\tilde{S}_k := S_{\tau_k} \in \tilde{\mathcal{S}}$. Thus we obtain an infinite sequence $\{\tilde{S}_k\}$, which is a recurrent Markov chain on $\tilde{\mathcal{S}}$ with its transition matrix given by the corresponding submatrix of $\tilde{P}^e$.

Now in view of (A.2), almost surely,

$$\gamma_1^{\tau_1} = 1, \quad \gamma_{\tau_1+1}^{\tau_2} = 1, \quad \cdots, \quad \gamma_{\tau_k+1}^{\tau_{k+1}} = 1, \quad \cdots \tag{A.4}$$

(recall that if $\tau_k + 1 > \tau_{k+1}$, $\gamma_{\tau_k+1}^{\tau_{k+1}} = 1$ by definition). Consider first a simpler case of the randomized stopping time τ that defines T: for any initial state S_0, $\tau \ge 1$ a.s. Then, $\{\tau_k\}$ is strictly increasing, and by multiplying the variables in (A.4) together, we have $\gamma_1^\infty = 1$ a.s. For the general case of τ assumed in the theorem, $\tau = 0$ is possible, but $\mathbf{P}^\pi(\tau \ge 1 \mid S_0 = s) > 0$ for all states $s \in \mathcal{S}$. This means that the event of τ_k being the same for all k greater than some (random) $\bar{k}$ has probability zero. So $\{\tau_k\}$ must converge to $+\infty$ almost surely, and we again obtain, by multiplying the variables in (A.4) together, that $\gamma_1^\infty = 1$ a.s. This contradicts the fact proved earlier, namely, that for any initial state S_0, $\gamma_1^\infty = 0$ a.s. So the assumption of a recurrent class $\tilde{\mathcal{S}} \subset \mathcal{S}$ for $\tilde{P}^e$ must be false. This proves Theorem 3.1.

Appendix B. Oblique Projection Viewpoint and Error Bound for TD

In this appendix we first explain Scherrer's interpretation of TD solutions as oblique projections (Scherrer, 2010), and we then give approximation error bounds for TD similar to those

given by Yu and Bertsekas (2010), which do not rely on contraction properties. We will explain these properties of TD in the context of generalized Bellman operators discussed in this paper. Although this was not the framework used in (Scherrer, 2010; Yu and Bertsekas, 2010) and our setup here is more general than the one discussed in those previous papers, the arguments and reasoning are essentially the same.

B.1 Solutions of TD as Oblique Projections of the Value Function

Let us start with the projected Bellman equation associated with TD/LSTD that we noted in Remark 3.2:

$$Tv - v \perp_{\zeta_\mathcal{S}} \mathcal{L}_\phi, \quad v \in \mathcal{L}_\phi,$$

where T is a generalized Bellman operator with v_π as its unique fixed point, and $\mathcal{L}_\phi$ is the approximation subspace. We can write this equation equivalently as

$$v = \Pi_{\zeta_\mathcal{S}} T v, \tag{B.1}$$

where $\Pi_{\zeta_\mathcal{S}}$ denotes the projection onto the approximation subspace $\mathcal{L}_\phi$ with respect to the $\zeta_\mathcal{S}$-weighted Euclidean norm. In the subsequent derivations, we will not use the fact that $\zeta_\mathcal{S}$ is the invariant probability measure induced by the behavior policy on $\mathcal{S}$, so the analyses we give in this appendix apply to any weighted Euclidean norm $\|\cdot\|_{\zeta_\mathcal{S}}$.

Scherrer (2010) first realized that the solution of the projected Bellman equation (B.1) can be viewed as an *oblique projection of the value function* v_π on the approximation subspace $\mathcal{L}_\phi$. This viewpoint provides an intuitive geometric interpretation of the TD solution and explains conceptually the source of its approximation bias. Analytically, this view also gives tight bounds on the approximation bias, as we will elaborate later in Section B.2.

An oblique projection is defined by two nonorthogonal subspaces of equal dimensions: it is the projection onto the first subspace orthogonally to the second (Saad, 2003), as illustrated in Figure 16. More precisely, for any two n-dimensional subspaces $\mathcal{L}_1, \mathcal{L}_2$ of $\Re^N$ such that no vector in $\mathcal{L}_2$ is orthogonal to $\mathcal{L}_1$, there is an associated *oblique projection operator* $\Pi_{\mathcal{L}_1\mathcal{L}_2} : \Re^N \to \mathcal{L}_1$ defined by

$$\Pi_{\mathcal{L}_1\mathcal{L}_2}\, x \in \mathcal{L}_1, \qquad x - \Pi_{\mathcal{L}_1\mathcal{L}_2}\, x \perp \mathcal{L}_2, \qquad \forall\, x \in \Re^N. \tag{B.2}$$

If the two subspaces are the same: $\mathcal{L}_1 = \mathcal{L}_2$ or if x lies in $\mathcal{L}_1$, then the oblique projection $\Pi_{\mathcal{L}_1\mathcal{L}_2} x$ is the same as $\Pi_{\mathcal{L}_1} x$, the orthogonal projection of x onto $\mathcal{L}_1$. In general this need not be the case and $\Pi_{\mathcal{L}_1\mathcal{L}_2}\, x \neq \Pi_{\mathcal{L}_1} x$ typically (cf. Figure 16). A matrix representation of the projection operator $\Pi_{\mathcal{L}_1\mathcal{L}_2}$ is given by

$$\Pi_{\mathcal{L}_1\mathcal{L}_2} = \Phi_1 \big(\Phi_2^\top \Phi_1\big)^{-1} \Phi_2^\top, \tag{B.3}$$

where Φ_1 and Φ_2 are $N \times n$ matrices whose columns form a basis of $\mathcal{L}_1$ and $\mathcal{L}_2$, respectively (see Saad 2003, Chap. 1.12). For comparison, a matrix representation of the orthogonal projection operator $\Pi_{\mathcal{L}_1}$ is $\Pi_{\mathcal{L}_1} = \Phi_1 \big(\Phi_1^\top \Phi_1\big)^{-1} \Phi_1^\top$. (Below we will use the same notation for a projection operator and its matrix representations.)

Back to the projected Bellman equation (B.1), let us assume it has a unique solution v_{TD} and express v_{TD} in terms of v_π. We have $v_{\text{TD}} = \Pi_{\zeta_\mathcal{S}} T v_{\text{TD}}$. By Theorem 3.1, v_π is the

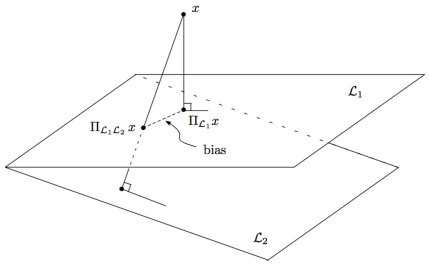

Figure 16: Oblique projection of x onto the subspace $\mathcal{L}_1$ orthogonally to the subspace $\mathcal{L}_2$.

unique solution of $v = Tv$. Recall that the generalized Bellman operator T is affine and can be expressed as $Tv = \tilde{r}_\pi + \tilde{P}_\pi v$ for some vector $\tilde{r}_\pi$ and substochastic matrix $\tilde{P}_\pi$. It follows that $\tilde{r}_\pi = (I - \tilde{P}_\pi)\, v_\pi$ and

$$\big(I - \Pi_{\zeta_\mathcal{S}} \tilde{P}_\pi\big)\, v_{\text{TD}} = \Pi_{\zeta_\mathcal{S}} \tilde{r}_\pi = \Pi_{\zeta_\mathcal{S}} \big(I - \tilde{P}_\pi\big)\, v_\pi. \tag{B.4}$$

Let the columns of Φ form a basis of the approximation subspace $\mathcal{L}_\phi$, and let D be the diagonal matrix with $\zeta_\mathcal{S}$ as its diagonal elements. Then a matrix representation of the projection operator $\Pi_{\zeta_\mathcal{S}}$ is $\Pi_{\zeta_\mathcal{S}} = \Phi \big(\Phi^\top D\, \Phi\big)^{-1} \Phi^\top D$. Using this representation of $\Pi_{\zeta_\mathcal{S}}$ and the fact $v_{\text{TD}} \in \mathcal{L}_\phi$, we obtain from (B.4) an expression of v_{TD} in terms of v_π:

$$v_{\text{TD}} = \Phi \big(\Phi^\top D (I - \tilde{P}_\pi)\, \Phi\big)^{-1} \Phi^\top D (I - \tilde{P}_\pi)\, v_\pi. \tag{B.5}$$

(Here the invertibility of the matrix $\Phi^\top D(I - \tilde{P}_\pi)\Phi$ is equivalent to our assumption that v_{TD} is the unique solution of (B.1).)

Let us compare the expression (B.5) with (B.3). We see that if the geometry on $\Re^N$ is determined by the usual Euclidean norm $\|\cdot\|_2$, then v_{TD} is an oblique projection of v_π for the two subspaces $\mathcal{L}_1 = \mathcal{L}_\phi$ and $\mathcal{L}_2 = \text{column-space}\big((I - \tilde{P}_\pi)^\top D \Phi\big)$.

Alternatively, consider the case where the geometry on $\Re^N$ is determined by some weighted Euclidean norm $\|\cdot\|_\xi$ with weights ξ (for example, $\xi = \zeta_\mathcal{S}$, which is one of the cases of interest in off-policy learning). In this case we can first scale each coordinate by the square root $\sqrt{\xi(s)}$ of its weight to reduce the case to that of the norm $\|\cdot\|_2$. Specifically, let $\perp_\xi$ denote orthogonality with respect to $\|\cdot\|_\xi$, and let Ξ denote the diagonal matrix that has ξ as its diagonal elements. For the linear mapping $h : v \mapsto \Xi^{1/2} v$, we have

$$\|v\|_\xi = \|h(v)\|_2, \qquad \text{and} \quad v_1 \perp_\xi v_2 \quad \Leftrightarrow \quad h(v_1) \perp h(v_2). \tag{B.6}$$

The second relation means that $\bar{v}$ is an oblique projection of v for two subspaces $\mathcal{L}_1, \mathcal{L}_2$ with respect to $\|\cdot\|_\xi$ (i.e., $\bar{v} \in \mathcal{L}_1$ and $v - \bar{v} \perp_\xi \mathcal{L}_2$), if and only if $h(\bar{v})$ is an oblique projection of $h(v)$ for the two subspaces $h(\mathcal{L}_1), h(\mathcal{L}_2)$ with respect to $\|\cdot\|_2$:

$$h(\bar{v}) \in h(\mathcal{L}_1), \qquad h(v) - h(\bar{v}) \perp h(\mathcal{L}_2).$$

With these facts in mind, we rewrite (B.5) equivalently as follows:

$$\Xi^{1/2}v_{\text{TD}} = \Xi^{1/2}\Phi \cdot \left(\Phi^\top D(I-\tilde{P}_\pi)\,\Xi^{-1}\Xi^{1/2}\cdot \Xi^{1/2}\Phi\right)^{-1}\cdot \Phi^\top D(I-\tilde{P}_\pi)\,\Xi^{-1}\Xi^{1/2}\cdot\Xi^{1/2}v_\pi$$
$$\implies \quad h(v_{\text{TD}}) = h(\Phi)\cdot\left(h(\Phi_2)^\top\cdot h(\Phi)\right)^{-1}h(\Phi_2)^\top\cdot h(v_\pi), \tag{B.7}$$

where

$$\Phi_2 = \Xi^{-1}(I-\tilde{P}_\pi)^\top D\Phi \tag{B.8}$$

and h applied to a matrix denotes the result of applying h to each column of that matrix. Comparing (B.7) with (B.3), we see that $h(v_{\text{TD}})$ is an oblique projection of $h(v_\pi)$ with respect to $\|\cdot\|_2$ for the two subspaces $h(\mathcal{L}_1)$, $h(\mathcal{L}_2)$, where

$$\mathcal{L}_1 = \mathcal{L}_\phi = \text{column-space}(\Phi), \qquad \mathcal{L}_2 = \text{column-space}(\Phi_2). \tag{B.9}$$

So based on the discussion earlier, with respect to the weighted Euclidean norm $\|\cdot\|_\xi$ on $\Re^N$, v_{TD} is an oblique projection of v_π for the two subspaces $\mathcal{L}_1, \mathcal{L}_2$.

Note that by (B.8), the second subspace $\mathcal{L}_2$ defining the above oblique projection is the image of the approximation subspace $\mathcal{L}_\phi$ under the linear transformation $\Xi^{-1}(I-\tilde{P}_\pi)^\top D$. Thus $\mathcal{L}_2$ *depends on the dynamics induced by the target policy as well as the generalized Bellman operator* T *that we choose*. Relating the oblique projection interpretation of v_{TD} to Figure 16, we can see where the approximation bias of TD, $v_{\text{TD}} - \Pi_\xi v_\pi$, comes from.

B.2 Approximation Error Bound

We now consider the approximation error of v_{TD} and use the oblique projection viewpoint to derive a sharp bound on the approximation bias $v_{\text{TD}} - \Pi_\xi v_\pi$. Before proceeding, however, let us first remind the reader that unless the norm $\|\cdot\|_{\zeta_\mathcal{S}}$ for the projection operator $\Pi_{\zeta_\mathcal{S}}$ is purposefully chosen, the composition of $\Pi_{\zeta_\mathcal{S}}$ with a generalized Bellman operator T is usually not a contraction, and thus error bounds for projected generalized Bellman equations usually cannot be obtained with contraction-based arguments. This is the case even for on-policy learning, as the following example shows.

Example B.1 (Non-contractive $\Pi_{\zeta_\mathcal{S}}T$) If the target policy π induces an irreducible Markov chain with invariant probability measure $\zeta_\mathcal{S}$, and if T is the Bellman operator for TD(λ) with a constant λ, then, as Tsitsiklis and Van Roy (1997) showed, $\Pi_{\zeta_\mathcal{S}}T$ is a contraction operator w.r.t. the weighted Euclidean norm $\|\cdot\|_{\zeta_\mathcal{S}}$. Consequently, the matrix $\Phi^\top D(\tilde{P}_\pi - I)\,\Phi$ associated with the TD(λ) algorithm is negative definite (Tsitsiklis and Van Roy, 1997). The derivation of the contraction property of $\Pi_{\zeta_\mathcal{S}}T$ in this case relies critically on the inequality $\zeta_\mathcal{S}^\top\tilde{P}_\pi < \zeta_\mathcal{S}^\top$. This inequality generally does not hold for the substochastic matrix $\tilde{P}_\pi$ in the generalized Bellman operator T, when λ is not constant. So, for non-constant λ, we can no longer expect $\Pi_{\zeta_\mathcal{S}}T$ to be a contraction or the matrix $\Phi^\top D(\tilde{P}_\pi - I)\,\Phi$ to be negative definite.

As an example, consider a simple two-state problem in which the system under the target policy π moves from one state to another in a cycle. Let $\pi^o = \pi$, let the discount factor γ be a constant, and let λ be a function of states with $\lambda(1) = 0$, $\lambda(2) = 1$. Then $\zeta_\mathcal{S}^\top = (0.5, 0.5)$ and $\tilde{P}_\pi = \begin{pmatrix}\gamma^2 & 0\\ \gamma & 0\end{pmatrix}$. For γ near 1, e.g., $\gamma = 0.95$, and for Φ as given below,

we can calculate the $\zeta_\mathcal{S}$-weighted norm of $\Pi_{\zeta_\mathcal{S}}\tilde{P}_\pi$ and the matrix associated with TD(λ):

$$\Phi = \begin{pmatrix}3 & 1\\ 1 & 1\end{pmatrix}, \qquad \left\|\Pi_{\zeta_\mathcal{S}}\tilde{P}_\pi\right\|_{\zeta_\mathcal{S}} = \left\|\tilde{P}_\pi\right\|_{\zeta_\mathcal{S}} \approx 1.31 > 1,$$
$$\Phi^\top D(\tilde{P}_\pi - I)\,\Phi = \begin{pmatrix}0.4862 & -0.1713\\ 0.7787 & -0.0738\end{pmatrix}.$$

The latter matrix is not negative definite; in fact, its eigenvalues have positive real parts, so it is not even a Hurwitz matrix (TD(λ) can diverge in this case). In the above, we have $\Pi_{\zeta_\mathcal{S}}\tilde{P}_\pi = \tilde{P}_\pi$, and while $\Pi_{\zeta_\mathcal{S}}\tilde{P}_\pi$ is not a contraction w.r.t. $\|\cdot\|_{\zeta_\mathcal{S}}$, it is still a contraction w.r.t. some matrix norm. If we now let $\Phi = (3,1)^\top$ instead, then the spectral radius of the matrix $\Pi_{\zeta_\mathcal{S}}\tilde{P}_\pi$ comes out as $\sigma(\Pi_{\zeta_\mathcal{S}}\tilde{P}_\pi) \approx 1.10 > 1$, so $\Pi_{\zeta_\mathcal{S}}\tilde{P}_\pi$ (and hence $\Pi_{\zeta_\mathcal{S}}T$) cannot be a contraction w.r.t. any matrix norm. ■

We now proceed to bound the bias term $v_{\text{TD}} - \Pi_\xi v_\pi$ relative to $\|v_\pi - \Pi_\xi v_\pi\|_\xi$, the distance between v_π and the approximation subspace measured with respect to $\|\cdot\|_\xi$. It is more transparent to derive the bound for the case of a general oblique projection operator $\Pi_{\mathcal{L}_1\mathcal{L}_2}$ with respect to the usual Euclidean norm $\|\cdot\|_2$, so let us do that first and then use the linear transformation $h(\cdot)$ to translate the result to TD, as we did earlier in the preceding subsection.

We bound the bias $\|\Pi_{\mathcal{L}_1\mathcal{L}_2}x - \Pi_{\mathcal{L}_1}x\|_2$ relative to $\|x - \Pi_{\mathcal{L}_1}x\|_2$, by calculating

$$\kappa := \sup_{x\in\Re^N}\frac{\|\Pi_{\mathcal{L}_1\mathcal{L}_2}x - \Pi_{\mathcal{L}_1}x\|_2}{\|x-\Pi_{\mathcal{L}_1}x\|_2} = \sup_{x\in\Re^N}\frac{\|\Pi_{\mathcal{L}_1\mathcal{L}_2}(x-\Pi_{\mathcal{L}_1}x)\|_2}{\|x-\Pi_{\mathcal{L}_1}x\|_2} \tag{B.10}$$

(where we treat $0/0 = 0$). This constant κ depends on the two subspaces $\mathcal{L}_1$, $\mathcal{L}_2$, and reflects the "angle" between them. It has several equivalent expressions, e.g.,

$$\kappa = \sup_{x\perp\mathcal{L}_1,\,\|x\|_2=1}\|\Pi_{\mathcal{L}_1\mathcal{L}_2}x\|_2 = \|\Pi_{\mathcal{L}_1\mathcal{L}_2}(I-\Pi_{\mathcal{L}_1})\|_2, \tag{B.11}$$

or with $\sigma(F)$ denoting the spectral radius of a square matrix F,

$$\kappa = \sqrt{\sigma\left(\Pi_{\mathcal{L}_1\mathcal{L}_2}(I-\Pi_{\mathcal{L}_1})\cdot(I-\Pi_{\mathcal{L}_1})^\top\Pi_{\mathcal{L}_1\mathcal{L}_2}^\top\right)} = \sqrt{\sigma\left(\Pi_{\mathcal{L}_1\mathcal{L}_2}\Pi_{\mathcal{L}_2\mathcal{L}_1} - \Pi_{\mathcal{L}_1}\right)}. \tag{B.12}$$

(After the definition of κ, each expression of κ in (B.10)-(B.12) follows from the preceding one; in particular, for the last expression in (B.12), we used the fact that $\Pi_{\mathcal{L}_1}^\top = \Pi_{\mathcal{L}_1}, \Pi_{\mathcal{L}_1\mathcal{L}_2}^\top = \Pi_{\mathcal{L}_2\mathcal{L}_1}$, and $\Pi_{\mathcal{L}_1}\Pi_{\mathcal{L}_2\mathcal{L}_1} = \Pi_{\mathcal{L}_1}$.)

We can express κ in terms of the spectral radius of an $n\times n$ matrix, similarly to what was done in (Yu and Bertsekas, 2010). In particular, we take the last expression of κ in (B.12) and rewrite the symmetric matrix in that expression using the matrix representations of the projection operators as follows:

$$\Pi_{\mathcal{L}_1\mathcal{L}_2}\Pi_{\mathcal{L}_2\mathcal{L}_1} - \Pi_{\mathcal{L}_1} = \Phi_1(\Phi_2^\top\Phi_1)^{-1}\Phi_2^\top\cdot\Phi_2(\Phi_1^\top\Phi_2)^{-1}\Phi_1^\top - \Phi_1(\Phi_1^\top\Phi_1)^{-1}\Phi_1^\top.$$

By a result in matrix theory (Horn and Johnson, 1985, Theorem 1.3.20), for any $N\times n$ matrix F_1 and $n\times N$ matrix F_2, $\sigma(F_1F_2) = \sigma(F_2F_1)$. Applying this result to the preceding

expression with $F_1 = \Phi_1$, we have that $\sigma\big(\Pi_{\mathcal{L}_1\mathcal{L}_2}\Pi_{\mathcal{L}_2\mathcal{L}_1} - \Pi_{\mathcal{L}_1}\big)$ is equal to the spectral radius of the matrix

$$(\Phi_2^\top\Phi_1)^{-1}(\Phi_2^\top\Phi_2)(\Phi_1^\top\Phi_2)^{-1}(\Phi_1^\top\Phi_1) - I.$$

Combing this with (B.12), we obtain that

$$\kappa^2 = \sigma(F) - 1, \qquad \text{where} \quad F = (\Phi_2^\top\Phi_1)^{-1}(\Phi_2^\top\Phi_2)(\Phi_1^\top\Phi_2)^{-1}(\Phi_1^\top\Phi_1). \tag{B.13}$$

Thus, for the above κ, the bound below holds for all $x \in \Re^N$ and with equality attained at some x:

$$\|\Pi_{\mathcal{L}_1\mathcal{L}_2}x - \Pi_{\mathcal{L}_1}x\|_2 \le \kappa\,\|x - \Pi_{\mathcal{L}_1}x\|_2. \tag{B.14}$$

We now translate the result (B.13)-(B.14) to our TD context. We want to bound the relative bias $\big\|v_{\text{TD}} - \Pi_\xi v_\pi\big\|_\xi / \big\|v_\pi - \Pi_\xi v_\pi\big\|_\xi$. As discussed earlier in Section B.1, we can replace $\|\cdot\|_\xi$ with $\|\cdot\|_2$ by using the linear transformation $h(\cdot)$ to scale the coordinates. In particular, by the two relations given in (B.6),

$$\frac{\big\|v_{\text{TD}} - \Pi_\xi v_\pi\big\|_\xi}{\big\|v_\pi - \Pi_\xi v_\pi\big\|_\xi} = \frac{\big\|h(v_{\text{TD}}) - \Pi\,h(v_\pi)\big\|_2}{\big\|h(v_\pi) - \Pi\,h(v_\pi)\big\|_2}, \tag{B.15}$$

where Π on the r.h.s. stands for the orthogonal projection onto $h(\mathcal{L}_\phi)$ with respect to $\|\cdot\|_2$. As shown by (B.7), $h(v_{\text{TD}})$ is an oblique projection of $h(v_\pi)$ for the two subspaces $h(\mathcal{L}_\phi)$ and $h(\mathcal{L}_2)$, where $\mathcal{L}_2$ is given by (B.8)-(B.9). According to (B.13), the constant κ for this oblique projection is $\sqrt{\sigma(F) - 1}$ where, if we take $\Phi_1 = \Phi$ and Φ_2 as defined by (B.8), F is now given by the expression in (B.13) with $h(\Phi_1), h(\Phi_2)$ in place of Φ_1, Φ_2, respectively. Thus, by (B.14) and (B.15) we obtain that

$$\big\|v_{\text{TD}} - \Pi_\xi v_\pi\big\|_\xi \le \kappa\,\big\|v_\pi - \Pi_\xi v_\pi\big\|_\xi \qquad \text{for} \quad \kappa = \sqrt{\sigma(F) - 1}, \tag{B.16}$$

where F is an $n \times n$ matrix given by

$$F = \big[h(\Phi_2)^\top h(\Phi_1)\big]^{-1} \cdot \big[h(\Phi_2)^\top h(\Phi_2)\big] \cdot \big[h(\Phi_1)^\top h(\Phi_2)\big]^{-1} \cdot \big[h(\Phi_1)^\top h(\Phi_1)\big] \tag{B.17}$$

for

$$\Phi_1 = \Phi, \qquad \Phi_2 = \Xi^{-1}(I - \tilde{P}_\pi)^\top D\Phi, \tag{B.18}$$

or more explicitly, after substituting the expressions of $h(\Phi_1)$ and $h(\Phi_2)$ in the formula of F and removing h, we have

$$F = \big(\Psi^\top\Phi\big)^{-1}\big(\Psi^\top\Xi^{-1}\Psi\big)\big(\Phi^\top\Psi\big)^{-1}\big(\Phi^\top\Xi\Phi\big), \quad \text{where} \quad \Psi = (I - \tilde{P}_\pi)^\top D\Phi.$$

Note that by the definition of κ, the bound (B.16) is a worst-case bound that depends only on the two subspaces involved in the oblique projection operator. In other words, given the approximation subspace $\mathcal{L}_\phi$, the dynamics described by $\tilde{P}_\pi$, the projection norm $\|\cdot\|_{\zeta_\mathcal{S}}$ and the norm $\|\cdot\|_\xi$ for measuring the approximation quality, the bound (B.16) is attained by a worst-case choice of the rewards $\tilde{r}_\pi$ for the target policy. In this sense, the bound (B.16) is tight.

Abstract

Neural Information Processing Systems (NIPS) is a top-tier annual conference in machine learning. The 2016 edition of the conference comprised more than 2,400 paper submissions, 3,000 reviewers, and 8,000 attendees. This represents a growth of nearly 40% in terms of submissions, 96% in terms of reviewers, and over 100% in terms of attendees as compared to the previous year. The massive scale as well as rapid growth of the conference calls for a thorough quality assessment of the peer-review process and novel means of improvement. In this paper, we analyze several aspects of the data collected during the review process, including an experiment investigating the efficacy of collecting ordinal rankings from reviewers. We make a number of key observations, provide suggestions that may be useful for subsequent conferences, and discuss open problems towards the goal of improving peer review.

Keywords: Peer review, post hoc analysis, NIPS, consistency, ordinal

∗. Authors contributed equally.

. Nihar Shah, Behzad Tabibian and Krikamol Muandet performed most of the data analysis reported in this paper. Behzad Tabibian and Krikamol Muandet were also the workflow team of NIPS 2016 and were responsible for all the programs, scripts and CMT-related issues during the review process. Isabelle Guyon and Ulrike von Luxburg were the program chairs of NIPS 2016.

1. Introduction

The review process for NIPS 2016 involved 2,425 papers submitted by 5,756 authors, 100 area chairs, and 3,242 active reviewers submitting 13,674 reviews in total. Designing a review process as fair as possible at this scale was a challenge. In order to scale, all parts of the process have to be as decentralized as possible. Just to get a feeling, if the two program chairs were supposed to take final decisions just for the 5% most challenging submissions, which means that they would have to read and decide on 150 papers — this is the scale of a whole conference such as COLT. Furthermore, the complexity of the logistics and software to manage the review process is rather high already. A controlled experiment (Lawrence and Cortes, 2014) from NIPS 2014 has shown that there is a high disagreement in the reviews. Hence the primary goal must be to keep bias and variance of the decisions as small as possible.

In this paper, we present an analysis of many aspects of the data collected throughout the review phase of the NIPS 2016 conference, performed subsequent to the completion of the review process. Our goal in this analysis is to examine various aspects of the data collected from the peer-review process to check for any systematic issues. Before delving into the details, we note the following limitations of this analysis:

- There is no ground truth ranking of the papers or knowledge of the set of papers which should ideally have been accepted.
- The analysis is post hoc, unlike the controlled experiment from NIPS 2014 (Lawrence and Cortes, 2014).
- The analysis primarily evaluates the ratings and rankings provided by reviewers, and does not study the textual comments provided by the reviewers.

The analysis is used to obtain insights into the peer-review process, usable suggestions for subsequent conferences, and important open problems towards improving peer-review in academia.

Here is a summary of our findings:

(i) there are very few positive bids by reviewers and area chairs (Section 3.1);

(ii) graph-theoretic techniques can be used to ensure a good reviewer assignment (Section 3.2);

(iii) there is significant miscalibration with respect to the rating scale (Section 3.3);

(iv) review scores provided by invited and volunteer reviewers have comparable biases and variance, and junior reviewers report a lower confidence (Section 3.4);

(v) there is little change in reviewer scores after rebuttals (Section 3.5);

(vi) there is no observable bias towards any research area in accepted papers (Section 3.6);

(vii) there is lower disagreement among reviewers in NIPS 2016 as compared to NIPS 2015 (Section 3.7);

(viii) a significant fraction of scores provided by the reviewers are tied, and ordinal rankings can ameliorate this issue (Section 3.8);

(ix) there are some inconsistencies in the reviews and these can be identified in an automated manner using ordinal rankings (Section 3.9).

We describe the review procedure followed at NIPS 2016 in Section 2. We present an elaborate description of the analysis and the results in Section 3. Alongside each analysis, we present a set of key observations, action items for future conferences, and some open problems that arise out of the analysis. We conclude the paper with a discussion in Section 4.

2. Review procedure

In this section, we present an overview of the design of the review process at NIPS 2016.

2.1 Selecting area chairs and reviewers

Area Chairs (ACs) are the backbone of the NIPS reviewing process. Their role is similar to that of an associate editor for a journal. Each AC typically handles 20-30 submissions, so with an estimated number of submissions between 2000 and 3000, we needed to recruit about 100 area chairs. As it is impossible to intimately know all the diverse research areas covered by NIPS, we came up with the following procedure. We asked the NIPS Board and all the ACs of NIPS from the past two years to nominate potential ACs for this year. In this manner, we covered the entire variety of NIPS topics and obtained qualified suggestions. We obtained around 350 suggestions. We asked the NIPS Board to go through the list of suggested ACs and vote in favor of suggested ACs. We also accounted for the distribution of subject areas of submitted papers of the previous year's NIPS conference. Combining all these inputs, we compiled a final list of ACs: by the end of January we had recruited exactly 100 ACs. In a subsequent step, we formed "buddy pairs" among the ACs. Based on the ACs preferences, each AC got assigned a buddy AC. We revisit the role of buddy pairs in more detail later.

The process of **recruiting reviewers** is time consuming, it essentially went on from January until the submission deadline at end of May. A significant departure from the review processes of NIPS from earlier years, this time we had two kinds of reviewers, "invited senior reviewers" (Pool 1) and "volunteer reviewers" (Pool 2):

- **Pool 1, invited senior reviewers:** We asked all ACs to suggest at least 30 reviewers who have completed their PhDs (however, this requirement was not strictly observed by all ACs). We then also asked all confirmed reviewers to "clone themselves" by inviting at least one researcher with a similar research background and with at least as good a qualification as themselves.

- **Pool 2, volunteer author-reviewers:** The rapid growth in the number of submissions at NIPS poses the formidable challenge of accordingly scaling the number of reviewers. An obvious means to achieve this objective is to ask authors to become reviewers as well. This idea has been used in the past, for example, to evaluate NSF grant proposals (Mervis, 2014) or to allocate telescope time (Merrifield and Saari, 2009). In order to implement this idea, without constraining unwilling authors, we requested authors to volunteer during the submission process by naming at least one author per paper as volunteer reviewers.

The area chairs were aware of the respective pools to which each of their reviewers belonged. The number of reviewers that we eventually ended up with writing reviews are as follows:

Number of reviewers	Senior researchers / faculty	Junior researchers / postdocs	PhD students	Not Specified	Total
Pool 1: Invited	1236	566	255	7	2064
Pool 2: Volunteer	143	206	827	2	1178

The total number of reviews in each category are as follows:

Number of reviews	Senior researchers / faculty	Junior researchers / postdocs	PhD students	Not Specified	Total
Pool 1: Invited	5759	2559	888	38	9244
Pool 2: Volunteer	576	795	3050	9	4430

2.2 Assignment of papers to reviewers and area chairs

The assignment of papers to area chairs was made in the following manner. Prior to the review process, the ACs and reviewers were allowed to see the list of submitted papers and "bid" whether they were interested or disinterested in handling/reviewing any paper. For any paper, an AC/reviewer could either indicate "Not Willing" or "In-a-pinch" – which we count as negative bids, or indicate "Willing" or "Eager" – which we count as positive bids, or choose to not bid for that paper. The Toronto paper matching system or TPMS was then employed to compute an affinity score for every AC (and reviewer) with every submitted paper based on the content of the paper and the academic profile of the AC or reviewer. In addition, every AC/reviewer as well as the submitter of every paper was asked to select a set of most relevant subject areas, and these subject areas were also employed to compute a similarity between every AC/reviewer and every paper.

Based on the similarity scores and bids, an overall similarity score is computed for every {paper, AC} and every {paper, reviewer} pair: score $= 2^b(s_{\text{affinity}} + s_{\text{subject}})/2$, where $s_{\text{affinity}} \in [0, 1]$ is the affinity score obtained from TPMS, $s_{\text{subject}} \in [0, 1]$ is the score obtained by comparing the subject areas of the paper and the subject areas selected by the AC or reviewer, and $b \in [-1, 1]$ is the bidding score provided by the AC or reviewer. Based on these overall similarity scores, a preliminary paper assignment to ACs was then produced in an automated manner using the TPMS assignment algorithm (Charlin and Zemel, 2013). The ACs were given a provision to decline handling certain papers for various reasons such as conflicts of interest. These papers were re-assigned manually by the program chairs.

The AC of each paper was responsible to first assign one senior, highly qualified reviewer manually. Two more invited reviewers from pool 1 and three volunteer reviewers from pool 2 were then assigned automatically to each paper using the same procedure as described above.

The ACs were asked to verify whether each of their assigned papers had at least 3 highly competent reviewers; the ACs could manually change reviewer assignments to ensure that this is the case. During the decision process, additional emergency reviewers were invited to provide complementary reviews if some of the reviewers had not turned in their reviews or if no consensus was reached among the selected reviewers.

2.3 Review criteria and scores

We completely changed the scoring method this year. In previous years, NIPS papers were rated using a single score between 1 and 10. A single score alone did not allow reviewers to give a differentiated quantitative appreciation on various aspects of paper quality. Furthermore, the role of the ACs was implicitly to combine the decisions of the reviewers (late integration) rather than combining the reviews to make the final decision (early integration). Introducing multiple scores allowed us to better separate the roles: the reviewers were in charge of evaluating the papers; the ACs were in charge of making decisions based on all the evaluations. Furthermore the multiple specialized scores allowed the ACs to guide reviewers to focus discussions on "facts" rather than "opinion" in the discussion phase. We asked reviewers to provide a separate score for each of the following four criteria:

- Technical quality,
- Novelty/originality,
- Potential impact or usefulness,
- Clarity and presentation.

The scores were on a scale of 1 to 5, with the following rubric provided to the reviewers:

5 = Award level (1/1000 submissions),

4 = Oral level (top 3% submissions),

3 = Poster level (top 30% submissions),

2 = Sub-standard for NIPS,

1 = Low or very low.

The scoring guidelines also reflect the hierarchy of the papers: the conference selects the top few papers for awards, the next best accepted papers are presented as oral presentations, and the remaining accepted papers are presented as posters at the conference. The scores provided by reviewers had to be complemented by justifications in designated text boxes. We also asked the reviewers to flag "fatal flaws" in the papers they reviewed. For each paper, we also asked the reviewers to declare their overall "level of confidence":

3 = Expert (read the paper in detail, know the area, quite certain of opinion),

2 = Confident (read it all, understood it all reasonably well),

1 = Less confident (might not have understood significant parts).

2.4 Discussions and rebuttals

Once most reviews were in, authors had the opportunity to look at the reviews and write a rebuttal. One section of the rebuttal was revealed to all the reviewers of the paper, and a second section was private and visible only to the ACs. Some reviews were still missing at

this point, but it would not have helped to delay the rebuttal deadline as the missing reviews trickled in only slowly. Subsequently, ACs and reviewers engaged in discussions about the pros and cons of the submitted papers. To support the ACs, we sent individual reports to all area chairs to flag papers whose reviews were of too low confidence, too high variance or where reviews were still missing. In many cases, area chairs recruited additional emergency reviewers to increase the overall quality of the decisions.

2.5 Decision procedure

The decision procedure involved making an acceptance or rejection decision for each paper, and furthermore, to select a subset of (the best) accepted papers for oral presentation.

We introduced a decentralized decision process based on pairs of ACs ("buddy pairs"). Each AC got assigned one buddy AC. Each pair of buddy ACs was responsible for all papers in their joint bag and made the accept/reject decisions jointly, following guidelines given by the program chairs. Difficult cases were taken to the program chairs, which included cases involving conflicts of interest and plagiarism. In order to harmonize decisions across buddy pairs, all area chairs had access to various statistics and histograms over the set of their papers and the set of all submitted papers. To decide which accepted paper would get an oral presentation, each buddy pair was asked to champion one or two papers from their joint bag as a candidate for an oral presentation. The final selection was then made by the program chairs, with the goals of exhibiting the diversity of NIPS papers and exposing the community with novel and thought-provoking ideas. In the end, 568 papers got accepted to the conference, and 45 of these papers were selected for oral presentations.

Like previous years, we adopted a "double blind" review policy. That is, the author(s) of each paper did not get to know the identity of the reviewers and vice versa throughout the review process. ACs got to know the identity of the reviewers and the author(s) for the papers under their responsibility. During the discussion phase, reviewers who reviewed the same papers got to know each other's identity. Lastly, PCs and program managers had access to all information about the submissions, the ACs, the reviewers, and the authors.

2.6 Experimental ordinal reviews

In the main NIPS 2016 review process, we elicited only cardinal scores from the reviewers – one score in 1 to 5 for each of four criteria. Subsequent to the review process, we then requested each reviewer to also provide a total ranking of the papers that they reviewed. We received rankings from a total of 2189 reviewers. Note that the collection of ordinal data was performed subsequent to the normal review submission but before release of the final decisions. The ordinal data was not used as a part of the decision procedure in the conference.

3. Detailed analysis

In this section, we present details of our analyses of the review data and the associated results. Each subsection contains one analysis and concludes with a summary that highlights the key observations, concrete action items for future conferences, and open problems that arise from the analysis.

The results are computed for a snapshot of reviews at the end of the review process when the acceptance decisions were made. This choice does not affect our results since there was very little change in the scores provided by reviewers across different time instants. All t-tests conducted correspond to two-sample t-tests with unequal variances. All mentions of p-values correspond to two-sided tail probabilities. All mentions of statistical significance correspond to a p-value threshold of 0.01 (we also provide the exact p-values alongside). Multiple testing is accounted for using the Bonferroni correction. The effect sizes refer to Cohen's d. Wherever applicable, the error bars in the figures represent 95% confidence intervals.

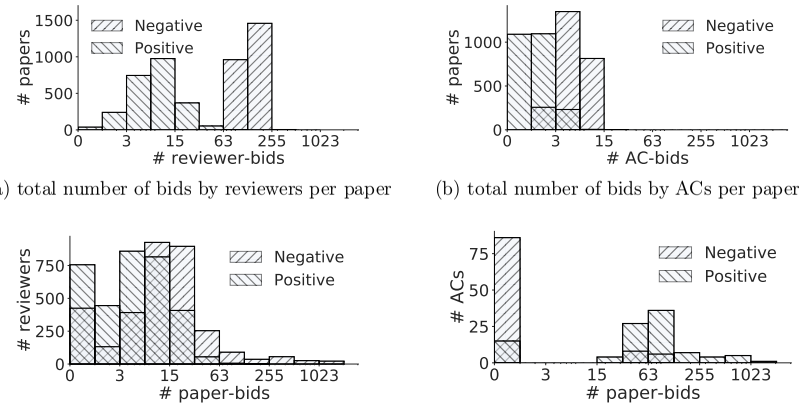
Wherever applicable, we also perform our analyses on a subset of the submitted papers which we term as the top 2k papers. The top 2k papers comprise all of the 568 accepted papers, and an equal number (568) of the rejected papers. The 568 rejected papers are chosen as those with the maximum mean score (where the mean for any paper is taken across all reviewers and all reviewers).

3.1 Reviewer and AC bids

A large number of conferences in computer science ask area chairs and/or reviewers to bid which papers they would like or not like to review, in order to obtain a better understanding of the expertise and the preferences of reviewers. Such an improved understanding is desirable as it leads to a more informed assignment of reviewers to papers, thereby improving the overall quality of the review process.

Figure 1 depicts the distribution of number of bids on papers submitted by area chairs and reviewers in NIPS 2016. Panels (a) and (b) of the figure depict the distribution of counts per paper for reviewers and area chairs respectively; panels (c) and (d) depict the distribution per area chairs and reviewers. The "not willing" and "in-a-pinch" bids were considered negative bids, whereas "willing" and "eager" bids were considered positive bids. From the data, we observe that there are very few positive bids, but a considerably higher number of negative bids.

The distribution of number of bids by reviewers is skewed by few reviewers who bid (positive and negative) on too many papers: 27% of reviewers make 90% of all bids, and 50% of reviewers make 90% of all positive bids. Moreover, there are 148 reviewers with no (positive or negative) bids and 1201 reviewers with at most 2 positive bids. In comparison, NIPS 2016 assigned at least 3 papers to most reviewers (and many other conferences also do likewise). We thus observe that a large number of reviewers do not even provide positive bids amounting to the number of papers they would review. As a consequence of the low number of bids by reviewers, we are left with 278 papers with at most 2 positive bids and 816 papers with at most 5 positive bids. In contrast, NIPS 2016 assigned 6 reviewers to most papers. There is thus a significant fraction of papers with fewer positive bids than the number of requisite reviewers. Finally there are 1090 papers with no positive bids by any AC.



(a) total number of bids by reviewers per paper

(b) total number of bids by ACs per paper

(c) number of bids per reviewer

(d) number of bids per AC

Figure 1: Histogram of number of positive and negative bids (x-axis; on a logarithmic scale) per entity (counts on y-axis) for various entities. The first column in each histogram represents number of entities with 0 bids. For example, the first column of panel (c) depicts that 756 reviewers made zero positive bids and 425 reviewers made zero negative bids.

Summary 1: Reviewer and AC bids

Key observations:

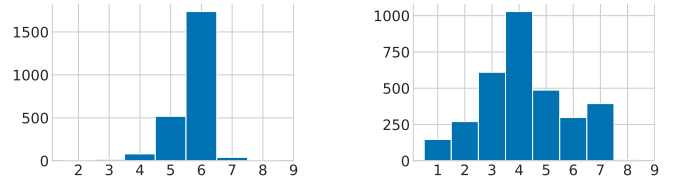
- There are very few positive bids by reviewers, with 278 papers receiving at most 2 positive bids and 816 papers receiving at most 5 positive bids.
- From the reviewers' side, the bids are highly skewed: 50% of reviewers make 90% of all positive bids, 148 reviewers make no (positive or negative) bids, and 1201 reviewers make at most 2 positive bids.
- There are 1090 papers with no positive bids by any AC.

Action items:

- When a reviewer or AC logs into the system, show unbid papers on top.
- Inform reviewers of the procedure employed to use their bids for assigning papers. Make reviewers aware of the benefits of bidding, such as receiving more relevant papers to read and serving the community by improving the review process.

Open problems:

- How to incentivize more (positive) bids so that the organizers understand preferences better for accurate reviewer assignment?
- Design a principled means of combining bids, paper content-reviewer profile similarity, and subject similarity.



(a) number of reviewers per paper (b) number of papers per reviewer

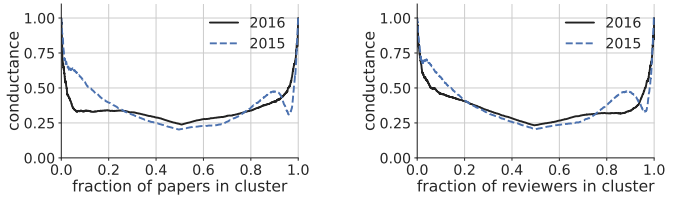
Figure 2: Histogram of number of reviews.

3.2 Reviewer assignment

Figure 2 depicts the histograms of the number of reviewers assigned per paper, and the number of papers handled by each reviewer.

In order to ensure that the information about each paper "spreads" across the entire system, it is important that there is no set of reviewers or papers that has only a small overlap with the remaining reviewers and papers (Olfati-Saber et al., 2007; Shah et al., 2016a). To analyze whether this was the case, we considered two graphs. We built a *reviewer graph* that has reviewers as vertices, and an edge between any two reviewers if there exists at least one paper that has been reviewed by both of them. Analogously we built a *paper graph*, where vertices represent papers, and we connect two papers by an edge if there exists a reviewer who has reviewed both papers. Note that the graph structure is in part dictated by a constraint on the maximum number of papers per reviewer as well as the specified number of reviewers per paper.

Our objective is to examine the structure of the graphs and determine if there were any separated communities of nodes. In order to do so, we employ a method based on spectral clustering. Formally, denote any graph as $G = (V, E)$ where V is set of nodes, and E is the set of (undirected) edges between nodes, and let $|V|$ denote the number of nodes in the graph. We can denote graph connectivity by its associated adjacency matrix A which is a $(|V| \times |V|)$ matrix; we have $A_{ij} = 1$ if there is an edge between nodes i and j and $A_{ij} = 0$ otherwise. With this notation, a quantity known as the "conductance" Φ of any set of nodes



(a) paper graph (b) reviewer graph

Figure 3: Conductance value as function of varying cluster size. The x-axes in these plots represent the normalized cluster size $k/|V|$.

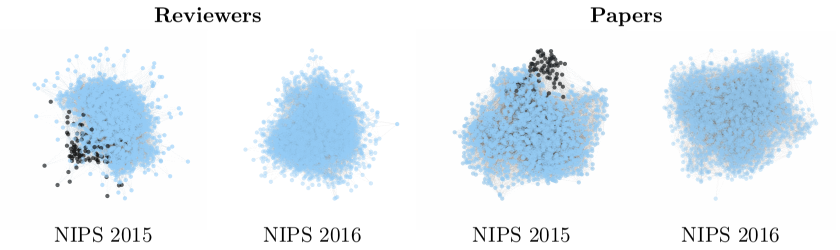


Figure 4: Graphs depicting connectivity of reviewers and that of papers for NIPS 2015 and NIPS 2016. The nodes in black (dark) show set of nodes identified by the local minima in the conductance plots (Figure 3) for NIPS 2015, and the remaining nodes are plotted in blue (light).

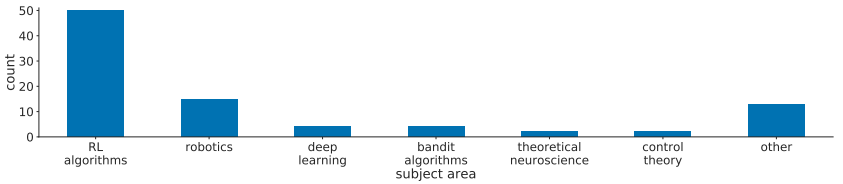

Figure 5: Histogram of subject areas in the identified cluster (from Figure 4) of reviewers in NIPS 2015 which is not well connected with the set of remaining reviewers.

$S \subset V$ is then defined as:

$$\Phi(S) = \frac{\sum_{i \in S, j \notin S} A_{ij}}{\max\{|S|, |V \backslash S|\}},$$

where $V \backslash S$ is the complement of set S. A lower value of the conductance indicates that the nodes in the cut are less connected to the remaining graph. Next, with a minor abuse of notation, the conductance of a graph as function of cluster sizes is defined as:

$$\Phi(k) = \min_{S \in V, |S| = k} \Phi(S),$$

for every $k \in \{1, \ldots, |V| - 1\}$. The plot of k versus $\Phi(k)$ is called a Network Community Profile or NCP plot (Leskovec et al., 2008). The NCP plot measures the quality of the least connected community (lowest conductance) in a large network, as a function of the size of the community. Although computing the function $\Phi(k)$ exactly may be computationally hard, an approximate value can be computed using a simple "second left eigenvector" procedure (Section 2.3 of Benson et al., 2015). A well connected graph would have a smooth plot of $\Phi(k)$ with a minima at around $k = |V|/2$.

Figure 3 shows the NCP plot for an increasing number of papers (respectively reviewers) in the paper graph (respectively reviewer graph). For reference we also plot the same curve

for graphs associated with NIPS 2015 conference. Both plots for NIPS 2015 have local minima at around $k = 0.96|V|$, indicating that there is a densely connected community of reviewers and papers that are not well connected with the rest of the graph. In contrast, the plot associated with NIPS 2016 decreases smoothly and reaches its global minimum when half of the nodes are in one cluster and the other half in another cluster, indicating an absence of such a fragmentation.

In Figure 4, we plot the graph of reviewers and papers using the algorithm of Fruchterman and Reingold (1991). In these figures we identify the set of nodes that are identified using the aforementioned NCP method; these nodes are colored black (dark) in the figure in contrast to the blue (light) color of the remaining nodes. We can see from the Figure 4 that these nodes are on the periphery of the network with lower connectivity compared to the rest of the graph.

We further examine the cluster of reviewers in NIPS 2015 which is not well connected with the rest. In Figure 5, we plot the decomposition of this set in terms of the primary subject areas indicated by the reviewers. Our analysis reveals that a bulk of this cluster comprises a single subject area—reinforcement learning. Conversely, 50 out of 78 reviewers who identified their primary subject area as reinforcement learning lie in this cluster. All in all, graph connectivity issues of this form can lead to increased noise or bias in the overall decisions. Our main message for future conferences is to employ such methods of graph analysis in order to catch issues of this form *at a global level* (not just local to individual ACs) before the reviews are assigned.

Summary 2: Reviewer assignment

Key observations:

- A cluster of papers and reviewers primarily in the reinforcement learning area are not well connected to the remaining papers and reviewers in the NIPS 2015 reviewer assignments. We did not find any such separated cluster in NIPS 2016.

Action items:

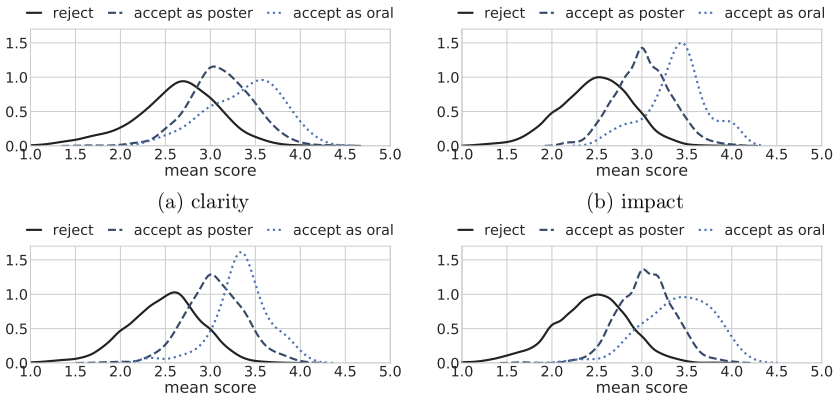
- Use graph-theoretic techniques to check global structure of graph for reviewer assignment.

Open problems:

- Design principled graph-theoretic techniques, tailored specifically to the nuances of peer-review graphs, to verify soundness of reviewer assignments.

3.3 Review-score distribution and mismatches in calibration

Recall from Section 2.3 that in the review process, for each criterion, the reviewers were asked to provide a score on a scale of 1 to 5. Specifically, they were asked to provide a score of 5 for submissions they considered as being in the top 0.1%, a score of 4 for submissions that they deemed to be in the top 3%, and a score of 3 for submissions they deemed to be in the top 30%. In this section, we compare the actual empirical distribution of reviewer scores with the distribution prescribed in the guidelines to reviewers.



(a) clarity (b) impact

(c) novelty (d) quality

Figure 6: Distribution of the mean value (across reviewers) of the score per paper for different criteria, separated according to the final decisions.

We begin by computing the distribution of the mean value (across reviewers) of the score per paper for different criteria, separated according to the final decisions. We plot these distributions in Figure 6 for each of the four criteria of clarity, impact, novelty, and quality separately.

At first glance, these histograms and numbers look quite reasonable. However, what was surprising to us was the percentage of papers that received any particular score – see Table 1. Even though the reviewers were asked to give a paper a score of 3 (poster level) or higher only if they think the paper lies in the top 30% of all papers, nearly 60% of the scores were 3 or higher. Similar effects occurred for scores 4 and 5.

One possible explanation for this phenomenon is that there were a large number of high-quality submissions to NIPS 2016. Such an improvement in quality has obvious upsides

	1 (low or very low)	2 (sub-standard)	3 (poster level: top 30%)	4 (oral level: top 3%)	5 (award level: top 0.1%)
Impact	6.6 %	36.4 %	45.9 %	10.7 %	0.4 %
Quality	6.7 %	38.3 %	45.0 %	9.6 %	0.4 %
Novelty	6.4 %	35.0 %	48.4 %	9.8 %	0.4 %
Clarity	7.1 %	28.1 %	48.9 %	14.7 %	1.2 %

Table 1: Distribution of the reviews according to the provided scores for each of the four criteria. The column headings indicate the guidelines that were provided to the reviewers. Observe that the percentage of reviews providing scores of 3, 4 or 5 is considerably higher than the requested values.

such as uplifting the overall experience of the conference. The downside is that the burden on selecting the accepted papers among all those good submissions is with the area chairs, who now still had to reduce the 60% good papers to 23% accepted papers. A second possible explanation is that the reviewers were not calibrated that well with respect to the paper quality. A third possible explanation is that the elicitation was in terms of a score in the set $\{1, 2, 3, 4, 5\}$ which represents a linear scale with equal spacing, whereas the text instructions expected reviewers to rate on a non-linear scale. This mismatch could be a source of bias in the elicited ratings. Using a linear rating scale when the actual elicitation is non-linear is a common practice in many conferences, and it will be useful to perform a similar analysis on the data from these conferences. In either case, we understand that this obviously led to the frustration of many authors, whose papers received good scores but were rejected.

In addition to scores for the four criteria, the reviewer could also indicate whether the paper had a "fatal flaw". We observe that 32% of all papers were flagged to have a "fatal flaw" by at least one reviewer.

Summary 3: Review-score distribution and mismatches in calibration

Key observations:

- The fraction of reviews with high ratings is significantly higher than what was asked from the reviewers. For instance, nearly 60% of scores are 3 or higher even though reviewers were asked of scores of 3 or higher only when they thought the paper was in the top 30% of submissions.

Action items:

- If eliciting ratings, do not use numbered scales (that is, do not use "1", "2", ...). Alternatively, one may employ other means of elicitation such as rankings.
- When making reviews visible to authors, show the percentile with respect to the data instead of absolute scores, e.g., provide feedback of the form "your paper is in the top 40% of all submitted papers in terms of novelty..."
- Include an expert in elicitation, survey methodology or user interface design to help to design what and how to ask (O'Hagan et al., 2006).

Open problems:

- Since each reviewer reviews only a small subset of the submitted papers, how to calibrate the reviews?
- What is the best interface for eliciting reviewer responses?
- What is the best way to present the review results to authors in order to provide most useful feedback and minimizing distress?

3.4 Different types of reviewers

In this section, we compare the reviews provided by the volunteer (pool 2) reviewers to those provided by the invited (pool 1) reviewers. The inclusion of volunteer reviewers has two important benefits: (a) It increases the transparency of the review process. (b) Volunteer

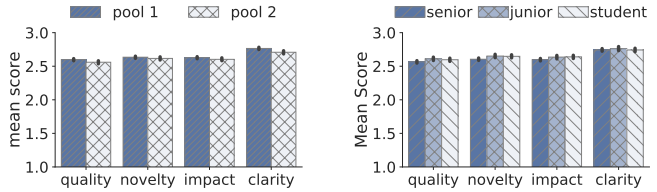
reviewers may be new today but in 2 years down the line they will gain experience and become useful to accommodate the massive growth of the conference. Given these benefits of including volunteer reviewers, this analysis looks for any systematic differences between the review scores provided by the two pools of reviewers.

Mean scores.

Junior reviewers are often perceived to be more critical than senior reviewers (Tomiyama, 2007; Toor, 2009). As Tomiyama (2007) notes, *"You submit your manuscript and then just pray it doesn't get sent to a junior faculty member – young faculty are merciless!"* In this section, we examine this hypothesis in the NIPS 2016 reviews. In Figure 7, we plot the mean score provided by each group of reviewers for each individual criterion. We apply a t-test on observed scores and compute the effect size to examine if there is a statistically significant difference in the underlying means of the scores provided by different categories of reviewers. For Pool 1 vs Pool 2, this analysis shows only clarity to have a statistically significant difference between the two pools after accounting for multiple testing. Specifically, the p-values (before accounting for multiple testing) and effect sizes for the four criteria are: novelty p=0.2143, d= 0.0264, quality p=0.0061, d= 0.0581, impact p=0.0961, d= 0.0353, and clarity p=1.91×10^{-04}, d= 0.0788. Sample sizes for Pool 1 and Pool 2 reviews are 9244 and 4430 respectively.

A similar analysis between senior researchers (e.g., faculty), junior researchers (e.g., postdocs), and PhD students reveals no significant difference between these categories. The remainder of this paragraph details the p-values and effect sizes. The p-values (before accounting for multiple testing) and effect sizes for senior researcher vs. junior researchers for the four criteria are: quality p=0.0071, d= −0.0662, novelty p=0.0037, d= −0.0704, impact p=0.0199, d= −0.0569, and clarity p=0.3064, d= −0.0253; for junior researcher vs. students: quality p=0.4662, d= 0.0164, novelty p=0.8247, d= 0.0049, impact p=0.8733,d= −0.0036, and clarity p=0.3529, d= 0.0209; for senior researcher vs. students: quality p=0.0440, d= −0.0454, novelty p=0.0499, d= −0.0629, impact p=0.0076, d= −0.0601 and clarity p=0.9968, d= 0.00009. The sample sizes for senior, junior and student reviews are: 6335, 3938, and 3354 respectively. This analysis excludes 47 reviews by reviewers who did not identify themselves as any of the above categories.

Self-reported confidence. We next study the difference in the self-reported confidence among different groups of reviewers. The mean value of reported confidence is plotted in



(a) invited and volunteer reviewers (b) senior, junior, and student reviewers

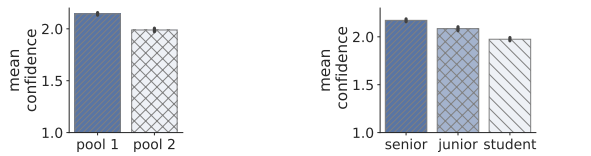
Figure 7: Mean of scores provided for different criteria grouped by different reviewer types.

Figure 8. In this case, we see a statistically significant correlation between seniority and self-reported confidence. Following are p-values (before accounting for multiple testing) and corresponding effect sizes: senior vs. junior researcher: p=4.1683×10^{-11}, d= 0.1604, senior researcher vs. PhD student: p=3.308×10^{-57}, d= 0.3577 and junior researcher vs. PhD student: p=8.074×10^{-15}, d= 0.1758. We observe a similar difference in confidence score and effect size between pool 1 and pool 2 reviewers: p=3.9679×10^{-44}, d= 0.2943.

Consistency. We now study the consistency within reviewers of pool 1 (invited), and within reviewers of pool 2 (volunteer). The consistency captures the amount of variance or disagreements in the reviews provided by that pool. As noted by Ragone et al. (2013), *"the disagreement among reviewers is a useful metric to check and monitor during the review process. Having a high disagreement means, in some way, that the judgment of the involved peers is not sufficient to state the value of the contribution itself. This metric can be useful to improve the quality of the review process..."*

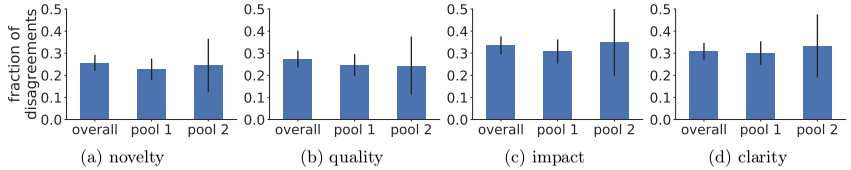
Concretely, consider any pair of reviewers within a given pool, any pair of papers that is reviewed by both the reviewers, and any criterion. We say that this pair of reviewers agrees on this pair of papers (for this criterion) if both reviewers rate the same paper higher than the other; we say that this pair disagrees if the paper rated higher by one reviewer is rated lower by the other. Ties are discarded. We count the total number of such agreements and disagreements within each of the two pools.

Figure 9 plots the fraction of disagreements within each of the two pools for the cardinal scores. At this aggregate level, we do not see enough difference to conclusively rate any one pool's intra-pool agreement above the other (note that the sample size for pool 2 is small, as listed below). Specifically, for the Pearson's chi-squared test and effect sizes of pool 1 vs. pool 2, the results for the four criteria (before accounting for multiple testing) are: novelty



(a) invited and volunteer reviewers (b) senior, junior, and student reviewers

Figure 8: Self-reported confidence grouped by different reviewer types.



(a) novelty (b) quality (c) impact (d) clarity

Figure 9: Proportions of inter-reviewer disagreements on each criterion.

p=0.9269 d= -0.0426, quality p=0.8648, d= 0.0039, impact p=0.7296, d= -0.0936, and clarity p=0.8029, d= -0.0709. The total sample sizes for the three categories of overall, pool 1 and pool 2 respectively across the four criteria are: novelty 554, 282 and 49; quality 523, 285 and 41; impact 513, 276 and 37; and clarity 572, 286 and 42. Section 3.8 presents similar consistency results for the two pools in the ordinal rankings. (We also attempted to run this analysis restricted to the top 2k papers, but this restriction results in a very low sample complexity and hence underpowered tests.)

Participation in discussions. One fact that caught our attention was the amount of participation in the discussion by the different reviewer groups: senior reviewers take much more active roles in the discussions than junior researchers. Please see Section 3.5.1 for details, where we provide a more detailed study of the discussion phase.

Summary 4: Different types of reviewers

Key observations:

- We find no evidence of a critical bias of junior reviewers (except for a small difference in the "clarity" criterion).
- Self-reported confidence correlates with seniority.
- Volunteer reviewers yield benefits of scalability and transparency, with no observable biases and a similar inter-reviewer agreement as the invited pool. These reviewers can soon be an asset in dealing with the rapid growth of conferences such as NIPS.

Action items:

- Continue to include volunteer reviewers with an appropriate moderation of their reviews.

Open problems:

- How do we make most effective use of volunteer reviewers in a manner that authors can trust, which reduces randomness in the peer-review process, and trains junior reviewers effectively?

3.5 Rebuttals and discussions

This section is devoted to the analysis of the rebuttal stage and the participation of reviewers in discussions. We begin with some summary statistics. The authors of 2188 papers submitted a rebuttal. There were a total of 12154 reviews that came in before the rebuttals started, and with some more reviews received after the rebuttal round, the total number of {reviewer, paper} pairs eventually ended up being 13674. Out of the 12154 reviews that were submitted before the rebuttals, the scores of only 1193 changed subsequently. These changed review scores were distributed among 886 papers.

There were 842 papers for which no reviewer participated in the discussions, 339 papers for which exactly one reviewer participated, and 436, 376, 218, 135 and 49 papers for which 2, 3, 4, 5 and 6 reviewers participated respectively. There were a total of 5255 discussion posts, and 4180 of the 13674 {reviewer, paper} pairs participated in the discussions.

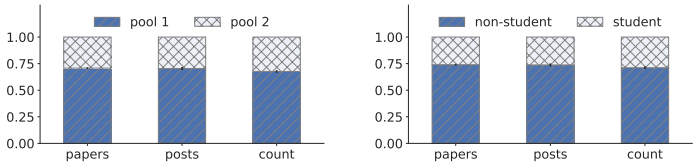
3.5.1 Who participates in discussions?

We compare the amount of participation of various groups of reviewers in the discussion phase of the review process.

Pool 1 (invited) versus pool 2 (volunteer) reviewers. We compare the participation of the reviewers in two pools in the discussions as follows, and plot the results in Figure 10(a). In order to set a baseline, we first compute the total number of {pool 1 reviewer, paper} pairs and the total number of {pool 2 reviewer, paper} pairs – these counts are computed irrespective of whether the reviewer participated in the discussions or not. We plot the proportions of these counts as the "count" bar in the figure. Next we compute the total number of posts made by pool 1 reviewers and that made by pool 2 reviewers – the resulting proportions are plotted as the "posts" bar in the figure. Finally, we compute the number of {pool 1 reviewer, paper} pairs in which that reviewer put at least one post in the discussion for that paper, and the number of {pool 2 reviewer, paper} pairs in which that reviewer put at least one post in the discussion for that paper. We plot the two proportions in the "papers" bar. The total sample sizes for the categories of counts, posts and papers are 13674, 5255 and 4180 respectively.

We tested whether the mean number of posts per {reviewer, paper} pair is identical for the two pools of reviewers. For the null hypothesis that the means are identical for the two pools of reviewers, the t-test yielded $p = 1.36 \times 10^{-4}$. We also conducted this analysis for the restriction of papers to the top 2k, and for this subset, the t-test yielded $p = 9.458 \times 10^{-4}$. We see a statistically significantly higher participation by the pool 1 reviewers as compared to the pool 2 reviewers in the discussions. However, the absolute amount of participation by either group is moderate at best, and the effect sizes are small with d= 0.0704 and d= 0.0894 for analysis of all papers and top 2k papers respectively.

Student versus non-student reviewers. We calculated the above three sets of quantities for student and non-student reviewers. Figure 10(b) depicts the results. We tested whether the mean number of posts per {reviewer, paper} pair for the student reviewers is identical to the non-student reviewers. For the null hypothesis that the means are identical, the t-test yielded $p = 3.016 \times 10^{-4}$. When restricted to the top 2k papers, the t-test yielded $p = 8.932 \times 10^{-4}$. We see a statistically significantly higher participation by the non-student reviewers as compared to the student reviewers in the discussions. However, the total amount



(a) invited and volunteer reviewers (b) student and non-student reviewers

Figure 10: Proportions of contributions from different types of reviewers in discussions ("posts" and "papers") and the total number of such reviewers ("count").

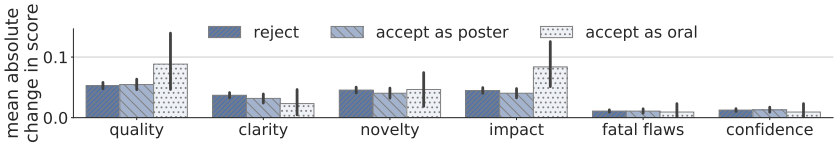


Figure 11: Mean absolute value of the change in the scores from before the rebuttal round to the end of the discussion phase.

of participation by either group is not too large, and the effect sizes are small with d= 0.0695 and d= 0.0929 respectively.

3.5.2 How do discussions change the scores?

A total of 1193 out of 12154 reviews that were submitted before rebuttals changed subsequently. These changed reviews were distributed among 886 papers. As a result, the amount of change in review scores is quite small. Figure 11 depicts the score change – in absolute value – averaged across all reviewers and all papers. While the allowed range of the scores is 1 to 5, the change in mean score is less than 0.1.

From the point of view of reviewers, we see a significant correlation between participation in the discussions and the final decisions. Specifically, for each paper we computed the mean of the scores given by all reviewers who participated in the discussions and the mean of the scores given by all reviewers who did not participate (when there was at least one reviewer of each type). We discarded this paper if both types of reviewers provided an identical mean score. If the participating reviewers gave a higher mean score than the non-participating reviewers and if the paper was accepted, we counted it as an agreement of the final decision with the participating reviewers. If the participating reviewers gave a lower mean score than the non-participating reviewers and if the paper was not accepted, then also we count it as an agreement of the final decision with the participating reviewers. Otherwise, we counted the paper as having a disagreement between the final decisions and the participating reviewers. From the data, we observe a statistically significant agreement of the final decisions and the participating reviewers with $p = 1.6 \times 10^{-6}$ with d= 0.13. We continue to observe a statistically significant correlation when this analysis is performed restricted to pool 1 reviewers ($p = 7.7 \times 10^{-4}$) or to pool 2 reviewers ($p = 1.3 \times 10^{-4}$) alone. Of course, we cannot tell the causality from this correlation, as to whether the discussions actually influenced the decisions or not.

All in all, we observe that only a small fraction of the reviews change scores following the rebuttals. Moreover the magnitude of this change in scores is very small. This observation suggests that this rebuttal process may not be very useful. That said, there are various qualitative aspects that are not accommodated in this quantitative aggregate statistic. First, it may be possible that more reviews changed with respect to the text comments but the reviewers just did not bother to change the scores – we are unable to check this property since there is no snapshot of the text comments before the rebuttal. Second, there are a reasonable number of discussion posts, however, we do not know what fraction of these posts where reviewers shifted from their earlier opinion. Third, the final decisions are correlated positively

with the reviewers who participated in discussions. Taking these factors into account, we think that the present rebuttal system should be put under the microscope regarding its value for the time and effort of such a large number of people. It may also be worth trying alternative systems of recourse for authors, such as a formal appeals process, that help to put more focus on the actual borderline cases.

Summary 5: Rebuttals and discussions

Key observations:

- There is little change in scores post-rebuttal and a moderate amount of discussion.
- Invited and non-student reviewers participate marginally more in the discussions.
- Final decisions correlated with scores given by reviewers who participated in discussions, even when stratified by individual pools.

Action items:

- Force every reviewer to change or confirm their scores after the end of the discussion session.

Open problems:

- How to incentivize reviewer participation in rebuttals/discussions?
- How to de-bias reviewers from their initial opinion?
- Compare the amount of discussion and changes in scores with that in open review processes (particularly when open reviews are used for conferences of this scale).
- Compare the efficiency of the rebuttal process with a post-decision appeal procedure to catch only cases that deserve discussion (i.e., possible mistakes).

3.6 Distribution across subject areas

Figure 12 plots scatter plot of the number of submitted papers and the number of accepted papers per (primary) subject area. Of course the proportions are not identical, but the plots do not show any systematic bias either towards or against any particular areas. A chi-square test of homogeneity of the two distributions failed to detect any significant difference between the two distributions: p=0.6029, $\chi^2(dof = 62, \#samples = 2425) = 57.51$.

Summary 6: Distribution across subject areas

Key observations:

- No observable bias across subject areas in terms of final acceptances.

Action items:

- Test for systematic biases for/against any subject area before announcing decisions.

Open problems:

- How to assimilate different, subjective opinions of reviewers across subject areas.

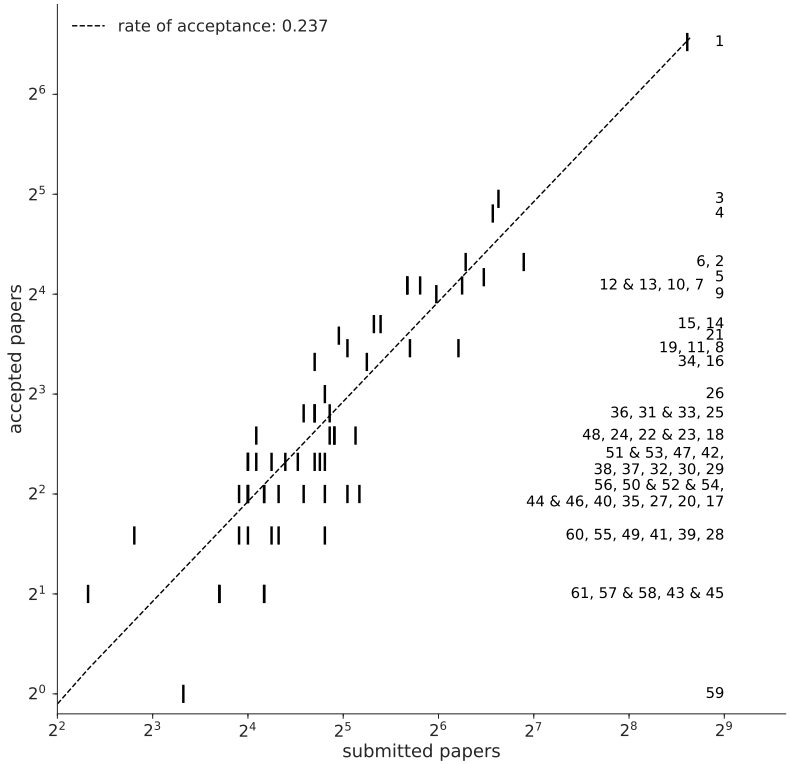

Figure 12: Number of accepted vs submitted papers per (primary) subject area. The indices of the subject areas are provided on the right of the corresponding points and their names are provided in Appendix A. For subject areas with same number of accepted papers, the labels associated with each subject area are listed (from left to right) in ascending order of number of submitted papers; if the number of submitted papers is also identical then the indices are grouped with an "&" sign. Both axes are on a logarithmic scale. The plot excludes subject area 62 since it had no accepted papers.

3.7 Quantifying the randomness

Quantifying the extent to which the outcome of a peer-review process is different from a random selection of papers is one of the most pressing questions for the scientific community (Somerville, 2016). In this section, we conduct two analyses to quantify the randomness in the review scores in NIPS 2016.

3.7.1 Messy middle model

The NIPS 2014 experiment (Lawrence and Cortes, 2014) led to the proposal of an interesting "messy middle" model (Price, 2014). The messy middle model postulates that the best and the worst papers are clear accepts and clear rejects respectively, whereas the papers in the middle suffer from random decisions that are independent of the content of the papers. The messy middle model is obviously a stylized model, but it nevertheless suggests an interesting investigation into the randomness in the reviews and decisions of the papers that lie in the middle. In this section, we describe such an investigation using the NIPS 2016 data.

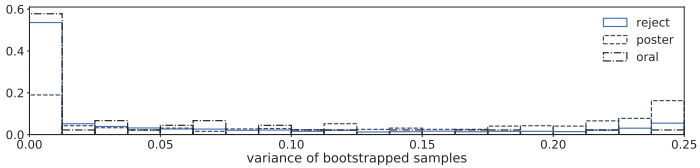
The messy middle model assumes random judgments for the middle papers. If the messy middle model were correct then for any pair of papers in the middle, and any pair of common reviewers, the probability of an agreement on the relative ranking of the two papers must be identical to the probability of disagreement. With this model in mind, we restrict attention to the papers in the middle, and then measure how far the agreements of the reviewers are from equiprobable agreements and disagreements. An analysis of this quantity for various notions of the "middle" papers yields insight into the messiness in the reviews for papers in the middle.

Procedure: We now describe the procedure employed for the analysis. Here we let n denote the total number of papers submitted to the conference and β denote the fraction of papers accepted to the conference (we have $n = 2425$ and $\beta = 0.237$ in NIPS 2016). The procedure is associated to two parameters: μ is the minimum number of samples required and α is a threshold of messiness. We choose $\mu = 100$ and $\alpha = 0.01$ in our subsequent analysis, noting that the overall conclusions are robust to these choices.

1. Rank order all papers with respect to their mean scores. Denote this ordering as Θ.
2. For every $t \in [0, 1]$ and $b \in [0, 1]$ (up to some granularity), do the following.
   - 2.1 Initialize variables $n_{\text{agree}}[t, b] = n_{\text{disagree}}[t, b] = 0$.
   - 2.2 Consider the set of papers obtained by removing the top t fraction of papers and bottom b fraction of papers from Θ. Denote this (unordered) set of "middle papers" as M.
   - 2.3 If $(\beta - t)n < \mu$ or $((1 - \beta) - b)n < \mu$ then continue to the next values of (t, b) in Step 2.
   - 2.4 Consider any pair of reviewers and any pair of papers in M that is reviewed by both the reviewers. We say that this pair of reviewers agrees on this pair of papers if both reviewers provide a higher mean score (mean computed across all criteria) to the same paper as compared to the other paper. We say that this pair disagrees if the paper rated higher by one reviewer (in terms of the mean score across the criteria) is rated lower by the other reviewer. Ties are discarded. We count the total number of such agreements (denoted as $n_{\text{agree}}[t, b]$) and disagreements (denoted as $n_{\text{disagree}}[t, b]$) within each of the two pools.
3. Find the largest value of $(1-t-b)$ such that we have $(n_{\text{agree}}[t, b]+n_{\text{disagree}}[t, b]) \geq \mu$ and $\frac{n_{\text{agree}}[t,b]}{n_{\text{agree}}[t,b]+n_{\text{disagree}}[t,b]} < 0.5+\alpha$. This largest value of $(1-t-b)$ is defined as the size of the messy middle.

Conference	Size of messy middle
NIPS 2015	45%
NIPS 2016	30%

(a) Size of the messy middle windows.



(b) Histogram of the variance of acceptance decisions (according to mean scores) of the papers in a bootstrapped analysis.

Figure 13: Amount of randomness in the reviews.

Let us spend a moment interpreting some steps of the procedure. Step 2.3 and the μ-condition in Step 3 ensure that there are a sufficient number of samples for any computation on the messy middle region. Specifically, the conditions $(\beta - t)n < \mu$ and $((1 - \beta) - b)n < \mu$ ensure existence of a sufficient number of papers above and below the acceptance threshold. Under this constraint, Step 3 then finds the largest window of papers in the middle such that the fraction of reviewer-agreements is at most $(0.5 + \alpha)$. If the objective is to minimize inter-reviewer disagreement (Cole et al., 1981; Whitehurst, 1984; Lindsey, 1988), then a *smaller* size of the window is a desirable property.

We can now use this analysis to compare messy middle window sizes for two or more conferences. When making such a comparison, we make one adjustment. In the last step (Step 3), we consider only those values of (t, b) such that $n_{\text{agree}}[t, b] + n_{\text{disagree}}[t, b] \geq \mu$ for both datasets. We compare the sizes of the messy middle considering only these values.

Results: We used this procedure to compute the size of the messy middle in NIPS 2016 and also in NIPS 2015. The granularity we used is 1/20, that is, $t, b \in \{0, 1/20, 2/20, \ldots, 1\}$. NIPS 2015 had a marginally higher average number of reviews per paper as compared to NIPS 2016. We set $\mu = 100$ and $\alpha = 0.01$ (note that the conclusions drawn below are robust to these choices). The results of the analysis are tabulated in Figure 13a.

In the NIPS 2016 data, we observe that the size of the messy middle is 30%. Specifically, if we remove the bottom 70% of papers (and none of the top papers) then we see that the inter-reviewer agreements are near-random, but farther from random otherwise. On the other hand, we observe that the size of the messy middle is 45% in the NIPS 2015 data, which occurs when removing 15% of the top papers and 40% of the bottom papers.

Such an analysis is useful in comparing the noise in the review data across conferences. It can particularly be useful to evaluate the effects of any changes made in the peer-review process. The ease of doing this post hoc analysis, without necessitating any controlled experiment, is a significant benefit to this approach of analysis. In order to enable comparisons of the size of the messy middle of NIPS 2016 with other conferences, we provide the values of

$\frac{n_{\text{agree}}[t,b]}{n_{\text{agree}}[t,b]+n_{\text{disagree}}[t,b]}$ and $(n_{\text{agree}}[t,b] + n_{\text{disagree}}[t,b])$ for the NIPS 2016 data for all values of (t, b) in Appendix B.

It is important to note that this post hoc analysis is not strictly comparable to the NIPS 2014 controlled experiment because we do not have access to a true ranking or a counterfactual. That said, since such an analysis can easily be performed post hoc using the data from reviews and does not require any special arrangement in the review process, it would be useful to see how these results compare to the data from other conferences.

3.7.2 A bootstrapped analysis

In this section, we conduct an analysis to measure the randomness in the reviews in the NIPS 2016 data compared to that of random selection. In our analysis, we first conduct 1000 iterations of the following procedure. For each paper, we consider the set of reviewers who reviewed this paper. We then choose the same number of reviewers uniformly at random with replacement from the set of original reviewers for this paper. We then take the mean of the scores across all criteria and across all the sampled reviewers for that paper. Next we rank order all papers in terms of these mean scores and choose the top 23.7% of the papers as "accepted" in this iteration and the others as rejected.

Our analysis focuses on the variance of the acceptance decisions for each paper. At the end of all iterations, for each paper, we compute the fraction of iterations in which the paper was accepted. Letting $\beta_i \in [0, 1]$ denote this fraction for any paper i, the variance in the acceptance decisions for this paper equals $\beta_i(1 - \beta_i)$. We plot a histogram of the computed variances (for every paper) in Figure 13b. For comparison, note that in an ideal world, the variance of the decisions for each paper would be zero. Observe that a large fraction of rejected papers as well as a large fraction of papers that were accepted as oral presentations have a near-zero variance. On the other hand, a notable fraction of papers accepted as posters as well as those rejected have a variance close to its largest possible value of $\frac{1}{4}$.

We conclude with a clarifying comment. In the NIPS 2016 data, the messy middle analysis outputs the top 30% of the papers as most noisy, while the bootstrap analysis shows a very low variance on the top (oral) papers. This may appear as a contradiction, but it is not. Notice that the messy middle analysis primarily focuses on the reviewers' opinions on the pairwise-relative values of reviews. On the other hand, the bootstrapped analysis focuses on values of reviews in relation to all other papers. Thus we have that there is a significant amount of disagreement at the top regarding which paper is better within the top set of papers, but a significant agreement that most of these papers are good enough for acceptance in an absolute sense.

Summary 7: Quantifying the randomness

Key observations:

- A notable subset of papers incurs "messy middle" randomness. The messy middle region is smaller in NIPS 2016 as compared to NIPS 2015.
- A bootstrapped analysis shows a significant variance in reviewer scores for a notable fraction of papers that are accepted as posters. A large fraction of papers accepted for oral presentations or rejected have near-zero variance.

Action items:

- Measure and compare post hoc goodness (using the analyses in this paper or through other methods) of various review processes in order to choose a good review process in a data-dependent manner.

Open problems:

- Principled design of statistical tests for post hoc comparison of goodness of different review processes.

3.8 Ordinal data collection

The data collected from the reviewers in the NIPS 2016 review process comprises cardinal ratings (in addition to the free-form text-based reviews) where reviewers score each paper on four criteria on a scale of 1 to 5. A second form of data collection that is popular in many applications, although not as much in conference reviews, is ordinal or comparative ranked data. The ordinal data collection procedure that we consider asks each reviewer to provide a total ordering of all papers that the reviewer reviewed.

There are various tradeoffs between collecting cardinal ratings and ordinal rankings. In the context of paper reviews, cardinal ratings make reviewers read each individual paper more carefully (and not make snap judgments), and can elicit more than a just one bit of information. On the other hand, ordinal rankings allow for nuanced comparative feedback, help avoid ties, and are free of various biases and calibration issues that otherwise arise in cardinal scores (Harzing et al., 2009; Krosnick and Alwin, 1988; Russell and Gray, 1994; Rankin and Grube, 1980; Cambre et al., 2018). We refer the reader to the papers by Barnett (2003); Stewart et al. (2005); Shah et al. (2016a,b); Heckel et al. (2016) and references therein for more details on ordinal data collection and processing. In the present paper, we present three sets of analyses with the ordinal rankings collected from reviewers.

3.8.1 Tie breaks

An ordinal ranking of the papers provided by a reviewer ensures that there are no ties in the reviewer's evaluations. On the other hand, asking cardinal scores can result in scores that are tied, thereby preventing an opportunity for the AC to discern a difference between the two papers from the provided scores.

In order to evaluate the prevalence of ties under cardinal scores, we performed the following computation. For every {`paper`, `paper`, `reviewer`} triplet such that the reviewer

reviewed both papers, and for any chosen criterion (i.e., quality, novelty, impact, and clarity), we computed whether the reviewer provided the same score to both papers or not. We totaled such ties and non-ties across all such triplets.

Figure 14 depicts the proportion of ties computed across all submitted papers. The total sample size is 26106. Observe that a significant fraction – exceeding 30% for each of the four criteria – of pairs of reviewer scores are tied. When only the top 2k papers were used in the calculation, the fraction of ties in each criterion further increases by approximately 10% to 15% of the respective value in the setting of all papers. In conclusion, these results reveal a significant proportion of ties in the cardinal scoring scheme. The use of ordinal rankings, on the other hand, does not suffer from such a drawback.

3.8.2 Consistency of ordinal ranking data

While there is substantial literature on benefits of collecting data in an ordinal ranking form, several past works also recommend verifying if the application setting under consideration is appropriate for ordinal rankings. For instance, Russell and Gray (1994) state the benefits of ranking for settings "where the items are highly discriminable"; Peng et al. (1997) ask respondents to rank 18 values in order of importance but observe unstable and inconsistent results; Harzing et al. (2009) argue that ranking generally requires a higher level of attention than rating and that asking respondents to rank more than a handful of statements puts a very high demand on their cognitive abilities. Accordingly, this section is devoted to performing sanity checks on the ordinal ranking data obtained in NIPS 2016. We do so by comparing certain measures of consistency of the ordinal data with the cardinal ratings for the four criteria.

Agreements within ordinal rankings. For every pair of papers that have two reviewers in common, we compute whether these two reviewers agree on the relative ordinal ranking of the two papers or if they disagree. In more detail, we say that a pair of reviewers agrees on a pair of papers if both reviewers rank the same paper higher than the other in their respective ordinal rankings; we say that this pair disagrees if the paper ranked higher by one reviewer is ranked lower by the other. Figure 15a depicts the proportion of disagreements for the ordinal rankings in the entire set of papers, as well as broken down by the type of reviewer. First,

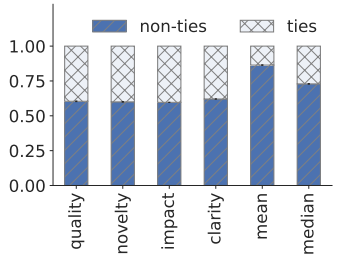


Figure 14: Proportion of ties in reviewer scores. The bars titled "mean" and "median" represent the mean and median scores across all four criteria.

observe that the ordinal rankings have a comparable level of consistency as that observed in the cardinal scores in Figure 9. Second, we observe no statistically significant difference between the two pools: p=0.9849 for Pearson's chi-squared test and effect size d= 0.0018. The sample sizes are 696, 348 and 56 for all reviewers, pool 1 and pool 2 respectively.

Agreement of ordinal rankings with cardinal ratings. Let us now evaluate how well the overall ordinal rankings associate with the cardinal scores given for the individual criteria. For every pair of papers that have a common reviewer, we compare whether the relative ordering of the cardinal scores for a given criterion agree with the ordinal ranking given by the reviewer for the pair of papers. We report the proportion of disagreements in Figure 15b. We observe the high amount of agreement of the ordinal rankings with the cardinal scores – for instance, the median cardinal score agrees in about 90% of cases with the overall ordinal rankings provided by the reviewers.

Agreement of ordinal rankings with final decisions. We finally compute the amount of agreement between the ordinal rankings provided by the reviewers and the final decisions of acceptance. We consider all {paper, paper, reviewer} triplets where the reviewer reviewed both papers, and one of these papers was eventually accepted and the other was rejected. For every such triplet, we evaluate whether the reviewer had ranked the accepted paper higher than the rejected paper ("agreement") or vice versa ("disagreement"). We report the proportion of agreements and disagreements in Figure 15c. We see that there are roughly five agreements for every disagreement.

When restricted to the top 2k papers, we observe that the disagreements of ordinal rankings with final decisions increase to 27-28% in all three categories (overall, pool 1 and pool 2) from 16-17% in the case of all papers. Note that the experiments on inter-reviewer agreements do not permit an effective analysis when restricted to top 2k papers as the sample size reduces quadratically (that is, reduces to a fraction $.47^2 \approx .2$ of the sample size with all papers).

3.8.3 Detecting anomalies

Ordinal rankings can be used to detect anomalies in reviews. We discuss this aspect in the Section 3.9.

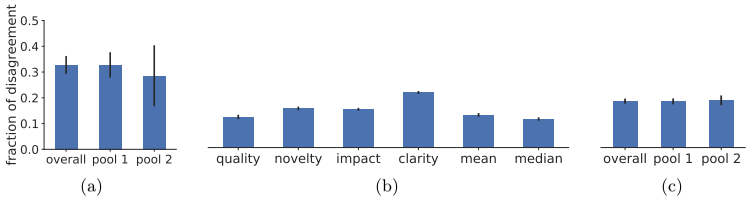

Figure 15: Fraction of disagreements (a) within ordinal rankings between different pairs of reviewer types; (b) between ordinal rankings and cardinal ratings ("mean" and "median" refer to the mean and median of the cardinal scores for the four criteria); and (c) between ordinal rankings and final acceptance decisions.

Summary 8: Ordinal data collection

Key observations:

- Ordinal rankings are a viable option for collecting reviewer opinions.
- There are a large number of ties in ratings provided by reviewers: there are more than 30% ties in each criterion and even greater fraction of ties in the top 2k papers.
- Ordinal rankings can be used to check inconsistencies in the reviews.

Action items:

- Use a hybrid collection method which elicits and combines cardinal ratings and ordinal rankings in a clever manner to avail benefits of both these types of data.

Open problems:

- Perform controlled experiments in order to quantify the benefits and possible problems with ordinal rankings.
- Design algorithms to efficiently combine cardinal ratings for criteria and ordinal overall rankings to provide useful guidelines to area chairs for their decisions.

3.9 Checking inconsistencies

In this section, we propose an automated technique to help reduce some human errors and inconsistencies in the review process. In particular, we propose to automatically check for inconsistencies in the review ratings provided by the reviewers. On finding any such inconsistency, we propose to then have the area chairs either manually investigate this inconsistency or to manually or automatically contact the reviewer requesting an explanation. In what follows, we propose two notions of inconsistencies in regards to the NIPS 2016 review process and quantify their presence in the NIPS 2016 review data.

Anomalies in criteria ratings. We investigate whether any reviewer indicated that paper "A" is strictly better than paper "B" in all four criteria, but rank paper "A" lower than paper "B" in the ordinal ranking. We find that there are 55 such pairs of reviews provided by 44 distinct reviewers. If we restrict attention to the top 2k papers, we find that that there are 10 such pairs of reviews provided by 10 distinct reviewers.[1]

Anomalies in fatal flaws. We now investigate if there are cases when a reviewer indicated a fatal flaw in a paper, but that reviewer ranked it above another paper that did not have a fatal flaw according to the reviewer. We found 349 such cases across 176 such reviewers. The proportion of such cases is similar among volunteer and invited reviewers. Among the top 2k papers, there are 55 such pairs across 33 reviewers.

One may think that the number of such cases is large because ordinal survey was done after the review process, so people may not have remembered the papers well or may not have done a thorough job as they knew it would not count towards the reviews. However,

1. Note that the total number of pairs of papers reduces more than 4-fold when moving from the set of all papers to the top 2k set.

the ordinal data actually is quite consistent with the cardinal data (Section 3.8.2). Hence we do not think such a large discrepancy with fatal flaws can be explained solely due to such a delay-related noise.

Two possible explanations for such anomalies are as follows. Either the reviewer may not have done an adequate job of the review, or the set of provided criteria are grossly inadequate to express reviewers' opinions. In either case, we suggest automatically checking for such inconsistencies (irrespective of whether ordinal or cardinal final ratings are used) during the review process, and contacting the respective reviewers to understand their reasoning.[2] We hope that such a checkpoint will be useful in improving the overall quality of the review process.

Summary 9: Checking inconsistencies

Key observations:

- 55 cases (across 44 reviewers) of a reviewer rating a paper higher than another for all criteria but inverting the relative ranking of the two papers in the overall ordering.
- 349 cases where a reviewer indicated a fatal flaw in a paper but ranked it higher than another paper without any indicated fatal flaw.

Action items:

- Check for inconsistencies in the reviews and contact respective reviewers.

Open problems:

- What other inconsistencies can be checked in an automated manner?

4. Discussion and conclusions

NIPS has historically been the terrain of much experimentation to improve the review process and this paper is our contribution to advance the state of the art in review process design. It is an on-going debate to which extent the decision process should be automated and what means could be used to automate it. We provide some elements to fuel this discussion. In this paper, we reported a post hoc analysis of the NIPS 2016 review process. Our analysis yielded useful insights into the peer-review process, suggested action items for future conferences, and resulted in several open problems towards improving the academic peer-review process, as enumerated throughout this paper.

Our tools include several means of detecting potential artifacts or biases, and statistical tests to validate hypotheses made: Comparing the distribution of topics in submitted papers and accepted papers; creating a graph of proximity of reviewers (according to commonly reviewed papers) and papers (according to common reviewers) to detect potential disconnected communities; test to compare two pools of reviewers; quantifying the noise in the review scores. We also observed that the histogram of scores obtained included a significantly larger

2. This analysis was performed after completion of the review process, and hence reviewers were not contacted for these inconsistencies.

fraction of papers than the guidelines suggested. This observation suggests a more careful design of the elicitation interface and the type of feedback provided to authors.

Selection biases that arise when recruiting reviewers and ACs in a review process of this scale are difficult to deal with. Some designs in the selection of reviewers lend themselves more to bias than others. In NIPS2016, we made some design choices of the review process with the intention of reducing these biases. For instance, the recruitment of volunteer author-reviewers helped increase the diversity of the reviewer pool. They were less prone to selection bias compared to selecting reviewers by invitation only, primarily based on AC recommendations. With respect to reducing bias across AC decisions, we introduced the "AC buddy system" in which pairs of ACs had to make decisions jointly about all their papers. This method scales well with the increase in number of papers, but is sub-optimal to calibrate well decisions since buddy pairs form disjoint decision units (no paper overlap between buddy pairs). However, decision processes based on a conference between several or all ACs, as done in earlier editions of the conference, are also not perfect because decisions are sometimes dominated by self-confident and/or opinionated ACs. Although the evidence we gathered from our analyses did not reveal any "obvious" bias, it does not mean that there is none. We hope that some designs of our review process will shed some lights on ways of improving bias-immune or bias-avoidance procedures for future conferences.

A major challenge facing the NIPS conference is that of scaling the review process with the rapid growth of the conference. To this end, we introduced the idea of inviting *volunteer* author reviewers. Training junior reviewers today will ensure a much larger and stronger reviewer pool in a few years from now. Recruiting more reviewers (between 4 and 6 per paper) ensured that each paper had a better chance to get a few competent reviews. We gave a strong role to the ACs who arbitrated between good and bad reviews and made the final decision. Some of the ACs systematically disregarded volunteer reviews, judging that they could not be trusted. Additionally, next to many PhD students, this brought a considerable amount of senior reviewers in the system as well. Our analysis did not reveal any systematic bias or additional variance in the invited reviewer pool. However, more senior reviewers seem to put more effort into providing detailed reviews, and participating to rebuttals and discussions. Hence we need to find means of encouraging and possibly educating more junior reviewers to participate in these aspects. As a means of self-assessment and encouragement, reviewers could receive statistics about review length, amount of agreement between reviewers, and participation to rebuttals and discussions, as well as figures concerning their own participation.

We evaluated how rebuttals and discussions change the scores. Although this concerns only a minority of papers, we believe that ACs have a key role in arbitrating decisions when there is a controversy and that this is not easy to monitor merely with scores. Since scores do not seem to be consistently updated by reviewers after rebuttal/discussions, maybe the review process should include a score confirmation to make sure that absence of change in score is not due to negligence. Mixing ordinal and cardinal scores may reduce the problems of reviewer calibration, tie breaking, and identifying anomalies possibly due to human error.

All in all, it is important to realize that in a review process of this scale, there is not a single person who really controls what is going on at all levels. Program chairs spend a lot of time on quality control, but definitely cannot control the decisions on all individual papers or the quality of individual reviewers. In the end, we have to trust the area chairs and

reviewers: the better reviews *all of us* provide, the better the outcome of the review process. We as a community must also continue to strive improving the peer-review process itself, via experiments, analysis, and open discussions. This topic in itself is a fertile ground for future research with many useful open problems including those enumerated throughout the paper.

Acknowledgments

We thank the two anonymous reviewers for their valuable suggestions in terms of improving both the content and the presentation of the paper. We thank the action editor Neil Lawrence for the prompt and efficient handling of the paper. This work would not have been possible without the support of the NIPS foundation and the entire committee of the NIPS 2016 conference. We thank the program chairs and program managers of the NIPS 2015 conference for their help during the organization. We thank Baiyu Chen for preliminary experiments conducted on ordinal data.

Isabelle Guyon acknowledges funding from the Paris-Saclay scientific foundation. Abstract

Using established principles from Statistics and Information Theory, we show that invariance to nuisance factors in a deep neural network is equivalent to information minimality of the learned representation, and that stacking layers and injecting noise during training naturally bias the network towards learning invariant representations. We then decompose the cross-entropy loss used during training and highlight the presence of an inherent overfitting term. We propose regularizing the loss by bounding such a term in two equivalent ways: One with a Kullbach-Leibler term, which relates to a PAC-Bayes perspective; the other using the information in the weights as a measure of complexity of a learned model, yielding a novel Information Bottleneck for the weights. Finally, we show that invariance and independence of the components of the representation learned by the network are bounded above and below by the information in the weights, and therefore are implicitly optimized during training. The theory enables us to quantify and predict sharp phase transitions between underfitting and overfitting of random labels when using our regularized loss, which we verify in experiments, and sheds light on the relation between the geometry of the loss function, invariance properties of the learned representation, and generalization error.

Keywords: Representation learning; PAC-Bayes; information bottleneck; flat minima; generalization; invariance; independence;

1. Introduction

Efforts to understand the empirical success of deep learning have followed two main lines: Representation learning and optimization. In optimization, a deep network is treated as a black-box family of functions for which we want to find parameters (*weights*) that yield good generalization. Aside from the difficulties due to the non-convexity of the loss function, the fact that deep networks are heavily over-parametrized presents a theoretical challenge: The bias-variance trade-off suggests they may severely overfit; yet, even without explicit regularization, they perform remarkably well in practice. Recent work suggests that this is related to properties of the loss landscape and to the implicit regularization performed by stochastic gradient descent (SGD), but the overall picture is still hazy (Zhang et al., 2017).

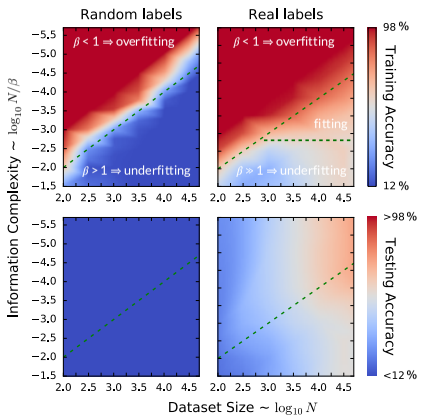

Figure 1: **(Left)** The AlexNet model of Zhang et al. (2017) achieves high accuracy (red) even when trained with random labels on CIFAR-10. Using the IB Lagrangian to limit information in the weights leads to a sharp transition to underfitting (blue) predicted by the theory (dashed line). To overfit, the network needs to memorize the dataset, and the information needed grows linearly. **(Right)** For real labels, the information sufficient to fit the data without overfitting saturates to a value that depends on the dataset, but somewhat independent of the number of samples. Test accuracy shows a uniform blue plot for random labels, while for real labels it increases with the number of training samples, and is higher near the critical regularizer value $\beta = 1$.

Representation learning, on the other hand, focuses on the properties of the representation learned by the layers of the network (the *activations*) while remaining largely agnostic to the particular optimization process used. In fact, the effectiveness of deep learning is often ascribed to the ability of deep networks to learn representations that are insensitive (invariant) to nuisances such as translations, rotations, occlusions, and also "disentangled," that is, separating factors in the high-dimensional space of data (Bengio, 2009). Careful engineering of the architecture plays an important role in achieving insensitivity to simple geometric nuisance transformations, like translations and small deformations; however, more complex and dataset-specific nuisances still need to be learned. This poses a riddle: *If neither the architecture nor the loss function explicitly enforce invariance and disentangling, how can these properties emerge consistently in deep networks trained by simple generic optimization?*

In this work, we address these questions by establishing information theoretic connections between these concepts. In particular, we show that: (a) a sufficient representation of the data is invariant if and only if it is minimal, *i.e.*, it contains the smallest amount of information, although may not have small dimension; (b) the information in the representation, along with its total correlation (a measure of disentanglement) are tightly bounded by the information that the weights contain about the dataset; (c) the information in the weights, which is related to overfitting (Hinton and Van Camp, 1993), flat minima (Hochreiter and Schmidhuber, 1997), and a PAC-Bayes upper-bound on the test error (Section 6),

can be controlled by implicit or explicit regularization. Moreover, we show that adding noise during the training is a simple and natural way of biasing the network towards invariant representations.

Finally, we perform several experiments with realistic architectures and datasets to validate the assumptions underlying our claims. In particular, we show that using the information in the weights to measure the complexity of a deep neural network (DNN), rather than the number of its parameters, leads to a sharp and theoretically predicted transition between overfitting and underfitting regimes for random labels, shedding light on the questions of Zhang et al. (2017).

1.1 Related work

The Information Bottleneck (IB) was introduced by Tishby et al. (1999) as a generalization of minimal sufficient statistics that allows trading off fidelity (sufficiency) and complexity of a representation. In particular, the IB Lagrangian reduces finding a minimal sufficient representation to a variational optimization problem. Later, Tishby and Zaslavsky (2015) and Shwartz-Ziv and Tishby (2017) advocated using the IB between the test data and the activations of a deep neural network, to study the sufficiency and minimality of the resulting representation. In parallel developments, the IB Lagrangian was used as a regularized loss function for learning representation, leading to new information theoretic regularizers (Achille and Soatto, 2018; Alemi et al., 2017a; Alemi et al., 2017b).

In this paper, we introduce an IB Lagrangian between the weights of a network and the training data, as opposed to the traditional one between the activations and the test datum. We show that the former can be seen both as a generalization of Variational Inference, related to Hinton and Van Camp (1993), and as a special case of the more general PAC-Bayes framework (McAllester, 2013), that can be used to compute high-probability upper-bounds on the test error of the network. One of our main contributions is then to show that, due to a particular duality induced by the architecture of deep networks, minimality of the weights (a function of the training dataset) and of the learned representation (a function of the test input) are connected: in particular we show that networks regularized either explicitly, or implicitly by SGD, are biased toward learning invariant and disentangled representations. The theory we develop could be used to explain the phenomena described in small-scale experiments in Shwartz-Ziv and Tishby (2017), whereby the initial fast convergence of SGD is related to sufficiency of the representation, while the later asymptotic phase is related to compression of the activations: While SGD is seemingly agnostic to the property of the learned representation, we show that it does minimize the information in the weights, from which the compression of the activations follows as a corollary of our bounds. Practical implementation of this theory on real large scale problems is made possible by advances in Stochastic Gradient Variational Bayes (Kingma and Welling, 2014; Kingma et al., 2015).

Representations learned by deep networks are observed to be insensitive to complex nuisance transformations of the data. To a certain extent, this can be attributed to the architecture. For instance, the use of convolutional layers and max-pooling can be shown to yield insensitivity to local group transformations (Bruna and Mallat, 2011; Anselmi et al., 2016; Soatto and Chiuso, 2016). But for more complex, dataset-specific, and in particular non-local, non-group transformations, such insensitivity must be acquired as

part of the learning process, rather than being coded in the architecture. We show that a sufficient representation is maximally insensitive to nuisances if and only if it is minimal, allowing us to prove that a regularized network is naturally biased toward learning invariant representations of the data.

Efforts to develop a theoretical framework for representation learning include Tishby and Zaslavsky (2015) and Shwartz-Ziv and Tishby (2017), who consider representations as stochastic functions that approximate minimal sufficient statistics, different from Bruna and Mallat (2011) who construct representations as (deterministic) operators that are invertible in the limit, while exhibiting reduced sensitivity ("stability") to small perturbations of the data. Some of the deterministic constructions are based on the assumption that the underlying data is spatially stationary, and therefore work best on textures and other visual data that are not subject to occlusions and scaling nuisances. Anselmi et al. (2016) develop a theory of invariance to locally compact groups, and aim to construct maximal ("distinctive") invariants, like Sundaramoorthi et al. (2009) that, however, assume nuisances to be infinite-dimensional groups (Grenander, 1993). These efforts are limited by the assumption that nuisances have a group structure. Such assumptions were relaxed by Soatto and Chiuso (2016) who advocate seeking for *sufficient* invariants, rather than *maximal* ones. We further advance this approach, but unlike prior work on sufficient dimensionality reduction, we do not seek to minimize the dimension of the representation, but rather its information content, as prescribed by our theory. Recent advances in Deep Learning provide us with computationally viable methods to train high-dimensional models and predict and quantify observed phenomena such as convergence to flat minima and transitions from overfitting to underfitting random labels, thus bringing the theory to fruition. Other theoretical efforts focus on complexity considerations, and explain the success of deep networks by ways of statistical or computational efficiency (Lee et al., 2017; Bengio, 2009; LeCun, 2012). "Disentanglement" is an often-cited property of deep networks (Bengio, 2009), but seldom formalized and studied analytically, although Ver Steeg and Galstyan (2015) has suggested studying it using the Total Correlation of the representation, also known as multi-variate mutual information, which we also use.

We connect invariance properties of the representation to the geometry of the optimization residual, and to the phenomenon of *flat minima* (Dinh et al., 2017).

Following (McAllester, 2013), we have also explored relations between our theory and the PAC-Bayes framework (Dziugaite and Roy, 2017). As we show, our theory can also be derived in the PAC-Bayes framework, without resorting to information quantities and the Information Bottleneck, thus providing both an independent and alternative derivation, and a theoretically rigorous way to upper-bound the optimal loss function. The use of PAC-Bayes theory to study the generalization properties of deep networks has been championed by Dziugaite and Roy (2017), who point out that minima that are flat in the sense of having a large volume, toward which stochastic gradient descent algorithms are implicitly or explicitly biased (Chaudhari and Soatto, 2018), naturally relates to the PAC-Bayes loss for the choice of a normal prior and posterior on the weights. This has been leveraged by Dziugaite and Roy (2017) to compute non-vacuous PAC-Bayes error bounds, even for deep networks.

2. Preliminaries

A training set $\mathcal{D} = \{\mathbf{x}, \mathbf{y}\}$, where $\mathbf{x} = \{x^{(i)}\}_{i=1}^{N}$ and $\mathbf{y} = \{y^{(i)}\}_{i=1}^{N}$), is a collection of N randomly sampled data points $x_i^{(i)}$ and their associated (usually discrete) labels. The samples are assumed to come from an unknown, possibly complex, distribution $p_\theta(x, y)$, parametrized by a parameter θ. Following a Bayesian approach, we also consider θ to be a random variable, sampled from some unknown prior distribution $p(\theta)$, but this requirement is not necessary (see Section 6). A test datum x is also a random variable. Given a test sample, our goal is to infer the random variable y, which is therefore referred to as our *task*.

We will make frequent use of the following standard information theoretic quantities (Cover and Thomas, 2012): Shannon entropy $H(x) = \mathbb{E}_p[-\log p(x)]$, conditional entropy $H(x|y) := \mathbb{E}_{\bar{y}}[H(x|y = \bar{y})] = H(x, y) - H(y)$, (conditional) mutual information $I(x; y|z) = H(x|z) - H(x|y, z)$, Kullbach-Leibler (KL) divergence $KL(p(x)||q(x)) = \mathbb{E}_p[\log p/q]$, cross-entropy $H_{p,q}(x) = \mathbb{E}_p[-\log q(x)]$, and total correlation $TC(z)$, which is also known as multi-variate mutual information and defined as

$$\mathrm{TC}(z) = \mathrm{KL}(\, p(z) \,\|\, \textstyle\prod_i p(z_i)\,),$$

where $p(z_i)$ are the marginal distributions of the components of z. Recall that the KL divergence between two distributions is always non-negative and zero if and only if they are equal. In particular $\mathrm{TC}(z)$ is zero if and only if the components of z are independent, in which case we say that z is *disentangled*. We often use of the following identity:

$$I(z; x) = \mathbb{E}_{x\sim p(x)}\, \mathrm{KL}(\, p(z|x) \,\|\, p(z)\,).$$

We say that x, z, y form a Markov chain, indicated with $x \to z \to y$, if $p(y|x, z) = p(y|z)$. The Data Processing Inequality (DPI) for a Markov chain $x \to z \to y$ ensures that $I(x; z) \geq I(x; y)$: If z is a (deterministic or stochastic) function of x, it cannot contain more information about y than x itself (we cannot create new information by simply applying a function to the data we already have).

2.1 General definitions and the Information Bottleneck Lagrangian

We say that z is a *representation* of x if z is a stochastic function of x, or equivalently if the distribution of z is fully described by the conditional $p(z|x)$. In particular we have the Markov chain $y \to x \to z$. We say that a representation z of x is **sufficient** for y if $y \perp\!\!\!\perp x \mid z$, or equivalently if $I(z; y) = I(x; y)$; it is **minimal** when $I(x; z)$ is smallest among sufficient representations. To study the trade-off between sufficiency and minimality, Tishby et al. (1999) introduces the Information Bottleneck Lagrangian

$$\mathcal{L}(p(z|x)) = H(y|z) + \beta\, I(z; x), \tag{1}$$

where β trades off sufficiency (first term) and minimality (second term); in the limit $\beta \to 0$, the IB Lagrangian is minimized when z is minimal and sufficient. It does not impose any restriction on disentanglement nor invariance, which we introduce next.

2.2 Nuisances for a task

A **nuisance** is any random variable that affects the observed data x, but is not informative to the task we are trying to solve. More formally, a random variable n is a nuisance for the task y if $y \perp\!\!\!\perp n$, or equivalently $I(y; n) = 0$. Similarly, we say that the representation z is **invariant** to the nuisance n if $z \perp\!\!\!\perp n$, or $I(z; n) = 0$. When z is not strictly invariant but it minimizes $I(z; n)$ among all sufficient representations, we say that the representation z is **maximally insensitive** to n.

One typical example of nuisance is a group G, such as translation or rotation, acting on the data. In this case, a deterministic representation f is invariant to the nuisances if and only if for all $g \in G$ we have $f(g \cdot x) = f(x)$. Our definition however is more general in that it is not restricted to deterministic functions, nor to group nuisances. An important consequence of this generality is that the observed data x can always be written as a deterministic function of the task y and of all nuisances n affecting the data, as explained by the following proposition.

Proposition 2.1 (Task-nuisance decomposition, Appendix C.1) *Given a joint distribution $p(x, y)$, where y is a discrete random variable, we can always find a random variable n independent of y such that $x = f(y, n)$, for some deterministic function f.*

3. Properties of optimal representations

To simplify the inference process, instead of working directly with the observed high dimensional data x, we want to use a representation z that captures and exposes only the information relevant for the task y. Ideally, such a representation should be (a) **sufficient** for the task y, *i.e.* $I(y; z) = I(y; x)$, so that information about y is not lost; among all sufficient representations, it should be (b) **minimal**, *i.e.* $I(z; x)$ is minimized, so that it retains as little about x as possible, simplifying the role of the classifier; finally, it should be (c) **invariant** to the effect of nuisances $I(z; n) = 0$, so that the final classifier will not overfit to spurious correlations present in the training dataset between nuisances n and labels y. Such a representation, if it exists, would not be unique, since any bijective mapping preserves all these properties. We can use this to our advantage and further aim to make the representation (d) maximally **disentangled**, *i.e.,* choose the one(s) for which $\mathrm{TC}(z)$ is minimal. This simplifies the classifier rule, since no information will be present in the higher-order correlations between the components of z.

Inferring a representation that satisfies all these properties may seem daunting. However, in this section we show that we only need to enforce (a) sufficiency and (b) minimality, from which invariance and disentanglement follow naturally thanks to the stacking of noisy layers of computation in deep networks. We will then show that sufficiency and minimality of the learned representation can also be promoted easily through implicit or explicit regularization during the training process.

Proposition 3.1 (Invariance and minimality, Appendix C.2) *Let n be a nuisance for the task y and let z be a sufficient representation of the input x. Suppose that z depends on n only through x (*i.e., *$n \to x \to z$). Then,*

$$I(z; n) \leq I(z; x) - I(x; y).$$

Moreover, there is a nuisance n such that equality holds up to a (generally small) residual ϵ

$$I(z;n) = I(z;x) - I(x;y) - \epsilon,$$

where $\epsilon := I(z;y|n) - I(x;y)$. In particular $0 \leq \epsilon \leq H(y|x)$, and $\epsilon = 0$ whenever y is a deterministic function of x. Under these conditions, a sufficient statistic z is invariant (maximally insensitive) to nuisances if and only if it is minimal.

Remark 3.2 Since $\epsilon \leq H(y|x)$, and usually $H(y|x) = 0$ or at least $H(y|x) \ll I(x;z)$, we can generally ignore the extra term.

An important consequence of this proposition is that we can construct invariants by simply reducing the amount of information z contains about x, while retaining the minimum amount $I(z;x)$ that we need for the task y. This provides the network a way to automatically learn invariance to complex nuisances, which is complementary to the invariance imposed by the architecture. Specifically, one way of enforcing minimality explicitly, and hence invariance, is through the IB Lagrangian.

Corollary 3.3 (Invariants from the Information Bottleneck) *Minimizing the IB Lagrangian*

$$\mathcal{L}(p(z|x)) = H(y|z) + \beta\, I(z;x),$$

in the limit $\beta \to 0$, yields a sufficient invariant representation z of the test datum x for the task y.

Remarkably, the IB Lagrangian can be seen as the standard cross-entropy loss, plus a regularizer $I(z;x)$ that promotes invariance. This fact, without proof, is implicitly used in Achille and Soatto (2018), who also provide an efficient algorithm to perform the optimization. Alemi et al. (2017a) also propose a related algorithm and empirically show improved resistance to adversarial nuisances. In addition to modifying the cost function, invariance can also be fostered by choice of architecture:

Corollary 3.4 (Bottlenecks promote invariance) *Suppose we have the Markov chain of layers*

$$x \to z_1 \to z_2,$$

and suppose that there is a communication or computation bottleneck between z_1 and z_2 such that $I(z_1;z_2) < I(z_1;x)$. Then, if z_2 is still sufficient, it is more invariant to nuisances than z_1. More precisely, for all nuisances n we have $I(z_2;n) \leq I(z_1;z_2) - I(x;y)$.

Such a bottleneck can happen for example because $\dim(z_2) < \dim(z_1)$, *e.g.*, after a pooling layer, or because the channel between z_1 and z_2 is noisy, *e.g.*, because of dropout.

Proposition 3.5 (Stacking increases invariance) *Assume that we have the Markov chain of layers*

$$x \to z_1 \to z_2 \to \ldots \to z_L,$$

and that the last layer z_L is sufficient of x for y. Then z_L is more insensitive to nuisances than all the preceding layers.

Notice, however, that the above corollary does not simply imply that the more layers the merrier, as it assumes that one has successfully trained the network (z_L is sufficient), which becomes increasingly difficult as the size grows. Also note that in some architectures, such as ResNets (He et al., 2016), the layers do not necessarily form a Markov chain because of skip connections; however, their "blocks" still do.

Proposition 3.6 (Actionable Information) *When $z = f(x)$ is a deterministic invariant, if it minimizes the IB Lagrangian it also maximizes Actionable Information (Soatto, 2013), which is $\mathcal{H}(x) := H(f(x))$.*

Although Soatto (2013) addressed maximal invariants, we only consider sufficient invariants, as advocated by (Soatto and Chiuso, 2016).

Information in the weights

Thus far we have discussed properties of representations in generality, regardless of how they are implemented or learned. Given a source of data (for example randomly generated, or from a fixed dataset), and given a (stochastic) training algorithm, the output weight w of the training process can be thought as a random variable (that depends on the stochasticity of the initialization, training steps and of the data). We can therefore talk about the information that the weights contain about the dataset $\mathcal{D}$ and the training procedure, which we denote by $I(w;\mathcal{D})$.

Two extreme cases consist of the trivial settings where we use the weights to memorize the dataset (the most extreme form of overfitting), or where the weights are constant, or pure noise (sampled from a process that is independent of the data). In between, the amount of information the weights contain about the training turns out to be an important quantity both in training deep networks, as well as in establishing properties of the resulting representation, as we discuss in the next section.

Note that in general we do not need to compute and optimize the quantity of information in the weights. Instead, we show that we can *control* it, for instance by injecting noise in the weights, drawn from a chosen distribution, in an amount that can be modulated between zero (thus in theory allowing full information about the training set to be stored in the weights) to an amount large enough that no information is left. We will leverage this property in the next sections to perform regularization.

4. Learning minimal weights

In this section, we let $p_\theta(x,y)$ be an (unknown) distribution from which we randomly sample a dataset $\mathcal{D}$. The parameter θ of the distribution is also assumed to be a random variable with an (unknown) prior distribution $p(\theta)$. For example p_θ can be a fairly general generative model for natural images, and θ can be the parameters of the model that generated our dataset. We then consider a deep neural network that implements a map $x \mapsto f_w(x) := q(\cdot\,|x,w)$ from an input x to a class distribution $q(y|x,w)$.[1] In full generality, and following a Bayesian approach, we let the weights w of the network be sampled from a parametrized

1. We use p to denote the real (and unknown) data distribution, while q denotes approximate distributions that are optimized during training.

distribution $q(w|\mathcal{D})$,whose parameters are optimized during training.[2] The network is then trained in order to minimize the expected cross-entropy loss[3]

$$H_{p,q}(\mathbf{y}|\mathbf{x},w) = \mathbb{E}_{\mathcal{D}=(\mathbf{x},\mathbf{y})}\mathbb{E}_{w\sim q(w|\mathcal{D})}\sum_{i=1}^{N} -\log q(y^{(i)}|x^{(i)},w),$$

in order for $q(y|x,w)$ to approximate $p_\theta(y|x)$.

One of the main problems in optimizing a DNN is that the cross-entropy loss in notoriously prone to overfitting. In fact, one can easily minimize it even for completely random labels (see Zhang et al. (2017), and Figure 1). The fact that, somehow, such highly over-parametrized functions manage to generalize when trained on real labels has puzzled theoreticians and prompted some to wonder whether this may be inconsistent with the intuitive interpretation of the bias-variance trade-off theorem, whereby unregularized complex models should overfit wildly. However, as we show next, there is no inconsistency if one measures complexity by the information content, and not the dimensionality, of the weights.

To gain some insights about the possible causes of over-fitting, we can use the following decomposition of the cross-entropy loss (we refer to Appendix C for the proof and the precise definition of each term):

$$H_{p,q}(\mathbf{y}|\mathbf{x},w) = \underbrace{H(\mathbf{y}|\mathbf{x},\theta)}_{\text{intrinsic error}} + \underbrace{I(\theta;\mathbf{y}|\mathbf{x},w)}_{\text{sufficiency}} + \mathbb{E}_{\mathbf{x},w}\underbrace{\mathrm{KL}(\, p(\mathbf{y}|\mathbf{x},w) \,\|\, q(\mathbf{y}|\mathbf{x},w)\,)}_{\text{efficiency}} - \underbrace{I(\mathbf{y};w|\mathbf{x},\theta)}_{\text{overfitting}}. \tag{2}$$

The first term of the right-hand side of (8) relates to the intrinsic error that we would commit in predicting the labels even if we knew the underlying data distribution p_θ; the second term measures how much information that the dataset has about the parameter θ is captured by the weights, the third term relates to the efficiency of the model and the class of functions f_w with respect to which the loss is optimized. The last, and only negative, term relates to how much information about the labels, but uninformative of the underlying data distribution, is memorized in the weights. Unfortunately, without implicit or explicit regularization, the network can minimize the cross-entropy loss (LHS), by just maximizing the last term of eq. (8), *i.e.,* by memorizing the dataset, which yields poor generalization.

To prevent the network from doing this, we can neutralize the effect of the negative term by adding it back to the loss function, leading to a regularized loss $L = H_{p,q}(\mathbf{y}|\mathbf{x},w) + I(\mathbf{y};w|\mathbf{x},\theta)$. However, computing, or even approximating, the value of $I(\mathbf{y},w|\mathbf{x},\theta)$ is at least as difficult as fitting the model itself.

We can, however, add an upper bound to $I(\mathbf{y};w|\mathbf{x},\theta)$ to obtain the desired result. In particular, we explore two alternate paths that lead to equivalent conclusions under different premises and assumptions: In one case, we use a PAC-Bayes upper-bound, which is $\mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, p(w)\,)$ where $p(w)$ is an arbitrary prior. In the other, we use the IB Lagrangian

2. Note that, while the two are somewhat related, here by $q(w|\mathcal{D})$ we denote the output distribution of the weights after training with our choice algorithm on the dataset $\mathcal{D}$, and not the Bayesian posterior of the weights given the dataset, which would be denoted $p(w|\mathcal{D})$. When $q(w|\mathcal{D})$ is a Dirac delta at a point, we recover the standard loss function for a MAP estimate of the weights.
3. Note that for generality here we treat the dataset $\mathcal{D}$ as a random variable. In practice, when a single dataset is given, the expectation w.r.t. the dataset can be ignored.

and upper-bound it with the information in the weights $I(w;\mathcal{D})$. We discuss this latter approach now, and look at the PAC-Bayes approach in Section 6.

Notice that to successfully learn the distribution p_θ, we only need to memorize in w the information about the latent parameters θ, that is we need $I(\mathcal{D};w) = I(\mathcal{D};\theta) \le H(\theta)$, which is bounded above by a constant. On the other hand, to overfit, the term $I(\mathbf{y};w|\mathbf{x},\theta) \le I(\mathcal{D};w|\theta)$ needs to grow linearly with the number of training samples N. We can exploit this fact to prevent overfitting by adding a Lagrange multiplier β to make the amount of information a constant with respect to N, leading to the regularized loss function

$$\mathcal{L}(q(w|\mathcal{D})) = H_{p,q}(\mathbf{y}|\mathbf{x},w) + \beta I(w;\mathcal{D}), \tag{3}$$

which, remarkably, has the same general form of an IB Lagrangian, and in particular is similar to (1), but now interpreted as a function of the weights w rather than the activations z. This use of the IB Lagrangian is, to the best of our knowledge, novel, as the role of the Information Bottleneck has thus far been confined to characterizing the activations of the network, and not as a learning criterion. Equation (3) can be seen as a generalization of other suggestions in the literature:

IB Lagrangian, Variational Learning and Dropout. Minimizing the information stored at the weights $I(w;\mathcal{D})$ was proposed as far back as Hinton and Van Camp (1993) as a way of simplifying neural networks, but no efficient algorithm to perform the optimization was known at the time. For the particular choice $\beta = 1$, the IB Lagrangian reduces to the variational lower-bound (VLBO) of the marginal log-likelihood $p(\mathbf{y}|\mathbf{x})$. Therefore, minimizing eq. (3) can also be seen as a generalization of variational learning. A particular case of this was studied by Kingma et al. (2015), who first showed that a generalization of Dropout, called Variational Dropout, could be used in conjunction with the *reparametrization trick* Kingma and Welling (2014) to minimize the loss efficiently.

Information in the weights as a measure of complexity. Just as Hinton and Van Camp (1993) suggested, we also advocate using the information regularizer $I(w;\mathcal{D})$ as a measure of the effective complexity of a network, rather than the number of parameters $\dim(w)$, which is merely an upper bound on the complexity. As we show in experiments, this allows us to recover a version of the bias-variance trade-off where networks with lower information complexity underfit the data, and networks with higher complexity overfit. In contrast, there is no clear relationship between number of parameters and overfitting (Zhang et al., 2017). Moreover, for random labels the information complexity allows us to precisely predict the overfitting and underfitting behavior of the network (Section 7).

4.1 Computable upper-bound to the loss

Unfortunately, computing $I(w,\mathcal{D}) = \mathbb{E}_{\mathcal{D}}\,\mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, q(w)\,)$ is still too complicated, since it requires us to know the marginal $q(w)$ over all possible datasets and trainings of the network. To avoid computing this term, we can use the more general upper-bound

$$\begin{aligned}\mathbb{E}_{\mathcal{D}}\,\mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, q(w)\,) &\le \mathbb{E}_{\mathcal{D}}\,\mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, q(w)\,) + \mathrm{KL}(\, q(w) \,\|\, p(w)\,) \\ &= \mathbb{E}_{\mathcal{D}}\,\mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, p(w)\,),\end{aligned}$$

where $p(w)$ is any fixed distribution of the weights. Once we instantiate the training set, we have a single sample of $\mathcal{D}$, so the expectation over $\mathcal{D}$ becomes trivial. This gives us the following upper bound to the optimal loss function

$$\mathcal{L}(q(w|\mathcal{D})) = H_{p,q}(\mathbf{y}|\mathbf{x}, w) + \beta \,\mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, p(w)\,) \tag{4}$$

Generally, we want to pick $p(w)$ in order to give the sharpest upper-bound, and to be a fully factorized distribution, *i.e.*, a distribution with independent components, in order to make the computation of the KL term easier. The sharpest upper-bound to $\mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, q(w)\,)$ that can be obtained using a factorized distribution p is obtained when $p(w) := \tilde{q}(w) = \prod_i q(w_i)$ where $q(w_i)$ denotes the marginal distributions of the components of $q(w)$. Notice that. once a training procedure is fixed, this may be approximated by training multiple times and approximating each marginal weight distribution. With this choice of prior, our final loss function becomes

$$\mathcal{L}(q(w|\mathcal{D})) = H_{p,q}(\mathbf{y}|\mathbf{x}, w) + \beta \,\mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, \tilde{q}(w)\,) \tag{5}$$

for some fixed distribution $\tilde{q}$ that approximates the real marginal distribution $q(w)$. The IB Lagrangian for the weights in eq. (3) can be seen as a generally intractable special case of eq. (5) that gives the sharpest upper-bound to our desired loss in this family of losses.

In the following, to keep the notation uncluttered, we will denote our upper bound $\mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, \tilde{q}(w)\,)$ to the mutual information $I(w;\mathcal{D})$ simply by $\tilde{I}(w;\mathcal{D})$, where

$$\tilde{I}(w;\mathcal{D}) := \mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, \tilde{q}(w)\,) = \mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, \textstyle\prod_i q(w_i)\,).$$

4.2 Bounding the information in the weights of a network

To derive precise and empirically verifiable statements about $\tilde{I}(w;\mathcal{D})$, we need a setting where this can be expressed analytically and optimized efficiently on standard architectures. To this end, following Kingma et al. (2015), we make the following modeling choices.

Modeling assumptions. Let w denote the vector containing all the parameters (weights) in the network, and let W^k denote the weight matrix at layer k. We assume an improper log-uniform prior on w, that is $\tilde{q}(w_i) = c/|w_i|$. Notice that this is the only scale-invariant prior (Kingma et al., 2015), and closely matches the real marginal distributions of the weights in a trained network (Achille and Soatto, 2018); we parametrize the weight distribution $q(w_i|\mathcal{D})$ during training as

$$w_i|\mathcal{D} \sim \epsilon_i \hat{w}_i,$$

where $\hat{w}_i$ is a learned mean, and $\epsilon_i \sim \log \mathcal{N}(-\alpha_i/2, \alpha_i)$ is i.i.d. multiplicative log-normal noise with mean 1 and variance $\exp(\alpha_i) - 1$.[4] Note that while Kingma et al. (2015) uses this parametrization as a local approximation of the Bayesian posterior for a given (log-uniform) prior, we rather *define* the distribution of the weights w after training on the dataset $\mathcal{D}$ to be $q(w|\mathcal{D})$.

4. For a log-normal $\log \mathcal{N}(\mu, \sigma^2)$ mean and variance are respectively $\exp(\mu + \sigma^2/2)$ and $[\exp(\sigma^2) - 1]\exp(2\mu + \sigma^2)$.

Proposition 4.1 (Information in the weights, Theorem C.4) *Under the previous modeling assumptions, the upper-bound to the information that the weights contain about the dataset is*

$$I(w;\mathcal{D}) \le \tilde{I}(w;\mathcal{D}) = -\frac{1}{2} \sum_{i=1}^{\dim(w)} \log \alpha_i + C,$$

where the constant C is arbitrary due to the improper prior.

Remark 4.2 (On the constant C) *To simplify the exposition, since the optimization is unaffected by any additive constant, in the following we abuse the notation and, under the modeling assumptions stated above, we rather* define $\tilde{I}(w;\mathcal{D}) := -\frac{1}{2}\sum_{i=1}^{\dim(w)} \log \alpha_i$. *Nekludov et al. (2017) also suggest a principled way of dealing with the arbitrary constant by using a proper log-uniform prior.*

Note that computing and optimizing this upper-bound to the information in the weights is relatively simple and efficient using the reparametrization trick of Kingma et al. (2015).

4.3 Flat minima have low information

Thus far we have suggested that adding the explicit information regularizer $I(w;\mathcal{D})$ prevents the network from memorizing the dataset and thus avoid overfitting, which we also confirm empirically in Section 7. However, real networks are not commonly trained with this regularizer, thus seemingly undermining the theory. However, even when not explicitly present, the term $I(w;\mathcal{D})$ is implicit in the use of SGD. In particular, Chaudhari and Soatto (2018) show that, under certain conditions, SGD introduces an entropic bias of a very similar form to the information in the weights described thus far, where the amount of information can be controlled by the learning rate and the size of mini-batches.

Additional indirect empirical evidence is provided by the fact that some variants of SGD (Chaudhari et al., 2017) bias the optimization toward "flat minima", that are local minima whose Hessian has mostly small eigenvalues. These minima can be interpreted exactly as having low information $I(w;\mathcal{D})$, as suggested early on by Hochreiter and Schmidhuber (1997): Intuitively, since the loss landscape is locally flat, the weights may be stored at lower precision without incurring in excessive inference error. As a consequence of previous claims, we can then see flat minima as having better generalization properties and, as we will see in Section 5, the associated representation of the data is more insensitive to nuisances and more disentangled. For completeness, here we derive a more precise relationship between flatness (measured by the nuclear norm of the loss Hessian), and the information content based on our model.

Proposition 4.3 (Flat minima have low information, Appendix C.5) *Let $\hat{w}$ be a local minimum of the cross-entropy loss $H_{p,q}(\mathbf{y}|\mathbf{x}, w)$, and let $\mathcal{H}$ be the Hessian at that point. Then, for the optimal choice of the posterior $w|\mathcal{D} = \epsilon \odot \hat{w}$ centered at $\hat{w}$ that optimizes the IB Lagrangian, we have*

$$I(w;\mathcal{D}) \le \tilde{I}(w;\mathcal{D}) \le \frac{1}{2} K[\log \|\hat{w}\|_2^2 + \log \|\mathcal{H}\|_* - K \log(K^2 \beta/2)]$$

where $K = \dim(w)$ and $\|\cdot\|_*$ denotes the nuclear norm.

Notice that a converse inequality, that is, low information implies flatness, needs not hold, so there is no contradiction with the results of Dinh et al. (2017). Also note that for $\tilde{I}(w;\mathcal{D})$ to be invariant to reparametrization one has to consider the constant C, which we have ignored (Remark 4.2). The connection between flatness and overfitting has also been studied by Neyshabur et al. (2017), including the effect of the number of parameters in the model.

In the next section, we prove one of our main results, that networks with low information in the weights realize invariant and disentangled representations. Therefore, invariance and disentanglement emerge naturally when training a network with implicit (SGD) or explicit (IB Lagrangian) regularization, and are related to flat minima.

5. Duality of the Bottleneck

The following proposition gives the fundamental link in our model between information in the weights, and hence flatness of the local minima, minimality of the representation, and disentanglement.

Proposition 5.1 (Appendix C.6) *Let $z = Wx$, and assume as before $W = \epsilon \odot \hat{W}$, with $\epsilon_{i,j} \sim \log\mathcal{N}(-\alpha_i/2, \alpha_i)$. Further assume that the marginals of $p(z)$ and $p(z|x)$ are both approximately Gaussian (which is reasonable for large $\dim(x)$ by the Central Limit Theorem). Then,*

$$I(z;x) + \mathrm{TC}(z) = -\frac{1}{2}\sum_{i=1}^{\dim(z)} \mathbb{E}_x \log \frac{\tilde{\alpha}_i \hat{W}_i^2 \cdot x^2}{\hat{W}_i \cdot \mathrm{Cov}(x)\hat{W}_i + \tilde{\alpha}_i \hat{W}_i^2 \cdot \mathbb{E}(x^2)}, \tag{6}$$

where W_i denotes the i-th row of the matrix W, and $\tilde{\alpha}_i$ is the noise variance $\tilde{\alpha}_i = \exp(\alpha_i) - 1$. In particular, $I(z;x) + \mathrm{TC}(z)$ is a monotone decreasing function of the weight variances α_i.

The above identity is difficult to apply in practice, but with some additional hypotheses, we can derive a cleaner uniform tight bound on $I(z;x) + \mathrm{TC}(z)$.

Proposition 5.2 (Uniform bound for one layer, Appendix C.7) *Let $z = Wx$, where $W = \epsilon \odot \hat{W}$, where $\epsilon_{i,j} \sim \log\mathcal{N}(-\alpha/2, \alpha)$; assume that the components of x are uncorrelated, and that their kurtosis is uniformly bounded.*[5] *Then, there is a strictly increasing function $g(\alpha)$ s.t. we have the uniform bound*

$$g(\alpha) \leq \frac{I(x;z) + TC(z)}{\dim(z)} \leq g(\alpha) + c,$$

where $c = O(1/\dim(x)) \leq 1$, $g(\alpha) = -\log(1 - e^{-\alpha})/2$ and α is related to $\tilde{I}(w;\mathcal{D})$ by $\alpha = \exp\{-I(W;\mathcal{D})/\dim(W)\}$. In particular, $I(x;z) + TC(z)$ is tightly bounded by $\tilde{I}(W;\mathcal{D})$ and increases strictly with it.

5. This is a technical hypothesis, always satisfied if the components x_i are IID, (sub-)Gaussian, or with uniformly bounded support.

The above theorems tells us that whenever we decrease the information in the weights, either by explicit regularization, or by implicit regularization (*e.g.*, using SGD), we automatically improve the minimality, and hence, by Proposition 3.1, the invariance, and the disentanglement of the learner representation. In particular, we obtain as a corollary that SGD is biased toward learning invariant and disentangled representations of the data. Using the Markov property of the layers, we can easily extend this bound to multiple layers:

Corollary 5.3 (Multi-layer case, Appendix C.8) *Let W^k for $k = 1, ..., L$ be weight matrices, with $W^k = \epsilon^k \odot \hat{W}^k$ and $\epsilon^k_{i,j} = \log\mathcal{N}(-\alpha^k/2, \alpha^k)$, and let $z_{i+1} = \phi(W^k z_k)$, where $z_0 = x$ and ϕ is any nonlinearity. Then,*

$$I(z_L;x) \leq \min_{k<L} \Big\{ \dim(z_k)\big[g(\alpha^k) + 1\big] \Big\}$$

where $\alpha^k = \exp\big\{-I(W^k;\mathcal{D})/\dim(W^k)\big\}$.

Remark 5.4 (Tightness) While the bound in Proposition 5.2 is tight, the bound in the multilayer case needs not be. This is to be expected: Reducing the information in the weights creates a bottleneck, but we do not know how much information about x will actually go through this bottleneck. Often, the final layers will let most of the information through, while initial layers will drop the most.

Remark 5.5 (Training-test transfer) We note that we did not make any (explicit) assumption about the test set having the same distribution of the training set. Instead, we make the less restrictive assumption of sufficiency: If the test distribution is entirely different from the training one – one may not be able to achieve sufficiency. This prompts interesting questions about measuring the distance between *tasks* (as opposed to just distance between distributions), which will be studied in future work.

6. Connection with PAC-Bayes bounds

In this section we show that using a PAC-Bayes bound, we arrive at the same regularized loss function eq. (5) we obtained using the Information Bottleneck, without the need of any approximation. By Theorem 2 of McAllester (2013), we have that for any fixed $\lambda > 1/2$, prior $p(w)$, and any weight distribution $q(w|\mathcal{D})$, the test error $L^{\text{test}}(q(w|\mathcal{D}))$ that the network commits using the weight distribution $q(w|\mathcal{D})$ is upper-bounded in expectation by

$$\mathbb{E}_{\mathcal{D}}[L^{\text{test}}(q(w|\mathcal{D}))] \leq \frac{1}{N(1-\frac{1}{2\lambda})}\Big(H_{p,q}(\mathbf{y}|\mathbf{x},w) + \lambda L_{\max}\mathbb{E}_{\mathcal{D}}[\mathrm{KL}(\,q(w|\mathcal{D})\,\|\,p(w)\,)]\Big), \tag{7}$$

where L_{max} is the maximum per-sample loss function, which for a classification problem we can assume to be upper-bounded, for example by clipping the cross-entropy loss at chance level. Notice that right hand side coincides, modulo a multiplicative constant, with eq. (4) that we derived as an approximation of the IB Lagrangian for the weights (eq. (3)).

Now, recall that since we have

$$\begin{aligned}\mathbb{E}_{\mathcal{D}}[\mathrm{KL}(\,q(w|\mathcal{D})\,\|\,q(w)\,)] &= \mathbb{E}_{\mathcal{D}}[\mathrm{KL}(\,q(w|\mathcal{D})\,\|\,p(w)\,)] - \mathrm{KL}(\,q(w)\,\|\,p(w)\,)\\ &\leq \mathbb{E}_{\mathcal{D}}[\mathrm{KL}(\,q(w|\mathcal{D})\,\|\,p(w)\,)],\end{aligned}$$

the sharpest PAC-Bayes upper-bound to the test error is obtained when $p(w) = q(w)$, in which case eq. (7) reduces (modulo a multiplicative constant) to the IB Lagrangian of the weights. That is, the IB Lagrangian for the weights can be considered as a special case of PAC-Bayes giving the sharpest bound.

Unfortunately, as we noticed in Section 4, the joint marginal $q(w)$ of the weights is not tractable. To circumvent the problem, we can instead consider that the sharpest PAC-Bayes upper-bound that can be obtained using a tractable factorized prior $p(w)$, which is obtained exactly when $p(w) = \tilde{q}(w) = \prod_i q(w_i)$ is the product of the marginals, leading again to our practical loss eq. (5).

On a last note, recall that under our modeling assumptions the marginal $\tilde{q}(w)$ is assumed to be an improper log-uniform distribution. While this has the advantage of being a non-informative prior that closely matches the real marginal of the weights of the network, it also has the disadvantage that it is only defined modulo an additive constant, therefore making the bound on the test error vacuous under our model.

The PAC-Bayes bounds has also been used by Dziugaite and Roy (2017) to study the generalization property of deep neural networks and their connection with the optimization algorithm. They use a Gaussian prior and posterior, leading to a non-vacuous generalization bound.

7. Empirical validation

7.1 Transition from overfitting to underfitting

As pointed out by Zhang et al. (2017), when a standard convolutional neural network (CNN) is trained on CIFAR-10 to fit random labels, the network is able to (over)fit them perfectly. This is easily explained in our framework: It means that the network is complex enough to memorize all the labels but, as we show here, it has to pay a steep price in terms of information complexity of the weights (Figure 2) in order to do so. On the other hand, when the information in the weights is bounded using and information regularizer, overfitting is prevented in a theoretically predictable way.

In particular, in the case of completely random labels, we have $I(\mathbf{y}; w|\mathbf{x}, \theta) = I(\mathbf{y}; w) \leq I(w; \mathcal{D})$, where the first equality holds since $\mathbf{y}$ is by construction random, and therefore independent of $\mathbf{x}$ and θ. In this case, the inequality used to derive eq. (3) is an equality, and the IBL is an optimal regularizer, and, regardless of the dataset size N, for $\beta > 1$ it should completely prevent memorization, while for $\beta < 1$ overfitting is possible. To see this, notice that since the labels are random, to decrease the classification error by $\log |\mathcal{Y}|$, where $|\mathcal{Y}|$ is the number of possible classes, we need to memorize a new label. But to do so, we need to store more information in the weights of the network, therefore increasing the second term $I(w; \mathcal{D})$ by a corresponding quantity. This trade-off is always favorable when $\beta < 1$, but it is not when $\beta > 1$. Therefore, the theoretically the optimal solution to *eq.* (1) is to memorize all the labels in the first case, and not memorize anything in the latter.

As discussed, for real neural networks we cannot directly minimize *eq.* (1), and we need to use a computable upper bound to $I(w; \mathcal{D})$ instead (Section 4.2). Even so, the empirical behavior of the network, shown in Figure 1, closely follows this prediction, and for various sizes of the dataset clearly shows a phase transition between overfitting and underfitting near the critical value $\beta = 1$. Notice instead that for real labels the situation is different:

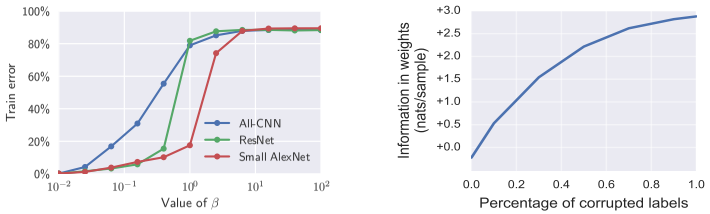

Figure 2: **(Left)** Plot of the training error on CIFAR-10 with random labels as a function of the parameter β for different models (see the appendix for details). As expected, all models show a sharp phase transition from complete overfitting to underfitting before the critical value $\beta = 1$. **(Right)** We measure the quantity of information in the weights necessary to overfit as we vary the percentage of corrupted labels under the same settings of Figure 1. To fit increasingly random labels, the network needs to memorize more information in the weights; the increase needed to fit entirely random labels is about the same magnitude as the size of a label (2.30 nats/sample).

The model is still able to overfit when $\beta < 1$, but importantly there is a large interval of $\beta > 1$ where the model can fit the data *without* overfitting to it. Indeed, as soon as $\beta N \propto I(w; \mathcal{D})$ is larger than the constant $H(\theta)$, the model trained on real data fits real labels without excessive overfitting (Figure 1).

Notice that, based on this reasoning, we expect the presence of a phase transition between an overfitting and an underfitting regime at the critical value $\beta = 1$ to be largely independent on the network architecture: To verify this, we train different architectures on a subset of 10000 samples from CIFAR-10 with random labels. As we can see on the left plot of Figure 2, even very different architectures show a phase transition at a similar value of β. We also notice that in the experiment ResNets has a sharp transition close to the critical β.

In the right plot of Figure 2 we measure the quantity information in the weights for different levels of corruption of the labels. To do this, we fix $\beta < 1$ so that the network is able to overfit, and for various level of corruption we train until convergence, and then compute $I(w; \mathcal{D})$ for the trained model. As expected, increasing the randomness of the labels increases the quantity of information we need to fit the dataset. For completely random labels, $I(w; \mathcal{D})$ increases by ~ 3 nats/sample, which the same order of magnitude as the quantity required to memorize a 10-class labels (2.30 nats/sample), as shown in Figure 2.

7.2 Bias-variance trade-off

The Bias-Variance trade-off is sometimes informally stated as saying that low-complexity models tend to underfit the data, while excessively complex models may instead overfit, so that one should select an adequate intermediate complexity. This is apparently at odds with the common practice in Deep Learning, where increasing the depth or the number of weights of the network, and hence increasing the "complexity" of the model measured by

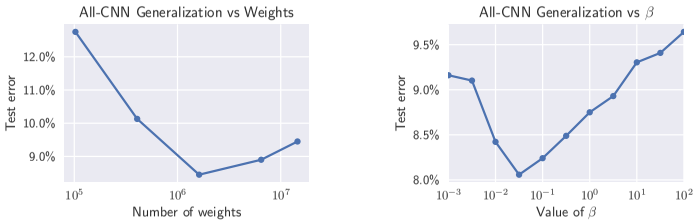

Figure 3: Plots of the test error obtained training the All-CNN architecture on CIFAR-10 (no data augmentation). **(Left)** Test error as we increase the number of weights in the network using weight decay but without any additional explicit regularization. Notice that increasing the number of weights the generalization error plateaus rather than increasing. **(Right)** Changing the value of β, which controls the amount of information in the weights, we obtain the characteristic curve of the bias-variance trade-off. This suggests that the quantity of information in the weights correlates well with generalization.

the number of parameters, does not seem to induce overfitting. Consequently, a number of alternative measures of complexity have been proposed that capture the intuitive bias-variance trade-off curve, such as different norms of the weights (Neyshabur et al., 2015).

From the discussion above, we have seen that the quantity of information in the weights, or alternatively its computable upperbound $\tilde{I}(w;\mathcal{D})$, also provides a natural choice to measure model complexity in relation to overfitting. In particular, we have already seen that models need to store increasingly more information to fit increasingly random labels (Figure 2). In Figure 3 we show that by controlling $\tilde{I}(w;\mathcal{D})$, which can be done easily by modulating β, we recover the right trend for the bias-variance tradeoff, whereas models with too little information tend to underfit, while models memorizing too much information tend to overfit.

7.3 Nuisance invariance

Corollary 5.3 shows that by decreasing the information in the weights $I(w;\mathcal{D})$, which can be done for example using eq. (3), the learned representation will be increasingly minimal, and therefore insensitive to nuisance factors n, as measured by $I(z;n)$. Here, we adapt a technique from the GAN literature Sønderby et al. (2017) that allows us to explicitly measure $I(z;n)$ and validate this effect, provided we can sample from the nuisance distribution $p(n)$ and from $p(x|n)$; that is, if given a nuisance n we can generate data x affected by that nuisance. Recall that by definition we have

$$\begin{aligned} I(z;n) &= \mathbb{E}_{n\sim p(n)}\,\mathrm{KL}(\,p(z|n)\,\|\,p(z)\,) \\ &= \mathbb{E}_{n\sim p(n)}\mathbb{E}_{z\sim p(z|n)}\log[p(z|n)/p(z)]. \end{aligned}$$

To approximate the expectations via sampling we need a way to approximate the likelihood ratio $\log p(\mathbf{z}|\mathbf{n})/p(\mathbf{z})$. This can be done as follows: Let $D(z;n)$ be a binary discriminator that given the representation z and the nuisance n tries to decide whether z is sampled

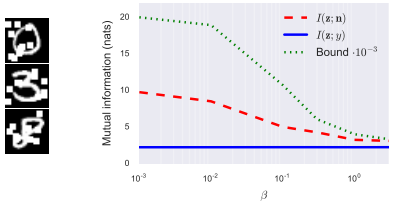

Figure 4: **(Left)** A few training samples generated adding nuisance clutter n to the MNIST dataset. **(Right)** Reducing the information in the weights makes the representation z learned by the digit classifier increasingly invariant to nuisances ($I(n;z)$ decreases), while sufficiency is retained ($I(z;y) = I(x;y)$ is constant). As expected, $I(z;n)$ is smaller but has a similar behavior to the theoretical bound in Theorem 5.3.

from the posterior distribution $p(z|n)$ or from the prior $p(z)$. Since by hypothesis we can generate samples from both distributions, we can generate data to train this discriminator. Intuitively, if the discriminator is not able to classify, it means that z is insensitive to changes of n. Precisely, since the optimal discriminator is

$$D^*(z;n) = \frac{p(z)}{p(z)+p(z|n)},$$

if we assume that D is close to the optimal discriminator D^*, we have

$$\log\frac{p(z|n)}{p(z)} = \log\frac{1-D^*(z;n)}{D^*(z;n)} \simeq \log\frac{1-D(z;n)}{D(z;n)}.$$

therefore we can use D to estimate the log-likelihood ratio, and so also the mutual information $I(z;n)$. Notice however that this comes with no guarantees on the quality of the approximation.

To test this algorithm, we add random occlusion nuisances to MNIST digits (Figure 4). In this case, the nuisance n is the occlusion pattern, while the observed data x is the occluded digit. For various values of β, we train a classifier on this data in order to learn a representation z, and, for each representation obtained this way, we train a discriminator as described above and we compute the resulting approximation of $I(z;n)$. The results in Figure 4 show that decreasing the information in the weights makes the representation increasingly more insensitive to n.

8. Discussion and conclusion

In this work, we have presented bounds, some of which are tight, that connect the amount of information in the weights, the amount of information in the activations, the invariance property of the network, and the geometry of the residual loss. These results leverage the structure of deep networks, in particular the multiplicative action of the weights, and the Markov property of the layers. This leads to the surprising result that reducing information

stored in the weights about the past (dataset) results in desirable properties of the learned internal representation of the test datum (future).

Our notion of representation is intrinsically stochastic. This simplifies the computation as well as the derivation of information-based relations. However, note that even if we start with a deterministic representation w, Proposition 4.3 gives us a way of converting it to a stochastic representation whose quality depends on the flatness of the minimum. Our theory uses, but does not depend on, the Information Bottleneck Principle, which dates back to over two decades ago, and can be re-derived in a different frameworks, for instance PAC-Bayes, which yield the same results and additional bounds on the test error.

This work focuses on the inference and learning of optimal representations, that seek to get the most out of the data we have for a specific task. This does not guarantee a good outcome since, due to the Data Processing Inequality, the representation can be easier to use but ultimately no more informative than the data themselves. An orthogonal but equally interesting issue is how to get the most informative data possible, which is the subject of active learning, experiment design, and perceptual exploration. Our work does not address transfer learning, where a representation trained to be optimal for a task is instead used for a different task, which will be subject of future investigations.

Appendix A. Details of the experiments

A.1 Random labels

We use a similar experimental setup as Zhang et al. (2017). In particular, we train a small version of AlexNet on a 28×28 central crop of CIFAR-10 with completely random labels. The dataset is normalized using the global channel-wise mean and variance, but no additional data augmentation is performed. The exact structure of the network is in Table 1. As common in practice we use batch normalization before all the ReLU nonlinearities, except for the first layer. Optimization of the IB Lagrangian loss function is performed similarly to Kingma et al. (2015) and Molchanov et al. (2017). We found that constraining the variance α_i of the weights to be the same for all weights in the same filter helps stabilizing the training process. We train with learning rates $\eta \in \{0.02, 0.005\}$ and select the best performing network of the two. Generally, we found that a higher learning rate is needed to overfit when the number of training samples N is small, while a lower learning rate is needed for larger N. We train with SGD with momentum 0.9 for 360 epochs reducing the learning rate by a factor of 10 every 140 epochs. We use a large batch-size of 500 to minimize the noise coming from SGD. No weight decay or other regularization methods are used.

The final plot is obtained by triangulating the convex envelope of the data points, and by interpolating their value on the resulting simplexes. Outside of the convex envelope (where the accuracy is mostly constant), the value was obtained by inpainting.

To measure the information content of the weights as the percentage of corrupted labels varies, we fix $\beta = 0.1$, $N = 30000$ and $\eta = 0.005$ and train the network on different corruption levels with the same settings as before.

To test the phase transition on multiple architectures, we train the Small AlexNet, the AllCNN network and a ResNet (see Table 1). For all architectures, we train with $N = 10000$ random labels, $\eta = 0.05$ and different values of β log-uniformly spaced in $[10^{-2}, 10^{2}]$.

A.2 Bias-variance trade-off

For this experiment we train the AllCNN architecture (Table 1) on the CIFAR-10 dataset with ZCA whitening Krizhevsky and Hinton (2009) and without any additional data augmentation. First, we train a standard network and change the number of filters (we multiplying the number of filters of all layers by the same constant) and train with $\eta = 0.05$, batch size 128, weight decay 0.001. Then, we use the standard number of layers and train instead with the IBL loss function with different values of β.

A.3 Nuisance invariance

The cluttered MNIST dataset is generated by adding ten 4×4 squares uniformly at random on the digits of the MNIST dataset (LeCun et al., 1998). For each level of β, we train the classifier in Table 1 on this dataset. The weights of all layers, excluding the first and last one, are threated as a random variable with multiplicative Gaussian noise (Appendix B) and optimized using the local reparameterization trick of Kingma et al. (2015). We use the last convolutional layer before classification as representation z.

The discriminator network used to estimate the log-likelihood ratio is constructed as follows: the inputs are the nuisance pattern n, which is a 28×28×1 image containing 10 random

Input 32x32
conv 64 ReLU
MaxPool 2x2
conv 64 + BN ReLU
MaxPool 2x2
FC 3136x384 + BN ReLU
FC 384x192 + BN ReLU
FC 192x10
softmax

Input 28x28
conv 96 + BN + ReLU conv 96 + BN + ReLU
conv 192 s2 + BN + ReLU
conv 192 + BN + ReLU conv 192 + BN + ReLU
conv 192 s2 + BN + ReLU
conv 192 + BN + ReLU conv 192 + BN + ReLU
conv 1x1x10 Average pooling 7x7
softmax

Input 28x28
conv 64
block 64 s1
block 128 s2
block 256 s3
block 512 s3
Average pooling 4x4 linear 10
softmax

Table 1: **(Left)** The Small AlexNet model used in the random label experiment, adapted from Zhang et al. (2017). All convolutions have a 5×5 kernel. The use of batch normalization makes the training procedure more stable, but did not significantly change the results of the experiments. **(Center)** All Convolutional Network (Springenberg et al., 2014) used as a classifier in the experiments. All convolutions but the last one use a 3×3 kernel, "s2" denotes a convolution with stride 2. The final representation we use are the activations of the last "conv 192" layer. **(Right)** The ResNet architecture (He et al., 2016) on which we test the phase transition. Each block with `f` filters and stride s is structured as follows: `BN -> ReLU -> conv f stride s -> BN -> ReLU -> conv f` with a skip connection between first ReLU and the output.

occluding squares, and the 7×7×192 representation z obtained from the classifier. First we preprocess n using the following network: `conv 48` → `conv 48` → `conv 96 s2` → `conv 96` → `conv 96` → `conv 96 s2`, where each conv block is a 3×3 convolution followed by batch normalization and ReLU. Then, we concatenate the 7×7×96 result with z along the feature maps, and the final discriminator output is obtained by applying the following network: `conv 192` → `conv 192` → `conv 1×1×192` → `conv 1×1×1` → `AvgPooling 7×7` → `sigmoid`.

A.4 Visualizing the representation

Even when we cannot generate data affected by nuisances like in the previous section, we can still visualize the information content of z to learn what nuisances are discarded in the representation. To this end, given a representation z, we want to learn to sample from a distribution $q(\hat{x}|z)$ of images that are maximally likely to have z as their representation. Formally, this means that we want a distribution $q(\hat{x}|z)$ that maximizes the amortized maximum a posteriori estimate of z:

$$\mathbb{E}_z \mathbb{E}_{\hat{x}\sim q(\hat{x}|z)}[\log p(\hat{x}|z)] = \mathbb{E}_z \underbrace{\mathbb{E}_{\hat{x}\sim q(\hat{x}|z)}[\log p(z|\hat{x})]}_{\text{Reconstruction error}} + \underbrace{\mathbb{E}_{\hat{x}\sim q(\hat{x})}[\log p(\hat{x})]}_{\text{Distance from prior}} + C.$$

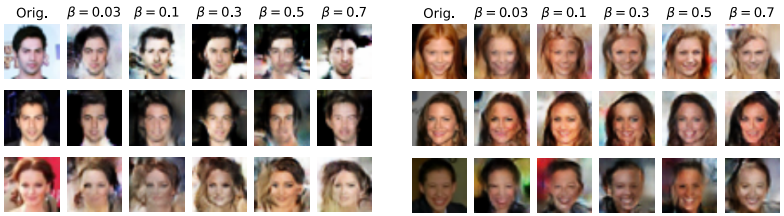

Figure 5: For different values of β, we show the image $\hat{x}$ reconstructed from a representation $z \sim p(z|x)$ of the original image x in the first column. For small β, z contains more information regarding x, thus the reconstructed image $\hat{x}$ is close to x, background included. Increasing β decreases the information in the weighs, thus the representation z becomes more invariant to nuisances: Reconstructed image matches important details in x that are preserved in z (*i.e.*, hair color, sex, expression), but background, hair style, and other nuisances are generated anew.

Unfortunately, the term $p(\hat{x})$ in the expression is difficult to estimate. However, Sønderby et al. (2017) notice that the modified gain function

$$\mathbb{E}_z\mathbb{E}_{\hat{x}\sim q(\hat{x}|z)}[\log p(\hat{x}|z)] \,+\, H(p(\hat{x})) \;\;=\;\; \mathbb{E}_z\mathbb{E}_{\hat{x}\sim q(\hat{x}|z)}[\log p(z|\hat{x})] \,-\, \mathrm{KL}(\, q(\hat{x}) \,\|\, p(\hat{x})\,) \,+\, C,$$

differs from the amortizes MAP only by a term $H(p(\hat{\mathbf{x}}))$, which has the positive effect of improving the exploration of the reconstruction, and contains the term $\mathrm{KL}(\, q(\hat{x}) \,\|\, p(\hat{x})\,)$, which can be estimated easily using the discriminator network of a GAN Sønderby et al. (2017). To maximize this gain, we can simply train a GAN with an additional reconstruction loss $-\log p(z|\hat{x})$.

To test this algorithm, we train a representation z to classify the 40 binary attributes in the CelebA face dataset (Yang et al., 2015), and then use the above loss function to train a GAN network to reconstruct an input image $\hat{x}$ from the representation z. The results in Figure 5 show that, as expected, increasing the value of β, and therefore reducing $I(w;\mathcal{D})$, generates samples that have increasingly more random backgrounds and hair style (nuisances), while retaining facial features. In other words, the representation z is increasingly insensitive to nuisances affecting the data, while information pertaining the task is retained in the reconstruction $\hat{x}$.

More precisely, we first train a classifier on the images from the CelebA datasets resized to 32×32, where the task is to recover the 40 binary attributes associated to each image. The classifier network is the same as the one in Table 1 with the following modifications: we use Exponential Linear Units (Clevert et al., 2015) for the activations, instead of ReLU, since invertible activations generally perform better when training a GAN, and we divide by two the number of output filters in all layers to reduce the training time. A sigmoid nonlinearity is applied to the final 40-way output of the network.

To generate the image $\hat{x}$ given the 8×8×96 representation z computed by the classifier, we use a similar structure to DCGAN (Radford et al., 2016), namely $z \rightarrow$ `conv 256` $\rightarrow$ `ConvT 256s2` $\rightarrow$ `ConvT 128s2` $\rightarrow$ `conv 3` $\rightarrow$ `tanh`, where `ConvT 256s2` denotes a transpose convolution with 256 feature maps and stride 2. All convolutions have a batch

normalization layer before the activations. Finally, the discriminator network is given by $\hat{x}$ $\rightarrow$ `conv 64s2` $\rightarrow$ `conv 128s2` $\rightarrow$ `ConvT 256s2` $\rightarrow$ `conv 1` $\rightarrow$ `sigmoid`. Here, all convolutions use batch normalization followed by Leacky ReLU activations.

In this experiment, we use Gaussian multiplicative noise which is slightly more stable during training (Appendix B). To stabilize the training of the GAN, we found useful to (1) scale down the "reconstruction error" term in the loss function and (2) slowly increase the weight of the reconstruction error up to the desired value during training.

Appendix B. Gaussian multiplicative noise

In developing the theory, we chose to use log-normal multiplicative noise for the weights: The main benefit is that with this choice the information in the weights $I(w;\mathcal{D})$ can be expressed in closed form, up to an arbitrary constant C which does not matter during the optimization process (but see also Neklyudov et al. (2017) for a principled approach to this problem that uses a proper log-uniform prior). Another possibility, suggested by Kingma et al. (2015) is to use Gaussian multiplicative noise with mean 1. Unfortunately, there is no analytical expression for $I(w;\mathcal{D})$ when using Gaussian noise, but $I(w;\mathcal{D})$ can still be approximated numerically with high precision (Molchanov et al., 2017), and it makes the training process slightly more stable. The theory holds with minimal changes also in this case, and we use this choice in some experiments.

Appendix C. Proofs of theorems

Lemma C.1 (Task-nuisance decomposition) *Given a joint distribution $p(x,y)$, where y a discrete random variable, we can always find a random variable n independent of y such that $x = f(y,n)$, for some deterministic function f.*

Proof Fix $n \sim \mathrm{Uniform}(0,1)$ to be the uniform distribution on $[0,1]$. We claim that, for a fixed value of y, there is a function $\Phi_y(n)$ such that $x|y = \Phi_{y*}(n)$, where $(\cdot)_*$ denotes the push-forward map of measures. Given the claim, let $\Phi(y,n) = (y, \Phi_y(n))$. Since y is a discrete random variable, $\Phi(y,n)$ is easily seen to be a measurable function and by construction $(x,y) \sim \Phi_*(y,n)$. To see the claim, notice that, since there exists a measurable isomorphism between $\mathbb{R}^n$ and $\mathbb{R}$ (Theorem 3.1.1 of Berberian (1988)), we can assume without loss of generality that $x \in \mathbb{R}$. In this case, by definition, we can take $\Phi_y(n) = F_y^{-1}(n)$ where $F_y(t) = \mathbb{P}[x < t \,|\, y]$ is the cumulative distribution function of $p(x|y)$. ■

Proposition C.2 (Invariance and minimality) *Let n be a nuisance for the task y and let z be a sufficient representation of the input x. Suppose that z depends on n only through x* (i.e., $n \rightarrow x \rightarrow z$)*. Then,*

$$I(z;n) \leq I(z;x) - I(x;y).$$

Moreover, there exists a nuisance n such that equality holds up to a (generally small) residual ϵ

$$I(z;n) = I(z;x) - I(x;y) - \epsilon,$$

where $\epsilon := I(z;y|n) - I(x;y)$. *In particular* $0 \leq \epsilon \leq H(y|x)$, *and* $\epsilon = 0$ *whenever* y *is a deterministic function of* x. *Under these conditions, a sufficient statistic* z *is invariant (maximally insensitive) to nuisances if and only if it is minimal.*

Proof By hypothesis, we have the Markov chain $(y, n) \to x \to z$; therefore, by the DPI, we have $I(z;y,n) \leq I(z;x)$. The first term can be rewritten using the chain rule as $I(z;y,n) = I(z;n) + I(z;y|n)$, giving us

$$I(z;n) \leq I(z;x) - I(z;y|n).$$

Now, since y and n are independent, $I(z;y|n) \geq I(z;y)$. In fact,

$$\begin{aligned} I(z;y|n) &= H(y|n) - H(y|z,n) \\ &= H(y) - H(y|z,n) \\ &\geq H(y) - H(y|z) = I(y;z). \end{aligned}$$

Substituting in the inequality above, and using the fact that z is sufficient, we finally obtain

$$I(z;n) \leq I(z;x) - I(z;y) = I(z;x) - I(x;y).$$

Moreover, let n be as in Lemma 2.1. Then, since x is a deterministic function of y and n, we have

$$I(z;x) = I(z;n,y) = I(z;n) + I(z;y|n),$$

and therefore

$$I(z;n) = I(z;x) - I(z;y|n) = I(z;x) - I(x;y) - \epsilon.$$

with ϵ defined as above. Using the sufficiency of z, the previous inequality for $I(z;y|n)$, the DPI, we get the chain of inequalities

$$\begin{aligned} \epsilon = I(z;y|n) - I(x;z) &\leq I(x;y|n) - I(x;y) \\ &\leq H(y|n) - H(y|n,z) - H(y) + H(y|x) \\ &\leq H(y) - H(y|n,z) - H(y) + H(y|x) \\ &= H(y|x) - H(y|n,z) \\ &\leq H(y|x) \end{aligned}$$

from which we obtain the desired bounds for ϵ. ∎

While the proof of the following theorem is quite simple, some clarifications on the notation are in order: We assume, following a Bayesian perspective, that the data is generated by some generative model $p(\mathbf{x}, \mathbf{y}|\theta)$, where the parameters θ of the model are sampled from some (unknown) prior $p(\theta)$. Given the parameters θ, the training dataset $\mathcal{D} = (\mathbf{x}, \mathbf{y}) \sim p(x, y|\theta)$ is composed of i.i.d. samples from the unknown distribution $p(x, y|\theta)$. The output of the training algorithm on the dataset $\mathcal{D}$ is a (generally simple, *e.g.*, normal or log-normal) distribution $q(w|\mathbf{x}, \mathbf{y})$ over the weights. Putting everything together, we have a well-defined joint distribution $p(\mathbf{x}, \mathbf{y}, \theta, w) = p(\theta)p(\mathbf{x}, \mathbf{y}|\theta)q(w|\mathbf{x}, \mathbf{y})$.

Given the weights w, the network then defines an inference distribution $q(\mathbf{y}|\mathbf{x}, w)$, which we know and can compute explicitly. Another distribution, which instead we do not know, is $p(\mathbf{y}|\mathbf{x}, w)$, which is obtained from $p(\mathbf{x}, \mathbf{y}, \theta, w)$ and express the optimal inference we could perform on the labels $\mathbf{y}$ using the information contained in the weights. In a well trained network, we want the distribution approximated by the network to match the optimal distribution $q(\mathbf{y}|\mathbf{x}, w) = p(\mathbf{y}|\mathbf{x}, w)$.

Finally, recall that the conditional entropy is defined as

$$H_p(y|z) := \mathbb{E}_{y,z\sim p(y,z)}[-\log p(y|z)],$$

where z can be one random variable or a tuple of random variables. When not specified, it is assumed that the cross-entropy is computed with respect to unknown underlying data distribution $p(\mathbf{x}, \mathbf{y}, w, \theta)$. Similarly, the conditional cross-entropy is defined as

$$\begin{aligned} H_{p,q}(y|z) :=& \mathbb{E}_{y,z\sim p(y,z)}[-\log q(y|z)] \\ =& \mathbb{E}_{y,z\sim p(y,z)}[-\log p(y|z)] + \mathbb{E}_{y,z\sim p(y,z)}[\log \frac{p(y|z)}{q(y|z)}] \\ =& H_p(y|z) + \mathbb{E}_{z\sim p(z)} \mathrm{KL}(\, p(y|z) \,\|\, q(y|z) \,). \end{aligned}$$

Proposition C.3 (Information Decomposition) *Let* $\mathcal{D} = (\mathbf{x}, \mathbf{y})$ *denote the training dataset, then for any training procedure, we have*

$$H_{p,q}(\mathbf{y}|\mathbf{x}, w) = H(\mathbf{y}|\mathbf{x}, \theta) + I(\theta; \mathbf{y}|\mathbf{x}, w) + \mathbb{E}_{\mathbf{x},w} \mathrm{KL}(\, p(\mathbf{y}|\mathbf{x}, w) \,\|\, q(\mathbf{y}|\mathbf{x}, w) \,) - I(\mathbf{y}; w|\mathbf{x}, \theta). \quad (8)$$

Proof Recall that cross-entropy can be written as

$$H_{p,q}(\mathbf{y}|\mathbf{x}, w) = H_p(\mathbf{y}|\mathbf{x}, w) + \mathbb{E}_{\mathbf{x},w} \mathrm{KL}(\, p(\mathbf{y}|\mathbf{x}, w) \,\|\, q(\mathbf{y}|\mathbf{x}, w) \,),$$

so we only have to prove that

$$H_p(\mathbf{y}|\mathbf{x}, w) = H_p(\mathbf{y}|\mathbf{x}, \theta) + I(\mathbf{y}; \theta|\mathbf{x}, w) - I(\mathbf{y}; w|\mathbf{x}, \theta),$$

which is easily done using the following identities:

$$\begin{aligned} I(\mathbf{y}; \theta|\mathbf{x}, w) &= H_p(\theta, \mathbf{y}|w) - H_p(\mathbf{y}|\theta, \mathbf{x}, w), \\ I(\mathbf{y}; w|\mathbf{x}, \theta) &= H_p(\mathbf{y}|\mathbf{x}, \theta) - H_p(\mathbf{y}|\mathbf{x}, \theta, w). \end{aligned}$$

∎

Proposition C.4 (Information in the weights) *Under the previous modeling assumptions, the upper-bound to the information that the weights contain about the dataset is*

$$I(w;\mathcal{D}) \leq \tilde{I}(w;\mathcal{D}) = -\frac{1}{2} \sum_{i=1}^{\dim(w)} \log \alpha_i + C,$$

where the constant C *is arbitrary due to the improper prior.*

Proof Recall that we defined the upperbound $\tilde{I}(\mathbf{w};\mathcal{D})$ as

$$\tilde{I}(\mathbf{w};\mathcal{D}) = \mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, \tilde{q}(w)\,),$$

where $\tilde{q}(w)$ is a factorized log-uniform prior. Since the KL divergence is reparametrization invariant, we have:

$$\begin{aligned}\mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, \tilde{q}(w)\,) &= \mathrm{KL}(\, \log \mathcal{N}(\mu,\alpha) \,\|\, \log \mathrm{Uniform}\,) \\ &= \mathrm{KL}(\, \mathcal{N}(\mu,\alpha) \,\|\, \mathrm{Uniform}\,) \\ &= H(\mathcal{N}(\mu,\alpha)) + \mathrm{const} \\ &= -\sum_{i=1}^{\dim(w)} \frac{1}{2}\log(\alpha_i) + \mathrm{const},\end{aligned}$$

where we have used the formula for the entropy of a Gaussian and the fact that the KL divergence of a distribution from the uniform prior is the entropy of the distribution modulo an arbitrary constant. ■

Proposition C.5 (Flat minima have low information) *Let $\hat{w}$ be a local minimum of the cross-entropy loss $H_{p,q}(\mathbf{y}|\mathbf{x},w)$, and let $\mathcal{H}$ be the Hessian at that point. Then, for the optimal choice of the posterior $w|\mathcal{D} = \epsilon \odot \hat{w}$ centered at $\hat{w}$ that optimizes the IB Lagrangian, we have*

$$I(w;\mathcal{D}) \le \tilde{I}(w;\mathcal{D}) \le \frac{1}{2}K[\log \|w\|_2^2 + \log \|H\|_* - K\log(K^2\beta/2)]$$

where $K = \dim(w)$ and $\|\cdot\|_*$ denotes the nuclear norm.

Proof First, we switch to a logarithmic parametrization of the weights, and let $h := \log|w|$ (we can ignore the sign of the weights since it is locally constant). In this parametrization, we can approximate the IB Lagrangian to second order as

$$\mathcal{L} = \mathbb{E}_{h\sim p(h|\mathcal{D})}[H_0 + [(h-h_0)\odot w]^T \mathcal{H}[(h-h_0)\odot w] - \frac{\beta}{2}\sum_i \log\alpha_i$$

where $H_0 = H(\mathbf{y}|\mathbf{x},\hat{w})$. Now, notice that since $q(w|\mathcal{D})$ is a log-normal distribution, we have $q(h|\mathcal{D}) \sim \mathcal{N}(h_0,\alpha)$.[6] Therefore, can compute the expectation exactly as

$$\mathcal{L} = H_0 + \sum_{i=1}^{\dim(w)} \alpha_i w_i^2 \mathcal{H}_{ii} - \frac{\beta}{2}\sum_i \log\alpha_i.$$

Optimizing w.r.t. α_i we get

$$\alpha_i = \frac{\beta}{2w_i^2\mathcal{H}_{ii}},$$

6. Note that for simplicity we have ignored the offset $\alpha/2$ in the mean of the log-normal distribution.

and plugging it back in the expression for $\tilde{I}(w;\mathcal{D})$ that we obtained in the previous proposition, we have

$$\tilde{I}(w;\mathcal{D}) = -\frac{1}{2}\sum_i \log\alpha_i = \frac{1}{2}\sum_i \log(w_i^2) + \log(\mathcal{H}_{ii}) - \log(\beta/2).$$

Finally, by Jensen's inequality, we have

$$\begin{aligned}\tilde{I}(w;\mathcal{D}) &\le \frac{1}{2}K[\log(\sum_i w_i^2) + \log(\sum_i \mathcal{H}_{ii}) - \log(K^2\beta/2)] \\ &= \frac{1}{2}K[\log(\|w\|_2^2) + \log(\|H\|_*) - \log(K^2\beta/2)],\end{aligned}$$

as we wanted. ■

Proposition C.6 *Let $z = Wx$, and assume as before $W = \epsilon\odot\hat{W}$, with $\epsilon_{i,j} \sim \log\mathcal{N}(-\alpha_i/2,\alpha_i)$. Further assume that the marginals of $q(z)$ and $q(z|x)$ are both approximately Gaussian (which is reasonable for large $\dim(x)$ by the Central Limit Theorem). Then,*

$$I(z;x) + \mathrm{TC}(z) = -\frac{1}{2}\sum_{i=1}^{\dim(z)} \mathbb{E}_x \log \frac{\tilde{\alpha}_i \hat{W}_i^2 \cdot x^2}{\hat{W}_i \cdot \mathrm{Cov}(x)\hat{W}_i + \tilde{\alpha}_i \hat{W}_i^2 \cdot \mathbb{E}(x^2)},$$

where W_i denotes the i-th row of the matrix W, and $\tilde{\alpha}_i$ is the noise variance $\tilde{\alpha}_i = \exp(\alpha_i)-1$. In particular, $I(z;x)+\mathrm{TC}(z)$ is a monotone decreasing function of the weight variances α_i.

Proof First, we consider the case in which $\dim(z) = 1$, and so $w := W$ is a single row vector. By hypothesis, $q(z)$ is approximately Gaussian, with mean and variance

$$\begin{aligned}\mu_1 &:= \mathbb{E}[z] = \mathbb{E}[\sum_i \epsilon_i\hat{w}_i x_i] = \sum_i \hat{w}_i \mathbb{E}[x_i] = \hat{w}\cdot\mathbb{E}[x] \\ \sigma_1^2 &:= \mathrm{var}[z] = \mathbb{E}[(\sum_i \epsilon_i\hat{w}_i x_i)^2] - (\mathbb{E}[\sum_i \epsilon_i\hat{w}_i x_i])^2, \\ &= \mathbb{E}[\sum_{i,j} \epsilon_i\epsilon_j\hat{w}_i\hat{w}_j x_i x_j] - \sum_{i,j}\hat{w}_i\hat{w}_j\mathbb{E}[x_i]\mathbb{E}[x_j] \\ &= \tilde{\alpha}\sum_i \hat{w}_i^2\mathbb{E}[x_i]^2 + \sum_{i,j}\hat{w}_i\hat{w}_j\,(\mathbb{E}[x_i x_j] - \mathbb{E}[x_i]\mathbb{E}[x_j]) \\ &= \tilde{\alpha}\hat{w}^2\cdot\mathbb{E}[x^2] + \hat{w}\cdot\mathrm{Cov}(x)\hat{w}.\end{aligned}$$

A similar computation gives us mean and variance of $q(z|x)$:

$$\begin{aligned}\mu_0 &:= \mathbb{E}[z|x] = \hat{w}\cdot x, \\ \sigma_0^2 &:= \mathrm{var}[z|x] = \tilde{\alpha}\hat{w}^2\cdot x^2.\end{aligned}$$

Since we are assuming $\dim(z) = 1$, we trivially have $\mathrm{TC}(z) = 0$, so we are only left with $I(z;x)$ which is given by

$$\begin{aligned} I(z;x) &= \mathbb{E}_x \,\mathrm{KL}(\, q(z|x) \,\|\, q(z)\,) \\ &= \mathbb{E}_x \,\mathrm{KL}(\, \mathcal{N}(\mu_0, \sigma_0^2) \,\|\, \mathcal{N}(\mu_1, \sigma_1^2)\,) \\ &= \frac{1}{2}\mathbb{E}_x \frac{\tilde{\alpha}\hat{w}^2 \cdot x^2 + (\hat{w}\cdot x - \hat{w}\cdot \mathbb{E}[x])^2}{\sigma_1^2} - 1 - \log\frac{\sigma_0^2}{\sigma_1^2} \\ &= -\frac{1}{2}\mathbb{E}_x \log \frac{\tilde{\alpha}\hat{w}^2 \cdot x^2}{\hat{w}\cdot \mathrm{Cov}(x)\hat{w} + \tilde{\alpha}\hat{w}^2 \cdot \mathbb{E}[x^2]}. \end{aligned}$$

Now, for the general case of $\dim(z) \geq 1$, notice that

$$\begin{aligned} I(\mathbf{z};\mathbf{x}) + \mathrm{TC}(\mathbf{z}) &= \mathbb{E}_x \,\mathrm{KL}(\, \prod_k q(z_i|\mathbf{x}) \,\|\, \prod_k q(z_i)\,) \\ &= \sum_{i=1}^{\dim(z)} \mathbb{E}_x \,\mathrm{KL}(\, q(z_i|\mathbf{x}) \,\|\, q(z_i)\,), \end{aligned}$$

where $q(z_i)$ is the marginal of the k-th component of z. We can then use the previous result for each component separately, and sum everything to get the desired identity. ■

Proposition C.7 (Uniform bound for one layer) *Let $z = Wx$, where $W = \epsilon \odot \hat{W}$, where $\epsilon_{i,j} \sim \log\mathcal{N}(-\alpha/2, \alpha)$; assume that the components of x are uncorrelated, and that their kurtosis is uniformly bounded. Then, there is a strictly increasing function $g(\alpha)$ s.t. we have the uniform bound*

$$g(\alpha) \leq \frac{I(x;z) + TC(z)}{\dim(z)} \leq g(\alpha) + c,$$

where $c = O(1/\dim(x)) \leq 1$, $g(\alpha) = \log(1 - e^{-\alpha})/2$ and α is related to $I(w;\mathcal{D})$ by $\alpha = \exp\{-I(W;\mathcal{D})/\dim(W)\}$. In particular, $I(x;z) + TC(z)$ is tightly bounded by $I(W;\mathcal{D})$ and increases strictly with it.

Proof To simplify the notation we do the case $\dim z = 1$, the general case being identical. Let $w := W$ be the only row of W. First notice that, since x is uncorrelated, we have

$$\hat{w}\cdot \mathrm{Cov}(x)\hat{w} = \sum_i w_i^2(\mathbb{E}[x_i^2] - \mathbb{E}[x_i]^2) \leq w^2 \cdot \mathbb{E}[x^2]$$

Therefore,

$$\begin{aligned} I(x;z) =& -\frac{1}{2}\mathbb{E}_x \log \frac{\tilde{\alpha}\hat{w}^2 \cdot x^2}{\hat{w}\cdot \mathrm{Cov}(x)\hat{w} + \tilde{\alpha}\hat{w}^2 \cdot \mathbb{E}[x^2]} \\ \leq& -\frac{1}{2}\mathbb{E}_x \log \frac{\tilde{\alpha}\hat{w}^2 \cdot x^2}{(1+\tilde{\alpha})\hat{w}^2 \cdot \mathbb{E}[x^2]} \\ =& \frac{1}{2}\log(1+\tilde{\alpha}^{-1}) \\ & -\frac{1}{2}\mathbb{E}_x \log\left[1 + \frac{\hat{w}^2\cdot(x^2 - \mathbb{E}[x^2])}{\hat{w}^2\cdot\mathbb{E}[x^2]}\right]. \end{aligned}$$

To conclude, we want to approximate the expectation of the logarithm using a Taylor expansion, but we first need to check that the variance of the term inside the logarithm is low, which is where we need the bound on the kurtosis. In fact, since the kurtosis is bounded, there is some constant C such that for all i

$$\frac{\mathbb{E}(x_i^2 - \mathbb{E}[x_i^2])^2}{\mathbb{E}[x_i^2]^2} \leq C.$$

Now,

$$\begin{aligned} \mathrm{var}\,\frac{\hat{w}^2\cdot(x^2 - \mathbb{E}[x^2])}{\hat{w}^2\cdot\mathbb{E}[x^2]} &= \frac{\sum_i \hat{w}_i^4 \mathbb{E}(x^2 - \mathbb{E}[x^2])^2}{\sum_{i,j}\hat{w}_i^2\hat{w}_j^2\mathbb{E}[x_i^2]\mathbb{E}[x_j^2]} \\ &\leq C\frac{\sum_i \hat{w}_i^4\mathbb{E}[x_i^2]^2}{\sum_{i,j}\hat{w}_i^2\hat{w}_j^2\mathbb{E}[x_i^2]\mathbb{E}[x_j^2]} \\ &= O(1/\dim(x)). \end{aligned}$$

Therefore, we can conclude

$$I(x;z) \leq \frac{1}{2}\log(1+\tilde{\alpha}^{-1}) + O(1/\dim(x)).$$

■

Corollary C.8 (Multi-layer case) *Let W^k for $k = 1, ..., L$ be weight matrices, with $W^k = \epsilon^k \odot \hat{W}^k$ and $\epsilon^k_{i,j} = \log\mathcal{N}(-\alpha^k/2, \alpha^k)$, and let $z_{i+1} = \phi(W^k z_k)$, where $z_0 = x$ and ϕ is any nonlinearity. Then,*

$$I(z_L;x) \leq \min_{k<L}\Big\{\dim(z_k)\big[g(\alpha^k) + 1\big]\Big\}$$

where $\alpha^k = \exp\big\{-I(W^k;\mathcal{D})/\dim(W^k)\big\}$.

Proof Since we have the Markov chain $x \to z_1 \to \ldots \to z_L$, by the Data Processing Inequality we have $I(z_L;x) \leq \min\{I(z_L;z_{L-1}), I(z_{L-1};x)\}$. Iterating this inequality, we have

$$I(z_L;x) \leq \min_{k<L} I(z_{k+1}, z_k).$$

Now, notice that $I(z_{k+1};z_k) \leq I(\phi(W^k z_k);z_k) \leq I(W^k z_k;z_k)$, since applying a deterministic function can only decrease the information. But $I(W^k z_k;z_k)$ is exactly the quantity we bounded in Corollary 5.2, leading us to the desired inequality. ■

Appendix D. Q&A

It is well-known that overfitting relates to the "effective number of degrees of freedom" that can be measured in a number of ways (Friedman et al., 2001,

Chapter 7). Why should we use the information in the weights? The information in the weights is indeed one particular choice of measure of complexity. One nice aspect is that it plays a central role in many different frameworks (minimum description length, variational inference, PAC-Bayes), and correlates well with the performance of a real network.

How do you compute the nuclear norm of the Hessian? It sounds expensive! We do not need to. What we show is that, if the optimization algorithm happens to find flat minima (nuclear norm being a proxy), then it automatically limits the information in the weights - which promotes good generalization. However, if one wanted to approximate the trace of the Hessian, it could be done in linear time (Bai et al., 1996, Prop 4.1).

A nuisance n should convey no information on y *given* x, so why imposing $I(y;n) = 0$ rather than $I(y;n|x) = 0$? While $I(y;n|x) = 0$ may seem intuitively the right condition, it is actually too weak. Suppose for example that y is a deterministic function of x (*i.e.*, the labels are perfectly determined by the data, as often is the case). Then, we would have $I(y;n|x) = 0$ for any n, which would imply that everything is a nuisance for the task, which of course is not intuitively the case.

Why is the dataset a random variable, if we only have one realization of it? The theory is almost identical in both the case of a fixed dataset and a randomly sampled dataset. We consider the case of a randomly sampled dataset since it is simpler and at the same time more general. Some expressions simplify slightly and are easier to interpret, but in the end a fixed training set is given either way.

The use of $KL(q(w|D)||\tilde{q}(w))$ where $q(w|D)$ is a "posterior" defined by a learning algorithm that returns w and $\tilde{q}(w)$ is a log-uniform prior is the basic PAC-Bayes bound, that, however, gives an vacuous generalization bound due to the improper prior. A generalization bound could be stated in terms of the length of a finite interval approximation of log-uniform prior. Indeed, this is the case. However, in the limit of the interval length going to infinity, the KL divergence would still be infinite, and the optimization would be slightly more complex. As simpler option to have a generalization-bound would be to use Gaussian prior and posterior Dziugaite and Roy (2017). However, computing a good PAC-Bayes upper-bound is outside the scope of the paper, and the use of a non-informative, scale invariant prior matches the empirical behavior of networks and simplifies the theoretical analysis.

Of course a minimal representation should be invariant to nuisance variation since that's what it means to be minimal for the task. While the result may be intuitive to some, compression and invariance are not the same thing, and we are unaware of an existing proof of the claim other than for special tasks like clustering, and for small perturbations.

How do you compute the information in the weights, since you only have a sample (one set of weights that the network converged to for a given dataset)? And how do you optimize it? That looks hard! We do not need to compute the information in the weights, since we can control it. Even if we do not do so explicitly, optimizing cross-entropy with SGD yields the right solution (the solution that minimizes

the IBL for the weights). We only have one sample of the weights if we anneal the learning rate to zero, but otherwise SGD produces a posterior distribution of the weights, even if we do not impose additional stochasticity. In many cases we do, for instance using Information Dropout (Achille and Soatto (2018)) or its simpler version, Dropout. A special case of the theory can be re-derived assuming an instantiated dataset and a set of weights, with the same results.

The use of $I(w;\mathcal{D})$ does not seem to upper bound the PAC-Bayes bound. The direction of inequality is the opposite. The IB Lagrangian for the weights is a particular case that gives the sharpest PAC-Bayes bound. Choosing $q(w)$ requires some attention: Once we fix a training procedure, we can (in theory) compute/approximate the marginal distribution $q(w)$ over the stochasticity of the data (if any) as well as the stochasticity of the training procedure. This marginal can then be used in the PAC-Bayes bound: This gives the sharpest bound (McAllester, 2013) and is also equivalent to an IBL since the term $\mathbb{E}_{\mathcal{D}} \mathrm{KL}(\, q(w|\mathcal{D}) \,\|\, q(w)\,)$ measures the mutual information between the training procedure and the weights. Since in general it is not possible to explicitly compute this bound, in practice we use less tight a bound based on a factorized approximation of the marginal. This opportunistic choice later turns out to play a role in disentanglement.

Abstract

Mean-field Variational Bayes (MFVB) is an approximate Bayesian posterior inference technique that is increasingly popular due to its fast runtimes on large-scale data sets. However, even when MFVB provides accurate posterior means for certain parameters, it often mis-estimates variances and covariances. Furthermore, prior robustness measures have remained undeveloped for MFVB. By deriving a simple formula for the effect of infinitesimal model perturbations on MFVB posterior means, we provide both improved covariance estimates and local robustness measures for MFVB, thus greatly expanding the practical usefulness of MFVB posterior approximations. The estimates for MFVB posterior covariances rely on a result from the classical Bayesian robustness literature that relates derivatives of posterior expectations to posterior covariances and includes the Laplace approximation as a special case. Our key condition is that the MFVB approximation provides good estimates of a select subset of posterior means—an assumption that has been shown to hold in many practical settings. In our experiments, we demonstrate that our methods are simple, general, and fast, providing accurate posterior uncertainty estimates and robustness measures with runtimes that can be an order of magnitude faster than MCMC.

Keywords: Variational Bayes; Bayesian robustness; Mean field approximation; Linear response theory; Laplace approximation; Automatic differentiation

1. Introduction

Most Bayesian posteriors cannot be calculated analytically, so in practice we turn to approximations. Variational Bayes (VB) casts posterior approximation as an optimization problem in which the objective to be minimized is the divergence, among a sub-class of tractable distributions, from the exact posterior. For example, one widely-used and relatively simple flavor of VB is "mean field variational Bayes" (MFVB), which employs Kullback-Leibler (KL) divergence and a factorizing exponential family approximation for the tractable sub-class of posteriors (Wainwright and Jordan, 2008). MFVB has been increasingly popular as an alternative to Markov Chain Monte Carlo (MCMC) in part due to its fast runtimes on large-scale data sets. Although MFVB does not come with any general accuracy guarantees (except asymptotic ones in special cases (Westling and McCormick, 2015; Wang and Blei, 2017)), MFVB produces posterior mean estimates of certain parameters that are accurate enough to be useful in a number of real-world applications (Blei et al., 2016). Despite this ability to produce useful point estimates for large-scale data sets, MFVB is limited as an inferential tool; in particular, MFVB typically underestimates marginal variances (MacKay, 2003; Wang and Titterington, 2004; Turner and Sahani, 2011). Moreover, to the best of our knowledge, techniques for assessing Bayesian robustness have not yet been developed for MFVB. It is these inferential issues that are the focus of the current paper.

Unlike the optimization approach of VB, an MCMC posterior estimate is an empirical distribution formed with posterior draws. MCMC draws lend themselves naturally to the approximate calculation of posterior moments, such as those required for covariances. In contrast, VB approximations lend themselves naturally to sensitivity analysis, since we can analytically differentiate the optima with respect to perturbations. However, as has long been known in the Bayesian robustness literature, the contrast between derivatives and moments is not so stark since, under mild regularity conditions that allow the exchange of integration and differentiation, there is a direct correspondence between derivatives and covariance (Gustafson, 1996b; Basu et al., 1996; Efron, 2015, Section 2.2 below).

Thus, in order to calculate local sensitivity to model hyperparameters, the Bayesian robustness literature re-casts derivatives with respect to hyperparameters as posterior covariances that can be calculated with MCMC. In order to provide covariance estimates for MFVB, we turn this idea on its head and use the sensitivity of MFVB posterior expectations to estimate their covariances. These sensitivity-based covariance estimates are referred to as "linear response" estimates in the statistical mechanics literature (Opper and Saad, 2001), so we refer to them here as *linear response variational Bayes* (LRVB) covariances. Additionally, we derive straightforward MFVB versions of hyperparameter sensitivity measures from the Bayesian robustness literature. Under the assumption that the posterior means of interest are well-estimated by MFVB for all the perturbations of interest, we establish that LRVB provides a good estimate of local sensitivities. In our experiments, we compare LRVB estimates to MCMC, MFVB, and Laplace posterior approximations. We find that the LRVB covariances, unlike the MFVB and Laplace approximations, match the MCMC approximations closely while still being computed over an order of magnitude more quickly than MCMC.

In Section 2 we first discuss the general relationship between Bayesian sensitivity and posterior covariance and then define local robustness and sensitivity. Next, in Section 3, we introduce VB and derive the linear system for the MFVB local sensitivity estimates. In Section 4, we show how to use the MFVB local sensitivity results to estimate covariances and calculate canonical Bayesian hyperparameter sensitivity measures. Finally, in Section 5, we demonstrate the speed and effectiveness of our methods with simple simulated data, an application of automatic differentiation variational inference (ADVI), and a large-scale industry data set.

2. Bayesian Covariances and Sensitivity

2.1 Local Sensitivity and Robustness

Denote an unknown model parameter by the vector $\theta \in \mathbb{R}^K$, assume a dominating measure for θ on $\mathbb{R}^K$ given by λ, and denote observed data by x. Suppose that we have a vector-valued hyperparameter $\alpha \in \mathcal{A} \subseteq \mathbb{R}^D$ that parameterizes some aspects of our model. For example, α might represent prior parameters, in which case we would write the prior density with respect to λ as $p(\theta|\alpha)$, or it might parameterize a class of likelihoods, in which case we could write the likelihood as $p(x|\theta, \alpha)$. Without loss of generality, we will include α in the definition of both the prior and likelihood. For the moment, let $p_\alpha(\theta)$ denote the posterior density of θ given x and α, as given by Bayes' Theorem (this definition of $p_\alpha(\theta)$ will be a special case of the more general Definition 2 below):

$$p_\alpha(\theta) := p(\theta|x, \alpha) = \frac{p(x|\theta, \alpha)\, p(\theta|\alpha)}{\int p(x|\theta', \alpha)\, p(\theta'|\alpha)\, \lambda(d\theta')} = \frac{p(x|\theta, \alpha)\, p(\theta|\alpha)}{p(x|\alpha)}.$$

We will assume that we are interested in a posterior expectation of some function $g(\theta)$ (e.g., a parameter mean, a posterior predictive value, or squared loss): $\mathbb{E}_{p_\alpha}[g(\theta)]$. In the current work, we will quantify the uncertainty of $g(\theta)$ by the posterior variance, $\mathrm{Var}_{p_\alpha}(g(\theta))$. Other measures of central tendency (e.g., posterior medians) or uncertainty (e.g., posterior quantiles) may also be good choices but are beyond the scope of the current work.

Note the dependence of $\mathbb{E}_{p_\alpha}[g(\theta)]$ on both the likelihood and prior, and hence on α, through Bayes' Theorem. The choice of a prior and choice of a likelihood are made by the modeler and are almost invariably a simplified representation of the real world. The choices are therefore to some extent subjective, and so one hopes that the salient aspects of the posterior would not vary under reasonable variation in either choice. Consider the prior, for example. The process of prior elicitation may be prohibitively time-consuming; two practitioners may have irreconcilable subjective prior beliefs, or the model may be so complex and high-dimensional that humans cannot reasonably express their prior beliefs as formal distributions. All of these circumstances might give rise to a range of reasonable prior choices. A posterior quantity is "robust" to the prior to the extent that it does not change much when calculated under these different prior choices.

Quantifying the sensitivity of the posterior to variation in the likelihood and prior is one of the central concerns of the field of robust Bayes (Berger et al., 2000). (We will not discuss the other central concern, which is the selection of priors and likelihoods that lead to robust estimators.) Suppose that we have determined that the hyperparameter α belongs to some open set $\mathcal{A}$, perhaps after expert prior elicitation. Ideally, we would calculate the extrema of $\mathbb{E}_{p_\alpha}[g(\theta)]$ as α ranges over all of $\mathcal{A}$. These extrema are a measure of *global robustness*, and their calculation is intractable or difficult except in special cases (Moreno, 2000; Huber, 2011, Chapter 15). A more practical alternative is to examine how much $\mathbb{E}_{p_\alpha}[g(\theta)]$ changes locally in response to small perturbations in the value of α near some tentative guess, $\alpha_0 \in \mathcal{A}$. To this end we define the *local sensitivity at* α_0 (Gustafson, 2000).

Definition 1 *The local sensitivity of* $\mathbb{E}_{p_\alpha}[g(\theta)]$ *to hyperparameter* α *at* α_0 *is given by*

$$\mathbf{S}_{\alpha_0} := \left.\frac{d\mathbb{E}_{p_\alpha}[g(\theta)]}{d\alpha}\right|_{\alpha_0}. \tag{1}$$

$\mathbf{S}_{\alpha_0}$, the local sensitivity, can be considered a measure of *local robustness* (Gustafson, 2000). Throughout the paper we will distinguish between sensitivity, which comprises objectively defined quantities such as $\mathbf{S}_{\alpha_0}$, and robustness, which we treat as a more subjective concept that may be informed by the sensitivity as well as other considerations. For example, even if one knows $\mathbf{S}_{\alpha_0}$ precisely, how much posterior change is too much change and how much prior variation is reasonable remain decisions to be made by the modeler. For a more in-depth discussion of how we use the terms sensitivity and robustness, see Appendix C.

The quantity $\mathbf{S}_{\alpha_0}$ can be interpreted as measuring sensitivity to hyperparameters within a small region near $\alpha = \alpha_0$ where the posterior dependence on α is approximately linear. Then local sensitivity provides an approximation to global sensitivity in the sense that, to first order,

$$\mathbb{E}_{p_\alpha}[g(\theta)] \approx \mathbb{E}_{p_{\alpha_0}}[g(\theta)] + \mathbf{S}_{\alpha_0}^\intercal(\alpha - \alpha_0).$$

Generally, the dependence of $\mathbb{E}_{p_\alpha}[g(\theta)]$ on α is not given in any closed form that is easy to differentiate. However, as we will now see, the derivative $\mathbf{S}_{\alpha_0}$ is equal, under mild regularity conditions, to a particular posterior covariance that can easily be estimated with MCMC draws.

2.2 Covariances and Sensitivity

We will first state a general result relating sensitivity and covariance and then apply it to our specific cases of interest as they arise throughout the paper, beginning with the calculation of $\mathbf{S}_{\alpha_0}$ from Section 2.1. Consider a general base density $p_0(\theta)$ defined relative to λ and define $\rho(\theta,\alpha)$ to be a λ-measurable log perturbation function that depends on $\alpha \in \mathcal{A} \subseteq \mathbb{R}^D$. We will require the following mild technical assumption:

Assumption 1 *For all* $\alpha \in \mathcal{A}$, $\rho(\theta,\alpha)$ *is continuously differentiable with respect to* α, *and, for a given* λ*-measurable* $g(\theta)$ *there exist* λ*-integrable functions* $f_0(\theta)$ *and* $f_1(\theta)$ *such that* $|p_0(\theta)\exp(\rho(\theta,\alpha))\,g(\theta)| < f_0(\theta)$ *and* $|p_0(\theta)\exp(\rho(\theta,\alpha))| < f_1(\theta)$.

Under Assumption 1 we can normalize the log-perturbed quantity $p_0(\theta)\exp(\rho(\theta,\alpha))$ to get a density in θ with respect to λ.

Definition 2 *Denote by* $p_\alpha(\theta)$ *the normalized posterior given* α*:*

$$p_\alpha(\theta) := \frac{p_0(\theta)\exp(\rho(\theta,\alpha))}{\int p_0(\theta')\exp(\rho(\theta',\alpha))\,\lambda(d\theta')}. \tag{2}$$

For example, $p_\alpha(\theta)$ defined in Section 2.1 is equivalent to taking $p_0(\theta) = p(\theta|x,\alpha_0)$ and $\rho(\theta,\alpha) = \log p(x|\theta,\alpha) + \log p(\theta|\alpha) - \log p(x|\theta,\alpha_0) - \log p(\theta|\alpha_0)$.

For a λ-measurable function $g(\theta)$, consider differentiating the expectation $\mathbb{E}_{p_\alpha}[g(\theta)]$ with respect to α:

$$\frac{d\mathbb{E}_{p_\alpha}[g(\theta)]}{d\alpha^\intercal} := \frac{d}{d\alpha}\int p_\alpha(\theta)\,g(\theta)\,\lambda(d\theta). \tag{3}$$

When evaluated at some $\alpha_0 \in \mathcal{A}$, this derivative measures the local sensitivity of $\mathbb{E}_{p_\alpha}[g(\theta)]$ to the index α at α_0. Define $\mathcal{A}_0 \subseteq \mathcal{A}$ to be an open ball containing α_0. Under Assumption 1 we assume without loss of generality that $\rho(\theta,\alpha_0) \equiv 0$ so that $p_0(\theta) = p_{\alpha_0}(\theta)$; if $\rho(\theta,\alpha_0)$ is non-zero, we can simply incorporate it into the definition of $p_0(\theta)$. Then, under Assumption 1, the derivative in Eq. (3) is equivalent to a particular posterior covariance.

Theorem 1 *Under Assumption 1 ,*

$$\left.\frac{d\mathbb{E}_{p_\alpha}[g(\theta)]}{d\alpha^\intercal}\right|_{\alpha_0} = \mathrm{Cov}_{p_0}\left(g(\theta), \left.\frac{\partial\rho(\theta,\alpha)}{\partial\alpha}\right|_{\alpha_0}\right). \tag{4}$$

Theorem 1 is a straightforward consequence of the Lebesgue dominated convergence theorem; see Appendix A for a detailed proof. Versions of Theorem 1 have appeared many times before; e.g., Diaconis and Freedman (1986); Basu et al. (1996); Gustafson (1996b); Pérez et al. (2006) have contributed variants of this result to the robustness literature.

By using MCMC draws from $p_0(\theta)$ to calculate the covariance on the right-hand side of Eq. (4), one can form an estimate of $d\mathbb{E}_{p_\alpha}[g(\theta)]/d\alpha^\intercal$ at $\alpha = \alpha_0$. One might also approach the problem of calculating $d\mathbb{E}_{p_\alpha}[g(\theta)]/d\alpha^\intercal$ using importance sampling as follows (Owen, 2013, Chapter 9). First, an importance sampling estimate of the dependence of $\mathbb{E}_{p_\alpha}[g(\theta)]$ on α can be constructed with weights that depend on α. Then, differentiating the weights with respect to α provides a sample-based estimate of $d\mathbb{E}_{p_\alpha}[g(\theta)]/d\alpha^\intercal$. We show in Appendix B that this importance sampling approach is equivalent to using MCMC samples to estimate the covariance in Theorem 1.

An immediate corollary of Theorem 1 allows us to calculate $\mathbf{S}_{\alpha_0}$ as a covariance.

Corollary 1 *Suppose that Assumption 1 holds for some* $\alpha_0 \in \mathcal{A}$, *some* $g(\theta)$, *and for*

$$\rho(\theta,\alpha) = \log p(x|\theta,\alpha) + \log p(\theta|\alpha) - \log p(x|\theta,\alpha_0) - \log p(\theta|\alpha_0).$$

Then Theorem 1 implies that

$$\mathbf{S}_{\alpha_0} = \mathrm{Cov}_{p_0}\left(g(\theta), \left.\frac{\partial\rho(\theta,\alpha)}{\partial\alpha}\right|_{\alpha_0}\right). \tag{5}$$

Corollary 1 can be found in Basu et al. (1996), in which a version of Corollary 1 is stated in the proof of their Theorem 1, as well as in Pérez et al. (2006) and Efron (2015). Note that the definition of $\rho(\theta,\alpha)$ does not contain any normalizing constants and so can typically be easily calculated. Given N_s MCMC draws $\{\theta_n\}_{n=1}^{N_s}$ from a chain that we assume to have reached equilibrium at the stationary distribution $p_0(\theta)$, one can calculate an estimate of $\mathbf{S}_{\alpha_0}$ using the sample covariance version of Eq. (4):

$$\hat{\mathbf{S}}_{\alpha_0} := \frac{1}{N_s}\sum_{n=1}^{N_s} g(\theta_n)\left.\frac{\partial\rho(\theta_n,\alpha)}{\partial\alpha}\right|_{\alpha_0} - \left(\frac{1}{N_s}\sum_{n=1}^{N_s} g(\theta_n)\right)\left(\frac{1}{N_s}\sum_{n=1}^{N_s}\left.\frac{\partial\rho(\theta_n,\alpha)}{\partial\alpha}\right|_{\alpha_0}\right) \tag{6}$$

for $\theta_n \sim p_0(\theta)$, where $n = 1, ..., N_s$.

3. Variational Bayesian Covariances and Sensitivity

3.1 Variational Bayes

We briefly review variational Bayes and state our key assumptions about its accuracy. We wish to find an approximate distribution, in some class $\mathcal{Q}$ of tractable distributions, selected to minimize the Kullback-Leibler divergence (KL divergence) between $q \in \mathcal{Q}$ and the exact log-perturbed posterior p_α. We assume that distributions in $\mathcal{Q}$ are parameterized by a finite-dimensional parameter η in some feasible set $\Omega_\eta \subseteq \mathbb{R}^{K_\eta}$.

Definition 3 *The approximating variational family is given by*

$$\mathcal{Q} \quad := \quad \{q : q = q(\theta;\eta) \text{ for } \eta \in \Omega_\eta\}. \tag{7}$$

Given $\mathcal{Q}$, we define the optimal $q \in \mathcal{Q}$, which we call $q_\alpha(\theta)$, as the distribution that minimizes the KL divergence $KL(q(\theta;\eta)\,||p_\alpha(\theta))$ from $p_\alpha(\theta)$. We denote the corresponding optimal variational parameters as η^*.

Definition 4 *The variational approximation $q_\alpha(\theta)$ to $p_\alpha(\theta)$ is defined by*

$$q_\alpha(\theta) := q(\theta;\eta^*) \quad := \quad \textit{argmin}_{q\in\mathcal{Q}}\{KL(q(\theta;\eta)\,||p_\alpha(\theta))\}, \tag{8}$$

where

$$KL(q(\theta;\eta)\,||p_\alpha(\theta)) = \mathbb{E}_{q(\theta;\eta)}[\log q(\theta;\eta) - \log p_\alpha(\theta)].$$

In the KL divergence, the (generally intractable) normalizing constant for $p_\alpha(\theta)$ does not depend on $q(\theta)$ and so can be neglected when optimizing. In order for the KL divergence to be well defined, we assume that both $p_0(\theta)$ and $q(\theta)$ are given with respect to the same base measure, λ, and that the support of $q(\theta)$ is contained in the support of $p_\alpha(\theta)$. We will require some additional mild regularity conditions in Section 3.2 below.

A common choice for the approximating family $\mathcal{Q}$ in Eq. (7) is the "mean field family" (Wainwright and Jordan, 2008; Blei et al., 2016),

$$\mathcal{Q}_{mf} := \left\{ q(\theta) : q(\theta) = \prod_k q(\theta_k;\eta_k) \right\}, \tag{9}$$

where k indexes a partition of the full vector θ and of the parameter vector η. That is, $\mathcal{Q}_{mf}$ approximates the posterior $p_\alpha(\theta)$ as a distribution that factorizes across sub-components of θ. This approximation is commonly referred to as "MFVB," for "mean field variational Bayes." Note that, in general, each function $q(\theta_k;\eta_k)$ in the product is different. For notational convenience we write $q(\theta_k;\eta_k)$ instead of $q_k(\theta_k;\eta_k)$ when the arguments make it clear which function we are referring to, much as the same symbol p is used to refer to many different probability distributions without additional indexing.

One may additionally assume that the components $q(\theta_k;\eta_k)$ are in a convenient exponential family. Although the exponential family assumption does not in general follow from a factorizing assumption, for compactness we will refer to both the factorization and the exponential family assumption as MFVB.

In an MFVB approximation, Ω_η could be a stacked vector of the natural parameters of the exponential families, or the moment parameterization, or perhaps a transformation of these parameters into an unconstrained space (e.g., the entries of the log-Cholesky decomposition of a positive definite information matrix). For more concrete examples, see Section 5. Although all of our experiments and much of our motivating intuition will use MFVB, our results extend to other choices of $\mathcal{Q}$ that satisfy the necessary assumptions.

3.2 Variational Bayes sensitivity

Just as MCMC approximations lend themselves to moment calculations, the variational form of VB approximations lends itself to sensitivity calculations. In this section we derive the sensitivity of VB posterior means to generic perturbations—a VB analogue of Theorem 1. In Section 4 we will choose particular perturbations to calculate VB prior sensitivity and, through Theorem 1, posterior covariances.

In Definition 4, the variational approximation is a function of α through the optimal parameters $\eta^*(\alpha)$, i.e., $q_\alpha(\theta) = q(\theta, \eta^*(\alpha))$. In turn, the posterior expectation $\mathbb{E}_{q_\alpha}[g(\theta)]$ is also a function of α, and its derivative at α_0—the local sensitivity of the variational approximation to α—has a closed form under the following mild technical conditions. As with p_0, define $q_0 := q_{\alpha_0}$, and define $\eta_0^* := \eta^*(\alpha_0)$.

All the following assumptions are intended to hold for a given $p_\alpha(\theta)$, approximating class $\mathcal{Q}$, λ-measurable function $g(\theta)$, and to hold for all $\alpha \in \mathcal{A}_0$ and all η in an open neighborhood of η_0^*.

Assumption 2 *The KL divergence at $KL(q(\theta;\eta)\,||p_0(\theta))$ and expected log perturbation $\mathbb{E}_{q(\theta;\eta)}[\rho(\theta,\alpha)]$ are twice continuously differentiable in η and α.*

Assumption 3 *There exists a strict local minimum, $\eta^*(\alpha)$, of $KL(q(\theta;\eta)\,||p_\alpha(\theta))$ in Eq. (8) such that $\eta^*(\alpha)$ is interior to Ω_η.*

Assumption 4 *The expectation $\mathbb{E}_{q(\theta;\eta)}[g(\theta)]$ is a continuously differentiable function of η.*

We define the following quantities for notational convenience.

Definition 5 *Define the following derivatives of variational expectations evaluated at the optimal parameters:*

$$\mathbf{H}_{\eta\eta} := \left.\frac{\partial^2 KL(q(\theta;\eta)\,||p_0(\theta))}{\partial\eta\partial\eta^\intercal}\right|_{\eta=\eta_0^*} \quad \mathbf{f}_{\alpha\eta} := \left.\frac{\partial^2 \mathbb{E}_{q(\theta;\eta)}[\rho(\theta,\alpha)]}{\partial\alpha\partial\eta^\intercal}\right|_{\eta=\eta_0^*,\alpha=\alpha_0} \quad \mathbf{g}_\eta := \left.\frac{\partial \mathbb{E}_{q(\theta;\eta)}[g(\theta)]}{\partial\eta^\intercal}\right|_{\eta=\eta_0^*}.$$

Since $g(\theta)$, α, and η are all vectors, the quantities $\mathbf{H}_{\eta\eta}$, $\mathbf{f}_{\alpha\eta}$, and $\mathbf{g}_\eta$ are matrices. We are now ready to state a VB analogue of Theorem 1.

Theorem 2 *Consider a variational approximation $q_\alpha(\theta)$ to $p_\alpha(\theta)$ as given in Definition 4 and a λ-measurable function $g(\theta)$. Then, under Assumptions 1–4 , using the definitions given in Definition 5, we have*

$$\left.\frac{d\mathbb{E}_{q_\alpha}[g(\theta)]}{d\alpha^\intercal}\right|_{\alpha_0} \quad = \quad \mathbf{g}_\eta \mathbf{H}_{\eta\eta}^{-1} \mathbf{f}_{\alpha\eta}^\intercal. \tag{10}$$

A proof of Theorem 2 is given in Appendix D. As with Theorem 1, by choosing the appropriate $\rho(\theta,\alpha)$ and evaluating $\mathbf{f}_{\alpha\eta}$, we can use Theorem 2 to calculate the exact sensitivity of VB solutions to any arbitrary local perturbations that satisfy the regularity conditions. Assumptions 1–4 are typically not hard to verify. For an example, see Appendix E, where we establish Assumptions 1–4 for a multivariate normal target distribution and a mean-field approximation.

Eq. (10) is formally similar to frequentist sensitivity estimates. For example, the pioneering paper of Cook (1986) contains a formula for assessing the curvature of a marginal likelihood surface (Cook, 1986, Equation 15) that, like our Theorem 2, represents the sensitivity as a linear system involving the Hessian of an objective function at its optimum. The geometric interpretation of local robustness suggested by Cook (1986) has been extended to Bayesian settings (see, for example, Zhu et al. (2007, 2011)). In addition to generality, one attractive aspect of their geometric approach is its invariance to parameterization. Investigating geometric interpretations of the present work may be an interesting avenue for future research.

3.3 Approximating with Variational Bayes

Recall that we are ultimately interested in $\mathbb{E}_{p_\alpha}[g(\theta)]$. Variational approximations and their sensitivity measures will be useful to the extent that both the variational means and sensitivities are close to the exact means and sensitivities. We formalize these desiderata as follows.

Condition 1 *Under Assumptions 1–4 and the quantities defined therein, we additionally have, for all* $\alpha \in \mathcal{A}$,

$$\mathbb{E}_{q_\alpha}\left[g\left(\theta\right)\right] \approx \mathbb{E}_{p_\alpha}\left[g\left(\theta\right)\right] \quad \textit{and} \tag{11}$$

$$\left.\frac{d\mathbb{E}_{q_\alpha}\left[g\left(\theta\right)\right]}{d\alpha^\intercal}\right|_{\alpha_0} \approx \left.\frac{d\mathbb{E}_{p_\alpha}\left[g\left(\theta\right)\right]}{d\alpha^\intercal}\right|_{\alpha_0} \tag{12}$$

We will not attempt to be precise about what we mean by the "approximately equal" sign, since we are not aware of any practical tools for evaluating quantitatively whether Condition 1 holds other than running both VB and MCMC (or some other slow but accurate posterior approximation) and comparing the results. However, VB has been useful in practice to the extent that Condition 1 holds true for at least some parameters of interest. We provide some intuition for when Condition 1 might hold in Section 5.1, and will evaluate Condition 1 in each of our experiments below by comparing the VB and MCMC posterior approximate means and sensitivities.

Since Condition 1 holds only for a particular choice of $g\left(\theta\right)$, it is weaker than the assumption that q_α is close to p_α in KL divergence, or even that all the posterior means are accurately estimated. For example, as discussed in Appendix B of Giordano et al. (2015) and in Section 10.1.2 of Bishop (2006), a mean-field approximation to a multivariate normal posterior produces inaccurate covariances and may have an arbitrarily bad KL divergence from p_α, but Condition 1 holds exactly for the location parameters. We discuss the multivariate normal example further in Section 4.1 and Section 5.1 below.

4. Calculation and Uses of Sensitivity

In this section, we discuss two applications of Theorem 1 and Theorem 2: calculating improved covariance estimates and prior sensitivity measures for MFVB. Throughout this section, we will assume that we can apply Theorem 1 and Theorem 2 unless stated otherwise.

4.1 Covariances for Variational Bayes

Consider the mean field approximating family, $\mathcal{Q}_{mf}$, from Section 3.1 and a fixed exact posterior $p_0\left(\theta\right)$. It is well known that the resulting marginal variances also tend to be under-estimated even when parameters means are well-estimated (see, e.g., (MacKay, 2003; Wang and Titterington, 2004; Turner and Sahani, 2011; Bishop, 2006, Chapter 10)). Even more obviously, any $q \in \mathcal{Q}_{mf}$ yields zero as its estimate of the covariance between sub-components of θ that are in different factors of the mean field approximating family. It is therefore unreasonable to expect that $\mathrm{Cov}_{q_0}\left(g\left(\theta\right)\right) \approx \mathrm{Cov}_{p_0}\left(g\left(\theta\right)\right)$. However, if Condition 1 holds, we may expect the sensitivity of MFVB means to certain perturbations to be accurate by Condition 1, and, by Theorem 1, we expect the corresponding covariances to be accurately estimated by the MFVB sensitivity. In particular, by taking $\rho\left(\theta, \alpha\right) = \alpha^\intercal g\left(\theta\right)$ and $\alpha_0 = 0$, we have by Condition 1 that

$$\left.\frac{d\mathbb{E}_{q_\alpha}\left[g\left(\theta\right)\right]}{d\alpha^\intercal}\right|_{\alpha=0} \approx \left.\frac{d\mathbb{E}_{p_\alpha}\left[g\left(\theta\right)\right]}{d\alpha^\intercal}\right|_{\alpha=0} = \mathrm{Cov}_{p_0}\left(g\left(\theta\right)\right). \tag{13}$$

We can consequently use Theorem 2 to provide an estimate of $\mathrm{Cov}_{p_0}\left(g\left(\theta\right)\right)$ that may be superior to $\mathrm{Cov}_{q_0}\left(g\left(\theta\right)\right)$. With this motivation in mind, we make the following definition.

Definition 6 *The linear response variational Bayes (LRVB) approximation,* $\mathrm{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right)$*, is given by*

$$\mathrm{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right) := \mathbf{g}_\eta \mathbf{H}_{\eta\eta}^{-1} \mathbf{g}_\eta^\intercal. \tag{14}$$

Corollary 2 *For a given* $p_0\left(\theta\right)$*, class* $\mathcal{Q}$*, and function* $g\left(\theta\right)$*, when Assumptions 1–4 and Condition 1 hold for* $\rho\left(\theta, \alpha\right) = \alpha^\intercal g\left(\theta\right)$ *and* $\alpha_0 = 0$*, then*

$$\mathrm{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right) \approx \mathrm{Cov}_{p_0}\left(g\left(\theta\right)\right).$$

The strict optimality of η_0^* in Assumption 3 guarantees that $\mathbf{H}_{\eta\eta}$ will be positive definite and symmetric, and, as desired, the covariance estimate $\mathrm{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right)$ will be positive semidefinite and symmetric. Since the optimal value of every component of $\mathbb{E}_{q_\alpha}\left[g\left(\theta\right)\right]$ may be affected by the log perturbation $\alpha^\intercal g\left(\theta\right)$, $\mathrm{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right)$ can estimate non-zero covariances between elements of $g\left(\theta\right)$ even when they have been partitioned into separate factors of the mean field approximation.

Note that $\mathrm{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right)$ and $\mathrm{Cov}_{q_0}\left(g\left(\theta\right)\right)$ differ only when there are at least some moments of p_0 that q_0 fails to accurately estimate. In particular, if q_α provided a good approximation to p_α for both the first and second moments of $g\left(\theta\right)$, then we would have $\mathrm{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right) \approx \mathrm{Cov}_{q_0}\left(g\left(\theta\right)\right)$ since, for q_0 and p_0,

$$\begin{gathered}\mathbb{E}_{q_0}\left[g\left(\theta\right)\right] \approx \mathbb{E}_{p_0}\left[g\left(\theta\right)\right] \text{ and} \\ \mathbb{E}_{q_0}\left[g\left(\theta\right) g\left(\theta\right)^\intercal\right] \approx \mathbb{E}_{p_0}\left[g\left(\theta\right) g\left(\theta\right)^\intercal\right] \Rightarrow \\ \mathrm{Cov}_{q_0}\left(g\left(\theta\right)\right) \approx \mathrm{Cov}_{p_0}\left(g\left(\theta\right)\right),\end{gathered}$$

and, for q_α and p_α,

$$\begin{gathered}\mathbb{E}_{q_\alpha}\left[g\left(\theta\right)\right] \approx \mathbb{E}_{p_\alpha}\left[g\left(\theta\right)\right] \Rightarrow \\ \mathrm{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right) \approx \mathrm{Cov}_{p_0}\left(g\left(\theta\right)\right).\end{gathered}$$

Putting these two approximate equalities together, we see that, when the first and second moments of q_α approximately match those of p_α,

$$\mathrm{Cov}_{q_0}\left(g\left(\theta\right)\right) \approx \mathrm{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right).$$

However, in general, $\mathrm{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right) \neq \mathrm{Cov}_{q_0}\left(g\left(\theta\right)\right)$. In this sense, any discrepancy between $\mathrm{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right)$ and $\mathrm{Cov}_{q_0}\left(g\left(\theta\right)\right)$ indicates an inadequacy of the variational approximation for at least the second moments of $g\left(\theta\right)$.

Let us consider a simple concrete illustrative example which will demonstrate both how $\mathrm{Cov}_{q_0}\left(g\left(\theta\right)\right)$ can be a poor approximation to $\mathrm{Cov}_{p_0}\left(g\left(\theta\right)\right)$ and how $\mathrm{Cov}^{LR}_{q_0}\left(g\left(\theta\right)\right)$ can improve the approximation for some moments but not others. Suppose that the exact posterior is a bivariate normal,

$$p_0\left(\theta\right) = \mathcal{N}\left(\theta | \mu, \mathbf{\Sigma}\right), \tag{15}$$

where $\theta = \left(\theta_1, \theta_2\right)^\intercal$, $\mu = \left(\mu_1, \mu_2\right)^\intercal$, $\mathbf{\Sigma}$ is invertible, and $\mathbf{\Lambda} := \mathbf{\Sigma}^{-1}$. One may think of μ and $\mathbf{\Sigma}$ as known functions of x via Bayes' theorem, for example, as given by a normal-normal conjugate model. Suppose we use the MFVB approximating family

$$\mathcal{Q}_{mf} = \left\{q\left(\theta\right) : q\left(\theta\right) = q\left(\theta_1\right) q\left(\theta_2\right)\right\}.$$

One can show (see Appendix E) that the optimal MFVB approximation to p_α in the family $\mathcal{Q}_{mf}$ is given by

$$\begin{aligned}q_0\left(\theta_1\right) &= \mathcal{N}\left(\theta_1 | \mu_1, \mathbf{\Lambda}_{11}^{-1}\right) \\ q_0\left(\theta_2\right) &= \mathcal{N}\left(\theta_2 | \mu_2, \mathbf{\Lambda}_{22}^{-1}\right).\end{aligned}$$

Note that the posterior mean of θ_1 is exactly estimated by the MFVB procedure:

$$\mathbb{E}_{q_0}\left[\theta_1\right] = \mu_1 = \mathbb{E}_{p_0}\left[\theta_1\right].$$

However, if $\mathbf{\Sigma}_{12} \neq 0$, then $\mathbf{\Lambda}_{11}^{-1} < \mathbf{\Sigma}_{11}$, and the variance of θ_1 is underestimated. It follows that the expectation of θ_1^2 is *not* correctly estimated by the MFVB procedure:

$$\mathbb{E}_{q_\alpha}\left[\theta_1^2\right] = \mu_1^2 + \mathbf{\Lambda}_{11}^{-1} < \mu_1^2 + \mathbf{\Sigma}_{11} = \mathbb{E}_{p_\alpha}\left[\theta_1^2\right].$$

An analogous statement holds for θ_2. Of course, the covariance is also mis-estimated if $\mathbf{\Sigma}_{12} \neq 0$ since, by construction of the MFVB approximation,

$$\mathrm{Cov}_{q_0}(\theta_1, \theta_2) = 0 \neq \mathbf{\Sigma}_{12} = \mathrm{Cov}_{p_0}(\theta_1, \theta_2).$$

Now let us take the log perturbation $\rho(\theta, \alpha) = \theta_1\alpha_1 + \theta_2\alpha_2$. For all α in a neighborhood of zero, the log-perturbed posterior given by Eq. (2) remains multivariate normal, so it remains the case that, as a function of α, $\mathbb{E}_{q_\alpha}[\theta_1] = \mathbb{E}_{p_\alpha}[\theta_1]$ and $\mathbb{E}_{q_\alpha}[\theta_2] = \mathbb{E}_{p_\alpha}[\theta_2]$. Again, see Appendix E for a detailed proof. Consequently, Condition 1 holds with equality (not approximate equality) when $g(\theta) = \theta$. However, since the second moments are not accurate (irrespective of α), Condition 1 does not hold exactly when $g(\theta) = (\theta_1^2, \theta_2^2)^\intercal$, nor when $g(\theta) = \theta_1\theta_2$. (Condition 1 may still hold approximately for second moments when $\mathbf{\Sigma}_{12}$ is small.) The fact that Condition 1 holds with equality for $g(\theta) = \theta$ allows us to use Theorem 1 and Theorem 2 to calculate $\mathrm{Cov}_{q_0}^{LR}(g(\theta)) = \mathrm{Cov}_{p_0}(g(\theta))$, even though $\mathbb{E}_{p_0}[\theta_1\theta_2]$ and $\mathbb{E}_{p_0}\left[(\theta_1^2, \theta_2^2)^\intercal\right]$ are mis-estimated.

In fact, when Condition 1 holds with equality for some θ_i, then the estimated covariance in Eq. (14) for all terms involving θ_i will be exact as well. Condition 1 holds with equality for the means of θ_i in the bivariate normal model above, and in fact holds for the general multivariate normal case, as described in Appendix E. Below, in Section 5, in addition to robustness measures, we will also report the accuracy of Eq. (14) for estimating posterior covariances. We find that, for most parameters of interest, particularly location parameters, $\mathrm{Cov}_{q_0}^{LR}(g(\theta))$ provides a good approximation to $\mathrm{Cov}_{p_0}(g(\theta))$.

4.2 Linear Response Covariances in Previous Literature

The application of sensitivity measures to VB problems for the purpose of improving covariance estimates has a long history under the name "linear response methods." These methods originated in the statistical physics literature (Tanaka, 2000; Opper and Saad, 2001) and have been applied to various statistical and machine learning problems (Kappen and Rodriguez, 1998; Tanaka, 1998; Welling and Teh, 2004; Opper and Winther, 2004). The current paper, which builds on this line of work and on our earlier work (Giordano et al., 2015), represents a simplification and generalization of classical linear response methods and serves to elucidate the relationship between these methods and the local robustness literature. In particular, while Giordano et al. (2015) focused on moment-parameterized exponential families, we derive linear-response covariances for generic variational approximations and connect the linear-response methodology to the Bayesian robustness literature.

A very reasonable approach to address the inadequacy of MFVB covariances is simply to increase the expressiveness of the model class $\mathcal{Q}$—although, as noted by Turner and Sahani (2011), increased expressiveness does not necessarily lead to better posterior moment estimates. This approach is taken by much of the recent VB literature (e.g., Tran et al., 2015a,b; Ranganath et al., 2016; Rezende and Mohamed, 2015; Liu and Wang, 2016). Though this research direction remains lively and promising, the use of a more complex class $\mathcal{Q}$ sometimes sacrifices the speed and simplicity that made VB attractive in the first place, and often without the relatively well-understood convergence guarantees of MCMC. We also stress that the current work is not necessarily at odds with the approach of increasing expressiveness. Sensitivity methods can be a supplement to any VB approximation for which our estimators, which require solving a linear system involving the Hessian of the KL divergence, are tractable.

4.3 The Laplace Approximation and Linear Response Covariances

In this section, we briefly compare linear response covariances to the Laplace approximation (Gelman et al., 2014, Chapter 13). The Laplace approximation to $p_0(\theta)$ is formed by first finding the "maximum *a posteriori*" (MAP) estimate,

$$\hat{\theta}_{Lap} := \operatorname*{argmax}_\theta p_0(\theta), \tag{16}$$

and then forming the multivariate normal posterior approximation

$$\mathbf{H}_{Lap} := -\left.\frac{\partial^2 p_0(\theta)}{\partial\theta\partial\theta^\intercal}\right|_{\hat{\theta}_{Lap}} \tag{17}$$

$$\mathrm{Cov}_{q_{Lap}}^{Lap}(\theta) := \mathbf{H}_{Lap}^{-1}$$

$$q_{Lap}(\theta) := \mathcal{N}\left(\theta|\hat{\theta}_{Lap}, \mathrm{Cov}_{q_{Lap}}^{Lap}(\theta)\right). \tag{18}$$

Since both LRVB and the Laplace approximation require the solution of an optimization problem (Eq. (8) and Eq. (16) respectively) and the estimation of covariances via an inverse Hessian of the optimization objective (Eq. (14) and Eq. (17) respectively), it will be instructive to compare the two approaches.

Following Neal and Hinton (1998), we can, in fact, view the MAP estimator as a special variational approximation, where we define

$$\mathcal{Q}_{Lap} := \Big\{ q(\theta;\theta_0) : \int q(\theta;\theta_0)\log p_0(\theta)\,\lambda(d\theta) = \log p_0(\theta_0) \text{ and } \int q(\theta;\theta_0)\log q(\theta;\theta_0)\,\lambda(d\theta) = Constant \Big\},$$

where the $Constant$ term is constant in θ_0. That is, $\mathcal{Q}_{Lap}$ consists of "point masses" at θ_0 with constant entropy. Generally such point masses may not be defined as densities with respect to λ, and the KL divergence in Eq. (8) may not be formally defined for $q \in \mathcal{Q}_{Lap}$. However, if $\mathcal{Q}_{Lap}$ can be approximated arbitrarily well by well-defined densities (e.g., normal distributions with variance fixed at an arbitrarily small number), then we can use $\mathcal{Q}_{Lap}$ as a heuristic tool for understanding the MAP estimator.

Since $\mathcal{Q}_{Lap}$ contains only point masses, the covariance of the variational approximation is the zero matrix: $\mathrm{Cov}_{q_{Lap}}(\theta) = 0$. Thus, as when one uses the mean field assumption, $\mathrm{Cov}_{q_{Lap}}(\theta)$ underestimates the marginal variances and magnitudes of the covariances of $\mathrm{Cov}_{p_0}(\theta)$. Of course, the standard Laplace approximation uses $\mathrm{Cov}_{q_{Lap}}^{Lap}(\theta)$, not $\mathrm{Cov}_{q_{Lap}}(\theta)$, to approximate $\mathrm{Cov}_{p_0}(\theta)$. In fact, $\mathrm{Cov}_{q_{Lap}}^{Lap}(\theta)$ is equivalent to a linear response covariance matrix calculated for the approximating family $\mathcal{Q}_{Lap}$:

$$KL(q(\theta;\theta_0)\,||p_0(\theta)) = -\log p_0(\theta_0) - Constant \Rightarrow$$

$$\hat{\theta}_{Lap} = \operatorname*{argmax}_\theta p_0(\theta) = \operatorname*{argmin}_{\theta_0} KL(q(\theta;\theta_0)\,||p_0(\theta)) = \theta_0^*$$

$$\mathbf{H}_{Lap} = -\left.\frac{\partial^2 p_0(\theta)}{\partial\theta\partial\theta^\intercal}\right|_{\hat{\theta}_{Lap}} = -\left.\frac{\partial^2 KL(q(\theta;\theta_0)\,||p_0(\theta))}{\partial\theta_0\partial\theta_0^\intercal}\right|_{\theta_0^*} = \mathbf{H}_{\eta\eta}.$$

So $\hat{\theta}_{Lap} = \theta_0^*$, $\mathbf{H}_{Lap} = \mathbf{H}_{\eta\eta}$, and $\mathrm{Cov}_{q_{Lap}}^{Lap}(\theta) = \mathrm{Cov}_{q_0}^{LR}(\theta)$ for the approximating family $\mathcal{Q}_{Lap}$.

From this perspective, the accuracy of the Laplace approximation depends precisely on the extent to which Condition 1 holds for the family of point masses $\mathcal{Q}_{Lap}$. Typically, VB approximations use a $\mathcal{Q}$ that is more expressive than $\mathcal{Q}_{Lap}$, and we might expect Condition 1 to be more likely to apply for a more expressive family. It follows that we might expect the LRVB covariance estimate $\mathrm{Cov}_{q_0}^{LR}$ for general $\mathcal{Q}$ to be more accurate than the Laplace covariance approximation $\mathrm{Cov}_{q_{Lap}}^{Lap}$. We demonstrate the validity of this intuition in the experiments of Section 5.

4.4 Local Prior Sensitivity for MFVB

We now turn to estimating prior sensitivities for MFVB estimates—the variational analogues of $\mathbf{S}_{\alpha_0}$ in Definition 1. First, we define the variational local sensitivity.

Definition 7 *The local sensitivity of* $\mathbb{E}_{q_\alpha}[g(\theta)]$ *to prior parameter* α *at* α_0 *is given by*

$$\mathbf{S}_{\alpha_0}^q := \left.\frac{d\mathbb{E}_{q_\alpha}[g(\theta)]}{d\alpha}\right|_{\alpha_0}.$$

Corollary 3 *Suppose that Assumptions 1–4 and Condition 1 hold for some $\alpha_0 \in \mathcal{A}$ and for*

$$\rho(\theta, \alpha) = \log p(x|\theta, \alpha) + \log p(\theta|\alpha) - \log p(x|\theta, \alpha_0) - \log p(\theta|\alpha).$$

Then $\mathbf{S}^q_{\alpha_0} \approx \mathbf{S}_{\alpha_0}$.

Corollary 3 states that, as with the covariance approximations in Section 4.1, $\mathbf{S}^q_{\alpha_0}$ is a useful approximation to $\mathbf{S}_{\alpha_0}$ to the extent that Condition 1 holds—that is, to the extent that the MFVB means are good approximations to the exact means for the prior perturbations $\alpha \in \mathcal{A}_0$.

Under the $\rho(\theta, \alpha)$ given in Corollary 3, Theorem 2 gives the following formula for the variational local sensitivity:

$$\mathbf{S}^q_{\alpha_0} = \mathbf{g}_\eta \mathbf{H}_{\eta\eta}^{-1} \frac{\partial}{\partial \eta^\intercal} \mathbb{E}_{q(\theta;\eta)} \left[\frac{\partial \rho(\theta, \alpha)}{\partial \alpha}\bigg|_{\alpha_0} \right] \bigg|_{\eta_0^*}. \tag{19}$$

We now use Eq. (19) to reproduce MFVB versions of some standard robustness measures found in the existing literature. A simple case is when the prior $p(\theta|\alpha)$ is believed to be in a given parametric family, and we are simply interested in the effect of varying the parametric family's parameters (Basu et al., 1996; Giordano et al., 2016). For illustration, we first consider a simple example where $p(\theta|\alpha)$ is in the exponential family, with natural sufficient statistic θ and log normalizer $A(\alpha)$, and we take $g(\theta) = \theta$. In this case,

$$\begin{aligned}
\log p(\theta|\alpha) &= \alpha^\intercal \theta - A(\alpha) \\
\mathbf{f}_{\alpha\eta} &= \frac{\partial}{\partial \eta^\intercal} \mathbb{E}_{q(\theta;\eta)} \left[\frac{\partial}{\partial \alpha} \left(\alpha^\intercal \theta - A(\alpha) \right)\bigg|_{\alpha_0} \right] \bigg|_{\eta_0^*} \\
&= \left(\frac{\partial}{\partial \eta^\intercal} \mathbb{E}_{q(\theta;\eta)}[\theta] - \frac{\partial}{\partial \eta^\intercal} \frac{\partial A(\alpha)}{\partial \alpha}\bigg|_{\alpha_0} \right) \bigg|_{\eta_0^*} \\
&= \frac{\partial}{\partial \eta^\intercal} \mathbb{E}_{q(\theta;\eta)}[\theta] \bigg|_{\eta_0^*} \\
&= \mathbf{g}_\eta.
\end{aligned}$$

Note that when $\mathbf{f}_{\alpha\eta} = \mathbf{g}_\eta$, Eq. (19) is equivalent to Eq. (14). So we see that

$$\mathbf{S}^q_{\alpha_0} = \mathrm{Cov}^{LR}_{q_0}(\theta).$$

In this case, the sensitivity is simply the linear response covariance estimate of the covariance, $\mathrm{Cov}^{LR}_{q_0}(\theta)$. By the same reasoning, the exact posterior sensitivity is given by

$$\mathbf{S}_{\alpha_0} = \mathrm{Cov}_{p_0}(\theta).$$

Thus, $\mathbf{S}^q_{\alpha_0} \approx \mathbf{S}_{\alpha_0}$ to the extent that $\mathrm{Cov}^{LR}_{q_0}(\theta) \approx \mathrm{Cov}_{p_0}(\theta)$, which again holds to the extent that Condition 1 holds. Note that if we had used a mean field assumption and had tried to use the direct, uncorrected response covariance $\mathrm{Cov}_{q_0}(\theta)$ to try to evaluate $\mathbf{S}^q_{\alpha_0}$, we would have erroneously concluded that the prior on one component, θ_{k_1}, would not affect the posterior mean of some other component, θ_{k_2}, for $k_2 \neq k_1$.

Sometimes it is easy to evaluate the derivative of the log prior even when it is not easy to normalize it. As an example, we will show how to calculate the local sensitivity to the concentration parameter of an LKJ prior (Lewandowski et al., 2009) under an inverse Wishart variational approximation. The LKJ prior is defined as follows. Let $\mathbf{\Sigma}$ (as part of θ) be an unknown $K \times K$ covariance matrix. Define the $K \times K$ scale matrix $\mathbf{M}$ such that

$$\mathbf{M}_{ij} = \begin{cases} \sqrt{\mathbf{\Sigma}_{ij}} & \text{if } i = j \\ 0 & \text{otherwise.} \end{cases}$$

Using $\mathbf{M}$, define the correlation matrix $\mathbf{R}$ as

$$\mathbf{R} = \mathbf{M}^{-1} \mathbf{\Sigma} \mathbf{M}^{-1}.$$

The LKJ prior on the covariance matrix $\mathbf{R}$ with concentration parameter $\alpha > 0$ is given by:

$$p_{\mathrm{LKJ}}(\mathbf{R}|\alpha) \propto |\mathbf{R}|^{\alpha - 1}.$$

The Stan manual recommends the use of p_{LKJ}, together with an independent prior on the diagonal entries of the scaling matrix $\mathbf{M}$, for the prior on a covariance matrix that appears in a hierarchical model (Stan Team, 2015, Chapter 9.13).

Suppose that we have chosen the variational approximation

$$q(\mathbf{\Sigma}) := \mathrm{InverseWishart}(\mathbf{\Sigma}|\mathbf{\Psi}, \nu),$$

where $\mathbf{\Psi}$ is a positive definite scale matrix and ν is the number of degrees of freedom. In this case, the variational parameters are $\eta = (\mathbf{\Psi}, \nu)$. We write η with the understanding that we have stacked only the upper-diagonal elements of $\mathbf{\Psi}$ since $\mathbf{\Psi}$ is constrained to be symmetric and η^* must be interior. As we show in Appendix G,

$$\mathbb{E}_q[\log p_{\mathrm{LKJ}}(\mathbf{R}|\alpha)] = (\alpha - 1) \left(\log|\mathbf{\Psi}| - \psi_K\left(\frac{\nu}{2}\right) - \sum_{k=1}^K \log\left(\frac{1}{2}\mathbf{\Psi}_{kk}\right) + K\psi\left(\frac{\nu - K + 1}{2}\right) \right) + Constant,$$

where $Constant$ contains terms that do not depend on α, and where ψ_K denotes the multivariate digamma function. Consequently, we can evaluate

$$\begin{aligned}
\mathbf{f}_{\alpha\eta} &= \frac{\partial}{\partial \eta^\intercal} \mathbb{E}_{q(\theta;\eta)} \left[\frac{\partial}{\partial \alpha} \log p(\mathbf{\Sigma}|\alpha) \right] \bigg|_{\eta=\eta_0^*, \alpha=\alpha_0} \\
&= \frac{\partial}{\partial \eta^\intercal} \left(\log|\mathbf{\Psi}| - \psi_K\left(\frac{n}{2}\right) - \sum_{k=1}^K \log\left(\frac{1}{2}\mathbf{\Psi}_{kk}\right) + K\psi\left(\frac{n - K + 1}{2}\right) \right) \bigg|_{\eta_0^*}.
\end{aligned} \tag{20}$$

This derivative has a closed form, but the bookkeeping required to represent an unconstrained parameterization of the matrix $\mathbf{\Psi}$ within η would be tedious. In practice, we evaluate terms like $\mathbf{f}_{\alpha\eta}$ using automatic differentiation tools (Baydin et al., 2018).

Finally, in cases where we cannot evaluate $\mathbb{E}_{q(\theta;\eta)}[\log p(\theta|\alpha)]$ in closed form as a function of η, we can use numerical techniques as described in Section 4.5. We thus view $\mathbf{S}^q_{\alpha_0}$ as the exact sensitivity to an approximate KL divergence.

4.5 Practical Considerations when Computing the Sensitivity of Variational Approximations

We briefly discuss practical issues in the computation of Eq. (10), which requires calculating the product $\mathbf{g}_\eta \mathbf{H}_{\eta\eta}^{-1}$ (or, equivalently, $\mathbf{H}_{\eta\eta}^{-1} \mathbf{g}_\eta^\intercal$ since $\mathbf{H}_{\eta\eta}$ is symmetric). Calculating $\mathbf{H}_{\eta\eta}$ and solving this linear system can be the most computationally intensive part of computing Eq. (10).

We first note that it can be difficult and time consuming in practice to manually derive and implement second-order derivatives. Even a small programming error can lead to large errors in Theorem 2. To ensure accuracy and save analyst time, we evaluated all the requisite derivatives using the Python `autograd` automatic differentiation library (Maclaurin et al., 2015) and the Stan math automatic differentiation library (Carpenter et al., 2015).

Note that the dimension of $\mathbf{H}_{\eta\eta}$ is as large as that of η, the parameters that specify the variational distribution $q(\theta; \eta)$. Many applications of MFVB employ many latent variables, the number of which may even scale with the amount of data—including several of the cases that we examine in Section 5. However, these applications typically have special structure that render $\mathbf{H}_{\eta\eta}$ sparse, allowing the practitioner to calculate $\mathbf{g}_\eta \mathbf{H}_{\eta\eta}^{-1}$

quickly. Consider, for example, a model with "global" parameters, θ_{glob}, that are shared by all the individual datapoint likelihoods, and "local" parameters, $\theta_{loc,n}$, associated with likelihood of a single datapoint indexed by n. By "global" and "local" we mean the likelihood and assumed variational distribution factorize as

$$p\left(x, \theta_{glob}, \theta_{loc,1}, ..., \theta_{loc,N}\right) = p\left(\theta_{glob}\right) \prod_{n=1}^{N} p\left(x|\theta_{loc,n}, \theta_{glob}\right) p\left(\theta_{loc,n}|\theta_{glob}\right) \tag{21}$$

$$q\left(\theta;\eta\right) = q\left(\theta_{glob};\eta_{glob}\right) \prod_{n=1}^{N} q\left(\theta_{loc,n};\eta_{n}\right) \text{ for all } q\left(\theta;\eta\right) \in \mathcal{Q}.$$

In this case, the second derivatives of the variational objective between the parameters for local variables vanish:

$$\text{for all } n \neq m, \frac{\partial^2 KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right)}{\partial\eta_{loc,n}\partial\eta_{loc,m}^{\intercal}} = 0.$$

The model in Section 5.3 has such a global / local structure; see Section 5.3.2 for more details. Additional discussion, including the use of Schur complements to take advantage of sparsity in the log likelihood, can be found in Giordano et al. (2015).

When even calculating or instantiating $\mathbf{H}_{\eta\eta}$ is prohibitively time-consuming, one can use conjugate gradient algorithms to approximately compute $\mathbf{H}_{\eta\eta}^{-1}\mathbf{g}_{\eta}^{\intercal}$ (Wright and Nocedal, 1999, Chapter 5). The advantage of conjugate gradient algorithms is that they approximate $\mathbf{H}_{\eta\eta}^{-1}\mathbf{g}_{\eta}^{\intercal}$ using only the Hessian-vector product $\mathbf{H}_{\eta\eta}\mathbf{g}_{\eta}^{\intercal}$, which can be computed efficiently using automatic differentiation without ever forming the full Hessian $\mathbf{H}_{\eta\eta}$. See, for example, the `hessian_vector_product` method of the Python `autograd` package (Maclaurin et al., 2015). Note that a separate conjugate gradient problem must be solved for each column of $\mathbf{g}_{\eta}^{\intercal}$, so if the parameter of interest $g\left(\theta\right)$ is high-dimensional it may be faster to pay the price for computing and inverting the entire matrix $\mathbf{H}_{\eta\eta}$. See 5.3.2 for more discussion of a specific example.

In Theorem 2, we require η_0^* to be at a true local optimum. Otherwise the estimated sensitivities may not be reliable (e.g., the covariance implied by Eq. (14) may not be positive definite). We find that the classical MFVB coordinate ascent algorithms (Blei et al. (2016, Section 2.4)) and even quasi-second order methods, such as BFGS (e.g., Regier et al., 2015), may not actually find a local optimum unless run for a long time with very stringent convergence criteria. Consequently, we recommend fitting models using second-order Newton trust region methods. When the Hessian is slow to compute directly, as in Section 5, one can use the conjugate gradient trust region method of Wright and Nocedal (1999, Chapter 7), which takes advantage of fast automatic differentiation Hessian-vector products without forming or inverting the full Hessian.

5. Experiments

We now demonstrate the speed and effectiveness of linear response methods on a number of simulated and real data sets. We begin with simple simulated data to provide intuition for how linear response methods can improve estimates of covariance relative to MFVB and the Laplace approximation. We then develop linear response covariance estimates for ADVI and apply them to four real-world models and data sets taken from the Stan examples library (Stan Team, 2017). Finally, we calculate both linear response covariances and prior sensitivity measures for a large-scale industry data set. In each case, we compare linear response methods with ordinary MFVB, the Laplace approximation, and MCMC. We show that linear response methods provide the best approximation to MCMC while still retaining the speed of approximate methods. Code and instructions to reproduce the results of this section can be found in the git repository `rgiordan/CovariancesRobustnessVBPaper`.

5.1 Simple Expository Examples

In this section we provide a sequence of simple examples comparing MFVB and LRVB with Laplace approximations. These examples provide intuition for the covariance estimate $\mathrm{Cov}_{q_0}^{LR}\left(g\left(\theta\right)\right)$ and illustrate how

the sensitivity analysis motivating $\mathrm{Cov}_{q_0}^{LR}\left(g\left(\theta\right)\right)$ differs from the local posterior approximation motivating $\mathrm{Cov}_{q_{Lap}}^{Lap}\left(g\left(\theta\right)\right)$.

For each example, we will explicitly specify the target posterior $p_0\left(\theta\right)$ using a mixture of normals. This will allow us to define known target distributions with varying degrees of skewness, over-dispersion, or correlation and compare the truth with a variational approximation. Formally, for some fixed K_z, component indicators z_k, $k = 1, ..., K_z$, component probabilities π_k, locations μ_k, and covariances Σ_k, we set

$$p\left(z\right) = \prod_{k=1}^{K_z} \pi_k^{z_k}$$

$$p_0\left(\theta\right) = \sum_z p\left(z\right) p\left(\theta|z\right) = \sum_z p\left(z\right) \prod_{k=1}^{K_z} \mathcal{N}\left(\theta; m_k, \mathbf{\Sigma}_k\right)^{z_k}.$$

The values π, m and Σ will be chosen to achieve the desired shape for each example using up to $K_z = 3$ components. There will be no need to state the precise values of π, m, and Σ; rather, we will show plots of the target density and report the marginal means and variances, calculated by Monte Carlo.[1]

We will be interested in estimating the mean and variance of the first component, so we take $g\left(\theta\right) = \theta_1$. Consequently, in order to calculate $\mathrm{Cov}_{q_0}^{LR}(\theta_1)$, we will be considering the perturbation $\rho\left(\theta, \alpha\right) = \alpha\theta_1$ with scalar α and $\alpha_0 = 0$.

For the variational approximations, we will use a factorizing normal approximation:

$$\mathcal{Q}_{mf} = \left\{ q\left(\theta\right) : q\left(\theta\right) = \prod_{k=1}^{K} \mathcal{N}\left(\theta_k; \mu_k, \sigma_k^2\right) \right\}.$$

In terms of Eq. (7), we take $\eta = \left(\mu_1, ..., \mu_K, \log\sigma_1, ..., \log\sigma_K\right)^{\intercal}$. Thus $\mathbb{E}_{q(\theta;\eta)}\left[g\left(\theta\right)\right] = \mathbb{E}_{q(\theta;\eta)}\left[\theta_1\right] = \mu_1$. In the examples below, we will use multiple distinct components in the definition of $p_0\left(\theta\right)$, so that $p_0\left(\theta\right)$ is non-normal and $p_0\left(\theta\right) \notin \mathcal{Q}_{mf}$.

Since the expectation $\mathbb{E}_{q(\theta;\eta)}\left[\log p\left(\theta\right)\right]$ is intractable, we replace the exact KL divergence with a Monte Carlo approximation using the "re-parameterization trick" (Kingma and Welling, 2013; Rezende et al., 2014; Titsias and Lázaro-Gredilla, 2014). Let $\circ$ denote the Hadamard (component-wise) product. Let $\xi_m \overset{iid}{\sim} \mathcal{N}\left(0, I_K\right)$ for $m = 1, ..., M$. We define

$$\theta_m := \sigma \circ \xi_m + \mu$$

$$KL_{approx}\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right) := -\frac{1}{M}\sum_{m=1}^{M} \log p_0\left(\theta_m\right) - \sum_{k=1}^{K} \log\sigma_k,$$

which is a Monte Carlo estimate of $KL\left(q\left(\theta;\eta\right)||p_0\left(\theta\right)\right)$. We found $M = 10000$ to be more than adequate for our present purposes of illustration. Note that we used the same draws ξ_m for both optimization and for the calculation of $\mathbf{H}_{\eta\eta}$ in order to ensure that the η_0^* at which $\mathbf{H}_{\eta\eta}$ was evaluated was in fact an optimum. This approach is similar to our treatment of ADVI; see Section 5.2 for a more detailed discussion.

5.1.1 MULTIVARIATE NORMAL TARGETS

If we take only a single component in the definition of $p_0\left(\theta\right)$ ($K_z = 1$), then $p_\alpha\left(\theta\right)$ is a multivariate normal distribution for all α, and the Laplace approximation $q_{Lap}\left(\theta\right)$ is equal to $p_\alpha\left(\theta\right)$ for all α. Furthermore, as discussed in Section 4.1 and Appendix E, the variational means $\mathbb{E}_{q_\alpha}\left[\theta\right] = \mu$ are exactly equal to the exact posterior mean $\mathbb{E}_{p_\alpha}\left[\theta\right] = m_1$ for all α (even though in general $\mathrm{Cov}_{q_0}\left(\theta\right) \neq \Sigma_1$). Consequently, for all α,

1. MFVB is often used to approximate the posterior when the Bayesian generative model for data x is a mixture model (e.g., Blei et al. (2003)). By contrast, we note for clarity that we are *not* using the mixture model as a generative model for x here. E.g., z is not one of the parameters composing θ, and we are not approximating the distribution of z in the variational distribution $q\left(\theta\right)$. Rather, we are using mixtures as a way of flexibly defining skewed and over-dispersed targets, $p\left(\theta\right)$.

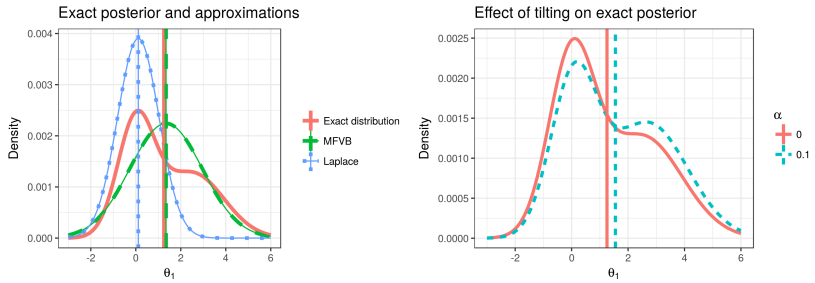

Figure 1: A univariate skewed distribution. Vertical lines show the location of the means.

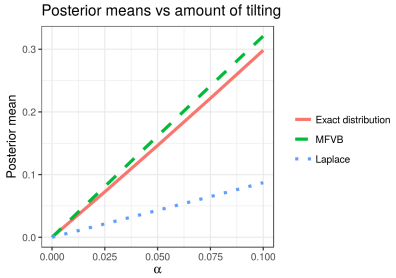

Metric	Exact	LRVB	MFVB	Laplace
mean	1.253		1.345	0.111
var	2.872	3.245	2.599	0.849

Figure 2: Effect of tilting on a univariate skew distribution.

the variational approximation, the Laplace approximation, and the exact $p_0(\theta)$ all coincide in their estimates of $\mathbb{E}[\theta]$, and by, Corollary 2, $\Sigma = \mathrm{Cov}_{p_0}(\theta) = \mathrm{Cov}^{LR}_{q_0}(\theta) = \mathrm{Cov}^{Lap}_{q_{Lap}}(\theta)$. Of course, if Σ is not diagonal, $\mathrm{Cov}_{q_0}(\theta) \neq \Sigma$ because of the mean field assumption. Since this argument holds for the whole vector θ, it holds *a fortiori* for our quantity of interest, the first component $g(\theta) = \theta_1$.

In other words, the Laplace approximation will differ only from the LRVB approximation when $p_0(\theta)$ is not multivariate normal, a situation that we will now bring about by adding new components to the mixture; i.e., by increasing K_z.

5.1.2 A Univariate Skewed Distribution
