$\ell_{2,1}$-RPCA Unlike RANSAC, modern methods for outlier detection in PCA are primarily based on convex optimization. One of the earliest and most important such methods is the $\ell_{2,1}$-RPCA method of Xu et al. (2012), which is in turn inspired by the Robust Principal Component Analysis (RPCA) algorithm of Candès et al. (2011). $\ell_{2,1}$-RPCA computes a $(\ell_* + \ell_{2,1})$-norm decomposition[2] of the data matrix, instead of the $(\ell_* + \ell_1)$-decomposition in Candès et al. (2011). More specifically, $\ell_{2,1}$-RPCA solves the optimization problem

$$\min_{\boldsymbol{L}, \boldsymbol{E}:\, \tilde{\boldsymbol{\mathcal{X}}} = \boldsymbol{L} + \boldsymbol{E}} \ \left\|\boldsymbol{L}\right\|_* + \lambda \left\|\boldsymbol{E}\right\|_{2,1}, \tag{3}$$

which attempts to decompose the data matrix $\tilde{\boldsymbol{\mathcal{X}}} = [\boldsymbol{\mathcal{X}}\ \boldsymbol{\mathcal{O}}]\boldsymbol{\Gamma}$ into the sum of a low-rank matrix $\boldsymbol{L}$, and a matrix $\boldsymbol{E}$ that has only a few non-zero columns. The idea is that $\boldsymbol{L}$ is associated with the inliers, having the form $\boldsymbol{L} = [\boldsymbol{\mathcal{X}}\ \boldsymbol{0}_{D \times M}]\boldsymbol{\Gamma}$, and $\boldsymbol{E}$ is associated with the outliers, having the form $\boldsymbol{E} = [\boldsymbol{0}_{D \times N}\ \boldsymbol{\mathcal{O}}]\boldsymbol{\Gamma}$. The optimization problem (3) is convex and admits theoretical guarantees

1. We note that the proof of Theorem 2 in Tsakiris and Vidal (2015) contained an inaccuracy which makes its statement incomplete. The complete statement is Theorem 11 in the present paper.
2. Here ℓ_* denotes the nuclear norm, which is the sum of the singular values of the matrix. Also, $\ell_{2,1}$ is defined as the sum of the Euclidean norms of the columns of a matrix.

and efficient algorithms based on the alternating direction method of multipliers (ADMM) (Gabay and Mercier, 1976). However, it is expected to succeed only when the intrinsic dimension d of the inliers is small enough (otherwise $[\boldsymbol{\mathcal{X}}\ \mathbf{0}_{D\times M}]$ will not be low-rank), and the outlier ratio is not too large (otherwise $[\mathbf{0}_{D\times N}\ \boldsymbol{\mathcal{O}}]$ will not be column-sparse). Finally, notice that $\ell_{2,1}$-RPCA does not require as input the subspace dimension d, because it does not directly compute an estimate for the subspace. Rather, the subspace can be obtained subsequently by applying classic PCA on $\boldsymbol{L}$, and now one does need an estimate for d.

SE-RPCA Separating outliers from low-rank inlier points can also be achieved by exploiting the *self-expressiveness* (SE) property of the data matrix, a notion popularized by the work of Elhamifar and Vidal (2011, 2013) in the area of subspace clustering (Vidal, 2011). Specifically, if a column $\tilde{\boldsymbol{x}}$ of $\tilde{\boldsymbol{\mathcal{X}}}$ is an inlier, then it can be expressed as a linear combination of d other inliers in $\tilde{\boldsymbol{\mathcal{X}}}$, while if $\tilde{\boldsymbol{x}}$ is an outlier, then in principle it requires D columns of $\tilde{\boldsymbol{\mathcal{X}}}$. The coefficient matrix $\boldsymbol{C}$ can be obtained as the solution to the convex optimization problem

$$\min_{\boldsymbol{C}} \ \|\boldsymbol{C}\|_1 \ \text{ s.t. } \ \tilde{\boldsymbol{\mathcal{X}}} = \tilde{\boldsymbol{\mathcal{X}}}\boldsymbol{C}, \ \ \text{Diag}(\boldsymbol{C}) = \mathbf{0}, \tag{4}$$

where the extra constraint prevents the trivial solution $\boldsymbol{C} = I$. Given $\boldsymbol{C}$, and under the hypothesis that d/D is small, a column of $\tilde{\boldsymbol{\mathcal{X}}}$ is declared as an outlier, if the ℓ_1 norm of the corresponding column of $\boldsymbol{C}$ is large; see Soltanolkotabi and Candès (2012) for an explicit formula. SE-RPCA admits theoretical guarantees (Soltanolkotabi and Candès, 2012) and efficient ADMM implementations (Elhamifar and Vidal, 2013). Moreover, the recent work of You et al. (2017) has demonstrated that the information contained in the self-expressive matrix $\boldsymbol{C}$ can be further exploited to identify the outliers by means of a random walk on the directed affinity graph defined by $\boldsymbol{C}$, thus yielding superior results than the simple thresholding of the norms of the columns of $\boldsymbol{C}$. In contrast to $\ell_{2,1}$-RPCA, which in principle fails in the presence of a very large number of outliers, SE-RPCA is still expected to perform well, since the existence of sparse *subspace-preserving* self-expressive patterns does not depend on the number of outliers present. Also, similarly to $\ell_{2,1}$-RPCA, SE-RPCA does not directly require an estimate for the subspace dimension d. Nevertheless, knowledge of d is necessary if one wants to furnish an actual subspace estimate, which entails removing the outliers (a judiciously chosen threshold would also be necessary here) and applying PCA.

REAPER Another robust subspace learning method that admits an interesting theoretical analysis is *REAPER* (Lerman et al., 2015), which is conceptually associated with the optimization problem

$$\min_{\boldsymbol{P}} \sum_{j=1}^{L} \left\|(\boldsymbol{I}_D - \boldsymbol{P})\tilde{\boldsymbol{x}}_j\right\|_2 \ \text{ s.t. } \ \boldsymbol{P} \ \text{ is an orthogonal projection} \quad \text{and} \quad \text{Trace}(\boldsymbol{P}) = d. \tag{5}$$

Here the vector $\tilde{\boldsymbol{x}}_j$ denotes the j-th column of $\tilde{\boldsymbol{\mathcal{X}}}$ and the matrix $\boldsymbol{P}$ denotes the orthogonal projection onto a d-dimensional linear subspace $\mathcal{S}$. Notice that $\boldsymbol{P}$ can be thought of as the product $\boldsymbol{P} = \boldsymbol{U}\boldsymbol{U}^\top$, where the columns of $\boldsymbol{U} \in \mathbb{R}^{D\times d}$ form an orthonormal basis for $\mathcal{S}$. Since the problem in (5) is non-convex, Lerman et al. (2015) relaxed it to the convex semi-definite program

$$\min_{\boldsymbol{P}} \sum_{j=1}^{L} \left\|(\boldsymbol{I}_D - \boldsymbol{P})\tilde{\boldsymbol{x}}_j\right\|_2 \ \text{ s.t. } \ \mathbf{0} \le \boldsymbol{P} \le \boldsymbol{I}_D, \ \ \text{Trace}\,(\boldsymbol{P}) = d, \tag{6}$$

and obtained an approximate solution $\boldsymbol{P}^*$ to (5) as the rank-d orthogonal projector that is closest to the global solution of (6), as measured by the nuclear norm. It was shown by Lerman et al. (2015) that the orthoprojector $\boldsymbol{P}^*$ obtained in this way is within a neighborhood of the orthoprojector corresponding to the true underlying inlier subspace. In practice, the semi-definite program (6) may become prohibitively expensive to solve even for moderate values of the ambient dimension D. As a consequence, the authors proposed an *Iteratively Reweighted Least Squares (IRLS)* scheme to obtain a numerical solution of (6), whose objective value was shown to converge to a neighborhood of the optimal objective value of problem (6).

One advantage of REAPER with respect to $\ell_{2,1}$-RPCA and SE-RPCA, is that its theoretical conditions allow for the subspace to have arbitrarily large relative dimension, providing that the outlier ratio is sufficiently small. It is interesting to note here that this is precisely the condition under which RANSAC (Huber, 1981) can handle large relative dimensions; the main difference though between RANSAC and REAPER is that the latter employs convex optimization, and for a fixed relative dimension and computational budget REAPER can tolerate considerably higher outlier ratios than RANSAC (see Fig. 6, §7).

COHERENCE PURSUIT (CoP) The recent work of Rahmani and Atia (2017) analyzes a simple yet efficient algorithm for detecting the inlier space from pairwise point coherences, hence called *Coherence Pursuit (CoP)*. The main insight behind CoP is that, under the hypothesis that the inliers lie in a low-dimensional subspace, inlier points tend to have significantly higher coherence with the rest of the points in the dataset, than outlier points. Hence the columns of the pairwise coherence matrix $\tilde{\boldsymbol{\mathcal{X}}}^\top\tilde{\boldsymbol{\mathcal{X}}}$ that have large norm are expected to correspond to inliers. Indeed, CoP orders the columns of $\tilde{\boldsymbol{\mathcal{X}}}^\top\tilde{\boldsymbol{\mathcal{X}}}$ in descending values for a given norm and selects sufficiently many of them from the top, until their span yields a d-dimensional subspace. Similarly to SE-RPCA, the performance of CoP is not expected to be significantly degraded as the number of outliers increases, as long as each outlier remains sufficiently incoherent with the rest of the dataset. As demonstrated by Rahmani and Atia (2017), CoP has a competitive performance and admits an extensive theoretical analysis.

L1-PCA* Finally, we mention the method L1-PCA* of Brooks et al. (2013), since it works with the orthogonal complement of the subspace, similarly to the proposed method of the present paper. Nevertheless, L1-PCA* is slightly unusual in that it learns ℓ_1 hyperplanes, i.e., hyperplanes that minimize the ℓ_1 distance to the points, as opposed to the Euclidean distance used by methods such as PCA and REAPER. Overall, no theoretical guarantees seem to be known for L1-PCA*, as far as the subspace learning problem is concerned. In addition, L1-PCA* requires solving $\mathcal{O}(D^2)$ linear programs, where D is the ambient dimension, which makes it computationally expensive.

3. Problem Formulation

In this section we formulate the problem addressed in this paper. We describe our data model (§3.1), and motivate the problem at a conceptual (§3.2) and computational level (§3.3).

3.1 Data model

We employ a deterministic noise-free data model, under which the given data is

$$\tilde{\boldsymbol{\mathcal{X}}} = [\boldsymbol{\mathcal{X}}\ \ \boldsymbol{\mathcal{O}}]\boldsymbol{\Gamma} = [\tilde{\boldsymbol{x}}_1, \ldots, \tilde{\boldsymbol{x}}_L] \in \mathbb{R}^{D\times L}, \tag{7}$$

where the N inliers $\boldsymbol{\mathcal{X}} = [\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N] \in \mathbb{R}^{D\times N}$ lie in the intersection of the unit sphere $\mathbb{S}^{D-1}$ with an unknown proper subspace $\mathcal{S}$ of $\mathbb{R}^D$ of unknown dimension $1 \leq d \leq D-1$, and the M outliers $\boldsymbol{\mathcal{O}} = [\boldsymbol{o}_1, \ldots, \boldsymbol{o}_M] \in \mathbb{R}^{D\times M}$ lie on the sphere $\mathbb{S}^{D-1}$. The unknown permutation $\boldsymbol{\Gamma}$ indicates that we do not know which point is an inlier and which point is an outlier. Finally, we assume that the points $\tilde{\boldsymbol{\mathcal{X}}}$ are in *general position*, in the sense that there are no relations among the columns of $\tilde{\boldsymbol{\mathcal{X}}}$ except for those implied by the inclusions $\boldsymbol{\mathcal{X}} \subset \mathcal{S}$ and $\tilde{\boldsymbol{\mathcal{X}}} \subset \mathbb{R}^D$. In particular, every D-tuple of columns of $\tilde{\boldsymbol{\mathcal{X}}}$ such that at most d points come from $\boldsymbol{\mathcal{X}}$ is linearly independent. Notice that as a consequence every d-tuple of inliers and every D-tuple of outliers are linearly independent, and also $\boldsymbol{\mathcal{X}} \cap \boldsymbol{\mathcal{O}} = \emptyset$. Finally, to avoid degenerate situations we will assume that $N \geq d+1$ and $M \geq D-d$.[3]

3.2 Conceptual formulation

Given $\tilde{\boldsymbol{\mathcal{X}}}$, we consider the problem of partitioning its columns into those that lie in $\mathcal{S}$ and those that don't. Since we have made no assumption about the dimension of $\mathcal{S}$, this problem is however not well posed because $\mathcal{S}$ can be anything from a line to a $(D-1)$-dimensional hyperplane, and hence $\boldsymbol{\mathcal{X}}$ lies inside every subspace that contains $\mathcal{S}$, which in turn may contain some elements of $\boldsymbol{\mathcal{O}}$. Instead, it is meaningful to search for a linear subspace of $\mathbb{R}^D$ that contains all of the inliers and perhaps a few outliers. Since we do not know the intrinsic dimension d of the inliers, a natural choice is to search for a hyperplane of $\mathbb{R}^D$ that contains all the inliers.

Problem 1 *Given the dataset $\tilde{\boldsymbol{\mathcal{X}}} = [\boldsymbol{\mathcal{X}} \;\; \boldsymbol{\mathcal{O}}]\,\boldsymbol{\Gamma}$, find a hyperplane $\mathcal{H}$ that contains all the inliers $\boldsymbol{\mathcal{X}}$.*

Notice that hyperplanes that contain all the inliers always exist: any non-zero vector $\boldsymbol{b}$ in the orthogonal complement $\mathcal{S}^\perp$ of the linear subspace $\mathcal{S}$ associated with the inliers defines a hyperplane (with normal vector $\boldsymbol{b}$) that contains all inliers $\boldsymbol{\mathcal{X}}$. Having such a hyperplane $\mathcal{H}_1$ at our disposal, we can partition our dataset as $\tilde{\boldsymbol{\mathcal{X}}} = \tilde{\boldsymbol{\mathcal{X}}}_1 \cup \tilde{\boldsymbol{\mathcal{X}}}_2$, where $\tilde{\boldsymbol{\mathcal{X}}}_1$ are the points of $\tilde{\boldsymbol{\mathcal{X}}}$ that lie in $\mathcal{H}_1$ and $\tilde{\boldsymbol{\mathcal{X}}}_2$ are the remaining points. Then by definition of $\mathcal{H}_1$, we know that $\tilde{\boldsymbol{\mathcal{X}}}_2$ will consist purely of outliers, in which case we can safely replace our original dataset $\tilde{\boldsymbol{\mathcal{X}}}$ with $\tilde{\boldsymbol{\mathcal{X}}}_1$ and reconsider the problem of robust PCA on $\tilde{\boldsymbol{\mathcal{X}}}_1$. We emphasize that $\tilde{\boldsymbol{\mathcal{X}}}_1$ will contain all the inliers $\boldsymbol{\mathcal{X}}$ together with at most $D-d-1$ outliers,[4] a number which may be dramatically smaller than the original number of outliers. Then one may apply existing methods such as Xu et al. (2012), Soltanolkotabi and Candès (2012) or Fischler and Bolles (1981) to finish the task of identifying the remaining outliers, as the following example demonstrates.

Example 1 *Suppose we have $N = 1000$ inliers lying in general position in a linear subspace of $\mathbb{R}^{100}$ of dimension $d = 90$. Suppose that the dataset is corrupted by $M = 1000$ outliers lying in general position in $\mathbb{R}^{100}$. Let $\mathcal{H}$ be a hyperplane that contains all 1000 inliers. Since the dimensionality of the inliers is 90 and the dimensionality of the hyperplane is 99, there are only $99 - 90 = 9$ linearly independent directions left for the hyperplane to fit, i.e., $\mathcal{H}$ will contain at most 9 outliers (it can not contain more outliers since this would violate the general position hypothesis). If we remove the points of the dataset that do not lie in $\mathcal{H}$, then we are left with 1000 inliers and at most 9 outliers. A simple application of RANSAC is expected to identify the remaining outliers in only a few trials.*

3. If the number of outliers is less than $D-d$, then the entire dataset is degenerate because it lies in a proper hyperplane of the ambient space, hence we can reduce the coordinate representation of the data and eventually satisfy the stated condition.
4. This comes from the assumption of general position.

Alternatively, if the true dimension d is known, one may keep working with the entire dataset $\tilde{\boldsymbol{\mathcal{X}}}$ (i.e., no point removal takes place) and search for a second hyperplane $\mathcal{H}_2$ that contains all the inliers, such that its normal vector $\boldsymbol{b}_2$ is linearly independent (e.g., orthogonal) from the normal vector $\boldsymbol{b}_1$ of $\mathcal{H}_1$. Then $\mathcal{H}_1 \cap \mathcal{H}_2$ is a linear subspace of dimension $D-2$ that contains all the inliers $\boldsymbol{\mathcal{X}}$, and as a consequence $\mathrm{Span}(\boldsymbol{\mathcal{X}}) = \mathcal{S} \subset \mathcal{H}_1 \cap \mathcal{H}_2$. Then a third hyperplane $\mathcal{H}_3 \supset \boldsymbol{\mathcal{X}}$ may be sought for, such that its normal vector $\boldsymbol{b}_3$ is not in $\mathrm{Span}(\boldsymbol{b}_1, \boldsymbol{b}_2)$, and so on. Repeating this process $c = \mathrm{codim}\,\mathcal{S} = D-d$ times, until c linearly independent hyperplanes[5] $\mathcal{H}_1, \ldots, \mathcal{H}_c$ have been found, each containing $\boldsymbol{\mathcal{X}}$, we arrive at a situation where $\bigcap_{k=1}^{c} \mathcal{H}_k$ is a subspace of dimension $d = \dim \mathcal{S}$ that contains $\mathcal{S}$ and thus it must be the case that $\bigcap_{k=1}^{c} \mathcal{H}_k = \mathcal{S}$. Hence we may declare a point to be an inlier if and only if the point lies in the intersection of these c hyperplanes.

3.3 Hyperplane pursuit by ℓ_1 minimization

In this section we propose an optimization framework for the computation of a hyperplane that solves Problem 1, i.e., a hyperplane that contains all the inliers. To proceed, we need a definition.

Definition 2 *A hyperplane $\mathcal{H}$ of $\mathbb{R}^D$ is called maximal with respect to the dataset $\tilde{\boldsymbol{\mathcal{X}}}$, if it contains a maximal number of data points in $\tilde{\boldsymbol{\mathcal{X}}}$, i.e., if for any other hyperplane $\mathcal{H}^\dagger$ of $\mathbb{R}^D$ we have that $\mathrm{Card}(\tilde{\boldsymbol{\mathcal{X}}} \cap \mathcal{H}) \geq \mathrm{Card}(\tilde{\boldsymbol{\mathcal{X}}} \cap \mathcal{H}^\dagger)$.*

In principle, hyperplanes that are maximal with respect to $\tilde{\boldsymbol{\mathcal{X}}}$, always solve Problem 1, as the next proposition shows (see §5.1 for the proof).

Proposition 3 *Suppose that $N \geq d+1$ and $M \geq D-d$, and let $\mathcal{H}$ be a hyperplane that is maximal with respect to the dataset $\tilde{\boldsymbol{\mathcal{X}}}$. Then $\mathcal{H}$ contains all the inliers $\boldsymbol{\mathcal{X}}$.*

In view of Proposition 3, we may restrict our search for hyperplanes that contain all the inliers $\boldsymbol{\mathcal{X}}$ to the subset of hyperplanes that are maximal with respect to the dataset $\tilde{\boldsymbol{\mathcal{X}}}$. The advantage of this approach is immediate: the set of hyperplanes that are maximal with respect to $\tilde{\boldsymbol{\mathcal{X}}}$ is in principle computable, since it is precisely the set of solutions of the following optimization problem

$$\min_{\boldsymbol{b}} \left\|\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}\right\|_0 \;\text{ s.t. }\; \boldsymbol{b} \neq 0. \tag{8}$$

The idea behind (8) is that a hyperplane $\mathcal{H} = \mathrm{Span}(\boldsymbol{b})^\perp$ contains a maximal number of columns of $\tilde{\boldsymbol{\mathcal{X}}}$ if and only if its normal vector $\boldsymbol{b}$ has a maximal *cosparsity* level with respect to the matrix $\tilde{\boldsymbol{\mathcal{X}}}^\top$, i.e., the number of non-zero entries of $\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}$ is minimal. Since (8) is a combinatorial problem admitting no efficient solution, we consider its natural relaxation

$$\min_{\boldsymbol{b}} \left\|\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}\right\|_1 \;\text{ s.t. }\; \left\|\boldsymbol{b}\right\|_2 = 1, \tag{9}$$

which in our context we will be referring to as *Dual Principal Component Pursuit* (DPCP). A major question that arises, to be answered in Theorem 11, is under what conditions every global solution of (9) is orthogonal to the inlier subspace $\mathrm{Span}(\boldsymbol{\mathcal{X}})$. A second major question, raised by the non-convexity of the constraint $\boldsymbol{b} \in \mathbb{S}^{D-1}$, is how to efficiently solve (9) with theoretical guarantees.

5. By the hyperplanes being linearly independent we mean that their normal vectors are linearly independent.

We emphasize here that the optimization problem (9) is far from new; interestingly, its earliest appearance in the literature that we are aware of is in Späth and Watson (1987), where the authors proposed to solve it by means of the recursion of convex problems given by[6]

$$\boldsymbol{n}_{k+1} := \operatorname*{argmin}_{\boldsymbol{b}^\top \hat{\boldsymbol{n}}_k = 1} \left\| \tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b} \right\|_1. \tag{10}$$

Notice that at each iteration of (10) the problem that is solved is computationally equivalent to a linear program; this makes the recursion (10) a very appealing candidate for solving the non-convex (9). Even though Späth and Watson (1987) proved the very interesting result that (10) converges to a critical point of (9) in a finite number of steps (see Appendix A), there is no reason to believe that in general (10) converges to a global minimum of (9).

Other works in which optimization problem (9) appears are Spielman et al. (2013); Qu et al. (2014); Sun et al. (2015c,d,b,a). More specifically, Spielman et al. (2013) propose to solve (9) by replacing the quadratic constraint $\boldsymbol{b}^\top \boldsymbol{b} = 1$ with a linear constraint $\boldsymbol{b}^\top \boldsymbol{w} = 1$ for some vector $\boldsymbol{w}$. In Qu et al. (2014); Sun et al. (2015b) (9) is approximately solved by alternating minimization, while a Riemannian trust-region approach is employed in Sun et al. (2015a). Finally, we note that problem (9) is closely related to the non-convex problem (5) associated with REAPER. To see this, suppose that the REAPER orthoprojector $\boldsymbol{\Pi}$ appearing in (5), represents the orthogonal projection to a hyperplane $\mathcal{U}$ with unit-ℓ_2 normal vector $\boldsymbol{b}$. In such a case $\boldsymbol{I}_D - \boldsymbol{\Pi} = \boldsymbol{b}\boldsymbol{b}^\top$ and it readily follows that problem (5) becomes identical to problem (9).

4. Dual Principal Component Pursuit Theory

In this section we establish our analysis framework and discuss our main theoretical results regarding the global optimum of the non-convex problem (9) as well as the recursion of convex relaxations in (10). We begin our theoretical investigation in §4.1 by establishing a connection between the *discrete* problems (9) and (10) and certain underlying *continuous* problems. The continuous problems do not depend on a finite set of inliers and outliers, rather on uniform distributions on the respective inlier and outlier spaces, and as such, are easier to analyze. The analysis of Theorems 5 and 6 reveals that the optimal solutions of the continuous analogue of (9) are orthogonal to the inlier space, and that the solutions of the continuous recursion corresponding to (10) converge to a normal vector to the inlier space, respectively. This suggests that under certain conditions on the distribution of the data, the same must be true for the *discrete* problem (9) and the *discrete* recursion (10), where the adjective *discrete* refers to the fact that these problems depend on a finite set of points. Our analysis of the discrete problems is inspired by the analysis of their continuous counterparts and the link between the two is formally captured through certain *discrepancy* bounds that we introduce in §4.2. In turn, these allow us to prove conditions under which we can characterize the global optimal of problem (9) as well as the convergence of recursion (10); this is done in §4.3 and the main results are Theorems 11 and 12, which are analogues of Theorems 5 and 6. These theorems suggest that both (9) and (10) are natural formulations for computing the orthogonal complement of a linear subspace in the presence of outliers. The proofs of all theorems as well as intermediate results are deferred to §5.

6. Being unaware of the work of Späth and Watson (1987), we independently proposed the same recursion in (Tsakiris and Vidal, 2015).

4.1 Formulation and theoretical analysis of the underlying continuous problems

In this section we show that the problems of interest (9) and (10) can be viewed as discrete versions of certain continuous problems, which are easier to analyze. To begin with, consider given outliers $\boldsymbol{\mathcal{O}} = [\boldsymbol{o}_1, \ldots, \boldsymbol{o}_M] \subset \mathbb{S}^{D-1}$ and inliers $\boldsymbol{\mathcal{X}} = [\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N] \subset \mathcal{S} \cap \mathbb{S}^{D-1}$, and recall the notation $\tilde{\boldsymbol{\mathcal{X}}} = [\boldsymbol{\mathcal{X}}\, \boldsymbol{\mathcal{O}}]\boldsymbol{\Gamma}$, where $\boldsymbol{\Gamma}$ is an unknown permutation. Next, for any $\boldsymbol{b} \in \mathbb{S}^{D-1}$ define the function $f_{\boldsymbol{b}} : \mathbb{S}^{D-1} \to \mathbb{R}$ by $f_{\boldsymbol{b}}(\boldsymbol{z}) = \left|\boldsymbol{b}^\top \boldsymbol{z}\right|$. Define also *discrete* measures $\mu_{\boldsymbol{\mathcal{O}}}$ and $\mu_{\boldsymbol{\mathcal{X}}}$ on $\mathbb{S}^{D-1}$ associated with the outliers and inliers respectively, as

$$\mu_{\boldsymbol{\mathcal{O}}}(\boldsymbol{z}) = \frac{1}{M}\sum_{j=1}^{M} \delta(\boldsymbol{z} - \boldsymbol{o}_j) \;\text{ and }\; \mu_{\boldsymbol{\mathcal{X}}}(\boldsymbol{z}) = \frac{1}{N}\sum_{j=1}^{N} \delta(\boldsymbol{z} - \boldsymbol{x}_j), \tag{11}$$

where $\delta(\cdot)$ is the Dirac function on $\mathbb{S}^{D-1}$, satisfying

$$\int_{\boldsymbol{z} \in \mathbb{S}^{D-1}} g(\boldsymbol{z}) \delta(\boldsymbol{z} - \boldsymbol{z}_0) d\mu_{\mathbb{S}^{D-1}} = g(\boldsymbol{z}_0), \tag{12}$$

for every $g : \mathbb{S}^{D-1} \to \mathbb{R}$ and every $\boldsymbol{z}_0 \in \mathbb{S}^{D-1}$; $\mu_{\mathbb{S}^{D-1}}$ is the uniform measure on $\mathbb{S}^{D-1}$.

With these definitions, we have that the objective function $\left\| \tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b} \right\|_1$ appearing in (9) and (10) is the sum of the weighted expectations of the function $f_{\boldsymbol{b}}$ under the measures $\mu_{\boldsymbol{\mathcal{O}}}$ and $\mu_{\boldsymbol{\mathcal{X}}}$, i.e.,

$$\left\| \tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b} \right\|_1 = \left\| \boldsymbol{\mathcal{O}}^\top \boldsymbol{b} \right\|_1 + \left\| \boldsymbol{\mathcal{X}}^\top \boldsymbol{b} \right\|_1 = \sum_{j=1}^{M} \left|\boldsymbol{b}^\top \boldsymbol{o}_j\right| + \sum_{j=1}^{N} \left|\boldsymbol{b}^\top \boldsymbol{x}_j\right| \tag{13}$$

$$= \sum_{j=1}^{M} \int_{\boldsymbol{z} \in \mathbb{S}^{D-1}} \left|\boldsymbol{b}^\top \boldsymbol{z}\right| \delta(\boldsymbol{z} - \boldsymbol{o}_j) d\mu_{\mathbb{S}^{D-1}} + \sum_{j=1}^{N} \int_{\boldsymbol{z} \in \mathbb{S}^{D-1}} \left|\boldsymbol{b}^\top \boldsymbol{z}\right| \delta(\boldsymbol{z} - \boldsymbol{x}_j) d\mu_{\mathbb{S}^{D-1}} \tag{14}$$

$$= \int_{\boldsymbol{z} \in \mathbb{S}^{D-1}} \left|\boldsymbol{b}^\top \boldsymbol{z}\right| \sum_{j=1}^{M} \delta(\boldsymbol{z} - \boldsymbol{o}_j) d\mu_{\mathbb{S}^{D-1}} + \int_{\boldsymbol{z} \in \mathbb{S}^{D-1}} \left|\boldsymbol{b}^\top \boldsymbol{z}\right| \sum_{j=1}^{N} \delta(\boldsymbol{z} - \boldsymbol{x}_j) d\mu_{\mathbb{S}^{D-1}} \tag{15}$$

$$= M\, \mathbb{E}_{\mu_{\boldsymbol{\mathcal{O}}}}(f_{\boldsymbol{b}}) + N\, \mathbb{E}_{\mu_{\boldsymbol{\mathcal{X}}}}(f_{\boldsymbol{b}}). \tag{16}$$

Hence, the optimization problem (9), which we repeat here for convenience,

$$\min_{\boldsymbol{b}} \left\| \tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b} \right\|_1 \;\text{ s.t. }\; \boldsymbol{b}^\top \boldsymbol{b} = 1, \tag{17}$$

is equivalent to the problem

$$\min_{\boldsymbol{b}} \left[M\, \mathbb{E}_{\mu_{\boldsymbol{\mathcal{O}}}}(f_{\boldsymbol{b}}) + N\, \mathbb{E}_{\mu_{\boldsymbol{\mathcal{X}}}}(f_{\boldsymbol{b}}) \right] \;\text{ s.t. }\; \boldsymbol{b}^\top \boldsymbol{b} = 1. \tag{18}$$

Similarly, the recursion (10), repeated here for convenience,

$$\boldsymbol{n}_{k+1} = \operatorname*{argmin}_{\boldsymbol{b}} \left\| \tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b} \right\|_1 \;\text{ s.t. }\; \boldsymbol{b}^\top \hat{\boldsymbol{n}}_k = 1, \tag{19}$$

is equivalent to the recursion

$$\boldsymbol{n}_{k+1} = \operatorname*{argmin}_{\boldsymbol{b}} \left[M\, \mathbb{E}_{\mu_{\boldsymbol{\mathcal{O}}}}(f_{\boldsymbol{b}}) + N\, \mathbb{E}_{\mu_{\boldsymbol{\mathcal{X}}}}(f_{\boldsymbol{b}}) \right] \;\text{ s.t. }\; \boldsymbol{b}^\top \hat{\boldsymbol{n}}_k = 1. \tag{20}$$

Now, the discrete measures $\mu_{\boldsymbol{\mathcal{O}}}, \mu_{\boldsymbol{\mathcal{X}}}$ of (11), are discretizations of the continuous measures $\mu_{\mathbb{S}^{D-1}}$, and $\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}}$ respectively, where the latter is the uniform measure on $\mathbb{S}^{D-1}\cap\mathcal{S}$. Hence, for the purpose of understanding the properties of the global minimizer of (18) and the limiting point of (20), it is meaningful to replace in (18) and (20) the discrete measures $\mu_{\boldsymbol{\mathcal{O}}}$ and $\mu_{\boldsymbol{\mathcal{X}}}$ by their continuous counterparts $\mu_{\mathbb{S}^{D-1}}$ and $\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}}$, and study the resulting *continuous* problems

$$\min_{\boldsymbol{b}} \left[M\,\mathbb{E}_{\mu_{\mathbb{S}^{D-1}}}(f_{\boldsymbol{b}}) + N\,\mathbb{E}_{\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}}}(f_{\boldsymbol{b}}) \right] \;\text{ s.t. }\; \boldsymbol{b}^\top\boldsymbol{b} = 1, \tag{21}$$

$$\boldsymbol{n}_{k+1} = \operatorname*{argmin}_{\boldsymbol{b}} \left[M\,\mathbb{E}_{\mu_{\mathbb{S}^{D-1}}}(f_{\boldsymbol{b}}) + N\,\mathbb{E}_{\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}}}(f_{\boldsymbol{b}}) \right] \;\text{ s.t. }\; \boldsymbol{b}^\top\hat{\boldsymbol{n}}_k = 1. \tag{22}$$

It is important to note that if these two continuous problems have the geometric properties of interest, i.e., if every global solution of (21) is a vector orthogonal to the inlier subspace, and similarly, if the sequence of vectors $\{\boldsymbol{n}_k\}$ produced by (22) converges to a vector $\boldsymbol{n}_{k^*}$ orthogonal to the inlier subspace, then this *correctness* of the continuous problems can be viewed as a first theoretical verification of the correctness of the *discrete* formulations (9) and (10). The objective of the rest of this section is to establish that this is precisely the case.

Before discussing our main two results in this direction, we note that the continuous objective function appearing in (21) and (22) can be re-written in a more suggestive form. To see what that is, define c_D as the average height of the unit hemisphere of $\mathbb{R}^D$, directly computed as

$$c_D := \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} |z_1| d\mu_{\mathbb{S}^{D-1}} = \frac{(D-2)!!}{(D-1)!!} \cdot \begin{cases} \frac{2}{\pi} & \text{if } D \text{ even}, \\ 1 & \text{if } D \text{ odd}, \end{cases} \tag{23}$$

where z_1 is the first coordinate of the vector $\boldsymbol{z}$, and the double factorial is defined as

$$k!! := \begin{cases} k(k-2)(k-4)\cdots 4\cdot 2 & \text{if } k \text{ even}, \\ k(k-2)(k-4)\cdots 3\cdot 1 & \text{if } k \text{ odd}. \end{cases} \tag{24}$$

Then we have the following result, whose proof can be found in §5.2.

Proposition 4 *The objective function of the continuous problem* (21) *can be rewritten as:*

$$M\,\mathbb{E}_{\mu_{\mathbb{S}^{D-1}}}(f_{\boldsymbol{b}}) + N\,\mathbb{E}_{\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}}}(f_{\boldsymbol{b}}) = \|\boldsymbol{b}\|_2 \left(Mc_D + Nc_d\cos(\phi)\right), \tag{25}$$

where ϕ is the principal angle between $\boldsymbol{b}$ and the subspace $\mathcal{S}$.

As a consequence of this result, when $\boldsymbol{b}\in\mathbb{S}^{D-1}$, the first term (the outlier term) of the objective function becomes a constant (Mc_D) and hence the outliers do not affect the optimal solution of (21). Moreover, the second term (the inlier term) of the objective function depends only on the cosine of the principal angle between $\boldsymbol{b}$ and the subspace, which is minimized when $\boldsymbol{b}$ is orthogonal to the subspace ($\phi = \pi/2$). This leads to the following result about the continuous problem, whose proof can be found in §5.3.

Theorem 5 *Any global solution to problem* (21) *must be orthogonal to $\mathcal{S}$.*

Observe that this result is true irrespective of the weight M of the outlier term or the weight N of the inlier term in the continuous objective function (25). Similarly, the next result, whose proof can be found in §5.4, shows that the solutions to the continuous recursion in (22) converge to a vector orthogonal to the inlier subspace in a finite number of steps, regardless of the outlier and inlier weights M, N.

Theorem 6 *Consider the sequence $\{\boldsymbol{n}_k\}_{k\geq 0}$ generated by recursion* (22)*, with $\hat{\boldsymbol{n}}_0 \in \mathbb{S}^{D-1}$. Let ϕ_0 be the principal angle of $\boldsymbol{n}_0$ from $\mathcal{S}$, and define $\alpha := Nc_d/Mc_D$. Then, as long as $\phi_0 > 0$, the sequence $\{\boldsymbol{n}_k\}_{k\geq 0}$ converges to a unit ℓ_2-norm element of $\mathcal{S}^\perp$ in a finite number k^* of iterations, where $k^* = 0$ if $\phi_0 = \pi/2$, $k^* = 1$ if $\tan(\phi_0) \geq 1/\alpha$, and $k^* \leq \left\lceil \frac{\tan^{-1}(1/\alpha)-\phi_0}{\sin^{-1}(\alpha\sin(\phi_0))} \right\rceil + 1$ otherwise.*

Notice the remarkable fact that according to Theorem 6, the continuous recursion (22) converges to a vector orthogonal to the inlier subspace $\mathcal{S}$ in a *finite* number of steps. Moreover, if the relation

$$\tan(\phi_0) \geq 1/\alpha = \frac{M}{N}\frac{c_D}{c_d}, \tag{26}$$

holds true, then this convergence occurs in a single step. One way to interpret (26) is to notice that as long as the angle ϕ_0 of the initial estimate $\hat{\boldsymbol{n}}_0$ from the inlier subspace is positive, and for any arbitrary but fixed number of outliers M, there is always a sufficiently large number N of inliers, such that (26) is satisfied and thus convergence occurs in one step. Likewise, condition (26) can also be satisfied if d/D is sufficiently small (so that c_D/c_d is small). Conversely, for any fixed number of inliers N and outliers M, there is always a sufficiently large angle ϕ_0 such that (26) is true, and thus (22) again converges in a single step. More generally, even when (26) is not true, the larger ϕ_0, N are, the smaller the quantity

$$\left\lceil \frac{\tan^{-1}(1/\alpha)-\phi_0}{\sin^{-1}(\alpha\sin(\phi_0))} \right\rceil \tag{27}$$

is, and thus according to Theorem 5 the faster (22) converges.

4.2 Discrepancy bounds between the continuous and discrete problems

The heart of our analysis framework is to bound the deviation of some underlying geometric quantities, which we call the *average outlier* and the *average inlier with respect to* $\boldsymbol{b}$, from their continuous counterparts. To begin with, recall our discrete objective function

$$\mathcal{J}_{\text{discrete}}(\boldsymbol{b}) = \left\|\tilde{\boldsymbol{\mathcal{X}}}^\top\boldsymbol{b}\right\|_1 = \left\|\boldsymbol{\mathcal{O}}^\top\boldsymbol{b}\right\|_1 + \left\|\boldsymbol{\mathcal{X}}^\top\boldsymbol{b}\right\|_1 \tag{28}$$

and its continuous counterpart

$$\mathcal{J}_{\text{continuous}}(\boldsymbol{b}) = \|\boldsymbol{b}\|_2 \left(Mc_D + Nc_d\cos(\phi)\right). \tag{29}$$

Now, notice that the term of the discrete objective that depends on the outliers $\boldsymbol{\mathcal{O}}$ can be written as

$$\left\|\boldsymbol{\mathcal{O}}^\top\boldsymbol{b}\right\|_1 = \sum_{j=1}^{M} |\boldsymbol{o}_j^\top\boldsymbol{b}| = \sum_{j=1}^{M} \boldsymbol{b}^\top \operatorname{Sign}(\boldsymbol{o}_j^\top\boldsymbol{b})\boldsymbol{o}_j = M\,\boldsymbol{b}^\top\boldsymbol{o}_{\boldsymbol{b}}, \tag{30}$$

where $\operatorname{Sign}(\cdot)$ is the sign function and $\boldsymbol{o}_b$ is the *average outlier with respect to* $\boldsymbol{b}$, defined as

$$\boldsymbol{o}_{\boldsymbol{b}} := \frac{1}{M}\sum_{j=1}^{M} \operatorname{Sign}(\boldsymbol{b}^\top\boldsymbol{o}_j)\boldsymbol{o}_j. \tag{31}$$

Defining a vector valued function $\boldsymbol{f}_{\boldsymbol{b}} : \mathbb{S}^{D-1} \to \mathbb{R}^D$ by $\boldsymbol{z} \in \mathbb{S}^{D-1} \overset{\boldsymbol{f}_{\boldsymbol{b}}}{\longmapsto} \text{Sign}(\boldsymbol{b}^\top \boldsymbol{z})\boldsymbol{z}$, we notice that

$$\boldsymbol{o}_{\boldsymbol{b}} = \frac{1}{M}\sum_{j=1}^{M} \boldsymbol{f}_{\boldsymbol{b}}(\boldsymbol{o}_j) = \frac{1}{M}\sum_{j=1}^{M} \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} f_{\boldsymbol{b}}(\boldsymbol{z})\delta(\boldsymbol{z}-\boldsymbol{o}_j)d\mu_{S^{D-1}} = \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} f_{\boldsymbol{b}}(\boldsymbol{z})d\mu_{\boldsymbol{\mathcal{O}}}(\boldsymbol{z}), \quad (32)$$

where $\mu_{\boldsymbol{\mathcal{O}}}(\boldsymbol{z})$ is defined in (11), and so $\boldsymbol{o}_{\boldsymbol{b}}$ is a discrete approximation to the continuous integral $\int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \boldsymbol{f}_{\boldsymbol{b}}(\boldsymbol{z})d\mu_{\mathbb{S}^{D-1}}$, whose value is given by the next Lemma (see §5.5 for the proof).

Lemma 7 *Recall the definition of c_D in* (23)*. For any $\boldsymbol{b} \in \mathbb{S}^{D-1}$ we have*

$$\int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \boldsymbol{f}_{\boldsymbol{b}}(\boldsymbol{z})d\mu_{\mathbb{S}^{D-1}} = \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \text{Sign}(\boldsymbol{b}^\top\boldsymbol{z})\boldsymbol{z}d\mu_{\mathbb{S}^{D-1}} = c_D\,\boldsymbol{b}. \quad (33)$$

In other words, the continuous average outlier with respect to $\boldsymbol{b}$ is $c_D\boldsymbol{b}$. We define $\epsilon_{\boldsymbol{\mathcal{O}},M}$ to be the maximum error between the discrete and continuous average outliers as $\boldsymbol{b}$ varies on $\mathbb{S}^{D-1}$, i.e.,

$$\epsilon_{\boldsymbol{\mathcal{O}},M} \coloneqq \max_{\boldsymbol{b}\in\mathbb{S}^{D-1}} \left\|c_D\,\boldsymbol{b} - \boldsymbol{o}_{\boldsymbol{b}}\right\|_2, \quad (34)$$

and we establish that the more *uniformly distributed* $\boldsymbol{\mathcal{O}} = [\boldsymbol{o}_1, \ldots, \boldsymbol{o}_M] \subset \mathbb{S}^{D-1}$ is the smaller $\epsilon_{\boldsymbol{\mathcal{O}},M}$ becomes. The notion of uniformity of $\boldsymbol{\mathcal{O}}$ that we use here is a deterministic one and is captured by the *spherical cap discrepancy* of the set $\boldsymbol{\mathcal{O}}$, defined as (Grabner et al., 1997; Grabner and Tichy, 1993)

$$\mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}}) := \sup_{\mathcal{C}} \left|\frac{1}{M}\sum_{j=1}^{M} \mathbb{I}_{\mathcal{C}}(\boldsymbol{o}_j) - \mu_{\mathbb{S}^{D-1}}(\mathcal{C})\right|. \quad (35)$$

In (35) the supremum is taken over all spherical caps $\mathcal{C}$ of the sphere $\mathbb{S}^{D-1}$, where a spherical cap is the intersection of $\mathbb{S}^{D-1}$ with a half-space of $\mathbb{R}^D$, and $\mathbb{I}_{\mathcal{C}}(\cdot)$ is the indicator function of $\mathcal{C}$, which takes the value 1 inside $\mathcal{C}$ and zero otherwise. The spherical cap discrepancy $\mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}})$ is precisely the supremum among all errors in approximating integrals of indicator functions of spherical caps via averages of such indicator functions on the point set $\boldsymbol{\mathcal{O}}$. Intuitively, $\mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}})$ captures how close the discrete measure $\mu_{\boldsymbol{\mathcal{O}}}$ (see equation (11)) associated with $\boldsymbol{\mathcal{O}}$ is to the measure $\mu_{\mathbb{S}^{D-1}}$. We will say that $\boldsymbol{\mathcal{O}}$ is uniformly distributed on $\mathbb{S}^{D-1}$ if $\mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}})$ is small. We note here that as a function of the number of points M, $\mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}})$ decreases with a rate of (Dick, 2014; Beck, 1984)

$$\sqrt{\log(M)}M^{-\frac{1}{2}-\frac{1}{2(D-1)}}. \quad (36)$$

As a consequence, to show that uniformly distributed points $\boldsymbol{\mathcal{O}}$ correspond to small $\epsilon_{\boldsymbol{\mathcal{O}},M}$, it suffices to bound the maximum integration error $\epsilon_{\boldsymbol{\mathcal{O}},M}$ from above by a quantity proportional to the spherical cap discrepancy $\mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}})$. Inequalities that bound from above the approximation error of the integral of a function in terms of the variation of the function and the discrepancy of a finite set of points (not necessarily the spherical cap discrepancy; there are several types of discrepancies) are widely known as *Koksma-Hlawka inequalites* (Kuipers and Niederreiter, 2012; Hlawka, 1971). Even though such inequalities exist and are well-known for integration of functions on the unit hypercube $[0,1]^D$ (Kuipers and Niederreiter, 2012; Hlawka, 1971; Harman, 2010), similar inequalities for integration of functions on the unit sphere $\mathbb{S}^{D-1}$ seem not to be known in general

(Grabner and Tichy, 1993), except if one makes additional assumptions on the distribution of the finite set of points (Grabner et al., 1997; Brauchart and Grabner, 2015). Nevertheless, the function $f_{\boldsymbol{b}} : \boldsymbol{z} \longmapsto |\boldsymbol{b}^\top\boldsymbol{z}|$ that is associated with $\epsilon_{\boldsymbol{\mathcal{O}},M}$ is simple enough to allow for a Koksma-Hlawka inequality of its own, as described in the next lemma, whose proof can be found in §5.6.[7]

Lemma 8 *Let $\boldsymbol{\mathcal{O}} = [\boldsymbol{o}_1, \ldots, \boldsymbol{o}_M]$ be a finite subset of $\mathbb{S}^{D-1}$. Then*

$$\epsilon_{\boldsymbol{\mathcal{O}},M} = \max_{\boldsymbol{b}\in\mathbb{S}^{D-1}} \left\|c_D\boldsymbol{b} - \boldsymbol{o}_{\boldsymbol{b}}\right\|_2 \leq \sqrt{5}\mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}}), \quad (37)$$

where $c_D, \boldsymbol{o}_{\boldsymbol{b}}$ and $\mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}})$ are defined in (23)*,* (31) *and* (35) *respectively.*

We now turn our attention to the inlier term $\left\|\tilde{\boldsymbol{\mathcal{X}}}^\top\boldsymbol{b}\right\|_1$ of the discrete objective function (28), which is slightly more complicated than the outlier term. We have

$$\left\|\boldsymbol{\mathcal{X}}^\top\boldsymbol{b}\right\|_1 = \sum_{j=1}^{N} |\boldsymbol{x}_j^\top\boldsymbol{b}| = \sum_{j=1}^{N} \boldsymbol{b}^\top \text{Sign}(\boldsymbol{x}_j^\top\boldsymbol{b})\boldsymbol{x}_j = N\,\boldsymbol{b}^\top\boldsymbol{x}_{\boldsymbol{b}}, \quad (38)$$

where

$$\boldsymbol{x}_{\boldsymbol{b}} \coloneqq \frac{1}{N}\sum_{j=1}^{N} \text{Sign}(\boldsymbol{b}^\top\boldsymbol{x}_j)\boldsymbol{x}_j = \frac{1}{N}\sum_{j=1}^{N} \boldsymbol{f}_{\boldsymbol{b}}(\boldsymbol{x}_j) = \int_{\boldsymbol{x}\in\mathbb{S}^{D-1}\cap\mathcal{S}} f_{\boldsymbol{b}}(\boldsymbol{x})d\mu_{\boldsymbol{\mathcal{X}}}(\boldsymbol{x}) \quad (39)$$

is the *average inlier with respect to $\boldsymbol{b}$*. Thus, $\boldsymbol{x}_{\boldsymbol{b}}$ is a discrete approximation of the integral

$$\int_{\boldsymbol{x}\in\mathbb{S}^{D-1}\cap\mathcal{S}} \boldsymbol{f}_{\boldsymbol{b}}(\boldsymbol{x})d\mu_{\mathbb{S}^{D-1}}, \quad (40)$$

whose value is given by the next lemma (see §5.7 for the proof).

Lemma 9 *For any $\boldsymbol{b} \in \mathbb{S}^{D-1}$ we have*

$$\int_{\boldsymbol{x}\in\mathbb{S}^{D-1}\cap\mathcal{S}} \boldsymbol{f}_{\boldsymbol{b}}(\boldsymbol{x})d\mu_{\mathbb{S}^{D-1}} = \int_{\boldsymbol{x}\in\mathbb{S}^{D-1}\cap\mathcal{S}} \text{Sign}(\boldsymbol{b}^\top\boldsymbol{x})\boldsymbol{x}d\mu_{\mathbb{S}^{D-1}} = c_d\,\hat{\boldsymbol{v}}, \quad (41)$$

where c_d is given by (23) *after replacing D with d, and $\boldsymbol{v}$ is the orthogonal projection of $\boldsymbol{b}$ onto $\mathcal{S}$.*

In other words, the continuous average inlier with respect to $\boldsymbol{b}$ is $c_d\hat{\boldsymbol{v}}$. We define $\epsilon_{\boldsymbol{\mathcal{X}}}$ to be the maximum error between the discrete and continuous average inliers as $\boldsymbol{b}$ varies on $\mathbb{S}^{D-1}$, which is the same as the maximum error as $\boldsymbol{b}$ varies on $\mathbb{S}^{D-1}\cap\mathcal{S}$, i.e.,

$$\epsilon_{\boldsymbol{\mathcal{X}},N} \coloneqq \max_{\boldsymbol{b}\in\mathbb{S}^{D-1}} \left\|c_d\,\widehat{\pi_{\mathcal{S}}(\boldsymbol{b})} - \boldsymbol{x}_{\boldsymbol{b}}\right\|_2 = \max_{\boldsymbol{b}\in\mathbb{S}^{D-1}\cap\mathcal{S}} \left\|c_d\,\boldsymbol{b} - \boldsymbol{x}_{\boldsymbol{b}}\right\|_2. \quad (42)$$

Then an almost identical argument as the one that established Lemma 8 gives that

$$\epsilon_{\boldsymbol{\mathcal{X}},N} \leq \sqrt{5}\mathfrak{S}_{d,N}(\boldsymbol{\mathcal{X}}), \quad (43)$$

where now the discrepancy $\mathfrak{S}_{d,N}(\boldsymbol{\mathcal{X}})$ of the inliers $\boldsymbol{\mathcal{X}}$ is defined exactly as in (35) except that M is replaced by N and the supremum is taken over all spherical caps of $\mathbb{S}^{D-1}\cap\mathcal{S} \cong \mathbb{S}^{d-1}$.

7. The authors are grateful to Prof. Glyn Harman for pointing out that such a result is possible as well as suggesting how to prove it.

4.3 Conditions for global optimality and convergence of the discrete problems

In this section we analyze the discrete problem (9) and the associated discrete recursion (10), where the adjective *discrete* refers to the fact that (9) and (10) depend on a finite set of points $\tilde{\boldsymbol{\mathcal{X}}} = [\boldsymbol{\mathcal{X}}\ \boldsymbol{\mathcal{O}}]\boldsymbol{\Gamma}$ sampled from the union of the space of outliers $\mathbb{S}^{D-1}$ and the space of inliers $\mathbb{S}^{D-1} \cap \mathcal{S}$. In §4.1 we showed that these two problems are discrete versions of the continuous problems (21) and (22), respectively. We further showed that the continuous problems possess the geometric property of interest, i.e., every global minimizer of (21) must be an element of $\mathcal{S}^{\perp} \cap \mathbb{S}^{D-1}$ (Theorem 5) and the recursion (22) produces a sequence of vectors that converges in a finite number of steps to an element of $\mathcal{S}^{\perp} \cap \mathbb{S}^{D-1}$ (Theorem 6). In this section we use the discrepancy bounds of §4.2 to show that under some conditions on the uniformity of $\boldsymbol{\mathcal{X}} = [\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N]$ and $\boldsymbol{\mathcal{O}} = [\boldsymbol{o}_1, \ldots, \boldsymbol{o}_M]$, a similar statement holds for problems (9) and (10). We start with a definition.

Definition 10 *Given a set $\boldsymbol{\mathcal{Y}} = [\boldsymbol{y}_1, \ldots, \boldsymbol{y}_L] \subset \mathbb{S}^{D-1}$ and an integer $K \leq L$, define $\mathcal{R}_{\boldsymbol{\mathcal{Y}},K}$ to be the maximum circumradius among all polytopes of the form*

$$\left\{ \sum_{i=1}^{K} \alpha_{j_i} \boldsymbol{y}_{j_i} \,:\, \alpha_{j_i} \in [-1,1] \right\}, \tag{44}$$

where $j_1, \ldots, j_K$ are distinct integers in $[L]$, and the circumradius of a bounded subset of $\mathbb{R}^D$ is the infimum over the radii of all Euclidean balls of $\mathbb{R}^D$ that contain that subset. With that, define

$$\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}} := \max_{K_1+K_2<D,\, K_2<d} (\mathcal{R}_{\boldsymbol{\mathcal{O}},K_1} + \mathcal{R}_{\boldsymbol{\mathcal{X}},K_2}). \tag{45}$$

The next theorem, proved in §5.8, states that if both inliers and outliers are sufficiently uniformly distributed, i.e., if the uniformity parameters $\epsilon_{\boldsymbol{\mathcal{X}},N}$ and $\epsilon_{\boldsymbol{\mathcal{O}},M}$ are sufficiently small, then every global solution of (9) must be orthogonal to the inlier subspace $\mathcal{S}$. More precisely,

Theorem 11 *Suppose that the ratio γ of outliers to inliers satisfies*

$$\gamma := \frac{M}{N} < \frac{1}{2\epsilon_{\boldsymbol{\mathcal{O}},M}} \min \left\{ c_d - \epsilon_{\boldsymbol{\mathcal{X}},N}, 2\left(c_d - \epsilon_{\boldsymbol{\mathcal{X}},N} - \frac{\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}}}{N} \right), \Gamma \right\}, \quad \textit{where} \tag{46}$$

$$\Gamma := \frac{c_d - \epsilon_{\boldsymbol{\mathcal{X}},N}}{2(3c_d - \epsilon_{\boldsymbol{\mathcal{X}},N})} \left[\sqrt{\mathscr{P}^2 + 8(3c_d - \epsilon_{\boldsymbol{\mathcal{X}},N})(c_d - \epsilon_{\boldsymbol{\mathcal{X}},N} - \frac{\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}}}{N})} - \mathscr{P} \right], \tag{47}$$

$$\mathscr{P} := 2\frac{\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}}}{N} + \epsilon_{\boldsymbol{\mathcal{X}},N} + c_d. \tag{48}$$

Then any global solution $\boldsymbol{b}^*$ to (9) must be orthogonal to $\mathrm{Span}(\boldsymbol{\mathcal{X}})$.

Towards interpreting Theorem 11, consider first the asymptotic case where we allow N and M to go to infinity, while keeping the ratio γ constant. Assuming that both inliers and outliers are perfectly well distributed in the limit, i.e., under the hypothesis that $\lim_{N\to\infty} \mathfrak{S}_{d,N}(\boldsymbol{\mathcal{X}}) = 0$ and $\lim_{M\to\infty} \mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}}) = 0$, Lemma 8 and inequality (43) give that $\lim_{N\to\infty} \epsilon_{\boldsymbol{\mathcal{X}},N} = 0$ and $\lim_{M\to\infty} \epsilon_{\boldsymbol{\mathcal{O}},M} = 0$, in which case (46) is satisfied. This suggests the interesting fact that (9) can possibly give a normal to the inliers even for arbitrarily many outliers, and irrespectively of the subspace dimension d. Along the same lines, for a given γ and under the point set uniformity hypothesis, we can always increase the number of inliers and outliers (thus decreasing $\epsilon_{\boldsymbol{\mathcal{X}},N}$ and

$\epsilon_{\boldsymbol{\mathcal{O}},M}$), while keeping γ constant, until (46) is satisfied, once again indicating that (9) can possibly yield a normal to the space of inliers irrespectively of their intrinsic dimension; this becomes evident in the numerical evaluation of Figs. 4(a)-4(c). Notice that the intrinsic dimension d of the inliers manifests itself through the quantity c_d, which we recall is a decreasing function of d. Consequently, the smaller d is the larger the RHS of (46) becomes, and so the easier it is to satisfy (46).

More explicitly (and less formally), because of (36) the quantities $\epsilon_{\boldsymbol{\mathcal{O}},M}, \epsilon_{\boldsymbol{\mathcal{X}},N}$ decay at an approximate rate of $1/\sqrt{M}, 1/\sqrt{N}$ respectively. In turn, this shows that the conditions (46) are satisfied if roughly $M < \mathcal{O}(N^2)$. To see this, note, e.g., that the first inequality in (46) reads

$$\frac{M}{N} < \frac{c_d - \epsilon_{\boldsymbol{\mathcal{X}},N}}{2\epsilon_{\boldsymbol{\mathcal{O}},M}}, \tag{49}$$

which roughly says that

$$\text{constant} \cdot \sqrt{M} \leq \text{constant} \cdot N - \text{constant} \cdot \sqrt{N}, \tag{50}$$

where by *constant* here we mean independent of M, N. A similar conclusion can be drawn from the rest inequalities in (46) [8]. In contrast, the analysis of the *haystack model* of REAPER (Lerman et al., 2015) gives $M < \mathcal{O}(N)$.

A similar phenomenon holds for the recursion of convex relaxations (10). Notice that according to Theorem 5, the continuous recursion converges in a finite number of iterations to a vector that is orthogonal to $\mathrm{Span}(\boldsymbol{\mathcal{X}}) = \mathcal{S}$, as long as the initialization $\hat{\boldsymbol{n}}_0$ does not lie in $\mathcal{S}$ (equivalently $\phi_0 > 0$). Intuitively, one should expect that in the discrete case, the conditions for the *discrete* recursion (10) to be successful, should be at least as strong as the conditions of Theorem 11, and strictly stronger than the condition $\phi_0 > 0$ of Theorem 6. Our next result, whose proof can be found in §5.9, formalizes this intuition.

Theorem 12 *Suppose that condition* (46) *holds true and consider the sequence $\{\boldsymbol{n}_k\}_{k\geq 0}$ generated by the recursion* (10)*. Let ϕ_0 be the principal angle of $\hat{\boldsymbol{n}}_0$ from $\mathrm{Span}(\boldsymbol{\mathcal{X}})$ and suppose that*

$$\cos(\phi_0) < \frac{c_d - \epsilon_{\boldsymbol{\mathcal{X}},N}}{2c_d(c_d + \epsilon_{\boldsymbol{\mathcal{X}},N})} \left[-\mathscr{Q} + \sqrt{\mathscr{Q}^2 + 4c_d(c_d - \mathscr{Q})} \right] - \frac{2\epsilon_{\boldsymbol{\mathcal{O}},M}}{c_d + \epsilon_{\boldsymbol{\mathcal{X}},N}} \frac{M}{N}, \tag{51}$$

$$\mathscr{Q} := \frac{\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}}}{N} + \epsilon_{\boldsymbol{\mathcal{O}},M} \frac{M}{N} + \epsilon_{\boldsymbol{\mathcal{X}},N}. \tag{52}$$

Then after a finite number of iterations the sequence $\{\boldsymbol{n}_k\}_{k\geq 0}$ converges to a unit ℓ_2-norm vector that is orthogonal to $\mathrm{Span}(\boldsymbol{\mathcal{X}})$.

First note that if (46) is true, then the expression of (51) always defines an angle between 0 and $\pi/2$. Moreover, Theorem 12 can be interpreted using the same asymptotic arguments as Theorem 11; notice in particular that the lower bound on the angle ϕ_0 tends to zero as M, N go to infinity with γ constant, i.e., the more uniformly distributed inliers and outliers are, the closer $\boldsymbol{n}_0$ is allowed to be to $\mathrm{Span}(\boldsymbol{\mathcal{X}})$. We also emphasize that Theorem 12 asserts the correctness of the linear programming recursions (10) as far as recovering a vector $\boldsymbol{n}_{k^*}$ orthogonal to $\mathcal{S} := \mathrm{Span}(\boldsymbol{\mathcal{X}})$ is concerned. Even though this was our initial motivation for posing problem (9), Theorem 12 does not assert in general that $\boldsymbol{n}_{k^*}$ is a global minimizer of problem (9). However, this is indeed the case, when the inlier subspace $\mathcal{S}$ is a hyperplane, i.e., $d = D - 1$. This is because, up to a sign, there is a unique vector $\boldsymbol{b} \in \mathbb{S}^{D-1}$ that is orthogonal to $\mathcal{S}$ (the normal vector to the hyperplane), which, under conditions (46) and (51), is the unique global minimizer of (9), as well as the limit point $\boldsymbol{n}_{k^*}$ of Theorem 12.

8. It is the subject of ongoing research to arrive at this conclusion by more formal means.

5. Proofs

In this section we provide the proofs of all claims stated in earlier sections.

5.1 Proof of Proposition 3

By the general position hypothesis on $\boldsymbol{\mathcal{X}}$ and $\boldsymbol{\mathcal{O}}$, any hyperplane that does not contain $\boldsymbol{\mathcal{X}}$ can contain at most $D-1$ points from $\tilde{\boldsymbol{\mathcal{X}}}$. We will show that there exists a hyperplane that contains more than $D-1$ points of $\tilde{\boldsymbol{\mathcal{X}}}$. Indeed, take d inliers and $D-d-1$ outliers and let $\mathcal{H}$ be the hyperplane generated by these $D-1$ points. Denote the normal vector to that hyperplane by $\boldsymbol{b}$. Since $\mathcal{H}$ contains d inliers, $\boldsymbol{b}$ will be orthogonal to these inliers. Since $\boldsymbol{\mathcal{X}}$ is in general position, every d-tuple of inliers is a basis for $\mathrm{Span}(\boldsymbol{\mathcal{X}})$. As a consequence, $\boldsymbol{b}$ will be orthogonal to $\mathrm{Span}(\boldsymbol{\mathcal{X}})$, and in particular $\boldsymbol{b} \perp \boldsymbol{\mathcal{X}}$. This implies that $\boldsymbol{\mathcal{X}} \subset \mathcal{H}$ and so $\mathcal{H}$ will contain $N + D - d - 1 \geq d + 1 + D - d - 1 > D - 1$ points of $\tilde{\boldsymbol{\mathcal{X}}}$.

5.2 Proof of Proposition 4

Writing $\boldsymbol{b} = \|\boldsymbol{b}\|_2 \hat{\boldsymbol{b}}$, and letting $\boldsymbol{R}$ be a rotation that takes $\hat{\boldsymbol{b}}$ to the first standard basis vector $\boldsymbol{e}_1$, we see that the first expectation in the LHS of (25) becomes equal to

$$\begin{aligned}
\mathbb{E}_{\mu_{\mathbb{S}^{D-1}}}(f_{\boldsymbol{b}}) &= \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} f_{\boldsymbol{b}}(\boldsymbol{z}) d\mu_{\mathbb{S}^{D-1}} = \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \left|\boldsymbol{b}^\top \boldsymbol{z}\right| d\mu_{\mathbb{S}^{D-1}} && (53)\\
&= \|\boldsymbol{b}\|_2 \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \left|\hat{\boldsymbol{b}}^\top \boldsymbol{z}\right| d\mu_{\mathbb{S}^{D-1}} = \|\boldsymbol{b}\|_2 \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \left|\boldsymbol{z}^\top \boldsymbol{R}^{-1}\boldsymbol{R}\hat{\boldsymbol{b}}\right| d\mu_{\mathbb{S}^{D-1}} && (54)\\
&= \|\boldsymbol{b}\|_2 \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} |\boldsymbol{z}^\top \boldsymbol{e}_1| d\mu_{\mathbb{S}^{D-1}} = \|\boldsymbol{b}\|_2 \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} |z_1| d\mu_{\mathbb{S}^{D-1}} = \|\boldsymbol{b}\|_2 c_D, && (55)
\end{aligned}$$

where $\boldsymbol{z} = (z_1, \ldots, z_D)^\top$ is the coordinate representation of $\boldsymbol{z}$. To see what the second expectation in the LHS of (25) evaluates to, decompose $\boldsymbol{b}$ as $\boldsymbol{b} = \pi_{\mathcal{S}}(\boldsymbol{b}) + \pi_{\mathcal{S}^\perp}(\boldsymbol{b})$, and note that because the support of the measure $\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}}$ is contained in $\mathcal{S}$, we must have that

$$\begin{aligned}
\mathbb{E}_{\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}}}(f_{\boldsymbol{b}}) &= \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \left|\boldsymbol{b}^\top \boldsymbol{z}\right| d\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}} = \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}\cap\mathcal{S}} \left|\boldsymbol{b}^\top \boldsymbol{z}\right| d\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}} && (56)\\
&= \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}\cap\mathcal{S}} \left|(\pi_{\mathcal{S}}(\boldsymbol{b}))^\top \boldsymbol{z}\right| d\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}} && (57)\\
&= \|\pi_{\mathcal{S}}(\boldsymbol{b})\|_2 \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}\cap\mathcal{S}} \left|\left(\widehat{\pi_{\mathcal{S}}(\boldsymbol{b})}\right)^\top \boldsymbol{z}\right| d\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}}. && (58)
\end{aligned}$$

Writing $\boldsymbol{z}'$ and $\boldsymbol{b}'$ for the coordinate representation of $\boldsymbol{z}$ and $\widehat{\pi_{\mathcal{S}}(\boldsymbol{b})}$ with respect to a basis of $\mathcal{S}$, and noting that $\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}} \cong \mu_{\mathbb{S}^{d-1}}$, we have that

$$\int_{\boldsymbol{z}\in\mathbb{S}^{D-1}\cap\mathcal{S}} \left|\left(\widehat{\pi_{\mathcal{S}}(\boldsymbol{b})}\right)^\top \boldsymbol{z}\right| d\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}} = \int_{\boldsymbol{z}'\in\mathbb{S}^{d-1}} \left|\boldsymbol{z}'^\top \boldsymbol{b}'\right| d\mu_{\mathbb{S}^{d-1}} = c_d, \tag{59}$$

where now c_d is the average height of the unit hemisphere of $\mathbb{R}^d$. Finally, noting that

$$\|\pi_{\mathcal{S}}(\boldsymbol{b})\|_2 = \|\boldsymbol{b}\|_2 \cos(\phi), \tag{60}$$

where ϕ is the principal angle of $\boldsymbol{b}$ from the subspace $\mathcal{S}$, we have that

$$\mathbb{E}_{\mu_{\mathbb{S}^{D-1}\cap\mathcal{S}}}(f_{\boldsymbol{b}}) = \|\boldsymbol{b}\|_2 c_d \cos(\phi). \tag{61}$$

5.3 Proof of Theorem 5

Because of the constraint $\boldsymbol{b}^\top \boldsymbol{b} = 1$ in (21), and using (25), problem (21) can be written as

$$\min_{\boldsymbol{b}} \ \left[Mc_D + Nc_d \cos(\phi)\right] \ \text{ s.t. } \ \boldsymbol{b}^\top \boldsymbol{b} = 1. \tag{62}$$

It is then immediate that the global minimum is equal to Mc_D and it is attained if and only if $\phi = \pi/2$, which corresponds to $\boldsymbol{b} \perp \mathcal{S}$.

5.4 Proof of Theorem 6

At iteration k the optimization problem associated with (22) is

$$\min_{\boldsymbol{b}\in\mathbb{R}^D} \ \mathcal{J}(\boldsymbol{b}) = \|\boldsymbol{b}\|_2 \left(Mc_D + Nc_d \cos(\phi)\right) \ \text{ s.t. } \ \boldsymbol{b}^\top \hat{\boldsymbol{n}}_k = 1, \tag{63}$$

where ϕ is the principal angle of $\boldsymbol{b}$ from the subspace $\mathcal{S}$.

Let ϕ_k be the principal angle of $\hat{\boldsymbol{n}}_k$ from $\mathcal{S}$, and let $\boldsymbol{n}_{k+1}$ be a global minimizer of (63), with principal angle from $\mathcal{S}$ equal to ϕ_{k+1}. We show that $\phi_{k+1} \geq \phi_k$. To see this, note that the decrease in the objective function at iteration k is

$$\begin{aligned}
\mathcal{J}(\hat{\boldsymbol{n}}_k) - \mathcal{J}(\boldsymbol{n}_{k+1}) :=& M\, c_D \left\|\hat{\boldsymbol{n}}_k\right\|_2 + N\, c_d \left\|\hat{\boldsymbol{n}}_k\right\|_2 \cos(\phi_k)\\
&- M\, c_D \left\|\boldsymbol{n}_{k+1}\right\|_2 - N\, c_d \left\|\boldsymbol{n}_{k+1}\right\|_2 \cos(\phi_{k+1}).
\end{aligned} \tag{64}$$

Since $\boldsymbol{n}_{k+1}^\top \hat{\boldsymbol{n}}_k = 1$, we must have that $\left\|\boldsymbol{n}_{k+1}\right\|_2 \geq 1 = \left\|\hat{\boldsymbol{n}}_k\right\|_2$. Now if $\phi_{k+1} < \phi_k$, then $\cos(\phi_{k+1}) > \cos(\phi_k)$. But then (64) implies that $\mathcal{J}(\boldsymbol{n}_{k+1}) > \mathcal{J}(\hat{\boldsymbol{n}}_k)$, which is a contradiction on the optimality of $\boldsymbol{n}_{k+1}$. Hence it must be the case that $\phi_{k+1} \geq \phi_k$, and so the sequence $\{\phi_k\}_k$ is non-decreasing. In particular, since $\phi_0 > 0$ by hypothesis, we must also have $\phi_k > 0$, i.e., $\hat{\boldsymbol{n}}_k \notin \mathcal{S}$, $\forall k \geq 0$.

Letting ψ_k be the angle of $\boldsymbol{b}$ from $\hat{\boldsymbol{n}}_k$, the constraint $\boldsymbol{b}^\top \hat{\boldsymbol{n}}_k = 1$ gives $0 \leq \psi_k < \pi/2$ and $\|\boldsymbol{b}\|_2 = 1/\cos(\psi_k)$, and so we can write the optimization problem (63) equivalently as

$$\min_{\boldsymbol{b}\in\mathbb{R}^D} \ \frac{Mc_D + Nc_d \cos(\phi)}{\cos(\psi_k)} \ \text{ s.t. } \ \boldsymbol{b}^\top \hat{\boldsymbol{n}}_k = 1. \tag{65}$$

If $\hat{\boldsymbol{n}}_k$ is orthogonal to $\mathcal{S}$, i.e., $\phi_k = \pi/2$, then $\mathcal{J}(\hat{\boldsymbol{n}}_k) = Mc_D \leq \mathcal{J}(\boldsymbol{b})$, $\forall \boldsymbol{b} : \boldsymbol{b}^\top \hat{\boldsymbol{n}}_k = 1$, with equality only if $\boldsymbol{b} = \hat{\boldsymbol{n}}_k$. As a consequence, $\boldsymbol{n}_{k'} = \hat{\boldsymbol{n}}_k$, $\forall k' > k$, and in particular if $\phi_0 = \pi/2$, then $k^* = 0$.

So suppose that $\phi_k < \pi/2$ and let $\hat{\boldsymbol{n}}_k^\perp$ be the normalized orthogonal projection of $\hat{\boldsymbol{n}}_k$ onto $\mathcal{S}^\perp$. We will prove that every global minimizer of problem (65) must lie in the two-dimensional plane $\mathcal{H} := \mathrm{Span}(\hat{\boldsymbol{n}}_k, \hat{\boldsymbol{n}}_k^\perp)$. To see this, let $\boldsymbol{b}$ have norm $1/\cos(\psi_k)$ for some $\psi_k < \pi/2$. If $\psi_k > \pi/2 - \phi_k$, then such a $\boldsymbol{b}$ can not be a global minimizer of (65), as the feasible vector $\hat{\boldsymbol{n}}_k^\perp / \sin(\phi_k) \in \mathcal{H}$ already gives a smaller objective, since

$$\mathcal{J}(\hat{\boldsymbol{n}}_k^\perp / \sin(\phi_k)) = \frac{Mc_D}{\sin(\phi_k)} = \frac{Mc_D}{\cos(\pi/2 - \phi_k)} < \frac{Mc_D + Nc_d \cos(\phi)}{\cos(\psi_k)} = \mathcal{J}(\boldsymbol{b}). \tag{66}$$

Thus, without loss of generality, we may restrict to the case where $\psi_k \leq \pi/2 - \phi_k$. Denote by $\hat{\boldsymbol{h}}_k$ the normalized projection of $\hat{\boldsymbol{n}}_k$ onto $\mathcal{S}$ and by $\hat{\boldsymbol{n}}^\dagger$ the vector that is obtained from $\hat{\boldsymbol{n}}_k$ by rotating it

towards $\hat{\boldsymbol{n}}_k^\perp$ by ψ_k. Note that both $\hat{\boldsymbol{h}}_k$ and $\hat{\boldsymbol{n}}_k^\dagger$ lie in $\mathcal{H}$. Letting $\Psi_k \in [0,\pi]$ be the spherical angle between the spherical arc formed by $\hat{\boldsymbol{n}}_k, \hat{\boldsymbol{b}}$ and the spherical arc formed by $\hat{\boldsymbol{n}}_k, \hat{\boldsymbol{h}}_k$, the spherical law of cosines gives

$$\cos(\angle \boldsymbol{b}, \hat{\boldsymbol{h}}_k) = \cos(\phi_k)\cos(\psi_k) + \sin(\phi_k)\sin(\psi_k)\cos(\Psi_k). \tag{67}$$

Now, Ψ_k is equal to π if and only if $\hat{\boldsymbol{n}}_k, \hat{\boldsymbol{h}}_k, \boldsymbol{b}$ are coplanar, i.e., if and only if $\boldsymbol{b} \in \mathcal{H}$. Suppose that $\boldsymbol{b} \notin \mathcal{H}$. Then $\Psi_k < \pi$, and so $\cos(\Psi_k) > -1$, which implies that

$$\cos(\angle \boldsymbol{b}, \hat{\boldsymbol{h}}_k) > \cos(\phi_k)\cos(\psi_k) - \sin(\phi_k)\sin(\psi_k) = \cos(\phi_k + \psi_k). \tag{68}$$

This in turn implies that the principal angle ϕ of $\boldsymbol{b}$ from $\mathcal{S}$ is strictly smaller than $\phi_k + \psi_k$, and so

$$\mathcal{J}(\boldsymbol{b}) = \frac{Mc_D + Nc_d\cos(\phi)}{\cos(\psi_k)} > \frac{Mc_D + Nc_d\cos(\phi_k+\psi_k)}{\cos(\psi_k)} = \mathcal{J}(\hat{\boldsymbol{n}}_k^\dagger/\cos(\psi_k)), \tag{69}$$

i.e., the feasible vector $\hat{\boldsymbol{n}}_k^\dagger/\cos(\psi_k) \in \mathcal{H}$ gives strictly smaller objective than $\boldsymbol{b}$.

To summarize, for the case where $\phi_k < \pi/2$, we have shown that any global minimizer $\boldsymbol{b}$ of (65) must i) have angle ψ_k from $\hat{\boldsymbol{n}}_k$ less or equal to $\pi/2 - \phi_k$, and ii) it must lie in $\mathrm{Span}(\hat{\boldsymbol{n}}_k, \hat{\boldsymbol{n}}_k^\perp)$. Hence, we can rewrite (65) in the equivalent form

$$\min_{\psi \in [-\pi/2+\phi_k, \pi/2-\phi_k]} \mathcal{J}_k(\psi) := \frac{Mc_D + Nc_d\cos(\phi_k+\psi)}{\cos(\psi_k)}, \tag{70}$$

where now ψ_k takes positive values as $\boldsymbol{b}$ approaches $\hat{\boldsymbol{n}}_k^\perp$ and negative values as it approaches $\hat{\boldsymbol{h}}_k$. The function $\mathcal{J}_k$ is continuous and differentiable in the interval $[-\pi/2+\phi_k, \pi/2-\phi_k]$, with derivative given by

$$\frac{\partial \mathcal{J}_k}{\partial \psi} = \frac{Mc_D\sin(\psi) - Nc_d\sin(\phi_k)}{\cos^2(\psi)}. \tag{71}$$

Setting the derivative to zero gives

$$\sin(\psi) = \alpha\sin(\phi_k). \tag{72}$$

If $\alpha\sin(\phi_k) \geq \sin(\pi/2 - \phi_k) = \cos(\phi_k)$, or equivalently $\tan(\phi_k) \geq 1/\alpha$, then $\mathcal{J}_k$ is strictly decreasing in the interval $[-\pi/2+\phi_k, \pi/2-\phi_k]$, and so it must attain its minimum precisely at $\psi = \pi/2 - \phi_k$, which corresponds to the choice $\boldsymbol{n}_{k+1} = \hat{\boldsymbol{n}}_k^\perp/\sin(\phi_k)$. Then by an earlier argument we must have that $\hat{\boldsymbol{n}}_{k'} \perp \mathcal{S}$, $\forall k' \geq k+1$. If, on the other hand, $\tan(\phi_k) < 1/\alpha$, then the equation (72) defines an angle

$$\psi_k^* := \sin^{-1}(\alpha\sin(\phi_k)) \in (0, \pi/2 - \phi_k), \tag{73}$$

at which $\mathcal{J}_k$ must attain its global minimum, since

$$\frac{\partial^2 \mathcal{J}_k}{\partial \psi^2}(\psi_k^*) = \frac{1}{\cos(\psi_k^*)} > 0. \tag{74}$$

As a consequence, if $\tan(\phi_k) < 1/\alpha$, then

$$\phi_{k+1} = \phi_k + \sin^{-1}(\alpha\sin(\phi_k)) < \pi/2. \tag{75}$$

We then see inductively that as long as $\tan(\phi_k) < 1/\alpha$, ϕ_k increases by a quantity which is bounded from below by $\sin^{-1}(\alpha\sin(\phi_0))$. Thus, ϕ_k will keep increasing until it becomes greater than the solution to the equation $\tan(\phi) = 1/\alpha$, at which point the global minimizer will be the vector $\boldsymbol{n}_{k+1} = \hat{\boldsymbol{n}}_k^\perp/\sin(\phi_k)$, and so $\hat{\boldsymbol{n}}_{k'} = \hat{\boldsymbol{n}}_{k+1}$, $\forall k' \geq k+1$. Finally, under the hypothesis that $\phi_k < \tan^{-1}(1/\alpha)$, we have

$$\phi_k = \phi_0 + \sum_{j=0}^{k-1} \sin^{-1}(\alpha\sin(\phi_j)) \geq \phi_0 + k\sin^{-1}(\alpha\sin(\phi_0)), \tag{76}$$

from where it follows that the maximal number of iterations needed for ϕ_k to become larger than $\tan^{-1}(1/\alpha)$ is $\left\lceil \frac{\tan^{-1}(1/\alpha)-\phi_0}{\sin^{-1}(\alpha\sin(\phi_0))} \right\rceil$, at which point at most one more iteration will be needed to achieve orthogonality to $\mathcal{S}$.

5.5 Proof of Lemma 7

Letting $\boldsymbol{R}$ be a rotation that takes $\boldsymbol{b}$ to the first canonical vector $\boldsymbol{e}_1$, i.e., $\boldsymbol{R}\boldsymbol{b} = \boldsymbol{e}_1$, we have that

$$\int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \mathrm{Sign}(\boldsymbol{b}^\top\boldsymbol{z})\boldsymbol{z}\,d\mu_{\mathbb{S}^{D-1}} = \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \mathrm{Sign}(\boldsymbol{b}^\top\boldsymbol{R}^\top\boldsymbol{R}\boldsymbol{z})\boldsymbol{z}\,d\mu_{\mathbb{S}^{D-1}} \tag{77}$$

$$= \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \mathrm{Sign}(\boldsymbol{e}_1^\top\boldsymbol{z})\boldsymbol{R}^\top\boldsymbol{z}\,d\mu_{\mathbb{S}^{D-1}} \tag{78}$$

$$= \boldsymbol{R}^\top \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \mathrm{Sign}(z_1)\boldsymbol{z}\,d\mu_{\mathbb{S}^{D-1}}, \tag{79}$$

where z_1 is the first cartesian coordinate of $\boldsymbol{z}$. Recalling the definition of c_D in equation (23), we see that

$$\int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \mathrm{Sign}(z_1)z_1\,d\mu_{\mathbb{S}^{D-1}} = \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} |z_1|\,d\mu_{\mathbb{S}^{D-1}} = c_D. \tag{80}$$

Moreover, for any $i > 1$, we have

$$\int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \mathrm{Sign}(z_1)z_i\,d\mu_{\mathbb{S}^{D-1}} = 0. \tag{81}$$

Consequently, the integral in (79) becomes

$$\int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \mathrm{Sign}(\boldsymbol{b}^\top\boldsymbol{z})\boldsymbol{z}\,d\mu_{\mathbb{S}^{D-1}} = \boldsymbol{R}^\top \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \mathrm{Sign}(z_1)\boldsymbol{z}\,d\mu_{\mathbb{S}^{D-1}} = \boldsymbol{R}^\top(c_D\boldsymbol{e}_1) = c_D\boldsymbol{b}. \tag{82}$$

5.6 Proof of Lemma 8

For any $\boldsymbol{b} \in \mathbb{S}^{D-1}$ we can write

$$c_D\boldsymbol{b} - \boldsymbol{o}_{\boldsymbol{b}} = \rho_1\boldsymbol{b} + \rho_2\boldsymbol{\zeta}, \tag{83}$$

for some vector $\boldsymbol{\zeta} \in \mathbb{S}^{D-1}$ orthogonal to $\boldsymbol{b}$, and so it is enough to show that $\sqrt{\rho_1^2 + \rho_2^2} \leq \sqrt{5}\mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}})$. Let us first bound from above $|\rho_1|$ in terms of $\mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}})$. Towards that end, observe that

$$\rho_1 = \boldsymbol{b}^\top(c_D\boldsymbol{b} - \boldsymbol{o}_{\boldsymbol{b}}) = c_D - \frac{1}{M}\sum_{j=1}^{M}\left|\boldsymbol{b}^\top\boldsymbol{o}_j\right| = \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} f_{\boldsymbol{b}}(\boldsymbol{z})d\mu_{\mathbb{S}^{D-1}} - \frac{1}{M}\sum_{j=1}^{M} f_{\boldsymbol{b}}(\boldsymbol{o}_j), \quad (84)$$

where the equality follows from the definition of c_D in (23) and recalling that $f_{\boldsymbol{b}}(\boldsymbol{z}) = \left|\boldsymbol{b}^\top\boldsymbol{z}\right|$. In other words, ρ_1 is the error in approximating the integral of $f_{\boldsymbol{b}}$ on $\mathbb{S}^{D-1}$ by the average of $f_{\boldsymbol{b}}$ on the point set $\boldsymbol{\mathcal{O}}$.

Now, notice that each *super-level set* $\left\{\boldsymbol{z} \in \mathbb{S}^{D-1} : f_{\boldsymbol{b}}(\boldsymbol{z}) \geq \alpha\right\}$ for $\alpha \in [0,1]$, is the union of two spherical caps, and also that

$$\sup_{\boldsymbol{z}\in\mathbb{S}^{D-1}} f_{\boldsymbol{b}}(\boldsymbol{z}) - \inf_{\boldsymbol{z}\in\mathbb{S}^{D-1}} f_{\boldsymbol{b}}(\boldsymbol{z}) = 1 - 0 = 1. \quad (85)$$

We these in mind, repeating the entire argument of the proof of Theorem 1 in (Harman, 2010) that lead to inequality (9) in (Harman, 2010), but now for a measurable function with respect to $\mu_{\mathbb{S}^{D-1}}$ (that would be $f_{\boldsymbol{b}}$), leads directly to

$$|\rho_1| \leq \mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}}). \quad (86)$$

For ρ_2 we have that

$$\rho_2 = \boldsymbol{\zeta}^\top(c_D\boldsymbol{b}) - \boldsymbol{\zeta}^\top\boldsymbol{o}_{\boldsymbol{b}} \quad (87)$$

$$= \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} \mathrm{Sign}\left(\boldsymbol{b}^\top\boldsymbol{z}\right)\boldsymbol{\zeta}^\top\boldsymbol{z}d\mu_{\mathbb{S}^{D-1}} - \frac{1}{M}\sum_{j=1}^{M}\mathrm{Sign}\left(\boldsymbol{b}^\top\boldsymbol{o}_j\right)\boldsymbol{\zeta}^\top\boldsymbol{o}_j \quad (88)$$

$$= \int_{\boldsymbol{z}\in\mathbb{S}^{D-1}} g_{\boldsymbol{b},\boldsymbol{\zeta}}(\boldsymbol{z})d\mu_{\mathbb{S}^{D-1}} - \frac{1}{M}\sum_{j=1}^{M} g_{\boldsymbol{b},\boldsymbol{\zeta}}(\boldsymbol{o}_j), \quad (89)$$

where $g_{\boldsymbol{b},\boldsymbol{\zeta}} : \mathbb{S}^{D-1} \to \mathbb{R}$ is defined as $g_{\boldsymbol{b},\boldsymbol{\zeta}}(\boldsymbol{z}) = \mathrm{Sign}\left(\boldsymbol{b}^\top\boldsymbol{z}\right)\boldsymbol{\zeta}^\top\boldsymbol{z}$. Then a similar argument as for ρ_1, with the difference that now

$$\sup_{\boldsymbol{z}\in\mathbb{S}^{D-1}} g_{\boldsymbol{b},\boldsymbol{\zeta}}(\boldsymbol{z}) - \inf_{\boldsymbol{z}\in\mathbb{S}^{D-1}} g_{\boldsymbol{b},\boldsymbol{\zeta}}(\boldsymbol{z}) = 1 - (-1) = 2, \quad (90)$$

leads to

$$|\rho_2| \leq 2\mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}}). \quad (91)$$

In view of (86), inequality (91) establishes that $\sqrt{\rho_1^2 + \rho_2^2} \leq \sqrt{5}\mathfrak{S}_{D,M}(\boldsymbol{\mathcal{O}})$, which concludes the proof of the lemma.

5.7 Proof of Lemma 9

Since $\boldsymbol{x}$ lies in $\mathcal{S}$, we have $\boldsymbol{f}_{\boldsymbol{b}}(\boldsymbol{x}) = \boldsymbol{f}_{\boldsymbol{v}}(\boldsymbol{x}) = \boldsymbol{f}_{\hat{\boldsymbol{v}}}(\boldsymbol{x})$, so that

$$\int_{\boldsymbol{x}\in\mathbb{S}^{D-1}\cap\mathcal{S}} \mathrm{Sign}(\boldsymbol{b}^\top\boldsymbol{x})\boldsymbol{x}d\mu_{\mathbb{S}^{D-1}} = \int_{\boldsymbol{x}\in\mathbb{S}^{D-1}\cap\mathcal{S}} \mathrm{Sign}(\hat{\boldsymbol{v}}^\top\boldsymbol{x})\boldsymbol{x}d\mu_{\mathbb{S}^{D-1}}. \quad (92)$$

Now express $\boldsymbol{x}$ and $\hat{\boldsymbol{v}}$ on a basis of $\mathcal{S}$, use Lemma 7 replacing D with d, and then switch back to the standard basis of $\mathbb{R}^D$.

5.8 Proof of Theorem 11

To prove the theorem we need the following lemma.

Lemma 13 *For any $\boldsymbol{b} \in \mathbb{S}^{D-1}$ we have that*

$$M(c_D + \epsilon_{\boldsymbol{\mathcal{O}},M}) \geq \left\|\boldsymbol{\mathcal{O}}^\top\boldsymbol{b}\right\|_1 \geq M(c_D - \epsilon_{\boldsymbol{\mathcal{O}},M}) \quad (93)$$

$$N(c_d + \epsilon_{\boldsymbol{\mathcal{X}},N})\cos(\phi) \geq \left\|\boldsymbol{\mathcal{X}}^\top\boldsymbol{b}\right\|_1 \geq N(c_d - \epsilon_{\boldsymbol{\mathcal{X}},N})\cos(\phi). \quad (94)$$

Proof We only prove the second inequality as the first is even simpler. Let $\boldsymbol{v} \neq \boldsymbol{0}$ be the orthogonal projection of $\boldsymbol{b}$ onto $\mathcal{S}$. By definition of $\epsilon_{\boldsymbol{\mathcal{X}},N}$, there exists a vector $\boldsymbol{\xi} \in \mathcal{S}$ of ℓ_2 norm less or equal to $\epsilon_{\boldsymbol{\mathcal{X}},N}$, such that

$$\boldsymbol{x}_{\boldsymbol{v}} = \boldsymbol{x}_{\boldsymbol{b}} = \frac{1}{N}\sum_{j=1}^{N}\mathrm{Sign}(\boldsymbol{b}^\top\boldsymbol{x}_j)\boldsymbol{x}_j = c_d\hat{\boldsymbol{v}} + \boldsymbol{\xi}. \quad (95)$$

Taking inner product of both sides with $\boldsymbol{b}$ gives

$$\frac{1}{N}\left\|\boldsymbol{\mathcal{X}}^\top\boldsymbol{b}\right\|_1 = c_d\cos(\phi) + \boldsymbol{b}^\top\boldsymbol{\xi}. \quad (96)$$

Now, the result follows by noting that $\left|\boldsymbol{b}^\top\boldsymbol{\xi}\right| \leq \epsilon_{\boldsymbol{\mathcal{X}},N}\cos(\phi)$, since the principal angle of $\boldsymbol{b}$ from $\mathrm{Span}(\boldsymbol{\xi})$ can not be less then ϕ. ■

Now, let $\boldsymbol{b}^*$ be an optimal solution of (9). Then $\boldsymbol{b}^*$ must satisfy the first order optimality relation

$$\boldsymbol{0} \in \lambda\boldsymbol{b}^* + \tilde{\boldsymbol{\mathcal{X}}}\,\mathrm{Sgn}(\tilde{\boldsymbol{\mathcal{X}}}^\top\boldsymbol{b}^*), \quad (97)$$

where λ is a scalar Lagrange multiplier parameter, and Sgn is the sub-differential of the ℓ_1 norm. For the sake of contradiction, suppose that $\boldsymbol{b}^* \not\perp \mathcal{S}$. If $\boldsymbol{b}^* \in \mathcal{S}$, then using Lemma 13 we have

$$M\,c_D + M\,\epsilon_{\boldsymbol{\mathcal{O}}} \geq \min_{\boldsymbol{b}\perp\mathcal{S},\boldsymbol{b}^\top\boldsymbol{b}=1}\left\|\boldsymbol{\mathcal{O}}^\top\boldsymbol{b}\right\|_1 \geq \left\|\boldsymbol{\mathcal{O}}^\top\boldsymbol{b}^*\right\|_1 + \left\|\boldsymbol{\mathcal{X}}^\top\boldsymbol{b}^*\right\|_1$$

$$\geq M\,c_D - M\,\epsilon_{\boldsymbol{\mathcal{O}}} + N\,c_d - N\,\epsilon_{\boldsymbol{\mathcal{X}}}, \quad (98)$$

which violates the first inequality of hypothesis (46). Hence, we can assume that $\boldsymbol{b}^* \notin \mathcal{S}$.

By the general position hypothesis as well as Proposition 14, $\boldsymbol{b}^*$ will be orthogonal to precisely $D-1$ points, among which K_1 points belong to $\boldsymbol{\mathcal{O}}$, say, without loss of generality, $\boldsymbol{o}_1, \ldots, \boldsymbol{o}_{K_1}$, and $0 \leq K_2 \leq d-1$ points belong to $\boldsymbol{\mathcal{X}}$, say $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{K_2}$. Then there must exist real numbers $-1 \leq \alpha_j, \beta_j \leq 1$, such that

$$\lambda\boldsymbol{b}^* + \sum_{j=1}^{K_1}\alpha_j\boldsymbol{o}_j + \sum_{j=K_1+1}^{M}\mathrm{Sign}(\boldsymbol{o}_j^\top\boldsymbol{b}^*)\boldsymbol{o}_j + \sum_{j=1}^{K_2}\beta_j\boldsymbol{x}_j + \sum_{j=K_2+1}^{N}\mathrm{Sign}(\boldsymbol{x}_j^\top\boldsymbol{b}^*)\boldsymbol{x}_j = \boldsymbol{0}. \quad (99)$$

Since $\mathrm{Sign}(\boldsymbol{o}_j^\top\boldsymbol{b}^*) = 0, \forall j \leq K_1$ and similarly $\mathrm{Sign}(\boldsymbol{x}_j^\top\boldsymbol{b}^*) = 0, \forall j \leq K_2$, we can equivalently write

$$\lambda\boldsymbol{b}^* + \sum_{j=1}^{K_1}\alpha_j\boldsymbol{o}_j + \sum_{j=1}^{M}\mathrm{Sign}(\boldsymbol{o}_j^\top\boldsymbol{b}^*)\boldsymbol{o}_j + \sum_{j=1}^{K_2}\beta_j\boldsymbol{x}_j + \sum_{j=1}^{N}\mathrm{Sign}(\boldsymbol{x}_j^\top\boldsymbol{b}^*)\boldsymbol{x}_j = \boldsymbol{0} \quad (100)$$

or more compactly

$$\lambda \boldsymbol{b}^* + \boldsymbol{\xi}_{\boldsymbol{\mathcal{O}}} + M\, \boldsymbol{o}_{\boldsymbol{b}^*} + \boldsymbol{\xi}_{\boldsymbol{\mathcal{X}}} + N\, \boldsymbol{x}_{\hat{\boldsymbol{v}}^*} = \boldsymbol{0}, \tag{101}$$

where $\hat{\boldsymbol{v}}^*$ is the normalized projection of $\boldsymbol{b}^*$ onto $\mathcal{S}$ (nonzero since $\boldsymbol{b}^* \not\perp \mathcal{S}$ by hypothesis), and

$$\boldsymbol{o}_{\boldsymbol{b}^*} := \frac{1}{M}\sum_{j=1}^{M} \mathrm{Sign}(\boldsymbol{o}_j^\top \boldsymbol{b}^*)\boldsymbol{o}_j, \qquad \boldsymbol{x}_{\hat{\boldsymbol{v}}^*} := \frac{1}{N}\sum_{j=1}^{N} \mathrm{Sign}(\boldsymbol{x}_j^\top \hat{\boldsymbol{v}}^*)\boldsymbol{x}_j, \tag{102}$$

$$\boldsymbol{\xi}_{\boldsymbol{\mathcal{O}}} := \sum_{j=1}^{K_1} \alpha_j \boldsymbol{o}_j, \qquad \boldsymbol{\xi}_{\boldsymbol{\mathcal{X}}} := \sum_{j=1}^{K_2} \beta_j \boldsymbol{x}_j. \tag{103}$$

From the definitions of $\epsilon_{\boldsymbol{\mathcal{O}},M}$ and $\epsilon_{\boldsymbol{\mathcal{X}},N}$ in (34) and (42) respectively, we have that

$$\boldsymbol{o}_{\boldsymbol{b}^*} = c_D\, \boldsymbol{b}^* + \boldsymbol{\eta}_{\boldsymbol{\mathcal{O}}}, \;\; ||\boldsymbol{\eta}_{\boldsymbol{\mathcal{O}}}||_2 \leq \epsilon_{\boldsymbol{\mathcal{O}},M} \tag{104}$$

$$\boldsymbol{x}_{\hat{\boldsymbol{v}}^*} = c_d\, \hat{\boldsymbol{v}}^* + \boldsymbol{\eta}_{\boldsymbol{\mathcal{X}}}, \;\; ||\boldsymbol{\eta}_{\boldsymbol{\mathcal{X}}}||_2 \leq \epsilon_{\boldsymbol{\mathcal{X}},N}, \tag{105}$$

and so (101) becomes

$$\lambda \boldsymbol{b}^* + \boldsymbol{\xi}_{\boldsymbol{\mathcal{O}}} + M\, c_D\, \boldsymbol{b}^* + M\, \boldsymbol{\eta}_{\boldsymbol{\mathcal{O}}} + \boldsymbol{\xi}_{\boldsymbol{\mathcal{X}}} + N\, c_d\, \hat{\boldsymbol{v}}^* + N\, \boldsymbol{\eta}_{\boldsymbol{\mathcal{X}}} = \boldsymbol{0}. \tag{106}$$

Since $\boldsymbol{b}^* \notin \mathcal{S}$, we have that $\boldsymbol{b}^*, \hat{\boldsymbol{v}}^*$ are linearly independent. Define the two-dimensional subspace $\mathcal{U} := \mathrm{Span}\,(\boldsymbol{b}^*, \hat{\boldsymbol{v}}^*)$ and project (106) onto $\mathcal{U}$ to get

$$\lambda \boldsymbol{b}^* + \pi_{\mathcal{U}}(\boldsymbol{\xi}_{\boldsymbol{\mathcal{O}}}) + M\, c_D\, \boldsymbol{b}^* + M\, \pi_{\mathcal{U}}(\boldsymbol{\eta}_{\boldsymbol{\mathcal{O}}}) + \pi_{\mathcal{U}}(\boldsymbol{\xi}_{\boldsymbol{\mathcal{X}}}) + N\, c_d\, \hat{\boldsymbol{v}}^* + N\, \pi_{\mathcal{U}}(\boldsymbol{\eta}_{\boldsymbol{\mathcal{X}}}) = \boldsymbol{0}. \tag{107}$$

Now, very vector $\boldsymbol{u}$ in the image of $\pi_{\mathcal{U}}$ can be written as a linear combination of $\boldsymbol{b}^*$ and $\hat{\boldsymbol{v}}^*$:

$$\boldsymbol{u} = [\boldsymbol{u}]_{\boldsymbol{b}^*}\, \boldsymbol{b}^* + [\boldsymbol{u}]_{\hat{\boldsymbol{v}}^*}\, \hat{\boldsymbol{v}}^*, \;\; \text{with} \;\; [\boldsymbol{u}]_{\boldsymbol{b}^*}, [\boldsymbol{u}]_{\hat{\boldsymbol{v}}^*} \in \mathbb{R}. \tag{108}$$

Taking inner product of $\boldsymbol{u}$ with $\boldsymbol{b}^*$ and $\hat{\boldsymbol{v}}^*$, we get respectively

$$\boldsymbol{u}^\top \boldsymbol{b}^* = [\boldsymbol{u}]_{\boldsymbol{b}^*} + [\boldsymbol{u}]_{\hat{\boldsymbol{v}}^*} \cos(\phi^*) \tag{109}$$

$$\boldsymbol{u}^\top \hat{\boldsymbol{v}}^* = [\boldsymbol{u}]_{\boldsymbol{b}^*} \cos(\phi^*) + [\boldsymbol{u}]_{\hat{\boldsymbol{v}}^*}, \tag{110}$$

where ϕ^* is the angle between $\boldsymbol{b}^*$ and $\hat{\boldsymbol{v}}^*$, i.e., the angle of $\boldsymbol{b}^*$ from $\mathcal{S}$. Solving with respect to $[\boldsymbol{u}]_{\hat{\boldsymbol{v}}^*}$, we obtain

$$[\boldsymbol{u}]_{\hat{\boldsymbol{v}}^*} = \frac{\boldsymbol{u}^\top \hat{\boldsymbol{v}}^* - \boldsymbol{u}^\top \boldsymbol{b}^* \cos(\phi^*)}{1 - \cos^2(\phi^*)}, \tag{111}$$

which in turn gives an upper bound on the magnitude of $[\boldsymbol{u}]_{\hat{\boldsymbol{v}}^*}$:

$$|[\boldsymbol{u}]_{\hat{\boldsymbol{v}}^*}| \leq \frac{1 + \cos(\phi^*)}{1 - \cos^2(\phi^*)}\, \|\boldsymbol{u}\|_2\,. \tag{112}$$

Going back to (107) and writing each vector as a linear combination of $\boldsymbol{b}^*$ and $\hat{\boldsymbol{v}}^*$, we obtain

$$\begin{aligned}&\lambda \boldsymbol{b}^* + [\pi_{\mathcal{U}}(\boldsymbol{\xi}_{\boldsymbol{\mathcal{O}}})]_{\boldsymbol{b}^*}\, \boldsymbol{b}^* + [\pi_{\mathcal{U}}(\boldsymbol{\xi}_{\boldsymbol{\mathcal{O}}})]_{\hat{\boldsymbol{v}}^*}\, \hat{\boldsymbol{v}}^* + M\, c_D\, \boldsymbol{b}^* + M\, [\pi_{\mathcal{U}}(\boldsymbol{\eta}_{\boldsymbol{\mathcal{O}}})]_{\boldsymbol{b}^*}\, \boldsymbol{b}^* + M\, [\pi_{\mathcal{U}}(\boldsymbol{\eta}_{\boldsymbol{\mathcal{O}}})]_{\hat{\boldsymbol{v}}^*}\, \hat{\boldsymbol{v}}^* + \\ &[\pi_{\mathcal{U}}(\boldsymbol{\xi}_{\boldsymbol{\mathcal{X}}})]_{\boldsymbol{b}^*}\, \boldsymbol{b}^* + [\pi_{\mathcal{U}}(\boldsymbol{\xi}_{\boldsymbol{\mathcal{X}}})]_{\hat{\boldsymbol{v}}^*}\, \hat{\boldsymbol{v}}^* + N\, c_d\, \hat{\boldsymbol{v}}^* + N\, [\pi_{\mathcal{U}}(\boldsymbol{\eta}_{\boldsymbol{\mathcal{X}}})]_{\boldsymbol{b}^*}\, \boldsymbol{b}^* + N\, [\pi_{\mathcal{U}}(\boldsymbol{\eta}_{\boldsymbol{\mathcal{X}}})]_{\hat{\boldsymbol{v}}^*}\, \hat{\boldsymbol{v}}^* = \boldsymbol{0}.\end{aligned} \tag{113}$$

Since $\mathcal{U}$ is a two-dimensional space, there exists a vector $\hat{\boldsymbol{\zeta}} \in \mathcal{U}$ that is orthogonal to $\boldsymbol{b}^*$ but not orthogonal to $\hat{\boldsymbol{v}}^*$. Projecting the above equation onto the line spanned by $\hat{\boldsymbol{\zeta}}$, we obtain the one-dimensional equation

$$([\pi_{\mathcal{U}}(\boldsymbol{\xi}_{\boldsymbol{\mathcal{O}}})]_{\hat{\boldsymbol{v}}^*} + M\, [\pi_{\mathcal{U}}(\boldsymbol{\eta}_{\boldsymbol{\mathcal{O}}})]_{\hat{\boldsymbol{v}}^*} + [\pi_{\mathcal{U}}(\boldsymbol{\xi}_{\boldsymbol{\mathcal{X}}})]_{\hat{\boldsymbol{v}}^*} + N\, c_d + N\, [\pi_{\mathcal{U}}(\boldsymbol{\eta}_{\boldsymbol{\mathcal{X}}})]_{\hat{\boldsymbol{v}}^*}) \cdot \hat{\boldsymbol{\zeta}}^\top \hat{\boldsymbol{v}}^* = 0. \tag{114}$$

Since $\hat{\boldsymbol{\zeta}}$ is not orthogonal to $\hat{\boldsymbol{v}}^*$, the above equation implies that

$$[\pi_{\mathcal{U}}(\boldsymbol{\xi}_{\boldsymbol{\mathcal{O}}})]_{\hat{\boldsymbol{v}}^*} + M\, [\pi_{\mathcal{U}}(\boldsymbol{\eta}_{\boldsymbol{\mathcal{O}}})]_{\hat{\boldsymbol{v}}^*} + [\pi_{\mathcal{U}}(\boldsymbol{\xi}_{\boldsymbol{\mathcal{X}}})]_{\hat{\boldsymbol{v}}^*} + N\, c_d + N\, [\pi_{\mathcal{U}}(\boldsymbol{\eta}_{\boldsymbol{\mathcal{X}}})]_{\hat{\boldsymbol{v}}^*} = 0, \tag{115}$$

which, in turn, implies that

$$N\, c_d \leq |[\pi_{\mathcal{U}}(\boldsymbol{\xi}_{\boldsymbol{\mathcal{O}}})]_{\hat{\boldsymbol{v}}^*}| + M\, |[\pi_{\mathcal{U}}(\boldsymbol{\eta}_{\boldsymbol{\mathcal{O}}})]_{\hat{\boldsymbol{v}}^*}| + |[\pi_{\mathcal{U}}(\boldsymbol{\xi}_{\boldsymbol{\mathcal{X}}})]_{\hat{\boldsymbol{v}}^*}| + N\, |[\pi_{\mathcal{U}}(\boldsymbol{\eta}_{\boldsymbol{\mathcal{X}}})]_{\hat{\boldsymbol{v}}^*}|\,. \tag{116}$$

Invoking the upper bound of (112) together with

$$\left\|\boldsymbol{\xi}_{\boldsymbol{\mathcal{O}}}\right\|_2 \leq \mathcal{R}_{\boldsymbol{\mathcal{O}},K_1},\; \left\|\boldsymbol{\xi}_{\boldsymbol{\mathcal{X}}}\right\|_2 \leq \mathcal{R}_{\boldsymbol{\mathcal{X}},K_2},\; \left\|\boldsymbol{\eta}_{\boldsymbol{\mathcal{O}}}\right\|_2 \leq \epsilon_{\boldsymbol{\mathcal{O}},M},\; \left\|\boldsymbol{\eta}_{\boldsymbol{\mathcal{X}}}\right\|_2 \leq \epsilon_{\boldsymbol{\mathcal{X}},N}, \tag{117}$$

and the definition of $\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}}$ (Definition 10), we get

$$N\, c_d \leq \frac{1 + \cos(\phi^*)}{1 - \cos^2(\phi^*)}\, (\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}} + M\, \epsilon_{\boldsymbol{\mathcal{O}},M} + N\, \epsilon_{\boldsymbol{\mathcal{X}},N})\,, \tag{118}$$

or equivalently

$$\begin{aligned}&N\, c_d\, \cos^2(\phi^*) + (\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}} + M\, \epsilon_{\boldsymbol{\mathcal{O}},M} + N\, \epsilon_{\boldsymbol{\mathcal{X}},N})\, \cos(\phi^*) \\ &+ (\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}} + M\, \epsilon_{\boldsymbol{\mathcal{O}},M} + N\, \epsilon_{\boldsymbol{\mathcal{X}},N} - N\, c_d) \geq 0.\end{aligned} \tag{119}$$

This is a quadratic polynomial in $\cos(\phi^*)$, whose constant term is negative by the second inequality of hypothesis (46), and thus has exactly one positive and one negative root. As consequence, this polynomial being non-negative together with the fact that $\cos(\phi^*) > 0$, implies that $\cos(\phi^*)$ must be greater than the positive root of the polynomial, i.e.,

$$\cos(\phi^*) \geq \frac{-\mathscr{Q} + \sqrt{\mathscr{Q}^2 + 4c_d(c_d - \mathscr{Q})}}{2c_d}, \;\; \mathscr{Q} := \frac{\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}}}{N} + \epsilon_{\boldsymbol{\mathcal{O}},M}\frac{M}{N} + \epsilon_{\boldsymbol{\mathcal{X}},N}. \tag{120}$$

On the other hand, by Lemma 13 we have

$$M(c_D + \epsilon_{\boldsymbol{\mathcal{O}},M}) \geq \min_{\hat{\boldsymbol{b}} \perp \mathcal{S}} \left\|\tilde{\boldsymbol{\mathcal{X}}}^\top \hat{\boldsymbol{b}}\right\|_1 \geq \left\|\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}^*\right\|_1 \geq M(c_D - \epsilon_{\boldsymbol{\mathcal{O}},M}) + N(c_d - \epsilon_{\boldsymbol{\mathcal{X}},N})\cos(\phi^*), \tag{121}$$

which implies that

$$2M\epsilon_{\boldsymbol{\mathcal{O}},M} \geq N(c_d - \epsilon_{\boldsymbol{\mathcal{X}},N})\frac{-\mathscr{Q} + \sqrt{\mathscr{Q}^2 + 4c_d(c_d - \mathscr{Q})}}{2c_d}. \tag{122}$$

This latter inequality is equivalent to the inequality

$$\begin{aligned}&2\epsilon_{\boldsymbol{\mathcal{O}},M}^2(3c_d - \epsilon_{\boldsymbol{\mathcal{X}},N})\left(\frac{M}{N}\right)^2 + \epsilon_{\boldsymbol{\mathcal{O}},M}(c_d - \epsilon_{\boldsymbol{\mathcal{X}},N})\left(2\frac{\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}}}{N} + \epsilon_{\boldsymbol{\mathcal{X}},N} + c_d\right)\frac{M}{N} \\ &- (c_d - \epsilon_{\boldsymbol{\mathcal{X}},N})^2\left(c_d - \epsilon_{\boldsymbol{\mathcal{X}},N} - \frac{\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}}}{N}\right) \geq 0,\end{aligned} \tag{123}$$

whose left-hand-side we view as quadratic polynomial in M/N. By the first two inequalities of hypothesis (46), the second term of this polynomial is positive, while the constant term is negative, and so this inequality is equivalent to M/N being greater or equal than the unique positive root of that polynomial. But this contradicts the third inequality of hypothesis (46). Consequently, the initial hypothesis of the proof that $\boldsymbol{b}^* \not\perp \mathcal{S}$ can not be true, and the theorem is proved.

A Geometric View of the Proof of Theorem 11. Let us provide some geometric intuition that underlies the proof of Theorem 11. It is instructive to begin our discussion by considering the case $d = 1, D = 2$, i.e. the inlier space is simply a line and the ambient space is a 2-dimensional plane. Since all points have unit ℓ_2-norm, every column of $\boldsymbol{\mathcal{X}}$ will be of the form $\hat{\boldsymbol{x}}$ or $-\hat{\boldsymbol{x}}$ for a fixed vector $\hat{\boldsymbol{x}} \in \mathcal{S}^1$ that spans the inlier space $\mathcal{S}$. In this setting, let us examine a global solution $\boldsymbol{b}^*$ of the optimization problem (9). We will start by assuming that such a $\boldsymbol{b}^*$ is not orthogonal to $\mathcal{S}$, and intuitively arrive at the conclusion that this can not be the case as long as there are *sufficiently many* inliers.

We will argue on an intuitive level that if $\boldsymbol{b}^* \not\perp \mathcal{S}$, then the principal angle ϕ^* of $\boldsymbol{b}^*$ from $\mathcal{S}$ needs to be small; this is captured precisely by (120) in the proof of the theorem. To see this, suppose $\boldsymbol{b}^* \not\perp \mathcal{S}$; then $\boldsymbol{b}^*$ will be non-orthogonal to every inlier, and by Proposition14 orthogonal to $D - 1 = 1$ outlier, say $\boldsymbol{o}_1$. The optimality condition (97) specializes to

$$\alpha_1 \boldsymbol{o}_1 + \underbrace{\sum_{j=1}^{M} \text{Sign}(\boldsymbol{o}_j^\top \boldsymbol{b}^*)\boldsymbol{o}_j}_{M\boldsymbol{o}_{\boldsymbol{b}^*}} + \sum_{j=1}^{N} \text{Sign}(\boldsymbol{x}_j^\top \boldsymbol{b}^*)\boldsymbol{x}_j + \lambda \boldsymbol{b}^* = \boldsymbol{0}, \tag{124}$$

where $-1 \leq \alpha_1 \leq 1$. Notice that the third term is simply $N\ \text{Sign}(\hat{\boldsymbol{x}}^\top \boldsymbol{b}^*)\hat{\boldsymbol{x}}$, and so

$$\alpha_1 \boldsymbol{o}_1 + M\ \boldsymbol{o}_{\boldsymbol{b}^*} + \lambda \boldsymbol{b}^* = -N\ \text{Sign}(\hat{\boldsymbol{x}}^\top \boldsymbol{b}^*)\hat{\boldsymbol{x}}. \tag{125}$$

Now, what (125) is saying is that the point $-N\ \text{Sign}(\hat{\boldsymbol{x}}^\top \boldsymbol{b}^*)\hat{\boldsymbol{x}}$ must lie inside the set

$$\text{Conv}(\pm \boldsymbol{o}_1) + \{M\boldsymbol{o}_{\boldsymbol{b}^*}\} + \text{Span}(\boldsymbol{b}^*) = \{\alpha_1 \boldsymbol{o}_1 + M\boldsymbol{o}_{\boldsymbol{b}^*} + \lambda \boldsymbol{b}^* : |\alpha_1| \leq 1, \lambda \in \mathbb{R}\}, \tag{126}$$

where the $+$ operator on sets is the Minkowski sum. Notice that the set $\text{Conv}(\pm \boldsymbol{o}_1) + M\boldsymbol{o}_{\boldsymbol{b}^*}$ is the translation of the line segment (polytope) $\text{Conv}(\pm \boldsymbol{o}_1)$ by $M\boldsymbol{o}_{\boldsymbol{b}^*}$. Then (125) says that if we draw all affine lines that originate from every point of $\text{Conv}(\pm \boldsymbol{o}_1) + M\boldsymbol{o}_{\boldsymbol{b}^*}$ and have direction $\boldsymbol{b}^*$, then one of these lines must meet the point $-N\ \text{Sign}(\hat{\boldsymbol{x}}^\top \boldsymbol{b}^*)\hat{\boldsymbol{x}}$. Let us illustrate this for the case where $M = N = 5$ and say it so happens that $\boldsymbol{b}^*$ has a rather large angle ϕ^* from $\mathcal{S}$, say $\phi^* = 45°$. Recall that $\boldsymbol{o}_{\boldsymbol{b}^*}$ is concentrated around $\boldsymbol{c}_D\, \boldsymbol{b}^*$ and for the case $D = 2$ we have $c_D = \frac{2}{\pi}$. As illustrated in Figure 1, because ϕ^* is large, the unbounded polytope $M\boldsymbol{o}_{\boldsymbol{b}^*} + \text{Conv}(\pm \boldsymbol{o}_1) + \text{Span}(\boldsymbol{b}^*)$ misses the point $-N\ \text{Sign}(\hat{\boldsymbol{x}}^\top \boldsymbol{b}^*)\hat{\boldsymbol{x}}$ thus making the optimality equation (125) infeasible. This indicates that critical vectors $\boldsymbol{b}^* \not\perp \mathcal{S}$ having large angles from $\mathcal{S}$ are unlikely to exist.

On the other hand, critical points $\boldsymbol{b}^* \not\perp \mathcal{S}$ may exist, but their angle ϕ^* from $\mathcal{S}$ needs to be small, as illustrated in Figure 2. However, such critical points can not be global minimizers, because small angles from $\mathcal{S}$ yield large objective values; this is captured precisely by equation (121) in the proof of the theorem. Hence the only possibility that critical points $\boldsymbol{b}^* \not\perp \mathcal{S}$ that are also global minimizers do exist is that the number of inliers is significantly less than the number of outliers, i.e. $N << M$, as illustrated in Figure 3. The precise notion of how many inliers should exist with respect to outliers is captured by condition (46) of Theorem 11.

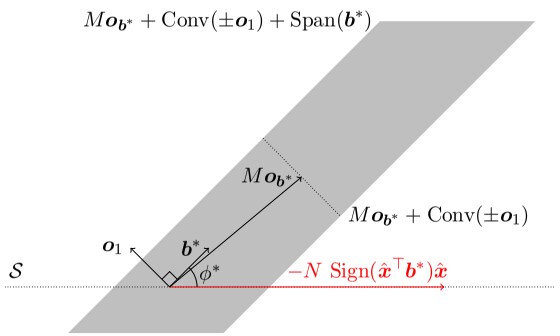

Figure 1: Geometry of the optimality condition (97) and (125) for the case $d = 1, D = 2, M = N = 5$. The polytope $M\boldsymbol{o}_{\boldsymbol{b}^*} + \text{Conv}(\pm \boldsymbol{o}_1) + \text{Span}(\boldsymbol{b}^*)$ misses the point $-N\ \text{Sign}(\hat{\boldsymbol{x}}^\top \boldsymbol{b}^*)\hat{\boldsymbol{x}}$ and so the optimality condition can not be true for both $\boldsymbol{b}^* \not\perp \mathcal{S} = \text{Span}(\hat{\boldsymbol{x}})$ and ϕ^* large.

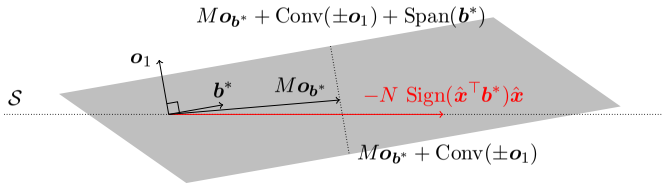

Figure 2: Geometry of the optimality condition (97) and (125) for the case $d = 1, D = 2, M = N = 5$. A critical $\boldsymbol{b}^* \not\perp \mathcal{S}$ exists, but its angle from $\mathcal{S}$ is small, so that the polytope $M\boldsymbol{o}_{\boldsymbol{b}^*} + \text{Conv}(\pm \boldsymbol{o}_1) + \text{Span}(\boldsymbol{b}^*)$ can contain the point $-N\ \text{Sign}(\hat{\boldsymbol{x}}^\top \boldsymbol{b}^*)\hat{\boldsymbol{x}}$. However, $\boldsymbol{b}^*$ can not be a global minimizer, since small angles from $\mathcal{S}$ yield large objective values.

We should note here that the picture for the general setting is analogous to what we described above, albeit harder to visualize: with reference to equation (100), the optimality condition says that every feasible point $\boldsymbol{b}^* \not\perp \mathcal{S}$ must have the following property: there exist $0 \leq K_2 \leq d - 1$ inliers $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{K_2}$ and $0 \leq K_1 \leq D - 1 - K_2$ outliers $\boldsymbol{o}_1, \ldots, \boldsymbol{o}_{K_1}$ to which $\boldsymbol{b}^*$ is orthogonal, and two points $\boldsymbol{\xi}_{\mathcal{O}} \in \text{Conv}(\pm \boldsymbol{o}_1 \pm \cdots \pm \boldsymbol{o}_{K_1}) + \boldsymbol{o}_{\boldsymbol{b}^*}$ and $\boldsymbol{\xi}_{\mathcal{X}} \in \text{Conv}(\pm \boldsymbol{x}_1 \pm \cdots \pm \boldsymbol{x}_{K_2}) + \boldsymbol{x}_{\boldsymbol{b}^*}$ that are joined by an affine line that is parallel to the line spanned by $\boldsymbol{b}^*$. In fact in our proof of Theorem 11 we reduced this general case to the case $d = 1, D = 2$ described above: this reduction is precisely taking place in equation (107), where we project the optimality equation onto the 2-dimensional subspace $\mathcal{U}$. The arguments that follow this projection consist of nothing more than a technical treatment of the intuition given above.

5.9 Proof of Theorem 12

First note that if (46) is true, then the expression of (51) always defines an angle between 0 and $\pi/2$. We start by establishing that $\hat{\boldsymbol{n}}_k$ does not lie in the inlier space $\mathcal{S}$. For $k = 0$ this is true by the

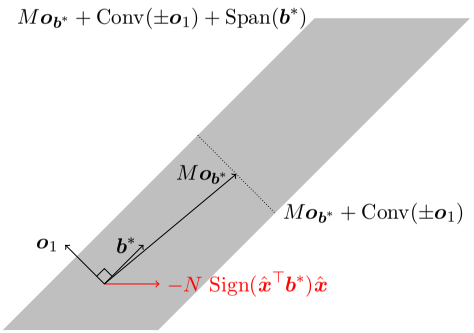

Figure 3: Geometry of the optimality condition (97) and (125) for the case $d = 1, D = 2, N << M$. Critical points $\boldsymbol{b}^* \not\perp \mathcal{S}$ do exist and moreover they can have large angle from $\mathcal{S}$. This is because N is small and so the polytope $M\boldsymbol{o}_{\boldsymbol{b}^*} + \mathrm{Conv}(\pm\boldsymbol{o}_1) + \mathrm{Span}(\boldsymbol{b}^*)$ contains the point $-N\ \mathrm{Sign}(\hat{\boldsymbol{x}}^\top \boldsymbol{b}^*)\hat{\boldsymbol{x}}$. Moreover, such critical points can be global minimizers. Condition (46) of Theorem 11 prevents such cases from occuring.

hypothesis (51). For the sake of contradiction suppose that $\hat{\boldsymbol{n}}_k \in \mathcal{S}$ for some $k > 0$. Note that

$$\left\|\tilde{\boldsymbol{\mathcal{X}}}^\top \hat{\boldsymbol{n}}_0\right\|_1 \geq \left\|\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{n}_1\right\|_1 \geq \left\|\tilde{\boldsymbol{\mathcal{X}}}^\top \hat{\boldsymbol{n}}_1\right\|_1 \geq \cdots \geq \left\|\tilde{\boldsymbol{\mathcal{X}}}^\top \hat{\boldsymbol{n}}_k\right\|_1. \tag{127}$$

Suppose first that $\hat{\boldsymbol{n}}_0 \perp \mathcal{S}$. Then (127) gives

$$\left\|\boldsymbol{\mathcal{O}}^\top \hat{\boldsymbol{n}}_0\right\|_1 \geq \left\|\boldsymbol{\mathcal{O}}^\top \hat{\boldsymbol{n}}_k\right\|_1 + \left\|\boldsymbol{\mathcal{X}}^\top \hat{\boldsymbol{v}}_k\right\|_1, \tag{128}$$

where $\hat{\boldsymbol{v}}_k$ is the normalized projection of $\hat{\boldsymbol{n}}_k$ onto $\mathcal{S}$ (and since $\hat{\boldsymbol{n}}_k \in \mathcal{S}$, these two are equal). Using Lemma 13, we take an upper bound of the LHS and a lower bound of the RHS of (128), and obtain

$$M\, c_D + M\, \epsilon_{\boldsymbol{\mathcal{O}},M} \geq M\, c_D - M\, \epsilon_{\boldsymbol{\mathcal{O}},M} + N\, c_d - N\, \epsilon_{\boldsymbol{\mathcal{X}},N}, \tag{129}$$

or equivalently

$$\frac{M}{N} \geq \frac{c_d - \epsilon_{\boldsymbol{\mathcal{X}},N}}{2\,\epsilon_{\boldsymbol{\mathcal{O}},M}}, \tag{130}$$

which contradicts the first inequality of (46). Consequently, $\hat{\boldsymbol{n}}_0 \not\perp \mathcal{S}$. Then (127) implies that

$$\left\|\boldsymbol{\mathcal{O}}^\top \hat{\boldsymbol{n}}_0\right\|_1 + \left\|\boldsymbol{\mathcal{X}}^\top \hat{\boldsymbol{n}}_0\right\|_1 \geq \left\|\boldsymbol{\mathcal{O}}^\top \hat{\boldsymbol{n}}_k\right\|_1 + \left\|\boldsymbol{\mathcal{X}}^\top \hat{\boldsymbol{n}}_k\right\|_1, \tag{131}$$

or equivalently

$$\left\|\boldsymbol{\mathcal{O}}^\top \hat{\boldsymbol{n}}_0\right\|_1 + \cos(\phi_0)\left\|\boldsymbol{\mathcal{X}}^\top \hat{\boldsymbol{v}}_0\right\|_1 \geq \left\|\boldsymbol{\mathcal{O}}^\top \hat{\boldsymbol{n}}_k\right\|_1 + \left\|\boldsymbol{\mathcal{X}}^\top \hat{\boldsymbol{v}}_k\right\|_1, \tag{132}$$

where $\hat{\boldsymbol{v}}_0$ is the normalized projection of $\hat{\boldsymbol{n}}_0$ onto $\mathcal{S}$. Once again, using Lemma 13 we obtain the following contradiction to (51):

$$M\, c_D + M\, \epsilon_{\boldsymbol{\mathcal{O}},M} + (N\, c_d + N\, \epsilon_{\boldsymbol{\mathcal{X}},N})\cos(\phi_0) \geq M\, c_D - M\, \epsilon_{\boldsymbol{\mathcal{O}},M} + N\, c_d - N\, \epsilon_{\boldsymbol{\mathcal{X}},N}. \tag{133}$$

Now let us complete the proof of the theorem. We know by Proposition 16 that the sequence $\{\boldsymbol{n}_k\}$ converges to a critical point $\boldsymbol{n}_{k^*}$ of problem (9) in a finite number of steps k^*, and we have already shown that $\boldsymbol{n}_{k^*} \notin \mathcal{S}$. If $\boldsymbol{n}_{k^*}$ is not orthogonal to $\mathcal{S}$, an identical argument as in the proof of Theorem 11 (with $\boldsymbol{n}_{k^*}$ in place of $\boldsymbol{b}^*$) shows that the principal angle ϕ_{k^*} of $\boldsymbol{n}_{k^*}$ from $\mathcal{S}$ satisfies

$$\cos(\phi_{k^*}) \geq \frac{-\mathscr{Q} + \sqrt{\mathscr{Q}^2 + 4c_d(c_d - \mathscr{Q})}}{2c_d}, \quad \mathscr{Q} := \frac{\mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}}}{N} + \epsilon_{\boldsymbol{\mathcal{O}},M}\frac{M}{N} + \epsilon_{\boldsymbol{\mathcal{X}},N}. \tag{134}$$

However, due to (127) and Lemma 13, we have that

$$M(c_D + \epsilon_{\boldsymbol{\mathcal{O}},M}) + N(c_d + \epsilon_{\boldsymbol{\mathcal{X}},N})\cos(\phi_0) \geq M(c_D - \epsilon_{\boldsymbol{\mathcal{O}},M}) + N(c_d - \epsilon_{\boldsymbol{\mathcal{X}},N})\cos(\phi_{k^*}), \tag{135}$$

which, after substituting the lower bound (134), contradicts (51). Thus $\boldsymbol{n}_{k^*} \perp \mathcal{S}$.

6. Dual Principal Component Pursuit Algorithms

We present algorithms based on the ideas discussed so far, for estimating the inlier linear subspace in the presence of outliers. Specifically, in §6.1 we describe the main algorithmic contribution of this paper, which is based on the implementation of the recursion (10) via linear programming. In §6.2 we propose an alternative way of computing dual principal components based on Iteratively Reweighted Least-Squares, which, as will be seen in §7 performs almost as well as recursion (6.1), yet it is significantly more efficient. Finally, in §6.3 we present a variation of the DPCP optimization problem (9) suitable for noisy data and propose a heuristic method for solving it.

6.1 DPCP via Linear Programming (DPCP-LP)

For the sake of an argument, suppose that there is no noise in the inliers, i.e., the inliers $\boldsymbol{\mathcal{X}}$ span a linear subspace $\mathcal{S}$ of dimension d. Then Theorem 12 suggests a mechanism for obtaining an element $\boldsymbol{b}_1$ of $\mathcal{S}^\perp$: run the recursion of linear programs (10) until the sequence $\hat{\boldsymbol{n}}_k$ converges and identify the limit point with $\boldsymbol{b}_1$. Due to computational constraints, in practice one usually terminates the recursion when the objective value $\left\|\tilde{\boldsymbol{\mathcal{X}}}^\top \hat{\boldsymbol{n}}_k\right\|_1$ converges within some small ε, or a maximal number $T_{\max}$ of iterations is reached, and obtains a normal vector $\boldsymbol{b}_1$. Having computed a vector $\boldsymbol{b}_1$, there are two possibilities: either $\mathcal{S}$ is a hyperplane of dimension $D-1$ or $\dim\mathcal{S} < D-1$. In the first case we can identify our subspace model with the hyperplane defined by the normal $\boldsymbol{b}_1$. If on the other hand $\dim\mathcal{S} < D-1$, we can proceed to find a second vector $\boldsymbol{b}_2 \perp \boldsymbol{b}_1$ that is approximately orthogonal to $\mathcal{S}$, and so on, until we have computed an orthogonal basis for the orthogonal complement of $\mathcal{S}$; this process naturally leads to Algorithm 1, in which c is an estimate for the codimension $D-d$ of the inlier subspace $\mathrm{Span}(\boldsymbol{\mathcal{X}})$.

Notice how the algorithm initializes $\boldsymbol{n}_0$: This is precisely the right singular vector of $\tilde{\boldsymbol{\mathcal{X}}}^\top$ that corresponds to the smallest singular value, after projection of $\tilde{\boldsymbol{\mathcal{X}}}$ onto $\mathrm{Span}(\boldsymbol{b}_1,\ldots,\boldsymbol{b}_{i-1})^\perp$. As it will be demonstrated in §7, this is a key choice, since it has the effect that the angle of $\boldsymbol{n}_0$ from the inlier subspace is typically large, a desirable property for the success of recursion (10) (see Theorem 12). We refer to Algorithm 1 as DPCP-LP, to emphasize that the optimization problem associated with each iteration of the recursion (10) is a linear program. In fact, at iteration k the optimization problem is

$$\min_{\boldsymbol{b}} \ \left\|\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}\right\|_1 \ \text{s.t.}\ \boldsymbol{b}^\top \hat{\boldsymbol{n}}_{k-1} = 1, \tag{136}$$

    end while
    $\boldsymbol{b}_i \leftarrow \hat{\boldsymbol{n}}_k$;
    $\mathcal{B} \leftarrow \mathcal{B} \cup \{\boldsymbol{b}_i\}$;
  end for
  return $\mathcal{B}$;
end procedure

which can equivalently be written as a standard linear program,

$$\min_{\boldsymbol{b}, \boldsymbol{u}^+, \boldsymbol{u}^-} \quad \begin{bmatrix} \mathbf{1}_{1\times N} & \mathbf{1}_{1\times N} \end{bmatrix} \begin{bmatrix} \boldsymbol{u}^+ \\ \boldsymbol{u}^- \end{bmatrix} \tag{137}$$

$$\text{s.t.} \quad \begin{bmatrix} \boldsymbol{I}_N & -\boldsymbol{I}_N & -\tilde{\boldsymbol{\mathcal{X}}}^\top \\ \mathbf{0}_{1\times N} & \mathbf{0}_{1\times N} & \hat{\boldsymbol{n}}_k^\top \end{bmatrix} \begin{bmatrix} \boldsymbol{u}^+ \\ \boldsymbol{u}^- \\ \boldsymbol{b} \end{bmatrix} = \begin{bmatrix} \mathbf{0}_{N\times 1} \\ 1 \end{bmatrix}, \ \boldsymbol{u}^+, \boldsymbol{u}^- \geq 0, \tag{138}$$

and can be solved efficiently with an optimized general purpose linear programming solver, such as Gurobi (Gurobi Optimization, 2015).

6.2 DPCP via Iteratively Reweighted Least-Squares (DPCP-IRLS)

Even though DPCP-LP (Algorithm 1) comes with theoretical guarantees as per Theorem 12, and moreover will be shown to have a rather remarkable performance (at least for synthetic data, see Fig. 6), it has the weakness that the linear programs (which are non-sparse) may become inefficient to solve in high dimensions and for a large number of data points. Moreover, even though DPCP-LP is theoretically applicable regardless of the subspace relative dimension d/D, its running time increases with the subspace codimension $c = D - d$, since the c basis elements of $\mathcal{S}^\perp$ are computed sequentially. This motivates us to generalize the DPCP problem (9) to an optimization problem that targets the entire orthogonal basis of $\mathcal{S}^\perp$:

$$\min_{\boldsymbol{B}\in\mathbb{R}^{D\times c}} \|\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{B}\|_{1,2} \ \text{s.t.} \ \boldsymbol{B}^\top\boldsymbol{B} = \boldsymbol{I}_c. \tag{139}$$

Algorithm 2 Dual Principal Component Pursuit via Iteratively Reweighted Least Squares

procedure DPCP-IRLS($\tilde{\boldsymbol{\mathcal{X}}}, c, \varepsilon, T_{\max}, \delta$)
  $k \leftarrow 0; \mathcal{J} \leftarrow 0; \Delta\mathcal{J} \leftarrow \infty$;
  $\boldsymbol{B}_0 \leftarrow \boldsymbol{W} \in \operatorname{argmin}_{\boldsymbol{B}\in\mathbb{R}^{D\times c}, \boldsymbol{B}^\top\boldsymbol{B}=\boldsymbol{I}_c} \|\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{B}\|_F$;
  while $k < T_{\max}$ and $\Delta\mathcal{J} > \varepsilon\mathcal{J}$ **do**
    $\mathcal{J} \leftarrow \|\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{B}_k\|_{1,2}$;
    $k \leftarrow k + 1$;
    $\boldsymbol{B}_k \leftarrow \operatorname{argmin}_{\boldsymbol{B}\in\mathbb{R}^{D\times c}, \boldsymbol{B}^\top\boldsymbol{B}=\boldsymbol{I}_c} \sum_{\tilde{\boldsymbol{x}}\in\tilde{\boldsymbol{\mathcal{X}}}} \|\boldsymbol{B}^\top\tilde{\boldsymbol{x}}\|_2^2 / \max\{\delta, \|\boldsymbol{B}_{k-1}^\top\tilde{\boldsymbol{x}}\|_2\}$;
    $\Delta\mathcal{J} \leftarrow \|\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{B}_{k-1}\|_{1,2} - \|\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{B}_k\|_{1,2}$;
  end while
  return $\boldsymbol{B}_k$;
end procedure

Notice that in (139), the $\ell_{1,2}$ matrix norm $\|\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{B}\|_{1,2}$ of $\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{B}$ is defined as the sum of the Euclidean norms of the rows of $\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{B}$, and as such, favors a solution $\boldsymbol{B}$ that results in a matrix $\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{B}$ that is row-wise sparse (notice that for $c = 1$ (139) reduces precisely to the DPCP problem (9)). In fact, Lerman et al. (2015) consider exactly the same problem (139), and proceed to relax it to a semi-definite convex program, which they solve via an *Iteratively Reweighted Least-Squares (IRLS)* scheme (Candès et al., 2008; Daubechies et al., 2010; Chartrand and Yin, 2008); while similar IRLS schemes appear in Zhang and Lerman (2014) and Lerman and Maunu (2017). Instead, we propose to solve (139) directly via IRLS (and not a convex relaxation of it as Lerman et al. (2015)): Given a $D \times c$ orthonormal matrix $\boldsymbol{B}_{k-1}$, we define for each point $\tilde{\boldsymbol{x}}_j$ a weight

$$w_{j,k} := \frac{1}{\max\{\delta, \|\boldsymbol{B}_{k-1}^\top \tilde{\boldsymbol{x}}_j\|_2\}}, \tag{140}$$

where $\delta > 0$ is a small constant that prevents division by zero. Then we obtain $\boldsymbol{B}_k$ as the solution to the quadratic problem

$$\min_{\boldsymbol{B}\in\mathbb{R}^{D\times c}} \sum_{j=1}^{L} w_{j,k} \|\boldsymbol{B}^\top \tilde{\boldsymbol{x}}_j\|_2^2 \ \text{s.t.} \ \boldsymbol{B}^\top\boldsymbol{B} = \boldsymbol{I}_c, \tag{141}$$

which is readily seen to be the c right singular vectors corresponding to the c smallest singular values of the weighted data matrix $\boldsymbol{W}_k \tilde{\boldsymbol{\mathcal{X}}}^\top$, where $\boldsymbol{W}_k$ is a diagonal matrix with $\sqrt{w_{j,k}}$ at position (j, j). We refer to the resulting Algorithm 2 as DPCP-IRLS; a study of its theoretical properties is deferred to future work.

6.3 Denoised DPCP (DPCP-d)

Clearly, problem (9) (and (139)) is tailored for noise-free inliers, since, when the inliers $\boldsymbol{\mathcal{X}}$ are contaminated by noise, the vector $\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}$ is no longer sparse, even if $\boldsymbol{b}$ is a true normal to the inlier subspace. As a consequence, it is natural to propose the following *DPCP-denoised* (DPCP-d)

Algorithm 3 Denoised Dual Principal Component Pursuit

procedure DPCP-d($\tilde{\boldsymbol{\mathcal{X}}}, \varepsilon, T_{\max}, \delta, \tau$)
  Compute a Cholesky factorization $\boldsymbol{L}\boldsymbol{L}^\top = \tilde{\boldsymbol{\mathcal{X}}}\tilde{\boldsymbol{\mathcal{X}}}^\top + \delta \boldsymbol{I}_D$;
  $k \leftarrow 0$; $\boldsymbol{y}_0 \leftarrow \boldsymbol{0}$; $\mathcal{J} \leftarrow 0$; $\Delta\mathcal{J} \leftarrow \infty$;
  $\boldsymbol{b}_0 \leftarrow \operatorname{argmin}_{\boldsymbol{b}\in\mathbb{R}^D:\, \|\boldsymbol{b}\|_2=1} \ \|\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}\|_2$;
  while $k < T_{\max}$ and $\Delta\mathcal{J} > \varepsilon\mathcal{J}$ **do**
    $\mathcal{J} \leftarrow \tau\|\boldsymbol{y}_k\|_1 + \frac{1}{2}\|\boldsymbol{y}_k - \tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}_k\|_2^2$
    $\boldsymbol{y}_{k+1} \leftarrow \mathcal{S}_\tau\left(\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}_k\right)$;
    $\boldsymbol{b}_{k+1} \leftarrow$ solution of $\boldsymbol{L}\boldsymbol{L}^\top \boldsymbol{\xi} = \tilde{\boldsymbol{\mathcal{X}}}\boldsymbol{y}_{k+1}$ by backward/forward propagation;
    $k \leftarrow k+1$;
    $\boldsymbol{b}_k \leftarrow \boldsymbol{b}_k / \|\boldsymbol{b}_k\|_2$;
    $\Delta\mathcal{J} \leftarrow \mathcal{J} - \left(\tau\|\boldsymbol{y}_k\|_1 + \frac{1}{2}\|\boldsymbol{y}_k - \tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}_k\|_2^2\right)$;
  end while
  return $(\boldsymbol{y}_k, \boldsymbol{b}_k)$;
end procedure

problem

$$\min_{\boldsymbol{b},\boldsymbol{y}:\, \|\boldsymbol{b}\|_2=1} \left[\tau\|\boldsymbol{y}\|_1 + \frac{1}{2}\|\boldsymbol{y} - \tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}\|_2^2\right], \tag{142}$$

where now the vector variable $\boldsymbol{y} \in \mathbb{R}^{N+M}$ is to be interpreted as a denoised vesion of the vector $\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}$. Interestingly, both problems (9) and (142) appear in Qu et al. (2014), in the quite different context of dictionary learning, where the authors propose to solve (142) via alternating minimization, in order to obtain an approximate solution to (9). Given $\boldsymbol{b}$, the optimal $\boldsymbol{y}$ is given by $\mathcal{S}_\tau(\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b})$, where $\mathcal{S}_\tau$ is the soft-thresholding operator applied element-wise on the vector $\tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}$. Given $\boldsymbol{y}$ the optimal $\boldsymbol{b}$ is a solution to the quadratically constrained least-squares problem

$$\min_{\boldsymbol{b}\in\mathbb{R}^D} \ \|\boldsymbol{y} - \tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}\|_2^2 \ \text{ s.t. } \ \|\boldsymbol{b}\|_2 = 1. \tag{143}$$

In the context of Qu et al. (2014), the coefficient matrix of the least-squares problem ($\tilde{\boldsymbol{\mathcal{X}}}^\top$ in our notation) has orthonormal columns. As a consequence, the solution to (143) is obtained in closed form by projecting the solution of the unconstrained least-squares problem $\min_{\boldsymbol{b}\in\mathbb{R}^D} \ \|\boldsymbol{y} - \tilde{\boldsymbol{\mathcal{X}}}^\top \boldsymbol{b}\|_2$ onto the unit sphere. However, in our context the assumption that $\tilde{\boldsymbol{\mathcal{X}}}^\top$ has orthonormal columns is in principle violated, so that the optimal $\boldsymbol{b}$ is no longer available in closed form. Even though using Lagrange multipliers one ends up with a polynomial equation for the Lagrange multiplier, it is known that computing the optimal value of the multiplier is a numerically challenging problem (Elden, 2002; Golub and Von Matt, 1991; Gander, 1980). For this reason we leave exact approaches for solving (143) to future investigations, and we instead propose to obtain a suboptimal $\boldsymbol{b}$ as Qu et al. (2014) do, i.e., by projecting onto the unit sphere the solution of the unconstrained least-squares problem. The resulting Algorithm 3 is very efficient, since the least-squares problems that

appear in the various iterations have the same coefficient matrix $\tilde{\boldsymbol{\mathcal{X}}}\tilde{\boldsymbol{\mathcal{X}}}^\top$, a factorization of which can be precomputed.[9] Moreover, Algorithm 3 can trivially be extended to compute multiple normal vectors, just as in Algorithm 1.

7. Experiments

In this section we evaluate the proposed algorithms experimentally. In §7.1 we investigate numerically the theoretical regime of success of recursion (10) predicted by Theorems 11 and 12. We also show that even when these sufficient conditions are violated, (10) can still converge to a normal vector to the subspace if initialized properly. Finally, in §7.2 we compare DPCP variants with state-of-the-art robust PCA algorithms for the purpose of outlier detection using synthetic data, and similarly in §7.3 using real images.

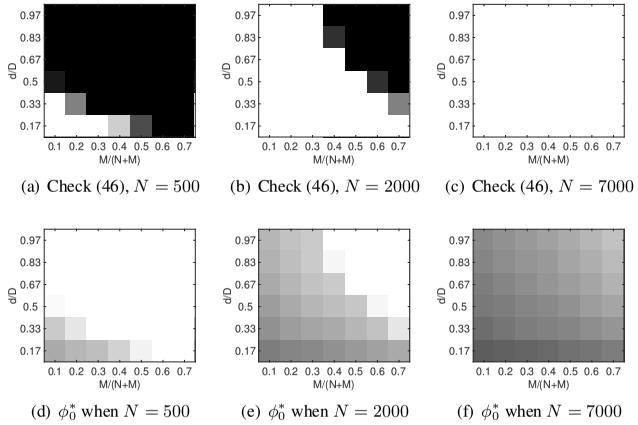
7.1 Numerical evaluation of the theoretical conditions of Theorems 11 and 12

We begin with a numerical evaluation of the theoretical condition (46) of Theorem 11, under which every global minimizer of the DPCP problem (9) is orthogonal to the inlier subspace $\mathcal{S}$. We also evaluate the initial minimal angle ϕ_0^* from $\mathcal{S}$ given in (51) of Theorem 12, which together with (46) guarantee the convergence of the linear programming recursion (10) to an element of $\mathcal{S}^\perp$. As explained in the discussion of Theorems 11 and 12, for any fixed outlier ratio, condition (46) will eventually be satisfied and also the angle ϕ_0^* will become arbitrarily small regardless of the subspace relative dimension d/D, provided that N is sufficiently large and that both inliers and outliers are uniformly distributed. Hence, we check whether (46) is true and also plot ϕ_0^* as we vary N for uniformly distributed inliers and outliers. Towards that end, we fix the ambient dimension as $D = 30$ and randomly sample a subspace $\mathcal{S}$ of varying dimension $d = [5 : 5 : 25\ 29]$ so that the relative subspace dimension d/D varies as $[5/30 : 5/30 : 25/30\ 29/30]$. We sample N inliers uniformly at random from $\mathcal{S} \cap \mathbb{S}^{D-1}$ for different values $N = 500, 2000, 7000$. For each value of N we also sample M outliers uniformly at random from $\mathbb{S}^{D-1}$ so that the percentage of outliers varies as $R := M/(N+M) = [0.1 : 0.1 : 0.7]$. For each dataset instance as above, we estimate the parameters $\epsilon_{\boldsymbol{\mathcal{X}},N}, \epsilon_{\boldsymbol{\mathcal{O}},M}, \mathcal{R}_{\boldsymbol{\mathcal{O}},\boldsymbol{\mathcal{X}}}$ appearing in (46) and (51) by Monte-Carlo simulation.

The top row of Fig. 4 shows whether condition (46) is true (white) or not (black) as we vary N. Notice that for $N = 500$, Fig. 4(a) shows a poor success regime. However, as we increase N to 2000, Fig. 4(b) shows that the success regime improves dramatically. Finally, as expected from our earlier theoretical arguments, for sufficiently large N, in particular for $N = 7000$, Fig. 4(c) shows that the sufficient condition (46) is satisfied regardless of outlier ratio or subspace relative dimension. Similarly, notice how the angle ϕ_0^*, plotted in the bottom row of Fig. 4 (black for 0° white for 90°), uniformly decreases as we increase N across all outlier ratios and relative dimensions.

Next, we show that the recursion (10), if initialized properly, is in fact able to converge in just a few iterations to a vector normal to the inlier subspace, even when the sufficient conditions of Theorem 12 are not satisfied. Towards that end, we maintain the same experimental setting as above using $N = 500$ and run (10) with a maximal number of iterations set to $T_{\max} = 10$ and a convergence accuracy set to 10^{-3}. Fig. 5(a) is a replicate of Fig. 4(a) and serves as a reminder that $N = 500$ results in a limited success regime as predicted by the theory; in particular the sufficient

9. The parameter δ in Algorithm 3 is a small positive number, typically 10^{-6}, which helps avoiding solving ill-conditioned linear systems.



(a) Check (46), $N = 500$ (b) Check (46), $N = 2000$ (c) Check (46), $N = 7000$

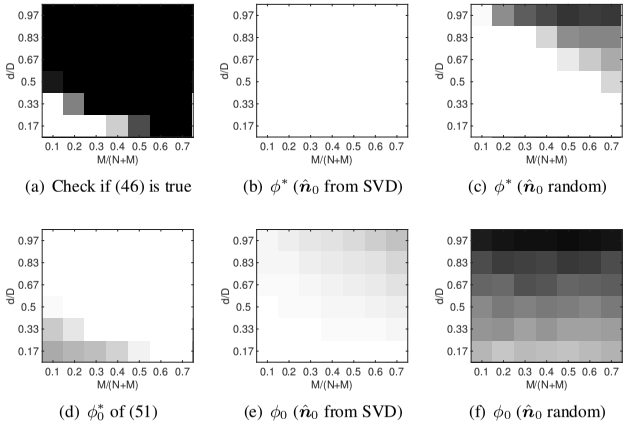
(d) ϕ_0^* when $N = 500$ (e) ϕ_0^* when $N = 2000$ (f) ϕ_0^* when $N = 7000$

Figure 4: Figs. 4(a)-4(c) check whether the condition (46) is satisfied (white) or not (black) for a fixed number N of inliers while varying the outlier ratio $M/(N+M)$ and the subspace relative dimension d/D. Figs. 4(d)-4(f) plot the minimum initial angle ϕ_0^* needed for convergence of the recursion of linear programs (10) as per Theorem 12 (0° corresponds to black and 90° corresponds to white). Results are averaged over 10 independent trials.

condition (46) is satisfied only for a small outlier ratio or small subspace relative dimensions. Even so, Fig. 5(b) shows that, when the recursion (10) is initialized using $\hat{\boldsymbol{n}}_0$ as the left singular vector of $\tilde{\boldsymbol{\mathcal{X}}}$ corresponding to the smallest singular value, then (10) converges in at most 10 iterations to a vector $\hat{\boldsymbol{n}}^*$ whose angle ϕ^* from the subspace is precisely 90°. This suggests that the sufficient condition (46) is much stronger than necessary, leaving room for future theoretical improvements. On the other hand, Fig. 5(c) shows that when $\hat{\boldsymbol{n}}_0$ is initialized uniformly at random, the recursion (10) does not always converge to a normal vector, particularly for high outlier ratios and relative dimensions. This reveals that initializing (10) from the SVD of the data is indeed a good strategy, which is further supported by Fig. 5(e), which plots the angle of the initialization from the subspace (contrast this to Fig. 5(f), which shows the angle of a random initialization from the subspace).

7.2 Comparative analysis using synthetic data

In this section we use the same synthetic experimental set-up as in §7.1 (with $N = 500$) to demonstrate the behavior of several methods relative to each other under uniform conditions, in the context of outlier rejection in single subspace learning. In particular, we test DPCP-LP (Algorithm 1), DPCP-IRLS (Algorithm 2), DPCP-d (Algorithm 3), RANSAC (Fischler and Bolles, 1981), SE-RPCA (Soltanolkotabi and Candès, 2012), ℓ_{21}-RPCA (Xu et al., 2012), the IRLS version of REAPER (Lerman et al., 2015), as well as Coherence Pursuit (CoP) (Rahmani and Atia, 2017); see §2 for details on these last five existing methods.

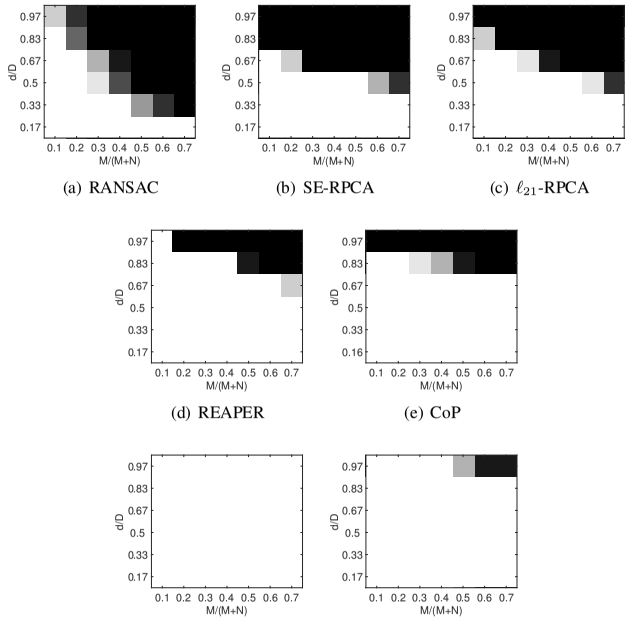


(a) Check if (46) is true (b) ϕ^* ($\hat{\boldsymbol{n}}_0$ from SVD) (c) ϕ^* ($\hat{\boldsymbol{n}}_0$ random)

(d) ϕ_0^* of (51) (e) ϕ_0 ($\hat{\boldsymbol{n}}_0$ from SVD) (f) ϕ_0 ($\hat{\boldsymbol{n}}_0$ random)

Figure 5: Convergence of recursion (10) in a regime of limited theoretical guarantees ($N = 500$) as concluded from Fig. 4. The number of inliers is fixed at $N = 500$. Fig. 5(a) plots whether the sufficient condition (46) is satisfied (white) or not (black) for varying outlier ratios $M/(N+M)$ and relative dimensions d/D. Figs. 5(b)-5(c) plot the angle ϕ^* (0° corresponds to black and 90° corresponds to white) from the inlier subspace of the vector $\hat{\boldsymbol{n}}^*$ that recursion (10) converges to, when $\hat{\boldsymbol{n}}_0$ is initialized from the SVD of the data or uniformly at random, respectively. Fig. 5(d) plots the minimum angle ϕ_0^* needed for the convergence of (10) to a normal vector in the inlier subspace as per Theorem 12, while Figs. 5(e)-5(f) plot the angle ϕ_0 of $\hat{\boldsymbol{n}}_0$ from the subspace, when it is initialized from the SVD of the data or uniformly at random, respectively. The results are averages over 10 independent trials.

For the methods that require an estimate of the subspace dimension d, such as RANSAC, REAPER, CoP, and all DPCP variants, we provide as input the true subspace dimension. The convergence accuracy of all methods is set to 10^{-3}. For REAPER we set the regularization parameter as $\delta = 10^{-6}$ and the maximum number of iterations equal to 100. For DPCP-d we set $\tau = 1/\sqrt{N+M}$ as suggested in Qu et al. (2014) and the maximum number of iterations to 1000. For RANSAC we set its thresholding parameter to 10^{-3}, and for fairness, we do not let it terminate earlier than the running time of DPCP-LP, unless the theoretically required number of iterations for a success probability 0.99 is reached (here we are using the ground truth outlier ratio). Both SE-RPCA and ℓ_{21}-RPCA are implemented with ADMM, with augmented Lagrange parameters 1000 and 100 respectively. For ℓ_{21}-RPCA λ is set to $3/(7\sqrt{M})$, as suggested in Xu et al. (2012). DPCP variants are initialized via the SVD of the data as in Algorithm 1. CoP is implemented using the code provided by its authors, and selects $3d$ points upon classic PCA gives the subspace estimate. Finally, the linear programs in DPCP-LP are solved via the generic LP solver Gurobi (Gurobi Optimization, 2015), while the maximum number of iterations for DPCP-LP is set to $T_{\max} = 10$.



(a) RANSAC (b) SE-RPCA (c) ℓ_{21}-RPCA

(d) REAPER (e) CoP

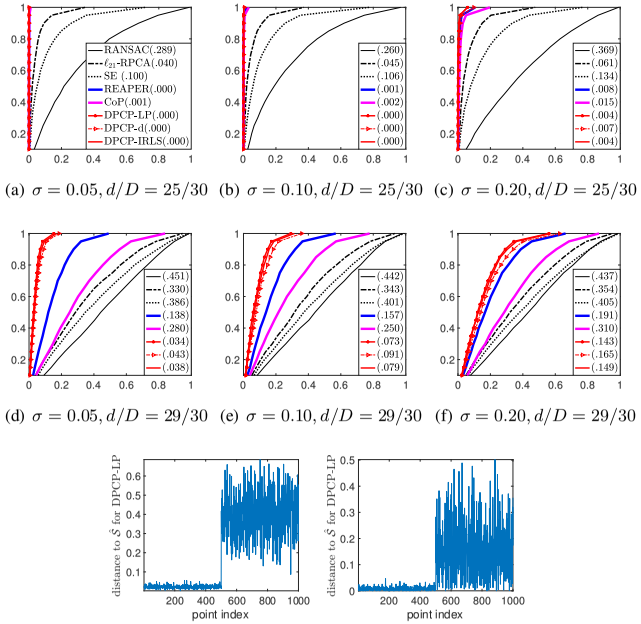
(f) DPCP-LP (g) DPCP-IRLS

Figure 6: Outlier/Inlier separation in the absence of noise over 10 independent trials. The horizontal axis is the outlier ratio defined as $M/(N+M)$, where M is the number of outliers and N is the number of inliers. The vertical axis is the relative inlier subspace dimension d/D; the dimension of the ambient space is $D = 30$. Success (white) is declared by the existence of a threshold that, when applied to the output of each method, perfectly separates inliers from outliers.

Absence of Noise We first investigate the potential of each of the above methods to perfectly distinguish outliers from inliers in the absence of noise.[10] Note that each method returns a *signal* $\boldsymbol{\alpha} \in \mathbb{R}_+^{N+M}$, which can be thresholded for the purpose of declaring outliers and inliers. For SE-RPCA, $\boldsymbol{\alpha}$ is the ℓ_1-norm of the columns of the coefficient matrix $\boldsymbol{C}$, while for ℓ_{21}-RPCA $\boldsymbol{\alpha}$ is the ℓ_2-norm of the columns of $\boldsymbol{E}$. Since RANSAC, REAPER, CoP, and DPCP variants directly return subspace models, for these methods $\boldsymbol{\alpha}$ is simply the distances of all points to the estimated subspace.

In Fig. 6 we depict success (white) versus failure (black), where success is interpreted as the existence of a threshold on $\boldsymbol{\alpha}$ that perfectly separates outliers and inliers. First observe that, as expected, RANSAC succeeds when there are very few outliers (10%) regardless of the inlier relative dimension d/D, since in such a case the probability of sampling outlier-free points is high. Similarly, RANSAC succeeds when d/D is small regardless of the outlier ratio, since in that case one needs only sample d points, and for a sufficient budget (say, the running time of DPCP-LP), the probability of one of these samples being outlier-free is again high. Moving on, and again as expected, both SE-RPCA and ℓ_{21}-RPCA succeed only for low to medium relative dimensions, since both methods are meant to exploit the low-rank structure of the inlier data, and thus fail when such a structure does not exist. Remarkably, even though CoP is a low-rank method in spirit, it performs surprisingly better than its low-rank alternatives SE-RPCA and ℓ_{21}-RPCA, giving perfect inlier/outlier separation regardless of the outlier ratio for relative dimensions $d/D \leq 2/3$. Further improvement is achieved by REAPER, which succeeds for as many as 40% outliers and as high a

10. We do not include DPCP-d for this experiment, since it only approximately solves the DPCP optimization problem, and hence it can not be expected to perfectly separate inliers from outliers, even when there is no noise (we have confirmed this experimentally).



(a) $\sigma = 0.05, d/D = 25/30$ (b) $\sigma = 0.10, d/D = 25/30$ (c) $\sigma = 0.20, d/D = 25/30$

(d) $\sigma = 0.05, d/D = 29/30$ (e) $\sigma = 0.10, d/D = 29/30$ (f) $\sigma = 0.20, d/D = 29/30$

(g) $\sigma = 0.05, d/D = 25/30$ (h) $\sigma = 0.05, d/D = 29/30$

Figure 7: Figs. 7(a)-7(f) show ROC curves for varying noise standard deviation $\sigma = 0.05, 0.1, 0.2$, and subspace relative dimension $d/D = 25/30, 29/30$ (number of inliers is $N = 500$ and outlier ratio is $M/(N+M) = 0.5$). The horizontal axis is False Positives ratio and the vertical axis is True Positives ratio. The number associated with each curve is the area above the curve; smaller numbers reflect more accurate performance. Figs. 7(g)-7(h) show the distance of the noisy points to the subspace estimated by DPCP-LP for noise $\sigma = 0.05$ for both relative dimensions under consideration.

Table 1: Mean running time of each method in seconds over 10 independent trials for the experimental setting of §7.2. We report only the extreme regimes corresponding to $d/D = 5/30, 29/30$ and $M/(N+M) = 0.1, 0.7$. The experiment is run in MATLAB on a standard Macbook-Pro with a dual core 2.5GHz Processor and a total of 4GB Cache memory.

$d/D : M/(N+M)$	$5/30 : 0.1$	$29/30 : 0.1$	$5/30 : 0.7$	$29/30 : 0.7$
RANSAC	0.097	0.410	23.31	2.83
SE-RPCA	4.485	4.519	58.94	79.07
ℓ_{21}-RPCA	0.048	0.014	0.185	0.180
REAPER	0.050	0.058	0.153	0.042
CoP	0.014	0.014	0.062	0.061
DPCP-LP	16.87	0.407	95.35	2.822
DPCP-IRLS	0.046	0.038	0.121	0.415

relative dimension as $25/30 \approx 0.83$. Yet, REAPER fails in the challenging case $d/D = 29/30$ as soon as there are more than 20% outliers. Remarkably, DPCP-LP allows for perfect outlier rejection across all outlier ratios and all relative dimensions, thus clearly improving the state-of-art in the high relative dimension regime. Moreover, DPCP-IRLS does almost as well as DPCP-LP thus being the second best method, except that it only fails in the hardest of regimes, i.e., for relative dimension $29/30 \approx 0.97$ and for more than 50% outliers.

Finally, it is important to comment on the running time of the methods. As Table 1 shows, DPCP-LP is admittedly the slowest among the methods, particularly for low relative dimensions, since in that case many dual principal components need to be computed. Indeed, for 10% outliers and $d/D = 5/30$ DPCP-LP computes $D - d = 25$ dual components and thus it takes about 17 seconds, as opposed to 0.4 seconds for the same amount of outliers but $d/D = 29/30$, since a single dual component is computed in this latter case. Similarly, for 70% outliers DPCP-LP takes about 95 seconds when $d/D = 5/30$ as opposed to about 3 seconds for $d/D = 29/30$. On the other hand, DPCP-IRLS is one order of magnitude faster than DPCP-LP and comparable to ℓ_{21}-RPCA and REAPER, which overall are the second fastest methods, with CoP being the fastest of all.

Presence of Noise Next, we fix $D = 30, N = 500, M/(N+M) = 0.5$, and investigate the performance of the methods, adding DPCP-d to the mix, in the presence of varying levels of noise for two cases of high relative dimension, i.e., $d/D = 25/30$ and $d/D = 29/30$. The inliers are corrupted by additive white Gaussian noise of zero mean and standard deviation $\sigma = 0.05, 0.1, 0.2$, with support in the orthogonal complement of the inlier subspace. The parameters of all methods are the same as earlier except for DPCP-d we set $\tau = \max\left\{\sigma, 1/\sqrt{N+M}\right\}$, while for RANSAC we set its threshold parameter equal to σ.

We evaluate the performance of each method by its corresponding ROC curve. Each point of an ROC curve corresponds to a certain value of a threshold, with the vertical coordinate of the point giving the percentage of inliers being correctly identified as inliers (True Positives), and the horizontal coordinate giving the number of outliers erroneously identified as inliers (False Positives). As a consequence, an ideal ROC curve should be concentrated to the top left of the plot, i.e., the area above the curve should be zero. The ROC curves[11] as well as the area above each curve are shown in Fig. 7. As expected, the low-rank methods RANSAC, SE-RPCA and ℓ_{21}-RPCA perform poorly for either relative dimension with performance being close to that of a random guess (inlier vs. outlier) for relative dimension $29/30$. On the other hand REAPER, CoP, DPCP-LP, DPCP-IRLS and DPCP-d perform almost perfectly well for $d/D = 25/30$, while REAPER starts failing for very high relative dimension $29/30$, even for as low noise standard devision as $\sigma = 0.05$ (of course this is to be expected because we already know from Fig. 6 that REAPER fails at this regime even in the absence of noise), and CoP fails completely. In contrast, the DPCP variants remain robust to noise in this challenging regime for as high noise as $\sigma = 0.1$. What is remarkable, is that both DPCP-LP and DPCP-IRLS, which are designed for noiseless data, are surprisingly robust to noise, and slightly outperform DPCP-d, the latter meant to handle noisy data. We attribute this fact to the suboptimal approach we followed in solving the DPCP-d problem, as well as to the lack of a suitable mechanism for optimally tuning its thresholding parameter.

11. We note that the vertical axis of all ROC curves in this paper starts from a ratio of 0.1 True Positives.

7.3 Comparative analysis using real data: Three-view geometry

In this section we perform an experimental evaluation of the proposed methods in the context of the three-view problem in computer vision using real data. In that setting one is given three images of the same static scene taken from different views, and the goal is to estimate the relative view poses, i.e., the rotations and translations that relate, say, view 1 to view 2 and 3 (e.g., see Figs 8(a)-8(b)). This task is of fundamental importance in many computer vision applications, such as 3D reconstruction, where a 3D model of a real-world scene is constructed from 2D images of the scene.

The trifocal tensor. The three images of the static scene may have been taken from three different cameras, or from a single moving camera. Regardless, the underlying three-view geometry is characterized by the constraints satisfied by any points lying in views $1, 2$ and 3 respectively, that correspond to the same 3D point (e.g., see Fig. 8(b)). To describe the nature of these constraints, we fix a coordinate system (x, y, z) for the 3D space, and identify view 1 with the plane $z = 1$ and its optical center with the origin $\mathbf{0}$ of the coordinate system. We refer to this view as *canonical view* $\mathcal{V}$. Then the projection $\mathcal{X}$ of a 3D point $\Xi = (\xi_1, \xi_2, \xi_3)^\top$ onto $\mathcal{V}$ is the intersection point of the plane $z = 1$ with the line that passes through Ξ and the origin, i.e., $\mathcal{X} = \lambda\Xi$ with $\lambda = 1/\xi_3$. For simplicity, we assume that views 2 ($\mathcal{V}'$) and 3 ($\mathcal{V}''$) are rotated and translated versions of the canonical view $\mathcal{V}$, i.e., there exist rotations $\boldsymbol{R}', \boldsymbol{R}'' \in \mathrm{SO}(3)$ and translations $\boldsymbol{t}', \boldsymbol{t}'' \in \mathbb{R}^3$, such that[12]

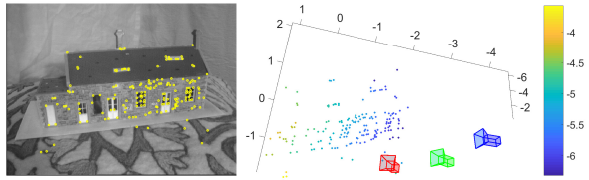
$$\mathcal{V} = \boldsymbol{R}'(\mathcal{V}') + \boldsymbol{t}' = \boldsymbol{R}''(\mathcal{V}'') + \boldsymbol{t}''. \tag{144}$$

The projection $\mathcal{X}'$ of the 3D point Ξ onto $\mathcal{V}'$ is the intersection of $\mathcal{V}'$ with the line that passes from Ξ and the optical center $-\boldsymbol{t}'$ of view 2. However, in practice $\mathcal{X}'$ is only known up to local pixel coordinates with respect to view 2. That is, we can only know the representation $\boldsymbol{x}'$ of $\mathcal{X}'$ with respect to a coordinate system where view 2 is the canonical view. In such a system of coordinates the point Ξ is represented as $\boldsymbol{R}'\Xi + \boldsymbol{t}'$ and hence $\boldsymbol{x}' = \lambda'(\boldsymbol{R}'\Xi + \boldsymbol{t}')$, where λ' is the inverse of the third coordinate of the vector $\boldsymbol{R}'\Xi + \boldsymbol{t}'$. Substituting $\Xi = (1/\lambda)\boldsymbol{x}$ in this equation yields a relation between the local representations[13] $\boldsymbol{x}, \boldsymbol{x}'$ of $\mathcal{X}, \mathcal{X}'$ in $\mathcal{V}$ and $\mathcal{V}'$ respectively as follows:

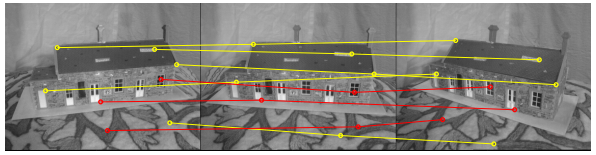
$$\frac{1}{\lambda'}\boldsymbol{x}' = \frac{1}{\lambda}\boldsymbol{R}'\boldsymbol{x} + \boldsymbol{t}'. \tag{145}$$

12. This geometry corresponds to *calibrated cameras*, where the camera projection parameters are known.
13. Without loss of generality we take the local system of coordinates of view 1 to be the same as the global system of coordinates.

(a) Three views of the same scene.



(b) Left: Example of points viewed by all three cameras. Right: Configuration of cameras and the same points depicted in 3D space. Color represents height.



(c) Examples of correct (yellow) and incorrect (red) point correspondences between the three views.

Figure 8: An example of three views of a static scene along with camera configurations and point correspondences (views $2, 4, 6$ of the Model House dataset, provided by the Visual Geometry Group, University of Oxford).

Now, for a vector $\boldsymbol{v} = (\alpha, \beta, \gamma)^\top \in \mathbb{R}^3$, denote by $[\boldsymbol{v}]$ the skew-symmetric matrix

$$[\boldsymbol{v}] = \begin{bmatrix} 0 & \gamma & -\beta \\ -\gamma & 0 & \alpha \\ \beta & -\alpha & 0 \end{bmatrix}, \tag{146}$$

and note that $[\boldsymbol{v}]\boldsymbol{v} = \boldsymbol{0}$. Multiplying equation (145) from the left by $[\boldsymbol{x}']$ gives

$$\frac{1}{\lambda}[\boldsymbol{x}']\boldsymbol{R}'\boldsymbol{x} + [\boldsymbol{x}']\boldsymbol{t}' = \boldsymbol{0}. \tag{147}$$

In exactly the same way, and letting $\boldsymbol{x}''$ be the representation of $\mathcal{X}''$ in the canonical coordinate system for view 3, we have a relationship

$$\frac{1}{\lambda}[\boldsymbol{x}'']\boldsymbol{R}''\boldsymbol{x} + [\boldsymbol{x}'']\boldsymbol{t}'' = \boldsymbol{0}. \tag{148}$$

Degenerate cases aside, equations (147)-(148) are equivalent to the condition

$$\text{Rank}\left(\begin{bmatrix} [\boldsymbol{x}']\boldsymbol{R}'\boldsymbol{x} & [\boldsymbol{x}']\boldsymbol{t}' \\ [\boldsymbol{x}'']\boldsymbol{R}''\boldsymbol{x} & [\boldsymbol{x}'']\boldsymbol{t}'' \end{bmatrix}\right) \leq 1, \tag{149}$$

which in turn is equivalent to the matrix equation[14]

$$[\boldsymbol{x}']\boldsymbol{R}'\boldsymbol{x}\,\boldsymbol{t}''^\top[\boldsymbol{x}'']^\top - [\boldsymbol{x}']\boldsymbol{t}'\boldsymbol{x}^\top\boldsymbol{R}''^\top[\boldsymbol{x}'']^\top = \boldsymbol{0}_{3\times 3}, \tag{150}$$

or more elegantly written as

$$[\boldsymbol{x}']\Big(\sum_{i=1}^{3} x_i \boldsymbol{T}_i\Big)[\boldsymbol{x}'']^\top = \boldsymbol{0}_{3\times 3}, \;\; \boldsymbol{x} = (x_1, x_2, x_3)^\top, \;\; \boldsymbol{T}_i := \boldsymbol{r}_i'\boldsymbol{t}''^\top - \boldsymbol{t}'\boldsymbol{r}_i''^\top, \; i = 1, 2, 3, \tag{151}$$

where $\boldsymbol{r}_i', \boldsymbol{r}_i''$ is the ith column of $\boldsymbol{R}', \boldsymbol{R}''$ respectively. Equation (151) consists of 9 *trilinear* constraints on the local representations $\boldsymbol{x}, \boldsymbol{x}', \boldsymbol{x}''$ of the imaged 3D point Ξ, among which a maximal number of four are linearly independent (Hartley and Zisserman, 2004). The matrices $(\boldsymbol{T}_1, \boldsymbol{T}_2, \boldsymbol{T}_3)$ are the slices of the so-called *trifocal tensor*[15] $\mathcal{T} \in \mathbb{R}^{3\times 3} \times \mathbb{R}^{3\times 3} \times \mathbb{R}^{3\times 3}$, which is the mathematical object that encodes the relative geometry of the calibrated three views: indeed, up to a change of coordinates there is a $1-1$ correspondence between trifocal tensors and camera views $\mathcal{V}, \mathcal{V}', \mathcal{V}''$; see Proposition 15 and Theorem 16 in Kileel (2017).

Trifocal tensor estimation as a hyperplane learning problem. Notice that the trilinear constraints (151) are linear in the entries of the tensor $\mathscr{T} = (\boldsymbol{T}_1, \boldsymbol{T}_2, \boldsymbol{T}_3)$, which in its unfolded form can be regarded as a vector $\mathbf{t} \in \mathbb{R}^{27}$. In fact, the space of (uncalibrated) trifocal tensors is an algebraic variety of $\mathbb{R}^{27}$ of dimension 18 (Alzati and Tortora, 2010; Aholt and Oeding, 2014). As already noted, every point correspondence $(\boldsymbol{x}, \boldsymbol{x}', \boldsymbol{x}'')$ contributes four linearly independent equations in $\mathbf{t}$; equivalently, every point correspondence cuts the variety with four hyperplanes. As it turns out though, only 3 of these hyperplanes are algebraically independent with respect to the variety[16], i.e., every generic point correspondence reduces the dimension of the variety by three (Kileel, 2017). As a result, one needs 6 correspondences to get a finite number of candidate trifocal tensors that agree with them. Adding a 7th correspondence allows us to uniquely determine $\mathbf{t}$ via solving a 28×27 homogeneous linear system of equations, while the relative poses $(\boldsymbol{R}', \boldsymbol{t}')$ and $(\boldsymbol{R}'', \boldsymbol{t}'')$ can be extracted from $\mathbf{t}$ by, e.g., the procedure described by Hartley and Zisserman (2004).

The above discussion suggests that given a set of $N' \geq 7$ generic and exact point correspondences $\{(\boldsymbol{x}_j, \boldsymbol{x}_j', \boldsymbol{x}_j'')\}_{j=1}^{N'}$, the coefficient vectors

$$\boldsymbol{c}_1^{(1)}, \boldsymbol{c}_2^{(1)}, \boldsymbol{c}_3^{(1)}, \boldsymbol{c}_4^{(1)}, \ldots, \boldsymbol{c}_1^{(j)}, \boldsymbol{c}_2^{(j)}, \boldsymbol{c}_3^{(j)}, \boldsymbol{c}_4^{(j)} \ldots, \boldsymbol{c}_1^{(N')}, \boldsymbol{c}_2^{(N')}, \boldsymbol{c}_3^{(N')}, \boldsymbol{c}_4^{(N')} \in \mathbb{R}^{27}, \tag{152}$$

of the resulting $N = 4N'$ linear equations span a hyperplane in $\mathbb{R}^{27}$ with normal vector $\mathbf{t}$. We will be referring to the vectors (152) as the *trilinear embeddings* of the point correspondences.

14. Here we have used the fact that for vectors $\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c}, \boldsymbol{d} \in \mathbb{R}^n$ the $2n \times 2$ matrix $\begin{bmatrix} \boldsymbol{a} & \boldsymbol{b} \\ \boldsymbol{c} & \boldsymbol{d} \end{bmatrix}$ has rank at most 1 if and only if $\boldsymbol{a}\boldsymbol{d}^\top - \boldsymbol{b}\boldsymbol{c}^\top = \boldsymbol{0}_{n\times n}$; thanks to Tianjiao Ding for this observation.
15. In the uncalibrated case, which is more relevant in computer vision applications, the trifocal tensor has exactly the same structure as in (151), with the only difference being that the matrices $\boldsymbol{R}', \boldsymbol{R}''$ are no longer rotations.
16. A more precise way to state this in algebraic-geometric language is that the ideal generated by these four equations has depth 3 in the quotient ring of the trifocal variety.

However, in practice one obtains such correspondences by matching points across images based on the similarity of some local features, such as *SIFT* (Lowe, 1999). As a result, it is typically the case that many of the produced correspondences are incorrect (see Fig. 8(c)), and the problem then becomes that of detecting inliers lying close to a hyperplane of $\mathbb{R}^{27}$, from a dataset corrupted by outliers. Equivalently, one is presented with a codimension 1 subspace learning problem, for which the proposed Dual Principal Component Pursuit (DPCP) is ideally suited; as we show next, the method can achieve superior performance than RANSAC, the latter being the traditional and up to date one of the most popular options in the computer vision community for such problems.

Data. We use the first three views of the datasets *Model House*, *Corridor* and *Merton College III*, provided by the Visual Geometry Group at Oxford University. Each dataset contains different views of the same static scene, together with the projection matrices of each view and high-quality (inlier) point correspondences. From each dataset we randomly pick $N' = 125$ inlier correspondences $\{(\boldsymbol{x}_j, \boldsymbol{x}'_j, \boldsymbol{x}''_j)\}_{j=1}^{N'}$. We further generate $100 \cdot M'/(N'+M')\% = 30\%, 40\%, 50\%$ outlier correspondences $\{(\boldsymbol{o}_j, \boldsymbol{o}'_j, \boldsymbol{o}''_j)\}_{j=1}^{M'}$ as follows: For each triplet $(\mathcal{V}, \mathcal{V}', \mathcal{V}'')$ of views we sample uniformly at random M' points from each view, and randomly match them in M' triplets. We normalize all data according to Hartley (1997) and form a unit ℓ_2-norm dataset $\tilde{\boldsymbol{\mathcal{X}}} = [\boldsymbol{\mathcal{X}}\ \boldsymbol{\mathcal{O}}]\boldsymbol{\Gamma} \in \mathbb{R}^{27\times 4(M'+N')}$ that consists of the trilinear embeddings (see (152)) of all inlier/outlier correspondences.

Algorithms. We compare REAPER and two variants of RANSAC (see §2) with the proposed fast DPCP variants DPCP-IRLS (Algorithm 2) and DPCP-d (Algorithm 3) in the context of outlier detection for trifocal tensor estimation[17]. REAPER, DPCP-IRLS and DPCP-d receive as input the dataset $\tilde{\boldsymbol{\mathcal{X}}}$ and are configured to learn a subspace of dimension 26 in $\mathbb{R}^{27}$ (a hyperplane) that fits $\tilde{\boldsymbol{\mathcal{X}}}$. So does the first RANSAC variant, called H-RANSAC (*Hyperplane*-RANSAC), which is the standard RANSAC that randomly samples 26 trilinear embeddings at each trial. The second variant, called H-G-RANSAC (*Hyperplane-Group*-RANSAC), is exactly as H-RANSAC except that it samples trilinear embeddings in groups of four (instead of individually), where each group is associated with a point correspondence[18]. For H-RANSAC we use as threshold the maximal distance among inlier trilinear embeddings to the hyperplane associated with the ground-truth trifocal tensor. For H-G-RANSAC we use the maximal average such distance among inlier trilinear embeddings in the same group. Regarding time budget, we note that the fastest method is DPCP-d, and then follows REAPER and DPCP-IRLS. For example, for the experiment we are considering and for 40% outliers, DPCP-d needs an average of about 1msec to converge as opposed to 16msec for DPCP-IRLS. Since RANSAC's performance is sensitive to the allocated time budget, we explore a high time budget regime (running time of DPCP-IRLS), as well as a low time budget regime (running time of DPCP-d), and for fairness, we also restrict the running time of rest of the methods accordingly.

Results. We use as a metric the *group precision* of the algorithms that corresponds to a *recall* value equal to 1: given a hyperplane estimate $\hat{\mathcal{H}}$, this induces an ordering of all the inlier/outlier point correspondences based on increasing average distance of the corresponding 4-tuples of trilinear embeddings to $\hat{\mathcal{H}}$. Letting α be the maximal such average distance that corresponds to an inlier point correspondence, our metric is the percentage of the inliers among all correspondences with average distance to $\hat{\mathcal{H}}$ less or equal than α. Tables 2, 3 and 4 report the precision of the algorithms for the three different scenes, *Corridor, Model House* and *Merton College III* respectively, for different outlier ratios and different time budgets.

17. The purely low-rank methods SE-RPCA and ℓ_2-RPCA are unsuitable for learning a hyperplane; since Coherence Pursuit (CoP) performed much better than them with synthetic data, we also included it in our experiments, but do not report its performance as it was not competitive with the other tested methods, i.e., RANSAC, REAPER and DPCP. Notice from Fig. 7 that with synthetic data CoP fails precisely at the case of a hyperplane.

18. Since the trilinear embeddings also lie in a union of coordinate hyperplanes irrelevant to the trifocal tensor, taking this grouping into consideration prevents the method from learning one of these hyperplanes. This is implicitly achieved by the RANSAC variant penalizing the *re-projection error*, most commonly used for trifocal tensor estimation. We have also tested this variant, however due to its higher complexity and the running time restrictions enforced in this experiment, it did not perform on par with the rest of the methods and hence we do not report its performance further. A group-based DPCP approach is the subject of current research.

Table 4: Algorithm precision when recall value is 1 for the three views of dataset *Merton College 3*.

Algorithm vs.	30% outliers		40% outliers		50% outliers	
% of outliers & time budget	high t.b.	low t.b.	high t.b.	low t.b.	high t.b.	low t.b.
H-RANSAC	0.698	0.723	0.607	0.620	0.505	0.515
H-G-RANSAC	**1.000**	0.980	0.992	0.906	**0.992**	0.546
REAPER-IRLS	**1.000**	0.992	0.984	0.919	0.839	0.786
DPCP-IRLS	**1.000**	0.992	**1.000**	0.936	**0.992**	0.794
DPCP-d	**1.000**	**1.000**	**1.000**	**1.000**	**0.992**	**0.992**

As a first observation note that H-RANSAC essentially fails for all three datasets, with a precision not exceeding 73.5 %, even for the case of 30% outliers. Moreover, its precision is higher for low time budget, which at first sight seems contradictory. Both phenomena are attributed to

a combination of insufficient time budget together with the fact that the dataset $\tilde{\mathcal{X}}$ also lies in a union of coordinate hyperplanes irrelevant to the trifocal tensor; this is evident by inspecting the zero structure of the trilinear embeddings, not shown here. As a result, given different time budgets H-RANSAC identifies different hyperplanes that fit a significant portion of the data, but with none coinciding with the trifocal tensor.

The aforementioned issue is remedied by H-G-RANSAC, which forces the estimated hyperplane to fit groups of trilinear embeddings respecting the underlying point-point-point correspondences. Indeed, this dramatically improves its performance and for the dataset *Model House* in Table 3 it is the best performing method for high time budget. However, H-G-RANSAC is not able to cope with 50% outliers at low time budget: its highest precision in that regime is only 66.5% for the dataset *Corridor* in Table 2.

On the other hand, DPCP-d is not only fast, but also very robust: in the challenging regime of 50% outliers it is the only method that gives 100% precision for the dataset *Corridor*, 95.4% for *Model House*, and 99.2% for *Merton College III*, while in this low time budget regime the second best method is DPCP-IRLS with precision 97.7%, 85.6% and 79.4% respectively. Interestingly, DPCP-d is performing uniformly better than DPCP-IRLS even if the latter is allowed to run to convergence (high time budget); we attribute this to the fact that DPCP-d is designed to explicitly handle noise. Overall, DPCP-d is the best performing method in low time budget across all datasets, and the best performing method in high budget for datasets *Corridor* and *Merton College III*. Finally, REAPER performs somewhere between DPCP-IRLS and H-G-RANSAC, outperforming DPCP-IRLS only on a few occasions. This is consistent with the experiment of Fig. 6 on synthetic data, according to which the advantage of DPCP over REAPER is precisely the codimension 1 case, where the latter fails.

In conclusion, even though RANSAC can have a very high precision given sufficient time budget, once the latter is restricted its performance can drop dramatically. This is particularly the case for large outlier ratios, a regime where an exponentially large time budget might be needed. Moreover, RANSAC is very sensitive to its thresholding parameter, which in the above experiment was set using knowledge of the ground truth. Clearly, such knowledge is not available in practice and different choices for this parameter are expected to only lead to performance degradation. On the other hand, DPCP-d was found to be the best method in the above experiment, combining low running time, high precision and robustness to its thresholding parameter, suggesting that the proposed Dual Principal Component Pursuit can be a useful or even superior alternative to popular approaches such as RANSAC, for three-view geometry or other computer vision applications.

8. Conclusions

We presented and studied a solution to the problem of robust principal component analysis in the presence of outliers, called *Dual Principal Component Pursuit (DPCP)*. The heart of the proposed method consisted of a non-convex ℓ_1 optimization problem on the sphere, for which a solution strategy based on a recursion of linear programs was analyzed. Rigorous mathematical analysis revealed that DPCP is a natural method for learning the inlier subspace in the presence of outliers, even in the challenging regime of large outlier ratios and high subspace relative dimensions. In fact, experiments on synthetic data showed that DPCP was the only method that could handle 70% outliers inside a 30-dimensional ambient space, irrespectively of the subspace dimension. Moreover, experiments with real images in the context of three-view geometry showed that DPCP can outperform popular alternatives such as RANSAC, suggesting its potential in computer vision applications.

Appendix A. Review of existing results on Problems (9) and (10)

In this appendix we state three results that are important for our mathematical analysis, already known in Späth and Watson (1987). For the sake of clarity and convenience, we have also taken the liberty of writing complete proofs of the statements, as not all of them can be found in Späth and Watson (1987).

Proposition 14 *Let $\boldsymbol{\mathcal{Y}} = [\boldsymbol{y}_1, \ldots, \boldsymbol{y}_L] \in D \times L$ be full rank. Then any global solution $\boldsymbol{b}^*$ to*

$$\min_{\boldsymbol{b}^\top \boldsymbol{b}=1} \left\|\boldsymbol{\mathcal{Y}}^\top \boldsymbol{b}\right\|_1, \tag{153}$$

must be orthogonal to $(D-1)$ linearly independent columns of $\boldsymbol{\mathcal{Y}}$.

Proof Let $\boldsymbol{b}^*$ be an optimal solution of (153). Then $\boldsymbol{b}^*$ must satisfy the first order optimality relation

$$\boldsymbol{0} \in \boldsymbol{\mathcal{Y}}\, \mathrm{Sgn}(\boldsymbol{\mathcal{Y}}^\top \boldsymbol{b}^*) + \lambda \boldsymbol{b}^*, \tag{154}$$

where λ is a scalar Lagrange multiplier parameter, and Sgn is the sub-differential of the ℓ_1 norm. Without loss of generality, let $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_K$ be the columns of $\boldsymbol{\mathcal{Y}}$ to which $\boldsymbol{b}^*$ is orthogonal. Then equation (154) implies that there exist real numbers $\alpha_1, \ldots, \alpha_K \in [-1, 1]$ such that

$$\sum_{j=1}^{K} \alpha_j \boldsymbol{y}_j + \sum_{j=K+1}^{L} \mathrm{Sign}(\boldsymbol{y}_j^\top \boldsymbol{b}^*) \boldsymbol{y}_j + \lambda \boldsymbol{b}^* = \boldsymbol{0}. \tag{155}$$

Now, suppose that the span of $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_K$ is of dimension less than $D-1$. Then there exists a unit norm vector $\boldsymbol{\zeta} \in \mathbb{S}^{D-1}$ that is orthogonal to all $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_K, \boldsymbol{b}^*$, and multiplication of (155) from the left by $\boldsymbol{\zeta}^\top$ gives

$$\sum_{j=K+1}^{L} \mathrm{Sign}(\boldsymbol{y}_j^\top \boldsymbol{b}^*) \boldsymbol{\zeta}^\top \boldsymbol{y}_j = 0. \tag{156}$$

Furthermore, we can choose a sufficiently small $\varepsilon > 0$, such that

$$\mathrm{Sign}(\boldsymbol{y}_j^\top \boldsymbol{b}^* + \varepsilon \boldsymbol{y}_j^\top \boldsymbol{\zeta}) = \mathrm{Sign}(\boldsymbol{y}_j^\top \boldsymbol{b}^*), \;\; \forall j \in [L]. \tag{157}$$

The above equation is trivially true for all j such that $\boldsymbol{y}_j^\top \boldsymbol{b}^* = 0$, because in that case $\boldsymbol{y}_j^\top \boldsymbol{\zeta} = 0$ by the definition of $\boldsymbol{\zeta}$. On the other hand, if $\boldsymbol{y}_j^\top \boldsymbol{b}^* \neq 0$, then a small perturbation ϵ will not change the sign of $\boldsymbol{y}_j^\top \boldsymbol{b}^*$. Consequently, we can write

$$\left|\boldsymbol{y}_j^\top (\boldsymbol{b}^* + \varepsilon \boldsymbol{\zeta})\right| = \left|\boldsymbol{y}_j^\top \boldsymbol{b}^*\right| + \varepsilon\, \mathrm{Sign}(\boldsymbol{y}_j^\top \boldsymbol{b}^*) \boldsymbol{y}_j^\top \boldsymbol{\zeta}, \; \forall j \in [L] \tag{158}$$

and so

$$\left\|\boldsymbol{\mathcal{Y}}^\top (\boldsymbol{b}^* + \varepsilon \boldsymbol{\zeta})\right\|_1 = \left\|\boldsymbol{\mathcal{Y}}^\top \boldsymbol{b}^*\right\|_1 + \varepsilon \sum_{j=K+1}^{L} \mathrm{Sign}(\boldsymbol{y}_j^\top \boldsymbol{b}^*) \boldsymbol{\zeta}^\top \boldsymbol{y}_j = \left\|\boldsymbol{\mathcal{Y}}^\top \boldsymbol{b}^*\right\|_1. \tag{159}$$

However,

$$\left\|\boldsymbol{b}^* + \varepsilon\boldsymbol{\zeta}\right\|_2 = \sqrt{1+\varepsilon^2} > 0, \tag{160}$$

and normalizing $\boldsymbol{b}^* + \varepsilon\boldsymbol{\zeta}$ to have unit ℓ_2 norm, we get a contradiction on $\boldsymbol{b}^*$ being a global solution. ■

Proposition 15 *Let $\boldsymbol{\mathcal{Y}} = [\boldsymbol{y}_1, \ldots, \boldsymbol{y}_L]$ be a $D \times L$ matrix of rank D. Then problem*

$$\min_{\boldsymbol{b}^\top \hat{\boldsymbol{n}}_k = 1} \left\|\boldsymbol{\mathcal{Y}}^\top \boldsymbol{b}\right\|_1 \tag{161}$$

admits a computable solution $\boldsymbol{n}_{k+1}$ that is orthogonal to $(D-1)$ linearly independent points of $\boldsymbol{\mathcal{Y}}$.

Proof Let $\boldsymbol{n}_{k+1}$ be a solution to $\min_{\boldsymbol{b}^\top \hat{\boldsymbol{n}}_k = 1} \left\|\boldsymbol{\mathcal{Y}}^\top \boldsymbol{b}\right\|_1$ that is orthogonal to less than $D-1$ linearly independent points of $\boldsymbol{\mathcal{Y}}$. Then we can find a unit norm vector $\boldsymbol{\zeta}$ that is orthogonal to the same points of $\boldsymbol{\mathcal{Y}}$ that $\boldsymbol{n}_{k+1}$ is orthogonal to, and moreover $\boldsymbol{\zeta} \perp \boldsymbol{n}_{k+1}$. In addition, we can find a sufficiently small $\varepsilon > 0$ such that

$$\left\|\boldsymbol{\mathcal{Y}}^\top(\boldsymbol{n}_{k+1} + \varepsilon\boldsymbol{\zeta})\right\|_1 = \left\|\boldsymbol{\mathcal{Y}}^\top \boldsymbol{n}_{k+1}\right\|_1 + \varepsilon \sum_{j:\, \boldsymbol{n}_{k+1} \not\perp \boldsymbol{y}_j} \operatorname{Sign}(\boldsymbol{y}_j^\top \boldsymbol{n}_{k+1}) \boldsymbol{\zeta}^\top \boldsymbol{y}_j, \tag{162}$$

where

$$\sum_{j:\, \boldsymbol{n}_{k+1} \not\perp \boldsymbol{y}_j} \operatorname{Sign}(\boldsymbol{y}_j^\top \boldsymbol{n}_{k+1}) \boldsymbol{\zeta}^\top \boldsymbol{y}_j \leq 0. \tag{163}$$

Since $\boldsymbol{n}_{k+1}$ is optimal, it must be the case that

$$\sum_{j:\, \boldsymbol{n}_{k+1} \not\perp \boldsymbol{y}_j} \operatorname{Sign}(\boldsymbol{y}_j^\top \boldsymbol{n}_{k+1}) \boldsymbol{\zeta}^\top \boldsymbol{y}_j = 0, \tag{164}$$

and so

$$\left\|\boldsymbol{\mathcal{Y}}^\top(\boldsymbol{n}_{k+1} + \varepsilon\boldsymbol{\zeta})\right\|_1 = \left\|\boldsymbol{\mathcal{Y}}^\top \boldsymbol{n}_{k+1}\right\|_1. \tag{165}$$

By (165) we see that as we vary ε the objective remains unchanged. Notice also that varying ε preserves all zero entries appearing in the vector $\boldsymbol{\mathcal{Y}}^\top \boldsymbol{n}_{k+1}$. Furthermore, because of (164), it is always possible to either decrease or increase ε until an additional zero is achieved, i.e., until $\boldsymbol{n}_{k+1} + \varepsilon\boldsymbol{\zeta}$ becomes orthogonal to a point of $\boldsymbol{\mathcal{Y}}$ that $\boldsymbol{n}_{k+1}$ is not orthogonal to. Then we can replace $\boldsymbol{n}_{k+1}$ with $\boldsymbol{n}_{k+1} + \varepsilon\boldsymbol{\zeta}$ and repeat the process, until we get some $\boldsymbol{n}_{k+1}$ that is orthogonal to $D-1$ linearly independent points of $\boldsymbol{\mathcal{Y}}$. ■

Proposition 16 *Let $\boldsymbol{\mathcal{Y}} = [\boldsymbol{y}_1, \ldots, \boldsymbol{y}_L]$ be a $D \times L$ matrix of rank D. Suppose that for each problem* (161) *a solution $\boldsymbol{n}_{k+1}$ is chosen such that $\boldsymbol{n}_{k+1}$ is orthogonal to $D-1$ linearly independent points of $\boldsymbol{\mathcal{Y}}$, in accordance with Proposition 15. Then the sequence $\{\boldsymbol{n}_k\}$ converges to a critical point of problem* (153) *in a finite number of steps.*

Proof If $\boldsymbol{n}_{k+1} = \hat{\boldsymbol{n}}_k$, then inspection of the first order optimality conditions of the two problems, reveals that $\hat{\boldsymbol{n}}_k$ is a critical point of $\min_{\boldsymbol{b}^\top \boldsymbol{b}=1} \left\|\boldsymbol{\mathcal{Y}}^\top \boldsymbol{b}\right\|_1$. If $\boldsymbol{n}_{k+1} \neq \hat{\boldsymbol{n}}_k$, then $\left\|\boldsymbol{n}_{k+1}\right\|_2 > 1$, and so $\left\|\boldsymbol{\mathcal{Y}}^\top \hat{\boldsymbol{n}}_{k+1}\right\|_1 < \left\|\boldsymbol{\mathcal{Y}}^\top \hat{\boldsymbol{n}}_k\right\|_1$. As a consequence, if $\boldsymbol{n}_{k+1} \neq \hat{\boldsymbol{n}}_k$, then $\hat{\boldsymbol{n}}_k$ can not arise as a solution for some $k' > k$. Now, because of Proposition 15, for each k, there is a finite number of candidate directions $\boldsymbol{n}_{k+1}$. These last two observations imply that the sequence $\{\boldsymbol{n}_k\}$ must converge in a finite number of steps to a critical point of $\min_{\boldsymbol{b}^\top \boldsymbol{b}=1} \left\|\boldsymbol{\mathcal{Y}}^\top \boldsymbol{b}\right\|_1$. ■

Abstract

With ever growing data volume and model size, an error-tolerant, communication efficient, yet versatile distributed algorithm has become vital for the success of many large-scale machine learning applications. In this work we propose m-PAPG, an implementation of the flexible proximal gradient algorithm in model parallel systems equipped with the partially asynchronous communication protocol. The worker machines communicate asynchronously with a controlled staleness bound s and operate at different frequencies. We characterize various convergence properties of m-PAPG: 1) Under a general non-smooth and non-convex setting, we prove that every limit point of the sequence generated by m-PAPG is a critical point of the objective function; 2) Under an error bound condition of convex objective functions , we prove that the optimality gap decays linearly for every s steps; 3) Under the Kurdyka-Łojasiewicz inequality and a sufficient decrease assumption , we prove that the sequences generated by m-PAPG converge to the same critical point, provided that a proximal Lipschitz condition is satisfied.

Keywords: proximal gradient, distributed system, model parallel, partially asynchronous, machine learning

1. Introduction

The composite minimization problem

$$\min_{\mathbf{x}\in\mathbb{R}^d} \; f(\mathbf{x}) + g(\mathbf{x}) \tag{1}$$

has drawn a lot of recent attention due to its ubiquity in machine learning and statistical applications. Typically, the first term

$$f(\mathbf{x}) := \frac{1}{n}\sum_{i=1}^{n} f_i(\mathbf{x}) \tag{2}$$

is a smooth loss function over n training samples that describes the fitness to data, and the second term g is a nonsmooth regularization function that encodes *a priori* information. We list below some popular examples under this framework.

- Lasso: least squares loss $f_i(\mathbf{x}) = (y_i - \mathbf{a}_i^\top \mathbf{x})^2$ and ℓ_1 norm regularizer $g(\mathbf{x}) = \|\mathbf{x}\|_1$;
- Logistic regression: logistic loss $f_i = \log(1 + \exp(-y_i \mathbf{a}_i^\top \mathbf{x}_i))$;
- Boosting: exponential loss $f_i(\mathbf{x}) = \exp(-y_i \mathbf{a}_i^\top \mathbf{x})$;
- Support vector machines: hinge loss $f_i(\mathbf{x}) = \max\{0, 1 - y_i \mathbf{a}_i^\top \mathbf{x}\}$ and (squared) ℓ_2 norm regularizer $g(\mathbf{x}) = \|\mathbf{x}\|_2^2$.

Over the years there is also a rising interest in using nonconvex losses f (mainly for robustness against outlying observations) Collobert et al. (2006); Wu and Liu (2007); Xu et al. (2006); Yu et al. (2015) and nonconvex regularizers g (mainly for smaller bias in statistical estimation) Fan and Li (2001); Zhang and Zhang (2012).

Due to the apparent importance of the composite minimization framework and the rapidly growing size in both dimension (d) and volume (n) of data, there is a strong need to develop a practical *parallel* system that can solve the problem in (1) efficiently and in a scale that is impossible for a single machine Agarwal and Duchi (2011); Bertsekas and Tsitsiklis (1989); Dean and Ghemawat (2008); Feyzmahdavian et al. (2014); Ho et al. (2013); Li et al. (2014); Low et al. (2012); Zaharia et al. (2010). Existing systems can be categorized by how communication among worker machines is managed: bulk synchronous (also called fully synchronous) Dean and Ghemawat (2008); Valiant (1990); Zaharia et al. (2010); Lorenzo and Scutari (2016), totally asynchronous Baudet (1978); Bertsekas and Tsitsiklis (1989); Low et al. (2012), and partially asynchronous (a.k.a. stale synchronous or chaotic) Agarwal and Duchi (2011); Bertsekas and Tsitsiklis (1989); Chazan and Miranker (1969); Feyzmahdavian et al. (2014); Ho et al. (2013); Li et al. (2014); Tseng (1991). Bulk synchronous parallel (BSP) systems explicitly force synchronization barriers so that the worker machines can stay on the same page to ensure correctness. However, in a real deployed parallel system, BSP usually suffers from the straggler problem, that is, the performance of the whole system is bottlenecked at the bandwidth of communication and the *slowest* worker machine. On the other hand, totally asynchronous systems do not put any constraint on synchronization, hence achieve much greater throughputs by potentially sacrificing the correctness of the algorithm. Partially asynchronous parallel (PAP) systems Bertsekas and Tsitsiklis (1989); Chazan and Miranker (1969) are a compromise between the previous two: it allows the worker machines to communicate asynchronously up to a controlled staleness and to perform updates at different paces. PAP is particularly suitable for machine learning applications, where iterative algorithms that are robust to small computational errors are usually favored for finding an appropriate solution. Due to its flexibility, the PAP mechanism has been the method of choice in many recent practical implementations Agarwal and Duchi (2011);

∗. The material in this paper is presented in part at the 19th International Conference on Artificial Intelligence and Statistics (AISTATS), Cadiz, Spain, 2016.

Feyzmahdavian et al. (2014); Ho et al. (2013); Li et al. (2014); Liu and Wright (2015); Recht et al. (2011).

Existing parallel systems can also be categorized by how computation is divided among worker machines: data parallel and model parallel. Data parallel systems usually distribute the computation involving each component function f_i in (2) into different worker machines, which is suitable when $n \gg d$, i.e., large data volume but moderate model size. In this setting the stochastic proximal gradient algorithm, along with the PAP protocol, has been shown to be quite effective in solving the composite problem (1) Agarwal and Duchi (2011); Feyzmahdavian et al. (2014); Ho et al. (2013); Li et al. (2014). Some other works developed ADMM-based algorithms for data parallelism Hong et al. (2016) and stochastic variance-reduced gradient algorithms under the PAP protocol Huo and Huang (2017); Fang and Lin (2017), and proved their effectiveness both theoretically and empirically. In this work, we focus on the "dual" model parallel regime where $d \gg n$, i.e., large model size but moderate data volume. In modern machine learning and statistics applications, it is not uncommon that the dimensionality of data largely exceeds its volume, for example, in computational biology, conducting an experimental study that involves many patients can be very expensive but for each patient, technology (e.g. next-generation genome sequencing) has advanced to a stage where taking a large number of measurements (model parameters) is relatively cheap. Deep neural networks are another example that calls for model parallelism. Not surprisingly, the design of a model parallel system is fundamentally different from that of a data parallel system, and so is the subsequent analysis.

To achieve model parallelism, the model $\mathbf{x}$ is partitioned into different (disjoint) blocks and is distributed among many worker machines. In this setting, the block proximal gradient algorithm has been proposed to solve the composite problem (1) Fercoq and Richtárik (2015); Lu and Xiao (2015); Richtárik and Takáč (2014), although under the more restrictive BSP protocol. Other works proposed ADMM-based algorithm for model parallelism to solve the sparse PCA problem Hajinezhad and Hong (2015). Under the PAP protocol, the only work that we are aware of is Bertsekas and Tsitsiklis (1989) which focused on a special case of (1) where g is an indicator function of a convex set, and Tseng (1991) which established a periodic linear rate of convergence under an error bound condition. Our main goal in this work is to provide a formal convergence analysis of the model parallel proximal gradient algorithm under the more flexible PAP communication protocol, and our results naturally extend those in Bertsekas and Tsitsiklis (1989); Tseng (1991) to allow nonsmooth and nonconvex functions.

Our main contributions in this work are: 1). We propose m-PAPG, an extension of the proximal gradient algorithm to the model parallel and partially asynchronous setting. In specific, the worker machines in the system can communicate with each other to synchronize the model parameters with staleness. 2). We provide a rigorous analysis of the convergence properties of m-PAPG, allowing both *nonsmooth* and *nonconvex* functions. In particular, we prove in Theorem 7 that any limit point of the sequences generated by m-PAPG is a critical point. 3) Under an additional error bound condition of convex objective functions, we prove in Theorem 9 that the function values generated by m-PAPG decays periodically linearly. 4) Lastly, using the Kurdyka-Łojasiewicz (KŁ) inequality Bolte et al. (2014) and under a sufficient decrease assumption, we prove in Theorem 11 that for functions that

satisfy a proximal Lipschitz condition the whole sequences of m-PAPG converge to a single critical point.

This paper proceeds as follows: We first set up the notations and definitions in Section 2. The proposed algorithm m-PAPG is presented in Section 3, and convergence analysis are detailed in Sections 4 to 6. The implementation of m-PAPG on a distributed system is detailed in Section 7, and numerical experiments are reported in Section 8. Section 9 concludes our work.

2. Preliminaries

We first recall some fundamental definitions that will be needed in our analysis. Throughout, $h : \mathbb{R}^d \to (-\infty, +\infty]$ denotes an extended real-valued function that is proper and closed, i.e., its domain $\operatorname{dom} h := \{\mathbf{x} : h(\mathbf{x}) < +\infty\}$ is nonempty and its sublevel set $\{\mathbf{x} : h(\mathbf{x}) \le \alpha\}$ is closed for all $\alpha \in \mathbb{R}$. Since the function h may not be smooth or convex, we need the following generalized notion of "derivative."

Definition 1 (Subdifferential and critical point, e.g. Rockafellar and Wets (1997)) *The Frechét subdifferential $\hat{\partial} h$ of h at $\mathbf{x} \in \operatorname{dom} h$ is the set of $\mathbf{u}$ such that*

$$\liminf_{\mathbf{z} \neq \mathbf{x}, \mathbf{z} \to \mathbf{x}} \frac{h(\mathbf{z}) - h(\mathbf{x}) - \mathbf{u}^\top(\mathbf{z} - \mathbf{x})}{\|\mathbf{z} - \mathbf{x}\|} \ge 0, \tag{3}$$

while the (limiting) subdifferential ∂h at $\mathbf{x} \in \operatorname{dom} h$ is the "closure" of $\hat{\partial} h$:

$$\{\mathbf{u} : \exists \mathbf{x}^k \to \mathbf{x}, h(\mathbf{x}^k) \to h(\mathbf{x}), \mathbf{u}^k \in \hat{\partial} h(\mathbf{x}^k), \mathbf{u}^k \to \mathbf{u}\}. \tag{4}$$

The critical points of h are $\operatorname{crit} h := \{\mathbf{x} : \mathbf{0} \in \partial h(\mathbf{x})\}$.

When h is continuously differentiable or convex, the subdifferential ∂h and the set of critical points $\operatorname{crit} h$ coincide with the usual notions. For a closed function h, its subdifferential is either nonempty at any point in its domain or the subgradient diverges to some "direction" (Rockafellar and Wets, 1997, Corollary 8.10).

Definition 2 (Distance and projection) *The distance function w.r.t. a closed set $\Omega \subseteq \mathbb{R}^d$ is defined as:*

$$\operatorname{dist}_\Omega(\mathbf{x}) := \min_{\mathbf{y} \in \Omega} \|\mathbf{y} - \mathbf{x}\|, \tag{5}$$

while the metric projection onto Ω is defined as:

$$\operatorname{proj}_\Omega(\mathbf{x}) := \operatorname*{argmin}_{\mathbf{y} \in \Omega} \|\mathbf{y} - \mathbf{x}\|, \tag{6}$$

where $\|\cdot\|$ is the usual Euclidean norm.

Note that $\operatorname{proj}_\Omega(\mathbf{x})$ is single-valued for all $\mathbf{x} \in \mathbb{R}^d$ if and only if Ω is convex.

Definition 3 (Proximal map, e.g. Rockafellar and Wets (1997)) *The proximal map of a closed and proper function h is (with parameter $\eta > 0$):*

$$\operatorname{prox}_h^\eta(\mathbf{x}) := \operatorname*{argmin}_{\mathbf{z} \in \mathbb{R}^d} h(\mathbf{z}) + \tfrac{1}{2\eta}\|\mathbf{z} - \mathbf{x}\|^2. \tag{7}$$

Occasionally, we will write prox_h *instead of* prox_h^1.

Clearly, for the indicator function $h(\mathbf{x}) = \iota_\Omega(\mathbf{x})$, which takes the value 0 for $\mathbf{x} \in \Omega$ and ∞ otherwise, its proximal map (with any $\eta > 0$) reduces to the metric projection proj_Ω. If h decreases slower than a quadratic function (in particular, when h is bounded below), then its proximal map is well-defined for all (small) η Rockafellar and Wets (1997). If h is convex, then its proximal map is always a singleton while for nonconvex h, the proximal map can be set-valued. In the latter case we will also abuse the notation $\mathrm{prox}_h^\eta(\mathbf{x})$ for an arbitrary element from that set. For convex functions, the proximal map is nonexpansive:

$$\forall\, \mathbf{x}, \mathbf{y} \in \mathbb{R}^d,\ \|\mathrm{prox}_h^\eta(\mathbf{x}) - \mathrm{prox}_h^\eta(\mathbf{y})\| \le \|\mathbf{x} - \mathbf{y}\|, \tag{8}$$

while for nonconvex functions this may not hold everywhere.

The proximal map is the key component of the proximal gradient algorithm Fukushima and Mine (1981) (a.k.a. forward-backward splitting):

$$\forall\, t = 0, 1, \ldots, \quad \mathbf{x}(t+1) = \mathrm{prox}_g^\eta(\mathbf{x}(t) - \eta \nabla f(\mathbf{x}(t))), \tag{9}$$

where ∇f is the (sub)gradient of f, and η is a suitable step size (that may change with t). It is known that when f is convex with L-Lipschitz continuous gradient and $0 < \eta < 2/L$, then $F_t := f(\mathbf{x}(t)) + g(\mathbf{x}(t))$ converges to the minimum at the rate $O(1/t)$ and $\mathbf{x}(t)$ converges to some minimizer $\mathbf{x}^*$. Accelerated versions Beck and Teboulle (2009); Nesterov (2013) where F_t converges at the faster rate $O(1/t^2)$ are also well-known. Recently, Bolte et al. (2014) proved that $\mathbf{x}(t)$ converges to a critical point even for nonconvex f and nonconvex and nonsmooth g as long as together they satisfy a certain KŁ inequality.

3. Formulation of m-PAPG

Recall the composite minimization problem:

$$\min_{\mathbf{x} \in \mathbb{R}^d} F(\mathbf{x}), \quad \text{where} \quad F(\mathbf{x}) = f(\mathbf{x}) + g(\mathbf{x}). \tag{P}$$

We are interested in the case where d is so large that implementing the proximal gradient algorithm (9) on a single machine is no longer feasible, hence distributed computation is necessary.

We consider a **model** parallel system with p machines in total. The machines are fully connected and can communicate with each other. Decompose the d model parameters into p disjoint groups. Formally, consider the decomposition $\mathbb{R}^d = \mathbb{R}^{d_1} \times \mathbb{R}^{d_2} \times \cdots \times \mathbb{R}^{d_p}$, and denote x_i and $\nabla_i f(\mathbf{x}) : \mathbb{R}^d \to \mathbb{R}^{d_i}$ as the i-th component of $\mathbf{x}$ and $\nabla f(\mathbf{x})$, respectively. Clearly, $\mathbf{x} = (x_1, x_2, \ldots, x_p)$ and $\nabla f = (\nabla_1 f, \nabla_2 f, \cdots, \nabla_p f)$. The i-th machine is responsible for updating the component $x_i \in \mathbb{R}^{d_i}$, and for the purpose of evaluating the partial gradient $\nabla_i f(\mathbf{x})$ we assume the i-th machine also has access to a local, full model parameter $\mathbf{x}^i \in \mathbb{R}^d$. The last assumption is made only to simplify our presentation; it can be removed for many machine learning problems, see for instance Richtárik and Takáč (2014); Zhou et al. (2016).

We make the following standard assumptions regarding problem (P):

Assumption 1 (Bounded Below) *The function $F = f + g$ is bounded below.*

Assumption 2 (Smooth) *The function f is L-smooth, i.e.,*

$$\forall\, \mathbf{x}, \mathbf{y} \in \mathbb{R}^d,\ \|\nabla f(\mathbf{x}) - \nabla f(\mathbf{y})\| \le L\|\mathbf{x} - \mathbf{y}\|. \tag{10}$$

Assumption 3 (Separable) *The function g is closed and separable, i.e., $g(\mathbf{x}) = \sum_{i=1}^p g_i(x_i)$.*

Assumption 1 simply allows us to have a finite minimum value and is usually satisfied in practice. The smoothness assumption is critical in two aspects: (1) It allows us to upper bound f by its quadratic expansion at the current iterate—a standard step in the convergence proof of gradient type algorithms:

$$\forall\, \mathbf{x}, \mathbf{y} \in \mathbb{R}^d,\ f(\mathbf{x}) \le f(\mathbf{y}) + \langle \mathbf{x} - \mathbf{y}, \nabla f(\mathbf{y}) \rangle + \tfrac{L}{2}\|\mathbf{x} - \mathbf{y}\|^2. \tag{11}$$

(2) It allows us to bound the inconsistencies in different machines due to asynchronous updates, see Theorem 4 below. The separable assumption makes model parallelism interesting and feasible, and is satisfied by many popular regularizers. Popular examples include vector norms such as ℓ_0, ℓ_1, $\ell_{1,2}$ (i.e., group norm), ℓ_2^2, elastic net, and matrix norms such as Frobenious norm, etc. We remark that both Assumption 2 and Assumption 3 can be relaxed using techniques in Beck and Teboulle (2012) and Yu et al. (2015), respectively. For brevity we do not pursue these extensions here. Note that we do *not* assume convexity on either f or g, and g need not even be continuous.

We now specify the m-PAPG algorithm for solving (P) under model parallelism and the PAP protocol. The separable assumption on g implies that

$$\mathrm{prox}_g^\eta(\mathbf{x}) = \big(\mathrm{prox}_{g_1}^\eta(x_1),\ \ldots\ ,\ \mathrm{prox}_{g_p}^\eta(x_p)\big). \tag{12}$$

Then, the update on machine i is defined as:

$$x_i \leftarrow \mathrm{prox}_{g_i}^\eta(x_i - \eta \nabla_i f(\mathbf{x}^i)). \tag{13}$$

That is, machine i computes a partial gradient mapping Nesterov (2013) w.r.t. the i-th component using the local component x_i and the local full model $\mathbf{x}^i$. To define the latter, consider a global clock shared by all machines and denote T_i as the set of active clocks when machine i performs an update. Note that the global clock is introduced solely for the purpose of our analysis, and the machines need not maintain it in a practical implementation. Denote $\tau_j^i(t)$ as the iteration of the block model x_j that is accessed by machine i at its t-th iteration. Then, the t-th iteration on machine i can be formally written as:

$$\begin{cases} \forall i,\ x_i(t+1) = \begin{cases} x_i(t), & t \notin T_i \\ \mathrm{prox}_{g_i}^\eta(x_i(t) - \eta \nabla_i f(\mathbf{x}^i(t))), & t \in T_i \end{cases}, \\ \text{(local)} \quad \mathbf{x}^i(t) = (x_1(\tau_1^i(t)),\ \ldots\ ,\ x_p(\tau_p^i(t))), \\ \text{(global)} \quad \mathbf{x}(t) = (x_1(t),\ \ldots\ ,\ x_p(t)). \end{cases} \tag{m-PAPG}$$

That is, machine i only performs its update operator at its active clocks. The local full model $\mathbf{x}^i(t)$ assembles all components from other machines, and is possibly a delayed version of the global model $\mathbf{x}(t)$, which assembles the most up-to-date component in each machine. Note that the global model is introduced for our analysis, and is not accessible in a real implementation. More specifically, $\tau_j^i(t) \le t$ models the communication delay among machines: when machine i conducts its t-th update it only has access to $x_j(\tau_j^i(t))$, a delayed version of the component $x_j(t)$ that is received by the i-th machine from the j-th machine.

We refer to the above algorithm as m-PAPG (for **m**odel parallel, **P**artially **A**synchronous, **P**roximal **G**radient).

In a practical distributed system, communication among machines is much slower than local computations, and the performance of a *synchronous* system is often bottlenecked at the *slowest* machine, due to the need of synchronization in every step. The delays $\tau_j^i(t)$ and active clocks T_i that we introduced in m-PAPG aim to address such issues. For our convergence proofs, we need the following assumptions:

Assumption 4 (Bounded Delay) $\exists s \in \mathbb{N},\ \forall i, \forall j, \forall t,\ 0 \le t - \tau_j^i(t) \le s,\ \tau_i^i(t) \equiv t.$

Assumption 5 (Frequent Update) $\exists s \in \mathbb{N},\ \forall i, \forall t, T_i \cap \{t, t+1, \cdots, t+s\} \neq \emptyset.$

Intuitively, Assumption 4 guarantees the information that machine i gathered from other machines at the t-th iteration are not too obsolete (bounded by at most s clocks apart). The assumption $\tau_i^i(t) \equiv t$ is natural since the i-th worker machine is maintaining x_i hence would always have the latest copy. Assumption 5 requires each machine to update at least once in every $s+1$ iterations, for otherwise some component x_i may not be updated at all. We remark that Assumption 4 and Assumption 5 are very natural and have been widely adopted in previous works Baudet (1978); Bertsekas and Tsitsiklis (1989); Chazan and Miranker (1969); Feyzmahdavian et al. (2014); Tseng (1991). Clearly, when $s = 0$ (i.e., no delay), m-PAPG reduces to the fully synchronous, model parallel proximal gradient algorithm.

Before closing this section, we provide a technical tool to control the inconsistency between the local models $\mathbf{x}^i(t)$ and the global model $\mathbf{x}(t)$. Recall that $(t)_+ = \max\{t, 0\}$ is the positive part of t.

Lemma 4 *Let Assumption 4 hold, then the global model* $\mathbf{x}(t)$ *and the local models* $\{\mathbf{x}^i(t)\}_{i=1}^p$ *satisfy:*

$$\forall i = 1, \cdots, p, \quad \|\mathbf{x}(t) - \mathbf{x}^i(t)\| \le \sum_{k=(t-s)_+}^{t-1} \|\mathbf{x}(k+1) - \mathbf{x}(k)\|, \tag{14}$$

$$\|\mathbf{x}^i(t+1) - \mathbf{x}^i(t)\| \le \sum_{k=(t-s)_+}^{t} \|\mathbf{x}(k+1) - \mathbf{x}(k)\|. \tag{15}$$

Proof Indeed, by the definitions in (m-PAPG):

$$\begin{aligned}
\|\mathbf{x}(t) - \mathbf{x}^i(t)\|^2 &= \sum_{j=1}^p \|x_j(t) - x_j(\tau_j^i(t))\|^2 \\
&\le \sum_{j=1}^p \left(\sum_{k=\tau_j^i(t)}^{t-1} \|x_j(k+1) - x_j(k)\| \right)^2 \\
&\le \sum_{j=1}^p \left(\sum_{k=(t-s)_+}^{t-1} \|x_j(k+1) - x_j(k)\| \right)^2 \\
&= \sum_{j=1}^p \sum_{k=(t-s)_+}^{t-1} \sum_{k'=(t-s)_+}^{t-1} \|x_j(k+1) - x_j(k)\| \|x_j(k'+1) - x_j(k')\| \\
&= \sum_{k=(t-s)_+}^{t-1} \sum_{k'=(t-s)_+}^{t-1} \sum_{j=1}^p \|x_j(k+1) - x_j(k)\| \|x_j(k'+1) - x_j(k')\| \\
&\le \sum_{k=(t-s)_+}^{t-1} \sum_{k'=(t-s)_+}^{t-1} \|\mathbf{x}(k+1) - \mathbf{x}(k)\| \|\mathbf{x}(k'+1) - \mathbf{x}(k')\| \\
&= \left(\sum_{k=(t-s)_+}^{t-1} \|\mathbf{x}(k+1) - \mathbf{x}(k)\| \right)^2,
\end{aligned}$$

where the first inequality is due to the triangle inequality; the second inequality is due to Assumption 4; and the last inequality follows from the Cauchy-Schwarz inequality.

Similarly,

$$\begin{aligned}
\|\mathbf{x}^i(t) - \mathbf{x}^i(t+1)\|^2 &= \sum_{j=1}^p \|x_j(\tau_j^i(t)) - x_j(\tau_j^i(t+1))\|^2 \\
&\le \sum_{j=1}^p \left(\sum_{k=\tau_j^i(t)}^{\tau_j^i(t+1)-1} \|x_j(k+1) - x_j(k)\| \right)^2 \\
&\le \sum_{j=1}^p \left(\sum_{k=(t-s)_+}^{t} \|x_j(k+1) - x_j(k)\| \right)^2,
\end{aligned}$$

and the rest of the proof is completely similar to the previous case. ■

4. Characterizing the limit points

In this section, we characterize the convergence property of the sequences generated by m-PAPG under very general conditions. Recall from Assumption 2 that ∇f is L-Lipschitz continuous. Our first result is as follows:

Theorem 5 *Let Assumptions 1 to 5 hold. If the step size* $\eta \in \left(0, \frac{1}{L(1+2\sqrt{ps})}\right)$*, then the sequence generated by m-PAPG is square summable, i.e.*

$$\sum_{t=0}^{\infty} \|\mathbf{x}(t+1) - \mathbf{x}(t)\|^2 < \infty. \tag{16}$$

In particular, $\lim_{t\to\infty} \|\mathbf{x}(t+1) - \mathbf{x}(t)\| = 0$ *and* $\lim_{t\to\infty} \|\mathbf{x}(t) - \mathbf{x}^i(t)\| = 0.$

Remark 6 *Our bound on the step size* η *is natural: If* $s = 0$*, i.e., there is no asynchronism then we recover the standard step size rule* $\eta < 1/L$ *(we can increase* η *by another factor of 2, had convexity on* g *been assumed). As staleness* s *increases, we need a smaller step size to*

"damp" the system to still ensure convergence. The factor $\sqrt{p}$ is another measurement of the degree of "dependency" among worker machines: Indeed, we can reduce $\sqrt{p}$ to $\sqrt{\sum_i L_i^2}/L$, where L_i is the Lipschitz constant of $\nabla_i f$ (cf. (21)).

Proof The last claim follows immediately from eq. (16) and eq. (14), so we only need to prove (16).

Consider machine i and any $t \in T_i$. Combining eq. (13) with eq. (m-PAPG) gives

$$x_i(t+1) = \operatorname{prox}_{g_i}^{\eta}(x_i(t) - \eta \nabla_i f(\mathbf{x}^i(t))). \tag{17}$$

Then, from Definition 3 of the proximal map we have for all $z \in \mathbb{R}^{d_i}$:

$$\begin{aligned} g_i(x_i(t+1)) + \frac{1}{2\eta}\|x_i(t+1) - x_i(t) + \eta \nabla_i f(\mathbf{x}^i(t))\|^2 \\ \leq g_i(z) + \frac{1}{2\eta}\left\|z - x_i(t) + \eta \nabla_i f(\mathbf{x}^i(t))\right\|^2. \end{aligned} \tag{18}$$

Set $z = x_i(t)$ and simplify, we obtain:

$$\begin{aligned} g_i(x_i(t+1)) - g_i(x_i(t)) \\ \leq -\frac{1}{2\eta}\|x_i(t+1) - x_i(t)\|^2 - \left\langle \nabla_i f(\mathbf{x}^i(t)), x_i(t+1) - x_i(t)\right\rangle. \end{aligned} \tag{19}$$

Note that if $t \notin T_i$, then $x_i(t+1) = x_i(t)$ and eq. (19) still holds. On the other hand, Assumption 2 implies that for all t (cf. (11)):

$$f(\mathbf{x}(t+1)) - f(\mathbf{x}(t)) \leq \langle \mathbf{x}(t+1) - \mathbf{x}(t), \nabla f(\mathbf{x}(t))\rangle + \frac{L}{2}\|\mathbf{x}(t+1) - \mathbf{x}(t)\|^2. \tag{20}$$

Adding up eq. (20) and eq. (19) (for all i) and recall $F = f + \sum_i g_i$, we have

$$\begin{aligned} &F(\mathbf{x}(t+1)) - F(\mathbf{x}(t)) - \tfrac{1}{2}(L - 1/\eta)\|\mathbf{x}(t+1) - \mathbf{x}(t)\|^2 \\ &\leq \sum_{i=1}^{p}\left\langle x_i(t+1) - x_i(t), \nabla_i f(\mathbf{x}(t)) - \nabla_i f(\mathbf{x}^i(t))\right\rangle \\ &\leq \sum_{i=1}^{p}\|x_i(t+1) - x_i(t)\| \cdot \|\nabla_i f(\mathbf{x}(t)) - \nabla_i f(\mathbf{x}^i(t))\| \\ &\overset{\text{(i)}}{\leq} \sum_{i=1}^{p}\|x_i(t+1) - x_i(t)\| \cdot L\|\mathbf{x}(t) - \mathbf{x}^i(t)\| \qquad (21) \\ &\overset{\text{(ii)}}{\leq} L \cdot \sum_{i=1}^{p}\|x_i(t+1) - x_i(t)\| \cdot \sum_{k=(t-s)_+}^{t-1}\|\mathbf{x}(k+1) - \mathbf{x}(k)\| \\ &\overset{\text{(iii)}}{\leq} \sqrt{p}L\|\mathbf{x}(t+1) - \mathbf{x}(t)\| \cdot \sum_{k=(t-s)_+}^{t-1}\|\mathbf{x}(k+1) - \mathbf{x}(k)\| \qquad (22) \\ &\overset{\text{(iv)}}{\leq} \frac{\sqrt{p}L}{2}\sum_{k=(t-s)_+}^{t-1}\left[\|\mathbf{x}(k+1) - \mathbf{x}(k)\|^2 + \|\mathbf{x}(t+1) - \mathbf{x}(t)\|^2\right] \\ &\leq \frac{\sqrt{p}Ls}{2}\|\mathbf{x}(t+1) - \mathbf{x}(t)\|^2 + \frac{\sqrt{p}L}{2}\sum_{k=(t-s)_+}^{t-1}\|\mathbf{x}(k+1) - \mathbf{x}(k)\|^2, \qquad (23) \end{aligned}$$

where (i) is due to the L-Lipschitz continuity of ∇f, (ii) follows from eq. (14), (iii) is the Cauchy-Schwarz inequality, and (iv) follows from the elementary inequality $ab \leq \frac{a^2+b^2}{2}$. Summing the above inequality over t from 0 to $m-1$ and rearranging we obtain

$$\begin{aligned} F(\mathbf{x}(m)) - F(\mathbf{x}(0)) &\leq \frac{1}{2}(L + \sqrt{p}Ls - 1/\eta)\sum_{t=0}^{m-1}\|\mathbf{x}(t+1) - \mathbf{x}(t)\|^2 \\ &\quad + \frac{L}{2}\sum_{t=0}^{m-1}\sum_{k=(t-s)_+}^{t-1}\|\mathbf{x}(k+1) - \mathbf{x}(k)\|^2 \\ &\leq \frac{1}{2}(L + 2\sqrt{p}Ls - 1/\eta)\sum_{t=0}^{m-1}\|\mathbf{x}(t+1) - \mathbf{x}(t)\|^2. \end{aligned}$$

Therefore, if we choose $0 < \eta < \frac{1}{L(1+2\sqrt{p}s)}$, then let $m \to \infty$ we deduce

$$\sum_{t=0}^{\infty}\|\mathbf{x}(t+1) - \mathbf{x}(t)\|^2 \leq \frac{2}{1/\eta - L - 2\sqrt{p}Ls}[F(\mathbf{x}(0)) - \inf_{\mathbf{z}} F(\mathbf{z})]. \tag{24}$$

By Assumption 1, F is bounded from below, hence the right-hand side is finite. ■

The first assertion of the above theorem states that the global sequence $\mathbf{x}(t)$ has square summable successive differences, while the second assertion implies that both the successive difference of the global sequence and the inconsistency between the local sequences and the global sequence diminish as the number of iterations grows. These two conclusions provide a prelimenary stability guarantee for m-PAPG.

Next, we prove that the limit points (if exist) of the sequences $\mathbf{x}(t)$ and $\mathbf{x}^i(t), i = 1, \ldots, p$ coincide, and they are critical points of F. Recall that the set of critical points of the function F is denoted as $\operatorname{crit} F$.

Theorem 7 *Consider the same setting as in Theorem 5. Then, the sequences $\{\mathbf{x}(t)\}$ and $\{\mathbf{x}^i(t)\}, i = 1, \ldots, p$, generated by m-PAPG share the same set of limit points, which is a subset of $\operatorname{crit} F$.*

Proof It is clear from Theorem 5 that $\{\mathbf{x}(t)\}$ and $\{\mathbf{x}^i(t)\}, i = 1, \ldots, p$, share the same set of limit points, and we need to show that any limit point of $\{\mathbf{x}(t)\}$ is also a critical point of F.

Let $\mathbf{x}^*$ be a limit point of $\{\mathbf{x}(t)\}$. By Theorem 1 it suffices to exhibit a sequence $\mathbf{x}(k)$ satisfying[1]

$$\mathbf{x}(k) \to \mathbf{x}^*,\ F(\mathbf{x}(k)) \to F(\mathbf{x}^*),\ \mathbf{0} \leftarrow \mathbf{u}(k) \in \partial F(\mathbf{x}(k)). \tag{25}$$

1. Technically, from Theorem 1 we should have the Frechét subdifferential $\hat{\partial} F$ in eq. (25), however, a standard argument allows us to use the more convenient subdifferential (Rockafellar and Wets, 1997, Proposition 8.7).

Let us first construct the subgradient sequence $\mathbf{u}(k)$. Consider machine i and any $\hat{t} \in T_i$, the optimality condition of eq. (17) gives

$$u_i(\hat{t}+1) := -\tfrac{1}{\eta}\left[x_i(\hat{t}+1) - x_i(\hat{t}) + \eta\nabla_i f(\mathbf{x}^i(\hat{t}))\right] \in \partial g_i(x_i(\hat{t}+1)). \tag{26}$$

It then follows that

$$\begin{aligned}
&\|u_i(\hat{t}+1) + \nabla_i f(\mathbf{x}(\hat{t}+1))\| \\
&\quad\le \|u_i(\hat{t}+1) + \nabla_i f(\mathbf{x}(\hat{t}))\| + \|\nabla_i f(\mathbf{x}(\hat{t}+1)) - \nabla_i f(\mathbf{x}(\hat{t}))\| \\
&\quad\overset{\text{(i)}}{\le} \left\|\tfrac{1}{\eta}\left[x_i(\hat{t}+1) - x_i(\hat{t})\right] + \nabla_i f(\mathbf{x}^i(\hat{t})) - \nabla_i f(\mathbf{x}(\hat{t}))\right\| + L\|\mathbf{x}(\hat{t}+1) - \mathbf{x}(\hat{t})\| \\
&\quad\overset{\text{(ii)}}{\le} \tfrac{1}{\eta}\|x_i(\hat{t}+1) - x_i(\hat{t})\| + L\|\mathbf{x}^i(\hat{t}) - \mathbf{x}(\hat{t})\| + L\|\mathbf{x}(\hat{t}+1) - \mathbf{x}(\hat{t})\| \\
&\quad\overset{\text{(iii)}}{\le} \tfrac{1}{\eta}\|x_i(\hat{t}+1) - x_i(\hat{t})\| + L\sum_{k=(\hat{t}-s)_+}^{\hat{t}} \|\mathbf{x}(k+1) - \mathbf{x}(k)\|,
\end{aligned} \tag{27}$$

where (i) and (ii) are due to the L-Lipschitz continuity of ∇f, and (iii) follows from eq. (14). Next, consider any other $t \notin T_i$ and $t \ge s$, we denote $\hat{t}$ as the *largest* element in the set $\{k \le t : k \in T_i\}$. By Assumption 5 $\hat{t}$ always exists and $t - \hat{t} \le s$. Since no update is performed on machine i at any clock in $[\hat{t}+1, t]$, we have $x_i(t+1) = x_i(\hat{t}+1)$. Thus, we can choose $u_i(t+1) = u_i(\hat{t}+1) \in \partial g_i(x_i(\hat{t}+1)) = \partial g_i(x_i(t+1))$, and obtain

$$\begin{aligned}
&\|u_i(t+1) + \nabla_i f(\mathbf{x}(t+1)) - u_i(\hat{t}+1) - \nabla_i f(\mathbf{x}(\hat{t}+1))\| \\
&\qquad= \|\nabla_i f(\mathbf{x}(t+1)) - \nabla_i f(\mathbf{x}(\hat{t}+1))\| \\
&\qquad\le \sum_{k=\hat{t}+1}^{t} \|\nabla_i f(\mathbf{x}(k+1)) - \nabla_i f(\mathbf{x}(k))\| \\
&\qquad\le \sum_{k=(t-s+1)_+}^{t} \|\nabla_i f(\mathbf{x}(k+1)) - \nabla_i f(\mathbf{x}(k))\| \\
&\qquad\le \sum_{k=(t-s+1)_+}^{t} L\|\mathbf{x}(k+1) - \mathbf{x}(k)\|.
\end{aligned} \tag{28}$$

$$\tag{29}$$

Combining the two cases in eq. (27) and eq. (29), we have for all t and all i:

$$\begin{aligned}
\|u_i(t+1) + \nabla_i f(\mathbf{x}(t+1))\| &\le \tfrac{1}{\eta}\|x_i(\hat{t}+1) - x_i(\hat{t})\| + L\sum_{k=(\hat{t}-s)_+}^{\hat{t}} \|\mathbf{x}(k+1) - \mathbf{x}(k)\| \\
&\quad + L\sum_{k=(t-s+1)_+}^{t} \|\mathbf{x}(k+1) - \mathbf{x}(k)\| \\
&\le (\tfrac{1}{\eta} + 2L)\sum_{k=(t-2s)_+}^{t} \|\mathbf{x}(k+1) - \mathbf{x}(k)\|,
\end{aligned}$$

where the last inequality uses the fact that $t - s \le \hat{t} \le t$. Observing that the right hand side of the above inequality does not depend on i, we can sum the square of the above inequality over i and further conclude that

$$\|\mathbf{u}(t+1) + \nabla f(\mathbf{x}(t+1))\| \le \sqrt{p}(\tfrac{1}{\eta} + 2L)\sum_{k=(t-2s)_+}^{t} \|\mathbf{x}(k+1) - \mathbf{x}(k)\|, \tag{30}$$

where $\mathbf{u}(t+1) = \big(u_1(t+1),\ \ldots\ ,\ u_p(t+1)\big) \in \partial g(\mathbf{x}(t+1))$. Therefore, by eq. (30) and Theorem 5 we deduce

$$\lim_{t\to\infty} \operatorname{dist}_{\partial F(\mathbf{x}(t+1))}(\mathbf{0}) \le \lim_{t\to\infty} \|\mathbf{u}(t+1) + \nabla f(\mathbf{x}(t+1))\| = 0. \tag{31}$$

Recall that $\mathbf{x}^*$ is a limit point of $\{\mathbf{x}(t)\}$, thus there exists a subsequence $\mathbf{x}(t_m) \to \mathbf{x}^*$. Next we verify the function value convergence in eq. (25). The challenge here is that the component function g is only closed, hence may not be continuous. For any $t \in T_i$, applying eq. (18) with $z = x_i^*$ and rearranging gives

$$\begin{aligned}
g_i(x_i(t+1)) &\le g_i(x_i^*) + \frac{1}{2\eta}\|x_i^* - x_i(t)\|^2 - \frac{1}{2\eta}\|x_i(t+1) - x_i(t)\|^2 \\
&\quad + \langle x_i^* - x_i(t+1), \nabla_i f(\mathbf{x}^i(t))\rangle \\
&= g_i(x_i^*) + \frac{1}{2\eta}\|x_i^* - x_i(t)\|^2 - \frac{1}{2\eta}\|x_i(t+1) - x_i(t)\|^2 \\
&\quad + \langle x_i^* - x_i(t+1), \nabla_i f(\mathbf{x}^*)\rangle + \langle x_i^* - x_i(t+1), \nabla_i f(\mathbf{x}^i(t)) - \nabla_i f(\mathbf{x}^*)\rangle.
\end{aligned} \tag{32}$$

We note that the above inequality holds only for the iterations $t \in T_i$. Next, observe that $\lim_{m\to\infty} \|\mathbf{x}(t_m) - \mathbf{x}^*\| = 0$. Since $\lim_{t\to\infty} \|\mathbf{x}(t+1) - \mathbf{x}(t)\| = 0$, we further conclude that

$$\lim_{m\to\infty} \max_{t\in[t_m - s, t_m + s]\cap T_i} \|\mathbf{x}(t) - \mathbf{x}^*\| = 0. \tag{33}$$

Moreover, note that $\lim_{t\to\infty} \|\mathbf{x}(t) - \mathbf{x}^i(t)\| = 0$. Then, the above equation further implies that

$$\begin{aligned}
&\lim_{m\to\infty} \max_{t\in[t_m - s, t_m + s]\cap T_i} \|\nabla_i f(\mathbf{x}^i(t)) - \nabla_i f(\mathbf{x}^*)\| \\
&\le L \lim_{m\to\infty} \max_{t\in[t_m - s, t_m + s]\cap T_i} \|\mathbf{x}^* - \mathbf{x}^i(t)\| \\
&\le L \lim_{m\to\infty} \max_{t\in[t_m - s, t_m + s]\cap T_i} \left[\|\mathbf{x}^* - \mathbf{x}(t)\| + \|\mathbf{x}(t) - \mathbf{x}^i(t)\|\right] = 0.
\end{aligned} \tag{34}$$

By Assumption 5, $[t_m - s, t_m + s] \cap T_i \ne \emptyset$ for all i. We can now take the limsup on both sides of eq. (32) and utilize eqs. (33) and (34) to obtain that

$$\limsup_{m\to\infty} \max_{t\in[t_m - s, t_m + s]\cap T_i} g_i(x_i(t+1)) \le g_i(x_i^*). \tag{35}$$

Denote $\hat{t}_m \in T_i$ as the largest element such that $\hat{t}_m \le t_m$. Note that $t_m - s \le \hat{t}_m$ due to the constraint on the maximum delay. It then follows that

$$\max_{t\in[t_m, t_m + s]} g_i(x_i(t+1)) = \max_{t\in[\hat{t}_m, t_m + s]\cap T_i} g_i(x_i(t+1)) \le \max_{t\in[t_m - s, t_m + s]\cap T_i} g_i(x_i(t+1)),$$

where the first equality is due to the fact that no update is performed during $[\hat{t}_m, t_m]$ and machine i updates only at its active clocks T_i, and the second inequality uses the fact that $\hat{t}_m \geq t_m - s$. Hence, we further obtain from (35) that

$$\limsup_{m\to\infty} \max_{t\in[t_m, t_m+s]} g_i(x_i(t+1)) \leq g_i(x_i^*). \tag{36}$$

To complete the proof, choose any $k_m \in [t_m, t_m + s]$. Since $\mathbf{x}(t_m) \to \mathbf{x}^*$, Theorem 5 implies that

$$\mathbf{x}(k_m) \to \mathbf{x}^*. \tag{37}$$

From eq. (36) we know for all i, $\limsup_{m\to\infty} g_i(x_i(k_m)) \leq g_i(x_i^*)$. On the other hand, it follows from the closedness of the function g_i (cf. Assumption 3) that $\liminf_{m\to\infty} g_i(x_i(k_m)) \geq g_i(x_i^*)$, thus in fact $\lim_{m\to\infty} g_i(x_i(k_m)) = g_i(x_i^*)$. Since f is continuous, we know

$$\lim_{m\to\infty} F(\mathbf{x}(k_m)) = \lim_{m\to\infty} f(\mathbf{x}(k_m)) + \sum_i g_i(x_i(k_m)) = F(\mathbf{x}^*). \tag{38}$$

Combining eq. (31), eq. (37) and eq. (38) we know from Theorem 1 that $\mathbf{x}^* \in \operatorname{crit} F$. ■

Theorem 7 further justifies m-PAPG by showing that any limit point it produces is necessarily a critical point. Of course, for convex functions any critical point is a global minimizer. The closest result to Theorem 5 and Theorem 7 we are aware of is (Bertsekas and Tsitsiklis, 1989, Proposition 7.5.3), where essentially the same conclusion was reached but under the much more restrictive assumption that g is an indicator function of a product *convex* set. Thus, our result is new even when g is a convex function such as the ℓ_1 norm that is widely used to promote sparsity. Furthermore, we allow g to be any closed separable function (convex or not), covering the many recent nonconvex regularization functions in machine learning and statistics (see e.g. Fan and Li (2001); Mazumder et al. (2011); Zhang (2010); Zhang and Zhang (2012)). We also note that the proof of Theorem 7 (for nonconvex g) involves significantly new ideas beyond those of Bertsekas and Tsitsiklis (1989).

We note that the existence of limit points can be guaranteed, for instance, if $\{\mathbf{x}(t)\}$ is bounded or the sublevel set $\{\mathbf{x} \mid F(\mathbf{x}) \leq \alpha\}$ is bounded for all $\alpha \in \mathbb{R}$. However, we have yet to prove that the sequence $\{\mathbf{x}(t)\}$ generated by m-PAPG does converge to one of the critical points, and we fill this gap under two complementary sets of assumptions on the objective function in Sections 5 and 6, respectively.

5. Convergence under Error Bound

In this section we prove that the global sequence $\{\mathbf{x}(t)\}$ produced by m-PAPG converges periodically linearly to a global minimizer, by assuming an error bound condition on the objective function in (P) and a convexity assumption that serves to simplify the presentation:

Assumption 6 (Convex) *The functions f and g in* (P) *are convex.*

Note that for convex functions g the proximal mapping $\operatorname{prox}_g^\eta$ is single valued for any $\eta > 0$. The error bound condition we need is as follows:

Assumption 7 (Error Bound) *For every $\alpha > 0$, there exist $\delta, \kappa > 0$ such that for all $\mathbf{x} \in \mathbb{R}^d$ with $f(\mathbf{x}) \leq \alpha$ and $\|\mathbf{x} - \operatorname{prox}_g(\mathbf{x} - \nabla f(\mathbf{x}))\| \leq \delta$,*

$$\operatorname{dist}_{\operatorname{crit} F}(\mathbf{x}) \leq \kappa \|\mathbf{x} - \operatorname{prox}_g(\mathbf{x} - \nabla f(\mathbf{x}))\|, \tag{39}$$

where recall that $\operatorname{crit} F$ *is the set of critical points of F.*

Equation (39) is a proximal extension of the Luo-Tseng error bound Luo and Tseng (1993) where g is the indicator function of a closed convex set. A prototypic convex function F satisfying (39) is the following:

$$F(\mathbf{x}) = f(A\mathbf{x}) + g(\mathbf{x}), \tag{40}$$

where f is strongly convex (i.e., $f - \frac{\mu}{2}\|\cdot\|^2$ is convex for some $\mu > 0$), A is a linear map, and g is either an indicator function of a convex set Luo and Tseng (1993) or the ℓ_p norm for $p \in [1, 2] \cup \{\infty\}$ Zhou et al. (2015). Many machine learning formulations such as Lasso and sparse logistic regression fit into this form. In fact, for convex functions F taking such form, the error bound condition in eq. (39) is recently shown to be equivalent to the following conditions Drusvyatskiy and Lewis (2016); Zhang (2016):

$$\begin{aligned} \text{Restricted strong convexity}: &\ \langle \mathbf{x} - \operatorname{prox}_g(\mathbf{x}), \mathbf{x} - \operatorname{proj}_{\operatorname{crit} F}(\mathbf{x})\rangle \geq \mu \cdot \operatorname{dist}^2_{\operatorname{crit} F}(\mathbf{x}), \\ \text{Quadratic growth}: &\ F(\mathbf{x}) - F^* \geq \mu \cdot \operatorname{dist}^2_{\operatorname{crit} F}(\mathbf{x}), \end{aligned}$$

where F^* is the minimum value of F and $\mu > 0$ is a constant. In general, the error bound condition in eq. (39) is not exclusive to convex functions. For instance, it holds for $f(\mathbf{x}) = \frac{1}{2}\|\mathbf{x}\|^2$ and any function g that has a unique global minimizer at 0 (such as the cardinality function $g(\mathbf{x}) = \|\mathbf{x}\|_0$). However, it is often quite challenging to establish the error bound condition for a large family of nonconvex functions.

We define the following nonnegative quantities that measure the progress of m-PAPG:

$$A(t) := F(\mathbf{x}(t)) - F^*, \ F^* := \inf_{\mathbf{x}} F(\mathbf{x}), \tag{41}$$

$$B(t) := \sum_{k=(t-s-1)_+}^{t-1} \|\mathbf{x}(k+1) - \mathbf{x}(k)\|^2, \tag{42}$$

In the following key lemma we relate the gap quantities defined above inductively.

Lemma 8 *Let Assumptions 1 to 7 hold. Then, we have*

$$\begin{aligned} &A(t+s+1) \leq A(t) - \tfrac{1}{2}(\tfrac{1}{\eta} - L - 2sL\sqrt{p})B(t+s+1) + \tfrac{1}{2}sL\sqrt{p}B(t) \\ &0 \leq A(t+s+1) \leq a_\eta B(t+s+1) + bB(t), \end{aligned}$$

where a_η and b are given in (53) *below.*

Proof The first inequality is obtained by summing the inequality eq. (23) over $t, t+1, \cdots, t+s$. So we need only prove the second inequality.

Let us introduce some notations to simplify the proof. For each machine i let t_i be the largest clock in $[t, t+s] \cap T_i$, and denote

$$\mathbf{z} = (x_1(t_1), \ \ldots \ , x_p(t_p)) \tag{43}$$

$$\mathbf{z}^+ = (x_1(t_1+1), \ \ldots \ , x_p(t_p+1)) = (x_1(t+s+1), \ \ldots \ , x_p(t+s+1)), \tag{44}$$

where the last equality is due to the maximality of each t_i. From the optimality condition of the proximal map $z_i^+ = \mathrm{prox}_{g_i}^{\eta}(z_i - \eta \nabla_i f(\mathbf{x}^i(t_i)))$ we deduce

$$\eta^{-1}(z_i - z_i^+) - \nabla_i f(\mathbf{x}^i(t_i)) \in \partial g_i(z_i^+). \tag{45}$$

Since the gradient of f is L-Lipschitz continuous and the function g is convex, we obtain

$$f(\mathbf{z}^+) - f(\bar{\mathbf{z}}) \le \sum_{i=1}^p \langle z_i^+ - \bar{z}_i, \nabla_i f(\bar{\mathbf{z}}) \rangle + \frac{L}{2}\|\mathbf{z}^+ - \bar{\mathbf{z}}\|^2,$$

$$g(\mathbf{z}^+) - g(\bar{\mathbf{z}}) \le \sum_{i=1}^p \langle z_i^+ - \bar{z}_i, \eta^{-1}(z_i - z_i^+) - \nabla_i f(\mathbf{x}^i(t_i)) \rangle,$$

where we define $\bar{\mathbf{z}} := \mathrm{proj}_{\mathrm{crit}\, F}(\mathbf{z})$, i.e., the projection of $\mathbf{z}$ onto the set of critical points of F, and the last inequality follows from eq. (45). Adding up the above two inequalities we obtain

$$\begin{aligned}
F(\mathbf{z}^+) - F^* - \tfrac{L}{2}\|\mathbf{z}^+ - \bar{\mathbf{z}}\|^2 &\le \sum_{i=1}^p \langle z_i^+ - \bar{z}_i, \nabla_i f(\bar{\mathbf{z}}) + \eta^{-1}(z_i - z_i^+) - \nabla_i f(\mathbf{x}^i(t_i)) \rangle \\
&\overset{\text{(i)}}{\le} \sum_{i=1}^p [\|z_i^+ - z_i\| + \|z_i - \bar{z}_i\|][\|\nabla_i f(\mathbf{x}^i(t_i)) - \nabla_i f(\bar{\mathbf{z}})\| + \eta^{-1}\|z_i - z_i^+\|] \\
&\overset{\text{(ii)}}{\le} \sum_{i=1}^p 4\left[\|z_i^+ - z_i\|^2 + \|z_i - \bar{z}_i\|^2 + \eta^{-2}\|z_i^+ - z_i\|^2 + \|\nabla_i f(\mathbf{x}^i(t_i)) - \nabla_i f(\bar{\mathbf{z}})\|^2\right] \\
&\le 4\left[\|\bar{\mathbf{z}} - \mathbf{z}\|^2 + (1+\eta^{-2})\|\mathbf{z}^+ - \mathbf{z}\|^2 + \sum_{i=1}^p L^2\|\mathbf{x}^i(t_i) - \bar{\mathbf{z}}\|^2\right],
\end{aligned}$$

where (i) is due to the Cauchy-Schwarz inequality and the triangle inequality, (ii) is due to the elementary inequality $(a+b)(c+d) \le 4(a^2+b^2+c^2+d^2)$, and the last inequality is due to the L-Lipschitz continuity of ∇f. Using again the triangle inequality we obtain from the above inequality that

$$\begin{aligned}
F(\mathbf{z}^+) - F^* &\le (L+4)\|\bar{\mathbf{z}} - \mathbf{z}\|^2 + (L+4+\tfrac{4}{\eta^2})\|\mathbf{z}^+ - \mathbf{z}\|^2 + 4L^2\sum_{i=1}^p \|\mathbf{x}^i(t_i) - \bar{\mathbf{z}}\|^2 \\
&\overset{\text{(i)}}{=} (L+4)\|\bar{\mathbf{z}} - \mathbf{z}\|^2 + \sum_{i=1}^p [(L+4+\tfrac{4}{\eta^2})\|x_i(t_i+1) - x_i(t_i)\|^2 + 4L^2\|\mathbf{x}^i(t_i) - \bar{\mathbf{z}}\|^2], \\
&\overset{\text{(ii)}}{\le} (L+4)\|\bar{\mathbf{z}} - \mathbf{z}\|^2 + (L+4+\tfrac{4}{\eta^2})B(t+s+1) + 4L^2\sum_{i=1}^p \|\mathbf{x}^i(t_i) - \bar{\mathbf{z}}\|^2,
\end{aligned} \tag{46}$$

$$\le (L+4+8L^2p)\|\bar{\mathbf{z}} - \mathbf{z}\|^2 + (L+4+\tfrac{4}{\eta^2})B(t+s+1) + 8L^2\sum_{i=1}^p \|\mathbf{x}^i(t_i) - \mathbf{z}\|^2, \tag{47}$$

where (i) is due to our definition of $\mathbf{z}$ and $\mathbf{z}^+$ in (43) and (44), and (ii) is due to the fact that $t_i \in [t, t+s]$ for all i.

We next bound the terms $\|\bar{\mathbf{z}} - \mathbf{z}\|^2$ and $\|\mathbf{x}^i(t_i) - \mathbf{z}\|^2$. We recall that $\mathbf{x}^i(t_i)$ corresponds to the local model on machine i at the iteration t_i. Since $t_i \in T_i$, the update rule for the i-th machine implies that

$$\begin{aligned}
\|x_i(t_i+1) - x_i(t_i)\| &= \|\mathrm{prox}_{g_i}^{\eta}(x_i(t_i) - \eta\nabla_i f(\mathbf{x}^i(t_i))) - x_i(t_i)\| \\
&\ge \|\mathrm{prox}_{g_i}^{\eta}(x_i(t_i) - \eta\nabla_i f(\mathbf{z})) - x_i(t_i)\| \\
&\quad - \|\mathrm{prox}_{g_i}^{\eta}(x_i(t_i) - \eta\nabla_i f(\mathbf{x}^i(t_i))) - \mathrm{prox}_{g_i}^{\eta}(x_i(t_i) - \eta\nabla_i f(\mathbf{z}))\| \\
&\overset{\text{(i)}}{\ge} \|\mathrm{prox}_{g_i}^{\eta}(x_i(t_i) - \eta\nabla_i f(\mathbf{z})) - x_i(t_i)\| - \eta L\|\mathbf{z} - \mathbf{x}^i(t_i)\|,
\end{aligned}$$

where (i) follows from the non-expansiveness of prox_g^{η} (recall that g is convex) and the L-Lipschitz continuity of ∇f. Rearranging the above inequality and summing over all i, we obtain

$$\begin{aligned}
\|\mathrm{prox}_g^{\eta}(\mathbf{z} - \eta\nabla f(\mathbf{z})) - \mathbf{z}\|^2 &\le \sum_{i=1}^p \Big[\|x_i(t_i+1) - x_i(t_i)\| + \eta L\|\mathbf{z} - \mathbf{x}^i(t_i)\|\Big]^2 \\
&\le 2\sum_{i=1}^p \Big[\|x_i(t_i+1) - x_i(t_i)\|^2 + \eta^2 L^2\|\mathbf{z} - \mathbf{x}^i(t_i)\|^2\Big].
\end{aligned} \tag{48}$$

The last term $\|\mathbf{z} - \mathbf{x}^i(t_i)\|^2$ can be further bounded as follows:

$$\begin{aligned}
\|\mathbf{z} - \mathbf{x}^i(t_i)\|^2 &= \sum_{j=1}^p \|x_j(t_j) - x_j(\tau_j^i(t_i))\|^2 \\
&= \sum_{j=1}^p \Big\| \sum_{k=\min\{t_j, \tau_j^i(t_i)\}}^{\max\{t_j, \tau_j^i(t_i)\}-1} x_j(k+1) - x_j(k) \Big\|^2 \\
&\le \sum_{j=1}^p \Big[\sum_{k=\min\{t_j, \tau_j^i(t_i)\}}^{\max\{t_j, \tau_j^i(t_i)\}-1} \|x_j(k+1) - x_j(k)\| \Big]^2 \\
&\overset{\text{(i)}}{\le} \sum_{j=1}^p 2s \sum_{k=t-s}^{t+s-1} \|x_j(k+1) - x_j(k)\|^2 \\
&= 2s \sum_{k=t-s}^{t+s-1} \|\mathbf{x}(k+1) - \mathbf{x}(k)\|^2 \\
&\le 2s[B(t) + B(t+s+1)],
\end{aligned} \tag{49}$$

where (i) is due to the fact that $t_j \in [t, t+s]$ and $\tau_j^i(t_i) \in [t-s, t+s]$. Combining (48) and (49) we obtain

$$\|\mathrm{prox}_g^{\eta}(\mathbf{z} - \eta\nabla f(\mathbf{z})) - \mathbf{z}\|^2 \le 2B(t+s+1) + 4ps\eta^2 L^2[B(t) + B(t+s+1)]. \tag{50}$$

Thanks to Theorem 5, we know for t sufficiently large, $\|\text{prox}_g^\eta(\mathbf{z}-\eta\nabla f(\mathbf{z}))-\mathbf{z}\| \le \eta\delta$. Since the function $\eta \mapsto \frac{1}{\eta}\|\text{prox}_g^\eta(\mathbf{z}-\eta\nabla f(\mathbf{z}))-\mathbf{z}\|$ is monotonically decreasing Sra (2012), we can apply the error bound condition in Assumption 7 for $\eta < 1$ and t sufficiently large, and obtain

$$\|\bar{\mathbf{z}}-\mathbf{z}\|^2 \le \kappa\|\mathbf{z}-\text{prox}_g(\mathbf{z}-\nabla f(\mathbf{z}))\|^2 \le \kappa\eta^{-2}\|\mathbf{z}-\text{prox}_g^\eta(\mathbf{z}-\eta\nabla f(\mathbf{z}))\|^2. \tag{51}$$

Finally, combining (46), (49), (50) and (51) we arrive at:

$$\begin{aligned} F(\mathbf{x}(t+s+1)) - F^* &= F(\mathbf{z}^+) - F^* \\ &\le (L+4+8L^2p)\|\bar{\mathbf{z}}-\mathbf{z}\|^2 + (L+4+\tfrac{4}{\eta^2})B(t+s+1) + 8L^2\sum_{i=1}^p \|\mathbf{x}^i(t_i)-\mathbf{z}\|^2, \\ &\le a_\eta B(t+s+1) + bB(t), \end{aligned} \tag{52}$$

where the coefficients are

$$a_\eta = L + 4 + 16psL^2 + 4ps\kappa L^2(L+4+8L^2p) + \tfrac{2}{\eta^2}(2+4\kappa+\kappa L), \tag{53}$$

$$b = 16psL^2 + 4ps\kappa L^2(L+4+8L^2p). \tag{54}$$

■

Theorem 8 improves the analysis of Tseng (1991) in three aspects: (1) it is shorter and simpler; (2) it allows any convex function g; and (3) the leading coefficient for $B(t)$ is reduced from $O(1/\eta)$ to $O(1)$. The two recursive relations in Lemma 8, as shown in (Tseng, 1991, Lemma 4.5), easily imply the following convergence guarantee.

Theorem 9 *Let Assumptions 1 to 7 hold. Then, there exists some $\eta_0 > 0$ such that if $0 < \eta < \eta_0$, then the sequences $\{A(t), B(t)\}$ generated by m-PAPG satisfy for all $r = 0, 1, 2, \cdots$*

$$A(r(s+1)) \le C_1(1-\gamma\eta)^r, \;\; B(r(s+1)) \le C_2(1-\gamma\eta)^r, \tag{55}$$

where $C_1, C_2, \gamma < 1/\eta$ are positive constants.

Hence, the gaps $A(t)$ and $B(t)$ that measure the progress of m-PAPG decrease by a constant factor $(1-\gamma\eta)$ for every $s+1$ steps, which makes intuitive sense since in the worst case each worker machine only performs one update in every $s+1$ steps. In other words, $(s+1)$ is the natural time scale for measuring progress here. Note that since $\|\mathbf{x}(t+s+1)-\mathbf{x}(t)\|^2 \le (s+1)B(t+s+1)$, it follows easily that the global sequence $\mathbf{x}(t)$ and consequently also the local sequences $\{\mathbf{x}^i(t)\}$ all converge to the same limit point in crit F at a $(s+1)$-periodically linear rate.

6. Convergence with KŁ inequality

The error bound condition considered in the previous section is not easy to verify in general. It has been discovered recently that the error bound condition is equivalent to other notions in optimization that can be verified in alternative ways Drusvyatskiy and Lewis (2016);

Zhang (2016), see e.g. (40). However, for nonconvex functions, sometimes even the simple ones, it remains a challenging task to verify if the error bound condition holds. This failure motivates us to investigate another property, the Kurdyka-Łojasiewicz (KŁ) inequality, that has been shown to be quite effective in dealing with nonconvex functions.

Definition 10 (KŁ property, (Bolte et al., 2014, Lemma 6)) *Let $\Omega \subset \text{dom}h$ be a compact set on which the function h is a constant. We say that h satisfies the KŁ property if there exist $\varepsilon, \lambda > 0$ such that for all $\bar{\mathbf{x}} \in \Omega$ and all $\mathbf{x} \in \{\mathbf{z} \in \mathbb{R}^d : \text{dist}_\Omega(\mathbf{z}) < \varepsilon\} \cap [\mathbf{z} : h(\bar{\mathbf{x}}) < h(\mathbf{z}) < h(\bar{\mathbf{x}}) + \lambda]$, it holds that*

$$\varphi'(h(\mathbf{x}) - h(\bar{\mathbf{x}})) \cdot \text{dist}_{\partial h(\mathbf{x})}(\mathbf{0}) \ge 1, \tag{56}$$

where the function $\varphi : [0, \lambda) \to \mathbb{R}_+, 0 \mapsto 0$, is continuous, concave, and has continuous and positive derivative φ' on $(0, \lambda)$.

The KŁ inequality in eq. (56) is an important tool to bound the trajectory length of a dynamical system (see Bolte et al. (2010); Kurdyka (1998) and the references therein for some historic developments). It has recently been used to analyze discrete-time algorithms in Absil et al. (2005) and proximal algorithms in Attouch and Bolte (2009); Attouch et al. (2010); Bolte et al. (2014). As we shall see, the function φ will serve as a Lyapunov potential function. Quite conveniently, most practical functions, in particular, the quasi-norm $\|\cdot\|_p$ for positive rational p, as well as convex functions with certain growth conditions, are KŁ. For a more detailed discussion of KŁ functions, including many familiar examples, see (Bolte et al., 2014, Section 5) and (Attouch et al., 2010, Section 4).

Following the recipe in Bolte et al. (2014), we need the following assumption to guarantee the algorithm is making *sufficient* progress:

Assumption 8 (Sufficient decrease) *There exists $\alpha > 0$ such that for all large t,*

$$F(\mathbf{x}(t+1)) \le F(\mathbf{x}(t)) - \alpha\|\mathbf{x}(t+1)-\mathbf{x}(t)\|^2. \tag{57}$$

The sufficient decrease assumption is automatically satisfied in many descent algorithms, e.g., the proximal gradient algorithm. However, in the partially asynchronous parallel (PAP) setting, it is highly nontrivial to satisfy the sufficient decrease assumption because of the complication due to communication delays and update skips. Note also that none of the worker machines actually has access to the global sequence $\mathbf{x}(t)$, so even verifying the sufficient decrease property is not trivial. To simplify the presentation, we first analyze the performance of m-PAPG using the KŁ inequality and taking the sufficient decrease property for granted, and later we we will give some verifiable conditions to justify this simplification.

Our first result in this section strengthens the convergence properties in Theorems 5 and 7 for m-PAPG:

Theorem 11 (Finite Length) *Let Assumptions 1 to 5 and 8 hold for m-PAPG, and let F satisfy the KL property in Theorem 10. Then, with step size $\eta \in \left(0, \frac{1}{L(1+2\sqrt{ps})}\right)$, every bounded sequence $\{\mathbf{x}(t)\}$ generated by m-PAPG satisfies*

$$\sum_{t=0}^{\infty} \|\mathbf{x}(t+1)-\mathbf{x}(t)\| < \infty, \tag{58}$$

$$\forall i = 1, \dots, p, \ \sum_{t=0}^{\infty} \|\mathbf{x}^i(t+1) - \mathbf{x}^i(t)\| < \infty. \tag{59}$$

Furthermore, $\{\mathbf{x}(t)\}$ and $\{\mathbf{x}^i(t)\}_{i=1}^p$ converge to the same critical point of F.

Proof We first show that eq. (58) implies eq. (59). Indeed, recall from (15):

$$\|\mathbf{x}^i(t+1) - \mathbf{x}^i(t)\| \le \sum_{k=(t-s)_+}^{t} \|\mathbf{x}(k+1) - \mathbf{x}(k)\|.$$

Therefore, summing for $t = 0, 1, \cdots, n$ gives

$$\begin{aligned}\sum_{t=0}^{n} \|\mathbf{x}^i(t+1) - \mathbf{x}^i(t)\| &\le \sum_{t=0}^{n} \sum_{k=(t-s)_+}^{t} \|\mathbf{x}(k+1) - \mathbf{x}(k)\| \\ &\le (2s+1) \sum_{t=0}^{n} \|\mathbf{x}(t+1) - \mathbf{x}(t)\|.\end{aligned}$$

The claim then follows by letting n tend to infinity.

By Theorem 5, the limit points of $\{\mathbf{x}(t)\}$ and $\{\mathbf{x}^i(t)\}_{i=1}^p$ coincide and are critical points of F. Thus, the only thing left to prove is the finite length property in eq. (58). By Assumption 8 and Assumption 1, the objective value $F(\mathbf{x}(t))$ decreases to a finite limit F^*. Since $\{\mathbf{x}(t)\}$ is assumed to be bounded, the set of its limit points Ω is nonempty and compact. Summing eq. (18) over all i and set $\mathbf{z} \in \Omega$, we obtain

$$g(\mathbf{x}(t+1)) \le g(\mathbf{z}) - \frac{1}{2\eta}\|\mathbf{x}(t+1) - \mathbf{x}(t)\|^2 - \sum_{i=1}^{p} \langle \nabla_i f(\mathbf{x}^i(t)), \mathbf{x}(t+1) - \mathbf{x}(t) \rangle.$$

Note that $\mathbf{x}(t+1) - \mathbf{x}(t) \to 0$. Also, since $\{\mathbf{x}(t)\}$ is bounded and $\mathbf{x}(t) - \mathbf{x}^i(t) \to 0$ for all i, $\{\mathbf{x}^i(t)\}_{i=1}^p$ are all bounded. we then take limsup on both sides and obtain that $\limsup_{t\to\infty} g(\mathbf{x}(t+1)) \le g(\mathbf{z})$. Together with the closedness of g we further obtain that $\lim_{t\to\infty} g(\mathbf{x}(t+1)) = g(\mathbf{z})$. Note that f is continuous, we thus conclude that $\lim_{t\to\infty} F(\mathbf{x}(t+1)) = F(\mathbf{z})$ for all $\mathbf{z} \in \Omega$. Note that $F(\mathbf{x}(t)) \downarrow F^*$. Thus for all $\mathbf{x}^* \in \Omega$, we have $F(\mathbf{x}^*) \equiv F^*$. Now fix $\varepsilon > 0$. Since Ω is compact, for t sufficiently large we have $\mathrm{dist}_\Omega(\mathbf{x}(t)) \le \varepsilon$. We now have all ingredients to apply the KŁ inequality in Theorem 10: for all sufficiently large t,

$$\varphi'(F(\mathbf{x}(t)) - F^*) \cdot \mathrm{dist}_{\partial F(\mathbf{x}(t))}(\mathbf{0}) \ge 1. \tag{60}$$

Since φ is concave, we obtain

$$\begin{aligned}\Delta_{t,t+1} &:= \varphi(F(\mathbf{x}(t)) - F^*) - \varphi(F(\mathbf{x}(t+1)) - F^*) \\ &\ge \varphi'(F(\mathbf{x}(t)) - F^*)(F(\mathbf{x}(t)) - F(\mathbf{x}(t+1))) \\ &\overset{\text{(i)}}{\ge} \frac{\alpha\|\mathbf{x}(t+1) - \mathbf{x}(t)\|^2}{\mathrm{dist}_{\partial F(\mathbf{x}(t))}(\mathbf{0})},\end{aligned} \tag{61}$$

where (i) follows from Assumption 8 and eq. (60). It is clear that the function φ (composed with F) serves as a Lyapunov function. Using the elementary inequality $2\sqrt{ab} \le a + b$ we obtain from eq. (61) that for t sufficiently large,

$$2\|\mathbf{x}(t+1) - \mathbf{x}(t)\| \le \tfrac{\delta}{\alpha}\Delta_{t,t+1} + \tfrac{1}{\delta}\mathrm{dist}_{\partial F(\mathbf{x}(t))}(\mathbf{0}),$$

where $\delta > 0$ will be specified later. Recalling the bound for $\partial F(\mathbf{x}(t))$ in eq. (30), and summing over t from m (sufficiently large) to n gives:

$$\begin{aligned}2\sum_{t=m}^{n} \|\mathbf{x}(t+1) - \mathbf{x}(t)\| &\le \sum_{t=m}^{n} \frac{\delta}{\alpha}\Delta_{t,t+1} + \sum_{t=m}^{n} \frac{1}{\delta}\mathrm{dist}_{\partial F(\mathbf{x}(t))}(\mathbf{0}) \\ &\overset{\text{(i)}}{\le} \frac{\delta}{\alpha}\varphi(F(\mathbf{x}(m)) - F^*) + \sum_{t=m}^{n} \frac{\sqrt{p}(1/\eta + 2L)}{\delta} \sum_{k=(t-2s)_+}^{t} \|\mathbf{x}(k+1) - \mathbf{x}(k)\| \\ &\le \frac{\delta}{\alpha}\varphi(F(\mathbf{x}(m)) - F^*) + \frac{(2s+1)\sqrt{p}(1/\eta + 2L)}{\delta} \sum_{k=(m-2s)_+}^{m-1} \|\mathbf{x}(k+1) - \mathbf{x}(k)\| \\ &\quad + \frac{(2s+1)\sqrt{p}(1/\eta + 2L)}{\delta} \sum_{t=m}^{n} \|\mathbf{x}(t+1) - \mathbf{x}(t)\|,\end{aligned}$$

where (i) is due to eq. (30). Setting $\delta = (2s+1)\sqrt{p}(1/\eta + 2L)$ and rearranging gives

$$\begin{aligned}\sum_{t=m}^{n} \|\mathbf{x}(t+1) - \mathbf{x}(t)\| &\le \frac{(2s+1)\sqrt{p}(1/\eta + 2L)}{\alpha}\varphi(F(\mathbf{x}(m)) - F^*) \\ &\quad + \sum_{k=(m-2s)_+}^{m-1} \|\mathbf{x}(k+1) - \mathbf{x}(k)\|.\end{aligned}$$

Since the right-hand side is finite, let n tend to infinity completes the proof for eq. (58). ■

Compared with (16) in Theorem 5, we now have the successive differences to be absolutely summable (instead of square summable). This is a significantly stronger result as it immediately implies that the whole sequence is Cauchy and hence convergent, whereas we cannot get the same conclusion from the square summable property in Theorem 5. We note that local maxima are excluded from being the limit in Theorem 11, due to Assumption 8. Also, the boundedness assumption on the trajectory $\{\mathbf{x}(t)\}$ is easy to satisfy, for instance, when F has bounded sublevel sets. We refer to (Attouch et al., 2010, Remark 3.3) for more conditions that imply the boundedness condition. Moreover, following similar arguments in Attouch et al. (2010) we can also determine the local convergence rates of the sequences generated by m-PAPG.

In the remaining part of this section we provide some justifications for the sufficient decrease property in Assumption 8. For simplicity we assume all worker machines perform updates in each time step t:

Assumption 9 $\forall i = 1, \cdots, p, \forall t, t \in T_i$.

Note that Assumption 9 is commonly adopted in the analysis of many recent parallel systems Agarwal and Duchi (2011); Feyzmahdavian et al. (2014); Ho et al. (2013); Li et al. (2014); Liu and Wright (2015); Recht et al. (2011). In fact, Assumption 9 is somewhat necessary to justify Assumption 8. This is because Assumption 8 requires a sufficient decrease of the function value at every iteration k, which may not hold under the PAP as all machines can be idle for s iterations in the worst case. In other words, to achieve convergence of $\{\mathbf{x}_k\}_k$

to a critical point in nonconvex optimization under the KL inequality, the parallel system should make a steady progress per-iteration. As we show next, this is guaranteed under Assumptions 9 and 10.

We will replace the sufficient decrease property in Assumption 8 with the following key property that turns out to be easier to verify:

Assumption 10 (Proximal Lipschitz) *We say a pair of functions f and g satisfy the proximal Lipschitz property on a sequence $\{\mathbf{x}(t)\}$ if for all η sufficiently small, there exists $L_\eta \in o(1)$, i.e. $L_\eta \to 0$ as $\eta \to 0$, such that for all large t,*

$$\|\Delta_\eta(\mathbf{x}(t)) - \Delta_\eta(\mathbf{x}(t+1))\| \leq L_\eta \|\mathbf{x}(t) - \mathbf{x}(t+1)\|, \tag{62}$$

where[2] $\Delta_\eta(\mathbf{x}) \in \operatorname{prox}_g^\eta(\mathbf{x} - \eta\nabla f(\mathbf{x})) - \mathbf{x}$.

The proximal Lipschitz assumption is motivated by the special case where $g \equiv 0$ and hence $\Delta_\eta(\mathbf{x}) = -\eta\nabla f(\mathbf{x})$ is η-Lipschitz, thanks to Assumption 2. As we have seen in previous sections, Lipschitz continuity plays a crucial role in our proof where a major difficulty is to control the inconsistencies among different worker machines due to communication delays. Similarly here, the proximal Lipschitz property, as we show next, allows us to remove the sufficient decrease property in Assumption 8—the seemingly strong assumption that we needed in proving our main result Theorem 11.

Let us first present a quick justification for Assumption 10.

Lemma 12 *Suppose the functions f and g both have Lipschitz continuous gradient, then Assumption 10 holds for any sequence $\{\mathbf{x}(t)\}$.*

Proof Let us denote L_f and L_g as the Lipschitz constant of the gradient ∇f and ∇g, respectively. Since $\Delta_\eta(\mathbf{x}) \in \operatorname{prox}_g^\eta(\mathbf{x} - \eta\nabla f(\mathbf{x})) - \mathbf{x}$, using the optimality condition for the proximal map, see for instance (Yu et al., 2015, Proposition 7(iii)), we have

$$\mathbf{x} + \Delta_\eta(\mathbf{x}) + \eta\nabla g\big(\mathbf{x} + \Delta_\eta(\mathbf{x})\big) = \mathbf{x} - \eta\nabla f(\mathbf{x}),$$

and similarly

$$\mathbf{z} + \Delta_\eta(\mathbf{z}) + \eta\nabla g\big(\mathbf{z} + \Delta_\eta(\mathbf{z})\big) = \mathbf{z} - \eta\nabla f(\mathbf{z}).$$

Subtracting one inequality from another, we obtain

$$\begin{aligned}\|\Delta_\eta(\mathbf{x}) - \Delta_\eta(\mathbf{z})\| &= \|\eta\nabla g(\mathbf{z} + \Delta_\eta(\mathbf{z})) - \eta\nabla g(\mathbf{x} + \Delta_\eta(\mathbf{x})) + \eta\nabla f(\mathbf{z}) - \eta\nabla f(\mathbf{x})\| \\ &\leq \eta L_g\|\mathbf{z} - \mathbf{x} + \Delta_\eta(\mathbf{z}) - \Delta_\eta(\mathbf{x})\| + \eta L_f\|\mathbf{z} - \mathbf{x}\| \\ &\leq \eta L_g\|\Delta_\eta(\mathbf{z}) - \Delta_\eta(\mathbf{x})\| + \eta(L_f + L_g)\|\mathbf{z} - \mathbf{x}\|.\end{aligned}$$

Rearranging we obtain

$$\|\Delta_\eta(\mathbf{x}) - \Delta_\eta(\mathbf{z})\| \leq \frac{\eta(L_f + L_g)}{1 - \eta L_g}\|\mathbf{z} - \mathbf{x}\|,$$

when $0 < \eta < 1/L_g$. Clearly, when η is mall, the leading coefficient $\frac{\eta(L_f+L_g)}{1-\eta L_g} \in \mathcal{O}(\eta) \subseteq o(1)$, and our proof is complete. ■

2. Should the proximal map be multi-valued, we contend with any single-valued selection.

It is clear that Lemma 12 captures the motivating case $g \equiv 0$, but also many other important functions, such as the widely-used regularization function $g = \|\cdot\|_p^p$ for any $p > 1$. We can now continue with our next result in this section.

Theorem 13 *Let Assumptions 1 to 4 and 9 hold for m-PAPG, and let F satisfy the KL property in Theorem 10. Fix any $r > 1$ with $C = \frac{r^{s+1}-1}{r-1}$ and step size η such that $\eta < \frac{1}{L(1+2\sqrt{p}C+2\sqrt{p}s)}$. If for each local sequence $\{\mathbf{x}^i(t)\}$ generated by m-PAPG, Assumption 10 holds with $L_\eta \leq \frac{r^2-1}{2pr^2C^2}$, and the global sequence $\{\mathbf{x}(t)\}$ is bounded, then the finite length properties in (58) and (59) hold. Then, Assumption 8 holds, and consequently, $\{\mathbf{x}(t)\}$ and $\{\mathbf{x}^i(t)\}_{i=1}^p$ converge to the same critical point of F based on Theorem 11.*

Theorem 13 assumes that $L_\eta \leq \frac{r^2-1}{2pr^2C^2}$. We note that L_η implicitly depends on the stepsize η, i.e., $L_\eta \to 0$ as $\eta \to 0$ (see Assumption 10). Thus, one can tune the stepsize η to be small enough such that L_η satisfies the requirement. As an example, if $g = \|\mathbf{x}\|_2^2$, then one can calculate that $L_\eta = \mathcal{O}(\eta)$. In this case, we should choose the stepsize to be roughly $\eta \leq \frac{r^2-1}{2pr^2C^2}$.

Proof Using the elementary inequality $\|a\|^2 - \|b\|^2 \leq 2\|a\|\|a-b\|$, we have for all t:

$$\begin{aligned}&\|\mathbf{x}(t+1) - \mathbf{x}(t)\|^2 - \|\mathbf{x}(t+2) - \mathbf{x}(t+1)\|^2 \\ &\quad\leq 2\|\mathbf{x}(t+1) - \mathbf{x}(t)\| \cdot \|(\mathbf{x}(t+1) - \mathbf{x}(t)) - (\mathbf{x}(t+2) - \mathbf{x}(t+1))\| \\ &\quad\leq 2\|\mathbf{x}(t+1) - \mathbf{x}(t)\| \cdot \sum_{i=1}^p \|(x_i(t+1) - x_i(t)) - (x_i(t+2) - x_i(t+1))\| \\ &\quad\overset{\text{(i)}}{\leq} 2\|\mathbf{x}(t+1) - \mathbf{x}(t)\| \cdot \sum_{i=1}^p \left\|\Delta_\eta(\mathbf{x}^i(t)) - \Delta_\eta(\mathbf{x}^i(t+1))\right\| \\ &\quad\overset{\text{(ii)}}{\leq} 2\|\mathbf{x}(t+1) - \mathbf{x}(t)\| \left(\sum_{i=1}^p L_\eta\|\mathbf{x}^i(t) - \mathbf{x}^i(t+1)\|\right) \\ &\quad\overset{\text{(iii)}}{\leq} 2pL_\eta\|\mathbf{x}(t+1) - \mathbf{x}(t)\| \cdot \sum_{k=(t-s)_+}^t \|\mathbf{x}(k+1) - \mathbf{x}(k)\|,\end{aligned} \tag{63}$$

where (i) is due to Assumption 9 hence $t \in T_i$ for all t, (ii) follows from Assumption 10, and (iii) is due to (15).

If for some $r > 1$ there exists some T such that for all $t \geq T$,

$$\sum_{k=(t-s)_+}^t \|\mathbf{x}(k+1) - \mathbf{x}(k)\| \geq C\|\mathbf{x}(t+1) - \mathbf{x}(t)\|, \tag{64}$$

where $C = \frac{r^{s+1}-1}{r-1} > s+1$ (since $r > 1$ and w.l.o.g. $s > 0$). Summing the index t from T to n yields

$$C\sum_{t=T}^n \|\mathbf{x}(t+1) - \mathbf{x}(t)\| \leq \sum_{t=T}^n \sum_{k=(t-s)_+}^t \|\mathbf{x}(k+1) - \mathbf{x}(k)\|$$

$$\leq (s+1)\sum_{t=(T-s)_+}^{n}\|\mathbf{x}(t+1)-\mathbf{x}(t)\|,$$

which after rearranging terms becomes

$$(C-s-1)\sum_{t=T}^{n}\|\mathbf{x}(t+1)-\mathbf{x}(t)\| \leq (s+1)\sum_{t=(T-s)_+}^{T-1}\|\mathbf{x}(t+1)-\mathbf{x}(t)\|.$$

Since the right hand side does not depend on n, letting n tend to infinity we conclude

$$\sum_{t=0}^{\infty}\|\mathbf{x}(t+1)-\mathbf{x}(t)\|<\infty, \tag{65}$$

and the proof of the finite length property would be complete.

Therefore, in the remaining part of the proof, we can assume (64) fails for infinitely many t. Take any such $t=\hat{t}$, we have

$$\sum_{k=(t-s)_+}^{t}\|\mathbf{x}(k+1)-\mathbf{x}(k)\| \leq C\|\mathbf{x}(t+1)-\mathbf{x}(t)\| \leq C^2\|\mathbf{x}(t+1)-\mathbf{x}(t)\|, \tag{66}$$

since $C>1$. Combining (63) and (66) we have for $t=\hat{t}$:

$$\begin{aligned}\|\mathbf{x}(t+1)-\mathbf{x}(t)\|^2-\|\mathbf{x}(t+2)-\mathbf{x}(t+1)\|^2 &\leq 2pL_\eta C^2\|\mathbf{x}(t+1)-\mathbf{x}(t)\|^2\\ &\leq \left(1-\frac{1}{r^2}\right)\|\mathbf{x}(t+1)-\mathbf{x}(t)\|^2,\end{aligned}$$

if η is small enough (recall that $L_\eta=o(1)$). After rearranging terms we conclude that for $t=\hat{t}$:

$$\|\mathbf{x}(t+1)-\mathbf{x}(t)\| \leq r\|\mathbf{x}(t+2)-\mathbf{x}(t+1)\|. \tag{67}$$

Using induction we can continue the same process for any $t\geq\hat{t}$. Indeed, suppose (67) is true for any $t\leq m-1$, then (63) holds (for any t), and (66) also holds: If $m\leq\hat{t}+s$, then

$$\begin{aligned}\sum_{k=(m-s)_+}^{m}\|\mathbf{x}(k+1)-\mathbf{x}(k)\| &= \sum_{k=(m-s)_+}^{\hat{t}}\|\mathbf{x}(k+1)-\mathbf{x}(k)\|+\sum_{k=\hat{t}+1}^{m}\|\mathbf{x}(k+1)-\mathbf{x}(k)\|\\ &\overset{\text{(i)}}{\leq} \sum_{k=(\hat{t}-s)_+}^{\hat{t}}\|\mathbf{x}(k+1)-\mathbf{x}(k)\|+\sum_{k=\hat{t}+1}^{m}r^{m-k}\|\mathbf{x}(m+1)-\mathbf{x}(m)\|\\ &\overset{\text{(ii)}}{\leq} C\left[\|\mathbf{x}(\hat{t}+1)-\mathbf{x}(\hat{t})\|+\sum_{k=\hat{t}+1}^{m}r^{m-k}\|\mathbf{x}(m+1)-\mathbf{x}(m)\|\right]\\ &\overset{\text{(iii)}}{\leq} C\sum_{k=\hat{t}}^{m}r^{m-k}\|\mathbf{x}(m+1)-\mathbf{x}(m)\|\\ &\overset{\text{(iv)}}{\leq} C^2\|\mathbf{x}(m+1)-\mathbf{x}(m)\|,\end{aligned}$$

where (i) is due to the induction hypothesis, (ii) is due to the definition of $\hat{t}$ and the fact that $C>1$, (iii) is due to again the induction hypothesis, and finally (iv) is due to the definition of C (recall $m\leq\hat{t}+s$). If $m>\hat{t}+s$, the same inequality, with C^2 replaced by C, would still hold (essentially dropping all the first terms on the right hand side of the above inequalities). Thus, (63) and (66) would imply again (67) for $t=m$.

Lastly, we recall from eq. (22) that for large t,

$$\begin{aligned}F(\mathbf{x}(t+1))-F(\mathbf{x}(t)) &\leq \tfrac{1}{2}(L-1/\eta)\|\mathbf{x}(t+1)-\mathbf{x}(t)\|^2\\ &\quad+\sqrt{p}L\|\mathbf{x}(t+1)-\mathbf{x}(t)\|\sum_{k=(t-s)_+}^{t-1}\|\mathbf{x}(k+1)-\mathbf{x}(k)\|.\\ &\leq \tfrac{1}{2}(L-1/\eta)\|\mathbf{x}(t+1)-\mathbf{x}(t)\|^2+\sqrt{p}CL\|\mathbf{x}(t+1)-\mathbf{x}(t)\|^2.\\ &\leq -\alpha\|\mathbf{x}(t+1)-\mathbf{x}(t)\|^2,\end{aligned}$$

where $\alpha=\frac{1}{2}(1/\eta-L-2\sqrt{p}CL)>0$ if η is small. Hence, the sufficient decrease property in Assumption 8 is verified and the finite length properties follow from Theorem 11. ■

Lastly, we show that Assumption 10 also holds for the important cardinality function $\|\mathbf{x}\|_0$ (number of nonzero entries).

Lemma 14 *Consider the same setting as in Theorem 5, then Assumption 10 holds for any function f and $g=\|\cdot\|_0$ on all local sequences $\{\mathbf{x}^i(t)\}$ of m-PAPG.*

Proof The crucial observation here is that for the cardinality function $g=\|\cdot\|_0$, its proximal map on the j-th entry can be chosen as:

$$\text{prox}_{g_j}^{\eta}(z_j)=\begin{cases} z_j, \text{ if } |z_j|>\sqrt{2\eta}\\ 0, \text{ otherwise}\end{cases}. \tag{68}$$

However, Theorem 5 implies that $\lim_{t\to\infty}\|\mathbf{x}^i(t+1)-\mathbf{x}^i(t)\|=0$. Thus, for t sufficiently large, the sequence $\{\mathbf{x}^i(t)\}$ will have the same support Ω (indices that have nonzero entries), for otherwise $\|\mathbf{x}^i(t+1)-\mathbf{x}^i(t)\|\geq\sqrt{2\eta}$ even if one index in the support changes. Therefore,

$$\begin{aligned}\|\Delta_\eta(\mathbf{x}^i(t+1))-\Delta_\eta(\mathbf{x}^i(t))\| &\overset{\text{(i)}}{\leq} \sum_{j\in\Omega}\|\text{prox}_{g_j}^{\eta}(x_j^i(t+1)-\eta\nabla_j f(\mathbf{x}^i(t+1)))-x_j^i(t+1)\\ &\qquad-\text{prox}_{g_j}^{\eta}(x_j^i(t)-\eta\nabla_j f(\mathbf{x}^i(t)))-x_j^i(t)\|\\ &\overset{\text{(ii)}}{\leq} \sum_{j\in\Omega}\|\eta\nabla_j f(\mathbf{x}^i(t+1))-\eta\nabla_j f(\mathbf{x}^i(t))\|\\ &\overset{\text{(iii)}}{\leq} \eta pL\|\mathbf{x}^i(t+1)-\mathbf{x}^i(t)\|,\end{aligned}$$

where (i) is the triangle inequality, (ii) uses the property of the proximal map (68), and (iii) is due to Assumption 2. ■

Note that similar results as Theorem 14 can be derived for the rank function, and more generally for functions whose proximal map is discontinuous with pieces satisfying Theorem 12 (for instance, the group cardinality norm $\|\cdot\|_{0,2}$).

7. Economical Implementation for Linear Models

In this section, we provide an economical implementation of m-PAPG on a distributed system for the widely used linear models:

$$\min_{\mathbf{x}\in\mathbb{R}^d} f(A\mathbf{x}) + g(\mathbf{x}), \tag{69}$$

where $A \in \mathbb{R}^{n\times d}$ corresponds to the data matrix. Typically $f : \mathbb{R}^n \to \mathbb{R}$ is the likelihood function and $g : \mathbb{R}^d \to \mathbb{R}$ is the regularizer. The data matrix A consists of n sample points and we have suppressed the labels in classification or the responses in regression. Support vector machines (SVM), Lasso, logistic regression, boosting, etc., all fit under this framework. Our interest here is when the model dimension d is much higher than the number of samples n (d can be up to hundreds of millions and n can be up to millions). This is also the usual setup in many computational biology and health care problems.

A direct implementation of m-PAPG can be inefficient in terms of both network communication and parameter storage. First, each machine needs to communicate with every other machine to synchronize the model blocks. This leads to a peer-to-peer network topology and result in a dense connection when the system holds hundreds of machines. Second, each machine needs to keep a local copy of the full model (i.e. $\mathbf{x}^i(t)$), which incurs a high storage cost when the dimension is high. Note that the local models $\mathbf{x}^i(t)$ are kept solely for the convenience of evaluating the partial gradient $\nabla_i f : \mathbb{R}^d \to \mathbb{R}^{d_i}$. For some problems such as the Lasso, a seemingly workaround is to pre-compute the Hessian $H = A^\top A$ and distribute the corresponding row blocks of H to each worker machine. This scheme, however, is problematic in the high dimensional setting: the pre-computation of the Hessian can be very costly, and each row block of H has a very large size ($d_i \times d$).

The above issues can be avoided by exploiting the structure of the linear model in eq. (69) and adopting the parameter server distributed system Ho et al. (2013); Li et al. (2014). The system dedicates a central server to store the key parameters, and let each worker machine to communicate only with the server. To be specific, we partition the data matrix A into p *column* blocks $A = [A_1, \ldots, A_p]$ and distribute the block $A_i \in \mathbb{R}^{n\times d_i}$ to machine i Boyd et al. (2010); Richtárik and Takáč (to appear) . Note the local update computed by machine i at the t-th iteration is

$$U_i(\mathbf{x}^i(t)) = \mathrm{prox}^\eta_{g_i}\big(x_i(t) - \eta A_i^\top f'(A\mathbf{x}^i(t))\big) - x_i(t). \tag{70}$$

Since machine i is in charge of updating the i-th block $x_i(t)$ of the global model, it suffices to have the matrix-vector product $A\mathbf{x}^i(t)$ to compute the local update in eq. (70) . If we initialize $\forall i,\ \mathbf{x}^i(0) \equiv \mathbf{0}$, then $A\mathbf{x}^i(t)$ can be written in a cumulative form as

$$A\mathbf{x}^i(t) = \sum_{j=1}^p A_j[\mathbf{x}^i(t)]_j = \sum_{j=1}^p \sum_{k=0}^{\tau_j^i(t)} \underbrace{A_j \mathbb{I}_{\{k\in T_j\}} U_j(\mathbf{x}^j(k))}_{\Delta_j(k)},$$

where recall that machine i only has access to a delayed copy $x_j(\tau_j^i(t))$ of the parameters in machine j. Hence, to evaluate the matrix-vector product, every machine needs to accumulate $\Delta_j(k)$ over all machines upto a delayed clock. Thus, we aggregate $\Delta_j(t) \in \mathbb{R}^n$ on the parameter server whenever it is generated and sent by the worker machines. In details,

Algorithm 1 Economic Implementation of m-PAPG

For the server:
  while recieves update Δ_i from machine i **do**
    $\blacktriangle \leftarrow \blacktriangle + \Delta_i$
  end while
  while machine i sends a pull request **do**
    send $\blacktriangle$ to machine i
  end while
For machine i at active clock $t \in T_i$:
  pull $\blacktriangle$ from the server
  $U_i \leftarrow \mathrm{prox}^\eta_{g_i}(x_i - \eta A_i^\top f'(\blacktriangle)) - x_i$
  send $\Delta_i = A_i U_i$ to the server
  update $x_i \leftarrow x_i + U_i$

the worker machines first pull this matrix-vector product (denoted as $\blacktriangle$) from the server to conduct the local computation in eq. (70). Then machine i performs the local update:

$$x_i(t+1) = x_i(t) + U_i(\mathbf{x}^i(t)). \tag{71}$$

Note that machine i does not maintain or update other blocks of parameters $x_j(t), j \neq i$. Lastly, machine i computes and sends the vector $\Delta_i(t) = A_i U_i(\mathbf{x}^i(t)) \in \mathbb{R}^n$ to the server, and the server immediately performs the aggregation:

$$\blacktriangle \leftarrow \blacktriangle + \Delta_i(t). \tag{72}$$

We summarize the above economical implementation in Algorithm 1, where $\blacktriangle$ denotes the aggregated matrix-vector product. The storage cost for each worker machine is $O(nd_i)$ (for storing A_i only). Each iteration requires two matrix-vector products that cost $O(nd_i)$ in the dense case, and the communication of a length n vector between the server and the worker machines. Note that the cost is significantly lower than the direct implementation.

8. Experiments

In this section, we empirically verify the convergence properties and time efficiency of m-PAPG. All data are generated via normal distribution with the columns being normalized to have unit norm. We first test the convergence properties of m-PAPG via a non-convex Lasso problem with the group regularizer $\|\cdot\|_{0,2}$, which takes the form

$$\min_{\mathbf{x}\in\mathbb{R}^d}\ \tfrac{1}{2}\|A\mathbf{x} - \mathbf{b}\|^2 + \lambda\|\mathbf{x}\|_{0,2}, \tag{73}$$

where we set sample size $n = 1000$ and dimension size $d = 2000$, and the group norm divides the whole model into 20 groups with equal dimension. We use 4 machines (cores) with each handling five groups of coordinates, and consider maximal staleness $s = 0, 10, 20, 30$, respectively. To better demonstrate the effect of staleness, we let machines only communicate when exceed the maximum staleness. This can be viewed as the worst case communication scheme and a larger s brings more staleness into the system. We set the learning rate to

have the form $\eta(\alpha s) = 1/(L_f + 2L\alpha s), \alpha > 0$, that is, a linear dependency on staleness s as suggested by Theorem 5. Then we run Algorithm 1 with different staleness and use $\eta(0), \eta(10), \eta^*(\alpha s)$, respectively, where $\eta^*(\alpha s)$ is the largest step size we tuned for each s that achieves a stable convergence. We track the global model $\mathbf{x}(t)$ and plot the results in Figure 1. Note that with the large step size $\eta(0)$ all instances (with nonzero staleness) diverge hence are not presented. With $\eta(10)$ (Figure 1, left), the staleness does not substantially affect the convergence in terms of the objective value. We note that the objective curves converge to slightly different minimal values due to the non-convexity of problem (73). With $\eta^*(\alpha s)$ (Figure 1, middle), it can be observed that adding a slight penalty αs on the learning rate suffices to achieve a stable convergence, and the penalty grows as s increases, which is intuitive since a larger staleness requires a smaller step size to cancel the inconsistency. In particular, for $s = 10$ the best convergence is comparable to the bulk synchronized case $s = 0$. (Figure 1, right) further shows the asymptotic convergence behavior of the global model $\mathbf{x}(t)$ under the step size $\eta^*(\alpha s)$. It is clear that a linear convergence is eventually attained, which confirms the finite length property in Theorem 11.

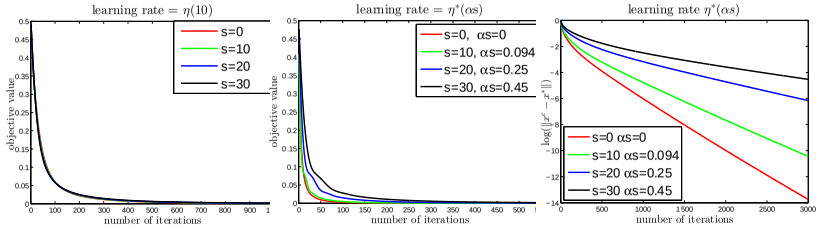

Figure 1: Convergence curves of m-PAPG under different staleness parameter s and step size η.

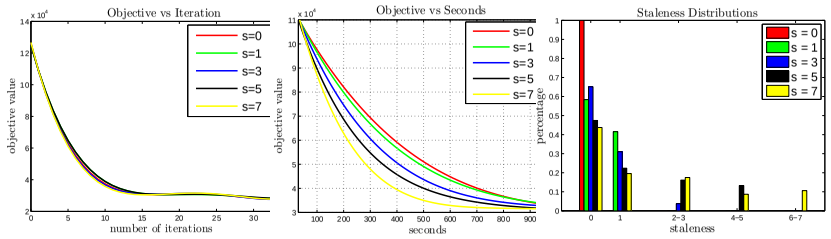

Figure 2: Efficiency of m-PAPG on a large scale Lasso problem.

Next, we verify the time and communication efficiency of m-PAPG via an l_1 regularized quadratic programming problem with very high dimensions, taking the form

$$\min_{\mathbf{x}} \ \tfrac{1}{2}\mathbf{x}^\top A^\top A\mathbf{x} + \lambda\|\mathbf{x}\|_1. \tag{74}$$

We generate samples of size $n = 1$Million and dimension $d = 100$Millions. We implement Algorithm 1 on Petuum Ho et al. (2013); Dai et al. (2014) — a stale synchronous parallel system which updates the local parameter caches via stale synchronous communications. The system contains 100 computing nodes and each is equipped with 16 AMD Opteron processors and 16GB RAM linked by 1Gbps ethernet. We fix the learning rate $\eta = 10^{-3}$ and consider maximum staleness $s = 0, 1, 3, 5, 7$, respectively. (Figure 2, left) shows that per-iteration progress is virtually indistinguishable among various staleness settings, which is consistent with our previous experiment. (Figure 2, middle) shows that system throughput is significantly higher when we introduce staleness. This is due to lower synchronization overheads, which offsets any potential loss due to staleness in progress per iteration. We also track the distributions of staleness during the experiments, where we record in ▲ the clocks of the freshest updates that accumulate from all the machines. Then whenever a machine pulls ▲ from the server, it compares its local clock with these clocks and records the clock differences. (Figure 2, right) shows the distributions of staleness under different maximal staleness settings. Observe that bulk synchronous ($s = 0$) peaks at staleness 0 by design, and the distribution concentrates in small staleness area due to the eager communication mechanism of Petuum. It can be seen that a small amount of staleness is sufficient to relax the communication bottlenecks without affecting the iterative convergence rate much.

9. Conclusion

We have proposed m-PAPG as an extension of the proximal gradient algorithm to the model parallel and partially asynchronous setting. m-PAPG allows worker machines to operate asynchronously as long as they are not too far apart, hence greatly improves the system throughput. The convergence properties of m-PAPG are thoroughly analyzed. In particular, we proved that: 1) every limit point of the sequences generated by m-PAPG is a critical point of the objective function; 2) under an additional error bound condition, the function values decay periodically linearly; 3) under the additional Kurdyka-Łojasiewicz inequality, the sequences generated by m-PAPG converge to the same critical point, provided that a proximal Lipschitz condition is satisfied. In the future we plan to further weaken the proximal Lipschitz condition so that our analysis can handle many more nonsmooth functions.

Refining the Confidence Level for Optimistic Bandit Strategies

Editor: Peter Auer

Abstract

This paper introduces the first strategy for stochastic bandits with unit variance Gaussian noise that is simultaneously minimax optimal up to constant factors, asymptotically optimal, and never worse than the classical upper confidence bound strategy up to universal constant factors. Preliminary empirical evidence is also promising. Besides this, a conjecture on the optimal form of the regret is shown to be false and a finite-time lower bound on the regret of any strategy is presented that very nearly matches the finite-time upper bound of the newly proposed strategy.

Keywords Stochastic bandits, sequential decision making, regret minimisation.

1. Introduction

Let $k > 1$ be the number of bandits (or arms) and $\mu \in \mathbb{R}^k$ be the unknown vector of mean payoffs so that $\mu_i \in \mathbb{R}$ is the expected payoff when playing the ith bandit (or arm). In each round $t \in [n] = \{1, 2, \ldots, n\}$ the player chooses an arm $A_t \in [k]$ based on past observations and (optionally) an independent source of randomness. After making her choice, the player observes a payoff $X_t = \mu_{A_t} + \eta_t$ where $\eta_1, \eta_2, \ldots, \eta_n$ is a sequence of independent standard Gaussian random variables. It is standard to minimise the expected pseudo-regret (from now on, just the regret). Let $\Delta_i(\mu) = \max_j \mu_j - \mu_i$ be the suboptimality gap for the ith arm. The regret over n rounds is

$$\mathcal{R}_n(\mu) = \mathbb{E}\left[\sum_{t=1}^{n} \Delta_{A_t}(\mu)\right] .$$

Because the regret depends on the unknown payoff vector, no strategy can hope to make the regret small for all μ simultaneously. There are a number of performance metrics in the literature, two of which are described below along with a new one. To spoil the surprise, the strategy introduced in the present article is simultaneously optimal with respect to all of them.

Worst-case optimality The *worst-case* regret of a strategy is the value of the regret it suffers when faced with the worst possible μ.

$$\mathcal{R}_n^{\text{WC}} = \sup_{\mu \in \mathbb{R}^k : \Delta(\mu) \in [0,1]^k} \mathcal{R}_n(\mu) .$$

The restriction to bounded suboptimality gaps is necessary to allow an algorithm to choose each arm at least once without suffering arbitrarily large regret. Generally problems with small suboptimality gaps are the most interesting. Provided that $n \geq k$ it is known that all algorithms suffer $\mathcal{R}_n^{\text{WC}} = \Omega(\sqrt{kn})$ (Auer et al., 1995).

Asymptotic optimality The worst-case regret obscures interesting structure in the problem that becomes relevant in practice. This motivates the study of a problem-dependent metric, which demands that strategies have smaller regret on 'easier' bandit instances. A strategy is called *asymptotically optimal* if

$$\lim_{n\to\infty} \frac{\mathcal{R}_n(\mu)}{\log(n)} = \sum_{i:\Delta_i(\mu)>0} \frac{2}{\Delta_i(\mu)} \qquad \text{for all } \mu \in \mathbb{R}^d .$$

The name is justified by the existence of policies satisfying the definition and lower bounds by Lai and Robbins (1985) and Burnetas and Katehakis (1996) showing that consistent policies (those with sub-polynomial regret on all μ) cannot do better.

The sub-UCB criteria While asymptotic analysis is quite insightful, the ultimate quantity of interest is the finite-time regret. To make a stab at quantifying this I say an algorithm is sub-UCB if there exist universal constants $C_1, C_2 > 0$ such that for all k, n and μ it holds that

$$\mathcal{R}_n(\mu) \leq C_1 \sum_{i=1}^{k} \Delta_i(\mu) + C_2 \sum_{i:\Delta_i(\mu)>0} \frac{\log(n)}{\Delta_i(\mu)} . \tag{1}$$

Of course UCB (Auer et al., 2002) satisfies Eq. (1), along with many other policies as shown in Table 2 in Appendix E, which outlines the long history of algorithms for stochastic finite-armed bandits. The study of this new metric can be justified in several ways. First, it provides a forgiving finite-time analogue of asymptotic optimality. Lai and Robbins (1985) derived asymptotic optimality by making a restriction on policies (the consistent ones). Consistency is an asymptotic notion, so it is not surprising that the resulting lower bound is also asymptotic. The sub-UCB notion is suggested by making a finite-time restriction on the worst case regret. Precisely, for any strategy the finite-time instance-dependent regret can be bounded in terms of the worst case regret by

$$\mathcal{R}_n(\mu) \geq \sup_{\varepsilon \in (0,1]} \sum_{i:\Delta_i(\mu)>0} \max\left\{0, \frac{2\log\left(\frac{n}{\mathcal{R}_n^{\text{WC}}}\right) + 2\log\left(\frac{\varepsilon\Delta_i(\mu)}{8}\right)}{(1+\varepsilon)\Delta_i(\mu)}\right\} \tag{2}$$

for all μ with $\max_i \Delta_i(\mu) \leq 1/2$ (Lattimore and Szepesvári, 2018). This means that if you demand a reasonable worst case bound, then the instance-dependent regret cannot be *much* better than sub-UCB. Note that the first sum in Eq. (1) is unavoidable for policies that always choose each arm at least once, which is also necessary for any algorithm to have reasonable worst case regret. The finite-time world is not as clean as the asymptotic and it is not easy to decide how tight Eq. (2) might be, which justifies the additional constant-factor allowance in Eq. (1) and the removal of the (typically negative) second logarithm term. The second justification for using Eq. (1) as a yardstick is that it is forgiving and yet recent policies that are minimax optimal up to constant factors do not satisfy it. One of the core contributions of this article is to correct these deficiencies. Note that Eq. (2) depends quite weakly on the worst case regret and is meaningful as long as $\mathcal{R}_n^{\text{WC}} = O(n^p)$ for p not too close to 1.

None of these criteria are perfect by themselves. Asymptotic optimality is achievable by policies with outrageous burn-in time and/or large minimax regret, minimax optimal policies may be unreasonably conservative on easy problems and sub-UCB policies may be far from asymptotically optimal.

Contributions The main contribution is a new strategy called ADA-UCB ('adaptive UCB') and analysis showing it is asymptotically optimal, minimax optimal and sub-UCB. No other algorithm is simultaneously minimax optimal and sub-UCB (see Table 2). Results are specialised to the Gaussian case with unit variance, but upper bounds can be generalised to subgaussian noise with known subgaussian constant at the price of increased constants (without losing asymptotic optimality) and longer proofs. The latter justifies the specialisation because it allows for an elegant concentration analysis via an embedding of Gaussian random walks into Brownian motion. Also included:

(a) Finite-time lower bounds showing the new strategy is close to optimal.

(b) A conjecture by Bubeck and Cesa-Bianchi (2012) is proven false.

(c) A generic analysis for a large class of strategies simplifying the analysis for existing strategies.

Beyond the concrete results, the approach used for deriving ADA-UCB by examining lower bounds will likely generalise to other noise models, and indeed, other sequential optimisation problems with an exploration/exploitation flavour. The contents of this article combines the best parts of two technical reports with improved results, intuition and analysis (Lattimore, 2015a, 2016b).

Notation For natural number n let $[n] = \{1, 2, \ldots, n\}$. Binary minimums and maximums are abbreviated by $\wedge$ and $\vee$ respectively. The complement of event A is A^c. Except where otherwise stated, it is assumed without loss of generality that $\mu_1 \geq \mu_2 \geq \ldots \geq \mu_k$. None of the proposed strategies depend on the labelling of the arms, so if this is not the case the indices can simply be re-ordered. The dependence of the suboptimality gap on the mean vector will usually be omitted when the context is clear: $\Delta_i = \Delta_i(\mu) = \max_j \mu_j - \mu_i$. Occasionally it is convenient to define $\mu_{k+1} = -\infty$ and $\Delta_{k+1} = \infty$. Let $T_i(t) = \sum_{s=1}^{t} \mathbb{1}_{\{A_s = i\}}$ be the number of times arm i has been chosen after round t and $\hat{\mu}_i(t) = \sum_{s=1}^{t} \mathbb{1}_{\{A_s=i\}} X_s / T_i(t)$ be the corresponding empirical estimate of its return. Let $\hat{\mu}_{i,s}$ be the empirical estimate of the mean of arm i after s samples from that arm so that $\hat{\mu}_{i,T_i(t)} = \hat{\mu}_i(t)$. Define σ-algebra $\mathcal{F}_t = \sigma(\xi, X_1, \ldots, X_t)$ to contain the information available to the strategy after round t, where ξ is an independent source of randomness that allows for randomness in the strategy. This means that formally a strategy is a sequence of random variables $(A_t)_t$ such that A_t is $\mathcal{F}_{t-1}$-measurable. It is assumed throughout that $n \geq k$. Finally, let $\overline{\log}(x) = \log((x+e)\log^{1/2}(x+e))$. A table of notation is available in Table 3 in the appendix.

2. The strategy

The ADA-UCB strategy chooses each arm once in arbitrary order for the first k rounds and subsequently $A_t = \arg\max_{i \in [k]} \gamma_i(t)$ where the index of arm i in round t is:

$$\gamma_i(t) = \hat{\mu}_i(t-1) + \sqrt{\frac{2}{T_i(t-1)} \overline{\log}\left(\frac{n}{H_i(t-1)}\right)},$$

$$\text{with} \quad H_i(t) = T_i(t) K_i(t) \quad \text{and} \quad K_i(t) = \sum_{j=1}^{k} \min\left\{1, \sqrt{\frac{T_j(t)}{T_i(t)}}\right\}.$$

At first sight the new index seems overly complicated. After the statement of the main regret guarantee I show how the strategy is derived in a principled fashion from *lower bounds* obtained

from information theoretic limits of the problem. Similar approaches have been used before, for example, by Agrawal et al. (1989) for reinforcement learning, and by Garivier and Kaufmann (2016) for pure exploration in bandits. One interesting consequence of this approach is that ADA-UCB is not a true index strategy in the sense that $\gamma_i(t)$ depends on random variables associated with other arms. An intriguing open question is whether or not there exists an index strategy for which all three performance criteria are met. A minor observation is that it is not clear whether or not a true index strategy should be allowed to depend on t or just on $n - t$ and the samples from the given arm.

Relation to other algorithms The index is the same as that used by Katehakis and Robbins (1995) except that $\log(t)$ has been replaced by $\overline{\log}(n/H_i(t-1))$. The change from $\log(\cdot)$ to $\overline{\log}(\cdot)$ is quite minor. Such inflations of the logarithmic term are typical for algorithms with finite-time guarantees. The main difference between ADA-UCB and previous work is the term inside the logarithm, often called the confidence level. The most common choice is the current round t, which is used by various versions of UCB, KL-UCB and BAYES-UCB (Katehakis and Robbins, 1995; Burnetas and Katehakis, 1996; Agrawal, 1995; Auer et al., 2002; Kaufmann et al., 2012; Cappé et al., 2013). Already in the early work by Lai (1987) there appeared an unnamed variant of UCB for which the confidence level was $n/T_i(t-1)$. Due to its similarity to KL-UCB (Cappé et al., 2013) this algorithm will be called KL-UCB* from now on. A variety of other choices have been used as shown in Table 1.

majority	t
Lai (1987)	n/T_i
Honda and Takemura (2010)	t/T_i
Audibert and Bubeck (2009)	$n/(kT_i)$
Degenne and Perchet (2016)	$t/(kT_i)$
Lattimore (2015a)	n/t

Table 1: Confidence levels

Computation A naive implementation of ADA-UCB requires a computation time that is quadratic in the number of arms in each round. Fortunately an incremental implementation leads to an algorithm with linear computation time by noting that:

(a) If $T_i(t-1) \leq T_{A_t}(t-1)$, then $\gamma_i(t+1) = \gamma_i(t)$.

(b) For arms i with $T_i(t-1) > T_{A_t}(t-1)$ the value of $K_i(t-1)$ may be computed incrementally by $K_i(t) = K_i(t-1) - \sqrt{(T_{A_t}(t)-1)/T_i(t)} + \sqrt{T_{A_t}(t)/T_i(t)}$.

(c) The index of A_t can be computed trivially in order k time.

The algorithm follows by maintaining a list of arms sorted by $T_i(t)$ and applying the above observations to incrementally update the indices. If all details are addressed carefully, then the computation required in round t is $O(\sum_{i=1}^{k} \mathbb{1}\{T_i(t-1) \geq T_{A_t}(t-1)\})$, which in the worst case is $O(k)$, but can be much smaller when a single arm is played significantly more often than any other.

Regret bound The theorem statement has a more complicated form than previous regret bounds for finite-armed bandits, mainly because it correctly deals with the case where there are many near-optimal arms that cannot be statistically identified within the time horizon. Define k_i and λ_i by

$$k_i = \sum_{j=1}^{k} \min\left\{1, \frac{\Delta_i}{\Delta_j}\right\} \qquad \text{and} \qquad \lambda_i = 1 + \frac{1}{\Delta_i^2} \overline{\log}\left(\frac{n\Delta_i^2}{k_i}\right).$$

The main theorem is below, which gives the best known finite-time guarantee for any strategy, as well as all three optimality criteria defined in the introduction.

Theorem 1 *Assume that $\mu_1 \geq \mu_2 \geq \cdots \geq \mu_k$. Then there exists a universal constant $C > 0$ such that the regret of* ADA-UCB *is bounded by*

$$\mathcal{R}_n(\mu) \leq C \min_{i \in [k]} \left(n\bar{\Delta}_i + \sum_{m>i} \Delta_m \lambda_m \right), \qquad \text{where } \bar{\Delta}_i = \frac{1}{i} \sum_{m=1}^{i} \Delta_m . \tag{3}$$

Furthermore:

(a) ADA-UCB *is minimax optimal up to constant factors: $\mathcal{R}_n^{\text{wc}} \leq C' \sqrt{kn}$.*

(b) ADA-UCB *is sub-UCB: $\mathcal{R}_n(\mu) \leq C \sum_{m:\Delta_m>0} \left(\Delta_m + \frac{\log(n)}{\Delta_m} \right)$.*

(c) ADA-UCB *is asymptotically optimal: $\lim_{n\to\infty} \frac{\mathcal{R}_n(\mu)}{\log(n)} = \sum_{i:\Delta_i>0} \frac{2}{\Delta_i}$.*

Remark 2 *The assumption on the order of the arms is purely for cosmetic purposes. The algorithm does not need this ordering and treats all arms symmetrically.*

Intuition for bound and strategy Let $\mu \in [0,1]^k$ and i be a suboptimal arm so that $\Delta_i = \Delta_i(\mu) > 0$. Set $\mu' \in [0,2]^k$ equal to μ except for $\mu'_i = \mu_i + 2\Delta_i$, which means that arm i has the largest mean for the bandit determined by μ'. Provided that n is sufficiently large, a sub-UCB strategy should play arm i logarithmically often if the mean payoff vector is μ, and linearly often for μ'. Let $\mathbb{E}$ and $\mathbb{E}'$ and $\mathbb{P}$ and $\mathbb{P}'$ denote the measures on the outcomes $A_1, X_1, \ldots, A_n, X_n$ when the strategy interacts with the bandits determined by μ and μ' respectively. Let $\delta \in (0,1]$ be such that

$$\mathbb{E}[T_i(n)] = \frac{2\log(1/\delta)}{(2\Delta_i)^2} . \tag{4}$$

Since μ and μ' are only different in the ith coordinate, the problem of minimising the regret is essentially equivalent to a hypothesis test on the mean of the ith arm, which satisfies $|\mu'_i - \mu_i| = 2\Delta_i$. Using this idea, a standard information-theoretic argument (see the section on lower bounds for formal details) shows that $\mathbb{P}'(T_i(n) \leq n/2) \gtrsim \delta$. Abbreviate $\Delta'_i = \Delta_i(\mu')$. Since $\Delta'_j = \mu'_i - \mu'_j \geq \Delta_i$ for all $j \neq i$ it holds that

$$\mathcal{R}_n(\mu') \geq \frac{n\Delta_i}{2} \mathbb{P}'(T_i(n) \leq n/2) \gtrsim n\Delta_i \delta/2 . \tag{5}$$

Assuming the strategy is sub-UCB, then there exists a (hopefully small) constant $C > 0$ such that

$$\mathcal{R}_n(\mu') \leq C \sum_{j:\Delta'_j>0} \left(\Delta'_j + \frac{\log(n)}{\Delta'_j} \right) \approx C \sum_{j:\Delta'_j>0} \frac{\log(n)}{\Delta'_j} , \tag{6}$$

where the approximation follows because $\Delta'_j \in [0,2]$ has been assumed. By Eqs. (5) and (6):

$$\delta \lesssim \frac{2C\log(n)}{n\Delta_i} \sum_{j:\Delta'_j>0} \frac{1}{\Delta'_j} = \frac{2C\log(n)}{n\Delta_i^2} \sum_{j\neq i} \frac{\Delta_i}{\Delta_j + \Delta_i} \leq \frac{2Ck_i \log(n)}{n\Delta_i^2} .$$

The regret guarantee given in Theorem 1 is now justified up to constant factors and an extraneous additive $\log\log(\cdot)$ term by substituting the above display into Eq. (4) and writing the regret as $\mathcal{R}_n(\mu) = \sum_{i=1}^k \Delta_i \mathbb{E}[T_i(n)]$. The idea behind ADA-UCB is to use the approximation $\Delta_i^{-2} \approx T_i(t-1)$. The approximation is poor when t is small, but becomes reasonable at the critical time when arm i should no longer be played. Specifically, if $T_i(t-1) \approx \Delta_i^{-2}$, then we should expect $T_j(t-1) \approx \min\{T_i(t-1), \Delta_j^{-2}\} \approx \min\{\Delta_i^{-2}, \Delta_j^{-2}\}$. Then

$$\frac{n}{H_i(t-1)} = \frac{n}{\sum_{j=1}^k \min\left\{T_i(t-1), \sqrt{T_i(t-1)T_j(t-1)}\right\}} \approx \frac{n}{\sum_{j=1}^k \min\left\{\frac{1}{\Delta_i^2}, \frac{1}{\Delta_i\Delta_j}\right\}} = \frac{n\Delta_i^2}{k_i} .$$

The implication is that the index dynamically tunes its confidence level using the pull counts to loosely estimate the gaps. The ideas in this section are made formal in the proof of Theorem 1 or the lower bound (§5).

3. Asymptotic analysis

The primary purpose of this section is to prove part (c) of Theorem 1. Along the way, a finite-time regret bound for a whole class of strategies is derived, including slightly modified versions of KL-UCB* (Lai, 1987) and the MOSS (**M**inimax **O**ptimal in the **S**tochastic **S**etting, Audibert and Bubeck 2009). The analysis leads to an optimal worst-case analysis of MOSS and KL-UCB*, but not ADA-UCB. The following theorem holds for the class of index strategies that choose $A_t = t$ for $1 \leq t \leq k$ and subsequently maximise

$$\gamma_i(t) = \hat{\mu}_i(t-1) + \sqrt{\frac{2}{T_i(t-1)} \overline{\log}\left(\frac{n}{J_i(t-1)T_i(t-1)} \right)} , \tag{7}$$

where $J_i(t-1)$ is $\mathcal{F}_{t-1}$-measurable and $J_i(t-1) \in [a,b]$ almost surely for constants $0 < a \leq b$. Except for minor differences in the leading constant and the logarithmic term, this index is the same as MOSS if $J_i(t-1) = k$, KL-UCB* if $J_i(t-1) = 1$ and ADA-UCB if $J_i(t-1) = K_i(t-1)$.

Theorem 3 *For any $\varepsilon \in (0, 1/2)$ and $1 \leq \ell \leq k$, the regret of the strategy in Eq. (7) is at most*

$$\mathcal{R}_n(\mu) \leq n\Delta_\ell + \frac{2c_1 b}{\varepsilon^2 \Delta_{\ell+1}} + \sum_{i>\ell} \left(2\Delta_i + \frac{1}{\Delta_i} \left(1 + \frac{1}{\varepsilon^2} + \frac{2\,\overline{\log}\left(\frac{n\Delta_i^2}{a}\right)}{(1-2\varepsilon)^2} \right) \right) .$$

Furthermore:

(a) $\lim_{n\to\infty} \mathcal{R}_n(\mu)/\log(n) = \sum_{i:\Delta_i>0} \frac{2}{\Delta_i}$.

(b) If $b \leq k$, then $\mathcal{R}_n^{\text{wc}} \leq C\sqrt{nk\left(1 + \log\left(\frac{k}{a}\right)\right)}$ where $C > 0$ is a universal constant.

Before the proof a little more notation is required. For each i and $\Delta > 0$ let $\zeta_i(\Delta)$ be a random variable given by

$$\zeta_i(\Delta) = 1 + \max\{s : \hat{\mu}_{i,s} > \mu_i + \Delta\} . \tag{8}$$

Clearly, $\zeta_i(\Delta)$ is surely monotone non-increasing in Δ and may be upper bounded in expectation using Lemma 13 in the appendix.

Proof [of Theorem 3] Let $\Delta \in \mathbb{R}$ be the smallest value such that

$$\hat{\mu}_{1,s} + \sqrt{\frac{2}{s}\overline{\log}\left(\frac{n}{bs}\right)} \leq \mu_1 - \Delta \qquad \text{for all } 1 \leq s \leq n\,,$$

which is chosen so that $\gamma_1(t) \geq \mu_1 - \Delta$ for all t. By part (a) of Lemma 12 with $\alpha = n/b$ and $d = 1$ and $\lambda_1 = \infty$ we have for any $x > 0$ that

$$\mathbb{P}\left(\Delta \geq x\right) \leq \frac{c_1 b h_\lambda(1/x^2)}{n} = \frac{c_1 b}{n x^2}\,. \tag{9}$$

Define random variable

$$\Lambda_i = 1 + \max\left\{\frac{1}{\Delta_i^2},\, \zeta_i(\varepsilon\Delta_i),\, \frac{2}{(1-2\varepsilon)^2\Delta_i^2}\overline{\log}\left(\frac{n\Delta_i^2}{a}\right)\right\}\,.$$

The definitions of the policy, Λ_i and Δ ensure that if $\Delta_i > \Delta/\varepsilon$, then $T_i(n) \leq \Lambda_i$ and by Lemma 13,

$$\mathbb{E}[\Lambda_i] \leq 2 + \frac{1}{\Delta_i^2}\left(1 + \frac{1}{\varepsilon^2} + \frac{2\overline{\log}\left(\frac{n\Delta_i^2}{a}\right)}{(1-2\varepsilon)^2}\right)\,. \tag{10}$$

Hence the regret of the strategy maximising the index in Eq. (7) is

$$\begin{aligned}
\mathcal{R}_n(\mu) &= \mathbb{E}\left[\sum_{i=1}^k \Delta_i T_i(n)\right] \\
&= \mathbb{E}\left[\sum_{i=1}^{\ell} \Delta_i T_i(n)\right] + \mathbb{E}\left[\sum_{i=\ell+1}^{k} \mathbb{1}\left\{\Delta_i \leq \frac{\Delta}{\varepsilon}\right\}\Delta_i T_i(n)\right] + \mathbb{E}\left[\sum_{i=\ell+1}^{k} \mathbb{1}\left\{\Delta_i > \frac{\Delta}{\varepsilon}\right\}\Delta_i T_i(n)\right] \\
&\leq n\Delta_\ell + \mathbb{E}\left[\frac{n\Delta}{\varepsilon}\mathbb{1}\left\{\Delta \geq \varepsilon\Delta_{\ell+1}\right\}\right] + \sum_{i>\ell}\Delta_i\mathbb{E}\left[\Lambda_i\right]\,.
\end{aligned} \tag{11}$$

The last expectation in Eq. (11) is bounded using Eq. (10),

$$\sum_{i>\ell}\Delta_i\mathbb{E}\left[\Lambda_i\right] \leq \sum_{i>\ell}\left(2\Delta_i + \frac{1}{\Delta_i}\left(1 + \frac{1}{\varepsilon^2} + \frac{2\overline{\log}\left(\frac{n\Delta_i^2}{a}\right)}{(1-2\varepsilon)^2}\right)\right)\,. \tag{12}$$

Given an arbitrary random variable X and constant $b \in \mathbb{R}$ it holds that

$$\mathbb{E}[X] \leq b\mathbb{P}\left(X \geq b\right) + \int_b^\infty \mathbb{P}\left(X \geq x\right)dx\,.$$

The first expectation in Eq. (11) is bounded by combining the above display with Eq. (9),

$$\begin{aligned}
\frac{n}{\varepsilon}\mathbb{E}\left[\Delta\mathbb{1}\left\{\Delta \geq \varepsilon\Delta_{\ell+1}\right\}\right] &\leq n\Delta_{\ell+1}\mathbb{P}\left(\Delta \geq \varepsilon\Delta_{\ell+1}\right) + \frac{n}{\varepsilon}\int_{\varepsilon\Delta_{\ell+1}}^\infty \mathbb{P}\left(\Delta \geq x\right)dx \\
&\leq \frac{c_1 b}{\varepsilon^2\Delta_{\ell+1}} + \frac{c_1 b}{\varepsilon}\int_{\varepsilon\Delta_{\ell+1}}^\infty \frac{dx}{x^2} = \frac{2c_1 b}{\varepsilon^2\Delta_{\ell+1}}\,,
\end{aligned}$$

which together with Eq. (12) and Eq. (11) completes the proof of the first part. The asymptotic result follows by choosing $\ell = \max\{i : \Delta_i = 0\}$ and $\varepsilon = \log^{-1/4}(n)$. The equality follows by the lower bound of Lai and Robbins (1985). The worst-case bound follows by choosing $\varepsilon = 1/4$ and tuning the cut-off ℓ. ■

The failure of MOSS Notice that if $J_i(t-1) = k$, then $a = b = k$ and except for a smaller inflated logarithm the resulting policy is the same as the variant proposed by Ménard and Garivier (2017). The troublesome term in the regret is the second term, which when $\ell = 1$ is approximately k/Δ_2. By contrast, for more conservative strategies this term is approximately $1/\Delta_2$, which is negligible. An especially challenging regime is when $\Delta_2 = 1/k$ and $\Delta_i = 1$ for $i > 2$. Suppose now that $n = k^3$ and k is large, then the regret of UCB on this problem should be

$$\mathcal{R}_n = O\left(k\log(k)\right)\,.$$

For MOSS, however, the regret on this problem is $\Omega(\sqrt{nk}) = \Omega(k^2)$, which for large k is arbitrarily worse than UCB. A vague explanation of the poor performance is that although there are k arms, all but two of them are so suboptimal that *effectively* it is a two-armed bandit. And yet MOSS is heavily tuned for the k-armed case and suffers as a consequence. A more precise argument is that distinguishing the first and second arms requires $T_2(t) \approx T_1(t) \approx 1/\Delta_2^2 = k^2$. But after playing these arms roughly k^2 times each the confidence level is $n/(kT_i(t)) \approx 1$ and the likelihood of misidentification is large enough that the regret is $\Omega(n\Delta_2) = \Omega(k^2) = \Omega(\sqrt{nk})$. Note that for ADA-UCB we would expect $K_i(t) \approx 2$ and the confidence level is approximately $n/k^2 = k$, which is exactly as large as necessary.

Remark 4 *An empirical study in this problem was given in a previous technical report (Lattimore, 2015a). In practice the failure does not become extreme until k is very large (approximately 1000).*

4. Finite-time analysis

In this section the remainder of Theorem 1 is proven. The argument is quite long, but never terribly complicated. The main novel challenge is to deal with the dependence of the index of one arm on the number of plays of other arms. The usual program for analysing strategies based on upper confidence bounds has two parts:

(a) Show that with high probability the index of the optimal arm is never much smaller than its mean.

(b) Show that the index of each suboptimal arm drops below the mean of the optimal arm after not too many plays with high probability.

The proof starts with (b), the main component of which is showing for suboptimal arms i that $H_i(t)$ grows at a reasonable rate. As discussed, this means showing that other arms are played sufficiently often. The following definitions spell out *which* arms will be played reasonably often. For each arm i

define a deterministic set of arms $V_i \subset [k]$ and random subset $W_i \subseteq V_i$ by

$$V_i = \{j \in [k] : j \text{ is even or } j \geq i\} \ . \tag{13}$$

$$W_i = \{i\} \cup \left\{ j \in V_i : \min_{1 \leq s \leq \Delta_i^{-2}} \hat{\mu}_{j,s} + \sqrt{\frac{2}{s} \log\left(\frac{n\Delta_i}{k_i \sqrt{s}}\right)} - \sqrt{\frac{2}{s}} \geq \mu_j \right\} \ . \tag{14}$$

The set W_i is a subset of V_i that includes arm i and those arms for which the empirical mean is always nearly as large as the true mean. We'll soon see that arms $j \in W_i$ will be played sufficiently often to ensure that $H_i(t)$ grows at the right rate. The exclusion of odd arms with $j < i$ from V_i is for technical reasons. In order to show that arm i is not played too often we need to show that its index drops sufficiently fast and that the index of some other arm is sufficiently large. The separation of the arms allows us to exploit the independence between the arms. Those arms not in V_i will be used to show that some index is large enough. Define

$$\delta_i = c_2 \sqrt{\frac{k_i}{n\Delta_i^2}} \qquad \text{and} \qquad \ell = \max\{i : \delta_i > 1/4\} \ . \tag{15}$$

It is shown in Lemma 21 in the appendix that there exists a universal constant $C > 0$ such that ℓ satisfies

$$n\bar{\Delta}_\ell + \sum_{m>\ell} \lambda_m \Delta_m \leq C \min_{i \in [k]} \left(n\bar{\Delta}_i + \sum_{m>i} \Delta_m \lambda_m \right) \ , \tag{16}$$

and so the rest of the proof is devoted to bounding the regret of ADA-UCB in terms of the left-hand-side of Eq. (16). Define F_i to be the event that the 'mass' of W_i is sufficiently large.

$$F_i = \mathbb{1}\left\{ \sum_{m \in W_i} \min\{1, \Delta_i/\Delta_m\} \geq k_i/8 \right\} \ . \tag{17}$$

Recall that $k_i = \sum_{m=1}^k \min\{1, \Delta_i/\Delta_m\}$. So F_i holds if the sum over the restricted set W_i is at most a factor of 8 smaller. The point is that if $j \in V_i$, then Lemma 12 implies $\mathbb{P}(j \notin W_i) \leq \delta_i \leq 1/4$. Later this will be combined with Hoeffding's bound to show that F_i occurs with high probability. And now the lemmas begin. First up is to show that arms $j \in W_i$ are played sufficiently often relative to arm i. This will then be used to show that $H_i(t)$ grows at the right rate, which leads to the conclusion of the proof of part (b) in the outline in Lemma 7.

Lemma 5 *If $A_t = i$ and $H_i(t-1) \leq k_i/\Delta_i^2$ and $T_i(t-1) \geq \zeta_i(\Delta_i) \vee 1/\Delta_i^2$, then for all $j \in W_i$,*

$$T_j(t-1) \geq \min\left\{ \frac{1}{2\Delta_j^2}, \frac{T_i(t-1)}{4\log\left(\frac{n}{H_i(t-1)}\right)} \right\} \ .$$

Proof If $i = j$ or $T_j(t-1) \geq T_i(t-1)$ or $T_j(t-1) \geq 1/(2\Delta_j^2)$, then we are done, so assume from now on that none of these are true.

$$\begin{aligned} \frac{k_i}{\Delta_i^2} \geq H_i(t-1) &= \sqrt{T_j(t-1)} \sum_{m=1}^k \min\left\{ \frac{T_i(t-1)}{\sqrt{T_j(t-1)}}, \sqrt{\frac{T_i(t-1)T_m(t-1)}{T_j(t-1)}} \right\} \\ &\geq \frac{\sqrt{T_j(t-1)}}{\Delta_i} \sum_{m=1}^k \min\left\{1, \sqrt{\frac{T_m(t-1)}{T_j(t-1)}}\right\} = \sqrt{T_j(t-1)} \frac{K_j(t-1)}{\Delta_i} \ , \end{aligned} \tag{18}$$

where the first inequality is assumed in the lemma statement and the second because $T_i(t-1) \geq T_j(t-1) \vee (1/\Delta_i^2)$. Therefore if $j \in W_i$, then

$$\begin{aligned} \mu_1 + \sqrt{\frac{2}{T_i(t-1)} \log\left(\frac{n}{H_i(t-1)}\right)} &\geq \hat{\mu}_i(t-1) + \sqrt{\frac{2}{T_i(t-1)} \log\left(\frac{n}{H_i(t-1)}\right)} \\ &= \gamma_i(t) \geq \gamma_j(t) = \hat{\mu}_j(t-1) + \sqrt{\frac{2}{T_j(t-1)} \log\left(\frac{n}{T_j(t-1)K_j(t-1)}\right)} \\ &\geq \hat{\mu}_j(t-1) + \sqrt{\frac{2}{T_j(t-1)} \log\left(\frac{n\Delta_i}{k_i\sqrt{T_j(t-1)}}\right)} \\ &\geq \mu_j + \sqrt{\frac{2}{T_j(t-1)}} \geq \mu_1 + \sqrt{\frac{1}{2T_j(t-1)}} \end{aligned} \tag{19}$$

where the first inequality follows from the assumption that $T_i(t-1) \geq \zeta_i(\Delta_i)$, which ensures that $\mu_1 = \mu_i + \Delta_i \geq \hat{\mu}_i(t-1)$. The second follows from Eq. (18). The inequalities in Eq. (19) from the definition of $j \in W_i$ and the assumption that $T_j(t-1) \geq 1/(2\Delta_j^2)$. Therefore

$$T_j(t-1) \geq \frac{T_i(t-1)}{4\log\left(\frac{n}{H_i(t-1)}\right)} \ . \qquad \blacksquare$$

The next lemma uses the previous result to show that if W_i is large enough (F_i holds), then $H_i(t-1)$ is reasonably large at the critical point when $T_i(t-1) \approx 1/\Delta_i^2$.

Lemma 6 *If F_i holds and $T_i(t-1) \geq \zeta_i(\Delta_i) \vee 128/\Delta_i^2$ and $A_t = i$, then*

$$\log\left(\frac{n}{H_i(t-1)}\right) \leq 2\log\left(\frac{n\Delta_i^2}{k_i}\right) \ .$$

Proof If $H_i(t-1) > k_i/\Delta_i^2$, then there is nothing more to do. Otherwise, by Lemma 5

$$\begin{aligned} H_i(t-1) &= \sum_{m=1}^k \min\left\{T_i(t-1), \sqrt{T_i(t-1)T_m(t-1)}\right\} \\ &\geq \sum_{m \in W_i} \min\left\{T_i(t-1), \sqrt{T_i(t-1)T_m(t-1)}\right\} \\ &\geq \sum_{m \in W_i} \min\left\{ T_i(t-1), \frac{T_i(t-1)}{2\log^{\frac{1}{2}}\left(\frac{n}{H_i(t-1)}\right)}, \frac{\sqrt{T_i(t-1)/2}}{\Delta_m} \right\} \qquad (20) \\ &\geq \frac{8\sum_{m \in W_i} \min\left\{\frac{1}{\Delta_i^2}, \frac{1}{\Delta_i\Delta_m}\right\}}{\log^{\frac{1}{2}}\left(\frac{n}{H_i(t-1)}\right)} \geq \frac{k_i}{\Delta_i^2 \log^{\frac{1}{2}}\left(\frac{n}{H_i(t-1)}\right)} \ , \qquad (21) \end{aligned}$$

where Eq. (20) follows from Lemma 5. The first inequality in Eq. (21) follows because $\log(x) \geq 1$ and the assumption $T_i(t-1) \geq 128/\Delta_i^2$, and the second because F_i holds. The result follows via

re-arrangement and some algebraic trickery with the $\overline{\log}(\cdot)$ function using Part (v) of Lemma 20 in the appendix. ■

For each arm i define random variable Λ_i that will be shown to be a high probability bound on $T_i(n)$ and approximately equal to λ_i in expectation.

$$\Lambda_i = 1 + \max\left\{\frac{128}{\Delta_i^2},\ \zeta_i(\Delta_i/3),\ \frac{36}{\Delta_i^2}\,\overline{\log}\left(\frac{n\Delta_i^2}{k_i}\right),\ \frac{18\mathbb{1}_{\{F_i^c\}}}{\Delta_i^2}\,\overline{\log}\left(n\Delta_i^2\right)\right\},$$

where $\zeta_i(\cdot)$ is defined in Eq. (8). The next lemma is a simple consequence of the previous two and shows that if $T_i(t-1)+1 \geq \Lambda_i$, then either arm i is not played or its index is smaller than the mean of the optimal arm by a margin of at least $\Delta_i/3$.

Lemma 7 *If $T_i(t-1)+1 \geq \Lambda_i$, then either $A_t \neq i$ or $\gamma_i(t) \leq \mu_1 - \Delta_i/3$.*

Proof If F_i does not occur, then $H_i(t-1) \geq T_i(t-1) \geq 1/\Delta_i^2$ and so

$$\gamma_i(t) = \hat{\mu}_i(t-1) + \sqrt{\frac{2\,\overline{\log}\left(\frac{n}{H_i(t-1)}\right)}{T_i(t-1)}} \leq \mu_i + \frac{\Delta_i}{3} + \sqrt{\frac{2\,\overline{\log}\left(n\Delta_i^2\right)}{T_i(t-1)}} \leq \mu_1 - \frac{\Delta_i}{3},$$

where the first inequality follows because $T_i(t-1)+1 \geq \Lambda_i \geq 1 + \zeta_i(\Delta_i/3)$ and the second because $H_i(t-1) = T_i(t-1)K_i(t-1) \geq T_i(t-1) \geq 1/\Delta_i^2$ and the definition of Λ_i and because $\mu_i + \Delta_i/3 = \mu_1 - 2\Delta_i/3$. Next suppose that F_i occurs, then either $A_t \neq i$ and the result is true, or $A_t = i$ and so by Lemma 6

$$\gamma_i(t) = \hat{\mu}_i(t-1) + \sqrt{\frac{2\,\overline{\log}\left(\frac{n}{H_i(t-1)}\right)}{T_i(t-1)}} \leq \mu_i + \frac{\Delta_i}{3} + \sqrt{\frac{4\,\overline{\log}\left(\frac{n\Delta_i^2}{k_i}\right)}{T_i(t-1)}} \leq \mu_1 - \frac{\Delta_i}{3}. \qquad ■$$

This essentially completes the first part of the proof by showing that if $T_i(t-1)+1 \geq \Lambda_i$, then arm i is either not played or its index is not too large. The next step is to show that with reasonable probability there is some near-optimal arm for which the index is big enough to prevent arm i from being played. The value of Λ_i has been carefully chosen to bound the number of times arm i can be played provided the index of some other arm is always larger than $\mu_1 - \Delta_i/3$. But more than this, Λ_i does not depend on the rewards for odd-index arms $j < i$ so is measurable with respect to the σ-algebra $\sigma(\hat{\mu}_{j,s} : j \in V_i, 1 \leq s \leq n)$. Define random variable $I \in [k]$ to be the arm with the largest mean such that there exists an odd $j < I+1$ with $\Delta_j \leq \Delta_{I+1}/6$ and

$$\min_{1\leq s\leq n} \hat{\mu}_{j,s} + \sqrt{\frac{2}{s}\,\overline{\log}\left(\frac{n}{sI + \sum_{m>I}\min\left\{s, \sqrt{s\Lambda_m}\right\}}\right)} > \mu_j - \frac{\Delta_{I+1}}{6}. \tag{22}$$

The definition of I implies that arms $i > I$ will not be played once their index drops far enough below the mean of the optimal arm. We should hope that I is small with reasonably high probability, with the best case being $I = 1$, which occurs when the optimal arm is always optimistic. Notice that I is well-defined because of the convention that $\Delta_{k+1} = \infty$. Let E_1 be the event that $I \leq \ell$, where ℓ is given in Eq. (15).

Lemma 8 *The regret of* ADA-UCB *is bounded by*

$$\mathcal{R}_n(\mu) \leq \mathbb{E}\left[\sum_{i>\ell}\Delta_i\Lambda_i\right] + n\mathbb{E}\left[\mathbb{1}_{\{E_1^c\}}\Delta_I\right] + \mathbb{E}\left[\mathbb{1}_{\{E_1\}}\sum_{i=1}^{\ell}\Delta_i T_i(n)\right].$$

Proof The first task is to show that $T_i(n) < \Lambda_i$ for all $i > I$, which follows by induction over rounds $k+1 \leq t \leq n$. Starting with the base case, note that when $t = k+1$ we have $T_i(t-1) = 1 < \Lambda_i$ for all i. Now suppose for $t \geq k+1$ that $T_i(t-1) < \Lambda_i$ for all $i > I$. By the definition of I there must exist an odd j with $\Delta_j \leq \Delta_{I+1}/6$ that satisfies Eq. (22). For this arm we have

$$\begin{aligned} H_j(t-1) &= \sum_{m=1}^{k}\min\left\{T_j(t-1), \sqrt{T_j(t-1)T_m(t-1)}\right\} \\ &< T_j(t-1)I + \sum_{m>I}\min\left\{T_j(t-1), \sqrt{T_j(t-1)\Lambda_m}\right\}. \end{aligned}$$

Therefore

$$\gamma_j(t) = \hat{\mu}_j(t-1) + \sqrt{\frac{2}{T_j(t-1)}\,\overline{\log}\left(\frac{n}{H_j(t-1)}\right)} > \mu_j - \Delta_{I+1}/6 \geq \mu_1 - \Delta_{I+1}/3.$$

It follows that if $i > I$ and $T_i(t-1)+1 \geq \Lambda_i$, then Lemma 7 implies $A_t \neq i$. Therefore $T_i(t) < \Lambda_i$ for all $i > I$, which completes the induction. Finally, since $\sum_{i=1}^k T_i(n) = n$ and using the definition of E_1 as the event that $I \leq \ell$, the regret may be bounded by

$$\mathcal{R}_n(\mu) = \mathbb{E}\left[\sum_{i=1}^{k}\Delta_i T_i(n)\right] \leq \mathbb{E}\left[\sum_{i>\ell}\Delta_i\Lambda_i\right] + n\mathbb{E}[\mathbb{1}_{\{E_1^c\}}\Delta_I] + \mathbb{E}\left[\mathbb{1}_{\{E_1\}}\sum_{i=1}^{\ell}\Delta_i T_i(n)\right]. \qquad ■$$

The last step in the proof of Theorem 1 is to bound each of the expectations in Lemma 8.

Lemma 9 *There exists a universal $C > 0$ such that:*

$$\textit{(i)}\ \ \mathbb{E}\left[\sum_{i>\ell}\Delta_i\Lambda_i\right] \leq C\sum_{i>\ell}\Delta_i\lambda_i \qquad \textit{(ii)}\ \ \mathbb{E}[\mathbb{1}_{\{E_1^c\}}\Delta_I] \leq C\left(n\bar{\Delta}_\ell + \sum_{i>\ell}\Delta_i\lambda_i\right)$$

$$\textit{(iii)}\ \ \mathbb{E}\left[\mathbb{1}_{\{E_1\}}\sum_{i=1}^{\ell}\Delta_i T_i(n)\right] \leq C\left(n\bar{\Delta}_\ell + \sum_{i>\ell}\Delta_i\lambda_i\right).$$

The proof of part *(i)* follows shortly. The proof of part *(ii)* is deferred to Appendix B. Very briefly, it follows somewhat directly from part (a) of Lemma 12 (notice the similarity between the lemma and Eq. (22) that defines Δ_I). Part *(iii)* would be trivial if one assumed that $\mathbb{E}[T_i(n)]$ is monotone non-increasing in i. This seems likely, but despite significant effort I was only able to show that this is approximately true using a complicated proof (details are in Appendix C).

Proof [of Lemma 9 (*i*)] The proof follows by bounding $\mathbb{E}[\Lambda_i]$ for each arm $i > \ell$. Naively bounding the max in the definition of Λ_i by a sum shows that

$$\mathbb{E}[\Lambda_i] \leq 1 + \frac{128}{\Delta_i^2} + \frac{36}{\Delta_i^2}\,\overline{\log}\left(\frac{n\Delta_i^2}{k_i}\right) + \mathbb{E}\left[\zeta_i\left(\frac{\Delta_i}{3}\right)\right] + \frac{18\mathbb{P}\left(F_i^c\right)}{\Delta_i^2}\,\overline{\log}\left(n\Delta_i^2\right). \tag{23}$$

The first three terms are non-random. The second last term is bounded using Lemma 13 by $\mathbb{E}[\zeta_i(\Delta_i/3)] \leq 1 + 18/\Delta_i^2$. For the last term we need to upper bound $\mathbb{P}(F_i^c)$, where F_i is the event defined in Eq. (17). In order to do this we need to show that W_i is reasonably large with high probability. Let $\chi_j = \mathbb{1}\{j \notin W_i\}$, which for $j \in V_i$ satisfies $\mathbb{E}[\chi_j] \leq \delta_i \leq 1/4$. Then

$$\mathbb{P}(F_i^c) = \mathbb{P}\left(\sum_{j \in W_i} \min\left\{1, \frac{\Delta_i}{\Delta_j}\right\} < \frac{k_i}{8}\right) \leq \mathbb{P}\left(\sum_{j \in V_i} (\chi_j - \mathbb{E}[\chi_j]) \min\left\{1, \frac{\Delta_i}{\Delta_j}\right\} > \frac{k_i}{4}\right)$$
$$\leq \exp\left(-\frac{k_i^2}{8\sum_{j \in V_i} \min\left\{1, \frac{\Delta_i}{\Delta_j}\right\}^2}\right) \leq \exp\left(-\frac{k_i}{8}\right),$$

where the first inequality follows from the facts that $\mathbb{E}[\chi_j] \leq 1/4$ and $\sum_{j \in V_i} \min\{1, \Delta_i/\Delta_j\} \geq k_i/2$ and the second inequality follows from Hoeffding's bound and the fact that χ_j are independent for $j \in V_i$. Therefore

$$\mathbb{P}(F_i^c)\,\overline{\log}\left(n\Delta_i^2\right) \leq \overline{\log}\left(n\Delta_i^2\right)\exp\left(-k_i/8\right) \leq 4\,\overline{\log}\left(\frac{n\Delta_i^2}{k_i}\right),$$

which holds because $k_i \geq 2$ is guaranteed for all suboptimal arms i. The proof is completed by substituting the above display into Eq. (23) and using the definition of $\lambda_i = 1 + \frac{1}{\Delta_i^2}\,\overline{\log}\left(\frac{n\Delta_i^2}{k_i}\right)$. ■

Proof [of Theorem 1] The finite-time bound Eq. (3) follows by substituting the bounds given in Lemma 9 into Lemma 8 and Eq. (16). Minimax and sub-UCB results are derived as corollaries of the finite-time bound Eq. (3) via Parts (iii) and (iv) of Lemma 21 in the appendix. The asymptotic analysis has been given already in §3. ■

5. A lower bound

I now formalise the intuitive argument for the regret guarantee given in §2. The results show that in a certain sense the upper bound in Theorem 1 is very close to optimal. The following lower bound holds for all strategies, but does not give a lower bound for all μ simultaneously. Related results have been proven by a variety of authors (Kulkarni and Lugosi, 2000; Bubeck et al., 2013; Salomon et al., 2013; Lattimore, 2015b), with the most related by Garivier et al. (2016b). The most significant difference between that work and the present article is that the lower-order terms are more carefully considered here, and besides this, the assumptions, and so also results, are different.

Theorem 10 *Fix a strategy and let $\mu \in \mathbb{R}^k$ be such that $n\Delta_i^2 \geq 2k_i \log(n)$ and $\Delta_i \leq 1$ for all i with $\Delta_i > 0$. Then one of the following holds:*

(a) $\mathcal{R}_n(\mu) \geq \frac{1}{2}\sum_{i:\Delta_i>0} \frac{1}{\Delta_i}\log\left(\frac{n\Delta_i^2}{2k_i\log(n)}\right)$.

(b) There exists a $\mu' \in \mathbb{R}^k$ and i with $\Delta_i > 0$ such that $\mathcal{R}_n(\mu') \geq \frac{1}{4}\sum_{i:\Delta_i'>0} \frac{1}{\Delta_i'}\log(n)$,

where $\mu_i' = \mu_i + 2\Delta_i$ and $\mu_j' = \mu_j$ for $j \neq i$ and $\Delta_i' = \Delta_i(\mu')$.

Proof Suppose that (a) does not hold, then there exists a suboptimal arm i such that

$$\mathbb{E}[T_i(n)] \leq \frac{1}{2\Delta_i^2}\log\left(\frac{n\Delta_i^2}{2k_i\log(n)}\right). \tag{24}$$

Let μ' be as defined in the second part of the lemma and write $\mathbb{P}'$ and $\mathbb{E}'$ for expectation when rewards are sampled from μ'. Then by Lemmas 18 and 19 in Appendix D we have

$$\mathbb{P}(T_i(n) \geq n/2) + \mathbb{P}'(T_i(n) < n/2) \geq \frac{k_i\log(n)}{n\Delta_i^2} \triangleq 2\delta.$$

By Markov's inequality and Eq. (24) and the fact that $k_i \geq 2$,

$$\mathbb{P}(T_i(n) \geq n/2) \leq \frac{2\mathbb{E}[T_i(n)]}{n} \leq \frac{1}{n\Delta_i^2}\log\left(\frac{n\Delta_i^2}{2k_i\log(n)}\right) \leq \frac{k_i\log(n)}{2n\Delta_i^2} = \delta.$$

Therefore $\mathbb{P}'(T_i(n) < n/2) \geq \delta$, which implies that

$$\mathcal{R}_n(\mu') \geq \frac{\delta n\Delta_i}{2} = \frac{1}{4}\sum_{j=1}^{k} \min\left\{\frac{1}{\Delta_i}, \frac{1}{\Delta_j}\right\}\log(n) \geq \frac{1}{4}\sum_{j:\Delta_j'>0}\frac{1}{\Delta_j'}\log(n).$$ ■

A conjecture is false It was conjectured by Bubeck and Cesa-Bianchi (2012) that the optimal regret might have approximately the following form.

$$\mathcal{R}_n(\mu) \leq C\sum_{i:\Delta_i>0}\left(\Delta_i + \frac{1}{\Delta_i}\,\overline{\log}\left(\frac{n}{H}\right)\right) \qquad \text{for all } \mu \text{ and } n \text{ and } k, \tag{25}$$

where $C > 0$ is a universal constant and $H = \sum_{i:\Delta_i>0}\Delta_i^{-2}$ is a quantity that appears in the best-arm identification literature (Bubeck et al., 2009; Audibert and Bubeck, 2010; Jamieson et al., 2014).

Theorem 11 *There does not exist a strategy for which Eq.* (25) *holds.*

Proof Let $k \geq 2$ and $\mu_1 = 0$ and $\mu_2 = -1/k$ and $\mu_i = -1$ for $i > 2$, which implies that $H = k^2 + k - 2 \geq n$. For the rest of the proof we view the horizon $n = k^2$ to be a function of k. Suppose that $\mathcal{R}_n(\mu) = o(k\log k)$, which must be true for any strategy witnessing Eq. (25). Then $\min_{i>2}\mathbb{E}[T_i(n)] = o(\log k)$. Let $i = \arg\min_{i>2}\mathbb{E}[T_i(n)]$ and define μ' to be equal to μ except for the ith coordinate, which has $\mu_i' = 1$. Let A be the event that $T_i(n) \geq n/2$ and let $\mathbb{P}$ and $\mathbb{P}'$ be measures on the space of outcomes induced by the interaction between the fixed strategy and the bandits determined by μ and μ' respectively. Then for all $\varepsilon > 0$,

$$\mathcal{R}_n(\mu) + \mathcal{R}_n(\mu') \geq \frac{n}{2}\left(\mathbb{P}(A) + \mathbb{P}'(A^c)\right) \geq \frac{n}{4}\exp\left(-\operatorname{KL}(\mathbb{P}, \mathbb{P}')\right)$$
$$= \frac{k^2}{4}\exp\left(-2\mathbb{E}[T_i(n)]\right) = \omega(k^{2-\varepsilon}),$$

By the assumption on $\mathcal{R}_n(\mu)$ and for suitably small ε we have $\mathcal{R}_n(\mu') = \omega(k^{2-\varepsilon})$. But as the number of arms $k \to \infty$ (and so also the horizon), this cannot be true for any policy satisfying Eq. (25), or even Eq. (1). Therefore the conjecture is not true. ■

6. Empirical evaluation

ADA-UCB is compared to UCB (Katehakis and Robbins, 1995), MOSS (Ménard and Garivier, 2017), THOMPSON SAMPLING (Agrawal and Goyal, 2012) and IMED (Honda and Takemura, 2015),[1] where the reference indicates the source of the algorithm. All algorithms choose each arm once and subsequently:

$$A_t^{\text{IMED}} = \arg\min_{i\in[k]} \frac{T_i(t-1)}{2}(\hat{\mu}_i(t-1) - \max_{j\in[k]} \hat{\mu}_j(t-1))^2 + \log(T_i(t-1))\,.$$

$$A_t^{\text{UCB}} = \arg\max_{i\in[k]} \hat{\mu}_i(t-1) + \sqrt{\frac{2\log(t)}{T_i(t-1)}}\,.$$

$$A_t^{\text{MOSS}} = \arg\max_{i\in[k]} \hat{\mu}_i(t-1) + \sqrt{\frac{2}{T_i(t-1)}\log_+\left(\frac{n}{kT_i(t-1)}\log_+^2\left(1+\frac{n}{kT_i(t-1)}\right)\right)}\,.$$

$$A_t^{\text{TS}} = \arg\max_{i\in[k]} \theta_i(t) \qquad \text{with } \theta_i(t) \sim \mathcal{N}(\hat{\mu}_i(t-1), 1/T_i(t-1))\,.$$

The logarithmic term used by Ménard and Garivier (2017) in their version of MOSS is larger than $\overline{\log}(\cdot)$ and this negatively affects its performance. If the variant proposed in Section 3 is used instead, then it becomes comparable to ADA-UCB on the experiments described below, but still fails on the computationally expensive experiment given in the previous technical report (Lattimore, 2015a). For all other algorithms I have chosen the variant for which (a) guarantees exist and (b) the empirical performance is best. In all plots N indicates the number of independent samples per data point and confidence bands are calculated at a 95% level. The first three plots in Figure 1 show the regret in the worst case regime where all suboptimal arms have the same suboptimality gap. Unsurprisingly the relative advantage of policies with well-tuned confidence levels increases with the number of arms. At its worst, UCB suffers about three times the regret of ADA-UCB. Coincidentally, $\sqrt{\log(10^4)} \approx 3.03$. Figure 2 shows the regret as a function of the horizon n on a fixed bandit with $k = 20$ arms (see caption of figure for means). The regret of ADA-UCB is again a little better than the alternatives.

7. Discussion

Anytime strategies The ADA-UCB strategy depends on the horizon n, which may sometimes be unknown. The natural idea is to replace n by t, which indeed leads to a reasonable strategy that enjoys the same guarantees as ADA-UCB provided the $\overline{\log}(\cdot)$ function is replaced by something fractionally larger. The analysis, however, is significantly longer and is not included. Interested readers may refer to the technical report (Lattimore, 2016b) for the core ideas, but more work is required to find a clean proof.

Multiple optimal arms The finite-time bound in Theorem 1 is the first that demonstrates an improvement when there are multiple (near-)optimal arms. The gain in terms of the expected regret is not very large because k_i (which grows as optimal arms are added) appears only in the denominator of the logarithm. There is, however, a more significant advantage when there are many optimal arms, which (up to a point) is an exponential decrease in the variance of most strategies. This can be

1. IMED is usually defined for bandits where the rewards have (semi-)bounded support, but Junya Honda kindly provided unpublished details of the adaptation to the Gaussian case.

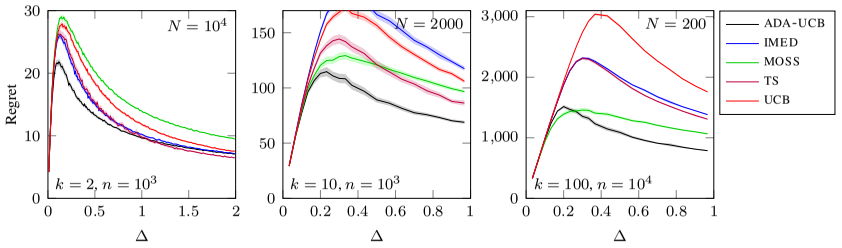

Figure 1: The regret of various algorithms as a function of Δ when $\mu = (\Delta, 0, \ldots, 0)$ and the number of arms is 2, 10 and 100 respectively. The y-axis shows the regret averaged over N independent samples for each data point.

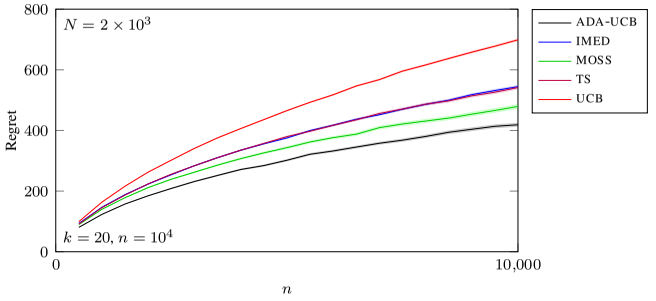

Figure 2: The regret of various algorithms as a function of the horizon for the Gaussian bandit with $k = 20$ arms and payoff vector $\mu = (0, -0.03, -0.03, -0.07, -0.07, -0.07, -0.15, -0.15, -0.15, -0.5, -0.5, -0.5, -0.5, -0.5, -0.5, -0.5, -0.5, -0.5, -1, -1)$. ADA-UCB is again outperforming the competitors. Note that IMED and THOMPSON SAMPLING are so similar they cannot be distinguished in the plot.

extracted from the analysis by observing that the high variance is caused by the possibility that an optimal arm is not sufficiently optimistic, but the probability of this occurring drops exponentially as the number of optimal arms increases.

Alternative noise models and other extensions The most obvious open question is how to generalise the results to a broader class of noise models and setups. I am quite hopeful that this is possible for noise from exponential families, though the analysis will necessarily become more complicated because the divergences become more cumbersome to work with than the squared distance that is the divergence in the Gaussian case. An alternative direction is to consider the

situation where the variance is also unknown, which has seen surprisingly little attention, but is now understood reasonably well (Honda and Takemura, 2014; Cowan et al., 2015). At the very least, the concentration analysis using Brownian motion could be applied, but I expect an adaptive confidence level will also yield theoretical and practical improvements. Another potential application of the ideas presented here would be to try and port them into other bandit strategies that depend on a confidence level such as BAYES-UCB (Kaufmann, 2016), or even linear bandits (Dani et al., 2008; Abbasi-Yadkori et al., 2011; Lattimore and Szepesvari, 2017).

Appendix A. Boundary crossing for Gaussian random walks

Let $Z_1, Z_2, \ldots$ be an infinite sequence of independent standard Gaussian random variables and $S_n = \sum_{t=1}^{n} Z_t$. The proof of Theorem 1 relies on a precise understanding of the behaviour of the random walk $(S_n)_n$. More specifically, what is the hitting probability that S_n ever crosses above a carefully chosen concave boundary. The following lemma is an easy consequence of the elegant analysis of boundary crossing probabilities for Brownian motion by Lerche (1986).

Lemma 12 *Let $d \in \{1, 2, \ldots\}$ and $\Delta > 0$, $\alpha > 0$, $\lambda \in [0, \infty]^d$ and $h_\lambda(t) = \sum_{i=1}^{d} \min\{t, \sqrt{t\lambda_i}\}$, then there exist constants $c_1 = 4$ and $c_2 = 12$ such that*

(a) $\mathbb{P}\left(\text{exists } t \geq 0 : S_t \geq \sqrt{2t \log\left(\frac{\alpha}{h_\lambda(t)}\right)} + t\Delta\right) \leq \frac{c_1 h_\lambda(1/\Delta^2)}{\alpha}$.

(b) $\mathbb{P}\left(\text{exists } t \leq \frac{1}{\Delta^2} : S_t \geq \sqrt{2t \log\left(\frac{\alpha}{t^{1/2}}\right)} - \sqrt{2t}\right) \leq \frac{c_2}{\sqrt{\alpha}\Delta}$.

The second lemma is a bound on the expected number of samples required before the empirical mean after t samples is close to its true value. The result is relatively standard in the literature, except that here the proofs are simplified by using the properties of Brownian motion.

Lemma 13 *If $\Delta > 0$ and $\zeta = 1 + \max\left\{t : \frac{S_t}{t} \geq \Delta\right\}$, then $\mathbb{E}[\zeta] \leq 1 + \frac{2}{\Delta^2}$.*

Subgaussian case A common relaxation of the Gaussian noise assumption is to assume the noise is 1-subgaussian, which means the reward X_t is chosen so that $\mathbb{E}[\exp(c(X_t - \mu_{A_t})) \mid \mathcal{F}_{t-1}] \leq \exp(c^2/2)$ almost surely for all $c \in \mathbb{R}$. Brownian motion cannot be used to analyse this situation, but Lemma 12 can still be proven for martingale subgaussian noise using the peeling trick on a carefully optimised grid (as used by Garivier (2013) and others). Besides a messier proof, the price is that the $\overline{\log}$ function must be increased slightly (but not so much that Theorem 1 needs to change). Lemma 13 is also easily adapted to the subgaussian setting. The only other lemma that needs modification is Lemma 15 in the appendix, which has the same flavour as Lemma 12 and is adaptable via a peeling trick.

The tangent approximation The connection to Brownian motion is made by noting the discrete time random walk S_t can be embedded in Brownian motion, which means that if B_t is a standard Brownian motion, then for any function $f : \mathbb{R} \to \mathbb{R}$ we have $\mathbb{P}(\text{exists } n \geq 0 : S_n \geq f(n)) \leq \mathbb{P}(\text{exists } n \geq 0 : B_n \geq f(n))$. The main tool of the analysis is called the tangent approximation, which was developed in a beautiful book by Lerche (1986) and is summarised in the following lemma.

Lemma 14 (§3 of Lerche (1986)) *Let $f : \mathbb{R} \to \mathbb{R}$ be a concave function with $f(x) \geq 0$ for all $x \geq 0$ and $\Lambda(t) = f(t) - tf'(t)$ be the intersection of the tangent to f at t with the y-axis, where if f is non-differentiable, then f' denotes any 'super-derivative' (gradient such that the tangent does not intersect the curve). Then*

$$\mathbb{P}\left(\textit{exists } t \geq 0 : B_t \geq f(t)\right) \leq \int_0^\infty \frac{\Lambda(t)}{\sqrt{2\pi t^3}} \exp\left(-\frac{f(t)^2}{2t}\right) dt\,.$$

Proof [of Lemma 12] Let B_t be a standard Brownian motion. Each part of the lemma will follow by analysing the probability that the Brownian motion hits the relevant boundary. For the first part let $f(t) = \sqrt{2t\,\overline{\log}(\alpha/h_\lambda(t))}$, which by simple calculus is monotone non-decreasing. Therefore the intersection of the tangent to $f(t) + t\Delta$ at t with the y-axis is $\Lambda(t) = f(t) - tf'(t) \leq f(t)$. By the tangent approximation:

$$\mathbb{P}(\exists t \geq 0 : B_t \geq f(t)) \leq \int_0^\infty \frac{f(t)}{\sqrt{2\pi t^3}} \exp\left(-\frac{(f(t)+t\Delta)^2}{2t}\right) dt \leq \int_0^\infty \frac{3h_\lambda(t)}{2\alpha\sqrt{\pi t}} \exp\left(-\frac{t\Delta^2}{2}\right) dt\,,$$

where the first inequality follows from Lemma 14 and the second from (iv) of Lemma 20 and since for positive $x, y \geq 0$ it holds that $(x+y)^2 \geq x^2 + y^2$.

$$\begin{aligned}
\int_0^\infty \frac{h_\lambda(t)}{t} \exp\left(-\frac{t\Delta^2}{2}\right) dt &= \sum_{i=1}^d \int_0^\infty \min\left\{1, \sqrt{\lambda_i/t}\right\} \exp\left(-\frac{t\Delta^2}{2}\right) dt \\
&= \sum_{i=1}^d \left(\frac{2 - 2\exp\left(-\frac{\lambda_i\Delta^2}{2}\right)}{\Delta^2} + \frac{\sqrt{2\pi\lambda_i}}{\Delta} \operatorname{erfc}\left(\Delta\sqrt{\frac{\lambda_i}{2}}\right)\right) \\
&\leq \sum_{i=1}^d \min\left\{ \frac{2+\sqrt{\pi}}{\Delta^2}, (1+\sqrt{2\pi})\frac{\sqrt{\lambda_i}}{\Delta} \right\} \leq (2+\sqrt{\pi}) h_\lambda(1/\Delta^2)\,,
\end{aligned}$$

where first inequality follows from the fact that $1 - e^{-x} \leq x$ and $\operatorname{erfc}(x) \leq \min\{1, 1/(2x)\}$. The result is completed by naively bounding the constants. For the second part, let $f(t) = \sqrt{2t\,\overline{\log}(\alpha/t^{1/2})} - \sqrt{2t}$, which is concave and monotone non-decreasing so that $\Lambda(t) = f(t) - tf'(t) \leq f(t)$. By Lemma 14,

$$\begin{aligned}
\mathbb{P}\left(\exists t \leq \frac{1}{\Delta^2} : B_t \geq \sqrt{2t\,\overline{\log}\left(\frac{\alpha}{s^{1/2}}\right)} - \sqrt{2t}\right) &\leq \int_0^{\frac{1}{\Delta^2}} \frac{f(t)}{\sqrt{2\pi t^3}} \exp\left(-\frac{f(t)^2}{2t}\right) dt \\
&\leq \int_0^{\frac{1}{\Delta^2}} \sqrt{\frac{\overline{\log}(\alpha/t^{1/2})}{\pi t^2}} \exp\left(-1 - \overline{\log}\left(\frac{\alpha}{t^{1/2}}\right) + 2\sqrt{\overline{\log}\left(\frac{\alpha}{t^{1/2}}\right)}\right) dt \\
&\leq \int_0^{\frac{1}{\Delta^2}} \frac{5dt}{\sqrt{\pi}\alpha^{1/2}t^{3/4}} \leq \frac{12}{\sqrt{\alpha\Delta}}\,,
\end{aligned}$$

where the second last inequality follows from part (vi) of Lemma 20. ■

Proof [of Lemma 13] The time inversion formula and reflection principle will imply the result (Hida, 1980, for example). Let B_s be a standard Brownian motion. Then for $t > 0$ we have

$$\mathbb{P}(\text{exists } s \geq t : B_s/s \geq \Delta) = \mathbb{P}(\text{exists } s \leq 1/t : B_s \geq \Delta) = 2\mathbb{P}\left(B_{1/t} \geq \Delta\right) \leq \exp\left(-\frac{t\Delta^2}{2}\right)\,,$$

where the first equality follows from the time inversion formula and the second from the reflection principle. The inequality is a standard Gaussian tail bound (Boucheron et al., 2013, Chap. 2). Therefore $\mathbb{E}[\zeta] \leq 1 + \int_0^\infty \exp(-t\Delta^2/2)dt = 1 + \frac{2}{\Delta^2}$, where the additive constant is due to the embedding of the discrete random walk in the continuous Brownian motion. ■

Appendix B. Proof of Lemma 9 *(ii)*

Some of the steps in this proof are simplified by using $C > 0$ for a universal positive constant that occasionally has a different value from one equation to the next. When these changes occur they are indicated by the $\overset{\times}{\leq}$ symbol. Let $i \in [k]$ and $j \notin V_i$ be such that $\Delta_j \leq \Delta_i/6$. By part (a) of Lemma 12,

$$\mathbb{P}\left(\min_{1\leq t\leq n} \gamma_j(t) \leq \mu_j - \frac{\Delta_i}{6}\Big|\Lambda_i, \ldots, \Lambda_k\right) \leq \frac{36c_1}{n}\left(\frac{i-1}{\Delta_i^2} + \sum_{m\geq i}\frac{\sqrt{\Lambda_m}}{\Delta_i}\right)\,.$$

It is important to note here that Lemma 12 could only be applied to control the conditional probability above because the random variables $\Lambda_i, \ldots, \Lambda_k$ are independent of $\hat{\mu}_{j,s}$ for all $1 \leq s \leq n$. Let

$$\Psi_i = \min\left\{1,\ \frac{36c_1}{n}\left(\frac{i-1}{\Delta_i^2} + \sum_{m\geq i}\frac{\sqrt{\Lambda_m}}{\Delta_i}\right)\right\}\,.$$

Let $m_i = \sum_{j\notin V_i} \mathbb{1}\{\Delta_j \leq \Delta_i/6\}$ be the number of arms that might satisfy Eq. (22) in the definition of I. Then by the previous display and the definition of I, $\mathbb{P}(I \geq i|\Lambda_i, \ldots, \Lambda_k) \leq \Psi_i^{m_i}$. It would be tempting to try and bound the expectation of Δ_I by taking a union bound over all arms, but this is not tight when many arms have nearly the same mean. Let $\mathcal{I} \subset [k]$ be empty if $i_1 = \ell + 1 > k$.

Otherwise $\mathcal{I} = \{i_1, i_2, \ldots, i_b\}$ where and $i_{j+1} = \min\left\{i : \Delta_i > 6\Delta_{i_j}\right\}$ and b is as large as possible so that $i_b \leq k$.

$$\mathbb{E}[\Delta_I] \leq 6\sum_{i\in\mathcal{I}} \mathbb{P}\left(I \geq i\right)\Delta_i = 6\sum_{i\in\mathcal{I}} \mathbb{E}\left[\mathbb{P}\left(I \geq i \middle| \Lambda_i, \ldots, \Lambda_k\right)\Delta_i\right]$$
$$\leq 6\sum_{i\in\mathcal{I}} \mathbb{E}\left[\Psi_i^{m_i}\Delta_i\right] = 6\mathbb{E}\left[\sum_{i\in\mathcal{I}} \Psi_i^{m_i}\Delta_i\right] \overset{\times}{\leq} C\mathbb{E}\left[\max_{i\in\mathcal{I}} \Psi_i^{m_i}\Delta_i\right].$$

Only the last step above is non-trivial. It follows by choosing a as the smallest value such that $\Psi_{i_a} < 1/2$ (or $a = b$ if such a choice does not exist). Then the contribution of $\Psi_i^{m_i}\Delta_i$ is decreasing exponentially in both directions away from i_a by the definition of $\mathcal{I}$ and the fact that $m_{i_{a+2}} \geq m_{i_a} + 1$.

Case 1 ($\Psi_i \geq 1/2$) By the definition of ℓ and the fact that $i > \ell$ we have $\delta_i \leq 1/4$ and so by Eq. (15), $k_i \leq n\Delta_i^2/(16c_2^2) \leq n\Delta_i^2(144c_1)$. Therefore

$$\frac{1}{2} \leq \frac{36c_1}{n}\left(\frac{i-1}{\Delta_i^2} + \sum_{m\geq i}\frac{\sqrt{\Lambda_m}}{\Delta_i}\right) \leq \frac{36c_1}{n}\left(\frac{k_i}{\Delta_i^2} + \sum_{m\geq i}\frac{\sqrt{\Lambda_m}}{\Delta_i}\right) \leq \frac{1}{4} + \frac{36c_1}{n}\sum_{m\geq i}\frac{\sqrt{\Lambda_m}}{\Delta_i}.$$

Rearranging and using the fact that $\Psi_i \leq 1$ and $\sqrt{\Lambda_m} \leq \Delta_m\Lambda_m$ shows that

$$\Psi_i^{m_i}\Delta_i \leq \Delta_i \leq \frac{C}{n}\sum_{m\geq i}\sqrt{\Lambda_m} \leq \frac{C}{n}\sum_{m>\ell}\Delta_m\Lambda_m.$$

Case 2 ($\Psi_i < 1/2$) By the definition of Ψ_i and the assumption that $\Psi_i < 1/2$ and $i > \ell$,

$$\Psi_i^{m_i}\Delta_i \leq \frac{36c_1 2^{1-m_i}}{n}\left(\frac{i-1}{\Delta_i} + \sum_{m\geq i}\sqrt{\Lambda_m}\right) \overset{\times}{\leq} \frac{C\ell 2^{1-m_{\ell+1}}}{n\Delta_{\ell+1}} + \frac{C}{n}\sum_{m>\ell}\Delta_m\Lambda_m.$$

The second term is already in the right form. For the first,

$$\frac{\ell 2^{1-m_{\ell+1}}}{n\Delta_{\ell+1}} \overset{\times}{\leq} \frac{C}{n\Delta_{\ell+1}} + \frac{\ell}{n\Delta_{\ell+1}}\mathbb{1}\left\{m_{\ell+1} < \ell/4\right\}$$
$$\overset{\times}{\leq} \frac{C}{n}\sum_{m>\ell}\Delta_m\Lambda_m + C\Delta_{\ell+1}\mathbb{1}\left\{m_{\ell+1} < \ell/4\right\} \overset{\times}{\leq} C\left(\bar{\Delta}_\ell + \frac{1}{n}\sum_{m>\ell}\Delta_m\Lambda_m\right),$$

where the last inequality follows since if $m_{\ell+1} < \ell/4$, then many arms $i \leq \ell$ must have means nearly as small as $\ell + 1$. The result is completed by part *(i)* of the lemma.

Appendix C. Proof of Lemma 9 *(iii)*

The proof relies on another concentration result.

Lemma 15 *There exists an $\varepsilon > 0$ such that for any arm j*

$$\mathbb{P}\left(\textit{exists } s \leq \frac{8n}{\ell} : \hat{\mu}_{j,s} + \sqrt{\frac{2}{s}\,\overline{\log}\left(\sqrt{\frac{n}{2\ell s}}\right)} \leq \mu_j + 2\sqrt{\frac{\varepsilon}{s}}\right) \leq \frac{1}{2}.$$

Proof The result follows by rescaling the time horizon and noting that if B_s is a Brownian motion, then for sufficiently small ε (for example, $1/200$).

$$\mathbb{P}\left(\text{exists } s \leq 8 : B_s \geq \sqrt{2s\,\overline{\log}\left(\frac{1}{\sqrt{2s}}\right)} - 2\sqrt{\varepsilon s}\right) \leq \frac{1}{2}.$$

The above bound does not depend on any variables and can be verified numerically (either by simulating Brownian motion or numerically solving the heat equation that characterises the density of the paths of Brownian motion). An analytical proof is also possible, but requires a modest increase in the definition $\overline{\log}(\cdot)$ if the tangent approximation is to yield a sufficiently tight bound. ■

We need a little more notation. First up is another set of 'usually optimistic' arms, $U \subset [k]$ defined by

$$U = \left\{j : \Delta_j \leq 4\bar{\Delta}_\ell \text{ and } \hat{\mu}_{j,s} + \sqrt{\frac{2}{s}\,\overline{\log}\sqrt{\frac{n}{2\ell s}}} \geq \mu_j + 2\sqrt{\frac{\varepsilon}{s}} \text{ for all } s \leq \frac{8n}{\ell}\right\}.$$

Let $\underline{\Delta} = \sqrt{\varepsilon\ell/(8n)}$ with $\varepsilon > 0$ as given in Lemma 15. Finally we need two more events E_2 and E_3 given by

$$E_2 = \left\{\sqrt{n\ell} + \sum_{m>\ell}\sqrt{\Lambda_m} \leq \sqrt{2n\ell}\right\} \qquad \text{and} \qquad E_3 = \left\{|U| \geq \frac{\ell}{8}\right\}. \tag{26}$$

Lemma 16 *If E_1, E_2, E_3 and $\Delta_i > 4\bar{\Delta}_\ell$, then $T_i(n) \leq \left\lceil \zeta_i(\underline{\Delta}) + \frac{24n}{\varepsilon\ell}\right\rceil$.*

Proof Proceeding by contradiction. Suppose the claim is not true, then there exists a round $t-1 < n$ such that $A_t = i$ and

$$T_i(t-1) = \left\lceil \zeta_i(\underline{\Delta}) + \frac{24n}{\varepsilon\ell}\right\rceil. \tag{27}$$

By the definition of $j \in U$,

$$H_j(t-1) \leq \sum_{m=1}^{k}\sqrt{T_j(t-1)T_m(t-1)} \leq \sqrt{T_j(t-1)}\left(\sqrt{\ell n} + \sum_{m>\ell}\sqrt{\Lambda_m}\right) \leq \sqrt{2T_j(t-1)\ell n}, \tag{28}$$

where the first inequality follows from the definition of $H_j(t-1)$, the second by splitting the sum and because E_1 holds (so that $T_m(n) \leq \Lambda_m$ for $m > \ell$) and Cauchy-Schwarz, the third follows because E_2 holds. Therefore arms $j \in U$ with $T_j(t-1) \leq 8n/\ell$ satisfy

$$\gamma_j(t) = \hat{\mu}_j(t-1) + \sqrt{\frac{2\,\overline{\log}\left(\frac{n}{H_j(t-1)}\right)}{T_j(t-1)}} \geq \mu_j + 2\sqrt{\frac{\varepsilon}{T_j(t-1)}}. \tag{29}$$

Furthermore, since $T_i(t-1) \geq \zeta_i(\underline{\Delta})$ and $A_t = i$ it holds that $\gamma_i(t) \geq \gamma_j(t)$ and so using Eq. (29) and the same argument as in Lemma 5 leads to

$$\begin{aligned}
\mu_i + \underline{\Delta} + \sqrt{\frac{2\,\overline{\log}\left(\frac{n}{H_i(t-1)}\right)}{T_i(t-1)}} &\geq \hat{\mu}_i(t-1) + \sqrt{\frac{2\,\overline{\log}\left(\frac{n}{H_i(t-1)}\right)}{T_i(t-1)}} \\
&\geq \hat{\mu}_j(t-1) + \sqrt{\frac{2\,\overline{\log}\left(\frac{n}{H_j(t-1)}\right)}{T_j(t-1)}} \geq \hat{\mu}_j(t-1) + \sqrt{\frac{2\,\overline{\log}\left(\sqrt{\frac{n}{2\ell T_j(t-1)}}\right)}{T_j(t-1)}} \\
&\geq \mu_j + 2\sqrt{\frac{\varepsilon}{T_j(t-1)}} \geq \mu_i + \underline{\Delta} + \sqrt{\frac{\varepsilon}{T_j(t-1)}}\,.
\end{aligned}$$

And by rearranging $\frac{2}{T_i(t-1)}\,\overline{\log}\left(\frac{n}{H_i(t-1)}\right) \geq \frac{\varepsilon}{T_j(t-1)}$. Therefore for all $j \in U$ we have

$$T_j(t-1) \geq \min\left\{\frac{8n}{\ell},\, \frac{\varepsilon T_i(t-1)}{\overline{\log}\left(\frac{n}{H_i(t-1)}\right)}\right\}. \tag{30}$$

Since $T_i(t-1) \geq 8n/(\varepsilon\ell)$, the definition of $H_i(t-1)$ implies that

$$\begin{aligned}
H_i(t-1) &= \sum_{j=1}^{k} \min\left\{T_i(t-1),\, \sqrt{T_i(t-1)T_j(t-1)}\right\} \\
&\geq \sum_{j\in U} \min\left\{T_i(t-1),\, T_j(t-1)\right\} \geq \frac{8|U|n}{\ell\,\overline{\log}\left(\frac{n}{H_i(t-1)}\right)} \geq \frac{n}{\overline{\log}\left(\frac{n}{H_i(t-1)}\right)}\,.
\end{aligned}$$

Then since E_3 holds, by Lemma 20(vii) we have $\overline{\log}(n/H_i(t-1)) \leq 3$. Therefore if $T_i(t-1) \geq 24n/(\varepsilon\ell)$, then another application of Eq. (30) shows that $T_j(t-1) \geq 8n/\ell$ and so $n > t-1 = \sum_{j=1}^{k} T_j(t-1) \geq \sum_{j\in U} T_j(t-1) \geq 8n|U|/\ell \geq n$, which is a contradiction. Therefore there does not exist a round $t-1$ where Eq. (27) holds and $A_t = i$ and the lemma follows. ■

Lemma 17 $\mathbb{P}\left(E_3^c\right) \leq 3/\ell$.

Proof By Markov's inequality, $m = \sum_{j\leq\ell} \mathbb{1}\left\{\Delta_j \leq 4\bar{\Delta}_\ell\right\} \geq \frac{3\ell}{4}$. Let $\chi_1, \ldots, \chi_m$ be a sequence of independent Bernoulli events given by $\chi_j = \mathbb{1}\left\{j \notin U\right\}$. Then by Lemma 15, $\mathbb{P}\left(\chi_j = 1\right) \leq 1/2$ and so Chebyshev's inequality implies that

$$\begin{aligned}
\mathbb{P}\left(E_3^c\right) &= \mathbb{P}\left(|U| < \frac{\ell}{8}\right) = \mathbb{P}\left(\sum_{j=1}^{m}(1-\chi_j) < \frac{\ell}{8}\right) = \mathbb{P}\left(\sum_{j=1}^{m}\chi_j > m - \frac{\ell}{8}\right) \\
&\leq \mathbb{P}\left(\sum_{j=1}^{m}(\chi_j - \mathbb{E}[\chi_j]) \geq \frac{m}{2} - \frac{\ell}{8}\right) \leq \frac{m/4}{\left(\frac{m}{2} - \frac{\ell}{8}\right)^2} \leq \frac{3}{\ell}\,.
\end{aligned}$$

■

At last all the tools are available to prove part (iii) of Lemma 9.

Proof [of Lemma 9 *(iii)*] The regret due to arms $i \leq \ell$ is decomposed

$$\mathbb{E}\left[\mathbb{1}_{\{E_1\}}\sum_{i\leq\ell}\Delta_i T_i(n)\right] \leq \mathbb{E}\left[\mathbb{1}_{\{E_2^c\}} n\Delta_\ell\right] + \mathbb{E}\left[\mathbb{1}_{\{E_1,E_2\}}\sum_{i\leq\ell}\Delta_i T_i(n)\right]. \tag{31}$$

The first term is bounded easily using the definition of E_2, Lemma 21(i) and Lemma 9(i).

$$\mathbb{E}\left[\mathbb{1}_{\{E_2^c\}} n\Delta_\ell\right] \leq C\sum_{m>\ell}\mathbb{E}\left[\sqrt{\Lambda_m}\right] \leq C\sum_{m>\ell}\Delta_m\lambda_m\,.$$

The second term in Eq. (31) is bounded using Lemmas 16 and 17. By noting that the contribution to the regret of arms i with $\Delta_i \leq 4\bar{\Delta}_\ell$ is at most $4n\bar{\Delta}_\ell$ it follows that

$$\begin{aligned}
\mathbb{E}\left[\mathbb{1}_{\{E_1,E_2\}}\sum_{i\leq\ell}\Delta_i T_i(n)\right] &\leq 4n\bar{\Delta}_\ell + n\Delta_\ell\mathbb{P}\left(E_3^c\right) \\
&\quad + \mathbb{E}\left[\mathbb{1}_{\{E_1,E_2,E_3\}}\sum_{i\leq\ell:\Delta_i>4\bar{\Delta}_\ell}\Delta_i\left(\zeta_i(\underline{\Delta}) + \left\lceil\frac{24n}{\varepsilon\ell}\right\rceil\right)\right].
\end{aligned}$$

The proof is completed since Lemma 17 implies that $n\Delta_\ell\mathbb{P}\left(E_3^c\right) \leq 3n\Delta_\ell/\ell \leq 3n\bar{\Delta}_\ell$ and Lemma 13 implies that

$$\begin{aligned}
\mathbb{E}\left[\mathbb{1}_{\{E_1,E_2,E_3\}}\sum_{i\leq\ell:\Delta_i>4\bar{\Delta}_\ell}\Delta_i\left(\zeta_i(\underline{\Delta}) + \left\lceil\frac{24n}{\varepsilon\ell}\right\rceil\right)\right] &\leq \mathbb{E}\left[\sum_{i\leq\ell}\Delta_i\left(\zeta_i(\underline{\Delta}) + \left\lceil\frac{24n}{\varepsilon\ell}\right\rceil\right)\right] \\
&\leq \sum_{i\leq\ell}\Delta_i\left(2 + \frac{40n}{\varepsilon\ell}\right) \leq Cn\bar{\Delta}_\ell\,.
\end{aligned}$$

■

Appendix D. Technical results

Here some lemmas that are either known or follow from uninteresting calculations. The first two are used for the lower bounds have have been seen before.

Lemma 18 (See Lemma 2.6 in Tsybakov 2008) *Let $\mathbb{P}$ and $\mathbb{P}'$ be measures on the same probability space and assume $\mathbb{P}'$ is absolutely continuous with respect to $\mathbb{P}$. Then for any event A, $\mathbb{P}\left(A\right) + \mathbb{P}'(A^c) \geq \exp(-\mathrm{KL}(\mathbb{P},\mathbb{P}'))/2$, where $\mathrm{KL}(\mathbb{P},\mathbb{P}')$ is the relative entropy between $\mathbb{P}$ and $\mathbb{P}'$.*

The next lemma has also been seen before. For example in the articles by Auer et al. (1995) or Gerchinovitz and Lattimore (2016) where the formalities are described in great detail.

Lemma 19 *Fix a strategy. Let $1 \leq i \leq k$ and $\mu \in \mathbb{R}^k$ and $\mu' \in \mathbb{R}^k$ be such that $\mu_j = \mu'_j$ for all $j \neq i$ and $\mu_i - \mu'_i = \Delta$. Then let $\mathbb{P}$ be the measure on $A_1, X_1, A_2, X_2, \ldots, A_n, X_n$ induced by the interaction of the strategy with rewards sampled using mean vector μ and $\mathbb{P}'$ be the same but with rewards sampled with means from μ'. Then $\mathrm{KL}(\mathbb{P},\mathbb{P}') = \mathbb{E}[T_i(n)]\Delta^2/2$, where the expectation is taken with respect to $\mathbb{P}$.*

Recall that $\overline{\log}(x) = \log((e+x)\log^{\frac{1}{2}}(e+x))$. Here are a few simple facts that make manipulating this unusual function a little easier.

Lemma 20 *The following hold:*

(i) $\overline{\log}$ *is concave and monotone increasing on* $[0, \infty)$.

(ii) $\overline{\log}(0) \geq 1$.

(iii) $\lim_{x\to\infty} \overline{\log}(x)/\log(x) = 1$.

(iv) $(\overline{\log}(x))^{1/2}\exp(-\overline{\log}(x)) \leq 3/(2x)$.

(v) If $x\overline{\log}^{\frac{1}{2}}(b/x) \geq a$, *then* $\overline{\log}(b/x) \leq 2\overline{\log}(b/a)$ *for all* $a, b > 0$.

(vi) $\sqrt{\overline{\log}(x)}\exp(-1-\overline{\log}(x)+2\sqrt{\overline{\log}(x)}) \leq 5\sqrt{1/x}$.

(vii) If $\overline{\log}(x) \geq x$, *then* $\overline{\log}(x) \leq 2$.

Proof (i) is proven by checking derivatives:

$$\frac{d}{dx}\overline{\log}(x) = \frac{\frac{1}{2\sqrt{\log(e+x)}} + \sqrt{\log(e+x)}}{(e+x)\sqrt{\log(e+x)}} \qquad \frac{d^2}{dx^2}\overline{\log}(x) = -\frac{1+\log(e+x)+2\log^2(e+x)}{2(e+x)^2\log^2(e+x)}\,.$$

The former is clearly positive and the latter negative, which shows that $\overline{\log}$ is monotone increasing and concave. Parts (ii) and (iii) are trivial. For (iv),

$$\begin{aligned}
&\overline{\log}^{\frac{1}{2}}(x)\exp(-\overline{\log}(x)) = \overline{\log}^{\frac{1}{2}}(x)\exp(-\log((e+x)\log^{\frac{1}{2}}(e+x))) \\
&= \frac{\overline{\log}^{\frac{1}{2}}(x)}{(e+x)\log^{\frac{1}{2}}(e+x)} = \frac{1}{e+x}\sqrt{\frac{\log(e+x)+\log\log^{\frac{1}{2}}(e+x)}{\log(e+x)}} \leq \frac{1}{e+x}\sqrt{1+\frac{1}{2e}} \leq \frac{3}{2x}\,.
\end{aligned}$$

For (v),

$$\overline{\log}\left(\frac{b}{x}\right) \leq \overline{\log}\left(\frac{b\,\overline{\log}^{\frac{1}{2}}(b/x)}{a}\right) \leq \overline{\log}\left(\frac{b}{a}\,\overline{\log}^{\frac{1}{2}}\left(\frac{b}{a}\,\overline{\log}^{\frac{1}{2}}\left(\frac{b}{a}\,\overline{\log}^{\frac{1}{2}}\left(\frac{b}{a}\cdots\right.\right.\right.\right. = z\,,$$

where the final equality serves as the definition of z. If $z \leq 2$, then $\overline{\log}(b/x) \leq z \leq 2 \leq 2\overline{\log}(b/a)$. Suppose now that $z \geq 2$. Let $u, v \geq 0$, then $\overline{\log}(uv) \leq \overline{\log}(u) + \overline{\log}(v)$ and if $u \geq 2$, then $u^2 - \overline{\log}(u) \geq u^2/2$. Therefore $z^2/2 \leq z^2 - \overline{\log}(z) \leq \overline{\log}(zb/a) - \overline{\log}(z) \leq \overline{\log}(b/a)$. Therefore $\overline{\log}(b/x) \leq z^2 \leq 2\overline{\log}(b/a)$ as required. For (vi), using a similar reasoning as (iv),

$$\begin{aligned}
\sqrt{x\,\overline{\log}(x)}\exp\left(-1-\overline{\log}(x)+2\,\overline{\log}^{\frac{1}{2}}(x)\right) &= \frac{\overline{\log}^{\frac{1}{2}}(x)\sqrt{x}\exp\left(2\,\overline{\log}^{\frac{1}{2}}(x)\right)}{e(e+x)\log^{\frac{1}{2}}(e+x)} \\
&\leq \sqrt{\frac{\overline{\log}(x)}{\log(e+x)}}(x+e)^{-\frac{1}{2}}\exp\left(2\,\overline{\log}^{\frac{1}{2}}(x)\right)\,.
\end{aligned}$$

Simple calculus shows that $\overline{\log}(x)/\log(e+x) \leq (1/2+e)/e$. Let $g(x) = (x+e)^{-\frac{1}{2}}\exp(2\,\overline{\log}^{\frac{1}{2}}(x))$. Then $\max_{x\geq 0} g(x) \leq 10.34 \leq 11$ by numerical calculation, which is valid by the following argument: First, the function g is twice differentiable, satisfies $g(0) > 0$, $g'(0) > 0$ and $\lim_{x\to\infty} g(x) = 0$. By taking the first derivative it is easy to see that g has a unique maximum in $x^* \in (0,\infty)$ with $g(x^*) > 0$. Therefore g is monotone increasing for $x < x^*$ and monotone decreasing afterwards for $x > x^*$. This means the maximiser may be found by a binary search with arbitrary precision. Therefore $\sqrt{x\,\overline{\log}(x)}\exp(-1-\overline{\log}(x)+2\,\overline{\log}^{\frac{1}{2}}(x)) \leq \frac{11}{e}\sqrt{(1/2+e)/e} \leq 5$. For (vii), if $x \geq 0$, then $\frac{d}{dx}\overline{\log}(x) \leq 3/(2e) \leq 1$. Therefore $\overline{\log}(x) - x$ is monotone non-increasing and the result follows by checking that $\overline{\log}(2) \leq 2$. ■

The second technical lemma provides some useful results relating to the optimisation problem appearing in Eq. (3) and the definition of ℓ in Eq. (15).

Lemma 21 *There exists a universal constant* $C > 0$ *such that:*

(i) $\Delta_\ell \leq C\sqrt{\frac{\ell}{n}}$ *or* $n\Delta_\ell \leq C\sum_{m>\ell}\frac{1}{\Delta_m}$.

(ii) $n\bar{\Delta}_\ell + \sum_{m>\ell}\Delta_m\lambda_m \leq C\min_{i\in[k]}\left(n\bar{\Delta}_i + \sum_{m>i}\Delta_m\lambda_m\right)$.

(iii) $\min_{i\in[k]}\left(n\bar{\Delta}_i + \sum_{m>i}\Delta_i\lambda_i\right) \leq C\sqrt{kn} + \sum_{m=1}^{k}\Delta_m$.

(iv) $\min_{i\in[k]}\left(n\bar{\Delta}_i + \sum_{m>i}\Delta_i\lambda_i\right) \leq C\sum_{m:\Delta_m>0}\left(\Delta_m + \frac{\log(n)}{\Delta_m}\right)$.

Proof For part *(i)*, by the definition of ℓ we have

$$\Delta_\ell < 4c_2\sqrt{\frac{k_\ell}{n}} = 4c_2\sqrt{\frac{\ell}{n} + \frac{\Delta_\ell}{n}\sum_{i>\ell}\frac{1}{\Delta_i}} \leq 4c_2\sqrt{\max\left\{\frac{\ell}{n}, \frac{\Delta_\ell}{n}\sum_{i>\ell}\frac{1}{\Delta_i}\right\}}\,.$$

The result follows by simplifying each of the two cases in the maximum. For part *(ii)*, let $i = \arg\min_j n\bar{\Delta}_j + \sum_{m>j}\Delta_m\lambda_m$.

Case 1 ($\ell > i$) Using the fact that for $m \leq \ell$ we have $\Delta_m \leq 16c_2^2 k_m/\Delta_m$ leads to

$$\begin{aligned}
n\bar{\Delta}_\ell + \sum_{m>\ell}\Delta_m\lambda_m &\leq n\bar{\Delta}_i + \frac{n}{\ell}\sum_{m=i+1}^{\ell}\Delta_m + \sum_{m>\ell}\Delta_m\lambda_m \\
&\leq n\bar{\Delta}_i + \frac{16c_2^2 n}{\ell}\sum_{m=i+1}^{\ell}\frac{k_m}{\Delta_m} + \sum_{m>\ell}\Delta_m\lambda_m \leq (1+32c_2^2)\left(n\bar{\Delta}_i + \sum_{m>i}\Delta_m\lambda_m\right)\,.
\end{aligned}$$

Case 2 ($\ell < i$) Using the fact that $\overline{\log}(x)/x \leq 3/2$ for $x \geq 1$ leads to

$$\sum_{m=\ell+1}^{i} \Delta_m \lambda_m = \sum_{m=\ell+1}^{i} \frac{n\Delta_m}{k_m} \cdot \frac{k_m}{n\Delta_m^2} \overline{\log}\left(\frac{n\Delta_m^2}{k_m}\right) + \sum_{m=\ell+1}^{i} \Delta_m$$
$$\leq \frac{3n}{2} \sum_{m=1}^{i} \frac{\Delta_m}{k_m} + \frac{n}{i} \sum_{m=\ell+1}^{i} \Delta_m \leq 7n\bar{\Delta}_i \,,$$

where the first inequality is true since $i/n \leq 1$ and by the definition of ℓ, if $m \geq \ell$, then $n\Delta_m^2/k_m \geq 16c_2^2 \geq 1$. The second inequality follows by letting $k(x) = \sum_{m=1}^{k} \min\{1, x/\Delta_m\}$ and noting that $x/k(x)$ is monotone increasing and by Markov's inequality $k(2\bar{\Delta}_i) \geq i/2$. Then for $\Delta_m \leq 2\bar{\Delta}_i$ it holds that $\Delta_m/k_m \leq 2\bar{\Delta}_i/k(2\bar{\Delta}_i) \leq 4\bar{\Delta}_i/i$ while for $\Delta_m > 2\bar{\Delta}_i$ we have $\Delta_m/k_m \leq 2\Delta_m/i$. Therefore

$$n\bar{\Delta}_\ell + \sum_{m>\ell} \Delta_m \lambda_m \leq n\bar{\Delta}_i + \sum_{m=\ell+1}^{i} \Delta_m \lambda_m + \sum_{m>i} \Delta_m \lambda_m \leq 8\left(n\bar{\Delta}_i + \sum_{m>i} \Delta_m \lambda_m\right)$$

The last two parts are straightforward. For *(iii)*, let $j = \max\{m : \Delta_m \leq 3\sqrt{k/n}\}$, which means that for $m > j$ it holds that $\overline{\log}(n\Delta_m^2/m) \leq 2\log(n\Delta_m^2/m)$. Then

$$\min_{i \in [k]} \left(n\bar{\Delta}_i + \sum_{m>i} \Delta_m \lambda_m\right) - \sum_{m=1}^{k} \Delta_m \leq n\bar{\Delta}_j + \sum_{m>j} \Delta_m(\lambda_m - 1)$$
$$\leq 3\sqrt{kn} + \sum_{m>j} \frac{1}{\Delta_m} \overline{\log}\left(\frac{n\Delta_m^2}{k_m}\right) \leq 3\sqrt{kn} + \sum_{m>j} \frac{2}{\Delta_m} \log\left(\frac{n\Delta_m^2}{m}\right)$$
$$\leq 3\sqrt{kn} + \frac{2}{3}\sqrt{\frac{n}{k}} \int_1^k \log\left(\frac{9k}{x}\right) dx = 3\sqrt{kn} + \frac{2}{3}\sqrt{nk}\,(1 + \log(9)) \leq 6\sqrt{kn}\,.$$

Rearranging completes the proof of *(iii)*. For part *(iv)*, first note that

$$\lambda_m = 1 + \frac{1}{\Delta_m^2} \overline{\log}\left(\frac{n\Delta_m^2}{k_m}\right) \leq 1 + \frac{\overline{\log}(n)}{\Delta_m^2} + \frac{\overline{\log}(\Delta_m^2)}{\Delta_m^2} \leq \frac{5}{2} + \frac{3/2 + \log(e+n)}{\Delta_m^2}\,.$$

The result follows by choosing $i = \max\{i : \Delta_i = 0\}$. ■

Appendix E. History

Table 2 outlines the long history of finite-armed stochastic bandits. It indicates which algorithms are asymptotically optimal and/or sub-UCB and the ratio (up to constant factors) by which they are minimax suboptimal. Empty cells represent results unknown at the time. Most papers do not provide minimax bounds, but they can be derived easily from finite-time bounds using the argument given by Bubeck and Cesa-Bianchi (2012), which I have done where possible. In some cases the finite-time bound cannot be used to derive the minimax bound and these results are marked as conjectures. Algorithms were omitted from the list if (a) I could not straightforwardly adapt their analysis to the

Gaussian noise model and/or frequentist regret (Honda and Takemura, 2011; Russo and Van Roy, 2014; Gutin and Farias, 2016), or (b) the algorithm depends on μ-dependent tuning such as SOFTMIX (Cesa-Bianchi and Fischer, 1998), ε-GREEDY (Auer et al., 2002), EXPLORE-THEN-COMMIT (Garivier et al., 2016a) and BOLTZMANN EXPLORATION (Cesa-Bianchi et al., 2017). Also omitted are algorithms designed for adversarial bandits, few of which are suitable for unbounded rewards and none are competitive with UCB for stochastic problems, but a nice survey of these algorithms is by Bubeck and Cesa-Bianchi (2012). The vast majority of the Bayesian literature is also omitted since it deals with discounted rewards. See the recent book by Gittins et al. (2011) for an overview of Bayesian algorithms.

Remark 22 *It must be emphasised that many of the algorithms in the table were designed for settings more general than Gaussian and the core contribution was actually this generality.*

Abstract

Support Vector Machines (SVMs) are classic supervised learning models for classification, regression and distribution estimation. A survey conducted by Kaggle in 2017 shows that 26% of the data mining and machine learning practitioners are users of SVMs. However, SVM training and prediction are very expensive computationally for large and complex problems. This paper presents an efficient and open source SVM software toolkit called ThunderSVM which exploits the high-performance of Graphics Processing Units (GPUs) and multi-core CPUs. ThunderSVM supports all the functionalities—including classification (SVC), regression (SVR) and one-class SVMs—of LibSVM and uses identical command line options, such that existing LibSVM users can easily apply our toolkit. ThunderSVM can be used through multiple language interfaces including C/C++, Python, R and MATLAB. Our experimental results show that ThunderSVM is generally an order of magnitude faster than LibSVM while producing identical SVMs. In addition to the high efficiency, we design our convex optimization solver in a general way such that SVC, SVR, and one-class SVMs share the same solver for the ease of maintenance. Documentation, examples, and more about ThunderSVM are available at `https://github.com/zeyiwen/thundersvm`.

Keywords: SVMs, GPUs, multi-core CPUs, efficiency, multiple interfaces

1. Introduction

Support Vector Machines (SVMs) have been widely used in many applications including document classification (D'Orazio et al., 2014), image classification (Pasolli et al., 2014), blood pressure estimation (Kachuee et al., 2015), disease detection (Bodnar and Salathé, 2013), and outlier detection (Roth, 2006). A survey conducted by Kaggle in 2017 shows that 26% of the data science practitioners use SVMs to solve their problems (Thomas, 2017). The open-source project LibSVM which supports classification (SVC), regression (SVR) and one-class SVMs has been widely used in many applications. LibSVM was developed in 2000 (Chang and Lin, 2011), and has been maintained since then. Despite the advantages of SVMs, SVM training and prediction are very expensive for large and complex problems.

Graphics Processing Units (GPUs) have been used to accelerate the solutions of many real-world applications (Dittamo and Cisternino, 2008), due to the abundant computing cores and high memory bandwidth of GPUs. In this paper, we introduce a toolkit named *ThunderSVM* which exploits GPUs and multi-core CPUs. The mission of our toolkit is to help users easily and efficiently apply SVMs to solve problems. It is worthy to point out that one way to train SVMs faster is to use kernel approximations. ThunderSVM aims to find an exact solution. ThunderSVM supports all the functionalities of LibSVM including SVC, SVR and one-class SVMs. We use the same command line input options as LibSVM, such that existing LibSVM users are able to easily switch to ThunderSVM. Moreover, ThunderSVM supports multiple interfaces such as C/C++, Python, R and MATLAB. ThunderSVM can run on Linux, Windows or Macintosh operating systems with or without GPUs. Empirical results show ThunderSVM is generally 10 times faster than LibSVM in all the functionalities. The full version of ThunderSVM, which is released under Apache License 2.0, can be found on GitHub at `https://github.com/zeyiwen/thundersvm`. The GitHub repository of ThunderSVM has attracted 700 stars and 85 forks as of July 24, 2018.

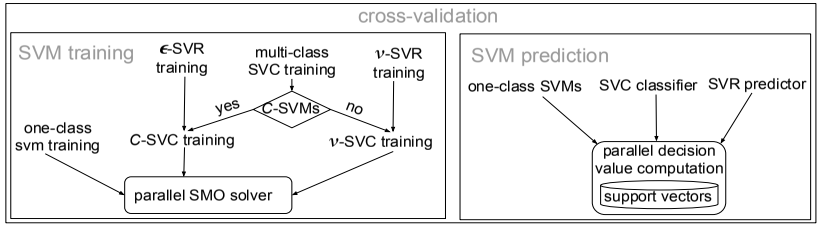

Figure 1: Overview of training and prediction

2. Overview and Design of ThunderSVM

Like LibSVM, ThunderSVM supports one-class SVMs, C-SVMs and ν-SVMs where C represents the regularization constant and ν represents the parameter controlling the training error. Both C-SVMs and ν-SVMs are used for classification and regression.

Figure 1 shows the overview of ThunderSVM which has many functionalities: one-class SVMs for distribution estimation, C-SVC and ν-SVC for SVM classification, and ϵ-SVR and ν-SVR for SVM regression. The training algorithms for those SVMs are built on top of a generic parallel SMO solver which is for solving quadratic optimization problems. Notably, the SVM training for regression (such as ϵ-SVR and ν-SVR) and the multi-class SVM training can be converted into the training of an SVM classifier. The prediction module is relatively simple, because the prediction is the same for one-class SVMs, C-SVMs and ν-SVMs. The prediction is essentially computing predicted values based on support vectors. ThunderSVM also contains the cross-validation functionality.

2.1 Design of Parallel SVM Training Algorithms

We have developed a series of optimizations for the training. First, ThunderSVM computes a number of rows of the kernel matrix in a batch, reuses the rows that are stored in the GPU

memory buffer, and solves multiple subproblems in that batch. Thus, ThunderSVM avoids performing a large number of small read/write operations to the high latency memory and reduces repeated kernel value computation. Moreover, we apply GPU shared memory to accelerate parallel reduction, and use the massive parallelism to update elements of arrays.

For solving each subproblem in the training, we use the SMO algorithm which consists of three key steps. Step (i): Find two extreme training instances which can potentially improve the currently trained SVM the most. Step (ii): Improve the two Lagrange multipliers of the two instances. Step (iii): Update the optimality indicators of all the training instances. We parallelize Step (i) and (iii). Step (ii) is computationally inexpensive, and we simply execute it sequentially. In Step (i), our key idea is to apply the parallel reduction (Merrill, 2015) twice for finding the two extreme training instances. In the parallel reduction, we first load the whole array from the GPU global memory to shared memory in a coalescent way, and then reduce the array size by two at each iteration until only one element left. In Step (iii), we dedicate one thread to update one optimality indicator to use the massive parallelism mechanism of the GPU. The training is terminated when the optimality condition is met or the SVMs cannot be further improved. More details about the training and the termination condition can be found in our supplementary material (Wen et al., 2017).

For solving the batch of subproblems, we propose techniques to exploit the properties of the batch of subproblems. First, to reduce access to the high latency memory, the kernel values needed for the batch are organized together and computed through matrix multiplication. As a result, we reduce a large number of small read/write operations to the high latency memory during kernel value computation. We use matrix operations from the high-performance library cuSparse (Nvidia, 2008) provided by NVIDIA. Second, to reduce repeated kernel value computation, we store the kernel values in a GPU buffer for efficient reuse during the optimization for the batch. Regarding the selection of the batch, we make use of the set of instances with the deepest gradients.

Training SVMs for regression (SVR) or for multi-class classification can be reduced to training SVMs for binary classification (SVC), as discussed in the previous study (Shevade et al., 2000). Two SVC training algorithms (C-SVC and ν-SVC) and training algorithm for one-class SVMs are essentially solving optimization problems using SMO. More details about the relationship of SVR and SVC, and SMO can be found in our supplementary material (Wen et al., 2017). The key task in the SVM training is to parallelize SMO, and the insight has been discussed above. The parallelism principles are applicable to CPUs.

2.2 Design of the Parallel Prediction Algorithm

Although ThunderSVM supports several algorithms (such as one-class SVMs, classification and regression), their underlying prediction algorithm is identical: a function based on the support vectors and their Lagrange multipliers. The function is $v = \sum_{i=1}^{n} y_i \alpha_i K(\boldsymbol{x}_i, \boldsymbol{x}_j) + b$ where $\boldsymbol{x}_j$ is the instance of interest for prediction; y_i and α_i are the label and Lagrange multiplier of the support vector $\boldsymbol{x}_i$, respectively; b is the bias of the SVM hyperplane; $K(\cdot, \cdot)$ is the kernel function. In ThunderSVM, we perform the prediction by evaluating the equation in parallel. First, we conduct a vector to matrix multiplication in parallel to obtain all the needed kernel values, where the vector is $\boldsymbol{x}_j$ and the matrix consists of all the support vectors. Then, the sum of the equation can be performed using a parallel reduction.

data set			elapsed time (sec)			speedup	
name	cardinality	dimension	ThunderSVM		LibSVM

Table 1: Comparison between ThunderSVM with LibSVM

3. Experimental Studies

We compare the efficiency on training SVMs for classification, regression and one-class SVMs (denoted by "OCSVM"). Five representative data sets are listed in Table 1. We conducted our experiments on a workstation running Linux with two Xeon E5-2640 v4 10 core CPUs, 256GB main memory and a Tesla P100 GPU of 12GB memory. ThunderSVM are implemented in CUDA-C and C++ with OpenMP. We used the Gaussian kernel. Five pairs of hyper-parameters (C, γ) for the data sets are (10, 0.125), (100, 0.125), (0.01, 1), (256, 0.125), and (64,7.8125) and are the same as the existing studies (Wen et al., 2014, 2018). More experimental evaluation can be found in our supplementary material. ThunderSVM when using GPUs is over 100 times faster than LibSVM. When running on CPUs, it is over 10 times faster than LibSVM. For prediction, ThunderSVM is also 10 to 100 times faster than LibSVM (Wen et al., 2017). We varied the hyper-parameters C from 0.01 to 100 and γ from 0.03 to 10, and ThunderSVM is 10 to 100 times faster than LibSVM.

4. Conclusion

In this paper, we present our software tool called "ThunderSVM" which supports all the functionalities of LibSVM. For ease of usage, ThunderSVM uses identical input command line options as LibSVM, and supports Python, R and Matlab. Empirical results show that ThunderSVM is generally 100 times faster than LibSVM in all the functionalities when GPUs are used. When running purely on CPUs, ThunderSVM is often 10 times faster than LibSVM. We hope this significant efficiency improvement would help practitioners in the community quickly solve their problems and enable SVMs to solve more complex problems.

Abstract

We present a robust generalization of the synthetic control method for comparative case studies. Like the classical method cf. Abadie and Gardeazabal (2003), we present an algorithm to estimate the unobservable counterfactual of a treatment unit. A distinguishing feature of our algorithm is that of de-noising the data matrix via singular value thresholding, which renders our approach robust in multiple facets: it automatically identifies a good subset of donors for the synthetic control, overcomes the challenges of missing data, and continues to work well in settings where covariate information may not be provided. We posit that the setting can be viewed as an instance of the Latent Variable Model and provide the first finite sample analysis (coupled with asymptotic results) for the estimation of the counterfactual. Our algorithm accurately imputes missing entries and filters corrupted observations in producing a consistent estimator of the underlying signal matrix, provided $p = \Omega(T^{-1+\zeta})$ for some $\zeta > 0$; here, p is the fraction of observed data and T is the time interval of interest. Under the same proportion of observations, we demonstrate that the mean-squared error in our counterfactual estimation scales as $\mathcal{O}(\sigma^2/p + 1/\sqrt{T})$, where σ^2 is the variance of the inherent noise. Additionally, we introduce a Bayesian framework to quantify the estimation uncertainty. Our experiments, using both synthetic and real-world datasets, demonstrate that our robust generalization yields an improvement over the classical synthetic control method.

1. Introduction

On November 8, 2016 in the aftermath of several high profile mass-shootings, voters in California passed Proposition 63 in to law BallotPedia (2016). Prop. 63 "outlaw[ed] the possession of ammunition magazines that [held] more than 10 rounds, requir[ed] background checks for people buying bullets," and was proclaimed as an initiative for "historic progress to reduce gun violence" McGreevy (2016). Imagine that we wanted to study the impact of Prop. 63 on the rates of violent crime in California.

Randomized control trials, such as A/B testings, have been successful in establishing effects of interventions by randomly exposing segments of the population to various types of interventions. Unfortunately, a randomized control trial is not applicable in this scenario since only one California exists. Instead, a statistical comparative study could be conducted where the rates of violent crime in California are compared to a "control" state after November 2016, which we refer to as the post-intervention period. To reach a statistically valid conclusion, however, the control state must be demonstrably similar to California sans the passage of a Prop. 63 style legislation. In general, there may not exist a natural control state for California, and subject-matter experts tend to disagree on the most appropriate state for comparison.

As a suggested remedy to overcome the limitations of a classical comparative study outlined above, Abadie et al. proposed a powerful, data-driven approach to construct a "synthetic" control unit absent of intervention Abadie et al. (2010); Abadie and Gardeazabal (2003); Abadie et al. (2011). In the example above, the synthetic control method would construct a "synthetic" state of California such that the rates of violent crime of that hypothetical state would best match the rates in California before the passage of Prop. 63. This synthetic California can then serve as a data-driven counterfactual for the period after the passage of Prop. 63. Abadie et al. propose to construct such a synthetic California by choosing a convex combination of other states (donors) in the United States. For instance, synthetic California might be 80% like New York and 20% like Massachusetts. This approach is nearly entirely data-driven and appeals to intuition. For optimal results, however, the method still relies on subjective covariate information, such as employment rates, and the presence of domain "experts" to help identify a useful subset of donors. The approach may also perform poorly in the presence of non-negligible levels of noise and missing data.

1.1 Overview of main contributions.

As the main result, we propose a simple, two-step robust synthetic control algorithm, wherein the first step de-noises the data and the second step learns a linear relationship between the treated unit and the donor pool under the de-noised setting. The algorithm is robust in two senses: first, it is fully data-driven in that it is able to find a good donor subset even in the absence of helpful domain knowledge or supplementary covariate information; and second, it provides the means to overcome the challenges presented by missing and/or noisy observations. As another important contribution, we establish analytic guarantees (finite sample analysis and asymptotic consistency) – that are missing from the literature – for a broader class of models.

Robust algorithm. A distinguishing feature of our work is that of de-noising the observation data via singular value thresholding. Although this spectral procedure is commonplace in the matrix completion arena, it is novel in the realm of synthetic control. Despite its simplicity, however, thresholding brings a myriad of benefits and resolves points of concern that have not been previously addressed. For instance, while classical methods have not even tackled the obstacle of missing data, our approach is well equipped to impute missing values as a consequence of the thresholding procedure. Additionally, thresholding can help prevent the model from overfitting to the idiosyncrasies of the data, providing a knob for practitioners to tune the "bias-variance" trade-off of their model and, thus, reduce their mean-squared error (MSE). From empirical studies, we hypothesize that thresholding may possibly render auxiliary covariate information (vital to several existing methods) a luxury as opposed to a necessity. However, as one would expect, the algorithm can only benefit from useful covariate and/or "expert" information and we do not advocate ignoring such helpful information, if available.

In the spirit of combatting overfitting, we extend our algorithm to include regularization techniques such as ridge regression and LASSO. We also move beyond point estimates in establishing a Bayesian framework, which allows one to quantitatively compute the uncertainty of the results

through posterior probabilities.

Theoretical performance. To the best of our knowledge, ours is the first to provide finite sample analysis of the MSE for the synthetic control method, in addition to guarantees in the presence of missing data. Previously, the main theoretical result from the synthetic control literature (cf. Abadie et al. (2010); Abadie and Gardeazabal (2003); Abadie et al. (2011)) pertained to bounding the bias of the synthetic control estimator; however, the proof of the result assumed that the latent parameters, which live in the simplex, have a perfect pre-treatment match in the noisy predictor variables – our analysis, on the other hand, removes this assumption. We begin by demonstrating that our de-noising procedure produces a consistent estimator of the latent signal matrix (Theorems 1, 2), proving that our thresholding method accurately imputes and filters missing and noisy observations, respectively. We then provide finite sample analysis that not only highlights the value of thresholding in balancing the inherent "bias-variance" trade-off of forecasting, but also proves that the prediction efficacy of our algorithm degrades gracefully with an increasing number of randomly missing data (Theorems 3, 7, and Corollary 4). Further, we show that a computationally beneficial pre-processing data aggregation step allows us to establish the asymptotic consistency of our estimator in generality (Theorem 5).

Additionally, we prove a simple linear algebraic fact that justifies the basic premise of synthetic control, which has not been formally established in literature, i.e. the linear relationship between the treatment and donor units that exists in the pre-intervention continues to hold in post-intervention period (Theorem 6). We introduce a latent variable model, which subsumes many of the models previously used in literature (e.g. econometric factor models). Despite this generality, a unifying theme that connects these models is that they all induce (approximately) low rank matrices, which is well suited for our method.

Experimental results. We conduct two sets of experiments: (a) on existing case studies from real world datasets referenced in Abadie et al. (2010, 2011); Abadie and Gardeazabal (2003), and (b) on synthetically generated data. Remarkably, while Abadie et al. (2010, 2011); Abadie and Gardeazabal (2003) use numerous covariates and employ expert knowledge in selecting their donor pool, our algorithm achieves similar results without any such assistance; additionally, our algorithm detects subtle effects of the intervention that were overlooked by the original synthetic control approach. Since it is impossible to simultaneously observe the evolution of a treated unit and its counterfactual, we employ synthetic data to validate the efficacy of our method. Using the MSE as our evaluation metric, we demonstrate that our algorithm is robust to varying levels of noise and missing data, reinforcing the importance of de-noising.

1.2 Related work.

Synthetic control has received widespread attention since its conception by Abadie and Gardeazabal in their pioneering work Abadie and Gardeazabal (2003); Abadie et al. (2010). It has been employed in numerous case studies, ranging from criminology Saunders et al. (2014) to health policy Kreif et al. (2015) to online advertisement to retail; other notable studies include Abadie et al. (2014); Billmeier and Nannicini (2013); Adhikari and Alm (2016); Aytug et al. (2016). In their paper on the state of applied econometrics for causality and policy evaluation, Athey and Imbens assert that synthetic control is "one of the most important development[s] in program evaluation in the past decade" and "arguably the most important innovation in the evaluation literature in the last fifteen years" Athey and Imbens (2016). In a somewhat different direction, Hsiao et al. introduce the panel data method Hsiao (2014); Hsiao et al. (2011), which seems to have a close bearing with some of the approaches of this work. In particular, to learn the weights of the synthetic control, Hsiao (2014); Hsiao et al. (2011) solve an ordinary least squares problem of Y on $\tilde{X}$, where Y is the data for the outcome variable of the treatment unit and $\tilde{X}$ includes other variables, e.g. covariates, and the outcome variable data from the donor units. However, Hsiao (2014); Hsiao et al. (2011) restrict the

subset of possible controls to units that are within the geographical or economic proximity of the treated unit. Therefore, there is still some degree of subjectivity in the choice of the donor pool. In addition, Hsiao (2014); Hsiao et al. (2011) do not include a "de-noising" step, which is a key feature of our approach. For an empirical comparison between the synthetic control and panel data methods, see Gardeazabal and Vega-Bayo (2016). It should be noted that Gardeazabal and Vega-Bayo (2016) also adapts the panel data method to automate the donor selection process. In this comparison study, the authors conclude that neither the synthetic control method nor the panel data method is vastly superior to the other. They suggest that the synthetic control method may be more useful when there are more time periods and covariates. However, when there is a poor pre-treatment match, the synthetical control method is not feasible while the panel data method can still be used, even though it may suffer from some extrapolation bias. But when a good pre-intervention match is found, the authors conclude that the synthetic control method tends to produce lower MSE, MAPE and mean-error. However, in another comparison study, Wan et al. (2018) compare and contrast the assumptions of both methods and note that the panel data method appears to outperform the synthetic control method in a majority of the simulations they conducted.

Among other notable bodies of work, Doudchenko and Imbens (2016) allows for an additive difference between the treated unit and donor pool, similar to the difference-in-differences (DID) method. Moreover, similar to our exposition, Doudchenko and Imbens (2016) relaxes the convexity aspect of synthetic control and proposes an algorithm that allows for unrestricted linearity as well as regularization. In an effort to infer the causal impact of market interventions, Brodersen et al. (2015) introduce yet another evaluation methodology based on a diffusion-regression state-space model that is fully Bayesian; similar to Abadie et al. (2010); Abadie and Gardeazabal (2003); Hsiao (2014); Hsiao et al. (2011), their model also generalizes the DID procedure. Due to the subjectivity in the choice of covariates and predictor variables, Ferman et al. (2016) provides recommendations for specification-searching opportunities in synthetic control applications. The recent work of Xu (2017) extends the synthetic control method to allow for multiple treated units and variable treatment periods as well as the treatment being correlated with unobserved units. Similar to our work, Xu (2017) computes uncertainty estimates; however, while Xu (2017) obtains these measurements via a parametric bootstrap procedure, we obtain uncertainty estimates under a Bayesian framework.

Matrix completion and factorization approaches are well-studied problems with broad applications (e.g. recommendation systems, graphon estimation, etc.). As shown profusely in the literature, spectral methods, such as singular value decomposition and thresholding, provide a procedure to estimate the entries of a matrix from partial and/or noisy observations Candès and Recht (2008). With our eyes set on achieving "robustness", spectral methods become particularly appealing since they de-noise random effects and impute missing information within the data matrix Jha et al. (2010). For a detailed discussion on the topic, see Chatterjee (2015); for algorithmic implementations, see Mazumder et al. (2010) and references there in. We note that our goal differs from traditional matrix completion applications in that we are using spectral methods to estimate a low-rank matrix, allowing us to determine a linear relationship between the rows of the mean matrix. This relationship is then projected into the future to determine the counterfactual evolution of a row in the matrix (treated unit), which is traditionally not the goal in matrix completion applications. Another line of work within this arena is to impute the missing entries via a nearest neighbor based estimation algorithm under a latent variable model framework Lee et al. (2016); Borgs et al. (2017).

There has been some recent work in using matrix norm methods in relation to causal inference, including for synthetic control. In Athey et al. (2017), the authors use matrix norm regularization techniques to estimate counterfactuals for panel data under settings that rely on the availability of a large number of units relative to the number of factors or characteristics, and under settings that involve limited number of units but plenty of history (synthetic control). This is different from our approach, which increases robustness by "de-noising" using matrix completion methods, and then using linear regression on the de-noised matrix, instead of relying on matrix norm regularizations.

Despite its popularity, there has been less theoretical work in establishing the consistency of the synthetic control method or its variants. Abadie et al. (2010) demonstrates that the bias of the synthetic control estimator can be bounded by a function that is close to zero when the pre-intervention period is large in relation to the scale of the transitory shocks, but under the additional condition that a perfect convex match between the pre-treatment noisy outcome and covariate variables for the treated unit and donor pool exists. Ferman and Pinto (2016) relaxes the assumption in Abadie et al. (2010), and derives conditions under which the synthetic control estimator is asymptotically unbiased under non-stationarity conditions. To our knowledge, however, no prior work has provided finite-sample analysis, analyzed the performance of these estimators with respect to the mean-squared error (MSE), established asymptotic consistency, or addressed the possibility of missing data, a common handicap in practice.

2. Background

2.1 Notation.

We will denote $\mathbb{R}$ as the field of real numbers. For any positive integer N, let $[N] = \{1, \dots, N\}$. For any vector $v \in \mathbb{R}^n$, we denote its Euclidean (ℓ_2) norm by $\|v\|_2$, and define $\|v\|_2^2 = \sum_{i=1}^n v_i^2$. We define its infinity norm as $\|v\|_\infty = \max_i |v_i|$. In general, the ℓ_p norm for a vector v is defined as $\|v\|_p = \left(\sum_{i=1}^n |v_i|^p\right)^{1/p}$. Similarly, for an $m \times n$ real-valued matrix $\boldsymbol{A} = [A_{ij}]$, its spectral/operator norm, denoted by $\|\boldsymbol{A}\|_2$, is defined as $\|\boldsymbol{A}\|_2 = \max_{1 \le i \le k} |\sigma_i|$, where $k = \min\{m, n\}$ and σ_i are the singular values of $\boldsymbol{A}$. The Moore-Penrose pseudoinverse $\boldsymbol{A}^\dagger$ of $\boldsymbol{A}$ is defined as

$$\boldsymbol{A}^\dagger = \sum_{i=1}^k (1/\sigma_i) y_i x_i^T, \quad \text{where} \quad \boldsymbol{A} = \sum_{i=1}^k \sigma_i x_i y_i^T, \tag{1}$$

with x_i and y_i being the left and right singular vectors of $\boldsymbol{A}$, respectively. We will adopt the shorthand notation of $\|\cdot\| \equiv \|\cdot\|_2$. To avoid any confusions between scalars/vectors and matrices, we will represent all matrices in bold, e.g. $\boldsymbol{A}$.

Let f and g be two functions defined on the same space. We say that $f(x) = \mathcal{O}(g(x))$ and $f(x) = \Omega(g(x))$ if and only if there exists a positive real number M and a real number x_0 such that for all $x \ge x_0$,

$$|f(x)| \le M|g(x)| \quad \text{and} \quad |f(x)| \ge M|g(x)|, \tag{2}$$

respectively.

2.2 Model.

The data at hand is a collection of time series with respect to an aggregated metric of interest (e.g. violent crime rates) comprised of both the treated unit and the donor pool outcomes. Suppose we observe $N \ge 2$ units across $T \ge 2$ time periods. We denote T_0 as the number of pre-intervention periods with $1 \le T_0 < T$, rendering $T - T_0$ as the length of the post-intervention stage. Without loss of generality, let the first unit represent the treatment unit – exposed to the intervention of interest at time $t = T_0 + 1$. The remaining donor units, $2 \le i \le N$, are unaffected by the intervention for the entire time period $[T] = \{1, \dots, T\}$.

Let X_{it} denote the measured value of metric for unit i at time t. We posit

$$X_{it} = M_{it} + \epsilon_{it}, \tag{3}$$

where M_{it} is the deterministic mean while the random variables ϵ_{it} represent zero-mean noise that are independent across i, t. Following the philosophy of latent variable models Chatterjee (2015); Lee et al. (2016); Aldous (1981); Hoover (1979, 1981), we further posit that for all $2 \le i \le N$, $t \in [T]$

$$M_{it} = f(\theta_i, \rho_t), \tag{4}$$

where $\theta_i \in \mathbb{R}^{d_1}$ and $\rho_t \in \mathbb{R}^{d_2}$ are latent feature vectors capturing unit and time specific information, respectively, for some $d_1, d_2 \ge 1$; the latent function $f : \mathbb{R}^{d_1} \times \mathbb{R}^{d_2} \to \mathbb{R}$ captures the model relationship. We note that this formulation subsumes popular econometric factor models, such as the one presented in Abadie et al. (2010), as a special case with (small) constants $d_1 = d_2$ and f as a bilinear function.

The treatment unit obeys the same model relationship during the pre-intervention period. That is, for $t \le T_0$

$$X_{1t} = M_{1t} + \epsilon_{1t}, \tag{5}$$

where $M_{1t} = f(\theta_1, \rho_t)$ for some latent parameter $\theta_1 \in \mathbb{R}^{d_1}$. If unit one was never exposed to the intervention, then the same relationship as (5) would continue to hold during the post-intervention period as well. In essence, we are assuming that the outcome random variables for *all* unaffected units follow the model relationship defined by (5) and (3). Therefore, the "synthetic control" would ideally help estimate the underlying counterfactual means $M_{1t} = f(\theta_1, \rho_t)$ for $T_0 < t \le T$ by using an appropriate combination of the post-intervention observations from the donor pool since the donor units are immune to the treatment.

To render this feasible, we make the key operating assumption (as done similarly in literature cf. Abadie et al. (2010, 2011); Abadie and Gardeazabal (2003)) that the mean vector of the treatment unit over the pre-intervention period, i.e. the vector $M_1^- = [M_{1t}]_{t \le T_0}$, lies within the span of the mean vectors within the donor pool over the pre-intervention period, i.e. the span of the donor mean vectors $M_i^- = [M_{it}]_{2 \le i \le N, t \le T_0}$ [1]. More precisely, we assume there exists a set of weights $\beta^* \in \mathbb{R}^{N-1}$ such that for all $t \le T_0$,

$$M_{1t} = \sum_{i=2}^N \beta_i^* M_{it}. \tag{6}$$

This is a reasonable and intuitive assumption, utilized in literature, hypothesizing that the treatment unit can be modeled as some combination of the donor pool. In fact, the set of weights β^* are the very definition of a synthetic control. Note, however, that in contrast to Abadie et al. (2010, 2011); Abadie and Gardeazabal (2003), we do not constrain the weights to be non-negative and sum to 1. This may reduce the interpretability of the synthetic control produced. We discuss ways to increase interpretability using our method in Section 3.4.2.

In order to distinguish the pre- and post-intervention periods, we use the following notation for all (donor) matrices: $\boldsymbol{A} = [\boldsymbol{A}^-, \boldsymbol{A}^+]$, where $\boldsymbol{A}^- = [A_{ij}]_{2 \le i \le N, j \in [T_0]}$ and $\boldsymbol{A}^+ = [A_{ij}]_{2 \le i \le N, T_0 < j \le T}$ denote the pre- and post-intervention submatrices, respectively; vectors will be defined in the same manner, i.e. $A_i = [A_i^-, A_i^+]$, where $A_i^- = [A_{it}]_{t \in [T_0]}$ and $A_i^+ = [A_{it}]_{T_0 < t \le T}$ denote the pre- and post-intervention subvectors, respectively, for the ith donor. Moreover, we will denote all vectors related to the treatment unit with the subscript "1", e.g. $A_1 = [A_1^-, A_1^+]$.

In contrast with the classical synthetic control work, we allow our model to be robust to incomplete observations. To model randomly missing data, the algorithm observes each data point X_{it} in the donor pool with probability $p \in (0, 1]$, independently of all other entries. While the assumption that p is constant across all rows and columns of our observation matrix is standard in literature, our results remain valid even in situations where the probability of observation is dependent on the row

1. We note that this is a minor departure from the literature on synthetic control starting in Abadie and Gardeazabal (2003) – in literature, the pre-intervention *noisy* observation (rather than the mean) vector X_1, is assumed to be a *convex* (rather than linear) combination of the noisy donor observations. We believe our setup is more reasonable since we do not want to fit noise.

and column latent parameters, i.e. $p_{ij} = g(\theta_i, \rho_j) \in (0, 1]$. In such situations, p_{ij} can be estimated as $\hat{p}_{ij}$ using consistent graphon estimation techniques described in a growing body of literature, e.g. see Borgs et al. (2017); Chatterjee (2015); Wolfe and Olhede; Yang et al.. These estimates can then be used in our analysis presented in Section 4.

3. Algorithm

3.1 Intuition.

We begin by exploring the intuition behind our proposed two-step algorithm: (1) *de-noising the data:* since the singular values of our observation matrix, $\boldsymbol{X} = [X_{it}]_{2 \le i \le N, t \in [T]}$, encode both signal and noise, we aim to discover a low rank approximation of $\boldsymbol{X}$ that only incorporates the singular values associated with useful information; simultaneously, this procedure will naturally impute any missing observations. We note that this procedure is similar to the algorithm proposed in Chatterjee (2015). (2) *learning β^*:* using the pre-intervention portion of the de-noised matrix, we learn the linear relationship between the treatment unit and the donor pool prior to estimating the post-intervention counterfactual outcomes. Since our objective is to produce accurate predictions, it is not obvious why the synthetic treatment unit should be a convex combination of its donor pool as assumed in Abadie et al. (2010); Abadie and Gardeazabal (2003); Abadie et al. (2014). In fact, one can reasonably expect that the treatment unit and some of the donor units may exhibit negative correlations with one another. In light of this intuition, we learn the optimal set of weights via linear regression, allowing for both positive and negative elements.

3.2 Robust algorithm (algorithm 1).

We present the details of our robust method in Algorithm 1 below. The algorithm utilizes two hyperparameters: (1) a thresholding hyperparameter $\mu \ge 0$, which serves as a knob to effectively trade-off between the bias and variance of the estimator, and (2) a regularization hyperameter $\eta \ge 0$ that controls the model complexity. We discuss the procedure for determining the hyperparameters in Section 3.4. To simplify the exposition, we assume the entries of $\boldsymbol{X}$ are bounded by one in absolute value, i.e. $|X_{it}| \le 1$.

3.3 Bayesian algorithm: measuring uncertainty (algorithm 2).

In order to quantitatively assess the uncertainty of our model, we will transition from a frequentist perspective to a Bayesian viewpoint. As commonly assumed in literature, we consider a zero-mean, isotropic Gaussian noise model (i.e. $\epsilon \sim \mathcal{N}(0, \sigma^2 \boldsymbol{I})$) and use the square loss for our cost function. We present the Bayesian method as Algorithm 2. Note that we perform step one of our robust algorithm exactly as in Algorithm 1; as a result, we only detail the alterations of step two in the Bayesian version (Algorithm 2).

3.4 Algorithmic features: the fine print.

3.4.1 Bounded entries transformation.

Several of our results, as well as the algorithm we propose, assume that the observation matrix is bounded such that $|X_{it}| \le 1$. For any data matrix, we can achieve this by using the following pre-processing transformation: suppose the entries of $\boldsymbol{X}$ belong to an interval $[a, b]$. Then, one can first pre-process the matrix $\boldsymbol{X}$ by subtracting $(a+b)/2$ from each entry, and dividing by $(b-a)/2$ to enforce that the entries lie in the range $[-1, 1]$. The reverse transformation, which can be applied at the end of the algorithm description above, returns a matrix with values contained in the original

Algorithm 1 Robust synthetic control

Step 1. De-noising the data: singular value thresholding (inspired by Chatterjee (2015)).

1. Define $\boldsymbol{Y} = [Y_{it}]_{2 \le i \le N, t \in [T]}$ with

$$Y_{it} = \begin{cases} X_{it} & \text{if } X_{it} \text{ is observed,} \\ 0 & \text{otherwise.} \end{cases} \tag{7}$$

2. Compute the singular value decomposition of $\boldsymbol{Y}$:

$$\boldsymbol{Y} = \sum_{i=1}^{N-1} s_i u_i v_i^T. \tag{8}$$

3. Let $S = \{i : s_i \ge \mu\}$ be the set of singular values above the threshold μ.

4. Define the estimator of $\boldsymbol{M}$ as

$$\hat{\boldsymbol{M}} = \frac{1}{\hat{p}} \sum_{i \in S} s_i u_i v_i^T, \tag{9}$$

where $\hat{p}$ is the maximum of the fraction of observed entries in $\boldsymbol{X}$ and $\frac{1}{(N-1)T}$.

Step 2. Learning and projecting

1. For any $\eta \ge 0$, let

$$\hat{\beta}(\eta) = \underset{v \in \mathbb{R}^{N-1}}{\arg\min} \left\| Y_1^- - (\hat{\boldsymbol{M}}^-)^T v \right\|^2 + \eta \|v\|^2. \tag{10}$$

2. Define the counterfactual means for the treatment unit as

$$\hat{M}_1 = \hat{\boldsymbol{M}}^T \hat{\beta}(\eta). \tag{11}$$

Algorithm 2 Bayesian robust synthetic control

Step 2. Learning and projecting

1. Estimate the noise variance via (bias-corrected) maximum likelihood, i.e.

$$\hat{\sigma}^2 = \frac{1}{T_0 - 1} \sum_{t=1}^{T_0} (Y_{1t} - \bar{Y})^2, \tag{12}$$

   where $\bar{Y}$ denotes the pre-intervention sample mean.

2. Compute posterior distribution parameters for an appropriate choice of the prior α:

$$\boldsymbol{\Sigma}_D = \left(\frac{1}{\hat{\sigma}^2} \hat{\boldsymbol{M}}^- (\hat{\boldsymbol{M}}^-)^T + \alpha \boldsymbol{I} \right)^{-1} \tag{13}$$

$$\beta_D = \frac{1}{\hat{\sigma}^2} \boldsymbol{\Sigma}_D \hat{\boldsymbol{M}}^- Y_1^-. \tag{14}$$

3. Define the counterfactual means for the treatment unit as

$$\hat{M}_1 = \hat{\boldsymbol{M}}^T \beta_D. \tag{15}$$

4. For each time instance $t \in [T]$, compute the model uncertainty (variance) as

$$\sigma_D^2(\hat{M}_{\cdot,t}) = \hat{\sigma}^2 + \hat{M}_{\cdot,t}^T \boldsymbol{\Sigma}_D \hat{M}_{\cdot,t}, \tag{16}$$

   where $\hat{M}_{\cdot,t} = [\hat{M}_{it}]_{2 \le i \le N}$ is the de-noised vector of donor outcomes at time t.

range. Specifically, the reverse transformation equates to multiplying the end result by $(b-a)/2$ and adding by $(a+b)/2$.

3.4.2 Solution interpretability.

For the practitioner who seeks a more interpretable solution, e.g. a convex combination of donors as per the original synthetic control estimator of Abadie et al. (2010, 2011); Abadie and Gardeazabal (2003), we recommend using an ℓ_1-regularization penalty in the learning procedure of step 2. Due to the geometry of LASSO, the resulting estimator will often be a sparse vector; in other words, LASSO effectively performs model selection and selects the most important donors that comprise the synthetic control. LASSO can also be beneficial if the number of donors exceeds the number of pre-treatment time periods. Specifically, for any $\eta > 0$, we define the LASSO estimator to be

$$\hat{\beta}(\eta) = \underset{v \in \mathbb{R}^{N-1}}{\arg\min} \left\| Y_1^- - (\hat{\boldsymbol{M}}^-)^T v \right\|^2 + \eta \|v\|_1.$$

For the purposes of this paper, we focus our attention on ridge regression and provide theoretical results in Section 4 under the ℓ_2-regularization setting. However, a closer examination of the LASSO estimator for synthetic control methods can be found in Li and Bell (2017).

3.4.3 Choosing the hyperparameters.

Here, we discuss several approaches to choosing the hyperparameter μ for the singular values; note that μ defines the set S that includes the singular values we wish to include in the imputation procedure. If it is known a priori that the underlying model is low rank with rank at most k, then it may make sense to choose μ such that $|S| = k$. A data driven approach, however, could be implemented based on cross-validation. Precisely, reserve a portion of the pre-intervention period for validation, and use the rest of the pre-intervention data to produce an estimate $\hat{\beta}(\eta)$ for each of the finitely many choices of μ $(s_1, \ldots, s_{N-1})$. Using each estimate $\hat{\beta}(\eta)$, produce its corresponding treatment unit mean vector over the validation period. Then, select the μ that achieves the minimum MSE with respect to the observed data. Finally, Chatterjee (2015) provides a universal approach to picking a threshold; similarly, we also propose another such universal threshold, (20), in Section 4.1. We utilize the data driven approach in our experiments in this work.

The regularization parameter, η, also plays a crucial role in learning the synthetic control and influences both the training and generalization errors. As is often the case in model selection, a popular strategy in estimating the ideal η is to employ cross-validation as described above. However, since time-series data often have a natural temporal ordering with causal effects, we also recommend employing the forward chaining strategy. Although the forward chaining strategy is similar to leave-one-out (LOO) cross-validation, an important distinction is that forward chaining does not break the temporal ordering in the training data. More specifically, for a particular candidate of η at every iteration $t \in [T_0]$, the learning process uses $[Y_{11}, \ldots, Y_{1,t-1}]$ as the training portion while reserving Y_{1t} as the validation point. As before, the average error is then computed and used to evaluate the model (characterized by the choice of η). The forward chaining strategy can also be used to learn the optimal μ.

3.4.4 Scalability.

In terms of scalability, the most computationally demanding procedure is that of evaluating the singular value decomposition (SVD) of the observation matrix. Given the ubiquity of SVD methods in the realm of machine learning, there are well-known techniques that enable computational and storage scaling for SVD algorithms. For instance, both Spark (through alternative least squares) and Tensor-Flow come with built-in SVD implementations. As a result, by utilizing the appropriate

computational infrastructure, our de-noising procedure, and algorithm in generality, can scale quite well. Also note that for a low rank structure, we typically only need to compute the top few singular values and vectors. Various truncated-SVD algorithms provide resource-efficient implementations to compute the top k singular values and vectors instead of the complete-SVD.

3.4.5 Low rank hypothesis.

The factor models that are commonly used in the Econometrics literature, cf. Abadie et al. (2010, 2011); Abadie and Gardeazabal (2003), often lead to a low rank structure for the underlying mean matrix $\boldsymbol{M}$. When f is nonlinear, $\boldsymbol{M}$ can still be well approximated by a low rank matrix for a large class of functions. For instance, if the latent parameters assumed values from a bounded, compact set, and if f was Lipschitz continuous, then it can be argued that $\boldsymbol{M}$ is well approximated by a low rank matrix, cf. see Chatterjee (2015) for a very simple proof. As the reader will notice, while we establish results for low rank matrix, the results of this work are robust to low rank approximations whereby the approximation error can be viewed as "noise". Lastly, as shown in Udell and Townsend (2017), many latent variable models can be well approximated (up to arbitrary accuracy ϵ) by low rank matrices. Specifically, Udell and Townsend (2017) shows that the corresponding low rank approximation matrices associated with "nice" functions (e.g. linear functions, polynomials, kernels, etc.) are of log-rank.

3.4.6 Covariate information.

Although the algorithm does not appear to rely on any helpful covariate information and the experimental results, presented in Section 5, suggest that it performs on par with that of the original synthetic control algorithm, we want to emphasize that we are not suggesting that practitioners should abandon the use of any additional covariate information or the application of domain knowledge. Rather, we believe that our key algorithmic feature – the de-noising step – may render covariates and domain expertise as luxuries as opposed to necessities for many practical applications. If the practitioner has access to supplementary predictor variables, we propose that step one of our algorithm be used as a pre-processing routine for de-noising the data before incorporating additional information. Moreover, other than the obvious benefit of narrowing the donor pool, domain expertise can also come in handy in various settings, such as determining the appropriate method for imputing the missing entries in the data. For instance, if it is known a priori that there is a trend or periodicity in the time series evolution for the units, it may behoove the practitioner to impute the missing entries using "nearest-neighbors" or linear interpolation.

4. Theoretical Results

In this section, we derive the finite sample and asymptotic properties of the estimators $\hat{\boldsymbol{M}}$ and $\hat{M}_1$. We begin by defining necessary notations and recalling a few operating assumptions prior to presenting the results, with the corresponding proofs relegated to the Appendix. To that end, we re-write (3) in matrix form as $\boldsymbol{X} = \boldsymbol{M} + \boldsymbol{E}$, where $\boldsymbol{E} = [\epsilon_{it}]_{2 \le i \le N, t \in [T]}$ denotes the noise matrix. We shall assume that the noise parameters ϵ_{it} are independent zero-mean random variables with bounded second moments. Specifically, for all $2 \le i \le N, t \in [T]$,

$$\mathbb{E}[\epsilon_{it}] = 0, \quad \text{and} \quad \text{Var}(\epsilon_{it}) = \sigma^2. \tag{17}$$

We shall also assume that the treatment unit noise in (5) obeys (17). Further, we assume the relationship in (6) holds. To simplify the following exposition, we assume that $|M_{ij}| \le 1$ and $|X_{ij}| \le 1$.

As previously discussed, we evaluate the accuracy of our estimated means for the treatment unit with respect to the deviation between $\hat{M}_1$ and M_1 measured in ℓ_2-norm, and similarly between $\hat{\boldsymbol{M}}$ and $\boldsymbol{M}$. Additionally, we aim to establish the validity of our pre-intervention linear model assumption (cf. (6)) and investigate how the linear relationship translates over to the post-intervention regime, i.e. if $M_1^- = (\boldsymbol{M}^-)^T \beta^*$ for some β^*, does M_1^+ (approximately) equal to $(\boldsymbol{M}^+)^T \beta^*$? If so, under what conditions? We present our results for the above aspects after a brief motivation of ℓ_2 regularization.

Combatting overfitting. One weapon to combat overfitting is to constrain the learning algorithm to limit the effective model complexity by fitting the data under a simpler hypothesis. This technique is known as regularization, and it has been widely used in practice. To employ regularization, we introduce a complexity penalty term into the objective function (10). For a general regularizer, the objective function takes the form

$$\hat{\beta}(\eta) = \underset{v \in \mathbb{R}^{N-1}}{\arg\min} \left\| Y_1^- - (\hat{\boldsymbol{M}}^-)^T v \right\|^2 + \eta \sum_{j=1}^{N-1} |v_j|^q, \tag{18}$$

for some choice of positive constants η and q. The first term measures the empirical error of the model on the given dataset, while the second term penalizes models that are too "complex" by controlling the "smoothness" of the model in order to avoid overfitting. In general, the impact/trade-off of regularization can be controlled by the value of the regularization parameter η. Via the use of Lagrange multipliers, we note that minimizing (18) is equivalent to minimizing (10) subject to the constraint that

$$\sum_{j=1}^{N-1} |v_j|^q \le c,$$

for some appropriate value of c. When $q = 2$, (18) corresponds to the classical setup known as *ridge regression* or *weight decay*. The case of $q = 1$ is known as the LASSO in the statistics literature; the ℓ_1-norm regularization of LASSO is a popular heuristic for finding a sparse solution. In either case, incorporating an additional regularization term encourages the learning algorithm to output a simpler model with respect to some measure of complexity, which helps the algorithm avoid overfitting to the idiosyncrasies within the observed dataset. Although the training error may suffer from the simpler model, empirical studies have demonstrated that the generalization error can be greatly improved under this new setting. Throughout this section, we will primarily focus our attention on the case of $q = 2$, which maintains our learning objective to be (convex) quadratic in the parameter v so that its exact minimizer can be found in closed form:

$$\hat{\beta}(\eta) = \left(\hat{\boldsymbol{M}}^- (\hat{\boldsymbol{M}}^-)^T + \eta \boldsymbol{I} \right)^{-1} \hat{\boldsymbol{M}}^- Y_1^-. \tag{19}$$

4.1 Imputation analysis.

In this section, we highlight the importance of our de-noising procedure and prescribe a universal threshold (similar to that of Chatterjee (2015)) that dexterously distinguishes signal from noise, enabling the algorithm to capture the appropriate amount of useful information (encoded in the singular values of $\boldsymbol{Y}$) while discarding out the randomness. Due to its universality, the threshold naturally adapts to the amount of structure within $\boldsymbol{M}$ in a purely data-driven manner. Specifically, for any choice of $\omega \in (0.1, 1)$, we find that choosing

$$\mu = (2 + \omega) \sqrt{T(\hat{\sigma}^2 \hat{p} + \hat{p}(1 - \hat{p}))}, \tag{20}$$

results in an estimator with strong theoretical properties for both interpolation and extrapolation (discussed in Section 4.2). Here, $\hat{p}$ and $\hat{\sigma}^2$ denote the unbiased maximum likelihood estimates of p and σ^2, respectively, and can be computed via (9) and (12).

The following Theorems (adapted from Theorems 2.1 and 2.7 of Chatterjee (2015)) demonstrate that Step 1 of our algorithm (detailed in Section 3.2) accurately imputes missing entries within our data matrix $\boldsymbol{X}$ when the signal matrix $\boldsymbol{M}$ is either low rank or generated by an $\mathcal{L}$-Lipschitz function. In particular, Theorems 1 and 2 state that Step 1 produces a consistent estimator of the underlying mean matrix $\boldsymbol{M}$ with respect to the (matrix) mean-squared-error, which is defined as

$$\text{MSE}(\hat{\boldsymbol{M}}) = \mathbb{E}\left[\frac{1}{(N-1)T}\sum_{i=2}^{N}\sum_{j=1}^{T}(\hat{M}_{ij} - M_{ij})^2\right]. \tag{21}$$

We say that $\hat{\boldsymbol{M}}$ is a consistent estimator of $\boldsymbol{M}$ if the right-hand side of (21) converges to zero as N and T grow without bound.

The following theorem demonstrates that $\hat{\boldsymbol{M}}$ is a good estimate of $\boldsymbol{M}$ when $\boldsymbol{M}$ is a low rank matrix, particularly when the rank of $\boldsymbol{M}$ is small compared to $(N-1)p$.

Theorem 1 (**Theorem 2.1 of Chatterjee (2015)**) *Suppose that $\boldsymbol{M}$ is rank k. Suppose that $p \geq \frac{T^{-1+\zeta}}{\sigma^2+1}$ for some $\zeta > 0$. Then using μ as defined in* (20)*,*

$$\text{MSE}(\hat{\boldsymbol{M}}) \leq C_1\sqrt{\frac{k}{(N-1)p}} + \mathcal{O}\Big(\frac{1}{(N-1)T}\Big), \tag{22}$$

where C_1 is a universal positive constant.

Suppose that the latent row and column feature vectors, $\{\theta_i\}$ and $\{\rho_j\}$, belong to some bounded, closed sets $K \subset \mathbb{R}^d$, where d is some arbitrary but fixed dimension. If we assume $f : K \times K \to [-1, 1]$ possesses desirable smoothness properties such as Lipschitzness, then $\hat{\boldsymbol{M}}$ is again a good estimate of $\boldsymbol{M}$.

Theorem 2 (**Theorem 2.7 of Chatterjee (2015)**) *Suppose f is a $\mathcal{L}$-Lipschitz function. Suppose that $p \geq \frac{T^{-1+\zeta}}{\sigma^2+1}$ for some $\zeta > 0$. Then using μ as defined in* (20)*,*

$$\text{MSE}(\hat{\boldsymbol{M}}) \leq C(K, d, \mathcal{L})\frac{(N-1)^{-\frac{1}{d+2}}}{\sqrt{p}} + \mathcal{O}\Big(\frac{1}{(N-1)T}\Big), \tag{23}$$

where $C(K, d, \mathcal{L})$ is a constant depending on K, d, and $\mathcal{L}$.

It is important to observe that the models under consideration for both Theorems 1 and 2 encompass the mean matrices, $\boldsymbol{M}$, generated as per many of the popular Econometric factor models often considered in literature and assumed in practice. Therefore, de-noising the data serves as an important imputing and filtering procedure for a wide array of applications.

4.2 Forecasting analysis: pre-intervention regime.

Similar to the setting for interpolation, the prediction performance metric of interest is the average mean-squared-error in estimating M_1^- using $\hat{M}_1^-$. Precisely, we define

$$\text{MSE}(\hat{M}_1^-) = \mathbb{E}\left[\frac{1}{T_0}\sum_{t=1}^{T_0}(M_{1t} - \hat{M}_{1t})^2\right]. \tag{24}$$

If the right-hand side of (33) approaches zero in the limit as T_0 grows without bound, then we say that $\hat{M}_1^-$ is a consistent estimator of M_1^- (note that our analysis here assumes that only $T_0 \to \infty$).

In what follows, we first state the finite sample bound on the average MSE between $\hat{M}_1^-$ and M_1^- for the most generic setup (Theorem 3). As a main Corollary of the result, we specialize the bound in the case where we use our prescribed universal threshold. Finally, we discuss a minor variation of the algorithm where the data is pre-processed, and specialize the above result to establish the consistency of our estimator (Theorem 5).

4.2.1 General result.

We provide a finite sample error bound for the most generic setting, i.e. for any choice of the threshold, μ, and regularization hyperparameter, η.

Theorem 3 *Let S denote the set of singular values included in the imputation procedure, i.e., the set of singular values greater than μ. Then for any $\eta \geq 0$ and $\mu \geq 0$, the pre-intervention error of the algorithm can be bounded as*

$$\text{MSE}(\hat{M}_1^-) \leq \frac{C_1}{p^2T_0}\mathbb{E}\Big(\lambda^* + \|\boldsymbol{Y} - p\boldsymbol{M}\| + \big\|(\hat{p} - p)\boldsymbol{M}^-\big\|\Big)^2 + \frac{2\sigma^2|S|}{T_0} + \frac{\eta\|\beta^*\|^2}{T_0} + C_2e^{-cp(N-1)T}. \tag{25}$$

Here, $\lambda_1, \ldots, \lambda_{N-1}$ are the singular values of $p\boldsymbol{M}$ in decreasing order and repeated by multiplicities, with $\lambda^* = \max_{i \notin S}\lambda_i$; C_1, C_2 and c are universal positive constants.

Bias-variance tradeoff. Let us interpret the result by parsing the terms in the error bound. The last term decays exponentially with $(N-1)T$, as long as the fraction of observed entries is such that, on average, we see a super-constant number of entries, i.e. $p(N-1)T \gg 1$. More interestingly, the first two terms highlight the "bias-variance tradeoff" of the algorithm with respect to the singular value threshold μ. Precisely, the size of the set S increases with a decreasing value of the hyperparameter μ, causing the second error term to increase. Simultaneously, however, this leads to a decrease in λ^*. Note that λ^* denotes the aspect of the "signal" within the matrix $\boldsymbol{M}$ that is not captured due to the thresholding through S. On the other hand, the second term, $|S|\sigma^2/T_0$, represents the amount of "noise" captured by the algorithm, but wrongfully interpreted as a signal, during the thresholding process. In other words, if we use a large threshold, then our model may fail to capture pertinent information encoded in $\boldsymbol{M}$; if we use a small threshold, then the algorithm may overfit the spurious patterns in the data. Thus, the hyperparameter μ provides a way to trade-off "bias" (first term) and "variance" (second term).

4.2.2 Goldilocks principle: a universal threshold.

Using the universal threshold defined in (20), we now highlight the prediction power of our estimator for any choice of η, the regularization hyperparameter. As described in Section 4.1, the prescribed threshold automatically captures the "correct" level of information encoded in the (noisy) singular values of $\boldsymbol{Y}$ in a data-driven manner, dependent on the structure of $\boldsymbol{M}$. However, unlike the statements in Theorems 1 and 2, the following bound does not require $\boldsymbol{M}$ to be low rank or f to be Lipschitz.

Corollary 4 *Suppose $p \geq \frac{T^{-1+\zeta}}{\sigma^2+1}$ for some $\zeta > 0$. Let $T \leq \alpha T_0$ for some constant $\alpha > 1$. Then for any $\eta \geq 0$ and using μ as defined in* (20)*, the pre-intervention error is bounded above by*

$$\text{MSE}(\hat{M}_1^-) \leq \frac{C_1}{p}(\sigma^2 + (1-p)) + \mathcal{O}(1/\sqrt{T_0}), \tag{26}$$

where C_1 is a universal positive constant.

As an implication, if $p = (1+\vartheta)\sqrt{T_0}/(1+\sqrt{T_0})$ and $\sigma^2 \leq \vartheta$, we have that $\text{MSE}(\hat{M}_1^-) = \mathcal{O}(1/\sqrt{T_0})$. More generally, Corollary 4 shows that by adroitly capturing the signal, the resulting error bound simply depends on the variance of the noise terms, σ^2, and the error introduced due to missing data. Ideally, one would hope to overcome the error term when T_0 is sufficiently large. This motivates the following setup.

4.2.3 Consistency.

We present a straightforward pre-processing step that leads to the consistency of our algorithm. The pre-processing step simply involves replacing the columns of $\boldsymbol{X}$ by the averages of subsets of its columns. This admits the same setup as before, but with the variance for each noise term reduced. An implicit side benefit of this approach is that required SVD step in the algorithm is now applied to a matrix of smaller dimensions.

To begin, partition the T_0 columns of the pre-intervention data matrix $\boldsymbol{X}^-$ into Δ blocks, each of size $\tau = \lfloor T_0/\Delta \rfloor$ except potentially the last block, which we shall ignore for theoretical purposes; in practice, however, the remaining columns can be placed into the last block. Let $B_j = \{(j-1)\tau + \ell : 1 \le \ell \le \tau\}$ denote the column indices of $\boldsymbol{X}^-$ within partition $j \in [\Delta]$. Next, we replace the τ columns within each partition by their average, and thus create a new matrix, $\bar{\boldsymbol{X}}^-$, with Δ columns and $N-1$ rows. Precisely, $\bar{\boldsymbol{X}}^- = [\bar{X}_{ij}]_{2 \le i \le N, j \in [\Delta]}$ with

$$\bar{X}_{ij} = \frac{1}{\tau} \sum_{t \in B_j} X_{it} \cdot D_{it}, \tag{27}$$

where

$$D_{it} = \begin{cases} 1 & \text{if } X_{it} \text{ is observed,} \\ 0 & \text{otherwise.} \end{cases}$$

For the treatment row, let $\bar{X}_{1j} = \frac{\hat{p}}{\tau} \sum_{t \in B_j} X_{1t}$ for all $j \in [\Delta]$[2]. Let $\bar{\boldsymbol{M}}^- = [\bar{M}_{ij}]_{2 \le i \le N, j \in [\Delta]}$ with

$$\bar{M}_{ij} = \mathbb{E}[\bar{X}_{ij}] \ = \frac{p}{\tau} \sum_{t \in B_j} M_{it}. \tag{28}$$

We apply the algorithm to $\bar{\boldsymbol{X}}^-$ to produce the estimate $\hat{\bar{\boldsymbol{M}}}^-$ of $\bar{\boldsymbol{M}}^-$, which is sufficient to produce $\hat{\beta}(\eta)$. This $\hat{\beta}(\eta)$ can be used to produce the post-intervention synthetic control means $\hat{M}_1^+ = [\hat{M}_{1t}]_{T_0 < t \le T}$ in a similar manner as before [3]: for $T_0 < t \le T$,

$$\hat{M}_{1t} = \sum_{i=2}^{N} \hat{\beta}_i(\eta) X_{it}. \tag{29}$$

For the pre-intervention period, we produce the estimator $\hat{\bar{M}}_1^- = [\hat{\bar{M}}_{1j}]_{j \in [\Delta]}$: for $j \in [\Delta]$,

$$\hat{\bar{M}}_{1j} = \sum_{i=2}^{N} \hat{\beta}_i(\eta) \hat{\bar{M}}_{ij}. \tag{30}$$

Our measure of estimation error is defined as

$$\mathrm{MSE}(\hat{\bar{M}}_1^-) = \mathbb{E}\left[\frac{1}{\Delta} \sum_{j=1}^{\Delta} (\bar{M}_{1j} - \hat{\bar{M}}_{1j})^2\right]. \tag{31}$$

For simplicity, we will analyze the case where each block contains at least one entry such that $\bar{\boldsymbol{X}}^-$ is completely observed. We now state the following result.

2. Although the statement in Theorem 5 assumes that an oracle provides the true p, we prescribe practitioners to use $\hat{p}$ since $\hat{p}$ converges to p almost surely by the Strong Law of Large Numbers.
3. In practice, one can first de-noise $\boldsymbol{X}^+$ via step one of Section 3, and use the entries of $\hat{\boldsymbol{M}}^+$ in (29).

Theorem 5 *Fix any $\gamma \in (0, 1/2)$ and $\omega \in (0.1, 1)$. Let $\Delta = T_0^{\frac{1}{2}+\gamma}$ and $\mu = (2+\omega)\sqrt{T_0^{2\gamma}(\hat{\sigma}^2\hat{p} + \hat{p}(1-\hat{p}))}$. Suppose $p \ge \frac{T_0^{-2\gamma}}{\sigma^2+1}$ is known. Then for any $\eta \ge 0$,*

$$\mathrm{MSE}(\hat{\bar{M}}_1^-) = \mathcal{O}(T_0^{-1/2+\gamma}). \tag{32}$$

We note that the method of (Abadie and Gardeazabal, 2003, Sec 2.3) learns the weights (here $\hat{\beta}(0)$) by pre-processing the data. One common pre-processing proposal is to also aggregate the columns, but the aggregation parameters are chosen by solving an optimization problem to minimize the resulting prediction error of the observations. In that sense, the above averaging of column is a simple, data agnostic approach to achieve a similar effect, and potentially more effectively.

4.3 Forecasting analysis: post-intervention regime.

For the post-intervention regime, we consider the average root-mean-squared-error in measuring the performance of our algorithm. Precisely, we define

$$\mathrm{RMSE}(\hat{M}_1^+) = \mathbb{E}\left[\frac{1}{\sqrt{T - T_0}} \left(\sum_{t > T_0}^{T} (M_{1t} - \hat{M}_{1t})^2\right)^{1/2}\right]. \tag{33}$$

The key assumption of our analysis is that the treatment unit signal can be written as a linear combination of donor pool signals. Specifically, we assume that this relationship holds in the pre-intervention regime, i.e. $M_1^- = (\boldsymbol{M}^-)^T \beta^*$ for some $\beta^* \in \mathbb{R}^{N-1}$ as stated in (6). However, the question still remains: does the same relationship hold for the post-intervention regime and if so, under what conditions does it hold? We state a simple linear algebraic fact to this effect, justifying the approach of synthetic control. It is worth noting that this important aspect has been amiss in the literature, potentially implicitly believed or assumed starting in the work by Abadie and Gardeazabal (2003).

Theorem 6 *Let Equation (6) hold for some β^*. Let $\mathrm{rank}(\boldsymbol{M}^-) = \mathrm{rank}(\boldsymbol{M})$. Then $M_1^+ = (\boldsymbol{M}^+)^T \beta^*$.*

If we assume that the linear relationship prevails in the post-intervention period, then we arrive at the following error bound.

Theorem 7 *Suppose $p \ge \frac{T^{-1+\zeta}}{\sigma^2+1}$ for some $\zeta > 0$. Suppose $\left\|\hat{\beta}(\eta)\right\|_\infty \le \psi$ for some $\psi > 0$. Let $\alpha' T_0 \le T \le \alpha T_0$ for some constants $\alpha', \alpha > 1$. Then for any $\eta \ge 0$ and using μ as defined in (20), the post-intervention error is bounded above by*

$$\mathrm{RMSE}(\hat{M}_1^+) \le \frac{C_1}{\sqrt{p}}(\sigma^2 + (1-p))^{1/2} + \frac{C_2 \|\boldsymbol{M}\|}{\sqrt{T_0}} \cdot \mathbb{E}\left\|\hat{\beta}(\eta) - \beta^*\right\| + \mathcal{O}(1/\sqrt{T_0}),$$

where C_1 and C_2 are universal positive constants.

Benefits of regularization. In order to motivate the use of regularization, we analyze the error bounds of Theorems 3 and 7 to observe how the pre- and post-intervention errors react to regularization. As seen from Theorem 3, the pre-intervention error *increases* linearly with respect to the choice of η. Intuitively, this increase in pre-intervention error derives from the fact that regularization reduces the model complexity, which biases the model and handicaps its ability to fit the data. At the same time, by restricting the hypothesis space and controlling the "smoothness" of the model, regularization prevents the model from overfitting to the data, which better equips the model to generalize to unseen

data. Therefore, a larger value of η *reduces* the post-intervention error. This can be seen by observing the second error term of Theorem 7, which is controlled by the expression $\left\|\hat{\beta}(\eta) - \beta^*\right\|$. In words, this error is a function of the learning algorithm used to estimate β^*. Interestingly, Farebrother (1976) demonstrates that there exists an $\eta > 0$ such that

$$\text{MSE}(\hat{\beta}(\eta)) \leq \text{MSE}(\hat{\beta}(0)),$$

without any assumptions on the rank of $\hat{\boldsymbol{M}}^-$. In other words, Farebrother (1976) demonstrates that regularization can decrease the MSE between $\hat{\beta}(\eta)$ and the true β^*, thus reducing the overall error. Ultimately, employing ridge regression introduces extraneous bias into our model, yielding a higher pre-intervention error. In exchange, regularization reduces the post-intervention error (due to smaller variance).

4.4 Bayesian analysis.

We now present a Bayesian treatment of synthetic control. By operating under a Bayesian framework, we allow practitioners to naturally encode domain knowledge into prior distributions while simultaneously avoiding the problem of overfitting. In addition, rather than making point estimates, we can now quantitatively express the uncertainty in our estimates with posterior probability distributions.

We begin by treating β^* as a random variable as opposed to an unknown constant. In this approach, we specify a prior distribution, $p(\beta)$, that expresses our apriori beliefs and preferences about the underlying parameter (synthetic control). Given some new observation for the donor units, our goal is to make predictions for the counterfactual treatment unit on the basis of a set of pre-intervention (training) data. For the moment, let us assume that the noise parameter σ^2 is a known quantity and that the noise is drawn from a Gaussian distribution with zero-mean; similarly, we temporarily assume $\boldsymbol{M}^-$ is also given. Let us denote the vector of donor estimates as $M_{\cdot t} = [M_{it}]_{2 \leq i \leq N}$; we define $X_{\cdot t}$ similarly. Denoting the pre-intervention data as $D = \{(Y_{1t}, M_{\cdot t}) : t \in [T_0]\}$, the likelihood function $p(Y_1^- \mid \beta, \boldsymbol{M}^-)$ is expressed as

$$p(Y_1^- \mid \beta, \hat{\boldsymbol{M}}^-) = \mathcal{N}((\boldsymbol{M}^-)^T\beta, \sigma^2\boldsymbol{I}), \tag{34}$$

an exponential of a quadratic function of β. The corresponding conjugate prior, $p(\beta)$, is therefore given by a Gaussian distribution, i.e. $\beta \sim \mathcal{N}(\beta \mid \beta_0, \boldsymbol{\Sigma}_0)$ with mean β_0 and covariance Σ_0. By using a conjugate Gaussian prior, the posterior distribution, which is proportional to the product of the likelihood and the prior, will also be Gaussian. Applying Bayes' Theorem (derivation unveiled below in Section G in the Appendix, we have that the posterior distribution is $p(\beta \mid D) = \mathcal{N}(\beta_D, \boldsymbol{\Sigma}_D)$ where

$$\boldsymbol{\Sigma}_D = \left(\boldsymbol{\Sigma}_0^{-1} + \frac{1}{\sigma^2}\boldsymbol{M}^-(\boldsymbol{M}^-)^T\right)^{-1} \tag{35}$$

$$\beta_D = \boldsymbol{\Sigma}_D\left(\frac{1}{\sigma^2}\boldsymbol{M}^-Y_1^- + \boldsymbol{\Sigma}_0^{-1}\beta_0\right). \tag{36}$$

For the remainder of this section, we shall consider a popular form of the Gaussian prior. In particular, we consider a zero-mean isotropic Gaussian with the following parameters: $\beta_0 = 0$ and $\boldsymbol{\Sigma}_0 = \alpha^{-1}\boldsymbol{I}$ for some choice of $\alpha > 0$. Since $\boldsymbol{M}^-$ is unobserved by the algorithm, we use the estimated $\hat{\boldsymbol{M}}^-$, computed as per step one of Section 3, as a proxy; therefore, we redefine our data as $D = \{(Y_{1t}, \hat{M}_{\cdot t}) : t \in [T_0]\}$.

Putting everything together, we have that $p(\beta \mid D) = \mathcal{N}(\beta_D, \boldsymbol{\Sigma}_D)$ whereby

$$\boldsymbol{\Sigma}_D = \left(\alpha\boldsymbol{I} + \frac{1}{\sigma^2}\hat{\boldsymbol{M}}^-(\hat{\boldsymbol{M}}^-)^T\right)^{-1} \tag{37}$$

$$\beta_D = \frac{1}{\sigma^2}\boldsymbol{\Sigma}_D\hat{\boldsymbol{M}}^-Y_1^- \tag{38}$$

$$= \frac{1}{\sigma^2}\left(\frac{1}{\sigma^2}\hat{\boldsymbol{M}}^-(\hat{\boldsymbol{M}}^-)^T + \alpha\boldsymbol{I}\right)^{-1}\hat{\boldsymbol{M}}^-Y_1^-. \tag{39}$$

4.4.1 Maximum a posteriori (MAP) estimation.

By using the zero-mean, isotropic Gaussian conjugate prior, we can derive a point estimate of β^* by maximizing the log posterior distribution, which we will show is equivalent to minimizing the regularized objective function of (10) for a particular choice of η. In essence, we are determining the optimal $\hat{\beta}$ by finding the most probable value of β^* given the data and under the influence of our prior beliefs. The resulting estimate is known as the maximum a posteriori (MAP) estimate.

We begin by taking the log of the posterior distribution, which gives the form

$$\ln p(\beta \mid D) = -\frac{1}{2\sigma^2}\left\|Y_1^- - (\hat{\boldsymbol{M}}^-)^T\beta\right\|^2 - \frac{\alpha}{2}\|\beta\|^2 + \text{const.}$$

Maximizing the above log posterior then equates to minimizing the quadratic regularized error (10) with $\eta = \alpha\sigma^2$. We define the MAP estimate, $\hat{\beta}_{\text{MAP}}$, as

$$\begin{aligned}\hat{\beta}_{\text{MAP}} &= \arg\max_{\beta \in \mathbb{R}^{N-1}} \ln p(\beta \mid D) \\ &= \arg\min_{\beta \in \mathbb{R}^{N-1}} \frac{1}{2}\left\|Y_1^- - (\hat{\boldsymbol{M}}^-)^T\beta\right\|^2 + \frac{\alpha\sigma^2}{2}\|\beta\|^2 \\ &= \left(\hat{\boldsymbol{M}}^-(\hat{\boldsymbol{M}}^-)^T + \alpha\sigma^2\boldsymbol{I}\right)^{-1}\hat{\boldsymbol{M}}^-Y_1^-. \end{aligned} \tag{40}$$

With the MAP estimate at hand, we then make predictions of the counterfactual as

$$\hat{M}_1 = \hat{\boldsymbol{M}}^T\hat{\beta}_{\text{MAP}}. \tag{41}$$

Therefore, we have seen that the MAP estimation is equivalent to ridge regression since the introduction of an appropriate prior naturally induces the additional complexity penalty term.

4.4.2 Fully Bayesian treatment.

Although we have treated β^* as a random variable attached with a prior distribution, we can venture beyond point estimates to be fully Bayesian. In particular, we will make use of the posterior distribution over β^* to marginalize over all possible values of β^* in evaluating the predictive distribution over Y_1^-. We will decompose the regression problem of predicting the counterfactual into two separate stages: the *inference* stage in which we use the pre-intervention data to learn the predictive distribution (defined shortly), and the subsequent *decision* stage in which we use the predictive distribution to make estimates. By separating the inference and decision stages, we can readily develop new estimators for different loss functions without having to relearn the predictive distribution, providing practitioners tremendous flexibility with respect to decision making.

Let us begin with a study of the inference stage. We evaluate the predictive distribution over Y_{1t}, which is defined as

$$\begin{aligned}p(Y_{1t} \mid \hat{M}_{\cdot t}, D) &= \int p(Y_{1t} \mid \hat{M}_{\cdot t}, \beta)\; p(\beta \mid D)\, d\beta \\ &= \mathcal{N}(\hat{M}_{\cdot t}^T\,\beta_D, \sigma_D^2), \end{aligned} \tag{42}$$

where

$$\sigma_D^2 = \sigma^2 + \hat{M}_{\cdot,t}^T \mathbf{\Sigma}_D \hat{M}_{\cdot,t}. \tag{43}$$

Note that $p(\beta \mid D)$ is the posterior distribution over the synthetic control parameter and is governed by (37) and (39). With access to the predictive distribution, we move on towards the decision stage, which consists of determining a particular estimate $\hat{M}_{1t}$ given a new observation vector $X_{\cdot t}$ (used to determine $\hat{M}_{\cdot t}$). Consider an arbitrary loss function $L(Y_{1t}, g(\hat{M}_{\cdot t}))$ for some function g. The expected loss is then given by

$$\begin{aligned}\mathbb{E}[L] &= \int \int L(Y_{1t}, g(\hat{M}_{\cdot t})) \cdot p(Y_{1t}, \hat{M}_{\cdot t})\, dY_{1t}\, d\hat{M}_{\cdot t} \\ &= \int \left(\int L(Y_{1t}, g(\hat{M}_{\cdot t})) \cdot p(Y_{1t} \mid \hat{M}_{\cdot t})\, dY_{1t} \right) p(\hat{M}_{\cdot t})\, d\hat{M}_{\cdot t},\end{aligned} \tag{44}$$

and we choose our estimator $\hat{g}(\cdot)$ as the function that minimizes the average cost, i.e.,

$$\hat{g}(\cdot) = \arg\min_{g(\cdot)} \mathbb{E}[L(Y_{1t}, g(\hat{M}_{\cdot t}))]. \tag{45}$$

Since $p(\hat{M}_{\cdot t}) \geq 0$, we can minimize (44) by selecting $\hat{g}(\hat{M}_{\cdot t})$ to minimize the term within the parenthesis for each individual value of Y_{1t}, i.e.,

$$\begin{aligned}\hat{M}_{1t} &= \hat{g}(\hat{M}_{\cdot t}) \\ &= \arg\min_{g(\cdot)} \int L(Y_{1t}, g(\hat{M}_{\cdot t})) \cdot p(Y_{1t} \mid \hat{M}_{\cdot t})\, dY_{1t}.\end{aligned} \tag{46}$$

As suggested by (46), the optimal estimate $\hat{M}_{1t}$ for a particular loss function depends on the model only through the predictive distribution $p(Y_{1t} \mid \hat{M}_{\cdot t}, D)$. Therefore, the predictive distribution summarizes all of the necessary information to construct the desired Bayesian estimator for any given loss function L.

4.4.3 Bayesian least-squares estimate.

We analyze the case for the squared loss function (MSE), a common cost criterion for regression problems. In this case, we write the expected loss as

$$\mathbb{E}[L] = \int \left(\int (Y_{1t} - g(\hat{M}_{\cdot t}))^2 \cdot p(Y_{1t} \mid \hat{M}_{\cdot t})\, dY_{1t} \right) p(\hat{M}_{\cdot t})\, d\hat{M}_{\cdot t}.$$

Under the MSE cost criterion, the optimal estimate is the mean of the predictive distribution, also known as the Bayes' least-squares (BLS) estimate:

$$\begin{aligned}\hat{M}_{1t} &= \mathbb{E}[Y_{1t} \mid \hat{M}_{\cdot t}, D] \\ &= \int Y_{1t}\ p(Y_{1t} \mid \hat{M}_{\cdot t}, D) dY_{1t} \\ &= \hat{M}_t^T\, \beta_D.\end{aligned} \tag{47}$$

Remark 8 *Since the noise variance σ^2 is usually unknown in practice, we can introduce another conjugate prior distribution $p(\beta, 1/\sigma^2)$ given by the Gaussian-gamma distribution. This prior yields a Student's t-distribution for the predictive probability distribution. Alternatively, one can estimate σ^2 via* (12).

5. Experiments

We begin by exploring two real-world case studies discussed in Abadie et al. (2010, 2011); Abadie and Gardeazabal (2003) that demonstrate the ability of the original synthetic control's algorithm to produce a reliable counterfactual reality. We use the same case-studies to showcase the "robustness" property of our proposed algorithm. Specifically, we demonstrate that our algorithm reproduces similar results even in presence of missing data, and without knowledge of the extra covariates utilized by prior works. We find that our approach, surprisingly, also discovers a few subtle effects that seem to have been overlooked in prior studies. In the following empirical studies, we will employ three different learning procedures as described in the robust synthetic control algorithm: (1) linear regression ($\eta = 0$), (2) ridge regression ($\eta > 0$), and (3) LASSO ($\zeta > 0$).

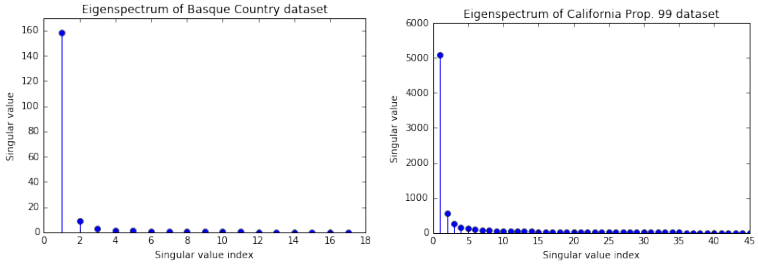
As described in Abadie et al. (2010, 2011, 2014), the synthetic control method allows a practitioner to evaluate the reliability of his or her case study results by running placebo tests. One such placebo test is to apply the synthetic control method to a donor unit. Since the control units within the donor pool are assumed to be unaffected by the intervention of interest (or at least much less affected in comparison), one would expect that the estimated effects of intervention for the placebo unit should be less drastic and divergent compared to that of the treated unit. Ideally, the counterfactuals for the placebo units would show negligible effects of intervention. Similarly, one can also perform exact inferential techniques that are similar to permutation tests. This can be done by applying the synthetic control method to every control unit within the donor pool and analyzing the gaps for every simulation, and thus providing a distribution of estimated gaps. In that spirit, we present the resulting placebo tests (for only the case of linear regression) for the Basque Country and California Prop. 99 case studies below to assess the significance of our estimates.

We will also analyze both case studies under a Bayesian setting. From our results, we see that our predictive uncertainty, captured by the standard deviation of the predictive distribution, is influenced by the number of singular values used in the de-noising process. Therefore, we have plotted the eigenspectrum of the two case study datasets below. Clearly, the bulk of the signal contained within the datasets is encoded into the top few singular values – in particular, the top two singular values. Given that the validation errors computed via forward chaining are nearly identical for low-rank settings (with the exception of a rank-1 approximation), we shall use a rank-2 approximation of the data matrix. In order to exhibit the role of thresholding in the interplay between bias and variance, we also plot the cases where we use threshold values that are too high (bias) or too low (variance). For each figure, the dotted blue line will represent our posterior predictive means while the shaded light blue region spans one standard deviation on both sides of the mean. As we shall see, our predictive uncertainty is smallest in the neighborhood around the pre-intervention period. However, the level of uncertainty increases as we deviate from the the intervention point, which appeals to our intuition.

In order to choose an appropriate choice of the prior parameter α, we first use forward-chaining for the ridge regression setting to find the optimal regularization hyperparameter η. By observing the expressions of (19) and (40), we see that $\eta = \alpha\sigma^2$ since ridge regression is closely related to MAP estimation for a zero-mean, isotropic Gaussian prior. Consequently, we choose $\alpha = \eta/\hat{\sigma}^2$ where η is the value obtained via forward chaining.

5.1 Basque Country

The goal of this case-study is to investigate the effects of terrorism on the economy of Basque Country using the neighboring Spanish regions as the control group. In 1968, the first Basque Country victim of terrorism was claimed; however, it was not until the mid-1970s did the terrorist activity become more rampant Abadie and Gardeazabal (2003). To study the economic ramifications of terrorism on Basque Country, we only use as data the per-capita GDP (outcome variable) of 17 Spanish regions from 1955-1997. We note that in Abadie and Gardeazabal (2003), 13 additional predictor variables



(a) Eigenspectrum of Basque data. **(b)** Eigenspectrum of California data.

Figure 1: Eigenspectrum

for each region were used including demographic information pertaining to one's educational status, and average shares for six industrial sectors.

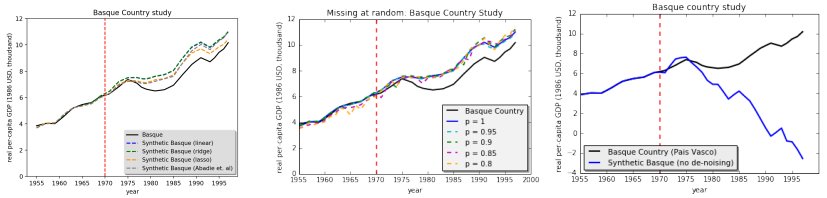
Results. Figure 2a shows that our method (for all three estimators) produces a very similar qualitative synthetic control to the original method even though we do not utilize additional predictor variables. Specifically, the synthetic control resembles the observed GDP in the pre-treatment period between 1955-1970. However, due to the large-scale terrorist activity in the mid-70s, there is a noticeable economic divergence between the synthetic and observed trajectories beginning around 1975. This deviation suggests that terrorist activity negatively impacted the economic growth of Basque Country.

One subtle difference between our synthetic control – for the case of linear and ridge regression – and that of Abadie and Gardeazabal (2003) is between 1970-75: our approach suggests that there was a small, but noticeable economic impact starting just prior to 1970, potentially due to first terrorist attack in 1968. Notice, however, that the original synthetic control of Abadie and Gardeazabal (2003) diverges only after 1975. Our LASSO estimator's trajectory also agrees with that of the original synthetic control method's, which is intuitive since both estimators seek sparse solutions.

To study the robustness of our approach with respect to missing entries, we discard each data point uniformly at random with probability $1 - p$. The resulting control for different values of p is presented in Figure 2b suggesting the robustness of our (linear) algorithm. Finally, we produce Figure 2c by applying our algorithm without the de-noising step. As evident from the Figure, the resulting predictions suffer drastically, reinforcing the value of de-noising. Intuitively, using an appropriate threshold μ equates to selecting the correct model complexity, which helps safeguard the algorithm from potentially overfitting to the training data.

Placebo tests. We begin by applying our robust algorithm to the Spanish region of Cataluna, a control unit that is not only similar to Basque Country, but also exposed to a much lower level of terrorism Abadie et al. (2011). Observing both the synthetic and observed economic evolutions of Cataluna in Figure 3a, we see that there is no identifiable treatment effect, especially compared to the divergence between the synthetic and observed Basque trajectories. We provide the results for the regions of Aragon and Castilla Y Leon in Figures 3b and 3c.

Finally, similar to Abadie et al. (2011), we plot the differences between our estimates and the observations for Basque Country and all other regionals, individually, as placebos. Note that Abadie et al. (2011) excluded five regions that had a poor pre-intervention fit but we keep all regions. Figure 4a shows the resulting plot for all regions with the solid black line being Basque Country. This



(a) Comparison of methods. **(b)** Missing data. **(c)** Impact of de-noising.

plot helps visualize the extreme post-intervention divergence between the predicted means and the observed values for Basque. Up until about 1990, the divergence for Basque Country is the most extreme compared to all other regions (placebo studies) lending credence to the belief that the effects of terrorism on Basque Country were indeed significant. Refer to Figure 4b for the same test but with Madrid and Balearic Islands excluded, as per Abadie et al. (2011). The conclusions drawn should remain the same, pointing to the robustness of our approach.

Bayesian approach. We plot the resulting Bayesian estimates in the figures below under varying thresholding conditions. It is interesting to note that our uncertainty grows dramatically once we include more than two singular values in the thresholding process. This confirms what our theoretical

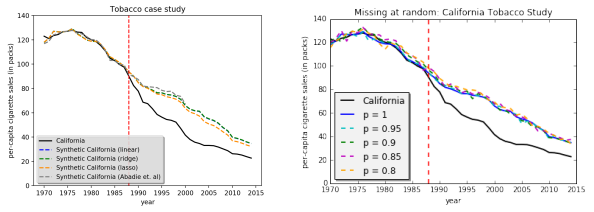
Figure 5: Trends in per-capita GDP between Basque Country vs. synthetic Basque Country.

results indicated earlier: choosing a smaller threshold, μ, would lead to a greater number of singular values retained which results in higher variance. On the other hand, notice that just selecting 1 singular value results in an apparently biased estimate which is overestimating the synthetic control. It appears that selecting the top two singular values balance the bias-variance tradeoff the best and is also agrees with our earlier finding that the data matrix appears to be of rank 2 or 3. Note that in this setting, we would find it hard to reject the null-hypothesis because the observations for the treated unit lie within the uncertainty band of the estimated synthetic control.

5.2 California Anti-tobacco Legislation

We study the impact of California's anti-tobacco legislation, Proposition 99, on the per-capita cigarette consumption of California. In 1988, California introduced the first modern-time large-scale anti-tobacco legislation in the United States Abadie et al. (2010). To analyze the effect of California's anti-tobacco legislation, we use the annual per-capita cigarette consumption at the state-level for all 50 states in the United States, as well as the District of Columbia, from 1970-2015. Similar to the previous case study, Abadie and Gardeazabal (2003) uses 6 additional observable covariates per state, e.g. retail price, beer consumption per capita, and percentage of individuals between ages of 15-24, to predict their synthetic California. Furthermore, Abadie and Gardeazabal (2003) discarded 12 states from the donor pool since some of these states also adopted anti-tobacco legislation programs or raised their state cigarette taxes, and discarded data after the year 2000 since many of the control units had implemented anti-tobacco measures by this point in time.

Results. As shown in Figure 6a, in the pre-intervention period of 1970-88, our control matches the observed trajectory. Post 1988, however, there is a significant divergence suggesting that the passage of Prop. 99 helped reduce cigarette consumption. Similar to the Basque case-study, our estimated effect is similar to that of Abadie and Gardeazabal (2003). As seen in Figure 6b, our algorithm is



(a) Comparison of methods. **(b)** Missing data.

(a) Colorado. **(b)** Iowa. **(c)** Wyoming.

Figure 7: Placebo Study: trends in per-capita cigarette sales for Colorado, Iowa, and Wyoming.

again robust to randomly missing data.

Placebo tests. We now proceed to apply the same placebo tests to the California Prop 99 dataset. Figures 7a, 7b, and 7c are three examples of the applied placebo tests on the remaining states (including District of Columbia) within the United States.

Finally, similar to Abadie et al. (2010), we plot the differences between our estimates and the actual observations for California and all other states, individually, as placebos. Note that Abadie et al. (2010) excluded twelve states but we keep all states. Figure 8a shows the resulting plot for all states with the solid black line being California. This plot helps visualize the extreme post-intervention divergence between the predicted means and the observed values for California. Up until about 1995, the divergence for California was clearly the most significant and consistent outlier compared to all other regions (placebo studies) lending credence to the belief that the effects of Proposition 99 were indeed significant. Refer to Figure 8b for the same test but with the same twelve states excludes as in Abadie et al. (2010). Just like the Basque Country case study, the exclusion of states should not affect the conclusions drawn.

Bayesian approach. Similar to the Basque Country case study, our predictive uncertainty increases as the number of singular values used in the learning process exceeds two. In order to gain some new insight, however, we will focus our attention to the resulting figure associated with three singular values, which is particularly interesting. Specifically, we observe that our predictive means closely match the counterfactual trajectory produced by the classical synthetic control method in both the pre- and post-intervention periods (up to year 2000), and yet our uncertainty for this estimate is significantly greater than our uncertainty associated with the estimate produced using two singular values. As a result, it may be possible that the classical synthetic control method overestimated the

Figure 9: Trends in per-capita cigarette sales between California vs. synthetic California.

effect of Prop. 99, even though the legislation did probably discourage the consumption of cigarettes – a conclusion reached by both our robust approach and the classical approach.

Remark 9 *We note that in Abadie et al. (2014), the authors ran two robustness tests to examine the sensitivity of their results (produced via the original synthetic control method) to alterations in the estimated convex weights – recall that the original synthetic control estimator produces a β^* that lies within the simplex. In particular, the authors first iteratively reproduced a new synthetic West Germany by removing one of the countries that received a positive weight in each iteration, demonstrating that their synthetic model is fairly robust to the exclusion of any particular country with positive weight. Furthermore, Abadie et al. (2014) examined the trade-off between the original method's ability to produce a good estimate and the sparsity of the given donor pool. In order to examine this tension, the authors restricted their synthetic West Germany to be a convex combination of only four, three, two, and a single control country, respectively, and found that, relative to the baseline synthetic West Germany (composed of five countries), the degradation in their goodness of fit was moderate.*

5.3 Synthetic simulations

We conduct synthetic simulations to establish the various properties of the estimates in both the pre- and post-intervention stages.

Experimental setup. For each unit $i \in [N]$, we assign latent feature θ_i by drawing a number uniformly at random in $[0, 1]$. For each time $t \in [T]$, we assign latent variable $\rho_t = t$. The mean value

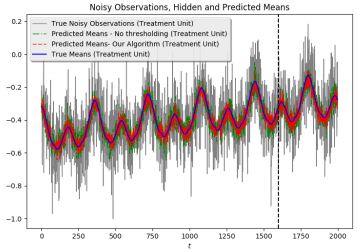

Figure 10: Treatment unit: noisy observations (gray) and true means (blue) and the estimates from our algorithm (red) and one where no singular value thresholding is performed (green). The plots show all entries normalized to lie in range $[-1, 1]$. Notice that the estimates in red generated by our model are much better at estimating the true underlying mean (blue) when compared to an algorithm which performs no singular value thresholding.

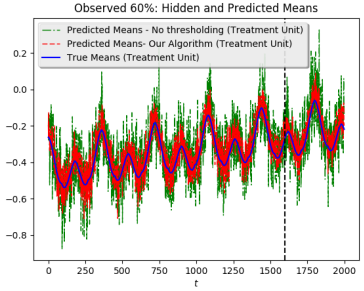

Figure 11: Same dataset as shown in Figure 10 but with 40% data missing at random. Treatment unit: not showing the noisy observations for clarity; plotting true means (blue) and the estimates from our algorithm (red) and one where no singular value thresholding is performed (green). The plots show all entries normalized to lie in range $[-1, 1]$.

$m_{it} = f(\theta_i, \rho_t)$. In the experiments described in this section, we use the following:

$$f(\theta_i, \rho_t) = \theta_i + (0.3 \cdot \theta_i \cdot \rho_t/T) * (\exp^{\rho_t/T}) + \cos(f_1\pi/180) + 0.5\sin(f_2\pi/180) + 1.5\cos(f_3\pi/180) - 0.5\sin(f_4 * \pi/180),$$

where f_1, f_2, f_3, f_4 define the periodicities: $f_1 = \rho_t \bmod (360)$, $f_2 = \rho_t \bmod (180)$, $f_3 = 2 \cdot \rho_t \bmod (360)$, $f_4 = 2.0 \cdot \rho_t \bmod (180)$. The observed value X_{it} is produced by adding i.i.d. Gaussian noise to mean with zero mean and variance σ^2. For this set of experiments, we use $N = 100, T = 2000$, while assuming the treatment was performed at $t = 1600$.

Training error approximates generalization error. For the first experimental study, we analyze the relationship between the pre-intervention MSE (training error) and the post-intervention MSE (generalization error). As seen in Table 1, the post-intervention MSE closely matches that of the

Table 1: Training vs. generalization error

Noise	Training error	Generalization error
3.1	0.48	0.53
2.5	0.31	0.34
1.9	0.19	0.22
1.3	0.09	0.1
0.7	0.027	0.03
0.4	0.008	0.009
0.1	0.0005	0.0006

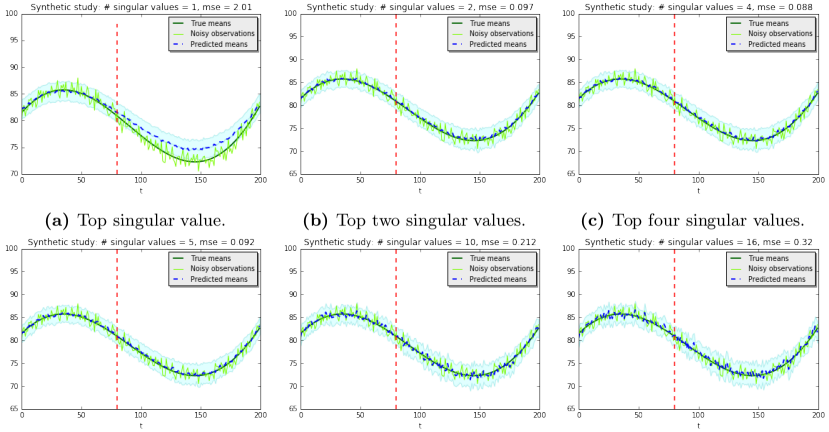
Table 2: Impact of thresholding

Noise	De-noising error	No De-noising error
3.1	0.122	0.365
2.5	0.079	0.238
1.9	0.046	0.138
1.6	0.032	0.098
1	0.013	0.038
0.7	0.006	0.018
0.4	0.002	0.005

pre-intervention MSE for varying noise levels, σ^2. Thus suggesting efficacy of our algorithm. Figures 10 and 11 plot the estimates of algorithm with no missing data (Figure 10) and with 40% randomly missing data (Figure 11) on the same underlying dataset. All entries in the plots were normalized to lie within $[-1, 1]$. These plots confirm the robustness of our algorithm. Our algorithm outperforms the algorithm with no singular value thresholding under all proportions of missing data. The estimates from the algorithm which performs no singular value thresholding (green) degrade significantly with missing data while our algorithm remains robust.

Benefits of de-noising. We now analyze the benefit of de-noising the data matrix, which is the main contribution of this work compared to the prior work. Specifically, we study the generalization error of method using de-noising via thresholding and without thresholding as in prior work. The results summarized in Table 2 show that for range of parameters the generalization error with de-noising is consistency better than that without de-noising.

Bayesian approach. From the synthetic simulations (figures below), we see that the number of singular values included in the thresholding process plays a crucial role in the model's prediction capabilities. If not enough singular values are used, then there is a significant loss of information (high bias) resulting in a higher MSE. On the other hand, if we include too many singular values, then the model begins to overfit to the dataset by misinterpreting noise for signal (high variance). As emphasized before, the goal is to find the simplest model that both fits the data and is also plausible, which is achieved when four singular values are employed.



(a) Top singular value. **(b)** Top two singular values. **(c)** Top four singular values.

(d) Top five singular values. **(e)** Top 10 singular values. **(f)** Top 16 singular values.

Figure 12: Bayesian Synthetic Control simulation.

6. Conclusion

The classical synthetic control method is recognized as a powerful and effective technique for causal inference for comparative case studies. In this work, we motivate a robust synthetic control algorithm, which attempts to improve on the classical method in the following regimes: (a) randomly missing data and (b) large levels of noise. We also demonstrate that the algorithm performs well even in the absence of covariate or expert information, but do *not* propose ignoring information which may eliminate "bad" donors. Our data-driven algorithm, and its Bayesian counterpart, uses singular value thresholding to impute missing data and "de-noise" the observations. Once "de-noised", we use regularized linear regression to determine the synthetic control. Motivating our algorithm is a modeling framework, specifically the Latent Variable Model, which is a generalization of the various factor models used in related work. We establish finite-sample bounds on the MSE between the estimated "synthetic" control and the latent *true* means of the treated unit of interest. In situations with plentiful data, we show that a simple data aggregation method can lead to an asymptotically consistent estimator. Experiments on synthetically generated data (where the *truth* is known) and on real-world case-studies allow us to demonstrate the promise of our approach, which is an improvement over the classical method.

Acknowledgments

We would like to thank Alberto Abadie for careful reading and comments that have helped in improving the manuscript.

Appendix A. Useful Theorems

We present useful theorems that we will frequently employ in our proofs.

Theorem 10 Perturbation of singular values.
Let $\boldsymbol{A}$ and $\boldsymbol{B}$ be two $m \times n$ matrices. Let $k = \min\{m, n\}$. Let $\lambda_1, \ldots, \lambda_k$ be the singular values of $\boldsymbol{A}$ in decreasing order and repeated by multiplicities, and let $\tau_1, \ldots, \tau_k$ be the singular values of $\boldsymbol{B}$ in decreasing order and repeated by multiplicities. Let $\delta_1, \ldots, \delta_k$ be the singular values of $\boldsymbol{A} - \boldsymbol{B}$, in any order but still repeated by multiplicities. Then,

$$\max_{1 \le i \le k} |\lambda_i - \tau_i| \le \max_{1 \le i \le k} |\delta_i|.$$

References for the proof of the above result can be found in Chatterjee (2015), for example.

Theorem 11 Poincaré separation Theorem.
Let $\boldsymbol{A}$ be a symmetric $n \times n$ matrix. Let $\boldsymbol{B}$ be the $m \times m$ matrix with $m \le n$, where $\boldsymbol{B} = \boldsymbol{P}^T \boldsymbol{A} \boldsymbol{P}$ for some orthogonal projection matrix $\boldsymbol{P}$. If the eigenvalues of $\boldsymbol{A}$ are $\sigma_1 \le \ldots \le \sigma_n$, and those of $\boldsymbol{B}$ are $\tau_1 \le \ldots \le \tau_m$, then for all $j < m + 1$,

$$\sigma_j \le \tau_j \le \sigma_{n-m+j}.$$

Remark 12 *In the case where $\boldsymbol{B}$ is the principal submatrix of $\boldsymbol{A}$ with dimensions $(n-1) \times (n-1)$, the above Theorem is also known as Cauchy's interlacing law.*

Theorem 13 Bernstein's Inequality.
Suppose that $X_1, \ldots, X_n$ are independent random variables with zero mean, and M is a constant such that $|X_i| \le M$ with probability one for each i. Let $S := \sum_{i=1}^n X_i$ and $v := Var(S)$. Then for any $t \ge 0$,

$$\mathbb{P}(|S| \ge t) \le 2 \exp\left(-\frac{3t^2}{6v + 2Mt}\right).$$

Theorem 14 Hoeffding's Inequality.
Suppose that $X_1, \ldots, X_n$ are independent random variables that are strictly bounded by the intervals $[a_i, b_i]$. Let $S := \sum_{i=1}^n X_i$. Then for any $t > 0$,

$$\mathbb{P}(|S - \mathbb{E}[S]| \ge t) \le 2 \exp\left(-\frac{2t^2}{\sum_{i=1}^n (b_i - a_i)^2}\right).$$

Theorem 15 Theorem 3.4 of Chatterjee (2015).
Take any two numbers m and n such that $1 \le m \le n$. Suppose that $\boldsymbol{A} = [A_{ij}]_{1 \le i \le m, 1 \le j \le n}$ is a matrix whose entries are independent random variables that satisfy, for some $\delta^2 \in [0, 1]$,

$$\mathbb{E}[A_{ij}] = 0, \quad \mathbb{E}[A_{ij}^2] \le \delta^2, \quad \textit{and} \quad |A_{ij}| \le 1 \quad \textit{a.s.}$$

Suppose that $\delta^2 \ge n^{-1+\zeta}$ for some $\zeta > 0$. Then, for any $\omega \in (0, 1)$,

$$\mathbb{P}(\|\boldsymbol{A}\| \ge (2 + \omega)\delta\sqrt{n}) \le C(\zeta) e^{-c\delta^2 n},$$

where $C(\zeta)$ depends only on ω and ζ, and c depends only on ω. The same result is true when $m = n$ and A is symmetric or skew-symmetric, with independent entries on and above the diagonal, all other assumptions remaining the same. Lastly, all results remain true if the assumption $\delta^2 \ge n^{-1+\zeta}$ is changed to $\delta^2 \ge n^{-1}(\log n)^{6+\zeta}$.

Remark 16 *The proof of Theorem 15 can be found in Chatterjee (2015) under Theorem 3.4.*

Appendix B. Useful Lemmas

We begin by proving (and providing) a series of useful lemmas that we will frequently use to derive our desired results.

Lemma 17 *Suppose $\boldsymbol{C}$ is an $m \times n$ matrix composed of an $m \times p$ submatrix $\boldsymbol{A}$ and an $m \times (n-p)$ submatrix $\boldsymbol{B}$, i.e., $\boldsymbol{C} = \left[\begin{array}{c|c} \boldsymbol{A} & \boldsymbol{B} \end{array}\right]$. Then, the spectral (operator) norms of $\boldsymbol{A}$ and $\boldsymbol{B}$ are bounded above by the spectral norm of $\boldsymbol{C}$,*

$$\max\{\|\boldsymbol{A}\|, \|\boldsymbol{B}\|\} \le \|\boldsymbol{C}\|.$$

Proof Without loss of generality, we prove the case for $\|\boldsymbol{A}\| \le \|\boldsymbol{C}\|$, since the same argument applies for $\|\boldsymbol{B}\|$. By definition,

$$\boldsymbol{C}^T \boldsymbol{C} = \begin{bmatrix} \boldsymbol{A}^T \boldsymbol{A} & \boldsymbol{A}^T \boldsymbol{B} \\ \boldsymbol{B}^T \boldsymbol{A} & \boldsymbol{B}^T \boldsymbol{B} \end{bmatrix}.$$

Let $\sigma_1, \ldots, \sigma_n$ be the eigenvalues of $\boldsymbol{C}^T \boldsymbol{C}$ in increasing order and repeated by multiplicities. Let $\tau_1, \ldots, \tau_p$ be the eigenvalues of $\boldsymbol{A}^T \boldsymbol{A}$ in increasing order and repeated by multiplicities. By the Poincaré separation Theorem 11, we have for all $j < p + 1$,

$$\sigma_j \le \tau_j \le \sigma_{n-p+j}.$$

Thus, $\tau_p \le \sigma_n$. Since the eigenvalues of $\boldsymbol{C}^T \boldsymbol{C}$ and $\boldsymbol{A}^T \boldsymbol{A}$ are the squared singular values of $\boldsymbol{C}$ and $\boldsymbol{A}$ respectively, we have

$$\sqrt{\tau_p} = \|\boldsymbol{A}\| \le \|\boldsymbol{C}\| = \sqrt{\sigma_n}.$$

We complete the proof by applying an identical argument for the case of $\|\boldsymbol{B}\|$. ■

Lemma 18 *Let $\boldsymbol{A}$ be any m by n matrix, and let $\boldsymbol{A}^\dagger$ be its corresponding pseudoinverse. Then, the matrices $\boldsymbol{P}_1 = \boldsymbol{A}\boldsymbol{A}^\dagger$ and $\boldsymbol{P}_2 = \boldsymbol{A}^\dagger \boldsymbol{A}$ are projection matrices.*

Proof We first prove that $\boldsymbol{P}_1$ is a projection matrix. In order to show $\boldsymbol{P}_1$ is a projection matrix, we must demonstrate that $\boldsymbol{P}_1$ satisfies two properties: namely, (1) $\boldsymbol{P}_1$ is symmetric, i.e. $\boldsymbol{P}_1^T = \boldsymbol{P}_1$, and (2) $\boldsymbol{P}_1$ is idempotent, i.e. $\boldsymbol{P}_1^2 = \boldsymbol{P}_1$.

Let $\boldsymbol{A} = \boldsymbol{Q}_1 \boldsymbol{\Sigma} \boldsymbol{Q}_2^T$ represent the SVD of $\boldsymbol{A}$, with the pseudoinverse expressed as $\boldsymbol{A}^\dagger = \boldsymbol{Q}_2 \boldsymbol{\Sigma}^+ \boldsymbol{Q}_1^T$. As a result,

$$\begin{aligned} \boldsymbol{P}_1 &= \boldsymbol{A}\boldsymbol{A}^\dagger \\ &= \boldsymbol{Q}_1 \boldsymbol{\Sigma} \boldsymbol{Q}_2^T \boldsymbol{Q}_2 \boldsymbol{\Sigma}^+ \boldsymbol{Q}_1^T \\ &= \boldsymbol{Q}_1 \boldsymbol{\Sigma} \boldsymbol{\Sigma}^+ \boldsymbol{Q}_1^T. \end{aligned}$$

Note that

$$\begin{aligned} \boldsymbol{P}_1^T &= (\boldsymbol{Q}_1 \boldsymbol{\Sigma} \boldsymbol{\Sigma}^+ \boldsymbol{Q}_1^T)^T \\ &= \boldsymbol{Q}_1 \boldsymbol{\Sigma} \boldsymbol{\Sigma}^+ \boldsymbol{Q}_1^T \\ &= \boldsymbol{P}_1, \end{aligned}$$

which proves that $\boldsymbol{P}_1$ is symmetric. Furthermore,

$$\begin{aligned}\boldsymbol{P}_1^2 &= (\boldsymbol{Q}_1\boldsymbol{\Sigma}\boldsymbol{\Sigma}^+\boldsymbol{Q}_1^T)\cdot(\boldsymbol{Q}_1\boldsymbol{\Sigma}\boldsymbol{\Sigma}^+\boldsymbol{Q}_1^T)\\ &= \boldsymbol{Q}_1\boldsymbol{\Sigma}\boldsymbol{\Sigma}^+\boldsymbol{\Sigma}\boldsymbol{\Sigma}^+\boldsymbol{Q}_1^T\\ &= \boldsymbol{Q}_1\boldsymbol{\Sigma}\boldsymbol{\Sigma}^+\boldsymbol{Q}_1^T\\ &= \boldsymbol{P}_1,\end{aligned}$$

which proves that $\boldsymbol{P}_1$ is idempotent. The same argument can be applied for $\boldsymbol{P}_2$. ■

Lemma 19 *The eigenvalues of a projection matrix are* 1 *or* 0.

Proof Let λ be an eigenvalue of the projection matrix $\boldsymbol{P}$ for some eigenvector v. Then, by definition of eigenvalues,

$$\boldsymbol{P}v = \lambda v.$$

However, by the idempotent property of projection matrices ($\boldsymbol{P}^2 = \boldsymbol{P}$), if we multiply the above equality by $\boldsymbol{P}$ on the left, then we have

$$\begin{aligned}\boldsymbol{P}(\boldsymbol{P}v) &= \boldsymbol{P}(\lambda v)\\ &= \lambda^2 v.\end{aligned}$$

Since $v \neq 0$, the eigenvalues of $\boldsymbol{P}$ can only be members $\mathbb{R}$ whereby $\lambda^2 = \lambda$. Ergo, we must have that $\lambda \in \{0, 1\}$. ■

Lemma 20 *Let $\boldsymbol{A} = \sum_{i=1}^m \sigma_i x_i y_i^T$ be the singular value decomposition of $\boldsymbol{A}$ with $\sigma_1, \ldots, \sigma_m$ in decreasing order and with repeated multiplicities. For any choice of $\mu \geq 0$, let $S = \{i : \sigma_i \geq \mu\}$. Define*

$$\hat{\boldsymbol{B}} = \sum_{i\in S} \sigma_i x_i y_i^T.$$

Let $\tau_1, \ldots, \tau_m$ be the singular values of $\boldsymbol{B}$ in decreasing order and repeated by multiplicities, with $\tau^* = \max_{i\notin S} \tau_i$. Then

$$\left\|\hat{\boldsymbol{B}} - \boldsymbol{B}\right\| \leq \tau^* + 2\|\boldsymbol{A} - \boldsymbol{B}\|.$$

Proof By Theorem 10, we have that $\sigma_i \leq \tau_i + \|\boldsymbol{A} - \boldsymbol{B}\|$ for all i. Applying triangle inequality, we obtain

$$\begin{aligned}\left\|\hat{\boldsymbol{B}} - \boldsymbol{B}\right\| &\leq \left\|\hat{\boldsymbol{B}} - \boldsymbol{A}\right\| + \|\boldsymbol{A} - \boldsymbol{B}\|\\ &= \max_{i\notin S} \sigma_i + \|\boldsymbol{A} - \boldsymbol{B}\|\\ &\leq \max_{i\notin S} \Big(\tau_i + \|\boldsymbol{A} - \boldsymbol{B}\|\Big) + \|\boldsymbol{A} - \boldsymbol{B}\|\\ &= \tau^* + 2\|\boldsymbol{A} - \boldsymbol{B}\|.\end{aligned}$$

■

Lemma 21 *Let $\boldsymbol{A} = \sum_{i=1}^m \sigma_i x_i y_i^T$ be the singular value decomposition of $\boldsymbol{A}$. Fix any $\delta > 0$ such that $\mu = (1+\delta)\|\boldsymbol{A} - \boldsymbol{B}\|$, and let $S = \{i : \sigma_i \geq \mu\}$. Define*

$$\hat{\boldsymbol{B}} = \sum_{i\in S} \sigma_i x_i y_i^T.$$

Then

$$\left\|\hat{\boldsymbol{B}} - \boldsymbol{B}\right\| \leq (2+\delta)\|\boldsymbol{A} - \boldsymbol{B}\|.$$

Proof By the definition of μ and hence the set of singular values S, we have that

$$\begin{aligned}\left\|\hat{\boldsymbol{B}} - \boldsymbol{B}\right\| &\leq \left\|\hat{\boldsymbol{B}} - \boldsymbol{A}\right\| + \|\boldsymbol{A} - \boldsymbol{B}\|\\ &= \max_{i\notin S} \sigma_i + \|\boldsymbol{A} - \boldsymbol{B}\|\\ &\leq (1+\delta)\|\boldsymbol{A} - \boldsymbol{B}\| + \|\boldsymbol{A} - \boldsymbol{B}\|\\ &= (2+\delta)\|\boldsymbol{A} - \boldsymbol{B}\|.\end{aligned}$$

■

Lemma 22 ***(Lemma 3.5 of Chatterjee (2015))*** *Let $\boldsymbol{A} = \sum_{i=1}^m \sigma_i x_i y_i^T$ be the singular value decomposition of $\boldsymbol{A}$. Fix any $\delta > 0$ and define $S = \{i : \sigma_i \geq (1+\delta)\|\boldsymbol{A} - \boldsymbol{B}\|\}$ such that*

$$\hat{\boldsymbol{B}} = \sum_{i\in S} \sigma_i x_i y_i^T.$$

Then

$$\left\|\hat{\boldsymbol{B}} - \boldsymbol{B}\right\|_F \leq K(\delta)(\|\boldsymbol{A} - \boldsymbol{B}\|\|\boldsymbol{B}\|_*)^{1/2},$$

where $K(\delta) = (4+2\delta)\sqrt{2/\delta} + \sqrt{2+\delta}$.

Proof The proof can be found in Chatterjee (2015). ■

Appendix C. Preliminaries.

To simplify the following exposition, we assume that $|M_{ij}| \leq 1$ and $|X_{ij}| \leq 1$. Recall that all entries of the pre-intervention treatment row are observed such that $Y_1^- = X_1^- = M_1^- + \epsilon_1^-$. On the other hand, every entry within the pre- and post-intervention periods for the donor units are observed independently of the other entries with some arbitrary probability p. Specifically, for all $2 \leq i \leq N$ and $j \in [T]$, we define $Y_{ij} = X_{ij}$ if X_{ij} is observed, and $Y_{ij} = 0$ otherwise. Consequently, observe that for all $i > 1$ and j,

$$\mathbb{E}[Y_{ij}] = pM_{ij}$$

and

$$\begin{aligned}\mathrm{Var}(Y_{ij}) &= \mathbb{E}[Y_{ij}^2] - (\mathbb{E}[Y_{ij}])^2\\ &= p\mathbb{E}[X_{ij}^2] - (pM_{ij})^2\\ &\leq p(\sigma^2 + M_{ij}^2) - (pM_{ij})^2\\ &= p\sigma^2 + pM_{ij}^2(1-p)\\ &\leq p\sigma^2 + p(1-p).\end{aligned}$$

Recall that $\hat{p}$ denotes the proportion of observed entries in $\boldsymbol{X}$ and $\hat{\sigma}^2$ represents the (unbiased) sample variance computed from the pre-intervention treatment row (12). Given the information above, we define, for any $\omega \in (0.1, 1)$, three events E_1, E_2, and E_3 as

$$\begin{aligned} E_1 &:= \{|\hat{p} - p| \leq \omega p/z\}, \\ E_2 &:= \{|\hat{\sigma}^2 - \sigma^2| \leq \omega\sigma^2/z\}, \\ E_3 &:= \{\|\boldsymbol{Y} - p\boldsymbol{M}\| \leq (2 + \omega/2)\sqrt{Tq}\}, \end{aligned}$$

where $q = \sigma^2 p + p(1-p)$; for reasons that will be made clear later, we choose $z = 60(\frac{\sigma^2+1}{\sigma^2})$. By Bernstein's Inequality, we have that

$$\mathbb{P}(E_1) \geq 1 - 2e^{-c_1(N-1)Tp},$$

for appropriately defined constant c_1. By Hoeffding's Inequality, we obtain

$$\mathbb{P}(E_2) \geq 1 - 2e^{-c_2 T\sigma^2}$$

for some positive constant c_2. Moreover, by Theorem 15,

$$\mathbb{P}(E_3) \geq 1 - Ce^{-c_3 Tq}$$

as long as $q = \sigma^2 p + p(1-p) \geq T^{-1+\zeta}$ for some $\zeta > 0$. In other words,

$$\begin{aligned} p(\sigma^2 + 1) &\geq p(\sigma^2 + (1-p)) \\ &\geq T^{-1+\zeta}. \end{aligned}$$

Consequently, assuming the event E_3 occurs, we require that $p \geq \frac{T^{-1+\zeta}}{\sigma^2+1}$ for some $\zeta > 0$.

Finally, as previously discussed, we will assume that both N and T grow without bound in our imputation analysis. However, in our forecasting analysis, only $T_0 \to \infty$.

Appendix D. Imputation Analysis

In this section, we prove that our key de-noising procedure produces a consistent estimator of the underlying mean matrix, thereby adroitly imputing the missing entries and filtering corrupted observations within our data matrix.

Lemma 23 *Let $\boldsymbol{M} = [M_{ij}]$ be defined as before. Suppose f is a Lipschitz function with Lipschitz constant $\mathcal{L}$ and the latent row and column feature vectors come from a compact space K of dimension d. Then for any small enough $\delta > 0$,*

$$\|\boldsymbol{M}\|_* \leq \delta(N-1)\sqrt{T} + C(K, d, \mathcal{L})\sqrt{(N-1)T\delta^{-d}},$$

where $C(K, d, L)$ is a constant that depends on K, d, and $\mathcal{L}$.

Proof The proof is a straightforward adaptation of the arguments from [Chatterjee (2015), Lemma 3.6]; however, we provide it here for completeness. By the Lipschitzness assumption, every entry in $\boldsymbol{M} = [M_{ij}] = [f(\theta_i, \rho_j)]$ is Lipschitz in both its arguments, space (i) and time (j). For any $\delta > 0$, it is not hard to see that one can find a finite covering $P_1(\delta)$ and $P_2(\delta)$ of K so that for any $\theta, \rho \in K$, there exists $\theta' \in P_1(\delta)$ and $\rho' \in P_2(\delta)$ such that

$$|f(\theta, \rho) - f(\theta', \rho')| \leq \delta.$$

Without loss of generality, let us consider the case where $P(\delta) = P_1(\delta) = P_2(\delta)$. For every latent row feature θ_i, let $p_1(\theta_i)$ be the unique element in $P(\delta)$ that is closest to θ_i. Similarly, for the latent column feature ρ_j, find the corresponding closest element in $P(\delta)$ and denote it by $p_2(\rho_j)$. Let $\boldsymbol{B} = [B_{ij}]$ be the matrix where $B_{ij} = f(p_1(\theta_i), p_2(\rho_j))$. Using the arguments from above, we have that for all i and j,

$$\|\boldsymbol{M} - \boldsymbol{B}\|_F^2 = \sum_{i,j} (f(\theta_i, \rho_j) - f(p_1(\theta_i), p_2(\rho_j)))^2 \ \leq (N-1)T\delta^2.$$

Therefore,

$$\begin{aligned} \|\boldsymbol{M}\|_* &\leq \|\boldsymbol{M} - \boldsymbol{B}\|_* + \|\boldsymbol{B}\|_* \\ &\overset{(a)}{\leq} \sqrt{N-1}\|\boldsymbol{M} - \boldsymbol{B}\|_F + \|\boldsymbol{B}\|_* \\ &\leq \delta(N-1)\sqrt{T} + \|\boldsymbol{B}\|_*, \end{aligned}$$

where (a) follows from the fact that $\|\boldsymbol{Q}\|_* \leq \sqrt{\text{rank}(\boldsymbol{Q})}\|\boldsymbol{Q}\|_F$ for any real-valued matrix $\boldsymbol{Q}$. In order to bound the nuclear norm of $\boldsymbol{B}$, note that (by its construction) for any two columns, say $j, j' \in [N-1]$, if $p_2(\rho_j) = p_2(\rho_{j'})$ then it follows that the columns of j and j' of $\boldsymbol{B}$ are identical. Thus, there can be at most $|P(\delta)|$ distinct columns (and rows) of $\boldsymbol{B}$. In other words, $\text{rank}(\boldsymbol{B}) \leq |P(\delta)|$. Ergo,

$$\begin{aligned} \|\boldsymbol{B}\|_* &\leq \sqrt{|P(\delta)|}\|\boldsymbol{B}\|_F \\ &\leq \sqrt{|P(\delta)|}\sqrt{(N-1)T}. \end{aligned}$$

Due to the Lipschitzness property of f and the compactness of the latent space, it can be shown that $|P(\delta)| \leq C(K, d, \mathcal{L})\delta^{-d}$ where $C(K, d, \mathcal{L})$ is a constant that depends only on K, d, and $\mathcal{L}$ (the Lipschitz constant of f). ■

Lemma 24 (**Theorem 1.1 of Chatterjee (2015)**) *Let $\hat{\boldsymbol{M}}$ and $\boldsymbol{M}$ be defined as before. Suppose that $p \geq \frac{T^{-1+\zeta}}{\sigma^2+1}$ for some $\zeta > 0$. Then using μ as defined in* (20)

$$\text{MSE}(\hat{\boldsymbol{M}}) \leq \frac{C_1\|\boldsymbol{M}\|_*}{(N-1)\sqrt{Tp}} + \mathcal{O}\Big(\frac{1}{(N-1)T}\Big),$$

where C_1 is a universal positive constant.

Proof Let $\delta > 0$ be defined by the relation

$$(1+\delta)\|\boldsymbol{Y} - p\boldsymbol{M}\| = (2+\omega)\sqrt{T\hat{q}},$$

where $\hat{q} = \hat{\sigma}^2\hat{p} + \hat{p}(1-\hat{p})$. Observe that if E_1, E_2, and E_3 happen, then

$$\begin{aligned}
1+\delta &\geq \frac{(2+\omega)\sqrt{T(\hat{\sigma}^2\hat{p}+\hat{p}(1-\hat{p}))}}{(2+\omega/2)\sqrt{T(\sigma^2 p + p(1-p))}} \\
&\geq \frac{(2+\omega)\sqrt{1-\omega/z}\sqrt{(1-\omega/z)\sigma^2 p + p(1-p-\omega p/z)}}{(2+\omega/2)\sqrt{\sigma^2 p + p(1-p)}} \\
&= \frac{(2+\omega)\sqrt{1-\omega/z}}{2+\omega/2}\sqrt{1-\frac{\omega}{z}\Big(\frac{\sigma^2+p}{\sigma^2+1-p}\Big)} \\
&\geq \frac{(2+\omega)\sqrt{1-\omega/z}}{2+\omega/2}\sqrt{1-\frac{\omega}{z}\Big(\frac{\sigma^2+1}{\sigma^2}\Big)} \\
&= \frac{(2+\omega)\sqrt{1-\omega/z}}{2+\omega/2}\sqrt{1-\frac{\omega}{60}} \\
&\geq \frac{2+\omega}{2+\omega/2}\Big(1-\frac{\omega}{60}\Big) \\
&\geq \Big(1+\frac{\omega}{5}\Big)\Big(1-\frac{\omega}{60}\Big) \\
&\geq 1+\frac{\omega}{5}-\frac{1}{50}.
\end{aligned}$$

Let $K(\delta)$ be the constant defined in Lemma 22. Since $\omega \in (0.1, 1)$, $\delta \geq \frac{10\omega-1}{50} > 0$ and

$$\begin{aligned}
K(\delta) &= (4+2\delta)\sqrt{2/\delta} + \sqrt{2+\delta} \\
&\leq 4\sqrt{1+\delta}\sqrt{2/\delta} + 2\sqrt{2(1+\delta)} + \sqrt{2(1+\delta)} \\
&= (4\sqrt{2/\delta} + 3\sqrt{2})\sqrt{1+\delta} \\
&\leq C_1\sqrt{1+\delta}
\end{aligned}$$

where C_1 is a constant that depends only on the choice of ω. By Lemma 22, if E_1, E_2 and E_3 occur, then

$$\begin{aligned}
\Big\|\hat{p}\hat{\boldsymbol{M}} - p\boldsymbol{M}\Big\|_F^2 &\leq C_2(1+\delta)\|\boldsymbol{Y} - p\boldsymbol{M}\|\|p\boldsymbol{M}\|_* \\
&\leq C_3\sqrt{T\hat{q}}\|p\boldsymbol{M}\|_* \\
&\leq C_4\sqrt{Tq}\|p\boldsymbol{M}\|_*
\end{aligned}$$

for an appropriately defined constant C_4. Therefore,

$$\begin{aligned}
p^2\Big\|\hat{\boldsymbol{M}} - \boldsymbol{M}\Big\|_F^2 &\leq C_5\hat{p}^2\Big\|\hat{\boldsymbol{M}} - \boldsymbol{M}\Big\|_F^2 \\
&\leq C_5\Big\|\hat{p}\hat{\boldsymbol{M}} - p\boldsymbol{M}\Big\|_F^2 + C_5(\hat{p}-p)^2\|\boldsymbol{M}\|_F^2 \\
&\leq C_6\sqrt{Tq}\|p\boldsymbol{M}\|_* + C_5(\hat{p}-p)^2(N-1)T,
\end{aligned}$$

where the last inequality follows from the boundedness assumption of $\boldsymbol{M}$. In general, since $|M_{ij}|$ and $|Y_{ij}| \leq 1$,

$$\begin{aligned}
\Big\|\hat{\boldsymbol{M}} - \boldsymbol{M}\Big\|_F &\leq \Big\|\hat{\boldsymbol{M}}\Big\|_F + \|\boldsymbol{M}\|_F \\
&\leq \sqrt{|S|}\Big\|\hat{\boldsymbol{M}}\Big\| + \|\boldsymbol{M}\|_F \\
&= \frac{\sqrt{|S|}}{\hat{p}}\|\boldsymbol{Y}\| + \|\boldsymbol{M}\|_F \\
&\leq (N-1)^{3/2}T\|\boldsymbol{Y}\| + \|\boldsymbol{M}\|_F \\
&\leq (N-1)^{3/2}T\sqrt{(N-1)T} + \sqrt{(N-1)T} \\
&\leq 2(N-1)^2T^{3/2}.
\end{aligned}$$

Let $E := E_1 \cap E_2 \cap E_3$. Applying DeMorgan's Law and the Union Bound,

$$\begin{aligned}
\mathbb{P}(E^c) &= \mathbb{P}(E_1^c \cup E_2^c \cup E_e^c) \\
&\leq \mathbb{P}(E_1^c) + \mathbb{P}(E_2^c) + \mathbb{P}(E_3^c) \\
&\leq C_7 e^{-c_8 T(p(N-1)+\sigma^2+q)} \\
&= C_7 e^{-c_8\phi T}, \qquad (48)
\end{aligned}$$

where we define $\phi := p(N-1) + \sigma^2 + q$ and C_7, c_8 are appropriately defined. Observe that $\mathbb{E}(\hat{p}-p)^2 = \frac{p(1-p)}{(N-1)T}$. Thus, by the law of total probability and noting that $\mathbb{P}(E) \leq 1$ (for appropriately defined constants),

$$\begin{aligned}
\mathbb{E}\Big\|\hat{\boldsymbol{M}} - \boldsymbol{M}\Big\|_F^2 &\leq \mathbb{E}\Big[\Big\|\hat{\boldsymbol{M}} - \boldsymbol{M}\Big\|_F^2 \mid E\Big] + \mathbb{E}\Big[\Big\|\hat{\boldsymbol{M}} - \boldsymbol{M}\Big\|_F^2 \mid E^c\Big]\mathbb{P}(E^c) \\
&\leq C_6 p^{-1}\sqrt{Tq}\|\boldsymbol{M}\|_* + C_5 p^{-1}(1-p) + C_9(N-1)^4T^3e^{-c_8\phi T} \\
&= C_6 p^{-1/2}T^{1/2}(\sigma^2+(1-p))^{1/2}\|\boldsymbol{M}\|_* + C_5 p^{-1}(1-p) + C_9(N-1)^4T^3e^{-c_8\phi T}.
\end{aligned}$$

Normalizing by $(N-1)T$, we obtain

$$\mathrm{MSE}(\hat{\boldsymbol{M}}) \leq \frac{C_{12}\|\boldsymbol{M}\|_*}{(N-1)\sqrt{Tp}} + \frac{C_5(1-p)}{(N-1)Tp} + C_{10}e^{-c_{11}\phi T}.$$

The proof is complete assuming constants are re-named. ■

D.1 Proof of Theorem 1

Theorem 1 (Theorem 2.1 of Chatterjee (2015)) *Suppose that $\boldsymbol{M}$ is rank k. Suppose that $p \geq \frac{T^{-1+\zeta}}{\sigma^2+1}$ for some $\zeta > 0$. Then using μ as defined in* (20)*,*

$$\mathrm{MSE}(\hat{\boldsymbol{M}}) \leq C_1\sqrt{\frac{k}{(N-1)p}} + \mathcal{O}\Big(\frac{1}{(N-1)T}\Big),$$

where C_1 is a universal positive constant.

Proof By the low rank assumption of $\boldsymbol{M}$, we have that

$$\begin{aligned}
\|\boldsymbol{M}\|_* &\leq \sqrt{\mathrm{rank}(\boldsymbol{M})}\|\boldsymbol{M}\|_F \\
&\leq \sqrt{k(N-1)T}.
\end{aligned}$$

The proof follows from a simple application of Lemma 24. ■

D.2 Proof of Theorem 2

Theorem 2 (Theorem 2.7 of Chatterjee (2015)) *Suppose f is a $\mathcal{L}$-Lipschitz function. Suppose that $p \geq \frac{T^{-1+\zeta}}{\sigma^2+1}$ for some $\zeta > 0$. Then using μ as defined in (20),*

$$\text{MSE}(\hat{\boldsymbol{M}}) \leq C(K,d,\mathcal{L})\frac{(N-1)^{-\frac{1}{d+2}}}{\sqrt{p}} + \mathcal{O}\Big(\frac{1}{(N-1)T}\Big),$$

where $C(K,d,\mathcal{L})$ is a constant depending on K, d, and $\mathcal{L}$.

Proof Since f is Lipschitz, we invoke Lemmas 23 and 24 and choose $\delta = (N-1)^{-1/(d+2)}$. This completes the proof. ■

Appendix E. Forecasting Analysis: Pre-Intervention Regime

Here, we will bound the pre-intervention ℓ_2 error of our estimator in order to measure its prediction power.

E.1 Linear Regression

In this section, we will analyze the performance of our algorithm when learning β^* via linear regression, i.e. $\eta = 0$. As a result, we will temporarily drop the dependency on η in this subsection such that $\hat{\beta} = \hat{\beta}(0)$. To ease the notational complexity of the following Lemma 25 proof, we will make use of the following notations for **only** in this subsection:

$$\boldsymbol{Q} := (\boldsymbol{M}^-)^T \tag{49}$$
$$\hat{\boldsymbol{Q}} := (\hat{\boldsymbol{M}}^-)^T \tag{50}$$

such that

$$M_1^- := \boldsymbol{Q}\beta^* \tag{51}$$
$$\hat{M}_1^- := \hat{\boldsymbol{Q}}\hat{\beta}. \tag{52}$$

Lemma 25 *Suppose $Y_1^- = M_1^- + \epsilon_1^-$ with $\mathbb{E}[\epsilon_{1j}] = 0$ and $Var(\epsilon_{1j}) \leq \sigma^2$ for all $j \in [T_0]$. Let β^* be defined as in (6) and let $\hat{\beta}$ be the minimizer of (10). Then for any $\mu \geq 0$ and $\eta = 0$,*

$$\mathbb{E}\Big\|M_1^- - \hat{M}_1^-\Big\|^2 \leq \mathbb{E}\Big\|(\boldsymbol{M}^- - \hat{\boldsymbol{M}}^-)^T\beta^*\Big\|^2 + 2\sigma^2|S|. \tag{53}$$

Proof Recall that for the treatment row, $Y_1^- = M_1^- + \epsilon_1^-$ with $M_1^- = \boldsymbol{Q}\beta^*$. Since $\hat{\beta}$, by definition, minimizes $\Big\|Y_1^- - \hat{\boldsymbol{Q}}v\Big\|$ for any $v \in \mathbb{R}^{N-1}$, we subsequently have

$$\begin{aligned}
\Big\|M_1^- - \hat{M}_1^-\Big\|^2 &= \Big\|(Y_1^- - \epsilon_1^-) - \hat{\boldsymbol{Q}}\hat{\beta}\Big\|^2 \\
&= \Big\|(Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}) + (-\epsilon_1^-)\Big\|^2 \\
&= \Big\|Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}\Big\|^2 + \big\|\epsilon_1^-\big\|^2 + 2\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}\rangle \\
&\leq \Big\|Y_1^- - \hat{\boldsymbol{Q}}\beta^*\Big\|^2 + \big\|\epsilon_1^-\big\|^2 + 2\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}\rangle \\
&= \Big\|(\boldsymbol{Q}\beta^* + \epsilon_1^-) - \hat{\boldsymbol{Q}}\beta^*\Big\|^2 + \big\|\epsilon_1^-\big\|^2 + 2\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}\rangle \\
&= \Big\|(\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^* + \epsilon_1^-\Big\|^2 + \big\|\epsilon_1^-\big\|^2 + 2\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}\rangle \\
&= \Big\|(\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^*\Big\|^2 + 2\big\|\epsilon_1^-\big\|^2 + 2\langle \epsilon_1^-, (\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^*\rangle + 2\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}\rangle.
\end{aligned}$$

Taking expectations, we arrive at the inequality

$$\mathbb{E}\Big\|\hat{M}_1^- - M_1^-\Big\|^2 \leq \mathbb{E}\Big\|(\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^*\Big\|^2 + 2\mathbb{E}\big\|\epsilon_1^-\big\|^2 + 2\mathbb{E}[\langle \epsilon_1^-, (\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^*\rangle] + 2\mathbb{E}[\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}\rangle]. \tag{54}$$

We will now deal with the two inner products on the right hand side of equation (54). First, observe that

$$\begin{aligned}
\mathbb{E}[\langle \epsilon_1^-, (\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^*\rangle] &= \mathbb{E}[(\epsilon_1^-)^T]\boldsymbol{Q}\beta^* - \mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}]\beta^* \\
&= -\mathbb{E}[(\epsilon_1^-)^T]\mathbb{E}[\hat{\boldsymbol{Q}}]\beta^* \\
&= 0,
\end{aligned}$$

since the additive noise terms are independent random variables that satisfy $\mathbb{E}[\epsilon_{ij}] = 0$ for all i and j by assumption, and $\hat{\boldsymbol{Q}} := (\hat{\boldsymbol{M}}^-)^T$ depends only on the noise terms for $i \neq 1$; i.e., the construction of $\hat{\boldsymbol{Q}} := (\hat{\boldsymbol{M}}^-)^T$ excludes the first row (treatment row), and thus depends solely on the donor pool.

For the other inner product term, we begin by recognizing that $(\epsilon_1^-)^T\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger\epsilon_1^-$ is a scalar random variable, which allows us to replace the random variable by its own trace. This is useful since the trace operator is a linear mapping and is invariant under cyclic permutations, i.e., $\text{tr}(\boldsymbol{AB}) = \text{tr}(\boldsymbol{BA})$. As a result,

$$\begin{aligned}
\mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger\epsilon_1^-] &= \mathbb{E}[\text{tr}((\epsilon_1^-)^T\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger\epsilon_1^-)] \\
&= \mathbb{E}[\text{tr}(\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger\epsilon_1^-(\epsilon_1^-)^T)] \\
&= \text{tr}\Big(\mathbb{E}[\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger\epsilon_1^-(\epsilon_1^-)^T]\Big) \\
&= \text{tr}\Big(\mathbb{E}[\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger]\mathbb{E}[\epsilon_1^-(\epsilon_1^-)^T]\Big) \\
&= \text{tr}\Big(\mathbb{E}[\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger]\sigma^2 I\Big) \\
&= \sigma^2\mathbb{E}[\text{tr}(\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger)] \\
&\overset{(a)}{=} \sigma^2\mathbb{E}[\text{rank}(\hat{\boldsymbol{Q}})] \\
&\leq \sigma^2|S|,
\end{aligned}$$

where (a) follows from the fact that $\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger$ is a projection matrix by Lemma 18. As a result, $\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger$ has $\text{rank}(\hat{\boldsymbol{Q}})$ eigenvalues equal to 1 and all other eigenvalues equal to 0 (by Lemma 19), and since the trace of a matrix is equal to the sum of its eigenvalues, $\text{tr}(\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger) = \text{rank}(\hat{\boldsymbol{Q}})$. Simultaneously, by the definition of $\hat{\boldsymbol{Q}} := (\hat{\boldsymbol{M}}^-)^T$, we have that the rank of $\hat{\boldsymbol{Q}} := (\hat{\boldsymbol{M}}^-)^T$ is at most $|S|$. Returning to the second inner product and recalling $\hat{\beta} = \hat{\boldsymbol{Q}}^\dagger Y_1^-$,

$$\begin{aligned}
\mathbb{E}[\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}\rangle] &= \mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}\hat{\beta}] - \mathbb{E}[(\epsilon_1^-)^T Y_1^-] \\
&= \mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger Y_1^-] - \mathbb{E}[(\epsilon_1^-)^T]M_1^- - \mathbb{E}[(\epsilon_1^-)^T\epsilon_1^-] \\
&= \mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger]M_1^- + \mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger\epsilon_1^-] - \mathbb{E}[(\epsilon_1^-)^T\epsilon_1^-] \\
&\overset{(a)}{=} \mathbb{E}[(\epsilon_1^-)^T]\mathbb{E}[\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger]M_1^- + \mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger\epsilon_1^-] - \mathbb{E}[(\epsilon_1^-)^T\epsilon_1^-] \\
&= \mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger\epsilon_1^-] - \mathbb{E}\|\epsilon_1^-\|^2 \\
&\leq \sigma^2|S| - \mathbb{E}\|\epsilon_1^-\|^2,
\end{aligned}$$

where (a) follows from the same independence argument used in evaluating the first inner product. Finally, we incorporate the above results to (54) to arrive at the inequality

$$\begin{aligned}
\mathbb{E}\left\|\hat{M}_1^- - M_1^-\right\|^2 &\leq \mathbb{E}\left\|(\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^*\right\|^2 + 2\mathbb{E}\|\epsilon_1^-\|^2 + 2(\sigma^2|S| - \mathbb{E}\|\epsilon_1^-\|^2) \\
&= \mathbb{E}\left\|(\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^*\right\|^2 + 2\sigma^2|S|.
\end{aligned}$$

■

Lemma 26 *For $\eta = 0$ and any $\mu \geq 0$, the pre-intervention error of the algorithm can be bounded as*

$$\text{MSE}(\hat{M}_1^-) \leq \frac{C_1}{p^2T_0}\mathbb{E}\Big(\lambda^* + \|\boldsymbol{Y} - p\boldsymbol{M}\| + \left\|(\hat{p} - p)\boldsymbol{M}^-\right\|\Big)^2 + \frac{2\sigma^2|S|}{T_0} + C_2e^{-cp(N-1)T}. \tag{55}$$

Here, $\lambda_1, \ldots, \lambda_{N-1}$ are the singular values of $p\boldsymbol{M}$ in decreasing order and repeated by multiplicities, with $\lambda^* = \max_{i \notin S}\lambda_i$; C_1, C_2 and c are universal positive constants.

Proof Recall that $E_1 := \{|\hat{p} - p| \leq \frac{\omega p}{z}\}$ for some choice of $\omega \in (0.1, 1)$. Thus, under the event E_1,

$$\begin{aligned}
p\left\|\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-\right\| &\leq C_1\hat{p}\left\|\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-\right\| \\
&\leq C_1\Big(\left\|\hat{p}\hat{\boldsymbol{M}}^- - p\boldsymbol{M}^-\right\| + \left\|(\hat{p} - p)\boldsymbol{M}^-\right\|\Big) \\
&\overset{(a)}{\leq} C_1\Big(\left\|\hat{p}\hat{\boldsymbol{M}} - p\boldsymbol{M}\right\| + \left\|(\hat{p} - p)\boldsymbol{M}^-\right\|\Big) \\
&\overset{(b)}{\leq} C_1\Big(\lambda^* + 2\|\boldsymbol{Y} - p\boldsymbol{M}\| + \left\|(\hat{p} - p)\boldsymbol{M}^-\right\|\Big)
\end{aligned}$$

where (a) follows from Lemma 17 and (b) follows from Lemma 20. In general, since $|M_{ij}|$ and $|Y_{ij}| \leq 1$,

$$\begin{aligned}
\left\|\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-\right\| &\overset{(a)}{\leq} \left\|\hat{\boldsymbol{M}}\right\| + \|\boldsymbol{M}^-\| \\
&= \frac{1}{\hat{p}}\|\boldsymbol{Y}\| + \left\|\boldsymbol{M}^-\right\| \\
&\leq (N-1)T\|\boldsymbol{Y}\| + \left\|\boldsymbol{M}^-\right\| \\
&\leq (N-1)T\sqrt{(N-1)T} + \sqrt{(N-1)T_0} \\
&\leq 2((N-1)T)^{3/2}.
\end{aligned} \tag{56}$$

(a) follows from a simple application of Lemma 17 and the triangle inequality of operator norms. By the law of total probability and $\mathbb{P}(E_1) \leq 1$,

$$\begin{aligned}
\mathbb{E}\left\|(\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-)^T\beta^*\right\|^2 &\leq \mathbb{E}\Big[\left\|(\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-)^T\beta^*\right\|^2 \mid E_1\Big] + \mathbb{E}\Big[\left\|(\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-)^T\beta^*\right\|^2 \mid E_1^c\Big]\mathbb{P}(E_1^c) \\
&\overset{(a)}{\leq} \mathbb{E}\Big[\left\|\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-\right\|^2 \mid E_1\Big]\|\beta^*\|^2 + \mathbb{E}\Big[\left\|\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-\right\|^2 \mid E_1^c\Big]\|\beta^*\|^2\mathbb{P}(E_1^c) \\
&\leq \frac{C_2}{p^2}\mathbb{E}\Big[\Big(\lambda^* + 2\|\boldsymbol{Y} - p\boldsymbol{M}\| + \left\|(\hat{p} - p)\boldsymbol{M}^-\right\|\Big)^2 \mid E_1\Big] + C_3((N-1)T)^{3/2}e^{-cp(N-1)T},
\end{aligned}$$

where (a) follows because the spectral norm is an induced norm, and the last inequality makes use of the results from above. Note that C_2 and C_3 are appropriately defined to depend on β^*. Moreover, for any non-negative valued random variable X and event E with $\mathbb{P}(E) \geq 1/2$,

$$\mathbb{E}[X \mid E] \leq \frac{\mathbb{E}[X]}{\mathbb{P}(E)} \leq 2\mathbb{E}[X]. \tag{57}$$

Using the fact that $\mathbb{P}(E_1) \geq 1/2$ for large enough T, N, we apply Lemma 25 to obtain (with appropriately defined constants C_4, C_5, c_6)

$$\begin{aligned}
\text{MSE}(\hat{M}_1^-) &\leq \frac{1}{T_0}\mathbb{E}\left\|(\boldsymbol{M}^- - \hat{\boldsymbol{M}}^-)^T\beta^*\right\|^2 + \frac{2\sigma^2|S|}{T_0} \\
&\leq \frac{C_4}{p^2T_0}\mathbb{E}\Big(\lambda^* + \|\boldsymbol{Y} - p\boldsymbol{M}\| + \left\|(\hat{p} - p)\boldsymbol{M}^-\right\|\Big)^2 + \frac{2\sigma^2|S|}{T_0} + C_5e^{-c_6p(N-1)T}.
\end{aligned} \tag{58}$$

The proof is completed assuming we re-label constants C_4, C_5, c_6 as C_1, C_2, and c, respectively. ■

E.2 Ridge Regression

In this section, we will prove our results for the ridge regression setting, i.e. $\eta > 0$. Let us begin by deriving the closed form expression of $\hat{\beta}(\eta)$.

Derivation of $\hat{\beta}(\eta)$. We derive the closed form solution for $\hat{\beta}(\eta)$ under the new objective function with the additional complexity penalty term:

$$\left\|Y_1^- - (\hat{\boldsymbol{M}}^-)^Tv\right\|^2 + \eta\|v\|^2 = (Y_1^-)^TY_1^- - 2v^T\hat{\boldsymbol{M}}^-Y_1^- + v^T\hat{\boldsymbol{M}}^-(\hat{\boldsymbol{M}}^-)^Tv + \eta v^Tv.$$

Setting the gradient of the above expression to zero and solving for v, we obtain

$$\nabla_v\left\{\left\|Y_1^- - (\hat{\boldsymbol{M}}^-)^Tv\right\|^2 + \eta\|v\|^2\right\}_{v=\hat{\beta}(\eta)} = -2\hat{\boldsymbol{M}}^-Y_1^- + 2\hat{\boldsymbol{M}}^-(\hat{\boldsymbol{M}}^-)^Tv + 2\eta v = 0.$$

Therefore,

$$\hat{\beta}(\eta) = \Big(\hat{\boldsymbol{M}}^-(\hat{\boldsymbol{M}}^-)^T + \eta\boldsymbol{I}\Big)^{-1}\hat{\boldsymbol{M}}^-Y_1^-.$$

Remark 27 *To ease the notational complexity of the following Lemmas 28 and 30 proofs, we will make use of the following notations for* **only** *this derivation: Let*

$$\boldsymbol{Q} := (\boldsymbol{M}^-)^T \tag{59}$$

$$\hat{\boldsymbol{Q}} := (\hat{\boldsymbol{M}}^-)^T \tag{60}$$

such that

$$M_1^- := \boldsymbol{Q}\beta^* \tag{61}$$
$$\hat{M}_1^- := \hat{\boldsymbol{Q}}\hat{\beta}. \tag{62}$$

Lemma 28 *Let $\boldsymbol{P}_\eta = \hat{\boldsymbol{Q}}(\hat{\boldsymbol{Q}}^T\hat{\boldsymbol{Q}}+\eta\boldsymbol{I})^{-1}\hat{\boldsymbol{Q}}^T$ denote the "hat" matrix under the quadratic regularization setting. Then, the non-zero singular values of $\boldsymbol{P}_\eta$ are $s_i^2/(s_i^2+\eta)$ for all $i \in S$.*

Proof Recall that the singular values of $\boldsymbol{Y}$ are s_i, while the singular values of $\hat{\boldsymbol{Q}}$ are those $s_i \geq \mu$. Let $\hat{\boldsymbol{Q}} = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T$ be the singular value decomposition of $\hat{\boldsymbol{Q}}$. Since $\boldsymbol{V}\boldsymbol{V}^T = \boldsymbol{I}$, we have that

$$\begin{aligned}
\boldsymbol{P}_\eta &= \hat{\boldsymbol{Q}}(\hat{\boldsymbol{Q}}^T\hat{\boldsymbol{Q}}+\eta\boldsymbol{I})^{-1}\hat{\boldsymbol{Q}}^T \\
&= \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T(\boldsymbol{V}\boldsymbol{\Sigma}^2\boldsymbol{V}^T+\eta\boldsymbol{I})^{-1}\boldsymbol{V}\boldsymbol{\Sigma}\boldsymbol{U}^T \\
&= \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T(\boldsymbol{V}\boldsymbol{\Sigma}^2\boldsymbol{V}^T+\eta\boldsymbol{V}\boldsymbol{V}^T)^{-1}\boldsymbol{V}\boldsymbol{\Sigma}\boldsymbol{U}^T \\
&= \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T\boldsymbol{V}(\boldsymbol{\Sigma}^2+\eta\boldsymbol{I})^{-1}\boldsymbol{V}^T\boldsymbol{V}\boldsymbol{\Sigma}\boldsymbol{U}^T \\
&= \boldsymbol{U}\boldsymbol{\Sigma}(\boldsymbol{\Sigma}^2+\eta\boldsymbol{I})^{-1}\boldsymbol{\Sigma}\boldsymbol{U}^T \\
&= \boldsymbol{U}\boldsymbol{D}\boldsymbol{U}^T,
\end{aligned}$$

where

$$\boldsymbol{D} = \operatorname{diag}\left(\frac{s_1^2}{s_1^2+\eta}, \ldots, \frac{s_{|S|}^2}{s_{|S|}^2+\eta}, 0, \ldots, 0\right).$$

■

Lemma 29 *Suppose $Y_1^- = M_1^- + \epsilon_1^-$ with $\mathbb{E}[\epsilon_{1j}] = 0$ and $Var(\epsilon_{1j}) \leq \sigma^2$ for all $j \in [T_0]$. Let β^* be defined as in (6), i.e. $M_1^- = (\boldsymbol{M}^-)^T\beta^*$, and let $\hat{\beta}(\eta)$ be the minimizer of (10). Then for any $\mu \geq 0$ and $\eta > 0$,*

$$\mathbb{E}\left\|M_1^- - \hat{M}_1^-\right\|^2 \leq \mathbb{E}\left\|(\boldsymbol{M}^- - \hat{\boldsymbol{M}}^-)^T\beta^*\right\|^2 + \eta\|\beta^*\|^2 - \eta\mathbb{E}\left\|\hat{\beta}(\eta)\right\|^2 + 2\sigma^2|S|. \tag{63}$$

Proof The following proof is a slight modification for the proof of Lemmas 25. In particular, observe that $\hat{\beta}(\eta)$ minimizes $\left\|Y_1^- - \hat{\boldsymbol{Q}}v\right\| + \eta\|v\|^2$ for any $v \in \mathbb{R}^{N-1}$. As a result,

$$\begin{aligned}
&\left\|M_1^- - \hat{M}_1^-\right\|^2 + \eta\left\|\hat{\beta}(\eta)\right\|^2 \\
&= \left\|(Y_1^- - \epsilon_1^-) - \hat{\boldsymbol{Q}}\hat{\beta}(\eta)\right\|^2 + \eta\left\|\hat{\beta}(\eta)\right\|^2 \\
&= \left\|(Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}(\eta)) + (-\epsilon_1^-)\right\|^2 + \eta\left\|\hat{\beta}(\eta)\right\|^2 \\
&= \left\|Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}(\eta)\right\|^2 + \eta\left\|\hat{\beta}(\eta)\right\|^2 + \left\|\epsilon_1^-\right\|^2 + 2\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}(\eta)\rangle \\
&\leq \left\|Y_1^- - \hat{\boldsymbol{Q}}\beta^*\right\|^2 + \eta\|\beta^*\|^2 + \left\|\epsilon_1^-\right\|^2 + 2\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}(\eta)\rangle \\
&= \left\|(\boldsymbol{Q}\beta^* + \epsilon_1^-) - \hat{\boldsymbol{Q}}\beta^*\right\|^2 + \eta\|\beta^*\|^2 + \left\|\epsilon_1^-\right\|^2 + 2\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}(\eta)\rangle \\
&= \left\|(\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^* + \epsilon_1^-\right\|^2 + \eta\|\beta^*\|^2 + \left\|\epsilon_1^-\right\|^2 + 2\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}(\eta)\rangle \\
&= \left\|(\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^*\right\|^2 + \eta\|\beta^*\|^2 + 2\left\|\epsilon_1^-\right\|^2 + 2\langle \epsilon_1^-, (\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^*\rangle + 2\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}(\eta)\rangle
\end{aligned}$$

Taking expectations, we have

$$\begin{aligned}
&\mathbb{E}\left\|\hat{M}_1^- - M_1^-\right\|^2 \\
&\quad\leq \mathbb{E}\left\|(\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^*\right\|^2 + \eta\left(\|\beta^*\|^2 - \mathbb{E}\left\|\hat{\beta}(\eta)\right\|^2\right) + 2\mathbb{E}\left\|\epsilon_1^-\right\|^2 + 2\mathbb{E}\langle \epsilon_1^-, (\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^*\rangle + 2\mathbb{E}\langle -\epsilon_1^-, Y_1^- - \hat{\boldsymbol{Q}}\hat{\beta}(\eta)\rangle.
\end{aligned}$$

As before, we have that $\mathbb{E}\langle \epsilon_1^-, (\boldsymbol{Q} - \hat{\boldsymbol{Q}})\beta^*\rangle = 0$ by the zero-mean and independence assumptions of the noise random variables. Similarly, note that

$$\begin{aligned}
\mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}\hat{\beta}(\eta)] &= \mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}(\hat{\boldsymbol{Q}}^T\hat{\boldsymbol{Q}}+\eta\boldsymbol{I})^{-1}\hat{\boldsymbol{Q}}^TY_1^-] \\
&= \mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}(\hat{\boldsymbol{Q}}^T\hat{\boldsymbol{Q}}+\eta\boldsymbol{I})^{-1}\hat{\boldsymbol{Q}}^T]M_1^- + \mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}(\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^T+\eta\boldsymbol{I})^{-1}\hat{\boldsymbol{Q}}^T\epsilon_1^-] \\
&= \mathbb{E}[(\epsilon_1^-)^T\hat{\boldsymbol{Q}}(\hat{\boldsymbol{Q}}^T\hat{\boldsymbol{Q}}+\eta\boldsymbol{I})^{-1}\hat{\boldsymbol{Q}}^T\epsilon_1^-] \\
&= \mathbb{E}[\operatorname{tr}((\epsilon_1^-)^T\hat{\boldsymbol{Q}}(\hat{\boldsymbol{Q}}^T\hat{\boldsymbol{Q}}+\eta\boldsymbol{I})^{-1}\hat{\boldsymbol{Q}}^T\epsilon_1^-)] \\
&= \mathbb{E}[\operatorname{tr}(\hat{\boldsymbol{Q}}(\hat{\boldsymbol{Q}}^T\hat{\boldsymbol{Q}}+\eta\boldsymbol{I})^{-1}\hat{\boldsymbol{Q}}^T\epsilon_1^-(\epsilon_1^-)^T)] \\
&= \operatorname{tr}(\mathbb{E}[\hat{\boldsymbol{Q}}(\hat{\boldsymbol{Q}}^T\hat{\boldsymbol{Q}}+\eta\boldsymbol{I})^{-1}\hat{\boldsymbol{Q}}^T\epsilon_1^-(\epsilon_1^-)^T]) \\
&= \operatorname{tr}(\mathbb{E}[\hat{\boldsymbol{Q}}(\hat{\boldsymbol{Q}}^T\hat{\boldsymbol{Q}}+\eta\boldsymbol{I})^{-1}\hat{\boldsymbol{Q}}^T]\mathbb{E}[\epsilon_1^-(\epsilon_1^-)^T]) \\
&= \sigma^2\mathbb{E}[\operatorname{tr}(\hat{\boldsymbol{Q}}(\hat{\boldsymbol{Q}}^T\hat{\boldsymbol{Q}}+\eta\boldsymbol{I})^{-1}\hat{\boldsymbol{Q}}^T)] \\
&\overset{(a)}{\leq} \sigma^2\mathbb{E}[\operatorname{tr}(\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger)] \\
&\overset{(b)}{=} \sigma^2\operatorname{rank}(\hat{\boldsymbol{Q}}) \\
&\leq \sigma^2|S|,
\end{aligned}$$

where (a) follows from Lemma 28, and as before, (b) follows because $\hat{\boldsymbol{Q}}\hat{\boldsymbol{Q}}^\dagger$ is a projection matrix. ■

Lemma 30 *For any $\eta > 0$ and $\mu \geq 0$, the pre-intervention error of the regularized algorithm can be bounded as*

$$\operatorname{MSE}(\hat{M}_1^-) \leq \frac{C_1}{p^2T_0}\mathbb{E}\left(\lambda^* + \|\boldsymbol{Y} - p\boldsymbol{M}\| + \left\|(\hat{p} - p)\boldsymbol{M}^-\right\|\right)^2 + \frac{2\sigma^2|S|}{T_0} + \frac{\eta\|\beta^*\|^2}{T_0} + C_2e^{-cp(N-1)T}.$$

Here, $\lambda_1, \ldots, \lambda_{N-1}$ are the singular values of $p\boldsymbol{M}$ in decreasing order and repeated by multiplicities, with $\lambda^* = \max_{i\notin S}\lambda_i$; C_1, C_2 and c are universal positive constants.

Proof The proof follows the same arguments as that of Lemma 26. ■

E.3 Combining linear and ridge regression.

E.3.1 Proof of Theorem 3

Theorem *3 For any $\eta \geq 0$ and $\mu \geq 0$, the pre-intervention error of the algorithm can be bounded as*

$$\operatorname{MSE}(\hat{M}_1^-) \leq \frac{C_1}{p^2T_0}\mathbb{E}\left(\lambda^* + \|\boldsymbol{Y} - p\boldsymbol{M}\| + \left\|(\hat{p} - p)\boldsymbol{M}^-\right\|\right)^2 + \frac{2\sigma^2|S|}{T_0} + \frac{\eta\|\beta^*\|^2}{T_0} + C_2e^{-cp(N-1)T}.$$

Here, $\lambda_1, \ldots, \lambda_{N-1}$ are the singular values of $p\boldsymbol{M}$ in decreasing order and repeated by multiplicities, with $\lambda^* = \max_{i\notin S}\lambda_i$; C_1, C_2 and c are universal positive constants.

Proof The proof follows from a simple amalgamation of Lemmas 26 and 30. ■

E.3.2 Proof of Corollary 4

Theorem 4 *Suppose $p \geq \frac{T^{-1+\zeta}}{\sigma^2+1}$ for some $\zeta > 0$. Let $T \leq \alpha T_0$ for some constant $\alpha > 1$. Then for any $\eta \geq 0$ and using μ as defined in (20), the pre-intervention error is bounded above by*

$$\text{MSE}(\hat{M}_1^-) \leq \frac{C_1}{p}(\sigma^2 + (1-p)) + \mathcal{O}(1/\sqrt{T_0}),$$

where C_1 is a universal positive constant.

Proof Since the singular value threshold $\mu = (2+\omega)\sqrt{T\hat{q}}$, let us define δ so that

$$(1+\delta)\|\boldsymbol{Y} - p\boldsymbol{M}\| = (2+\omega)\sqrt{T\hat{q}},$$

where $\hat{q} = \hat{\sigma}^2\hat{p} + \hat{p}(1-\hat{p})$; recall that $q = \sigma^2 p + p(1-p)$. If E_3 happens, then we know that $\delta \geq 0$. Therefore, assuming E_1, E_2, and E_3 happens, Lemma 21 states that

$$\begin{aligned}\left\|\hat{p}\hat{\boldsymbol{M}} - p\boldsymbol{M}\right\| &\leq (2+\delta)\|\boldsymbol{Y} - p\boldsymbol{M}\| \\ &\leq 2(1+\delta)\|\boldsymbol{Y} - p\boldsymbol{M}\| \\ &= (4+2\omega)\sqrt{T\hat{q}} \\ &\leq C_1\sqrt{Tq} \end{aligned} \tag{64}$$

for an appropriately defined constant C_1. Therefore,

$$\begin{aligned} p\left\|\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-\right\| &\leq C_2\hat{p}\left\|\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-\right\| \\ &\leq C_2\Big(\left\|\hat{p}\hat{\boldsymbol{M}}^- - p\boldsymbol{M}^-\right\| + \left\|(\hat{p}-p)\boldsymbol{M}^-\right\|\Big) \\ &\overset{(a)}{\leq} C_2\Big(\left\|\hat{p}\hat{\boldsymbol{M}} - p\boldsymbol{M}\right\| + \left\|(\hat{p}-p)\boldsymbol{M}^-\right\|\Big) \\ &\leq C_2\Big(C_1\sqrt{Tq} + \left\|(\hat{p}-p)\boldsymbol{M}^-\right\|\Big) \end{aligned} \tag{65}$$

where (a) follows from Lemma 17. Applying the logic that led to (56), we have that, in general,

$$\left\|\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-\right\| \leq 2((N-1)T)^{3/2}. \tag{66}$$

Let $E := E_1 \cap E_2 \cap E_3$. Further, using the same argument that led to (48), we have

$$\mathbb{P}(E^c) \leq C_3 e^{-c_4\phi T}$$

where we define $\phi := p(N-1) + \sigma^2 + q$ and C_3, c_4 are appropriately defined. Thus, by the law of total probability and noting that $\mathbb{P}(E) \leq 1$,

$$\begin{aligned}\mathbb{E}\left\|(\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-)^T\beta^*\right\|^2 &\leq \mathbb{E}\Big[\left\|(\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-)^T\beta^*\right\|^2 \mid E\Big] + \mathbb{E}\Big[\left\|(\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-)^T\beta^*\right\|^2 \mid E^c\Big]\mathbb{P}(E^c) \\ &\overset{(a)}{\leq} \mathbb{E}\Big[\left\|\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-\right\|^2 \mid E\Big]\|\beta^*\|^2 + \mathbb{E}\Big[\left\|\hat{\boldsymbol{M}}^- - \boldsymbol{M}^-\right\|^2 \mid E^c\Big]\|\beta^*\|^2\mathbb{P}(E^c) \\ &\leq \frac{C_5}{p^2}\mathbb{E}\Big[\Big(\sqrt{Tq} + \left\|(\hat{p}-p)\boldsymbol{M}^-\right\|\Big)^2 \mid E\Big] + C_6((N-1)T)^3 e^{-c_4\phi T}, \end{aligned} \tag{67}$$

where (a) follows because the spectral norm is an induced norm and the last inequality makes use of the results from above. Note that C_5 and C_6 are appropriately defined to depend on β^*. Using the

fact that $\mathbb{P}(E) \geq 1/2$ for large enough T, N, we apply Lemmas 25 and 30 as well as (57) to obtain (with appropriately defined constants C_7, C_8, c_9)

$$\begin{aligned}\text{MSE}(\hat{M}_1^-) &\leq \frac{1}{T_0}\mathbb{E}\left\|(\boldsymbol{M}^- - \hat{\boldsymbol{M}}^-)^T\beta^*\right\|^2 + \frac{2\sigma^2|S|}{T_0} + \frac{\eta\|\beta^*\|^2}{T_0} \\ &\leq \frac{C_7}{p^2T_0}\mathbb{E}\Big(\sqrt{Tq} + \left\|(\hat{p}-p)\boldsymbol{M}^-\right\|\Big)^2 + \frac{2\sigma^2(N-1)}{T_0} + \frac{\eta\|\beta^*\|^2}{T_0} + C_8 e^{-c_9\phi T}. \end{aligned} \tag{68}$$

From Jensen's Inequality, $\mathbb{E}|\hat{p}-p| \leq \sqrt{\text{Var}(\hat{p})}$ where $\text{Var}(\hat{p}) = \frac{p(1-p)}{(N-1)T}$. Therefore,

$$\begin{aligned}\mathbb{E}\Big(\sqrt{Tq}\left\|(\hat{p}-p)\boldsymbol{M}^-\right\|\Big) &\leq \frac{q^{1/2}\sqrt{p(1-p)}}{\sqrt{N-1}}\left\|\boldsymbol{M}^-\right\| \\ &\leq \sqrt{qp(1-p)T_0}. \end{aligned}$$

At the same time,

$$\begin{aligned}\mathbb{E}\left\|(\hat{p}-p)\boldsymbol{M}^-\right\|^2 &= \mathbb{E}(\hat{p}-p)^2 \cdot \left\|\boldsymbol{M}^-\right\|^2 \\ &\leq \frac{p(1-p)T_0}{T} \\ &\leq p(1-p). \end{aligned}$$

Putting everything together, we arrive at the inequality

$$\begin{aligned}\text{MSE}(\hat{M}_1^-) &\leq \frac{C_7}{p^2T_0}\Big(qT + p(1-p) + 2\sqrt{qp(1-p)T_0}\Big) + \frac{2\sigma^2(N-1)}{T_0} + \frac{\eta\|\beta^*\|^2}{T_0} + C_8 e^{-c_9\phi T} \\ &= \frac{C_{10}q}{p^2} + \frac{C_7(1-p)}{pT_0} + \frac{C_{11}(q(1-p))^{1/2}}{p^{3/2}\sqrt{T_0}} + \frac{2\sigma^2(N-1)}{T_0} + \frac{\eta\|\beta^*\|^2}{T_0} + C_8 e^{-c_9\phi T} \\ &= \frac{C_{10}}{p}(\sigma^2 + (1-p)) + \mathcal{O}(1/\sqrt{T_0}). \end{aligned}$$

The proof is complete assuming we re-label C_{10} as C_1. ■

E.3.3 Proof of Theorem 5

Theorem 5 *Fix any $\gamma \in (0, 1/2)$ and $\omega \in (0.1, 1)$. Let $\Delta = T_0^{\frac{1}{2}+\gamma}$ and $\mu = (2+\omega)\sqrt{T_0^{2\gamma}(\hat{\sigma}^2\hat{p} + \hat{p}(1-\hat{p}))}$. Suppose $p \geq \frac{T_0^{-2\gamma}}{\sigma^2+1}$ is known. Then for any $\eta \geq 0$,*

$$\text{MSE}(\hat{\hat{M}}_1^-) = \mathcal{O}(T_0^{-1/2+\gamma}).$$

Proof To establish Theorem 5, we shall follow the proof of Corollary 4, using the block partitioned matrices instead. Recall that $\tau = T_0/\Delta$ where $\Delta = T_0^{1/2+\gamma}$. For analytical simplicity, we define the random variable

$$D_{it} = \begin{cases} 1 & \text{w.p. } p, \\ 0 & \text{otherwise,} \end{cases}$$

whose definition will soon prove to be useful. As previously described in Section 4, for all $i > 1$ and $j \in [\Delta]$, we define

$$\bar{X}_{ij} = \frac{1}{\tau}\sum_{t \in B_j} X_{it} \cdot D_{it}$$

and

$$\bar{M}_{ij} = \frac{p}{\tau} \sum_{t \in B_j} M_{it}.$$

Let us also define $\bar{\boldsymbol{E}}^- = [\bar{\epsilon}_{ij}]_{2 \le i \le N, j \le \Delta}$ with entries

$$\bar{\epsilon}_{ij} = \frac{1}{\tau} \sum_{t \in B_j} \epsilon_{it} \cdot D_{it}. \tag{69}$$

For the first row (treatment unit), since we know p by assumption, we define for all $j \in [\Delta]$

$$\begin{aligned} \bar{X}_{1j} &= \frac{p}{\tau} \sum_{t \in B_j} X_{1t} && (70) \\ &= \frac{p}{\tau} \sum_{t \in B_j} (M_{1t} + \epsilon_{1t}) \\ &= \frac{p}{\tau} \sum_{t \in B_j} M_{1t} + \frac{p}{\tau} \sum_{t \in B_j} \epsilon_{1t} \\ &= \bar{M}_{1j} + \bar{\epsilon}_{1j}, && (71) \end{aligned}$$

whereby $\bar{M}_{1j} = \frac{p}{\tau} \sum_{t \in B_j} M_{1t}$ and $\bar{\epsilon}_{1j} = \frac{p}{\tau} \sum_{t \in B_j} \epsilon_{1t}$. Under these constructions, the noise entries remain zero-mean random variables for all i, j, i.e. $\mathbb{E}[\bar{\epsilon}_{ij}] = 0$. However, the variance of each noise term is now rescaled, i.e. for $i = 1$

$$\begin{aligned} \mathrm{Var}(\bar{\epsilon}_{1j}) &= \frac{p^2}{\tau^2} \sum_{t \in B_j} \mathrm{Var}(\epsilon_{1t}) \\ &= \frac{\sigma^2}{\tau}, \end{aligned}$$

and for $i > 1$,

$$\begin{aligned} \mathrm{Var}(\bar{\epsilon}_{ij}) &= \frac{1}{\tau^2} \sum_{t \in B_j} \mathrm{Var}(\epsilon_{it} \cdot D_{it}) \\ &\overset{(a)}{\le} \frac{1}{\tau^2} \sum_{t \in B_j} (\sigma^2 p(1-p) + \sigma^2 p^2) \\ &\le \frac{\sigma^2}{\tau}. \end{aligned}$$

(a) used the fact that for any two independent random variables, X and Y, $\mathrm{Var}(XY) = \mathrm{Var}(X)\mathrm{Var}(Y) + \mathrm{Var}(X)(\mathbb{E}[Y])^2 + \mathrm{Var}(Y)(\mathbb{E}[X])^2$. Thus, for all i, j, $\mathrm{Var}(\bar{\epsilon}_{ij}) \le \sigma^2/\tau := \bar{\sigma}^2$.

We now show that the key assumption of (6) still holds under this setting with respect to the newly defined variables. In particular, for every partition $j \in [\Delta]$ of row one,

$$\begin{aligned} \bar{M}_{1j} &= \frac{p}{\tau} \sum_{t \in B_j} M_{1t} \\ &= \frac{p}{\tau} \sum_{t \in B_j} \Big(\sum_{k=2}^{N} \beta_k^* M_{kt} \Big) \\ &= \sum_{k=2}^{N} \beta_k^* \Big(\frac{p}{\tau} \sum_{t \in B_j} M_{kt} \Big) \\ &= \sum_{k=2}^{N} \beta_k^* \bar{M}_{kj}. \end{aligned}$$

As a result, we can express $\bar{M}_1^- = (\bar{\boldsymbol{M}}^-)^T \beta^*$ for the same β^* as in (6).

Following a similar setup as before, we define the matrix $\bar{\boldsymbol{Y}}^- = [\bar{Y}_{ij}]_{2 \le i \le N, j \le \Delta}$. Since we have assumed that each block contains at least one observed entry, we subsequently have that $\bar{Y}_{ij} = \bar{X}_{ij}$ for all i and j. We now proceed with our analysis in the exact same manner with the only difference being our newly defined set of variables and parameters. For completeness, we will highlight certain details below.

To begin, observe that $\mathbb{E}[\bar{Y}_{ij}] = \bar{M}_{ij}$ while

$$\mathrm{Var}(\bar{Y}_{ij}) \le \frac{\sigma^2 p + p(1-p)}{\tau}.$$

Consequently, we redefine the event $E_3 := \{ \|\bar{\boldsymbol{Y}}^- - \bar{\boldsymbol{M}}^-\| \le (2+\omega)\sqrt{\Delta \bar{q}} \}$ for some choice $\omega \in (0.1, 1)$ and for $\bar{q} = \frac{\sigma^2 p + p(1-p)}{\tau}$. By Theorem 15, it follows that $\mathbb{P}(E_3) \ge 1 - C' e^{-c\bar{q}\Delta}$.

Similar to before, let δ be defined by the relation

$$(1+\delta)\|\bar{\boldsymbol{Y}}^- - \bar{\boldsymbol{M}}^-\| = (2+\omega)\sqrt{\Delta \hat{\bar{q}}},$$

where $\hat{\bar{q}} = \frac{\hat{\sigma}^2 \hat{p} + \hat{p}(1-\hat{p})}{\tau}$. Letting $E = E_1 \cap E_2 \cap E_3$ and using arguments ((64), (65), (56)) that led us to (67), we obtain

$$\begin{aligned} \mathbb{E}\Big\| (\hat{\boldsymbol{M}}^- - \bar{\boldsymbol{M}}^-)^T \beta^* \Big\|^2 &\le \mathbb{E}\Big[\Big\| (\hat{\boldsymbol{M}}^- - \bar{\boldsymbol{M}}^-)^T \beta^* \Big\|^2 \mid E \Big] + \mathbb{E}\Big[\Big\| (\hat{\boldsymbol{M}}^- - \bar{\boldsymbol{M}}^-)^T \beta^* \Big\|^2 \mid E^c \Big] \mathbb{P}(E^c) \\ &\le C_1 \Delta \bar{q} + C_2 e^{-c_3 \phi \Delta}, \end{aligned}$$

where $\phi := p(N-1) + \sigma^2 + \bar{q}$. Utilizing Lemmas 25 and 30 gives us (for appropriately defined constants and defining $q = \sigma^2 p + p(1-p)$ as before such that $\bar{q} = q/\tau$)

$$\begin{aligned} \mathrm{MSE}(\hat{\bar{M}}_1^-) &\le C_1 \bar{q} + \frac{2\bar{\sigma}^2 k}{\Delta} + \frac{\eta \|\beta^*\|^2}{\Delta} + C_4 e^{-c_5 \phi \Delta}. \\ &= \frac{C_1 q}{\tau} + \frac{2\sigma^2 k}{\tau \Delta} + \frac{\eta \|\beta^*\|^2}{\Delta} + C_4 e^{-c_5 \frac{q}{\tau} \Delta} \\ &= \frac{C_1 q}{T_0^{1/2-\gamma}} + \frac{2\sigma^2 k}{T_0} + \frac{\eta \|\beta^*\|^2}{T_0^{1/2+\gamma}} + C_4 e^{-c_5 q T_0^{2\gamma}} \\ &= \mathcal{O}(T_0^{-1/2+\gamma}). \end{aligned}$$

This concludes the proof. ∎

Appendix F. Forecasting Analysis: Post-Intervention Regime

We now bound the post-intervention ℓ_2 error of our estimator.

F.1 Proof of Theorem 6

Theorem 6 *Let Equation* (6) *hold for some* $\beta^* \in \mathbb{R}^{N-1}$. *Let* $\text{rank}(\boldsymbol{M}^-) = \text{rank}(\boldsymbol{M})$. *Then* $M_1^+ = (\boldsymbol{M}^+)^T\beta^*$.

Proof Suppose we begin with only the matrix $\boldsymbol{M}^-$, i.e. $\boldsymbol{M} = \boldsymbol{M}^-$. From the assumption that $M_1^- = (\boldsymbol{M}^-)^T\beta^*$, we have for $t \le T_0$

$$M_{1t} = \sum_{j=2}^{N} \beta_j^* M_{jt}.$$

Suppose that we now add an extra column to $\boldsymbol{M}^-$ so that $\boldsymbol{M}$ is of dimension $N \times (T_0+1)$. Since $\text{rank}(\boldsymbol{M}^-) = \text{rank}(\boldsymbol{M})$, we have for $j \in [N]$

$$M_{j,T_0+1} = \sum_{t=1}^{T_0} \pi_t M_{jt},$$

for some set of weights $\pi \in \mathbb{R}^{T_0}$. In particular, for the first row we have

$$\begin{aligned} M_{1,T_0+1} &= \sum_{t=1}^{T_0} \pi_t M_{1t} \\ &= \sum_{t=1}^{T_0} \pi_t \Big(\sum_{j=2}^{N} \beta_j^* M_{jt} \Big) \\ &= \sum_{j=2}^{N} \beta_j^* \Big(\sum_{t=1}^{T_0} \pi_t M_{jt} \Big) \\ &= \sum_{j=2}^{N} \beta_j^* M_{j,T_0+1}. \end{aligned}$$

By induction, we observe that for any number of columns added to $\boldsymbol{M}^-$ such that $\text{rank}(\boldsymbol{M}^-) = \text{rank}(\boldsymbol{M})$, we must have $M_1^+ = (\boldsymbol{M}^+)^T\beta^*$ where $\boldsymbol{M}^+ = [M_{it}]_{2\le i\le N, T_0<t\le T}$. ■

F.2 Proof of Theorem 7

Theorem 7 *Suppose* $p \ge \frac{T^{-1+\zeta}}{\sigma^2+1}$ *for some* $\zeta > 0$. *Suppose* $\left\|\hat{\beta}(\eta)\right\|_\infty \le \psi$ *for some* $\psi > 0$. *Let* $\alpha' T_0 \le T \le \alpha T_0$ *for some constants* $\alpha', \alpha > 1$. *Then for any* $\eta \ge 0$ *and using* μ *as defined in* (20), *the post-intervention error is bounded above by*

$$\text{RMSE}(\hat{M}_1^+) \le \frac{C_1}{\sqrt{p}}(\sigma^2 + (1-p))^{1/2} + \frac{C_2\|\boldsymbol{M}\|}{\sqrt{T_0}} \cdot \mathbb{E}\left\|\hat{\beta}(\eta) - \beta^*\right\| + \mathcal{O}(1/\sqrt{T_0}),$$

where C_1 *and* C_2 *are universal positive constants.*

Proof We will prove Theorem 7 by drawing upon techniques and results from prior proofs. We begin by applying triangle inequality to obtain

$$\begin{aligned} \left\|\hat{M}_1^+ - M_1^+\right\| &= \left\|(\hat{\boldsymbol{M}}^+)^T\hat{\beta}(\eta) - (\boldsymbol{M}^+)^T\beta^*\right\| \\ &= \left\|(\hat{\boldsymbol{M}}^+)^T\hat{\beta}(\eta) - (\boldsymbol{M}^+)^T\beta^* + (\boldsymbol{M}^+)^T\hat{\beta}(\eta) - (\boldsymbol{M}^+)^T\hat{\beta}(\eta)\right\| \\ &\le \left\|(\hat{\boldsymbol{M}}^+ - \boldsymbol{M}^+)^T\hat{\beta}(\eta)\right\| + \left\|(\boldsymbol{M}^+)^T(\hat{\beta}(\eta) - \beta^*)\right\|. \end{aligned}$$

Taking expectations and using the property of induced norms gives

$$\begin{aligned} \mathbb{E}\left\|\hat{M}_1^+ - M_1^+\right\| &\le \mathbb{E}\Big[\left\|\hat{\boldsymbol{M}}^+ - \boldsymbol{M}^+\right\| \cdot \left\|\hat{\beta}(\eta)\right\|\Big] + \|\boldsymbol{M}^+\| \cdot \mathbb{E}\left\|\hat{\beta}(\eta) - \beta^*\right\| \\ &\le \sqrt{N}\psi \cdot \mathbb{E}\left\|\hat{\boldsymbol{M}}^+ - \boldsymbol{M}^+\right\| + \|\boldsymbol{M}^+\| \cdot \mathbb{E}\left\|\hat{\beta}(\eta) - \beta^*\right\|, \end{aligned} \tag{72}$$

where the last inequality uses the boundedness assumption of $\hat{\beta}(\eta)$. Observe that the first term on the right-hand side of (72) is similar to that of (53) and (63) with the main difference being (72) uses the post-intervention submatrices, $\hat{\boldsymbol{M}}^+$ and $\boldsymbol{M}^+$, as opposed to the pre-intervention submatrices, $\hat{\boldsymbol{M}}^-$ and $\boldsymbol{M}^-$, in (53) and (63). Therefore, using (57) and the arguments that led to (67), it follows that (with appropriate constants C_1, C_2, c_3)

$$\mathbb{E}\left\|\hat{\boldsymbol{M}}^+ - \boldsymbol{M}^+\right\| \le \frac{C_1}{p}\mathbb{E}\Big(\sqrt{Tq} + \left\|(\hat{p}-p)\boldsymbol{M}^+\right\|\Big) + C_2((N-1)T)^{3/2}e^{-c_3\phi T},$$

where the slight modification arises due to the fact that we are now operating in the post-intervention regime. In particular, $\|\boldsymbol{M}^+\| \le \sqrt{(N-1)(T-T_0)}$ and $\left\|\hat{\boldsymbol{M}}^+\right\| \le ((N-1)T)^{3/2}$. Further, note that q and ϕ are defined exactly as before, i.e. $q = \sigma^2 p + p(1-p)$ and $\phi = p(N-1) + \sigma^2 + q$. Following the proof of Corollary 4, we apply Jensen's Inequality to obtain

$$\begin{aligned} \mathbb{E}\left\|(\hat{p}-p)\boldsymbol{M}^+\right\| &= \mathbb{E}|\hat{p}-p| \cdot \left\|\boldsymbol{M}^+\right\| \\ &\le \sqrt{\frac{p(1-p)}{(N-1)T}} \cdot \sqrt{(N-1)(T-T_0)} \\ &\le \sqrt{p(1-p)}. \end{aligned}$$

Putting the above results together, we have (for appropriately defined constants)

$$\begin{aligned} \text{RMSE}(\hat{M}_1^+) &\le \frac{C_1\sqrt{N}\psi}{p\sqrt{T-T_0}}\Big(\sqrt{Tq} + \sqrt{p(1-p)}\Big) + \frac{\|\boldsymbol{M}^+\|}{\sqrt{T-T_0}} \cdot \mathbb{E}\left\|\hat{\beta}(\eta) - \beta^*\right\| + C_4 e^{-c_5\phi T} \\ &\overset{(a)}{\le} \frac{C_6\sqrt{q}}{p} + \frac{C_7\sqrt{1-p}}{\sqrt{pT_0}} + \frac{C_8\|\boldsymbol{M}\|}{\sqrt{T_0}} \cdot \mathbb{E}\left\|\hat{\beta}(\eta) - \beta^*\right\| + C_4 e^{-c_5\phi T} \\ &= \frac{C_6}{\sqrt{p}}(\sigma^2 + (1-p))^{1/2} + \frac{C_8\|\boldsymbol{M}\|}{\sqrt{T_0}} \cdot \mathbb{E}\left\|\hat{\beta}(\eta) - \beta^*\right\| + \mathcal{O}(1/\sqrt{T_0}), \end{aligned}$$

where (a) follows from Lemma 17. Renaming constants would provide the desired result. ■

Appendix G. A Bayesian Perspective

Derivation of posterior parameters.

The following is based on the derivation presented in Section 2.2.3 of Bishop (2006), and is presented here for completeness. Suppose we are given a multivariate Gaussian marginal distribution $p(x)$ paired with a multivariate Gaussian conditional distribution $p(y \mid x)$ – where x and y may have differing dimensions – and we are interested in computing the posterior distribution over x, i.e. $p(x \mid y)$. We will derive the posterior parameters of $p(x \mid y)$ here. Without loss of generality, suppose

$$\begin{aligned} p(x) &= \mathcal{N}(x \mid \mu, \boldsymbol{\Lambda}^{-1}) \\ p(y \mid x) &= \mathcal{N}(y \mid \boldsymbol{A}x + b, \boldsymbol{\Sigma}^{-1}), \end{aligned}$$

where $\mu, \boldsymbol{A}$, and b are parameters that govern the means, while $\boldsymbol{\Lambda}$ and $\boldsymbol{\Sigma}$ are precision (inverse covariance) matrices.

We begin by finding the joint distribution over x and y. Ignoring the terms that are independent of x and y and encapsulating them into the "const." expression, we obtain

$$\begin{aligned} \ln p(x, y) &= \ln p(x) + \ln p(y \mid x) \\ &= -\frac{1}{2}(x-\mu)^T \boldsymbol{\Lambda}(x-\mu) - \frac{1}{2}(y - \boldsymbol{A}x - b)^T \boldsymbol{\Sigma}(y - \boldsymbol{A}x - b) + \text{const.} \\ &= -\frac{1}{2}x^T(\boldsymbol{\Lambda} + \boldsymbol{A}^T\boldsymbol{\Sigma}\boldsymbol{A})x - \frac{1}{2}y^T\boldsymbol{\Sigma}y + \frac{1}{2}x^T\boldsymbol{A}^T\boldsymbol{\Sigma}y + \text{const.} \\ &= -\frac{1}{2}\begin{bmatrix} x \\ y \end{bmatrix}^T \begin{bmatrix} \boldsymbol{\Lambda} + \boldsymbol{A}^T\boldsymbol{\Sigma}\boldsymbol{A} & -\boldsymbol{A}^T\boldsymbol{\Sigma} \\ -\boldsymbol{\Sigma}\boldsymbol{A} & \boldsymbol{\Sigma} \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} + \text{const.} \\ &= -\frac{1}{2}z^T\boldsymbol{Q}z + \text{const.}, \end{aligned}$$

where $z = [x, y]^T$, and

$$\boldsymbol{Q} = \begin{bmatrix} \boldsymbol{\Lambda} + \boldsymbol{A}^T\boldsymbol{\Sigma}\boldsymbol{A} & -\boldsymbol{A}^T\boldsymbol{\Sigma} \\ -\boldsymbol{\Sigma}\boldsymbol{A} & \boldsymbol{\Sigma} \end{bmatrix}$$

is the precision matrix. Applying the matrix inversion formula, we have that the covariance matrix of z is

$$\text{Var}(z) = \boldsymbol{Q}^{-1} = \begin{bmatrix} \boldsymbol{\Lambda}^{-1} & \boldsymbol{\Lambda}^{-1}\boldsymbol{A}^T \\ \boldsymbol{A}\boldsymbol{\Lambda}^{-1} & \boldsymbol{\Sigma}^{-1} + \boldsymbol{A}\boldsymbol{\Lambda}^{-1}\boldsymbol{A}^T \end{bmatrix}.$$

After collecting the linear terms over z, we find that the mean of the Gaussian distribution over z is defined as

$$\mathbb{E}[z] = \boldsymbol{Q}^{-1}\begin{bmatrix} \boldsymbol{\Lambda}\mu - \boldsymbol{A}^T\boldsymbol{\Sigma}b \\ \boldsymbol{\Sigma}b \end{bmatrix}.$$

Now that we have the parameters over the joint distribution of x and y, we find that the posterior distribution parameters over x are

$$\begin{aligned} \mathbb{E}[x \mid y] &= (\boldsymbol{\Lambda} + \boldsymbol{A}^T\boldsymbol{\Sigma}\boldsymbol{A})^{-1}\{\boldsymbol{A}^T\boldsymbol{\Sigma}(y-b) + \boldsymbol{\Lambda}\mu\} \\ \text{Var}(x \mid y) &= (\boldsymbol{\Lambda} + \boldsymbol{A}^T\boldsymbol{\Sigma}\boldsymbol{A})^{-1}. \end{aligned}$$

Reverse Iterative Volume Sampling for Linear Regression*

Michał Dereziński MDEREZIN@UCSC.EDU
Manfred K. Warmuth MANFRED@UCSC.EDU

University of California Santa Cruz

Editor: Michael Mahoney

Abstract

We study the following basic machine learning task: Given a fixed set of input points in $\mathbb{R}^d$ for a linear regression problem, we wish to predict a hidden response value for each of the points. We can only afford to attain the responses for a small subset of the points that are then used to construct linear predictions for all points in the dataset. The performance of the predictions is evaluated by the total square loss on all responses (the attained as well as the remaining hidden ones). We show that a good approximate solution to this least squares problem can be obtained from just dimension d many responses by using a joint sampling technique called volume sampling. Moreover, the least squares solution obtained for the volume sampled subproblem is an unbiased estimator of optimal solution based on all n responses. This unbiasedness is a desirable property that is not shared by other common subset selection techniques.

Motivated by these basic properties, we develop a theoretical framework for studying volume sampling, resulting in a number of new matrix expectation equalities and statistical guarantees which are of importance not only to least squares regression but also to numerical linear algebra in general. Our methods also lead to a regularized variant of volume sampling, and we propose the first efficient algorithm for volume sampling which makes this technique a practical tool in the machine learning toolbox. Finally, we provide experimental evidence which confirms our theoretical findings.

Keywords: volume sampling, linear regression, row sampling, active learning, optimal design

1. Introduction

As an introductory case, consider linear regression in one dimension. We are given n non-zero points x_i. Each point has a hidden real response (or target value) y_i. Assume that obtaining the responses is expensive and the learner can afford to request the responses y_i for only a small number of indices i. After receiving the requested responses, the learner determines an approximate linear least squares solution. In the one dimensional homogeneous case, this is just a single weight. How many response values does the learner need to request so that the total square loss of its approximate solution on all n points is "close" to the total loss of the optimal linear least squares solution found with the knowledge of all responses? We will show here that just *one* response suffices if the index i is chosen proportional to x_i^2. When the learner uses the approximate solution $w_i^* = \frac{y_i}{x_i}$, then its expected loss equals 2 times the loss of the optimum w^* that is computed based on all responses (See Figure 1). Moreover, the approximate solution w_i^* is an unbiased estimator for the optimum w^*:

$$\mathbb{E}_i\left[\sum_j (x_j \frac{y_i}{x_i} - y_j)^2\right] = 2\sum_j (x_j w^* - y_j)^2 \quad \text{and} \quad \mathbb{E}_i\left[\frac{y_i}{x_i}\right] = w^*, \quad \text{when } P(i) \sim x_i^2.$$

*. This paper is an expanded version of two conference papers (Dereziński and Warmuth, 2017, 2018).

We will extend these formulas to higher dimensions and to sampling more responses by making use of a joint sampling distribution called *volume sampling*. We next break down our contributions into four parts.

Least squares with dimension many responses. Consider the case when the points $\mathbf{x}_i$ lie in $\mathbb{R}^d$. Let $\mathbf{X}$ denote a full rank $n \times d$ matrix that has the n transposed points $\mathbf{x}_i^\top$ as rows, and let $\mathbf{y} \in \mathbb{R}^n$ be the vector of responses. Now the goal is to minimize the (total) square loss,

$$L(\mathbf{w}) = \sum_{i=1}^n (\mathbf{x}_i^\top \mathbf{w} - y_i)^2 = \|\mathbf{X}\mathbf{w} - \mathbf{y}\|^2,$$

over all linear weight vectors $\mathbf{w} \in \mathbb{R}^d$. Let $\mathbf{w}^*$ denote the optimal such weight vector. We want to minimize the square loss based on a small number of responses we attained for a subset of rows. Again, the learner is initially given the fixed set of n rows (i.e. fixed design), but none of the responses. It is then allowed to choose a random subset of d indices, $S \subseteq \{1..n\}$, and obtains the responses for the corresponding d rows. The learner proceeds to find the optimal linear least squares solution $\mathbf{w}^*(S)$ for the subproblem $(\mathbf{X}_S, \mathbf{y}_S)$. where $\mathbf{X}_S$ is the subset of d rows of $\mathbf{X}$ indexed by S and $\mathbf{y}_S$ the corresponding d responses from the response vector $\mathbf{y}$. As a generalization of the one-dimensional distribution that chooses an index based on the squared length, set S of size d is chosen proportional to the squared volume of the parallelepiped spanned by the rows of $\mathbf{X}_S$. This squared volume equals $\det(\mathbf{X}_S^\top \mathbf{X}_S)$. Using elementary linear algebra, we will show that *volume sampling* the set S assures that $\mathbf{w}^*(S)$ is a good approximation to $\mathbf{w}^*$ in the following sense: In expectation, the square loss (on all n row response pairs) of $\mathbf{w}^*(S)$ is equal $d+1$ times the square loss of $\mathbf{w}^*$ (when $\mathbf{X}$ is in general position):

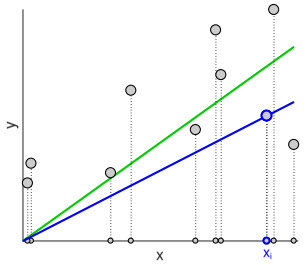

Figure 1: The expected loss of $w_i^* = \frac{y_i}{x_i}$ (blue line) based on one response y_i is twice the loss of the optimum w^* (green line).

$$\mathbb{E}[L(\mathbf{w}^*(S))] = (d+1)\, L(\mathbf{w}^*), \quad \text{when } P(S) \sim \det(\mathbf{X}_S^\top \mathbf{X}_S).$$

Furthermore, we will show that for any sampling procedure that attains less than d responses, the ratio between the expected loss and the loss of the optimum cannot be bounded by a constant.

Unbiased pseudoinverse estimator. There is a direct connection between solving linear least squares problems and the pseudoinverse $\mathbf{X}^+$ of matrix $\mathbf{X}$: For an $n-$dimensional response vector $\mathbf{y}$, the optimal solution is $\mathbf{w}^* = \text{argmin}_{\mathbf{w}} \|\mathbf{X}\mathbf{w} - \mathbf{y}\|^2 = \mathbf{X}^+\mathbf{y}$. Similarly $\mathbf{w}^*(S) = (\mathbf{X}_S)^+\mathbf{y}_S$ is the solution for the subproblem $(\mathbf{X}_S, \mathbf{y}_S)$. We propose a new implementation of volume sampling called *reverse iterative sampling* which enables a novel proof technique for obtaining elementary expectation formulas for pseudoinverses based on volume sampling.

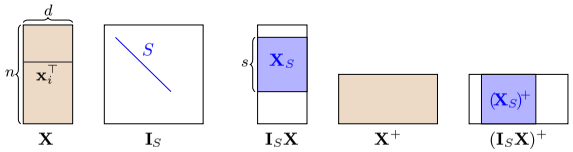

Figure 2: Shapes of the matrices. The indices of S may not be consecutive.

Suppose that our goal is to estimate the pseudoinverse $\mathbf{X}^+$ based on the pseudoinverse of a subset of rows. Recall that for a subset $S \subseteq \{1..n\}$ of s row indices (where the size s is fixed and $s \geq d$), we let $\mathbf{X}_S$ be the submatrix of the s rows indexed by S (see Figure 2). Consider a version of $\mathbf{X}$ in which all but the rows of S are zero. This matrix equals $\mathbf{I}_S\mathbf{X}$, where the selection matrix $\mathbf{I}_S$ is an n-dimensional diagonal matrix with $(\mathbf{I}_S)_{ii} = 1$ if $i \in S$ and 0 otherwise.

For the set S of fixed size $s \geq d$ row indices chosen proportional to $\det(\mathbf{X}_S^\top \mathbf{X}_S)$, we can prove the following two expectation formulas (for the second equality, $\mathbf{X}$ must be in general position):

$$\mathbb{E}[(\mathbf{I}_S\mathbf{X})^+] = \mathbf{X}^+ \quad \text{and} \quad \mathbb{E}\Big[\underbrace{(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}}_{(\mathbf{I}_S\mathbf{X})^+(\mathbf{I}_S\mathbf{X})^{+\top}}\Big] = \frac{n-d+1}{s-d+1}\underbrace{(\mathbf{X}^\top\mathbf{X})^{-1}}_{\mathbf{X}^+\mathbf{X}^{+\top}}.$$

Note that $(\mathbf{I}_S\mathbf{X})^+$ has the $d \times n$ shape of $\mathbf{X}^+$ where the s columns indexed by S contain $(\mathbf{X}_S)^+$ and the remaining $n-s$ columns are zero. The expectation of this matrix is $\mathbf{X}^+$ even though $(\mathbf{X}_S)^+$ is clearly not a submatrix of $\mathbf{X}^+$. This expectation formula now implies that for any size $s \geq d$, if S of size s is drawn by volume sampling, then $\mathbf{w}^*(S)$ is an unbiased estimator[1] for $\mathbf{w}^*$, i.e.

$$\mathbb{E}[\mathbf{w}^*(S)] = \mathbb{E}[(\mathbf{X}_S)^+\mathbf{y}_S] = \mathbb{E}[(\mathbf{I}_S\mathbf{X})^+\mathbf{y}] = \mathbb{E}[(\mathbf{I}_S\mathbf{X})^+]\,\mathbf{y} = \mathbf{X}^+\mathbf{y} = \mathbf{w}^*.$$

The second expectation formula can be viewed as a second moment of the pseudoinverse estimator $(\mathbf{I}_S\mathbf{X})^+$, and it can be used to compute a useful notion of matrix variance with applications in random matrix theory:

$$\mathbb{E}[(\mathbf{I}_S\mathbf{X})^+(\mathbf{I}_S\mathbf{X})^{+\top}] - \mathbb{E}[(\mathbf{I}_S\mathbf{X})^+]\mathbb{E}[(\mathbf{I}_S\mathbf{X})^+]^\top = \frac{n-s}{s-d+1}\mathbf{X}^+\mathbf{X}^{+\top}.$$

Regularized volume sampling. We also develop a new regularized variant of volume sampling, which extends reverse iterative sampling to selecting subsets of size smaller than d, and leads to a useful extension of the above matrix variance formula. Namely, for any $\lambda \geq 0$, our λ-regularized procedure for sampling subsets S of size s satisfies

$$\mathbb{E}\big[(\mathbf{X}_S^\top\mathbf{X}_S + \lambda\mathbf{I})^{-1}\big] \preceq \frac{n-d_\lambda+1}{s-d_\lambda+1}(\mathbf{X}^\top\mathbf{X} + \lambda\mathbf{I})^{-1},$$

where $d_\lambda \overset{def}{=} \operatorname{tr}(\mathbf{X}(\mathbf{X}^\top\mathbf{X} + \lambda\mathbf{I})^{-1}\mathbf{X}^\top) \leq d$ is a standard notion of statistical dimension. Crucially, the above bound holds for subset sizes $s \geq d_\lambda$, which can be much smaller than the dimension d.

Under the additional assumption that response vector $\mathbf{y}$ is generated by a linear transformation distorted with bounded white noise, the expected bound on $(\mathbf{X}_S^\top\mathbf{X}_S + \lambda\mathbf{I})^{-1}$ leads to strong variance bounds for the ridge regression estimator. Specifically, we prove that when $\mathbf{y} = \mathbf{X}\widetilde{\mathbf{w}} + \boldsymbol{\xi}$, with $\boldsymbol{\xi}$ having mean zero and bounded variance $\operatorname{Var}[\boldsymbol{\xi}] \preceq \sigma^2\mathbf{I}$, then if S is sampled according to λ-regularized volume sampling with $\lambda \leq \frac{\sigma^2}{\|\widetilde{\mathbf{w}}\|^2}$, we can obtain the following bound on the mean squared prediction error (MSPE):

$$\mathbb{E}_S\mathbb{E}_{\boldsymbol{\xi}}\left[\frac{1}{n}\|\mathbf{X}(\mathbf{w}_\lambda^*(S) - \widetilde{\mathbf{w}})\|^2\right] \leq \frac{\sigma^2 d_\lambda}{s-d_\lambda+1},$$

1. For size $s = d$ volume sampling, the fact that $\mathbb{E}[\mathbf{w}^*(S)] = \mathbf{w}^*$ can be found in an early paper (Ben-Tal and Teboulle, 1990). They give a direct proof based on Cramer's rule.

where $\mathbf{w}_\lambda^*(S) = (\mathbf{X}_S^\top\mathbf{X}_S + \lambda\mathbf{I})^{-1}\mathbf{X}_S^\top\mathbf{y}_S$ is the ridge regression estimator for the subproblem $(\mathbf{X}_S, \mathbf{y}_S)$. Our new lower bounds show that the above upper bound for regularized volume sampling is essentially optimal with respect to the choice of a subsampling procedure.

Algorithms and experiments. The only known polynomial time algorithm for size $s > d$ volume sampling was recently proposed by Li et al. (2017) with time complexity $O(n^4 s)$. In this paper we give two new algorithms using our general framework of reverse iterative sampling: one with deterministic runtime of $O((n-s+d)nd)$, and a second one that with high probability finishes in time $O(nd^2)$. Thus both algorithms improve on the state-of-the-art by a factor of at least n^2 and make volume sampling nearly as efficient as the comparable i.i.d. sampling technique called leverage score sampling. Our experiments on real datasets confirm the efficiency of our algorithms and show that for small sample sizes s, volume sampling is more effective than leverage score sampling for the task of subset selection for linear regression.

1.1 Related Work

Volume sampling is a type of determinantal point process (DPP) (Kulesza and Taskar, 2012). DPP's have been given a lot of attention in the literature with many applications to machine learning, including recommendation systems (Gartrell et al., 2016) and clustering (Kang, 2013). Many exact and approximate methods for efficiently generating samples from this distribution have been proposed (Deshpande and Rademacher, 2010; Kulesza and Taskar, 2011), making it a useful tool in the design of randomized algorithms. Most of those methods focus on sampling $s \leq d$ elements. In this paper, we study volume sampling sets of size $s \geq d$, which was proposed by Avron and Boutsidis (2013) and motivated with applications in graph theory, linear regression, matrix approximation and more.

The problem of selecting a subset of the rows of the input matrix for solving a linear regression task has been extensively studied in statistics literature under the terms *optimal design* (Fedorov, 1972) and *pool-based active learning* (Sugiyama and Nakajima, 2009). Various criteria for subset selection have been proposed, like A-optimality and D-optimality. For example, A-optimality seeks to minimize $\operatorname{tr}((\mathbf{X}_S^\top\mathbf{X}_S)^{-1})$, which is combinatorially hard to optimize exactly. We show that for size $s \geq d$ volume sampling, $\mathbb{E}[(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}] = \frac{n-d+1}{s-d+1}(\mathbf{X}^\top\mathbf{X})^{-1}$, which provides an approximate randomized solution of the sampled inverse covariance matrix rather than just its trace.

In the field of computational geometry a variant of volume sampling was used to obtain optimal bounds for low-rank matrix approximation. In this task, the goal is to select a small subset of rows of a matrix $\mathbf{X} \in \mathbb{R}^{n\times d}$ (much fewer than the rank of $\mathbf{X}$, which is bounded by d), so that a good low-rank approximation of $\mathbf{X}$ can be constructed from those rows. Deshpande et al. (2006) showed that volume sampling of size $s < d$ index sets obtains optimal multiplicative bounds for this task and polynomial time algorithms for size $s < d$ volume sampling were given in Deshpande and Rademacher (2010) and Guruswami and Sinop (2012). We show in this paper that for linear regression, fewer than rank many rows do not suffice to obtain multiplicative bounds. This is why we focus on volume sampling sets of size $s \geq d$ (recall that, for simplicity, we assume that $\mathbf{X}$ is full rank).

Computing approximate solutions to linear regression has been explored in the domain of numerical linear algebra (see Mahoney (2011) for an overview). Here, multiplicative bounds on the loss of the approximate solution can be achieved via two approaches. The first approach relies on sketching the input matrix $\mathbf{X}$ and the response vector $\mathbf{y}$ by multiplying both by the same suitably chosen random matrix. Algorithms which use sketching to generate a smaller input matrix for a given linear regression problem are computationally efficient (Sarlos, 2006; Clarkson and Woodruff,

2013), but they require all of the responses from the original problem to generate the sketch and are thus not suitable for the goal of using as few response values as possible. The second approach is based on subsampling the rows of the input matrix and only asking for the responses of the sampled rows. The learner optimally solves the sampled subproblem[2] and then uses the obtained weight vector for its prediction on all rows. The selected subproblem is known under the term "$\mathbf{b}$-agnostic minimal coreset" in (Boutsidis et al., 2013; Drineas et al., 2008) since it is selected without knowing the response vector (denoted as the vector $\mathbf{b}$). The second approach coincides with the goals of this paper but the focus here is different in a number of ways. First, we focus on the smallest sample size for which a multiplicative loss bound is possible: Just d volume sampled rows are sufficient to achieve a multiplicative bound with a fixed factor, while $d-1$ are not sufficient. A second focus here is the efficiency and the combinatorics of volume sampling. The previous work is mostly based on i.i.d. sampling using the statistical leverage scores (Drineas et al., 2012). As we show in this paper, leverage scores are the marginals of volume sampling and any i.i.d. sampling method requires sample size $\Omega(d \log d)$ to achieve multiplicative loss bounds for linear regression. On the other hand, the rows obtained from volume sampling are *selected jointly* and this makes the chosen subset more informative and brings the required sample size down to d. Third, we focus on the fact that the estimators produced from volume sampling are unbiased and therefore can be averaged to get more accurate estimators. Using our methods, averaging immediately leads to an unbiased estimator with expected loss $1+\epsilon$ times the optimum based on sampling d^2/ϵ responses in total. We leave it as an open problem to construct a $1+\epsilon$ factor unbiased estimator from sampling only $O(d/\epsilon)$ responses. If unbiasedness is not a concern, then such an estimator has recently been found (Chen and Price, 2017).

1.2 Outline of the Paper

In the next section, we define volume sampling as an instance of a more general procedure we call reverse iterative sampling, and we use this methodology to prove closed form matrix expressions for the expectation of the pseudoinverse estimator $(\mathbf{I}_S\mathbf{X})^+$ and its square $(\mathbf{I}_S\mathbf{X})^+(\mathbf{I}_S\mathbf{X})^{+\top}$, when S is sampled by volume sampling. Central to volume sampling is the Cauchy-Binet formula for determinants. As a side, we produce a number of short self-contained proofs for this formula and show that leverage scores are the marginals of volume sampling. Then in Section 3 we formulate the problem of solving linear regression from a small number of responses, and state the upper bound for the expected square loss of the volume sampled least squares estimator (Theorem 8), followed by a discussion and related lower bounds. In Section 3.3, we prove Theorem 8 and an additional related matrix expectation formula. We next discuss in Section 3.4 how unbiased estimators can easily be averaged for improving the expected loss and discuss open problems for constructing unbiased estimators. A new regularized variant of volume sampling is proposed in Section 4, along with the statistical guarantees it offers for computing subsampled ridge regression estimators. Next, we present efficient volume sampling algorithms in Section 5, based on the reverse iterative sampling paradigm, which are then experimentally evaluated in Section 6. Finally, Section 7 concludes the paper by suggesting a future research direction.

2. Note that those methods typically require additional rescaling of the subproblem, whereas the techniques proposed in this paper do not require any rescaling.

2. Reverse Iterative Sampling

Let n be an integer dimension. For each subset $S \subseteq \{1..n\}$ of size s we are given a matrix formula $\mathbf{F}(S)$. Our goal is to sample set S of size s using some sampling process and then develop concise expressions for $\mathbb{E}_{S:|S|=s}[\mathbf{F}(S)]$. Examples of formula classes $\mathbf{F}(S)$ will be given below.

We represent the sampling by a directed acyclic graph (DAG), with a single root node corresponding to the full set $\{1..n\}$. Starting from the root, we proceed along the edges of the graph, iteratively removing elements from the set S (see Figure 3). Concretely, consider a DAG with levels $s = n, n-1, ..., d$. Level s contains $\binom{n}{s}$ nodes for sets $S \subseteq \{1..n\}$ of size s. Every node S at level $s > d$ has s directed edges to the nodes $S - \{i\}$ (also denoted S_{-i}) at the next lower level. These edges are labeled with a conditional probability vector $P(S_{-i}|S)$, where the event S occurs if the sampling process visits node S as it traces a (directed) path in the DAG from the root node $\{1..n\}$ to a node at level d. Such paths have $n-d$ edges. It is natural to assign probabilities to shorter paths as well going from any node to a node at a lower level. The probability of such a path is again the product of its edge probabilities. It also follows that the probability $P(S)$ of visiting node S (via a path from the root) is the sum of the probabilities of all paths from root to S. Finally, the probability $P(\{1..n\})$ of the root node is 1 and more generally, the total probability of all nodes at each layer is 1.

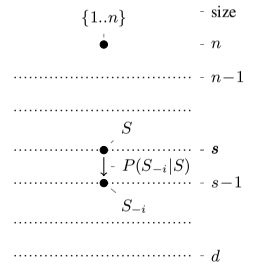

Figure 3: Reverse iterative sampling.

We associate a formula $\mathbf{F}(S)$ with each set node S in the DAG. The following key equality lets us compute expectations.

Lemma 1 *If for all $S \subseteq \{1..n\}$ of size greater than d we have*

$$\mathbf{F}(S) = \sum_{i \in S} P(S_{-i}|S)\mathbf{F}(S_{-i}),$$

then for any $s \in \{d..n\}$: $\mathbb{E}_{S:|S|=s}[\mathbf{F}(S)] = \sum_{S:|S|=s} P(S)\mathbf{F}(S) = \mathbf{F}(\{1..n\})$.

Proof Suffices to show that expectations at successive layers s and $s-1$ are equal for $s > d$:

$$\sum_{S:|S|=s} P(S)\,\mathbf{F}(S) = \sum_{S:|S|=s} P(S) \sum_{i \in S} P(S_{-i}|S)\,\mathbf{F}(S_{-i}) = \sum_{S:|S|=s} \sum_{i \in S} P(S)P(S_{-i}|S)\mathbf{F}(S_{-i})$$
$$= \sum_{T:|T|=s-1} \underbrace{\sum_{j \notin T} P(T_{+j})P(T|T_{+j})}_{P(T)}\,\mathbf{F}(T).$$

Note that the r.h.s. of the first line has one summand per edge leaving level s, and the r.h.s. of the second line has one summand per edge arriving at level $s-1$. Now the last equality holds because the edges leaving level s are exactly those arriving at level $s-1$, and the summand for each edge in both expressions is equivalent. ■

2.1 Volume Sampling

Given a tall full rank matrix $\mathbf{X} \in \mathbb{R}^{n\times d}$ and a sample size $s \in \{d..n\}$, volume sampling chooses subset $S \subseteq \{1..n\}$ of size s with probability proportional to squared volume spanned by the columns of submatrix[3] $\mathbf{X}_S$ and this squared volume equals $\det(\mathbf{X}_S^\top \mathbf{X}_S)$. The following theorem uses the above DAG setup to compute the normalization constant for this distribution. Note that all subsets S of volume 0 will be ignored, since they are unreachable in the proposed sampling procedure.

Theorem 2 *Let $\mathbf{X} \in \mathbb{R}^{n\times d}$, where $d \le n$ and $\det(\mathbf{X}^\top\mathbf{X}) > 0$. For any set S of size $s > d$ for which $\det(\mathbf{X}_S^\top\mathbf{X}_S) > 0$, define the probability of the edge from S to S_{-i} for $i \in S$ as:*

$$P(S_{-i}|S) \overset{def}{=} \frac{\det(\mathbf{X}_{S_{-i}}^\top \mathbf{X}_{S_{-i}})}{(s-d)\det(\mathbf{X}_S^\top\mathbf{X}_S)} = \frac{1-\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i}{s-d}, \quad \textbf{(reverse iterative volume sampling)}$$

where $\mathbf{x}_i^\top$ is the i-th row of $\mathbf{X}$. In this case $P(S_{-i}|S)$ is a proper probability distribution. If $\det(\mathbf{X}_S^\top\mathbf{X}_S) = 0$, then simply set $P(S_{-i}|S)$ to $\frac{1}{s}$. With these definitions, $\sum_{S:|S|=s} P(S) = 1$ for all $s \in \{d..n\}$ and the probability of all paths from the root to any subset S of size at least d is

$$P(S) = \frac{\det(\mathbf{X}_S^\top\mathbf{X}_S)}{\binom{n-d}{s-d}\det(\mathbf{X}^\top\mathbf{X})}. \qquad \textbf{(volume sampling)}$$

The rewrite of the ratio $\frac{\det(\mathbf{X}_{S_{-i}}^\top \mathbf{X}_{S_{-i}})}{\det(\mathbf{X}_S^\top\mathbf{X}_S)}$ as $1-\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i$ is Sylvester's Theorem for determinants. Incidentally, this is the only property of determinants used in this section.

The theorem also implies a generalization of the Cauchy-Binet formula to size $s \ge d$ sets:

$$\sum_{S:|S|=s} \det(\mathbf{X}_S^\top\mathbf{X}_S) = \binom{n-d}{s-d}\det(\mathbf{X}^\top\mathbf{X}). \tag{1}$$

When $s = d$, then the binomial coefficient is 1 and the above becomes the vanilla Cauchy-Binet formula. The below proof of the theorem thus results in a minimalist proof of this classical formula as well. The proof uses the reverse iterative sampling (Figure 3) and the fact that all paths from the root to node S have the same probability. For the sake of completeness we also give a more direct inductive proof of the above generalized Cauchy-Binet formula in Appendix A.

Proof First, for any node S s.t. $s > d$ and $\det(\mathbf{X}_S^\top\mathbf{X}_S) > 0$, the probabilities out of S sum to 1:

$$\sum_{i\in S} P(S_{-i}|S) = \sum_{i\in S} \frac{1-\mathrm{tr}((\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i\mathbf{x}_i^\top)}{s-d} = \frac{s-\mathrm{tr}((\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{X}_S^\top\mathbf{X}_S)}{s-d} = \frac{s-d}{s-d} = 1.$$

It remains to show the formula for the probability $P(S)$ of all paths ending at node S. If $\det(\mathbf{X}_S^\top\mathbf{X}_S) = 0$, then one edge on any path from the root to S has probability 0. This edge goes from a superset of S with positive volume to a superset of S that has volume 0. Since all paths have probability 0, $P(S) = 0$ in this case.

Now assume $\det(\mathbf{X}_S^\top\mathbf{X}_S) > 0$ and consider any path from the root $\{1..n\}$ to S. There are $(n-s)!$ such paths all going through sets with positive volume. The fractions of determinants in the probabilities along each path telescope and the additional factors accumulate to the same product. So the probability of all paths from the root to S is the same and the total probability into S is

$$\frac{(n-s)!}{(n-d)\dots(s-d+1)}\frac{\det(\mathbf{X}_S^\top\mathbf{X}_S)}{\det(\mathbf{X}^\top\mathbf{X})} = \frac{1}{\binom{n-d}{s-d}}\frac{\det(\mathbf{X}_S^\top\mathbf{X}_S)}{\det(\mathbf{X}^\top\mathbf{X})}. \qquad \blacksquare$$

An immediate consequence of the above sampling procedure is the following composition property of volume sampling, which states that this distribution is closed under subsampling. We also give a direct proof to highlight the combinatorics of volume sampling.

Corollary 3 *For any $\mathbf{X} \in \mathbb{R}^{n\times d}$ and $n \ge t > s \ge d$, the following hierarchical sampling procedure:*

$$T \overset{t}{\sim} \mathbf{X} \qquad \textit{(size } t \textit{ volume sampling from } \mathbf{X}\textit{)},$$
$$S \overset{s}{\sim} \mathbf{X}_T \qquad \textit{(size } s \textit{ volume sampling from } \mathbf{X}_T\textit{)}$$

returns a set S which is distributed according to size s volume sampling from $\mathbf{X}$.

Proof We start with the Law of Total Probability and then use the probability formula for volume sampling from the above theorem. Here $P(T \cap S)$ means the probability of all paths going through node T at level t and ending up at the final node S at level s. If $S \not\subseteq T$, then $P(T \cap S) = 0$.

$$\begin{aligned} P(S) &= \sum_{T:\, S\subseteq T} \overbrace{P(S\,|\,T)\qquad P(T)}^{P(T\cap S)} \\ &= \sum_{T:\, S\subseteq T} \frac{\det(\mathbf{X}_S^\top\mathbf{X}_S)}{\binom{t-d}{s-d}\cancel{\det(\mathbf{X}_T^\top\mathbf{X}_T)}} \quad \frac{\cancel{\det(\mathbf{X}_T^\top\mathbf{X}_T)}}{\binom{n-d}{t-d}\det(\mathbf{X}^\top\mathbf{X})} \\ &= \binom{n-s}{t-s}\frac{\det(\mathbf{X}_S^\top\mathbf{X}_S)}{\binom{t-d}{s-d}\binom{n-d}{t-d}\det(\mathbf{X}^\top\mathbf{X})} = \frac{\det(\mathbf{X}_S^\top\mathbf{X}_S)}{\binom{n-d}{s-d}\det(\mathbf{X}^\top\mathbf{X})}. \end{aligned}$$

Note that for all sets T containing S, the probability $P(T \cap S)$ is the same, and there are $\binom{n-s}{t-s}$ such sets. $\blacksquare$

The main competitor of volume sampling is i.i.d. sampling of the rows of $\mathbf{X}$ w.r.t. the statistical leverage scores. For an input matrix $\mathbf{X} \in \mathbb{R}^{n\times d}$, the leverage score of the i-th row $\mathbf{x}_i^\top$ of $\mathbf{X}$ is defined as

$$l_i \overset{def}{=} \mathbf{x}_i^\top(\mathbf{X}^\top\mathbf{X})^{-1}\mathbf{x}_i.$$

Recall that this quantity appeared in the definition of conditional probability $P(S_{-i}|S)$ in Theorem 2, where the leverage score was computed w.r.t. the submatrix $\mathbf{X}_S$. In fact, there is a more basic relationship between leverage scores and volume sampling: If set S is sampled according to size $s = d$ volume sampling, then the leverage score l_i of row i is the marginal probability $P(i \in S)$ of selecting i-th row into S. A general formula for the marginals of size s volume sampling is given in the following proposition:

3. For sample size $s = d$, the rows and columns of $\mathbf{X}_S$ have the same length and $\det(\mathbf{X}_S^\top\mathbf{X}_S)$ is also the squared volume spanned by the rows $\mathbf{X}_S$.

Proposition 4 *Let $\mathbf{X} \in \mathbb{R}^{n\times d}$ be a full rank matrix and $s \in \{d..n\}$. If $S \subseteq \{1..n\}$ is sampled according to size s volume sampling, then for any $i \in \{1..n\}$,*

$$P(i \in S) = \frac{s-d}{n-d} + \frac{n-s}{n-d}\overbrace{\mathbf{x}_i^\top(\mathbf{X}^\top\mathbf{X})^{-1}\mathbf{x}_i}^{l_i}.$$

Proof Instead of $P(i \in S)$ we will first compute $P(i \notin S)$:

$$\begin{aligned}
P(i \notin S) &= \sum_{S:|S|=s, i\notin S} \frac{\det(\mathbf{X}_S^\top\mathbf{X}_S)}{\binom{n-d}{s-d}\det(\mathbf{X}^\top\mathbf{X})} \\
&= \sum_{S:|S|=s, i\notin S} \frac{\sum_{T\subseteq S:|T|=d}\det(\mathbf{X}_T^\top\mathbf{X}_T)}{\binom{n-d}{s-d}\det(\mathbf{X}^\top\mathbf{X})} \\
&= \frac{\overbrace{\sum_{T:|T|=d, i\notin T}\det((\mathbf{X}_{-i})_T^\top(\mathbf{X}_{-i})_T)}^{\det(\mathbf{X}_{-i}^\top\mathbf{X}_{-i})}}{\binom{n-d}{s-d}\det(\mathbf{X}^\top\mathbf{X})}\ \binom{n-d-1}{s-d} \\
&= \frac{n-s}{n-d}\left(1 - \mathbf{x}_i^\top(\mathbf{X}^\top\mathbf{X})^{-1}\mathbf{x}_i\right),
\end{aligned}$$

where we used Cauchy-Binet twice and the fact that every set $T : |T| = d,\ i \notin T$ appears in $\binom{n-d-1}{s-d}$ sets $S : |S| = s,\ i \notin S$. Now, the marginal probability follows from the fact that $P(i \in S) = 1 - P(i \notin S)$. ■

2.2 Expectation Formulas for Volume Sampling

All expectations in the remainder of the paper are w.r.t. volume sampling. We use the short-hand $\mathbb{E}[\mathbf{F}(S)]$ for expectation with volume sampling where the size of the sampled set is fixed to s. The expectation formulas for two choices of $\mathbf{F}(S)$ are proven in Theorems 5 and 6. By Lemma 1 it suffices to show $\mathbf{F}(S) = \sum_{i\in S} P(S_{-i}|S)\mathbf{F}(S_{-i})$ for volume sampling. We also present a related expectation formula (Theorem 7), which is proven later using different techniques.

Recall that $\mathbf{X}_S$ is the submatrix of rows indexed by $S \subseteq \{1..n\}$. We also use a version of $\mathbf{X}$ in which all but the rows of S are zeroed out. This matrix equals $\mathbf{I}_S\mathbf{X}$ where $\mathbf{I}_S$ is an n-dimensional diagonal matrix with $(\mathbf{I}_S)_{ii} = 1$ if $i \in S$ and 0 otherwise (see Figure 2).

Theorem 5 *Let $\mathbf{X} \in \mathbb{R}^{n\times d}$ be a tall full rank matrix (i.e. $n \geq d$). For $s \in \{d..n\}$, let $S \subseteq \{1..n\}$ be a size s volume sampled set over $\mathbf{X}$. Then*

$$\mathbb{E}[(\mathbf{I}_S\mathbf{X})^+] = \mathbf{X}^+.$$

For the special case of $s = d$, this fact was known in the linear algebra literature (Ben-Tal and Teboulle, 1990; Ben-Israel, 1992). It was shown there using elementary properties of the determinant such as Cramer's rule.[4] The proof methodology developed here based on reverse iterative volume sampling is very different. We believe that this fundamental formula lies at the core of why volume sampling is important in many applications. In this work, we focus on its application to linear regression. However, Avron and Boutsidis (2013) discuss many problems where controlling the pseudoinverse of a submatrix is essential. For those applications, it is important to establish variance bounds for the above expectation and volume sampling once again offers very concrete guarantees. We obtain them by showing the following formula, which can be viewed as a second moment for this estimator.

4. Using the composition property of volume sampling (Corollary 3), the $s > d$ case of the theorem can be reduced to the $s = d$ case. However, in this paper we give a different self-contained proof for Theorem 5.

Theorem 6 *Let $\mathbf{X} \in \mathbb{R}^{n\times d}$ be a full rank matrix and $s \in \{d..n\}$. If size s volume sampling over $\mathbf{X}$ has full support, then*

$$\mathbb{E}[\ \underbrace{(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}}_{(\mathbf{I}_S\mathbf{X})^+(\mathbf{I}_S\mathbf{X})^{+\top}}\ ] = \frac{n-d+1}{s-d+1}\underbrace{(\mathbf{X}^\top\mathbf{X})^{-1}}_{\mathbf{X}^+\mathbf{X}^{+\top}}.$$

In the case when volume sampling does not have full support, then the matrix equality "=" above is replaced by the positive-definite inequality "$\preceq$".

The condition that size s volume sampling over $\mathbf{X}$ has full support is equivalent to $\det(\mathbf{X}_S^\top\mathbf{X}_S) > 0$ for all $S \subseteq \{1..n\}$ of size s. Note that if size s volume sampling has full support, then size $t > s$ also has full support. So full support for the smallest size d (often phrased as $\mathbf{X}$ being *in general position*) implies that volume sampling w.r.t. any size $s \geq d$ has full support.

The above theorem immediately gives an expectation formula for the Frobenius norm $\|(\mathbf{I}_S\mathbf{X})^+\|_F$ of the estimator:

$$\mathbb{E}\left[\|(\mathbf{I}_S\mathbf{X})^+\|_F^2\right] = \mathbb{E}[\mathrm{tr}((\mathbf{I}_S\mathbf{X})^+(\mathbf{I}_S\mathbf{X})^{+\top})] = \frac{n-d+1}{s-d+1}\|\mathbf{X}^+\|_F^2. \tag{2}$$

This norm formula was shown by Avron and Boutsidis (2013), with numerous applications. Theorem 6 can be viewed as a much stronger pre-trace version of the known norm formula. Also our proof techniques are quite different and much simpler. Note that if size s volume sampling for $\mathbf{X}$ does not have full support, then (2) becomes an inequality.

We now mention a second application of the above theorem in the context of linear regression for the case when the response vector $\mathbf{y}$ is modeled as a noisy linear transformation, i.e., $\mathbf{y} = \mathbf{X}\widetilde{\mathbf{w}} + \boldsymbol{\xi}$ for some $\widetilde{\mathbf{w}} \in \mathbb{R}^d$ and a random noise vector $\boldsymbol{\xi} \in \mathbb{R}^n$ (detailed discussion in Section 4). In this case the matrix $(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}$ can be interpreted as the covariance matrix of least-squares estimator $\mathbf{w}^*(S)$ (for a fixed set S) and Theorem 6 gives an exact formula for the covariance matrix of $\mathbf{w}^*(S)$ under volume sampling. In Section 4, we give an extended version of this result which provides even stronger guarantees for regularized least-squares estimators under this model (Theorem 16).

Note that except for the above application, all results in this paper hold for arbitrary response vectors $\mathbf{y}$. By combining Theorems 5 and 6, we can also obtain a covariance-type formula[5] for the pseudoinverse matrix estimator:

$$\begin{aligned}
&\mathbb{E}[((\mathbf{I}_S\mathbf{X})^+ - \mathbb{E}[(\mathbf{I}_S\mathbf{X})^+])\ ((\mathbf{I}_S\mathbf{X})^+ - \mathbb{E}[(\mathbf{I}_S\mathbf{X})^+])^\top] \\
&= \mathbb{E}[(\mathbf{I}_S\mathbf{X})^+(\mathbf{I}_S\mathbf{X})^{+\top}] - \mathbb{E}[(\mathbf{I}_S\mathbf{X})^+]\,\mathbb{E}[(\mathbf{I}_S\mathbf{X})^+]^\top \\
&= \frac{n-d+1}{s-d+1}\,\mathbf{X}^+\mathbf{X}^{+\top} - \mathbf{X}^+\mathbf{X}^{+\top} = \frac{n-s}{s-d+1}\,\mathbf{X}^+\mathbf{X}^{+\top}.
\end{aligned} \tag{3}$$

5. This notion of "covariance" is used in random matrix theory, i.e. for a random matrix $\mathbf{M}$, we analyze $\mathbb{E}[(\mathbf{M} - \mathbb{E}[\mathbf{M}])(\mathbf{M} - \mathbb{E}[\mathbf{M}])^\top]$. See for example Tropp (2012).

We now give the background for a third matrix expectation formula for volume sampling. Pseudoinverses can be used to compute the projection matrix onto the span of columns of matrix $\mathbf{X}$, which is defined as follows:

$$\mathbf{P}_{\mathbf{X}} \stackrel{def}{=} \mathbf{X} \overbrace{(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top}^{\mathbf{X}^+}.$$

Applying Theorem 5 leads us immediately to the following unbiased matrix estimator for the projection matrix:

$$\mathbb{E}[\mathbf{X}(\mathbf{I}_S\mathbf{X})^+] = \mathbf{X}\,\mathbb{E}[(\mathbf{I}_S\mathbf{X})^+] = \mathbf{X}\mathbf{X}^+ = \mathbf{P}_{\mathbf{X}}.$$

Note that this matrix estimator $\mathbf{X}(\mathbf{I}_S\mathbf{X})^+$ is closely connected to linear regression: It can be used to transform the response vector $\mathbf{y}$ into the prediction vector $\widehat{\mathbf{y}}(S)$ of subsampled least squares solution $\mathbf{w}^*(S)$ as follows:

$$\widehat{\mathbf{y}}(S) = \mathbf{X} \underbrace{(\mathbf{I}_S\mathbf{X})^+\mathbf{y}}_{\mathbf{w}^*(S)}.$$

In this case, volume sampling once again provides a covariance-type matrix expectation formula.

Theorem 7 *Let $\mathbf{X} \in \mathbb{R}^{n\times d}$ be a full rank matrix. If matrix $\mathbf{X}$ is in general position and $S \subseteq \{1..n\}$ is sampled according to size d volume sampling, then*

$$\mathbb{E}[\underbrace{(\mathbf{X}(\mathbf{I}_S\mathbf{X})^+)^2}_{(\mathbf{I}_S\mathbf{X})^{+\top}\mathbf{X}^\top\mathbf{X}(\mathbf{I}_S\mathbf{X})^+}] - \mathbf{P}_{\mathbf{X}} = d\,(\mathbf{I} - \mathbf{P}_{\mathbf{X}}).$$

If $\mathbf{X}$ is not in general position, then the matrix equality "=" is replaced by the positive-definite inequality "$\preceq$".

Note that this third expectation formula is limited to sample size $s = d$. It is a direct consequence of Theorem 8 given in the next section which relates the expected loss of a subsampled least squares estimator to the loss of the optimum least squares estimator. Unlike the first two formulas given in theorems 5 and 6, its proof does not rely on the methodology of Lemma 1, i.e., on showing that the expectations at all levels of a certain DAG associated with the sampling process are the same. We defer the proof of this third expectation formula to the end of Section 3.3. No extension of this third formula to sample size $s > d$ is known.

Proof of Theorem 5 We apply Lemma 1 with $\mathbf{F}(S) = (\mathbf{I}_S\mathbf{X})^+$. It suffices to show $\mathbf{F}(S) = \sum_{i\in S} P(S_{-i}|S)\mathbf{F}(S_{-i})$ for $P(S_{-i}|S) = \frac{1-\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i}{s-d}$, i.e.:

$$(\mathbf{I}_S\mathbf{X})^+ = \sum_{i\in S} \frac{1-\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i}{s-d} \underbrace{(\mathbf{I}_{S_{-i}}\mathbf{X})^+}_{(\mathbf{X}_{S_{-i}}^\top\mathbf{X}_{S_{-i}})^{-1}(\mathbf{I}_{S_{-i}}\mathbf{X})^\top}.$$

We first apply Sherman-Morrison to $(\mathbf{X}_{S_{-i}}^\top\mathbf{X}_{S_{-i}})^{-1} = (\mathbf{X}_S^\top\mathbf{X}_S - \mathbf{x}_i\mathbf{x}_i^\top)^{-1}$ on the r.h.s. of the above:

$$\sum_i \frac{1-\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i}{s-d} \left((\mathbf{X}_S^\top\mathbf{X}_S)^{-1} + \frac{(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}}{1-\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i}\right)((\mathbf{I}_S\mathbf{X})^\top - \mathbf{x}_i\mathbf{e}_i^\top).$$

Next we expand the last two factors into 4 terms. The expectation of the first $(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}(\mathbf{I}_S\mathbf{X})^\top$ is $(\mathbf{I}_S\mathbf{X})^+$ (which is the l.h.s.) and the expectations of the remaining three terms times $s-d$ sum to 0:

$$-\sum_{i\in S}(1-\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i)\,(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i\mathbf{e}_i^\top + \cancel{(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\sum_{i\in S}\mathbf{x}_i\mathbf{x}_i^\top}(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}(\mathbf{I}_S\mathbf{X})^\top$$
$$-\sum_{i\in S}(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i\,(\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i)\mathbf{e}_i^\top = 0. \quad \blacksquare$$

In Appendix B we give an alternate proof using a derivative argument.

Proof of Theorem 6 Choose $\mathbf{F}(S) = \frac{s-d+1}{n-d+1}(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}$. By Lemma 1 it suffices to show $\mathbf{F}(S) = \sum_{i\in S} P(S_{-i}|S)\mathbf{F}(S_{-i})$ for volume sampling:

$$\frac{\cancel{s-d+1}}{\cancel{n-d+1}}(\mathbf{X}_S^\top\mathbf{X}_S)^{-1} = \sum_{i\in S}\frac{1-\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i}{\cancel{s-d}}\frac{\cancel{s-d}}{\cancel{n-d+1}}(\mathbf{X}_{S_{-i}}^\top\mathbf{X}_{S_{-i}})^{-1}.$$

To show this we apply Sherman-Morrison to $(\mathbf{X}_{S_{-i}}^\top\mathbf{X}_{S_{-i}})^{-1}$ on the r.h.s.:

$$\sum_{i\in S}(1-\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i)\left((\mathbf{X}_S^\top\mathbf{X}_S)^{-1} + \frac{(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}}{1-\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i}\right)$$
$$= (s-d)(\mathbf{X}_S^\top\mathbf{X}_S)^{-1} + \cancel{(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\sum_{i\in S}\mathbf{x}_i\mathbf{x}_i^\top}(\mathbf{X}_S^\top\mathbf{X}_S)^{-1} = (s-d+1)\,(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}.$$

If some denominators $1-\mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S)^{-1}\mathbf{x}_i$ are zero, then we only sum over i for which the denominators are positive. In this case the above matrix equality becomes a positive-definite inequality $\preceq$. $\blacksquare$

3. Linear Regression with Smallest Number of Responses

Our main motivation for studying volume sampling came from asking the following simple question. Suppose we want to solve a d-dimensional linear regression problem with an input matrix $\mathbf{X}$ of n rows in $\mathbb{R}^d$ and a response vector $\mathbf{y} \in \mathbb{R}^n$, i.e. find $\mathbf{w} \in \mathbb{R}^d$ that minimizes the least squares loss $\|\mathbf{X}\mathbf{w} - \mathbf{y}\|^2$ on all n rows. We use $L(\mathbf{w})$ to denote this loss. The optimal weight vector minimizes $L(\mathbf{w})$, i.e.

$$\mathbf{w}^* \stackrel{def}{=} \operatorname*{argmin}_{\mathbf{w}\in\mathbb{R}^d} L(\mathbf{w}) = \mathbf{X}^+\mathbf{y}.$$

Computing it requires access to the input matrix $\mathbf{X}$ and the response vector $\mathbf{y}$. Assume we are given $\mathbf{X}$ but the access to response vector $\mathbf{y}$ is restricted. We are allowed to pick a random subset $S \subseteq \{1..n\}$ of fixed size s for which the responses $\mathbf{y}_S$ for the submatrix $\mathbf{X}_S$ are revealed to us, and then must produce a weight vector $\mathbf{w}(\mathbf{X}, S, \mathbf{y}_S) \in \mathbb{R}^d$ from a subset of row indices S of the input matrix $\mathbf{X}$ and the corresponding responses $\mathbf{y}_S$. Our goal in this paper is to find a distribution on the subsets S of size s and a *weight function* $\mathbf{w}(\mathbf{X}, S, \mathbf{y}_S)$ s.t.[6]

$$\forall\,(\mathbf{X},\mathbf{y}) \in \mathbb{R}^{n\times d}\times\mathbb{R}^{n\times 1}: \quad \mathbb{E}\left[L(\mathbf{w}(\mathbf{X}, S, \mathbf{y}_S))\right] \le (1+c)\,L(\mathbf{w}^*),$$

6. Since the learner is given $\mathbf{X}$, it is natural to define the optimal multiplicative constant specialized for each $\mathbf{X}$: $c_{\mathbf{X},s} = \min_c \min_{P(\cdot),\mathbf{w}(\cdot)} \max_{\mathbf{y}} \mathbb{E}_P\left[L(\mathbf{w}(\mathbf{X}, S, \mathbf{y}_S))\right] \le (1+c)\,L(\mathbf{w}^*)$, where the domain for distribution $P(\cdot)$ and weight function $\mathbf{w}(\cdot)$ are sets of size s. Showing specialized bounds for $c_{\mathbf{X},s}$ is left for future research.

where c must be a fixed constant (that is independent of $\mathbf{X}$ and $\mathbf{y}$). Throughout the paper we use the one argument shorthand $\mathbf{w}(S)$ for the weight function $\mathbf{w}(\mathbf{X}, S, \mathbf{y}_S)$. We assume that attaining response values is expensive and ask the question: What is the smallest number of responses (i.e. smallest size of S) for which such a multiplicative bound is possible? We will use volume sampling to show that attaining d response values is sufficient and show that less than d responses is not.

Before we state our main upper bound based on volume sampling, we make the following key observation: If for the subproblem $(\mathbf{X}_S, \mathbf{y}_S)$ there is a weight vector $\mathbf{w}(S)$ that has loss zero, then the algorithm has to predict with such a consistent weight vector. This is because in that case the responses $\mathbf{y}_S$ can be extended to a response vector $\mathbf{y}$ for all of $\mathbf{X}$ s.t. $L(\mathbf{w}^*) = 0$. Thus since we aim for a multiplicative loss bound, we force the algorithm to predict with the optimum solution $\mathbf{w}^*(S) \stackrel{def}{=} (\mathbf{X}_S)^+ \mathbf{y}_S$ whenever the subproblem $(\mathbf{X}_S, \mathbf{y}_S)$ has loss 0. In particular, when $|S| = d$ and $\mathbf{X}_S$ has full rank, then there is a unique consistent solution $\mathbf{w}^*(S)$ for the subproblem and the learner must use the weight function $\mathbf{w}(S) = \mathbf{w}^*(S)$.

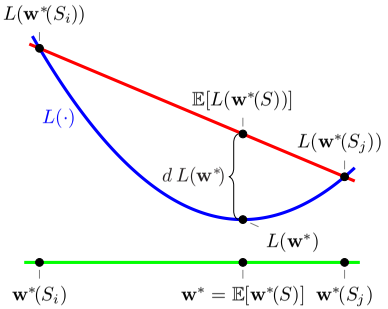

Figure 4: Unbiased estimator $\mathbf{w}^*(S)$ in expectation suffers loss $(d+1)\,L(\mathbf{w}^*)$.

Theorem 8 *If the input matrix $\mathbf{X} \in \mathbb{R}^{n\times d}$ is in general position, then for any response vector $\mathbf{y} \in \mathbb{R}^n$, the expected square loss (on all n rows of $\mathbf{X}$) of the optimal solution $\mathbf{w}^*(S)$ for the subproblem $(\mathbf{X}_S, \mathbf{y}_S)$, with the d-element set S obtained from volume sampling, is given by*

$$\mathbb{E}[L(\mathbf{w}^*(S))] = (d+1)\,L(\mathbf{w}^*).$$

If $\mathbf{X}$ is not in general position, then the expected loss is upper-bounded by $(d+1)\,L(\mathbf{w}^*)$.

There are no range restrictions on the n points and response values in this bound. Also, as discussed in the introduction, this bound is already non-obvious for dimension 1, when the multiplicative factor is 2 (See Figure 1 for a visualization). Note that if there is a bias term in dimension 1, then the factor becomes 3.

In dimension d, it is instructive to look at the case when the square loss of the optimum solution is zero, i.e. there is a weight vector $\mathbf{w}^* \in \mathbb{R}^d$ s.t. $\mathbf{X}\mathbf{w}^* = \mathbf{y}$. In this case the response values of any d linearly independent rows of $\mathbf{X}$ determine the optimum solution and the multiplicative loss formula of the theorem clearly holds. The formula specifies how noise-free case generalizes gracefully to the noisy case in that for volume sampling, the expected square loss of the solution obtained from d row response pairs is always by a factor of at most $d+1$ larger than the square loss of the optimum solution. Moreover, since $\mathbb{E}[\mathbf{w}^*(S)] = \mathbf{w}^*$ and the loss function $L(\cdot)$ is convex, we have by Jensen's inequality that

$$\mathbb{E}\big[L(\mathbf{w}^*(S))\big] \geq L\big(\mathbb{E}[\mathbf{w}^*(S)]\big) = L(\mathbf{w}^*).$$

The above theorem now states that the gap $\mathbb{E}[L(\mathbf{w}^*(S))] - L(\mathbf{w}^*)$ in Jensen's inequality (which coincides with the "regret" of the estimator) equals $d\,L(\mathbf{w}^*)$, when the expectation is w.r.t. size d volume sampling and $\mathbf{X}$ is in general position (See Figure 4 for a schematic). As we will show in Section 3.4, this gap also equals the variance $\mathbb{E}[\|\mathbf{X}\mathbf{w}^*(S) - \mathbf{X}\mathbf{w}^*\|^2]$ of the predictions since the estimator is unbiased. In summary:

$$\underbrace{\mathbb{E}\big[L(\mathbf{w}^*(S))\big] - L(\overbrace{\mathbf{w}^*}^{\mathbb{E}[\mathbf{w}^*(S)]})}_{\text{regret}} = \underbrace{d\,L(\mathbf{w}^*)}_{\text{gap in Jensen's}} = \underbrace{\mathbb{E}\big[\|\mathbf{X}\mathbf{w}^*(S) - \mathbf{X}\mathbf{w}^*\|^2\big]}_{\text{variance}}.$$

We now make a number of observations and present some lower bounds that highlight the upper bound of the above theorem. Then, in Section 3.3 we prove the theorem and a matrix expectation formula implied by it.

3.1 When X is not in General Position

The above theorem gives an equality for the expected loss of a volume-sampled solution. However, this equality is only guaranteed to hold when matrix $\mathbf{X}$ is in general position. We give a minimal example problem where the matrix $\mathbf{X}$ is not in general position and the equality of Theorem 8 turns into a strict inequality. This shows that for the equality, the general position assumption is necessary. If we apply even an infinitesimal additive perturbation to the matrix $\mathbf{X}$ of the example problem, then the resulting matrix $\mathbf{X}_\epsilon$ is in general position and the equality holds. Note that even though the optimum loss $L(\mathbf{w}^*)$ does not change significantly under such a perturbation, the expected sampling loss $\mathbb{E}[L(\mathbf{w}^*(S))]$ has to jump sufficiently to close the gap in the inequality. In our minimal example problem, $n = 3$ and $d = 2$, and

$$\mathbf{X} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \\ 1 & 0 \end{pmatrix}, \quad \mathbf{y} = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}.$$

We have three 2-element subsets to sample from: $S_1 = \{1,2\},\ S_2 = \{2,3\},\ S_3 = \{1,3\}$. Notice that the first two rows of $\mathbf{X}$ are identical, which means that the probability of sampling set S_1 is 0 in the volume sampling process. The other two subsets, S_2 and S_3, form identical submatrices $\mathbf{X}_{S_2} = \mathbf{X}_{S_3}$. Therefore they are equally probable. The optimal weight vectors for these sets are $\mathbf{w}^*(S_2) = (0,0)^\top$ and $\mathbf{w}^*(S_3) = (0,1)^\top$. Also $\mathbf{w}^* = (0, \frac{1}{2})^\top$ and the expected loss is bounded as:

$$\mathbb{E}[L(\mathbf{w}^*(S))] = \underbrace{\frac{1}{2}\overbrace{L(\mathbf{w}^*(S_2))}^{1} + \frac{1}{2}\overbrace{L(\mathbf{w}^*(S_3))}^{1}}_{1} \ < \ \underbrace{\overbrace{(d+1)}^{3}\overbrace{L(\mathbf{w}^*)}^{1/2}}_{3/2}.$$

Now consider a slightly perturbed input matrix

$$\mathbf{X}_\epsilon = \begin{pmatrix} 1 & 1+\epsilon \\ 1 & 1 \\ 1 & 0 \end{pmatrix},$$

where $\epsilon > 0$ is arbitrarily small (We keep the response vector $\mathbf{y}$ the same). Now, there is no $d \times d$ submatrix that is singular, so the upper bound from Theorem 8 must be tight. The reason is that even though subset S_1 still has very small probability, its loss is very large, so the expectation is significantly affected by this component, no matter how small ϵ is. We see this directly in the calculations. Let $\mathbf{w}^*$ and $\mathbf{w}^*(S_i)$ be the corresponding solutions for the perturbed problem and its subproblems. The volumes of the subproblems and their losses are:

$$\begin{array}{ll} \det(\mathbf{X}_{S_1}^\top \mathbf{X}_{S_1}) = \epsilon^2 & L(\mathbf{w}^*(S_1)) = \epsilon^{-2} \\ \det(\mathbf{X}_{S_2}^\top \mathbf{X}_{S_2}) = 1 & L(\mathbf{w}^*(S_2)) = 1 \\ \det(\mathbf{X}_{S_3}^\top \mathbf{X}_{S_3}) = (1+\epsilon)^2 & L(\mathbf{w}^*(S_3)) = (1+\epsilon)^{-2} \end{array} \qquad L(\mathbf{w}^*) = \frac{1}{2(1+\epsilon+\epsilon^2)}.$$

Note that for each subproblem, the product of volume times loss is equal to 1. Now the expected loss can be easily computed, and we can see that the gap in the bound disappears (the denominator is the normalizing constant for volume sampling):

$$\mathbb{E}[L(\mathbf{w}^*(S))] = \frac{1+1+1}{\epsilon^2+1+(1+\epsilon)^2} = (d+1)\ L(\mathbf{w}^*).$$

3.2 Lower Bounds and the Importance of Joint Sampling

The factor $d+1$ in Theorem 8 cannot, in general, be improved when selecting only d responses:

Proposition 9 *For any d, there exists a least squares problem $(\mathbf{X}, \mathbf{y})$ with $d+1$ rows in $\mathbb{R}^d$ such that for every d-element index set $S \subseteq \{1\,..\,d+1\}$, we have*

$$L(\mathbf{w}^*(S)) = (d+1)\ L(\mathbf{w}^*).$$

Proof Choose the input vectors $\mathbf{x}_i$ (and rows $\mathbf{x}_i^\top$) as the $d+1$ corners of any simplex in $\mathbb{R}^d$ centered at the origin and choose all $d+1$ responses as the same non-zero value α. For any α, the optimal solution $\mathbf{w}^*$ will be the all-zeros vector with loss

$$L(\mathbf{w}^*) = (d+1)\ \alpha^2.$$

On the other hand, taking any size d subset of indices $S \subseteq \{1\,..\,d+1\}$, the subproblem solution $\mathbf{w}^*(S)$ will only produce loss on the left out input vector $\mathbf{x}_i$, indexed with $i \notin S$. To obtain the prediction on x_i, we use a simple geometric argument. Observe that since the simplex is centered, we can write the origin of $\mathbb{R}^d$ in terms of the corners of the simplex as

$$\mathbf{0} = \sum_k \mathbf{x}_k = \mathbf{x}_i + d\,\bar{\mathbf{x}}_{-i}, \qquad \text{where } \bar{\mathbf{x}}_{-i} \stackrel{def}{=} \frac{1}{d}\sum_{k\neq i} \mathbf{x}_k.$$

Thus, the left out input vector $\mathbf{x}_i$ equals $-d\,\bar{\mathbf{x}}_{-i}$. The prediction of $\mathbf{w}^*(S)$ on this vector is

$$\widehat{y}_i = \mathbf{x}_i^\top \mathbf{w}^*(S) = -d\left(\frac{1}{d}\sum_{k\neq i} \mathbf{x}_k^\top\right)\mathbf{w}^*(S) = -\sum_{k\neq i} \mathbf{x}_k^\top \mathbf{w}^*(S) = -d\alpha.$$

It follows that the loss of $\mathbf{w}^*(S)$ equals

$$L(\mathbf{w}^*(S)) = (\widehat{y}_i - y_i)^2 = (-d\alpha - \alpha)^2 = (d+1)^2\alpha^2 = (d+1)\,L(\mathbf{w}^*). \qquad \blacksquare$$

Moreover, it is easy to show that no *deterministic* algorithm for selecting d rows (without knowing the responses) can guarantee a multiplicative loss bound with a factor less than n/d (Boutsidis et al., 2013). For the sake of completeness, we show this here for $d = 1$:

Proposition 10 *For any $n \times 1$ input matrix $\mathbf{X}$ of all 1's and any deterministic algorithm that chooses some singleton set $S = \{i\}$, there is a response vector $\mathbf{y}$ for which the loss of the subproblem and the optimal loss are related as follows:*

$$L(\mathbf{w}^*(S)) = n\,L(\mathbf{w}^*).$$

Proof If the response vector $\mathbf{y}$ is the vector of n 1's except for a single 0 at index i, then we have

$$\underbrace{L(\overbrace{\mathbf{w}^*(\{i\})}^{0})}_{n-1} = n\ \underbrace{L(\overbrace{\mathbf{w}^*}^{\frac{n-1}{n}})}_{\frac{n-1}{n}}. \qquad \blacksquare$$

Note that for the 1-dimensional example used in the proof, volume sampling would pick the set S uniformly. For this distribution, the multiplicative factor drops from n down to 2, that is $\mathbb{E}[L(\mathbf{w}^*(S))] = \frac{1}{n}(n-1) + \frac{n-1}{n}1 = 2\ L(\mathbf{w}^*)$.

The importance of joint sampling. Three properties of volume sampling play a crucial role in achieving a multiplicative loss bound:

a) *Randomness.* No deterministic algorithm guarantees such a bound (see Proposition 10).

b) *The chosen submatrices must have full rank.* Choosing any rank deficient submatrix with positive probability, does not allow for a multiplicative bound (see Propositions 11 and 12).

c) *Jointness.* No i.i.d. sampling procedure can achieve a multiplicative loss bound with $O(d)$ responses (see Corollary 13).

By jointly selecting subset S, volume sampling ensures that the corresponding input vectors $\mathbf{x}_i$ are well spread out in the input space $\mathbb{R}^d$. In particular, volume sampling does not put any probability mass on sets S such that the rank of submatrix $\mathbf{X}_S$ is less than d. Intuitively, selecting rank deficient row subsets should not be effective, since such a choice leads to an under-determined least squares problem. We make this simple statement more precise by showing that any randomized algorithm, that with positive probability selects a rank deficient row subset, cannot achieve a multiplicative loss bound. Intuitively if the algorithm picks a rank deficient subset then it is not clear how it should select the weight vector $\mathbf{w}(S)$ given input matrix $\mathbf{X}$, subset S and responses $\mathbf{y}_S$. We reasoned before that $\mathbf{w}(S)$ must have loss 0 on the subproblem $(\mathbf{X}_S, \mathbf{y}_S)$. However if $\mathrm{rank}(\mathbf{X}_S) < d$, then the choice of the weight vector $\mathbf{w}(S)$ with loss 0 is not unique and this causes positive loss for some response vector $\mathbf{y}$.

Proposition 11 *If for any input matrix $\mathbf{X}$, the algorithm samples a rank deficient subset S of rows with positive probability, then the expected loss of the algorithm cannot be bounded by a constant times the optimum loss for all response vectors $\mathbf{y}$.*

Note that this means in particular that if $\mathbf{X}$ has rank d, then sampling $d-1$ size subsets with positive probability does not allow for a constant factor approximation.

Proof Let S be a rank deficient subset chosen with probability $P(S) > 0$. Since in our setup the bound has to hold for all response vectors $\mathbf{y}$ we can imagine an adversary choosing a worst-case $\mathbf{y}$. This adversary gives all rows of $\mathbf{X}_S$ the response value zero. Let $\mathbf{w}(S)$ be the plane produced by the algorithm when choosing S and receiving the responses 0 for $\mathbf{X}_S$. Let $i \in \{1..n\}$ s.t. $\mathbf{x}_i^\top \notin$ row-span$(\mathbf{X}_S)$ and let $\mathbf{w}^*$ be any weight vector that gives response value 0 to all rows of $\mathbf{X}_S$ and response value $\mathbf{x}_i^\top \mathbf{w}(S) + Y$ to $\mathbf{x}_i$. The adversary chooses $\mathbf{y}$ as $\mathbf{X}\mathbf{w}^*$, i.e. it gives all points $\mathbf{x}_j$ not indexed by S and different from $\mathbf{x}_i$ the response values $\mathbf{x}_j^\top \mathbf{w}^*$ as well. Now $\mathbf{w}^*$ has total loss 0 but $\mathbf{w}(S)$ has loss Y^2 on $\mathbf{x}_i$ and the algorithm's expected total loss is $\geq P(S)\,Y^2$. $\blacksquare$

We now strengthen the above proposition in that whenever the sample S is rank deficient then the loss of the optimum is zero while the loss of the algorithm is positive. However note that this proposition is weaker than the above in that it only holds for specific input matrices.

Proposition 12 *Let $d \leq n$ and let $\mathbf{X}$ be any input matrix of rank d consisting of n standard basis row vectors in $\mathbb{R}^d$. Then for any randomized learning algorithm that with probability p selects a subset S s.t. $\mathrm{rank}(\mathbf{X}_S) < d$ and any weight function $\mathbf{w}(\cdot)$, there is a response vector $\mathbf{y}$, satisfying:*

$$L(\mathbf{w}^*) = 0, \quad \textit{and} \quad L(\mathbf{w}(S)) > 0 \quad \textit{with probability at least } p.$$

Proof Let $Q = \{1, 2, \ldots, 2^n\}$. The adversarial response vector $\mathbf{y}$ is constructed by carefully selecting one of the weight vectors $\mathbf{w}^* \in Q^d$, and setting the response vector $\mathbf{y}$ to $\mathbf{X}\mathbf{w}^*$. This ensures that $L(\mathbf{w}^*) = 0$ and since $\mathbf{X}$ consists of standard basis row vectors, the components of $\mathbf{y}$ lie in Q as well. Note that if the learner does not discover $\mathbf{w}^*$ exactly, it will incur positive loss. Let $\mathcal{H}$ be the set of all rank deficient sets in $\mathbf{X}$, i.e. those that lack at least one of the standard basis vectors:

$$\mathcal{H} = \{S \subseteq \{1..n\} \ : \ \mathrm{rank}(\mathbf{X}_S) < d\}.$$

Suppose that given matrix $\mathbf{X}$, the learner uses weight function $\mathbf{w}(S, \mathbf{y}_S)$. (Note that for the sake of concreteness we stopped using the single argument shorthand for the weight function during this proof.) We will count the number of possible inputs to this function, when S is a rank deficient index set of the rows of $\mathbf{X}$ and the response vector $\mathbf{y}_S$ is consistent with some $\mathbf{w}^* \in Q^d$. For any fixed rank deficient set S, let t be the number of distinct basis vectors appearing in $\mathbf{X}_S$. Clearly $t \leq d-1$. Fix a subset $T \subseteq S$ of size t s.t. $\mathbf{X}_T$ contains all t basis vectors of $\mathbf{X}_S$ exactly once (Thus the basis vectors in $\mathbf{X}_{S\setminus T}$ are all duplicates). Since $\mathbf{y} \in Q^n$, the components of $\mathbf{y}_S$ also lie in Q and $\mathbf{y}_S$ is determined by the responses of $\mathbf{y}_T$. Clearly there are at most $|Q|^{d-1}$ choices for $\mathbf{y}_T$. It follows that the number of possible input pairs $(S, \mathbf{y}_S)$ for function $\mathbf{w}(\cdot,\cdot)$ under the above restrictions can be bounded as

$$\left|\left\{(S, \mathbf{y}_S) \ : \ [S \in \mathcal{H}] \text{ and } [\mathbf{y}_S = \mathbf{X}_S\mathbf{w}^* \text{ for } \mathbf{w}^* \in Q^d]\right\}\right| \leq \underbrace{|\mathcal{H}|}_{<2^n} \underbrace{\max_{S\in\mathcal{H}} |\{\mathbf{X}_S\mathbf{w}^* \ : \ \mathbf{w}^* \in Q^d\}|}_{\leq |Q|^{d-1}}$$
$$< 2^n |Q|^{d-1} = |Q^d|.$$

So for every weight function $\mathbf{w}(\cdot,\cdot)$, there exists $\mathbf{w}^* \in Q^d$ that is not present in the set $\{\mathbf{w}(S, \mathbf{y}_S) : S \in \mathcal{H}\}$. Selecting $\mathbf{y} = \mathbf{X}\mathbf{w}^*$ for the adversarial response vector, we guarantee that the learner picks the wrong solution for every rank deficient set S and therefore receives positive loss w.p. at least p. ■

Using Proposition 12, we show that any i.i.d. row sampling distribution (like for example leverage score sampling) requires $\Omega(d \log d)$ samples to get any multiplicative loss bound, either with high probability or in expectation.

Corollary 13 *Let $d \leq n$ and let $\mathbf{X}$ be any input matrix of rank d consisting of n standard basis row vectors in $\mathbb{R}^d$. Then for any randomized learning algorithm which selects a random multiset $S \subseteq \{1..n\}$ of size $|S| \leq (d-1)\ln(d)$ via i.i.d. sampling from any distribution and uses any weight function $\mathbf{w}(S)$, there is a response vector $\mathbf{y}$ satisfying:*

$$L(\mathbf{w}^*) = 0, \quad \textit{and} \quad L(\mathbf{w}(S)) > 0 \quad \textit{with probability at least } 1/2.$$

Proof Any i.i.d. sample of size at most $(d-1)\ln(d)$ with probability at least $1/2$ does not contain all of the unique standard basis vectors (Coupon Collector Problem[7]). Thus, with probability at least $1/2$ submatrix $\mathbf{X}_S$ has rank less than d. Now, for any such algorithm we can use Proposition 12 to select a consistent adversarial response vector $\mathbf{y}$ such that with probability at least $1/2$ the loss $L(\mathbf{w}(S))$ is positive. ■

Note that the corollary requires $\mathbf{X}$ to be of a restricted form that contains a lot of duplicate rows. It is open whether this corollary still holds when $\mathbf{X}$ is an arbitrary full rank matrix.

3.3 Proof of the Loss Expectation Formula

First, we discuss several key connections between linear regression and volume, which are used in the proof. Note that the loss $L(\mathbf{w}^*)$ suffered by the optimum weight vector can be written as $\|\widehat{\mathbf{y}} - \mathbf{y}\|^2$, the squared Euclidean distance between prediction vector $\widehat{\mathbf{y}} = \mathbf{X}\mathbf{w}^*$ and the response vector $\mathbf{y}$. Since $\widehat{\mathbf{y}}$ is minimizing the distance from $\mathbf{y}$ to the subspace of $\mathbb{R}^n$ spanning the feature vectors $\{\mathbf{f}_1, \ldots, \mathbf{f}_d\}$ (columns of $\mathbf{X}$), it has to be the *projection* of $\mathbf{y}$ onto that subspace (see Figure 5). We denote this projection as $\mathbf{P}_\mathbf{X}\,\mathbf{y}$, as defined in Section 2.2. Note that $\mathbf{P}_\mathbf{X}$ is a linear mapping from $\mathbb{R}^n$ onto the column span of the matrix $\mathbf{X}$ such that

$$\text{for } \mathbf{u} \in \mathrm{span}(\mathbf{X}) \quad \mathbf{u} = \mathbf{P}_\mathbf{X}\,\mathbf{y} \ \Leftrightarrow \ \mathbf{P}_\mathbf{X}\,(\mathbf{u} - \mathbf{y}) = \mathbf{0} \ \Leftrightarrow \ \mathbf{X}^\top(\mathbf{u} - \mathbf{y}) = \mathbf{0}. \tag{4}$$

We next give a second geometric interpretation of the length $\|\widehat{\mathbf{y}} - \mathbf{y}\|^2$. Let $\mathcal{P}$ be the parallelepiped formed by the d column/feature vectors of the input matrix $\mathbf{X}$. Furthermore, consider the extended input matrix produced by adding the response vector $\mathbf{y}$ to $\mathbf{X}$ as an extra column:

$$\widetilde{\mathbf{X}} \stackrel{def}{=} (\mathbf{X}, \mathbf{y}) \in \mathbb{R}^{n\times(d+1)}. \tag{5}$$

Using the "base × height" formula we can relate the volume of $\mathcal{P}$ to the volume of $\widetilde{\mathcal{P}}$, the parallelepiped formed by the $d+1$ columns of $\widetilde{\mathbf{X}}$. Observe that $\widetilde{\mathcal{P}}$ has $\mathcal{P}$ as one of its faces, with the response vector $\mathbf{y}$ representing the edge that protrudes from that face. Hence the volume of $\widetilde{\mathcal{P}}$ is the product of the volume of $\mathcal{P}$ and the distance between $\mathbf{y}$ and $\mathrm{span}(\mathbf{X})$. This distance equals $\|\widehat{\mathbf{y}} - \mathbf{y}\|$, since as discussed above, $\widehat{\mathbf{y}}$ is the projection of $\mathbf{y}$ onto $\mathrm{span}(\mathbf{X})$. Thus we have

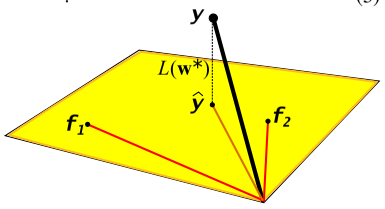

Figure 5: Prediction vector $\widehat{\mathbf{y}}$ is a projection of $\mathbf{y}$ onto the span of feature vectors $\mathbf{f}_i$.

$$\det(\widetilde{\mathbf{X}}^\top\widetilde{\mathbf{X}}) = \det(\mathbf{X}^\top\mathbf{X})\, L(\mathbf{w}^*). \tag{6}$$

Next, we present a proposition whose corollary is key to proving Theorem 8. Suppose that we select one test row from the input matrix and use the remaining $n-1$ row response pairs as the training set. The proposition relates the loss of the obtained solution on the test row to the total leave-one-out loss an all rows.

Proposition 14 *For any index $i \in \{1..n\}$, let $\mathbf{w}^*(-i)$ be the solution to the reduced linear regression problem $(\mathbf{X}_{-i}, \mathbf{y}_{-i})$. Then*

7. This was proven for uniform sampling in Theorem 1.24 of Auger and Doerr (2011). It can be shown that uniform sampling is the best case for Coupon Collector Problem (Holst, 2001), so the bound holds for any i.i.d. sampling.

$$L(\mathbf{w}^*(-i)) - L(\mathbf{w}^*) = \overbrace{\mathbf{x}_i^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_i}^{\frac{\det(\mathbf{X}^\top \mathbf{X}) - \det(\mathbf{X}_{-i}^\top \mathbf{X}_{-i})}{\det(\mathbf{X}^\top \mathbf{X})}} \quad \ell_i(\mathbf{w}^*(-i)),$$

where $\ell_i(\mathbf{w}) \stackrel{def}{=} (\mathbf{x}_i^\top \mathbf{w} - y_i)^2$ *is the square loss of* $\mathbf{w}$ *on the* i*-th point.*

An algebraic proof of this proposition essentially appears in the proof of Theorem 11.7 in Cesa-Bianchi and Lugosi (2006). For the sake of completeness we give a new geometric proof of this proposition in Appendix C using basic properties of volume, thus stressing the connection to volume sampling.

Note that if matrix $\mathbf{X}$ has exactly $n = d + 1$ rows and the training matrix $\mathbf{X}_{-i}$ is full rank, then $\mathbf{w}^*(-i)$ has loss zero on all training rows. In this case we obtain a simpler relationship than the proposition.

Corollary 15 *If* $\mathbf{X}$ *has* $d + 1$ *rows and* $\operatorname{rank}(\mathbf{X}_{-i}) = d$*, then defining* $\widetilde{\mathbf{X}}$ *as in (5), we have*

$$\det(\widetilde{\mathbf{X}}^\top \widetilde{\mathbf{X}}) = \det(\mathbf{X}_{-i}^\top \mathbf{X}_{-i})\ \ell_i(\mathbf{w}^*(-i)).$$

Proof By Proposition 14 and the fact that $L(\mathbf{w}^*(-i)) = \ell_i(\mathbf{w}^*(-i))$, we have

$$\det(\mathbf{X}^\top \mathbf{X})\ L(\mathbf{w}^*) = \det(\mathbf{X}_{-i}^\top \mathbf{X}_{-i})\ \ell_i(\mathbf{w}^*(-i)).$$

The corollary now follows from the "base $\times$ height" formula for volume. ■

We are now ready to present the proof of Theorem 8. Recall that our goal is to find the expected loss $\mathbb{E}[L(\mathbf{w}^*(S))]$, where S is a size d volume sampled set.

Proof of Theorem 8 First, we rewrite the expectation as follows:

$$\begin{aligned}\mathbb{E}[L(\mathbf{w}^*(S))] &= \sum_{S,|S|=d} P(S) L(\mathbf{w}^*(S)) = \sum_{S,|S|=d} P(S) \sum_{j=1}^{n} \ell_j(\mathbf{w}^*(S)) \\ &= \sum_{S,|S|=d} \sum_{j \notin S} P(S)\ \ell_j(\mathbf{w}^*(S)) = \sum_{T,|T|=d+1} \sum_{j \in T} P(T_{-j})\ \ell_j(\mathbf{w}^*(T_{-j})). \qquad (7)\end{aligned}$$

We now use Corollary 15 on the matrix $\mathbf{X}_T$ and test row $\mathbf{x}_j^\top$ (assuming $\operatorname{rank}(\mathbf{X}_{T_{-j}}) = d$):

$$P(T_{-j})\ \ell_j(\mathbf{w}^*(T_{-j})) = \frac{\det(\mathbf{X}_{T_{-j}}^\top \mathbf{X}_{T_{-j}})}{\det(\mathbf{X}^\top \mathbf{X})}\ \ell_j(\mathbf{w}^*(T_{-j})) = \frac{\det(\widetilde{\mathbf{X}}_T^\top \widetilde{\mathbf{X}}_T)}{\det(\mathbf{X}^\top \mathbf{X})}. \qquad (8)$$

Since the summand does not depend on the index $j \in T$, the inner summation in (7) becomes a multiplication by $d + 1$. This lets us write the expected loss as:

$$\mathbb{E}[L(\mathbf{w}^*(S))] = \frac{d+1}{\det(\mathbf{X}^\top \mathbf{X})} \sum_{T,|T|=d+1} \det(\widetilde{\mathbf{X}}_T^\top \widetilde{\mathbf{X}}_T) \stackrel{(1)}{=} (d+1) \frac{\det(\widetilde{\mathbf{X}}^\top \widetilde{\mathbf{X}})}{\det(\mathbf{X}^\top \mathbf{X})} \stackrel{(2)}{=} (d+1)\, L(\mathbf{w}^*), \qquad (9)$$

where (1) follows from the Cauchy-Binet formula and (2) is an application of the "base $\times$ height" formula. If $\mathbf{X}$ is not in general position, then for some summands in (8), $\operatorname{rank}(\mathbf{X}_{T_{-j}}) < d$ and $P(T_{-j}) = 0$. Thus the left-hand side of (8) is 0, while the right-hand side is non-negative, so (9) becomes an inequality, completing the proof of Theorem 8. ■

Lifting expectations to matrix form. We can now show the matrix expectation formula of Theorem 7 as a corollary to the loss expectation formula of Theorem 8. The key observation is that the loss formula holds for arbitrary response vector $\mathbf{y}$, which allows us to "lift" it to the matrix form.

Proof of Theorem 7 Note, that the loss of least squares estimator can be written in terms of the projection matrix $\mathbf{P}_\mathbf{X}$:

$$L(\mathbf{w}^*) = \|\mathbf{y} - \widehat{\mathbf{y}}\|^2 = \|(\mathbf{I} - \mathbf{P}_\mathbf{X})\mathbf{y}\|^2 = \mathbf{y}^\top (\mathbf{I} - \mathbf{P}_\mathbf{X})^2 \mathbf{y} \stackrel{(*)}{=} \mathbf{y}^\top (\mathbf{I} - \mathbf{P}_\mathbf{X})\, \mathbf{y},$$

where in $(*)$ we used the following property of a projection matrix: $\mathbf{P}_\mathbf{X}^2 = \mathbf{P}_\mathbf{X}$. Writing the loss expectation of the subsampled estimator in the same form, we obtain:

$$\begin{aligned}\mathbb{E}[L(\mathbf{w}^*(S))] &= \mathbb{E}[\|\mathbf{y} - \widehat{\mathbf{y}}(S)\|^2] = \mathbb{E}[\|(\mathbf{I} - \mathbf{X}(\mathbf{I}_S\mathbf{X})^+)\mathbf{y}\|^2] \\ &= \mathbb{E}[\mathbf{y}^\top (\mathbf{I} - \mathbf{X}(\mathbf{I}_S\mathbf{X})^+)^2\, \mathbf{y}] = \mathbf{y}^\top \mathbb{E}[(\mathbf{I} - \mathbf{X}(\mathbf{I}_S\mathbf{X})^+)^2]\, \mathbf{y}.\end{aligned}$$

Crucially, we are able to extract the response vector $\mathbf{y}$ out of the expectation formula, which allows us to write the formula from Theorem 8 as follows:

$$\mathbf{y}^\top\, \mathbb{E}[(\mathbf{I} - \mathbf{X}(\mathbf{I}_S\mathbf{X})^+)^2]\, \mathbf{y} = \mathbf{y}^\top (d+1)(\mathbf{I} - \mathbf{P}_\mathbf{X})\, \mathbf{y}, \quad \forall \mathbf{y} \in \mathbb{R}^n.$$

We now use the following elementary fact: If for two symmetric matrices $\mathbf{A}$ and $\mathbf{B}$, we have $\mathbf{y}^\top \mathbf{A}\mathbf{y} = \mathbf{y}^\top \mathbf{B}\mathbf{y},\ \forall \mathbf{y} \in \mathbb{R}^n$, then $\mathbf{A} = \mathbf{B}$.[8] This gives the matrix expectation formula:

$$\mathbb{E}[(\mathbf{I} - \mathbf{X}(\mathbf{I}_S\mathbf{X})^+)^2] = (d+1)(\mathbf{I} - \mathbf{P}_\mathbf{X}).$$

Expanding square on the l.h.s. of the above and applying Theorem 5, we obtain the covariance-type equivalent form stated in Theorem 7:

$$\begin{aligned}&\mathbf{I} - 2\overbrace{\mathbb{E}[\mathbf{X}(\mathbf{I}_S\mathbf{X})^+]}^{\mathbf{P}_\mathbf{X}} + \mathbb{E}[(\mathbf{X}(\mathbf{I}_S\mathbf{X})^+)^2] = (d+1)(\mathbf{I} - \mathbf{P}_\mathbf{X}) \\ \iff\quad &\mathbb{E}[(\mathbf{X}(\mathbf{I}_S\mathbf{X})^+)^2] - \mathbf{P}_\mathbf{X} = d\,(\mathbf{I} - \mathbf{P}_\mathbf{X}).\end{aligned}$$

■

3.4 Averaging Unbiased Estimators and the Open Problem for Worst-case Responses

As discussed at the beginning of Section 3, our goal is to find a way to sample a small index set S and construct a weight function $\mathbf{w}(S)$ which uses responses $\mathbf{y}_S$ so that $\mathbb{E}[L(\mathbf{w}(S))] \leq (1 + c)\ L(\mathbf{w}^*)$, where the multiplicative factor $1 + c$ is bounded for all input matrices $\mathbf{X}$ and all response vectors $\mathbf{y}$. Recall that $L(\cdot)$ denotes the square loss on all rows and $\mathbf{w}^*$ is the optimal solution based on all responses. We show in the previous subsections that the smallest size of S for which this goal can be achieved is d (There is no sampling procedure for sets of size less than d and weight function $\mathbf{w}(S)$ for which this factor is finite). We also prove that when sets S of size d are drawn proportional to

8. Similarly, if $\mathbf{y}^\top \mathbf{A}\mathbf{y} \leq \mathbf{y}^\top \mathbf{B}\mathbf{y},\ \forall \mathbf{y} \in \mathbb{R}^n$, then the positive-definite inequality $\mathbf{A} \preceq \mathbf{B}$ holds for the matrices.

the squared volume of $\mathbf{X}_S$ (i.e. $\det(\mathbf{X}_S^\top \mathbf{X}_S)$), then $\mathbb{E}[L(\mathbf{w}^*(S))] \leq (d+1)L(\mathbf{w}^*)$, where the factor $d+1$ is optimal for some $\mathbf{X}$ and $\mathbf{y}$. Here $\mathbf{w}^*(S)$ denotes the linear least squares solution for the subproblem $(\mathbf{X}_S, \mathbf{y}_S)$.

A natural more general goal is to get arbitrarily close to the optimum loss. That is, for any ϵ, what is the smallest sample size $|S| = s$ for which there is a sampling distribution over subsets S and a weight function $\mathbf{w}(S)$ built from $\mathbf{X}$ and $\mathbf{y}_S$, such that $\mathbb{E}[L(\mathbf{w}(S))] \leq (1+\epsilon)\, L(\mathbf{w}^*)$. A related bound for i.i.d. leverage score sampling states that a sample size of $O(d \log d + \frac{d}{\epsilon})$ suffices to achieve a $1+\epsilon$ factor *with high probability* (Hsu, 2017; Dereziński, 2018), however this does not imply multiplicative bounds *in expectation*.[9]

We conjecture that some form of volume sampling can be used to achieve the $1+\epsilon$ factor with sample size $O(\frac{d}{\epsilon})$, in expectation. How close can we get with the techniques presented in this paper? We showed that size d volume sampling achieves a factor of $1+d$, but we do not know how to generalize this proof to sample size larger than d. However, one unique property of the volume-sampled estimator $\mathbf{w}^*(S)$ that can be useful here is that it is an *unbiased estimator* of $\mathbf{w}^*$. As we shall see now, this basic property has many benefits. For any unbiased estimator (i.e. $\mathbb{E}[\mathbf{w}(S)] = \mathbf{w}^*$) and optimal prediction vector $\widehat{\mathbf{y}} = \mathbf{X}\mathbf{w}^*$, consider the following rudimentary version of a bias-variance decomposition:

$$\mathbb{E}\underbrace{\|\mathbf{X}\,\mathbf{w}(S) - \mathbf{y}\|^2}_{L(\mathbf{w}(S))} = \mathbb{E}\,\|\mathbf{X}\,\mathbf{w}(S) - \widehat{\mathbf{y}} + \widehat{\mathbf{y}} - \mathbf{y}\|^2 = \mathbb{E}\,\|\mathbf{X}\,\mathbf{w}(S) - \widehat{\mathbf{y}}\|^2 + \underbrace{\|\widehat{\mathbf{y}} - \mathbf{y}\|^2}_{L(\mathbf{w}^*)}. \tag{10}$$

The unbiasedness of the estimator assures that the cross term $(\mathbf{X}\overbrace{\mathbb{E}[\mathbf{w}(S)]}^{\mathbf{w}^*} - \widehat{\mathbf{y}})^\top(\widehat{\mathbf{y}} - \mathbf{y})$ is 0. Therefore a $1+c$ factor loss bound is equivalent to a c factor variance bound, i.e.

$$\overbrace{\mathbb{E}[L(\mathbf{w}(S))] \leq (1+c)\, L(\mathbf{w}^*)}^{\text{loss bound}} \quad \Longleftrightarrow \quad \overbrace{\mathbb{E}\,\|\mathbf{X}\,\mathbf{w}(S) - \widehat{\mathbf{y}}\|^2 \leq c\, L(\mathbf{w}^*)}^{\text{variance bound}}. \tag{11}$$

To reduce the variance of any unbiased estimator $\mathbf{w}(S)$ (i.e. $\mathbb{E}[\mathbf{w}(S)] = \mathbf{w}^*$) with sample size s, we can draw k independent samples $S_1, \ldots, S_k$ of size s each and predict with the average estimator $\frac{1}{k}\sum_{j=1}^k \mathbf{w}(S_j)$. If the loss bound from (11) holds for $\mathbf{w}(S)$, then the average estimator satisfies

$$\mathbb{E}\Big[L\Big(\frac{1}{k}\sum\nolimits_j \mathbf{w}(S_j)\Big)\Big] \leq \Big(1 + \frac{c}{k}\Big)\, L(\mathbf{w}^*).$$

Setting $k = c/\epsilon$, we need $t = s\,c/\epsilon$ responses to get a $1+\epsilon$ approximation. We showed that size $s = d$ volume sampling achieves factor $c = d$. So with our current proof techniques, we need $t = d^2/\epsilon$ responses to get a $1+\epsilon$ factor approximation, for $\epsilon \in (0, d]$.[10]

9. Also, the weight vectors produced from i.i.d. leverage score sampling are not unbiased.

10. Thus when averaging the estimators of $k = t/d$ independent volume sampled sets of size d,

$$\underbrace{\mathbb{E}\Big[L\Big(\frac{1}{k}\sum\nolimits_j \mathbf{w}^*(S_j)\Big)\Big] - L(\mathbf{w}^*)}_{\text{regret}} = \underbrace{\frac{d^2 L(\mathbf{w}^*)}{t}}_{\text{prediction variance}}, \quad \text{when } \mathbf{X} \text{ is in general position.}$$

The basic open problem for worst-case responses is the following: Is there a size $O(d/\epsilon)$ *unbiased estimator* that achieves a $1+\epsilon$ factor approximation?[11] By the above averaging method this is equivalent to the following question: Is there a size $O(d)$ unbiased estimator that achieves a constant factor? This is because once we have an unbiased estimator that achieves a constant factor, then by averaging $1/\epsilon$ copies, we get the $1+O(\epsilon)$ factor. Ideally the special unbiased estimators resulting from a version of volume sampling can achieve this feat. We conclude this section with our favorite open problem: Is there a version of $O(d)$ size volume sampling that achieves a constant factor approximation?

In the next section we make some minimal statistical assumptions on the response vector which let us prove much stronger bounds: We assume that the response vector is linear plus bounded noise of mean zero. In particular we show that with this noise model, $O(d)$ size volume sampling achieves a constant factor approximation.

4. Regularized Volume Sampling for Learning with Noisy Responses

Volume sampling, as defined in Section 2.1, has certain fundamental limitations. Namely, it is undefined whenever matrix $\mathbf{X}$ is not full rank or if we wish to sample a subset S of size smaller than the dimension d. Motivated by these limitations, we propose a regularized variant, called λ-regularized volume sampling, which we define through a generalization of the reverse iterative sampling procedure:

$$P(S_{-i} \,|\, S) \propto \frac{\det(\mathbf{X}_{S_{-i}}^\top \mathbf{X}_{S_{-i}} + \lambda \mathbf{I})}{\det(\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})}. \tag{12}$$

Algorithm 1 λ-regularized v. sampling

$S \leftarrow \{1..n\}$
while $|S| > s$
  $\forall_{i \in S}\colon\ h_i \leftarrow \frac{\det(\mathbf{X}_{S_{-i}}^\top \mathbf{X}_{S_{-i}} + \lambda \mathbf{I})}{\det(\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})}$
  Sample $i \propto h_i$ out of S
  $S \leftarrow S - \{i\}$
end
return S

The normalization factor of this conditional probability (i.e. the sum of (12) over $i \in S$) can be computed using Sylvester's theorem:

$$\begin{aligned}\sum_{i \in S} \frac{\det(\mathbf{X}_{S_{-i}}^\top \mathbf{X}_{S_{-i}} + \lambda \mathbf{I})}{\det(\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})} &= \sum_{i \in S} \big(1 - \mathbf{x}_i^\top (\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})^{-1} \mathbf{x}_i\big) \\ &= |S| - \operatorname{tr}\big(\mathbf{X}_S (\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})^{-1} \mathbf{X}_S^\top\big) \\ &= |S| - d + \lambda \operatorname{tr}\big((\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})^{-1}\big). \end{aligned} \tag{13}$$

Note that in the special case of no regularization (i.e. $\lambda = 0$) the last trace vanishes and (13) is equal to $|S| - d$, so we recover volume sampling from Section 2.1. However, when $\lambda > 0$, then the last term is non-zero and depends on the entire matrix $\mathbf{X}_S$. This makes regularized volume sampling more complicated and certain equalities proven in previous sections for $\lambda = 0$ no longer hold. In particular, the analogous closed form of the sampling probability $P(S)$ given in Theorem 2 is not recovered because the paths from node $\{1..n\}$ to node S in the graph of Figure 3 do not all have the same probability. However, the proof technique we developed for reverse iterative sampling can still be applied, resulting in the following extension of the variance formula of Theorem 6:

11. In a recent paper (Chen and Price, 2017) a $1+\epsilon$ factor approximation has been achieved with $O(d/\epsilon)$ examples (for $\epsilon \in (0, 1]$), but the guarantee holds with high probability (and not in expectation) and the estimator is not unbiased.

Theorem 16 *For any $\mathbf{X} \in \mathbb{R}^{n\times d}$, $\lambda \geq 0$, let S be sampled according to λ-regularized size s volume sampling from $\mathbf{X}$. Then,*

$$\mathbb{E}\big[(\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})^{-1}\big] \preceq \frac{n - d_\lambda + 1}{s - d_\lambda + 1}(\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1}$$

for any $s \geq d_\lambda \overset{def}{=} \operatorname{tr}(\mathbf{X}(\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1}\mathbf{X}^\top)$.

Constant d_λ is a common notion of statistical dimension often referred to as the effective degrees of freedom. If λ_i are the eigenvalues of $\mathbf{X}^\top \mathbf{X}$, then $d_\lambda = \sum_{i=1}^d \frac{\lambda_i}{\lambda_i + \lambda}$. Note that d_λ is decreasing with λ and, when $\mathbf{X}$ is full rank, $d_0 = d$. Thus, unlike Theorem 6, the above result offers meaningful bounds for sampling sets S of size smaller than d.

Proof To obtain Theorem 16, we use essentially the same methodology as described in Lemma 1, except in the regularized case equality is replaced with inequality. Recall that using Sylvester's theorem we can compute the unnormalized conditional probability from (12) as:

$$h_i = \frac{\det(\mathbf{X}_{S_{-i}}^\top \mathbf{X}_{S_{-i}} + \lambda \mathbf{I})}{\det(\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})} = 1 - \mathbf{x}_i^\top (\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})^{-1}\mathbf{x}_i.$$

From now on, we will use $\mathbf{Z}_\lambda(S) = \mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I}$ as a shorthand in the proofs. Next, letting $M = \sum_{i\in S} h_i$, we compute unnormalized expectation by applying the Sherman-Morrison formula:

$$\begin{aligned}
M\,\mathbb{E}\big[(\mathbf{X}_{S_{-i}}^\top \mathbf{X}_{S_{-i}} + \lambda \mathbf{I})^{-1} \,|\, S\big] &= \sum_{i\in S} h_i \mathbf{Z}_\lambda(S_{-i})^{-1} = \sum_{i\in S} h_i \left(\mathbf{Z}_\lambda(S)^{-1} + \frac{\mathbf{Z}_\lambda(S)^{-1}\mathbf{x}_i\mathbf{x}_i^\top \mathbf{Z}_\lambda(S)^{-1}}{1 - \mathbf{x}_i^\top \mathbf{Z}_\lambda(S)^{-1}\mathbf{x}_i}\right) \\
&= M\,\mathbf{Z}_\lambda(S)^{-1} + \mathbf{Z}_\lambda(S)^{-1}\Big(\sum_{i\in S} \mathbf{x}_i\mathbf{x}_i^\top\Big)\mathbf{Z}_\lambda(S)^{-1} \\
&= M\,\mathbf{Z}_\lambda(S)^{-1} + \mathbf{Z}_\lambda(S)^{-1}(\mathbf{Z}_\lambda(S) - \lambda \mathbf{I})\mathbf{Z}_\lambda(S)^{-1} \\
&= M\,\mathbf{Z}_\lambda(S)^{-1} + \mathbf{Z}_\lambda(S)^{-1} - \lambda \mathbf{Z}_\lambda(S)^{-2} \\
&\preceq (M+1)\,\mathbf{Z}_\lambda(S)^{-1}.
\end{aligned}$$

Finally, the normalization factor M (which we already computed in (13)) can be lower-bounded using the λ-statistical dimension d_λ of matrix $\mathbf{X}$:

$$M = \sum_{i\in S}(1 - \mathbf{x}_i^\top \mathbf{Z}_\lambda(S)^{-1}\mathbf{x}_i) = s - d + \lambda \operatorname{tr}(\mathbf{Z}_\lambda(S)^{-1}) \geq s - \Big(\underbrace{d - \lambda \operatorname{tr}(\mathbf{Z}_\lambda(\{1..n\})^{-1})}_{d_\lambda}\Big).$$

Putting the bounds together, we obtain that:

$$\mathbb{E}\big[(\mathbf{X}_{S_{-i}}^\top \mathbf{X}_{S_{-i}} + \lambda \mathbf{I})^{-1} \,|\, S\big] \preceq \frac{s - d_\lambda + 1}{s - d_\lambda}(\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})^{-1}.$$

To prove Theorem 16 it remains to chain the conditional expectations along the sequence of subsets obtained by λ-regularized volume sampling:

$$\mathbb{E}\big[\mathbf{Z}_\lambda(S)^{-1}\big] \preceq \left(\prod_{t=s+1}^{n} \frac{t - d_\lambda + 1}{t - d_\lambda}\right) \mathbf{Z}_\lambda(\{1..n\})^{-1} = \frac{n - d_\lambda + 1}{s - d_\lambda + 1}(\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1}. \quad \blacksquare$$

4.1 Ridge Regression with Noisy Responses

We apply the above result to obtain statistical guarantees for subsampling with regularized estimators. Given a matrix $\mathbf{X} \in \mathbb{R}^{n\times d}$, we consider the task of fitting a linear model to a vector of responses $\mathbf{y} = \mathbf{X}\widetilde{\mathbf{w}} + \boldsymbol{\xi}$, where $\widetilde{\mathbf{w}} \in \mathbb{R}^d$ and the noise $\boldsymbol{\xi} \in \mathbb{R}^n$ is a mean zero random vector with covariance matrix $\operatorname{Var}[\boldsymbol{\xi}] \preceq \sigma^2 \mathbf{I}$ for some $\sigma > 0$. A classical solution to this task is the ridge estimator:

$$\mathbf{w}_\lambda^* = \operatorname*{argmin}_{\mathbf{w}\in\mathbb{R}^d} \|\mathbf{X}\mathbf{w} - \mathbf{y}\|^2 + \lambda\|\mathbf{w}\|^2 = (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1}\mathbf{X}^\top \mathbf{y}.$$

As a consequence of Theorem 16, we show that if S is sampled with λ-regularized volume sampling from $\mathbf{X}$, then the ridge estimator for the subproblem $(\mathbf{X}_S, \mathbf{y}_S)$

$$\mathbf{w}_\lambda^*(S) = (\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})^{-1}\mathbf{X}_S^\top \mathbf{y}_S$$

has strong generalization properties with respect to the full problem $(\mathbf{X}, \mathbf{y})$ in terms of the mean squared prediction error (MSPE) and mean squared error (MSE).

Theorem 17 *Let $\mathbf{X} \in \mathbb{R}^{n\times d}$ and $\widetilde{\mathbf{w}} \in \mathbb{R}^d$, and suppose that $\mathbf{y} = \mathbf{X}\widetilde{\mathbf{w}} + \boldsymbol{\xi}$, where $\boldsymbol{\xi}$ is a mean zero vector with $\operatorname{Var}[\boldsymbol{\xi}] \preceq \sigma^2 \mathbf{I}$. Let S be sampled according to λ-regularized size $s \geq d_\lambda$ volume sampling from $\mathbf{X}$ and $\mathbf{w}_\lambda^*(S)$ be the λ-ridge estimator of $\widetilde{\mathbf{w}}$ computed from subproblem $(\mathbf{X}_S, \mathbf{y}_S)$. Then, if $\lambda \leq \frac{\sigma^2}{\|\widetilde{\mathbf{w}}\|^2}$, we have*

$$\begin{aligned}
&\textit{(mean squared prediction error)} \quad \mathbb{E}_S\mathbb{E}_{\boldsymbol{\xi}}\Big[\frac{1}{n}\|\mathbf{X}(\mathbf{w}_\lambda^*(S) - \widetilde{\mathbf{w}})\|^2\Big] \leq \frac{\sigma^2 d_\lambda}{s - d_\lambda + 1}, \\
&\textit{(mean squared error)} \qquad\quad \mathbb{E}_S\mathbb{E}_{\boldsymbol{\xi}}\big[\|\mathbf{w}_\lambda^*(S) - \widetilde{\mathbf{w}}\|^2\big] \leq \frac{\sigma^2 n \operatorname{tr}((\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1})}{s - d_\lambda + 1}.
\end{aligned}$$

Next, we present two lower bounds for MSPE of a subsampled ridge estimator which show that the statistical guarantees achieved by regularized volume sampling are nearly optimal for $s \gg d_\lambda$ and better than standard approaches for $s = O(d_\lambda)$. In particular, we show that non-i.i.d. nature of volume sampling is essential if we want to achieve good generalization when the number of responses is close to d_λ. Namely for certain data matrices, any i.i.d. subsampling procedure (such as i.i.d. leverage score sampling) requires at least $d_\lambda \ln(d_\lambda)$ responses to achieve MSPE below σ^2. In contrast volume sampling obtains that bound for any matrix with $2d_\lambda$ responses.

Theorem 18 *For any $p \geq 1$ and $\sigma \geq 0$, there is $d \geq p$ such that for any sufficiently large n divisible by d, there exists a matrix $\mathbf{X} \in \mathbb{R}^{n\times d}$ such that*

$$d_\lambda(\mathbf{X}) \geq p \quad \textit{for any} \quad 0 \leq \lambda \leq \sigma^2,$$

and for each of the following two statements there is a vector $\widetilde{\mathbf{w}} \in \mathbb{R}^d$ for which the corresponding regression problem $\mathbf{y} = \mathbf{X}\widetilde{\mathbf{w}} + \boldsymbol{\xi}$ with $\operatorname{Var}[\boldsymbol{\xi}] = \sigma^2 \mathbf{I}$ satisfies that statement:

a) For any subset $S \subseteq \{1..n\}$ of size s,

$$\mathbb{E}_{\boldsymbol{\xi}}\Big[\frac{1}{n}\|\mathbf{X}(\mathbf{w}_\lambda^*(S) - \widetilde{\mathbf{w}})\|^2\Big] \geq \frac{\sigma^2 d_\lambda}{s + d_\lambda};$$

b) For multiset $S \subseteq \{1..n\}$ of size $s \leq (d_\lambda - 1)\ln(d_\lambda)$, sampled i.i.d. from any distribution over $\{1..n\}$,

$$\mathbb{E}_S \mathbb{E}_{\boldsymbol{\xi}}\Big[\frac{1}{n}\|\mathbf{X}(\mathbf{w}^*_\lambda(S) - \widetilde{\mathbf{w}})\|^2\Big] \geq \sigma^2.$$

Proof of Theorem 17 Standard analysis for the ridge regression estimator follows by performing bias-variance decomposition of the error, and then selecting λ so that bias can be appropriately bounded. We will recall this calculation for a fixed subproblem $(\mathbf{X}_S, \mathbf{y}_S)$. First, we compute the bias of the ridge estimator for a fixed set S (recall the shorthand $\mathbf{Z}_\lambda(S) = \mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I}$):

$$\begin{aligned}
\text{Bias}_{\boldsymbol{\xi}}[\mathbf{w}^*_\lambda(S)] &= \mathbb{E}[\mathbf{w}^*_\lambda(S)] - \widetilde{\mathbf{w}} = \mathbb{E}_{\boldsymbol{\xi}}\left[\mathbf{Z}_\lambda(S)^{-1}\mathbf{X}_S^\top \mathbf{y}_S\right] - \widetilde{\mathbf{w}} \\
&= \mathbf{Z}_\lambda(S)^{-1}\mathbf{X}_S^\top\left(\mathbf{X}_S\widetilde{\mathbf{w}} + \mathbb{E}_{\boldsymbol{\xi}}[\boldsymbol{\xi}_S]\right) - \widetilde{\mathbf{w}} \\
&= (\mathbf{Z}_\lambda(S)^{-1}\mathbf{X}_S^\top\mathbf{X}_S - \mathbf{I})\widetilde{\mathbf{w}} = -\lambda\,\mathbf{Z}_\lambda(S)^{-1}\widetilde{\mathbf{w}}.
\end{aligned}$$

Similarly, the covariance matrix of $\mathbf{w}^*_\lambda(S)$ is given by:

$$\begin{aligned}
\text{Var}_{\boldsymbol{\xi}}[\mathbf{w}^*_\lambda(S)] &= \mathbf{Z}_\lambda(S)^{-1}\mathbf{X}_S^\top \text{Var}_{\boldsymbol{\xi}}[\boldsymbol{\xi}_S]\mathbf{X}_S\mathbf{Z}_\lambda(S)^{-1} \\
&\preceq \sigma^2\mathbf{Z}_\lambda(S)^{-1}\mathbf{X}_S^\top\mathbf{X}_S\mathbf{Z}_\lambda(S)^{-1} = \sigma^2(\mathbf{Z}_\lambda(S)^{-1} - \lambda\,\mathbf{Z}_\lambda(S)^{-2}).
\end{aligned}$$

Mean squared error of the ridge estimator for a fixed subset S can now be bounded by:

$$\begin{aligned}
\mathbb{E}_{\boldsymbol{\xi}}\left[\|\mathbf{w}^*_\lambda(S) - \widetilde{\mathbf{w}}\|^2\right] &= \text{tr}(\text{Var}_{\boldsymbol{\xi}}[\mathbf{w}^*_\lambda(S)]) + \|\text{Bias}_{\boldsymbol{\xi}}[\mathbf{w}^*_\lambda(S)]\|^2 \\
&\leq \sigma^2\text{tr}(\mathbf{Z}_\lambda(S)^{-1} - \lambda\mathbf{Z}_\lambda(S)^{-2}) + \lambda^2\text{tr}(\mathbf{Z}_\lambda(S)^{-2}\widetilde{\mathbf{w}}\widetilde{\mathbf{w}}^\top) \\
&\leq \sigma^2\text{tr}(\mathbf{Z}_\lambda(S)^{-1}) + \lambda\text{tr}(\mathbf{Z}_\lambda(S)^{-2})(\lambda\|\widetilde{\mathbf{w}}\|^2 - \sigma^2) \qquad (14) \\
&\leq \sigma^2\text{tr}(\mathbf{Z}_\lambda(S)^{-1}), \qquad (15)
\end{aligned}$$

where in (14) we applied Cauchy-Schwartz inequality for matrix trace, and in (15) we used the assumption that $\lambda \leq \frac{\sigma^2}{\|\widetilde{\mathbf{w}}\|^2}$. Thus, taking expectation over the sampling of set S, we get

$$\begin{aligned}
\mathbb{E}_S\mathbb{E}_{\boldsymbol{\xi}}\left[\|\mathbf{w}^*_\lambda(S) - \widetilde{\mathbf{w}}\|^2\right] &\leq \sigma^2\mathbb{E}_S\left[\text{tr}(\mathbf{Z}_\lambda(S)^{-1})\right] \\
\text{(Theorem 16)} \quad &\leq \sigma^2\frac{n - d_\lambda + 1}{s - d_\lambda + 1}\text{tr}(\mathbf{Z}_\lambda(\{1..n\})^{-1}) \qquad (16) \\
&\leq \frac{\sigma^2\, n\,\text{tr}((\mathbf{X}^\top\mathbf{X} + \lambda\mathbf{I})^{-1})}{s - d_\lambda + 1}.
\end{aligned}$$

Next, we bound the mean squared prediction error. As before, we start with the standard bias-variance decomposition for fixed set S:

$$\begin{aligned}
\mathbb{E}_{\boldsymbol{\xi}}\left[\|\mathbf{X}(\mathbf{w}^*_\lambda(S) - \widetilde{\mathbf{w}})\|^2\right] &= \text{tr}(\text{Var}_{\boldsymbol{\xi}}[\mathbf{X}\mathbf{w}^*_\lambda(S)]) + \|\mathbf{X}(\mathbb{E}_{\boldsymbol{\xi}}[\mathbf{w}^*_\lambda(S)] - \widetilde{\mathbf{w}})\|^2 \\
&\leq \sigma^2\text{tr}(\mathbf{X}(\mathbf{Z}_\lambda(S)^{-1} - \lambda\,\mathbf{Z}_\lambda(S)^{-2})\mathbf{X}^\top) + \lambda^2\text{tr}(\mathbf{Z}_\lambda(S)^{-1}\mathbf{X}^\top\mathbf{X}\mathbf{Z}_\lambda(S)^{-1}\widetilde{\mathbf{w}}\widetilde{\mathbf{w}}^\top) \\
&\leq \sigma^2\text{tr}(\mathbf{X}\mathbf{Z}_\lambda(S)^{-1}\mathbf{X}^\top) + \lambda\,\text{tr}(\mathbf{X}\mathbf{Z}_\lambda(S)^{-2}\mathbf{X}^\top)(\lambda\|\widetilde{\mathbf{w}}\|^2 - \sigma^2) \\
&\leq \sigma^2\text{tr}(\mathbf{X}\mathbf{Z}_\lambda(S)^{-1}\mathbf{X}^\top).
\end{aligned}$$

Once again, taking expectation over subset S, we have

$$\begin{aligned}
\mathbb{E}_S\mathbb{E}_{\boldsymbol{\xi}}\left[\frac{1}{n}\|\mathbf{X}(\mathbf{w}^*_\lambda(S) - \widetilde{\mathbf{w}})\|^2\right] &\leq \frac{\sigma^2}{n}\mathbb{E}_S\left[\text{tr}(\mathbf{X}\mathbf{Z}_\lambda(S)^{-1}\mathbf{X}^\top)\right] = \frac{\sigma^2}{n}\text{tr}(\mathbf{X}\,\mathbb{E}_S[\mathbf{Z}_\lambda(S)^{-1}]\,\mathbf{X}^\top) \\
\text{(Theorem 16)} \quad &\leq \frac{\sigma^2}{n}\frac{n - d_\lambda + 1}{s - d_\lambda + 1}\text{tr}(\mathbf{X}\mathbf{Z}_\lambda(\{1..n\})^{-1}\mathbf{X}^\top) \leq \frac{\sigma^2 d_\lambda}{s - d_\lambda + 1}. \qquad (17)
\end{aligned}$$

The key part of proving both bounds is the application of Theorem 16. For MSE, we only used the trace version of the inequality (see (16)), however to obtain the bound on MSPE we used the more general positive semi-definite inequality in (17). ■

Proof of Theorem 18 Let $d = \lceil p \rceil + 1$ and $n \geq \lceil \sigma^2 \rceil d(d-1)$ be divisible by d. We define

$$\mathbf{X} \overset{def}{=} [\mathbf{I}, ..., \mathbf{I}]^\top \in \mathbb{R}^{n \times d}, \qquad \widetilde{\mathbf{w}}^\top \overset{def}{=} [a\sigma, ..., a\sigma] \in \mathbb{R}^d$$

for some $a > 0$. For any $\lambda \leq \sigma^2$, the λ-statistical dimension of $\mathbf{X}$ is

$$d_\lambda = \text{tr}(\mathbf{X}\,\mathbf{Z}_\lambda(\{1..n\})^{-1}\mathbf{X}^\top) \geq \frac{\lceil \sigma^2 \rceil d(d-1)}{\lceil \sigma^2 \rceil (d-1) + \lambda} \geq \frac{d(d-1)}{d - 1 + 1} \geq p.$$

Let $S \subseteq \{1..n\}$ be any set of size s, and for $i \in \{1..d\}$ let $s_i \overset{def}{=} |\{i \in S : \mathbf{x}_i = \mathbf{e}_i\}|$. The prediction variance of estimator $\mathbf{w}^*_\lambda(S)$ is equal to

$$\begin{aligned}
\text{tr}\big(\text{Var}_{\boldsymbol{\xi}}[\mathbf{X}\mathbf{w}^*_\lambda(S)]\big) &= \sigma^2\text{tr}(\mathbf{X}(\mathbf{Z}_\lambda(S)^{-1} - \lambda\mathbf{Z}_\lambda(S)^{-2})\mathbf{X}^\top) \\
&= \frac{\sigma^2 n}{d}\sum_{i=1}^d\left(\frac{1}{s_i + \lambda} - \frac{\lambda}{(s_i + \lambda)^2}\right) = \frac{\sigma^2 n}{d}\sum_{i=1}^d\frac{s_i}{(s_i + \lambda)^2}.
\end{aligned}$$

The prediction bias of estimator $\mathbf{w}^*_\lambda(S)$ is equal to

$$\begin{aligned}
\|\mathbf{X}(\mathbb{E}_{\boldsymbol{\xi}}[\mathbf{w}^*_\lambda(S)] - \widetilde{\mathbf{w}})\|^2 &= \lambda^2\widetilde{\mathbf{w}}^\top\mathbf{Z}_\lambda(S)^{-1}\mathbf{X}^\top\mathbf{X}\mathbf{Z}_\lambda(S)^{-1}\widetilde{\mathbf{w}} \\
&= \frac{\lambda^2 a^2\sigma^2 n}{d}\,\text{tr}\big(\mathbf{Z}_\lambda(S)^{-2}\big) = \frac{\lambda^2 a^2\sigma^2 n}{d}\sum_{i=1}^d\frac{1}{(s_i + \lambda)^2}.
\end{aligned}$$

Thus, MSPE of estimator $\mathbf{w}^*_\lambda(S)$ is given by:

$$\begin{aligned}
\mathbb{E}_{\boldsymbol{\xi}}\left[\frac{1}{n}\|\mathbf{X}(\mathbf{w}^*_\lambda(S) - \widetilde{\mathbf{w}})\|^2\right] &= \frac{1}{n}\text{tr}\big(\text{Var}_{\boldsymbol{\xi}}[\mathbf{X}\mathbf{w}^*_\lambda(S)]\big) + \frac{1}{n}\|\mathbf{X}(\mathbb{E}_{\boldsymbol{\xi}}[\mathbf{w}^*_\lambda(S)] - \widetilde{\mathbf{w}})\|^2 \\
&= \frac{\sigma^2}{d}\sum_{i=1}^d\left(\frac{s_i}{(s_i + \lambda)^2} + \frac{a^2\lambda^2}{(s_i + \lambda)^2}\right) = \frac{\sigma^2}{d}\sum_{i=1}^d\frac{s_i + a^2\lambda^2}{(s_i + \lambda)^2}.
\end{aligned}$$

Next, we find the λ that minimizes this expression. Taking the derivative with respect to λ we get:

$$\frac{\partial}{\partial\lambda}\left(\frac{\sigma^2}{d}\sum_{i=1}^d\frac{s_i + a^2\lambda^2}{(s_i + \lambda)^2}\right) = \frac{\sigma^2}{d}\sum_{i=1}^d\frac{2s_i(\lambda - a^{-2})}{(s_i + \lambda)^3}.$$

Thus, since at least one s_i has to be greater than 0, for any set S the derivative is negative for $\lambda < a^{-2}$ and positive for $\lambda > a^{-2}$, and the unique minimum of MSPE is achieved at $\lambda = a^{-2}$, regardless of which subset S is chosen. So, as we are seeking a lower bound, we can focus on the case of $\lambda = a^{-2}$.

Proof of part a. Let $a = 1$. As shown above, we can assume that $\lambda = 1$. In this case the formula simplifies to:

$$\mathbb{E}_{\boldsymbol{\xi}}\Big[\frac{1}{n}\|\mathbf{X}(\mathbf{w}^*_\lambda(S) - \widetilde{\mathbf{w}})\|^2\Big] = \frac{\sigma^2}{d}\sum_{i=1}^{d}\frac{s_i+1}{(s_i+1)^2} = \frac{\sigma^2}{d}\sum_{i=1}^{d}\frac{1}{s_i+1}$$
$$\overset{(*)}{\geq} \frac{\sigma^2}{\frac{s}{d}+1} = \frac{\sigma^2 d}{s+d} \geq \frac{\sigma^2 d_\lambda}{s+d_\lambda},$$

where $(*)$ follows by applying Jensen's inequality to convex function $\phi(x) = \frac{1}{x+1}$.

Proof of part b. Let $a = \sqrt{2d}$. As shown above, we can assume that $\lambda = 1/(2d)$. Suppose that multiset S is sampled i.i.d. from some distribution over set $\{1..n\}$. Similarly as in Corollary 13, we exploit the Coupon Collector's problem, i.e. that if $|S| \leq (d-1)\ln(d)$, then with probability at least $1/2$ there is $i \in \{1..d\}$ such that $s_i = 0$ (i.e., one of the unit vectors $\mathbf{e}_i$ was never selected). Thus, MSPE can be lower-bounded as follows:

$$\mathbb{E}_S\mathbb{E}_{\boldsymbol{\xi}}\Big[\frac{1}{n}\|\mathbf{X}(\mathbf{w}^*_\lambda(S) - \widetilde{\mathbf{w}})\|^2\Big] \geq \frac{1}{2}\,\frac{\sigma^2}{d}\,\frac{s_i + a^2\lambda^2}{(s_i+\lambda)^2} = \frac{\sigma^2}{2d}\,\frac{2d\lambda^2}{\lambda^2} = \sigma^2. \qquad \blacksquare$$

5. Efficient Algorithms for Volume Sampling

In this section we propose algorithms for efficiently performing volume sampling. This addresses the question posed by Avron and Boutsidis (2013), asking for a polynomial-time algorithm for the case when the size of set S is $s > d$. Deshpande and Rademacher (2010) gave an algorithm for the case when $s = d$, which was later improved by Guruswami and Sinop (2012), running in time $O(nd^3)$. Recently, Li et al. (2017) offered an algorithm for arbitrary s, which has complexity $O(n^4 s)$. We propose two new methods, which use our reverse iterative sampling technique to achieve faster running times for volume sampling of any size s. Both algorithms apply to the more general setting of λ-regularized volume sampling (described in Section 4), and produce standard volume sampling as a special case for $\lambda = 0$ and $s \geq d$. The first algorithm has a deterministic runtime of $O((n-s+d)nd)$, whereas the second one is an accelerated version which with high probability finishes in time $O(nd^2)$. Thus, we obtain a direct improvement over Li et al. (2017) by a factor of at least n^2, and in the special case of $s = d$, by a factor of d over the algorithm of Guruswami and Sinop (2012).

Our algorithms implement reverse iterative sampling from Theorem 2. We start with the full index set $S = \{1..n\}$. In one step of the algorithm, we remove one row from set S. After removing q rows, we are left with the index set of size $n - q$ that is distributed according to volume sampling for row set size $n - q$, and we proceed until our set S has the desired size s. The primary cost of the procedure is updating the conditional distribution $P(S_{-i}|S)$ at every step. It is convenient to store it using the unnormalized weights defined in (12) which, via Sylvester's theorem, can be computed as $h_i = 1 - \mathbf{x}_i^\top(\mathbf{X}_S^\top\mathbf{X}_S + \lambda\mathbf{I})^{-1}\mathbf{x}_i$ (For the sake of generality we state the methods for λ-regularized

volume sampling). Doing this naively, we would first compute $(\mathbf{X}_S^\top\mathbf{X}_S + \lambda\mathbf{I})^{-1}$ which takes $O(nd^2)$ time[12]. After that for each i, we would multiply this matrix by $\mathbf{x}_i$ in time $O(d^2)$ to get the h_i's. The overall runtime of this naive method becomes:

$$\overbrace{\#\text{ of steps}}^{n-s} \times \Big(\overbrace{\text{compute } (\mathbf{X}_S^\top\mathbf{X}_S + \lambda\mathbf{I})^{-1}}^{O(nd^2)} + \overbrace{\#\text{ of weights}}^{\leq n} \times \overbrace{\text{compute } h_i}^{O(d^2)}\Big) \;=\; O((n-s)nd^2).$$

Both the computation of matrix inverse and the weights h_i can be made more efficient. First, the matrix $(\mathbf{X}_S^\top\mathbf{X}_S + \lambda\mathbf{I})^{-1}$ can be computed from the one obtained in the previous step by using the Sherman-Morrison formula. This lets us update it in $O(d^2)$ time instead of $O(nd^2)$. Furthermore, we propose two strategies for dealing with the cost of maintaining the weights:

a) Update all h_i's at every step using Sherman-Morrison;

b) Use rejection sampling and only compute the h_i's needed for the rejection trials (This avoids computing all h_i's, but makes the computation of each needed h_i more expensive).

As we can see, there is a trade-off between those strategies. In the following lemma, we will show that updating the value of h_i, given its value in the previous step only costs $O(d)$ time as opposed to $O(d^2)$. However, the number of h_i's that need to be computed for rejection sampling (explained shortly) can be far smaller.

Lemma 19 *For any matrix $\mathbf{X} \in \mathbb{R}^{n\times d}$, set $S \subseteq \{1..n\}$ and two distinct indices $i, j \in S$, we have*

$$1 - \mathbf{x}_j^\top(\mathbf{X}_{S_{-i}}^\top\mathbf{X}_{S_{-i}} + \lambda\mathbf{I})^{-1}\mathbf{x}_j = h_j - (\mathbf{x}_j^\top\mathbf{v})^2,$$

where $h_j = 1 - \mathbf{x}_j^\top(\mathbf{X}_S^\top\mathbf{X}_S + \lambda\mathbf{I})^{-1}\mathbf{x}_j$ and $\mathbf{v} = \frac{1}{\sqrt{h_i}}(\mathbf{X}_S^\top\mathbf{X}_S + \lambda\mathbf{I})^{-1}\mathbf{x}_i$.

Proof Letting $\mathbf{Z}_\lambda(S) = \mathbf{X}_S^\top\mathbf{X}_S + \lambda\mathbf{I}$, we have

$$\begin{aligned}
h_j - (\mathbf{x}_j^\top\mathbf{v})^2 &= 1 - \mathbf{x}_j^\top\mathbf{Z}_\lambda(S)^{-1}\mathbf{x}_j - \frac{(\mathbf{x}_j^\top\mathbf{Z}_\lambda(S)^{-1}\mathbf{x}_i)^2}{1 - \mathbf{x}_i^\top\mathbf{Z}_\lambda(S)^{-1}\mathbf{x}_i} \\
&= 1 - \mathbf{x}_j^\top\mathbf{Z}_\lambda(S)^{-1}\mathbf{x}_j - \frac{\mathbf{x}_j^\top\mathbf{Z}_\lambda(S)^{-1}\mathbf{x}_i\mathbf{x}_i^\top\mathbf{Z}_\lambda(S)^{-1}\mathbf{x}_j}{1 - \mathbf{x}_i^\top\mathbf{Z}_\lambda(S)^{-1}\mathbf{x}_i} \\
&= 1 - \mathbf{x}_j^\top\left(\mathbf{Z}_\lambda(S)^{-1} + \frac{\mathbf{Z}_\lambda(S)^{-1}\mathbf{x}_i\mathbf{x}_i^\top\mathbf{Z}_\lambda(S)^{-1}}{1 - \mathbf{x}_i^\top\mathbf{Z}_\lambda(S)^{-1}\mathbf{x}_i}\right)\mathbf{x}_j \\
&\overset{(*)}{=} 1 - \mathbf{x}_j^\top(\mathbf{X}_{S_{-i}}^\top\mathbf{X}_{S_{-i}} + \lambda\mathbf{I})^{-1}\mathbf{x}_j,
\end{aligned}$$

where $(*)$ follows from the Sherman-Morrison formula. $\blacksquare$

Thus the overall time complexity of reverse iterative sampling when using the first strategy goes down by a factor of d compared to the naive version (except for an initialization cost which stays at $O(nd^2)$).

Theorem 20 *Algorithm RegVol produces an index set S of rows distributed according to λ-regularized size s volume sampling over $\mathbf{X}$ in time $O((n-s+d)nd)$.*

12. We are primarily interested in the case where $n \geq d$ and we state our time bounds under that assumption. However, when $\lambda > 0$, our techniques can be easily adapted to the case of $n < d$.

Proof Using Lemma 19 for h_i and the Sherman-Morrison formula for $\mathbf{Z}$, the following invariants hold at the beginning of the **while** loop:

$$h_i = 1 - \mathbf{x}_i^\top (\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})^{-1} \mathbf{x}_i \qquad \text{and} \qquad \mathbf{Z} = (\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})^{-1}.$$

Runtime: Computing the initial $\mathbf{Z} = (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1}$ takes $O(nd^2)$, as does computing the initial values of h_j's. Inside the **while** loop, updating h_j's takes $O(|S|d) = O(nd)$ and updating $\mathbf{Z}$ takes $O(d^2)$. The overall runtime becomes $O(nd^2 + (n-s)nd) = O((n-s+d)nd)$. ■

Algorithm 2 RegVol($\mathbf{X}, s, \lambda$)

$\mathbf{Z} \leftarrow (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1}$
$\forall_{i \in \{1..n\}} \quad h_i \leftarrow 1 - \mathbf{x}_i^\top \mathbf{Z} \mathbf{x}_i$
$S \leftarrow \{1..n\}$
while $|S| > s$
  Sample $i \propto h_i$ out of S
  $S \leftarrow S - \{i\}$
  $\mathbf{v} \leftarrow \mathbf{Z}\mathbf{x}_i / \sqrt{h_i}$
  $\forall_{j \in S} \quad h_j \leftarrow h_j - (\mathbf{x}_j^\top \mathbf{v})^2$
  $\mathbf{Z} \leftarrow \mathbf{Z} + \mathbf{v}\mathbf{v}^\top$
end
return S

Algorithm 3 FastRegVol($\mathbf{X}, s, \lambda$)

$\mathbf{Z} \leftarrow (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1}$
$S \leftarrow \{1..n\}$
while $|S| > \max\{s, 2d\}$
  repeat
    Sample i uniformly out of S
    $h_i \leftarrow 1 - \mathbf{x}_i^\top \mathbf{Z} \mathbf{x}_i$
    Sample $A \sim \text{Bernoulli}(h_i)$
  until $A = 1$
  $S \leftarrow S - \{i\}$
  $\mathbf{Z} \leftarrow \mathbf{Z} + h_i^{-1} \mathbf{Z}\mathbf{x}_i\mathbf{x}_i^\top \mathbf{Z}$
end
if $s < 2d$, $\quad S \leftarrow \text{RegVol}(\mathbf{X}_S, s, \lambda)$ $\quad$ **end**
return S

Next we present algorithm FastRegVol, which is based on the rejection sampling strategy. Our key observation is that updating the full conditional distribution $P(S_{-i}|S)$ is wasteful, since the distribution changes very slowly throughout the procedure. Moreover, the unnormalized weights h_i, which are computed in the process are all bounded by 1. Thus, to sample from the correct distribution at any given iteration, we can employ rejection sampling as follows:

1: Sample i uniformly from set S,
2: Compute h_i,
3: Accept with probability h_i,
4: Otherwise, draw another sample.

Note that this rejection sampling can be employed locally, within each iteration of the algorithm. Thus, one rejection does not revert us back to the beginning of the algorithm. Moreover, if the probability of acceptance is high, then this strategy requires computing only a small number of weights per iteration of the algorithm, as opposed to updating all of them. This turns out to be the case for a majority of the steps of the algorithm, except at the very end (for $s \leq 2d$), were the conditional probabilities start changing more drastically. At that point, it becomes more efficient to use the first algorithm, RegVol.

Theorem 21 *For any $\lambda, s \geq 0$, and $\delta \in (0,1)$, algorithm FastRegVol samples according to λ-regularized size s volume sampling, and with probability at least $1-\delta$ runs in time*

$$O\Big(\Big(n + \log\big(n/d\big)\log\big(1/\delta\big)\Big)d^2\Big).$$

Proof We analyze the efficiency of rejection sampling in FastRegVol. Let R_t be a random variable corresponding to the number of trials needed in the **repeat** loop from line 4 in FastRegVol at the point when $|S| = t$. Note that conditioning on the algorithm's history, R_t is distributed according to geometric distribution $\text{Ge}(q_t)$ with success probability:

$$q_t = \frac{1}{t}\sum_{i \in S}\big(1 - \mathbf{x}_i^\top (\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})^{-1}\mathbf{x}_i\big) \geq \frac{t-d}{t} \geq \frac{1}{2}.$$

Thus, even though variables R_t are not themselves independent, they can be upper-bounded by a sequence of independent variables $\widehat{R}_t \sim \text{Ge}(\frac{t-d}{t})$. The expectation of the total number of trials in FastRegVol, $\bar{R} = \sum_t R_t$, can thus be bounded as follows:

$$\mathbb{E}[\bar{R}] \leq \sum_{t=2d}^{n} \mathbb{E}[\widehat{R}_t] = \sum_{t=2d}^{n} \frac{t}{t-d} \leq 2n.$$

Next, we will obtain a similar bound with high probability instead of in expectation. Here, we will have to use the fact that the variables $\widehat{R}_t$ are independent, which means that we can upper-bound their sum with high probability using standard concentration bounds for geometric distribution. For example, using Corollary 2.2 from Janson (2018) one can immediately show that with probability at least $1-\delta$ we have $\bar{R} = O(n \ln \delta^{-1})$. However, more careful analysis shows an even better dependence on δ.

Lemma 22 *Let $\widehat{R}_t \sim \text{Ge}(\frac{t-d}{t})$ be independent random variables. Then, w.p. at least $1-\delta$,*

$$\sum_{t=2d}^{n} \widehat{R}_t = O\Big(n + \log\big(n/d\big)\log\big(1/\delta\big)\Big).$$

Each trial of rejection sampling requires computing one weight h_i in time $O(d^2)$. The overall time complexity of FastRegVol thus includes computation and updating of matrix $\mathbf{Z}$ (in time $O(nd^2)$), rejection sampling which takes $O\left(\left(n + \log\left(\frac{n}{d}\right)\log\left(\frac{1}{\delta}\right)\right)d^2\right)$ time, and (if $s < 2d$) the RegVol portion, taking $O(d^3)$. ■

Proof of Lemma 22 As observed by Janson (2018), tail-bounds for the sum of geometric random variables depend on the minimum acceptance probability among those variables. Note that for the vast majority of $\widehat{R}_t$'s the acceptance probability is very close to 1, so intuitively we should be able to take advantage of this to improve our tail bounds. To that end, we partition the variables into groups of roughly similar acceptance probability and then separately bound the sum of variables in each group. Let $J = \log(\frac{n}{d})$ (w.l.o.g. assume that J is an integer). For $1 \leq j \leq J$, let $I_j = \{d2^j, d2^j + 1, .., d2^{j+1}\}$ represent the j-th partition. We use the following notation for each partition:

$$\bar{R}_j \stackrel{def}{=} \sum_{t \in I_j} R_t, \qquad \mu_j \stackrel{def}{=} \mathbb{E}[\bar{R}_j], \qquad r_j \stackrel{def}{=} \min_{t \in I_j} \frac{t-d}{t}, \qquad \gamma_j \stackrel{def}{=} \frac{\log(\delta^{-1})}{d2^{j-2}} + 3.$$

Now, we apply Theorem 2.3 of Janson (2018) to $\bar{R}_j$, obtaining

$$P(\bar{R}_j \geq \gamma_j \mu_j) \leq \gamma_j^{-1}(1-r_j)^{(\gamma_j - 1 - \ln \gamma_j)\mu_j} \overset{(1)}{\leq} (1-r_j)^{\gamma_j \mu_j / 4} \overset{(2)}{\leq} 2^{-j\gamma_j d 2^{j-2}},$$

where (1) follows since $\gamma_j \geq 3$, and (2) holds because $\mu_j \geq d2^j$ and $r_j \geq 1 - 2^{-j}$. Moreover, for the chosen γ_j we have

$$j\gamma_j d 2^{j-2} = j\log(\delta^{-1}) + 3jd2^{j-2} \geq \log(\delta^{-1}) + j = \log(2^j \delta^{-1}).$$

Let A denote the event that $\bar{R}_j \leq \gamma_j \mu_j$ for all $j \leq J$. Applying union bound, we get

$$P(A) \geq 1 - \sum_{j=1}^{J} P(\bar{R}_j \geq \gamma_j \mu_j) \geq 1 - \sum_{j=1}^{J} 2^{-\log(2^j \delta^{-1})} = 1 - \sum_{j=1}^{J} \frac{\delta}{2^j} \geq 1 - \delta.$$

If A holds, then we obtain the desired bound:

$$\begin{aligned} \sum_{t=2d}^{n} \widehat{R}_t &\leq \sum_{j=1}^{J} \gamma_j \mu_j \leq \sum_{j=1}^{J} \left(\frac{\log(\delta^{-1})}{d2^{j-2}} + 3 \right) d2^{j+1} = 8J\log(\delta^{-1}) + 6\sum_{j=1}^{J} d2^j \\ &= O\Big(\log\left(n/d\right) \log\left(1/\delta\right) + n \Big). \end{aligned}$$

■

6. Experiments

In this section we experimentally evaluate the proposed volume sampling algorithms in terms of runtime and in the task of subsampling for linear regression. We use regularization both for sampling and for prediction, as discussed in Section 4. The list of implemented algorithms is:

a) Regularized volume sampling (algorithms FastRegVol and RegVol),

b) Leverage score sampling[13] (LSS) – a popular i.i.d. sampling technique (Mahoney, 2011), where examples are selected w.p. $P(i) = (\mathbf{x}_i^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_i)/d$.

The experiments were performed on several benchmark linear regression datasets from the libsvm repository (Chang and Lin, 2011). Table 1 lists those datasets along with running times for sampling dimension many columns with each method. Dataset MSD was too big for RegVol to finish in reasonable time, however FastRegVol finished in less than 40 seconds. In Figure 6 we plot the runtime against varying values of n (using portions of the datasets), to compare how FastRegVol and RegVol scale with respect to the data size. We observe that FastRegVol exhibits linear dependence on n, thus it is much better suited for running on large datasets.

Dataset	$n \times d$	RegVol	FastRegVol	LSS
cadata	21k×8	33.5s	0.9s	0.1s
MSD	464k×90	>24hr	39s	12s
cpusmall	8k×12	1.7s	0.4s	0.07s
abalone	4k×8	0.5s	0.2s	0.03s

Table 1: List of regression datasets with runtime comparison between RegVol and FastRegVol. We also provide the runtime for i.i.d. sampling with exact leverage scores (LSS).

13. Regularized variants of leverage scores have also been considered in context of kernel ridge regression Alaoui and Mahoney (2015). However, in our experiments regularizing leverage scores did not provide any improvements.

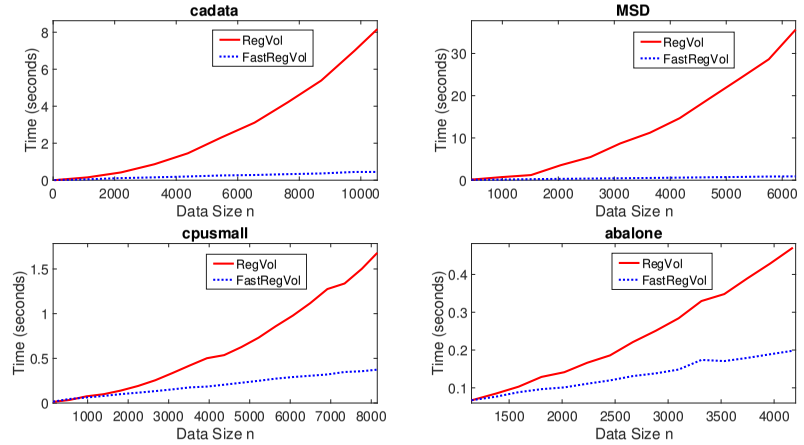

Figure 6: Comparison of runtime between FastRegVol and RegVol on four libsvm regression datasets (Chang and Lin, 2011), with the methods ran on data subsets of varying size (n).

6.1 Subset Selection for Ridge Regression

We applied volume sampling to the task of subset selection for linear regression, by evaluating the subsampled ridge estimator $\mathbf{w}_\lambda^*(S)$ using the average loss over the full dataset, i.e.,

$$\text{Average Loss:} \quad \frac{1}{n}\|\mathbf{X}\mathbf{w}_\lambda^*(S) - \mathbf{y}\|^2, \quad \text{where} \quad \mathbf{w}_\lambda^*(S) = (\mathbf{X}_S^\top \mathbf{X}_S + \lambda \mathbf{I})^{-1} \mathbf{X}_S^\top \mathbf{y}_S.$$

We evaluated the estimators for a range of subset sizes and values of λ, when the subsets are sampled according to λ-regularized volume sampling[14] and leverage score sampling. The results were averaged over 20 runs of each experiment. For clarity, Figure 7 shows the results only with one value of λ for each dataset, chosen so that the subsampled ridge estimator performed best (on average over all samples of preselected size s). Note that for leverage scores we did the appropriate rescaling of the instances before solving for $\mathbf{w}_\lambda^*(S)$ for the sampled subproblems (see Mahoney (2011) for details). Volume sampling does not require any rescaling. The results on all datasets show that when only a small number of responses s is obtainable, then regularized volume sampling offers better estimators than leverage score sampling (as predicted by Theorems 17 and 18). The lower bound from Theorem 18b can be observed for dataset cpusmall, where $d = 12$ and $d \log d \approx 30$.

7. Conclusions

Volume sampling is a joint sampling procedures that produces more diverse samples than i.i.d. sampling. We developed a method for proving exact matrix expectation formulas for volume sampling giving further credence to the fact that this is a fundamental sampling procedure. We also made significant progress on finding an efficient implementation of this sampling procedure: Our

14. Our experiments suggest that using the same λ for sampling and for computing the ridge estimator works best.

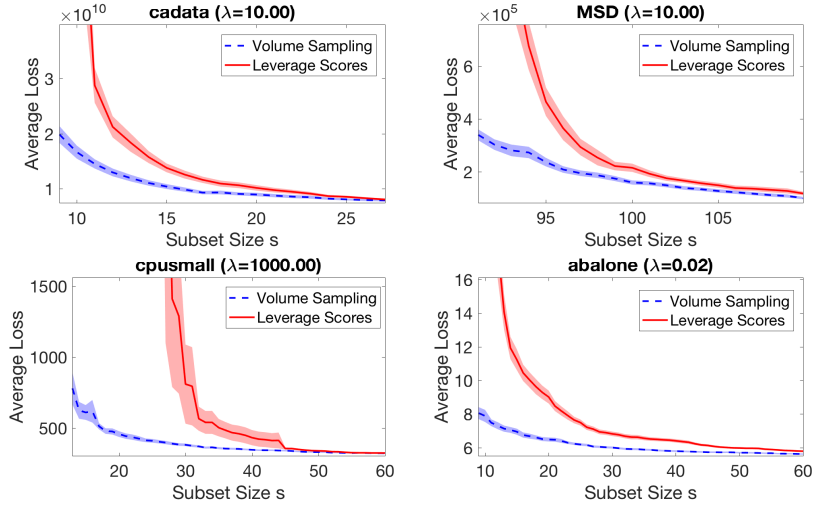

Figure 7: Comparison of loss of the subsampled ridge estimator when using regularized volume sampling vs using leverage score sampling on four datasets.

new reverse iterative volume sampling algorithm runs in time $O(nd^2)$. Note that this running time is within a constant factor of i.i.d. sampling with exact leverage scores and is a remarkable feat since volume sampling was only recently shown to be polynomial (that is $O(n^4 s)$ in Li et al. (2017)).

A final long ranging question is how to generalize volume sampling and the exact matrix expectation formulas to higher order tensors.

Thanks to Daniel Hsu and Wojciech Kotłowski for many valuable discussions. This research was supported by NSF grant IIS-1619271.

Appendix A. Inductive Proof of Cauchy-Binet

The most common form of the Cauchy-Binet equation deals with two real $n \times d$ matrices $\mathbf{A}, \mathbf{B}$: $\sum_{S:|S|=d} \det(\mathbf{A}_S^\top \mathbf{B}_S) = \det(\mathbf{A}^\top \mathbf{B})$. It is easy to generalize volume sampling and Theorem 2 to this "asymmetric" version. Here we give an alternate inductive proof.

For $i \in \{1..n\}$, let $\mathbf{a}_i, \mathbf{b}_i$ denote the i-th row of $\mathbf{A}, \mathbf{B}$, respectively. For $S \subseteq \{1..n\}$, $\mathbf{A}_S$ consists of all rows indexed by S, and $\mathbf{A}_{-i}$, all except for the i-th row.

Theorem 23 *For $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{n\times d}$ and $n-1 \geq s \geq d$:*

$$\det(\mathbf{A}^\top \mathbf{B}) = \frac{1}{\binom{n-d}{s-d}} \sum_{S:|S|=s} \det(\mathbf{A}_S^\top \mathbf{B}_S).$$

Proof S is a size s subset of a set of size n. We rewrite the range restriction $n-1 \geq s \geq d$ for size s as $1 \leq n-s \leq n-d$ and induct on $n-s$. For the base case, $n-s=1$ or $s=n-1$, we need to show that

$$\det(\mathbf{A}^\top \mathbf{B}) = \frac{1}{n-d} \sum_{i=1}^{n} \det(\mathbf{A}_{-i}^\top \mathbf{B}_{-i}).$$

This clearly holds if $\det(\mathbf{A}^\top \mathbf{B}) = 0$. Otherwise, by Sylvester's Theorem

$$\sum_{i=1}^{n} \frac{\det(\overbrace{\mathbf{A}_{-i}^\top \mathbf{B}_{-i}}^{\mathbf{A}^\top \mathbf{B} - \mathbf{a}_i \mathbf{b}_i^\top})}{\det(\mathbf{A}^\top \mathbf{B})} = \sum_{i=1}^{n} (1 - \mathbf{a}_i^\top (\mathbf{A}^\top \mathbf{B})^{-1} \mathbf{b}_i) = n - \overbrace{\mathrm{tr}((\mathbf{A}^\top \mathbf{B})^{-1} \mathbf{A}^\top \mathbf{B})}^{d}.$$

Induction: Assume $2 \leq n-s \leq n-d$.

$$\begin{aligned}
\det(\mathbf{A}^\top \mathbf{B}) &\overset{\text{base case}}{=} \frac{1}{n-d} \sum_{i=1}^{n} \det(\mathbf{A}_{-i}^\top \mathbf{B}_{-i}) \\
&\overset{\text{ind. step}}{=} \frac{1}{n-d} \sum_{i=1}^{n} \sum_{S:|S|=s,\, i\notin S} \frac{1}{\binom{n-1-d}{s-d}} \det(\mathbf{A}_S^\top \mathbf{B}_S) \\
&= \underbrace{\frac{n-s}{n-d} \frac{1}{\binom{n-1-d}{s-d}}}_{\frac{1}{\binom{n-d}{s-d}}} \sum_{S:|S|=s} \det(\mathbf{A}_S^\top \mathbf{B}_S).
\end{aligned}$$

Note that for the induction step, S is a subset of size s from a set of size $n-1$ and we have the range restriction $1 \leq n-1-s \leq n-1-d$. Clearly, $n-1-s$ is one smaller than $n-s$. For the last equality, notice that each set $S : |S| = s$ is counted $n-s$ times in the double sum. ■

Appendix B. Alternate Proof of Theorem 5

We make use of the following derivative for determinants by Petersen and Pedersen (2012):

$$\text{For symmetric } \mathbf{C}: \quad \frac{\partial \det(\mathbf{X}^\top \mathbf{C} \mathbf{X})}{\partial \mathbf{X}} = 2 \det(\mathbf{X}^\top \mathbf{C} \mathbf{X}) \mathbf{C} \mathbf{X} (\mathbf{X}^\top \mathbf{C} \mathbf{X})^{-1}.$$

The proof begins with generalized Cauchy-Binet for size s volume sampling:

$$\sum_S \det(\mathbf{X}^\top \mathbf{I}_S \mathbf{X}) = \binom{n-d}{s-d} \det(\mathbf{X}^\top \mathbf{X}).$$

Now, we take a derivative w.r.t. $\mathbf{X}$ on both sides

$$\begin{aligned}
&\sum_S 2 \det(\mathbf{X}^\top \mathbf{I}_S \mathbf{X}) \ (\mathbf{I}_S \mathbf{X})^{+\top} = \binom{n-d}{s-d} \ 2 \det(\mathbf{X}^\top \mathbf{X}) \ \mathbf{X}^{+\top} \\
\iff \quad &\underbrace{\sum_S \frac{\det(\mathbf{X}^\top \mathbf{I}_S \mathbf{X})}{\binom{n-d}{s-d} \det(\mathbf{X}^\top \mathbf{X})} \ (\mathbf{I}_S \mathbf{X})^{+\top}}_{\mathbb{E}[(\mathbf{I}_S \mathbf{X})^{+\top}]} = \mathbf{X}^{+\top}.
\end{aligned}$$

Appendix C. Proof of Proposition 14

The main idea behind the proof is to construct variants of the input matrix $\mathbf{X}$ and relate their volumes. We use the following standard properties of the determinant:

Proposition 24 *For any matrix* $\mathbf{M}$, $\det(\mathbf{M}^\top\mathbf{M}) = \det(\widetilde{\mathbf{M}}^\top\widetilde{\mathbf{M}})$ *where* $\widetilde{\mathbf{M}}$ *is produced from* $\mathbf{M}$ *through the following operations:*

a) $\widetilde{\mathbf{M}}$ *equals* $\mathbf{M}$ *except that column* $\mathbf{m}_j$ *is replaced by* $\mathbf{m}_j + \alpha\mathbf{m}_i$*, where* $\mathbf{m}_i$ *is another column of* $\mathbf{M}$*;*

b) $\widetilde{\mathbf{M}}$ *equals* $\mathbf{M}$ *except that two rows are swapped.*

Recall that our goal is to prove the following formula for any $\mathbf{X}, \mathbf{y}$ and $i \in \{1..n\}$:

$$\det(\mathbf{X}^\top\mathbf{X})\left(L(\mathbf{w}^*(-i)) - L(\mathbf{w}^*)\right) = \left(\det(\mathbf{X}^\top\mathbf{X}) - \det(\mathbf{X}_{-i}^\top\mathbf{X}_{-i})\right)\ell_i(\mathbf{w}^*(-i)).$$

By Proposition 24b, we can assume w.l.o.g. that $i = n$, i.e. that the test row in Proposition 14 is the last row of $\mathbf{X}$. As discussed in Section 3.3, the columns of $\mathbf{X}$ are the feature vectors, denoted by $\mathbf{f}_1, \ldots, \mathbf{f}_d$. Moreover, the optimal prediction vector on the full dataset, $\widehat{\mathbf{y}} = \mathbf{X}\mathbf{w}^*$, is a projection of $\mathbf{y}$ onto the subspace spanned by the features/columns of $\mathbf{X}$, denoted as $\widehat{\mathbf{y}} = \mathbf{P}_\mathbf{X}\,\mathbf{y}$. Let us define a vector $\overline{\mathbf{y}}$ as

$$\overline{\mathbf{y}}^\top \stackrel{def}{=} (\text{——}\widehat{\mathbf{y}}_{-n}^\top\text{——}, y_n), \tag{18}$$

where $\widehat{\mathbf{y}}_{-n} \stackrel{def}{=} \mathbf{X}_{-n}\mathbf{w}^*(-n)$ is the optimal prediction vector for the training problem $(\mathbf{X}_{-n}, \mathbf{y}_{-n})$. Note, that if $\operatorname{rank}(\mathbf{X}_{-n}) < d$, then $\mathbf{w}^*(-n)$ may not be unique, but we can pick any weight vector as long as it minimizes the loss on the training set $\{1..n-1\}$. Next, we show the following lemma:

Lemma 25 *The best achievable loss for the problem* $(\mathbf{X}, \mathbf{y})$ *can be decomposed as follows:*

$$L(\mathbf{w}^*) = L(\mathbf{w}^*(-n)) - \ell_n(\mathbf{w}^*(-n)) + \|\overline{\mathbf{y}} - \widehat{\mathbf{y}}\|^2. \tag{19}$$

Proof First, we will show that $\overline{\mathbf{y}}$ is the projection of $\mathbf{y}$ onto the subspace spanned by all features and the unit vector $\mathbf{e}_n \in \mathbb{R}^n$ (where n corresponds to the test row). That is, we want to show that $\overline{\mathbf{y}} = \mathbf{P}_{(\mathbf{X},\mathbf{e}_n)}\,\mathbf{y}$. Denote $\widetilde{\mathbf{y}}$ as that projection. Observe that $\widetilde{y}_n = y_n$, because if this was not true, we could construct a vector $\widetilde{\mathbf{y}} + (y_n - \widetilde{y}_n)\mathbf{e}_n$ that is closer to $\mathbf{y}$ than $\widetilde{\mathbf{y}}$ and lies in $\operatorname{span}(\mathbf{X}, \mathbf{e}_n)$. Thus, the projection does not incur any loss along the n-th dimension and can be reduced to the remaining $n-1$ dimensions, which corresponds to solving the training problem $(\mathbf{X}_{-n}, \mathbf{y}_{-n})$. Using the definition of $\overline{\mathbf{y}}$ in (18), this shows that $\widetilde{\mathbf{y}} = \mathbf{P}_{(\mathbf{X},\mathbf{e}_n)}\,\mathbf{y}$ equals $\overline{\mathbf{y}}$.

Next, we will show that $\widehat{\mathbf{y}}$ is the projection of $\overline{\mathbf{y}}$ onto $\operatorname{span}(\mathbf{X})$, i.e. that $\mathbf{P}_\mathbf{X}\,\overline{\mathbf{y}} = \widehat{\mathbf{y}}$. By the linearity of projection, we have

$$\begin{aligned}\mathbf{P}_\mathbf{X}\,\overline{\mathbf{y}} &= \mathbf{P}_\mathbf{X}(\overline{\mathbf{y}} - \mathbf{y} + \mathbf{y}) \\ &= \mathbf{P}_\mathbf{X}(\overline{\mathbf{y}} - \mathbf{y}) + \mathbf{P}_\mathbf{X}\,\mathbf{y} \\ &= \mathbf{P}_\mathbf{X}(\overline{\mathbf{y}} - \mathbf{y}) + \widehat{\mathbf{y}}.\end{aligned}$$

We already showed that $\overline{\mathbf{y}} = \mathbf{P}_{(\mathbf{X},\mathbf{e}_n)}\,\mathbf{y}$. Therefore, the vector $\overline{\mathbf{y}} - \mathbf{y}$ is orthogonal to the column vectors of $\mathbf{X}$, and thus $\mathbf{P}_\mathbf{X}(\overline{\mathbf{y}} - \mathbf{y}) = 0$. This shows that $\mathbf{P}_\mathbf{X}\,\overline{\mathbf{y}} = \widehat{\mathbf{y}}$.

Finally, note that since $\overline{\mathbf{y}}$ is the projection of $\mathbf{y}$ onto $\operatorname{span}(\mathbf{X}, \mathbf{e}_n)$ and $\widehat{\mathbf{y}} \in \operatorname{span}(\mathbf{X}, \mathbf{e}_n)$, vector $\overline{\mathbf{y}} - \mathbf{y}$ is orthogonal to vector $\overline{\mathbf{y}} - \widehat{\mathbf{y}}$ and by the Pythagorean Theorem we have

$$\|\widehat{\mathbf{y}} - \mathbf{y}\|^2 = \|\overline{\mathbf{y}} - \mathbf{y}\|^2 + \|\overline{\mathbf{y}} - \widehat{\mathbf{y}}\|^2.$$

Using the definition of $\overline{\mathbf{y}}$ in (18), we have

$$\|\overline{\mathbf{y}} - \mathbf{y}\|^2 = \|\widehat{\mathbf{y}}_{-n} - \mathbf{y}_{-n}\|^2 = L(\mathbf{w}^*(-n)) - \ell_n(\mathbf{w}^*(-n)),$$

concluding the proof of the lemma. ■

Proof of Proposition 14 We construct a matrix $\overline{\mathbf{X}}$, adding vector $\overline{\mathbf{y}}$ as an extra column to matrix $\mathbf{X}$:

$$\overline{\mathbf{X}} \stackrel{def}{=} (\mathbf{X}\,,\,\overline{\mathbf{y}}) = \left(\begin{array}{c|c} \mathbf{X}_{-n} & \widehat{\mathbf{y}}_{-n} \\ \hline \mathbf{x}_n^\top & y_n \end{array}\right). \tag{20}$$

Applying "base $\times$ height" and Lemma 25, we compute the volume spanned by $\overline{\mathbf{X}}$:

$$\det(\overline{\mathbf{X}}^\top\overline{\mathbf{X}}) = \det(\mathbf{X}^\top\mathbf{X})\,\|\overline{\mathbf{y}} - \widehat{\mathbf{y}}\|^2 = \det(\mathbf{X}^\top\mathbf{X})\,(L(\mathbf{w}^*) - L(\mathbf{w}^*(-n)) + \ell_n(\mathbf{w}^*(-n))). \tag{21}$$

Next, we use the fact that volume is preserved under elementary column operations (Proposition 24a). Note, that prediction vector $\widehat{\mathbf{y}}_{-n}$ is a linear combination of the columns of $\mathbf{X}_{-n}$, with the coefficients given by $\mathbf{w}^*(-n)$. Therefore, looking at the block structure of $\overline{\mathbf{X}}$ (see (20)), we observe that performing column operations on the last column of $\overline{\mathbf{X}}$ with coefficients given by negative $\mathbf{w}^*(-n)$, we can zero out that column except for its last element:

$$\overline{\mathbf{y}} - \mathbf{X}\,\mathbf{w}^*(-n) = r\,\mathbf{e}_n,$$

where $r \stackrel{def}{=} y_n - \mathbf{x}_n^\top\mathbf{w}^*(-n)$ (see transformation (a) in (22)). Now, we consider two cases, depending on whether or not r equals zero. If $r \neq 0$, then we further transform the matrix by a second transformation (b), which zeros out the last row (the test row) using column operations. The entire sequence of operations, resulting in a matrix we call $\overline{\mathbf{X}}_0$, is shown below:

$$\overline{\mathbf{X}} = \left(\begin{array}{c|c} \mathbf{X}_{-n} & \widehat{\mathbf{y}}_{-n} \\ \hline \mathbf{x}_n^\top & y_n \end{array}\right) \stackrel{\text{(a)}}{\to} \left(\begin{array}{c|c} \mathbf{X}_{-n} & 0 \\ \hline \mathbf{x}_n^\top & r \end{array}\right) \stackrel{\text{(b)}}{\to} \left(\begin{array}{c|c} \mathbf{X}_{-n} & 0 \\ \hline 0 & r \end{array}\right) = \overline{\mathbf{X}}_0. \tag{22}$$

Note, that due to the block-diagonal structure of $\overline{\mathbf{X}}_0$, its volume can be easily described by the "base $\times$ height" formula:

$$\det(\overline{\mathbf{X}}_0^\top\overline{\mathbf{X}}_0) = \det(\mathbf{X}_{-n}^\top\mathbf{X}_{-n})\,r^2 = \det(\mathbf{X}_{-n}^\top\mathbf{X}_{-n})\,\ell_n(\mathbf{w}^*(-n)). \tag{23}$$

Since $\det(\overline{\mathbf{X}}^\top\overline{\mathbf{X}}) = \det(\overline{\mathbf{X}}_0^\top\overline{\mathbf{X}}_0)$, we can combine (21) and (23) to obtain the desired result.

Finally, if $r = 0$ we cannot perform transformation (b). However, in this case matrix $\overline{\mathbf{X}}$ has volume 0, and moreover, $\ell_n(\mathbf{w}^*(-n)) = r^2 = 0$, so once again we have

$$\det(\overline{\mathbf{X}}^\top\overline{\mathbf{X}}) = 0 = \det(\mathbf{X}_{-n}^\top\mathbf{X}_{-n})\,\ell_n(\mathbf{w}^*(-n)),$$

which concludes the proof of Proposition 14. ■

Abstract

A new class of non-homogeneous state-affine systems is introduced for use in reservoir computing. Sufficient conditions are identified that guarantee first, that the associated reservoir computers with linear readouts are causal, time-invariant, and satisfy the fading memory property and second, that a subset of this class is universal in the category of fading memory filters with stochastic almost surely uniformly bounded inputs. This means that any discrete-time filter that satisfies the fading memory property with random inputs of that type can be uniformly approximated by elements in the non-homogeneous state-affine family.

Keywords: reservoir computing, universality, state-affine systems, SAS, echo state networks, ESN, echo state affine systems, machine learning, fading memory property, linear training, stochastic signal treatment

1. Introduction

A ***reservoir computer (RC)*** (Jaeger (2010), Jaeger and Haas (2004), Maass et al. (2002), Maass (2011), Crook (2007), Verstraeten et al. (2007), Lukoševičius and Jaeger (2009)) or a ***RC system*** is a specific type of recurrent neural network determined by two maps, namely a ***reservoir*** $F : \mathbb{R}^N \times \mathbb{R}^n \longrightarrow \mathbb{R}^N$, $n, N \in \mathbb{N}$, and a ***readout*** map $h : \mathbb{R}^N \to \mathbb{R}$ that under certain hypotheses transform (or filter) an infinite discrete-time input $\mathbf{z} = (\ldots, \mathbf{z}_{-1}, \mathbf{z}_0, \mathbf{z}_1, \ldots) \in (\mathbb{R}^n)^{\mathbb{Z}}$ into an output signal $\mathbf{y} \in \mathbb{R}^{\mathbb{Z}}$ of the same type using the state-space transformation given by:

$$\begin{cases} \mathbf{x}_t = F(\mathbf{x}_{t-1}, \mathbf{z}_t), & (1.1) \\ y_t = h(\mathbf{x}_t), & (1.2) \end{cases}$$

where $t \in \mathbb{Z}$ and the dimension $N \in \mathbb{N}$ of the state vectors $\mathbf{x}_t \in \mathbb{R}^N$ will be referred to as the number of virtual ***neurons*** of the system. The expressions (1.1)-(1.2) determine a nonlinear state-space system and many of its dynamical properties (stability, controlability) have been studied for decades in the literature from that point of view.

This notion of reservoir computer (also known as ***liquid state machine***) is a significant generalization of the definitions found in the literature, where the readout map h is consistently taken to be linear. In many supervised machine learning applications, the reservoir map is randomly generated (see, for instance, the echo state networks in Jaeger (2010), Jaeger and Haas (2004)) and the memoryless readout is trained so that the output matches a given ***teaching signal*** that we denote by $\mathbf{d} \in \mathbb{R}^{\mathbb{Z}}$. Two important advantages of this approach lay on the fact that they reduce the training of a dynamic task to a static problem and, moreover, if the reservoir map is *rich* enough, good performances can be indeed attained with just linear readouts that are trained via a (eventually regularized) linear regression that minimizes the Euclidean distance between the output $\mathbf{y}$ and the teaching signal $\mathbf{d}$. These features circumvent well-known difficulties in the training of generic recurrent neural networks having to do with bifurcation phenomena (Doya (1992)) and that, despite recent progress in the regularization and training of deep RNN structures (see, for instance Graves et al. (2013), Pascanu et al. (2013), Zaremba et al. (2014), and references therein), render classical gradient descent methods non-convergent.

The interest for reservoir computing in both the machine learning and the signal processing communities has strongly increased in the last years. One of the main reasons for this fact is that some RC implementations are based on the computational capacities of certain non-neural dynamical systems (Crutchfield et al. (2010)), which opens the door to physical (optical or optoelectronic) realizations that have already been built using dedicated hardware (see, for instance, Jaeger et al. (2007), Atiya and Parlos (2000), Appeltant et al. (2011), Rodan and Tino (2011), Vandoorne et al. (2011), Larger et al. (2012), Paquot et al. (2012), Brunner et al. (2013), Vandoorne et al. (2014), Vinckier et al. (2015)) and that have shown unprecedented information processing speeds.

There are two central questions that need to be addressed when designing a machine learning paradigm, namely, the ***capacity*** and the ***universality*** problems. The capacity problem concerns generically the estimation of the error that is going to be committed in the execution of a specific task. In statistical learning and in the approximation theoretical treatment of static neural networks, this estimation has taken the form of generic bounds that incorporate various architecture parameters of the system like in Pisier (1981), Jones (1992), Barron (1993), Kurkova and Sanguineti (2005). In the specific context of reservoir computing, and in dynamic learning in general, one is interested in various notions of memory capacity that have been the subject of much research (Jaeger (2002), White et al. (2004), Ganguli et al. (2008), Hermans and Schrauwen (2010), Dambre et al. (2012), Grigoryeva et al. (2015), Couillet et al. (2016), Grigoryeva et al. (2016a)).

The universality problem consists in showing that the set of input/output functionals that can be generated with a specific architecture is dense in a sufficiently rich class, like the one containing, for example, all continuous or even all measurable functionals. For classical machine learning paradigms like neural networks, this question has given rise to well-known results that show that they can be considered as universal approximators in a static and deterministic setup (see, for instance, Kolmogorov (1956), Arnold (1957), Sprecher (1965, 1996, 1997), Cybenko (1989), Hornik et al. (1989), Rüschendorf and Thomsen (1998)).

There is no general recipe that allows one to conclude the universality of a given machine learning approach. The proof strategy depends much on the specific paradigm and, more importantly, on the nature of the inputs and the outputs. In the context of reservoir computing there are several situations for which universality has been established when the inputs/outputs are deterministic. There are two features that influence significantly the level of mathematical sophistication that is needed to conclude universality: first, the compactness of the time domain under consideration and second, if one works in continuous or discrete time. In the following paragraphs we briefly review the results that have already been obtained and, in passing, we present and put in context the contributions contained in this paper.

The compactness of the time domain is crucial because, as we will see later on, universality can be obtained as a consequence of various versions of the Stone-Weierstrass Theorem, which are invariably formulated for functions defined on a compact metric space. When the time domain is compact, this property is naturally inherited by the spaces relevant in the proofs. However, when it is not, it can still be secured using functionals that satisfy a condition introduced in Boyd and Chua (1985) known as the ***fading memory property***. The distinction between continuous and discrete time inputs is justified by the availability in the continuous setup of different tools coming from functional analysis that do not exist for discrete time.

Reservoir computing universality for compact time domains is a corollary of classical results in systems theory. Indeed, in the continuous time setup, it can be established for linear systems using polynomial readouts and for bilinear systems using linear readouts (see Fliess (1976), Sussmann (1976)). In the discrete-time setup, the situation is more convoluted when the readout is linear and required the introduction in Fliess and Normand-Cyrot (1980) of the so-called (homogeneous) ***state-affine systems (SAS)*** (see also Sontag (1979a,b)). The extension of these results to continuous non-compact time intervals was carried out in Boyd and Chua (1985) for fading memory filters using exponentially stable linear RCs with polynomial readouts and their bilinear counterparts with linear readouts (see also Maass and Sontag (2000) and Maass et al. (2002, 2004, 2007)). An extension to the non-compact discrete-time setup based on the Stone-Weierstrass theorem is, to our knowledge, not available in the literature and it is one of the main contributions of this paper. This problem has only been tackled from an internal approximation point of view, which consists in uniformly approximating the reservoir and readout maps in (1.1)-(1.2) in order to obtain an approximation of the resulting filter; this strategy has been introduced in Matthews (1992, 1993) for absolutely summable systems. The proofs in those works were unfortunately based on an invalid compactness assumption. Even though corrections were proposed in Perryman (1996) and in Stubberud and Perryman (1997b), this approach yields, in the best of cases, universality only within the reservoir filter category, while we aim at proving that statement in the much larger category of fading memory filters.

The paper is structured in three sections:

- All the notation and main definitions which are used later on in the paper are provided in Section 2. Important concepts like filters, reservoir filters, and the fading memory property are discussed.
- Section 3 contains two different universality results. The first one in Subsection 3.1 shows that the entire family of fading memory RCs itself is universal, as well as the much smaller one containing all the linear reservoirs with polynomial readouts, when certain spectral restrictions are imposed on the reservoir matrices (see below for details). The second universality result is contained in Subsection 3.2 and is one of the main contributions of the paper. Here we restrict ourselves to reservoir computers with linear readouts which are closer to the type of RCs used in applications. We introduce a non-homogeneous variant of the state-affine systems in Fliess and Normand-Cyrot (1980) and identify sufficient conditions that guarantee that the associated reservoir computers with linear readouts are causal, time-invariant, and satisfy the echo state and the fading memory properties. Finally, we state a universality result for a subset of this class which is shown to be universal in the category of fading memory filters with uniformly bounded inputs.
- These universality statements are generalized to the stochastic setup for almost surely uniformly bounded inputs in Section 4. In particular, it is shown that any discrete-time filter that has the fading memory property with almost surely uniformly bounded stochastic inputs can be uniformly approximated by elements in the non-homogeneous state-affine family.

Despite some preexisting work on the uniform approximation in probability of stochastic systems with finite memory (see Perryman (1996), Perryman and Stubberud (1997), Stubberud and Perryman (1997a)), the universality result in the stochastic setup is, to our knowledge, the first of its type in the literature and opens the door to new developments in the learning of stochastic processes and their obvious applications to forecasting (see Galtier et al. (2014)). In the deterministic setup, RC has been very successful (see, for instance, Jaeger and Haas (2004), Pathak et al. (2017, 2018)) in the learning of the attractors of various dynamical systems. This approach is used for forecasting by path continuation of synthetically learnt proxies, which has led to several orders of magnitude accuracy improvements with respect to most standard dynamical systems forecasting techniques based on Takens' Theorem (Takens (1981)). We expect that the results in this paper should lead to comparable improvements in the density forecasting of stochastic processes.

2. Notation, definitions, and preliminary discussions

Vector and matrix notations. Polynomials. A column vector is denoted by a bold lower case symbol like $\mathbf{r}$ and $\mathbf{r}^\top$ indicates its transpose. Given a vector $\mathbf{v}\in\mathbb{R}^n$, we denote its entries by v_i or v^i, depending on the context, with $i\in\{1,\ldots,n\}$; we also write $\mathbf{v}=(v_i)_{i\in\{1,\ldots,n\}}$. We denote by $\mathbb{M}_{n,m}$ the space of real $n\times m$ matrices with $m,n\in\mathbb{N}$. When $n=m$, we use the symbol $\mathbb{M}_n$ to refer to the space of square matrices of order n. $\mathbb{D}_n\subset\mathbb{M}_n$ is the set of diagonal matrices of order n and $\mathbb{D}$ denotes the set of diagonal matrices of any order. Given a vector $\mathbf{v}\in\mathbb{R}^n$, we denote by $\mathrm{diag}(\mathbf{v})$ the diagonal matrix in $\mathbb{M}_n$ with the elements of $\mathbf{v}$ as diagonal entries. $\mathbb{N}\mathrm{il}_n^k\subset\mathbb{M}_n$ is the set of nilpotent matrices in $\mathbb{M}_n$ of index $k\leq n$, that is, $A\in\mathbb{N}\mathrm{il}_n^k$ if and only if $A\in\mathbb{M}_n$, $A^k=0$, and $A^l\neq 0$ for any $l<k$. $\mathbb{N}\mathrm{il}$ denotes the set of nilpotent matrices of any order and any index. Given a matrix $A\in\mathbb{M}_{n,m}$, we denote its components by A_{ij} and we write $A=(A_{ij})$, with $i\in\{1,\ldots,n\}$, $j\in\{1,\ldots m\}$. Given a vector $\mathbf{v}\in\mathbb{R}^n$, the symbol $\|\mathbf{v}\|$ stands for its Euclidean norm. For any $A\in\mathbb{M}_{n,m}$, $\|A\|_2$ denotes its matrix norm induced by the Euclidean norms in $\mathbb{R}^m$ and $\mathbb{R}^n$, and satisfies that $\|A\|_2=\sigma_{\max}(A)$, with $\sigma_{\max}(A)$ the largest singular value of A (Example 5.6.6 in Horn and Johnson (2013)). $\|A\|_2$ is sometimes referred to as the spectral norm of A (Horn and Johnson (2013)).

Let V_1,V_2,W_1,W_2 be vector spaces. The symbols $V_1\oplus V_2$ and $V_1\otimes V_2$ denote the corresponding direct sum and tensor product vector spaces (Hungerford (1974)), respectively, of V_1 and V_2. Given any $\mathbf{v}_1\in V_1$ and $\mathbf{v}_2\in V_2$, the vectors $\mathbf{v}_1\oplus\mathbf{v}_2\in V_1\oplus V_2$ and $\mathbf{v}_1\otimes\mathbf{v}_2\in V_1\otimes V_2$ are the direct sum and the (pure) tensor product of $\mathbf{v}_1$ and $\mathbf{v}_2$, respectively. Given two linear maps $A_1:V_1\longrightarrow W_1$ and $A_2:V_2\longrightarrow W_2$, we denote by $A_1\oplus A_2:V_1\oplus V_2\longrightarrow W_1\oplus W_2$ and $A_1\otimes A_2:V_1\otimes V_2\longrightarrow W_1\otimes W_2$ the associated direct sum and tensor product maps, respectively, defined by $A_1\oplus A_2\left(\mathbf{v}_1\oplus\mathbf{v}_2\right):=A_1\left(\mathbf{v}_1\right)\oplus A_2\left(\mathbf{v}_2\right)$ and $A_1\otimes A_2\left(\mathbf{v}_1\otimes\mathbf{v}_2\right):=A_1\left(\mathbf{v}_1\right)\otimes A_2\left(\mathbf{v}_2\right)$. The matrix representation of $A_1\oplus A_2$ is obtained by concatenating in a block diagonal matrix the matrix representations of A_1 and A_2. As to the matrix representation of $A_1\otimes A_2$ it is obtained via the Kronecker product of the matrix representations of A_1 and A_2 (Horn and Johnson (2013)).

Given an element $\mathbf{z}\in\mathbb{R}^n$, we denote by $\mathbb{R}[\mathbf{z}]$ the real-valued multivariate polynomials on $\mathbf{z}$ with real coefficients. Analogously, $\mathrm{Pol}(\mathbb{R}^n,\mathbb{R})$ will denote the set of real-valued polynomials on $\mathbb{R}^n$. When $z\in\mathbb{R}$ and $m,n\in\mathbb{N}$, we define the set $\mathbb{M}_{m,n}[z]$ of $\mathbb{M}_{m,n}$-valued polynomials on z with coefficients in $\mathbb{M}_{m,n}$ as

$$\mathbb{M}_{m,n}[z]:=\{A_0+zA_1+z^2A_2+\cdots+z^rA_r\mid r\in\mathbb{N},A_0,A_1,A_2,\ldots,A_r\in\mathbb{M}_{m,n}\}. \tag{2.1}$$

$\mathbb{N}\mathrm{il}_n^k[z]\subset\mathbb{M}_n[z]$ is the set of nilpotent $\mathbb{M}_n$-valued polynomials on z of index k, that is, $p(z)\in\mathbb{N}\mathrm{il}_n^k[z]$ whenever k is the smallest natural number for which $p(z)^k=\mathbf{0}$, for all $z\in\mathbb{R}$. $\mathbb{N}\mathrm{il}[z]$ is the set of matrix-valued nilpotent polynomials on z of any order and any index.

Sequence spaces. $\mathbb{N}$ denotes the set of natural numbers with the zero element included. $\mathbb{Z}$ (respectively, $\mathbb{Z}_+$ and $\mathbb{Z}_-$) are the integers (respectively, the positive and the negative integers). The symbol $(\mathbb{R}^n)^{\mathbb{Z}}$ denotes the set of infinite real sequences of the form $\mathbf{z}=(\ldots,\mathbf{z}_{-1},\mathbf{z}_0,\mathbf{z}_1,\ldots)$, $\mathbf{z}_i\in\mathbb{R}^n$, $i\in\mathbb{Z}$; $(\mathbb{R}^n)^{\mathbb{Z}_-}$ and $(\mathbb{R}^n)^{\mathbb{Z}_+}$ are the subspaces consisting of, respectively, left and right infinite sequences:

$(\mathbb{R}^n)^{\mathbb{Z}_-} = \{\mathbf{z} = (\ldots, \mathbf{z}_{-2}, \mathbf{z}_{-1}, \mathbf{z}_0) \mid \mathbf{z}_i \in \mathbb{R}^n, i \in \mathbb{Z}_-\}$, $(\mathbb{R}^n)^{\mathbb{Z}_+} = \{\mathbf{z} = (\mathbf{z}_0, \mathbf{z}_1, \mathbf{z}_2, \ldots) \mid \mathbf{z}_i \in \mathbb{R}^n, i \in \mathbb{Z}_+\}$. Analogously, $(D_n)^{\mathbb{Z}}$, $(D_n)^{\mathbb{Z}_-}$, and $(D_n)^{\mathbb{Z}_+}$ stand for (semi-)infinite sequences with elements in the subset $D_n \subset \mathbb{R}^n$. In most cases we shall use in these infinite product spaces either the product topology (see Chapter 2 in Munkres (2014)) or the topology induced by the supremum norm $\|\mathbf{z}\|_\infty := \sup_{t\in\mathbb{Z}} \{\|\mathbf{z}_t\|\}$. The symbols $\ell^\infty(\mathbb{R}^n)$ and $\ell^\infty_\pm(\mathbb{R}^n)$ will be used to denote the Banach spaces formed by the elements in those infinite product spaces that have a finite supremum norm $\|\cdot\|_\infty$. The symbol $B_n(\mathbf{v}, M) \subset \mathbb{R}^n$, denotes the open ball of radius $M > 0$ and center $\mathbf{v} \in \mathbb{R}^n$ with respect to the Euclidean norm. The bars over sets stand for topological closures, in particular, $\overline{B_n(\mathbf{v}, M)}$ is the closed ball.

Filters. We will refer to the maps of the type $U : (D_n)^{\mathbb{Z}} \longrightarrow \mathbb{R}^{\mathbb{Z}}$ as ***filters*** or ***operators*** and to those like $H : (D_n)^{\mathbb{Z}} \longrightarrow \mathbb{R}$ (or $H : (D_n)^{\mathbb{Z}_\pm} \longrightarrow \mathbb{R}$) as ***functionals***. A filter U is called ***causal*** when for any two elements $\mathbf{z}, \mathbf{w} \in (D_n)^{\mathbb{Z}}$ that satisfy that $\mathbf{z}_\tau = \mathbf{w}_\tau$ for all $\tau \leq t$, for any given $t \in \mathbb{Z}$, we have that $U(\mathbf{z})_t = U(\mathbf{w})_t$. Let $U_\tau : (D_n)^{\mathbb{Z}} \longrightarrow (D_n)^{\mathbb{Z}}$, $\tau \in \mathbb{Z}$, be the time delay operator defined by $U_\tau(\mathbf{z})_t := \mathbf{z}_{t-\tau}$. The filter U is called ***time-invariant*** when it commutes with the time delay operator, that is, $U_\tau \circ U = U \circ U_\tau$ (in this expression, the two time delay operators U_τ have to be understood as defined in the appropriate sequence spaces). We recall (see, for instance, Boyd and Chua (1985)) that there is a bijection between causal time-invariant filters and functionals on $(D_n)^{\mathbb{Z}_-}$. Indeed, given a time-invariant filter U, we can associate to it a functional $H_U : (D_n)^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$ via the assignment $H_U(\mathbf{z}) := U(\mathbf{z}^e)_0$, where $\mathbf{z}^e \in (D_n)^{\mathbb{Z}}$ is an arbitrary extension of $\mathbf{z} \in (D_n)^{\mathbb{Z}_-}$ to $(D_n)^{\mathbb{Z}}$. Conversely, for any functional $H : (D_n)^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$, we can define a time-invariant causal filter $U_H : (D_n)^{\mathbb{Z}} \longrightarrow \mathbb{R}^{\mathbb{Z}}$ by $U_H(\mathbf{z})_t := H((\mathbb{P}_{\mathbb{Z}_-} \circ U_{-t})(\mathbf{z}))$, where U_{-t} is the $(-t)$-time delay operator and $\mathbb{P}_{\mathbb{Z}_-} : (D_n)^{\mathbb{Z}} \longrightarrow (D_n)^{\mathbb{Z}_-}$ is the natural projection. It is easy to verify that:

$$\begin{aligned} H_{U_H} &= H, \quad \text{for any functional} \quad H : (D_n)^{\mathbb{Z}_-} \longrightarrow \mathbb{R}, \\ U_{H_U} &= U, \quad \text{for any causal time-invariant filter} \quad U : (D_n)^{\mathbb{Z}} \longrightarrow \mathbb{R}^{\mathbb{Z}}. \end{aligned}$$

Additionally, let $H_1, H_2 : (D_n)^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$ and $\lambda \in \mathbb{R}$, then $U_{H_1+\lambda H_2}(\mathbf{z}) = U_{H_1}(\mathbf{z}) + \lambda U_{H_2}(\mathbf{z})$, for any $\mathbf{z} \in (\mathbb{R}^n)^{\mathbb{Z}}$. In the following pages and when the discussion will take place in a causal and time-invariant setup, we will use the term filter to denote exchangeably the associated functional and the filter itself.

Reservoir filters. Consider now the RC system determined by (1.1)–(1.2). It is worth mentioning that, unlike in those expressions, the reservoir and the readout maps are in general defined only on subsets $D_N, D'_N \subset \mathbb{R}^N$ and $D_n \subset \mathbb{R}^n$ and not on the entire Euclidean spaces $\mathbb{R}^N$ and $\mathbb{R}^n$, that is, $F : D_N \times D_n \longrightarrow D'_N$ and $h : D'_N \to \mathbb{R}$. Reservoir systems determine a filter when the following existence and uniqueness property holds: for each $\mathbf{z} \in (D_n)^{\mathbb{Z}}$ there exists a unique $\mathbf{x} \in (D_N)^{\mathbb{Z}}$ such that for each $t \in \mathbb{Z}$, the relation (1.1) holds. This condition is known in the literature as the ***echo state property*** (see Jaeger (2010), Yildiz et al. (2012)) and has deserved much attention in the context of echo state networks (Jaeger and Haas (2004), Buehner and Young (2006), Bai Zhang et al. (2012), Wainrib and Galtier (2016), Manjunath and Jaeger (2013)). The echo state property formulated for infinite (or semi-infinite) inputs guarantees that the output of the filter at any given time does not depend on initial conditions. We emphasize that this is a genuine condition that is not automatically satisfied by all RC systems.

We will denote by $U^F : (D_n)^{\mathbb{Z}} \longrightarrow (D_N)^{\mathbb{Z}}$ the filter determined by the reservoir map via (1.1), that is, $U^F(\mathbf{z})_t := \mathbf{x}_t \in D_N$, and by $U^F_h : (D_n)^{\mathbb{Z}} \longrightarrow \mathbb{R}^{\mathbb{Z}}$ the one determined by the entire reservoir system, that is, $U^F_h(\mathbf{z})_t := h\left(U^F(\mathbf{z})_t\right) = y_t$. U^F_h will be called the ***reservoir filter*** associated to the RC system (1.1)–(1.2). The filters U^F and U^F_h are causal by construction and it can also be shown that they are necessarily time-invariant (Grigoryeva and Ortega (2018)). We can hence associate to U^F_h a ***reservoir functional*** $H^F_h : (D_n)^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$ determined by $H^F_h := H_{U^F_h}$.

Weighted norms and the fading memory property (FMP). Let $w : \mathbb{N} \longrightarrow (0, 1]$ be a decreasing sequence with zero limit. We define the associated ***weighted norm*** $\|\cdot\|_w$ on $(\mathbb{R}^n)^{\mathbb{Z}_-}$ associated to the

weighting sequence w as the map:

$$\begin{array}{rccc} \|\cdot\|_w : & (\mathbb{R}^n)^{\mathbb{Z}_-} & \longrightarrow & \overline{\mathbb{R}^+} \\ & \mathbf{z} & \longmapsto & \|\mathbf{z}\|_w := \sup_{t\in\mathbb{Z}_-}\{\|\mathbf{z}_t w_{-t}\|\}, \end{array}$$

where $\|\cdot\|$ denotes the Euclidean norm in $\mathbb{R}^n$. It is worth noting that the space

$$\ell^\infty_w(\mathbb{R}^n) := \left\{\mathbf{z} \in (\mathbb{R}^n)^{\mathbb{Z}_-} \mid \|\mathbf{z}\|_w < \infty\right\}, \tag{2.2}$$

endowed with weighted norm $\|\cdot\|_w$ forms a Banach space (Grigoryeva and Ortega (2018)).

All along the paper, we will work with ***uniformly bounded*** families of sequences, both in the deterministic and the stochastic setups. The two main properties of these subspaces in relation with the weighted norms are spelled out in the following two lemmas.

Lemma 1 *Let $M > 0$ and let K_M be the set of elements in $(\mathbb{R}^n)^{\mathbb{Z}_-}$ which are uniformly bounded by M, that is,*

$$K_M := \left\{\mathbf{z} \in (\mathbb{R}^n)^{\mathbb{Z}_-} \mid \|\mathbf{z}_t\| \leq M \quad \text{for all} \quad t \in \mathbb{Z}_-\right\} = \overline{B_n(\mathbf{0}, M)}^{\mathbb{Z}_-}, \tag{2.3}$$

with $\overline{B_n(\mathbf{0}, M)} \subset \mathbb{R}^n$ the closed ball of radius M and center $\mathbf{0}$ in $\mathbb{R}^n$ with respect to the Euclidean norm. Then, for any weighting sequence w and $\mathbf{z} \in K_M$, we have that $\|\mathbf{z}\|_w < \infty$.

Additionally, let $\lambda, \rho \in (0, 1)$ and let $w, w^\rho, w^{1-\rho}$ be the weighting sequences given by $w_t := \lambda^t$, $w^\rho_t := \lambda^{\rho t}$, $w^{1-\rho}_t := \lambda^{(1-\rho)t}$, $t \in \mathbb{N}$. Then, the series $\sum_{t=0}^\infty \|\mathbf{z}_{-t}\| w_t$ is absolutely convergent and satisfies the inequalities:

$$\sum_{t=0}^\infty \|\mathbf{z}_{-t}\| w_t = \sum_{t=0}^\infty \|\mathbf{z}_{-t}\| \lambda^t \leq \|\mathbf{z}\|_{w^{1-\rho}} \frac{1}{1-\lambda^\rho}, \tag{2.4}$$

$$\sum_{t=0}^\infty \|\mathbf{z}_{-t}\| w_t = \sum_{t=0}^\infty \|\mathbf{z}_{-t}\| \lambda^t \leq \|\mathbf{z}\|_{w^\rho} \frac{1}{1-\lambda^{1-\rho}}. \tag{2.5}$$

The following result is a discrete-time version of Lemma 1 in Boyd and Chua (1985) that is easily obtained by noticing that in the discrete-time setup all functions are trivially continuous if we consider the discrete topology for their domains and, moreover, all families of functions are equicontinuous. A proof is given in the appendices for the sake of completeness.

Lemma 2 *Let $M > 0$ and let K_M be as in (2.3). Let $w : \mathbb{N} \longrightarrow (0, 1]$ be a weighting sequence. Then K_M is a compact topological space when endowed with the relative topology inherited from the norm topology in the Banach space $(\ell^\infty_w(\mathbb{R}^n), \|\cdot\|_w)$.*

Definition 3 *Let $D_n \subset \mathbb{R}^n$ and let $H_U : (D_n)^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$ be the functional associated to the causal and time-invariant filter $U : (D_n)^{\mathbb{Z}} \longrightarrow \mathbb{R}^{\mathbb{Z}}$. We say that U has the **fading memory property (FMP)** whenever there exists a weighting sequence $w : \mathbb{N} \longrightarrow (0, 1]$ such that the map $H_U : ((D_n)^{\mathbb{Z}_-}, \|\cdot\|_w) \longrightarrow \mathbb{R}$ is continuous. This means that for any $\mathbf{z} \in (D_n)^{\mathbb{Z}_-}$ and any $\epsilon > 0$, there exists a $\delta(\epsilon) > 0$ such that for any $\mathbf{s} \in (D_n)^{\mathbb{Z}_-}$ that satisfies that*

$$\|\mathbf{z} - \mathbf{s}\|_w = \sup_{t\in\mathbb{Z}_-}\{\|(\mathbf{z}_t - \mathbf{s}_t) w_{-t}\|\} < \delta(\epsilon), \quad \text{then} \quad |H_U(\mathbf{z}) - H_U(\mathbf{s})| < \epsilon.$$

*If the weighting sequence w is such that $w_t = \lambda^t$, for some $\lambda \in (0, 1)$ and all $t \in \mathbb{N}$, then U is said to have the λ-**exponential fading memory property**.*

Remark 4 This formulation of the fading memory property is due to Boyd and Chua (1985) and it is the key concept that allowed these authors to extend to non-compact time intervals the first filter universality results formulated in the classical works Fréchet (1910), Wiener (1958), Brilliant (1958), and George (1959), always under compactness assumptions on the input space and the time interval in which inputs are defined.

Remark 5 In the context of reservoir filters, the fading memory property is in some occasions related to the ***Lyapunov stability*** of the autonomous system associated to the reservoir map by setting the input sequence equal to zero. This connection has been made explicit, for example, for discrete-time nonlinear state-space models that are affine in their inputs, and have direct feed-through term in the output (Zang and Iglesias (2004)) or for time delay reservoirs (Grigoryeva et al. (2016b)).

Remark 6 Time-invariant fading memory filters always have the ***bounded input, bounded output (BIBO)*** property. Indeed, if for simplicity we consider functionals H_U that map the zero input to zero, that is $H_U(\mathbf{0}) = 0$, and we want bounded outputs such that $|H_U(\mathbf{z})| < k$, for a given constant $k > 0$, by Definition 3 it suffices to consider inputs $\mathbf{z} \in (\mathbb{R}^N)^{\mathbb{Z}_-}$ such that $\|\mathbf{z}\|_\infty := \sup_{t\in\mathbb{Z}_-}\{\|\mathbf{z}_t\|\} < \delta(k)$. Indeed, if H_U has the FMP with respect to a weighting sequence w, then $\|\mathbf{z}\|_w \leq \|\mathbf{z}\|_\infty < \delta(k)$ and hence $|H_U(\mathbf{z})| < k$, as required. Another important dynamical implication of the fading memory property is the ***uniqueness of steady states*** or, equivalently, the asymptotic independence of the dynamics on the initial conditions. See Theorem 6 in Boyd and Chua (1985) for details about this fact.

The following lemma, which will be used later on in the paper, spells out how the FMP depends on the weighting sequence used to define it.

Lemma 7 *Let $D_n \subset \mathbb{R}^n$ and let $H_U : (D_n)^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$ be the functional associated to the causal and time-invariant filter $U : (D_n)^{\mathbb{Z}} \longrightarrow (\mathbb{R})^{\mathbb{Z}}$. If H_U has the FMP with respect to a given weighting sequence w, then it also has it with respect to any other weighting sequence w' which satisfies*

$$\frac{w_t}{w'_t} < \lambda, \quad \textit{for a fixed} \quad \lambda > 0 \quad \textit{and for all} \quad t \in \mathbb{N}.$$

In particular, the thesis of the lemma holds when w' dominates w, that is when $\lambda = 1$.

It can be shown (see Grigoryeva and Ortega (2018)) that when in this lemma the set $(D_n)^{\mathbb{Z}_-}$ is made of uniformly bounded sequences, that is, $(D_n)^{\mathbb{Z}_-} = K_M$, with K_M as in (2.3) then, if a filter has the FMP with respect to a given weighting sequence, it necessarily has the same property with respect to any other weighting sequence.

3. Universality results in the deterministic setup

The goal of this section is identifying families of reservoir filters that are able to uniformly approximate any time-invariant, causal, and fading memory filter with deterministic inputs with any desired degree of accuracy. Such families of reservoir computers are said to be ***universal***.

The main mathematical tool that we use is the Stone-Weierstrass theorem for polynomial subalgebras of real-valued functions defined on compact metric spaces. This approach provides us with universal families of filters as long as we can prove that, roughly speaking, their elements form polynomial algebras using a product defined in the space of functionals. More specifically, if $D_n \subset \mathbb{R}^n$ and $H_{U_1}, H_{U_2} : (D_n)^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$ are the functionals associated to the causal and time-invariant filters $U_1, U_2 : (D_n)^{\mathbb{Z}} \longrightarrow \mathbb{R}^{\mathbb{Z}}$, we readily define their product $H_{U_1} \cdot H_{U_2} : (D_n)^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$ and linear combination $H_{U_1} + \lambda H_{U_2} : (D_n)^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$, $\lambda \in \mathbb{R}$, as

$$\left(H_{U_1} \cdot H_{U_2}\right)(\mathbf{z}) := H_{U_1}(\mathbf{z}) \cdot H_{U_2}(\mathbf{z}), \quad \left(H_{U_1} + \lambda H_{U_2}\right)(\mathbf{z}) := H_{U_1}(\mathbf{z}) + \lambda H_{U_2}(\mathbf{z}), \quad \mathbf{z} \in (D_n)^{\mathbb{Z}_-}. \tag{3.1}$$

This section contains two different universality results. The first one shows that polynomial algebras of filters generated by reservoir systems using the operations in (3.1) that have the fading memory property and that separate points, are able to approximate any fading memory filter. Two important consequences of this result are that the entire family of fading memory RCs itself is universal, as well as the one containing all the linear reservoirs with polynomial readouts, when certain spectral restrictions are imposed on the reservoir matrices (see below for details). In the second result, we restrict ourselves to reservoir computers with linear readouts and introduce the non-homogeneous state-affine family in order to be able to obtain a similar universality statement. The linearity restriction on the readouts makes this universality statement closer to the type of RCs used in applications and to the standard notion of reservoir system that one commonly finds in the literature (see Lukoševičius and Jaeger (2009)).

The first result can be seen as a discrete-time version of the one in Boyd and Chua (1985) for continuous-time filters, while the second one is an extension to infinite time intervals of the main approximation result in Fliess and Normand-Cyrot (1980), which was originally formulated for compact time intervals using homogeneous state-affine systems.

3.1 Universality for fading memory RCs with non-linear readouts

The following statement is a direct consequence of the compactness result in Lemma 2.3 and the Stone-Weierstrass, as formulated in Theorem 7.3.1 in Dieudonné (1969). See Appendix 6.4 for a detailed proof.

All along this subsection, we work with reservoir filters with uniformly bounded inputs in a set $K_M \subset (\mathbb{R}^n)^{\mathbb{Z}_-}$, as defined in (2.3). These filters are generated by reservoir systems $F : D_N \times \overline{B_n(\mathbf{0}, M)} \longrightarrow D_N$ and $h : D_N \to \mathbb{R}$, for some $n, N \in \mathbb{N}$, $M > 0$, and $D_N \subset \mathbb{R}^N$.

Theorem 8 *Let $K_M \subset (\mathbb{R}^n)^{\mathbb{Z}_-}$ be a subset of the type defined in (2.3), I an index set, and let*

$$\mathcal{R} := \{H^{F_i}_{h_i} : K_M \longrightarrow \mathbb{R} \mid h_i \in C^\infty(D_{N_i}), F_i : D_{N_i} \times \overline{B_n(\mathbf{0}, M)} \longrightarrow D_{N_i}, i \in I, N_i \in \mathbb{N}\} \tag{3.2}$$

be a set of reservoir filters defined on K_M that have the FMP with respect to a given weighted norm $\|\cdot\|_w$. Let $\mathcal{A}(\mathcal{R})$ be the polynomial algebra generated by $\mathcal{R}$, that is, the set formed by finite products and linear combinations of elements in $\mathcal{R}$ according to the operations defined in (3.1). If the algebra $\mathcal{A}(\mathcal{R})$ contains the constant functionals and separates the points in K_M, then any causal, time-invariant fading memory filter $H : K_M \longrightarrow \mathbb{R}$ can be uniformly approximated by elements in $\mathcal{A}(\mathcal{R})$, that is, $\mathcal{A}(\mathcal{R})$ is dense in the set $(C^0(K_M), \|\cdot\|_w)$ of real-valued continuous functions on $(K_M, \|\cdot\|_w)$. More explicitly, this implies that for any fading memory filter H and any $\epsilon > 0$, there exist a finite set of indices $\{i_1, \ldots, i_r\} \subset I$ and a polynomial $p : \mathbb{R}^r \longrightarrow \mathbb{R}$ such that

$$\|H - H^F_h\|_\infty := \sup_{\mathbf{z}\in K_M}\{|H(\mathbf{z}) - H^F_h(\mathbf{z})|\} < \epsilon \quad \textit{with} \quad h := p(h_{i_1}, \ldots, h_{i_r}) \quad \textit{and} \quad F := (F_{i_1}, \ldots, F_{i_r}).$$

An important fact is that *the polynomial algebra $\mathcal{A}(\mathcal{R})$ generated by a set formed by fading memory reservoir filters is made of fading memory reservoir filters.* Indeed, let $h_i \in C^\infty(D_{N_i})$, $F_i : D_{N_i} \times \overline{B_n(\mathbf{0}, M)} \longrightarrow D_{N_i}$, $i \in \{1, 2\}$, and $\lambda \in \mathbb{R}$. Then, the product $H^{F_1}_{h_1} \cdot H^{F_2}_{h_2}$ and the linear combination $H^{F_1}_{h_1} + \lambda H^{F_2}_{h_2}$ filters, as they were defined in (3.1), are such that

$$H^{F_1}_{h_1} \cdot H^{F_2}_{h_2} = H^F_h, \quad \text{with} \quad h := h_1 \cdot h_2 \in C^\infty(D_{N_1} \times D_{N_2}), \tag{3.3}$$

$$H^{F_1}_{h_1} + \lambda H^{F_2}_{h_2} = H^F_{h'}, \quad \text{with} \quad h' := h_1 + \lambda h_2 \in C^\infty(D_{N_1} \times D_{N_2}), \tag{3.4}$$

and where $F : (D_{N_1} \times D_{N_2}) \times \overline{B_n(\mathbf{0}, M)} \longrightarrow (D_{N_1} \times D_{N_2})$ is given by

$$F(((\mathbf{x}_1)_t, (\mathbf{x}_2)_t), \mathbf{z}_t) := (F_1((\mathbf{x}_1)_t, \mathbf{z}_t), F_2((\mathbf{x}_2)_t, \mathbf{z}_t)), \tag{3.5}$$

for any $((\mathbf{x}_1)_t,(\mathbf{x}_2)_t)\in D_{N_1}\times D_{N_2}$, $\mathbf{z}_t\in\overline{B_n(\mathbf{0},M)}$, and $t\in\mathbb{Z}_-$. We emphasize that the functionals H_h^F and $H_{h'}^F$ in (3.3) and (3.4) are well defined because if the reservoir maps F_1 and F_2 satisfy the echo state property then so does F. Indeed, if $\mathbf{x}_1\in(D_{N_1})^{\mathbb{Z}}$ and $\mathbf{x}_2\in(D_{N_2})^{\mathbb{Z}}$ are the solutions of the reservoir equation (1.1) for F_1 and F_2 associated to the input $\mathbf{z}\in K_M$, then so is $(\mathbf{x}_1,\mathbf{x}_2)\in(D_{N_1}\times D_{N_2})^{\mathbb{Z}}$, defined by $(\mathbf{x}_1,\mathbf{x}_2)_t:=((\mathbf{x}_1)_t,(\mathbf{x}_2)_t)$, for F in (3.5).

This observation has as a consequence that the set formed by *all* the RC systems that have the echo state property and the FMP with respect to a given weighted norm $\|\cdot\|_w$ form a polynomial algebra that contains the constant functions (they can be obtained by using as readouts constant elements in $C^\infty(D_{N_i})$) and separates points (take the trivial reservoir map $F(\mathbf{x},\mathbf{z})=\mathbf{z}$ and use the separation property of $C^\infty(D_{N_i})$ together with time-invariance). This remark and Theorem 8 yield the following corollary.

Corollary 9 *Let $K_M\subset(\mathbb{R}^n)^{\mathbb{Z}_-}$ be a subset as defined in* (2.3) *and let*

$$\mathcal{R}_w:=\{H_h^F:K_M\longrightarrow\mathbb{R}\mid h\in C^\infty(D_N),F:D_N\times\overline{B_n(\mathbf{0},M)}\longrightarrow D_N,N\in\mathbb{N}\}\tag{3.6}$$

be the set of all reservoir filters with uniformly bounded inputs in K_M and that have the FMP with respect to a given weighted norm $\|\cdot\|_w$. Then $\mathcal{R}_w$ is universal, that is, it is dense in the set $(C^0(K_M),\|\cdot\|_w)$ of real-valued continuous functions on $(K_M,\|\cdot\|_w)$.

Remark 10 The stability of reservoir filters under products and linear combinations in (3.3)-(3.4) is a feature that allows us, in Corollary 9 and in some of the results that follow later on, to identify families of reservoir filters that are able to approximate any fading memory filter. This fact is a requirement for the application of the Stone-Weierstrass theorem but does not mean that we have to carry those operations out in the construction of approximating filters, which would indeed be difficult to implement in specific applications.

According to the previous corollary, reservoir filters that have the FMP are able to approximate any time-invariant fading memory filter. We now show that actually a much smaller family of reservoirs suffices to do that, namely, certain classes of linear reservoirs with polynomial readouts. Consider the RC system determined by the expressions

$$\begin{cases}\mathbf{x}_t=A\mathbf{x}_{t-1}+\mathbf{c}\mathbf{z}_t,\quad A\in\mathbb{M}_N,\mathbf{c}\in\mathbb{M}_{N,n},&(3.7)\\ y_t=h(\mathbf{x}_t),\quad h\in\mathbb{R}[\mathbf{x}].&(3.8)\end{cases}$$

If this system has a reservoir filter associated (the next result provides a sufficient condition for this to happen) we denote by $H_h^{A,\mathbf{c}}:K_M\longrightarrow\mathbb{R}$ the associated functional and we refer to it as the ***linear reservoir functional*** determined by $A,\mathbf{c}$, and the polynomial h. These filters exhibit the following universality property that is proved in Appendix 6.5.

Corollary 11 *Let $K_M\subset(\mathbb{R}^n)^{\mathbb{Z}_-}$ be a subset of the type defined in* (2.3) *and let $0<\epsilon<1$. Consider the set $\mathcal{L}_\epsilon$ formed by all the linear reservoir systems as in* (3.7)-(3.8) *determined by matrices $A\in\mathbb{M}_N$ such that $\sigma_{\max}(A)<1-\epsilon$. Then, the elements in $\mathcal{L}_\epsilon$ generate λ_ρ-exponential fading memory reservoir functionals, with $\lambda_\rho:=(1-\epsilon)^\rho$, for any $\rho\in(0,1)$. Equivalently, $\mathcal{L}_\epsilon\subset\mathcal{R}_{w^\rho}$, with $w_t^\rho:=\lambda_\rho^t$, and $\mathcal{R}_{w^\rho}$ as in* (3.6)*. These functionals can be explicitly written as:*

$$H_h^{A,\mathbf{c}}(\mathbf{z})=h\left(\sum_{i=0}^{\infty}A^i\mathbf{c}\mathbf{z}_{-i}\right),\quad \textit{for any}\quad \mathbf{z}\in K_M.\tag{3.9}$$

This family is dense in $(C^0(K_M),\|\cdot\|_{w^\rho})$.

The same universality result can be stated for the following two smaller subfamilies of $\mathcal{L}_\epsilon$:

(i) *The family $\mathcal{DL}_\epsilon\subset\mathcal{L}_\epsilon$ formed by the linear reservoir systems in $\mathcal{L}_\epsilon$ determined by diagonal matrices $A\in\mathbb{D}$ such that $\sigma_{\max}(A)<1-\epsilon$.*

(ii) *The family $\mathcal{NL}\subset\mathcal{L}_\epsilon$ formed by the linear reservoir systems determined by nilpotent matrices $A\in\mathbb{N}\text{il}$.*

Remark 12 The elements in the family $\mathcal{NL}$ belong automatically to $\mathcal{L}_\epsilon$ because the eigenvalues of a nilpotent matrix are always zero. This implies that if a linear reservoir system is determined by a nilpotent matrix $A\in\mathbb{N}\text{il}_N^k$ of index $k\leq N$, then the reservoir functional $H_h^{A,\mathbf{c}}$ is automatically well-defined and given by a finite version of (3.9), that is,

$$H_h^{A,\mathbf{c}}(\mathbf{z})=h\left(\sum_{i=0}^{k-1}A^i\mathbf{c}\mathbf{z}_{-i}\right),\quad \text{for any}\quad \mathbf{z}\in K_M.\tag{3.10}$$

3.2 State-affine systems and universality for fading memory RCs with linear readouts

As it was explained in the introduction, the standard notion of reservoir computing that one finds in the literature concerns architectures with linear readouts. It is is particularly convenient to work with RCs that have this feature in machine learning applications since in that case the training reduces to solving a linear regression problem. That makes training feasible when there is need for a high number of neurons, as it happens in many cases. This point makes relevant the identification of families of reservoirs that are universal when the readout is restricted to be linear, which is the subject of this subsection. In order to simplify the presentation, we restrict ourselves in this case to one-dimensional input signals, that is, all along this section we set $n=1$. The extension to the general case is straightforward, even though more convoluted to write down (see Remark 22).

Definition 13 *Let $N\in\mathbb{N}$, $\mathbf{W}\in\mathbb{R}^N$, and let $p(z)\in\mathbb{M}_N[z]$ and $q(z)\in\mathbb{M}_{N,1}[z]$ be two polynomials on the variable z with matrix coefficients, as they were introduced in* (2.1)*. The* ***non-homogeneous state-affine system (SAS)*** *associated to p,q and $\mathbf{W}$ is the reservoir system determined by the state-space transformation:*

$$\begin{cases}\mathbf{x}_t=p(z_t)\mathbf{x}_{t-1}+q(z_t),&(3.11)\\ y_t=\mathbf{W}^\top\mathbf{x}_t.&(3.12)\end{cases}$$

Our next result spells out a sufficient condition that guarantees that the SAS reservoir system (3.11)-(3.12) has the echo state property. Moreover, it provides an explicit expression for the unique causal and time-invariant solution associated to a given input.

Proposition 14 *Consider a non-homogeneous state-affine system as in* (3.11)-(3.12) *determined by polynomials p,q, and a vector $\mathbf{W}$, with inputs defined on $I^{\mathbb{Z}}$, $I:=[-1,1]$. Assume that*

$$K_1:=\max_{z\in I}\|p(z)\|_2=\max_{z\in I}\sigma_{\max}(p(z))<1.\tag{3.13}$$

Then, the reservoir system (3.11)-(3.12) *has the echo state property and for each input $\mathbf{z}\in I^{\mathbb{Z}}$ it has a unique causal and time-invariant solution given by*

$$\begin{cases}\mathbf{x}_t=\displaystyle\sum_{j=0}^{\infty}\left(\prod_{k=0}^{j-1}p(z_{t-k})\right)q(z_{t-j}),&(3.14)\\ y_t=\mathbf{W}^\top\mathbf{x}_t,&(3.15)\end{cases}$$

where

$$\prod_{k=0}^{j-1} p(z_{t-k}) := p(z_t)\cdot p(z_{t-1})\cdots p(z_{t-j+1}).$$

Let now $K_2 := \max_{z\in I}\|q(z)\|_2$. *Then,*

$$\|\mathbf{x}_t\| \leq \frac{K_2}{1-K_1}, \quad \textit{for all} \quad t\in\mathbb{Z}. \tag{3.16}$$

We will denote by $U^{p,q}_{\mathbf{W}} : I^{\mathbb{Z}} \longrightarrow \mathbb{R}^{\mathbb{Z}}$ *and* $H^{p,q}_{\mathbf{W}} : I^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$ *the corresponding SAS reservoir filter and SAS functional, respectively.*

The next result presents two alternative conditions that imply the hypothesis $\max_{z\in I}\|p(z)\|_2 < 1$ in the previous proposition and that are easier to verify in practice.

Lemma 15 *Let* $p(z)\in\mathbb{M}_N[z]$ *be the polynomial given by*

$$p(z) := A_0 + zA_1 + z^2A_2 + \cdots + z^{n_1}A_{n_1}, \quad n_1\in\mathbb{N}.$$

Suppose that $z\in I$ *and consider the following three conditions:*

(i) *There exists a constant* $0<\lambda<1$, *such that* $\|A_i\|_2 = \sigma_{\max}(A_i) < \lambda$, *for any* $i\in\{0,1,\ldots,n_1\}$, *and that at the same time satisfies that* $\lambda(n_1+1)<1$.

(ii) $B_p := \|A_0\|_2 + \|A_1\|_2 + \cdots + \|A_{n_1}\|_2 < 1$.

(iii) $M_p := \max_{z\in I}\|p(z)\|_2 < 1$.

Then, condition **(i)** *implies* **(ii)** *and condition* **(ii)** *implies* **(iii)**.

We emphasize that since Proposition 14 was proved using condition **(iii)** in the previous lemma then, any of the three conditions in that statement imply the echo state property for (3.14)-(3.15) and the time-invariance of the corresponding solutions. The next result shows that the same situation holds in relation with the fading memory property.

Proposition 16 *Consider a non-homogeneous state-affine system as in* (3.11)-(3.12) *determined by polynomials* p,q, *and a vector* $\mathbf{W}$, *with inputs defined on* $I^{\mathbb{Z}}$, $I:=[-1,1]$. *If the polynomial* p *satisfies any of the three conditions in Lemma 15 then the corresponding reservoir filter has the fading memory property. More specifically, if* p *satisfies condition* **(i)** *in Lemma 15, then* $H^{p,q}_{\mathbf{W}} : (I^{\mathbb{Z}_-}, \|\cdot\|_{w^\rho}) \longrightarrow \mathbb{R}$ *is continuous with* $w^\rho_t := (n_1+1)^{\rho t}\lambda^{\rho t}$ *and* $\rho\in(0,1)$ *arbitrary. The same conclusion holds for conditions* **(ii)** *and* **(iii)** *with* $w^\rho_t := B_p^{\rho t}$ *and* $w^\rho_t := M_p^{\rho t}$, *respectively.*

The importance of SAS in relation to the universality problem has to do with the fact that they form a polynomial algebra which allows us, under certain conditions, to use the Stone-Weierstrass theorem to prove a density statement. Before we show that, we observe that for any two polynomials $p_1(z)\in\mathbb{M}_{N_1,M_1}[z]$ and $p_2(z)\in\mathbb{M}_{N_2,M_2}[z]$ given by

$$p_1(z) := A^1_0 + zA^1_1 + z^2A^1_2 + \cdots + z^{n_1}A^1_{n_1}, \tag{3.17}$$
$$p_2(z) := A^2_0 + zA^2_1 + z^2A^2_2 + \cdots + z^{n_2}A^2_{n_2}, \tag{3.18}$$

with $n_1,n_2\in\mathbb{N}$, their direct sum and their tensor product are also polynomials in z with matrix coefficients. More explicitly, $p_1\oplus p_2(z)\in\mathbb{M}_{N_1+N_2,M_1+M_2}[z]$ and is written as

$$p_1\oplus p_2(z) = A^1_0\oplus A^2_0 + zA^1_1\oplus A^2_1 + z^2A^1_2\oplus A^2_2 + \cdots + z^{n_2}A^1_{n_2}\oplus A^2_{n_2} + z^{n_2+1}A^1_{n_2+1}\oplus\mathbf{0} + \cdots + z^{n_1}A^1_{n_1}\oplus\mathbf{0}, \tag{3.19}$$

where we assumed that $n_2\leq n_1$. Analogously, their tensor product $p_1\otimes p_2(z)\in\mathbb{M}_{N_1\cdot N_2,M_1\cdot M_2}[z]$ and is written as

$$p_1\otimes p_2(z) = \sum_{i=0}^{n_1}\sum_{j=0}^{n_2} z^{i+j}A^1_i\otimes A^2_j. \tag{3.20}$$

The next result shows that the products and the linear combinations of SAS reservoir functionals are SAS reservoir functionals. Additionally, it makes explicit the polynomials that determine the corresponding SAS reservoir systems.

Proposition 17 *Let* $H^{p_1,q_1}_{\mathbf{W}_1}, H^{p_2,q_2}_{\mathbf{W}_2} : I^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$ *be two SAS reservoir functionals associated to two corresponding time-invariant SAS reservoir systems. Assume that the two polynomials with matrix coefficients* $p_1(z)\in\mathbb{M}_{N_1}[z]$ *and* $p_2(z)\in\mathbb{M}_{N_2}[z]$ *satisfy that* $\|p_1(z)\|_2 < 1-\epsilon$ *and* $\|p_2(z)\|_2 < 1-\epsilon$ *for all* $z\in I := [-1,1]$ *and a given* $0<\epsilon<1$. *Then, with the notation introduced in the expressions* (3.19) *and* (3.20), *we have that:*

(i) *For any* $\lambda\in\mathbb{R}$, *the linear combination of the SAS reservoir functionals* $H^{p_1,q_1}_{\mathbf{W}_1} + \lambda H^{p_2,q_2}_{\mathbf{W}_2}$ *is a SAS reservoir functional and:*

$$H^{p_1,q_1}_{\mathbf{W}_1} + \lambda H^{p_2,q_2}_{\mathbf{W}_2} = H^{p_1\oplus p_2, q_1\oplus q_2}_{\mathbf{W}_1\oplus\lambda\mathbf{W}_2}. \tag{3.21}$$

(ii) *The product of the SAS reservoir functionals* $H^{p_1,q_1}_{\mathbf{W}_1}\cdot H^{p_2,q_2}_{\mathbf{W}_2}$ *is a SAS reservoir functional and:*

$$H^{p_1,q_1}_{\mathbf{W}_1}\cdot H^{p_2,q_2}_{\mathbf{W}_2} = H^{p,q_1\oplus q_2\oplus(q_1\otimes q_2)}_{\mathbf{0}\oplus\mathbf{0}\oplus(\mathbf{W}_1\otimes\mathbf{W}_2)}, \tag{3.22}$$

where $p(z)\in\mathbb{M}_{N_{12}}[z]$, $N_{12} := N_1+N_2+N_1\cdot N_2$, *is the polynomial with matrix coefficients in* $\mathbb{M}_{N_{12}}$ *whose block-matrix expression for the three summands in* $\mathbb{R}^{N_1}\oplus\mathbb{R}^{N_2}\oplus\left(\mathbb{R}^{N_1}\otimes\mathbb{R}^{N_2}\right)$ *is:*

$$p(z) := \begin{pmatrix} p_1(z) & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & p_2(z) & \mathbf{0} \\ p_1\otimes q_2(z) & q_1\otimes p_2(z) & p_1\otimes p_2(z) \end{pmatrix}. \tag{3.23}$$

The expression $p_1\otimes p_2(z)\in\mathbb{M}_{N_1\cdot N_2}[z]$ *denotes the element defined in* (3.20). *The symbol* $p_1\otimes q_2(z)$ *(respectively,* $q_1\otimes p_2(z)$*) denotes the matrix of the linear map from* $\mathbb{R}^{N_1}$ *(respectively,* $\mathbb{R}^{N_2}$*) to* $\mathbb{R}^{N_1}\otimes\mathbb{R}^{N_2}$ *that associates to any* $\mathbf{v}_1\in\mathbb{R}^{N_1}$ *the element* $(p_1(z)\mathbf{v}_1)\otimes q_2(z)$ *(respectively,* $q_1(z)\otimes(p_2(z)\mathbf{v}_2)$, *with* $\mathbf{v}_2\in\mathbb{R}^{N_2}$*). When all the polynomials in* (3.23) *are written in terms of monomials using the conventions that we just mentioned and we factor out the different powers of the variable* z, *we obtain a polynomial with matrix coefficients in* $\mathbb{M}_{N_{12}}$ *and with degree* $\deg(p)$ *equal to*

$$\deg(p) = \max\left\{\deg(p_1)\cdot\deg(q_2), \deg(q_1)\cdot\deg(p_2), \deg(p_1)\cdot\deg(p_2)\right\}.$$

The equalities (3.21) *and* (3.22) *show that the SAS family forms a polynomial algebra.*

Remark 18 Notice that the linear reservoir equation (3.7) is a particular case of the SAS reservoir equation (3.11) that is obtained by taking for p and q polynomials of degree zero and one, respectively. Regarding that specific case, Proposition 17 shows that linear reservoirs with linear readouts do not form a polynomial algebra. Indeed, as it can be seen in (3.22), the product of two SAS filters involves the tensor product $q_1\otimes q_2$ which, when q_1 and q_2 come from a linear filter, it has degree two and it is hence not compatible with a linear reservoir filter.

Theorem 19 (Universality of SAS reservoir computers) *Let* $I^{\mathbb{Z}_-}\subset\mathbb{R}^{\mathbb{Z}_-}$ *be the subset of real uniformly bounded sequences in* $I := [-1,1]$ *as in* (2.3), *that is,*

$$I^{\mathbb{Z}_-} := \{\mathbf{z}\in\mathbb{R}^{\mathbb{Z}_-} \mid z_t\in[-1,1], \textit{ for all } \quad t\leq 0\},$$

and let $\mathcal{S}_\epsilon$ be the family of functionals $H^{p,q}_{\mathbf{W}} : I^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$ induced by the state-affine systems defined in (3.11)-(3.12) *that satisfy that $M_p := \max_{z\in I} \|p(z)\|_2 < 1-\epsilon$ and $M_q := \max_{z\in I} \|q(z)\|_2 < 1-\epsilon$. The family $\mathcal{S}_\epsilon$ forms a polynomial subalgebra of $\mathcal{R}_{w^\rho}$ (as defined in* (3.6)*) with $w^\rho_t := (1-\epsilon)^{\rho t}$ and $\rho \in (0,1)$ arbitrary, made of fading memory reservoir filters that contains the constant functions and separates points. The subfamily $\mathcal{S}_\epsilon$ is hence dense in the set $(C^0(I^{\mathbb{Z}_-}), \|\cdot\|_{w^\rho})$ of real-valued continuous functions on $(I^{\mathbb{Z}_-}, \|\cdot\|_{w^\rho})$.*

This statement implies that any causal, time-invariant fading memory filter $H : I^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$ can be uniformly approximated by elements in $\mathcal{S}_\epsilon$. More specifically, for any fading memory filter H and any $\epsilon > 0$, there exist a natural number $N \in \mathbb{N}$, polynomials $p(z) \in \mathbb{M}_N[z], q(z) \in \mathbb{M}_{N,1}[z]$ with $M_p, M_q < 1-\epsilon$, and a vector $\mathbf{W} \in \mathbb{R}^N$ such that

$$\|H - H^{p,q}_{\mathbf{W}}\|_\infty := \sup_{z\in I^{\mathbb{Z}_-}} \{|H(z) - H^{p,q}_{\mathbf{W}}(z)|\} < \epsilon.$$

The same universality result can be stated for the smaller subfamily $\mathcal{NS}_\epsilon \subset \mathcal{S}_\epsilon$ formed by SAS reservoir systems determined by nilpotent polynomials $p(z) \in \mathbb{N}\mathrm{il}[z]$.

Remark 20 As it is stated in Theorem 19, it is the condition **(iii)** in Lemma 15 that yields a universal family of SAS fading memory reservoirs. As it can deduced from its proof (available in the Appendix 6.10), the families determined by conditions **(i)** or **(ii)** in that lemma contain SAS fading memory reservoirs but they do not form a polynomial algebra. In such cases, and according to Theorem 8, it is the algebras generated by them and not the families themselves that are universal.

Remark 21 A continuous-time analog of the universality result that we just proved can be obtained using the bilinear systems considered in Section 5.3 of Boyd and Chua (1985). In discrete time, but only when the number of time steps is finite, this universal approximation property is exhibited by homogeneous state-affine systems, that is, by setting $q(z) = \mathbf{0}$ in (3.11)-(3.12) (see Fliess and Normand-Cyrot (1980)).

Remark 22 Generalization to multidimensional signals. When the input signal is defined in $I_n^{\mathbb{Z}}$, with $I_n := [-1,1]^n$, a SAS family with the same universality properties can be defined by replacing the polynomials p and q in Definition 13, by polynomials of degree r and s of the form:

$$\begin{aligned} p(\mathbf{z}) &= \sum_{\substack{i_1,\ldots,i_n\in\{0,\ldots,r\}\\ i_1+\cdots+i_n\leq r}} z_1^{i_1}\cdots z_n^{i_n} A_{i_1,\ldots,i_n}, \quad A_{i_1,\ldots,i_n} \in \mathbb{M}_N, \quad \mathbf{z}\in I_n \\ q(\mathbf{z}) &= \sum_{\substack{i_1,\ldots,i_n\in\{0,\ldots,s\}\\ i_1+\cdots+i_n\leq s}} z_1^{i_1}\cdots z_n^{i_n} B_{i_1,\ldots,i_n}, \quad B_{i_1,\ldots,i_n} \in \mathbb{M}_{N,1}, \quad \mathbf{z}\in I_n. \end{aligned}$$

Remark 23 SAS with trigonometric polynomials. An analogous construction can be carried out using trigonometric polynomials of the type:

$$\begin{aligned} p(\mathbf{z}) &= \sum_{\substack{i_1,\ldots,i_n\in\{0,\ldots,r\}\\ i_1+\cdots+i_n\leq r}} \cos\left(i_1\cdot z_1+\cdots+i_n\cdot z_n\right) A_{i_1,\ldots,i_n}, \quad A_{i_1,\ldots,i_n} \in \mathbb{M}_N, \quad \mathbf{z}\in I_n \\ q(\mathbf{z}) &= \sum_{\substack{i_1,\ldots,i_n\in\{0,\ldots,s\}\\ i_1+\cdots+i_n\leq s}} \cos\left(i_1\cdot z_1+\cdots+i_n\cdot z_n\right) B_{i_1,\ldots,i_n}, \quad B_{i_1,\ldots,i_n} \in \mathbb{M}_{N,1}, \quad \mathbf{z}\in I_n. \end{aligned}$$

In this case, it is easy to establish that the resulting SAS family forms a polynomial algebra by invoking Proposition 17 and by reformulating the expressions (3.19) and (3.20) using the trigonometric identity

$$\cos(\theta)\cos(\phi) = \frac{1}{2}\left(\cos(\theta-\phi)+\cos(\theta+\phi)\right).$$

Additionally, the corresponding SAS family includes the linear family and hence the point separation property can be established as in the proof of Theorem 19 in the Appendix 6.10.

4. Reservoir universality results in the stochastic setup

This section extends the previously stated deterministic universality results to a setup in which the reservoir inputs and outputs are stochastic, that is, the reservoir is not driven anymore by infinite sequences but by discrete-time stochastic processes. We emphasize that we restrict our discussion to reservoirs that are deterministic and hence the only source of randomness in the systems considered is the stochastic nature of the input.

The results that follow are mainly based on the observation that if we adopt a uniform approximation criterion and we assume that the random inputs satisfy almost surely the uniform boundedness that we used as hypothesis in Section 3, then important features like the fading memory property or universality are naturally inherited in the stochastic setup from the deterministic case. This fact is what we call the ***deterministic-stochastic transfer principle*** and it is contained in the statement of Theorem 27 below. In particular, this result can be easily applied to show that all the universal families with deterministic inputs introduced in Section 3 are also universal in the stochastic setup when the input processes considered produce paths that, up to a set of measure zero, are uniformly bounded.

The stochastic setup. All along this section we work on a probability space $(\Omega, \mathcal{A}, \mathbb{P})$. If a condition defined on this probability space holds everywhere except for a set with zero measure, we will say that the relation is true ***almost surely***. Let $\mathbf{X} : \Omega \longrightarrow B$ be a random variable with $(B, \|\cdot\|_B)$ a normed space endowed with a σ-algebra (for example, but not necessarily, its Borel σ-algebra). Let

$$\|\mathbf{X}\|_{L^\infty} := \operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{X}(\omega)\|_B\} = \inf\left\{\rho\in\overline{\mathbb{R}^+} \mid \|\mathbf{X}\|_B \leq \rho \quad \text{almost surely}\right\}, \tag{4.1}$$

We denote by $L^\infty(\Omega, B)$ the classes of B-valued almost surely equal random variables whose norms have a finite essential supremum or that, equivalently, have almost surely bounded norms, that is,

$$L^\infty(\Omega, B) := S_B/\sim_B, \tag{4.2}$$

where

$$S_B := \{\mathbf{X} : \Omega \longrightarrow B \ \text{ random variable} \mid \|\mathbf{X}\|_{L^\infty} < \infty\}, \tag{4.3}$$

and $\sim_B$ is the equivalence relation defined on S_B as follows: two random variables $\mathbf{Y}$ and $\mathbf{Z}$ with finite $\|\cdot\|_{L^\infty}$ norm are $\sim_B$-equivalent if and only if $\mathbb{P}(\{\omega\in\Omega : \mathbf{Y}(\omega) \neq \mathbf{Z}(\omega)\}) = 0$. As it is customary in the literature, we will not make a distinction in what follows between the elements in S_B and the classes in the quotient $L^\infty(\Omega, B)$. Using this identification we recall, for example, that $L^\infty(\Omega, B)$ is a vector space with the operations

$$(\mathbf{X} + \lambda\mathbf{Y})(\omega) := \mathbf{X}(\omega) + \lambda\mathbf{Y}(\omega) \tag{4.4}$$

for any $\mathbf{X}, \mathbf{Y} \in L^\infty(\Omega, B)$, $\lambda \in \mathbb{R}$, $\omega \in \Omega$. Moreover, $(L^\infty(\Omega, B), \|\cdot\|_{L^\infty})$ is a normed space. We emphasize that $L^\infty(\Omega, B)$ is in general not a Banach space (see pages 42 and 46 in Ledoux and Talagrand (1991)). It can be shown that whenever B is finite dimensional or, more generally, a separable Banach space, then the space $L^\infty(\Omega, B)$ is also a Banach space (Pisier (2016)).

Given an element $\mathbf{X} \in L^\infty(\Omega, B)$, we denote by $\mathrm{E}[\mathbf{X}]$ its expectation. The following lemma collects some elementary results that will be needed later on and shows, in particular, that the expectation $\mathrm{E}[\mathbf{X}]$ as well as that of all the powers $\|\mathbf{X}\|_B^k$ of its norm are finite for all the elements $\mathbf{X} \in L^\infty(\Omega, B)$.

Lemma 24 *Let $\mathbf{X} \in L^\infty(\Omega, B)$ and let $C \in \overline{\mathbb{R}^+}$. Then:*

(i) $\|\mathbf{X}\|_B \leq \|\mathbf{X}\|_{L^\infty}$ *almost surely.*

(ii) $\|\mathbf{X}\|_{L^\infty} \leq C$ *if and only if* $\|\mathbf{X}\|_B \leq C$ *almost surely.*

(iii) $\|\mathbf{X}\|_B \leq C$ *almost surely if and only if* $\mathrm{E}\left[\|\mathbf{X}\|_B^k\right] \leq C^k$ *for any* $k \in \mathbb{N}$.

(iv) *Let $B=\mathbb{R}^n$, then the components X_i of $\mathbf{X}$, $i\in\{1,\ldots,n\}$, are such that $\mathrm{E}[X_i]\leq\|\mathbf{X}\|_{L^\infty}$.*

The first point in this lemma explains why we will refer to the elements of $L^\infty(\Omega,B)$ as ***almost surely bounded*** random variables.

Stochastic inputs and outputs. The filters that we will consider in this section have ***almost surely bounded stochastic processes*** as inputs and outputs. Recall that a discrete-time stochastic process is a map of the type:

$$\begin{array}{rccc}\mathbf{z}: & \mathbb{Z}\times\Omega & \longrightarrow & \mathbb{R}^n \\ & (t,\omega) & \longmapsto & \mathbf{z}_t(\omega),\end{array} \tag{4.5}$$

such that, for each $t\in\mathbb{Z}$, the assignment $\mathbf{z}_t:\Omega\longrightarrow\mathbb{R}^n$ is a random variable. For each $\omega\in\Omega$, we will denote by $\mathbf{z}(\omega):=\{\mathbf{z}_t(\omega)\in\mathbb{R}^n\mid t\in\mathbb{Z}\}$ the ***realization*** or the ***sample path*** of the process $\mathbf{z}$. The results that follow are presented for stochastic processes indexed by $\mathbb{Z}$ but are equally valid for $\mathbb{Z}_+$ and $\mathbb{Z}_-$.

Recall that a map of the type (4.5) is a $\mathbb{R}^n$-valued stochastic process if and only if the corresponding map $\mathbf{z}:\Omega\longrightarrow(\mathbb{R}^n)^{\mathbb{Z}}$ into path space (designated with the same symbol) is a random variable when in $(\mathbb{R}^n)^{\mathbb{Z}}$ we consider the product sigma algebra generated by cylinder sets (Chapter 1 in Comets and Meyre (2006)). Then, the space of $\mathbb{R}^n$-valued stochastic processes can be made into a vector space with the same operations as in (4.4) and we can define in this space a norm $\|\cdot\|_{L^\infty}$ using the same prescription as in (4.1) by considering $(\mathbb{R}^n)^{\mathbb{Z}}$ as a normed space with the supremum norm $\|\cdot\|_\infty$, that is,

$$\|\mathbf{z}\|_{L^\infty}:=\operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}(\omega)\|_\infty\}=\operatorname*{ess\,sup}_{\omega\in\Omega}\left\{\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\}\right\}. \tag{4.6}$$

The following lemma provides an alternative characterization of the norm $\|\cdot\|_{L^\infty}$ that will be very useful in the proofs of the results that follow and in which the supremum and the essential supremum have been interchanged. The last statement contained in it complements part **(ii)** of Lemma 24 for processes.

Lemma 25 *Let $\mathbf{z}:\Omega\longrightarrow(\mathbb{R}^n)^{\mathbb{Z}}$ be a stochastic process. Then,*

$$\|\mathbf{z}\|_{L^\infty}:=\operatorname*{ess\,sup}_{\omega\in\Omega}\left\{\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\}\right\}=\sup_{t\in\mathbb{Z}}\left\{\operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}_t(\omega)\|\}\right\}. \tag{4.7}$$

Equivalently, using the notation in (4.1)*,*

$$\|\mathbf{z}\|_{L^\infty}:=\left\|\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\}\right\|_{L^\infty}=\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t\|_{L^\infty}\}. \tag{4.8}$$

These equalities imply that for any non-negative real number $C\geq 0$, the process $\mathbf{z}$ satisfies that $\|\mathbf{z}\|_{L^\infty}\leq C$ if and only if $\|\mathbf{z}_t\|_{L^\infty}\leq C$ for all $t\in\mathbb{Z}$ or, equivalently, if and only if $\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t\|_{L^\infty}\}\leq C$.

Consider now the space $L^\infty\left(\Omega,(\mathbb{R}^n)^{\mathbb{Z}}\right)$ of processes with finite $\|\cdot\|_{L^\infty}$ norm. We refer to the elements of $L^\infty\left(\Omega,(\mathbb{R}^n)^{\mathbb{Z}}\right)$ as ***almost surely bounded time series***. Additionally, consider the space $L^\infty\left(\Omega,\ell^\infty(\mathbb{R}^n)\right)$ of processes whose paths are all uniformly bounded, that is, they lay in the Banach space $(\ell^\infty(\mathbb{R}^n),\|\cdot\|_\infty)$. According to the definition in (4.2), we have for both these spaces that

$$L^\infty\left(\Omega,(\mathbb{R}^n)^{\mathbb{Z}}\right):=S_{(\mathbb{R}^n)^{\mathbb{Z}}}/\sim_{(\mathbb{R}^n)^{\mathbb{Z}}},\quad L^\infty\left(\Omega,\ell^\infty(\mathbb{R}^n)\right):=S_{\ell^\infty(\mathbb{R}^n)}/\sim_{\ell^\infty(\mathbb{R}^n)}$$

with

$$S_{(\mathbb{R}^n)^{\mathbb{Z}}}:=\left\{\mathbf{z}:\mathbb{Z}\times\Omega\longrightarrow\mathbb{R}^n\ \text{ stochastic process, }\mathbf{z}(\omega)\in(\mathbb{R}^n)^{\mathbb{Z}},\ \text{for all }\omega\in\Omega\mid\|\mathbf{z}\|_{L^\infty}<\infty\right\},$$

$$S_{\ell^\infty(\mathbb{R}^n)}:=\left\{\mathbf{z}:\mathbb{Z}\times\Omega\longrightarrow\mathbb{R}^n\ \text{ stochastic process, }\mathbf{z}(\omega)\in\ell^\infty(\mathbb{R}^n),\ \text{for all }\omega\in\Omega\mid\|\mathbf{z}\|_{L^\infty}<\infty\right\},$$

and with the almost sure equality equivalence relations $\sim_{\ell^\infty(\mathbb{R}^n)}$ and $\sim_{(\mathbb{R}^n)^{\mathbb{Z}}}$ between stochastic processes with paths in $\ell^\infty(\mathbb{R}^n)$ and $(\mathbb{R}^n)^{\mathbb{Z}}$, respectively. The following result shows that the normed spaces $L^\infty\left(\Omega,(\mathbb{R}^n)^{\mathbb{Z}}\right)$ and $L^\infty\left(\Omega,\ell^\infty(\mathbb{R}^n)\right)$ are isomorphic.

Lemma 26 *In the setup that we just introduced the inclusion $\iota:S_{\ell^\infty(\mathbb{R}^n)}\hookrightarrow S_{(\mathbb{R}^n)^{\mathbb{Z}}}$ is equivariant with respect to the equivalence relations $\sim_{\ell^\infty(\mathbb{R}^n)}$ and $\sim_{(\mathbb{R}^n)^{\mathbb{Z}}}$ and drops to an isomorphism of normed spaces $\phi:\left(L^\infty\left(\Omega,(\mathbb{R}^n)^{\mathbb{Z}}\right),\|\cdot\|_{L^\infty}\right)\longrightarrow\left(L^\infty\left(\Omega,\ell^\infty(\mathbb{R}^n)\right),\|\cdot\|_{L^\infty}\right)$. Equivalently, the following diagram commutes*

$$\begin{array}{ccc} S_{\ell^\infty(\mathbb{R}^n)} & \xhookrightarrow{\ \iota\ } & S_{(\mathbb{R}^n)^{\mathbb{Z}}} \\ \Pi_{\sim_{\ell^\infty(\mathbb{R}^n)}}\downarrow & & \downarrow\Pi_{\sim_{(\mathbb{R}^n)^{\mathbb{Z}}}} \\ L^\infty\left(\Omega,\ell^\infty(\mathbb{R}^n)\right) & \xrightarrow{\ \phi\ } & L^\infty\left(\Omega,(\mathbb{R}^n)^{\mathbb{Z}}\right),\end{array}$$

where $\Pi_{\sim_{\ell^\infty(\mathbb{R}^n)}}$ and $\Pi_{\sim_{(\mathbb{R}^n)^{\mathbb{Z}}}}$ are the canonical projections.

Let now w be a weighting sequence and let $\|\cdot\|_w$ be the associated weighted norm in $(\mathbb{R}^n)^{\mathbb{Z}_-}$. If we replace in (4.6) the ℓ^∞ norm $\|\cdot\|_\infty$ by the weighted norm $\|\cdot\|_w$, we obtain a weighted norm $\|\cdot\|_{L^\infty_w}$ in the space of processes $\mathbf{z}:\mathbb{Z}_-\times\Omega\longrightarrow\mathbb{R}^n$ indexed by $\mathbb{Z}_-$ as:

$$\|\mathbf{z}\|_{L^\infty_w}:=\operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}(\omega)\|_w\}=\operatorname*{ess\,sup}_{\omega\in\Omega}\left\{\sup_{t\in\mathbb{Z}_-}\{\|\mathbf{z}_t(\omega)\|w_{-t}\}\right\}. \tag{4.9}$$

We will denote by $L^\infty_w\left(\Omega,(\mathbb{R}^n)^{\mathbb{Z}_-}\right)$ the space of processes with finite $\|\cdot\|_{L^\infty_w}$ norm. A result similar to Lemma 26 shows that the normed spaces $\left(L^\infty_w\left(\Omega,(\mathbb{R}^n)^{\mathbb{Z}_-}\right),\|\cdot\|_{L^\infty_w}\right)$ and $\left(L^\infty\left(\Omega,\ell^\infty_w(\mathbb{R}^n)\right),\|\cdot\|_{L^\infty_w}\right)$ are isomorphic. Additionally, as in Lemma 25, we have that for any $\mathbf{z}\in L^\infty_w\left(\Omega,(\mathbb{R}^n)^{\mathbb{Z}_-}\right)$:

$$\|\mathbf{z}\|_{L^\infty_w}:=\operatorname*{ess\,sup}_{\omega\in\Omega}\left\{\sup_{t\in\mathbb{Z}_-}\{\|\mathbf{z}_t(\omega)\|w_{-t}\}\right\}=\sup_{t\in\mathbb{Z}_-}\left\{\operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}_t(\omega)\|w_{-t}\}\right\}. \tag{4.10}$$

Deterministic filters in a stochastic setup. As we already pointed out, we consider filters U that have almost surely bounded processes as inputs and outputs. The same conventions as in the deterministic setup are used in the identification of the different signals, namely, $\mathbf{z}$ denotes the filter input process and the symbol y is reserved for the output process. Let now $D_n\subset\mathbb{R}^n$ and let $D_n^{L^\infty_{\mathbb{Z}}}\subset L^\infty(\Omega,(\mathbb{R}^n)^{\mathbb{Z}})$ be a subset formed by processes whose paths take values in D_n almost surely. In the sequel we will restrict our attention to intrinsically ***deterministic filters*** $U:D_n^{L^\infty_{\mathbb{Z}}}\longrightarrow L^\infty(\Omega,\mathbb{R}^{\mathbb{Z}})$ that are obtained by presenting almost surely bounded stochastic inputs $\mathbf{z}\in D_n^{L^\infty_{\mathbb{Z}}}\subset L^\infty(\Omega,(\mathbb{R}^n)^{\mathbb{Z}})$ to filters $U:(D_n)^{\mathbb{Z}}\longrightarrow\mathbb{R}^{\mathbb{Z}}$ similar to those introduced in the previous section, which explains why we use the same symbol for both. This is explicitly carried out by defining the output process $U(\mathbf{z})\in L^\infty(\Omega,\mathbb{R}^{\mathbb{Z}})$ using the convention

$$(U(\mathbf{z}))(\omega):=U(\mathbf{z}(\omega)),\quad\omega\in\Omega, \tag{4.11}$$

where on the right hand side it is the filter $U:(D_n)^{\mathbb{Z}}\longrightarrow\mathbb{R}^{\mathbb{Z}}$ which is applied to the paths $\mathbf{z}(\omega):=\{\mathbf{z}_t(\omega)\in\mathbb{R}^n\mid t\in\mathbb{Z}\}\in(D_n)^{\mathbb{Z}}$ of the process $\mathbf{z}$. We call these filters deterministic because, in view of (4.11) the dependence of the image process $(U(\mathbf{z}))(\omega)\in\in L^\infty(\Omega,\mathbb{R}^{\mathbb{Z}})$ on the probability space takes place exclusively through the dependence $\mathbf{z}(\omega)$ in the input. In this section we reserve the symbol U to denote deterministic filters $U:D_n^{L^\infty_{\mathbb{Z}}}\longrightarrow L^\infty(\Omega,\mathbb{R}^{\mathbb{Z}})$. We draw attention to the fact that assuming that

the filters map into almost surely bounded processes is a genuine hypothesis that needs to be verified in each specific case considered.

The concepts of causality and time-invariance are defined as in the deterministic case by replacing equalities by almost sure equalities in the corresponding identities. More explicitly, we say that the filter $U : D_n^{L_{\mathbb{Z}}^\infty} \longrightarrow L^\infty(\Omega, \mathbb{R}^{\mathbb{Z}})$ is time-invariant when for any $\tau \in \mathbb{Z}$ and any $\mathbf{z} \in D_n^{L_{\mathbb{Z}}^\infty}$, we have that

$$(U_\tau \circ U)(\mathbf{z}) = (U \circ U_\tau)(\mathbf{z}), \quad \text{almost surely.}$$

Analogously, we say that the filter is causal with stochastic inputs when for any two elements $\mathbf{z}, \mathbf{w} \in D_n^{L_{\mathbb{Z}}^\infty}$ that satisfy that $\mathbf{z}_\tau = \mathbf{w}_\tau$ almost surely, for any $\tau \leq t$ and for a given $t \in \mathbb{Z}$, we have that $U(\mathbf{z})_t = U(\mathbf{w})_t$, almost surely. Causal and time-invariant deterministic filters produce almost surely causal and time-invariant filters when stochastic inputs are presented to them.

In this setup, there is also a correspondence between causal and time-invariant filters $U : D_n^{L_{\mathbb{Z}}^\infty} \longrightarrow L^\infty(\Omega, \mathbb{R}^{\mathbb{Z}})$ and functionals $H_U : D_n^{L_{\mathbb{Z}_-}^\infty} \longrightarrow L^\infty(\Omega, \mathbb{R})$, where $D_n^{L_{\mathbb{Z}_-}^\infty} := \mathbb{P}_{\mathbb{Z}_-}\left(D_n^{L_{\mathbb{Z}}^\infty}\right)$.

Given a weighting sequence $w : \mathbb{N} \longrightarrow (0, 1]$ and a time-invariant filter $U : D_n^{L_{\mathbb{Z}_-}^\infty} \longrightarrow L^\infty(\Omega, \mathbb{R}^{\mathbb{Z}})$ with stochastic inputs, we will say that U has the ***fading memory property*** with respect to the weighting sequence w when the corresponding functional $H_U : \left(D_n^{L_{\mathbb{Z}_-}^\infty}, \|\cdot\|_{L_w^\infty}\right) \longrightarrow L^\infty(\Omega, \mathbb{R})$ is a continuous map.

Let $M > 0$ and define, using Lemma 25,

$$K_M^{L^\infty} := \left\{\mathbf{z} \in L^\infty(\Omega, (\mathbb{R}^n)^{\mathbb{Z}_-}) \mid \|\mathbf{z}\|_{L^\infty} \leq M\right\} = \left\{\mathbf{z} \in L^\infty(\Omega, (\mathbb{R}^n)^{\mathbb{Z}_-}) \mid \|\mathbf{z}_t\|_{L^\infty} \leq M, \text{ for all } t \in \mathbb{Z}_-\right\}. \tag{4.12}$$

The sets $K_M^{L^\infty}$ are the stochastic counterparts of the sets K_M in the deterministic setup; we will say that $K_M^{L^\infty}$ is a set of ***almost surely uniformly bounded processes***. A stochastic analog of Lemma 1 can be formulated for them with K_M replaced by $K_M^{L^\infty}$, the norm $\|\cdot\|$ by $\|\cdot\|_{L^\infty}$, and the weighted norm $\|\cdot\|_w$ by $\|\cdot\|_{L_w^\infty}$. Indeed, the following result shows that the fading memory and the universality properties are naturally inherited by deterministic filters with almost surely uniformly bounded inputs. We call this fact the ***deterministic-stochastic transfer principle***.

Theorem 27 (Deterministic-stochastic transfer principle) *Let $M > 0$ and let K_M and $K_M^{L^\infty}$ be the sets of deterministic and stochastic inputs defined in (2.3) and (4.12), respectively. The following properties hold true:*

(i) *Let $H : (K_M, \|\cdot\|_w) \longrightarrow \mathbb{R}$ be a causal and time-invariant filter. Then H has the fading memory property if and only if the corresponding filter with almost surely uniformly bounded inputs has almost surely bounded outputs, that is, $H : (K_M^{L^\infty}, \|\cdot\|_{L_w^\infty}) \longrightarrow L^\infty(\Omega, \mathbb{R})$, and it has the fading memory property.*

(ii) *Let $\mathcal{T} := \{H_i : (K_M, \|\cdot\|_w) \longrightarrow \mathbb{R} \mid i \in I\}$ be a family of causal and time-invariant fading memory filters. Then, $\mathcal{T}$ is dense in the set $(C^0(K_M), \|\cdot\|_w)$ if and only if the corresponding family with inputs in $K_M^{L^\infty}$ is universal in the set of continuous maps of the type $H : (K_M^{L^\infty}, \|\cdot\|_{L_w^\infty}) \longrightarrow L^\infty(\Omega, \mathbb{R})$.*

A first universality result using RC systems. The following paragraphs contain a stochastic analog of Theorem 8 which shows that any fading memory filter with almost surely uniformly bounded inputs can be approximated using the elements of a polynomial algebra of reservoir filters with the same kind of inputs, provided that it contains the constant functionals and has the separation property. We note that, as in the deterministic case, the existence of the reservoir filter associated to a reservoir system like (1.1)-(1.2) is guaranteed only in the presence of the echo state property. The next lemma

shows that this property is inherited by deterministic fading memory reservoir filters with almost surely bounded inputs.

Lemma 28 *Consider a reservoir system determined by the relations (1.1)-(1.2) and the maps $F : D_N \times \overline{B_n(\mathbf{0}, M)} \longrightarrow D_N$ and $h : D_N \to \mathbb{R}$, for some $n, N \in \mathbb{N}$, $M > 0$, and $D_N \subset \mathbb{R}^N$. If the reservoir system has the echo state and the fading memory properties then so does the corresponding system with stochastic inputs in $K_M^{L^\infty}$ which, additionally, has an associated reservoir functional $H_h^F : (K_M^{L^\infty}, \|\cdot\|_{L_w^\infty}) \longrightarrow L^\infty(\Omega, \mathbb{R})$ with almost surely bounded outputs that satisfies the fading memory property.*

Theorem 29 *Let $M > 0$ and let $K_M^{L^\infty}$ be the set of almost surely uniformly bounded processes introduced in (4.12). Consider the set $\mathcal{R}$*

$$\mathcal{R} := \{H_{h_i}^{F_i} : K_M^{L^\infty} \longrightarrow L^\infty(\Omega, \mathbb{R}) \mid h_i \in \mathrm{Pol}(\mathbb{R}^{N_i}, \mathbb{R}), F_i : \mathbb{R}^{N_i} \times \mathbb{R}^n \longrightarrow \mathbb{R}^{N_i}, i \in I, N_i \in \mathbb{N}\} \tag{4.13}$$

formed by deterministic fading memory reservoir filters with respect to a given weighted norm $\|\cdot\|_w$ and driven by stochastic inputs in $K_M^{L^\infty}$. Let $\mathcal{A}(\mathcal{R})$ be the polynomial algebra generated by $\mathcal{R}$. If the algebra $\mathcal{A}(\mathcal{R})$ has the separation property and contains all the constant functionals, then any deterministic, causal, time-invariant fading memory filter $H : (K_M^{L^\infty}, \|\cdot\|_{L_w^\infty}) \longrightarrow L^\infty(\Omega, \mathbb{R})$ can be uniformly approximated by elements in $\mathcal{A}(\mathcal{R})$, that is, for any $\epsilon > 0$, there exist a finite set of indices $\{i_1, \ldots, i_r\} \subset I$ and a polynomial $p : \mathbb{R}^r \longrightarrow \mathbb{R}$ such that

$$\|H - H_h^F\|_\infty := \sup_{\mathbf{z} \in K_M^{L^\infty}} \{\|H(\mathbf{z}) - H_h^F(\mathbf{z})\|_{L^\infty}\} < \epsilon \quad \text{with} \quad h := p(h_{i_1}, \ldots, h_{i_r}) \quad \text{and} \quad F := (F_{i_1}, \ldots, F_{i_r}).$$

In the next paragraphs we identify, as in the deterministic case, families of reservoirs that satisfy the hypotheses of this theorem and where we will eventually impose linearity constraints on the readout function. The following corollary to Theorem 29 is the stochastic analog of Corollary 9.

Corollary 30 *Let $M > 0$ and let $K_M^{L^\infty}$ be the set of almost surely uniformly bounded processes introduced in (4.12). Let*

$$\mathcal{R}_w := \{H_h^F : K_M^{L^\infty} \longrightarrow L^\infty(\Omega, \mathbb{R}) \mid h \in \mathrm{Pol}(\mathbb{R}^N, \mathbb{R}), F : \mathbb{R}^N \times \mathbb{R}^n \longrightarrow \mathbb{R}^N, N \in \mathbb{N}\} \tag{4.14}$$

be the set of all the reservoir filters defined on $K_M^{L^\infty}$ that have the FMP with respect to a given weighted norm $\|\cdot\|_{L_w^\infty}$. Then $\mathcal{R}_w$ is universal, that is, for any time-invariant fading memory filter $H : (K_M^{L^\infty}, \|\cdot\|_{L_w^\infty}) \longrightarrow L^\infty(\Omega, \mathbb{R})$ and any $\epsilon > 0$, there exists a reservoir filter $H_h^F \in \mathcal{R}_w$ such that $\|H - H_h^F\|_\infty := \sup_{\mathbf{z} \in K_M^{L^\infty}} \{\|H(\mathbf{z}) - H_h^F(\mathbf{z})\|_{L^\infty}\} < \epsilon$.

Linear reservoir computers with stochastic inputs are universal. As it was the case in the deterministic setup, we can prove in the stochastic case that the linear RC family introduced in (3.7)-(3.8) suffices to achieve universality. The proof of the following statement is a direct consequence of Corollary 11 and Theorem 27.

Corollary 31 *Let $M > 0$ and let $K_M^{L^\infty}$ be the set of almost surely uniformly bounded processes introduced in (4.12). Let $\mathcal{L}_\epsilon$ be the family introduced in Corollary 11 and formed by all the linear reservoir filters $H_p^{A,\mathbf{c}}$ determined by matrices $A \in \mathbb{M}_N$ such that $\sigma_{\max}(A) < 1 - \epsilon$. The elements in $\mathcal{L}_\epsilon$ map $K_M^{L^\infty}$ into $L^\infty(\Omega, \mathbb{R})$ and are time-invariant fading memory filters with respect to the weighted norm $\|\cdot\|_{w^\rho}^{L^\infty}$ associated to $w_t^\rho := (1 - \epsilon)^{\rho t}$, for any $\rho \in (0, 1)$. Moreover, they are universal, that is, for any time-invariant and causal fading memory filter $H : (K_M^{L^\infty}, \|\cdot\|_{L_{w^\rho}^\infty}) \longrightarrow L^\infty(\Omega, \mathbb{R})$ and any $\varepsilon > 0$, there exists $H_p^{A,\mathbf{c}} \in \mathcal{L}_\epsilon$ such that $\|H - H_p^{A,\mathbf{c}}\|_\infty := \sup_{\mathbf{z} \in K_M^{L^\infty}} \{\|H(\mathbf{z}) - H_p^{A,\mathbf{c}}(\mathbf{z})\|_{L^\infty}\} < \varepsilon$.*

The same universality result can be stated for the subfamily $\mathcal{DL}_\epsilon \subset \mathcal{L}_\epsilon$, formed by the linear reservoir systems in $\mathcal{L}_\epsilon$ determined by diagonal matrices, and for $\mathcal{NL} \subset \mathcal{L}_\epsilon$, formed by the linear reservoir systems determined by nilpotent matrices.

Remark 32 The linear reservoir filters in $\mathcal{NL}$ determined by nilpotent matrices have been used in Gonon and Ortega (2018) to formulate a L^p version of these universality results.

Remark 33 The previous corollary has interesting consequences in the realm of time series analysis. Indeed, many well-known parametric time series models consist in autoregressive relations, possibly nonlinear, driven by independent or uncorrelated innovations. The parameter constraints that are imposed on them in order to ensure that they have (second order) stationary solutions imply, in may situations, that the resulting filter has the FMP. In those cases, Corollary 31 allows us to conclude that when those models are driven by almost surely uniformly bounded innovations, they can be arbitrarily well approximated by a polynomial function of a vector autoregressive model (VAR) of order 1. This statement applies, for example, to any stationary ARMA (see Box and Jenkins (1976), Brockwell and Davis (2006)) or GARCH model (see Engle (1982), Bollerslev (1986), Francq and Zakoian (2010)) driven by almost surely uniformly bounded innovations.

State-affine reservoir computers with almost surely uniformly bounded inputs are universal. As it was the case in the deterministic setup, non-homogeneous SAS are universal time-invariant fading memory filters in the stochastic framework with almost surely uniformly bounded inputs. Their advantage with respect to the families proposed in the previous corollary is that they use a linear readout which is of major importance in practical implementations. More specifically, the following result holds true as a direct consequence of Theorem 19 and the equivalence stated in Theorem 27.

Theorem 34 (Universality of SAS reservoir computers with almost surely uniformly bounded inputs) *Let $K_I^{L^\infty} \subset L^\infty(\Omega, \mathbb{R}^{\mathbb{Z}_-})$ be the set of almost surely and uniformly bounded processes in the interval $I = [-1, 1]$, that is,*

$$K_I^{L^\infty} := \left\{ z \in L^\infty(\Omega, \mathbb{R}^{\mathbb{Z}_-}) \mid \|z_t\|_{L^\infty} \leq 1, \quad \text{for all} \quad t \in \mathbb{Z}_- \right\}.$$

Let $\mathcal{S}_\epsilon$ be the family of functionals $H^{p,q}_{\mathbf{W}} : K_I^{L^\infty} \longrightarrow L^\infty(\Omega, \mathbb{R})$ induced by the state-affine systems defined in (3.11)-(3.12) and that satisfy $M_p := \max_{z \in I} \|p(z)\| < 1 - \epsilon$ and $M_q := \max_{z \in I} \|q(z)\| < 1 - \epsilon$. The family $\mathcal{S}_\epsilon$ forms a polynomial subalgebra of $\mathcal{R}_{w^\rho}$ (as defined in (4.14)) with $w_t^\rho := (1 - \epsilon)^{\rho t}$, made of fading memory reservoir filters that map into $L^\infty(\Omega, \mathbb{R})$.

Moreover, for any time-invariant and causal fading memory filter $H : (K_I^{L^\infty}, \|\cdot\|_{L^\infty_{w^\rho}}) \longrightarrow L^\infty(\Omega, \mathbb{R})$ and any $\epsilon > 0$, there exist a natural number $N \in \mathbb{N}$, polynomials $p(z) \in \mathbb{M}_{N,N}[z], q(z) \in \mathbb{M}_{N,1}[z]$ with $M_p, M_q < 1 - \epsilon$, and a vector $\mathbf{W} \in \mathbb{R}^N$ such that

$$\|H - H^{p,q}_{\mathbf{W}}\|_\infty := \sup_{z \in K_I^{L^\infty}} \{\|H(z) - H^{p,q}_{\mathbf{W}}(z)\|_{L^\infty}\} < \epsilon.$$

The same universality result can be stated for the smaller subfamily $\mathcal{NS}_\epsilon \subset \mathcal{S}_\epsilon$ formed by SAS reservoir systems determined by nilpotent polynomials $p(z) \in \mathbb{N}\mathrm{il}[z]$.

5. Conclusion

This paper studies and proposes solutions for the universality problem in the approximation of fading memory filters using reservoir computer (RC) systems. RCs are a particular type of recurrent neural networks that have important applications both in machine learning and in signal processing where they exhibit superb information processing performances. Their importance is also linked to the possibility of building highly efficient hardware realizations. RC systems are in general defined as nonlinear state-space systems determined by a reservoir and a readout map. In many supervised machine learning applications the readout is chosen to be linear and the reservoir map is randomly generated, which reduces the training of a dynamic task to a static regression problem and allows to circumvent well-known difficulties in the training of generic recurrent neural networks.

The universality question that we addressed consists in finding families of RCs as simple as possible such that the set of input/output functionals that can be generated with them is dense in a sufficiently rich class. The work presented here is the dynamic counterpart of a statement of this type for neural networks in a static and deterministic setup in which they have been proved to be universal approximators.

The RC universality results stated in the paper correspond to two different situations in which the inputs are either deterministic and uniformly bounded or stochastic and almost surely uniformly bounded. In both cases we proved two different universality statements. First, we showed that the family of fading memory RCs is universal in the much larger fading memory filters category. The same applies to the much smaller RC family containing just linear reservoirs with polynomial readouts, when certain spectral restrictions are imposed on the reservoir maps. The second result concerns exclusively reservoir computers with linear readouts, which are closer to the type of RCs used in applications and hardware implementations. More specifically, we introduced the family of what we called non-homogeneous state-affine systems and identified sufficient conditions that guarantee that the associated reservoir computers with linear readouts are causal, time-invariant, and satisfy the echo state and the fading memory properties. Finally, we stated a universality result for a subset of this class which was shown to be universal in the same fading memory filters category as above. These universality statements are then generalized to the stochastic setup for almost surely uniformly bounded inputs. In particular, we showed that any discrete-time filter that has the fading memory property with almost surely uniformly bounded stochastic inputs can be uniformly approximated by elements in the non-homogeneous state-affine family. All the density statements in the paper are formulated with respect to natural uniform approximation norms that appear in each of the different cases considered.

Despite preexisting work, these universality results are, to our knowledge, the first of their type in the semi-infinite discrete-time inputs setup. In the stochastic case they open the door to new developments in the learning theory of stochastic processes.

6. Appendices

6.1 Proof of Lemma 1

Let $w : \mathbb{N} \longrightarrow (0, 1]$ be an arbitrary weighting sequence. Then, for any $\mathbf{z} \in K_M$:

$$\|\mathbf{z}\|_w := \sup_{t \in \mathbb{Z}_-} \{\|\mathbf{z}_t w_{-t}\|\} = \sup_{t \in \mathbb{Z}_-} \{\|\mathbf{z}_t\| w_{-t}\} \leq M \cdot 1 = M < \infty.$$

Regarding the inequalities (2.4) and (2.5), notice that if $w_t = \lambda^t$ then:

$$\begin{aligned}\sum_{t=0}^{\infty} \|\mathbf{z}_{-t}\| w_t = \sum_{t=0}^{\infty} \|\mathbf{z}_{-t}\| \lambda^t = \sum_{t=0}^{\infty} \|\mathbf{z}_{-t}\| (\lambda^{1-\rho} \lambda^\rho)^t = \sum_{t=0}^{\infty} \|\mathbf{z}_{-t}\| \lambda^{(1-\rho)t} \lambda^{\rho t} \\ \leq \sum_{t=0}^{\infty} \sup_{i \in \mathbb{N}} \left\{ \|\mathbf{z}_{-i}\| \lambda^{(1-\rho)i} \right\} \lambda^{\rho t} = \sup_{i \in \mathbb{N}} \left\{ \|\mathbf{z}_{-i}\| \lambda^{(1-\rho)i} \right\} \sum_{t=0}^{\infty} \lambda^{\rho t} = \|\mathbf{z}\|_{w^{1-\rho}} \frac{1}{1 - \lambda^\rho},\end{aligned}$$

which proves (2.4). The proof of (2.5) is similar and follows from noticing that:

$$\sum_{t=0}^{\infty} \|\mathbf{z}_{-t}\| \lambda^{(1-\rho)t} \lambda^{\rho t} \leq \sum_{t=0}^{\infty} \sup_{i \in \mathbb{N}} \left\{ \|\mathbf{z}_{-i}\| \lambda^{\rho i} \right\} \lambda^{(1-\rho)t)} = \sup_{i \in \mathbb{N}} \left\{ \|\mathbf{z}_{-i}\| \lambda^{\rho i} \right\} \sum_{t=0}^{\infty} \lambda^{(1-\rho)t} = \|\mathbf{z}\|_{w^\rho} \frac{1}{1 - \lambda^{1-\rho}}. \quad \blacksquare$$

6.2 Proof of Lemma 2

We recall first that by Lemma 1 we have that $\|\mathbf{z}\|_w < \infty$, for any $\mathbf{z} \in K_M$. Second, since $(\ell_w^\infty(\mathbb{R}^n), \|\cdot\|_w)$ is a Banach space (Grigoryeva and Ortega (2018)), it is hence metrizable and therefore so is $(K_M, \|\cdot\|_w)$ when endowed with the relative topology (see, for instance, Exercise 1, Chapter 2, §21, Munkres (2014)). We will then conclude the compactness of $(K_M, \|\cdot\|_w)$ by showing that this space is sequentially compact (see, for example, Theorem 28.2 in Munkres (2014)). We proceed by using the strategy in the proof of Lemma 1 in Boyd and Chua (1985).

For any $m \in \mathbb{N}$, let K_M^m be the set obtained by projecting into $(\mathbb{R}^n)^{\{-m,\ldots,-1,0\}}$ the elements of $K_M \subset (\mathbb{R}^n)^{\mathbb{Z}_-}$. Given an element $\mathbf{z} \in K_M$, we will denote by $\mathbf{z}^{(m)} := (\mathbf{z}_{-m}, \ldots, \mathbf{z}_0)$ its projection into K_M^m. Additionally, notice that $K_M^m = \overline{B_n(\mathbf{0}, M)}^{m+1}$ is compact (and hence sequentially compact) with the product topology, since it is a product of closed balls $\overline{B_n(\mathbf{0}, M)} \subset \mathbb{R}^n$ which are compact.

Let $\{\mathbf{z}(n)\}_{n\in\mathbb{N}} \subset K_M$ be a sequence of elements in K_M. The argument that we just stated proves that for any $k \in \mathbb{N}$, there is a subset $\mathbb{N}_k \subset \mathbb{N}$ and an element $\mathbf{z}^{(k)} \in K_M^k$ such that

$$\max_{t\in\{-k,\ldots,0\}} \left\| \mathbf{z}_t(n) - \mathbf{z}_t^{(k)} \right\| \longrightarrow 0, \quad \text{as } n \to \infty,\ n \in \mathbb{N}_k.$$

Moreover, the sets $\mathbb{N}_k$ can be constructed so that $\mathbb{N} \supset \mathbb{N}_1 \supset \mathbb{N}_2 \supset \cdots$ and so that $\mathbf{z}^{(k)}$ extends $\mathbf{z}^{(l)}$ when $k \geq l$. This implies the existence of an element $\mathbf{z} \in K_M$ such that, for each $k \in \mathbb{N}$,

$$\max_{t\in\{-k,\ldots,0\}} \|\mathbf{z}_t(n) - \mathbf{z}_t\| \longrightarrow 0, \quad \text{as } n \to \infty,\ n \in \mathbb{N}_k,$$

and hence there exists an increasing subsequence n_k such that $n_k \in \mathbb{N}_k$ and that for each k_0,

$$\max_{t\in\{-k_0,\ldots,0\}} \|\mathbf{z}_t(n_k) - \mathbf{z}_t\| \longrightarrow 0, \quad \text{as } k \longrightarrow \infty. \tag{6.1}$$

We conclude by showing that the sequence $\{\mathbf{z}(n_k)\}_{k\in\mathbb{N}}$ converges in $(K_M, \|\cdot\|_w)$ to the element $\mathbf{z} \in K_M$. First, given that $w_t \longrightarrow 0$ as $t \longrightarrow \infty$, then for any $\varepsilon > 0$ there exists k_0 such that $w_k < \varepsilon/2M$, for any $k \geq k_0$. Additionally, since $\mathbf{z}(n_k), \mathbf{z} \in K_M$ for any $k \in \mathbb{N}$, we have that

$$\sup_{t\leq -k_0} \{\|\mathbf{z}_t(n_k) - \mathbf{z}_t\| w_{-t}\} \leq 2Mw_{k_0} < \varepsilon. \tag{6.2}$$

Now, by (6.1) there exists k_1 such that for any $k \geq k_1$

$$\sup_{t\in\{-k_0,\ldots,0\}} \{\|\mathbf{z}_t(n_k) - \mathbf{z}_t\| w_{-t}\} < \sup_{t\in\{-k_0,\ldots,0\}} \{\|\mathbf{z}_t(n_k) - \mathbf{z}_t\|\} < \varepsilon. \tag{6.3}$$

Consequently, (6.2) and (6.3) imply that for any $k > \max\{k_0, k_1\}$, $\|\mathbf{z}(n_k) - \mathbf{z}\|_w < \varepsilon$, as required. ■

6.3 Proof of Lemma 7

Let $\delta^w(\epsilon)$ be the epsilon-delta relation for the FMP associated to the weighting sequence w. We now show that H_U has the FMP with respect to w' via the epsilon-delta relation given by $\delta^{w'}(\epsilon) := \delta^w(\epsilon)/\lambda$. Indeed, for any $\epsilon > 0$ and any $\mathbf{z}, \mathbf{s} \in K$ such that $\|\mathbf{z} - \mathbf{s}\|_{w'} < \delta^{w'}(\epsilon)$, we have that

$$\|\mathbf{z}-\mathbf{s}\|_w = \sup_{t\in\mathbb{Z}_-} \{\|\mathbf{z}_t-\mathbf{s}_t\|w_{-t}\} = \sup_{t\in\mathbb{Z}_-} \left\{\|\mathbf{z}_t - \mathbf{s}_t\| \frac{w_{-t}}{w'_{-t}} w'_{-t}\right\} < \lambda \sup_{t\in\mathbb{Z}_-} \{\|\mathbf{z}_t-\mathbf{s}_t\|w'_{-t}\} < \lambda\|\mathbf{z}-\mathbf{s}\|_{w'} < \lambda\delta^{w'}(\epsilon) = \delta^w(\epsilon),$$

and consequently, since H_U has the FMP with respect to the weighting sequence w, we can conclude that $|H_U(\mathbf{z}) - H_U(\mathbf{s})| < \epsilon$. This shows that the implication

$$\|\mathbf{z} - \mathbf{s}\|_{w'} < \delta^{w'}(\epsilon) \Longrightarrow |H_U(\mathbf{z}) - H_U(\mathbf{s})| < \epsilon$$

holds, as required. ■

6.4 Proof of Theorem 8

Since the elements in $\mathcal{R}$ have the FMP with respect to a given weighted norm $\|\cdot\|_w$, then so do those in $\mathcal{A}(\mathcal{R})$ since polynomial combinations of continuous elements of the form $H_{h_i}^{F_i} : (K_M, \|\cdot\|_w) \longrightarrow \mathbb{R}$ are also continuous. Therefore, under that hypothesis, $\mathcal{A}(\mathcal{R})$ is a polynomial subalgebra of the algebra $(C^0(K_M), \|\cdot\|_w)$ of real-valued continuous functions on $(K_M, \|\cdot\|_w)$. Since by hypothesis $\mathcal{A}(\mathcal{R})$ contains the constant functionals and separates the points in K_M and, by Lemma 2, the set $(K_M, \|\cdot\|_w)$ is compact, the Stone-Weierstrass theorem (Theorem 7.3.1 in Dieudonné (1969)) implies that $\mathcal{A}(\mathcal{R})$ is dense in $(C^0(K_M), \|\cdot\|_w)$, which concludes the proof. ■

6.5 Proof of Corollary 11

In order to show that the reservoir systems in $\mathcal{L}_\epsilon$ induce reservoir filters, we first show that they have the echo state property by using the following lemma, whose proof can be found in Grigoryeva and Ortega (2018).

Lemma 35 *Let $D_N \subset \mathbb{R}^N$ and $D_n \subset \mathbb{R}^n$ and let $F : D_N \times D_n \longrightarrow D_N$ be a continuous reservoir map. Suppose that F is a contraction map with contraction constant $0 < r < 1$, that is:*

$$\|F(\mathbf{x}, \mathbf{z}) - F(\mathbf{y}, \mathbf{z})\| \leq r \|\mathbf{x} - \mathbf{y}\|, \quad \textit{for all } \mathbf{x}, \mathbf{y} \in D_N \textit{ and all } \mathbf{z} \in D_n,$$

then the corresponding reservoir system has the echo state property.

We start now by noting that the condition $\sigma_{\max}(A) < 1 - \epsilon < 1$ implies that the reservoir map $F(\mathbf{x}, \mathbf{z}) := A\mathbf{x} + \mathbf{cz}$ associated to (3.7) is a contracting map with constant $\sigma_{\max}(A)$ which, by hypothesis, is smaller than one. Indeed,

$$\|F(\mathbf{x}, \mathbf{z}) - F(\mathbf{y}, \mathbf{z})\| = \|A(\mathbf{x} - \mathbf{y})\| \leq \sigma_{\max}(A) \|\mathbf{x} - \mathbf{y}\| \quad \text{for all } \mathbf{x}, \mathbf{y} \in D_N \text{ and all } \mathbf{z} \in D_n.$$

By Lemma 35 we can conclude that this reservoir system has a reservoir filter associated that we now show is explicitly given by (3.9). We start by proving that the conditions $\sigma_{\max}(A) < 1 - \epsilon < 1$ and that the elements in K_M are uniformly bounded by a constant M imply that the infinite sum in (3.9) is convergent. Let $n, m \in \mathbb{N}$ be such that $n < m$ and let $S_n := \sum_{i=0}^n A^i \mathbf{c} z_{-i}$. Now:

$$\|S_n - S_m\| = \left\| \sum_{j=n+1}^m A^i \mathbf{c}\mathbf{z}_{-i} \right\| \leq \sum_{j=n+1}^m \|A\|_2^i \|\mathbf{c}\|_2 \|\mathbf{z}_{-i}\| \leq M \|\mathbf{c}\|_2 \sum_{j=n+1}^m \sigma_{\max}(A)^i$$
$$\leq M \|\mathbf{c}\|_2 \sum_{j=n+1}^\infty \sigma_{\max}(A)^i = M \|\mathbf{c}\|_2 \frac{\sigma_{\max}(A)^{n+1}}{1 - \sigma_{\max}(A)}.$$

The condition $\sigma_{\max}(A) < 1 - \epsilon < 1$ implies that $M \|\mathbf{c}\|_2 \frac{\sigma_{\max}(A)^{n+1}}{1-\sigma_{\max}(A)} = M \frac{\sigma_{\max}(\mathbf{c})\sigma_{\max}(A)^{n+1}}{1-\sigma_{\max}(A)} \to 0$ as $n \to \infty$ and hence $\{S_n\}_{n\in\mathbb{N}}$ is a Cauchy sequence in $\mathbb{R}^N$ that consequently converges.

The fact that the filter determined by the expression (3.9) is a solution of the recursions (3.7)-(3.8) is a straightforward verification. In order to carry it out, it suffices to use that the filter $U_h^{A,\mathbf{c}}(\mathbf{z})$ associated to the functional $H_h^{A,\mathbf{c}}(\mathbf{z})$ is given by

$$U_h^{A,\mathbf{c}}(\mathbf{z})_t = h\left(\sum_{i=0}^\infty A^i \mathbf{c}\mathbf{z}_{t-i}\right),$$

and that the time series $\widetilde{\mathbf{x}}_t$ defined by $\widetilde{\mathbf{x}}_t := \sum_{i=0}^\infty A^i \mathbf{c}\mathbf{z}_{t-i}$ satisfies the recursion relation (3.7).

We now verify by hand that the filters $U_h^{A,\mathbf{c}}$ are time-invariant. Let $\mathbf{z} \in K_M$ and $t, \tau \in \mathbb{N}$ arbitrary and let U_τ be the corresponding time delay operator, then:

$$\left(U_h^{A,\mathbf{c}} \circ U_\tau\right)(\mathbf{z})_t = \left(U_h^{A,\mathbf{c}}\left(U_\tau(\mathbf{z})\right)\right)_t = h\left(\sum_{i=0}^{\infty} A^i \mathbf{c} U_\tau(\mathbf{z})_{t-i}\right) = h\left(\sum_{i=0}^{\infty} A^i \mathbf{c}\mathbf{z}_{t-i-\tau}\right) \tag{6.4}$$

At the same time,

$$\left(U_\tau \circ U_h^{A,\mathbf{c}}\right)(\mathbf{z})_t = \left(U_\tau\left(U_h^{A,\mathbf{c}}(\mathbf{z})\right)\right)_t = U_h^{A,\mathbf{c}}(\mathbf{z})_{t-\tau} = h\left(\sum_{i=0}^{\infty} A^i \mathbf{c}\mathbf{z}_{t-\tau-i}\right),$$

which coincides with (6.4) and proves the time-invariance of $U_h^{A,\mathbf{c}}$.

The next step consists in showing that the elements in $\mathcal{L}_\epsilon$ are λ_ρ-exponential fading memory filters, with $\lambda_\rho := (1-\epsilon)^\rho$, for any $\rho \in (0,1)$, that is, $\mathcal{L}_\epsilon \subset \mathcal{R}_{w^\rho}$, with $w^\rho : \mathbb{N} \to (0,1]$ the sequence given by $w_t^\rho := (1-\epsilon)^{\rho t}$. Let $\|\cdot\|_{w^\rho}$ be the associated weighted norm in K_M and let $\mathbf{z} \in K_M$ be an arbitrary element. We start by noting that the continuity of the readout map $h : D_N \to \mathbb{R}$ implies that for any $\varepsilon > 0$ there exists an element $\delta(\varepsilon) > 0$ such that for any $\mathbf{v} \in D_N$ that satisfies

$$\left\|\mathbf{v} - \sum_{i=0}^{\infty} A^i \mathbf{c}\mathbf{z}_{t-i}\right\| < \delta(\varepsilon), \quad \text{then} \quad \left|h(\mathbf{v}) - h\left(\sum_{i=0}^{\infty} A^i \mathbf{c}\mathbf{z}_{t-i}\right)\right| < \varepsilon. \tag{6.5}$$

We now show that for any $\mathbf{s} \in K_M$ such that

$$\|\mathbf{s} - \mathbf{z}\|_{w^\rho} < \frac{\delta(\varepsilon)\left(1-(1-\epsilon)^{1-\rho}\right)}{\sigma_{\max}(\mathbf{c})}, \quad \text{then} \quad \left|H_h^{A,\mathbf{c}}(\mathbf{s}) - H_h^{A,\mathbf{c}}(\mathbf{z})\right| < \varepsilon. \tag{6.6}$$

Indeed,

$$\begin{aligned}\left\|\sum_{i=0}^{\infty} A^i \mathbf{c}\mathbf{s}_{t-i} - \sum_{i=0}^{\infty} A^i \mathbf{c}\mathbf{z}_{t-i}\right\| &= \left\|\sum_{i=0}^{\infty} A^i \mathbf{c}(\mathbf{s}_{t-i} - \mathbf{z}_{t-i})\right\| \leq \sum_{i=0}^{\infty} \left\|A^i \mathbf{c}(\mathbf{s}_{t-i} - \mathbf{z}_{t-i})\right\| \\ &\leq \sum_{i=0}^{\infty} \sigma_{\max}(A^i) \left\|\mathbf{c}(\mathbf{s}_{t-i} - \mathbf{z}_{t-i})\right\| \leq \sum_{i=0}^{\infty} \sigma_{\max}(A)^i \left\|\mathbf{c}(\mathbf{s}_{t-i} - \mathbf{z}_{t-i})\right\| \leq \sum_{i=0}^{\infty} (1-\epsilon)^i \left\|\mathbf{c}(\mathbf{s}_{t-i} - \mathbf{z}_{t-i})\right\|.\end{aligned}$$

If we now use (2.5) in Lemma 1 and the hypothesis in (6.6), we can conclude that

$$\sum_{i=0}^{\infty} (1-\epsilon)^i \left\|\mathbf{c}(\mathbf{s}_{t-i} - \mathbf{z}_{t-i})\right\| \leq \sigma_{\max}(\mathbf{c}) \sum_{i=0}^{\infty} (1-\epsilon)^i \left\|(\mathbf{s}_{t-i} - \mathbf{z}_{t-i})\right\| \leq \frac{\sigma_{\max}(\mathbf{c})\|\mathbf{s} - \mathbf{z}\|_{w^\rho}}{1-(1-\epsilon)^{1-\rho}} < \delta(\varepsilon),$$

which proves the continuity of the map $H_h^{A,\mathbf{c}} : (K_M, \|\cdot\|_{w^\rho}) \longrightarrow \mathbb{R}$ and hence shows that $H_h^{A,\mathbf{c}}$ is a λ_ρ-exponential fading memory filter.

In order to establish the universality statement in the corollary we will proceed, as in the proof of Theorem 8, by showing that $\mathcal{L}_\epsilon$ is a polynomial algebra that contains the constant functionals and separates the points in K_M and then by invoking the Stone-Weierstrass theorem using the compactness of $(K_M, \|\cdot\|_{w^\rho})$.

In order to show that $(\mathcal{L}_\epsilon, \|\cdot\|_{w^\rho})$ is a polynomial algebra, notice first that if $A_1, A_2 \in \mathbb{M}_N$ are such that $\sigma_{\max}(A_1), \sigma_{\max}(A_2) < 1-\epsilon$, then

$$\sigma_{\max}(A_1 \oplus A_2) = \max\left(\sigma_{\max}(A_1), \sigma_{\max}(A_2)\right) < 1-\epsilon. \tag{6.7}$$

If we now take $\mathbf{c}_i \in \mathbb{M}_{N_i,n}$, $i \in \{1,2\}$ and h_1, h_2 two real-valued polynomials in N_1 and N_2 variables, respectively, we have by the first part of the corollary that we just proved that the filter functionals $H_{h_1}^{A_1,\mathbf{c}_1}$ and $H_{h_2}^{A_2,\mathbf{c}_2}$ are well defined. Additionally, by (3.3)-(3.4) so are the combinations $H_{h_1}^{A_1,\mathbf{c}_1} \cdot H_{h_2}^{A_2,\mathbf{c}_2}$ and $H_{h_1}^{A_1,\mathbf{c}_1} + \lambda H_{h_2}^{A_2,\mathbf{c}_2}$ that satisfy:

$$H_{h_1}^{A_1,\mathbf{c}_1} \cdot H_{h_2}^{A_2,\mathbf{c}_2} = H_{h_1 \cdot h_2}^{A_1 \oplus A_2, \mathbf{c}_1 \oplus \mathbf{c}_2}, \quad H_{h_1}^{A_1,\mathbf{c}_1} + \lambda H_{h_2}^{A_2,\mathbf{c}_2} = H_{h_1 \oplus \lambda h_2}^{A_1 \oplus A_2, \mathbf{c}_1 \oplus \mathbf{c}_2}, \quad \lambda \in \mathbb{R}. \tag{6.8}$$

Using the relations (6.8) and (6.7), we can conclude that both $H_{h_1}^{A_1,\mathbf{c}_1} \cdot H_{h_2}^{A_2,\mathbf{c}_2}$ and $H_{h_1}^{A_1,\mathbf{c}_1} + \lambda H_{h_2}^{A_2,\mathbf{c}_2}$ belong to $\mathcal{L}_\epsilon \subset \mathcal{R}_{w^\rho}$. This implies that $(\mathcal{L}_\epsilon, \|\cdot\|_{w^\rho})$ is a polynomial subalgebra of $(\mathcal{R}_{w^\rho}, \|\cdot\|_{w^\rho})$

Since $\mathcal{L}_\epsilon$ contains the constant functionals (just take constant readout maps h), in order to conclude the proof, it is enough to show that the elements in $\mathcal{L}_\epsilon$ separate points in K_M. In the proof of this statement we need the following elementary fact about analytic functions.

Lemma 36 *Let $M > 0$ and let $\mathbf{z} \in [-M, M]^{\mathbb{Z}_-}$. Define the real valued function $f_{\mathbf{z}}(x) := \sum_{j=0}^{\infty} z_{-j} x^j$. This function is real analytic in the interval $(-1,1)$. Moreover, if $\mathbf{z} \neq \mathbf{0}$, then there exists a point $x_0 \in (-1,1)$ such that $f_{\mathbf{z}}(x_0) \neq 0$.*

Proof of the lemma. We note first that for any $x \in (-1,1)$ and any $s \in \mathbb{N}$ we have that

$$\left|\sum_{j=0}^{s} z_{-j} x^j\right| \leq \sum_{j=0}^{s} |z_{-j}| \left|x^j\right| \leq M \sum_{j=0}^{s} |x|^j \leq \frac{M}{1-|x|}.$$

Taking the limit $s \to \infty$, we obtain that

$$|f_{\mathbf{z}}(x)| \leq \frac{M}{1-|x|}, \quad \text{for all } x \in (-1,1),$$

which proves the first claim in the lemma. Now, by the uniqueness theorem for the representation of analytic functions by power series (see Brown and Churchill (2009), page 217), the series $\sum_{j=0}^{\infty} z_{-j} x^j$ is the Taylor expansion around 0 of $f_{\mathbf{z}}(x)$. Since $\mathbf{z} \neq \mathbf{0}$ by hypothesis, some of the derivatives of $f_{\mathbf{z}}(x)$ are non-zero and hence this function cannot be flat, which implies that there exists a point $x_0 \in (-1,1)$ such that $f_{\mathbf{z}}(x_0) \neq 0$. ▼

We now show that the elements in $\mathcal{L}_\epsilon$ separate points in K_M. Take $\mathbf{z}_1, \mathbf{z}_2 \in K_M \subset (\mathbb{R}^n)^{\mathbb{Z}_-}$ such that $\mathbf{z}_1 \neq \mathbf{z}_2$ and let $A \in \mathbb{M}(n,n)$, with $\sigma_{\max}(A) < 1-\epsilon$, and $\mathbf{c} := \mathbb{I}_n$. Let $U^{A,\mathbf{c}} : K_M \longrightarrow (\mathbb{R}^n)^{\mathbb{Z}_-}$ be the linear filter associated to A and $\mathbf{c}$ via the recursion (3.7). Using the preceding arguments we have that

$$U^{A,\mathbf{c}}(\mathbf{z})_t = \sum_{j=0}^{\infty} A^j \mathbf{z}_{t-j}. \tag{6.9}$$

Since $\mathbf{z}_1 \neq \mathbf{z}_2$, then there exists and index $i \in \{1, \ldots, n\}$ and $t \in \mathbb{Z}_-$ such that $\left(z_1^i\right)_t \neq \left(z_2^i\right)_t$. Let now $b \in (-1+\epsilon, 1-\epsilon)$ and let $A_b := \operatorname{diag}(0, \ldots, 0, b, 0, \ldots, 0) \in \mathbb{D}_n$ be the matrix that has the element b in the i-th entry. It is easy to see using (6.9) that

$$U^{A_b,\mathbf{c}}(\mathbf{z})_t = \left(0, \ldots, 0, \sum_{j=0}^{\infty} b^j z_{t-j}^i, 0, \ldots, 0\right)^\top, \quad \text{with} \quad \sum_{j=0}^{\infty} b^j z_{t-j}^i \quad \text{in the } i\text{-th entry.} \tag{6.10}$$

Let $\mathbf{s} := \mathbf{z}_1 - \mathbf{z}_2 \neq \mathbf{0}$. Notice that by (6.10) we have that $U^{A_b,\mathbf{c}}(\mathbf{s})_0 = \left(0, \ldots, 0, \sum_{j=0}^{\infty} b^j s_{-j}^i, 0, \ldots, 0\right)^\top$. Given that the vector $\mathbf{s}^i \in \mathbb{R}^{\mathbb{Z}_-}$ is non-zero, Lemma 36, implies the existence of an element $b_0 \in$

$(-1+\epsilon, 1-\epsilon)$ such that $U^{A_{b_0},\mathbf{c}}(\mathbf{s})_0 \neq \mathbf{0}$, which is equivalent to $U^{A_{b_0},\mathbf{c}}(\mathbf{z}_1)_0 \neq U^{A_{b_0},\mathbf{c}}(\mathbf{z}_2)_0$. Using the polynomial $h(\mathbf{x}) := x_i \in \mathbb{R}$, the previous relation implies that $U_h^{A_{b_0},\mathbf{c}}(\mathbf{z}_1)_0 \neq U_h^{A_{b_0},\mathbf{c}}(\mathbf{z}_2)_0$ or, equivalently,

$$H_h^{A_{b_0},\mathbf{c}}(\mathbf{z}_1) \neq H_h^{A_{b_0},\mathbf{c}}(\mathbf{z}_2), \quad \text{as required.}$$

We conclude the proof by establishing the universality the families $\mathcal{DL}_\epsilon$ and $\mathcal{NL}$ formed by the linear reservoir filters generated by diagonal and nilpotent matrices, respectively. First, in the case of $\mathcal{DL}_\epsilon$, the statement is a consequence of (6.8) and of the fact that when the matrices A_1 and A_2 are diagonal, then the matrix associated to the linear map $A_1 \oplus A_2$ is also diagonal. Additionally, notice that the point separation property for $\mathcal{L}_\epsilon$ has been proved using diagonal matrices in (6.10) and hence it also holds for $\mathcal{DL}_\epsilon$. The claim follows from the Stone-Weierstrass theorem.

Finally, in the case of $\mathcal{NL}$, the proof also follows from (6.8) since it is straightforward to see that when the matrices A_1 and A_2 are nilpotent, then the matrix associated to the linear map $A_1 \oplus A_2$ is also nilpotent. It is only the point separation property of $\mathcal{N}$ that requires a separate argument that we provide in the following lines. Let $\mathbf{z}_1, \mathbf{z}_2 \in K_M$ such that $\mathbf{z}_1 \neq \mathbf{z}_2$ and let $t_0 \in \mathbb{N}$ be the first time index for which $(\mathbf{z}_1)_{-t_0} \neq (\mathbf{z}_2)_{-t_0}$, that is, $(\mathbf{z}_1)_{-t} = (\mathbf{z}_2)_{-t}$, for all $t \in \{0, 1, \ldots, t_0 - 1\}$. Let now $i_0 \in \{1, \ldots, n\}$ be such that $\left(z_1^{i_0}\right)_{-t_0} \neq \left(z_2^{i_0}\right)_{-t_0}$. Let now $A_{t_0+1} \in \mathbb{N}\mathrm{il}_{t_0+1}^{t_0+1}$ be the upper shift matrix in dimension t_0+1, that is, $A_{t_0+1} \in \mathbb{M}_{t_0+1}$ is by definition a superdiagonal matrix with a diagonal of ones above the main diagonal, and construct an element $\mathbf{c} \in \mathbb{M}_{t_0+1,n}$ whose last row is given by a vector of zeros with the exception of a one in the entry i_0. The nilpotency of A_{t_0+1} implies

$$U^{A_{t_0+1},\mathbf{c}}(\mathbf{z})_0 = \sum_{j=0}^{t_0} A_{t_0+1}^j \mathbf{c} \mathbf{z}_{-j}.$$

When we apply this expression to $\mathbf{z}_1$ and $\mathbf{z}_2$, since $(\mathbf{z}_1)_{-t} = (\mathbf{z}_2)_{-t}$, for all $t \in \{0, 1, \ldots, t_0 - 1\}$, we obtain that

$$U^{A_{t_0+1},\mathbf{c}}(\mathbf{z}_1 - \mathbf{z}_2)_0 = A_{t_0+1}^{t_0} \mathbf{c}(\mathbf{z_1} - \mathbf{z_2})_{-t_0} = \left(0, \ldots, 0, \left(z_1^{i_0}\right)_{-t_0} - \left(z_2^{i_0}\right)_{-t_0}\right)^\top \neq \mathbf{0}.$$

Using the polynomial $h(\mathbf{x}) := x_{t_0+1}$, this relation implies that $U_h^{A_{t_0+1},\mathbf{c}}(\mathbf{z}_1)_0 \neq U_h^{A_{t_0+1},\mathbf{c}}(\mathbf{z}_2)_0$ or, equivalently, $H_h^{A_{t_0+1},\mathbf{c}}(\mathbf{z}_1) \neq H_h^{A_{t_0+1},\mathbf{c}}(\mathbf{z}_2)$, as required. ■

6.6 Proof of Proposition 14

We start by noting, as we did in the proof of Corollary 11, that the condition (3.13) implies that the reservoir map associated to (3.11) is a contraction and hence, by Lemma 35, it satisfies the echo state property and has a well-defined associated filter.

We now prove that the condition (3.13) implies the convergence of the series in the expression (3.14). Let $K_1 := \max_{z\in I} \|p(z)\|_2 = \max_{z\in I} \sigma_{\max}(p(z)) < 1$ and $K_2 := \max_{z\in I} \|q(z)\|_2 = \max_{z\in I} \sigma_{\max}(q(z))$; notice that K_1 and K_2 are well-defined due to the compactness of I. Let now $n, m \in \mathbb{N}$ be such that $n < m$ and let $S_n := \sum_{j=0}^n \left(\prod_{k=0}^{j-1} p(z_{t-k})\right) q(z_{t-j}) \in \mathbb{R}^N$. Then,

$$\begin{aligned}\|S_n - S_m\| &= \left\| \sum_{j=n+1}^{m} \left(\prod_{k=0}^{j-1} p(z_{t-k})\right) q(z_{t-j}) \right\| \leq \sum_{j=n+1}^{m} \left\| \prod_{k=0}^{j-1} p(z_{t-k}) \right\|_2 \|q(z_{t-j})\| \\ &\leq \sum_{j=n+1}^{m} \prod_{k=0}^{j-1} \|p(z_{t-k})\|_2 \|q(z_{t-j})\| \leq K_2 \sum_{j=n+1}^{m} K_1^j \leq K_2 \sum_{j=n+1}^{\infty} K_1^j = \frac{K_2 K_1^{n+1}}{1-K_1}.\end{aligned}$$

The condition $K_1 < 1$ implies that $\frac{K_2 K_1^{n+1}}{1-K_1} \to 0$ as $n \to \infty$ and hence $\{S_n\}_{n\in\mathbb{N}}$ is a Cauchy sequence in $\mathbb{R}^N$ that consequently converges. This proves the convergence of the infinite series in (3.14) and the causal character of the filter that it defines. The time-invariance can also be easily established by mimicking the verification that we carried out in the proof of Corollary 11. We now prove that (3.14) is indeed a solution of (3.11):

$$\begin{aligned}p(z_t)\mathbf{x}_{t-1} + q(z_t) &= p(z_t)\left(\sum_{j=0}^{\infty}\left(\prod_{k=0}^{j-1} p(z_{t-1-k})\right) q(z_{t-1-j})\right) + q(z_t) = q(z_t) + p(z_t)q(z_{t-1}) \\ &+ p(z_t)p(z_{t-1})q(z_{t-2}) + p(z_t)p(z_{t-1})p(z_{t-2})q(z_{t-3}) + \cdots = \sum_{j=0}^{\infty}\left(\prod_{k=0}^{j-1} p(z_{t-k})\right) q(z_{t-j}) = \mathbf{x}_t.\end{aligned}$$

We conclude by proving the inequality in (3.16). Note first that for any $m \in \mathbb{N}$,

$$\begin{aligned}\left\|\sum_{j=0}^{m}\left(\prod_{k=0}^{j-1} p(z_{t-k})\right) q(z_{t-j})\right\| &\leq \sum_{j=0}^{m}\left\|\prod_{k=0}^{j-1} p(z_{t-k})\right\|_2 \|q(z_{t-j})\| \\ &\leq \sum_{j=0}^{m}\prod_{k=0}^{j-1} \|p(z_{t-k})\|_2 \|q(z_{t-j})\| \leq \frac{K_2\left(1-K_1^{m+1}\right)}{1-K_1},\end{aligned}$$

and hence, by the continuity of the norm and for any $t \in \mathbb{Z}$:

$$\|\mathbf{x}_t\| = \lim_{m\to\infty}\left\|\sum_{j=0}^{m}\left(\prod_{k=0}^{j-1} p(z_{t-k})\right) q(z_{t-j})\right\| \leq \lim_{m\to\infty}\frac{K_2\left(1-K_1^{m+1}\right)}{1-K_1} = \frac{K_2}{1-K_1}. \quad ■$$

6.7 Proof of Lemma 15

(i) $\Longrightarrow$ (ii): $\|A_0\|_2 + \|A_1\|_2 + \cdots + \|A_n\|_2 < \sum_{i=0}^{n_1} \lambda = \lambda(n_1+1) < 1$.
(ii) $\Longrightarrow$ (iii): $\|p(z)\|_2 = \|A_0 + zA_1 + z^2A_2 + \cdots + z^{n_1}A_{n_1}\|_2 \leq \|A_0\|_2 + |z|\|A_1\|_2 + |z^2|\|A_2\|_2 + \cdots + |z^{n_1}|\|A_{n_1}\|_2 < \|A_0\|_2 + \|A_1\|_2 + \cdots + \|A_{n_1}\|_2 < 1$. ■

6.8 Proof of Proposition 16

We start by formulating and proving an elementary result that will be needed later on.

Lemma 37 *Let $\mathbf{f} : U \subset \mathbb{R}^n \longrightarrow \mathbb{M}_m$ be a differentiable function defined on the convex set U. For any $\mathbf{z} \in U$ denote by $\partial_i \mathbf{f}(\mathbf{z}) \in \mathbb{M}_m$ the matrix containing the partial derivatives of the components of $\mathbf{f}$ with respect to their ith-entry, $i \in \{1, \ldots, n\}$. Then, for any $\mathbf{x}, \mathbf{y} \in U$ we have:*

$$\|\mathbf{f}(\mathbf{y}) - \mathbf{f}(\mathbf{x})\|_2 \leq \sqrt{nm} \max_{i\in\{1,\ldots,n\}}\left(\sup_{\mathbf{z}\in U}\{\|\partial_i \mathbf{f}(\mathbf{z})\|_2\}\right)\|\mathbf{x} - \mathbf{y}\|. \tag{6.11}$$

Proof. Given $A = (A_{i,j}) \in \mathbb{M}_{n,m}$, let $\|A\|_F := \mathrm{tr}\left(A^\top A\right) = \sum_{i=1}^n \sum_{j=1}^m A_{i,j}^2$ be its Frobenius norm. Recall (see Theorem 5.6.34 and Exercise 5.6.P24 in Horn and Johnson (2013)) that

$$\|A\|_2 \leq \|A\|_F \leq \sqrt{r}\,\|A\|_2, \tag{6.12}$$

where r is the rank of A. Consider now $\mathbf{x}, \mathbf{y} \in U$ arbitrary and let $D\mathbf{f}(\mathbf{z}) : \mathbb{R}^n \longrightarrow \mathbb{M}_m$ be the differential of $\mathbf{f}$ evaluated at $\mathbf{z} \in U$. The convexity of U implies that the Mean Value Inequality holds (see Theorem 2.4.8 in Abraham et al. (1988)) and hence:

$$\|\mathbf{f}(\mathbf{y}) - \mathbf{f}(\mathbf{x})\|_F \leq \sup_{t\in[0,1]} \{\|D\mathbf{f}((1-t)\mathbf{x} + t\mathbf{y})\|_2 \|\mathbf{x} - \mathbf{y}\|\}. \tag{6.13}$$

The first inequality in (6.12) and (6.13) imply that

$$\|\mathbf{f}(\mathbf{y}) - \mathbf{f}(\mathbf{x})\|_2 \leq \sup_{\mathbf{z}\in U} \{\|D\mathbf{f}(\mathbf{z})\|_2 \|\mathbf{x} - \mathbf{y}\|\}. \tag{6.14}$$

At the same time, notice that by (6.12)

$$\|D\mathbf{f}(\mathbf{z})\|_2^2 \leq \|D\mathbf{f}(\mathbf{z})\|_F^2 = \sum_{i=1}^{n}\sum_{j=1}^{m}\sum_{k=1}^{m} \partial_i f_{jk}^2(\mathbf{z}) = \sum_{i=1}^{n} \|\partial_i \mathbf{f}(\mathbf{z})\|_F^2$$
$$\leq m\sum_{i=1}^{n} \|\partial_i \mathbf{f}(\mathbf{z})\|_2^2 \leq mn \max_{i\in\{1,..,n\}} \left(\|\partial_i \mathbf{f}(\mathbf{z})\|_2^2\right).$$

This inequality, together with (6.14), imply the statement (6.11) since the maximum and the supremum can be trivially exchanged. ▼

We now carry out the proof of the proposition under the hypothesis **(iii)** in Lemma 15 which is implied by the other two. The modifications necessary to establish the result under the other two hypotheses are straightforward. Consider two arbitrary elements $\mathbf{z}, \mathbf{s} \in I^{\mathbb{Z}_-}$. Then, by the Cauchy-Schwarz and Minkowski inequalities:

$$|H^{p,q}_{\mathbf{W}}(\mathbf{z}) - H^{p,q}_{\mathbf{W}}(\mathbf{s})| = \left|\mathbf{W}^\top \left[\sum_{j=0}^{\infty}\left(\left(\prod_{k=0}^{j-1} p(z_{-k})\right) q(z_{-j}) - \left(\prod_{k=0}^{j-1} p(s_{-k})\right) q(s_{-j})\right)\right]\right|$$
$$\leq \|\mathbf{W}\| \sum_{j=0}^{\infty} \left\|a_j(\underline{z_{-j+1}})q(z_{-j}) - a_j(\underline{s_{-j+1}})q(s_{-j})\right\|, \quad \text{where} \quad a_j(\underline{z_{-j+1}}) := \prod_{k=0}^{j-1} p(z_{-k}). \tag{6.15}$$

We now bound the right hand side of (6.15) as follows:

$$\sum_{j=0}^{\infty} \left\|a_j(\underline{z_{-j+1}})q(z_{-j}) - a_j(\underline{s_{-j+1}})q(s_{-j})\right\|$$
$$= \sum_{j=0}^{\infty} \left\|a_j(\underline{z_{-j+1}})q(z_{-j}) + a_j(\underline{z_{-j+1}})q(s_{-j}) - a_j(\underline{z_{-j+1}})q(s_{-j}) - a_j(\underline{s_{-j+1}})q(s_{-j})\right\|$$
$$\leq \sum_{j=0}^{\infty} \left\|a_j(\underline{z_{-j+1}})\right\|_2 \|q(z_{-j}) - q(s_{-j})\| + \left\|a_j(\underline{z_{-j+1}}) - a_j(\underline{s_{-j+1}})\right\|_2 \|q(s_{-j})\| \tag{6.16}$$

If L_q is a Lipschitz constant of $q : I \longrightarrow \mathbb{R}^N$ then

$$\left\|a_j(\underline{z_{-j+1}})\right\|_2 \|q(z_{-j}) - q(s_{-j})\| \leq M_p^j L_q |z_{-j} - s_{-j}|, \tag{6.17}$$

which inserted in (6.16) and in (6.15) implies that

$$|H^{p,q}_{\mathbf{W}}(\mathbf{z}) - H^{p,q}_{\mathbf{W}}(\mathbf{s})| \leq \|\mathbf{W}\| L_q \left[\sum_{j=0}^{\infty} M_p^j |z_{-j} - s_{-j}| + \sum_{j=0}^{\infty} \left\|a_j(\underline{z_{-j+1}}) - a_j(\underline{s_{-j+1}})\right\|_2\right] \tag{6.18}$$

We now bound above the second summand in (6.18) using the inequality (6.11) in the statement of Lemma 37 as well as the following identity:

$$a_j(\underline{z_{-j+1}}) - a_j(\underline{s_{-j+1}}) = \sum_{l=0}^{j-1}(p(s_0)\cdots p(s_{-(l-1)})\cdot p(z_{-l})\cdot p(z_{-(l+1)})\cdots p(z_{-(j-1)})$$
$$- p(s_0)\cdots p(s_{-(l-1)})\cdot p(s_{-l})\cdot p(z_{-(l+1)})\cdots p(z_{-(j-1)})). \tag{6.19}$$

This equality simply follows from writing:

$$\begin{aligned}
a_j(\underline{z_{-j+1}}) - a_j(\underline{s_{-j+1}}) &= \prod_{l=0}^{j-1} p(z_{-l}) - \prod_{l=0}^{j-1} p(s_{-l}) = p(z_0)p(z_{-1})\cdots p(z_{-(j-1)}) - p(s_0)p(s_{-1})\cdots p(s_{-(j-1)}) \\
&= p(z_0)p(z_{-1})\cdots p(z_{-(j-1)}) - p(s_0)p(s_{-1})\cdots p(s_{-(j-1)}) \\
&+ \Big\{ p(s_0)p(z_{-1})\cdots p(z_{-(j-1)}) - p(s_0)p(z_{-1})\cdots p(z_{-(j-1)}) \\
&+ p(s_0)p(s_{-1})p(z_{-2})\cdots p(z_{-(j-1)}) - p(s_0)p(s_{-1})p(z_{-2})\cdots p(z_{-(j-1)}) \\
&+\cdots + p(s_0)\cdots p(s_{-(l-1)})p(z_{-l})p(z_{-(l+1)})\cdots p(z_{-(j-1)}) - p(s_0)\cdots p(s_{-(l-1)})p(z_{-l})p(z_{-(l+1)})\cdots p(z_{-(j-1)}) \\
&+ \cdots + p(s_0)\cdots p(s_{-(j-2)})p(z_{-(j-1)}) - p(s_0)\cdots p(s_{-(j-2)})p(z_{-(j-1)}) \Big\} \\
&= \sum_{l=0}^{j-1}(p(s_0)\cdots p(s_{-(l-1)})\cdot p(z_{-l})\cdot p(z_{-(l+1)})\cdots p(z_{-(j-1)}) \\
&\qquad - p(s_0)\cdots p(s_{-(l-1)})\cdot p(s_{-l})\cdot p(z_{-(l+1)})\cdots p(z_{-(j-1)})),
\end{aligned}$$

where the $2(j-1)$ summands inside the braces are obtained by adding and subtracting polynomials recursively constructed out of $a_j(\underline{z_{-j+1}})$ by changing the variables of the first k factors, $k \in \{1, \cdots, j-1\}$. We then combine all the $(2k-1)$-th with the $(2k+2)-th$ summands of the resulting expression in order to obtain the first $j-1$ terms in the sum in (6.19). Then the last j-th term results from combining the second with the one before last summands, that is, $p(s_0)p(s_{-1})\cdots p(s_{-(j-1)})$ and $p(s_0)\cdots p(s_{-(j-2)})p(z_{-(j-1)})$, respectively.

Using the relation (6.19) we can write:

$$\left\|a_j(\underline{z_{-j+1}}) - a_j(\underline{s_{-j+1}})\right\|_2 \leq \sum_{l=0}^{j-1} \left\|p(s_0)\cdots p(s_{-(l-1)})\cdot(p(z_{-l}) - p(s_{-l}))\cdot p(z_{-(l+1)})\cdots p(z_{-(j-1)})\right\|_2$$
$$\leq \sum_{l=0}^{j-1} \|p(s_0)\|_2 \cdots \left\|p(s_{-(l-1)})\right\|_2 \cdot \|p(z_{-l}) - p(s_{-l})\|_2 \cdot \left\|p(z_{-(l+1)})\right\|_2 \cdots \left\|p(z_{-(j-1)})\right\|_2$$
$$\leq M_p^{j-1}\sqrt{N}\sup_{z\in I}\{\|p'(z)\|_2\} \sum_{l=1}^{j} |z_{-j+l} - s_{-j+l}|,$$

where the last inequality is a consequence of (6.11). Let $M_{p'} := \sqrt{N}\sup_{z\in I}\{\|p'(z)\|_2\}$, then

$$\left\|a_j(\underline{z_{-j+1}}) - a_j(\underline{s_{-j+1}})\right\|_2 \leq \frac{M_{p'}}{M_p} M_p^j \sum_{l=1}^{j} |z_{-j+l} - s_{-j+l}| = \frac{M_{p'}}{M_p} \sum_{l=1}^{j} M_p^l M_p^{j-l} \left|z_{-(j-l)} - s_{-(j-l)}\right|$$

Since the last term in this inequality is one summand of the Cauchy product of the series with general terms M_p^j and $M_p^j\left|z_{-j}-s_{-j}\right|$ and these two series are absolutely convergent (recall the statement (2.4)), we can conclude (see, for instance, §8.24 in Apostol (1974)) that

$$\sum_{j=0}^{\infty}\left\|a_j(\underline{z_{-j+1}})-a_j(\underline{s_{-j+1}})\right\|_2 \leq \frac{M_{p'}}{M_p}\sum_{j=0}^{\infty}\sum_{l=1}^{j}M_p^l M_p^{j-l}\left|z_{-(j-l)}-s_{-(j-l)}\right| \\ = \frac{M_{p'}}{M_p}\frac{1}{1-M_p}\sum_{j=0}^{\infty}M_p^j\left|z_{-j}-s_{-j}\right|.$$

If we now substitute this relation in (6.18) and we use Lemma 1 with weighting sequences $w_t^\rho := M_p^{\rho t}$, for any $\rho\in(0,1)$, we obtain that:

$$\begin{aligned}\left|H_{\mathbf{W}}^{p,q}(\mathbf{z})-H_{\mathbf{W}}^{p,q}(\mathbf{s})\right| &\leq \|\mathbf{W}\|\,L_q\left(1+\frac{M_{p'}}{M_p}\frac{1}{1-M_p}\right)\sum_{j=0}^{\infty}M_p^j\left|z_{-j}-s_{-j}\right| \\ &\leq \|\mathbf{W}\|\,L_q\left(1+\frac{M_{p'}}{M_p}\frac{1}{1-M_p}\right)\left(\frac{1}{1-M_p^{1-\rho}}\right)\|\mathbf{z}-\mathbf{s}\|_{w^\rho},\end{aligned}$$

which proves the continuity of the map $H_{\mathbf{W}}^{p,q}:(I^{\mathbb{Z}_-},\|\cdot\|_{w^\rho})\longrightarrow\mathbb{R}$, as required. ■

6.9 Proof of Proposition 17

We first recall that since by hypothesis the reservoir functionals $H_{\mathbf{W}_1}^{p_1,q_1}, H_{\mathbf{W}_2}^{p_2,q_2}$ are well-defined then, by the comments that follow (3.5), so are $H_{\mathbf{W}_1}^{p_1,q_1}+\lambda H_{\mathbf{W}_2}^{p_2,q_2}$ and $H_{\mathbf{W}_1}^{p_1,q_1}\cdot H_{\mathbf{W}_2}^{p_2,q_2}$.

The proof of (**i**) is a straightforward verification. As to (**ii**), denote first by y_t^1, y_t^2 and $\mathbf{x}_t^1,\mathbf{x}_t^2$ the outputs and the state variables, respectively, of the SAS corresponding to the two functionals that we are considering. We note first that by (3.12):

$$y_t^1\cdot y_t^2=\mathbf{W}_1^\top\mathbf{x}_t^1\cdot\mathbf{W}_2^\top\mathbf{x}_t^2=(\mathbf{W}_1\otimes\mathbf{W}_2)^\top(\mathbf{x}_t^1\otimes\mathbf{x}_t^2).$$

Using (3.11) it can be readily verified that the time evolution of the tensor product $\mathbf{x}_t^1\otimes\mathbf{x}_t^2$ is given by

$$\begin{aligned}\mathbf{x}_t^1\otimes\mathbf{x}_t^2 &= (p_1(z_t)\otimes p_2(z_t))(\mathbf{x}_{t-1}^1\otimes\mathbf{x}_{t-1}^2)+p_1(z_t)\mathbf{x}_{t-1}^1\otimes q_2(z_t)+q_1(z_t)\otimes p_2(z_t)\mathbf{x}_{t-1}^2+q_1(z_t)\otimes q_2(z_t), \\ &= (p_1\otimes p_2)(z_t)(\mathbf{x}_{t-1}^1\otimes\mathbf{x}_{t-1}^2)+p_1(z_t)\mathbf{x}_{t-1}^1\otimes q_2(z_t)+q_1(z_t)\otimes p_2(z_t)\mathbf{x}_{t-1}^2+(q_1\otimes q_2)(z_t),\end{aligned}$$

which proves (3.23) and hence (3.22).

In order to show that the reservoir functionals on the right hand side of (3.21) and (3.22) are well-defined we prove the following lemma.

Lemma 38 *Let $p_1(z)\in\mathbb{M}_{N_1,M_1}[z]$ and $p_2(z)\in\mathbb{M}_{N_2,M_2}[z]$ be two polynomials with matrix coefficients and assume that they satisfy that $\|p_1(z)\|_2<1-\epsilon$ and $\|p_2(z)\|_2<1-\epsilon$ for all $z\in I:=[-1,1]$ and a given $0<\epsilon>1$. Then:*

(i) $\|p_1\oplus p_2(z)\|_2<1-\epsilon$,

(ii) $\|p_1\otimes p_2(z)\|_2<1-\epsilon$,

for all $z\in I:=[-1,1]$.

Proof of the lemma. Let $\mathbf{x}=\mathbf{x}_1\oplus\mathbf{x}_2\in\mathbb{R}^{M_1}\oplus\mathbb{R}^{M_2}$. Then, in order to prove part **(i)** note that

$$\begin{aligned}\|(p_1\oplus p_2)(z)\cdot\mathbf{x}\|^2 &= \|(p_1(z)\cdot\mathbf{x}_1,p_2(z)\cdot\mathbf{x}_2)\|^2=\|p_1(z)\cdot\mathbf{x}_1\|^2+\|p_2(z)\cdot\mathbf{x}_2\|^2 \\ &\leq \|p_1(z)\|_2^2\|\mathbf{x}_1\|^2+\|p_2(z)\|_2^2\|\mathbf{x}_2\|^2\leq(1-\epsilon)^2\left(\|\mathbf{x}_1\|^2+\|\mathbf{x}_2\|^2\right)=(1-\epsilon)^2\|\mathbf{x}\|^2.\end{aligned}$$

This inequality implies that

$$\|p_1\oplus p_2(z)\|_2=\sup_{\mathbf{x}\neq\mathbf{0}}\left\{\frac{\|(p_1\oplus p_2)(z)\cdot\mathbf{x}\|}{\|\mathbf{x}\|}\right\}\leq\sup_{\mathbf{x}\neq\mathbf{0}}\left\{\frac{(1-\epsilon)\|\mathbf{x}\|}{\|\mathbf{x}\|}\right\}=1-\epsilon,\quad\text{as required.}$$

As to the statement in part **(ii)**:

$$\|p_1\otimes p_2(z)\|_2=\sigma_{\max}(p_1\otimes p_2(z))=\sigma_{\max}(p_1(z))\sigma_{\max}(p_2(z))=\|p_1(z)\|_2\|p_2(z)\|_2<(1-\epsilon)^2<(1-\epsilon).\ \blacktriangledown$$

Now, the first part of this lemma and Proposition 14 guarantee that $H_{\mathbf{W}_1\oplus\lambda\mathbf{W}_2}^{p_1\oplus p_2,q_1\oplus q_2}$ is well-defined. The same conclusion holds for $H_{\mathbf{0}\oplus\mathbf{0}\oplus(\mathbf{W}_1\otimes\mathbf{W}_2)}^{p,q_1\oplus q_2\oplus(q_1\otimes q_2)}$ because due to the block diagonal character of (3.23) then $\sigma_{\max}(p(z))=\sigma_{\max}((p_1(z)\oplus p_2(z)\oplus(p_1\otimes p_2)(z))=\|p_1(z)\oplus p_2(z)\oplus(p_1\otimes p_2)(z)\|_2$. By parts **(i)** and **(ii)** in Lemma 38 we can conclude that $\|p(z)\|_2<1-\epsilon$ for all $z\in[-1,1]$ and, again by Proposition 14, the reservoir functional $H_{\mathbf{0}\oplus\mathbf{0}\oplus(\mathbf{W}_1\otimes\mathbf{W}_2)}^{p,q_1\oplus q_2\oplus(q_1\otimes q_2)}$ is well-defined. ■

6.10 Proof of Theorem 19

Note first that the hypothesis $M_p<1-\epsilon<1$ on the polynomials p associated to the elements in $\mathcal{S}_\epsilon$ implies, by Propositions 14 and 16, that this family is made of time-invariant reservoir filters that have the FMP with respect to weighting sequences of the form $w_t^p:=M_p^{pt}$, $\rho\in(0,1)$. Additionally, using Lemma 7 and the hypothesis $M_p<1-\epsilon$, for a fixed given $\epsilon\in(0,1)$, we can conclude that all the reservoir filters in $\mathcal{S}_\epsilon$ have the FMP with the common weighting sequence $w_t^\rho:=(1-\epsilon)^{\rho t}$, $\rho\in(0,1)$.

The elements in $\mathcal{S}_\epsilon$ form a polynomial algebra as a consequence of Lemma 38 and Proposition 17. Moreover, the family $\mathcal{S}_\epsilon$ has the point separation property and contains all the constant functionals. Indeed, since $\mathcal{S}_\epsilon$ includes the linear family $\mathcal{L}_\epsilon$, we recall that in Appendix 6.5 we proved that given $\mathbf{z}_1,\mathbf{z}_2\in K_M\subset(\mathbb{R}^n)^{\mathbb{Z}_-}$ such that $\mathbf{z}_1\neq\mathbf{z}_2$, there exists $A\in\mathbb{M}(n,n)$, with $\sigma_{\max}(A)<1-\epsilon$ and $\mathbf{c}:=\mathbb{I}_n$ such that $U^{A,\mathbf{c}}(\mathbf{z}_1)_0\neq U^{A,\mathbf{c}}(\mathbf{z}_2)_0$. The point separation property follows from choosing any vector $\mathbf{W}\in\mathbb{R}^N$ such that $\mathbf{W}^\top(U^{A,\mathbf{c}}(\mathbf{z}_1))_0\neq\mathbf{W}^\top(U^{A,\mathbf{c}}(\mathbf{z}_2))_0$, which implies that $U_{\mathbf{W}}^{A,\mathbf{c}}(\mathbf{z}_1)_0\neq U_{\mathbf{W}}^{A,\mathbf{c}}(\mathbf{z}_2)_0$ and hence $H_{U_{\mathbf{W}}^{A,\mathbf{c}}}(\mathbf{z}_1)\neq H_{U_{\mathbf{W}}^{A,\mathbf{c}}}(\mathbf{z}_2)$, as required.

All the constant functionals can be obtained by taking for p the zero polynomial and for q the constant polynomials (q has degree zero). In that case, the state variables are a constant sequence $\mathbf{x}_t=q$ and the associated functional is the constant map $H_{\mathbf{W}}^{0,q}(\mathbf{z})=\mathbf{W}^\top q$, for all $\mathbf{z}\in K_M$.

The universality result follows hence from the Stone-Weierstrass Theorem and the compactness of $(I^{\mathbb{Z}_-},\|\cdot\|_{w^\rho})$ established in Lemma 2.

Finally, we prove the statement regarding the family $\mathcal{NS}_\epsilon$ determined by nilpotent polynomials p. First, by expressions (3.21), (3.22), and (3.23), it is easy to show that this family is a polynomial algebra. The only point that requires some detail is the fact that the k-th power of the polynomial p in (3.23) that is obtained in the product of the two SAS reservoir functionals $H_{\mathbf{W}_1}^{p_1,q_1}$ and $H_{\mathbf{W}_2}^{p_2,q_2}$ is given by

$$p^k(z):=\begin{pmatrix}p_1^k(z) & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & p_2^k(z) & \mathbf{0} \\ p_1^k\otimes q_2^{k-1}(z) & q_1^{k-1}\otimes p_2^k(z) & p_1^k\otimes p_2^k(z)\end{pmatrix},$$

which shows that if p_1 and p_2 are nilpotent then so is the associated polynomial p. The point separation property is, again, inherited from the proof of linear case provided in the Appendix 6.5. ■

6.11 Proof of Lemma 24

(i) Let $A := \left\{\rho \in \overline{\mathbb{R}_+} \mid \|\mathbf{X}\|_B \leq \rho \quad \text{almost surely}\right\}$. It suffices to show that $\|\mathbf{X}\|_{L^\infty} := \inf A \in A$, which implies that $\|\mathbf{X}\|_B \leq \|\mathbf{X}\|_{L^\infty}$ almost surely. Indeed, consider the sequence $\|\mathbf{X}\|_{L^\infty} + 1/j$, $j \in \mathbb{N}$. By the approximation property of the infimum, there exists a decreasing sequence of numbers $\{\rho_j\}_{j\in\mathbb{N}} \subset A$ in A satisfying $\|\mathbf{X}\|_{L^\infty} \leq \rho_j < \|\mathbf{X}\|_{L^\infty} + 1/j$ for all $j \in \mathbb{N}$. Define $F := \{\omega \in \Omega \mid \|\mathbf{X}(\omega)\|_B > \|\mathbf{X}\|_{L^\infty}\}$ and $F_j := \{\omega \in \Omega \mid \|\mathbf{X}(\omega)\|_B > \rho_j\}$. It is easy to see that $F_j \subset F_{j+1}$, $j \in \mathbb{N}$ and that $\lim_{j\to\infty} F_j = F$ and, consequently, (see Lemma 5, page 7 in Grimmett and Stirzaker (2001)) $\lim_{j\to\infty} \mathbb{P}(F_j) = \mathbb{P}(F)$. Since by construction $\mathbb{P}(F_j) = 0$ for all $j \in \mathbb{N}$ then $\mathbb{P}(F) = 0$ necessarily, which shows that $\|\mathbf{X}\|_{L^\infty} \in A$, as required.
(ii) If $\|\mathbf{X}\|_{L^\infty} \leq C$ then by part **(i)**, $\|\mathbf{X}\|_B \leq \|\mathbf{X}\|_{L^\infty} \leq C$ almost surely. Conversely, if $\|\mathbf{X}\|_B \leq C$ almost surely, then $C \in A = \left\{\rho \in \overline{\mathbb{R}^+} \mid \|\mathbf{X}\|_B \leq \rho \quad \text{almost surely}\right\}$. Consequently, $\|\mathbf{X}\|_{L^\infty} = \inf A \leq C \in A$, as required.
(iii) Suppose first that $\|\mathbf{X}\|_B \leq C$ almost surely and define $F := \{\omega \in \Omega \mid \|\mathbf{X}(\omega)\|_B > C\}$. By hypothesis, we have that $\mathbb{P}(F) = 0$ and $\mathbb{P}(\Omega \setminus F) = 1$. Then,

$$\begin{aligned}\mathrm{E}\left[\|\mathbf{X}\|_B^k\right] &= \int_\Omega \|\mathbf{X}\|_B^k \, d\mathbb{P} = \int_{\Omega\setminus F} \|\mathbf{X}\|_B^k \, d\mathbb{P} + \int_F \|\mathbf{X}\|_B^k \, d\mathbb{P} \\ &= \int_{\Omega\setminus F} \|\mathbf{X}\|_B^k \, d\mathbb{P} \leq \int_{\Omega\setminus F} C^k d\mathbb{P} = C^k \mathbb{P}(\Omega \setminus F) = C^k,\end{aligned}$$

as required. Conversely, assume that $\mathrm{E}\left[\|\mathbf{X}\|_B^k\right] \leq C^k$, for any $k \in \mathbb{N}$, and define

$$F_n := \left\{\omega \in \Omega \mid \|\mathbf{X}(\omega)\|_B > C + \frac{1}{n}\right\},$$

for all $n \geq 1$. It is easy to see that $F_n \subset F_{n+1}$ and that $\lim_{n\to\infty} F_n = F$ and, consequently, (see Lemma 5, page 7 in Grimmett and Stirzaker (2001)) $\lim_{n\to\infty} \mathbb{P}(F_n) = \mathbb{P}(F)$. Now,

$$\begin{aligned}C^k &\geq \mathrm{E}\left[\|\mathbf{X}\|_B^k\right] = \int_\Omega \|\mathbf{X}\|_B^k \, d\mathbb{P} = \int_{\Omega\setminus F_n} \|\mathbf{X}\|_B^k \, d\mathbb{P} + \int_{F_n} \|\mathbf{X}\|_B^k \, d\mathbb{P} \\ &\geq \int_{F_n} \|\mathbf{X}\|_B^k \, d\mathbb{P} \geq \int_{F_n} \left(C + \frac{1}{n}\right)^k d\mathbb{P} = \left(C + \frac{1}{n}\right)^k \mathbb{P}(F_n),\end{aligned}$$

which implies that $\mathbb{P}(F_n) \leq C^k / \left(C + \frac{1}{n}\right)^k$ for any $k \in \mathbb{N}$ and hence, by taking the limit $k \to \infty$, we can conclude that $\mathbb{P}(F_n) = 0$. Consequently, $\mathbb{P}(F) = \lim_{n\to\infty} \mathbb{P}(F_n) = 0$, which shows that $\|\mathbf{X}\|_B \leq C$ almost surely.
(iv) Let $||\cdot||$ denote the Euclidean norm on $\mathbb{R}^n$. Since $|X_i| \leq \|\mathbf{X}\|$ always and by part **(i)** $\|\mathbf{X}\| \leq \|\mathbf{X}\|_{L^\infty}$ almost surely, we can conclude that $|X_i| \leq \|\mathbf{X}\|_{L^\infty}$ almost surely. This implies that $X_i \in L^\infty(\Omega, \mathbb{R})$ and hence the statement follows from part **(iii)**. ■

6.12 Proof of Lemma 25

We start by proving by contradiction that

$$\operatorname*{ess\,sup}_{\omega\in\Omega}\left\{\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\}\right\} \geq \sup_{t\in\mathbb{Z}}\left\{\operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}_t(\omega)\|\}\right\}. \tag{6.20}$$

Indeed, suppose that

$$\operatorname*{ess\,sup}_{\omega\in\Omega}\left\{\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\}\right\} < \sup_{t\in\mathbb{Z}}\left\{\operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}_t(\omega)\|\}\right\}. \tag{6.21}$$

By the approximation property of the supremum (see Theorem 1.14 in Apostol (1974)), there exists $t_0 \in \mathbb{Z}$ such that

$$\operatorname*{ess\,sup}_{\omega\in\Omega}\left\{\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\}\right\} < \operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}_{t_0}(\omega)\|\} \leq \sup_{t\in\mathbb{Z}}\left\{\operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}_t(\omega)\|\}\right\}. \tag{6.22}$$

However, $\|\mathbf{z}_{t_0}(\omega)\| \leq \sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\}$ for all $\omega \in \Omega$ and hence by part **(i)** in Lemma 24

$$\|\mathbf{z}_{t_0}(\omega)\| \leq \sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\} \leq \operatorname*{ess\,sup}_{\omega\in\Omega}\left\{\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\}\right\}, \quad \text{almost surely.}$$

Now, by part **(ii)** in Lemma 24, this implies that

$$\operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}_{t_0}(\omega)\|\} \leq \operatorname*{ess\,sup}_{\omega\in\Omega}\left\{\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\}\right\}.$$

However, this expression is in contradiction with the first inequality in (6.22) and hence the assumption (6.21) cannot be correct. This argument implies that the inequality (6.20) holds.

We now prove the reverse inequality, that is,

$$\operatorname*{ess\,sup}_{\omega\in\Omega}\left\{\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\}\right\} \leq \sup_{t\in\mathbb{Z}}\left\{\operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}_t(\omega)\|\}\right\}. \tag{6.23}$$

By part **(ii)** of Lemma 24, this inequality holds if and only if

$$\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\} \leq \sup_{t\in\mathbb{Z}}\left\{\operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}_t(\omega)\|\}\right\}, \quad \text{almost surely.} \tag{6.24}$$

Now, by part **(i)** in Lemma 24, we have that $\|\mathbf{z}_t(\omega)\| \leq \operatorname{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}_t(\omega)\|\}$, almost surely and for each fixed $t \in \mathbb{Z}$. Let $A_t \subset \Omega$ be the zero-measure set such that $\|\mathbf{z}_t(\omega)\| > \operatorname{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}_t(\omega)\|\}$ for all $\omega \in A_t$. Let $A := \bigcup_{t\in\mathbb{Z}} A_t$. Notice that $\mathbb{P}(A) = \mathbb{P}\left(\bigcup_{t\in\mathbb{Z}} A_t\right) \leq \sum_{t\in\mathbb{Z}} \mathbb{P}(A_t) = 0$ and hence $B := A^{\mathsf{c}}$ has measure one and

$$\|\mathbf{z}_t(\omega)\| \leq \operatorname*{ess\,sup}_{\omega\in\Omega}\{\|\mathbf{z}_t(\omega)\|\}, \quad \text{for all } \omega \in B \text{ and all } t \in \mathbb{Z}.$$

Since B has measure one, this inequality is equivalent to (6.24), which guarantees that (6.23) holds. The inequalities (6.20) and (6.23) that we just proved imply that the equality (4.7) holds true. ■

6.13 Proof of Lemma 26

It is obvious that $S_{\ell^\infty(\mathbb{R}^n)} \subset S_{(\mathbb{R}^n)^\mathbb{Z}}$ and hence the inclusion map

$$\iota : S_{\ell^\infty(\mathbb{R}^n)} \hookrightarrow S_{(\mathbb{R}^n)^\mathbb{Z}}, \tag{6.25}$$

is well-defined. The equivariance with respect to the equivalence relations $\sim_{\ell^\infty(\mathbb{R}^n)}$ and $\sim_{(\mathbb{R}^n)^\mathbb{Z}}$ follows trivially from noticing that if $\mathbf{z}_1, \mathbf{z}_2 \in S_{\ell^\infty(\mathbb{R}^n)}$ are such that $\mathbf{z}_1 \sim_{\ell^\infty(\mathbb{R}^n)} \mathbf{z}_2$ one obviously have that $\iota(\mathbf{z})_1 \sim_{(\mathbb{R}^n)^\mathbb{Z}} \iota(\mathbf{z}_2)$. This shows the existence of the projected map ϕ that makes the diagram

$$\begin{array}{ccc} S_{\ell^\infty(\mathbb{R}^n)} & \xhookrightarrow{\ \iota\ } & S_{(\mathbb{R}^n)^\mathbb{Z}} \\ {\scriptstyle \Pi_{\sim_{\ell^\infty(\mathbb{R}^n)}}}\downarrow & & \downarrow{\scriptstyle \Pi_{\sim_{(\mathbb{R}^n)^\mathbb{Z}}}} \\ L^\infty\left(\Omega, \ell^\infty(\mathbb{R}^n)\right) & \xrightarrow{\ \phi\ } & L^\infty\left(\Omega, (\mathbb{R}^n)^\mathbb{Z}\right), \end{array}$$

commutative where $\Pi_{\sim_{\ell^\infty(\mathbb{R}^n)}}$ and $\Pi_{\sim_{(\mathbb{R}^n)^\mathbb{Z}}}$ map the elements in $S_{\ell^\infty(\mathbb{R}^n)}$ and $S_{(\mathbb{R}^n)^\mathbb{Z}}$ onto their corresponding equivalence classes with respect to the associated equivalence relations. One can easily prove that the norm preservation following the diagram. It is a straightforward exercise to verify that ϕ is injective and preserves the norm $\|\cdot\|_{L^\infty}$. In order to show that ϕ is surjective, let $\mathbf{z} \in L^\infty\left(\Omega, (\mathbb{R}^n)^\mathbb{Z}\right)$. Given that $\|\mathbf{z}\|_{L^\infty} < \infty$ or, equivalently, $\operatorname{ess\,sup}_{\omega\in\Omega}\{\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\}\} < \infty$, by part **(i)** in Lemma 24, this implies that

$$\sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\} < \infty, \quad \text{almost surely.} \tag{6.26}$$

Since the elements in the spaces in $L^\infty\left(\Omega, \ell^\infty(\mathbb{R}^n)\right)$ and $L^\infty\left(\Omega, (\mathbb{R}^n)^\mathbb{Z}\right)$ are equivalence classes containing almost surely equal random variables, we can take another representative $\mathbf{z}^* : \Omega \longrightarrow (\mathbb{R}^n)^\mathbb{Z}$ for the class containing $\mathbf{z} \in L^\infty\left(\Omega, (\mathbb{R}^n)^\mathbb{Z}\right)$ defined as

$$\mathbf{z}^*(\omega) := \begin{cases} \mathbf{z}(\omega), & \text{when} \quad \sup_{t\in\mathbb{Z}}\{\|\mathbf{z}_t(\omega)\|\} < \infty, \\ 0, & \text{otherwise.} \end{cases}$$

Since the processes $\mathbf{z}$ and $\mathbf{z}^*$ differ by (6.26) only in a set of zero measure, they are equal in $L^\infty\left(\Omega, (\mathbb{R}^n)^\mathbb{Z}\right)$ but, this time, $\mathbf{z}^* \in L^\infty\left(\Omega, \ell^\infty(\mathbb{R}^n)\right)$ and $\phi(\mathbf{z}^*) = \mathbf{z}$, as required. ■

6.14 Proof of Theorem 27

Proof of part (i). All along this proof we will denote the elements in K_M with a lower bold case ($\mathbf{z} \in K_M$) and those in $K_M^{L^\infty}$ with an upper bold case ($\mathbf{Z} \in K_M^{L^\infty}$).

We first assume that the functional $H : (K_M, \|\cdot\|_w) \longrightarrow \mathbb{R}$ has the fading memory property. This means that H is a continuous map and since by Lemma 2 the space $(K_M, \|\cdot\|_w)$ is compact, then so is the image $H(K_M)$ as a subset of the real line. This implies that there exists a finite real number $L > 0$ such that $H(K_M) \subset [-L, L]$. Let now $\mathbf{Z} \in K_M^{L^\infty}$; the condition $\|\mathbf{Z}\|_{L^\infty} \leq M$ is equivalent to $\|\mathbf{Z}_t\| \leq M$, for all $t \in \mathbb{Z}_-$, almost surely, and hence implies that $H(\mathbf{Z}) \in [-L, L]$, almost surely or, equivalently, that $\|H(\mathbf{Z})\|_{L^\infty} \leq L$. This, in turn, implies that $H(\mathbf{Z}) \in L^\infty(\Omega, \mathbb{R})$ for any $\mathbf{Z} \in K_M^{L^\infty}$, as required.

We now show that $H : (K_M^{L^\infty}, \|\cdot\|_{L^\infty_w}) \longrightarrow L^\infty(\Omega, \mathbb{R})$ has the FMP. The FMP hypothesis on $H : (K_M, \|\cdot\|_w) \longrightarrow \mathbb{R}$ implies that for any $\mathbf{z} \in K_M$ and any $\epsilon > 0$ there exists a $\delta(\epsilon) > 0$ such that for any $\mathbf{s} \in K_M$ that satisfies that

$$\|\mathbf{z} - \mathbf{s}\|_w = \sup_{t\in\mathbb{Z}_-}\{\|(\mathbf{z}_t - \mathbf{s}_t)w_{-t}\|\} < \delta(\epsilon), \quad \text{then} \quad |H(\mathbf{z}) - H(\mathbf{s})| < \epsilon. \tag{6.27}$$

Moreover, since by Lemma 2 the space $(K_M, \|\cdot\|_w)$ is compact, the Uniform Continuity Theorem (Theorem 7.3 in Munkres (2014)) guarantees that the relation $\delta(\epsilon)$ does not depend on the point $\mathbf{z} \in K_M$.

We now prove the statement by showing that for any $\epsilon > 0$ and $\mathbf{Z} \in K_M^{L^\infty}$ then $\|H(\mathbf{Z}) - H(\mathbf{S})\|_{L^\infty} < \epsilon$, for all $\mathbf{S} \in K_M^{L^\infty}$ such that $\|\mathbf{Z} - \mathbf{S}\|_{L^\infty_w} < \delta(\epsilon)$. Indeed, the inequality $\|\mathbf{Z} - \mathbf{S}\|_{L^\infty_w} < \delta(\epsilon)$ holds if and only if $\sup_{t\in\mathbb{Z}_-}\{\|\mathbf{Z}_t - \mathbf{S}_t\|_{L^\infty} w_{-t}\} < \delta(\epsilon)$. Given that for any $l \in \mathbb{Z}_-$ we have that $\|\mathbf{Z}_l - \mathbf{S}_l\|_{L^\infty} w_{-l} \leq \sup_{t\in\mathbb{Z}_-}\{\|\mathbf{Z}_t - \mathbf{S}_t\|_{L^\infty} w_{-t}\} < \delta(\epsilon)$, part **(ii)** in Lemma 24 implies that $\|\mathbf{Z}_l - \mathbf{S}_l\| w_{-l} < \delta(\epsilon)$ almost surely for any $l \in \mathbb{Z}_-$ and hence $\sup_{t\in\mathbb{Z}_-}\{\|\mathbf{Z}_t - \mathbf{S}_t\| w_{-t}\} = \|\mathbf{Z} - \mathbf{S}\|_w < \delta(\epsilon)$, almost surely. This implies, using (6.27), that $|H(\mathbf{Z}) - H(\mathbf{S})| < \epsilon$, almost surely, which by part **(ii)** in Lemma 24 implies that $\|H(\mathbf{Z}) - H(\mathbf{S})\|_{L^\infty} < \epsilon$, as required.

Conversely, if $H : (K_M^{L^\infty}, \|\cdot\|_{L^\infty_w}) \longrightarrow L^\infty(\Omega, \mathbb{R})$ has the fading memory property then so does $H : (K_M, \|\cdot\|_w) \longrightarrow \mathbb{R}$ because $K_M \subset K_M^{L^\infty}$ and $\|\mathbf{z}\| = \|\mathbf{z}\|_{L^\infty}$ for the elements $\mathbf{z} \in K_M$.

Proof of part (ii). We suppose first that $\mathcal{T}$ is dense in the set $(C^0(K_M), \|\cdot\|_w)$ and show that the corresponding family with intputs in $K_M^{L^\infty}$ is universal. Let $H : (K_M^{L^\infty}, \|\cdot\|_{L^\infty_w}) \longrightarrow L^\infty(\Omega, \mathbb{R})$ be an arbitrary causal and time-invariant FMP filter and let $H_S \in \mathcal{T}$ be such that $\sup_{\mathbf{z}\in K_M}\{\|H(\mathbf{z}) - H_S(\mathbf{z})\|_{L^\infty}\} < \epsilon$. The existence of H_S is ensured by the density hypothesis on $\mathcal{T}$. We show that

this ensures that $\sup_{\mathbf{Z}\in K_M^{L^\infty}}\{\|H(\mathbf{Z}) - H_S(\mathbf{Z})\|_{L^\infty}\} < \epsilon$. Indeed, this conclusion is true if $\|H(\mathbf{Z}) - H_S(\mathbf{Z})\|_{L^\infty} < \epsilon$ for any $\mathbf{Z} \in K_M^{L^\infty}$ which, by part **(ii)** in Lemma 24 is equivalent to $|H(\mathbf{Z}) - H_S(\mathbf{Z})| < \epsilon$ almost surely, for any $\mathbf{Z} \in K_M^{L^\infty}$. This condition is in turn true because as $\mathbf{Z} \in K_M^{L^\infty}$, then $\|\mathbf{Z}_t\| \leq M$ almost surely for all $t \in \mathbb{Z}_-$ and hence $\mathbf{Z} \in K_M$ almost surely. Since H_S approximates H for deterministic inputs, we have that $|H(\mathbf{Z}) - H_S(\mathbf{Z})| < \epsilon$ almost surely, as required.

Conversely, if the family $\mathcal{T}$ with intputs in $K_M^{L^\infty}$ is universal in the set of continuous maps of the type $H : (K_M^{L^\infty}, \|\cdot\|_{L^\infty_w}) \longrightarrow L^\infty(\Omega, \mathbb{R})$ we can easily show that $\mathcal{T}$ is dense in $(C^0(K_M), \|\cdot\|_w)$. Let $H \in (C^0(K_M), \|\cdot\|_w)$ and let $H_S : (K_M^{L^\infty}, \|\cdot\|_{L^\infty_w}) \longrightarrow L^\infty(\Omega, \mathbb{R})$ be the element that, for a given $\epsilon > 0$, satisfies $\|H - H_S\|_{L^\infty} = \sup_{\mathbf{Z}\in K_M^{L^\infty}}\{\|H(\mathbf{Z}) - H_S(\mathbf{Z})\|_{L^\infty}\} < \epsilon$. Given that, as we pointed out, $K_M \subset K_M^{L^\infty}$ and $\|\mathbf{z}\| = \|\mathbf{z}\|_{L^\infty}$, for the elements $\mathbf{z} \in K_M$, we have

$$\|H - H_S\| = \sup_{\mathbf{z}\in K_M}\{\|H(\mathbf{z}) - H_S(\mathbf{z})\|\} = \sup_{\mathbf{z}\in K_M}\{\|H(\mathbf{z}) - H_S(\mathbf{z})\|_{L^\infty}\} \leq \sup_{\mathbf{Z}\in K_M^{L^\infty}}\{\|H(\mathbf{Z}) - H_S(\mathbf{Z})\|_{L^\infty}\} < \epsilon. \quad ■$$

6.15 Proof of Lemma 28

As we pointed out in Section 2, if the reservoir system determined by $F : D_N \times \overline{B_n(\mathbf{0}, M)} \longrightarrow D_N$ and $h : D_N \to \mathbb{R}$ has the echo state property, a result in Grigoryeva and Ortega (2018) guarantees that the associated filter is automatically causal and time-invariant. This implies the existence of a functional $H_h^F : (\mathbb{R}^n)^{\mathbb{Z}_-} \longrightarrow \mathbb{R}$ that, by hypothesis, has the fading memory property. The rest of the statement is a consequence of part **(i)** in Theorem 27. ■

6.16 Proof of Theorem 29

We first notice that the polynomial algebra $\mathcal{A}(\mathcal{R})$ is, by Theorem 8 and the first part of Theorem 27, made of fading memory reservoir filters that map into $L^\infty(\Omega, \mathbb{R})$. Using the other hypotheses in the statement we can easily conclude that the family $\mathcal{A}(\mathcal{R})$ satisfies the thesis of Theorem 8 and it is hence universal in the deterministic setup. The result follows from the second part of Theorem 27. ■

Acknowledgments: We thank Philipp Harms and Herbert Jaeger for carefully looking at early versions of this work and for making suggestions that have significantly improved some of our results. We thank Josef Teichmann for fruitful discussions. We also thank the editor and two remarkable anonymous referees whose input has significantly improved the presentation and the contents of the paper. The authors acknowledge partial financial support of the French ANR "BIPHOPROC" project (ANR-14-OHRI-0002-02) as well as the hospitality of the Centre Interfacultaire Bernoulli of the Ecole Polytechnique Fédérale de Lausanne during the program "Stochastic Dynamical Models in Mathematical Finance, Econometrics, and Actuarial Sciences" that made possible the collaboration that led to some of the results included in this paper. Glossary of Symbols

$\ell^\infty_w(\mathbb{R}^n)$	Banach space of semi-infinite sequences with finite weighted norm
$\mathbb{D}$	Space of diagonal matrices of any order
$\mathbb{D}_n$	Space of diagonal matrices of order $n \in \mathbb{N}$
$\mathbb{M}_n$	Space of square matrices of order $n \in \mathbb{N}$
$\mathbb{M}_{m,n}[z]$	$\mathbb{M}_{m,n}$-valued polynomials on z with coefficients in $\mathbb{M}_{m,n}$

$\mathbb{M}_{n,m}$	Space of real $n \times m$ matrices with $m, n \in \mathbb{N}$
$\mathbb{N}\mathrm{il}$	Space of nilpotent matrices of any order and any index
$\mathbb{N}\mathrm{il}[z]$	Space of matrix-valued nilpotent polynomials on z of any order and any index
$\mathbb{N}\mathrm{il}_n^k$	Space of nilpotent matrices of index $k \in \mathbb{N}$ in $\mathbb{M}_n$
$\mathbb{N}\mathrm{il}_n^k[z]$	Space of nilpotent $\mathbb{M}_n$-valued polynomials on z with coefficients in $\mathbb{M}_n$ of index k
$\mathcal{A}(\mathcal{R})$	Polynomial algebra generated by the set $\mathcal{R}$ of reservoir filters defined on K_M
$\mathcal{DL}_\epsilon$	Set of linear reservoir systems determined by diagonal matrices $A \in \mathbb{D}$ such that $\sigma_{\max}(A) < 1 - \epsilon$
$\mathcal{L}_\epsilon$	Set of linear reservoir systems determined by matrices $A \in \mathbb{M}_N$ such that $\sigma_{\max}(A) < 1 - \epsilon$
$\mathcal{NL}$	Set of linear reservoir systems determined by nilpotent matrices $A \in \mathbb{N}\mathrm{il}$
$\mathcal{NS}_\epsilon$	Subfamily of $\mathcal{S}_\epsilon$ formed by SAS reservoir systems determined by nilpotent polynomials p
$\mathcal{R}$	Set of reservoir filters defined on K_M
$\mathcal{S}_\epsilon$	State affine reservoir systems (SAS) $H^{p,q}_{\mathbf{W}} : I^{\mathbb{Z}-} \longrightarrow \mathbb{R}$ with $M_p < 1-\epsilon$ and $M_q < 1-\epsilon$
$B_n(\mathbf{0}, M)$	Ball of radius M and center $\mathbf{0}$ in $\mathbb{R}^n$ with respect to the Euclidean norm
$F : \mathbb{R}^N \times \mathbb{R}^n \longrightarrow \mathbb{R}^N$	Reservoir map
$H_U : (\mathbb{R}^n)^{\mathbb{Z}-} \longrightarrow \mathbb{R}$	Functional associated to the causal and time-invariant filter $U : (\mathbb{R}^n)^{\mathbb{Z}} \longrightarrow \mathbb{R}^{\mathbb{Z}}$
$h : \mathbb{R}^N \to \mathbb{R}$	Generic readout map
$H_h^{A,\mathbf{c}} : K_M \longrightarrow \mathbb{R}$	Linear reservoir functional determined by $A, \mathbf{c}$, and the polynomial h
$H^{p,q}_{\mathbf{W}} : I^{\mathbb{Z}-} \longrightarrow \mathbb{R}$	SAS reservoir functional
K_M	Space of semi-infinite sequences that are uniformly bounded by M
$K_M^{L^\infty}$	Space of semi-infinite processes that are almost surely uniformly bounded by M
$L^\infty\left(\Omega, (\mathbb{R}^n)^{\mathbb{Z}}\right)$	Space of almost surely bounded time series or discrete-time stochastic processes with values in $\mathbb{R}^n$
$L^\infty_w\left(\Omega, (\mathbb{R}^n)^{\mathbb{Z}-}\right)$	Space of time series or discrete-time stochastic processes with values in $\mathbb{R}^n$ with finite L^∞_w-norm
N	Number of virtual neurons. Dimension of the reservoir state vectors
n	Dimension of the elements of the input signal
$U_h^F : (\mathbb{R}^n)^{\mathbb{Z}} \longrightarrow \mathbb{R}^{\mathbb{Z}}$	Reservoir filter
$U^F : (\mathbb{R}^n)^{\mathbb{Z}} \longrightarrow (\mathbb{R}^N)^{\mathbb{Z}}$	Filter determined by the reservoir map F
$U : (\mathbb{R}^n)^{\mathbb{Z}} \longrightarrow \mathbb{R}^{\mathbb{Z}}$	Filter with inputs in $\mathbb{R}^n$ and outputs in $\mathbb{R}$
$U_h^{A,\mathbf{c}} : K_M \longrightarrow \mathbb{R}^{\mathbb{Z}}$	Linear reservoir filter determined by $A, \mathbf{c}$, and the polynomial h
$U_H : (\mathbb{R}^n)^{\mathbb{Z}} \longrightarrow \mathbb{R}^{\mathbb{Z}}$	Causal and time-invariant filter associated to the functional $H : (\mathbb{R}^n)^{\mathbb{Z}-} \longrightarrow \mathbb{R}$
$U^{p,q}_{\mathbf{W}} : I^{\mathbb{Z}} \longrightarrow \mathbb{R}^{\mathbb{Z}}$	SAS reservoir filter
$w : \mathbb{N} \longrightarrow (0, 1]$	Weighting sequence
$\mathbf{x}$	(Semi)-infinite sequence containing the reservoir states. The elements of this sequence are denoted by $\mathbf{x}_t \in \mathbb{R}^N$
$\mathbf{y}$	(Semi)-infinite output signal. The elements of this sequence are denoted by $y_t \in \mathbb{R}$
$\mathbf{z}$	(Semi)-infinite input signal. The elements of this sequence are denoted by $\mathbf{z}_t \in \mathbb{R}^n$

Deep Hidden Physics Models: Deep Learning of Nonlinear Partial Differential Equations

Editor: Manfred Opper

Abstract

We put forth a deep learning approach for discovering nonlinear partial differential equations from scattered and potentially noisy observations in space and time. Specifically, we approximate the unknown solution as well as the nonlinear dynamics by two deep neural networks. The first network acts as a prior on the unknown solution and essentially enables us to avoid numerical differentiations which are inherently ill-conditioned and unstable. The second network represents the nonlinear dynamics and helps us distill the mechanisms that govern the evolution of a given spatiotemporal data-set. We test the effectiveness of our approach for several benchmark problems spanning a number of scientific domains and demonstrate how the proposed framework can help us accurately learn the underlying dynamics and forecast future states of the system. In particular, we study the Burgers', Korteweg-de Vries (KdV), Kuramoto-Sivashinsky, nonlinear Schrödinger, and Navier-Stokes equations.

Keywords: Systems Identification, Data-driven Scientific Discovery, Physics Informed Machine Learning, Predictive Modeling, Nonlinear Dynamics, Big Data

1. Introduction

Recent advances in machine learning in addition to new data recordings and sensor technologies have the potential to revolutionize our understanding of the physical world in modern application areas such as neuroscience, epidemiology, finance, and dynamic network analysis where first-principles derivations may be intractable (Rudy et al., 2017). In particular, many concepts from statistical learning can be integrated with classical methods in applied mathematics to help us discover sufficiently sophisticated and accurate mathematical models of complex dynamical systems directly from data. This integration of nonlinear dynamics and machine learning opens the door for principled methods for model construction, predictive modeling, nonlinear control, and reinforcement learning strategies. The literature on data-driven discovery of dynamical systems (Crutchfield and McNamara, 1987) is vast and encompasses equation-free modeling (Kevrekidis et al., 2003), artificial neural networks (Raissi et al., 2018a; Gonzalez-Garcia et al., 1998; Anderson et al., 1996; Rico-Martinez et al., 1992), nonlinear regression (Voss et al., 1999), empirical dynamic modeling (Sugihara et al., 2012; Ye et al., 2015), modeling emergent behavior (Roberts, 2014), automated inference of dynamics (Schmidt et al., 2011; Daniels and Nemenman, 2015a,b), normal form identification in climate (Majda et al., 2009), nonlinear Laplacian spectral analysis (Giannakis and Majda, 2012), modeling emergent behavior (Roberts, 2014), Koopman analysis (Mezić, 2005; Budišić et al., 2012; Mezić, 2013; Brunton et al., 2017), automated inference of dynamics (Schmidt et al., 2011; Daniels and Nemenman, 2015a,b), and symbolic regression (Bongard and Lipson, 2007; Schmidt and Lipson, 2009). More recently, sparsity (Tibshirani, 1996) has been used to determine the governing dynamical system (Brunton et al., 2016; Mangan et al., 2016; Wang et al., 2011; Schaeffer et al., 2013; Ozoliņš et al., 2013; Mackey et al., 2014; Brunton et al., 2014; Proctor et al., 2014; Bai et al., 2014; Tran and Ward, 2016).

Less well studied is how to discover closed form mathematical models of the physical world expressed by partial differential equations from scattered data collected in space and time. Inspired by recent developments in *physics-informed deep learning* (Raissi et al., 2017c,d), we construct structured nonlinear regression models that can uncover the dynamic dependencies in a given set of spatio-temporal data, and return a closed form model that can be subsequently used to forecast future states. In contrast to recent approaches to systems identification (Brunton et al., 2016; Rudy et al., 2017), here we do not need to have direct access or approximations to temporal or spatial derivatives. Moreover, we are using a richer class of function approximators to represent the nonlinear dynamics and consequently we do not have to commit to a particular family of basis functions. Specifically, we consider nonlinear partial differential equations of the general form

$$u_t = \mathcal{N}(t, x, u, u_x, u_{xx}, \ldots), \tag{1}$$

where $\mathcal{N}$ is a nonlinear function of time t, space x, solution u and its derivatives.[1] Here, the subscripts denote partial differentiation in either time t or space x.[2] Given a set of scattered and potentially noisy observations of the solution u, we are interested in learning the nonlinear function $\mathcal{N}$ and consequently identifying an infinite dimensional dynamical system (i.e., partial differential equation) that governs the evolution of the observed spatio-temporal data.

For instance, let us assume that we would like to discover the Burger's equation (Basdevant et al., 1986) in one space dimension $u_t = -uu_x + 0.1u_{xx}$. Although not pursued in the current work, a viable approach (Rudy et al., 2017) to tackle this problem is to create a dictionary of possible terms and write the following expansion

$$\begin{aligned}\mathcal{N}(t, x, u, u_x, u_{xx}, \ldots) \;=\; & \alpha_{0,0} + \alpha_{1,0}u + \alpha_{2,0}u^2 + \alpha_{3,0}u^3 + \\ & \alpha_{0,1}u_x + \alpha_{1,1}uu_x + \alpha_{2,1}u^2u_x + \alpha_{3,1}u^3u_x + \\ & \alpha_{0,2}u_{xx} + \alpha_{1,2}uu_{xx} + \alpha_{2,2}u^2u_{xx} + \alpha_{3,2}u^3u_{xx} + \\ & \alpha_{0,3}u_{xxx} + \alpha_{1,3}uu_{xxx} + \alpha_{2,3}u^2u_{xxx} + \alpha_{3,3}u^3u_{xxx}.\end{aligned}$$

1. The solution $u = (u_1, \ldots, u_n)$ could be n dimensional in which case u_x denotes the collection of all element-wise first order derivatives $\frac{\partial u_1}{\partial x}, \ldots, \frac{\partial u_n}{\partial x}$. Similarly, u_{xx} includes all element-wise second order derivatives $\frac{\partial^2 u_1}{\partial x^2}, \ldots, \frac{\partial^2 u_n}{\partial x^2}$.
2. The space $x = (x_1, x_2, \ldots, x_m)$ could be a vector of dimension m. In this case, u_x denotes the collection of all first order derivative $u_{x_1}, u_{x_2}, \ldots, u_{x_m}$ and u_{xx} represents the set of all second order derivatives $u_{x_1x_1}, u_{x_1x_2}, \ldots, u_{x_1x_m}, \ldots, u_{x_mx_m}$.

Given the aforementioned large collection of candidate terms for constructing the partial differential equation, one could then use sparse regression techniques (Rudy et al., 2017) to determine the coefficients $\alpha_{i,j}$ and consequently the right-hand-side terms that are contributing to the dynamics. A huge advantage of this approach is the interpretability of the learned equations. However, there are two major drawbacks associated with this method.

First, it relies on numerical differentiation to compute the derivatives involved in equation (1). Derivatives are taken either using finite differences for clean data or with polynomial interpolation in the presence of noise. Numerical approximations of derivatives are inherently ill-conditioned and unstable (Baydin et al., 2015) even in the absence of noise in the data. This is due to the introduction of truncation and round-off errors inflicted by the limited precision of computations and the chosen value of the step size for finite differencing. Thus, this approach requires far more data points than library functions. This need for using a large number of points lies more in the numerical evaluation of derivatives than in supplying sufficient data for the regression.

Second, in applying the algorithm (Rudy et al., 2017) outlined above we assume that the chosen library is sufficiently rich to have a sparse representation of the time dynamics of the dataset. However, when applying this approach to a dataset where the dynamics are in fact unknown it is not unlikely that the basis chosen above is insufficient. Specially, in higher dimensions (i.e., for input x or output u) the required number of terms to include in the library increases exponentially. Moreover, an additional issue with this approach is that it can only estimate parameters appearing as coefficients. For example, this method cannot estimate parameters of a partial differential equation (e.g., the sine-Gordon equation) involving a term like $\sin(\alpha u(x))$ with α being the unknown parameter, even if we include sines and cosines in the dictionary of possible terms.

One could avoid the first drawback concerning numerical differentiation by assigning prior distributions in the forms of Gaussian processes (Raissi et al., 2017b; Raissi and Karniadakis, 2017; Raissi et al., 2017a, 2018b) or neural networks (Raissi et al., 2017c,d) to the unknown solution u. Derivatives of the prior on u can now be evaluated at machine precision using symbolic or automatic differentiation (Baydin et al., 2015). This removes the requirement for having or generating data on derivatives of the solution u. This is enabling as it allows us to work with noisy observations of the solution u, scattered in space and time. Moreover, this approach requires far fewer data points than the method proposed in (Rudy et al., 2017) simply because, as explained above, the need for using a large number of data points was due to the numerical evaluation of derivatives. The choice to place a prior on the unknown solution u is motivated by modern techniques for solving forward and inverse problems involving partial differential equations, where the unknown solution is approximated either by a neural network (Raissi et al., 2017c,d; Raissi, 2018; Raissi et al., 2018a) or a Gaussian process (Raissi et al., 2018b; Raissi and Karniadakis, 2017; Raissi et al., 2017a,b; Raissi, 2017; Perdikaris et al., 2017; Raissi and Karniadakis, 2016).

The second drawback can be addressed in a similar fashion by approximating the nonlinear function $\mathcal{N}$ (see equation 1) with a neural network. Representing the nonlinear function

$\mathcal{N}$ by a deep neural network is the novelty of the current work. Deep neural networks are a richer family of function approximators and consequently we do not have to commit to a particular class of basis functions such as polynomials or sines and cosines. This expressiveness comes at the cost of losing interpretability of the learned dynamics. However, there is nothing hindering the use of a particular class of basis functions in order obtain more interpretable equations (Raissi et al., 2017d).

2. Solution methodology

We proceed by approximating both the solution u and the nonlinear function $\mathcal{N}$ with two deep neural networks[3] and define a *deep hidden physics model* f to be given by

$$f := u_t - \mathcal{N}(t, x, u, u_x, u_{xx}, \ldots). \tag{2}$$

We obtain the derivatives of the neural network u with respect to time t and space x by applying the chain rule for differentiating compositions of functions using automatic differentiation (Baydin et al., 2015). It is worth emphasizing that automatic differentiation is different from, and in several aspects superior to, numerical or symbolic differentiation; two commonly encountered techniques of computing derivatives. Numerical differentiation entails the finite difference approximation of derivatives using values of the original function evaluated at some sample points. Due to the introduction of truncation and round-off errors inflicted by the limited precision of computations and the chosen value of the step size for finite differencing, numerical approximations of derivatives are inherently ill-conditioned and unstable (Baydin et al., 2015). Symbolic differentiation uses expression manipulation in computer algebra systems such as Mathematica, Maxima, and Maple. Symbolic methods require models to be defined as closed-form expressions, ruling out or severely limiting algorithmic control flow and expressivity (Baydin et al., 2015).

Without proper introduction, one might assume that automatic differentiation is either a type of numerical or symbolic differentiation (Baydin et al., 2015). Confusion can arise because automatic differentiation does in fact provide numerical values of derivatives (as opposed to derivative expressions) and it does so by using symbolic rules of differentiation (but keeping track of derivative values as opposed to the resulting expressions), giving it a two-sided nature that is partly symbolic and partly numerical (Baydin et al., 2015). In its most basic description (Baydin et al., 2015), automatic differentiation relies on the fact that all numerical computations are ultimately compositions of a finite set of elementary operations for which derivatives are known. Combining the derivatives of the constituent operations through the chain rule gives the derivative of the overall composition. This allows accurate evaluation of derivatives at machine precision with ideal asymptotic efficiency and only a small constant factor of overhead. In particular, to compute the derivatives involved in equation (2) we rely on Tensorflow (Abadi et al., 2016) which is a popular and relatively well documented open source software library for automatic differentiation and deep learning computations. In TensorFlow, before a model is run, its computational graph is defined

3. Representing the solution u by a deep neural network is inspired by recent developments in *physics-informed deep learning* (Raissi et al., 2017c,d), while approximating the nonlinear function $\mathcal{N}$ by another network is the novelty of this work.

statically rather than dynamically as for instance in PyTorch (Paszke et al., 2017). This is an important feature as it allows us to create and compile the entire computational graph for a *deep hidden physics model* (2) only once and keep it fixed throughout the training procedure. This leads to significant reduction in the computational cost of the proposed framework.

Parameters of the neural networks u and $\mathcal{N}$ can be learned by minimizing the sum of squared errors loss function

$$SSE := \sum_{i=1}^{N} \left(|u(t^i, x^i) - u^i|^2 + |f(t^i, x^i)|^2 \right), \tag{3}$$

where $\{t^i, x^i, u^i\}_{i=1}^N$ denote the training data on u. The term $|u(t^i, x^i) - u^i|^2$ tries to fit the data by adjusting the parameters of the neural network u while the term $|f(t^i, x^i)|^2$ learns the parameters of the network $\mathcal{N}$ by trying to satisfy the partial differential equation (1) at the collocation points (t^i, x^i). Training the parameters of the neural networks u and $\mathcal{N}$ can be performed simultaneously by minimizing the sum of squared error (3) or in a sequential fashion by training u first and $\mathcal{N}$ second.

How can we make sure that the algorithm presented above results in an acceptable function $\mathcal{N}$? One answer would be to solve the learned equations and compare the resulting solution to the solution of the exact partial differential equation. However, it should be pointed out that the learned function $\mathcal{N}$ is a *black-box* function; i.e., we do not know its functional form. Consequently, none of the classical partial differential equation solvers such as finite differences, finite elements or spectral methods are applicable here. Therefore, to solve the learned equations we have no other choice than to resort to modern black-box solvers such as *physic informed neural networks* (PINNs) introduced in (Raissi et al., 2017c). The steps involved in PINNs as solvers[4] are similar to equations (1), (2), and (3) with the nonlinear function $\mathcal{N}$ being known and the data residing on the boundary of the domain.

In the following, to keep the paper self-contained, we briefly explain the PINNs algorithm (Raissi et al., 2017c) for solving non-linear partial differential equations in as few sentences as possible. The PINNs algorithm is very general and for a more detailed exposure we refer the interested reader to (Raissi et al., 2017c). However, for pedagogical purposes, we explain the algorithm by applying it to the problem of solving the Burgers' equation (see section 3.1) as an example accompanied by periodic boundary conditions; i.e.,

$$\begin{aligned} &u_t + uu_x - 0.1u_{xx} = 0, \quad x \in [-8, 8], \\ &u(0, x) = -\sin(\pi x/8), \\ &u(t, -8) = u(t, 8), \\ &u_x(t, -8) = u_x(t, 8). \end{aligned}$$

We approximate the unknown solution $u(t, x)$ to the Burgers' equation by a deep neural network. Consequently, the corresponding *physic informed neural network* (PINN) takes

4. PINNs have also been used in (Raissi et al., 2017d) to solve inverse problems involving nonlinear partial differential equations in cases where the physics of the problem are well understood and the nonlinear function $\mathcal{N}$ is known up to a set of parameters.

the form

$$f := u_t + uu_x - 0.1u_{xx}.$$

To be precise, for the cases studied in the current work, the physic informed neural network $f(t, x)$ has a form similar to $f := \mathcal{N}(u, u_x, u_{xx})$ for some pre-trained (see equation 3) neural network $\mathcal{N}$ with its parameters being kept fixed. We acquire the required derivatives to compute the residual network f by applying the chain rule for differentiating compositions of functions using automatic differentiation (Baydin et al., 2015). The shared parameters between the neural networks $u(t, x)$ and $f(t, x)$ can be learned by minimizing the mean squared errors loss function

$$MSE = MSE_0 + MSE_b + MSE_f,$$

where

$$\begin{aligned} MSE_0 &= \tfrac{1}{N_0} \textstyle\sum_{i=1}^{N_0} |u(0, x_0^i) - u_0^i|^2, \\ MSE_b &= \tfrac{1}{N_b} \textstyle\sum_{i=1}^{N_b} \left(|u(t_b^i, -8) - u(t_b^i, 8)|^2 + |u_x(t_b^i, -8) - u_x(t_b^i, 8)|^2 \right), \\ MSE_f &= \tfrac{1}{N_f} \textstyle\sum_{i=1}^{N_f} |f(t_f^i, x_f^i)|^2. \end{aligned}$$

Here, $\{x_0^i, h_0^i\}_{i=1}^{N_0}$ denote the initial data generated in this example by the initial function $-\sin(\pi x/8)$, $\{t_b^i\}_{i=1}^{N_b}$ correspond to the collocation points on the boundary, and $\{t_f^i, x_f^i\}_{i=1}^{N_f}$ represents the collocation points on the residual network $f(t, x)$. Consequently, MSE_0 corresponds to the loss on the initial data, MSE_b enforces the periodic boundary conditions, and MSE_f penalizes the Burgers' equation for not being satisfied on the collocation points. This example encapsulates all of the important ingredients of the PINNs algorithm (Raissi et al., 2017c) and can be straightforwardly generalized to arbitrary partial differential equations where the boundary conditions should be treated on a case by case basis (see Raissi et al., 2017c).

3. Results

The proposed framework provides a universal treatment of nonlinear partial differential equations of fundamentally different nature. This generality will be demonstrated by applying the algorithm to a wide range of canonical problems spanning a number of scientific domains including the Burgers', Korteweg-de Vries (KdV), Kuramoto-Sivashinsky, nonlinear Schrödinger, and Navier-Stokes equations. These examples are motivated by the pioneering work of Rudy et al. (2017). All data and codes used in this manuscript are publicly available on GitHub at `https://github.com/maziarraissi/DeepHPMs`.

3.1 Burgers' equation

Let us start with the Burgers' equation arising in various areas of engineering and applied mathematics, including fluid mechanics, nonlinear acoustics, gas dynamics, and traffic flow (Basdevant et al., 1986). In one space dimension, the Burgers' equation reads as

$$u_t = -uu_x + 0.1u_{xx}. \tag{4}$$

To obtain a set of training and test data, we simulate the Burger's equation (4) using conventional spectral methods. Specifically, starting from an initial condition $u(0,x) = -\sin(\pi x/8)$, $x \in [-8,8]$ and assuming periodic boundary conditions, we integrate equation (4) up to the final time $t = 10$. We use the Chebfun package (Driscoll et al., 2014) with a spectral Fourier discretization with 256 modes and a fourth-order explicit Runge-Kutta temporal integrator with time-step size 10^{-4}. The solution is saved every $\Delta t = 0.05$ to give us a total of 201 snapshots. Out of this data-set, we generate a smaller training subset, scattered in space and time, by randomly sub-sampling 10000 data points from time $t = 0$ to $t = 6.7$. We call the portion of the domain from time $t = 0$ to $t = 6.7$ the training portion. The rest of the domain from time $t = 6.7$ to the final time $t = 10$ will be referred to as the test portion. Using this terminology, we are in fact sub-sampling from the original dataset only in the training portion of the domain. Given the training data, we are interested in learning $\mathcal{N}$ as a function of the solution u and its derivatives up to the 2nd order[5]; i.e.,

$$u_t = \mathcal{N}(u, u_x, u_{xx}). \tag{5}$$

We represent the solution u by a 5-layer deep neural network with 50 neurons per hidden layer. Furthermore, we let $\mathcal{N}$ to be a neural network with 2 hidden layers and 100 neurons per hidden layer. As for the activation functions, we use $\sin(x)$. In general, the choice of a neural network's architecture (e.g., number of layers/neurons and form of activation functions) is crucial and in many cases still remains an art that relies on one's ability to balance the trade off between *expressivity* and *trainability* of the neural network (Raghu et al., 2016). Our empirical findings so far indicate that deeper and wider networks are usually more expressive (i.e., they can capture a larger class of functions) but are often more costly to train (i.e., a feed-forward evaluation of the neural network takes more time and the optimizer requires more iterations to converge). Moreover, the sinusoid (i.e., $\sin(x)$) activation function seems to be numerically more stable than $\tanh(x)$, at least while computing the residual neural network f (see equation 2). However, these observations should be interpreted as conjectures rather than as firm results[6]. In this work, we have tried to choose the neural networks' architectures in a consistent fashion throughout the manuscript. Consequently, there might exist other architectures that improve some of the results reported in the current work.

The neural networks u and $\mathcal{N}$ are trained by minimizing the sum of squared errors loss of equation (3). To illustrate the effectiveness of our approach, we solve the learned partial differential equation (5), along with periodic boundary conditions and the same initial condition as the one used to generate the original dataset, using the PINNs algorithm (Raissi et al., 2017c). The original dataset alongside the resulting solution of the learned partial differential equation are depicted in figure 1. This figure indicates that our algorithm is able to accurately identify the underlying partial differential equation with a relative L^2-error of 4.78e-03. It should be highlighted that the training data are collected in roughly two-thirds of the domain between times $t = 0$ and $t = 6.7$. The algorithm is thus extrapolating from

5. A detailed study of the choice of the order will be provided later in this section.
6. We encourage the interested reader to check out the codes corresponding to this paper on GitHub at `https://github.com/maziarraissi/DeepHPMs` and experiment with different choices for the neural networks' architectures.

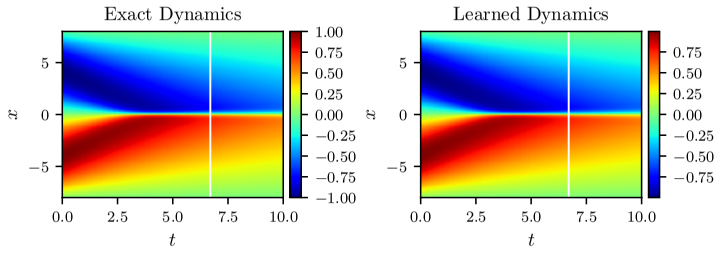

Figure 1: *Burgers equation:* A solution to the Burger's equation (left panel) is compared to the corresponding solution of the learned partial differential equation (right panel). The identified system correctly captures the form of the dynamics and accurately reproduces the solution with a relative L^2-error of 4.78e-03. It should be emphasized that the training data are collected in roughly two-thirds of the domain between times $t = 0$ and $t = 6.7$ represented by the white vertical lines. The algorithm is thus extrapolating from time $t = 6.7$ onwards. The relative L^2-error on the training portion of the domain is 3.89e-03.

	Clean data	1% noise	2% noise	5% noise
Relative L^2-error	4.78e-03	2.64e-02	1.09e-01	4.56e-01

Table 1: *Burgers' equation:* Relative L^2-error between solutions of the Burgers' equation and the learned partial differential equation as a function of noise corruption level in the data. Here, the total number of training data as well as the neural network architectures are kept fixed.

time $t = 6.7$ onwards. The relative L^2-error on the training portion of the domain is 3.89e-03.

Furthermore, we performed a systematic study of the reported results in figure 1 with respect to noise levels in the data by keeping the total number of training observations as well as the neural network architectures fixed to the settings described above. In particular, we added white noise with magnitude equal to one, two, and five percent of the standard deviation of the solution function. The results of this study are summarized in table 1. The key observation here is that less noise in the data enhances the performance of the algorithm. Our experience so far indicates that the negative consequences of more noise in the data can be remedied to some extent by obtaining more data. Another fundamental point to make is that the choice of the neural network architectures, i.e., activation functions and number of layers/neurons, is of great importance. However, in many cases of practical interest, this choice still remains an art, and systematic studies with respect to the neural network architectures often fail to reveal consistent patterns (Raissi et al., 2017c,d, 2018a). We usually observe some variability and non monotonic trends in systematic studies pertaining to the network architectures. In this regard, there exist a series of open questions

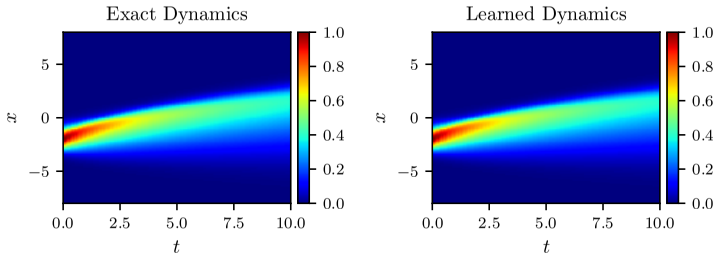

Figure 2: *Burgers equation:* A solution to the Burger's equation (left panel) is compared to the corresponding solution of the learned partial differential equation (right panel). The identified system correctly captures the form of the dynamics and accurately reproduces the solution with a relative L^2-error of 3.44e-02. It should be highlighted that the algorithm is trained on a dataset totally different from the one used in this figure.

mandating further investigations. For instance, how common techniques such as batch normalization, drop out, and L^1/L^2 regularization (Goodfellow et al., 2016) could enhance the robustness of the proposed algorithm with respect to the neural network architectures as well as noise in the data.

To further scrutinize the performance of the algorithm, let us change the initial condition to $-\exp(-(x+2)^2)$ and solve the Burgers' equation (4) using a classical partial differential equation solver. In particular, the new data-set (Rudy et al., 2017) contains 101 time snapshots of a solution to the Burgers' equation (4) with a Gaussian initial condition, propagating into a traveling wave. The snapshots are $\Delta t = 0.1$ apart and stretch from time $t = 0$ to $t = 10$. The spatial discretization of each snapshot involves a uniform grid with 256 cells. We compare the resulting solution to the one obtained by solving the learned partial differential equation (5) using the PINNs algorithm (Raissi et al., 2017c). It is worth emphasizing that the algorithm is trained on the dataset depicted in figure 1 and is being tested on a totally different dataset as shown in figure 2. The surprising result reported in figure 2 is a strong indication that the algorithm is capable of accurately identifying the underlying partial differential equation. The algorithm has not seen even a single observation of the dataset shown in figure 2 during model training and is yet capable of achieving a relatively accurate approximation of the true solution. The identified system reproduces the solution to the Burgers' equation with a relative L^2-error of 3.44e-02.

However, the aforementioned result seems to be sensitive to making the nonlinear function $\mathcal{N}$ of equation (5) depend on either time t or space x, or both. For instance, if we look for equations of the form $u_t = \mathcal{N}(x, u, u_x, u_{xx})$, the relative L^2-error between the exact and the learned solutions corresponding to figure 2 increases to 4.25e-01. Similarly, if we look for equations of the form $u_t = \mathcal{N}(t, u, u_x, u_{xx})$, the relative L^2-error increases to 2.58e-01.

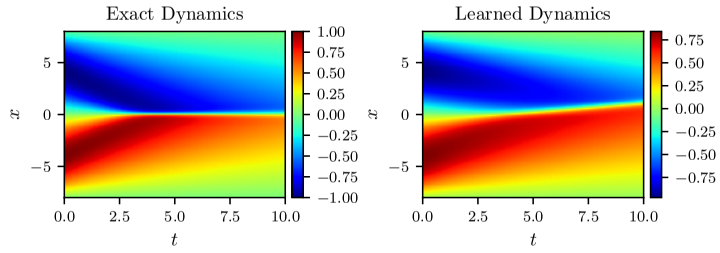

Figure 3: *Burgers equation:* A solution to the Burger's equation (left panel) is compared to the corresponding solution of the learned partial differential equation (right panel). The algorithm fails to generalize to the new test data. The relative L^2-error between the exact and the learned solutions is equal to 2.99e-01. Here, we are training on the dataset presented in figure 2 and testing on the one depicted in figure 1. In other words, we are swapping the roles of these two datasets. This observation suggests that the dynamics (see figure 1) generated by $-\sin(\pi x/8)$ as the initial condition is a reacher one compared to the dynamics (see figure 2) generated by $\exp(-(x+2)^2)$. This is also evident from a visual comparison of the two datasets given in figures 1 and 2.

Moreover, if we make the nonlinear function $\mathcal{N}$ both time and space dependent the relative L^2-error increases even further to 1.46e+00. A possible explanation for this behavior could be that some of the dynamics in the training data is now being explained by time t or space x. This makes the algorithm over-fit to the training data and consequently harder for it to generalize to datasets it has never seen before. Based on our experience more data seems to help resolve this issue. Another interesting observation is that if we train on the dataset presented in figure 2 and test on the one depicted in figure 1, i.e., swap the roles of these two datasets, the algorithm fails to generalize to the new test data. To be precise, as depicted in figure 3, the relative L^2-error between the exact and the learned solutions is now equal to 2.99e-01. This observation suggests that the dynamics (see figure 1) generated by $-\sin(\pi x/8)$ as the initial condition is a richer one compared to the dynamics (see figure 2) generated by $\exp(-(x+2)^2)$. This is also evident from a visual comparison of the datasets given in figures 1 and 2.

Let us now take a closer look at equation (5) and ask: what would happen if we included derivatives of higher order than two in our formulation? As will be demonstrated in the following, the algorithm proposed in the current work is capable of handling such cases, however, this is a fundamental question worthy of a moment of reflection. The choice of the order of the partial differential equation (5) determines the form and the number of boundary conditions needed to end up with a well-posed problem. For instance, in the one dimensional setting of equation (5) including a third order derivative requires three boundary conditions, namely $u(t,-8) = u(t,8)$, $u_x(t,-8) = u_x(t,8)$, and $u_{xx}(t,-8) = u_{xx}(t,8)$,

	1st order	2nd order	3rd order	4th order
Relative L^2-error	1.14e+00	1.29e-02	3.42e-02	5.54e-02

Table 2: *Burgers' equation:* Relative L^2-error between solutions of the Burgers' equation and the learned partial differential equation as a function of the highest order of spatial derivatives included in our formulation. For instance, the case corresponding to the 3rd order means that we are looking for a nonlinear function $\mathcal{N}$ such that $u_t = \mathcal{N}(u, u_x, u_{xx}, u_{xxx})$. Here, the total number of training data as well as the neural network architectures are kept fixed and the data are assumed to be noiseless.

assuming period boundary conditions. Consequently, in cases of practical interest, the available information on the boundary of the domain could help us determine the order of the partial differential equation we are try to identify. With this in mind, let us study the robustness of our framework with respect to the highest order of the derivatives included in equation (5). As for the boundary conditions, we use $u(t,-8) = u(t,8)$ and $u_x(t,-8) = u_x(t,8)$ when solving the identified partial differential equation regardless of the initial choice of its order. The results are summarized in table 2. The first column of table 2 demonstrates that a single first order derivative is clearly not enough to capture the second order dynamics of the Burgers' equation. Moreover, the method seems to be generally robust with respect to the number and order of derivatives included in the nonlinear function $\mathcal{N}$. Therefore, in addition to any information residing on the domain boundary, studies such as table 2, albeit for training or validation datasets, could help us choose the best order for the underlying partial differential equation. In this case, table 2 suggests the order of the equation to be two.

In addition, it must be stated that including higher order derivatives comes at the cost of reducing the speed of the algorithm due to the growth in the complexity of the resulting computational graph for the corresponding *deep hidden physics model* (see equation 2). Also, another drawback is that higher order derivatives are usually less accurate specially if one uses single precision floating-point system (float32) rather than double precision (float64). It is true that automatic differentiation enables us to evaluate derivatives at machine precision, however, for float32 the machine epsilon is approximately 1.19e-07. For improved performance in terms of speed of the algorithm and constrained by usual GPU (graphics processing unit) platforms we often end up using float32 which boils down to committing an error of approximately 1.19e-07 while computing the required derivatives. The aforementioned issues do not seem to be too serious since computer infrastructure (both hardware and software) for deep learning is constantly improving.

3.2 The KdV equation

As a mathematical model of waves on shallow water surfaces one could consider the Korteweg-de Vries (KdV) equation. The KdV equation reads as

$$u_t = -uu_x - u_{xxx}. \tag{6}$$

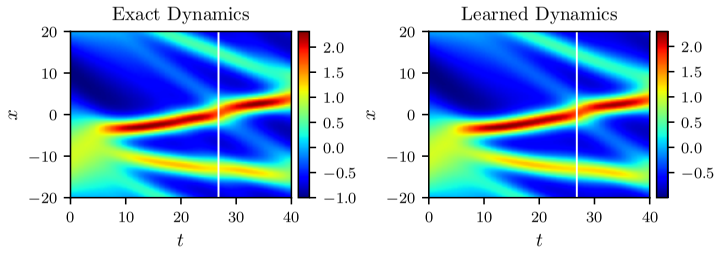

Figure 4: *The KdV equation:* A solution to the KdV equation (left panel) is compared to the corresponding solution of the learned partial differential equation (right panel). The identified system correctly captures the form of the dynamics and accurately reproduces the solution with a relative L^2-error of 6.28e-02. It should be emphasized that the training data are collected in roughly two-thirds of the domain between times $t = 0$ and $t = 26.8$ represented by the white vertical lines. The algorithm is thus extrapolating from time $t = 26.8$ onwards. The relative L^2-error on the training portion of the domain is 3.78e-02.

To obtain a set of training data we simulate the KdV equation (6) using conventional spectral methods. In particular, we start from an initial condition $u(0,x) = -\sin(\pi x/20)$, $x \in [-20, 20]$ and assume periodic boundary conditions. We integrate equation (6) up to the final time $t = 40$. We use the Chebfun package (Driscoll et al., 2014) with a spectral Fourier discretization with 512 modes and a fourth-order explicit Runge-Kutta temporal integrator with time-step size 10^{-4}. The solution is saved every $\Delta t = 0.2$ to give us a total of 201 snapshots. Out of this data-set, we generate a smaller training subset, scattered in space and time, by randomly sub-sampling 10000 data points from time $t = 0$ to $t = 26.8$. In other words, we are sub-sampling from the original dataset only in the training portion of the domain from time $t = 0$ to $t = 26.8$. Given the training data, we are interested in learning $\mathcal{N}$ as a function of the solution u and its derivatives up to the 3rd order[7]; i.e.,

$$u_t = \mathcal{N}(u, u_x, u_{xx}, u_{xxx}). \tag{7}$$

We represent the solution u by a 5-layer deep neural network with 50 neurons per hidden layer. Furthermore, we let $\mathcal{N}$ to be a neural network with 2 hidden layers and 100 neurons per hidden layer. As for the activation functions, we use $\sin(x)$. These two networks are trained by minimizing the sum of squared errors loss of equation (3). To illustrate the effectiveness of our approach, we solve the learned partial differential equation (7) using the PINNs algorithm (Raissi et al., 2017c). We assume periodic boundary conditions and the same initial condition as the one used to generate the original dataset. The resulting solution of the learned partial differential equation as well as the exact solution of the KdV equation are depicted in figure 4. This figure indicates that our algorithm is capable of accurately identifying the underlying partial differential equation with a relative L^2-error of

7. A detailed study of the choice of the order is provided in section 3.1 for the Burgers' equation.

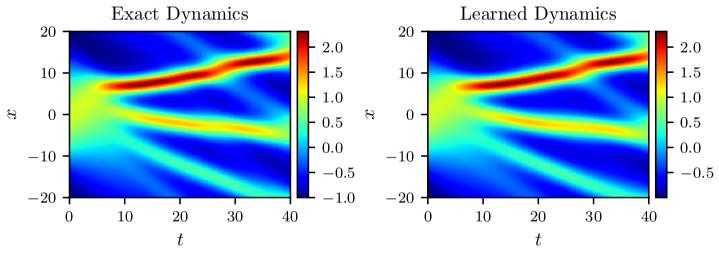

Figure 5: *The KdV equation:* A solution to the KdV equation (left panel) is compared to the corresponding solution of the learned partial differential equation (right panel). The identified system correctly captures the form of the dynamics and accurately reproduces the solution with a relative L^2-error of 3.44e-02. It should be highlighted that the algorithm is trained on a dataset different from the one shown in this figure.

6.28e-02. It should be highlighted that the training data are collected in roughly two-thirds of the domain between times $t = 0$ and $t = 26.8$. The algorithm is thus extrapolating from time $t = 26.8$ onwards. The corresponding relative L^2-error on the training portion of the domain is 3.78e-02.

To test the algorithm even further, let us change the initial condition to $\cos(-\pi x/20)$ and solve the KdV equation (6) using the conventional spectral method outlined above. We compare the resulting solution to the one obtained by solving the learned partial differential equation (5) using the PINNs algorithm (Raissi et al., 2017c). It is worth emphasizing that the algorithm is trained on the dataset depicted in figure 4 and is being tested on a different dataset as shown in figure 5. The surprising result reported in figure 5 strongly indicates that the algorithm is accurately learning the underlying partial differential equation; i.e., the nonlinear function $\mathcal{N}$. The algorithm hasn't seen the dataset shown in figure 5 during model training and is yet capable of achieving a relatively accurate approximation of the true solution. To be precise, the identified system reproduces the solution to the KdV equation with a relative L^2-error of 3.44e-02.

3.3 Kuramoto-Sivashinsky equation

As a canonical model of a pattern forming system with spatio-temporal chaotic behavior we consider the Kuramoto-Sivashinsky equation. In one space dimension the Kuramoto-Sivashinsky equation reads as

$$u_t = -uu_x - u_{xx} - u_{xxxx}. \tag{8}$$

We generate a dataset containing a direct numerical solution of the Kuramoto-Sivashinsky (8) equation with 512 spatial points and 251 snapshots. To be precise, assuming periodic boundary conditions, we start from the initial condition $u(0, x) = -\sin(\pi x/10)$, $x \in$

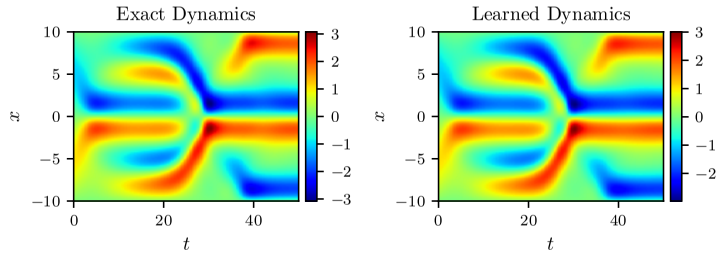

Figure 6: *Kuramoto-Sivashinsky equation:* A solution to the Kuramoto-Sivashinsky equation (left panel) is compared to the corresponding solution of the learned partial differential equation (right panel). The identified system correctly captures the form of the dynamics and reproduces the solution with a relative L^2-error of 7.63e-02.

$[-10, 10]$ and integrate equation (8) up to the final time $t = 50$. We employ the Chebfun package (Driscoll et al., 2014) with a spectral Fourier discretization with 512 modes and a fourth-order explicit Runge-Kutta temporal integrator with time-step size 10^{-5}. The snapshots are saved every $\Delta t = 0.2$. From this dataset, we create a smaller training subset, scattered in space and time, by randomly sub-sampling 10000 data points from time $t = 0$ to the final time $t = 50.0$. Given the resulting training data, we are interested in learning $\mathcal{N}$ as a function of the solution u and its derivatives up to the 4rd order[8]; i.e.,

$$u_t = \mathcal{N}(u, u_x, u_{xx}, u_{xxx}, u_{xxxx}). \tag{9}$$

We let the solution u to be represented by a 5-layer deep neural network with 50 neurons per hidden layer. Furthermore, we approximate the nonlinear function $\mathcal{N}$ by a neural network with 2 hidden layers and 100 neurons per hidden layer. As for the activation functions, we use $\sin(x)$. These two networks are trained by minimizing the sum of squared errors loss of equation (3). To demonstrate the effectiveness of our approach, we solve the learned partial differential equation (9) using the PINNs algorithm (Raissi et al., 2017c). We assume the same initial and boundary conditions as the ones used to generate the original dataset. The resulting solution of the learned partial differential equation alongside the exact solution of the Kuramoto-Sivashinsky equation are depicted in figure 6. This figure indicates that our algorithm is capable of identifying the underlying partial differential equation with a relative L^2-error of 7.63e-02. Here and in the rest of the current manuscript, the test and training datasets appear to be the same. However, it should be emphasized that during test time the only pieces of information given to the PINNs algorithm are the initial and boundary data in addition to the learned function $\mathcal{N}$. This means that results such as figure 6 are sufficient to clearly communicate the message that the algorithm has approximately learned the correct equations. Moreover, whether a particular dataset is rich enough so that

8. A detailed study of the choice of the order is provided in section 3.1 for the Burgers' equation.

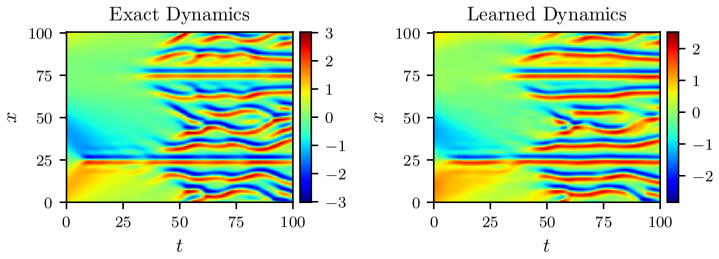

Figure 7: *Kuramoto-Sivashinsky equation:* A solution to the Kuramoto-Sivashinsky equation is depicted in the left panel. The corresponding solution of the learned partial differential equation is shown in the right panel. This problem remains stubbornly unsolved in the face of the algorithm proposed in the current work. In fact, the identified system reproduces the solution with a relative L^2-error of 4.17e-01, which is unsatisfactorily large.

the algorithm generalizes to other datasets generated by different initial conditions is a fundamentally different question which has been extensively studied so far in the manuscript using the Burgers' and KdV examples.

However, it must be mentioned that we are avoiding the regimes where the Kuramoto-Sivashinsky equation becomes chaotic. For instance, by changing the domain to $[0, 32\pi]$ and the initial condition to $\cos(x/16)(1 + \sin(x/16))$ and by integrating the Kuramoto-Sivashinsky equation (8) up to the final time $t = 100$, one could end up with a relatively complicated solution as depicted in the left panel of figure 7. This problem remains stubbornly unsolved in the face of the algorithm proposed in the current work as well as the PINNs framework introduced in (Raissi et al., 2017c,d). In fact, the identified system (see figure 7) reproduces the solution with a relative L^2-error of 4.17e-01, which is unsatisfactorily large. According to our empirical findings, making the neural network for $u(t, x)$ more expressive does not seem to help resolve this issue. As a matter of fact, it is not difficult for a plain vanilla neural network to approximate the function depicted in the left panel of figure 7. However, as we compute the derivatives required in equation (2), minimizing the loss function (3) becomes a challenge. More precisely, the optimizer does not seem to converge to the right values for the parameters of the neural networks (see figure 7). Understanding what makes this problem hard to solve should be at the core of future extensions of this line of research. One possible explanation could be that the resulting optimization problem inherits the complicated nature of the underlying partial differential equation. Moreover, it could indeed be the case that the algorithm proposed in the current work is learning the underlying dynamics correctly while the PINNs algorithm (Raissi et al., 2017c) is failing to solve the learned partial differential equation. The PINNs algorithm (Raissi et al., 2017c) as a solver is admittedly not yet mature but is currently our only option. Devising black-box

solvers for partial differential equations is still in its infancy and more collaborative work is needed to set the foundations in this field.

3.4 Nonlinear Schrödinger equation

The one-dimensional nonlinear Schrödinger equation is a classical field equation that is used to study nonlinear wave propagation in optical fibers and/or waveguides, Bose-Einstein condensates, and plasma waves. This example aims to highlight the ability of our framework to handle complex-valued solutions as well as different types of nonlinearities in the governing partial differential equations. The nonlinear Schrödinger equation is given by

$$\psi_t = 0.5i\psi_{xx} + i|\psi|^2\psi. \tag{10}$$

Let u denote the real part of ψ and v the imaginary part. Then, the nonlinear Schrödinger equation can be equivalently written as a system of partial differential equations

$$\begin{aligned} u_t &= -0.5v_{xx} - (u^2 + v^2)v, \\ v_t &= 0.5u_{xx} + (u^2 + v^2)u. \end{aligned} \tag{11}$$

In order to assess the performance of our method, we simulate equation (10) using conventional spectral methods to create a high-resolution data set. Specifically, starting from an initial state $\psi(0, x) = 2\ \mathrm{sech}(x)$ and assuming periodic boundary conditions $\psi(t, -5) = \psi(t, 5)$ and $\psi_x(t, -5) = \psi_x(t, 5)$, we integrate equation (10) up to a final time $t = \pi/2$ using the Chebfun package (Driscoll et al., 2014). We are in fact using a spectral Fourier discretization with 512 modes and a fourth-order explicit Runge-Kutta temporal integrator with time-step $\Delta t = \pi/2 \cdot 10^{-6}$. The solution is saved approximately every $\Delta t = 0.0031$ to give us a total of 501 snapshots. Out of this data-set, we generate a smaller training subset, scattered in space and time, by randomly sub-sampling 10000 data points from time $t = 0$ up to the final time $t = \pi/2$. Given the resulting training data, we are interested in learning two nonlinear functions $\mathcal{N}_1$ and $\mathcal{N}_2$ as functions of the solutions u, v and their derivatives up to the 2nd order[9]; i.e.,

$$\begin{aligned} u_t &= \mathcal{N}_1(u, v, u_x, v_x, u_{xx}, v_{xx}), \\ v_t &= \mathcal{N}_2(u, v, u_x, v_x, u_{xx}, v_{xx}). \end{aligned} \tag{12}$$

We represent the solutions u and v by two 5-layer deep neural networks with 50 neurons per hidden layer. Furthermore, we let $\mathcal{N}_1$ and $\mathcal{N}_2$ to be two neural networks with 2 hidden layers and 100 neurons per hidden layer. As for the activation functions, we use $\sin(x)$. These four networks are trained by minimizing a sum of squared errors loss function similar to equation (3). To illustrate the effectiveness of our approach, we solve the learned partial differential equation (12), along with periodic boundary conditions and the same initial condition as the one used to generate the original dataset, using the PINNs algorithm (Raissi et al., 2017c). The original dataset (in absolute values, i.e., $|\psi| = \sqrt{u^2 + v^2}$) alongside the resulting solution (also in absolute values) of the learned partial differential equation are depicted in figure 8. This figure indicates that our algorithm is able to accurately identify the underlying partial differential equation with a relative L^2-error of 6.28e-03.

9. A detailed study of the choice of the order is provided in section 3.1 for the Burgers' equation.

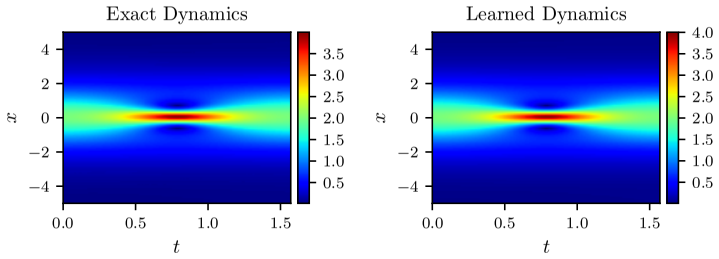

Figure 8: *Nonlinear Schrödinger equation:* Absolute value of a solution to the nonlinear Schrödinger equation (left panel) is compared to the absolute value of the corresponding solution of the learned partial differential equation (right panel). The identified system correctly captures the form of the dynamics and accurately reproduces the absolute value of the solution with a relative L^2-error of 6.28e-03.

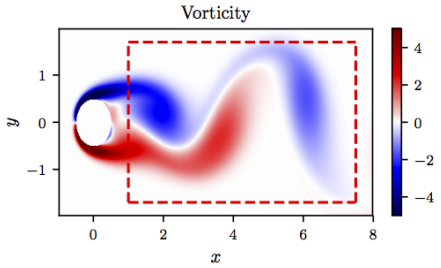

Figure 9: *Navier-Stokes equation:* A snapshot of the vorticity field of a solution to the Navier-Stokes equations for the fluid flow past a cylinder. The dashed red box in this panel specifies the sampling region.

3.5 Navier-Stokes equation

Let us consider the Navier-Stokes equation in two dimensions[10] (2D) given explicitly by

$$w_t = -uw_x - vw_y + 0.01(w_{xx} + w_{yy}), \tag{13}$$

where w denotes the vorticity, u the x-component of the velocity field, and v the y-component. To generate a training dataset for this problem we follow the exact same instructions as the ones provided in (Kutz et al., 2016; Rudy et al., 2017). Specifically,

10. It is straightforward to generalize the proposed framework to the Navier-Stokes equation in three dimensions (3D).

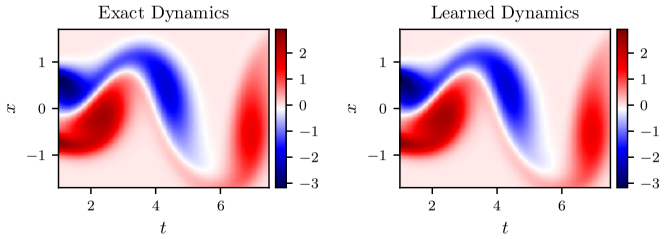

Figure 10: *Navier-Stokes equation:* A randomly picked snapshot of a solution to the Navier-Stokes equation (left panel) is compared to the corresponding snapshot of the solution of the learned partial differential equation (right panel). The identified system correctly captures the form of the dynamics and accurately reproduces the solution with a relative L^2-error of 5.79e-03 in space and time.

we simulate the Navier-Stokes equations describing the two-dimensional fluid flow past a circular cylinder at Reynolds number 100 using the Immersed Boundary Projection Method (Taira and Colonius, 2007; Colonius and Taira, 2008). This approach utilizes a multi-domain scheme with four nested domains, each successive grid being twice as large as the previous one. Length and time are nondimensionalized so that the cylinder has unit diameter and the flow has unit velocity. Data is collected on the finest domain with dimensions 9×4 at a grid resolution of 449×199. The flow solver uses a 3rd-order Runge Kutta integration scheme with a time step of $\Delta t = 0.02$, which has been verified to yield well-resolved and converged flow fields. After simulation converges to steady periodic vortex shedding, 151 flow snapshots are saved every $\Delta t = 0.02$. We use a small portion of the resulting data-set for model training. In particular, we subsample 50000 data points, scattered in space and time, in the rectangular region (dashed red box) downstream of the cylinder as shown in figure 9.

Given the training data, we are interested in learning $\mathcal{N}$ as a function of the stream-wise u and transverse v velocity components in addition to the vorticity w and its derivatives up to the 2nd order[11]; i.e.,

$$w_t = \mathcal{N}(u, v, w, w_x, w_{xx}). \tag{14}$$

We represent the solution w by a 5-layer deep neural network with 200 neurons per hidden layer. Furthermore, we let $\mathcal{N}$ to be a neural network with 2 hidden layers and 100 neurons per hidden layer. As for the activation functions, we use $\sin(x)$. These two networks are trained by minimizing the sum of squared errors loss

$$SSE := \sum_{i=1}^{N} \left(|w(t^i, x^i, y^i) - w^i|^2 + |f(t^i, x^i, y^i)|^2 \right),$$

11. A detailed study of the choice of the order is provided in this section 4 for the Burgers' equation.

where $\{t^i, x^i, u^i, v^i, w^i\}_{i=1}^N$ denote the training data on u and $f(t^i, x^i, y^i)$ is given by

$$f(t^i, x^i, y^i) := w_t(t^i, x^i, y^i) - \mathcal{N}(u^i, v^i, w(t^i, x^i, y^i), w_x(t^i, x^i, y^i), w_{xx}(t^i, x^i, y^i)).$$

To illustrate the effectiveness of our approach, we solve the learned partial differential equation (14), in the region specified in figure 9 by the dashed red box, using the PINNs algorithm (Raissi et al., 2017c). We use the exact solution to provide us with the required Dirichlet boundary conditions as well as the initial condition needed to solve the learned partial differential equation (14). A randomly picked snapshot of the vorticity field in the original dataset alongside the corresponding snapshot of the solution of the learned partial differential equation are depicted in figure 10. This figure indicates that our algorithm is able to accurately identify the underlying partial differential equation with a relative L^2-error of 5.79e-03 in space and time.

4. Summary and Discussion

We have presented a deep learning approach for extracting nonlinear partial differential equations from spatio-temporal datasets. The proposed algorithm leverages recent developments in automatic differentiation to construct efficient algorithms for learning infinite dimensional dynamical systems using deep neural networks. In order to validate the performance of our approach we had no other choice than to rely on black-box solvers (see Raissi et al., 2017c). This signifies the importance of developing general purpose partial differential equation solvers. Developing these types of solvers is still in its infancy and more collaborative work is needed to bring them to the maturity level of conventional methods such as finite elements, finite differences, and spectral methods which have been around for more than half a century or so.

There exist a series of open questions mandating further investigations. For instance, many real-world partial differential equations depend on parameters and, when the parameters are varied, they may go through bifurcations (e.g., the Reynold number for the Navier-Stokes equations). Here, the goal would be to collect data from the underlying dynamics corresponding to various parameter values, and infer the parameterized partial differential equation. Another exciting avenue of future research would be to apply convolutional architectures (Goodfellow et al., 2016) for mitigating the complexity associated with partial differential equations with very high-dimensional inputs. These types of equations appear routinely in dynamic programming, optimal control, or reinforcement learning. We envision that the proposed framework, as outlined in the current work, can be straightforwardly extended to such high-dimensional cases. Early evidence of this claim can be found in (Raissi, 2018), where the author devises an algorithm that is scalable to high-dimensions and is capable of circumventing the tyranny of numerical discretization. In addition, the approach advocated in the current work is also highly scalable to the big data regimes encountered while studying such high-dimensional cases simply because the data can be processed in mini-batches.

Moreover, a quick glance at the list of nonlinear partial differential equations on Wikipedia reveals that many of these equations take the form specified in equation (1). However, a

handful of them do not take this form, including the Boussinesq type equation $u_{tt} - u_{xx} - 2\alpha(uu_x)_x - \beta u_{xxtt} = 0$. It would be interesting to extend the framework outlined in the current work to incorporate all such cases. In addition, it would be an exciting continuation of the current work to extend the proposed methodology to stochastic partial differential equations. In fact, independent realizations of the underlying noise process (e.g., Brownian motion) could act as training data (Raissi, 2018). In the end, it is not always clear what measurements of a dynamical system to take. Even if we did know, collecting these measurements might be prohibitively expensive. It is well-known that time-delay coordinates of a single variable can act as additional variables. It might be interesting to investigate this idea for the infinite dimensional setting of partial differential equations. In terms of applications, it would be intriguing to see how the proposed framework would perform on Geostationary Operational Environmental Satellites (GOES) data (e.g., sea surface temperature data) which could be retrieved from `https://podaac.jpl.nasa.gov/`.

Abstract

In this paper we introduce OpenEnsembles, a Python toolkit for performing and analyzing ensemble clustering. Ensemble clustering is the process of creating many clustering solutions for a given dataset and utilizing the relationships observed across the ensemble to identify final solutions, which are more robust, stable or better than the individual solutions within the ensemble. The OpenEnsembles library provides a unified interface for applying transformations to data, clustering data, visualizing individual clustering solutions, visualizing and finishing the ensemble, and calculating validation metrics for a clustering solution for any given partitioning of the data. We have documented examples of using OpenEnsembles to create, analyze, and visualize a number of different types of ensemble approaches on toy and example datasets. OpenEnsembles is released under the GNU General Public License version 3, can be installed via Conda or the Python Package Index (pip), and is available at `https://github.com/NaegleLab/OpenEnsembles`.

Keywords: Unsupervised Learning, Ensembles, Clustering, Ensemble Clustering, Finishing Techniques

1. Introduction

Clustering, a type of unsupervised learning, has been instrumental in a large number of fields for reducing data dimensionality, identifying important features, and uncovering the underlying structure of relationships that give rise to the sampled data under consideration. However, a single clustering result may represent a spurious solution (such as when an algorithm is stuck in a local minima) or instead represent just one of many possible structures within of complex data (such as when partitioning of an image identifies underlying shapes but fails to find differences in lighting). Ensemble clustering can be used to overcome the limitations of a single clustering solution by clustering repeatedly, each time making some perturbation to either the data or the approach to clustering. The ensemble of clustering results provides more information about the structure of the underlying data, and how likely any particular grouping of objects is across the ensemble. There are several aspects to performing ensemble clustering, which include: (i) determining and implementing the appropriate perturbations, (ii) deriving a single clustering result that is representative of all the clustering solutions in the ensemble (finishing), and (iii) assessing the results of the finished ensemble, in comparison to the results of an individual solution, to understand the structure and quality of solutions (validation metrics). Our previous review on clustering in biological data covers the types of ensemble clustering and its applications (Ronan et al., 2016) in detail, where Figure 1 contains a table of example ensemble approaches and their motivations. Here, we describe the open source Python toolkit for easily implementing, visualizing, and analyzing ensemble clustering.

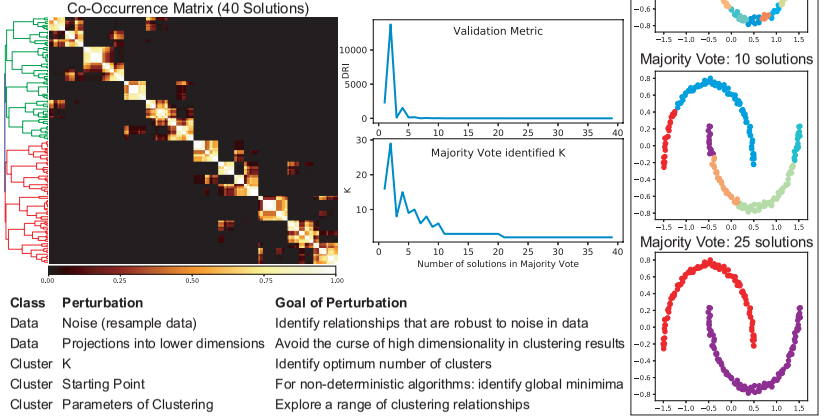
2. Architecture

There are three main OpenEnsembles classes that pair with the main aspects of ensemble clustering: data (storing and manipulating data), cluster (clustering data), and validation (assessing the degree of success of a clustering solution according to an objective such as compactness or connectedness). A common feature across these classes is that they are container objects for housing data, either data matrices (data class), clustering solutions (cluster class), or validation metric results of a clustering solution (validation class). Additionally, each class has a primary function (to transform, cluster, or calculate), where the classes create a common interface for interacting with a variety of transformations, clustering algorithms, and validation metrics. Interacting with any specific transformation of data, retrieving a specific clustering solution or validation metric is done by using the user-defined dictionary key that describes the specific instance. Here we will demonstrate many of the OpenEnsembles features by recreating the first publication of the use of ensemble clustering – Ana Fred's use of ensembles to form a final solution through the majority vote across many non-deterministic k-means solutions (Fred, 2001). OpenEnsembles is built using many open source Python projects, including: scikit-learn (Pedregosa et al., 2012), Pandas (McKinney, 2010), Matplotlib (Hunter, 2007), NetworkX (Hagberg et al., 2008), and NumPy (Walt et al., 2011).

Data

Data is instantiated using a pandas DataFrame object, therefore all the flexibility of loading data from different file formats can be used to coerce the data of interest into an OpenEnsembles data object and metadata can be retained for future analysis. Once instantiated, data can be transformed or used as the basis for clustering or plotting. The *data* container class keeps track of new transformations of the 'parent' data with user-defined keys. Figure 1 shows the instantiation of an OpenEnsembles data object with 200 samples making two half-moon structures. Available transformations currently include: log, principal component analysis (PCA), range scaling, z-score, and internal normalization (such as normalizing to a specific data feature).

```
1  import pandas as pd
2  from sklearn import datasets
3  import openensembles as oe
4  #Set up a dataset and put in pandas DataFrame.
5  x, y = datasets.make_moons(n_samples=200, shuffle=True, noise=0.02, random_state=None)
6  df = pd.DataFrame(x)
7  #instantiate the oe data object
8  dataObj = oe.data(df, [1,2])
9  #instantiate an oe clustering object
10 c = oe.cluster(dataObj)
11 c_MV_arr = []
12 val_arr = []
13 for i in range(0,39):
14     # add a new clustering solution, with a unique name
15     name = 'kmeans_' + str(i)
16     c.cluster('parent', 'kmeans', name, K=16, init = 'random', n_init = 1)
17     # calculate a new majority vote solution, where c has one more solution on each iteration
18     c_MV_arr.append(c.finish_majority_vote(threshold=0.5))
19     #calculate the determinant ratio metric for each majority vote solution
20     v = oe.validation(dataObj, c_MV_arr[i])
21     val_name = v.calculate('det_ratio', 'majority_vote', 'parent')
22     val_arr.append(v.validation[val_name])
23 #calculate the co-occurrence matrix
24 coMat = c.co_occurrence_matrix()
```



Class	Perturbation	Goal of Perturbation
Data	Noise (resample data)	Identify relationships that are robust to noise in data
Data	Projections into lower dimensions	Avoid the curse of high dimensionality in clustering results
Cluster	K	Identify optimum number of clusters
Cluster	Starting Point	For non-deterministic algorithms: identify global minimima
Cluster	Parameters of Clustering	Explore a range of clustering relationships

Figure 1: **Code and outputs of OpenEnsembles.** An ensemble approach (Fred, 2001) to find stable and optimal solutions from the combination of many solutions of the non-deterministic k-means algorithm with majority vote. Code for plotting figure panels is not included (for brevity). K-means can only find clusters that are spheroidally shaped, but as an ensemble, it can identify alternate structures. DRI stands for determinant ratio index – a measure of connectedness in clusters

Cluster

The cluster class is instantiated based on an OpenEnsembles data object, on which all clustering will be performed. OpenEnsembles provides a common interface to clustering, currently providing an interface to all available scikit-learn clustering algorithms. For example, code line 16 (Figure 1) shows how OpenEnsembles is used to call k-means clustering, with K=16 clusters, on the 'parent' data source. Any algorithmic parameters desired are then passed as a dictionary of variable parameters. For example, here, in order to reproduce Ana Fred's original study, we have to overwrite the default arguments of scikit-learn's k-means algorithm, which has ensemble clustering baked into it to lend increased determinism. By looping around OpenEnsembles clustering with random initializations, we are producing

a new clustering solution each time, which is added to the clustering object container and is accessed using the unique key (here it is k-means_⟨number⟩).

Often, one wants to produce a final partition derived from consensus across the ensemble of solutions – i.e. 'finish' the ensemble by building a final, single partitioning of the data. In the current version of OpenEnsembles, we have implemented majority vote as proposed by Ana Fred (Fred, 2001) and mixture models as proposed by Topchy et al. (Topchy et al., 2005). Additionally, there are two finishing techniques that operate on the co-occurrence matrix, as we have proposed previously (Schaberg et al., 2017) (Naegle et al., 2012). An entry in the co-occurrence matrix is the number of times a pair of objects cluster across the ensemble. One method treats the co-occurrence matrix as a similarity matrix and uses linkage clustering to identify clusters (Figure 1). The second method treats the co-occurrence matrix as an adjacency matrix and then finds complete subgraphs within the thresholded co-occurrence matrix via k-cliques and percolation Palla et al. (2005). Final partitions are returned as clustering objects and can be plotted and evaluated like any other clustering solution (Figure 1).

Validation

Quantitative evaluation of how well data is clustered, according to a particular objective function, is called a validation metric. Different validation metrics prioritize different aspects of clustering outcomes such as connectivity, compactness, or separation. We have written a Python package of 28 validation metrics, covering the breadth of the clValid R package of validation metrics (Brock et al., 2008). These validation metrics are available for direct use, or through the OpenEnsembles validation class, which wraps calls to validation metrics for a unified interface with other OpenEnsembles classes. As one can see from the determinant ratio index plot in Figure 1, as the number of clustering solutions in the ensemble increases, the solution both (a) stabilizes and (b) correctly identifies the number of inherent, connected clusters within the data.

Conclusion

Implementation and analysis of ensemble clustering may now be done within in succinct and readable Python code (here, roughly 20 lines of code to reproduce an entire paper of results, Figure 1). Beyond the main functionality of OpenEnsembles, to perform, finish, and validate clustering solutions on data, OpenEnsembles also contains features for calculating co-occurrence, mutual information (overlap/similarity between clustering solutions), and plotting of data and matrices generated. Future work will ideally incorporate expanded selections of algorithms and fuzzy partitioning of data, which is especially amenable to ensemble clustering.

Abstract

Minibatching is a very well studied and highly popular technique in supervised learning, used by practitioners due to its ability to accelerate training through better utilization of parallel processing power and reduction of stochastic variance. Another popular technique is importance sampling—a strategy for preferential sampling of more important examples also capable of accelerating the training process. However, despite considerable effort by the community in these areas, and due to the inherent technical difficulty of the problem, there is virtually no existing work combining the power of importance sampling with the strength of minibatching. In this paper we propose the first practical *importance sampling for minibatches* and give simple and rigorous complexity analysis of its performance. We illustrate on synthetic problems that for training data of certain properties, our sampling can lead to several orders of magnitude improvement in training time. We then test the new sampling on several popular data sets, and show that the improvement can reach an order of magnitude.

keywords: empirical risk minimization; importance sampling; minibatching; variance-reduced methods; convex optimization

1. Introduction

Supervised learning is a widely adopted learning paradigm with important applications such as regression, classification and prediction. The most popular approach to training supervised learning models is via empirical risk minimization (ERM). In ERM, the practitioner collects data composed of example-label pairs, and seeks to identify the best predictor by minimizing the empirical risk, i.e., the average risk associated with the predictor over the training data.

With ever increasing demand for accuracy of the predictors, largely due to successful industrial applications, and with ever more sophisticated models that need to be trained, such as deep neural networks Hinton (2007); Krizhevsky et al. (2012), or multiclass classification Huang et al. (2012), increasing volumes of data are used in the training phase. This leads to huge and hence extremely computationally intensive ERM problems.

Batch algorithms—methods that need to look at all the data before taking a single step to update the predictor—have long been known to be prohibitively impractical to use. Typical examples of batch methods are gradient descent and classical quasi-Newton methods. One of the most popular algorithms for overcoming the deluge-of-data issue is stochastic gradient descent (SGD), which can be traced back to a seminal work of Robbins and Monro (1951). In SGD, a single random example is selected in each iteration, and the predictor is updated using the information obtained by computing the gradient of the loss function associated with this example. This leads to a much more fine-grained iterative process, but at the same time introduces considerable stochastic noise, which eventually—typically after one or a few passes over the data—effectively halts the progress of the method, rendering it unable to push the training error (empirical risk) to the realm of small values.

1.1 Strategies for dealing with stochastic noise

Several approaches have been proposed to deal with the issue of stochastic noise in the finite-data regime. The most important of these are i) decreasing stepsizes, ii) minibatching, iii) importance sampling and iv) variance reduction via "shift", listed here from historically first to the most modern.

The first strategy, *decreasing stepsizes*, takes care of the noise issue by a gradual and direct scale-down process, which ensures that SGD converges to the ERM optimum Zhang (2004). However, an unwelcome side effect of this is a considerable slowdown of the iterative process Bottou (2010). For instance, the convergence rate is sublinear even if the function to be minimized is strongly convex.

The second strategy, *minibatching*, deals with the noise by utilizing a random set of examples in the estimate of the gradient, which effectively decreases the variance of the estimate Shalev-Shwartz et al. (2011). However, this has the unwelcome side-effect of requiring more computation. On the other hand, if a parallel processing machine is available, the computation can be done concurrently, which ultimately leads to speedup. This strategy does not result in an improvement of the convergence rate (unless progressively larger minibatch sizes are used, at the cost of further computational burden Friedlander and Schmidt (2012)), but can lead to massive improvement of the leading constant, which ultimately means acceleration (almost linear speedup for sparse data) Takáč et al. (2013).

The third strategy, *importance sampling*, operates by a careful data-driven design of the probabilities of selecting examples in the iterative process, leading to a reduction of the variance of the stochastic gradient thus selected. Typically, the overhead associated with computing the sampling probabilities and with sampling from the resulting distribution is negligible, and hence the net effect is speedup. In terms of theory, for standard SGD this improves a non-dominant term in the complexity. On the other hand, when SGD is combined with variance reduction, then this strategy leads to the improvement of the leading constant in the complexity estimate, typically via replacing the maximum of certain data-dependent quantities by their average Richtárik and Takáč (2016b); Konečný et al. (2017); Zhao and Zhang (2015); Qu et al. (2015); Needell et al. (2014); Csiba and Richtárik (2015); Csiba et al. (2015).

∗. This author would like to acknowledge support from the EPSRC Grant EP/K02325X/1, *Accelerated Coordinate Descent Methods for Big Data Optimization* and the EPSRC Fellowship EP/N005538/1, *Randomized Algorithms for Extreme Convex Optimization*.

Finally, and most recently, there has been a considerable amount of research activity due to the ground-breaking realization that one can gain the benefits of SGD (cheap iterations) without having to pay through the side effects mentioned above (e.g., halt in convergence due to decreasing stepsizes or increase of workload due to the use of minibatches) in the finite data regime. The result, in theory, is that for strongly convex losses (for example), one does not have to suffer sublinear convergence any more, but instead a fast linear rate "kicks in". In practice, these methods dramatically surpass all previous existing approaches.

The main algorithmic idea is to change the search direction itself, via a properly designed and cheaply maintainable *"variance-reducing shift"* (control variate). Methods in this category are of two types: those operating in the primal space (i.e., directly on ERM) and those operating in a dual space (i.e., with the dual of the ERM problem). Methods of the primal variety include SAG Schmidt et al. (2013), SVRG Johnson and Zhang (2013), S2GD Konečný and Richtárik (2017), proxSVRG Xiao and Zhang (2014), SAGA Defazio et al. (2014), mS2GD Konečný et al. (2016) and MISO Mairal (2015). Methods of the dual variety work by updating randomly selected dual variables, which correspond to examples. These methods include SCD Shalev-Shwartz and Tewari (2011), RCDM Nesterov (2012); Richtárik and Takáč (2014), SDCA Shalev-Shwartz and Zhang (2013b), Hydra Richtárik and Takáč (2016a); Fercoq et al. (2014), mSDCA Takáč et al. (2013), APCG Lin et al. (2015), AsySPDC Liu and Wright (2015), RCD Necoara and Patrascu (2014), APPROX Fercoq and Richtárik (2015), SPDC Zhang and Xiao (2015), ProxSDCA Shalev-Shwartz and Zhang (2012), ASDCA Shalev-Shwartz and Zhang (2013a), IProx-SDCA Zhao and Zhang (2015), and QUARTZ Qu et al. (2015).

1.2 Combining strategies

We wish to stress that the key strategies, mini-batching, importance sampling and variance-reducing shift, should be seen as orthogonal tricks, and as such they can be combined, achieving an amplification effect. For instance, the first primal variance-reduced method allowing for mini-batching was Konečný et al. (2016); while dual-based methods in this category include Shalev-Shwartz and Zhang (2013a); Qu et al. (2015); Csiba and Richtárik (2015). Variance-reduced methods with importance sampling include Nesterov (2012); Richtárik and Takáč (2014); Richtárik and Takáč (2016b); Qu and Richtárik (2016) for general convex minimization problems, and Zhao and Zhang (2015); Qu et al. (2015); Needell et al. (2014); Csiba and Richtárik (2015) for ERM.

2. Contributions

Despite considerable effort of the machine learning and optimization research communities, virtually no importance sampling for minibatches was previously proposed, nor analyzed.[1]. The reason for this lies in the underlying theoretical and computational difficulties associated with the design and successful implementation of such a sampling. One needs to come up with a way to focus on a reasonable set of subsets (minibatches) of the examples to be used in each iteration (issue: there are many subsets; which ones to choose?), assign meaningful data-dependent non-uniform probabilities to them (issue: how?), and then be able to sample these subsets according to the chosen distribution (issue: this could be computationally expensive).

1. A brief note in Richtárik and Takáč (2016b) is an exception, but the sampling is different from ours, was not implemented nor tested, leads to the necessity to solve a linear program and hence is impractical. Another exception is Harikandeh et al. (2015).

The tools that would enable one to consider these questions did not exist until recently. However, due to a recent line of work on analyzing variance-reduced methods utilizing what is known as *arbitrary sampling* Richtárik and Takáč (2016b); Qu et al. (2015); Qu and Richtárik (2016); Qu and Richtárik (2016); Csiba and Richtárik (2015), we are able to ask these questions and provide answers. In this work we design a novel family of samplings—*bucket samplings*—and a particular member of this family—*importance sampling for minibatches*. We illustrate the power of this sampling in combination with the reduced-variance dfSDCA method for ERM. This method is a primal variant of SDCA, first analyzed by Shalev-Shwartz (2015), and extended by Csiba and Richtárik (2015) to the arbitrary sampling setting. However, our sampling can be combined with any stochastic method for ERM, such as SGD or S2GD, and extends beyond the realm of ERM, to convex optimization problems in general. However, for simplicity, we do not discuss these extensions in this work.

We analyze the performance of the new sampling theoretically, and by inspecting the results we are able to comment on when can one expect to be able to benefit from it. We illustrate on synthetic data sets with varying distributions of example sizes that our approach can lead to *dramatic speedups* when compared against standard (uniform) minibatching, of *one or more degrees of magnitude*. We then test our method on real data sets and confirm that the use of importance minibatching leads to up to an order of magnitude speedup. Based on our experiments and theory, we predict that for real data with particular shapes and distributions of example sizes, importance sampling for minibatches will operate in a favourable regime, and can lead to speedup higher than one order of magnitude.

2.1 Related work

The idea of using non-uniform sampling in the parallel regime is by no means new. In the following we highlight several recent approaches in a chronological order and we describe their main differences to our method.

The first attempt for a potential speed-up using a non-uniform parallel sampling was proposed in Richtárik and Takáč (2016b). However, to compute the optimal probability vector one has to solve a linear programming problem, which can easily be more complex than the original problem. The authors do not propose a practical version, which would overcome this issue.

The approach described in Zhao and Zhang (2014) uses the idea of a stratified sampling, which is a well-known strategy in statistics. The authors use clustering to group the examples into several partitions and sample an example from each of the partitions uniformly. This approach is similar to ours, with two main differences: i) we do not need clustering for our approach (it can be computationally very expensive) ii) we allow non-uniform sampling inside each of the partitions, which leads to the main speed-up in our work.

Instead of directly improving the convergence rate of the methods, the authors in Csiba and Richtárik (2015) propose a strategy to improve the synchronized parallel implementation of a method by a load-balancing scheme. The method divides the examples into

groups, which have similar sum of the amount of nonzero entries. When each core processes a single group, it should take the same time to finish as all the other groups, which leads to shorter waiting time in synchronization. Although this is a non-uniform parallel sampling, this approach takes a completely different direction than our method. The only speedup of the method proposed in the above work is achieved due to a shorter waiting time during the synchronization between parallel processing units, while the method proposed in this work directly decreases the iteration complexity.

Lastly, in Harikandeh et al. (2015) the authors actually propose a scheme for importance sampling with minibatches. In the paper they assume, that they can sample a minibatch with a fixed size (without repetition), such that the probabilities of sampling individual examples will be proportional to some given values. However, this is easier said than done—until our work there was no sampling scheme, which would allow for such minibatches. Therefore, the authors theoretically described an idea, which can be used in practice using our scheme.

3. The Problem

Let $\mathbf{X} \in \mathbb{R}^{d\times n}$ be a data matrix in which features are represented in rows and examples in columns, and let $y \in \mathbb{R}^n$ be a vector of labels corresponding to the examples. Our goal is to find a linear predictor $w \in \mathbb{R}^d$ such that $x_i^\top w \sim y_i$, where the pair $x_i, y_i \in \mathbb{R}^d \times \mathbb{R}$ is sampled from the underlying distribution over data-label pairs. In the L2-regularized Empirical Risk Minimization problem, we find w by solving the optimization problem

$$\min_{w\in\mathbb{R}^d} \left[P(w) := \frac{1}{n}\sum_{i=1}^n \phi_i(\mathbf{X}_{:i}^\top w) + \frac{\lambda}{2}\|w\|_2^2 \right], \tag{1}$$

where $\phi_i : \mathbb{R} \to \mathbb{R}$ is a loss function associated with example-label pair $(\mathbf{X}_{:i}, y_i)$, and $\lambda > 0$. For instance, the square loss function is given by $\phi_i(t) = 0.5(t - y_i)^2$. Our results are not limited to L2-regularized problems though: an arbitrary strongly convex regularizer can be used instead Qu et al. (2015). We shall assume throughout that the loss functions are convex and $1/\gamma$-smooth, where $\gamma > 0$. The latter means that for all $x, y \in \mathbb{R}$ and all $i \in [n] := \{1, 2, \ldots, n\}$, we have

$$|\phi_i'(x) - \phi_i'(y)| \le \frac{1}{\gamma}|x - y|.$$

This setup includes ridge and logistic regression, smoothed hinge loss, and many other problems as special cases Shalev-Shwartz and Zhang (2013b). Again, our sampling can be adapted to settings with non-smooth losses, such as the hinge loss.

4. The Algorithm

In this paper we illustrate the power of our new sampling in tandem with Algorithm 1 (dfSDCA) for solving (1).

The method has two parameters. A "sampling" $\hat{S}$, which is a random set-valued mapping Richtárik and Takáč (2016) with values being subsets of $[n]$, the set of examples. No

Algorithm 1 dfSDCA Csiba and Richtárik (2015)

Parameters: Sampling $\hat{S}$, stepsize $\theta > 0$
Initialization: Choose $\alpha^{(0)} \in \mathbb{R}^n$,
set $w^{(0)} = \frac{1}{\lambda n}\sum_{i=1}^n \mathbf{X}_{:i}\alpha_i^{(0)}$, $p_i = \mathbf{Prob}(i \in \hat{S})$
for $t \ge 1$ **do**
  Sample a fresh random set S_t according to $\hat{S}$
  for $i \in S_t$ **do**
    $\Delta_i = \phi_i'(\mathbf{X}_{:i}^\top w^{(t-1)}) + \alpha_i^{(t-1)}$
    $\alpha_i^{(t)} = \alpha_i^{(t-1)} - \theta p_i^{-1}\Delta_i$
  end for
  $w^{(t)} = w^{(t-1)} - \sum_{i\in S_t} \theta(n\lambda p_i)^{-1}\Delta_i \mathbf{X}_{:i}$
end for

assumptions are made on the distribution of $\hat{S}$ apart from requiring that p_i is positive for each i, which simply means that each example has to have a chance of being picked. The second parameter is a stepsize θ, which should be as large as possible, but not larger than a certain theoretically allowable maximum depending on P and $\hat{S}$, beyond which the method could diverge.

Algorithm 1 maintains n "dual" variables, $\alpha_1^{(t)}, \ldots, \alpha_n^{(t)} \in \mathbb{R}$, which act as variance-reduction shifts. This is most easily seen in the case when we assume that $S_t = \{i\}$ (no minibatching). Indeed, in that case we have

$$w^{(t)} = w^{(t-1)} - \frac{\theta}{n\lambda p_i}(g_i^{(t-1)} + \mathbf{X}_{:i}\alpha_i^{(t-1)}),$$

where $g_i^{(t-1)} := \mathbf{X}_{:i}\Delta_i$ is the stochastic gradient. If θ is set to a proper value, as we shall see next, then it turns out that for all $i \in [n]$, α_i is converging $\alpha_i^* := -\phi_i'(\mathbf{X}_{:i}^\top w^*)$, where w^* is the solution to (1), which means that the shifted stochastic gradient converges to zero. This means that its variance is progressively vanishing, and hence no additional strategies, such as decreasing stepsizes or minibatching are necessary to reduce the variance and stabilize the process. In general, dfSDCA in each step picks a random subset of the examples, denoted as S_t, updates variables $\alpha_i^{(t)}$ for $i \in S_t$, and then uses these to update the predictor w.

4.1 Complexity of dfSDCA

In order to state the theoretical properties of the method, we define

$$E^{(t)} := \frac{\lambda}{2}\|w^{(t)} - w^*\|_2^2 + \frac{\gamma}{2n}\|\alpha^{(t)} - \alpha^*\|_2^2.$$

Most crucially to this paper, we assume the knowledge of parameters $v_1, \ldots, v_n > 0$ for which the following ESO[2] inequality holds

$$\mathbf{E}\left[\left\|\sum_{i\in S_t} h_i \mathbf{X}_{:i}\right\|^2\right] \le \sum_{i=1}^n p_i v_i h_i^2 \tag{2}$$

2. ESO = Expected Separable Overapproximation Richtárik and Takáč (2016); Qu and Richtárik (2016).

holds for all $h \in \mathbb{R}^n$. Tight and easily computable formulas for such parameters can be found in Qu and Richtárik (2016). For instance, whenever $\mathbf{Prob}(|S_t| \leq \tau) = 1$, inequality (2) holds with $v_i = \tau\|\mathbf{X}_{:i}\|^2$. However, this is a conservative choice of the parameters. Convergence of dfSDCA is described in the next theorem.

Theorem 1 (Csiba and Richtárik (2015)) *Assume that all loss functions $\{\phi_i\}$ are convex and $1/\gamma$ smooth. If we run Algorithm 1 with parameter θ satisfying the inequality*

$$\theta \leq \min_i \frac{p_i n\lambda\gamma}{v_i + n\lambda\gamma}, \tag{3}$$

where $\{v_i\}$ satisfy (2), then the potential $E^{(t)}$ decays exponentially to zero as

$$\mathbf{E}\left[E^{(t)}\right] \leq e^{-\theta t}E^{(0)}.$$

Moreover, if we set θ equal to the upper bound in (3) so that

$$\frac{1}{\theta} = \max_i \left(\frac{1}{p_i} + \frac{v_i}{p_i n\lambda\gamma}\right) \tag{4}$$

then

$$t \geq \frac{1}{\theta}\log\left(\frac{(1+\lambda\gamma)E^{(0)}}{\lambda\gamma\epsilon}\right) \qquad \Rightarrow \qquad \mathbf{E}[P(w^{(t)}) - P(w^*)] \leq \epsilon.$$

5. Bucket Sampling

We shall first explain the concept of "standard" importance sampling.

5.1 Standard importance sampling

Assume that $\hat{S}$ always picks a single example only. In this case, (2) holds for $v_i = \|\mathbf{X}_{:i}\|^2$, independently of $p := (p_1, \ldots, p_n)$ Qu and Richtárik (2016). This allows us to choose the sampling probabilities as $p_i \sim v_i + n\lambda\gamma$, which ensures that (4) is minimized. This is *importance sampling*. The number of iterations of dfSDCA is in this case proportional to

$$\frac{1}{\theta^{(\text{imp})}} := n + \frac{\sum_{i=1}^n v_i}{n\lambda\gamma}.$$

If uniform probabilities are used, the average in the above formula gets replaced by the maximum:

$$\frac{1}{\theta^{(\text{unif})}} := n + \frac{\max_i v_i}{\lambda\gamma}.$$

Hence, one should expect the following *speedup* when comparing the importance and uniform samplings:

$$\sigma := \frac{\max_i \|\mathbf{X}_{:i}\|^2}{\frac{1}{n}\sum_{i=1}^n \|\mathbf{X}_{:i}\|^2}. \tag{5}$$

If $\sigma = 10$ for instance, then dfSDCA with importance sampling is $10\times$ faster than dfSDCA with uniform sampling.

5.2 Uniform minibatch sampling

In machine learning, the term "minibatch" is virtually synonymous with a special sampling, which we shall here refer to by the name τ-nice sampling Richtárik and Takáč (2016). Sampling $\hat{S}$ is τ-nice if it picks uniformly at random from the collection of all subsets of $[n]$ of cardinality τ. Clearly, $p_i = \tau/n$ and, moreover, it was show by Qu and Richtárik (2016) that (2) holds with $\{v_i\}$ defined by

$$v_i^{(\tau\text{-nice})} = \sum_{j=1}^d \left(1 + \frac{(|J_j|-1)(\tau-1)}{n-1}\right)\mathbf{X}_{ji}^2, \tag{6}$$

where $J_j := \{i \in [n] : \mathbf{X}_{ji} \neq 0\}$. In the case of τ-nice sampling we have the stepsize and complexity given by

$$\theta^{(\tau\text{-nice})} = \min_i \frac{\tau\lambda\gamma}{v_i^{(\tau\text{-nice})} + n\lambda\gamma}, \tag{7}$$

$$\frac{1}{\theta^{(\tau\text{-nice})}} = \frac{n}{\tau} + \frac{\max_i v_i^{(\tau\text{-nice})}}{\tau\lambda\gamma}. \tag{8}$$

Learning from the difference between the uniform and importance sampling of single example (Section 5.1), one would ideally wish the importance minibatch sampling, which we are yet to define, to lead to complexity of the type (8), where the maximum is replaced by an average.

5.3 Bucket sampling: definition

We now propose a family of samplings, which we call *bucket samplings*. Let $B_1, \ldots, B_\tau$ be a partition of $[n] = \{1, 2, \ldots, n\}$ into τ nonempty sets ("buckets").

Definition 2 (Bucket sampling) *We say that $\hat{S}$ is a bucket sampling if for all $i \in [\tau]$, $|\hat{S} \cap B_i| = 1$ with probability 1.*

Informally, a bucket sampling picks one example from each of the τ buckets, forming a minibatch. Hence, $|\hat{S}| = \tau$ and $\sum_{i\in B_l} p_i = 1$ for each $l = 1, 2 \ldots, \tau$, where, as before, $p_i := \mathbf{Prob}(i \in \hat{S})$. Notice that given the partition, the vector $p = (p_1, \ldots, p_n)$ *uniquely determines* a bucket sampling. Hence, we have a family of samplings indexed by a single n-dimensional vector. Let $\mathcal{P}_B$ be the set of all vectors $p \in \mathbb{R}^n$ describing bucket samplings associated with partition $B = \{B_1, \ldots, B_\tau\}$. Clearly,

$$\mathcal{P}_B = \left\{p \in \mathbb{R}^n : \sum_{i\in B_l} p_i = 1 \text{ for all } l \;\&\; p_i \geq 0 \text{ for all } i\right\}.$$

Note, that the sampling inside each bucket B_i can be performed in $\mathcal{O}(\log|B_i|)$ time using a binary tree, with an initial overhead and memory of $\mathcal{O}(|B_i|\log|B_i|)$, as explained in Nesterov (2012).

5.4 Optimal bucket sampling

The optimal bucket sampling is that for which (4) is minimized, which leads to a complicated optimization problem:

$$\min_{p\in\mathcal{P}_B} \max_i \frac{1}{p_i} + \frac{v_i}{p_i n\lambda\gamma} \quad \text{subject to } \{v_i\} \text{ satisfy (2).}$$

A particular difficulty here is the fact that the parameters $\{v_i\}$ depend on the vector p in a complicated way. In order to resolve this issue, we prove the following result.

Theorem 3 *Let $\hat{S}$ be a bucket sampling described by partition $B = \{B_1, \dots, B_\tau\}$ and vector p. Then the ESO inequality (2) holds for parameters $\{v_i\}$ set to*

$$v_i = \sum_{j=1}^{d} \left(1 + \left(1 - \tfrac{1}{\omega'_j}\right)\delta_j\right)\mathbf{X}_{ji}^2, \tag{9}$$

where $J_j := \{i \in [n] \,:\, \mathbf{X}_{ji} \neq 0\}$, $\delta_j := \sum_{i\in J_j} p_i$ and $\omega'_j := |\{l \,:\, J_j \cap B_l \neq \emptyset\}|$.

Observe that J_j is the set of examples which express feature j, and ω'_j is the number of buckets intersecting with J_j. Clearly, that $1 \leq \omega'_j \leq \tau$ (if $\omega'_j = 0$, we simply discard this feature from our data as it is not needed). Note that the effect of the quantities $\{\omega'_j\}$ on the value of v_i is small. Indeed, unless we are in the extreme situation when $\omega'_j = 1$, which has the effect of neutralizing δ_j, the quantity $1 - 1/\omega'_j$ is between $1 - 1/2$ and $1 - 1/\tau$. Hence, for simplicity, we could instead use the slightly more conservative parameters:

$$v_i = \sum_{j=1}^{d} \left(1 + \left(1 - \frac{1}{\tau}\right)\delta_j\right)\mathbf{X}_{ji}^2.$$

5.5 Uniform bucket sampling

Assume all buckets are of the same size: $|B_l| = n/\tau$ for all l. Further, assume that $p_i = 1/|B_l| = \tau/n$ for all i. Then $\delta_j = \tau|J_j|/n$, and hence Theorem 3 says that

$$v_i^{(\text{unif})} = \sum_{j=1}^{d} \left(1 + \left(1 - \frac{1}{\omega'_j}\right)\frac{\tau|J_j|}{n}\right)\mathbf{X}_{ji}^2, \tag{10}$$

and in view of (4), the complexity of dfSDCA with this sampling becomes

$$\frac{1}{\theta^{(\text{unif})}} = \frac{n}{\tau} + \frac{\max_i v_i^{(\text{unif})}}{\tau\lambda\gamma}. \tag{11}$$

Formula (6) is very similar to the one for τ-nice sampling (10), despite the fact that the sets/minibatches generated by the uniform bucket sampling have a special structure with respect to the buckets. Indeed, it is easily seen that the difference between between $1 + \frac{\tau|J_j|}{n}$ and $1 + \frac{(\tau-1)(|J_j|-1)}{(n-1)}$ is negligible. Moreover, if either $\tau = 1$ or $|J_j| = 1$ for all j, then $\omega'_j = 1$ for all j and hence $v_i = \|\mathbf{X}_{:i}\|^2$. This is also what we get for the τ-nice sampling.

quantity \ iteration	1	2	3	4	5	6
$\max_i(\lvert p_i^{\text{new}} - p_i^{\text{old}}\rvert)$	$7\cdot10^{-5}$	$7\cdot10^{-6}$	$7\cdot10^{-7}$	$8\cdot10^{-8}$	$8\cdot10^{-9}$	$9\cdot10^{-10}$
$\|p^{\text{new}} - p^{\text{old}}\|_2$	$1\cdot10^{-3}$	$2\cdot10^{-4}$	$2\cdot10^{-5}$	$2\cdot10^{-6}$	$2\cdot10^{-7}$	$2\cdot10^{-8}$

Table 1: Example of the convergence speed of the alternating optimization scheme for $w8a$ data set (see Table 5) with $\tau = 8$. The table demonstrates the difference in probabilities for two successive iterations (p^{old} and p^{new}). We observed a similar behaviour for all data sets and all choices of τ.

6. Importance Minibatch Sampling

In the light of Theorem 3, we can formulate the problem of searching for the optimal bucket sampling as

$$\min_{p\in\mathcal{P}_B} \max_i \frac{1}{p_i} + \frac{v_i}{p_i n\lambda\gamma} \quad \text{subject to } \{v_i\} \text{ satisfy (9).} \tag{12}$$

Still, this is not an easy problem. *Importance minibatch sampling* arises as an approximate solution of (12). Note that the uniform minibatch sampling is a feasible solution of the above problem, and hence we should be able to improve upon its performance.

6.1 Approach 1: alternating optimization

Given a probability distribution $p \in \mathcal{P}_B$, we can easily find v using Theorem 3. On the other hand, for any fixed v, we can minimize (12) over $p \in \mathcal{P}_B$ by choosing the probabilities in each group B_l and for each $i \in B_l$ via

$$p_i = \frac{n\lambda\gamma + v_i}{\sum_{j\in B_l} n\lambda\gamma + v_j}. \tag{13}$$

This leads to a natural alternating optimization strategy. An example of the standard convergence behaviour of this scheme is showed in Table 6.1. Empirically, this strategy converges to a pair (p^*, v^*) for which (13) holds. Therefore, the resulting complexity will be

$$\frac{1}{\theta^{(\tau\text{-imp})}} = \frac{n}{\tau} + \max_{l\in[\tau]} \frac{\frac{\tau}{n}\sum_{i\in B_l} v_i^*}{\tau\lambda\gamma}. \tag{14}$$

We can compare this result against the complexity of τ-nice in (8). We can observe that the terms are very similar, up to two differences. First, the importance minibatch sampling has a maximum over group averages instead of a maximum over everything, which leads to speedup, other things equal. On the other hand, $v^{(\tau\text{-nice})}$ and v^* are different quantities. The alternating optimization procedure for computation of (v^*, p^*) is costly, as one iteration takes a pass over all data. Therefore, in the next subsection we propose a closed form formula which, as we found empirically, offers nearly optimal convergence rate.

6.2 Approach 2: practical formula

For each group B_l, let us choose for all $i \in B_l$ the probabilities as follows:

$$\boxed{p_i^* = \frac{n\lambda\gamma + v_i^{(\text{unif})}}{\sum_{k\in B_l} n\lambda\gamma + v_k^{(\text{unif})}}} \tag{15}$$

where $v_i^{(\text{unif})}$ is given by (10). Note that computing all $v_i^{(\text{unif})}$ can be done by visiting every non-zero entry of $\mathbf{X}$ once and and computing all p_i^* is a simple re-weighting. This is the same computational cost as for standard serial importance sampling. Also, this process can be straightforwardly parallelized, fully utilizing all the cores, which leads to τ times faster computations. The overhead of using this sampling approach is therefore at most one pass over the data, which is negligible in most scenarios considered.

After doing some simplifications, the associated complexity result is

$$\frac{1}{\theta^{(\tau\text{-imp})}} = \max_l \left\{ \left(\frac{n}{\tau} + \frac{\frac{\tau}{n}\sum_{i\in B_l} v_i^{(\text{unif})}}{\tau\lambda\gamma} \right) \beta_l \right\}, \tag{16}$$

where

$$\beta_l := \max_{i\in B_l} \frac{n\lambda\gamma + s_i}{n\lambda\gamma + v_i^{(\text{unif})}}, \qquad s_i := \sum_{j=1}^{d} \left(1 + \left(1 - \frac{1}{\omega_j'} \right) \sum_{k\in J_j} p_k^* \right) \mathbf{X}_{ji}^2.$$

We would ideally want to have $\beta_l = 1$ for all l (this is what we get for importance sampling without minibatches). If $\beta_l \approx 1$ for all l, then the complexity $1/\theta^{(\tau\text{-imp})}$ is an improvement on the complexity of the uniform minibatch sampling since the maximum of group averages is always better than the maximum of all elements $v_i^{(\text{uni})}$:

$$\frac{n}{\tau} + \frac{\max_l \left(\frac{\tau}{n}\sum_{i\in B_l} v_i^{(\text{unif})} \right)}{\tau\lambda\gamma} \le \frac{n}{\tau} + \frac{\max_i v_i^{(\text{unif})}}{\tau\lambda\gamma}.$$

Indeed, the difference can be very large.

Finally, we would like to comment on the choice of the partitions $B_1, \ldots, B_\tau$, as they clearly affect the convergence rate. The optimal choice of the partitions is given by minimizing in $B_1, \ldots, B_\tau$ the maximum over group sums in (16), which is a complicated optimization problem. Instead, we used random partitions of the same size in our experiments, which we believe is a good solution for the partitioning problem. The logic is simple: the minimum of the maximum over the group sums will be achieved, when all the group sums have similar values. If we set the partitions to the same size and we distribute the examples randomly, there is a good chance that the group sums will have similar values (especially for large amounts of data).

7. Experiments

We now comment on the results of our numerical experiments, with both synthetic and real data sets. We plot the optimality gap $P(w^{(t)}) - P(w^*)$ and in the case of real data also

the test error (vertical axis) against the computational effort (horizontal axis). We measure computational effort by the number of effective passes through the data divided by τ. We divide by τ as a normalization factor; since we shall compare methods with a range of values of τ. This is reasonable as it simply indicates that the τ updates are performed in parallel. Hence, what we plot is an implementation-independent model for time.

We compared two algorithms:

1) **τ-nice**: dfSDCA using the τ-nice sampling with stepsizes given by (7) and (6),

2) **τ-imp**: dfSDCA using τ-importance sampling (i.e., importance minibatch sampling) defined in Subsection 6.2.

As the methods are randomized, we always plot the average over 5 runs. For each data set we provide two plots. In the left figure we plot the convergence of τ-nice for different values of τ, and in the right figure we do the same for τ-importance. The horizontal axis has the same range in both plots, so they are easily comparable. The values of τ we used to plot are $\tau \in \{1, 2, 4, 8, 16, 32\}$. In all experiments we used the logistic loss: $\phi_i(z) = \log(1 + e^{-y_i z})$ and set the regularizer to $\lambda = \max_i \|\mathbf{X}_{:i}\|/n$. We will observe the theoretical and empirical ratio $\theta^{(\tau\text{-imp})}/\theta^{(\tau\text{-nice})}$. The theoretical ratio is computed from the corresponding theory. The empirical ratio is the ratio between the horizontal axis values at the moments when the algorithms reached the precision 10^{-10}.

7.1 Artificial data

We start with experiments using artificial data, where we can control the sparsity pattern of $\mathbf{X}$ and the distribution of $\{\|\mathbf{X}_{:i}\|^2\}$. We fix $n = 50,000$ and choose $d = 10,000$ and $d = 1,000$. For each feature we sampled a random sparsity coefficient $\omega_i' \in [0, 1]$ to have the average sparsity $\omega' := \frac{1}{d}\sum_i^d \omega_i'$ under control. We used two different regimes of sparsity: $\omega' = 0.1$ (10% nonzeros) and $\omega' = 0.8$ (80% nonzeros). After deciding on the sparsity pattern, we rescaled the examples to match a specific distribution of norms $L_i = \|\mathbf{X}_{:i}\|^2$; see Table 2. The code column shows the corresponding code in Julia to create the vector of norms L. The distributions can be also observed as histograms in Figure 1.

label	code	σ
extreme	L = ones(n);L[1] = 1000	980.4

7.2 Real data

We used several publicly available data sets[3], summarized in Table 5, which we randomly split into a train (80%) and a test (20%) part. The test error is measured by the empirical risk (1) on the test data without a regularizer. The resulting test error was compared against the best achievable test error, which we computed by minimizing the corresponding risk. Experimental results are in Figure 7.3 and Figure 7.3. The theoretical and empirical speedup table for these data sets can be found in Table 6.

7.3 Conclusion

In all experiments, τ-importance sampling performs significantly better than τ-nice sampling. The theoretical speedup factor computed by $\theta^{(\tau\text{-imp})}/\theta^{(\tau\text{-nice})}$ provides an excellent estimate of the actual speedup. We can observe that on denser data the speedup is higher than on sparse data. This matches the theoretical intuition for v_i for both samplings. Similar behaviour can be also observed for the test error, which is pleasing. As we observed for artificial data, for extreme data sets the speedup can be arbitrary large, even several orders of magnitude. *A rule of thumb: if one has data with large σ, practical speedup from using importance minibatch sampling will likely be dramatic.*

8. Proof of Theorem 3

8.1 Three lemmas

We first establish three lemmas, and then proceed with the proof of the main theorem. With each sampling $\hat{S}$ we associate an $n \times n$ "probability matrix" defined as follows: $\mathbf{P}_{ij}(\hat{S}) = \mathbf{Prob}(i \in \hat{S}, j \in \hat{S})$. Our first lemma characterizes the probability matrix of the bucket sampling.

Lemma 4 *If $\hat{S}$ is a bucket sampling, then*

$$\mathbf{P}(\hat{S}) = pp^\top \circ (\mathbf{E} - \mathbf{B}) + \mathrm{Diag}(p), \tag{17}$$

where $\mathbf{E} \in \mathbb{R}^{n\times n}$ is the matrix of all ones,

$$\mathbf{B} := \sum_{l=1}^{\tau} \mathbf{P}(B_l), \tag{18}$$

and $\circ$ denotes the Hadamard (elementwise) product of matrices. Note that $\mathbf{B}$ is the 0-1 matrix given by $\mathbf{B}_{ij} = 1$ if and only if i, j belong to the same bucket B_l for some l.

Proof Let $\mathbf{P} = \mathbf{P}(\hat{S})$. By definition

$$\mathbf{P}_{ij} = \begin{cases} p_i & i = j \\ p_i p_j & i \in B_l,\ j \in B_k,\ l \neq k \\ 0 & \text{otherwise.} \end{cases}$$

It only remains to compare this to (17). ■

Lemma 5 *Let J be a nonempty subset of $[n]$, let $\mathbf{B}$ be as in Lemma 4 and put $\omega'_J := |\{l : J \cap B_l \neq \emptyset\}|$. Then*

$$\mathbf{P}(J) \circ \mathbf{B} \succeq \frac{1}{\omega'_J}\mathbf{P}(J). \tag{19}$$

Proof For any $h \in \mathbb{R}^n$, we have

$$h^\top \mathbf{P}(J) h = \left(\sum_{i\in J} h_i\right)^2 = \left(\sum_{l=1}^{\tau} \sum_{i\in J\cap B_l} h_i\right)^2 \leq \omega'_J \sum_{l=1}^{\tau} \left(\sum_{i\in J\cap B_l} h_i\right)^2 = \omega'_J \sum_{l=1}^{\tau} h^\top \mathbf{P}(J\cap B_l) h,$$

where we used the Cauchy-Schwarz inequality. Using this, we obtain

$$\mathbf{P}(J) \circ \mathbf{B} \overset{(18)}{=} \mathbf{P}(J) \circ \sum_{l=1}^{\tau} \mathbf{P}(B_l) = \sum_{l=1}^{\tau} \mathbf{P}(J) \circ \mathbf{P}(B_l) = \sum_{l=1}^{\tau} \mathbf{P}(J \cap B_l) \overset{(8.1)}{\succeq} \frac{1}{\omega'} \mathbf{P}(J).$$

■

Lemma 6 *Let J be any nonempty subset of $[n]$ and $\hat{S}$ be a bucket sampling. Then*

$$\mathbf{P}(J) \circ pp^\top \preceq \left(\sum_{i\in J} p_i\right) \mathrm{Diag}(\mathbf{P}(J \cap \hat{S})). \tag{20}$$

Proof Choose any $h \in \mathbb{R}^n$ and note that

$$h^\top (\mathbf{P}(J) \circ pp^\top) h = \left(\sum_{i\in J} p_i h_i\right)^2 = \left(\sum_{i\in J} x_i y_i\right)^2,$$

where $x_i = \sqrt{p_i} h_i$ and $y_i = \sqrt{p_i}$. It remains to apply the Cauchy-Schwarz inequality:

$$\sum_{i\in J} x_i y_i \leq \sum_{i\in J} x_i^2 \sum_{i\in J} y_i^2$$

and notice that the i-th element on the diagonal of $\mathbf{P}(J \cap \hat{S})$ is p_i for $i \in J$ and 0 for $i \notin J$ ■

8.2 Proof of Theorem 3

By Theorem 5.2 in Qu and Richtárik (2016), we know that inequality (2) holds for parameters $\{v_i\}$ set to

$$v_i = \sum_{j=1}^{d} \lambda'(\mathbf{P}(J_j \cap \hat{S}))\mathbf{X}_{ji}^2,$$

where $\lambda'(\mathbf{M})$ is the largest normalized eigenvalue of symmetric matrix $\mathbf{M}$ defined as

$$\lambda'(\mathbf{M}) := \max_h \left\{ h^\top \mathbf{M} h \ :\ h^\top \mathrm{Diag}(\mathbf{M}) h \leq 1 \right\}.$$

Furthermore,

$$\begin{aligned} \mathbf{P}(J_j \cap \hat{S}) &= \mathbf{P}(J_j) \circ \mathbf{P}(\hat{S}) \\ &\overset{(17)}{=} \mathbf{P}(J_j) \circ pp^\top - \mathbf{P}(J_j) \circ pp^\top \circ \mathbf{B} + \mathbf{P}(J_j) \circ \mathrm{Diag}(p) \\ &\overset{(19)}{\preceq} \left(1 - \frac{1}{\omega'_J}\right) \mathbf{P}(J_j) \circ pp^\top + \mathbf{P}(J_j) \circ \mathrm{Diag}(p) \\ &\overset{(20)}{\preceq} \left(1 - \frac{1}{\omega'_J}\right) \delta_j \mathrm{Diag}(\mathbf{P}(J_j \cap \hat{S})) + \mathrm{Diag}(\mathbf{P}(J_j \cap \hat{S})), \end{aligned}$$

whence $\lambda'(\mathbf{P}(J_j \cap \hat{S})) \leq 1 + (1 - 1/\omega'_j)\,\delta_j$, which concludes the proof.

Abstract

For massive and heterogeneous modern datasets, it is of fundamental interest to provide guarantees on the accuracy of estimation when computational resources are limited. In the application of rank aggregation, for the Plackett-Luce model, we provide a hierarchy of rank-breaking mechanisms ordered by the complexity in thus generated sketch of the data. This allows the number of data points collected to be gracefully traded off against computational resources available, while guaranteeing the desired level of accuracy. Theoretical guarantees on the proposed generalized rank-breaking implicitly provide such trade-offs, which can be explicitly characterized under certain canonical scenarios on the structure of the data. Further, the proposed generalized rank-breaking algorithm involves set-wise comparisons as opposed to traditional pairwise comparisons. The maximum likelihood estimate of pairwise comparisons is computed efficiently using the celebrated minorization maximization algorithm (Hunter, 2004). To compute the pseudo-maximum likelihood estimate of the set-wise comparisons, we provide a generalization of the minorization maximization algorithm and give guarantees on its convergence.

Keywords: Rank aggregation, Plackett-Luce model, Sample and Computational tradeoff.

1. Introduction

In classical statistical inference, we are typically interested in characterizing how more data points improve the accuracy, with little restrictions or considerations on computational aspects of solving the inference problem. However, with massive growths of the amount of data available and also the complexity and heterogeneity of the collected data, computational resources, such as time and memory, are major bottlenecks in many modern applications. As a solution, recent advances in learning theory introduce hierarchies of algorithmic solutions, ordered by the respective computational complexity, for several fundamental machine learning applications in Bousquet and Bottou (2008); Shalev-Shwartz and Srebro (2008); Chandrasekaran and Jordan (2013); Agarwal et al. (2012); Lucic et al. (2015). Guided by sharp analyses on the sample complexity, these approaches provide theoretically sound guidelines that allow the analyst the flexibility to fall back to simpler algorithms to enjoy the full merit of the improved run-time.

Inspired by these advances, we study the time-data tradeoff in rank aggregation. In many applications such as election, policy making, polling, and recommendation systems, we want to aggregate individual preferences to produce a global ranking that best represents the collective social preference. We assume that the data comes from a parametric family of choice models, and learns the parameters that determine the global ranking. Traditionally, each revealed preference is assumed to have one of the following three structures. *Pairwise comparison*, where one item is preferred over another, is common in sports and chess matches. *Best-out-of-κ comparison*, where one is chosen among a set of κ alternatives, is common in historical purchase data. *κ-way comparison*, where we observe a linear ordering of a set of κ candidates, is used in some elections and surveys. We will refer to such structures as *traditional* in comparisons to modern datasets with non-traditional structures. For such traditional preferences, efficient schemes for rank aggregation have been proposed, such as Ford Jr. (1957); Hunter (2004); Hajek et al. (2014); Chen and Suh (2015), which we explain in detail in Section 2.1. However, modern datasets are unstructured and heterogeneous. As Khetan and Oh (2016) show, this can lead to significant increase in the computational complexity, requiring exponential run-time in the size of the problem in the worst case.

To alleviate this computational challenge, we propose a hierarchy of estimators which we call *generalized rank-breaking*, ordered in increasing computational complexity and achieving increasing accuracy. The key idea is to break down the heterogeneous revealed preferences into simpler pieces of ordinal relations, and apply an estimator tailored for those simple structures treating each piece as independent. Several aspects of rank-breaking makes this problem interesting and challenging. A priori, it is not clear which choices of the simple ordinal relations are rich enough to be statistically efficient and yet lead to tractable estimators. Even if we identify which ordinal relations to extract, the ignored correlations among those pieces can lead to an inconsistent estimate, unless we choose carefully which pieces to include and which to omit in the estimation. We further want sharp analysis on the sample complexity, which reveals how computational and statistical efficiencies trade off. We would like to address all these challenges in providing generalized rank-breaking methods.

2. Problem formulation.

We study the problem of aggregating ordinal data based on users' preferences that are expressed in the form of *partially ordered sets (poset)*. A poset is a collection of ordinal relations among items. For example, consider a poset $\{(i_6 \prec \{i_5, i_4\}), (i_5 \prec i_3), (\{i_3, i_4\} \prec \{i_1, i_2\})\}$ over items $\{i_1, \ldots, i_6\}$, where $(i_6 \prec \{i_5, i_4\})$ indicates that item i_5 and i_4 are both preferred over item i_6. Such a relation is extracted from, for example, the user giving a 2-star rating to i_5 and i_4 and a 1-star to i_6.

We assume there are n users and d items. We denote the set of n users by $[n] = \{1, \ldots, n\}$ and the set of d items by $[d]$. We assume that each user $j \in [n]$ is presented with a subset of items $S_j \subseteq [d]$, and independently provides her ordinal preference in the form of a poset, where the ordering is drawn from the Plackett-Luce (PL) model. Since, an ordering drawn from the PL model is consistent, a poset can be represented as a directed acyclic graph (DAG). Let $\mathcal{G}_j$ denote the DAG representation of the poset provided by the user j over $S_j \subseteq [d]$ according to the PL model with weights θ^*. The task is to learn $\widehat{\theta}$, an estimate of the true weights θ^*. Below is an example of a DAG $\mathcal{G}_j$. We use index i to denote items and j to denote users.

Plackett-Luce model. The PL model is a popular choice model from operations research and psychology, used to model how people make choices under uncertainty. It is a special case of *random utility models*, where each item i is parametrized by a latent true utility $\theta_i \in \mathbb{R}$. When offered with

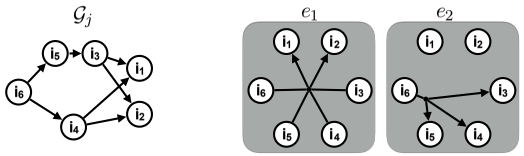

Figure 1: An example of $\mathcal{G}_j$ for user j's consistent poset, and two rank-breaking hyper edges extracted from it: $e_1 = (\{i_6, i_5, i_4, i_3\} \prec \{i_2, i_1\})$ and $e_2 = (\{i_6\} \prec \{i_5, i_4, i_3\})$.

S_j, the user samples the perceived utility U_i for each item independently according to $U_i = \theta_i + Z_i$, where Z_i's are i.i.d. noise. In particular, the PL model assumes Z_i's follow the standard Gumbel distribution. The observed poset is a partial observation of the ordering according to this perceived utilities. We discuss possible extensions to general class of random utility models in Section 2.1.

The particular choice of the Gumbel distribution has several merits, largely stemming from the fact that the Gumbel distribution has a log-concave pdf and is inherently memoryless. In our analyses, we use the log-concavity to show that our proposed algorithm is a concave maximization (Remark 1) and the memoryless property forms the basis of our rank-breaking idea. Precisely, the PL model is statistically equivalent to the following procedure. Consider a ranking as a mapping from a position in the rank to an item, i.e. $\sigma_j : [|S_j|] \to S_j$. It can be shown that the PL model is generated by first independently assigning each item $i \in S_j$ an unobserved value Y_i, exponentially distributed with mean $e^{-\theta_i}$, and the resulting ranking σ_j is inversely ordered in Y_i's so that $Y_{\sigma_j(1)} \le Y_{\sigma_j(2)} \le \cdots \le Y_{\sigma_j(|S_j|)}$.

This inherits the memoryless property of exponential variables, such that $\mathbb{P}(Y_1 < Y_2 < Y_3) = \mathbb{P}(Y_1 < \{Y_2, Y_3\})\mathbb{P}(Y_2 < Y_3)$, leading to a simple interpretation of the PL model as sequential choices:

$$\mathbb{P}_\theta(i_3 \prec i_2 \prec i_1) \;=\; \mathbb{P}_\theta(\{i_3, i_2\} \prec i_1)\mathbb{P}_\theta(i_3 \prec i_2) \;=\; \frac{e^{\theta_{i_1}}}{e^{\theta_{i_1}} + e^{\theta_{i_2}} + e^{\theta_{i_3}}} \times \frac{e^{\theta_{i_2}}}{e^{\theta_{i_2}} + e^{\theta_{i_3}}} \,.$$

In general, for true utility θ^*, we have

$$\mathbb{P}_{\theta^*}[\sigma_j] \;=\; \prod_{i=1}^{|S_j|-1} \frac{e^{\theta^*_{\sigma_j(i)}}}{\sum_{i'=i}^{|S_j|} e^{\theta^*_{\sigma_j(i')}}} \,.$$

We assume that the true utility $\theta^* \in \Omega_b$ where

$$\Omega_b \;=\; \left\{ \theta \in \mathbb{R}^d \;\middle|\; \sum_{i \in [d]} \theta_i = 0, |\theta_i| \le b \text{ for all } i \in [d] \right\}. \tag{1}$$

Notice that centering of θ ensures its uniqueness as PL model is invariant under shifting of θ. The bound b on θ_i is written explicitly to capture the dependence in our main results. We interchangeably refer θ as utilities and weights.

Maximum Likelihood Estimate of DAG. Probability of observing a DAG $\mathcal{G}_j$ is the sum of probabilities of all possible rankings that are consistent with it. Precisely, under the PL model, for

a DAG $\mathcal{G}_j$, we have,

$$\mathbb{P}_\theta[\mathcal{G}_j] \;=\; \sum_{\sigma \in \mathcal{G}_j} \mathbb{P}_\theta[\sigma] \,,$$

where we slightly abuse the notation $\mathcal{G}_j$ to denote the set of all rankings σ that are consistent with the observation. For example, if $\mathcal{G}_j$ consists of only one hyper edge $e_1 = (\{i_3\} \prec \{i_2, i_1\})$ then $\mathbb{P}[\mathcal{G}_j] = \mathbb{P}(i_3 \prec i_2 \prec i_1) + \mathbb{P}(i_3 \prec i_1 \prec i_2)$. The maximum likelihood estimate (MLE) maximizes log-likelihood of observing $\mathcal{G}_j$ for each j:

$$\widehat{\theta} \;\in\; \arg\max_{\theta \in \Omega_b} \left\{ \sum_{j=1}^{n} \log \mathbb{P}_\theta[\mathcal{G}_j] \right\}. \tag{2}$$

When $\mathcal{G}_j$ has a *traditional* structure as explained earlier in this section, then the optimization is a simple multinomial logit regression, that can be solved efficiently with off-the-shelf convex optimization tools. Hajek et al. (2014) provides full analysis of the statistical complexity of this MLE under traditional structures. For general posets, it can be shown that the above optimization is a concave maximization, using similar techniques as Remark 1. However, the summation over rankings in $\mathcal{G}_j$ can involve number of terms super exponential in the size $|S_j|$, in the worst case. This renders MLE intractable and impractical.

Pairwise rank-breaking. A common remedy to this computational blow-up is to use rank-breaking. Rank-breaking traditionally refers to *pairwise rank-breaking*, where a bag of all the pairwise comparisons is extracted from observations $\{\mathcal{G}_j\}_{j \in [n]}$ and is applied to estimators that are tailored for pairwise comparisons, treating each paired outcome as independent. This is one of the motivations behind the algorithmic advances in the popular topic of aggregation from pairwise comparisons in (Ford Jr., 1957; Hunter, 2004; Negahban et al., 2014; Shah et al., 2015a; Maystre and Grossglauser, 2015).

It is computationally efficient to apply maximum likelihood estimator assuming independent pairwise comparisons, which takes $O(d^2)$ operations to evaluate. However, this computational gain comes at the cost of statistical efficiency. Azari Soufiani et al. (2014) showed that if we include all paired comparisons, then the resulting estimate can be statistically inconsistent due to the ignored correlations among the paired orderings, even with infinite samples. In the example from Figure 1, there are 12 paired relations implied by the DAG: $(i_6 \prec i_5), (i_6 \prec i_4), (i_6 \prec i_3), \ldots, (i_3 \prec i_1), (i_4 \prec i_1)$. In order to get a consistent estimate, Azari Soufiani et al. (2014) provide a rule for choosing which pairs to include, and Khetan and Oh (2016) provide an estimator that optimizes how to weigh each of those chosen pairs to get the best finite sample complexity bound. However, such a consistent pairwise rank-breaking results in throwing away many of the ordered relations, resulting in significant loss in accuracy. For example, including any paired relation from $\mathcal{G}_j$ in the example results in a biased estimator. None of the pairwise orderings can be used from $\mathcal{G}_j$, without making the estimator inconsistent as shown in Azari Soufiani et al. (2013). Whether we include all paired comparisons or only a subset of consistent ones, there is a significant loss in accuracy as illustrated in Figure 4. For the precise condition for consistent rank-breaking we refer to (Azari Soufiani et al., 2013, 2014; Khetan and Oh, 2016).

The state-of-the-art approaches operate on either one of the two extreme points on the computational and statistical trade-off. The MLE in (2) requires $O(\sum_{j \in [n]} |S_j|!)$ summations to just

evaluate the objective function, in the worst case. On the other hand, the pairwise rank-breaking requires only $O(d^2)$ summations, but suffers from significant loss in the sample complexity. Ideally, we would like to give the analyst the flexibility to choose a target computational complexity she is willing to tolerate, and provide an algorithm that achieves the optimal trade-off at the chosen operating point.

Contribution. We introduce a novel *generalized rank-breaking* that bridges the gap between MLE and pairwise rank-breaking. Our approach allows the user the freedom to choose the level of computational resources to be used, and provides an estimator tailored for the desired complexity. We prove that the proposed estimator is tractable and consistent, and provide an upper bound and a lower bound on the error rate in the finite sample regime. The analysis explicitly characterizes the dependence on the topology of the data. This in turn provides a guideline for designing surveys and experiments in practice, in order to maximize the sample efficiency. The proposed generalized rank-breaking mechanism involves set-wise comparisons as opposed to traditional pairwise comparisons. In order to compute the rank-breaking estimate, we generalize the celebrated minorization maximization algorithm for computing maximum likelihood estimate of pairwise comparisons (Hunter, 2004) to more general set-wise comparisons and give guarantees on its convergence.

2.1 Related work

In classical statistics, one is interested in the tradeoff between the sample size and the accuracy, with little considerations to the computational complexity or time. As more computations are typically required with increasing availability of data, the computational resources are often the bottleneck. Recently, a novel idea known as "algorithmic weakening" has been investigated to overcome such a bottleneck, in which a hierarchy of algorithms is proposed to allow for faster algorithms at the expense of decreased accuracy. When guided by sound theoretical analyses, this idea allows the statistician to achieve the same level of accuracy and *save* time when more data is available. This is radically different from classical setting where processing more data typically requires more computational time.

Depending on the application, several algorithmic weakenings have been studied. In the application of supervised learning, Bousquet and Bottou (2008) proposed the idea that weaker approximate optimization algorithms are sufficient for learning when more data is available. Various gradient based algorithms are analyzed that show the time-accuracy-sample tradeoff. In a similar context, Shalev-Shwartz and Srebro (2008) analyze a particular implementation of support vector machine and show that the target accuracy can be achieved faster when more data is available, by running the iterative algorithm for shorter amount of time. In the application of de-noising, Chandrasekaran and Jordan (2013) provide a hierarchy of convex relaxations where constraints are defined by convex geometry with increasing complexity. For unsupervised learning, Lucic et al. (2015) introduce a hierarchy of data representations that provide more representative elements when more data is available at no additional computation. Standard clustering algorithms can be applied to thus generated summary of the data, requiring less computational complexity.

In the application of rank aggregation, we follow the principle of algorithmic weakening and propose a novel rank-breaking to allow the practitioner to navigate gracefully the time-sample trade off as shown in the Figure 2. We propose a hierarchy of estimators indexed by $M \in \mathbb{Z}^+$ indicating how complex the estimator is (defined formally in Section 3). Figure 2 shows the result of a experiment on synthetic datasets on how much time (in seconds) and how many samples are

required to achieve a target accuracy. If we are given more samples, then it is possible to achieve the target accuracy, which in this example is MSE$\leq 0.3d^2 \times 10^{-6}$, with fewer operations by using a simpler estimator with smaller M. The details of the experiment is explained in Figure 4.

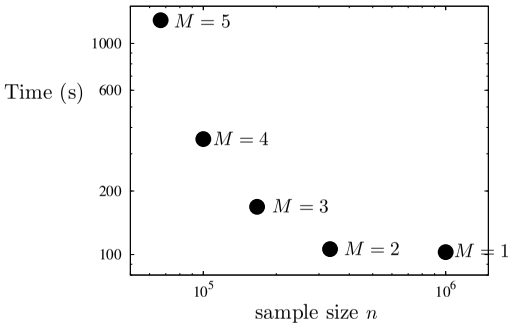

Figure 2: Depending on how much computational resources are available, the various choices of M achieve different operating points on the time-data trade-off to achieve some fixed target accuracy $\varepsilon > 0$. If more samples are available, one can resort to faster methods with smaller M while achieving the same level of accuracy.

Rank aggregation under the PL model has been studied extensively under the *traditional* scenario dating back to Zermelo (1929) who first introduced the PL model for pairwise comparisons. Various approaches for estimating the PL weights from traditional samples have been proposed. The problem can be formulated as a convex optimization that can be solved efficiently using the off-the-shelf solvers. However, tailored algorithms for finding the optimal solution have been proposed in Ford Jr. (1957) and Hunter (2004), which iteratively finds the fixed point of the KKT condition. Negahban et al. (2014) introduce Rank Centrality, a novel spectral ranking algorithm which formulates a random walk from the given data, and show that the stationary distribution provides accurate estimates of the PL weights. Maystre and Grossglauser (2015) provide a connection between those previous approaches, and give a unified random walk approach that finds the fixed point of the KKT conditions.

On the theoretical side, when samples consist of pairwise comparisons, Simons and Yao (1999) first established consistency and asymptotic normality of the maximum likelihood estimate when all teams play against each other. For a broader class of scenarios where we allow for sparse observations, where the number of total comparisons grow linearly in the number of teams, Negahban et al. (2014) show that Rank Centrality achieves optimal sample complexity by comparing it to a lower bound on the minimax rate. For a more general class of traditional observations, including pairwise comparisons, Hajek et al. (2014) provide similar optimal guarantee for the maximum likelihood estimator. Chen and Suh (2015) introduced Spectral MLE that applies Rank Centrality followed by MLE, and showed that the resulting estimate is optimal in L_∞ error as well as the previously analyzed L_2 error. Shah et al. (2015a) study a new measure of the error induced by the

Laplacian of the comparisons graph and prove a sharper upper and lower bounds that match up to a constant factor.

However, in modern applications, the computational complexity of the existing approaches blow-up due to the heterogeneity of modern datasets. Although, statistical and computational tradeoffs have been investigated under other popular choice models such as the Mallows models by Betzler et al. (2014) or stochastically transitive models by Shah et al. (2015b), the algorithmic solutions do not apply to random utility models and the analysis techniques do not extend. We provide a novel rank-breaking algorithms and provide finite sample complexity analysis under the PL model. This approach readily generalizes to some RUMs such as the flipped Gumbel distribution. However, it is also known from Azari Soufiani et al. (2014), that for general RUMs there is no consistent rank-breaking, and the proposed approach does not generalize.

3. Generalized rank-breaking

Given $\mathcal{G}_j$'s representing the users' preferences, *generalized rank-breaking* extracts a set of ordered relations and applies an estimator treating each ordered relation as independent. Concretely, for each $\mathcal{G}_j$, we first extract a maximal ordered partition $\mathcal{P}_j$ of S_j that is consistent with $\mathcal{G}_j$. An ordered partition is a partition with a linear ordering among the subsets, e.g. $\mathcal{P}_j = (\{i_6\} \prec \{i_5, i_4, i_3\} \prec \{i_2, i_1\})$ for $\mathcal{G}_j$ from Figure 1. This is maximal, since we cannot further partition any of the subsets without creating artificial ordered relations that are not present in the original $\mathcal{G}_j$.

To precisely define maximal ordered partition $\mathcal{P}_j$, first, let's define an ordered partition $\widetilde{\mathcal{P}}_j$ of S_j that is consistent with $\mathcal{G}_j$. Consider disjoint subsets $\mathcal{C}_1, \cdots, \mathcal{C}_{\ell_j} \subseteq S_j$ such that their union is S_j that is $\cup_{a=1}^{\ell_j} C_a = S_j$. The subsets $\mathcal{C}_1, \cdots, \mathcal{C}_{\ell_j}$ define an ordered partition

$$\widetilde{\mathcal{P}}_j = \mathcal{C}_1 \prec \mathcal{C}_2 \prec \cdots \prec \mathcal{C}_{\ell_j} ,$$

if each ordered relation that can be read from this linear ordering of subsets is present in the DAG $\mathcal{G}_j$. Let $|\mathcal{P}_j|$ denote the size of the partition, that is $|\mathcal{P}_j| = \ell_j$. A maximal ordered partition $\mathcal{P}_j$ is the one which has the largest size.

$$\mathcal{P}_j = \arg\max_{\widetilde{\mathcal{P}}_j} \left\{ |\widetilde{\mathcal{P}}_j| \right\} .$$

In the following we provide an algorithm to find a maximal ordered partition $\mathcal{P}_j$ of S_j that is consistent with a given $\mathcal{G}_j$.

Finding Maximal Ordered Partition. Given a DAG $\mathcal{G}_j$, a corresponding maximal ordered partition $\mathcal{P}_j$ can be extracted by recursively finding common ancestors of the sink-nodes of the vertex induced sub-graph starting with the DAG $\mathcal{G}_j$. Algorithm 1 gives a pseudocode to find $\mathcal{P}_j$'s. Common ancestors of all the sink nodes of a DAG can be found in time $O(d^{2.6})$ using fast algorithms given in (Czumaj et al., 2007; Bender et al., 2005). Therefore, computational complexity of the Algorithm 1 is $O(d^{3.6})$. In line 2, Algorithm 1, $V(\mathcal{G})$ denotes the set of vertices of DAG $\mathcal{G}$. In line 5, $\mathcal{G}(S)$ denote the vertex induced subgraph of graph $\mathcal{G}$ corresponding to vertex set S. Note that Algorithm 1 returns a unique maximal ordered partition $\mathcal{P}_j$ for a given DAG $\mathcal{G}_j$.

In general there is no one-to-one mapping from a DAG $\mathcal{G}_j$ to its maximal ordered partition $\mathcal{P}_j$. There may be many ordered relations present in $\mathcal{G}_j$ that are not represented in the ordered

Algorithm 1 Finding Maximal Ordered Partition

Require: DAG $\mathcal{G}_j$
Ensure: maximal ordered partition $\mathcal{P}_j$
1: $\mathcal{G} \leftarrow \mathcal{G}_j$, $\mathcal{P}_j = \{\}$
2: **while** $|V(\mathcal{G})| > 0$ **do**
3: $S \leftarrow$ Common ancestors of all sink-nodes of DAG $\mathcal{G}$ (Czumaj et al., 2007)
4: $\mathcal{P}_j \leftarrow \mathcal{P}_j \succ \{V(\mathcal{G}) \setminus S\}$
5: $\mathcal{G} \leftarrow \mathcal{G}(S)$
6: **end while**

partition $\mathcal{P}_j$. This gives a many-to-one mapping from $\mathcal{G}_j$ to $\mathcal{P}_j$. In our generalized rank-breaking framework, we can only use those ordered relations that can be represented in an ordered partition. This is required for the estimator to be consistent. This is the cost we pay to reduce computational complexity from $O(|S_j|!)$, complexity of MLE of DAG (2), to $O(M!)$ for a suitably desired $M \in \mathbb{Z}^+$ as explained below. However, if the DAG $\mathcal{G}_j$ represents a full ranking or a traditional structure then its maximal ordered partition $\mathcal{P}_j$ will represent all the ordered relations present in $\mathcal{G}_j$ and our rank-breaking will reduce to MLE of the DAG $\mathcal{G}_j$. In such a case, all the subsets of $\mathcal{P}_j$ will have cardinality one except the least preferred set which can have more than one item in case of best-out-of κ comparison.

Rank-Breaking Graph. The extracted maximal ordered partition $\mathcal{P}_j$ is represented by a directed hypergraph $G_j(S_j, E_j)$, which we call a *rank-breaking graph*. Each edge $e = (B(e), T(e)) \in E_j$ is a directed hyper edge from a subset of nodes $B(e) \subseteq S_j$ to another subset $T(e) \subseteq S_j$. The number of edges in E_j is $|\mathcal{P}_j| - 1$. For each subset in $\mathcal{P}_j$ except for the least preferred subset, there is a corresponding edge whose *top-set* $T(e)$ is the subset, and the *bottom-set* $B(e)$ is the set of all items less preferred than $T(e)$. For the example in Figure 1, we have $E_j = \{e_1, e_2\}$ where $e_1 = (B(e_1), T(e_1)) = (\{i_6, i_5, i_4, i_3\}, \{i_2, i_1\})$ and $e_2 = (B(e_2), T(e_2) = (\{i_6\}, \{i_5, i_4, i_3\})$ extracted from $\mathcal{G}_j$. Algorithm 2 gives the precise method to construct a rank-breaking graph.

Algorithm 2 Constructing Rank-Breaking Graph

Require: maximal ordered partition $\mathcal{P}_j = \mathcal{C}_1 \prec \mathcal{C}_2 \prec \cdots \prec \mathcal{C}_{\ell_j}$ of set S_j
Ensure: directed hypergraph $G_j(S_j, E_j)$
1: construct directed hypergraph $G_j(S_j, E_j = \{\})$
2: **for** $a = 2$ to ℓ_j **do**
3: construct hyper edge e between top-set $T(e) = \mathcal{C}_a$ and bottom-set $B(e) = \cup_{a'=1}^{a-1} \mathcal{C}_{a'}$
4: $E_j \leftarrow E_j \cup e$
5: **end for**
6: Return $G_j(S_j, E_j)$

Denote the probability that $T(e)$ is preferred over $B(e)$ when $T(e) \cup B(e)$ is offered as

$$\mathbb{P}_\theta(e) \;=\; \mathbb{P}_\theta\big(B(e) \prec T(e)\big) \;=\; \sum_{\sigma \in \Lambda_{T(e)}} \frac{\exp\left(\sum_{c=1}^{|T(e)|} \theta_{\sigma(c)}\right)}{\prod_{u=1}^{|T(e)|} \left(\sum_{c'=u}^{|T(e)|} \exp\left(\theta_{\sigma(c')}\right) + \sum_{i \in B(e)} \exp\left(\theta_i\right)\right)} , \qquad (3)$$

which follows from the definition of the PL model, where $\Lambda_{T(e)}$ is the set of all rankings over $T(e)$. The computational complexity of evaluating this probability is determined by the size of the *top-set* $|T(e)|$, as it involves $(|T(e)|!)$ summations.

In the subsequent results, we show that by maximizing likelihood of the hyper edges assuming they are independent we get a consistent estimator. Therefore, our approach provides flexibility to choose which hyper edge to include in the likelihood maximization function. We let the analyst choose the order $M \in \mathbb{Z}^+$ depending on how much computational resource is available, and include only those edges with $|T(e)| \leq M$ in the likelihood objective function.

If in a given G_j there are no hyper edges with top sets of size less than M, then the analyst does not get any ordered relations from that rank-breaking graph under her computational constraint reflected in the particular choice of M. Artificially reducing the size of the top-sets so as to get the hyper edges with top sets of size less than M implies we need to add new ordered relations that are not present in the DAG provided by the user. Such an estimator could result in a non-zero bias. A concrete example of such cases has been studied in Azari Soufiani et al. 2013, where the authors showed that for $M = 1$, applying rank-breaking to those comparisons with top-set larger than one results in non-zero bias.

We emphasize that M is chosen by the analyst and our estimator works for any choice of $M \in \mathbb{Z}^+$. Given unlimited computational resources, an analyst would chose $M = d$, and all the hyper edges would be included in the likelihood objective function.

Sampling. We assume that for each $j \in [n]$, the topology of DAG $\mathcal{G}_j$ which represent the partial preference order provided by the j-th user is fixed apriori. Also, the set of hyper edges $e \in E_j$ of each rank breaking graph $G_j(S_j, E_j)$ that are included in the likelihood objective function are fixed apriori. The randomness that we observe is in the position of the S_j items in the DAG $\mathcal{G}_j$. For an hyper edge $e \in E_j$, the randomness is in which items of the set S_j appear in the bottom $|B(e)|$ positions and the bottom $|T(e)| + |B(e)|$ positions in the preference order of the user j. Note that this precisely captures the randomness due to the PL model in the observed DAG $\mathcal{G}_j$. We do not impose any restrictions on the topology of the DAG $\mathcal{G}_j$'s and each of them can be different. Further, our analysis captures effect of their topologies on the statistical efficiency of the estimation.

Pseudo-MLE of Rank-Breaking Graph. We apply the MLE for comparisons over paired subsets, assuming all hyper edges in the rank-breaking graph G_j are independently drawn. Precisely, for any choice of $M \in \mathbb{Z}^+$, we propose *order-M rank-breaking estimate*, which is the solution that maximizes the log-likelihood under the independence assumption:

$$\begin{aligned} \widehat{\theta} &\in \arg\max_{\theta \in \Omega_b} \mathcal{L}_{\mathrm{RB}}(\theta)\,, \text{ where} \\ \mathcal{L}_{\mathrm{RB}}(\theta) &= \sum_{j \in [n]} \sum_{e \in E_j : |T(e)| \leq M} \ln \mathbb{P}_\theta(e)\,. \end{aligned} \tag{4}$$

Due to independence assumption, we refer to it as pseudo-MLE. In a special case when $M = 1$, this can be transformed into the traditional pairwise rank-breaking, where (i) this is a concave maximization; (ii) the estimate is (asymptotically) unbiased and consistent as shown in Azari Soufiani et al. (2013, 2014); and (iii) the finite sample complexity have been analyzed in Khetan and Oh (2016). Although, this order-1 rank-breaking provides a significant gain in computational efficiency, the information contained in higher-order edges are unused, resulting in a significant loss in accuracy.

We provide the analyst the freedom to choose the computational complexity he/she is willing to tolerate. However, for general M, it has not been known if the optimization in (4) is tractable and/or if the solution is consistent. Since $\mathbb{P}_\theta(B(e) \prec T(e))$ as explicitly written in (3) is a sum of log-concave functions, it is not clear if the sum is also log-concave. Due to the ignored dependency in the formulation (4), it does not follow immediately that the resulting estimate is consistent.

We first establish that (4) is a concave maximization, Section 3.1. Though one can use any off-the-shelf convex maximization tool to compute $\widehat{\theta}$, we provide an efficient minorization-maximization (MM) algorithm for estimating $\widehat{\theta}$, Section 3.2. In Section 3.3, we show that the MM algorithm converges to the unique global optimal solution $\widehat{\theta}$ under the standard assumption given by Ford Jr. (1957) for pairwise comparisons. Under the same assumption, we show that the estimate $\widehat{\theta}$ is consistent, Section 3.4. In Section 3.5, we give the complete algorithm to compute $\widehat{\theta}$ using the proposed MM algorithm, given $\mathcal{G}_j$'s representing users' preferences. In Section 4 and Section 6, we provide a sharp analysis of the performance in the finite sample regime, characterizing the trade-off between computation and sample size, and verify the results from the numerical experiments.

3.1 Concavity of likelihood of rank-breaking graph

In the following, we show that likelihood of a hyper edge is log-concave for a family of Random Utility Models including the PL model.

Remark 1 *$\mathcal{L}_{\mathrm{RB}}(\theta)$ is concave in $\theta \in \mathbb{R}^d$.*

Proof Recall that $\mathbb{P}_\theta(B(e) \prec T(e))$ is the probability that an agent ranks the collection of items $T(e)$ above $B(e)$ when offered $S = B(e) \cup T(e)$. We want to show that $\mathbb{P}_\theta(B(e) \prec T(e))$ is log-concave under the PL model. We prove a slightly general result which works for a family of RUMs in the location family. RUM are defined as a probabilistic model where there is a real-valued utility parameter θ_i associated with each items $i \in S$, and an agent independently samples random utilities $\{U_i\}_{i \in S}$ for each item i with conditional distribution $\mu_i(\cdot|\theta_i)$. Then the ranking is obtained by sorting the items in decreasing order as per the observed random utilities U_i's. *Location family* is a subset of RUMs where the shapes of μ_i's are fixed and the only parameters are the means of the distributions. For location family, the noisy utilities can be written as $U_i = \theta_i + Z_i$ for i.i.d. random variable Z_i's. In particular, it is PL model when Z_i's follow the independent standard Gumbel distribution. We will show that for the location family if the probability density function for each Z_i's is log-concave then $\log \mathbb{P}_\theta(B(e) \prec T(e))$ is concave. The desired claim follows as the pdf of standard Gumbel distribution is log-concave. We use the following Theorem from Prékopa (1980). A similar technique was used to prove concavity when $|T(e)| = 1$ in Azari Soufiani et al. (2012).

Lemma 2 (Extension of Theorem 9 in Prékopa (1980)) *Suppose $g_1(\theta, Y), \cdots, g_r(\theta, Y)$ are concave functions in $\mathbb{R}^{2q}$, where $\theta, Y \in \mathbb{R}^q$, and Z is a $q-$component random vector whose probability distribution is logarithmic concave in $\mathbb{R}^q$, then the function*

$$h(\theta) = \mathbb{P}[g_1(\theta, Z) \geq 0, \cdots, g_r(\theta, Z) \geq 0], \qquad \text{for } \theta \in \mathbb{R}^q$$

is logarithmic concave on $\mathbb{R}^q$. Moreover, concavity is strict if the probability density function of Z is strictly logarithmic concave and $\theta \neq \tilde{\theta}$ implies $H(\theta) \neq H(\tilde{\theta})$. Where $H(\theta)$ is

$$H(\theta) \equiv \left\{ Y \;\middle|\; g_i(\theta, Y) \geq 0, \quad i = 1, \cdots, r \right\}.$$

Proof Theorem 9 in Prékopa (1980) proves concavity. The strict concavity follows from the fact that for a strictly logarithmic concave measure the following inequality is strict if $H(\theta) \neq H(\tilde{\theta})$.

$$\mathbb{P}[Z \in \lambda H(\theta) + (1-\lambda)H(\tilde{\theta})] \;\; \geq \;\; \mathbb{P}[Z \in \lambda H(\theta)]^{\lambda} \mathbb{P}[Z \in (1-\lambda)H(\tilde{\theta})]^{1-\lambda}\,,$$

where $\lambda \in (0,1)$. For a detailed proof, we refer the reader to the proof of Theorem 9 in Prékopa (1980). ■

To apply the above lemma to get concavity, let $q = |S|$, $r = 1$, $g_1(\theta, Y) = \min_{i \in T(e)}\{\theta_i + Y_i\} - \max_{i' \in B(e)}\{\theta_{i'} + Y_{i'}\}$. Observe that $g_1(\theta, Y)$ is concave in $\mathbb{R}^{2q}$, and $\mathbb{P}_\theta(B(e) \prec T(e)) = \mathbb{P}(g_1(\theta, Z) \geq 0)$. We use strict concavity part of the lemma in the subsequent section. ■

3.2 Minorization-maximization algorithm for pseudo-MLE of rank-breaking graph

We give a minorization-maximization algorithm for computing $\widehat{\theta}$ defined in (4). It is inspired from the MM algorithm given by Hunter (2004) for the case of pairwise comparisons and full-ranking. For any fixed parameter $\theta^{(t)} \in \mathbb{R}^d$, and a hyper edge e in a rank breaking graph G, define $Q(e, \theta; \theta^{(t)})$ as

$$Q(e,\theta;\theta^{(t)}) \;\; \equiv \;\; \sum_{\sigma \in \Lambda_{T(e)}} \left(\frac{\mathbb{P}_{\theta^{(t)}}(e,\sigma)}{\mathbb{P}_{\theta^{(t)}}(e)} \sum_{u=1}^{|T(e)|} \left(\theta_{\sigma(u)} - \frac{\sum_{c'=u}^{|T(e)|} \exp\left(\theta_{\sigma(c')}\right) + \sum_{i \in B(e)} \exp\left(\theta_i\right)}{\sum_{c'=u}^{|T(e)|} \exp\left(\theta^{(t)}_{\sigma(c')}\right) + \sum_{i \in B(e)} \exp\left(\theta^{(t)}_i\right)} \right) \right)\,,$$

where $\mathbb{P}_\theta(e, \sigma)$ is defined such that $\mathbb{P}_\theta(e) = \sum_{\sigma \in \Lambda_{T(e)}} \mathbb{P}_\theta(e, \sigma)$. Recall from Equation (3) that $\Lambda_{T(e)}$ is the set of all rankings over $T(e)$.

$$\mathbb{P}_\theta(e,\sigma) \;\; \equiv \;\; \frac{\exp\left(\sum_{c=1}^{|T(e)|} \theta_{\sigma(c)}\right)}{\prod_{u=1}^{|T(e)|} \left(\sum_{c'=u}^{|T(e)|} \exp\left(\theta_{\sigma(c')}\right) + \sum_{i \in B(e)} \exp\left(\theta_i\right) \right)}.$$

We show that $Q(e, \theta; \theta^{(t)})$ minorizes $\ln(\mathbb{P}_\theta(e))$ at $\theta^{(t)}$. It is equal to $\ln(\mathbb{P}_\theta(e))$, up to a constant, if and only if $\theta^{(t)} = \theta$.

Lemma 3

$$Q(e,\theta;\theta^{(t)}) + f(e,\theta^{(t)}) \;\; \leq \;\; \ln(\mathbb{P}_\theta(e)) \quad \textit{with equality if } \theta = \theta^{(t)}\,,$$

where $f(e, \theta^{(t)})$ is a function of the hyper edge e and the parameter $\theta^{(t)}$, it does not depend upon θ.

We give a proof of the Lemma in Section 7.1. It follows that for any $Q(e, \theta; \theta^{(t)})$ satisfying minorizing condition in the above lemma,

$$Q(e,\theta;\theta^{(t)}) \;\geq\; Q(e,\theta^{(t)};\theta^{(t)}) \quad \text{implies} \quad \ln(\mathbb{P}_\theta(e)) \;\geq\; \ln(\mathbb{P}_{\theta^{(t)}}(e))\,. \tag{5}$$

Property (5) suggests an iterative algorithm in which we let $\theta^{(t)}$ be the parameter vector before the t-th iteration and define $\theta^{(t+1)}$ to be the maximizer of the $Q(e, \theta; \theta^{(t)})$. Since this algorithm consists of alternately creating a minorizing function $Q(e, \theta; \theta^{(t)})$ and then maximizing it, it is called an MM

algorithm (Hunter and Lange, 2000). To compute $\widehat{\theta}$ in (4), starting from an arbitrary initialization $\theta^{(1)}$, we estimate $\theta^{(t+1)}$ by maximizing

$$\theta^{(t+1)} \;\; = \;\; \arg\max_{\theta \in \mathbb{R}^d} \left\{ \sum_{j=1}^{n} \sum_{e \in E_j : |T(e)| \leq M} Q(e,\theta;\theta^{(t)}) \right\}.$$

Since the parameters $\{\theta_i\}_{i \in [d]}$ are separated in $Q(e, \theta; \theta^{(t)})$, its maximization can be explicitly accomplished as, for $i \in [d]$

$$e^{\theta_i^{(t+1)}} = \frac{N_i}{\sum_{j=1}^{n} \sum_{e \in E_j : |T(e)| \leq M} \sum_{\sigma \in \Lambda_{T(e)}} \frac{\mathbb{P}_{\theta^{(t)}}(e,\sigma)}{\mathbb{P}_{\theta^{(t)}}(e)} \sum_{u=1}^{|T(e)|} \delta_{i,e,\sigma,u} \left(\sum_{c'=u}^{|T(e)|} \exp\left(\theta^{(t)}_{\sigma(c')}\right) + \sum_{i \in B(e)} \exp\left(\theta^{(t)}_i\right) \right)^{-1}}\,, \tag{6}$$

where N_i is the total number of hyper edges in which the i-th item is in the top set.

$$N_i \;\; = \;\; \sum_{j=1}^{n} \sum_{e \in E_j : |T(e)| \leq M} \mathbb{I}[i \in T(e)]\,.$$

$\delta_{i,e,\sigma,u}$ is the indicator variable defined as

$$\delta_{i,e,\sigma,u} = \begin{cases} 1\,, & \text{if } i \in \{T(e) \cup B(e)\} \text{ and } \sigma^{-1}(i) \geq u\,, \\ 0\,, & \text{otherwise.} \end{cases}$$

3.3 Convergence properties of the MM algorithm

In the following we show that $\lim_{t \to \infty} \theta^{(t)}$, (6), converges to the global optimal solution of the pseudo-likelihood objective given in (4) under standard assumption on the observed comparisons.

For pairwise comparisons, Ford Jr. (1957) noted that if it is possible to partition the set of items into two subsets A and B such that there are never any inter-set comparisons, then there is no basis for rating any item in set A with respect to any item in set B. On the other hand, if in all the inter-set comparisons, items from set A are preferred over the items in set B, then if all the parameters θ_i belonging to set A are doubled and the resulting vector θ renormalized, the likelihood must increase; thus the likelihood has no maximizer. The following assumption (Ford Jr., 1957) eliminates these possibilities.

Assumption 4 *In every possible partition of the items into two nonempty subsets, some item in the second set is preferred over some item in the first set at least once.*

Assumption 4 has a graph-theoretic interpretation. Suppose, items are denoted by nodes of a graph G and a directed edge (i, j) represents that the there is at least one user who prefers item i over item j. Then the Assumption 4 is equivalent to the statement that there is a path from i to j for all nodes i and j of the graph G. This assumption implies that there exists a unique maximizer of the log-likelihood function of pairwise comparisons.

In our setting, Assumption 4 makes sense if we interpret item i being preferred over item j to mean that there exists a hyper edge e such that the item i is in its top set $T(e)$ and the item j is in its bottom set $B(e)$. In the following theorem, we prove the convergence properties of the MM algorithm.

Theorem 5 *Under Assumption 4 the iterative minorization-maximization algorithm given in Equation* (6) *produces a sequence* $\theta^{(1)}, \theta^{(2)}, \cdots$ *guaranteed to converge to the unique estimate of the optimization problem given in Equation* (4).

Proof In general, it is always not possible to prove that the sequence of parameters $\theta^{(t)}$ defined by an MM algorithm converges at all. Nonetheless, it is often possible to obtain convergence results in specific cases. For pairwise comparisons, using property of stationary point, Ford Jr. (1957) showed that the MM algorithm converges to the unique maximum likelihood estimate under Assumption 4. Hunter (2004) established strict concavity of the likelihood function under Assumption 4 and proved the same result using the Liapounov's theorem. We follow the approach used by Hunter (2004). The following Liapounov's theorem guarantees that the MM algorithm converges to the stationary point of the pseudo log-likelihood objective (4). In Lemma 7, we show that the likelihood function (4) has a unique stationary point, namely the global maximizer. Which concludes that the MM algorithm converges to the unique global optimal solution irrespective of its starting point.

Lemma 6 (Liapounov's theorem) *Suppose* $M : \Omega \to \Omega$ *is continuous and* $\mathcal{L}_{\mathrm{RB}} : \Omega \to \mathbb{R}$ *is differentiable and for all* $\theta \in \Omega$ *we have* $\mathcal{L}_{\mathrm{RB}}(M(\theta)) \geq \mathcal{L}_{\mathrm{RB}}(\theta)$*, with equality only if* θ *is a stationary point of* $\mathcal{L}_{\mathrm{RB}}(\cdot)$*. Then, for arbitrary* $\theta^{(1)} \in \Omega$*, any limit point of the sequence* $\{\theta^{(t+1)} = M(\theta^{(t)})\}_{t\geq 1}$ *is a stationary point of* $\mathcal{L}_{\mathrm{RB}}(\theta)$.

Let $\Omega = \{\theta \in \mathbb{R}^d | \sum_{i\in[d]} \theta_i = 0\}$ be the parameter space Ω_b defined in (1) with $b = \infty$. Taking M to be the map implicitly defined by one iteration of the MM algorithm, we have $\mathcal{L}_{\mathrm{RB}}(M(\theta)) \geq \mathcal{L}_{\mathrm{RB}}(\theta)$ from (5). $\mathcal{L}_{\mathrm{RB}}(M(\theta)) = \mathcal{L}_{\mathrm{RB}}(\theta)$ implies that θ is a stationary point which follows from the fact that the differentiable minorizing function Q is a tangent to the log-likelihood $\mathcal{L}_{\mathrm{RB}}(\theta)$ at the current iterate $\theta^{(t)}$. Therefore, $\lim_{t\to\infty} \theta^{(t)}$, defined by the MM algorithm in (6) converges to the stationary point of the pseudo-likelihood objective (4). It remains to prove that $\mathcal{L}_{\mathrm{RB}}(\theta)$ has a unique stationary point, the global maximizer.

Lemma 7 *Under Assumption 4* $\mathcal{L}_{\mathrm{RB}}(\theta)$ *has a unique stationary point.*

Proof First, in Lemma 8, we show that $\mathcal{L}_{\mathrm{RB}}(\theta)$ is an upper compact function under the Assumption 4. $\mathcal{L}_{\mathrm{RB}}(\theta)$ is defined to be upper compact if, for any constant c, the set $\{\theta \in \Omega : \mathcal{L}_{\mathrm{RB}}(\theta) \geq c\}$ is a compact set of the parameter space Ω. Second, in Lemma 9, we show that $\mathcal{L}_{\mathrm{RB}}(\theta)$ is strictly concave. Since upper compactness implies the existence of at least one limit point and strict concavity implies the existence of at most one stationary point, we conclude that $\mathcal{L}_{\mathrm{RB}}(\theta)$ has a unique stationary point. ■

■

Lemma 8 $\mathcal{L}_{\mathrm{RB}}(\theta)$ *defined in Equation* (4) *is an upper compact function of* θ *under the Assumption 4.*

Proof We prove upper compactness following the idea of Hunter (2004). Consider what happens to $\mathcal{L}_{\mathrm{RB}}(\theta)$ when θ approaches the boundary of Ω. If $\tilde{\theta}$ lies on the boundary of Ω, then $\tilde{\theta}_i \to -\infty$ and $\tilde{\theta}_j \to \infty$ for some items i and j. If items are nodes of a directed graph in which edge (i, i') represent that there is at least one user who prefers i over i', then Assumption 4 implies that a directed path exists from i to j. Therefore, there must be some item a with $\tilde{\theta}_a \to -\infty$ which is preferred over item b with $\tilde{\theta}_b > C$, for some constant C. That is there exists an hyper edge e with $a \in T(e)$ and $b \in B(e)$. Which means that for $\theta \in \Omega$, taking limits in

$$\begin{aligned}\mathcal{L}_{\mathrm{RB}}(\theta) &\leq \ln \mathbb{P}_\theta(e) \\ &= \ln\left(\sum_{\sigma\in\Lambda_{T(e)}} \frac{\exp\left(\sum_{c=1}^{|T(e)|}\theta_{\sigma(c)}\right)}{\prod_{u=1}^{|T(e)|}\left(\sum_{c'=u}^{|T(e)|}\exp\left(\theta_{\sigma(c')}\right)+\sum_{i\in B(e)}\exp\left(\theta_i\right)\right)}\right)\end{aligned}$$

gives $\lim_{\theta\to\tilde{\theta}} \mathcal{L}_{\mathrm{RB}}(\theta) = -\infty$. Thus, for any given constant c, the set $\{\theta \in \Omega : \mathcal{L}_{\mathrm{RB}}(\theta) \geq c\}$ is a closed and bounded set, and hence a compact set. ■

Lemma 9 $\mathcal{L}_{\mathrm{RB}}(\theta)$ *defined in Equation* (4) *is strictly concave in* θ.

Proof To prove strict concavity, we use Lemma 2. Define $\widetilde{\Omega} = \{\theta \in \mathbb{R}^d | \theta_1 = 0\}$, a reparameterization of the set $\Omega = \{\theta \in \mathbb{R}^d | \sum_{i\in[d]} \theta_i = 0\}$. To apply Lemma 2 to prove strict concavity of log-likelihood of an hyper edge e, take $g_{ij}(\theta, Y) = (\theta_i + Y_i) - (\theta_j + Y_j)$, for all $i \in T(e)$ and $j \in B(e)$. Consider $\theta, \tilde{\theta} \in \widetilde{\Omega}$. $H(\theta) = H(\tilde{\theta})$ implies that $\theta_i - \theta_j = \tilde{\theta}_i - \tilde{\theta}_j$, for all $i \in T(e)$ and $j \in B(e)$. This follows from the fact that for a fixed parameter θ, the hyper planes $\{g_{ij}(\theta, Y) \geq 0\}_{ij}$ are linearly independent. Thus, Assumption 4 combined with the fact that $\theta_1 = \tilde{\theta}_1$ means that $\theta = \tilde{\theta}$. Since the Gumbel distribution has strictly logarithmic concave density function, we conclude that $\mathcal{L}_{\mathrm{RB}}(\theta)$ is strictly concave. ■

3.4 Consistency of pseudo-MLE of rank-breaking graph

In order to discuss consistency of the proposed approach, we need to specify how we sample the set of items to be offered S_j and also which partial ordering over S_j is to be observed. Here, we consider a simple but canonical scenario for sampling ordered relations, and show the proposed method is consistent for all non-degenerate cases. Later, in Section 4, we study a more general sampling scenario, when we analyze the order-M estimator in the finite sample regime.

We define a canonical sampling scenario in the following. There is a set of ℓ integers $(m_1, \ldots, m_\ell)$ whose sum is strictly less than d. A new arriving user is presented with all d items and is asked to provide her top m_1 items as an unordered set, and then the next m_2 items, and so on. This is sampling from the PL model and observing an ordered partition with $(\ell + 1)$ subsets of sizes m_a's, and the last subset includes all remaining items. We apply the generalized rank-breaking to get rank-breaking graphs $\{G_j\}$ with ℓ edges each, and order-M estimate is computed. We show that this is consistent, i.e. asymptotically unbiased in the limit of the number of users n.

Remark 10 *Under the* PL *model and the above sampling scenario, the order-*M *rank-breaking estimate* $\widehat{\theta}$ *in* (4) *is consistent for all choices of* $M \geq \min_{a\in\ell} m_a$.

Proof It is sufficient to show that (a) the estimate $\widehat{\theta}$, (4) is unique under the above sampling scenario, and (b) expectation of the gradient of $\mathcal{L}_{\mathrm{RB}}(\theta^*)$ is zero, i.e, $\mathbb{E}_{\theta^*}[\nabla \mathcal{L}_{\mathrm{RB}}(\theta^*)] = 0$, (Azari Soufiani et al., 2013). For the above sampling scenario in the limit of the number of users n, Assumption 4 is satisfied. Therefore, from Lemma 7, the estimate $\widehat{\theta}$, (4) is unique. In Lemma 13, we show that $\mathbb{E}_{\theta^*}[\nabla \mathcal{L}_{\mathrm{RB}}(\theta^*)] = 0$. We would like to mention that the Lemma 13 crucially relies on the memoryless property of the PL model.

■

3.5 Algorithm to estimate $\widehat{\theta}$ given DAG $\mathcal{G}_j$'s

Summarizing the rank-breaking approach explained in the previous sections, we give Algorithm 3, an algorithm to compute $\widehat{\theta}$, (4), an estimate of θ^*. Algorithm 3 takes as input DAG $\mathcal{G}_j$'s generated under PL model with parameter θ^*, rank-breaking order $M \in \mathbb{Z}^+$, a desired error threshold ϵ, and returns $\widehat{\theta}$.

Algorithm 3 Estimate θ^* given DAG $\mathcal{G}_j$'s.

Require: DAG $\{\mathcal{G}_j\}_{1\le j\le n}$ generated under PL model with parameter θ^*, rank-breaking order M, error threshold ϵ
Ensure: $\widehat{\theta}$ - an estimate of θ^*
find maximal ordered partitions $\{\mathcal{P}_j\}_{1\le j\le n}$ consistent with $\{\mathcal{G}_j\}_{1\le j\le n}$ [Algorithm 1]
construct rank breaking graph $\{G_j(S_j, E_j)\}_{1\le j\le n}$ from $\{\mathcal{P}_j\}_{1\le j\le n}$ [Algorithm 2]

return $\widehat{\theta}$

4. Analysis of the Algorithm

We first summarize the notations defined so far and introduce some new notations that are used in our theoretical results. We define a *comparison graph* that captures the topology of the offer sets S_j. Our upper and lower bounds both depend on the spectral properties of the comparison graph. Then, we present main theoretical analyses and numerical simulations confirming the theoretical results.

Notations. Following is a summary of all the notations defined above. Also, we introduce some new notations that are used in our theoretical results. We use n to denote the number of users providing partial rankings, indexed by $j \in [n]$ where $[n] = \{1, 2, \ldots, n\}$. We use d to denote the number of items, indexed by $i \in [d]$. Given rank-breaking graphs $\{G_j(S_j, E_j)\}_{j\in[n]}$ extracted from the DAGs $\{\mathcal{G}_j\}$, we first define the order M rank-breaking graphs $\{G_j^{(M)}(S_j, E_j^{(M)})\}$, where $E_j^{(M)}$ is a subset of E_j that includes only those edges $e_j \in E_j$ with $|T(e_j)| \le M$. This represents those edges that are included in the estimation for a choice of M. For finite sample analysis, the following quantities capture how the error depends on the topology of the data collected. Let $\kappa_j \equiv |S_j|$ and $\ell_j \equiv |E_j^{(M)}|$. We index each edge e_j in $E_j^{(M)}$ by $a \in [\ell_j]$ and define $m_{j,a} \equiv |T(e_{j,a})|$, size of top-set, for the a-th hyper edge of the j-th rank-breaking graph, and $r_{j,a} \equiv |T(e_{j,a})| + |B(e_{j,a})|$, sum of size of the top-set and the bottom-set. We let $p_j \equiv \sum_{a\in[\ell_j]} m_{j,a}$ denote the effective sample size for the observation $G_j^{(M)}$.

$$m_{j,a} \equiv |T(e_{j,a})|\,, \quad \text{size of top-set for the } e_{j,a} \text{ hyper edge of rank-breaking graph } G_j^{(M)}. \tag{7}$$

$$r_{j,a} \equiv |T(e_{j,a})| + |B(e_{j,a})|\,, \quad \text{sum of size of the top-set and the bottom-set for the } E_{j,a}. \tag{8}$$

$$p_j \equiv \sum_{a\in[\ell_j]} m_{j,a}\,, \quad \text{sum of size of all top-sets of } G_j^{(M)} \text{ (which are smaller than } M). \tag{9}$$

Notice that although we do not explicitly write the dependence on M, all of the above quantities implicitly depend on the choice of M. For ease of notations, we remove the superscript M from $G_j^{(M)}$ in the following.

For a ranking σ over S, i.e., σ is a mapping from $[|S|]$ to S, let σ^{-1} denote the inverse mapping. For a vector x, let $\|x\|_2$ denote the standard l_2 norm. Let $\mathbf{1}$ denote the all-ones vector and $\mathbf{0}$ denote the all-zeros vector with the appropriate dimension. Let $\mathcal{S}^d$ denote the set of $d \times d$ symmetric matrices with real-valued entries. For $X \in \mathcal{S}^d$, let $\lambda_1(X) \le \lambda_2(X) \le \cdots \le \lambda_d(X)$ denote eigenvalues of X sorted in increasing order. Let $\mathrm{Tr}(X) = \sum_{i=1}^d \lambda_i(X)$ denote trace of X and $\|X\| = \max\{|\lambda_1(X)|, |\lambda_d(X)|\}$ denote spectral norm of X. For two matrices $X, Y \in \mathcal{S}^d$, we write $X \succeq Y$ if $X - Y$ is positive semi-definite, i.e., $\lambda_1(X - Y) \ge 0$. Let e_i denote a unit vector in $\mathbb{R}^d$ along the i-th direction.

4.1 Comparison graph

We define a comparison graph $\mathcal{H}([d], E)$ as a weighted undirected graph with weights

$$A_{ii'} = \sum_{j\in[n]: i,i'\in S_j} \frac{p_j}{\kappa_j(\kappa_j - 1)}.$$

That is we put an edge (i, i') if there exists a user j whose offerings is a set S_j such that $i, i' \in S_j$. Define a diagonal matrix $D = \mathrm{diag}(A\mathbf{1})$, and the corresponding graph Laplacian $L = D - A$ such that

$$L \equiv \sum_{j=1}^n \frac{p_j}{\kappa_j(\kappa_j - 1)} \sum_{i<i'\in S_j} (e_i - e_{i'})(e_i - e_{i'})^\top. \tag{10}$$

It is immediate that $\lambda_1(L) = 0$ with $\mathbf{1}$ as the eigenvector. There are remaining $d-1$ eigenvalues that sum to $\mathrm{Tr}(L) = \sum_j p_j$. The rescaled $\lambda_2(L)$ and $\lambda_d(L)$ capture the dependency on the topology:

$$\alpha \equiv \frac{\lambda_2(L)(d-1)}{\mathrm{Tr}(L)} \quad , \quad \beta \equiv \frac{\mathrm{Tr}(L)}{\lambda_d(L)(d-1)}. \tag{11}$$

In an ideal case where the graph is well connected, then the spectral gap of the Laplacian is large. The chosen rescaling ensures that if all the non-zero eigenvalues are of the same order then there

exists constants $0 \le c_1, c_2 \le 1$ such that $c_1 \le \alpha \le 1$ and $c_2 < \beta \le 1$. If the graph is connected then c_1 is strictly greater than zero. If $\lambda_2(L) = \cdots = \lambda_d(L)$ then $\alpha = \beta = 1$. We will show that the performance of our estimator depends upon topology of the comparison graph through these two parameters. The larger the rescaled spectral gap α the smaller the error we get with the same effective sample size. The rescaled largest eigenvalue β along with α determine how many samples are required for the analysis to hold. In general, α and β depend upon both the topology of the offer sets S_j and the topology of the rank-breaking graphs G_j, through the edge weights $A_{ii'}$. However, if topology of all the rank-breaking graphs G_j's is same then the comparison graph $\mathcal{H}$ and α, β depend only upon the topology of the offer sets S_j. For such a comparison graph, Khetan and Oh (2016) provides a detailed discussion on the spectral gap for various canonical graphs following the setup given in Shah et al. (2015a).

The concavity of $\mathcal{L}_{\mathrm{RB}}(\theta)$ also depends on the following quantities.

$$\gamma_1 \equiv \min_{j,a} \left\{ \left(\frac{r_{j,a} - m_{j,a}}{\kappa_j} \right)^{2e^{2b}-2} \right\}, \quad \gamma_2 \equiv \min_{j,a} \left\{ \left(\frac{r_{j,a} - m_{j,a}}{r_{j,a}} \right)^{2} \right\}. \tag{12}$$

The parameter γ_1 incorporates asymmetry in probabilities of items being ranked at different positions depending upon their weight θ^*_i. Recall that b is the upper bound on $\|\theta^*\|_\infty$, Equation 1. The parameter γ_1 is 1 for $b = 0$ that is when all the items have the same weight θ^*_i, and it decreases exponentially with increase in b. The exponential decrease is tight and reflects the fact that under PL model probability of the highest weight item being ranked last is exponentially smaller than its probability of being ranked first.

Suppose the number of items d grows to infinity and the rank-breaking graphs G_j's are determined such that size of the offered subsets κ_j's are increasing with d that is $\kappa_j = \Theta(d)$. If all the top-set sizes are much smaller than the size of the rank-breaking edge such that, $m_{j,a} = o(r_{j,a})$ and $r_{j,a} = \Theta(\kappa_j)$, then for $b = O(1)$, γ_1 can be made arbitrarily close to one, for large enough problem size d. On the other hand, when either $r_{j,a}$ is much smaller than κ_j or if $r_{j,a} = \Theta(\kappa_j)$ but $r_{j,a} - m_{j,a} = O(1)$ then γ_1 can be arbitrarily close to zero and accuracy of the parameter estimation can degrade significantly as stronger alternatives will have small chance of showing up in the bottom set. The value of γ_1 is quite sensitive to b. The parameter γ_2 controls the range of the size of the top-set with respect to the size of the bottom-set for which the error decays with the rate of 1/(size of the top-set). It does not depend upon the size of of the rank-breaking edge, $r_{j,a}$, in comparison to the offer set size κ_j. It only depends upon the size of the top sets $m_{j,a}$ in comparison to the size of the rank breaking edge $r_{j,a}$. If size of top sets $m_{j,a} = o(r_j, a)$ then γ_2 would be close to one. The dependence of accuracy on γ_1, γ_2 is demonstrated in simulations in Figure 5.

We define the following additional quantities that control our upper bound. The dependence in γ_3 and ν are due to weakness in the analysis, and ensures that the Hessian matrix is strictly negative definite.

$$\gamma_3 \equiv 1 - \max_{j,a} \left\{ \frac{4e^{16b}}{\gamma_1} \frac{m^2_{j,a} r^2_{j,a} \kappa^2_j}{(r_{j,a} - m_{j,a})^5} \right\}, \quad \nu \equiv \max_{j,a} \left\{ \frac{m_{j,a} \kappa^2_j}{(r_{j,a} - m_{j,a})^2} \right\}. \tag{13}$$

For our analysis to hold we need $\gamma_3 > 0$ which in addition to the conditions needed for γ_1 being close to one require that $m_{j,a} \le c\sqrt{r_{j,a}}$, for a sufficiently small positive constant c. We believe this is a limitation on our analysis and the results should hold for any values of $m_{j,a} = o(r_{j,a})$. For

the special case when $m_{j,a} \le 3$ for all j, a, we provide a tighter result that does not depend upon γ_3. However, in general getting rid of γ_3 is challenging. ν shows up in the number of samples required for our analysis to hold. Note that the quantities defined in this section implicitly depend on the choice of M, which controls the necessary computational power, via the definition of the rank-breaking graphs $\{G_j^{(M)}\}_{j \in [n]}$.

4.2 Upper bound on the achievable error

We provide an upper bound on the error for the order-M rank-breaking Algorithm 3, showing the explicit dependence on the topology of the offered sets $\{S_j\}_{j \in [n]}$. Recall from the sampling assumptions in Section 3 that we assume the topology of the observed DAG $\mathcal{G}_j$'s, and the rank-breaking order M is fixed apriori. The randomness that we observe is in the position of S_j items in the DAG $\mathcal{G}_j$. For an hyper edge $e \in E_j$, the randomness is in which items of the set S_j appear in the bottom $|B(e)|$ positions and the bottom $|T(e)| + |B(e)|$ positions in the preference order of the user j. This precisely captures the randomness due to the PL model in the observed DAG $\mathcal{G}_j$. The following theorem provides an upper bound on the achieved error, and a proof is provided in Section 7.

Theorem 11 *Suppose there are n users, d items parametrized by $\theta^* \in \Omega_b$, and each user $j \in [n]$ is presented with a set of offerings $S_j \subseteq [d]$ and the user provides a partial ordering under the PL model consistent with the topology of the apriori fixed DAG $\mathcal{G}_j$. For a choice of $M \in \mathbb{Z}^+$, if $\gamma_3 > 0$ and the effective sample size $\sum_{j=1}^n p_j$ is large enough such that*

$$\sum_{j=1}^{n} p_j \ge \frac{2^{14} e^{20b} \nu^2}{(\alpha \gamma_1 \gamma_2 \gamma_3)^2 \beta} \frac{p_{\max}}{\kappa_{\min}} d \log d \,, \tag{14}$$

where $b \equiv \max_i |\theta^*_i|$ is the dynamic range, $p_{\max} = \max_{j \in [n]} p_j$, $\kappa_{\min} = \min_{j \in [n]} \kappa_j$, α is the (rescaled) spectral gap, β is the (rescaled) spectral radius in (11)*, and γ_1, γ_2, γ_3, and ν are defined in* (12) *and* (13)*, then the generalized rank-breaking estimator in* (4) *achieves*

$$\frac{1}{\sqrt{d}} \|\widehat{\theta} - \theta^*\|_2 \le \frac{40 e^{7b}}{\alpha \gamma_1 \gamma_2^{3/2} \gamma_3} \sqrt{\frac{d \log d}{\sum_{j=1}^n p_j}} \,, \tag{15}$$

with probability at least $1 - 3e^3 d^{-3}$. Moreover, for $M \le 3$ the above bound holds with γ_3 replaced by one, giving a tighter result.

Note that the dependence on the choice of M is not explicit in the bound, but rather is implicit in the construction of the comparison graph and the number of effective samples.

Suppose the number of items d is large enough and the size of the offered subsets κ_j's and the size of the rank breaking edges $r_{j,a}$'s are increasing with d, that is there exists positive constants c_1, c_2 such that $\kappa_j \ge c_1 d$, and $r_{j,a} \ge c_2 \kappa_j$. Then for $b = O(1)$ there exists a universal constant c_3 such that if top-set sizes $m_{j,a} \le c_3 (r_{j,a})^{1/3}$ then there exists constants $0 < c_4, c_5, c_6 \le 1$ such that $c_4 \le \gamma_1 < 1$, $c_5 \le \gamma_2 < 1$ and $c_6 \le \gamma_3 < 1$. Further, if the comparison graph $\mathcal{H}$ is well connected then there exists a constant $0 < c_7, c_8 \le 1$ such that the rescaled spectral gap $c_7 \le \alpha \le 1$ and rescaled largest eigenvalue $c_8 \le \beta \le 1$. In this ideal case, the condition on the effective sample size is met with $\sum_j p_j = O(d \log d)$, (14). Therefore the effective sample size $\sum_{j=1}^n p_j = \Omega(d \log d)$ is sufficient to

ensure $\|\widehat{\theta}-\theta^*\|_2 = o(\sqrt{d})$ which is only a logarithmic factor larger than the number of parameters. We need $m_{j,a} \le c_3(r_{j,a})^{1/3}$ to satisfy $(\nu^2 p_{\max})/\kappa_{\min} = O(1)$, otherwise $m_{j,a} \le c_3(r_{j,a})^{1/2}$ is sufficient to ensure $\gamma_3 > 0$. We believe that dependence in γ_3 is weakness of our analysis and there is no dependence as long as $m_{j,a} < r_{j,a}$. For, rank-breaking order $M \le 3$, we are able to give tighter results where there is no dependence on γ_3.

As explained above, in the ideal case, for large enough problem size d, there exists a positive constant C such that $\|\widehat{\theta}-\theta^*\|_2^2 \le Cd^2 \log d/(\sum_{j=1}^n p_j)$. Recall from the construction of the likelihood objective function, $\mathcal{L}_{\mathrm{RB}}(\theta) = \sum_{j\in[n]} \sum_{e\in E_j:|T(e)|\le M} \ln \mathbb{P}_\theta(e)$. If we fix all the problem parameters including topology of the DAG $\mathcal{G}_j$'s and increase M then $p_j = \sum_{a\in[\ell_j]} m_{j,a}$ increases. Therefore, by increasing M we can get the same number of effective samples $\sum_{j=1}^n p_j$ with smaller number of rankings n. However, increasing M increases computational complexity as $M!$. Therefore, to achieve a fixed target accuracy $\|\widehat{\theta}-\theta^*\|_2$, an analyst can trade-off the required number of rankings with the budgeted computational complexity.

If the DAG $\mathcal{G}_j$'s are complete graph that is each user provides a full ranking over the offered subset S_j, we get $m_{j,a} = 1$, $\ell_j = \kappa_j - 1$, and the total effective sample size $\sum_j p_j = \sum_{j\in[n]}(\kappa_j - 1)$. Therefore, from the above theorem, $\sum_{j\in[n]}(\kappa_j - 1) = \Omega(d \log d)$ is sufficient to ensure $\|\widehat{\theta}-\theta^*\|_2 = o(\sqrt{d})$. It matches with the results for full rankings given in Hajek et al. (2014); Khetan and Oh (2016).

Unordered vs. ordered top-m ranking. In the ideal case, a perhaps surprising observation is that, for a ranking j, sizes of the top-sets $\{m_{j,a}\}_{a\in[\ell_j]}$ impacts estimation accuracy only via $p_j = \sum_{a\in[\ell_j]} m_{j,a}$, when $m_{j,a}$'s are sufficiently small in comparison to $r_{j,a}$'s, sum of the top-set size and the bottom-set size. In particular, for estimation accuracy it does not matter whether users reveal their top-m choices in the ordered way $\{i_1\} \succ \{i_2\} \succ \cdots \succ \{i_m\} \succ \{i_{m+1}, \cdots, i_k\}$ or the unorderd way $\{i_1, i_2, \cdots, i_m\} \succ \{i_{m+1}, \cdots i_k\}$, when m is sufficiently small in comparison to k. Numerical results in Figure 5 confirm this.

Proof idea. The analysis of the optimization in (4) shows that, with high probability, $\mathcal{L}_{\mathrm{RB}}(\theta)$ is strictly concave with $\lambda_2(H(\theta)) \le -C_b\gamma_1\gamma_2\gamma_3\lambda_2(L) < 0$ for all $\theta \in \Omega_b$ (Lemma 15), and the gradient is also bounded with $\|\nabla\mathcal{L}_{\mathrm{RB}}(\theta^*)\| \le C_b'\gamma_2^{-1/2}(\sum_j p_j \log d)^{1/2}$ (Lemma 14). This leads to Theorem 11:

$$\|\widehat{\theta}-\theta^*\|_2 \;\le\; \frac{2\|\nabla\mathcal{L}_{\mathrm{RB}}(\theta^*)\|}{-\lambda_2(H(\theta))} \;\le\; C_b'' \frac{\sqrt{\sum_j p_j \log d}}{\gamma_1\gamma_2^{3/2}\gamma_3\lambda_2(L)}\,,$$

where C_b, C_b', and C_b'' are constants that only depend on b, and $\lambda_2(H(\theta))$ is the second largest eigenvalue of a negative semidefinite Hessian matrix $H(\theta)$ of $\mathcal{L}_{\mathrm{RB}}(\theta)$. Recall that $\theta^\top \mathbf{1} = 0$ since we restrict our search in Ω_b. Hence, the error depends on $\lambda_2(H(\theta))$ instead of $\lambda_1(H(\theta))$ whose corresponding eigenvector is the all-ones vector.

4.3 Lower bound on computationally unbounded estimators

Suppose $M = d$. We prove a fundamental lower bound on the achievable error rate that holds for any *unbiased* estimator with no restrictions on the computational complexity. For each (j,a),

define $\eta_{j,a}$ as

$$\eta_{j,a} \;\equiv\; \sum_{u=0}^{m_{j,a}-1} \Big(\frac{1}{r_{j,a}-u} + \frac{u(m_{j,a}-u)}{m_{j,a}(r_{j,a}-u)^2}\Big) + \sum_{u<u'\in[m_{j,a}-1]} \frac{2u}{m_{j,a}(r_{j,a}-u)} \frac{m_{j,a}-u'}{r_{j,a}-u'} \tag{16}$$

$$< \sum_{u=0}^{m_{j,a}-1} \Big(\frac{1}{m_{j,a}-u} + \frac{u}{m_{j,a}(m_{j,a}-u)}\Big) + \sum_{u<u'\in[m_{j,a}-1]} \frac{2u}{m_{j,a}(m_{j,a}-u)} \tag{17}$$

$$= \sum_{u=0}^{m_{j,a}-1} \Big(\frac{1}{m_{j,a}-u} + \frac{u}{m_{j,a}(m_{j,a}-u)} + \frac{2u(m_{j,a}-1-u)}{m_{j,a}(m_{j,a}-u)}\Big) = m_{j,a}\,,$$

where (17) follows from the fact that (16) is monotonically strictly decreasing in $r_{j,a}$ for $r_{j,a} \ge m_{j,a}$. Since by definition $r_{j,a} > m_{j,a}$, we substitute $r_{j,a} = m_{j,a}$ to get a strict upper bound.

Theorem 12 *Let $\mathcal{U}$ denote the set of all unbiased estimators of θ^* that are centered such that $\widehat{\theta}\mathbf{1} = 0$, and let $\mu = \max_{j\in[n],a\in[\ell_j]}\{m_{j,a} - \eta_{j,a}\}$. For all $b > 0$,*

$$\inf_{\widehat{\theta}\in\mathcal{U}} \sup_{\theta^*\in\Omega_b} \mathbb{E}[\|\widehat{\theta}-\theta^*\|^2] \;\ge\; \max\left\{ \frac{(d-1)^2}{\sum_{j=1}^n \sum_{a=1}^{\ell_j}(m_{j,a}-\eta_{j,a})}\,,\; \frac{1}{\mu}\sum_{i=2}^{d}\frac{1}{\lambda_i(L)} \right\}. \tag{18}$$

The proof relies on the Cramer-Rao bound and is provided in Section 7.6. Since $0 < \eta_{j,a} < m_{j,a}$, the mean squared error is lower bounded by $(d-1)^2/(\sum_{j=1}^n \sum_{a=1}^{\ell_j} m_{j,a}) = (d-1)^2/(\sum_{j=1}^n p_j)$, where $\sum_{j=1}^n p_j$ is the effective sample size. Comparing it to the upper bound in (15), this is tight up to a logarithmic factor when (a) the topology of the data is well-behaved such that all the quantities $\gamma_1, \gamma_2, \gamma_3, \alpha, \beta$ are greater than a positive constant $c \le 1$; and (b) there is no limit on the computational power and M can be made as large as we need. For full-rankings, this bound reduces to the one given in Hajek et al. (2014); Khetan and Oh (2016). For full rankings, $\sum_{a=1}^{\ell_j}(m_{j,a} - \eta_{j,a}) = (\kappa_j - 1)^2/\kappa_j$.

The bound in Eq. (18) further gives a tighter lower bound, capturing the dependency in $\eta_{j,a}$'s and $\lambda_i(L)$'s. The second term in (18) implies we get a tighter bound when $\lambda_2(L)$ is smaller. If the comparison graph $\mathcal{H}$ is disconnected that is $\lambda_2(L) = 0$, the bound shows that θ^* can not be estimated.

To understand the impact of $\eta_{j,a}$ on MSE, we plot $(m_{j,a} - \eta_{j,a})/r_{j,a}$ as a function of $m_{j,a}/r_{j,a}$ for different values of $r_{j,a}$ in Figure 3. Recall that $m_{j,a}$ is the size of the top-set, (7) and $r_{j,a}$ is the sum of size of the top-set and the bottom-set, (8). We vary $m_{j,a}$ from 1 to $r_{j,a} - 1$, for $r_{j,a}$ in $\{2, 4, 8, 16, 32, 256, 1024\}$. From the Theorem 12, contribution of an hyper edge $e_{j,a}$ to the effective samples is $(m_{j,a} - \eta_{j,a})$. Since $\eta_{j,a}$ increases with $m_{j,a}$, a natural question is what is the optimal value of $m_{j,a}$ that gives the smallest MSE, for a fixed $r_{j,a}$. Figure 3 shows that $(m_{j,a} - \eta_{j,a})/r_{j,a}$ achieves its maximum value at $m/r \approx 0.8$ when r is sufficiently large. It also shows that $(m_{j,a} - \eta_{j,a}) \ge c\, m_{j,a}$, for $m_{j,a}/r_{j,a} \le c_1 (\approx 0.8)$, for positive constants $c, c_1 < 1$, when $r_{j,a}$ is large. That is the contribution of an hyper edge $e_{j,a}$ to the effective sample size is at least $c\, m_{j,a}$ for $m_{j,a}/r_{j,a} \le c_1$. Comparing this with the lower bound for top-$m_{j,a}$ ranking given in Khetan and Oh (2016), it can be concluded that the (unobserved) relative ordering among the items in the top-set of the hyper edge $e_{j,a}$ has limited impact on the MSE. Khetan and Oh (2016) show in the their lower bound that the contribution of top-m ranking on the effective sample size is m.

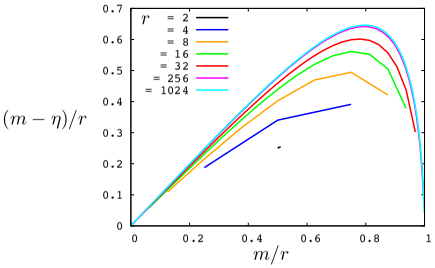

Figure 3: It shows how η varies as a function of m, size of the top-set, for a fixed value of r, sum of top-set and the bottom-set sizes, Equation (16).

Note that the lower bound is derived for the easiest case, $b = 0$, when all the items $i \in [d]$ have the same weight $\theta^*_i = \theta^*_0$. Therefore, the above conclusion that the relative ordering among the items in the top-set of the hyper edge $e_{j,a}$ has limited impact on the accuracy can be made only for this case when all the items have the same PL weight. However, the upper bound shows that this conclusion holds true in general. The 'unordered vs. ordered top-m ranking' paragraph in the previous section explains that for the ideal case when $m_{j,a}$ is sufficiently small in comparison to $r_{j,a}$, the relative ordering has limited impact.

Recall that in the upper bound, γ_1 and γ_2 capture the impact of $m_{j,a}/r_{j,a}$ on the effective number of samples. However, for $b = 0$, $\gamma_1 = 1$, and for $b > 0$ it captures asymmetry in the probability of the highest weight item appearing in bottom set. $\gamma_2 = \min_{j,a} \left\{ \left(\frac{r_{j,a} - m_{j,a}}{r_{j,a}} \right)^2 \right\}$ captures the role played by $\eta_{j,a}$ in the lower bound.

5. Numerical results

We provide extensive numerical results on simulated and real-world datasets confirming our theoretical results and performance gains of the generalized rank-breaking algorithm over the pairwise rank-breaking algorithm.

5.1 Simulated datasets

In the following, we give numerical results confirming our theoretical results. Our numerical experiments show that the dependence of MSE on $n, d, \kappa_j, r_{j,a}, m_{j,a}, \ell_j$ as given in Theorem 11, Equation (15) holds true, even when the conditions for the theorem to hold are not met. For the theorem to hold, it is required that the number of items d, the set sizes κ_j and the hyper edge sizes $r_{j,a}$ are sufficiently large such that $\gamma_3 > 0$ and the number of effective samples satisfies (14). However, in all our experiments the number of items $d <= 512$ and $b = 2$, therefore from (13) $\gamma_3 < 0$, and also the condition in (14) is not met.

In particular, in our numerical setting $\gamma_1 =$

Impact of the number of independent rankings n and the number of rank-breaking hyper edges ℓ_j on accuracy. Figure 4 (first panel) shows the accuracy-sample tradeoff for

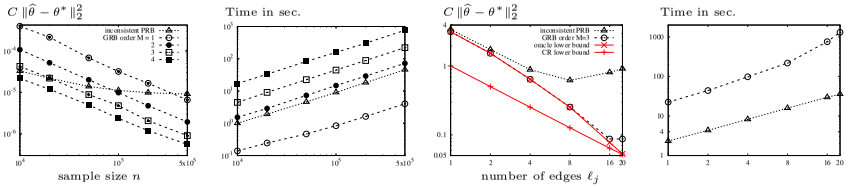

Figure 4: On the first panel, we fix $d = 256$, $\kappa = 32$, $\ell = 4$, $m_a = a$ for $a \in \{1, 2, 3, 4\}$, and sample posets from the canonical scenario explained in Section 3.4. On the third panel, we let $n = 10^5$, $d = 512$, $\kappa = 64$, $m_a = 3$ for all $a \in [\ell]$ and vary $\ell \in \{1, 2, 4, 8, 16\}$. The second and the fourth panel show the computation time for the first and the third panel respectively. The PL weights are chosen uniformly spaced over $[-2, 2]$. Smaller error is achieved when using more computational resources with larger M and using all paired comparisons results in an inconsistent Pairwise Rank-Breaking (PRB) whose error does not vanish with sample size (first panel). Generalized Rank-Breaking (GRB) utilizes all the observations achieving the oracle lower bound (third panel).

increasing computation M on the same data. As predicted by the anlaysis, generalized rank-breaking (GRB) is consistent (Remark 10) and the mean square error (MSE) decays at the rate $(1/n)$, and decreases with increase in M, order of rank-breaking (Theorem 11). For comparison, we also plot the MSE achieved by pairwise rank-breaking (PRB) approach where we include all paired relations derived from data, which we call *inconsistent PRB*. As predicted by Azari Soufiani et al. (2014), this results in an inconsistent estimate, whose MSE does not vanish as we increase the sample size. Notice that including all paired comparisons increases bias, but also decreases variance of the estimate. Hence, when sample size is limited and variance is dominating the bias, it is actually beneficial to include those biased paired relations to gain in variance at the cost of increased bias. Theoretical analysis of such a bias-variance tradeoff is outside the scope of this paper, but proposes an interesting research direction.

In the third panel, the GRB with $M = 3$ achieves decreasing MSE, whereas for PRB the increased bias dominates the MSE. For comparisons, we provide the error achieved by an oracle estimator who knows the exact ordering among those items belonging to the top-sets and runs MLE. For example, if $\ell = 2$, the GRB observes an ordering $(\{i_1, i_2, i_4, i_5, \ldots\} \prec \{i_{17}, i_3, i_6\} \prec \{i_9, i_2, i_{11}\})$ whereas the oracle estimator has extra information on the ordering among those top sets, i.e. $(\{i_1, i_2, i_4, i_5, \ldots\} \prec i_{17} \prec i_3 \prec i_6 \prec i_9 \prec i_2 \prec i_{11}\})$. Perhaps surprisingly, GRB is able to achieve a similar performance without this significant extra information, unless ℓ is large. The performance degradation in large ℓ regime stems from the fact that the ratio of m_a and r_a approaches 1 for a close to ℓ when ℓ is large. Therefore the parameters γ_1 and γ_2 become small, and the upper bound MSE increases consequentially. The normalization constant C is $1/d^2$ for the first panel and nm/d^2 for the third panel. All the numerical results in this paper are averaged over 10 instances. Standard error is very small in all the results, therefore we do not give error bars, except in the first panel in Figure 4.

Impact of the top-set size m and the set-size κ on accuracy. In Figure 5, the first and the third panel, we compare performance of our algorithm with pairwise breaking, Cramer Rao

lower bound and oracle MLE lower bound. Oracle MLE knows relative ordering of items in the top-sets $T(e)$ and hence is strictly better than the GRB. For the settings chosen, Oracle MLE gets the ordered ranking of top-m items whereas GRB gets unordered top-m items. As predicted by our analysis, GRB matches with the oracle MLE which means relative ordering of top-m items among themselves is statistically insignificant when m is sufficiently small in comparison to $r = \kappa$. For $r = \kappa = 32$ in the first panel, MSE decays as m increases from 1 to 5. However, when $r = \kappa = 16$ in the third panel, for the same increase of m from 1 to 5 MSE starts increasing when m grows beyond 4. The reason is that the quantities γ_1 and γ_2 get smaller as m increases, and the upper bound increases consequently. The normalization constant C is n/d^2 for these two panels.

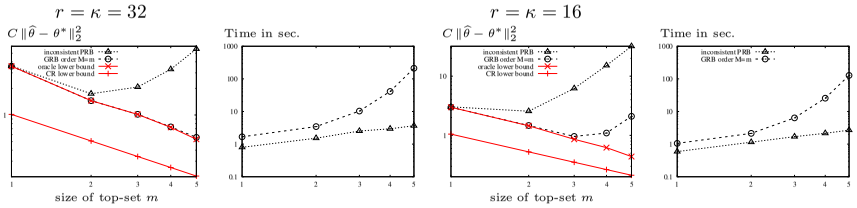

Figure 5: PRB: pairwise rank-breaking, GRB: generalized rank-breaking. θ^* is chosen uniformly spaced over $[-2, 2]$ and $d = 512$, $n = 10^5$ and number of hyperedges $\ell = 1$. The second and the fourth panel show the computation time for the first and the third panel respectively. MSE decreases as m increases when r, sum of the size of the top-set and the bottom-set is sufficiently large (first panel). When r is small, with increase in m MSE initially decreases but as m grows large MSE starts increasing (third panel).

Impact of the dynamic range b on accuracy. In Figure 6, we show the impact of b and $r = \kappa$ on the accuracy for fixed $m = 4$. When κ is small, γ_2 is small, and hence error is large; when b is large γ_1 is exponentially small, and hence error is significantly large. This is different from learning Mallows models in Ali and Meilă (2012) where peaked distributions are easier to learn, and is related to the fact that we are not only interested in recovering the (ordinal) ranking but also the (cardinal) weight. The normalization constant C is nm/d^2.

5.2 Real-world datasets

On sushi preferences (Kamishima, 2003) and jester dataset (Goldberg et al., 2001), we improve over pairwise breaking and achieve same performance as the oracle MLE.

Sushi dataset. There are $d = 100$ types of sushi. Full rankings over subsets S_j of size $\kappa = 10$ are provided by $n = 5000$ individuals. The offering subsets S_j are chosen uniformly at random from the entire set d. We set the ground truth θ^* to be the MLE of the PL weights over the entire data. In the left panel of Figure 7, for each $m \in \{3, 4, 5, 6\}$, we remove the known ordering among the top-m and bottom-$(10 - m)$ sushi in each set, and run our estimator with one rank-breaking hyper edge between top-m and bottom-$(10 - m)$ items. We compare our algorithm with inconsistent pairwise breaking (using optimal choice of parameters from Khetan and Oh (2016)) and the oracle MLE. For $m \leq 6$, the proposed rank-breaking performs as good as the oracle who knows the relative

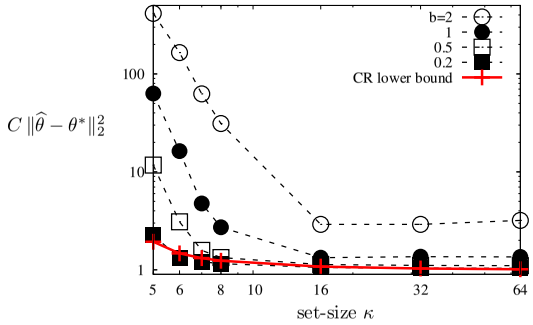

Figure 6: $d = 512$, $n = 10^5$ and θ^* is chosen uniformly spaced over $[-2, 2]$. Number of hyper edges $\ell = 1$ with $r = \kappa$ and $m = 4$. MSE increases as the dynamic range b gets large.

ordering among the top m items. In other words, an individual providing a set of ordered top-6 sushi or a set of unordered top-6 sushi statistically reveals the same information, for the purpose of estimating the ground truth parameters. As predicted by our theory, error decreases with increase in top-set size m.

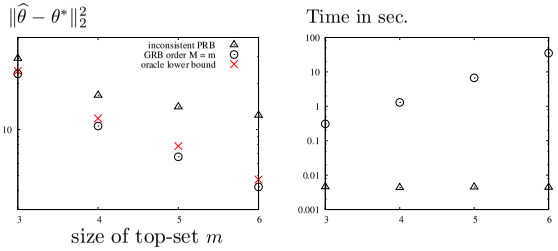

Figure 7: The sushi dataset has $d = 100$, $n = 5000$, and $\kappa = 10$. The right panel shows computation time. Generalized rank-breaking improves over pairwise RB and performs as good as oracle MLE on sushi dataset.

Jester dataset. It consists of continuous ratings between -10 to $+10$ of 100 jokes on sets of size κ, $36 \leq \kappa \leq 100$, by 24,983 users. We convert cardinal ratings into ordinal full rankings. The ground truth θ^* is set to be the MLE of the PL weights over the entire data. For $m \in \{2, 3, 4, 5\}$, we convert each full ranking into a poset that has $\ell = \lfloor \kappa/m \rfloor$ partitions of size m, by removing known relative ordering from each partition. The leads to total number of effective samples $\sum_j p_j = \sum_j \sum_{a \in [\ell_j]} m_{j,a} = \sum_j (\kappa_j - m)$, which is approximately equal for each $m \in \{2, 3, 4, 5\}$. However, with increasing m, the quantities $\gamma_1, \gamma_2, \gamma_3$ become smaller and hence the error increases (third panel in Figure 8). Figure 8 compares the three algorithms for two different settings. In the first

panel, we fix $m = 4$ and vary the number of samples n. Mean square error decreases with increase in the number of samples. In the third panel, we use $n = 5000$ samples, and vary $m \in \{2, 3, 4, 5\}$.

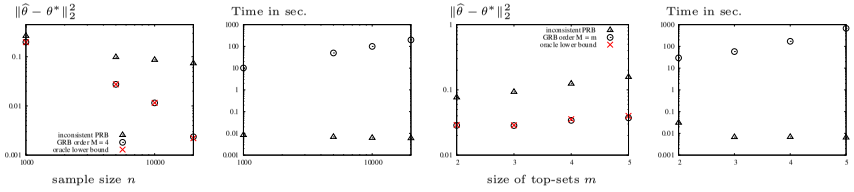

Figure 8: The jester dataset which has $d = 100$, $n = 24,983$, and $36 \leq \kappa_j \leq 100$. The second and the fourth panel show the computation time for the first and the third panel respectively. Generalized rank-breaking improves over pairwise RB and performs as good as oracle MLE on jester dataset.

6. Computational and statistical tradeoff

For estimators with limited computational power, however, the lower bound Theorem 12 fails to capture the dependency on the allowed computational power. Understanding such fundamental trade-offs is a challenging problem, which has been studied only in a few special cases, e.g. planted clique problem (Deshpande and Montanari, 2015; Meka et al., 2015). This is outside the scope of this paper, and we instead investigate the trade-off achieved by the proposed rank-breaking approach. When we are limited on computational power, Theorem 11 implicitly captures this dependence when order-M rank-breaking is used. The dependence is captured indirectly via the resulting rank-breaking $\{G_{j,a}\}_{j\in[n],a\in[\ell_j]}$ and the topology of it. We make this trade-off explicit by considering a simple but canonical example. Suppose $\theta^* \in \Omega_b$ with $b = O(1)$. Each user gives an i.i.d. partial ranking, where all items are offered and the partial ranking is based on an ordered partition with $\ell_j = \lfloor \sqrt{2c}d^{1/3} \rfloor$ subsets for a constant c. The top subset has size $m_{j,1} = 1$, and the a-th subset has size $m_{j,a} = a$, up to $a < \ell_j$. The choice of ℓ_j with a sufficiently small constant c ensures that all the conditions of the ideal case explained in the previous section for holding the Theorem 11 are satisfied.

Computation. For a choice of M such that $M \leq \ell_j - 1$, we consider the computational complexity in computing $\theta^{(t)}$, (6) in one iteration of the minorization-maximization algorithm, which scales as $T(M, n) = O(M! \times dn)$. A detailed analysis of the convergence rate of the MM algorithm is outside the scope of this paper.

Accuracy. Under the canonical setting, for $M \leq \ell_j - 1$, Laplacian matrix L of the comparison graph $\mathcal{H}$ is $L = nM(M+1)/(2d(d-1))\big(d\mathbb{I} - \mathbf{1}\mathbf{1}^\top\big)$. All the non-zero eigenvalues of this complete graph are equal, $\lambda_2(L) = \cdots = \lambda_d(L) = \mathrm{Tr}(L)/(d-1)$. Therefore, the resclaed spectral gap $\alpha = 1$, and the rescaled largest eigenvalue $\beta = 1$. Since the effective sample size is $\sum_{j,a} m_{j,a}\mathbb{I}\{m_{j,a} \leq M\} = nM(M+1)/2$, it follows from Theorem 11 that the (rescaled) root mean squared error is $O(\sqrt{(d\log d)/(nM^2)})$. In order to achieve a smaller target error rate of ε for a fixed problem size d, an analyst can increase the rank-breaking order M and/or increase n that is collect more i.i.d. rankings. Fixing the rank-breaking order M, we need to collect $n = \Omega((d\log d)/(\varepsilon^2 M^2))$ i.i.d. rankings. The resulting trade-off between run-time and root mean squared error ε is $T(\varepsilon) \propto (M!(d^2\log d)/(\varepsilon^2 M^2)$. The computational complexity is quadratic in the target error ϵ, when we can collect more rankings. On the other hand, fixing the number of rankings n, we need to choose $M = \Omega((1/\varepsilon)\sqrt{(d\log d)/n})$. The resulting trade-off between run-time and root mean squared error ε is $T(\epsilon) \propto (\lceil(1/\varepsilon)\sqrt{(d\log d)/n}\rceil)!dn$. The computational complexity is super exponential in the target error ϵ, for a fixed problem size d and the number of rankings n. Super exponential complexity is unavoidable as computing likelihood is super exponential in M. However, our approach provides flexibility to the analyst to choose between collecting more rankings n or increasing the rank-breaking order M to achieve the desired target error. We show numerical experiment under this canonical setting in Figure 4 (left) with $d = 256$ and $M \in \{1, 2, 3, 4, 5\}$, illustrating the trade-off in practice.

7. Proofs

We provide the proofs of the main results.

7.1 Proof of Lemma 3

In the following, we show that $Q(e, \theta; \theta^{(t)})$ minorizes $\ln(\mathbb{P}_\theta(e))$ at $\theta^{(t)}$. Using Jensen's inequality $\ln(\mathbb{E}[X]) \geq \mathbb{E}[\ln(X)]$, for any given parameter $\theta^{(t)} \in \mathbb{R}^d$, we have,

$$
\begin{aligned}
& \ln(\mathbb{P}_\theta(e)) \\
= \; & \ln\big(\mathbb{P}_\theta\big(B(e) \prec T(e)\big)\big) \\
= \; & \ln\left(\sum_{\sigma\in\Lambda_{T(e)}} \frac{\exp\left(\sum_{c=1}^{|T(e)|}\theta_{\sigma(c)}\right)}{\prod_{u=1}^{|T(e)|}\left(\sum_{c'=u}^{|T(e)|}\exp\left(\theta_{\sigma(c')}\right) + \sum_{i\in B(e)}\exp\left(\theta_i\right)\right)}\right) \\
\geq \; & \sum_{\sigma\in\Lambda_{T(e)}} \frac{\mathbb{P}_{\theta^{(t)}}(e,\sigma)}{\mathbb{P}_{\theta^{(t)}}(e)} \ln\left(\frac{\exp\left(\sum_{c=1}^{|T(e)|}\theta_{\sigma(c)}\right)}{\prod_{u=1}^{|T(e)|}\left(\sum_{c'=u}^{|T(e)|}\exp\left(\theta_{\sigma(c')}\right) + \sum_{i\in B(e)}\exp\left(\theta_i\right)\right)} \frac{\mathbb{P}_{\theta^{(t)}}(e)}{\mathbb{P}_{\theta^{(t)}}(e,\sigma)}\right) \qquad (19) \\
= \; & \sum_{\sigma\in\Lambda_{T(e)}} \frac{\mathbb{P}_{\theta^{(t)}}(e,\sigma)}{\mathbb{P}_{\theta^{(t)}}(e)} \sum_{u=1}^{|T(e)|}\left(\theta_{\sigma(u)} - \ln\left(\sum_{c'=u}^{|T(e)|}\exp\left(\theta_{\sigma(c')}\right) + \sum_{i\in B(e)}\exp\left(\theta_i\right)\right)\right) \\
& + \sum_{\sigma\in\Lambda_{T(e)}} \frac{\mathbb{P}_{\theta^{(t)}}(e,\sigma)}{\mathbb{P}_{\theta^{(t)}}(e)} \ln\left(\frac{\mathbb{P}_{\theta^{(t)}}(e)}{\mathbb{P}_{\theta^{(t)}}(e,\sigma)}\right) \\
\geq \; & \sum_{\sigma\in\Lambda_{T(e)}} \frac{\mathbb{P}_{\theta^{(t)}}(e,\sigma)}{\mathbb{P}_{\theta^{(t)}}(e)} \sum_{u=1}^{|T(e)|}\left(\theta_{\sigma(u)} - \frac{\sum_{c'=u}^{|T(e)|}\exp\left(\theta_{\sigma(c')}\right) + \sum_{i\in B(e)}\exp\left(\theta_i\right)}{\sum_{c'=u}^{|T(e)|}\exp\left(\theta^{(t)}_{\sigma(c')}\right) + \sum_{i\in B(e)}\exp\left(\theta^{(t)}_i\right)}\right) + f(e,\theta^{(t)}) \\
\equiv \; & Q(e,\theta;\theta^{(t)})\,.
\end{aligned}
$$

Note that inequality in (19) is tight if $\theta_t = \theta$. The last inequality follows from the fact that for any positive x and y, we have

$$-\ln x \geq 1 - \ln y - (x/y) \quad \text{with equality if and only if } x = y.$$

Therefore, $Q(e, \theta; \theta^{(t)})$ minorizes $\ln(\mathbb{P}_\theta(e))$ and is equal to $\ln(\mathbb{P}_\theta(e))$ if and only if $\theta^{(t)} = \theta$.

7.2 Proof of Theorem 11

We define few additional notations. $p \equiv (1/n)\sum_{j=1}^{n} p_j$. $V(e_{j,a}) \equiv T(e_{j,a}) \cup B(e_{j,a})$ for all $j \in [n]$ and $a \in [\ell_j]$. Note that by definition of rank-breaking edge $e_{j,a}$, $V(e_{j,a})$ is a random set of items that are ranked in bottom $r_{j,a}$ positions in a set of S_j items by the user j.

The proof sketch is inspired from Khetan and Oh (2016). The main difference and technical challenge is in showing the strict concavity of $\mathcal{L}_{\mathrm{RB}}(\theta)$ when restricted to Ω_b. We want to prove an upper bound on $\Delta = \widehat{\theta} - \theta^*$, where $\widehat{\theta}$ is the sample dependent solution of the optimization (4) and θ^* is the true utility parameter from which the samples are drawn. Since $\widehat{\theta}, \theta^* \in \Omega_b$, it follows that $\Delta\mathbf{1} = 0$. Since $\widehat{\theta}$ is the maximizer of $\mathcal{L}_{\mathrm{RB}}(\theta)$, we have the following inequality,

$$\mathcal{L}_{\mathrm{RB}}(\widehat{\theta}) - \mathcal{L}_{\mathrm{RB}}(\theta^*) - \langle \nabla \mathcal{L}_{\mathrm{RB}}(\theta^*), \Delta \rangle \;\geq\; -\langle \nabla \mathcal{L}_{\mathrm{RB}}(\theta^*), \Delta \rangle \;\geq\; -\|\nabla \mathcal{L}_{\mathrm{RB}}(\theta^*)\|_2 \|\Delta\|_2, \tag{20}$$

where the last inequality uses the Cauchy-Schwartz inequality. By the mean value theorem, there exists a $\theta = c\widehat{\theta} + (1-c)\theta^*$ for some $c \in [0,1]$ such that $\theta \in \Omega_b$ and

$$\mathcal{L}_{\mathrm{RB}}(\widehat{\theta}) - \mathcal{L}_{\mathrm{RB}}(\theta^*) - \langle \nabla \mathcal{L}_{\mathrm{RB}}(\theta^*), \Delta \rangle \;=\; \frac{1}{2}\Delta^\top H(\theta)\Delta \leq -\frac{1}{2}\lambda_2(-H(\theta))\|\Delta\|_2^2, \tag{21}$$

where $\lambda_2(-H(\theta))$ is the second smallest eigen value of $-H(\theta)$. We will show in Lemma 15 that $-H(\theta)$ is positive semi definite with one eigenvalue at zero with a corresponding eigen vector $\mathbf{1} = [1, \ldots, 1]^\top$. The last inequality follows since $\Delta^\top \mathbf{1} = 0$. Combining Equations (20) and (21),

$$\|\Delta\|_2 \;\leq\; \frac{2\|\nabla \mathcal{L}_{\mathrm{RB}}(\theta^*)\|_2}{\lambda_2(-H(\theta))},$$

where we used the fact that $\lambda_2(-H(\theta)) > 0$ from Lemma 15. The following technical lemmas prove that the norm of the gradient is upper bounded by $\gamma_2^{-1/2} e^b \sqrt{6np \log d}$ with high probability and the second smallest eigen value of negative of the Hessian is lower bounded by $(1/8)\, e^{-6b}\alpha\gamma_1\gamma_2\gamma_3(np/(d-1))$. This finishes the proof of Theorem 11.

The (random) gradient of the log likelihood in (4) can be written as the following, where the randomness is in which items ended up in the top set $T(e_{j,a})$ and the bottom set $B(e_{j,a})$:

$$\nabla_i \mathcal{L}_{\mathrm{RB}}(\theta) \;=\; \sum_{j=1}^{n}\sum_{a=1}^{\ell_j} \sum_{\substack{\mathcal{C}\subseteq S_j,\\ |\mathcal{C}|=r_{j,a}-1}} \mathbb{I}\{\, V(e_{j,a}) = \{\mathcal{C}, i\}\,\} \frac{\partial \log \mathbb{P}_\theta(e_{j,a})}{\partial \theta_i}\,.$$

Note that we are intentionally decomposing each summand as a summation over all $\mathcal{C}$ of size $r_{j,a}-1$, such that we can separate the analysis of the expectation in the following lemma. The random variable $\mathbb{I}\{\{\mathcal{C}, i\} = V(e_{j,a})\}$ indicates that we only include one term for any given instance of the sample. Note that the event $\mathbb{I}\{\{\mathcal{C}, i\} = V(e_{j,a})\}$ is equivalent to the event that the $\{\mathcal{C}, i\}$ items are ranked in bottom $r_{j,a}$ positions in the set S_j, that is $V(e_{j,a})$ items are ranked in bottom $r_{j,a}$ positions in the set S_j.

Lemma 13 *If the j-th poset is drawn from the PL model with weights θ^* then for any given $\mathcal{C}' \subseteq S_j$ with $|\mathcal{C}'| = r_{j,a}$,*

$$\mathbb{E}\left[\mathbb{I}\{\mathcal{C}' = V(e_{j,a})\} \frac{\partial \log \mathbb{P}_{\theta^*}(e_{j,a})}{\partial \theta_i^*} \middle| \{e_{j,a'}\}_{a'<a}\right] \;=\; 0\,.$$

First, this lemma implies that $\mathbb{E}\big[\mathbb{I}\{\,\mathcal{C}' = V(e_{j,a})\,\}\frac{\partial \log \mathbb{P}_{\theta^*}(e_{j,a})}{\partial \theta_i^*}\big] = 0$. Secondly, the above lemma allows us to construct a vector-valued martingale and apply a generalization of Azuma-Hoeffding's tail bound on the norm to prove the following concentration of measure. This proves the desired bound on the gradient.

Lemma 14 *If n posets are independently drawn over d items from the PL model with weights θ^* then with probability at least $1 - 2e^3 d^{-3}$,*

$$\|\nabla \mathcal{L}_{\mathrm{RB}}(\theta^*)\| \leq \gamma_2^{-1/2} e^b \sqrt{6np \log d}\,,$$

where γ_2 depend on the choice of the rank-breaking and are defined in Section 4.1.

We will prove in (26) that the Hessian matrix $H(\theta) \in \mathcal{S}^d$ with $H_{ii'}(\theta) = \frac{\partial^2 \mathcal{L}_{\mathrm{RB}}(\theta)}{\partial \theta_i \partial \theta_{i'}}$ can be expressed as

$$-H(\theta) = \sum_{j=1}^{n}\sum_{a=1}^{\ell_j}\sum_{i<i'\in S_j} \mathbb{I}\{(i,i') \subseteq V(e_{j,a})\} \left(\frac{\partial^2 \log \mathbb{P}_\theta(e_{j,a})}{\partial \theta_i \partial \theta_{i'}} (e_i - e_{i'})(e_i - e_{i'})^\top \right). \tag{22}$$

It is easy to see that $H(\theta)\mathbf{1} = 0$. The following lemma proves a lower bound on the second smallest eigenvalue $\lambda_2(-H(\theta))$ in terms of re-scaled spectral gap α of the comparison graph $\mathcal{H}$ defined in Section 4.1.

Lemma 15 *Under the hypothesis of Theorem 11, if the assumptions in Equation (14) are satisfied then with probability at least $1 - d^{-3}$, the following holds for any $\theta \in \Omega_b$:*

$$\lambda_2(-H(\theta)) \;\geq\; \frac{e^{-6b}\alpha\gamma_1\gamma_2\gamma_3}{8} \frac{np}{(d-1)}\,,$$

and $\lambda_1(-H(\theta)) = 0$ with corresponding eigenvector $\mathbf{1}$.

This finishes the proof of the desired claim.

7.3 Proof of Lemma 13

Recall that $e_{j,a}$ is a random event where randomness is in which items ended up in the top-set $T(e_{j,a})$ and the bottom-set $B(e_{j,a})$, and $\mathbb{P}_{\theta^*}(e_{j,a}) = \mathbb{P}_{\theta^*}[B(e_{j,a}) \prec T(e_{j,a})]$ that is the probability of observing $B(e_{j,a}) \prec T(e_{j,a})$ when the offer set is $B(e_{j,a}) \cup T(e_{j,a})$ as defined in (3). Define, $\mathbb{P}_{\theta^*,S_j}[e_{j,a}|V(e_{j,a}) = \mathcal{C}']$ to be the conditional probability of observing $B(e_{j,a}) \prec T(e_{j,a})$, when the offer set is S_j, conditioned on the event that $V(e_{j,a}) = \mathcal{C}'$. Note that we have put subscript S_j in $\mathbb{P}_{\theta^*}$ to specify that the offer set is S_j. Observe that for any set $\mathcal{C}' \subseteq S_j$, the event $\{\mathcal{C}' = V(e_{j,a})\}$ is equivalent to $\mathcal{C}'$ items being ranked in bottom $r_{j,a}$ positions when the offer set is S_j. In other words, it is conditioned on the event that the subset $V(e_{j,a})$ items are ranked in bottom $r_{j,a}$ positions when the offer set is S_j. In Equation (23), we show that under PL model

$$\mathbb{P}_{\theta^*,S_j}[e_{j,a}|V(e_{j,a}) = \mathcal{C}'] = \mathbb{P}_{\theta^*}[e_{j,a}]\,.$$

Also, by conditioning on any outcome of $\{e_{j,a'}\}_{a'<a}$ it can be checked that

$$\mathbb{P}_{\theta^*,S_j}[e_{j,a}|V(e_{j,a}) = \mathcal{C}', \{e_{j,a'}\}_{a'<a}] = \mathbb{P}_{\theta^*,S_j}[e_{j,a}|V(e_{j,a}) = \mathcal{C}'].$$

Therefore, we have

$$\begin{aligned}
&\mathbb{E}\Big[\frac{\partial \log \mathbb{P}_{\theta^*}\big[e_{j,a}\big]}{\partial \theta_i^*}\Big| V(e_{j,a})=\mathcal{C}', \{e_{j,a'}\}_{a'<a}\Big] \\
&= \mathbb{E}\Big[\frac{\partial \log \mathbb{P}_{\theta^*,S_j}\big[e_{j,a}|V(e_{j,a})=\mathcal{C}', \{e_{j,a'}\}_{a'<a}\big]}{\partial \theta_i^*}\Big| V(e_{j,a})=\mathcal{C}', \{e_{j,a'}\}_{a'<a}\Big] \\
&= \sum_{\substack{e_{j,a}:V(e_{j,a})=\mathcal{C}' \\ \{e_{j,a'}\}_{a'<a}}} \mathbb{P}_{\theta^*,S_j}\Big[e_{j,a}\Big|V(e_{j,a})=\mathcal{C}', \{e_{j,a'}\}_{a'<a}\Big]\, \frac{\partial}{\partial \theta_i^*} \log \mathbb{P}_{\theta^*,S_j}\Big[e_{j,a}\Big|V(e_{j,a})=\mathcal{C}', \{e_{j,a'}\}_{a'<a}\Big] \\
&= \frac{\partial}{\partial \theta_i^*} \sum_{e_{j,a}:V(e_{j,a})=\mathcal{C}'} \mathbb{P}_{\theta^*,S_j}\Big[e_{j,a}\Big|V(e_{j,a})=\mathcal{C}'\Big] = \frac{\partial}{\partial \theta_i^*} 1 = 0\,,
\end{aligned}$$

where we used $\{e_{j,a} : V(e_{j,a}) = \mathcal{C}'\} = \{e_{j,a} : V(e_{j,a}) = \mathcal{C}', \{e_{j,a'}\}_{a'<a}\}$ which follows from the definition of rank-breaking edges $e_{j,a}$. This proves the desired claim. It remains to show that

$$\mathbb{P}_{\theta^*,S_j}[e_{j,a}|V(e_{j,a})=\mathcal{C}'] = \mathbb{P}_{\theta^*}[e_{j,a}]\,.$$

This follows from the fact that under PL model for any disjoint set of items $\{\mathcal{C}_i\}_{i\in[\ell]}$ such that $\cup_{i=1}^{\ell}\mathcal{C}_i = S$,

$$\mathbb{P}\big(\mathcal{C}_\ell \prec \mathcal{C}_{\ell-1} \prec \cdots \prec \mathcal{C}_1\big) = \mathbb{P}\big(\mathcal{C}_\ell \prec \mathcal{C}_{\ell-1}\big)\mathbb{P}\big(\{\mathcal{C}_\ell, \mathcal{C}_{\ell-1}\} \prec \mathcal{C}_{\ell-2}\big)\cdots\mathbb{P}\big(\{\mathcal{C}_\ell, \mathcal{C}_{\ell-1}, \cdots, \mathcal{C}_2\} \prec \mathcal{C}_1\big)\,, \quad (23)$$

where $\mathbb{P}(\mathcal{C}_{i_1} \prec \mathcal{C}_{i_2})$ is the probability that $\mathcal{C}_{i_2}$ items are ranked higher than $\mathcal{C}_{i_1}$ items when the offer set is $\{\mathcal{C}_{i_1} \cup \mathcal{C}_{i_2}\}$.

7.4 Proof of Lemma 14

We view $\nabla\mathcal{L}_{\mathrm{RB}}(\theta^*)$ as the final value of a discrete time vector-valued martingale with values in $\mathbb{R}^d$. Define $\nabla\mathcal{L}_{\mathrm{RB}}^{(e_{j,a})} \in \mathbb{R}^d$ as the gradient vector arising out of each rank-breaking edge $\{e_{j,a}\}_{j\in[n],a\in[\ell_j]}$ as

$$\nabla_i \mathcal{L}_{\mathrm{RB}}^{(e_{j,a})}(\theta^*) \;\equiv\; \sum_{\mathcal{C}\subseteq S_j} \mathbb{I}\big\{V(e_{j,a}) = \{\mathcal{C}, i\}\big\} \nabla_i \log \mathbb{P}_{\theta^*}(e_{j,a})\,,$$

such that $\nabla\mathcal{L}_{\mathrm{RB}}(\theta^*) = \sum_{j\in[n]}\sum_{a\in[\ell_j]} \nabla\mathcal{L}_{\mathrm{RB}}^{(e_{j,a})}$. We take $\nabla\mathcal{L}_{\mathrm{RB}}^{(e_{j,a})}$ as the incremental random vector in a martingale of $\sum_{j=1}^{n}\ell_j$ time steps. Let $H_{j,a}$ denote (the sigma algebra of) the history up to $e_{j,a}$ and define a sequence of random vectors in $\mathbb{R}^d$:

$$Z_{j,a} \;\equiv\; \mathbb{E}[\nabla\mathcal{L}_{\mathrm{RB}}^{(e_{j,a})}(\theta^*)|H_{j,a}]\,,$$

with the convention that $Z_{1,1} = \mathbb{E}[\nabla\mathcal{L}_{\mathrm{RB}}^{(e_{j,a})}(\theta^*)] = 0$ as proved in Lemma 13. It also follows from Lemma 13 that $\mathbb{E}[Z_{j,a+1}|Z_{j,a}] = Z_{j,a}$ for $a < \ell_j$. Also, from the independence of samples, it follows that $\mathbb{E}[Z_{j+1,1}|Z_{j,\ell_j}] = Z_{j,\ell_j}$. Applying a generalized version of the vector Azuma-Hoeffding inequality which readily follows from [Theorem 1.8, Hayes (2005)], we have

$$\mathbb{P}\big[\,\|\nabla\mathcal{L}_{\mathrm{RB}}(\theta^*)\| \geq \delta\,\big] \;\leq\; 2e^3 \exp\left(-\frac{\delta^2}{\sum_{j=1}^{n}\sum_{a=1}^{\ell_j} m_{j,a} 2\gamma_2^{-1} e^{2b}}\right),$$

where we used $\|\nabla\mathcal{L}_{\mathrm{RB}}^{(e_{j,a})}\|^2 \leq m_{j,a}2\gamma_2^{-1}e^{2b}$. Choosing $\delta = \gamma_2^{-1}e^b\sqrt{6np\log d}$ gives the desired bound.

Now we are left to show that $\|\nabla\mathcal{L}_{\mathrm{RB}}^{(e_{j,a})}\|^2 \leq 2m_{j,a}\gamma_2^{-1}e^{2b}$ for any $\theta \in \Omega_b$. Recall that $\sigma \in \Lambda_{T(e_{j,a})}$ is the set of all full rankings over $T(e_{j,a})$ items. In rest of the proof, with a slight abuse of notations, we extend each of these ranking σ over $T(e_{j,a}) \cup B(e_{j,a})$ items in the following way. Consider any full ranking $\tilde{\sigma}$ over $B(e_{j,a})$ items. Then for each $\sigma \in \Lambda_{T(e_{j,a})}$, the extension is such that $\sigma(|T(e_{j,a})| + c) = \tilde{\sigma}(c)$ for $1 \leq c \leq |B(e_{j,a})|$. The choice of ranking $\tilde{\sigma}$ will have no impact on any of the following mathematical expressions. From the definition of $\mathbb{P}_\theta(e_{j,a})$ (3), we have, for any $i \in V(e_{j,a})$,

$$\begin{aligned}
\frac{\partial \mathbb{P}_\theta(e_{j,a})}{\partial \theta_i} &= \mathbb{I}\{i \in T(e_{j,a})\}\mathbb{P}_\theta(e_{j,a}) \\
&\quad - \underbrace{\sum_{\sigma\in\Lambda_{T(e_{j,a})}} \underbrace{\frac{\exp\left(\sum_{c=1}^{m_{j,a}}\theta_{\sigma(c)}\right)}{\prod_{u=1}^{m_{j,a}}\left(\sum_{c'=u}^{r_{j,a}}\exp\left(\theta_{\sigma(c')}\right)\right)}}_{\equiv A_\sigma} \underbrace{\left(\sum_{u'=1}^{m_{j,a}} \frac{\mathbb{I}\{\sigma^{-1}(i) \geq u'\}\exp(\theta_i)}{\sum_{c'=u'}^{r_{j,a}}\exp\left(\theta_{\sigma(c')}\right)}\right)}_{\equiv B_{\sigma,i}}}_{\equiv E_i}\,. \qquad (24)
\end{aligned}$$

Note that $A_\sigma, B_{\sigma,i}$ and E_i depend on $e_{j,a}$. Observe that for any $1 \leq u' \leq m_{j,a}$ and any $\sigma \in \Lambda_{T(e_{j,a})}$,

$$\sum_{i\in V(e_{j,a})} \mathbb{I}\{\sigma^{-1}(i) \geq u'\}\exp(\theta_i) = \sum_{c'=u'}^{r_{j,a}} \exp\left(\theta_{\sigma(c')}\right).$$

Therefore, $\sum_{i\in V(e_{j,a})} B_{\sigma,i} = m_{j,a}$. It follows that

$$\sum_{i\in V(e_{j,a})} E_i \;=\; \sum_{\sigma\in\Lambda_{T(e_{j,a})}} A_\sigma\Big(\sum_{i\in V(e_{j,a})} B_{\sigma,i}\Big) \;=\; m_{j,a}\sum_{\sigma\in\Lambda_{T(e_{j,a})}} A_\sigma \;=\; m_{j,a}\mathbb{P}_\theta(e_{j,a})\,, \qquad (25)$$

where the last equality follows from the definition of $\mathbb{P}_\theta(e_{j,a})$ (4). Also, since for any i, i', $e^{(\theta_i-\theta_{i'})} \leq e^{2b}$; for any i, $B_{\sigma,i} \leq e^{2b}\sum_{k=r_{j,a}-m_{j,a}+1}^{r_{j,a}}(1/k) \leq e^{2b}(1+\log(r_{j,a}/(r_{j,a}-m_{j,a}+1))) \leq \gamma_2^{-1}e^{2b}$, where the last inequality follows from the definition of γ_2 (12) and the fact that $x \leq \sqrt{1+\log x}$ for all $x \geq 1$. Therefore, $E_i \leq \gamma_2^{-1}e^{2b}\sum_{\sigma\in\Lambda_{T(e_{j,a})}} A_\sigma = \gamma_2^{-1}e^{2b}\mathbb{P}_\theta(e_{j,a})$. We have $\partial\log\mathbb{P}_\theta(e_{j,a})/\partial\theta_i = (1/\mathbb{P}_\theta(e_{j,a}))\partial\mathbb{P}_\theta(e_{j,a})/\partial\theta_i = \mathbb{I}\{i \in T(e_{j,a})\} - E_i/\mathbb{P}_\theta(e_{j,a})$. Since $|T(e_{j,a})| = m_{j,a}$, $\|\nabla\mathcal{L}_{\mathrm{RB}}^{(e_{j,a})}\|^2 \leq m_{j,a} + \sum_{i\in V(e_{j,a})}(E_i/\mathbb{P}_\theta(e_{j,a}))^2 \leq 2m_{j,a}\gamma_2^{-1}e^{2b}$, where we used (25) and the fact that $\gamma_2^{-1} \geq 1$.

7.4.1 Proof of Lemma 15

First, we prove (22). For brevity, remove $\{j,a\}$ from $\mathbb{P}_\theta(e_{j,a})$. From Equations (24) and (25), and $|T(e_{j,a})| = m_{j,a}$, we have $\sum_{i\in V(e_{j,a})}\frac{\partial}{\partial\theta_i}\mathbb{P}_\theta(e) = m_{j,a}\mathbb{P}_\theta(e) - m_{j,a}\mathbb{P}_\theta(e) = 0$. It follows that

$$\begin{aligned}
&\sum_{i\in V(e_{j,a})}\left(\frac{\partial^2\log\mathbb{P}_\theta(e)}{\partial\theta_{i'}\partial\theta_i}\right) = \\
&\frac{1}{\mathbb{P}_\theta(e)}\frac{\partial}{\partial\theta_{i'}}\left(\sum_{i\in V(e_{j,a})}\left(\frac{\partial\mathbb{P}_\theta(e)}{\partial\theta_i}\right)\right) - \frac{1}{(\mathbb{P}_\theta(e))^2}\frac{\partial\mathbb{P}_\theta(e)}{\partial\theta_{i'}}\left(\sum_{i\in V(e_{j,a})}\left(\frac{\partial\mathbb{P}_\theta(e)}{\partial\theta_i}\right)\right) = 0\,. \qquad (26)
\end{aligned}$$

Since by definition $\mathcal{L}_{\mathrm{RB}}(\theta) = \sum_{j=1}^{n}\sum_{a=1}^{\ell_j}\log \mathbb{P}_\theta(e_{j,a})$, and $H_{ii'}(\theta) = \frac{\partial^2 \mathcal{L}_{\mathrm{RB}}(\theta)}{\partial\theta_i \partial\theta_{i'}}$ which is a symmetric matrix, Equation (26) implies that it can be expressed as given in Equation (22). It follows that all-ones is an eigenvector of $H(-\theta)$ with the corresponding eigenvalue being zero.

To get a lower bound on $\lambda_2(-H(\theta))$, we apply Weyl's inequality

$$\lambda_2(-H(\theta)) \geq \lambda_2(\mathbb{E}[-H(\theta)]) - \|H(\theta) - \mathbb{E}[H(\theta)]\|\,.$$

We will show in (27) that $\lambda_2(\mathbb{E}[-H(\theta)]) \geq e^{-6b}\alpha\gamma_1\gamma_2\gamma_3(np/(4(d-1)))$ and in (39) that $\|H(\theta) - \mathbb{E}[H(\theta)]\| \leq 16e^{4b}\nu\sqrt{\frac{p_{\max}}{\kappa_{\min}}\frac{np}{\beta(d-1)}\log d}$. Putting these together,

$$\begin{aligned}\lambda_2(-H(\theta)) &\geq e^{-6b}\alpha\gamma_1\gamma_2\gamma_3\frac{np}{4(d-1)} - 16e^{4b}\nu\sqrt{\frac{p_{\max}}{\kappa_{\min}}\frac{np}{\beta(d-1)}\log d}\\ &\geq \frac{e^{-6b}\alpha\gamma_1\gamma_2\gamma_3}{8}\frac{np}{(d-1)}\,,\end{aligned}$$

where the last inequality follows from the assumption on $n\kappa_{\min}$ given in (14).

To prove a lower bound on $\lambda_2(\mathbb{E}[-H(\theta)])$, we claim that for $\theta \in \Omega_b$,

$$\begin{aligned}\mathbb{E}\big[-H(\theta)\big] &\succeq e^{-6b}\gamma_1\gamma_2\gamma_3\sum_{j=1}^{n}\frac{p_j}{4\kappa_j(\kappa_j-1)}\sum_{i<i'\in S_j}(e_i-e_{i'})(e_i-e_{i'})^\top \qquad (27)\\ &= \frac{e^{-6b}\gamma_1\gamma_2\gamma_3}{4}L\,,\end{aligned}$$

where $L \in \mathcal{S}^d$ is defined in (10). Using $\lambda_2(L) = np\alpha/(d-1)$ from (11), we have $\lambda_2(-H(\theta)) \geq e^{-6b}\alpha\gamma_1\gamma_2\gamma_3(np/(4(d-1)))$. To prove (27), notice that

$$\mathbb{E}[-H(\theta)_{ii'}] = \mathbb{E}\Big[\sum_{j\in[n]}\sum_{a\in[\ell_j]}\mathbb{I}\big\{(i,i')\subseteq V(e_{j,a})\big\}\frac{\partial^2\log\mathbb{P}_\theta(e_{j,a})}{\partial\theta_i\partial\theta_{i'}}\Big]\,, \qquad (28)$$

when $i \neq i'$. We will show that for any $i \neq i' \in V(e_{j,a})$,

$$\frac{\partial^2\log\mathbb{P}_\theta(e_{j,a})}{\partial\theta_i\partial\theta_{i'}} \geq \begin{cases}\frac{e^{-2b}m_{j,a}}{r_{j,a}^2} & \text{if } i,i'\in B(e_{j,a})\\ -\frac{e^{4b}m_{j,a}^2}{(r_{j,a}-m_{j,a}+1)^2} & \text{otherwise}\,.\end{cases} \qquad (29)$$

We need to bound the probability of two items appearing in the bottom-set $B(e_{j,a})$ and in the top-set $T(e_{j,a})$.

Lemma 16 *Consider a ranking σ over a set $S \subseteq [d]$ such that $|S| = \kappa$. For any two items $i, i' \in S$, $\theta \in \Omega_b$, and $1 \leq \ell, \ell_1, \ell_2 \leq \kappa - 1$,*

$$\begin{aligned}\mathbb{P}_\theta\big[\sigma^{-1}(i), \sigma^{-1}(i') > \ell\big] &\geq \frac{e^{-4b}(\kappa-\ell)(\kappa-\ell-1)}{\kappa(\kappa-1)}\left(1-\frac{\ell}{\kappa}\right)^{2e^{2b}-2}, \qquad (30)\\ \mathbb{P}_\theta\big[\sigma^{-1}(i) = \ell\big] &\leq \frac{e^{6b}}{\kappa-\ell}\,, \qquad (31)\\ \mathbb{P}_\theta\big[\sigma^{-1}(i) = \ell_1, \sigma^{-1}(i') = \ell_2\big] &\leq \frac{e^{10b}}{(\kappa-\ell_1-1)(\kappa-\ell_2)}\,. \qquad (32)\end{aligned}$$

where the probability $\mathbb{P}_\theta$ is with respect to the sampled ranking resulting from PL weights $\theta \in \Omega_b$.

Substituting $\ell = \kappa_j - r_{j,a} + m_{j,a}$ in (30), and $\ell, \ell_1, \ell_2 \leq \kappa_j - r_{j,a} + m_{j,a}$ in (31) and (32), we have,

$$\begin{aligned}\mathbb{P}_\theta\big[(i,i')\subseteq B(e_{j,a})\big] &\geq \frac{e^{-4b}(r_{j,a}-m_{j,a})^2}{4\kappa_j(\kappa_j-1)}\Big(\frac{r_{j,a}-m_{j,a}}{\kappa_j}\Big)^{2e^{2b}-2}, \qquad (33)\\ \mathbb{P}_\theta\big[i\in T(e_{j,a}), i'\in B(e_{j,a})\big] &\leq m_{j,a}\max_{\ell\in[\kappa_j-r_{j,a}+m_{j,a}]}\mathbb{P}(\sigma^{-1}(i)=\ell)\\ &\leq \frac{e^{6b}m_{j,a}}{r_{j,a}-m_{j,a}}\,, \qquad (34)\\ \mathbb{P}_\theta\big[(i,i')\subseteq T(e_{j,a})\big] &\leq m_{j,a}^2\max_{\ell_1,\ell_2\in[\kappa_j-r_{j,a}+m_{j,a}]}\mathbb{P}(\sigma^{-1}(i)=\ell_1,\sigma^{-1}(i')=\ell_2)\\ &\leq \frac{e^{10b}m_{j,a}^2}{2\,(r_{j,a}-m_{j,a}-1)(r_{j,a}-m_{j,a})}\,, \qquad (35)\end{aligned}$$

where (33) uses $r_{j,a} - m_{j,a} - 1 \geq (r_{j,a} - m_{j,a})/4$, (34) uses $\mathbb{P}_\theta[i \in T(e_{j,a}), i' \in B(e_{j,a})] \leq \mathbb{P}_\theta[i \in T(e_{j,a})]$, and (34)-(35) uses counting on the possible choices. The bound in (35) is smaller than the one in (34) as per our assumption that $\gamma_3 > 0$.

Using Equations (28)-(29) and (33)-(35), and the definitions of $\gamma_1, \gamma_2, \gamma_3$ from Section 4.1, we get

$$\begin{aligned}&\mathbb{E}[-H(\theta)_{ii'}] \geq\\ &\sum_{j\in[n]}\sum_{a\in[\ell_j]}\Big\{\underbrace{\Big(\frac{r_{j,a}-m_{j,a}}{\kappa_j}\Big)^{2e^{2b}-2}}_{\geq\gamma_1}\underbrace{\Big(\frac{r_{j,a}-m_{j,a}}{r_{j,a}}\Big)^{2}}_{\geq\gamma_2}\frac{e^{-6b}m_{j,a}}{4\kappa_j(\kappa_j-1)} - \frac{e^{6b}m_{j,a}}{r_{j,a}-m_{j,a}}\frac{e^{4b}m_{j,a}^2}{(r_{j,a}-m_{j,a}+1)^2}\Big\}\\ &\geq \sum_{j,a}\frac{\gamma_1\gamma_2 e^{-6b}m_{j,a}}{4\kappa_j(\kappa_j-1)}\underbrace{\Big(1-\frac{4e^{16b}}{\gamma_1}\frac{m_{j,a}^2r_{j,a}^2\kappa_j^2}{(r_{j,a}-m_{j,a})^5}\Big)}_{\geq\gamma_3}\,.\end{aligned}$$

This combined with (22) proves the desired claim (27). Further, in Appendix 7.7, we show that if $m_{j,a} \leq 3$ for all $\{j,a\}$ then $\frac{\partial^2\log\mathbb{P}_\theta(e_{j,a})}{\partial\theta_i\partial\theta_{i'}}$ is non-negative even for $i \neq i' \in T(e_{j,a})$, and $i \in T(e_{j,a}), i' \in B(e_{j,a})$ as opposed to a negative lower-bound given in (29). Therefore, bound on $\mathbb{E}[-H(\theta)]$ in (27) can be tightened by a factor of γ_3.

To prove claim (29), define the following for $\sigma \in \Lambda_{T(e_{j,a})}$,

$$\begin{aligned}A_\sigma &\equiv \frac{\exp\big(\sum_{c=1}^{m_{j,a}}\theta_{\sigma(c)}\big)}{\prod_{u=1}^{m_{j,a}}\big(\sum_{c'=u}^{r_{j,a}}\exp\big(\theta_{\sigma(c')}\big)\big)}\,, B_\sigma \equiv \sum_{u'=1}^{m_{j,a}}\frac{1}{\sum_{c'=u'}^{r_{j,a}}\exp\big(\theta_{\sigma(c')}\big)}\,,\\ B_{\sigma,i} &\equiv \sum_{u'=1}^{m_{j,a}}\frac{\mathbb{I}\{\sigma^{-1}(i)\geq u'\}}{\sum_{c'=u'}^{r_{j,a}}\exp\big(\theta_{\sigma(c')}\big)}\,, C_\sigma \equiv \sum_{u'=1}^{m_{j,a}}\frac{1}{\big(\sum_{c'=u'}^{r_{j,a}}\exp\big(\theta_{\sigma(c')}\big)\big)^2}\,,\\ C_{\sigma,i} &\equiv \sum_{u'=1}^{m_{j,a}}\frac{\mathbb{I}\{\sigma^{-1}(i)\geq u'\}}{\big(\sum_{c'=u'}^{r_{j,a}}\exp\big(\theta_{\sigma(c')}\big)\big)^2}\,, C_{\sigma,i,i'} \equiv \sum_{u'=1}^{m_{j,a}}\frac{\mathbb{I}\{\sigma^{-1}(i),\sigma^{-1}(i')\geq u'\}}{\big(\sum_{c'=u'}^{r_{j,a}}\exp\big(\theta_{\sigma(c')}\big)\big)^2}\,. \qquad (36)\end{aligned}$$

First, a few observations about the expression of A_σ. For any $\sigma \in \Lambda_{T(e_{j,a})}$ and any $i \in V(e_{j,a})$, θ_i is in the numerator if and only if $i \in T(e_{j,a})$, since in all the rankings that are consistent with

the observation $e_{j,a}$, $T(e_{j,a})$ items are ranked in top $m_{j,a}$ positions. For any $\sigma \in \Lambda_{T(e_{j,a})}$ and any $i \in B(e_{j,a})$, θ_i is in all the product terms $\prod_{u=1}^{m_{j,a}}(\cdot)$ of the denominator, since in all the consistent rankings these items are ranked below $m_{j,a}$ position. For any $i \in T(e_{j,a})$, θ_i appears in product term corresponding to index u if and only if item i is ranked at position u or lower than u in the ranking $\sigma \in \Lambda_{T(e_{j,a})}$. Now, observe that B_σ is defined such that the partial derivative of A_σ with respect to any $i \in B(e_{j,a})$ is $-A_\sigma B_\sigma e^{\theta_i}$, and $B_{\sigma,i}$ is defined such that the partial derivative of A_σ with respect to any $i \in T(e_{j,a})$ is $A_\sigma - A_\sigma B_\sigma e^{\theta_i}$. Further, observe that $-C_\sigma e^{\theta_i}$ is the partial derivative of B_σ with respect to $i \in B(e_{j,a})$, $-C_{\sigma,i}e^{\theta_i}$ is the partial derivative of $B_{\sigma,i}$ with respect to $i \in T(e_{j,a})$, and $-C_{\sigma,i}e^{\theta_{i'}}$ is the partial derivative of $B_{\sigma,i}$ with respect to $i' \in B(e_{j,a})$. $-C_{\sigma,i,i'}e^{\theta_{i'}}$ is the partial derivative of $B_{\sigma,i}$ with respect to $i' \neq i \in T(e_{j,a})$.

For ease of notation, we omit subscript (j,a) whenever it is clear from the context. Also, we use $\sum_\sigma$ to denote $\sum_{\sigma\in\Lambda_{T(e_{j,a})}}$. With the above defined notations, from (4), we have, $\mathbb{P}_\theta(e) = \sum_\sigma A_\sigma$. With the above given observations for the notations in (36), first partial derivative of $\mathbb{P}_\theta(e)$ can be expressed as following:

$$\frac{\partial \mathbb{P}_\theta(e)}{\partial \theta_i} = \begin{cases} \sum_\sigma \left(A_\sigma - A_\sigma B_{\sigma,i} e^{\theta_i}\right) & \text{if } i \in T(e_{j,a}) \\ \sum_\sigma \left(-A_\sigma B_\sigma e^{\theta_i}\right) & \text{if } i \in B(e_{j,a})\,. \end{cases} \tag{37}$$

It follows that for $i \neq i' \in V(e_{j,a})$,

$$\begin{aligned} &\frac{\partial^2 \mathbb{P}_\theta(e)}{\partial\theta_i \partial\theta_{i'}} \\ &= \begin{cases} \sum_\sigma \left((A_\sigma (B_\sigma)^2 + A_\sigma C_\sigma) e^{(\theta_i+\theta_{i'})}\right) & \text{if } i,i' \in B(e_{j,a}) \\ \sum_\sigma \left(A_\sigma - A_\sigma B_{\sigma,i'} e^{\theta_{i'}} + (A_\sigma B_{\sigma,i} B_{\sigma,i'} + A_\sigma C_{\sigma,i,i'}) e^{(\theta_i+\theta_{i'})} - A_\sigma B_{\sigma,i} e^{\theta_i}\right) & \text{if } i,i' \in T(e_{j,a}) \\ \sum_\sigma \left((A_\sigma B_\sigma B_{\sigma,i} + A_\sigma C_{\sigma,i}) e^{(\theta_i+\theta_{i'})} - A_\sigma B_\sigma e^{\theta_{i'}}\right) & \text{otherwise}\,. \end{cases} \end{aligned}$$

Using $\frac{\partial^2 \log \mathbb{P}_\theta(e)}{\partial\theta_i\partial\theta_{i'}} = \frac{1}{\mathbb{P}_\theta(e)}\frac{\partial^2 \mathbb{P}_\theta(e)}{\partial\theta_i\partial\theta_{i'}} - \frac{1}{(\mathbb{P}_\theta(e))^2}\frac{\partial \mathbb{P}_\theta(e)}{\partial\theta_i}\frac{\partial \mathbb{P}_\theta(e)}{\partial\theta_{i'}}$, with above derived first and second derivatives, and after following some algebra, we have

$$\begin{aligned} &\frac{(\mathbb{P}_\theta(e))^2}{e^{(\theta_i+\theta_{i'})}} \frac{\partial^2 \log \mathbb{P}_\theta(e)}{\partial\theta_i\partial\theta_{i'}} \\ &= \begin{cases} (\sum_\sigma A_\sigma)(\sum_\sigma A_\sigma (B_\sigma)^2) - (\sum_\sigma A_\sigma B_\sigma)^2 + (\sum_\sigma A_\sigma)(\sum_\sigma A_\sigma C_\sigma) & \text{if } i,i' \in B(e_{j,a}) \\ (\sum_\sigma A_\sigma)(\sum_\sigma A_\sigma B_{\sigma,i} B_{\sigma,i'} + A_\sigma C_{\sigma,i,i'}) - (\sum_\sigma A_\sigma B_{\sigma,i})(\sum_\sigma A_\sigma B_{\sigma,i'}) & \text{if } i,i' \in T(e_{j,a}) \\ (\sum_\sigma A_\sigma)(\sum_\sigma A_\sigma B_\sigma B_{\sigma,i} + A_\sigma C_{\sigma,i}) - (\sum_\sigma A_\sigma B_\sigma)(\sum_\sigma A_\sigma B_{\sigma,i}) & \text{otherwise}\,. \end{cases} \end{aligned} \tag{38}$$

Observe that from Cauchy-Schwartz inequality $(\sum_\sigma A_\sigma)(\sum_\sigma A_\sigma (B_\sigma)^2) - (\sum_\sigma A_\sigma B_\sigma)^2 \geq 0$. Also, we have $e^{(\theta_i+\theta_{i'})} C_\sigma \geq e^{-2b}(m/r^2)$ and $e^{\theta_i} B_{\sigma,i} \leq e^{\theta_i} B_\sigma \leq e^{2b}(m/(r-m+1))$ for any $i \in V(e_{j,a})$. This proves the desired claim (29).

Next we need to upper bound deviation of $-H(\theta)$ from its expectation. From (38), we have, $\left|\frac{\partial^2 \log \mathbb{P}_\theta(e_{j,a})}{\partial\theta_i\partial\theta_{i'}}\right| \leq 3e^{4b} m_{j,a}^2/(r_{j,a}-m_{j,a}+1)^2 \leq 3e^{4b}\nu m_{j,a}/(\kappa_j(\kappa_j-1))$, where the last inequality

follows from the definition of ν (13). Therefore,

$$\begin{aligned} -H(\theta) &\preceq 3e^{4b}\nu \sum_{j=1}^n \sum_{a=1}^{\ell_j} \sum_{i<i'\in S_j} \mathbb{I}\{(i,i') \subseteq V(e_{j,a})\} \frac{m_{j,a}}{\kappa_j(\kappa_j-1)} (e_i - e_{i'})(e_i-e_{i'})^\top \\ &\preceq 3e^{4b}\nu \sum_{j=1}^n \sum_{i<i'\in S_j} \frac{\sum_{a=1}^{\ell_j} m_{j,a}}{\kappa_j(\kappa_j-1)} (e_i-e_{i'})(e_i-e_{i'})^\top \equiv \sum_{j=1}^n y_j L_j\,, \end{aligned}$$

where $y_j = (3e^{4b}\nu p_j)/(\kappa_j(\kappa_j-1))$ and $L_j = \sum_{i<i'\in S_j}(e_i-e_{i'})(e_i-e_{i'})^\top = \kappa_j \mathrm{diag}(e_{S_j}) - e_{S_j}e_{S_j}^\top$ for $e_{S_j} = \sum_{i\in S_j} e_i$. Observe that $\|y_j L_j\| \leq (3e^{4b}\nu p_{\max})/\kappa_{\min}$. Moreover, $L_j^2 \preceq \kappa_j L_j$, and it follows that

$$\sum_{j=1}^n y_j^2 L_j^2 \preceq 9e^{8b}\nu^2 \sum_{j=1}^n \frac{p_j^2}{\kappa_j^2(\kappa_j-1)^2}\kappa_j L_j \preceq \frac{9e^{8b}\nu^2 p_{\max}}{\kappa_{\min}} L\,,$$

where we used the fact that $L = (p_j/(\kappa_j(\kappa_j-1)))\sum_{j=1}^n L_j$, for L defined in (10). Using $\lambda_d(L) = np/(\beta(d-1))$ from (11), it follows that $\|\sum_{j=1}^n \mathbb{E}_\theta[y_j^2 Y_j^2]\| \leq \frac{9e^{8b}\nu^2 p_{\max}}{\kappa_{\min}}\frac{np}{\beta(d-1)}$. By the matrix Bernstien inequality, with probability at least $1-d^{-3}$,

$$\begin{aligned} \|H(\theta) - \mathbb{E}[H(\theta)]\| &\leq 12e^{4b}\nu\sqrt{\frac{p_{\max}}{\kappa_{\min}}\frac{np}{\beta(d-1)}\log d} + \frac{8e^{4b}\nu p_{\max}\log d}{\kappa_{\min}} \\ &\leq 16e^{4b}\nu\sqrt{\frac{p_{\max}}{\kappa_{\min}}\frac{np}{\beta(d-1)}\log d}\,, \end{aligned} \tag{39}$$

where the last inequality follows from the assumption on $n\kappa_{\min}$ given in (14).

7.5 Proof of Lemma 16

Claim (30)**:** Since providing a lower bound on $\mathbb{P}_\theta\left[\sigma^{-1}(i), \sigma^{-1}(i') > \ell\right]$ for arbitrary θ is challenging, we construct a new set of parameters $\{\widetilde{\theta}_j\}_{j\in[d]}$ from the original θ. These new parameters are constructed such that it is both easy to compute the probability and also provides a lower bound on the original distribution. Define $\widetilde{\alpha}_{i,i',\ell,\theta}$ as

$$\widetilde{\alpha}_{i,i',\ell,\theta} \equiv \max_{\ell'\in[\ell]} \max_{\substack{\Omega\subseteq S\setminus\{i,i'\} \\ :|\Omega|=\kappa-\ell'}} \left\{ \frac{\exp(\theta_i)+\exp(\theta_{i'})}{\left(\sum_{j\in\Omega}\exp(\theta_j)\right)/|\Omega|} \right\}, \tag{40}$$

and $\alpha_{i,i',\ell,\theta} = \left\lceil \widetilde{\alpha}_{i,i',\ell,\theta} \right\rceil$. For ease of notation we remove the subscript from α and $\widetilde{\alpha}$. We denote the sum of the weights by $W \equiv \sum_{j\in S}\exp(\theta_j)$. We define a new set of parameters $\{\widetilde{\theta}_j\}_{j\in S}$:

$$\widetilde{\theta}_j = \begin{cases} \log(\widetilde{\alpha}/2) & \text{for } j = i \text{ or } i'\,, \\ 0 & \text{otherwise}\,. \end{cases}$$

Similarly define $\widetilde{W} \equiv \sum_{j\in S}\exp(\widetilde{\theta}_j) = \kappa - 2 + \widetilde{\alpha}$. We have,

$$\begin{aligned}
&\mathbb{P}_\theta\Big[\sigma^{-1}(i), \sigma^{-1}(i') > \ell\Big] \\
&= \sum_{\substack{j_1\in S\\ j_1\neq i,i'}} \left(\frac{\exp(\theta_{j_1})}{W} \sum_{\substack{j_2\in S\\ j_2\neq i,i', j_1}} \left(\frac{\exp(\theta_{j_2})}{W-\exp(\theta_{j_1})} \cdots \left(\sum_{\substack{j_\ell\in S\\ j_\ell\neq i,i',\\ j_1,\cdots,j_{\ell-1}}} \frac{\exp(\theta_{j_\ell})}{W-\sum_{k=j_1}^{j_{\ell-1}}\exp(\theta_k)}\right)\cdots\right)\right) \\
&= \sum_{\substack{j_1\in S\\ j_1\neq i,i'}} \left(\frac{\exp(\theta_{j_1})}{W-\exp(\theta_{j_1})} \cdots \sum_{\substack{j_{\ell-1}\in S\\ j_{\ell-1}\neq i,i',\\ j_1,\cdots,j_{\ell-2}}} \left(\frac{\exp(\theta_{j_{\ell-1}})}{W-\sum_{k=j_1}^{j_{\ell-1}}\exp(\theta_k)} \sum_{\substack{j_\ell\in S\\ j_\ell\neq i,i',\\ j_1,\cdots,j_{\ell-1}}} \left(\frac{\exp(\theta_{j_\ell})}{W}\right)\cdots\right)\right)
\end{aligned} \tag{41}$$

Consider the second-last summation term in the above equation and let $\Omega_\ell = S\setminus\{i,i',j_1,\ldots,j_{\ell-2}\}$. Observe that, $|\Omega_\ell| = \kappa-\ell$ and from equation (40), $\frac{\exp(\theta_i)+\exp(\theta_{i'})}{\sum_{j\in\Omega_\ell}\exp(\theta_j)} \le \frac{\widetilde{\alpha}}{\kappa-\ell}$. We have,

$$\begin{aligned}
&\sum_{j_{\ell-1}\in\Omega_\ell} \frac{\exp(\theta_{j_{\ell-1}})}{W-\sum_{k=j_1}^{j_{\ell-1}}\exp(\theta_k)} \\
&= \sum_{j_{\ell-1}\in\Omega_\ell} \frac{\exp(\theta_{j_{\ell-1}})}{W-\sum_{k=j_1}^{j_{\ell-2}}\exp(\theta_k)-\exp(\theta_{j_{\ell-1}})} \\
&\ge \frac{\sum_{j_{\ell-1}\in\Omega_\ell}\exp(\theta_{j_{\ell-1}})}{W-\sum_{k=j_1}^{j_{\ell-2}}\exp(\theta_k)-\big(\sum_{j_{\ell-1}\in\Omega_\ell}\exp(\theta_{j_{\ell-1}})\big)/|\Omega_\ell|} \qquad (42)\\
&= \frac{\sum_{j_{\ell-1}\in\Omega_\ell}\exp(\theta_{j_{\ell-1}})}{\exp(\theta_i)+\exp(\theta_{i'})+\sum_{j_{\ell-1}\in\Omega_\ell}\exp(\theta_{j_{\ell-1}})-\big(\sum_{j_{\ell-1}\in\Omega_\ell}\exp(\theta_{j_{\ell-1}})\big)/|\Omega_\ell|} \\
&= \left(\frac{\exp(\theta_i)+\exp(\theta_{i'})}{\sum_{j_{\ell-1}\in\Omega_\ell}\exp(\theta_{j_{\ell-1}})}+1-\frac{1}{\kappa-\ell}\right)^{-1} \\
&\ge \left(\frac{\widetilde{\alpha}}{\kappa-\ell}+1-\frac{1}{\kappa-\ell}\right)^{-1} \qquad (43)\\
&= \frac{\kappa-\ell}{\widetilde{\alpha}+\kappa-\ell-1} = \sum_{j_{\ell-1}\in\Omega_\ell}\frac{\exp(\widetilde{\theta}_{j_{\ell-1}})}{\widetilde{W}-\sum_{k=j_1}^{j_{\ell-1}}\exp(\widetilde{\theta}_k)}\,, \qquad (44)
\end{aligned}$$

where (42) follows from the Jensen's inequality and the fact that for any $c>0$, $0<x<c$, $\frac{x}{c-x}$ is convex in x. Equation (43) follows from the definition of $\widetilde{\alpha}_{i,i',\ell,\theta}$, (40), and the fact that $|\Omega_\ell| = \kappa-\ell$. Equation (44) uses the definition of $\{\widetilde{\theta}_j\}_{j\in S}$.

Consider $\{\Omega_{\widetilde{\ell}}\}_{2\le\widetilde{\ell}\le\ell-1}$, $|\Omega_{\widetilde{\ell}}| = \kappa-\widetilde{\ell}$, corresponding to the subsequent summation terms in (41). Observe that $\frac{\exp(\theta_i)+\exp(\theta_{i'})}{\sum_{j\in\Omega_{\widetilde{\ell}}}\exp(\theta_j)} \le \alpha/|\Omega_{\widetilde{\ell}}|$. Therefore, each summation term in equation (41) can be

lower bounded by the corresponding term where $\{\theta_j\}_{j\in S}$ is replaced by $\{\widetilde{\theta}_j\}_{j\in S}$. Hence, we have

$$\begin{aligned}
&\mathbb{P}_\theta\Big[\sigma^{-1}(i), \sigma^{-1}(i') > \ell\Big] \\
&\ge \sum_{\substack{j_1\in S\\ j_1\neq i,i'}} \left(\frac{\exp(\widetilde{\theta}_{j_1})}{\widetilde{W}-\exp(\widetilde{\theta}_{j_1})} \cdots \sum_{\substack{j_{\ell-1}\in S\\ j_{\ell-1}\neq i,i',\\ j_1,\cdots,j_{\ell-2}}} \left(\frac{\exp(\widetilde{\theta}_{j_{\ell-1}})}{\widetilde{W}-\sum_{k=j_1}^{j_{\ell-1}}\exp(\widetilde{\theta}_k)} \sum_{\substack{j_\ell\in S\\ j_\ell\neq i,i',\\ j_1,\cdots,j_{\ell-1}}} \left(\frac{\exp(\theta_{j_\ell})}{W}\right)\cdots\right)\right) \\
&\ge e^{-4b} \sum_{\substack{j_1\in S\\ j_1\neq i,i'}} \left(\frac{\exp(\widetilde{\theta}_{j_1})}{\widetilde{W}-\exp(\widetilde{\theta}_{j_1})} \cdots \sum_{\substack{j_{\ell-1}\in S\\ j_{\ell-1}\neq i,i',\\ j_1,\cdots,j_{\ell-2}}} \left(\frac{\exp(\widetilde{\theta}_{j_{\ell-1}})}{\widetilde{W}-\sum_{k=j_1}^{j_{\ell-1}}\exp(\widetilde{\theta}_k)} \sum_{\substack{j_\ell\in S\\ j_\ell\neq i,i',\\ j_1,\cdots,j_{\ell-1}}} \left(\frac{\exp(\widetilde{\theta}_{j_\ell})}{\widetilde{W}}\right)\cdots\right)\right) \\
&= \big(e^{-4b}\big)\mathbb{P}_{\widetilde{\theta}}\Big[\sigma^{-1}(i), \sigma^{-1}(i') > \ell\Big]\,.
\end{aligned} \tag{45}$$

The second inequality uses $\frac{\exp(\theta_i)}{W} \ge e^{-2b}/\kappa$ and $\frac{\exp(\widetilde{\theta}_i)}{\widetilde{W}} \le e^{2b}/\kappa$. Observe that $\exp(\widetilde{\theta}_j) = 1$ for all $j\neq i,i'$ and $\exp(\widetilde{\theta}_i)+\exp(\widetilde{\theta}_{i'}) = \widetilde{\alpha} \le \lceil\widetilde{\alpha}\rceil = \alpha \ge 1$. Therefore, we have

$$\begin{aligned}
\mathbb{P}_{\widetilde{\theta}}\Big[\sigma^{-1}(i), \sigma^{-1}(i') > \ell\Big] &= \binom{\kappa-2}{\ell}\frac{\ell!}{(\kappa-2+\widetilde{\alpha})(\kappa-2+\widetilde{\alpha}-1)\cdots(\kappa-2+\widetilde{\alpha}-(\ell-1))} \\
&\ge \frac{(\kappa-2)!}{(\kappa-\ell-2)!}\frac{1}{(\kappa+\alpha-2)(\kappa+\alpha-3)\cdots(\kappa+\alpha-(\ell+1))} \\
&\ge \frac{(\kappa-\ell+\alpha-2)(\kappa-\ell+\alpha-3)\cdots(\kappa-\ell-1)}{(\kappa+\alpha-2)(\kappa+\alpha-3)\cdots(\kappa-1)} \\
&\ge \frac{(\kappa-\ell)(\kappa-\ell-1)}{\kappa(\kappa-1)}\left(1-\frac{\ell}{\kappa+1}\right)^{\alpha-2}.
\end{aligned} \tag{46}$$

Claim (30) follows by combining Equations (45) and (46) and using the fact that $\alpha \le 2e^{2b}$.

Claim (31)**:** Define,

$$\widetilde{\alpha}_{\ell,\theta} \equiv \min_{i\in S}\min_{\ell'\in[\ell]}\min_{\substack{\Omega\in S\setminus\{i\}\\ :|\Omega|=\kappa-\ell'+1}} \left\{\frac{\exp(\theta_i)}{\big(\sum_{j\in\Omega}\exp(\theta_j)\big)/|\Omega|}\right\}. \tag{47}$$

Also, define $\alpha_{\ell,\theta} \equiv \lfloor\widetilde{\alpha}_{\ell,\theta}\rfloor$. Note that $\alpha_{\ell,\theta}\ge 0$ and $\widetilde{\alpha}_{\ell,\theta} \le e^{2b}$. We denote the sum of the weights by $W \equiv \sum_{j\in S}\exp(\theta_j)$. Analogous to the proof of claim (30), we define the new set of parameters $\{\widetilde{\theta}_j\}_{j\in S}$:

$$\widetilde{\theta}_j = \begin{cases} \log(\widetilde{\alpha}_{\ell,\theta}) & \text{for } j = i\,,\\ 0 & \text{otherwise}\,. \end{cases}$$

Similarly define $\widetilde{W} \equiv \sum_{j\in S}\exp(\widetilde{\theta}_j) = \kappa - 1 + \widetilde{\alpha}_{\ell,\theta}$. Using the techniques similar to the ones used in proof of claim (30), we have,

$$\mathbb{P}_\theta\Big[\sigma^{-1}(i) = \ell\Big] \le e^{4b}\mathbb{P}_{\widetilde{\theta}}\Big[\sigma^{-1}(i) = \ell\Big]\,. \tag{48}$$

Observe that $\exp(\widetilde{\theta}_j) = 1$ for all $j \neq i$ and $\exp(\widetilde{\theta}_i) = \widetilde{\alpha}_{\ell,\theta} \geq \lfloor \widetilde{\alpha}_{\ell,\theta} \rfloor = \alpha_{\ell,\theta} \geq 0$. Therefore, we have

$$\begin{aligned}
\mathbb{P}_{\widetilde{\theta}}\Big[\sigma^{-1}(i) = \ell\Big] &= \binom{\kappa-1}{\ell-1} \frac{\widetilde{\alpha}_{\ell,\theta}(\ell-1)!}{(\kappa-1+\widetilde{\alpha}_{\ell,\theta})(\kappa-2+\widetilde{\alpha}_{\ell,\theta})\cdots(\kappa-\ell+\widetilde{\alpha}_{\ell,\theta})} \\
&\leq \frac{(\kappa-1)!}{(\kappa-\ell)!} \frac{e^{2b}}{(\kappa-1+\alpha_{\ell,\theta})(\kappa-2+\alpha_{\ell,\theta})\cdots(\kappa-\ell+\alpha_{\ell,\theta})} \\
&\leq \frac{e^{2b}}{\kappa}\left(1 - \frac{\ell}{\kappa+\alpha_{\ell,\theta}}\right)^{\alpha_{\ell,\theta}-1} \leq \frac{e^{2b}}{\kappa-\ell}\,. \qquad (49)
\end{aligned}$$

Claim 31 follows by combining Equations (48) and (49).

Claim (32)**:** Again, we construct a new set of parameters $\{\widetilde{\theta}_j\}_{j\in[d]}$ from the original θ using $\widetilde{\alpha}_{\ell,\theta}$ defined in (47):

$$\widetilde{\theta}_j = \begin{cases} \log(\widetilde{\alpha}_{\ell,\theta}) & \text{for } j \in \{i, i'\}\,, \\ 0 & \text{otherwise}\,. \end{cases}$$

Similarly define $\widetilde{W} \equiv \sum_{j\in S}\exp(\widetilde{\theta}_j) = \kappa - 2 + 2\widetilde{\alpha}_{\ell,\theta}$. Using the techniques similar to the ones used in proof of claim (30), we have,

$$\mathbb{P}_{\theta}\Big[\sigma^{-1}(i) = \ell_1, \sigma^{-1}(i') = \ell_2\Big] \leq e^{8b}\mathbb{P}_{\widetilde{\theta}}\Big[\sigma^{-1}(i) = \ell_1, \sigma^{-1}(i') = \ell_2\Big] \qquad (50)$$

Observe that $\exp(\widetilde{\theta}_j) = 1$ for all $j \neq i, i'$ and $\exp(\widetilde{\theta}_i) = \exp(\widetilde{\theta}_{i'}) = \widetilde{\alpha}_{\ell,\theta} \geq \lfloor \widetilde{\alpha} \rfloor_{\ell,\theta} = \alpha_{\ell,\theta} \geq 0$. Therefore, we have

$$\begin{aligned}
&= \mathbb{P}_{\widetilde{\theta}}\Big[\sigma^{-1}(i) = \ell_1, \sigma^{-1}(i') = \ell_2\Big] \\
&= \Bigg(\frac{\binom{\kappa-2}{\ell_2-2}\widetilde{\alpha}^2_{\ell,\theta}(\ell_2-2)!}{(\kappa-2+2\widetilde{\alpha}_{\ell,\theta})(\kappa-1+2\widetilde{\alpha}_{\ell,\theta})\cdots(\kappa-2+2\widetilde{\alpha}_{\ell,\theta}-(\ell_1-1))} \\
&\quad \frac{1}{(\kappa-2+\widetilde{\alpha}_{\ell,\theta}-(\ell_1-1))\cdots(\kappa-2+\widetilde{\alpha}_{\ell,\theta}-(\ell_2-2))}\Bigg) \\
&\leq \frac{(\kappa-2)!}{(\kappa-\ell_2)!}\frac{e^{4b}}{(\kappa-2)(\kappa-1)\cdots(\kappa-\ell_1-1)(\kappa-\ell_1-1)\cdots(\kappa-\ell_2)} \\
&\leq \frac{e^{4b}}{(\kappa-\ell_1-1)(\kappa-\ell_2)}\,. \qquad (51)
\end{aligned}$$

Claim 32 follows by combining Equations (50) and (51).

7.6 Proof of Theorem 12

Let $H(\theta) \in \mathcal{S}^d$ be Hessian matrix such that $H_{ii'}(\theta) = \frac{\partial^2 \mathcal{L}_{\mathrm{RB}}(\theta)}{\partial\theta_i \partial\theta_{i'}}$. The Fisher information matrix is defined as $I(\theta) = -\mathbb{E}_\theta[H(\theta)]$. From lemma 1, $\mathcal{L}_{\mathrm{RB}}(\theta)$ is concave. This implies that $I(\theta)$ is positive-semidefinite and from (22) its smallest eigenvalue is zero with all-ones being the corresponding eigenvector. Fix any unbiased estimator $\widehat{\theta}$ of $\theta \in \Omega_b$. Since, $\widehat{\theta} \in \mathcal{U}$, $\widehat{\theta} - \theta$ is orthogonal to $\mathbf{1}$. The

Cramer-Rao lower bound then implies that $\mathbb{E}[\|\widehat{\theta} - \theta^*\|^2] \geq \sum_{i=2}^d \frac{1}{\lambda_i(I(\theta))}$. Taking supremum over both sides gives

$$\sup_\theta \mathbb{E}[\|\widehat{\theta} - \theta^*\|^2] \geq \sup_\theta \sum_{i=2}^d \frac{1}{\lambda_i(I(\theta))} \geq \sum_{i=2}^d \frac{1}{\lambda_i(I(\mathbf{0}))}\,.$$

In the following, we will show that

$$\begin{aligned}
I(\mathbf{0}) &= -\mathbb{E}_\theta[H(\mathbf{0})] \preceq \sum_{j=1}^n \sum_{a=1}^{\ell_j} \frac{m_{j,a} - \eta_{j,a}}{\kappa_j(\kappa_j - 1)} \sum_{i<i'\in S_j} (e_i - e_{i'})(e_i - e_{i'})^\top \\
&\preceq \max_{j,a}\big\{m_{j,a} - \eta_{j,a}\big\}\, L\,. \qquad (52)
\end{aligned}$$

Using Jensen's inequality, we have $\sum_{i=2}^d \frac{1}{\lambda_i(I(\mathbf{0}))} \geq \frac{(d-1)^2}{\sum_{i=2}^d \lambda_i(I(\mathbf{0}))} = \frac{(d-1)^2}{\mathrm{Tr}(I(\mathbf{0}))}$. From (52), we have $\mathrm{Tr}(I(\mathbf{0})) \leq \sum_{j,a}(m_{j,a} - \eta_{j,a})$. From (52), we have $\sum_{i=2}^d 1/\lambda_i(I(\mathbf{0})) \geq (1/\max\{m_{j,a} - \eta_{j,a}\})\sum_{i=1}^d 1/\lambda_i(L)$. This proves the desired claim.

Now we are left to show claim (52). Consider a rank-breaking edge $e_{j,a}$. Using notations defined in lemma 15, in particular Equation (36), and omitting subscript $\{j, a\}$ whenever it is clear from the context, we have, for any $i \in V(e_{j,a})$,

$$\frac{\partial^2 \mathbb{P}_\theta(e_{j,a})}{\partial^2\theta_i} = \begin{cases} \sum_\sigma\big(-A_\sigma B_\sigma e^{\theta_i} + A_\sigma(B_\sigma)^2 e^{2\theta_i} + A_\sigma C_\sigma e^{\theta_i}\big) & \text{if } i \in B(e_{j,a}) \\ \sum_\sigma\big(A_\sigma - 3A_\sigma B_{\sigma,i}e^{\theta_i} + A_\sigma C_{\sigma,i})e^{2\theta_i} + A_\sigma(B_{\sigma,i})^2 e^{2\theta_i}\big) & \text{if } i \in T(e_{j,a})\,, \end{cases}$$

and using (37), we have

$$\frac{\partial^2 \log \mathbb{P}_\theta(e_{j,a})}{\partial^2\theta_i}\Big|_{\theta=\mathbf{0}} = \begin{cases} \big((C_\sigma - B_\sigma)\big)_{\theta=\mathbf{0}} & \text{if } i \in B(e_{j,a}) \\ \big(\frac{1}{m_{j,a}!}\sum_\sigma\big(C_{\sigma,i} - B_{\sigma,i} + (B_{\sigma,i})^2\big) - \big(\sum_\sigma \frac{B_{\sigma,i}}{m_{j,a}!}\big)^2\big)_{\theta=\mathbf{0}} & \text{if } i \in T(e_{j,a})\,, \end{cases}$$

where $\sigma \in \Lambda_{T(e_{j,a})}$ and the subscript $\theta = 0$ indicates the the respective quantities are evaluated at $\theta = 0$. From the definitions given in (36), for $\theta = \mathbf{0}$, we have $B_\sigma - C_\sigma = \sum_{u=0}^{m-1}\frac{(r-u-1)}{(r-u)^2}$ and, $\sum_\sigma(B_{\sigma,i} - C_{\sigma,i})/(m!) = \frac{1}{m}\sum_{u=0}^{m-1}\frac{(m-u)(r-u-1)}{(r-u)^2}$. Also, $\sum_\sigma B_{\sigma,i}/(m!) = \frac{1}{m}\sum_{u=0}^{m-1}\frac{m-u}{r-u}$ and $\sum_\sigma(B_{\sigma,i})^2/(m!) = \frac{1}{m}\sum_{u=0}^{m-1}\big(\sum_{u'=0}^{u}\frac{1}{r-u'}\big)^2$. Combining all these and, using $\mathbb{P}_{\theta=\mathbf{0}}[i \in T(e_{j,a})] = m/\kappa$ and $\mathbb{P}_{\theta=\mathbf{0}}[i \in B(e_{j,a})] = (r-m)/\kappa$, and after following some algebra, we have for any $i \in S_j$,

$$\begin{aligned}
&-\mathbb{E}\left[\frac{\partial^2 \log \mathbb{P}_\theta(e_{j,a})}{\partial^2\theta_i}\Big|_{\theta=\mathbf{0}}\right] \\
&= \frac{1}{\kappa}\Bigg(m - \sum_{u=0}^{m-1}\frac{1}{r-u} - \frac{1}{m}\sum_{u=0}^{m-1}\frac{u(m-u)}{(r-u)^2} - \frac{1}{m}\sum_{u=0}^{m-2}\frac{2u}{r-u}\Bigg(\sum_{u'>u}^{m-1}\frac{m-u'}{r-u'}\Bigg)\Bigg) \\
&= \frac{m_{j,a} - \eta_{j,a}}{\kappa_j}\,, \qquad (53)
\end{aligned}$$

where $\eta_{j,a}$ is defined in (16). Since row-sums of $H(\theta)$ are zeroes, (22), and for $\theta = \mathbf{0}$, all the items are exchangeable, we have for any $i \neq i' \in S_j$,

$$\mathbb{E}\left[\frac{\partial^2 \log \mathbb{P}_\theta(e_{j,a})}{\partial\theta_i\partial\theta_{i'}}\Big|_{\theta=\mathbf{0}}\right] = \frac{m_{j,a} - \eta_{j,a}}{\kappa_j(\kappa_j - 1)}\,,$$

The claim (52) follows from the expression of $H(\theta)$, Equation (22).

To verify (53), observe that $(r-m)(B_\sigma - C_\sigma) + m(\sum_\sigma B_{\sigma,i}/(m!)) = m - \sum_{u=0}^{m-1} \frac{1}{r-u}$. And,

$$\begin{aligned}
&\frac{1}{m}\Big(\sum_{u=0}^{m-1}\frac{m-u}{r-u}\Big)^2 - \sum_{u=0}^{m-1}\Big(\sum_{u'=0}^{u}\frac{1}{r-u'}\Big)^2 \\
&= \sum_{u=0}^{m-1}\left(\frac{(m-u)^2}{m(r-u)^2} - \frac{m-u}{(r-u)^2}\right) + \sum_{0\le u<u'\le m-1}\left(\frac{2(m-u)(m-u')}{m(r-u)(r-u')} - \frac{2(m-u')}{(r-u)(r-u')}\right) \\
&= \sum_{u=0}^{m-1}\frac{-u(m-u)}{m(r-u)^2} + \sum_{0\le u<u'\le m-1}\frac{-2u(m-u')}{m(r-u)(r-u')}\,.
\end{aligned}$$

7.7 Tightening of Lemma 15

Recall that $\mathbb{P}_\theta(e_{j,a})$ is same as probability of $\mathbb{P}_\theta[T(e_{j,a}) \succ B(e_{j,a})]$ that is the probability that an agent ranks $T(e_{j,a})$ items above $B(e_{j,a})$ items when provided with a set comprising $V(e_{j,a})$ items. As earlier, for brevity of notations, we omit subscript $\{j,a\}$ whenever it is clear from the context. For $m = 1$ or 2, it is easy to check that all off-diagonal elements in hessian matrix of $\log \mathbb{P}_\theta(e)$ are non-negative. However, since number of terms in summation in $\mathbb{P}_\theta(e)$ grows as $m!$, for $m \ge 3$ the straight-forward approach becomes too complex. Below, we derive expressions for cross-derivatives in hessian, for general m, using alternate definition (sorting of independent exponential r.v.'s in increasing order) of PL model, where the number of terms grow only as 2^m. However, we are unable to analytically prove that the cross-derivatives are non-negative for $m > 2$. Feeding these expressions in MATLAB and using symbolic computation, for $m = 3$, we can simplify these expressions and it turns out that they are sum of only positive numbers. For $m = 4$, with limited computational power it becomes intractable. We believe that it should hold for any value of $m < r$. Using (29), we need to check only for cross-derivatives for the case when $i \ne i' \in T(e_{j,a})$ or $i \in T(e_{j,a}), i' \in B(e_{j,a})$. Since, minimum of exponential random variables is an exponential random variable, we can assume that $|B(e_{j,a})| = 1$ that is $r = m+1$. Define $\lambda_i \equiv e^{\theta_i}$. Without loss of generality, assume $T(e_{j,a}) = \{2, \cdots, m+1\}$ and $B(e_{j,a}) = \{1\}$. Define $C_x = \prod_{i=3}^{m+1}(1-e^{-\lambda_i x})$. Then, using the alternate definition of the PL model, we have, $\mathbb{P}_\theta(e) = \int_0^\infty C_x(1-e^{-\lambda_2 x})\lambda_1 e^{-\lambda_1 x}dx$. Following some algebra, $\frac{\partial^2 \log \mathbb{P}_\theta(e)}{\partial\theta_1\partial\theta_2} \ge 0$ is equivalent to $A_1 \ge 0$, where $A_1 \equiv$

$$\left(\int C_x\big(xe^{-\lambda_1 x} - xe^{-\lambda x}\big)dx\right)\left(\int C_x x e^{-\lambda x}dx\right) - \left(\int C_x(e^{\lambda_1 x} - e^{-\lambda x})dx\right)\left(\int C_x x^2 e^{-\lambda x}dx\right),$$

where all integrals are from 0 to ∞ and, $\lambda \equiv \lambda_1 + \lambda_2$. Consider A_1 as a function of λ_1. Since $A_1(\lambda_1) = 0$ for $\lambda_1 = \lambda$, showing $\partial A_1/\partial\lambda_1 \le 0$ for $0 \le \lambda_1 \le \lambda$ would suffice. Following some algebra, and using $\lambda_1 \le \lambda$, $\partial A_1/\partial\lambda_1 \le 0$ is equivalent to $A_2(\lambda_1) \equiv \big(\int_0^\infty C_x x e^{-\lambda_1 x}\big)/\big(\int_0^\infty C_x x^2 e^{-\lambda_1 x}\big)$ being monotonically non-decreasing in λ_1. To further simplify the condition, define $f^{(0)}(y) = 1/y^2$, $g^{(0)}(y) = 1/y^3$ and, $f^{(1)}(y) = f^{(0)}(y) - f^{(0)}(y+\lambda_3)$, and recursively $f^{(m-1)}(y) = f^{(m-2)}(y) - f^{(m-2)}(y+\lambda_{m+1})$. Similarly define $g^{(0)}, \cdots, g^{(m-1)}$. Using these recursively defined functions,

$$\begin{aligned}
2A_2(\lambda_1) &= \frac{f^{(m-1)}(\lambda_1)}{g^{(m-1)}(\lambda_1)}\,, \\
\text{for } m=3,\ 2A_2(\lambda_1) &= \frac{\lambda_1^{-2} - (\lambda_1+\lambda_3)^{-2} - (\lambda_1+\lambda_4)^{-2} + (\lambda_1+\lambda_3+\lambda_4)^{-2}}{\lambda_1^{-3} - (\lambda_1+\lambda_3)^{-3} - (\lambda_1+\lambda_4)^{-3} + (\lambda_1+\lambda_3+\lambda_4)^{-3}}\,.
\end{aligned}$$

Therefore, we need to show that $A_2(\lambda_1)$ is monotonically non-decreasing in $\lambda_1 \ge 0$ for any non-negative $\lambda_3, \cdots, \lambda_m$, and that would suffice to prove that the cross-derivatives arising from $i \in T(e_{j,a}), i' \in B(e_{j,a})$ are non-negative.

For cross-derivatives arising from $i \ne i' \in T(e_{j,a})$, define $B_x = \prod_{i=4}^{m+1}(1-e^{\lambda_i x})e^{-\lambda_1 x}$. $\frac{\partial^2 \log \mathbb{P}_\theta(e)}{\partial\theta_2\partial\theta_3} \ge 0$ is equivalent to $A_3 \ge 0$, where $A_3 \equiv$

$$\begin{aligned}
&\left(\int B_x(1-e^{-\lambda_2 x})(1-e^{-\lambda_3 x})dx\right)\left(\int B_x x^2 e^{-(\lambda_2+\lambda_3)x}dx\right) \\
&-\left(\int B_x(1-e^{-\lambda_2 x})xe^{-\lambda_3 x}dx\right)\left(\int B_x(1-e^{-\lambda_3 x})xe^{-\lambda_2 x}dx\right),
\end{aligned}$$

where all integrals are from 0 to ∞. For $m = 3$, using MATLAB one can check that the above stated conditions hold true. Therefore both types of cross-derivatives are non-negative.

Abstract

We prove that stochastic gradient descent efficiently converges to the global optimizer of the maximum likelihood objective of an unknown linear time-invariant dynamical system from a sequence of noisy observations generated by the system. Even though the objective function is non-convex, we provide polynomial running time and sample complexity bounds under strong but natural assumptions. Linear systems identification has been studied for many decades, yet, to the best of our knowledge, these are the first polynomial guarantees for the problem we consider.

Key-words: non-convex optimization, linear dynamical system, stochastic gradient descent, generalization bounds, time series, over-parameterization

1. Introduction

Many learning problems are by their nature sequence problems where the goal is to fit a model that maps a sequence of input words $x_1, \ldots, x_T$ to a corresponding sequence of observations $y_1, \ldots, y_T$. Text translation, speech recognition, time series prediction, video captioning and question answering systems, to name a few, are all sequence to sequence learning problems. For a sequence model to be both expressive and parsimonious in its parameterization, it is crucial to equip the model with memory thus allowing its prediction at time t to depend on previously seen inputs.

Recurrent neural networks form an expressive class of non-linear sequence models. Through their many variants, such as long-short-term-memory Hochreiter and Schmidhuber (1997), recurrent neural networks have seen remarkable empirical success in a broad range of domains. At the core, neural networks are typically trained using some form of (stochastic) gradient descent. Even though the training objective is non-convex, it is widely observed in practice that gradient descent quickly approaches a good set of model parameters. Understanding the effectiveness of gradient descent for non-convex objectives on theoretical grounds is a major open problem in this area.

If we remove all non-linear state transitions from a recurrent neural network, we are left with the state transition representation of a linear dynamical system. Notwithstanding, the natural training objective for linear systems remains non-convex due to the composition of multiple linear operators in the system. If there is any hope of eventually understanding recurrent neural networks, it will be inevitable to develop a solid understanding of this special case first.

To be sure, linear dynamical systems are important in their own right and have been studied for many decades independently of machine learning within the control theory community. Control theory provides a rich set techniques for identifying and manipulating linear systems. The learning problem in this context corresponds to "linear dynamical system identification". Maximum likelihood estimation with gradient descent is a popular heuristic for dynamical system identification Ljung (1998). In the context of machine learning, linear systems play an important role in numerous tasks. For example, their estimation arises as subroutines of reinforcement learning in robotics Levine and Koltun (2013), location and mapping estimation in robotic systems Durrant-Whyte and Bailey (2006), and estimation of pose from video Rahimi et al. (2005).

In this work, we show that gradient descent efficiently minimizes the maximum likelihood objective of an unknown linear system given noisy observations generated by the system. More formally, we receive noisy observations generated by the following *time-invariant linear system*:

$$\begin{aligned} h_{t+1} &= Ah_t + Bx_t \\ y_t &= Ch_t + Dx_t + \xi_t \end{aligned} \tag{1.1}$$

Here, A, B, C, D are linear transformations with compatible dimensions and we denote by $\Theta = (A, B, C, D)$ the parameters of the system. The vector h_t represents the hidden state of the model at time t. Its dimension n is called the *order* of the system. The stochastic noise variables $\{\xi_t\}$ perturb the output of the system which is why the model is called an *output error model* in control theory. We assume the variables are drawn i.i.d. from a distribution with mean 0 and variance σ^2.

Throughout the paper we focus on *controllable* and *externally stable* systems. A linear system is externally stable (or *equivalently bounded-input bounded-output stable*) if and only if the spectral radius of A, denoted $\rho(A)$, is strictly bounded by 1. Controllability is a mild non-degeneracy assumption that we formally define later. Without loss of generality, we further assume that the transformations B, C and D have bounded Frobenius norm. This can be achieved by a rescaling of the output variables. We assume we have N pairs of sequences (x, y) as training examples,

$$S = \left\{ (x^{(1)}, y^{(1)}), \ldots, (x^{(N)}, y^{(N)}) \right\}.$$

Each input sequence $x \in \mathbb{R}^T$ of length T is drawn from a distribution and y is the corresponding output of the system above generated from an unknown initial state h. We allow the unknown initial state to vary from one input sequence to the next. This only makes the learning problem more challenging.

Our goal is to fit a linear system to the observations. We parameterize our model in exactly the same way as (1.1). That is, for linear mappings $(\hat{A}, \hat{B}, \hat{C}, \hat{D})$, the trained model

is defined as:

$$\hat{h}_{t+1} = \hat{A}\hat{h}_t + \hat{B}x_t\,, \qquad \hat{y}_t = \hat{C}\hat{h}_t + \hat{D}x_t \tag{1.2}$$

The *(population) risk* of the model is obtained by feeding the learned system with the correct initial states and comparing its predictions with the ground truth in expectation over inputs and errors. Denoting by $\hat{y}_t$ the t-th prediction of the trained model starting from the correct initial state that generated y_t, and using $\widehat{\Theta}$ as a short hand for $(\hat{A}, \hat{B}, \hat{C}, \hat{D})$, we formally define population risk as:

$$f(\widehat{\Theta}) = \mathop{\mathbb{E}}_{\{x_t\},\{\xi_t\}}\left[\frac{1}{T}\sum_{t=1}^{T}\|\hat{y}_t - y_t\|^2\right] \tag{1.3}$$

Note that even though the prediction $\hat{y}_t$ is generated from the correct initial state, the learning algorithm does not have access to the correct initial state for its training sequences.

While the squared loss objective turns out to be non-convex, it has many appealing properties. Assuming the inputs x_t and errors ξ_t are drawn independently from a Gaussian distribution, the corresponding population objective corresponds to maximum likelihood estimation. In this work, we make the weaker assumption that the inputs and errors are drawn independently from possibly different distributions. The independence assumption is certainly idealized for some learning applications. However, in control applications the inputs can often be chosen by the controller rather than by nature. Moreover, the outputs of the system at various time steps are correlated through the unknown hidden state and therefore not independent even if the inputs are.

1.1 Our results

We show that we can efficiently minimize the population risk using projected stochastic gradient descent. The bulk of our work applies to single-input single-output (SISO) systems meaning that inputs and outputs are scalars $x_t, y_t \in \mathbb{R}$. However, the hidden state can have arbitrary dimension n. Every controllable SISO admits a convenient canonical form called *controllable canonical form* that we formally introduce later in Section 1.7. In this canonical form, the transition matrix A is governed by n parameters $a_1, \ldots, a_n$ which coincide with the coefficients of the characteristic polynomial of A. The minimal assumption under which we might hope to learn the system is that the spectral radius of A is smaller than 1. However, the set of such matrices is non-convex and does not have enough structure for our analysis.[1] We will therefore make additional assumptions. The assumptions we need differ between the case where we are trying to learn A with n parameter system, and the case where we allow ourselves to over-specify the trained model with $n' > n$ parameters. The former is sometimes called proper learning, while the latter is called improper learning. In the improper case, we are essentially able to learn any system with spectral radius less than 1 under a mild separation condition on the roots of the characteristic polynomial. Our assumption in the proper case is stronger and we introduce it next.

1. In both the controllable canonical form and the standard parameterization of the matrix A, the set of matrices with spectral radius less than 1 is not convex.

1.2 Proper learning

Suppose the state transition matrix A has characteristic polynomial $\det(zI - A) = z^n + a_1 z^{n-1} + \cdots + a_n$, which turns out to by and large decide the difficulty of the learning according to our analysis. (In fact, we will parameterize A in a way so that the coefficients of the characteristic polynomials are the parameters of learning problem. See Section 1.7 for the detailed setup.) Consider the corresponding polynomial $q(z) = 1 + a_1 z + a_2 z^2 + \cdots + a_n z^n$ over the complex numbers $\mathbb{C}$.

We will require the state transition matrix satisfy that the image of the unit circle on the complex plane under the polynomial q is contained in the cone of complex numbers whose real part is larger than their absolute imaginary part. Formally, for all $z \in \mathbb{C}$ such that $|z| = 1$, we require that $\Re(q(z)) > |\Im(q(z))|$. Here, $\Re(z)$ and $\Im(z)$ denote the real and imaginary part of z, respectively. We illustrate this condition in Figure 1 on the right for a degree 4 system.

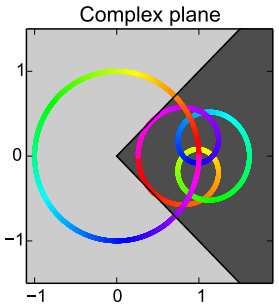

Figure 1: An example of polynomial q that satisfies our assumption. The unit circle is the collection of the inputs of q and the other curve shows the corresponding outputs (with the corresponding colors.) We see the image of the polynomial stays in the wedge which contains all the complex number z satisfying $\Re(q(z)) > |\Im(q(z))|$.

Our assumption has three important implications. First, it implies (via Rouché's theorem) that the spectral radius of A is smaller than 1 and therefore ensures the stability of the system. Second, the vectors satisfying our assumption form a convex set in $\mathbb{R}^n$. Finally, it ensures that the objective function is *weakly quasi-convex*, a condition we introduce later when we show that it enables stochastic gradient descent to make sufficient progress.

We note in passing that our assumption can be satisfied via the ℓ_1-norm constraint $\|a\|_1 \le \sqrt{2}/2$. Moreover, if we pick random Gaussian coefficients with expected norm bounded by $o(1/\sqrt{\log n})$, then the resulting vector will satisfy our assumption with probability $1 - o(1)$. Roughly speaking, the assumption requires the roots of the characteristic polynomial $p(z) = z^n + a_1 z^{n-1} + \cdots + a_n$ are relatively dispersed inside the unit circle. (For comparison, on the other end of the spectrum, the polynomial $p(z) = (z - 0.99)^n$ have all its roots colliding at the same point and doesn't satisfy the assumption.)

Theorem 1.1 (Informal) *Under our assumption, projected stochastic gradient descent, when given N sample sequence of length T, returns parameters $\widehat{\Theta}$ with population risk*

$$\mathbb{E}\, f(\widehat{\Theta}) \le f(\Theta) + O\left(\sqrt{\frac{n^5 + \sigma^2 n^3}{TN}}\right).$$

Here the expectation on LHS is with respect to the randomness of the algorithm. Recall that $f(\Theta)$ is the population risk of the optimal system, and σ^2 refers to the variance of the noise variables. We also assume that the inputs x_t are drawn from a pairwise independent distribution with mean 0 and variance 1. Note, however, that this does not imply

independence of the outputs as these are correlated by a common hidden state. The stated version of our result glosses over the fact that we need our assumption to hold with a small amount of slack; a precise version follows in Section 4. Our theorem establishes a polynomial convergence rate for stochastic gradient descent. Since each iteration of the algorithm only requires a sequence of matrix operations and an efficient projection step, the running time is polynomial, as well. Likewise, the sample requirements are polynomial since each iteration requires only a single fresh example. An important feature of this result is that the error decreases with both the length T and the number of samples N. The dependency on the dimension n, on the other hand, is likely to be quite loose, and tighter bounds are left for future work.

The algorithm requires a (polynomial-time) projection step to a convex set at every iteration (formally defined in Section 4 and Algorithm 1). Computationally, it can be a bottleneck, although it is unlikely to be required in practice and may be an artifact of our analysis.

1.3 The power of over-parameterization

Endowing the model with additional parameters compared to the ground truth turns out to be surprisingly powerful. We show that we can essentially remove the assumption we previously made in proper learning. The idea is simple. If p is the characteristic polynomial of A of degree n. We can find a system of order $n' > n$ such that the characteristic polynomial of its transition matrix becomes $p \cdot p'$ for some polynomial p' of order $n' - n$. This means that to apply our result we only need the polynomial $p \cdot p'$ to satisfy our assumption. At this point, we can choose p' to be an approximation of the inverse p^{-1}. For sufficiently good approximation, the resulting polynomial $p \cdot p'$ is close to 1 and therefore satisfies our assumption. Such an approximation exists generically for $n' = O(n)$ under mild non-degeneracy assumptions on the roots of p. In particular, any small random perturbation of the roots would suffice.

Theorem 1.2 (Informal) *Under a mild non-degeneracy assumption, stochastic gradient descent returns parameters $\widehat{\Theta}$ corresponding to a system of order $n' = O(n)$ with population risk*

$$f(\widehat{\Theta}) \leq f(\Theta) + O\left(\sqrt{\frac{n^5 + \sigma^2 n^3}{TN}}\right),$$

when given N sample sequences of length T.

We remark that the idea we sketched also shows that, in the extreme, improper learning of linear dynamical systems becomes easy in the sense that the problem can be solved using linear regression against the outputs of the system. However, our general result interpolates between the proper case and the regime where linear regression works. We discuss in more details in Section 6.3.

1.4 Multi-input multi-output systems

Both results we saw immediately extend to single-input multi-output (SIMO) systems as the dimensionality of C and D are irrelevant for us. The case of multi-input multi-output

(MIMO) systems is more delicate. Specifically, our results carry over to a broad family of multi-input multi-output systems. However, in general MIMO systems no longer enjoy canonical forms like SISO systems. In Section 7, we introduce a natural generalization of controllable canonical form for MIMO systems and extend our results to this case.

1.5 Related work

System identification is a core problem in dynamical systems and has been studied in depth for many years. The most popular reference on this topic is the text by Ljung Ljung (1998). Nonetheless, the list of non-asymptotic results on identifying linear systems from noisy data is surprisingly short. Several authors have recently tried to estimate the sample complexity of dynamical system identification using machine learning tools Vidyasagar and Karandikar (2008); Campi and Weyer (2002); Weyer and Campi (1999). All of these result are rather pessimistic with sample complexity bounds that are exponential in the degree of the linear system and other relevant quantities. Contrastingly, we prove that gradient descent has an associated polynomial sample complexity in all of these parameters. Moreover, all of these papers only focus on how well empirical risk approximates the true population risk and do not provide guarantees about any algorithmic schemes for minimizing the empirical risk.

The only result to our knowledge which provides polynomial sample complexity for identifying linear dynamical systems is in Shah *et al* Shah et al. (2012). Here, the authors show that if certain *frequency domain* information about the linear dynamical system is observed, then the linear system can be identified by solving a second-order cone programming problem. This result is about improper learning only, and the size of the resulting system may be quite large, scaling as the $(1 - \rho(A))^{-2}$. As we describe in this work, very simple algorithms work in the improper setting when the system degree is allowed to be polynomial in $(1 - \rho(A))^{-1}$. Moreover, it is not immediately clear how to translate the frequency-domain results to the time-domain identification problem discussed above.

Our main assumption about the image of the polynomial $q(z)$ is an appeal to the theory of passive systems. A system is passive if the dot product between the input sequence u_t and output sequence y_t are strictly positive. Physically, this notion corresponds to systems that cannot create energy. For example, a circuit made solely of resistors, capacitors, and inductors would be a passive electrical system. If one added an amplifier to the internals of the system, then it would no longer be passive. The set of passive systems is a subset of the set of stable systems, and the subclass is somewhat easier to work with mathematically. Indeed, Megretski used tools from passive systems to provide a relaxation technique for a family of identification problems in dynamical systems Megretski (2008). His approach is to lower bound a nonlinear least-squares cost with a convex functional. However, he does not prove that his technique can identify any of the systems, even asymptotically. Stoica and Söderström Söderström and Stoica (1982); Stoica and Söderström (1982, 1984) and later Bazanella *et al.* Bazanella et al. (2008); Eckhard and Bazanella (2011) prove the quasi-convexity of a cost function under a passivity condition in the context of system identification, but no sample complexity or global convergence proofs are provided.

1.6 Proof overview

The first important step in our proof is to develop population risk in Fourier domain where it is closely related to what we call *idealized risk*. Idealized risk essentially captures the ℓ_2-difference between the *transfer function* of the learned system and the ground truth. The transfer function is a fundamental object in control theory. Any linear system is completely characterized by its transfer function $G(z) = C(zI - A)^{-1}B$. In the case of a SISO, the transfer function is a rational function of degree n over the complex numbers and can be written as $G(z) = s(z)/p(z)$. In the canonical form introduced in Section 1.7, the coefficients of $p(z)$ are precisely the parameters that specify A. Moreover, $z^n p(1/z) = 1 + a_1 z + a_2 z^2 + \cdots + a_n z^n$ is the polynomial we encountered in the introduction. Under the assumption illustrated earlier, we show in Section 3 that the idealized risk is *weakly quasi-convex* (Lemma 3.3). Quasi-convexity implies that gradients cannot vanish except at the optimum of the objective function; we review this (mostly known) material in Section 2. In particular, this lemma implies that in principle we can hope to show that gradient descent converges to a global optimum. However, there are several important issues that we need to address. First, the result only applies to idealized risk, not our actual population risk objective. Therefore it is not clear how to obtain unbiased gradients of the idealized risk objective. Second, there is a subtlety in even defining a suitable empirical risk objective. The reason is that risk is defined with respect to the correct initial state of the system which we do not have access to during training. We overcome both of these problems. In particular, we design an almost unbiased estimator of the gradient of the idealized risk in Lemma 5.4 and give variance bounds of the gradient estimator (Lemma 5.5).

Our results on improper learning in Section 6 rely on a surprisingly simple but powerful insight. We can extend the degree of the transfer function $G(z)$ by extending both numerator and denominator with a polynomial $u(z)$ such that $G(z) = s(z)u(z)/p(z)u(z)$. While this results in an equivalent system in terms of input-output behavior, it can dramatically change the geometry of the optimization landscape. In particular, we can see that only $p(z)u(z)$ has to satisfy the assumption of our proper learning algorithm. This allows us, for example, to put $u(z) \approx p(z)^{-1}$ so that $p(z)u(z) \approx 1$, hence trivially satisfying our assumption. A suitable inverse approximation exists under light assumptions and requires degree no more than $d = O(n)$. Algorithmically, there is almost no change. We simply run stochastic gradient descent with $n + d$ model parameters rather than n model parameters.

1.7 Preliminaries

For complex matrix (or vector, number) C, we use $\Re(C)$ to denote the real part and $\Im(C)$ the imaginary part, and $\bar{C}$ the conjugate and $C^* = \bar{C}^\top$ its conjugate transpose . We use $|\cdot|$ to denote the absolute value of a complex number c. For complex vector u and v, we use $\langle u, v\rangle = u^* v$ to denote the inner product and $\|u\| = \sqrt{u^* u}$ is the norm of u. For complex matrix A and B with same dimension, $\langle A, B\rangle = \mathrm{tr}(A^* B)$ defines an inner product, and $\|A\|_F = \sqrt{\mathrm{tr}(A^* A)}$ is the Frobenius norm. For a square matrix A, we use $\rho(A)$ to denote the spectral radius of A, that is, the largest absolute value of the elements in the spectrum of A. We use I_n to denote the identity matrix with dimension $n \times n$, and we drop the subscript when it's clear from the context.We let e_i denote the i-th standard basis vector.

A SISO of order n is in *controllable canonical form* if A and B have the following form

$$A = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ -a_n & -a_{n-1} & -a_{n-2} & \cdots & -a_1 \end{bmatrix} \qquad B = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix} \tag{1.4}$$

We will parameterize $\hat{A}, \hat{B}, \hat{C}, \hat{D}$ accordingly. We will write $A = \mathrm{CC}(a)$ for brevity, where a is used to denote the unknown last row $[-a_n, \ldots, -a_1]$ of matrix A. We will use $\hat{a}$ to denote the corresponding training variables for a. Since here B is known, so $\hat{B}$ is no longer a trainable parameter, and is forced to be equal to B. Moreover, C is a row vector and we use $[c_1, \cdots, c_n]$ to denote its coordinates (and similarly for $\hat{C}$).

A SISO is *controllable* if and only if the matrix $[B \mid AB \mid A^2 B \mid \cdots \mid A^{n-1}B]$ has rank n. This statement corresponds to the condition that all hidden states should be reachable from some initial condition and input trajectory. Any controllable system admits a controllable canonical form Heij et al. (2007). For vector $a = [a_n, \ldots, a_1]$, let $p_a(z)$ denote the polynomial

$$p_a(z) = z^n + a_1 z^{n-1} + \cdots + a_n \,. \tag{1.5}$$

When a defines the matrix A that appears in controllable canonical form, then p_a is precisely the characteristic polynomial of A. That is, $p_a(z) = \det(zI - A)$.

2. Gradient descent and quasi-convexity

It is known that under certain mild conditions (stochastic) gradient descent converges even on non-convex functions to local minimum Ge et al. (2015); Lee et al. (2016). Though usually for concrete problems the challenge is to prove that there is no spurious local minimum other than the target solution. Here we introduce a condition similar to the quasi-convexity notion in Hazan et al. (2015), which ensures that any point with vanishing gradient is the optimal solution . Roughly speaking, the condition says that at any point θ the negative of the gradient $-\nabla f(\theta)$ should be positively correlated with direction $\theta^* - \theta$ pointing towards the optimum. Our condition is slightly weaker than that in Hazan et al. (2015) since we only require quasi-convexity and smoothness with respect to the optimum, and this (simple) extension will be necessary for our analysis.

Definition 2.1 (Weak quasi-convexity) *We say an objective function f is τ-*weakly-quasi-convex *(*τ*-WQC) over a domain $\mathcal{B}$ with respect to global minimum θ^* if there is a positive constant $\tau > 0$ such that for all $\theta \in \mathcal{B}$,*

$$\nabla f(\theta)^\top (\theta - \theta^*) \geq \tau(f(\theta) - f(\theta^*)) \,. \tag{2.1}$$

We further say f is Γ-weakly-smooth if for for any point θ, $\|\nabla f(\theta)\|^2 \leq \Gamma(f(\theta) - f(\theta^*))$.

Note that indeed any Γ-smooth function in the usual sense (that is, $\|\nabla^2 f\| \leq \Gamma$) is $O(\Gamma)$-weakly-smooth. For a random vector $X \in \mathbb{R}^n$, we define it's variance to be $\mathrm{Var}[X] = \mathbb{E}[\|X - \mathbb{E}X\|^2]$.

Definition 2.2 *We call $\mathfrak{r}(\theta)$ an unbiased estimator of $\nabla f(\theta)$ with variance V if it satisfies $\mathbb{E}[\mathfrak{r}(\theta)] = \nabla f(\theta)$ and $\mathrm{Var}[\mathfrak{r}(\theta)] \le V$.*

Projected stochastic gradient descent over some closed convex set $\mathcal{B}$ with *learning rate* $\eta > 0$ refers to the following algorithm in which $\Pi_{\mathcal{B}}$ denotes the Euclidean projection onto $\mathcal{B}$:

$$\begin{aligned}
&\textbf{for } k = 0 \text{ to } K-1: \\
&\quad w_{k+1} = \theta_k - \eta \mathfrak{r}(\theta_k) \\
&\quad \theta_{k+1} = \Pi_{\mathcal{B}}(w_{k+1}) \\
&\textbf{return } \theta_j \text{ with } j \text{ uniformly picked from } 1, \dots, K
\end{aligned} \tag{2.2}$$

The following Proposition is well known for convex objective functions (corresponding to 1-weakly-quasi-convex functions). We extend it (straightforwardly) to the case when τ-WQC holds with any positive constant τ.

Proposition 2.3 *Suppose the objective function f is τ-weakly-quasi-convex and Γ-weakly-smooth, and $\mathfrak{r}(\cdot)$ is an unbiased estimator for $\nabla f(\theta)$ with variance V. Moreover, suppose the global minimum θ^* belongs to $\mathcal{B}$, and the initial point θ_0 satisfies $\|\theta_0 - \theta^*\| \le R$. Then projected gradient descent (2.2) with a proper learning rate returns θ_K in K iterations with expected error*

$$\mathbb{E} f(\theta_K) - f(\theta^*) \le O\left(\max\left\{\frac{\Gamma R^2}{\tau^2 K}, \frac{R\sqrt{V}}{\tau\sqrt{K}}\right\}\right).$$

Remark 2.4 *It's straightforward to see (from the proof) that the algorithm tolerates inverse exponential bias, namely bias on the order of $\exp(-\Omega(n))$, in the gradient estimator. Technically, suppose $\mathbb{E}[\mathfrak{r}(\theta)] = \nabla f(\theta) \pm \zeta$ then $f(\theta_K) \le O\left(\max\left\{\frac{\Gamma R^2}{\tau^2 K}, \frac{R\sqrt{V}}{\tau\sqrt{K}}\right\}\right) + \mathrm{poly}(K)\cdot\zeta$. Throughout the paper, we assume that the error that we are shooting for is inverse polynomial, namely $1/n^C$ for some absolute constant C, and therefore the effect of inverse exponential bias is negligible.*

We defer the proof of Proposition 2.3 to Appendix A which is a simple variation of the standard convergence analysis of stochastic gradient descent (see, for example, Bottou (1998)). Finally, we note that the sum of two quasi-convex functions may no longer be quasi-convex. However, if a sequence functions is τ-WQC with respect to a common point θ^*, then their sum is also τ-WQC. This follows from the linearity of gradient operation.

Proposition 2.5 *Suppose functions $f_1, \dots, f_n$ are individually τ-weakly-quasi-convex in $\mathcal{B}$ with respect to a common global minimum θ^* , then for non-negative $w_1, \dots, w_n$ the linear combination $f = \sum_{i=1}^n w_i f_i$ is also τ-weakly-quasi-convex with respect to θ^* in $\mathcal{B}$.*

3. Population risk in frequency domain

We next establish conditions under which risk is weakly-quasi-convex. Our strategy is to first approximate the risk functional $f(\widehat{\Theta})$ by what we call *idealized risk*. This approximation

of the objective function is fairly straightforward; we justify it toward the end of the section. We can show that

$$f(\widehat{\Theta}) \approx \|D - \hat{D}\|^2 + \textstyle\sum_{k=0}^{\infty} \left(\hat{C}\hat{A}^k B - CA^k B\right)^2. \tag{3.1}$$

The leading term $\|D - \hat{D}\|^2$ is convex in $\hat{D}$ which appears nowhere else in the objective. It therefore doesn't affect the convergence of the algorithm (up to lower order terms) by virtue of Proposition 2.5, and we restrict our attention to the remaining terms.

Definition 3.1 (Idealized risk) *We define the* idealized risk *as*

$$g(\hat{A}, \hat{C}) = \sum_{k=0}^{\infty} \left(\hat{C}\hat{A}^k B - CA^k B\right)^2. \tag{3.2}$$

We now use basic concepts from control theory (see Heij et al. (2007); Hespanha (2009) for more background) to express the idealized risk (3.2) in Fourier domain. The *transfer function* of the linear system is

$$G(z) = C(zI - A)^{-1}B. \tag{3.3}$$

Note that $G(z)$ is a rational function over the complex numbers of degree n and hence we can find polynomials $s(z)$ and $p(z)$ such that $G(z) = \frac{s(z)}{p(z)}$, with the convention that the leading coefficient of $p(z)$ is 1. In controllable canonical form (1.4), the coefficients of p will correspond to the last row of the A, while the coefficients of s correspond to the entries of C. Also note that

$$G(z) = \sum_{t=1}^{\infty} z^{-t} C A^{t-1} B = \sum_{t=1}^{\infty} z^{-t} r_{t-1}$$

The sequence $r = (r_0, r_1, \dots, r_t, \dots) = (CB, CAB, \dots, CA^tB, \dots)$ is called the *impulse response* of the linear system. The behavior of a linear system is uniquely determined by the impulse response and therefore by $G(z)$. Analogously, we denote the transfer function of the learned system by $\widehat{G}(z) = \hat{C}(zI - \hat{A})^{-1}B = \hat{s}(z)/\hat{p}(z)$. The idealized risk (3.2) is only a function of the impulse response $\hat{r}$ of the learned system, and therefore it is only a function of $\widehat{G}(z)$.

Recall that $C = [c_1, \dots, c_n]$ is defined in Section 1.7. For future reference, we note that by some elementary calculation (see Lemma B.1), we have

$$G(z) = C(zI - A)^{-1}B = \frac{c_1 + \cdots + c_n z^{n-1}}{z^n + a_1 z^{n-1} + \cdots + a_n}, \tag{3.4}$$

which implies that $s(z) = c_1 + \cdots + c_n z^{n-1}$ and $p(z) = z^n + a_1 z^{n-1} + \cdots + a_n$.

With these definitions in mind, we are ready to express idealized risk in Fourier domain.

Proposition 3.2 *Suppose $p_{\hat{a}}(z)$ has all its roots inside unit circle, then the idealized risk $g(\hat{a}, \hat{C})$ can be written in the Fourier domain as*

$$g(\hat{A}, \hat{C}) = \int_0^{2\pi} \left|\widehat{G}(e^{i\theta}) - G(e^{i\theta})\right|^2 \mathrm{d}\theta.$$

Proof Note that $G(e^{i\theta})$ is the Fourier transform of the sequence $\{r_k\}$ and so is $\widehat{G}(e^{i\theta})$ the Fourier transform[2] of $\hat{r}_k$. Therefore by Parseval' Theorem, we have that

$$g(\hat{A},\hat{C}) = \sum_{k=0}^{\infty} \|\hat{r}_k - r_k\|^2 = \int_0^{2\pi} |\widehat{G}(e^{i\theta}) - G(e^{i\theta})|^2 d\theta\,. \tag{3.5}$$

■

3.1 Quasi-convexity of the idealized risk

Now that we have a convenient expression for risk in Fourier domain, we can prove that the idealized risk $g(\hat{A},\hat{C})$ is weakly-quasi-convex when $\hat{a}$ is not so far from the true a in the sense that $p_a(z)$ and $\hat{p}_a(z)$ have an angle less than $\pi/2$ for every z on the unit circle. We will use the convention that a and $\hat{a}$ refer to the parameters that specify A and $\hat{A}$, respectively.

Lemma 3.3 *For $\tau > 0$ and every $\hat{C}$, the idealized risk $g(\hat{A},\hat{C})$ is τ-weakly-quasi-convex over the domain*

$$\mathcal{N}_\tau(a) = \left\{ \hat{a} \in \mathbb{R}^n \colon \Re\left(\frac{p_a(z)}{p_{\hat{a}}(z)}\right) \geq \tau/2, \forall\ z \in \mathbb{C},\ \text{s.t. } |z| = 1 \right\}. \tag{3.6}$$

Proof We first analyze a single term $h = |\widehat{G}(z) - G(z)|^2$. Recall that $\widehat{G}(z) = \hat{s}(z)/\hat{p}(z)$ where $\hat{p}(z) = p_{\hat{a}}(z) = z^n + \hat{a}_1 z^{n-1} + \cdots + \hat{a}_n$. Note that z is fixed and h is a function of $\hat{a}$ and $\hat{C}$. Then it is straightforward to see that

$$\frac{\partial h}{\partial \hat{s}(z)} = 2\Re\left\{ \frac{1}{\hat{p}(z)} \left(\frac{\hat{s}(z)}{\hat{p}(z)} - \frac{s(z)}{p(z)}\right)^* \right\}. \tag{3.7}$$

and

$$\frac{\partial h}{\partial \hat{p}(z)} = -2\Re\left\{ \frac{\hat{s}(z)}{\hat{p}(z)^2} \left(\frac{\hat{s}(z)}{\hat{p}(z)} - \frac{s(z)}{p(z)}\right)^* \right\}. \tag{3.8}$$

Since $\hat{s}(z)$ and $\hat{p}(z)$ are linear in $\hat{C}$ and $\hat{a}$ respectively, by chain rule we have that

$$\begin{aligned}
\langle \frac{\partial h}{\partial \hat{a}}, \hat{a} - a\rangle + \langle \frac{\partial h}{\partial \hat{C}}, \hat{C} - C\rangle &= \frac{\partial h}{\partial \hat{p}(z)} \langle \frac{\partial \hat{p}(z)}{\partial \hat{a}}, \hat{a} - a\rangle + \frac{\partial h}{\partial \hat{s}(z)} \langle \frac{\partial \hat{s}(z)}{\partial \hat{C}}, \hat{C} - C\rangle \\
&= \frac{\partial h}{\partial \hat{p}(z)} (\hat{p}(z) - p(z)) + \frac{\partial h}{\partial \hat{s}(z)} (\hat{s}(z) - s(z))\,.
\end{aligned}$$

2. The Fourier transform exists since $\|r_k\|^2 = \|\hat{C}\hat{A}^k\hat{B}\|^2 \leq \|\hat{C}\|\|\hat{A}^k\|\|\hat{B}\| \leq c\rho(\hat{A})^k$ where c doesn't depend on k and $\rho(\hat{A}) < 1$.

Plugging the formulas (3.7) and (3.8) for $\frac{\partial h}{\partial \hat{s}(z)}$ and $\frac{\partial h}{\partial \hat{p}(z)}$ into the equation above, we obtain that

$$\begin{aligned}
\langle \frac{\partial h}{\partial \hat{a}}, \hat{a} - a\rangle + \langle \frac{\partial h}{\partial \hat{C}}, \hat{C} - C\rangle &= 2\Re\left\{ \frac{-\hat{s}(z)(\hat{p}(z) - p(z)) + \hat{p}(z)(\hat{s}(z) - s(z))}{\hat{p}(z)^2} \left(\frac{\hat{s}(z)}{\hat{p}(z)} - \frac{s(z)}{p(z)}\right)^* \right\} \\
&= 2\Re\left\{ \frac{\hat{s}(z)p(z) - s(z)\hat{p}(z)}{\hat{p}(z)^2} \left(\frac{\hat{s}(z)}{\hat{p}(z)} - \frac{s(z)}{p(z)}\right)^* \right\} \\
&= 2\Re\left\{ \frac{p(z)}{\hat{p}(z)} \left|\frac{\hat{s}(z)}{\hat{p}(z)} - \frac{s(z)}{p(z)}\right|^2 \right\} \\
&= 2\Re\left\{ \frac{p(z)}{\hat{p}(z)} \right\} \left|\widehat{G}(z) - G(z)\right|^2.
\end{aligned}$$

Hence $h = |\widehat{G}(z) - G(z)|^2$ is τ-weakly-quasi-convex with $\tau = 2\min_{|z|=1} \Re\left\{\frac{p(z)}{\hat{p}(z)}\right\}$. This implies our claim, since by Proposition 3.2, the idealized risk g is convex combination of functions of the form $|\widehat{G}(z) - G(z)|^2$ for $|z| = 1$. Moreover, Proposition 2.5 shows that convex combination preserves weak quasi-convexity. ■

For future reference, we also prove that the idealized risk is $O(n^2/\tau_1^4)$-weakly smooth.

Lemma 3.4 *The idealized risk $g(\hat{A},\hat{C})$ is Γ-weakly smooth with $\Gamma = O(n^2/\tau_1^4)$.*

Proof By equation (3.8) and the chain rule we get that

$$\frac{\partial g}{\partial \hat{C}} = \int_{\mathbb{T}} \frac{\partial |\widehat{G}(z) - G(z)|^2}{\partial p(z)} \cdot \frac{\partial p(z)}{\partial \hat{C}} dz = \int_{\mathbb{T}} 2\Re\left\{ \frac{1}{\hat{p}(z)} \left(\frac{\hat{s}(z)}{\hat{p}(z)} - \frac{s(z)}{p(z)}\right)^* \right\} \cdot [1, \ldots, z^{n-1}] dz\,.$$

therefore we can bound the norm of the gradient by

$$\left\| \frac{\partial g}{\partial \hat{C}} \right\|^2 \leq \left(\int_{\mathbb{T}} \left| \frac{\hat{s}(z)}{\hat{p}(z)} - \frac{s(z)}{p(z)} \right|^2 dz \right) \cdot \left(\int_{\mathbb{T}} 4\|[1, \ldots, z^{n-1}]\|^2 \cdot |\frac{1}{p(z)}|^2 dz \right) \leq O(n/\tau_1^2) \cdot g(\hat{A},\hat{C})\,.$$

Similarly, we could show that $\left\|\frac{\partial g}{\partial \hat{a}}\right\|^2 \leq O(n^2/\tau_1^2) \cdot g(\hat{A},\hat{C})$. ■

3.2 Justifying idealized risk

We need to justify the approximation we made in Equation (3.1).

Lemma 3.5 *Assume that ξ_t and x_t are drawn i.i.d. from an arbitrary distribution with mean 0 and variance 1. Then the population risk $f(\widehat{\Theta})$ can be written as,*

$$f(\widehat{\Theta}) = (\hat{D} - D)^2 + \sum_{k=1}^{T-1} \left(1 - \frac{k}{T}\right) \left(\hat{C}\hat{A}^{k-1}B - CA^{k-1}B\right)^2 + \sigma^2\,. \tag{3.9}$$

The idealized risk is upper bound of the population risk $f(\widehat{\Theta})$ according to equation (3.1) and (3.9). We don't have to quantify the gap between them because later in Algorithm 1, we will directly optimize the idealized risk by constructing an estimator of its gradient, and thus the optimization will guarantee a bounded idealized risk which translates to a bounded population risk. See Section 5 for details.

Proof [Proof of Lemma 3.5] Under the distributional assumptions on ξ_t and x_t, we can calculate the objective functions above analytically. We write out $y_t, \hat{y}_t$ in terms of the inputs,

$$y_t = Dx_t + \sum_{k=1}^{t-1} CA^{t-k-1}Bx_k + CA^{t-1}h_0 + \xi_t\,, \qquad \hat{y}_t = \hat{D}x_t + \sum_{k=1}^{t-1} \hat{C}\hat{A}^{t-k-1}\hat{B}x_k + CA^{t-1}h_0\,.$$

Therefore, using the fact that x_t's are independent and with mean 0 and covariance I, the expectation of the error can be calculated (formally by Claim B.2),

$$\mathbb{E}\left[\|\hat{y}_t - y_t\|^2\right] = \|\hat{D} - D\|_F^2 + \textstyle\sum_{k=1}^{t-1} \left\|\hat{C}\hat{A}^{t-k-1}\hat{B} - CA^{t-k-1}B\right\|_F^2 + \mathbb{E}[\|\xi_t\|^2]\,. \tag{3.10}$$

Using $\mathbb{E}[\|\xi_t\|^2] = \sigma^2$, it follows that

$$f(\widehat{\Theta}) = \|\hat{D} - D\|_F^2 + \textstyle\sum_{k=1}^{T-1} \left(1 - \frac{k}{T}\right)\left\|\hat{C}\hat{A}^{k-1}\hat{B} - CA^{k-1}B\right\|_F^2 + \sigma^2\,. \tag{3.11}$$

Recall that under the controllable canonical form (1.4), $B = e_n$ is known and therefore $\hat{B} = B$ is no longer a variable. Then the expected objective function (3.11) simplifies to

$$f(\widehat{\Theta}) = (\hat{D} - D)^2 + \textstyle\sum_{k=1}^{T-1} \left(1 - \frac{k}{T}\right)\left(\hat{C}\hat{A}^{k-1}B - CA^{k-1}B\right)^2 + \sigma^2\,.$$

■

The previous lemma does not yet control higher order contributions present in the idealized risk. This requires additional structure that we introduce in the next section.

4. Effective relaxations of spectral radius

The previous section showed quasi-convexity of the idealized risk. However, several steps are missing towards showing finite sample guarantees for stochastic gradient descent. In particular, we will need to control the variance of the stochastic gradient at any system that we encounter in the training. For this purpose we formally introduce our main assumption now and show that it serves as an effective relaxation of spectral radius. This results below will be used for proving convergence of stochastic gradient descent in Section 5.

Consider the following convex region $\mathcal{C}$ in the complex plane,

$$\mathcal{C} = \{z\colon \Re z \geq (1+\tau_0)|\Im z|\} \cap \{z\colon \tau_1 < \Re z < \tau_2\}\,. \tag{4.1}$$

where $\tau_0, \tau_1, \tau_2 > 0$ are constants that are considered as fixed constant throughout the paper. Our bounds will have polynomial dependency on these parameters. Pictorially, this convex set is pretty much the dark area in Figure 1 (with the corner chopped). This set in $\mathbb{C}$ induces a convex set in the parameter space which is a subset of the transition matrix with spectral radius less than α.

Definition 4.1 *We say a polynomial $p(z)$ is* α-acquiescent *if $\{p(z)/z^n\colon |z| = \alpha\} \subseteq \mathcal{C}$. A linear system with transfer function $G(z) = s(z)/p(z)$ is α-acquiescent if the denominator $p(z)$ is.*

The set of coefficients $a \in \mathbb{R}^n$ defining acquiescent systems form a convex set. Formally, for a positive $\alpha > 0$, define the convex set $\mathcal{B}_\alpha \subseteq \mathbb{R}^n$ as

$$\mathcal{B}_\alpha = \left\{a \in \mathbb{R}^n : \{p_a(z)/z^n\colon |z| = \alpha\} \subseteq \mathcal{C}\right\}. \tag{4.2}$$

We note that definition (4.2) is equivalent to the definition $\mathcal{B}_\alpha = \left\{a \in \mathbb{R}^n : \{z^n p(1/z)\colon |z| = 1/\alpha\} \subseteq \mathcal{C}\right\}$, which is the version that we used in introduction for simplicity. Indeed, we can verify the convexity of $\mathcal{B}_\alpha$ by definition and the convexity of $\mathcal{C}$: $a, b \in B_\alpha$ implies that $p_a(z)/z^n, p_b(z)/z^n \in \mathcal{C}$ and therefore, $p_{(a+b)/2}(z)/z^n = \frac{1}{2}(p_a(z)/z^n + p_b(z)/z^n) \in \mathcal{C}$. We also note that the parameter α in the definition of acquiescence corresponds to the spectral radius of the companion matrix. In particular, an acquiescent system is stable for $\alpha < 1$.

Lemma 4.2 *Suppose $a \in \mathcal{B}_\alpha$, then the roots of polynomial $p_a(z)$ have magnitudes bounded by α. Therefore the controllable canonical form $A = \mathrm{CC}(a)$ defined by a has spectral radius $\rho(A) < \alpha$.*

Proof Define holomorphic function $f(z) = z^n$ and $g(z) = p_a(z) = z^n + a_1 z^{n-1} + \cdots + a_n$. We apply the symmetric form of Rouche's theorem Estermann (1962) on the circle $\mathcal{K} = \{z : |z| = \alpha\}$. For any point z on $\mathcal{K}$, we have that $|f(z)| = \alpha^n$, and that $|f(z) - g(z)| = \alpha^n \cdot |1 - p_a(z)/z^n|$. Since $a \in \mathcal{B}_\alpha$, we have that $p_a(z)/z^n \in \mathcal{C}$ for any z with $|z| = \alpha$. Observe that for any $c \in \mathcal{C}$ we have that $|1 - c| < 1 + |c|$, therefore we have that

$$|f(z) - g(z)| = \alpha^n |1 - p_a(z)/z^n| < \alpha^n(1 + |p_a(z)|/|z^n|) = |f(z)| + |p_a(z)| = |f(z)| + |g(z)|\,.$$

Hence, using Rouche's Theorem, we conclude that f and g have same number of roots inside circle $\mathcal{K}$. Note that function $f = z^n$ has exactly n roots in $\mathcal{K}$ and therefore g have all its n roots inside circle $\mathcal{K}$. ■

The following lemma establishes the fact that $\mathcal{B}_\alpha$ is a monotone family of sets in α. The proof follows from the maximum modulo principle of the harmonic functions $\Re(z^n p(1/z))$ and $\Im(z^n p(1/z))$. We defer the short proof to Section C.1. We remark that there are larger convex sets than $\mathcal{B}_\alpha$ that ensure bounded spectral radius. However, in order to also guarantee monotonicity and the no blow-up property below, we have to restrict our attention to $\mathcal{B}_\alpha$.

Lemma 4.3 (Monotonicity of $\mathcal{B}_\alpha$) *For any $0 < \alpha < \beta$, we have that $\mathcal{B}_\alpha \subset \mathcal{B}_\beta$.*

Our next lemma entails that acquiescent systems have well behaved impulse responses.

Lemma 4.4 (No blow-up property) *Suppose $a \in \mathcal{B}_\alpha$ for some $\alpha \leq 1$. Then the companion matrix $A = \mathrm{CC}(a)$ satisfies*

$$\sum_{k=0}^{\infty} \|\alpha^{-k} A^k B\|^2 \leq 2\pi n \alpha^{-2n}/\tau_1^2. \tag{4.3}$$

Moreover, it holds that for any $k \geq 0$,

$$\|A^k B\|^2 \leq \min\{2\pi n/\tau_1^2, 2\pi n \alpha^{2k-2n}/\tau_1^2\}\,.$$

Proof [Proof of Lemma 4.4]

Let $f_\lambda = \sum_{k=0}^{\infty} e^{i\lambda k}\alpha^{-k}A^k B$ be the Fourier transform of the series $\alpha^{-k}A^k B$. Then using Parseval's Theorem, we have

$$\begin{aligned}\sum_{k=0}^{\infty}\|\alpha^{-k}A^k B\|^2 &= \int_0^{2\pi}|f_\lambda|^2 d\lambda = \int_0^{2\pi}|(I-\alpha^{-1}e^{i\lambda}A)^{-1}B|^2 d\lambda \\ &= \int_0^{2\pi}\frac{\sum_{j=1}^{n}\alpha^{2j}}{|p_a(\alpha e^{-i\lambda})|^2}d\lambda \leq \int_0^{2\pi}\frac{n}{|p_a(\alpha e^{-i\lambda})|^2}d\lambda. \qquad (4.4)\end{aligned}$$

where at the last step we used the fact that $(I-wA)^{-1}B = \frac{1}{p_a(w^{-1})}[w^{-1}, w^{-2}\ldots, z^{-n}]^\top$ (see Lemma B.1), and that $\alpha \leq 1$. Since $a \in \mathcal{B}_\alpha$, we have that $|q_a(\alpha^{-1}e^{i\lambda})| \geq \tau_1$, and therefore $p_a(\alpha e^{-i\lambda}) = \alpha^n e^{-in\lambda}q(e^{i\lambda}/\alpha)$ has magnitude at least $\tau_1\alpha^n$. Plugging in this into equation (4.4), we conclude that

$$\sum_{k=0}^{\infty}\|\alpha^{-k}A^k B\|^2 \leq \int_0^{2\pi}\frac{n}{|p_a(\alpha e^{-i\lambda})|^2}d\lambda \leq 2\pi n\alpha^{-2n}/\tau_1^2.$$

Finally we establish the bound for $\|A^k B\|^2$. By Lemma 4.3, we have $\mathcal{B}_\alpha \subset \mathcal{B}_1$ for $\alpha \leq 1$. Therefore we can pick $\alpha = 1$ in equation (4.3) and it still holds. That is, we have that

$$\sum_{k=0}^{\infty}\|A^k B\|^2 \leq 2\pi n/\tau_1^2.$$

This also implies that $\|A^k B\|^2 \leq 2\pi n/\tau_1^2$. ■

4.1 Efficiently computing the projection

In our algorithm, we require a projection onto $\mathcal{B}_\alpha$. However, the only requirement of the projection step is that it projects onto a set contained inside $\mathcal{B}_\alpha$ that also contains the true linear system. So a variety of subroutines can be used to compute this projection or an approximation. First, the explicit projection onto $\mathcal{B}_\alpha$ is representable by a semidefinite program. This is because each of the three constrains can be checked by testing if a trigonometric polynomial is non-negative. A simple inner approximation can be constructed by requiring the constraints to hold on an a finite grid of size $O(n)$. One can check that this provides a tight, polyhedral approximation to the set $\mathcal{B}_\alpha$, following an argument similar to Appendix C of Bhaskar *et al* Bhaskar et al. (2013). Projection to this polyhedral takes at most $O(n^{3.5})$ time by linear programming and potentially can be made faster by using fast Fourier transform. See Section F for more detailed discussion on why projection on a polytope suffices. Furthermore, sometimes we can replace the constraint by an ℓ_1 or ℓ_2-constraint if we know that the system satisfies the corresponding assumption. Removing the projection step entirely is an interesting open problem.

5. Learning acquiescent systems

Next we show that we can learn acquiescent systems.

Theorem 5.1 *Suppose the true system Θ is α-acquiescent and satisfies $\|C\| \leq 1$. Then with N samples of length $T \geq \Omega(n + 1/(1-\alpha))$, stochastic gradient descent (Algorithm 1) with projection set $\mathcal{B}_\alpha$ returns parameters $\widehat{\Theta} = (\hat{A}, \hat{B}, \hat{C}, \hat{D})$ with population risk*

$$\mathbb{E}\, f(\widehat{\Theta}) \leq f(\Theta) + O\left(\frac{n^2}{N} + \sqrt{\frac{n^5 + \sigma^2 n^3}{TN}}\right), \qquad (5.1)$$

where $O(\cdot)$-notation hides polynomial dependencies on $1/(1-\alpha)$, $1/\tau_0, 1/\tau_1, \tau_2$, and $R = \|a\|$. The expectation is taken over the randomness of the algorithms and the examples.

Algorithm 1 Projected stochastic gradient descent with partial loss

For $i = 0$ to N:

1. Take a fresh sample $((x_1, \ldots, x_T), (y_1, \ldots, y_T))$. Let $\tilde{y}_t$ be the simulated outputs[3] of system $\widehat{\Theta}$ on inputs x and initial states $h_0 = 0$.
2. Let $T_1 = T/4$. Run stochastic gradient descent[4] on loss function $\ell((x,y),\widehat{\Theta}) = \frac{1}{T-T_1}\sum_{t>T_1}\|\tilde{y}_t - y_t\|^2$. Concretely, let $G_A = \frac{\partial \ell}{\partial \hat{a}}$, $G_C = \frac{\partial \ell}{\partial \hat{C}}$, and , $G_D = \frac{\partial \ell}{\partial \hat{D}}$, we update
$$[\hat{a}, \hat{C}, \hat{D}] \to [\hat{a}, \hat{C}, \hat{D}] - \eta[G_A, G_C, G_D]\,.$$
3. Project $\widehat{\Theta} = (\hat{a}, \hat{C}, \hat{D})$ to the set $\mathcal{B}_\alpha \otimes \mathbb{R}^n \otimes \mathbb{R}$.

Recall that T is the length of the sequence and N is the number of samples. The first term in the bound (5.1) comes from the smoothness of the population risk and the second comes from the variance of the gradient estimator of population risk (which will be described in detail below). An important (but not surprising) feature here is the variance scale in $1/T$ and therefore for long sequence actually we got $1/N$ convergence instead of $1/\sqrt{N}$ (for relatively small N).

Computational complexity: Step 2 in each iteration of the algorithm takes $O(Tn)$ arithmetic operations, and the projection step takes $O(n^{3.5})$ time to solve an linear programming problem. The project step is unlikely to be required in practice and may be an artifact of our analysis.

We can further balance the variance of the estimator with the number of samples by breaking each long sequence of length T into $\Theta(T/n)$ short sequences of length $\Theta(n)$, and then run back-propagation (1) on these TN/n shorter sequences. This leads us to the following bound which gives the right dependency in T and N as we expected: TN should be counted as the true number of samples for the sequence-to-sequence model.

4. Note that $\tilde{y}_t$ is different from $\hat{y}_t$ defined in equation (1.2) which is used to define the population risk: here $\hat{y}_t$ is obtained from the (wrong) initial state $h_0 = 0$ while $\hat{y}_t$ is obtained from the correct initial state.
4. See Algorithm Box 3 for a detailed back-propagation algorithm that computes the gradient.

Corollary 5.2 *Under the assumption of Theorem 5.1, Algorithm 2 returns parameters* $\widehat{\Theta}$ *with population risk*

$$\mathbb{E}\, f(\widehat{\Theta}) \le f(\Theta) + O\left(\sqrt{\frac{n^5+\sigma^2 n^3}{TN}}\right),$$

where $O(\cdot)$*-notation hides polynomial dependencies on* $1/(1-\alpha)$, $1/\tau_0, 1/\tau_1, \tau_2$, *and* $R = \|a\|$.

Algorithm 2 Projected stochastic gradient descent for long sequences
Input: N samples sequences of length T
Output: Learned system $\widehat{\Theta}$

1. Divide each sample of length T into $T/(\beta n)$ samples of length βn where β is a large enough constant. Then run algorithm 1 with the new samples and obtain $\widehat{\Theta}$.

We remark the the gradient computation procedure takes time linear in Tn since one can use chain-rule (also called back-propagation) to compute the gradient efficiently . For completeness, Algorithm 3 gives a detailed implementation. Finally and importantly, we remark that although we defined the population risk as the expected error with respected to sequence of length T, actually our error bound generalizes to any longer (or shorter) sequences of length $T' \gg \max\{n, 1/(1-\alpha)\}$. By the explicit formula for $f(\widehat{\Theta})$ (Lemma 3.5) and the fact that $\|CA^kB\|$ decays exponentially for $k \gg n$ (Lemma 4.4), we can bound the population risk on sequences of different lengths. Concretely, let $f_{T'}(\widehat{\Theta})$ denote the population risk on sequence of length T', we have for all $T' \gg \max\{n, 1/(1-\alpha)\}$,

$$f_{T'}(\widehat{\Theta}) \le 1.1 f(\widehat{\Theta}) + \exp(-(1-\alpha)\min\{T, T'\}) \le O\left(\sqrt{\frac{n^5+\sigma^2 n^3}{TN}}\right).$$

We note that generalization to longer sequence does deserve attention. Indeed in practice, it's usually difficult to train non-linear recurrent networks that generalize to longer sequences than the training data.

We could hope to achieve linear convergence by showing that the empirical risk also satisfies the weakly-quasi-convexity. Then, we can re-use the samples and hope to use strong optimization tools (such as SVRG) to achieve the linear convergence. This is beyond the scope of this paper and left to future work.

Our proof of Theorem 5.1 simply consists of three parts: a) showing the idealized risk is weakly quasi-convex in the convex set $\mathcal{B}_\alpha$ (Lemma 5.3); b) designing an (almost) unbiased estimator of the gradient of the idealized risk (Lemma 5.4); c) variance bounds of the gradient estimator (Lemma 5.5).

First of all, using the theory developed in Section 3 (Lemma 3.3 and Lemma 3.4), it is straightforward to verify that in the convex set $\mathcal{B}_\alpha \otimes \mathbb{R}^n$, the idealized risk is both weakly-quasi-convex and weakly-smooth.

Lemma 5.3 *Under the condition of Theorem 5.1, the idealized risk* (3.2) *is* τ*-weakly-quasi-convex in the convex set* $\mathcal{B}_\alpha \otimes \mathbb{R}^n$ *and* Γ*-weakly smooth, where* $\tau = \Omega(\tau_0\tau_1/\tau_2)$ *and* $\Gamma = O(n^2/\tau_1^4)$.

Proof [Proof of Lemma 5.3] It suffices to show that for all $\hat{a}, a \in \mathcal{B}_\alpha$, it satisfies $\hat{a} \in \mathcal{N}_\tau(a)$ for $\tau = \Omega(\tau_0\tau_1/\tau_2)$. Indeed, by the monotonicity of the family of sets $\mathcal{B}_\alpha$ (Lemma 4.3), we have that $\hat{a}, a \in \mathcal{B}_1$, which by definition means for every z on unit circle, $p_a(z)/z^n, p_{\hat{a}}(z)/z^n \in \mathcal{C}$. By definition of $\mathcal{C}$, for any point $w, \hat{w} \in \mathcal{C}$, the angle ϕ between w and $\hat{w}$ is at most $\pi - \Omega(\tau_0)$ and ratio of the magnitude is at least τ_1/τ_2, which implies that $\Re(w/\hat{w}) = |w|/|\hat{w}| \cdot \cos(\phi) \ge \Omega(\tau_0\tau_1/\tau_2)$. Therefore $\Re(p_a(z)/p_{\hat{a}}(z)) \ge \Omega(\tau_0\tau_1/\tau_2)$, and we conclude that $\hat{a} \in \mathcal{N}_\tau(a)$. The smoothness bound was established in Lemma 3.4. ■

Towards designing an unbiased estimator of the gradient, we note that there is a small caveat here that prevents us to just use the gradient of the empirical risk, as commonly done for other (static) problems. Recall that the population risk is defined as the expected risk with *known* initial state h_0, while in the training we don't have access to the initial states and therefore using the naive approach we couldn't even estimate population risk from samples without knowing the initial states.

We argue that being able to handle the missing initial states is indeed desired: in most of the interesting applications h_0 is unknown (or even to be learned). Moreover, the ability of handling unknown h_0 allows us to break a long sequence into shorter sequences, which helps us to obtain Corollary 5.2. Here the difficulty is essentially that we have a supervised learning problem with missing data h_0. We get around it by simply ignoring first $T_1 = \Omega(T)$ outputs of the system and setting the corresponding errors to 0. Since the influence of h_0 to any outputs later than time $k \ge T_1 \gg \max\{n, 1/(1-\alpha)\}$ is inverse exponentially small, we could safely assume $h_0 = 0$ when the error earlier than time T_1 is not taken into account.

This small trick also makes our algorithm suitable to the cases when these early outputs are actually not observed. This is indeed an interesting setting, since in many sequence-to-sequence model Sutskever et al. (2014), there is no output in the first half fraction of iterations (of course these models have non-linear operation that we cannot handle).

The proof of the correctness of the estimator is almost trivial and deferred to Section C.

Lemma 5.4 *Under the assumption of Theorem 5.1, suppose* $\hat{a}, a \in \mathcal{B}_\alpha$. *Then in Algorithm 1, at each iteration,* G_A, G_C *are unbiased estimators of the gradient of the idealized risk* (3.2) *in the sense that:*

$$\mathbb{E}\,[G_A, G_C] = \left[\frac{\partial g}{\partial \hat{a}}, \frac{\partial g}{\partial \hat{C}}\right] \pm \exp(-\Omega((1-\alpha)T)). \tag{5.2}$$

Finally, we control the variance of the gradient estimator.

Lemma 5.5 *The (almost) unbiased estimator* (G_A, G_C) *of the gradient of* $g(\hat{A}, \hat{C})$ *has variance bounded by*

$$\mathrm{Var}\,[G_A] + \mathrm{Var}\,[G_C] \le \frac{O\left(n^3\Lambda^2/\tau_1^6 + \sigma^2 n^2 \Lambda/\tau_1^4\right)}{T}.$$

where $\Lambda = O(\max\{n, 1/(1-\alpha)\log 1/(1-\alpha)\})$.

Note that Lemma 5.5 does not directly follow from the Γ-weakly-smoothness of the population risk, since it's not clear whether the loss function $\ell((x,y),\widehat{\Theta})$ is also Γ-smooth for every sample. Moreover, even if it could work out, from smoothness the variance bound can be only as small as Γ^2, while the true variance scales linearly in $1/T$. Here the discrepancy comes from that smoothness implies an upper bound of the expected squared norm of the gradient, which is equal to the variance plus the expected squared mean. Though typically for many other problems variance is on the same order as the squared mean, here for our sequence-to-sequence model, actually the variance decreases in length of the data, and therefore the bound of variance from smoothness is pessimistic.

We bound directly the variance instead. It's tedious but simple in spirit. We mainly need Lemma 4.4 to control various difference sums that shows up from calculating the expectation. The only tricky part is to obtain the $1/T$ dependency which corresponds to the cancellation of the contribution from the cross terms. In the proof we will basically write out the variance as a (complicated) function of $\hat{A},\hat{C}$ which consists of sums of terms involving $(\hat{C}\hat{A}^kB - CA^kB)$ and $\hat{A}^kB$. We control these sums using Lemma 4.4. The proof is deferred to Section C.

Finally we are ready to prove Theorem 5.1. We essentially just combine Lemma 5.3, Lemma 5.4 and Lemma 5.5 with the generic convergence Proposition 2.3. This will give us low error in idealized risk and then we relate the idealized risk to the population risk.

Proof [Proof of Theorem 5.1] We consider $g'(\hat{A},\hat{C},\hat{D}) = (\hat{D}-D)^2 + g(\hat{A},\hat{C})$, an extended version of the idealized risk which takes the contribution of $\hat{D}$ into account. By Lemma 5.4 we have that Algorithm 1 computes G_A, G_C which are almost unbiased estimators of the gradients of g' up to negligible error $\exp(-\Omega((1-\alpha)T))$, and by Lemma C.2 we have G_D is an unbiased estimator of g' with respect to $\hat{D}$. Moreover by Lemma 5.5, these unbiased estimator has total variance $V = \frac{O(n^5+\sigma^2n^3)}{T}$ where $O(\cdot)$ hides dependency on τ_1 and $(1-\alpha)$. Applying Proposition 2.3 (which only requires an unbiased estimator of the gradient of g'), we obtain that after T iterations, we converge to a point with $g'(\hat{a},\hat{C},\hat{D}) \le O\left(\frac{n^2}{N} + \sqrt{\frac{n^5+\sigma^2n^3}{TN}}\right)$. Then, by Lemma 3.5 we have $f(\widehat{\Theta}) \le g'(\hat{a},\hat{C},\hat{D}) + \sigma^2 = g'(\hat{a},\hat{C},\hat{D}) + f(\Theta) \le O\left(\frac{n^2}{N} + \sqrt{\frac{n^5+\sigma^2n^3}{TN}}\right) + f(\Theta)$ which completes the proof. ■

6. The power of improper learning

We observe an interesting and important fact about the theory in Section 5: it solely requires a condition on the characteristic function $p(z)$. This suggests that the geometry of the training objective function depends mostly on the denominator of the transfer function, even though the system is uniquely determined by the transfer function $G(z) = s(z)/p(z)$. This might seem to be an undesirable discrepancy between the behavior of the system and our analysis of the optimization problem.

However, we can actually exploit this discrepancy to design improper learning algorithms that succeed under much weaker assumptions. We rely on the following simple observation about the invariance of a system $G(z) = \frac{s(z)}{p(z)}$. For an arbitrary polynomial $u(z)$ of leading

coefficient 1, we can write $G(z)$ as

$$G(z) = \frac{s(z)u(z)}{p(z)u(z)} = \frac{\tilde{s}(z)}{\tilde{p}(z)}\,,$$

where $\tilde{s} = su$ and $\tilde{p} = pu$. Therefore the system $\tilde{s}(z)/\tilde{p}(z)$ has identical behavior as G. Although this is a redundant representation of $G(z)$, it should counted as an acceptable solution. After all, learning the minimum representation[5] of linear system is impossible in general. In fact, we will encounter an example in Section 6.1.

While not changing the behavior of the system, the extension from $p(z)$ to $\tilde{p}(z)$, does affect the geometry of the optimization problem. In particular, if $\tilde{p}(z)$ is now an α-acquiescent characteristic polynomial as defined in Definition 4.1, then we could find it simply using stochastic gradient descent as shown in Section 5. Observe that we don't require knowledge of $u(z)$ but only its existence. Denoting by d the degree of u, the algorithm itself is simply stochastic gradient descent with $n+d$ model parameters instead of n.

Our discussion motivates the following definition.

Definition 6.1 *A polynomial $p(z)$ of degree n is* α-acquiescent by extension of degree d *if there exists a polynomial $u(z)$ of degree d and leading coefficient 1 such that $p(z)u(z)$ is α-acquiescent.*

For a transfer function $G(z)$, we define it's $\mathcal{H}_2$ norm as

$$\|G\|_{\mathcal{H}_2}^2 = \frac{1}{2\pi}\int_0^{2\pi} |G(e^{i\theta})|^2 d\theta\,.$$

We assume (with loss of generality) that the true transfer function $G(z)$ has bounded $\mathcal{H}_2$ norm, that is, $\|G\|_{\mathcal{H}_2} \le 1$. This can be achieve by a rescaling[6] of the matrix C.

Theorem 6.2 *Suppose the true system has transfer function $G(z) = s(z)/p(z)$ with a characteristic function $p(z)$ that is α-acquiescent by extension of degree d, and $\|G\|_{\mathcal{H}_2} \le 1$, then projected stochastic gradient descent with $m = n+d$ states (that is, Algorithm 2 with m states) returns a system $\widehat{\Theta}$ with population risk*

$$f(\widehat{\Theta}) \le O\left(\sqrt{\frac{m^5+\sigma^2m^3}{TK}}\right)\,.$$

where the $O(\cdot)$ notation hides polynomial dependencies on $\tau_0, \tau_1, \tau_2, 1/(1-\alpha)$.

The theorem follows directly from Corollary 5.2 (with some additional care about the scaling.

Proof [Proof of Theorem 6.2] Let $\tilde{p}(z) = p(z)u(z)$ be the acquiescent extension of $p(z)$. Since $\tau_2 \ge |u(z)p(z)| = |\tilde{p}(z)| \ge \tau_0$ on the unit circle, we have that $|\tilde{s}(z)| = |s(z)||u(z)| =$

5. The minimum representation of a transfer function $G(z)$ is defined as the representation $G(z) = s(z)/p(z)$ with $p(z)$ having minimum degree.
6. In fact, this is a natural scaling that makes comparing error easier. Recall that the population risk is essentially $\|\hat{G} - G\|_{\mathcal{H}_2}$, therefore rescaling C so that $\|G\|_{\mathcal{H}_2} = 1$ implies that when error $\ll 1$ we achieve non-trivial performance.

$s(z) \cdot O_\tau(1/p(z))$. Therefore we have that $\tilde{s}(z)$ satisfies that $\|\tilde{s}\|_{\mathcal{H}_2} = O_\tau(\|s(z)/p(z)\|_{\mathcal{H}_2}) = O_\tau(\|G(z)\|_{\mathcal{H}_2}) \le O_\tau(1)$. That means that the vector C that determines the coefficients of $\tilde{s}$ satisfies that $\|C\| \le O_\tau(1)$, since for a polynomial $h(z) = b_0 + \cdots + b_{n-1}z^{n-1}$, we have $\|h\|_{\mathcal{H}_2} = \|b\|$. Therefore we can apply Corollary 5.2 to complete the proof. ■

In the rest of this section, we discuss in subsection 6.1 the instability of the minimum representation in subsection, and in subsection 6.2 we show several examples where the characteristic function $p(z)$ is not α-acquiescent but is α-acquiescent by extension with small degree d.

As a final remark, the examples illustrated in the following sub-sections may be far from optimally analyzed. It is beyond the scope of this paper to understand the optimal condition under which $p(z)$ is acquiescent by extension.

6.1 Instability of the minimum representation

We begin by constructing a contrived example where the minimum representation of $G(z)$ is not stable at all and as a consequence one can't hope to recover the minimum representation of $G(z)$.

Consider $G(z) = \frac{s(z)}{p(z)} := \frac{z^n - 0.8^{-n}}{(z-0.1)(z^n - 0.9^{-n})}$ and $G'(z) = \frac{s'(z)}{p'(z)} := \frac{1}{z-0.1}$. Clearly these are the minimum representations of the $G(z)$ and $G'(z)$, which also both satisfy acquiescence. On the one hand, the characteristic polynomial $p(z)$ and $p'(z)$ are very different. On the other hand, the transfer functions $G(z)$ and $G'(z)$ have almost the same values on unit circle up to exponentially small error,

$$|G(z) - G'(z)| \le \frac{0.8^{-n} - 0.9^{-n}}{(z-0.1)(z-0.9^{-n})} \le \exp(-\Omega(n)) .$$

Moreover, the transfer functions $G(z)$ and $\hat{G}(z)$ are on the order of $\Theta(1)$ on unit circle. These suggest that from an (inverse polynomially accurate) approximation of the transfer function $G(z)$, we cannot hope to recover the minimum representation in any sense, even if the minimum representation satisfies acquiescence.

6.2 Power of improper learning in various cases

We illustrate the use of improper learning through various examples below.

6.2.1 Example: artificial construction

We consider a simple contrived example where improper learning can help us learn the transfer function dramatically. We will show an example of characteristic function which is not 1-acquiescent but $(\alpha+1)/2$-$(\alpha+1)/2$-acquiescent by extension of degree 3.

Let n be a large enough integer and α be a constant. Let $J = \{1, n-1, n\}$ and $\omega = e^{2\pi i/n}$, and then define $p(z) = z^3 \prod_{j\in[n], j\notin J}(z - \alpha\omega^j)$. Therefore we have that

$$p(z)/z^n = z^3 \prod_{j\in[n], j\in J}(1 - \alpha\omega^j/z) = \frac{1 - \alpha^n/z^n}{(1-\omega/z)(1-\omega^{-1}/z)(1-1/z)} \tag{6.1}$$

Taking $z = e^{-i\pi/2}$ we have that $p(z)/z^n$ has argument (phase) roughly $-3\pi/4$, and therefore it's not in $\mathcal{C}$, which implies that $p(z)$ is *not* 1-acquiescent. On the other hand, picking $u(z) = (z-\omega)(z-1)(z-\omega^{-1})$ as the helper function, from equation (6.1) we have $p(z)u(z)/z^{n+3} = 1 - \alpha^n/z^n$ takes values inverse exponentially close to 1 on the circle with radius $(\alpha+1)/2$. Therefore $p(z)u(z)$ is $(\alpha+1)/2$-acquiescent.

6.2.2 Example: characteristic function with separated roots

A characteristic polynomial with well separated roots will be acquiescent by extension. Our bound will depend on the following quantity of p that characterizes the separateness of the roots.

Definition 6.3 *For a polynomial $h(z)$ of degree n with roots $\lambda_1, \ldots, \lambda_n$ inside unit circle, define the quantity $\Gamma(\cdot)$ of the polynomial h as:*

$$\Gamma(h) := \sum_{j\in[n]} \left| \frac{\lambda_j^n}{\prod_{i\neq j}(\lambda_i - \lambda_j)} \right| .$$

Lemma 6.4 *Suppose $p(z)$ is a polynomial of degree n with distinct roots inside circle with radius α. Let $\Gamma = \Gamma(p)$, then $p(z)$ is α-acquiescent by extension of degree $d \quad = O(\max\{(1-\alpha)^{-1}\log(\sqrt{n}\Gamma \cdot \|p\|_{\mathcal{H}_2}), 0\})$.*

Our main idea to extend $p(z)$ by multiplying some polynomial u that approximates p^{-1} (in a relatively weak sense) and therefore pu will always take values in the set $\mathcal{C}$. We believe the following lemma should be known though for completeness we provide the proof in Section D.

Lemma 6.5 (Approximation of inverse of a polynomial) *Suppose $p(z)$ is a polynomial of degree n and leading coefficient 1 with distinct roots inside circle with radius α, and $\Gamma = \Gamma(p)$. Then for $d = O(\max\{(\frac{1}{1-\alpha}\log\frac{\Gamma}{(1-\alpha)\zeta}, 0\})$, there exists a polynomial $h(z)$ of degree d and leading coefficient 1 such that for all z on unit circle,*

$$\left| \frac{z^{n+d}}{p(z)} - h(z) \right| \le \zeta .$$

Proof [Proof of Lemma 6.4] Let $\gamma = 1 - \alpha$. Using Lemma 6.5 with $\zeta = 0.5\|p\|_{\mathcal{H}_\infty}^{-1}$, we have that there exists polynomial u of degree $d = O(\max\{\frac{1}{1-\alpha}\log(\Gamma\|p\|_{\mathcal{H}_\infty}), 0\})$ such that

$$\left| \frac{z^{n+d}}{p(z)} - u(z) \right| \le \zeta .$$

Then we have that

$$\left| p(z)u(z)/z^{n+d} - 1 \right| \le \zeta|p(z)| < 0.5 .$$

Therefore $p(z)u(z)/z^{n+d} \in \mathcal{C}_{\tau_0,\tau_1,\tau_2}$ for constant τ_0, τ_1, τ_2. Finally noting that for degree n polynomial we have $\|h\|_{\mathcal{H}_\infty} \le \sqrt{n} \cdot \|h\|_{\mathcal{H}_2}$, which completes the proof. ■

6.2.3 Example: Characteristic polynomial with random roots

We consider the following generative model for characteristic polynomial of degree $2n$. We generate n complex numbers $\lambda_1, \ldots, \lambda_n$ uniformly randomly on circle with radius $\alpha < 1$, and take $\lambda_i, \bar{\lambda}_i$ for $i = 1, \ldots, n$ as the roots of $p(z)$. That is, $p(z) = (z-\lambda_1)(z-\bar{\lambda}_1)\ldots(z-\lambda_n)(z-\bar{\lambda}_n)$. We show that with good probability (over the randomness of λ_i's), polynomial $p(z)$ will satisfy the condition in subsection 6.2.2 so that it can be learned efficiently by our improper learning algorithm.

Theorem 6.6 *Suppose $p(z)$ with random roots inside circle of radius α is generated from the process described above. Then with high probability over the choice of p, we have that $\Gamma(p) \le \exp(\widetilde{O}(\sqrt{n}))$ and $\|p\|_{\mathcal{H}_2} \le \exp(\tilde{O}(\sqrt{n}))$. As a corollary, $p(z)$ is α-acquiescent by extension of degree $\widetilde{O}((1-\alpha)^{-1}n)$.*

Towards proving Theorem 6.6, we need the following lemma about the expected distance of two random points with radius ρ and r in log-space.

Lemma 6.7 *Let $x \in \mathbb{C}$ be a fixed point with $|x| = \rho$, and λ uniformly drawn on the circle with radius r. Then $\mathbb{E}\left[\ln|x-\lambda|\right] = \ln\max\{\rho, r\}$.*

Proof When $r \neq \rho$, let N be an integer and $\omega = e^{2i\pi/N}$. Then we have that

$$\mathbb{E}[\ln|x-\lambda| \mid r] = \lim_{N\to\infty} \frac{1}{N}\sum_{k=1}^{N} \ln|x - r\omega^k| \tag{6.2}$$

The right hand of equation (6.2) can be computed easily by observing that $\frac{1}{N}\sum_{k=1}^{N}\ln|x - r\omega^k| = \frac{1}{N}\ln\left|\prod_{k=1}^{N}(x-r\omega^k)\right| = \frac{1}{N}\ln|x^N - r^N|$. Therefore, when $\rho > r$, we have $\lim_{N\to\infty}\frac{1}{N}\sum_{k=1}^{N}\ln|x - r\omega^k| = \lim_{N\to\infty}\rho + \frac{1}{N}\ln|(x/\rho)^N - (r/\rho)^N| = \ln\rho$. On the other hand, when $\rho < r$, we have that $\lim_{N\to\infty}\frac{1}{N}\sum_{k=1}^{N}\ln|x - r\omega^k| = \ln r$. Therefore we have that $\mathbb{E}[\ln|x-\lambda| \mid r] = \ln(\max\rho, r)$. For $\rho = r$, similarly proof (with more careful concern of regularity condition) we can show that $\mathbb{E}[\ln|x-\lambda| \mid r] = \ln r$. ■

Now we are ready to prove Theorem 6.6.

Proof [Proof of Theorem 6.6] Fixing index i, and the choice of λ_i, we consider the random variable $Y_i = \ln(\frac{|\lambda_i|^{2n}}{\prod_{j\neq i}|\lambda_i-\lambda_j|\prod_{j\neq i}|\lambda_i-\bar{\lambda}_j|})n\ln|\lambda_i| - \sum_{j\neq i}\ln|\lambda_i - \lambda_j|$. By Lemma 6.7, we have that $\mathbb{E}[Y_i] = n\ln|\lambda_i| - \sum_{j\neq i}\mathbb{E}[\ln|\lambda_i-\lambda_j|] = \ln(1-\delta)$. Let $Z_j = \ln|\lambda_i - \lambda_j|$. Then we have that Z_j are random variable with mean 0 and ψ_1-Orlicz norm bounded by 1 since $\mathbb{E}[e^{\ln|\lambda_i-\lambda_j|} - 1] \le 1$. Therefore by Bernstein inequality for sub-exponential tail random variable (for example, (Ledoux and Talagrand, 2013, Theorem 6.21)), we have that with high probability $(1-n^{-10})$, it holds that $\left|\sum_{j\neq i} Z_j\right| \le \widetilde{O}(\sqrt{n})$ where $\widetilde{O}$ hides logarithmic factors. Therefore, with high probability, we have $|Y_i| \le \widetilde{O}(\sqrt{n})$.

Finally we take union bound over all $i \in [n]$, and obtain that with high probability, for $\forall i \in [n], |Y_i| \le \widetilde{O}(\sqrt{n})$, which implies that $\sum_{i=1}^{n}\exp(Y_i) \le \exp(\widetilde{O}(\sqrt{n}))$. With similar technique, we can prove that $\|p\|_{\mathcal{H}_2} \le \exp(\tilde{O}(\sqrt{n}))$. ■

6.2.4 Example: Passive systems

We will show that with improper learning we can learn almost all passive systems, an important class of stable linear dynamical system as we discussed earlier. We start off with the definition of a strict-input passive system.

Definition 6.8 (Passive System, c.f Kottenstette and Antsaklis (2010)) *A SISO linear system is strict-input passive if and only if for some $\tau_0 > 0$ and any z on unit circle, $\Re(G(z)) \ge \tau_0$.*

In order to learn the passive system, we need to add assumptions in the definition of strict passivity. To make it precise, we define the following subsets of complex plane: For positive constant τ_0, τ_1, τ_2, define

$$\mathcal{C}^{+}_{\tau_0,\tau_1,\tau_2} = \{z \in \mathbb{C} : |z| \le \tau_2, \Re(z) \ge \tau_1, \Re(z) \ge \tau_0|\Im(z)|\}. \tag{6.3}$$

We say a transfer function $G(z) = s(z)/p(z)$ is (τ_0, τ_1, τ_2)-strict input passive if for any z on unit circle we have $G(z) \in \mathcal{C}^{+}_{\tau_0,\tau_1,\tau_2}$. Note that for small constant τ_0, τ_1 and large constant τ_2, this basically means the system is strict-input passive.

Now we are ready to state our main theorem in this subsection. We will prove that passive systems could be learned improperly with a constant factor more states (dimensions), assuming $s(z)$ has all its roots strictly inside unit circles and $\Gamma(s) \le \exp(O(n))$.

Theorem 6.9 *Suppose $G(z) = s(z)/p(z)$ is (τ_0, τ_1, τ_2)-strict-input passive. Moreover, suppose the roots of $s(z)$ have magnitudes inside circle with radius α and $\Gamma = \Gamma(s) \le \exp(O(n))$ and $\|p\|_{\mathcal{H}_2} \le \exp(O(n))$. Then $p(z)$ is α-acquiescent by extension of degree $d = O_{\tau,\alpha}(n)$, and as a consequence we can learn $G(z)$ with $n+d$ states in polynomial time.*

Moreover, suppose in addition we assume that $G(z) \in \mathcal{C}_{\tau_0,\tau_1,\tau_2}$ for every z on unit circle. Then $p(z)$ is α-acquiescent by extension of degree $d = O_{\tau,\alpha}(n)$.

The proof of Theorem 6.9 is similar in spirit to that of Lemma 6.4, and is deferred to Section D.

6.3 Improper learning using linear regression

In this subsection, we show that under stronger assumption than α-acquiescent by extension, we can improperly learn a linear dynamical system with linear regression, up to some fixed bias.

The basic idea is to fit a linear function that maps $[x_{k-\ell}, \ldots, x_k]$ to y_k. This is equivalent to a dynamical system with ℓ hidden states and with the companion matrix A in (1.4) being chosen as $a_\ell = 1$ and $a_{\ell-1} = \cdots = a_1 = 0$. In this case, the hidden states exactly memorize all the previous ℓ inputs, and the output is a linear combination of the hidden states.

Equivalently, in the frequency space, this corresponds to fitting the transfer function $G(z) = s(z)/p(z)$ with a rational function of the form $\frac{c_1 z^{\ell-1} + \cdots + c_1}{z^{\ell-1}} = c_1 z^{-(\ell-1)} + \cdots + c_n$. The following is a sufficient condition on the characteristic polynomial $p(x)$ that guarantees the existence of such fitting,

Definition 6.10 *A polynomial $p(z)$ of degree n is extremely-acquiescent by extension of degree d with bias ε if there exists a polynomial $u(z)$ of degree d and leading coefficient 1 such that for all z on unit circle,*

$$\left|p(z)u(z)/z^{n+d} - 1\right| \le \varepsilon \tag{6.4}$$

We remark that if $p(z)$ is 1-acquiescent by extension of degree d, then there exists $u(z)$ such that $p(z)u(z)/z^{n+d} \in \mathcal{C}$. Therefore, equation (6.4) above is a much stronger requirement than acquiescence by extension.[7]

When $p(z)$ is extremely-acquiescent, we see that the transfer function $G(z) = s(z)/p(z)$ can be approximated by $s(z)u(z)/z^{n+d}$ up to bias ε. Let $\ell = n+d+1$ and $s(z)u(z) = c_1 z^{\ell-1} + \cdots + c_\ell$. Then we have that $G(z)$ can be approximated by the following dynamical system of ℓ hidden states with ε bias: we choose $A = \mathrm{CC}(a)$ with $a_\ell = 1$ and $a_{\ell-1} = \cdots = a_1 = 0$, and $C = [c_1, \ldots, c_\ell]$. As we have argued previously, such a dynamical system simply memorizes all the previous ℓ inputs, and therefore it is equivalent to linear regression from the feature $[x_{k-\ell}, \ldots, x_k]$ to output y_k.

Proposition 6.11 (Informal) *If the true system $G(z) = s(z)/p(z)$ satisfies that $p(z)$ is extremely-acquiescent by extension of degree d. Then using linear regression we can learn mapping from $[x_{k-\ell}, \ldots, x_k]$ to y_k with bias ε and polynomial sampling complexity.*

We remark that with linear regression the bias ε will only go to zero as we increase the length ℓ of the feature, but not as we increase the number of samples. Moreover, linear regression requires a stronger assumption than the improper learning results in previous subsections do. The latter can be viewed as an interpolation between the proper case and the regime where linear regression works.

7. Learning multi-input multi-output (MIMO) systems

We consider multi-input multi-output systems with the transfer functions that have a common denominator $p(z)$,

$$G(z) = \frac{1}{p(z)} \cdot S(z) \tag{7.1}$$

where $S(z)$ is an $\ell_{\text{in}} \times \ell_{\text{out}}$ matrix with each entry being a polynomial with real coefficients of degree at most n and $p(z) = z^n + a_1 z^{n-1} + \cdots + a_n$. Note that here we use ℓ_{in} to denote the dimension of the inputs of the system and ℓ_{out} the dimension of the outputs.

Although a special case of a general MIMO system, this class of systems still contains many interesting cases, such as the transfer functions studied in Fazel et al. (2001, 2004), where $G(z)$ is assumed to take the form $G(z) = R_0 + \sum_{i=1}^{n} \frac{R_i}{z-\lambda_i}$, for $\lambda_1, \ldots, \lambda_n \in \mathbb{C}$ with conjugate symmetry and $R_i \in \mathbb{C}^{\ell_{\text{out}} \times \ell_{\text{in}}}$ satisfies that $R_i = \bar{R}_j$ whenever $\lambda_i = \bar{\lambda}_j$.

In order to learn the system $G(z)$, we parametrize $p(z)$ by its coefficients $a_1, \ldots, a_n$ and $S(z)$ by the coefficients of its entries. Note that each entry of $S(z)$ depends on $n+1$ real

7. We need $(1-\delta)$-acquiescence by extension in previous subsections for small $\delta > 0$, though this is merely additional technicality needed for the sample complexity. We ignore this difference between $1-\delta$-acquiescence and 1-acquiescence and for the purpose of this subsection

coefficients and therefore the collection of coefficients forms a third order tensor of dimension $\ell_{\text{out}} \times \ell_{\text{in}} \times (n+1)$. It will be convenient to collect the leading coefficients of the entries of $S(z)$ into a matrix of dimension $\ell_{\text{out}} \times \ell_{\text{in}}$, named D, and the rest of the coefficients into a matrix of dimension $\ell_{\text{out}} \times \ell_{\text{in}} n$, denoted by C. This will be particularly intuitive when a state-space representation is used to learn the system with samples as discussed later. We parameterize the training transfer function $\hat{G}(z)$ by $\hat{a}$, $\hat{C}$ and $\hat{D}$ using the same way.

Let's define the risk function in the frequency domain as,

$$g(\hat{A}, \hat{C}, \hat{D}) = \int_0^{2\pi} \left\| G(e^{i\theta}) - \hat{G}(e^{i\theta}) \right\|_F^2 d\theta \,. \tag{7.2}$$

The following lemma is an analog of Lemma 3.3 for the MIMO case. Itss proof actually follows from a straightforward extension of the proof of Lemma 3.3 by observing that matrix $S(z)$ (or $\hat{S}(z)$) commute with scalar $p(z)$ and $\hat{p}(z)$, and that $\hat{S}(z), \hat{p}(z)$ are linear in $\hat{a}, \hat{C}$.

Lemma 7.1 *The risk function $g(\hat{a}, \hat{C})$ defined in (7.2) is τ-weakly-quasi-convex in the domain*

$$\mathcal{N}_\tau(a) = \left\{ \hat{a} \in \mathbb{R}^n \colon \Re\left(\frac{p_a(z)}{p_{\hat{a}}(z)}\right) \ge \tau/2, \forall\, z \in \mathbb{C},\ \text{s.t. } |z| = 1 \right\} \otimes \mathbb{R}^{\ell_{\text{in}} \times \ell_{\text{out}} \times n'}$$

Finally, as alluded before, we use a particular state space representation for learning the system in time domain with example sequences. It is known that any transfer function of the form (7.1) can be realized uniquely by the state space system of the following special case of Brunovsky normal form Brunovsky (1970),

$$A = \begin{bmatrix} 0 & I_{\ell_{\text{in}}} & 0 & \cdots & 0 \\ 0 & 0 & I_{\ell_{\text{in}}} & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & I_{\ell_{\text{in}}} \\ -a_n I_{\ell_{\text{in}}} & -a_{n-1} I_{\ell_{\text{in}}} & -a_{n-2} I_{\ell_{\text{in}}} & \cdots & -a_1 I_{\ell_{\text{in}}} \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ I_{\ell_{\text{in}}} \end{bmatrix}, \tag{7.3}$$

and,

$$C \in \mathbb{R}^{\ell_{\text{out}} \times n\ell_{\text{in}}}, \quad D \in \mathbb{R}^{\ell_{\text{out}} \times \ell_{\text{in}}} \,.$$

The following Theorem is a straightforward extension of Corollary 5.2 and Theorem 6.2 to the MIMO case.

Theorem 7.2 *Suppose transfer function $G(z)$ of a MIMO system takes form (7.1), and has norm $\|G\|_{\mathcal{H}_2} \le 1$. If the common denominator $p(z)$ is α-acquiescent by extension of degree d then projected stochastic gradient descent over the state space representation (7.3) will return $\widehat{\Theta}$ with risk*

$$f(\widehat{\Theta}) \le \frac{\mathrm{poly}(n+d, \sigma, \tau, (1-\alpha)^{-1})}{TN} \,.$$

We note that since A and B are simply the tensor product of $I_{\ell_{\text{in}}}$ with $\mathrm{CC}(a)$ and e_n, the no blow-up property (Lemma 4.4) for $A^k B$ still remains true. Therefore to prove Theorem 7.2, we essentially only need to run the proof of Lemma 5.5 with matrix notation and matrix norm. We defer the proof to the full version.

8. Simulations

In this section, we provide proof-of-concepts experiments on synthetic data. We will demonstrate that

1) plain SGD tends to blow up even with relatively small learning rate, especially on hard instances

2) SGD with our projection step converges with reasonably large learning rate, and with over-parameterization the final error is competitive

3) SGD with gradient clipping has the strongest performance in terms both of the convergence speed and the final error

Here gradient clipping refers to the technique of using a normalized gradient instead of the true gradient. Specifically, for some positive hyper parameter B, we follow the approximate gradient

$$g_{\text{clip}} = \begin{cases} g & \text{if } \|g\| \leq B \\ Bg/\|g\| & otherwise \end{cases}$$

This method is commonly applied in training recurrent neural networks Pascanu et al. (2013).

Bullet 1) suggests that stability is indeed a real concern. Bullet 2) corroborates our theoretical study. Finding 3) suggests the instability of SGD partly arises from the noise in the batches, and such noise is reduced by the gradient clipping. Our experiments suggest that the landscape of the objective function may be even nicer than what is predicted by our theoretical development. It remains possible that the objective has no non-global local minima, possibly even outside the convex set to which our algorithm projects.

We generate the true system with state dimension $d = 20$ by randomly picking the conjugate pairs of roots of the characteristic polynomial inside the circle with radius $\rho = 0.95$ and randomly generating the vector C from standard normal distribution. The distribution of the norm of the impulse response r (defined in Section 3) of such systems has a heavy-tail. When the norm of r is several magnitudes larger than the median it's difficult to learn the system. Thus we select systems with reasonable $\|r\|$ for experiments, and we observe that the difficulty of learning increases as $\|r\|$ increases. The inputs of the dynamical model are generated from standard normal distribution with length $T = 500$. We note that we generate new fresh inputs and outputs at every iterations and therefore the training loss is equal to the test loss (in expectation.) We use initial learning rate 0.01 in the projected gradient descent and SGD with gradient clipping. We use batch size 100 for all experiments, and decay the learning rate at 200K and 250K iteration by a factor of 10 in all experiments.

Acknowledgments

We thank Amir Globerson, Alexandre Megretski, Pablo A. Parrilo, Yoram Singer, Peter Stoica, and Ruixiang Zhang for helpful discussions. We are indebted to Mark Tobenkin for pointers to relevant prior work. We also thank Alexandre Megretski for helpful feedback, insights into passive systems and suggestions on how to organize Section 3.

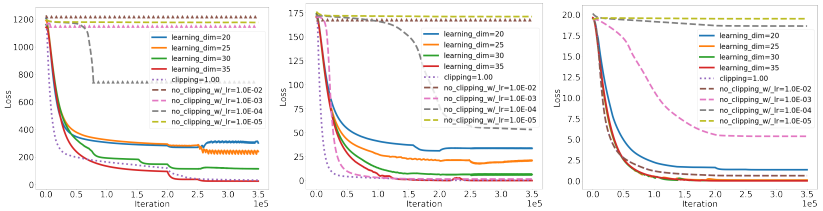

Figure 2: The performance of projected stochastic gradient descent with over-parameterization, vanilla SGD, and SGD with gradient clipping, on three different instance of dynamical systems with true state dimension = 20. The solid lines are from our proposed projected SGD with (over-parameterized) state dimension = 20, 25, 30, 35. The dot line corresponds to SGD with gradient clipped to Frobenius norm 1. The dashed lines correspond vanilla SGD and the triangle marker means the error blows up to infinity. The plot demonstrates the effect of the over-parameterization to our our algorithm. We note that the loss are different scales because the true systems in these three instances have different norms of impulse responses (which is equal to the loss of zero fitting).

Appendix A. Background on optimization

The proof below uses the standard analysis of gradient descent for non-smooth objectives and demonstrates that the argument still works for weakly-quasi-convex functions.

Proof [Proof of Proposition 2.3] We start by using the weakly-quasi-convex condition and then the rest follows a variant of the standard analysis of non-smooth projected sub-gradient descent[8]. We conditioned on θ_k, and have that

$$\begin{aligned}
\tau(f(\theta_k) - f(\theta^*)) &\le \nabla f(\theta_k)^\top(\theta_k - \theta^*) = \mathbb{E}[\mathfrak{r}(\theta_k)^\top(\theta_k - \theta^*) \mid \theta_k] \\
&= \mathbb{E}\left[\frac{1}{\eta}(\theta_k - w_{k+1})(\theta_k - \theta^*) \mid \theta_k\right] \\
&= \frac{1}{\eta}\left(\mathbb{E}\left[\|\theta_k - w_{k+1}\|^2 \mid \theta_k\right] + \|\theta_k - \theta^*\|^2 - \mathbb{E}\left[\|w_{k+1} - \theta^*\|^2 \mid \theta_k\right]\right) \\
&= \eta\,\mathbb{E}\left[\|\mathfrak{r}(\theta_k)\|^2\right] + \frac{1}{\eta}\left(\|\theta_k - \theta^*\|^2 - \mathbb{E}\left[\|w_{k+1} - \theta^*\|^2 \mid \theta_k\right]\right) \qquad \text{(A.1)}
\end{aligned}$$

where the first inequality uses weakly-quasi-convex and the rest of lines are simply algebraic manipulations. Since θ_{k+1} is the projection of w_{k+1} to $\mathcal{B}$ and θ^* belongs to $\mathcal{B}$, we have $\|w_{k+1} - \theta^*\| \ge \|\theta_{k+1} - \theta^*\|$. Together with (A.1), and

$$\mathbb{E}\left[\|\mathfrak{r}(\theta_k)\|^2\right] = \|\nabla f(\theta_k)\|^2 + \mathrm{Var}[\mathfrak{r}(\theta_k)] \le \Gamma(f(\theta_k) - f(\theta^*)) + V,$$

8. Although we used weak smoothness to get a slightly better bound

we obtain that

$$\tau(f(\theta_k)-f(\theta^*)) \le \eta\Gamma(f(\theta_k)-f(\theta^*)) + \eta V + \frac{1}{\eta}\left(\|\theta_k-\theta^*\|^2 - \mathbb{E}\left[\|\theta_{k+1}-\theta^*\|^2 \mid \theta_k\right]\right).$$

Taking expectation over all the randomness and summing over k we obtain that

$$\sum_{k=0}^{K-1}\mathbb{E}\left[f(\theta_k)-f(\theta^*)\right] \le \frac{1}{\tau-\eta\Gamma}\left(\eta KV + \frac{1}{\eta}\|\theta_0-\theta^*\|^2\right) \le \frac{1}{\tau-\eta\Gamma}\left(\eta KV + \frac{1}{\eta}R^2\right).$$

where we use the assumption that $\|\theta_0-\theta^*\| \le R$. Suppose $K \ge \frac{4R^2\Gamma^2}{V\tau^2}$, then we take $\eta = \frac{R}{\sqrt{VK}}$. Therefore we have that $\tau-\eta\Gamma \ge \tau/2$ and therefore

$$\sum_{k=0}^{K-1}\mathbb{E}\left[f(\theta_k)-f(\theta^*)\right] \le \frac{4R\sqrt{V}\sqrt{K}}{\tau}. \tag{A.2}$$

On the other hand, if $K \le \frac{4R^2\Gamma^2}{V\tau^2}$, we pick $\eta = \frac{\tau}{2\Gamma}$ and obtain that

$$\sum_{k=0}^{K-1}\mathbb{E}\left[f(\theta_k)-f(\theta^*)\right] \le \frac{2}{\tau}\left(\frac{\tau KV}{2\Gamma} + \frac{2\Gamma R^2}{\tau}\right) \le \frac{8\Gamma R^2}{\tau^2}. \tag{A.3}$$

Therefore using equation (A.3) and (A.2) we obtain that when choosing η properly according to K as above,

$$\mathop{\mathbb{E}}_{k\in[K]}\left[f(\theta_k)-f(\theta^*)\right] \le \max\left\{\frac{8\Gamma R^2}{\tau^2 K}, \frac{4R\sqrt{V}}{\tau\sqrt{K}}\right\}.$$

■

Appendix B. Toolbox

Lemma B.1 *Let $B = e_n \in \mathbb{R}^{n\times 1}$ and $\lambda \in [0, 2\pi]$, $w \in \mathbb{C}$. Suppose A with $\rho(A)\cdot|w| < 1$ has the controllable canonical form $A = \mathrm{CC}(a)$. Then*

$$(I-wA)^{-1}B = \frac{1}{p_a(w^{-1})}\begin{bmatrix} w^{-1} \\ w^{-2} \\ \vdots \\ w^{-n}\end{bmatrix}$$

where $p_a(x) = x^n + a_1x^{n-1} + \cdots + a_n$ is the characteristic polynomial of A.

Proof let $v = (I-wA)^{-1}B$ then we have $(I-wA)v = B$. Note that $B = e_n$, and $I-wA$ is of the form

$$I - wA = \begin{bmatrix} 1 & -w & 0 & \cdots & 0 \\ 0 & 1 & -w & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & -w \\ a_nw & a_{n-1}w & a_{n-2}w & \cdots & 1+a_1w \end{bmatrix} \tag{B.1}$$

Therefore we obtain that $v_k = wv_{k+1}$ for $1 \le k \le n-1$. That is, $v_k = v_0w^{-k}$ for $v_0 = v_1w^1$. Using the fact that $((I-wA)v)_n = 1$, we obtain that $v_0 = p_a(w^{-1})^{-1}$ where $p_a(\cdot)$ is the polynomial $p_a(x) = x^n + a_1x^{n-1} + \cdots + a_n$. Then we have that $u(I-wA)^{-1}B = \frac{u_1w^{-1}+\cdots+u_nw^{-n}}{p_a(w^{-1})}$ ■

Lemma B.2 *Suppose $x_1, \ldots, x_n$ are independent variables with mean 0 and covariance matrices and I, $U_1, \ldots, U_d$ are fixed matrices, then*

$$\mathbb{E}\left[\|\sum_{k=1}^n U_kx_k\|^2\right] = \sum_{k=1}^n \|U_k\|_F^2.$$

Proof We have that

$$\mathbb{E}\left[\|\sum_{k=1}^n U_kx_k\|_F^2\right] = \mathbb{E}\sum_{k,\ell}^n \mathrm{tr}(U_kx_kx_\ell^\top U_\ell^\top) = \sum_k^n \mathrm{tr}(U_kx_kx_k^\top U_k^\top) = \sum_{k=1}^n \|U_k\|_F^2$$

■

Appendix C. Missing proofs in Sections 4 and 5

C.1 Monotonicity of acquiescence: Proof of Lemma 4.3

Lemma C.1 (Lemma 4.3 restated) *For any $0 < \alpha < \beta$, we have that $\mathcal{B}_\alpha \subset \mathcal{B}_\beta$.*

Proof Let $q_a(z) = 1 + a_1z + \cdots + a_nz^n$. Note that $q(z^{-1}) = p_a(z)/z^n$. Therefore we note that $B_\alpha = \{a : q_a(z) \in \mathcal{C}, \forall |z| = 1/\alpha\}$. Suppose $a \in \mathcal{B}_\alpha$, then $\Re(q_a(z)) \ge \tau_1$ for any z with $|z| = 1/\alpha$. Since $\Re(q_a(z))$ is the real part of the holomorphic function $q_a(z)$, its a harmonic function. By maximum (minimum) principle of the harmonic functions, we have that for any $|z| \le 1/\alpha$, $\Re(q_a(z)) \ge \inf_{|z|=1/\alpha}\Re(q_a(z)) \ge \tau_1$. In particular, it holds that for $|z| = 1/\beta < 1/\alpha$, $\Re(q_a(z)) \ge \tau_1$. Similarly we can prove that for z with $|z| = 1/\beta$, $\Re(q_a(z)) \ge (1+\tau_0)\Im(q_a(z))$, and other conditions for a being in $\mathcal{B}_\beta$. ■

C.2 Proof of Lemma 5.4

Lemma 5.4 follows directly from the following general Lemma which also handles the multi-input multi-output case. It can be seen simply from calculation similar to the proof of Lemma 3.5. We mainly need to control the tail of the series using the no-blow up property (Lemma 4.4) and argue that the wrong value of the initial states h_0 won't cause any trouble to the partial loss function $\ell((x,y),\widehat{\Theta})$ (defined in Algorithm 1). This is simply because after time $T_1 = T/4$, the influence of the initial state is already washed out.

Lemma C.2 *In algorithm 3 the values of G_A, G_C, G_D are equal to the gradients of $g(\hat{A},\hat{C})+(\hat{D}-D)^2$ with respect to $\hat{A}$, $\hat{C}$ and $\hat{D}$ up to inverse exponentially small error.*

Proof [Proof of Lemma C.2] We first show that the partial empirical loss function $\ell((x,y),\widehat{\Theta})$ has expectation almost equal to the idealized risk (up to the term for $\hat{D}$ and exponential small error),

$$\mathbb{E}[\ell((x,y),\widehat{\Theta})] = g(\hat{A},\hat{C}) + (\hat{D}-D)^2 \pm \exp(-\Omega((1-\alpha)T)).$$

This can be seen simply from similar calculation to the proof of Lemma 3.5. Note that

$$y_t = Dx_t + \sum_{k=1}^{t-1} CA^{t-k-1}Bx_k + CA^{t-1}h_0 + \xi_t \quad \text{and} \quad \tilde{y}_t = \hat{D}x_t + \sum_{k=1}^{t-1} \hat{C}\hat{A}^{t-k-1}\hat{B}x_k\,. \tag{C.1}$$

Therefore noting that when $t \geq T_1 \geq \Omega(T)$, we have that $\|CA^{t-1}h_0\| \leq \exp(-\Omega((1-\alpha)T)$ and therefore the effect of h_0 is negligible. Then we have that

$$\begin{aligned}
\mathbb{E}[\ell((x,y),\widehat{\Theta})] &= \frac{1}{T-T_1}\,\mathbb{E}\left[\sum_{t>T_1}^{T} \|y_t - y_t\|^2\right] \pm \exp(-\Omega((1-\alpha)T)) \\
&= \|\hat{D}-D\|^2 + \frac{1}{T-T_1}\sum_{T\geq t>T_1}\sum_{0\leq j\leq t-1} \|\hat{C}\hat{A}^jB - CA^jB\|^2 \pm \exp(-\Omega((1-\alpha)T)) \\
&= \|\hat{D}-D\|^2 + \sum_{j=0}^{T_1} \|\hat{C}\hat{A}^jB - CA^jB\|^2 + \sum_{T\geq j\geq T_1} \frac{T-j}{T-T_1}\|\hat{C}\hat{A}^jB - CA^jB\|^2 \pm \exp(-\Omega((1-\alpha)T)) \\
&= \|\hat{D}-D\|^2 + \sum_{j=0}^{\infty} \|\hat{C}\hat{A}^jB - CA^jB\|^2 \pm \exp(-\Omega((1-\alpha)T))\,.
\end{aligned}$$

where the first line use the fact that $\|CA^{t-1}h_0\| \leq \exp(-\Omega((1-\alpha)T)$, the second uses equation (3.10) and the last line uses the no-blowing up property of A^kB (Lemma 4.4).

Similarly, we can prove that the gradient of $\mathbb{E}[\ell((x,y),\widehat{\Theta})]$ is also close to the gradient of $g(\hat{A},\hat{C}) + (\hat{D}-D)^2$ up to inverse exponential error. ■

C.3 Proof of Lemma 5.5

Proof [Proof of Lemma 5.5] Both G_A and G_C can be written in the form of a quadratic form (with vector coefficients) of $x_1,\ldots,x_T$ and $\xi_1,\ldots,\xi_T$. That is, we will write

$$G_A = \sum_{s,t} x_s x_t u_{st} + \sum_{s,t} x_s \xi_t u'_{st} \quad \text{and} \quad G_C = \sum_{s,t} x_s x_t v_{st} + \sum_{s,t} x_s \xi_t v'_{st}\,.$$

where u_{st} and v_{st} are vectors that will be calculated later. By Lemma C.3, we have that

$$\mathrm{Var}\left[\sum_{s,t} x_s x_s u_{st} + \sum_{s,t} x_s \xi_t u'_{st}\right] \leq O(1)\sum_{s,t}\|u_{st}\|^2 + O(\sigma^2)\sum_{s,t}\|u'_{st}\|^2\,. \tag{C.2}$$

Therefore in order to bound from above $\mathrm{Var}[G_A]$, it suffices to bound $\sum\|u_{st}\|^2$ and $\sum\|u'_{st}\|^2$, and similarly for G_C.

We begin by writing out u_{st} for fixed $s,t\in[T]$ and bounding its norm. We use the same set of notations as int the proof of Lemma 5.4. Recall that we set $r_k = CA^kB$ and $\hat{r}_k = \hat{C}\hat{A}^kB$, and $\Delta r_k = \hat{r}_k - r_k$. Moreover, let $z_k = \hat{A}^kB$. We note that the sums of $\|z_k\|^2$ and r_k^2 can be controlled. By the assumption of the Lemma, we have that

$$\sum_{k=t}^{\infty}\|z_k\|^2 \leq 2\pi n\tau_1^{-2}, \quad \|z_k\|^2 \leq 2\pi n\alpha^{2k-2n}\tau_1^{-2}\,. \tag{C.3}$$

$$\sum_{k=t}^{\infty}\Delta r_k^2 \leq 4\pi n\tau_1^{-2}, \quad \|\Delta r_k\|^2 \leq 4\pi n\alpha^{2k-2n}\tau_1^{-2}\,. \tag{C.4}$$

which will be used many times in the proof that follows.

We calculate the explicit form of G_A using the explicit back-propagation Algorithm 3. We have that in Algorithm 3,

$$\hat{h}_k = \textstyle\sum_{j=1}^{k}\hat{A}^{k-j}Bx_j = \sum_{j=1}^{k} z_{k-j}x_j \tag{C.5}$$

and

$$\Delta h_k = \sum_{j=k}^{T}(\hat{A}^\top)^{j-k}\hat{C}^\top\Delta y_j = \sum_{j=k}^{T}\alpha^{j-k}(\hat{A}^\top)^{j-k}\hat{C}^\top\mathbf{1}_{j>T_1}\left(\xi_j + \sum_{\ell=1}^{j}\Delta r_{j-\ell}x_\ell\right) \tag{C.6}$$

Then using $G_A = \sum_{k\geq 2} B^\top\Delta h_k h_{k-1}'^\top$ and equation (C.5) and equation (C.6) above, we have that

$$\begin{aligned}
u_{st} &= \textstyle\sum_{k=2}^{T}\left(\sum_{j\geq\max\{k,s,T_1+1\}}\Delta r_{j-s}\hat{C}\hat{A}^{j-k}B\right)\mathbf{1}_{k\geq t+1}\cdot\hat{A}^{k-t-1}B \\
&= \textstyle\sum_{k=2}^{T}\left(\sum_{j\geq\max\{k,s,T_1+1\}}\Delta r_{j-s}\hat{r}_{j-k}\right)\mathbf{1}_{k\geq t+1}\cdot z_{k-t-1}\,.
\end{aligned} \tag{C.7}$$

and that,

$$u'_{st} = \sum_{k=2}^{T} z_{k-1-s}\cdot\mathbf{1}_{k\geq s+1}\cdot\hat{r}'_{t-k}\cdot\mathbf{1}_{t>\max\{T_1,k\}} = \sum_{s+1\leq k\leq t} z_{k-1-s}\cdot\hat{r}'_{t-k}\cdot\mathbf{1}_{t>\max\{T_1\}} \tag{C.8}$$

Towards bounding $\|u_{st}\|$, we consider four different cases. Let $\Lambda = \Omega\left(\{\max\{n,(1-\alpha)^{-1}\log(\frac{1}{1-\alpha})\}\right)$ be a threshold.

Case 1: When $0\leq s-t\leq\Lambda$, we rewrite u_{st} by rearranging equation (C.7),

$$\begin{aligned}
u_{st} &= \sum_{T\geq k\geq s} z_{k-t-1}\sum_{j\geq\max\{k,T_1+1\}}\Delta r_{j-s}\hat{r}_{j-k} + \sum_{t<k<s} z_{k-t-1}\sum_{j\geq\max\{s,T_1+1\}}\Delta r_{j-s}\hat{r}_{j-k} \\
&= \sum_{\ell\geq 0,\ell\geq T_1+1-s}\Delta r_\ell\sum_{s\leq k\leq l+s,k\leq T}\hat{r}_{\ell+s-k}z_{k-t-1} + \sum_{\ell\geq 0,\ell\geq T_1+1-s}\Delta r_\ell\sum_{s>k>t}\hat{r}_{\ell+s-k}z_{k-t-1}
\end{aligned}$$

where at the second line, we did the change of variables $\ell = j - s$. Then by Cauchy-Schartz inequality, we have,

$$\|u_{st}\|^2 \le 2\left(\sum_{\ell\ge 0,\ell\ge T_1+1-s}\Delta r_\ell^2\right)\underbrace{\left(\sum_{\ell\ge 0,\ell\ge T_1+1-s}\left\|\sum_{s\le k\le l+s,k\le T}\hat{r}_{\ell+s-k}z_{k-t-1}\right\|^2\right)}_{T_1}$$
$$+2\left(\sum_{\ell\ge 0,\ell\ge T_1+1-s}\Delta r_\ell^2\right)\underbrace{\left(\sum_{\ell\ge 0,\ell\ge T_1+1-s}\left\|\sum_{s>k>t}\hat{r}_{\ell+s-k}z_{k-t-1}\right\|^2\right)}_{T_2}. \tag{C.9}$$

We could bound the contribution from Δr_k^2 ssing equation (C.4), and it remains to bound terms T_1 and T_2. Using the tail bounds for $\|z_k\|$ (equation (C.3)) and the fact that $|\hat{r}_k| = |\hat{C}\hat{A}^k B| \le \|\hat{A}^k B\| = \|z_k\|$, we have that

$$T_1 = \sum_{\ell\ge 0,\ell\ge T_1+1-s}\left\|\sum_{s\le k\le l+s,k\le T}\hat{r}_{\ell+s-k}z_{k-t-1}\right\|^2 \le \sum_{\ell\ge 0}\left(\sum_{s\le k\le \ell+s}|\hat{r}_{\ell+s-k}|\|z_{k-t-1}\|\right)^2. \tag{C.10}$$

We bound the inner sum of RHS of (C.10) using the fact that $\|z_k\|^2 \le O(n\alpha^{2k-2n}/\tau_1^2)$ and obtain that,

$$\sum_{s\le k\le \ell+s}|\hat{r}_{\ell+s-k}|\|z_{k-t-1}\| \le \sum_{s\le k\le \ell+s}O(n\alpha^{(\ell+s-t-1)-2n}/\tau_1^2)$$
$$\le O(\ell n\alpha^{(\ell+s-t-1)-2n}/\tau_1^2). \tag{C.11}$$

Note that equation (C.11) is particular effective when $\ell > \Lambda$. When $\ell \le \Lambda$, we can refine the bound using equation (C.3) and obtain that

$$\sum_{s\le k\le \ell+s}|\hat{r}_{\ell+s-k}|\|z_{k-t-1}\| \le \left(\sum_{s\le k\le \ell+s}|\hat{r}_{\ell+s-k}|^2\right)^{1/2}\left(\sum_{s\le k\le \ell+s}\|z_{k-t-1}\|^2\right)^{1/2}$$
$$\le O(\sqrt{n}/\tau_1)\cdot O(\sqrt{n}/\tau_1) = O(n/\tau_1^2). \tag{C.12}$$

Plugging equation (C.12) and (C.11) into equation (C.10), we have that

$$\sum_{\ell\ge 0}\left(\sum_{s\le k\le \ell+s}|\hat{r}_{\ell+s-k}|\|z_{k-t-1}\|\right)^2 \le \sum_{\Lambda\ge\ell\ge 0}O(n^2/\tau_1^4)+\sum_{\ell>\Lambda}O(\ell^2n^2\alpha^{2(\ell+s-t-1)-4n}/\tau_1^4)$$
$$\le O(n^2\Lambda/\tau_1^4)+O(n^2/\tau_1^4) = O(n^2\Lambda/\tau_1^4). \tag{C.13}$$

For the second term in equation (C.9), we bound similarly,

$$T_2 \le \sum_{\ell\ge 0,\ell\ge T_1+1-s}\left\|\sum_{s>k>t}\hat{r}_{\ell+s-k}z_{k-t-1}\right\|^2 \le O(n^2\Lambda/\tau_1^4). \tag{C.14}$$

Therefore using the bounds for T_1 and T_2 we obtain that,

$$\|u_{st}\|^2 \le O(n^3\Lambda/\tau_1^6) \tag{C.15}$$

Case 2: When $s - t > \Lambda$, we tighten equation (C.13) by observing that,

$$T_1 \le \sum_{\ell\ge 0}\left(\sum_{s\le k\le \ell+s}|\hat{r}_{\ell+s-k}|\|z_{k-t-1}\|\right)^2 \le \alpha^{2(s-t-1)-4n}\sum_{\ell\ge 0}O(\ell^2n^2\alpha^{2\ell}/\tau_1^4)$$
$$\le \alpha^{s-t-1}\cdot O(n^2/(\tau_1^4(1-\alpha)^3)). \tag{C.16}$$

where we used equation (C.11). Similarly we can prove that

$$T_2 \le \alpha^{s-t-1}\cdot O(n^2/(\tau_1^4(1-\alpha)^3)).$$

Therefore, we have when $s - t \ge \Lambda$,

$$\|u_{st}\|^2 \le O(n^3/((1-\alpha)^3\tau_1^6))\cdot\alpha^{s-t-1}. \tag{C.17}$$

Case 3: When $-\Lambda \le s-t \le 0$, we can rewrite u_st and use the Cauchy-Schwartz inequality and obtain that

$$u_{st} = \sum_{T\ge k\ge t+1}z_{k-t-1}\sum_{j\ge\max\{k,T_1+1\}}\Delta r_{j-s}\hat{r}_{j-k} = \sum_{\ell\ge 0,\ell\ge T_1+1-s}\Delta r_\ell\sum_{t+1\le k\le l+s,k\le T}\hat{r}_{\ell+s-k}z_{k-t-1}.$$

and,

$$\|u_{st}\|^2 \le \left(\sum_{\ell\ge 0,\ell\ge T_1+1-s}\Delta r_\ell^2\right)\left(\sum_{\ell\ge 0,\ell\ge T_1+1-s}\left\|\sum_{t+1\le k\le l+s,k\le T}\hat{r}_{\ell+s-k}z_{k-t-1}\right\|^2\right).$$

Using almost the same arguments as in equation (C.11) and (C.12), we that

$$\sum_{t+1\le k\le \ell+s}|\hat{r}_{\ell+s-k}|\cdot\|z_{k-t-1}\| \le O(\ell n\alpha^{(\ell+s-t-1)-2n}/\tau_1^2)$$
$$\text{and}\qquad \sum_{t+1\le k\le \ell+s}|\hat{r}_{\ell+s-k}|\cdot\|z_{k-t-1}\| \le O(\sqrt{n}/\tau_1)\cdot O(\sqrt{n}/\tau_1) = O(n/\tau_1^2).$$

Then using a same type of argument as equation (C.13), we can have that

$$\sum_{\ell\ge 0,\ell\ge T_1+1-s}\left\|\sum_{t+1\le k\le l+s,k\le T}\hat{r}'_{\ell+s-k}z'_{k-t-1}\right\|^2 \le O(n^2\Lambda/\tau_1^4)+O(n^2/\tau_1^4)$$
$$= O(n^2\Lambda/\tau_1^4).$$

It follows that in this case $\|u_{st}\|$ can be bounded with the same bound in (C.15).

Case 4: When $s - t \le -\Lambda$, we use a different simplification of u_{st} from above. First of all, it follows (C.7) that

$$\begin{aligned}\|u_{st}\| &\le \sum_{k=2}^{T}\left(\sum_{j\ge\max\{k,s,T_1+1\}} \|\Delta r_{j-s}\hat{r}'_{j-k}z_{k-t-1}\|\mathbf{1}_{k\ge t+1}\right) \\ &\le \sum_{k\ge t+1}\|z'_{k-t-1}\| \sum_{j\ge\max\{k,T_1+1\}} |\Delta r_{j-s}\hat{r}'_{j-k}|\,.\end{aligned} \tag{C.18}$$

Since $j - s \ge k - s > 4n$ and it follows that

$$\begin{aligned}\sum_{j\ge\max\{k,T_1+1\}} |\Delta r_{j-s}\hat{r}'_{j-k}| &\le \sum_{j\ge\max\{k,T_1+1\}} O(\sqrt{n}/\tau_1\cdot\alpha^{j-s-n})\cdot O(\sqrt{n}/\tau_1\cdot\alpha^{j-k-n}) \\ &\le O(n/(\tau_1^2(1-\alpha))\cdot\alpha^{k-s-n})\end{aligned}$$

Then we have that

$$\begin{aligned}\|u_{st}\|^2 &\le \sum_{k\ge t+1}\|z'_{k-t-1}\| \sum_{j\ge\max\{k,T_1+1\}} |\Delta r_{j-s}\hat{r}'_{j-k}| \\ &\le \left(\sum_{k\ge t+1}\|z'_{k-t-1}\|^2\right)\left(\sum_{k\ge t+1}\left(\sum_{j\ge\max\{k,T_1+1\}} |\Delta r_{j-s}\hat{r}'_{j-k}|\right)^2\right) \\ &\le O(n/\tau_1^2)\cdot O(n^2/(\tau_1^4(1-\alpha)^3)\alpha^{t-s}) = O(n^3/(\tau_1^6\delta^3)\alpha^{t-s})\end{aligned}$$

Therefore, using the bound for $\|u_{st}\|^2$ obtained in the four cases above, taking sum over s, t, we obtain that

$$\begin{aligned}\sum_{1\le s,t\le T}\|u_{st}\|^2 &\le \sum_{s,t\in[T]:|s-t|\le\Lambda} O(n^3\Lambda/\tau_1^6) + \sum_{s,t:|s-t|\ge\Lambda} O(n^3/(\tau_1^6(1-\alpha)^3)\alpha^{|t-s|-1}) \\ &\le O(Tn^3\Lambda^2/\tau_1^6) + O(n^3/\tau_1^6) = O(Tn^3\Lambda^2/\tau_1^6)\,.\end{aligned} \tag{C.19}$$

We finished the bounds for $\|u_{st}\|$ and now we turn to bound $\|u'_{st}\|^2$. Using the formula for u'_{st} (equation C.8), we have that for $t \le s+1$, $u'_{st} = 0$. For $s + \Lambda \ge t \ge s + 2$, we have that by Cauchy-Schwartz inequality,

$$\|u'_{st}\| \le \left(\sum_{s+1\le k\le t}\|z_{k-1-s}\|^2\right)^{1/2}\left(\sum_{s+1\le k\le t}|\hat{r}'_{t-k}|^2\right)^{1/2} \le O(n/\tau_1^2) \le O(n/\tau_1^2)\,.$$

On the other hand, for $t > s + \Lambda$, by the bound that $|\hat{r}'_k|^2 \le \|z'_k\|^2 \le O(n\alpha^{2k-2n}/\tau_1^2)$, we have,

$$\begin{aligned}\|u'_{st}\| &\le \sum_{s+1\le k\le t-1}\|z_{k-1-s}\|\cdot|\hat{r}'_{t-k}| \le \sum_{s+1\le k\le t-1} n\alpha^{t-s-1}/\tau_1^2 \\ &\le O(n(t-s)\alpha^{t-s-1}/\tau_1^2)\,.\end{aligned}$$

Therefore taking sum over s, t, similarly to equation (C.19),

$$\sum_{s,t\in[T]}\|u'_{st}\|^2 \le O(Tn^2\Lambda/\tau_1^4)\,. \tag{C.20}$$

Then using equation (C.2) and equation (C.19) and (C.20), we obtain that

$$\mathrm{Var}[\|G_A\|^2] \le O\left(Tn^3\Lambda^2/\tau_1^6 + \sigma^2Tn^2\Lambda/\tau_1^4\right).$$

Hence, it follows that

$$\mathrm{Var}[G_A] \le \frac{1}{(T-T_1)^2}\mathrm{Var}[G_A] \le \frac{O\left(n^3\Lambda^2/\tau_1^6 + \sigma^2n^2\Lambda/\tau_1^4\right)}{T}\,.$$

We can prove the bound for G_C similarly. ∎

Lemma C.3 *Let $x_1, \ldots, x_T$ be independent random variables with mean 0 and variance 1 and 4-th moment bounded by $O(1)$, and u_{ij} be vectors for $i, j \in [T]$. Moreover, let $\xi_1, \ldots, \xi_T$ be independent random variables with mean 0 and variance σ^2 and u'_{ij} be vectors for $i, j \in [T]$. Then,*

$$\mathrm{Var}\left[\textstyle\sum_{i,j} x_ix_ju_{ij} + \sum_{i,j} x_i\xi_ju'_{ij}\right] \le O(1)\textstyle\sum_{i,j}\|u_{ij}\|^2 + O(\sigma^2)\sum_{i,j}\|u'_{ij}\|^2\,.$$

Proof

Note that the two sums in the target are independent with mean 0, therefore we only need to bound the variance of both sums individually. The proof follows the linearity of expectation and the independence of x_i's:

$$\begin{aligned}\mathbb{E}\left[\left\|\textstyle\sum_{i,j} x_ix_ju_{ij}\right\|^2\right] &= \sum_{i,j}\sum_{k,\ell}\mathbb{E}\left[x_ix_jx_kx_\ell u_{ij}^\top u_{k\ell}\right] \\ &= \sum_i\mathbb{E}[u_{ii}^\top u_{ii}x_i^4] + \sum_{i\ne j}\mathbb{E}[u_{ii}^\top u_{jj}x_i^2x_j^2] + \sum_{i,j}\mathbb{E}\left[x_i^2x_j^2(u_{ij}^\top u_{ij} + u_{ij}^\top u_{ji})\right] \\ &\le \sum_{i,j}u_{ii}^\top u_{jj} + O(1)\sum_{i,j}\|u_{ij}+u_{ji}\|^2 \\ &= \|\textstyle\sum_i u_{ii}\|^2 + O(1)\sum_{i,j}\|u_{ij}\|^2\end{aligned}$$

where at second line we used the fact that for any monomial x^α with an odd degree on one of the x_i's, $\mathbb{E}[x^\alpha] = 0$. Note that $\mathbb{E}[\sum_{i,j} x_ix_ju_{ij}] = \sum_i u_{ii}$. Therefore,

$$\mathrm{Var}\left[\textstyle\sum_{i,j} x_ix_ju_{ij}\right] = \mathbb{E}\left[\|\textstyle\sum_{i,j} x_ix_ju_{ij}\|^2\right] - \|\mathbb{E}[\textstyle\sum_{i,j} x_ix_ju_{ij}]\|^2 \le O(1)\textstyle\sum_{i,j}\|u_{ij}\|^2 \tag{C.21}$$

Similarly, we can control $\mathrm{Var}\left[\sum_{i,j} x_i\xi_ju'_{ij}\right]$ by $O(\sigma^2)\sum_{i,j}\|u'_{ij}\|^2$. ∎

Appendix D. Missing proofs in Section 6

D.1 Proof of Lemma 6.5

Towards proving Lemma 6.5, we use the following lemma to express the inverse of a polynomial as a sum of inverses of degree-1 polynomials.

Lemma D.1 *Let $p(z) = (z-\lambda_1)\dots(z-\lambda_n)$ where λ_j's are distinct. Then we have that*

$$\frac{1}{p(z)} = \sum_{j=1}^{n} \frac{t_j}{z-\lambda_j}, \qquad \text{where} \quad t_j = \left(\prod_{i\neq j}(\lambda_j-\lambda_i)\right)^{-1}. \tag{D.1}$$

Proof [Proof of Lemma D.1] By interpolating constant function at points $\lambda_1,\dots,\lambda_n$ using Lagrange interpolating formula, we have that

$$1 = \sum_{j=1}^{n} \frac{\prod_{i\neq j}(x-\lambda_i)}{\prod_{i\neq j}(\lambda_j-\lambda_i)} \cdot 1 \tag{D.2}$$

Dividing $p(z)$ on both sides we obtain equation (D.1). ■

The following lemma computes the Fourier transform of function $1/(z-\lambda)$.

Lemma D.2 *Let $m \in \mathbb{Z}$, and $\mathcal{K}$ be the unit circle in complex plane, and $\lambda \in \mathbb{C}$ inside the $\mathcal{K}$. Then we have that*

$$\int_{\mathcal{K}} \frac{z^m}{z-\lambda}\,\mathrm{d}z = \begin{cases} 2\pi i\lambda^m & \text{for } m \geq 0 \\ 0 & \text{o.w.} \end{cases}$$

Proof [Proof of Lemma D.2] For $m \geq 0$, since z^m is a holomorphic function, by Cauchy's integral formula, we have that

$$\int_{\mathcal{K}} \frac{z^m}{z-\lambda}\,\mathrm{d}z = 2\pi i\lambda^m.$$

For $m < 0$, by changing of variable $y = z^{-1}$ we have that

$$\int_{\mathcal{K}} \frac{z^m}{z-\lambda}\,\mathrm{d}z = \int_{\mathcal{K}} \frac{y^{-m-1}}{1-\lambda y}\,\mathrm{d}y.$$

since $|\lambda y| = |\lambda| < 1$, then we by Taylor expansion we have,

$$\int_{\mathcal{K}} \frac{y^{-m-1}}{1-\lambda y}\,\mathrm{d}y = \int_{\mathcal{K}} y^{-m-1}\left(\sum_{k=0}^{\infty}(\lambda y)^k\right)\,\mathrm{d}y.$$

Since the series λy is dominated by $|\lambda|^k$ which converges, we can switch the integral with the sum. Note that y^{-m-1} is holomorphic for $m < 0$, and therefore we conclude that

$$\int_{\mathcal{K}} \frac{y^{-m-1}}{1-\lambda y}\,\mathrm{d}y = 0.$$

■

Now we are ready to prove Lemma 6.5.

Proof [Proof of Lemma 6.5] Let $m = n+d$. We compute the Fourier transform of $z^m/p(z)$. That is, we write

$$\frac{e^{im\theta}}{p(e^{i\theta})} = \sum_{k=-\infty}^{\infty} \beta_k e^{ik\theta}.$$

where

$$\beta_k = \frac{1}{2\pi}\int_0^{2\pi} \frac{e^{i(m-k)\theta}}{p(e^{i\theta})}d\theta = \frac{1}{2\pi i}\int_{\mathcal{K}} \frac{z^{m-k-1}}{p(z)}\,\mathrm{d}z$$

By Lemma D.1, we write

$$\frac{1}{p(z)} = \sum_{j=1}^{n} \frac{t_j}{z-\lambda_j}.$$

Then it follows that

$$\beta_k = \frac{1}{2\pi i}\sum_{j=1}^{n} t_j \int_{\mathcal{K}} \frac{z^{m-k-1}}{z-\lambda_j}\,\mathrm{d}z$$

Using Lemma D.2, we obtain that

$$\beta_k = \begin{cases} \sum_{j=1}^{n} t_j\lambda_j^{m-k-1} & \text{if } -\infty \leq k \leq m-1 \\ 0 & \text{o.w.} \end{cases} \tag{D.3}$$

We claim that

$$\sum_{j=1}^{n} t_j\lambda_j^{n-1} = 1, \qquad \text{and} \qquad \sum_{j=1}^{n} t_j\lambda_j^{s} = 0, \quad 0 \leq s < n-1.$$

Indeed these can be obtained by writing out the lagrange interpolation for polynomial $f(x) = x^s$ with $s \leq n-1$ and compare the leading coefficient. Therefore, we further simplify β_k to

$$\beta_k = \begin{cases} \sum_{j=1}^{n} t_j\lambda_j^{m-k-1} & \text{if } -\infty < k < m-n \\ 1 & \text{if } k = m-n \\ 0 & \text{o.w.} \end{cases} \tag{D.4}$$

Let $h(z) = \sum_{k\geq 0}\beta_k z^k$. Then we have that $h(z)$ is a polynomial with degree $d = m-n$ and leading term 1. Moreover, for our choice of d,

$$\left|\frac{z^m}{p(z)} - h(z)\right| = \left|\sum_{k<0}\beta_k z^k\right| \leq \sum_{k<0}|\beta_k| \leq \max_j |t_j|(1-\lambda_j)^n \sum_{k<0}(1-\gamma)^{d-k-1}$$
$$\leq \Gamma(1-\gamma)^d/\gamma < \zeta.$$

■

D.2 Proof of Theorem 6.9

Theorem 6.9 follows directly from a combination of Lemma D.3 and Lemma D.4 below. Lemma D.3 shows that the denominator of a function (under the stated assumptions) can be extended to a polynomial that takes values in $\mathcal{C}^+$ on unit circle. Lemma D.4 shows that it can be further extended to another polynomial that takes values in $\mathcal{C}$.

Lemma D.3 *Suppose the roots of s are inside circle with radius $\alpha < 1$, and $\Gamma = \Gamma(s)$. If transfer function $G(z) = s(z)/p(z)$ satisfies that $G(z) \in \mathcal{C}_{\tau_0,\tau_1,\tau_2}$ (or $G(z) \in \mathcal{C}^+_{\tau_0,\tau_1,\tau_2}$) for any z on unit circle, then there exists $u(z)$ of degree $d = O_\tau(\max\{(\frac{1}{1-\alpha}\log\frac{\sqrt{n}\Gamma\cdot\|p\|_{\mathcal{H}_2}}{1-\alpha}, 0\})$ such that $p(z)u(z)/z^{n+d} \in \mathcal{C}_{\tau_0',\tau_1',\tau_2'}$ (or $p(z)u(z)/z^{n+d} \in \mathcal{C}^+_{\tau_0',\tau_1',\tau_2'}$ respectively) for $\tau' = \Theta_\tau(1)$, where $O_\tau(\cdot), \Theta_\tau(\cdot)$ hide the polynomial dependencies on τ_0, τ_1, τ_2.*

Proof [Proof of Lemma D.3] By the fact that $G(z) = s(z)/p(z) \in \mathcal{C}_{\tau_0,\tau_1,\tau_2}$, we have that $p(z)/s(z) \in \mathcal{C}_{\tau_0',\tau_1',\tau_2'}$ for some τ' that polynomially depend on τ. Using Lemma 6.5, there exists $u(z)$ of degree d such that

$$\left|\frac{z^{n+d}}{s(z)} - u(z)\right| \le \zeta\,.$$

where we set $\zeta \ll \min\{\tau_0', \tau_1'\}/\tau_2' \cdot \|p\|_{\mathcal{H}_\infty}^{-1}$. Then we have that

$$\left|p(z)u(z)/z^{n+d} - \frac{p(z)}{s(z)}\right| \le |p(z)|\zeta \ll \min\{\tau_0', \tau_1'\}. \tag{D.5}$$

It follows from equation (D.5) implies that that $p(z)u(z)/z^{n+d} \in \mathcal{C}_{\tau_0'',\tau_1'',\tau_2''}$, where τ'' polynomially depends on τ. The same proof still works when we replace $\mathcal{C}$ by $\mathcal{C}^+$. ■

Lemma D.4 *Suppose $p(z)$ of degree n and leading coefficient 1 satisfies that $p(z) \in \mathcal{C}^+_{\tau_0,\tau_1,\tau_2}$ for any z on unit circle. Then there exists $u(z)$ of degree d such that $p(z)u(z)/z^{n+d} \in \mathcal{C}_{\tau_0',\tau_1',\tau_2'}$ for any z on unit circle with $d = O_\tau(n)$ and $\tau_0', \tau_1', \tau_2' = \Theta_\tau(1)$, where $O_\tau(\cdot), \Theta_\tau(\cdot)$ hide the dependencies on τ_0, τ_1, τ_2.*

Proof [Proof of Lemma D.4] We fix z on unit circle first. Let's defined $\sqrt{p(z)/z^n}$ be the square root of $p(z)/z^n$ with principle value. Let's write $p(z)/z^n = \tau_2(1 + (\frac{p(z)}{\tau_2 z^n} - 1))$ and we take Taylor expansion for $\frac{1}{\sqrt{p(z)/z^n}} = \tau_2^{-1/2}(1 + (\frac{p(z)}{\tau_2 z^n} - 1))^{-1/2} = \tau_2^{-1/2}\left(\sum_{k=0}^{\infty}(\frac{p(z)}{\tau_2 z^n} - 1)^k\right)$. Note that since $\tau_1 < |p(z)| < \tau_2$, we have that $|\frac{p(z)}{\tau_2 z^n} - 1| < 1 - \tau_1/\tau_2$. Therefore truncating the Taylor series at $k = O_\tau(1)$ we obtain a polynomial a rational function $h(z)$ of the form

$$h(z) = \textstyle\sum_{j\ge 0}^{k}(\frac{p(z)}{\tau_2 z^n} - 1)^j\,,$$

which approximates $\frac{1}{\sqrt{p(z)/z^n}}$ with precision $\zeta \ll \min\{\tau_0, \tau_1\}/\tau_2$, that is, $\left|\frac{1}{\sqrt{p(z)/z^n}} - h(z)\right| \le \zeta$. Therefore, we obtain that $\left|\frac{p(z)h(z)}{z^n} - \sqrt{p(z)/z^n}\right| \le \zeta|p(z)/z^n| \le \zeta\tau_2$. Note that since $p(z)/z^n \in \mathcal{C}^+_{\tau_0,\tau_1,\tau_2}$, we have that $\sqrt{p(z)/z^n} \in \mathcal{C}_{\tau_0',\tau_1',\tau_2'}$ for some constants $\tau_0', \tau_1', \tau_2'$. Therefore $\frac{p(z)h(z)}{z^n} \in \mathcal{C}_{\tau_0',\tau_1',\tau_2'}$. Note that $h(z)$ is not a polynomial yet. Let $u(z) = z^{nk}h(z)$ and then $u(z)$ is polynomial of degree at most nk and $p(z)u(z)/z^{(n+1)k} \in \mathcal{C}_{\tau_0',\tau_1',\tau_2'}$ for any z on unit circle. ■

Appendix E. Back-propagation implementation

In this section we give a detailed implementation of using back-propagation to compute the gradient of the loss function. The algorithm is for general MIMO case with the parameterization (7.3). To obtain the SISO sub-case, simply take $\ell_{\text{in}} = \ell_{\text{out}} = 1$.

Algorithm 3 Back-propagation

Parameters: $\hat{a} \in \mathbb{R}^n$, $\hat{C} \in \mathbb{R}^{\ell_{\text{in}} \times n\ell_{\text{out}}}$, and $\hat{D} \in \mathbb{R}^{\ell_{\text{in}} \times \ell_{\text{out}}}$. Let $\hat{A} = \text{MCC}(\hat{a}) = \text{CC}(\hat{a}) \otimes I_{\ell_{\text{in}}}$ and $\hat{B} = e_n \otimes I_{\ell_{\text{in}}}$.
Input: samples $((x^{(1)}, y^1), \ldots, x^{(N)}, y^{(N)})$ and projection set $\mathcal{B}_\alpha$.

for each sample $(x^{(j)}, y^j) = ((x_1, \ldots, x_T), (y_1, \ldots, y_T))$ **do**
  Feed-forward pass:
    $h_0 = 0 \in \mathbb{R}^{n\ell_{\text{in}}}$.
    for $k = 1$ to T
      $\hat{h}_k \leftarrow \hat{A}\hat{h}_{k-1} + \hat{B}x_k$, $\hat{y}_t \leftarrow \hat{C}h_k + \hat{D}x_k$ and $\hat{h}_k \leftarrow \hat{A}h_{k-1} + \hat{B}x_k$.
    end for
  Back-propagation:
    $\Delta h_{T+1} \leftarrow 0$, $G_A \leftarrow 0$, $G_C \leftarrow 0$. $G_D \leftarrow 0$
    $T_1 \leftarrow T/4$
    for $k = T$ to 1
      if $k > T_1$, $\Delta y_k \leftarrow \hat{y}_k - y_k$, o.w. $\Delta y_k \leftarrow 0$. Let $\Delta h_k \leftarrow \hat{C}^\top \Delta y_k + \hat{A}^\top \Delta h_{k+1}$.
      update $G_C \leftarrow G_C + \frac{1}{T-T_1}\Delta y_k \hat{h}_k$, $G_A \leftarrow G_A - \frac{1}{T-T_1}B^\top \Delta h_k \hat{h}_{k-1}^\top$, and $G_D \leftarrow G_D + \frac{1}{T-T_1}\Delta y_k x_k$.
    end for
  Gradient update: $\hat{A} \leftarrow \hat{A} - \eta \cdot G_A$, $\hat{C} \leftarrow \hat{C} - \eta \cdot G_C$, $\hat{D} \leftarrow \hat{D} - \eta \cdot G_D$.
  Projection step: Obtain $\hat{a}$ from $\hat{A}$ and set $\hat{a} \leftarrow \Pi_{\mathcal{B}}(\hat{a})$, and $\hat{A} = \text{MCC}(\hat{a})$
end for

Appendix F. Projection to the set $\mathcal{B}_\alpha$

In order to have a fast projection algorithm to the convex set $\mathcal{B}_\alpha$, we consider a grid $\mathcal{G}_M$ of size M over the circle with radius α. We will show that $M = O_\tau(n)$ will be enough to approximate the set $\mathcal{B}_\alpha$ in the sense that projecting to the approximating set suffices for the convergence.

Let $\mathcal{B}'_{\alpha,\tau_0,\tau_1,\tau_2} = \{a : p_a(z)/z^n \in \mathcal{C}_{\tau_0,\tau_1,\tau_2}, \forall z \in \mathcal{G}_M\}$ and $\mathcal{B}_{\alpha,\tau_0,\tau_1,\tau_2} = \{a : p_a(z)/z^n \in \mathcal{C}_{\tau_0,\tau_1,\tau_2}, \forall |z| = \alpha\}$. Here $\mathcal{C}_{\tau_0,\tau_1,\tau_2}$ is defined the same as before though we used the subscript

to emphasize the dependency on τ_i's,

$$\mathcal{C}_{\tau_0,\tau_1,\tau_2} = \{z : \Re z \geq (1+\tau_0)|\Im z|\} \cap \{z : \tau_1 < \Re z < \tau_2\}\,. \tag{F.1}$$

We will first show that with $M = O_\tau(n)$, we can make $\mathcal{B}'_{\alpha,\tau_1,\tau_2,\tau_3}$ to be sandwiched within to two sets $\mathcal{B}_{\alpha,\tau_0,\tau_1,\tau_2}$ and $\mathcal{B}_{\alpha,\tau'_0,\tau'_1,\tau'_2}$.

Lemma F.1 *For any $\tau_0 > \tau'_0, \tau_1 > \tau'_1, \tau_2 < \tau'_2$, we have that for $M = O_\tau(n)$, there exists $\kappa_0, \kappa_1, \kappa_2$ that polynomially depend on τ_i, τ'_i's such that $\mathcal{B}_{\alpha,\tau_0,\tau_1,\tau_2} \subset \mathcal{B}'_{\alpha,\kappa_0,\kappa_1,\kappa_2} \subset \mathcal{B}_{\alpha,\tau'_0,\tau'_1,\tau'_2}$*

Before proving the lemma, we demonstrate how to use the lemma in our algorithm: We will pick $\tau'_0 = \tau_0/2$, $\tau'_1 = \tau_1/2$ and $\tau'_2 = 2\tau_2$, and find κ_i's guaranteed in the lemma above. Then we use $\mathcal{B}'_{\alpha,\kappa_0,\kappa_1,\kappa_2}$ as the projection set in the algorithm (instead of $\mathcal{B}_{\alpha,\tau_0,\tau_1,\tau_2}$)). First of all, the ground-truth solution Θ is in the set $\mathcal{B}'_{\alpha,\kappa_0,\kappa_1,\kappa_2}$. Moreover, since $\mathcal{B}'_{\alpha,\kappa_0,\kappa_1,\kappa_2} \subset \mathcal{B}_{\alpha,\tau'_0,\tau'_1,\tau'_2}$, we will guarantee that the iterates $\widehat{\Theta}$ will remain in the set $\mathcal{B}_{\alpha,\tau'_0,\tau'_1,\tau'_2}$ and therefore the quasi-convexity of the objective function still holds[9].

Note that the set $\mathcal{B}'_{\alpha,\kappa_0,\kappa_1,\kappa_2}$ contains $O(n)$ linear constraints and therefore we can use linear programming to solve the projection problem. Moreover, since the points on the grid forms a Fourier basis and therefore Fast Fourier transform can be potentially used to speed up the projection. Finally, we will prove Lemma F.1. We need S. Bernstein's inequality for polynomials.

Theorem F.2 (Bernstein's inequality, see, for example, Schaeffer (1941)) *Let $p(z)$ be any polynomial of degree n with complex coefficients. Then,*

$$\sup_{|z|\leq 1} |p'(z)| \leq n \sup_{|z|\leq 1} |p(z)|.$$

We will use the following corollary of Bernstein's inequality.

Corollary F.3 *Let $p(z)$ be any polynomial of degree n with complex coefficients. Then, for $m = 20n$,*

$$\sup_{|z|\leq 1} |p'(z)| \leq 2n \sup_{k\in[m]} |p(e^{2ik\pi/m})|.$$

Proof For simplicity let $\tau = \sup_{k\in[m]} |p(e^{2ik\pi/m})|$, and let $\tau' = \sup_{k\in[m]} |p(e^{2ik\pi/m})|$. If $\tau' \leq 2\tau$ then we are done by Bernstein's inequality. Now let's assume that $\tau' > 2\tau$. Suppose $p(z) = \tau'$. Then there exists k such that $|z - e^{2\pi ik/m}| \leq 4/m$ and $|p(e^{2\pi ik/m})| \leq \tau$. Therefore by Cauchy mean-value theorem we have that there exists ξ that lies between z and $e^{2\pi ik/m}$ such that $p'(\xi) \geq m(\tau' - \tau)/4 \geq 1.1n\tau'$, which contradicts Bernstein's inequality. ■

Lemma F.4 *Suppose a polynomial of degree n satisfies that $|p(w)| \leq \tau$ for every $w = \alpha e^{2i\pi k/m}$ for some $m \geq 20n$. Then for every z with $|z| = \alpha$ there exists $w = \alpha e^{2i\pi k/m}$ such that $|p(z) - p(w)| \leq O(n\alpha\tau/m)$.*

9. with a slightly worse parameter up to constant factor since τ_i's are different from τ_i's up to constant factors

Proof Let $g(z) = p(\alpha z)$ by a polynomial of degree at most n. Therefore we have $g'(z) = \alpha p(z)$. Let $w = \alpha e^{2i\pi k/m}$ such that $|z - w| \leq O(\alpha/m)$. Then we have

$$\begin{aligned}
|p(z) - p(w)| = |g(z/\alpha) - p(w/\alpha)| &\leq \sup_{|x|\leq 1} |g'(x)| \cdot \frac{1}{\alpha}|z - w| \\
&\qquad \text{(By Cauchy's mean-value Theorem)} \\
&\leq \sup_{|x|\leq 1} |p'(x)| \cdot |z - w| \leq n\tau|z - w|\,. \quad \text{(Corallary F.3)} \\
&\leq O(\alpha n\tau/m)\,.
\end{aligned}$$

■

Now we are ready to prove Lemma F.1.

Proof [Proof of Lemma F.1] We choose $\kappa_i = \frac{1}{2}(\tau_i + \tau'_i)$.The first inequality is trivial. We prove the second one. Consider a such that $a \in \mathcal{B}_{\alpha,\kappa_0,\kappa_1,\kappa_2}$. We wil show that $a \in \mathcal{B}'_{\alpha,\tau'_0,\tau'_1,\tau'_2}$. Let $q_a(z) = p(z^{-1})z^n$. By Lemma F.4, for every z with $|z| = 1/\alpha$, we have that there exists $w = \alpha^{-1}e^{2\pi ik/M}$ for some integer k such that $|q_a(z) - q_a(w)| \leq O(\tau_2 n/(\alpha M))$. Therefore let $M = cn$ for sufficiently large c (which depends on τ_i's), we have that for every z with $|z| = 1/\alpha$, $q_a(z) \in \mathcal{C}_{\tau'_0,\tau'_1,\tau'_2}$. This completes the proof. ■

Abstract

We consider a distributed learning approach in supervised learning for a large class of spectral regularization methods in an reproducing kernel Hilbert space (RKHS) framework. The data set of size n is partitioned into $m = O(n^\alpha)$, $\alpha < \frac{1}{2}$, disjoint subsamples. On each subsample, some spectral regularization method (belonging to a large class, including in particular Kernel Ridge Regression, L^2-boosting and spectral cut-off) is applied. The regression function f is then estimated via simple averaging, leading to a substantial reduction in computation time. We show that minimax optimal rates of convergence are preserved if m grows sufficiently slowly (corresponding to an upper bound for α) as $n \to \infty$, depending on the smoothness assumptions on f and the intrinsic dimensionality. In spirit, the analysis relies on a classical bias/stochastic error analysis.

Keywords: Distributed Learning, Spectral Regularization, Minimax Optimality

1. Introduction

Distributed learning (DL) algorithms are a standard tool for reducing computational burden in machine learning problems where massive datasets are involved. Assuming a complexity cost (for time and/or memory) of $O(n^\beta)$ ($\beta > 1$, $\beta \in [2,3]$ being common) of the base learning algorithm without parallelization, dividing randomly data of cardinality n into m disjoint, equally-sized subsamples and processing them in parallel using the same base learning algorithm has therefore complexity cost of $O(m.(n/m)^\beta) = O(n^\beta/m^{\beta-1})$, roughly gaining a factor $m^{\beta-1}$ (for time and memory) compared to the single machine approach. The final output is obtained from averaging the individual outputs.

Recently, DL was studied in several machine learning contexts. In point estimation (Li et al., 2013), matrix factorization (Mackey et al., 2011), smoothing spline models and testing (Cheng and Shang, 2016), local average regression (Chang et al., 2017), in classification (Hsieh et al., 2014; Guo et al., 2015), and also in kernel ridge regression (Zhang et al., 2013; Lin et al., 2017; Xu et al., 2016).

In this paper, we study the DL approach for the statistical learning problem

$$Y_i := f(X_j) + \epsilon_i \,, j = 1 \,, \ldots, n \,, \tag{1}$$

at random i.i.d. data points $X_1, \ldots, X_n$ drawn according to a probability distribution ν on $\mathcal{X}$, where ϵ_j are independent centered noise variables. The unknown regression function f is real-valued and belongs to some reproducing kernel Hilbert space with bounded kernel K. We partition the given data set $D = \{(X_1, Y_1), \ldots, (X_n, Y_n)\} \subset \mathcal{X} \times \mathbb{R}$ into m disjoint equal-size subsamples $D_1, \ldots, D_m$. On each subsample D_j, we compute a local estimator $\hat{f}^\lambda_{D_j}$, using a spectral regularization method. The final estimator for the target function f is obtained by simple averaging: $\bar{f}^\lambda_D := \frac{1}{m}\sum_{j=1}^m \hat{f}^\lambda_{D_j}$.
The non-distributed setting ($m = 1$) has been studied in the recent paper of Blanchard and Mücke (2017), building the root position of our results in the distributed setting, where weak and strong minimax optimal rates of convergence are established. Our aim is to extend these results to distributed learning and to derive minimax optimal rates. We again apply a fairly large class of spectral regularization methods, including the popular kernel ridge regression (KRR), L^2-boosting and spectral cut-off. Using the same notation as Blanchard and Mücke (2017), we let

$$T : f \in \mathcal{H}_K \mapsto \int f(x)K(x,\cdot)d\nu(x) \in \mathcal{H}_K$$

denote the kernel integral operator associated to K and the sampling measure ν. We denote $\bar{T} = \kappa^{-2}T$, with κ^2 the upper bound of K. Our rates of convergence are governed by a *source condition* assumption on f of the form

$$\Omega(r,R) := \{f \in \mathcal{H}_K : f = \bar{T}^r h, \ \|h\|_{\mathcal{H}_K} \leq R\}$$

for some constants $r, R > 0$ as well as by the *ill-posedness* of the problem, as measured by an assumed power decay of the eigenvalues of T with exponent $b > 1$. We show that for $s \in [0, \frac{1}{2}]$ in the sense of p-th moment ($p \geq 1$) expectation

$$\left\| \bar{T}^s (f - \bar{f}^{\lambda_n}_D) \right\|_{\mathcal{H}_K} \lesssim R \left(\frac{\sigma^2}{R^2 n} \right)^{\frac{(r+s)}{2r+1+1/b}} , \tag{2}$$

for an appropriate choice of the regularization parameter λ_n , depending on the global sample size n as well as on R and the noise variance σ^2 (but not on the number m of subsample sets). Note that $s = 0$ corresponds to the reconstruction error (i.e. $\mathcal{H}_K$-norm), and $s = \frac{1}{2}$ to the

prediction error (i.e., $L^2(\nu)$-norm). The symbol $\lesssim$ means that the inequality holds up to a multiplicative constant that can depend on various parameters entering in the assumptions of the result, but not on n, m, σ, nor R. An important assumption is that the inequality $q \geq r + s$ should hold, where q is the *qualification* of the regularization method, a quantity defined in the classical theory of inverse problems (see Section 2.3 for a precise definition). Basic problems are the choice of the regularization parameter on the subsamples and, most importantly, the proper choice of m, since it is well known that choosing m too large gives a suboptimal convergence rate in the limit $n \to \infty$ (see, e.g., Xu et al., 2016).

Our approach to this problem is based on a relatively classical bias-variance decomposition principle. Choosing the global regularization parameter as the optimal choice for a *single* sample of size n results in a bias estimate which is identical for all subsamples, is unchanged by averaging, and is straightforward from the single-sample analysis. On the other hand, the reduced sample size of each of the m individual subsamples causes an inflation of variance. However, since the m subsamples are independent, so are the outputs of the learning algorithm applied to each one of them; as a consequence averaging reduces the inflated variance sufficiently to get minimax optimality. We can write the variance as a sum of independent random variables, allowing to successfully apply a Rosenthal's inequality in the Hilbert space setting due to Pinelis (1994). The technical "limiting factors" in this argument give rise to the limitation on the number of subsamples m; for m larger than the allowed range, some remainder terms are no longer negligible using our proof technique, and rate optimality is not guaranteed any longer.

The outline of the paper is as follows. Section 2 contains notation and the setting. Section 3 states our main result on distributed learning. Section 4 presents numerical studies. A concluding discussion in Section 5 contains a more detailed comparison of our results with related results available in the literature. Section 6 contains the proofs of the theorems.

2. Notation, statistical model and distributed learning algorithm

In this section, we specify the mathematical background and the statistical model for (distributed) regularized learning. We have included this section for self sufficiency and reader convenience. It essentially repeats the setting in Blanchard and Mücke (2017) in summarized form.

2.1 Kernel-induced operators

We assume that the input space $\mathcal{X}$ is a standard Borel space endowed with a probability measure ν, the output space is equal to $\mathbb{R}$. We let K be a real-valued positive semidefinite kernel on $\mathcal{X} \times \mathcal{X}$ which is bounded by κ^2. The associated reproducing kernel Hilbert space will be denoted by $\mathcal{H}_K$. It is assumed that all functions $f \in \mathcal{H}_K$ are measurable and bounded in supremum norm, i.e. $\|f\|_\infty \leq \kappa \|f\|_{\mathcal{H}_K}$ for all $f \in \mathcal{H}_K$. Therefore, $\mathcal{H}_K$ is a subset of $L^2(\mathcal{X}, \nu)$, with $S : \mathcal{H}_K \longrightarrow L^2(\mathcal{X}, \nu)$ being the inclusion operator, satisfying

$\|S\| \leq \kappa$. The adjoint operator $S^* : L^2(\mathcal{X}, \nu) \longrightarrow \mathcal{H}_K$ is identified as

$$S^* g = \int_{\mathcal{X}} g(x) K_x \, \nu(dx) \, ,$$

where K_x denotes the element of $\mathcal{H}_K$ equal to the function $t \mapsto K(x,t)$. The covariance operator $T : \mathcal{H}_K \longrightarrow \mathcal{H}_K$ is given by

$$T = \int_{\mathcal{X}} \langle \cdot, K_x \rangle_{\mathcal{H}_K} K_x \, \nu(dx) \, ,$$

which can be shown to be positive self-adjoint trace class (and hence is compact). The empirical versions of these operators, corresponding formally to taking the empirical distribution $\widehat{\nu}_n = \frac{1}{n} \sum_{i=1}^n \delta_{x_i}$ in place of ν in the above formulas, are given by

$$S_{\mathbf{x}} : \mathcal{H}_K \longrightarrow \mathbb{R}^n \, , \qquad (S_{\mathbf{x}} f)_j = \langle f, K_{x_j} \rangle_{\mathcal{H}_K} \, ,$$

$$S_{\mathbf{x}}^* : \mathbb{R}^n \longrightarrow \mathcal{H}_K \, , \qquad S_{\mathbf{x}}^* \mathbf{y} = \frac{1}{n} \sum_{j=1}^n y_j K_{x_j} \, ,$$

$$T_{\mathbf{x}} := S_{\mathbf{x}}^* S_{\mathbf{x}} : \mathcal{H}_K \longrightarrow \mathcal{H}_K \, , \qquad T_{\mathbf{x}} = \frac{1}{n} \sum_{j=1}^n \langle \cdot, K_{x_j} \rangle_{\mathcal{H}_K} K_{x_j} \, .$$

We introduce the shortcut notation $\bar{T} = \kappa^{-2} T$ and $\bar{T}_{\mathbf{x}} := \kappa^{-2} T_{\mathbf{x}}$, ensuring $\|\bar{T}\| \leq 1$ and $\|\bar{T}_x\| \leq 1$, for any $x \in \mathcal{X}$. Similarly, $\bar{S} = \kappa^{-1} S$ and $\bar{S}_{\mathbf{x}_j} := \kappa^{-1} S_{\mathbf{x}_j}$, ensuring $\|\bar{S}\| \leq 1$ and $\|\bar{S}_x\| \leq 1$, for any $x \in \mathcal{X}$. The numbers μ_j are the positive eigenvalues of $\bar{T}$ satisfying $0 < \mu_{j+1} \leq \mu_j$ for all $j > 0$ and $\mu_j \searrow 0$.

2.2 Noise assumption and prior classes

In our setting of kernel learning, the sampling is assumed to be random i.i.d., where each observation point (X_i, Y_i) follows the model $Y = f_\rho(X) + \varepsilon$. For (X, Y) having distribution ρ, we assume that the conditional expectation wrt. ρ of Y given X exists and belongs to $\mathcal{H}_K$, that is, it holds for ν-almost all $x \in X$:

$$\mathbb{E}_\rho[Y | X = x] = \bar{S}_x f_\rho \, , \text{ for some } f_\rho \in \mathcal{H}_K \, . \tag{3}$$

Furthermore, we will make the following assumption on the observation noise distribution: There exists $\sigma > 0$ and $M > 0$ such that for any $l \geq 2$

$$\mathbb{E}[\, |Y - \bar{S}_X f_\rho|^l \, | \, X \,] \leq \frac{1}{2} l! \sigma^2 M^{l-2} \, , \quad \nu - \text{a.s.} \tag{4}$$

To derive nontrivial rates of convergence, we concentrate our attention on specific subsets (also called *models*) of the class of probability measures. If $\mathcal{P}$ denotes the set of all probability distributions on $\mathcal{X}$, we define classes of sampling distributions by introducing a decay

condition on the *effective dimension* $\mathcal{N}(\lambda)$, being a measure for the complexity of $\mathcal{H}_K$ with respect to the marginal distribution ν: For $\lambda \in (0,1]$ we set

$$\mathcal{N}(\lambda) = \mathrm{Trace}[\ (\bar{T}+\lambda)^{-1}\bar{T}\ ]\ . \tag{5}$$

Note that $\mathcal{N}(\lambda) \leq 1$. For any $b > 1$ we introduce

$$\mathcal{P}^{<}(b) := \{\nu \in \mathcal{P}:\ \mathcal{N}(\lambda) \leq C_b(\kappa^2\lambda)^{-\frac{1}{b}}\ \}\ . \tag{6}$$

In De Vito and Caponnetto, 2006, Proposition 3, it is shown that such a condition is implied by polynomially decreasing eigenvalues of $\bar{T}$. More precisely, if the eigenvalues μ_i satisfy $\mu_j \leq \beta/j^b\ \ \forall j \geq 1$ or $b > 1$ and $\beta > 0$, then

$$\mathcal{N}(\lambda) \leq \frac{\beta^{\frac{1}{b}}b}{b-1}(\kappa^2\lambda)^{-\frac{1}{b}}\ .$$

For a subset $\Omega \subseteq \mathcal{H}_K$, we let $\mathcal{K}(\Omega)$ be the set of regular conditional probability distributions $\rho(\cdot|\cdot)$ on $\mathcal{B}(\mathbb{R})\times\mathcal{X}$ such that (3) and (4) hold for some $f_\rho \in \Omega$. We will focus on a *Hölder-type source condition*, i.e. given $r > 0, R > 0$ and $\nu \in \mathcal{P}$, we define

$$\Omega(r,R) := \{f \in \mathcal{H}_K : f = \bar{T}^r h,\ \|h\|_{\mathcal{H}_K} \leq R\}. \tag{7}$$

Then the class of models which we will consider will be defined as

$$\mathcal{M}(r,R,\mathcal{P}')\ :=\ \{\ \rho(dx,dy) = \rho(dy|x)\nu(dx)\ :\ \rho(\cdot|\cdot) \in \mathcal{K}(\Omega(r,R)),\ \nu \in \mathcal{P}'\ \}\ , \tag{8}$$

with $\mathcal{P}' = \mathcal{P}^{<}(b)$. As a consequence, the class of models depends not only on the smoothness properties of the solution (reflected in the parameters $R > 0,\ r > 0$), but also essentially on spectral properties of $\bar{T}$, reflected in $\mathcal{N}(\lambda)$.

2.3 Spectral regularization

In this subsection, we introduce the class of linear regularization methods based on spectral theory for self-adjoint linear operators. These are standard methods for finding stable solutions for ill-posed inverse problems. Originally, these methods were developed in the deterministic context (see Engl et al., 2000). Later on, they have been applied to probabilistic problems in machine learning (see, e.g., Bauer et al., 2007; De Vito and Caponnetto, 2006; Dicker et al., 2017 or Blanchard and Mücke, 2017).

Definition 1 (Regularization function) *Let $g : (0,1]\times[0,1] \longrightarrow \mathbb{R}$ be a function and write $g_\lambda = g(\lambda,\cdot)$. The family $\{g_\lambda\}_\lambda$ is called regularization function, if the following conditions hold:*

(i) There exists a constant $D' < \infty$ such that for any $0 < \lambda \leq 1$

$$\sup_{0\leq t\leq 1}|tg_\lambda(t)| \leq D'\ . \tag{9}$$

(ii) There exists a constant $E < \infty$ such that for any $0 < \lambda \leq 1$

$$\sup_{0\leq t\leq 1}|g_\lambda(t)| \leq \frac{E}{\lambda}\ . \tag{10}$$

(iii) Defining the residual *$r_\lambda(t) := 1 - g_\lambda(t)t$, there exists a constant $\gamma_0 < \infty$ such that for any $0 < \lambda \leq 1$*

$$\sup_{0\leq t\leq 1}|r_\lambda(t)| \leq \gamma_0\ .$$

It has been shown in e.g. Gerfo et al. (2008), Dicker et al. (2017), Blanchard and Mücke (2017) that attainable learning rates are essentially linked with the qualification of the regularization $\{g_\lambda\}_\lambda$, being the maximal q such that for any $0 < \lambda \leq 1$

$$\sup_{0\leq t\leq 1}|r_\lambda(t)|t^q \leq \gamma_q\lambda^q. \tag{11}$$

for some constant $\gamma_q > 0$. Note that by (iii) , using interpolation, we have validity of (11) also for any $q' \in [0,q]$ with constant $\gamma_{q'} = \gamma_0^{1-\frac{q'}{q}}\gamma_q^{\frac{q'}{q}}$.

The most popular examples include:

Example 1 *(Tikhonov Regularization, Kernel Ridge Regression) The choice $g_\lambda(t) = \frac{1}{\lambda+t}$ corresponds to Tikhonov regularization. In this case we have $D' = E = \gamma_0 = 1$. The qualification of this method is $q = 1$ with $\gamma_q = 1$.*

Example 2 *(Landweber Iteration, gradient descent) The Landweber Iteration (gradient descent algorithm with constant stepsize) is defined by*

$$g_k(t) = \sum_{j=0}^{k-1}(1-t)^j\ \ \text{with } k = 1/\lambda \in \mathbb{N}\ .$$

We have $D' = E = \gamma_0 = 1$. The qualification q of this algorithm can be arbitrary with $\gamma_q = 1$ if $0 < q \leq 1$ and $\gamma_q = q^q$ if $q > 1$.

Example 3 (ν- method) *The $\nu-$ method belongs to the class of so called semi-iterative regularization methods. This method has finite qualification $q = \nu$ with γ_q a positive constant. Moreover, $D = 1$ and $E = 2$. The filter is given by $g_k(t) = p_k(t)$, a polynomial of degree $k-1$, with regularization parameter $\lambda \sim k^{-2}$, which makes this method much faster as e.g. gradient descent.*

2.4 Distributed learning algorithm

We let $D = \{(x_j, y_j)\}_{j=1}^n \subset \mathcal{X} \times \mathcal{Y}$ be the dataset, which we partition into m disjoint subsamples[1] $D_1, \ldots, D_m$, each having size $\frac{n}{m}$. Denote the jth data subsample by $(\mathbf{x}_j, \mathbf{y}_j) \in (\mathcal{X} \times \mathbb{R})^{\frac{n}{m}}$. On each subsample we compute a local estimator for a suitable a-priori parameter choice $\lambda = \lambda_n$ according to

$$f_{D_j}^{\lambda_n} := g_{\lambda_n}(\bar{T}_{\mathbf{x}_j}) \bar{S}_{\mathbf{x}_j}^* \mathbf{y}_j \ . \tag{12}$$

By f_D^λ we will denote the estimator using the whole sample $m = 1$. The final estimator is given by simple averaging of the local ones:

$$\bar{f}_D^\lambda := \frac{1}{m} \sum_{j=1}^m f_{D_j}^\lambda \ . \tag{13}$$

3. Main results

This section presents our main results. Theorem 3 and Theorem 4 contain separate estimates on the approximation error and the sample error and lead to Corollary 5 which gives an upper bound for the error $\left\| \bar{T}^s (f_\rho - \bar{f}_D^\lambda) \right\|_{\mathcal{H}_K}$ and presents an upper rate of convergence for the sequence of distributed learning algorithms.

For the sake of the reader we recall Theorem 6, which was already shown in Blanchard and Mücke (2017), presenting the minimax optimal rate for the single machine problem. This yields an estimate on the difference between the single machine and the distributed learning algorithm in Corollary 7.

We want to track the precise behavior of these rates not only for what concerns the exponent in the number of examples n, but also in terms of their scaling (multiplicative constant) as a function of some important parameters (namely the noise variance σ^2 and the complexity radius R in the source condition, see Remark 9 below). For this reason, we introduce a notion of a family of rates over a family of models. More precisely, we consider an indexed family $(\mathcal{M}_\theta)_{\theta \in \Theta}$, where for all $\theta \in \Theta$, $\mathcal{M}_\theta$ is a class of Borel probability distributions on $\mathcal{X} \times \mathbb{R}$ satisfying the basic general assumptions (3) and (4). We consider rates of convergence in the sense of the p-th moments of the estimation error, where $1 \leq p < \infty$ is a fixed real number.

1. For the sake of simplicity, throughout this paper we assume that n is divisible by m. This could always be achieved by disregarding some data; alternatively, it is straightforward to show that admitting one smaller block in the partition does not affect the asymptotic results of this paper. We shall not try to discuss this point in greater detail. In particular, we shall not analyze in which general framework our simple averages could be replaced by weighted averages.

As already mentioned in the introduction, our proofs are based on a classical bias-variance decomposition as follows: Introducing

$$\tilde{f}_D^\lambda = \frac{1}{m} \sum_{j=1}^m g_\lambda(\bar{T}_{\mathbf{x}_j}) \bar{T}_{\mathbf{x}_j} f_\rho \ , \tag{14}$$

we write

$$\begin{aligned} \bar{T}^s (f_\rho - \bar{f}_D^\lambda) &= \bar{T}^s (f_\rho - \tilde{f}_D^\lambda) + \bar{T}^s (\tilde{f}_D^\lambda - \bar{f}_D^\lambda) \\ &= \frac{1}{m} \sum_{j=1}^m \bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j}) f_\rho + \frac{1}{m} \sum_{j=1}^m \bar{T}^s g_\lambda(\bar{T}_{\mathbf{x}_j}) (\bar{T}_{\mathbf{x}_j} f_\rho - \bar{S}_{\mathbf{x}_j}^* \mathbf{y}_j) \ . \end{aligned} \tag{15}$$

In all the forthcoming results in this section, we assume:

Assumption 2 *Let $s \in [0, \frac{1}{2}]$, $p \geq 1$ and consider the model $\mathcal{M}_{\sigma,M,R} := \mathcal{M}(r, R, \mathcal{P}^<(b))$ where $r > 0$ and $b > 1$ are fixed, and $\theta = (R, M, \sigma)$ varies in $\Theta = \mathbb{R}_+^3$. Given a sample $D \subset (\mathcal{X} \times \mathbb{R})$ of size n, define $\bar{f}_D^{\lambda_n}$, $f_D^{\lambda_n}$ as in Section 2.4 and $\tilde{f}_D^{\lambda_n}$ as in* (14)*, using a regularization function of qualification $q \geq r + s$, with parameter sequence*

$$\lambda_n := \lambda_{n,(\sigma,R)} := \min \left(\left(\frac{\sigma^2}{R^2 n} \right)^{\frac{b}{2br+b+1}}, 1 \right) \ , \tag{16}$$

independent on M. Define the sequence

$$a_n := a_{n,(\sigma,R)} := R \left(\frac{\sigma^2}{R^2 n} \right)^{\frac{b(r+s)}{2br+b+1}} \ . \tag{17}$$

We recall that we shall always assume that n is a multiple of m. With these preparations, our main results are:

Theorem 3 (Approximation error) *Under Assumption 2, we have: If the number m_n of subsample sets satisfies*

$$m_n \leq n^\alpha \ , \quad \alpha < \frac{2b \min\{r, 1\}}{2br + b + 1} \ , \tag{18}$$

then

$$\sup_{(\sigma,M,R) \in \mathbb{R}_+^3} \limsup_{n \to \infty} \sup_{\rho \in \mathcal{M}_{\sigma,M,R}} \frac{\left[\mathbb{E}_{\rho^{\otimes n}} \left\| \bar{T}^s (f_\rho - \tilde{f}_D^{\lambda_n}) \right\|_{\mathcal{H}_K}^p \right]^{\frac{1}{p}}}{a_n} < \infty \ .$$

Theorem 4 (Sample Error) *Under Assumption 2, we have: If the number m_n of subsample sets satisfies*

$$m_n \leq n^\alpha \,, \quad \alpha < \frac{2br}{2br+b+1} \,, \tag{19}$$

Then

$$\sup_{(\sigma,M,R)\in\mathbb{R}^3_+} \limsup_{n\to\infty} \sup_{\rho\in\mathcal{M}_{\sigma,M,R}} \frac{\left[\mathbb{E}_{\rho^{\otimes n}} \left\|\bar{T}^s(\tilde{f}_D^{\lambda_n} - \bar{f}_D^{\lambda_n})\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}}}{a_n} < \infty \,.$$

And, as consequence (by (15) and applying the triangle inequality for the L^p-norm):

Corollary 5 *Under Assumption 2, we have: If the number m_n of subsample sets satisfies*

$$m_n \leq n^\alpha \,, \quad \alpha < \frac{2b\min\{r,1\}}{2br+b+1} \,, \tag{20}$$

then the sequence (17) *is an upper rate of convergence in L^p for all $p>0$, for the interpolation norm of parameter s, for the sequence of estimated solutions $(\bar{f}_D^{\lambda_{n,(\sigma,R)}})$ over the family of models $(\mathcal{M}_{\sigma,M,R})_{(\sigma,M,R)\in\mathbb{R}^3_+}$, i.e.*

$$\sup_{(\sigma,M,R)\in\mathbb{R}^3_+} \limsup_{n\to\infty} \sup_{\rho\in\mathcal{M}_{\sigma,M,R}} \frac{\left[\mathbb{E}_{\rho^{\otimes n}} \left\|\bar{T}^s(f_\rho - \bar{f}_D^{\lambda_n})\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}}}{a_n} < \infty \,.$$

Theorem 6 (Blanchard and Mücke, 2017) *The sequence* (17) *is an upper rate of convergence in L^p for all $p>0$, for the interpolation norm of parameter s, for the sequence of estimated solutions $(f_D^{\lambda_{n,(\sigma,R)}})$ over the family of models $(\mathcal{M}_{\sigma,M,R})_{(\sigma,M,R)\in\mathbb{R}^3_+}$, i.e.*

$$\sup_{(\sigma,M,R)\in\mathbb{R}^3_+} \limsup_{n\to\infty} \sup_{\rho\in\mathcal{M}_{\sigma,M,R}} \frac{\left[\mathbb{E}_{\rho^{\otimes n}} \left\|\bar{T}^s(f_\rho - f_D^{\lambda_n})\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}}}{a_n} < \infty \,.$$

Combining Corollary 5 with Theorem 6 by applying the triangle inequality immediately yields:

Corollary 7 *If the number m_n of subsample sets satisfies*

$$m_n \leq n^\alpha \,, \quad \alpha < \frac{2b\min\{r,1\}}{2br+b+1} \,, \tag{21}$$

then

$$\sup_{(\sigma,M,R)\in\mathbb{R}^3_+} \limsup_{n\to\infty} \sup_{\rho\in\mathcal{M}_{\sigma,M,R}} \frac{\left[\mathbb{E}_{\rho^{\otimes n}} \left\|\bar{T}^s(f_D^{\lambda_n} - \bar{f}_D^{\lambda_n})\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}}}{a_n} < \infty \,.$$

Remark 8 *Our results in the distributed setting slightly differ from those obtained in Theorem 6 from Blanchard and Mücke (2017) in two several respects:*

- *While in the single machine approach, rates of convergence are obtained for any $p>0$, the proofs in Section 6 only hold for $p \geq 1$ due to loss of subadditivity of p-th moments for $0<p<1$.*
- *While the upper upper rates of convergence in Blanchard and Mücke (2017) are derived over classes of marginals ν induced by assuming a decay condition for the eigenvalues of $\bar{T}$, we somewhat enlarge this class by assuming a decay condition for $\mathcal{N}(\lambda)$ in* (6)*. Theorem 6 also holds under this weaker condition. Note that it is an open problem if lower rates of convergence can also be obtained by weakening the condition for eigenvalue decay.*

Remark 9 (Signal-to-noise-ratio) *Our results show that the choice of the regularization parameter λ_n in* (16) *and thus the rate of convergence a_n in* (17) *highly depend on the signal-to-noise-ratio $\frac{\sigma^2}{R^2}$, a quantity which naturally appears in the theory of regularization of ill-posed inverse problems. As a general rule, the degree of regularization should increase with the level of noise in the data, i.e., the importance of the priors should increase as the model fit decreases. Our theoretical results precisely show this behavior.*

4. Numerical studies

In this section we numerically study the error in $\mathcal{H}_K$-norm, corresponding to $s=0$ in Corollary 5 (in expectation with $p=2$) both in the single machine and distributed learning setting. Our main interest is to study the upper bound for our theoretical exponent α, parametrizing the size of subsamples in terms of the total sample size, $m=n^\alpha$, in different smoothness regimes. In addition we shall demonstrate in which way parallelization serves as a form of regularization.

More specifically, we let $\mathcal{H}_K = H_0^1[0,1]$ be the Sobolev space consisting of absolutely continuous functions f on $[0,1]$ with weak derivative of order 1 in $L^2[0,1]$, with boundary condition $f(0)=f(1)=0$. The reproducing kernel is given by $K(x,t)=x\wedge t - xt$. For all experiments in this section, we simulate data from the regression model

$$Y_i = f_\rho(X_i) + \epsilon_i \,, \qquad i=1,\dots,n \,,$$

where the input variables $X_i \sim Unif[0,1]$ are uniformly distributed and the noise variables $\varepsilon_i \sim N(0,\sigma^2)$ are normally distributed with standard deviation $\sigma=0.005$. We choose the target function f_ρ according to two different cases, namely $r<1$ (*low smoothness regime*) and $r=\infty$ (*high smoothness regime*). To accurately determine the degree of smoothness $r>0$, we apply Proposition 10 below by explicitly calculating the Fourier coefficients $(\langle f_\rho, e_j\rangle_{\mathcal{H}_K})_{j\in\mathbb{N}}$, where $e_j(x)=\frac{\sqrt{2}}{\pi j}\cos(\pi j x)$, for $j\in\mathbb{N}^*$, forms an ONB of $\mathcal{H}_K$. Recall that the rate of eigenvalue decay is explicitly given by $b=2$, meaning that we have full control over all parameters in (21). We need the following characterization:

Proposition 10 (Engl et al., 2000, Prop. 3.13) *Let $\mathcal{H}_K, \mathcal{H}_2$ be separable Hilbert spaces and $S : \mathcal{H}_K \longrightarrow \mathcal{H}_2$ be a compact linear operator with singular system* [2] $\{\sigma_j, \varphi_j, \psi_j\}$. *Denoting by $S^\dagger$ the generalized inverse*[3] *of S, one has for any $r > 0$ and $g \in \mathcal{H}_2$:*

g is in the domain of $S^\dagger$ and $S^\dagger g \in \mathrm{Im}((S^*S)^r)$ if and only if

$$\sum_{j=0}^{\infty} \frac{|\langle g, \psi_j \rangle_{\mathcal{H}_2}|^2}{\sigma_j^{2+4r}} < \infty .$$

In our case, $\mathcal{H}_K$ is as above, $\mathcal{H}_2$ is $L^2([0,1])$ with Lebesgue measure and $S : H_0^1[0,1] \to L^2([0,1])$ is the inclusion. Since $H_0^1[0,1]$ is dense in $L^2([0,1])$, we know that $(\mathrm{Im}(S))^\perp$ is trivial, giving $SS^\dagger = id$ on $\mathrm{Im}(S)$. Furthermore, $\varphi_j = e_j$ is a normalized eigenbasis of $T = S^*S$ with eigenvalues $\sigma_j^2 = (\pi j)^{-2}$. With $\psi_j = \frac{S\varphi_j}{\|S\varphi_j\|_{L^2}}$ we obtain for $f \in H_0^1[0,1]$

$$\langle Sf, \psi_j \rangle_{L^2} = \left\langle Sf, \frac{Se_j}{\|Se_j\|} \right\rangle_{L^2} = \left\langle f, \frac{S^*Se_j}{\|Se_j\|} \right\rangle_{H_0^1} = \sigma_j \langle f, e_j \rangle_{H_0^1}.$$

Thus, applying Proposition 10 gives

Corollary 11 *For S and $T = S^*S$ defined in Section 2, we have for any $r > 0$: $f \in \mathrm{Im}(T^r)$ if and only if*

$$\sum_{j=1}^{\infty} j^{4r} |\langle f, e_j \rangle_{L^2}|^2 < \infty .$$

Thus, as expected, abstract smoothness measured by the parameter r in the source condition corresponds in this special case to decay of the classical Fourier coefficients which by the classical theory of Fourier series measures smoothness of the periodic continuation of $f \in L^2([0,1])$ to the real line.

4.1 Low smoothness regime

We choose $f_\rho(x) = \frac{1}{2}x(1-x)$ which clearly belongs to $\mathcal{H}_K$. A straightforward calculation gives the Fourier coefficient $\langle f_\rho, e_j \rangle = -2(\pi j)^{-2}$ for j odd (vanishing for j even). Thus, by the above criterion, f_ρ satisfies the source condition $f_\rho \in Ran(\bar{T}^r)$ precisely for $0 < r < 0.75$. (Observe that although f_ρ is smooth on $[0,1]$, its periodic continuation on the real line is not, hence the low smoothness regime.) According to Theorem 6, the worst case rate in the single machine problem is given by $n^{-\gamma}$, with $\gamma = 0.25$. Regularization is done using the $\nu-$ method (see Example 3), with qualification $q = \nu = 1$. Recall that the stopping index

2. i.e., the φ_j are the normalized eigenfunctions of S^*S with eigenvalues σ_j^2 and $\psi_j = S\varphi_j/\|S\varphi_j\|$; thus $S = \sum \sigma_j \langle \varphi_j, \cdot \rangle \psi_j$.
3. the unique unbounded linear operator with domain $\mathrm{Im}(S) \oplus (\mathrm{Im}(S))^\perp$ in $\mathcal{H}_2$ vanishing on $(\mathrm{Im}(S))^\perp$ and satisfying $SS^\dagger = 1$ on $\mathrm{Im}(S)$, with range orthogonal to the null space $N(S)$.

k_{stop} serves as the regularization parameter λ, where $k_{stop} \sim \lambda^{-2}$. We consider sample sizes from $500, \ldots, 9000$. In the model selection step, we estimate the performance of different models and choose the *oracle stopping time* $\hat{k}_{oracle}$ by minimizing the reconstruction error:

$$\hat{k}_{oracle} = \arg\min_k \left(\frac{1}{M} \sum_{j=1}^{M} \left\| f_\rho - \hat{f}_j^k \right\|_{\mathcal{H}_K}^2 \right)^{\frac{1}{2}}$$

over $M = 30$ runs.

In the model assessment step, we partition the dataset into $m \sim n^\alpha$ subsamples, for any $\alpha \in \{0, 0.05, 0.1, \ldots, 0.85\}$. On each subsample we regularize using the oracle stopping time $\hat{k}_{oracle}$ (determined by using the whole sample). Corresponding to Corollary 5, the accuracy should be comparable to the one using the whole sample as long as $\alpha < 0.5$. In Figure 1 (left panel) we plot the reconstruction error $\|\bar{f}^{\hat{k}} - f_\rho\|_{\mathcal{H}_K}$ versus the ratio $\alpha = \log(m)/\log(n)$ for different sample sizes. We execute each simulation $M = 30$ times. The plot supports our theoretical finding. The right panel shows the reconstruction error versus the total number of samples using different partitions of the data. The black curve ($\alpha = 0$) corresponds to the baseline error ($m = 0$, no partition of data). Error curves below a threshold $\alpha < 0.6$ are roughly comparable, whereas curves above this threshold show a gap in performances.

In another experiment we study the performances in case of (very) different regularization: Only partitioning the data (no regularization), underregularization (higher stopping index) and overregularization (lower stopping index). The outcome of this experiment amplifies the regularization effect of parallelizing. Figure 2 shows the main point: Overregularization is always hopeless, underregularization is better. In the extreme case of (almost) no regularization, there is a sharp minimum in the reconstruction error which is only slightly larger than the minimax optimal value for the oracle regularization parameter and which is achieved at an attractively large degree of parallelization. Qualitatively, this agrees very well with the intuitive notion that parallelizing serves as regularization.

We emphasize that numerical results seem to indicate that parallelization is possible to a slightly larger degree than indicated by our theoretical estimate. A similar result was reported in the paper Zhang et al. (2013), which also treats the low smoothness case.

4.2 High smoothness regime

We choose $f_\rho(x) = \frac{1}{2\pi}\sin(2\pi x)$, which corresponds to just one non-vanishing Fourier coefficient and by our criterion Corollary 11 has $r = \infty$. In view of our main Corollary 5 this requires a regularization method with higher qualification; we take the *Gradient Descent* method (see Example 2).

The appearance of the term $2b\min\{1, r\}$ in our theoretical result 5 gives a predicted value $\alpha = 0$ (and would imply that parallelization is strictly forbidden for infinite smoothness). More specifically, the left panel in Figure 3 shows the absence of any plateau for the reconstruction error as a function of α. This corresponds to the right panel showing that

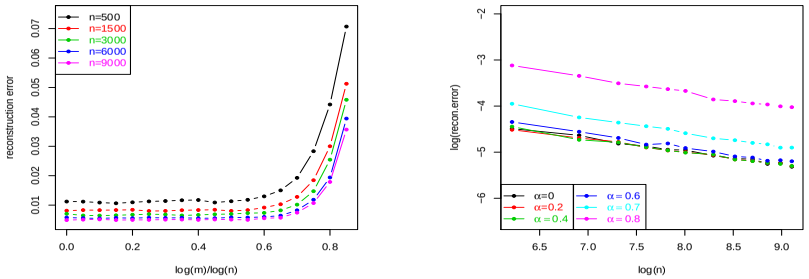

Figure 1: The reconstruction error $\|\bar{f}_D^{k_{oracle}} - f_\rho\|_{\mathcal{H}_K}$ in the low smoothness case. Left plot: Reconstruction error curves for various (but fixed) total sample sizes, as a function of the number m of subsamples. Right plot: Reconstruction error curves for various subsample number scalings $m = n^\alpha$, as a function of the sample size (on log-scale).

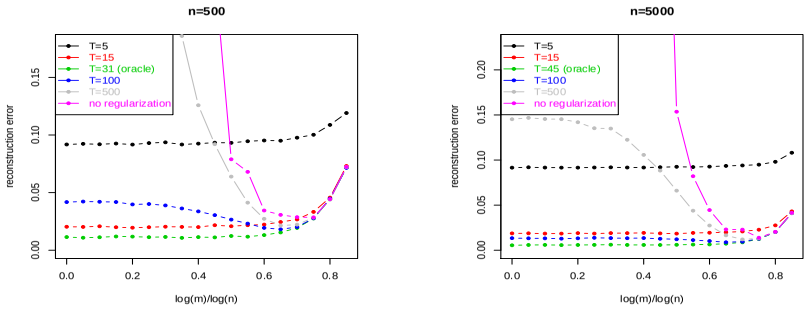

Figure 2: The reconstruction error $\|\bar{f}_D^{\lambda} - f_\rho\|_{\mathcal{H}_K}$ in the low smoothness case. Left plot: Error curves for different stopping times for $n = 500$, as a function of the number m of subsamples. Right plot: Error curves for different stopping times for $n = 5000$, as a function of the number m of subsamples.

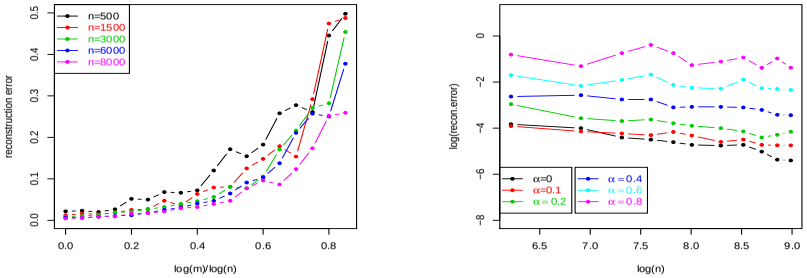

Figure 3: The reconstruction error $\|\bar{f}_D^{\lambda_{oracle}} - f_\rho\|_{\mathcal{H}_K}$ in the high smoothness case. Left plot: Reconstruction error curves for various (but fixed) sample sizes as a function of the number m of subsamples. Right plot: Reconstruction error curves for various subsample number scalings $m = n^\alpha$, as a function of the sample size (on log-scale).

no group of values of α performs roughly equivalently, meaning that we do not have any optimality guarantees.

Plotting different values of regularization in Figure 4 we again identify overregularization as hopeless, while severe underregularization exhibits a sharp minimum in the reconstruction error. But its value at roughly 0.25 is much less attractive compared to the case of low smoothness where the error is an order of magnitude less.

5. Discussion

Minimax Optimality: We have shown that for a large class of spectral regularization methods the error of the distributed algorithm $\|\bar{T}^s(\bar{f}_D^{\lambda_n} - f_\rho)\|_{\mathcal{H}_K}$ satisfies the same upper bound as the error $\left\|\bar{T}^s(f_D^{\lambda_n} - f_\rho)\right\|_{\mathcal{H}_K}$ for the single machine problem, if the regularization parameter λ_n is chosen according to (16), provided the number of subsamples grows sufficiently slowly with the sample size n. Since, the rates for the latter are minimax optimal (Blanchard and Mücke, 2017), our rates in Corollary 5 are minimax optimal also.

Comparison with other results: Zhang et al. (2013) derive minimax-optimal rates in three settings: finite rank kernels, sub-Gaussian decay of eigenvalues of the kernel and polynomial decay, provided m satisfies a certain upper bound, depending on the rate of decay of the eigenvalues under two crucial assumptions on the eigenfunctions of the integral operator associated to the kernel: For any $j \in \mathbb{N}$

$$\mathbb{E}[\phi_j(X)^{2k}] \leq \rho^{2k} \,, \tag{22}$$

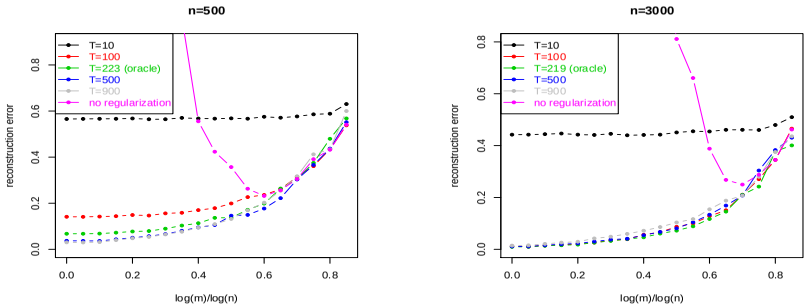

Figure 4: The reconstruction error $\|\bar{f}_D^{\lambda} - f_\rho\|$ in the high smoothness case. Left plot: Error curves for different stopping times for $n = 500$ samples, as a function of the number of subsamples. Right plot: Error curves for different stopping times for $n = 5000$ samples, as a function of the number of subsamples.

for some $k \geq 2$ and $\rho < \infty$ or even stronger, it is assumed that the eigenfunctions are uniformly bounded, i.e.

$$\sup_{x \in \mathcal{X}} |\phi_j(x)| \leq \rho \,, \tag{23}$$

or any $j \in \mathbb{N}$ and some $\rho < \infty$. We shall describe in more detail the case of polynomially decaying eigenvalues, which corresponds to our setting. Assuming eigenvalue decay $\mu_j \lesssim j^{-b}$ with $b > 1$, the authors choose a regularization parameter $\lambda_n = n^{-\frac{b}{b+1}}$ and

$$m \lesssim \left(\frac{n^{\frac{b(k-4)-k}{b+1}}}{\rho^{4k} \log^k(n)} \right)^{\frac{1}{k-2}} \,.$$

leading to an error in L^2-norm

$$\mathbb{E}[\|\bar{f}_D^{\lambda_n} - f_\rho\|_{L^2}^2] \lesssim n^{-\frac{b}{b+1}} \,,$$

being minimax optimal. Note that this choice of λ_n and the resulting rate correspond to our case $r = 0$, i.e., no smoothness of f_ρ is assumed (just that f_ρ belongs to the RKHS).

For $k < 4$ the bound becomes less meaningful (compared to the case where $k \geq 4$) since $m \to 0$ as $n \to \infty$ in this case (for any sort of eigenvalue decay). On the other hand, if k and b might be taken arbitrarily large, corresponding to almost bounded eigenfunctions and arbitrarily large polynomial decay of eigenvalues, m might be chosen proportional to $n^{1-\epsilon}$, for any $\epsilon > 0$. As might be expected, replacing the L^{2k} bound on the eigenfunctions by a bound in L^∞, gives an upper bound on m which simply is the limit for $k \to \infty$ in the

bound given above, namely

$$m \lesssim \frac{n^{\frac{b-1}{b+1}}}{\rho^4 \log n} \,,$$

which for large b behaves as above. Granted bounds on the eigenfunctions in L^{2k} for (very) large k, this is a strong result. While the decay rate of the eigenvalues can be determined by the smoothness of K (see, e.g., Ferreira and Menegatto, 2009 and references therein), it is a widely open question which general properties of the kernel imply estimates as in (22) and (23) on the eigenfunctions.

Zhou (2002) even gives a counterexample and presents a C^∞ Mercer kernel on $[0, 1]$ where the eigenfunctions of the corresponding integral operator are *not* uniformly bounded. Thus, smoothness of the kernel is not a sufficient condition for (23) to hold.

Moreover, we point out that the upper bound (22) on the eigenfunctions (and thus the upper bound for m in Zhang et al., 2013) depends on the unknown marginal distribution ν. Only the strongest assumption, a bound in sup-norm (23), does not depend on ν. Concerning this point, our approach is "agnostic".

As already mentioned in the Introduction, these bounds on the eigenfunctions have been eliminated by Lin et al. (2017), for KRR, imposing polynomial decay of eigenvalues as above. This is very similar to our approach. As a general rule, our bounds on m and the bounds obtained by Lin et al. (2017) are worse than the bounds of Zhang et al. (2013) for eigenfunctions in (or close to) L^∞, but in the complementary case where nothing is known on the eigenfunctions m still can be chosen as an increasing function of n, namely $m = n^\alpha$. More precisely, choosing λ_n as in (16), Lin et al. (2017) derive as an upper bound

$$m \lesssim n^\alpha \,, \qquad \alpha = \frac{2br}{2br + b + 1} \,,$$

with r being the smoothness parameter arising in the source condition. We recall here that due to our assumption $q \geq r + s$, the smoothness parameter r is restricted to the interval $(0, \frac{1}{2}]$ for KRR ($q = 1$) and L^2-risk ($s = \frac{1}{2}$).

Our results (which hold for a general class of spectral regularization methods) are in some ways comparable to those of Lin et al. (2017). Specialized to KRR, our estimates for the exponent α in $m = O(n^\alpha)$ coincide with the result of Lin et al. (2017). Furthermore, we emphasize that Zhang et al. (2013) and Lin et al. (2017) estimate the DL-error only for $s = 1/2$ in our notation (corresponding to $L^2(\nu)-$norm), while our result holds for all values of $s \in [0, 1/2]$ which smoothly interpolates between $L^2(\nu)$-norm and RKHS-norm and, in addition, for all values of $p \in [1, \infty)$. Thus, our results also apply to the case of non-parametric inverse regression, where one is particularly interested in the reconstruction error, i.e. $\mathcal{H}_K$-norm (see, e.g., Blanchard and Mücke, 2017). Additionally, we precisely analyze the dependence of the noise variance σ^2 and the complexity radius R in the source condition.

Concerning general strategy, while Lin et al. (2017) use a novel second order decomposition in an essential way, our approach is more classical. We clearly distinguish between estimat-

ing the approximation error and the sample error. The bias using a subsample should be of the same order as when using the whole sample, whereas the estimation error is higher on each subsample, but gets reduced by averaging by writing the variance as a sum of i.i.d. random variables (which allows to use Rosenthal's inequality).

Finally, we want to mention the recent works of Lin and Zhou (2018) and Guo et al. (2017), which were worked out indepently from our work. Guo et al. (2017) also treat general spectral regularization methods (going beyond kernel ridge) and obtain essentially the same results, but with error bounds only in L^2-norm, excluding inverse learning problems. Lin and Zhou (2018) investigate distributed learning on the example of gradient descent algorithms, which have infinite qualification and allow larger smoothness of the regression function. They are able to improve the upper bound for the number of local machines to

$$m \lesssim \frac{n^\alpha}{\log^5(n)+1}\,, \qquad \alpha < \frac{br}{2br+b+1},$$

which is larger in the case $r > 2$. In the intermediate case $1 < r < 2$, our bound in (20) is still better. An interesting feature is the fact that it is possible to allow more local machines by using additional unlabeled data. This indicates that finding the upper bound for the number of machines in the high smoothness regime is still an open problem.

Adaptivity: It is clear from the theoretical results that both the regularization parameter λ and the allowed cardinality of subsamples m depend on the parameters r and b, which in general are unknown. Thus, an adaptive approach to both parameters b and r for choosing λ and m is of interest. To the best of our knowledge, there are yet no rigorous results on adaptivity in this more general sense. Progress in this field may well be crucial in finally assessing the relative merits of the distributed learning approach as compared with alternative strategies to effectively deal with large data sets.

We sketch an alternative naive approach to adaptivity, based on hold-out in the direct case, where we consider each $f \in \mathcal{H}_K$ also as a function in $L^2(\mathcal{X},\nu)$. We split the data $\mathbf{z} \in (\mathcal{X}\times\mathcal{Y})^n$ into a training and validation part $\mathbf{z} = (\mathbf{z}^t, \mathbf{z}^v)$ of cardinality m_t, m_v. We further subdivide $\mathbf{z}^t$ into m_k subsamples, roughly of size m_t/m_k, where $m_k \le m_t$, $k = 1, 2, \ldots$ is some strictly decreasing sequence. For each k and each subsample $\mathbf{z}_j$, $1 \le j \le m_k$, we define the estimators $\hat{f}^\lambda_{\mathbf{z}_j}$ as in (12) and their average

$$\bar{f}^\lambda_{k,\mathbf{z}^t} := \frac{1}{m_k}\sum_{j=1}^{m_k} \hat{f}^\lambda_{\mathbf{z}_j}\,. \tag{24}$$

Here, λ varies in some sufficiently fine lattice Λ. Then evaluation on $\mathbf{z}^v$ gives the associated empirical L^2- error

$$\mathrm{Err}^\lambda_k(\mathbf{z}^v) := \frac{1}{m_v}\sum_{i=1}^{m_v}(y^v_i - \bar{f}^\lambda_{k,\mathbf{z}^t}(x^v_i))^2\,, \quad \mathbf{z}^v = (\mathbf{y}^v, \mathbf{x}^v)\,, \quad \mathbf{y}^v = (y^v_1,\ldots,y^v_{m_v})\,, \tag{25}$$

leading us to define

$$\hat{\lambda}_k := \mathrm{argmin}_{\lambda\in\Lambda}\mathrm{Err}^\lambda_k(\mathbf{z}^v)\,, \qquad \mathrm{Err}(k) := \mathrm{Err}^{\hat{\lambda}_k}_k(\mathbf{z}^v). \tag{26}$$

Then, an appropriate stopping criterion for k might be to stop at

$$k^* := \min\{k \ge 3\ :\ \Delta(k) \le \delta \inf_{2\le j<k}\Delta(j)\}\,, \qquad \Delta(j) := |\mathrm{Err}(j) - \mathrm{Err}(j-1)|\,, \tag{27}$$

for some $\delta < 1$ (which might require tuning). The corresponding regularization parameter is $\hat{\lambda} = \hat{\lambda}_{k^*}$, given by (26). At least intuitively, it is then reasonable to define a purely data driven estimator as

$$\widehat{f}_n := \bar{f}^{\hat{\lambda}}_{k^*,\mathbf{z}^t}\,. \tag{28}$$

Note that the training data $\mathbf{z}^t$ enter the definition of $\widehat{f}_n$ via the explicit formula (24) encoding our kernel based approach, while $\mathbf{z}^v$ serves to determine $(k^*, \hat{\lambda}^*)$ via minimization of the empirical L^2-error and a criterion, which tells one to stop where $\mathrm{Err}(j)$ does not appreciably improve anymore. It is open if such a procedure achieves optimal rates, and we leave this for future research.

6. Proofs

For ease of reading we make use of the following conventions:

- for a (bounded) linear operator A, $\|A\|$ denotes the operator norm;
- we are interested in a precise dependence of multiplicative constants on the parameters σ, M, R, m, n and η. (To be clear about the role of the latter quantity: the proofs rely on high-probability statements on deviations, typically holding with high probability $1-\eta$.)
- the dependence of multiplicative constants on various other parameters, including the kernel parameter κ, the interpolating parameter $s \in [0, \frac{1}{2}]$, the parameters arising from the regularization method, $b > 1$, $\beta > 0$, $r > 0$, etc. will (generally) be omitted and simply indicated by the symbol $\blacktriangle$.
- the dependence of the norm parameter p will also be indicated, but will not be given explicitly.
- the values of $C_\blacktriangle$ and $C_{\blacktriangle,p}$ might change from line to line.
- the expression "for n sufficiently large" means that the statement holds for $n \ge n_0$, with n_0 potentially depending on all model parameters (including σ, M and R), but not on η.

6.1 Preliminaries

Proposition 12 (Guo et al., 2017, Proposition 1) *Define*

$$\mathcal{B}_n(\lambda) := \left[1 + \left(\frac{2}{n\lambda} + \sqrt{\frac{\mathcal{N}(\lambda)}{n\lambda}}\right)^2\right]. \tag{29}$$

For any $\lambda > 0$, $\eta \in (0,1]$, with probability at least $1-\eta$ one has

$$\left\|(\bar{T}_{\mathbf{x}}+\lambda)^{-1}(\bar{T}+\lambda)\right\| \leq 8\log^2(2\eta^{-1})\mathcal{B}_n(\lambda)\ . \tag{30}$$

Corollary 13 *Let $\eta \in (0,1)$. For $n \in \mathbb{N}$ let $\tilde{\lambda}_n$ be implicitly defined as the unique solution of $\mathcal{N}(\tilde{\lambda}_n) = n\tilde{\lambda}_n$. Then for any $\lambda \in [\max(\tilde{\lambda}_n, n^{-1}), 1]$, one has*

$$\mathcal{B}_n(\lambda) \leq 10\ .$$

In particular,

$$\left\|(\bar{T}_{\mathbf{x}}+\lambda)^{-1}(\bar{T}+\lambda)\right\| \leq 80\log^2(2\eta^{-1})$$

holds with probability at least $1-\eta$.

We remark that the trace of $\bar{T}$ is bounded by 1. This ensures that the interval $[\tilde{\lambda}_n, 1]$ is non-empty.

Proof [of Corollary 13] Let $\tilde{\lambda}_n$ be defined via $\mathcal{N}(\tilde{\lambda}_n) = n\tilde{\lambda}_n$. Since $\mathcal{N}(\lambda)/\lambda$ is decreasing, we have for any $\lambda \geq \tilde{\lambda}_n$

$$\sqrt{\frac{\mathcal{N}(\lambda)}{n\lambda}} \leq \sqrt{\frac{\mathcal{N}(\tilde{\lambda}_n)}{n\tilde{\lambda}_n}} = 1\ .$$

Inserting this bound as well as $n\lambda \geq 1$ into (29) and (30) leads to the conclusion. ■

Corollary 14 *Assume the marginal distribution ν of $\mathcal{X}$ belongs to $\mathcal{P}^<(b,\beta)$ with $b > 1$ and $\beta > 0$. If λ_n is defined by (16) and if*

$$m_n \leq n^\alpha\ , \qquad \alpha < \frac{2br}{2br+b+1}\ ,$$

one has

$$\mathcal{B}_{\frac{n}{m_n}}(\lambda_n) \leq 2\ ,$$

provided n is sufficiently large.

Proof [of Corollary 14] We can for starters assume that n is sufficiently large so that $\lambda_n < 1$, i.e. $\lambda_n = \left(\frac{\sigma^2}{R^2 n}\right)^{\frac{b}{2br+b+1}}$ from (16). Recall that $\nu \in \mathcal{P}^<(b,\beta)$ implies $\mathcal{N}(\lambda_n) \leq C_\blacktriangle \lambda_n^{-\frac{1}{b}}$. Looking at the terms entering in $\mathcal{B}_{\frac{n}{m}}(\lambda_n)$, see (29), we have first, using the definition of λ_n in (16):

$$\frac{\mathcal{N}(\lambda_n)}{\frac{n}{m}\lambda_n} \leq C_\blacktriangle m\frac{\lambda_n^{-\frac{b+1}{b}}}{n} = C_\blacktriangle \frac{m}{n}\left(\frac{nR^2}{\sigma^2}\right)^{\frac{b+1}{2br+b+1}}\ ,$$

which (for fixed R, σ and other parameters entering in $C_\blacktriangle$) is $O(m_n n^{-\frac{2br}{2br+r+1}})$, and hence $o(1)$ provided

$$m_n \leq n^\alpha\ , \qquad \alpha < \frac{2br}{2br+b+1}\ .$$

For the second term entering in $\mathcal{B}_{\frac{n}{m}}(\lambda_n)$, we have

$$\frac{1}{\frac{n}{m}\lambda_n} = \frac{m}{n}\left(\frac{nR^2}{\sigma^2}\right)^{\frac{b}{2br+b+1}}\ ,$$

which is $O(m_n n^{-\frac{2br+1}{2br+b+1}}) = o(1)$, provided

$$m_n \leq n^\alpha\ , \qquad \alpha < \frac{2br+1}{2br+b+1}\ ,$$

which is implied by the previous stronger condition. ■

We shortly illustrate how Corollary 13 and Proposition 12 will be used. Let $u \in [0,1]$, $\tilde{\lambda}_n \leq \lambda$ as above and $f \in \mathcal{H}_K$. We have for any bounded operator A

$$\begin{aligned}\left\|\bar{T}^u A\right\| &= \left\|\bar{T}^u(\bar{T}+\lambda)^{-u}(\bar{T}+\lambda)^u(\bar{T}_{\mathbf{x}}+\lambda)^{-u}(\bar{T}_{\mathbf{x}}+\lambda)^u A\right\| \\ &\leq \left\|\bar{T}^u(\bar{T}+\lambda)^{-u}\right\| \left\|(\bar{T}+\lambda)^u(\bar{T}_{\mathbf{x}}+\lambda)^{-u}\right\| \left\|(\bar{T}_{\mathbf{x}}+\lambda)^u A\right\| \\ &\leq 8\log^{2u}(2\eta^{-1})\mathcal{B}_n(\lambda)^u \left\|(\bar{T}_{\mathbf{x}}+\lambda)^u A\right\|\ ,\end{aligned} \tag{31}$$

with probability at least $1-\eta$, for any $\eta \in (0,1)$; for the last inequality we have used that the first factor is less than 1, and for the second factor Proposition 12 in combination with the Cordes inequality (see Proposition 22 in the Appendix). In particular, for any $\max(\tilde{\lambda}_n, n^{-1}) \leq \lambda$ (with $\tilde{\lambda}_n$ as in Corollary 13)

$$\left\|\bar{T}^u A\right\| \leq 80^u \log^{2u}(2\eta^{-1}) \left\|(\bar{T}_{\mathbf{x}}+\lambda)^u A\right\|\ , \tag{32}$$

with probability at least $1-\eta$.

In the following, we constantly use (31). Furthermore, to bound terms involving residuals we will frequently use the following estimate: for $v \geq 0, u \in [0,2]$, and provided $u+v \leq q$ (q being the qualification):

$$\begin{aligned}\sup_{t\in[0,1]} |r_\lambda(t)t^v(t+\lambda)^u| &\leq 2\left(\sup_{t\in[0,1]} \left|r_\lambda(t)t^{v+u}\right| + \lambda^u \sup_{t\in[0,1]} |r_\lambda(t)t^v|\right) \\ &\leq C_\blacktriangle \lambda^{v+u},\end{aligned} \tag{33}$$

using twice (11) since $q \geq u+v$.

6.2 Approximation error bound

Recall that ν denotes the X-marginal of the sampling distribution ρ and $\mathcal{P}$ the set of all probability distributions on the input space $\mathcal{X}$.

Lemma 15 *Let $\nu \in \mathcal{P}$, $v \in \mathbb{R}$ and let $\mathbf{x} \in \mathcal{X}^{\frac{n}{m}}$ be an i.i.d. sample of size n/m, drawn according to ν. Assume the regularization $(g_\lambda)_\lambda$ has qualification $q \geq v+1+s$. Then with probability at least $1-\eta$:*

$$\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}})\bar{T}_{\mathbf{x}}^v(\bar{T}-\bar{T}_{\mathbf{x}})\right\| \leq C_{\blacktriangle}\log^4(4\eta^{-1})\lambda^{s+v+1}\mathcal{B}_{\frac{n}{m}}^{s+1}(\lambda)\left(\frac{m}{n\lambda}+\sqrt{\frac{m\mathcal{N}(\lambda)}{n\lambda}}\right).$$

Proof [of Lemma 15] From (30),(31) and from Proposition 20 recalled in the Appendix, one has

$$\begin{aligned}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}})\bar{T}_{\mathbf{x}}^v(\bar{T}-\bar{T}_{\mathbf{x}})\right\| &\leq C_{\blacktriangle}\log^{2(s+1)}(4\eta^{-1})\mathcal{B}_{\frac{n}{m}}^{s+1}(\lambda)\\ &\qquad \left\|(\bar{T}_{\mathbf{x}}+\lambda)^s r_\lambda(\bar{T}_{\mathbf{x}})\bar{T}_{\mathbf{x}}^v(\bar{T}_{\mathbf{x}}+\lambda)\right\|\left\|(\bar{T}+\lambda)^{-1}(\bar{T}-\bar{T}_{\mathbf{x}})\right\|\\ &\leq C_{\blacktriangle}\log^4(4\eta^{-1})\lambda^{s+v+1}\mathcal{B}_{\frac{n}{m}}^{s+1}(\lambda)\left(\frac{m}{n\lambda}+\sqrt{\frac{m\mathcal{N}(\lambda)}{n\lambda}}\right),\end{aligned}$$

for any $\lambda \in (0,1]$, $\eta \in (0,1]$, with probability at least $1-\eta$. We also used that $s \leq \frac{1}{2}$, and the estimate (33). ∎

Lemma 16 *Let $\nu \in \mathcal{P}$, $v \in \mathbb{R}$ and let $\mathbf{x} \in \mathcal{X}^{\frac{n}{m}}$ be an i.i.d. sample of size n/m drawn according to ν. Assume the regularization $(g_\lambda)_\lambda$ has qualification $q \geq v+s$. Then for any $\lambda \in (0,1]$, $\eta \in (0,1]$, with probability at least $1-\eta$*

$$\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}})\bar{T}_{\mathbf{x}}^v\right\| \leq C_{\blacktriangle}\log^{2s}(2\eta^{-1})\mathcal{B}_{\frac{n}{m}}^{s}(\lambda)\lambda^{s+v},$$

for some $C_{\blacktriangle} < \infty$.

Proof [of Lemma 16] Using (31), (33), since $q \geq v+s$, it holds

$$\begin{aligned}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}})\bar{T}_{\mathbf{x}}^v\right\| &\leq C_{\blacktriangle}\log^{2s}(2\eta^{-1})\mathcal{B}_{\frac{n}{m}}^{s}(\lambda)\left\|(\bar{T}_{\mathbf{x}}+\lambda)^s r_\lambda(\bar{T}_{\mathbf{x}})\bar{T}_{\mathbf{x}}^v\right\|\\ &\leq C_{\blacktriangle}\log^{2s}(2\eta^{-1})\mathcal{B}_{\frac{n}{m}}^{s}(\lambda)\lambda^{s+v},\end{aligned}$$

with probability at least $1-\eta$. ∎

Proposition 17 (Expectation of approximation error) *Let $f_\rho \in \Omega(r,R)$, $\lambda \in (0,1]$ and let $\mathcal{B}_{\frac{n}{m}}(\lambda)$ be defined in (29). Assume the regularization has qualification $q \geq r+s$. For any $p \geq 1$ one has:*

1. *If $r \leq 1$, then*

$$\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s(f_\rho - \tilde{f}_D^\lambda)\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}} \leq C_{\blacktriangle,p}R\,\lambda^{s+r}\,\mathcal{B}_{\frac{n}{m}}^{s+r}(\lambda).$$

2. *If $r > 1$, then*

$$\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s(f_\rho - \tilde{f}_D^\lambda)\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}} \leq C_{\blacktriangle,p}R\lambda^s\mathcal{B}_{\frac{n}{m}}^{s+1}(\lambda)\left(\lambda^r + \lambda\left(\frac{m}{n\lambda}+\sqrt{\frac{m\mathcal{N}(\lambda)}{n\lambda}}\right)\right).$$

In 1. and 2. the constant $C_{\blacktriangle,p}$ does not depend on $(\sigma, M, R) \in \mathbb{R}_+^3$.

Proof [of Proposition 17] Since $f_\rho \in \Omega(r,R)$,

$$\begin{aligned}\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s(f_\rho - \tilde{f}_D^\lambda)\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}} &= \left[\mathbb{E}_{\rho^{\otimes n}}\left\|\frac{1}{m}\sum_{j=1}^m \bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})f_\rho\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}}\\ &\leq \frac{1}{m}\sum_{j=1}^m\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})f_\rho\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}}\\ &\leq \frac{R}{m}\sum_{j=1}^m\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^r\right\|^p\right]^{\frac{1}{p}}. \qquad (34)\end{aligned}$$

The first inequality is just the triangle inequality for the p-norm $\|f\|_p = \mathbb{E}[\|f\|_{\mathcal{H}_K}^p]^{\frac{1}{p}}$. We bound the expectation for each separate subsample of size $\frac{n}{m}$ by first deriving a probabilistic estimate and then we integrate.

Consider first the case where $r \leq 1$. Using (31), the Cordes inequality (Proposition 22 in the Appendix), and (33) one has for any $j = 1, \ldots, m$,

$$\begin{aligned}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^r\right\| &\leq C_{\blacktriangle}\log^{2(s+r)}(4\eta^{-1})\mathcal{B}_{\frac{n}{m}}^{s+r}(\lambda)\left\|(\bar{T}_{\mathbf{x}_j}+\lambda)^s r_\lambda(\bar{T}_{\mathbf{x}_j})(\bar{T}_{\mathbf{x}_j}+\lambda)^r\right\|\\ &\leq C_{\blacktriangle}\log^3(4\eta^{-1})\lambda^{s+r}\mathcal{B}_{\frac{n}{m}}^{s+r}(\lambda),\end{aligned}$$

with probability at least $1-\eta$ and where $\mathcal{B}_{\frac{n}{m}}(\lambda)$ is defined in (29). Recall that the regularization has qualification $q \geq r+s$. By integration one has

$$\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^r\right\|^p\right]^{\frac{1}{p}} \leq C_{\blacktriangle,p}\,\lambda^{s+r}\,\mathcal{B}_{\frac{n}{m}}^{s+r}(\lambda),$$

for some $C_{\blacktriangle,p} < \infty$, not depending on σ, M, R. Finally, from (34)

$$\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s(f_\rho - \tilde{f}_D^\lambda)\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}} \leq C_{\blacktriangle,p}R\,\lambda^{s+r}\,\mathcal{B}_{\frac{n}{m}}^{s+r}(\lambda).$$

In the case where $r \geq 1$, we write $r = k+u$, with $k = \lfloor r \rfloor$ and $u = r-k < 1$. We shall use the decomposition

$$\bar{T}^k = \sum_{l=0}^{k-1}\bar{T}_{\mathbf{x}}^l(\bar{T}-\bar{T}_{\mathbf{x}})\bar{T}^{k-(l+1)} + \bar{T}_{\mathbf{x}}^k. \qquad (35)$$

We proceed by bounding (34) according to decomposition (35) . For any $j = 1, \dots, m$, one has

$$\begin{aligned}\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^{k+u}\right\|^p\right]^{\frac{1}{p}} &\leq \sum_{l=0}^{k-1}\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^l_{\mathbf{x}_j}(\bar{T}-\bar{T}_{\mathbf{x}_j})\bar{T}^{k-(l+1)+u}\right\|^p\right]^{\frac{1}{p}} \\ &\quad + \left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^k_{\mathbf{x}_j}\bar{T}^u\right\|^p\right]^{\frac{1}{p}} \\ &\leq \sum_{l=0}^{k-1}\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^l_{\mathbf{x}_j}(\bar{T}-\bar{T}_{\mathbf{x}_j})\right\|^p\right]^{\frac{1}{p}} \\ &\quad + \left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^k_{\mathbf{x}_j}\bar{T}^u\right\|^p\right]^{\frac{1}{p}} . \end{aligned} \tag{36}$$

Here we use that $\left\|\bar{T}^{k-(l+1)+u}\right\|$ is bounded by 1. By Lemma 16 and by (31), (33), with probability at least $1-\eta$

$$\begin{aligned}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^k_{\mathbf{x}_j}\bar{T}^u\right\| &\leq C_{\blacktriangle}\log^{2(s+u)}(2\eta^{-1})\mathcal{B}^{s+u}_{\frac{n}{m}}(\lambda)\left\|(\bar{T}_{\mathbf{x}_j}+\lambda)^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^k_{\mathbf{x}_j}(\bar{T}_{\mathbf{x}_j}+\lambda)^u\right\| \\ &\leq C_{\blacktriangle}\log^{2(s+u)}(2\eta^{-1})\mathcal{B}^{s+u}_{\frac{n}{m}}(\lambda)\lambda^{s+r},\end{aligned}$$

and thus integration yields

$$\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^r_{\mathbf{x}_j}\bar{T}^u\right\|^p\right]^{\frac{1}{p}} \leq C_{\blacktriangle,p}\mathcal{B}^{s+u}_{\frac{n}{m}}(\lambda)\lambda^{s+r} . \tag{37}$$

For estimating the first term in (36) we may use Lemma 15. For any $l = 0, \dots, k-1$, we have $l+s+1 \leq k+s \leq r+s \leq q$, hence for any $j = 1, \dots, m$ with probability at least $1-\eta$

$$\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^l_{\mathbf{x}_j}(\bar{T}-\bar{T}_{\mathbf{x}_j})\right\| \leq C_{\blacktriangle}\log^4(8\eta^{-1})\lambda^{s+l+1}\mathcal{B}^{s+1}_{\frac{n}{m}}(\lambda)\left(\frac{m}{n\lambda}+\sqrt{\frac{m\mathcal{N}(\lambda)}{n\lambda}}\right) .$$

Again by integration, since $\lambda^l \leq 1$ for any $l = 0, \dots, k-1$, one has

$$\sum_{l=0}^{k-1}\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s r_\lambda(\bar{T}_{\mathbf{x}_j})\bar{T}^l_{\mathbf{x}_j}(\bar{T}-\bar{T}_{\mathbf{x}_j})\right\|^p\right]^{\frac{1}{p}} \leq C_{\blacktriangle,p}\lfloor r\rfloor\lambda^{s+1}\mathcal{B}^{s+1}_{\frac{n}{m}}(\lambda)\left(\frac{m}{n\lambda}+\sqrt{\frac{m\mathcal{N}(\lambda)}{n\lambda}}\right) . \tag{38}$$

Finally, combining (37) and (38) into (36), then (34), gives in the case where $r > 1$

$$\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s(f_\rho - \tilde{f}^\lambda_D)\right\|^p_{\mathcal{H}_K}\right]^{\frac{1}{p}} \leq C_{\blacktriangle,p}\lambda^s\mathcal{B}^{s+1}_{\frac{n}{m}}(\lambda)\left(\lambda^r + \lambda\left(\frac{m}{n\lambda}+\sqrt{\frac{m\mathcal{N}(\lambda)}{n\lambda}}\right)\right) .$$

The rest of the proof follows from (36).

■

Proof [of Theorem 3] Let λ_n be as defined by (16). According to Corollary 14, we have $\mathcal{B}_{\frac{n}{m_n}}(\lambda_n) \leq 2$ provided $\alpha < \frac{2br}{2br+b+1}$, for n sufficiently large. We can also assume n sufficiently large so that $\lambda_n < 1$, i.e., $R\lambda_n^{r+s} = a_n$ (from (16), (17)). Under these conditions, we immediately obtain from the first part of Proposition 17 in the case where $r \leq 1$

$$\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s(f_\rho - \tilde{f}^{\lambda_n}_D)\right\|^p_{\mathcal{H}_K}\right]^{\frac{1}{p}} \leq C_{\blacktriangle,p}R\,\lambda_n^{s+r} = C_{\blacktriangle,p}\,a_n .$$

We turn to the case where $r > 1$. We apply the second part of Proposition 17. By Corollary 14 we have

$$\begin{aligned}\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s(f_\rho - \tilde{f}^{\lambda_n}_D)\right\|^p_{\mathcal{H}_K}\right]^{\frac{1}{p}} &\leq C_{\blacktriangle,p}R\lambda_n^s\mathcal{B}^{s+1}_{\frac{n}{m_n}}(\lambda_n)\left(\lambda_n^r + \lambda_n\left(\frac{m_n}{n\lambda_n}+\sqrt{\frac{m_n\mathcal{N}(\lambda_n)}{n\lambda_n}}\right)\right) \\ &\leq C_{\blacktriangle,p}\,R\lambda_n^s\,\left(\lambda_n^r + \lambda_n\left(\frac{m_n}{n\lambda_n}+\sqrt{m_n}\frac{R}{\sigma}\lambda_n^r\right)\right),\end{aligned}$$

where we used that $\mathcal{N}(\lambda_n) \leq C_{\blacktriangle}\lambda_n^{-1/b}$ and $\sigma\sqrt{\frac{\lambda_n^{-\frac{1}{b}}}{n\lambda_n}} = R\lambda_n^r$ coming from the definition of λ_n, and $\lambda_n < 1$. Furthermore,

$$\frac{m_n}{n\lambda_n} = o\left(\sqrt{m}_n\lambda_n^r\right) ,$$

provided

$$m_n \leq n^\alpha , \qquad \alpha < \frac{2(br+1)}{2br+b+1} .$$

Finally, for n sufficiently large, $\frac{R}{\sigma}\sqrt{m_n}\lambda_n \leq 1$, provided that

$$\alpha < \frac{2b}{2br+b+1} .$$

As a result, for any $p \geq 1$:

$$\limsup_{n\to\infty}\sup_{\rho\in\mathcal{M}_{\sigma,M,R}}\frac{\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s(f_\rho - \tilde{f}^{\lambda_n}_D)\right\|^p_{\mathcal{H}_K}\right]^{\frac{1}{p}}}{a_n} \leq C_{\blacktriangle,p} ,$$

for some $C_{\blacktriangle,p} < \infty$, not depending on σ, M, R. ■

6.3 Sample error bound

The main idea for deriving an upper bound for the sample error is to identify it as a sum of unbiased Hilbert space-valued i.i.d. variables and then to apply a suitable version of Rosenthal's inequality.

Given $\lambda \in (0,1]$, we define the random variable $\xi_\lambda : (\mathcal{X}\times\mathbb{R})^{\frac{n}{m}} \longrightarrow \mathcal{H}_K$ by

$$\xi_\lambda(\mathbf{x},\mathbf{y}) := \bar{T}^s g_\lambda(\bar{T}_\mathbf{x})(\bar{T}_\mathbf{x} f_\rho - \bar{S}^*_\mathbf{x}\mathbf{y}) \,.$$

Recall that according to Assumption (3), the conditional expectation w.r.t. ρ of Y given X satisfies

$$\mathbb{E}_\rho[Y|X=x] = \bar{S}_x f_\rho \,,$$

implying that ξ_λ has zero expectation (since $\bar{T}_\mathbf{x} = \bar{S}^*_\mathbf{x}\bar{S}_\mathbf{x}$). Thus,

$$\bar{T}^s(\tilde{f}^\lambda_D - \bar{f}^\lambda_D) \;=\; \frac{1}{m}\sum_{j=1}^m \xi_\lambda(\mathbf{x}_j,\mathbf{y}_j) \tag{39}$$

is a sum of centered i.i.d. random variables.

Furthermore, we need the following result (Pinelis, 1994, Theorem 5.2) , which generalizes Rosenthal's (1970) inequalities (originally only formulated for real valued random variables) to random variables with values in a Banach space. For Hilbert spaces this looks particularly nice.

Proposition 18 *Let $\mathcal{H}$ be a Hilbert space and $\xi_1,\dots,\xi_m$ be a finite sequence of independent, mean zero $\mathcal{H}$- valued random variables. If $2 \le p < \infty$, then there exists a constant $C_p > 0$, only depending on p, such that*

$$\left(\mathbb{E}\Big\| \frac{1}{m}\sum_{j=1}^m \xi_j \Big\|^p_\mathcal{H}\right)^{\frac{1}{p}} \;\le\; \frac{C_p}{m}\;\max\left\{\left(\sum_{j=1}^m \mathbb{E}\|\xi_j\|^p_\mathcal{H}\right)^{\frac{1}{p}}, \left(\sum_{j=1}^m \mathbb{E}\|\xi_j\|^2_\mathcal{H}\right)^{\frac{1}{2}}\right\}. \tag{40}$$

We remark in passing that Dirksen (2011), Corollary 1.22, establishes the interesting result that in addition to the upper bound in (40) there is also a corresponding lower bound where the constant C_p is replaced by another constant $C'_p > 0$, only depending on p.

Proposition 19 (Expectation of sample error) *Let ρ be a source distribution belonging to $\mathcal{M}_{\sigma,M,R}$, $s \in [0,\frac{1}{2}]$ and let $\lambda \in (0,1]$. Define $\mathcal{B}_{\frac{n}{m}}(\lambda)$ as in* (29)*. Assume the regularization has qualification $q \ge r+s$. For any $p \ge 1$ one has:*

$$\left[\mathbb{E}_{\rho^{\otimes n}}\big\|\bar{T}^s(\tilde{f}^\lambda_D - \bar{f}^\lambda_D)\big\|^p_{\mathcal{H}_K}\right]^{\frac{1}{p}} \le C_{\blacktriangle,p}\, m^{-\frac{1}{2}}\mathcal{B}_{\frac{n}{m}}(\lambda)^{\frac{1}{2}+s}\lambda^s\left(\frac{mM}{n\lambda} + \sigma\sqrt{\frac{m\mathcal{N}(\lambda)}{n\lambda}}\right),$$

where C_p does not depend on $(\sigma,M,R) \in \mathbb{R}^3_+$.

Proof [of Proposition 19] Let $\lambda \in (0,1]$ and $p \ge 2$. From Proposition 18

$$\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s\tilde{f}^\lambda_D - \bar{f}^\lambda_D\right\|^p_{\mathcal{H}_K}\right]^{\frac{1}{p}} = \left[\mathbb{E}_{\rho^{\otimes n}}\left\|\frac{1}{m}\sum_{j=1}^m \xi_\lambda(\mathbf{x}_j,\mathbf{y}_j)\right\|^p_{\mathcal{H}_K}\right]^{\frac{1}{p}}$$
$$\le \frac{C_p}{m}\;\max\left\{\left(\sum_{j=1}^m\left[\mathbb{E}_{\rho^{\otimes n}}\|\xi_\lambda(\mathbf{x}_j,\mathbf{y}_j)\|^p_{\mathcal{H}_K}\right]\right)^{\frac{1}{p}}, \left(\sum_{j=1}^m\left[\mathbb{E}_{\rho^{\otimes n}}\|\xi_\lambda(\mathbf{x}_j,\mathbf{y}_j)\|^2_{\mathcal{H}_K}\right]\right)^{\frac{1}{2}}\right\}. \tag{41}$$

Again, the estimates in expectation will follow from integrating a bound holding with high probability. By (31), one has for any $j = 1,\dots,m$,

$$\begin{aligned}\|\xi_\lambda(\mathbf{x}_j,\mathbf{y}_j)\|_{\mathcal{H}_K} &= \|\bar{T}^s g_\lambda(\bar{T}_{\mathbf{x}_j})(\bar{T}_{\mathbf{x}_j} f_\rho - \bar{S}^*_{\mathbf{x}_j}\mathbf{y}_j)\|_{\mathcal{H}_K} \\ &\le 8\log^{2s}(4\eta^{-1})\mathcal{B}_{\frac{n}{m}}(\lambda)^s\|(\bar{T}_{\mathbf{x}_j}+\lambda)^s g_\lambda(\bar{T}_{\mathbf{x}_j})(\bar{T}_{\mathbf{x}_j} f_\rho - \bar{S}^*_{\mathbf{x}_j}\mathbf{y}_j)\|_{\mathcal{H}_K}\,, \end{aligned}\tag{42}$$

holding with probability at least $1-\frac{\eta}{2}$, where $\mathcal{B}_{\frac{n}{m}}(\lambda)$ is defined in (29). We proceed by splitting:

$$(\bar{T}_{\mathbf{x}_j}+\lambda)^s g_\lambda(\bar{T}_{\mathbf{x}_j})(\bar{T}_{\mathbf{x}_j} f_\rho - \bar{S}^\star_{\mathbf{x}_j}\mathbf{y}_j) = H^{(1)}_{\mathbf{x}_j}\cdot H^{(2)}_{\mathbf{x}_j}\cdot h^\lambda_{\mathbf{z}_j}\,,$$

with

$$\begin{aligned} H^{(1)}_{\mathbf{x}_j} &:= ||(\bar{T}_{\mathbf{x}_j}+\lambda)^s g_\lambda(\bar{T}_{\mathbf{x}_j})(\bar{T}_{\mathbf{x}_j}+\lambda)^{\frac{1}{2}}||, \\ H^{(2)}_{\mathbf{x}_j} &:= ||(\bar{T}_{\mathbf{x}_j}+\lambda)^{-\frac{1}{2}}(\bar{T}+\lambda)^{\frac{1}{2}}||, \\ h^\lambda_{\mathbf{z}_j} &:= ||(\bar{T}+\lambda)^{-\frac{1}{2}}(\bar{T}_{\mathbf{x}_j} f_\rho - \bar{S}^\star_{\mathbf{x}_j}\mathbf{y}_j)||_{\mathcal{H}_K}\,. \end{aligned}$$

The first term is estimated using (9),(10) and gives for $s \in [0,\frac{1}{2}]$

$$\begin{aligned} H^{(1)}_{\mathbf{x}_j} &\le \sup_{t\in[0,1]}\left(g_\lambda(t)(t+\lambda)^{s+\frac{1}{2}}\right) \\ &\le 2\Big(\sup_{t\in[0,1]} g_\lambda(t)t^{s+\frac{1}{2}} + \lambda^{s+\frac{1}{2}}\sup_{t\in[0,1]} g_\lambda(t)\Big) \\ &\le 2\Big(\Big(\sup_{t\in[0,1]} g_\lambda(t)\Big)^{\frac{1}{2}-s}\Big(\sup_{t\in[0,1]} g_\lambda(t)t\Big)^{s+\frac{1}{2}} + \lambda^{s+\frac{1}{2}}\sup_{t\in[0,1]} g_\lambda(t)\Big) \\ &\le C_\blacktriangle\lambda^{s-\frac{1}{2}}\,. \end{aligned}\tag{43}$$

The second term is now bounded using (31) once more. One has with probability at least $1-\frac{\eta}{4}$

$$H^{(2)}_{\mathbf{x}_j} \le 8\log(8\eta^{-1})\mathcal{B}_{\frac{n}{m}}(\lambda)^{\frac{1}{2}}\,. \tag{44}$$

Finally, $h^\lambda_{\mathbf{z}_j}$ is estimated using Proposition 21:

$$h^\lambda_{\mathbf{z}_j} \le 2\log(8\eta^{-1})\left(\frac{mM}{n\sqrt{\lambda}} + \sigma\sqrt{\frac{m\mathcal{N}(\lambda)}{n}}\right), \tag{45}$$

holding with probability at least $1-\frac{\eta}{4}$. Thus, combining (43), (44) and (45) with (42) gives for any $j = 1,\dots,m$,

$$\|\xi_\lambda(\mathbf{x}_j,\mathbf{y}_j)\|_{\mathcal{H}_K} \le C_\blacktriangle\log^{2(s+1)}(8\eta^{-1})\mathcal{B}_{\frac{n}{m}}(\lambda)^{\frac{1}{2}+s}\lambda^s\left(\frac{mM}{n\lambda} + \sigma\sqrt{\frac{m\mathcal{N}(\lambda)}{n\lambda}}\right),$$

with probability at least $1-\eta$. Integration gives for any $p \ge 2$:

$$\sum_{j=1}^m\left[\mathbb{E}_{\rho^{\otimes n}}\big\|\xi_\lambda(\mathbf{x}_j,\mathbf{y}_j)\big\|^p_{\mathcal{H}_K}\right] \le C_{\blacktriangle,p}\, m\mathcal{A}^p\,,$$

with

$$\mathcal{A} := \mathcal{A}_{\frac{n}{m}}(\lambda) := \mathcal{B}_{\frac{n}{m}}(\lambda)^{\frac{1}{2}+s}\lambda^s \left(\frac{mM}{n\lambda} + \sigma\sqrt{\frac{m\mathcal{N}(\lambda)}{n\lambda}}\right) .$$

Combining this with (41) implies, since $p \geq 2$:

$$\begin{aligned}\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s(\tilde{f}_D^{\lambda} - \bar{f}_D^{\lambda})\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}} &\leq \frac{C_{\blacktriangle,p}}{m}\max\left((m\mathcal{A}^p)^{\frac{1}{p}}, (m\mathcal{A}^2)^{\frac{1}{2}}\right) \\ &= \frac{C_{\blacktriangle,p}}{m}\,\mathcal{A}\max\left(m^{\frac{1}{p}}, m^{\frac{1}{2}}\right) \\ &= \frac{C_{\blacktriangle,p}}{\sqrt{m}}\,\mathcal{A}\,,\end{aligned}$$

where $C_{\blacktriangle,p}$ does not depend on $(\sigma, M, R) \in \mathbb{R}_+^3$. The result for the case $1 \leq p \leq 2$ immediately follows from Hölder's inequality. ■

Proof [of Theorem 4] Let λ_n be as defined by (16); as earlier we assume n is big enough so that $\lambda_n < 1$. According to Corollary 14, we have $\mathcal{B}_{\frac{n}{m}}(\lambda_n) \leq 2$ provided $\alpha < \frac{2br}{2br+b+1}$ and n is sufficiently large. Under this condition we immediately obtain from Proposition 19:

$$\begin{aligned}\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s(\tilde{f}_D^{\lambda_n} - \bar{f}_D^{\lambda_n})\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}} &\leq \frac{C_{\blacktriangle,p}}{\sqrt{m}}\,\lambda_n^s \left(\frac{mM}{n\lambda_n} + \sigma\sqrt{\frac{m\mathcal{N}(\lambda_n)}{n\lambda_n}}\right) \\ &\leq C_{\blacktriangle,p}\lambda_n^s \left(\frac{\sqrt{m}M}{n\lambda_n} + \sigma\sqrt{\frac{\lambda_n^{-\frac{1}{b}}}{n\lambda_n}}\right) ,\end{aligned}$$

where we used again that $\mathcal{N}(\lambda_n) \leq C_{\blacktriangle}\lambda_n^{-1/b}$; now

$$\frac{\sqrt{m}_n M}{n\lambda_n} = o\left(\sigma\sqrt{\frac{\lambda_n^{-1/b}}{n\lambda_n}}\right) ,$$

provided

$$m_n \leq n^{\alpha} , \qquad \alpha < \frac{2(br+1)}{2br+b+1} .$$

Recalling that $\sigma\sqrt{\frac{\lambda_n^{-1/b}}{n\lambda_n}} = R\lambda_n^r = \lambda_n^{-s}a_n$, we arrive at

$$\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s(\tilde{f}_D^{\lambda_n} - \bar{f}_D^{\lambda_n})\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}} \leq C_{\blacktriangle,p}\, a_n .$$

As a result, for any $p \geq 1$:

$$\limsup_{n\to\infty}\sup_{\rho\in\mathcal{M}_{\sigma,M,R}} \frac{\left[\mathbb{E}_{\rho^{\otimes n}}\left\|\bar{T}^s(\tilde{f}_D^{\lambda_n} - \bar{f}_D^{\lambda_n})\right\|_{\mathcal{H}_K}^p\right]^{\frac{1}{p}}}{a_n} \leq C_{\blacktriangle,p} ,$$

for some $C_{\blacktriangle,p}$, not depending on the model parameters $(\sigma, M, R) \in \mathbb{R}_+^3$, thus leading to the conclusion. ■

Appendix A

Proposition 20 (see e.g. Blanchard and Mücke, 2017, Proposition 5.3) *For any $n \in \mathbb{N}$, $\lambda \in (0,1]$ and $\eta \in (0,1)$, one has with probability at least $1-\eta$:*

$$\left\|(\bar{T}+\lambda)^{-1}(\bar{T}-\bar{T}_{\mathbf{x}})\right\|_{\mathrm{HS}} \leq 2\log(2\eta^{-1})\left(\frac{2}{n\lambda} + \sqrt{\frac{\mathcal{N}(\lambda)}{n\lambda}}\right) ,$$

where $\|.\|_{HS}$ denotes the Hilbert-Schmidt norm. (Since the operator norm is bounded by the Hilbert-Schmidt norm, the above statement also holds for the operator norm.)

Proposition 21 (see e.g. Blanchard and Mücke, 2017, Proposition 5.2) *For $n \in \mathbb{N}$, $\lambda \in (0,1]$ and $\eta \in (0,1]$, it holds with probability at least $1-\eta$:*

$$\left\|(\bar{T}+\lambda)^{-\frac{1}{2}}\ \left(\bar{T}_{\mathbf{x}}f_\rho - \bar{S}_{\mathbf{x}}^{\star}\mathbf{y}\right)\right\|_{\mathcal{H}_K} \leq 2\log(2\eta^{-1})\left(\frac{M}{n\sqrt{\lambda}} + \sqrt{\frac{\sigma^2\mathcal{N}(\lambda)}{n}}\right) .$$

Proposition 22 (Cordes Inequality, see e.g. Bhatia, 1997, Theorem IX.2.1-2) *Let A, B be to self-adjoint, positive operators on a Hilbert space. Then for any $s \in [0,1]$:*

$$\|A^sB^s\| \leq \|AB\|^s . \tag{46}$$

Abstract

Quadratic discriminant analysis (QDA) is a standard tool for classification due to its simplicity and flexibility. Because the number of its parameters scales quadratically with the number of the variables, QDA is not practical, however, when the dimensionality is relatively large. To address this, we propose a novel procedure named DA-QDA for QDA in analyzing high-dimensional data. Formulated in a simple and coherent framework, DA-QDA aims to directly estimate the key quantities in the Bayes discriminant function including quadratic interactions and a linear index of the variables for classification. Under appropriate sparsity assumptions, we establish consistency results for estimating the interactions and the linear index, and further demonstrate that the misclassification rate of our procedure converges to the optimal Bayes risk, even when the dimensionality is exponentially high with respect to the sample size. An efficient algorithm based on the alternating direction method of multipliers (ADMM) is developed for finding interactions, which is much faster than its competitor in the literature. The promising performance of DA-QDA is illustrated via extensive simulation studies and the analysis of four real datasets.

Keywords: Bayes Risk, Consistency, High Dimensional Data, Linear Discriminant Analysis, Quadratic Discriminant Analysis, Sparsity

1. Introduction

Classification is a central topic in statistical learning and data analysis. Due to its simplicity for producing quadratic decision boundaries, quadratic discriminant analysis (QDA) has become an important technique for classification, adding an extra layer of flexibility to the linear discriminant analysis (LDA); see Hastie et al. (2009). Despite its usefulness, the number of the parameters needed by QDA scales squarely with that of the variables, making it quickly inapplicable for problems with large or even moderate dimensionality. This problem is extremely eminent in the era of big data, as one often encounters datasets with the dimensionality larger, often times substantially larger, than the sample size. This paper aims to develop a novel classification approach named DA-QDA, short for Direct Approach for QDA to make QDA useful for analyzing ultra-high dimensional data.

For ease of presentation, we focus on binary problems where observations are from two classes. Suppose that the observations from class 1 follow $X \sim N(\mu_1, \Sigma_1)$ and those from class 2 satisfy $Y \sim N(\mu_2, \Sigma_2)$, where $\mu_k \in \mathbb{R}^p, k = 1, 2$ are the mean vectors and $\Sigma_k \in \mathbb{R}^{p\times p}, k = 1, 2$ are the two covariance matrices. Compared with LDA, it is assumed that $\Sigma_1 \neq \Sigma_2$ in QDA, which gives rise to a class boundary that is quadratic in terms of the variables. Bayes' rule classifies a new observation z to class 1 if $\pi_1 f(z|\mu_1, \Sigma_1) > \pi_2 f(z|\mu_2, \Sigma_2)$, where $f(z|\mu, \Sigma)$ is the probability density function of a multivariate normal distribution with mean μ and variance Σ, and π_1 and π_2 are the two prior probabilities. Following simple algebra, the Bayes discriminant function for a new observation z is seen as

$$D(z) = (z - \mu)^T \Omega (z - \mu) + \delta^T (z - \mu) + \eta,$$

where $\mu = (\mu_1 + \mu_2)/2$ is the mean of the two centroids, $\Omega = \Sigma_2^{-1} - \Sigma_1^{-1}$ is the difference of the two precision matrices, $\delta = (\Sigma_1^{-1} + \Sigma_2^{-1})(\mu_1 - \mu_2)$, and $\eta = 2\log(\pi_1/\pi_2) + \frac{1}{4}(\mu_1 - \mu_2)^T \Omega(\mu_1 - \mu_2) + \log|\Sigma_2| - \log|\Sigma_1|$; see for example Anderson (2003). Note that the discriminant function becomes that of LDA when $\Sigma_1 = \Sigma_2 = \Sigma$. Completely analogous to a two-way interaction model in linear regression, δ in $D(z)$ can be seen as a linear index of the variables whose nonzero entries play the role of main effects, whereas the nonzero entries in Ω can be understood as interactions of second-order between the variables. Although there are other ways to represent the discriminant function, $D(z)$ is used as it is a quadratic function of $z - \mu$, making the discriminant function location-invariant with respect to the coordinates. For easy reference, we shall call subsequently the parameters Ω, δ, μ, and η in the Bayes discriminant function collectively as Bayes components.

1.1 Our contributions

We highlight the main contributions of this paper as follows.

1. DA-QDA is the first *direct* approach for sparse QDA in a high dimensional setup. That is, Ω, δ, μ, and η in the Bayes discriminant function are directly estimated with only sparse assumptions on Ω and δ but not on other intermediate quantities;

2. For estimating Ω, an intermediate step of DA-QDA and a problem of interest in its own right, we develop a new algorithm which is much more computationally and memory efficient than its competitor. See Section 2.1;

3. We develop new theory to show the theoretical attractiveness of the DA-QDA. In particular, the theory for estimating δ is new. See Section 3;

4. The problem of finding the right intercept η is of considerable interest but a general theory on estimated η is lacking (Hastie et al., 2009). We provide a first theory for the convergence property of our estimated η. See Section 3.4;

5. In extensive simulation study and real data analysis, the DA-QDA approach outperforms many of its competitors, especially when variables under considerable interact. See Section 4.

1.2 Literature review

As more and more modern datasets are high-dimensional, the problem of classification in this context has received increasing attention as the usual practice of using empirical estimates for the Bayes components is no longer applicable. Bickel and Levina (2004) first highlighted that LDA is equivalent to random guessing in the worst case scenario when the dimensionality is larger than the sample size. Scientifically and practically in many problems, however, the components in the Bayes discriminant function can be assumed sparse. In the problem we study in this paper, loosely speaking, the notion of sparsity entertains that the two-way interaction representation of the model only admits a small number of main effects and interactions. In the past few years, a plethora of methods built on suitable sparsity assumptions have been proposed to estimate the main effects as in LDA; see for example Shao et al. (2011), Cai and Liu (2011), Fan et al. (2012), Mai et al. (2012), Mai and Zou (2013), and Jiang et al. (2015). Other related linear methods for high-dimensional classification can be found in Leng (2008), Witten and Tibshirani (2011), Pan et al. (2016), Mai et al. (2015), among others.

As pointed out by Fan et al. (2015b) and Sun and Zhao (2015), it has been increasingly recognized that the assumption of a common covariance matrix across different classes, needed by LDA, can be restrictive in many practical problems. The extra layer of flexibility offered by QDA that deals with two-way variable interactions makes it extremely attractive for such problems. Li and Shao (2015) studied sparse QDA by making sparsity assumptions on $\mu_2 - \mu_1, \Sigma_1, \Sigma_2$ and $\Sigma_1 - \Sigma_2$ and proposed their sparse estimates. The assumptions made are not directly on the key quantities needed in the discriminant function $D(z)$. In addition, good estimates of these four quantities do not necessarily translate to better classification, a phenomenon similarly argued and observed by Cai and Liu (2011) and Mai et al. (2012) for LDA. Fan et al. (2015b) proposed a screening method to identify interactions when Ω admits a two block sparse structure after permutation, before applying penalized logistic regression on the identified interactions and all the main effects to estimate a sparser model. Their method cannot deal with problems where the support of Ω is in general positions. Further, the use of a separate second-step penalized logistic regression to determine important interactions and main effects is less appealing from a methodological perspective. Fan et al. (2015a) suggested a Rayleigh quotient based method for which all the fourth cross-moments of the predictors have to be estimated. Despite all these efforts, a direct yet simple approach for QDA with less stringent assumptions than in Li and Shao (2015) for high-dimensional analysis is missing.

The proposed DA-QDA approach in this paper aims to overcome the difficulties mentioned above. In particular, compared with Li and Shao (2015), we only make sparsity assumptions on Ω and δ and estimate these two quantities directly in DA-QDA. Compared to Fan et al. (2015b), we allow the interactions in Ω in general positions, without resorting to a second stage approach for interactions and main effects selection. Compared with Fan et al. (2015a), we operate directly on QDA for which only second cross-moments of the variables are needed.

DA-QDA can also be understood as a novel attempt to select interactions in the discriminant function that correspond to the nonzero entries in Ω. The problem of interaction selection is a problem of its own importance and has been studied extensively recently for regression problems. See, for example, Hao and Zhang (2014) and references therein. The problem of estimating Ω alone has also attracted attention lately in a different context. To understand how the structure of a network differs between different conditions and to find the common structures of two different Gaussian graphical models, Zhao et al. (2014) proposed a direct approach for estimating Ω by formulating their procedure via the Dantzig selector. A severe limitation is that their linear programming procedure needs to deal with $O(p^2)$ constraints, and the memory requirement by the large constraint matrix is of the order $O(p^4)$. As a result, an iteration of the algorithm in Zhao et al. (2014) requires $O(sp^4)$ computations, where s is the cardinality of the support of Ω. Apparently, their method does not scale well to high dimensional data. In Zhao et al. (2014), problems with maximum size $p = 120$ were attempted and it was reported that a long time was needed to run their method. In contrast, we use a lasso formulation and develop a new algorithm based on the alternating direction methods of multipliers (ADMM) for estimating Ω. The memory requirement of our algorithm is of the order $O(p^2)$ and its computational cost is of the order $O(p^3)$ per iteration, enabling DA-QDA to easily handle much larger problems.

The rest of the paper is organized as follows. Section 2 outlines the main DA-QDA methodology for estimating Ω and δ. A novel algorithm based on ADMM for estimating Ω is developed. Section 3 investigates the theory of DA-QDA and provides various consistency results for estimating Ω, δ, and η, as well as establishing the consistency of the misclassification risk relative to the Bayes risk. Section 4 presents extensive numerical studies and analysis of four real datasets. Comparison with other classification methods demonstrates that DA-QDA is very competitive in estimating the sparsity pattern and the parameters of interest. We provide a short discussion and outline future directions of research in Section 5. All the proofs are relegated to the Appendix.

2. DA-QDA Methodology

To obtain an estimator for the Bayes discriminant function $D(z)$, we propose direct estimators for the two of its Bayes components $\Omega = \Sigma_2^{-1} - \Sigma_1^{-1}$ and $\delta = (\Sigma_1^{-1} + \Sigma_2^{-1})(\mu_1 - \mu_2)$ under appropriate sparsity assumptions. Given data $X_j,\ j = 1,..,n_1$ from class 1 and $Y_k,\ k = 1,...,n_2$ from class 2, we can estimate μ_i and $\Sigma_i,\ i = 1, 2$, via their sample versions as

$$\hat{\mu}_1 = \frac{1}{n_1}\sum_{j=1}^{n_1} X_j,\ \hat{\mu}_2 = \frac{1}{n_2}\sum_{j=1}^{n_2} Y_j;$$

$$\hat{\Sigma}_1 = \frac{1}{n_1}\sum_{j=1}^{n_1}(X_j - \hat{\mu}_1)(X_j - \hat{\mu}_1)^T,\ \hat{\Sigma}_2 = \frac{1}{n_2}\sum_{j=1}^{n_2}(Y_j - \hat{\mu}_2)(Y_j - \hat{\mu}_2)^T.$$

When $p >> \max\{n_1, n_2\}$, $\hat{\Sigma}_1$ and $\hat{\Sigma}_2$ are degenerate and cannot be directly used for estimating Ω. Denote the DA-QDA estimates of Ω as $\hat{\Omega}$ and δ as $\hat{\delta}$ which will be obtained as

in (2) and (8) respectively. For a given scalar η, our DA-QDA procedure classifies a new observation z in to class 1 if

$$\left[z-\frac{\hat{\mu}_1+\hat{\mu}_2}{2}\right]^T\hat{\Omega}\left[z-\frac{\hat{\mu}_1+\hat{\mu}_2}{2}\right]+\hat{\delta}^T\left[z-\frac{\hat{\mu}_1+\hat{\mu}_2}{2}\right]+\eta>0, \tag{1}$$

and classifies z into class 2 otherwise. From (1), we emphasize again that the nonzero entries in $\hat{\Omega}$ are the interactions of the variables that contribute to the classification rule, while the nonzero entries in $\hat{\delta}$ are the main effects of the variables that are used for classification. In the linear discriminant analysis when $\Sigma_1=\Sigma_2$, the rule in (1) becomes the LDA rule which is linear in the variables. As $\eta=2\log(\pi_1/\pi_2)+\frac{1}{4}(\mu_1-\mu_2)^T\Omega(\mu_1-\mu_2)+\log|\Sigma_2|-\log|\Sigma_1|$ is a scalar, we can choose η as $\hat{\eta}$ using a simple grid search, bypassing the need to estimate the determinants of Σ_1 and Σ_2. This is the strategy implemented in Section 4 and its analytical justification is provided in Section 3.4. Thus in the following, we shall focus on the estimation of Ω and δ, under certain sparsity assumptions on these two quantities.

2.1 Estimating Ω

Recall $\Omega=\Sigma_2^{-1}-\Sigma_1^{-1}$. It may be attempting to first estimate Σ_1^{-1} and Σ_2^{-1} as intermediate quantities before taking their difference. It is known, however, that accurate estimation of a covariance matrix or its inverse can be difficult in general in high dimensions unless additional assumptions are imposed (cf. Bickel and Levina (2008)). Because Ω is the quantity of interest that appears in the Bayes' rule, we propose to estimate it directly. To proceed, we note that $\Sigma_2\Omega\Sigma_1=\Sigma_1\Omega\Sigma_2=\Sigma_1-\Sigma_2$. If we define a loss function as $Tr\left(\Omega^T\Sigma_1\Omega\Sigma_2\right)/2-Tr\left(\Omega(\Sigma_1-\Sigma_2)\right)$, the loss function is minimized when Ω satisfies $\Sigma_2\Omega\Sigma_1=\Sigma_1-\Sigma_2$ or $\Omega=\Sigma_2^{-1}-\Sigma_1^{-1}$. This simple observation motivates the following penalized loss formulation for estimating Ω by replacing $\Sigma_j, j=1,2$ by their empirical estimates as

$$\hat{\Omega}=\arg\min_{\Omega\in R^{p\times p}}\ \frac{1}{2}Tr\left(\Omega^T\hat{\Sigma}_1\Omega\hat{\Sigma}_2\right)-Tr\left(\Omega(\hat{\Sigma}_1-\hat{\Sigma}_2)\right)+\lambda\|\Omega\|_1, \tag{2}$$

where $\|\Omega\|_1$ is the ℓ_1 penalty of the vectorized Ω to encourage sparsity and λ is the tuning parameter. To obtain a symmetric estimator for Ω, we may simply use $\hat{\Omega}_0=\frac{1}{2}(\hat{\Omega}+\hat{\Omega}^T)$ after $\hat{\Omega}$ is obtained. Because the second derivative of the above loss function is $\hat{\Sigma}_2\otimes\hat{\Sigma}_1$ which is nonnegative definite, the formulation in (2) is a convex problem and can be solved by a convex optimization algorithm.

We now develop an ADMM algorithm to solve for $\hat{\Omega}$ in (2) (Boyd et al., 2011; Zhang and Zou, 2014). First write the optimization problem in (2) as

$$\min_{\Omega\in R^{p\times p}}\ \frac{1}{2}Tr\left(\Omega^T\hat{\Sigma}_1\Omega\hat{\Sigma}_2\right)-Tr\left(\Omega(\hat{\Sigma}_1-\hat{\Sigma}_2)\right)+\lambda\|\Psi\|_1,\ s.t.\ \Psi=\Omega. \tag{3}$$

From this, we can form the augmented Lagrangian as

$$\begin{aligned}L(\Omega,\Psi,\Lambda) &= \frac{1}{2}Tr\left(\Omega^T\hat{\Sigma}_1\Omega\hat{\Sigma}_2\right)-Tr\left(\Omega(\hat{\Sigma}_1-\hat{\Sigma}_2)\right)+\lambda\|\Psi\|_1\\ &\quad +Tr\left(\Lambda(\Omega-\Psi)\right)+\frac{\rho}{2}\|\Omega-\Psi\|_F^2,\end{aligned}$$

where $\|\cdot\|_F$ is the Frobenius norm of a matrix and ρ is a parameter in the ADMM algorithm. See Section 4 for more details. Given the current estimate $\Omega^k,\Psi^k,\Lambda^k$, we update successively

$$\Omega^{k+1}=\arg\min_{\Omega\in R^{p\times p}}L(\Omega,\Psi^k,\Lambda^k), \tag{4}$$

$$\Psi^{k+1}=\arg\min_{\Psi\in R^{p\times p}}L(\Omega^{k+1},\Psi,\Lambda^k), \tag{5}$$

$$\Lambda^{k+1}=\Lambda^k+\rho(\Omega^{k+1}-\Psi^{k+1}). \tag{6}$$

Write $\hat{\Sigma}_i=U_iD_iU_i^T$ as the eigenvalue decomposition of $\hat{\Sigma}_i$ where $D_i=\mathrm{diag}(d_{i1},\cdots,d_{ip})$, $i=1,2$. Denote $A^k=(\hat{\Sigma}_1-\hat{\Sigma}_2)-\Lambda^k+\rho\Psi^k$ and organize the diagonals of $(D_2\otimes D_1+\rho I)^{-1}$ in a matrix B, where $B_{jk}=1/(d_{1j}d_{2k}+\rho)$. The following proposition provides explicit solutions for (4) and (5) which ensures efficient updation of our algorithm in each step.

Proposition 1 *Given Ψ^k, Λ^k, ρ and λ, the solution for (4) is given as:*

$$\Omega^{k+1}=U_1[B\circ(U_1^TA^kU_2)]U_2^T;$$

Given Ω^{k+1},Λ^k and ρ, the solution for (5) is given as:

$$\Psi^{k+1}=S(\Omega^{k+1}+\frac{\Lambda^k}{\rho},\frac{\lambda}{\rho}), \tag{7}$$

where S is known as the soft-thresholding operator on a matrix. Namely, the (i,j) entry of $S(A,b)$ for a matrix $A=(a_{ij})$ is $sign(a_{ij})(|a_{ij}|-b)_+$ where $(c)_+=c$ for $c>0$ and $(c)_+=0$ otherwise.

Note that for a given ρ, when updating Ω, we only need to update A^k which involves simple matrix subtraction, and then use matrix multiplication. Therefore the update in (4) can be efficiently implemented. Following is a brief derivation on how we obtain the explicit solutions given in Proposition 1. For (4), note that the derivative of L with respect to Ω is

$$\hat{\Sigma}_1\Omega\hat{\Sigma}_2-(\hat{\Sigma}_1-\hat{\Sigma}_2)+\Lambda^k+\rho(\Omega-\Psi^k)=(\hat{\Sigma}_1\Omega\hat{\Sigma}_2+\rho\Omega)-(\hat{\Sigma}_1-\hat{\Sigma}_2)+\Lambda^k-\rho\Psi^k,$$

which can be written as

$$(\hat{\Sigma}_2\otimes\hat{\Sigma}_1+\rho I)vec(\Omega)=vec\left((\hat{\Sigma}_1-\hat{\Sigma}_2)-\Lambda^k+\rho\Psi^k\right),$$

where vec is the vector operator. We have

$$vec(\Omega)=(\hat{\Sigma}_2\otimes\hat{\Sigma}_1+\rho I)^{-1}vec\left((\hat{\Sigma}_1-\hat{\Sigma}_2)-\Lambda^k+\rho\Psi^k\right).$$

Using the equality $vec(AXB)=(B^T\otimes A)vec(X)$, and

$$\begin{aligned}(\hat{\Sigma}_2\otimes\hat{\Sigma}_1+\rho I)^{-1} &= [(U_2\otimes U_1)(D_2\otimes D_1+\rho I)(U_2^T\otimes U_1^T)]^{-1}\\ &= (U_2\otimes U_1)(D_2\otimes D_1+\rho I)^{-1}(U_2^T\otimes U_1^T),\end{aligned}$$

we have

$$\begin{aligned}
& (\hat{\Sigma}_2 \otimes \hat{\Sigma}_1 + \rho I)^{-1} vec(A^k) \\
= \; & [(U_2 \otimes U_1)(D_2 \otimes D_1 + \rho I)(U_2^T \otimes U_1^T)]^{-1} vec(A^k) \\
= \; & (U_2 \otimes U_1)(D_2 \otimes D_1 + \rho I)^{-1}(U_2^T \otimes U_1^T) vec(A^k) \\
= \; & (U_2 \otimes U_1)(D_2 \otimes D_1 + \rho I)^{-1} vec(U_1^T A^k U_2) \\
= \; & (U_2 \otimes U_1) vec\left(B \circ (U_1^T A^k U_2)\right) \\
= \; & vec\left(U_1[B \circ (U_1^T A^k U_2)]U_2^T\right)
\end{aligned}$$

where $\circ$ is the Hadamard product. Therefore,

$$\Omega = U_1[B \circ (U_1^T A^k U_2)]U_2^T.$$

Next we examine (5). Ignoring terms that are independent of Ψ, we just need to minimize

$$\frac{\rho}{2} Tr(\Psi^T \Psi) - \rho Tr((\Omega^{k+1})^T \Psi) - Tr((\Lambda^k)^T \Psi) + \lambda \|\Psi\|_1,$$

and the solution can be easily seen as (7). Again, the update for Γ can be efficiently implemented.

Our algorithm can be now summarized as following.

1. Initialize Ω, Ψ and Λ. Fix ρ. Compute SVD $\hat{\Sigma}_1 = U_1 D_1 U_1^T$ and $\hat{\Sigma}_2 = U_2 D_2 U_2^T$, and compute B where $B_{jk} = 1/(d_{1j} d_{2k} + \rho)$. Repeat steps 2-4 until convergence;

2. Compute $A = (\hat{\Sigma}_1 - \hat{\Sigma}_2) - \Lambda + \rho\Psi$. Then update Ω as $\Omega = U_1[B \circ (U_1^T A U_2)]U_2^T$;

3. Update Ψ by soft-thresholding $\Omega + \frac{\Lambda}{\rho}$ elementwise by $\frac{\lambda}{\rho}$;

4. Update Λ by $\Lambda \leftarrow \Lambda + \rho(\Omega - \Psi)$.

Note that the algorithm involves singular value decomposition of $\hat{\Sigma}_1$ and $\hat{\Sigma}_2$ only once. The rest of the algorithm only involves matrix addition and multiplication. Thus, the algorithm is extremely efficient. Compared with Zhao et al. (2014) whose algorithm has computational complexity of the order at least $O(p^4)$ and a memory requirement of $O(p^4)$, our algorithm has a memory requirement of the order $O(p^2)$ and computational complexity of $O(p^3)$. As a result, our method can handle much larger problems. As a first order method for convex problems, the convergence of ADMM algorithms is in general of rate $O(k^{-1})$, where k is the number of iterations. Convergence analysis of ADMM algorithms under different assumptions has been well established in some very recent optimization literatures; see for example, Nishihara et al. (2015), Hong and Luo (2017) and Chen et al. (2017). By verifying the assumptions in Hong and Luo (2017), we can established similar linear convergence results for our algorithm; see Lemma 1 in the Appendix for more details.

2.2 The linear index δ

After having estimated Ω as $\hat{\Omega}$, we discuss the estimation of the linear index $\delta = (\Sigma_1^{-1} + \Sigma_2^{-1})(\mu_1 - \mu_2)$. We develop a procedure that avoids estimating Σ_1^{-1} and Σ_2^{-1}. First note that

$$\Sigma_1 \delta = \Sigma_1(\Sigma_1^{-1} + \Sigma_2^{-1})(\mu_1 - \mu_2) = 2(\mu_1 - \mu_2) + \Sigma_1 \Omega(\mu_1 - \mu_2),$$
$$\Sigma_2 \delta = \Sigma_2(\Sigma_1^{-1} + \Sigma_2^{-1})(\mu_1 - \mu_2) = 2(\mu_1 - \mu_2) - \Sigma_2 \Omega(\mu_1 - \mu_2),$$

and

$$(\Sigma_1 + \Sigma_2)\delta = 4(\mu_1 - \mu_2) + (\Sigma_1 - \Sigma_2)\Omega(\mu_1 - \mu_2).$$

The last equation is the derivative of $\delta^T(\Sigma_1 + \Sigma_2)\delta/2 - \{4(\mu_1 - \mu_2) + (\Sigma_1 - \Sigma_2)\Omega(\mu_1 - \mu_2)\}^T \delta$. Motivated by this, we estimate δ by a direct method using the lasso regularization, similar to the one in Mai et al. (2012), as

$$\hat{\delta} = \arg\min_{\delta \in R^p} \; \frac{1}{2}\delta^T(\hat{\Sigma}_1 + \hat{\Sigma}_2)\delta - \hat{\gamma}^T \delta + \lambda_\delta \|\delta\|_1, \tag{8}$$

where $\hat{\gamma} = 4(\hat{\mu}_1 - \hat{\mu}_2) + (\hat{\Sigma}_1 - \hat{\Sigma}_2)\hat{\Omega}(\hat{\mu}_1 - \hat{\mu}_2)$, $\|\cdot\|_1$ is the vector ℓ_1 penalty and λ_δ is a tuning parameter. The optimization in (8) is a standard lasso problem and is easy to solve using existing lasso algorithms. We remark that (8) is much more challenging to analyze theoretically than the method in Mai et al. (2012), since the accuracy of $\hat{\Omega}$ as an estimator of Ω has to be carefully quantified in $\hat{\gamma}$.

We emphasize that our framework is extremely flexible and can accommodate additional constraints. As a concrete example, let's consider enforcing the so-called strong heredity principle in that an interaction is present unless the corresponding main effects are both present, i.e. if $\Omega_{jk} \neq 0$ then $\delta_j \neq 0$ and $\delta_k \neq 0$; see for example Hao and Zhang (2016). Denote $\mathcal{I} \subset \{1, \ldots, p\}$ as the set such that for any $j, k \in \mathcal{I}$ there exists some $\hat{\Omega}_{jk} \neq 0$. We can change the penalty in (8) as $\|\delta_{\mathcal{I}^C}\|_1$ such that the variables in $\mathcal{I}$ are not penalized. Due to space limitation, this line of research will not be studied in the current paper.

3. Theory

We show that our method can consistently select the true nonzero interaction terms in Ω and the true nonzero terms in δ. In addition, we provide explicit upper bounds for the estimation error under l_∞ norm. For classification, we further show that the misclassification rate of our DA-QDA rule converges to the optimal Bayes risk under some sparsity assumptions. For simplicity in this section we assume that $n_1 \asymp n_2$ and write $n = \min\{n_1, n_2\} - 1$. Instead of assuming $\mu_2 - \mu_1$, Σ_1, Σ_2 and $\Sigma_1 - \Sigma_2$ to be sparse as in Li and Shao (2015), we only assume that Ω and δ are sparse. For the estimation of Ω, the rate in Corollary 1 is similar to the one in Theorem 3 of Zhao et al. (2014). However, as we pointed out previously, our method is computationally much more efficient and scales better to large-dimensional problems. In addition, our work is the first direct estimation approach for sparse QDA. Importantly, the results for estimating δ are new.

Note that when estimating δ as in (8), we have used $\hat{\Omega}$ as a plug-in estimator for Ω. Consequently, from Corollaries 1 and 2, the error rate of $\hat{\delta}$ in estimating δ is a factor times of that of $\hat{\Omega}$ in estimating Ω. However, in the DA-QDA discriminant function defined as

in (1), $\hat{\Omega}$ appears in the first term which is a product of three components while $\hat{\delta}$ appears in the second term which is a product of two components. As a consequence, the overall estimation error rates of these two terms become equal. This implies that even though the estimating error of $\hat{\Omega}$ might aggregate in the estimation of δ, it does not affect the convergence rate of the classification error at all. Below we provide theory for estimating Ω, δ, and η, as well as quantifying the overall misclassification error rate.

3.1 Theory for estimating Ω

We first introduce some notation. We assume that $\Omega = (\Omega_{ij})_{1\le i,j\le p}$ is sparse with support $S = \{(i,j) : \Omega_{ij} \neq 0\}$ and we use S^c to denote the complement of S. Let d be the maximum node degree in Ω. For a vector $x = (x_1, \ldots, x_p)^T$, the l_q norm is defined as $|x|_q = (\sum_{i=1}^p |x_i|^q)^{1/q}$ for any $1 \le q < \infty$ and the l_∞ norm is defined as $|x|_\infty = \max_{1\le i\le p} |x_i|$. For any matrix $M = (m_{ij})_{1\le i,j\le p}$, its entrywise l_1 norm is defined as $||M||_1 = \sum_{1\le i,j\le p} |m_{ij}|$ and its entrywise l_∞ norm is written as $||M||_\infty = \max_{1\le i,j\le p} |m_{ij}|$. We use $|||M|||_{1,\infty} = \max_{1\le i\le p} \sum_{j=1}^p |m_{ij}|$ to denote the l_1/l_∞ norm induced matrix-operator norm. We denote $\Gamma = \Sigma_2 \otimes \Sigma_1$ and $\hat{\Gamma} = \hat{\Sigma}_2 \otimes \hat{\Sigma}_1$. Write $\Sigma_k = (\sigma_{kij})_{1\le i,j\le p}$, $\hat{\Sigma}_k = (\hat{\sigma}_{kij})_{1\le i,j\le p}$ for $k = 1, 2$. By the definition of Kronecker product, Γ is a $p^2 \times p^2$ matrix indexed by vertex pairs in that $\Gamma_{(i,j),(k,l)} = \sigma_{1ik}\sigma_{2jl}$. Denote $\Delta_i = \hat{\Sigma}_i - \Sigma_i$ for $i = 1, 2$, $\Delta_\Gamma = \hat{\Gamma} - \Gamma, \Delta_{\Gamma^T} = \hat{\Gamma}^T - \Gamma^T$, and $\epsilon_i = ||\Delta_i||_\infty$, $\epsilon = \max\{\epsilon_1, \epsilon_2\}$. $B = \max\{||\Sigma_1||_\infty, ||\Sigma_2||_\infty\}$, $B_\Sigma = \max\{||\Sigma_1||_{1,\infty}, ||\Sigma_2||_{1,\infty}\}$ and $B_\Gamma = ||\Gamma_{S,S}^{-1}||_{1,\infty}$, $B_{\Gamma^T} = ||(\Gamma_{S,S}^T)^{-1}||_{1,\infty}$, $B_{\Gamma,\Gamma^T} = \max\{B_\Gamma, B_{\Gamma^T}\}$.

To establish the model selection consistency of our estimator, we assume the following irrepresentability condition:

$$\alpha = 1 - \max_{e\in S^c} |\Gamma_{e,S}\Gamma_{S,S}^{-1}|_1 > 0.$$

This condition was first introduced by Zhao and Yu (2006) and Zou (2006) to establish the model selection consistency of the lasso. The following theorem gives the model selection consistency and the rate of convergence for the estimation of Ω.

Theorem 1 *Assume that $\alpha > 0$ and $d^2B^2B_\Sigma^2B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}} \to 0$. For any $c > 2$, by choosing $\lambda = \kappa_1 d^2B^2B_\Sigma^2B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}}$ for some large enough constant $\kappa_1 > 0$, we have with probability greater than $1 - p^{2-c}$,*

(i) $\hat{\Omega}_{S^c} = 0$;

(ii) there exists a large enough constant $\kappa_2 > 0$ such that

$$||\hat{\Omega} - \Omega||_\infty < \kappa_2 d^2B^2B_\Sigma^2B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}}.$$

Theorem 1 states that if the irrepresentability condition is satisfied, the support of Ω is estimated consistently, and the rate of convergence of estimating Ω under l_∞ norm is of order $O\left(d^2B^2B_\Sigma^2B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}}\right)$, which depends on the sparsity of Σ_1, Σ_2 and their Kronecker product. For example, our assumption $d^2B^2B_\Sigma^2B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}} \to 0$ implies that

$B = \max\{||\Sigma_1||_\infty, ||\Sigma_2||_\infty\}$ can diverge in a rate of $o(d^{-1}B_\Sigma^{-1}B_{\Gamma,\Gamma^T}^{-1}(\frac{n}{\log p})^{1/4})$. From the proof of Theorem 1, we have the following corollary.

Corollary 1 *Assume that $\alpha > 0$, $B_\Sigma < \infty$ and $B_{\Gamma,\Gamma^T} < \infty$. For any constant $c > 2$, choosing $\lambda = Cd^2\sqrt{\frac{\log p}{n}}$ for some constant $C > 0$, if $d^2\sqrt{\frac{\log p}{n}} \to 0$, we have with probability greater than $1 - p^{2-c}$, $\hat{\Omega}_{S^c} = 0$ and*

$$||\hat{\Omega} - \Omega||_\infty = O\left(d^2\sqrt{\frac{\log p}{n}}\right).$$

Similar to Condition 2 in Zhao et al. (2014), the assumption $B_{\Gamma,\Gamma^T} < \infty$ in Corollary 1 is closely related to the mutual incoherence property introduced in Donoho and Huo (2001). In fact, it holds when imposing the usual mutual incoherence condition on the inverses of the submatrices (indexed by S) of Σ_1 and Σ_2. Since d is the maximum node degree in Ω, the number of nonzero entries in Ω is of order $O(dp)$. the rate $O\left(d^2\sqrt{\frac{\log p}{n}}\right)$ we obtained in Corollary 1 is better than the rate in Theorem 3 of Zhao et al. (2014). However, in the case where only O(d) covariates and some of their interactions are important, our rate is the same as the one in Zhao et al. (2014).

3.2 Theory for estimating δ

Let $D = \{i : \delta_i \neq 0\}$ be the support of δ and let d_δ be its cardinality. Denote $A_1 = ||\Omega||_{1,\infty}$, $A_2 = ||(\Omega^{-1})_{\cdot,D}||_{1,\infty}$, $\epsilon_\mu = \max\{|\mu_1 - \hat{\mu}_1|_\infty, |\mu_2 - \hat{\mu}_2|_\infty\}$. We define $A_\Sigma = ||\Sigma_{D,D}^{-1}||_{1,\infty}$ where $\Sigma = (\Sigma_1 + \Sigma_2)/2$ and write $\hat{\Sigma} = (\hat{\Sigma}_1 + \hat{\Sigma}_2)/2$, $\gamma = 4(\mu_1 - \mu_2) + (\Sigma_1 - \Sigma_2)\Omega(\mu_1 - \mu_2)$, $\Delta_\mu = \mu_1 - \mu_2$, $\hat{\Delta}_\mu = \hat{\mu}_1 - \hat{\mu}_2$, $A_\gamma = ||\gamma||_\infty$ and $||\hat{\Omega} - \Omega||_\infty = \epsilon_\Omega$.

To establish the model selection consistency of our estimator $\hat{\delta}$, we assume the following irrepresentability condition:

$$\alpha_\delta = 1 - \max_{e\in D^c} |\Sigma_{e,D}\Sigma_{D,D}^{-1}|_1 > 0.$$

Let $d_0 = \max\{d, d_\delta\}$. The following theorem gives the model selection consistency and the rate of convergence for the estimation of δ.

Theorem 2 *Assume that $\alpha_\delta > 0$, $|\Omega(\mu_1 - \mu_2)|_1 = O(d_0^2)$, $\|\Omega\|_\infty < \infty$, $A_\gamma < \infty$ and $d_0^3A_\Sigma^2B^2B_\Sigma^3B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}} \to 0$. Under the same assumptions in Theorem 1, for any $c > 2$, by choosing $\lambda_\delta = \kappa_3 d_0^3A_\Sigma^2B^2B_\Sigma^3B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}}$, for some large enough constant κ_3, we have, with probability greater than $1 - p^{2-c}$,*

(i) $\hat{\delta}_{D^c} = 0$;

(ii) there exists a large enough constant $\kappa_4 > 0$ such that,

$$||\hat{\delta} - \delta||_\infty < \kappa_4 d_0^3A_\Sigma^2B^2B_\Sigma^3B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}}.$$

From Theorem 2 and Corollary 1 we immediately have:

Corollary 2 *Suppose the assumptions of Corollary 1 and Theorem 2 hold and assume that* $A_\Sigma < \infty$. *For any constant* $c > 2$, *by choosing* $\lambda_\delta = Cd_0^3\sqrt{\frac{\log p}{n}}$ *for some large enough constant* $C > 0$, *we have with probability greater than* $1 - p^{2-c}$,

$$||\hat{\delta} - \delta||_\infty = O\left(d_0^3\sqrt{\frac{\log p}{n}}\right).$$

When $\Sigma_1 = \Sigma_2$, δ reduces to $2\Sigma_1^{-1}(\mu_1 - \mu_2)$, which is proportional to the direct discriminant variable β in Mai et al. (2012), Cai and Liu (2011) and Fan et al. (2012), and variables in $D = \{i : \delta_i \neq 0\}$ are linear discriminative features contributing to the Bayes rule. From the proof of Theorem 2 and the rate given in Theorem 2, we can see that when $A_\gamma < \infty$, $||\hat{\delta} - \delta||_\infty$ is of order $O(A_\Sigma\lambda_\delta)$. This is consistent to the result obtained in Theorem 1 of Mai et al. (2012) for the $\Sigma_1 = \Sigma_2$ case.

3.3 Misclassification rate

In this subsection, we study the asymptotic behavior of the misclassification rate for a given η and postpone the theory when η is estimated to Section 3.4. Let $R(i|j)$ and $R_n(i|j)$ be the probabilities that a new observation from class j is misclassified to class i by Bayes' rule and the DA-QDA rule respectively. Suppose $2\log(\pi_1/\pi_2) = \eta - \frac{1}{4}(\mu_1 - \mu_2)^T\Omega(\mu_1 - \mu_2) - \log|\Sigma_2| + \log|\Sigma_1|$. The optimal Bayes risk is given as

$$R = \pi_1 R(2|1) + \pi_2 R(1|2),$$

and the misclassification rate of the DA-QDA rule takes the following form:

$$R_n = \pi_1 R_n(2|1) + \pi_2 R_n(1|2).$$

Suppose $z_i \sim N(\mu_i, \Sigma_i)$ for $i = 1, 2$. Denote the density of $(z_i - \mu)^T\Omega(z_i - \mu) + \delta^T(z_i - \mu) + \eta$ as $F_i(z)$. For any constant c, define

$$u_c = \max\{\operatorname{ess\,sup}_{z\in[-c,c]}F_i(z), i = 1, 2\},$$

where ess sup denotes the essential supremum which is defined as supremum on almost everywhere of the support, i.e., except on a set of measure zero. Let $s := \|S\|_0$ be the number of nonzero elements in Ω. The following theorem establishes upper bounds for the misclassification rate difference between R_n and R.

Theorem 3 *Assuming that there exist constants* $C_\mu > 0, C_\Sigma > 1$ *such that* $\max\{|\mu_1|_\infty, |\mu_2|_\infty\} \leq C_\mu$, *and* $C_\Sigma^{-1} \leq \min\{\lambda_p(\Sigma_1), \lambda_p(\Sigma_2)\} \leq \max\{\lambda_1(\Sigma_1), \lambda_1(\Sigma_2)\} \leq C_\Sigma$ *where* $\lambda_i(\Sigma_j)$ *denotes the ith largest eigenvalue of* Σ_j. *Under the assumptions of Theorems 1 and 2, we have:*

(i) if $sd_0^2B^2B_\Sigma^2B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}} + d_0^2A_\Sigma^2B^2B_\Sigma^3B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}} \to 0$ *and there exist positive constants* c, U_c *such that* $u_c \leq U_c < \infty$, *then*

$$R_n - R = O_p\left(sd_0^2B^2B_\Sigma^2B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}} + d_0^2A_\Sigma^2B^2B_\Sigma^3B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}}\right);$$

(ii) if $\left(sd_0^2B^2B_\Sigma^2B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}} + d_0^2A_\Sigma^2B^2B_\Sigma^3B_{\Gamma,\Gamma^T}^2\sqrt{\frac{\log p}{n}}\right)(1 + u_c) \to 0$ *for some positive constant* c, *then with probability greater than* $1 - 3p^{2-c}$ *for some constant* $c > 2$,

$$R_n - R = O\left((1 + u_c) \times \left(sd_0^2B^2B_\Sigma^2B_{\Gamma,\Gamma^T}^2\log p\sqrt{\frac{\log p}{n}} + d_0^2A_\Sigma^2B^2B_\Sigma^3B_{\Gamma,\Gamma^T}^2\frac{\log p}{\sqrt{n}}\right)\right).$$

Theorem 3 (i) indicates that under appropriate sparsity assumptions, our DA-QDA rule is optimal in that its misclassification rate converges to the optimal Bayes risk in probability. The second statement of Theorem 3 states that under stronger conditions, R_n converges to R with overwhelming probability. From Corollary 1 and Corollary 2 and the above theorem, we immediately have:

Corollary 3 *Under the assumptions of Corollary 1, Corollary 2 and Theorem 3, we have,*

(i) if $sd_0^2\sqrt{\frac{\log p}{n}} \to 0$ *and there exist positive constants* c, U_c *such that* $u_c \leq U_c < \infty$, *then*

$$R_n - R = O_p\left(sd_0^2\sqrt{\frac{\log p}{n}}\right);$$

(ii) if $(1 + u_c)sd_0^2\sqrt{\frac{\log^3 p}{n}} \to 0$ *for some constant* $c > 0$, *then with probability greater than* $1 - 3p^{2-c}$ *for some constant* $c > 2$,

$$R_n - R = O\left(sd_0^2(1 + u_c)\sqrt{\frac{\log^3 p}{n}}\right).$$

We remark that the assumption $u_c \leq U_c$ for some constants c and U_c is similar to Condition (C4) in Li and Shao (2015), and our assumption is weaker in that we only assume the densities $F_i(z)$ is bounded in a neighborhood of zero while Condition (C4) in Li and Shao (2015) states that the densities are bounded everywhere.

3.4 Choice of η

The question of choosing the scalar η is critical for classification but receives little attention in existing literature; see Mai et al. (2012) for a detailed discussion for the LDA case. In this section, we propose to choose η by minimizing the in-sample misclassification error and establish analytical results for the estimation of η and the misclassification rate. With some abuse of notation, let (z_i, l_i) be our data where $z_i's$ are the covariates and $l_i's$ are the labels, i.e., $l_i \in \{0, 1\}$. To obtain $\hat{\eta}$, we seek to minimize the in-sample misclassification error given $\hat{\mu}, \hat{\delta}$ and $\hat{\Omega}$:

$$\hat{\eta} = arg\min_e \frac{1}{n}\sum_{i=1}^n |I\{\hat{D}(z_i, e) > 0\} - l_i|,$$

where $\hat{D}(z, e) = (z - \hat{\mu})^T\hat{\Omega}(z - \hat{\mu}) + \hat{\delta}^T(z - \hat{\mu}) + e$. We write $d(z) = (z - \mu)^T\Omega(z - \mu) + \delta^T(z - \mu)$ and $\hat{d}(z) = (z - \hat{\mu})^T\hat{\Omega}(z - \hat{\mu}) + \hat{\delta}^T(z - \hat{\mu})$ and hence we have

$$\hat{D}(z_i, e) = \hat{d}(z_i) + e.$$

Then the object function becomes

$$\frac{1}{n}\sum_{i=1}^{n}|I\{\hat{d}(z_i)+e>0\}-l_i|.$$

Without loss of generality, we can assume $\hat{d}(z_1)<\hat{d}(z_2)<\cdots<\hat{d}(z_n)$. For any e we define the index $k(e)$ to be the largest $\hat{d}(z_k)$ that satisfies $\hat{d}(z_k)<-e<\hat{d}(z_{k+1})$. Thus, the optimization can be further simplified as

$$\hat{\eta}=arg\min_{e}\frac{1}{n}\Big[\sum_{i=1}^{k(e)}l_i+\sum_{i=k(e)+1}^{n}(1-l_i)\Big].$$

Solving the above problem is simple. One just needs to compute the values of the object function for $k=0,1,2,\cdots,n$ and find the index k^* that minimizes its value. The optimal $\hat{\eta}$ can then be found as any value satisfying

$$\hat{\eta}\in(-\hat{d}(z_{k^*+1}),\ \ -\hat{d}(z_{k^*})).$$

Next we establish the asymptotic results for $\hat{\eta}$ and the misclassification rate. For a given e, we use $R(d,e)$ and $R(\hat{d},e)$ to denote the misclassification rate associated with discriminant function $D(z,e)=d(z)+e$ and discriminant function $\hat{D}(z,e)=\hat{d}(z)+e$ respectively. Analogously, the in-sample misclassification rate of $D(z,e)$ and $\hat{D}(z,e)$ are denoted as $R_n(d,e)$ and $R_n(\hat{d},e)$. From the optimality of the Bayes rule, we know that $\eta=2\log(\pi_1/\pi_2)+\frac{1}{4}(\mu_1-\mu_2)^T\Omega(\mu_1-\mu_2)+\log|\Sigma_2|-\log|\Sigma_1|$ is the unique minimizer of $R(d,\cdot)$ and we denote the corresponding optimal Bayes misclassification rate as $R=R(d,\eta)$. On the other hand, $\hat{\eta}$ is a minimizer of $R_n(\hat{d},e)$. In order to make the estimation problem feasible, we assume that there is exists a constant c_η such that $|\eta|\le c_\eta<\infty$. The following proposition indicates that, although the 0-1 loss used for computing the misclassification rate is neither continuous nor convex, the misclassification rate has a desirable property.

Proposition 2 *$R(d,e)$ is strictly monotone increasing in $e\in[\eta,\infty)$ and strictly monotone decreasing in $e\in(-\infty,\eta]$.*

From Proposition 2 and following Theorem 5.7 of Van der Vaart (2000), we establish the following theorem, which indicates that the estimator $\hat{\eta}$ is consistent and the resulting misclassification rate using the estimated rule $\hat{D}(z,\hat{\eta})$ tends to the optimal Bayes misclassification rate in probability.

Theorem 4 *Let $\hat{\eta}$ be a minimizer of $R_n(\hat{d},e)$. Under the assumptions of Theorem 3, we have:*

(i) $\hat{\eta}\to\eta$ in probability;

(ii) $R_n(\hat{d},\hat{\eta})\to R$ in probability.

4. Numerical Study

In this section, we provide extensive numerical evidence to show the empirical performance of DA-QDA by comparing it to its competitors, including the sparse QDA (sQDA, Li and Shao (2015)), the innovated interaction screening for sparse quadratic discriminant analysis (IIS-SQDA, Fan et al. (2015b)), penalized logistic regression with only main effects considered (PLR), penalized logistic regression with all interaction terms (PLR2), the direct approach for sparse LDA (DSDA, Mai et al. (2012)), the conventional LDA (LDA), the conventional QDA (QDA) and the oracle procedure (Oracle). The oracle procedure uses the true underlying model and serves as the optimal risk bound for comparison. We evaluate all methods via nine synthetic datasets and four real datasets. In addition, we also include L1-regularized SVM (L-SVM) and kernel SVM (K-SVM, with Gaussian kernel) performance as a benchmark in the real data analysis.

To fit DA-QDA, we employ ADMM to estimate Ω and the coordinate-wise descent algorithm (Friedman et al., 2010) to fit δ. Once Ω and δ are given, we then find the value of η by a simple linear search, minimizing the in-sample misclassification error. The rate parameter ρ in ADMM is set according to the optimal criterion suggested by Ghadimi et al. (2015). The other two tuning parameters, λ for estimating Ω and λ_δ for estimating δ, are chosen by 5-fold cross-validation, where the loss function is chosen to be the out-of-sample misclassification rate. To reduce the searching complexity, we are currently using a searching path rather than grid based tuning to avoid redundant computation and in-memory parallelism to distribute the computational tasks. It is worth noting that the calculation for each individual tuning pair (λ, λ_δ) can be made completely independent such that it is possible to distribute the entire calculation to multiple threads in a parallel fashion. One can also tune the parameters using the objective functions in (2) and (8) separately. However, we found that this strategy did not often lead to better classification results than tuning them jointly. This is possibly due to the complex shape of the misclassification surface as a function of these two tuning parameters. We implemented sQDA in Matlab with the leave-one-out-cross-validation (Li and Shao, 2015) to tune the three parameters. We employ Matlab's built-in function *fitcdiscr* to fit LDA and QDA and the R package *dsda* (Mai et al., 2012) to fit DSDA. For PLR, PLR2 and the second stage fit of IIS-SQDA which is a penalized logistic regression, we use the *glmnet* package and set $\alpha=0.5$ as the elastic net parameter. Other values of α was tried but did not change the result much. The other tuning parameter in *glmnet* is chosen by 10-fold cross-validation to minimize out-of-sample classification error. For the first stage of *IIS-SQDA* which is a screening step, we adopt the oracle-assisted approach proposed in Fan et al. (2015b), i.e., using the true Σ_1 and Σ_2 to compute the transformed variables used for screening as discussed in Fan et al. (2015b). To seek an appropriate screening size, we preserve the top $10, 30$ or 50 variables for each experiment to form interaction terms and report the best result (smallest misclassification error) for *IIS-SQDA*.

4.1 Synthetic data

For synthetic data, we use the same setup in Fan et al. (2015b). Observations are simulated from $N(u_1,\Sigma_1)$ and $N(u_2,\Sigma_2)$ where $u_2=0$. Recall $\Omega_1=\Sigma_1^{-1}$ and $\Omega_2=\Sigma_2^{-1}$. We set $u_1=\Sigma_1\beta$ for $\beta=(0.6,0.8,0,\cdots,0)^T$. We consider three different dimensions $p=50,\ 200,$ or 500 with $n_1=n_2=100$. The parameters Ω_1,Ω_2 and β are set as follows.

- Model 1: This model is Model 3 in Fan et al. (2015b) where Ω_1 is a band matrix with $(\Omega_1)_{ii}=1$ and $\Omega_{ij}=0.3$ for $|i-j|=1$. We set $\Omega_2=\Omega_1+\Omega$, where Ω is a symmetric

and sparse matrix with $\Omega_{10,\ 10} = -0.3758, \Omega_{10,\ 30} = 0.0616, \Omega_{10,\ 50} = 0.2037, \Omega_{30,\ 30} = -0.5482, \Omega_{30,\ 50} = 0.0286$, and $\Omega_{50,\ 50} = -0.4614$. The other 3 nonzero entries in the lower triangle of Ω are determined by symmetry.

- Model 2: We set $(\Omega_1)_{ij} = 0.5^{|i-j|}$ and let $\Omega_2 = \Omega_1 + \Omega$, where $\Omega = I_p$.
- Model 3: Ω_1 is the same as Model 2 and $\Omega_2 = \Omega_1$.
- Model 4: Ω_1 is the same as Model 2 and Ω is a band matrix defined as $(\Omega)_{ii} = 1$ and $(\Omega)_{ij} = 0.5$ for $|i-j| = 1$. Let $\Omega_2 = \Omega_1 + \Omega$.
- Model 5: $\Omega_1 = I_p$ and $\Omega_2 = \Omega_1 + \Omega$ where Ω is a random sparse symmetric matrix with conditional number 10 and non-zero density $n_1/p^2 \times 0.7$ (generated by *sprandsym* in Matlab).
- Models 6 and 7: These are Cases 9 and 10 in Srivastava et al. (2007). For Models 6 and 7, we generate the covariance by the following process: We first sample an $p \times p$ matrix R_1 where each entry is an i.i.d uniform random variable between $[0, 1]$. Then Ω_1 is defined to be $\Omega_1 = (R_1^T R_1)^{-1}$ which is a dense matrix. Matrix Ω_2 is generated similarly. For Model 6 the means are set as $u_1 = u_2 = 0$ while for Model 7, u_1 and u_2 are generated by random sampling over uniform distributions.
- Models 8 and 9: These are Cases 10 and 11 in Srivastava et al. (2007) where we generate the same $p \times p$ matrix R_1 as in Model 6. Then Ω_1 is defined to be $\Omega_1 = (R_1^T R_1 R_1^T R_1)^{-1}$ representing the ellipsoidal covariances, which often have only one strong eigenvalue and many relatively smaller ones. Matrix Ω_2 is similarly generated. The means are set as $u_1 = u_2 = 0$ for Model 8 and generated by random sampling for Model 9.

Model 1 is a model where Ω is a sparse two-block matrix after permutation. This is a model that favors IIS-SQDA. In Model 2, the difference between Ω_1 and Ω_2 is a diagonal matrix, and IIS-SQDA is expected to underperform as its screening step for identifying variables that are involved in interaction would retain all the variables. Model 3 is obviously a model that favors the linear discriminant analysis (LDA) as $\Omega = 0$, and in particular favors the sparse LDA (DSDA). This model is simulated to test whether methods designed for sparse QDA work satisfactorily in situations where LDA works the best. In Model 4, the difference matrix Ω is a tridiagonal matrix where the screening step of IIS-SQDA is expected to underperform. Finally, in Model 5, Ω admits a random sparse structure having $0.7n_1 = 70$ nonzero entries regardless of the dimension p. In Model 6 - 9, the covariance matrices are dense and so are Ω and δ. These cases are to test DA-QDA in scenarios where the sparse assumption fails to hold and the features are highly correlated. Model 6 and 8 are two difficult cases for linear methods as the means of the two classes are also the same. Our implementation of IIS-SQDA is applied only to Models 2 - 9 while the results for Model 1 are directly cited from Fan et al. (2015b).

For models 1 - 5, we simulate 100 synthetic datasets for each model and record for each method under comparison: 1) The misclassification rate (MR), 2) The false positives for main effects and interactions (FP.main for δ and FP.inter for Ω), 3) The false negatives for main effects and interactions (FN.main for δ and FN.inter for Ω). The results are

summarized in Tables 1, 2, 3, 4 and 5 for the five models under consideration. For the dense models, we compare the misclassification rates over 100 replications, and the results are summarized in Table 6.

From these tables, we can observe the following phenomena.

1. For Model 1 where the setup favors IIS-SQDA, IIS-SQDA performs the best in terms of variable selection. DA-QDA performs similarly in terms of the misclassification rate. These two methods outperform LDA and QDA (when $p = 50$), and PLR, PLR2, DSDA by a large margin in classification error.
2. For Model 2, as expected, IIS-SQDA is outperformed by DA-QDA by a large margin. Interestingly, PLR2 performs the second best. Linear classifiers including PLR and DSDA perform quite badly.
3. For Model 3, DSDA, IIS-SQDA and DA-QDA perform best and similarly. It is interesting that DA-QDA performs on par with DSDA even when the model clearly favors sparse linear classifiers.
4. For Model 4, DA-QDA outperforms all other methods again by a large margin.
5. For Model 5, DA-QDA performs the best and by a large margin when p becomes large.
6. For Models 6 - 9, the ordinary QDA performs the best for all low dimensional cases, which is as expected as the covariances of the the two classes are sufficiently different. When the dimension goes higher, DA-QDA achieves a high precision for some really difficult cases which is pretty surprising, considering the matrices are now all dense. The advantage mostly comes from that DA-QDA only imposes the sparse assumption on Ω and δ instead of the original precision matrices as for sQDA. In addition, DA-QDA performs better than IIS-SQDA.

To summarize, DA-QDA achieves the smallest misclassification rate in most examples and competitive performance in selecting main and interaction effects. IIS-SQDA is the preferred approach if Ω is a two-block diagonal matrix after permutation as is the case for Model 1. PLR2 generally performs better than (sparse) linear classifiers when interactions exist.

4.2 Real data

In this section, we investigate the performance of DA-QDA by analyzing four real data sets and compare it to the other classifiers discussed in the simulation study and we also include L1-regularized SVM (L-SVM) and kernel SVM (K-SVM, with Gaussian kernel) for more comprehensive comparison.

Quora answer classifier. This is a data challenge available at `http://www.quora.com/challenges#answer_classifier`. The training data set contains 4,500 answers from QUORA which have been annotated with either "good" or "bad". For each answer, 21 features (20 of which are effective) were extracted from the original sentences. The goal of this challenge is to automatically classify a new answer based on the 20 features. Since the dimension $p = 20$ is relatively small, we can compare DA-QDA to all the methods discussed

in the simulation via 10-fold cross-validation. In particular, we randomly split the data into ten parts, fit a model to the nine parts of the data, and report the misclassification error on the part that is left out. The average misclassification errors and the standard errors for various methods are in Table 7. Interestingly, LDA performs much better than QDA, suggesting that if we stop the analysis here, we might simply have preferred to use the linear classifier LDA. However, the story becomes different if sparse models are considered. In particular, PLR, PLR2, IIS-SQDA and DA-QDA all outperform the non-sparse models significantly with DA-QDA performing the best.

Table 7: Misclassification rate (%) for the Quora answer data under 10-fold cross-validation

Gastrointestinal Lesions This dataset (P. Mesejo et al., 2016) contains the features extracted from a database of colonoscopic videos showing three types of gastrointestinal lesions, hyperplasic, adenoma and serrated adenoma. The original task is a multi-class classification problem, which is simplified to a binary classification task aiming at identifying adenoma. The data set contains 152 samples (76 original samples each with two different light conditions) and 768 features. We select the top 200 features with the largest absolute values of the two sample t statistics and perform a 10-fold corss-validation. The average misclassification errors and the standard errors are reported in Table 8. The data is predominated by the main effects as the logistic regression achieves the best with DA-QDA as the runner-up.

Pancreatic cancer RNA-seq data The dataset (Weinstein et al., 2013) is part of the RNA-Seq (HiSeq) PANCAN data set and is a random extraction of gene expressions of patients having different types of tumor: BRCA, KIRC, COAD, LUAD and PRAD. The dataset contains 801 patients and 20531 genes. In this task, we aim to distinguish BRCA against the other cancers. Similar to the previous study, we select 500 genes with the largest absolute values of the two sample t statistics for further analysis. Since most methods achieve 0 misclassification error in 10-fold cross-validation test, to increase the difficulty, we randomly split the dataset in two equal subsets, train on one subset and test on the other. We repeat this procedure 50 times to obtain the following Table 9. The L1 regularized SVM achieves the smallest misclassification error among all the methods. Similar as the previous dataset, the difference between cancers is dominated by main factors as the LDA

Table 8: Misclassification rate (%) for gastrointestinal lesions under 10-fold cross-validation

Method	mean	standard error
DA-QDA	33.33	0.00

IIS-SQDA	40.00	1.02
L-SVM	44.00	1.85
k-SVM	46.67	0.00

has already achieved a surprisingly low misclassification rate (0.22%). The dataset also shows that DA-QDA can also perform well when the difference between the covariance matrices is small.

Prostate cancer Taken from `ftp://stat.ethz.ch/Manuscripts/dettling/prostate.rda`, this data contains genetic expression levels for $N = 6033$ genes of 102 individuals. The first 50 are normal control subjects while the rest are prostate cancer patients. More details of the data can be found in Singh et al. (2002), Dettling (2004) and Efron (2010). The goal is to identify genes that are linked with prostate cancer and predict potential patients and the difficulty of this task lies in the interactions among genes. The existence of interactions can often complicate the analysis and produce unreliable inference if they are ignored. For example, Figure 1 displays the pair of 118^{th} and 182^{th} gene. We can see the marginal distributions of each gene does not differ too much between the patients and the normal subjects (the middle and the right panels), suggesting that their main effects may not be important for distinguishing the two classes. In the left panel of Figure 1, however, we can identify some joint pattern that distinguishes the two groups. It can be seen that

most patients are allocated in the red triangle while most normal subjects are within the blue triangle, indicating the existence of some interaction effect that might be useful for classification.

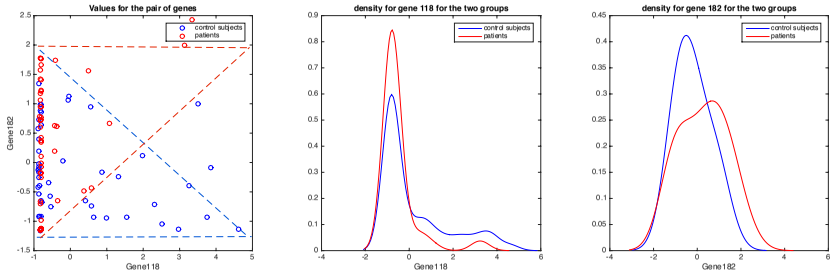

Figure 1: The plot for the gene 118 and gene 182. Left: joint scatter plot; Middle: marginal density of gene 118; Right: marginal density of gene 182.

For this data, we follow the same method in Cai and Liu (2011), retaining only the top 200 or 500 genes with the largest absolute values of the two sample t statistics. The average misclassification errors and the standard errors using 10-fold cross-validation for various methods are reported in Table 10. Note that since $p \gg n$, LDA and QDA were excluded. We can see again that DA-QDA is on par with L1 regularized SVM and outperforms all the other methods by a large margin, regardless of the number of the genes that were used for analysis.

Table 10: Misclassification rate (%) for the prostate cancer data under 10-fold cross-validation

5. Conclusion

We have proposed a novel method named DA-QDA for high-dimensional quadratic discriminant analysis. This is the first method aiming at directly estimating the quantities in the QDA discriminant function. The proposed framework is simple, fast to implement and enjoys excellent theoretical properties. We have demonstrated via extensive simulation and four data analyses that DA-QDA performs competitively under various circumstances.

We conclude by identifying three directions for future research. First, though the discussion of the paper is focused on binary problems, we can extend DS-QDA to handle multi-class problems as follows. When there are $k \geq 2$ classes, we can apply the DA-QDA approach to classes 1 and j, where $j = 2, \ldots, k$, in a pairwise manner. For a new sample z, denote the DA-QDA classifier between class 1 and class j as $\hat{D}_j(z)$ and suppose $D_i(z)$ is the smallest among $\{D_j(z), j = 2, \ldots, k\}$. By Bayes' rule, we can then classifier z into class i if $D_i(z) > 0$ and class 1 otherwise. Second, it is also interesting to see whether our theoretical results are optimal and in what sense. Finally, the proposed framework is extremely flexible. As a concrete example, if Ω is a two block sparse matrix after permutation as in Fan et al. (2015b), we can change the penalty $\|\Omega\|_1$ in (2) to one that encourages row sparsity, for example to $\|\Omega\|_{1,2} = \sum_{j=1}^{p} \|\Omega_{i,:}\|_2$ which is the sum of the ℓ_2 norms of the rows. It will be interesting to see how well this procedure compares with IIS-SQDA in Fan et al. (2015b). This topic is beyond the scope of the current paper and will be pursued elsewhere.

Appendix A. Appendix A. Technical Lemmas and Proofs

A.1 Linear convergence of the ADMM algorithm

The following lemma establishes the linear convergence of our proposed ADMM algorithm in solving (3).

Lemma 1 *Given $\hat{\Sigma}_1, \hat{\Sigma}_2$ and λ, suppose that the ADMM scheme in (4)-(6) generates a solution sequence $\{\Omega^r, \Psi^r, \Lambda^r\}$. We have that $\{\Omega^r, \Psi^r\}$ converges linearly to an optimal solution of (3), and that $\|\Omega^r - \Psi^r\|_F$ converges linearly to zero.*

Proof Note that equation (3) is a special case of (1.1) of Hong and Luo (2017) with two blocks: $f(\Omega, \Psi) = f_1(\Omega) + f_2(\Psi)$ where, $f_1(\Omega) = \frac{1}{2} Tr\left(\Omega^T \hat{\Sigma}_1 \Omega \hat{\Sigma}_2\right) - Tr\left(\Omega(\hat{\Sigma}_1 - \hat{\Sigma}_2)\right)$ and $f_2(\Psi) = \lambda\|\Psi\|_1$. Note that $Tr\left(\Omega^T \hat{\Sigma}_1 \Omega \hat{\Sigma}_2\right) = vec(\Omega)^T(\hat{\Sigma}_2 \otimes \hat{\Sigma}_1)vec(\Omega)$. Let $\hat{\Sigma}_2 \otimes \hat{\Sigma}_1 = U^T \Lambda U$ be the eigenvalue decomposition of the symmetric matrix $\hat{\Sigma}_2 \otimes \hat{\Sigma}_1$, and denote $A_1 := U^T \Lambda^{1/2} U$. Let $g_1(x) = x^T x$ be a function defined on $R^{p^2} \mapsto R$, and $h_1(x) = tr(x(\hat{\Sigma}_1 - \hat{\Sigma}_2))$, $h_2 = \lambda|x|_1$ be functions defined on $R^{p^2} \mapsto R$. We then have $f_1(\Omega) = g_1(A_1 vec(\Omega)) + h_1(vec(\Omega))$ and $f_2(\Psi) = h_2(vec(\Psi))$. Clearly given $\hat{\Sigma}_1, \hat{\Sigma}_2$ and λ, the gradient

of g_1 is uniformly Lipschitz continuous and h_1, h_2 are both polyhedral. The lemma follows immediately from Theorem 3.1 of Hong and Luo (2017). ■

A.2 Proofs of Theorem 1

We first introduce some technical lemmas and the proof of Theorem 1 will be given after these lemmas.

Lemma 2 *Suppose $\lambda_{\max}(\Sigma_k) < \epsilon_0 < \infty$ for $k = 1, 2$. There exist constants $C_0, C_1, C_2 > 0$ depending on ϵ_0 only, such that for any $|v| \leq C_0$,*

$$P(|\hat{\sigma}_{kij} - \sigma_{kij}| > v) \leq C_1 \exp(-C_2(n_k - 1)v^2) \leq C_1 \exp(-C_2 n v^2).$$

Proof Denote $X = (X_1, \ldots, X_{n_1})^T$. Let Λ be an orthogonal matrix with the last row being $(n^{-1/2}, \ldots, n^{-1/2})$ and define $Z = (z_1, \ldots, z_n) = \Lambda X$. We then have $z_1, \ldots, z_{n-1} \sim N(\mathbf{0}, \Sigma)$ and they are independent to each other. Note that $n_1 \hat{\Sigma}_1 = X^T(I_p - \mathbf{1}\mathbf{1}^T)X = Z^T \Lambda(I_p - \mathbf{1}\mathbf{1}^T)\Lambda^T Z = \sum_{i=1}^{n-1} z_i z_i^T$. This together with Lemma A.3 of Bickel and Levina (2008) prove Lemma 2. ■

Remark. Denote $\sigma^2 = \max\{\sigma_{1ii}, \sigma_{2ii}, i = 1, \ldots, p\}$. From Lemma 1 of Ravikumar et al. (2011) we can see that Lemma 2 is true for $C_1 = 4$, $C_2 = [128(1 + 4\sigma^2)^2\sigma^4]^{-1}$ and $v = 8(1 + 4\sigma^2)\sigma^2$.

Lemma 3 *Assume that,*

$$B_{\Gamma, \Gamma^T} < \frac{1}{3(d^2\epsilon_1\epsilon_2 + Bd^2(\epsilon_1 + \epsilon_2))}. \tag{9}$$

Let $R(\Delta_\Gamma) = (\Gamma_{S,S} + \Delta_\Gamma)^{-1} - \Gamma_{S,S}^{-1} + \Gamma_{S,S}^{-1}(\Delta_\Gamma)_{S,S}\Gamma_{S,S}^{-1}$. We then have

$$||R(\Delta_\Gamma)||_\infty \leq 3||(\Delta_\Gamma)_{S,S}||_\infty ||(\Delta_{\Gamma^T})_{S,S}||_{1,\infty} B_\Gamma B_{\Gamma^T}^2, \tag{10}$$

and

$$||R(\Delta_\Gamma)||_{1,\infty} \leq 3||(\Delta_\Gamma)_{S,S}||_{1,\infty} ||(\Delta_{\Gamma^T})_{S,S}||_{1,\infty} B_\Gamma B_{\Gamma^T}^2. \tag{11}$$

Moreover, we also have

$$||\hat{\Gamma}_{S,S}^{-1} - \Gamma_{S,S}^{-1}||_\infty \leq 3d^2(\epsilon^2 + 2B\epsilon)^2 B_\Gamma B_{\Gamma^T}^2 + (\epsilon^2 + 2B\epsilon)B_\Gamma^2, \tag{12}$$

$$||\hat{\Gamma}_{S,S}^{-1} - \Gamma_{S,S}^{-1}||_{1,\infty} \leq 3d^4(\epsilon^2 + 2B\epsilon)^2 B_\Gamma B_{\Gamma^T}^2 + d^2(\epsilon^2 + 2B\epsilon)B_\Gamma^2. \tag{13}$$

Proof Note that

$$\Delta_\Gamma = \Delta_2 \otimes \Delta_1 + \Delta_2 \otimes \Sigma_1 + \Sigma_2 \otimes \Delta_1.$$

Consequently by (9) we have $||\Gamma_{S,S}^{-1}||_{1,\infty}||(\Delta_\Gamma)_{S,S}||_{1,\infty} \leq 1/3$. (10) and (11) can then be proved using the same arguments as in Appendix B of Ravikumar et al. (2011). Note that

$$||(\Delta_\Gamma)_{S,S}||_\infty \leq \epsilon^2 + 2B\epsilon,$$

and

$$\max\{||(\Delta_\Gamma)_{S,S}||_{1,\infty}, ||(\Delta_{\Gamma^T})_{S,S}||_{1,\infty}\} \leq d^2(\epsilon^2 + 2B\epsilon),$$

we have

$$\begin{aligned} ||\hat{\Gamma}_{S,S}^{-1} - \Gamma_{S,S}^{-1}||_\infty &\leq ||R(\Delta_\Gamma)||_\infty + ||\Gamma_{S,S}^{-1}(\Delta_\Gamma)_{S,S}\Gamma_{S,S}^{-1}||_\infty \\ &\leq 3d^2(\epsilon^2+2B\epsilon)^2 B_\Gamma B_{\Gamma^T}^2 + ||(\Delta_\Gamma)_{S,S}||_\infty ||\Gamma_{S,S}^{-1}||_{1,\infty}^2 \\ &\leq 3d^2(\epsilon^2+2B\epsilon)^2 B_\Gamma B_{\Gamma^T}^2 + (\epsilon^2+2B\epsilon)B_\Gamma^2. \end{aligned}$$

This proves (12). (13) can be proved similarly. ■

Lemma 4 *Assume that (9) and the following assumptions hold:* $\alpha > 0$, $\epsilon < \min\left\{B, \frac{\alpha\lambda}{2(2-\alpha)}\right\}$ *and*

$$\begin{aligned} &3d^2\epsilon B B_{\Gamma,\Gamma^T}[1 + (B_\Sigma^2 + 3d^2\epsilon B B_{\Gamma,\Gamma^T})(9d^2\epsilon B B_{\Gamma,\Gamma^T}+1)B_{\Gamma,\Gamma^T}] \\ &\leq C_\alpha \alpha \min\{\lambda, 1\} \end{aligned} \tag{14}$$

where $C_\alpha = \frac{\alpha\lambda+2\epsilon\alpha-4\epsilon}{2B\alpha\lambda+\alpha\lambda+2\epsilon\alpha}$. *We have:*

(i) $vec(\hat{\Omega})_S = 0$.

(ii) $||\hat{\Omega} - \Omega||_\infty < 2\lambda B_{\Gamma,\Gamma^T} + 9d^2\epsilon B B_{\Gamma,\Gamma^T}^2(3d^2\epsilon B B_{\Gamma,\Gamma^T}+1)(2B+2\lambda)$.

Proof (i) Suppose $\tilde{\Omega}$ is the solution of:

$$\tilde{\Omega} = \min_{\Omega \in R^{p\times p}, \Omega_{S^c}=0} \frac{1}{2}Tr\left(\Omega^T\hat{\Sigma}_1\Omega\hat{\Sigma}_2\right) - Tr\left(\Omega(\hat{\Sigma}_1 - \hat{\Sigma}_2)\right) + \lambda\|\Omega\|_1. \tag{15}$$

We prove Lemma 4 (i) by showing that $\hat{\Omega} = \tilde{\Omega}$. Due to the convexity of (3) in the main paper, we only need to show that the derivative of (3) is zero at $\tilde{\Omega}$. Equivalently, we need to show that for any $1 \leq i, j \leq p$ we have,

$$|\hat{\Sigma}_1\tilde{\Omega}\hat{\Sigma}_2 - (\hat{\Sigma}_1 - \hat{\Sigma}_2)|_{i,j} \leq \lambda. \tag{16}$$

By taking the first derivative of (15) we obtain,

$$\{\hat{\Sigma}_1\tilde{\Omega}\hat{\Sigma}_2 - (\hat{\Sigma}_1 - \hat{\Sigma}_2) + \lambda Z\}_S = \mathbf{0}, \tag{17}$$

where $Z = (Z_{ij})_{1\leq i,j\leq p}$ with $Z_{ij} = 0$ for $(i,j) \in S^c$, $Z_{ij} = \text{sign}(\tilde{\Omega}_{ij})$ for $(i,j) \in S$ and $\tilde{\Omega}_{ij} \neq 0$, $Z_{ij} \in [-1,1]$ for $(i,j) \in S$ and $\tilde{\Omega}_{ij} = 0$. Therefore (16) is true for any $(i,j) \in S$. Using the vector operator, (17) becomes

$$\{(\hat{\Sigma}_2 \otimes \hat{\Sigma}_1)vec(\tilde{\Omega}) - vec(\hat{\Sigma}_1 - \hat{\Sigma}_2) + \lambda vec(Z)\}_S = \mathbf{0}.$$

Equivalently we have

$$vec(\tilde{\Omega})_S = \hat{\Gamma}_{S,S}^{-1}[vec(\hat{\Sigma}_1 - \hat{\Sigma}_2)_S - \lambda vec(Z)_S]. \tag{18}$$

Note that the left hand side of (16) equals $|\hat{\Sigma}_1\tilde{\Omega}\hat{\Sigma}_2 - \Sigma_1 + \Sigma_2 - (\Delta_1 - \Delta_2)|_{i,j}$. Using the vector operator and the fact that $\tilde{\Omega}_{S^c} = \mathbf{0}$, to show that (16) is true for any $e \in S^c$, we only need to show that

$$|\hat{\Gamma}_{e,S}vec(\tilde{\Omega})_S - \Gamma_{e,S}vec(\Omega)_S - vec(\Delta_1 - \Delta_2)_e| \leq \lambda. \tag{19}$$

Here we have use the fact that $\Gamma_{e,S}vec(\Omega)_S = vec(\Sigma_1 - \Sigma_2)_e$. By (18) and the fact that $vec(\Omega)_S = \Gamma_{S,S}^{-1}vec(\Sigma_1 - \Sigma_2)_S$ we have,

$$\begin{aligned} &|\hat{\Gamma}_{e,S}vec(\tilde{\Omega})_S - \Gamma_{e,S}vec(\Omega)_S - vec(\Delta_1 - \Delta_2)_e| \\ = \;& |\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1}[vec(\hat{\Sigma}_1 - \hat{\Sigma}_2)_S - \lambda vec(Z)_S] \\ & -\Gamma_{e,S}\Gamma_{S,S}^{-1}vec(\Sigma_1 - \Sigma_2)_S - vec(\Delta_1 - \Delta_2)_e| \\ \leq \;& |[\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1} - \Gamma_{e,S}\Gamma_{S,S}^{-1}]vec(\Sigma_1 - \Sigma_2)_S| \\ & +|\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1}vec(\hat{\Sigma}_1 - \hat{\Sigma}_2 - \Sigma_1 + \Sigma_2)_S| + \|\Delta_1 - \Delta_2\|_\infty + \lambda|\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1}|_1 \\ \leq \;& 2B|\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1} - \Gamma_{e,S}\Gamma_{S,S}^{-1}|_1 + (\epsilon_1+\epsilon_2+\lambda)|\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1}|_1 + \epsilon_1 + \epsilon_2. \end{aligned}$$

Consequently, (19) is true if

$$\begin{aligned} &\max_{e\in S^c} 2B|\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1} - \Gamma_{e,S}\Gamma_{S,S}^{-1}|_1 + 2\epsilon(1 + |\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1}|_1) \leq (1-C_\alpha)\alpha\lambda, \\ &\max_{e\in S^c}|\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1}|_1 \leq 1 - (1-C_\alpha)\alpha. \end{aligned} \tag{20}$$

Next we finish this proof by showing that (20) is true under the assumptions of this lemma.

By Lemma 3 we have for any $e \in S^c$,

$$\begin{aligned} &|\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1} - \Gamma_{e,S}\Gamma_{S,S}^{-1}|_1 \\ \leq \;& |(\hat{\Gamma}_{e,S} - \Gamma_{e,S})\Gamma_{S,S}^{-1}|_1 + |\Gamma_{e,S}(\hat{\Gamma}_{S,S}^{-1} - \Gamma_{S,S}^{-1})|_1 \\ & +|(\hat{\Gamma}_{e,S} - \Gamma_{e,S})(\hat{\Gamma}_{S,S}^{-1} - \Gamma_{S,S}^{-1})|_1 \\ \leq \;& |\hat{\Gamma}_{e,S} - \Gamma_{e,S}|_1||\Gamma_{S,S}^{-1}||_{1,\infty} + ||\hat{\Gamma}_{S,S}^{-1} - \Gamma_{S,S}^{-1}||_{1,\infty}B_\Sigma^2 \\ & +|\hat{\Gamma}_{e,S} - \Gamma_{e,S}|_1||\hat{\Gamma}_{S,S}^{-1} - \Gamma_{S,S}^{-1}||_{1,\infty} \\ \leq \;& d^2(\epsilon^2+2B\epsilon)B_{\Gamma,\Gamma^T} + d^2[B_\Sigma^2 + d^2(\epsilon^2+2B\epsilon)] \\ & \times[3d^2(\epsilon^2+2B\epsilon)B_{\Gamma,\Gamma^T}+1](\epsilon^2+2B\epsilon)B_{\Gamma,\Gamma^T}^2 \\ \leq \;& 3d^2\epsilon B B_{\Gamma,\Gamma^T}[1 + (B_\Sigma^2 + 3d^2\epsilon B B_{\Gamma,\Gamma^T})(9d^2\epsilon B B_{\Gamma,\Gamma^T}+1)B_{\Gamma,\Gamma^T}] \\ \leq \;& C_\alpha\alpha\min\{\lambda,1\}. \end{aligned}$$

Consequently, $\max_{e\in S^c}|\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1}|_1 \leq C_\alpha\alpha\min\{\lambda,1\} + (1-\alpha) \leq 1 - (1-C_\alpha)\alpha$, and

$$\begin{aligned} &\max_{e\in S^c} 2B|\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1} - \Gamma_{e,S}\Gamma_{S,S}^{-1}|_1 + 2\epsilon(1 + |\hat{\Gamma}_{e,S}\hat{\Gamma}_{S,S}^{-1}|_1) \\ \leq \;& 2BC_\alpha\alpha\lambda + 2\epsilon[2 - (1-C_\alpha)\alpha] \\ = \;& (1-C_\alpha)\alpha\lambda. \end{aligned}$$

(ii) From (i) we have $\hat{\Omega} = \tilde{\Omega}$. By (18) and the fact that $vec(\Omega)_S = \Gamma^{-1}_{S,S} vec(\Sigma_1 - \Sigma_2)_S$, we have

$$\begin{aligned} ||\hat{\Omega} - \Omega||_\infty &= |vec(\tilde{\Omega}) - vec(\Omega)|_\infty \\ &= |\hat{\Gamma}^{-1}_{S,S}[vec(\hat{\Sigma}_1 - \hat{\Sigma}_2)_S - \lambda vec(Z)_S] - \Gamma^{-1}_{S,S} vec(\Sigma_1 - \Sigma_2)_S|_\infty \\ &\leq \lambda||\hat{\Gamma}^{-1}_{S,S}||_{1,\infty} + |\hat{\Gamma}^{-1}_{S,S} vec(\Delta_1 - \Delta_2)_S|_\infty \\ &\quad + |(\hat{\Gamma}^{-1}_{S,S} - \Gamma^{-1}_{S,S}) vec(\Sigma_1 - \Sigma_2)|_\infty \\ &\leq (\lambda + 2\epsilon)||\hat{\Gamma}^{-1}_{S,S}||_{1,\infty} + 2B||\hat{\Gamma}^{-1}_{S,S} - \Gamma^{-1}_{S,S}||_{1,\infty} \\ &\leq (\lambda + 2\epsilon)||\Gamma^{-1}_{S,S}||_{1,\infty} + (2B + \lambda + 2\epsilon)||\hat{\Gamma}^{-1}_{S,S} - \Gamma^{-1}_{S,S}||_{1,\infty}. \end{aligned}$$

By (13) and the assumption that $2\epsilon < \alpha\lambda/(2-\alpha) < \alpha\lambda < \lambda$ we immediately have

$$\begin{aligned} & ||\hat{\Omega} - \Omega||_\infty \\ \leq\ & (\lambda + 2\epsilon)B_\Gamma + 3[d^4(\epsilon^2 + 2B\epsilon)^2 B_\Gamma B^2_{\Gamma^T} + d^2(\epsilon^2 + 2B\epsilon)B^2_\Gamma](2B + \lambda + 2\epsilon) \\ <\ & 2\lambda B_{\Gamma,\Gamma^T} + 9d^2\epsilon B B^2_{\Gamma,\Gamma^T}(3d^2\epsilon B B_{\Gamma,\Gamma^T} + 1)(2B + 2\lambda). \end{aligned}$$

■

Proof of Theorem 1

From Lemma 2 we have that with probability greater than $1 - p^{2-c}$, $\epsilon \leq \{(c\log p + \log C_1)/C_2 n\}^{1/2}$. With some abuse of notations, we denote $\epsilon = \{(c\log p + \log C_1)/C_2 n\}^{1/2}$. Choose

$$\lambda = \max\left\{8\alpha^{-1}, \frac{3(2-\alpha)(2B+1)}{1-\alpha} d^2 B B_{\Gamma,\Gamma^T}[1 + 2(B^2_\Sigma + 1/3)B_{\Gamma,\Gamma^T}]\right\} \times \sqrt{\frac{c\log p + \log C_1}{C_2 n}},$$

for some $c > 2$ and since $d^2 B^2 B^2_\Sigma B^2_{\Gamma,\Gamma^T}\sqrt{\frac{\log p}{n}} \to 0$ we can assume that the sample size n is large enough such that

$$\begin{aligned} n\ >\ & (c\log p + \log C_1) \times \max\{(C_2 \min(B^2, 1))^{-1}, 81 B^2 d^4 B^2_{\Gamma,\Gamma^T} C_2^{-1}, \\ & 9(C_2\alpha)^{-1} B^2 B^2_{\Gamma,\Gamma^T}[1 + 2(B^2_\Sigma + 1/3)B_{\Gamma,\Gamma^T}]^2\}. \end{aligned}$$

Clearly under the assumptions of Theorem 1 we have $\lambda = O\left(d^2 B^2 B^2_\Sigma B^2_{\Gamma,\Gamma^T}\sqrt{\frac{\log p}{n}}\right)$. We firstly verify that the assumptions in Lemmas 3 and 4 are true for the given λ, n and ϵ.

(i) By noticing that $\frac{8\epsilon}{\alpha} < \lambda$, $\frac{\alpha}{8} < \frac{\alpha}{4(2-\alpha)}$ and $n > (C_2 B^2)^{-1}(c\log p + \log C_1)$ we immediately have

$$\epsilon < \min\left\{B, \frac{\alpha\lambda}{4(2-\alpha)}\right\} < \min\left\{B, \frac{\alpha\lambda}{2(2-\alpha)}\right\}.$$

(ii) $n > 81 B^2 d^4 B^2_{\Gamma,\Gamma^T}(c\log p + \log C_1)/C_2$ implies $B_{\Gamma,\Gamma^T} < \frac{1}{9d^2 B\epsilon}$. Together with $\epsilon < B$ from (i) we can see that Assumption (9) holds.

(iii) Since $\epsilon < \frac{\alpha\lambda}{2(2-\alpha)}$, we have

$$C_\alpha > \frac{\alpha\lambda - 4\epsilon}{2B\alpha\lambda + \alpha\lambda} > \frac{\alpha\lambda - 2\alpha\lambda/(2-\alpha)}{2B\alpha\lambda + \alpha\lambda} = \frac{1-\alpha}{(2-\alpha)(2B+1)}.$$

Together with $B_{\Gamma,\Gamma^T} < \frac{1}{9d^2 B\epsilon}$, we have

$$\begin{aligned} & 3d^2\epsilon B B_{\Gamma,\Gamma^T}[1 + (B^2_\Sigma + 3d^2\epsilon B B_{\Gamma,\Gamma^T})(9d^2\epsilon B B_{\Gamma,\Gamma^T} + 1)B_{\Gamma,\Gamma^T}] \\ <\ & 3d^2\epsilon B B_{\Gamma,\Gamma^T}[1 + 2(B^2_\Sigma + 1/3)B_{\Gamma,\Gamma^T}] \\ \leq\ & \frac{1-\alpha}{(2-\alpha)(2B+1)}\lambda \\ <\ & C_\alpha\lambda. \end{aligned}$$

(14) is then true since $n > 9(C_2\alpha)^{-1} B^2 B^2_{\Gamma,\Gamma^T}[1 + 2(B^2_\Sigma + 1/3)B_{\Gamma,\Gamma^T}]^2(c\log p + \log C_1)$ implies

$$3\epsilon B B_{\Gamma,\Gamma^T}[1 + (B^2_\Sigma + 3d^2\epsilon B B_{\Gamma,\Gamma^T})(9d^2\epsilon B B_{\Gamma,\Gamma^T} + 1)B_{\Gamma,\Gamma^T}] \leq \alpha.$$

(i), (ii) and (iii) and Lemma 4 imply that

$$\begin{aligned} ||\hat{\Omega} - \Omega||_\infty &< 2\lambda B_{\Gamma,\Gamma^T} + 9d^2\epsilon B B^2_{\Gamma,\Gamma^T}(3d^2\epsilon B B_{\Gamma,\Gamma^T} + 1)(2B + 2\lambda) \\ &\leq 2\lambda B_{\Gamma,\Gamma^T} + 12 d^2\epsilon B B^2_{\Gamma,\Gamma^T}(2B + 2\lambda) \\ &= \frac{14}{3}\lambda B_{\Gamma,\Gamma^T} + 24 d^2\epsilon B^2 B^2_{\Gamma,\Gamma^T}. \end{aligned}$$

A.3 Proofs of Theorem 2

We first introduce some technical lemmas and the proof of Theorem 2 will be given after these lemmas.

Lemma 5 *Assume that $A_\Sigma d_\delta \epsilon < 1$ we have*

$$||\hat{\Sigma}^{-1}_{D,D} - \Sigma^{-1}_{D,D}||_{1,\infty} \leq \frac{A^2_\Sigma d_\delta \epsilon}{1 - A_\Sigma d_\delta \epsilon}.$$

Proof This lemma can be easily proved using the following observation:

$$\begin{aligned} ||\hat{\Sigma}^{-1}_{D,D} - \Sigma^{-1}_{D,D}||_{1,\infty} &\leq ||\hat{\Sigma}^{-1}_{D,D}||_{1,\infty}||\hat{\Sigma}_{D,D} - \Sigma_{D,D}||_{1,\infty}||\Sigma^{-1}_{D,D}||_{1,\infty} \\ &\leq (A_\Sigma + ||\hat{\Sigma}^{-1}_{D,D} - \Sigma^{-1}_{D,D}||_{1,\infty}) d_\delta \epsilon A_\Sigma. \end{aligned}$$

■

Lemma 6

$$|\hat{\gamma} - \gamma|_\infty \leq 8\epsilon_\mu + 2(\epsilon + B_\Sigma \epsilon_\Omega A_2 + d\epsilon\epsilon_\Omega A_2)|\Omega(\mu_1 - \mu_2)|_1 + 2(B + \epsilon)(A_1 + d\epsilon_\Omega)\epsilon_\mu.$$

Proof

$$\begin{aligned}|\gamma-\hat{\gamma}|_\infty &\le 4|\hat{\Delta}_\mu-\Delta_\mu|_\infty+|(\Delta_1-\Delta_2)\Omega\Delta_\mu|_\infty+|(\hat{\Sigma}_1-\hat{\Sigma}_2)(\hat{\Omega}-\Omega)\Delta_\mu|_\infty\\ &\quad+|(\hat{\Sigma}_1-\hat{\Sigma}_2)\hat{\Omega}(\hat{\Delta}_\mu-\Delta_\mu)|_\infty.\end{aligned}$$

Lemma 6 can then be proved using the following facts:

$$|\hat{\Delta}_\mu-\Delta_\mu|_\infty\le 2\epsilon_\mu$$

$$|\mu_1-\mu_2|_1\le||(\Omega^{-1})_{\cdot,D}||_{1,\infty}|\Omega(\mu_1-\mu_2)|_1=A_2|\Omega(\mu_1-\mu_2)|_1;$$

$$|(\Delta_1-\Delta_2)\Omega\Delta_\mu|_\infty\le 2\epsilon|\Omega(\mu_1-\mu_2)|_1;$$

$$\begin{aligned}|(\hat{\Sigma}_1-\hat{\Sigma}_2)(\hat{\Omega}-\Omega)\Delta_\mu|_\infty &\le ||(\Sigma_1-\Sigma_2)(\hat{\Omega}-\Omega)||_\infty|\Delta_\mu|_1+||(\Delta_1-\Delta_2)(\hat{\Omega}-\Omega)||_\infty|\Delta_\mu|_1\\ &\le 2B_\Sigma\epsilon_\Omega|\mu_1-\mu_2|_1+2d\epsilon\epsilon_\Omega|\mu_1-\mu_2|_1;\end{aligned}$$

$$\begin{aligned}|(\hat{\Sigma}_1-\hat{\Sigma}_2)\hat{\Omega}(\hat{\Delta}_\mu-\Delta_\mu)|_\infty &\le 2(B+\epsilon)|\hat{\Omega}(\hat{\Delta}_\mu-\Delta_\mu)|_1\\ &\le 2(B+\epsilon)[||\Omega||_{1,\infty}|\hat{\Delta}_\mu-\Delta_\mu|_\infty+d\epsilon_\Omega|\hat{\Delta}_\mu-\Delta_\mu|_\infty]\\ &\le 2(B+\epsilon)(A_1+d\epsilon_\Omega)\epsilon_\mu.\end{aligned}$$

■

Proof of Theorem 2 Using similar arguments as in Lemma 2, there exists a constant $C_\epsilon>0$ such that $\max\{\epsilon,\epsilon_\mu\}\le C_\epsilon\{(c\log p+\log C_1)/C_{2\delta}n\}^{1/2}$. Similar to the proof of Theorem 1, we choose

$$\begin{aligned}\lambda_\delta &= \max\Big\{\frac{2(2-\alpha_\delta)C_\epsilon}{\alpha_\delta}[4+(2+B_\Sigma A_2)|\Omega(\mu_1-\mu_2)|_1+2B(A_1+C_3)],\\ &\quad\frac{d_\delta(5A_\Sigma+2B_\Sigma A_\Sigma^2)}{C_\delta\alpha_\delta}\times(C_3+1)\Big\}\sqrt{\frac{c\log p+\log C_1}{C_{2\delta}n}},\end{aligned}$$

where $C_3=\frac{14}{3}\max\Big\{\frac{8}{\alpha},\frac{3(2-\alpha)(2B+1)}{1-\alpha}d^2BB_{\Gamma,\Gamma^T}[1+2(B_\Sigma^2+\frac{1}{3})B_{\Gamma,\Gamma^T}]\Big\}B_{\Gamma,\Gamma^T}+24d^2B^2B_{\Gamma,\Gamma^T}^2$, and assume that n is large enough such that

$$\begin{aligned}n &> (c\log p+\log C_1)\times\max\{C_{2\delta}^{-1},2C_2^{-1}A_\Sigma^2d_\delta^2,C_2^{-1}(A_2+1)^2d^2,\\ &\quad C_2^{-1}C_\delta^{-2}\alpha_\delta^{-2}d_\delta^2(5A_\Sigma+2B_\Sigma A_\Sigma^2)^2\},\end{aligned}$$

where $0<C_\delta=\frac{\alpha_\delta\lambda_\delta-(2-\alpha_\delta)K\gamma}{\alpha_\delta\lambda_\delta(1+A_\gamma+K_\gamma)}<1$ and $C_{2\delta}=\min\{C_2,(2\sigma^2)^{-1}\}\times\min\{B^2,1\}$.

(i) Suppose $\tilde{\delta}$ is the solution of:

$$\tilde{\delta}=\min_{\delta\in R^p,\delta_{D^c}=0}\frac{1}{2}\delta^T(\hat{\Sigma}_1+\hat{\Sigma}_2)\delta-\hat{\gamma}^T\delta+\lambda_\delta\|\delta\|_1,$$

We first show that $\hat{\delta}=\tilde{\delta}$. It sufficies to show that for any $e\in D^c$,

$$|2\hat{\Sigma}_{e,D}\tilde{\delta}_D-\hat{\gamma}_e|\le\lambda_\delta.$$

By the definition of $\tilde{\delta}$ we have

$$\{2\hat{\Sigma}\tilde{\delta}-\hat{\gamma}+\lambda_\delta Z\}_D=\mathbf{0},$$

where $Z=(Z_1,\ldots,Z_p)^T$ with $Z_i=0$ for $i\in D^c$, $Z_i=\text{sign}(\tilde{\delta})$ for $i\in D$ and $\tilde{\delta}\neq 0$, $Z_i\in[-1,1]$ for $i\in D$ and $\tilde{\delta}=0$. Consequently, we have $\tilde{\delta}_D=\frac{1}{2}\hat{\Sigma}_{D,D}^{-1}(\hat{\gamma}_D-\lambda_\delta Z_D)$. Together with the fact that $\Sigma_{e,D}\Sigma_{D,D}^{-1}\gamma_D=2\Sigma_{e,D}\Sigma_{D,D}^{-1}\Sigma_{D,D}\delta_D=\gamma_e$, we have

$$\begin{aligned}|2\hat{\Sigma}_{e,D}\tilde{\delta}_D-\hat{\gamma}_e| &= |\hat{\Sigma}_{e,D}\hat{\Sigma}_{D,D}^{-1}(\hat{\gamma}_D-\lambda_\delta Z_D)-\hat{\gamma}_e|\\ &\le |(\hat{\Sigma}_{e,D}\hat{\Sigma}_{D,D}^{-1}-\Sigma_{e,D}\Sigma_{D,D}^{-1})\gamma_D|+|\hat{\Sigma}_{e,D}\hat{\Sigma}_{D,D}^{-1}(\hat{\gamma}_D-\gamma_D)|\\ &\quad+\lambda_\delta|\hat{\Sigma}_{e,D}\hat{\Sigma}_{D,D}^{-1}|_1+|\gamma_e-\hat{\gamma}_e|\\ &\le |(\hat{\Sigma}_{e,D}\hat{\Sigma}_{D,D}^{-1}-\Sigma_{e,D}\Sigma_{D,D}^{-1})|_1|\gamma_D|_\infty+\\ &\quad|\hat{\Sigma}_{e,D}\hat{\Sigma}_{D,D}^{-1}|_1|(\hat{\gamma}_D-\gamma_D)|_\infty+\lambda_\delta|\hat{\Sigma}_{e,D}\hat{\Sigma}_{D,D}^{-1}|_1+|\gamma_e-\hat{\gamma}_e|.\end{aligned}\tag{21}$$

For simplicity, in the following, inequalities will be derived without mentioning whether they hold "with probability greater than $1-p^{2-c}$". For example, since $n>2C_2^{-1}A_\Sigma^2d_\delta^2(c\log p+\log C_1)$, we have $A_\Sigma d_\delta\epsilon<1/2$ with probability greater than $1-p^{2-c}$ and we shall repeatedly use this inequality without mentioning it holds with probability greater than $1-p^{2-c}$. Since $n>C_{2\delta}^{-1}(c\log p+\log C_1)$, by (17) of Ravikumar et al. (2011) and Theorem 1, we also have $\epsilon_\Omega\le(C_3+1)\{(c\log p+\log C_1)/C_{2\delta}n\}^{1/2}:=\epsilon_0$.

From Lemma 5 we have,

$$\begin{aligned}&|\hat{\Sigma}_{e,D}\hat{\Sigma}_{D,D}^{-1}-\Sigma_{e,D}\Sigma_{D,D}^{-1}|_1\\ \le\ &|(\hat{\Sigma}_{e,D}-\Sigma_{e,D})\Sigma_{D,D}^{-1}|_1+|\Sigma_{e,D}(\hat{\Sigma}_{D,D}^{-1}-\Sigma_{D,D}^{-1})|_1+|(\hat{\Sigma}_{e,D}-\Sigma_{e,D})(\hat{\Sigma}_{D,D}^{-1}-\Sigma_{D,D}^{-1})|_1\\ \le\ &|\hat{\Sigma}_{e,D}-\Sigma_{e,D}|_1|\Sigma_{D,D}^{-1}|_{1,\infty}+|\Sigma_{e,D}|_1||\hat{\Sigma}_{D,D}^{-1}-\Sigma_{D,D}^{-1}||_{1,\infty}\\ &+|\hat{\Sigma}_{e,D}-\Sigma_{e,D}|_1||\hat{\Sigma}_{D,D}^{-1}-\Sigma_{D,D}^{-1})||_{1,\infty}\\ \le\ &d_\delta\epsilon A_\Sigma+d_\delta(B+\epsilon)||\hat{\Sigma}_{D,D}^{-1}-\Sigma_{D,D}^{-1}||_{1,\infty}\\ \le\ &d_\delta\epsilon A_\Sigma+\frac{d_\delta(B_\Sigma+d_\delta\epsilon)A_\Sigma^2\epsilon}{1-A_\Sigma d_\delta\epsilon}.\end{aligned}\tag{22}$$

Combining (21), (22) and Lemma 6 we have:

$$\begin{aligned}&|2\hat{\Sigma}_{e,D}\tilde{\delta}_D-\hat{\gamma}_e|\\ \le\ &\left\{\epsilon A_\Sigma+\frac{(B+d_\delta\epsilon)A_\Sigma^2\epsilon}{1-A_\Sigma d_\delta\epsilon}\right\}A_\gamma d_\delta+\left(2-\alpha_\delta+d_\delta\epsilon A_\Sigma+\frac{d_\delta(B_\Sigma+d_\delta\epsilon)A_\Sigma^2\epsilon}{1-A_\Sigma d_\delta\epsilon}\right)K_\gamma\\ &+\lambda_\delta\left(1-\alpha_\delta+d_\delta\epsilon A_\Sigma+\frac{d_\delta(B_\Sigma+d_\delta\epsilon)A_\Sigma^2\epsilon}{1-A_\Sigma d_\delta\epsilon}\right),\end{aligned}$$

where

$$K_\gamma=2\epsilon_\mu[4+(2+B_\Sigma A_2)|\Omega(\mu_1-\mu_2)|_1+2B(A_1+C_3)],$$

and we have used the fact that $\epsilon < B$, $d_\delta \epsilon A_2 < 1, d\epsilon < 1$ and hence $8\epsilon_\mu + 2(\epsilon + B_\Sigma \epsilon_\Omega A_2 + d\epsilon\epsilon_\Omega A_2)|\Omega(\mu_1 - \mu_2)|_1 + 2(B+\epsilon)(A_1 + d\epsilon_\Omega)\epsilon_\mu < K_\gamma$. Assume that

$$d_\delta \epsilon A_\Sigma + \frac{d_\delta(B_\Sigma + d_\delta\epsilon)A_\Sigma^2 \epsilon}{1 - A_\Sigma d_\delta \epsilon} \leq C_\delta \alpha_\delta \min\{\lambda_\delta, 1\}, \tag{23}$$

where $C_\delta = \frac{\alpha_\delta \lambda_\delta - (2-\alpha_\delta)K\gamma}{\alpha_\delta \lambda_\delta (1 + A_\gamma + K_\gamma)}$. It can be seen that $0 < C_\delta < 1$. We then have

$$\begin{aligned} |2\hat{\Sigma}_{e,D}\tilde{\delta}_D - \hat{\gamma}_e| &\leq \lambda_\delta A_\gamma C_\delta \alpha_\delta + (2-\alpha_\delta)K_\gamma + C_\delta \alpha_\delta \lambda_\delta K_\gamma + (1 - \alpha_\delta + C_\delta\alpha_\delta)\lambda_\delta \\ &= \lambda_\delta. \end{aligned}$$

Next we complete the Proof of this part by showing that (23) holds.

Since $n > C_2^{-1} C_\delta^{-2} \alpha_\delta^{-2} d_\delta^2 (5A_\Sigma + 2B_\Sigma A_\Sigma^2)^2 (c \log p + \log C_1)$, we have

$$d_\delta \epsilon A_\Sigma + \frac{d_\delta(B_\Sigma + d_\delta\epsilon)A_\Sigma^2 \epsilon}{1 - A_\Sigma d_\delta \epsilon} \leq d_\delta \epsilon A_\Sigma + 4 d_\delta A_\Sigma \epsilon + 2 B_\Sigma A_\Sigma^2 d_\delta \epsilon \leq C_\delta \alpha_\delta.$$

On the other hand, since $\lambda_\delta \geq \frac{d_\delta(5A_\Sigma + 2B_\Sigma A_\Sigma^2)}{C_\delta \alpha_\delta}\epsilon_0$, we have

$$d_\delta \epsilon A_\Sigma + \frac{d_\delta(B_\Sigma + \epsilon d_\delta)A_\Sigma^2 \epsilon}{1 - A_\Sigma d_\delta \epsilon} \leq \lambda_\delta C_\delta \alpha_\delta.$$

(ii) Use the fact that $A_\Sigma d_\delta \epsilon < 1/2$ we have:

$$\begin{aligned} |\hat{\delta}_D - \delta_D|_\infty &= \frac{1}{2}|\hat{\Sigma}_{D,D}^{-1}(\hat{\gamma}_D - \lambda_\delta Z_D) - \Sigma_{D,D}^{-1}\gamma_D| \\ &\leq |(\hat{\Sigma}_{D,D}^{-1} - \Sigma_{D,D}^{-1})\hat{\gamma}_D|_\infty + |\Sigma_{D,D}^{-1}(\hat{\gamma}_D - \gamma_D)|_\infty + \lambda_\delta |\hat{\Sigma}_{D,D}^{-1}|_{1,\infty} \\ &\leq \frac{A_\Sigma^2 d_\delta \epsilon}{1 - A_\Sigma d_\delta \epsilon}(A_\gamma + |\hat{\gamma}_D - \gamma_D|_\infty) + A_\Sigma |\hat{\gamma}_D - \gamma_D|_\infty \\ &\quad + \lambda_\delta \left(A_\Sigma + \frac{A_\Sigma^2 d_\delta \epsilon}{1 - A_\Sigma d_\delta \epsilon} \right) \\ &\leq \frac{A_\gamma A_\Sigma^2 d_\delta \epsilon}{1 - A_\Sigma d_\delta \epsilon} + K_\gamma \left[\frac{A_\Sigma^2 d_\delta \epsilon}{1 - A_\Sigma d_\delta \epsilon} + A_\Sigma \right] \\ &\quad + \lambda_\delta \left(A_\Sigma + \frac{A_\Sigma^2 d_\delta \epsilon}{1 - A_\Sigma d_\delta \epsilon} \right) \\ &\leq 2A_\gamma A_\Sigma^2 d_\delta \epsilon + 2K_\gamma A_\Sigma + 2\lambda_\delta A_\Sigma. \end{aligned}$$

This theorem is proved by plugging in $K_\gamma = 2\epsilon_\mu[4 + (2 + B_\Sigma A_2)|\Omega(\mu_1 - \mu_2)|_1 + 2B(A_1 + C_3)]$.

A.4 Proofs of Theorem 3

Proof (i) With some abuse of notations we write $d(z) = (z-\mu)^T \Omega (z-\mu) + \delta^T (z - \mu)$ and $\hat{d}(z) = (z - \hat{\mu})^T \hat{\Omega}(z - \hat{\mu}) + \hat{\delta}^T (z - \hat{\mu})$.

$$\begin{aligned} R_n(1|2) &= P(\hat{d}(z) + \eta > 0 | z \sim N(\mu_2, \Sigma_2)) \\ &= P(d(z) + \eta > d(z) - \hat{d}(z) | z \sim N(\mu_2, \Sigma_2)). \end{aligned}$$

Denote $z = (z_1, \ldots, z_p)^T$. Note that $z^T(\Omega - \hat{\Omega})z \leq \sum_{ij} |z_i z_j (\Omega - \hat{\Omega})_{ij}|$, by noticing that $E|z_i z_j| \leq (Ez_i^2 + Ez_j^2)/2 \leq C_\mu^2 + C_\Sigma$, we have $z^T(\Omega - \hat{\Omega})z = O_p(s||\Omega - \hat{\Omega}||_\infty)$. Using a similar argument for bounding $|z^T\Omega\mu - z\hat{\Omega}\hat{\mu}|$, $|\mu^T\Omega\mu - \hat{\mu}^T\hat{\Omega}\hat{\mu}|$, $(\delta - \hat{\delta})^T z$ and $\delta^T\mu - \hat{\delta}^T\hat{\mu}$ we obtain,

$$\begin{aligned} &|d(z) - \hat{d}(z)| \\ = \; & O_p\left(s d_0^2 B^2 B_\Sigma^2 B_{\Gamma,\Gamma^T}^2 \sqrt{\frac{\log p}{n}} + d_0^2 A_\Sigma^2 B^2 B_\Sigma^3 B_{\Gamma,\Gamma^T}^2 \sqrt{\frac{\log p}{n}} \right). \end{aligned} \tag{24}$$

From Assumption 1 and (24) and the mean value theorem, we have:

$$\begin{aligned} &R_n(1|2) - R(1|2) \\ = \; & \int_0^{d(z) - \hat{d}(z)} F_2(z) dz \\ = \; & O_p\left(s d_0^2 B^2 B_\Sigma^2 B_{\Gamma,\Gamma^T}^2 \sqrt{\frac{\log p}{n}} + d_0^2 A_\Sigma^2 B^2 B_\Sigma^3 B_{\Gamma,\Gamma^T}^2 \sqrt{\frac{\log p}{n}} \right). \end{aligned}$$

(i) is proved by noticing that the above equality is also true for $R_n(2|1) - R(2|1)$.

(ii) Let $\Phi(\cdot)$ be the cumulative distribution function of a standard normal random variable. We have any constant $C_z > 0$,

$$P(|z|_\infty > C_z \sqrt{\log p}) \leq p\left[1 - \Phi\left(\frac{C\sqrt{\log p} + C_\mu}{C_\Sigma^{1/2}} \right) \right].$$

From Lemma 11 of Liu et al. (2009) we have when p is large enough, by choosing $C_z > \sqrt{2(c-1)} C_\Sigma^{1/2}$,

$$p\left[1 - \Phi\left(\frac{C_z\sqrt{\log p} + C_\mu}{C_\Sigma^{1/2}} \right) \right] \leq p^{2-c}.$$

This together with Theorems 1 and 2 and the proof in (i), we have with probability greater than $1 - 3p^{2-c}$,

$$\begin{aligned} &|d(z) - \hat{d}(z)| \\ = \; & O_p\left(s d_0^2 B^2 B_\Sigma^2 B_{\Gamma,\Gamma^T}^2 \log p \sqrt{\frac{\log p}{n}} + d_0^2 A_\Sigma^2 B^2 B_\Sigma^3 B_{\Gamma,\Gamma^T}^2 \frac{\log p}{\sqrt{n}} \right). \end{aligned}$$

The rest of the proof is similar to that in the proof of (i). ■

A.5 Proof of Proposition 2

Proof Suppose $e_1 > e_2 \geq \eta$. Denote $c_i = |\Sigma_1\Sigma_2^{-1}|^{1/2}\exp\{\frac{1}{2}[e_i - \frac{1}{4}(\mu_1-\mu_2)^T\Omega(\mu_1-\mu_2)]\}$ for $i = 1, 2$. We have,

$$\begin{aligned} R(d, e_i) &= \pi_1 \int_{D(z,e_1)<0} f_1(z)dz + \pi_2 \int_{D(z,e_i)>0} f_2(z)dz \\ &= \int_{f_1(z)/f_2(z)<c_i^{-1}} \pi_1 f_1(z)dz + \int_{f_1(z)/f_2(z)>c_i^{-1}} \pi_2 f_2(z)dz. \end{aligned}$$

Since $e_1 > e_2 \geq \eta$, it can be easily shown that $c_1 > c_2 \geq \pi_1/\pi_2$. Consequently we have

$$R(d, e_1) - R(d, e_2) = -\int_{c_1^{-1}<f_1(z)/f_2(z)<c_2^{-1}} [\pi_1 f_1(z) - \pi_2 f_2(z)]dz > 0.$$

Therefore, $R(d, e)$ is strictly monotone increasing on $e \in [\eta, \infty)$. The second statement can be similarly proved. ■

A.6 Proofs of Theorem 4

We first introduce some technical lemmas and the proof of Theorem 4 will be given after these lemmas.

For any constant c, define $l_c = \min\{\text{ess}\inf_{z\in[-c,c]} F_i(z), i = 1, 2\}$.

Lemma 7 *For any constant $c > 0$, we have for any $-c \leq \epsilon_\eta \leq c$, $R(d, \eta + \epsilon_\eta) - R(d, \eta) \leq \pi_2 u_c|\epsilon_\eta|$ and $R(d, \eta + \epsilon_\eta) - R(d, \eta) \geq \epsilon_\eta^2 \exp(-c/2)\pi_2 l_c/4$.*

Proof Let's consider $0 \leq \epsilon_\eta \leq c$ first. Note that

$$R(d, \eta + \epsilon_\eta) - R(d, \eta) = \int_{-\epsilon_\eta<D(z,\eta)<0} [\pi_2 f_2(z) - \pi_1 f_1(z)]dz.$$

We have

$$R(d, \eta + \epsilon_\eta) - R(d, \eta) \leq \int_{-\epsilon_\eta<D(z,\eta)<0} \pi_2 f_2(z)dz = \pi_2 \int_{-\epsilon_\eta}^{0} F_2(z)dz \leq \pi_2 u_c \epsilon_\eta.$$

By noticing that $1 - \exp(-x/2) - x\exp(-c/2)/2$ is an increasing function in $[0, c]$ we have

$$\begin{aligned} R(d, \eta + \epsilon_\eta) - R(d, \eta) &\geq \int_{-\epsilon_\eta<D(z,\eta)<-\epsilon_\eta/2} [\pi_2 f_2(z) - \pi_1 f_1(z)]dz \\ &\geq \int_{-\epsilon_\eta<D(z,\eta)<-\epsilon_\eta/2} [1 - \exp(-\epsilon_\eta/2)]\pi_2 f_2(z)dz \\ &\geq \int_{-\epsilon_\eta<D(z,\eta)<-\epsilon_\eta/2} \epsilon_\eta \exp(-c/2)\pi_2 f_2(z)/2dz \\ &\geq \epsilon_\eta^2 \exp(-c/2)\pi_2 l_c/4. \end{aligned}$$

The lemma is then proved using a same argument as above for $-c \leq \epsilon_\eta < 0$. ■

Clearly 7 holds when c is set to be c_η. Noted from the proof of Lemma 7 that the bounds do not depend on η, we can claim that the bounds holds uniformly in $\epsilon_\eta \in [-c_\eta, c_\eta]$. Similarly, it can be shown that:

Lemma 8 *Suppose $\hat{d} - d = O_p(\Delta_d)$ with $\Delta_d \to 0$, we have $R(\hat{d}, e) - R(d, e) = O_p(\Delta_d u_c)$ uniformly in $e \in [-c_\eta, c_\eta]$.*

Lemma 9 *Under the assumptions of Theorem 3, $R_n(\hat{d}, e) \to R(d, e)$ in probability uniformly in $e \in [-c_\eta, c_\eta]$.*

Proof Denote all the samples in the two classes as $\{z_i, i = 1, \ldots, n_1 + n_2\}$ and denote the estimator obtained by leaving the ith sample out as $\hat{d}_{-i}$. Similarly we use $\hat{d}_{-(i,j)}$ to denote the estimator obtained by leaving the ith and jth samples out. From (24), we immediately have that for any $e \in [-c_\eta, c_\eta]$,

$$\begin{aligned} & EI\{\hat{d}(z_i) + e > 0\} - EI\{\hat{d}_{-i}(z_i) + e > 0\} \\ = \; & EI\{d(z_i) + e > 0\} - EI\{d(z_i) + e > 0\} + o(1) \\ = \; & o(1). \end{aligned}$$

Together with Lemma 8 we have

$$ER_n(\hat{d}, e) - R(d, e) = ER(\hat{d}_{-i}, e) + o(1) - R(d, e) \to 0, \tag{25}$$

uniformly in $e \in [-c_\eta, c_\eta]$. Note that

$$Var(I\{\hat{d}(z_i) + e > 0\}) \leq \frac{1}{4},$$

and for any $(i, j) \in \{(k, l) : 1 \leq k, l \leq n_1 + n_2, i \neq j\}$,

$$\begin{aligned} & Cov(I\{\hat{d}(z_i) + e > 0\}, I\{\hat{d}(z_j) + e > 0\}) \\ = \; & Cov(I\{\hat{d}_{-(i,j)}(z_i) + e > 0\}, I\{\hat{d}_{-(i,j)}(z_j) + e > 0\}) + o(1) \\ = \; & Cov(I\{d(z_i) + e > 0\}, I\{d(z_j) + e > 0\}) + o(1), \end{aligned}$$

where the last step can be obtained using (24) and Lemma 8 and the $o(1)$ term does not depend on e. Since z_i, z_j are independent, we immediately have

$$Var(R_n(\hat{d}, e)) \to 0, \tag{26}$$

uniformly in $e \in [-c_\eta, c_\eta]$. The lemma is then proved by Markov's inequality and the uniform convergence of the bias (25) and the variance (26) of $R_n(\hat{d}, e)$. ■

Proof of Theorem 4
The result that $\hat{\eta} \to \eta$ can be obtained by Proposition 2, Lemma 9 and Theorem 5.7 of Van der Vaart (2000). The second statement immediately follows from Theorem 3.

Distribution-Specific Hardness of Learning Neural Networks

Ohad Shamir OHAD.SHAMIR@WEIZMANN.AC.IL
Weizmann Institute of Science, Rehovot, Israel

Editor: Amir Globerson

Abstract

Although neural networks are routinely and successfully trained in practice using simple gradient-based methods, most existing theoretical results are negative, showing that learning such networks is difficult, in a worst-case sense over all data distributions. In this paper, we take a more nuanced view, and consider whether specific assumptions on the "niceness" of the input distribution, or "niceness" of the target function (e.g. in terms of smoothness, non-degeneracy, incoherence, random choice of parameters etc.), are sufficient to guarantee learnability using gradient-based methods. We provide evidence that neither class of assumptions alone is sufficient: On the one hand, for any member of a class of "nice" target functions, there are difficult input distributions. On the other hand, we identify a family of simple target functions, which are difficult to learn even if the input distribution is "nice". To prove our results, we develop some tools which may be of independent interest, such as extending Fourier-based hardness techniques developed in the context of statistical queries (Blum et al., 1994), from the Boolean cube to Euclidean space and to more general classes of functions.

Keywords: neural networks, computational hardness, distributional assumptions, gradient-based methods

1. Introduction

Artificial neural networks have seen a dramatic resurgence in recent years, and have proven to be a highly effective machine learning method in computer vision, natural language processing, and other challenging AI problems. Moreover, successfully training such networks is routinely performed using simple and scalable gradient-based methods, in particular stochastic gradient descent.

Despite this success, our theoretical understanding of the computational tractability of such methods is quite limited, with most results being negative. For example, as discussed in Livni et al. (2014), learning even depth-2 networks in a formal PAC learning framework is computationally hard in the worst case, and even if the algorithm is allowed to return arbitrary predictors. As common in such worst-case results, these are proven using rather artificial constructions, quite different than the real-world problems on which neural networks are highly successful. In particular, since the PAC framework focuses on *distribution-free* learning (where the distribution generating the examples is unknown and rather arbitrary), the hardness results rely on carefully crafted distributions, which allows one to relate the learning problem to (say) an NP-hard problem or breaking a cryptographic system. However, what if we insist on "natural" distributions? Is it possible to show that neural networks learning becomes computationally tractable? Can we show that they can be learned using the standard heuristics employed in practice, such as stochastic gradient descent?

To understand what a "natural" distribution refers to, we need to separate the distribution over examples (given as input-output pairs $(\mathbf{x}, y)$) into two components:

- *The input distribution* $p(\mathbf{x})$: "Natural" input distributions on Euclidean space tend to have properties such as smoothness, non-degeneracy, incoherence etc.
- *The target function* $h(\mathbf{x})$: In PAC learning, it is assumed that the output y equals $h(\mathbf{x})$, where h is some unkown target function from the hypothesis class we are considering. In studying neural networks, it is common to consider the class of all networks which share some fixed architecture (e.g. feedforward networks of a given depth and width). However, one may argue that the parameters of real-world networks (e.g. the weights of each neuron) are not arbitrary, but exhibit various features such as non-degeneracy or some "random like" appearance. Indeed, networks with a random structure have been shown to be more amenable to analysis in various situations (see for instance Daniely et al., 2016; Arora et al., 2014; Choromanska et al., 2015, and references therein).

Empirical evidence seems to suggest that many pairs of input distributions and target functions are computationally tractable to learn, using standard methods. However, how do we characterize these pairs? Would appropriate assumptions on one of them be sufficient to show learnability?

In this paper, we investigate these two components, and provide evidence that *neither one* of them alone is generally enough to guarantee computationally tractable learning, at least with methods resembling those used in practice. Specifically, we focus on simple, shallow ReLU networks, assume that the data can be perfectly predicted by some such network, and even allow *over-parametrization* (a.k.a. over-specification or improper learning), in the sense that we allow the learning algorithm to output a predictor which is possibly larger and more complex than the target function (this technique increases the power of the learner, and was shown to make the learning problem easier in theory and in practice, e.g. Livni et al. 2014; Safran and Shamir 2016; Soudry and Carmon 2016). Even under such favorable conditions, we show the following:

- **Hardness for "natural" target functions.** For each individual target function coming from a simple class of small, shallow ReLU networks (even if its parameters are chosen randomly or in some other oblivious way), we show that no algorithm invariant to linear transformations can successfully learn it w.r.t. all input distributions in polynomial time (this corresponds, for instance, to standard gradient-based methods together with data whitening or preconditioning). This result is based on a reduction from learning intersections of halfspaces. Although that problem is known to be hard in the worst-case over both input distributions and target functions, we essentially show that invariant algorithms as above do not "distinguish" between worst-case and average-case: If one can learn a particular target function with such an algorithm, then the algorithm can learn nearly all target functions in that class.
- **Hardness for "natural" input distributions.** We show that target functions of the form $\mathbf{x} \mapsto \psi(\mathbf{w}^\top \mathbf{x})$ for any periodic ψ are generally difficult to learn using

gradient-based methods, even if the input distribution is fixed and belongs to a very broad class of smooth input distributions (including, for instance, Gaussians and mixtures of Gaussians). Note that such functions can essentially be constructed by simple shallow networks, and can be seen as an extension of generalized linear models (see McCullagh and Nelder 1989 for a survey). Unlike the previous result, which relies on a computational hardness assumption, the results here are geometric in nature, and imply that the gradient of the objective function, nearly everywhere, contains virtually no signal on the underlying target function. Therefore, any algorithm which relies on gradient information cannot learn such functions. Interestingly, the difficulty here is *not* in having a plethora of spurious local minima or saddle points—the associated stochastic optimization problem may actually have no such critical points. Instead, the objective function may exhibit properties such as *flatness* nearly everywhere, unless one is already very close to the global optimum. This highlights a potential pitfall in non-convex learning, which occurs already for a slight extension of generalized linear models, and even for "nice" input distributions.

Together, these results indicate that in order to explain the practical success of neural network learning with gradient-based methods, one would need to employ a careful combination of assumptions on both the input distribution and the target function, and that results with even a "partially" distribution-free flavor (which are common, for instance, in convex learning problems) may be difficult to attain here.

To prove our results, we develop some tools which may be of independent interest. In particular, the techniques used to prove hardness of learning functions of the form $\mathbf{x} \mapsto \psi(\mathbf{w}^\top \mathbf{x})$ are based on Fourier analysis, and have some close connections to hardness results on learning Boolean functions such as parities in the well-known framework of learning from statistical queries (Kearns, 1998): In both cases, one essentially shows that the Fourier transform of the target function has very small support, and hence does not "correlate" with most functions, making it difficult to learn using certain methods. However, we consider a more general and arguably more natural class of input distributions over Euclidean space, rather than distributions on the Boolean cube. In a sense, we show that learning general periodic functions over Euclidean space is difficult (at least with gradient-based methods), for the same reasons that learning parities over the Boolean cube is difficult in the statistical queries framework. This connection has recently been formalized and extended in Song et al. (2017) (see discussion below).

1.1 Related Work

Recent years have seen quite a few papers on the theory of neural network learning. Below, we only briefly mention those most relevant to our paper.

In a very elegant work, Janzamin et al. (2015) have shown that a certain method based on tensor decompositions allows one to provably learn simple neural networks by a combination of assumptions on the input distribution and the target function. However, a drawback of their method is that it requires rather precise knowledge of the input distribution and its derivatives, which is rarely available in practice. In contrast, our focus is on algorithms which do not utilize such knowledge. Other works which show computationally-efficient

learnability of certain neural networks under sufficiently strong distributional assumptions include Arora et al. (2014); Livni et al. (2014); Andoni et al. (2014); Zhang et al. (2015).

In the context of learning functions over the Boolean cube, it is known that even if we restrict ourself to a particular input distribution (as long as it satisfies some mild conditions), it is difficult to learn parity functions using statistical query algorithms (Kearns, 1998; Blum et al., 1994), which also include gradient-based methods (Feldman et al., 2015). Since parities can be implemented with small real-valued networks, this implies that for "most" input distributions on the Boolean cube, there are neural networks which are unlikely to be learnable with gradient-based methods. However, data provided to neural networks in practice are not in the form of Boolean vectors, but rather vectors of floating-point numbers. Moreover, some assumptions on the input distribution, such as smoothness and Gaussianity, only make sense once we consider the support to be Euclidean space rather than the Boolean cube. Perhaps these are enough to guarantee computational tractability? A contribution of this paper is to show that this is not the case, and to formally demonstrate how phenomena similar to the Boolean case also occurs in Euclidean space, using appropriate target functions and distributions.

Related to the above, Song et al. (2017) recently showed that statistical query algorithms indeed cannot learn certain neural networks, using target functions similar to those we consider in Sec. 4, and for log-concave input distributions[1]. In contrast, our result for such target functions is specific to gradient-based methods, but applies to a different large family of distributions, not necessarily log-concave. Furthermore, we note that the challenges in fitting ridge functions $\mathbf{x} \mapsto \psi(\mathbf{w}^\top \mathbf{x})$ for certain ψ (when $\mathbf{x}$ is standard Gaussian and one attempts to fit the target function using a function of the same form) was also studied in Donoho and Johnstone (1989).

Finally, we note that Klivans and Kothari (2014) provides improper-learning hardness results, which hold even for a standard Gaussian distribution on Euclidean space, and for any algorithm. However, unlike our paper, their focus is on hardness of agnostic learning (where the target function is arbitrary and does not have to correspond to a given class), the results are specific to the standard Gaussian distribution, and the proofs are based on a reduction from the Boolean case.

The paper is structured as follows: In Sec. 2, we formally present some notation and concepts used throughout the paper. In Sec. 3, we provide our hardness results for natural target functions, and in Sec. 4, we provide our hardness results for natural input distributions. All proofs are presented in Sec. 5.

2. Preliminaries

We generally let bold-faced letters denote vectors. Given a complex-valued number $z = a + ib$, we let $\overline{z} = a - ib$ denote its complex conjugate, and $|z| = \sqrt{a^2 + b^2}$ denote its modulus. Given a function f, we let ∇f denote its gradient and $\nabla^2 f$ denote its Hessian (assuming they exist).

Neural Networks. Our results focus on learning predictors which can be described by simple and shallow (depth 2 or 3) neural networks. A standard feedforward neural network

1. The arXiv technical report on which our paper is based was published in September 2016, whereas their arXiv technical report was published in July 2017.

is composed of neurons, each of which computes the mapping $\mathbf{x} \mapsto \sigma(\mathbf{w}^\top \mathbf{x} + b)$, where $\mathbf{w}, b$ are parameters and σ is a scalar activation function, for example the popular ReLU function $[z]_+ = \max\{0, z\}$. These neurons are arranged in parallel in layers, so the output of each layer can be compactly represented as $\mathbf{x} \mapsto \sigma(W^\top \mathbf{x} + \mathbf{b})$, where W is a matrix (each column corresponding to the parameter vector of one of the neurons), $\mathbf{b}$ is a vector, and σ applies an activation function on the coordinates of $W^\top \mathbf{x}$. In vanilla feedforward networks, such layers are connected to each other, so given an input $\mathbf{x}$, the output equals

$$\sigma_k(W_k^\top \sigma_{k-1}(W_{k-1}^\top \dots \sigma_2(W_2^\top \sigma_1(W_1^\top \mathbf{x} + \mathbf{b}_1) + \mathbf{b}_2) \dots + \mathbf{b}_{k-1}) + \mathbf{b}_k),$$

where W_i, b_i, σ_i are parameter of the i-th layer. The number of layers k is denoted as the depth of the network, and the maximal number of columns in W_i is denoted as the width of the network. For simplicity, in this paper we focus on networks which output a real-valued number, and measure our performance with respect to the squared loss (that is, given an input-output example $(\mathbf{x}, y)$, where $\mathbf{x}$ is a vector and $y \in \mathbb{R}$, the loss of a predictor p on the example is $(p(\mathbf{x}) - y)^2$).

Gradient-Based Methods. Gradient-based methods are a class of optimization algorithms for solving problems of the form $\min_{\mathbf{w} \in \mathcal{W}} F(\mathbf{w})$ (for some given function F and assuming $\mathbf{w}$ is a vector in Euclidean space), based on computing $\nabla F(\mathbf{w})$ of approximations of $\nabla F(\mathbf{w})$ at various points $\mathbf{w}$. Perhaps the simplest such algorithm is gradient descent, which initializes deterministically or randomly at some point $\mathbf{w}_1$, and iteratively performs updates of the form $\mathbf{w}_{t+1} = \mathbf{w}_t - \eta_t \nabla F(\mathbf{w}_t)$, where $\eta_t > 0$ is a step size parameter. In the context of statistical supervised learning problems, we are usually interested in solving problems of the form $\min_{\mathbf{w} \in \mathcal{W}} \mathbb{E}_{\mathbf{x} \sim \mathcal{D}}[\ell(f(\mathbf{w}, \mathbf{x}), h(\mathbf{x}))]$, where $\{\mathbf{x} \mapsto f(\mathbf{w}, \mathbf{x}) : \mathbf{w} \in \mathcal{W}\}$ is some class of predictors, h is a target function, and ℓ is some loss function. Since the distribution $\mathcal{D}$ is generally unknown, one cannot compute the gradient of this function w.r.t. $\mathbf{w}$ directly, but can still compute approximations, e.g. by sampling one $\mathbf{x}$ at random and computing the gradient (or sub-gradient) of $\ell(f(\mathbf{w}, \mathbf{x}), h(\mathbf{x}))$. The same approach can be used to solve empirical approximations of the above, i.e. $\min_{\mathbf{w} \in \mathcal{W}} \frac{1}{m} \sum_{i=1}^m \ell(f(\mathbf{w}, \mathbf{x}_i), h(\mathbf{x}_i))$ for some data set $\{(\mathbf{x}_i, h(\mathbf{x}_i))\}_{i=1}^m$. These are generally known as stochastic gradient methods, and are one of the most popular and scalable machine learning methods in practice.

PAC Learning. For the results of Sec. 3, we will rely on the following standard definition of PAC learning with respect to Boolean functions: Given a hypothesis class $\mathcal{H}$ of functions from $\{0,1\}^d$ to $\{0,1\}$, we say that a learning algorithm PAC-learns $\mathcal{H}$ if for any $\epsilon \in (0,1)$, any distribution $\mathcal{D}$ over $\{0,1\}^d$, and any $h^\star \in \mathcal{H}$, if the algorithm is given oracle access to i.i.d. samples $(\mathbf{x}, h^\star(\mathbf{x}))$ where $\mathbf{x}$ is sampled according to $\mathcal{D}$, then in time $\mathrm{poly}(d, 1/\epsilon)$, the algorithm returns a function $f : \{0,1\}^d \mapsto \{0,1\}$ (which can be evaluated in $\mathrm{poly}(d)$ time) such that $\Pr_{\mathbf{x} \sim \mathcal{D}}(f(\mathbf{x}) \neq h^\star(\mathbf{x})) \leq \epsilon$ with high probability (for our purposes, it will be enough to consider any constant close to 1). Note that in the definition above, we allow f not to belong to the hypothesis class $\mathcal{H}$. This is often denoted as "improper" learning, and allows the learning algorithm more power than in "proper" learning, where f must be a member of $\mathcal{H}$.

3. Natural Target Functions

In this section, we consider simple target functions parameterized by vectors $\mathbf{w}_1, \dots, \mathbf{w}_n$, of the form

$$\mathbf{x} \;\mapsto\; \left[\sum_{i=1}^n [\langle \mathbf{w}_i, \mathbf{x} \rangle]_+\right]_+ - \left[\sum_{i=1}^n [\langle \mathbf{w}_i, \mathbf{x} \rangle]_+ - 1\right]_+ ,$$

where $[z]_+ = \max\{0, z\}$ is the ReLU function, which correspond to standard depth-3 ReLU networks with $2n$ neurons in the first layer and 2 neurons in the second layer. Equivalently, these functions can also be written as

$$\mathbf{x} \mapsto \left[\sum_{i=1}^n [\langle \mathbf{w}_i, \mathbf{x} \rangle]_+\right]_{[0,1]} ,$$

where $[z]_{[0,1]} = \min\{1, \max\{0, z\}\}$ is the clipping operation on the interval $[0,1]$. For the rest of this section, we will use the latter formulation for convenience. Letting $W = [\mathbf{w}_1, \dots, \mathbf{w}_n]$, we can write such predictors as $\mathbf{x} \mapsto h(W^\top \mathbf{x})$ for an appropriate fixed function h. Our goal would be to show that *individually* for any such target function (regardless of how W is chosen, as long as it has full column rank), and any polynomial-time learning algorithm satisfying some conditions, there exists an input distribution on which it must fail.

We begin by noting that some algorithmic assumption is *necessary* to get such a target-function-specific result. Indeed, if we fix the target function in advance, we can always "learn" by the following algorithm: return the target function, regardless of the training data. To avoid such trivial scenarios, we will consider algorithms which exhibit certain natural invariances to the coordinate system used. One very natural invariance is with respect to orthogonal transformations: For example, if we rotate the input instances $\mathbf{x}_i$ in a fixed manner, then an orthogonally-invariant algorithm will return a predictor which still makes the same predictions on those instances. Formally, this invariance is defined as follows:

Definition 1 *Let $\mathcal{A}$ be an algorithm which inputs a data set $(\{\mathbf{x}_i, y_i\})_{i=1}^m$ (where $\mathbf{x}_i \in \mathbb{R}^d$) and outputs a predictor $\mathbf{x} \mapsto f(W^\top \mathbf{x})$ (for some function f and matrix W dependent on the data set). We say that $\mathcal{A}$ is* orthogonally-invariant*, if for any orthogonal matrix $M \in \mathbb{R}^{d \times d}$, if we feed the algorithm with $\{M\mathbf{x}_i, y_i\}_{i=1}^m$, the algorithm returns a predictor $\mathbf{x} \mapsto f(W_M^\top \mathbf{x})$, where f is the same as before and W_M is such that $W_M^\top M \mathbf{x}_i = W^\top \mathbf{x}_i$ for all $\mathbf{x}_i$.*

Remark 2 *The definition as stated refers to deterministic algorithms. For stochastic algorithms, we will understand orthogonal invariance to mean orthogonal invariance conditioned on any realization of the algorithm's random coin flips.*

For example, standard gradient and stochastic gradient descent methods for optimizing W (possibly with coordinate-oblivious regularization, such as L_2 regularization) can be easily shown to be orthogonally-invariant[2]. However, for our results we will need to make

2. Essentially, this is because the gradient of any function $g(W^\top \mathbf{x}) = g(\langle \mathbf{w}_1, \mathbf{x} \rangle, \dots, \langle \mathbf{w}_k, \mathbf{x} \rangle)$ w.r.t. any $\mathbf{w}_i$ is proportional to $\mathbf{x}$. Thus, if we multiply $\mathbf{x}$ by an orthogonal M, the gradient also gets multiplied by M. Since $M^\top M = I$, the inner products of instances $\mathbf{x}$ and gradients remain the same. Therefore, by induction, it can be shown that any algorithm which operates by incrementally updating some iterate by linear combinations of gradients will be rotationally invariant.

a somewhat stronger invariance assumption, namely invariance to general invertible linear transformations of the data (not necessarily just orthogonal). This is formally defined as follows:

Definition 3 *An algorithm $\mathcal{A}$ is* linearly-invariant*, if it satisfies Definition 1 for any invertible matrix $M \in \mathbb{R}^{d\times d}$ (rather than just orthogonal ones).*

One well-known example of such an algorithm (which is also invariant to affine transformations) is the Newton method (Boyd and Vandenberghe, 2004). More relevant to our purposes, linear invariance occurs whenever an orthogonally-invariant algorithm preconditions or "whitens" the data so that its covariance has a fixed structure (e.g. the identity matrix, possibly after a dimensionality reduction if the data is rank-deficient). For example, even though gradient descent methods are not linearly invariant, they become so if we precede them by such a preconditioning step. This is formalized in the following theorem:

Theorem 4 *Let $\mathcal{A}$ be any algorithm which given $\{\mathbf{x}_i, y_i\}_{i=1}^m$, computes the whitening matrix $P = D^{-1}U^\top$ (where $X = [\mathbf{x}_1\ \mathbf{x}_2\ \ldots\ \mathbf{x}_m]$, $X = UDV^\top$ is a thin[3] SVD decomposition of X), feeds $\{P\mathbf{x}_i, y_i\}_{i=1}^m$ to an orthogonally-invariant algorithm, and given the output predictor $\mathbf{x} \mapsto f(W^\top\mathbf{x})$, returns the predictor $\mathbf{x} \mapsto f((P^\top W)^\top\mathbf{x})$. Then $\mathcal{A}$ is linearly-invariant.*

It is easily verified that the covariance matrix of the transformed instances $P\mathbf{x}_1, \ldots, P\mathbf{x}_m$ is the $r \times r$ identity matrix (where $r = \mathrm{Rank}(X)$), so this is indeed a whitening transform. We note that whitening is a very common preprocessing heuristic, and even when not done explicitly, scalable approximate whitening and preconditioning methods are very common and widely recognized as useful for training neural networks (for example, Adagrad and batch normalization, see Duchi et al. 2011 and Ioffe and Szegedy 2015).

To show our result, we rely on a reduction from a PAC-learning problem known to be computationally hard, namely learning intersections of halfspaces. These are Boolean predictors parameterized by $\mathbf{w}_1, \ldots, \mathbf{w}_n \in \mathbb{R}^d$ and $b_1, \ldots, b_n \in \mathbb{R}$, which compute a mapping of the form

$$\mathbf{x} \ \to \ \bigwedge_{i=1}^{n} \left(\langle \mathbf{w}_i, \mathbf{x}\rangle \geq b_i\right)$$

(where we let 1 correspond to 'true' and 0 to 'false'). The problem of PAC-learning intersections of halfspaces over the Boolean cube ($\mathbf{x} \in \{0,1\}^d$) has been well-studied. In particular, two known hardness results are the following:

- Klivans and Sherstov (2009) show that under a certain well-studied cryptographic assumption (hardness of finding unique shortest vectors in a high-dimensional lattice), no algorithm can PAC-learn intersection of $n_d = d^\delta$ halfspaces (where δ is any positive constant), even if the coordinates of $\mathbf{w}_i$ and b_i are all integers, and $\max_i \|(\mathbf{w}_i, b_i)\| \leq \mathrm{poly}(d)$.

3. That is, if X is of size $d \times m$, then U is of size $d \times \mathrm{Rank}(X)$, D is of size $\mathrm{Rank}(X) \times \mathrm{Rank}(X)$, and V is of size $m \times \mathrm{Rank}(X)$.

- Daniely and Shalev-Shwartz (2016) show that under an assumption related to the hardness of refuting random K-SAT formulas, no algorithm can PAC-learn intersections of $n_d = \omega(\log(d))$ halfspaces (as $d \to \infty$), even if the coordinates of $\mathbf{w}_i$ and b_i are all integers, and $\max_i \|(\mathbf{w}_i, b_i)\| = \mathcal{O}(d)$.

In the theorem below, we will use the result of Daniely and Shalev-Shwartz (2016), which applies to an intersection of a smaller number of halfspaces, and with smaller norms. However, similar results can be shown using Klivans and Sherstov (2009), at the cost of worse polynomial dependencies on d.

The main result of this section is the following:

Theorem 5 *Consider any network $h(W_\star^\top\mathbf{x}) = [\sum_{i=1}^{n_d}[\langle \mathbf{w}_i^\star, \mathbf{x}\rangle]_+]_{[0,1]}$ (where the columns of $W_\star$ are $\mathbf{w}_1^\star \ldots \mathbf{w}_n^\star$), which satisfies the following:*

- *$n_d = \omega(\log(d))$ as $d \to \infty$*
- *$\max_i \|\mathbf{w}_i^\star\| = \mathcal{O}(d)$*
- *$\mathbf{w}_1^\star \ldots \mathbf{w}_n^\star$ are linearly independent, so the smallest singular value $s_{\min}(W_\star)$ of $W_\star$ is strictly positive.*

Then under the assumption stated in Daniely and Shalev-Shwartz (2016), there is no linearly-invariant algorithm which for any $\epsilon > 0$ and any distribution $\mathcal{D}$ over vectors of norm $\frac{\mathcal{O}(d\sqrt{dn_d})}{\min\{1, s_{\min}(W_\star)\}}$, given only access to samples $(\mathbf{x}, h(W_\star^\top\mathbf{x}))$ where $\mathbf{x} \sim \mathcal{D}$, runs in time $\mathrm{poly}(d, 1/\epsilon)$ and returns with high probability a predictor $\mathbf{x} \mapsto f(W^\top\mathbf{x})$ such that

$$\mathbb{E}_{\mathbf{x}\sim\mathcal{D}}\left[\left(f(W^\top\mathbf{x}) - h(W_\star^\top\mathbf{x})\right)^2\right] \leq \epsilon.$$

Note that the result holds even if the returned predictor $f(W^\top\mathbf{x})$ has a different structure than $h(W_\star^\top\mathbf{x})$, and W is of a larger size than $W_\star$. Thus, it applies even if the algorithm implements over-parametrization and attempts to train a network larger than $h(W_\star^\top\mathbf{x})$.

The proof (which is provided in Sec. 5) can be sketched as follows: First, the hardness assumption for learning intersection of halfspaces is shown to imply hardness of learning networks $\mathbf{x} \mapsto h(W^\top\mathbf{x})$ as described above (and even if W has linearly independent columns—a restriction which will be important later). However, this only implies that no algorithm can learn $\mathbf{x} \mapsto h(W^\top\mathbf{x})$ for *all* W and all input distributions $\mathcal{D}$. In contrast, we want to show that learning would be difficult even for *some fixed* $W_\star$. To do so, we show that if an algorithm is linearly invariant, then the ability to learn with respect to some W and all distributions $\mathcal{D}$ means that we can learn with respect to all W and all $\mathcal{D}$. Roughly speaking, we argue that for linearly-invariant algorithms, "average-case" and "worst-case" hardness are the same here. Intuitively, this is because given some arbitrary $W, \mathcal{D}$, we can create a different input distribution $\tilde{\mathcal{D}}$, so that $W, \tilde{\mathcal{D}}$ "look like" $W_\star, \mathcal{D}$ under some linear transformation (see Figure 1 for an illustration). Therefore, a linearly-invariant algorithm which succeeds on one will also succeed on the other.

A bit more formally, let us fix some $W_\star$ (with linearly independent columns), and suppose we have a linearly-invariant algorithm which can successfully learn $\mathbf{x} \mapsto h(W_\star^\top\mathbf{x})$ with

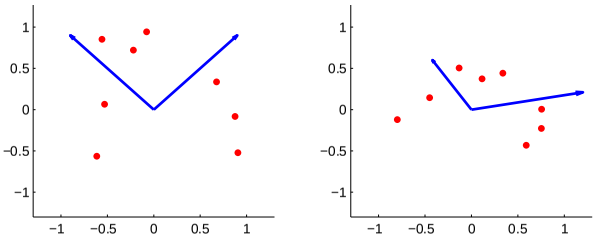

Figure 1: Correspondence between $W_\star, \mathcal{D}$ (left figure) and $W, \tilde{\mathcal{D}}$ (right figure). Arrows correspond to columns of $W_\star$ and W, and dots correspond to the support of $\mathcal{D}$ and $\tilde{\mathcal{D}}$. $\tilde{\mathcal{D}}$ is constructed so that the same linear transformation mapping $W_\star$ to W also maps $\mathcal{D}$ to $\tilde{\mathcal{D}}$.

respect to any input distribution. Let $W, \mathcal{D}$ be some other matrix and distribution with respect to which we wish to learn (where W has full column rank and is of the same size as $W_\star$). Then it can be shown that there is an invertible matrix M such that $W = M^\top W_\star$. Since the algorithm successfully learns $\mathbf{x} \mapsto h(W_\star^\top \mathbf{x})$ with respect to any input distribution, it would also successfully learn if we use the input distribution $\tilde{\mathcal{D}}$ defined by sampling $\mathbf{x} \sim \mathcal{D}$ and returning $M\mathbf{x}$. This means that the algorithm would succesfully learn from data distributed as

$$(\mathbf{x}, h(W_\star^\top \mathbf{x}))\ ,\ \mathbf{x} \sim \tilde{\mathcal{D}} \iff (M\mathbf{x}, h(W_\star^\top (M\mathbf{x})))\ ,\ \mathbf{x} \sim \mathcal{D} \iff (M\mathbf{x}, h(W^\top \mathbf{x}))\ ,\ \mathbf{x} \sim \mathcal{D}.$$

Since the algorithm is linearly-invariant, it can be shown that this implies successful learning from $(\mathbf{x}, h(W^\top \mathbf{x}))$ where $\mathbf{x} \sim \mathcal{D}$, as required.

In the sketch above, we have ignored some technical issues. For example, we need to be careful that M has a bounded spectral norm, so that it induces a linear transformation which does not distort norms by too much (as all our arguments apply for input distributions supported on a bounded domain). A second issue is that if we apply a linearly-invariant algorithm on a data set transformed by M, then the invariance is only with respect to the data, not necessarily with respect to new instances $\mathbf{x}$ sampled from the same distribution (and this restriction is necessary for results such as Thm. 4 to hold without further assumptions). However, it can be shown that if the data set is large enough, invariance will still occur with high probability over the sampling of $\mathbf{x}$, which is sufficient for our purposes.

4. Natural Input Distributions

In this section, we consider the difficulty of gradient-based methods to learn certain target functions, even with respect to smooth, well-behaved distributions over $\mathbb{R}^d$. Specifically, we will consider functions of the form $\mathbf{x} \mapsto \psi(\mathbf{w}^{\star\top}\mathbf{x})$, where $\mathbf{w}^\star$ is a vector of bounded norm and ψ is a periodic function. Note that if ψ is continuous and piecewise linear, then $\psi(\mathbf{w}^{\star\top}\mathbf{x})$ can be implemented by a depth-2 neural ReLU network on any bounded subset

of the domain. More generally, any continuous periodic function can be approximated arbitrarily well by such networks.

Our formal results rely on Fourier analysis and are a bit technical. Hence, we precede them with an informal description, outlining the main ideas and techniques, and presenting a specific case study which may be of independent interest (Subsection 4.1). The formal results are presented in Subsection 4.2.

4.1 Informal Description of Results and Techniques

Consider a target function of the form $\mathbf{x} \mapsto \psi(\mathbf{w}^{\star\top}\mathbf{x})$, and an input distribution with density function $\varphi^2(\cdot)$, where φ is some non-negative function (we consider the density as the square of some function in order to simplify notation later on). Suppose we attempt to learn this target function (with respect to the squared loss) using *some* hypothesis class, which can be parameterized by a bounded-norm vector $\mathbf{v}$ in some subset $\mathcal{V}$ of an Euclidean space (not necessarily of the same dimensionality as $\mathbf{w}^\star$), so each predictor in the class can be written as $\mathbf{x} \mapsto f(\mathbf{v}, \mathbf{x})$ for some fixed mapping f. Thus, our goal is essentially to solve the stochastic optimization problem

$$\min_{\mathbf{v}:\mathbf{v}\in\mathcal{V}} \mathbb{E}_{\mathbf{x}\sim\varphi^2}\left[\left(f(\mathbf{v},\mathbf{x}) - \psi(\mathbf{w}^{\star\top}\mathbf{x})\right)^2\right]. \tag{1}$$

In this section, we study the geometry of this objective function, and show that under mild conditions on f, and assuming the norm of $\mathbf{w}^\star$ is reasonably large, the gradient of the objective function with respect to $\mathbf{w}$ is almost independent of $\mathbf{w}^\star$, in the following sense: If we fix any $\mathbf{w}$ and choose $\mathbf{w}^\star$ uniformly at random, the gradient will be extremely concentrated around a fixed value which is independent of $\mathbf{w}^\star$ (e.g. exponentially small in $\|\mathbf{w}^\star\|^2$ for a Gaussian or a mixture of Gaussians). Therefore, assuming $\|\mathbf{w}^\star\|$ is reasonably large, any standard gradient-based method will follow a trajectory nearly independent of $\mathbf{w}^\star$. In fact, in practice we do not even have access to exact gradients of Eq. (1), but only to noisy and biased versions of it (e.g. if we perform stochastic gradient descent, and certainly if we use finite-precision computations). In that case, the noise will completely obliterate the exponentially small signal about $\mathbf{w}^\star$ in the gradients, and will make the trajectory essentially independent of $\mathbf{w}^\star$. As a result, assuming ψ and the distribution is such that the function $\psi(\mathbf{w}^{\star\top}\mathbf{x})$ is sensitive to the direction of $\mathbf{w}^\star$, it follows that these methods will fail to optimize Eq. (1) successfully. Finally, we note that in practice, it is common to solve not Eq. (1) directly, but rather its empirical approximation with respect to some fixed finite training set. Still, by concentration of measure, this empirical objective would converge to the one in Eq. (1) given enough data, so the same issues will occur.

An important feature of our results is that they make virtually no structural assumptions on the predictors $\mathbf{x} \mapsto f(\mathbf{v}, \mathbf{x})$. In particular, they can represent arbitrary classes of neural networks (as well as other predictor classes). Thus, our results imply that target functions of the form $\mathbf{x} \mapsto \psi(\mathbf{w}^{\star\top}\mathbf{x})$, where ψ is periodic, would be difficult to learn using gradient-based methods, even if we allow improper learning and consider predictor classes of a different structure.

To explain how such results are attained, let us study a concrete special case (not necessarily in the context of neural networks). Consider the target function $\mathbf{x} \mapsto \cos(2\pi\mathbf{w}^{\star\top}\mathbf{x})$,

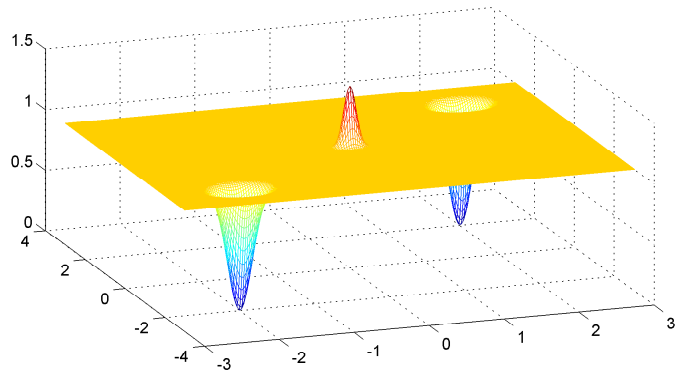

Figure 2: Graphical depiction of the objective function in Eq. (2), in 2 dimensions and where $\mathbf{w}^\star = (2,2)$.

and the hypothesis class (parameterized by $\mathbf{w}$) of functions $\mathbf{x} \mapsto \cos(2\pi \mathbf{w}^\top \mathbf{x})$. Thus, Eq. (1) takes the form

$$\min_{\mathbf{w}} \mathbb{E}_{\mathbf{x}\sim\varphi^2}\left[\left(\cos(2\pi \mathbf{w}^\top \mathbf{x}) - \cos(2\pi \mathbf{w}^{\star\top}\mathbf{x})\right)^2\right]. \tag{2}$$

Furthermore, suppose the input distribution φ^2 is a standard Gaussian on $\mathbb{R}^d$. In two dimensions and for $\mathbf{w}^\star = (2,2)$, the objective function in Eq. (1) turns out to have the form illustrated in Figure 2. This objective function has only three critical points: A global maximum at $\mathbf{0}$, and two global minima at $\mathbf{w}^\star$ and $-\mathbf{w}^\star$. Nevertheless, it would be difficult to optimize using gradient-based methods, since it is extremely *flat* everywhere except close to the critical points. As we will see shortly, the same phenomenon occurs in higher dimensions. In high dimensions, if the direction of $\mathbf{w}^\star$ is chosen randomly, we will be overwhelmingly likely to initialize far from the global minima, and hence will start in a flat plateau in which most gradient-based methods will stall[4].

We now turn to explain why Eq. (2) has the form shown in Figure 2. This will also help to illustrate our proof techniques, which apply much more generally. The main idea is to analyze the Fourier transform of Eq. (2). Letting $\cos_{\mathbf{w}}$ denote the function $\mathbf{x} \mapsto \cos(2\pi \mathbf{w}^\top \mathbf{x})$, we can write Eq. (2) as

$$\int \left(\cos(2\pi \mathbf{w}^\top \mathbf{x}) - \cos(2\pi \mathbf{w}^{\star\top}\mathbf{x})\right)^2 \varphi^2(\mathbf{x})d\mathbf{x} \;=\; \left\|\cos_{\mathbf{w}}\cdot\varphi - \cos_{\mathbf{w}^\star}\cdot\varphi\right\|^2,$$

where $\|\cdot\|$ is the standard norm over the space $L^2(\mathbb{R}^d)$ of square integrable functions. By standard properties of the Fourier transform (as described in Sec. 2), this squared norm

4. Although there are techniques to overcome flatness (e.g. by normalizing the gradient, see Nesterov 1984; Hazan et al. 2015), in our case the normalization factor will be huge and require extremely precise gradient information, which as discussed earlier, is unrealistic here.

of a function equals the squared norm of the function's Fourier transform, which equals in turn

$$\left\|\widehat{\cos_{\mathbf{w}}\cdot\varphi} - \widehat{\cos_{\mathbf{w}}\cdot\varphi}\right\|^2 \;=\; \left\|\widehat{\cos_{\mathbf{w}}} * \hat{\varphi} - \widehat{\cos_{\mathbf{w}^\star}} * \hat{\varphi}\right\|^2.$$

$\widehat{\cos_{\mathbf{w}}}(\boldsymbol{\xi})$ can be shown to equal $\frac{1}{2}\left(\delta(\boldsymbol{\xi}-\mathbf{w}) + \delta(\boldsymbol{\xi}+\mathbf{w})\right)$, where $\delta(\cdot)$ is Dirac's delta function (a "generalized" function which satisfies $\delta(\mathbf{z}) = 0$ for all $\mathbf{z} \neq \mathbf{0}$, and $\int \delta(\mathbf{z})d\mathbf{z} = 1$). Plugging this into the above and simplifying, we get

$$\begin{aligned}&\frac{1}{4}\left\|\hat{\varphi}(\cdot-\mathbf{w}) + \hat{\varphi}(\cdot+\mathbf{w}) - \hat{\varphi}(\cdot-\mathbf{w}^\star) - \hat{\varphi}(\cdot+\mathbf{w}^\star)\right\|^2 \\ &= \frac{1}{4}\int_{\boldsymbol{\xi}} \left|\hat{\varphi}(\boldsymbol{\xi}-\mathbf{w}) + \hat{\varphi}(\boldsymbol{\xi}+\mathbf{w}) - \hat{\varphi}(\boldsymbol{\xi}-\mathbf{w}^\star) - \hat{\varphi}(\boldsymbol{\xi}+\mathbf{w}^\star)\right|^2 d\boldsymbol{\xi}, \end{aligned} \tag{3}$$

where $\hat{\varphi}(\cdot - \mathbf{w})$ stands for the function $\mathbf{x} \mapsto \hat{\varphi}(\mathbf{x}-\mathbf{w})$, etc. If φ^2 is a standard Gaussian, $\hat{\varphi}(\boldsymbol{\xi})$ can be shown to equal the Gaussian-like function $(4\pi)^{d/2}a^{-\|\boldsymbol{\xi}\|^2}$ where $a = \exp(4\pi^2)$. Plugging back, the expression above is proportional to

$$\int_{\boldsymbol{\xi}} \left(\left(a^{-\|\boldsymbol{\xi}-\mathbf{w}\|^2} + a^{-\|\boldsymbol{\xi}+\mathbf{w}\|^2}\right) - \left(a^{-\|\boldsymbol{\xi}-\mathbf{w}^\star\|^2} + a^{-\|\boldsymbol{\xi}+\mathbf{w}^\star\|^2}\right)\right)^2 d\boldsymbol{\xi}. \tag{4}$$

The expression in each inner parenthesis can be viewed as a mixture of two Gaussian-like functions, with centers at $\mathbf{w}, -\mathbf{w}$ (or $\mathbf{w}^\star, -\mathbf{w}^\star$). Thus, if $\mathbf{w}$ is far from $\mathbf{w}^\star$, these two mixtures will have nearly disjoint support, and Eq. (4) will have nearly the same value regardless of $\mathbf{w}$—in other words, it is very flat. Since this equation is nothing more than a re-formulation of the original objective function in Eq. (2) (up to a constant), we get a similar behavior for Eq. (2) as well.

This behavior extends, however, much more generally than the specific objective in Eq. (2). First of all, we can replace the standard Gaussian distribution φ^2 by any distribution such that $\hat{\varphi}$ has a localized support. This would still imply that Eq. (3) refers to the difference of two functions with nearly disjoint support, and the same flatness phenomenon will occur. Second, we can replace the cos function by any periodic function ψ. By properties of the Fourier transform of periodic functions, we still get localized functions in the Fourier domain (more precisely, the Fourier transform will be localized around integer multiples of $\mathbf{w}$, up to scaling). Finally, instead of considering hypothesis classes of predictors $\mathbf{x} \mapsto \psi(\mathbf{w}^\top \mathbf{x})$ similar to the target function, we can consider quite arbitrary mappings $\mathbf{x} \mapsto f(\mathbf{w}, \mathbf{x})$. Even though this function may no longer be localized in the Fourier domain, it is enough that only the target function $\mathbf{x} \mapsto \psi(\mathbf{w}^{\star\top}\mathbf{x})$ will be localized: That implies that regardless how f looks like, under a random choice of $\mathbf{w}^\star$, only a minuscule portion of the L_2 mass of f overlaps with the target function, hence getting sufficient signal on $\mathbf{w}^\star$ will be difficult.

As mentioned in the introduction, these techniques and observations are closely related to hardness results in the statistical queries literature, and can indeed be applied to that framework as shown recently in Song et al. (2017).

4.2 Formal Results

We now turn to provide a more formal statement of our results. The distributions we will consider consist of arbitrary mixtures of densities, whose square roots have Fourier transforms with rapidly decaying tails. More precisely, we have the following definition:

Definition 6 *Let $\epsilon(r)$ be some function from $[0,\infty)$ to $[0,1]$. A function $\varphi^2 : \mathbb{R}^d \to \mathbb{R}$ is* $\epsilon(r)$ Fourier-concentrated *if its square root φ belongs to $L^2(\mathbb{R}^d)$, and satisfies*

$$\|\hat{\varphi} \cdot \mathbf{1}_{\geq r}\| \;\leq\; \|\hat{\varphi}\|\,\epsilon(r),$$

where $\mathbf{1}_{\geq r}$ is the indicator function of $\{\mathbf{x} : \|\mathbf{x}\| \geq r\}$.

A canonical example is Gaussian distributions: Given a (non-degenerate, zero-mean) Gaussian density function φ^2 with covariance matrix Σ, its square root φ is proportional to a Gaussian with covariance 2Σ, and its Fourier transform $\hat{\varphi}$ is well-known to be proportional to a Gaussian with covariance $(2\Sigma)^{-1}$. By standard Gaussian concentration results, it follows that φ^2 is Fourier-concentrated with $\epsilon(r) = \exp(-\Omega(\lambda_{\min} r^2))$ where $\lambda_{\min}$ is the minimal eigenvalue of Σ. A similar bound can be shown when the Gaussian has some arbitrary mean. More generally, it is well-known that smooth functions (differentiable to sufficiently high order with integrable derivatives) have Fourier transforms with rapidly decaying tails. For example, if we consider the broad class of *Schwartz* functions (characterized by having values and all derivatives decaying faster than polynomially in r), then the Fourier transform of any such function is also a Schwartz function, which implies super-polynomial decay of $\epsilon(r)$ (see for instance Hunter and Nachtergaele 2001, Chapter 11 and Proposition 11.25).

We now formally state our main result for this section. We consider *any* predictor of the form $\mathbf{x} \mapsto f(\mathbf{v}, \mathbf{x})$, where f is some fixed function and $\mathbf{v}$ is a parameter vector coming from some domain $\mathcal{V}$, which we will assume w.l.o.g. to be a subset of some Euclidean space[5] (for example, f can represent a network of a given architecture, with weights specified by $\mathbf{v}$). When learning f based on data coming from an underlying distribution, we are essentially attempting to solve the optimization problem

$$\min_{\mathbf{v}\in\mathcal{V}} F_{\mathbf{w}^\star}(\mathbf{v}) := \mathbb{E}_{\mathbf{x}\sim\varphi^2}\left[\left(f(\mathbf{v},\mathbf{x}) - \psi(\mathbf{w}^{\star\top}\mathbf{x})\right)^2\right].$$

Assuming that F is differentiable w.r.t. $\mathbf{w}$, any gradient-based method to solve this problem proceeds by computing (or approximating) $\nabla F_{\mathbf{w}^\star}(\mathbf{v})$ at various points $\mathbf{v}$. However, the following theorem shows that at *any* $\mathbf{v}$, and *regardless* of the type of predictor or network one is attempting to train, the gradient at $\mathbf{v}$ is virtually independent of the underlying target function, and hence provides very little signal:

Theorem 7 *Suppose that*

- *$\psi : \mathbb{R} \to [-1,+1]$ is a periodic function of period 1, which has bounded variation on every finite interval.*
- *φ^2 is a density function on $\mathbb{R}^d$, which can be written as a (possibly infinite) mixture $\varphi^2 = \sum_i \alpha_i \varphi_i^2$, where each φ_i^2 is $\epsilon(r)$ Fourier-concentrated.*
- *At some fixed $\mathbf{v}$, $\mathbb{E}_{\mathbf{x}\sim\varphi^2}\left\|\frac{\partial}{\partial \mathbf{v}} f(\mathbf{v},\mathbf{x})\right\|^2 \leq G_{\mathbf{v}}$ for some $G_{\mathbf{v}}$.*

5. More generally, our analysis is applicable to any separable Hilbert space.

Then for some universal positive constants c_1, c_2, c_3, if $d \geq c_1$, and if $\mathbf{w}^\star \in \mathbb{R}^d$ is a vector of norm $2r$ chosen uniformly at random, then

$$Var_{\mathbf{w}^\star}\left(\nabla F_{\mathbf{w}^\star}(\mathbf{v})\right) := \mathbb{E}_{\mathbf{w}^\star}\left\|\nabla F_{\mathbf{w}^\star}(\mathbf{v}) - \mathbb{E}_{\mathbf{w}^\star}[\nabla F_{\mathbf{w}^\star}(\mathbf{v})]\right\|^2 \leq\; c_2 G_{\mathbf{v}}\left(\exp(-c_3 d) + \sum_{n=1}^{\infty}\epsilon(nr)\right).$$

Note that bounded variation is weaker than, say, Lipschitz continuity. Also, we note that the mixture assumption is used in a rather limited sense: most of the proof is devoted to establishing the bound w.r.t. Fourier-concentrated densities, and the result is then extended to mixtures by Jensen's inequality (see the proof for details).

Assuming $\epsilon(r)$ decays rapidly with r—say, exponentially in r^2 as is the case for a mixture of Gaussians—we get that the bound in the theorem is on the order of $\exp(-\Omega(\min\{d, r^2\}))$. Overall, the theorem implies that if r, d are moderately large, the gradient of $F_{\mathbf{w}^\star}$ at any point $\mathbf{v}$ is extremely concentrated around a fixed value, independent of $\mathbf{w}^\star$. This implies that gradient-based methods, which attempt to optimize $F_{\mathbf{w}^\star}$ via gradient information, are unlikely to succeed.

One way to formalize this argument is to consider any iterative algorithm (possibly randomized), which relies on an *ε-approximate* gradient oracle to optimize $F_{\mathbf{w}^\star}$: At every iteration t, the algorithm chooses a point $\mathbf{v}_t \in \mathcal{V}$, and receives a vector $\mathbf{g}_t$ such that $|\nabla F_{\mathbf{w}^\star}(\mathbf{v}_t) - \mathbf{g}_t| \leq \varepsilon$. More formally, we can define such oracles and algorithms as follows:

Definition 8 (Approximate Gradient Oracle) *$O_{F,\epsilon}$ is an ε-approximate gradient oracle w.r.t. the function F on a domain $\mathcal{V}$, if given any input $\mathbf{v} \in \mathcal{V}$, it returns a fixed vector $\mathbf{g}$ such that $|\nabla F(\mathbf{v}) - \mathbf{g}| \leq \varepsilon$.*

Definition 9 (Approximate Gradient-Based Method) *Given a domain $\mathcal{V}$, we say that an algorithm A is a T-iterations, ε-approximate gradient-based method, if there exists some (deterministic or randomized) $\mathbf{v}_1 \in \mathcal{V}$ and (deterministic or randomized) functions $\{f_i : \mathcal{V}^i \to \mathcal{V}\}_{i=1}^{T-1}$, such that for any function F on $\mathcal{V}$, the output $\mathbf{v}_T \in \mathcal{V}$ of A given F can be written recursively as $\mathbf{v}_{t+1} = f_t(O_{F,\epsilon}(\mathbf{v}_1), \ldots, O_{F,\epsilon}(\mathbf{v}_t))$ for some approximate gradient oracle $O_{F,\epsilon}$.*

In our case, we will be interested in ε such that ε^3 is on the order of the bound in Thm. 7. Since the bound is extremely small for moderate d, r (say, smaller than machine precision), our definition of approximate gradient-based methods are a realistic model of gradient-based methods on finite-precision machines, even if one attempts to compute the gradients accurately. The following theorem implies that if the number of iterations is not extremely large (on the order of $1/\varepsilon$, e.g. $\exp(\Omega(\min\{d, r^2\})$ iterations for Gaussian mixtures), then with high probability, an approximate gradient-based method will return the same predictor independent of $\mathbf{w}^\star$. However, since the objective function $F_{\mathbf{w}^\star}$ is generally highly sensitive to the choice of $\mathbf{w}^\star$, this means that no such method can train a reasonable predictor.

Theorem 10 *Assume the conditions of Thm. 7, and let*

$$\varepsilon = \sqrt[3]{c_2(\sup_{\mathbf{v}\in\mathcal{V}} G_{\mathbf{v}})\left(\exp(-c_3 d) + \sum_{n=1}^{\infty}\epsilon(nr)\right)}$$

be the cube root of the bound specified there (uniformly over all $\mathbf{v} \in \mathcal{V}$). Then there exist a choice of approximate gradient oracles $\{O_{F_{\mathbf{w}^*,\varepsilon}} : \|\mathbf{w}^*\| = 2r\}$, such that the following holds for any $p \in (0,1)$ and any $\lfloor p/\varepsilon \rfloor$-iterations, ε-approximate gradient-based method A: Conditioned on an event which holds with probability $1-p$ over the random choice of $\mathbf{w}^\star$, the distribution of the output of A given $F_{\mathbf{w}^*}$ is fixed independent of $\mathbf{w}^*$.

5. Proofs

5.1 Proof of Thm. 4

Let P_M denote the whitening matrix employed if we transform the instances X by some invertible $d \times d$ matrix M (that is, X becomes MX), and P the whitening matrix employed for the original data.

Using the same notation as in the theorem, it is easily verified that $PX = V^\top$, and $P_M MX = V_M^\top$, where $U_M D_M V_M^\top$ is an SVD decomposition of the matrix MX. Since both $V^\top$ and $V_M^\top$ are $\mathrm{Rank}(X) \times m$ matrices with rows consisting of orthonormal vectors, they are related by an orthogonal transformation (i.e. there is an orthogonal matrix R_M such that $R_M V^\top = V_M^\top$). Therefore, $R_M PX = P_M MX$. Since the data is fed to an orthogonally-invariant algorithm, its output W_M satisfies $W_M^\top P_M MX = W^\top PX$. This in turn implies $W_M^\top R_M PX = W^\top PX$, and hence $W_M^\top R_M V^\top = W^\top V^\top$. Multiplying both sides on the right by V and taking a transpose, we get that $R_M^\top W_M = W$, and hence $W_M = R_M W$. In words, W and W_M are the same up to an orthogonal transformation R_M depending on M. Therefore,

$$(P_M^\top W_M)^\top MX = W_M^\top P_M MX = W^\top R_M^\top R_M PX = W^\top PX = (P^\top W)^\top X,$$

so we see that the returned predictor makes the same predictions over the data set, independent of the transformation matrix M.

5.2 Proof of Thm. 5

We start with the following auxiliary theorem, which reduces the hardness result of Daniely and Shalev-Shwartz (2016) to one about neural networks of the type we discuss here:

Theorem 11 *Under the assumption stated in Daniely and Shalev-Shwartz (2016), the following holds for any $n_d = \omega(\log(d))$ (as $d \to \infty$):*

There is no algorithm running in time poly$(d, 1/\epsilon)$, which for any distribution $\mathcal{D}$ on $\{0,1\}^d$, and any $h(W^\top \mathbf{x}) = [\sum_{i=1}^{n_d} [\langle \mathbf{w}_i, \mathbf{x}\rangle]_+]_{[0,1]}$ (where $W = [\mathbf{w}_1, \mathbf{w}_2 \dots \mathbf{w}_{n_d}]$ and $\max_i \|\mathbf{w}_i\|$ is $\mathcal{O}(d)$), given only access to samples $(\mathbf{x}, h(W^\top \mathbf{x}))$ where $\mathbf{x} \sim \mathcal{D}$, returns with high probability a function f such that

$$\mathbb{E}_{\mathbf{x}\sim\mathcal{D}}\left[\left(f(\mathbf{x}) - h(W^\top \mathbf{x})\right)^2\right] \le \epsilon.$$

Proof Suppose for the sake of contradiction that there exists an algorithm $\mathcal{A}$ which for any distribution and $h(W^\top \mathbf{x})$ as described in the theorem, returns a function f such that $\mathbb{E}_{\mathbf{x}\sim\mathcal{D}}[(f(\mathbf{x}) - h(W^\top \mathbf{x}))^2] \le \epsilon$ with high probability.

In particular, let us focus on distributions $\mathcal{D}$ supported on $\{0,1\}^{d-1} \times \{1\}$. For these distributions, we argue that any intersection of halfspaces on $\mathbb{R}^{d-1}$ specified by $\mathbf{w}_1, \dots, \mathbf{w}_{n_d} \in \mathbb{R}^{d-1}$ with integer coordinates, and integer $b_1, \dots, b_n$, can be specified as $\mathbf{x} \mapsto 1 - h(W^\top \mathbf{x})$ for some function h as described in the theorem statement. To see this, note that for any $\mathbf{w}_i, b_i$ and $\mathbf{x} = (\mathbf{x}', 1)$ in the support of $\mathcal{D}$, $[\langle(-\mathbf{w}_i, b_i), \mathbf{x}\rangle]_+ = [-\langle \mathbf{w}_i, \mathbf{x}'\rangle + b_i]_+$ is a non-negative integer, hence

$$\left[\sum_{i=1}^{n_d} [\langle(-\mathbf{w}_i, b_i), \mathbf{x}\rangle]_+\right]_{[0,1]} = \left[\sum_{i=1}^{n_d} [-\langle \mathbf{w}_i, \mathbf{x}'\rangle + b_i]_+\right]_{[0,1]} = \bigvee_{i=1}^{n_d} \left(-\langle \mathbf{w}_i, \mathbf{x}'\rangle + b_i > 0\right)$$
$$= \bigvee_{i=1}^{n_d} \left(\langle \mathbf{w}_i, \mathbf{x}'\rangle < b_i\right) = \neg\left(\bigwedge_{i=1}^{n_d} \left(\langle \mathbf{w}_i, \mathbf{x}'\rangle \ge b_i\right)\right).$$

Therefore, for any distribution over examples labelled by an intersection of halfspaces $\mathbf{x} \mapsto 1 - h(W^\top \mathbf{x})$ (with integer-valued coordinates and bounded norms), by feeding $\mathcal{A}$ with $\{\mathbf{x}_i, 1 - y_i\}_{i=1}^m$, the algorithm returns a function f, such that with high probability, $\mathbb{E}_{\mathbf{x}}\left(f(\mathbf{x}) - h(W^\top \mathbf{x})\right)^2 \le \epsilon$, and therefore

$$\mathbb{E}_{\mathbf{x}}\left(\left(1 - f(\mathbf{x})\right) - \left(1 - h(W^\top \mathbf{x})\right)\right)^2 \le \epsilon.$$

In particular, if we consider the Boolean function $\tilde{f}(\mathbf{x}) = 1 - \mathrm{rnd}(f(\mathbf{x}))$, where $\mathrm{rnd}(z) = 0$ if $z \le 1/2$ and $\mathrm{rnd}(z) = 1$ if $z > 1/2$, we argue that $\Pr_{\mathbf{x}}(\tilde{f}(\mathbf{x}) \ne 1 - h(W^\top \mathbf{x})) \le 8\epsilon$. Since ϵ is arbitrary, and $1 - h(W^\top \mathbf{x})$ specifies an intersection of halfspaces, this would contradict the hardness result of Daniely and Shalev-Shwartz (2016), and therefore prove the theorem. This argument follows from the following chain of inequalities, where $\mathbf{1}$ denotes the indicator function:

$$\begin{aligned}
\Pr\left(\tilde{f}(\mathbf{x}) \ne g(\mathbf{x})\right) &= \Pr(f(\mathbf{x}) > 1/2 \ \wedge \ g(\mathbf{x}) = 1) + \Pr(f(\mathbf{x}) \le 1/2 \ \wedge \ g(\mathbf{x}) = 0) \\
&= \mathbb{E}\left[\mathbf{1}\left(f(\mathbf{x}) > 1/2 \ \wedge \ g(\mathbf{x}) = 1\right)\right] + \mathbb{E}\left[\mathbf{1}\left(f(\mathbf{x}) \le 1/2 \ \wedge \ g(\mathbf{x}) = 0\right)\right] \\
&\le \mathbb{E}\left[4\left(\left(1 - f(\mathbf{x})\right) - g(\mathbf{x})\right)^2\right] + \mathbb{E}\left[4\left(\left(1 - f(\mathbf{x})\right) - g(\mathbf{x})\right)^2\right] \\
&\le 8 \cdot \mathbb{E}\left[\left(\left(1 - f(\mathbf{x})\right) - g(\mathbf{x})\right)^2\right] \ \le \ 8\epsilon.
\end{aligned}$$

■

Proposition 12 *Thm. 11 holds even if we restrict $\mathbf{w}_1, \dots, \mathbf{w}_{n_d}$ to be linearly independent, with $s_{\min}(W) \ge 1$.*

Proof Suppose for the sake of contradiction that there exists an algorithm $\mathcal{A}$ which succeeds for any W as stated above. We will describe how to use $\mathcal{A}$ to get an algorithm which succeeds for any W as described in Thm. 11, hence reaching a contradiction.

Specifically, suppose we have access to samples $(\mathbf{x}, h(W^\top \mathbf{x}))$, where $\mathbf{x}$ is supported on $\{0,1\}^d$, and where W is any matrix as described in Thm. 11. We do the following: We

map every $\mathbf{x}$ to $\tilde{\mathbf{x}} \in \{0,1\}^{d+n_d}$ by $\tilde{\mathbf{x}} = (\mathbf{x}, 0, \ldots, 0)$, run $\mathcal{A}$ on the transformed samples $(\tilde{\mathbf{x}}, h(W^\top \mathbf{x}))$ to get some predictor $\tilde{f} : \{0,1\}^{d+n_d} \mapsto \mathbb{R}$, and return the predictor $f(\mathbf{x}) = \tilde{f}((\mathbf{x}, 0, \ldots, 0))$.

To see why this reduction works, we note that the mapping $\mathbf{x} \mapsto \tilde{\mathbf{x}}$ we have defined, where $\mathbf{x}$ is distributed according to $\mathbf{x}$, induces a distribution $\tilde{\mathcal{D}}$ on $\{0,1\}^{d+n_d}$. Let $\tilde{W}$ be the $(d+n_d)\times n_d$ matrix $[W; I_{n_d}]$ (that is, we add another $n_d \times n_d$ unit matrix below W). We have $\tilde{W}^\top \tilde{W} = W^\top W + I_{n_d}$, so the minimal eigenvalue of $\tilde{W}^\top \tilde{W}$ is at least 1, hence $s_{\min}(\tilde{W}) \geq 1$, so $\tilde{W}$ satisfies the conditions in the proposition. Moreover, the norm of each column of $\tilde{W}$ is larger than the norm of the corresponding column in W by at most 1, so the norm constraint in Thm. 11 still holds. Finally, $\tilde{W}\tilde{\mathbf{x}} = W\mathbf{x}$ for all $\mathbf{x}$, and therefore $h_{\tilde{W}}(\tilde{\mathbf{x}}) = h_W(\mathbf{x})$. Thus, the distribution of $(\tilde{\mathbf{x}}, h(W^\top \mathbf{x})) = (\tilde{\mathbf{x}}, h(\tilde{W}^\top \mathbf{x}))$ (which is used to feed the algorithm $\mathcal{A}$) is a valid distribution corresponding to the conditions of the proposition and Thm. 11 (only in dimension $d + n_d \leq 2d$ instead of d), so $\mathcal{A}$ returns with high probability a predictor $\tilde{f}$ such that

$$\mathbb{E}_{\tilde{\mathbf{x}}\sim\tilde{\mathcal{D}}}\left[\left(\tilde{f}(\tilde{\mathbf{x}}) - h(\tilde{W}^\top \tilde{\mathbf{x}})\right)^2\right] \leq \epsilon.$$

However, $\tilde{f}(\tilde{\mathbf{x}}) = f(\mathbf{x})$, $h(\tilde{W}^\top \tilde{\mathbf{x}}) = h(W^\top \mathbf{x})$, so the returned predictor f satisfies

$$\mathbb{E}_{\mathbf{x}\sim\mathcal{D}}\left[\left(f(\mathbf{x}) - h(W^\top \mathbf{x})\right)^2\right] \leq \epsilon.$$

This contradicts Thm. 11, which states that no efficient algorithm can return such a predictor for *any* sufficiently large dimension d and norm bound $\mathcal{O}(d)$. ■

In the definitions of orthogonal invariance and linear invariance, we only required the invariance to hold with respect to instances $\mathbf{x}_i$ in the data set. A stronger condition is that the invariance is satisfied for any $\mathbf{x} \in \mathbb{R}^d$. However, the following lemma shows that invariance w.r.t. a data set sampled i.i.d. from some distribution is sufficient to imply invariance w.r.t. "nearly all" $\mathbf{x}$ (under the same distribution):

Lemma 13 *Suppose the data set $\{\mathbf{x}_i, y_i\}_{i=1}^m$ is sampled i.i.d. from some distribution (where $\mathbf{x}_i \in \mathbb{R}^d$), then the following holds with probability at least $1-\delta$ for any $\delta \in (0,1)$: For any invertible M and linearly-invariant algorithm (or orthogonal M and orthogonally-invariant algorithm), conditioned on the algorithm's internal randomness, the returned matrices W and W_M (with respect to the original data and the data transformed by M respectively) satisfy*

$$\Pr_{\mathbf{x}}(W_M^\top M\mathbf{x} \neq W^\top \mathbf{x}) \leq \frac{d}{\delta(m+1)}.$$

Proof It is enough to prove that with probability at least $1-\delta$ over the sampling of $\mathbf{x}_1, \ldots, \mathbf{x}_m$,

$$\Pr_{\mathbf{x}}(\mathbf{x} \notin \mathrm{span}(\mathbf{x}_1, \ldots, \mathbf{x}_m)) \leq \frac{d}{\delta(m+1)}. \tag{5}$$

This is because the event $W_M^\top M\mathbf{x}_i = W^\top \mathbf{x}_i$ for all i means that $W_M^\top M\mathbf{x} = W^\top \mathbf{x}$ for any $\mathbf{x}$ in the span of $\mathbf{x}_1, \ldots, \mathbf{x}_m$.

Let $\mathbf{x}_1, \ldots, \mathbf{x}_{m+1}$ be sampled i.i.d. according to $\mathcal{D}$. Considering probabilities over this sample, we have

$$\sum_{j=1}^{m+1} \Pr\left(\mathbf{x}_j \notin \mathrm{span}(\mathbf{x}_1, \ldots, \mathbf{x}_{j-1})\right) \;=\; \mathbb{E}\left[\sum_{j=1}^{m+1} \mathbf{1}\left(\mathbf{x}_j \notin \mathrm{span}(\mathbf{x}_1, \ldots, \mathbf{x}_{j-1})\right)\right] \leq d, \tag{6}$$

where the latter inequality is because each $\mathbf{x}_j$ is a d-dimensional vector, hence the number of times we can get a vector not in the span of the previous ones is at most d. Moreover, since the vectors are sampled i.i.d, we have

$$\Pr(\mathbf{x}_{j+1} \notin \mathrm{span}(\mathbf{x}_1 \ldots \mathbf{x}_j)) \leq \Pr(\mathbf{x}_{j+1} \notin \mathrm{span}(\mathbf{x}_1 \ldots \mathbf{x}_{j-1})) = \Pr(\mathbf{x}_j \notin \mathrm{span}(\mathbf{x}_1 \ldots \mathbf{x}_{j-1})),$$

so the probabilities in Eq. (6) monotonically decrease with j. Thus, Eq. (6) implies

$$(m+1)\Pr\left(\mathbf{x}_{m+1} \notin \mathrm{span}(\mathbf{x}_1, \ldots, \mathbf{x}_m)\right) \leq d \quad\Rightarrow\quad \Pr\left(\mathbf{x}_{m+1} \notin \mathrm{span}(\mathbf{x}_1, \ldots, \mathbf{x}_m)\right) \leq \frac{d}{m+1}.$$

This is equivalent to

$$\mathbb{E}_{\mathbf{x}_1,\ldots,\mathbf{x}_m\sim\mathcal{D}}\left[\Pr_{\mathbf{x}_{m+1}}\left(\mathbf{x}_{m+1} \notin \mathrm{span}(\mathbf{x}_1, \ldots, \mathbf{x}_m) | \mathbf{x}_1, \ldots, \mathbf{x}_m\right)\right] \leq \frac{d}{m+1},$$

so by Markov's inequality, with probability at least $1-\delta$ over the sampling of $\mathbf{x}_1, \ldots, \mathbf{x}_m$,

$$\Pr_{\mathbf{x}_{m+1}}\left(\mathbf{x}_{m+1} \notin \mathrm{span}(\mathbf{x}_1, \ldots, \mathbf{x}_m)\right) \leq \frac{d}{\delta(m+1)}.$$

Since $\mathbf{x}_{m+1}$ is sampled independently, Eq. (5) and hence the lemma follows. ■

With these results in hand, we can finally turn to prove Thm. 5. Suppose for the sake of contradiction that there exists an efficient linearly-invariant algorithm $\mathcal{A}$, which for any distribution $\mathcal{D}$ supported on vectors of norm $\mathcal{O}\left(d\sqrt{2dn_d}\right) / \min\{1, s_{\min}(W_\star)\}$, returns w.h.p. a predictor $\mathbf{x} \mapsto f(\tilde{W}^\top \mathbf{x})$ such that

$$\mathbb{E}_{\mathbf{x}\sim\mathcal{D}^\star}\left[\left(f(\tilde{W}^\top \mathbf{x}) - h(W_\star^\top \mathbf{x})\right)^2\right] \leq \epsilon.$$

We will show that the very same algorithm, if given $\mathrm{poly}(d, 1/\epsilon)$ samples, can successfully learn w.r.t. *any* $d \times n_d$ matrix W and any distribution $\mathcal{D}$ satisfying Proposition 12 and Thm. 11, contradicting those results.

In what follows, we assume without loss of generality that f maps to $[0,1]$: If that is not the case, we can simply consider the predictor $\hat{f}(W^\top \mathbf{x})$, where $\hat{f}(z) = \max\{0, \min\{1, f(z)\}\}$, and note that since h returns values in $[0,1]$, then for any input $\mathbf{x}$,

$$((\hat{f}(W^\top \mathbf{x}) - h(W_\star^\top \mathbf{x}))^2 \;\leq\; (f(W^\top \mathbf{x}) - h(W_\star^\top \mathbf{x}))^2,$$

hence the expected squared loss of $\mathbf{x} \mapsto \hat{f}(W^\top \mathbf{x})$ is only smaller than $\mathbf{x} \mapsto f(W^\top \mathbf{x})$

Indeed, let W and $\mathcal{D}$ be an arbitrary matrix and distribution which satisfy the conditions of both Thm. 11 and 12 (namely, $\mathcal{D}$ is a distribution on $\{0,1\}^d$, and $W = [\mathbf{w}_1, \ldots, \mathbf{w}_{n_d}]$

satisfies $\max_i \|\mathbf{w}_i\| \leq \mathcal{O}(d)$ as well as $s_{\min}(W) \geq 1$). We first argue that there exists a $d \times d$ invertible matrix M such that

$$W = M^\top W_\star \quad , \quad \|M\| = \frac{\mathcal{O}(d\sqrt{2n_d})}{\min\{1, s_{\min}(W_\star)\}}. \tag{7}$$

To see this, note that W and $W_\star$ are of the same size and our conditions imply that both of them have full column rank. Thus, we can simply augment them to invertible $d \times d$ matrices $[W\ \hat{W}]$ and $[W_\star\ \hat{W}_\star]$, where the columns of $\hat{W}$ (respectively $\hat{W}_\star$) are an orthonormal basis for the subspace orthogonal to the column space of W (respectively $W_\star$), and choosing $M^\top = [W\ \hat{W}][W_\star\ \hat{W}_\star]^{-1}$. Thus,

$$\|M\| \leq \left\|[W\ \hat{W}]\right\| \cdot \left\|[W_\star\ \hat{W}_\star]^{-1}\right\|. \tag{8}$$

$\left\|[W\ \hat{W}]\right\|$ can be upper bounded by the Frobenius norm, which by the assumption on W from Thm. 11 and the fact that $\hat{W}$ has orthogonal columns, is $\sqrt{\mathcal{O}(d)^2 \cdot n_d + 1 \cdot (d - n_d)} = \mathcal{O}(\sqrt{d^2 n_d}) = \mathcal{O}(d\sqrt{n_d})$. Also, $\left\|[W_\star\ \hat{W}_\star]^{-1}\right\|$ can be upper bounded by the inverse square root of the smallest eigenvalue of

$$[W_\star\ \hat{W}_\star]^\top [W_\star\ \hat{W}_\star] \ = \ \begin{bmatrix} W_\star^\top W_\star & 0 \\ 0 & \hat{W}_\star^\top \hat{W}_\star \end{bmatrix} \ = \ \begin{bmatrix} W_\star^\top W_\star & 0 \\ 0 & I \end{bmatrix} \tag{9}$$

(where I is the unit matrix), which equals $1/\min\{1, s_{\min}(W_\star)\}$. Plugging these bounds into Eq. (8), we get Eq. (7).

Now, consider the following: Suppose we run the algorithm $\mathcal{A}$ using the data points $(M\mathbf{x}_i, h(W_\star^\top(M\mathbf{x}_i)))$, $i = 1, 2, \ldots, m$, where $\mathbf{x}_i$ is sampled from $\mathcal{D}$. Since $\mathbf{x}_i \in \{0,1\}^d$, and $\|\mathbf{x}_i\| \leq \sqrt{d}$, it follows from Eq. (7) that $M\mathbf{x}_i$ is always of norm at most $\|M\|\,\|\mathbf{x}_i\| \leq \|M\|\sqrt{d} = \mathcal{O}(d\sqrt{dn_d})/\min\{1, s_{\min}(W_\star)\}$, and the outputs correspond to the network specified by $W_\star$. Therefore, by assumption, the algorithm $\mathcal{A}$ would return w.h.p. a matrix $\tilde{W}_M$ such that

$$\mathbb{E}_{\mathbf{x}\sim\mathcal{D}}\left[\left(f(\tilde{W}_M^\top(M\mathbf{x})) - h(W_\star^\top(M\mathbf{x}))\right)^2\right] \leq \epsilon.$$

By Eq. (7), $W_\star^\top M = (M^\top W_\star)^\top = W^\top$, so this is equivalent to

$$\mathbb{E}_{\mathbf{x}\sim\mathcal{D}}\left[\left(f((\tilde{W}_M^\top M\mathbf{x}) - h(W^\top\mathbf{x}))\right)^2\right] \leq \epsilon. \tag{10}$$

Let $\tilde{W}_I$ be the matrix returned by $\mathcal{A}$ if we had fed it with the samples $\{(\mathbf{x}_i, h(W^\top\mathbf{x}_i))\}_{i=1}^m$ (or equivalently, $\{(\mathbf{x}_i, h(W_\star^\top(M\mathbf{x}_i)))\}_{i=1}^m$)[6]. Let $E_\mathbf{x}$ be the event (conditioned on the samples used by the algorithm) that a freshly sampled $\mathbf{x} \sim \mathcal{D}$ satisfies $\tilde{W}_M^\top M\mathbf{x} = \tilde{W}_I^\top\mathbf{x}$. By Lemma 13, w.h.p. over the samples fed to the algorithm, $\Pr_\mathbf{x}(E_\mathbf{x}) = 1 - \mathcal{O}(d/m)$. Therefore,

6. Note that if the algorithm is stochastic, both $\tilde{W}_M$ and $\tilde{W}_I$ are not fixed given the data, but also depend on the algorithm's internal randomness. However, the proof will still follow by conditioning on any possible realization of this randomness.

w.h.p. over the samples $\mathbf{x}_1, \ldots, \mathbf{x}_m$,

$$\begin{aligned}
&\mathbb{E}_{\mathbf{x}\sim\mathcal{D}}\left[\left(f(\tilde{W}_I^\top\mathbf{x}) - h(W^\top\mathbf{x})\right)^2\right] \\
&= \Pr_\mathbf{x}(E_\mathbf{x}) \cdot \mathbb{E}_\mathbf{x}\left[\left(f(\tilde{W}_I^\top\mathbf{x}) - h(W^\top\mathbf{x})\right)^2 \middle| E_\mathbf{x}\right] + \Pr_\mathbf{x}(\neg E_\mathbf{x}) \cdot \mathbb{E}_\mathbf{x}\left[\left(f(\tilde{W}_I^\top\mathbf{x}) - h(W^\top\mathbf{x})\right)^2 \middle| \neg E_\mathbf{x}\right] \\
&\leq \Pr_\mathbf{x}(E_\mathbf{x}) \cdot \mathbb{E}_\mathbf{x}\left[\left(f(\tilde{W}_M^\top M\mathbf{x}) - h(W^\top\mathbf{x})\right)^2 \middle| E_\mathbf{x}\right] + \Pr_\mathbf{x}(\neg E_\mathbf{x}) \cdot 1 \\
&= \mathbb{E}_\mathbf{x}\left[\left(f(\tilde{W}_M^\top M\mathbf{x}) - h(W^\top\mathbf{x})\right)^2 \mathbf{1}(E_\mathbf{x})\right] + \mathcal{O}\left(\frac{d}{m}\right) \\
&\leq \mathbb{E}_\mathbf{x}\left[\left(f(\tilde{W}_M^\top M\mathbf{x}) - h(W^\top\mathbf{x})\right)^2\right] + \mathcal{O}\left(\frac{d}{m}\right) \quad \leq \quad \epsilon + \mathcal{O}\left(\frac{d}{m}\right),
\end{aligned}$$

where we used the facts that both f and h map to $[0,1]$, a union bound and Eq. (10). Now, recall that $\tilde{W}_I$ refers to the output of the algorithm, given samples $\{(\mathbf{x}_i, h(W^\top\mathbf{x}_i))\}_{i=1}^m$ where $m = \text{poly}(d, 1/\epsilon)$. Thus, we have shown that w.h.p., as long as the algorithm is fed with $m \geq d/\epsilon$ samples[7], the algorithm returns $\tilde{W}_I$ which satisfies

$$\mathbb{E}_{\mathbf{x}\sim\mathcal{D}}\left[\left(f(\tilde{W}_I^\top\mathbf{x}) - h(W^\top\mathbf{x})\right)^2\right] \ = \ \mathcal{O}(\epsilon).$$

This means that the algorithm succesfully learns the hypothesis $\mathbf{x} \mapsto h(W^\top\mathbf{x})$ with respect to the distribution $\mathcal{D}$. Since ϵ is arbitrarily small and $W, \mathcal{D}$ were chosen arbitrarily, the result follows.

5.3 Proof of Thm. 7

To prove the theorem, we will require some tools from Fourier analysis on Euclidean space. We will consider functions from $\mathbb{R}^d$ to the reals $\mathbb{R}$ or complex numbers $\mathbb{C}$, and view them as elements in the Hilbert space $L^2(\mathbb{R}^d)$ of square integrable functions, equipped with the inner product

$$\langle f, g\rangle = \int_\mathbf{x} f(\mathbf{x}) \cdot \overline{g(\mathbf{x})} d\mathbf{x}$$

and the norm $\|f\| = \sqrt{\langle f, f\rangle}$. We use fg or $f \cdot g$ as shorthand for the function $\mathbf{x} \mapsto f(\mathbf{x})g(\mathbf{x})$. Any function $f \in L^2(\mathbb{R}^d)$ has a Fourier transform $\hat{f} \in L^2(\mathbb{R}^d)$, which for absolutely integrable functions can be defined as

$$\hat{f}(\mathbf{w}) = \int \exp\left(-2\pi i\mathbf{x}^\top\mathbf{w}\right) f(\mathbf{x}) d\mathbf{x}, \tag{11}$$

where $\exp(iz) = \cos(z) + i \cdot \sin(z)$, i being the imaginary unit. In the proofs, we will use the following well-known properties of the Fourier transform:

- Linearity: For scalars a, b and functions f, g, $\widehat{af + bg} = a\hat{f} + b\hat{g}$.

7. Even if the algorithm does not require that many samples, we can still artificially add more samples—these are merely used to ensure that its linear invariance is with respect to a sufficiently large data set.

- Isometry: $\langle f, g\rangle = \langle \hat{f}, \hat{g}\rangle$ and $\|f\| = \|\hat{f}\|$.
- Convolution: $\widehat{fg} = \hat{f} * \hat{g}$, where $*$ denotes the convolution operation: $(f*g)(\mathbf{w}) = \int f(\mathbf{z}) \cdot g(\mathbf{w}-\mathbf{z})\, d\mathbf{z}$.

We now turn to prove the theorem. First, we note that for any function q, $\mathbb{E}_{\mathbf{x}\sim\varphi^2}[q(\mathbf{x})] = \sum_i \alpha_i \cdot \mathbb{E}_{\mathbf{x}\sim\varphi_i^2}[q(\mathbf{x})]$. Thus, it is enough to prove the bound in the theorem when φ^2 consists of a single element whose square root is Fourier-concentrated. For a mixture $\varphi^2 = \sum_i \alpha_i \varphi_i^2$, the result follows by applying the bound for each φ_i^2 individually, and using Jensen's inequality.

To simplify notation a bit, we let $\psi_{\mathbf{w}}(\cdot)$ stand for the function $\psi(\langle \mathbf{w}, \cdot\rangle)$, and let $h(\cdot - \mathbf{v})$ (where $\mathbf{v}$ is some vector and h is a function on $\mathbb{R}^d$) stand for the function $\mathbf{x} \mapsto h(\mathbf{x}-\mathbf{v})$. Also, we will use several times the fact that for any two $L^2(\mathbb{R}^d)$ functions h_1, h_2,

$$\langle h_1(\cdot-\mathbf{v}), h_2(\cdot-\mathbf{v})\rangle \;=\; \int h_1(\mathbf{x}-\mathbf{v})\overline{h_2(\mathbf{x}-\mathbf{v})}d\mathbf{x} \;=\; \int h_1(\mathbf{x})\overline{h_2(\mathbf{x})}d\mathbf{x} = \langle h_1, h_2\rangle\,.$$

In other words, inner products (and hence also norms) in $L^2(\mathbb{R}^d)$ are invariant to a shift in coordinates.

The proof is a combination of a few lemmas, presented below.

Lemma 14 *For any $\mathbf{w}$, it holds that $\psi_{\mathbf{w}}\varphi \in L^2(\mathbb{R}^d)$, and satisfies*

$$\widehat{\psi_{\mathbf{w}}\varphi}(\mathbf{x}) \;=\; \sum_{z\in\mathbb{Z}} a_z \cdot \hat{\varphi}(\mathbf{x} - z\mathbf{w})$$

for any $\mathbf{x}$, where $\mathbb{Z}$ is the set of integers and a_z are complex-valued coefficients (corresponding to the Fourier series expansion of ψ, hence depending only on ψ) which satisfy $\sum_{z\in\mathbb{Z}} |a_z|^2 \le 1$.

Proof First, we note that $\psi_{\mathbf{w}}\varphi \in L^2(\mathbb{R}^d)$, since both $\psi_{\mathbf{w}}$ and φ are locally integrable[8] by the theorem's conditions, and satisfy

$$\|\psi_{\mathbf{w}}\varphi\|^2 = \int \psi_{\mathbf{w}}^2(\mathbf{x})\varphi^2(\mathbf{x})d\mathbf{x} = \int \psi^2(\mathbf{w}^\top\mathbf{x})\varphi^2(\mathbf{x})d\mathbf{x} \le \int \varphi^2(\mathbf{x})d\mathbf{x} = 1 < \infty.$$

As a result, $\widehat{\psi_{\mathbf{w}}\varphi}$ exists as a function in $L^2(\mathbb{R}^d)$. Since ψ is a function of bounded variation, it is equal everywhere to its Fourier series expansion:

$$\psi(x) = \sum_{z\in\mathbb{Z}} a_z \exp\left(2\pi i z x\right),$$

where i is the imaginary unit (note that since ψ is real-valued, the imaginary components eventually cancel out, but it will be more convenient for us to represent the Fourier series in this compact form). By Parseval's identity, $\sum_z |a_z|^2 = \int_{-1/2}^{1/2} \psi^2(x)dx$, which is at most 1 (since $\psi(x) \in [-1,+1]$).

8. Namely, integrable on any compact subset of their domain.

Based on this equation, we have

$$\psi_{\mathbf{w}}(\mathbf{x}) = \psi(\mathbf{w}^\top\mathbf{x}) = \sum_{z\in\mathbb{Z}} a_z \exp\left(2\pi i z \mathbf{w}^\top\mathbf{x}\right).$$

We now wish to compute the Fourier transform of the above[9]. First, we note that the Fourier transform of $\exp(2\pi i \langle \mathbf{v}, \cdot\rangle)$ is given by $\delta(\cdot - \mathbf{v})$, where δ is the Dirac delta function (a so-called generalized function which satisfies $\delta(\mathbf{x}) = 0$ for all $\mathbf{x} \neq \mathbf{0}$, and $\int \delta(\mathbf{x})d\mathbf{x} = 1$). Based on this and the linearity of the Fourier transform, we have that

$$\hat{\psi}_{\mathbf{w}}(\mathbf{x}) \;=\; \sum_{z\in\mathbb{Z}} a_z \cdot \delta\left(\mathbf{x} - z\mathbf{w}\right),$$

and therefore, by the convolution property of the Fourier transform, we have

$$\begin{aligned}\widehat{\psi_{\mathbf{w}}\varphi}(\mathbf{x}) = \left(\hat{\psi}_{\mathbf{w}} * \hat{\varphi}\right)(\mathbf{x}) &= \int \hat{\psi}_{\mathbf{w}}(\mathbf{z}) \cdot \hat{\varphi}(\mathbf{x}-\mathbf{z})d\mathbf{z} \\ &= \sum_{z\in\mathbb{Z}} a_z \cdot \int \delta(\mathbf{z} - z\mathbf{w}) \cdot \hat{\varphi}(\mathbf{x}-\mathbf{z})d\mathbf{z} \\ &= \sum_{z\in\mathbb{Z}} a_z \cdot \hat{\varphi}(\mathbf{x} - z\mathbf{w})\end{aligned}$$

as required. ■

Lemma 15 *For any distinct integers $z_1 \neq z_2$ and any $\mathbf{w}$ such that $\|\mathbf{w}\| = 2r$, it holds that*

$$\langle\; |\hat{\varphi}(\cdot - z_1\mathbf{w})| \;,\; |\hat{\varphi}(\cdot - z_2\mathbf{w})| \;\rangle \;\le\; 2\cdot\epsilon(|z_1 - z_2|r).$$

Proof Let $\Delta = |z_2 - z_1|r$, and $\mathbf{v} = (z_2 - z_1)\mathbf{w}$, so $\mathbf{v}$ is a vector of norm 2Δ. Since the inner product is invariant to shifting the coordinates, we can assume without loss of generality that $z_1 = 0$, and our goal is to bound $\langle|\hat{\varphi}|, |\hat{\varphi}(\cdot - \mathbf{v})|\rangle$.

Using the convention that $\mathbf{1}_{\le\Delta}$ is the indicator of $\{\mathbf{x} : \|\mathbf{x}\| \le \Delta\}$, and $\mathbf{1}_{>\Delta}$ is the indicator for its complement, we have

$$\begin{aligned}\langle|\hat{\varphi}|\,, |\hat{\varphi}(\cdot-\mathbf{v})|\rangle &= \langle|\hat{\varphi}| \;,\; |\hat{\varphi}(\cdot-\mathbf{v})|\,\mathbf{1}_{\le\Delta}\rangle + \langle|\hat{\varphi}| \;,\; |\hat{\varphi}(\cdot-\mathbf{v})|\,\mathbf{1}_{>\Delta}\rangle \\ &= \langle|\hat{\varphi}| \;,\; |\hat{\varphi}(\cdot-\mathbf{v})|\,\mathbf{1}_{\le\Delta}\rangle + \langle|\hat{\varphi}|\,\mathbf{1}_{>\Delta} \;,\; |\hat{\varphi}(\cdot-\mathbf{v})|\rangle \\ &\le \|\hat{\varphi}\|\,\|\hat{\varphi}(\cdot-\mathbf{v})\mathbf{1}_{\le\Delta}\| \;+\; \|\hat{\varphi}\mathbf{1}_{>\Delta}\|\,\|\hat{\varphi}(\cdot-\mathbf{v})\|\,,\end{aligned}$$

where in the last step we used Cauchy-Schwartz. Using the fact that norms and inner products are invariant to coordinate shifting, the above is at most

$$\begin{aligned}&\|\hat{\varphi}\|\,\|\hat{\varphi}\mathbf{1}_{\le\Delta}(\cdot+\mathbf{v})\| + \|\hat{\varphi}\mathbf{1}_{>\Delta}\|\,\|\hat{\varphi}\| \\ &\qquad = \|\hat{\varphi}\|\left(\sqrt{\int |\hat{\varphi}(\mathbf{x})|^2\mathbf{1}_{\|\mathbf{x}+\mathbf{v}\|\le\Delta}d\mathbf{x}} + \sqrt{\int |\hat{\varphi}(\mathbf{x})|^2\mathbf{1}_{>\Delta}(\mathbf{x})d\mathbf{x}}\right).\end{aligned}$$

9. Strictly speaking, this function does not have a Fourier transform in the sense of Eq. (11), since the associated integrals do not converge. However, the function still has a well-defined Fourier transform in the more general sense of a generalized function or distribution (see Hunter and Nachtergaele 2001 for a survey). In the derivation below, we will simply rely on some standard formulas from the Fourier analysis literature, and refer to Hunter and Nachtergaele (2001) for their formal justifications.

By the triangle inequality and the assumption $\|\mathbf{v}\| = 2\Delta$, the event $\|\mathbf{x}+\mathbf{v}\| \leq \Delta$ implies $\|\mathbf{x}\| \geq \Delta$. Therefore, the above can be upper bounded by

$$2\left\|\hat{\varphi}\right\| \sqrt{\int |\hat{\varphi}(\mathbf{x})|^2 \mathbf{1}_{\geq\Delta}(\mathbf{x}) d\mathbf{x}} \;=\; 2\left\|\hat{\varphi}\right\| \cdot \left\|\hat{\varphi} \cdot \mathbf{1}_{\geq\Delta}\right\|.$$

Since φ is Fourier-concentrated, this is at most $2\epsilon(\Delta)\left\|\hat{\varphi}\right\|^2 = 2\epsilon(\Delta)\left\|\varphi\right\|^2 = 2\epsilon(\Delta)$, where we use the isometry of the Fourier transform and the assumption that $\|\varphi\|^2 = \int \varphi^2(\mathbf{x})d\mathbf{x} = 1$. Plugging back the definition of Δ, the result follows. ■

Lemma 16 *It holds that*

$$\sum_{z_1 \neq z_2 \in \mathbb{Z}} |a_{z_1}| \cdot |a_{z_2}| \cdot \epsilon(r|z_1 - z_2|) \;\leq\; 2\sum_{n=1}^{\infty} \epsilon(nr)$$

Proof For simplicity, define $\epsilon'(x) = \epsilon(x)$ for all $x > 0$, and $\epsilon(0) = 0$. Then the expression in the lemma equals

$$\begin{aligned}
&\sum_{z_1,z_2\in\mathbb{Z}} |a_{z_1}| \cdot |a_{z_2}| \cdot \epsilon'(|z_1 - z_2|r) \\
&= \sum_{z_1,z_2\in\mathbb{Z}} \left(|a_{z_1}|\sqrt{\epsilon'(|z_1 - z_2|r)}\right)\left(|a_{z_2}|\sqrt{\epsilon'(|z_1 - z_2|r)}\right) \\
&\leq \sqrt{\sum_{z_1,z_2\in\mathbb{Z}} |a_{z_1}|^2 \epsilon'(|z_1 - z_2|r)} \sqrt{\sum_{z_1,z_2\in\mathbb{Z}} |a_{z_2}|^2 \epsilon'(|z_1 - z_2|r)} \\
&= \sum_{z_1,z_2\in\mathbb{Z}} |a_{z_1}|^2 \epsilon'(|z_1 - z_2|r)
\end{aligned}$$

where in the last step we used the fact that the two inner square roots are the same up to a different indexing. Recalling the definition of ϵ' and that $\sum_z |a_z|^2 \leq 1$, the above is at most

$$\begin{aligned}
&\sum_{z_1\in\mathbb{Z}} |a_{z_1}|^2 \sum_{z_2\in\mathbb{Z}} \epsilon'(|z_1 - z_2|r) \;\leq\; \sup_{z_1\in\mathbb{Z}} \sum_{z_2\in\mathbb{Z}} \epsilon'(|z_1 - z_2|r) \\
&= \left(\epsilon'(0) + 2\sum_{n=1}^{\infty} \epsilon'(nr)\right) \;=\; 2\sum_{n=1}^{\infty} \epsilon(nr)\,.
\end{aligned}$$

■

Lemma 17 *For any $g \in L^2(\mathbb{R}^d)$, if $d \geq 40$, and we sample $\mathbf{w}$ uniformly at random from $\{\mathbf{w} : \|\mathbf{w}\| = 2r\}$, it holds that*

$$\mathbb{E}\left[\left(\left\langle g, \widehat{\psi_{\mathbf{w}}\varphi}\right\rangle - a_0 \left\langle g, \hat{\varphi}\right\rangle\right)^2\right] \;\leq\; 10\left\|g\right\|^2 \left(\exp(-d/20) + \sum_{n=1}^{\infty} \epsilon(nr)\right)$$

where a_0 is the coefficient from Lemma 14.

Proof By symmetry, given any function f of $\mathbf{w}$, the expectation $\mathbb{E}_{\mathbf{w}}[f(\mathbf{w})]$ (where $\mathbf{w}$ is uniform on a sphere) can be equivalently written as $\mathbb{E}_{\mathbf{w}\in\mathcal{W}}\mathbb{E}_U[f(U\mathbf{w})] = \mathbb{E}_U\mathbb{E}_{\mathbf{w}\in\mathcal{W}}[f(U\mathbf{w})]$, where U is a rotation matrix chosen uniformly at random (so that for any $\mathbf{w}$, $U\mathbf{w}$ is uniformly distributed on the sphere of radius $\|\mathbf{w}\|$), and $\mathbb{E}_{\mathbf{w}\in\mathcal{W}}$ refers to a uniform distribution of $\mathbf{w}$ over some finite set $\mathcal{W}$ of vectors of norm $2r$. In particular, we will choose $\mathcal{W} = \{\mathbf{w}_1, \ldots, \mathbf{w}_{\lceil\exp(d/20)\rceil}\}$ which satisfies the following:

$$\forall i \;\; \|\mathbf{w}_i\| = 2r \;\;,\;\; \forall i \neq j \;\; |\mathbf{w}_i^\top \mathbf{w}_j| < 2r^2. \tag{12}$$

The existence of such a set follows from standard concentration of measure arguments[10].

Thus, our goal is to bound $\mathbb{E}_U\mathbb{E}_{\mathbf{w}\in\mathcal{W}}\mathbb{E}\left[\left(\left\langle g, \widehat{\psi_{\mathbf{w}}\varphi}\right\rangle - a_0\left\langle g, \hat{\varphi}\right\rangle\right)^2\right]$. In fact, we will prove the bound stated in the lemma for any U, and will focus on $U = I$ without loss of generality (the argument for other U is exactly the same). First, by applying Lemma 14, we have

$$\begin{aligned}
\mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left(\left\langle g, \widehat{\psi_{\mathbf{w}}\varphi}\right\rangle - a_0\left\langle g, \hat{\varphi}\right\rangle\right)^2\right] &= \mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left(\left\langle g, \sum_{z\in\mathbb{Z}} a_z \hat{\varphi}(\cdot - z\mathbf{w})\right\rangle - a_0\left\langle g, \hat{\varphi}\right\rangle\right)^2\right] \\
&= \mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left\langle g, \sum_{z\in\mathbb{Z}\setminus\{0\}} a_z \hat{\varphi}(\cdot - z\mathbf{w})\right\rangle^2\right].
\end{aligned} \tag{13}$$

For any $\mathbf{w} \in \mathcal{W}$, let

$$A_{\mathbf{w}} = \{\mathbf{x} \in \mathbb{R}^d \;:\; \exists z \in \mathbb{Z}\setminus\{0\} \; s.t. \; \|\mathbf{x} - z\mathbf{w}\| < r\}.$$

In words, each $A_{\mathbf{w}}$ corresponds to the union of open balls of radius r around $\pm\mathbf{w}, \pm 2\mathbf{w}, \pm 3\mathbf{w}\ldots$. An important property of these sets is that they are disjoint: $A_{\mathbf{w}} \cap A_{\mathbf{w}'} = \emptyset$ for any distinct $\mathbf{w}, \mathbf{w}' \in \mathcal{W}$. To see why, note that if there was some $\mathbf{x}$ in both of them, it would imply $\|\mathbf{x} - z_1\mathbf{w}\| < r$ and $\|\mathbf{x} - z_2\mathbf{w}'\| < r$ for some non-zero $z_1, z_2 \in \mathbb{Z}$, hence $\|z_1\mathbf{w} - z_2\mathbf{w}'\| < 2r$ by the triangle inequality. Squaring both sides and performing some simple manipulations (using the facts that $\|\mathbf{w}\| = \|\mathbf{w}'\| = 2r$ and $|z_1|, |z_2| \geq 1$), we would get

$$2|z_1 z_2| \cdot \left|\mathbf{w}^\top \mathbf{w}'\right| > 4r^2(z_1^2 + z_2^2 - 1) \geq 2r^2(z_1^2 + z_2^2) \;\;\Rightarrow\;\; \left|\mathbf{w}^\top \mathbf{w}'\right| \geq r^2\left(\left|\frac{z_1}{z_2}\right| + \left|\frac{z_2}{z_1}\right|\right) \geq 2r^2,$$

where we used the fact that $x + 1/x \geq 2$ for all $x > 0$. This contradicts the assumption on $\mathcal{W}$ (see Eq. 12), and establishes that $\{A_{\mathbf{w}}\}_{\mathbf{w}\in\mathcal{W}}$ are indeed disjoint sets.

We now continue by analyzing Eq. (13). Letting $\mathbf{1}_{A_{\mathbf{w}}}$ be the indicator function to the set $A_{\mathbf{w}}$, and $\mathbf{1}_{A_{\mathbf{w}}^C}$ be the indicator of its complement, and recalling that $(a+b)^2 \leq 2(a^2+b^2)$, we can upper bound Eq. (13) by

$$2 \cdot \mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left\langle g, \mathbf{1}_{A_{\mathbf{w}}} \sum_{z\in\mathbb{Z}\setminus\{0\}} a_z \hat{\varphi}(\cdot - z\mathbf{w})\right\rangle^2\right] + 2 \cdot \mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left\langle g, \mathbf{1}_{A_{\mathbf{w}}^C} \sum_{z\in\mathbb{Z}\setminus\{0\}} a_z \hat{\varphi}(\cdot - z\mathbf{w})\right\rangle^2\right]. \tag{14}$$

10. For any two vectors $\mathbf{w}, \mathbf{w}'$ picked uniformly at random from a ball of radius $2r$, $\Pr(|\mathbf{w}^\top \mathbf{w}'| \geq 2r^2) = 2\Pr\left(\left(\frac{1}{2r}\mathbf{w}\right)^\top \left(\frac{1}{2r}\mathbf{w}'\right) > \frac{1}{2}\right) \leq 2\exp\left(-\frac{d}{8}\right)$ (see Boucheron et al. 2013, Section 7.2), so by a union bound, the probability that Eq. (12) is not satisfied is at most $2\lceil\exp(d/20)\rceil^2 \exp(-d/8)$. This can be verified to be strictly less than 1 if $d \geq 40$, hence such a set exists under the lemma's conditions.

We consider each expectation separately. Starting with the first one, we have

$$\begin{aligned}
\mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left\langle g, \mathbf{1}_{A_\mathbf{w}}\sum_{z\in\mathbb{Z}\setminus\{0\}} a_z\hat{\varphi}(\cdot - z\mathbf{w})\right\rangle^2\right] &= \mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left\langle g, \mathbf{1}_{A_\mathbf{w}}\left(\widehat{\psi_\mathbf{w}\varphi} - a_0\hat{\varphi}\right)\right\rangle^2\right] \\
&= \mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left\langle \mathbf{1}_{A_\mathbf{w}}g, \widehat{\psi_\mathbf{w}\varphi} - a_0\hat{\varphi}\right\rangle^2\right] \le \mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left\|\mathbf{1}_{A_\mathbf{w}}g\right\|^2\left\|\widehat{\psi_\mathbf{w}\varphi} - a_0\hat{\varphi}\right\|^2\right] \\
&\le 2\cdot\mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left\|\mathbf{1}_{A_\mathbf{w}}g\right\|^2\left(\left\|\widehat{\psi_\mathbf{w}\varphi}\right\|^2 + \|a_0\hat{\varphi}\|^2\right)\right] \\
&= 2\cdot\mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left\|\mathbf{1}_{A_\mathbf{w}}g\right\|^2\left(\|\psi_\mathbf{w}\varphi\|^2 + |a_0|^2\cdot\|\hat{\varphi}\|^2\right)\right].
\end{aligned}$$

Since we have $\|\hat{\varphi}\| = \|\varphi\| = 1$, $|a_0|^2 \le \sum_z |a_z|^2 \le 1$, and $\|\psi_\mathbf{w}\varphi\|^2 = \int \psi_\mathbf{w}^2(\mathbf{x})\varphi^2(\mathbf{x})d\mathbf{x} \le \int \varphi^2(\mathbf{x})d\mathbf{x} = 1$, the above is at most

$$\begin{aligned}
4\cdot\mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left\|\mathbf{1}_{A_\mathbf{w}}g\right\|^2\right] &\le \frac{4}{|\mathcal{W}|}\sum_{\mathbf{w}\in\mathcal{W}}\int 1_{A_\mathbf{w}}(\mathbf{x})|g(\mathbf{x})|^2 d\mathbf{x} \\
&= \frac{4}{|\mathcal{W}|}\int\left(\sum_{\mathbf{w}\in\mathcal{W}} 1_{A_\mathbf{w}}(\mathbf{x})\right)|g(\mathbf{x})|^2 d\mathbf{x}.
\end{aligned}$$

Since $A_\mathbf{w}$ are disjoint sets, $\sum_{\mathbf{w}\in\mathcal{W}} \mathbf{1}_{A_\mathbf{w}}(\mathbf{x}) \le 1$ for any $\mathbf{x}$, so the above is at most

$$\frac{4}{|\mathcal{W}|}\int |g(\mathbf{x})|^2 d\mathbf{x} \le 4\exp(-d/20)\,\|g\|^2. \tag{15}$$

We now turn to analyze the second expectation in Eq. (14), namely

$$\mathbb{E}_{\mathbf{w}\in\mathcal{W}}\left[\left\langle g, \mathbf{1}_{A_\mathbf{w}^C}\sum_{z\in\mathbb{Z}\setminus\{0\}} a_z\hat{\varphi}(\cdot - z\mathbf{w})\right\rangle^2\right].$$

We will upper bound the expression deterministically for any $\mathbf{w}$, so we may drop the expectation. Applying Cauchy-Schwartz, it is at most

$$\|g\|^2\cdot\left\|\mathbf{1}_{A_\mathbf{w}^C}\sum_{z\in\mathbb{Z}\setminus\{0\}} a_z\hat{\varphi}(\cdot - z\mathbf{w})\right\|^2 = \|g\|^2\left(\sum_{z_1,z_2\in\mathbb{Z}\setminus\{0\}} a_{z_1}\overline{a_{z_2}}\left\langle \mathbf{1}_{A_\mathbf{w}^C}\hat{\varphi}(\cdot - z_1\mathbf{w}), \hat{\varphi}(\cdot - z_2\mathbf{w})\right\rangle\right). \tag{16}$$

We now divide the terms in the sum above to two cases:

- If $z_1 = z_2$, then $\left\langle \mathbf{1}_{A_\mathbf{w}^C}\hat{\varphi}(\cdot - z_1\mathbf{w}), \hat{\varphi}(\cdot - z_2\mathbf{w})\right\rangle$ equals

$$\int \mathbf{1}_{A_\mathbf{w}^C}(\mathbf{x})|\hat{\varphi}(\mathbf{x} - z_1\mathbf{w})|^2 d\mathbf{x}. = \int \mathbf{1}_{A_\mathbf{w}^C}(\mathbf{x} + z_1\mathbf{w})|\hat{\varphi}(\mathbf{x})|^2 d\mathbf{x},$$

and by definition of $A_\mathbf{w}^C$ and the assumption $z_1 \ne 0$, we have $\mathbf{1}_{A_\mathbf{w}^C}(\mathbf{x} + z_1\mathbf{w}) = 1$ only if $\|\mathbf{x}\| \ge r$. Therefore, as φ is Fourier-concentrated, the above is at most

$$\int_{\mathbf{x}:\|\mathbf{x}\|\ge r} |\hat{\varphi}(\mathbf{x})|^2 d\mathbf{x} \le \epsilon^2(r)\cdot\|\hat{\varphi}\|^2 = \epsilon^2(r)\cdot\|\varphi\|^2 = \epsilon^2(r).$$

- If $z_1 \ne z_2$, then by Lemma 15,

$$\left\langle \mathbf{1}_{A_\mathbf{w}^C}\hat{\varphi}(\cdot - z_1\mathbf{w}), \hat{\varphi}(\cdot - z_2\mathbf{w})\right\rangle \le \langle|\hat{\varphi}(\cdot - z_1\mathbf{w})|, |\hat{\varphi}(\cdot - z_2\mathbf{w})|\rangle \le 2\epsilon(|z_1 - z_2|r).$$

Plugging these two cases back into Eq. (16), we get the upper bound

$$\|g\|^2\left(\sum_{z\in\mathbb{Z}\setminus\{0\}} |a_z|^2\epsilon^2(r) + 2\sum_{z_1\ne z_2\in\mathbb{Z}} |a_{z_1}|\cdot|a_{z_2}|\cdot\epsilon(|z_1 - z_2|r)\right).$$

Noting that $\sum_z |a_z|^2 \le 1$, and applying Lemma 16, the above is at most

$$\|g\|^2\left(\epsilon^2(r) + 4\sum_{n=1}^\infty \epsilon(nr)\right) \le 5\,\|g\|^2\sum_{n=1}^\infty \epsilon(nr),$$

where we used the fact that $\epsilon^2(r) \le \epsilon(r) \le \sum_{n=1}^\infty \epsilon(nr)$. Recalling this is an upper bound on the second expectation in Eq. (14), and that the first expectation is upper bounded as in Eq. (15), we get that Eq. (14) (and hence the expression in the lemma statement) is at most

$$10\,\|g\|^2\left(\exp(-d/20) + \sum_{n=1}^\infty \epsilon(nr)\right)$$

as required. ■

With these lemmas in hand, we can now turn to prove the theorem. We have that

$$\mathrm{Var}_{\mathbf{w}^\star}\left[\nabla F_{\mathbf{w}^\star}(\mathbf{v})\right] = \mathbb{E}_{\mathbf{w}^\star}\left\|\nabla F_{\mathbf{w}^\star}(\mathbf{v}) - \mathbb{E}_{\mathbf{w}^\star}[\nabla F_{\mathbf{w}^\star}(\mathbf{v})]\right\|^2 \le \mathbb{E}_{\mathbf{w}^\star}\left\|\nabla F_{\mathbf{w}^\star}(\mathbf{v}) - \mathbf{p}\right\|^2$$

for any vector $\mathbf{p}$ which is not dependent of $\mathbf{w}^\star$ (this $\mathbf{p}$ will be determined later). Recalling the definition of the objective function F, and letting $\mathbf{g}(\mathbf{x}) = (g_1(\mathbf{x}), g_2(\mathbf{x}), \ldots) = \frac{\partial}{\partial\mathbf{v}}f(\mathbf{v},\mathbf{x})$, the above equals

$$\begin{aligned}
&\mathbb{E}_{\mathbf{w}^\star}\left\|\mathbb{E}_{\mathbf{x}\sim\varphi^2}\left[\left(f(\mathbf{v},\mathbf{x}) - \psi(\mathbf{w}^{\star\top}\mathbf{x})\right)\mathbf{g}(\mathbf{x})\right] - \mathbf{p}\right\|^2 \\
&= \sum_i \mathbb{E}_{\mathbf{w}^\star}\left(\mathbb{E}_{\mathbf{x}\sim\varphi^2}\left[f(\mathbf{v},\mathbf{x})g_i(\mathbf{x}) - \psi(\mathbf{w}^{\star\top}\mathbf{x})g_i(\mathbf{x})\right] - p_i\right)^2 \\
&= \sum_i \mathbb{E}_{\mathbf{w}^\star}\left(\langle\varphi g_i, \varphi f(\mathbf{v},\cdot)\rangle - \langle\varphi g_i, \varphi\psi_{\mathbf{w}^\star}\rangle - p_i\right)^2
\end{aligned}$$

Let us now choose $\mathbf{p}$ so that $p_i = \langle\varphi g_i, \varphi f(\mathbf{v},\cdot)\rangle - \langle\varphi g_i, a_0\varphi\rangle$ (note that this choice is indeed independent of $\mathbf{w}^\star$). Plugging back and applying Lemma 17 (using the L^2 function $\widehat{\varphi g_i}$ for each i), we get

$$\begin{aligned}
\sum_i \mathbb{E}_{\mathbf{w}^\star}\left(\langle\varphi g_i, \varphi\psi_{\mathbf{w}^\star}\rangle - \langle\varphi g_i, a_0\varphi\rangle\right)^2 &= \sum_i \mathbb{E}_{\mathbf{w}^\star}\left(\left\langle\widehat{\varphi g_i}, \widehat{\varphi\psi_{\mathbf{w}^\star}}\right\rangle - \langle\widehat{\varphi g_i}, a_0\widehat{\varphi}\rangle\right)^2 \\
&\le 10\sum_i \|\widehat{\varphi g_i}\|^2\left(\exp(-d/20) + \sum_{n=1}^\infty \epsilon(nr)\right),
\end{aligned}$$

and since

$$\sum_{i=1}^{d} \|\varphi g_i\|^2 \;=\; \sum_{i=1}^{d} \int g_i^2(\mathbf{x})\varphi^2(\mathbf{x})d\mathbf{x} \;=\; \int \|\mathbf{g}(\mathbf{x})\|^2 \varphi^2(\mathbf{x}) \;=\; \mathbb{E}_{\mathbf{x}\sim\varphi^2} \|\mathbf{g}(\mathbf{x})\|^2 \;\leq\; G_{\mathbf{v}}^2,$$

the theorem follows.

5.4 Proof of Thm. 10

For any $\mathbf{w}^*$, we define the oracle $O_{F_{\mathbf{w}^*},\epsilon}$ as follows:

$$O_{F_{\mathbf{w}^*},\epsilon}(\mathbf{v}) = \begin{cases} \mathbb{E}_{\mathbf{w}^\star}[\nabla F_{\mathbf{w}^\star}(\mathbf{v})] & \text{if } |\nabla F_{\mathbf{w}^\star}(\mathbf{v}) - \mathbb{E}_{\mathbf{w}^\star}[\nabla F_{\mathbf{w}^\star}(\mathbf{v})]| \leq \varepsilon \\ \nabla F_{\mathbf{w}^\star}(\mathbf{v}) & \text{otherwise} \end{cases},$$

where the expectation is with respect to a uniform choice of $\mathbf{w}^*$ over vectors of norm $2r$. This is an approximate gradient oracle by definition.

Below, we will prove the theorem statement assuming that the algorithm A is deterministic: Namely, that there is some event holding with probability at least $1-p$ (over the choice of $\mathbf{w}^*$), such that the algorithm's output is some fixed vector $\bar{\mathbf{v}}$ independent of $\mathbf{w}^*$. This can be extended to randomized A, by considering any possible realization of A's random coin flips: Formally, let A_c be the deterministic algorithm, derived from A by fixing its random coin flips to some fixed sequence c. The deterministic proof implies that there is some event E_c and a fixed $\bar{\mathbf{v}}_c$ (independent of $\mathbf{w}^*$) such that $\Pr_{\mathbf{w}^*}(E_c) \geq 1-p$ and $\Pr_{\mathbf{w}^*}(A_C(F_{\mathbf{w}^*}) = \bar{\mathbf{v}}_c | E_c) = 1$ (where we use $A_c(F)$ as shorthand for A_C given the function F). But now, consider the joint probability space over $\mathbf{w}^*$ and random coin flips C, and define the event E as

$$\bigvee_c (C = c \;\wedge\; E_c)$$

(namely, that the event E_c occured for the corresponding realization c of the coin flips). Since this is a disjunction of disjoint events, we have that

$$\Pr(E) = \sum_c \Pr(C = c \wedge E_c) = \sum_c \Pr(C = c)\Pr(E_c | C = c) \geq \sum_c \Pr(C = c)\cdot(1-p) = 1-p,$$

and moreover, if E occurs, then the distribution of $A_C(F_{\mathbf{w}^*})$ is identical to $\bar{\mathbf{v}}_C$ (depending only on the random coin flips C, but not on $\mathbf{w}^*$), which is exactly what the theorem states.

We now return to the proof, assuming A is deterministic. It is enough to show that with probability at least $1-p$, the oracle will only return responses of the form $\mathbb{E}_{\mathbf{w}^\star}[\nabla F_{\mathbf{w}^\star}(\mathbf{v})]$, which is clearly independent of $\mathbf{w}^\star$. Since the algorithm's output can depend on $\mathbf{w}^\star$ only through the oracle responses, this will prove the required result.

The (deterministic) algorithm's first point $\mathbf{v}_1$ is fixed before receiving any information from the oracle, and is therefore independent of $\mathbf{w}^\star$. By Thm. 7, we have that $\mathrm{Var}_{\mathbf{w}^\star}(\nabla F_{\mathbf{w}^\star}(\mathbf{v}_1)) \leq \varepsilon^3$, which by Chebyshev's inequality, implies that

$$\Pr\left(|\nabla F_{\mathbf{w}^\star}(\mathbf{v}_1) - \mathbb{E}_{\mathbf{w}^\star}[\nabla F_{\mathbf{w}^\star}(\mathbf{v}_1)]| > \varepsilon\right) \;\leq\; \varepsilon,$$

where the probability is over the choice of $\mathbf{w}^\star$. Assuming the event above does not occur, the oracle returns $\mathbb{E}_{\mathbf{w}^\star}[\nabla F_{\mathbf{w}^\star}(\mathbf{v})]$, which does not depend on the actual choice of $\mathbf{w}^\star$. This

means that the next point $\mathbf{v}_2$ chosen by the algorithm is again sampled from some fixed distribution $\mathcal{D}_2$, which might depend on the algorithm's internal randomness, but not on $\mathbf{w}^\star$. Again by Thm. 7 and Chebyshev's inequality,

$$\Pr\left(|\nabla F_{\mathbf{w}^\star}(\mathbf{v}_2) - \mathbb{E}_{\mathbf{w}^\star}[\nabla F_{\mathbf{w}^\star}(\mathbf{v}_2)]| > \varepsilon\right) \;\leq\; \varepsilon.$$

Repeating this argument and applying a union bound, it follows that as long as the number of iterations T satisfies $T\varepsilon \leq p$ (or equivalently $T \leq p/\varepsilon$), the oracle reveals no information whatsoever on the choice of $\mathbf{w}^\star$ all point chosen by the algorithm (and hence also its output) are independent of $\mathbf{w}^\star$ as required.

Goodness-of-Fit Tests for Random Partitions via Symmetric Polynomials

Editor: Animashree Anandkumar

Abstract

We consider goodness-of-fit tests with i.i.d. samples generated from a categorical distribution $(p_1, ..., p_k)$. For a given $(q_1, ..., q_k)$, we test the null hypothesis whether $p_j = q_{\pi(j)}$ for some label permutation π. The uncertainty of label permutation implies that the null hypothesis is composite instead of being singular. In this paper, we construct a testing procedure using statistics that are defined as indefinite integrals of some symmetric polynomials. This method is aimed directly at the invariance of the problem, and avoids the need of matching the unknown labels. The asymptotic distribution of the testing statistic is shown to be chi-squared, and its power is proved to be nearly optimal under a local alternative hypothesis. Various degenerate structures of the null hypothesis are carefully analyzed in the paper. A two-sample version of the test is also studied.

Keywords: hypothesis testing, elementary symmetric polynomials, Lagrange interpolating polynomials, Vandermonde matrix, minimax optimality

1. Introduction

Consider a categorical distribution parameterized by $(p_1, ..., p_k)$. We have i.i.d. observations $X_1, ..., X_n$ that follow $\mathbb{P}(X_i = j) = p_j$. A classical goodness-of-fit testing problem is to test whether or not $p_j = q_j$ for $j \in [k]$, where $q_1, ..., q_k$ are some given numbers. One solution is given by the famous Pearson's chi-squared test (**?**). In this traditional formulation, it is assumed that the labels $(1, ..., k)$ of $(p_1, ..., p_k)$ correspond to those of $(q_1, ..., q_k)$, so that p_j can be directly compared with q_j for each $j \in [k]$. However, this assumption is not satisfied in some interesting applications. We give three examples below:

1. *Clustering models.* In a typical probabilistic setting of cluster analysis, the event $\{X_i = j\}$ means that the ith item belongs to the jth cluster, and p_j is the population frequency of the jth cluster. Here, the cluster label j does not carry any real meaning, and is present only for notational convenience. In a cluster analysis setting, the underlying object of interest is the partition of the n items instead of the cluster labels. In other words, what really matters to statisticians is the value of $\mathbb{I}\{X_i = X_{i'}\}$ (the indicator function of the event) for every pair $i \neq i'$. Therefore, a clustering model with population frequency $(p_1, ..., p_k)$ is equivalent to that with $(p_{\pi(1)}, ..., p_{\pi(k)})$ with some permutation π.

2. *Word frequency analysis.* Consider two text corpora of two different languages. The word frequencies are denoted by $(p_1, ..., p_k)$ and $(q_1, ..., q_k)$, respectively. An interesting problem in comparative linguistics is to study whether the two languages share common features by comparing $(p_1, ..., p_k)$ with $(q_1, ..., q_k)$. For languages that are not necessarily etymologically related, the correspondence between words of the two languages are usually unclear or unknown. Therefore, a reasonable comparison of word frequencies between two languages can be conducted through comparing $(p_1, ..., p_k)$ with a reordered vector $(q_{\pi(1)}, ..., q_{\pi(k)})$ for some permutation π.

3. *Simple substitution cipher.* In cryptography, a simple substitution cypher changes every character in a message to a different character systematically. Let $\{1, ..., k\}$ be a finite alphabet of characters, and $(Y_1, ..., Y_n)$ denote a message to be encrypted. A simple substitution cypher is defined by a permutation σ on the alphabet $\{1, ..., k\}$. This results in the encrypted message $(X_1, ..., X_n)$ with $X_i = \sigma(Y_i)$ for each $i \in [n]$. Suppose each Y_i is independently distributed by $\mathbb{P}(Y_i = j) = q_j$. Then, each X_i independently follows $\mathbb{P}(X_i = j) = p_j$, where $p_j = q_{\pi(j)}$ with $\pi = \sigma^{-1}$. If only the encrypted message is observed, inference of the probability vector $(q_1, ..., q_k)$ is only possible up to an unknown permutation.

Inspired by the above examples, in this paper, we consider a twist of the traditional formulation of the hypothesis testing problem. We consider the following null hypothesis:

$$H_0 : p_j = q_{\pi(j)}, \quad \text{for some } \pi \in S_k, \tag{1}$$

where $(q_1, ..., q_k)$ is a known vector and S_k is the set of all permutations of $[k]$. This null hypothesis implies that the labels $1, ..., k$ do not have any meaning. For example, the vectors $\left(\frac{1}{2}, \frac{1}{4}, \frac{1}{4}\right)$ and $\left(\frac{1}{4}, \frac{1}{4}, \frac{1}{2}\right)$ are considered equivalent. Given i.i.d. observations $X_1, ..., X_n$, one can immediately define summary statistics $n_j = \sum_{i=1}^n \mathbb{I}\{X_i = j\}$ for $j \in [k]$, which are sufficient. Since the labels of $n_1, ..., n_k$ are irrelevant, these sufficient statistics result in a random partition of the integer n. There are two ways to code such a random partition (**?**): (i) by the order statistics $n_{(1)} \geq n_{(2)} \geq ... \geq n_{(k)}$; (ii) by the numbers of terms of various sizes $m_l = \sum_{j=1}^k \mathbb{I}\{n_j = l\}$ for $l \in [n]$. It is easy to see that $\sum_{l=1}^n m_l = k$ and $\sum_{l=1}^n l m_l = n$. These two representations are equivalent because one can be derived from the other.

Inference of the probability vector $(p_1, ..., p_k)$ up to a label permutation using random partitions have been extensively studied in Bayesian statistics. The problem serves as a foundation for random partition models, cluster analysis and species distribution modeling. Priors that induce various exchangeable properties have been developed for the equivalent class $\{(p_{\pi(1)}, ..., p_{\pi(k)}) : \pi \in S_k\}$. See **????????** and references therein. In this paper, we take a frequentist point of view that is complementary to the Bayesian literature, and we do not treat the equivalent class $\{(p_{\pi(1)}, ..., p_{\pi(k)}) : \pi \in S_k\}$ as random. The theory of hypothesis testing is developed within a frequentist decision-theoretic framework.

With the unknown permutation π in the null hypothesis, the classical chi-squared test by Pearson does not work anymore. Our idea of the test is based on the following class of statistics:

$$\left\{\sum_{j=1}^k f(n_j) : f \in \mathcal{F}\right\}, \tag{2}$$

where $\mathcal{F}$ is the class of all measurable functions. For each $f \in \mathcal{F}$, the distribution of $\sum_{j=1}^k f(n_j)$ is identical for $p_j = q_{\pi(j)}$ with any $\pi \in S_k$. This is because (2) is a class of statistics that are invariant to the label permutation π. That is, $\sum_{j=1}^k f(n_j) = \sum_{j=1}^k f(n_{\pi(j)})$ for any $\pi \in S_k$. Moreover, it is easy to see that these statistics are all functions of the random partition because $\sum_{j=1}^k f(n_j) = \sum_{j=1}^k f(n_{(j)})$.

Choosing an appropriate class of f's is important. We propose to use k functions $f_1, ..., f_k$ that satisfy the *identifiability* and the *orthogonality* conditions. The identifiability condition requires that the k equations $\sum_{j=1}^k f_l(p_j) = \sum_{j=1}^k f_l(q_j)$ for $l \in [k]$ hold if and only if $p_j = q_{\pi(j)}$ for some $\pi \in S_k$. With this condition, testing whether the null hypothesis holds is equivalent to testing whether the k equations hold. The orthogonality condition requires that the k vectors $(f_l'(q_1), ..., f_l'(q_k))^T$ for $l \in [k]$ are orthogonal to each other. Intuitively speaking, this condition ensures that the information carried by the k statistics $\sum_{j=1}^k f_l(n_j)$ for $l \in [k]$ are mutually exclusive, which is a key ingredient that leads to optimal power under a local alternative.

In this paper, we choose $f_1, ..., f_k$ to be indefinite integrals of Lagrange interpolation polynomials. The choice of these polynomials satisfies the above-mentioned *identifiability* and *orthogonality* conditions. We prove that the testing statistic constructed from the k functions is asymptotically distributed by a chi-squared distribution. Moreover, we show that the power of the test is nearly optimal under a local alternative hypothesis within a decision-theoretic framework.

Our approach that uses symmetric polynomials bypasses the problem of unknown permutation π. It falls into the general umbrella of methods of moments, which are commonly used for problems that impose equivalence relations to the signals through the action of a group of transformations. For example, various method-of-moments techniques have been applied to problems including Gaussian mixture models (**?**), mixed membership models (**?**), dictionary learning (**?**), topic models (**??**) and multi-reference alignment (**?**). Recently, this idea was also applied to the problems of network testing by **??**, where the group action there is row and column permutations of the adjacency matrix of a random network.

The rest of the paper is organized as follows. In Section 2, we introduce definitions of some useful symmetric polynomials and the related Vandermonde matrix. Before getting into the testing problem for random partitions, we first solve an easier version of the problem with Gaussian observations in Section 3 and Section 4. The test using random partitions is given in Section 5. The optimality of our test is discussed in Section 6. In Section 8, we consider a two-sample version of the problem. Numerical experiments of the proposed testing procedures are given in Section 7. Finally, Section 9 is a discussion section, where we briefly analyze the property of the test on the boundary of degeneracy and discuss some open problems. The proofs of all results in the paper are given in Section 10.

We close this section by introducing the notation used in the paper. For $a, b \in \mathbb{R}$, let $a \vee b = \max(a, b)$ and $a \wedge b = \min(a, b)$. For an integer m, $[m]$ denotes the set $\{1, 2, ..., m\}$. Given a set S, $|S|$ denotes its cardinality, and $\mathbb{I}_S$ is the associated indicator function. We use $\mathbb{P}$ and $\mathbb{E}$ to denote generic probability and expectation whose distribution is determined from the context. The noncentral chi-squared distribution with degrees of freedom k and noncentrality parameter δ^2 is denoted as χ^2_{k,δ^2}. We will also use χ^2_{k,δ^2} for the associated random variables.

2. Symmetric Polynomials and Vandermonde Matrix

Define a polynomial with roots $\mu_1, ..., \mu_k \in \mathbb{R}$ by

$$f(t) = \prod_{j=1}^k (t - \mu_j).$$

It can be organized as

$$f(t) = \sum_{j=0}^k (-1)^{k-j} e_{k-j}(\mu_1, ..., \mu_k) t^j. \tag{3}$$

The coefficient before t^j is $(-1)^{k-j} e_{k-j}(\mu_1, ..., \mu_k)$, and $e_{k-j}(\mu_1, ..., \mu_k)$ is called the elementary symmetric polynomial. For $l \in \{1, ..., k\}$, the lth elementary symmetric polynomial is

$$e_l(\mu_1, ..., \mu_k) = \sum_{1 \le j_1 < \cdots < j_l \le k} \mu_{j_1} \cdots \mu_{j_l}.$$

When $l = 0$, we use the convention $e_0(\mu_1, ..., \mu_k) = 1$.

The elementary symmetric polynomials can be efficiently calculated through Newton's identities. Define the lth power sum

$$p_l(\mu_1, ..., \mu_k) = \sum_{j=1}^k \mu_j^l. \tag{4}$$

Newton's identities can be summarized through the formula

$$e_l(\mu_1, ..., \mu_k) = \frac{1}{l} \sum_{j=1}^l (-1)^{j-1} e_{l-j}(\mu_1, ..., \mu_k) p_j(\mu_1, ..., \mu_k), \tag{5}$$

for $l = 1, ..., k$.

Finally, we introduce an interesting relation between elementary symmetric polynomials and Vandermonde matrix (see Chapter 0.9.11 of **?**). Given $\mu_1, ..., \mu_k$ that take k distinct values, define a matrix $E(\mu_1, ..., \mu_k) \in \mathbb{R}^{k \times k}$, whose (j, l)th entry is

$$(-1)^{j-1} \frac{e_{k-j}(\mu_1, ..., \mu_{l-1}, \mu_{l+1}, ..., \mu_k)}{\prod_{j \in [k] \setminus \{l\}} (\mu_j - \mu_l)}. \tag{6}$$

The Vandermonde matrix $V(\mu_1, ..., \mu_k) \in \mathbb{R}^{k \times k}$ has μ_j^{l-1} on its (j, l)th entry. Interestingly, we have

$$E(\mu_1, ..., \mu_k) V(\mu_1, ..., \mu_k) = V(\mu_1, ..., \mu_k) E(\mu_1, ..., \mu_k) = I_k. \tag{7}$$

This relation implies a formula for the determinant of $E(\mu_1, ..., \mu_k)$:

$$\det(E(\mu_1, ..., \mu_k)) = \frac{1}{\det(V(\mu_1, ..., \mu_k))} = \frac{1}{\prod_{1 \le j < l \le k} (\mu_l - \mu_j)}. \tag{8}$$

3. The Gaussian Case

Before working with categorical distributions, we first study data generated from a Gaussian distribution. This allows us to grasp the mathematical essence of the problem without dealing with the dependence and heteroskedasticity of categorical distributions. We consider a Gaussian random vector $X \sim N(\theta, n^{-1}I_k)$. The mean vector $\theta \in \mathbb{R}^k$ consists of k numbers $\theta_1, ..., \theta_k$. Throughout the paper, we assume $k \geq 2$ and it is a constant that does not vary with n. We would like to test whether the k numbers are identical to $\mu_1, ..., \mu_k$ after some permutation of labels. To be rigorous, introduce a distance between two vectors θ and μ,

$$\ell(\theta, \mu) = \min_{\pi \in S_k} \sqrt{\sum_{j=1}^{k} (\theta_j - \mu_{\pi(j)})^2},$$

where S_k is the set of all permutations on $[k]$. Then, the hypothesis testing problem is

$$H_0 : \ell(\theta, \mu) = 0, \quad H_1 : \ell(\theta, \mu) > 0.$$

Throughout this section, we assume $\min_{j \neq l} |\mu_j - \mu_l| > 0$. The case $\min_{j \neq l} |\mu_j - \mu_l| = 0$ is degenerate and will be studied in the next section.

We use the notation μ_π to denote a k-dimensional vector whose jth entry is $\mu_{\pi(j)}$. Then, the null hypothesis can also be written as

$$\theta \in \{\mu_\pi : \pi \in S_k\}.$$

In other words, there is an equivalent class of probability distributions $\{N(\mu_\pi, n^{-1}I_k) : \pi \in S_k\}$. Thus, it is natural to consider summary statistics whose distributions are invariant under this equivalent class. This leads to the class of summary statistics

$$\left\{ \sum_{j=1}^{k} f(X_j) : f \in \mathcal{F} \right\},$$

where $\mathcal{F}$ is the set of all measurable functions. For $X \sim N(\theta, n^{-1}I_k)$, it is easy to see that the distribution of $\sum_{j=1}^{k} f(X_j)$ only depends on the equivalent class $\{N(\theta_k, n^{-1}I_k) : \pi \in S_k\}$. This fact holds for an arbitrary $f \in \mathcal{F}$.

Since the degree of freedom of the null hypothesis is k, our strategy is to construct a testing procedure based on $\left\{\sum_{j=1}^{k} f_l(X_j) : l \in [k]\right\}$. In other words, we need to choose the k functions $f_1(\cdot), ..., f_k(\cdot)$. The following two conditions are proposed:

1. **Identifiability**. Assume $\min_{j \neq l} |\mu_j - \mu_l| > 0$. Then the equations

$$\sum_{j=1}^{k} f_l(\theta_j) = \sum_{j=1}^{k} f_l(\mu_j), \quad l = 1, ..., k, \tag{9}$$

hold, if and only if $\ell(\theta, \mu) = 0$.

2. **Orthogonality**. Assume $\min_{j \neq l} |\mu_j - \mu_l| > 0$. Then for any $l, h \in [h]$,

$$\sum_{j=1}^{k} f_l'(\mu_j) f_h'(\mu_j) = \begin{cases} 1, & l = h, \\ 0, & l \neq h. \end{cases}$$

We give a few remarks regarding the two conditions. The first condition of identifiability is natural. It is required by the structure of the problem, and is necessary for the test to have power under the alternative hypothesis. The second condition implies information independence among the k summary statistics.

The k functions we propose to satisfy the two conditions are

$$f_l(t) = \frac{\int \prod_{j \in [k] \setminus \{l\}} (t - \mu_j)}{\prod_{j \in [k] \setminus \{l\}} (\mu_l - \mu_j)}, \quad l = 1, ..., k. \tag{10}$$

The derivatives $f_l'(t) = \frac{\prod_{j \in [k] \setminus \{l\}} (t - \mu_j)}{\prod_{j \in [k] \setminus \{l\}} (\mu_l - \mu_j)}$ are called Lagrange interpolating polynomials, and it is easy to check that the second condition of orthogonality holds. Now we check the first condition of identifiability. By (3), we have

$$\prod_{j \in [k] \setminus \{l\}} (t - \mu_j) = \sum_{j=0}^{k-1} (-1)^{k-1-j} e_{k-1-j}(\mu_1, ..., \mu_{l-1}, \mu_{l+1}, ..., \mu_k) t^j.$$

This implies

$$f_l(t) = \sum_{j=1}^{k} (-1)^{k-j} \frac{e_{k-j}(\mu_1, ..., \mu_{l-1}, \mu_{l+1}, ..., \mu_k)}{\prod_{j \in [k] \setminus \{l\}} (\mu_l - \mu_j)} \frac{t^j}{j}. \tag{11}$$

Therefore, the equations (9) can be written as

$$\sum_{j=1}^{k} (-1)^{k-j} \frac{e_{k-j}(\mu_1, ..., \mu_{l-1}, \mu_{l+1}, ..., \mu_k)}{\prod_{j \in [k] \setminus \{l\}} (\mu_l - \mu_j)} \Delta_j = 0, \quad l = 1, ..., k.$$

where $\Delta_j = \frac{1}{j} \sum_{h=1}^{k} \theta_h^j - \frac{1}{j} \sum_{h=1}^{k} \mu_h^j$. In view of the definition of the matrix $E(\mu_1, ..., \mu_k)$ in (6), we have a compact organization of the equations

$$E(\mu_1, ..., \mu_k)\Delta = 0.$$

When the assumption $\min_{j \neq l} |\mu_j - \mu_l| > 0$ holds, the matrix $E(\mu_1, ..., \mu_k)$ has full rank and is invertible according to (7) and (8), which immediately implies $\Delta = 0$. Equivalently,

$$p_j(\theta_1, ..., \theta_k) = p_j(\mu_1, ..., \mu_k), \quad j = 1, ..., k.$$

The definition of the power sum $p_j(\cdots)$ is given in (4). By Newton's identities (5), we have

$$e_j(\theta_1, ..., \theta_k) = e_j(\mu_1, ..., \mu_k), \quad j = 1, ..., k.$$

Finally, the relation between elementary symmetric polynomials and roots in (3) implies that $\prod_{j=1}^{k} (t - \theta_j)$ and $\prod_{j=1}^{k} (t - \mu_j)$ are the same polynomials. Hence, we obtain the conclusion $\ell(\theta, \mu) = 0$. The other direction trivially holds. This verifies the condition of identifiability for the functions $f_1, ..., f_k$.

Remark 1 *The computation of the statistic $\sum_{j=1}^k f_l(X_j)$ for each $l \in [k]$ is straightforward, thanks to the formula (11). According to (11), we can write*

$$\sum_{j=1}^k f_l(X_j) = \sum_{i=1}^k (-1)^{k-i} \frac{e_{k-i}(\mu_1, ..., \mu_{l-1}, \mu_{l+1}, ..., \mu_k)}{\prod_{i \in [k] \setminus \{l\}} (\mu_l - \mu_i)} \frac{\sum_{j=1}^k X_j^i}{i}.$$

In other words, $\sum_{j=1}^k f_l(X_j)$ is a linear combination of empirical moments $\{\sum_{j=1}^k X_j^i : i \in [k]\}$. To compute the elementary symmetric polynomial $e_{k-i}(\mu_1, ..., \mu_{l-1}, \mu_{l+1}, ..., \mu_k)$ in the coefficient, one can recursively apply Newton's identities (5). The overall complexity of computing $\sum_{j=1}^k f_l(X_j)$ requires $O(k^2)$ products.

We propose the testing statistic

$$T = n \sum_{l=1}^k \left(\sum_{j=1}^k f_l(X_j) - \sum_{j=1}^k f_l(\mu_j) \right)^2. \tag{12}$$

When the value of T is large, the equations (9) are unlikely to hold. Thus, the null hypothesis will be rejected when T exceeds some threshold. The asymptotic distribution of T can be derived under the null hypothesis.

Condition A 1 *Assume $\mu_1, ..., \mu_k$ are k different numbers that do not vary with n.*

Some possible extensions beyond Condition A will be discussed in Section 6.

Theorem 2 *Under Condition A, $T \rightsquigarrow \chi_k^2$ as $n \to \infty$ under the null hypothesis.*

For a chi-squared random variable χ_k^2, define a number $\chi_k^2(\alpha)$ such that

$$\mathbb{P}\left(\chi_k^2 \le \chi_k^2(\alpha)\right) = 1 - \alpha.$$

Then, a testing function is

$$\phi_\alpha = \mathbb{I}\left\{T > \chi_k^2(\alpha)\right\}.$$

By Theorem 2, its asymptotic Type-1 error is α. The next result characterizes the regime where the asymptotic power of the test tends to 1. It is a consequence of the fact that the functions $f_1, ..., f_k$ satisfy the identifiability condition.

Theorem 3 *Under Condition A, the following two statements are equivalent*

1. $\lim_{n\to\infty} \sqrt{n}\ell(\theta, \mu) = \infty$;
2. $\lim_{n\to\infty} \mathbb{P}_\theta\left(T > \chi_k^2(\alpha)\right) = 1$, *for any constant* $\alpha \in (0, 1)$,

where the probability $\mathbb{P}_\theta$ denotes $N(\theta, n^{-1} I_k)$.

Theorem 3 shows that $\lim_{n\to\infty} \sqrt{n}\ell(\theta, \mu) = \infty$ is the necessary and sufficient condition for the asymptotic power of the test to be one. For a local alternative such that $\sqrt{n}\ell(\theta, \mu) = O(1)$, the test will have a non-trivial power between 0 and 1. This contiguous regime will be studied in Section 6.

4. Degeneracy of the Problem

In the last section, we construct a chi-squared test under the assumption that $\min_{j\neq l} |\mu_j - \mu_l| > 0$. When $\min_{j\neq l} |\mu_j - \mu_l| = 0$, the identifiability condition of the functions $f_1, ..., f_k$ defined in (10) does not hold. We need to construct summary statistics based on new functions in this degenerate case.

Assume there is a partition of the set $[k]$. That is, for some $d \le k$, we have $\cup_{h=1}^d \mathcal{C}_h = [k]$, and for any $g, h \in [d]$ such that $g \neq h$, $\mathcal{C}_g \cap \mathcal{C}_h = \varnothing$. We assume

$$\mu_j = \nu_h, \text{ for all } j \in \mathcal{C}_h.$$

Moreover, we require that $\min_{g\neq h} |\nu_g - \nu_h| > 0$. To motivate the appropriate functions that we will propose, we consider two extreme cases. The first case is when $d = k$. Then, the condition $\min_{j\neq l} |\mu_j - \mu_l| > 0$ still holds, and we can still use the functions $f_1, ..., f_k$ defined in (10). The second case is when $d = 1$. This implies $\mu_1 = \mu_2 = \cdots = \mu_k = \nu_1$. Then, we can use the function

$$g(t) = (t - \nu_1)^2. \tag{13}$$

This leads to an obvious chi-squared statistic $T_g = n \sum_{j=1}^k g(X_j)$.

For a general d, we need to borrow ideas from both extreme cases. We define functions $f_1, ..., f_d$ that are modifications from (10). Define

$$f_h(t) = \frac{\int \prod_{g\in[d]\setminus\{h\}} (t - \nu_g)}{\prod_{g\in[d]\setminus\{h\}} (\nu_h - \nu_g)}, \quad h = 1, ..., d. \tag{14}$$

We also need another function to ensure identifiability. Define

$$g(t) = \frac{\prod_{g=1}^d (t - \nu_g)^2}{\sum_{g=1}^d \prod_{h\in[d]\setminus\{g\}} (t - \nu_h)^2}. \tag{15}$$

The function $g(t)$ is well defined when $d \ge 2$. When $d = 1$, we use the definition given by (13). The following proposition shows that the functions $f_1, ..., f_d, g$ together ensure identifiability via the equations

$$\sum_{j=1}^k f_h(\theta_j) = \sum_{j=1}^k f_h(\mu_j), \quad h = 1, ..., d, \tag{16}$$

and

$$\sum_{j=1}^k g(\theta_j) = \sum_{j=1}^k g(\mu_j). \tag{17}$$

Proposition 4 *Assume $\min_{g\neq h} |\nu_g - \nu_h| > 0$. We have the following conclusions.*

1. *When $d = 1$, the equation (17) holds if and only if $\ell(\theta, \mu) = 0$.*
2. *When $2 \le d \le k - 1$, the equations (16) and (17) hold if and only if $\ell(\theta, \mu) = 0$.*
3. *When $d = k$, the equation (16) holds if and only if $\ell(\theta, \mu) = 0$.*

The first conclusion of the above proposition is obvious. The last conclusion is proved in Section 3. Here we show the second conclusion. Using a similar argument that we used in Section 3, the equations (16) can be written as

$$E(\nu_1, ..., \nu_d)\Delta = 0,$$

where $\Delta \in \mathbb{R}^d$ is a vector with the hth entry being $\Delta_h = \frac{1}{h}\sum_{j=1}^k \theta_j^h - \frac{1}{h}\sum_{j=1}^k \mu_j^h$. In other words, we have

$$\sum_{j=1}^k \theta_j^h = \sum_{j=1}^k \mu_j^h, \quad \text{for } h = 1, ..., d.$$

The equation (17) immediately implies that each θ_j only takes value in the set $\{\nu_1, ..., \nu_d\}$. Therefore, there exists a partition $[k] = \cup_{h=1}^d \mathcal{D}_h$ such that $\mathcal{D}_g \cap \mathcal{D}_h = \varnothing$ for all $g \neq h$, and $\theta_j = \nu_g$ for all $j \in \mathcal{D}_g$. This leads to

$$\sum_{j=1}^k \theta_j^h = \sum_{g=1}^d |\mathcal{D}_g| \nu_g^h.$$

We also have

$$\sum_{j=1}^k \mu_j^h = \sum_{g=1}^d |\mathcal{C}_g| \nu_g^h.$$

Hence, we obtain the equations

$$\sum_{g=1}^d |\mathcal{D}_g| \nu_g^h = \sum_{g=1}^d |\mathcal{C}_g| \nu_g^h, \quad \text{for } h = 0, 1, ..., d-1.$$

The equation for $h = 0$ holds because $\sum_{g=1}^d |\mathcal{D}_g| = \sum_{g=1}^d |\mathcal{C}_g| = k$. Again, with matrix notation, these equations can be written as $V(\nu_1, ..., \nu_d)r = 0$, where $V(\nu_1, ..., \nu_d)$ is the Vandermonde matrix, and $r \in \mathbb{R}^d$ is a vector with its gth entry being $r_g = |\mathcal{D}_g| - |\mathcal{C}_g|$. When $\min_{g \neq h} |\nu_g - \nu_h| > 0$ holds, $V(\nu_1, ..., \nu_d)$ has full rank, which leads to $|\mathcal{D}_g| = |\mathcal{C}_g|$ for all $g = 1, ..., d$. Finally, we can conclude that $\ell(\theta, \mu) = 0$. The other direction is obvious.

The above proof actually shows that the function f_d is not needed when $d \leq k - 1$. The equation with $h = d$ in (16) is redundant for identifiability. The second conclusion of Proposition 4 would still hold without it. However, we still keep it for the convenience of analyzing the proposed test.

We propose two testing statistics. Define

$$T_f = n \sum_{h=1}^d \frac{1}{|\mathcal{C}_h|} \left(\sum_{j=1}^k f_h(X_j) - \sum_{j=1}^k f_h(\mu_j) \right)^2, \tag{18}$$

and

$$T_g = n \sum_{j=1}^k g(X_j). \tag{19}$$

We present asymptotic distributions of T_f and T_g. Since the case $d = 1$ is trivial, we only present results for $d \geq 2$.

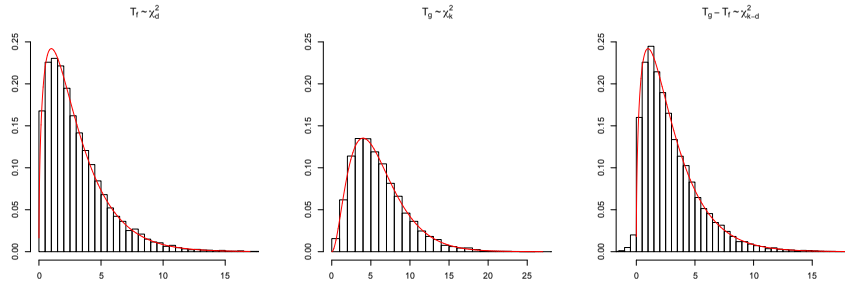

Figure 1: histograms of testing statistics with $\mu = (1, 3, 3, 3, 5, 5)$, $k = 6$, $d = 3$ and $n = 200$.

Condition B 1 *Assume $\mu_1, ..., \mu_k$ are k numbers that do not vary with n. Moreover, $\mu_j = \nu_h$ for all $j \in \mathcal{C}_h$, $h \in [d]$.*

Theorem 5 *Under Condition B, $T_f \rightsquigarrow \chi^2_d$, $T_g \rightsquigarrow \chi^2_k$ and $T_g - T_f \rightsquigarrow \chi^2_{k-d}$ as $n \to \infty$ under the null hypothesis.*

Interestingly, Theorem 5 exhibits an analysis-of-variance type of result. The three statistics all exhibit asymptotic chi-square distributions (see Figure 1). The statistic T_g dominates T_f in probability under the null hypothesis. An analogous analysis-of-variance type of result continues to hold under a local alternative (see Theorem 23). We define the testing function as

$$\phi_\alpha = \mathbb{I}\{T_f > \chi^2_d(\alpha)\} \vee \mathbb{I}\{T_g > \chi^2_k(\alpha)\},$$

where we use the notation $a \vee b$ for $\max(a, b)$. Since under the null hypothesis, $T_g \geq T_f$ in probability, the asymptotic Type-1 error is just the probability of the event $\{T_g > \chi^2_k(\alpha)\}$, which tends to α as $n \to \infty$. In fact, as we will show later in Section 6, the behavior of the testing function mainly depends on the statistic T_g in the contiguous neighborhood of the null hypothesis. The statistic T_f helps to ensure that the testing function has asymptotic power 1 as soon as $\sqrt{n}\ell(\theta, \mu) \to \infty$. Without T_f, the identifiability property of the test established in Proposition 4 would break down, and the test would lose power outside of the contiguous neighborhood of the null hypothesis. The next theorem rigorously establishes this fact.

Theorem 6 *Under Condition B, the following two statements are equivalent*

1. $\lim_{n\to\infty} \sqrt{n}\ell(\theta, \mu) = \infty$;
2. $\lim_{n\to\infty} \mathbb{P}_\theta \left(T_f > \chi^2_d(\alpha) \text{ or } T_g > \chi^2_k(\alpha) \right) = 1$, *for any constant* $\alpha \in (0, 1)$,

where the probability $\mathbb{P}_\theta$ denotes $N(\theta, n^{-1}I_k)$.

5. The Case of Categorical Distribution

Now we are ready to transfer our wisdom from Gaussian distribution to categorical distribution. Consider i.i.d. observations $X_1, ..., X_n$ from a categorical distribution $(p_1, ..., p_k)$. To be specific, for each $i \in [n]$ and $j \in [k]$, $\mathbb{P}(X_i = j) = p_j$. Throughout this section, we use $\mathbb{P}_p$ to denote the probability distribution of $X_1, ..., X_n$. We would like to test whether the k numbers $p_1, ..., p_k$ are identical to some given $q_1, ...q_k$ after a permutation of labels. Introduce a distance between the two vectors p and q,

$$\ell(p, q) = \min_{\pi \in S_k} 2\sqrt{\sum_{j=1}^{k} (\sqrt{p_j} - \sqrt{q_{\pi(j)}})^2}. \tag{20}$$

The hypothesis testing problem is

$$H_0 : \ell(p, q) = 0, \quad H_1 : \ell(p, q) > 0.$$

For each $j \in [k]$, define

$$\hat{p}_j = \frac{1}{n} \sum_{i=1}^{n} \mathbb{I}\{X_i = j\}.$$

Pearson's chi-squared test (**?**) is defined as $\chi^2 = n \sum_{j=1}^{k} \frac{(\hat{p}_j - q_j)^2}{q_j}$, which is asymptotically distributed as χ^2_{k-1} when $p = q$. However, this test only works when the null hypothesis is simple. Here, our null hypothesis is composite, and there is uncertainty from the underlying permutation of the labels.

Our idea is to borrow the solution for the Gaussian case in Section 3. Intuitively, the vector $(\hat{p}_1, ..., \hat{p}_k)$ is asymptotically Gaussian after some normalization. However, the normalization step brings extra difficulty for this problem. In the definition of Pearson's chi-squared test, each $\hat{p}_j$ is normalized by $\sqrt{q_j}$ because of the heteroskedasticity and dependence structure of the vector $(\hat{p}_1, ..., \hat{p}_k)$. This normalization does not work in our setting because the underlying label is not given, and we do not know which $\sqrt{q_j}$ to use. To overcome this issue, we adopt the technique of variance-stabilizing transformation (**?**), and directly work with $\sqrt{\hat{p}_j}$.

This leads to a modification of the definition of the function $f_l(\cdot)$, and the new definition is given by

$$f_l(t) = \frac{\int \prod_{j \in [k] \setminus \{l\}} (\sqrt{t} - \sqrt{q_j})}{\prod_{j \in [k] \setminus \{l\}} (\sqrt{q_l} - \sqrt{q_j})}, \quad l = 1, ..., k. \tag{21}$$

The testing statistic is

$$T = 4n \sum_{l=1}^{k} \left(\sum_{j=1}^{k} f_l(\hat{p}_j) - \sum_{j=1}^{k} f_l(q_j) \right)^2. \tag{22}$$

Similar to the discussion in Section 3, when the value of T is large, the equations (9) are unlikely to hold. Thus, the null hypothesis will be rejected when T exceeds some threshold. The asymptotic distribution of T can be derived under the null hypothesis.

Condition C 1 *Assume $q_1, ..., q_k$ are k different numbers in $(0, 1)$ that do not vary with n.*

Some possible extensions beyond Condition C will be discussed in Section 6.

Theorem 7 *Under Condition C, $T \rightsquigarrow \chi^2_{k-1}$ as $n \to \infty$ under the null hypothesis.*

For a chi-squared random variable χ^2_{k-1}, define a number $\chi^2_{k-1}(\alpha)$ such that

$$\mathbb{P}\left(\chi^2_{k-1} \le \chi^2_{k-1}(\alpha)\right) = 1 - \alpha.$$

Then, a testing function is

$$\phi_\alpha = \mathbb{I}\left\{T > \chi^2_{k-1}(\alpha)\right\}.$$

By Theorem 7, its asymptotic Type-1 error is α. The next result characterizes the regime where the asymptotic power of the test tends to 1. It is a consequence of the fact that the functions $f_1, ..., f_k$ satisfy the identifiability condition, though with slightly different definitions.

Theorem 8 *Under Condition C, the following two statements are equivalent*

1. $\lim_{n\to\infty} \sqrt{n}\ell(p, q) = \infty$;
2. $\lim_{n\to\infty} \mathbb{P}_p\left(T > \chi^2_{k-1}(\alpha)\right) = 1$, *for any constant* $\alpha \in (0, 1)$,

where the probability $\mathbb{P}_p$ is defined in the beginning of this section.

Next, we study the degenerate case where the k numbers $q_1, ..., q_k$ only take d values. There is a partition $[k] = \cup_{h=1}^{d} \mathcal{C}_h$ such that for any $g \neq h$, $\mathcal{C}_g \cap \mathcal{C}_h = \varnothing$. We assume the following condition.

Condition D 1 *Asume $q_1, ..., q_k$ are k numbers in $(0, 1)$ that do not vary with n. Moreover, $q_j = r_h$ for all $j \in \mathcal{C}_h$, $h \in [d]$.*

The approach we take is similar to that in Section 4, assisted with the technique of variance-stabilizing transformation. Define

$$f_h(t) = \frac{\int \prod_{g \in [d] \setminus \{h\}} (\sqrt{t} - \sqrt{r_g})}{\prod_{g \in [d] \setminus \{h\}} (\sqrt{r_h} - \sqrt{r_g})}, \quad h = 1, ..., d, \tag{23}$$

and

$$g(t) = \frac{\prod_{g=1}^{d} (\sqrt{t} - \sqrt{r_g})^2}{\sum_{g=1}^{d} \prod_{h \in [d] \setminus \{g\}} (\sqrt{t} - \sqrt{r_h})^2}. \tag{24}$$

Then, define the testing statistics

$$T_f = 4n \sum_{h=1}^{d} \frac{1}{|\mathcal{C}_h|} \left(\sum_{j=1}^{k} f_h(\hat{p}_j) - \sum_{j=1}^{k} f_h(q_j) \right)^2, \tag{25}$$

and

$$T_g = 4n \sum_{j=1}^{k} g(\hat{p}_j). \tag{26}$$

The properties of T_f and T_g are given by the following theorem. Again, the case $d = 1$ is trivial, and we only present results for $d \ge 2$.

Theorem 9 *Under Condition D, $T_g \rightsquigarrow \chi^2_{k-1}$, $T_f \rightsquigarrow \chi^2_{d-1}$ and $T_g - T_f \rightsquigarrow \chi^2_{k-d}$ as $n \to \infty$ under the null hypothesis.*

We define the testing function

$$\phi_\alpha = \mathbb{I}\{T_f > \chi^2_{d-1}(\alpha)\} \vee \mathbb{I}\{T_g > \chi^2_{k-1}(\alpha)\}.$$

By Theorem 9, the Type-1 error of this test converges to α. Though T_f is dominated by T_g under the null hypothesis, both are needed to ensure the power goes to 1 under the alternative.

Theorem 10 *Under Condition D, the following two statements are equivalent*

1. $\lim_{n\to\infty} \sqrt{n}\ell(p,q) = \infty$;
2. $\lim_{n\to\infty} \mathbb{P}_p\left(T_f > \chi^2_{d-1}(\alpha) \text{ or } T_g > \chi^2_{k-1}(\alpha)\right) = 1$, *for any constant* $\alpha \in (0,1)$,

where the probability $\mathbb{P}_p$ is defined in the beginning of this section.

6. Optimality of the Test

In this section, we study the optimality issue of the testing problem from a decision-theoretic perspective. The goal is to understand the fundamental limit of the problem and establish optimality results of the proposed testing procedures. We propose to study the setting where a null hypothesis is tested against a local alternative. This leads to a nontrivial power function and a precise asymptotic characterization of the minimax risk of the test. Depending on whether the data generating process is Gaussian or categorical, and whether the null hypothesis is degenerate or not, the optimality of the test will be studied in four different cases.

6.1 Gaussian Distribution: Non-Degenerate Case

We first consider the non-degenerate situation. That is, we assume that $\mu_1, ..., \mu_k$ are k different numbers. In Section 3, we impose the assumption that the k numbers $\mu_1, ..., \mu_k$ do not depend on n. This assumption can be made significantly weaker. For two indices j and l that are not equal, define

$$\eta_{jl} = \frac{1}{\mu_j - \mu_l} \prod_{h\in[k]\setminus\{j,l\}} \frac{\mu_l - \mu_h}{\mu_j - \mu_h}.$$

It characterizes the relative difference between μ_j and μ_l in the background of the set $\{\mu_1, ..., \mu_k\}$.

Condition M1 1 *Assume* $\lim_{n\to\infty} \max_{j\neq l} \frac{|\eta_{jl}|}{\sqrt{n}} = 0$.

To understand Condition M1, we can interpret $|\eta_{jl}| + |\eta_{lj}|$ as approximately the inverse distance between μ_j and μ_l. Therefore, we allow the possibility that $|\mu_j - \mu_l|$ converges to 0, but not as fast as $n^{-1/2}$. Otherwise, the data cannot tell the difference between $\mu_j \neq \mu_l$ and $\mu_j = \mu_l$, which is equivalent to the degenerate case. Recall that the number k is assumed to be a constant that does not vary with n throughout the paper.

Consider the testing problem

$$H_0 : \theta \in \Theta_0 = \{\theta : \ell(\theta, \mu) = 0\}, \quad H_1 : \theta \in \Theta_\delta = \left\{\theta : \ell(\theta, \mu) = \frac{\delta}{\sqrt{n}}\right\}. \tag{27}$$

That is, we test the null hypothesis against its contiguous alternative. The choice of H_1 ensures a non-trivial asymptotic power. We measure the testing error via the minimax risk function

$$R_n(k,\delta) = \inf_{0\le\phi\le 1} \left\{ \sup_{\theta\in\Theta_0} \mathbb{P}_\theta \phi + \sup_{\theta\in\Theta_\delta} \mathbb{P}_\theta(1-\phi) \right\}.$$

The probability symbol $\mathbb{P}_\theta$ stands for $N(\theta, n^{-1}I_k)$. Throughout the paper, we assume k and δ are fixed constants independent of n.

We first present the lower bound.

Theorem 11 *Under Condition M1, for sufficiently large n, we have*

$$R_n(k,\delta) \ge \inf_{t>0} \left(\mathbb{P}\left(\chi^2_k > t\right) + \mathbb{P}(\chi^2_{k,\delta^2} \le t) \right).$$

Theorem 11 gives the benchmark of the problem. Using the proposed testing statistic T defined in (12), we can achieve this benchmark.

Theorem 12 *Consider the testing procedure $\phi = \mathbb{I}\{T > t^*\}$, where T is defined in (12), and*

$$t^* = \operatorname*{argmin}_{t>0} \left(\mathbb{P}\left(\chi^2_k > t\right) + \mathbb{P}(\chi^2_{k,\delta^2} \le t) \right).$$

Under Condition M1, we have

$$\sup_{\theta\in\Theta_0} \mathbb{P}_\theta \phi + \sup_{\theta\in\Theta_\delta} \mathbb{P}_\theta(1-\phi) \le (1+o(1)) \inf_{t>0} \left(\mathbb{P}\left(\chi^2_k > t\right) + \mathbb{P}(\chi^2_{k,\delta^2} \le t) \right),$$

as $n \to \infty$.

Theorem 12 characterizes both Type-1 and Type-2 error of the test $\phi = \mathbb{I}\{T > t^*\}$. The conclusion holds for any local alternative with $\delta \in (0,\infty)$. It complements the result of Theorem 3. Combining Theorem 11 and Theorem 12, we conclude that the minimax testing error has the following asymptotic formula

$$R_n(k,\delta) = (1+o(1)) \inf_{t>0} \left(\mathbb{P}\left(\chi^2_k > t\right) + \mathbb{P}(\chi^2_{k,\delta^2} \le t) \right),$$

and this error can be achieved by the test $\phi = \mathbb{I}\{T > t^*\}$ with some carefully chosen t^* only depending on k and δ.

6.2 Gaussian Distribution: Degenerate Case

Now we consider situations of degeneracy. In Section 4, it is assumed that $\mu_1, ..., \mu_k$ only take d different values. This assumption can be relaxed. Here, we assume the k numbers $\mu_1, ..., \mu_k$ can be approximately clustered into d groups. Given d different numbers $\nu_1, ..., \nu_d$, for any pair $g \neq h$, define

$$\bar{\eta}_{gh} = \frac{1}{\nu_g - \nu_h} \prod_{l \in [k] \setminus \{g,h\}} \frac{\nu_h - \nu_l}{\nu_g - \nu_l}. \tag{28}$$

Condition M2 1 *Assume* $\lim_{n\to\infty} \max_{g\neq h} \frac{|\bar{\eta}_{gh}|}{\sqrt{n}} = 0$ *and there is a partition* $\mathcal{C}_1, ..., \mathcal{C}_d$ *of* $[k]$, *such that* $\limsup_{n\to\infty} \max_{1\leq g\leq d} \max_{j\in\mathcal{C}_g} \sqrt{n}|\mu_j - \nu_g| = 0$.

This condition says that $\mu_1, ..., \mu_k$ can be approximately clustered into d groups. The within-group distance is of a smaller order than $n^{-1/2}$, and the between-group distance is of a larger order than $n^{-1/2}$.

Consider the same local testing problem (27). The lower bound of the degenerate setting is given by the following theorem.

Theorem 13 *Under Condition M2,* $n \to \infty$, *we have*

$$R_n(k, \delta) \geq (1 + o(1)) \inf_{t>0} \left(\mathbb{P}\left(\chi^2_k > t\right) + \mathbb{P}(\chi^2_{k,\delta^2} \leq t) \right).$$

This lower bound can be achieved asymptotically using the testing statistics T_f and T_g defined in (18) and (19).

Theorem 14 *Consider the testing procedure* $\phi = \mathbb{I}\{T_f > t^*\} \vee \mathbb{I}\{T_g > t^*\}$, *where* T_f *and* T_g *are defined in (18) and (19), and*

$$t^* = \operatorname*{argmin}_{t>0} \left(\mathbb{P}\left(\chi^2_k > t\right) + \mathbb{P}(\chi^2_{k,\delta^2} \leq t) \right).$$

Under Condition M_2, *we have*

$$\sup_{\theta\in\Theta_0} \mathbb{P}_\theta \phi + \sup_{\theta\in\Theta_\delta} \mathbb{P}_\theta(1-\phi) \leq (1 + o(1)) \inf_{t>0} \left(\mathbb{P}\left(\chi^2_k > t\right) + \mathbb{P}(\chi^2_{k,\delta^2} \leq t) \right),$$

as $n \to \infty$.

Theorem 14 shows that the test $\phi = \mathbb{I}\{T_f > t^*\} \vee \mathbb{I}\{T_g > t^*\}$ achieves the optimal error asymptotically under a local alternative. As we will show in Theorem 23, $T_g \geq T_f$ in probability under a local alternative that $\sqrt{n}\ell(\theta, \mu) = \delta \in (0, \infty)$. Therefore, the test $\phi = \mathbb{I}\{T_f > t^*\} \vee \mathbb{I}\{T_g > t^*\}$ is asymptotically equivalent to $\mathbb{I}\{T_g > t^*\}$, and the latter only uses T_g. Though the role of the statistic T_f is negligible for a local alternative, we have already shown in Theorem 6 that as soon as $\sqrt{n}\ell(\theta, \mu) \to \infty$, the effect of using T_f starts to kick in and it is necessary to use both T_f and T_g for the asymptotic power to approach one.

6.3 Categorical Distribution: Non-Degenerate Case

We study the fundamental limit of testing for the categorical distribution. In Section 5, we assume $q_1, ..., q_k$ are k different numbers that do not depend on n. In this section, we consider a condition that is significantly weaker. Define

$$\zeta_{jl} = \frac{1}{\sqrt{q_j} - \sqrt{q_l}} \prod_{h \in [k] \setminus \{j,l\}} \frac{\sqrt{q_l} - \sqrt{q_h}}{\sqrt{q_j} - \sqrt{q_h}}.$$

Similar to the definition of η_{jl}, ζ_{jl} characterizes the relative difference between $\sqrt{q_j}$ and $\sqrt{q_l}$ in the background of the set $\{\sqrt{q_1}, ..., \sqrt{q_k}\}$.

Condition M3 1 *Assume* $\lim_{n\to\infty} \max_{j\neq l} \frac{|\zeta_{jl}|}{\sqrt{n}} = 0$ *and* $\min_{1\leq j\leq k} nq_j(1 - q_j) \to \infty$.

Compared with Condition M1, the extra requirement $\min_{1\leq j\leq k} nq_j(1 - q_j) \to \infty$ in Condition M3 ensures that each q_j is bounded away from 0 and 1 with a gap at least of order n^{-1}. If this extra requirement does not hold, q_j would be asymptotically equivalent to 0 or 1, which results in a degenerate variance.

Consider the testing problem

$$H_0 : p \in \mathcal{P}_0 = \{p : \ell(p, q) = 0\}, \quad H_1 : p \in \mathcal{P}_\delta = \left\{ p : \ell(p, q) = \frac{\delta}{\sqrt{n}} \right\}. \tag{29}$$

Recall that the distance $\ell(\cdot, \cdot)$ is defined in (20).

We present the lower bound.

Theorem 15 *Under Condition M3, as* $n \to \infty$, *we have*

$$R_n(k, \delta) \geq (1 + o(1)) \inf_{t>0} \left(\mathbb{P}\left(\chi^2_{k-1} > t\right) + \inf_{\{\delta_1,\delta_2:\delta_1^2+\delta_2^2=\delta^2\}} \mathbb{P}(\chi^2_{k-1,\delta_1^2} + \delta_2^2 \leq t) \right).$$

Theorem 15 gives the benchmark of the problem. Using the testing statistic T defined in (22), we can achieve this benchmark.

Theorem 16 *Consider the testing procedure* $\phi = \mathbb{I}\{T > t^*\}$, *where* T *is defined in (22), and*

$$t^* = \operatorname*{argmin}_{t>0} \left(\mathbb{P}\left(\chi^2_{k-1} > t\right) + \sup_{\{\delta_1,\delta_2:\delta_1^2+\delta_2^2=\delta^2\}} \mathbb{P}(\chi^2_{k-1,\delta_1^2} + \delta_2^2 \leq t) \right).$$

Under Condition M3, we have

$$\sup_{\theta\in\mathcal{P}_0} \mathbb{P}_\theta \phi + \sup_{\theta\in\mathcal{P}_\delta} \mathbb{P}_\theta(1-\phi) \leq (1+o(1)) \inf_{t>0} \left(\mathbb{P}\left(\chi^2_{k-1} > t\right) + \sup_{\{\delta_1,\delta_2:\delta_1^2+\delta_2^2=\delta^2\}} \mathbb{P}(\chi^2_{k-1,\delta_1^2} + \delta_2^2 \leq t) \right),$$

as $n \to \infty$.

The upper bound given by Theorem 16 does not exactly match the lower bound given by Theorem 15. The difference lies in the Type-2 error. For the lower bound, we get $\inf_{\{\delta_1,\delta_2:\delta_1^2+\delta_2^2=\delta^2\}} \mathbb{P}(\chi^2_{k-1,\delta_1^2}+\delta_2^2 \leq t)$, while for the upper bound, it is $\sup_{\{\delta_1,\delta_2:\delta_1^2+\delta_2^2=\delta^2\}} \mathbb{P}(\chi^2_{k-1,\delta_1^2}+\delta_2^2 \leq t)$. These two quantities are close, because for any δ_1 and δ_2 that satisfy $\delta_1^2 + \delta_2^2 = \delta^2$, the expectation of $\chi^2_{k-1,\delta_1^2} + \delta_2^2$ is always $k - 1 + \delta^2$. Therefore, the test using the statistic T is nearly optimal.

6.4 Categorical Distribution: Degenerate Case

Finally, we study the categorical distribution with the presence of degeneracy. In Section 5, we consider the situation where $q_1, ..., q_k$ take d different values. Here, we propose a much weaker condition. Given d different numbers $r_1, ..., r_d \in (0,1)$, for any pair $g \neq h$, define

$$\bar{\zeta}_{gh} = \frac{1}{\sqrt{r_g} - \sqrt{r_h}} \prod_{l \in [k] \setminus \{g,h\}} \frac{\sqrt{r_h} - \sqrt{r_l}}{\sqrt{r_g} - \sqrt{r_l}}.$$

Condition M4 1 *Assume* $\lim_{n\to\infty} \max_{j \neq l} \frac{|\bar{\zeta}_{jl}|}{\sqrt{n}} = 0$, $\min_{1 \leq j \leq k} nq_j(1-q_j) \to \infty$, *and there is a partition* $\mathcal{C}_1, ..., \mathcal{C}_d$ *of* $[k]$, *such that* $\limsup_{n\to\infty} \max_{1 \leq g \leq d} \max_{j \in \mathcal{C}_g} \sqrt{n}|\sqrt{q_j} - \sqrt{r_g}| = 0$.

Condition M4 has the same interpretation as Condition M2. The extra requirement $\min_{1 \leq j \leq k} nq_j(1-q_j) \to \infty$ is also needed in Condition M3 to prevent the variance from being degenerate.

The lower bound of the local testing problem (29) is given by the next theorem.

Theorem 17 *Under Condition M4, as* $n \to \infty$, *we have*

$$R_n(k, \delta) \geq (1 + o(1)) \inf_{t>0} \left(\mathbb{P}\left(\chi^2_{k-1} > t\right) + \inf_{\{\delta_1, \delta_2 : \delta_1^2 + \delta_2^2 = \delta^2\}} \mathbb{P}(\chi^2_{k-1, \delta_1^2} + \delta_2^2 \leq t) \right).$$

For the matching upper bound, we can use the proposed testing statistics T_f and T_g defined in (25) and (26).

Theorem 18 *Consider the testing procedure* $\phi = \mathbb{I}\{T_f > t^*\} \vee \mathbb{I}\{T_g > t^*\}$, *where* T_f *and* T_g *are defined in (25) and (26), and*

$$t^* = \operatorname*{argmin}_{t>0} \left(\mathbb{P}\left(\chi^2_{k-1} > t\right) + \sup_{\{\delta_1, \delta_2 : \delta_1^2 + \delta_2^2 = \delta^2\}} \mathbb{P}(\chi^2_{k-1, \delta_1^2} + \delta_2^2 \leq t) \right).$$

Under Condition M4, we have

$$\sup_{\theta \in \mathcal{P}_0} \mathbb{P}_\theta \phi + \sup_{\theta \in \mathcal{P}_\delta} \mathbb{P}_\theta(1-\phi) \leq (1+o(1)) \inf_{t>0} \left(\mathbb{P}\left(\chi^2_{k-1} > t\right) + \sup_{\{\delta_1, \delta_2 : \delta_1^2 + \delta_2^2 = \delta^2\}} \mathbb{P}(\chi^2_{k-1, \delta_1^2} + \delta_2^2 \leq t) \right),$$

as $n \to \infty$.

7. Numerical Studies

In this section, we conduct numerical experiments to verify the theoretical properties of the proposed testing procedures. In each of the following scenarios, we compute power functions of α-level tests for $\alpha = 0.05$ with various sample sizes.

Scenario 1. Consider $X \sim N(\theta, n^{-1}I_k)$, and we test the null hypothesis $\ell(\theta, \mu) = 0$ with μ specified as $\mu = (1, 2, 3, 4, 5)$.

Scenario 2. Consider $X \sim N(\theta, n^{-1}I_k)$, and we test the null hypothesis $\ell(\theta, \mu) = 0$ with μ specified as $\mu = (1, 3, 3, 3, 5, 5)$.

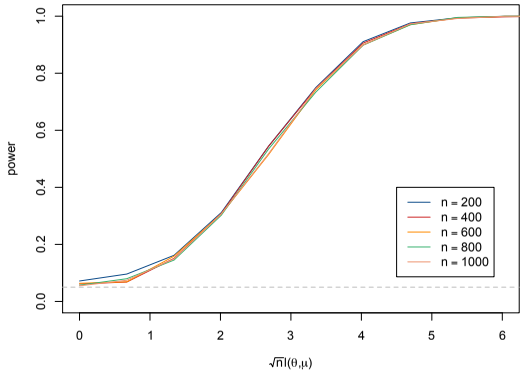

Figure 2: Power Curve of Scenario 1

Scenario 3. Consider $X_1, ..., X_n \sim (p_1, ..., p_k)$, and we test the null hypothesis $\ell(p, q) = 0$ with q specified as $q = (0.1, 0.2, 0.3, 0.4)$.

Scenario 4. Consider $X_1, ..., X_n \sim (p_1, ..., p_k)$, and we test the null hypothesis $\ell(p, q) = 0$ with q specified as $q = (0.1, 0.1, 0.4, 0.4)$.

Scenario 5. Consider $X_1, ..., X_n \sim (p_1, ..., p_k)$ and $Y_1, ..., Y_m \sim (q_1, ..., q_k)$, and we test the null hypothesis $\ell(p, q) = 0$. We set $p = (0.1, 0.1, 0.4, 0.4)$ and q to be local perturbations of p in a $O(n^{-1/2})$ neighborhood of p.

The numerical results of the five scenarios are summarized in Figures 2-6. The power curves are plotted in the contiguous regimes where $\ell(\theta, \mu) = O(n^{-1/2})$ or $\ell(p, q) = O(n^{-1/2})$. The grey dashed lines correspond to the nominal 0.05 level of the tests.

In Scenario 1, we vary θ in a local $O(n^{-1/2})$ neighborhood of the null hypothesis μ. It is clear that the power function is increasing with respect to $\sqrt{n}\ell(\theta, \mu)$. Moreover, with different sample sizes, the curves match well with each other. This verifies the conclusion of Theorem 3 that the magnitude of $\sqrt{n}\ell(\theta, \mu)$ asymptotically determines the power of the test. We observe in Figure 2 that the power is very close to 1 when $\sqrt{n}\ell(\theta, \mu)$ is greater than 6. The value of the power at $\sqrt{n}\ell(\theta, \mu) = 0$ corresponds to the Type-1 error in the null hypothesis. The actually Type-1 error is slightly greater than the nominal 0.05 level, but the approximations are reasonable for relatively large sample sizes.

Scenario 2 considers a harder null hypothesis with a degenerate $\mu = (1, 3, 3, 3, 5, 5)$. A 0.05-level test studied in Section 4 requires both testing statistics T_f and T_g. Similar to what is observed in Scenario 1, Figure 3 shows that the power approaches 1 at about $\sqrt{n}\ell(\theta, \mu) = 7$, which is predicted by Theorem 6. However, when $\sqrt{n}\ell(\theta, \mu) = 0$, the actual Type-1 errors are consistently larger than the nominal level 0.05, especially when the sample sizes are relatively small.

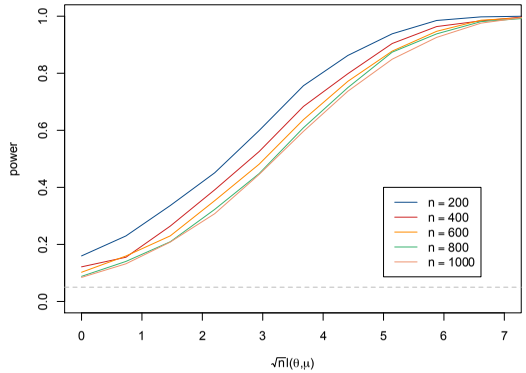

Figure 3: Power Curve of Scenario 2

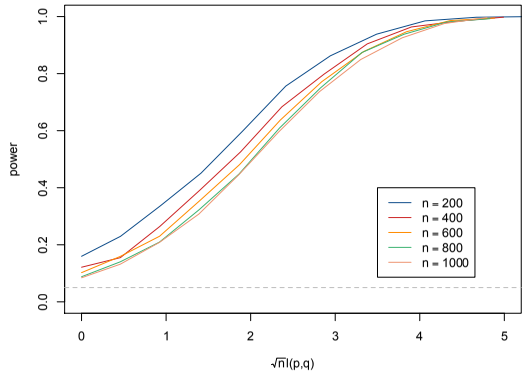

Figure 4: Power Curve of Scenario 3

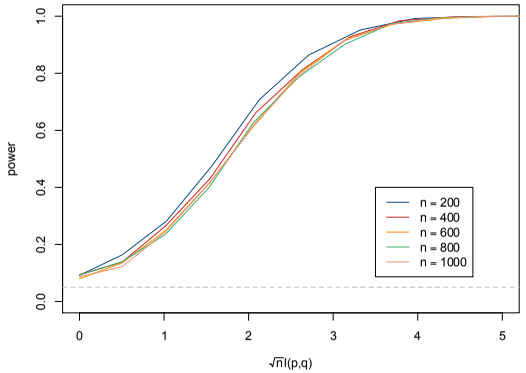

Figure 5: Power Curve of Scenario 4

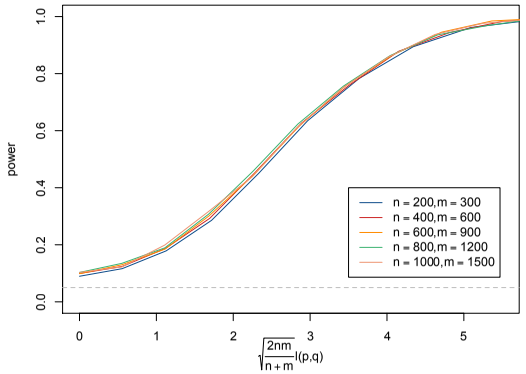

Figure 6: Power Curve of Scenario 5

Scenario 3 and Scenario 4 consider categorical distributions with a non-degenerate null $q = (0.1, 0.2, 0.3, 0.4)$ and a degenerate null $q = (0.1, 0.1, 0.4, 0.4)$, respectively. Again, Theorem 8 and Theorem 10 are verified by Figure 4 and Figure 5. The actual Type-1 errors are also larger than the nominal one, and are closer to 0.05 with larger sample sizes.

Finally in Scenario 5, we consider experiments of the two-sample test. According to the definitions of the testing statistics in (30) and (31), it is $\sqrt{\frac{2nm}{n+m}}\ell(p,q)$ that determines the power function asymptotically. Figure 6 shows that different power curves well match each other as functions of $\sqrt{\frac{2nm}{n+m}}\ell(p,q)$. As is predicted by Theorem 20, the power is close to 1 at a reasonably large value of $\sqrt{\frac{2nm}{n+m}}\ell(p,q)$.

A common theme in the above numerical results is that the actual Type-1 errors are always larger than the nominal one. We will give an explanation of this phenomenon in Section 9. Roughly speaking, whenever the null exhibits an ambiguous clustering structure, the asymptotic distribution of the testing statistic under the null is a noncentral chi-square distribution. Though a larger sample size helps to make the noncentrality parameter vanish (Figures 2-6), it still results in an estimate of Type-1 error that is too optimistic with a finite sample size. There are potentially two ways to overcome this difficulty. One is to appeal to a second-order correction, and the other is to estimate the noncentrality parameter in the null distribution. We leave this interesting topic as a future project.

8. Two-Sample Test

Consider two categorical distributions $(p_1, ..., p_k)$ and $(q_1, ..., q_k)$. Suppose we observe i.i.d. observations $X_1, ..., X_n$ from $(p_1, ..., p_k)$ and i.i.d. observations $Y_1, ..., Y_m$ from $(q_1, ..., q_k)$. We assume that $X_1, ..., X_n$ are independent of $Y_1, ..., Y_m$. The hypothesis testing problem we study in this section is

$$H_0 : \ell(p,q) = 0, \quad H_1 : \ell(p,q) > 0,$$

where the distance $\ell(\cdot,\cdot)$ is defined in (20). The two-sample testing problem is harder than the one-sample version that we have just studied. The major difficulty is that the definitions of the functions (23) and (24) all depend on the values of $(p_1, ..., p_k)$ and $(q_1, ..., q_k)$ under the null hypothesis, which is not available anymore in the two-sample scenario.

Our idea is to estimate the unknown $(p_1, ..., p_k)$ and $(q_1, ..., q_k)$ from the data, and then construct data-driven versions of (23) and (24).

For each $j \in [k]$, define $\hat{p}_j = \frac{1}{n}\sum_{i=1}^n \mathbb{I}\{X_i = j\}$. Next, we will apply a variable clustering procedure to $(\hat{p}_1, ..., \hat{p}_k)$. The goal is to find a partition $\underline{\mathcal{C}}_1, ..., \underline{\mathcal{C}}_{\underline{d}}$ of $[k]$ according to

$$j \sim l \quad \text{if} \quad \sqrt{n}|\sqrt{\hat{p}_j} - \sqrt{\hat{p}_l}| \le \lambda_n.$$

Algorithmically, one can first sort the vector $(\hat{p}_1, ..., \hat{p}_k)$, and then find the partition sequentially. There exists a permutation $\sigma \in S_k$, such that we can rank the empirical frequencies as $\hat{p}_{\sigma(1)} \le \hat{p}_{\sigma(2)} \le ... \le \hat{p}_{\sigma(k)}$. Let $\hat{j}_1$ be the largest j such that $\sqrt{n}|\sqrt{\hat{p}_{\sigma(j)}} - \sqrt{\hat{p}_{\sigma(1)}}| \le \lambda_n$, where λ_n is some threshold to be specified later. Then, the first cluster is defined as $\underline{\mathcal{C}}_1 = \left\{\sigma(1), \sigma(2), ..., \sigma(\hat{j}_1)\right\}$. Similarly, we can define the second cluster as $\underline{\mathcal{C}}_2 = \{\sigma(\hat{j}_1 + 1), ..., \sigma(\hat{j}_2)\}$, where $\hat{j}_2$ is the largest j such that $\sqrt{n}|\sqrt{\hat{p}_{\sigma(j)}} - \sqrt{\hat{p}_{\sigma(\hat{j}_1)}}| \le \lambda_n$. We continue this operation until we obtain a partition $\underline{\mathcal{C}}_1, ..., \underline{\mathcal{C}}_{\underline{d}}$ of $[k]$. Here, $\underline{d}$ is the number of clusters estimated from the data. Now, for each $g \in [\underline{d}]$, we find the center of the cluster by $\sqrt{\underline{r}_g} = \frac{1}{|\underline{\mathcal{C}}_g|}\sum_{j\in\underline{\mathcal{C}}_g}\sqrt{\hat{p}_j}$. With the numbers $\underline{r}_1, ..., \underline{r}_{\underline{d}}$, we define

$$\underline{f}_h(t) = \frac{\int \prod_{g\in[\underline{d}]\setminus\{h\}}(\sqrt{t} - \sqrt{\underline{r}_g})}{\prod_{g\in[\underline{d}]\setminus\{h\}}(\sqrt{\underline{r}_h} - \sqrt{\underline{r}_g})}, \quad h = 1, ..., \underline{d},$$

and

$$\underline{g}(t) = \frac{\prod_{g=1}^{\underline{d}}(\sqrt{t} - \sqrt{\underline{r}_g})^2}{\sum_{g=1}^{\underline{d}}\prod_{h\in[\underline{d}]\setminus\{g\}}(\sqrt{t} - \sqrt{\underline{r}_h})^2}.$$

We repeat the above procedure on the observations $Y_1, ..., Y_m$. For each $j \in [k]$, define $\hat{q}_j = \frac{1}{m}\sum_{i=1}^m \mathbb{I}\{Y_i = j\}$. Then, apply the same variable clustering procedure on $(\hat{q}_1, ..., \hat{q}_k)$, and we obtain a partition $\overline{\mathcal{C}}_1, ..., \overline{\mathcal{C}}_{\overline{d}}$ of $[k]$. For each $g \in [\overline{d}]$, define $\sqrt{\overline{r}_g} = \frac{1}{|\overline{\mathcal{C}}_g|}\sum_{j\in\overline{\mathcal{C}}_g}\sqrt{\hat{q}_j}$. Analogous definitions of $\underline{f}_h$'s and $\underline{g}$ are given by

$$\overline{f}_h(t) = \frac{\int \prod_{g\in[\overline{d}]\setminus\{h\}}(\sqrt{t} - \sqrt{\overline{r}_g})}{\prod_{g\in[\overline{d}]\setminus\{h\}}(\sqrt{\overline{r}_h} - \sqrt{\overline{r}_g})}, \quad h = 1, ..., \overline{d},$$

and

$$\overline{g}(t) = \frac{\prod_{g=1}^{\overline{d}}(\sqrt{t} - \sqrt{\overline{r}_g})^2}{\sum_{g=1}^{\overline{d}}\prod_{h\in[\overline{d}]\setminus\{g\}}(\sqrt{t} - \sqrt{\overline{r}_h})^2}.$$

Now we can define testing statistics for this problem:

$$\begin{aligned} T_f &= \frac{2nm}{n+m}\sum_{h=1}^{\underline{d}}\frac{1}{|\underline{\mathcal{C}}_h|}\left(\sum_{j=1}^k \underline{f}_h(\hat{p}_j) - \sum_{j=1}^k \underline{f}_h(\hat{q}_j)\right)^2 \\ &\quad + \frac{2nm}{n+m}\sum_{h=1}^{\overline{d}}\frac{1}{|\overline{\mathcal{C}}_h|}\left(\sum_{j=1}^k \overline{f}_h(\hat{p}_j) - \sum_{j=1}^k \overline{f}_h(\hat{q}_j)\right)^2, \end{aligned} \tag{30}$$

and

$$T_g = \frac{2nm}{n+m}\left(\sum_{j=1}^k \underline{g}(\hat{q}_j) + \sum_{j=1}^k \overline{g}(\hat{p}_j)\right). \tag{31}$$

The asymptotic distributions of the testing statistics under the null distribution are given below.

Condition E 1 *Asume $q_1, ..., q_k$ are k numbers in $(0,1)$ that do not vary with n. Moreover, there exists a $d \ge 2$ and a partition $[k] = \cup_{h=1}^d \mathcal{C}_h$, such that $q_j = r_h$ for all $j \in \mathcal{C}_h$, $h \in [d]$.*

Theorem 19 *Assume λ_n is a diverging sequence that satisfies $\lambda_n = o(\sqrt{n})$ and we also assume $\frac{m}{n+m} \to \beta \in (0,1)$. Under Condition E, we have*

$$\begin{aligned} T_g &\rightsquigarrow \frac{1}{2}\beta\mathcal{X}_1 + \frac{1}{2}(1-\beta)\mathcal{X}_2 + \mathcal{X}_3, \\ T_f &\rightsquigarrow \mathcal{X}_3, \\ T_g - T_f &\rightsquigarrow \frac{1}{2}\beta\mathcal{X}_1 + \frac{1}{2}(1-\beta)\mathcal{X}_2, \end{aligned}$$

as $n \to \infty$ under the null hypothesis, where $\mathcal{X}_1$, $\mathcal{X}_2$ and $\mathcal{X}_3$ are independent random variables distributed as χ^2_{k-d}, χ^2_{k-d} and χ^2_{d-1}, respectively.

Let $\mathcal{X}(\alpha)$ be the number that satisfies $\mathbb{P}\left(\frac{1}{2}\beta\mathcal{X}_1 + \frac{1}{2}(1-\beta)\mathcal{X}_2 + \mathcal{X}_3 > \mathcal{X}(\alpha)\right) = \alpha$. We define the testing function as

$$\phi_\alpha = \mathbb{I}\{T_f > \mathcal{X}(\alpha)\} \vee \mathbb{I}\{T_g > \mathcal{X}(\alpha)\}.$$

Theorem 19 implies that this test has asymptotic Type-1 error α. The next result characterizes the power behavior of the test.

Theorem 20 *Assume λ_n is a diverging sequence that satisfies $\lambda_n = o(\sqrt{n})$ and we also assume $\frac{m}{n+m} \to \beta \in (0,1)$. Under Condition E, the following two statements are equivalent*

1. $\lim_{n\to\infty} \sqrt{n}\ell(p,q) = \infty$;
2. $\lim_{n\to\infty} \mathbb{P}_{p,q}\left(T_f > \mathcal{X}(\alpha) \text{ or } T_g > \mathcal{X}(\alpha)\right) = 1$, *for any constant* $\alpha \in (0,1)$,

where the probability $\mathbb{P}_{p,q}$ stands for the joint distribution of $X_1, ..., X_n, Y_1, ..., Y_m$.

Theorem 20 assumes Condition E. That is, $q_1, ..., q_k$ are fixed numbers do that depend on n, and $p_1, ..., p_k$ are allowed to vary with n. One can also assume an analogous condition for $p_1, ..., p_k$ as fixed numbers that satisfy Condition E, and allow $q_1, ..., q_k$ to vary with n.

9. Discussion and Future Directions

The testing procedures that we propose and analyze in this paper critically depend on the structure of null hypothesis. In Section 3, the mean vector $(\mu_1, ..., \mu_k)^T$ is assumed to consist of k distinct numbers, and the testing statistic is constructed based on the functions $f_1, ..., f_k$ defined in (10). In Section 4, we assume $(\mu_1, ..., \mu_k)^T$ consists of k numbers that take values in $\{\nu_1, ..., \nu_d\}$ for some $d \le k$. For this degenerate setting, we use the functions $f_1, ..., f_d$ and g defined in (14) and (15) to construct the testing statistics.

Much weaker assumptions are considered in Section 6. In Section 6.1, we allow $|\mu_j - \mu_l|$ to converge to 0, but require the difference should be of a larger order than $n^{-1/2}$ for every $j \neq l$. This extends the assumption in Section 3 that $\mu_1, ..., \mu_k$ are k distinct numbers that do not vary with n. In Section 6.2, we consider the setting where $|\nu_g - \nu_h|$ is of a larger order than $n^{-1/2}$ for every $g \neq h$, and $|\mu_j - \nu_h|$ is of a smaller order than $n^{-1/2}$ for every $j \in \mathcal{C}_h$. This setting extends the assumption used in Section 4. It turns out that the asymptotic distributions of the proposed testing statistics (Theorem 2 and Theorem 5) are still valid under these more general conditions (see Theorem 22 and Theorem 23 in Section 10.1).

However, the conditions in Section 6.1 and Section 6.2 still do not cover all situations. By requiring the within-cluster distance to be of a smaller order than $n^{-1/2}$ and the between-cluster distance to be of a larger order than $n^{-1/2}$, the numbers $\mu_1, ..., \mu_k$ enjoy an approximately exact clustering structure, because for each $j \neq l$, we either have $\sqrt{n}|\mu_j - \mu_l| \to 0$ or $\sqrt{n}|\mu_j - \mu_l| \to \infty$, depending on whether j and l are in the same cluster or not. A possible situation $\sqrt{n}|\mu_j - \mu_l| \asymp 1$ is excluded.

In this section, we discuss a situation where the clustering structure of the numbers $\mu_1, ..., \mu_k$ is ambiguous. Consider a partition $\mathcal{C}_1, ..., \mathcal{C}_d$ of $[k]$. Define $\nu_h = \frac{1}{|\mathcal{C}_h|}\sum_{j\in\mathcal{C}_g} \mu_j$. Instead of assuming the within-cluster distance is of a smaller order than $n^{-1/2}$, we consider the situation where $n\sum_{h=1}^d \sum_{j\in\mathcal{C}_h}(\mu_j - \nu_h)^2$ is of a constant order. Moreover, we also assume the between-cluster distance $|\nu_g - \nu_h|$ is of a larger order than $n^{-1/2}$ for every $g \neq h$. This is without loss of generality, because if there is some $g \neq h$, such that $|\nu_g - \nu_h| = O(n^{-1/2})$, then $\mathcal{C}_g$ and $\mathcal{C}_h$ can be combined into a single cluster. Recall the definition of $\bar{\eta}_{gh}$ in (28), we formalize this ambiguous clustering structure into the following condition.

Condition M2' 1 *For the partition $\mathcal{C}_1, ..., \mathcal{C}_d$ and clustering centers $\nu_1, ..., \nu_d$ defined above, assume $\lim_{n\to\infty} \max_{g\neq h} \frac{|\bar{\eta}_{gh}|}{\sqrt{n}} = 0$, and $\tau^2 = \lim_{n\to\infty} n\sum_{h=1}^d \sum_{j\in\mathcal{C}_h}(\mu_j - \nu_h)^2 \in [0, \infty)$.*

Note that Condition M2 is a special case of Condition M2' when $\tau^2 = 0$. The next theorem gives the asymptotic distribution of the testing statistics T_f and T_g defined in (18) and (19) under the null hypothesis.

Theorem 21 *Assume Condition M2' holds. Then we have $T_g \rightsquigarrow \chi^2_{k,\tau^2}$, $T_f \rightsquigarrow \chi^2_d$ and $T_g - T_f \rightsquigarrow \chi^2_{k-d,\tau^2}$ as $n \to \infty$ under the null hypothesis $X \sim N(\mu, n^{-1}I_k)$.*

It is interesting to see that the asymptotic distribution of T_g is a noncentral chi-squared distribution even under the null hypothesis. The noncentrality parameter τ^2 characterizes the within-cluster distance of $\mu_1, ..., \mu_k$ with respect to the partition $\mathcal{C}_1, ..., \mathcal{C}_d$. Theorem 21 is reduced to Theorem 5 when $\tau^2 = 0$.

Define a number $\chi^2_{k,\tau^2}(\alpha)$ that satisfies $\mathbb{P}(\chi^2_{k,\tau^2} \le \chi^2_{k,\tau^2}(\alpha)) = 1 - \alpha$. Then, an α-level testing function is $\phi_\alpha = \mathbb{I}\{T_g > \chi^2_{k,\tau^2}(\alpha)\} \vee \mathbb{I}\{T_f > \chi^2_{k,\tau^2}(\alpha)\}$. Compared with the null hypothesis where $\tau^2 = 0$, a nonzero τ^2 requires a higher rejection level. This means the test will have less power under a contiguous alternative, compared with the situation where $\tau^2 = 0$. Suppose $\tilde{\tau}^2 = \lim_{n\to\infty} n\sum_{h=1}^d \sum_{j\in\mathcal{C}_h}(\theta_j - \nu_h)^2 \in (0, \infty)$. Then, one can also show that $T_g \rightsquigarrow \chi^2_{k,\tilde{\tau}^2}$ under the alternative $X \sim N(\theta, n^{-1}I_k)$. Therefore, the test ϕ_α starts to have power when $\tilde{\tau}^2$ exceeds τ^2. When $\tilde{\tau}^2$ is close to or even smaller then τ^2, this test will not have any power under the alternative. On the other hand, outside of the contiguous regime where $\sqrt{n}\ell(\theta, \mu) \to \infty$, we must have $\tilde{\tau}^2 = \infty$, and then the test will have asymptotic power 1.

From what we have just discussed, we can see that the structure of $\mu_1, ..., \mu_k$ plays a critical role on the solution of the problem. The discussion also applies to the case of categorical distributions and we can obtain similar conclusions there. Theorem 21 characterizes the asymptotic distribution of the testing statistics when $\mu_1, ..., \mu_k$ exhibit an ambiguous clustering structure, right on the edge of degeneracy. This results in a non-trivial behavior

of the power function. Exact characterization of optimality of the testing problem (as what we have done in Section 6) on the edge of degeneracy remains open, and we shall consider this problem as a future project.

Finally, we discussed a list of open problems that can be viewed as natural extensions of the results in the paper.

1. *Growing or infinite support size.* The paper focuses on the case where k is a fixed integer that does not depend on n. The case with a growing k or even $k = \infty$ is of potential importance in many high-dimensional data analysis situations. This requires new techniques because for a probability vector $p = (p_1, ..., p_k)$ with a growing or an infinite k, many p_j's have extremely small values.

2. *Testing a parametric family with permutation invariance.* An extension to the null hypothesis (1) is

$$H_0 : p(j) = f_\lambda(\pi(j)) \quad \text{for some } \lambda \in \Lambda \text{ and some } \pi \in S_k.$$

   Here, $\{f_\lambda(j)\}$ is a discrete distribution with an unknown parameter $\lambda \in \Lambda$. An example is Poisson(λ). Without the permutation $\pi \in S_k$, the null hypothesis becomes $p = f_\lambda$ for some $\lambda \in \Lambda$, which is a classical goodness-of-fit test of a parametric family **??**.

3. *Non-asymptotic study of minimax separation.* This paper considers testing procedures that enjoy asymptotic optimality (Section 6). An important theoretical problem is to understand the minimax separation ρ^* for which one can consistently test the null $\ell(p, q) = 0$ against the alternative $\ell(p, q) > \rho$ if and only if $\rho > \rho^*$. With the permutation invariance, the null hypothesis is a non-convex set, which is in contrast to a convex case that was recently studied by **?**.

4. *Other group invariance.* Permutation invariance is a special case of group invariance. A more general question is to consider a null hypothesis that is invariant with respect to other group actions. A recent work **?** considered a group of cyclic shifts. It would be interesting to understand the method of invariance in a general group theoretic framework.

10. Proofs

In this section, we present the proofs of all results in the paper. In Section 10.1, we derive the asymptotic distributions of the proposed testing statistics in various settings. These results are used to derive Theorem 2, Theorem 5, Theorem 7, Theorem 9, Theorem 19 and Theorem 21. Then, in Section 10.2, we analyze the powers of the proposed tests, which include the proofs of Theorem 3, Theorem 6, Theorem 8, Theorem 10 and Theorem 20. Finally, in Section 10.3, we give proofs of all results in Section 6.

10.1 Asymptotic Distribution of the Testing Statistics

We first present and prove four theorems of the proposed testing statistics in various settings.

Theorem 22 *In addition to Condition M1, assume*

$$\lim_{n\to\infty} \sqrt{n}\ell(\theta, \mu) = \delta \in [0, \infty).$$

Then, as n tends to infinity, $T \rightsquigarrow \chi^2_{k,\delta^2}$.

Proof We first calculate the derivatives of $f_l(t)$. The first derivative is

$$f_l'(t) = \frac{\prod_{j\in[k]\setminus\{l\}}(t - \mu_j)}{\prod_{j\in[k]\setminus\{l\}}(\mu_l - \mu_j)}.$$

Therefore, $f_l'(\mu_l) = 1$. For any $j \neq l$, we give a bound for $\sup_{|t-\mu_j|\le n^{-1/2}\epsilon} |f_l'(t)|$. The following inequality is useful.

$$|\eta_{lh}| + |\eta_{hl}| = \frac{1}{|\mu_l - \mu_h|}\left(\prod_{j\in[k]\setminus\{l,h\}}\left|\frac{\mu_l - \mu_j}{\mu_h - \mu_j}\right| + \prod_{j\in[k]\setminus\{l,h\}}\left|\frac{\mu_h - \mu_j}{\mu_l - \mu_j}\right|\right) \ge \frac{2}{|\mu_l - \mu_h|}. \quad (32)$$

Note that

$$\begin{aligned}
|f_l'(t)| &= \frac{|t - \mu_j|}{|\mu_l - \mu_j|}\left|\prod_{h\in[k]\setminus\{l,j\}}\frac{t - \mu_h}{\mu_l - \mu_h}\right| \\
&= \frac{|t - \mu_j|}{|\mu_l - \mu_j|}\left|\prod_{h\in[k]\setminus\{l,j\}}\left(\frac{t - \mu_j}{\mu_l - \mu_h} + \frac{\mu_j - \mu_h}{\mu_l - \mu_h}\right)\right| \\
&\le \frac{|t - \mu_j|}{|\mu_l - \mu_j|}2^{k-2}\left(\left|\prod_{h\in[k]\setminus\{l,j\}}\left(\frac{t - \mu_j}{\mu_l - \mu_h}\right)\right| + \left|\prod_{h\in[k]\setminus\{l,j\}}\left(\frac{\mu_j - \mu_h}{\mu_l - \mu_h}\right)\right|\right) \\
&\le 2^{k-2}|t - \mu_j|^{k-1}\left(\frac{|\eta_{lj}| + |\eta_{jl}|}{2}\right)\prod_{h\in[k]\setminus\{l,j\}}\left(\frac{|\eta_{lh}| + |\eta_{hl}|}{2}\right) + 2^{k-2}|t - \mu_j||\eta_{lj}|.
\end{aligned}$$

Therefore, we have the bound

$$\kappa_1(\epsilon) = \max_{j\neq l}\sup_{|t-\mu_j|\le n^{-1/2}\epsilon}|f_l'(t)| \le 2^{k-2}\left[\max_{j\neq l}\left(\frac{\epsilon|\eta_{jl}|}{\sqrt{n}}\right)^{k-2} + \max_{j\neq l}\left(\frac{\epsilon|\eta_{jl}|}{\sqrt{n}}\right)\right]. \quad (33)$$

The above bound is useful for $k \ge 3$. For $k = 2$, it is easy to see

$$\kappa_1(\epsilon) = \max_{j\neq l}\sup_{|t-\mu_j|\le n^{-1/2}\epsilon}|f_l'(t)| \le \max_{j\neq l}\left(\frac{\epsilon|\eta_{jl}|}{\sqrt{n}}\right). \quad (34)$$

The second derivative of $f_l(t)$ is

$$f_l''(t) = \sum_{j\in[k]\setminus\{l\}}\frac{1}{(\mu_l - \mu_j)}\prod_{h\in[k]\setminus\{l,j\}}\frac{t - \mu_h}{\mu_l - \mu_h}.$$

We give a bound for $\sup_{|t-\mu_l|\le n^{-1/2}\epsilon}|f_l''(t)|$. Similar calculation gives

$$\kappa_2(\epsilon)=\max_{1\le l\le k}\sup_{|t-\mu_l|\le n^{-1/2}\epsilon}|f_l''(t)|\le k\max_{j\neq l}|\eta_{jl}|\max_{j\neq l}\left(1+\frac{\epsilon|\eta_{jl}|}{\sqrt{n}}\right)^{k-2}. \tag{35}$$

Now we are ready to derive the asymptotic distribution of T. We write the observation as $X_j=\theta_j+n^{-1/2}Z_j$, with $Z_j\sim N(0,1)$ independently. The condition $\lim_{n\to\infty}\sqrt{n}\ell(\theta,\mu)=\delta$ implies that there is some n_0, such that for any $n>n_0$, we have

$$n\ell^2(\theta,\mu)\le C_n\delta^2,$$

where C_n is an sequence that tends to infinity arbitrarily slowly. In particular, we require that C_n satisfies $C_n\to\infty$ and $\frac{C_n^{3/2}\max_{j\neq l}|\eta_{jl}|}{\sqrt{n}}\to 0$. The existence of such sequence C_n is guaranteed by the assumption $\frac{\max_{j\neq l}|\eta_{jl}|}{\sqrt{n}}\to 0$. Thus, there exists a $\pi\in S_k$, possibly depending on n, such that

$$\max_{1\le j\le k}(\theta_j-\mu_{\pi(j)})^2\le\frac{C_n\delta^2}{n}.$$

Since k does not depend on n, $\max_{1\le j\le k}Z_j^2\le C_n$ with probability that goes to 1. By triangle inequality,

$$\max_{1\le j\le k}|X_j-\mu_{\pi(j)}|\le\frac{\sqrt{C_n}(1+\sqrt{\delta^2})}{\sqrt{n}}, \tag{36}$$

with probability that goes to 1. We use Taylor expansion. For j such that $\pi(j)=l$, we have

$$f_l(X_j)-f_l(\mu_{\pi(j)})=(X_j-\mu_{\pi(j)})+\frac{1}{2}f_l''(\xi_{jl})(X_j-\mu_{\pi(j)})^2,$$

where we have used the fact that $f_l'(\mu_l)=1$. For j such that $\pi(j)\neq l$, we have

$$f_l(X_j)-f_l(\mu_{\pi(j)})=f_l'(\xi_{jl})(X_j-\mu_{\pi(j)}).$$

Therefore,

$$\begin{aligned}&\left|\sum_{j=1}^k f_l(X_j)-\sum_{j=1}^k f_l(\mu_j)-(X_{\pi^{-1}(l)}-\mu_l)\right|\\ \le\;&\frac{1}{2}|f_l''(\xi_{\pi^{-1}(l)l})|(X_{\pi^{-1}(l)}-\mu_l)^2+\sum_{j\neq\pi^{-1}(l)}|f_l'(\xi_{jl})||X_j-\mu_{\pi(j)}|.\end{aligned}$$

The number ξ_{jl} is between X_j and $\mu_{\pi(j)}$, which implies

$$\max_{j,l}|\xi_{jl}-\mu_{\pi(j)}|\le\max_{1\le j\le k}|X_j-\mu_{\pi(j)}|\le\frac{\sqrt{C_n}(1+\sqrt{\delta^2})}{\sqrt{n}}. \tag{37}$$

Using the bounds (33), (34), (35), (36) and (37), we have

$$\begin{aligned}&\left|\sum_{j=1}^k f_l(X_j)-\sum_{j=1}^k f_l(\mu_j)-(X_{\pi^{-1}(l)}-\mu_l)\right|\\ \le\;&\frac{1}{2}\frac{C_n(1+\sqrt{\delta^2})^2}{n}\kappa_2\left(\sqrt{C_n}(1+\sqrt{\delta^2})\right)\\ &+(k-1)\kappa_1\left(\sqrt{C_n}(1+\sqrt{\delta^2})\right)\frac{\sqrt{C_n}(1+\sqrt{\delta^2})}{\sqrt{n}}.\end{aligned} \tag{38}$$

Therefore,

$$\begin{aligned}&\left|T-n\sum_{l=1}^k(X_{\pi^{-1}(l)}-\mu_l)^2\right|\\ \le\;&n\sum_{l=1}^k\left|\left(\sum_{j=1}^k f_l(X_j)-\sum_{j=1}^k f_l(\mu_j)\right)^2-(X_{\pi^{-1}(l)}-\mu_l)^2\right|\\ \le\;&2n\sum_{l=1}^k|X_{\pi^{-1}(l)}-\mu_l|\left|\sum_{j=1}^k f_l(X_j)-\sum_{j=1}^k f_l(\mu_j)-(X_{\pi^{-1}(l)}-\mu_l)\right|\\ &+n\sum_{l=1}^k\left|\sum_{j=1}^k f_l(X_j)-\sum_{j=1}^k f_l(\mu_j)-(X_{\pi^{-1}(l)}-\mu_l)\right|^2\\ \le\;&2k\sqrt{n}\sqrt{C_n}(1+\sqrt{\delta^2})\left|\sum_{j=1}^k f_l(X_j)-\sum_{j=1}^k f_l(\mu_j)-(X_{\pi^{-1}(l)}-\mu_l)\right|\\ &+kn\left|\sum_{j=1}^k f_l(X_j)-\sum_{j=1}^k f_l(\mu_j)-(X_{\pi^{-1}(l)}-\mu_l)\right|^2.\end{aligned}$$

By (38), the bound for $\left|T-n\sum_{l=1}^k(X_{\pi^{-1}(l)}-\mu_l)^2\right|$ is of order $\frac{C_n^{3/2}\max_{j\neq l}|\eta_{jl}|}{\sqrt{n}}\to 0$. Finally, it is easy to see that

$$n\sum_{l=1}^k(X_{\pi^{-1}(l)}-\mu_l)^2\sim\chi^2_{k,\delta_n^2},$$

where $\delta_n^2=n\|\theta-\mu_\pi\|^2\to\delta^2$. Therefore, T converges to χ^2_{k,δ^2} in distribution. ■

Theorem 23 *In addition to Condition M2, assume*

$$\lim_{n\to\infty}\sqrt{n}\ell(\theta,\mu)=\delta\in[0,\infty).$$

Then, as n tends to infinity, $T_g\rightsquigarrow\chi^2_{k,\delta^2}$, and $T_g\ge T_f$ in probability. Moreover, if $\delta^2=0$, we have $T_g\rightsquigarrow\chi^2_k$, $T_f\rightsquigarrow\chi^2_d$ and $T_g-T_f\rightsquigarrow\chi^2_{k-d}$.

Proof The case $d = 1$ is obvious. We only prove the case $d \geq 2$. Similar to the inequality (32), we have $|\bar{\eta}_{gh}| + |\bar{\eta}_{hg}| \geq \frac{2}{|\nu_g - \nu_h|}$. By Condition M2, we have

$$\frac{\max_{1\leq g\leq d} \max_{j\in\mathcal{C}_g} |\mu_j - \nu_g|}{\min_{g\neq h} |\nu_g - \nu_h|} = o(1).$$

The observation is $X_j = \theta_j + n^{-1/2} Z_j$ with $Z_j \sim N(0,1)$ independently. Use the notation $L = \max_{1\leq g\leq d} \max_{j\in\mathcal{C}_g} \sqrt{n}|\mu_j - \nu_g| = o(1)$. Under the assumption of the theorem, there exists a sequence C_n that satisfies $C_n \to \infty$, $C_n^2 L \to 0$ and $\frac{C_n^{3/2} \max_{g\neq h} |\bar{\eta}_{gh}|}{\sqrt{n}} \to 0$, such that $\max_{1\leq j\leq k} Z_j^2 \leq C_n$ with probability tending to 1. Similar to the bound (36), the assumption $\lim_{n\to\infty} \sqrt{n}\ell(\theta,\mu) = \delta < \infty$ implies the existence of $\pi \in S_k$ such that

$$\max_{1\leq j\leq k} |X_j - \mu_{\pi(j)}| \leq \frac{\sqrt{C_n}(1+\sqrt{\delta^2})}{\sqrt{n}}.$$

We first study the asymptotic distribution of T_g. Note that

$$\max_{1\leq g\leq d} \max_{j\in\mathcal{C}_g} |X_{\pi^{-1}(j)} - \nu_g| \leq \frac{\sqrt{C_n}(1+\sqrt{\delta^2}) + L}{\sqrt{n}}. \tag{39}$$

Together with Condition M2 and the choice of C_n, we can immediately deduce

$$\frac{\max_{1\leq g\leq d} \max_{j\in\mathcal{C}_g} |X_{\pi^{-1}(j)} - \nu_g|}{\min_{g\neq h} |\nu_g - \nu_h|} \leq \max_{g\neq h} |\bar{\eta}_{gh}| \frac{\sqrt{C_n}(1+\sqrt{\delta^2}) + L}{\sqrt{n}} = o(1).$$

The function $g(t)$ can be written as

$$\frac{1}{g(t)} = \sum_{g=1}^{d} \frac{1}{(t-\nu_g)^2}.$$

For each $j \in \mathcal{C}_g$, we have

$$\frac{(X_{\pi^{-1}(j)} - \nu_g)^2}{g(X_{\pi^{-1}(j)})} = 1 + \sum_{h\in[d]\setminus\{g\}} \frac{(X_{\pi^{-1}(j)} - \nu_g)^2}{(X_{\pi^{-1}(j)} - \nu_h)^2}.$$

Thus,

$$\left| \frac{g(X_{\pi^{-1}(j)})}{(X_{\pi^{-1}(j)} - \nu_g)^2} - 1 \right| \leq \frac{\sum_{h\in[d]\setminus\{g\}} \frac{(X_{\pi^{-1}(j)} - \nu_g)^2}{(X_{\pi^{-1}(j)} - \nu_h)^2}}{1 + \sum_{h\in[d]\setminus\{g\}} \frac{(X_{\pi^{-1}(j)} - \nu_g)^2}{(X_{\pi^{-1}(j)} - \nu_h)^2}} \leq \sum_{h\in[d]\setminus\{g\}} \frac{(X_{\pi^{-1}(j)} - \nu_g)^2}{(X_{\pi^{-1}(j)} - \nu_h)^2}, \tag{40}$$

where the bound on the right hand side above can be bounded by

$$\sum_{h\in[d]\setminus\{g\}} \frac{2(X_{\pi^{-1}(j)} - \nu_g)^2}{(\nu_g - \nu_h)^2 - 2(X_{\pi^{-1}(j)} - \nu_h)^2} \leq 4d \max_{g\neq h} |\bar{\eta}_{gh}| \frac{\sqrt{C_n}(1+\sqrt{\delta^2}) + L}{\sqrt{n}}.$$

Together with (39), we have

$$\begin{aligned} & |g(X_{\pi^{-1}(j)}) - (X_{\pi^{-1}(j)} - \nu_g)^2| \\ = \; & (X_{\pi^{-1}(j)} - \nu_g)^2 \left| \frac{g(X_{\pi^{-1}(j)})}{(X_{\pi^{-1}(j)} - \nu_g)^2} - 1 \right| \\ \leq \; & 4d \max_{g\neq h} |\bar{\eta}_{gh}| \left(\frac{\sqrt{C_n}(1+\sqrt{\delta^2}) + L}{\sqrt{n}} \right)^3. \end{aligned}$$

Therefore

$$\begin{aligned} & \left| T_g - n \sum_{h=1}^{d} \sum_{j\in\mathcal{C}_h} (X_{\pi^{-1}(j)} - \nu_h)^2 \right| \\ \leq \; & n \sum_{h=1}^{d} \sum_{j\in\mathcal{C}_h} \left| g(X_{\pi^{-1}(j)}) - (X_{\pi^{-1}(j)} - \nu_g)^2 \right| \\ \leq \; & 4kd \max_{g\neq h} |\bar{\eta}_{gh}| \frac{\left(\sqrt{C_n}(1+\sqrt{\delta^2}) + L\right)^3}{\sqrt{n}} = o(1). \end{aligned} \tag{41}$$

For each $j \in \mathcal{C}_h$,

$$\begin{aligned} & n|(X_{\pi^{-1}(j)} - \nu_h)^2 - (X_{\pi^{-1}(j)} - \mu_j)^2| \\ \leq \; & n|\nu_h - \mu_j||X_{\pi^{-1}(j)} - \nu_h + X_{\pi^{-1}(j)} - \mu_j| \\ \leq \; & L\left(2\sqrt{C_n}(1+\sqrt{\delta^2}) + L\right) = o(1). \end{aligned}$$

Thus,

$$\left| T_g - n \sum_{h=1}^{d} \sum_{j\in\mathcal{C}_h} (X_{\pi^{-1}(j)} - \mu_j)^2 \right| \tag{42}$$

has a bound that tends to 0. Observe that

$$n \sum_{h=1}^{d} \sum_{j\in\mathcal{C}_h} (X_{\pi^{-1}(j)} - \mu_j)^2 \sim \chi^2_{k,\delta_n^2},$$

where

$$\delta_n^2 = n \sum_{j=1}^{k} (\theta_j - \mu_{\pi(j)})^2 \rightsquigarrow \delta^2.$$

Thus, $T_g \rightsquigarrow \chi^2_{k,\delta^2}$.

Next we derive the asymptotic distribution of T_f. Similar to (33), (34) and (35), we also have

$$\kappa_1(\epsilon) = \max_{g\neq h} \sup_{|t-\nu_g|\leq n^{-1/2}\epsilon} |f_h'(t)| \leq 2^{d-2} \left[\max_{g\neq h} \left(\frac{\epsilon|\bar{\eta}_{gh}|}{\sqrt{n}} \right)^{d-2} + \max_{g\neq h} \left(\frac{\epsilon|\bar{\eta}_{gh}|}{\sqrt{n}} \right) \right], \tag{43}$$

for $d \geq 3$,

$$\kappa_1(\epsilon) = \max_{g \neq h} \sup_{|t-\nu_g| \leq n^{-1/2}\epsilon} |f_h'(t)| \leq \max_{g \neq h} \left(\frac{\epsilon |\bar{\eta}_{gh}|}{\sqrt{n}} \right), \tag{44}$$

for $d = 2$, and

$$\kappa_2(\epsilon) = \max_{1 \leq h \leq d} \sup_{|t-\nu_h| \leq n^{-1/2}\epsilon} |f_h''(t)| \leq d \max_{g \neq h} |\bar{\eta}_{gh}| \max_{g \neq h} \left(1 + \frac{\epsilon |\bar{\eta}_{gh}|}{\sqrt{n}} \right)^{d-2}. \tag{45}$$

For any $j \in \mathcal{C}_g$,

$$\begin{aligned} & f_g(X_{\pi^{-1}(j)}) - f_g(\mu_j) \\ = \; & f_g(X_{\pi^{-1}(j)}) - f_g(\nu_g) + f_g(\nu_g) - f_g(\mu_j) \\ = \; & f_g'(\nu_g)(X_{\pi^{-1}(j)} - \mu_j) + \frac{1}{2} f_g''(\xi_{jg})(X_{\pi^{-1}(j)} - \nu_g)^2 - \frac{1}{2} f_g''(\bar{\xi}_{jg})(\mu_j - \nu_g)^2. \end{aligned}$$

For any $j \in \mathcal{C}_h$ with any $h \neq g$,

$$f_g(X_{\pi^{-1}(j)}) - f_g(\mu_j) = f_g'(\tilde{\xi}_{jg})(X_{\pi^{-1}(j)} - \mu_j).$$

By the fact that $f_g'(\nu_g) = 1$, we have

$$\begin{aligned} & \left| \sum_{j=1}^k f_g(X_j) - \sum_{j=1}^k f_g(\mu_j) - \sum_{j \in \mathcal{C}_g} (X_{\pi^{-1}(j)} - \mu_j) \right| \\ \leq \; & \frac{1}{2} \sum_{j \in \mathcal{C}_g} |f_g''(\xi_{jg})| (X_{\pi^{-1}(j)} - \nu_g)^2 + \frac{1}{2} \sum_{j \in \mathcal{C}_g} |f_g''(\bar{\xi}_{jg})| (\mu_j - \nu_g)^2 \\ & \sum_{h \in [d] \setminus \{g\}} \sum_{j \in \mathcal{C}_h} |f_g'(\tilde{\xi}_{jg})| |X_{\pi^{-1}(j)} - \mu_j|. \end{aligned}$$

The number ξ_{jg} is between $X_{\pi^{-1}(j)}$ and ν_g, the number $\bar{\xi}_{jg}$ is between μ_j and ν_g, and the number $\tilde{\xi}_{jg}$ is between $X_{\pi^{-1}(j)}$ and μ_j. Thus,

$$|\xi_{jg} - \nu_g| \leq |X_{\pi^{-1}(j)} - \nu_g| \leq \frac{\sqrt{C_n}(1 + \sqrt{\delta^2}) + L}{\sqrt{n}},$$

$$|\bar{\xi}_{jg} - \nu_g| \leq |\mu_j - \nu_g| \leq \frac{L}{\sqrt{n}},$$

and

$$|\tilde{\xi}_{jg} - \mu_j| \leq |X_{\pi^{-1}(j)} - \mu_j| \leq \frac{\sqrt{C_n}(1 + \sqrt{\delta^2})}{\sqrt{n}}.$$

Using the bounds (43), (44) and (45), we can deduce

$$\begin{aligned} & \left| \sum_{j=1}^k f_g(X_j) - \sum_{j=1}^k f_g(\mu_j) - \sum_{j \in \mathcal{C}_g} (X_{\pi^{-1}(j)} - \mu_j) \right| \\ \leq \; & k \frac{(\sqrt{C_n}(1 + \sqrt{\delta^2}) + L)^2}{n} \kappa_2 \left(\sqrt{C_n}(1 + \sqrt{\delta^2}) + L \right) \\ & + k \kappa_1 \left(\sqrt{C_n}(1 + \sqrt{\delta^2}) \right) \frac{\sqrt{C_n}(1 + \sqrt{\delta^2})}{\sqrt{n}}. \end{aligned}$$

Similar to the proof of Theorem (32), we can show that

$$\left| T_f - n \sum_{h=1}^d \frac{1}{|\mathcal{C}_h|} \left(\sum_{j \in \mathcal{C}_h} (X_{\pi^{-1}(j)} - \mu_j) \right)^2 \right| \tag{46}$$

has a bound of order $\frac{C_n^{3/2} \max_{j \neq l} |\eta_{jl}|}{\sqrt{n}} \to 0$. Note that when $\delta^2 = 0$,

$$n \sum_{h=1}^d \frac{1}{|\mathcal{C}_h|} \left(\sum_{j \in \mathcal{C}_h} (X_{\pi^{-1}(j)} - \mu_j) \right)^2 \sim \chi_d^2.$$

Thus, $T_f \rightsquigarrow \chi_d^2$.

Finally, we derive the asymptotic distribution for $T_g - T_f$. The bounds for (42) and (46) imply that

$$\left| T_g - T_f - n \sum_{h=1}^d \sum_{j \in \mathcal{C}_h} (X_{\pi^{-1}(j)} - \mu_j)^2 + n \sum_{h=1}^d \frac{1}{|\mathcal{C}_h|} \left(\sum_{j \in \mathcal{C}_h} (X_{\pi^{-1}(j)} - \mu_j) \right)^2 \right|$$

has a bound that tends to zero. Thus, the asymptotic distribution of $T_g - T_f$ is the same as that of

$$\begin{aligned} & n \sum_{h=1}^d \sum_{j \in \mathcal{C}_h} (X_{\pi^{-1}(j)} - \mu_j)^2 - n \sum_{h=1}^d \frac{1}{|\mathcal{C}_h|} \left(\sum_{j \in \mathcal{C}_h} (X_{\pi^{-1}(j)} - \mu_j) \right)^2 \\ = \; & n \sum_{h=1}^d \sum_{j \in \mathcal{C}_h} \left(X_{\pi^{-1}(j)} - \frac{1}{|\mathcal{C}_h|} \sum_{j \in \mathcal{C}_h} X_{\pi^{-1}(j)} - \left(\mu_j - \frac{1}{|\mathcal{C}_h|} \sum_{j \in \mathcal{C}_h} \mu_j \right) \right)^2, \end{aligned}$$

which is χ_{k-d}^2 when $\delta^2 = 0$. Therefore, $T_g - T_f \rightsquigarrow \chi_{k-d}^2$. Without the condition $\delta^2 = 0$, we can still claim $T_g \geq T_f$ in probability. ■

Theorem 24 *For $\pi = \operatorname{argmin}_{\pi \in S_k} \|\sqrt{p} - \sqrt{q_\pi}\|$, define*

$$\delta_1^2 = 4n \sum_{l=1}^k (1 - p_l) \left(\sqrt{p_l} - \sqrt{q_{\pi(l)}} \right)^2, \tag{47}$$

and

$$\delta_2^2 = 4n \sum_{l=1}^k p_l \left(\sqrt{p_l} - \sqrt{q_{\pi(l)}} \right)^2. \tag{48}$$

Assume $\limsup_{n \to \infty} (\delta_1^2 + \delta_2^2) < \infty$. Then, under Condition M3, $T - \delta_2^2 \rightsquigarrow \chi_{k-1, \delta_1^2}^2$, as n tends to infinity.

Proof The proof is almost the same as that of Theorem 22, and therefore we will omit some overlapping details. Largely speaking, we can replace the t, μ_j, θ_j, X_j by $\sqrt{t}, \sqrt{q_j}, \sqrt{p_j}, \sqrt{\hat{p}_j}$, and most parts in the proof of Theorem 22 will go through. Here are a few different details. We write $\sqrt{\hat{p}_j} = \sqrt{p}_j + n^{-1/2}Z_j/2$, with $Z_j = 2\sqrt{n}(\sqrt{\hat{p}_j} - \sqrt{p}_j)$. Condition M3 implies that $\max_{1\le j\le k} Z_j^2 = O_P(1)$. Thus, the inequality (36) in the proof of Theorem 22 can be replaced by $\max_{1\le j\le k} |\sqrt{\hat{p}_j} - \sqrt{q_{\pi(j)}}| \le \frac{\sqrt{C_n}(1+\sqrt{\delta^2})}{\sqrt{n}}$. Then, following the same argument in the proof of Theorem 22, we have

$$\left| T - 4n\sum_{l=1}^{k} (\sqrt{\hat{p}_l} - \sqrt{q_{\pi(l)}})^2 \right| = o_P(1),$$

and it is sufficient to study the asymptotic distribution of $4n\sum_{l=1}^{k}(\sqrt{\hat{p}_l} - \sqrt{q_{\pi(l)}})^2$. Let Δ be a vector with the lth entry being $2\sqrt{n}(\sqrt{\hat{p}_l} - \sqrt{q_{\pi(l)}})$. Then, we have $4n\sum_{l=1}^{k}(\sqrt{\hat{p}_l} - \sqrt{q_{\pi(l)}})^2 = \|Z + \Delta\|^2$. Under Condition M3, $Z \rightsquigarrow N(0, I_k - \sqrt{p}\sqrt{p}^T)$ by Lindeberg's central limit theorem together with an argument of delta's method. Therefore, there exists a random vector W that satisfies $W \rightsquigarrow N(0, I_k)$ and $Z = (I_k - \sqrt{p}\sqrt{p}^T)W$. This gives

$$\begin{aligned} \|Z + \Delta\|^2 &= \|(I_k - \sqrt{p}\sqrt{p}^T)W + (I_k - \sqrt{p}\sqrt{p}^T)\Delta + \sqrt{p}\sqrt{p}^T\Delta\|^2 \\ &= \|(I_k - \sqrt{p}\sqrt{p}^T)W + (I_k - \sqrt{p}\sqrt{p}^T)\Delta\|^2 + \|\sqrt{p}\sqrt{p}^T\Delta\|^2, \end{aligned}$$

where $\|(I_k - \sqrt{p}\sqrt{p}^T)W + (I_k - \sqrt{p}\sqrt{p}^T)\Delta\|^2 \rightsquigarrow \chi^2_{k-1,\delta_1^2}$ and $\|\sqrt{p}\sqrt{p}^T\Delta\|^2 = \delta_2^2$. ■

Theorem 25 *For $\pi = \mathrm{argmin}_{\pi\in S_k} \|\sqrt{p} - \sqrt{q_\pi}\|$, define*

$$\delta_1^2 = 4n\sum_{l=1}^{k}(1 - p_l)\left(\sqrt{p_l} - \sqrt{q_{\pi(l)}}\right)^2,$$

and

$$\delta_2^2 = 4n\sum_{l=1}^{k} p_l\left(\sqrt{p_l} - \sqrt{q_{\pi(l)}}\right)^2.$$

Assume $\limsup_{n\to\infty}(\delta_1^2 + \delta_2^2) < \infty$. Then, under Condition M4, $T_g - \delta_2^2 \rightsquigarrow \chi^2_{k-1,\delta_1^2}$, as n tends to infinity. Moreover, $T_g \ge T_f$ in probability. Furthermore, when $\delta_1^2 + \delta_2^2 = 0$, $T_g \rightsquigarrow \chi^2_{k-1}$, $T_f \rightsquigarrow \chi^2_{d-1}$ and $T_g - T_f \rightsquigarrow \chi^2_{k-d}$.

Proof The proof is largely the same as that of Theorem 24. We only need to replace the $t, \mu_j, \theta_j, \nu_h, X_j$ in the proof of Theorem 24 by $\sqrt{t}, \sqrt{q_j}, \sqrt{p_j}, \sqrt{r_h}, \sqrt{\hat{p}_j}$. Then, by the same argument, we have

$$\left| T_g - 4n\sum_{h=1}^{d}\sum_{j\in\mathcal{C}_h} (\sqrt{\hat{p}_{\pi^{-1}(j)}} - \sqrt{q_j})^2 \right| = o_P(1),$$

and

$$\left| T_g - T_f - 4n\sum_{h=1}^{d}\sum_{j\in\mathcal{C}_h} (\sqrt{\hat{p}_{\pi^{-1}(j)}} - \sqrt{q_j})^2 + 4n\sum_{h=1}^{d}\frac{1}{|\mathcal{C}_h|}\left(\sum_{j\in\mathcal{C}_h}(\sqrt{\hat{p}_{\pi^{-1}(j)}} - \sqrt{q_j})\right)^2 \right| = o_P(1).$$

The same argument in the proof of Theorem 24 implies that $T_g - \delta_2^2 \rightsquigarrow \chi^2_{k-1,\delta_1^2}$. The conclusion $T_g \ge T_f$ in probability can be deduced by

$$\begin{aligned} & 4n\sum_{h=1}^{d}\sum_{j\in\mathcal{C}_h} (\sqrt{\hat{p}_{\pi^{-1}(j)}} - \sqrt{q_j})^2 - 4n\sum_{h=1}^{d}\frac{1}{|\mathcal{C}_h|}\left(\sum_{j\in\mathcal{C}_h}(\sqrt{\hat{p}_{\pi^{-1}(j)}} - \sqrt{q_j})\right)^2 \\ = \; & 4n\sum_{h=1}^{d}\sum_{j\in\mathcal{C}_h}\left(\sqrt{\hat{p}_{\pi^{-1}(j)}} - \sqrt{q_j} - \frac{1}{|\mathcal{C}_h|}\sum_{j\in\mathcal{C}_h}(\sqrt{\hat{p}_{\pi^{-1}(j)}} - \sqrt{q_j})\right)^2 \ge 0. \end{aligned}$$

Now we derive the results under the null distribution. Recall the definition of Z_j in the proof of Theorem 24. The asymptotic distributions of T_g, T_f and $T_g - T_f$ are the same of those of

$$\sum_{j=1}^{k} Z_j^2, \quad \sum_{h=1}^{d}\frac{1}{|\mathcal{C}_h|}\left(\sum_{j\in\mathcal{C}_h} Z_j\right)^2, \quad \sum_{j=1}^{k} Z_j^2 - \sum_{h=1}^{d}\frac{1}{|\mathcal{C}_h|}\left(\sum_{j\in\mathcal{C}_h} Z_j\right)^2,$$

respectively under the null hypothesis. According to the argument in the proof of Theorem 24, $Z = (I_k - \sqrt{q}\sqrt{q}^T)W$ with $W \rightsquigarrow N(0, I_k)$. Therefore, $\sum_{j=1}^{k} Z_j^2 \rightsquigarrow \chi^2_{k-1}$.

Define a $k \times d$ matrix Q with $Q_{jh} = \frac{1}{\sqrt{|\mathcal{C}_h|}}$ if $j \in \mathcal{C}_h$ and $Q_{jh} = 0$ if $j \notin \mathcal{C}_h$. It is easy to see that QQ^T is a projection matrix and $Q^TQ = I_d$. Define a vector $\gamma \in \mathbb{R}^d$ whose hth entry is $\gamma_h = \sqrt{|\mathcal{C}_h|r_h}$. It is easy to see that γ is a unit vector. Moreover, we have $\sqrt{q} = Q\gamma$. With the new notation, we get

$$\sum_{h=1}^{d}\frac{1}{|\mathcal{C}_h|}\left(\sum_{j\in\mathcal{C}_h} Z_j\right)^2 = \|Q^TZ\|^2.$$

The covariance of Q^TZ is

$$Q^T(I_k - \sqrt{q}\sqrt{q}^T)Q = I_d - \gamma\gamma^T.$$

Therefore, $\|Q^TZ\|^2 \rightsquigarrow \chi^2_{d-1}$. Finally,

$$\sum_{j=1}^{k} Z_j^2 - \sum_{h=1}^{d}\frac{1}{|\mathcal{C}_h|}\left(\sum_{j\in\mathcal{C}_h} Z_j\right)^2 = \|Z\|^2 - \|Q^TZ\|^2 = Z^T(I_k - QQ^T)Z = W^T(I_k - QQ^T)W.$$

Therefore, its asymptotic distribution is χ^2_{k-d}. ■

The results of Theorem 2, Theorem 5, Theorem 7 and Theorem 9 are special cases of Theorem 22, Theorem 23, Theorem 24 and Theorem 25. Next, we give proofs of Theorem 19 and Theorem 21.

Proof [Proof of Theorem 19] Without loss of generality, we can assume that $p_1 = q_1 \leq p_2 = q_2 \leq ... \leq p_k = q_k$. This is just to simplify the notation. In general, such a rearrangement can always be done with extra notation of permutations. Then, $\mathcal{C}_g = \{j_g+1, j_g+2, ..., j_{g+1}\}$ for $g \in [d]$. According to the assumption, $\min_{g\neq h} \min_{j\in\mathcal{C}_g} \min_{l\in\mathcal{C}_h} \sqrt{n}|\sqrt{p_j} - \sqrt{p_l}| = o(1)$. Moreover, it is easy to see that $\max_{j\in[k]} \sqrt{n}|\sqrt{\hat{p}_j} - \sqrt{p_j}| = O_P(1)$ and $\max_{j\in[k]} \sqrt{m}|\sqrt{\hat{q}_j} - \sqrt{q_j}| = O_P(1)$. This leads to the conclusion

$$\mathbb{P}\left(\underline{\mathcal{C}}_g = \overline{\mathcal{C}}_g = \mathcal{C}_g \text{ for all } g \in [d] \text{ and } \underline{d} = \overline{d} = d\right) \to 1,$$

under Condition E.

From now on, the analysis is on the event $\{\underline{\mathcal{C}}_g = \overline{\mathcal{C}}_g = \mathcal{C}_g \text{ for all } g \in [d] \text{ and } \underline{d} = \overline{d} = d\}$. Define $\underline{Z}_j = 2\sqrt{n}(\sqrt{\hat{p}_j} - \sqrt{p_j})$ and $\overline{Z}_j = 2\sqrt{m}(\sqrt{\hat{q}_j} - \sqrt{q_j})$ for $j \in [k]$. The definition implies that $\max_{j\in[k]} |\underline{Z}_j| = O_P(1)$ and $\max_{j\in[k]} |\overline{Z}_j| = O_P(1)$. The definitions of $\underline{r}_g$ and $\overline{r}_g$ give

$$2\sqrt{n}(\sqrt{\underline{r}_g} - \sqrt{r_g}) = \frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g} \underline{Z}_j \quad \text{and} \quad 2\sqrt{m}(\sqrt{\overline{r}_g} - \sqrt{r_g}) = \frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g} \overline{Z}_j.$$

Given that $p_j = q_j = r_g$ for all $j \in \mathcal{C}_g$, we have $\sqrt{n}|\sqrt{\hat{q}_j} - \sqrt{\underline{r}_g}| = O_P(1)$ and $\sqrt{n}|\sqrt{\hat{p}_j} - \sqrt{\overline{r}_g}| = O_P(1)$ for all $j \in \mathcal{C}_g$. We also have $|\sqrt{\hat{q}_j} - \sqrt{\underline{r}_h}|^{-1} = O_P(1)$ and $|\sqrt{\hat{p}_j} - \sqrt{\overline{r}_h}|^{-1} = O_P(1)$ for all $j \in \mathcal{C}_g$ and $h \neq g$.

We first analyze $\underline{g}(t)$. By its definition,

$$\frac{1}{\underline{g}(t)} = \sum_{h=1}^{d} \frac{1}{(\sqrt{t} - \sqrt{\underline{r}_h})^2}.$$

Thus, for any $j \in \mathcal{C}_g$,

$$\frac{(\sqrt{\hat{q}_j} - \sqrt{\underline{r}_g})^2}{\underline{g}(\hat{q}_j)} = 1 + \sum_{h\in[d]\setminus\{g\}} \frac{(\sqrt{\hat{q}_j} - \sqrt{\underline{r}_g})^2}{(\sqrt{\hat{q}_j} - \sqrt{\underline{r}_h})^2}.$$

Similar to the argument in (40), we get

$$\left|\frac{\underline{g}(\hat{q}_j)}{(\sqrt{\hat{q}_j} - \sqrt{\underline{r}_g})^2} - 1\right| \leq \sum_{h\in[d]\setminus\{g\}} \frac{(\sqrt{\hat{q}_j} - \sqrt{\underline{r}_g})^2}{(\sqrt{\hat{q}_j} - \sqrt{\underline{r}_h})^2} = O_P(n^{-1}).$$

With some rearragangements, we get

$$\left|\frac{2nm}{n+m}\sum_{j\in[k]} \underline{g}(\hat{q}_j) - \frac{2nm}{n+m}\sum_{g=1}^{d}\sum_{j\in\mathcal{C}_g} (\sqrt{\hat{q}_j} - \sqrt{\underline{r}_g})^2\right| = o_P(1).$$

A similar argument also gives

$$\left|\frac{2nm}{n+m}\sum_{j\in[k]} \overline{g}(\hat{p}_j) - \frac{2nm}{n+m}\sum_{g=1}^{d}\sum_{j\in\mathcal{C}_g} (\sqrt{\hat{p}_j} - \sqrt{\overline{r}_g})^2\right| = o_P(1).$$

Therefore, we obtain the following approximation

$$\left|T_g - \frac{2nm}{m+n}\sum_{g=1}^{d}\sum_{j\in\mathcal{C}_g}\left(\frac{1}{2\sqrt{n}}\underline{Z}_j - \frac{1}{2\sqrt{m}}\frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\overline{Z}_j\right)^2 - \frac{2nm}{m+n}\sum_{g=1}^{d}\sum_{j\in\mathcal{C}_g}\left(\frac{1}{2\sqrt{m}}\overline{Z}_j - \frac{1}{2\sqrt{n}}\frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\underline{Z}_j\right)^2\right| = o_P(1).$$

Since

$$\begin{aligned}&\sum_{j\in\mathcal{C}_g}\left(\frac{1}{2\sqrt{n}}\underline{Z}_j - \frac{1}{2\sqrt{m}}\frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\overline{Z}_j\right)^2\\ =\ &\sum_{j\in\mathcal{C}_g}\left(\frac{1}{2\sqrt{n}}\underline{Z}_j - \frac{1}{2\sqrt{n}}\frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\underline{Z}_j\right)^2 + |\mathcal{C}_g|\left(\frac{1}{2\sqrt{n}}\frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\underline{Z}_j - \frac{1}{2\sqrt{m}}\frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\overline{Z}_j\right)^2,\end{aligned}$$

and

$$\begin{aligned}&\sum_{j\in\mathcal{C}_g}\left(\frac{1}{2\sqrt{m}}\overline{Z}_j - \frac{1}{2\sqrt{n}}\frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\underline{Z}_j\right)^2\\ =\ &\sum_{j\in\mathcal{C}_g}\left(\frac{1}{2\sqrt{m}}\overline{Z}_j - \frac{1}{2\sqrt{m}}\frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\overline{Z}_j\right)^2 + |\mathcal{C}_g|\left(\frac{1}{2\sqrt{n}}\frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\underline{Z}_j - \frac{1}{2\sqrt{m}}\frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\overline{Z}_j\right)^2,\end{aligned}$$

we have

$$\left|T_g - \frac{m}{2(n+m)}\sum_{g=1}^{d}\sum_{j\in\mathcal{C}_g}\left(\underline{Z}_j - \frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\underline{Z}_j\right)^2 - \frac{n}{2(n+m)}\sum_{g=1}^{d}\sum_{j\in\mathcal{C}_g}\left(\overline{Z}_j - \frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\overline{Z}_j\right)^2 - \sum_{g=1}^{d}|\mathcal{C}_g|\left(\frac{1}{|\mathcal{C}_g|}\sum_{j\in\mathcal{C}_g}\left(\sqrt{\frac{m}{m+n}}\underline{Z}_j - \sqrt{\frac{n}{m+n}}\overline{Z}_j\right)\right)^2\right| = o_P(1). \tag{49}$$

Next, we analyze $\underline{f}_h(t)$. By its definition,

$$\frac{d\underline{f}_h(t)}{d\sqrt{t}} = \frac{\prod_{g\in[d]\setminus\{h\}}(\sqrt{t} - \sqrt{\underline{r}_g})}{\prod_{g\in[d]\setminus\{h\}}(\sqrt{\underline{r}_h} - \sqrt{\underline{r}_g})}.$$

Therefore, we have

$$\max_{g\in[d]}\sup_{\sqrt{n}|\sqrt{t}-\sqrt{r_g}|\leq\lambda_n}\left|\frac{d\underline{f}_g(t)}{d\sqrt{t}} - 1\right| = o_P(1) \quad \text{and} \quad \max_{g\in[d]\setminus\{h\}}\sup_{\sqrt{n}|\sqrt{t}-\sqrt{r_g}|\leq\lambda_n}\left|\frac{d\underline{f}_h(t)}{d\sqrt{t}}\right| = o_P(1).$$

Using Taylor expansion, we get

$$\sum_{j=1}^{k} \underline{f}_h(\hat{p}_j) - \sum_{j=1}^{k} \underline{f}_h(\hat{q}_j) = \sum_{j\in\mathcal{C}_h} (\sqrt{\hat{p}_j} - \sqrt{\hat{q}_j}) + o_P(1) \sum_{j=1}^{k} |\sqrt{\hat{p}_j} - \sqrt{\hat{q}_j}|.$$

Then, we have

$$\left| \frac{2nm}{n+m} \sum_{h=1}^{d} \frac{1}{|\mathcal{C}_h|} \left(\sum_{j=1}^{k} \underline{f}_h(\hat{p}_j) - \sum_{j=1}^{k} \underline{f}_h(\hat{q}_j) \right)^2 - \frac{2nm}{n+m} \sum_{h=1}^{d} \frac{1}{|\mathcal{C}_h|} \left(\sum_{j\in\mathcal{C}_h} (\sqrt{\hat{p}_j} - \sqrt{\hat{q}_j}) \right)^2 \right| = o_P(1).$$

The same argument also leads to

$$\left| \frac{2nm}{n+m} \sum_{h=1}^{d} \frac{1}{|\mathcal{C}_h|} \left(\sum_{j=1}^{k} \overline{f}_h(\hat{p}_j) - \sum_{j=1}^{k} \overline{f}_h(\hat{q}_j) \right)^2 - \frac{2nm}{n+m} \sum_{h=1}^{d} \frac{1}{|\mathcal{C}_h|} \left(\sum_{j\in\mathcal{C}_h} (\sqrt{\hat{p}_j} - \sqrt{\hat{q}_j}) \right)^2 \right| = o_P(1).$$

Hence, we have the following approximation,

$$\left| T_f - \sum_{g=1}^{d} |\mathcal{C}_g| \left(\frac{1}{|\mathcal{C}_g|} \sum_{j\in\mathcal{C}_g} \left(\sqrt{\frac{m}{m+n}} \underline{Z}_j - \sqrt{\frac{n}{m+n}} \overline{Z}_j \right) \right)^2 \right| = o_P(1). \tag{50}$$

According to the argument in the proof of Theorem 24, $\underline{Z} = (I_k - \sqrt{p}\sqrt{p}^T)\underline{W}$ with $\underline{W} \rightsquigarrow N(0, I_k)$. Similarly, we also have $\overline{Z} = (I_k - \sqrt{q}\sqrt{q}^T)\overline{W}$ with $\overline{W} \rightsquigarrow N(0, I_k)$. Note that $\overline{W}$ is independent of $\underline{W}$. Recall the definition of the matrix Q and the vector γ in the proof of Theorem 25. Then,

$$\begin{aligned}
\sum_{g=1}^{d} \sum_{j\in\mathcal{C}_g} \left(\underline{Z}_j - \frac{1}{|\mathcal{C}_g|} \sum_{j\in\mathcal{C}_g} \underline{Z}_j \right)^2 &= \underline{Z}^T (I_k - QQ^T) \underline{Z}, \\
\sum_{g=1}^{d} \sum_{j\in\mathcal{C}_g} \left(\overline{Z}_j - \frac{1}{|\mathcal{C}_g|} \sum_{j\in\mathcal{C}_g} \overline{Z}_j \right)^2 &= \overline{Z}^T (I_k - QQ^T) \overline{Z}, \\
\sum_{g=1}^{d} |\mathcal{C}_g| \left(\frac{1}{|\mathcal{C}_g|} \sum_{j\in\mathcal{C}_g} \left(\sqrt{\frac{m}{m+n}} \underline{Z}_j - \sqrt{\frac{n}{m+n}} \overline{Z}_j \right) \right)^2 &= \left\| Q^T \left(\sqrt{\frac{m}{m+n}} \underline{Z} - \sqrt{\frac{n}{m+n}} \overline{Z} \right) \right\|^2.
\end{aligned}$$

Furthermore, we have

$$\begin{aligned}
\underline{Z}^T (I_k - QQ^T) \underline{Z} &= \underline{W}^T (I_k - QQ^T) \underline{W}, \\
\overline{Z}^T (I_k - QQ^T) \overline{Z} &= \overline{W}^T (I_k - QQ^T) \overline{W}, \\
\left\| Q^T \left(\sqrt{\frac{m}{m+n}} \underline{Z} - \sqrt{\frac{n}{m+n}} \overline{Z} \right) \right\|^2 &= \left\| (I_k - \gamma\gamma^T) Q^T \left(\sqrt{\frac{m}{m+n}} \underline{W} - \sqrt{\frac{n}{m+n}} \overline{W} \right) \right\|^2.
\end{aligned}$$

Therefore, the three terms above are asymptotically independent, and their asymptotic distributions are χ^2_{k-d}, χ^2_{k-d} and χ^2_{d-1} under the null, respectively. ■

Proof [Proof of Theorem 21] We will borrow notation and arguments used in the proof of Theorem 23. For example, we keep using the notation $L = \max_{1\le g\le d} \max_{j\in\mathcal{C}_g} \sqrt{n}|\mu_j - \nu_g|$. However, under Condition M2', we have $L = O(1)$ instead of $L = o(1)$. Let C_n be a diverging sequence that satisfies $C_n \to \infty$ and $\frac{C_n^{3/2} \max_{g\neq h} |\overline{n}_{gh}|}{\sqrt{n}} \to 0$. Then, we can use the same analysis in the proof of Theorem 23 that leads to (41) and (46). Note that the only difference is $L = O(1)$, and it will not affect the conclusions of (41) and (46). We still have

$$\left| T_g - n \sum_{h=1}^{d} \sum_{j\in\mathcal{C}_h} (X_{\pi^{-1}(j)} - \nu_h)^2 \right| = o_P(1),$$

and

$$\left| T_f - n \sum_{h=1}^{d} \frac{1}{|\mathcal{C}_h|} \left(\sum_{j\in\mathcal{C}_h} (X_{\pi^{-1}(j)} - \mu_j) \right)^2 \right| = o_P(1).$$

By the fact that

$$\begin{aligned}
& n \sum_{h=1}^{d} \sum_{j\in\mathcal{C}_h} (X_{\pi^{-1}(j)} - \nu_h)^2 - n \sum_{h=1}^{d} \frac{1}{|\mathcal{C}_h|} \left(\sum_{j\in\mathcal{C}_h} (X_{\pi^{-1}(j)} - \mu_j) \right)^2 \\
= \; & n \sum_{h=1}^{d} \sum_{j\in\mathcal{C}_h} (X_{\pi^{-1}(j)} - \nu_h)^2 - n \sum_{h=1}^{d} |\mathcal{C}_h| \left(\frac{1}{|\mathcal{C}_h|} \sum_{j\in\mathcal{C}_h} (X_{\pi^{-1}(j)} - \nu_h) \right)^2 \\
= \; & n \sum_{h=1}^{d} \sum_{j\in\mathcal{C}_h} \left(X_{\pi^{-1}(j)} - \frac{1}{|\mathcal{C}_h|} \sum_{j\in\mathcal{C}_h} X_{\pi^{-1}(j)} \right)^2,
\end{aligned}$$

we also have

$$\left| T_g - T_f - n \sum_{h=1}^{d} \sum_{j\in\mathcal{C}_h} \left(X_{\pi^{-1}(j)} - \frac{1}{|\mathcal{C}_h|} \sum_{j\in\mathcal{C}_h} X_{\pi^{-1}(j)} \right)^2 \right| = o_P(1).$$

Therefore, under the null hypothesis $X \sim N(\mu, n^{-1} I_k)$, we have $T_g \rightsquigarrow \chi^2_{k,\tau^2}$, $T_f \rightsquigarrow \chi^2_d$ and $T_g - T_f \rightsquigarrow \chi^2_{k-d,\tau^2}$. ■

10.2 Power Analysis

In this section, we give proofs of Theorem 3, Theorem 6, Theorem 8, Theorem 10 and Theorem 20.

Proof [Proof of Theorem 3] We first assume $n\ell(\theta, \mu)^2 \to \infty$ and derive $T \to \infty$ in probability. Note that for each $\pi \in S_k$,

$$n \sum_{j=1}^{k} (\theta_j - \mu_{\pi(j)})^2 \le 2n \sum_{j=1}^{k} (X_j - \theta_j)^2 + 2n \sum_{j=1}^{k} (X_j - \mu_{\pi(j)})^2.$$

Therefore,

$$n\ell(\theta,\mu)^2 \le 2\sum_{j=1}^{k} Z_j^2 + 2n\ell(X,\mu)^2,$$

where $Z_j \sim N(0,1)$. The fact that $2\sum_{j=1}^{k} Z_j^2 = O_P(1)$ and the assumption $n\ell(\theta,\mu)^2 \to \infty$ implies that $n\ell(X,\mu)^2 \to \infty$ in probability. Suppose we can show $T = O_P(1)$ implies $n\ell(X,\mu)^2 = O_P(1)$, then $n\ell(X,\mu)^2 \to \infty$ in probability must implies $T \to \infty$ in probability.

Now we suppose a bound $T \le B = O(1)$, and it is sufficient to derive a bound for $n\ell(X,\mu)^2$. For each $j = 1,...,k$, we shorthand the power sums $p_j(X_1,...,X_k)$ and $p_j(\mu_1,...,\mu_k)$ by $p_j(X)$ and $p_j(\mu)$. Similarly, the elementary symmetric polynomials $e_j(X_1,...,X_k)$ and $e_j(\mu_1,...,\mu_k)$ are shorthanded by $e_j(X)$ and $e_j(\mu)$. Define a vector $\Delta \in \mathbb{R}^k$ with the jth entry being $\Delta_j = \frac{1}{j}\sum_{h=1}^{k} X_h^j - \frac{1}{j}\sum_{h=1}^{k} \mu_h^j$. Recall the definition of the matrix $E(\mu_1,...,\mu_k)$. Then,

$$T = n\|E(\mu_1,...,\mu_k)\Delta\|^2.$$

We use $\lambda_{\max}(\cdot)$ and $\lambda_{\min}(\cdot)$ to denote the largest and the smallest eigenvalues. By the fact that $V(\mu_1,...,\mu_k)E(\mu_1,...,\mu_k) = I_k$, we have

$$T \ge n\lambda_{\min}(E(\mu_1,...,\mu_k)^T E(\mu_1,...,\mu_k))\|\Delta\|^2 \ge \frac{n\|\Delta\|^2}{\lambda_{\max}(V(\mu_1,...,\mu_k)^T V(\mu_1,...,\mu_k))}.$$

The bound $T \le B$ then leads to

$$\|\Delta\|^2 \le \frac{\lambda_{\max}(V(\mu_1,...,\mu_k)^T V(\mu_1,...,\mu_k))B}{n} = O\left(\frac{B}{n}\right). \tag{51}$$

Therefore, $|p_j(X) - p_j(\mu)|^2 = O(B/n)$ for each $j \in [k]$. By Newton's identities, we can deduce $|e_j(X) - e_j(\mu)|^2 = O(B/n)$ for each $j \in [k]$. Define

$$f(t) = \prod_{j=1}^{k}(t-\mu_j), \quad \hat{f}(t) = \prod_{j=1}^{k}(t-X_j).$$

The relation between the two polynomials and the elementary symmetric polynomials is given in (3). Using (3), we give a bound for $|f(X_l)|$.

$$|f(X_l)| = |f(X_l) - \hat{f}(X_l)| \le \sum_{j=0}^{k} |e_{k-j}(X) - e_{k-j}(\mu)||X_l|^j.$$

Since $|X_l|^2 \le p_2(X) \le p_2(\mu) + |p_2(X) - p_2(\mu)| = O(1)$, we have $|f(X_l)|^2 = O(B/n)$. The following proposition is useful and will be proved in the end.

Proposition 26 *For any $\mu_1,...,\mu_k$, we have*

$$|f(t)| \ge \min_{1\le j\le k}|t-\mu_j| \prod_{1\le j<l\le k}\left|\frac{\mu_j-\mu_l}{2}\right|.$$

By this inequality, we have

$$\max_{1\le l\le k}\min_{1\le j\le k}(X_l-\mu_j)^2 = O\left(\frac{B}{n}\right). \tag{52}$$

Therefore, there exists a sequence $\sigma(1),...,\sigma(k)$ such that

$$\max_{1\le j\le k}(X_j-\mu_{\sigma(j)})^2 = O\left(\frac{B}{n}\right).$$

Since

$$\prod_{j=1}^{k}|t-\mu_{\sigma(j)}| \le 2^k\prod_{j=1}^{k}|t-X_j| + 2^k\prod_{j=1}^{k}|X_j-\mu_{\sigma(j)}| = 2^k|\hat{f}(t)| + O\left(\left(\frac{B}{n}\right)^{k/2}\right),$$

and

$$|\hat{f}(\mu_l)| = |\hat{f}(\mu_l) - f(\mu_l)| \le \sum_{j=0}^{k}|e_{k-j}(X) - e_{k-j}(\mu)||\mu_l|^j = O\left(\sqrt{\frac{B}{n}}\right),$$

we have

$$\prod_{j=1}^{k}|\mu_l-\mu_{\sigma(j)}| = O\left(\sqrt{\frac{B}{n}}\right),$$

which holds for every $l = 1,...,k$. The fact that $\mu_1,...,\mu_k$ are k different fixed number implies σ must be an element of S_k. Hence, the bound (52) implies $n\ell(X,\mu)^2 = O(B)$, and the proof of one direction is complete.

For the other direction, it is sufficient to show that $n\ell(\theta,\mu) = O(1)$ implies $T = O_P(1)$. This can be shown using the same argument in the proof of Theorem 22. ■

Proof [Proof of Proposition 26] We first consider the case $k = 2$, where $f(t) = (t-\mu_1)(t-\mu_2)$. Suppose $|t-\mu_1| \le |t-\mu_2|$, then $|t-\mu_2| \ge \frac{|\mu_1-\mu_2|}{2}$. Thus, $|f(t)| \ge \frac{|\mu_1-\mu_2|}{2}\min\{|t-\mu_1|, |t-\mu_2|\}$. The same argument also works when $|t-\mu_1| > |t-\mu_2|$. When $k = 3$,

$$\begin{aligned} |f(t)| &\ge |t-\mu_3|\frac{|\mu_1-\mu_2|}{2}\min\{|t-\mu_1|, |t-\mu_2|\} \\ &= \frac{|\mu_1-\mu_2|}{2}\min\left\{|t-\mu_1||t-\mu_3|, |t-\mu_2||t-\mu_3|\right\}. \end{aligned}$$

The inequality for $k = 2$ can be used to lower bound both $|t-\mu_1||t-\mu_3|$ and $|t-\mu_2||t-\mu_3|$. This gives the desired result for $k = 3$. A standard mathematical induction argument leads to inequality for all k. ■

Proof [Proof of Theorem 6] According to the argument that we have used in the proof of Theorem 3, we need to show $T_f = O_P(1)$ and $T_g = O_P(1)$ imply $n\ell(X,\mu)^2 = O_P(1)$ for the proof of the first direction.

Suppose $T_f \le B_1 = O(1)$ and $T_g \le B_2 = O(1)$. It is sufficient to derive a bound for $n\ell(X,\mu)^2$. We first derive an inequality for $g(t)$. Since

$$\max_{1\le g\le d}\prod_{h\in[d]\setminus\{g\}}(t-\nu_h)^2 \le \sum_{g=1}^{d}\prod_{h\in[d]\setminus\{g\}}(t-\nu_h)^2 \le d\max_{1\le g\le d}\prod_{h\in[d]\setminus\{g\}}(t-\nu_h)^2,$$

we have

$$\frac{1}{d}\min_{1\le g\le d}(t-\nu_g)^2 \le g(t) \le \min_{1\le g\le d}(t-\nu_g)^2. \tag{53}$$

Therefore, $T_g \le B_2$ implies that $\sum_{j=1}^{k}\min_{1\le g\le d}(X_j-\nu_g)^2 \le \frac{dB_2}{n}$. This implies the existence of a sequence $\sigma(1),...,\sigma(k)$ such that $\max_{1\le j\le k}(X_j-\nu_{\sigma(j)})^2 \le \frac{dB_2}{n} = O(B_2/n)$. It further implies $\max_{1\le h\le d}\max_{1\le j\le k}|X_j^h-\nu_{\sigma(j)}^h| = O(\sqrt{B_2/n})$. Define $\hat{\mathcal{C}}_g = \{j\in[k]:\sigma(j)=g\}$ for each $g\in[d]$. Then

$$\sum_{h=1}^{d-1}\left(\sum_{j=1}^{k}X_j^h - \sum_{g=1}^{d}|\hat{\mathcal{C}}_g|\nu_g^h\right)^2 = O\left(\frac{B_2}{n}\right).$$

Using the same argument in deriving (51), we can also get the bound

$$\sum_{h=1}^{d-1}\left(\sum_{j=1}^{k}X_j^h - \sum_{g=1}^{d}|\mathcal{C}_g|\nu_g^h\right)^2 = O\left(\frac{B_1}{n}\right).$$

The inequalities in the last two displays, together with the equality $\sum_{g=1}^{d}|\hat{\mathcal{C}}_g| = \sum_{g=1}^{d}|\mathcal{C}_g|$, give

$$\sum_{h=0}^{d-1}\left(\sum_{g=1}^{d}|\hat{\mathcal{C}}_g|\nu_g^h - \sum_{g=1}^{d}|\mathcal{C}_g|\nu_g^h\right)^2 = O\left(\frac{B_1+B_2}{n}\right).$$

Define a vector $r\in\mathbb{R}^d$, with its gth entry being $|\hat{\mathcal{C}}_g|-|\mathcal{C}_g|$. Then,

$$\sum_{h=0}^{d-1}\left(\sum_{g=1}^{d}|\hat{\mathcal{C}}_g|\nu_g^h - \sum_{g=1}^{d}|\mathcal{C}_g|\nu_g^h\right)^2 = \|V(\nu_1,...,\nu_d)r\|^2 \ge \lambda_{\min}(V(\nu_1,...,\nu_d)^TV(\nu_1,...,\nu_d))\|r\|^2.$$

When $\nu_1,...,\nu_d$ are d different numbers, we have $\lambda_{\min}(V(\nu_1,...,\nu_d)^TV(\nu_1,...,\nu_d))>0$, and thus $\|r\|^2 = O\left(\frac{B_1+B_2}{n}\right)$. Since $\|r\|^2$ is an integer, we must have $\|r\|^2=0$, which gives $|\hat{\mathcal{C}}_g| = |\mathcal{C}_g|$ for any $g\in[d]$. From this we can deduce that $n\ell(X,\mu)^2 = O(B_2)$.

For the other direction, it is sufficient to show that $n\ell(\theta,\mu)^2 = O(1)$ implies $T_f = O_P(1)$ and $T_g = O_P(1)$. This can be shown using the same argument in the proof of Theorem 23. ■

Proof [Proofs of Theorem 8 and Theorem 10] The proofs are the same as those of Theorem 3 and Theorem 6. ■

Proof [Proof of Theorem 20] First of all, we have $\max_{j\in[k]}\sqrt{n}|\sqrt{\hat{q}_j}-\sqrt{q_j}| = O_P(1)$. This gives that $\mathbb{P}(\overline{\mathcal{C}}_g = \mathcal{C}_g \text{ for all } g\in[d] \text{ and } \overline{d}=d)\to 1$. From now on, the analysis is on the event $\{\overline{\mathcal{C}}_g = \mathcal{C}_g \text{ for all } g\in[d] \text{ and } \overline{d}=d\}$. Since we also have $\max_{j\in[k]}\sqrt{n}|\sqrt{\hat{p}_j}-\sqrt{p_j}| = O_P(1)$, the statement $n\ell(p,q)^2\to\infty$ is equivalent to $n\ell(\hat{p},q)^2\to\infty$ in probability. Therefore, we only need to establish the equivalence between $n\ell(\hat{p},q)^2\to\infty$ in probability and the power of the test goes to one.

In the first direction of the proof, we suppose that $T_f \le B_1 = O_P(1)$ and $T_g \le B_2 = O_P(1)$, and we will show $n\ell(\hat{p},q)^2 = O_P(1)$. The bound $T_g \le B_2 = O_P(1)$ implies that

$$\frac{2nm}{n+m}\sum_{j=1}^{k}\overline{g}(\hat{p}_j) \le B_2.$$

By the definition of $\overline{g}(\cdot)$, we have $\overline{g}(t) \ge d^{-1}\min_{g\in[d]}(\sqrt{t}-\sqrt{r_g})^2$. This implies the bound

$$\sum_{j=1}^{k}\min_{g\in[d]}\left(\sqrt{\hat{p}_j}-\sqrt{r_g}\right)^2 \le \frac{dB_2(n+m)}{nm} = O_P(n^{-1}).$$

Since $\max_{g\in[d]}\sqrt{n}|\sqrt{r_g}-\sqrt{r_g}| = O_P(1)$, we deduce

$$\sum_{j=1}^{k}\min_{g\in[d]}\left(\sqrt{\hat{p}_j}-\sqrt{r_g}\right)^2 = O_P(n^{-1}).$$

Then, there must exist $\sigma(1),...,\sigma(k)$ such that $\max_{j\in[k]}|\sqrt{\hat{p}_j}-\sqrt{r_{\sigma(j)}}|^2 = O_P(n^{-1})$. It further implies that $\max_{h\in[d]}\max_{j\in[k]}|(\sqrt{\hat{p}_j})^h-(\sqrt{r_{\sigma(j)}})^h| = O_P(n^{-1/2})$. Define $\hat{\mathcal{C}}_g = \{j\in[k]:\sigma(j)=g\}$ for each $g\in[d]$. Then, we have

$$\sum_{h=1}^{d-1}\left(\sum_{j=1}^{k}(\sqrt{\hat{p}_j})^h - \sum_{g=1}^{d}|\hat{\mathcal{C}}_g|(\sqrt{r_g})^h\right)^2 = O_P(n^{-1}). \tag{54}$$

Note that

$$\begin{aligned}
T_f &\ge \frac{2nm}{n+m}\sum_{h=1}^{d}\frac{1}{|\mathcal{C}_h|}\left(\sum_{j=1}^{k}\overline{f}_h(\hat{p}_j)-\sum_{j=1}^{k}\overline{f}_h(\hat{q}_j)\right)^2\\
&\ge \frac{2nm}{d(n+m)}\sum_{h=1}^{d}\left(\sum_{j=1}^{k}\overline{f}_h(\hat{p}_j)-\sum_{j=1}^{k}\overline{f}_h(\hat{q}_j)\right)^2\\
&= \frac{2nm}{d(n+m)}\|E(\sqrt{r}_1,...,\sqrt{r}_d)\Delta\|^2,
\end{aligned}$$

where Δ is a d-dimensional vector with $\Delta_h = \frac{1}{h}\sum_{j=1}^{k}(\sqrt{\hat{p}_j})^h - \frac{1}{h}\sum_{j=1}^{k}(\sqrt{\hat{q}_j})^h$. Thus, the bound $T_f \le B_1 = O_P(1)$ implies that

$$\|E(\sqrt{r}_1,...,\sqrt{r}_d)\Delta\|^2 = O_P(n^{-1}).$$

Since $\lambda_{\min}(E(\sqrt{r_1},...,\sqrt{r_d})^T E(\sqrt{r_1},...,\sqrt{r_d}))$ is a positive constant that is bounded away from 0, and

$$|\lambda_{\min}(E(\sqrt{\bar{r}_1},...,\sqrt{\bar{r}_d})^T E(\sqrt{\bar{r}_1},...,\sqrt{\bar{r}_d})) - \lambda_{\min}(E(\sqrt{r_1},...,\sqrt{r_d})^T E(\sqrt{r_1},...,\sqrt{r_d}))| = o_P(1),$$

we have $\|\Delta\|^2 = O_P(n^{-1})$, which further leads to

$$\sum_{h=1}^{d-1}\left(\sum_{j=1}^{k}(\sqrt{\hat{p}_j})^h - \sum_{g=1}^{d}|\mathcal{C}_g|(\sqrt{r_g})^h\right)^2 = O_P(n^{-1}), \tag{55}$$

by using the fact that $\max_{j\in[k]}\sqrt{n}|\sqrt{\hat{q}_j}-\sqrt{q_j}| = O_P(1)$ and Condition E. The two inequalities (54) and (55), together with the fact that $\sum_{g=1}^d|\hat{\mathcal{C}}_g| = \sum_{g=1}^d|\mathcal{C}_g|$, imply

$$\sum_{h=0}^{d-1}\left(\sum_{g=1}^{d}|\hat{\mathcal{C}}_g|(\sqrt{r_g})^h - \sum_{g=1}^{d}|\mathcal{C}_g|(\sqrt{r_g})^h\right)^2 = O_P(n^{-1}).$$

The same argument used in the proof of Theorem 6 implies that $|\hat{\mathcal{C}}_g| = |\mathcal{C}_g|$ for all $g \in [d]$. Therefore, together with $\max_{j\in[k]}|\sqrt{\hat{p}_j} - \sqrt{r_{\sigma(j)}}|^2 = O_P(n^{-1})$, we obtain the conclusion $n\ell(\hat{p}, q) = O_P(1)$.

For the other direction, when $n\ell(p,q)^2 = O(1)$, the approximations (49) and (50) in the proofs of Theorem 19 hold with bounds at the order of $O_P(1)$. This leads to $T_f = O_P(1)$ and $T_g = O_P(1)$. ■

10.3 Minimax Upper and Lower Bounds

In this section, we prove all results in Section 6. We first give proofs for the lower bounds, and then for the upper bounds.

Proof [Proof of Theorem 11] We first observe an inequality $|\eta_{jl}|+|\eta_{lj}| \geq \frac{2}{|\mu_l-\mu_j|}$, which has been derived in the proof of Theorem 22. Thus, Condition M1 implies $\sqrt{n}|\mu_j - \mu_l| \to \infty$ for any $j \neq l$. Consider the set

$$\bar{\Theta}_\delta = \left\{\theta : \|\theta - \mu\| = \frac{\delta}{\sqrt{n}}\right\}.$$

For each $\theta \in \bar{\Theta}_\delta$, $|\theta_j - \mu_j|^2 \leq \frac{\delta^2}{n}$, which implies μ_j is the closest element to θ_j in the set $\{\mu_1,...,\mu_k\}$. Therefore, $\ell(\theta,\mu) = \|\theta-\mu\| = \delta/\sqrt{n}$, which implies $\bar{\Theta}_\delta \subset \Theta_\delta$. This gives the lower bound

$$R_n(k,\delta) \geq \inf_{0\leq\phi\leq 1}\left\{\mathbb{P}_\mu\phi + \sup_{\theta\in\bar{\Theta}_\delta}\mathbb{P}_\theta(1-\phi)\right\}.$$

Consider the uniform distribution Π on $\bar{\Theta}_\delta$. Then,

$$R_n(k,\delta) \geq \inf_{0\leq\phi\leq 1}\left\{\mathbb{P}_\mu\phi + \int\mathbb{P}_\theta(1-\phi)d\Pi(\theta)\right\}.$$

By Neyman-Pearson lemma, the optimal testing function ϕ is given by

$$\phi = \left\{\frac{d\int\mathbb{P}_\theta d\Pi(\theta)}{d\mathbb{P}_\mu} > 1\right\}.$$

Using the property of Π, we have

$$\begin{aligned}\frac{d\int\mathbb{P}_\theta d\Pi(\theta)}{d\mathbb{P}_\mu} &= \int\frac{d\mathbb{P}_\theta}{d\mathbb{P}_\mu}d\Pi(\theta)\\ &= \int\exp\left(-\frac{n}{2}\|\theta-\mu\|^2 + n\langle X-\mu,\theta-\mu\rangle\right)d\Pi(\theta)\\ &= e^{-\delta^2/2}\int\exp\left(n\langle X-\mu,\theta-\mu\rangle\right)d\Pi(\theta).\end{aligned}$$

Let $\bar{\Pi}$ be the uniform distribution on the unit sphere $\{\theta : \|\theta\| = 1\}$, and then we have

$$\int\exp\left(n\langle X-\mu,\theta-\mu\rangle\right)d\Pi(\theta) = \int\exp\left(\delta\sqrt{n}\langle X-\mu,\theta\rangle\right)d\bar{\Pi}(\theta).$$

Let f be the marginal density of the first coordinate of $\theta \sim \bar{\Pi}$. Then, $f(t) \propto (1-t^2)^{\frac{k-3}{2}}$. The uniformity of $\bar{\Pi}$ implies that

$$\int\exp\left(\delta\sqrt{n}\langle X-\mu,\theta\rangle\right)d\bar{\Pi}(\theta) = \frac{\int_{-1}^1\exp\left(\delta\sqrt{n}\|X-\mu\|t\right)(1-t^2)^{\frac{k-3}{2}}dt}{\int_{-1}^1(1-t^2)^{\frac{k-3}{2}}dt}. \tag{56}$$

Therefore, we can write the quantity in the above display as $F(\sqrt{n}\|X-\mu\|)$. Since

$$F'(x) = \frac{\int_0^1(e^{\delta xt}-e^{-\delta xt})\delta t(1-t^2)^{\frac{k-3}{2}}dt}{\int_{-1}^1(1-t^2)^{\frac{k-3}{2}}dt} > 0, \text{ for } x > 0,$$

the testing statistic $\frac{d\int\mathbb{P}_\theta d\Pi(\theta)}{d\mathbb{P}_\mu}$ is an increasing function of $\|X-\mu\|^2$. This implies

$$\phi = \left\{n\|X-\mu\|^2 \geq t\right\},$$

for some $t > 0$. Note that $n\|X-\mu\|^2 \sim \chi^2_k$ under $\mathbb{P}_\mu$, and $n\|X-\mu\|^2 \sim \chi^2_{k,\delta^2}$ under any $\mathbb{P}_\theta$ with $\theta \in \bar{\Theta}_\delta$. Hence,

$$R_n(k,\delta) \geq \inf_{t>0}\left\{\mathbb{P}(\chi^2_k \geq t) + \mathbb{P}(\chi^2_{k,\delta^2} < t)\right\}.$$

This completes the proof. ■

Proof [Proof of Theorem 13] Since $|\bar{\eta}_{gh}| + |\bar{\eta}_{hg}| \geq \frac{2}{|\nu_g-\nu_h|}$, it is implied by Condition M2 that $\sqrt{n}|\nu_g - \nu_h| \to \infty$ for any $g \neq h$. Moreover, for any $j \in \mathcal{C}_h$, $|\mu_j - \nu_h| = o(n^{-1/2})$. Under these assumptions, for any θ such that $\|\theta-\mu\| = \frac{\delta}{\sqrt{n}}$, there exists a $\pi \in S_k$ that depends

on θ and $\|\theta_\pi - \mu\| = \ell(\theta,\mu) = \frac{\delta}{\sqrt{n}}(1+\epsilon_\theta)$. Moreover, $|\epsilon_\theta| = o(1)$ uniformly over all θ that satisfies $\|\theta - \mu\| = \frac{\delta}{\sqrt{n}}$. Define

$$\theta' = \mu + \frac{1}{1+\epsilon_\theta}(\theta - \mu). \tag{57}$$

Then, $\|\theta' - \mu\| = \frac{\delta_\theta}{\sqrt{n}}$ and $\ell(\theta',\mu) = \frac{\delta}{\sqrt{n}}$, where $\delta_\theta = \frac{\delta}{1+\epsilon_\theta}$. We use the notation R to denote the operator $R : \theta \mapsto R(\theta) = \theta'$ defined by (57). By the definition, a useful property is $\frac{R(\theta)-\mu}{\|R(\theta)-\mu\|} = \frac{\theta-\mu}{\|\theta-\mu\|}$. Consider the set

$$\bar{\Theta}_\delta = \left\{ R(\theta) : \|\theta - \mu\| = \frac{\delta}{\sqrt{n}} \right\}.$$

This definition immediately implies $\bar{\Theta}_\delta \subset \Theta_\delta$. Note that each element in $\bar{\Theta}_\delta$ can be represented as

$$R(\theta) = \mu + \frac{\delta_\theta}{\sqrt{n}} \frac{\theta - \mu}{\|\theta - \mu\|}.$$

Since there is a one-to-one relation between $\frac{\theta-\mu}{\|\theta-\mu\|}$ and a unit vector v, we can also write each element in $\bar{\Theta}_\delta$ as $\mu + \frac{\delta_v}{\sqrt{n}}v$. Consider a uniform probability measure $\bar{\Pi}$ on $\{v : \|v\| = 1\}$. Then, by the same argument in the proof of Theorem 11,

$$R_n(k,\delta) \geq \inf_{0\leq\phi\leq 1} \left\{ \mathbb{P}_\mu \phi + \int \mathbb{P}_{\mu + \frac{\delta_v}{\sqrt{n}}v}(1-\phi) d\bar{\Pi}(v) \right\},$$

and the likelihood ratio is

$$\mathcal{L} = \int \frac{d\mathbb{P}_{\mu+\frac{\delta_v}{\sqrt{n}}v}}{d\mathbb{P}_\mu} d\bar{\Pi}(v) = \int \exp\left(-\delta_v^2/2 + \delta_v\sqrt{n}\left\langle X - \mu, v\right\rangle\right) d\bar{\Pi}(v).$$

Under the assumption, there exist δ_- and δ_+ such that $\delta_- \leq \delta_v \leq \delta_+$ for all v and $\delta_-/\delta = 1 + o(1)$ and $\delta_+/\delta = 1 + o(1)$. We introduce the upper and lower brackets of $\mathcal{L}$ as

$$\begin{aligned}
\mathcal{L}_- &= \min\left\{ \int \exp\left(-\delta_+^2/2 + \delta_-\sqrt{n}\left\langle X-\mu, v\right\rangle\right) d\bar{\Pi}(v), \right. \\
&\qquad \left. \int \exp\left(-\delta_+^2/2 + \delta_+\sqrt{n}\left\langle X-\mu, v\right\rangle\right) d\bar{\Pi}(v) \right\}, \\
\mathcal{L}_+ &= \min\left\{ \int \exp\left(-\delta_-^2/2 + \delta_-\sqrt{n}\left\langle X-\mu, v\right\rangle\right) d\bar{\Pi}(v), \right. \\
&\qquad \left. \int \exp\left(-\delta_-^2/2 + \delta_+\sqrt{n}\left\langle X-\mu, v\right\rangle\right) d\bar{\Pi}(v) \right\}.
\end{aligned}$$

The definitions imply $\mathcal{L}_- \leq \mathcal{L} \leq \mathcal{L}_+$. Define the function

$$F_\delta(x) = \frac{\int_{-1}^1 \exp(\delta x t)(1-t^2)^{\frac{k-3}{2}} dt}{\int_{-1}^1 (1-t^2)^{\frac{k-3}{2}} dt}. \tag{58}$$

By (56), we have

$$\begin{aligned}
\mathcal{L}_- &= e^{-\delta_+^2/2}\min\{F_{\delta_-}(\sqrt{n}\|X-\mu\|), F_{\delta_+}(\sqrt{n}\|X-\mu\|)\}, \\
\mathcal{L}_+ &= e^{-\delta_-^2/2}\max\{F_{\delta_-}(\sqrt{n}\|X-\mu\|), F_{\delta_+}(\sqrt{n}\|X-\mu\|)\}.
\end{aligned}$$

Define $\phi = \mathbb{I}\{\mathcal{L} > 1\}$, $\phi_- = \mathbb{I}\{\mathcal{L}_- > 1\}$ and $\phi_+ = \mathbb{I}\{\mathcal{L}_+ > 1\}$. We have the inequality $\phi_- \leq \phi \leq \phi_+$. For $\theta = \mathbb{E}X = \mu$, $\|\sqrt{n}(X-\mu)\|^2 \sim \chi_k^2$. Thus, let $Z \sim N(0, I_k)$, and then we have

$$\begin{aligned}
\mathbb{P}_\mu \phi &\geq \mathbb{P}_\mu(\mathcal{L}_- > 1) \\
&= \mathbb{P}\left(e^{-\delta_+^2/2}\min\{F_{\delta_-}(\|Z\|), F_{\delta_+}(\|Z\|)\} > 1\right) \\
&\to \mathbb{P}\left(e^{-\delta^2/2}F_\delta(\|Z\|) > 1\right).
\end{aligned}$$

For the alternative $\theta = \mu + \frac{\delta_v}{\sqrt{n}}v \in \bar{\Theta}_\delta$, $\|\sqrt{n}(X-\mu)\|^2 \sim \chi_{k^2,\delta_v^2}$, where $\delta_v^2 \in [\delta_-, \delta_+]$. Then,

$$\begin{aligned}
\mathbb{P}_{\mu+\frac{\delta_v}{\sqrt{n}}v}(1-\phi) &\geq \mathbb{P}_{\mu+\frac{\delta_v}{\sqrt{n}}v}(\mathcal{L}_+ \leq 1) \\
&= \mathbb{P}\left(e^{-\delta_-^2/2}\max\{F_{\delta_-}(\|Z+\delta_v v\|), F_{\delta_+}(\|Z+\delta_v v\|)\} \leq 1\right) \\
&\geq \mathbb{P}\left(e^{-\delta_-^2/2}\max\{F_{\delta_-}(\|Z+\delta_+ v\|), F_{\delta_+}(\|Z+\delta_+ v\|)\} \leq 1\right) \\
&\to \mathbb{P}\left(e^{-\delta^2/2}F_\delta(\|Z+\delta v\|) \leq 1\right)
\end{aligned}$$

Note that $\mathbb{P}\left(e^{-\delta^2/2}F_\delta(\|Z+\delta v\|) \leq 1\right)$ is independent of v. Therefore, by the fact that $F_\delta(x)$ is increasing on $x > 0$, we have

$$\begin{aligned}
R_n(k,n) &\geq \mathbb{P}_\mu(\mathcal{L}_- > 1) + \inf_{\|v\|=1} \mathbb{P}_{\mu+\frac{\delta_v}{\sqrt{n}}v}(\mathcal{L}_+ \leq 1) \\
&\geq (1+o(1))\left\{ \mathbb{P}\left(e^{-\delta^2/2}F_\delta(\|Z\|) > 1\right) + \inf_{\|v\|=1} \mathbb{P}\left(e^{-\delta^2/2}F_\delta(\|Z+\delta v\|) \leq 1\right) \right\} \\
&\geq (1+o(1)) \inf_{t>0}\left\{ \mathbb{P}(\chi_k^2 \geq t) + \mathbb{P}(\chi_{k,\delta^2}^2 < t) \right\}.
\end{aligned}$$

The proof is complete. ■

Proof [Proof of Theorem 15] Note that Condition M3 implies $\sqrt{n}|\sqrt{q_j} - \sqrt{q_l}| \to \infty$ for any $j \neq l$. Consider the set

$$\bar{\mathcal{P}}_\delta = \left\{ p : \|\sqrt{p} - \sqrt{q}\| = \frac{\delta}{\sqrt{n}} \right\}.$$

For each $p \in \bar{\mathcal{P}}_\delta$, $|\sqrt{p_j} - \sqrt{q_j}|^2 \leq \frac{\delta^2}{n}$, which implies $\sqrt{q_j}$ is the closest element to $\sqrt{p_j}$ in the set $\{\sqrt{q_1}, ..., \sqrt{q_k}\}$. Therefore, $\ell(p,q) = \|\sqrt{p} - \sqrt{q}\| = \delta/\sqrt{n}$, which implies $\bar{\mathcal{P}}_\delta \subset \mathcal{P}_\delta$. This gives the lower bound

$$R_n(k,\delta) \geq \inf_{0\leq\phi\leq 1} \left\{ \mathbb{P}_q \phi + \sup_{p\in\bar{\mathcal{P}}_\delta} \mathbb{P}_p(1-\phi) \right\}.$$

Let Π be the uniform distribution on the sphere $\{v : \|v - \sqrt{q}\| = \delta/\sqrt{n}\}$. Then,

$$R_n(k,\delta) \geq \inf_{0\leq\phi\leq 1}\left\{\mathbb{P}_q\phi + \int \mathbb{P}_p(1-\phi)d\Pi(\sqrt{p})\right\}.$$

By Neyman-Pearson lemma, the optimal testing function ϕ is given by

$$\phi = \left\{\frac{d\int \mathbb{P}_p d\Pi(\sqrt{p})}{d\mathbb{P}_q} > 1\right\}.$$

By the definition, we have

$$\mathcal{L} = \frac{d\int \mathbb{P}_p d\Pi(\sqrt{p})}{d\mathbb{P}_q} = \int \exp\left(n\sum_{j=1}^k q_j \log\frac{p_j}{q_j} + n\sum_{j=1}^k(\hat{p}_j - q_j)\log\frac{p_j}{q_j}\right)d\Pi(\sqrt{p}),$$

where $\hat{p}_j = \frac{1}{n}\sum_{i=1}^n \mathbb{I}\{X_i = j\}$. Note that $\log\sqrt{\frac{p_j}{q_j}} = \log\left(1 + \frac{\sqrt{p_j}-\sqrt{q_j}}{\sqrt{q_j}}\right)$. By Condition M3, $\max_{1\leq j\leq k}\left|\frac{\sqrt{p_j}-\sqrt{q_j}}{\sqrt{q_j}}\right| = o(1)$. Therefore,

$$\max_{1\leq j\leq k}\frac{\left|\log\sqrt{\frac{p_j}{q_j}} - \frac{\sqrt{p_j}-\sqrt{q_j}}{\sqrt{q_j}}\right|}{\left|\frac{\sqrt{p_j}-\sqrt{q_j}}{\sqrt{q_j}}\right|^2} = O(1), \tag{59}$$

and

$$\max_{1\leq j\leq k}\frac{\left|\log\sqrt{\frac{p_j}{q_j}} - \frac{\sqrt{p_j}-\sqrt{q_j}}{\sqrt{q_j}} + \frac{1}{2}\left(\frac{\sqrt{p_j}-\sqrt{q_j}}{\sqrt{q_j}}\right)^2\right|}{\left|\frac{\sqrt{p_j}-\sqrt{q_j}}{\sqrt{q_j}}\right|^3} = O(1). \tag{60}$$

Since

$$\sum_{j=1}^k q_j\left[\frac{\sqrt{p_j}-\sqrt{q_j}}{\sqrt{q_j}} - \frac{1}{2}\left(\frac{\sqrt{p_j}-\sqrt{q_j}}{\sqrt{q_j}}\right)^2\right] = -\|\sqrt{p}-\sqrt{q}\|^2.$$

By (60), we have

$$\sum_{j=1}^k q_j\log\frac{p_j}{q_j} = -(1+o(1))2\|\sqrt{p}-\sqrt{q}\|^2.$$

Under Condition M3, $\hat{p}_j/p_j = 1 + o_P(1)$, and this implies $\hat{p}_j/q_j = 1 + o_P(1)$. Therefore,

$$\sum_{j=1}^k(\hat{p}_j - q_j)\frac{\sqrt{p_j}-\sqrt{q_j}}{\sqrt{q_j}} = 2(1+o_P(1))\sum_{j=1}^k(\sqrt{\hat{p}_j}-\sqrt{q_j})(\sqrt{p_j}-\sqrt{q_j}). \tag{61}$$

By (59), we have

$$\sum_{j=1}^k(\hat{p}_j - q_j)\log\frac{p_j}{q_j} = 4(1+o_P(1))\sum_{j=1}^k(\sqrt{\hat{p}_j}-\sqrt{q_j})(\sqrt{p_j}-\sqrt{q_j}). \tag{62}$$

The approximations (61) and (62) imply the existence of δ_- and δ_+ that satisfies $\delta_- = (1+o(1))\delta$, $\delta_+ = (1+o(1))\delta$. Moreover, on an event E with probability $1-o(1)$ under both null and alternative, the following inequalities hold:

$$-2\delta_+^2 \leq n\sum_{j=1}^k q_j\log\frac{p_j}{q_j} \leq -2\delta_-^2,$$

$$\sum_{j=1}^k(\hat{p}_j - q_j)\log\frac{p_j}{q_j} \leq \max\left\{\frac{4\delta_-}{\sqrt{n}}\left\langle\sqrt{\hat{p}}-\sqrt{q}, \frac{\sqrt{p}-\sqrt{q}}{\|\sqrt{p}-\sqrt{q}\|}\right\rangle, \frac{4\delta_+}{\sqrt{n}}\left\langle\sqrt{\hat{p}}-\sqrt{q}, \frac{\sqrt{p}-\sqrt{q}}{\|\sqrt{p}-\sqrt{q}\|}\right\rangle\right\},$$

and

$$\sum_{j=1}^k(\hat{p}_j - q_j)\log\frac{p_j}{q_j} \geq \min\left\{\frac{4\delta_-}{\sqrt{n}}\left\langle\sqrt{\hat{p}}-\sqrt{q}, \frac{\sqrt{p}-\sqrt{q}}{\|\sqrt{p}-\sqrt{q}\|}\right\rangle, \frac{4\delta_+}{\sqrt{n}}\left\langle\sqrt{\hat{p}}-\sqrt{q}, \frac{\sqrt{p}-\sqrt{q}}{\|\sqrt{p}-\sqrt{q}\|}\right\rangle\right\}.$$

We introduce the upper and lower brackets of the $\mathcal{L}$ as

$$\begin{aligned}
\mathcal{L}_- &= \min\left\{\int\exp\left(-2\delta_+^2 + 4\delta_-\sqrt{n}\left\langle\sqrt{\hat{p}}-\sqrt{q}, v\right\rangle\right)d\bar{\Pi}(v),\right. \\
&\qquad \left.\int\exp\left(-2\delta_+^2 + 4\delta_+\sqrt{n}\left\langle\sqrt{\hat{p}}-\sqrt{q}, v\right\rangle\right)d\bar{\Pi}(v)\right\}, \qquad (63)\\
\mathcal{L}_+ &= \max\left\{\int\exp\left(-2\delta_-^2 + 4\delta_-\sqrt{n}\left\langle\sqrt{\hat{p}}-\sqrt{q}, v\right\rangle\right)d\bar{\Pi}(v),\right. \\
&\qquad \left.\int\exp\left(-2\delta_-^2 + 4\delta_+\sqrt{n}\left\langle\sqrt{\hat{p}}-\sqrt{q}, v\right\rangle\right)d\bar{\Pi}(v)\right\}, \qquad (64)
\end{aligned}$$

where $\bar{\Pi}$ is the uniform distribution on the unit sphere $\{v : \|v\| = 1\}$. By (56), we have

$$\begin{aligned}
\mathcal{L}_- &= e^{-2\delta_+^2}\min\{F_{2\delta_-}(2\sqrt{n}\|\sqrt{\hat{p}}-\sqrt{q}\|), F_{2\delta_+}(2\sqrt{n}\|\sqrt{\hat{p}}-\sqrt{q}\|)\},\\
\mathcal{L}_+ &= e^{-2\delta_-^2}\max\{F_{2\delta_-}(2\sqrt{n}\|\sqrt{\hat{p}}-\sqrt{q}\|), F_{2\delta_+}(2\sqrt{n}\|\sqrt{\hat{p}}-\sqrt{q}\|)\}.
\end{aligned}$$

where $F_\delta(x)$ is defined in (58). Note that $4n\|\sqrt{\hat{p}}-\sqrt{q}\|^2 \rightsquigarrow \chi^2_{k-1}$ under the null and $4n\|\sqrt{\hat{p}}-\sqrt{q}\|^2 - \delta_2^2 \rightsquigarrow \chi^2_{k-1,\delta_1^2}$, with $\delta_1^2 = \delta_1(p)^2$ and $\delta_2^2 = \delta_2(p)^2$ defined in (47) and (48), under the alternative. Define $\phi = \mathbb{I}\{\mathcal{L} > 1\}$, $\phi_- = \mathbb{I}\{\mathcal{L}_- > 1\}$, $\phi_+ = \mathbb{I}\{\mathcal{L}_+ > 1\}$ and $\phi^* = \mathbb{I}\{\mathcal{L}^* > 1\}$. Then, we have the inequality $\phi_-\mathbb{I}_E \leq \phi\mathbb{I}_E \leq \phi_+\mathbb{I}_E$. For $q = p$, we have

$$\begin{aligned}
\mathbb{P}_q\phi &= \mathbb{P}_q\phi\mathbb{I}_E + \mathbb{P}_q\phi\mathbb{I}_{E^c}\\
&\geq \mathbb{P}_q\phi_-\mathbb{I}_E\\
&\geq \mathbb{P}_q(\mathcal{L}_- > 1) - \mathbb{P}_q(E^c)\\
&= \mathbb{P}_q\left(e^{-2\delta_+^2}\min\{F_{2\delta_-}(2\sqrt{n}\|\sqrt{\hat{p}}-\sqrt{q}\|), F_{2\delta_+}(2\sqrt{n}\|\sqrt{\hat{p}}-\sqrt{q}\|)\} > 1\right) - \mathbb{P}_q(E^c)\\
&\to \mathbb{P}\left(e^{-2\delta^2}F_{2\delta}\left(\sqrt{\chi^2_{k-1}}\right) > 1\right).
\end{aligned}$$

For the alternative, we have

$$\begin{aligned}
\mathbb{P}_p(1-\phi) &= \mathbb{P}_p(1-\phi)\mathbb{I}_E + \mathbb{P}_p(1-\phi)\mathbb{I}_{E^c} \\
&\leq \mathbb{P}_p(1-\phi_+)\mathbb{I}_E + \mathbb{P}_p(E^c) \\
&\leq \mathbb{P}_p(1-\phi_+) + \mathbb{P}_p(E^c) \\
&= \mathbb{P}_p\left(e^{-2\delta_-^2}\max\{F_{2\delta_-}(2\sqrt{n}\|\sqrt{\hat{p}}-\sqrt{q}\|), F_{2\delta_+}(2\sqrt{n}\|\sqrt{\hat{p}}-\sqrt{q}\|)\} \leq 1\right) + \mathbb{P}_p(E^c) \\
&\to \mathbb{P}\left(e^{-2\delta^2}F_{2\delta}\left(\sqrt{\chi^2_{k-1,\delta_1(p)^2}+\delta_2(p)^2}\right) \leq 1\right) \\
&\geq \inf_{\{\delta_1,\delta_2:\delta_1^2+\delta_2^2=\delta^2\}} \mathbb{P}\left(e^{-2\delta^2}F_{2\delta}\left(\sqrt{\chi^2_{k-1,\delta_1^2}+\delta_2^2}\right) \leq 1\right).
\end{aligned}$$

By the fact that $F_\delta(x)$ is increasing on $x > 0$, we have

$$\begin{aligned}
R_n(k,\delta) &\geq (1+o(1))\left\{\mathbb{P}\left(e^{-2\delta^2}F_{2\delta}\left(\sqrt{\chi^2_{k-1}}\right) > 1\right) + \right. \\
&\qquad \left. \inf_{\{\delta_1,\delta_2:\delta_1^2+\delta_2^2=\delta^2\}} \mathbb{P}\left(e^{-2\delta^2}F_{2\delta}\left(\sqrt{\chi^2_{k-1,\delta_1^2}+\delta_2^2}\right) \leq 1\right)\right\} \\
&\geq (1+o(1))\inf_{t>0}\left(\mathbb{P}\left(\chi^2_{k-1} > t\right) + \inf_{\{\delta_1,\delta_2:\delta_1^2+\delta_2^2=\delta^2\}} \mathbb{P}(\chi^2_{k-1,\delta_1^2}+\delta_2^2 \leq t)\right).
\end{aligned}$$

The proof is complete. ■

Proof [Proof of Theorem 17] It is implied by Condition M4 that $\sqrt{n}|\sqrt{r_g}-\sqrt{r_h}| \to \infty$ for any $g \neq h$. Moreover, for any $j \in \mathcal{C}_h$, $|\sqrt{q_j}-\sqrt{r_h}| = o(n^{-1/2})$. Under these assumptions, for any p such that $\|\sqrt{p}-\sqrt{q}\| = \frac{\delta}{\sqrt{n}}$, there exists a $\pi \in S_k$ that depends on p and $\|\sqrt{p_\pi}-\sqrt{q}\| = \ell(p,q) = \frac{\delta}{\sqrt{n}}(1+\epsilon_\theta)$. Moreover, $|\epsilon_\theta| = o(1)$ uniformly over all p that satisfies $\|\sqrt{p}-\sqrt{q}\| = \frac{\delta}{\sqrt{n}}$. Define

$$p' = \left(\sqrt{q} + \frac{1}{1+\epsilon_\theta}(\sqrt{p}-\sqrt{q})\right)^2. \tag{65}$$

Then, $\|\sqrt{p}-\sqrt{q}\| = \frac{\delta_\theta}{\sqrt{n}}$ and $\ell(p',q) = \frac{\delta}{\sqrt{n}}$, where $\delta_\theta = \frac{\delta}{1+\epsilon_\theta}$. We use the notation R to denote the operator $R : p \mapsto R(p)$ defined by (65). By the definition, a useful property is $\frac{\sqrt{R(p)}-\sqrt{q}}{\|\sqrt{R(p)}-\sqrt{q}\|} = \frac{\sqrt{p}-\sqrt{q}}{\|\sqrt{p}-\sqrt{q}\|}$. Consider the set

$$\bar{\mathcal{P}}_\delta = \left\{R(p) : \|\sqrt{p}-\sqrt{q}\| = \frac{\delta}{\sqrt{n}}\right\}.$$

This definition immediately implies $\bar{\mathcal{P}}_\delta \subset \mathcal{P}_\delta$. Note that each element in $\bar{\mathcal{P}}_\delta$ can be represented as

$$R(p) = \left(\sqrt{q} + \frac{\delta_\theta}{\sqrt{n}}\frac{\sqrt{p}-\sqrt{q}}{\|\sqrt{p}-\sqrt{q}\|}\right)^2.$$

Since there is a one-to-one relation between $\frac{\sqrt{p}-\sqrt{q}}{\|\sqrt{p}-\sqrt{q}\|}$ and a unit vector v, we can also write each element in $\bar{\mathcal{P}}_\delta$ as $\left(\sqrt{q}+\frac{\delta_v}{\sqrt{n}}v\right)^2$. Consider a uniform probability measure $\bar{\Pi}$ on $\{v : \|v\| = 1\}$. Then, by the same argument in the proof of Theorem 11,

$$R_n(k,\delta) \geq \inf_{0\leq\phi\leq 1}\left\{\mathbb{P}_q\phi + \int \mathbb{P}_{\left(\sqrt{q}+\frac{\delta_v}{\sqrt{n}}v\right)^2}(1-\phi)d\bar{\Pi}(v)\right\},$$

and the likelihood ratio is

$$\mathcal{L} = \int \frac{d\mathbb{P}_{\left(\sqrt{q}+\frac{\delta_v}{\sqrt{n}}v\right)^2}}{d\mathbb{P}_q}d\bar{\Pi}(v).$$

Using the same arguments in the proofs of Theorem 13 and Theorem 15, there exist δ_- and δ_+, with which we can define $\mathcal{L}_-$ and $\mathcal{L}_+$ as in (63) and (64) with the desired properties. Then, the same argument in the proof of Theorem 15 leads to the desired result. ■

Proof [Proof of Theorem 12] By studying the proof of Theorem 22, the only probabilistic argument in approximation is that $\max_{1\leq j\leq k} Z_j^2 \leq C_n$ in probability. Since this event is independent of θ, the in-probability argument can be made uniformly over $\theta \in \Theta_\delta$ and $\theta \in \Theta_0$. ■

Proof [Proof of Theorem 14] By Theorem 23, $T_g \geq T_f$ in probability. This implies that $\mathbb{P}_\theta\phi = \mathbb{P}_\theta(T_g > t^*)$ and $\mathbb{P}_\theta(1-\phi) = \mathbb{P}_\theta(T_g \leq t^*)$ under both null and alternative distributions. Then, by the same argument in the proof of Theorem 12, we obtain the desired conclusion. ■

Proof [Proofs of Theorem 16 and Theorem 18] Similar to the argument used in the proof of Theorem 12, the results directly follow the conclusions of Theorem 24 and Theorem 25. ■

Abstract

This paper proposes a new approach to construct high quality space-filling sample designs. First, we propose a novel technique to quantify the space-filling property and optimally trade-off uniformity and randomness in sample designs in arbitrary dimensions. Second, we connect the proposed metric (defined in the spatial domain) to the quality metric of the design performance (defined in the spectral domain). This connection serves as an analytic framework for evaluating the qualitative properties of space-filling designs in general. Using the theoretical insights provided by this spatial-spectral analysis, we derive the notion of optimal space-filling designs, which we refer to as space-filling spectral designs. Third, we propose an efficient estimator to evaluate the space-filling properties of sample designs in arbitrary dimensions and use it to develop an optimization framework for generating high quality space-filling designs. Finally, we carry out a detailed performance comparison on two different applications in varying dimensions: a) image reconstruction and b) surrogate modeling for several benchmark optimization functions and a physics simulation code for inertial confinement fusion (ICF). Our results clearly evidence the superiority of the proposed space-filling designs over existing approaches, particularly in high dimensions.

Keywords: design of experiments, space-filling, poisson-disk sampling, surrogate modeling, regression

1. Introduction

Exploratory analysis and inference in high dimensional parameter spaces is a ubiquitous problem in science and engineering. As a result, a wide-variety of machine learning tools and optimization techniques have been proposed to address this challenge. In its most generic formulation, one is interested in analyzing a high-dimensional function $f : \mathcal{D} \to \mathbb{R}$ defined on the d-dimensional domain $\mathcal{D}$. A typical approach for such an analysis is to first create an initial sampling $\mathcal{X} = \{\mathbf{x_i} \in \mathcal{D}\}_{i=1}^{N}$ of $\mathcal{D}$, evaluate f at all $\mathbf{x_i}$, and perform subsequent analysis and learning using only the resulting tuples $\{(\mathbf{x_i}, f(\mathbf{x_i}))\}_{i=1}^{N}$. Despite the widespread use of this approach, a critical question that still persists is: how should one obtain a high quality initial sampling $\mathcal{X}$ for which the data $f(\mathcal{X})$ is acquired or generated? This challenge is typically referred to as Design of Experiments (DoE) and solutions have been proposed as early as (Fisher, 1935) that optimized agricultural experiments. Subsequently, DoE has received significant attention from researchers in different fields (Garud et al., 2017). It is also an important *building block* for a wide variety of machine learning applications, such as, supervised machine learning, neural network training, image reconstruction, reinforcement learning, etc. (for a detailed discussion see Section 10). In several scenarios, it has been shown that success crucially depends on the quality of the initial sampling $\mathcal{X}$. Currently, a plethora of sampling solutions exist in the literature with a wide-range of assumptions and statistical guarantees; see (Garud et al., 2017; Owen, 2009) for a detailed review of related methods. Conceptually, most approaches aim to cover the sampling domain as uniformly as possible, in order to generate the so called *space-filling* experimental designs (Joseph, 2016)[1]. However, it is well know that uniformity alone does not necessarily lead to high performance. For example, optimal sphere packings lead to highly uniform designs, yet are well known to cause strong aliasing artifacts most easily perceived by the human visual system in many computer graphics applications. Instead, a common assumption is that a good design should balance uniformity and randomness[2]. Unfortunately, an exact definition for what should be considered a good space-filling design remains elusive.

Most common approaches use various scalar metrics to encapsulate different notions of ideal sampling properties. One popular metric is the discrepancy of an experimental design, defined as an appropriate ℓ_p norm of the ratio of points within all (hyper-rectangular) sub-volumes of $\mathcal{D}$ and the corresponding volume ratio. In other words, discrepancy quantifies the non-uniformity of a sample design. The most prominent examples of so called *discrepancy sequences* are Quasi-Monte Carlo (QMC) methods and their variants (Caflisch, 1998). In their classical form, discrepancy sequences are deterministic though extensions to incorporate randomess have been proposed, for example, using digital scrambling (Owen, 1995). Nevertheless, by optimizing for discrepancy these techniques focus almost exclusively on uniformity, and consequently even optimized QMC patterns can be quite structured and create

1. The term "space-filling" is used widely in the literature on design of experiments. However, in most cases, space-filling is meant in an intuitive sense and as a synonym for "evenly or uniformly spread". Later in this paper, we will provide a technical definition of space-filling property and what should be considered a good sample design.
2. In this paper, by randomness we mean that sample points are uniformly distributed over space. Here "uniform" is used in the sense that sample points follow a uniform probability distribution over the sampling region and that each location is equally likely to be selected as sample location, not in the sense that they are "evenly dispersed over the sampling region.

aliasing artifacts. Furthermore, even the fastest known strategies for evaluating popular discrepancy measures require $O(N^2d)$ operations making evaluation, let alone optimization, for discrepancy difficult even for moderate dimensions. Finally, for most discrepancy measures, the optimal achievable values are not known. This makes it difficult to determine whether a poorly performing sample design (e.g., in terms of generalization (or test error) in a regression application and reconstruction error in an image reconstruction application) is due to the insufficiency of the chosen discrepancy measure or due to ineffective optimization.

Another class of metrics to describe sample designs are based on geometric distances. These can be used directly by, for example, optimizing the maximin or minimax distance of a sample design (Schlomer et al., 2011) or indirectly by enforcing empty disk conditions. The latter is the basis for the so-called Poisson disk samples (Lagae and Dutr, 2008), which aim to generate random points such that no two samples can be closer than a given minimal distance r_{min}, i.e. enforcing an empty disc of radius r_{min} around each sample. Typically, Poisson-type samples are characterized by the *relative radius*, ρ, defined as the ratio of the minimum disk radius r_{min} and the maximum possible disk radius r_{max} for N samples to cover the sampling domain. Similar to the discrepancy sequences, maximin and minimax designs exclusively consider uniformity, are difficult to optimize for especially in higher dimensions, and often lead to very regular patterns. Poisson disk samples use ρ to trade off randomness (lower ρ values) and uniformity (higher ρ values). A popular recommendation in 2-d is to aim for $0.65 \leq \rho \leq 0.85$ as a good compromise. However, there does not exist any theoretical guidance for choosing ρ and hence, optimal values for higher dimensions are not known. As discussed in more detail in Section 2, there also exist a wide variety of techniques that combine different metrics and heuristics. For example, Latin Hypercube sampling (LHS) aims to spread the sample points uniformly by stratification, and one can potentially optimize the resulting design using maximin or minimax techniques (Jin et al., 2005).

In general, scalar metrics to evaluate the quality of a sample design tend not to be very descriptive. Especially in high dimensions different designs with, for example, the same ρ can exhibit widely different performance and for some discrepancy sequences the optimal designs converge to random samples in high dimensions (Morokoff and Caflisch, 1994; Wang and Sloan, 2008). Furthermore, one rarely knows the best achievable value of the metric, i.e. the lowest possible discrepancy, for a given problem which makes evaluating and comparing sampling designs difficult. Finally, most metrics are expensive to compute and not easily optimized. This makes it challenging in practice to create good designs in high dimensions and with large sample sizes.

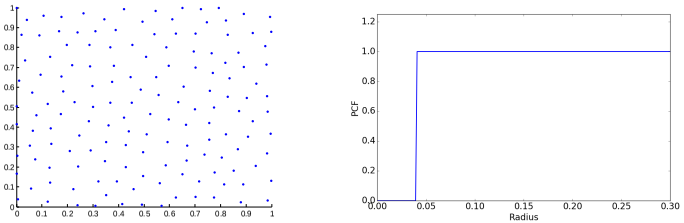
To alleviate this problem, we propose a new technique to quantify the space-filling property, which enables us to systematically trade-off uniformity and randomness, consequently producing better quality sampling designs. More specifically, we use tools from statistical mechanics to connect the qualitative performance (in the spectral domain) of a sampling pattern with its spatial properties characterized by the pair correlation function (PCF). The PCF measures the distribution of point samples as a function of distances, thus, providing a holistic view of the space-filling property (See Figure 1(b)). Furthermore, we establish the connection between the PCF and the power spectral density (PSD) via the $1-$D Hankel transform in arbitrary dimensions, thus providing a relation between the PCF and the quality metric of sampling quality to help subsequent design and analysis.

Using insights from the analysis of space-filling designs in the spectral domain, we provide design guidelines to systematically trade-off uniformity and randomness for a good sampling pattern. The analytical tractability of the PCF enables us to perform theoretical analysis in the spectral domain to derive the structure of optimal space-filling designs, referred to as *space-filling spectral design* in the rest of this paper. Next, we develop an edge corrected kernel density estimator based technique to measure the space-filling property via PCFs in arbitrary dimensions. In contrast to existing PCF estimation techniques, the proposed PCF estimator is both accurate and computationally efficient. Based on this estimator, we develop a systematic optimization framework and a novel algorithm to synthesize space-filling spectral designs. In particular, we propose to employ a weighted least-squares based gradient descent optimization, coupled with the proposed PCF estimator, to accurately match the optimal space-filling spectral design defined in terms of the PCF.

Note that there is a strong connection between the proposed space-filling spectral designs and coverage based designs such as Poisson Disk Sampling (PDS) (Gamito and Maddock, 2009). However, the major difference lies in the metric/criterion these techniques use to estimate and optimize the space-filling designs. Furthermore, existing works on PDS focus primarily on algorithmic issues, such as worst-case running times and numerical issues associated with providing high-quality implementations. However, different PDS methods often demonstrate widely different performances which raises the questions of how to evaluate the qualitative properties of different PDS patterns and how to define an optimal PDS pattern? We argue that, coverage (ρ) based metrics alone are insufficient for understanding the statistical aspects of PDS. This makes it difficult to generate high quality PDS patterns. As we will demonstrate below, existing PDS approaches largely ignore the randomness objective and instead concentrate exclusively on the coverage objective resulting in inferior sampling patterns compared to space-filling spectral designs, especially in high dimensions. Note that on the other hand, the proposed PCF based metric does not have these limitations and enables a comprehensive analysis of statistical properties of space-filling designs (including PDS), while producing higher quality sampling patterns compared to the state-of-the-art PDS approaches.

In (Kailkhura et al., 2016a), we use the PCF to understand the nature of PDS and provided theoretical bounds on the sample size of achievable PDS. Here we significantly extend our previous work and provide a more comprehensive analysis of the problem along with a novel space-filling spectral designs, an edge corrected PCF estimator, an optimization approach to synthesize the space-filling spectral designs and a detailed evaluation of the performance of the proposed sample design. The main contributions of this paper can be summarized as follows:

- We provide a novel technique to quantify the space-filling property of sample designs in arbitrary dimensions and systematically trade-off uniformity and randomness.
- We use tools from statistical mechanics to connect the qualitative performance (in the spectral domain) of a sample design with its spatial properties characterized by the PCF.
- We develop a computationally efficient edge corrected kernel density estimator based technique to estimate the space-filling property in arbitrary dimensions.



(a) (b)

Figure 1: A sample design that balances *randomness* and *uniformity*. (a) Point distribution, and (b) Pair correlation function.

- Using theoretical insights obtained via spectral analysis of point distributions, we provide design guidelines for optimal space-filling designs.
- We devise a systematic optimization framework and a gradient descent optimization algorithm to generate high quality space-filling designs.
- We demonstrate the superiority of proposed space-filling spectral samples compared to existing space-filling approaches through rigorous empirical studies on two different applications: *a*) image reconstruction and *b*) surrogate modeling on several benchmark optimization functions and an inertial confinement fusion (ICF) simulation code.

2. Related Work

In this section, we provide a brief overview of existing approaches for creating space-filling sampling patterns. Note that the prior art for this long-studied research area is too extensive to cover in detail, and hence we recommend interested readers to refer to (Garud et al., 2017; Owen, 2009) for a more comprehensive review.

2.1 Latin Hypercube Sampling

Monte-Carlo methods form an important class of techniques for space-filling sample design. However, it is well known that Monte-Carlo methods are characterized by high variance in the resulting sample distributions. Consequently, variance reduction methods are employed in practice to improve the performance of simple Monte Carlo techniques. One example is stratified sampling using the popular Latin Hypercube Sampling (LHS) (McKay, 1992; Packham, 2015). Since its inception, several variants of LHS have been proposed with the goal of achieving better space-filling properties, in addition to reducing variance. A notable improvement in this regard are techniques that achieve LHS space filling not only in one-dimensional projections, but also in higher dimensions. For example, Tang (Tang, 1993; Leary et al., 2003) introduced orthogonal-array-based Latin hypercube sampling to improve space-filling in higher dimensional subspaces. Furthermore, a variety of space-filling criteria

such as entropy, integrated mean square error, minimax and maximin distances, have been utilized for optimizing LHS (Jin et al., 2005). A particularly effective and widely adopted metric is the maximin distance criterion, which maximizes the minimal distance between points to avoid designs with points too close to one another (Morris and Mitchell, 1995). A detailed study on LHS and its variants can be found in (Koehler and Owen, 1996).

2.2 Quasi Monte Carlo Sampling

Following the success of Monte-Carlo methods, Quasi-Monte Carlo (QMC) sampling was introduced in (Halton, 1964) and since then has become the de facto solution in a wide-range of applications (Caflisch, 1998; Wang and Sloan, 2008). The core idea of QMC methods is to replace the random or pseudo-random samples in Monte-Carlo methods with well-chosen deterministic points. These deterministic points are chosen such that they are highly uniform, which can be quantified using the measure of discrepancy. Low-discrepancy sequences along with bounds on their discrepancy were introduced in the 1960's by Halton (Halton, 1964) and Sobol (Sobol, 1967), and are still in use today. However, despite their effectiveness, a critical limitation of QMC methods is that error bounds and statistical confidence bounds of the resulting designs cannot be obtained due to the deterministic nature of low-discrepancy sequences. In order to alleviate this challenge, randomized quasi-Monte Carlo (RQMC) sampling has been proposed (LEcuyer and Lemieux, 2005), and in many cases shown to be provably better than the classical QMC techniques (Owen and Tribble, 2005). This has motivated the development of other randomized quasi-Monte Carlo techniques, for example, methods based on digital scrambling (Owen, 1995).

2.3 Poisson Disk Sampling

While discrepancy-based designs have been popular among uncertainty quantification researchers, the computer graphics community has had long-standing success with coverage-based designs. In particular, Poisson disk sampling (PDS) is widely used in applications such as image/volume rendering. The authors in (Dippe and Wold, 1985; Cook, 1986) were the first to introduce PDS for turning regular aliasing patterns into featureless noise, which makes them perceptually less visible. Their work was inspired by the seminal work of Yellott *et.al.* (Yellott, 1983), who observed that the photo-receptors in the retina of monkeys and humans are distributed according to a Poisson disk distribution, thus explaining its effectiveness in imaging.

Due to the broad interest created by the initial work on PDS, a large number of approaches to generate Poisson disk distributions have been developed over the last decade (Gamito and Maddock, 2009; Ebeida et al., 2012, 2011; Ip et al., 2013; Bridson, 2007; Oztireli and Gross, 2012; Heck et al., 2013; Wei, 2008; Dunbar and Humphreys, 2006; Wei, 2010; Balzer et al., 2009; Geng et al., 2013; Yan and Wonka, 2012a, 2013; Ying et al., 2013b, 2014; Hou et al., 2013; Ying et al., 2013a; Guo et al., 2014; Wachtel et al., 2014; Xu et al., 2014; Ebeida et al., 2014; de Goes et al., 2012; Zhou et al., 2012). Most Poisson disk sample generation methods are based on dart throwing (Dippe and Wold, 1985; Cook, 1986), which attempts to generate as many darts as necessary to cover the sampling domain while not violating the Poisson disk criterion. Given the desired disk size r_{min} (or coverage ρ), dart throwing generates random samples and rejects or accepts each sample based on its distance

to the previously accepted samples. Despite its effectiveness, its primary shortcoming is the choice of termination condition, since the algorithm does not know whether or not the domain is fully covered. Hence, in practice, the algorithm has poor convergence, which in turn makes it computationally expensive. On the other hand, dart throwing is easy to implement and applicable to any sampling domain, even non-Euclidean. For example, Anirudh *et.al.* use a dart throwing technique to generate Poisson disk samples on the Grassmannian manifold of low-dimensional linear subspaces (Anirudh et al., 2017).

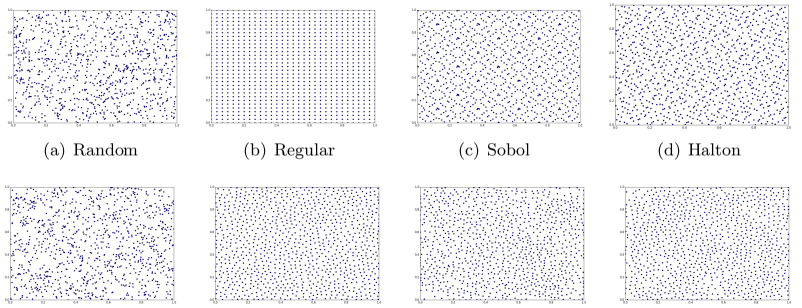
Reducing the computational complexity of PDS generation, particularly in low and moderate dimensions, has been the central focus of many existing efforts. To this end, approximate techniques that produce sample sets with characteristics similar to Poisson disk have been developed. Early examples (McCool and Fiume, 1992) are relatively simple and can be used for a wide range of sampling domains, but the gain in computational efficacy is limited. Other methods partition the space into grid cells in order to allow parallelization across the different cells and achieve linear time algorithms (Bridson, 2007). Another class of approaches, referred to as *tile-based* methods, have been developed for generating a large number of Poisson disk samples in 2-D. Broadly, these methods either start with a smaller set of samples, often obtained using other PDS techniques, and tile these samples (Wachtel et al., 2014), or alternatively use a regular tile structure for placing each sample (Ostromoukhov et al., 2004). With the aid of efficient data structures, these methods can generate a large number of samples efficiently. Unfortunately, these approximations can lead to low sample quality due to artifacts induced at tile boundaries and the inherent non-random nature of tilings. More recently, many researchers have explored the idea of partitioning the sampling space in order to avoid generating new samples that will be ultimately rejected by dart throwing. While some of these methods only work in $2-$D (Dunbar and Humphreys, 2006; Ebeida et al., 2011), the efficiency of other methods that are designed for higher dimensions (Gamito and Maddock, 2009; Ebeida et al., 2012) drops exponentially with increasing dimensions. Finally, relaxation methods that iteratively increase the Poisson disk radius of a sample set (McCool and Fiume, 1992) by re-positioning the samples also exist. However, these methods have the risk of converging to a regular pattern with tight packing unless randomness is explicitly enforced (Balzer et al., 2009; Schlomer et al., 2011).

A popular variant of PDS is the maximal PDS (MPDS) distribution, where the *maximality* constraint requires that the sample disks overlap, in the sense that they cover the whole domain leaving no room to insert an additional point. In practice, maximal PDS tends to outperform traditional PDS due to better coverage. However, algorithmically guaranteeing maximality requires expensive checks causing the resulting algorithms to be slow in moderate (2-5) and practically unfeasible in higher (7 and above) dimensions. Though strategies to alleviate this limitation have been proposed in (Ebeida et al., 2012), the inefficiency of MPDS algorithms in higher dimensions still persists. Interestingly, a common limitation of all existing MPDS approaches is that there is no direct control over the number of samples produced by the algorithm, which makes the use of these algorithms difficult in practice, since optimizing samples for a given sample budget is the most common approach.

As discussed in Section 1, the metrics used by the space-filling designs discussed above do not provide insights into how to systematically trade-off uniformity and randomness. Thereby, making the design and optimization of sampling pattern a cumbersome process. To alleviate this problem, we propose a novel metric for assessing the space-filling property

and connect the proposed metric (defined in the spatial domain) to the quality metric of design performance (defined in the spectral domain).

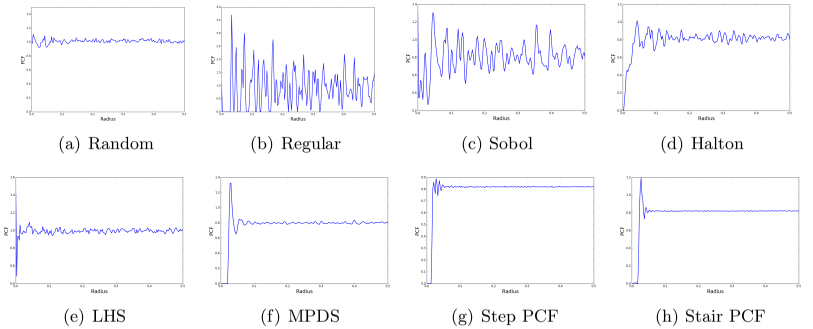
3. A Metric for Assessing Space-filling Property



(a) Random (b) Regular (c) Sobol (d) Halton

(e) LHS (f) MPDS (g) Step PCF (h) Stair PCF

Figure 2: Visualization of 2-d point distributions obtained using different sample design techniques. In all cases, the number of samples N was fixed at 1000.

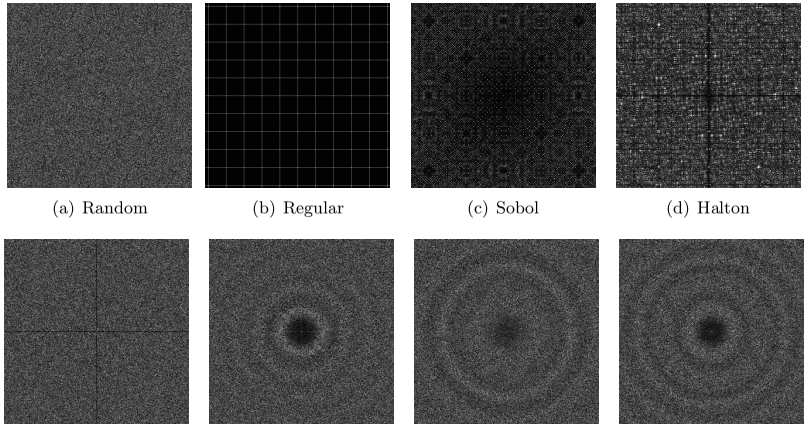


(a) Random (b) Regular (c) Sobol (d) Halton

(e) LHS (f) MPDS (g) Step PCF (h) Stair PCF

Figure 3: *Space-filling Metric*: Pair correlation functions, corresponding to the samples in Figure 2, characterize the coverage (and randomness) of point distributions obtained using different techniques.

In this section we first provide a definition of a space-filling design. Subsequently, we propose a metric to quantify space-filling properties of sample designs.



(a) Random (b) Regular (c) Sobol (d) Halton

(e) LHS (f) MPDS (g) Step PCF (h) Stair PCF

Figure 4: *Performance Quality Metric*: Power spectral density is used to characterize the effectiveness of sample designs, through the distribution of power in different frequencies.

3.1 Space-filling Designs

Without any prior knowledge of the function f of interest, a reasonable objective when creating $\mathcal{X}$ is that the samples should be random to provide an equal chance of finding features of interest, e.g., local minima in an optimization problem, anywhere in $\mathcal{D}$. However, to avoid sampling only parts of the parameter space, a second objective is to cover the space in $\mathcal{D}$ uniformly, in order to guarantee that all sufficiently large features are found. Therefore, a good space-filling design can be defined as follows:

Definition 1 *A space-filling design is a set of samples that are distributed according to a uniform probability distribution (Objective 1: Randomness) but no two samples are closer than a given minimum distance r_{min} (Objective 2: Coverage).*

Next, we describe the metric that we use to quantify the space-filling property of a sample design. The proposed metric is based on the spatial statistic, *pair correlation function* (PCF) and we will show that this metric is directly linked to the quality metric of design performance defined in the spectral domain.

3.2 Pair Correlation Function as a Space-filling Metric

In contrast to existing scalar space-filling metrics such as discrepancy, and coverage, the PCF characterizes the distribution of sample distances, thus providing a comprehensive description of the sample designs. A precise definition of the PCF can be given in terms

of the intensity λ and product density β of a point process (Illian et al., 2008; Oztireli and Gross, 2012).

Definition 2 *Let us denote the intensity of a point process $\mathcal{X}$ as $\lambda(\mathcal{X})$, which is the average number of points in an infinitesimal volume around $\mathcal{X}$. For isotropic point processes, this is a constant value. To define the product density β, let $\{B_i\}$ denote the set of infinitesimal spheres around the points, and $\{dV_i\}$ indicate the volume measures of B_i. Then, we have*[3] *$Pr(\mathbf{X_1} = \mathbf{x_1}, \cdots, \mathbf{X_N} = \mathbf{x_N}) = \beta(\mathbf{x_1}, \cdots, \mathbf{x_N}) dV_1 \cdots dV_N$ which represents the probability of having points $\mathbf{x_i}$ in the infinitesimal spheres $\{B_i\}$. In the isotropic case, for a pair of points, β depends only on the distance between the points, hence one can write $\beta(\mathbf{x_i}, \mathbf{x_j}) = \beta(||\mathbf{x_i} - \mathbf{x_j}||) = \beta(r)$ and $Pr(r) = \beta(r) dV_i dV_j$. The PCF is then defined as*

$$G(r) = \frac{\beta}{\lambda^2}. \tag{1}$$

Note that the PCF characterizes spatial properties of a sample design. However, in several cases, it is easier to link the quality metric of a sample design to its spectral properties. Therefore, we establish a connection between the spatial property of a sample design defined in PCF space to its spectral properties.

3.3 Connecting Spatial Properties and Spectral Properties of Space-filling Designs

Fourier analysis is a standard approach for understanding the qualitative properties of sampling patterns. Hence, we propose to analyze the spectral properties of sample designs, using tools such as the power spectral density, in order to assess their quality. For isotropic samples, a quality metric of interest is the radially-averaged power spectral density, which describes how the signal power is distributed over different frequencies.

Definition 3 *For a finite set of N points, $\{\mathbf{x}_j\}_{j=1}^N$, in a region with unit volume, the power spectral density of the sampling function $\sum_{j=1}^N \delta(\mathbf{x} - \mathbf{x}_j)$ is formally defined as*

$$P(\mathbf{k}) = \frac{1}{N}|S(\mathbf{k})|^2 = \frac{1}{N}\sum_{j,\ell} e^{-2\pi i \mathbf{k}.(\mathbf{x}_\ell - \mathbf{x}_j)}, \tag{2}$$

where $|.|$ denotes the l^2-norm and $S(\mathbf{k})$ denotes the Fourier transform of the sampling function.

The radially-averaged power spectral density (PSD) is denoted using $P(k)$. Next, we show that the connection between spectral properties of a d-dimensional isotropic sample design and its corresponding pair correlation function can be obtained via the d-dimensional Fourier transform or more efficiently using the 1-d Hankel transform.

3. We denote a realization of random variables $\mathbf{X}_1, \cdots, \mathbf{X}_N$ by $\mathbf{x}_1, \cdots, \mathbf{x}_N$.

Proposition 4 *For an isotropic sample design with N points, $\{\mathbf{x}_j\}_{j=1}^N$, in a d-dimensional region with unit volume, the pair correlation function $G(r)$ and radially averaged power spectral density $P(k)$ are related as follows:*

$$G(r) = 1 + \frac{V}{2\pi N} H\left[P(k) - 1\right] \tag{3}$$

where V is the volume of the sampling region and $H[.]$ denotes the 1-d Hankel transform, defined as

$$H(f(k)) = \int_0^\infty k J_0(kr) f(k) dk,$$

with $J_0(.)$ denoting the Bessel function of order zero.

Proof Note that PSD and PCF of a sample design are related via the d-dimensional Fourier transform as follows:

$$\begin{aligned} P(\mathbf{k}) &= 1 + \frac{N}{V} F\left(G(\mathbf{r}) - 1\right) \\ &= 1 + \frac{N}{V} \int_{\mathbb{R}^d} \left(G(\mathbf{r}) - 1\right) \exp(-i\mathbf{k}.\mathbf{r}) d\mathbf{r}. \end{aligned}$$

It can be shown that, for radially symmetric or isotropic functions, the above relationship simplifies to

$$P(k) = 1 + 2\pi \frac{N}{V} H\left[G(r) - 1\right].$$

Next, using the inverse property of the Hankel transform, i.e.,

$$H_0^{-1}(f(r)) = \int_0^\infty r J_0(kr) f(r) dr,$$

we have

$$G(r) = 1 + \frac{V}{2\pi N} H\left[P(k) - 1\right]. \tag{4}$$

■

Proposition 4 is important as it enables us to qualitatively understand space-filling designs by first mapping them into the PCF space constructed based on spatial distances between points and, then, evaluating and understanding spectral properties of sample designs.

In Figure 3, we show the PCF[4] of some commonly used 2-d sample designs ($N = 1000$) illustrated in Figure 2. As can be observed, both regular grid samples and QMC sequences have significant oscillations in their PCFs, which can be attributed to their structured nature. Regular grid sample design demonstrates a large disk radius r_{min} ($G(r) = 0$ for $0 \leq r \leq r_{min}$) as every sample is at least r_{min} apart from the rest of the samples, which in turn implies a better coverage. However, in practice, they perform poorly (e.g., in terms of generalization (or test error) in regression application and reconstruction error in image reconstruction application) compared to randomized sample designs and this can

4. Note that for non-isotropic sample designs, d-dimensional PCF (Illian et al., 2008) can be more descriptive.

be understood by studying their spectral properties. In contrast, random sample (Monte-Carlo) designs have a constant PCF with nearly no oscillations, since point samples are uncorrelated, thus, $P(r) = \lambda dx \lambda dy$ and theoretically have $G(r) = 1$, $\forall r$. Furthermore, the LHS design has a similar PCF as random designs with the exception of a small, yet non-zero, r_{min}.

Other variants of PDS like MPDS, Step PCF and Stair PCF designs attempt to trade-off between coverage ($G(r) = 0$ for $0 \leq r \leq r_{min}$) and randomness $G(r) = 1$, for $r > r_{min}$. Note that the Step and the Stair PCF methods are space-filling spectral designs proposed later in this paper. However, upon a careful comparison, it can be seen that MPDS has a larger peak and more oscillations in its PCF compared to the proposed designs. In fact, our empirical studies show that the amount of oscillations in the PCF of the MPDS design significantly increases with dimensions.

Next, in Figure 4, we show the corresponding PSDs of the different sample designs. It can be seen that, oscillations in PCF directly correspond to oscillations in PSDs. For example, the oscillatory behavior of the PCF for regular and QMC sequences cause a non-uniform distribution of power in their corresponding PSDs. Furthermore, the larger peak height in the PCF of MPDS implies that a large amount of power is concentrated in a small frequency band instead of power being distributed over all frequencies. In Section 5, we will analyze the effect of the shape of PCF on the performance of a sample design in detail.

It is important to note that, not every PCF (or PSD) is physically realizable by a sample design. In fact, there are two necessary mathematical conditions [5] that a sample design must satisfy to be realizable.

Definition 5 (Realizability) *A PCF can be defined to be potentially realizable through a sample design, if it satisfies the following conditions:*

- *its PCF must be non-negative, i.e., $G(r) \geq 0$, $\forall r$, and*
- *its corresponding PSD must be non-negative, i.e., $P(k) \geq 0$, $\forall k$.*

As both the PSD and the PCF characteristics are strongly tied to each other (as shown in Proposition 4), these two conditions limit the space of realizable space-filling spectral designs. The results from this section will serve as tools for qualitatively understanding and, thus, designing optimal space-filling spectral designs in the following sections.

4. Space-filling Spectral Designs

In this section, we first formalize desired characteristics of a good space-filling design, as given in Definition 1. Next, we will describe the proposed framework for creating space-filling spectral designs.

Definition 6 *A set $\mathcal{X}$ of N random samples $\{\mathbf{X_i}\}_{i=1}^N$ in a sampling domain $\mathcal{D}$ can be characterized as a space-filling design, if $\mathcal{X} = \{\mathbf{X_i} = \mathbf{x_i} \in \mathcal{D};\ i = 1, \cdots N\}$ satisfy the following two objectives:*

5. Whether or not these two conditions are not only necessary but also sufficient is still an open question (however, no counterexamples are known).

- $\forall \mathbf{X_i} \in \mathcal{X},\ \forall \triangle\mathcal{D} \subseteq \mathcal{D}\ :\ Pr(\mathbf{X_i} = \mathbf{x_i} \in \triangle\mathcal{D}) = \int_{\triangle\mathcal{D}} \mathbf{dX}$
- $\forall \mathbf{x_i}, \mathbf{x_j} \in \mathcal{X}\ :\ ||\mathbf{x_i} - \mathbf{x_j}|| \geq r_{min}$

where r_{min} is referred to as the coverage radius.

In the above definition, the first objective states that the probability of a random sample $\mathbf{X_i} \in \mathcal{X}$ falling inside a subset $\triangle\mathcal{D}$ of $\mathcal{D}$ is equal to the hyper-volume of $\triangle\mathcal{D}$ (uniform distribution). The second condition enforces the minimum distance constraint between point sample pairs for improving coverage.

A Poisson design enforces the first condition alone, in which case the number of samples that fall inside any subset $\triangle\mathcal{D} \subseteq \mathcal{D}$ obeys a discrete Poisson distribution. Though easier to implement, Poisson sampling often produces distributions where the samples are grouped into clusters and leaves holes in possibly the regions of interest. In other words, this increases the risk of missing important features, when only the samples are used for analysis. Consequently, a sample design that distributes random samples in a uniform manner across $\mathcal{D}$ is preferred, so that clustering patterns are not observed. The coverage condition explicitly eliminates the clustering behavior by preventing samples from being closer than $r_{\min}$. A space-filling design can be defined conveniently in the PCF domain and we refer to this as the space-filling spectral design, due to its direct connection to the spectral domain properties.

4.1 Defining a Space-filling Spectral Design in Spatial Domain

For Poisson design, point locations are not correlated and, therefore, $P(r) = \lambda dx \lambda dy$. This implies that for Poisson designs $G(r) = 1$. Similarly, for space-filling designs, due to the minimum distance constraint between the point sample pairs, we do not have any point samples in the region $0 \leq r < r_{\min}$. Consequently, space-filling spectral designs are defined as a step pair correlation function in the spatial domain (*Step PCF*).

Proposition 7 *Given the desired coverage radius r_{min}, a space-filling spectral design is defined in the spatial domain as*

$$G(r - r_{min}) = \begin{cases} 0 & \text{if } r < r_{min} \\ 1 & \text{if } r \geq r_{min}. \end{cases}$$

As a consequence of Proposition 4, space-filling spectral designs can equivalently be defined in the spectral domain.

4.2 Defining a Space-filling Spectral Design in Spectral Domain

We derive the power spectral density of the space-filling spectral design using the connection established in Section 3. Following our earlier notation, we denote the d-dimensional power spectral density by $P(\mathbf{k})$ and d-dimensional PCF by $G(\mathbf{r})$.

Proposition 8 *(Kailkhura et al., 2016a) Given the desired coverage radius r_{min}, a d-dimensional space-filling spectral design $\mathcal{X}$, with N sample points in a sampling domain $\mathcal{D}$ of volume V, can be defined in the PSD domain as*

$$P(k) = 1 - \frac{N}{V}\left(\frac{2\pi r_{min}}{k}\right)^{\frac{d}{2}} J_{\frac{d}{2}}(k r_{min})$$

where $J_{\frac{d}{2}}(.)$ is the Bessel function of order $d/2$.

Proof We know that,

$$P(\mathbf{k}) = 1 + \frac{N}{V} F\left(G(\mathbf{r}) - 1\right), \tag{5}$$

$$= 1 + \frac{N}{V}\int_{\mathbb{R}^d} (G(\mathbf{r}) - 1)\exp(-i\mathbf{k}.\mathbf{r}) d\mathbf{r}, \tag{6}$$

where $F(.)$ denotes the d-dimensional Fourier transform. Note that for the radially symmetric or isotropic functions, i.e., $G(r)$ where $r = ||\mathbf{r}||$, the above relationship simplifies to

$$P(k) = 1 + \frac{N}{V}(2\pi)^{\frac{d}{2}} k^{1-\frac{d}{2}} H_{\frac{d}{2}-1}\left(r^{\frac{d}{2}-1}(G(r) - 1)\right), \tag{7}$$

where

$$H_v(f(r))(k) = \int_0^\infty r J_v(kr) f(r) dr$$

is the 1−d Hankel transform of order v with J being the Bessel function. To derive the PSD of a step function, we first evaluate the Hankel transform of $f(r) = r^{\frac{d}{2}-1}(G(r) - 1)$ where $G(r)$ is a step function.

$$\begin{aligned} H_{\frac{d}{2}-1}\left(r^{\frac{d}{2}-1}(G(r) - 1)\right) &= \int_0^\infty r^{\frac{d}{2}} J_{\frac{d}{2}-1}(kr)\left(G(r) - 1\right) dr \\ &= -\int_0^{r_{\min}} r^{\frac{d}{2}} J_{\frac{d}{2}-1}(kr) dr \\ &= -\frac{r_{\min}^{\frac{d}{2}}}{k} J_{\frac{d}{2}}(k r_{\min}) \end{aligned}$$

Using this expression in (7), we obtain

$$P(k) = 1 - \frac{N}{V}\left(\frac{2\pi r_{\min}}{k}\right)^{\frac{d}{2}} J_{\frac{d}{2}}(k r_{\min}). \tag{8}$$

■

This proposition connects the spatial properties of a space-filling spectral design, defined via the PCF, to its spectral properties. The motivation for this is the fact that in several cases, it is easier to link the qualitative performance of a sample design to its spectral properties. In the next section, we will develop the relation between spectral properties and an qualitatives measure of the performance, which in turn provides us guidelines for designing better space-filling spectral sampling patterns.

5. Qualitative Analysis of Space-filling Spectral Designs

In this section, we derive insights regarding the qualitative performance of space-filling spectral designs. To this end, we analyze the impact of the shape of the PCF on the reconstruction performance. Further, for a tractable analysis, we consider the task of recovering the class of periodic functions using space-filling spectral designs and analyze the reconstruction error as a function of their spectral properties. The analysis presented in this section will clarify how the shape of the PCF of a sample design directly impacts its reconstruction performance.

5.1 Analysis of Reconstruction Error for Periodic Functions

Let us denote the Fourier transform of the sample design $\mathcal{X}$ by $\mathcal{S}$. The function to be sampled and its corresponding Fourier representation are denoted by $\mathcal{I}$ and $\hat{\mathcal{I}}(k)$ respectively. Now, the spectrum of the sampled function is given by $\hat{\mathcal{I}}_s(k) = \mathcal{S} * \hat{\mathcal{I}}(k)$. Note that a sampling pattern with a finite number of points is comprised of two components, a DC peak at the origin and a noisy remainder $\bar{\mathcal{S}}$. Thus, equivalently, we have $\hat{\mathcal{I}}_s(k) = \{N\delta(k) + \bar{\mathcal{S}}\} * \hat{\mathcal{I}}(k)$. The error introduced in the process of function reconstruction is the difference between the reconstructed and the original functions:

$$\mathcal{E}(k) = |\hat{\mathcal{I}}_s(k)/N - \mathcal{I}(k)|^2 = |\bar{\mathcal{S}} * \hat{\mathcal{I}}(k)/N|^2$$

where we have divided the R.H.S. by N to normalize the energy of $\mathcal{I}_s$. For error analysis, we focus on the low frequency content of the error term, since the high frequency components are removed during the reconstruction process.

Denoting the power spectrum without the DC component by $\bar{\mathcal{P}}(k)$, for a constant function the error simplifies to

$$\mathcal{E}(k) \propto |\bar{\mathcal{S}}(k)|^2 \propto \bar{\mathcal{P}}(k). \tag{9}$$

This, as stated above, allows for the characterization of the error in terms of the spectral properties of the sampling pattern used.

Next, we consider an important class of functions, the family of periodic functions, for further analysis. All periodic functions with a finite period can be expressed as a Fourier series[6], which is a summation of sine and cosine terms

$$\mathcal{I}(x) = a_0 + \sum_{m=1}^{M} a_m cos(2\pi m x) + \sum_{m=1}^{M} b_m sin(2\pi m x).$$

The Fourier transform of this function is equivalently a summation of pulses:

$$\hat{\mathcal{I}}(k) = a_0\delta(k) + \sum_{m=1}^{M} a_m \left(\frac{1}{2}(\delta(k-m) + \delta(k+m)\right) + \sum_{m=1}^{M} b_m \left(\frac{1}{2}(\delta(k+m) - \delta(k-m))\right).$$

6. In the subsequent analysis, the number of terms in the Fourier series, M, is an arbitrary value which can be replaced by infinity for non-differentiable/discontinuous functions. Note that the Fourier series of periodic functions that are smooth (no discontinuity and no sharp corners) is finite.

Making substitutions, $a_m + b_m = A_m$, $a_m - b_m = B_m$, we obtain

$$\mathcal{E}(k) = \frac{1}{4N^2}\left|4a_0\bar{\mathcal{S}}(k) + \sum_{m=1}^{M}\left(A_m\bar{\mathcal{S}}(k+m) + B_m\bar{\mathcal{S}}(k-m)\right)\right|^2.$$

The reconstruction error can then be upper bounded as follows:

$$\mathcal{E}(k) \leq \frac{1}{4N}\left[4a_0^2\bar{\mathcal{P}}(k) + \sum_{m=1}^{M}\left(A_m^2\bar{\mathcal{P}}(k+m) + B_m^2\bar{\mathcal{P}}(k-m)\right)\right]. \tag{10}$$

In the case of a single sinusoidal function, $cos(2\pi f x)$, using triangle inequality, this becomes (Heck et al., 2013)

$$\mathcal{E}(k) \leq \frac{1}{4N}\left[\bar{\mathcal{P}}(k+f) + \bar{\mathcal{P}}(k-f) + 2\sqrt{\bar{\mathcal{P}}(k+f)\bar{\mathcal{P}}(k-f)}\right]. \tag{11}$$

Even though this is only an upper bound and the theoretic analysis is restricted to periodic functions, we have empirically found that it accurately predicts the characteristics of the sampling error for a broad range of complex functions and provides useful guidelines (more details are provided in Section 9).

The above analysis implies that to assess the quality of the sample designs, one can analyze their spectral behavior. More specifically, the above analysis suggests that to minimize the reconstruction error (Eq. (10) and (11)): (a) the power spectra of the sample design should be close to zero, and (b) for errors to be broadband white noise (uniform over frequencies), the power spectra should be a constant. Note that in several applications, e.g., image reconstruction, most relevant information is predominantly at low frequencies. In such scenarios, this naturally leads to the following criteria for sample designs: (a) the spectrum should be close to zero for low frequencies which indicates the range of frequencies that can be represented with almost no error, (b) the spectrum should be a constant for high frequencies or contain minimal amount of oscillations in the power spectrum. However, as we will see next, there exist a trade-off between low frequency power and high frequency oscillations in power spectra.

5.2 Effect of PCF Characteristics on Sampling Performance

Based on the two criteria discussed above, we assess the effect of the shape of the PCF on the quality of space-filling designs in the spectral domain. Note that PCFs of the samples constructed in practice (Figure 2) often demonstrates the following characteristics: (a) presence of a zero-region characterized by r_{min}, (b) a large peak around r_{min}, and (c) damped oscillations. To model and analyze these characteristics, we consider the following parametric PCF family[7]

$$\begin{aligned} G(r; r_{\min}, \delta, a, c) &= G(r - r_{\min}) + (a-1)\left(G(r - r_{\min}) - G(r - r_{\min} - \delta)\right) \\ &+ \frac{a-1}{4r}\exp(-r/2)\sin(c \times r - c)G(r - r_{\min}) \end{aligned} \tag{12}$$

7. Note that there exist a broad range of parametric space-filling spectral designs. However, finding PCFs that are realizable is a nontrivial problem because the space of functions that obey the realizability conditions is not easy to parametrize.

where $G(r - r_{\min})$ is the Step function, peak width $\delta \geq 0$ and the peak height $a \geq 1$ and last term in (12) corresponds to damped oscillations. This family is a generalization of Step PCF, with additional parameterization of peak height and oscillations in the PCF.

5.2.1 Effect of Peak Height on Spectral Properties

In order to study the impact of increasing peak height in the PCF on the PSD characteristics, we conduct an empirical study. We compute the PSD of a sample design with the following parameters: $N = 195, r_{\min} = 0.02, \delta = 0.005$. Note that we vary the PCF peak height a, which actually reflects the behavior of existing coverage based PDS algorithms. As shown in Figure 5(a), increasing a results in both significantly *higher* low frequency power and *larger* high frequency oscillations. As expected, the PSD of the Step PCF (or $a = 1$) performs the best, i.e., the spectrum is close to zero for low frequencies and constant for high frequencies.

5.2.2 Effect of Disk Radius on Spectral Properties

Next, we study the importance of choosing an appropriate $r_{\min}$ (or coverage ρ) while generating sample distributions. In Figure 5(b), we show the PSD for $N = 195$ and $a = 1$, with varying disk radius values $r_{\min}$. For a fixed sample budget, as we increase the radius, we observe two contrasting changes in the PSD: (i) the spectrum tends to be close to zero at low frequencies and (ii) an increase in oscillations for high frequencies. Consequently, there is a trade-off between low frequency power and high frequency oscillations in power spectra which can be controlled by varying $r_{\min}$. However, the increase in oscillations are less significant compared to the gain in the zero-region. Furthermore, in several applications, low frequency content is more informative, and hence one may still attempt to maximize r_{min} or coverage.

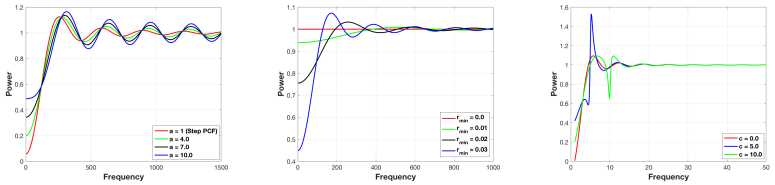
5.2.3 Effect of Oscillations on Spectral Properties

Finally, we study the effect of oscillations in the PCF on the power distribution in the spectral domain. In Figure 5(c), we plot the PSD for $a = 1$ with varying amounts of oscillations controlled via the parameter c. It can be seen that introducing oscillations in the PCF results in significantly *higher* low frequency power and *larger* high frequency oscillations. As expected, the PSD of the Step PCF (or $c = 0$) behaves the best.

In summary, the discussion in this section suggests that the PCF of an ideal space-filling spectral design should have the following three properties: (a) large r_{min}, (b) small peak height, and (c) low oscillations. Since, the Step PCF satisfies these three properties, it is expected to be a good space-filling spectral design. Next, we consider the problem of optimizing the parameter of the Step PCF design, i.e. r_{min}.

6. Optimization of Step PCF based Space-filling Spectral Designs

The proposed space-filling metric enjoys mathematical tractability and is supported by theoretical results as defined in Section 4. This enables us to obtain new insights for optimizing Step PCF based space-filling spectral designs. In particular, (a) For a fixed $r_{\min}$, we obtain the maximum number of point samples in any arbitrary dimension d, (b) For a



(a) (b) (c)

Figure 5: (a) Effect of peak height in the PCF on power spectra, (b) Effect of disk radius in the PCF on power spectra, (c) Effect of oscillations in the PCF on power spectra.

fixed sampling budget N, we derive the maximum achievable $r_{\min}$ in arbitrary dimension d.

6.1 Case 1: Fixed $r_{\min}$

The problem of finding the maximum number of point samples in a Step PCF based space-filling spectral design with a given disk radius $r_{\min}$ can be formalized as follows:

$$\begin{aligned} \text{maximize} \quad & N \\ \text{subject to} \quad & P(k) \geq 0, \ \forall k \\ & G(r - r_{\min}) \geq 0, \ \forall r, \end{aligned} \tag{13}$$

where $P(k) = 1 - \frac{N}{V}\left(\frac{2\pi r_{\min}}{k}\right)^{\frac{d}{2}} J_{\frac{d}{2}}(k r_{\min})$. Note that a space-filling spectral design has to satisfy realizability constraints as defined in Definition 5.

Proposition 9 *(Kailkhura et al., 2016a) For a fixed disk radius r_{min}, the maximum number of point samples possible for a realizable Step PCF based space-filling spectral design in the sampling region with volume V can be approximated as*

$$N \approx \frac{V\Gamma\left(\frac{d}{2}+1\right)}{\pi^{\frac{d}{2}} r_{min}^{d}}.$$

Proof Using the definition of the Step PCF function, the constraint $G(r - r_{\min})$ is trivially satisfied. Note that the constraint $P(k) \geq 0, \ \forall k$ is equivalent to $\min_k P(k) \geq 0$. In other

words,

$$\begin{aligned}
&\min_k 1-\rho\left(\frac{2\pi r_{\min}}{k}\right)^{\frac{d}{2}} J_{\frac{d}{2}}(kr_{\min}) \geq 0 \\
\Leftrightarrow\ &\max_k \rho\left(\frac{2\pi r_{\min}}{k}\right)^{\frac{d}{2}} J_{\frac{d}{2}}(kr_{\min}) \leq 1 \\
\Leftrightarrow\ &\rho\,(2\pi)^{\frac{d}{2}}\, r_{\min}^d \max_k \left(\frac{J_{\frac{d}{2}}(kr_{\min})}{(kr_{\min})^{\frac{d}{2}}}\right) \leq 1 \\
\Leftrightarrow\ &\rho\,(2\pi)^{\frac{d}{2}}\, r_{\min}^d \frac{1}{2^{\frac{d}{2}}\Gamma\left(\frac{d}{2}+1\right)} \lesssim 1 \qquad (14)\\
\Leftrightarrow\ &N \lesssim \frac{V\Gamma\left(\frac{d}{2}+1\right)}{(\pi)^{\frac{d}{2}}\, r_{\min}^d}
\end{aligned}$$

where, in (14) we have used the fact that $J_v(x) \approx (x/2)^v/\Gamma(v+1)$ and $\rho = N/V$. ■

Note that for the 2-dimensional case, we have $\frac{J_1(kr_{\min})}{kr_{\min}} = \text{jinc}(kr_{\min})$ where jinc(.) is the sombrero function (sometimes called besinc function or jinc function). Now using the fact that jinc(x) has the maximum value equal to $1/2$, for a fixed disk radius $r_{\min}$, the maximum number of point samples possible in a 2-d Step PCF based space-filling spectral design is given by

$$N = V/\pi(r_{\min})^2,$$

which again corroborates our bound in Proposition 9.

6.2 Case 2: Fixed N

Alternately, we can also derive the bound for the disk radius of Step PCF with a fixed sampling budget N as follows:

$$\begin{aligned}
&\text{maximize} && r_{\min} \\
&\text{subject to} && P(k) \geq 0,\ \forall k \\
& && G(r - r_{\min}) \geq 0,\ \forall r
\end{aligned} \qquad (15)$$

Proposition 10 *(Kailkhura et al., 2016a) For a fixed sampling budget N, the maximum possible disk radius r_{min} for a realizable Step PCF based space-filling spectral design in the sampling region with volume V can be approximated as*

$$r_{min} \approx \sqrt[d]{\frac{V\Gamma\left(\frac{d}{2}+1\right)}{\pi^{\frac{d}{2}}N}}.$$

Proof The proof is similar to the one in Proposition 9. ■

6.3 Relative Radius of Step PCF

As mentioned before, the current literature characterizes coverage by the fraction ρ of the maximum possible radius r_{max} for N samples to cover the sampling domain, such that $r_{min} = \rho r_{max}$. The maximum possible disk radius is achieved by the deterministic hexagonal lattice (Schreiber, 1943) and can be approximated in a d dimensional sampling region as $r_{max} \approx \sqrt[d]{\frac{A_d}{C_d N}}$. Here, A_d is the hypervolume of the sampling domain and $C_d = V_d/r^d$ with V_d being the hypervolume of a hypersphere with radius r. Note that a uniformly distributed point set can have a relative radius of 0, and the relative radius of a hexagonal lattice equals 1 (in 2-d). Next, we derive a closed-form expression for the relative radius of Step PCF based design.

Proposition 11 *For a fixed sampling budget N, the maximum relative radius ρ for Step PCF based space-filling spectral design in the sampling region with volume V is given by $\rho = \frac{1}{2\sqrt[d]{\eta_d}}$ where η_d is maximal density of a sphere packing in d-dimensions.*

Proof Let us denote by $r_{max} = \arg\min_r \eta_d$, then, the maximal density of a sphere packing with N samples in d-dimensions is given by

$$\eta_d = \frac{N\pi^{d/2}}{\Gamma(1+\frac{d}{2})}\frac{r_{max}^d}{V} \qquad (16)$$

$$\Leftrightarrow\ \eta_d = \left(\frac{r_{max}}{r_{min}}\right)^d \qquad (17)$$

$$\Leftrightarrow\ \rho = \frac{1}{2\sqrt[d]{\eta_d}} \qquad (18)$$

where equality in (17) uses Proposition (10). ■

For $d = 2$ and 3, the relative radius simplifies to:

$$\rho = 0.5\sqrt[2]{\frac{\pi\sqrt{3}}{6}},\ \textbf{for } d = 2, \text{ and}$$

$$\rho = 0.5\sqrt[3]{\frac{\pi\sqrt{2}}{6}},\ \textbf{for } d = 3.$$

Note that finding the maximal density of a sphere packing for an arbitrary high dimension (except in $d = 2, 3$ and recently in $8, 24$ (viazovska, 2017; Cohn et al., 2017)) is an open problem. Note that best known packings are often lattices, thus, we use the best known lattices to be an approximation of r_{max} in our analysis[8].

In Figure 6, we plot the relative radius $\rho = r_{min}/r_{max}$ of Step PCF for different dimensions d. It is interesting to notice that the relative radius of Step PCF based designs

8. We use relative radius as a metric only for analysis and not for design optimization.

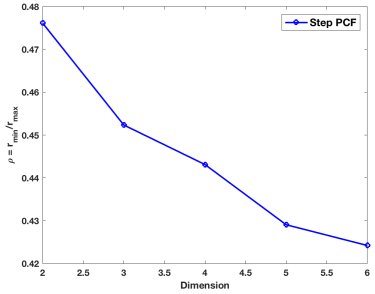


Figure 6: Relative radius $\rho = r_{min}/r_{max}$ of Step PCF based space-filling spectral design for different dimensions d.

increases as the dimension d increases, i.e., Step PCF based designs approach a more regular pattern. Further, note that for a fixed sampling budget both r_{min} and r_{max} increase as the number of dimensions increases. The Step PCF based designs maintain randomness by keeping the PCF flat, but this comes at a cost: the disk radius r_{min} of these patterns is very small (as can be seen from Figure 6). For several applications, covering the space better (by trading-off randomness) is more important. In the next section, we will propose a new class of space-filling spectral designs that can achieve a much higher r_{min} at the small cost of compromising randomness by introducing a single peak into an otherwise flat PCF.

7. Space-filling Spectral Designs with Improved Coverage

To improve the coverage of Step PCF base space-filling spectral design, in this section, we propose a novel space-filling spectral design which systematically trades-off randomness with coverage of the resulting samples. Note that the randomness property can be relaxed either by increasing the peak height of the PCF, or by increasing the amounts oscillations in the PCF (as discussed in Section 5.2). For simplicity[9], we adopt the former strategy and use only the peak height parameter. More specifically, as an alternative to Step PCF, we design the following generalization which we refer as the Stair PCF design.

7.1 Stair PCF based Space-filling Spectral Design

Now, we define the proposed *Stair* PCF based space-filling design and quantify the gains achieved in the coverage characteristics (*i.e.* r_{min}).

Stair PCF in the Spatial Domain: The Stair PCF construction is defined as follows:

9. In our initial experiments, we found that increasing the peak height alone is sufficient for trading-off randomness to maximize coverage, and performs better than trading-off randomness by increasing oscillations in the PCF.

$$G(r; r_0, r_1, P_0) = f(r - r_1) + P_0 \left(f(r - r_0) - f(r - r_1)\right), \tag{19}$$
$$\text{with } f(r - r_0) = \left\{ \begin{array}{ll} 0 & \text{if } r \leq r_0 \\ 1 & \text{if } r > r_0 \end{array} \right\},$$
$$\text{where } r_0 \leq r_1 \text{ and } P_0 \geq 1.$$

This family of space-filling spectral designs has three interesting properties:

- except for a single peak in the region $r_0 \leq r \leq r_1$, the PCF is flat, thus, does not compromise randomness entirely,
- both the height and width of the peak can be optimized to maximize coverage,
- the Step PCF based spectral design can be derived as as a special case of this construction.

Now, the problem boils down to finding the combinations of the three parameters (r_0, r_1, P_0) that are realizable and yield a good sample design (discussed in Section 7.2). A representative example of Stair PCF is shown in Figure (7(a)).

Stair PCF in the Spectral Domain: Following the analysis in the earlier sections, we derive the power spectral density of Stair PCF based space-filling spectral designs.

Proposition 12 *The power spectral density of a Stair PCF based space-filling spectral designs, $G(r; r_0, r_1, P_0)$, with N samples in the sampling region with volume V is given by*

$$P(k) = 1 - \frac{N}{V} P_0 \left(\frac{2\pi r_0}{k}\right)^{\frac{d}{2}} J_{\frac{d}{2}}(kr_0) - \frac{N}{V}(1 - P_0) \left(\frac{2\pi r_1}{k}\right)^{\frac{d}{2}} J_{\frac{d}{2}}(kr_1).$$

Proof Using results from Section 4.2, we have

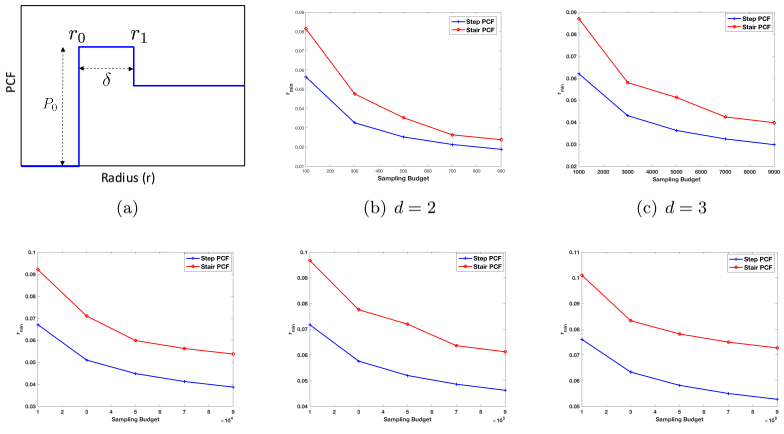
$$P(k) = 1 + \frac{N}{V} (2\pi)^{\frac{d}{2}} k^{1-\frac{d}{2}} H_{\frac{d}{2}-1} \left(r^{\frac{d}{2}-1}(G(r) - 1)\right). \tag{20}$$

To derive the PSD of a Stair function, we first evaluate the Hankel transform of $f(r) = (G(r) - 1)$ where $G(r)$ is a Stair function.

$$\begin{aligned} H_{\frac{d}{2}-1} \left(r^{\frac{d}{2}-1}(G(r) - 1)\right) &= \int_0^\infty r^{\frac{d}{2}} J_{\frac{d}{2}-1}(kr) \left(G(r) - 1\right) dr \\ &= -P_0 \int_0^{r_0} r^{\frac{d}{2}} J_{\frac{d}{2}-1}(kr) dr - (1 - P_0) \int_0^{r_1} r^{\frac{d}{2}} J_{\frac{d}{2}-1}(kr) dr \\ &= -P_0 \frac{r_0^{\frac{d}{2}}}{k} J_{\frac{d}{2}}(kr_0) - (1 - P_0) \frac{r_1^{\frac{d}{2}}}{k} J_{\frac{d}{2}}(kr_1) \end{aligned}$$

Using this expression in (20),

$$P(k) = 1 - \frac{N}{V} P_0 \left(\frac{2\pi r_0}{k}\right)^{\frac{d}{2}} J_{\frac{d}{2}}(kr_0) - \frac{N}{V}(1 - P_0) \left(\frac{2\pi r_1}{k}\right)^{\frac{d}{2}} J_{\frac{d}{2}}(kr_1). \tag{21}$$



(a) (b) $d = 2$ (c) $d = 3$

(d) $d = 4$ (e) $d = 5$ (f) $d = 6$

Figure 7: (a) Pair correlation function of Stair PCF based designs, (b)-(f) Maximum Disk Radius For Step and Stair PCF for dimensions 2 to 6.

■

Next, we empirically evaluate the gain in coverage achieved by Stair PCF based designs compared to the Step PCF based designs.

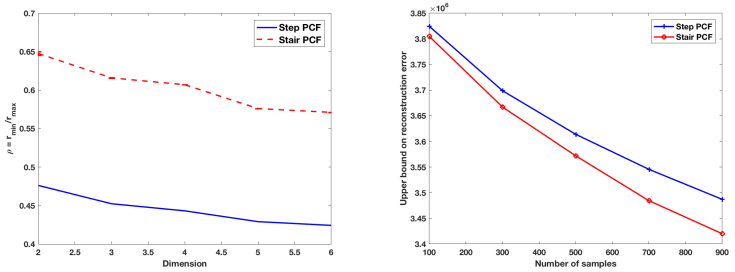
7.2 Coverage Gain with Stair PCF

Ideally, the optimal Stair PCF should be obtained by simultaneously maximizing r_0 ($:= r_{min}$) and minimizing P_0. Furthermore, not all PCFs in the Stair PCF family are realizable. Due to the realizability conditions, the parameters cannot be adjusted independently. The main challenge, therefore, is to find the combinations of the three parameters (r_0, r_1, P_0) that is realizable and yield a good sample design. Unlike Step PCF, the closed form expression for the optimal parameters (r_0, r_1, P_0) are difficult to obtain, and, therefore, we explore this family of PCF patterns empirically by searching configurations for which:

- the disk radius r_0 is as high as possible, and
- the PCF is flat with minimal increase in the peak height P_0.

7.2.1 Disk Radius r_{min} vs. Sample Budget N

In this section, we show the increase in coverage (or r_{min}) obtained by compromising randomness by increasing peak height in the PCF. We constrain the peak height to be below $P_0 \leq 1.5$ and analyze the gain in r_{min} due to this small compromise in randomness. Furthermore, we assume that $r_{min}^{step} \leq r_0 \leq 2 \times r_{min}^{step}$ and $r_0 \leq r_1 \leq 1.5 \times r_0$. In Figures 7(b)



(a) (b)

Figure 8: (a) Gain in the relative radius ρ achieved with the Stair PCF constructions, in comparison to the Step PCF constructions; (b) Upper bound on the reconstruction error of Step and Stair PCF based constructions.

through 7(f), we compare the maximum r_{min} achieved by the Step and Stair PCF designs, for varying sample sizes in dimensions 2 to 6. It can be seen that introducing a small peak in the PCF results in a significant increase in the coverage. This gain can be observed for all sampling budgets in all dimensions. Furthermore, as expected, for low sampling budgets maximal gain is observed, and should decrease with increasing N as the r_{min} for both the families will asymptotically (in N) converge to zero.

7.2.2 Relative Radius ρ vs. Dimension d

In this section, we study the increase in relative radius ρ due to the introduction of a peak in the PCF. Again, we assume that $P_0 \leq 1.5$, $r_{min}^{step} \leq r_0 \leq 2 \times r_{min}^{step}$ and $r_0 \leq r_1 \leq 1.5 \times r_0$. In Figure 8(a), we show the maximum $\rho = r_{min}/r_{max}$ achieved by the Step and Stair PCFs for different dimensions d. For Stair PCF, we do not have a closed form expression of ρ, thus, we obtain the maximum achievable r_{min} empirically for various sampling budgets and plot the mean (with standard deviation) behavior of the ρ. It can be seen that introducing a small peak in the PCF results in a significant increase in the relative radius. This gain can be observed at all sampling budgets in all dimensions. This also corroborates the recommendation of using $0.65 \leq \rho \leq 0.85$ in practice for coverage based designs and suggests that in higher dimensions ρ should be higher.

7.2.3 Analysis of Reconstruction Error Upper Bound

We also assess the reconstruction quality of the Step and Stair PCF based spectral designs, on the class of periodic functions considered in Section 5.1, for varying sampling budgets. Here, we consider the setup where $0 \leq k \leq 1000$ and $0 \leq f \leq 1000$. In Figure 8(b), we plot the average reconstruction error upper bounds as given in (11) for Step and Stair PCF. As expected, for both sample designs, the reconstruction error decreases with an

increase in the sampling budget. More interestingly, the reconstruction error of Stair PCF is lower compared to the reconstruction error of Step PCF, thus showing the effectiveness of increased coverage in sample designs.

8. Synthesis of Space-filling Spectral Designs

In this section, we describe the proposed approach for synthesizing sample designs that match the optimal (Stair or Step) PCF characteristics. Existing approaches for PCF matching such as (Oztireli and Gross, 2012; Kailkhura et al., 2016b) rely on kernel density estimators to evaluate the PCF of a point set. A practical limitation of these approaches is the lack of an efficient PCF estimator in high dimensions. More specifically, these estimators are biased due to lack of an appropriate edge correction strategy. This bias in PCF estimation arises due to the fact that sample hyper-spheres used in calculating point-pattern statistics may fall partially outside the study region and will produce a biased estimate of the PCF unless a correction is applied. The effect of this bias is barely noticeable in 2 dimensions and hence existing PCF matching algorithms have ignored this. However, this problem becomes severe in higher dimensions, thus, making the matching algorithm highly inaccurate. To address this crucial limitation, we introduce an edge corrected estimator for computing the PCF of sample designs in arbitrary dimensions. Following this, we describe a gradient descent based optimization technique to synthesize samples that match the desired PCF.

8.1 PCF Estimation in High Dimensions with Edge Correction

In order to create an unbiased PCF estimator, we propose to employ an edge corrected kernel density estimator, defined as follows:

$$\hat{G}(r) = \frac{V_W}{\gamma_W}\frac{V_W}{N}\frac{1}{S_E(N-1)}\sum_{i=1}^{N}\sum_{\substack{j=1\\ i\neq j}}^{N} k\left(r - |x_i - x_j|\right) \tag{22}$$

where $k(.)$ denotes the kernel function; here we use the classical Gaussian kernel

$$k(z) = \frac{1}{\sqrt{\pi}\sigma}\exp\left(-\frac{z^2}{2\sigma^2}\right). \tag{23}$$

In the above expression, V_W indicates the volume of the sampling region. When the sampling region is a hyper-cube with length 1, we have $V_W = 1$. Let S_E denote the area of hyper-sphere with radius r which is given by

$$S_E = \frac{dr^{d-1}\pi^{\frac{d}{2}}}{\Gamma(1+\frac{d}{2})}.$$

Also, we denote the surface area of the sampling region by S_W, which is expressed as

$$S_W = r^{d-1}\sin^{d-2}\phi_1 \sin^{d-3}\phi_2 \cdots \sin\phi_{d-2}.$$

The term $\frac{V_W}{\gamma_W}$ performs edge correction to handle the unboundedness of the estimator, where γ_W is an isotropic set covariance function given by

$$\gamma_W = \frac{1}{S_E}\int\limits_{\substack{0\leq\phi_{d-1}\leq 2\pi\\ 0\leq\phi_i\leq\pi, i=1 \text{ to } d-2}} S_W \gamma d\phi_1 \cdots d\phi_{d-1} \tag{24}$$

where $\gamma = \prod_{p=1}^{d}(1-|x^p|)$ with

$$\begin{aligned}
x^1 &= r\cos\phi_1\\
x^2 &= r\sin\phi_1\cos\phi_2\\
x^3 &= r\sin\phi_1\sin\phi_2\cos\phi_3\\
&\vdots\\
x^{d-1} &= r\sin\phi_1\cdots\sin\phi_{d-2}\cos\phi_{d-1}\\
x^d &= r\sin\phi_1\cdots\sin\phi_{d-2}\sin\phi_{d-1}.
\end{aligned}$$

In Figure 9(a), we show that by using an approximate edge correction factor (using the same factor as $d = 2$), the PCF is wrongly estimated. Moreover, as the dimension increases, the estimated PCF moves farther away from the true PCF very quickly.

Note that the calculation of the correct edge correction factor requires the evaluation of a multi-dimensional integral which is computationally expensive in high dimensions. In this paper, we provide a closed form approximation of γ_W (using polynomial regression of order 2) in different dimensions $d = 2$ to 6 when $r \leq 1.0$. More specifically, we have the following approximation $\hat{\gamma_W} = 1 - a_1 r + a_2 r^2$ where a_1 and a_2 are as given below.

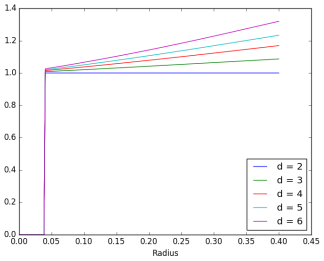
Dimension	$d=2$	$d=3$	$d=4$	$d=5$	$d=6$
a_1	$4/\pi$	1.47	1.63	1.75	1.89
a_2	$1/\pi$	0.54	0.72	0.87	1.04

It can be observed from Figures 9(b) through 9(f) that the proposed approximations are quite tight.

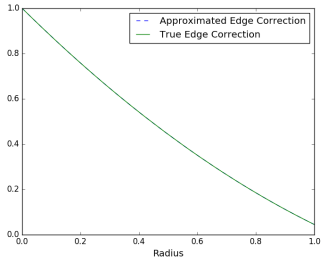
8.2 Synthesis Algorithm

The underlying idea of the proposed algorithm is to iteratively transform an initial random input sample design such that its PCF matches the target PCF. In particular, we propose a non-linear least squares formulation to optimize for the desired space-filling properties. Let us denote the target PCF by $G^*(r)$. We discretize the radius r into m points $\{r_j\}_{j=1}^{m}$ and minimize the sum of the weighted squares of errors between the target PCF $G^*(r_j)$ and the curve-fit function (kernel density estimator of PCF) $G(r_j)$ over m points. This scalar-valued goodness-of-fit measure is referred to as the *chi-squared error* criterion and can be posed as a non-linear weighted least squares problem as follows.

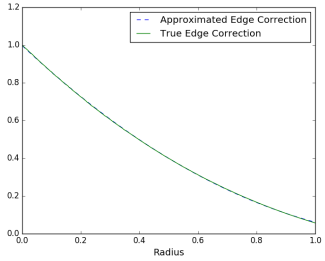
$$\arg\min \sum_{j=1}^{M}\left(\frac{G(r_j) - G^*(r_j)}{w_j}\right)^2,$$



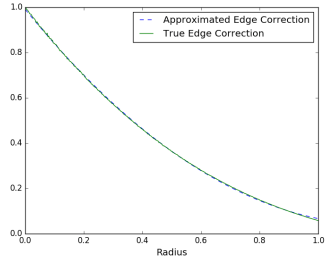
(a)



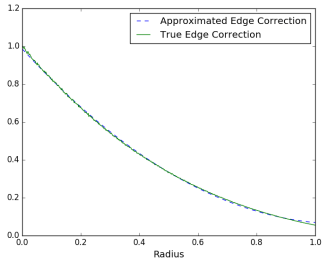
(b) $d = 2$



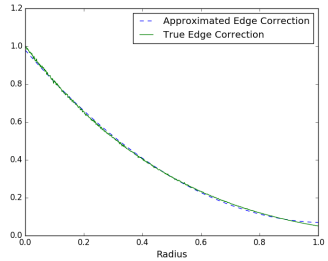
(c) $d = 3$



(d) $d = 4$



(e) $d = 5$



(f) $d = 6$

Figure 9: (a) Incorrect PCF estimation due to the use of an approximate edge correction factor, (b)-(f) Effectiveness of the approximation edge correction, obtained using polynomial regression, in comparison to the true edge correction from the evaluation of a multi-dimensional integral, for dimensions 2 to 6.

where w_j indicates the weight (importance) assigned to the fitting error at radius r_j. This optimization problem can be efficiently solved using a variant of gradient descent algorithm (discussed next), that in our experience converges quickly. In the simplest cases of uniform weights the solution tends to produce a higher fitting error at lower radii r_j. To address this challenge we use a non-uniform distribution for the weights $\{w_j\}$. These weights are initialized to be uniform and are updated in an adaptive fashion in the gradient descent iterations. The weight w_j at gradient descent iteration $t+1$ is given by (Kailkhura et al., 2016b):

$$w_j = \frac{1}{|G^t(r_j) - G^*(r_j)|}$$

where $G^t(r_j)$ is the value of the PCF at radius r_j during the gradient descent iteration t. Note that PCF matching is a highly non-convex problem. We found that the following trick further helps solve PCF matching problem more efficiently.

8.2.1 One Sided PCF Smoothing

We propose to perform one sided smoothing of the target PCF which is given as follows:

$$\hat{G}^*(r) = \begin{cases} (cr)^b & \text{if } r < r_{\min} \\ 1 & \text{if } r \geq r_{\min}. \end{cases}$$

where c is some pre-specified constant and $b > 1$ is the smoothing constant obtained via cross-validation. More specifically, we add polynomial noise in the low radius region of the PCF. This can also be interpreted as polynomial approximation of the PCF in the low radii regime. We have noticed that sometimes adding a controlled amount of Gaussian noise instead of polynomial noise also improves the performance.

8.2.2 Edge Corrected Gradient Descent

The non-linear least squares problem is solved iteratively using gradient descent. Starting with a random point set $X = \{x_i\}_{i=1}^N$, we iteratively update x_i in the negative gradient direction of the objective function. At each iteration k, this can be formally stated as

$$x_i^{k+1} = x_i^k - \lambda \frac{\Delta_i}{|\Delta_i|},$$

where λ is the step size and $\Delta_i = \{\Delta_i^k\}_{k=1}^d$ in the normalized edge corrected gradient is given by

$$\Delta_i^p = \sum_{i \neq l} \frac{(x_l^p - x_i^p)}{|x_l - x_i|} \sum_{j=1}^{m} \frac{G(r_j)^k - G^*(r_j)}{w_j(1 - a_1 r_j + a_2 r_j^2) r_j^{d-1}} \left(|x_l - x_i| - r_j\right) k\left(r_j - |x_i - x_l|\right). \tag{25}$$

We re-evaluate the PCF $G(r_j)^k$ of the updated point set after each iteration using the unbiased estimator from the previous section.

The pseudocode of the algorithm is provided in Algorithm 1.

Algorithm 1 Space-filling Spectral Sample Design using PCF Matching Algorithm

return X ▷ Space-filling Spectral Samples

In Figure 10, we compare the behavior of the proposed PCF matching algorithm with and without the one sided PCF smoothing. The target PCF is designed using a Step PCF design with r_{min} as given in Proposition 10. PCF matching is carried out with varying sampling budget, $N = 100,\ 200,\ 400,\ 600,\ 800$ for $d = 2,\ 3,\ 4,\ 5,\ 6$, respectively. The variances of the Gaussian kernel were set at $\sigma^2 = 0.0065,\ 0.007,\ 0.01,\ 0.01,\ 0.01$ for $d = 2,\ 3,\ 4,\ 5,\ 6$, respectively and the step size for the gradient descent algorithm was fixed at 0.001. The value of b was obtained using cross-validation. The initial point set was generated randomly (uniform) in the unit hyper-cube and matching was carried for 100 gradient descent iterations. It can be observed that the proposed algorithm produces an accurate fit to the target, and that the smoothing actually leads to improved performance.

In Figure 11, we demonstrate the synthesis of a Stair PCF based spectral design, using parameters $P_0 = 1.2, \delta = 0.025$. Similar to the previous case, PCF matching is carried out with varying sampling budget, $N = 100,\ 200,\ 400,\ 600,\ 800$, for $d = 2,\ 3,\ 4,\ 5,\ 6$ respectively. The variances of the Gaussian kernel were set at $\sigma^2 = 0.0065,\ 0.007,\ 0.01,\ 0.01,\ 0.01$ for $d = 2,\ 3,\ 4,\ 5,\ 6$, respectively and the step size for the gradient descent algorithm was fixed at 0.001. We found that matching the Stair PCF is more challenging for a gradient descent optimization compared to the Step PCF. When a random point set is used for initialization, reaching convergence takes much longer. However, choosing the initial point set intelligently improves the quality of matching significantly. In all our experiments, we used the maximal PDS (Ebeida et al., 2012) to initialize the optimization and matching was carried for 100 gradient descent iterations. We observed that another reasonable choice for the initialization is a regular grid sample, and interestingly in most cases it matches the performance of the MPDS initialization. Furthermore, one sided PCF smoothing does not provide significant improvements in this case, particularly in higher dimensions.

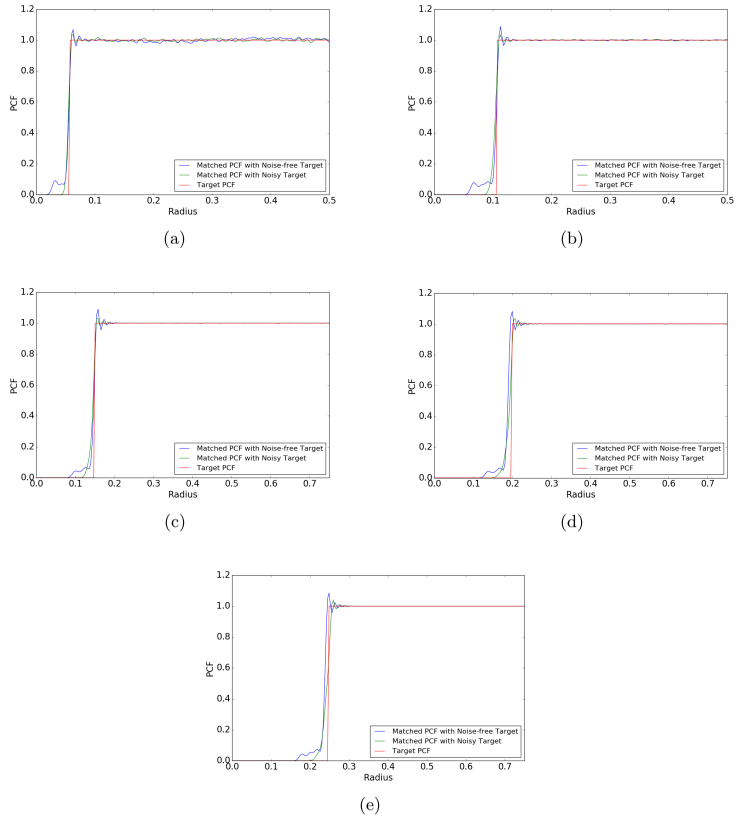

Figure 10: Step PCF synthesis using one sided PCF smoothing technique. (a) $d = 2$ (b) $d = 3$ (c) $d = 4$ (d) $d = 5$ (e) $d = 6$.

9. Experiments

In this section, we evaluate the qualitative performance of proposed space-filling spectral designs and present comparisons to popularly adopted space-filling designs, such as LHS, QMC and MPDS. Note that currently there does not exist any PDS synthesis approach which can generate sample sets with a desired size N while achieving user-specified spatial characteristics (e.g. relative radius). In all PDS synthesis approaches, there is no control over the number of samples generated by the algorithm which makes the use of these al-

gorithms difficult in practice. However, the proposed approach can control both N and r_{min} simultaneously. For our qualitative comparison, we perform three empirical studies, in dimensions 2 to 6 : (a) image reconstruction, (b) regression on several benchmark optimization functions, and (c) surrogate modeling for an inertial confinement fusion (ICF) simulation code.

Table 1: Impact of different space-filling designs on image reconstruction performance. In all cases, we show the reconstructed images and their PSNR values.

9.1 Image Reconstruction

In this experiment, we consider the problem of designing sample distributions for image reconstruction. More specifically, we consider the commonly used zone plate test function:

$$z(r) = (1 + \cos(\alpha r^2))/2,$$

with varying levels of complexity (or frequency content) α. Note that we choose the zone plate for our study over natural images, since it shows the response for a wide range of frequencies and aliasing effects that are not masked by image features. For all zone plate renderings in this paper, we have tiled toroidal sets of 1000 2-dimensional points over the image-plane and utilized a Lanczos filter with a support of width 4 for resampling. Further, we also report the peak signal-to-noise ratio (PSNR) as a quantitative error measure:

$$\text{PSNR} = 20 \log_{10} \frac{1}{\text{MSE}},$$

where MSE is the mean squared error. However, it is well known in the image processing community that PSNR can be a weak surrogate for visual quality (as we will see later) and, therefore, we also show the reconstructed images.

Table 1 illustrates the reconstructions obtained using different space-filling designs, for varying values of α. It can be observed from the results that the QMC sequences produce a large amount of aliasing artifacts in the high frequency regions, which can be directly linked to the oscillations in their corresponding PCFs. On the other hand, LHS design recovers a small amount of low-frequencies, and maps most of the frequencies to white noise due to its small r_{min} and near-constant PCF. In contrast, sample designs which attempt to trade-off between coverage and randomness properties, i.e., MPDS and the proposed spectral space-filling designs (as seen in Figure 3), have superior reconstruction quality. These designs reduce the aliasing artifacts, have cleaner low frequency content (upper left corner)) and map all high frequencies (bottom right corner) to white noise. More interestingly, we see that for low complexity cases, i.e., lower α, the MPDS performs the best followed by the proposed Stair and Step PCF respectively. For moderately complex images, the Stair PCF performs the best followed by the Step and the MPDS. Finally, for highly complex images, the Step PCF performs the best followed by the Stair and the MPDS. These observations corroborate our discussion in Section 5.2 that an increase in r_{min} (coverage) in the PCF results in an increase in the range of low frequencies that can be recovered without aliasing, and equivalently reduction in the amount of oscillations (or an increase in randomness) in the PCF leads to reduced oscillations in the PSD, which in turn indicates a systematic mapping of high frequency content to white noise. Note that when $\alpha = 0.007$, both LHS and Sobol designs have PSNR greater than (or equal to) the PSNR of Step PCF design. However, the quality of the reconstructed image by Step PCF is far superior compared to the one by LHS and Sobol designs. This further corroborates our claim on PSNR being a weak surrogate and justifies the use of reconstructed images itself as a performance metric.

9.2 Regression Modeling for Benchmark Optimization Functions

In this study, we consider the problem of fitting regression models to analytical functions and perform a comparative study of different sample designs, in terms of their generalization

performance. More specifically, we consider a set of benchmark analytic functions between dimensions 2 and 6, that are commonly used in global optimization tests (Jamil and Yang, 2013). They are chosen due to their diversity in terms of their complexity and shapes. We compare the performance of proposed space-filling spectral designs (Step, Stair) with coverage based designs (MPDS), low-discrepancy designs (Halton and Sobol), latin hypercube sampling and random sampling. Appendix A lists the set of functions used in our experiments. In each case, we fit a random forest regressor with 30 trees and repeated for 20 independent realizations of sample designs. We evaluate the generalization performance on 10^6 regular grid based test samples. Finally, we report mean (horizontal lines) and standard deviation (vertical lines) of 3 popular quality metrics (over 20 realizations) to quantify the performance of the resulting regression models: mean squared error (MSE), relative average absolute error (AAE), and the R^2-statistic. The metrics are defined as follows:

$$MSE(\mathbf{y}, \hat{\mathbf{y}}) = \frac{\sum_{i=1}^{N} (y_i - \hat{y}_i)^2}{N}, \tag{26}$$

$$AAE(\mathbf{y}, \hat{\mathbf{y}}) = \frac{\sum_{i=1}^{N} |y_i - \hat{y}_i|}{N * STD(\mathbf{y})}, \tag{27}$$

$$R^2(\mathbf{y}, \hat{\mathbf{y}}) = 1 - \frac{\sum_{i=1}^{N} (y_i - \hat{y}_i)^2}{\sum_{i=1}^{N} (y_i - MEAN(\mathbf{y}))^2} \tag{28}$$

where $\mathbf{y} = f(\mathbf{x})$ are the true function values and $\hat{\mathbf{y}}$ are the predicted values.

Tables 2 through 6 show the performance of different space-filling designs for various analytic functions in dimensions 2 to 6, respectively[10]. We see that, for $d = 2$ (Table 2), LHS and Halton sequences perform better compared to the rest of the sample designs on most of the test functions. However, on some functions, e.g., GoldsteinPrice, Stair PCF and MPDS perform better. Therefore, none of the sample designs consistently guarantee superior performance. For $d = 3$ (Table 3), we see that Stair PCF design and MPDS (followed by Sobol sequences) perform consistently better compared to the rest of the approaches. As we go higher in dimensions, i.e., $d > 3$, we notice a significant gain in the performance of Stair PCF based space-filling spectral designs. Interesting, the amount of performance gain of Stair PCF based design increases as we go higher in dimensions. The reason for the poor regression performance of QMC sequences and LHS for $d > 3$ is due to their poor space-filling properties in high dimensions (Wang and Sloan, 2008). In comparison, both space-filling spectral designs and MPDS have good space-filling properties. We found that Stair PCF design and MPDS have similar coverage characteristics (r_{min}). However, the difference in their performance can be attributed to the fact that MPDS designs have significantly more oscillations in their PCF compared to an equivalent Stair PCF based space-filling spectral design, i.e. violation of the randomness objective.

10. Non-monotonicity of the error curves represents over-fitting and is more prominent with conventional sample designs.

Table 2: Impact of sample design on generalization performance of regression models fit to benchmark analytical functions in 2 dimensions. LHS and Halton sequences perform slightly better compared to rest of the sample designs.

9.3 Surrogate Model Design for an Inertial Confinement Fusion (ICF) Simulator

In this subsection, we consider the problem of designing surrogate models for an inertial confinement fusion (ICF) simulator developed at the National Ignition Facility (NIF). The NIF is aimed at demonstrating inertial confinement fusion (ICF), that is, thermonuclear ignition and energy gain in a laboratory setting. The goal is to focus 192 beams of the most energetic laser built so far onto a tiny capsule containing frozen deuterium. Under the right conditions, the resulting pressure will collapse the target to the point of ignition where hydrogen starts to fuse and produce massive amounts of energy, effectively creating a small star which can be harnessed for energy production. Though significant progress has been made, the ultimate goal of "ignition" has not yet been reached.

NIF employs an adaptive pipeline: perform experiments, use post-shot simulations to understand the experimental results, and design new experiments with parameter settings that are expected to improve performance. From an analysis viewpoint, the goal is to search the parameter space to find the region that leads to near-optimal performance. The dataset

Table 3: Impact of sample design on generalization performance of regression models fit to benchmark analytical functions in 3 dimensions. While the Stair PCF and MPDS designs are consistently better than the other methods, the amount of performance gain is minimal.

Function	MSE	AAE	R2-Statistic
BoxBetts			Hartmann3			Wolfe			Helical Valley			
considered here is a so called engineering or macro-physics simulation ensemble in which an implosion is simulated using different input parameters, such as, laser power, pulse shape etc. From these simulations, scientists extract a set of drivers, physical quantities believed to determine the behavior of the resulting implosion. These drivers are then analyzed with respect to the energy yield to better understand how to optimize future experiments. As one can expect, the success of this pipeline heavily depends on the quality of samples used for post-shot simulations.

We use the NIF 1-d HYDRA simulator (Marinak et al., 2001) and compare the performance of proposed space-filling spectral designs with existing approaches (random, LHS, Halton and Sobol and MPDS). For each simulation run, a large number of output quantities, such as peak velocity, yield, etc., are computed, and subsequently used to describe the resulting implosion. We vary the number of input parameters between 2 and 6, and fix the remaining variables to their default values. In each case, we fit a random forest regressor with 30 trees and repeated for 20 independent realizations of sample designs. We evaluated

Table 4: Impact of sample design on generalization performance of regression models fit to benchmark analytical functions in 4 dimensions. Stair PCF and MPDS designs demonstrate appreciable gains over popular sample design choices.

the reconstruction performance on 10^5 regular grid based test samples using the metrics in the previous experiment.

Table 7 shows the regression performance of the different sample designs for various output quantities in dimensions 2 to 6. We observe that regression error patterns are consistent with our observations in Section 9.2. The proposed Stair PCF based design consistently performs the best (followed by MPDS) for $d \geq 3$. Furthermore, the performance gain with the Stair PCF based design improves as we go higher in dimensions. This performance gain can be credited to their ability to achieve better space-filling properties in high dimensions by intelligently balancing the trade-off between coverage and randomness, and the effectiveness of the proposed metric (PCF) adopted for design and optimization.

10. Applications of Design of Experiments in Machine Learning Problems

In addition to the experiments presented in the paper, the proposed experiment design methodologies have a broader impact on several classical machine learning (ML) formulations. In its simplest form, the proposed sample designs can be used to create training data in supervised learning problems. In particular, optimized sample designs can provide significant performance gains in application areas where efficient data acquisition is required, e.g. machine learning for scientific data analysis (Karpatne et al., 2017). One such use case was considered in Section 9.3 of this paper for inertial confinement fusion (ICF) studies. We demonstrated that supervised models learned using samples from the proposed exper-

Table 5: Impact of sample design on generalization performance of regression models fit to benchmark analytical functions in 5 dimensions. In higher dimensions, conventional methods such as the LHS and QMC perform very poorly, while Stair PCF design significantly outperforms all competing methods, because of improved trade-off between coverage and randomness properties.

Trid			Hartmann6			
iment design produce highly generalizable models, i.e., have significantly lower prediction error for unseen input conditions. Furthermore, utilizing the notion of space-filling spectral designs to incorporate the prior information on signal structure (e.g., low dimensionality, sparsity) will be particularly useful for image analysis and computer vision tasks. Though not discussed, the analytical framework developed in this paper, can be extended beyond

Table 7: Performance of surrogate models for the NIF 1−d HYDRA simulator using different sample design techniques, with varying number of input parameters. While the conventional sample designs achieve reasonable performance in low dimensions, the proposed Stair PCF based design is consistently superior as the dimension of the input space grows.

Euclidean spaces to non-linear, embedded manifolds. For example, Anirudh et.al. (Anirudh et al., 2017) proposed a dart throwing technique to generate Poisson disk samples on the

Grassmannian manifold of low-dimensional linear subspaces. Despite the effectiveness of such heuristic techniques over other randomized sampling strategies, generating space-filling spectral designs on embedded manifolds is challenging since it is non-trivial to create equivalent definitions of the PSD and the PCF metrics for non-Euclidean domains.

Furthermore, there is a connection between the sample design problem considered in this paper and the classic ML task of active learning. In many practical scenarios, it is possible to use information gleaned from previous observations to improve the sampling process. As more samples are obtained, one can learn how to improve the sampling process by deciding where to sample next. These sampling feedback techniques are more generally known as adaptive sampling in the statistics literature. Note that, several popular design of experiment techniques have been extended to adaptive sampling scenarios (Yan and Wonka, 2012b). A natural extension of our work is towards builds importance sampling techniques, guided by spectral properties. In addition to these conventional applications, more recently, optimized sample designs have been used to improve the convergence characteristics of neural network training process. Several efforts are currently being undertaken for effective mini-batch sampling and studying their effect on the convergence rate of training algorithms. Similarly, one could develop improved mini-batch sampling strategies through the analytical framework of space-filling spectral designs. Similarly, hyper-parameter optimization in deep learning is another application area where optimized sample design can be very useful (Bergstra and Bengio, 2012). Finally, space-filling spectral designs are also applicable in reinforcement learning (Sutton and Barto, 1998) and Bayesian optimization (Snoek et al., 2012) where a key requirement is to effectively balance between exploration and exploitation.

11. Conclusion and Future Directions

In this work, we considered the problem of constructing high quality space-filling designs. We proposed the use of pair correlation function (PCF) to quantify the space-filling property and systematically traded-off coverage and randomness in sample designs in arbitrary dimensions. Next, we linked PCF to the power spectral density (PSD) to analyze the qualitative measure of the design performance. Using the insights provided by this spatial-spectral analysis, we proposed novel space-filling spectral designs. We also provided an efficient PCF estimator to evaluate the space-filling properties of sample designs in arbitrary dimensions. Next, we devised a gradient descent based optimization algorithm to generate high quality space-filling designs. Superiority of proposed space-filling spectral designs were shown on two different applications in 2 to 6 dimensions: a) image reconstruction and b) surrogate modeling on several benchmark optimization functions and an inertial confinement fusion (ICF) simulation code. There are still many interesting questions that remain to be explored in the future work such as an analysis of the problem for non-linear manifolds. Note that some analytical methodologies used in this paper are certainly exploitable for studying and designing space-filling designs in different manifolds. Other questions such as PCF parameterizations for other variants of space-filling designs, adaptive and importance sampling, and optimization approaches to synthesize them can also be investigated.

Abstract

We study the density estimation problem with observations generated by certain dynamical systems that admit a unique underlying invariant Lebesgue density. Observations drawn from dynamical systems are not independent and moreover, usual mixing concepts may not be appropriate for measuring the dependence among these observations. By employing the $\mathcal{C}$-mixing concept to measure the dependence, we conduct statistical analysis on the consistency and convergence of the kernel density estimator. Our main results are as follows: First, we show that with properly chosen bandwidth, the kernel density estimator is universally consistent under L_1-norm; Second, we establish convergence rates for the estimator with respect to several classes of dynamical systems under L_1-norm. In the analysis, the density function f is only assumed to be Hölder continuous or pointwise Hölder controllable which is a weak assumption in the literature of nonparametric density estimation and also more realistic in the dynamical system context. Last but not least, we prove that the same convergence rates of the estimator under L_∞-norm and L_1-norm can be achieved when the density function is Hölder continuous, compactly supported, and bounded. The bandwidth selection problem of the kernel density estimator for dynamical system is also discussed in our study via numerical simulations.

Keywords: Kernel density estimation, dynamical system, dependent observations, $\mathcal{C}$-mixing process, universal consistency, convergence rates, covering number, learning theory

1. Introduction

Dynamical systems are now ubiquitous and are vital in modeling complex systems, especially when they admit recurrence relations. Statistical inference for dynamical systems has drawn continuous attention across various fields, the topics of which include parameter estimation, invariant measure estimation, forecasting, noise detection, among others. For instance, in the statistics and machine learning community, the statistical inference for certain dynamical systems have been recently studied in Suykens et al. (1995); Suykens and Vandewalle (2000); Suykens et al. (2002); Zoeter and Heskes (2005); Anghel and Steinwart (2007); Steinwart and Anghel (2009); Deisenroth and Mohamed (2012); McGoff et al. (2015a); Hang and Steinwart (2017), just to name a few. We refer the reader to a recent survey in McGoff et al. (2015b) for a general depiction of this topic. The purpose of this study is to investigate the density estimation problem for dynamical systems via a classical nonparametric approach, i.e., kernel density estimation.

The commonly considered density estimation problem can be stated as follows. Let x_1, x_2, $\ldots, x_n$ be observations drawn independently from an unknown distribution P on $\mathbb{R}^d$ with the density f. Density estimation is concerned with the estimation of the underlying density f. Accurate estimation of the density is important for many machine learning tasks such as regression, classification, and clustering problems and also plays an important role in many real-world applications. Nonparametric density estimators are popular since weaker assumptions are applied to the underlying probability distribution. Typical nonparametric density estimators include the histogram and kernel density estimator. In this study, we are interested in the latter one, namely, *kernel density estimator*, which is also termed as *Parzen-Rosenblatt estimator* (Parzen, 1962; Rosenblatt, 1956) and takes the following form

$$f_n(x) = \frac{1}{nh^d} \sum_{i=1}^{n} K\left(\frac{x - x_i}{h}\right). \tag{1}$$

Here, $h := h_n > 0$ is a bandwidth parameter and K is a smoothing kernel. In the literature, point-wise and uniform consistency and convergence rates of the estimator f_n to the unknown truth density f under various distance measurements, e.g., L_1, L_2, and L_∞, have been established by resorting to the regularity assumptions on the smoothing kernel $\mathcal{K}$, the density f, and the decay of the bandwidth sequence $\{h_n\}$. Besides the theoretical concerns on the consistency and convergence rates, another practical issue one usually needs to address is the choice of the bandwidth parameter h_n, which is also called the *smoothing parameter*. It plays a crucial role in the bias-variance trade-off in kernel density estimation. In the literature, approaches to choosing the smoothing parameter include least-squares cross-validation (Bowman, 1984; Rudemo, 1982), biased cross-validation (Scott and Terrell, 1987), plug-in method (Park and Marron, 1990; Sheather and Jones, 1991), the double kernel method (Devroye, 1989), and also the method based on a discrepancy principle (Eggermont and LaRiccia, 2001). We refer the reader to Jones et al. (1996a) for a general overview and to Wand and Jones (1994); Cao et al. (1994); Jones et al. (1996b); Devroye (1997) for more detailed reviews.

Note that studies on the kernel density estimator (1) mentioned above heavily rely on the assumption that the observations are drawn in an i.i.d fashion. In the literature of statistics and machine learning, it is commonly accepted that the i.i.d assumption on the

given data can be very much restrictive in real-world applications. Having realized this, researchers turn to weaken this i.i.d assumption by assuming that the observations are weakly dependent under various notions of weakly dependence which include α-mixing, β-mixing, and ϕ-mixing (Bradley, 2005). There has been a flurry of work to attack this problem with theoretical and practical concerns, see e.g., Györfi (1981); Masry (1983, 1986); Robinson (1983); Masry and Györfi (1987); Tran (1989b); Györfi and Masry (1990); Tran (1989a); Hart and Vieu (1990); Yu (1993) and Hall et al. (1995), under the above notions of dependence. These studies were conducted under various notions of sample dependence. In fact, as Györfi and Lugosi (1992) pointed out, for samples that are ergodic, kernel density estimation is not universally consistent under the usual conditions. A counter example was devised there showing the existence of an ergodic sequence of uniformly distributed random variables based on which the kernel density estimation almost surely does not tend to zero in the L_1 sense. On the other hand, the assumed correlation among the observations complicates the kernel density estimation problem from a technical as well as practical view and also brings inherent barriers. This is because, more frequently, the analysis on the consistency and convergence rates of the kernel density estimator (1) is proceeded by decomposing the error term into bias and variance terms, which correspond to data-free and data-dependent error terms, respectively. The data-free error term can be tackled by using techniques from the approximation theory while the data-dependent error term is usually dealt with by exploiting arguments from the empirical process theory such as concentration inequalities. As a result, due to the existence of dependence among observations and various notions of the dependence measurement, the techniques, and results concerning the data-dependent error term are in general not universally applicable. On the other hand, it has been also pointed out that the bandwidth selection in kernel density estimation under dependence also departures from the independent case, see e.g., Hart and Vieu (1990); Hall et al. (1995).

In fact, when the observations $x_1, x_2, \ldots, x_n \in \mathbb{R}^d$ are generated by certain ergodic measure-preserving dynamical systems, the problem of kernel density estimation can be even more involved. To explain, let us consider a discrete-time ergodic measure-preserving dynamical system described by the sequence $(T^n)_{n\geq 1}$ of iterates of an unknown map $T : \Omega \to \Omega$ with $\Omega \subset \mathbb{R}^d$ and a unique invariant measure P which possesses a density f with respect to the Lebesgue measure (rigorous definitions will be given in the sequel). That is, we have

$$x_i = T^i(x_0), \quad i = 1, 2, \ldots, n, \tag{2}$$

where x_0 is the initial state. It is noticed that in this case the usual mixing concepts are not general enough to characterize the dependence among observations generated by (2) (Maume-Deschamps, 2006; Steinwart and Anghel, 2009; Hang and Steinwart, 2017). On the other hand, existing theoretical studies on the consistency or convergence rates of the kernel density estimator for i.i.d. observations frequently assume that the density function f is sufficiently smooth, e.g., first-order or even second-order smoothness. However, more often than not, this requirement can be stringent in the dynamical system context. It is well-known that (see e.g., Liverani (1995); Baladi (2000)) piecewise expanding maps (or Lasota-Yorke maps) admit a density f which only belongs to the space BV, i.e., functions

of bounded variation. Typical examples are the Gauss map in Example 3 and the β-maps in Example 1 (see Subsection 2.2).

In this study, the kernel density estimation problem with observations generated by dynamical systems (2) is approached by making use of a more general concept for measuring the dependence of observations, namely, the so-called $\mathcal{C}$-mixing process (refer to Section 2 for the definition). Proposed in Maume-Deschamps (2006) and recently investigated in Hang and Steinwart (2017), the $\mathcal{C}$-mixing concept is shown to be more general and powerful in measuring dependence among observations generated by dynamical systems and can accommodate a large class of dynamical systems. There, a Bernstein-type exponential inequality for $\mathcal{C}$-mixing processes was established and its applications to some learning schemes were explored.

Our main purpose in this paper is to conduct some theoretical analysis and practical implementations on the kernel density estimator for dynamical systems. The primary concern is the consistency and convergence rates of the kernel density estimator (1) with observations generated by dynamical systems (2). The consistency and convergence analysis is conducted under L_1-norm, and L_∞-norm, respectively. We show that under mild assumptions on the smoothing kernel, with properly chosen bandwidth, the estimator is universally consistent under L_1-norm. When the probability distribution P possesses a polynomial or exponential decay outside of a radius-r ball in its support, under the Hölder continuity assumptions on the kernel function and the density, we obtain almost optimal convergence rates under L_1-norm. Moreover, when the probability distribution P is compactly supported, which is a frequently encountered setting in the dynamical system context, we prove that stronger convergence results of the estimator can be developed, i.e., convergence results under L_∞-norm which are shown to be of the same order with its L_1-norm convergence rates. Finally, with regard to the practical implementation of the estimator, we also discuss the bandwidth selection problem by performing numerical comparisons among several typical existing selectors that include least squares cross-validation and its variants for dependent observations, and the double kernel method. We show that the double kernel bandwidth selector proposed in Devroye (1989) can in general work well. Moreover, according to our numerical experiments, we find that bandwidth selection for kernel density estimator of dynamical systems is usually ad-hoc in the sense that its performance may depend on the considered dynamical system.

The rest of this paper is organized as follows. Section 2 is a warm-up section for the introduction of some notations, definitions and assumptions that are related to the kernel density estimation problem and dynamical systems. We provide our main results on the consistency and convergence rates of the kernel density estimator in Section 3. Some comments and discussions concerning the main results will be also provided in this section. The main analysis on bounding error terms is presented in Section 4. We discuss the bandwidth selection problem in Section 5 and provide some numerical simulations. All the proofs of Section 3 and Section 4 can be found in Section 6. We end this paper in Section 7.

2. Preliminaries

2.1 Notations

Throughout this paper, λ^d is denoted as the Lebesgue measure on $\mathbb{R}^d$ and $\|\cdot\|$ is an arbitrary norm on $\mathbb{R}^d$. We denote B_r as the centered ball of $\mathbb{R}^d$ with radius r, that is,

$$B_r := \{x = (x_1, \ldots, x_d) \in \mathbb{R}^d : \|x\| \leq r\}.$$

Recall that for $1 \leq p < \infty$, the ℓ_p^d-norm is defined as $\|x\|_{\ell_p^d} := (x_1^p + \cdots + x_d^p)^{1/p}$, and the ℓ_∞^d-norm is defined as $\|x\|_{\ell_\infty^d} := \max_{i=1,\ldots,d} |x_i|$. Let $(\Omega, \mathcal{A}, \mu)$ be a probability space. We denote $L_p(\mu)$ as the space of (equivalence classes of) measurable functions $g : \Omega \to \mathbb{R}$ with finite L_p-norm $\|g\|_p$. Then $L_p(\mu)$ together with $\|g\|_p$ forms a Banach space. Moreover, if $\mathcal{A}' \subset \mathcal{A}$ is a sub-σ-algebra, then $L_p(\mathcal{A}', \mu)$ denotes the space of all $\mathcal{A}'$-measurable functions $g \in L_p(\mu)$. Finally, for a Banach space E, we write B_E for its closed unit ball.

In what follows, the notation $a_n \lesssim b_n$ means that there exists a positive constant c such that $a_n \leq c\, b_n$, for all $n \in \mathbb{N}$. With a slight abuse of notation, in this paper, c, c' and C are used interchangeably for positive constants while their values may vary across different lemmas, propositions, theorems, and corollaries.

2.2 Dynamical Systems and $\mathcal{C}$-mixing Processes

In this subsection, we first introduce the dynamical systems of interest, namely, ergodic measure-preserving dynamical systems. Mathematically, an *ergodic measure-preserving dynamical system* is a system $(\Omega, \mathcal{A}, \mu, T)$ with a mapping $T : \Omega \to \Omega$ that is measure-preserving, i.e., $\mu(A) = \mu(T^{-1}A)$ for all $A \in \mathcal{A}$, and ergodic, i.e., $T^{-1}A = A$ implies $\mu(A) = 0$ or 1. In this study, we are confined to the dynamical systems in which Ω is a subset of $\mathbb{R}^d$, μ is a probability measure that is absolutely continuous with respect to the Lebesgue measure λ^d and admits a unique invariant Lebesgue density f. In order to include a larger variety of density functions that commonly appear in dynamical systems, we introduce a new measurement of continuity that is a generalization of the α-Hölder continuity, which is defined as follows:

Definition 1 (Pointwise α-Hölder Controllable) *A density function $f : \mathbb{R}^d \to [0, \infty)$ is called pointwise α-Hölder controllable, if for λ^d-almost all $x \in \mathbb{R}^d$ there exists a constant $c(x) \geq 0$ and a radius $r(x) > 0$ such that for all $x' \in \mathbb{R}^d$ with $\|x'\| < r(x)$ we have*

$$|f(x + x') - f(x)| \leq c(x)\|x'\|^\alpha .$$

Moreover, f is called uniformly pointwise α-Hölder controllable, if

$$r_0 := \operatorname{ess\,inf}_{x \in \Omega} r(x) > 0 .$$

Note that the an α-Hölder continuous function can be recognized as a special case of the α-Hölder controllable functions with $c(x)$ and $r(x)$ being some universal constant $c > 0$ and $r > 0$.

In our study, it is assumed that the observations $x_1, x_2, \cdots, x_n$ are generated by the discrete-time dynamical system (2). Below we list several typical examples of discrete-time dynamical systems that satisfy the above assumptions (Lasota and Mackey, 1985):

Example 1 (β-Map) *For $\beta > 1$, the β-map is defined as*

$$T(x) = \beta x \mod 1, \quad x \in (0, 1),$$

with a unique invariant Lebesgue density given by

$$f(x) = c_\beta \sum_{i \geq 0} \beta^{-(i+1)} \mathbf{1}_{[0, T^i(1)]}(x),$$

where c_β is a constant chosen such that f has integral 1.

Example 2 (Logistic Map) *The Logistic map defined by*

$$T(x) = 4x(1 - x), \quad x \in (0, 1)$$

admits the unique invariant Lebesgue density

$$f(x) = \frac{1}{\pi\sqrt{x(1-x)}} \cdot \mathbf{1}_{(0,1)}(x), \quad x \in \mathbb{R}.$$

Moreover, for all $\alpha \in (0, 1/2)$, the density f is α-Hölder controllable with

$$c(x) := \begin{cases} 0 & \text{if } x < 0 \\ x^{-1/2-\alpha} & \text{if } 0 < x < 1/4 \\ 4 & \text{if } 1/4 \leq x \leq 3/4 \\ (1-x)^{-1/2-\alpha} & \text{if } 3/4 \leq x < 1 \\ 0 & \text{if } x > 1 . \end{cases}$$

and

$$r(x) := \begin{cases} -x & \text{if } x < 0 \\ x/2 & \text{if } 0 < x < 1/4 \\ 1/4 & \text{if } 1/4 \leq x \leq 3/4 \\ 1 - x/2 & \text{if } 3/4 \leq x < 1 \\ x - 1 & \text{if } x > 1 . \end{cases} \tag{3}$$

Example 3 (Gauss Map) *The Gauss map is defined by*

$$T(x) = \frac{1}{x} \mod 1, \quad x \in (0, 1),$$

with a unique invariant Lebesgue density

$$f(x) = \frac{1}{\log 2} \cdot \frac{1}{1+x} \cdot \mathbf{1}_{[0,1]}(x), \quad x \in \mathbb{R}.$$

Moreover, since the restriction $f_{|[0,1]}$ is Lipschitz continuous with Lipschitz constant $\frac{1}{\log 2}$, it is easy to check that f is pointwise 1-Hölder controllable with $r(x)$ given by (3) and $c(x) := \frac{1}{\log 2} \cdot \mathbf{1}_{(0,1)}(x)$.

We now introduce the notion for measuring the dependence among observations from dynamical systems, namely, $\mathcal{C}$-mixing process. To this end, let us assume that $(X, \mathcal{B})$ is a measurable space with $X \subset \mathbb{R}^d$. Let $\mathcal{X} := (X_n)_{n\geq 1}$ be an X-valued stochastic process on $(\Omega, \mathcal{A}, \mu)$, and for $1 \leq i \leq j \leq \infty$, denote by $\mathcal{A}_i^j$ the σ-algebra generated by $(X_i, \ldots, X_j)$. Let $\Gamma : \Omega \to X$ be a measurable map. μ_Γ is denoted as the Γ-image measure of μ, which is defined as $\mu_\Gamma(B) := \mu(\Gamma^{-1}(B))$, $B \subset X$ measurable. The process $\mathcal{X}$ is called *stationary* if $\mu_{(X_{i_1+j},\ldots,X_{i_n+j})} = \mu_{(X_{i_1},\ldots,X_{i_n})}$ for all $n, j, i_1, \ldots, i_n \geq 1$. Denote $P := \mu_{X_1}$. Moreover, for $\psi, \varphi \in L_1(\mu)$ satisfying $\psi\varphi \in L_1(\mu)$, we denote the correlation of ψ and φ by

$$\operatorname{cor}(\psi, \varphi) := \int_\Omega \psi\, \varphi \,\mathrm{d}\mu - \int_\Omega \psi \,\mathrm{d}\mu \cdot \int_\Omega \varphi \,\mathrm{d}\mu\,.$$

It is shown that several dependency coefficients for $\mathcal{X}$ can be expressed in terms of such correlations for restricted sets of functions ψ and φ. In order to introduce the notion, we also need to define a new norm which introduces restrictions on ψ and φ considered here. Throughout this paper, $\mathcal{C}(X)$ is denoted as a subspace of bounded measurable functions $g : X \to \mathbb{R}$ and that we have a semi-norm $|||\cdot|||$ on $\mathcal{C}(X)$. For $g \in \mathcal{C}(X)$, we define the $\mathcal{C}$-norm $\|\cdot\|_\mathcal{C}$ by

$$\|g\|_\mathcal{C} := \|g\|_\infty + |||g|||. \tag{4}$$

Additionally, we need to introduce the following restrictions on the semi-norm $|||\cdot|||$.

Assumption A *We assume that the following two restrictions on the semi-norm $|||\cdot|||$ hold:*

(i) $|||g||| = 0$ *for all constant functions* $g \in \mathcal{C}(X)$*;*

(ii) $|||e^g||| \leq \left\|e^g\right\|_\infty |||g|||, \qquad g \in \mathcal{C}(X).$

Note that the first constraint on the semi-norm in Assumption A implies its shift invariance on $\mathbb{R}$ while the inequality constraint can be viewed as an abstract *chain rule* if one views the semi-norm as a norm describing aspects of the smoothness of g. In fact, it is easy to show that the following function classes, which are probably also the most frequently considered in the dynamical system context, satisfy Condition (i) in Assumption A. Moreover, they also satisfy Condition (ii) in Assumption A, as shown in Hang and Steinwart (2017):

- $L_\infty(X)$: The class of bounded functions on X;
- $BV(X)$: The class of bounded variation functions on X;
- $C_{b,\alpha}(X)$: The class of bounded and α-Hölder continuous functions on X;
- $\operatorname{Lip}(X)$: The class of Lipschitz continuous functions on X;
- $C^1(X)$: The class of continuously differentiable functions on X.

The corresponding semi-norms are

$$\begin{aligned}
|||g|||_{L_\infty(X)} &:= 0,\\
|||g|||_{BV(X)} &:= \|g\|_{BV(X)},\\
|||g|||_{C_{b,\alpha}(X)} &:= |g|_\alpha := \sup_{x\neq x'} \frac{|g(x) - g(x')|}{|x - x'|^\alpha},\\
|||g|||_{\operatorname{Lip}(X)} &:= |g|_1,\\
|||g|||_{C^1(X)} &:= \sum_{i=1}^d \left\| \frac{\partial g}{\partial x_i} \right\|_\infty.
\end{aligned}$$

Throughout this paper, we assume that for all $r \geq 1$, there exists a function $g \in \mathcal{C}$ and a constant K such that $\mathbf{1}_{B^c_{r/2}} \leq g \leq 1$ and $|||g||| \leq K$. It is easily to see that this holds for function sets $\mathcal{C} = \operatorname{Lip}$, $C_{b,\alpha}$, C^1 etc.

Definition 2 ($\mathcal{C}$-mixing Process) *Let $(\Omega, \mathcal{A}, \mu)$ be a probability space, $(X, \mathcal{B})$ be a measurable space, $\mathcal{X} := (X_i)_{i\geq 1}$ be an X-valued, stationary process on Ω, and $\|\cdot\|_\mathcal{C}$ be defined by (4) for some semi-norm $|||\cdot|||$. Then, for $n \geq 1$, we define the $\mathcal{C}$-mixing coefficients by*

$$\phi_\mathcal{C}(\mathcal{X}, n) := \sup\left\{\operatorname{cor}(\psi, g(X_{k+n})) : k \geq 1, \psi \in B_{L_1(\mathcal{A}_1^k,\mu)}, g \in B_{\mathcal{C}(X)}\right\},$$

and the time-reversed $\mathcal{C}$-mixing coefficients by

$$\phi_{\mathcal{C},rev}(\mathcal{X}, n) := \sup\left\{\operatorname{cor}(g(X_k), \varphi) : k \geq 1, g \in B_{\mathcal{C}(X)}, \varphi \in B_{L_1(\mathcal{A}_{k+n}^\infty,\mu)}\right\}.$$

Let $(d_n)_{n\geq 1}$ be a strictly positive sequence converging to 0. We say that $\mathcal{X}$ ***is*** **(time-reversed) $\mathcal{C}$-mixing** *with rate $(d_n)_{n\geq 1}$, if we have $\phi_{\mathcal{C},rev}(\mathcal{X}, n) \leq d_n$ for all $n \geq 1$. Moreover, if $(d_n)_{n\geq 1}$ is of the form*

$$d_n := c_0 \exp\left(-bn^\gamma\right), \qquad n \geq 1,$$

for some constants $c_0 > 0$, $b > 0$, and $\gamma > 0$, then $\mathcal{X}$ is called **geometrically *(time-reversed) $\mathcal{C}$-mixing***.

Remark 3 *In Definition 2, if $|||\cdot||| = 0$, we obtain the classical ϕ-mixing coefficients. If $|||\cdot||| \neq 0$, the resulting $\mathcal{C}$-norm satisfies $\|\cdot\|_\mathcal{C} \geq \|\cdot\|_\infty$ and therefore, the mixing coefficients admit fewer functions. Thus, the considered functions must be "smoother" than the ones in the ϕ-mixing case and therefore statistical changes of small spatial nature in x do not have such a large impact on h, if h is smooth. In other words, even if the trajectory $x_1, \ldots, x_n$ stays in a certain region for a while, this does not impact the empirical average $\frac{1}{n}\sum_{i=1} h(x_i)$ as much as it would for non-smooth h. As a result, the concentration properties in this case hold similarly as in the i.i.d. case.*

From the above definition, we see that a $\mathcal{C}$-mixing process is defined in association with an underlying function space. For the above listed function spaces, i.e., $L_\infty(X)$, $BV(X)$, $C_{b,\alpha}(X)$, $\operatorname{Lip}(X)$, and $C^1(X)$, the increase of the smoothness enlarges the class of the

associated stochastic processes, as illustrated in Hang and Steinwart (2017). Note that the classical ϕ-mixing process is essentially a $\mathcal{C}$-mixing process associated with the function space $L_\infty(X)$. Note also that not all α-mixing processes are $\mathcal{C}$-mixing, and vice versa. We refer the reader to Hang and Steinwart (2017) for the relations among α-, ϕ- and $\mathcal{C}$-mixing processes.

On the other hand, under the above notations and definitions, from Theorem 4.7 in Maume-Deschamps (2006), we know that Logistic map in Example 2 is geometrically time-reversed $\mathcal{C}$-mixing with $\mathcal{C} = \mathrm{Lip}(0,1)$ while Theorem 4.4 in Maume-Deschamps (2006) (see also Chapter 3 in Baladi (2000)) indicates that Gauss map in Example 3 is geometrically time-reversed $\mathcal{C}$-mixing with $\mathcal{C} = BV(0,1)$. Example 1 is also geometrically time-reversed $\mathcal{C}$-mixing with $\mathcal{C} = BV(0,1)$ according to Maume-Deschamps (2006). For more examples of geometrically time-reversed $\mathcal{C}$-mixing dynamical systems, the reader is referred to Section 2 in Hang and Steinwart (2017). Besides, there also exist several high-dimensional examples. For instance, piecewise expanding maps (Baladi, 2000, Chapter 3), hyperbolic and Smale's Axiom A diffeomorphisms (Baladi, 2000, Chapter 4), and Anosov diffeomorphisms (Baladi, 2001; Lasota and Mackey, 1985).

2.3 Kernel Density Estimators for Dynamical Systems

In this subsection, we formulate kernel density estimators for dynamical systems that admit a unique underlying invariant Lebesgue density. The existence and uniqueness of an invariant measure (and the corrsponding invariant density) and smooth invariant measure is a classical problem in the theory of dynamical systems (Katok and Hasselblatt, 1995; Baladi, 2000; Lasota and Mackey, 1985). Perhaps the first existence theorem for continuous maps goes back to Krylov and Bogolyubov, see e.g. (Katok and Hasselblatt, 1995, Theorem 4.1.1). Then Lasota and Yorke (1973) proved the existence theorem for piecewise expanding maps. Since then, results concerning the existence for many other dynamical systems such as uniformly hyperbolic attractors and nonuniformly hyperbolic uni-modal maps have been established, see e.g. Baladi (2000). From the discussion after Theorem 2.1 in Baladi (2000) we know that mixing (thus ergodic) implies the uniqueness among all absolutely continuous invariant measures and smoothness ensures the existence of the invariant measure.

For the smoothing kernel K in the kernel density estimator, in this paper we consider its following general form, namely, d-dimensional smoothing kernel:

Definition 4 *A bounded, monotonically decreasing function $K : [0,\infty) \to [0,\infty)$ is a* ***d-dimensional smoothing kernel*** *if*

$$\int_{\mathbb{R}^d} K(\|x\|)\,\mathrm{d}x =: \kappa \in (0,\infty). \tag{5}$$

The choice of the norm in Definition 4 does not matter since all norms on $\mathbb{R}^d$ are equivalent. To see this, let $\|\cdot\|'$ be another norm on $\mathbb{R}^d$ satisfying $\kappa \in (0,\infty)$. From the equivalence of the two norms on $\mathbb{R}^d$, one can find a positive constant c such that $\|x\| \le c\|x\|'$ holds for all $x \in \mathbb{R}$. Therefore, easily we have

$$\int_{\mathbb{R}^d} K(\|x\|')\,\mathrm{d}x \le \int_{\mathbb{R}^d} K\left(\|x\|/c\right)\,\mathrm{d}x = c^d \int_{\mathbb{R}^d} K(\|x\|)\,\mathrm{d}x < \infty.$$

In what follows, without loss of generality, we assume that the constant κ in Definition 4 equals to 1.

Lemma 5 *A bounded, monotonically decreasing function $K : [0,\infty) \to [0,\infty)$ is a d-dimensional smoothing kernel if and only if*

$$\int_0^\infty K(r) r^{d-1}\,\mathrm{d}r \in (0,\infty).$$

Proof From the above discussions, it suffices to consider the integration constraint for the kernel function K with respect to the Euclidean norm $\|\cdot\|_{\ell_2^d}$. We thus have

$$\int_{\mathbb{R}^d} K\big(\|x\|_{\ell_2^d}\big)\,\mathrm{d}x = d\tau_d \int_0^\infty K(r) r^{d-1}\,\mathrm{d}r,$$

where $\tau_d = \pi^{d/2}/\Gamma\left(\frac{d}{2}+1\right)$ is the volume of the unit ball $B_{\ell_2^d}$ of the Euclidean space ℓ_2^d. This completes the proof of Lemma 5. ∎

Let $r \in [0,+\infty)$ and denote $\mathbf{1}_A$ as the indicator function. Several common examples of d-dimensional smoothing kernels $K(r)$ include the Naive kernel $\mathbf{1}_{[0,1]}(r)$, the Triangle kernel $(1-r)\mathbf{1}_{[0,1]}(r)$, the Epanechnikov kernel $(1-r^2)\mathbf{1}_{[0,1]}(r)$, and the Gaussian kernel e^{-r^2}. In this paper, we are interested in the kernels that satisfy the following restrictions on their shape and regularity:

Assumption B *For a fixed function space $\mathcal{C}(X)$, we make the following assumptions on the d-dimensional smoothing kernel K:*

(i) *K is Hölder continuous with exponent β with $\beta \in (0,1]$;*

(ii) *$\kappa_\upsilon := \int_0^\infty K(r) r^{\upsilon+d-1}\,\mathrm{d}r < \infty$ for some $\upsilon \in (0,\infty)$;*

(iii) *For some $R > 0$, K satisfies $K(r) = 0$ for all $r > R$;*

(iv) *For all $x \in \mathbb{R}^d$, we have $K(\|x - \cdot\|/h) \in \mathcal{C}(X)$ and there exists a function $\varphi : (0,\infty) \to (0,\infty)$ such that*

$$\sup_{x\in\mathbb{R}^d} |||K(\|x-\cdot\|/h)||| \le \varphi(h).$$

It is easy to verify that for $\mathcal{C} = \mathrm{Lip}$, Assumption B is met for the Triangle kernel, the Epanechnikov kernel, and the Gaussian kernel. Particularly, Condition (iv) holds for all these kernels with $|||\cdot|||$ being the Lipschitz norm and $\varphi(h) \le \mathcal{O}(h^{-1})$. Moreover, as we shall see below, not all the conditions in Assumption B are required for the analysis conducted in this study and conditions assumed on the kernel will be specified explicitly.

We now show that given a d-dimensional smoothing kernel K as in Definition 4, one can easily construct a probability density on $\mathbb{R}^d$.

Definition 6 (K-Smoothing of a Measure) *Let K be a d-dimensional smoothing kernel and Q be a probability measure on $\mathbb{R}^d$. Then, for $h > 0$,*

$$f_{Q,h}(x) := f_{Q,K,h}(x) := h^{-d} \int_{\mathbb{R}^d} K\left(\|x - x'\|/h\right) \mathrm{d}Q(x'), \qquad x \in \mathbb{R}^d,$$

*is called a K-**smoothing of** Q.*

It is not difficult to see that $f_{Q,h}$ defines a probability density on $\mathbb{R}^d$ since Fubini's theorem yields that

$$\begin{aligned}\int_{\mathbb{R}^d} f_{Q,h}(x)\,\mathrm{d}x &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} h^{-d} K\left(\|x - x'\|/h\right) \mathrm{d}Q(x')\,\mathrm{d}x \\ &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} K(\|x\|)\,\mathrm{d}x\,\mathrm{d}Q(x') = 1.\end{aligned}$$

Let us denote $K_h : \mathbb{R}^d \to [0, +\infty)$ as

$$K_h(x) := h^{-d} K\left(\|x\|/h\right),\ x \in \mathbb{R}^d. \tag{6}$$

Note that K_h also induces a density function on $\mathbb{R}^d$ since there holds $\|K_h\|_1 = 1$.

For the sake of notational simplification, in what follows, we introduce the convolution operator $*$. Under this notation, we then see that $f_{Q,h}$ is the density of the measure that is the convolution of the measure Q and $\nu_h = K_h\,\mathrm{d}\lambda^d$. Recalling that P is a probability measure on $\mathbb{R}^d$ with the corresponding density function f, by taking $Q := P$ with $\mathrm{d}P = f\,\mathrm{d}\lambda^d$, we have

$$f_{P,h} = K_h * f = f * K_h = K_h * \mathrm{d}P. \tag{7}$$

Since $K_h \in L_\infty(\mathbb{R}^d)$ and $f \in L_1(\mathbb{R}^d)$, from Proposition 8.8 in Folland (1999), we know that $f_{P,h}$ is uniformly continuous and bounded. Specifically, when Q is the empirical measure $D_n = \frac{1}{n}\sum_{i=1}^n \delta_{x_i}$, the *kernel density estimator for dynamical systems* in this study can be expressed as

$$f_{D_n,h}(x) = K_h * \mathrm{d}D_n(x) = n^{-1}h^{-d}\sum_{i=1}^n K\left(\|x - x_i\|/h\right). \tag{8}$$

From now on, for notational simplicity, we will suppress the subscript n of D_n and denote $D := D_n$, e.g., $f_{D,h} := f_{D_n,h}$.

3. Main Results and Statements

In this section, we present main results on the consistency and convergence rates of $f_{D,h}$ to the true density f under L_1-norm and also L_∞-norm for some special cases. We also present some comments and discussions on the obtained main results.

Recall that $f_{D,h}$ is a nonparametric density estimator and so the criterion that measures its goodness-of-fit matters, which, for instance, includes L_1-distance, L_2-distance, and L_∞-distance. In the literature of kernel density estimation, probably the most frequently

employed criterion is the L_2-distance of the difference between $f_{D,h}$ and f, since it entails an exact bias-variance decomposition and can be analyzed relatively easily by using Taylor expansion involved arguments. However, it is argued in Devroye and Györfi (1985) (see also Devroye and Lugosi (2001)) that L_1-distance could be a more reasonable choice since: it is invariant under monotone transformations; it is always well-defined as a metric on the space of density functions; it is also proportional to the total variation metric and so leads to better visualization of the closeness to the true density function than L_2-distance. As to the L_∞-distance, it measures the worst-case goodness-of-fit of the estimator.

3.1 Results on Consistency

We first present results on the consistency property of the kernel density estimator $f_{D,h}$ in the sense of L_1-norm. A kernel density estimator $f_{D,h}$ is said to be *consistent* in the sense of L_1-norm if $f_{D,h}$ converges to f almost surely under L_1-norm.

Theorem 7 *Let K be a d-dimensional smoothing kernel that satisfies Conditions (i) and (iv) in Assumption B. Let $\mathcal{X} := (X_n)_{n\geq 1}$ be an X-valued stationary geometrically (time-reversed) $\mathcal{C}$-mixing process on $(\Omega, \mathcal{A}, \mu)$ with $\|\cdot\|_{\mathcal{C}}$ being defined for some semi-norm $|||\cdot|||$ that satisfies Assumption A. If*

$$h_n \to 0 \quad \textit{and} \quad \frac{nh_n^d}{(\log n)^{(2+\gamma)/\gamma}} \to \infty, \quad \textit{as} \quad n \to \infty,$$

then the kernel density estimator f_{D,h_n} is universally consistent in the sense of L_1-norm.

The consistency result in Theorem 7 is independent of the probability distribution P and is therefore of the universal type. In particular, these results apply to the examples provided in Section 2.2, i.e., β-map, Logistic map, and Gauss map.

3.2 Results on Convergence Rates under L_1-Norm

We now show that if certain tail assumptions on P are imposed, convergence rates can be obtained under L_1-norm. Here, we consider three different situations, namely, the tail of the probability distribution P has a polynomial decay, exponential decay and disappears, respectively.

Theorem 8 *Let K be a d-dimensional smoothing kernel that satisfies Assumption B. Assume that the density f is α-Hölder continuous with $\alpha \leq \beta$. Let $\mathcal{X} := (X_n)_{n\geq 1}$ be an X-valued stationary geometrically (time-reversed) $\mathcal{C}$-mixing process on $(\Omega, \mathcal{A}, \mu)$ with $\|\cdot\|_{\mathcal{C}}$ being defined for some semi-norm $|||\cdot|||$ that satisfies Assumption A. We consider the following cases:*

(i) $P\left(B_r^c\right) \lesssim r^{-\eta d}$ *for some $\eta > 0$ and for all $r \geq 1$;*

(ii) $P\left(B_r^c\right) \lesssim e^{-ar^\eta}$ *for some $a > 0$, $\eta > 0$ and for all $r \geq 1$;*

(iii) $P\left(B_{r_0}^c\right) = 0$ *for some $r_0 \geq 1$.*

For the above cases, if $n \geq n_0$ with n_0 given in the proof, and the sequences h_n are of the following forms:

(i) $h_n = \left(\frac{(\log n)^{(2+\gamma)/\gamma}}{n}\right)^{\frac{1+\eta}{(1+\eta)(2\alpha+d)-\alpha}}$;

(ii) $h_n = \left(\frac{(\log n)^{(2+\gamma)/\gamma}}{n}\right)^{\frac{1}{2\alpha+d}} (\log n)^{-\frac{d}{\gamma}\cdot\frac{1}{2\alpha+d}}$;

(iii) $h_n = \left((\log n)^{(2+\gamma)/\gamma}/n\right)^{\frac{1}{2\alpha+d}}$;

then with probability μ *at least* $1-\frac{1}{n}$*, there holds*

$$\|f_{D,h_n} - f\|_1 \le \varepsilon_n,$$

where the convergence rates

(i) $\varepsilon_n \lesssim \left(\frac{(\log n)^{(2+\gamma)/\gamma}}{n}\right)^{\frac{\alpha\eta}{(1+\eta)(2\alpha+d)-\alpha}}$;

(ii) $\varepsilon_n \lesssim \left(\frac{(\log n)^{(2+\gamma)/\gamma}}{n}\right)^{\frac{\alpha}{2\alpha+d}} (\log n)^{\frac{d}{\gamma}\cdot\frac{\alpha+d}{2\alpha+d}}$;

(iii) $\varepsilon_n \lesssim \left((\log n)^{(2+\gamma)/\gamma}/n\right)^{\frac{\alpha}{2\alpha+d}}$.

Notice that the above Theorem 8 holds only when the underlying density function f is α-Hölder continuous. However, as shown in Examples 2 and 3, instead of being α-Hölder continuous, density functions of commonly used dynamical systems often only satisfy a weaker continuity condition such as the pointwise α-Hölder controllable condition. Therefore, for this case, we are encouraged to establish convergence rates under certain tail condition of the probability distribution. Unfortunately, as will be shown in Proposition 11 later, in general, we are not able to give explicit expressions of the convergence rates as in Theorem 8. Nevertheless, for certain dynamical systems mentioned in this paper, we are still able to derive convergence rates explicitly as follows:

Example 4 *Consider the Gauss map from Example 3 with the resulting density*

$$f(x) = \frac{1}{\log 2}\cdot\frac{1}{1+x}, \quad x \in (0,1)$$

and functions $r(\cdot)$ *and* $c(\cdot)$ *as specified in Example 3. Then, for* $\Omega := (0,1)$*, if we pick a smoothing kernel with* $K(r) = 0$ *for all* $r > 1$ *and* $h_n = \left((\log n)^{(2+\gamma)/\gamma}/n\right)^{1/(2+d)}$*, then we obtain the convergence rate*

$$\left((\log n)^{(2+\gamma)/\gamma}/n\right)^{\frac{1}{2+d}}.$$

Example 5 *Consider the logistic map of Example 2 with resulting density*

$$f(x) = \frac{1}{\pi\sqrt{x(1-x)}}, \quad x \in (0,1),$$

an $\alpha \in (0, 1/2)$ *and the corresponding functions* $r(\cdot)$ *and* $c(\cdot)$ *specified in Example 2. As in Example 4, we choose* $\Omega := (0,1)$*, and pick a smoothing kernel with* $K(r) = 0$ *for all* $r > 1$*, then we obtain approximately the convergence rate*

$$\left((\log n)^{(2+\gamma)/\gamma}/n\right)^{\frac{1}{2+2d}}.$$

Both of the above-mentioned two densities are not continuous at the end points 0 and 1, but $f_{P,h}$ turns out to be continuous everywhere. Therefore, uniform approximation is not be possible. However, as shown in the above examples, the uniform approximation can be achieved if we remove both of the neighbourhood around the critical points 0 and 1. This phenomenon can be apparently observed from Figures 1 and 2 in Section 5.

3.3 Results on Convergence Rates under L_∞-Norm

We now state our main results on the convergence of $f_{D,h}$ to f under L_∞-norm.

Theorem 9 *Let* $\mathcal{X} := (X_n)_{n\ge1}$ *be an* X*-valued stationary geometrically (time-reversed)* $\mathcal{C}$*-mixing process on* $(\Omega, \mathcal{A}, \mu)$ *with* $\|\cdot\|_{\mathcal{C}}$ *being defined for some semi-norm* $|||\cdot|||$ *that satisfies Assumption A.*

(i) Let K *be a* d*-dimensional smoothing kernel that satisfies Conditions* (i) *and* (iv) *in Assumption B. Assume that there exists a constant* $r_0 \ge 1$ *such that* $\Omega \subset B_{r_0} \subset \mathbb{R}^d$ *and the density function* f *is* α*-Hölder continuous with* $\alpha \le \beta$ *and* $\|f\|_\infty < \infty$*.*

(ii) Let K *be a* d*-dimensional smoothing kernel that satisfies Conditions* (iii) *and* (iv) *in Assumption B, and* f *is pointwise* α*-Hölder controllable. Fix an* $\Omega \subset \mathbb{R}^d$ *with* $\{x \in \mathbb{R}^d : f(x) > 0 \text{ and } r(x) \text{ exists}\} \subset \Omega$ *and define* $\Omega^{+hR} := \{x \in \mathbb{R}^d : \inf_{x''\in\Omega}\|x - x''\| \le hR\}$*. Moreover, we define* $X_h^* := \{x \in \mathbb{R}^d : r(x) > hR\}$ *and assume that function* $x \mapsto c(x)$ *is bounded on* $X_h^* \cap \Omega^{+hR}$*.*

Then, for both cases (i) *and* (ii)*, all* $n \ge n_0^*$ *with* n_0^* *that will be given in the proof, by choosing*

$$h_n = \left((\log n)^{(2+\gamma)/\gamma}/n\right)^{\frac{1}{2\alpha+d}},$$

with probability μ *at least* $1-\frac{1}{n}$*, there holds*

$$\|f_{D,h_n} - f\|_\infty \lesssim \left((\log n)^{(2+\gamma)/\gamma}/n\right)^{\frac{\alpha}{2\alpha+d}}. \tag{9}$$

In Theorems 8 and 9, one needs to ensure that $n \ge n_0$ with n_0 and $n \ge n_0^*$ being specified later. One may also note that due to the involvement of the term $\varphi(h_n)$, the numbers n_0 and n_0^* depend on the h_n. However, recalling that for the Triangle kernel, the Epanechnikov kernel, and the Gaussian kernel, we have $\varphi(h_n) \le \mathcal{O}(h_n^{-1})$, which, together with the choices of h_n in Theorems 8 and 9, implies that n_0 and n_0^* are well-defined. It should be also remarked that in the scenario where the density function f is compactly supported and bounded, the convergence rate of $f_{D,h}$ to f is not only obtainable, but also the same with that derived under L_1-norm. This is indeed an interesting observation since convergence under L_∞-norm implies convergence under L_1-norm.

3.4 Comments and Discussions

This section presents some comments on the obtained theoretical results on the consistency and convergence rates of $f_{D,h}$ and compares them with related findings in the literature.

We highlight that in our analysis the density function f is only assumed to be Hölder continuous. As pointed out in the introduction, in the context of dynamical systems, this seems to be more than a reasonable assumption. On the other hand, the consistency and the convergence results obtained in our study, are of type "with high probability" due to the use of the Bernstein-type exponential inequality that takes into account the variance information of the random variables. From our analysis and the obtained theoretical results, one can also easily observe the influence of the dependence among observations. For instance, from Theorem 7 we see that with increasing dependence among observations (corresponding to smaller γ), in order to ensure the universal consistency of f_{D,h_n}, the decay of h_n (with respect to n^{-1}) is required to be faster. This is in fact also the case if we look at results on the convergence rates in Theorems 8 and 9. Moreover, the influence of the dependence among observations is also indicated there. That is, an increase of the dependence among observations may slow down the convergence of $f_{D,h}$ in the sense of both L_1-norm and L_∞-norm. It is also interesting to note that when γ tends to infinity, which corresponds to the case where observations can be roughly treated as independent ones, meaningful convergence rates can be also deduced. It turns out that, up to a logarithmic factor, the established convergence rates (9) under L_∞-norm, namely, $\mathcal{O}(((\log n)^{(2+\gamma)/\gamma}/n)^{\alpha/(2\alpha+d)})$, match the optimal rates in the i.i.d. case, see, e.g., Khas′minskii (1979) and Stone (1983).

As mentioned in the introduction, there exist several studies in the literature that address the kernel density estimation problem for dynamical systems. For example, Bosq and Guégan (1995) conducted some first studies and showed the point-wise consistency and the convergence (in expectation) of the kernel density estimator. The convergence rates obtained in their study are of the type $\mathcal{O}(n^{-4/(4+2d)})$, which are conducted in terms of the variance of $f_{D,h}$. The notion they used for measuring the dependence among observations is α-mixing coefficient (see A_3 in Bosq and Guégan (1995)). Considering the density estimation problem for one-dimensional dynamical systems, Prieur (2001) presented some studies on the kernel density estimator $f_{D,h}$ by developing a central limit theorem and apply it to bound the variance of the estimator. Further some studies on the kernel density estimation of the invariant Lebesgue density for dynamical systems were conducted in Blanke et al. (2003). By considering both dynamical noise and observational noise, point-wise convergence of the estimator $f_{D,h}$ in expectation was established, i.e., the convergence of $\mathbb{E}f_{D,h}(x) - f(x)$ for any $x \in \mathbb{R}^d$. Note further that these results rely on the second-order smoothness and boundedness of f. Therefore, the second-order smoothness assumption on the density function together with the point-wise convergence in expectation makes it different from our work. In particular, under the additional assumption on the tail of the noise distribution, the convergence of $\mathbb{E}(f_{D,h}(x) - f(x))^2$ for any fixed $x \in \mathbb{R}^d$ is of the order $\mathcal{O}(n^{-2/(2+\beta d)})$ with $\beta \geq 1$. Concerning the convergence of $f_{D,h}$ in a dynamical system setup, Maume-Deschamps (2006) also presented some interesting studies which in some sense also motivated our work here. By using also the $\mathcal{C}$-mixing concept as adopted in our study to measure the dependence among observations from dynamical systems, she presented the point-wise convergence of $f_{D,h}$ with the help of Hoeffding-type exponential inequality (see Proposition 3.1 in Maume-Deschamps (2006)). The assumption applied on f is that it is bounded from below and also α-Hölder continuous (more precisely, f is assumed to be α-*regular*, see Assumption 2.3 in Maume-Deschamps (2006)). Hence, from the above discussions, we suggest that the work we present in this study is essentially different from that in Maume-Deschamps (2006).

4. Error Analysis

We conduct error analysis for the kernel density estimator $f_{D,h}$ in this section by establishing its consistency and convergence rates, which are stated in the above section in terms of the L_1-distance and L_∞-distance. The downside of using L_1-distance is that it does not admit an exact bias-variance decomposition and the usual Taylor expansion involved techniques for error estimation may not apply directly. Nonetheless, if we introduce the intermediate estimator $f_{P,h}$ in (7), obviously the following inequality holds

$$\|f_{D,h} - f\|_1 \leq \|f_{D,h} - f_{P,h}\|_1 + \|f_{P,h} - f\|_1. \tag{10}$$

The consistency and convergence analysis in our study will be mainly conducted in the L_1 sense with the help of inequality (10). Besides, for some specific case, i.e., when the density f is compactly supported, we are also concerned with the consistency and convergence of $f_{D,h}$ to f under L_∞-norm. In this case, there also holds the following inequality

$$\|f_{D,h} - f\|_\infty \leq \|f_{D,h} - f_{P,h}\|_\infty + \|f_{P,h} - f\|_\infty. \tag{11}$$

It is easy to see that the first error term on the right-hand side of (10) or (11) is stochastic due to the empirical measure D while the second one is deterministic because of its sampling-free nature. Loosely speaking, the first error term corresponds to the variance of the estimator $f_{D,h}$, while the second one can be treated as its bias although (10) or (11) is not an exact error decomposition. In our study, we proceed with the consistency and convergence analysis on $f_{D,h}$ by bounding the two error terms, respectively.

4.1 Bounding the Deterministic Error Term

Our first theoretical result on bounding the deterministic error term shows that, given a d-dimensional kernel K, the L_1-distance between its K-smooth of the measure P, i.e., $f_{P,h}$, and f can be arbitrarily small by choosing the bandwidth appropriately. Moreover, under mild assumptions on the regularity of f and K, the L_∞-distance between the two quantities possesses a polynomial decay with respect to the bandwidth h.

Proposition 10 *Let K be a d-dimensional smoothing kernel.*

(i) For any $\varepsilon > 0$, there exists $0 < h_\varepsilon \leq 1$ such that for any $h \in (0, h_\varepsilon]$ we have

$$\|f_{P,h} - f\|_1 \leq \varepsilon.$$

(ii) If K satisfies Condition (ii) in Assumption B and f is α-Hölder continuous with $\alpha \leq \upsilon$, then there exists a constant $c > 0$ such that for all $h > 0$ we have

$$\|f_{P,h} - f\|_\infty \leq ch^\alpha.$$

(iii) If K satisfies Condition (ii) in Assumption B and f is uniformly pointwise α-Hölder controllable with $\alpha \leq \upsilon$, then there exists a constant $c > 0$ such that for all $h > 0$ and λ^d-almost all $x \in \mathbb{R}^d$ we have

$$|f_{P,h}(x) - f(x)| \leq c\, c(x) h^{\alpha} + c f(x) h^{\upsilon} + \int_{B^c_{r_0/(2h)}} K(\|x'\|)\, f(x + hx')\, \mathrm{d}x' .$$

(iv) Assume that K satisfies Condition (iii) in Assumption B and f is pointwise α-Hölder controllable. We fix an $\Omega \subset \mathbb{R}^d$ such that

$$\{x \in \mathbb{R}^d : f(x) > 0 \text{ and } r(x) \text{ exists } \} \subset \Omega ,$$

and we define $\Omega^{+hR} := \{x \in \mathbb{R}^d : \inf_{x'' \in \Omega} \|x - x''\| \leq hR\}$. For λ^d-almost all $x \notin \Omega^{+hR}$ we then have $|f_{P,h}(x) - f(x)| = 0$. Moreover, there exists a constant $c > 0$ such that for all $x \in \Omega^{+hR}$ for which $r(x)$ exists we have

$$|f_{P,h}(x) - f(x)| \leq c\, c(x) h^{\alpha} + c \cdot \|K\|_{\infty} f(x) \left| R - \frac{r(x)}{h} \right|_+ + \|K\|_{\infty} h^{-d} \int_{r(x) \leq \|x'\| \leq hR} f(x + x')\, \mathrm{d}x' .$$

We now show that the L_1-distance between $f_{P,h}$ and f can be upper bounded by their difference (in the sense of L_∞-distance) on a compact domain of $\mathbb{R}^d$ together with their difference (in the sense of L_1-distance) outside this domain. As we shall see later, this observation will entail us to consider different classes of the true density f. The following result is crucial in our subsequent analysis on the consistency and convergence rates of $f_{D,h}$.

Proposition 11 *Assume that K is a d-dimensional smoothing kernel that satisfies Condition (ii) in Assumption B.*

(i) There exists a constant $c_1 > 0$ such that for all $h \leq 1$ and $r \geq 1$, we have

$$\|f_{P,h} - f\|_1 \leq c_1 r^d \|f_{P,h} - f\|_{\infty} + c_1 P(B^c_{r/2}) + c_1 (h/r)^{\upsilon}.$$

(ii) Assume that f is uniformly pointwise α-Hölder controllable with $\alpha \leq \upsilon$. For $r > 0$ we define

$$H(r) := \int_{B_r} c(x)\, \mathrm{d}x.$$

Then there exists a constant $c_2 > 0$ such that for all $h > 0$ and $r \geq 1$ we have

$$\|f_{P,h} - f\|_1 \leq c_2 h^{\alpha} H(r) + c_2 P(B^c_{r/2}) + c_2 h^{\upsilon} .$$

(iii) Assume that K satisfies Condition (iii) in Assumption B and f is pointwise α-Hölder controllable. Furthermore, we pick an Ω as in Proposition 10. Then there exists a constant $c_3 > 0$ such that for all $h > 0$ and $r > 0$ we have

$$\|f_{P,h} - f\|_1 \leq c_3\, H(\infty)\, h^{\alpha} + c_3 P\big(\{x : r(x) \leq hR\}\big) + c_3\, h^{-d} \int_{\Omega^{+hR}} \int_{r(x) \leq \|x'\| \leq hR} f(x + x')\, \mathrm{d}x'\, \mathrm{d}x .$$

(iv) Let K, f, and Ω satisfy the conditions in (iii). We define $X^*_h := \{x \in \mathbb{R}^d : r(x) > hR\}$ and assume that function $x \mapsto c(x)$ is bounded on $X^*_h \cap \Omega^{hR}$, then there is another constant $c_4 > 0$ such that for all $h > 0$ we have

$$\sup_{x \in X^*_h} |f_{P,h}(x) - f(x)| \leq c_4 \sup_{x \in X^*_h \cap \Omega^{hR}} |c(x)| \cdot h^{\alpha} .$$

4.2 Bounding the Stochastic Error Term

We now proceed with the estimation of the stochastic error term $\|f_{D,h} - f_{P,h}\|_1$ by establishing probabilistic oracle inequalities. For the sake of readability, let us start with an overview of the analysis conducted in this subsection for bounding the stochastic error term.

4.2.1 An Overview of the Analysis

In this study, the stochastic error term is tackled by using capacity-involved arguments and the Bernstein-type inequality established in Hang and Steinwart (2017). In the sequel, for any fixed $x \in \Omega \subset \mathbb{R}^d$, we write

$$k_{x,h} := h^{-d} K(\|x - \cdot\|/h), \tag{12}$$

and we further denote the centered random variable $\widetilde{k}_{x,h}$ on Ω as

$$\widetilde{k}_{x,h} := k_{x,h} - \mathbb{E}_P k_{x,h}. \tag{13}$$

It thus follows that

$$\mathbb{E}_D \widetilde{k}_{x,h} = \mathbb{E}_D k_{x,h} - \mathbb{E}_P k_{x,h} = f_{D,h}(x) - f_{P,h}(x),$$

and consequently we have

$$\|f_{D,h} - f_{P,h}\|_1 = \int_{\mathbb{R}^d} |\mathbb{E}_D \widetilde{k}_{x,h}|\, \mathrm{d}x,$$

and

$$\|f_{D,h} - f_{P,h}\|_{\infty} = \sup_{x \in \Omega} |\mathbb{E}_D \widetilde{k}_{x,h}|.$$

As a result, in order to bound $\|f_{D,h} - f_{P,h}\|_1$, it suffices to bound the supremum of the empirical process $\mathbb{E}_D \widetilde{k}_{x,h}$ indexed by $x \in \mathbb{R}^d$. For any $r > 0$, there holds

$$\|f_{D,h} - f_{P,h}\|_1 = \int_{B_r} |\mathbb{E}_D \widetilde{k}_{x,h}|\, \mathrm{d}x + \int_{B^c_r} |\mathbb{E}_D \widetilde{k}_{x,h}|\, \mathrm{d}x.$$

The second term of the right-hand side of the above equality can be similarly dealt with as in the proof of Proposition 11. In order to bound the first term, we define $\widetilde{\mathcal{K}}_{h,r}$ as the function set of $\widetilde{k}_{x,h}$ that corresponds to x which lies on a radius-r ball of $\mathbb{R}^d$:

$$\widetilde{\mathcal{K}}_{h,r} := \big\{\widetilde{k}_{x,h} : x \in B_r\big\} \subset L_\infty(\mathbb{R}^d).$$

The idea here is to apply capacity-involved arguments and the Bernstein-type exponential inequality in Hang and Steinwart (2017) to the function set $\widetilde{\mathcal{K}}_{h,r}$ and the associated empirical process $\mathbb{E}_D \widetilde{k}_{x,h}$. The difference between $f_{D,h}$ and $f_{P,h}$ under the L_∞-norm can be bounded analogously. Therefore, to further our analysis, we first need to bound the capacity of $\widetilde{\mathcal{K}}_{h,r}$ in terms of covering numbers.

4.2.2 Bounding the Capacity of the Function Set $\widetilde{\mathcal{K}}_{h,r}$

Definition 12 (Covering Number) *Let (X,d) be a metric space and $A \subset X$. For $\varepsilon > 0$, the ε-**covering number** of A is denoted as*

$$\mathcal{N}(A,d,\varepsilon) := \min\left\{ n \geq 1 : \exists\, x_1, \cdots, x_n \in X \text{ such that } A \subset \bigcup_{i=1}^{n} B_d(x_i,\varepsilon) \right\},$$

where $B_d(x,\varepsilon) := \{x' \in X : d(x,x') \leq \varepsilon\}$.

For any fixed $r \geq 1$, we consider the function set

$$\mathcal{K}_{h,r} := \{k_{x,h} : x \in B_r\} \subset L_\infty(\mathbb{R}^d).$$

The following proposition provides an estimate of the covering number of $\mathcal{K}_{h,r}$.

Proposition 13 *Let K be a d-dimensional smoothing kernel that satisfies Condition (i) in Assumption B and $h \in (0,1]$. Then there exists a positive constant c' such that for all $\varepsilon \in (0,1]$, we have*

$$\mathcal{N}(\mathcal{K}_{h,r}, \|\cdot\|_\infty, \varepsilon) \leq c' r^d h^{-d-\frac{d^2}{\beta}} \varepsilon^{-\frac{d}{\beta}}.$$

4.2.3 Oracle Inequalities under L_1-Norm, and L_∞-Norm

We now establish oracle inequalities for the kernel density estimator (8) under L_1-norm, and L_∞-norm, respectively. These oracle inequalities will be crucial in establishing the consistency and convergence results of the estimator. Recall that the considered kernel density estimation problem is based on samples from an X-valued $\mathcal{C}$-mixing process which is associated with an underlying function class $\mathcal{C}(X)$. As shown below, the established oracle inequality holds without further restrictions on the support of the density function.

Proposition 14 *Suppose that Assumption B holds. Let $\mathcal{X} := (X_n)_{n\geq 1}$ be an X-valued stationary geometrically (time-reversed) $\mathcal{C}$-mixing process on $(\Omega,\mathcal{A},\mu)$ with $\|\cdot\|_{\mathcal{C}}$ being defined for some semi-norm $|||\cdot|||$ that satisfies Assumption A. Then for all $0 < h \leq 1$, $r \geq 1$ and $\tau \geq 1$, there exists an $n_0 \in \mathbb{N}$ such that for all $n \geq n_0$, with probability μ at least $1 - 3e^{-\tau}$, there holds*

$$\|f_{D,h} - f_{P,h}\|_1 \lesssim \sqrt{\frac{(\log n)^{2/\gamma} r^d (\tau + \log \frac{nr}{h})}{h^d n}} + \frac{(\log n)^{2/\gamma} r^d (\tau + \log \frac{nr}{h})}{h^d n} + P(B_{r/4}^c) + \sqrt{\frac{32\tau(\log n)^{2/\gamma}}{n}} + \left(\frac{h}{r}\right)^\beta.$$

Here n_0 will be given explicitly in the proof.

Our next result shows that when the density function f is compactly supported and bounded, an oracle inequality under L_∞-norm can be also derived.

Proposition 15 *Let K be a d-dimensional kernel function that satisfies Conditions (i) and (iii) in Assumption B. Let $\mathcal{X} := (X_n)_{n\geq 1}$ be an X-valued stationary geometrically (time-reversed) $\mathcal{C}$-mixing process on $(\Omega,\mathcal{A},\mu)$ with $\|\cdot\|_{\mathcal{C}}$ being defined for some semi-norm $|||\cdot|||$ that satisfies Assumption A. Assume that there exists a constant $r_0 \geq 1$ such that $\Omega \subset B_{r_0} \subset \mathbb{R}^d$ and the density function f satisfies $\|f\|_\infty < \infty$. Then for all $0 < h \leq 1$ and $\tau > 0$, there exists an $n_0^* \in \mathbb{N}$ such that for all $n \geq n_0^*$, with probability μ at least $1 - e^{-\tau}$, there holds*

$$\|f_{D,h} - f_{P,h}\|_\infty \lesssim \sqrt{\frac{\|f\|_\infty (\tau + \log(\frac{nr_0}{h}))(\log n)^{2/\gamma}}{h^d n}} + \frac{K(0)(\tau + \log(\frac{nr_0}{h}))(\log n)^{2/\gamma}}{h^d n}.$$

Here n_0^* will be given explicitly in the proof.

In Proposition 15, the kernel K is only required to satisfy Conditions (i) and (iii) in Assumption B whereas the condition that $\int_0^\infty K(r) r^{\beta+d-1}\,\mathrm{d}r < \infty$ for some $\beta > 0$ is not needed. This is again due to the compact support assumption of the density function f as stated in Proposition 15.

5. Bandwidth Selection and Simulation Studies

This section discusses the model selection problem of the kernel density estimator (8) by performing numerical simulation studies. In the context of kernel density estimation, model selection is mainly referred to the choice of the smoothing kernel K and the selection of the kernel bandwidth h, which are of crucial importance for the practical implementation of the data-driven density estimator. According to our experimental experience and also the empirical observations reported in Maume-Deschamps (2006), it seems that the choice of the kernel or the noise does not have a significant influence on the performance of the estimator. Therefore, our emphasis will be placed on the bandwidth selection problem in our simulation studies.

5.1 Several Bandwidth Selectors

In the literature of kernel density estimation, various bandwidth selectors have been proposed, several typical examples of which have been alluded to in the introduction. When turning to the case with dependent observations, the bandwidth selection problem has been also drawing much attention, see e.g., Hart and Vieu (1990); Chu and Marron (1991); Hall et al. (1995); Yao and Tong (1998). Among existing bandwidth selectors, probably the most frequently employed ones are based on the cross-validation ideas. For cross-validation bandwidth selectors, one tries to minimize the integrated squared error (ISE) of the empirical estimator $f_{D,h}$ where

$$\mathrm{ISE}(h) := \int (f_{D,h} - f)^2 = \int f_{D,h}^2 - 2\int f_{D,h} \cdot \int f + \int f^2.$$

Note that on the right-hand side of the above equality, the last term $\int f^2$ is independent of h and so the minimization of $\mathrm{ISE}(h)$ is equivalent to minimize

$$\int f_{D,h}^2 - 2\int f_{D,h} \cdot \int f.$$

It is shown that with i.i.d observations, an unbiased estimator of the above quantity, which is termed as least squares cross-validation (LSCV), is given as follows:

$$\mathrm{LSCV}(h) := \int f_{D,h}^2 - \frac{2}{n}\sum_{i=1}^{n} \hat{f}_{-i,h}(x_i), \tag{14}$$

where the leave-one-out density estimator $\hat{f}_{-i,h}$ is defined as

$$\hat{f}_{-i,h}(x) := \frac{1}{n-1}\sum_{j\neq i}^{n} K_h(x - x_j).$$

When the observations are dependent, it is shown that cross-validation can produce much under-smoothed estimates, see e.g., Hart and Wehrly (1986); Hart and Vieu (1990). Observing this, Hart and Vieu (1990) proposed the modified least squares cross-validation (MLSCV), which is defined as follows

$$\mathrm{MLSCV}(h) := \int f_{D,h}^2 - \frac{2}{n}\sum_{i=1}^{n} \hat{f}_{-i,h,l_n}(x_i), \tag{15}$$

where l_n is set to 1 or 2 as suggested in Hart and Vieu (1990) and

$$\hat{f}_{-i,h,l_n}(x) := \frac{1}{\#\{j : |j-i| > l_n\}} \sum_{|j-i|>l_n} K_h(x - x_j).$$

The underlying intuition of proposing MLSCV is that when estimating the density of a fixed point, ignoring observations in the vicinity of this point may be help in reducing the influence of dependence among observations. However, when turning to the L_1 point of view, the above bandwidth selectors may not work well due to the use of the least squares criterion. Alternatively, Devroye (1989) proposed the double kernel bandwidth selector that minimizes the following quantity

$$\mathrm{DKM}(h) := \int |f_{D,h,K} - f_{D,h,L}|, \tag{16}$$

where $f_{D,h,K}$ and $f_{D,h,L}$ are kernel density estimators based on the kernels K and L, respectively. Some rigorous theoretical treatments on the effectiveness of the above bandwidth selector were made in Devroye (1989).

Our purpose in simulation studies is to conduct empirical comparisons among the above bandwidth selectors in the dynamical system context instead of proposing new approaches.

5.2 Experimental Setup

In our experiments, observations $x_1, \cdots, x_n$ are generated from the following model[1]

$$\begin{cases} \tilde{x}_i = T^i(x_0), \\ x_i = \tilde{x}_i + \varepsilon_i, \end{cases} \quad i = 1, \cdots, n, \tag{17}$$

1. Note that here the observational noise is assumed for the considered dynamical system (17), which differs from (2) and can be a more realistic setup from an empirical and experimental viewpoint. In fact, it is observed also in Maume-Deschamps (2006) that the influence of low SNR noise is not obvious in density estimation. We therefore adopt this setup in our experiments. All the observations reported in this experimental section apply to the noiseless case (2).

where $\varepsilon_i \sim \mathcal{N}(0, \sigma^2)$, σ is set to 0.01 and the initial state x_0 is randomly generated based on the density f. For the map T in (17), we choose Logistic map in Example 2 and Gauss map in Example 3. We vary the sample size among $\{5\times 10^2, 10^3, 5\times 10^3, 10^4\}$, implement bandwidth selection procedures over 20 replications and select the bandwidth from a grid of values in the interval $[h_L, h_U]$ with 100 equispaced points. Here, h_L is set as the minimum distance between consecutive points x_i, $i = 1, \cdots, n$ (Devroye and Lugosi, 1997), while h_U is chosen according to the *maximal smoothing principle* proposed in Terrell (1990). Throughout our experiments, we use the Gaussian kernel for the kernel density estimators.

In our experiments, we conduct comparisons among the above-mentioned bandwidth selectors which are, respectively, denoted as follows:

- LSCV: the least squares cross-validation given in (14);
- MLSCV-1: the modified least squares cross-validation in (15) with $l_n = 1$;
- MLSCV-2: the modified least squares cross-validation in (15) with $l_n = 2$;
- DKM: the double kernel method defined in (16) where the two kernels used here are the Epanechnikov kernel and the Triangle kernel, respectively.

In the experiments, due to the known density functions for Logistic map and Gauss map, and in accordance with our previous analysis from the L_1 point of view, the criterion of comparing different selected bandwidths is the following absolute mean error (AME):

$$\mathrm{AME}(h) = \frac{1}{m}\sum_{i=1}^{m} |f_{D,h}(u_i) - f(u_i)|,$$

where $u_1, \cdots, u_m$ are m equispaced points in the interval $[0, 1]$ and m is set to 10000. We also compare the selected bandwidth with the one that has the minimum absolute mean error which serves as a ***baseline*** method in our experiments.

5.3 Simulation Results and Observations

The AMEs of the above bandwidth selectors for Logistic map in Example 2 and Gauss map in Example 3 over 20 replications are averaged and recorded in Tables 1 and 2 below.

In Figs. 1 and 2, we also plot the kernel density estimators for Logistic map in Example 2 and Gauss map in Example 3 with different bandwidths and their true density functions with different sample sizes. The sample size of each panel, in Figs. 1 and 2, from up to bottom, is 10^3, 10^4, and 10^5, respectively. In each panel, the densely dashed black curve represents the true density, the dotted blue curve is the estimated density function with the bandwidth selected by the baseline method while the solid red curve stands for the estimated density with the bandwidth selected by the double kernel method. All density functions in Figs. 1 and 2 are plotted with 100 equispaced points in the interval $(0, 1)$.

From Tables 1 and 2, and Figs. 1 and 2, we see that the true density functions of Logistic map and Gauss map can be approximated well with enough observations and the double kernel method works slightly better than the other three methods for the two dynamical systems. In fact, according to our experimental experience, we find that the bandwidth selector of the kernel density estimator for a dynamical system is usually ad-hoc. That

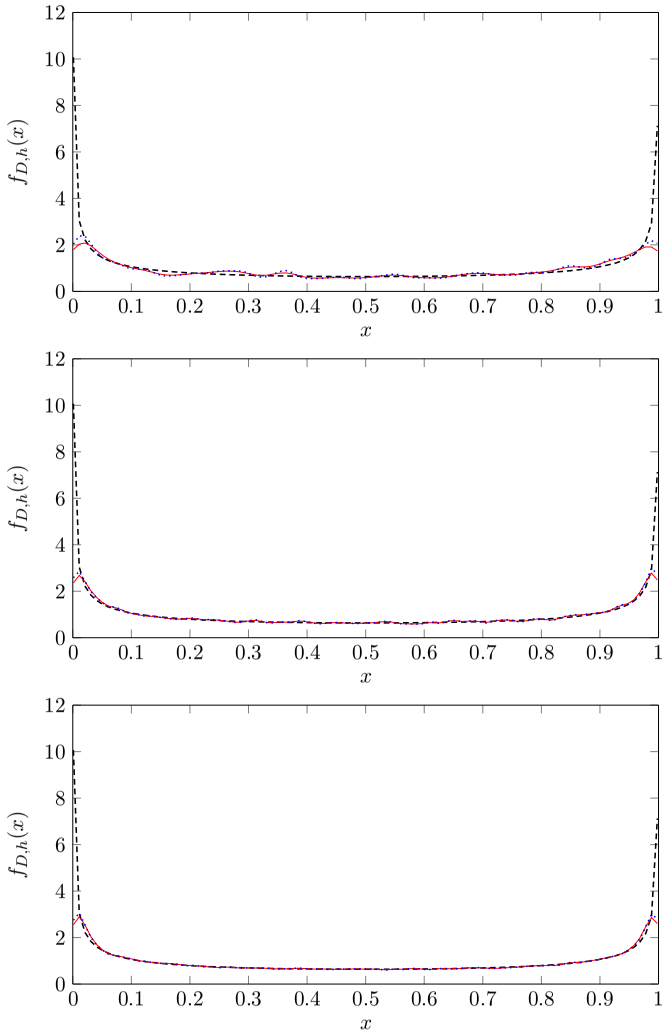

Figure 1: Plots of the kernel density estimators $f_{D,h}$ for Logistic map in Example 2 with different bandwidths and its true density with different sample sizes. The sample size of each panel, from up to bottom, is 10^3, 10^4, and 10^5, respectively. In each panel, the dashed black curve represents the true density of Logistic map, the dotted blue curve is the estimated density of Logistic map with the bandwidth selected by the baseline method while the solid red curve stands for the estimated density of Logistic map with the bandwidth selected by the double kernel method. All curves are plotted with 100 equispaced points in the interval $(0, 1)$.

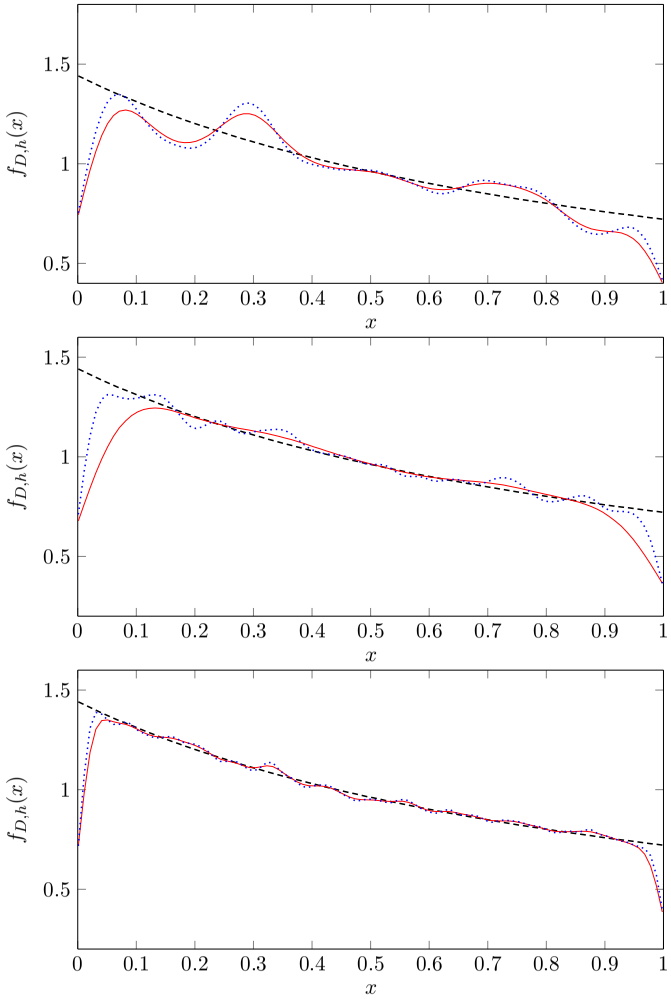

Figure 2: Plots of the kernel density estimators $f_{D,h}$ for Gauss map in Example 3 with different bandwidths and its true density with different sample sizes. The sample size of each panel, from up to bottom, is 10^3, 10^4, and 10^5, respectively. In each panel, the dashed black curve represents the true density of Gauss map, the dotted blue curve is the estimated density of Gauss map with the bandwidth selected by the baseline method while the solid red curve stands for the estimated density of Gauss map with the bandwidth selected by the double kernel method. All curves are plotted with 100 equispaced points in the interval $(0, 1)$.

Table 1: The AMEs of Different Bandwidth Selectors for Logistic Map in Example 2

sample size	LSCV	MLSCV-1	MLSCV-2	DKM	Baseline
5×10^2	.3372	.3369	.3372	.3117	.3013
1×10^3	.2994	.2994	.2994	.2804	.2770
5×10^3	.2422	.2422	.2422	.2340	.2326
1×10^4	.2235	.2235	.2235	.2220	.2192

Table 2: The AMEs of Different Bandwidth Selectors for Gauss Map in Example 3

sample size	LSCV	MLSCV-1	MLSCV-2	DKM	Baseline
5×10^2	.1027	.1026	.1059	.1181	.0941
1×10^3	.0925	.0933	.0926	.0925	.0878
5×10^3	.0626	.0626	.0626	.0586	.0585
1×10^4	.0454	.0454	.0454	.0440	.0439

is, for existing bandwidth selectors, there seems no a universal optimal one that can be applicable to all dynamical systems and outperforms the others. Therefore, further exploration and insights on the bandwidth selection problem in the dynamical system context certainly deserve future study. On the other hand, we also notice that due to the presence of dependence among observations generated by dynamical systems, the sample size usually needs to be large enough to approximate the density function well. This can be also seen from the plotted density functions in Figs. 1 and 2 with varying sample sizes.

Aside from the above observations, not surprisingly, from Figs. 1 and 2, we also observe the *boundary effect* (Gasser et al., 1985) from the kernel density estimators for dynamical systems, which seems to be even more significant than the i.i.d case. From a practical implementation view, some special studies are arguably called for addressing this problem.

6. Proofs

The following lemma is needed for the proof of Example 2.

Lemma 16 *For $x, h \geq 0$ with $x \geq 2h$ and $p \in (0,1)$ we have*

$$x - h \geq 2^{p-1} x^{1-p} h^p \,.$$

Proof [of Lemma 16] For $c := 2^{p-1}$, $x \geq 0$, and $h \geq 0$ we define $g_h(x) := cx^{1-p}h^p - x + h$, so that our goal is to show $g_h(x) \leq 0$ for all $x \geq 2h$. To this end, we first note that

$$g_h(2h) = c(2h)^{1-p}h^p - h = c2^{1-p}h^{1-p}h^p - h = 0\,,$$

that is, the assertion is true for $x = 2h$. To show the inequality for $x > 2h$, we note that $g_h'(x) = (1-p)cx^{-p}h^p - 1$. A simple calculation then shows that g_h' has its only zero at $x^* := ((1-p)c)^{1/p}h$. Moreover, since $g_h''(x) = (1-p)(-p)cx^{-1-p}h^p < 0$ we see that g_h has a global maximum at x^* and no (local) minimum. Consequently, g_h is decreasing on $[x^*, \infty)$,

so that it suffices to show that $x^* \leq 2h$. The latter, however is equivalent to $(1-p)c \leq 2^p$, and by the definition of c, this inequality is satisfied if and only if $(1-p)/2 \leq 1$. Since the latter is obviously true, we obtain the assertion. ∎

Proof [of Example 2] Here we only need to show that the density f is α-controllable with the specified functions. Moreover, this is obvious for $x < 0$ and $x > 1$. Moreover, the first and second derivatives of f on $(1/8, 7/8)$ are

$$f'(x) = -\frac{1-2x}{2\pi(x(1-x))^{3/2}} \qquad \text{and} \qquad f''(x) = \frac{8x^2 - 8x + 3}{4\pi(x(1-x))^{5/2}}\,.$$

Clearly, this gives $f''(x) \geq 1$ for all $x \in (1/8, 7/8)$ and hence f' is increasing on this interval. Using the symmetry of f' around $x = 1/2$ we then obtain

$$\sup_{x \in (1/8, 7/8} |f'(x)| = |f'(1/8)| = \frac{3}{8\pi} \cdot \Big(\frac{64}{7}\Big)^{3/2} \leq 4\,.$$

Consequently, the restriction $f_{|[1/8,7/8]}$ is Lipschitz continuous with constant not exceeding 4. This shows the assertion for $x \in [1/4, 3/4]$. Therefore, it remains to consider the cases $0 < x < 1/4$ and $3/4 < x < 1$, and due to the symmetry of f we may actually restrict our considerations to $0 < x < 1/4$. Let us therefore fix an $x \in (0, 1/4)$. For h with $|h| < r(x)$, that is $h \in (-x/2, x/2)$, we then find

$$\pi|f(x+h) - f(x)| = \frac{\big|\sqrt{x(1-x)} - \sqrt{(x+h)(1-x-h)}\big|}{\sqrt{x(1-x)(1-x-h)(x+h)}}\,. \tag{18}$$

Moreover, we have $1 - x > 3/4$ and $1 - x - h > 5/8$ and hence we find

$$\frac{1}{\sqrt{x(x+h)(1-x-h)(1-x)}} \leq \sqrt{\frac{32}{15}} \cdot \frac{1}{\sqrt{x(x+h)}}\,. \tag{19}$$

Our next goal is to bound the numerator in (18). To this end, we define

$$g(x,h) := \sqrt{x(1-x)} - \sqrt{(x+h)(1-x-h)}\,, \qquad h, x \in [0, 1/4]\,.$$

Note that the function $t \mapsto \sqrt{t(1-t)}$ is increasing on $[0, 1/2]$ and hence we have $g(x,h) \geq 0$ if $h \in [-1/4, 0]$ and $g(x,h) \leq 0$ if $h \in [0, 1/4]$. Now, our goal is to establish

$$\big|g(x,h)\big| \leq |h|^{1/2}\,, \qquad x \in [0, 1/4],\ h \in (-x/2, 1/4] \tag{20}$$

In the case $h \in [0, 1/4]$ our preliminary considerations on g show that (20) is equivalent to

$$(x+h)(1-x-h) \leq h + x(1-x) + 2\sqrt{hx(1-x)}\,.$$

Moreover, simple algebraic transformations show that the latter is equivalent to $-2xh - h^2 \leq 2\sqrt{hx(1-x)}$, which is obviously true. This shows (20) for $h \in [0, 1/4]$. Now, in the case $h \in (-x/2, 0]$ we first observe that we have

$$\big|g(x,h)\big| = \big|g(x+h, -h)\big|\,.$$

Let us write $\tilde{x} := x + h$ and $\tilde{h} := -h$. Then we have $\tilde{h} \in [0, x/2) \subset [0, 1/4]$ and $\tilde{x} \in (x/2, x] \subset (0, 1/4]$. Using (20) in the already proven case $\tilde{h} \in [0, 1/4]$ we then find

$$\bigl|g(x,h)\bigr| = \bigl|g(\tilde{x},\tilde{h})\bigr| \leq |\tilde{h}|^{1/2} = |h|^{1/2}\,,$$

which finishes the proof of (20).

Now combining (19) with (20) we find

$$\pi\,|f(x+h) - f(x)| \leq \sqrt{\frac{32}{15}} \cdot \frac{\sqrt{|h|}}{\sqrt{x(x+h)}}.$$

Let us first consider the case $h \in (-x/2, 0]$. Then Lemma 16 applied to $p := 2\varepsilon$ and $\tilde{h} := -h$ gives

$$\frac{1}{\sqrt{x+h}} = \frac{1}{\sqrt{x-\tilde{h}}} \leq 2^{(1-p)/2} x^{(p-1)/2} \tilde{h}^{-p/2} = 2^{1/2-\varepsilon} x^{-1/2+\varepsilon} |h|^{-\varepsilon}$$

Inserting this inequality in the previous inequality thus shows

$$|f(x+h) - f(x)| \leq \frac{1}{\pi} \cdot \sqrt{\frac{64}{15}} \cdot x^{-1+\varepsilon}\,|h|^{1/2-\varepsilon} \leq x^{-1+\varepsilon}\,|h|^{1/2-\varepsilon}\,. \tag{21}$$

Moreover, for $h \in [0, x/2)$ we have $x+h \geq x-h$, and hence the previous considerations actually give (21) for all $h \in (-x/2, x/2)$. Since for $\varepsilon := 1/2-\alpha$ we have both $-1+\varepsilon = -1/2-\alpha$ and $1/2-\varepsilon = \alpha$, we then obtain the assertion. ∎

The following lemma, which will be used several times in the sequel, supplies the key to the proof of Propositions 11 and 10.

Lemma 17 *Assume that K is a d-dimensional smoothing kernel that satisfies Condition (ii) of Assumption B. Then there exists a constant $c_1 > 0$ such that for all $r > 0$ we have*

$$\int_{B_r^c} K(\|x\|)\,\mathrm{d}x \leq c_1 r^{-\upsilon}\,. \tag{22}$$

Moreover, for all probability measures Q on $\mathbb{R}^d$ and all $h > 0$ and $r > 0$ the functions $k_{x,h}$, which are defined in (12) for all $x \in \mathbb{R}^d$, satisfy

$$\int_{B_r^c} \mathbb{E}_Q k_{x,h}\,\mathrm{d}x \leq \kappa\, Q(B_{r/2}^c) + c_1 2^\upsilon\,(h/r)^\upsilon\,. \tag{23}$$

Proof [of Lemma 17] For the proof of (22) we fix a constant $\tilde{c} \geq 1$ such that we have $\tilde{c}^{-1}\,\|\cdot\|_{\ell_2^d} \leq \|\cdot\| \leq \tilde{c}\,\|\cdot\|_{\ell_2^d}$. Since K is monotonically decreasing, we then find

$$\begin{aligned}
\int_{B_r^c} K(\|x\|)\,\mathrm{d}x \leq \int_{B_r^c} K(\tilde{c}^{-1}\,\|x\|_{\ell_2^d})\,\mathrm{d}x &\leq \int_{\tilde{c}^{-1} r}^\infty K(\tilde{c}^{-1}t) t^{d-1}\,\mathrm{d}t \\
&= \tilde{c}^d \int_{\tilde{c}^{-2}\,r}^\infty K(t) t^{d-1}\,\mathrm{d}t \\
&\leq \tilde{c}^{d+2\upsilon} \int_{\tilde{c}^{-2}\,r}^\infty K(t) r^{-\upsilon} t^{d+\upsilon-1}\,\mathrm{d}t \\
&\leq \tilde{c}^{d+2\upsilon}\,\kappa_\upsilon\, r^{-\upsilon}\,,
\end{aligned}$$

where in the last step we used Condition (ii) of Assumption B.

For the proof of (23) we first observe that for $t_0 > 0$, we have

$$\begin{aligned}
\int_{B_r^c} \mathbb{E}_Q k_{x,h}\,\mathrm{d}x &= \int_{B_r^c} \int_{\mathbb{R}^d} h^{-d} K\left(\|x - x'\|/h\right)\,\mathrm{d}Q(x')\,\mathrm{d}x \\
&= \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} K(\|x\|) \mathbf{1}_{B_r^c}(hx + x')\,\mathrm{d}x\,\mathrm{d}Q(x') \\
&= \int_{\mathbb{R}^d} K(\|x\|) \int_{\mathbb{R}^d} \mathbf{1}_{B_r^c}(hx + x')\,\mathrm{d}Q(x')\,\mathrm{d}x \\
&\leq \int_{B_{t_0}} K(\|x\|) \int_{\mathbb{R}^d} \mathbf{1}_{B_r^c}(hx + x')\,\mathrm{d}Q(x')\mathrm{d}x + \int_{B_{t_0}^c} K(\|x\|)\,\mathrm{d}x.
\end{aligned}$$

Moreover, it is easy to see that $\mathbf{1}_{B_r^c}(hx + x') = 1$ if and only if $\|hx + x'\| \geq r$. Now we set $t_0 := \frac{r}{2h}$. In this case, if we additionally have $x \in B_{t_0}$, then $\|x'\| \geq r - h\|x\| \geq r - ht_0 = r/2$. Using (22) we thus find

$$\begin{aligned}
\int_{B_r^c} \mathbb{E}_Q k_{x,h}\,\mathrm{d}x &\leq \int_{B_{t_0}} K(\|x\|) Q(B_{r/2}^c)\,\mathrm{d}x + \int_{B_{t_0}^c} K(\|x\|)\,\mathrm{d}x \\
&\leq \kappa\, Q(B_{r/2}^c) + c_1\, t_0^{-\upsilon}\,.
\end{aligned} \tag{24}$$

By $t_0 = \frac{r}{2h}$ we then find the assertion. ∎

The following technical lemma is needed in the proof of Proposition 10.

Lemma 18 *For all $0 \leq a \leq b$ and $d \geq 1$ we have*

$$b^d - a^d \leq d \cdot b^{d-1} \cdot (b - a)\,. \tag{25}$$

Proof [of Lemma 18] In the case $b = 0$ there is nothing to prove. Moreover, in the case $b > 0$, we first observe by deviding by b^d that (25) is equivalent to

$$1 - \left(\frac{a}{b}\right)^d \leq d \cdot \left(1 - \frac{a}{b}\right).$$

Consequently, it suffices to show

$$1 - t^d \leq d\,(1 - t)\,, \qquad t \in [0, 1]\,. \tag{26}$$

To this end, we define $h(t) = d\,(1-t) - 1 + t^d$ for $t \in [0, 1]$. This gives $h'(t) = -d + dt^{d-1}$ and a simple check then shows $h'(t) \leq 0$ for all $t \in [0, 1]$. Moreover, we have $h(1) = 0$ and combining both we thus find $h(t) \geq 0$ for all $t \in [0, 1]$. This shows (26). ∎

Proof [of Proposition 10] *(i).* Since the space of continuous and compactly supported functions $C_c(\mathbb{R}^d)$ is dense in $L_1(\mathbb{R}^d)$, we can find $\bar{f} \in C_c(\mathbb{R}^d)$ such that

$$\|f - \bar{f}\|_1 \leq \varepsilon/3,\ \ \forall \varepsilon > 0.$$

Therefore, for any $\varepsilon > 0$, we have

$$\begin{aligned}\|f_{P,h} - f\|_1 &= \int_{\mathbb{R}^d} |f * K_h - f| \,\mathrm{d}x \\ &\le \int_{\mathbb{R}^d} |f * K_h - \bar{f} * K_h| \,\mathrm{d}x + \int_{\mathbb{R}^d} |\bar{f} * K_h - \bar{f}| \,\mathrm{d}x + \int_{\mathbb{R}^d} |f - \bar{f}| \,\mathrm{d}x \qquad (27) \\ &\le \frac{2\varepsilon}{3} + \int_{\mathbb{R}^d} |\bar{f} * K_h - \bar{f}| \,\mathrm{d}x,\end{aligned}$$

where K_h is defined in (6) and the last inequality follows from the fact that

$$\|f * K_h - \bar{f} * K_h\|_1 \le \|f - \bar{f}\|_1 \le \varepsilon/3.$$

The above inequality is due to Young's inequality (8.7) in Folland (1999). Moreover, there exist a constant $M > 0$ such that $\operatorname{supp}(\bar{f}) \subset B_M$ and a constant $r > 0$ such that

$$\int_{B_r^c} K(\|x\|) \,\mathrm{d}x \le \frac{\varepsilon}{9\|\bar{f}\|_1}.$$

Now we define $L : \mathbb{R}^d \to [0, \infty)$ by

$$L(x) := \mathbf{1}_{[-r,r]}(\|x\|) K(\|x\|)$$

and $L_h : \mathbb{R}^d \to [0, \infty)$ by

$$L_h(x) := h^{-d} L(x/h).$$

Then we have

$$\begin{aligned}\int_{\mathbb{R}^d} |\bar{f} * K_h - \bar{f}| \,\mathrm{d}x &\le \int_{\mathbb{R}^d} |\bar{f} * K_h - \bar{f} * L_h| \,\mathrm{d}x + \int_{\mathbb{R}^d} |\bar{f} * L_h - \bar{f}| \,\mathrm{d}x \\ &\le \|\bar{f}\|_1 \|K_h - L_h\|_1 + \int_{\mathbb{R}^d} \left| \bar{f} * L_h - \bar{f} \int_{\mathbb{R}^d} L_h \,\mathrm{d}x \right| \mathrm{d}x \\ &\quad + \int_{\mathbb{R}^d} \left| \bar{f} * \int_{\mathbb{R}^d} (L_h - K_h) \,\mathrm{d}x \right| \mathrm{d}x \\ &\le 2\|\bar{f}\|_1 \|K_h - L_h\|_1 + \int_{\mathbb{R}^d} \left| \bar{f} * L_h - \bar{f} \int_{\mathbb{R}^d} L_h \,\mathrm{d}x \right| \mathrm{d}x.\end{aligned}$$

Moreover, we have

$$\begin{aligned}\|K_h - L_h\|_1 &= \int_{\mathbb{R}^d} \frac{1}{h^d} \left| \mathbf{1}_{[-r,r]}\left(\frac{\|x\|}{h}\right) K\left(\frac{\|x\|}{h}\right) - K\left(\frac{\|x\|}{h}\right) \right| \mathrm{d}x \\ &= \int_{\mathbb{R}^d} \left| \mathbf{1}_{[-r,r]}(\|x\|) K(\|x\|) - K(\|x\|) \right| \mathrm{d}x \\ &= \int_{B_r^c} K(\|x\|) \,\mathrm{d}x \le \frac{\varepsilon}{9\|\bar{f}\|_1}.\end{aligned}$$

Finally, for $h \le 1$, we have

$$\begin{aligned}\int_{\mathbb{R}^d} \left| \bar{f} * L_h - \bar{f} \int_{\mathbb{R}^d} L_h \,\mathrm{d}x \right| \mathrm{d}x &= \int_{\mathbb{R}^d} \left| \int_{\mathbb{R}^d} \big(\bar{f}(x - x') - \bar{f}(x)\big) L_h(x') \,\mathrm{d}x' \right| \mathrm{d}x \\ &\le \int_{B_{r+M}} \int_{\mathbb{R}^d} |\bar{f}(x - x') - \bar{f}(x)| L_h(x') \,\mathrm{d}x' \,\mathrm{d}x.\end{aligned}$$

Since $\bar{f}$ is uniformly continuous, there exists a constant $h_\varepsilon > 0$ such that for all $h \le h_\varepsilon$ and $\|x'\| \le rh$, we have

$$|\bar{f}(x - x') - \bar{f}(x)| \le \varepsilon' := \frac{\varepsilon}{9(r + M)^d \lambda^d(B_1)}.$$

Consequently we obtain

$$\int_{\mathbb{R}^d} |\bar{f}(x - x') - \bar{f}(x)| L_h(x') \,\mathrm{d}x' \le \varepsilon' \int_{B_{rh}} L_h(x') \,\mathrm{d}x' \le \varepsilon' \int_{\mathbb{R}^d} K_h \,\mathrm{d}x = \varepsilon'.$$

Therefore, we obtain

$$\int_{\mathbb{R}^d} \left| \bar{f} * L_h - \bar{f} \int_{\mathbb{R}^d} L_h \,\mathrm{d}x \right| \mathrm{d}x \le \int_{B_{r+M}} \varepsilon' \,\mathrm{d}x = \frac{\varepsilon}{9} \qquad (28)$$

and consequently the assertion can be proved by combining estimates in (27) and (28).

(ii). The α-Hölder continuity of f tells us that for any $x \in \mathbb{R}^d$, there holds

$$\begin{aligned}|f_{P,h}(x) - f(x)| &= \left| \frac{1}{h^d} \int_{\mathbb{R}^d} K\left(\frac{\|x - x'\|}{h}\right) f(x') \,\mathrm{d}x' - f(x) \right| \\ &= \left| \int_{\mathbb{R}^d} K(\|x'\|) f(x + hx') \,\mathrm{d}x' - f(x) \right| \\ &= \left| \int_{\mathbb{R}^d} K(\|x'\|) \big(f(x + hx') - f(x)\big) \,\mathrm{d}x' \right| \\ &\le c_1 \int_{\mathbb{R}^d} K(\|x'\|) \big(h\|x'\|\big)^\alpha \,\mathrm{d}x' \\ &\le c_2 \int_{\mathbb{R}^d} K\big(\|x'\|_{\ell_2^d}\big) h^\alpha \|x'\|_{\ell_2^d}^\alpha \,\mathrm{d}x' \\ &\le c_3 h^\alpha \int_0^\infty K(r) r^{\alpha + d - 1} \,\mathrm{d}r \\ &\le c_3 \kappa_\alpha h^\alpha,\end{aligned}$$

where $c_1, c_2, c_3 > 0$ are suitable constants.

(iii). For fixed $h > 0$ we define $r := \frac{r_0}{2h}$. A quick calculation then yields $hr = r_0/2 < r_0$. Following the proof of *(ii)* and using that f is uniformly pointwise α-Hölder controllable,

we thus find for λ^d-almost all $x \in \mathbb{R}^d$:

$$\begin{aligned}
|f_{P,h}(x) - f(x)| &= \left| \int_{\mathbb{R}^d} K(\|x'\|) \big(f(x+hx') - f(x)\big)\, \mathrm{d}x' \right| \\
&\le \int_{B_r} K(\|x'\|) \big|f(x+hx') - f(x)\big|\, \mathrm{d}x' + \int_{B_r^c} K(\|x'\|) \big|f(x+hx') - f(x)\big|\, \mathrm{d}x' \\
&\le c(x) \int_{B_r} K(\|x'\|) \big(h\|x'\|\big)^\alpha \, \mathrm{d}x' + f(x) \int_{B_r^c} K(\|x'\|)\, \mathrm{d}x' \\
&\quad + \int_{B_r^c} K(\|x'\|)\, f(x+hx')\, \mathrm{d}x' \\
&\le c_2\, c(x) h^\alpha + c_1 f(x) r^{-\upsilon} + \int_{B_r^c} K(\|x'\|)\, f(x+hx')\, \mathrm{d}x'
\end{aligned}$$

where the first term is estimated similarly to the first part of the proof of (22), and the second term is directly estimated by (22). The definition of r then yields the result.

(iv). Let us fix an $h > 0$. Following the proof of *(ii)* and using that f is pointwise α-Hölder controllable, we then obtain for $x \in \mathbb{R}^d$ with $r(x) > hR$:

$$\begin{aligned}
|f_{P,h}(x) - f(x)| &= \left| \int_{\mathbb{R}^d} K(\|x'\|) \big(f(x+hx') - f(x)\big)\, \mathrm{d}x' \right| \\
&\le \int_{B_R} K(\|x'\|) \big|f(x+hx') - f(x)\big|\, \mathrm{d}x' \qquad (29) \\
&\le c(x) h^\alpha \int_{B_R} K(\|x'\|)\, \|x'\|^\alpha \, \mathrm{d}x' \\
&\le c \cdot c(x) \cdot h^\alpha \,, \qquad (30)
\end{aligned}$$

where c is a suitable constant bounding the integral in the second to last line. In particular, this shows the assertion for all $x \in \Omega^{+hR}$ for which $r(x)$ exists and satisfies $r(x) > hR$.

Let us now consider the case $x \in \Omega^{+hR}$ with $r(x) \le hR$. Here, (29) and a repetition of the estimates around (30) give

$$\begin{aligned}
|f_{P,h}(x) - f(x)| &\le \int_{B_R} K(\|x'\|) \big|f(x+hx') - f(x)\big|\, \mathrm{d}x' \\
&= \int_{\|x'\| < \frac{r(x)}{h}} K(\|x'\|) \big|f(x+hx') - f(x)\big|\, \mathrm{d}x' \\
&\quad + \int_{\frac{r(x)}{h} \le \|x'\| \le R} K(\|x'\|) \big|f(x+hx') - f(x)\big|\, \mathrm{d}x' \\
&\le c \cdot c(x) \cdot h^\alpha + \int_{\frac{r(x)}{h} \le \|x'\| \le R} K(\|x'\|) \big|f(x+hx') - f(x)\big|\, \mathrm{d}x' \,.
\end{aligned}$$

To bound the second integral, we first observe that

$$\begin{aligned}
&\int_{\frac{r(x)}{h} \le \|x'\| \le R} K(\|x'\|) \big|f(x+hx') - f(x)\big|\, \mathrm{d}x' \\
&\le \int_{\frac{r(x)}{h} \le \|x'\| \le R} K(\|x'\|)\, f(x+hx')\, \mathrm{d}x' + \int_{\frac{r(x)}{h} \le \|x'\| \le R} K(\|x'\|)\, f(x)\, \mathrm{d}x' \\
&\le \|K\|_\infty h^{-d} \int_{r(x) \le \|x'\| \le hR} f(x+x')\, \mathrm{d}x' + \|K\|_\infty f(x) \int_{\frac{r(x)}{h} \le \|x'\| \le R} 1\, \mathrm{d}x' \,.
\end{aligned}$$

It thus remains to bound the second integral. To this end, observe that for $C := \mathrm{vol}_d(B_{\|\cdot\|})$ we have

$$\int_{\frac{r(x)}{h} \le \|x'\| \le R} 1\, \mathrm{d}x' = C\left(R^d - \left(\frac{r(x)}{h}\right)^d\right) \le dCR^{d-1}\left(R - \frac{r(x)}{h}\right),$$

where the last inequality is due to Lemma 18. Combining all estimates yields the assertion for all $x \in \Omega^{+hR}$ for which $r(x)$ exists and satisfies $r(x) \le hR$.

Let us finally consider the case of an $x \notin \Omega^{+hR}$ for which $r(x)$ exists. Then we obviously have $x \notin \Omega$ and since $r(x)$ exists we conclude that $f(x) = 0$. Moreover, the definition of Ω^{+hR} gives $\|x - x''\| > hR$ for all $x'' \in \Omega$. Let us now fix an x' with $\|x'\| \le R$. Assume we had $x + hx' \in \Omega$. For $x'' := x + hx'$ we would then find $hR < \|x - x''\| = \|hx'\| \le hR$, which is impossible. Consequently, we have $x + hx' \notin \Omega$, and thus we obtain $f(x+hx') = 0$ for λ^d-almost all x' with $\|x'\| \le R$. Combining our considerations with (29) leads to

$$|f_{P,h}(x) - f(x)| \le \int_{\|x'\| \le R} K(\|x'\|) \big|f(x+hx') - f(x)\big|\, \mathrm{d}x' = 0\,,$$

and hence we have shown the assertion. ∎

Proof [of Proposition 11] *(i).* We decompose $\|f_{P,h} - f\|_1$ as follows

$$\begin{aligned}
\|f_{P,h} - f\|_1 &= \int_{B_r} |f_{P,h}(x) - f(x)|\, \mathrm{d}x + \int_{B_r^c} |f_{P,h}(x) - f(x)|\, \mathrm{d}x \qquad (31) \\
&\le \lambda^d(B_r) \|f_{P,h} - f\|_\infty + \int_{B_r^c} \mathbb{E}_P k_{x,h}\, \mathrm{d}x + \int_{B_r^c} f\, \mathrm{d}x \\
&\le \lambda^d(B_1)\, r^d\, \|f_{P,h} - f\|_\infty + \int_{B_r^c} \mathbb{E}_P k_{x,h}\, \mathrm{d}x + P\left(B_r^c\right). \qquad (32)
\end{aligned}$$

Combining (32) and (24), we obtain the desired assertion.

(ii). Since f is pointwise α-Hölder controllable, *(iii)* of Proposition 10 tells us that

$$\begin{aligned}
\int_{B_r} |f_{P,h}(x) - f(x)|\, \mathrm{d}x &\le c h^\alpha \cdot \int_{B_r} c(x)\, \mathrm{d}x + c h^\upsilon + \int_{B_r} \int_{B_{r_0/(2h)}^c} K(\|x'\|)\, f(x+hx')\, \mathrm{d}x'\, \mathrm{d}x \\
&= c\, H(r)\, h^\alpha + c h^\upsilon + \int_{B_{r_0/(2h)}^c} K(\|x'\|) \int_{B_r} f(x+hx')\, \mathrm{d}x\, \mathrm{d}x' \\
&\le c\, H(r)\, h^\alpha + c h^\upsilon + \int_{B_{r_0/(2h)}^c} K(\|x'\|)\, \mathrm{d}x' \\
&\le c\, H(r)\, h^\alpha + \tilde{c}\, h^\upsilon \,,
\end{aligned}$$

where in the last step we used (22). Combining this estimate with the decomposition (31) and the inequality (24) then yields the assertion.

(iii). In this case, *(iv)* of Proposition 10 gives

$$\begin{aligned}\int_{\mathbb{R}^d} |f_{P,h}(x) - f(x)|\,\mathrm{d}x &= \int_{\Omega^{+hR}} |f_{P,h}(x) - f(x)|\,\mathrm{d}x \\ &\le c\,h^\alpha \int_{\Omega^{+hR}} c(x)\,\mathrm{d}x + c\cdot\|K\|_\infty \int_{\Omega^{+hR}} f(x)\left|R - \frac{r(x)}{h}\right|_+ \mathrm{d}x \\ &\quad + \|K\|_\infty h^{-d} \int_{\Omega^{+hR}} \int_{r(x)\le\|x'\|\le hR} f(x+x')\,\mathrm{d}x'\,\mathrm{d}x\,.\end{aligned}$$

Moreover, we have

$$\begin{aligned}\int_{\Omega^{+hR}} f(x)\left|R - \frac{r(x)}{h}\right|_+ \mathrm{d}x &\le \int_{\mathbb{R}^d} f(x)\left|R - \frac{r(x)}{h}\right|_+ \mathrm{d}x \\ &= \int_{r(x)\le hR} \Big(R - \frac{r(x)}{h}\Big)\,P(dx) \\ &\le R\cdot P(\{x : r(x)\le hR\})\,,\end{aligned}$$

which, together with our previous estimate gives the assertion.

(iv). Let us consider the partition $X_h^* = \big(X_h^*\cap\Omega^{+hR}\big)\cup\big(X_h^*\cap(\mathbb{R}^d\setminus\Omega^{+hR})\big)$. For $x\in X_h^*\cap(\mathbb{R}^d\setminus\Omega^{+hR})$, the first assertion of *(iv)* of Proposition 10 then shows $|f_{P,h}(x)-f(x)|=0$, and hece the assertion is true for these x. Moreover, for $X_h^*\cap\Omega^{+hR}$, the second assertion of *(iv)* of Proposition 10 gives

$$\begin{aligned}|f_{P,h}(x) - f(x)| &\le c\,c(x)h^\alpha + c\cdot\|K\|_\infty f(x)\left|R - \frac{r(x)}{h}\right|_+ \\ &\quad + \|K\|_\infty h^{-d}\int_{r(x)\le\|x'\|\le hR} f(x+x')\,\mathrm{d}x'\,,\end{aligned}$$

and since the second and third term vanish on X_h^* we obtain the assertion. ■

To prove Proposition 13, we need the following lemmas.

Lemma 19 *Let (X,d) and (Y,e) be metric spaces and $T: X\to Y$ be an α-Hölder continuous function with constant c. Then, for $A\subset X$ and all $\varepsilon>0$ we have*

$$\mathcal{N}(T(A), e, c\varepsilon^\alpha) \le \mathcal{N}(A,d,\varepsilon).$$

Proof [of Lemma 19] Let $x_1,\dots,x_n$ be an ε-net of A, that is, $A\subset\bigcup_{i=1}^n B_d(x_i,\varepsilon)$. For $i=1,\cdots,n$, we set $y_i := T(x_i)$. Now, it only suffices to show that this gives a $c\varepsilon^\alpha$-net of $T(A)$.

In fact, supposing that $y\in T(B_d(x_i,\varepsilon))$, then there exists $x\in B_d(x_i,\varepsilon)$ such that $T(x)=y$. This implies

$$e(T(x),T(x_i)) \le cd^\alpha(x,x_i) \le c\varepsilon^\alpha.$$

Therefore, we have $T(B_d(x_i,\varepsilon))\subset B_e(y_i,c\varepsilon^\alpha)$. That is, $y_1,\dots,y_n$ is a $c\varepsilon^\alpha$-net of $T(A)$. This completes the proof of Lemma 19. ■

Remark 20 *We remark that when X is a Banach space with the norm $\|\cdot\|$, then for any $c>0$ there holds*

$$\mathcal{N}(cA,\|\cdot\|,\varepsilon) = \mathcal{N}\left(A,\|\cdot\|,\varepsilon/c\right).$$

Lemma 21 *Let $\|\cdot\|'$ be another norm on $\mathbb{R}^d$. Then for all $\varepsilon\in(0,1]$ we have*

$$\mathcal{N}(B_1,\|\cdot\|',\varepsilon) \lesssim \varepsilon^{-d}.$$

Proof [of Lemma 21] It is a straightforward conclusion of Proposition 1.3.1 in Carl and Stephani (1990) and Lemma 6.21 in Steinwart and Christmann (2008). ■

Lemma 22 *Let K be a d-dimensional smoothing kernel that satisfies Conditions (i) in Assumption B. Let $h>0$ be the bandwidth parameter, and $k_{x,h}$ be defined in (12) for any $x\in\mathbb{R}^d$. Then we have*

$$\sup_{y\in\mathbb{R}^d}|k_{x,h}(y)-k_{x',h}(y)| \le \frac{c}{h^{\beta+d}}\|x-x'\|^\beta,\ \ x,x'\in\mathbb{R}^d,$$

where c is a positive constant.

Proof [of Lemma 22] From the definition of $k_{x,h}$ and the fact that K is a d-dimensional β-Hölder continuous kernel, we have

$$\begin{aligned}|k_{x,h}(y)-k_{x',h}(y)| &= \frac{1}{h^d}\left|K\Big(\frac{\|x-y\|}{h}\Big) - K\Big(\frac{\|x'-y\|}{h}\Big)\right| \\ &\le \frac{c}{h^d}\left|\frac{\|x-y\|}{h} - \frac{\|x'-y\|}{h}\right|^\beta \\ &\le ch^{-(\beta+d)}\|x-x'\|^\beta,\end{aligned}$$

where c is a positive constant. The desired conclusion is thus obtained. ■

Proof [of Proposition 13] Lemma 22 reveals that $\mathcal{K}_{h,r}$ is the image of Hölder continuous map $B_r\to L_\infty(\mathbb{R}^d)$ with the constant $ch^{-(\beta+d)}$. By Lemmas 19 and 21 we obtain

$$\begin{aligned}\mathcal{N}(\mathcal{K}_{h,r},\|\cdot\|_\infty,\varepsilon) &\le \mathcal{N}\left(B_r,\|\cdot\|,\Big(\frac{\varepsilon h^{\beta+d}}{c}\Big)^{1/\beta}\right) \\ &= \mathcal{N}\left(B_1,\|\cdot\|,\Big(\frac{\varepsilon h^{\beta+d}}{cr^\beta}\Big)^{1/\beta}\right) \\ &\le c'\left(\frac{\varepsilon h^{\beta+d}}{r^\beta}\right)^{-d/\beta},\end{aligned}$$

where c' is a constant independent of ε. This completes the proof of Proposition 13. ■

The following Bernstein-type exponential inequality, which was developed recently in Hang and Steinwart (2017), will serve as one of the main ingredients in the consistency and convergence analysis of the kernel density estimator (8). It can be stated in the following general form:

Theorem 23 (Bernstein Inequality (Hang and Steinwart, 2017)) *Assume that $\mathcal{X} := (X_n)_{n\geq 1}$ is an X-valued stationary geometrically (time-reversed) $\mathcal{C}$-mixing process on $(\Omega, \mathcal{A}, \mu)$ with $\|\cdot\|_{\mathcal{C}}$ be defined by (4) for some semi-norm $|||\cdot|||$ satisfying Condition (ii) in Assumption A, and $P := \mu_{X_1}$. Moreover, let $g : X \to \mathbb{R}$ be a function such that $g \in \mathcal{C}(X)$ with $\mathbb{E}_P g = 0$ and assume that there exist some $A > 0$, $B > 0$, and $\sigma \geq 0$ such that $|||g||| \leq A$, $\|g\|_\infty \leq B$, and $\mathbb{E}_P g^2 \leq \sigma^2$. Then, for all $\tau > 0$, $k \in \mathbb{N}$, and*

$$n \geq n_0 := \max\left\{\min\left\{m \geq 3 : m \geq \left(\frac{808c_0(3A+B)}{B}\right)^{\frac{1}{k}} \text{ and } \frac{m}{(\log m)^{\frac{2}{\gamma}}} \geq 4\right\}, e^{\frac{k+1}{b}}\right\},$$

with probability μ at least $1 - 4e^{-\tau}$, there holds

$$\left|\frac{1}{n}\sum_{i=1}^n g(X_i)\right| \leq \sqrt{\frac{8(\log n)^{\frac{2}{\gamma}}\sigma^2\tau}{n}} + \frac{8(\log n)^{\frac{2}{\gamma}}B\tau}{3n}.$$

Proof [of Proposition 14] Let the notations $k_{x,h}$ and $\widetilde{k}_{x,h}$ be defined in (12) and (13), respectively, that is, $k_{x,h} := h^{-d}K(\|x - \cdot\|/h)$, and $\widetilde{k}_{x,h} := k_{x,h} - \mathbb{E}_P k_{x,h}$. We first assume that $x \in \mathbb{R}^d$ is fixed and then estimate $\mathbb{E}_D\widetilde{k}_{x,h}$ by using Bernstein's inequality in Theorem 23. For this purpose, we shall verify the following conditions: Obviously, we have $\mathbb{E}_P\widetilde{k}_{x,h} = 0$. Moreover, simple estimates yield

$$\|\widetilde{k}_{x,h}\|_\infty \leq 2\|k_{x,h}\|_\infty \leq 2h^{-d}\|K\|_\infty \leq 2h^{-d}K(0)$$

and

$$\mathbb{E}_P\widetilde{k}^2_{x,h} \leq \mathbb{E}_P k^2_{x,h} = \int_{\mathbb{R}^d} k^2_{x,h}(x')\mathrm{d}P(x').$$

Finally, the first condition in Assumption A and Condition (iv) in Assumption B imply

$$|||\widetilde{k}_{x,h}||| \leq |||k_{x,h}||| \leq h^{-d}\sup_{x\in\mathbb{R}^d}|||K\left(\|x - \cdot\|/h\right)||| \leq h^{-d}\varphi(h).$$

Now we can apply the Bernstein-type inequality in Theorem 23 and obtain that for $n \geq n_1$, for any fixed $x \in \mathbb{R}^d$, with probability μ at most $4e^{-\tau}$, there holds

$$|\mathbb{E}_D\widetilde{k}_{x,h}| \geq \sqrt{\frac{8\tau(\log n)^{2/\gamma}\int_{\mathbb{R}^d} k^2_{x,h}(x')\mathrm{d}P(x')}{n}} + \frac{16\tau(\log n)^{2/\gamma}K(0)}{3h^d n}, \tag{33}$$

where

$$n_1 := \max\left\{\min\left\{m \geq 3 : m \geq \left(\frac{808c_0(3h^{-d}\varphi(h) + K(0))}{2K(0)}\right)^{\frac{1}{d+1}} \text{ and } \frac{m}{(\log m)^{\frac{2}{\gamma}}} \geq 4\right\}, e^{\frac{d+1}{b}}\right\}. \tag{34}$$

Consider the function set $\widetilde{\mathcal{K}}_{h,r} := \{\widetilde{k}_{x,h} : x \in B_r\}$. We choose $y_1, \ldots, y_m \in B_r$ such that $\{k_{y_1,h}, \ldots, k_{y_m,h}\}$ is a minimal $\varepsilon/2$-net of $\mathcal{K}_{h,r} = \{k_{x,h} : x \in B_r\}$ with respect to $\|\cdot\|_\infty$. Noticing the following relation

$$\|\widetilde{k}_{x,h} - \widetilde{k}_{y_j,h}\|_\infty \leq 2\|k_{x,h} - k_{y_j,h}\|_\infty \leq \varepsilon,$$

we know that $\{\widetilde{k}_{y_1,h}, \ldots, \widetilde{k}_{y_m,h}\}$ is an ε-net of $\widetilde{\mathcal{K}}_{h,r}$ with respect to $\|\cdot\|_\infty$. Note that here we have $m = \mathcal{N}(\mathcal{K}_{h,r}, \|\cdot\|_\infty, \frac{\varepsilon}{2})$, since the net is minimal. From Proposition 13, we know that there exists a positive constant c independent of ε such that $\log m \leq c\log\frac{r}{h\varepsilon}$. From the estimate in (33) and a union bound argument, with probability μ at least $1 - 4me^{-\tau}$, the following estimate holds

$$\sup_{j=1,\ldots,m}|\mathbb{E}_D\widetilde{k}_{y_j,h}| \leq \sqrt{\frac{8\tau(\log n)^{2/\gamma}\int_{\mathbb{R}^d} k^2_{y_j,h}(x')\mathrm{d}P(x')}{n}} + \frac{16\tau(\log n)^{2/\gamma}K(0)}{h^d n}.$$

By a simple variable transformation, we see that with probability μ at least $1 - e^{-\tau}$, there holds

$$\sup_{j=1,\ldots,m}|\mathbb{E}_D\widetilde{k}_{y_j,h}| \leq \sqrt{\frac{8(\log n)^{2/\gamma}\int_{\mathbb{R}^d} k^2_{y_j,h}(x')\mathrm{d}P(x')(\tau + \log(4m))}{n}} + \frac{16(\log n)^{2/\gamma}K(0)(\tau + \log(4m))}{h^d n}.$$

Recalling that $\{k_{y_1,h}, \ldots, k_{y_m,h}\}$ is an $\varepsilon/2$-net of $\mathcal{K}_{h,r}$, this implies that, for any $x \in B_r$, there exists y_j such that $\|k_{x,h} - k_{y_j,h}\|_\infty \leq \varepsilon/2$. Then we have

$$\begin{aligned}\left||\mathbb{E}_D\widetilde{k}_{x,h}| - |\mathbb{E}_D\widetilde{k}_{y_j,h}|\right| &\leq \left|\mathbb{E}_D\widetilde{k}_{x,h} - \mathbb{E}_D\widetilde{k}_{y_j,h}\right| \\ &\leq |\mathbb{E}_D k_{x,h} - \mathbb{E}_D k_{y_j,h}| + |\mathbb{E}_P k_{x,h} - \mathbb{E}_P k_{y_j,h}| \\ &\leq \|k_{x,h} - k_{y_j,h}\|_{L_1(D)} + \|k_{x,h} - k_{y_j,h}\|_{L_1(P)} \\ &\leq \varepsilon,\end{aligned}$$

and consequently

$$|\mathbb{E}_D\widetilde{k}_{x,h}| \leq |\mathbb{E}_D\widetilde{k}_{y_j,h}| + \varepsilon. \tag{35}$$

By setting $a := 8(\log n)^{2/\gamma}(\tau + \log(4m))/n$, we have

$$\begin{aligned}\left|\sqrt{a\int_{\mathbb{R}^d} k^2_{x,h}(x')\,\mathrm{d}P(x')} - \sqrt{a\int_{\mathbb{R}^d} k^2_{y_j,h}(x')\,\mathrm{d}P(x')}\right| &= \left|\|\sqrt{a}k_{x,h}\|_{L_2(P)} - \|\sqrt{a}k_{y_j,h}\|_{L_2(P)}\right| \\ &\leq \sqrt{a}\|k_{x,h} - k_{y_j,h}\|_{L_2(P)} \\ &\leq \sqrt{a}\varepsilon/2.\end{aligned}$$

This together with inequality (35) implies that for any $x \in B_r$, there holds

$$\begin{aligned}|\mathbb{E}_D\widetilde{k}_{x,h}| &\le |\mathbb{E}_D\widetilde{k}_{y_j,h}| + 2\varepsilon \\ &\le \sqrt{a\int_{\mathbb{R}^d} k^2_{y_j,h}(x')\,\mathrm{d}P(x')} + \frac{2aK(0)}{h^d} + \varepsilon \\ &\le \sqrt{a\int_{\mathbb{R}^d} k^2_{x,h}(x')\,\mathrm{d}P(x')} + \frac{\sqrt{a}\varepsilon}{2} + \frac{2aK(0)}{h^d} + \varepsilon.\end{aligned}$$

Consequently we have

$$\begin{aligned}\int_{B_r} |\mathbb{E}_D\widetilde{k}_{x,h}|\,\mathrm{d}x \le \int_{B_r} \sqrt{a\int_{\mathbb{R}^d} k^2_{x,h}(x')\,\mathrm{d}P(x')}\,\mathrm{d}x \\ + r^d\lambda^d(B_1)\cdot\frac{2aK(0)}{h^d} + r^d\lambda^d(B_1)(\sqrt{a}/2+1)\varepsilon.\end{aligned}$$

Now recall that for $E \subset \mathbb{R}^d$ and $g : E \to \mathbb{R}$, Hölder's inequality implies

$$\|g\|_{\frac{1}{2}} = \left(\int_{\mathbb{R}^d} |\mathbf{1}_E|^{\frac{1}{2}}|g|^{\frac{1}{2}}\,\mathrm{d}x\right)^2 \le \int_{\mathbb{R}^d} |\mathbf{1}_E|\,\mathrm{d}x \int_{\mathbb{R}^d} |g|\,\mathrm{d}x = \mu(E)\cdot\|g\|_1.$$

This tells us that

$$\int_{B_r}\sqrt{a\int_{\mathbb{R}^d} k^2_{x,h}(x')\,\mathrm{d}P(x')}\,\mathrm{d}x \le \sqrt{\mu(B_r)}\cdot\sqrt{\int_{B_r} a\int_{\mathbb{R}^d} k^2_{x,h}(x')\,\mathrm{d}P(x')\,\mathrm{d}x}.$$

Moreover, there holds

$$\begin{aligned}\int_{B_r}\int_{\mathbb{R}^d} k^2_{x,h}(x')\,\mathrm{d}P(x')\,\mu(\mathrm{d}x) &= \int_{\mathbb{R}^d}\int_{B_r} h^{-2d}K^2\left(\|x-x'\|/h\right)\,\mathrm{d}x\,\mathrm{d}P(x') \\ &\le \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} h^{-2d}K^2\left(\|x\|/h\right)\,\mathrm{d}x\,\mathrm{d}P(x') \\ &= h^{-d}\int_{\mathbb{R}^d} K^2(\|x\|)\,\mathrm{d}x \\ &\le K(0)h^{-d}.\end{aligned}$$

We now set $\varepsilon = \frac{1}{n}$ and obtain $\log(4m) \le c\log\frac{nr}{h}$. Thus we have

$$\begin{aligned}\int_{B_r}|\mathbb{E}_D\widetilde{k}_{x,h}|\,\mathrm{d}x &\lesssim \sqrt{\frac{(\log n)^{2/\gamma}r^d(\tau+\log(4m))}{h^d n}} + \frac{(\log n)^{2/\gamma}r^d(\tau+\log(4m))}{h^d n} \\ &\quad + \sqrt{\frac{(\log n)^{2/\gamma}(\tau+\log(4m))}{n}}\cdot\frac{r^d}{n} \\ &\lesssim \sqrt{\frac{(\log n)^{2/\gamma}r^d(\tau+\log\frac{nr}{h})}{h^d n}} + \frac{(\log n)^{2/\gamma}r^d(\tau+\log\frac{nr}{h})}{h^d n}.\end{aligned} \tag{36}$$

Now we need to estimate the corresponding integral over B_r^c. By definition we have

$$\int_{B_r^c}|\mathbb{E}_D\widetilde{k}_{x,h}|\,\mathrm{d}x \le \int_{B_r^c}\mathbb{E}_D k_{x,h}\,\mathrm{d}x + \int_{B_r^c}\mathbb{E}_P k_{x,h}\,\mathrm{d}x.$$

From Lemma 17 we obtain

$$\int_{B_r^c}\mathbb{E}_D k_{x,h}\,\mathrm{d}x \lesssim D(B^c_{r/2}) + \left(\frac{h}{r}\right)^\beta = \frac{1}{n}\sum_{i=1}^n \mathbf{1}_{B^c_{r/2}}(x_i) + \left(\frac{h}{r}\right)^\beta,$$

and

$$\int_{B_r^c}\mathbb{E}_P k_{x,h}\,\mathrm{d}x \lesssim P(B^c_{r/2}) + \left(\frac{h}{r}\right)^\beta.$$

Since $r \ge 1$, we can construct a function g with $\mathbf{1}_{B^c_{r/2}} \le g \le \mathbf{1}_{B^c_{r/4}}$ and there exists a function $\psi(r)$ such that $\|\|g\|\| \le \psi(r)$. Applying Bernstein inequality in Theorem 23 with respect to this function g, it is easy to see that when $n \ge n_2$, with probability μ at least $1-2e^{-\tau}$, there holds

$$\mathbb{E}_D g - \mathbb{E}_P g \le \sqrt{\frac{8\tau(\log n)^{2/\gamma}}{n}} + \frac{8\tau(\log n)^{2/\gamma}}{3n},$$

where

$$n_2 := \max\left\{\min\left\{m \ge 3 : m^2 \ge 808c_0(3\psi(r)+1) \text{ and } \frac{m}{(\log m)^{\frac{2}{\gamma}}} \ge 4\right\}, e^{\frac{3}{b}}\right\}.$$

This implies that with probability μ at least $1-2e^{-\tau}$, there holds

$$\begin{aligned}D(B^c_{r/2}) = \frac{1}{n}\sum_{i=1}^n \mathbf{1}_{B^c_{r/2}}(x_i) &\le \mathbb{E}_D g \\ &\le \mathbb{E}_P g + \sqrt{\frac{8\tau(\log n)^{2/\gamma}}{n}} + \frac{8\tau(\log n)^{2/\gamma}}{3n} \\ &\le \mathbb{E}_P\mathbf{1}_{B^c_{r/4}}(x_i) + \sqrt{\frac{8\tau(\log n)^{2/\gamma}}{n}} + \frac{8\tau(\log n)^{2/\gamma}}{3n}\end{aligned}$$

and consequently we obtain

$$\int_{B_r^c}|\mathbb{E}_D\widetilde{k}_{x,h}|\,\mathrm{d}x \lesssim P(B^c_{r/4}) + \sqrt{\frac{32\tau(\log n)^{2/\gamma}}{n}} + \left(\frac{h}{r}\right)^\beta. \tag{37}$$

By combining estimates in (36) and (37), and taking $n_0 = \max\{n_1, n_2\}$, we have accomplished the proof of Proposition 14. ∎

Remark 24 *Let us briefly discuss the choice of the function $\psi(r)$ in the proof of Proposition 14. For example, in the case $\mathcal{C}(X) = \mathrm{Lip}(\mathbb{R})$, we can choose*

$$g(x) := \begin{cases} 1, & \text{for } |x| > r, \\ 0, & \text{for } |x| < r/4, \\ -\frac{4x}{3r} - \frac{1}{3}, & \text{for } -r \le x \le -r/4, \\ \frac{4x}{3r} - \frac{1}{3}, & \text{for } r/4 \le x \le r. \end{cases}$$

Then we have $\|\|g\|\| \le \frac{4}{3r} \le 4/3$ and therefore, n_2 is well-defined. Moreover, it is easily seen that even for smoother underlying functions classes like C^1 we can construct a function g such that $\|\|g\|\| < \infty$.

Proof [of Proposition 15] Recalling the definitions of $k_{x,h}$ and $\widetilde{k}_{x,h}$ given in (12) and (13), we have

$$\|f_{D,h} - f_{P,h}\|_\infty = \sup_{x\in\Omega} |\mathbb{E}_D \widetilde{k}_{x,h}|.$$

To prove the assertion, we first estimate $\mathbb{E}_D f_{x,h}$ for fixed $x \in \mathbb{R}^d$ using the Bernstein inequality in Theorem 23. For this purpose, we first verify the following conditions: Obviously, we have $\mathbb{E}_P \widetilde{k}_{x,h} = 0$. Then, simple estimates imply

$$\|\widetilde{k}_{x,h}\|_\infty \le 2\|k_{x,h}\|_\infty \le 2h^{-d}\|K\|_\infty \le 2h^{-d}K(0)$$

and

$$\mathbb{E}_P \widetilde{k}^2_{x,h} \le \mathbb{E}_P k^2_{x,h} = h^{-d} \int_{\mathbb{R}^d} K^2\left(\|x - x'\|/h\right) f(x') h^{-d}\,\mathrm{d}x' \lesssim \|f\|_\infty h^{-d}.$$

Finally, the first condition in Assumption A and Condition (iv) in Assumption B yield

$$\|\|\widetilde{k}_{x,h}\|\| \le \|\|k_{x,h}\|\| \le h^{-d} \sup_{x\in\mathbb{R}^d} \|\|K\left(\|x - \cdot\|/h\right)\|\| \le h^{-d}\varphi(h).$$

Therefore, we can apply the Bernstein inequality in Theorem 23 and obtain that for $n \ge n_0^*$, for any fixed $x \in \mathbb{R}^d$, with probability μ at least $1 - 4e^{-\tau}$, there holds

$$|\mathbb{E}_D \widetilde{k}_{x,h}| \lesssim \sqrt{\frac{\tau\|f\|_\infty (\log n)^{2/\gamma}}{h^d n}} + \frac{K(0)\tau(\log n)^{2/\gamma}}{3h^d n}, \tag{38}$$

where

$$n_0^* := \max\left\{ \min\left\{ m \ge 3 : m \ge \left(\frac{808c_0(3h^{-d}\varphi(h) + K(0))}{2K(0)}\right)^{\frac{1}{d+1}} \text{ and } \frac{m}{(\log m)^{\frac{2}{\gamma}}} \ge 4 \right\}, e^{\frac{d+1}{b}} \right\}. \tag{39}$$

Let us consider the following function set

$$\mathcal{K}'_{h,r_0} := \left\{ \widetilde{k}_{x,h} : x \in B_{r_0} \right\}$$

and choose $y_1, \ldots, y_m \in B_{r_0}$ such that $\{k_{y_1,h}, \ldots, k_{y_m,h}\}$ is a minimal $\varepsilon/2$-net of $\mathcal{K}_{h,r_0}$ with respect to $\|\cdot\|_\infty$ and $m = \mathcal{N}(\mathcal{K}_{h,r_0}, \|\cdot\|_\infty, \frac{\varepsilon}{2})$. As in the proof of Proposition 14, one can show that $\widetilde{k}_{y_1,h}, \ldots, \widetilde{k}_{y_m,h}$ is an ε-net of $\mathcal{K}'_{h,r_0}$. Again from Proposition 13 we know that there holds $\log(4m) \lesssim \log \frac{r_0}{h\varepsilon}$. This in connection with (38) implies that the following union bound

$$\sup_{j=1,..,m} |\mathbb{E}_D \widetilde{k}_{y_j,h}| \lesssim \sqrt{\frac{\|f\|_\infty(\tau + \log(4m))(\log n)^{2/\gamma}}{h^d n}} + \frac{K(0)(\tau + \log(4m))(\log n)^{2/\gamma}}{h^d n}$$

holds with probability μ at least $1 - e^{-\tau}$. For any $x \in B_{r_0}$, there exists a y_j such that $\|k_{x,h} - k_{y_j,h}\|_\infty \le \varepsilon$. Then we have

$$\begin{aligned} \left||\mathbb{E}_D \widetilde{k}_{x,h}| - |\mathbb{E}_D \widetilde{k}_{y_j,h}|\right| &\le |\mathbb{E}_D \widetilde{k}_{x,h} - \mathbb{E}_D \widetilde{k}_{y_j,h}| \\ &\le |\mathbb{E}_D k_{x,h} - \mathbb{E}_D k_{y_j,h}| + |\mathbb{E}_P k_{x,h} - \mathbb{E}_P k_{y_j,h}| \\ &\le \|k_{x,h} - k_{y_j,h}\|_{L_1(D)} + \|k_{x,h} - k_{y_j,h}\|_{L_1(P)} \\ &\le \varepsilon, \end{aligned}$$

and consequently with probability μ at least $1 - e^{-\tau}$, there holds

$$\begin{aligned} |\mathbb{E}_D \widetilde{k}_{x,h}| &\le |\mathbb{E}_D \widetilde{k}_{y_j,h}| + \varepsilon \\ &\lesssim \sqrt{\frac{\|f\|_\infty(\tau + \log(4m))(\log n)^{2/\gamma}}{h^d n}} + \frac{K(0)(\tau + \log(4m))(\log n)^{2/\gamma}}{h^d n} + \varepsilon \end{aligned}$$

for any $x \in B_{r_0}$. By setting $\varepsilon = \frac{1}{n}$, we obtain $\log(4m) \lesssim \log \frac{nr_0}{h}$. Thus, with probability μ at least $1 - e^{-\tau}$, we have

$$\begin{aligned} |\mathbb{E}_D \widetilde{k}_{x,h}| &\lesssim \sqrt{\frac{\|f\|_\infty(\tau + \log(\frac{nr_0}{h}))(\log n)^{2/\gamma}}{h^d n}} + \frac{K(0)(\tau + \log(\frac{nr_0}{h}))(\log n)^{2/\gamma}}{h^d n} + \frac{1}{n} \\ &\lesssim \sqrt{\frac{\|f\|_\infty(\tau + \log(\frac{nr_0}{h}))(\log n)^{2/\gamma}}{h^d n}} + \frac{K(0)(\tau + \log(\frac{nr_0}{h}))(\log n)^{2/\gamma}}{h^d n}. \end{aligned}$$

By taking the supremum of the left hand side of the above inequality over x, we complete the proof of Proposition 15. ∎

Proof [of Theorem 7] Without loss of generality, we assume that $h_n \le 1$. Since $h_n \to 0$, Proposition 10 implies that $\|f_{P,h} - f\|_1 \le \varepsilon$. We set

$$r_n := \left(\frac{nh_n^d}{(\log n)^{(2+2\gamma)/\gamma}}\right)^{1/d} \to \infty \tag{40}$$

and we can also assume w.l.o.g that $r_n \ge 2$. Moreover, there exists a constant n'_1 such that

$$P(B^c_{r_n/2}) \le \varepsilon, \ \forall\, n \ge n'_1.$$

For any $0 < \delta < 1$, we select $\tau := \log(1/\delta)$. Then there exists a constant n_2' such that $\log \frac{nr_n}{h_n} \geq \tau$ for all $n \geq n_2'$. On the other hand, with the above choice of r_n, we have

$$\log \frac{nr_n}{h_n} \leq \log\left(\frac{n^{1/d}h_n}{(\log n)^{(2+2\gamma)/\gamma}} \cdot \frac{n}{h_n}\right) \leq (1+d^{-1})\log n \lesssim \log n.$$

Thus, for all $n \geq \max\{n_1', n_2'\}$, we have

$$\frac{(\log n)^{2/\gamma} r_n^d \log(\frac{nr_n}{h_n})}{nh_n^d} \lesssim \frac{(\log n)^{2/\gamma} r_n^d \log n}{nh_n^d} = \frac{1}{\log n} \to 0.$$

Thus, following from Proposition 14, when n is sufficient large, for any $\varepsilon > 0$, with probability μ at least $1 - 3\delta$, there holds

$$\|f_{D,h_n} - f\|_1 \lesssim \varepsilon.$$

Therefore, with properly chosen δ, one can show that f_{D,h_n} converges to f under L_1-norm almost surely. We have completed the proof of Theorem 7. ■

Proof [of Theorem 8] *(i)* Combining the estimates in Proposition 14 and Proposition 11, we know that with probability μ at least $1 - 2e^{-\tau}$, there holds

$$\begin{aligned}\|f_{D,h} - f\|_1 &\lesssim \sqrt{\frac{(\log n)^{2/\gamma} r^d (\tau + \log(\frac{nr}{h_n}))}{h_n^d n}} + \frac{(\log n)^{2/\gamma} r^d (\tau + \log(\frac{nr}{h_n}))}{h_n^d n} \\ &\quad + \frac{\tau(\log n)^{2/\gamma}}{n} + P\big(B_r^c\big) + r^d h_n^\alpha + \left(\frac{h_n}{r}\right)^\beta \\ &\lesssim \sqrt{\frac{(\log n)^{2/\gamma} r^d (\tau + \log(\frac{nr}{h_n}))}{h_n^d n}} + \frac{\tau(\log n)^{2/\gamma}}{n} + P\big(B_r^c\big) + r^d h_n^\alpha + \left(\frac{h_n}{r}\right)^\beta.\end{aligned}$$

Let $\tau := \log n$ and later we will see from the choices of h_n and r_n that there exists some constant c such that $\log(\frac{nr}{h})$ can be bounded by $c \log n$. Therefore, with probability μ at least $1 - \frac{1}{n}$ there holds

$$\begin{aligned}\|f_{D,h} - f\|_1 &\lesssim \sqrt{\frac{r^d (\log n)^{(2+\gamma)/\gamma}}{h_n^d n}} + r^{-\eta d} + r^d h_n^\alpha \\ &\lesssim r^d \left(\frac{\log n}{nr^d}\right)^{\frac{\alpha}{2\alpha+d}} + r^{-\eta d} \\ &\lesssim \left(\frac{(\log n)^{(2+\gamma)/\gamma}}{n}\right)^{\frac{\alpha\eta}{(1+\eta)(2\alpha+d)-\alpha}},\end{aligned}$$

by choosing

$$h_n = \left(\frac{(\log n)^{(2+\gamma)/\gamma}}{n}\right)^{\frac{1+\eta}{(1+\eta)(2\alpha+d)-\alpha}} \quad \text{and} \quad r := r_n = \left(\frac{n}{(\log n)^{(2+\gamma)/\gamma}}\right)^{\frac{\alpha}{d(1+\eta)(2\alpha+d)-\alpha d}}.$$

(ii) Similar to case *(i)*, one can show that with probability μ at least $1 - \frac{1}{n}$ there holds

$$\begin{aligned}\|f_{D,h} - f\|_1 &\lesssim \sqrt{\frac{r^d (\log n)^{(2+\gamma)/\gamma}}{h_n^d n}} + e^{-ar^\eta} + r^d h_n^\alpha \\ &\lesssim r^d \left(\frac{(\log n)^{(2+\gamma)/\gamma}}{nr^d}\right)^{\frac{\alpha}{2\alpha+d}} + e^{-ar^\eta} \\ &\lesssim \left(\frac{(\log n)^{(2+\gamma)/\gamma}}{n}\right)^{\frac{\alpha}{2\alpha+d}} (\log n)^{\frac{d}{\eta}\cdot\frac{\alpha+d}{2\alpha+d}},\end{aligned}$$

by choosing

$$h_n = \left(\frac{(\log n)^{(2+\gamma)/\gamma}}{n}\right)^{\frac{1}{2\alpha+d}} (\log n)^{-\frac{d}{\eta}\cdot\frac{1}{2\alpha+d}} \quad \text{and} \quad r_n = (\log n)^{\frac{1}{\eta}}.$$

(iii) From Proposition 11 we see that with confidence $1 - \frac{1}{n}$, there holds

$$\|f_{D,h} - f_{P,h}\|_1 \lesssim \sqrt{\frac{r_0^d (\log n)^{(2+\gamma)/\gamma}}{h_n^d n}} + h_n^\alpha \lesssim \left((\log n)^{(2+\gamma)/\gamma}/n\right)^{\frac{\alpha}{2\alpha+d}},$$

where h_n is chosen as

$$h_n = \left((\log n)^{(2+\gamma)/\gamma}/n\right)^{\frac{1}{2\alpha+d}}.$$

The proof of Theorem 8 is completed. ■

Proof [of Theorem 9] The desired estimate is an easy consequence if we combine the estimates in Proposition 15 and Proposition 10 *(ii)* for case (i), Proposition 15 and Proposition 11 *(iv)* for case (ii), respectively, and choose

$$h_n = \left((\log n)^{(2+\gamma)/\gamma}/n\right)^{\frac{1}{2\alpha+d}}.$$

We omit the details of the proof here. ■

To prove the initial Examples 4 and 5, we need the following lemma.

Lemma 25 *Let $g : \mathbb{R} \to [0,\infty)$ be an Lebesgue integrable function with $f(x) = 0$ for all $x \notin [0,1]$ and $f(x) \leq cx^{-\gamma}$ for some constants $c > 0$ and $\gamma \in [0,1)$ and all $x \in (0, 1/2]$. We define $r(x) := |x|/2$ for $x \in \mathbb{R}$. Then for all $h \in (0, 1/8]$ we have the following two inequalities.*

$$\int_{r(x)\leq h} f(x)\,\mathrm{d}x \leq \frac{2c}{1-\gamma} h^{1-\gamma}$$

$$h^{-1}\int_{-h}^{1/2}\int_{r(x)\leq|x'|\leq h} f(x+x')\,\mathrm{d}x'\,\mathrm{d}x \leq \frac{10c}{1-\gamma} h^{1-\gamma}.$$

Proof [of Lemma 25] The first inequality simply follows from

$$\int_{r(x)\le h} f(x)\,\mathrm{d}x = \int_0^{2h} f(x)\,\mathrm{d}x \le c\int_0^{2h} x^{-\gamma}\,\mathrm{d}x \le \frac{2c}{1-\gamma}h^{1-\gamma}\,.$$

For the proof of the second inequality, we first observe that, for $x\in[0,2h]$, we have

$$\begin{aligned}\int\limits_{r(x)\le|x'|\le h} f(x+x')\,\mathrm{d}x' &= \int\limits_{x\le 2|x'|\le 2h} f(x+x')\,\mathrm{d}x'\\ &= \int\limits_{-h}^{-x/2} f(x+x')\,\mathrm{d}x' + \int\limits_{x/2}^{h} f(x+x')\,\mathrm{d}x'\\ &= \int\limits_{-h+x}^{x/2} f(x')\,\mathrm{d}x' + \int\limits_{3x/2}^{h+x} f(x')\,\mathrm{d}x'. \end{aligned} \tag{41}$$

Let us consider the first term in the last equation. For the case where $x\in[0,h)$, we have

$$\int_{-h+x}^{x/2} f(x')\mathrm{d}x' = \int_0^{x/2} f(x')\mathrm{d}x' \le c\int_0^{x/2}(x')^{-\gamma}\mathrm{d}x' = \frac{c}{1-\gamma}\left(\frac{x}{2}\right)^{1-\gamma} \le \frac{c}{1-\gamma}h^{1-\gamma},$$

and for the case where $x\in(h,2h]$, we have

$$\int_{-h+x}^{x/2} f(x')\mathrm{d}x' \le c\int_{-h+x}^{x/2}(x')^{-\gamma}\mathrm{d}x' = \frac{c}{1-\gamma}\left[\left(\frac{x}{2}\right)^{1-\gamma} - (x-h)^{1-\gamma}\right] \le \frac{c}{1-\gamma}h^{1-\gamma}.$$

Therefore, for all $x\in[0,2h]$, we obtain

$$\int_{-h+x}^{x/2} f(x')\mathrm{d}x' \le \frac{c}{1-\gamma}h^{1-\gamma}. \tag{42}$$

On the other hand, for the second term, there holds

$$\begin{aligned}\int_{3x/2}^{h+x} f(x')\mathrm{d}x' \le c\int_{3x/2}^{h+x}(x')^{-\gamma}\mathrm{d}x' &= \frac{c}{1-\gamma}\left[(h+x)^{1-\gamma} - \left(\frac{3x}{2}\right)^{1-\gamma}\right]\\ &\le \frac{c}{1-\gamma}(3h)^{1-\gamma} \le \frac{3c}{1-\gamma}h^{1-\gamma}. \end{aligned} \tag{43}$$

Combining the estimates (41), (42), and (43), we obtain

$$\int\limits_{r(x)\le|x'|\le h} f(x+x')\,\mathrm{d}x' \le \frac{4c}{1-\gamma}h^{1-\gamma}\,,$$

while for $x\in(2h,1/2]$ the integral vanishes since $\{x' : r(x)\le|x'|\le h\}=\emptyset$. Moreover, for $x\in[-h,0)$, we have

$$\begin{aligned}\int\limits_{r(x)\le|x'|\le h} f(x+x')\,\mathrm{d}x' = \int\limits_{-x\le 2|x'|\le 2h} f(x+x')\,\mathrm{d}x' &= \int\limits_{-2h\le 2x'\le x} f(x+x')\,\mathrm{d}x' + \int\limits_{-x}^{2h} f(x+x')\,\mathrm{d}x'\\ &= \int_{-x}^{2h} f(x+x')\,\mathrm{d}x'\\ &\le c\int_0^{2h+x}(x')^{-\gamma}\,\mathrm{d}x'\\ &\le \frac{2c}{1-\gamma}h^{1-\gamma}\,. \end{aligned}$$

We these estimates we then conclude that

$$\int_{-h}^{1/2}\int_{r(x)\le|x'|\le h} f(x+x')\,\mathrm{d}x'\,\mathrm{d}x = \int_{-h}^{2h}\int_{r(x)\le|x'|\le h} f(x+x')\,\mathrm{d}x'\,\mathrm{d}x \tag{44}$$

$$\le \frac{10c}{1-\gamma}h^{2-\gamma}\,, \tag{45}$$

and hence we have shown the assertion. ■

Proof [of Example 4] We can choose $R=1$, $\Omega^{+hR}=\Omega^{+h}=[-h,1+h]$, and

$$X_h^* = (-\infty,-h)\cup(2h,1-2h)\cup(1+h,\infty)\,.$$

Moreover, we have already seen in Example 3 that we can pick $\alpha=1$ with bounded function $x\mapsto c(x)$. Consequently, *(iv)* of Proposition 11 shows

$$\sup_{x\in X_h^*}|f_{P,h}(x)-f(x)| \le c\,h$$

for some constant $c>0$ and all $h>0$. Moreover, Lemma 25 applied to both critical points $x=0$ and $x=1$ with $\gamma=0$ in combination with *(iii)* of Proposition 11 shows

$$\|f_{P,h}-f\|_1 \le c\,h$$

for another constant $c>0$ and all $h\in(0,1/8]$. Proposition 14 then yields the assertion. ■

Proof [of Example 5] We again choose $R=1$, $\Omega^{+hR}=\Omega^{+h}=[-h,1+h]$, and

$$H(\infty) = \int_{\mathbb{R}} c(x)\,\mathrm{d}x < \infty$$

Consequently, Lemma 25 applied to both critical points $x=0$ and $x=1$ with $\gamma=1/2$ in combination with *(iii)* of Proposition 11 shows

$$\|f_{P,h}-f\|_1 \le c\,h^{\alpha}$$

for some constant $c>0$ and all $h\in(0,1/8]$. Again, Proposition 14 then yields the desired result. ■

7. Conclusion

In the present paper, we studied the kernel density estimation problem for dynamical systems admitting a unique invariant Lebesgue density by using the $\mathcal{C}$-mixing coefficient to measure the dependence among observations. The main results presented in this paper are the consistency and convergence rates of the kernel density estimator in the sense of L_1-norm and L_∞-norm. With a properly chosen bandwidth, we showed that the kernel density estimator is universally consistent. Under mild assumptions on the kernel function and the density function, we established convergence rates for the estimator. For instance, when the density function is bounded and compactly supported, both L_1-norm and L_∞-norm convergence rates with the same order can be achieved for general geometrically time-reversed $\mathcal{C}$-mixing dynamical systems. The convergence mentioned here is of type "with high probability" due to the use of a Bernstein-type exponential inequality and this makes the present study different from the existing related studies. We also discussed the model selection problem of the kernel density estimation in the dynamical system context by carrying out numerical experiments.

Abstract

Methods of transfer learning try to combine knowledge from several related tasks (or domains) to improve performance on a test task. Inspired by causal methodology, we relax the usual covariate shift assumption and assume that it holds true for a *subset* of predictor variables: the conditional distribution of the target variable given this subset of predictors is invariant over all tasks. We show how this assumption can be motivated from ideas in the field of causality. We focus on the problem of Domain Generalization, in which no examples from the test task are observed. We prove that in an adversarial setting using this subset for prediction is optimal in Domain Generalization; we further provide examples, in which the tasks are sufficiently diverse and the estimator therefore outperforms pooling the data, even on average. If examples from the test task are available, we also provide a method to transfer knowledge from the training tasks and exploit all available features for prediction. However, we provide no guarantees for this method. We introduce a practical method which allows for automatic inference of the above subset and provide corresponding code. We present results on synthetic data sets and a gene deletion data set.

Keywords: Transfer learning, Multi-task learning, Causality, Domain adaptation, Domain generalization.

1. Introduction

Standard approaches to supervised learning assume that training and test data can be modeled as an i.i.d. sample from a distribution $\mathbb{P} := \mathbb{P}^{(\mathbf{X},Y)}$. The inputs $\mathbf{X}$ are often vectorial, and the outputs Y may be labels (classification) or continuous values (regression). The i.i.d. setting is theoretically well understood and yields remarkable predictive accuracy in problems such as image classification, speech recognition and machine translation (e.g., Schmidhuber, 2015; Krizhevsky et al., 2012). However, many real world problems do not fit into this setting. The field of transfer learning attempts to address the scenario in which distributions may change between training and testing. We focus on two different problems within transfer learning: domain generalization and multi-task learning. We begin by describing these two problems, followed by a discussion of existing assumptions made to address the problem of knowledge transfer, as well as the new assumption we assay in this paper.

1.1 Domain generalization and multi-task learning

Assume that we want to predict a target $Y \in \mathbb{R}$ from some predictor variable $\mathbf{X} \in \mathbb{R}^p$. Consider D training (or source) tasks[1] $\mathbb{P}^1, \dots, \mathbb{P}^D$ where each $\mathbb{P}^k$ represents a probability distribution generating data $(\mathbf{X}^k, Y^k) \sim \mathbb{P}^k$. At training time, we observe a sample $\left(\mathbf{X}_i^k, Y_i^k\right)_{i=1}^{n_k}$ for each source task $k \in \{1, \dots, D\}$; at test time, we want to predict the target values of an unlabeled sample from the task T of interest. We wish to learn a map $f : \mathbb{R}^p \to \mathbb{R}$ with small expected squared loss $\mathcal{E}_{\mathbb{P}^T}(f) = \mathbb{E}_{(\mathbf{X}^T, Y^T) \sim \mathbb{P}^T}(Y^T - f(\mathbf{X}^T))^2$ on the test task T.

In domain generalization (DG) (e.g., Muandet et al., 2013), we have $T = D + 1$, that is, we are interested in using information from the source tasks in order to predict Y^{D+1} from $\mathbf{X}^{D+1}$ in a related yet unobserved test task $\mathbb{P}^{D+1}$. To beat simple baseline techniques, regularity conditions on the differences of the tasks are required. Indeed, if the test task differs significantly from the source tasks, we may run into the problem of negative transfer (Pan and Yang, 2010) and DG becomes impossible (Ben-David et al., 2010).

If examples from the test task are available during training (e.g., Pan and Yang, 2010; Baxter, 2000), we refer to the problem as asymmetric multi-task learning (AMTL). If the objective is to improve performance in all the training tasks (e.g., Caruana, 1997), we call the problem symmetric multi-task learning (SMTL), see Table 1 for a summary of these settings. In multi-task learning (MTL), which includes both AMTL and SMTL, if infinitely many labeled data are available from the test task, it is impossible to beat a method that learns on the test task and ignores the training tasks.

1.2 Prior work

A first family of methods assumes that **covariate shift** holds (e.g., Quionero-Candela et al., 2009; Schweikert et al., 2009). This states that for all $k \in \{1, \dots, D, T\}$, the conditional distributions $Y^k \,|\, \mathbf{X}^k$ are **invariant** between tasks. Therefore, the differences in the joint distribution of $\mathbf{X}^k$ and Y^k originate from a difference in the marginal distribution of $\mathbf{X}^k$. Under covariate shift, for instance, if an unlabeled sample from the test task is available at training in the DG setting, the training sample can be re-weighted via importance sampling (Gretton et al., 2009; Shimodaira, 2000; Sugiyama et al., 2008) so that it becomes representative of the test task.

∗. Most of this work was done while JP was at the Max Planck Institute for Intelligent Systems in Tübingen.

1. In this work, we use the expression "task" and "domain" interchangeably.

method	training data from	test domain
Domain Generalization (DG)	$(\mathbf{X}^1, Y^1), \ldots, (\mathbf{X}^D, Y^D)$	$T := D + 1$
	$(\mathbf{X}^1, Y^1), \ldots, (\mathbf{X}^D, Y^D), \mathbf{X}^{D+1}$	
Asymm. Multi-Task Learning (AMTL)	$(\mathbf{X}^1, Y^1), \ldots, (\mathbf{X}^D, Y^D)$	$T := D$
	$(\mathbf{X}^1, Y^1), \ldots, (\mathbf{X}^D, Y^D), \mathbf{X}^D$	
Symm. Multi-Task Learning (SMTL)	$(\mathbf{X}^1, Y^1), \ldots, (\mathbf{X}^D, Y^D)$	all
	$(\mathbf{X}^1, Y^1), \ldots, (\mathbf{X}^D, Y^D), \mathbf{X}^1, \ldots, \mathbf{X}^D$	

Table 1: Taxonomy for domain generalization (DG) and multi-task learning (AMTL and SMTL). Each problem can either be used without (first line) or with (second line) additional unlabeled data.

Another line of work focuses on **sharing parameters** between tasks. This idea originates in the hierarchical Bayesian literature (Bonilla et al., 2007; Gao et al., 2008). For instance, Lawrence and Platt (2004) introduce a model for MTL in which the mapping f_k in each task $k \in \{1, \ldots, D, T\}$ is drawn independently from a common Gaussian Process (GP), and the likelihood of the latent functions depends on a shared parameter θ. A similar approach is introduced by Evgeniou and Pontil (2004): they consider an SVM with weight vector $w^k = w_0 + v^k$, where w_0 is shared across tasks and v^k is task specific. This allows for tasks to be similar (in which case v^k does not have a significant contribution to predictions) or quite different. Daumé III et al. (2010) use a related approach for MTL when there is one source and one target task. Their method relies on the idea of augmented feature space, which they obtain using two features maps $\Phi^s(\mathbf{X}^s) = (\mathbf{X}^s, \mathbf{X}^s, 0)$ for the source examples and $\Phi^t(\mathbf{X}^t) = (\mathbf{X}^t, 0, \mathbf{X}^t)$ for the target examples. They then train a classifier using these augmented features. Moreover, they propose a way of using available unlabeled data from the target task at training.

An alternative family of methods is based on learning a set of **common features** for all tasks (Argyriou et al., 2007a; Romera-Paredes et al., 2012; Argyriou et al., 2007b; Raina et al., 2007). For instance, Argyriou et al. (2007a,b) propose to learn a set of low dimensional features shared between tasks using L^1 regularization, and then learn all tasks independently using these features. In Raina et al. (2007), the authors construct a similar set of features using L^1 regularization but make use of only unlabeled examples. Chen et al. (2012) proposes to build shared feature mappings which are robust to noise by using autoencoders.

Finally, the assumption introduced in this paper is based on a **causal** view on domain adaptation and transfer.

Schölkopf et al. (2012) relate multi-task learning with the independence between cause and mechanism. This notion is closely related to exogeneity (Zhang et al., 2015b), which roughly states that a causal mechanism mapping a cause X to Y should not depend on the distribution of X. Additionally, Zhang et al. (2013) consider the problem of target and conditional shift when the target variable is causal for the features. They assume that there exists a linear mapping between the covariates in different tasks, and the parameters of this

mapping only depend on the distribution of the target variable. Moreover, Zhang et al. (2015a) argue that the availability of multiple domains is sufficient to drop this previous assumption when the distribution of Y^k and the conditional $\mathbf{X}^k \,|\, Y^k$ change independently. The conditional in the test task can then be written as a linear mixture of the conditionals in the source domains. The concept of invariant conditionals and exogeneity can also be used for causal discovery (Peters et al., 2016; Zhang et al., 2015b; Peters et al., 2017).

1.3 Contribution

Taking into account causal knowledge, **our approach** to DG and MTL assumes that covariate shift holds only for a subset of the features. From the point of view of causal modeling (Pearl, 2009), assuming invariance of conditionals makes sense if the conditionals represent causal mechanisms (e.g., Hoover, 1990), see Section 2.3 for details. Intuitively, we expect that a causal mechanism is a property of the physical world, and it does not depend on what we feed into it. If the input (which in this case coincides with the covariates) shifts, the mechanism should thus remain invariant (Hoover, 1990; Janzing and Schölkopf, 2010; Peters et al., 2016). In the anticausal direction, however, a shift of the input usually leads to a changing conditional (Schölkopf et al., 2012). In practice, prediction problems are often not causal — we should allow for the possibility that the set of predictors contains variables that are causal, anticausal, or confounded, i.e., statistically dependent variables without a directed causal link with the target variable. We thus expect that there is a *subset* S^* of predictors, referred to as an **invariant set**, for which the covariate shift assumption holds true, i.e., the conditionals of output given predictor $Y^k \,|\, \mathbf{X}^k_{S^*}$ are invariant across $k \in \{1, \ldots, D, T\}$. If S^* is a strict subset of all predictors, this relaxes full covariate shift. We prove that knowing S^* leads to robust properties for DG. Once an invariant set is known, traditional methods for covariate shift can be applied as a black box, see Figure 1. In the MTL setting, when labeled or unlabeled examples from the test task are available during training, we might not want to discard the features outside of S^* for prediction. Hence, we also propose a method to leverage the knowledge of the invariant set S^* and the available examples from the test task in order to outperform a method that learns only on the test task.

Finally, note that in this work, we concentrate on the linear setting, keeping in mind that this has specific implications for covariate shift.

1.4 Organization of the paper

Section 2 formally describes our approach and its underlying assumptions; in particular, we assume that an invariant set S^* is known. For DG, we prove in Section 2.1 that predicting using only features in S^* is optimal in an adversarial setting. Moreover, we present an example in which we compare our proposed estimator with pooling the training data, a standard technique for DG. In MTL, when additional labeled examples from T are available, one might want to use all available features for prediction. Section 2.2 provides a method to address this. We discuss a link to causal inference in Section 2.3. Often, an invariant set S^* is not known a priori. Section 3 presents a method for inferring an invariant set from data. Section 4 contains experiments on simulated and real data.

2. Exploiting invariant conditional distributions in transfer learning

Consider a transfer learning regression problem with source tasks $\mathbb{P}^1, \ldots, \mathbb{P}^D$, where $(\mathbf{X}^k, Y^k) \sim \mathbb{P}^k$ for $k \in \{1, \ldots, D\}$.[2] We now formulate our main assumptions.

(A1) There exists a subset $S^* \subseteq \{1, \ldots, p\}$ of predictor variables such that

$$Y^k \,|\, \mathbf{X}^k_{S^*} \overset{d}{=} Y^{k'} \,|\, \mathbf{X}^{k'}_{S^*} \quad \forall k, k' \in \{1, \ldots, D\}. \tag{1}$$

We say that S^* is an **invariant set** which leads to invariant conditionals. Here, $\overset{d}{=}$ denotes equality in distribution.

(A1') This invariance also holds in the test task T, i.e., (1) holds for all $k, k' \in \{1, \ldots, D, T\}$.

(A2) The conditional distribution of Y given an invariant set S^* is linear: there exists $\alpha \in \mathbb{R}^{|S^*|}$ and a random variable ϵ such that for all $k \in \{1, \ldots, D\}$, $[Y^k \,|\, \mathbf{X}^k_{S^*} = x] \overset{d}{=} \alpha^t x + \epsilon^k$, that is $Y^k = \alpha^t \mathbf{X}^k_{S^*} + \epsilon^k$, with $\epsilon^k \perp\!\!\!\perp \mathbf{X}^k_{S^*}$ and for all $k \in \{1, \ldots, D\}$, $\epsilon^k \overset{d}{=} \epsilon$.

Assumption (A1') is stronger than (A1) only in the DG setting, where, of course, (A1') and (A2) imply the linearity also in the test task T. While Assumption (A1) is testable from training data, see Section 3, (A1') is not. In covariate shift, one usually assumes that (A1') holds for the set of all features. Therefore, (A1') is a weaker condition than covariate shift, see Figure 1. We regard this assumption as a building block that can be combined with any method for covariate shift, applied to the subset S^*. It is known that it can be arbitrarily hard to exploit the assumption of covariate shift in practice (Ben-David et al., 2010). In a general setting, for instance, assumptions about the support of the training distributions $\mathbb{P}^1, \ldots, \mathbb{P}^D$ and the test distribution $\mathbb{P}^T$ must be made for methods such as re-weighting to be expected to work (e.g., Gretton et al., 2009). The aim of our work is not to solve the full covariate shift problem, but to elucidate a relaxation of covariate shift in which it holds given only a subset of the features. We concentrate on linear relations (A2), which circumvents the issue of overlapping supports, for example.

For the remainder of this section, we assume that we are given an invariant subset S^* that satisfies (A1) and (A2). Note that we will also require (A1') for DG. In MTL, the invariance can be tested on the labeled data available from the test task, so (A1) and (A1') are equivalent.

We show how the knowledge of S^* can be exploited for the DG problem (Section 2.1) and in the MTL case (Section 2.2). Here and below, we focus on linear regression using squared loss

$$\mathcal{E}_{\mathbb{P}^T}(\beta) = \mathbb{E}_{(\mathbf{X}^T, Y^T) \sim \mathbb{P}^T}(Y^T - \beta^t \mathbf{X}^T)^2 \tag{2}$$

(the superscript T corresponds to the test task, not to be confused with the transpose, indicated by superscript t). We denote by $\mathcal{E}_{\mathbb{P}^1, \ldots, \mathbb{P}^D}(\beta)$ the squared error averaged over the training tasks $k \in \{1, \ldots, D\}$.

2. We assume throughout this work the existence of densities and that random variables have finite variance.

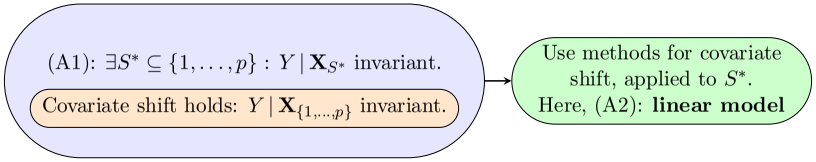

Figure 1: Assumption (A1) (blue) is a relaxation of covariate shift (orange): the covariate shift assumption is a special case of (A1) with $S^* = \{1, \ldots, p\}$. Given the invariant set S^*, methods for covariate shift can be applied.

2.1 Domain generalization (DG): no labels from the test task

We first study the DG setting in which we receive no labeled examples from the test task during training time. Throughout this subsection, we assume that additionally to (A1) and (A2), assumption (A1') holds. It is important to appreciate that (A1') is a strong assumption that is not testable on the training data: it is an assumption about the test task. We believe no nontrivial statement about DG is possible without an assumption of this type.

Now, we introduce our proposed estimator, which uses the conditional mean of the target variable given the invariant set in the training tasks. We prove that this estimator is optimal in an adversarial setting.

Proposed estimator. The optimal predictor obtained by minimizing (2) is the conditional mean

$$\beta^{opt} := \arg\min_{\beta \in \mathbb{R}^p} \mathcal{E}_{\mathbb{P}^T}(\beta), \tag{3}$$

which is not available during training time. Given an invariant set S^* satisfying (A1), (A1') and (A2), we propose to use the corresponding conditional expectation as an estimator. In other words, let $\beta^{S^*} = \arg\min_{\beta \in \mathbb{R}^{|S^*|}} (Y^1 - \beta^t \mathbf{X}^1_{S^*})^2$ be the vector obtained by minimizing the squared loss in the training tasks using only predictors in S^*. We propose as a predictor the vector $\beta^{CS(S^*)} \in \mathbb{R}^p$ obtained by adding zeros to β^{S^*} in the dimensions corresponding to covariates outside of S^*. More formally, we propose to use as a predictor

$$\begin{array}{ccc} \mathbb{R}^p & \to & \mathbb{R} \\ \mathbf{x} & \mapsto & \mathbb{E}[Y^1 \,|\, \mathbf{X}^1_{S^*} = \mathbf{x}_{S^*}] \end{array} \quad \text{and write} \quad \mathbb{E}[Y^1 \,|\, \mathbf{X}^1_{S^*} = \mathbf{x}_{S^*}] = \left(\beta^{CS(S^*)}\right)^t \mathbf{x}. \tag{4}$$

Because of (A1), the conditional expectation in (4) is the same in all training tasks. In the limit of infinitely many data, given a subset S, $\beta^{CS(S)}$ is obtained by pooling the training tasks and regressing using only features in S. In particular, $\beta^{CS} := \beta^{CS(\{1,\ldots,p\})}$ is the estimator obtained when assuming traditional covariate shift.

Optimality in an adversarial setting. In an adversarial setting, predictor (4) satisfies the following optimality condition; as for the other results, the proof is provided in Appendix A. We state and prove a more general, nonlinear version of Theorem 1 in Appendix A.1.

Theorem 1 (Adversarial) *Consider* $(\mathbf{X}^1, Y^1) \sim \mathbb{P}^1$,..., $(\mathbf{X}^D, Y^D) \sim \mathbb{P}^D$ *and an invariant set* S^* *satisfying (A1) and (A2). The proposed estimator satisfies an optimality statement over the set of distributions such that (A1') holds: we have*

$$\beta^{CS(S^*)} \in \arg\min_{\beta \in \mathbb{R}^p} \sup_{\mathbb{P}^T \in \mathcal{P}} \mathcal{E}_{\mathbb{P}^T}(\beta),$$

where $\beta^{CS(S^*)}$ *is defined in* (4) *and* $\mathcal{P}$ *contains all distributions over* $(\mathbf{X}^T, Y^T)$, $T = D + 1$, *that are absolutely continuous with respect to the same product measure* μ *and satisfy* $Y^T \,|\, \mathbf{X}^T_{S^*} \stackrel{d}{=} Y^1 \,|\, \mathbf{X}^1_{S^*}$.

Unlike the optimal predictor β^{opt}, the proposed estimator (4) can be learned from the data available in the training tasks. Given a sample $(\mathbf{X}^k_1, Y^k_1), \ldots, (\mathbf{X}^k_{n_k}, Y^k_{n_k})$ from tasks $k \in \{1, \ldots, D\}$, we can estimate the conditional mean in (4) by regressing Y^k on $\mathbf{X}^k_{S^*}$. Due to (A1), we may also pool the data over the different tasks and use

$$(\mathbf{X}^1_1, Y^1_1), \ldots, (\mathbf{X}^1_{n_1}, Y^1_{n_1}), (\mathbf{X}^2_1, Y^2_1), \ldots, (\mathbf{X}^D_{n_D}, Y^D_{n_D})$$

as a training sample for this regression.

One may also compare the proposed estimator with pooling the training tasks, a standard baseline in transfer learning which corresponds to assuming that usual covariate shift holds. Focusing on a specific example, Proposition 2 in the following paragraph shows that when the test tasks become diverse, predicting using (4) outperforms pooling on average over all tasks.

Comparison against pooling the data. We proved that the proposed estimator (4) does well on an adversarial setting, in the sense that it minimizes the largest error on a task in $\mathcal{P}$. The following result provides an example in which we can analytically compare the proposed estimator with the estimator obtained from pooling the training data, which is a benchmark in transfer learning. We prove that in this setting, the proposed estimator outperforms pooling the data on average over test tasks when the tasks become more diverse.

Let $\mathbf{X}^k_{S^*}$ be a vector of independent Gaussian variables in task k. Let the target Y^k satisfy

$$Y^k = \alpha^t \mathbf{X}^k_{S^*} + \epsilon^k, \tag{5}$$

where for each $k \in \{1, \ldots, D\}$, ϵ^k is Gaussian and independent of $\mathbf{X}^k_{S^*}$. We have $\mathbf{X}^k = (\mathbf{X}^k_{S^*}, Z^k)$, where

$$Z^k = \gamma^k Y^k + \eta^k,$$

for some $\gamma^k \in \mathbb{R}$ and where η^k is Gaussian and independent of Y^k.[3] Moreover, assume that the training tasks are balanced. We compare properties of estimator $\beta^{CS(S^*)}$ defined in Equation (4) against the least squares estimator obtained from pooling the training data. In this setting, the tasks differ in coefficients γ^k, which are randomly sampled. We prove that the squared loss averaged over unseen test tasks is always larger for the pooled approach, when coefficients γ^k are centered around zero. In the case where they are centered around a non-zero mean, we prove that when the variance between tasks (in this case, for coefficients γ^k) becomes large enough, the invariant approach also outperforms pooling the data.

3. Using the notation introduced later in Section 2.3, this corresponds to a Gaussian SEM with DAG shown in Fig. 3.

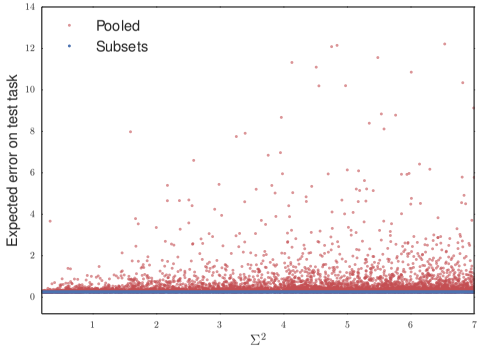

Figure 2: The figure shows expected errors for the pooled approach and the proposed method, see Equation (6). $\mu = 0$. We consider two training tasks over $10,000$ simulations. In each, we randomly sample the variance of each covariate in $\mathbf{X}$, the variance of η, and γ. σ^2 is the same in all tasks. As predicted by Proposition Proposition 2 observe that the error from the pooled approach (red) is systematically higher than the error from the prediction using only the invariant subset (blue), and both the error and its variance become large as the variance Σ^2 of coefficients γ^k increases.

Proposition 2 (Average performance) *Consider the model described previously. Moreover, assume that the tasks differ as follows: the coefficients* $\gamma^1, \ldots, \gamma^D, \gamma^T = \gamma^{D+1}$ *are i.i.d. with mean zero and variance* $\Sigma^2 > 0$. *The tasks do not differ elsewhere. In particular, the distribution of* $X^k_{S^*}$ *is the same for all tasks. Then the least squares predictor obtained from pooling the* D *training tasks* $\beta^{CS} = (\beta^{CS}_{S^*}, \beta^{CS}_Z)$ *satisfies:*

$$\mathbb{E}_{\gamma^T}\left(\mathcal{E}_{\mathbb{P}^T}\left(\beta^{CS}\right)\right) \geq \mathbb{E}_{\gamma^T}\left(\mathcal{E}_{\mathbb{P}^T}\left(\beta^{CS(S^*)}\right)\right) = \sigma^2. \tag{6}$$

In particular, this implies the following:

$$\mathbb{E}_{\gamma^1,\ldots,\gamma^D,\gamma^T}\left(\mathcal{E}_{\mathbb{P}^T}\left(\beta^{CS}\right)\right) \geq \mathbb{E}_{\gamma^1,\ldots,\gamma^D,\gamma^T}\left(\mathcal{E}_{\mathbb{P}^T}\left(\beta^{CS(S^*)}\right)\right) = \sigma^2. \tag{7}$$

Moreover, if the coefficients $\gamma^1, \ldots, \gamma^D, \gamma^T$ *are i.i.d. with non-zero mean* μ, (6) *holds for fixed* $\gamma^1, \ldots, \gamma^D$ *if* $\Sigma^2 \geq P(\mu)$, *where* P *is a polynomial in* μ, *see Appendix A.2 for details.*

The proof of Proposition 2 can be found in Appendix A.2. Figure 2 visualizes Proposition 2 for two training tasks, it shows the expected errors for the pooled and invariant approaches, see (6), as the variance Σ^2 increases. Recall that Σ^2 corresponds to the variance of coefficients γ^k, and thus indicates how different the tasks are. The expected errors are computed using the analytic expression found in the proof of Proposition 2. As predicted by Proposition 2, the expected error of the pooled approach always exceeds the one of the proposed method (the coefficients γ^k are centered around zero), see Equation (6). As Σ^2 tends to

zero, γ^k is close to zero in all tasks, which explains the equality of both the pooled and invariant errors for the limit case Σ approaching 0. For coefficients γ^k centered around a non zero value, Equation (6) does not necessarily hold for small Σ^2.

Proposition 2 presents a setting in which the invariant approach outperforms pooling the data when the test errors are averaged over γ, i.e., $\mathbb{E}_{\gamma^T}\left(\mathcal{E}_{\mathbb{P}^T}\left(\beta^{CS}\right)\right) \geq \mathbb{E}_{\gamma^T}\left(\mathcal{E}_{\mathbb{P}^T}\left(\beta^{CS}\right)\right)$. It is also clear to see that the equality of the distribution of ϵ^k in Equation (5) for all $k \in \{1,\dots,D\}$ leads to $\mathrm{Var}_\gamma\left(\mathcal{E}_{\mathbb{P}^T}\left(\beta^{CS(S^*)}\right)\right) = 0$, thus our invariant estimator minimizes the variance of the test errors across all related tasks.

2.2 Multi-task learning (MTL): combining invariance and task-specific information

In MTL, a labeled sample $\left(\mathbf{X}_i^T, Y_i^T\right)_{i=1}^{n_T}$ is available from the test task and the goal is to transfer knowledge from the training tasks. As before, we are given an invariant set S^* satisfying (A1) and (A2). Can we combine the invariance assumption with the new labeled sample and perform better than a method that trains only on the data in the test task? According to (A1) and (A2), the target satisfies $Y^k = \alpha^t \mathbf{X}_{S^*}^k + \epsilon^k$, where the noise ϵ^k has zero mean and finite variance, is independent of $\mathbf{X}_{S^*}^k$ and has the same distribution in the different tasks $k \in \{1,\dots,D,T\}$. Our objective is to use the knowledge gained from the training tasks to get a better estimate of β^{opt} defined in Equation (3). We describe below a way to tackle this using missing data methods.

Missing data approach In this section, we specify how we propose to tackle MTL by framing it as a missing data problem. While the idea is presented in the context of AMTL, it can be used for SMTL in the same way. In order to motivate the method, assume that for each $k \in \{1,\dots,D,T\}$, there exists another probability distribution $\mathbb{Q}^k$ with density q^k having the following properties: (i) when restricted to $(\mathbf{X}_{S^*}^k, Y^k)$, $\mathbb{Q}^k$ coincides with $\mathbb{P}^k$, (ii) the conditional $q^T(y \,|\, \mathbf{x}_{S^*}, \mathbf{x}_N)$ coincides with $p^T(y \,|\, \mathbf{x}_{S^*}, \mathbf{x}_N)$ on the test task and (iii) $q(y \,|\, \mathbf{x}_{S^*}, \mathbf{x}_N) := q^k(y \,|\, \mathbf{x}_{S^*}, \mathbf{x}_N)$ is the same in all tasks (which is not satisfied by $\mathbb{P}^k$, of course). The goal of learning the regression model from Y on $\mathbf{X}_{S^*}$ and $\mathbf{X}_N$ in $\mathbb{P}^T$ coincides with the task of learning the same regression model in $\mathbb{Q}^T$. Property (iii) implies that we can pool the data from all tasks $\mathbb{Q}^k$. This is not possible, of course, for the given data, which we have received from the distributions $\mathbb{P}^k$. But now assume that in all training tasks, we only have access to the marginal $(\mathbf{X}_{S^*}^k, Y^k)$ from $\mathbb{Q}^k$. Any method that addresses the regression under these constraints be used with the data available because of (i). We first prove the existence of such distributions $\mathbb{Q}^k$:

Proposition 3 (Correctness of transfer) *Let S^* be an invariant set verifying (A1) and (A2). For $k \in \{1,\dots,D,T\}$, denote by $(\mathbf{x}, y) \mapsto p^k(\mathbf{x}, y)$ the density of $\mathbb{P}^k$. Then there exists a function $q : \mathbb{R}^p \to \mathbb{R}^+$ such that for each $k \in \{1,\dots,D,T\}$, there exists a distribution $\mathbb{Q}^k$ with density q^k such that for all $(\mathbf{x}, y) \in \mathbb{R}^{d+1}$, for all $k \in \{1,\dots,D,T\}$,*

i) $q^k(\mathbf{x}_{S^*}, y) = p^k(\mathbf{x}_{S^*}, y)$,
ii) $q^T(y \,|\, \mathbf{x}_{S^*}, \mathbf{x}_N) = p^T(y \,|\, \mathbf{x}_{S^*}, \mathbf{x}_N)$,
iii) $q^k(y \,|\, \mathbf{x}_{S^*}, \mathbf{x}_N) = q(y \,|\, \mathbf{x}_{S^*}, \mathbf{x}_N)$.

The proof for Proposition 3 can be found in Appendix A.3. Following the previous intuition, for the training tasks $k \in \{1,\dots,D\}$, we hide the data of $\mathbf{X}_N^k$ and pretend the data in each

task $k \in \{1,\dots,D,T\}$ come from $\mathbb{Q}^k$. Note that some of the data are only missing for the training tasks. More precisely, $\mathbf{X}_N^k$ is missing for $k \in \{1,\dots,D\}$, while because of (i) in Proposition 3, $(\mathbf{X}_{S^*}^k, Y^k)$ is available for all tasks $k \in \{1,\dots,D,T\}$. We thus pool the data and learn a regression model of Y versus $(\mathbf{X}_{S^*}, \mathbf{X}_N)$ by maximizing the likelihood of the observed data.

We formalize the problem as follows. Let $(\mathbf{Z}_i)_{i=1}^n = (\mathbf{X}_{S^*,i}, \mathbf{X}_{N,i}, Y_i)_{i=1}^n$ be a pooled sample of the available data from the training tasks and the test task, in which $\mathbf{X}_{N,i}$ is considered missing if $\mathbf{X}_i$ is drawn from one of the training tasks. Here, $n = \sum_{k=1}^T n_k$ is the total number of training and test examples. Denote by $\mathbf{Z}_{obs,i}$ the components of $\mathbf{Z}_i$ which are not missing. In particular, $\mathbf{Z}_{obs,i} = \mathbf{Z}_i$ if i is drawn from the test task and $\mathbf{Z}_{obs,i} = (\mathbf{X}_{S^*,i}, Y_i)$ otherwise. Moreover, let Σ be a $(p+1) \times (p+1)$ positive definite matrix, and Σ_i is the submatrix of Σ which corresponds to the observed features for example i. If example i is drawn from a training task, Σ_i is of size $(|S^*|+1) \times (|S^*|+1)$, and $(p+1) \times (p+1)$ otherwise. The log-likelihood based on the observed data for matrix Σ satisfies:

$$\ell(\Sigma) = \text{const} - \frac{1}{2}\sum_{i=1}^{n} \det\left(\Sigma_i\right) - \frac{1}{2}\mathbf{Z}_{obs,i}^T \Sigma_i^{-1} \mathbf{Z}_{obs,i}, \tag{8}$$

and our goal is to find Σ which maximizes (8). This model for the likelihood assumes that the data is multi-variate Gaussian with covariance matrix Σ.

When all data are observed, the least squares estimator β^{opt} can be seen as the result of a two step procedure. First, (8) is maximized for the sample covariance matrix. Then, one computes the conditional mean $\mathbb{E}[Y \,|\, \mathbf{X} = \mathbf{x}]$ of the estimated joint distribution of ($\mathbf{X}$,Y). In the case of missing data, however, the sample covariance matrix does no longer maximize (8), see paragraph *'A naive estimator for comparison'* below. Instead, we maximize (8) using EM.

Chapter 11 in Little and Rubin (1986) provides the update equations for optimizing Equation (8) using EM. More precisely, given an estimate Σ^r of the covariance matrix at step r, the algorithm goes as follows.

E step: For an example i, we define

$$\mathbf{Z}_i^r := \begin{cases} \mathbf{Z}_i \text{ if example } i \text{ is from the test task,} \\ (\mathbf{X}_{S^*,i}, \mathbb{E}(\mathbf{X}_N^r \,|\, \mathbf{Z}_{obs,i}), Y_i) \text{ otherwise.} \end{cases}$$

Here, we are essentially imputing the data for $\mathbf{X}_N$ in the training tasks by the conditional mean given the observed data, using the current estimate of the covariance matrix Σ^r. The conditional expectation is computed using the current estimate Σ^r and the Gaussian conditioning formula:

$$\mathbb{E}(\mathbf{X}_N^r \,|\, \mathbf{Z}_{obs,i}) = \Sigma_{NZ_{obs}}^r (\Sigma_{Z_{obs}}^r)^{-1} \mathbf{Z}_{obs,i},$$

where $\Sigma_{NZ_{obs}}^r$ is the submatrix of Σ^r corresponding to the cross-covariance between $\mathbf{X}_N$ and $(\mathbf{X}_{S^*}, Y)$, and $\Sigma_{Z_{obs}}^r$ is the submatrix corresponding to the covariance of $(\mathbf{X}_{S^*}, Y)$. For examples from the test task, we simply copy the example, since $\mathbb{P}^T = \mathbb{Q}^T$. Moreover, define

$$C_{N,i}^r := \begin{cases} 0 \text{ if example } i \text{ is from the test task,} \\ \mathrm{Cov}(\mathbf{X}_N^r \,|\, \mathbf{Z}_{obs,i}) = \Sigma_N^r - \Sigma_{NZ_{obs}}^r (\Sigma_{Z_{obs}}^r)^{-1} \Sigma_{Z_{obs}N}^r \text{ otherwise.} \end{cases}$$

M step: compute the sample covariance given the imputed data:

$$\Sigma^{r+1} = \frac{1}{n}\mathbb{E}\left(\sum_{i=1}^{n} \mathbf{Z}_i^r (\mathbf{Z}_i^r)^t \,|\, \mathbf{Z}_{obs,i}, \Sigma^r\right) = \frac{1}{n}\sum_{i=1}^{n} \mathbf{Z}_i^r (\mathbf{Z}_i^r)^t + C_i^r,$$

where C_i^r is a $(p+1)\times(p+1)$ matrix whose submatrix corresponding to features in N is $C_{N,i}^r$, and the remaining elements are 0. The intuition for the M step is simple: we compute the sample covariance with the values imputed for $\mathbf{X}_N$. Since these values are being imputed, matrix C adds uncertainty for the corresponding values.

Once the algorithm has converged, we can read off the regression coefficient from the joint covariance matrix as $\mathbb{E}[Y \,|\, \mathbf{X}_{S^*} = \mathbf{x}_{S^*}]$. The whole procedure is initialized with the sample covariance matrix computed with the available labeled sample from T.

Incorporating unlabeled data The previous method also allows us to incorporate unlabeled data from the test task. Indeed, assume that an unlabeled sample $\mathbf{X}^T = (\mathbf{X}_{S^*}^T, \mathbf{X}_N^T)$ from the test task is also available at training time. This can be incorporated in the previous framework since the label Y can be considered to be missing (as opposed to $\mathbf{X}_N^T$ previously). We can then write $\mathbf{Z}_i^r = (\mathbf{X}_{S^*,i}, \mathbf{X}_{N,i}, \mathbb{E}(Y_i^r \,|\, \mathbf{Z}_{obs,i}))$ for the unlabeled data, thus imputing the value of Y in in the E-step by the conditional mean given $(\mathbf{X}_{S^*,i}, \mathbf{X}_{N,i})$. The added covariance is then $C_{Y,i}^r = \mathrm{Var}(Y)^r - \Sigma_{YZ_{obs}}^r (\Sigma_{Z_{obs}}^r)^{-1} \Sigma_{Z_{obs}Y}^r$. The rest of the algorithm remains unchanged.

A naive estimator for comparison In the population setting, Proposition 5 in Appendix A.4 provides an expression for β^{opt} as a function of α and ϵ from Assumption (A2). As in the previous paragraph, one could try to estimate the covariance matrix of $(\mathbf{X}, Y)$ using the knowledge of α and ϵ from the training tasks, and then read off the regression coefficients. In the presence of a finite amount of labeled and unlabeled data from the test task, a naive approach would thus plug in the knowledge of α and ϵ as follows: the entries of $\hat{\Sigma}_{\mathbf{X},Y}$ that correspond to the covariances between $\mathbf{X}_{S^*}$ and Y are replaced with $\hat{\Sigma}_{\mathbf{X}_{S^*}} \cdot \alpha$, and the entry corresponding to the variance of Y is replaced by $\alpha^t \hat{\Sigma}_{\mathbf{X}_{S^*}} \alpha + \mathrm{Var}(\epsilon)$. This, however, often performs worse than forgetting about α and using the data in the test domain only, see Figure 5 (left). Why is this the case? The naive solution described above leads to a matrix Σ that does not only *not* maximize (8) but that often is not even positive definite. One needs to optimize over the free parameters of Σ, which corresponds to the covariance between $\mathbf{X}_N$ and Y, given the constraint of positive definiteness. For comparison, we modified the naive approach as follows. First, we find a positive definite matrix satisfying the desired constraints. In order to do this, we solve a semi-definite Program (SDP) with a trivial objective which always equals zero. Then, we maximize the likelihood (8) over the free parameters of Σ with a Nelder-Mead simplex algorithm. The constrained optimization problem can be shown to be convex in the neighborhood of the optimum (Zwiernik et al., 2017, Sec. 3) if the number of data in the test domain grows. While gradients can be computed for this problem, gradient-based methods seem to perform poorly in practice (experiments are not shown for gradient based methods).

In an idealized scenario, infinite amount of unlabeled data in the test and labeled data in the training tasks could provide us with $\Sigma_{\mathbf{X}}$, $\Sigma_{(\mathbf{X}_{S^*},Y)}$ and $\mathrm{Var}(Y)$. We could then plug in these values into Σ and optimize over the remaining parameters, see $\beta^{CS(cau+,i.d.)}$ in

Figure 5 (left). In practice, we have to estimate $\Sigma_{\mathbf{X}}$, $\Sigma_{(\mathbf{X}_{S^*},Y)}$ and $\mathrm{Var}(Y)$ from data. Thus, the EM approach mentioned above constitutes the more principled approach.

2.3 Relation to causality

In this section, we provide a brief introduction to causal notions in order to motivate our method. More specifically, we show that under some conditions, the set S^* of causal parents verifies Assumptions (A1) and (A1'). Structural equation models (SEMs) (Pearl, 2009) are one possibility to formalize causal statements. We say that a distribution over random variables $\mathbf{X} = (X_1, \ldots, X_p)$ is induced by a structural equation model with corresponding graph $\mathcal{G}$ if each variable X_j can be written as a deterministic function of its parents $\mathbf{PA}_j^{\mathcal{G}}$ (in $\mathcal{G}$) and some noise variable N_j:

$$X_j = f_j(X_{\mathbf{PA}_j^{\mathcal{G}}}, N_j)\,, \quad j = 1, \ldots, p\,. \tag{9}$$

Here, the graph is required to be acyclic and the noise variables are assumed to be jointly independent. An SEM comes with the ability to describe *interventions*. Intervening in the system corresponds to replacing one of the structural equations (9). The resulting joint distribution is called an intervention distribution. Changing the equation for variable X_j usually affects the distribution of its children for example, but never the distribution of its parents. Consider now an SEM over variables $(\mathbf{X}, Y)$. Here, we do not specify the graphical relation between Y and the other nodes: Y may or may not have children or parents. Suppose further that the different tasks $\mathbb{P}^1, \ldots, \mathbb{P}^D$ are intervention distributions of an underlying SEM with graph structure $\mathcal{G}$. If the target variable has not been intervened on, then the set $S^* := \mathbf{PA}_Y^{\mathcal{G}}$ satisfies Assumptions (A1) and (A1'). This means that as long as the interventions will not take place at the target variable, the set S^* of causal parents will satisfy Assumptions (A1) and (A1').

Recently, Peters et al. (2016) have given several sufficient conditions for the identifiability of the causal parents in the linear Gaussian framework. E.g., if the interventions take place at informative locations, or if we see sufficiently many different interventions, the set of causal parents is the *only* set S^* that satisfies Assumptions (A1) and (A1'). If there exists more than one set leading to invariant predictions, they consider the intersection of all such subsets. In this sense, seeing more environments helps for identifying the causal structure. In this work, we are interested in prediction rather than causal discovery. Therefore, we try to find a trade-off between models that predict well and invariant models that generalize well to other domains. That is, in the DG setting, we are interested in the subset which leads to invariant conditionals and minimizes the prediction error across training tasks.

If the tasks $\mathbb{P}^k$ correspond to interventions in an SEM, we may construct an extended SEM with a parent-less environment variable E that points into the intervened variables. Then, $\mathbb{P}^k$ equals the distribution of $(\mathbf{X}, Y) \,|\, E = k$, see (Peters et al., 2016, Appendix C). If the distribution of $(\mathbf{X}, Y, E)$ is Markov and faithful w.r.t. the extended graph, the smallest set S that leads to invariant conditionals and to best prediction is a subset of the Markov blanket of Y: certainly, it contains all parents of Y; if it includes a descendant of Y, this must be a child of Y (which yields better prediction and still blocks any path from Y to E); analogously, any contained ancestor of a child of Y must be a parent of that child.

3. Learning invariant conditionals

In the previous section, we have seen how a known invariant subset $S^* \subseteq \{1, \dots, p\}$ of predictors leading to invariant conditionals $Y^k \,|\, \mathbf{X}^k_{S^*}$, see Assumptions (A1) and (A1'), can be beneficial in the problems of DG and MTL. In practice, such a set S^* is often unknown. We now present a method that aims at *inferring* an invariant subset from data. Throughout this paper, we denote by S any subset of features, while S^+ is an invariant set (which is not necessarily unique) for which (A1) holds. Such a subset S^+ *does not necessarily satisfy both Assumptions (A1) and (A1').* Indeed, in DG, only (A1) is testable in the training data. More precisely, if several invariant sets which satisfy (A1) are found, and only some of them satisfy (A1'), we cannot find these from data. We therefore have to add a criterion allowing us to select among several invariant sets. The method we propose provides an estimator $\hat{S}$ for an invariant subset S^+, which is chosen as the subset satisfying Assumption (A1) which maximizes predictive accuracy on a validation set. In MTL, we still write S^+, even if we could then write S^* as (A1') becomes testable. It is summarized in Algorithm 1, code is provided in `https://github.com/mrojascarulla/causal_transfer_learning`.

3.1 Our method.

Algorithm 1: Subset search

Inputs: Sample $(\mathbf{x}_i^k, y_i^k)_{i=1}^{n_k}$ for tasks $k \in \{1, \dots, D\}$, threshold δ for independence test.

Outputs: Estimated invariant subset $\hat{S}$.

Set $S_{acc} = \{\}$, MSE $= \{\}$.
for $S \subseteq \{1, \dots, p\}$ **do**
  linearly regress Y on $\mathbf{X}_S$ and compute the residuals $R_{\beta^{CS(S)}}$ on a validation set.
  compute $H = \text{HSIC}_b\left((R_{\beta^{CS(S)},i}, K_i)_{i=1}^n\right)$ and the corresponding p-value p^* (or the p-value from an alternative test, e.g., Levene test.).
  if $p^* > \delta$ **then**
    compute $\widehat{\mathcal{E}}_{\mathbb{P}^{1,\dots,D}}(\beta^{CS(S)})$, the empirical estimate of $\mathcal{E}_{\mathbb{P}^{1,\dots,D}}(\beta^{CS(S)})$ on a validation set.
    S_{acc}.add(S), MSE.add($\widehat{\mathcal{E}}_{\mathbb{P}^{1,\dots,D}}(\beta^{CS(S)})$)
  end
end
Select $\hat{S}$ according to *RULE*, see Section 3.4.

Consider a set of D tasks, a target variable Y^k and a vector $\mathbf{X}^k$ of p predictor variables in task k. For $\beta \in \mathbb{R}^p$, we define the residual in task k as:

$$R^k_\beta = Y^k - \beta^t \mathbf{X}^k, \quad k \in \{1, \dots, D\}. \tag{10}$$

By Assumptions (A1) and (A2), there exists a subset S^+ and some vector $\beta^{CS(S^+)}$ such that for all $j \notin S^+$, $\beta_j^{CS(S^+)} = 0$ and $R^1_{\beta^{CS(S^+)}} \overset{d}{=} \dots \overset{d}{=} R^D_{\beta^{CS(S^+)}}$. Such a set S^+ is not necessarily unique. As stated in (Peters et al., 2016), the number of invariant subsets decreases as more

Algorithm 2: Greedy subset search

Inputs: Sample $(\mathbf{x}_i^k, y_i^k)_{i=1}^{n_k}$ for tasks $k \in \{1, \dots, D\}$, threshold δ for independence test.

Outputs: Estimated invariant set $\hat{S}greedy$.

Set $S_{acc} = \{\}$, $\hat{S}_{current}\{\}$, MSE $= \{\}$.
for $i \in \{1, \dots, n_{iters}\}$ **do**
  Set $stat_{min} = \infty$.
  for $S \in \mathcal{S}_{\hat{S}_{current}}$ **do**
    linearly regress Y on $\mathbf{X}_S$ and compute the residuals $R_{\beta^{CS(S)}}$ on a validation set.
    compute $H = \text{HSIC}_b\left((R_{\beta^{CS(S)},i}, K_i)_{i=1}^n\right)$ and the corresponding p-value p^* (or the p-value from an alternative test, e.g. Levene test.).
    if $p^* > \delta$ **then**
      compute $\widehat{\mathcal{E}}_{\mathbb{P}^{1,\dots,D}}(\beta^{CS(S)})$, the empirical estimate of $\mathcal{E}_{\mathbb{P}^{1,\dots,D}}(\beta^{CS(S)})$ on a validation set.
      S_{acc}.add(S), MSE.add($\widehat{\mathcal{E}}_{\mathbb{P}^{1,\dots,D}}(\beta^{CS(S)})$),
      set $\hat{S}_{current} = S$.
    end
    else if $H < stat_{min}$ **then**
      set $\hat{S}_{current} = S$, $stat_{min} = H$.
    end
  end
end
Select $\hat{S}$ according to *RULE*, see Section 3.4.

different tasks are observed at training time. We propose to do an exhaustive search over subsets S of predictors and statistically test for equality of the distribution of the residuals in the training tasks, see the section below. Among the accepted subsets, we select the subset $\hat{S}$ which leads to the smallest error on a validation set. This is a fundamental difference to the method proposed by Peters et al. (2016). Indeed, while our method addresses the transfer problem, Peters et al. (2016) is about causal discovery. Algorithm 1 finds an invariant subset which also leads to the lowest validation error. This subset may contain covariates which are non causal, see Section 4.3 for further details. On the other hand, Peters et al. (2016) estimate the causal parents (with coverage guarantee). Such an approach has a different purpose and performs very badly both in DG and MTL: e.g., when all tasks are identical, it uses the empty set as predictors, while our method selects the full set of predictors.

In Section 3.3, we propose two solutions for when the number of predictors p is too large for an exhaustive search: a greedy method and variable selection. While the algorithms are presented using linear regression, the extension to a nonlinear framework is straightforward. In particular, linear regression can be replaced by a nonlinear regression method.

3.2 Statistical tests for equality of distributions.

In order to test whether a subset S leads to invariant conditionals, we can use a statistical test to check whether the residuals $R^k_{\beta^{CS(S)}}$ have the same distribution in all tasks $k \in \{1, \dots, D\}$. We propose two possible methods.

For Gaussian data, one can use a Levene test (Levene, 1960) to test whether the residuals have the same variance in all tasks; their means are zero as long as an intercept is included in the regression model.

As an alternative, we propose a nonparametric D-sample test by testing whether the residuals are independent of the task index. This test is a direct application of HSIC (Gretton et al., 2007) but to our knowledge, is novel. Suppose that the index of the task can be considered as a random variable K. We consider the sample $Z = (R_{\beta^S,i}, K_i)_{i=1}^n$ as drawn from a joint distribution over residuals and task indices, where $n = \sum_{k=1}^D n_k$ and $K_i \in \{1, \dots, D\}$ is a discrete value indicating the index of the corresponding task. The residuals have the same distribution in all training tasks if and only if R_{β^S} and K are independent. Two characteristic kernels are used: a kernel κ is used for embedding the residuals and a trivial kernel d such that $d(i, j) = \delta_{ij}$ is used for K. Let therefore $\mathrm{HSIC}(R_{\beta^S}, K)$ denote the value of the HSIC (Gretton et al., 2007) between R_{β^S} and K, and let $\mathrm{HSIC}_b(Z)$ be the corresponding test statistic. A subset S is accepted if if leads to accepting the null hypothesis of independence between R_{β^S} and K at level δ.

Both in the case of the Levene test and the D-sample test, the test outputs a p-value p^*, and we accept the null H_0 if $p^* > \delta$. Among these accepted subsets, we output the set $\hat{S}$ which leads to the smallest loss on a validation set. The test level δ is given as an input to our method and allows for a trade-off between predictive accuracy and exploiting invariance. As δ tends to zero, the null is accepted for all subsets and we then select all features, which is equivalent to covariate shift. When δ approaches one, no subset is accepted as invariant. Our method then reduces to the mean prediction. In order to compute p-values, a Gamma approximation is used for the distribution of $\mathrm{HSIC}_b(Z)$ under the null.

For non-additive models, one may even apply a conditional independence test (e.g., Zhang et al., 2011; Fukumizu et al., 2008) to test whether K is independent of $Y \,|\, \mathbf{X}_S$.

3.3 Scalability to a large number of predictors

When the number of features p is large, full subset search is computationally not feasible. We propose two solutions for this scenario. If one has reasons to believe that the signal is sparse, that is the true set S^* is small, one may use a **variable selection** technique such as the Lasso (Tibshirani, 1996) as a first step. Under the assumptions described in Section 2.3, we know that the invariant set with the best prediction in the training tasks can be assumed to be a subset of the relevant features (which here equals the Markov blanket of Y). Thus, if variable screening is satisfied ,i.e., one selects all relevant variables and possibly more, the pre-selection step does not change the result of Algorithm 1 in the limit of infinitely many data. For linear models with ℓ_1 penalization, variable screening is a well studied problem, see, e.g., compatibility and β_{min} conditions (Bühlmann and van de Geer, 2011, Chapter 2.5).

Alternatively, one may perform a **greedy search** over subsets when full subset search is not feasible. Denote by $\mathcal{S}_S$ the collection of neighboring sets of a set S obtained by adding or

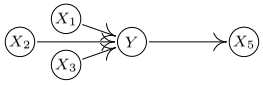

Figure 3: Example of a directed acyclic graph, see Section 2.3. If Y is not intervened on, the conditional $Y \,|\, X_1, X_2, X_3$ remains invariant.

removing exactly one predictor in S. If no subset has been accepted at a given iteration, we select the neighbor leading to the smallest test statistic. If a neighbor is accepted, we select the one which leads to the smallest training error. We start with the p subsets with only one element, and allow to add or remove a single predictor at each step, see Algorithm 2. As often for greedy methods, there is no theoretical guarantee.

3.4 Subset selection in MTL

In DG, among the accepted subsets, we select the set $\hat{S}$ which leads to the lowest validation error. In MTL, however, a labeled sample from the test task T is available at training time. Therefore, Algorithm 1 is slightly modified. First, we get all the sets for which H_0 is accepted. Then, we select the accepted set $\hat{S}$ which leads to the smallest 5 fold cross validation error. For each subset, we compute the least squares coefficients using the procedure described in Section 2.2, and measure the prediction error on the held out validation set. Using the notation of Algorithm 1, let S_{acc} be the set of subsets accepted as invariant, and let MSE be the set of their corresponding squared errors on the validation set. The following rules are used for selecting an invariant set in DG and MTL.

i) ***RULE* for DG**: Return $\hat{S} = S_{acc}[\arg\min \mathrm{MSE}]$.
ii) ***RULE* for MTL**: Define $CV_{acc} = \{\}$. For each set $S \subseteq S_{acc}$, do $CV_{acc}.\mathrm{add}(CV_S)$, where CV_S is the 5-fold cross validation error over the labeled test data obtained by optimizing (8) using EM with subset S.
Return $\hat{S} = S_{acc}[\arg\min CV_{acc}]$.

Given a set of $k \in \{1, \dots, T\}$ training tasks, a collection of sets $\hat{S}_1, \dots, \hat{S}_u$ (eventually empty) is obtained, all of which lead to accepting the null hypothesis of invariance between the training tasks in DG. Our methods use the MSE on a validation set as a criterion for selecting a subset among these u candidates. This is a design choice which is dependent on the specific application, and can be modified. For instance, if being conservative is important, the MSE may be an inappropriate choice. One may be then interested in combining confidence intervals for the accepted sets. One idea is to consider all accepted sets at the same time, one of which is, with probability $1-\alpha$, the set S^* from Assumption (A1'). These sets yield different predictions, one of which stems from S^*, again, with probability $1-\alpha$. In some settings, it might be helpful to output the whole set of predictions. If one is interested in confidence intervals, these may be combined by taking its union. Heinze-Deml et al. (2018) discuss this idea in the context of prediction under interventions.

estimator	description
$\beta^{CS(cau)}$	Linear regr. with true causal predictors (often unknown in practice).
$\beta^{CS(\hat{S})}$	Finding the invariant set $\hat{S}$ using full subset search and performing lin. regr. using predictors in $\hat{S}$. $\hat{S}greedy$ corresponds to finding the invariant set using a greedy procedure. $\hat{S}Lasso$ corresponds to doing variable selection using Lasso as a first step, then doing full subset search on the selected features.
β^{CS}	Pooling the training data and using linear regr.
$\beta^{CS(\hat{S}+)}$	Finding the invariant set $\hat{S}$ using full subset search and solve the optimization problem described in 'A naive estimator for comparison'.
$\beta^{CS(\hat{S}\sharp)}$	Finding the invariant set $\hat{S}$ using full subset search and maximizing (8) for MTL using EM.
β^{mean}	Pooling the training data and outputting the mean of the target.
β^{dom}	Linear regression using only the available labeled sample from T.
β^{MTL}	Multi-task feature learning estimator (Argyriou et al., 2007a).
β^{DICA}	DICA (Muandet et al., 2013) with rbf kernel.
β^{mDA}	Pooling the training data and an unlabeled sample from T, learning features using mSDA (Chen et al., 2012) with one layer and linear output, then using linear regr.

Table 2: Estimators used in the numerical experiments. A '+' next to a subset S corresponds to the method for MTL described in the last paragraph of Section 2.2.

4. Experiments

We compare our estimator to different methods, which are summarized in Table 2. $\beta^{CS(cau)}$ uses the ground truth for S^* when it is available, $\beta^{CS(\hat{S})}$ corresponds to full search using Algorithm 1, β^{CS} uses the pooled training data, β^{MTL} performs the Multi-task feature learning algorithm (Argyriou et al., 2007a) for the MTL setting and β^{DICA} performs DICA (Muandet et al., 2013) for DG. For DICA, which is a nonlinear method, the kernel matrices are constructed using an rbf kernel, and the length-scale of the kernel is selected according to the median heuristic. In the MTL setting, we combine the invariance with task specific information by optimizing (8) using EM, resulting in regression coefficients $\beta^{CS(\hat{S}\sharp)}$ and $\beta^{CS(cau\sharp)}$ when the ground truth is known. Finally, $\beta^{CS(cau\sharp,UL)}$ indicates that unlabeled data from T was also available. For reference, Figure 5 (left) provides results for $\beta^{CS(\hat{S}+)}$ and $\beta^{CS(cau+)}$, which correspond to the estimators obtained by solving the constrained optimization problem described in the paragraph *'A naive estimator for comparison'* of Section 2.2 ($\beta^{CS(cau+)}$ uses the ground truth for S^* and α), while β^{naive} imputes the covariance matrices but does not optimize the free parameters. $\beta^{CS(cau+,i.d.)}$ (infinite data) also assumes that we know the ground truth for the entries of the covariance matrix for the test task corresponding to the covariance of $\mathbf{X}$, the covariance between $\mathbf{X}_{S^*}$ and Y, and the variance of Y.

4.1 Synthetic data set

In this section, we generate a synthetic data set in which the causal structure of the problem is known. For all experiments, we choose $\delta = 0.05$ as a rejection level for the statistical test in Algorithms 1 and 2. Moreover, we use 40% of the training examples to fit the linear

models in Algorithms 1 and 2, and the remaining data as validation. The sensitivity to the choice of δ is discussed in Section 4.2.

Generative process of the data For each task $k \in \{1, 2, \ldots, D, T\}$, we sample a set of causal variables from a multivariate Gaussian

$$\mathbf{X}^k_{S^*} \sim \mathcal{N}(0, \Sigma^k_{S^*})$$

where the covariance matrix $\Sigma^k_{S^*}$ is drawn from a Wishart distribution $\mathcal{W}(U^k_{S^*}, p)$, where $U^k_{S^*}$ is computed as $V^k(V^k)^t$. Here, V^k is a $(|S|, |S|)$ matrix of standard Gaussian random variables.

The target variable Y^k is drawn as

$$Y^k = \alpha \mathbf{X}^k_{S^*} + \epsilon^k$$

where $\epsilon^k \sim \mathcal{N}(0, 2)$ (the standard deviation of ϵ^k is 6 for the non sparse DG experiment with 30 predictors, see the bottom of Figure 4).

We sample the remaining predictor variables as

$$\mathbf{X}^k_N = \gamma^k Y^k + \beta^k (\mathbf{X}^k_{S^*})_C + \eta^k$$

where $\eta^k \sim \mathcal{N}(0, \Sigma^k_N)$. $(\mathbf{X}^k_{S^*})_C$ is a subset of $\mathbf{X}^k_{S^*}$ of size $|C|$ which generates both the target Y^k and $\mathbf{X}_N T^k$. γ^k of size $|N|$ is computed as $\gamma^k = (1-\lambda)\gamma_0 + \lambda g^k$, where $\lambda \in [0, 1]$, γ_0 is the same in all tasks while g^k is task dependent. Both γ_0 and g^k are drawn from a standard Gaussian. Similarly to γ^k, β^k is a $(|C|, |N|)$ matrix computed as $\beta^k = (1-\lambda)\beta_0 + \lambda b^k$. Σ^k_N is sampled similarly to $\Sigma^k_{S^*}$. Finally, α is sampled from a standard Gaussian distribution.

The generative process and hyper-parameters are the same for all the experiments (DG and MTL).

Results Our goal is to linearly predict target Y^T using predictors $\mathbf{X}^T = (\mathbf{X}^T_{S^*}, \mathbf{X}^T_N)$ on the test task. Given regression coefficient β, we measure the performance in the test task using the logarithm of the empirical estimator of $\mathcal{E}_{\mathbb{P}^T}(\beta)$.

In Figure 4, we are in the DG setting (thus, no labeled examples from T are observed at training). 4000 examples per training task are available for the top left and right plots, while only 1000 examples per task are available on the bottom because of computational reasons. We report the log average empirical MSE over left out test tasks. We study both sparse and non sparse settings (in which full search is not feasible). On the upper left and upper right, we see that when more than four training tasks are available, both the full search and greedy approaches are able to recover an invariant set, and outperform pooling the data for any number of training tasks. When more than five training tasks are observed, $\beta^{CS(\hat{S})}$ performs like $\beta^{CS(cau)}$, which uses knowledge of the ground truth. On the bottom, full search is not feasible, and $\beta^{CS(\hat{S}greedy)}$ outperforms other approaches.

In Figure 5 (top left), we consider an AMTL setting, in which large amounts of labeled data (36000) from the training tasks and unlabeled data from the test task (50000) are available. Both S and N are of size 3, such that $\mathbf{X}$ is 6-dimensional. For all MTL experiments, 6 training tasks are available. We report the percentage of simulations for which the population MSE of a given approach outperforms β^{dom}. We see that $\beta^{CS(cau+,i.d.)}$ systematically outperforms β^{dom}. Moreover, $\beta^{CS(cau+)}$ and $\beta^{CS(\hat{S}+)}$ also perform well, and positive

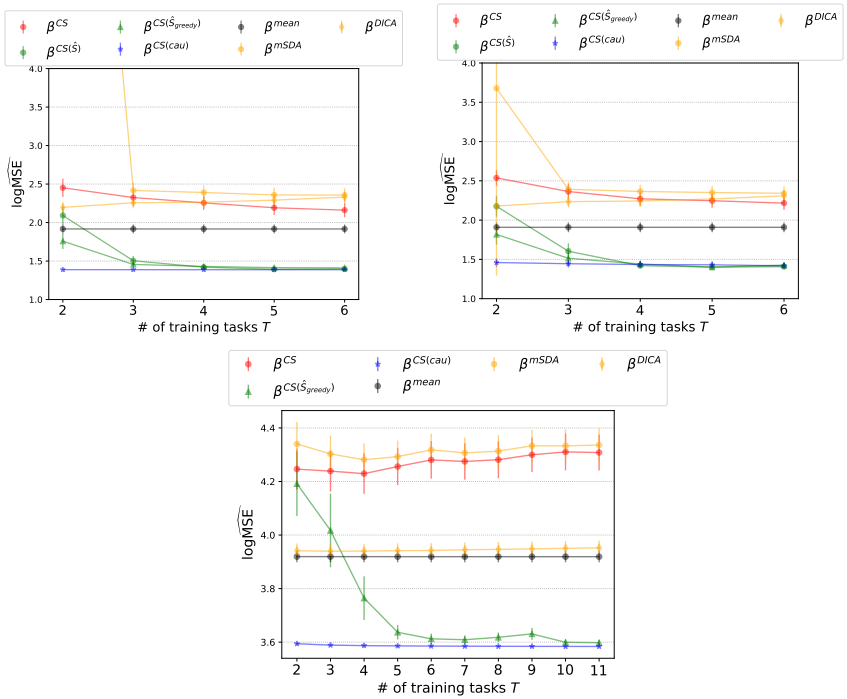

Figure 4: DG setting. Logarithm of the empirical squared error in the test task for the different estimators in the DG setting. The results show averages and 95% confidence intervals for the mean performance over 100 repetitions. We vary the number of tasks D available at training time. Upper left: both S and N are of size 3, such that $\mathbf{X}$ is 6-dimensional. $|C|$ is of size one. Upper right: 30 noise variables are added to $\mathbf{X}$. Variable selection using the Lasso is used prior to computing $\beta^{CS(\hat{S})}$, while $\beta^{CS(\hat{S}greedy)}$ uses all predictors. Bottom: both S and N are of size 15. Full search is not computationally feasible in this setting and only the greedy procedure can be used. Other methods such as β^{CS}, β^{mSDA} and β^{DICA} often perform badly, which explains why in comparison β^{mean} appears to performs well.

transfer is effective. However, a prohibitively large amount of labeled and unlabeled data is needed for these approaches, and the differences become non-significant for all methods except $\beta^{CS(cau+,i.d.)}$. This shows the limitation of this family of approaches. In a setting with only 900 examples per training task in SMTL, we plot in Figure 6 the histogram of the error difference $\Delta = \mathcal{E}(\beta^{dom}) - \mathcal{E}(\beta)$ for $\beta^{CS(cau\sharp)}$. Figure 5 (top right) corresponds to the same setting, but we vary the number of unlabeled data available (we only plot methods

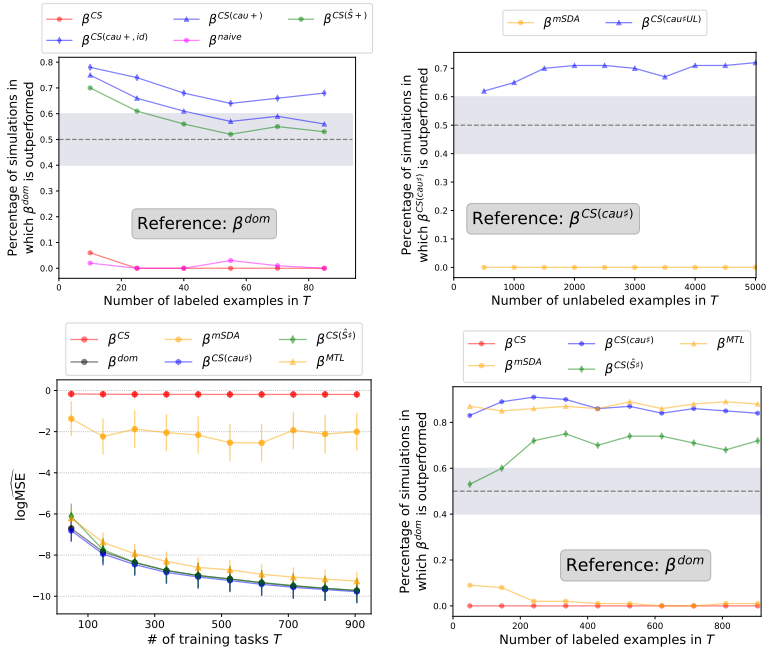

Figure 5: MTL setting. Percentage of repetitions (out of 100) for which the corresponding method outperforms β^{dom} (or $\beta^{CS(cau\sharp)}$ for the top right plot). Both S and N are of size 3, such that $\mathbf{X}$ is 6-dimensional. Upper left: AMTL setting. This plot shows that the methods $\beta^{CS(\hat{S}+)}$ and $\beta^{CS(cau+)}$ presented in Section 2.2 perform well, but a large amount of data is necessary: 50000 unlabeled examples from T and 36000 training examples are available. The naive method β^{naive} performs poorly. Upper right: in the SMTL setting, we fix the number of training data (500 per task) and vary the amount of unlabeled data available from the test task. We report the percentage of scenarios in which the corresponding method outperforms $\beta^{CS(cau\sharp)}$ this time (which uses no unlabeled data). While β^{mDA} always performs worse than $\beta^{CS(cau\sharp)}$ and does not exploit the unlabeled data, we see that $\beta^{CS(cau\sharp,UL)}$ performs better as the amount of unlabeled data increases. Bottom: SMTL setting, and we vary the number of labeled examples available in each training task. Here, significantly less labeled data was available in the training tasks (from 50 to 1000 per task). In this setting, the methods using unlabeled data were given 100 unlabeled examples. Bottom left: logarithm of the empirical squared error in the test task for different estimators. Bottom right: percentage of repetitions (out of 100) for which the corresponding method outperforms β^{dom}.

that use unlabeled data, and $\beta^{CS(cau\sharp)}$ is used as reference instead of β^{dom}). In Figure 5 (bottom) we consider an SMTL setting in which only 100 unlabeled data points are avail-

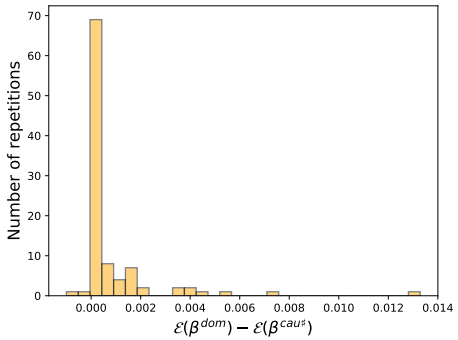

Figure 6: In the SMTL setting, 900 examples from each of the training tasks are available (this corresponds to the data point furthest to the right in the bottom plot of Figure 5). We run 100 repetitions and plot the histograms of $\Delta = \mathcal{E}(\beta^{dom}) - \mathcal{E}(\beta^{CS(cau\sharp)})$. The proposed estimator outperform β^{dom}: for a large proportion of the repetitions, $\Delta > 0$. More importantly, the distribution of Δ is heavily skewed in the positive values. In other words, when β^{dom} outperforms $\beta^{CS(cau\sharp)}$, the difference in performance is small, while the difference is often larger for the converse.

able, and only few labeled examples are available in each task. Here, we see that $\beta^{CS(cau\sharp)}$, $\beta^{CS(\hat{S}\sharp)}$ and β^{MTL} perform well, while other methods do not. In terms of MSE (bottom left), the difference in performance between the top competing methods is not statistically significant.

Time complexity The most expensive component of our method is the estimation of the invariant subset. In the DG experiment in Figure 4, with $n = 4000$ examples available for each of the 6 tasks, and $p = 6$ predictors, full subset search takes 0.067 seconds and greedy search 0.037, where the results are averaged over 100 repetitions. With $p = 10$, full search averages at 1.57 seconds, and greedy search 0.0396. With $p = 30$, where full search is not feasible, greedy search averages at 1.21 seconds. In the MTL experiment in Figure 5, the EM algorithm runs for 0.00105 seconds on average over 100 repetitions. As a reference, in MTL, linear regression averages at 0.000301 seconds and mSDA at 0.0547 seconds.

4.2 Sensitivity to the acceptance level δ

Both Algorithm 1 and its greedy version Algorithm 2 receive an acceptance level δ as input for the statistical test. In our other experiments, we chose the standard value of $\delta = 0.05$. Figure 8 shows the error on the test tasks in the DG setting for both methods for different values of δ. The setting is the same as in the left of Figure 4 for three training tasks. β^{CS} and $\beta^{CS(cau)}$ are provided as reference. For $\delta = 0$, all subsets are accepted as invariant,

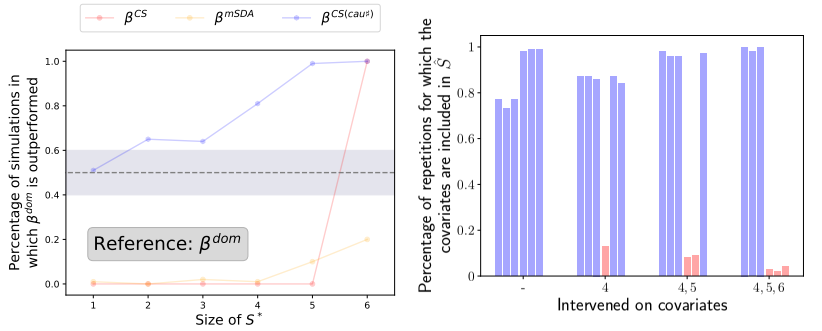

Figure 7: *Left*: SMTL setting with 6 tasks and 900 examples per task. We plot the percentage of repetitions (over 100) for which the given methods outperform β^{dom}, as a function of the size of the invariant set S^*. We see that as S^* becomes larger, more information is transferred from the training tasks, and as such the performance of $\beta^{CS(cau\sharp)}$ improves. When S^* is the full set, our method behaves like pooling the data. *Right*: Covariates selected by Algorithm 1 when the training tasks contain interventions only on some of the covariates. The bars represent the percentage of repetitions (out of 100) for which the corresponding covariates were selected. When there are no interventions in the training tasks, meaning that all the training tasks follow the same distribution, Algorithm 1 systematically selects *all* covariates for prediction. When more interventions are performed, however, the corresponding covariates (in red) are excluded in a large number of the repetitions.

thus both methods behave like pooling the data. After a critical value of δ, no subset is accepted, and both algorithms return the subset with the largest p-value.

4.3 Informativeness and subset estimation

The estimation of an invariant subset involves finding a subset for which the residuals have the same distribution across tasks. It is desirable, however, that the selected subset is one which explains the data best. This is ensured by selecting the subset which leads to the smallest error on a validation set. Therefore, some covariates in N may be included in a selected subset *if there are no interventions on this covariates in the training tasks*. More precisely, if including a covariate does not lead to a statistically measurable difference in the distribution of the residuals between the training tasks, it is advantageous in general to include it in the selected subset since the data is better explained.

We illustrate this in Figure 7 (right) in the setting previously described with $p = 6$. We estimate an invariant subset using Algorithm 1 over 100 repetitions in the following scenarios: i) all the covariates have the same distribution across tasks, ii) one, two or three covariates in N are subject to interventions between the tasks. Figure 7 (right) show the proportion of repetitions for which each covariate is included in the selected subset. We see that, as expected, covariates in N for which there are no interventions are included

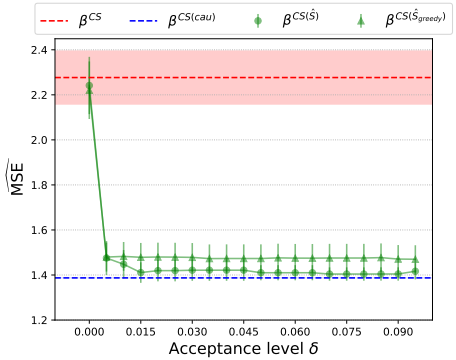

Figure 8: Logarithm of the empirical squared error in the test task in the DG setting as a function of the acceptance level of the statistical test δ in Algorithm 1. The setup corresponds to $t = 3$ in Figure 4 (left), also over 100 repetitions. For $\delta = 0$, all subsets are accepted, so the full set of predictors, which minimizes the validation squared error, is selected. Algorithm 1 then returns β^{CS}. As δ increases, no subset is accepted, and Algorithm 1 returns the subset with the largest p-value.

in the selected subset in a large portion of the repetitions, while the other covariates are excluded. This highlights that Algorithm 1 can only exclude covariates whose distribution shifts between training tasks. If being conservative is important for the problem at hand, one can modify Algorithm 1 accordingly, see the end of Section 3.4.

Moreover, in Figure 7 (left) we consider a similar setting, and we compute the performance against β^{dom} in an SMTL setting as the size of the invariant set increases. We see that as the size of the invariant set increases, the performance of $\beta^{CS(cau^\sharp)}$ improves, since more information is being transferred from the training tasks. When $p = 6$, traditional covariate shift holds, and $\beta^{CS(cau^\sharp)}$ performs on par with β^{pool}.

4.4 Gene perturbation experiment

We apply our method to gene perturbation data provided by Kemmeren et al. (2014). This data set consists of the m-RNA expression levels of $p = 6170$ genes $X_1, \ldots, X_p$ of the Saccharomyces cerevisiae (yeast). It contains both $n_{obs} = 160$ observational data points and $n_{int} = 1479$ data points from intervention experiments. In each of these interventions, one known gene (out of p genes) is deleted. In the following, we consider two different tasks. The observational sample is drawn from the first task, and the pooled n_{int} interventions are drawn from the second task.

Motivation In order to gain an intuition about the experiments we are presenting, consider Figure 9. We select as a target a gene Y out of the p genes, and our goal is to predict the activity of Y given the remaining $p-1$ genes as features. Some of these $p-1$ genes are

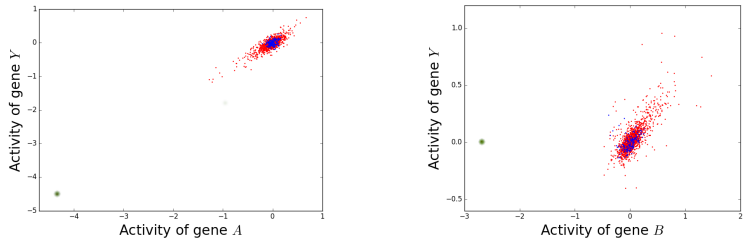

Figure 9: Example of the expression of pairs of genes, where A is causal (left) and B is non-causal (right) of target Y. The blue points are from the observational sample (task 1), the red dots are the interventional sample (task 2), and the green point corresponds to the single interventions in which A and B are intervened on respectively. On the left, a model learned on the data in red and blue would still perform well on the intervention point, which is not the case on the right.

causal of the activation of Y. For example, Figure 9 shows on the x-axis the activity of two genes (gene A on the left, gene B on the right) such that:

- The expressions of A and B are strongly correlated with the expression of Y.
- A is causal of Y (here, we use the definition of a causal effect proposed by Peters et al. (2016)).
- B is non-causal of Y (anticausal or confounded).

In Figure 9 (left), the blue points correspond to the 160 data points from the observational sample, which corresponds to the first task. The red dots are the 1478 data points from the interventional sample, except for the single data point for which A is intervened on, and constitute the second task. The plot on Figure 9 (right) is constructed analogously for B. We can indeed see that in the pooled sample from task 1 and 2, A and B are both strongly correlated with target Y.

The key difference between both plots are the green points. On Figure 9 (left), the green dot corresponds to the single intervention experiment in which gene A is intervened on. Similarly, the green dot on Figure 9 (right) is the single point in which B is intervened on. Our goal is to consider the DG setting in which the test task consists on this single intervention point.

For the causal gene A, one expects that a change in the activity of A should translate into a proportional change in the activity of Y. We observe that, in the particular example of the left plot, a linear regression model from A to Y trained only on the pooled data from tasks 1 and 2 (blue and red in Figure 9) would lead to a small prediction error on the intervened point (in green). That is, $S^* = \{A\}$ might be a good candidate for a set satisfying Assumptions (A1), (A1') and (A2). For the non-causal gene B, however, intervening on B leaves the activity of Y unchanged, and the linear model learned on the data from tasks 1 and 2 performs badly on the test point in green. In such case, a candidate set is the empty set $S^* = \{\}$, leading to prediction using the mean of the target in the training data. A model which is aiming to test in these challenging intervention points should therefore

include causal genes as features, but exclude non-causal genes. In these experiments, we aim at testing whether we can exclude non-causal genes such as B automatically.

Setup We address the problem of predicting the activity of a given gene from the remaining genes. We are looking at the following:

- We consider p different **problems**. In each problem $j \in \{1, \dots, p\}$, we aim at predicting the activity $Y = X_j$ of gene j using $(X_\ell)_{\ell \neq j}$ as features.
- In each problem $j \in \{1, \dots, p\}$, two **training tasks** $k \in \{1, 2\}$ are available. The data from the first task is the observational sample, and the data from the second task are all the n_{int} interventions (we shall subsequently remove some points for testing, see below).

The goal is now to apply our method to each of the problems and estimate an invariant subset. Due to the large number of predictors, we first select the 10 top predictor variables using the Lasso and then apply Algorithm 1 to select a set of invariant predictors $\hat{S}$, see $\beta^{\hat{S}Lasso}$ in Table 2. We denote the indices of the features selected using Lasso by $L = (L_1, \dots, L_{10})$.

The procedure is then evaluated as follows: for each problem $j \in \{1, \dots, p\}$, we first find the genes in $(X_{L_1}, \dots, X_{L_{10}})$ for which an interventional example is available. Note that this might not hold for all selected genes, since only $n_{int} < p$ interventions are available. We then iterate the following procedure (this is within the context of *the same problem*): for each gene in $(X_{L_1}, \dots, X_{L_{10}})$ for which an intervention is available,

- we put aside the example corresponding to this intervention from the training data (in the motivation example, this would correspond to the green point).
- we estimate an invariant subset $\hat{S} \subseteq L$ using Algorithm 1 with the remaining observational and interventional data.
- we test all methods on the single intervention point which was put aside.

We expect two different scenarios, as explained in the motivation paragraph above: (1) if the intervened gene is a *cause* of the target gene, it should still be a good predictor (see Section 2.3); then, it should be beneficial to have this gene included in the set of predictors $\hat{S}$. (2) if the intervened gene is anticausal or confounded (we refer to this scenario as *non-causal*), the statistical relation to the target gene might change dramatically after the intervention and therefore, one may not want to base the prediction on this gene. In order to see this effect and understand how the different approaches for DG in Table 2 handle the problem, we consider two groups of experiments.

(1) we select the target genes Y for which one of the features in L is causal for the activity of Y and for which an intervention experiment is available. 39 problems fall in this causal scenario.

(2) out of the remaining problems we chose target genes with (non-causal) predictors that have been intervened on and — in order to increase the difficulty of the problem — that are strongly correlated with the target gene. We therefore select 269 cases for which a Pearson correlation test (the null hypothesis corresponds to no correlation) outputs a p-value equal to zero.

Results Figure 10 shows box plots for the errors of the different methods for the causal problems (1) on the top left and for the non-causal problems (2) in the top right. We do not plot outliers in order to improve presentation. Figure 10 (top left) presents the causal

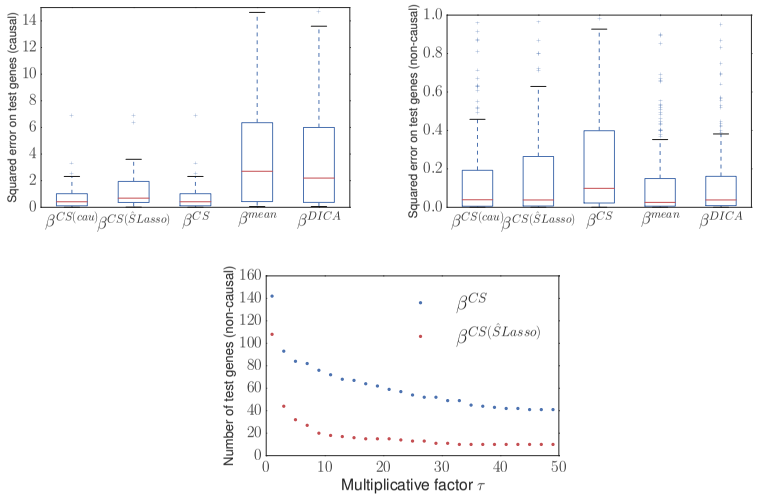

Figure 10: In the causal problems (top left), interventions are performed on causal genes. As expected, the input genes continue to be good predictors, and β^{CS} works well. In the non-causal problems (top right), one of the inputs is intervened upon and becomes a poor predictor, impairing the performance of β^{CS}. The mean predictor β^{mean} uses none of the predictors, and therefore works comparatively well in this scenario. Our proposed estimator $\beta^{CS(\hat{S})}$ provides reasonable estimates in both the causal and non-causal settings, while other methods only perform well in one of the scenarios. β^{DICA} performs similarly to β^{mean} in both scenarios, and is therefore outperformed by other methods in the causal problems (note that β^{DICA} uses all available features). Bottom: in the non-causal scenario (2), we plot the number of test genes for which the squared error for β^{CS} is larger than τ times the squared error for $\beta^{CS(\hat{S})}$, and vice-versa, where τ is plotted on the x-axis. This plot shows the number of genes for which one of the method does significantly worse than the other. By this measure, $\beta^{CS(\hat{S}Lasso)}$ outperforms β^{CS} for all values of τ.

scenario. As expected, pooling does well in this setting. Figure 10 (bottom) shows that in the non-causal problems (2), prediction using an invariant subset leads to less severe mistakes on test genes compared to pooling the tasks.

For comparison, since we know which predictors are being intervened on at test time, we included a method that makes use of causal knowledge: $\beta^{CS(cau)}$ uses all 10 predictors in the causal problems (1) and all but the intervened gene in the non-causal problems (2). In practice, this causal knowledge is often not available. We regard it as promising that the fully automated procedure $\beta^{CS(\hat{S}Lasso)}$ performs comparably to $\beta^{CS(cau)}$.

5. Conclusions and further directions

We propose a method for transfer learning that is motivated by causal modeling and exploits a set of invariant predictors. If the underlying causal structure is known and the tasks correspond to interventions on variables other than the target variable, the causal parents of the target variable constitute such a set of invariant predictors. We prove that predicting using an invariant set is optimal in an adversarial setting in DG. If the invariant structure is not known, we propose an algorithm that automatically detects an invariant subset, while also focusing on good prediction. In practice, we see that our algorithm successfully finds a set of predictors leading to invariant conditionals when enough training tasks are available. Our method can incorporate additional data from the test task (MTL) and yields good performance on synthetic data. Although an invariant set may not always exist, our experiment on real data indicates that exploiting invariance leads to methods which are robust against transfer.

As we saw in the DG and MTL experiments, $\beta^{\hat{S}}$ does not always performs as well as β^{cau}, which uses the ground truth. We believe that alternative methods for estimating the set $\hat{S}$ may close this gap. Furthermore, extending our framework to nonlinearities seems straightforward and may prove to be useful in many applications. For instance, we provide a general, nonlinear version of Theorem 1 in Appendix A. Moreover, Algorithms 1 and 2 are presented in a linear setting. However, the extension to a nonlinear framework is straightforward. In particular, the linear regression can be replaced by a nonlinear regression method. We expect that there may be feature maps leading to invariant conditionals that are different from a subset.

We expect our method to be favorable in (adversarial-like) situations with strong differences between the tasks, such as the gene experiment in Section 4.4. We also evaluated our method on the School dataset (Bakker and Heskes, 2003), but found that we do not do better than pooling the data (we also do not do worse, the results are not shown). We believe this may be due to the fact that the difference between the tasks in this dataset are not too large.

We believe, finally, that the link to causal assumptions and the exploitation of causal structure may lend itself well to proving additional theoretical results on transfer learning.

Appendix A.

In this Appendix, we provide proofs for the theoretical results in the paper, as well as an extension of Theorem 1.

A.1 A nonlinear extension of Theorem 1

The extension of Theorem 1 to a nonlinear setting is straightforward. Given a subset S^* leading to invariant predictions, the proposed predictor is defined as the conditional expectation

$$f_{S^*}: \begin{array}{ccc} \mathbb{R}^p & \to & \mathbb{R} \\ \mathbf{x} & \mapsto & = \mathbb{E}[Y^1 \,|\, \mathbf{X}^1_{S^*} = \mathbf{x}_{S^*}]. \end{array} \tag{11}$$

The following theorem states that f_{S^*} is optimal over the set of continuous functions $\mathcal{C}^0$ in an adversarial setting.

Theorem 4 *Consider D tasks $(\mathbf{X}^1, Y^1) \sim \mathbb{P}^1, \ldots, (\mathbf{X}^D, Y^D) \sim \mathbb{P}^D$ that satisfy Assumption (A1). Then the estimator f_{S^*} in (11) satisfies*

$$f_{S^*} \in \operatorname*{arg\,min}_{f \in \mathcal{C}^0} \sup_{\mathbb{P}^T \in \mathcal{P}} \mathbb{E}_{(\mathbf{X}^T, Y^T) \sim \mathbb{P}^T} \left(Y^T - f(\mathbf{X}^T)\right)^2 ,$$

where $\mathcal{P}$ contains all distributions over $(\mathbf{X}^T, Y^T)$ that are absolutely continuous with respect to the same product measure μ and satisfy $Y^T \,|\, \mathbf{X}^T_{S^*} \overset{d}{=} Y^1 \,|\, \mathbf{X}^1_{S^*}$.

Proof

Consider a function f that is possibly different from f_{S^*}, see (11). For each distribution $\mathbb{Q} \in \mathcal{P}$, we will now construct a distribution $\mathbb{P} \in \mathcal{P}$ such that

$$\int (y - f(\mathbf{x}))^2 \, d\mathbb{P} \geq \int (y - f_{S^*}(\mathbf{x}))^2 \, d\mathbb{Q} \,.$$

In this proof, we assume that the probability distributions in $\mathcal{P}$ are absolutely continuous with respect to Lebesgue measure. The extension to the case where they are absolutely continuous with respect to a same product measure μ is straightforward. Let us therefore assume that $\mathbb{Q}$ has a density $(\mathbf{x}, y) \mapsto q(\mathbf{x}, y)$. Define $\mathbb{P}$ to be the distribution that corresponds to $p(\mathbf{x}, y) := q(\mathbf{x}_{S^*}, y) \cdot q(\mathbf{x}_N)$, where $\mathbf{x}_N$ contains all components of $\mathbf{x}$ that are not in S^*. In the distribution $\mathbb{P}$, the random vector $\mathbf{X}_N$ is independent of $(\mathbf{X}_{S^*}, Y)$. But then

$$\begin{aligned}
&\int (y - f(\mathbf{x}))^2 \, d\mathbb{P} \\
&= \int_{\mathbf{x}_N} \int_{\mathbf{x}_{S^*}, y} (y - f(\mathbf{x}_{S^*}, \mathbf{x}))^2 \, p(\mathbf{x}_{S^*}, y) \, d\mathbf{x}_{S^*} \, dy \, p(\mathbf{x}_N) \, d\mathbf{x}_N \\
&\geq \int_{\mathbf{x}_N} \int_{\mathbf{x}_{S^*}, y} (y - f_{S^*}(\mathbf{x}_{S^*}))^2 \, p(\mathbf{x}_{S^*}, y) \, d\mathbf{x}_{S^*} \, dy \, p(\mathbf{x}_N) \, d\mathbf{x}_N \\
&= \int_{\mathbf{x}, y} (y - f_{S^*}(\mathbf{x}_{S^*}))^2 \, q(\mathbf{x}_{S^*}, \mathbf{x}_N, y) \, d\mathbf{x}_{S^*} \, dy \, d\mathbf{x}_N \\
&= \int (y - f_{S^*}(\mathbf{x}))^2 \, d\mathbb{Q}.
\end{aligned}$$

■

A.2 Proof of Proposition 2

We consider three variables and the following generative process: $Y^k = \alpha^t \mathbf{X}^k_{S^*} + \epsilon^k$, $Z^k = \gamma^k Y^k + \eta^k$, where $\epsilon^k \sim \mathcal{N}(0, \sigma^2)$, $\eta^k \sim \mathcal{N}(0, \sigma^2_\eta)$ and $(\mathbf{X}^k_{S^*})_j \sim \mathcal{N}(0, (\sigma_X)^2_j)$. In this model, γ^k is the parameter responsible for the difference between the tasks, while the other parameters are shared between the tasks.

At training time, D tasks are available. We first aim to obtain an explicit formula for the linear regression coefficients $\beta^{CS} = (\beta^{CS}_{S^*}, \beta^{CS}_Z)$ obtained from pooling all the training tasks together. Denote by $\mathbf{X}$, Y and Z the pooled training data. For fixed $\gamma^1, \dots, \gamma^D$, the expected loss in the training data satisfies for coefficient β verifies:

$$\begin{aligned}\mathbb{E}\left(\left(Y - (\beta_X)^t\mathbf{X} - \beta_Z Z\right)^2\right) &= \frac{1}{D}\sum_{k=1}^{D}\mathbb{E}\left(Y^k - (\beta_X)^t\mathbf{X}^k - \beta_Z Z^k\right)^2 \\ &= \beta_X^t \mathrm{diag}(\sigma_X^2)\beta_X + \frac{\beta_Z^2}{D}\left(\sigma_\eta^2 D + V_Y\overline{\gamma^2}\right) + 2(\beta_Z\frac{\bar\gamma}{D} - 1)\alpha^t\mathrm{diag}(\sigma_X^2)\beta_X + V_Y - 2\frac{\bar\gamma}{D}V_Y\beta_Z, \end{aligned} \tag{12}$$

where $V_Y = \alpha^t\mathrm{diag}(\sigma_X^2)\alpha + \epsilon^2$. By differentiating (12) with respect to β, we obtain the following expression for the pooled coefficients:

$$\beta_Z^{CS} = \frac{\bar\gamma\sigma^2}{V_Y^2\overline{\gamma^2} + D\sigma_\eta^2 - \frac{\bar\gamma^2}{D}\alpha^t\mathrm{diag}(\sigma_X^2)\alpha} \quad \text{and} \quad \beta^{CS}_{S^*} = (1 - \frac{\bar\gamma}{D}\beta_Z^{CS})\alpha,$$

where $\overline{\gamma^2} = \sum_{k=1}^D(\gamma^k)^2$ and $\bar\gamma = \sum_{k=1}^D\gamma^k$. Consider now an unseen test task with coefficient γ^T. The expected loss on the test task using the pooled coefficients is:

$$\begin{aligned}\mathcal{E}_{\mathbb{P}^T}(\beta^{CS}) = \mathbb{E}\left((Y^T - (\beta_X^{CS})^t\mathbf{X}^T - \beta_Z^{CS}Z^T)^2\right) &= \left(\beta_X^{CS}\right)^t\mathrm{diag}(\sigma_X^2)\beta_X^{CS} + (\beta_Z^{CS})^2\left(V_Y(\gamma^T)^2 + \sigma_\eta^2\right) \\ &+ 2\beta_Z^{CS}\gamma^T\alpha^t\mathrm{diag}(\sigma_X^2)\beta_X^{CS} + V_Y \\ &- 2\alpha^t\mathrm{diag}(\sigma_X^2)\beta_X^{CS} - 2\beta_Z^{CS}V_Y\gamma^T. \end{aligned} \tag{13}$$

Therefore, the expectation with respect to γ^T is:

$$\mathbb{E}_{\gamma^T}\left(\mathcal{E}_{\mathbb{P}^T}(\beta^{CS})\right) = (\beta_X^{CS})^t\mathrm{diag}(\sigma_X^2)\beta_X^{CS} + (\beta_Z^{CS})^2\left(V_Y\Sigma^2 + \sigma_\eta^2\right) + V_Y - 2\alpha^t\mathrm{diag}(\sigma_X^2)\beta_X^{CS}$$

Denote by $\mathcal{E}_{\mathbb{P}^T}(\beta^S) = \sigma^2$ the expected loss when using the invariant conditional predictor $\beta^{S^*} = (\alpha, 0)$. Then:
