We present an approximate Bayesian inference approach for estimating the intensity of a inhomogeneous Poisson process, where the intensity function is modelled using a Gaussian process (GP) prior via a sigmoid link function. Augmenting the model using a latent marked Poisson process and Pólya–Gamma random variables we obtain a representation of the likelihood which is conjugate to the GP prior. We estimate the posterior using a variational free–form mean field optimisation together with the framework of sparse GPs. Furthermore, as alternative approximation we suggest a sparse Laplace's method for the posterior, for which an efficient expectation–maximisation algorithm is derived to find the posterior's mode. Both algorithms compare well against exact inference obtained by a Markov Chain Monte Carlo sampler and standard variational Gauss approach solving the same model, while being one order of magnitude faster. Furthermore, the performance and speed of our method is competitive with that of another recently proposed Poisson process model based on a quadratic link function, while not being limited to GPs with squared exponential kernels and rectangular domains.

Keywords: Poisson process; Cox process; Gaussian process; data augmentation; variational inference

1. Introduction

Estimating the intensity rate of discrete events over a continuous space is a common problem for real world applications such as modeling seismic activity (Ogata, 1998), neural data (Brillinger, 1988), forestry (Stoyan and Penttinen, 2000) and so forth. A particularly common approach is a Bayesian model based on a so–called Cox process (Cox, 1955). The observed events are assumed to be generated from a Poisson process, whose intensity function is modeled as another random process with a given prior probability measure. The problem of inference for such type of models has also attracted interest in the Bayesian machine learning community in recent years. Møller et al. (1998); Brix and Diggle (2001); Cunningham et al. (2008) assumed that the intensity function is sampled from a Gaussian Process (GP) prior (Rasmussen and Williams, 2006). However, to restrict the intensity function of the Poisson process to nonnegative values, a common strategy is to choose a nonlinear link function which takes the GP as its argument and returns a valid intensity. Based on the success of variational approximations to deal with complex Gaussian process models, the inference problem for such Poisson models has attracted considerable interest in the machine learning community.

While powerful black–box variational Gaussian inference algorithms are available which can be applied to arbitrary link–functions, the choice of link–functions is not only crucial for defining the prior over intensities but can also be important for the efficiency of variational inference. The 'standard' choice of Cox processes with an exponential link function was treated in (Hensman et al., 2015). However, variational Gaussian inference for this link function has the disadvantage that the posterior variance becomes decoupled from the observations (Lloyd et al., 2015).[1] An interesting choice is the quadratic link function of (Lloyd et al., 2015) for which integrations over the data domain, which are necessary for sparse GP inference, can be (for specific kernel) computed analytically.[2] For both models, the minimisation of the variational free energies is performed by gradient descent techniques.

In this paper we will deal with approximate inference for a model with a sigmoid link–function. This model was introduced by (Adams et al., 2009) together with a MCMC sampling algorithm which was further improved by (Gunter et al., 2014) and (Teh and Rao, 2011). Kirichenko and van Zanten (2015) have shown that the model has favourable (frequentist) theoretical properties provided priors and hyperparameters are chosen appropriately. In contrast to a direct variational Gaussian approximation for the posterior distribution of the latent function, we will introduce an alternative type of variational approximation which is specially designed for the *sigmoidal Gaussian Cox process*. We build on recent work on Bayesian logistic regression by data augmentation with Pólya–Gamma random variables (Polson et al., 2013). This approach was already used in combination with GPs (Linderman et al., 2015; Wenzel et al., 2017), for stochastic processes in discrete time (Linderman et al., 2017), and for jump processes (Donner and Opper, 2017). We extend this method to an augmentation by a latent, marked Poisson process, where the marks are distributed according to a Pólya–Gamma distribution.[3] In this way, the augmented likelihood becomes conjugate to a GP distribution. Using a combination of a mean–field variational approximation together with sparse GP approximations (Csató and Opper, 2002; Csató, 2002; Titsias, 2009) we obtain explicit analytical variational updates leading to fast inference. In addition, we show that the same augmentation can be used for the computation of the maximum a posteriori (MAP) estimate by an expectation–maximisation (EM) algorithm. With this we obtain a Laplace approximation to the non–augmented posterior.

The paper is organised as follows: In section 2, we introduce the sigmoidal Gaussian Cox process model and its transformation by the variable augmentation. In section 3, we derive a variational mean field method and an EM–algorithm to obtain the MAP estimate, followed by the Laplace approximation of the posterior. Both methods are based on a sparse GP approximation to make the infinite dimensional problem tractable. In section 4, we demonstrate the performance of our method on synthetic data sets and compare with the results of a Monte Carlo sampling method for the model and the variational approximation of Hensman et al. (2015), which we modify to solve the Cox–process model with the scaled sigmoid link function. Then we compare our method to the state-of-the-art inference

algorithm (Lloyd et al., 2015) on artificial and real data sets with up to 10^4 observations. Section 5 presents a discussion and an outlook.

2. The Inference problem

We assume that N events $\mathcal{D} = \{\boldsymbol{x}_n\}_{n=1}^N$ are generated by a Poisson process. Each point $\boldsymbol{x}_n$ is a d–dimensional vector in the compact domain $\mathcal{X} \subset \mathbb{R}^d$. The goal is to infer the varying *intensity function* $\Lambda(\boldsymbol{x})$ (the mean measure of the process) for all $\boldsymbol{x} \in \mathcal{X}$ based on the likelihood

$$L(\mathcal{D}|\Lambda) = \exp\left(-\int_{\mathcal{X}} \Lambda(\boldsymbol{x}) d\boldsymbol{x}\right) \prod_{n=1}^{N} \Lambda(\boldsymbol{x}_n),$$

which is equal (up to a constant) to the density of a Poisson process having intensity Λ (see Appendix C and (Konstantopoulos et al., 2011)) with respect to a Poisson process with unit intensity. In a Bayesian framework, a prior over the intensity makes Λ a random process. Such a doubly stochastic point process is called *Cox process* (Cox, 1955). Since one needs $\Lambda(\boldsymbol{x}) \geq 0$, Adams et al. (2009) suggested a reparametrization of the intensity function by $\Lambda(\boldsymbol{x}) = \lambda\sigma(g(\boldsymbol{x}))$, where $\sigma(x) = (1 + e^{-x})^{-1}$ is the sigmoid function and λ is the maximum intensity rate. Hence, the intensity $\Lambda(\boldsymbol{x})$ is positive everywhere, for any arbitrary function $g(\boldsymbol{x}) : \mathcal{X} \to \mathbb{R}$ and the inference problem is to determine this function. Throughout this work we assume that $g(\cdot)$ will be modelled as a GP (Rasmussen and Williams, 2006) and the resulting process is called *sigmoidal Gaussian Cox process*. The likelihood for g becomes

$$L(\mathcal{D}|g, \lambda) = \exp\left(-\int_{\mathcal{X}} \lambda\sigma(g(\boldsymbol{x})) d\boldsymbol{x}\right) \prod_{n=1}^{N} \lambda\sigma(g_n), \tag{1}$$

where $g_n \doteq g(\boldsymbol{x}_n)$. For Bayesian inference we define a GP prior measure P_{GP} with zero mean and covariance kernel $k(\boldsymbol{x}, \boldsymbol{x}') : \mathcal{X} \times \mathcal{X} \to \mathbb{R}^+$. λ has as prior density (with respect to the ordinary Lebesgue measure) $p(\lambda)$ which we take to be a Gamma density with shape-, and rate parameter α_0 and β_0, respectively. Hence, for the prior we get the product measure $dP_{\mathrm{prior}} = dP_{\mathrm{GP}} \times p(\lambda)d\lambda$. The posterior density $\boldsymbol{p}$ (with respect to the prior measure) is given by

$$\boldsymbol{p}(g, \lambda|\mathcal{D}) \doteq \frac{dP_{\mathrm{posterior}}}{dP_{\mathrm{prior}}}(g, \lambda|\mathcal{D}) = \frac{L(\mathcal{D}|g, \lambda)}{\mathbb{E}_{P_{\mathrm{prior}}}[L(\mathcal{D}|g, \lambda)]}. \tag{2}$$

The normalising expectation in the denominator on the right hand side is with respect to the probability measure P_{prior}. To deal with the infinite dimensionality of GPs and Poisson processes we require a minimum of extra notation. We introduce densities or *Radon–Nikodým derivatives* such as defined in Equation (2) (see Appendix C or de G. Matthews et al. (2016)) with respect to infinite dimensional measures by boldface symbols $\boldsymbol{p}(\boldsymbol{z})$. On the other hand, non–bold densities $p(\boldsymbol{z})$ denote densities in the 'classical' sense, which means they are with respect to Lebesgue measure $d\boldsymbol{z}$.

Bayesian inference for this model is known to be doubly intractable (Murray et al., 2006). The likelihood in Equation (1) contains the integral of g over the space $\mathcal{X}$ in the exponent and the normalisation of the posterior in Equation (2) requires calculating expectation of Equation (1). In addition inference is hampered by the fact, that likelihood (1) depends

non–linearly on g (through sigmoid and exponent of sigmoid). In the following we tackle this by an augmentation scheme for the likelihood, such that it becomes conjugate to a GP prior and we subsequently can derive an analytic form of a variational posterior given one simple mean field assumption (Section 3).

2.1. Data augmentation I: Latent Poisson process

We will briefly introduce a data augmentation scheme by a latent Poisson process which forms the basis of the sampling algorithm of Adams et al. (2009). We will then extend this method further to an augmentation by a *marked* Poisson process. We focus on the exponential term in Equation (1). Utilizing the well known property of the sigmoid that $\sigma(x) = 1 - \sigma(-x)$ we can write

$$\exp\left(-\int_{\mathcal{X}} \lambda\sigma(g(\boldsymbol{x})) d\boldsymbol{x}\right) = \exp\left(-\int_{\mathcal{X}} (1 - \sigma(-g(\boldsymbol{x}))) \lambda d\boldsymbol{x}\right). \tag{3}$$

The left hand side has the form of a characteristic functional of a Poisson process. Generally, for a random set of points $\Pi_{\mathcal{Z}} = \{\boldsymbol{z}_m; \boldsymbol{z}_m \in \mathcal{Z}\}$ on a space $\mathcal{Z}$ and with a function $h(\boldsymbol{z})$, this is defined as

$$\mathbb{E}_{P_\Lambda}\left[\prod_{\boldsymbol{z}_m \in \Pi_{\mathcal{Z}}} e^{h(\boldsymbol{z}_m)}\right] = \exp\left(-\int_{\mathcal{Z}} \left(1 - e^{h(\boldsymbol{z})}\right) \Lambda(\boldsymbol{z}) d\boldsymbol{z}\right), \tag{4}$$

where P_Λ is the probability measure of a Poisson process with intensity $\Lambda(\boldsymbol{z})$. Equation (4) can be derived by Campbell's theorem (see Appendix A and (Kingman, 1993, chap. 3)) and identifies a Poisson process uniquely.

Setting $h(\boldsymbol{z}) = \ln\sigma(-g(\boldsymbol{z}))$, and $\mathcal{Z} = \mathcal{X}$, and combining Equation (3) and (4) we obtain the likelihood used by Adams et al. (2009, Eq. 4). However, in this work we make use of another augmentation, before invoking Campbell's theorem. This will result in a likelihood which is conjugate to the model priors and further simplifies inference.

2.2. Data augmentation II: Pólya–Gamma variables and marked Poisson process

Following Polson et al. (2013) we represent the inverse of the hyperbolic cosine as a scaled Gaussian mixture model

$$\cosh^{-b}(z/2) = \int_0^\infty e^{-\frac{z^2}{2}\omega} p_{\mathrm{PG}}(\omega|b, 0) d\omega, \tag{5}$$

where p_{PG} is a *Pólya–Gamma* density (Appendix B). We further define the *tilted* Pólya–Gamma density by

$$p_{\mathrm{PG}}(\omega|b, c) \propto e^{-\frac{c^2}{2}\omega} p_{\mathrm{PG}}(\omega|b, 0), \tag{6}$$

where $b > 0$ and c are parameters. We will not need an explicit form of this density, since the subsequently derived inference algorithms will only require the first moments. Those can be obtained directly from the moment generating function, which can be calculated straightforwardly from Equation (5) and (6) (see Appendix B). Equation (5) allows us to

rewrite the sigmoid function as

$$\sigma(z) = \frac{e^{\frac{z}{2}}}{2\cosh(\frac{z}{2})} = \int_0^\infty e^{f(\omega,z)} p_{\mathrm{PG}}(\omega|1,0)d\omega, \tag{7}$$

where we define

$$f(\omega, z) \doteq \frac{z}{2} - \frac{z^2}{2}\omega - \ln 2.$$

Setting $z = -g(\boldsymbol{x})$ in Equation (3) and substituting Equation (7) we get

$$\exp\left(-\int_{\mathcal{X}} \lambda\left(1-\sigma(-g(\boldsymbol{x}))\right) d\boldsymbol{x}\right) = \exp\left(-\int_{\mathcal{X}\times\mathbb{R}^+} \left(1 - e^{f(\omega,-g(\boldsymbol{x}))}\right)\ p_{\mathrm{PG}}(\omega|1,0)\ \lambda d\omega d\boldsymbol{x}\right). \tag{8}$$

Finally, we apply Campbell's theorem (Equation (4)) to Equation (8). The space is a product space $\mathcal{Z} = \hat{\mathcal{X}} \doteq \mathcal{X} \times \mathbb{R}^+$ and the intensity $\Lambda(\boldsymbol{x}, \omega) = \lambda p_{\mathrm{PG}}(\omega|1,0)$. This results in the final representation of the exponential in Equation (8)

$$\exp\left(-\int_{\hat{\mathcal{X}}} \left(1 - e^{f(\omega,-g(\boldsymbol{x}))}\right) \Lambda(\boldsymbol{x},\omega)\ d\omega d\boldsymbol{x}\right) = \mathbb{E}_{P_\Lambda}\left[\prod_{(\boldsymbol{x},\omega)_m \in \Pi_{\hat{\mathcal{X}}}} e^{f(\omega_m,-g_m)}\right].$$

Interestingly, the new Poisson process $\Pi_{\hat{\mathcal{X}}}$ with measure P_Λ has the form of a *marked* Poisson process (Kingman, 1993, chap. 5), where the latent Pólya-Gamma variables ω_m denote the 'marks' being independent random variables at each location $\boldsymbol{x}_m$. It is straightforward to sample such processes by first sampling the inhomogeneous Poisson process on domain $\mathcal{X}$ (for example by 'thinning' a process with constant rate (Lewis and Shedler, 1979; Adams et al., 2009)) and then drawing a mark ω on each event independently from the density $p_{\mathrm{PG}}(\omega|1,0)$.

Finally, using the Pólya–Gamma augmentation also for the discrete likelihood factors corresponding to the observed events in Equation (1) we obtain the following joint likelihood of the model

$$\begin{aligned} L(\mathcal{D}, \boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}|g,\lambda) &\doteq \frac{dP_{\mathrm{joint}}}{dP_{\mathrm{aug}}}(\mathcal{D}, \boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}|g,\lambda) \\ &= \prod_{(\boldsymbol{x},\omega)_m \in \Pi_{\hat{\mathcal{X}}}} e^{f(\omega_m,-g_m)} \prod_{n=1}^N \lambda e^{f(\omega_n,g_n)}, \end{aligned} \tag{9}$$

where we define the prior measure of augmented variables as $P_{\mathrm{aug}} = P_\Lambda \times P_{\boldsymbol{\omega}_N}$ and where $\boldsymbol{\omega}_N = \{\omega_n\}_{n=1}^N$ are the Pólya–Gamma variables for the observations $\mathcal{D}$ with the prior measure $dP_{\boldsymbol{\omega}_N} = \prod_{n=1}^N p(\omega_n|1,0)d\omega_n$. This augmented representation of the likelihood contains the function $g(\cdot)$ only linearly and quadratically in the exponents and is thus conjugate to the GP prior of $g(\cdot)$. Note that the original likelihood in Equation (1) can be recovered by $\mathbb{E}_{P_{\mathrm{aug}}}\left[L(\mathcal{D}, \boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}|g,\lambda)\right] = L(\mathcal{D}|g,\lambda)$.

3. Inference in the augmented space

Based on the augmentation we define a posterior density for the joint model with respect to the product measure $P_{\mathrm{prior}} \times P_{\mathrm{aug}}$

$$\begin{aligned} \boldsymbol{p}(\boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}, g, \lambda|\mathcal{D}) &\doteq \frac{dP_{\mathrm{posterior}}}{d(P_{\mathrm{prior}} \times P_{\mathrm{aug}})}(\boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}, g, \lambda|\mathcal{D}) \\ &= \frac{L(\mathcal{D}, \boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}|g,\lambda)}{L(\mathcal{D})}, \end{aligned} \tag{10}$$

where the denominator is the marginal likelihood $L(\mathcal{D}) = \mathbb{E}_{P_{\mathrm{prior}} \times P_{\mathrm{aug}}}\left[L(\mathcal{D}, \boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}|g,\lambda)\right]$. The posterior density of Equation (10) could be sampled using Gibbs sampling with explicit, tractable conditional densities. Similar to the variational approximation in the next section, one can show that the conditional measure of the point sets $\Pi_{\hat{\mathcal{X}}}$ and the variables $\boldsymbol{\omega}_N$, given the function $g(\cdot)$ and maximal intensity λ is a product of a specific marked Poisson process and independent (tilted) Pólya–Gamma densities. On the other hand, the distribution over function $g(\cdot)$ conditioned on $\Pi_{\hat{\mathcal{X}}}$ and $\boldsymbol{\omega}_N$ is a Gaussian process. Note, however, one needs to sample this GP only at the finite points $\boldsymbol{x}_m$ in the random set $\Pi_{\hat{\mathcal{X}}}$ and the fixed set $\mathcal{D}$.

3.1. Variational mean–field approximation

For variational inference one assumes that the desired posterior probability measure belongs to a family of measures for which the inference problem is tractable. Here we make a simple structured mean field assumption in order to fully utilise its conjugate structure: We approximate the posterior measure by

$$P_{\mathrm{posterior}}(\boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}, g, \lambda|\mathcal{D}) \approx Q_1(\boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}) \times Q_2(g,\lambda), \tag{11}$$

meaning that the dependencies between the Pólya–Gamma variables $\boldsymbol{\omega}_N$ and the marked Poisson process $\Pi_{\hat{\mathcal{X}}}$ on the one hand, and the function g and the maximal intensity λ on the other hand, are neglected. As we will see in the following, this simple mean–field assumption allows us to derive the posterior approximation analytically.

The variational approximation is optimised by minimising the Kullback–Leibler divergence between exact and approximated posteriors. This is equivalent to maximising the lower bound on the marginal likelihood of the observations

$$\mathcal{L}(\boldsymbol{q}) = \mathbb{E}_Q\left[\log\left\{\frac{L(\mathcal{D}, \boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}|g,\lambda)}{\boldsymbol{q}_1(\boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}})\boldsymbol{q}_2(g,\lambda)}\right\}\right] \leq \log L(\mathcal{D}), \tag{12}$$

where Q is the probability measure of the variational posterior in Equation (11) and we introduced approximate likelihoods

$$\boldsymbol{q}_1(\boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}) \doteq \frac{dQ_1}{dP_{\mathrm{aug}}}(\boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}), \qquad \boldsymbol{q}_2(g,\lambda) \doteq \frac{dQ_2}{dP_{\mathrm{prior}}}(g,\lambda).$$

Using standard arguments for mean field variational inference (Bishop, 2006, chap. 10) and Equation (11), one can then show that the optimal factors satisfy

$$\ln \boldsymbol{q}_1\left(\boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}\right) = \mathbb{E}_{Q_2}\left[\log L(\mathcal{D}, \boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}|g,\lambda)\right] + \mathrm{const.} \tag{13}$$

and

$$\ln \boldsymbol{q}_2(g,\lambda) = \mathbb{E}_{Q_1}\left[\log L(\mathcal{D}, \boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}|g,\lambda)\right] + \text{const.}\,, \tag{14}$$

respectively. These results lead to an iterative scheme for optimising $\boldsymbol{q}_1$ and $\boldsymbol{q}_2$ in order to increase the lower bound in Equation (12) in every step. From the structure of the likelihood one derives two further factorisations:

$$\boldsymbol{q}_1(\boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}) = \boldsymbol{q}_1(\boldsymbol{\omega}_N)\boldsymbol{q}_1(\Pi_{\hat{\mathcal{X}}}), \tag{15}$$
$$\boldsymbol{q}_2(g,\lambda) = \boldsymbol{q}_2(g)\boldsymbol{q}_2(\lambda), \tag{16}$$

where the densities are defined with respect to the measures $dP(\boldsymbol{\omega}_N)$, dP_Λ, dP_{GP}, and $p(\lambda)d\lambda$, respectively. The subsequent section describes these updates explicitly.

Optimal Pólya–Gamma density Following Equation (13) and (15) we obtain

$$\boldsymbol{q}_1(\boldsymbol{\omega}_N) = \prod_{n=1}^{N} \frac{\exp\left(-\frac{c_1^{(n)}}{2}\omega_n\right)}{\cosh^{-1}\left(c_1^{(n)}/2\right)} = \prod_{n=1}^{N} \frac{p_{\text{PG}}\left(\omega_n|1,c_1^{(n)}\right)}{p_{\text{PG}}\left(\omega_n|1,0\right)},$$

where the factors are *tilts* of the prior Pólya-Gamma densities (see Equation (6) and Appendix B) with $c_1^{(n)} = \sqrt{\mathbb{E}_{Q_2}\left[g_n^2\right]}$. By simple density transformation we obtain the density with respect to the Lebesgue measure as

$$q_1(\boldsymbol{\omega}_N) = \boldsymbol{q}_1(\boldsymbol{\omega}_N)\left|\frac{dP_{\boldsymbol{\omega}_N}}{d\boldsymbol{\omega}_N}\right| = \prod_{n=1}^{N} p_{\text{PG}}\left(\omega_n|1,c_1^{(n)}\right), \tag{17}$$

being a product of *tilted* Pólya–Gamma densities.

Optimal Poisson process Using Equation (13) and (15) we obtain

$$\boldsymbol{q}_1(\Pi_{\hat{\mathcal{X}}}) = \frac{\prod_{(\boldsymbol{x},\omega)_m \in \Pi_{\hat{\mathcal{X}}}} e^{\mathbb{E}_{Q_2}[f(\omega_m,-g_m)]}\lambda_1}{\exp\left(\int_{\hat{\mathcal{X}}}\left(e^{\mathbb{E}_{Q_2}[f(\omega,-g(\boldsymbol{x}))]}-1\right)\lambda_1 p_{\text{PG}}(\omega|1,0)d\boldsymbol{x}d\omega\right)}, \tag{18}$$

with $\lambda_1 \doteq e^{\mathbb{E}_{Q_2}[\log\lambda^*]}$. Note, that $\mathbb{E}_{Q_2}\left[f(\omega_m,-g_m)\right]$ involves the expectations $\mathbb{E}_{Q_2}\left[g_m\right]$ and $\mathbb{E}_{Q_2}\left[(g_m)^2\right]$. One can show, that Equation (18) is again a marked Poisson process with intensity

$$\begin{aligned}\Lambda_1(\boldsymbol{x},\omega) =& \lambda_1 \frac{\exp\left(-\frac{\mathbb{E}_{Q_2}[g(\boldsymbol{x})]}{2}\right)}{2\cosh\left(\frac{c_1(\boldsymbol{x})}{2}\right)} p_{\text{PG}}\left(\omega|1,c_1(\boldsymbol{x})\right) \\ =& \lambda_1\sigma(-c_1(\boldsymbol{x}))\exp\left(\frac{c_1(\boldsymbol{x})-\mathbb{E}_{Q_2}\left[g(\boldsymbol{x})\right]}{2}\right) p_{\text{PG}}\left(\omega|1,c_1(\boldsymbol{x})\right)\end{aligned} \tag{19}$$

where $c_1(\boldsymbol{x}) = \sqrt{\mathbb{E}_{Q_2}\left[g(\boldsymbol{x})^2\right]}$ (for a proof see Appendix D).

Optimal Gaussian process From Equation (14) and (16) we obtain the optimal approximation of the posterior likelihood (note that this is defined relative to GP prior)

$$\boldsymbol{q}_2(g) \propto e^{U(g)},$$

where the effective log–likelihood is given by

$$U(g) = \mathbb{E}_{Q_1}\left[\sum_{(\boldsymbol{x},\omega)_m \in \Pi_{\hat{\mathcal{X}}}} f(\omega_m, -g_m)\right] + \sum_{n=1}^{N}\mathbb{E}_{Q_1}\left[f(\omega_n, g(\boldsymbol{x}_n))\right].$$

The first expectation is over the variational Poisson process $\Pi_{\hat{\mathcal{X}}}$ and the second one over the Pólya–Gamma variables $\boldsymbol{\omega}_N$. These can be easily evaluated (see Appendix A) and one finds

$$U(g) = -\frac{1}{2}\int_{\mathcal{X}} A(\boldsymbol{x})g(\boldsymbol{x})^2 d\boldsymbol{x} + \int_{\mathcal{X}} B(\boldsymbol{x})g(\boldsymbol{x})d\boldsymbol{x}, \tag{20}$$

with

$$\begin{aligned}A(\boldsymbol{x}) =& \sum_{n=1}^{N}\mathbb{E}_{Q_1}\left[\omega_n\right]\delta(\boldsymbol{x}-\boldsymbol{x}_n) + \int_0^\infty \omega\Lambda_1(\boldsymbol{x},\omega)d\omega, \\ B(\boldsymbol{x}) =& \frac{1}{2}\sum_{n=1}^{N}\delta(\boldsymbol{x}-\boldsymbol{x}_n) - \frac{1}{2}\int_0^\infty \Lambda_1(\boldsymbol{x},\omega)d\omega,\end{aligned}$$

where $\delta(\cdot)$ is the Dirac delta function. The expectations and integrals over ω are

$$\begin{aligned}&\mathbb{E}_{Q_1}\left[\omega_n\right] = \frac{1}{2c_1^{(n)}}\tanh\left(\frac{c_1^{(n)}}{2}\right), \\ &\int_0^\infty \Lambda_1(\boldsymbol{x},\omega)d\omega = \lambda_1\sigma(-c_1(\boldsymbol{x}))\exp\left(\frac{c_1(\boldsymbol{x})-\mathbb{E}_{Q_2}\left[g(\boldsymbol{x})\right]}{2}\right) \doteq \Lambda_1(\boldsymbol{x}), \\ &\int_0^\infty \omega\Lambda_1(\boldsymbol{x},\omega)d\omega = \frac{1}{2c_1(\boldsymbol{x})}\tanh\left(\frac{c_1(\boldsymbol{x})}{2}\right)\Lambda_1(\boldsymbol{x}).\end{aligned}$$

The resulting variational distribution defines a Gaussian process. Because of the mean–field assumption the integrals in Equation (20) do not require integration over random variables, but only solving two deterministic integrals over space $\mathcal{X}$. However, those integrals depend on function g over the entire space and it is not possible for a general kernel to compute the marginal posterior density at an input $\boldsymbol{x}$ in closed form. For specific GP kernel operators, which are the inverses of differential operators, a solution in terms of linear partial differential equations would be possible. This could be of special interest for one–dimensional problems where Matern kernels with integer parameters (Rasmussen and Williams, 2006) fulfill this condition. Here, the problem becomes equivalent to inference for a (continuous time) Gaussian hidden Markov model and could be solved by performing a forward–backward algorithm (Solin, 2016). This would reduce the computations to the solution of ordinary differential equations. We will discuss details of such an approach elsewhere. To deal with general kernels we will resort instead to a the well known variational sparse GP approximation with inducing points.

Optimal sparse Gaussian process The sparse variational Gaussian approximation follows the standard approach (Csató and Opper, 2002; Csató, 2002; Titsias, 2009) and its generalisation to a continuum likelihood (Batz et al., 2018; de G. Matthews et al., 2016). For completeness, we repeat the derivation here and more detailed in Appendix E. We approximate $\boldsymbol{q}_2(g)$ by a sparse likelihood GP $\boldsymbol{q}_2^s(g)$ with respect to the GP prior

$$\frac{dQ_2^s}{dP}(g) = \boldsymbol{q}_2^s(\boldsymbol{g}_s), \tag{21}$$

which depends only on a finite dimensional vector of function values $\boldsymbol{g}_s = (g(\boldsymbol{x}_1), \ldots, g(\boldsymbol{x}_L))^\top$ at a set of *inducing points* $\{\boldsymbol{x}_l\}_{l=1}^L$. With this approach it is again possible to marginalise out exactly all the infinitely many function values outside of the set of inducing points. The sparse likelihood $\boldsymbol{q}_2^s$ is optimised by minimising the Kullback–Leibler divergence

$$\mathrm{D}_{\mathrm{KL}}(Q_2^s \| Q_2) = \mathbb{E}_{Q_2^s}\left[\log \frac{\boldsymbol{q}_2^s(g)}{\boldsymbol{q}_2(g)}\right].$$

A short computation (Appendix E) shows that

$$q_2^s(\boldsymbol{g}_s) \propto e^{U^s(\boldsymbol{g}_s)} \qquad \text{with } U^s(\boldsymbol{g}_s) = \mathbb{E}_{P(g|\boldsymbol{g}_s)}\left[U(g)\right],$$

where the conditional expectation is with respect to the GP prior measure given the function $\boldsymbol{g}_s$ at the inducing points. The explicit calculation requires the conditional expectations of $g(\boldsymbol{x})$ and of $(g(\boldsymbol{x}))^2$. We get

$$\mathbb{E}_{P(g|\boldsymbol{g}_s)}\left[g(\boldsymbol{x})\right] = \boldsymbol{k}_s(\boldsymbol{x})^\top K_s^{-1} \boldsymbol{g}_s, \tag{22}$$

where $\boldsymbol{k}_s(\boldsymbol{x}) = (k(\boldsymbol{x}, \boldsymbol{x}_1), \ldots, k(\boldsymbol{x}, \boldsymbol{x}_L))^\top$ and K_s is the kernel matrix between inducing points. For the second expectation, we get

$$\mathbb{E}_{P(g|\boldsymbol{g}_s)}\left[g^2(\boldsymbol{x})\right] = \left(\mathbb{E}_{P(g|\boldsymbol{g}_s)}\left[g(\boldsymbol{x})\right]\right)^2 + \text{const.} \tag{23}$$

The constant equals the conditional variance of $g(\boldsymbol{x})$ which does not depend on the sparse set $\boldsymbol{g}_s$, but only on the locations of the sparse points. Because we are dealing now with a finite problem we can define the 'ordinary' posterior density of the GP at the inducing points with respect to the Lebesgue measure $d\boldsymbol{g}_s$. From Equation (20), (22), and (23), we conclude that the sparse posterior at the inducing variables is a multivariate Gaussian density

$$q_2^s(\boldsymbol{g}_s) = \mathcal{N}(\boldsymbol{\mu}_2^s, \Sigma_2^s), \tag{24}$$

with the covariance matrix given by

$$\Sigma_2^s = \left[K_s^{-1} \int_{\mathcal{X}} A(\boldsymbol{x}) \boldsymbol{k}_s(\boldsymbol{x}) \boldsymbol{k}_s(\boldsymbol{x})^\top d\boldsymbol{x}\, K_s^{-1} + K_s^{-1}\right]^{-1}, \tag{25}$$

and the mean

$$\boldsymbol{\mu}_2^s = \Sigma_2^s \left(K_s^{-1} \int_{\mathcal{X}} B(\boldsymbol{x}) \boldsymbol{k}_s(\boldsymbol{x}) d\boldsymbol{x}\right). \tag{26}$$

In contrast to other variational approximations (see for example (Lloyd et al., 2015; Hensman et al., 2015)) we obtain a closed analytic form of the variational posterior mean and

covariance which holds for arbitrary GP kernels. However, these results depend on finite dimensional integrals over the space $\mathcal{X}$ which cannot be computed analytically. This is different to the sparse approximation for the Poisson model with square link function (Lloyd et al., 2015), where similar integrals in the case of the squared exponential kernel can be obtained analytically. Hence, we resort to a simple Monte–Carlo integration, where *integration points* are sampled uniformly on $\mathcal{X}$ as

$$I_F = \int_{\mathcal{X}} F(\boldsymbol{x}) d\boldsymbol{x} \approx \frac{|\mathcal{X}|}{R} \sum_{r=1}^{R} F(\boldsymbol{x}_r).$$

The set of integration points $\{\boldsymbol{x}_r\}_{r=1}^R$ is drawn uniformly from the space $\mathcal{X}$.

Finally, from Equation (21) and (24) we obtain the mean function and the variance of the sparse approximation for every point $\boldsymbol{x} \in \mathcal{X}$, which is

$$\mu_2(\boldsymbol{x}) = \mathbb{E}_{Q_2}\left[g(\boldsymbol{x})\right] = \boldsymbol{k}_s(\boldsymbol{x})^\top K_s^{-1} \boldsymbol{\mu}_2^s, \tag{27}$$

and variance

$$(s_2(\boldsymbol{x}))^2 = k(\boldsymbol{x}, \boldsymbol{x}) - \boldsymbol{k}_s(\boldsymbol{x})^\top K_s^{-1} \left(\mathbf{I} - \Sigma_2^s K_s^{-1}\right) \boldsymbol{k}_s(\boldsymbol{x}), \tag{28}$$

where $\mathbf{I}$ is the identity matrix.

Optimal density for maximal intensity λ From Equation (14) we identify the optimal density as a Gamma density

$$q_2(\lambda) = \mathrm{Gamma}(\lambda | \alpha_2, \beta_2) = \frac{\beta_2^{\alpha_2}(\lambda)^{\alpha_2 - 1} \mathrm{e}^{-\beta_2 \lambda}}{\Gamma(\alpha_2)}, \tag{29}$$

where $\alpha_2 = N + \mathbb{E}_{Q_1}\left[\mathbf{1}_\Pi(\boldsymbol{x})\right] + \alpha_0$, $\beta_2 = \beta_0 + \int_{\mathcal{X}} d\boldsymbol{x}$ and $\Gamma(\cdot)$ is the gamma function. $\mathbf{1}_\Pi(\boldsymbol{x})$ denotes the indicator function being 1 if $\boldsymbol{x} \in \Pi$ and 0 otherwise and the integral is again solved by Monte Carlo integration. This defines the required expectations for updating q_1 by $\mathbb{E}_{Q_2}\left[\lambda\right] = \frac{\alpha_2}{\beta_2}$ and $\mathbb{E}_{Q_2}\left[\log \lambda\right] = \psi(\alpha_2) - \log \beta_2$, where $\psi(\cdot)$ is the digamma function.

Hyperparameters Hyperparameters of the model are (i) the covariance parameters $\boldsymbol{\theta}$ of the GP, (ii) the locations of the inducing points $\{\boldsymbol{x}_l\}_{l=1}^L$, and (iii) the prior parameters α_0, β_0 for the maximal intensity λ. The covariance parameters (i) $\boldsymbol{\theta}$ are optimised by gradient ascent following the gradient of the lower bound in Equation (12) with respect to $\boldsymbol{\theta}$ (Appendix F). As gradient ascent algorithm we employ the ADAM algorithm (Kingma and Ba, 2014). We perform always one step after the variational posterior q is updated as described before. (ii) The locations of the sparse GP $\{\boldsymbol{x}_l\}_{l=1}^L$ could in principle be optimised as well, but we keep them fixed and position them on a regular grid over the space $\mathcal{X}$. From this choice it follows that K_s is a Toeplitz matrix, when the kernel is translationally invariant. This could be inverted in $\mathcal{O}(L(\log L)^2)$ instead of $\mathcal{O}(L^3)$ operations (Press et al., 2007) but we do not employ this fact. Finally, (iii) the value for prior parameters α_0 and β_0 are chosen such that $p(\lambda)$ has a mean twice and standard deviation once the intensity one would expect for a homogeneous Poisson Process observing $\mathcal{D}$. The complete variational procedure is outlined in Algorithm 1.

Algorithm 1: Variational Bayes algorithm for sigmoidal Gaussian Cox process.

Init: $\mathbb{E}_Q\left[g(\boldsymbol{x})\right], \mathbb{E}_Q\left[(g(\boldsymbol{x}))^2\right]$ at $\mathcal{D}$ and integration points, and $\mathbb{E}_Q\left[\lambda\right], \mathbb{E}_Q\left[\log\lambda\right]$
while $\mathcal{L}$ *not converged* **do**
  Update q_1
    PG distributions at observations: $q_1(\boldsymbol{\omega}_N)$ with Eq. (17)
    Rate of latent process: $\Lambda_1(\boldsymbol{x}, \omega)$ at integration points with Eq. (19)
  Update q_2
    Sparse GP distribution: $\Sigma_2^s, \boldsymbol{\mu}_2^s$ with Eq. (25), (26)
    GP at $\mathcal{D}$ and integration points: $\mathbb{E}_{Q_2}\left[g(\boldsymbol{x})\right], \mathbb{E}_{Q_2}\left[(g(\boldsymbol{x}))^2\right]$ with Eq. (27), (28)
    Gamma-distribution of λ: α_2, β_2 with Eq. (29)
  Update kernel parameters with gradient ascent
end

3.2. Laplace approximation

In this section we will show that our variable augmentation method is well suited for computing a Laplace approximation (Bishop, 2006, chap. 4) to the joint posterior of the GP function $g(\cdot)$ and the maximal intensity λ as an alternative to the previous variational scheme. To do so we need the maximum a posteriori (MAP) estimate (equal to the mode of the posterior distribution) and a second order Taylor expansion around this mode. The augmentation method will be used to compute the MAP estimator iteratively using an EM algorithm.

Obtaining the MAP estimate In general, a proper definition of the posterior mode would be necessary, because the GP posterior is over a space of functions, which is an infinite dimensional object and does not have a density with respect to Lebesgue measure. A possibility to avoid this problem would be to discretise the spatial integral in the likelihood and to approximate the posterior by a multivariate Gaussian density for which the mode can then be computed by setting the gradient equal to zero. In this paper, we will use a different approach which defines the mode directly in function space and allows us to utilise the sparse GP approximation developed previously for the computations. A mathematically proper way would be to derive the MAP estimator by maximising a properly penalised log–likelihood. As discussed e.g. in Rasmussen and Williams (2006, chap. 6) for GP models with likelihoods which depend on finitely many inputs only, this penalty is given by the squared reproducing kernel Hilbert space (RKHS) norm that corresponds to the GP kernel. Hence, we would have

$$(g^*, \lambda^*) = \operatorname{argmin}_{g\in\mathcal{H}_k,\lambda}\left\{-\ln L(\mathcal{D}|g,\lambda) - \ln p(\lambda) + \frac{1}{2}\|g\|^2_{\mathcal{H}_k}\right\},$$

where $\|g\|^2_{\mathcal{H}_k}$ is the RKHS norm for the kernel k. This penalty term can be understood as a proper generalisation of a Gaussian log–prior density to function space. We will not give a formal definition here but work on a more heuristic level in the following. Rather than attempting a direct optimisation, we will use an EM algorithm instead, applying the

variable augmentation with the Poisson process and Pólya–Gamma variables introduced in the previous sections. In this case, the likelihood part of the resulting '$\mathcal{Q}$–function'

$$\mathcal{Q}((g,\lambda)|(g,\lambda)^{\text{old}}) \doteq \mathbb{E}_{P(\boldsymbol{\omega}_N,\Pi_{\hat{\mathcal{X}}}|(g,\lambda)^{\text{old}})}\left[\ln L(\mathcal{D},\boldsymbol{\omega}_N,\Pi_{\hat{\mathcal{X}}}|g,\lambda)\right] + \ln p(\lambda) - \frac{1}{2}\|g\|^2_{\mathcal{H}_k}, \quad (30)$$

that needs to be maximised in the M–step becomes (as in the variational approach before) the likelihood of *a Gaussian model* in the GP function g. Hence, we can argue that the function g which maximises $\mathcal{Q}$ is equal to the *posterior mean* of the resulting Gaussian model and can be computed without discussing the explicit form of the RKHS norm.

The conditional probability measure $P(\boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}|(g,\lambda)^{\text{old}})$ is easily obtained similar to the optimal measure Q_1 by not averaging over g and λ. This gives us straightforwardly the density

$$\boldsymbol{p}(\boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}|(g,\lambda)^{\text{old}}) = \boldsymbol{p}(\boldsymbol{\omega}_N|(g,\lambda)^{\text{old}})\boldsymbol{p}(\Pi_{\hat{\mathcal{X}}}|(g,\lambda)^{\text{old}}).$$

The first factor is

$$p(\boldsymbol{\omega}_N|(g,\lambda)^{\text{old}}) = \boldsymbol{p}(\boldsymbol{\omega}_N|(g,\lambda)^{\text{old}})\left|\frac{dP_{\boldsymbol{\omega}_N}}{d\boldsymbol{\omega}_N}\right| = \prod_{n=1}^{N} p_{\text{PG}}\left(\omega_n|1,\tilde{c}_n\right),$$

with $\tilde{c}_n = |g_n^{\text{old}}|$. The latent point process $\Pi_{\hat{\mathcal{X}}}$ is again a Poisson process density

$$\boldsymbol{p}(\Pi_{\hat{\mathcal{X}}}|(g,\lambda)^{\text{old}}) = \frac{dP_{\tilde{\Lambda}}}{dP_{\Lambda}}(\Pi_{\hat{\mathcal{X}}}|(g,\lambda)^{\text{old}}),$$

where the intensity is

$$\tilde{\Lambda}(\boldsymbol{x},\omega) = \lambda^{\text{old}}\sigma(-g^{\text{old}}(\boldsymbol{x}))p_{\text{PG}}\left(\omega|1,\tilde{c}(\boldsymbol{x})\right),$$

with $\tilde{c}(\boldsymbol{x}) = |g^{\text{old}}(\boldsymbol{x})|$. The first term in the $\mathcal{Q}$–function is

$$\begin{aligned} U(g,\lambda) &\doteq \mathbb{E}_{P(\boldsymbol{\omega}_N,\Pi_{\hat{\mathcal{X}}}|(g,\lambda)^{\text{old}})}\left[\ln L(\mathcal{D},\boldsymbol{\omega}_N,\Pi_{\hat{\mathcal{X}}}|g,\lambda)\right] \\ &= -\frac{1}{2}\int_{\mathcal{X}}\tilde{A}(\boldsymbol{x})g(\boldsymbol{x})^2 d\boldsymbol{x} + \int_{\mathcal{X}}\tilde{B}(\boldsymbol{x})g(\boldsymbol{x})d\boldsymbol{x}, \end{aligned}$$

with

$$\begin{aligned} \tilde{A}(\boldsymbol{x}) &= \sum_{n=1}^{N}\mathbb{E}_{P(\omega_n|(g,\lambda)^{\text{old}})}\left[\omega_n\right]\delta(\boldsymbol{x}-\boldsymbol{x}_n) + \int_0^\infty \mathbb{E}_{P(\omega|(g,\lambda)^{\text{old}})}\left[\omega\right]\tilde{\Lambda}(\boldsymbol{x},\omega)d\omega, \\ \tilde{B}(\boldsymbol{x}) &= \frac{1}{2}\sum_{n=1}^{N}\delta(\boldsymbol{x}-\boldsymbol{x}_n) - \frac{1}{2}\int_0^\infty \tilde{\Lambda}(\boldsymbol{x},\omega)d\omega. \end{aligned}$$

We have already tackled almost identical log–likelihood expressions in Section 3.1 (see Equation (20)). While for specific priors (with precision kernels given by differential operators) an exact treatment in terms of solutions of ODEs or PDEs is possible, we will again resort to the sparse GP approximation instead. The sparse version $U^s(\boldsymbol{g}_s,\lambda)$ is obtained by replacing $g(\boldsymbol{x}) \to \mathbb{E}_{P(g|\boldsymbol{g}_s)}\left[g(\boldsymbol{x})\right]$ in $U(g,\lambda)$. From this we obtain the sparse $\mathcal{Q}$–function as

$$\mathcal{Q}^s((\boldsymbol{g}_s,\lambda)|(\boldsymbol{g}_s,\lambda)^{\text{old}}) \doteq U^s(\boldsymbol{g}_s,\lambda) + \ln p(\lambda) - \frac{1}{2}\boldsymbol{g}_s^\top K_s^{-1}\boldsymbol{g}_s. \quad (31)$$

The function values $\boldsymbol{g}_s$ and the maximal intensity λ that maximise Equation (31) can be found analytically by solving

$$\frac{\partial \mathcal{Q}^s}{\partial \boldsymbol{g}_s} = \mathbf{0} \text{ and } \frac{\partial \mathcal{Q}^s}{\partial \lambda} = 0.$$

The final MAP estimate is obtained after convergence of the EM algorithm and the desired sparse MAP solution for $g(x)$ is given by (see Equation (27))

$$g_{MAP}(\boldsymbol{x}) = \boldsymbol{k}_s(\boldsymbol{x})^\top K_s^{-1} \boldsymbol{g}^s$$

As for the variational scheme, integrals over the space $\mathcal{X}$ are approximated by Monte–Carlo integration. An alternative derivation of the sparse MAP solution can be based on restricting the minimisation of (30) to functions which are linear combinations of kernels centred at the inducing points and using the definition of the RKHS norm (see (Rasmussen and Williams, 2006, chap. 6)).

Sparse Laplace posterior To complete the computation of the Laplace approximation, we need to evaluate the quadratic fluctuations around the MAP solution. We will also do this with the previously obtained sparse approximation. The idea is that from the converged MAP solution, we define a sparse likelihood of the Poisson model via the replacement

$$L^s(\boldsymbol{g}_s, \lambda) \doteq L(\mathcal{D}|\mathbb{E}_{P(g|\boldsymbol{g}_s)}[g], \lambda)$$

For this sparse likelihood it is easy to compute the Laplace posterior using second derivatives. Here, the change of variables $\rho = \ln \lambda$ will be made to ensure that $\lambda > 0$. This results in an effective log–normal density over the maximal intensity rate λ. While we do not address hyperparameter selection for the Laplace posterior in this work, a straightforward approach, as suggested by Flaxman et al. (2017), could be to use cross validation to optimise the kernel parameters while finding the MAP estimate or to use the Laplace approximation to approximate the evidence. As in the variational case the inducing point locations $\{\boldsymbol{x}_l\}_{l=1}^L$ will be on a regular grid over space $\mathcal{X}$.

Note that for the Laplace approximation, the augmentation scheme is only used to compute the MAP estimate in an efficient way. There are no further mean–field approximations involved. This also implies, that dependencies between $\boldsymbol{g}_s$ and λ are retained.

3.3. Predictive density

Both variational and Laplace approximation yield a posterior distribution q over $\boldsymbol{g}_s$ and λ. The GP approximation at any given points in $\mathcal{X}$ is given by

$$q(g(\boldsymbol{x})) = \int\int p(g(\boldsymbol{x})|\boldsymbol{g}_s) q(\boldsymbol{g}_s, \lambda)\, d\boldsymbol{g}_s d\lambda,$$

which for both methods results in a normal density. To find the posterior mean of the intensity function at a point $\boldsymbol{x} \in \mathcal{X}$ one needs to compute

$$\mathbb{E}_Q[\Lambda(\boldsymbol{x})] = \mathbb{E}_Q\left[\lambda \int_{-\infty}^{\infty} \sigma(g(\boldsymbol{x}))\right].$$

For variational and Laplace posterior the expectation over λ can be computed analytically, leaving the expectation over $g(\boldsymbol{x})$, which is computed numerically via quadrature methods. To evaluate the performance of inference results we are interested in computing the likelihood on test data $\mathcal{D}_{\text{test}}$, generated from the ground truth. We will consider two methods:

Sampling GPs g from the posterior we calculate the (log) mean of the test likelihood

$$\begin{aligned}\ell(\mathcal{D}_{\text{test}}) &= \ln \mathbb{E}_P\left[L(\mathcal{D}_{\text{test}}|\Lambda)|\mathcal{D}\right] \approx \ln \mathbb{E}_Q\left[L(\mathcal{D}_{\text{test}}|\Lambda)\right] \\ &= \ln \mathbb{E}_Q\left[\exp\left(-\int_{\mathcal{X}} \lambda\sigma(g(\boldsymbol{x}))d\boldsymbol{x}\right) \prod_{\boldsymbol{x}_n \in \mathcal{D}_{\text{test}}} \lambda\sigma(g(\boldsymbol{x}_n))\right]\end{aligned} \tag{32}$$

where the integral in the exponent is approximated by Monte–Carlo integration. The expectation is approximated by averaging over 2×10^3 samples from the inferred posterior Q of λ and g at the observations of $\mathcal{D}_{\text{test}}$ and the integration points.
Instead of sampling one can also obtain an analytic approximation for the log test likelihood in Equation (32) by a second order Taylor expansion around the mean of the obtained posterior. Applying this idea to the variational mean field posterior we get

$$\begin{aligned}\ell(\mathcal{D}_{\text{test}}) \approx &\ln L(\mathcal{D}_{\text{test}}|\Lambda_Q) + \frac{1}{2}\mathbb{E}_Q\left[(\boldsymbol{g}_s - \boldsymbol{\mu}_2^s)^\top \mathbf{H}_{\boldsymbol{g}_s}\big|_{\Lambda_Q} (\boldsymbol{g}_s - \boldsymbol{\mu}_2^s)\right] \\ &+ \frac{1}{2} H_\lambda|_{\Lambda_Q} \operatorname{Var}_Q(\lambda),\end{aligned} \tag{33}$$

where $\Lambda_Q(\boldsymbol{x}) = \mathbb{E}_Q[\lambda]\, \sigma(\mathbb{E}_Q[g(\boldsymbol{x})])$ and $\mathbf{H}_{\boldsymbol{g}_s}\big|_{\Lambda_Q}$, $H_\lambda|_{\Lambda_Q}$ are the second order derivative of the likelihood in Equation (1) with respect to $\boldsymbol{g}_s$ and λ at Λ_Q. While an approximation only involving the first term would neglect the uncertainties in the posterior (as done by John and Hensman (2018)), the second and third term take these into account.

4. Results

Generating data from the model To evaluate the two newly developed algorithms we generate data according to the sigmoidal Gaussian Cox process model

$$\begin{aligned} g &\sim \boldsymbol{p}_{\text{GP}}(\cdot|0, k), \\ \mathcal{D} &\sim \boldsymbol{p}_\Lambda(\cdot), \end{aligned}$$

where $\boldsymbol{p}_\Lambda(\cdot)$ is the Poisson process density over sets of point with $\Lambda(\boldsymbol{x}) = \lambda\sigma(g(\boldsymbol{x}))$ and $\boldsymbol{p}_{\text{GP}}(\cdot|0, k)$ is a GP density with mean 0 and covariance function k. As kernel we choose a squared exponential function

$$k(\boldsymbol{x}, \boldsymbol{x}') = \theta \prod_{i=1}^{d} \exp\left(-\frac{(x_i - x_i')^2}{2\nu_i^2}\right),$$

where the hyperparameters are scalar θ and length scales $\boldsymbol{\nu} = (\nu_1, \ldots, \nu_d)^\top$. Sampling of the inhomogeneous Poisson process is done via *thinning* (Lewis and Shedler, 1979; Adams et al., 2009). We assume that hyperparameters are known for subsequent experiments with data sampled from the generative model.

Benchmarks for sigmoidal Gaussian Cox process inference We compare the proposed algorithms to two alternative inference methods for the sigmoidal Gaussian Cox process model. As an exact inference method we use the sampling approach of Adams et al. (2009)[4]. In terms of speed, a competitor is a different variational approach given by Hensman et al. (2015) who proposed to discretise space $\mathcal{X}$ in several regular bins with size Δ. Then the likelihood in Equation (1) is approximated by

$$L(\mathcal{D}|\lambda\sigma(g(\boldsymbol{x}))) \approx \prod_i p_{\text{po}}(n_i|\lambda\sigma(g(\boldsymbol{x}_i))\Delta),$$

where p_{po} is the Poisson distribution conditioned on the mean parameter, $\boldsymbol{x}_i$ is the centre of bin i, and n_i the number of observations within this bin. Using a (sparse) Gaussian variational approximation the corresponding Kullback–Leibler divergence is minimised by gradient ascent to find the optimal posterior over the GP g and a point estimate for λ. This method was originally proposed for the log Cox-process ($\Lambda(\boldsymbol{x}) = e^{g(\boldsymbol{x})}$), but with the elegant GPflow package (Matthews et al., 2017) implementation of the scaled sigmoid link function is straightforward. It should be noted, that this method requires numerical integration over the sigmoid link function to evaluate the variational lower bound at every spatial bin and every gradient step, since it does not make use of our augmentation scheme (see Section 5 for discussion, how the proposed augmentation can be used for this model). We refer to this inference algorithm as 'variational Gauss'. To have fair comparison between the different methods, the inducing points for all algorithms (except for the sampler) are equal and the number of bins used to discretise the domain $\mathcal{X}$ for the variational Gauss algorithm is set equal to the number of integration points used for the MC integration in the variational mean field and the Laplace method.

Experiments on data from generative model As an illustrative example we sample a one dimensional Poisson process with the generative model and perform inference with the sampler (2×10^3 samples after 10^3 burn-in iterations), the mean field algorithm, the Laplace approximation and the variational Gauss. In Figure 1 **(a)**–**(d)** the different posterior mean intensity functions with their standard deviations are shown. For **(b)**–**(d)** 50 regularly spaced inducing points are used. For **(b)**–**(c)** 2×10^3 random integration points are drawn uniformly over the space $\mathcal{X}$, while for **(d)** $\mathcal{X}$ is discretised into the same number of bins. All algorithms recover the true intensity well. The mean field and the Laplace algorithm show smaller posterior variance compared to the sampler. The fastest inference result is obtained by the Laplace algorithm in 0.02 s, followed by the mean field (0.09), variational Gauss (80) and the sampler (1.8×10^3). The fast convergence of the Laplace and the variational mean field algorithm is illustrated in Figure 1 **(e)**, where objective functions of our two algorithms (minus the maximum they converged to) is shown as a function of run time. Both algorithms reach a plateau in only a few (~ 6) iterations. To compare performance in terms of log expected test likelihood ℓ_{test} (test sets $\mathcal{D}_{\text{test}}$ sampled from the ground truth), we averaged results over ten independent data sets. The posterior of the sampler yields the highest value with 875.5, while variational ($\ell_{\text{test}} = 686.2$, approximation by Equation (33) yields 686.5), variational Gauss (686.7) and Laplace (686.1) yield all similar results (see also Figure 4 **(a)**). The posterior density of the maximal intensity λ is shown in Figure 1 **(f)**.

4. To increase efficiency, the GP values g are sampled by elliptical slice sampling (Murray et al., 2010).

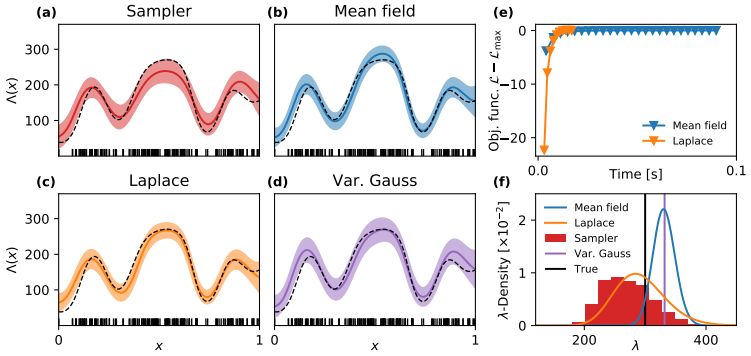

Figure 1: **Inference on 1D dataset.** **(a)**–**(d)** Inference result for sampler, mean field algorithm, Laplace approximation, and variational Gauss. Solid coloured lines denote the mean intensity function, shaded areas mean ± standard deviation, and dashed black lines the true rate functions. Vertical bars are observations $\mathcal{D}$. **(e)** Convergence of mean field and EM algorithm. Objective functions (Lower bound for mean–field and log likelihood for EM algorithm, shifted such that convergence is at 0) as function of run time (triangle marks one finished iteration of the respective algorithm). **(f)** Inferred posterior densities over the maximal intensity λ. Variational Gauss provides only a point estimate. Black vertical bar denotes the true λ.

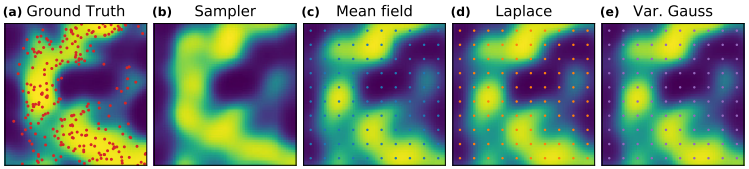

Figure 2: **Inference on 2D dataset.** **(a)** Ground truth intensity function $\Lambda(\boldsymbol{x})$ with observed dataset $\mathcal{D}$ (red dots).**(b)**–**(e)** Mean posterior intensity of the sampler, mean field algorithm, Laplace, and variational Gauss are shown. 100 inducing points on a regular grid (shown as coloured points) and 2500 integration points/bins are used.

In Figure 2 we show inference results for a two dimensional Cox process example. 10×10 inducing points and 2500 integration points/bins are used for mean field, Laplace and variational Gauss algorithm. The posterior mean of sampler **(b)**, of the mean field **(c)**, of the Laplace **(d)** and of the variational Gauss algorithm **(e)** recover the true intensity rate $\Lambda(\boldsymbol{x})$ **(a)** well.

To evaluate the role of the number of inducing points and number of integration points we generate 10 test sets $\mathcal{D}_{\text{test}}$ from a process with the same intensity as in Figure 2**(a)**. We evaluate the log expected likelihood (Equation (32)) on these test sets and compute the average. The result is shown for different numbers of inducing points (Figure 3**(a)** with 2500 integration points) and different numbers of integration points (Figure 3**(b)** with 10×10 inducing points). To account for randomness of integration points the fitting is repeated five times and the shaded area is between the minimum and maximum obtained by these fits. For all approximate algorithms the log predictive test likelihood saturates already for few inducing points (≈ 49 (7×7)) of the sparse GP. However, as expected, the inference approximations are slightly inferior to the sampler. The log expected test likelihood is hardly affected by the number of integration points as shown in Figure 3 **(b)**. Also the approximated test likelihood for the mean field algorithm in Equation (33) yields good estimates of the sampled value (dashed line in **(a)** and **(b)**). In terms of runtime (Figure 4 **(c)**–**(d)**) the mean field algorithm and the Laplace approximation are superior by more than one order of magnitude to the variational Gauss algorithm for this particular example. Difference increases with increasing number of inducing points.

In Figure 4 the four algorithms are compared on five different data sets sampled from the generative model. As we observed for the previous examples the three different approximating algorithms yield qualitatively similar performance in terms of log test likelihood ℓ_{test}, but the sampler is superior. Again the approximated test likelihood in Equation (33) (blue star) provides good estimate of the sampled value. In addition we provide the approximated root mean squared error (RMSE, evaluated on a fine grid and normalised by maximal intensity λ) between inferred mean and ground truth. In terms of run time the mean field and Laplace algorithm are by at least on order of magnitude faster than the vari-

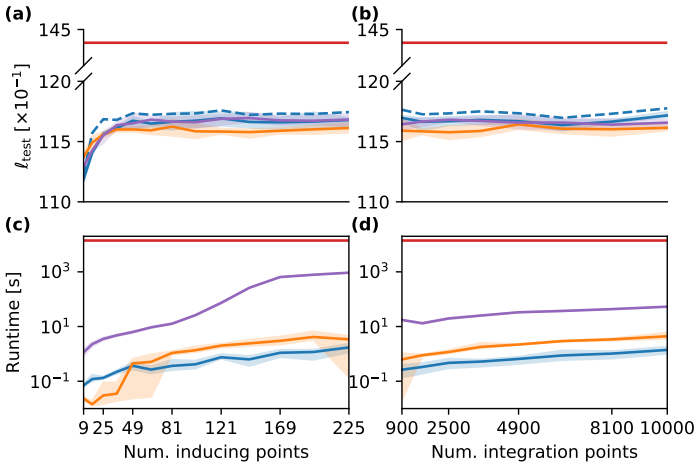

Figure 3: **Evaluation of inference.** **(a)** The log expected predictive likelihood averaged over ten test sets as a function of the number of inducing points. Number of integration points/bins is fixed to 2500. Results for sampler in (red), mean field (blue), Laplace (orange), and variational Gauss (purple) algorithm. Solid line denotes mean over five fits (same data), and shaded area denotes min. and max. result. Dashed blue line shows the approximated log expected predictive likelihood for the mean field algorithm. **(b)** Same as (a), but as function of number of integration points. Number of inducing points is fixed to 10×10. Below: Run time of the different algorithms as function of number of inducing points **(c)** and number of integration points **(d)**. Data are the same as in Figure 2.

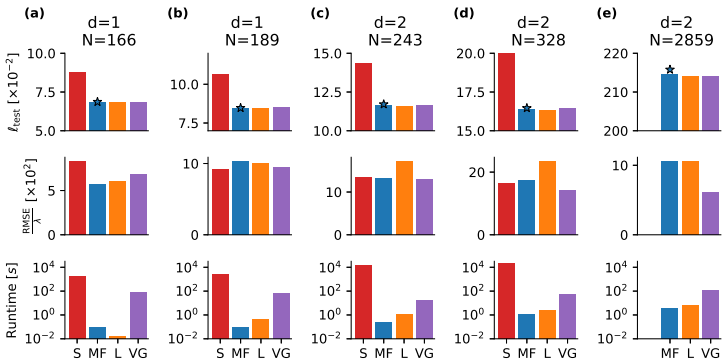

Figure 4: **Performance on different artificial datasets.** The sampler (S), the mean field algorithm (MF), the Laplace (L), and variational Gauss (VG) are compared on five different datasets with d–dimensions and N observations (one column corresponds to one dataset). Top row: Log expected test likelihood of the different inference results. The star denotes the approximated test likelihood of the variational algorithm. Center row: The approximated root mean squared error (normalised by true maximal intensity rate λ). Bottom row: Run time in seconds. The dataset **(e)** is intractable for the sampler due to the many observations. Data in Figure 1 and 2 correspond to **(a)** and **(c)**.

ational Gauss algorithm. In general, the mean–field algorithm seems to be slightly faster than the Laplace.

General data sets and comparison to the approach of Lloyd et al. Next, we test our variational mean field algorithm on data sets not coming from the generative model. On such data sets we do not know, whether our model provides a good prior. As discussed previously an alternative model was proposed by Lloyd et al. (2015) making use of the link function $\Lambda(\boldsymbol{x}) = g^2(\boldsymbol{x})$. While the sigmoidal Gaussian Cox process with the proposed augmentation scheme has analytic updates for the variational posterior, in case of the squared Gaussian Cox process the likelihood integral can be solved analytically and does not need to be sampled (if the kernel is a squared exponential and the domain is rectangular). Both algorithms rely on the sparse GP approximation. To compare the two methods empirically first we consider one dimensional data generated using a known intensity function. We choose $\Lambda(x) = 2\exp(-x/15) + \exp(-(x-25)^2/100)$ on an interval $[0, 50]$ already proposed by Adams et al. (2009). We generate three training and test sets, where we scale this rate function by factors of 1, 10, and 100 and fit the sigmoidal and squared Gaussian Cox

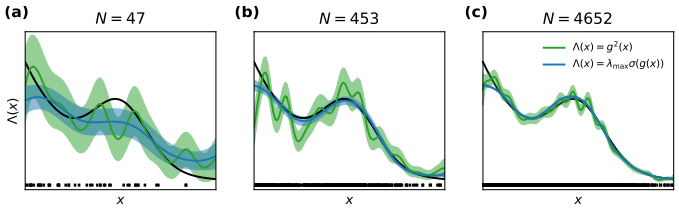

Figure 5: **1D example.** Observations (black bars) are sampled from the same function (black line) scaled by **(a)** 1, **(b)** 10, and **(c)** 100. Blue and green line show the mean posterior of the sigmoidal and squared Gaussian Cox process, respectively. Shaded area denotes mean ± standard deviation.

	$\Lambda(x) = \lambda_{\max}\sigma(g(x))$			$\Lambda(x) = g^2(x)$		
N	Runtime [s]	RMSE	ℓ_{test}	Runtime [s]	RMSE	ℓ_{test}
47	0.27 ± 0.30	0.24 ± 0.02	-43.43 ± 0.42	0.41 ± 0.05	0.24	-44.26 ± 0.09
453	0.50 ± 0.04	0.97 ± 0.13	720.81 ± 0.28	0.23 ± 0.05	2.11	710.43 ± 1.38
4652	0.41 ± 0.01	7.68 ± 0.75	17497.31 ± 2.13	0.79 ± 0.09	8.16	17496.75 ± 1.65

Table 1: **Benchmarks for Figure 5** The mean and standard deviation of runtime, RMSE, and log expected test likelihood for Figure 5**(a)**–**(c)** obtained from 5 fits. Note that the RMSE for $\Lambda(\boldsymbol{x}) = g^2(\boldsymbol{x})$ has no standard deviation, because the inference algorithm is deterministic.

process with their corresponding variational algorithm to each training set[5]. The number of inducing points is 40 in this example. For our variational mean field algorithm we used 5000 integration points. The posterior intensity $\Lambda(\boldsymbol{x})$ for the three data sets can be seen in Figure 5. The model with the sigmoidal link function infers smoother posterior functions with smaller variance compared to the posterior with the squared link function. For data sets shown in Figure 5 we run the fits five times and report mean and standard deviation of runtime, RMSE and log expected test likelihood ℓ_{test} in Table 1. Run times of the two algorithms are comparable, where for the intermediate data set the algorithm with the squared link function is faster while for the largest data set the one with the sigmoidal link function converges first. RMSE and ℓ_{test} are also comparable except for the intermediate data set, where the sigmoidal model is the superior one.

Next we deal with two real world two dimensional data sets for comparison. The first one is neuronal data, where spiking activity was recorded from a mouse, that was freely moving in an arena (For The Biology Of Memory and Sargolini, 2014; Sargolini et al., 2006). Here we consider as data $\mathcal{D}$ the position of the mouse when the recorded cell fired and the observations are randomly assigned to either training or test set. In Figure 6 **(a)**

5. We thank Chris Lloyd and Tom Gunter for providing the code for inferring the variational posterior of the squared Gaussian Cox process.

the observations in the training set ($N = 583$) are shown. In Figure 6 **(b)** and **(c)** the variational posterior's mean intensity $\Lambda(\boldsymbol{x})$ is shown obtained for the sigmoidal and the squared link function, respectively, inferred with a regular grid of 20×20 inducing points. As in Figure 5 we see that the sigmoidal posterior is the smoother one. The major difference between the two algorithms (apart from the link function) is the fact that for the sigmoidal model we are required to sample an interval over the space. We investigate the effect of the number of integration points in terms of runtime[6] and log expected test likelihood in Figure 6 **(d)**. First, we observe regardless of the number of integration points that the variational posterior of the squared link function yields the superior expected test likelihood. For the sigmoidal model the test likelihood does not improve significantly with more integration points. Runtimes of both algorithms are comparable, when 5000 integration points are chosen. A speed up for our mean field algorithm is achieved by first fitting the model with 1000 integration points and once converged, redrawing the desired number of integration points and rerun the algorithm (dotted line in Figure 6**(d)**). This method allows for a significant speed up without loss in terms of test likelihood ℓ_{test}. The variational mean-field algorithm with the sigmoid link function is faster with up to 5000 integration points and equally fast with 10000 integration points.

As second data set we consider the Porto taxi data set (Moreira-Matias et al., 2013). This data contains trajectories of taxi travels from the years 2013/14 in the city of Porto. As John and Hensman (2018) we consider the pick-ups as observations of a Poisson process[7]. We consider 20000 taxi rides randomly split into training and test set ($N = 10017$ and $N = 9983$, respectively). The training set is shown in Figure 6**(e)**. Inducing points are positioned on a regular grid of 20×20. The variational posterior mean of the respective intensity is shown in Figure 6 **(f)** and **(g)**. With as many data points as in these data the differences between the two models are more subtle as compared to **(b)** and **(c)**. In terms of test likelihood ℓ_{test} the variational posterior of the sigmoidal model (with ≥ 2000 integration points) outperforms the model with squared link function (Figure 6 **(h)**). For similar test likelihoods ℓ_{test} our variational algorithm is $\sim 2\times$ faster than the variational posterior with squared link function. The results show that the choice of number of integration points reduces to the question of speed vs accuracy trade–off. As for the previous data set, the strategy of first fitting the posterior with 1000 integration points and then with the desired number of integration points (dotted line) proves that we can get a significant speed up without loosing predictive power.

5. Discussion and Outlook

Using a combination of two known variable augmentation methods, we derive a conjugate representation for the posterior measure of a sigmoidal Gaussian Cox process. The approximation of the augmented posterior by a simple mean field factorisation yields an efficient variational algorithm. The rationale behind this method is that the variational updates in the conjugate model are explicit and analytical and do not require (black–box) gradient

6. Note, that - in contrast to Figures 3 and 4 - the runtime is displayed on linear scale, meaning both algorithms are of same order of magnitude.
7. As John and Hensman (2018) report some regions to be highly peaked we consider only pickups happening within the coordinates $(41.147, -8.58)$ and $(41.18, -8.65)$ in order to exclude those regions.

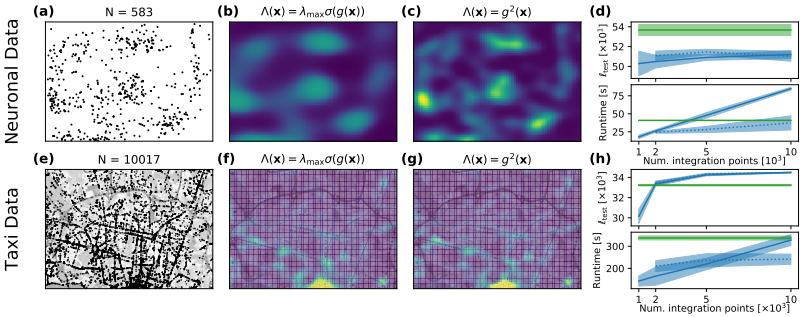

Figure 6: **Fits to real world data sets.** **(a)** Position of the mouse while the recorded neuron spiked. **(b)** Posterior mean obtained by the variational mean–field algorithm for the sigmoidal Gaussian Cox process. **(c)** Same as in (b) for the variational approximation of the squared Gaussian Cox process. **(d)** Log expected test–likelihood ℓ_{test} and runtime as function of number of integration points for both algorithms. The dotted line is obtained by first fitting the sigmoidal model with 1000 integration points and then with the number that is indicated on the x-axis. Shaded area is mean $\pm$ standard deviation obtained in 5 repeated fits. **(e)**–**(h)** Same as (a)–(d), but for a data set, where the observations are positions of taxi pick–ups in the city of Porto.

descent methods. In fact, a comparison with a different variational algorithm for the same model - not based on augmentation, but on direct approximation of the posterior with a Gaussian - shows that the qualities of inference for both approaches are similar, while the mean field algorithm is at least one order of magnitude faster. We use the same variable augmentation method for computation of the MAP estimate for the (unaugmented) posterior by a fast EM algorithm. This is finally applied to the calculation of Laplace's approximation. Both methods yield an explicit result for the approximate GP posterior. Since the corresponding effective likelihood contains a continuum of the GP latent variables, the exact computations of means and marginal variances would require the inversion of a linear operator instead of a simpler matrix inverse. While for specific priors, this problem could be solved by PDE or ODE methods, we resort to a well known sparse GP approach with inducing points in this paper. We can apply this to arbitrary kernels but need to solve spatial integrals over the domain. These can be (at least for moderate dimensionality) well approximated by simple Monte Carlo integration. Advantage of this approach is, that one is not limited to rectangular domains. The only requirement is that the volume $|\mathcal{X}|$ is known. An alternative Poisson model for which similar spatial integrals can be performed analytically (Lloyd et al., 2015) within the sparse GP approximation (limited to squared exponential kernels and rectangular domains) is based on a quadratic link function (Lloyd et al., 2015; Flaxman et al., 2017; John and Hensman, 2018). We compare our variational algorithm with the variational algorithm of Lloyd et al. (2015) on different data sets and observe that both algorithms act on the same order of magnitude in terms of runtime (with slight advantages for our variational mean field algorithm). As expected, we show that whether one or the other model is better in predictive power is highly data dependent.

As an alternative to the Monte Carlo integration in our approach we could avoid the infinite dimensionality of the latent GP from the beginning by working with a binning scheme for the Poisson observations as in Hensman et al. (2015). It would be straightforward to adopt our augmentation method to this case. The resulting Poisson likelihoods would then be augmented by pairs of Poisson and Pólya–Gamma variables (see Donner and Opper (2017)) for each bin. This approach could be favourable when the number of observed data points becomes very large, because the discretisation method does not scale with the number data points but with the resolution of discretisation. However, we do expect, that any approach based on either spatial discretisation or on the sparse, inducing point method would become problematic for large or high dimensional domains $\mathcal{X}$. Alternative methods based on spectral representations of kernels (Knollmüller et al., 2017; John and Hensman, 2018) are promising for tackling those problems.

It will be interesting to apply the variable augmentation method to other Bayesian models with the sigmoid link function. For example, the inherent boundedness of the resulting intensity can be crucial for point processes such as the nonlinear *Hawkes process* (Hawkes, 1971) which is widely used for modelling stock market data (Embrechts et al., 2011) or seismic activity (Ogata, 1998). For other point process models the sigmoid function appears naturally. We mention the kinetic Ising model, a Markov jump process (Donner and Opper, 2017) which was originally introduced to model the dynamics of classical spin systems in physics. More recently it was used to model the joint activity of neurons (Dunn et al., 2015). Finally, a Gaussian process density model introduced by (Murray et al., 2009) can be treated by the augmentations developed in this work (Donner and Opper, 2018).

Appendix A. Poisson processes

In this paragraph we briefly summarise those properties of a Poisson process, which are relevant for this work. For a thorough and more complete description we recommend the concise book by Kingman (1993), particularly chapter 3 and 5.

We consider a general space $\mathcal{Z}$ and a countable subset $\Pi_{\mathcal{Z}} = \{\boldsymbol{z}; \boldsymbol{z} \in \mathcal{Z}\}$.

Definition of a Poisson process A random countable subset $\Pi_{\mathcal{Z}} \subset \mathcal{Z}$ is a Poisson process on $\mathcal{Z}$, if

i) for any sequence of disjoint subsets $\{\mathcal{Z}_k \subset \mathcal{Z}\}_{k=1}^K$ the cardinality of the union $N(\mathcal{Z}_k) \doteq |\{\Pi_{\mathcal{Z}} \cap \mathcal{Z}_k\}|$ is independent of $N(\mathcal{Z}_l)$ for all $l \neq k$.

ii) $N(\mathcal{Z}_k)$ is Poisson distributed with mean $\int_{\mathcal{Z}_k} \Lambda(\boldsymbol{z}) d\boldsymbol{z}$, and mean measure $\Lambda(\boldsymbol{z}) : \mathcal{X} \to \mathbb{R}^+$.

If the mean measure is constant ($\Lambda(\boldsymbol{z}) = \Lambda$) the Poisson process is *homogeneous*, and *inhomogeneous* otherwise.

Campbell's Theorem Let $\Pi_{\mathcal{Z}}$ be a Poisson process on $\mathcal{Z}$ with mean measure $\Lambda(\boldsymbol{z})$. Furthermore, we define a function $h(\boldsymbol{z}) : \mathcal{Z} \to \mathbb{R}$ and the sum

$$H(\Pi_{\mathcal{Z}}) = \sum_{\boldsymbol{z} \in \Pi_{\mathcal{Z}}} h(\boldsymbol{z}).$$

If $\Lambda(\boldsymbol{z}) < \infty$ for $\boldsymbol{z} \in \mathcal{Z}$, then

$$\mathbb{E}_{P_\Lambda}\left[e^{\xi H(\Pi_{\mathcal{Z}})}\right] = \exp\left\{\int_{\mathcal{Z}} \left(e^{\xi h(\boldsymbol{z})} - 1\right) \Lambda(\boldsymbol{z}) d\boldsymbol{z}\right\}, \tag{36}$$

for any $\xi \in \mathbb{C}$, such that the integral converges. P_Λ is the probability measure of a Poisson process with intensity $\Lambda(\boldsymbol{z})$. Mean and variance are obtained as

$$\mathbb{E}_{P_\Lambda}\left[H(\Pi_{\mathcal{Z}})\right] = \int_{\mathcal{Z}} h(\boldsymbol{z}) \Lambda(\boldsymbol{z}) d\boldsymbol{z},$$
$$\mathrm{Var}_{P_\Lambda}\left[H(\Pi_{\mathcal{Z}})\right] = \int_{\mathcal{Z}} [h(\boldsymbol{z})]^2 \Lambda(\boldsymbol{z}) d\boldsymbol{z}.$$

Note, that Equation (36) defines the *characteristic functional* of a Poisson process.

Marked Poisson process Let $\Pi_{\mathcal{Z}} = \{\boldsymbol{z}_n\}_{n=1}^N$ a Poisson process on $\mathcal{Z}$ with intensity $\Lambda(\boldsymbol{z})$. Then $\Pi_{\hat{\mathcal{Z}}} = \{(\boldsymbol{z}_n, \boldsymbol{m}_n)\}_{n=1}^N$ is again a Poisson process on the product space $\hat{\mathcal{Z}} = \mathcal{Z} \times \mathcal{M}$, if $\boldsymbol{m}_n \sim p(\boldsymbol{m}_n|\boldsymbol{z}_n)$ is drawn independently at each $\boldsymbol{z}_n$. The $\boldsymbol{m}_n \in \mathcal{M}$ are the so–called 'marks', and the resulting Process is a *marked Poisson process* with intensity

$$\Lambda(\boldsymbol{z}, \boldsymbol{m}) = \Lambda(\boldsymbol{z}) p(\boldsymbol{m}|\boldsymbol{z}).$$

It is straightforward to extend Campbell's theorem and to show that the characteristic functional of such a process is

$$\mathbb{E}_{P_\Lambda}\left[e^{\xi H(\Pi_{\hat{\mathcal{Z}}})}\right] = \exp\left\{\int_{\hat{\mathcal{Z}}} \left(e^{\xi h(\boldsymbol{z},\boldsymbol{m})} - 1\right) \Lambda(\boldsymbol{z}, \boldsymbol{m})\, d\boldsymbol{m} d\boldsymbol{z}\right\}, \tag{37}$$

with $h(\boldsymbol{z}, \boldsymbol{m}) : \hat{\mathcal{Z}} \to \mathbb{R}$ and $H(\Pi_{\hat{\mathcal{Z}}}) = \sum_{(\boldsymbol{z},\boldsymbol{m}) \in \Pi_{\hat{\mathcal{Z}}}} h(\boldsymbol{z}, \boldsymbol{m})$.

Appendix B. The Pólya-Gamma density

The Pólya-Gamma density (Polson et al., 2013) has the useful property, that it allows to represent the inverse hyperbolic cosine by an infinite Gaussian mixture as

$$\cosh^{-b}(c/2) = \int_0^\infty \exp\left(-\frac{c^2}{2}\omega\right) p_{\mathrm{PG}}(\omega|b, 0) d\omega,$$

with parameter $b > 0$. Furthermore, one can define a *tilted Pólya-Gamma density* as

$$p_{\mathrm{PG}}(\omega|b, c) = \frac{\exp\left(-\frac{c^2}{2}\omega\right)}{\cosh^{-b}(c/2)} p_{\mathrm{PG}}(\omega|b, 0).$$

From those two equations the moment generating function can be obtained from the basic definition, being

$$\int_0^\infty e^{\xi\omega} p_{\mathrm{PG}}(\omega|b, c) d\omega = \frac{\cosh^b(c/2)}{\cosh^b\left(\sqrt{\frac{c^2/2 - \xi}{2}}\right)},$$

and differentiating with respect to ξ at $\xi = 0$ yields the first moment

$$\mathbb{E}_{p_{\mathrm{PG}}}[\omega] = \frac{b}{2c} \tanh(c/2).$$

Appendix C. Variational inference for stochastic processes

Densities for random processes A stochastic process X with probability measure $P(X)$ often has no density with respect to Lebesgue measure, since X can be an infinite dimensional object such as a function for the case of a Gaussian process. However, one can define densities with respect to another (reference) measure $R(X)$ written as

$$\boldsymbol{p}(X) = \frac{dP}{dR}(X), \tag{38}$$

if $R(X)$ is absolutely continuous with respect to $P(X)$ (if $R(X) = 0$ then $P(X) = 0$). Using such a density, expectations are

$$\mathbb{E}_P[f(X)] = \int f(X) dP(X) = \int f(x) \boldsymbol{p}(x) dR(X) = \mathbb{E}_R[f(x)\boldsymbol{p}(x)].$$

The density in Equation (38) is known as the *Radon–Nikodým derivative* of R with respect to P (Konstantopoulos et al., 2011).

Poisson process density As specific example consider the prior density of the Poisson process in Equation (9), which is defined with respect to a reference measure

$$\boldsymbol{p}_\Lambda(\Pi_{\mathcal{Z}}) = \frac{dP_\Lambda}{dP_{\Lambda_0}}(\Pi_{\mathcal{Z}}) = \exp\left(-\int_{\mathcal{Z}} (\Lambda(\boldsymbol{z}) - \Lambda_0(\boldsymbol{z})) d\boldsymbol{z}\right) \prod_{\boldsymbol{z}_n \in \Pi_{\mathcal{Z}}} \frac{\Lambda(\boldsymbol{z}_n)}{\Lambda_0(\boldsymbol{z}_n)},$$

where P_{Λ_0} is the probability measure with intensity Λ_0 and the expectation is defined as

$$\mathbb{E}_{P_\Lambda}\left[\sum_{\boldsymbol{z}_n\in\Pi_\mathcal{Z}} u(\boldsymbol{z}_n)\right] = \mathbb{E}_{P_{\Lambda_0}}\left[\boldsymbol{p}_\Lambda(\Pi_\mathcal{Z})\sum_{\boldsymbol{z}_n\in\Pi_\mathcal{Z}} u(\boldsymbol{z}_n)\right]. \tag{39}$$

Calculating the expectation of $e^{\xi H(\Pi_\mathcal{Z})}$ with Equation (39) we identify the characteristic function of a Poisson process (see Equation (37)) with intensity $\Lambda(\boldsymbol{z})$.

Kullback-Leibler divergence Using these densities we can express the Kullback-Leibler divergence between two probability measures.

The KL–divergence between $\boldsymbol{q}(X)$ and $\boldsymbol{p}(X)$ is defined as

$$\mathrm{D}_{\mathrm{KL}}(Q\|P) = \mathbb{E}_Q\left[\log\frac{dQ}{dP}(X)\right] = \int \log\frac{\boldsymbol{q}(X)}{\boldsymbol{p}(X)} dQ(X),$$

where

$$\boldsymbol{q}(X) = \frac{dQ}{dR}(X),$$

and where $R(X)$ also is absolutely continuous to $Q(X)$. The KL–divergence does not depend on the reference measure $R(X)$.

Appendix D. The posterior point process is a marked Poisson process

Here we prove that the optimal variational posterior point process in Equation (18) again is a Poisson process using Campbell's theorem. As posterior process in Equation (18) one gets

$$\boldsymbol{q}(\Pi_\mathcal{Z}) = \frac{dQ}{dP_\lambda}(\Pi_\mathcal{Z}) = \frac{\prod_{\boldsymbol{z}_m\in\Pi_\mathcal{Z}} e^{f(\boldsymbol{z}_m)}}{\mathbb{E}_{P_\lambda}\left[\prod_{\boldsymbol{z}_m\in\Pi_\mathcal{Z}} e^{f(\boldsymbol{z}_m)}\right]} = \frac{\prod_{\boldsymbol{z}_m\in\Pi_\mathcal{Z}} e^{f(\boldsymbol{z}_m)}}{\exp\left(\int_\mathcal{Z}(e^{f(\boldsymbol{z})}-1)\lambda(\boldsymbol{z})d\boldsymbol{z}\right)},$$

where $\Pi_\mathcal{Z}$ is some random set of points on space $\mathcal{Z}$ and P_λ is a random Poisson measure with intensity $\lambda(\boldsymbol{z})$. To proof, that the resulting point process density $\boldsymbol{q}(\Pi_\mathcal{Z})$ is again a Poisson process we calculate the characteristic functional for some arbitrary function $h:\mathcal{Z}\to\mathbb{R}$

$$\begin{aligned}
\mathbb{E}_Q\left[\prod_{\boldsymbol{z}_m\in\Pi_\mathcal{Z}} e^{h(\boldsymbol{z}_m)}\right] &= \frac{\mathbb{E}_{P_\lambda}\left[\prod_{\boldsymbol{z}_m\in\Pi_\mathcal{Z}} e^{h(\boldsymbol{z}_m)+f(\boldsymbol{z}_m)}\right]}{\exp\left(\int_\mathcal{Z}(e^{f(\boldsymbol{z})}-1)\lambda(\boldsymbol{z})d\boldsymbol{z}\right)} \\
&= \frac{\exp\left(\int_\mathcal{Z}(e^{h(\boldsymbol{z})+f(\boldsymbol{z})}-1)\lambda(\boldsymbol{z})d\boldsymbol{z}\right)}{\exp\left(\int_\mathcal{Z}(e^{f(\boldsymbol{z})}-1)\lambda(\boldsymbol{z})d\boldsymbol{z}\right)} \\
&= \exp\left(\int_\mathcal{Z}(e^{h(\boldsymbol{z})}-1)e^{f(\boldsymbol{z})}\lambda(\boldsymbol{z})d\boldsymbol{z}\right) \\
&= \exp\left(\int_\mathcal{Z}(e^{h(\boldsymbol{z})}-1)\Lambda_Q(\boldsymbol{z})d\boldsymbol{z}\right).
\end{aligned}$$

We identify the last row as the generating functional of a Poisson process (37) with $\xi=1$. The intensity of the process is $\Lambda_Q(\boldsymbol{z}) = e^{f(\boldsymbol{z})}\lambda(\boldsymbol{z})$. With the fact that a Poisson process is uniquely characterised by its generating function (Kingman, 1993, chap. 3), the proof is complete.

Appendix E. Sparse Gaussian process approximation

To solve the inference problem for the function g, we define a sparse GP, using the same prior P, but by an effective likelihood which depends on a finite set of function values $\boldsymbol{g}_s = (g_1,\ldots,g_L)^\top$ only. Hence, we get

$$\frac{dQ_2^s}{dP}(g) = \boldsymbol{q}_2^s(\boldsymbol{g}_s) \tag{40}$$

and the sparse posterior measure is

$$dQ_2^s(g) = \boldsymbol{q}_2^s(\boldsymbol{g}_s)dP(g) = dP(g|\boldsymbol{g}_s)\times\boldsymbol{q}_2^s(\boldsymbol{g}_s)dP(\boldsymbol{g}_s),$$

where the last equality holds true, since Equation (40) only depends on $\boldsymbol{g}_s$. The KL–divergence between the full posterior density

$$\boldsymbol{q}_2(g) = \frac{dQ_2}{dP}(g) = \frac{e^{U(g)}}{\mathbb{E}_P\left[e^{U(g)}\right]}$$

and the sparse one $\boldsymbol{q}_2^s(\boldsymbol{g}_s)$ is given by

$$\begin{aligned}
\mathrm{D}_{\mathrm{KL}}(Q_2^s\|Q_2) &= \mathbb{E}_{Q_2^s}\left[\log\frac{\boldsymbol{q}_2^s(\boldsymbol{g}_s)}{\boldsymbol{q}_2(g)}\right] = \mathbb{E}_{P(\boldsymbol{g}_s)}\left[\boldsymbol{q}_2^s(\boldsymbol{g}_s)\mathbb{E}_{P(g|\boldsymbol{g}_s)}\left[\log\frac{\boldsymbol{q}_2^s(\boldsymbol{g}_s)}{e^{U(g)}}\right]\right] + \text{const.} \\
&= \mathbb{E}_{P(\boldsymbol{g}_s)}\left[\boldsymbol{q}_2^s(\boldsymbol{g}_s)\log\frac{\boldsymbol{q}_2^s(\boldsymbol{g}_s)}{e^{\mathbb{E}_{P(g|\boldsymbol{g}_s)}[U(g)]}}\right] + \text{const.}
\end{aligned}$$

From this we derive directly the posterior density for the sparse GP

$$\boldsymbol{q}_2^s(g) \propto e^{U^s(\boldsymbol{g}_s)},$$

with the sparse log–likelihood

$$U^s(\boldsymbol{g}_s) = \mathbb{E}_{P(g|\boldsymbol{g}_s)}[U(g)] = \int U(g)dP(g|\boldsymbol{g}_s).$$

Appendix F. Lower bound & hyperparameter optimization

The lower bound in Equation (12) is given by

$$\begin{aligned}
\mathcal{L}(\boldsymbol{q}) =& \mathbb{E}_Q\left[\log \frac{L(\mathcal{D}, \boldsymbol{\omega}_N, \Pi_{\hat{\mathcal{X}}}|g,\lambda)}{\boldsymbol{q}_1(\boldsymbol{\omega}_N)\boldsymbol{q}_1(\Pi_{\hat{\mathcal{X}}})\boldsymbol{q}_2^s(g)\boldsymbol{q}_2(\lambda)}\right] \\
=& \int_{\hat{\mathcal{X}}} \left(\mathbb{E}_Q\left[f(\omega,-g(\boldsymbol{x}))\right] - \mathbb{E}_Q\left[\log\Lambda_1\right] + \mathbb{E}_Q\left[\log\lambda\right] + 1\right)\Lambda_1(\boldsymbol{x},\omega)d\boldsymbol{x}d\omega \\
& - \int_{\hat{\mathcal{X}}} \Lambda_1(\boldsymbol{x},\omega)d\boldsymbol{x}d\omega \\
& + \sum_{n=1}^{N}\left(\mathbb{E}_Q\left[f(\omega_n,g_n)\right] + \mathbb{E}_Q\left[\log\lambda\right] - \cosh\left(\frac{c_1^{(n)}}{2}\right) + \frac{\left(c_1^{(n)}\right)^2}{2}\mathbb{E}_Q\left[\omega_n\right]\right) \\
& - \frac{1}{2}trace(K_s^{-1}(\Sigma_2^s + \boldsymbol{\mu}_2^s(\boldsymbol{\mu}_2^s)^\top)) - \frac{1}{2}\log\det(2\pi K_s) + \frac{1}{2}\log\det(2\pi e\Sigma_2^s) \\
& + \alpha_0\log\beta_0 - \log(\Gamma(\alpha_0)) + (\alpha_0-1)\mathbb{E}_Q\left[\log\lambda\right] - \beta_0\mathbb{E}_Q\left[\lambda\right] \\
& + \alpha_2 - \log\beta_2 + \log\Gamma(\alpha_2) + (1-\alpha_2)\psi(\alpha_2).
\end{aligned}$$

To optimise the covariance kernel parameters $\boldsymbol{\theta}$ we differentiate the lower bound with respect to these parameters and perform then gradient ascent. The gradient for one specific parameter θ is given by

$$\begin{aligned}
\frac{\partial\mathcal{L}(\boldsymbol{q})}{\partial\theta} =& \int_{\hat{\mathcal{X}}} \frac{\partial\mathbb{E}_Q\left[f(\omega,-g(\boldsymbol{x}))\right]}{\partial\theta}\Lambda_1(\boldsymbol{x},\omega)d\boldsymbol{x}d\omega + \sum_{n=1}^{N}\frac{\partial\mathbb{E}_Q\left[f(\omega_n,g(\boldsymbol{x}_n))\right]}{\partial\theta} \\
& - \frac{1}{2}\frac{trace(K_s^{-1}(\Sigma_2^s + \boldsymbol{\mu}_2^s(\boldsymbol{\mu}_2^s)^\top))}{\partial\theta} - \frac{1}{2}\frac{\partial\log\det(2\pi K_s)}{\partial\theta} \\
=& \int_{\hat{\mathcal{X}}} \frac{\partial\mathbb{E}_Q\left[f(\omega,-g(\boldsymbol{x}))\right]}{\partial\theta}\Lambda_1(\boldsymbol{x},\omega)d\boldsymbol{x}d\omega + \sum_{n=1}^{N}\frac{\partial\mathbb{E}_Q\left[f(\omega_n,g(\boldsymbol{x}_n))\right]}{\partial\theta} \\
& + \frac{1}{2}trace\left(K_s^{-1}\frac{\partial K_s}{\partial\theta}K_s^{-1}(\Sigma_2^s + \boldsymbol{\mu}_2^s(\boldsymbol{\mu}_2^s)^\top)\right) \\
& - \frac{1}{2}trace\left(K_s^{-1}\frac{\partial K_s}{\partial\theta}\right).
\end{aligned}$$

The derivatives of function $\mathbb{E}_Q\left[f(\omega,g(\boldsymbol{x}))\right]$ are

$$\frac{\partial\mathbb{E}_Q\left[f(\omega,g(\boldsymbol{x}))\right]}{\partial\theta} = \frac{1}{2}\left(\frac{\partial\mathbb{E}_Q\left[g(\boldsymbol{x})\right]}{\partial\theta} - \frac{\partial\mathbb{E}_Q\left[g(\boldsymbol{x})^2\right]}{\partial\theta}\mathbb{E}_Q\left[\omega\right]\right),$$

with

$$\begin{aligned}
\frac{\partial\mathbb{E}_Q\left[g(\boldsymbol{x})\right]}{\partial\theta} =& \frac{\partial\boldsymbol{\kappa}(\boldsymbol{x})}{\partial\theta}\boldsymbol{\mu}_2^s, \\
\frac{\partial\mathbb{E}_Q\left[g(\boldsymbol{x})^2\right]}{\partial\theta} =& \frac{\partial\tilde{k}(\boldsymbol{x},\boldsymbol{x})}{\partial\theta} + \frac{\partial\boldsymbol{\kappa}(\boldsymbol{x})}{\partial\theta}^\top\left(\Sigma_2^s + \boldsymbol{\mu}_2^s(\boldsymbol{\mu}_2^s)^\top\right)\boldsymbol{\kappa}(\boldsymbol{x}) + \boldsymbol{\kappa}(\boldsymbol{x})^\top\left(\Sigma_2^s + \boldsymbol{\mu}_2^s(\boldsymbol{\mu}_2^s)^\top\right)\frac{\partial\boldsymbol{\kappa}(\boldsymbol{x})}{\partial\theta},
\end{aligned}$$

where $\boldsymbol{\kappa}(\boldsymbol{x}) = \boldsymbol{k}_s(\boldsymbol{x})^\top K_s^{-1}$ and $\tilde{k}(\boldsymbol{x},\boldsymbol{x}) = k(\boldsymbol{x},\boldsymbol{x}) - \boldsymbol{k}_s(\boldsymbol{x})K_s^{-1}\boldsymbol{k}_s(\boldsymbol{x})^\top$. The remaining two terms are:

$$\begin{aligned}
\frac{\partial\tilde{k}(\boldsymbol{x},\boldsymbol{x})}{\partial\theta} =& \frac{\partial k(\boldsymbol{x},\boldsymbol{x})}{\partial\theta} - \frac{\partial\boldsymbol{\kappa}(\boldsymbol{x})}{\partial\theta}\boldsymbol{k}_s(\boldsymbol{x}) - \boldsymbol{\kappa}(\boldsymbol{x})\frac{\partial\boldsymbol{k}_s(\boldsymbol{x})}{\partial\theta}, \\
\frac{\partial\boldsymbol{\kappa}(\boldsymbol{x})}{\partial\theta} =& \frac{\partial\boldsymbol{k}_s(\boldsymbol{x})}{\partial\theta}^\top K_s^{-1} - \boldsymbol{k}_s(\boldsymbol{x})K_s^{-1}\frac{\partial K_s}{\partial\theta}K_s^{-1}.
\end{aligned}$$

After each variational step the hyperparameters are updated by

$$\boldsymbol{\theta}_{\text{new}} = \boldsymbol{\theta}_{\text{old}} + \varepsilon\frac{\partial\mathcal{L}(q)}{\partial\boldsymbol{\theta}},$$

where ε is the step size.

Abstract

This paper deals with inference and prediction for multiple correlated time series, where one also has the choice of using a candidate pool of contemporaneous predictors for each target series. Starting with a structural model for time series, we use Bayesian tools for model fitting, prediction and feature selection, thus extending some recent works along these lines for the univariate case. The Bayesian paradigm in this multivariate setting helps the model avoid overfitting, as well as captures correlations among multiple target time series with various state components. The model provides needed flexibility in selecting a different set of components and available predictors for each target series. The cyclical component in the model can handle large variations in the short term, which may be caused by external shocks. Extensive simulations were run to investigate properties such as estimation accuracy and performance in forecasting. This was followed by an empirical study with one-step-ahead prediction on the max log return of a portfolio of stocks that involve four leading financial institutions. Both the simulation studies and the extensive empirical study confirm that this multivariate model outperforms three other benchmark models, viz. a model that treats each target series as independent, the autoregressive integrated moving average model with regression (ARIMAX), and the multivariate ARIMAX (MARIMAX) model.

Keywords: Multivariate Time Series, Feature Selection, Bayesian Model Averaging, Cyclical Component, Estimation and Prediction

1. Introduction

The analysis of "Big Data" through the application of a new breed of analytical tools for manipulating and analyzing vast caches of data, is one of the cutting edge new areas. As a byproduct of the extensive use of the internet in collecting data on economic transactions, such data are growing exponentially every day. According to (Varian, 2014) and the references therein, Google has 30 trillion URLs and crawls over 20 billion of those each day. Conventional statistical and econometric techniques become increasingly inadequate to deal with such big data problems. For a good introduction to the new trends in data science, see (Blei and Smyth, 2017). Machine Learning as a field of computer science has strong ties to mathematical optimization and delivers methods, theory and applications, giving computers the ability to learn without being explicitly programmed (see a classical book, Mohri et al., 2012). Machine Learning indeed helps in developing high-performance computer tools, which often provide useful predictions in the presence of challenging computational needs. However, the result is one that we might call "pure prediction" and is not necessarily based on substantive knowledge. Also, typical assumptions such as the data being independent and identically (or at least independently) distributed, are not satisfactory when dealing with time stamped data, which is driven by multiple "predictors" or "features". We need to employ time series analysis for such series of data that are dependent, such as macroeconomic indicators of the national economy, enterprise operational management, market forecasting, weather and hydrology prediction.

Our focus here is on new techniques that work well for feature selection problems in time series applications. Scott and Varian (2014, 2015) introduced and further explored the Bayesian Structural Time Series (BSTS) model, a technique that can be used for feature selection, time series forecasting, nowcasting, inferring causal relationships (see Brodersen et al., 2015 and Peters et al., 2017), among others. One main ingredient of the BSTS model is that the time series aspect is handled through the Kalman filter (see Harvey, 1990; Durbin and Koopman, 2002; Petris et al., 2009) while taking into account the trend, seasonality, regression, and other common time series factors. The second aspect is the "spike and slab" variable selection, which was developed by George and McCulloch (1997) and Madigan and Raftery (1994), by which the most important regression predictors are selected at each step. The third aspect is the Bayesian model averaging (see Hoeting et al., 1999), which combines the feature selection results and prediction calculation. All these three parts have natural Bayesian interpretations and tend to play well together so that the resulting BSTS model discovers not only correlations but also causations in the underlying data. Some excellent related literature includes, but is not limited to the following: Dy and Brodley (2004); Cortes and Vapnik (1995); Guyon and Elisseeff (2003); Koo et al. (2007); Bach et al. (2013); Keerthi and Lin (2003); Nowozin and Lampert (2011); Krishnapuram et al. (2005); Caron et al. (2006); Csató and Opper (2002).

In this paper, we extend the BSTS model to the multivariate target time series with various components, and label it the Multivariate Bayesian Structural Time Series (MBSTS) model. For instance, the MBSTS model can be used to explicitly model the correlations between different stock returns in a portfolio through the covariance structure specified by Σ_t, see Equation (1). In this model, we allow a cyclical component with a shock damping parameter to specially model the influence of a shock to the time series, in addition to a standard local linear trend component, a seasonal component, and a regression component. One motivation for this is provided by the 2007–2008 financial crisis to the stock market. In examples with simulated data, the properties of our model such as estimation and prediction accuracy is investigated. As an illustration, through an empirical case study, we predict the max log returns over 5 consecutive business days of a stock portfolio with 4 stocks: Bank of America (BOA), Capital One Financial Corporation (COF), J.P. Morgan (JPM) and Wells Fargo (WFC), using domestic Google trends and 8 stock technical indicators as predictors.

Extensive analysis on both simulated data and real stock market data verifies that the MBSTS model gives much better prediction accuracy compared to the univariate BSTS model, the autoregressive integrated moving average with regression (ARIMAX) model, and the multivariate ARIMAX (MARIMAX) model. Some of the reasons for this can be seen in the following: the MBSTS model is strong in forecasting since it incorporates information of different components in the target time series, rather than merely historical values of the

same component; the Bayesian paradigm and the MCMC algorithm can perform variable selection at the same time during model training and thus prevent overfitting, even if some spurious predictors are added into the candidate pool; the MBSTS model benefits from taking correlations among multiple target time series into account, which helps boost the forecasting power and is a significant improvement over the univariate BSTS model.

The rest of the paper is organized as follows. In Section 2, we build the basic model framework. Extensive simulations are carried out in Section 3 to examine how the model performs under various conditions. In Section 4, an empirical study on the stock portfolio is done to show how well our model performs with real-world data. Section 5 concludes with some final remarks.

2. The MBSTS Model

In this section, we introduce the MBSTS model including model structure, state components, prior elicitation and posterior inference. Then we describe the algorithm for training the model and performing forecasts. In the sequel, the symbol " $\sim$ " and the superscript "(i)" will denote a column vector and the i-th component of a vector respectively, such as a $m \times 1$ vector $\tilde{y}_t = [y_t^{(1)}, \cdots, y_t^{(m)}]^T$.

2.1 Structural Time Series

Structural time series models belong to state space models for time series data given by the following set of equations:

$$\tilde{y}_t = Z_t^T \alpha_t + \tilde{\epsilon}_t, \qquad \tilde{\epsilon}_t \sim N_m(0, \Sigma_t), \tag{1}$$

$$\alpha_{t+1} = T_t \alpha_t + R_t \eta_t, \qquad \eta_t \sim N_q(0, Q_t), \tag{2}$$

$$\alpha_0 \sim N_d(\mu_0, \Sigma_0). \tag{3}$$

Equation (1) is called the observation equation, as it links the $m \times 1$ vector $\tilde{y}_t$ of observations at time t with a $d \times 1$ vector α_t denoting the unobserved latent states, where d is the total number of latent states for all entries in $\tilde{y}_t$. Equation (2) is called the transition equation because it defines how the latent states evolve over time. The model matrices Z_t, T_t, and R_t typically contain unknown parameters and known values which are often set as 0 and 1. Z_t is a $d \times m$ output matrix, T_t is a $d \times d$ transition matrix, and R_t is a $d \times q$ control matrix. The $m \times 1$ vector $\tilde{\epsilon}_t$ denotes observation errors with a $m \times m$ variance-covariance matrix Σ_t, and η_t is a q-dimensional system error with a $q \times q$ state diffusion matrix Q_t, where $q \leq d$. Note that any linear dependencies in the state vector can be moved from Q_t to R_t, hence Q_t can be set as a full rank variance matrix.

Structural time series models constructed in terms of components have a direct interpretation. For example, one may consider the classical decomposition in which a series can be seen as the sum of trend, season, cycle and regression components. In general, the model in state space form can be written as:

$$\tilde{y}_t = \tilde{\mu}_t + \tilde{\tau}_t + \tilde{\omega}_t + \tilde{\xi}_t + \tilde{\epsilon}_t, \qquad \tilde{\epsilon}_t \overset{iid}{\sim} N_m(0, \Sigma_\epsilon), \quad t = 1, 2 \ldots, n, \tag{4}$$

where $\tilde{y}_t$, $\tilde{\mu}_t$, $\tilde{\tau}_t$, $\tilde{\omega}_t$, $\tilde{\xi}_t$ and $\tilde{\epsilon}_t$ are m-dimension vectors, representing target time series, linear trend component, seasonal component, cyclical component, regression component and observation error terms respectively. Based on the state space form, α_t is the collection of these components, namely $\alpha_t = [\tilde{\mu}_t^T, \tilde{\tau}_t^T, \tilde{\omega}_t^T, \tilde{\xi}_t^T]^T$. Here Σ_ϵ is a $m \times m$ matrix, positive definite and is assumed to be constant over time for simplicity. Structural time series models allow us to examine the time series and flexibly select suitable components for trend, seasonality, and either static or dynamic regression. In the current model, all state components are assembled independently, with each component yielding an additive contribution to $\tilde{y}_t$. The flexibility of the model allows us to include different model components for each target series.

2.2 Components of State

The first component is a local linear trend. The specification of a time series model for the trend component varies according to the features displayed by the series under investigation and any prior knowledge. The most elementary structural model deals with a series whose underlying level changes over time. Moreover, it also sometimes displays a steady upward or downward movement, suggesting to incorporate a slope or a drift into the model for the trend. The resulting model, a generalization of the local linear trend model where the slope exhibits stationarity instead of obeying a random walk, is expressed in the form as:

$$\tilde{\mu}_{t+1} = \tilde{\mu}_t + \tilde{\delta}_t + \tilde{u}_t, \qquad \tilde{u}_t \overset{iid}{\sim} N_m(0, \Sigma_\mu), \tag{5}$$

$$\tilde{\delta}_{t+1} = \tilde{D} + \tilde{\rho}(\tilde{\delta}_t - \tilde{D}) + \tilde{v}_t, \qquad \tilde{v}_t \overset{iid}{\sim} N_m(0, \Sigma_\delta), \tag{6}$$

where $\tilde{\delta}_t$ and $\tilde{D}$ are m-dimension vectors. $\tilde{\delta}_t$ is the expected increase in $\tilde{\mu}_t$ between times t and $t+1$, so it can be thought as the slope at time t and $\tilde{D}$ is the long-term slope. The parameter $\tilde{\rho}$ is a $m \times m$ diagonal matrix, whose diagonal entries $0 \leq \rho_{ii} \leq 1$ for $i = 1, 2, \cdots, m$, represent the learning rates at which the local trend is updated for $\{y_t^{(i)}\}_{i=1,2,\cdots,m}$. Thus, the model balances short-term information with long-term information. When $\rho_{ii} = 1$, the corresponding slope becomes a random walk.

The second component is the one that captures seasonality. One frequently used model in the time domain is:

$$\tau_{t+1}^{(i)} = -\sum_{k=0}^{S_i - 2} \tau_{t-k}^{(i)} + w_t^{(i)}, \qquad \tilde{w}_t = [w_t^{(1)}, \cdots, w_t^{(m)}]^T \overset{iid}{\sim} N_m(0, \Sigma_\tau), \tag{7}$$

where S_i represents the number of seasons for $y^{(i)}$ and a m-dimension vector $\tilde{\tau}_t$ denotes their joint contribution to the observed target time series $\tilde{y}_t$. When we add a seasonal component, S_i seasonal effects are set in the state space form for $y^{(i)}$. However, only one seasonal effect has error term based on equation (7) and other effects are represented by itself in a deterministic equation. More specifically, the part of the transition matrix T_t representing the seasonal effects is an $(S_i - 1) \times (S_i - 1)$ matrix with -1 along the top row, 1 along the subdiagonal and 0 elsewhere. In addition, the expectation of the summation of S_i seasonal effects for $y^{(i)}$ is zero with variance equal to the i-th diagonal element of Σ_τ.

For each target series $y^{(i)}$, the model allows for various seasonal components with different periods as shown in equation (7). For instance, we might include a seasonal component with $S_i = 7$ to capture day-of-the-week effect for target series $y^{(i)}$, and $S_j = 30$ indicating day-of-the-month effect for another target series $y^{(j)}$ when modeling daily data. The corresponding seasonal transition matrix in state space setting is a 6×6 matrix and a 29×29 matrix with nonzero error variance for $y^{(i)}$ and $y^{(j)}$ respectively.

The third component is the one accounting for cyclical effects in the series. In economics, the term "business cycle" broadly refers to recurrent, not exactly periodic, deviations around the long-term path of the series. A model with a cyclical component is capable of reproducing commonly acknowledged essential features, such as the presence of strong autocorrelation, recurrence and alternation of phases, dampening of fluctuations, and zero long run persistence. A stochastic trend model of a seasonally adjusted economic time series does not capture the short-term movement of the series by itself. Including a serially correlated stationary component, the short-term movement could be captured, and this is the model incorporating cyclical effect (see Harvey et al., 2007). The cycle component is postulated as:

$$\begin{aligned} \tilde{\omega}_{t+1} &= \tilde{\varrho}\widehat{\cos(\lambda)}\tilde{\omega}_t + \tilde{\varrho}\widehat{\sin(\lambda)}\tilde{\omega}_t^\star + \tilde{\kappa}_t, \qquad \tilde{\kappa}_t \overset{iid}{\sim} N_m(0, \Sigma_\omega), \\ \tilde{\omega}_{t+1}^\star &= -\tilde{\varrho}\widehat{\sin(\lambda)}\tilde{\omega}_t + \tilde{\varrho}\widehat{\cos(\lambda)}\tilde{\omega}_t^\star + \tilde{\kappa}_t^\star, \qquad \tilde{\kappa}_t^\star \overset{iid}{\sim} N_m(0, \Sigma_\omega), \end{aligned} \tag{8}$$

where $\tilde{\varrho}$, $\widehat{\sin(\lambda)}$, $\widehat{\cos(\lambda)}$ are $m \times m$ diagonal matrices with diagonal entries equal to ϱ_{ii} (a damping factor for target series $y^{(i)}$ such that $0 < \varrho_{ii} < 1$), $\sin(\lambda_{ii})$ where $\lambda_{ii} = 2\pi/q_i$ is the frequency with q_i being a period such that $0 < \lambda_{ii} < \pi$, and $\cos(\lambda_{ii})$ respectively. When λ_{ii} is 0 or π, the model degenerates to the AR(1) process. The damping factor should be strictly less than one for stationary purpose. When the damping factor is bigger than one, there will be no restriction for the cyclical movement, resulting in extending the amplitude of the cycle.

These three time series components are illustrated in Figure 1. The big difference between the cyclical component and the seasonal component is the damping factor. The amplitude of the cyclical component will decay as time goes by, which can be applied to target time series affected by external shocks. Here Σ_μ, Σ_δ, Σ_τ and Σ_ω are $m \times m$ variance-covariance matrices for error terms of different time series components, and for simplicity we assume they are diagonal.

The fourth component is the regression component with static coefficients written as follows:

$$\xi_t^{(i)} = \beta_i^T x_t^{(i)}. \tag{9}$$

Here $\tilde{\xi}_t = [\xi_t^{(1)}, \cdots, \xi_t^{(m)}]^T$ is the collection of all elements in the regression component. For target series $y^{(i)}$, $x_t^{(i)} = [x_{t1}^{(i)}, \ldots, x_{tk_i}^{(i)}]^T$ is the pool of all available predictors at time t, and $\beta_i = [\beta_{i1}, \ldots, \beta_{ij}, \ldots, \beta_{ik_i}]^T$ represents corresponding static regression coefficients. All predictors are supposed to be contemporaneous with a known lag, which can be easily incorporated by shifting the corresponding predictors in time.

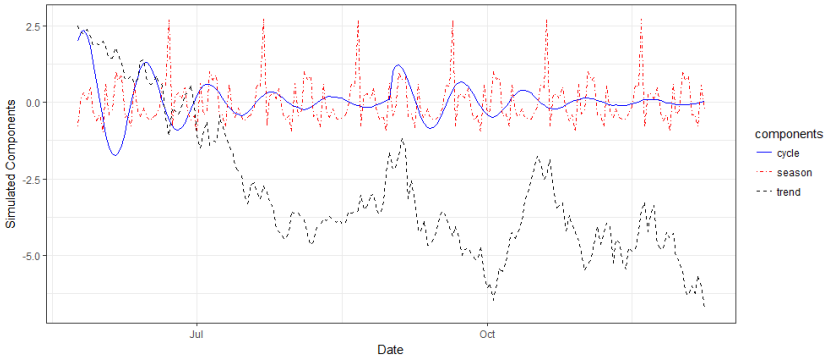

Figure 1: Simulated time series components include generalized linear trend, seasonality and cycle, generated by equations (5), (6), (7) and (8) with $\tilde{\rho} = [0.6]$, $\tilde{D} = [0]$, $\Sigma_\mu = [0.5^2]$, $\Sigma_\delta = [0.08^2]$, $S = 30$, $\Sigma_\tau = [0.01^2]$, $\lambda = \pi/10$, $\tilde{\varrho} = [0.97]$ and $\Sigma_\omega = [0.01^2]$, to show different contributions in explaining variations in target time series.

2.3 Spike and Slab Regression

In feature selection, a high degree of sparsity is expected, in the sense that coefficients of the vast majority of predictors are expected to be zero. A natural way to represent sparsity in the Bayesian paradigm is through the spike and slab coefficients. One advantage of working in a fully Bayesian setting is that we do not need to commit to a fixed set of predictors.

2.3.1 Matrix Representation

In order to assign appropriate prior distributions to parameters, we first combine $\tilde{y}_t$, $\tilde{\mu}_t$, $\tilde{\tau}_t$, $\tilde{\omega}_t$, $\tilde{\epsilon}_t$ into a $n \times m$ matrix as follows: $Y = [\tilde{y}_1, \ldots, \tilde{y}_t, \ldots, \tilde{y}_n]^T$, $M = [\tilde{\mu}_1, \ldots, \tilde{\mu}_t, \ldots, \tilde{\mu}_n]^T$, $T = [\tilde{\tau}_1, \ldots, \tilde{\tau}_t, \ldots, \tilde{\tau}_n]^T$, $W = [\tilde{\omega}_1, \ldots, \tilde{\omega}_t, \ldots, \tilde{\omega}_n]^T$ and $E = [\tilde{\epsilon}_1, \ldots, \tilde{\epsilon}_t, \ldots, \tilde{\epsilon}_n]^T$. Then the model can be written in a long matrix form as follows:

$$\tilde{Y} = \tilde{M} + \tilde{T} + \tilde{W} + X\beta + \tilde{E}, \tag{10}$$

where $\tilde{Y} = vec(Y)$, $\tilde{M} = vec(M)$, $\tilde{T} = vec(T)$, $\tilde{W} = vec(W)$, $\tilde{E} = vec(E)$, and X, β are written as:

$$X = \begin{bmatrix} X_1 & 0 & 0 & \ldots & 0 \\ 0 & X_2 & 0 & \ldots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \ldots & X_m \end{bmatrix}, \qquad \beta = \begin{bmatrix} \beta_1 \\ \beta_2 \\ \vdots \\ \beta_m \end{bmatrix}, \tag{11}$$

where X_i being a $n \times k_i$ matrix, representing all observations of k_i candidate predictors for $y^{(i)}$, which is all observations of the i-th target series. The regression matrix X is of dimension $(nm \times K)$ with $K = \sum_{i=1}^{m} k_i$. Moreover, X_i and X_j can be the same or only contain a portion of common predictors. The regression coefficients for $y^{(i)}$ denoted as $\beta_i = [\beta_{i1}, \ldots, \beta_{ij}, \ldots, \beta_{ik_i}]^T$ is a k_i-dimension vector. Reformulating the model in this way facilitates the mathematical derivation in selecting a different set of available predictors at each iteration for $y^{(i)}$.

2.3.2 Prior distribution and elicitation

We define $\gamma_{ij} = 1$ if $\beta_{ij} \neq 0$, and $\gamma_{ij} = 0$ if $\beta_{ij} = 0$. Then $\gamma = [\gamma_1, \ldots, \gamma_m]$ where $\gamma_i = [\gamma_{i1}, \ldots, \gamma_{ik_i}]$. Denote β_γ as the subset of elements of β where $\beta_{ij} \neq 0$, and let X_γ be the subset of columns of X where $\gamma_{ij} = 1$. The spike prior is written as:

$$\gamma \sim \prod_{i=1}^{m} \prod_{j=1}^{k_i} \pi_{ij}^{\gamma_{ij}} (1 - \pi_{ij})^{1-\gamma_{ij}}, \qquad i = 1, \cdots, m, \tag{12}$$

where π_{ij} is the prior inclusion probability of the j-th predictor for the i-th target time series. Equation (12) is often further simplified by setting all the π_{ij} for $j = 1, 2, \cdots, k_i$ as the same value π_i for $y^{(i)}$ if prior information about effects of specific predictors on each target series are not available. With sufficient prior information available, assigning different subjectively determined values to π_{ij} might provide more robust results without a great amount of computational burden. An easy way to elicit π_i is to ask researchers for an "expected model size", so that if one expects q_i nonzero predictors for $y^{(i)}$, then $\pi_i = q_i/k_i$, where k_i is the total number of candidate predictors for the i-th target series. Under some circumstances, π_{ij} could be set as 0 or 1, for some specific predictors of $y^{(i)}$, forcing certain variables to be excluded or included. The spike prior can be specified by researchers in different distributional forms.

The natural conjugate prior for the multivariate model with the same set of predictors has the conjugate prior on β depending on Σ_ϵ. However, the multivariate extension with different set of predictors in each equation will destroy the conjugacy (Rossi et al. (2012)). Conjugate priors such as the normal distribution and the inverse Wishart distribution can still be used in a nonconjugate context, since models can be conjugate conditional on some other parameters. In order to obtain this conditional conjugate, we stack up the regression equations into one shown in equation (11). A simple slab prior specification is to make β and Σ_ϵ prior independent (see Griffiths, 2003):

$$\begin{aligned} p(\beta, \Sigma_\epsilon, \gamma) &= p(\beta|\gamma)p(\Sigma_\epsilon|\gamma)p(\gamma), \\ \beta|\gamma &\sim N_K(b_\gamma, A_\gamma^{-1}), \\ \Sigma_\epsilon|\gamma &\sim IW(v_0, V_0), \end{aligned} \tag{13}$$

where b_γ is the vector of prior means and $A_\gamma = \kappa X_\gamma^T X_\gamma / n$ is the full-model prior information matrix, with κ the number of observations worth of weight on the prior mean vector b_γ. If $X_\gamma^T X_\gamma$ is not positive definite due to perfect collinearity among predictors, $A_\gamma = \kappa(\omega X_\gamma^T X_\gamma + (1-\omega) diag(X_\gamma^T X_\gamma))/n$ can be used instead to guarantee propriety. Given analysts' specification, A_γ can be set in other forms. Here, $IW(v_0, V_0)$ is the inverse

Wishart distribution with v_0 the number of degrees of freedom and V_0 a $m \times m$ scale matrix. Although these priors are not conjugate, they are conditionally conjugate.

Equation (13) is the so-called "slab" because one can choose the prior parameters to make it only very weakly informative (close to flat), conditional on γ. The vector b_γ encodes our prior expectation about the value of each element of β_γ. In practice, one usually sets $b = 0$. The values of v_0 and V_0 can be set by asking analysts for an expected R^2 form the regression, and a number of observations worth of weight v_0, which must be greater than the dimension of $\tilde{y}_t$ plus one. Then $V_0 = (v_0 - m - 1) * (1 - R^2) * \Sigma_y$, where Σ_y is the variance-covariance matrix for multiple target time series Y.

Prior distributions of other variance-covariance matrices can be expressed as:

$$\Sigma_u \sim IW(w_u, W_u), \quad \text{for } u \in \{\mu, \delta, \tau, \omega\}. \tag{14}$$

By the assumption that all components are independent of each other, the prior distributions in multivariate form can reduced to their univariate counterparts since the matrices are diagonal. In other words, each diagonal entry of these matrices follows inverse gamma distributions as introduced in BSTS.

2.3.3 Posterior Inference

By the law of total probability, the full likelihood function is given by

$$p(\tilde{Y}^\star, \beta, \Sigma_\epsilon, \gamma) = p(\tilde{Y}^\star|\beta, \Sigma_\epsilon, \gamma) \times p(\beta|\gamma) \times p(\Sigma_\epsilon|\gamma) \times p(\gamma), \tag{15}$$

$$p(\tilde{Y}^\star|\beta, \Sigma_\epsilon, \gamma) \propto |\Sigma_\epsilon|^{-n/2} \exp\left(-\frac{1}{2}(\tilde{Y}^\star - X_\gamma\beta_\gamma)^T(\Sigma_\epsilon^{-1} \otimes I_n)(\tilde{Y}^\star - X_\gamma\beta_\gamma)\right), \tag{16}$$

$$p(\beta|\gamma) \propto |A_\gamma|^{1/2} \exp\left(-\frac{1}{2}(\beta_\gamma - b_\gamma)^T A_\gamma (\beta_\gamma - b_\gamma)\right), \tag{17}$$

$$p(\Sigma_\epsilon|\gamma) \propto |\Sigma_\epsilon|^{-(v_0+m+1)/2} \exp\left(tr(-\frac{1}{2}V_0\Sigma_\epsilon^{-1})\right), \tag{18}$$

where $\tilde{Y}^\star = \tilde{Y} - \tilde{M} - \tilde{T} - \tilde{W}$ is the multiple target time series $\tilde{Y}$ with time series components (trend, seasonality and cycle) subtracted out. Conditional on Σ_ϵ, one can introduce a normal prior, standardize the observations to remove correlation, and produce a posterior. However, we cannot find a convenient prior to integrate out Σ_ϵ from this conditional posterior. We tackle this issue by transforming equation $\tilde{Y}^\star = X\beta + \tilde{E}$ into a system with uncorrelated errors, using the square root of the variance-covariance matrix, $\Sigma_\epsilon = U^T U$. That is, if we multiply $((U^{-1})^T \otimes I_n)$ both sides of the equation, by the fact that $(U^{-1})^T \Sigma_\epsilon U^{-1} = I$, the transformed system has uncorrelated errors:

$$\begin{gathered} \hat{Y}^\star = \hat{X}\beta + \hat{E}, \quad \hat{Y}^\star = ((U^{-1})^T \otimes I_n)\tilde{Y}^\star, \quad \hat{X} = ((U^{-1})^T \otimes I_n)X, \\ \mathrm{Var}(\hat{E}) = \mathbb{E}((U^{-1})^T \otimes I_n)\tilde{E}\tilde{E}^T((U^{-1})^T \otimes I_n)] = I_m \otimes I_n. \end{gathered} \tag{19}$$

Then the full conditional distribution of $\beta|\hat{Y}^\star, \Sigma_\epsilon, \gamma$ can be expressed as:

$$p(\beta|\hat{Y}^\star, \Sigma_\epsilon, \gamma) \propto \exp\left(-\frac{1}{2}((\hat{Y}^\star - \hat{X}_\gamma\beta_\gamma)^T(\hat{Y}^\star - \hat{X}_\gamma\beta_\gamma) + (\beta_\gamma - b_\gamma)^T A_\gamma(\beta_\gamma - b_\gamma))\right). \tag{20}$$

Let us combine the two terms in exponential:

$$\begin{aligned}&(\hat{Y}^\star - \hat{X}_\gamma\beta_\gamma)^T(\hat{Y}^\star - \hat{X}_\gamma\beta_\gamma) + (\beta_\gamma - b_\gamma)^T A_\gamma(\beta_\gamma - b_\gamma)\\ =&\beta_\gamma^T(\hat{X}_\gamma^T\hat{X}_\gamma + A_\gamma)\beta_\gamma - \beta_\gamma^T(\hat{X}_\gamma^T\hat{Y}^\star + A_\gamma b_\gamma) - (\hat{X}_\gamma^T\hat{Y}^\star + A_\gamma b_\gamma)^T\beta_\gamma + Const \qquad (21)\\ =&(\beta_\gamma - \tilde{\beta}_\gamma)^T(\hat{X}_\gamma^T\hat{X}_\gamma + A_\gamma)(\beta_\gamma - \tilde{\beta}_\gamma) + Const,\end{aligned}$$

where $\tilde{\beta}_\gamma = (\hat{X}_\gamma^T\hat{X}_\gamma + A_\gamma)^{-1}(\hat{X}_\gamma^T\hat{Y}^\star + A_\gamma b_\gamma)$. Then, a normal prior for β_γ is conjugate with the conditional likelihood for the transformed system:

$$\beta|\hat{Y}^\star, \Sigma_\epsilon, \gamma \sim N_K(\tilde{\beta}_\gamma, (\hat{X}_\gamma^T\hat{X}_\gamma + A_\gamma)^{-1}). \qquad (22)$$

As A_γ gets smaller, the prior becomes flatter. The mean $\tilde{\beta}_\gamma$ can be recognized as the generalized least squares estimator.

The posterior of $\Sigma_\epsilon|\hat{Y}^\star, \beta, \gamma$ is in the inverted Wishart form. To see this, firstly recall that given β_γ we can observe or compute the errors $\tilde{E}$. Then the problem becomes a standard inference problem of a variance-covariance matrix using a multivariate normal sample. From equations (15), (16), (17) and (18), we know that

$$p(\Sigma_\epsilon|\tilde{Y}^\star, \beta, \gamma) \propto |\Sigma_\epsilon|^{-(n+v_0+m+1)/2}\exp\left(-\frac{1}{2}\{\tilde{E}_\gamma^T(\Sigma_\epsilon^{-1}\otimes I_n)\tilde{E}_\gamma + tr(V_0\Sigma_\epsilon^{-1})\}\right), \qquad (23)$$

where $\tilde{E}_\gamma = \tilde{Y}^\star - X_\gamma\beta_\gamma$. The terms in the exponential part can be expressed in a trace form:

$$\tilde{E}_\gamma^T(\Sigma_\epsilon^{-1}\otimes I_n)\tilde{E}_\gamma = vec(E_\gamma)^T(\Sigma_\epsilon^{-1}\otimes I_n)vec(E_\gamma) = tr(E_\gamma^T E_\gamma\Sigma_\epsilon^{-1}), \qquad (24)$$

where $E_\gamma = Y^\star - X_\gamma^\star B_\gamma$, $Y^\star = Y - M - T - W$, $X_\gamma^\star = [X_1, X_2, \ldots, X_M]_\gamma$ is a $(n \times K)$ matrix, and B_γ is a $(K \times m)$ matrix expressed as follows:

$$B_\gamma = \begin{bmatrix}\beta_1 & 0 & 0 & \ldots & 0\\ 0 & \beta_2 & 0 & \ldots & 0\\ \vdots & \vdots & \vdots & \ddots & \vdots\\ 0 & 0 & 0 & \ldots & \beta_m\end{bmatrix}_\gamma. \qquad (25)$$

Then the full conditional distribution of Σ_ϵ is inverted Wishart as follows:

$$p(\Sigma_\epsilon|\tilde{Y}^\star, \beta, \gamma) \propto |\Sigma_\epsilon|^{-(n+v_0+m+1)/2}\exp\left(-\frac{1}{2}\{tr[(E_\gamma^T E_\gamma + V_0)\Sigma_\epsilon^{-1}]\}\right), \qquad (26)$$

$$\Sigma_\epsilon|\tilde{Y}^\star, \beta, \gamma \sim IW(v_0 + n, E_\gamma^T E_\gamma + V_0). \qquad (27)$$

Note that, if we let the prior precision goes to zero, the posterior on Σ_ϵ would center over the sum of squared residuals matrices.

Since there is no conjugacy in this prior setting, we can not get an analytic solution of the marginal distribution of γ. However, the conditional distribution of $\gamma|\Sigma_\epsilon, \tilde{Y}^\star$ can be

derived by the properties of conditional conjugacy. The joint probability density function $p(\Sigma_\epsilon, \tilde{Y}^\star, \gamma)$ can be obtained as follows:

$$\begin{aligned}p(\Sigma_\epsilon, \tilde{Y}^\star, \gamma) =& \int_{-\infty}^{+\infty} p(\beta, \Sigma_\epsilon, \tilde{Y}^\star, \gamma)d\beta\\ \propto&|\Sigma_\epsilon|^{-(v_0+m++n+1)/2}\exp\left(-\frac{1}{2}\{tr(V_0\Sigma_\epsilon^{-1}) + (\hat{Y}^\star)^T\hat{Y}^\star\}\right) \qquad (28)\\ &\times\frac{|A_\gamma|^{1/2}p(\gamma)}{|\hat{X}_\gamma^T\hat{X}_\gamma + A_\gamma|^{1/2}}\exp\left(-\frac{1}{2}\{b_\gamma^T A_\gamma b_\gamma - Z_\gamma^T(\hat{X}_\gamma^T\hat{X}_\gamma + A_\gamma)^{-1}Z_\gamma\}\right),\end{aligned}$$

where $Z_\gamma = (\hat{X}_\gamma^T\hat{Y}^\star + A_\gamma b_\gamma)$. Then the conditional distribution of $\gamma|\Sigma_\epsilon, \tilde{Y}^\star$ can be expressed as:

$$p(\gamma|\Sigma_\epsilon, \tilde{Y}^\star) = C(\Sigma_\epsilon, \tilde{Y}^\star)\frac{|A_\gamma|^{1/2}p(\gamma)}{|\hat{X}_\gamma^T\hat{X}_\gamma + A_\gamma|^{1/2}}\exp\left(-\frac{1}{2}\{b_\gamma^T A_\gamma b_\gamma - Z_\gamma^T(\hat{X}_\gamma^T\hat{X}_\gamma + A_\gamma)^{-1}Z_\gamma\}\right), \qquad (29)$$

where $C(\Sigma_\epsilon, \tilde{Y}^\star)$ is a normalizing constant that only depends on Σ_ϵ and $\tilde{Y}^\star$. Note that, matrices needed to be computed here are of low dimension, in the sense that equation (29) places positive probabilities on coefficients being zero, leading to the sparsity of these matrices. In general, as a feature of the full posterior distribution, sparsity in this model enables equation (29) to be evaluated in an inexpensive way.

Next we need to derive conditional posterior of Σ_u for $u \in \{\mu, \delta, \tau, \omega\}$. Given the draws of states, parameters drawn are straightforward for all state components except the static regression coefficients. All time series components that solely depend on their variance parameters would translate their draws back to the error terms and accumulate sums of squares. For the reason that inverse Wishart distribution is the conjugate prior of a multivariate normal distribution with known mean and variance-covariance, the posterior distribution is still inverse Wishart distributed

$$\Sigma_u|u \sim IW(w_u + n, W_u + AA^T), \quad \text{for } u \in \{\mu, \delta, \tau, \omega\}, \qquad (30)$$

where $A = [\tilde{A}_1, \ldots, \tilde{A}_n]$ is a $m \times n$ matrix, representing a collection of residues of each time series component.

2.4 Markov Chain Monte Carlo

Markov chain Monte Carlo (MCMC) methods are a class of algorithms to sample from a probability distribution based on constructing a Markov chain that has the desired distribution as its equilibrium distribution. The state of the chain after a number of steps is then used as a sample from the desired distribution. The quality of the sample improves as an increasing function of the number of steps.

2.4.1 Model Training

Let $\theta = (\Sigma_\mu, \Sigma_\delta, \Sigma_\tau, \Sigma_\omega)$ denotes the set of state component parameters. The posterior distribution of the model can be simulated by a Markov chain Monte Carlo algorithm given in Algorithm 1. Looping through the five steps yields a sequence of draws $\tilde{\psi} = (\alpha, \theta, \gamma, \Sigma_\epsilon, \beta)$

from a Markov chain with stationary distribution $p(\tilde{\psi}|Y)$, the posterior distribution of $\tilde{\psi}$ given Y.

Algorithm 1 MBSTS Model Training

1: Draw the latent state $\alpha = (\tilde{\mu}, \tilde{\delta}, \tilde{\tau}, \tilde{\omega})$ from given model parameters and $\tilde{Y}$, namely $p(\alpha|\tilde{Y}, \theta, \gamma, \Sigma_\epsilon, \beta)$, using the posterior simulation algorithm from Durbin and Koopman (2002).
2: Draw time series state component parameters θ given α, namely simulating $\theta \sim p(\theta|\tilde{Y}, \alpha)$ based on equation (30).
3: Loop over i in an random order, draw each $\gamma_i|\gamma_{-i}, \tilde{Y}, \alpha, \Sigma_\epsilon$, namely simulating $\gamma \sim p(\gamma|\tilde{Y}^\star, \Sigma_\epsilon)$ one by one based on equation (29), using the stochastic search variable selection (SSVS) algorithm from George and McCulloch (1997).
4: Draw β given Σ_ϵ, γ, α and $\tilde{Y}$, namely simulating $\beta \sim p(\beta|\Sigma_\epsilon, \gamma, \tilde{Y}^\star)$ based on equation (22).
5: Draw Σ_ϵ given γ, α, β and $\tilde{Y}$, namely simulating $\Sigma_\epsilon \sim p(\Sigma_\epsilon|\gamma, \tilde{Y}^\star, \beta)$ based on equation (27).

2.4.2 Target Series Forecasting

As typically in Bayesian data analysis, forecasts using our model are based on the posterior predictive distribution. Given draws of model parameters and latent states from their posterior distribution, we can draw samples from the posterior predictive distribution. Let $\hat{Y}$ represents the set of values to be forecast. The posterior predictive distribution of $\hat{Y}$ can be expressed as follows:

$$p(\hat{Y}|Y) = \int p(\hat{Y}|\tilde{\psi}) p(\tilde{\psi}|Y) d\tilde{\psi} \tag{31}$$

where $\tilde{\psi}$ is the set of all the model parameters and latent states randomly drawn from $p(\tilde{\psi}|Y)$. We can draw samples of $\hat{Y}$ from $p(\hat{Y}|\tilde{\psi})$ by simply iterating equations (5), (6), (7), (8) and (9) to move forward from initial values of states α with initial values of parameters θ, β and Σ_ϵ. In the one-step-ahead forecast, we draw samples from the multivariate normal distribution with mean equal to $\tilde{\mu}_n + \tilde{\delta}_n + \sum_{k=0}^{S-2} \tilde{\tau}_{n-k} + \tilde{\varrho}\widehat{cos(\lambda)}\tilde{\omega}_n + \tilde{\varrho}\widehat{sin(\lambda)}\tilde{\omega}_n^\star + \beta^{(k)} x_{n+1}$ and variance equal to $\Sigma_\epsilon + \Sigma_\mu + \Sigma_\tau + \Sigma_\omega$. Therefore, the samples drawn in this way have the same distribution as those simulated directly from the posterior predictive distribution.

Note that, the predictive probability density is not conditioned on parameter estimates, and inclusion or exclusion of predictors with static regression coefficients, all of which have been integrated out. Thus, through Bayesian model averaging, we commit neither to any particular set of covariates which helps avoid arbitrary selection, nor to point estimates of their coefficients which prevents overfitting. By the multivariate nature in our MBSTS model, the correlations among multiple target series are naturally taken into account, when sampling for prediction values of several target series. The posterior predictive density in equation (31), is defined as a joint distribution over all predicted target series, rather than as a collection of univariate distributions, which enables us to properly forecast multiple target series as a whole instead of predicting them individually. This is crucial, especially when

generating summary statistics, such as mean and variance-covariance from joint empirical distribution of forecast values.

3. Application to Simulated Data

In order to investigate the properties of our model, in this section, we analyze computer-generated data through a series of independent simulations. We generated multiple data sets with different time spans, local trends, number of regressors, dimensions of target series and correlations among several target series to analyze three aspects of generated data: accuracy in parameter estimation, ability to select the correct variables, and forecast performance of the model.

3.1 Generated Data

To check whether the estimation error and estimation standard deviation decrease as sample size increases, we built four different models in equation (32), each of which generates two target time series data with different numbers of observations (50, 100, 200, 400, 800, 1600, 3200). These data sets are simulated using latent states and a static regression component with four explanatory variables, one of which has no effect on each target series with zero coefficient. Specifically, each target series was generated with a different set of state components and explanatory variables, while the insignificant variable for each target series is not the same.

The latent states were generated using a local linear trend component with and without a global slope, a seasonality component with period equal to four, and/or a cyclical component with $\lambda = \pi/10$ for both target series. All initial values are drawn from normal distribution with a mean of zero. The detailed model description is presented as follows:

$$\begin{aligned}
\tilde{y}_t &= \tilde{\alpha}_t + B^T \tilde{x}_t + \tilde{\epsilon}_t \\
Model\ 1: \ \tilde{y}_t &= \tilde{\mu}_t + B^T \tilde{x}_t + \tilde{\epsilon}_t \qquad \tilde{\alpha}_t = \tilde{\mu}_t \\
Model\ 2: \ \tilde{y}_t &= \tilde{\mu}'_t + B^T \tilde{x}_t + \tilde{\epsilon}_t \qquad \tilde{\alpha}_t = \tilde{\mu}'_t \\
Model\ 3: \ \tilde{y}_t &= \tilde{\mu}'_t + \tilde{\tau}_t + B^T \tilde{x}_t + \tilde{\epsilon}_t \qquad \tilde{\alpha}_t = \tilde{\mu}'_t + \tilde{\tau}_t \\
Model\ 4: \ \tilde{y}_t &= \tilde{\mu}'_t + \tilde{\tau}_t + \tilde{\omega}_t + B^T \tilde{x}_t + \tilde{\epsilon}_t \qquad \tilde{\alpha}_t = \tilde{\mu}'_t + \tilde{\tau}_t + \tilde{\omega}_t
\end{aligned} \tag{32}$$

$$\begin{gathered}
\tilde{\epsilon}_t \overset{iid}{\sim} N_2(0, \Sigma_\epsilon) \qquad \Sigma_\epsilon = \begin{bmatrix} 1.1 & 0.7 \\ 0.7 & 0.9 \end{bmatrix} \\
B = \begin{bmatrix} 2 & -1 & -0.5 & 0 \\ -1.5 & 4 & 0 & 2.5 \end{bmatrix}^T \qquad \tilde{x}_t = [x_{t1}, x_{t2}, x_{t3}, x_{t4}]^T \\
x_{t1} \overset{iid}{\sim} N(5, 5^2) \quad x_{t2} \overset{iid}{\sim} Pois(10) \quad x_{t3} \overset{iid}{\sim} B(1, 0.5) \quad x_{t4} \overset{iid}{\sim} N(-2, 5^2)
\end{gathered} \tag{33}$$

$$\begin{gathered}
\tilde{\mu}_{t+1} = \begin{bmatrix} \mu_{1,t+1} \\ \mu_{2,t+1} \end{bmatrix} = \begin{bmatrix} \mu_{1,t} \\ \mu_{2,t} \end{bmatrix} + \begin{bmatrix} \delta_{1,t} \\ 0 \end{bmatrix} + \begin{bmatrix} u_{1,t} \\ u_{2,t} \end{bmatrix} \\
\delta_{1,t} \overset{iid}{\sim} N(\delta_{1,t-1}, 0.08^2) \qquad \begin{bmatrix} u_{1,t} \\ u_{2,t} \end{bmatrix} \overset{iid}{\sim} N_2\left(\begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 0.5^2 & 0 \\ 0 & 1 \end{bmatrix} \right)
\end{gathered} \tag{34}$$

$$\begin{aligned}\tilde{\mu}'_{t+1} &= \begin{bmatrix}\mu'_{1,t+1}\\ \mu'_{2,t+1}\end{bmatrix} = \begin{bmatrix}\mu'_{1,t}\\ \mu'_{2,t}\end{bmatrix} + \begin{bmatrix}\delta'_{1,t}\\ \delta'_{2,t}\end{bmatrix} + \begin{bmatrix}u_{1,t}\\ u_{2,t}\end{bmatrix}\\ \begin{bmatrix}\delta'_{1,t}\\ \delta'_{2,t}\end{bmatrix} &\overset{iid}{\sim} N_2\left(\begin{bmatrix}0.6\delta'_{1,t-1}+0.4*0.02\\ \delta'_{2,t-1}\end{bmatrix}, \begin{bmatrix}0.08^2 & 0\\ 0 & 0.16^2\end{bmatrix}\right)\end{aligned} \tag{35}$$

$$\tilde{\tau}_{t+1} = \begin{bmatrix}\tau_{1,t+1}\\ \tau_{2,t+1}\end{bmatrix} = \begin{bmatrix}-\sum_{k=0}^{2}\tau_{1,t-k}\\ 0\end{bmatrix} + \begin{bmatrix}w_{1,t}\\ 0\end{bmatrix} \qquad w_{1,t} \overset{iid}{\sim} N(0, 0.01^2) \tag{36}$$

$$\begin{aligned}\tilde{\omega}_{t+1} &= \begin{bmatrix}\omega_{1,t+1}\\ \omega_{2,t+1}\end{bmatrix} = \begin{bmatrix}0\\ 0.5*\cos(\lambda_{22})\omega_{2,t}\end{bmatrix} + \begin{bmatrix}0\\ 0.5*\sin(\lambda_{22})\omega^{\star}_{2,t}\end{bmatrix} + \begin{bmatrix}0\\ \kappa_{2,t}\end{bmatrix}\\ \tilde{\omega}^{\star}_{t+1} &= \begin{bmatrix}\omega^{\star}_{1,t+1}\\ \omega^{\star}_{2,t+1}\end{bmatrix} = \begin{bmatrix}0\\ -0.5*\sin(\lambda_{22})\omega_{2,t}\end{bmatrix} + \begin{bmatrix}0\\ 0.5*\cos(\lambda_{22})\omega^{\star}_{2,t}\end{bmatrix} + \begin{bmatrix}0\\ \kappa^{\star}_{2,t}\end{bmatrix}\\ \kappa_{2,t} &\overset{iid}{\sim} N(0, 0.01^2) \qquad \kappa^{\star}_{2,t} \overset{iid}{\sim} N(0, 0.01^2).\end{aligned} \tag{37}$$

To check the model performance with more than two series, two more data sets were generated by Model 5 and Model 6 according to equations (38) and (39), respectively, where for simplicity we consider latent states only include a generalized local linear trend with and without a global slope. The specific settings are given below:

$$\begin{aligned}&Model\ 5: \ \tilde{y}_t = \tilde{\mu}''_t + B^T\tilde{x}_t + \tilde{\epsilon}_t \qquad \tilde{\epsilon}_t \overset{iid}{\sim} N_3(0, \Sigma_\epsilon)\\ &B = \begin{bmatrix}2 & -1 & -0.5 & 0\\ -1.5 & 4 & 0 & 2.5\\ 3 & 0 & 3.5 & -2\end{bmatrix}^T \qquad \Sigma_\epsilon = \begin{bmatrix}1.1 & 0.7 & 0.7\\ 0.7 & 0.9 & 0.7\\ 0.7 & 0.7 & 1.0\end{bmatrix}\\ &\tilde{\mu}''_{t+1} = \begin{bmatrix}\mu''_{1,t+1}\\ \mu''_{2,t+1}\\ \mu''_{3,t+1}\end{bmatrix} = \begin{bmatrix}\mu''_{1,t}\\ \mu''_{2,t}\\ \mu''_{3,t}\end{bmatrix} + \begin{bmatrix}\delta''_{1,t}\\ \delta''_{2,t}\\ \delta''_{3,t}\end{bmatrix} + \begin{bmatrix}u_{1,t}\\ u_{2,t}\\ u_{3,t}\end{bmatrix}\\ &\begin{bmatrix}\delta''_{1,t}\\ \delta''_{2,t}\\ \delta''_{3,t}\end{bmatrix} \overset{iid}{\sim} N_3\left(\begin{bmatrix}0.6\delta''_{1,t-1}+0.4*0.02\\ \delta''_{2,t-1}\\ 0.3\delta''_{3,t-1}+0.7*0.01\end{bmatrix}, \begin{bmatrix}0.08^2 & 0 & 0\\ 0 & 0.16^2 & 0\\ 0 & 0 & 0.12^2\end{bmatrix}\right)\\ &\begin{bmatrix}u_{1,t}\\ u_{2,t}\\ u_{3,t}\end{bmatrix} \overset{iid}{\sim} N_3\left(\begin{bmatrix}0\\ 0\\ 0\end{bmatrix}, \begin{bmatrix}0.5^2 & 0 & 0\\ 0 & 1 & 0\\ 0 & 0 & 0.7^2\end{bmatrix}\right).\end{aligned} \tag{38}$$

$$\begin{aligned}&Model\ 6: \ \tilde{y}_t = \tilde{\mu}'''_t + B^T\tilde{x}_t + \tilde{\epsilon}_t \qquad \tilde{\epsilon}_t \overset{iid}{\sim} N_4(0, \Sigma_\epsilon)\\ &B = \begin{bmatrix}2 & -1 & -0.5 & 0\\ -1.5 & 4 & 0 & 2.5\\ 3 & 0 & 3.5 & -2\\ 0 & 1 & 1.5 & -0.5\end{bmatrix}^T \qquad \Sigma_\epsilon = \begin{bmatrix}1.1 & 0.7 & 0.7 & 0.7\\ 0.7 & 0.9 & 0.7 & 0.7\\ 0.7 & 0.7 & 1.0 & 0.7\\ 0.7 & 0.7 & 0.7 & 1.2\end{bmatrix}\\ &\tilde{\mu}'''_{t+1} = \begin{bmatrix}\mu'''_{1,t+1}\\ \mu'''_{2,t+1}\\ \mu'''_{3,t+1}\\ \mu'''_{4,t+1}\end{bmatrix} = \begin{bmatrix}\mu'''_{1,t}\\ \mu'''_{2,t}\\ \mu'''_{3,t}\\ \mu'''_{4,t}\end{bmatrix} + \begin{bmatrix}\delta'''_{1,t}\\ \delta'''_{2,t}\\ \delta'''_{3,t}\\ \delta'''_{4,t}\end{bmatrix} + \begin{bmatrix}u_{1,t}\\ u_{2,t}\\ u_{3,t}\\ u_{4,t}\end{bmatrix}\\ &\begin{bmatrix}\delta'''_{1,t}\\ \delta'''_{2,t}\\ \delta'''_{3,t}\\ \delta'''_{4,t}\end{bmatrix} \overset{iid}{\sim} N_4\left(\begin{bmatrix}0.6\delta'''_{1,t-1}+0.4*0.02\\ \delta'''_{2,t-1}\\ 0.3\delta'''_{3,t-1}+0.7*0.01\\ 0.5\delta'''_{4,t-1}\end{bmatrix}, \begin{bmatrix}0.08^2 & 0 & 0 & 0\\ 0 & 0.16^2 & 0 & 0\\ 0 & 0 & 0.12^2 & 0\\ 0 & 0 & 0 & 0.10^2\end{bmatrix}\right)\\ &\begin{bmatrix}u_{1,t}\\ u_{2,t}\\ u_{3,t}\\ u_{4,t}\end{bmatrix} \overset{iid}{\sim} N_4\left(\begin{bmatrix}0\\ 0\\ 0\\ 0\end{bmatrix}, \begin{bmatrix}0.5^2 & 0 & 0 & 0\\ 0 & 1 & 0 & 0\\ 0 & 0 & 0.7^2 & 0\\ 0 & 0 & 0 & 0.6^2\end{bmatrix}\right).\end{aligned} \tag{39}$$

Model 7 was used to generate data to examine the accuracy in Bayesian point and interval estimations and covariates inclusion probabilities. The model is described as follows:

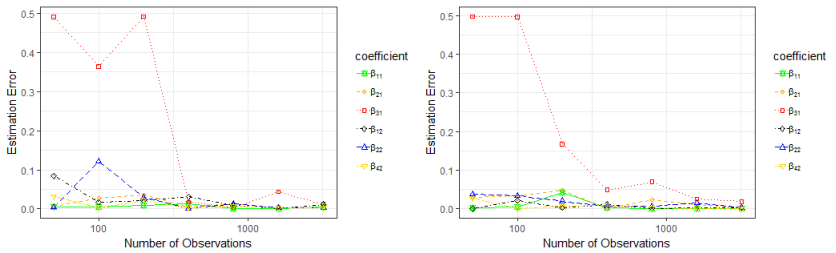
$$\begin{aligned}&Model\ 7: \ \tilde{y}_t = \tilde{\mu}'_t + \tilde{\tau}_t + \tilde{\omega}_t + diag(B^T\tilde{x}_t) + \tilde{\epsilon}_t \qquad \tilde{\epsilon}_t \overset{iid}{\sim} N_2(0, \Sigma_\epsilon)\\ &B = \begin{bmatrix}2 & -1 & -0.5 & 0 & 1.5 & -2 & 0 & 3.5\\ -1.5 & 4 & 0 & 2.5 & -1 & 0 & -3 & 0.5\end{bmatrix}^T\\ &\tilde{x}_t = \begin{bmatrix}x_{t1} & x_{t2} & x_{t3} & x_{t4} & x_{t5} & x_{t6} & x_{t7} & x^{\star}_{t8}\\ x_{t1} & x^{\star}_{t2} & x_{t3} & x_{t4} & x_{t5} & x_{t6} & x_{t7} & x_{t8}\end{bmatrix}^T\\ &x_{t5} \overset{iid}{\sim} N(-5, 5^2) \quad x_{t6} \overset{iid}{\sim} Pois(15) \quad x_{t7} \overset{iid}{\sim} Pois(20) \quad x_{t8} \overset{iid}{\sim} N(0, 10^2),\end{aligned} \tag{40}$$

where $x^{\star}_2$, $x^{\star}_5$ and $x^{\star}_8$ are variables whose values were obtained by rearranging a partial portion of data values for x_2, x_5 and x_8, and the $diag()$ operator extracts diagonal entries in the matrix to form a column vector. In Model 7, the first target series was generated by (x_1, x_2, x_3, x_4, x_5, x_6, x_7, $x^{\star}_8$) and the second target series was generated by (x_1, $x^{\star}_2$, x_3, x_4, x_5, x_6, x_7, x_8). Therefore, when explanatory variables (x_1, $x^{\star}_2$, x_3, x_4, $x^{\star}_5$, x_6, x_7, $x^{\star}_8$) are used for model training, regression coefficients of $x^{\star}_2$ (resp. $x^{\star}_5$) for the first target series generation are expected not to reflect the true linear relationship between $y^{(1)}$ and x_2 (resp. x_5). Similarly, regression coefficients of $x^{\star}_5$ (resp. $x^{\star}_8$) for the second target series generation are expected not to reflect the true linear relationship between $y^{(2)}$ and x_5 (resp. x_8). In sum, each distinct target series has a unique pattern generated by a particular set of explanatory variables and state components (the first target series affected by seasonality, not cyclical effect; the second target series affected by cyclical effect, not seasonality). Then we apply the MBSTS model on generated data sets to study its different properties.

3.2 Estimation and Model Selection Accuracy

From three perspectives, we explored properties of our model. More specifically, they include how the number of observations affects Bayesian estimation accuracy, how likely the 90% credible interval contains the true values of coefficients, and how possible the model selects the most important explanatory variables and ignores variables that do not contribute as desired, with results given in Figures 2, 3 and 4, respectively.

With the advent of the "big data" era, a huge amount of time series data are available to be analyzed from various sources. In the first analysis, we want to check whether a larger sample size improves the model performance in terms of Bayesian point estimation accuracy. After model training, we drew 2000 samples for each coefficient to be estimated during MCMC iterations. To reduce the influence of initial values on posterior inferences, we discarded an initial portion of the Markov chain samples. Specifically based on trial and error, the first 200 drawn samples were removed and the rest of them were used to build a sample posterior distribution for each parameter.

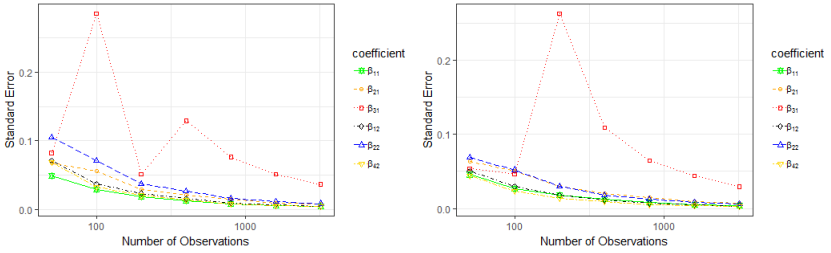


(a) Model 1 (b) Model 2

(c) Model 3 (d) Model 4

Figure 2: Estimation error for regression coefficients with different sample size. (a), (b), (c) and (d) display results using generated data sets by four different models in equation (32).

Based on the theory of Bayesian estimation, the sample mean from posterior distribution is considered to be the best point estimator for unknown parameters in terms of the mean squared error. We firstly consider the estimation error defined as the absolute value of difference between the true value and its Bayesian point estimate. The plots in Figure 2 illustrate how estimation errors of coefficients change as the sample size increases. The first target series was generated not using covariate x_4, while the second target series was generated not using covariate x_3, as shown in equation (33). Those zero coefficients are not displayed in these line plots. Figure 2 shows that only the estimation error for coefficient β_{31} goes down dramatically when sample size expands in these four cases. The remaining estimation errors stay almost the same regardless of different sample sizes, which implies that the number of observations significantly affect only the point estimation accuracy of coefficients for binary variables, not for numerical or ordinal variables. Even if only a small amount of data is available, our approach still performs well when binary or factor variables are not involved in the analysis.

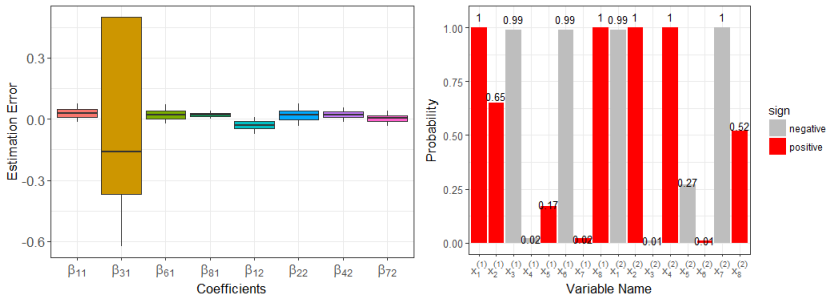


(a) Model 1 (b) Model 2

(c) Model 3 (d) Model 4

Figure 3: Standard error for regression coefficients with different sample size. Here, standard error is the empirical standard deviation of draws from equation (22). (a), (b), (c) and (d) display results using generated data sets by four different models in equation (32).

The sample standard error, defined as the posterior standard deviation of the regression coefficient, is used to illustrate the spread of the Bayesian estimator. To further explore other properties of the posterior distribution of draws, the standard errors were checked for each coefficient with different sample sizes. Figure 3 shows that all standard errors for covariates' coefficients except β_{31} gradually decline with a larger amount of data. The standard error for coefficients β_{31} peaks when the number of observations is 100 for Model 1 or 200 for models 2, 3 and 4, and then begin to drop very sharply. In general, a larger sample size helps shrink the standard errors of all coefficients, especially for binary or factor covariates' coefficients, as one would expect. In other words, collecting more data allows us to shrink the dispersion of the posterior empirical distribution from Monte Carlo draws, and hence build a narrower credible interval.



(a) Boxplot with 90% Credible Interval (b) Inclusion Probability

Figure 4: Empirical posterior distribution of estimated coefficients and indicators. (a) Box plots of the difference between draws from equation (22) and true values of regression coefficients. The top and bottom correspond to the 95% upper bound and 5% low bound, respectively. (b) Bar plot of empirical inclusion probability illustrates the proportion of Monte Carlo draws with $\gamma_{ij} = 1$. The red color shows positive estimated values of regression coefficients, while gray color displays negative values.

In the second analysis, we assess the coverage properties of the posterior credible intervals based on the empirical posterior distribution of each covariate's coefficients. In other words, the 90% credible interval contains the ground truth in 90% of the simulations. In Model 7 equation (40), $x_8^\star$ instead of x_8 was used to generate the first target series $y^{(1)}$, and $x_2^\star$ instead of x_2 was used to generate the second target series $y^{(2)}$. Therefore, when the explanatory variables (x_1, $x_2^\star$, x_3, x_4, $x_5^\star$, x_6, x_7, $x_8^\star$) are used for model training, the resulting coefficients β_{21} and β_{51} for $y^{(1)}$ as well as β_{52} and β_{82} for $y^{(2)}$, cannot reveal a true linear relationship. The box plot in Figure 4 displays the empirical posterior distribution of estimated coefficients for significant explanatory variables whose values were not randomly shuffled, and indicates that the true values of all coefficients are within 90% credible intervals. In addition, we can see that the 90% credible interval of binary covariates' coefficients is much wider than others, due to their larger standard errors.

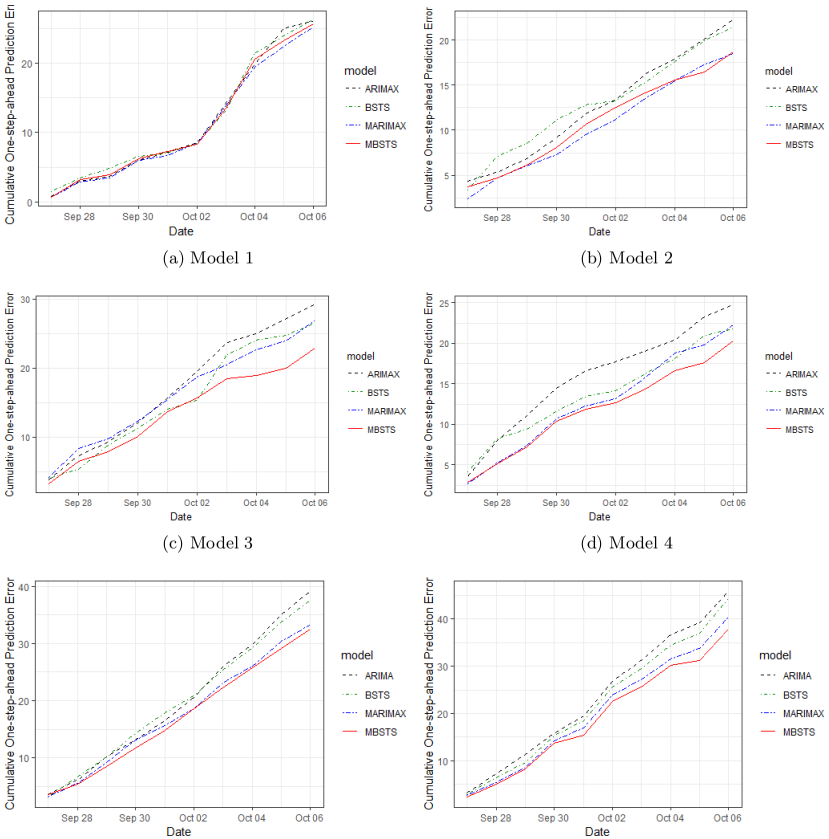
In the third analysis, one important property of our model is to reduce data dimension by variable selection in model training. In Figure 4, the bar plot of empirical inclusion probabilities based on the proportion of MCMC draws shows a clear picture of which variables are used to generate data and which are the ones with shuffled values. For the first target series $y^{(1)}$, the empirical inclusion probabilities of covariates x_1, x_3, x_6 and x_8 as one or close to one indicate that they were all, or almost all, selected during MCMC iterations, which is exactly how the data set was generated; the covariates x_4 and x_7 with zero coefficients indicate that they are rarely selected during MCMC iterations. Some covariates with partially shuffled values, such as x_2 and x_5, are more likely be selected than those with no effect on this target series, but they are not so important as x_1, x_3, x_6 and x_8. Similar striking results were achieved for the second target series. Moreover, we can see that as expected, the inclusion probability of $x_5^\star$ is just 0.17 (resp. 0.27) for the first (resp. second) target series. In a word, our MBSTS model is good at variables selection, even if the variation of each target series is explained by a different set of explanatory variables.

It is worth emphasizing that our model performs very well in terms of estimation accuracy and variables selection ability, even if each target series has a different set of latent states and explanatory variables from others. However, all preceding results depend on the assumption that the model structure remains intact throughout the modeling period. In other words, even though the model is built on the idea of multiple non-stationary components such as a time-varying local trend, seasonal effect, and potentially dynamic regression coefficients, the structure itself remains unchanged. If the model structure does change over time (e.g. local trend disappears or the static regression coefficients become dynamic), the estimation accuracy may suffer. Therefore, a preliminary data exploration and acquiring a background knowledge about the data set before applying our model is suggested, although it has the strength in allowing users to adjust the model components flexibly for each target series.

3.3 Model Performance Comparison

The generated data sets were split into a certain period of training data and a subsequent period of testing set. The standard approach would use the training data to develop the model that would then be applied to obtain predictions for the testing period. We use a growing window approach, which simply adds one new observation in the test set to the existing training set, obtaining a new model with fresher data and then constantly forecasting a new value in the test set.

To evaluate the performance of the MBSTS model, we use three other models: autoregressive integrated moving average model with regression (ARIMAX), multivariate ARIMAX (MARIMAX), and the BSTS model, as benchmark models. We replace ARIMAX and MARIMAX with seasonal ARIMAX (SARIMAX) and multivariate seasonal ARIMAX (MSARIMAX), when seasonality exists. In this study, applying the growing window approach, all models were trained by the training set and then were used to make a one-step-ahead prediction. More specifically, the univariate BSTS and ARIMAX were trained for each target time series individually, but MBSTS and MARIMAX were applied on the mul-



(a) Model 1 (b) Model 2

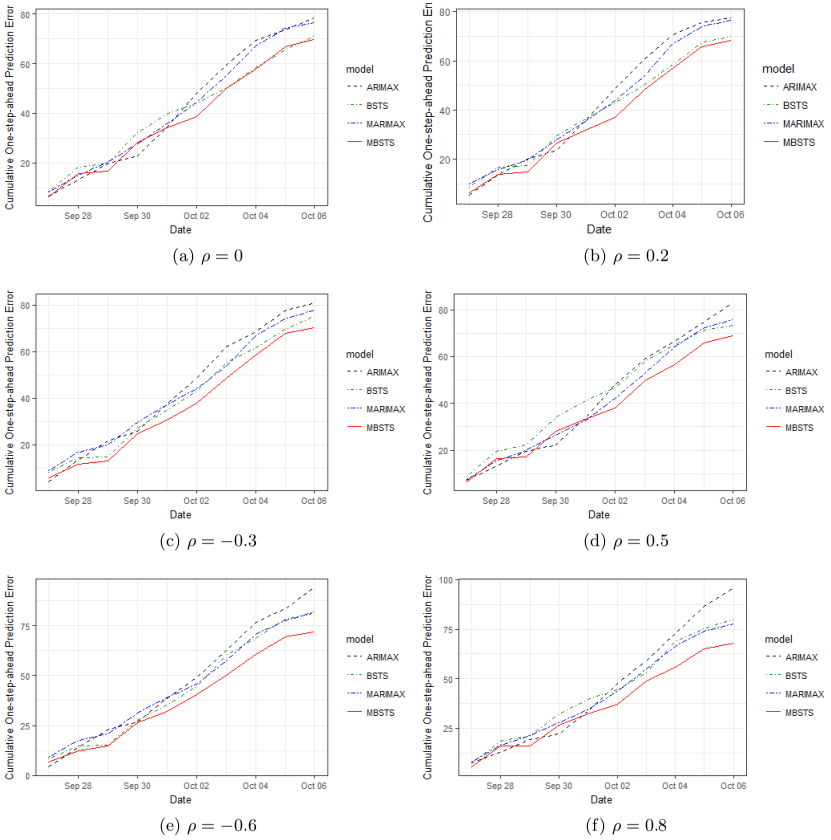
(c) Model 3 (d) Model 4

(e) Model 5 (f) Model 6

Figure 5: Cumulative absolute one-step-ahead prediction error for generated multiple target series containing different components. (a)-(f) display results using generated data sets by six different models in equations (32), (38) and (39). Three other benchmark models (BSTS, ARIMAX and MARIMAX) are also trained and used to make a prediction.

tidimensional series data set as a whole. Then we compared the performances of the other three models with that of MBSTS in terms of cumulative one-step ahead prediction errors. The prediction error at each step PE_t is defined by summing up the absolute values of the

differences between the true values and their own predicted values over all target time series, i.e. $\sum_{i=1}^{m} |y_t^{(i)} - \hat{y}_t^{(i)}|$. Figure 5 and Figure 6 are generated to demonstrate our model's comparison performance under the influence of complexity in different kinds and numbers of multiple target time series, and under various correlations ($\rho = 0, 0.2, -0.3, 0.5, -0.6, 0.8$), respectively.



(a) $\rho = 0$ (b) $\rho = 0.2$

(c) $\rho = -0.3$ (d) $\rho = 0.5$

(e) $\rho = -0.6$ (f) $\rho = 0.8$

Figure 6: Cumulative absolute one-step-ahead prediction error for generated multiple target series with different correlations. (a)-(f) display results using generated data sets by equation (40) with various correlation coefficients in Σ_t. Other three benchmark models (BSTS, ARIMAX and MARIMAX) are also trained and used to make a prediction.

Figure 5 shows cumulative one-step-ahead prediction errors of six time series models, which were trained using a set of data sets with each containing one thousand observations generated by equations (32), (38) and (39). We can see that the MBSTS model does not show an obvious advantage in the first two plots, since the generated target time series have only a local trend or a linear trend. However, the MBSTS model beats other benchmark models in plot 3 and plot 4, where the target series contain seasonality or cycle components. Clearly, the BSTS or MBSTS model has a strong ability to capture seasonality and cycle embodied in the series. The performance evaluations in plot 5 (three target time series) and plot 6 (four target time series) demonstrate the forecast advantage of our MBSTS model over other benchmark models, even with an increased number of target series. In general, the multivariate models outperform their corresponding univariate ones due to the influence of correlations among multiple target time series. Moreover, BSTS is better than ARIMAX, and MBSTS outperforms all other models, thanks to the Bayesian model averaging and time series structure of target series.

Figure 6 provides a clear picture of an impressive fact: the higher correlation among multiple target time series, the better performance of the MBSTS model over other models. Generally, the MBSTS model outperforms the traditional ARIMAX or MARIMAX model for the reason that averaging algorithm helps hedge against selecting the "wrong" set of predictors in prediction steps. The gaps of cumulative prediction errors between models in a multivariate version and their univariate counterparts increase as multiple target time series have stronger correlations. Therefore, it is better to model multiple target time series as a whole by MBSTS rather than model them individually by BSTS, especially when strong correlations appear in the multiple target time series, as illustrated in Figure 6

4. Application to Empirical Data

Predicting stock prices (for example, of a group of leading companies) is extremely important to Wall Street practitioners for investment and/or risk management purposes. In the following, we forecast the future values of stock portfolio return using the proposed MBSTS model and compare its performance with three other benchmark models: BSTS, ARIMAX and MARIMAX. In this section, we analyze the data of Bank of America (BOA), Capital One Financial Corporation (COF), J.P. Morgan (JPM) and Wells Fargo (WFC). The daily data sample is from 11/27/2006 to 11/03/2017 and obtained from Google Finance.

4.1 Target Time Series

We perceive the stock as worthwhile in terms of trading when its future price is predicted to vary more than $p\%$ of its current price. In this context, we forecast the trend of stock movements in the next $k(=5)$ transaction days, which is especially helpful when liquidation risk is in consideration given a sign of sale, and useful to avoid a large amount purchase driving up the stock prices given a sign of buying. In this study, we provide daily predictions sequentially of the overall price dynamics in the next k transaction days.

Following Torgo (2011), we approximate the daily average price as: $\bar{P}_t = (C_t+H_t+L_t)/3$, where C_t, H_t and L_t are the close, high and low quotes for day t respectively. However, instead of using the arithmetic returns, we are interested in the log return V_t defined as $V_t = \{\log(\bar{P}_{t+j}/C_t)\}_{j=1}^{k}$. We consider the indicator variable $y_t = \max\{v \in V_t\}$, the maximum

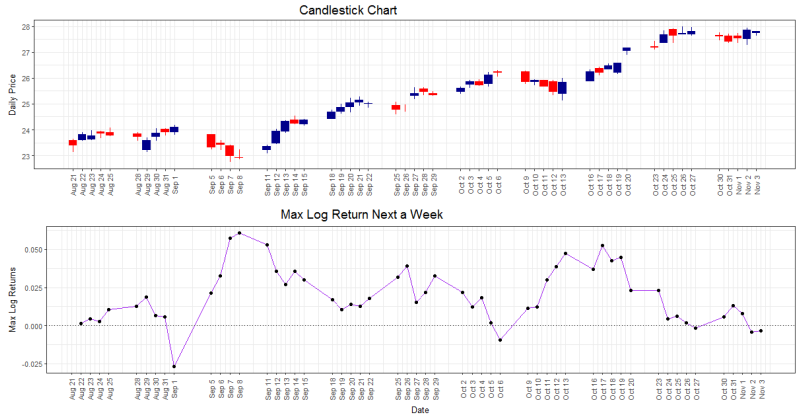


Figure 7: The candlestick chart and max log return. The top panel displays a candlestick chart of BOA from Aug 21st to Nov 3rd, containing information such as open and closing quotes. The bottom panel shows corresponding max log returns over the next five transaction days, which is the target time series.

value of log returns over the next k transaction days. A high positive value of y_t means that there is at least one future daily price that is much higher than today's close quote, indicating potential opportunities to issue a buy order, as we predict the prices will rise. A trivial value of y_t around zero can be seen as the sign of no action that should be taken at this moment. In this study, we calculated y_t for four leading companies in the financial industry (BOA, COF, JPM and WFC), whose stock prices are affected by economic activities. Visualization of a part of the daily prices time series and their corresponding y_t indicators for BOA can be seen in Figure 7.

4.2 Predictors

To better capture market information and different properties of the stock price time series and to facilitate the forecasting task, we use the following fundamental and technical predictors.

Fundamental Part Fundamental analysis claims that markets may incorrectly price a security in the short run but will eventually correct it. Profits can be achieved by purchasing the undervalued security and then waiting for the market to recognize its "mistake" and bounce back to the fundamental value. Since macroeconomy has a significant effect on the financial market, economical analysis plays an important role in fundamental analysis in giving a precise stock return prediction.

For economic analysis, we know that it is difficult to collect important economic indicators on a daily basis. However, starting from the year 2004, Google has been collecting the daily volume of searches related to various aspects of macroeconomics. This database is publicly available as "Google Domestic Trends". In a recent study, Preis et al. (2013) showed correlations between Google domestic trends and the equity market. In this study, we use the Google domestic trends data as a representation of the public interest in various macroeconomic factors, and include 27 domestic trends which are listed in Table 1 with their abbreviations.

Trend	Abbr.	Trend	Abbr.
Advertising & marketing	advert	Air travel	airtvl
Auto buyers	auto	Auto financing	autoby
Automotive	autofi	Business & industrial	bizind
Bankruptcy	bnkrpt	Commercial Lending	comlnd
Computers & electronics	comput	Construction	constr
Credit cards	crcard	Durable goods	durble
Education	educat	Finance & investing	invest
Financial planning	finpln	Furniture	furntr
Insurance	insur	Jobs	jobs
Luxury goods	luxury	Mobile & wireless	mobile
Mortgage	mtge	Real estate	rlest
Rental	rental	Shopping	shop
Small business	smallbiz	Travel	travel
Unemployment	unempl		

Table 1: Google domestic trends

Technical Part Technical analysis claims that useful information is already reflected in stock prices. We selected a representative set of technical indicators to capture the volatility, close location value, potential reversal, momentum and trend of each stock. Eight variables are calculated for each company as listed in Table 2:

Variable	Abbr.
Chaikin volatility	ChaVol
Yang and Zhang Volatility historical estimator	Vol
Arms' Ease of Movement Value	EMV
Moving Average Convergence/Divergence	MACD
Money Flow Index	MFI
Aroon Indicator	AROON
Parabolic Stop-and-Reverse	SAR
Close Location Value	CLV

Table 2: Stock Technical Predictors

- The ChaVol indicator depicts volatility by calculating the difference between the high and low for each period or trading bar, and measures the difference between two moving averages of a volume weighted accumulation distribution line.

- The Vol indicator has the minimum estimation error, and is independent of drift and opening gaps, which can be interpreted as a weighted average of the Rogers and Satchell estimator, the close-open volatility, and the open-close volatility.

- The EMV indicator is a momentum indicator developed by Richard W. Arms, Jr., which takes into account both volume and price changes to quantify the ease (or difficulty) of price movements.

- The MACD indicator is a trading indicator used in stock prices' technical analysis, created by Gerald Appel in the late 1970s, supposed to reveal changes in the strength, direction, momentum and duration of a trend in a stock's price.

- The MFI indicator is a ratio of positive and negative money flow over time and starts with the typical price for each period. It is an oscillator that uses both price and volume to measure buying and selling pressure, created by Gene Quong and Avrum Soudack.

- The AROON indicator is a technical indicator used to identify trends in an underlying security and the likelihood that the trends will reverse, including "Aroon up" (resp. "Aroon down") for measurement of the strength of the uptrend (resp. downtrend), and reports the time it takes for the price to reach the highest and lowest points over a given time period.

- The SAR indicator is a method proposed by J. Welles Wilder, Jr., to find potential reversals in the market price direction of traded goods such as securities.

- The CLV indicator is used to measure the closes quote relative to the day's high and low, which varies in range between -1 and $+1$.

4.3 Training Result

It is worth noting that all predictors do not show obvious trends and most of them are stationary in the sense that their unit-root null hypotheses have p-values less than 0.05 in the augmented Dickey-Fuller test (see Said and Dickey, 1984). However, some of them indicate seasonal patterns. We can remove seasonal patterns of these predictors by subtracting the estimated seasonal component computed by the STL procedure (see Cleveland et al., 1990). Then we test our MBSTS model with and without deseasonalizing the predictors.

These eight technical predictors are calculated for each financial institution and then exclusive to others. Domestic Google trends serve as common predictors available to all companies. Based on the forecast output, the model trained without deseasonal predictors performs better than the corresponding one with deseasonal predictors. Therefore, the training results shown in Figure 8 are from a model with original predictors.

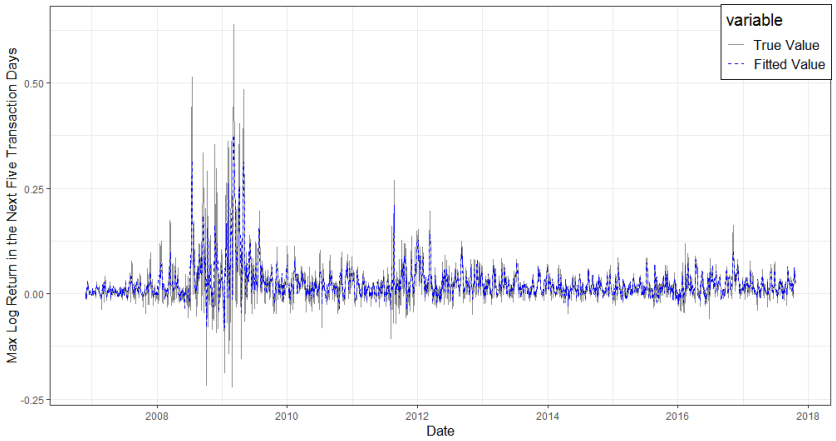

Figure 8: True and fitted values of max log returns from 11/27/2006 to 10/20/2017 (BOA)

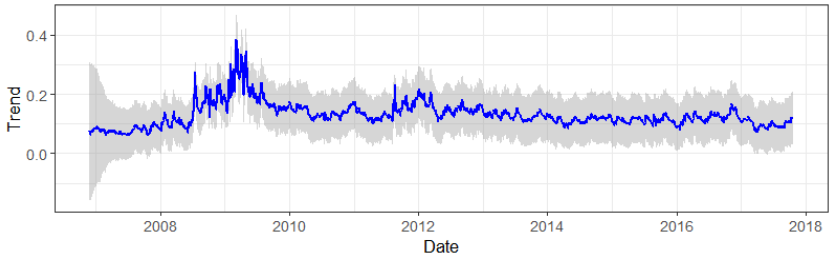
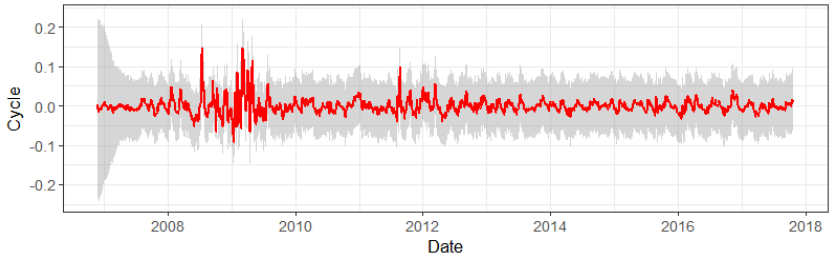
4.3.1 Decomposition of State Components

The business cycle describes the fluctuations in economic activities that an economy experiences over a period of time. It typically involves shifts over time between periods of expansions and recessions, which has a great impact on institutions in financial industry, especially investment and commercial banks. We use BOA as an example to illustrate target series and its corresponding state components. Visually checking the time series of max log returns over the next five transaction days in Figure 8, we see strong fluctuations during 2008-2009, which is right after the outbreak of the subprime mortgage crisis. There is also an obvious subsequent strong variation during 2012. Therefore, in order to capture recurrent economic shocks, it is necessary to incorporate the cyclical component in our model. In fact, applying the trend-cycle model can capture both short-term and long-term movements of the series.

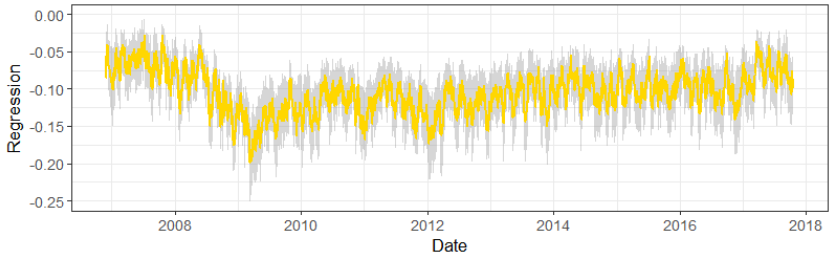
By spectral analysis, we find the corresponding period equals 274, which is almost one year of transaction days. Through cross validation, we find the optimal damping factor equals 0.95 in terms of cumulative one-step prediction errors. Figure 9 shows how much variation in the max log return time series is explained by the trend, cyclical and regression components. The trend component shows the highest peak is around 2009, and provides a general picture of how the series would evolve in the long run. The comparatively stronger variation between 2009 and 2012 is reflected in the cyclical component, which captures the economic shocks that occurred. The fluctuations gradually become stable as the effects of shocks diminish. Both trend and cyclical components handle the series with unequal variances over time. On the contrary, the regression component varies more frequently but with no obvious peaks. It accounts for local movements without the impact of external



(a) Trend Component



(b) Cyclical Component



(c) Regression Component

Figure 9: Contributions of state components to max log return (BOA). The fitted target series is decomposed into three state components: (a) trend (local level in this example) component, (b) cycle component and (c) regression component, with shaded areas indicating the 90% confidence bands based on MCMC draws.

shocks. In sum, decomposing the target time series into three components provides us enough information on how each component contributes in explaining variations.

4.3.2 Feature Selection

Thanks to the spike and slab regression, one advantage of the MBSTS model is that feature selection and model training can be done simultaneously, which prevents overfitting and avoids redundant or spurious predictors. That is, the MBSTS model is flexible in that it selects a different set of predictors for each target time series during the MCMC iterations. Moreover, we can set a different model size for each target time series by assigning appropriate values to the prior inclusion probabilities $\{\pi_{ij}\}$. The empirical posterior inclusion probability, as a useful indicator of the importance of one specific predictor, is the proportion of number of times that the predictor is selected to the total count of MCMC iterations. A higher inclusion probability indicates more variation of target time series can be explained by that predictor, whose chance of being selected depends on equation (29).

Figure 10 displays the predictors whose empirical posterior inclusion probabilities are greater than 0.2 for four companies. For the predictors with empirical inclusion probabilities equal to one, we can see that Bank of America has seven, Capital One Financial Corporation has eight, J.P. Morgan has four, and Wells Fargo has three. That is, the sets of predictors are different among these four companies; hence, the expected model size for each company also differs from each other. In general, sparsity was produced by our algorithm, and the size of the resulting model for each company is much less that of the total number of candidate predictors.

No such domestic Google trends contribute significantly to the variations of max log returns for all companies. Different sets of domestic Google trends capture the variations of max log returns of these four companies; more specifically, "mobile", "constr" and "comput" are the most important economic indicators for Bank of America, "unempl", "rental", "furntr", "finpln" and "comput" for Capital One Financial Corporation, "jobs" for J.P. Morgan and Wells Fargo. Among all the technical predictors, MFI, EMV and CLV were favored by the sampling algorithm for all companies, indicating the importance of these predictors in explaining the variations of max log returns.

4.4 Target Series Forecast

Time series forecasting is challenging, especially when it comes to multivariate target time series. One strength of our model is that it can make predictions for multiple target time series (i.e. max log returns of a stock portfolio) with a great number of contemporaneous predictors. Moreover, the Bayesian paradigm together with the spike-slab regression and MCMC algorithm can further improve prediction accuracy through model averaging technique. Similar to the performance analysis on simulated data, we compared the MBSTS model's performance using real financial market data with three other benchmark models: BSTS, ARIMAX and MARIMAX, measured by cumulative one-step-ahead prediction errors.

Each bars is colored (red or gray) according to the sign (positive or negative) of the estimated value of the corresponding regression coefficient.

4.4.1 Model Comparison

Figure 11 shows the cumulative one-step-ahead prediction errors of these four models without and with deseasonalized predictors, respectively. We can see that the MBSTS model outperforms other benchmark models with smaller cumulative prediction errors at almost every step in these two cases. We can also see that models with original predictors outperform those using deseasonalized predictors. There are two obvious reasons to explain why the MBSTS model is the best. Firstly, benefiting from the multivariate setting, it captures the inherent correlations of multiple target time series after subtracting the effects of trend, seasonality and cycle components; these enables MBSTS to outperform the univariate BSTS model that is trained by each target time series individually. Secondly, Bayesian

Other three benchmark models (BSTS, ARIMAX and MARIMAX) were also trained to make predictions.

model averaging helps avoid arbitrary selection and sticking to a fixed set of predictors, and the cyclical component can capture dramatic shocks to variations in target time series with diminishing impact, both of which enable our MBSTS model to outperform the MARIMAX model.

4.4.2 Trading Strategy

In finance, a trading strategy is a set of objective rules defining the conditions that must be met for a trade entry or exit action. Thanks to the strong prediction power, our model can provide supplemental guidelines to trading, given the current information of domestic Google trends and technical indexes. In other words, security strategists can decide when and how to trade based on the predictions from the MBSTS model.

Figure 12 shows one-step-ahead predictions by the MBSTS model for these four companies over two weeks. The shaded areas are the 40% prediction intervals generated by draws from the posterior distribution of $\hat{y}$. All true values are covered by the prediction intervals. The predicted value of max log return can be used as an indicator of whether to trade a stock or not. For example, if the lower bound of the predicted max log return is a large positive number, it is a strong signal that future prices will go substantially above the closing price of that day, thus buying this stock that day should be seriously considered. When the predicted value is positive but not large enough to cover transaction cost, it is a weak buying signal and a second thought should be given before making a decision. Selling or shorting the stock is suggested if the predicted max log return in the next five transaction days, is negative.

Black lines with dots represent the true values, while red line with dots indicate predicted values. The gray shaded areas are 40% prediction bands.

5. Conclusion

In this paper, we have proposed a Multivariate Bayesian Structural Time Series (MBSTS) model for dealing with multiple target time series (e.g. max log returns of a stock portfolio), which helps in feature selection and forecasting in the presence of related external information. We evaluated the forecast performance of our model using both simulated and empirical data, and found that the MBSTS model outperforms three other benchmark models: BSTS, ARIMAX and MARIMAX. This superior performance can be attributed mainly to the following three reasons. Firstly, the MBSTS model derives its strength in forecasting from the fact that it incorporates information about other variables, rather than merely historical values of its own. Secondly, the Bayesian paradigm and the MCMC algorithm can perform variable selection at the same time as model training and thus prevent

overfitting even if some spurious predictors are added into the candidate pool. Thirdly, the MBSTS model benefits from taking correlations among multiple target time series into account, which helps boost the forecasting power. Therefore, this model, as expected, is able to provide more accurate forecasts than the univariate BSTS model and the traditional time series models such as ARIMA or MARIMA, when multiple target time series need to be modeled.

The excellent performance of the MBSTS model comes with high computation requirements in the MCMC iterations. Clearly, one would also not expect this model to show significant advantages over the univariate BSTS model, when multiple target series are independent of each other. But some preliminary exploratory analysis as well as professional insight would help to tell whether correlations in multiple target time series are strong enough in specific cases. Two open questions that are currently under investigation include: whether and how prior information such as model size and estimated coefficients can improve estimation accuracy and forecasting performance; the other is how to adjust this model to satisfy the need of analysis of non-Gaussian observations. Overall, it is fair to conclude that the MBSTS model offers practitioners a very good option to model or forecast multiple correlated target time series with a pool of available predictors.

Abstract

Advances in the field of inverse reinforcement learning (IRL) have led to sophisticated inference frameworks that relax the original modeling assumption of observing an agent behavior that reflects only a single intention. Instead of learning a global behavioral model, recent IRL methods divide the demonstration data into parts, to account for the fact that different trajectories may correspond to different intentions, e.g., because they were generated by different domain experts. In this work, we go one step further: using the intuitive concept of *subgoals*, we build upon the premise that even a single trajectory can be explained more efficiently *locally* within a certain context than globally, enabling a more compact representation of the observed behavior. Based on this assumption, we build an implicit intentional model of the agent's goals to forecast its behavior in unobserved situations. The result is an integrated Bayesian prediction framework that significantly outperforms existing IRL solutions and provides smooth policy estimates consistent with the expert's plan. Most notably, our framework naturally handles situations where the intentions of the agent change over time and classical IRL algorithms fail. In addition, due to its probabilistic nature, the model can be straightforwardly applied in active learning scenarios to guide the demonstration process of the expert.

Keywords: Learning from Demonstration, Inverse Reinforcement Learning, Bayesian Nonparametric Modeling, Subgoal Inference, Graphical Models, Gibbs Sampling

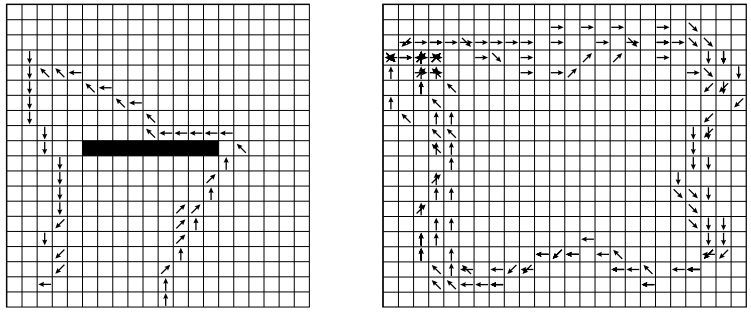
1. Introduction

Inverse reinforcement learning (IRL) refers to the problem of inferring the intention of an agent, called *the expert*, from observed behavior. Under the Markov decision process (MDP) formalism (Sutton and Barto, 1998), that intention is encoded in the form of a reward function, which provides the agent with instantaneous feedback for each situation encountered during the decision-making process. Classical IRL methods (Ng and Russell, 2000; Abbeel and Ng, 2004; Ziebart et al., 2008; Ramachandran and Amir, 2007; Levine et al., 2011) assume there exists a single *global* reward model that explains the entire set of demonstrations provided by the expert. In order to relax this rather restrictive modeling assumption, recent IRL methods allow that the agent's intention can change over time (Nguyen et al., 2015), or they presume that the demonstration data set is inherently composed of several parts (Dimitrakakis and Rothkopf, 2011), where different trajectories reflect the intentions of different domain experts.

In this work, we go a step further and start from the premise that — even in the case of a single expert or trajectory — the demonstrated behavior can be explained more efficiently *locally* (i.e., within a certain context) than by a global reward model. As an illustrative example, we may consider the task shown in Figure 1a, where the expert approaches a set of intermediate target positions before finally heading toward a global goal state. Similarly, in Figure 1b, the agent eventually returns to its initial position, from where the cyclic process repeats. Despite the simplicity of these tasks, the encoding of such behaviors in a global intention model requires a reward structure that comprises a comparably large number of redundant state-action-based rewards. Alternative modeling strategies rely on task-dependent expansions of the agent's state representation, e.g., to memorize the last visited goal (Krishnan et al., 2016), or they resort to more general decision-making frameworks like semi-MDPs/options (Bradtke and Duff, 1994; Sutton et al., 1999) in order to achieve the necessary level of task abstraction.

In this paper, we present a substantially simpler modeling framework that requires only minimal adaptations to the standard MDP formalism but comes with a hypothesis space of behavioral models that is sufficiently large to cover a broad class of expert policies. The key insight that motivates our approach is that many tasks, like those in Figure 1, can be decomposed into smaller subtasks that require considerably less modeling effort. The resulting low-level task descriptions can then be used as building blocks to synthesize arbitrarily complex behavioral strategies through a suitable sequencing of subtasks. This offers the possibility to learn comparably simple task representations using the intuitive concept of *subgoals*, which is achieved by efficiently encoding the expert behavior using task-adapted partitionings of the system state space/the expert data.

The proposed framework builds upon the method of Bayesian nonparametric inverse reinforcement learning (BNIRL, Michini and How, 2012), which can be used to build a subgoal representation of a task based on demonstration data — however, without learning the underlying subgoal relationships or providing a policy model that can generalize the strategy of the demonstrator. In order to address this limitation, we generalize the BNIRL model using insights from our previous works on nonparametric subgoal modeling (Šošić et al., 2018a) and policy recognition (Šošić et al., 2018b), building a compact intentional model of the expert's behavior that explicitly describes the local dependencies between the



(a) sequenced target positions (Michini and How, 2012)

(b) cyclic behavior

Figure 1: Two simple behavior examples that motivate the subgoal principle. The setting is based on the grid world dynamics described in Section 5.1. In both cases, a task description based on a global reward function is inefficient as it requires many state-action-based rewards to explain the observed trajectory structures. However, the data can be described efficiently through subgoal-based encodings. Both scenarios are analyzed in detail in Section 5.

demonstrations and the underlying subgoal structure. The result is an integrated Bayesian prediction framework that exploits the spatio-temporal context of the demonstrations and is capable of producing smooth policy estimates that are consistent with the expert's plan. Furthermore, capturing the full posterior information of the data set enables us to apply the proposed approach in an active learning setting, where the data acquisition process is controlled by the posterior predictive distribution of our model.

In our experimental study, we compare the proposed approach with common baseline methods on a variety of benchmark tasks and real-world scenarios. The results reveal that our approach performs significantly better than the original BNIRL model and alternative IRL solutions on all considered tasks. Interestingly enough, our algorithm outperforms the baselines even when the expert's true reward structure is dense and the underlying subgoal assumption is violated.

1.1 Related Work

The idea of decomposing complex behavior into smaller parts has been around for long and researchers have approached the problem in many different ways. While the overall field of methods is too large to be covered here, most existing approaches can be clearly categorized according to certain criteria. Often, two approaches differ in their exact problem formulation, i.e., we can distinguish between *active* methods, where the learning algorithm can interact freely with the environment (e.g., hierarchical reinforcement learning, Botvinick, 2012; Al-Emran, 2015), and *passive* methods, where the behavioral model is trained solely through observation (learning from demonstration, Argall et al., 2009). Furthermore, we

can discriminate between methods that build an explicit intentional model of the underlying task (IRL and option-based models, Choi and Kim, 2012; Sutton et al., 1999), and such that work directly on the control/trajectory level (skill learning, movement primitives, Konidaris et al., 2012; Schaal et al., 2005). The latter distinction is sometimes also referred to as *intentional/subintentional* approaches (Albrecht and Stone, 2017; Panella and Gmytrasiewicz, 2017). In order to give a concise summary of the work that is most relevant to ours, we restrict ourselves to passive approaches, with a focus on intentional methods, the field of which is considerably smaller. For an overview of active approaches, we refer to existing literature, e.g., the work by Daniel et al. (2016a).

First, there is the class of methods that pursue a decomposition of the observed behavior on the global level, using trajectory-based IRL approaches. For example, Dimitrakakis and Rothkopf (2011) proposed a hierarchical prior over reward functions to account for the fact that different trajectories in a data set could reflect different behavioral intentions, e.g., because they were generated by different domain experts. Similarly, Babeş-Vroman et al. (2011) follow an expectation-maximization-based clustering approach to group individual trajectories according to their underlying reward functions. Choi and Kim (2012) generalized this idea by proposing a nonparametric Bayesian model in which the number of intentions is a priori unbounded.

While the above methods consider the expert data at a global scale, our work is concerned with the problem of *subgoal modeling*, which is often conducted in the form of option-based reasoning (Sutton et al., 1999). For instance, Tamassia et al. (2015) proposed a clustering approach based on state distances to find a minimal set of options that can explain the expert behavior. While the method provides a simple alternative to handcrafting options, it does not allow any probabilistic treatment of the data and involves many ad-hoc design choices. Going in the same direction, Daniel et al. (2016a) presented a more principled, probabilistic option framework based on expectation-maximization. Not only is the framework capable of inferring sub-policies automatically, it can be also used in a reinforcement learning context for intra-option learning. However, the resulting behavioral model is based on point estimates of the policy parameters, and the number of sub-policies needs to be specified manually. The latter problem was solved by Krishnan et al. (2016), who proposed a hierarchical nonparametric IRL framework to learn a sequential representation of the demonstrated task, based on a set of transition regions that are defined through local changes in linearity of the observed behavior. However, in contrast to the work by Daniel et al. (2016a), inference is not performed jointly but in several isolated stages where, again, each stage only propagates a point estimate of the associated model parameters. Moreover, the temporal relationship of the demonstration data, used to identify the local linearity changes, is considered only in an ad-hoc fashion with the help of a windowing function.

Another general class of models, which explicitly addresses this issue, employs a hidden Markov model (HMM) structure to establish a temporal relationship between the demonstrations. For instance, the work presented by Nguyen et al. (2015) can be regarded as a generalization of the model by Babeş-Vroman et al. (2011), which extends the expectation-maximization framework by imposing a Markov structure on the reward model. Similarly, Niekum et al. (2012) use an extended HMM to segment the demonstrations into vector autoregressive models, in order to learn a suitable set of movement primitives. However, the learning of those primitives is done in a post-processing step, meaning that the quality of

the final representation crucially depends on the success of the initial segmentation stage. In contrast, the method by Rueckert et al. (2013) automatically learns the position and timing of subgoals in the form of via-points, but the number of via-points is assumed to be known and the system objective gets finally encoded in form of a global cost function. Recently, Lioutikov et al. (2017) presented a related approach based on probabilistic movement primitives that jointly solves the segmentation and learning step for an unknown number of primitives, using an expectation-maximization framework. Yet, the model operates purely on the trajectory level and cannot reveal the latent intentions of the demonstrator. Another variant of the approach by Niekum et al. (2012) that explicitly addresses this problem was proposed by Surana and Srivastava (2014). In their paper, the authors propose to replace the HMM emission model with an MDP model, in order to infer a policy model from the segmented trajectories instead of recognizing changes in the dynamics. The model was later extended by Ranchod et al. (2015), who augmented the HMM representation with a beta process model to facilitate skill sharing across trajectories. While the resulting model formulation is highly flexible, its major drawback is that inference becomes computationally expensive as it involves multiple IRL iterations per Gibbs step.

In contrast to the HMM-based solutions, which by their sequential nature focus on the *temporal* relationship of subtasks, the approach presented in this paper establishes a more general correlation structure between demonstrations by employing *non-exchangeable prior distributions* over subgoal assignments, i.e., without committing to purely temporal factorizations of subgoals. This results in a compact model representation (e.g., it avoids the need of estimating latent subgoal transition probabilities required in an HMM structure) and adds the flexibility to capture both, the temporal and the spatial dependencies between subtasks.

1.2 Paper Outline

The organization of the paper is as follows: in Section 2, we briefly revisit the BNIRL model and discuss its limitations, which forms the basis for our work. Section 3 then introduces a new intentional subgoal framework, which addresses the shortcomings of BNIRL discussed in Section 2. In Section 4, we derive a sampling-based inference scheme for our model and explain how the new framework can be used for subgoal extraction and action prediction. Experimental results on both synthetic and real-world data are presented in Section 5 before we finally conclude our work in Section 6.

2. Bayesian Nonparametric Inverse Reinforcement Learning

The purpose of this section is to recapitulate the principle of Bayesian nonparametric inverse reinforcement learning. After briefly discussing all building blocks of the model, we focus on the limitations of the framework, which motivates the need for an extended model formulation and finally leads to a new inference approach, presented afterwards in Section 3.

2.1 Revisiting the BNIRL Framework

Following the common IRL paradigm (Ng and Russell, 2000; Zhifei and Joo, 2012), the goal of BNIRL is to infer the intentions of an agent based on demonstration data. Starting from a standard MDP model, the problem is formalized on a finite state space $\mathcal{S}$, assuming a

time-invariant state transition model $T : \mathcal{S} \times \mathcal{S} \times \mathcal{A} \to [0, 1]$, where $\mathcal{A}$ is a finite set of actions available to the agent at each state. For notational convenience, we represent the states in $\mathcal{S}$ by the integer values $\{1, \dots, |\mathcal{S}|\}$, where $|\mathcal{S}|$ denotes the cardinality of the state space.

In BNIRL, it is assumed that we can observe a number of expert demonstrations provided in the form of state-action pairs, $\mathcal{D} \coloneqq \{(s_d, a_d)\}_{d=1}^{D}$, where each pair $(s_d, a_d) \in \mathcal{S} \times \mathcal{A}$ consists of a state s_d visited by the agent and the corresponding action a_d taken. Herein, D denotes the size of the demonstration set. Throughout the rest of this paper, we will use the shorthand notations $\mathbf{s} \coloneqq \{s_d\}_{d=1}^{D}$ and $\mathbf{a} \coloneqq \{a_d\}_{d=1}^{D}$ to access the collections of expert states and actions individually. Note that the BNIRL model makes no assumptions about the temporal ordering of the demonstrations, i.e., each state-action pair is considered to have arisen from a specific but arbitrary time instant of the agent's decision-making process. We will come back to this point later in Sections 2.2 and 3.3.

In contrast to the classical MDP formalism and most other IRL frameworks, BNIRL does *not* presuppose that the observed expert behavior necessarily originates from a single underlying reward function. Instead, it introduces the concept of *subgoals* (and corresponding *subgoal assignments*) with the underlying assumption that, at each decision instant, the expert selects a particular subgoal to plan the next action. Each subgoal is herein represented by a certain reward function defined on the system state space; in the simplest case, it corresponds to a single reward mass placed at a particular goal state in $\mathcal{S}$, which we identify with a reward function $R_g : \mathcal{S} \to \{0, C\}$ of the form

$$R_g(s) \coloneqq \begin{cases} C & \text{if } g = s, \\ 0 & \text{otherwise,} \end{cases} \tag{1}$$

where $g \in \{1, \dots, |\mathcal{S}|\}$ indicates the subgoal location and $C \in (0, \infty)$ is some positive constant (compare Şimşek et al., 2005; Stolle and Precup, 2002; Tamassia et al., 2015).

Although in principle it is legitimate to associate each subgoal with an arbitrary reward structure to encode more complex forms of goal-oriented behavior (see, for example, Ranchod et al., 2015), the restriction to the reward function class in Equation (1) is sufficient in the sense that the same behavioral complexity can be synthesized through a combination of subgoals. This is made possible by the nonparametric nature of BNIRL, i.e., because the number of possible subgoals is assumed to be unbounded. The use of the reward model in Equation (1) has the advantage, however, that posterior inference about the expert's subgoals becomes computationally tractable, as will be explained in Section 4.5. In the following, we therefore focus on the above reward model and summarize the infinite collection of subgoals in the multiset $\mathcal{G} \coloneqq \{g_k\}_{k=1}^{\infty} \in \bigtimes_{k=1}^{\infty} \mathcal{S}$, where we adopt the assumption that $p(\mathcal{G} \,|\, \mathbf{s}) = \prod_{k=1}^{\infty} p_g(g_k \,|\, \mathbf{s})$.[1]

The subgoal assignment in BNIRL is achieved using a set of indicator variables $\tilde{\mathbf{z}} \coloneqq \{\tilde{z}_d \in \mathbb{N}\}_{d=1}^{D}$, which annotate each demonstration pair (s_d, a_d) with its unique subgoal index. The prior distribution $p(\tilde{\mathbf{z}})$ is modeled by a Chinese restaurant process (CRP, Aldous, 1985),

1. Notice that the subgoal prior distribution in the original BNIRL formulation does not take the state variable $\mathbf{s}$ as an argument. Nonetheless, the authors of BNIRL suggest to restrict the support of the distribution to the set of visited states, which indeed implies a conditioning on $\mathbf{s}$.

which assigns the event that indicator $\tilde{z}_d$ points to the jth subgoal the prior probability

$$p(\tilde{z}_d = j \,|\, \tilde{\mathbf{z}}_{\setminus d}) \propto \begin{cases} n_j & \text{if } j \in \{1, \dots, K\}, \\ \alpha & \text{if } j = K + 1, \end{cases}$$

where $\tilde{\mathbf{z}}_{\setminus d} \coloneqq \{\tilde{z}_d\} \setminus \tilde{z}_d$ is a shorthand notation for the collection of all indicator variables except $\tilde{z}_d$. Further, n_j denotes the number of assignments to the jth subgoal in $\tilde{\mathbf{z}}_{\setminus d}$, K represents the number of distinct entries in $\tilde{\mathbf{z}}_{\setminus d}$, and $\alpha \in [0, \infty)$ is a parameter controlling the diversity of assignments.

Having targeted a particular subgoal $g_{\tilde{z}_d}$ while being at some state s_d, the expert is assumed to choose the next action a_d according to a softmax decision rule, $\pi : \mathcal{A} \times \mathcal{S} \times \mathcal{S} \to [0, 1]$, which weighs the expected returns of all actions against one another,

$$\pi(a_d \,|\, s_d, g_{\tilde{z}_d}) \coloneqq \frac{\exp\left\{\beta Q^*(s_d, a_d \,|\, g_{\tilde{z}_d})\right\}}{\sum_{a \in \mathcal{A}} \exp\left\{\beta Q^*(s_d, a \,|\, g_{\tilde{z}_d})\right\}}. \tag{2}$$

Herein, $Q^*(s, a \,|\, g)$ denotes the state-action value (or *Q-value*, Sutton and Barto, 1998) of action a at state s under an optimal policy for the subgoal reward function R_g,

$$Q^*(s, a \,|\, g) \coloneqq \max_{\bar{\pi}} \mathbb{E}\left[\sum_{n=0}^{\infty} \gamma^n R_g(s_{t=n}) \;\middle|\; s_{t=0} = s, a_{t=0} = a, \bar{\pi}\right], \tag{3}$$

where the expectation is with respect to the stochastic state-action sequence induced by the fixed policy $\bar{\pi} : \mathcal{S} \to \mathcal{A}$, with initial action a executed at the starting state s. The explicit notation $s_{t=n}$ and $a_{t=n}$ is used to disambiguate the temporal index of the decision-making process from the demonstration index of the state-action pairs $\{(s_d, a_d)\}$.

The softmax policy π models the expert's (in-)ability to maximize the future expected return in view of the targeted subgoal, while the coefficient $\beta \in [0, \infty)$ is used to express the expert's level of confidence in the optimal action. Combined with the subgoal prior distribution p_g and the partitioning model $p(\tilde{\mathbf{z}})$, we obtain the joint distribution of all demonstrated actions $\mathbf{a}$, subgoals $\mathcal{G}$, and subgoal assignments $\tilde{\mathbf{z}}$ as

$$p(\mathbf{a}, \tilde{\mathbf{z}}, \mathcal{G} \,|\, \mathbf{s}) = p(\tilde{\mathbf{z}}) \prod_{k=1}^{\infty} p_g(g_k \,|\, \mathbf{s}) \prod_{d=1}^{D} \pi(a_d \,|\, s_d, g_{\tilde{z}_d}). \tag{4}$$

The structure of this distribution is visualized in form of a Bayesian network in Figure 2a. It is worth emphasizing that π — although referred to as the likelihood model for the state-action *pairs* in the original BNIRL paper — is really just a model for the actions *conditional on the states*. In contrast to what is stated in the original paper, the distribution in Equation (4) therefore takes the form of a *conditional* distribution (i.e., conditional on $\mathbf{s}$), which does not provide any generative model for the state variables.

Posterior inference in BNIRL refers to the (approximate) computation of the conditional distribution $p(\tilde{\mathbf{z}}, \mathcal{G} \,|\, \mathcal{D})$, which allows to identify potential subgoal locations and the corresponding subgoal assignments based on the available demonstration data. For further details, the reader is referred to the original paper (Michini and How, 2012).

2.2 Limitations of BNIRL

Subgoal-based inference is a well-motivated approach to IRL and the BNIRL framework has shown promising results in a variety of real-world scenarios. Yet, the model formulation by Michini and How (2012) comes with a number of significant conceptual limitations, which we explain in detail in the following paragraphs.

Limitation 1: Subgoal Exchangeability and Posterior Predictive Policy

The central limitation of BNIRL is that the framework is restricted to pure subgoal extraction and does *not* inherently provide a reasonable mechanism to generalize the expert behavior based on the inferred subgoals. The reason lies in the particular design of the framework, which, at its heart, treats the subgoal assignments $\tilde{\mathbf{z}}$ as *exchangeable random variables* (Aldous, 1985). By implication, the induced partitioning model $p(\tilde{\mathbf{z}})$ is agnostic about the covariate information contained in the data set and the resulting behavioral model is unable to propagate the expert knowledge to new situations.

To illustrate the problem, let us investigate the predictive action distribution that arises from the original BNIRL formulation. For simplicity and without loss of generality, we may assume that we have perfectly inferred all subgoals $\mathcal{G}$ and corresponding subgoal assignments $\tilde{\mathbf{z}}$ from the demonstration set $\mathcal{D}$. Denoting by $a^* \in \mathcal{A}$ the predicted action at some

new state $s^* \in \mathcal{S}$, the BNIRL model yields

$$\begin{aligned} p(a^* \mid s^*, \mathcal{D}, \tilde{\mathbf{z}}, \mathcal{G}) &= \sum_{\tilde{z}^* \in \mathbb{N}} p(a^*, \tilde{z}^* \mid s^*, \mathcal{D}, \tilde{\mathbf{z}}, \mathcal{G}) \\ &= \sum_{\tilde{z}^* \in \mathbb{N}} p(a^* \mid \tilde{z}^*, s^*, \mathcal{D}, \tilde{\mathbf{z}}, \mathcal{G}) p(\tilde{z}^* \mid s^*, \mathcal{D}, \tilde{\mathbf{z}}, \mathcal{G}) \\ &\overset{(\star)}{=} \sum_{\tilde{z}^* \in \mathbb{N}} p(a^* \mid \tilde{z}^*, s^*, g_{\tilde{z}^*}) p(\tilde{z}^* \mid \tilde{\mathbf{z}}), \end{aligned} \tag{5}$$

where $\tilde{z}^* \in \mathbb{N}$ is the latent subgoal index belonging to s^*. Note that $p(a^* \mid \tilde{z}^*, s^*, g_{\tilde{z}^*})$ can either represent the softmax decision rule $\pi(a^* \mid s^*, g_{\tilde{z}^*})$ from Equation (2) or an optimal (deterministic) policy for subgoal $g_{\tilde{z}^*}$, depending on whether we aspire to describe the *noisy expert behavior* at s^* or want to determine an *optimal action* according to the inferred reward model. The last equality in Equation (5), indicated by $(\star)$, follows from the conditional independence properties implied by Equation (4), which can be easily verified using d-separation (Koller and Friedman, 2009) on the graphical model in Figure 2a.

As Equation (5) reveals, the predictive model is characterized by the posterior distribution $p(\tilde{z}^* \mid s^*, \mathcal{D}, \tilde{\mathbf{z}}, \mathcal{G})$ of the latent subgoal assignment $\tilde{z}^*$ of state s^* — the intuition being that, in order to generalize the expert's plan to a new situation, we need to take into account the gathered information about what would be a likely subgoal targeted by the expert at s^*. However, in BNIRL, the distribution $p(\tilde{z}^* \mid s^*, \mathcal{D}, \tilde{\mathbf{z}}, \mathcal{G})$ is modeled *without consideration of the query state s^*, or any other observed variable*. By conditional independence (Equation 4), the distribution effectively reduces $(\star)$ to the CRP prior $p(\tilde{z}^* \mid \tilde{\mathbf{z}})$, which, due to its intrinsic exchangeability property, only considers the subgoal frequencies of the readily inferred assignments $\tilde{\mathbf{z}}$. Clearly, a subgoal assignment mechanism based solely on frequency information is of little use when it comes to predicting the expert behavior as it will inevitably ignore the structural information contained in the demonstration set and always return the same subgoal probabilities at all query states, regardless of the agent's actual situation. By contrast, a reasonable assignment mechanism should inherently take into account the context of the agent's current state s^* when deciding about the next action.

While the authors of BNIRL discuss the action selection problem in their paper and propose an assignment strategy for new states based on action marginalization, their approach does not provide a satisfactory solution to the problem because the alleged conditioning on the query state (see Equation 19 in the original paper, Michini and How, 2012) has no effect on the involved subgoal indicator variable, as shown by Equation (5) above. The only way to remedy the problem without modifying the model is to use an external post-processing scheme like the waypoint method, discussed in the next section.

Limitation 2: Spatial and Temporal Context

The waypoint method, described at full length in a follow-up paper by Michini et al. (2015), is a post-processing routine to convert the subgoals identified through BNIRL into a valid option model (Sutton et al., 1999). The obtained model reconstructs the high-level plan of the demonstrator by sequencing the inferred subgoals in a way that complies with the spatio-temporal relationships of the expert's decisions as observed during the demonstration phase. To this end, the required initiation and termination sets of the option-policies are

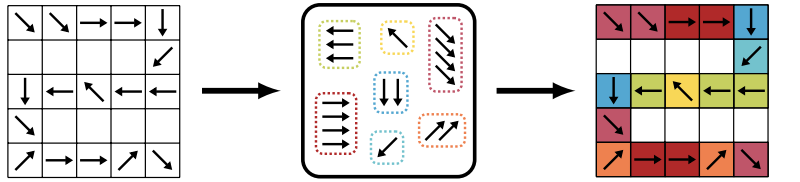

Figure 3: A diagram to illustrate the implications of the exchangeability assumption in BNIRL. Similar to a bag-of-words model (Blei et al., 2003; Yang et al., 2007), the BNIRL partitioning mechanism ignores the spatio-temporal context of the data, which makes it difficult to discriminate demonstration noise from a real change of the agent's intentions. Note that the diagram illustrates the partitioning process in a simplified way as it only shows the effect of the prior $p(\tilde{\mathbf{z}})$ but neglects the impact of the likelihood model π. While the latter *does* indeed consider the state context of the actions, it cannot account for spatial or temporal patterns in the data as it processes all state-action pairs separately.

constructed by considering the state distances to the identified subgoals as well as their temporal ordering prescribed by the expert.

When combined with BNIRL, this method allows to synthesize a behavioral model that mimics the observed expert behavior. However, the strategy comes with a number of significant drawbacks:

(i) Using the waypoint method, the spatio-temporal relationships between the individual demonstrations are explored only in a post-hoc fashion and are largely ignored during the actual inference procedure (the state information enters via the likelihood model π but is not considered by the partitioning model $p(\tilde{\mathbf{z}})$, as explained in Limitation 1). This lack of context-awareness makes the inference mechanism overly prone to demonstration noise (see Figure 3 and results in Section 5).

(ii) Measuring proximities to subgoals in order to determine the right visitation order requires some form of distance metric defined on the state space. If the system states correspond to physical locations, constructing such a metric is usually straightforward. However, in the general case where states encode arbitrary abstract information (see example in Section 5.2), it can become difficult to design that metric by hand. Unfortunately, the BNIRL framework does not provide any solution to this problem.

(iii) The waypoint method cannot be applied to multiple unaligned trajectories (e.g., obtained from different experts) or in cases where the data set does not carry any temporal information. This situation occurs, for instance, when the expert data is provided as separate state-action pairs with unknown timestamps and not given in form of coherent trajectories (see again example in Section 5.2).

(iv) Assigning a particular visitation order to the inferred subgoals is meaningful only if the expert eventually reaches those subgoals during the demonstration phase (or if, at least, the subgoals lie "close" to the visited states in terms of the aforementioned distance metric). Finding subgoals with such properties can be guaranteed by constraining the support of the subgoal prior distribution p_g to states that are near to the expert data (see footnote on page 6) but this reduces the flexibility of the model and potentially disables compact encodings of the task (Figure 4).

Limitation 3: Inconsistency under Time-Invariance

Reasoning about the intentions of an agent, there are two basic types of behavior one may encounter:

- either the agent follows a static strategy to optimize a fixed objective (as assumed in the standard MDP formalism, Sutton and Barto, 1998), or
- the intentions of the agent change over time.

The latter is clearly the more general case but also poses a more difficult inference problem in that it requires us both, to identify the intentions of the agent and to understand their temporal relationship. The static scenario, in contrast, implies that there exists an optimal policy for the task in form of a simple state-to-action mapping $\pi : \mathcal{S} \to \mathcal{A}$ (Puterman, 1994), which from the very beginning imprints a specific structure on the inference problem.

The BNIRL model generally falls into the second category since it freely allocates its subgoals per *decision instant* and not per state, allowing a flexible change of the agent's objective. Yet, it is important to understand that the model does not actually distinguish between the two described scenarios. As explained in Limitation 2, the temporal aspect of the data is not explicitly modeled by the BNIRL framework, even though the waypoint method subsequently tries to capture the overall chronological order of events. As a consequence, the model is not tailored to either of the two scenarios: on the one hand, it ignores the valuable temporal context that is needed in the time-varying case to reliably discriminate demonstration noise from a real change of the agent's intention. On the other hand, the model is agnostic about the predefined time-invariant nature of the optimal policy in the static scenario. This lack of structure not only makes the inference problem harder than necessary in both cases; it also allows the model to learn inconsistent data representations in the static case since the same state can be potentially assigned to more than one subgoal, violating the above-mentioned state-to-action rule (Figure 5).

Limitation 4: Subgoal Likelihood Model

Apart from the discussed limitations of the BNIRL partitioning model, it turns out there are two problematic issues concerning the softmax likelihood model in Equation (2). On the following pages, we demonstrate that the specific form of the model encodes a number of properties that are indeed contradictory to our intuitive understanding of subgoals. While these properties are less critical for the final prediction of the expert behavior, it turns out they drastically affect the *localization* of subgoals. Since the cause of these effects is somewhat hidden in the model equation, we defer the detailed explanation to Section 3.1.

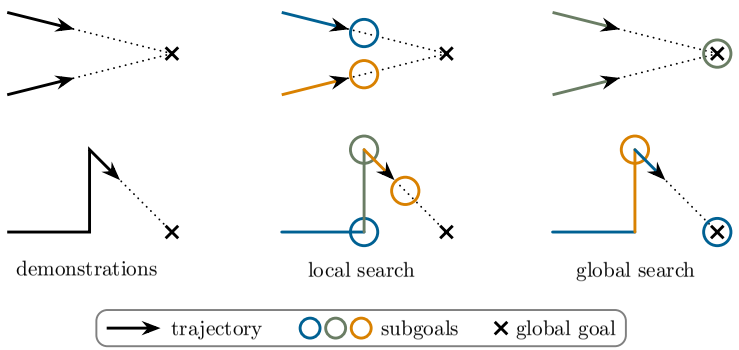

Figure 4: Difference between local (constrained) and global (unconstrained) subgoal search. The top and the bottom row depict two different sets of demonstration data (solid lines), together with potential goal/subgoal locations (crosses/circles) that explain the observed behavior. Color indicates the corresponding subgoal assignment of each trajectory segment. **Top:** two trajectories approaching the same goal. **Bottom:** the agent is heading toward a global goal, gets temporarily distracted, and then follows up on its original plan. **Left:** observed trajectories. **Center:** example partitioning under the assumption that the expert reached all subgoals during the demonstration. **Right:** example partitioning without restriction on the subgoal locations, yielding a more compact encoding of the task.

(a) time-varying intentions (b) time-invariant intentions

Figure 5: Schematic comparison of the two basic behavior types, illustrated using two different agent trajectories. Color indicates the temporal progress. (a) Time-varying intentions may cause the agent to perform a different action when revisiting a state (dotted circle). (b) By contrast, time-invariant intentions imply a simple state-to-action policy: the agent has no incentive to perform a different action at an already visited state since — by definition — the underlying objective has remained unchained. Diverging actions, as observed at the crossing point in the left subfigure, can therefore only be explained as a result of suboptimal behavior.

Limitation 5: State-Action Demonstrations

Lastly, a minor problem of the original BNIRL framework is that the inference algorithm expects the demonstration data to be provided in the form of state-action pairs, which requires full access to the expert's action record. This assumption is restrictive from a practical point of view as it confines the application of the model to settings with laboratory-like conditions that allow a complete monitoring of the expert. For this reason, it is important to note that an estimate of the expert's action sequence can be recovered through BNIRL with the help of an additional sampling stage (omitted in the original paper), provided that we know the successor state reached by the expert after each decision. For the marginalized inference scheme described in this paper, we present the corresponding sampling stage in Section 4.4.

3. Nonparametric Spatio-Temporal Subgoal Modeling

In this section, we introduce a redesigned inference framework, which, in analogy to BNIRL, we refer to as *distance-dependent Bayesian nonparametric IRL* (ddBNIRL). We derive the model by making a series of modifications to the original BNIRL framework that address the previously described shortcomings on the conceptual level. Rethinking each part of the original framework, we begin with a discussion of the commonly used softmax action selection strategy (Equation 2) in the context of subgoal inference, which finally leads to a redesign of the subgoal likelihood model (Limitation 4). Next, we focus on the subgoal allocation mechanism itself and introduce two closely related model formulations, each targeting one of the basic behavior types described in Figure 5, thereby addressing Limitations 1, 2 and 3. For the time-invariant case, we begin with an intermediate model that introduces a subtle yet important structural modification to the BNIRL framework. In a second step, we generalize that new model to account for the spatial structure of the control problem, which finally allows us to extrapolate the expert behavior to unseen situations. As part of this generalization, we present a new state space metric that arises naturally in the context of subgoal inference (see Limitation 2, second point). Lastly, we tackle the time-varying case and present a variant of the model that explicitly considers the temporal aspect of the subgoal problem. A solution to Limitation 5 is discussed later in Section 4.

In contrast to BNIRL, both presented models can be used likewise for *subgoal extraction* and *action prediction*. Moreover, sticking with the Bayesian methodology, the presented approach provides complete posterior information at all levels.

3.1 The Subgoal Likelihood Model

Like many other approaches found in the (I)RL literature, BNIRL exploits a softmax weighting (Equation 2) to transform the Q-values of an optimal policy into a valid subgoal likelihood model. The softmax action rule has its origin in RL where it is known as the Boltzmann exploration strategy (Cesa-Bianchi et al., 2017; Sutton and Barto, 1998), which is commonly applied to cope with the *exploration-exploitation dilemma* (Ghavamzadeh et al., 2015). In recent years, however, it has also become the de facto standard for describing the (imperfect) decision-making strategy of an observed demonstrator (see, for example, Dimitrakakis and Rothkopf, 2011; Ramachandran and Amir, 2007; Rothkopf and Dimitrakakis, 2011; Choi and Kim, 2012; Neu and Szepesvári, 2007; Babeş-Vroman et al., 2011).

In the following paragraphs, we focus on the implications of this model on the subgoal extraction problem and show that it contradicts our intuitive understanding of what characteristics a reasonable subgoal model should have. In particular, we argue that the subgoal posterior distribution arising from the BNIRL softmax model is of limited use for inferring the latent intention of the agent, due to subgoal artifacts caused by the system dynamics that cannot be reconciled with the evidence provided by the demonstrations. Based on these insights, we propose an alternative transformation scheme that is more consistent with the subgoal principle.

3.1.1 Scale of the Reward Function

The first implication of the softmax likelihood model concerns the choice of the uncertainty coefficient β. To explain the problem, we consider the thought experiment of an agent located at some state s targeting a particular subgoal g. The likelihood $\pi(a \,|\, s, g)$ in Equation (2) quantifies the probability that the agent decides for a specific action a, based on the corresponding state-action values $Q(\cdot, s \,|\, g)$. Since those values are linear in the underlying reward function R_g (Equation 3), the softmax likelihood model implies that the expert's ability to maximize the long-term reward, reflected by the spread of the probability mass in $\pi(\cdot \,|\, s, g)$, rises with the magnitude C of the assumed subgoal reward (more concentrated probability mass signifies a higher confidence in the action choice). In other words, assuming a higher goal reward virtually increases our level of confidence in the expert, even though the difficulty of the underlying task and the optimal policy remain unchanged. Nonetheless, the BNIRL model requires us to readjust the uncertainty coefficient β in order to keep both models consistent. However, as the model provides no reference level for the expert's uncertainty across different scenarios, the choice of β becomes nontrivial. Yet, the parameter has a significant impact on the granularity of the learned subgoal model as it trades off purposeful goal-oriented behavior against random decisions.

Note that the described effect is not specific to the subgoal reward model in Equation (1) but is really a consequence of the softmax transformation in Equation (2). In fact, the same problem occurs when the model is applied in a regular MDP environment with arbitrary reward function, for example, when the agent is provided an additional constant reward at all states. Clearly, such a constant reward provides no further information about the underlying task and should hence not affect the agent's belief about the optimal choice of actions (compare discussion on constant reward functions and transformations of rewards, Ng and Russell, 2000; Ng et al., 1999). Based on these two observations, our intuition tells us that we seek for a rationality model that is *invariant to affine transformations of the reward signal*, meaning that any two reward functions $R : \mathcal{S} \to \mathbb{R}$ and $\bar{R} \coloneqq xR + y$ with $x \in (0, \infty), y \in \mathbb{R}$, should give rise to the same intentional representation. As we shall see in Section 3.1.3, this can be achieved by modeling the behavior of an agent based on the *relative advantages* of actions rather than on their absolute expected returns.

3.1.2 Impact of the Transition Dynamics

The second implication of the softmax likelihood model is less immediate and inherently tied to the dynamics of the system. To explain the problem, we consider a scenario where we have a precise idea about the potential goals of the expert. For our example, we adopt

the grid world dynamics described in Section 5.1 and consider a simple upward-directed trajectory of state-action pairs, which we aspire to explain using a single (sub-)goal. The complete setting is depicted in Figure 6.

Intuitively, the shown demonstration set should lead to goals that are located in the upper region of the state space and concentrated around the vertical center line. Moreover, as we move away from that center line, we expect to observe a smooth decrease in the subgoal likelihood, while the rate of the decay should reflect our assumed level of confidence in the expert. As it turns out, the induced BNIRL subgoal posterior distribution, shown in the top row for different values of β, contradicts this intuition. In particular, we observe that the model yields unreasonably high posterior values at the upper border states and corners of the state space, which, according to our intuitive understanding of the problem, cannot be justified by the given demonstration set.

To pin down the cause of this effect, we recall from Equation (2) that the likelihood of an action grows with the corresponding Q-value. Hence, we need to ask what causes the Q-values of the demonstrated actions to be large when the subgoal is assumed to be located at one of the upper corner/border states of the space. Using Bellman's principle, we can express the optimal Q-function for any subgoal g as

$$\begin{aligned} Q^*(s,a\,|\,g) &= R_g(s) + \gamma\,\mathbb{E}_T\big[V^*(s'\,|\,g)\,|\,s,a\big] \\ &= R_g(s) + \gamma\,\mathbb{E}_T\big[\mathbb{E}_{\rho^{\pi_g}}[R_g(s'')\,|\,s']\,|\,s,a\big] \\ &= R_g(s) + \gamma\,\mathbb{E}_T\big[C\rho^{\pi_g}(g\,|\,s')\,|\,s,a\big], \end{aligned} \tag{6}$$

where $V^*(s\,|\,g) \coloneqq \max_{a\in\mathcal{A}} Q^*(s,a\,|\,g)$, $\pi_g(s) \coloneqq \arg\max_{a\in\mathcal{A}} Q^*(s,a\,|\,g)$ is the optimal policy for subgoal g, and C is the subgoal reward from Equation (1). Lastly, $\rho^{\pi_g}(s'\,|\,s) \coloneqq \sum_{t=0}^{\infty}\gamma^t p_t(s'\,|\,s,\pi_g)$ denotes the (improper) discounted state distribution generated by executing policy π_g from the considered initial state s, where $p_t(s'\,|\,s,\pi_g)$ refers to the probability of reaching state s' from state s under policy π_g after exactly t steps, which is defined implicitly via the transition model T.

The outer expectation in Equation (6) accounts for the stochastic transition to the successor state s', while the inner expectation evaluates the expected cumulative reward over all states s'' that are reachable from s'. It is important to note that — by the construction of the Q-function — only the first move of the agent to state s' depends on the choice of action a whereas all remaining moves (i.e., the argument of the expectation in the last line) are purely determined by the system dynamics and the subgoal policy π_g. Focusing on that inner part, we conclude that, *regardless of the chosen action* a, the Q-values will be large whenever the assumed subgoal induces a high state visitation frequency ρ^{π_g} at its own location g. The latter is fulfilled if

(i) the chance of reaching the goal in a small number of steps is high so that the effect of discounting is small and/or

(ii) the controlled transition dynamics $T(s'\,|\,s,\pi_g(s))$ that are induced by the subgoal lead to a high chance of hitting the goal frequently.

Note that the first condition implies that the model generally prefers subgoals that are close to the demonstration set — a property that cannot be justified in all cases. For example, the recording of the demonstrations could have simply ended before the expert was able to

reach the goal (Figure 5). Yet, if desired, this proximity property should be more naturally attributed to the subgoal prior model $p_g(g\,|\,\mathbf{s})$.

Moreover, we observe that the second condition depends primarily on the system dynamics T, which can be more or less strongly influenced by the actions of the agent, depending on the scenario. In fact, in a pathological example, T could be even independent of the agent's decisions, meaning that the agent has no control over its state. An example illustrating this extreme case would be a scenario where the agent gets always driven to the same terminal state, regardless of the executed policy. Although it is somewhat pointless speak of "subgoals" in this context, that terminal state would exhibit a high subgoal likelihood according to the softmax model because the corresponding visitation frequency would be inevitably large. A softened variant of this condition can occur at corner/border states (i.e., states in which the agent experiences fewer degrees of freedom and which are hence more difficult to leave than others) and transition states (i.e., states that must be passed in order to get from certain regions of the space to others), which naturally exhibit an increased visitation frequency due to the characteristics of the environment.

In our example in Figure 6, we can observe the symptoms of both described conditions clearly. In particular, for an upward-directed policy as it is implied by the shown demonstration set, the induced state visitation distribution exhibits increased values at exactly the aforementioned border and corner states (due to the reflections occurring to the agent when hitting the state space boundary) as well as close to the trajectory ending (caused by the proximity condition).

3.1.3 The Normalized Likelihood Model

To address these problems, we modify the likelihood model using a rescaling of the involved Q-values. Let $Q^{\wedge}(s\,|\,g)$ and $Q^{\vee}(s\,|\,g)$ denote the maximum and minimum Q-values at state s for subgoal g, i.e., $Q^{\wedge}(s\,|\,g) \coloneqq \max_{a\in\mathcal{A}} Q^*(s,a\,|\,g)$ and $Q^{\vee}(s\,|\,g) \coloneqq \min_{a\in\mathcal{A}} Q^*(s,a\,|\,g)$. We then define the normalized state-action value function $Q^{\bullet}: \mathcal{S}\times\mathcal{A}\times\mathcal{S}\to[0,1]$ as

$$Q^{\bullet}(s,a\,|\,g) \coloneqq \begin{cases} \frac{Q^*(s,a\,|\,g)-Q^{\vee}(s\,|\,g)}{Q^{\wedge}(s\,|\,g)-Q^{\vee}(s\,|\,g)} & \text{if } Q^{\wedge}(s\,|\,g) \neq Q^{\vee}(s\,|\,g), \\ \epsilon & \text{otherwise,} \end{cases} \tag{7}$$

where $\epsilon\in(0,1]$ is an arbitrary constant that is canceled out in Equation (8). In contrast to the Bellman state-action value function Q^*, which quantifies the expected return of an action, the normalized function $Q^{\bullet}$ assesses the return of that action in relation to the returns of all other actions. This concept is similar to that of the advantage function (Baird, 1993) with the important difference that the values returned by $Q^{\bullet}$ are normalized to the range $[0,1]$ and thus serve as an indicator for the *relative* quality of actions. Accordingly, the values can be interpreted as *relative advantages* (i.e., relative to the maximum possible advantage among all actions). The normalized subgoal likelihood model is then constructed analogously to the BNIRL likelihood model,

$$\pi^{\bullet}(a_d\,|\,s_d,g_{\tilde{z}_d}) \propto \exp\big\{\beta Q^{\bullet}(s_d,a_d\,|\,g_{\tilde{z}_d})\big\}. \tag{8}$$

The key property of this model is that it is invariant to affine transformations of the reward function, as summarized by the following proposition.

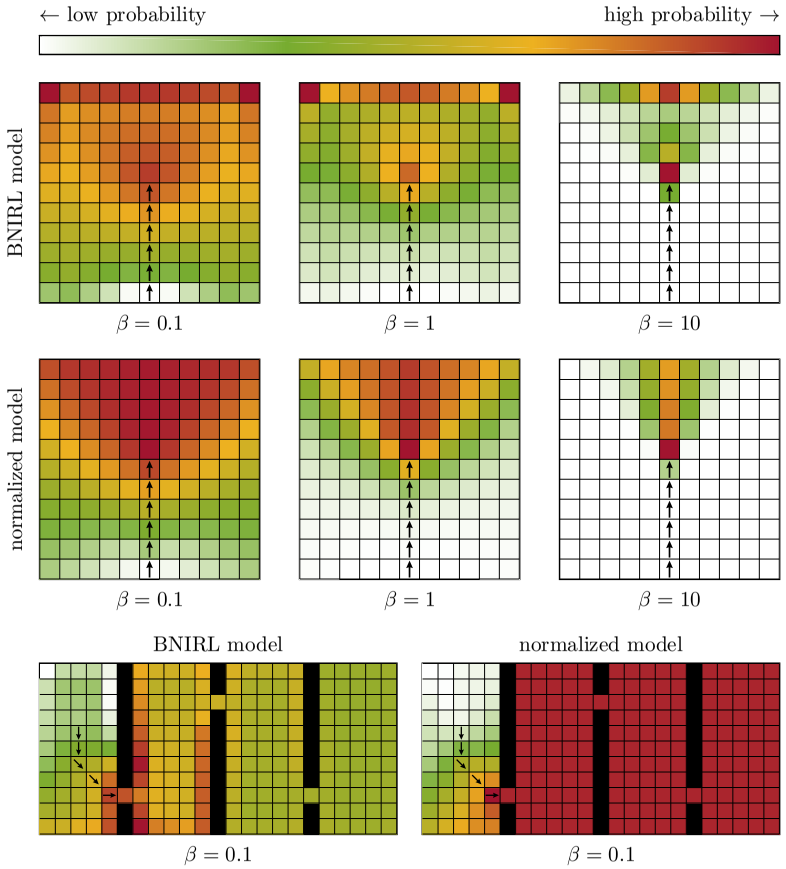

Figure 6: Comparison of the subgoal posterior distributions induced by the original BNIRL likelihood model and by the proposed normalized model, based on the grid world dynamics described in Section 5.1 and a uniform subgoal prior distribution p_g. The range of the shown color scheme is to be understood per subfigure. Black squares indicate wall states. The BNIRL likelihood model yields unreasonably high subgoal posterior mass at the border states and corners of the state space (due to locally increased state visitation probabilities arising from wall reflections) as well as at trajectory endings (caused by the implicit proximity property of the model)—see Section 3.1.2 for details. Both effects are mitigated by the proposed normalized likelihood model, which describes the action-selection process of the agent using relative advantages of actions instead of absolute returns.

Proposition 1 (Affine Invariance) *Consider an MDP with reward function $R : \mathcal{S} \to \mathbb{R}$ and let $Q^*(s, a \,|\, R)$ denote the corresponding optimal state-action value function. For the corresponding normalized function $Q^\bullet$ it holds that $Q^\bullet(s, a \,|\, R) = Q^\bullet(s, a \,|\, xR + y)$ $\forall x \in (0, \infty), y \in \mathbb{R}, s \in \mathcal{S}, a \in \mathcal{A}$. Hence, the subgoal likelihood model in Equation (8) is invariant to affine transformations of R.*

Proof Due to the linear dependence of Q^* on the reward function R (Equation 3) it holds that $Q^*(s, a \,|\, xR + y) = xQ^*(s, a \,|\, R) + \frac{y}{1-\gamma}$. Using this relationship in Equation (7), it follows immediately that $Q^\bullet(s, a \,|\, R) = Q^\bullet(s, a \,|\, xR + y)$. ■

Using the proposed likelihood model offers several advantages. First of all, it enables a more generic choice of the uncertainty coefficient β (Section 3.1.1). This is because the returned Q$^\bullet$-values lie in the fixed range [0,1], where 0 always indicates the lowest and 1 indicates the highest confidence. For example, setting $\beta = \log(\beta')$ for some $\beta' \in (0, \infty)$ always corresponds to the assumption that the expert chooses the optimal action with a probability that is β' times higher than the probability of choosing the least favorable action, irrespective of the underlying system model.

Moreover, as the results in Figure 6 reveal, the induced subgoal posterior distribution is notably closer to our expectation. The reason for this is twofold: first, a likelihood computation based on relative advantages mitigates the influence of the transition dynamics discussed in Section 3.1.2. This is because the described cumulation effect of the state visitation distribution ρ^{π_g} (Equation 6) is present in the returns of all actions and is thus reduced through the proposed normalization. For instance, if the agent in our grid world follows a policy that is all upward directed (as shown in the example), the induced state visitation distribution exhibits increased values at the upper border states of the world, even if we manipulated the *first* action of the agent (as considered in the Bellman Q-function). Accordingly, the original model would indicate an increased subgoal likelihood at those states. The normalized model, by contrast, is less affected as it constructs the likelihood by considering the increased visitation frequencies *relative* to each other.

Second, since the normalization diminishes the effect of the discounting, the subgoal posterior distribution is less concentrated around the trajectory ending and shows significant mass along the extrapolated path of the agent. This property allows us to identify far located states as potential goal locations, which adds more flexibility to the inferred subgoal constellation (compare Figure 4). As an illustrating example, consider the scenario shown in the bottom part of Figure 6. We observe that the normalized model assigns high posterior mass to all states in the right three corridors since any subgoal located in those corridors explains the demonstration set equally well. Here, the difference between the two models is even more pronounced because the transition dynamics have a strong impact on the agent behavior due to the added wall states. For further details, we refer to Section 5.1, where we provide additional insights into the subgoal inference mechanism.

3.2 Modeling Time-Invariant Intentions

With our redesigned likelihood model, we now focus on the partitioning structure of the model. Herein, we first consider the case where the intentions of the agent are constant with

respect to time. As explained in Limitation 3, this setting is consistent with the standard MDP formalism in the sense that the optimal policy for the considered task can be described in the form of a state-to-action mapping.

As a first step, to account for this relation, we establish a link between the model partitioning structure and the underlying system state space by replacing the demonstration-based indicators $\tilde{\mathbf{z}} = \{\tilde{z}_d \in \mathbb{N}\}_{d=1}^{D}$ with a new set of variables $\mathbf{z} \coloneqq \{z_i \in \mathbb{N}\}_{i=1}^{|\mathcal{S}|}$. Unlike $\tilde{\mathbf{z}}$, these new indicators do not operate directly on the data but are instead tied to the elements in $\mathcal{S}$. Although they formally represent a new type of variable, we can still imagine that their distribution follows a CRP. This yields an intermediate model of the form

$$p(\mathbf{a}, \mathbf{z}, \mathcal{G} \,|\, \mathbf{s}) = p(\mathbf{z}) \prod_{k=1}^{\infty} p_g(g_k \,|\, \mathbf{s}) \prod_{d=1}^{D} \pi^{\bullet}(a_d \,|\, s_d, g_{\mathbf{z}_{s_d}}),$$

whose structure is illustrated in Figure 2b. To see the difference to Equation (4), notice the way the subgoals are indexed in this model.

The intermediate model makes it possible to reason about the policy (or, more suggestively, the underlying state-to-action rule approximated by the expert) at visited parts of the state space. Yet, the model is unable to extrapolate the gathered information to unvisited states, for the reasons explained in Section 2.2. This problem can be solved by replacing the exchangeable prior distribution over subgoal assignments induced by the CRP with a non-exchangeable one, in order to account explicitly for the covariate state information contained in the demonstration set. Based on our insights from Bayesian policy recognition (Šošić et al., 2018b), we use the distance-dependent Chinese restaurant process (ddCRP, Blei and Frazier, 2011) for this purpose, which allows a very intuitive handling of the state context, as explained below. For alternatives, we point to the survey paper by Foti and Williamson (2015).

In contrast to the CRP, which assigns states to partitions, the ddCRP assigns states to other states, based on their pairwise distances. These "to-state" assignments are described by a set of indicators $\mathbf{c} \coloneqq \{c_i \in \mathcal{S}\}_{i=1}^{|\mathcal{S}|}$ with prior distribution $p(\mathbf{c}) = \prod_{i=1}^{|\mathcal{S}|} p(c_i)$,

$$p(c_i = j) = \begin{cases} \nu & \text{if } i = j, \\ f(\Delta_{i,j}) & \text{otherwise,} \end{cases} \tag{9}$$

for $i, j \in \mathcal{S}$. Herein, $\nu \in [0, \infty)$ is called the self-link parameter of the process, $\Delta_{i,j}$ denotes the distance from state i to state j, and $f : [0, \infty) \to [0, \infty)$ is a monotone decreasing score function. Note that the distances $\{\Delta_{i,j}\}$ can be obtained via a suitable metric defined on the state space, which may be furthermore used for calibrating the score function f (see subsequent section). The state partitioning structure itself is then determined by the connected components of the induced ddCRP graph (Figure 7). Our joint distribution, visualized in Figure 2c, thus reads as

$$p(\mathbf{a}, \mathbf{c}, \mathcal{G} \,|\, \mathbf{s}) = p(\mathbf{c}) \prod_{k=1}^{\infty} p_g(g_k \,|\, \mathbf{s}) \prod_{d=1}^{D} \pi^{\bullet}(a_d \,|\, s_d, g_{\mathbf{z}(\mathbf{c})|_{s_d}}), \tag{10}$$

where $\mathbf{z}(\mathbf{c})|_s$ denotes the subgoal label of state s arising from the considered indicator set $\mathbf{c}$. In order to highlight the state dependence of the underlying subgoal mechanism, we refer to this model as ddBNIRL-S.

3.2.1 The Canonical State Metric for Spatial Subgoal Modeling

The use of the ddCRP as a prior model for the state partitioning in Equation (10) inevitably requires some notion of distance between any two states of the system, in order to compute the involved function scores $\{f(\Delta_{i,j})\}$. When no such distances are provided by the problem setting (see Limitation 2, second point), a suitable (quasi-)metric can be derived from the transition dynamics of the system, which turns out to be the canonical choice for the ddBNIRL-S model. Consider the Markov chain governing the state process $\{s_{t=n}\}_{n=1}^{\infty}$ of an agent for some specific policy π. For any ordered pair of states (i, j), the chain naturally induces a value $\mathrm{T}_{i \to j}^{\pi}$, called a *hitting time* (Taylor and Karlin, 1984; Tewari and Bartlett, 2008), which represents the expected number of steps required until the state process, initialized at i, eventually reaches state j for the first time,

$$\mathrm{T}_{i \to j}^{\pi} \coloneqq \mathbb{E}\big[\min\{n \in \mathbb{N} : s_{t=n} = j\} \,|\, s_0 = i, \pi\big].$$

In the context of our subgoal problem, the natural quasi-metric to measure the directed distance between two states i and j is thus given by the time it takes to reach the goal state j from the starting state i under the corresponding optimal subgoal policy $\pi_j(s) = \arg\max_{a \in \mathcal{A}} Q^*(s, a \,|\, j)$, i.e., $\Delta_{i,j} \coloneqq \mathrm{T}_{i \to j}^{\pi_j}$. For ddBNIRL-S (as well as for the waypoint method in BNIRL), this choice is particularly appealing since the subgoal policies $\{\pi_j\}$ are already available within the inference procedure after the state-action values have been computed for the likelihood model (more on this in Section 4.5). The corresponding distances $\{\Delta_{i,j}\}$ can be obtained efficiently in a single policy evaluation step since $\Delta_{i,j}$ corresponds to the optimal (negative) expected return at the starting state i for the special setting where the respective target state j is made absorbing with zero reward while all other states are assigned a reward of -1.

3.2.2 Choice of the Score Function

From Equation (9) it is evident that the ddCRP model favors partitioning structures that result from the connection of nearby states. In the context of the subgoal problem, this property translates to the prior assumption that, most likely, each subgoal is approached by the expert from only one specific localized region in the system state space. While this assumption may be reasonable for some tasks, other tasks require that certain target states be approached more than one time, from different regions in the system state space. In such cases, it is beneficial if the model can reuse the same subgoal in various contexts, in order to obtain a more efficient task encoding (Figure 4).

From a mathematical point of view, the prerequisite for learning such encodings is that the score function f does not shrink to zero at large distance values, so that there remains a non-zero probability of connecting states that are far apart from each other. This can be achieved, for example, by representing f as a convex combination of a monotone decreasing zero-approaching function $\bar{f} : [0, \infty) \to [0, \infty)$ and some constant offset $\kappa \in (0, 1]$,

$$f(\Delta) = (1 - \kappa)\bar{f}(\Delta) + \kappa,$$

where $\bar{f}$ is chosen, e.g., as a radial basis function (Šošić et al., 2018b). Note that, in order to implement a desired degree of locality in the model, the scale of the decay function f (or $\bar{f}$, respectively) can be further calibrated based on the quantiles of the distribution of the given distances $\{\Delta_{i,j}\}$.

3.3 Modeling Time-Varying Intentions

For the case of changing expert intentions, we need to keep the flexibility of BNIRL to select a new subgoal at each decision instant, instead of restricting our policy to target a unique subgoal per state (Figure 5). Hence, we retain the basic BNIRL structure in this case and define the subgoal allocation mechanism using a set of data-related indicator variables. However, in contrast to BNIRL, which makes no assumptions about the temporal relationship of the subgoals and thus allows arbitrary changes of the expert's intentions (Section 2.1), we design our joint distribution in a way that favors smooth action plans in which the expert persistently follows a subgoal over an extended period of time. Again, we can make use of the ddCRP properties to encode the underlying smoothness assumption, but this time using a score function defined on the *temporal distance* between demonstration pairs. For this purpose, we require an additional piece of information, namely the unique timestamp of each demonstration example. Accordingly, we need to assume that our data set is of the form $\widetilde{\mathcal{D}} \coloneqq \{(s_d, a_d, t_d)\}_{d=1}^{D}$, where t_d denotes the recording time of the dth demonstration pair (s_d, a_d).[2]

The prior distribution over data partitionings can then be written as $p(\tilde{\mathbf{c}}) = \prod_{d=1}^{D} p(\tilde{c}_d)$,

$$p(\tilde{c}_d = d') \propto \begin{cases} \nu & \text{if } d = d', \\ f(\widetilde{\Delta}_{d,d'}) & \text{otherwise,} \end{cases}$$

where the indices $d, d' \in \{1, \dots, D\}$ range over the size of the demonstration set. Herein, $\widetilde{\Delta}_{d,d'} \coloneqq |t_d - t_{d'}|$ denotes the temporal distance between the data points d and d'. As before, we use the "$\sim$"-notation to distinguish the data-related partitioning variables $\tilde{\mathbf{c}}$, $\tilde{\mathbf{z}}$ and distances $\{\widetilde{\Delta}_{d,d'}\}$ from their state-space-related counterparts $\mathbf{c}$, $\mathbf{z}$ and $\{\Delta_{i,j}\}$ used in ddBNIRL-S. Note, however, that the score function f is independent of the underlying model type and may be chosen as described in Section 3.2.1, with a scale calibrated to the duration of the demonstrated task.

With that, we obtain our temporal subgoal model as

$$p(\mathbf{a}, \tilde{\mathbf{c}}, \mathcal{G} \mid \mathbf{s}) = p(\tilde{\mathbf{c}}) \prod_{k=1}^{\infty} p_g(g_k \mid \mathbf{s}) \prod_{d=1}^{D} \pi^{\bullet}(a_d \mid s_d, g_{\tilde{\mathbf{z}}(\tilde{\mathbf{c}})|_d}), \tag{11}$$

where $\tilde{\mathbf{z}}(\tilde{\mathbf{c}})|_d$ refers to the subgoal label of the dth demonstration pair induced by the given assignment $\tilde{\mathbf{c}}$. Analogous to our spatial subgoal model, we refer to this model as ddBNIRL-T. The structural differences between all models can be seen from Figure 2.

3.3.1 Relationship to BNIRL

Since the distance-dependent CRP contains the classical CRP as a special case for a specific choice of distance metric and score function (Blei and Frazier, 2011), the ddBNIRL-T model can be considered a strict generalization of the original BNIRL framework (neglecting the likelihood normalization in Section 3.1). In the same way, ddBNIRL-S generalizes

2. Note that the timestamps $\{t_d\}$ are naturally available if the demonstrations are recorded in trajectory form, where we observe several consecutive state-action pairs. In fact, the temporal information of the data is also required for the waypoint method to work (Limitation 2), even though the authors of BNIRL formally assume to have access to the reduced data set of state-action pairs only.

the intermediate model presented in Section 3.2 (Figure 2). However, although the BNIRL model can be recovered from ddBNIRL, it is important to note that the sampling mechanisms of both frameworks are fundamentally different. Whereas in BNIRL the subgoal assignments are sampled directly, the clustering structure in ddBNIRL is defined *implicitly* via the assignment variables $\mathbf{c}$ and $\tilde{\mathbf{c}}$, respectively. As explained by Blei and Frazier (2011), this has the effect that the Markov chain governing the Gibbs sampler mixes significantly faster because several cluster assignments can be altered in a single step, which effectively realizes a blocked Gibbs sampler (Roberts and Sahu, 1997).

3.4 Static versus Dynamic Subgoal Allocation

With the model structures described in Sections 3.2 and 3.3, we have presented two alternative views on the subgoal problem. Naturally, the question arises which of the two approaches is better suited for a particular application scenario. As explained in the previous paragraphs, the main difference between the two models lies in their structure, i.e., in the way subgoals are allocated. While ddBNIRL-S relies on a static assignment mechanism that consistently links the individual states of a system to their corresponding subgoals, ddBNIRL-T allocates its subgoals per demonstration pair. The latter means that different state-action pairs observed at the *same* state can be explained using *different* intentional settings (Figure 5). To answer the above question, we hence need to ask under which conditions an observed decision-making process can be described via a static assignment rule that *uniquely* characterizes each system state, and in which situations we require a more flexible model that allows to take into account additional side information.

From decision-making theory, we know that the optimal solutions for time-invariant MDPs can be formulated as a deterministic *time-invariant* Markov policies (Puterman, 1994), the class of which is fully covered by the static ddBNIRL-S framework.[3] Therefore, assuming that the transition dynamics of our system are constant with respect to time and that the agent acts rationally while having complete knowledge of the environment, there exist only two plausible reasons why we would potentially observe the agent execute a time-variant policy:

- either, the reward model of the agent changes over time,
- or, the observed decision-making process is not Markovian with respect to the assumed state space model (i.e., the agent's decisions depend on additional context information that is not explicitly captured in our state representation).

Accordingly, if we assume that the Markov property holds (meaning that the chosen state representation is sufficiently rich to capture the decision-making strategy of the agent), the only theoretical justification to prefer a dynamic subgoal model like ddBNIRL-T over a static one such as ddBNIRL-T would be if we assume that the intentions of the agent are truly time-dependent.

Practically speaking, however, there can be several reasons why a given state representation might not fulfill the Markov requirement. One obvious explanation would be that the actual state space of the demonstrator is not perfectly known. This situation occurs, for

3. While we omit a rigorous proof here, this can be seen intuitively by noticing that any state-to-action rule that is optimal for a given MDP reward function can be synthesized via ddBNIRL-S by assuming an individual subgoal for each state in the extreme case.

example, if not all state context available to the agent is observable by the modeler. Another potential situation is when the strategy of the agent depends on information that is independent of the system dynamics and hence deliberately excluded from the state variable (i.e., parameters that are unaffected by the actions of the agent, such as the preselection of a specific high-level strategy). A generic framework for such settings is described by Daniel et al. (2016b), where the agent learns multiple sub-policies that are triggered depending on context information that is treated separately from the state.

To an external observer who is unaware of that context information, the resulting policy of the agent would potentially appear time-dependent, in which case the only chance to disentangle the individual sub-policies would be to resort to a dynamic subgoal encoding, such as provided by ddBNIRL-T. However, if the context is known (like the temporal information in Section 3.3 as a particular example), both approaches can be used equivalently and will only differ in the resulting state representation. More specifically, we can either fall back on the static ddBNIRL-S model by augmenting the state variable with the context information accordingly, or we can resort to the dynamic subgoal allocation scheme of ddBNIRL-T, using a distance metric that accounts for the context. Conversely, when considered in a purely time-invariant setting (where the context is described by some other known quantity), ddBNIRL-S and ddBNIRL-T can be regarded as two sides of the same coin, i.e., both can be used to describe the time-invariant policy of an observed demonstrator but they differ in the way the side information is represented.

4. Prediction and Inference

Having introduced the ddBNIRL framework, we now explain how it can be used to generalize a given expert behavior. To this end, we first focus on the task of action prediction at a given query state, and then explain in a second step how to extract the necessary information from the demonstration data. Along the way, we also give insights into the implicit intentional model learned through the framework.

Note: In order to keep the level of redundancy at a minimum, the following considerations are based on the ddBNIRL-S model. The results for ddBNIRL-T follow straightforwardly; the only change in the equations is the way the subgoals are referenced. To obtain the corresponding expressions, we simply replace the assignment variables $\mathbf{c}$ with $\tilde{\mathbf{c}}$ and change the cluster definition in Equation (16) to $\mathcal{C}_k \coloneqq \{d \in \{1,\dots,D\} : \tilde{\mathbf{z}}(\tilde{\mathbf{c}})|_d = k\}$. Accordingly, all occurrences of $\mathbf{z}(\mathbf{c})|_{s^*}$ change to $\tilde{\mathbf{z}}(\tilde{\mathbf{c}})|_{d^*}$, $\mathbf{z}(\mathbf{c})|_{s_d}$ becomes $\tilde{\mathbf{z}}(\tilde{\mathbf{c}})|_d$, and $s_d \in \mathcal{C}_k$ is replaced with $d \in \mathcal{C}_k$.

4.1 Action Prediction

Similar to the work by Abbeel and Ng (2004), we consider the task of predicting an action $a^* \in \mathcal{A}$ at some query state $s^* \in \mathcal{S}$ that is optimal with respect to the expert's *unknown* reward model. However, in contrast to most existing IRL methods, our approach is not based on point estimates of the expert's reward function but takes into account the entire hypothesis space of reward models. This allows us to obtain the full posterior predictive policy from the expert data. Mathematically, the task is formulated as computing the predictive action distribution $p(a^* \mid s^*, \mathcal{D})$, which captures the full information about the expert

behavior contained in the demonstration set $\mathcal{D}$. We start by expanding that distribution with the help of the latent state assignments $\mathbf{c}$,

$$p(a^* \mid s^*, \mathcal{D}) = \sum_{\mathbf{c} \in \mathcal{S}^{|\mathcal{S}|}} p(a^* \mid s^*, \mathcal{D}, \mathbf{c}) p(\mathbf{c} \mid \mathcal{D}).$$

The conditional distribution $p(a^* \mid s^*, \mathcal{D}, \mathbf{c})$ can be expressed in terms of the posterior distribution of the subgoal targeted at the query state s^*,

$$p(a^* \mid s^*, \mathcal{D}) = \sum_{\mathbf{c} \in \mathcal{S}^{|\mathcal{S}|}} p(\mathbf{c} \mid \mathcal{D}) \sum_{i \in \mathcal{S}} p(a^* \mid s^*, \mathbf{c}, g_{\mathbf{z}(\mathbf{c})|_{s^*}} = i) p(g_{\mathbf{z}(\mathbf{c})|_{s^*}} = i \mid \mathcal{D}, \mathbf{c}),$$

where we used the fact that the prediction a^* is conditionally independent of the demonstration set $\mathcal{D}$ given the state partitioning structure and the corresponding subgoal assigned to s^* (that is, given $\mathbf{c}$ and $g_{\mathbf{z}(\mathbf{c})|_{s^*}}$). From the joint distribution in Equation (10), it follows that

$$p(g_k \mid \mathcal{D}, \mathbf{c}) = \frac{1}{Z_k(\mathcal{D}, \mathbf{c})} p_g(g_k \mid \mathbf{s}) \prod_{d : \mathbf{z}(\mathbf{c})|_{s_d} = k} \pi(a_d \mid s_d, g_k), \tag{12}$$

where $Z_k(\mathcal{D}, \mathbf{c})$ is the corresponding normalizing constant,

$$Z_k(\mathcal{D}, \mathbf{c}) \coloneqq \sum_{i \in \mathrm{supp}(p_g)} p_g(g_k = i \mid \mathbf{s}) \prod_{d : \mathbf{z}(\mathbf{c})|_{s_d} = k} \pi(a_d \mid s_d, g_k = i). \tag{13}$$

Using this relationship, we get

$$\begin{aligned} p(a^* \mid s^*, \mathcal{D}) = \sum_{\mathbf{c} \in \mathcal{S}^{|\mathcal{S}|}} \frac{1}{Z_k(\mathcal{D}, \mathbf{c})} p(\mathbf{c} \mid \mathcal{D}) \sum_{i \in \mathrm{supp}(p_g)} p_g(g_{\mathbf{z}(\mathbf{c})|_{s^*}} = i \mid \mathbf{s}) \ \dots \\ \dots \times \prod_{d : \mathbf{z}(\mathbf{c})|_{s_d} = \mathbf{z}(\mathbf{c})|_{s^*}} \pi(a_d \mid s_d, g_{\mathbf{z}(\mathbf{c})|_{s^*}} = i) p(a^* \mid s^*, \mathbf{c}, g_{\mathbf{z}(\mathbf{c})|_{s^*}} = i). \end{aligned}$$

In contrast to the summation over subgoal locations i, whose computational complexity is determined by the support of the subgoal prior distribution p_g and which grows at most linearly with the size of $\mathcal{S}$, the marginalization with respect to the indicator variables $\mathbf{c}$ involves the summation of $|\mathcal{S}|^{|\mathcal{S}|}$ terms and becomes quickly intractable even for small state spaces. Therefore, we approximate this operation via Monte Carlo integration, which yields

$$p(a^* \mid s^*, \mathcal{D}) \approx \frac{1}{N} \sum_{n=1}^{N} \sum_{i \in \mathrm{supp}(p_g)} p(g_{\mathbf{z}(\mathbf{c}^{\{n\}})|_{s^*}} = i \mid \mathcal{D}, \mathbf{c}^{\{n\}}) p(a^* \mid s^*, \mathbf{c}^{\{n\}}, g_{\mathbf{z}(\mathbf{c}^{\{n\}})|_{s^*}} = i),$$

where $\mathbf{c}^{\{n\}} \sim p(\mathbf{c} \mid \mathcal{D})$. The final prediction step can then be performed, for example, via the maximum a posteriori (MAP) policy estimate,

$$\hat{\pi}(s^*) \coloneqq \arg\max_{a^* \in \mathcal{A}} p(a^* \mid s^*, \mathcal{D}). \tag{14}$$

The inference task, hence, reduces to the computation of the posterior samples $\{\mathbf{c}^{\{n\}}\}$, which is described in the next section.

4.2 Partition Inference

Based on the joint model in Equation (10), we obtain the posterior distribution $p(\mathbf{c} \mid \mathcal{D})$ in factorized form as

$$p(\mathbf{c} \mid \mathcal{D}) = p(\mathbf{c}) \prod_{k=1}^{\infty} \sum_{g_k \in \mathrm{supp}(p_g)} p_g(g_k \mid \mathbf{s}) \prod_{d=1}^{D} \pi(a_d \mid s_d, g_{\mathbf{z}(\mathbf{c})|_{s_d}})$$
$$= p(\mathbf{c}) \prod_{k=1}^{|\mathbf{z}(\mathbf{c})|} \sum_{g_k \in \mathrm{supp}(p_g)} p_g(g_k \mid \mathbf{s}) \prod_{d: s_d \in \mathcal{C}_k} \pi(a_d \mid s_d, g_k), \tag{15}$$

where $\mathcal{C}_k$ denotes the kth state cluster induced by the assignment $\mathbf{c}$,

$$\mathcal{C}_k \coloneqq \{s \in \mathcal{S} : \mathbf{z}(\mathbf{c})|_s = k\}, \tag{16}$$

and $|\mathbf{z}(\mathbf{c})|$ is the total number of clusters defined by $\mathbf{c}$. As explained by Blei and Frazier (2011), the indicator samples $\{\mathbf{c}^{\{n\}}\}$ can be efficiently generated using a fast-mixing Gibbs chain. Starting from a given ddCRP graph defined by the subset of indicators $\mathbf{c}_{\setminus i} \coloneqq \{c_j\} \setminus c_i$, the insertion of an additional edge c_i will result in one of three possible outcomes, as illustrated in Figure 7: in the case of adding a self-loop ($c_i = i$), the underlying partitioning structure stays unaffected. Setting $c_i \neq i$ either leaves the structure unchanged (if the target state is already in the same cluster as state i) or creates a new link between two clusters. In the latter case, the involved clusters are merged, which corresponds to a merging of the associated sums in Equation (15). According to these three cases, the conditional distribution for the Gibbs procedure is obtained as

$$p(c_i = j \mid \mathbf{c}_{\setminus i}, \mathcal{D}) \;\propto\; \begin{cases} \nu & \text{if } i = j, \\ f(d_{i,j}) & \text{if no clusters are merged,} \\ f(d_{i,j}) \frac{\mathcal{L}(\mathcal{C}_{z_i} \cup \mathcal{C}_{z_j})}{\mathcal{L}(\mathcal{C}_{z_i}) \cdot \mathcal{L}(\mathcal{C}_{z_j})} & \text{if clusters } \mathcal{C}_{z_i} \text{ and } \mathcal{C}_{z_j} \text{ are merged.} \end{cases} \tag{17}$$

Herein, $\mathcal{L}(\mathcal{C})$ denotes the marginal action likelihood of all demonstrations accumulated in cluster $\mathcal{C}$,

$$\mathcal{L}(\mathcal{C}) = \sum_{g \in \mathrm{supp}(p_g)} p_g(g \mid \mathbf{s}) \prod_{d: s_d \in \mathcal{C}} \pi(a_d \mid s_d, g), \tag{18}$$

which further represents the normalizing constant for the posterior distribution of the cluster subgoal (Equation 13). Accordingly, the fraction in Equation (17) can be interpreted as the likelihood ratio of the partitioning defined by $\mathbf{c}_{\setminus i}$ and the merged structure after inserting the new edge c_i.

4.3 Subgoal Inference

It is important to note that the inference method described in Sections 4.1 and 4.2 is based on a collapsed sampling scheme where all subgoals of our model are marginalized out. In fact, the ddBNIRL framework differs from BNIRL and other IRL methods in that the reward model of the expert is never made explicit for predicting new actions. Nonetheless, if desired (e.g., for the purpose of analyzing the expert's intentions), an estimate of the subgoal locations can be obtained in a post-hoc fashion from the subgoal posterior distribution in Equation (12) for any given assignment $\mathbf{c}$. Examples are provided in Figure 8.

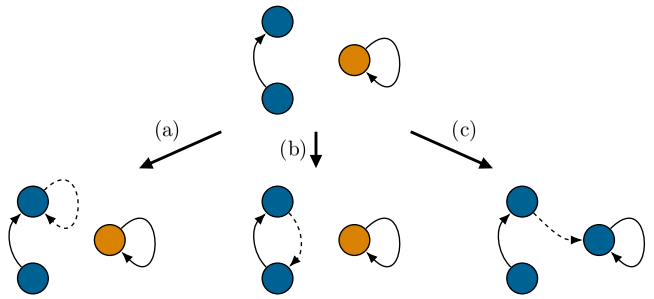

Figure 7: Insertion of an edge (dashed arrow) to the ddCRP graph. Colors indicate the cluster memberships of the nodes, which are defined implicitly via the connected components of the graph. (a) Adding a self-loop or (b) inserting an edge between two already connected nodes does not alter the clustering structure. (c) Adding an edge between two unconnected components merges the associated clusters.

4.4 Action Inference

As mentioned in Section 2.2, the original BNIRL algorithm requires complete knowledge of the expert's action record $\mathbf{a}$, which limits the range of potential application scenarios. For this reason, we generalize our inference scheme to the case where we have access to state information only, provided in the form of an alternative data set $\overline{\mathcal{D}} \coloneqq \{(s_d, \bar{s}_d)\}_{d=1}^{D}$, where $\bar{s}_d$ refers to the state visited by the expert immediately after s_d. In this setting, inference can be performed by extending the Gibbs procedure with an additional collapsed sampling stage,

$$p(a_d \mid \mathbf{a}_{\setminus d}, \overline{\mathcal{D}}, \mathbf{c}) \propto T(\bar{s}_d \mid s_d, a_d) \sum_{i \in \mathrm{supp}(p_g)} p_g(g_{\mathbf{z}(\mathbf{c})|_{s_d}} = i) \prod_{d': \mathbf{z}(\mathbf{c})|_{s_{d'}} = \mathbf{z}(\mathbf{c})|_{s_d}} \pi(a_{d'} \mid s_{d'}, g_{\mathbf{z}(\mathbf{c})|_{s_d}} = i), \tag{19}$$

which, for a fixed assignment $\mathbf{c}$, recovers an estimate of the latent action set $\mathbf{a}$ from the observed state transitions. Note that knowledge of the transition model T is required for this step as it provides the necessary link between the expert's actions and the observed successor states. The same extension is possible for the ddBNIRL-T model, provided that the transition timestamps $\{t_d\}$ are known (Section 3.3).

4.5 Computational Complexity

As a last point in this section, we would like to discuss the computational complexity of our approach. For this purpose, here a quick reminder on the used notation: we write $|\mathcal{S}|$ and $|\mathcal{A}|$ for the cardinalities of the state and action space, respectively, and use the letter D for the size of the demonstration set. Further, we write $\mathcal{C}_k$ to refer to the kth state cluster (ddBNIRL-S) or data cluster (ddBNIRL-T). In the subsequent paragraphs, we additionally use the notation $N_D(\mathcal{C}_k)$ to access the number of demonstration data points associated with

cluster $\mathcal{C}_k$, K to indicate the number of clusters in the current iteration, $N_g \coloneqq |\text{supp}(p_g)|$ as a shorthand for the size of the support of the subgoal prior distribution, and N_c for the number of indicator variables, i.e., $N_c \coloneqq |S|$ for ddBNIRL-S and $N_c \coloneqq D$ for ddBNIRL-T.

Initialization Phase: Common to all discussed models (including BNIRL) is that they depend on a preceding planning phase, where we compute, potentially in parallel, the state-action value functions (Equation 3) for all N_g considered subgoals, which allows us to construct the subgoal likelihood model (Equation 2 or 8). The overall computational complexity of this procedure is of order $\mathcal{O}(N_g \mathbb{C}_{\text{MDP}}(|\mathcal{S}|, |\mathcal{A}|))$, where $\mathbb{C}_{\text{MDP}}(x, y)$ denotes the complexity of the used planning routine to (approximately) solve an MDP of size x with a total number of y actions. Using a value iteration algorithm, for instance, this can be achieved in $\mathcal{O}(\mathbb{C}_{\text{MDP}}(|\mathcal{S}|, |\mathcal{A}|)) = \mathcal{O}(|\mathcal{S}|^2|\mathcal{A}|)$ steps (Littman et al., 1995). If we assume that the expert reaches all subgoals during the demonstration phase (Michini and How, 2012), we can restrict the support of the subgoal prior to the visited states, so that N_g is upper-bounded by $\min(|\mathcal{S}|, D)$. Note that there exist approximation techniques that make the computation tractable in large/continuous state spaces (see discussion in Section 6).

Before we start the sampling procedure, we compute all single-cluster likelihoods $\{\mathcal{L}(\mathcal{C}_k)\}$ and pairwise likelihoods $\{\mathcal{L}(\mathcal{C}_k \cup \mathcal{C}_{k'})\}$ according to Equation (18), based on some (random) initial cluster structure. The likelihood computation for the kth cluster $\mathcal{C}_k$ involves a product over $N_D(\mathcal{C}_k)$ data points, which needs to be calculated for each of the N_g subgoals before taking their weighted average. This step has to be executed (potentially in parallel) for all clusters. However, because each demonstration is associated with exactly one cluster (either directly as in ddBNIRL-T or via the corresponding state variable as in ddBNIRL-S) and hence $\sum_k N_D(\mathcal{C}_k) = D$, the total complexity for computing all single-cluster likelihoods is of order $\mathcal{O}(N_g D)$, irrespective of the actual cluster structure. A similar line of reasoning applies to the computation of the pairwise likelihoods, yielding the same complexity order. Yet, for the latter we need to consider all possible cluster combinations. Assuming an initial number of K clusters, there are in total $K(K-1)/2$ pairwise likelihoods to be computed. Hence, the overall complexity of the initialization phase can be summarized as $\mathcal{O}(N_g D K^2)$.

Partition Inference: For the partition inference, the bulk of the computation lies in the repeated construction of the likelihood term in Equation (17), which needs to be updated whenever the cluster structure changes. To analyze the complexity, we consider the sampling step of an individual assignment variable c_i (or likewise $\tilde{c}_i$). In the worst case, removing the edge that belongs to c_i from the ddCRP graph divides the associated cluster into two parts (Figure 7), so that two new single-cluster likelihoods need to be computed. With the upper bound D on the number of data points associated with the cluster before the division, this operation is of worst-case complexity $\mathcal{O}(N_g D)$ (see initialization phase). Irrespective of whether a division occurs, we then need to compute all pairwise cluster likelihoods with the (new) cluster connected via c_i. For a total of $K-1$ possible choices, this is done in $\mathcal{O}(N_g D K)$ operations (see initialization phase). After assigning the indicator, we move on to the next variable where the process repeats. If we assume, for simplicity, that the number of clusters stays constant during a full Gibbs cycle, the total complexity of updating all cluster assignments is hence of order $\mathcal{O}(N_g D K N_c)$. A (pessimistic) upper bound for the general case can be obtained by assuming that each data point defines its own cluster, in

which case the complexity increases to $\mathcal{O}(N_g D^2 N_c)$. Note that, in order to identify the new cluster structure after changing an assignment, we additionally need to track the connected components of the underlying ddCRP graph. As explained by Kapron et al. (2013), this can be done in polylogarithmic worst-case time.

Action Sampling: In order compute the conditional probability distribution of a particular action a_d, we need to evaluate a product involving all actions that belong to the same cluster as action a_d (Equation 19). First, we can compute the product over all actions except a_d itself, where the number of involved terms is again upper-bounded by D. Appending the term that belongs to a_d for all possible action choices requires another $|\mathcal{A}|$ operations. These two steps need to be repeated for all possible subgoals, yielding an upper bound on the complexity of order $\mathcal{O}(N_g(D + |\mathcal{A}|))$. For a full Gibbs cycle, which involves sampling all D action variables, the overall (worst-case) complexity is hence of order $\mathcal{O}(N_g(D + |\mathcal{A}|)D)$.

5. Experimental Results

In this section, we present experimental results for our framework. The evaluation is separated into four parts:

(i) a proof of concept and conceptual comparison to BNIRL (Section 5.1),
(ii) a performance comparison with related algorithms (Section 5.2),
(iii) a real data experiment conducted on a KUKA robot (Section 5.3) and
(iv) an active learning task (Section 5.4).

5.1 Proof of Concept

To illustrate the conceptual differences to BNIRL and provide additional insights into the latent intentional model learned through our framework, we begin with the motivating data set from Figure 1a, which had been originally presented by Michini and How (2012). The considered system environment, defined by $|\mathcal{S}| = 20 \times 20 = 400$ grid positions, is again shown in the top left corner of Figure 8. Nine of those positions correspond to inaccessible wall states, marked by the horizontal black bar. At the valid states, the expert can choose from an action set comprising a total of eight actions, each initiating a noisy state transition toward one of the (inter-)cardinal directions. The observed state-action pairs are depicted in the form of arrows, whose colors indicate the MAP partitioning learned through BNIRL. The remaining subfigures show the results of the ddBNIRL framework, which were obtained from a posterior sample returned by the respective algorithm (ddBNIRL-S/T) at a low temperature in a simulated annealing schedule (Kirkpatrick et al., 1983).

Comparing the obtained results, we observe the following main differences to the original approach:

(i) Unlike BNIRL, the proposed framework allows to choose between a spatial and a temporal encoding of the observed task, providing the possibility to account explicitly for the type of demonstrated behavior (static/dynamic). As explained in Section 3.3.1, the context-unaware (yet in principle dynamic) vanilla BNIRL inference scheme is still included as a special case.

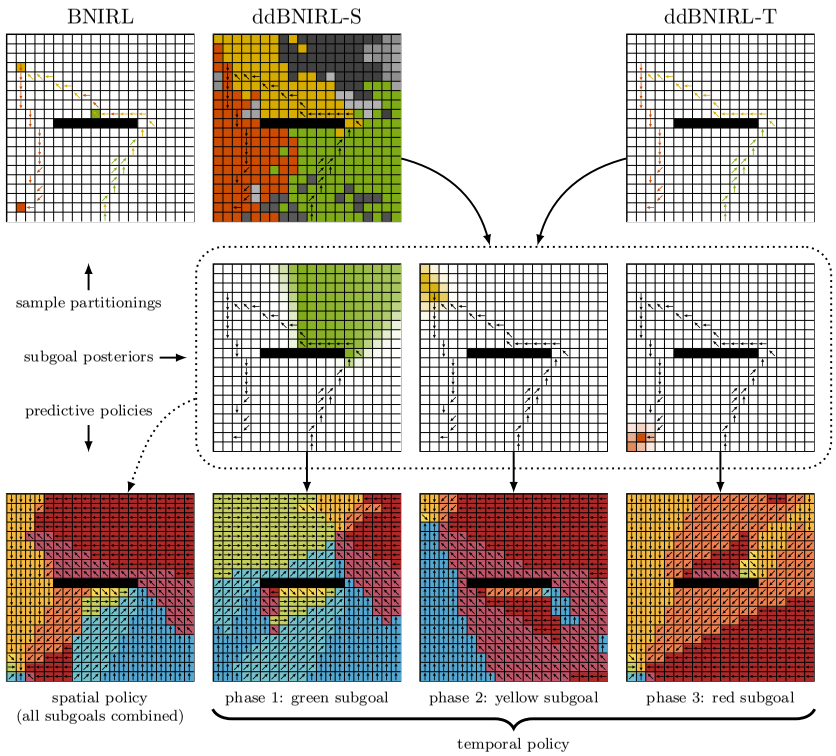

Figure 8: Results on the BNIRL data set (Michini and How, 2012). **Top row:** demonstration data and sample partitionings generated by the different inference algorithms. **Center row:** subgoal posterior distributions associated with the partitions found by ddBNIRL-S and ddBNIRL-T. For a clearer overview, the corresponding BNIRL distributions are omitted (see Figure 6 for a comparison). **Bottom row:** time-invariant ddBNIRL-S policy model synthesized from all three detected subgoals (left) and temporal phases identified by ddBNIRL-T (right). The background colors have no particular meaning and were added only to highlight the structures of the policies. Because of its missing generalization mechanism, BNIRL does not itself provide a reasonable predictive policy model (Limitation 1).

(ii) Exploiting the spatial/temporal context of the data, the ddBNIRL solution is inherently robust to demonstration noise, giving rise to notably smoother partitioning structures (top row). This effect is particularly pronounced in the case of real data, as we shall see later in Section 5.3.2.

(iii) For each state partition or trajectory segment, we obtain an implicit representation of the associated subgoal in the form of a posterior distribution, without the need of assigning point estimates (center row). It is striking that the posterior distribution corresponding to the green state partition has a comparably large spread on the upper side of the wall. This can be explained intuitively by the fact that any subgoal located in this high posterior region could have potentially caused the green state sequence, which circumvents the wall from the right. At the same time, the green area of high posterior values exhibits a sharp boundary on the left side since a subgoal located in the upper left region of the state space would have more likely resulted in a trajectory approaching from the left.

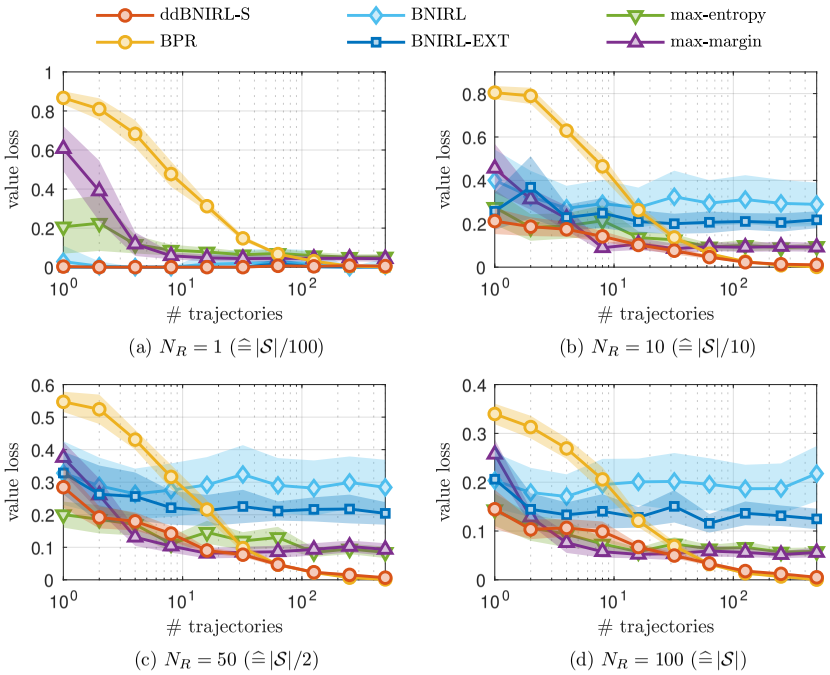
(iv) In contrast to BNIRL, which has no built-in generalization mechanism (Limitation 1), our method returns a predictive policy model comprising the full posterior action information at all states. Note that we only show the resulting MAP policy estimates here (bottom row), computed according to Equation (14). Additional results concerning the posterior uncertainty are provided in Sections 5.3 and 5.4.

The example illustrates how the synthesis of the predictive policy differs between ddBNIRL-S (bottom left) and ddBNIRL-T (bottom row, rightmost three subfigures). While ddBNIRL-T uses a set of (conditionally) independent policy models to describe the different identified behavioral phases, ddBNIRL-S maps the entire subgoal schedule onto a single time-invariant policy representation. Looking closer at the learned models, we recognize that the ddBNIRL-S solution in fact realizes a spatial combination of the three temporal ddBNIRL-T components, where each component is activated in the corresponding cluster region of the state space. This gives us two alternative interpretations of the same behavior.

5.2 Random MDP Scenario

Our next experiment is designed to provide insights into the generalization abilities of the framework. For this purpose, we consider a class of randomly generated MDPs similar to the Garnet problems (Bhatnagar et al., 2009). The transition dynamics $\{T(\cdot \mid s, a)\}$ are sampled independently from a symmetric Dirichlet distribution with a concentration parameter of 0.01, where we choose $|\mathcal{S}| = 100$ and $|\mathcal{A}| = 10$. For each repetition of the experiment, N_R states are selected uniformly at random and assigned rewards that are, in turn, sampled uniformly from the interval $[0, 1]$. All other states contain zero reward. Next, we compute an optimal deterministic MDP policy π^* with respect to a discount factor of $\gamma = 0.9$ and generate a number of expert trajectories of length 10. Herein, we let the expert select the optimal action with probability 0.9 and a random, suboptimal action with probability 0.1. The obtained state sequences are passed to the algorithms and we compute the normalized value loss of the reconstructed policies according to

$$\mathrm{L}(\pi^*, \hat{\pi}) := \frac{\|\mathbf{V}^* - \mathbf{V}^{\hat{\pi}}\|_2}{\|\mathbf{V}^*\|_2}, \tag{20}$$



(a) $N_R = 1$ ($\widehat{=}\,|\mathcal{S}|/100$) (b) $N_R = 10$ ($\widehat{=}\,|\mathcal{S}|/10$)

(c) $N_R = 50$ ($\widehat{=}\,|\mathcal{S}|/2$) (d) $N_R = 100$ ($\widehat{=}\,|\mathcal{S}|$)

Figure 9: Comparison of all inference methods in the random MDP scenario for different reward densities. Shown are the empirical mean values and standard deviations of the resulting value losses, obtained from 100 Monte Carlo runs. The graphs show a clear difference between BNIRL, BNIRL-EXT and ddBNIRL-S, which illustrates the importance of considering the spatial context for subgoal extraction.

where $\mathbf{V}^*$ and $\mathbf{V}^{\hat{\pi}}$ represent, respectively, the vectorized value functions of the optimal policy π^* and the reconstruction $\hat{\pi}$.

Since the considered system belongs to the class of time-invariant MDPs, ddBNIRL-S lends itself as the natural choice to model the expert behavior. As baseline methods, we adopt our subintentional Bayesian policy recognition framework (BPR, Šošić et al., 2018b), as well as maximum-margin IRL (Abbeel and Ng, 2004), maximum-entropy IRL (Ziebart et al., 2008), and vanilla BNIRL. Due to the missing generalization abilities of BNIRL (Limitation 1) and because the waypoint method (Section 2.2) does not straightforwardly apply to the considered scenario of multiple unaligned trajectories, we further compare our algorithm to an extension of BNIRL, which we refer to as BNIRL-EXT. Mimicking the ddBNIRL-S principle, the method accounts for the spatial context of the demonstrations

by assigning each state to the BNIRL subgoal that is targeted by the closest (see metric in Section 3.2.1) state-action pair — however, these assignments are made *after* the actual subgoal inference. When compared to ddBNIRL-S, this provides a reference of how much can be gained by considering the spatial relationship of the data *during* the inference. For the experiment, both ddBNIRL-S and BNIRL(-EXT) are augmented with their corresponding action sampling stages (Section 4.4) since the action sequences of the expert are discarded from the data set, in order to enable a fair comparison to the remaining algorithms.

Figure 9 shows the value loss over the size of the demonstration set for different reward settings. For small N_R, both BNIRL(-EXT) and ddBNIRL-S significantly outperform the reference methods. This is because the sparse reward structure allows for an efficient subgoal-based encoding of the expert behavior, which enables the algorithms to reconstruct the policy even from minimal amounts of demonstration data. However, the BNIRL(-EXT) solutions drastically deteriorate for denser reward structures. In particular, we observe a clear difference in performance between the cases where

(i) we do not account for the spatial information in the partitioning model (BNIRL),

(ii) include it in a post-processing step (BNIRL-EXT), and

(iii) exploit it during the inference itself (ddBNIRL-S),

which demonstrates the importance of processing the context information. Most tellingly, ddBNIRL-S outperforms the baseline methods even in the dense reward regimes, although the subgoal-based encoding loses its efficiency here. In fact, the results reveal that the proposed approach combines the merits of both model types, i.e., the sample efficiency of the intentional models (max-margin/max-entropy) required for small data set sizes, as well as the asymptotic accuracy and fully probabilistic nature of the subintentional Bayesian framework (BPR).[4]

5.3 Robot Experiment

In the next experiment, we test the ddBNIRL framework on various real data sets, which we recorded on a KUKA lightweight robotic arm (Figure 10) via kinesthetic teaching. Videos of all demonstrated tasks can be found at `http://www.spg.tu-darmstadt.de/jmlr2018`.

The system has seven degrees of freedom, corresponding to the seven joints of the arm. Each joint is equipped with a torque sensor and an angle encoder, providing recordings of joint angles, velocities and accelerations. For our experiments, we only consider the xy-Cartesian coordinates spanning the transverse plane, which we computed from the raw measurements using a forward kinematic model. The data was recorded at a sampling rate of 50 Hz and further downsampled by a factor of 10, yielding an effective sample rate of 5 Hz, which provided a sufficient temporal resolution for the considered scenario.

The goal of the experiment is to learn a set of high-level intentional models for the recorded behavior types by partitioning the data sets into meaningful parts that can be used to predict the desired motion direction of the expert. For simplicity and to demonstrate the

4. The comparably large loss of BPR for small data set sizes can be explained by the fact that the framework is based on a more general policy model in which the expert behavior is assumed to be *inherently* stochastic, in contrast to the here considered setting where stochasticity arises merely a consequence of suboptimal decision-making.

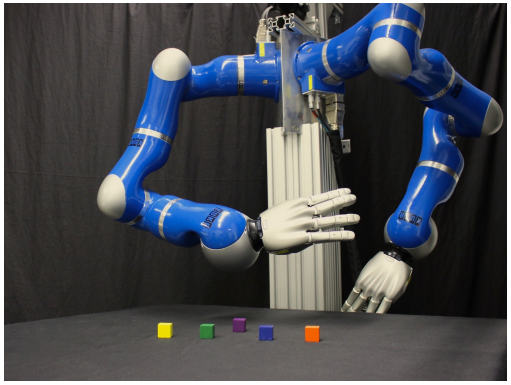


Figure 10: KUKA lightweight robotic arm.

algorithm's robustness to modeling errors, we adopt the simplistic transition model from Section 5.1 with the same action set containing the eight (inter-)cardinal motion directions. The high measurement accuracy of the end-effector position allows us to extract these high-level actions directly from the raw data, i.e., by selecting the directions with the smallest angular deviations from the ground truth (see example in Figure 11a). The underlying state space is obtained by discretizing the part of the coordinate range that is covered by the measurements into blocks of predefined size (see next sections for details). Apart from this discretization step and the aforementioned data downsampling, no preprocessing is applied.

5.3.1 Spatial Partitioning

First, we consider a case where the expert behavior can be described using a time-invariant policy model, which we aspire to capture via ddBNIRL-S. For our example, we consider the "Cycle" task shown in the video and in Figure 14. The same setting is analyzed using the time-variant ddBNIRL-T model in Section 5.3.2, which allows a direct comparison of the two approaches. The task consists in approaching a number of target positions, indicated by a set of markers (see video), before eventually returning to the initial state. The setting can be regarded as a real-world version of the "Loop" problem described by Michini and How (2012). As explained in their paper, classical IRL algorithms that rely on a global state-based reward model (such as max-margin IRL and max-entropy IRL) completely fail on this problem, due to the periodic nature of the task.

Figure 11a shows the downsampled and discretized data set (black arrows) obtained from four expert trajectories (white lines). For visualization purposes, the discretization block size is chosen as $2\,\mathrm{cm} \times 2\,\mathrm{cm}$, giving rise to a total of $18 \times 24 = 432$ states. As in the top row of Figure 8 (ddBNIRL-S), the coloring of the background indicates the learned partitioning structure, computed from a low-temperature posterior sample. We observe that the found state clusters clearly reveal the modular structure of the task, providing an intuitive and interpretable explanation of the data. However, although the induced policy

Dark background indicates high uncertainty. (d) Illustration of the final predictive model, comprising both the action information and the prediction uncertainty.

model (Figure 11b) smoothly captures the cyclic nature of the task, we cannot expect to obtain trustworthy predictions in the center region of the state space, due to the lack of additional demonstration data that would be required to unveil the expert's true intention in that region. Clearly, a point estimate such as the shown MAP policy cannot reflect this prediction uncertainty since it does not carry any confidence information. Yet, following a Bayesian approach, we can naturally quantify the prediction uncertainty at any query state s^* based on the shape of the corresponding posterior predictive action distribution $p(a^* \mid s^*, \mathcal{D})$. A straightforward option is, for example, to consider the prediction entropy,

defined as

$$H(s^*) \coloneqq \sum_{a^* \in \mathcal{A}} p(a^* \mid s^*, \mathcal{D}) \log p(a^* \mid s^*, \mathcal{D}).$$

In order to obtain an unbiased approximation of the true *non-tempered* predictive distribution $p(a^* \mid s^*, \mathcal{D})$, we run a second Gibbs chain with unaltered temperature in parallel to the tempered chain. The resulting entropy estimates are summarized in an uncertainty map (Figure 11c), which we overlaid on the original prediction result to produce the final figure shown at the bottom right. Note that the obtained posterior uncertainty information of the model can be further used in an active learning setting, as demonstrated in Section 5.4.

5.3.2 Temporal Partitioning

Next, we turn our attention to the ddBNIRL-T model, which we test against the vanilla BNIRL approach. For this purpose, we consider the full collection of tasks shown in the supplementary video, which comprises different time-dependent expert behaviors of varying complexity. In order to obtain a quantitative performance measure for our evaluation, we conducted a manual segmentation of all recorded trajectories, thereby creating a set of ground truth subgoal labels for all observed decision times. The result of this segmentation step is depicted in the appendix (Figure 14, center column). Note that the ground truth subgoals are assumed immediately at the ends of the corresponding segments.

The left and right column of Figure 14 show, respectively, the partitioning structures found by BNIRL and ddBNIRL-T, based on a uniform subgoal prior distribution with support at the visited states. The underlying state discretization block size is chosen as $1\,\mathrm{cm} \times 1\,\mathrm{cm}$, as indicated by the regular grid in the background. A simple visual comparison of the learned structures reveals the clear superiority of ddBNIRL-T over vanilla BNIRL on this problem set.

For our quantitative comparison, we consider the instantaneous subgoal localization errors of the two models over the entire course of a demonstration (Figure 12). Herein, the instantaneous localization error for a given state-action pair is measured in terms of the Euclidean distance between the grid location of the ground truth subgoal associated with the pair and the corresponding subgoal location predicted by the model. Note that the predictions of both models are based on the *entire* trajectory data of an experiment, considering the full posterior information after completing the demonstration. For ddBNIRL-T, which does not directly return a subgoal location estimate but instead provides access to the full subgoal posterior distribution, the error is computed with respect to the MAP subgoal locations $\{\hat{g}_k\}$,

$$\hat{g}_k \coloneqq \operatorname*{arg\,max}_{g_k \in \mathrm{supp}(p_g)} p(g_k \mid \mathcal{D}, \tilde{\mathbf{c}}),$$

using the ddBNIRL-T version of Equation (12) — see note at the beginning of Section 4.

The black dots in the figure indicate the time instants where the ground truth annotations change. At those time instants, we observe significantly increased localization errors for both models, which can be explained by the fact that the ground truth annotation is somewhat subjective around the switching points (see labeling in Figure 14). Also, we notice a comparably high error at the beginning and the end of some trajectories, which stems from the imperfect synchronization between the recording interval and the execution

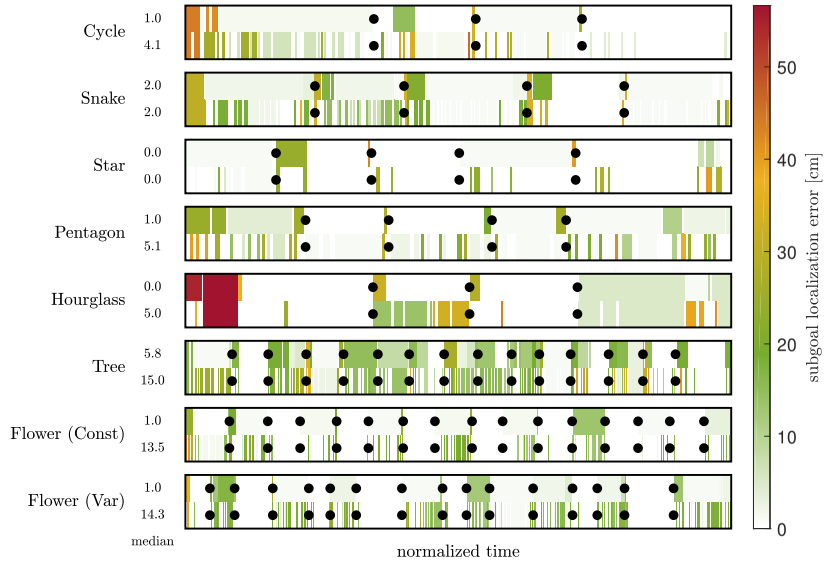

Figure 12: Instantaneous subgoal localization errors of ddBNIRL-T (upper rows) and BNIRL (lower rows) for the eight recorded data sets. The black dots indicate the subgoal switching times in the corresponding ground truth subgoal annotation, depicted in the center column of Figure 14. On average, the localization error of ddBNIRL-T is significantly lower compared to the BNIRL approach, as indicated by the median values shown on the left. For a qualitative comparison of the underlying partitioning structures, see Appendix A.

of the task (recall that we skipped the corresponding data preprocessing step). Hence, to capture the accuracy in a single figure of performance, we consider the median localization error of each time series, as it masks out these outliers and provides a more realistic error quantification than the sample mean. The obtained values are shown next to the error plots in Figure 12, indicating that the ddBNIRL-T localization error is in the range of the discretization interval in most cases. *Compared to BNIRL, the proposed method yields an error reduction of more than 70% on average.*

5.4 Active Learning

In Section 5.3, we saw that the posterior predictive action distribution $p(a^* \mid s^*, \mathcal{D})$ provides a natural way to quantify the prediction uncertainty of our model at any given query state s^*. This offers the opportunity to apply the framework in an active learning setting, since the

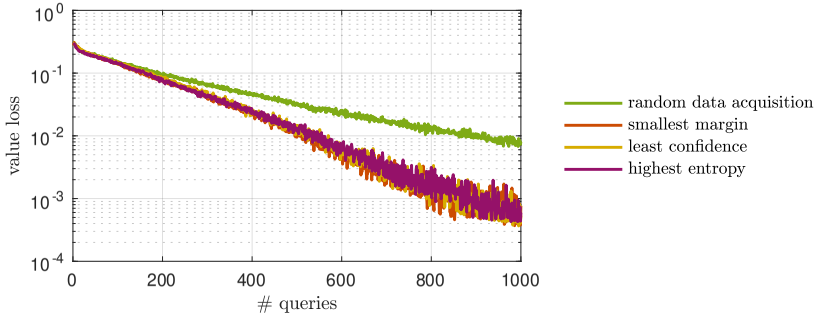

Figure 13: Comparison between random data acquisition and active learning in the random MDP scenario. Shown are the empirical mean value losses of the obtained policy models over the number of data queries, obtained from 200 Monte Carlo runs.

induced uncertainty map (see example in Figure 11c) indicates in which parts of the state space the trained model can process further instructions from the expert most effectively.

To demonstrate the basic procedure, we reconsider the random MDP problem from Section 5.2 in an active learning context, where we compare different active strategies with the previously used random data acquisition scheme. As an initialization for the learning procedure, we request a single state-action pair (s_1, a_1) from the demonstrator, which we store in the initial data set $\mathcal{D}_1 \coloneqq \{(s_1, a_1)\}$. Herein, the state s_1 is drawn uniformly at random from $\mathcal{S}$ and the action $a_1 \sim \pi_E(a \,|\, s_1)$ is generated according to the noisy expert policy $\pi_E : \mathcal{A} \times \mathcal{S} \to [0, 1]$ described in Section 5.2. Continuing from this point, each of the considered active learning algorithms requests a series of subsequent demonstrations $((s_2, a_2), (s_3, a_3), \ldots)$, inducing a sequence of data sets $(\mathcal{D}_1, \mathcal{D}_2, \mathcal{D}_3, \ldots)$, where the next query state s_{d+1} is chosen according to the specific data acquisition criterion f_{acq} of the algorithm evaluated on the current predictive model,

$$\begin{aligned} \mathcal{D}_{d+1} &= \mathcal{D}_d \cup \{(s_{d+1}, a_{d+1})\} \\ s_{d+1} &= \operatorname*{arg\,max}_{s^* \in \mathcal{S}} f_{\text{acq}}\big[p(a^* \,|\, s^*, \mathcal{D}_d)\big] \\ a_{d+1} &\sim \pi_E(a \,|\, s_{d+1}). \end{aligned}$$

The purpose of the acquisition criterion is to assess the uncertainty of the model at all possible query states, so that the next demonstration can be requested in the high uncertainty region of the state space (see *uncertainty sampling*, Settles, 2010). For our experiment, we consider the following three common choices,

- highest entropy: $f_{\text{acq}}(p) \coloneqq -\sum_{a \in \mathcal{A}} p(a) \log p(a)$,
- least confidence: $f_{\text{acq}}(p) \coloneqq 1 - \max_{a \in \mathcal{A}} p(a)$,
- smallest margin: $f_{\text{acq}}(p) \coloneqq p(\hat{a}_2) - p(\hat{a}_1)$,

where $\hat{a}_1$ and $\hat{a}_2$ denote, respectively, the most likely and second most likely action according to the considered distribution p, i.e., $\hat{a}_1 \coloneqq \arg\max_{a \in \mathcal{A}} p(a)$ and $\hat{a}_2 \coloneqq \arg\max_{a \in \mathcal{A} \setminus \hat{a}_1} p(a)$. At each iteration, we compute the value losses (Equation 20) of the induced policy models and compare them with the corresponding loss obtained from random data acquisition. The resulting curves are delineated in Figure 13. As expected, the learning speed of the model is significantly improved under all active acquisition schemes, which reduces the number of expert demonstrations required to successfully learn the observed task.

6. Conclusion

Building upon the principle of Bayesian nonparametric inverse reinforcement learning, we proposed a new framework for data-efficient IRL that leverages the context information of the demonstration set to learn a predictive model of the expert behavior from small amounts of training data. Central to our framework are two model architectures, one designed for learning spatial subgoal plans, the other to capture time-varying intentions. In contrast to the original BNIRL model, both architectures explicitly consider the covariate information contained in the demonstration set, giving rise to predictive models that are inherently robust to demonstration noise. While the original BNIRL model can be recovered as a special case of our framework, the conducted experiments show a drastic improvement over the vanilla BNIRL approach in terms of the achieved subgoal localization accuracy, which stems from both an improved likelihood model and a context-aware clustering of the data. Most notably, our framework outperforms all tested reference methods in the analyzed benchmark scenarios while it additionally captures the full posterior information about the learned subgoal representation. The resulting prediction uncertainty about the expert behavior, reflected by the posterior predictive action distribution, provides a natural basis to apply our method in an active learning setting where the learning system can request additional demonstration data from the expert.

The current limitation of our approach is that both presented architectures require an MDP model with discrete state and action space. While the subgoal principle carries over straightforwardly to continuous metric spaces, the construction of the likelihood model becomes difficult in these environments as it requires knowledge of the optimal state-action value functions for all potential subgoal locations. However, for BNIRL, there exist several ways to approximate the likelihood in these cases (Michini et al., 2013) and the same concepts apply equally to ddBNIRL. Thus, an interesting future study would be to compare the efficacy of both model types on larger problems involving continuous spaces, where it appears even more natural to follow a distance-based approach.

Abstract

We examine gradient descent on unregularized logistic regression problems, with homogeneous linear predictors on linearly separable datasets. We show the predictor converges to the direction of the max-margin (hard margin SVM) solution. The result also generalizes to other monotone decreasing loss functions with an infimum at infinity, to multi-class problems, and to training a weight layer in a deep network in a certain restricted setting. Furthermore, we show this convergence is very slow, and only logarithmic in the convergence of the loss itself. This can help explain the benefit of continuing to optimize the logistic or cross-entropy loss even after the training error is zero and the training loss is extremely small, and, as we show, even if the validation loss increases. Our methodology can also aid in understanding implicit regularization in more complex models and with other optimization methods.

Keywords: gradient descent, implicit regularization, generalization, margin, logistic regression

1. Introduction

It is becoming increasingly clear that implicit biases introduced by the optimization algorithm play a crucial role in deep learning and in the generalization ability of the learned models (Neyshabur et al., 2014, 2015; Zhang et al., 2017; Keskar et al., 2017; Neyshabur et al., 2017; Wilson et al., 2017). In particular, minimizing the training error, without explicit regularization, over models with more parameters and capacity than the number of training examples, often yields good generalization. This is despite the fact that the empirical optimization problem being highly underdetermined. That is, there are many global minima of the training objective, most of which will not generalize well, but the optimization algorithm (*e.g.* gradient descent) biases us toward a particular minimum that *does* generalize well. Unfortunately, we still do not have a good understanding of the biases introduced by different optimization algorithms in different situations.

We do have an understanding of the implicit regularization introduced by early stopping of stochastic methods or, at an extreme, of one-pass (no repetition) stochastic gradient descent (Hardt et al., 2016). However, as discussed above, in deep learning we often benefit from implicit bias even when optimizing the training error to convergence (without early stopping) using stochastic or batch methods. For loss functions with attainable, finite minimizers, such as the squared loss, we have some understanding of this: in particular, when minimizing an underdetermined least squares problem using gradient descent starting from the origin, it can be shown that we will converge to the minimum Euclidean norm solution. However, the logistic loss, and its generalization the cross-entropy loss which is often used in deep learning, do not admit finite minimizers on separable problems. Instead, to drive the loss toward zero and thus minimize it, the norm of the predictor must diverge toward infinity.

Do we still benefit from implicit regularization when minimizing the logistic loss on separable data? Clearly the norm of the predictor itself is not minimized, since it grows to infinity. However, for prediction, only the direction of the predictor, *i.e.* the normalized $\mathbf{w}(t)/\left\|\mathbf{w}(t)\right\|$, is important. How does $\mathbf{w}(t)/\left\|\mathbf{w}(t)\right\|$ behave as $t\to\infty$ when we minimize the logistic (or similar) loss using gradient descent on separable data, *i.e.*, when it is possible to get zero misclassification error and thus drive the loss to zero?

In this paper, we show that even without any explicit regularization, for all linearly separable datasets, when minimizing logistic regression problems using gradient descent, we have that $\mathbf{w}(t)/\left\|\mathbf{w}(t)\right\|$ converges to the L_2 maximum margin separator, *i.e.* to the solution of the hard margin SVM for homogeneous linear predictors. This happens even though neither the norm $\|\mathbf{w}\|$, nor the margin constraint, are part of the objective or explicitly introduced into optimization. More generally, we show the same behavior for generalized linear problems with any smooth, monotone strictly decreasing, lower bounded loss with an exponential tail. Furthermore, we characterize the rate of this convergence, and show that it is rather slow, wherein for almost all datasets, the distance to the max-margin predictor decreasing only as $O(1/\log(t))$, and in some degenerate datasets, the rate further slows down to $O(\log\log(t)/\log(t))$. This explains why the predictor continues to improve even when the training loss is already extremely small. We emphasize that this bias is specific to gradient descent, and changing the optimization algorithm, *e.g.* using adaptive learning rate methods such as ADAM (Kingma and Ba, 2015), changes this implicit bias.

2. Main Results

Consider a dataset $\{\mathbf{x}_n, y_n\}_{n=1}^N$, with $\mathbf{x}_n\in\mathbb{R}^d$ and binary labels $y_n\in\{-1,1\}$. We analyze learning by minimizing an empirical loss of the form

$$\mathcal{L}\left(\mathbf{w}\right)=\sum_{n=1}^{N}\ell\left(y_n\mathbf{w}^\top\mathbf{x}_n\right). \tag{1}$$

where $\mathbf{w}\in\mathbb{R}^d$ is the weight vector. To simplify notation, we assume that all the labels are positive: $\forall n:\ y_n=1$ — this is true without loss of generality, since we can always re-define $y_n\mathbf{x}_n$ as $\mathbf{x}_n$.

We are particularly interested in problems that are linearly separable, and the loss is smooth strictly decreasing and non-negative:

Assumption 1 *The dataset is linearly separable:* $\exists\mathbf{w}_*$ *such that* $\forall n:\ \mathbf{w}_*^\top\mathbf{x}_n>0$.

Assumption 2 $\ell\left(u\right)$ *is a positive, differentiable, monotonically decreasing to zero*[1]*, (so* $\forall u:\ \ell\left(u\right)>0, \ell'\left(u\right)<0$, $\lim_{u\to\infty}\ell\left(u\right)=\lim_{u\to\infty}\ell'\left(u\right)=0$*), a* β*-smooth function,* i.e. *its derivative is* β*-Lipshitz and* $\lim_{u\to-\infty}\ell'\left(u\right)\neq 0$.

1. The requirement of non-negativity and that the loss asymptotes to zero is purely for convenience. It is enough to require the loss is monotone decreasing and bounded from below. Any such loss asymptotes to some constant, and is thus equivalent to one that satisfies this assumption, up to a shift by that constant.

Assumption 2 includes many common loss functions, including the logistic, exp-loss[2] and probit losses. Assumption 2 implies that $\mathcal{L}(\mathbf{w})$ is a $\beta\sigma_{\max}^2(\mathbf{X})$-smooth function, where $\sigma_{\max}(\mathbf{X})$ is the maximal singular value of the data matrix $\mathbf{X} \in \mathbb{R}^{d\times N}$.

Under these conditions, the infimum of the optimization problem is zero, but it is not attained at any finite $\mathbf{w}$. Furthermore, no finite critical point $\mathbf{w}$ exists. We consider minimizing eq. 1 using Gradient Descent (GD) with a fixed learning rate η, *i.e.,* with steps of the form:

$$\mathbf{w}(t+1) = \mathbf{w}(t) - \eta\nabla\mathcal{L}(\mathbf{w}(t)) = \mathbf{w}(t) - \eta\sum_{n=1}^{N}\ell'\left(\mathbf{w}(t)^\top\mathbf{x}_n\right)\mathbf{x}_n. \tag{2}$$

We do not require convexity. Under Assumptions 1 and 2, gradient descent converges to the global minimum (*i.e.* to zero loss) even without it:

Lemma 1 *Let $\mathbf{w}(t)$ be the iterates of gradient descent (eq. 2) with $\eta < 2\beta^{-1}\sigma_{\max}^{-2}(\mathbf{X})$ and any starting point $\mathbf{w}(0)$. Under Assumptions 1 and 2, we have: (1) $\lim_{t\to\infty}\mathcal{L}(\mathbf{w}(t)) = 0$, (2) $\lim_{t\to\infty}\|\mathbf{w}(t)\| = \infty$, and (3) $\forall n : \lim_{t\to\infty}\mathbf{w}(t)^\top\mathbf{x}_n = \infty$.*

Proof Since the data is linearly separable, $\exists\mathbf{w}_*$ which linearly separates the data, and therefore

$$\mathbf{w}_*^\top\nabla\mathcal{L}(\mathbf{w}) = \sum_{n=1}^{N}\ell'\left(\mathbf{w}^\top\mathbf{x}_n\right)\mathbf{w}_*^\top\mathbf{x}_n.$$

For any finite $\mathbf{w}$, this sum cannot be equal to zero, as a sum of negative terms, since $\forall n : \mathbf{w}_*^\top\mathbf{x}_n > 0$ and $\forall u : \ell'(u) < 0$. Therefore, there are no finite critical points $\mathbf{w}$, for which $\nabla\mathcal{L}(\mathbf{w}) = \mathbf{0}$. But gradient descent on a smooth loss with an appropriate stepsize is always guaranteed to converge to a critical point: $\nabla\mathcal{L}(\mathbf{w}(t)) \to \mathbf{0}$ (see, *e.g.* Lemma 10 in Appendix A.4, slightly adapted from Ganti (2015), Theorem 2). This necessarily implies that $\|\mathbf{w}(t)\| \to \infty$ while $\forall n : \mathbf{w}(t)^\top\mathbf{x}_n > 0$ for large enough t—since only then $\ell'\left(\mathbf{w}(t)^\top\mathbf{x}_n\right) \to 0$. Therefore, $\mathcal{L}(\mathbf{w}) \to 0$, so GD converges to the global minimum. ■

The main question we ask is: can we characterize the direction in which $\mathbf{w}(t)$ diverges? That is, does the limit $\lim_{t\to\infty}\mathbf{w}(t)/\|\mathbf{w}(t)\|$ always exist, and if so, what is it?

In order to analyze this limit, we will need to make a further assumption on the tail of the loss function:

Definition 2 *A function $f(u)$ has a "tight exponential tail", if there exist positive constants c, a, μ_+, μ_-, u_+ and u_- such that*

$$\forall u > u_+ : f(u) \le c\left(1+\exp\left(-\mu_+ u\right)\right)e^{-au}$$
$$\forall u > u_- : f(u) \ge c\left(1-\exp\left(-\mu_- u\right)\right)e^{-au}.$$

Assumption 3 *The negative loss derivative $-\ell'(u)$ has a tight exponential tail (Definition 2).*

For example, the exponential loss $\ell(u) = e^{-u}$ and the commonly used logistic loss $\ell(u) = \log(1+e^{-u})$ both follow this assumption with $a = c = 1$. We will assume $a = c = 1$ — without loss of generality, since these constants can be always absorbed by re-scaling $\mathbf{x}_n$ and η.

We are now ready to state our main result:

2. The exp-loss does not have a global β smoothness parameter. However, if we initialize with $\eta < 1/\mathcal{L}(\mathbf{w}(0))$ then it is straightforward to show the gradient descent iterates maintain bounded local smoothness.

Theorem 3 *For any dataset which is linearly separable (Assumption 1), any β-smooth decreasing loss function (Assumption 2) with an exponential tail (Assumption 3), any stepsize $\eta < 2\beta^{-1}\sigma_{\max}^{-2}(\mathbf{X})$ and any starting point $\mathbf{w}(0)$, the gradient descent iterates (as in eq. 2) will behave as:*

$$\mathbf{w}(t) = \hat{\mathbf{w}}\log t + \boldsymbol{\rho}(t)\ , \tag{3}$$

where $\hat{\mathbf{w}}$ is the L_2 max margin vector (the solution to the hard margin SVM):

$$\hat{\mathbf{w}} = \underset{\mathbf{w}\in\mathbb{R}^d}{\operatorname{argmin}}\|\mathbf{w}\|^2 \ \text{ s.t. } \mathbf{w}^\top\mathbf{x}_n \ge 1, \tag{4}$$

and the residual grows at most as $\|\boldsymbol{\rho}(t)\| = O(\log\log(t))$, and so

$$\lim_{t\to\infty}\frac{\mathbf{w}(t)}{\|\mathbf{w}(t)\|} = \frac{\hat{\mathbf{w}}}{\|\hat{\mathbf{w}}\|}.$$

Furthermore, for almost all data sets (all except measure zero), the residual $\rho(t)$ is bounded.

Proof Sketch We first understand intuitively why an exponential tail of the loss entail asymptotic convergence to the max margin vector: Assume for simplicity that $\ell(u) = e^{-u}$ exactly, and examine the asymptotic regime of gradient descent in which $\forall n : \mathbf{w}(t)^\top\mathbf{x}_n \to \infty$, as is guaranteed by Lemma 1. If $\mathbf{w}(t)/\|\mathbf{w}(t)\|$ converges to some limit $\mathbf{w}_\infty$, then we can write $\mathbf{w}(t) = g(t)\mathbf{w}_\infty + \boldsymbol{\rho}(t)$ such that $g(t) \to \infty$, $\forall n : \mathbf{x}_n^\top\mathbf{w}_\infty > 0$, and $\lim_{t\to\infty}\boldsymbol{\rho}(t)/g(t) = 0$. The gradient can then be written as:

$$-\nabla\mathcal{L}(\mathbf{w}) = \sum_{n=1}^{N}\exp\left(-\mathbf{w}(t)^\top\mathbf{x}_n\right)\mathbf{x}_n = \sum_{n=1}^{N}\exp\left(-g(t)\mathbf{w}_\infty^\top\mathbf{x}_n\right)\exp\left(-\boldsymbol{\rho}(t)^\top\mathbf{x}_n\right)\mathbf{x}_n\ . \tag{5}$$

As $g(t) \to \infty$ and the exponents become more negative, only those samples with the largest (*i.e.*, least negative) exponents will contribute to the gradient. These are precisely the samples with the smallest margin $\operatorname{argmin}_n\mathbf{w}_\infty^\top\mathbf{x}_n$, aka the "support vectors". The negative gradient (eq. 5) would then asymptotically become a non-negative linear combination of support vectors. The limit $\mathbf{w}_\infty$ will then be dominated by these gradients, since any initial conditions become negligible as $\|\mathbf{w}(t)\| \to \infty$ (from Lemma 1). Therefore, $\mathbf{w}_\infty$ will also be a non-negative linear combination of support vectors, and so will its scaling $\hat{\mathbf{w}} = \mathbf{w}_\infty/\left(\min_n\mathbf{w}_\infty^\top\mathbf{x}_n\right)$. We therefore have:

$$\hat{\mathbf{w}} = \sum_{n=1}^{N}\alpha_n\mathbf{x}_n \qquad \forall n\ \left(\alpha_n \ge 0 \text{ and } \hat{\mathbf{w}}^\top\mathbf{x}_n = 1\right)\ \text{OR}\ \left(\alpha_n = 0 \text{ and } \hat{\mathbf{w}}^\top\mathbf{x}_n > 1\right) \tag{6}$$

These are precisely the KKT conditions for the SVM problem (eq. 4) and we can conclude that $\hat{\mathbf{w}}$ is indeed its solution and $\mathbf{w}_\infty$ is thus proportional to it.

To prove Theorem 3 rigorously, we need to show that $\mathbf{w}(t)/\|\mathbf{w}(t)\|$ has a limit, that $g(t) = \log(t)$ and to bound the effect of various residual errors, such as gradients of non-support vectors and the fact that the loss is only approximately exponential. To do so, we substitute eq. 3 into the gradient descent dynamics (eq. 2), with $\mathbf{w}_\infty = \hat{\mathbf{w}}$ being the max margin vector and $g(t) = \log t$. We then show that, except when certain degeneracies occur, the increment in the norm of $\boldsymbol{\rho}(t)$ is bounded by $C_1 t^{-\nu}$ for some $C_1 > 0$ and $\nu > 1$, which is a converging series. This happens because the increment in the max margin term, $\hat{\mathbf{w}}\left[\log(t+1) - \log(t)\right] \approx \hat{\mathbf{w}}t^{-1}$, cancels out the dominant t^{-1} term in the gradient $-\nabla\mathcal{L}(\mathbf{w}(t))$ (eq. 5 with $g(t) = \log(t)$ and $\mathbf{w}_\infty^\top\mathbf{x}_n = 1$).

Degenerate and Non-Degenerate Data Sets An earlier conference version of this paper (Soudry et al., 2018) included a partial version of Theorem 3, which only applies to almost all data sets, in which case we can ensure the residual $\rho(t)$ is bounded. This partial statement (for almost all data sets) is restated and proved as Theorem 9 in Appendix A. It applies, *e.g.* with probability one for data sampled from any absolutely continuous distribution. It does not apply in "degenerate" cases where some of the support vectors $\mathbf{x}_n$ (for which $\hat{\mathbf{w}}^\top \mathbf{x}_n = 1$) are associated with dual variables that are zero ($\alpha_n = 0$) in the dual optimum of 4. As we show in Appendix B, this only happens on measure zero data sets. Here, we prove the more general result which applies for all data sets, including degenerate data sets. To do so, in Theorem 13 in Appendix C we provide a more complete characterization of the iterates $\mathbf{w}(t)$ that explicitly specifies all unbounded components even in the degenerate case. We then prove the Theorem by plugging in this more complete characterization and showing that the residual is bounded, thus also establishing Theorem 3.

Parallel Work on the Degenerate Case Following the publication of our initial version, and while preparing this revised version for publication, we learned of parallel work by Ziwei Ji and Matus Telgarsky that also closes this gap. Ji and Telgarsky (2018) provide an analysis of the degenerate case, establishing converges to the max margin predictor by showing that $\left\| \frac{\mathbf{w}(t)}{\|\mathbf{w}(t)\|} - \frac{\hat{\mathbf{w}}}{\|\hat{\mathbf{w}}\|} \right\| = O\left(\sqrt{\frac{\log\log t}{\log t}}\right)$. Our analysis provides a more precise characterization of the iterates, and also shows the convergence is actually quadratically faster (see Section 3). However, Ji and Telgarsky go even further and provide a characterization also when the data is non-separable but $\mathbf{w}(t)$ still goes to infinity.

More Refined Analysis of the Residual In some non-degenerate cases, we can further characterize the asymptotic behavior of $\boldsymbol{\rho}(t)$. To do so, we need to refer to the KKT conditions (eq. 6) of the SVM problem (eq. 4) and the associated support vectors $\mathcal{S} = \operatorname{argmin}_n \hat{\mathbf{w}}^\top \mathbf{x}_n$. We then have the following Theorem, proved in Appendix A:

Theorem 4 *Under the conditions and notation of Theorem 3, for almost all datasets, if in addition the support vectors span the data (*i.e. $\operatorname{rank}(\mathbf{X}_\mathcal{S}) = \operatorname{rank}(\mathbf{X})$*, where $\mathbf{X}_\mathcal{S}$ is a matrix whose columns are only those data points $\mathbf{x}_n$ s.t. $\hat{\mathbf{w}}^\top \mathbf{x}_n = 1$), then $\lim_{t\to\infty} \boldsymbol{\rho}(t) = \hat{\mathbf{w}}$, where $\hat{\mathbf{w}}$ is a solution to*

$$\forall n \in \mathcal{S}: \ \eta \exp\left(-\mathbf{x}_n^\top \hat{\mathbf{w}}\right) = \alpha_n \tag{7}$$

Analogies with Boosting Perhaps most similar to our study is the line of work on understanding AdaBoost in terms its implicit bias toward large L_1-margin solutions, starting with the seminal work of Schapire et al. (1998). Since AdaBoost can be viewed as coordinate descent on the exponential loss of a linear model, these results can be interpreted as analyzing the bias of coordinate descent, rather then gradient descent, on a monotone decreasing loss with an exact exponential tail. Indeed, with small enough step sizes, such a coordinate descent procedure does converge precisely to the maximum L_1-margin solution (Zhang et al., 2005; Telgarsky, 2013). In fact, Telgarsky (2013) also generalizes these results to other losses with tight exponential tails, similar to the class of losses we consider here.

Also related is the work of Rosset et al. (2004). They considered the regularization path $\mathbf{w}_\lambda = \arg\min \mathcal{L}(\mathbf{w}) + \lambda \|\mathbf{w}\|_p^p$ for similar loss functions as we do, and showed that $\lim_{\lambda\to 0} \mathbf{w}_\lambda / \|\mathbf{w}_\lambda\|_p$ is proportional to the maximum L_p margin solution. That is, they showed how adding infinitesimal L_p (*e.g.* L_1 and L_2) regularization to logistic-type losses gives rise to the corresponding max-margin predictor.[3] However, Rosset et al. do not consider the effect of the optimization algorithm, and instead add explicit regularization. Here we are specifically interested in the bias implied by the algorithm *not* by adding (even infinitesimal) explicit regularization. We see that coordinate descent gives rise to the max L_1 margin predictor, while gradient descent gives rise to the max L_2 norm predictor. In Section 4.3 and in follow-up work (Gunasekar et al., 2018) we discuss also other optimization algorithms, and their implied biases.

Non-homogeneous linear predictors In this paper we focused on homogeneous linear predictors of the form $\mathbf{w}^\top \mathbf{x}$, similarly to previous works (*e.g.*, Rosset et al. (2004); Telgarsky (2013)). Specifically, we did not have the common intercept term: $\mathbf{w}^\top \mathbf{x} + b$. One may be tempted to introduce the intercept in the usual way, *i.e.*, by extending all the input vectors $\mathbf{x}_n$ with an additional $'1'$ component. In this extended input space, naturally, all our results hold. Therefore, we converge in direction to the L_2 max margin solution (eq. 4) in the extended space. However, if we translate this solution to the original $\mathbf{x}$ space we obtain

$$\operatorname*{argmin}_{\mathbf{w}\in\mathbb{R}^d, b\in\mathbb{R}} \|\mathbf{w}\|^2 + b^2 \text{ s.t. } \mathbf{w}^\top \mathbf{x}_n + b \geq 1,$$

which is not the L_2 max margin (SVM) solution

$$\operatorname*{argmin}_{\mathbf{w}\in\mathbb{R}^d, b\in\mathbb{R}} \|\mathbf{w}\|^2 \text{ s.t. } \mathbf{w}^\top \mathbf{x}_n + b \geq 1,$$

where we do not have a b^2 penalty in the objective.

3. Implications: Rates of convergence

The solution in eq. 3 implies that $\mathbf{w}(t) / \|\mathbf{w}(t)\|$ converges to the normalized max margin vector $\hat{\mathbf{w}} / \|\hat{\mathbf{w}}\|$. Moreover, this convergence is very slow— logarithmic in the number of iterations. Specifically, our results imply the following tight rates of convergence:

Theorem 5 *Under the conditions and notation of Theorem 3, for any linearly separable data set, the normalized weight vector converges to the normalized max margin vector in L_2 norm*

$$\left\| \frac{\mathbf{w}(t)}{\|\mathbf{w}(t)\|} - \frac{\hat{\mathbf{w}}}{\|\hat{\mathbf{w}}\|} \right\| = O\left(\frac{\log\log t}{\log t}\right), \tag{8}$$

with this rate improving to $O(1/\log(t))$ for almost every dataset; and in angle

$$1 - \frac{\mathbf{w}(t)^\top \hat{\mathbf{w}}}{\|\mathbf{w}(t)\| \|\hat{\mathbf{w}}\|} = O\left(\left(\frac{\log\log t}{\log t}\right)^2\right), \tag{9}$$

with this rate improving to $O(1/\log^2(t))$ for almost every dataset; and the margin converges as

$$\frac{1}{\|\hat{\mathbf{w}}\|} - \frac{\min_n \mathbf{x}_n^\top \mathbf{w}(t)}{\|\mathbf{w}(t)\|} = O\left(\frac{1}{\log t}\right). \tag{10}$$

On the other hand, the loss itself decreases as

$$\mathcal{L}(\mathbf{w}(t)) = O\left(\frac{1}{t}\right). \tag{11}$$

3. In contrast, with non-vanishing regularization (*i.e.*, $\lambda > 0$), $\arg\min_\mathbf{w} \mathcal{L}(\mathbf{w}) + \lambda \|\mathbf{w}\|_p^p$ is generally *not* a max margin solution.

All the rates in the above Theorem are a direct consequence of Theorem 3, except for avoiding the $\log\log t$ factor for the degenerate cases in eq. 10 and eq. 11 (*i.e.*, establishing that the rates $1/\log t$ and $1/t$ always hold)—this additional improvement is a consequence of the more complete characterization of Theorem 13. Full details are provided in Appendix D. In this appendix, we also provide a simple construction showing all the rates in Theorem 5 are tight (except possibly for the $\log\log t$ factors).

The sharp contrast between the tight logarithmic and $1/t$ rates in Theorem 5 implies that the convergence of $\mathbf{w}(t)$ to the max-margin $\hat{\mathbf{w}}$ can be logarithmic in the loss itself, and we might need to wait until the loss is exponentially small in order to be close to the max-margin solution. This can help explain why continuing to optimize the training loss, even after the training error is zero and the training loss is extremely small, still improves generalization performance—our results suggests that the margin could still be improving significantly in this regime.

A numerical illustration of the convergence is depicted in Figure 1. As predicted by the theory, the norm $\|\mathbf{w}(t)\|$ grows logarithmically (note the semi-log scaling), and $\mathbf{w}(t)$ converges to the max-margin separator, but only logarithmically, while the loss itself decreases very rapidly (note the log-log scaling).

An important practical consequence of our theory, is that although the margin of $\mathbf{w}(t)$ keeps improving, and so we can expect the population (or test) misclassification error of $\mathbf{w}(t)$ to improve for many datasets, the same cannot be said about the expected population loss (or test loss)! At the limit, the direction of $\mathbf{w}(t)$ will converge toward the max margin predictor $\hat{\mathbf{w}}$. Although $\hat{\mathbf{w}}$ has zero training error, it will not generally have zero misclassification error on the population, or on a test or a validation set. Since the norm of $\mathbf{w}(t)$ will increase, if we use the logistic loss or any other convex loss, the loss incurred on those misclassified points will also increase. More formally, consider the logistic loss $\ell(u) = \log(1+e^{-u})$ and define also the hinge-at-zero loss $h(u) = \max(0,-u)$. Since $\hat{\mathbf{w}}$ classifies all training points correctly, we have that on the training set $\sum_{n=1}^{N} h(\hat{\mathbf{w}}^\top \mathbf{x}_n) = 0$. However, on the population we would expect some errors and so $\mathbb{E}[h(\hat{\mathbf{w}}^\top \mathbf{x})] > 0$. Since $\mathbf{w}(t) \approx \hat{\mathbf{w}} \log t$ and $\ell(\alpha u) \to \alpha h(u)$ as $\alpha \to \infty$, we have:

$$\mathbb{E}[\ell(\mathbf{w}(t)^\top \mathbf{x})] \approx \mathbb{E}[\ell((\log t)\hat{\mathbf{w}}^\top \mathbf{x})] \approx (\log t)\mathbb{E}[h(\hat{\mathbf{w}}^\top \mathbf{x})] = \Omega(\log t). \tag{12}$$

That is, the population loss increases logarithmically while the margin and the population misclassification error improve. Roughly speaking, the improvement in misclassification does not out-weight the increase in the loss of those points still misclassified.

The increase in the test loss is practically important because the loss on a validation set is frequently used to monitor progress and decide on stopping. Similar to the population loss, the validation loss will increase logarithmically with t, if there is at least one sample in the validation set which is classified incorrectly by the max margin vector (since we would not expect zero validation error). More precisely, as a direct consequence of Theorem 3 (as shown on Appendix D):

Corollary 6 *Let ℓ be the logistic loss, and $\mathcal{V}$ be an independent validation set, for which $\exists \mathbf{x} \in \mathcal{V}$ such that $\mathbf{x}^\top \hat{\mathbf{w}} < 0$. Then the validation loss increases as*

$$\mathcal{L}_{\text{val}}\left(\mathbf{w}\left(t\right)\right) = \sum_{\mathbf{x}\in\mathcal{V}} \ell\left(\mathbf{w}\left(t\right)^\top \mathbf{x}\right) = \Omega(\log(t)).$$

This behavior might cause us to think we are over-fitting or otherwise encourage us to stop the optimization. However, this increase does not actually represent the model getting worse, merely

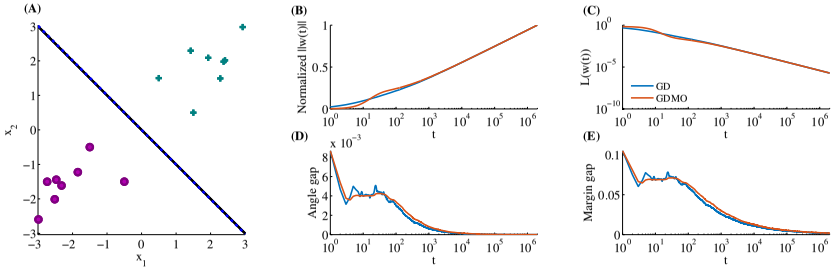

Figure 1: Visualization of or main results on a synthetic dataset in which the L_2 max margin vector $\hat{\mathbf{w}}$ is precisely known. **(A)** The dataset (positive and negatives samples ($y = \pm 1$) are respectively denoted by $'+'$ and $'\circ'$), max margin separating hyperplane (black line), and the asymptotic solution of GD (dashed blue). For both GD and GD with momentum (GDMO), we show: **(B)** The norm of $\mathbf{w}\left(t\right)$, normalized so it would equal to 1 at the last iteration, to facilitate comparison. As expected (eq. 3), the norm increases logarithmically; **(C)** the training loss. As expected, it decreases as t^{-1} (eq. 11); and **(D&E)** the angle and margin gap of $\mathbf{w}\left(t\right)$ from $\hat{\mathbf{w}}$ (eqs. 9 and 10). As expected, these are logarithmically decreasing to zero. **Implementation details:** The dataset includes four support vectors: $\mathbf{x}_1 = (0.5, 1.5)\,, \mathbf{x}_2 = (1.5, 0.5)$ with $y_1 = y_2 = 1$, and $\mathbf{x}_3 = -\mathbf{x}_1$, $\mathbf{x}_4 = -\mathbf{x}_2$ with $y_3 = y_4 = -1$ (the L_2 normalized max margin vector is then $\hat{\mathbf{w}} = (1,1)/\sqrt{2}$ with margin equal to $\sqrt{2}$), and 12 other random datapoints (6 from each class), that are not on the margin. We used a learning rate $\eta = 1/\sigma^2_{\max}\left(\mathbf{X}\right)$, where $\sigma^2_{\max}\left(\mathbf{X}\right)$ is the maximal singular value of $\mathbf{X}$, momentum $\gamma = 0.9$ for GDMO, and initialized at the origin.

$\|\mathbf{w}(t)\|$ getting larger, and in fact the model might be getting better (increasing the margin and possibly decreasing the error rate).

4. Extensions

4.1. Multi-Class Classification with Cross-Entropy Loss

So far, we have discussed the problem of binary classification, but in many practical situations we have more then two classes. For multi-class problems, the labels are the class indices $y_n \in [K] \triangleq \{1, \ldots, K\}$ and we learn a predictor $\mathbf{w}_k$ for each class $k \in [K]$. A common loss function in multi-class classification is the following cross-entropy loss with a softmax output, which is a generalization of the logistic loss:

$$\mathcal{L}\left(\{\mathbf{w}_k\}_{k\in[K]}\right) = -\sum_{n=1}^{N} \log\left(\frac{\exp\left(\mathbf{w}_{y_n}^\top \mathbf{x}_n\right)}{\sum_{k=1}^{K}\exp\left(\mathbf{w}_k^\top \mathbf{x}_n\right)}\right) \tag{13}$$

What do the linear predictors $\mathbf{w}_k(t)$ converge to if we minimize the cross-entropy loss by gradient descent on the predictors? In Appendix E we analyze this problem for separable data, and show that

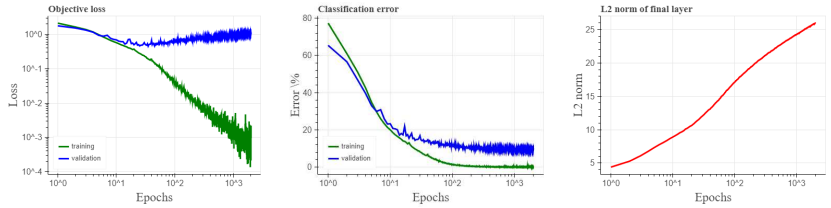

Figure 2: Training of a convolutional neural network on CIFAR10 using stochastic gradient descent with constant learning rate and momentum, softmax output and a cross entropy loss, where we achieve 8.3% final validation error. We observe that, approximately: (1) The training loss decays as a t^{-1}, (2) the L_2 norm of last weight layer increases logarithmically, (3) after a while, the validation loss starts to increase, and (4) in contrast, the validation (classification) error slowly improves.

again, the predictors diverge to infinity and the loss converges to zero. Furthermore, we prove the following Theorem:

Theorem 7 *For almost all multiclass datasets (*i.e.*, except for a measure zero) which are linearly separable (i.e. the constraints in eq. 15 below are feasible), any starting point* $\mathbf{w}(0)$ *and any small enough stepsize, the iterates of gradient descent on 13 will behave as:*

$$\mathbf{w}_k(t) = \hat{\mathbf{w}}_k \log(t) + \boldsymbol{\rho}_k(t), \tag{14}$$

where the residual $\boldsymbol{\rho}_k(t)$ *is bounded and* $\hat{\mathbf{w}}_k$ *is the solution of the K-class SVM:*

$$\operatorname{argmin}_{\mathbf{w}_1,\ldots,\mathbf{w}_k} \sum_{k=1}^{K} ||\mathbf{w}_k||^2 \; s.t. \; \forall n, \forall k \neq y_n : \mathbf{w}_{y_n}^\top \mathbf{x}_n \geq \mathbf{w}_k^\top \mathbf{x}_n + 1. \tag{15}$$

4.2. Deep networks

So far we have only considered linear prediction. Naturally, it is desirable to generalize our results also to non-linear models and especially multi-layer neural networks.

Even without a formal extension and description of the precise bias, our results already shed light on how minimizing the cross-entropy loss with gradient descent can have a margin maximizing effect, how the margin might improve only logarithmically slow, and why it might continue to improve even as the validation loss increases. These effects are demonstrated in Figure 2 and Table 1 which portray typical training of a convolutional neural network using unregularized gradient descent[4]. As can be seen, the norm of the weight increases, but the validation error continues decreasing, albeit very slowly (as predicted by the theory), even after the training error is zero and the training loss is extremely small. We can now understand how even though the loss is already extremely small, some sort of margin might be gradually improving as we continue optimizing. We can also observe how the validation loss increases despite the validation error decreasing, as discussed in Section 3.

4. Code available here: `https://github.com/paper-submissions/MaxMargin`

Epoch	50	100	200	400	2000	4000

Train loss	0.1	0.03	0.02	0.002	10^{-4}	$3 \cdot 10^{-5}$
Train error	4%	1.2%	0.6%	0.07%	0%	0%
Validation loss	0.52	0.55	0.77	0.77	1.01	1.18
Validation error	12.4%	10.4%	11.1%	9.1%	8.92%	8.9%

Table 1: Sample values from various epochs in the experiment depicted in Fig. 2.

As an initial advance toward tackling deep network, we can point out that for several special cases, our results may be directly applied to multi-layered networks. First, somewhat trivially, our results may be applied directly to the last weight layer of a neural network if the last hidden layer becomes fixed and linearly separable after a certain number of iterations. This can become true, either approximately, if the input to the last hidden layer is normalized (*e.g.*, using batch norm), or exactly, if the last hidden layer is quantized (Hubara et al., 2018).

Second, as we show next, our results may be applied exactly on deep networks if only a single weight layer is being optimized, and, furthermore, after a sufficient number of iterations, the activation units stop switching and the training error goes to zero.

Corollary 8 *We examine a multilayer neural network with component-wise ReLU functions* $f(z) = \max[z, 0]$*, and weights* $\{\mathbf{W}_l\}_{l=1}^{L}$*. Given input* $\mathbf{x}_n$ *and target* $y_n \in \{-1, 1\}$*, the DNN produces a scalar output*

$$u_n = \mathbf{W}_L f\left(\mathbf{W}_{L-1} f\left(\cdots \mathbf{W}_2 f\left(\mathbf{W}_1 \mathbf{x}_n\right)\right)\right)$$

and has loss $\ell(y_n u_n)$*, where* ℓ *obeys assumptions 2 and 3.*

If we optimize a single weight layer $\mathbf{w}_l = \operatorname{vec}\left(\mathbf{W}_l^\top\right)$ *using gradient descent, so that* $\mathcal{L}(\mathbf{w}_l) = \sum_{n=1}^{N} \ell\left(y_n u_n(\mathbf{w}_l)\right)$ *converges to zero, and* $\exists t_0$ *such that* $\forall t > t_0$ *the ReLU inputs do not switch signs, then* $\mathbf{w}_l(t) / \left\|\mathbf{w}_l(t)\right\|$ *converges to*

$$\hat{\mathbf{w}}_l = \operatorname*{argmin}_{\mathbf{w}_l} \|\mathbf{w}_l\|^2 \;\text{ s.t. }\; y_n u_n(\mathbf{w}_l) \geq 1.$$

Proof We examine the output of the network given a single input $\mathbf{x}_n$, for $t > t_0$**.** Since the ReLU inputs do not switch signs, we can write $\mathbf{v}_l$, the output of layer l, as

$$\mathbf{v}_{l,n} = \prod_{m=1}^{l} \mathbf{A}_{m,n} \mathbf{W}_m \mathbf{x}_n \,,$$

where we defined $\mathbf{A}_{l,n}$ for $l < L$ as a diagonal 0-1 matrix, which diagonal is the ReLU slopes at layer l, sample n, and $\mathbf{A}_{L,n} = 1$. Additionally, we define

$$\boldsymbol{\delta}_{l,n} = \mathbf{A}_{l,n} \prod_{m=L}^{l+1} \mathbf{W}_m^\top \mathbf{A}_{m,n} \,;\; \tilde{\mathbf{x}}_{l,n} = \boldsymbol{\delta}_{l,n} \otimes \mathbf{u}_{l-1,n} \,.$$

Using this notation we can write

$$u_n(\mathbf{w}_l) = v_{L,n} = \prod_{m=1}^{L} \mathbf{A}_{m,n} \mathbf{W}_m \mathbf{x}_n = \boldsymbol{\delta}_{l,n}^\top \mathbf{W}_l \mathbf{u}_{l-1,n} = \tilde{\mathbf{x}}_{l,n}^\top \mathbf{w}_l \,. \tag{16}$$

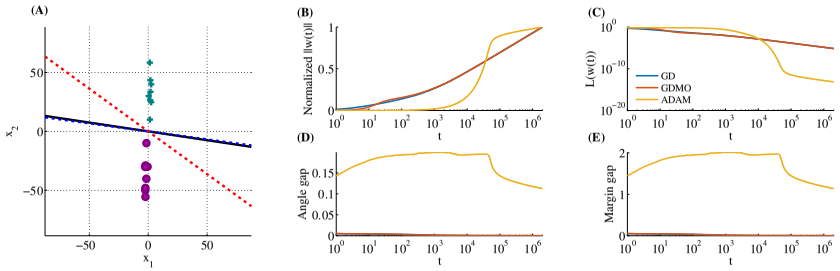

Figure 3: Same as Fig. 1, except we multiplied all x_2 values in the dastaset by 20, and also train using ADAM. The final weight vector produced after $2 \cdot 10^6$ epochs of optimization using ADAM (red dashed line) does not converge to L2 max margin solution (black line), in contrast to GD (blue dashed line), or GDMO.

This implies that

$$\mathcal{L}(\mathbf{w}_l) = \sum_{n=1}^{N} \ell\left(y_n u_n(\mathbf{w}_l)\right) = \sum_{n=1}^{N} \ell\left(y_n \tilde{\mathbf{x}}_{l,n}^\top \mathbf{w}_l\right),$$

which is the same as the original linear problem. Since the loss converges to zero, the dataset $\{\tilde{\mathbf{x}}_{l,n}, y_n\}_{n=1}^N$ must be linearly separable. Applying Theorem 3, and recalling that $u(\mathbf{w}_l) = \tilde{\mathbf{x}}_l^\top \mathbf{w}_l$ from eq. 16, we prove this corollary. ■

Importantly, this case is non-convex, unless we are optimizing the last layer. Note we assumed ReLU functions for simplicity, but this proof can be easily generalized for any other piecewise linear constant activation functions (*e.g.*, leaky ReLU, max-pooling).

Lastly, in a follow-up work (Gunasekar et al., 2018b), given a few additional assumptions, extended our results to linear predictors which can be written as a homogeneous polynomial in the parameters. These results seem to indicate that, in many cases, GD operating on exp-tailed loss with positively homogeneous predictors aims to a specific direction. This is the direction of the max margin predictor minimizing the L_2 norm in the parameter space. It is not yet clear how to generally translate such an implicit bias in the parameter space to the implicit bias in the predictor space — except in special cases, such as deep linear neural nets, as we have shown in (Gunasekar et al., 2018b). Moreover, in non-linear neural nets, there are many equivalent max-margin solutions which minimize the L_2 norm of the parameters. Therefore, it is natural to expect that GD would have additional implicit biases, which select a specific subset of these solutions.

4.3. Other optimization methods

In this paper we examined the implicit bias of gradient descent. Different optimization algorithms exhibit different biases, and understanding these biases and how they differ is crucial to understanding

and constructing learning methods attuned to the inductive biases we expect. Can we characterize the implicit bias and convergence rate in other optimization methods?

In Figure 1 we see that adding momentum does not qualitatively affect the bias induced by gradient descent. In Figure 4 in Appendix F we also repeat the experiment using stochastic gradient descent, and observe a similar asymptotic bias (this was later proved in Nacson et al. (2018)). This is consistent with the fact that momentum, acceleration and stochasticity do not change the bias when using gradient descent to optimize an under determined least squares problem. It would be beneficial, though, to rigorously understand how much we can generalize our result to gradient descent variants, and how the convergence rates might change in these cases.

On the other hand, as an example of how changing the optimization algorithm does change the bias, consider adaptive methods, such as AdaGrad (Duchi et al., 2011) and ADAM (Kingma and Ba, 2015). In Figure 3 we show the predictors obtained by ADAM and by gradient descent on a simple data set. Both methods converge to zero training error solutions. But although gradient descent converges to the L_2 max margin predictor, as predicted by our theory, ADAM does not. The implicit bias of adaptive methods has in fact been a recent topic of interest, with Hoffer et al. (2017) and Wilson et al. (2017) suggesting they lead to worse generalization, and Wilson et al. (2017) providing examples of the differences in the bias for linear regression problems with the squared loss. Can we characterize the bias of adaptive methods for logistic regression problems? Can we characterize the bias of other optimization methods, providing a general understanding linking optimization algorithms with their biases?

In a follow-up paper (Gunasekar et al., 2018) provided initial answers to these questions. Gunasekar et al. (2018) derived a precise characterization of the limit direction of steepest descent for general norms when optimizing the exp-loss, and show that for adaptive methods such as Adagrad the limit direction can depend on the initial point and step size and is thus not as predictable and robust as with non-adaptive methods.

4.4. Other loss functions

In this work we focused on loss functions with exponential tail and observed a very slow, logarithmic convergence of the normalized weight vector to the L_2 max margin direction. A natural question that follows is how does this behavior change with types of loss function tails. Specifically, does the normalized weight vector always converge to the L_2 max margin solution? How is the convergence rate affected? Can we improve the convergence rate beyond the logarithmic rate found in this work?

In a follow-up work Nacson et al. (2018) provided partial answers to these questions. They proved that the exponential tail has the optimal convergence rate, for tails for which $\ell'(u)$ is of the form $\exp(-u^\nu)$ with $\nu > 0.25$. They then conjectured, based on heuristic analysis, that the exponential tail is optimal among all possible tails. Furthermore, they demonstrated that polynomial or heavier tails do not converge to the max margin solution. Lastly, for the exponential loss they proposed a normalized gradient scheme which can significantly improve convergence rate, achieving $O(\log(t)/\sqrt{t})$.

4.5. Matrix Factorization

With multi-layered neural networks in mind, Gunasekar et al. (2017) recently embarked on a study of the implicit bias of under-determined matrix factorization problems, where the *squared loss* of the linear observation of a matrix is minimized by gradient descent on its factorization. Since a

matrix factorization can be viewed as a two-layer network with linear activations, this is perhaps the simplest deep model one can study in full, and can thus provide insight and direction to studying more complex neural networks. Gunasekar et al. conjectured, and provided theoretical and empirical evidence, that gradient descent on the factorization for an under-determined problem converges to the minimum nuclear norm solution, but only if the initialization is infinitesimally close to zero and the step-sizes are infinitesimally small. With finite step-sizes or finite initialization, Gunasekar et al. could not characterize the bias.

The follow-up paper (Gunasekar et al., 2018) studied this same problem with exponential loss instead of squared loss. Under additional assumptions on the asymptotic convergence of update directions and gradient directions, they were able to relate the direction of gradient descent iterates on the factorized parameterization asymptotically to the maximum margin solution with unit nuclear norm. Unlike the case of squared loss, the result for exponential loss are independent of initialization and with only mild conditions on the step size. Here again, we see the asymptotic nature of exponential loss on separable data nullifying the initialization effects thereby making the analysis simpler compared to squared loss.

5. Summary

We characterized the implicit bias induced by gradient descent on homogeneous linear predictors when minimizing smooth monotone loss functions with an exponential tail. This is the type of loss commonly being minimized in deep learning. We can now rigorously understand:

1. How gradient descent, without early stopping, induces implicit L_2 regularization and converges to the maximum L_2 margin solution, when minimizing for binary classification with logistic loss, exp-loss, or other exponential tailed monotone decreasing loss, as well as for multi-class classification with cross-entropy loss. Notably, even though the logistic loss and the exp-loss behave very different on non-separable problems, they exhibit the same behaviour for separable problems. This implies that the non-tail part does not affect the bias. The bias is also independent of the step-size used (as long as it is small enough to ensure convergence) and is also independent on the initialization (unlike for least square problems).

2. The convergence of the direction of gradient descent updates to the maximum L_2 margin solution, however is very slow compared to the convergence of training loss, which explains why it is worthwhile continuing to optimize long after we have zero training error, and even when the loss itself is already extremely small.

3. We should not rely on plateauing of the training loss or on the loss (logistic or exp or cross-entropy) evaluated on a validation data, as measures to decide when to stop. Instead, we should look at the 0–1 error on the validation dataset. We might improve the validation and test errors even when when the decrease in the training loss is tiny and even when the validation loss itself increases.

Perhaps that gradient descent leads to a max L_2 margin solution is not a big surprise to those for whom the connection between L_2 regularization and gradient descent is natural. Nevertheless, we are not familiar with any prior study or mention of this fact, let alone a rigorous analysis and study of how this bias is exact and independent of the initial point and the step-size. Furthermore, we also analyze the rate at which this happens, leading to the novel observations discussed above. Even more

importantly, we hope that our analysis can open the door to further analysis of different optimization methods or in different models, including deep networks, where implicit regularization is not well understood even for least square problems, or where we do not have such a natural guess as for gradient descent on linear problems. Analyzing gradient descent on logistic/cross-entropy loss is not only arguably more relevant than the least square loss, but might also be technically easier.

Appendix

Appendix A. Proof of Theorems 3 and 4 for almost every dataset

In the following sub-sections we first prove Theorem 9 below, which is a version of Theorem 3, specialized for almost every dataset. We then prove Theorem 4 (which is already stated for almost every dataset).

Theorem 9 *For almost every dataset which is linearly separable (Assumption 1), any β-smooth decreasing loss function (Assumption 2) with an exponential tail (Assumption 3), any stepsize $\eta < 2\beta^{-1}\sigma_{\max}^{-2}(\mathbf{X})$ and any starting point $\mathbf{w}(0)$, the gradient descent iterates (as in eq. 2) will behave as:*

$$\mathbf{w}(t) = \hat{\mathbf{w}}\log t + \boldsymbol{\rho}(t)\ , \tag{17}$$

where $\hat{\mathbf{w}}$ is the L_2 max margin vector

$$\hat{\mathbf{w}} = \underset{\mathbf{w}\in\mathbb{R}^d}{\operatorname{argmin}} \|\mathbf{w}\|^2 \ \text{ s.t. } \forall n:\ \mathbf{w}^\top\mathbf{x}_n \geq 1,$$

the residual $\rho(t)$ is bounded, and so

$$\lim_{t\to\infty}\frac{\mathbf{w}(t)}{\|\mathbf{w}(t)\|} = \frac{\hat{\mathbf{w}}}{\|\hat{\mathbf{w}}\|}.$$

In the following proofs, for any solution $\mathbf{w}(t)$, we define

$$\mathbf{r}(t) = \mathbf{w}(t) - \hat{\mathbf{w}}\log t - \tilde{\mathbf{w}},$$

where $\hat{\mathbf{w}}$ and $\tilde{\mathbf{w}}$ follow the conditions of Theorems 3 and 4, *i.e.* $\hat{\mathbf{w}}$ is the L_2 is the max margin vector defined above, and $\tilde{\mathbf{w}}$ is a vector which satisfies eq. 7:

$$\forall n\in\mathcal{S}:\ \eta\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right) = \alpha_n\,, \tag{18}$$

where we recall that we denoted $\mathbf{X}_\mathcal{S}\in\mathbb{R}^{d\times|\mathcal{S}|}$ as the matrix whose columns are the support vectors, a subset $\mathcal{S}\subset\{1,\ldots,N\}$ of the columns of $\mathbf{X} = [\mathbf{x}_1,\ldots,\mathbf{x}_N]\in\mathbb{R}^{d\times N}$.

In Lemma 12 (Appendix B) we prove that for almost every dataset $\boldsymbol{\alpha}$ is uniquely defined, there are no more then d support vectors and $\alpha_n\neq 0$, $\forall n\in\mathcal{S}$. Therefore, eq. 18 is well-defined in those cases. If the support vectors do not span the data, then the solution $\tilde{\mathbf{w}}$ to eq. 18 might not be unique. In this case, we can use any such solution in the proof.

We furthermore denote the minimum margin to a non-support vector as:

$$\theta = \min_{n\notin\mathcal{S}}\mathbf{x}_n^\top\hat{\mathbf{w}} > 1\,, \tag{19}$$

and by C_i,ϵ_i,t_i ($i\in\mathbb{N}$) various positive constants which are independent of t. Lastly, we define $\mathbf{P}_1\in\mathbb{R}^{d\times d}$ as the orthogonal projection matrix[5] to the subspace spanned by the support vectors (the columns of $\mathbf{X}_\mathcal{S}$), and $\bar{\mathbf{P}}_1 = \mathbf{I} - \mathbf{P}_1$ as the complementary projection (to the left nullspace of $\mathbf{X}_\mathcal{S}$).

5. This matrix can be written as $\mathbf{P}_1 = \mathbf{X}_\mathcal{S}\mathbf{X}_\mathcal{S}^+$, where $\mathbf{M}^\dagger$ is the Moore-Penrose pseudoinverse of $\mathbf{M}$.

A.1. Simple proof of Theorem 9

In this section we first examine the special case that $\ell(u) = e^{-u}$ and take the continuous time limit of gradient descent: $\eta\to 0$, so

$$\dot{\mathbf{w}}(t) = -\nabla\mathcal{L}(\mathbf{w}(t))\ .$$

The proof in this case is rather short and self-contained (*i.e.*, does not rely on any previous results), and so it helps to clarify the main ideas of the general (more complicated) proof which we will give in the next sections.

Recall we defined

$$\mathbf{r}(t) = \mathbf{w}(t) - \log(t)\,\hat{\mathbf{w}} - \tilde{\mathbf{w}}\,. \tag{20}$$

Our goal is to show that $\|\mathbf{r}(t)\|$ is bounded, and therefore $\boldsymbol{\rho}(t) = \mathbf{r}(t) + \tilde{\mathbf{w}}$ is bounded. Eq. 20 implies that

$$\dot{\mathbf{r}}(t) = \dot{\mathbf{w}}(t) - \frac{1}{t}\hat{\mathbf{w}} = -\nabla\mathcal{L}(\mathbf{w}(t)) - \frac{1}{t}\hat{\mathbf{w}} \tag{21}$$

and therefore

$$\begin{aligned}
&\frac{1}{2}\frac{d}{dt}\|\mathbf{r}(t)\|^2 = \dot{\mathbf{r}}^\top(t)\,\mathbf{r}(t)\\
&= \sum_{n=1}^{N}\exp\left(-\mathbf{x}_n^\top\mathbf{w}(t)\right)\mathbf{x}_n^\top\mathbf{r}(t) - \frac{1}{t}\hat{\mathbf{w}}^\top\mathbf{r}(t)\\
&= \left[\sum_{n\in\mathcal{S}}\exp\left(-\log(t)\,\hat{\mathbf{w}}^\top\mathbf{x}_n - \tilde{\mathbf{w}}^\top\mathbf{x}_n - \mathbf{x}_n^\top\mathbf{r}(t)\right)\mathbf{x}_n^\top\mathbf{r}(t) - \frac{1}{t}\hat{\mathbf{w}}^\top\mathbf{r}(t)\right]\\
&+ \left[\sum_{n\notin\mathcal{S}}\exp\left(-\log(t)\,\hat{\mathbf{w}}^\top\mathbf{x}_n - \tilde{\mathbf{w}}^\top\mathbf{x}_n - \mathbf{x}_n^\top\mathbf{r}(t)\right)\mathbf{x}_n^\top\mathbf{r}(t)\right],
\end{aligned} \tag{22}$$

where in the last equality we used eq. 20 and decomposed the sum over support vectors $\mathcal{S}$ and non-support vectors. We examine both bracketed terms. Recall that $\hat{\mathbf{w}}^\top\mathbf{x}_n = 1$ for $n\in\mathcal{S}$, and that we defined (in eq. 18) $\tilde{\mathbf{w}}$ so that $\sum_{n\in\mathcal{S}}\exp\left(-\tilde{\mathbf{w}}^\top\mathbf{x}_n\right)\mathbf{x}_n = \hat{\mathbf{w}}$. Thus, the first bracketed term in eq. 22 can be written as

$$\begin{aligned}
&\frac{1}{t}\sum_{n\in\mathcal{S}}\exp\left(-\tilde{\mathbf{w}}^\top\mathbf{x}_n - \mathbf{x}_n^\top\mathbf{r}(t)\right)\mathbf{x}_n^\top\mathbf{r}(t) - \frac{1}{t}\sum_{n\in\mathcal{S}}\exp\left(-\tilde{\mathbf{w}}^\top\mathbf{x}_n\right)\mathbf{x}_n^\top\mathbf{r}(t)\\
=&\frac{1}{t}\sum_{n\in\mathcal{S}}\exp\left(-\tilde{\mathbf{w}}^\top\mathbf{x}_n\right)\left(\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right) - 1\right)\mathbf{x}_n^\top\mathbf{r}(t) \leq 0,
\end{aligned} \tag{23}$$

since $\forall z,\ z(e^{-z}-1)\leq 0$. Furthermore, since $\forall z\ e^{-z}z\leq 1$ and $\theta = \operatorname{argmin}_{n\notin\mathcal{S}}\mathbf{x}_n^\top\hat{\mathbf{w}} > 1$ (eq. 19), the second bracketed term in eq. 22 can be upper bounded by

$$\sum_{n\notin\mathcal{S}}\exp\left(-\log(t)\,\hat{\mathbf{w}}^\top\mathbf{x}_n - \tilde{\mathbf{w}}^\top\mathbf{x}_n\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)\mathbf{x}_n^\top\mathbf{r}(t) \leq \frac{1}{t^\theta}\sum_{n\notin\mathcal{S}}\exp\left(-\tilde{\mathbf{w}}^\top\mathbf{x}_n\right). \tag{24}$$

Substituting eq. 23 and 24 into eq. 22 and integrating, we obtain, that $\exists C, C'$ such that

$$\forall t_1, \forall t > t_1:\ \|\mathbf{r}(t)\|^2 - ||\mathbf{r}(t_1)||^2 \leq C\int_{t_1}^{t}\frac{dt}{t^\theta} \leq C' < \infty\,,$$

since $\theta > 1$ (eq. 19). Thus, we showed that $\mathbf{r}(t)$ is bounded, which completes the proof for the special case. ■

A.2. Complete proof of Theorem 9

Next, we give the proof for the general case (non-infinitesimal step size, and exponentially-tailed functions). Though it is based on a similar analysis as in the special case we examined in the previous section, it is somewhat more involved since we have to bound additional terms.

First, we state two auxiliary lemmata, that are proven below in appendix sections A.4 and A.5:

Lemma 10 *Let $\mathcal{L}(\mathbf{w})$ be a β-smooth non-negative objective. If $\eta < 2\beta^{-1}$, then, for any $\mathbf{w}(0)$, with the GD sequence*

$$\mathbf{w}(t+1) = \mathbf{w}(t) - \eta \nabla \mathcal{L}(\mathbf{w}(t)) \tag{25}$$

we have that $\sum_{u=0}^{\infty} \|\nabla \mathcal{L}(\mathbf{w}(u))\|^2 < \infty$ and therefore $\lim_{t\to\infty} \|\nabla \mathcal{L}(\mathbf{w}(t))\|^2 = 0$.

Lemma 11 *We have*

$$\exists C_1, t_1 : \forall t > t_1 : \ (\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) \le C_1 t^{-\min(\theta, 1+1.5\mu_+, 1+0.5\mu_-)} . \tag{26}$$

Additionally, $\forall \epsilon_1 > 0$, $\exists C_2, t_2$, such that $\forall t > t_2$, if

$$\|\mathbf{P}_1 \mathbf{r}(t)\| \ge \epsilon_1, \tag{27}$$

then the following improved bound holds

$$(\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) \le -C_2 t^{-1} < 0 . \tag{28}$$

Our goal is to show that $\|\mathbf{r}(t)\|$ is bounded, and therefore $\boldsymbol{\rho}(t) = \mathbf{r}(t) + \tilde{\mathbf{w}}$ is bounded. To show this, we will upper bound the following equation

$$\|\mathbf{r}(t+1)\|^2 = \|\mathbf{r}(t+1) - \mathbf{r}(t)\|^2 + 2(\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) + \|\mathbf{r}(t)\|^2 \tag{29}$$

First, we note that first term in this equation can be upper-bounded by

$$\begin{aligned}
&\|\mathbf{r}(t+1) - \mathbf{r}(t)\|^2 \\
&\overset{(1)}{=} \|\mathbf{w}(t+1) - \hat{\mathbf{w}}\log(t+1) - \tilde{\mathbf{w}} - \mathbf{w}(t) + \hat{\mathbf{w}}\log(t) + \tilde{\mathbf{w}}\|^2 \\
&\overset{(2)}{=} \|-\eta \nabla \mathcal{L}(\mathbf{w}(t)) - \hat{\mathbf{w}}[\log(t+1) - \log(t)]\|^2 \\
&= \eta^2 \|\nabla \mathcal{L}(\mathbf{w}(t))\|^2 + \|\hat{\mathbf{w}}\|^2 \log^2\left(1 + t^{-1}\right) + 2\eta \hat{\mathbf{w}}^\top \nabla \mathcal{L}(\mathbf{w}(t)) \log\left(1 + t^{-1}\right) \\
&\overset{(3)}{\le} \eta^2 \|\nabla \mathcal{L}(\mathbf{w}(t))\|^2 + \|\hat{\mathbf{w}}\|^2 t^{-2}
\end{aligned} \tag{30}$$

where in (1) we used eq. 20, in (2) we used eq. 2, and in (3) we used $\forall x > 0 : \ x \ge \log(1+x) > 0$, and also that

$$\hat{\mathbf{w}}^\top \nabla \mathcal{L}(\mathbf{w}(t)) = \sum_{n=1}^{N} \ell'\left(\mathbf{w}(t)^\top \mathbf{x}_n\right) \hat{\mathbf{w}}^\top \mathbf{x}_n \le 0 , \tag{31}$$

since $\hat{\mathbf{w}}^\top \mathbf{x}_n \ge 1$ (from the definition of $\hat{\mathbf{w}}$) and $\ell'(u) \le 0$.

Also, from Lemma 10 we know that

$$\|\nabla \mathcal{L}(\mathbf{w}(t))\|^2 = o(1) \text{ and } \sum_{t=0}^{\infty} \|\nabla \mathcal{L}(\mathbf{w}(t))\|^2 < \infty . \tag{32}$$

Substituting eq. 32 into eq. 30, and recalling that a $t^{-\nu}$ power series converges for any $\nu > 1$, we can find C_0 such that

$$\|\mathbf{r}(t+1) - \mathbf{r}(t)\|^2 = o(1) \text{ and } \sum_{t=0}^{\infty} \|\mathbf{r}(t+1) - \mathbf{r}(t)\|^2 = C_0 < \infty . \tag{33}$$

Note that this equation also implies that $\forall \epsilon_0$

$$\exists t_0 : \forall t > t_0 : |\|\mathbf{r}(t+1)\| - \|\mathbf{r}(t)\|| < \epsilon_0 . \tag{34}$$

Next, we would like to bound the second term in eq. 29. From eq. 26 in Lemma 11, we can find t_1, C_1 such that $\forall t > t_1$:

$$(\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) \le C_1 t^{-\min(\theta, 1+1.5\mu_+, 1+0.5\mu_-)} . \tag{35}$$

Thus, by combining eqs. 35 and 33 into eq. 29, we find

$$\begin{aligned}
&\|\mathbf{r}(t)\|^2 - \|\mathbf{r}(t_1)\|^2 \\
&= \sum_{u=t_1}^{t-1} \left[\|\mathbf{r}(u+1)\|^2 - \|\mathbf{r}(u)\|^2\right] \\
&\le C_0 + 2\sum_{u=t_1}^{t-1} C_1 u^{-\min(\theta, 1+1.5\mu_+, 1+0.5\mu_-)}
\end{aligned}$$

which is a bounded, since $\theta > 1$ (eq. 19) and $\mu_-, \mu_+ > 0$ (Definition 2). Therefore, $\|\mathbf{r}(t)\|$ is bounded. ■

A.3. Proof of Theorem 4

All that remains now is to show that $\|\mathbf{r}(t)\| \to 0$ if $\operatorname{rank}(\mathbf{X}_{\mathcal{S}}) = \operatorname{rank}(\mathbf{X})$, and that $\tilde{\mathbf{w}}$ is unique given $\mathbf{w}(0)$. To do so, this proof will continue where the proof of Theorem 3 stopped, using notations and equations from that proof.

Since $\mathbf{r}(t)$ has a bounded norm, its two orthogonal components $\mathbf{r}(t) = \mathbf{P}_1 \mathbf{r}(t) + \bar{\mathbf{P}}_1 \mathbf{r}(t)$ also have bounded norms (recall that $\mathbf{P}_1, \bar{\mathbf{P}}_1$ were defined in the beginning of appendix section A). From eq. 2, $\nabla \mathcal{L}(\mathbf{w})$ is spanned by the columns of $\mathbf{X}$. If $\operatorname{rank}(\mathbf{X}_{\mathcal{S}}) = \operatorname{rank}(\mathbf{X})$, then it is also spanned by the columns of $\mathbf{X}_{\mathcal{S}}$, and so $\bar{\mathbf{P}}_1 \nabla \mathcal{L}(\mathbf{w}) = 0$. Therefore, $\bar{\mathbf{P}}_1 \mathbf{r}(t)$ is not updated during GD, and remains constant. Since $\tilde{\mathbf{w}}$ in eq. 20 is also bounded, we can absorb this constant $\bar{\mathbf{P}}_1 \mathbf{r}(t)$ into $\tilde{\mathbf{w}}$ without affecting eq. 7 (since $\forall n \in \mathcal{S} : \ \mathbf{x}_n^\top \bar{\mathbf{P}}_1 \mathbf{r}(t) = 0$). Thus, without loss of generality, we can assume that $\mathbf{r}(t) = \mathbf{P}_1 \mathbf{r}(t)$.

We define the set

$$\mathcal{T} = \{t > \max[t_2, t_0] : \|\mathbf{r}(t)\| < \epsilon_1\} .$$

By contradiction, we assume that the complementary set is not finite,

$$\bar{\mathcal{T}} = \{t > \max[t_2, t_0] : \|\mathbf{r}(t)\| \geq \epsilon_1\} .$$

Additionally, the set $\mathcal{T}$ is not finite: if it were finite, it would have had a finite maximal point $t_{\max} \in \mathcal{T}$, and then, combining eqs. 28, 29, and 33, we would find that $\forall t > t_{\max}$

$$\|\mathbf{r}(t)\|^2 - \|\mathbf{r}(t_{\max})\|^2 = \sum_{u=t_{\max}}^{t-1} \left[\|\mathbf{r}(u+1)\|^2 - \|\mathbf{r}(u)\|^2\right] \leq C_0 - 2C_2 \sum_{u=t_{\max}}^{t-1} u^{-1} \to -\infty ,$$

which is impossible since $\|\mathbf{r}(t)\|^2 \geq 0$. Furthermore, eq. 33 implies that

$$\sum_{u=0}^{t} \|\mathbf{r}(u+1) - \mathbf{r}(t)\|^2 = C_0 - h(t)$$

where $h(t)$ is a positive monotone function decreasing to zero. Let t_3, t be any two points such that $t_3 < t$, $\{t_3, t_3+1, \dots t\} \subset \bar{\mathcal{T}}$, and $(t_3 - 1) \in \mathcal{T}$. For all such t_3 and t, we have

$$\begin{aligned}
\|\mathbf{r}(t)\|^2 &\leq \|\mathbf{r}(t_3)\|^2 + \sum_{u=t_3}^{t-1} \left[\|\mathbf{r}(u+1)\|^2 - \|\mathbf{r}(u)\|^2\right] \\
&= \|\mathbf{r}(t_3)\|^2 + \sum_{u=t_3}^{t-1} \left[\|\mathbf{r}(u+1) - \mathbf{r}(u)\|^2 + 2(\mathbf{r}(u+1) - \mathbf{r}(u))^\top \mathbf{r}(u)\right] \\
&\leq \|\mathbf{r}(t_3)\|^2 + h(t_3) - h(t-1) - 2C_2 \sum_{u=t_3}^{t-1} u^{-1} \\
&\leq \|\mathbf{r}(t_3)\|^2 + h(t_3) . \qquad (36)
\end{aligned}$$

Also, recall that $t_3 > t_0$, so from eq. 34, we have that $|\|\mathbf{r}(t_3)\| - \|\mathbf{r}(t_3 - 1)\|| < \epsilon_0$. Since $\|\mathbf{r}(t_3 - 1)\| < \epsilon_1$ (from $\mathcal{T}$ definition), we conclude that $\|\mathbf{r}(t_3)\| \leq \epsilon_1 + \epsilon_0$. Moreover, since $\bar{\mathcal{T}}$ is an infinite set, we can choose t_3 as large as we want. This implies that $\forall \epsilon_2 > 0$ we can find t_3 such that $\epsilon_2 > h(t_3)$, since $h(t)$ is a monotonically decreasing function. Therefore, from eq. 36, $\forall \epsilon_1, \epsilon_0, \epsilon_2$, $\exists t_3 \in \bar{\mathcal{T}}$ such that

$$\forall t > t_3 : \ \|\mathbf{r}(t)\|^2 \leq \epsilon_1 + \epsilon_0 + \epsilon_2 .$$

This implies that $\|\mathbf{r}(t)\| \to 0$.

Lastly, we note that since $\bar{\mathbf{P}}_1 \mathbf{r}(t)$ is not updated during GD, we have that $\bar{\mathbf{P}}_1(\tilde{\mathbf{w}} - \mathbf{w}(0)) = 0$. This sets $\tilde{\mathbf{w}}$ uniquely, together with eq. 7. ■

A.4. Proof of Lemma 10

Lemma 10 *Let $\mathcal{L}(\mathbf{w})$ be a β-smooth non-negative objective. If $\eta < 2\beta^{-1}$, then, for any $\mathbf{w}(0)$, with the GD sequence*

$$\mathbf{w}(t+1) = \mathbf{w}(t) - \eta \nabla \mathcal{L}(\mathbf{w}(t)) \qquad (25)$$

we have that $\sum_{u=0}^{\infty} \|\nabla \mathcal{L}(\mathbf{w}(u))\|^2 < \infty$ and therefore $\lim_{t\to\infty} \|\nabla \mathcal{L}(\mathbf{w}(t))\|^2 = 0$.

This proof is a slightly modified version of the proof of Theorem 2 in (Ganti, 2015). Recall a well-known property of β-smooth functions:

$$\left|f(\mathbf{x}) - f(\mathbf{y}) - \nabla f(\mathbf{y})^\top (\mathbf{x} - \mathbf{y})\right| \leq \frac{\beta}{2} \|\mathbf{x} - \mathbf{y}\|^2 . \qquad (37)$$

From the β-smoothness of $\mathcal{L}(\mathbf{w})$

$$\begin{aligned}
\mathcal{L}(\mathbf{w}(t+1)) &\leq \mathcal{L}(\mathbf{w}(t)) + \nabla \mathcal{L}(\mathbf{w}(t))^\top (\mathbf{w}(t+1) - \mathbf{w}(t)) + \frac{\beta}{2} \|\mathbf{w}(t+1) - \mathbf{w}(t)\|^2 \\
&= \mathcal{L}(\mathbf{w}(t)) - \eta \|\nabla \mathcal{L}(\mathbf{w}(t))\|^2 + \frac{\beta \eta^2}{2} \|\nabla \mathcal{L}(\mathbf{w}(t))\|^2 \\
&= \mathcal{L}(\mathbf{w}(t)) - \eta \left(1 - \frac{\beta \eta}{2}\right) \|\nabla \mathcal{L}(\mathbf{w}(t))\|^2
\end{aligned}$$

Thus, we have

$$\frac{\mathcal{L}(\mathbf{w}(t)) - \mathcal{L}(\mathbf{w}(t+1))}{\eta\left(1 - \frac{\beta\eta}{2}\right)} \geq \|\nabla \mathcal{L}(\mathbf{w}(t))\|^2$$

which implies

$$\sum_{u=0}^{t} \|\nabla \mathcal{L}(\mathbf{w}(u))\|^2 \leq \sum_{u=0}^{t} \frac{\mathcal{L}(\mathbf{w}(u)) - \mathcal{L}(\mathbf{w}(u+1))}{\eta\left(1 - \frac{\beta\eta}{2}\right)} = \frac{\mathcal{L}(\mathbf{w}(0)) - \mathcal{L}(\mathbf{w}(t+1))}{\eta\left(1 - \frac{\beta\eta}{2}\right)} .$$

The right hand side is upper bounded by a finite constant, since $L(\mathbf{w}(0)) < \infty$ and $0 \leq \mathcal{L}(\mathbf{w}(t+1))$. This implies

$$\sum_{u=0}^{\infty} \|\nabla \mathcal{L}(\mathbf{w}(u))\|^2 < \infty ,$$

and therefore $\|\nabla \mathcal{L}(\mathbf{w}(t))\|^2 \to 0$. ■

A.5. Proof of Lemma 11

Recall that we defined $\mathbf{r}(t) = \mathbf{w}(t) - \hat{\mathbf{w}} \log t - \tilde{\mathbf{w}}$, with $\hat{\mathbf{w}}$ and $\tilde{\mathbf{w}}$ follow the conditions of the Theorems 3 and 4, *i.e*, $\hat{\mathbf{w}}$ is the L_2 max margin vector and (eq. 4), and eq. 7 holds

$$\forall n \in \mathcal{S} : \ \eta \exp\left(-\mathbf{x}_n^\top \tilde{\mathbf{w}}\right) = \alpha_n .$$

Lemma 11 *We have*

$$\exists C_1, t_1 : \forall t > t_1 : \ (\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) \leq C_1 t^{-\min(\theta, 1+1.5\mu_+, 1+0.5\mu_-)} . \qquad (26)$$

Additionally, $\forall \epsilon_1 > 0$, $\exists C_2, t_2$, such that $\forall t > t_2$, if

$$\|\mathbf{P}_1 \mathbf{r}(t)\| \geq \epsilon_1, \qquad (27)$$

then the following improved bound holds

$$(\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) \leq -C_2 t^{-1} < 0 . \qquad (28)$$

From Lemma 1, $\forall n: \lim_{t\to\infty} \mathbf{w}(t)^\top \mathbf{x}_n = \infty$. In addition, from assumption 3 the negative loss derivative $-\ell'(u)$ has an exponential tail e^{-u} (recall we assume $a = c = 1$ without loss of generality). Combining both facts, we have positive constants μ_-, μ_+, t_- and t_+ such that $\forall n$

$$\forall t > t_+ : -\ell'\left(\mathbf{w}(t)^\top \mathbf{x}_n\right) \le \left(1 + \exp\left(-\mu_+ \mathbf{w}(t)^\top \mathbf{x}_n\right)\right) \exp\left(-\mathbf{w}(t)^\top \mathbf{x}_n\right) \tag{38}$$

$$\forall t > t_- : -\ell'\left(\mathbf{w}(t)^\top \mathbf{x}_n\right) \ge \left(1 - \exp\left(-\mu_- \mathbf{w}(t)^\top \mathbf{x}_n\right)\right) \exp\left(-\mathbf{w}(t)^\top \mathbf{x}_n\right) \tag{39}$$

Next, we examine the expression we wish to bound, recalling that $\mathbf{r}(t) = \mathbf{w}(t) - \hat{\mathbf{w}} \log t - \tilde{\mathbf{w}}$:

$$\begin{aligned}
&\left(\mathbf{r}(t+1) - \mathbf{r}(t)\right)^\top \mathbf{r}(t) \\
&= \left(-\eta \nabla \mathcal{L}(\mathbf{w}(t)) - \hat{\mathbf{w}} \left[\log(t+1) - \log(t)\right]\right)^\top \mathbf{r}(t) \\
&= -\eta \sum_{n=1}^{N} \ell'\left(\mathbf{w}(t)^\top \mathbf{x}_n\right) \mathbf{x}_n^\top \mathbf{r}(t) - \hat{\mathbf{w}}^\top \mathbf{r}(t) \log\left(1 + t^{-1}\right) \\
&= \hat{\mathbf{w}}^\top \mathbf{r}(t) \left[t^{-1} - \log\left(1 + t^{-1}\right)\right] - \eta \sum_{n \notin \mathcal{S}} \ell'\left(\mathbf{w}(t)^\top \mathbf{x}_n\right) \mathbf{x}_n^\top \mathbf{r}(t) \\
&- \eta \sum_{n \in \mathcal{S}} \left[t^{-1} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) + \ell'\left(\mathbf{w}(t)^\top \mathbf{x}_n\right)\right] \mathbf{x}_n^\top \mathbf{r}(t)
\end{aligned} \tag{40}$$

where in last line we used eqs. 6 and 7 to obtain

$$\hat{\mathbf{w}} = \sum_{n \in \mathcal{S}} \alpha_n \mathbf{x}_n = \eta \sum_{n \in \mathcal{S}} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \mathbf{x}_n .$$

We examine the three terms in eq. 40. The first term can be upper bounded by

$$\begin{aligned}
&\hat{\mathbf{w}}^\top \mathbf{r}(t) \left[t^{-1} - \log\left(1 + t^{-1}\right)\right] \\
&\le \max\left[\hat{\mathbf{w}}^\top \mathbf{r}(t), 0\right] \left[t^{-1} - \log\left(1 + t^{-1}\right)\right] \\
&\overset{(1)}{\le} \max\left[\hat{\mathbf{w}}^\top \mathbf{P}_1 \mathbf{r}(t), 0\right] t^{-2} \\
&\overset{(2)}{\le} \begin{cases} \|\hat{\mathbf{w}}\| \epsilon_1 t^{-2} & , \text{ if } \|\mathbf{P}_1 \mathbf{r}(t)\| \le \epsilon_1 \\ o\left(t^{-1}\right) & , \text{ if } \|\mathbf{P}_1 \mathbf{r}(t)\| > \epsilon_1 \end{cases}
\end{aligned} \tag{41}$$

where in (1) we used that $\bar{\mathbf{P}}_1 \hat{\mathbf{w}} = \bar{\mathbf{P}}_1 \mathbf{X}_{\mathcal{S}} \boldsymbol{\alpha} = 0$ from eq. 6, and in (2) we used that $\hat{\mathbf{w}}^\top \mathbf{r}(t) = o(t)$, since

$$\begin{aligned}
\hat{\mathbf{w}}^\top \mathbf{r}(t) &= \hat{\mathbf{w}}^\top \left(\mathbf{w}(0) - \eta \sum_{u=0}^{t} \nabla \mathcal{L}(\mathbf{w}(u)) - \hat{\mathbf{w}} \log(t) - \tilde{\mathbf{w}}\right) \\
&\le \hat{\mathbf{w}}^\top \left(\mathbf{w}(0) - \tilde{\mathbf{w}} - \hat{\mathbf{w}} \log(t)\right) - \eta t \min_{0 \le u \le t} \hat{\mathbf{w}}^\top \nabla \mathcal{L}(\mathbf{w}(u)) = o(t)
\end{aligned}$$

where in the last line we used that $\nabla \mathcal{L}(\mathbf{w}(t)) = o(1)$, from Lemma 10.

Next, we upper bound the second term in eq. 40. From eq. 38 $\exists t'_+$, such that $\forall > t_0 > t'_+$,

$$\ell'(\mathbf{w}(t)^\top \mathbf{x}_n) \le 2 \exp(-\mathbf{w}(t)^\top \mathbf{x}_n). \tag{42}$$

Therefore, $\forall t > t'_+$:

$$\begin{aligned}
&-\eta \sum_{n \notin \mathcal{S}} \ell'\left(\mathbf{w}(t)^\top \mathbf{x}_n\right) \mathbf{x}_n^\top \mathbf{r}(t) \\
&\le -\eta \sum_{n \notin \mathcal{S}: \mathbf{x}_n^\top \mathbf{r}(t) \ge 0} \ell'\left(\mathbf{w}(t)^\top \mathbf{x}_n\right) \mathbf{x}_n^\top \mathbf{r}(t) \\
&\overset{(1)}{\le} \eta \sum_{n \notin \mathcal{S}: \mathbf{x}_n^\top \mathbf{r}(t) \ge 0} 2 \exp\left(-\mathbf{w}(t)^\top \mathbf{x}_n\right) \mathbf{x}_n^\top \mathbf{r}(t) \\
&\overset{(2)}{\le} \eta \sum_{n \notin \mathcal{S}: \mathbf{x}_n^\top \mathbf{r}(t) \ge 0} 2 t^{-\mathbf{x}_n^\top \hat{\mathbf{w}}} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n - \mathbf{x}_n^\top \mathbf{r}(t)\right) \mathbf{x}_n^\top \mathbf{r}(t) \\
&\overset{(3)}{\le} \eta \sum_{n \notin \mathcal{S}: \mathbf{x}_n^\top \mathbf{r}(t) \ge 0} 2 t^{-\mathbf{x}_n^\top \hat{\mathbf{w}}} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \\
&\overset{(4)}{\le} \eta N \exp\left(-\min_n \tilde{\mathbf{w}}^\top \mathbf{x}_n\right) t^{-\theta}
\end{aligned} \tag{43}$$

where in (1) we used eq. 42, in (2) we used $\mathbf{w}(t) = \hat{\mathbf{w}} \log t + \tilde{\mathbf{w}} + \mathbf{r}(t)$, in (3) we used $xe^{-x} \le 1$ and $\mathbf{x}_n^\top \mathbf{r}(t) \ge 0$,and in (4) we used $\theta > 1$, from eq. 19.

Lastly, we will bound the sum in the third term in eq. 40

$$-\eta \sum_{n \in \mathcal{S}} \left[t^{-1} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) + \ell'\left(\mathbf{w}(t)^\top \mathbf{x}_n\right)\right] \mathbf{x}_n^\top \mathbf{r}(t) . \tag{44}$$

We examine each term n in this sum, and divide into two cases, depending on the sign of $\mathbf{x}_n^\top \mathbf{r}(t)$.

First, if $\mathbf{x}_n^\top \mathbf{r}(t) \ge 0$, then term n in eq. 44 can be upper bounded $\forall t > t_+$, using eq. 38, by

$$\eta t^{-1} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \left[\left(1 + t^{-\mu_+} \exp\left(-\mu_+ \tilde{\mathbf{w}}^\top \mathbf{x}_n\right)\right) \exp\left(-\mathbf{x}_n^\top \mathbf{r}(t)\right) - 1\right] \mathbf{x}_n^\top \mathbf{r}(t) \tag{45}$$

We further divide into cases:

1. If $\left|\mathbf{x}_n^\top \mathbf{r}(t)\right| \le C_0 t^{-0.5\mu_+}$, then we can upper bound eq. 45 with

$$\eta \exp\left(-(1 + \mu_+) \min_n \tilde{\mathbf{w}}^\top \mathbf{x}_n\right) C_0 t^{-1-1.5\mu_+} . \tag{46}$$

2. If $\left|\mathbf{x}_n^\top \mathbf{r}(t)\right| > C_0 t^{-0.5\mu_+}$, then we can find $t''_+ > t'_+$ to upper bound eq. 45 $\forall t > t''_+$:

$$\begin{aligned}
&\eta t^{-1} e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n} \left[\left(1 + t^{-\mu_+} e^{-\mu_+ \tilde{\mathbf{w}}^\top \mathbf{x}_n}\right) \exp\left(-C_0 t^{-0.5\mu_+}\right) - 1\right] \mathbf{x}_n^\top \mathbf{r}(t) \\
&\overset{(1)}{\le} \eta t^{-1} e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n} \left[\left(1 + t^{-\mu_+} e^{-\mu_+ \tilde{\mathbf{w}}^\top \mathbf{x}_n}\right) \left(1 - C_0 t^{-0.5\mu_+} + C_0^2 t^{-\mu_+}\right) - 1\right] \mathbf{x}_n^\top \mathbf{r}(t) \\
&\le \eta t^{-1} e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n} \left[\left(1 - C_0 t^{-0.5\mu_+} + C_0^2 t^{-\mu_+}\right) e^{-\mu_+ \min_n \tilde{\mathbf{w}}^\top \mathbf{x}_n} t^{-\mu_+} - C_0 t^{-0.5\mu_+} + C_0^2 t^{-\mu_+}\right] \mathbf{x}_n^\top \mathbf{r}(t) \\
&\overset{(2)}{\le} 0, \ \forall t > t''_+
\end{aligned} \tag{47}$$

where in (1) we used the fact that $e^{-x} \le 1 - x + x^2$ for $x \ge 0$ and in (2) we defined t''_+ so that the previous expression is negative — since $t^{-0.5\mu_+}$ decreases slower than $t^{-\mu_+}$.

3. If $\left|\mathbf{x}_n^\top \mathbf{r}(t)\right| \geq \epsilon_2$, then we define $t'''_+ > t''_+$ such that $t'''_+ > \exp\left(\min_n \tilde{\mathbf{w}}^\top \mathbf{x}_n\right)\left[e^{0.5\epsilon_2}-1\right]^{-1/\mu_+}$, and therefore $\forall t > t'''_+$, we have $\left(1+t^{-\mu_+}\exp\left(-\mu_+ \tilde{\mathbf{w}}^\top \mathbf{x}_n\right)\right)e^{-\epsilon_2} < e^{-0.5\epsilon_2}$.

   This implies that $\forall t > t'''_+$ we can upper bound eq. 45 by

$$-\eta \exp\left(-\max_n \tilde{\mathbf{w}}^\top \mathbf{x}_n\right)\left(1-e^{-0.5\epsilon_2}\right)\epsilon_2 t^{-1}. \tag{48}$$

Second, if $\mathbf{x}_n^\top \mathbf{r}(t) < 0$, we again further divide into cases:

1. If $\left|\mathbf{x}_n^\top \mathbf{r}(t)\right| \leq C_0 t^{-0.5\mu_-}$, then, since $-\ell'\left(\mathbf{w}(t)^\top \mathbf{x}_n\right) > 0$, we can upper bound term n in eq. 44 with

$$\eta t^{-1}\exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right)\left|\mathbf{x}_n^\top \mathbf{r}(t)\right| \leq \eta \exp\left(-\min_n \tilde{\mathbf{w}}^\top \mathbf{x}_n\right) C_0 t^{-1-0.5\mu_-} \tag{49}$$

2. If $\left|\mathbf{x}_n^\top \mathbf{r}(t)\right| > C_0 t^{-0.5\mu_-}$, then, using eq. 39 we upper bound term n in eq. 44 with

$$\begin{aligned}
&\eta\left[-t^{-1}e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n} - \ell'\left(\mathbf{w}(t)^\top \mathbf{x}_n\right)\right]\mathbf{x}_n^\top \mathbf{r}(t)\\
\leq&\eta\left[-t^{-1}e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n} + \left(1-\exp\left(-\mu_- \mathbf{w}(t)^\top \mathbf{x}_n\right)\right)\exp\left(-\mathbf{w}(t)^\top \mathbf{x}_n\right)\right]\mathbf{x}_n^\top \mathbf{r}(t)\\
=&\eta t^{-1}e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n}\left[1-\exp\left(-\mathbf{r}(t)^\top \mathbf{x}_n\right)\left(1-\left[t^{-1}e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n}\exp\left(-\mathbf{r}(t)^\top \mathbf{x}_n\right)\right]^{\mu_-}\right)\right]\left|\mathbf{x}_n^\top \mathbf{r}(t)\right|
\end{aligned} \tag{50}$$

   Next, we will show that $\exists t'_- > t_-$ such that the last expression is strictly negative $\forall t > t'_-$. Let $M > 1$ be some arbitrary constant. Then, since $\left[t^{-1}e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n}\exp\left(-\mathbf{r}(t)^\top \mathbf{x}_n\right)\right]^{\mu_-} = \exp\left(-\mu_- \mathbf{w}(t)^\top \mathbf{x}_n\right) \to 0$ from Lemma 1, $\exists t_M > \max(t_-, Me^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n})$ such that $\forall t > t_M$, if $\exp\left(-\mathbf{r}(t)^\top \mathbf{x}_n\right) \geq M > 1$ then

$$\exp\left(-\mathbf{r}(t)^\top \mathbf{x}_n\right)\left(1-\left[t^{-1}e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n}\exp\left(-\mathbf{r}(t)^\top \mathbf{x}_n\right)\right]^{\mu_-}\right) \geq M' > 1. \tag{51}$$

   Furthermore, if $\exists t > t_M$ such that $\exp\left(\mathbf{r}(t)^\top \mathbf{x}_n\right) < M$, then

$$\begin{aligned}
&\exp\left(-\mathbf{r}(t)^\top \mathbf{x}_n\right)\left(1-\left[t^{-1}e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n}\exp\left(-\mathbf{r}(t)^\top \mathbf{x}_n\right)\right]^{\mu_-}\right)\\
>&\exp\left(-\mathbf{r}(t)^\top \mathbf{x}_n\right)\left(1-\left[t^{-1}e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n}M\right]^{\mu_-}\right).
\end{aligned} \tag{52}$$

   which is lower bounded by

$$\begin{aligned}
&\left(1+C_0 t^{-0.5\mu_-}\right)\left(1-t^{-\mu_-}\left[e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n}M\right]^{\mu_-}\right)\\
\geq&1+C_0 t^{-0.5\mu_-} - t^{-\mu_-}\left[e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n}M\right]^{\mu_-} - t^{-1.5\mu_-}\left[e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_n}M\right]^{\mu_-} C_0
\end{aligned}$$

since $\left|\mathbf{x}_n^\top \mathbf{r}(t)\right| > C_0 t^{-0.5\mu_-}$, $\mathbf{x}_n^\top \mathbf{r}(t) < 0$ and $e^x \geq 1+x$. In this case last line is strictly larger than 1 for sufficiently large t. Therefore, after we substitute eqs. 51 and 52 into 50, we find that $\exists t'_- > t_M > t_-$ such that $\forall t > t'_-$, term k in eq. 44 is strictly negative

$$\eta\left[-t^{-1}e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_k} - \ell'\left(\mathbf{w}(t)^\top \mathbf{x}_k\right)\right]\mathbf{x}_k^\top \mathbf{r}(t) < 0 \tag{53}$$

3. If $\left|\mathbf{x}_k^\top \mathbf{r}(t)\right| \geq \epsilon_2$, which is a special case of the previous case ($\left|\mathbf{x}_k^\top \mathbf{r}(t)\right| > C_0 t^{-0.5\mu_-}$) then $\forall t > t'_-$, either eq. 51 or 52 holds. Furthermore, in this case, $\exists t''_- > t'_-$ and $M'' > 1$ such that $\forall t > t''_-$ eq. 52 can be lower bounded by

$$\exp(\epsilon_2)\left(1-\left[t^{-1}e^{-\tilde{\mathbf{w}}^\top \mathbf{x}_k}M\right]^{\mu_-}\right) > M'' > 1.$$

   Substituting this, together with eq. 51, into eq. 50, we can find $C'_0 > 0$ such we can upper bound term k in eq. 44 with

$$-C'_0 t^{-1}, \forall t > t''_-. \tag{54}$$

To conclude, we choose $t_0 = \max\left[t'''_+, t''_-\right]$:

1. If $\|\mathbf{P}_1 \mathbf{r}(t)\| \geq \epsilon_1$ (as in Eq. 27), we have that

$$\max_{n\in\mathcal{S}}\left|\mathbf{x}_n^\top \mathbf{r}(t)\right|^2 \overset{(1)}{\geq} \frac{1}{|\mathcal{S}|}\sum_{n\in\mathcal{S}}\left|\mathbf{x}_n^\top \mathbf{P}_1 \mathbf{r}(t)\right|^2 = \frac{1}{|\mathcal{S}|}\left\|\mathbf{X}_\mathcal{S}^\top \mathbf{P}_1 \mathbf{r}(t)\right\|^2 \overset{(2)}{\geq} \frac{1}{|\mathcal{S}|}\sigma_{\min}^2(\mathbf{X}_\mathcal{S})\epsilon_1^2 \tag{55}$$

   where in (1) we used $\mathbf{P}_1^\top \mathbf{x}_n = \mathbf{x}_n\ \forall n \in \mathcal{S}$, in (2) we denoted by $\sigma_{\min}(\mathbf{X}_\mathcal{S})$, the minimal non-zero singular value of $\mathbf{X}_\mathcal{S}$ and used eq. 27. Therefore, for some k, $\left|\mathbf{x}_k^\top \mathbf{r}\right| \geq \epsilon_2 \triangleq \sqrt{|\mathcal{S}|^{-1}\sigma_{\min}^2(\mathbf{X}_\mathcal{S})\epsilon_1^2}$. In this case, we denote C''_0 as the minimum between C'_0 (eq. 54) and $\eta\exp\left(-\max_n \tilde{\mathbf{w}}^\top \mathbf{x}_n\right)\left(1-e^{-0.5\epsilon_2}\right)\epsilon_2$ (eq. 48). Then we find that eq. 44 can be upper bounded by $-C''_0 t^{-1} + o\left(t^{-1}\right), \forall t > t_0$, given eq. 27. Substituting this result, together with eqs. 41 and 43 into eq. 40, we obtain $\forall t > t_0$

$$\left(\mathbf{r}(t+1)-\mathbf{r}(t)\right)^\top \mathbf{r}(t) \leq -C''_0 t^{-1} + o\left(t^{-1}\right).$$

   This implies that $\exists C_2 < C''_0$ and $\exists t_2 > t_0$ such that eq. 28 holds. This implies also that eq. 26 holds for $\|\mathbf{P}_1 \mathbf{r}(t)\| \geq \epsilon_1$.

2. Otherwise, if $\|\mathbf{P}_1 \mathbf{r}(t)\| < \epsilon_1$, we find that $\forall t > t_0$, each term in eq. 44 can be upper bounded by either zero (eqs. 47 and 53), or terms proportional to $t^{-1-1.5\mu_+}$ (eq. 46) or $t^{-1-0.5\mu_-}$, (eq. 49). Combining this together with eqs. 41, 43 into eq. 40 we obtain (for some positive constants C_3, C_4, C_5, and C_6)

$$\left(\mathbf{r}(t+1)-\mathbf{r}(t)\right)^\top \mathbf{r}(t) \leq C_3 t^{-1-1.5\mu_+} + C_4 t^{-1-0.5\mu_-} + C_5 t^{-2} + C_6 t^{-\theta}.$$

   Therefore, $\exists t_1 > t_0$ and C_1 such that eq. 26 holds. ■

Appendix B. Generic solutions of the KKT conditions in eq. 6

Lemma 12 *For almost all datasets there is a unique $\boldsymbol{\alpha}$ which satisfies the KKT conditions (eq. 6):*

$$\hat{\mathbf{w}} = \sum_{n=1}^N \alpha_n \mathbf{x}_n \qquad \forall n\ \left(\alpha_n \geq 0 \text{ and } \hat{\mathbf{w}}^\top \mathbf{x}_n = 1\right) \text{ OR } \left(\alpha_n = 0 \text{ and } \hat{\mathbf{w}}^\top \mathbf{x}_n > 1\right)$$

Furthermore, in this solution $\alpha_n \neq 0$ if $\hat{\mathbf{w}}^\top \mathbf{x}_n = 1$, i.e., *$\mathbf{x}_n$ is a support vector ($n \in \mathcal{S}$), and there are at most d such support vectors.*

For almost every set $\mathbf{X}$, no more than d points $\mathbf{x}_n$ can be on the same hyperplane. Therefore, since all support vectors must lie on the same hyperplane, there can be at most d support vectors, for almost every $\mathbf{X}$.

Given the set of support vectors, $\mathcal{S}$, the KKT conditions of eq. 6 entail that $\alpha_n = 0$ if $n \notin \mathcal{S}$ and

$$\mathbf{1} = \mathbf{X}_{\mathcal{S}}^{\top}\hat{\mathbf{w}} = \mathbf{X}_{\mathcal{S}}^{\top}\mathbf{X}_{\mathcal{S}}\boldsymbol{\alpha}_{\mathcal{S}}\,, \tag{56}$$

where we denoted $\boldsymbol{\alpha}_{\mathcal{S}}$ as $\boldsymbol{\alpha}$ restricted to the support vector components. For almost every set $\mathbf{X}$, since $d \geq |\mathcal{S}|$, $\mathbf{X}_{\mathcal{S}}^{\top}\mathbf{X}_{\mathcal{S}} \in \mathbb{R}^{|\mathcal{S}|\times|\mathcal{S}|}$ is invertible. Therefore, $\boldsymbol{\alpha}_{\mathcal{S}}$ has the unique solution

$$\left(\mathbf{X}_{\mathcal{S}}^{\top}\mathbf{X}_{\mathcal{S}}\right)^{-1}\mathbf{1} = \boldsymbol{\alpha}_{\mathcal{S}}\,. \tag{57}$$

This implies that $\forall n \in \mathcal{S}$, α_n is equal to a rational function in the components of $\mathbf{X}_S$, *i.e.*, $\alpha_n = p_n\left(\mathbf{X}_{\mathcal{S}}\right)/q_n\left(\mathbf{X}_{\mathcal{S}}\right)$, where p_n and q_n are polynomials in the components of $\mathbf{X}_S$. Therefore, if $\alpha_n = 0$, then $p_n\left(\mathbf{X}_{\mathcal{S}}\right) = 0$, so the components of $\mathbf{X}_{\mathcal{S}}$ must be at a root of the polynomial p_n. The roots of the polynomial p_n have measure zero, unless $\forall \mathbf{X}_{\mathcal{S}}:\ p_n\left(\mathbf{X}_{\mathcal{S}}\right) = 0$. However, p_n cannot be identically equal to zero, since, for example, if $\mathbf{X}_{\mathcal{S}}^{\top} = \left[\mathbf{I}_{|\mathcal{S}|\times|\mathcal{S}|}, \mathbf{0}_{|\mathcal{S}|\times(d-|\mathcal{S}|)}\right]$, then $\mathbf{X}_{\mathcal{S}}^{\top}\mathbf{X}_{\mathcal{S}} = \mathbf{I}_{|\mathcal{S}|\times|\mathcal{S}|}$, and so in this case $\forall n \in \mathcal{S}$, $\alpha_n = 1 \neq 0$, from eq. 57.

Therefore, for a given $\mathcal{S}$, the event that "eq. 56 has a solution with a zero component" has a zero measure. Moreover, the union of these events, for all possible $\mathcal{S}$, also has zero measure, as a finite union of zero measures sets (there are only finitely many possible sets $\mathcal{S} \subset \{1,\ldots,N\}$). This implies that, for almost all datasets $\mathbf{X}$, $\alpha_n = 0$ only if $n \notin \mathcal{S}$. Furthermore, for almost all datasets the solution $\boldsymbol{\alpha}$ is unique: for each dataset, $\mathcal{S}$ is uniquely determined, and given $\mathcal{S}$, the solution eq. 56 is uniquely given by eq. 57. ■

Appendix C. Completing the proof of Theorem 3 for zero measure cases

In the preceding Appendices, we established Theorem 4, which only applied when all support vectors are associated with non-zero coefficients. This characterizes almost all data sets, *i.e.* all except for measure zero. We now turn to presenting and proving a more complete characterization of the limit behaviour of gradient descent, which covers all data sets, including those degenerate data sets not covered by Theorem 4, thus establishing Theorem 3.

In order to do so, we first have to introduce additional notation and a recursive treatment of the data set. We will define a sequence of data sets $\bar{\mathbf{P}}_m\mathbf{X}_{\bar{\mathcal{S}}_m}$ obtained by considering only a subset $\bar{\mathcal{S}}_m$ of the points, and projecting them using the projection matrix $\bar{\mathbf{P}}_m$. We start, for $m = 0$, with the full original data set, *i.e.* $\bar{\mathcal{S}}_0 = \{1,\ldots,N\}$ and $\bar{\mathbf{P}}_0 = \mathbf{I}_{d\times d}$. We then define $\hat{\mathbf{w}}_m$ as the max margin predictor for $\bar{\mathbf{P}}_{m-1}\mathbf{X}_{\bar{\mathcal{S}}_{m-1}}$, *i.e.*:

$$\hat{\mathbf{w}}_m = \underset{\mathbf{w}\in\mathbb{R}^d}{\operatorname{argmin}} \|\mathbf{w}\|^2 \ \text{ s.t. } \mathbf{w}^{\top}\bar{\mathbf{P}}_{m-1}\mathbf{x}_n \geq 1\ \forall n \in \bar{\mathcal{S}}_{m-1}\,. \tag{58}$$

In particular, $\hat{\mathbf{w}}_1$ is the max margin predictor for the original data set. We then denote $\mathcal{S}_m^+$ the indices of non-support vectors for 58, $\mathcal{S}_m$ the indices of support vector of 58 with non-zero coefficients for the dual variables corresponding to the margin constraints (for some dual solution), and $\bar{\mathcal{S}}_m$ the set

of support vector with zero coefficients. That is:

$$\begin{aligned}
\mathcal{S}_m^+ &= \left\{n \in \bar{\mathcal{S}}_{m-1} | \hat{\mathbf{w}}_m^{\top}\bar{\mathbf{P}}_{m-1}\mathbf{x}_n > 1\right\}\\
\mathcal{S}_m^= &= \left\{n \in \bar{\mathcal{S}}_{m-1} | \hat{\mathbf{w}}_m^{\top}\bar{\mathbf{P}}_{m-1}\mathbf{x}_n = 1\right\} = \bar{\mathcal{S}}_m \setminus \mathcal{S}_m^+\\
\mathcal{S}_m &= \left\{n \in \mathcal{S}_m^= | \exists \boldsymbol{\alpha} \in \mathbb{R}_{\geq 0}^N : \hat{\mathbf{w}}_m = \sum_{k=1}^{N}\alpha_k\bar{\mathbf{P}}_{m-1}\mathbf{x}_k, \alpha_n > 0, \forall i \notin \mathcal{S}_m^=:\ \alpha_i = 0\right\}\\
\bar{\mathcal{S}}_m &= \mathcal{S}_m^= \setminus \mathcal{S}_m\,.
\end{aligned} \tag{59}$$

The problematic degenerate case, not covered by the analysis of Theorem 4, is when there are support vectors with zero coefficients, *i.e.*, when $\bar{\mathcal{S}}_m \neq \emptyset$. In this case we recurse on these zero-coefficient support vectors (*i.e.*, on $\bar{\mathcal{S}}_m$), but only consider their components orthogonal to the non-zero-coefficient support vectors (*i.e.*, not spanned by points in $\mathcal{S}_m$). That is, we project using:

$$\bar{\mathbf{P}}_m = \bar{\mathbf{P}}_{m-1}\left(\mathbf{I}_d - \mathbf{X}_{\mathcal{S}_m}\mathbf{X}_{\mathcal{S}_m}^{\dagger}\right) \tag{60}$$

where we denoted $\mathbf{A}^{\dagger}$ as the Moore-Penrose pseudo-inverse of $\mathbf{A}$. We also denote $\mathbf{P}_m = \mathbf{I}_d - \bar{\mathbf{P}}_m$.

This recursive treatment continues as long as $\bar{\mathcal{S}}_m \neq \emptyset$, defining a sequence $\hat{\mathbf{w}}_m$ of max margin predictors, for smaller and lower dimensional data sets $\bar{\mathbf{P}}_{m-1}\mathbf{X}_{\bar{\mathcal{S}}_{m-1}}$. We stop when $\bar{\mathcal{S}}_m = \emptyset$ and denote the stopping stage M—that is, M is the minimal m such that $\bar{\mathcal{S}}_m = \emptyset$. Our characterization will be in terms of the sequence $\hat{\mathbf{w}}_1,\ldots,\hat{\mathbf{w}}_M$. As established in Lemma 12 of Appendix B, for almost all data sets we will not have support vectors with non-zero coefficients, and so we will have $M = 1$, and so the characterization only depends on the max margin predictor $\hat{\mathbf{w}}_1$ of the original data set. But, even for the measure zero of data sets in which $M > 1$, we provide the following more complete characterization:

Theorem 13 *For all datasets which are linearly separable (Assumption 1) and given a β-smooth loss function (Assumption 2) with an exponential tail (Assumption 3), gradient descent (as in eq. 2) with step size $\eta < 2\beta^{-1}\sigma_{\max}^{-2}\left(\mathbf{X}\right)$ and any starting point $\mathbf{w}(0)$, the iterates of gradient descent can be written as:*

$$\mathbf{w}\left(t\right) = \sum_{m=1}^{M}\hat{\mathbf{w}}_m\log^{\circ m}\left(t\right) + \boldsymbol{\rho}\left(t\right)\,, \tag{61}$$

where $\log^{\circ m}\left(t\right) = \overbrace{\log\log\cdots\log}^{m\,\text{times}}\left(t\right)$, $\hat{\mathbf{w}}_m$ is the L_2 max margin vector defined in eq. 58, and the residual $\boldsymbol{\rho}\left(t\right)$ is bounded.

C.1. Auxiliary notation

We say that a function $f:\mathbb{N}\to\mathbb{R}$ is absolutely summable if $\sum_{t=1}^{\infty}|f\left(t\right)| < \infty$, and then we denote $f\left(t\right) \in L_1$. Furthermore, we define

$$\mathbf{r}\left(t\right) = \mathbf{w}\left(t\right) - \sum_{m=1}^{M}\left[\hat{\mathbf{w}}_m\log^{\circ m}\left(t\right) + \tilde{\mathbf{w}}_m + \sum_{k=1}^{m-1}\frac{\breve{\mathbf{w}}_{k,m}}{\prod_{r=k}^{m-1}\log^{\circ r}\left(t\right)}\right]$$

where $\tilde{\mathbf{w}}_m$ and $\breve{\mathbf{w}}_{k,m}$ are defined next, and additionally, we denote

$$\tilde{\mathbf{w}} = \sum_{m=1}^{M} \tilde{\mathbf{w}}_m \,.$$

We define, $\forall m \geq 1$, $\tilde{\mathbf{w}}_m$ as the solution of

$$\forall m \geq 1 : \forall n \in \mathcal{S}_m : \eta \sum_{n \in \mathcal{S}_m} \exp\left(-\sum_{k=1}^{m} \tilde{\mathbf{w}}_k^\top \mathbf{x}_n\right) \bar{\mathbf{P}}_{m-1} \mathbf{x}_n = \hat{\mathbf{w}}_m \,, \tag{62}$$

such that

$$\mathbf{P}_{m-1} \tilde{\mathbf{w}}_m = 0 \,\text{and}\, \bar{\mathbf{P}}_m \tilde{\mathbf{w}}_m = 0. \tag{63}$$

The existence and uniqueness of the solution, $\tilde{\mathbf{w}}_m$ are proved in appendix section C.4.

Lastly, we define, $\forall m > k \geq 1$, $\check{\mathbf{w}}_{k,m}$ as the solution of

$$\sum_{n \in \mathcal{S}_m} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \mathbf{P}_{m-1} \mathbf{x}_n = \sum_{k=1}^{m-1} \left[\sum_{n \in \mathcal{S}_k} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \mathbf{x}_n \mathbf{x}_n^\top\right] \check{\mathbf{w}}_{k,m} \tag{64}$$

such that

$$\mathbf{P}_{k-1} \check{\mathbf{w}}_{k,m} = 0 \,\text{and}\, \bar{\mathbf{P}}_k \check{\mathbf{w}}_{k,m} = 0 \,. \tag{65}$$

The existence and uniqueness of the solution $\check{\mathbf{w}}_{k,m}$ are proved in appendix section C.5.

Together, eqs. 62-65 entail the existence of a unique decomposition, $\forall m \geq 1$:

$$\hat{\mathbf{w}}_m = \eta \sum_{n \in \mathcal{S}_m} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \mathbf{x}_n - \eta \sum_{k=1}^{m-1} \left[\sum_{n \in \mathcal{S}_k} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \mathbf{x}_n \mathbf{x}_n^\top\right] \check{\mathbf{w}}_{k,m} \tag{66}$$

given the constraints in eqs. 63 and 65 hold.

C.2. Proof of Theorem 13

In the following proofs, for any solution $\mathbf{w}(t)$, we define

$$\boldsymbol{\tau}(t) = \sum_{m=2}^{M} \hat{\mathbf{w}}_m \log^{\circ m}(t) + \sum_{m=1}^{M} \sum_{k=1}^{m-1} \frac{\check{\mathbf{w}}_{k,m}}{\prod_{r=k}^{m-1} \log^{\circ r}(t)}$$

noting that

$$\|\boldsymbol{\tau}(t+1) - \boldsymbol{\tau}(t)\| \leq \frac{C_\tau}{t \log(t)}$$

and

$$\mathbf{r}(t) = \mathbf{w}(t) - \hat{\mathbf{w}}_1 \log(t) - \tilde{\mathbf{w}} - \boldsymbol{\tau}(t) \tag{67}$$

where $\tilde{\mathbf{w}}$ follow the conditions of Theorem 13. Our goal is to show that $\|\mathbf{r}(t)\|$ is bounded. To show this, we will upper bound the following equation

$$\|\mathbf{r}(t+1)\|^2 = \|\mathbf{r}(t+1) - \mathbf{r}(t)\|^2 + 2\left(\mathbf{r}(t+1) - \mathbf{r}(t)\right)^\top \mathbf{r}(t) + \|\mathbf{r}(t)\|^2 \tag{68}$$

First, we note that $\exists t_0$ such that $\forall t > t_0$ the first term in this equation can be upper bounded by

$$\begin{aligned}
&||\mathbf{r}(t+1) - \mathbf{r}(t)||^2 \\
&\overset{(1)}{=} ||\mathbf{w}(t+1) - \hat{\mathbf{w}}_1 \log(t+1) - \boldsymbol{\tau}(t+1) - \mathbf{w}(t) + \hat{\mathbf{w}}_1 \log(t) + \boldsymbol{\tau}(t)||^2 \\
&\overset{(2)}{=} ||-\eta \nabla L(\mathbf{w}(t)) - \hat{\mathbf{w}}_1 (\log(t+1) - \log(t)) - (\boldsymbol{\tau}(t+1) - \boldsymbol{\tau}(t))||^2 \\
&= \eta^2 ||\nabla L(\mathbf{w}(t))||^2 + \|\hat{\mathbf{w}}_1\|^2 \log^2\left(1 + t^{-1}\right) + \|\boldsymbol{\tau}(t+1) - \boldsymbol{\tau}(t)\|^2 \\
&+ 2\eta \nabla L(\mathbf{w}(t))^\top \left(\hat{\mathbf{w}}_1 \log\left(1 + t^{-1}\right) + \boldsymbol{\tau}(t+1) - \boldsymbol{\tau}(t)\right) \\
&+ 2\hat{\mathbf{w}}_1^\top (\boldsymbol{\tau}(t+1) - \boldsymbol{\tau}(t)) \log\left(1 + t^{-1}\right) \\
&\overset{(3)}{\leq} \eta^2 ||\nabla L(\mathbf{w}(t))||^2 + \|\hat{\mathbf{w}}_1\|^2 t^{-2} + C_\tau^2 t^{-2} \log^{-2}(t) + 2C_\tau \|\hat{\mathbf{w}}_1\| t^{-2} \log^{-1}(t) \;\;, \forall t > t_0
\end{aligned} \tag{69}$$

where in (1) we used eq. 67, in (2) we used eq. 2 and in (3) we used $\forall x > 0 : x \geq \log(1+x) > 0$, and also using $\ell'(\mathbf{w}(t)^\top \mathbf{x}_n) < 0$ for large enough t, we have that

$$\left(\hat{\mathbf{w}}_1 \log\left(1 + t^{-1}\right) + \boldsymbol{\tau}(t+1) - \boldsymbol{\tau}(t)\right)^\top \nabla \mathcal{L}(\mathbf{w}(t)) \leq \sum_{n=1}^{N} \ell'(\mathbf{w}(t)^\top \mathbf{x}_n) \left(\hat{\mathbf{w}}_1^\top \mathbf{x}_n \log\left(1 + t^{-1}\right) - \frac{\|\mathbf{x}_n\| C'_\tau}{t \log(t)}\right) \tag{70}$$

which is negative for sufficiently large t_0 (since $\log\left(1 + t^{-1}\right)$ decreases as t^{-1}, which is slower then $1/(t \log(t))$), $\forall n : \hat{\mathbf{w}}_1^\top \mathbf{x}_n \geq 1$ and $\ell'(u) \leq 0$.

Also, from Lemma 10 we know that:

$$\|\nabla \mathcal{L}(\mathbf{w}(t))\|^2 = o(1) \text{ and } \sum_{u=0}^{\infty} \|\nabla \mathcal{L}(\mathbf{w}(u))\|^2 < \infty \tag{71}$$

Substituting eq. 71 into eq. 69, and recalling that $t^{-\nu_1} \log^{-\nu_2}(t)$ converges for any $\nu_1 > 1$ and any ν_2, and so

$$\kappa_0(t) \triangleq \|\mathbf{r}(t+1) - \mathbf{r}(t)\|^2 \in L_1 \,. \tag{72}$$

Also, in the next subsection we will prove that

Lemma 14 *Let $\kappa_1(t)$ and $\kappa_2(t)$ be functions in L_1, then*

$$(\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) \leq \kappa_1(t) \|\mathbf{r}(t)\| + \kappa_2(t) \tag{73}$$

Thus, by combining eqs. 73 and 72 into eq. 68, we find

$$\|\mathbf{r}(t+1)\|^2 \leq \kappa_0(t) + 2\kappa_1(t) \|\mathbf{r}(t)\| + 2\kappa_2(t) + \|\mathbf{r}(t)\|^2$$

On this result we apply the following lemma (with $\phi(t) = \|\mathbf{r}(t)\|$, $h(t) = 2\kappa_1(t)$, and $z(t) = \kappa_0(t) + 2\kappa_2(t)$), which we prove in appendix C.6:

Lemma 15 *Let $\phi(t), h(t), z(t)$ be three functions from $\mathbb{N}$ to $\mathbb{R}_{\geq 0}$, and C_1, C_2, C_3 be three positive constants. Then, if $\sum_{t=1}^{\infty} h(t) \leq C_1 < \infty$, and*

$$\phi^2(t+1) \leq z(t) + h(t) \phi(t) + \phi^2(t) \tag{74}$$

we have

$$\phi^2(t+1) \leq C_2 + C_3 \sum_{u=1}^{t} z(u) \tag{75}$$

and obtain that

$$\|\mathbf{r}(t+1)\|^2 \leq C_2 + C_3 \sum_{u=1}^{t} \left(\kappa_0(u) + 2\kappa_2(u)\right) \leq C_4 < \infty\,,$$

since we assumed that $\forall i = 0,1,2:\ \kappa_i(t) \in L_1$. This completes our proof. ■

C.3. Proof of Lemma 14

Before we prove Lemma 14, we prove the following auxilary Lemma:

Lemma 16 *Consider the function* $f(t) = t^{-\nu_1}(\log(t))^{-\nu_2}(\log\log(t))^{-\nu_3}\ldots(\log^{\circ M}(t))^{-\nu_{M+1}}$. *If* $\exists m_0 \leq M+1$ *such that* $\nu_{m_0} > 1$ *and for all* $m' < m_0, \nu_{m'} = 1$, *then* $f(t) \in L_1$.

Proof To prove Lemma 16, we will show that the improper integeral $\int_{t_1}^{\infty} f(t)dt$ for any $t_1 > 0$ is bounded, *i.e.*, $\forall t_1 > 0, \int_{t_1}^{\infty} f(t)dt < C$. Using the integeral test for convergence (or Maclaurin–Cauchy test) this in turn implies that $\forall t_1 > 0, \sum_{t_1}^{\infty} f(t) < C$, and thus $f(t) \in L_1$.

First, if $m_0 > 1$, then $\nu_1 = \nu_2 \ldots = \nu_{m_0-1} = 1$ and $\nu_{m_0} = 1+\epsilon$ for some $\epsilon > 0$. Using change of variables $y = \log^{\circ(m_0-1)}(t)$, we have

$$\mathrm{d}y = \left(t\prod_{r=1}^{m_0-2}\log^{\circ r}(t)\right)^{-1}\mathrm{d}t = t^{-\nu_1}\prod_{r=1}^{m_0-2}\left(\log^{\circ r}(t)\right)^{-\nu_{r+1}}\mathrm{d}t$$

and for all $m > m_0$, $\left(\log^{\circ(m-1)}(t)\right)^{-\nu_m} = \left(\log^{\circ(m-m_0)}(y)\right)^{-\nu_m} \leq (\log(y))^{|\nu_m|}$. Thus, denoting $\tilde{\nu} = \sum_{m=m_0+1}^{M+1}|\nu_m|$ and $\log^{\circ(m_0-1)}(t_1) = y_1$, we have

$$\int_{t_1}^{\infty} f(t)\mathrm{d}t = \int_{y_1}^{\infty} y^{-\nu_{m_0}} \prod_{m=m_0+1}^{M+1}\left(\log^{\circ m-m_0}(y)\right)^{-\nu_m}\mathrm{d}(y) \leq \int_{y_1}^{\infty}\frac{(\log(y))^{\tilde{\nu}}}{y^{1+\epsilon}}\mathrm{d}y. \tag{76}$$

For $m_0 = 1$, we have $\nu_1 = 1+\epsilon$ for some $\epsilon > 0$, and for $m > 1$, $\left(\log^{\circ(m-1)}(t)\right)^{-\nu_m} \leq (\log(t))^{|\nu_m|}$. Thus, denoting, $\tilde{\nu} = \sum_{m=2}^{M+1}|\nu_m|$, we have $\int_{t_1}^{\infty} f(t)\mathrm{d}t \leq \int_{t_1}^{\infty}\frac{(\log(t))^{\tilde{\nu}}}{t^{1+\epsilon}}\mathrm{d}t$.

Thus, for any m_0, we only need to show that for all $t_1 > 0, \epsilon > 0$ and $\tilde{\nu} > 0$, $\int_{t_1}^{\infty}\frac{(\log(t))^{\tilde{\nu}}}{t^{1+\epsilon}}\mathrm{d}t < \infty$.

Let us now look at $\int_{t_1}^{\infty}\frac{(\log(t))^{\tilde{\nu}}}{t^{1+\epsilon}}\mathrm{d}t$. using $u = (\log(t))^{\tilde{\nu}}$ and $\mathrm{d}v = \frac{1}{t^{1+\epsilon}}$, we have $\mathrm{d}u = \tilde{\nu}t^{-1}(\log(t))^{\tilde{\nu}-1}$ and $v = -\frac{1}{\epsilon t^{\epsilon}}$. Using integration by parts, $\int u\mathrm{d}v = uv - \int v\mathrm{d}u$, we have

$$\int\frac{(\log(t))^{\tilde{\nu}}}{t^{1+\epsilon}}\mathrm{d}t = -\frac{(\log(t))^{\tilde{\nu}}}{\epsilon t^{\epsilon}} + \frac{\tilde{\nu}}{\epsilon}\int\frac{(\log(t))^{\tilde{\nu}-1}}{t^{1+\epsilon}}\mathrm{d}t$$

Recursing the above equation K times such that $\tilde{\nu} - K < 0$, we have positive constants $c_0, c_1, \ldots c_K > 0$ independent of t, such that

$$\begin{aligned}\int_{t_1}^{\infty}\frac{(\log(t))^{\tilde{\nu}}}{t^{1+\epsilon}}\mathrm{d}t &= \left[-\sum_{k=0}^{K-1}\frac{c_k(\log(t))^{\tilde{\nu}-k}}{\epsilon t^{\epsilon}}\right]_{t=t_1}^{\infty} + c_K\int_{t=t_1}^{\infty}\frac{(\log(t))^{\tilde{\nu}-K}}{t^{1+\epsilon}}\mathrm{d}t \\ &\overset{(1)}{=} \sum_{k=0}^{K-1}\frac{c_k(\log(t_1))^{\tilde{\nu}-k}}{\epsilon t_1^{\epsilon}} + c_K\int_{t=t_1}^{\infty}\frac{(\log(t))^{\tilde{\nu}-K}}{t^{1+\epsilon}}\mathrm{d}t \\ &\overset{(2)}{\leq} \sum_{k=0}^{K-1}\frac{c_k(\log(t_1))^{\tilde{\nu}-k}}{\epsilon t_1^{\epsilon}} + c_K\int_{t=t_1}^{\infty}\frac{1}{t^{1+\epsilon}}\overset{(3)}{} \\ &= \sum_{k=0}^{K-1}\frac{c_k(\log(t_1))^{\tilde{\nu}-k}}{\epsilon t_1^{\epsilon}}y + \frac{c_K}{\epsilon t_1^{\epsilon}} < \infty\end{aligned} \tag{77}$$

where (1) follows as $\sum_{k=0}^{K-1}\frac{c_k(\log(t))^{\tilde{\nu}-k}}{\epsilon t^{\epsilon}} \overset{t\to\infty}{\to} 0$, (2) follows as K is chosen such that $\tilde{\nu} - K < 0$ and hence for all $t > 0$, $(\log(t))^{\tilde{\nu}-K} < 1$. This completes the proof of the lemma. ■

Lemma 14 *Let* $\kappa_1(t)$ *and* $\kappa_2(t)$ *be functions in* L_1, *then*

$$\left(\mathbf{r}(t+1) - \mathbf{r}(t)\right)^{\top}\mathbf{r}(t) \leq \kappa_1(t)\|\mathbf{r}(t)\| + \kappa_2(t) \tag{73}$$

Proof Recall that we defined

$$\mathbf{r}(t) = \mathbf{w}(t) - \mathbf{q}(t) \tag{78}$$

where

$$\mathbf{q}(t) = \sum_{m=1}^{M}\left[\hat{\mathbf{w}}_m\log^{\circ m}(t) + \mathbf{h}_m(t)\right]. \tag{79}$$

$$\mathbf{h}_m(t) = \tilde{\mathbf{w}}_m + \sum_{k=1}^{m-1}\frac{\check{\mathbf{w}}_{k,m}}{\prod_{r=k}^{m-1}\log^{\circ r}(t)} \tag{80}$$

with $\hat{\mathbf{w}}_m$, $\tilde{\mathbf{w}}_m$ and $\check{\mathbf{w}}_{k,m}$ defined in eqs. 58, 62 and 64, respectively. We note that

$$\|\mathbf{q}(t+1) - \mathbf{q}(t) - \dot{\mathbf{q}}(t)\| \leq C_q t^{-2} \in L_1 \tag{81}$$

where

$$\dot{\mathbf{q}}(t) = \sum_{m=1}^{M}\hat{\mathbf{w}}_m\frac{1}{t\prod_{r=1}^{m-1}\log^{\circ r}(t)} + \dot{\mathbf{h}}_m(t)\,. \tag{82}$$

Additionally, we define C_h, C_h' so that

$$\|\mathbf{h}_m(t)\| \leq \|\tilde{\mathbf{w}}_m\| + \sum_{k=1}^{m}\|\check{\mathbf{w}}_{k,m}\| \leq C_h \tag{83}$$

and

$$\left\|\dot{\mathbf{h}}_m(t)\right\| \leq \frac{C_h'}{t\left(\prod_{r=1}^{m-2}\log^{\circ r}(t)\right)\left(\log^{\circ(m-1)}(t)\right)^2} \in L_1\,. \tag{84}$$

We wish to calculate

$$\begin{aligned}
&(\mathbf{r}(t+1)-\mathbf{r}(t))^\top \mathbf{r}(t)\\
&\overset{(1)}{=}[\mathbf{w}(t+1)-\mathbf{w}(t)-[\mathbf{q}(t+1)-\mathbf{q}(t)]]^\top \mathbf{r}(t)\\
&\overset{(2)}{=}[-\eta\nabla\mathcal{L}(\mathbf{w}(t))-\dot{\mathbf{q}}(t)]^\top \mathbf{r}(t)-[\mathbf{q}(t+1)-\mathbf{q}(t)-\dot{\mathbf{q}}(t)]^\top \mathbf{r}(t)
\end{aligned} \tag{85}$$

where in (1) we used eq. 78 and in (2) we used the definition of GD in eq. 2. We can bound the second term using Cauchy-Shwartz inequality and eq. 81:

$$[\mathbf{q}(t+1)-\mathbf{q}(t)-\dot{\mathbf{q}}(t)]^\top \mathbf{r}(t) \leq \|\mathbf{q}(t+1)-\mathbf{q}(t)-\dot{\mathbf{q}}(t)\|\,\|\mathbf{r}(t)\| \leq C_q t^{-2}\|\mathbf{r}(t)\|\,.$$

Next, we examine the second term in eq. 85

$$\begin{aligned}
&[-\eta\nabla\mathcal{L}(\mathbf{w}(t))-\dot{\mathbf{q}}(t)]^\top \mathbf{r}(t)\\
&=\left[-\eta\sum_{n=1}^{N}\ell'(\mathbf{w}(t)^\top\mathbf{x}_n)\,\mathbf{x}_n-\dot{\mathbf{q}}(t)\right]^\top \mathbf{r}(t)\\
&\overset{(1)}{=}-\sum_{m=1}^{M}\dot{\mathbf{h}}_m(t)^\top \mathbf{r}(t)-\eta\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m^+}\ell'(\mathbf{w}(t)^\top\mathbf{x}_n)\,\mathbf{x}_n^\top\mathbf{r}(t)\\
&+\left[\eta\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}-\ell'(\mathbf{w}(t)^\top\mathbf{x}_n)\,\mathbf{x}_n-\sum_{m=1}^{M}\hat{\mathbf{w}}_m\frac{1}{t\prod_{r=1}^{m-1}\log^{\circ r}(t)}\right]^\top \mathbf{r}(t)\,,
\end{aligned} \tag{86}$$

where in (1) recall from eq. 59 that $\mathcal{S}_m, \mathcal{S}_m^+$ are mutually exclusive and $\cup_{m=1}^M \mathcal{S}_m \cup \mathcal{S}_m^+ = [N]$.

Next we upper bound the three terms in eq. 86.

To bound the first term in eq. 86 we use Cauchy-Shartz, and eq. 84.

$$\sum_{m=1}^{M}\dot{\mathbf{h}}_m(t)^\top \mathbf{r}(t) \leq \sum_{m=1}^{M}\left\|\dot{\mathbf{h}}_m(t)\right\|\|\mathbf{r}(t)\| \leq \frac{MC_h'}{t\left(\prod_{r=1}^{m-2}\log^{\circ r}(t)\right)\left(\log^{\circ(m-1)}(t)\right)^2}\|\mathbf{r}(t)\|$$

In bounding the second term in eq. 86, note that for tight exponential tail loss, since $\mathbf{w}(t)^\top\mathbf{x}_n \to \infty$, for large enough t_0, we have $-\ell'(\mathbf{w}(t)^\top\mathbf{x}_n) \leq (1+\exp(-\mu_+\mathbf{w}(t)^\top\mathbf{x}_n))\exp(-\mathbf{w}(t)^\top\mathbf{x}_n) \leq 2\exp(-\mathbf{w}(t)^\top\mathbf{x}_n)$ for all $t > t_0$. The first term in eq. 86 can be bounded by the following set of

inequalities, for $t > t_0$,

$$\begin{aligned}
&\eta\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m^+}-\ell'(\mathbf{w}(t)^\top\mathbf{x}_n)\,\mathbf{x}_n^\top\mathbf{r}(t) \leq \eta\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m^+:\mathbf{x}_n^\top\mathbf{r}(t)\geq 0}-\ell'(\mathbf{w}(t)^\top\mathbf{x}_n)\,\mathbf{x}_n^\top\mathbf{r}(t)\\
&\overset{(1)}{\leq}2\eta\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m^+:\mathbf{x}_n^\top\mathbf{r}(t)\geq 0}\exp\left(-\sum_{l=1}^{M}\left[\hat{\mathbf{w}}_l^\top\mathbf{x}_n\log^{\circ l}(t)+\mathbf{x}_n^\top\mathbf{h}_l(t)\right]-\mathbf{x}_n^\top\mathbf{r}(t)\right)\mathbf{x}_n^\top\mathbf{r}(t)\\
&\overset{(2)}{\leq}2\eta\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m^+:\mathbf{x}_n^\top\mathbf{r}(t)\geq 0}\exp\left(-\sum_{l=1}^{M}\left[\hat{\mathbf{w}}_l^\top\mathbf{x}_n\log^{\circ l}(t)+\mathbf{x}_n^\top\mathbf{h}_l(t)\right]\right)\\
&\overset{(3)}{\leq}2\eta\sum_{m=1}^{M}\left|\mathcal{S}_m^+\max_{n\in\mathcal{S}_m^+}\right|\exp\left(M\|\mathbf{x}_n\|C_h\right)\exp\left(-\sum_{l=1}^{M}\hat{\mathbf{w}}_l^\top\mathbf{x}_n\log^{\circ l}(t)\right)\\
&\overset{(4)}{\leq}\begin{cases}\sum_{m=1}^{M}\frac{2\eta\left|\mathcal{S}_m^+\right|\exp\left(M\max_{n\in\mathcal{S}_m^+}\|\mathbf{x}_n\|C_h\right)}{t\left(\prod_{k=1}^{m-1}\log^{\circ k}(t)\right)\left(\log^{\circ m-1}(t)\right)^{\theta_m}\left(\prod_{k=m}^{M-1}(\log^{\circ m}(t))^{\hat{\mathbf{w}}_k^\top\mathbf{x}_n}\right)} & \text{if } M>1\\ \frac{2\eta\left|\mathcal{S}_1^+\right|\exp(\max_n\|\mathbf{x}_n\|C_h)}{t^{\theta_1}} & \text{if } M=1\end{cases} \in L_1.
\end{aligned} \tag{87}$$

where in (1) we used eqs. 78 and 79, in (2) we used that $\forall x: xe^{-x} \leq 1$ and $\mathbf{x}_n^\top\mathbf{r}(t) \geq 0$, (3) we used eq. 83 and in (4) we denoted $\theta_m = \min_{n\in\mathcal{S}_m^+}\hat{\mathbf{w}}_m^\top\mathbf{x}_n > 1$ and the last line is integrable based on Lemma 16.

Next, we bound the last term in eq. 86. For exponential tailed losses (Assumption 3), since $\mathbf{w}(t)^\top\mathbf{x}_n \to \infty$, we have positive constants $\mu_-, \mu_+ > 0$, t_- and t_+ such that $\forall n$

$$\begin{aligned}
&\forall t > t_+ : -\ell'\left(\mathbf{w}(t)^\top\mathbf{x}_n\right) \leq \left(1+\exp\left(-\mu_+\mathbf{w}(t)^\top\mathbf{x}_n\right)\right)\exp\left(-\mathbf{w}(t)^\top\mathbf{x}_n\right)\\
&\forall t > t_- : -\ell'\left(\mathbf{w}(t)^\top\mathbf{x}_n\right) \geq \left(1-\exp\left(-\mu_-\mathbf{w}(t)^\top\mathbf{x}_n\right)\right)\exp\left(-\mathbf{w}(t)^\top\mathbf{x}_n\right)
\end{aligned}$$

We define $\gamma_n(t)$ as

$$\gamma_n(t) = \begin{cases}(1+\exp(-\mu_+\mathbf{w}(t)^\top\mathbf{x}_n) & \text{if } \mathbf{r}(t)^\top\mathbf{x}_n \geq 0\\ (1-\exp(-\mu_-\mathbf{w}(t)^\top\mathbf{x}_n) & \text{if } \mathbf{r}(t)^\top\mathbf{x}_n < 0\end{cases}. \tag{88}$$

This implies $t > \max(t_+, t_-)$, $-\ell'(\mathbf{w}(t)^\top\mathbf{x}_n)\,\mathbf{x}_n^\top\mathbf{r}(t) \leq \gamma_n(t)\exp\left(-\mathbf{w}^\top(t)\,\mathbf{x}_n\right)\mathbf{x}_n$.

From this result, we have the following set of inequalities:

$$\eta\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}-\ell'(\mathbf{w}(t)^\top\mathbf{x}_n)\,\mathbf{x}_n^\top\mathbf{r}\,(t)\le\eta\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\gamma_n(t)\exp\left(-\mathbf{w}\,(t)^\top\mathbf{x}_n\right)\mathbf{x}_n^\top\mathbf{r}\,(t)$$

$$\overset{(1)}{=}\eta\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\gamma_n(t)\exp\left(-\sum_{l=1}^{M}\left[\hat{\mathbf{w}}_l^\top\mathbf{x}_n\log^{ol}(t)+\mathbf{x}_n^\top\breve{\mathbf{w}}_l+\sum_{k=1}^{l-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{k,l}}{\prod_{r=k}^{l-1}\log^{or}(t)}\right]-\mathbf{x}_n^\top\mathbf{r}\,(t)\right)\mathbf{x}_n^\top\mathbf{r}\,(t)$$

$$\overset{(2)}{=}\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\frac{\eta\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\,(t)\right)\mathbf{x}_n^\top\mathbf{r}\,(t)}{t\prod_{r=1}^{m-1}\log^{or}(t)}\exp\left(-\sum_{k=1}^{m}\sum_{l=k+1}^{M}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{k,l}}{\prod_{r=k}^{l-1}\log^{or}(t)}\right)$$

$$\overset{(3)}{=}\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\frac{\eta\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\,(t)\right)\mathbf{x}_n^\top\mathbf{r}\,(t)}{t\prod_{r=1}^{m-1}\log^{or}(t)}\exp\left(-\sum_{l=m+1}^{M}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l}}{\prod_{r=m}^{l-1}\log^{or}(t)}\right)\psi_m\,(t)$$

$$\le\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\frac{\eta\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\,(t)\right)\mathbf{x}_n^\top\mathbf{r}\,(t)}{t\prod_{r=1}^{m-1}\log^{or}(t)}\psi_m\,(t)\left[\left(1-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)\right.$$
$$\left.+\exp\left(-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)-\left(1-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)\right]\tag{89}$$

where in (1) we used eqs. 78 and 79, and in (2) we used $\mathbf{P}_{k-1}\breve{\mathbf{w}}_{k,m}=0$ from eq. 65 (so $\mathbf{x}_n^\top\breve{\mathbf{w}}_{k,l}=0$ if $m<k$) and in (3) defined

$$\psi_m\,(t)=\exp\left(-\sum_{k=1}^{m-1}\sum_{l=k+1}^{M}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{k,l}}{\prod_{r=k}^{l-1}\log^{or}(t)}\right).\tag{90}$$

Note $\exists t_\psi$ such that $\forall t>t_\psi$, we can bound $\psi_m\,(t)$ by

$$\exp\left(\frac{-M\max_n\|\mathbf{x}_n\|\,C_h}{\log^{\circ(m-1)}(t)}\right)\le\psi_m\,(t)\le 1\,.\tag{91}$$

Thus, the third term in 86 is given by

$$\eta\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}-\ell'(\mathbf{w}(t)^\top\mathbf{x}_n)\,\mathbf{x}_n^\top\mathbf{r}\,(t)-\sum_{m=1}^{M}\frac{\tilde{\mathbf{w}}_m^\top\mathbf{r}\,(t)}{t\prod_{r=1}^{m-1}\log^{or}(t)}$$
$$\overset{(1)}{\le}\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\frac{\eta\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\,(t)\right)\mathbf{x}_n^\top\mathbf{r}\,(t)}{t\prod_{r=1}^{m-1}\log^{or}(t)}\psi_m\,(t)\left[\exp\left(-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)\right.$$
$$\left.-\left(1-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)\right]$$
$$+\sum_{m=1}^{M}\left[\sum_{n\in\mathcal{S}_m}\frac{\eta\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\,(t)\right)\mathbf{x}_n^\top\mathbf{r}\,(t)}{t\prod_{r=1}^{m-1}\log^{or}(t)}\psi_m\,(t)\left(1-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)\right.$$
$$\left.-\frac{\mathbf{r}(t)^\top\hat{\mathbf{w}}_m}{t\prod_{r=1}^{m-1}\log^{or}(t)}\right],\tag{92}$$

where (1) follows from the bound in eq. 89.

We examine the first term in eq. 92

$$\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\frac{\eta\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\,(t)\right)\mathbf{x}_n^\top\mathbf{r}\,(t)}{t\prod_{r=1}^{m-1}\log^{or}(t)}\psi_m\,(t)$$
$$\cdot\left[\exp\left(-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)-\left(1-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)\right]$$

$\forall t>t_1>t_\psi$, where we will determine t_1 later. We have the following for all $m\in[M]$

$$\sum_{n\in\mathcal{S}_m}\frac{\eta\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\,(t)\right)\mathbf{x}_n^\top\mathbf{r}\,(t)}{t\prod_{r=1}^{m-1}\log^{or}(t)}\psi_m\,(t)$$
$$\cdot\left[\exp\left(-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)-\left(1-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)\right]$$
$$\overset{(1)}{\le}\sum_{\substack{n\in\mathcal{S}_m:\\ \mathbf{x}_n^\top\mathbf{r}(t)\ge 0}}\frac{\eta\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\psi_m\,(t)}{t\prod_{r=1}^{m-1}\log^{or}(t)}\left[\exp\left(-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)-\left(1-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)\right]$$
$$\overset{(2)}{\le}\sum_{\substack{n\in\mathcal{S}_m:\\ \mathbf{x}_n^\top\mathbf{r}(t)\ge 0}}\frac{\eta\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)(t)}{t\prod_{r=1}^{m-1}\log^{or}\psi_m\,(t)}\left(\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}\right)^2\in L_1\,,\tag{93}$$

where we set $t_1>0$ such that $\forall t>t_1$ the term in the square bracket is positive and

$$\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\breve{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}(t)}>-1\,,$$

in (1) we used that since $e^{-x}\ge 1-x$, and also from using $e^{-x}x\le 1$ and in (2) we use that $\forall x\ge -1$ we have that $e^{-x}\le 1-x+x^2$ and $\psi_m\,(t)\le 1$ from eq. 91.

We examine the second term in eq. 92 using the decomposition of $\hat{\mathbf{w}}_m$ from eq. 66

$$\sum_{m=1}^{M}\left[\sum_{n\in\mathcal{S}_m}\frac{\eta\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right)}{t\prod_{r=1}^{m-1}\log^{or}\left(t\right)}\psi_m\left(t\right)\left(1-\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\tilde{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}\left(t\right)}\right)-\frac{\mathbf{x}_n^\top\hat{\mathbf{w}}_m}{t\prod_{r=1}^{m-1}\log^{or}\left(t\right)}\right]$$

$$\overset{(1)}{=}\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\frac{\eta\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right)}{t\prod_{r=1}^{m-1}\log^{or}\left(t\right)}\left(\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)\psi_m\left(t\right)-1\right)$$

$$-\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\frac{\eta\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right)\psi_m(t)}{t\prod_{r=1}^{m-1}\log^{or}\left(t\right)}\sum_{l=m}^{M-1}\frac{\mathbf{x}_n^\top\tilde{\mathbf{w}}_{m,l+1}}{\prod_{r=m}^{l}\log^{or}\left(t\right)}$$

$$+\sum_{m=1}^{M}\sum_{k=1}^{m-1}\sum_{n\in\mathcal{S}_k}\frac{\eta\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right)\mathbf{x}_n^\top\tilde{\mathbf{w}}_{k,m}}{\prod_{r=1}^{m-1}t\log^{or}\left(t\right)}$$

$$\overset{(2)}{=}\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\frac{\eta\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right)}{t\prod_{r=1}^{m-1}\log^{or}\left(t\right)}\left(\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)\psi_m\left(t\right)-1\right)$$

$$-\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\sum_{l=m}^{M-1}\frac{\eta\gamma_n(t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right)\psi_m(t)\mathbf{x}_n^\top\tilde{\mathbf{w}}_{m,l+1}}{t\prod_{r=1}^{l}\log^{or}\left(t\right)}$$

$$+\sum_{k=1}^{M}\sum_{n\in\mathcal{S}_k}\sum_{m=k}^{M-1}\frac{\eta\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right)\mathbf{x}_n^\top\tilde{\mathbf{w}}_{k,m+1}}{\prod_{r=1}^{m}t\log^{or}\left(t\right)}$$

$$\overset{(3)}{=}\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\left[\frac{1}{t\prod_{r=1}^{m-1}\log^{or}\left(t\right)}-\sum_{k=m}^{M-1}\frac{\mathbf{x}_n^\top\tilde{\mathbf{w}}_{m,k+1}}{t\prod_{r=1}^{k}\log^{or}\left(t\right)}\right]\eta\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\left(\gamma_n(t)\psi_m\left(t\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)-1\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right)$$

$$:=\sum_{m=1}^{M}\sum_{n\in\mathcal{S}_m}\Gamma_{m,n}(t), \tag{94}$$

where in (1) we used eq. 66, in (2) we re-arranged the order of summation in the last term, and in (3) we just use a change of variables.

Next, we examine $\Gamma_{m,n}(t)$ for each m and $n\in\mathcal{S}_m$ in eq. 94. Note that, $\exists t_2>t_\psi$ such that $\forall t>t_2$ we have

$$\left|\sum_{k=m}^{M-1}\frac{\mathbf{x}_n^\top\tilde{\mathbf{w}}_{m,k+1}}{t\prod_{r=1}^{k}\log^{or}\left(t\right)}\right|\leq\frac{0.5}{t\prod_{r=1}^{m-1}\log^{or}\left(t\right)}.$$

In this case, $\forall t>t_2$

$$\Gamma_{m,n}(t)\overset{(1)}{\leq}\eta\left[\frac{\kappa(n,t)}{t\prod_{r=1}^{m-1}\log^{or}\left(t\right)}\right]\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)\left(\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)-1\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right), \tag{95}$$

where in (1) follows from the definition of t_2, wherein

$$\kappa_n(t)=\begin{cases}1.5 & \text{if }\left(\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)-1\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right)>0\\ 0.5 & \text{if }\left(\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)-1\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right)<0\end{cases}.$$

1. First, if $\mathbf{x}_n^\top\mathbf{r}\left(t\right)>0$, then $\gamma_n(t)=(1+\exp(-\mu_+\mathbf{w}(t)^\top\mathbf{x}_n))>0$.

We further divide into two cases. In the following C_0, C_1 are some constants independent of t.

(a) If $\left|\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right|>C_0t^{-0.5\mu_+}$, then we have the following

$$\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)$$

$$\overset{(1)}{\leq}\left(1+\exp\left(-\mu_+\sum_{l=1}^{M}\left[\hat{\mathbf{w}}_l^\top\mathbf{x}_n\log^{ol}(t)+\mathbf{h}_l^\top\mathbf{x}_n\right]\right)\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)$$

$$\overset{(2)}{\leq}\left(1+\frac{\exp(\mu_+C_h\left\|\mathbf{x}_n\right\|)}{\left(t\prod_{r=1}^{m-1}\log^{or}\left(t\right)\right)^{\mu_+}}\right)\exp(-C_0t^{-0.5\mu_+})$$

$$\overset{(3)}{\leq}\left(1+C_1t^{-\mu_+}\right)\left(1-C_0t^{-0.5\mu_+}+0.5C_0^2t^{-\mu_+}\right),\forall t>t'_+$$

$$\leq 1-C_0t^{-0.5\mu_+}\left(1+C_1t^{-\mu_+}\right)+0.5C_0^2t^{-\mu_+}\left(1+C_1t^{-\mu_+}\right)\overset{(4)}{\leq}1,\forall t>t''_+, \tag{96}$$

where in (1), we use $\psi_m(t)\leq1$ from eq. 91 and using eq. 78, in (2) we used bound on $\mathbf{h}_m$ from eq. 83, in (3) for some large enough $t'_+>t_+$, we have $\frac{\exp(\mu_+C_h\|\mathbf{x}_n\|)}{\left(\prod_{r=1}^{m-1}\log^{or}(t)\right)^{\mu_+}}\leq C_1$, and for the second term we used the inequality $e^{-x}\leq1-x+0.5x^2$ for $x>0$, and (4) holds asymptotically for $t>t''_+$ for large enough $t''_+>t'_+$ as $C_0t^{-0.5\mu_+}$ converges slower than $0.5C_0^2t^{-\mu_+}$ to 0.

Thus, using eq. 96 in eq. 95, $\forall t>\max\left(t_2,t''_+\right)$, we have

$$\Gamma_{m,n}(t)\leq\left[\frac{\eta\kappa(n,t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)}{t\prod_{r=1}^{m-1}\log^{or}\left(t\right)}\right]\left(\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)-1\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right)\leq0$$

(b) If $0<\mathbf{x}_n^\top\mathbf{r}\left(t\right)<C_0t^{-0.5\mu_+}$, then we have the following: $\psi_m(t)\leq1$ from eq. 91, $\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)\leq1$ as $\mathbf{x}_n^\top\mathbf{r}\left(t\right)>0$, and since $\mathbf{w}(t)^\top\mathbf{x}_n\to\infty$, for large enough $t>t'''_+$, $\gamma_n(t)=\left(1+\exp\left(-\mu_+\mathbf{w}(t)^\top\mathbf{x}_n\right)\right)\leq2$

This gives us, $\left(\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)-1\right)\mathbf{x}_n^\top\mathbf{r}\left(t\right)\leq\mathbf{x}_n^\top\mathbf{r}\left(t\right)\leq C_0t^{-0.5\mu_+}$, and using this in eq. 95, $\forall t>\max\left(t_2,t'_+\right)$

$$\Gamma_{m,n}(t)\leq\left[\frac{\eta\kappa(n,t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)}{t\prod_{r=1}^{m-1}\log^{or}\left(t\right)}\right]C_0t^{-0.5\mu_+}\in L_1.$$

2. Second, if $\mathbf{x}_n^\top\mathbf{r}\left(t\right)\leq0$, then $\gamma_n(t)=(1-\exp(-\mu_-\mathbf{w}(t)^\top\mathbf{x}_n))\in(0,1)$. We again divide into following special cases.

(a) If $\left|\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right|\leq C_0\left(\log^{o(m-1)}(t)\right)^{-0.5\tilde{\mu}_-}$, where $\tilde{\mu}_-=\min\left(\mu_-,1\right)$, then we have

$$\Gamma_{m,n}(t)\leq\left[\frac{1.5\eta\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)}{t\prod_{r=1}^{m-1}\log^{or}\left(t\right)}\right]\left(1-\gamma_n(t)\psi_m\left(t\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)\right)\left|\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right|$$

$$\overset{(1)}{\leq}\left[\frac{1.5\eta\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)}{t\prod_{r=1}^{m-2}\log^{or}\left(t\right)}\right]C_0\left(\log^{o(m-1)}(t)\right)^{-1-0.5\tilde{\mu}_-}\in L_1.$$

where in (1) we used that $\left(1-\gamma_n(t)\psi_m\left(t\right)\exp\left(-\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right)\right)<1$ and $\left|\mathbf{x}_n^\top\mathbf{r}\left(t\right)\right|\leq C_0\left(\log^{o(m-1)}(t)\right)^{-0.5\tilde{\mu}_-}$.

(b) If $\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)<1$, then, from eq. 91

$$\frac{-M\max_n\|\mathbf{x}_n\|C_h}{\log^{\circ(m-1)}(t)}\le\log\psi_m(t)<\mathbf{x}_n^\top\mathbf{r}(t)\,. \tag{97}$$

In this case, since $\gamma_n(t)=1-\exp(-\mathbf{w}(t)^\top\mathbf{x}_n)<1$, we also have $\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)<1$, and hence $\left(\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)-1\right)\mathbf{x}_n^\top\mathbf{r}(t)>0$. Thus, $\forall t>t_2$, in 95, $\kappa_n(t)=1.5$, and we have

$$\Gamma_{m,n}(t)\le\left[\frac{1.5\eta\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)}{t\prod_{r=1}^{m-1}\log^{\circ r}(t)}\right]\left(1-\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)\right)\left|\mathbf{x}_n^\top\mathbf{r}(t)\right|$$
$$\overset{(1)}{\le}\left[\frac{1.5\eta\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)}{t\prod_{r=1}^{m-1}\log^{\circ r}(t)}\right]\frac{M\max_n\|\mathbf{x}_n\|C_h}{\log^{\circ(m-1)}(t)}\le\frac{C_2}{t\prod_{r=1}^{m-2}\log^{\circ r}(t)\left(\log^{\circ(m-1)}(t)\right)^2}\in L_1,$$

where (1) follows from $\left(1-\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)\right)<1$ and the bound on $|\mathbf{x}_n^\top\mathbf{r}(t)|=-\mathbf{x}_n^\top\mathbf{r}(t)$ from eq. 97.

(c) If $\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)>1$, and $\left|\mathbf{x}_n^\top\mathbf{r}(t)\right|>C_0\left(\log^{\circ(m-1)}(t)\right)^{-0.5\tilde{\mu}_-}$, where $\tilde{\mu}_=\min(1,\mu_-)$.
Since, $\mathbf{x}_n^\top\mathbf{w}(t)\to\infty$ and $\psi_m(t)\to1$ from eq. 90, for large enough $t'_->t_-$, we have $\forall t>t'_-$, $\psi_m(t)>0.5$ and $\gamma_n(t)=(1-\exp(-\mu_-\mathbf{x}_n^\top\mathbf{w}(t)))>0.5$. Let $\tau>\max(4,t'_-)$ be an arbitrarily large constant. For all $t>\tau$, if $\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)>\tau\ge4$, then $\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)>0.25\tau\ge1$.
On the other hand, if there exists $t>\tau\ge4$, such that $\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)<\tau$, then for some constants C_1,C_2 we have the following

(i) $\exp(-\mathbf{x}_n^\top\mathbf{r}(t))=\exp(|\mathbf{x}_n^\top\mathbf{r}(t)|)\ge\left(1+C_0\left(\log^{\circ(m-1)}(t)\right)^{-0.5\tilde{\mu}_-}\right)$, since $e^x>1+x$ for all x,

(ii) $\psi_m(t)\ge\exp\left(-C_1\left(\log^{\circ(m-1)}(t)\right)^{-1}\right)\ge\left(1-C_1\left(\log^{\circ(m-1)}(t)\right)^{-1}\right)$ from eq. 91 and again using $e^x>1+x$ for all x,

(iii)

$$\gamma_n(t)=\left(1-\left[\frac{\exp(-\mathbf{h}_l(t)^\top\mathbf{x}_n)\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)}{t\prod_{r=1}^{m-1}\log^{\circ r}(t)}\right]^{\mu_-}\right)$$
$$\ge\left(1-\left[\frac{\exp(-C_h\|x_n\|)\tau}{t\prod_{r=1}^{m-1}\log^{\circ r}(t)}\right]^{\mu_-}\right)\ge\left(1-\left(C_2\log^{\circ(m-1)}(t)\right)^{-\mu_-}\right),\forall t>t''_-$$

where the last inequality follows as for large enough $t''_->t'_-$, we have $\frac{\exp(-C_h\|x_n\|)\tau}{t\prod_{r=1}^{m-2}\log^{\circ r}(t)}\le C_2$.

Using the above inequalities, we have

$$\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)$$
$$\ge\left(1+C_0\left(\log^{\circ(m-1)}(t)\right)^{-0.5\tilde{\mu}_-}\right)\left(1-C_1\left(\log^{\circ(m-1)}(t)\right)^{-1}\right)\left(1-C_2\left(\log^{\circ(m-1)}(t)\right)^{-\mu_-}\right)$$
$$\overset{(1)}{\ge}1+C_0\left(\log^{\circ(m-1)}(t)\right)^{-0.5\tilde{\mu}_-}-C_1\left(\log^{\circ(m-1)}(t)\right)^{-1}-C_2\left(\log^{\circ(m-1)}(t)\right)^{-\mu_-}$$
$$-C_0C_2\left(\log^{\circ(m-1)}(t)\right)^{-\mu_-0.5\tilde{\mu}_-}-C_0C_1\left(\log^{\circ(m-1)}(t)\right)^{-1-0.5\tilde{\mu}_-}\overset{(2)}{\ge}1,\forall t>t'''_-, \tag{98}$$

where in (1) we dropped the other positive terms, and (2) follows for large enough $t'''_->t''_-$ as the $C_0\log\left(\log^{\circ(m-1)}(t)\right)^{-0.5\tilde{\mu}_-}$ converges to 0 more slowly than the other negative terms. Finally, using eq. 98 in eq. 95, we have for all $t>\max(t_2,\tau,t_\psi,t'''_-)$

$$\Gamma_{m,n}(t)\le\left[\frac{\eta\kappa(n,t)\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}\right)}{t\prod_{r=1}^{m-1}\log^{\circ r}(t)}\right]\left(1-\gamma_n(t)\psi_m(t)\exp\left(-\mathbf{x}_n^\top\mathbf{r}(t)\right)\right)\left|\mathbf{x}_n^\top\mathbf{r}(t)\right|\le0 \tag{99}$$

Collecting all the terms from the above special cases, and substituting back into eq. 85, we note that all terms are either negative, in L_1, or of the form $f(t)\|\mathbf{r}(t)\|$, where $f(t)\in L_1$, thus proving the lemma. ■

C.4. Proof of the existence and uniqueness of the solution to eqs. 62-63

We wish to prove that $\forall m\ge1$:

$$\sum_{n\in\mathcal{S}_m}\exp\left(-\sum_{k=1}^m\tilde{\mathbf{w}}_k^\top\mathbf{x}_n\right)\bar{\mathbf{P}}_{m-1}\mathbf{x}_n=\hat{\mathbf{w}}_m\,, \tag{100}$$

such that

$$\mathbf{P}_{m-1}\tilde{\mathbf{w}}_m=0\,\text{and}\,\bar{\mathbf{P}}_m\tilde{\mathbf{w}}_m=0, \tag{101}$$

we have a unique solution. From eq. 101, we can modify eq. 100 to

$$\sum_{n\in\mathcal{S}_m}\exp\left(-\sum_{k=1}^m\tilde{\mathbf{w}}_k^\top\bar{\mathbf{P}}_{k-1}\mathbf{x}_n\right)\bar{\mathbf{P}}_{m-1}\mathbf{x}_n=\hat{\mathbf{w}}_m\,,.$$

To prove this, without loss of generality, and with a slight abuse of notation, we will denote $\mathcal{S}_m$ as $\mathcal{S}_1$, $\bar{\mathbf{P}}_{m-1}\mathbf{x}_n$ as $\mathbf{x}_n$ and $\beta_n=\exp\left(-\sum_{k=1}^{m-1}\tilde{\mathbf{w}}_k^\top\bar{\mathbf{P}}_{k-1}\mathbf{x}_n\right)$, so we can write the above equation as

$$\sum_{n\in\mathcal{S}_1}\mathbf{x}_n\beta_n\exp\left(-\mathbf{x}_n^\top\tilde{\mathbf{w}}_1\right)=\hat{\mathbf{w}}_1$$

In the following Lemma 17 we prove this equation $\forall\boldsymbol{\beta}\in\mathbb{R}_{>0}^{|\mathcal{S}_1|}$.

Lemma 17 *$\forall \boldsymbol{\beta} \in \mathbb{R}_{>0}^{|\mathcal{S}_1|}$ we can find a unique $\tilde{\mathbf{w}}$ such that*

$$\sum_{n\in\mathcal{S}_1} \mathbf{x}_n \beta_n \exp\left(-\mathbf{x}_n^\top \tilde{\mathbf{w}}_1\right) = \hat{\mathbf{w}}_1 \tag{102}$$

and for $\forall \mathbf{z} \in \mathbb{R}^d$ such that $\mathbf{z}^\top \mathbf{X}_{\mathcal{S}_1} = 0$ we would have $\tilde{\mathbf{w}}_1^\top \mathbf{z} = 0$.

Proof Let $K = \operatorname{rank}(\mathbf{X}_{\mathcal{S}_1})$. Let and $\mathbf{U} = [\mathbf{u}_1, \ldots, \mathbf{u}_d] \in \mathbb{R}^{d\times d}$ be a set of orthonormal vectors (*i.e.*, $\mathbf{U}\mathbf{U}^\top = \mathbf{U}^\top\mathbf{U} = \mathbf{I}$) such that $\mathbf{u}_1 = \hat{\mathbf{w}}_1 / \|\hat{\mathbf{w}}_1\|$, and

$$\forall \mathbf{z} \neq 0, \forall n \in \mathcal{S}_1 : \mathbf{z}^\top [\mathbf{u}_1, \ldots, \mathbf{u}_K]^\top \mathbf{x}_n \neq 0\,, \tag{103}$$

while

$$\forall i > K : \forall n \in \mathcal{S}_1 : \mathbf{u}_i^\top \mathbf{x}_n = 0\,. \tag{104}$$

In other words, $\mathbf{u}_1$ is in the direction of $\hat{\mathbf{w}}_1$, $[\mathbf{u}_1, \ldots, \mathbf{u}_K]$ are in the space spanned by the columns of $\mathbf{X}_{\mathcal{S}_1}$, and $[\mathbf{u}_{K+1}, \ldots, \mathbf{u}_d]$ are orthogonal to the columns of $\mathbf{X}_{\mathcal{S}_1}$.

We define $\mathbf{v}_n = \mathbf{U}^\top \mathbf{x}_n$ and $\mathbf{s} = \mathbf{U}^\top \tilde{\mathbf{w}}_1$. Note that $\forall i > K : v_{i,n} = 0\, \forall n \in \mathcal{S}_1$ from eq. 104, and $\forall i > K : s_i = 0$, since for $\forall \mathbf{z} \in \mathbb{R}^d$ such that $\mathbf{z}^\top \mathbf{X}_{\mathcal{S}_1} = 0$ we would have $\tilde{\mathbf{w}}_1^\top \mathbf{z} = 0$. Lastly, equation 102 becomes

$$\sum_{n\in\mathcal{S}_1} \mathbf{x}_n \beta_n \exp\left(-\sum_{j=1}^K s_j v_{j,n}\right) = \hat{\mathbf{w}}_1\,. \tag{105}$$

Multiplying by $\mathbf{U}^\top$ from the left, we obtain

$$\forall i \leq K : \sum_{n\in\mathcal{S}_1} v_{i,n}\beta_n \exp\left(-\sum_{j=1}^K s_j v_{j,n}\right) = \mathbf{u}_i^\top \hat{\mathbf{w}}_1\,.$$

Since $\mathbf{u}_1 = \hat{\mathbf{w}}_1 / \|\hat{\mathbf{w}}_1\|$, we have that

$$\forall i \leq K : \sum_{n\in\mathcal{S}_1} v_{i,n}\beta_n \exp\left(-\sum_{j=1}^K s_j v_{j,n}\right) = \|\hat{\mathbf{w}}_1\|\, \delta_{i,1}\,. \tag{106}$$

We recall that $v_{1,n} = \hat{\mathbf{w}}_1^\top \mathbf{x}_n / \|\hat{\mathbf{w}}_1\| = 1/\|\hat{\mathbf{w}}_1\|, \forall n \in \mathcal{S}_1$. Given $\{s_j\}_{j=2}^K$, we examine eq. 106 for $i = 1$,

$$\exp\left(-\frac{s_1}{\|\hat{\mathbf{w}}_1\|}\right)\left[\sum_{n\in\mathcal{S}_1} \beta_n \exp\left(-\sum_{j=2}^K s_j v_{j,n}\right)\right] = \|\hat{\mathbf{w}}_1\|^2\,.$$

This equation always has the unique solution

$$s_1 = \|\hat{\mathbf{w}}_1\| \log\left[\|\hat{\mathbf{w}}_1\|^{-2} \sum_{n\in\mathcal{S}_1} \beta_n \exp\left(-\sum_{j=2}^K s_j v_{j,n}\right)\right], \tag{107}$$

given $\{s_j\}_{j=2}^K$. Next, we similarly examine eq. 106 for $2 \leq i \leq K$ as a function of s_i

$$\sum_{n\in\mathcal{S}_1} \beta_n v_{i,n} \exp\left(-s_1/\|\hat{\mathbf{w}}_1\| - \sum_{j=2}^K s_j v_{j,n}\right) = 0\,. \tag{108}$$

multiplying by $\exp(s_1/\|\hat{\mathbf{w}}_1\|)$ we obtain

$$0 = \sum_{n\in\mathcal{S}_1} \beta_n v_{i,n} \exp\left(-\sum_{j=2}^K s_j v_{j,n}\right) = -\frac{\partial}{\partial s_i}\left[E(s_2, \ldots, s_K)\right]\,,$$

where we defined

$$E(s_2, \ldots, s_K) = \sum_{n\in\mathcal{S}_1} \beta_n \exp\left(-\sum_{j=2}^K s_j v_{j,n}\right)\,.$$

Therefore, any critical point of $E(s_2, \ldots, s_K)$ would be a solution of eq. 108 for $2 \leq i \leq K$, and substituting this solution into eq. 107 we obtain s_1. Since $\beta_n > 0$, $E(s_2, \ldots, s_K)$ is a convex function, as positive linear combination of convex function (exponential). Therefore, any finite critical point is a global minimum. All that remains is to show that a finite minimum exists and that it is unique.

From the definition of $\mathcal{S}_1$, $\exists \boldsymbol{\alpha} \in \mathbb{R}_{>0}^{|\mathcal{S}_1|}$ such that $\hat{\mathbf{w}}_1 = \sum_{n\in\mathcal{S}_1} \alpha_n \mathbf{x}_n$. Multiplying this equation by $\mathbf{U}^\top$ we obtain that $\exists \boldsymbol{\alpha} \in \mathbb{R}_{>0}^{|\mathcal{S}_1|}$ such that $2 \leq i \leq K$

$$\sum_{n\in\mathcal{S}_1} v_{i,n}\alpha_n = 0\,. \tag{109}$$

Therefore, $\forall (s_2, \ldots, s_K) \neq \mathbf{0}$ we have that

$$\sum_{n\in\mathcal{S}_1} \left(\sum_{j=2}^K s_j v_{j,n}\right) \alpha_n = 0\,. \tag{110}$$

Recall, from eq. 103 that $\forall (s_2, \ldots, s_K) \neq \mathbf{0}, \exists n \in \mathcal{S}_1 : \sum_{j=2}^K s_j v_{j,n} \neq 0$, and that $\alpha_n > 0$. Therefore, eq. 110 implies that $\exists n \in \mathcal{S}_1$ such that $\sum_{j=2}^K s_j v_{j,n} > 0$ and also $\exists m \in \mathcal{S}_1$ such that $\sum_{j=2}^K s_j v_{j,m} < 0$.

Thus, in any direction we take a limit in which $|s_i| \to \infty\ \forall 2 \leq i \leq K$, we obtain that $E(s_2, \ldots, s_K) \to \infty$, since at least one exponent in the sum diverge. Since $E(s_2, \ldots, s_K)$, is a continuous function, it implies it has a finite global minimum. This proves the existence of a finite solution. To prove uniqueness we will show the function is strictly convex, since the hessian is (strictly) positive definite, *i.e.*, that the following expression is strictly positive:

$$\begin{aligned}
&\sum_{i=2}^K \sum_{k=2}^K q_i q_k \frac{\partial}{\partial s_i}\frac{\partial}{\partial s_k} E(s_2, \ldots, s_K)\,. \\
&= \sum_{n\in\mathcal{S}_1} \beta_n \left(\sum_{i=2}^K q_i v_{i,n}\right)\left(\sum_{k=2}^K q_k v_{k,n}\right) \exp\left(-\sum_{j=2}^K s_j v_{j,n}\right) \\
&= \sum_{n\in\mathcal{S}_1} \beta_n \left(\sum_{i=2}^K q_i v_{i,n}\right)^2 \exp\left(-\sum_{j=2}^K s_j v_{j,n}\right)\,.
\end{aligned}$$

the last expression is indeed strictly positive since $\forall \mathbf{q} \neq \mathbf{0}, \exists n \in \mathcal{S}_1 : \sum_{j=2}^K q_j v_{j,n} \neq 0$, from eq. 103. Thus, there exists a unique solution $\tilde{\mathbf{w}}_1$. ■

C.5. Proof of the existence and uniqueness of the solution to eqs. 64-65

Lemma 18 *For $\forall m > k \geq 1$, the equations*

$$\sum_{n\in\mathcal{S}_m} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \mathbf{P}_{m-1}\mathbf{x}_n = \sum_{k=1}^{m-1}\left[\sum_{n\in\mathcal{S}_k} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \mathbf{x}_n\mathbf{x}_n^\top\right] \check{\mathbf{w}}_{k,m} \tag{111}$$

under the constraints

$$\mathbf{P}_{k-1}\check{\mathbf{w}}_{k,m} = 0 \,\text{and}\, \bar{\mathbf{P}}_k\check{\mathbf{w}}_{k,m} = 0 \tag{112}$$

have a unique solution $\check{\mathbf{w}}_{k,m}$.

Proof For this proof we denote $\mathbf{X}_{\mathcal{S}_k}$ as the matrix which columns are $\{\mathbf{x}_n | n \in \mathcal{S}_k\}$, the orthogonal projection matrix $\mathbf{Q}_k = \mathbf{P}_k\bar{\mathbf{P}}_{k-1}$where $\mathbf{Q}_k\mathbf{Q}_m = 0\ \forall k \neq m$, $\mathbf{Q}_k\bar{\mathbf{P}}_m = 0\ \forall k < m$, and

$$\forall m : \mathbf{I} = \mathbf{P}_m + \bar{\mathbf{P}}_m = \sum_{k=1}^{m} \mathbf{Q}_k + \bar{\mathbf{P}}_m \tag{113}$$

We will write $\check{\mathbf{w}}_{k,m} = \mathbf{W}_{k,m}\mathbf{u}_{k,m}$, where $\mathbf{u}_{k,m} \in \mathbb{R}^{d_k}$ and $\mathbf{W}_{k,m} \in \mathbb{R}^{d\times d_k}$ is a full rank matrix such that $\mathbf{Q}_k\mathbf{W}_{k,m} = \mathbf{W}_{k,m}$, so

$$\check{\mathbf{w}}_{k,m} = \mathbf{Q}_k\check{\mathbf{w}}_{k,m} = \mathbf{Q}_k\mathbf{W}_{k,m}\mathbf{u}_{k,m}\,. \tag{114}$$

and, furthermore,

$$\operatorname{rank}\left[\mathbf{X}_{\mathcal{S}_k}^\top\mathbf{Q}_k\mathbf{W}_{k,m}\right] = \operatorname{rank}\left(\mathbf{X}_{\mathcal{S}_k}^\top\mathbf{Q}_k\right) = d_k\,. \tag{115}$$

Recall that $\forall m : \bar{\mathbf{P}}_m\mathbf{P}_m = \mathbf{0}$ and $\forall k \geq 1$, $\forall n \in \mathcal{S}_m\ \bar{\mathbf{P}}_{m+k}\mathbf{x}_n = \mathbf{0}$. Therefore, $\forall \mathbf{v} \in \mathbb{R}^d$, $\mathbf{P}_{k-1}\mathbf{Q}_k\mathbf{v} = \mathbf{0}$, $\bar{\mathbf{P}}_k\mathbf{Q}_k\mathbf{v} = \mathbf{0}$. Thus, $\check{\mathbf{w}}_{k,m}$ eq. 114 implies the constraints in eq. 112 hold.

Next, we prove the existence and uniqueness of the solution $\check{\mathbf{w}}_{k,m}$ for each $k = 1,\ldots,m$ separately. We multiply eq. 111 from the left by the identity matrix, decomposed to orthogonal projection matrices as in eq. 113. Since each matrix projects to an orthogonal subspace, we can solve each product separately.

The product with $\bar{\mathbf{P}}_m$ is equal to zero for both sides of the equation. The product with $\mathbf{Q}_k$ is equal to

$$\sum_{n\in\mathcal{S}_m} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \mathbf{Q}_k\mathbf{P}_{m-1}\mathbf{x}_n = \left[\sum_{n\in\mathcal{S}_k} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \mathbf{Q}_k\mathbf{x}_n\mathbf{x}_n^\top\right] \check{\mathbf{w}}_{k,m}\,.$$

Substituting eq. 114, and multiplying by $\mathbf{W}_{k,m}^\top$ from the right, we obtain

$$\sum_{n\in\mathcal{S}_m} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \mathbf{W}_{k,m}^\top\mathbf{Q}_k\mathbf{P}_{m-1}\mathbf{x}_n = \left[\sum_{n\in\mathcal{S}_k} \exp\left(-\tilde{\mathbf{w}}^\top \mathbf{x}_n\right) \mathbf{W}_{k,m}^\top\mathbf{Q}_k\mathbf{x}_n\mathbf{x}_n^\top\mathbf{Q}_k\mathbf{W}_{k,m}\right] \mathbf{u}_{k,m}\,. \tag{116}$$

Denoting $\mathbf{E}_k \in \mathbb{R}^{|\mathcal{S}_k|\times|\mathcal{S}_k|}$ as diagonal matrix for which $E_{nn,k} = \exp\left(-\frac{1}{2}\tilde{\mathbf{w}}^\top\mathbf{x}_n\right)$, the matrix in the square bracket in the left hand side can be written as

$$\mathbf{W}_{k,m}^\top\mathbf{Q}_k\mathbf{X}_{\mathcal{S}_k}\mathbf{E}_k\mathbf{E}_k\mathbf{X}_{\mathcal{S}_k}^\top\mathbf{Q}_k\mathbf{W}_{k,m}\,. \tag{117}$$

Since $\operatorname{rank}\left(\mathbf{A}\mathbf{A}^\top\right) = \operatorname{rank}\left(\mathbf{A}\right)$ for any matrix $\mathbf{A}$, the rank of this matrix is equal to

$$\operatorname{rank}\left[\mathbf{E}\mathbf{X}_{\mathcal{S}_k}\mathbf{Q}_k\mathbf{W}_{k,m}\right] \overset{(1)}{=} \operatorname{rank}\left[\mathbf{X}_{\mathcal{S}_k}\mathbf{Q}_k\mathbf{W}_{k,m}\right] \overset{(2)}{=} d_k$$

where in (1) we used that $\mathbf{E}_k$ is diagonal and non-zero, and in (2) we used eq. 115. This implies that the $d_k \times d_k$ matrix in eq. 117 is full rank, and so eq. 116 has a unique solution $\mathbf{u}_{k,m}$. Therefore, there exists a unique solution $\check{\mathbf{w}}_{k,m}$. ■

C.6. Proof of Lemma 15

Lemma 15 *Let $\phi(t), h(t), z(t)$ be three functions from $\mathbb{N}$ to $\mathbb{R}_{\geq 0}$, and C_1, C_2, C_3 be three positive constants. Then, if $\sum_{t=1}^{\infty} h(t) \leq C_1 < \infty$, and*

$$\phi^2(t+1) \leq z(t) + h(t)\,\phi(t) + \phi^2(t) \tag{74}$$

we have

$$\phi^2(t+1) \leq C_2 + C_3\sum_{u=1}^{t} z(u) \tag{75}$$

Proof We define $\psi(t) = z(t) + h(t)$, and start from eq. 74

$$\begin{aligned}
&\phi^2(t+1)\\
&\leq z(t) + h(t)\,\phi(t) + \phi^2(t)\\
&\leq z(t) + h(t)\max\left[1, \phi^2(t)\right] + \phi^2(t)\\
&\leq z(t) + h(t) + h(t)\,\phi^2(t) + \phi^2(t)\\
&\leq \psi(t) + (1+h(t))\,\phi^2(t)\\
&\leq \psi(t) + (1+h(t))\,\psi(t-1) + (1+h(t))\,(1+h(t-1))\,\phi^2(t-1)\\
&\leq \psi(t) + (1+h(t))\,\psi(t-1) + (1+h(t))\,(1+h(t-1))\,\psi(t-2)\\
&+ (1+h(t))\,(1+h(t-1))\,(1+h(t-2))\,\phi^2(t-2)
\end{aligned}$$

we keep iterating eq. 74, until we obtain

$$\begin{aligned}
&\leq \left[\prod_{m=1}^{t-1}\left(1+h\left(t-m\right)\right)\right]\phi\left(t_1\right)+\sum_{k=0}^{t-t_1}\left[\prod_{m=0}^{k-1}\left(1+h\left(t-m\right)\right)\right]\psi\left(t-k\right)\\
&\leq \left[\exp\left(\sum_{m=1}^{t-1}h\left(t-m\right)\right)\right]\phi\left(t_1\right)+\sum_{k=0}^{t-1}\left[\exp\left(\sum_{m=1}^{k-1}h\left(t-m\right)\right)\right]\psi\left(t-k\right)\\
&\leq \exp\left(C\right)\left[\phi\left(1\right)+\sum_{k=0}^{t-1}\psi\left(t-k\right)\right]\\
&\leq \exp\left(C\right)\left[\phi\left(1\right)+\sum_{u=1}^{t}\psi\left(u\right)\right]\\
&\leq \exp\left(C\right)\left[\phi\left(1\right)+\sum_{u=1}^{t}\left(z\left(u\right)+h\left(u\right)\right)\right]\\
&\leq \exp\left(C\right)\left[\phi\left(1\right)+C+\sum_{u=1}^{t}z\left(u\right)\right]
\end{aligned}$$

Therefore, the Lemma holds with $C_2=\left(\phi\left(1\right)+C\right)\exp\left(C\right)$ and $C_3=\exp\left(C\right)$. ■

Appendix D. Calculation of convergence rates

In this section we calculate the various rates mentioned in section 3.

D.1. Proof of Theorem 5

From Theorems 4 and 13, we can write $\mathbf{w}\left(t\right)=\hat{\mathbf{w}}\log t+\boldsymbol{\rho}\left(t\right)$, where $\boldsymbol{\rho}\left(t\right)$ has a bounded norm for almost all datasets, while in zero measure case $\boldsymbol{\rho}\left(t\right)$ contains additional $O(\log\log(t))$ components which are orthogonal to the support vectors in $\mathcal{S}_1$, and, asymptotically, have a positive angle with the other support vectors. In this section we first calculate the various convergence rates for the non-degenerate case of Theorem 4, and then write the correction in the zero measure cases, if there is such a correction.

First, we calculated of the normalized weight vector (eq. 8), for almost every dataset:

$$\begin{aligned}
&\frac{\mathbf{w}\left(t\right)}{\left\|\mathbf{w}\left(t\right)\right\|}\\
&=\frac{\boldsymbol{\rho}\left(t\right)+\hat{\mathbf{w}}\log t}{\sqrt{\boldsymbol{\rho}\left(t\right)^{\top}\boldsymbol{\rho}\left(t\right)+\hat{\mathbf{w}}^{\top}\hat{\mathbf{w}}\log^2 t+2\boldsymbol{\rho}\left(t\right)^{\top}\hat{\mathbf{w}}\log t}}\\
&=\frac{\boldsymbol{\rho}\left(t\right)/\log t+\hat{\mathbf{w}}}{\left\|\hat{\mathbf{w}}\right\|\sqrt{1+2\boldsymbol{\rho}\left(t\right)^{\top}\hat{\mathbf{w}}/\left(\left\|\hat{\mathbf{w}}\right\|^2\log t\right)+\left\|\boldsymbol{\rho}\left(t\right)\right\|^2/\left(\left\|\hat{\mathbf{w}}\right\|^2\log^2 t\right)}}\\
&=\frac{1}{\left\|\hat{\mathbf{w}}\right\|}\left(\boldsymbol{\rho}\left(t\right)\frac{1}{\log t}+\hat{\mathbf{w}}\right)\left[1-\frac{\boldsymbol{\rho}\left(t\right)^{\top}\hat{\mathbf{w}}}{\left\|\hat{\mathbf{w}}\right\|^2\log t}+\left[\frac{3}{2}\left(\frac{\boldsymbol{\rho}\left(t\right)^{\top}\hat{\mathbf{w}}}{\left\|\hat{\mathbf{w}}\right\|^2}\right)^2-\frac{\left\|\boldsymbol{\rho}\left(t\right)\right\|^2}{2\left\|\hat{\mathbf{w}}\right\|^2}\right]\frac{1}{\log^2 t}+O\left(\frac{1}{\log^3 t}\right)\right] \qquad (118)\\
&=\frac{\hat{\mathbf{w}}}{\left\|\hat{\mathbf{w}}\right\|}+\left(\frac{\boldsymbol{\rho}\left(t\right)}{\left\|\hat{\mathbf{w}}\right\|}-\frac{\hat{\mathbf{w}}}{\left\|\hat{\mathbf{w}}\right\|}\frac{\boldsymbol{\rho}\left(t\right)^{\top}\hat{\mathbf{w}}}{\left\|\hat{\mathbf{w}}\right\|^2}\right)\frac{1}{\log t}+O\left(\frac{1}{\log^2 t}\right)\\
&=\frac{\hat{\mathbf{w}}}{\left\|\hat{\mathbf{w}}\right\|}+\left(\mathbf{I}-\frac{\hat{\mathbf{w}}\hat{\mathbf{w}}^{\top}}{\left\|\hat{\mathbf{w}}\right\|^2}\right)\frac{\boldsymbol{\rho}\left(t\right)}{\left\|\hat{\mathbf{w}}\right\|}\frac{1}{\log t}+O\left(\frac{1}{\log^2 t}\right),
\end{aligned}$$

where to obtain eq. 118 we used $\frac{1}{\sqrt{1+x}}=1-\frac{1}{2}x+\frac{3}{4}x^2+O\left(x^3\right)$, and in the last line we used the fact that $\boldsymbol{\rho}\left(t\right)$ has a bounded norm for almost every dataset. Thus, in this case

$$\left\|\frac{\mathbf{w}\left(t\right)}{\left\|\mathbf{w}\left(t\right)\right\|}-\frac{\hat{\mathbf{w}}}{\left\|\hat{\mathbf{w}}\right\|}\right\|=O\left(\frac{1}{\log t}\right).$$

For the measure zero cases, we instead have from eq. 61, $\mathbf{w}(t)=\sum_{m=1}^{M}\hat{\mathbf{w}}\log^{\circ m}(t)+\rho(t)$, where $\|\rho(t)\|$ is bounded (Theorem 3). Let $\tilde{\rho}(t)=\sum_{m=2}^{M}\hat{\mathbf{w}}\log^{\circ m}(t)+\rho(t)$, such that $\mathbf{w}(t)=\hat{\mathbf{w}}\log(t)+\tilde{\rho}(t)$ with $\tilde{\rho}(t)=O(\log\log(t))$. Repeating the same calculations as above, we have for the degenerate cases,

$$\left\|\frac{\mathbf{w}\left(t\right)}{\left\|\mathbf{w}\left(t\right)\right\|}-\frac{\hat{\mathbf{w}}}{\left\|\hat{\mathbf{w}}\right\|}\right\|=O\left(\frac{\log\log t}{\log t}\right)$$

Next, we use eq. 118 to calculate the angle (eq. 9)

$$\begin{aligned}
&\frac{\mathbf{w}(t)^\top \hat{\mathbf{w}}}{\|\mathbf{w}(t)\|\|\hat{\mathbf{w}}\|} \\
=&\frac{\hat{\mathbf{w}}^\top}{\|\hat{\mathbf{w}}\|^2}\left(\boldsymbol{\rho}(t)\frac{1}{\log t}+\hat{\mathbf{w}}\right)\left(1-\frac{1}{\log t}\frac{\boldsymbol{\rho}(t)^\top\hat{\mathbf{w}}}{\|\hat{\mathbf{w}}\|^2}+\left[\frac{3}{4}\left(2\frac{\boldsymbol{\rho}(t)^\top\hat{\mathbf{w}}}{\|\hat{\mathbf{w}}\|^2}\right)^2-\frac{\|\boldsymbol{\rho}(t)\|^2}{2\|\hat{\mathbf{w}}\|^2}\right]\frac{1}{\log^2 t}+O\left(\frac{1}{\log^3 t}\right)\right) \\
=&1+\frac{2\|\boldsymbol{\rho}(t)\|^2}{\|\hat{\mathbf{w}}\|^2}\left[\left(\frac{\boldsymbol{\rho}(t)^\top\hat{\mathbf{w}}}{\|\hat{\mathbf{w}}\|\|\boldsymbol{\rho}(t)\|}\right)^2-\frac{1}{4}\right]\frac{1}{\log^2 t}+O\left(\frac{1}{\log^3 t}\right)
\end{aligned}$$

for almost every dataset. Thus, in this case

$$\frac{\mathbf{w}(t)^\top \hat{\mathbf{w}}}{\|\mathbf{w}(t)\|\|\hat{\mathbf{w}}\|}=O\left(\frac{1}{\log^2 t}\right)$$

Repeating the same calculation for the measure zero case, we have instead

$$\frac{\mathbf{w}(t)^\top \hat{\mathbf{w}}}{\|\mathbf{w}(t)\|\|\hat{\mathbf{w}}\|}=O\left(\left(\frac{\log\log t}{\log t}\right)^2\right)$$

Next, we calculate the margin (eq. 10)

$$\begin{aligned}
&\min_n \frac{\mathbf{x}_n^\top \mathbf{w}(t)}{\|\mathbf{w}(t)\|}-\frac{1}{\|\hat{\mathbf{w}}\|} \\
&=\min_n \mathbf{x}_n^\top\left[\left(\frac{\boldsymbol{\rho}(t)}{\|\hat{\mathbf{w}}\|}-\frac{\hat{\mathbf{w}}}{\|\hat{\mathbf{w}}\|}\frac{\boldsymbol{\rho}(t)^\top\hat{\mathbf{w}}}{\|\hat{\mathbf{w}}\|^2}\right)\frac{1}{\log t}+O\left(\frac{1}{\log^2 t}\right)\right] \\
&=\frac{1}{\|\hat{\mathbf{w}}\|}\left(\min_n \mathbf{x}_n^\top\boldsymbol{\rho}(t)-\frac{\boldsymbol{\rho}(t)^\top\hat{\mathbf{w}}}{\|\hat{\mathbf{w}}\|^2}\right)\frac{1}{\log t}+O\left(\frac{1}{\log^2 t}\right) \qquad (119)
\end{aligned}$$

for almost every dataset, where in eq. 119 we used eq. 19. Interestingly the measure zero case has a similar convergence rate, since after a sufficient number of iterations, the $O(\log\log(t))$ correction is orthogonal to $\mathbf{x}_k$, where $k=\mathrm{argmin}_n \mathbf{x}_n^\top \mathbf{w}(t)$. Thus, for all datasets,

$$\min_n \mathbf{x}_n^\top \mathbf{w}(t)-\frac{1}{\|\hat{\mathbf{w}}\|}=O\left(\frac{1}{\log t}\right) \qquad (120)$$

Calculation of the training loss (eq. 11):

$$\begin{aligned}
\mathcal{L}(\mathbf{w}(t)) &\leq \sum_{n=1}^N\left(1+\exp\left(-\mu_+\mathbf{w}(t)^\top\mathbf{x}_n\right)\right)\exp\left(-\mathbf{w}(t)^\top\mathbf{x}_n\right) \\
&=\sum_{n=1}^N\left(1+\exp\left(-\mu_+\left(\boldsymbol{\rho}(t)+\hat{\mathbf{w}}\log t\right)^\top\mathbf{x}_n\right)\right)\exp\left(-\left(\boldsymbol{\rho}(t)+\hat{\mathbf{w}}\log t\right)^\top\mathbf{x}_n\right) \\
&=\sum_{n=1}^N\left(1+t^{-\mu_+\hat{\mathbf{w}}^\top\mathbf{x}_n}\exp\left(-\mu_+\boldsymbol{\rho}(t)^\top\mathbf{x}_n\right)\right)\exp\left(-\boldsymbol{\rho}(t)^\top\mathbf{x}_n\right)t^{-\hat{\mathbf{w}}^\top\mathbf{x}_n} \\
&=\frac{1}{t}\sum_{n\in\mathcal{S}}e^{-\boldsymbol{\rho}(t)^\top\mathbf{x}_n}+O\left(t^{-\max(\theta,1+\mu_+)}\right).
\end{aligned}$$

Thus, for all datasets $\mathcal{L}(\mathbf{w}(t))=O(t^{-1})$. Note that the zero measure case has the same behavior, since after a sufficient number of iterations, the $O(\log\log(t))$ correction has a non-negative angle with all the support vectors.

Next, we give an example demonstrating the bounds above, for the non-degenerate case, are strict. Consider optimization with and exponential loss $\ell(u)=e^{-u}$, and a single data point $\mathbf{x}=(1,0)$. In this case $\hat{\mathbf{w}}=(1,0)$ and $\|\hat{\mathbf{w}}\|=1$. We take the limit $\eta\to 0$, and obtain the continuous time version of GD:

$$\dot{w}_1(t)=\exp(-w(t))\ ;\ \dot{w}_2(t)=0.$$

We can analytically integrate these equations to obtain

$$w_1(t)=\log(t+\exp(w_1(0)))\ ;\ w_2(t)=w_2(0).$$

Using this example with $w_2(0)>0$, it is easy to see that the above upper bounds are strict in the non-degenerate case. ■

D.2. Validation error lower bound

Lastly, recall that $\mathcal{V}$ is a set of indices for validation set samples. We calculate of the validation loss for logistic loss, if the error of the L_2 max margin vector has some classification errors on the validation, *i.e.,* $\exists k\in\mathcal{V}:\ \hat{\mathbf{w}}^\top\mathbf{x}_k<0$*:*

$$\begin{aligned}
\mathcal{L}_{\text{val}}(\mathbf{w}(t)) &= \sum_{n\in\mathcal{V}}\log\left(1+\exp\left(-\mathbf{w}(t)^\top\mathbf{x}_n\right)\right) \\
&\geq \log\left(1+\exp\left(-\mathbf{w}(t)^\top\mathbf{x}_k\right)\right) \\
&= \log\left(1+\exp\left(-\left(\boldsymbol{\rho}(t)+\hat{\mathbf{w}}\log t\right)^\top\mathbf{x}_k\right)\right) \\
&= \log\left(\exp\left(-\left(\boldsymbol{\rho}(t)+\hat{\mathbf{w}}\log t\right)^\top\mathbf{x}_k\right)\left(1+\exp\left(\left(\boldsymbol{\rho}(t)+\hat{\mathbf{w}}\log t\right)^\top\mathbf{x}_k\right)\right)\right) \\
&\geq -\left(\boldsymbol{\rho}(t)+\hat{\mathbf{w}}\log t\right)^\top\mathbf{x}_k+\log\left(1+\exp\left(\left(\boldsymbol{\rho}(t)+\hat{\mathbf{w}}\log t\right)^\top\mathbf{x}_k\right)\right) \\
&\geq -\log t\hat{\mathbf{w}}^\top\mathbf{x}_k+\boldsymbol{\rho}(t)^\top\mathbf{x}_k
\end{aligned}$$

Thus, for all datasets $\mathcal{L}_{\text{val}}(\mathbf{w}(t))=\Omega(\log(t))$.

Appendix E. Softmax output with cross-entropy loss

We examine multiclass classification. In the case the labels are the class index $y_n\in\{1,\ldots,K\}$ and we have a weight matrix $\mathbf{W}\in\mathbb{R}^{K\times d}$ with $\mathbf{w}_k$ being the k-th row of $\mathbf{W}$.

Furthermore, we define $\mathbf{w}=\mathrm{vec}(\mathbf{W}^\top)$, a basis vector $\mathbf{e}_k\in\mathbb{R}^K$ so that$(\mathbf{e}_k)_i=\delta_{ki}$, and the matrix $\mathbf{A}_k\in\mathbb{R}^{dK\times d}$ so that $\mathbf{A}_k=\mathbf{e}_k\otimes\mathbf{I}_d$, where $\otimes$ is the Kronecker product and $\mathbf{I}_d$ is the d-dimension identity matrix. Note that $\mathbf{A}_k^\top\mathbf{w}=\mathbf{w}_k$.

Consider the cross entropy loss with softmax output

$$\mathcal{L}(\mathbf{W})=-\sum_{n=1}^N\log\left(\frac{\exp\left(\mathbf{w}_{y_n}^\top\mathbf{x}_n\right)}{\sum_{k=1}^K\exp\left(\mathbf{w}_k^\top\mathbf{x}_n\right)}\right)$$

Using our notation, this loss can be re-written as

$$\mathcal{L}(\mathbf{w}) = -\sum_{n=1}^{N} \log\left(\frac{\exp\left(\mathbf{w}^\top \mathbf{A}_{y_n}\mathbf{x}_n\right)}{\sum_{k=1}^{K}\exp\left(\mathbf{w}^\top \mathbf{A}_k\mathbf{x}_n\right)}\right) = \sum_{n=1}^{N}\log\left(\sum_{k=1}^{K}\exp\left(\mathbf{w}^\top\left(\mathbf{A}_k-\mathbf{A}_{y_n}\right)\mathbf{x}_n\right)\right) \tag{121}$$

Therefore

$$\nabla\mathcal{L}(\mathbf{w}) = \sum_{n=1}^{N}\frac{\sum_{k=1}^{K}\exp\left(\mathbf{w}^\top\left(\mathbf{A}_k-\mathbf{A}_{y_n}\right)\mathbf{x}_n\right)\left(\mathbf{A}_k-\mathbf{A}_{y_n}\right)\mathbf{x}_n}{\sum_{r=1}^{K}\exp\left(\mathbf{w}^\top\left(\mathbf{A}_r-\mathbf{A}_{y_n}\right)\mathbf{x}_n\right)} = \sum_{n=1}^{N}\sum_{k=1}^{K}\frac{1}{\sum_{r=1}^{K}\exp\left(\mathbf{w}^\top\left(\mathbf{A}_r-\mathbf{A}_k\right)\mathbf{x}_n\right)}\left(\mathbf{A}_k-\mathbf{A}_{y_n}\right)\mathbf{x}_n\,.$$

If, again, we make the assumption that the data is linearly separable, *i.e.*, in our notation

Assumption 4 $\exists\mathbf{w}_*$ *such that* $\mathbf{w}_*^\top\left(\mathbf{A}_k-\mathbf{A}_{y_n}\right)\mathbf{x}_n<0\;\forall k\neq y_n$.

then the expression

$$\mathbf{w}_*^\top\nabla\mathcal{L}(\mathbf{w}) = \sum_{n=1}^{N}\sum_{k=1}^{K}\frac{\mathbf{w}_*^\top\left(\mathbf{A}_k-\mathbf{A}_{y_n}\right)\mathbf{x}_n}{\sum_{r=1}^{K}\exp\left(\mathbf{w}^\top\left(\mathbf{A}_r-\mathbf{A}_k\right)\mathbf{x}_n\right)}\,.$$

is strictly negative for any finite $\mathbf{w}$. However, from Lemma 10, in gradient descent with an appropriately small learning rate, we have that $\nabla L(\mathbf{w}(t))\to\mathbf{0}$. This implies that: $\|\mathbf{w}(t)\|\to\infty$, and $\forall k\neq y_n, \exists r:\ \mathbf{w}(t)^\top\left(\mathbf{A}_r-\mathbf{A}_k\right)\mathbf{x}_n\to\infty$, which implies $\forall k\neq y_n, \max_k\mathbf{w}(t)^\top\left(\mathbf{A}_k-\mathbf{A}_{y_n}\right)\mathbf{x}_n\to-\infty$. Examining the loss (eq. 121) we find that $\mathcal{L}(\mathbf{w}(t))\to\mathbf{0}$ in this case. Thus, we arrive to an equivalent Lemma to Lemma 1, for this case:

Lemma 19 *Let* $\mathbf{w}(t)$ *be the iterates of gradient descent (eq. 2) with an appropriately small learning rate, for cross-entropy loss operating on a softmax output, under the assumption of strict linear separability (Assumption 4), then: (1)* $\lim_{t\to\infty}\mathcal{L}(\mathbf{w}(t))=0$*, (2)* $\lim_{t\to\infty}\|\mathbf{w}(t)\|=\infty$*, and (3)* $\forall n,k\neq y_n:\ \lim_{t\to\infty}\mathbf{w}(t)^\top\left(\mathbf{A}_{y_n}-\mathbf{A}_k\right)\mathbf{x}_n=\infty$.

Using Lemma 10 and Lemma 19, we prove the following Theorem (equivalent to Theorem 3) in the next section:

Theorem 7 *For almost all multiclass datasets (*i.e.*, except for a measure zero) which are linearly separable (i.e. the constraints in eq. 15 below are feasible), any starting point* $\mathbf{w}(0)$ *and any small enough stepsize, the iterates of gradient descent on 13 will behave as:*

$$\mathbf{w}_k(t) = \hat{\mathbf{w}}_k\log(t)+\boldsymbol{\rho}_k(t), \tag{14}$$

where the residual $\boldsymbol{\rho}_k(t)$ *is bounded and* $\hat{\mathbf{w}}_k$ *is the solution of the K-class SVM:*

$$\text{argmin}_{\mathbf{w}_1,\ldots,\mathbf{w}_k}\sum_{k=1}^{K}||\mathbf{w}_k||^2 \;s.t.\;\forall n,\forall k\neq y_n:\mathbf{w}_{y_n}^\top\mathbf{x}_n\geq\mathbf{w}_k^\top\mathbf{x}_n+1. \tag{15}$$

E.1. Notations and Definitions

To prove Theorem 7 we require additional notation. we define $\tilde{\mathbf{x}}_{n,k}\triangleq\left(\mathbf{A}_{y_n}-\mathbf{A}_k\right)\mathbf{x}_n$. Using this notation, we can re-write eq. 15 (K-class SVM) as

$$\arg\min_{\mathbf{w}}\|\mathbf{w}\|^2 \text{ s.t. } \forall n,\forall k\neq y_n:\mathbf{w}^\top\tilde{\mathbf{x}}_{n,k}\geq 1 \tag{122}$$

From the KKT optimality conditions, we have for some $\alpha_{n,k}\geq 0$,

$$\hat{\mathbf{w}} = \sum_{n=1}^{N}\sum_{k=1}^{K}\alpha_{n,k}\tilde{\mathbf{x}}_{n,k}\mathbf{1}_{\{n\in\mathcal{S}_k\}} \tag{123}$$

In addition, for each of the K classes, we define $\mathcal{S}_k=\arg\min_n(\hat{\mathbf{w}}_{y_n}-\hat{\mathbf{w}}_k)^\top\mathbf{x}_n$ (the k'th class support vectors).
Using this definition, we define $\mathbf{X}_{\mathcal{S}_k}\in\mathcal{R}^{dK\times|S_k|}$ as the matrix which columns are $\tilde{\mathbf{x}}_{n,k},\ \forall n\in\mathcal{S}_k$.
We also define $\mathcal{S}\triangleq\bigcup_{k=1}^{K}\mathcal{S}_k$ and $\tilde{\mathbf{X}}_{\mathcal{S}}\triangleq\bigcup_{k=1}^{K}\mathbf{X}_{\mathcal{S}_k}$.
We recall that we defined $\mathbf{W}\in\mathbb{R}^{K\times d}$ with $\mathbf{w}_k$ being the k-th row of $\mathbf{W}$ and $\mathbf{w}=\text{vec}(\mathbf{W}^\top)$. Similarly, we define:
1. $\hat{\mathbf{W}}\in\mathbb{R}^{K\times d}$ with $\hat{\mathbf{w}}_k$ being the k-th row of $\hat{\mathbf{W}}$
2. $\mathbf{P}\in\mathbb{R}^{K\times d}$ with $\boldsymbol{\rho}_k$ being the k-th row of $\mathbf{P}$
3. $\tilde{\mathbf{W}}\in\mathbb{R}^{K\times d}$ with $\tilde{\mathbf{w}}_k$ being the k-th row of $\tilde{\mathbf{W}}$
and $\hat{\mathbf{w}}=\text{vec}(\hat{\mathbf{W}}^\top)$, $\boldsymbol{\rho}=\text{vec}(\mathbf{P}^\top)$, $\tilde{\mathbf{w}}=\text{vec}(\tilde{\mathbf{W}}^\top)$.
Using our notations, eq. 14 can be re-written as $\mathbf{w}=\hat{\mathbf{w}}\log(t)+\boldsymbol{\rho}(t)$ when $\boldsymbol{\rho}(t)$ is bounded.
For any solution $\mathbf{w}(t)$, we define

$$\mathbf{r}(t)=\mathbf{w}(t)-\hat{\mathbf{w}}\log t-\tilde{\mathbf{w}}, \tag{124}$$

where $\hat{\mathbf{w}}$ is the concatenation of $\hat{\mathbf{w}}_1,\ldots,\hat{\mathbf{w}}_k$ which are the K-class SVM solution, so

$$\forall k,\ \forall n\in\mathcal{S}_k:\tilde{\mathbf{x}}_{n,k}^\top\hat{\mathbf{w}}=1\ ;\ \theta=\min_k\left[\min_{n\notin\mathcal{S}_k}\tilde{\mathbf{x}}_{n,k}^\top\hat{\mathbf{w}}\right]>1 \tag{125}$$

and $\tilde{\mathbf{w}}$ satisfies the equation:

$$\forall k,\ \forall n\in\mathcal{S}_k\ :\ \eta\exp((\tilde{\mathbf{w}}_k-\tilde{\mathbf{w}}_{y_n})^\top\mathbf{x}_n)=\alpha_{n,k} \tag{126}$$

This equation has a unique solution for almost every data set according to Lemma 12.
For each of the K classes, we define $\mathbf{P}_1^k\in\mathcal{R}^{d\times d}$ as the orthogonal projection matrix to the subspace spanned by the support vector of the k'th class, and $\bar{\mathbf{P}}_1^k=\mathbf{I}-\mathbf{P}_1^k$ as the complementary projection.
Finally, we define $\mathbf{P}_1\in\mathcal{R}^{Kd\times Kd}$ and $\bar{\mathbf{P}}_1\in\mathcal{R}^{Kd\times Kd}$ as follows:

$$\mathbf{P}_1=\text{diag}(\mathbf{P}_1^1,\mathbf{P}_1^2,\ldots,\mathbf{P}_1^K)\ ,\ \bar{\mathbf{P}}_1=\text{diag}(\bar{\mathbf{P}}_1^1,\bar{\mathbf{P}}_1^2,\ldots,\bar{\mathbf{P}}_1^K)$$

$$(\mathbf{P}_1+\bar{\mathbf{P}}_1=\mathbf{I}\in\mathcal{R}^{Kd\times Kd})$$

In the following section we will also use $\mathbf{1}_{\{A\}}$, the indicator function, which is 1 if A is satisfied and 0 otherwise.

E.2. Auxiliary Lemma

Lemma 20 *We have*

$$\exists C_1, t_1 \ : \ \forall t > t_1 : (\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) \leq C_1 t^{-\theta} + C_2 t^{-2} \tag{127}$$

Additionally, $\forall \epsilon_1 > 0$, $\exists C_2, t_2$, such that $\forall t > t_2$, such that if

$$||\mathbf{P}_1 \mathbf{r}(t)|| > \epsilon_1 \tag{128}$$

then we can improve this bound to

$$(\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) \leq -C_3 t^{-1} < 0 \tag{129}$$

We prove the Lemma below, in appendix section E.4

E.3. Proof of Theorem 7

Our goal is to show that $||\mathbf{r}(t)||$ is bounded, and therefore $\boldsymbol{\rho}(t) = \mathbf{r}(t) + \tilde{\mathbf{w}}$ is bounded.
To show this, we will upper bound the following equation

$$\|\mathbf{r}(t+1)\|^2 = \|\mathbf{r}(t+1) - \mathbf{r}(t)\|^2 + 2(\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) + \|\mathbf{r}(t)\|^2 \tag{130}$$

First, we note that first term in this equation can be upper-bounded by

$$\begin{aligned}
&\|\mathbf{r}(t+1) - \mathbf{r}(t)\|^2 \\
&\overset{(1)}{=} \|\mathbf{w}(t+1) - \hat{\mathbf{w}}\log(t+1) - \tilde{\mathbf{w}} - \mathbf{w}(t) + \hat{\mathbf{w}}\log(t) + \tilde{\mathbf{w}}\|^2 \\
&\overset{(2)}{=} \|-\eta\nabla\mathcal{L}(\mathbf{w}(t)) - \hat{\mathbf{w}}[\log(t+1) - \log(t)]\|^2 \\
&= \eta^2\|\nabla\mathcal{L}(\mathbf{w}(t))\|^2 + \|\hat{\mathbf{w}}\|^2\log^2\left(1+t^{-1}\right) + 2\eta\hat{\mathbf{w}}^\top\nabla\mathcal{L}(\mathbf{w}(t))\log\left(1+t^{-1}\right) \\
&\overset{(3)}{\leq} \eta^2\|\nabla\mathcal{L}(\mathbf{w}(t))\|^2 + \|\hat{\mathbf{w}}\|^2 t^{-2},
\end{aligned} \tag{131}$$

where in (1) we used eq. 124, in (2) we used eq 2.2, and in (3) we used $\forall x > 0 : x \geq \log(1+x) > 0$, and also that

$$\hat{\mathbf{w}}^\top\nabla\mathcal{L}(\mathbf{w}) = \sum_{n=1}^{N}\sum_{k=1}^{K}\frac{\hat{\mathbf{w}}^\top(\mathbf{A}_{y_n} - \mathbf{A}_k)\mathbf{x}_n}{\sum_{r=1}^{K}\exp(\mathbf{w}^\top(\mathbf{A}_r - \mathbf{A}_k)\mathbf{x}_n)} < 0 \tag{132}$$

since $\hat{\mathbf{w}}^\top(\mathbf{A}_r - \mathbf{A}_k)\mathbf{x}_n = (\hat{\mathbf{w}}_r - \hat{\mathbf{w}}_{y_n})\mathbf{x}_n < 0, \forall k \neq y_n$ (we recall that $\hat{\mathbf{w}}_k$ is the K-class SVM solution).
Also, from Lemma 10 we know that

$$\|\nabla\mathcal{L}(\mathbf{w}(t))\|^2 = o(1) \text{ and } \sum_{t=0}^{\infty}\|\nabla\mathcal{L}(\mathbf{w}(t))\|^2 < \infty\,. \tag{133}$$

Substituting eq. 133 into eq. 131, and recalling that a $t^{-\nu}$ power series converges for any $\nu > 1$, we can find C_0 such that

$$\|\mathbf{r}(t+1) - \mathbf{r}(t)\|^2 = o(1) \text{ and } \sum_{t=0}^{\infty}\|\mathbf{r}(t+1) - \mathbf{r}(t)\|^2 = C_0 < \infty\,. \tag{134}$$

Note that this equation also implies that $\forall \epsilon_0$

$$\exists t_0 : \forall t > t_0 : |\|\mathbf{r}(t+1)\| - \|\mathbf{r}(t)\|| < \epsilon_0\,. \tag{135}$$

Next, we would like to bound the second term in eq. 130. From eq. 127 in Lemma 20, we can find t_1, C_1 such that $\forall t > t_1$:

$$(\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) \leq C_1 t^{-\theta} + C_2 t^{-2} \tag{136}$$

Thus, by combining eqs. 136 and 134 into eq. 130, we find:

$$\begin{aligned}
&||\mathbf{r}(t)||^2 - ||\mathbf{r}(t_1)||^2 \\
&= \sum_{u=t_1}^{t-1}\left[||\mathbf{r}(u+1)||^2 - ||\mathbf{r}(u)||^2\right] \\
&\leq C_0 + 2\sum_{u=t_1}^{t-1}\left[C_1 u^{-\theta} + C_2 u^{-2}\right]
\end{aligned}$$

which is bounded, since $\theta > 1$ (eq. 125). Therefore, $||\mathbf{r}(t)||$ is bounded.

E.4. Proof of Lemma 20

Lemma 20 *We have*

$$\exists C_1, t_1 \ : \ \forall t > t_1 : (\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) \leq C_1 t^{-\theta} + C_2 t^{-2} \tag{127}$$

Additionally, $\forall \epsilon_1 > 0$, $\exists C_2, t_2$, such that $\forall t > t_2$, such that if

$$||\mathbf{P}_1 \mathbf{r}(t)|| > \epsilon_1 \tag{128}$$

then we can improve this bound to

$$(\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) \leq -C_3 t^{-1} < 0 \tag{129}$$

We wish to bound $(\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t)$. First, we recall we defined $\tilde{\mathbf{x}}_{n,k} \triangleq (\mathbf{A}_{y_n} - \mathbf{A}_k)\mathbf{x}_n$.

$$\begin{aligned}
&(\mathbf{r}(t+1) - \mathbf{r}(t))^\top \mathbf{r}(t) = (-\eta\nabla\mathcal{L}(\mathbf{w}(t)) - \hat{\mathbf{w}}[\log(t+1) - \log(t)])^\top \mathbf{r}(t) \\
&= \left(\eta\sum_{n=1}^{N}\frac{\sum_{k=1}^{K}\exp(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,k})\tilde{\mathbf{x}}_{n,k}}{\sum_{r=1}^{K}\exp(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,r})} - \hat{\mathbf{w}}\log(1+t^{-1})\right)^\top \mathbf{r}(t) \\
&= \hat{\mathbf{w}}^\top\mathbf{r}(t)[t^{-1} - \log(1+t^{-1})] \qquad (137) \\
&+ \eta\sum_{n=1}^{N}\sum_{k=1}^{K}\left[\frac{\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,k}\right)\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)}{\sum_{r=1}^{K}\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,r}\right)} - t^{-1}\exp\left(-\tilde{\mathbf{w}}^\top\tilde{\mathbf{x}}_{n,k}\right)\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)\mathbf{1}_{\{n\in\mathcal{S}_k\}}\right], \qquad (138)
\end{aligned}$$

where in the last line we used eqs. 123 and 126 to obtain

$$\hat{\mathbf{w}} = \eta\sum_{n=1}^{N}\sum_{k=1}^{K}\alpha_{n,k}\tilde{\mathbf{x}}_{n,k}\mathbf{1}_{\{n\in\mathcal{S}_k\}} = \eta\sum_{n=1}^{N}\sum_{k=1}^{K}\exp\left(-\tilde{\mathbf{w}}^\top\tilde{\mathbf{x}}_{n,k}\right)\tilde{\mathbf{x}}_{n,k}\mathbf{1}_{\{n\in\mathcal{S}_k\}},$$

where $\mathbf{1}_{\{A\}}$ is the indicator function which is 1 if A is satisfied and 0 otherwise.

The first term can be upper bounded by

$$\begin{aligned}
&\hat{\mathbf{w}}^\top \mathbf{r}\left(t\right)\left[t^{-1}-\log\left(1+t^{-1}\right)\right]\\
\leq&\max\left[\hat{\mathbf{w}}^\top \mathbf{r}\left(t\right),0\right]\left[t^{-1}-\log\left(1+t^{-1}\right)\right]\\
\overset{(1)}{\leq}&\max\left[\hat{\mathbf{w}}^\top \mathbf{P}_1\mathbf{r}\left(t\right),0\right]t^{-2}\\
\overset{(2)}{\leq}&\begin{cases}\|\hat{\mathbf{w}}\|\epsilon_1 t^{-2} & ,\text{ if }\left\|\mathbf{P}_1\mathbf{r}\left(t\right)\right\|\leq\epsilon_1\\ o\left(t^{-1}\right) & ,\text{ if }\left\|\mathbf{P}_1\mathbf{r}\left(t\right)\right\|>\epsilon_1\end{cases}
\end{aligned}\tag{139}$$

where in (1) we used that $\mathbf{P}_2\hat{\mathbf{w}}=0$, and in (2) we used that $\hat{\mathbf{w}}^\top\mathbf{r}\left(t\right)=o\left(t\right)$, since

$$\begin{aligned}
\hat{\mathbf{w}}^\top\mathbf{r}\left(t\right)&=\hat{\mathbf{w}}^\top\left(\mathbf{w}\left(0\right)-\eta\sum_{u=0}^{t}\nabla\mathcal{L}\left(\mathbf{w}\left(u\right)\right)-\hat{\mathbf{w}}\log\left(t\right)-\tilde{\mathbf{w}}\right)\\
&\leq\hat{\mathbf{w}}^\top\left(\mathbf{w}\left(0\right)-\tilde{\mathbf{w}}-\hat{\mathbf{w}}\log\left(t\right)\right)-\eta t\min_{0\leq u\leq t}\hat{\mathbf{w}}^\top\nabla\mathcal{L}\left(\mathbf{w}\left(u\right)\right)=o\left(t\right)
\end{aligned}$$

where in the last line we used that $\nabla\mathcal{L}\left(\mathbf{w}\left(t\right)\right)=o\left(1\right)$, from Lemma 10.
Next, we wish to upper bound the second term in eq. 137:

$$\eta\sum_{n=1}^{N}\sum_{k=1}^{K}\left[\frac{\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,k}\right)\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)}{\sum_{r=1}^{K}\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,r}\right)}-t^{-1}\exp\left(-\tilde{\mathbf{w}}^\top\tilde{\mathbf{x}}_{n,k}\right)\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)\mathbf{1}_{\{n\in\mathcal{S}_k\}}\right]\tag{140}$$

We examine each term n in the sum:

$$\begin{aligned}
&\sum_{k=1}^{K}\left[\frac{\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,k}\right)\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)}{\sum_{r=1}^{K}\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,r}\right)}-t^{-1}\exp\left(-\tilde{\mathbf{w}}^\top\tilde{\mathbf{x}}_{n,k}\right)\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)\mathbf{1}_{\{n\in\mathcal{S}_k\}}\right]\\
&=\sum_{k=1}^{K}\left[\frac{\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,k}\right)\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)}{1+\sum_{\substack{r=1\\r\neq y_n}}^{K}\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,r}\right)}-t^{-1}\exp\left(-\tilde{\mathbf{w}}^\top\tilde{\mathbf{x}}_{n,k}\right)\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)\mathbf{1}_{\{n\in\mathcal{S}_k\}}\right]\\
&\overset{(1)}{\leq}\sum_{k=1}^{K}\left(\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,k}\right)-t^{-1}\exp\left(-\tilde{\mathbf{w}}^\top\tilde{\mathbf{x}}_{n,k}\right)\mathbf{1}_{\{n\in\mathcal{S}_k\}}\right)\mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)\geq 0\}}\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)\\
&+\sum_{k=1}^{K}\left(\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,k}\right)\left(1-\sum_{\substack{r=1\\r\neq y_n}}^{K}\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,r}\right)\right)\right.\\
&\left.-t^{-1}\exp\left(-\tilde{\mathbf{w}}^\top\tilde{\mathbf{x}}_{n,k}\right)\mathbf{1}_{\{n\in\mathcal{S}_k\}}\right)\mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)<0\}}\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)\\
&=\sum_{k=1}^{K}\left(\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,k}\right)-t^{-1}\exp\left(-\tilde{\mathbf{w}}^\top\tilde{\mathbf{x}}_{n,k}\right)\mathbf{1}_{\{n\in\mathcal{S}_k\}}\right)\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)\\
&-\sum_{k=1}^{K}\sum_{\substack{r=1\\r\neq y_n}}^{K}\exp\left(-\mathbf{w}(t)^\top(\tilde{\mathbf{x}}_{n,k}+\tilde{\mathbf{x}}_{n,r})\right)\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)\mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)<0\}}\\
&\overset{(2)}{\leq}\sum_{k=1}^{K}\left(\exp\left(-\mathbf{w}(t)^\top\tilde{\mathbf{x}}_{n,k}\right)-t^{-1}\exp\left(-\tilde{\mathbf{w}}^\top\tilde{\mathbf{x}}_{n,k}\right)\mathbf{1}_{\{n\in\mathcal{S}_k\}}\right)\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)\\
&-K^2\exp\left(-\mathbf{w}(t)^\top(\tilde{\mathbf{x}}_{n,k_1}+\tilde{\mathbf{x}}_{n,r_1})\right)\tilde{\mathbf{x}}_{n,k_1}^\top\mathbf{r}(t)\mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k_1}^\top\mathbf{r}(t)<0\}},
\end{aligned}\tag{141}$$

where in (1) we used $\forall x\geq 0:\ 1-x\leq\frac{1}{1+x}\leq 1$ and in (2) we defined:

$$(k_1,r_1)=\underset{k,r}{\operatorname{argmax}}\left|\exp\left(-\mathbf{w}(t)^\top(\tilde{\mathbf{x}}_{n,k}+\tilde{\mathbf{x}}_{n,r})\right)\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)\mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}(t)<0\}}\right|$$

Recalling that $\mathbf{w}(t) = \hat{\mathbf{w}}\log(t) + \tilde{\mathbf{w}} + \mathbf{r}(t)$, eq. 141 can be upper bounded by

$$\sum_{k=1}^{K} t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k}\right) \tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \geq 0\ ,\ n \notin \mathcal{S}_k\}}$$
$$+ \sum_{k=1}^{K} t^{-1} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \left[\exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k}\right) - 1\right] \tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \geq 0\ ,\ n \in \mathcal{S}_k\}}$$
$$+ \sum_{k=1}^{K} t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k}\right) \tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) < 0\ ,\ n \notin \mathcal{S}_k\}}$$
$$+ \sum_{k=1}^{K} t^{-1} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \left[\exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k}\right) - 1\right] \tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) < 0\ ,\ n \in \mathcal{S}_k\}}$$
$$- K^2 \exp(-\mathbf{w}(t)^\top \tilde{\mathbf{x}}_{n,r_1}) t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}\right) \exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k_1}\right) \tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) < 0\}}$$
$$\overset{(1)}{\leq} K t^{-\theta} \exp\left(-\min_{n,k} \tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) + \phi(t), \tag{142}$$

where in (1) we used $xe^{-x} < 1,\ \forall x:\ (e^{-x}-1)x < 0, \theta = \min_k \left[\min_{n \notin \mathcal{S}_k} \tilde{\mathbf{x}}_{n,k}^\top \hat{\mathbf{w}}\right] > 1$ (eq. 125) and denoted:

$$\phi(t) = \sum_{k=1}^{K} t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k}\right) \tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) < 0,\ n \notin \mathcal{S}_k\}}$$
$$+ \sum_{k=1}^{K} t^{-1} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \left[\exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k}\right) - 1\right] \tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) < 0, n \in \mathcal{S}_k\}}$$
$$- K^2 \exp(-\mathbf{w}(t)^\top \tilde{\mathbf{x}}_{n,r_1}) t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}\right) \exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k_1}\right) \tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) < 0\}}.$$

We use the fact that $\forall x:\ (e^{-x}-1)x < 0$ and therefore $\forall (n,k)$:

$$t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k}\right) \tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) < 0\}} < 0$$
$$t^{-1} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \left[\exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k}\right) - 1\right] \tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) < 0\}} < 0, \tag{143}$$

to show that $\phi(t)$ is strictly negative. If $\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r} \geq 0$ then from the last two equations:

$$\phi(t) = \sum_{k=1}^{K} t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k}\right) \tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) < 0,\ n \notin \mathcal{S}_k\}}$$
$$+ \sum_{k=1}^{K} t^{-1} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \left[\exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k}\right) - 1\right] \tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) < 0,\ n \in \mathcal{S}_k\}} < 0 \tag{144}$$

If $\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r} < 0$ then we note that $-\tilde{\mathbf{x}}_{n,r_1}^\top \mathbf{r}(t) \leq -\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t)$ since:
1. If $\tilde{\mathbf{x}}_{n,r_1}^\top \mathbf{r}(t) \geq 0$ then this is immediate since $-\tilde{\mathbf{x}}_{n,r_1}^\top \mathbf{r}(t) \leq 0 \leq -\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t)$.
2. If $\tilde{\mathbf{x}}_{n,r_1}^\top \mathbf{r}(t) < 0$ then from (k_1, r_1) definition:

$$\left|\exp\left(-\mathbf{w}(t)^\top (\tilde{\mathbf{x}}_{n,k_1} + \tilde{\mathbf{x}}_{n,r_1})\right) \tilde{\mathbf{x}}_{n,r_1}^\top \mathbf{r}(t)\right| \leq \left|\exp\left(-\mathbf{w}(t)^\top (\tilde{\mathbf{x}}_{n,k_1} + \tilde{\mathbf{x}}_{n,r_1})\right) \tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t)\right|,$$

and therefore

$$-\tilde{\mathbf{x}}_{n,r_1}^\top \mathbf{r}(t) = \left|\tilde{\mathbf{x}}_{n,r_1}^\top \mathbf{r}(t)\right| \leq \left|\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t)\right| = -\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t).$$

We divide into cases:
1. If $n \notin \mathcal{S}_{k_1}$ then we examine the sum

$$t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}\right) \exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k_1}\right) \tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) < 0\}}$$
$$- K^2 \exp(-\mathbf{w}(t)^\top \tilde{\mathbf{x}}_{n,r_1}) t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}\right) \exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k_1}\right) \tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) < 0\}}$$

The first term is negative and the second is positive. From Lemma 19 $\mathbf{w}(t)^\top \tilde{\mathbf{x}}_{n,r_1} \to \infty$. Therefore $\exists t_3$ so that $\forall t > t_3:\ \exp(-\mathbf{w}(t)^\top \tilde{\mathbf{x}}_{n,r_1}) < K^2$ and therefore this sum is strictly negative since

$$\left|\frac{K^2 \exp(-\mathbf{w}(t)^\top \tilde{\mathbf{x}}_{n,r_1}) t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}\right)\right) \exp\left(-\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t)\right) \tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) < 0\}}}{t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}\right) \exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k_1}\right) \tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) < 0\}}}\right|$$
$$= \left|K^2 \exp(-\mathbf{w}(t)^\top \tilde{\mathbf{x}}_{n,r_1})\right| < 1,\ \forall t > t_3$$

2. If $n \in \mathcal{S}_{k_1}$ then we examine the sum

$$t^{-1} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}\right) \left[\exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k_1}\right) - 1\right] \tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) < 0\}}$$
$$- K^2 \exp(-\mathbf{w}(t)^\top \tilde{\mathbf{x}}_{n,r_1}) t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}\right) \exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k_1}\right) \tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) < 0\}}$$

a. If $|\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t)| > C_0$ then $\exists t_4$ such that $\forall t > t_4$ this sum can be upper bounded by zero since

$$\left|\frac{K^2 \exp(-\mathbf{w}(t)^\top \tilde{\mathbf{x}}_{n,r_1}) t^{-\hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}\right)\right) \exp\left(-\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t)\right) \tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) < 0\}}}{t^{-1} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k_1}\right) \left[\exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k_1}\right) - 1\right] \tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) \mathbf{1}_{\{\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) < 0\}}}\right|$$
$$= \frac{K^2 \exp(-\mathbf{w}(t)^\top \tilde{\mathbf{x}}_{n,r_1})}{1 - \exp\left(\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k_1}\right)} \leq \frac{K^2 \exp(-\mathbf{w}(t)^\top \tilde{\mathbf{x}}_{n,r_1})}{1 - \exp\left(-C_0\right)} < 1,\ \forall t > t_4 \tag{145}$$

where in the last transition we used Lemma 19.
b. If $|\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t)| \leq C_0$ then we can find constant C_5 so that eq. 145 can be upper bounded by

$$K^2 t^{-\hat{\mathbf{w}}^\top (\tilde{\mathbf{x}}_{n,k_1} + \tilde{\mathbf{x}}_{n,r_1})} \exp\left(-\tilde{\mathbf{w}}^\top (\tilde{\mathbf{x}}_{n,k_1} + \tilde{\mathbf{x}}_{n,r_1})\right) \exp\left(2C_0\right) C_0 \leq C_5 t^{-2}, \tag{146}$$

since $-\tilde{\mathbf{x}}_{n,r_1}^\top \mathbf{r}(t) \leq -\tilde{\mathbf{x}}_{n,k_1}^\top \mathbf{r}(t) \leq C_0$ and by definition, $\forall (n,k):\ \hat{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k} \geq 1$.
Therefore, eq. 141 can be upper bounded by

$$K t^{-\theta} \exp\left(-\min_{n,k} \tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) + C_5 t^{-2} \tag{147}$$

If, in addition, $\exists k, n \in \mathcal{S}_k:\ |\tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t)| > \epsilon_2$ then

$$t^{-1} \exp\left(-\tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \left[\exp\left(-\mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k}\right) - 1\right] \tilde{\mathbf{x}}_{n,k}^\top \mathbf{r}(t) \tag{148}$$
$$\leq \begin{cases} -t^{-1} \exp\left(-\max_{n,k} \tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \left[1 - \exp\left(-\epsilon_2\right)\right] \epsilon_2 & , \text{ if } \mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k} \geq 0 \\ -t^{-1} \exp\left(-\max_{n,k} \tilde{\mathbf{w}}^\top \tilde{\mathbf{x}}_{n,k}\right) \left[\exp\left(\epsilon_2\right) - 1\right] \epsilon_2 & , \text{ if } \mathbf{r}(t)^\top \tilde{\mathbf{x}}_{n,k} < 0 \end{cases} \tag{149}$$

and we can improve this bound to

$$-C''t^{-1} < 0, \tag{150}$$

where C'' is the minimum between $\exp\left(-\max_{n,k}\tilde{\mathbf{w}}^\top\tilde{\mathbf{x}}_{n,k}\right)\left[1-\exp\left(-\epsilon_2\right)\right]\epsilon_2$ and $\exp\left(-\max_{n,k}\tilde{\mathbf{w}}^\top\tilde{\mathbf{x}}_{n,k}\right)\left[\exp\left(\epsilon_2\right)-1\right]\epsilon_2$. To conclude:
1. If $\|\mathbf{P}_1\mathbf{r}\left(t\right)\| \geq \epsilon_1$ (as in Eq. 139), we have that

$$\max_{k,n\in\mathcal{S}_k}\left|\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}\left(t\right)\right|^2 \overset{(1)}{\geq} \frac{1}{|\mathcal{S}|}\sum_{k,n\in\mathcal{S}_k}\left|\tilde{\mathbf{x}}_{n,k}^\top\mathbf{P}_1\mathbf{r}\left(t\right)\right|^2 = \frac{1}{|\mathcal{S}|}\left\|\mathbf{X}_\mathcal{S}^\top\mathbf{P}_1\mathbf{r}\left(t\right)\right\|^2 \overset{(2)}{\geq} \frac{1}{|\mathcal{S}|}\sigma_{\min}^2\left(\mathbf{X}_\mathcal{S}\right)\epsilon_1^2 \tag{151}$$

where in (1) we used $\mathbf{P}_1^\top\tilde{\mathbf{x}}_{n,k} = \tilde{\mathbf{x}}_{n,k}\ \forall k,\ n\in\mathcal{S}_k$, in (2) we denoted by $\sigma_{\min}\left(\mathbf{X}_\mathcal{S}\right)$, the minimal non-zero singular value of $\mathbf{X}_\mathcal{S}$ and used eq. 128. Therefore, for some (n,k), $\left|\tilde{\mathbf{x}}_{n,k}^\top\mathbf{r}\right| \geq \epsilon_2 \triangleq |\mathcal{S}|^{-1}\sigma_{\min}^2\left(\mathbf{X}_\mathcal{S}\right)\epsilon_1^2$. If $||\mathbf{P}_1\mathbf{r}(t)|| \geq \epsilon_1$, then combining eq. 139 with eq. 150 we find that eq. 137 can be upper bounded by:

$$\left(\mathbf{r}(t+1)-\mathbf{r}(t)\right)^\top\mathbf{r}(t) \leq -C''t^{-1}+o(t^{-1})$$

This implies that $\exists C_2 < C''$ and $\exists t_2 > 0$ such that eq. 129 holds. This implies also that eq. 127 holds for $||\mathbf{P}_1\mathbf{r}(t)|| \geq \epsilon_1$.
2. If $||\mathbf{P}_1 r(t)|| < \epsilon_1$, we obtain (for some positive constants C_3, C_4):

$$\left(\mathbf{r}(t+1)-\mathbf{r}(t)\right)^\top\mathbf{r}(t) \leq C_3t^{-\theta}+C_4t^{-2}$$

Therefore, $\exists t_1 > 0$ and C_1 such that eq. 127 holds.

Appendix F. An experiment with stochastic gradient descent

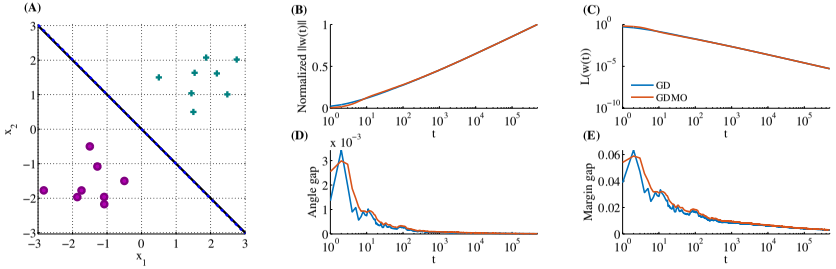

Figure 4: Same as Fig. 1, except stochastic gradient decent is used (with mini-batch of size 4), instead of GD.

Abstract

In learning theory, the *VC dimension* of a concept class $\mathscr{C}$ is the most common way to measure its "richness." A fundamental result says that the number of examples needed to learn an unknown target concept $c \in \mathscr{C}$ under an unknown distribution D, is tightly determined by the VC dimension d of the concept class $\mathscr{C}$. Specifically, in the PAC model

$$\Theta\Big(\frac{d}{\varepsilon} + \frac{\log(1/\delta)}{\varepsilon}\Big)$$

examples are necessary and sufficient for a learner to output, with probability $1-\delta$, a hypothesis h that is ε-close to the target concept c (measured under D). In the related *agnostic* model, where the samples need not come from a $c \in \mathscr{C}$, we know that

$$\Theta\Big(\frac{d}{\varepsilon^2} + \frac{\log(1/\delta)}{\varepsilon^2}\Big)$$

examples are necessary and sufficient to output an hypothesis $h \in \mathscr{C}$ whose error is at most ε worse than the error of the best concept in $\mathscr{C}$.

Here we analyze *quantum* sample complexity, where each example is a coherent quantum state. This model was introduced by Bshouty and Jackson (1999), who showed that quantum examples are more powerful than classical examples in some fixed-distribution settings. However, Atıcı and Servedio (2005), improved by Zhang (2010), showed that in the PAC setting (where the learner has to succeed for every distribution), quantum examples cannot be much more powerful: the required number of quantum examples is

$$\Omega\Big(\frac{d^{1-\eta}}{\varepsilon} + d + \frac{\log(1/\delta)}{\varepsilon}\Big) \text{ for arbitrarily small constant } \eta > 0.$$

Our main result is that quantum and classical sample complexity are in fact equal up to constant factors in both the PAC and agnostic models. We give two proof approaches. The first is a fairly simple information-theoretic argument that yields the above two classical bounds and yields the same bounds for quantum sample complexity up to a $\log(d/\varepsilon)$ factor. We then give a second approach that avoids the log-factor loss, based on analyzing the behavior of the "Pretty Good Measurement" on the quantum state-identification problems that correspond to learning. This shows classical and quantum sample complexity are equal up to constant factors for every concept class $\mathscr{C}$.

1. Introduction

1.1. Sample complexity and VC dimension

Machine learning is one of the most successful parts of AI, with impressive practical applications in areas ranging from image processing and speech recognition, to even beating Go champions. Its theoretical aspects have been deeply studied, revealing beautiful structure and mathematical characterizations of when (efficient) learning is or is not possible in various settings.

1.1.1. The PAC setting

Leslie Valiant (1984)'s Probably Approximately Correct (PAC) learning model gives a precise complexity-theoretic definition of what it means for a concept class to be (efficiently) learnable. For simplicity we will (without loss of generality) focus on concepts that are Boolean functions, $c : \{0,1\}^n \to \{0,1\}$. Equivalently, a concept c is a subset of $\{0,1\}^n$, namely $\{x : c(x) = 1\}$. Let $\mathscr{C} \subseteq \{f : \{0,1\}^n \to \{0,1\}\}$ be a concept class. This could for example be the class of functions computed by disjunctive normal form (DNF) formulas of a certain size, or Boolean circuits or decision trees of a certain depth.

The goal of a learning algorithm (the learner) is to probably approximate some unknown *target concept* $c \in \mathscr{C}$ from random *labeled examples*. Each labeled example is of the form $(x, c(x))$ where x is distributed according to some unknown distribution D over $\{0,1\}^n$. After processing a number of such examples (hopefully not too many), the learner outputs some *hypothesis* h. We say that h is *ε-approximately correct* (w.r.t. the target concept c) if its error probability under D is at most ε: $\Pr_{x\sim D}[h(x) \neq c(x)] \leq \varepsilon$. Note that the learning phase and the evaluation phase (i.e., whether a hypothesis is approximately correct) are according to the same distribution D—as if the learner is taught and then tested by the same teacher. An (ε, δ)-learner for the concept class $\mathscr{C}$ is one whose hypothesis is probably approximately correct:

> For all target concepts $c \in \mathscr{C}$ and distributions D:
> Pr[the learner's output h is ε-approximately correct] $\geq 1-\delta$,

where the probability is over the sequence of examples and the learner's internal randomness. Note that we leave the learner the freedom to output an h which is not in $\mathscr{C}$. If always $h \in \mathscr{C}$, then the learner is called a *proper* PAC-learner.

Of course, we want the learner to be as efficient as possible. Its *sample complexity* is the worst-case number of examples it uses, and its *time complexity* is the worst-case running time of the learner. In this paper we focus on sample complexity. This allows us to ignore technical issues of how the runtime of an algorithm is measured, and in what form the hypothesis h is given as output by the learner.

The sample complexity of a concept class $\mathscr{C}$ is the sample complexity of the most efficient learner for $\mathscr{C}$. It is a function of ε, δ, and of course of $\mathscr{C}$ itself. One of the most fundamental results in learning theory is that the sample complexity of $\mathscr{C}$ is tightly determined by a combinatorial parameter called the *VC dimension* of $\mathscr{C}$, due to and named after Vapnik and Chervonenkis (1971). The VC dimension of $\mathscr{C}$ is the size of the biggest $\mathcal{S} \subseteq \{0,1\}^n$ that can be labeled in all $2^{|\mathcal{S}|}$ possible ways by concepts from $\mathscr{C}$: for each sequence of $|\mathcal{S}|$

binary labels for the elements of $\mathcal{S}$, there is a $c \in \mathscr{C}$ that has that labeling.[1] Knowing this VC dimension (and ε, δ) already tells us the sample complexity of $\mathscr{C}$ up to constant factors. Blumer et al. (1989) proved that the sample complexity of $\mathscr{C}$ is lower bounded by $\Omega(d/\varepsilon + \log(1/\delta)/\varepsilon)$, and they proved an upper bound that was worse by a $\log(1/\varepsilon)$-factor. In very recent work, Hanneke (2016) (improving on Simon (2015)) got rid of this $\log(1/\varepsilon)$-factor for PAC learning,[2] showing that the lower bound of Blumer et al. is in fact optimal: the sample complexity of $\mathscr{C}$ in the PAC setting is

$$\Theta\Big(\frac{d}{\varepsilon} + \frac{\log(1/\delta)}{\varepsilon}\Big). \tag{1}$$

1.1.2. The agnostic setting

The PAC model assumes that the labeled examples are generated according to a target concept $c \in \mathscr{C}$. However, in many learning situations that is not a realistic assumption, for example when the examples are noisy in some way or when we have no reason to believe there is an underlying target concept at all. The *agnostic* model of learning, introduced by Haussler (1992) and Kearns et al. (1994), takes this into account. Here, the examples are generated according to a distribution D on $\{0,1\}^{n+1}$. The error of a specific concept $c : \{0,1\}^n \to \{0,1\}$ is defined to be $\mathrm{err}_D(c) = \Pr_{(x,b)\sim D}[c(x) \neq b]$. When we are restricted to hypotheses in $\mathscr{C}$, we would like to find the hypothesis that minimizes $\mathrm{err}_D(c)$ over all $c \in \mathscr{C}$. However, it may require very many examples to do that exactly. In the spirit of the PAC model, the goal of the learner is now to output an $h \in \mathscr{C}$ whose error is at most an additive ε worse than that of the best (= lowest-error) concepts in $\mathscr{C}$.

Like in the PAC model, the optimal sample complexity of such agnostic learners is tightly determined by the VC dimension of $\mathscr{C}$: it is

$$\Theta\Big(\frac{d}{\varepsilon^2} + \frac{\log(1/\delta)}{\varepsilon^2}\Big), \tag{2}$$

where the lower bound was proven by Vapnik and Chervonenkis (1974) (see also Simon (1996)), and the upper bound was proven by Talagrand (1994). Shalev-Shwartz and Ben-David (2014) call Eq. (1) and Eq. (2) the "Fundamental Theorem of PAC learning."

1.2. Our results

In this paper we are interested in *quantum* sample complexity. Here a *quantum example* for some concept $c : \{0,1\}^n \to \{0,1\}$, according to some distribution D, corresponds to an $(n+1)$-qubit state

$$\sum_{x\in\{0,1\}^n} \sqrt{D(x)}|x, c(x)\rangle.$$

In other words, instead of a random labeled example, an example is now given by a coherent quantum superposition where the square-roots of the probabilities become the amplitudes.[3]

1. Such an $\mathcal{S}$ is said to be *shattered* by $\mathscr{C}$.
2. Hanneke's learner is not proper, meaning that its hypothesis h is not always in $\mathscr{C}$. It is known that the extra $\log(1/\varepsilon)$-factor is sometimes necessary for *proper* PAC learners.
3. We could allow more general quantum examples $\sum_{x\in\{0,1\}^n} \alpha_x|x, c(x)\rangle$, where we only require $|\alpha_x|^2 = D(x)$. However, that will not affect our results since our lower bounds apply to quantum examples where we know the amplitudes are square-rooted probabilities. Adding more degrees of freedom to quantum examples does not make learning easier.

This model was introduced by Bshouty and Jackson (1999), who showed that DNF formulas are learnable in polynomial time from quantum examples when D is uniform. For learning DNF under the uniform distribution from *classical* examples, Verbeurgt (1990) gave the best upper bound of quasipolynomial time. With the added power of "membership queries," where the learner can actively ask for the label of any x of his choice, DNF formulas are known to be learnable in polynomial time under uniform D by a result of Jackson (1997), but *without* membership queries polynomial-time learnability is a longstanding open problem (see Daniely and Shalev-Shwartz (2016) for a recent hardness result) .

How reasonable are examples that are given as a coherent superposition rather than as a random sample? They may seem unreasonable a priori because quantum superpositions seem very fragile and are easily collapsed by measurement, but if we accept the "church of the larger Hilbert space" view on quantum mechanics, where the universe just evolves unitarily without any collapses, then they may become more palatable. It is also possible that the quantum examples are generated by some coherent quantum process that acts like the teacher.

How many quantum examples are needed to learn a concept class $\mathscr{C}$ of VC dimension d? Since a learner can just measure a quantum example in order to obtain a classical example, the *upper* bounds on classical sample complexity trivially imply the same upper bounds on quantum sample complexity. But what about the lower bounds? Are there situations where quantum examples are more powerful than classical? Indeed there are. We already mentioned the results of Bshouty and Jackson (1999) for learning DNF under the uniform distribution without membership queries. Another good example is the learnability of the concept class of linear functions over $\mathbb{F}_2$, $\mathscr{C} = \{c(x) = a \cdot x : a \in \{0,1\}^n\}$, again under the uniform distribution D. It is easy to see that a classical learner needs about n examples to learn an unknown $c \in \mathscr{C}$ under this D. However, if we are given one quantum example

$$\sum_{x\in\{0,1\}^n} \sqrt{D(x)}|x, c(x)\rangle = \frac{1}{\sqrt{2^n}} \sum_{x\in\{0,1\}^n} |x, a \cdot x\rangle,$$

then a small modification of the Bernstein and Vazirani (1997) algorithm can recover a (and hence c) with probability $1/2$. Hence $O(1)$ quantum examples suffice to learn c exactly, with high probability, under the uniform distribution. Atıcı and Servedio (2009) used similar ideas to learning *k-juntas* (concepts depending on only k of their n variables) from quantum examples under the uniform distribution. However, PAC learning requires a learner to learn c under *all possible* distributions D, not just the uniform one. The success probability of the Bernstein-Vazirani algorithm deteriorates sharply when D is far from uniform, but that does not rule out the existence of other quantum learners that use $o(n)$ quantum examples and succeed for all D.

Our main result in this paper is that quantum examples are not actually more powerful than classical labeled examples in the PAC model and in the agnostic model: we prove that the lower bounds on classical sample complexity of Eq. (1) and Eq. (2) hold for quantum examples as well. Accordingly, despite several distribution-specific speedups, quantum examples do not significantly reduce sample complexity if we require our learner to work

for all distributions D. This should be contrasted with the situation when considering the *time complexity* of learning. Servedio and Gortler (2004) considered a concept class (already considered in the literature by Kearns and Valiant (1994)) that can be PAC-learned in polynomial time by a quantum computer, even with only classical examples, but that cannot be PAC-learned in polynomial time by a classical learner unless Blum integers can be factored in polynomial time (which is widely believed to be false).

Earlier work on quantum sample complexity had already gotten close to extending the lower bound of Eq. (1) to PAC learning from quantum examples. Atıcı and Servedio (2005) first proved a lower bound of $\Omega(\sqrt{d}/\varepsilon + d + \log(1/\delta)/\varepsilon)$, which was subsequently improved by Zhang (2010) to

$$\Omega\Big(\frac{d^{1-\eta}}{\varepsilon} + d + \frac{\log(1/\delta)}{\varepsilon}\Big) \text{ for arbitrarily small constant } \eta > 0. \tag{3}$$

Here we optimize these bounds, removing the η and achieving the optimal lower bound for quantum sample complexity in the PAC model (Eq. (1)).

We also show that the lower bound (Eq. (2)) for the agnostic model extends to quantum examples. As far as we know, in contrast to the PAC model, no earlier results were known for quantum sample complexity in the agnostic model.

We have two different proof approaches, which we sketch below.

1.2.1. An information-theoretic argument

In Section 3 we give a fairly intuitive information-theoretic argument that gives optimal lower bounds for classical sample complexity, and that gives nearly-optimal lower bounds for quantum sample complexity. Let us first see how we can prove the classical PAC lower bound of Eq. (1). Suppose $\mathcal{S} = \{s_0, s_1, \ldots, s_d\}$ is shattered by $\mathscr{C}$ (we now assume VC dimension $d+1$ for ease of notation). Then we can consider a distribution D that puts probability $1-4\varepsilon$ on s_0 and probability $4\varepsilon/d$ on each of $s_1, \ldots, s_d$.[4] For every possible labeling $(\ell_1 \ldots \ell_d) \in \{0,1\}^d$ of $s_1, \ldots, s_d$ there will be a concept $c \in \mathscr{C}$ that labels s_0 with 0, and labels s_i with ℓ_i for all $i \in \{1, \ldots, d\}$. Under D, most examples will be $(s_0, 0)$ and hence give us no information when we are learning one of those 2^d concepts. Suppose we have a learner that ε-approximates c with high probability under this D using T examples. Informally, our information-theoretic argument has the following three steps:

1. In order to ε-approximate c, the learner has to learn the c-labels of at least $3/4$ of the $s_1, \ldots, s_d$ (since together these have 4ε of the D-weight, and we want an ε-approximation). As all 2^d labelings are possible, the T examples together contain $\Omega(d)$ bits of information about c.

2. T examples give at most T times as much information about c as one example.

3. One example gives only $O(\varepsilon)$ bits of information about c, because it will tell us one of the labels of $s_1, \ldots, s_d$ only with probability 4ε (and otherwise it just gives $c(s_0) = 0$).

4. We remark that the distributions used here (and later in the agnostic setting) for proving lower bounds on quantum sample complexity have been used in the literature before for analyzing classical sample complexity.

Putting these steps together implies $T = \Omega(d/\varepsilon)$.[5] This argument for the PAC setting is similar to an algorithmic-information argument of Apolloni and Gentile (1998) and an information-theoretic argument for variants of the PAC model with noisy examples by Gentile and Helmbold (2001).

As far as we know, this type of reasoning has not yet been applied to the sample complexity of *agnostic* learning. To get good lower bounds there, we consider a set of distributions D_a, indexed by d-bit string a. These distributions still have the property that if a learner gets ε-close to the minimal error, then it will have to learn $\Omega(d)$ bits of information about the distribution (i.e., about a). Hence the first step of the argument remains the same. The second step of our argument also remains the same, and the third step shows an upper bound of $O(\varepsilon^2)$ on the amount of information that the learner can get from one example. This then implies $T = \Omega(d/\varepsilon^2)$. We can also reformulate this for the case where we want the *expected* additional error of the hypothesis over the best classifier in $\mathscr{C}$ to be at most ε, which is how lower bounds are often stated in learning theory. We emphasize that our information-theoretic proof is simpler than the proofs in Anthony and Bartlett (2009); Audibert (2009); Shalev-Shwartz and Ben-David (2014); Kontorovich and Pinelis (2016).

This information-theoretic approach recovers the optimal classical bounds on sample complexity, but also generalizes readily to the quantum case where the learner gets T quantum examples. To obtain lower bounds on quantum sample complexity we use the same distributions D (now corresponding to a coherent quantum state) and basically just need to re-analyze the third step of the argument. In the PAC setting we show that one quantum example gives at most $O(\varepsilon \log(d/\varepsilon))$ bits of information about c, and in the agnostic setting it gives $O(\varepsilon^2 \log(d/\varepsilon))$ bits. This implies lower bounds on sample complexity that are only a logarithmic factor worse than the optimal classical bounds for the PAC setting (Eq. (1)) and the agnostic setting (Eq. (2)). This is not quite optimal yet, but already better than the previous best known lower bound (Eq. (3)). The logarithmic loss in step 3 is actually inherent in this information-theoretic argument: in some cases a quantum example *can* give roughly $\varepsilon \log d$ bits of information about c, for example when c comes from the concept class of linear functions.

1.2.2. A state-identification argument

In order to get rid of the logarithmic factor we then try another proof approach, which views learning from quantum examples as a quantum state-identification problem: we are given T copies of the quantum example for some concept c and need to ε-approximate c from this. In order to render ε-approximation of c equivalent to exact identification of c, we use good linear error-correcting codes, restricting to concepts whose d-bit labeling of the elements of the shattered set $s_1, \ldots, s_d$ corresponds to a codeword. We then have $2^{\Omega(d)}$ possible concepts, one for each codeword, and need to identify the target concept from a quantum state that is the tensor product of T identical quantum examples.

State-identification problems have been well studied, and many tools are available for analyzing them. In particular, the so-called "Pretty Good Measurement" (PGM, also referred to as "square root measurement" by Eldar and Forney Jr (2001)) is a specific measurement

5. The other part of the lower bound of Eq. (1) does not depend on d and is fairly easy to prove.

that one can always use for state identification, and whose success probability is no more than quadratically worse than that of the very best measurement (even better, in our application the PGM *is* the optimal measurement). In Section 4 we use Fourier analysis to give an exact analysis of the average success probability of the PGM on the state-identification problems that come from both the PAC and the agnostic model. This analysis could be useful in other settings as well. Here it implies that the number of quantum examples, T, is lower bounded by Eq. (1) in the PAC setting, and by Eq. (2) in the agnostic setting.

Using the Pretty Good Measurement, we are also able to prove lower bounds for PAC learning under *random classification noise*, which models the real-world situation that the learning data can have some errors. Classically in the random classification noise model (introduced by Angluin and Laird (1988)), instead of obtaining labeled examples $(x, c(x))$ for some unknown $c \in \mathscr{C}$, the learner obtains *noisy examples* (x, b_x), where $b_x = c(x)$ with probability $1-\eta$ and $b_x = 1-c(x)$ with probability η, for some *noise rate* $\eta \in [0, 1/2)$. Similarly, in the quantum learning model we could naturally define a *noisy quantum example* as an $(n+1)$-qubit state

$$\sum_{x\in\{0,1\}^n} \sqrt{(1-\eta)D(x)}|x, c(x)\rangle + \sqrt{\eta D(x)}|x, 1-c(x)\rangle.$$

Using the PGM, we are able to show that the quantum sample complexity of PAC learning a concept class $\mathscr{C}$ under random classification noise is:

$$\Omega\Big(\frac{d}{(1-2\eta)^2\varepsilon} + \frac{\log(1/\delta)}{(1-2\eta)^2\varepsilon}\Big). \tag{4}$$

We remark here that the best known classical sample complexity lower bound (see Simon (1996)) under the random classification noise is equal to the quantum sample complexity lower bound proven in Eq. (4).

1.3. Related work

Here we briefly mention related work on quantum learning, referring to our survey Arunachalam and de Wolf (2017) for more details. In this paper we focus on *sample* complexity, which is a fundamental information-theoretic quantity. Sample complexity concerns a form of "passive" learning: the learner gets a number of examples at the start of the process, and then has to extract enough information about the target concept from these. We may also consider more active learning settings, in particular ones where the learner can make membership queries (i.e., learn the label $c(x)$ for any x of his choice). Servedio and Gortler (2004) showed that in this setting, classical and quantum complexity are polynomially related. They also exhibit an example of a factor-n speed-up from quantum membership queries using the Bernstein-Vazirani algorithm. Jackson et al. (2002) showed how quantum membership queries can improve Jackson (1997)'s classical algorithm for learning DNF with membership queries under the uniform distribution.

For *quantum exact learning* (also referred to as the *oracle identification* problem in the quantum literature), Kothari (2014) resolved a conjecture of Hunziker et al. (2010), that states that for any concept class $\mathscr{C}$, the number of quantum membership queries required to exactly identify a concept $c \in \mathscr{C}$ is $O(\frac{\log|\mathscr{C}|}{\sqrt{\hat{\gamma}^{\mathscr{C}}}})$, where $\hat{\gamma}^{\mathscr{C}}$ is a combinatorial parameter

of the concept class $\mathscr{C}$ which we shall not define here (see Atıcı and Servedio (2005) for a precise definition). Montanaro (2012) showed how low-degree polynomials over a finite field can be identified more efficiently using quantum algorithms.

In many ways the *time* complexity of learning is at least as important as the sample complexity. We already mentioned that Servedio and Gortler (2004) exhibited a concept class based on factoring Blum integers that can be learned in quantum polynomial time but not in classical polynomial time, unless Blum integers can be factored efficiently. Under the weaker (and widely believed) assumption that one-way functions exist, they exhibited a concept class that can be learned exactly in polynomial time using quantum membership queries, but that takes superpolynomial time to learn from classical membership queries. Gavinsky (2012) introduced a model of learning called "Predictive Quantum" (PQ), a variation of quantum PAC learning, and exhibited a *relational* concept class that is polynomial-time learnable in PQ, while any "reasonable" classical model requires an exponential number of classical examples to learn the concept class.

Aïmeur et al. (2006, 2013) considered a number of quantum algorithms in learning contexts such as clustering via minimum spanning tree, divisive clustering, and k-medians, using variants of Grover (1996)'s algorithm to improve the time complexity of the analogous classical algorithms. Recently, there have been some quantum machine learning algorithms based on Harrow et al. (2009)'s algorithm (commonly referred to as the HHL algorithm) for solving (in a weak sense) very well-behaved linear systems. However, these algorithms often come with some fine print that limits their applicability, and their advantage over classical is not always clear. We refer the reader to the fine print by Aaronson (2015) for references and caveats. There has also been some work on quantum training of neural networks by Wiebe et al. (2016a,b).

In addition to learning classical objects such as Boolean functions, one may also study the learnability of *quantum* objects. In particular, Aaronson (2007) studied how well n-qubit quantum states can be learned from measurement results. In general, an n-qubit state ρ is specified by $\exp(n)$ many parameters, and $\exp(n)$ measurement results on equally many copies of ρ are needed to learn a good approximation of ρ (say, in trace distance). However, Aaronson showed an interesting and surprisingly efficient PAC-like result: from $O(n)$ measurement results, with measurements chosen i.i.d. according to an unknown distribution D on the set of all possible two-outcome measurements, we can learn an n-qubit quantum state $\widetilde{\rho}$ that has roughly the same expectation value as ρ for "most" possible two-outcome measurements. In the latter, "most" is again measured under D, just like in the usual PAC learning the error of the learner's hypothesis is evaluated under the same distribution D that generated the learner's examples. Accordingly, $O(n)$ rather than $\exp(n)$ measurement results suffice to approximately learn an n-qubit state for most practical purposes.

The use of Fourier analysis in analyzing the success probability of the Pretty Good Measurement in quantum state identification appears in a number of earlier works. By considering the dihedral hidden subgroup problem (DHSP) as a state-identification problem, Bacon et al. (2006) show that the PGM is the optimal measurement for DHSP and prove a lower bound on the sample complexity of $\Omega(\log|\mathscr{G}|)$ for a dihedral group $\mathscr{G}$ using Fourier analysis. Ambainis and Montanaro (2014) view the "search with wildcard" problem as a state-identification problem. Using ideas similar to ours, they show that the (x, y)-th entry of the Gram matrix for the ensemble depends on the Hamming distance between x

and y, allowing them to use Fourier analysis to obtain an upper bound on the success probability of the state-identification problem using the PGM.

1.4. Organization

In Section 2 we formally define the classical and quantum learning models and introduce the Pretty Good Measurement. In Section 3 we prove our information-theoretic lower bounds both for classical and quantum learning. In Section 4 we prove an optimal quantum lower bound for PAC and agnostic learning by viewing the learning process as a state-identification problem. We conclude in Section 5 with a conclusion of the results and some open questions for further work.

2. Preliminaries

2.1. Notation

Let $[n] = \{1, \ldots, n\}$. For $x, y \in \{0,1\}^d$, the bit-wise sum $x + y$ is over $\mathbb{F}_2$, the *Hamming distance* $d_H(x, y)$ is the number of indices on which x and y differ, $|x + y|$ is the Hamming weight of the string $x + y$ (which equals $d_H(x, y)$), and $x \cdot y = \sum_i x_i y_i$ (where the sum is over $\mathbb{F}_2$). For a vector $z \in \mathbb{R}^d$, the *norm of* z is defined as $\|z\| = (\sum_i z_i^2)^{1/2}$. For an n-dimensional vector space, the standard basis is denoted by $\{e_i \in \{0,1\}^n : i \in [n]\}$, where e_i is the vector with a 1 in the i-th coordinate and 0's elsewhere. We write log for logarithm to base 2, and ln for base e. We will often use the bijection between the sets $\{0,1\}^k$ and $[2^k]$ throughout this paper. Let $1_{[A]}$ be the indicator for an event A, and let $\delta_{x,y} = 1_{[x=y]}$. We denote random variables in bold, such as $\mathbf{A}$, $\mathbf{B}$.

For a Boolean function $f : \{0,1\}^m \to \{0,1\}$ and $M \in \mathbb{F}_2^{m \times k}$ we define $f \circ M : \{0,1\}^k \to \{0,1\}$ as $(f \circ M)(x) := f(Mx)$ (where the matrix-vector product is over $\mathbb{F}_2$) for all $x \in \{0,1\}^k$. For a distribution $D : \{0,1\}^n \to [0,1]$, let $\mathrm{supp}(D) = \{x \in \{0,1\}^n : D(x) \neq 0\}$. By $x \sim D$, we mean x is sampled according to the distribution D, i.e., $\Pr[\mathbf{X} = x] = D(x)$.

If M is a positive semidefinite (psd) matrix, we define $\sqrt{M}$ as the unique psd matrix that satisfies $\sqrt{M} \cdot \sqrt{M} = M$, and $\sqrt{M}(i, j)$ as the (i, j)-th entry of $\sqrt{M}$. For a matrix $A \in \mathbb{R}^{m \times n}$, we denote the singular values of A by $\sigma_1(A) \geq \sigma_2(A) \geq \cdots \geq \sigma_{\min\{m,n\}}(A) \geq 0$. The spectral norm of A is $\|A\| = \max_{x \in \mathbb{R}^n, \|x\|=1} \|Ax\| = \sigma_1$. Given a set of d-dimensional vectors $U = \{u_1, \ldots, u_n\} \in \mathbb{R}^d$, the Gram matrix V corresponding to the set U is the $n \times n$ psd matrix defined as $V(i, j) = u_i^t u_j$ for $i, j \in [n]$, where u_i^t is the row vector that is the transpose of the column vector u_i.

A technical tool used in our analysis of state-identification problems is Fourier analysis on the Boolean cube. We will just introduce the basics of Fourier analysis here, referring to O'Donnell (2014) for more. Define the inner product between functions $f, g : \{0,1\}^n \to \mathbb{R}$ as

$$\langle f, g \rangle = \mathop{\mathbb{E}}_x [f(x) \cdot g(x)]$$

where the expectation is uniform over $x \in \{0,1\}^n$. For $S \subseteq [n]$ (equivalently $S \in \{0,1\}^n$), let $\chi_S(x) := (-1)^{S \cdot x}$ denote the parity of the variables (of x) indexed by the set S. It is easy to see that the set of functions $\{\chi_S\}_{S \subseteq [n]}$ forms an orthonormal basis for the space of

real-valued functions over the Boolean cube. Hence every f can be decomposed as

$$f(x) = \sum_{S \subseteq [n]} \widehat{f}(S)(-1)^{S \cdot x} \qquad \text{for all } x \in \{0,1\}^n,$$

where $\widehat{f}(S) = \langle f, \chi_S \rangle = \mathbb{E}_x[f(x) \cdot \chi_S(x)]$ is called a *Fourier coefficient* of f.

2.2. Learning in general

In machine learning, a concept class $\mathscr{C}$ over $\{0,1\}^n$ is a set of concepts $c : \{0,1\}^n \to \{0,1\}$. We refer to a concept class $\mathscr{C}$ as being *trivial* if either $\mathscr{C}$ contains only one concept, or $\mathscr{C}$ contains two concepts c_0, c_1 with $c_0(x) = 1 - c_1(x)$ for every $x \in \{0,1\}^n$. For $c : \{0,1\}^n \to \{0,1\}$, we will often refer to the tuple $(x, c(x)) \in \{0,1\}^{n+1}$ as a *labeled example*, where $c(x)$ is the *label* of x.

A central combinatorial concept in learning is the Vapnik and Chervonenkis (1971) dimension, also referred to as the *VC dimension*. Fix a concept class $\mathscr{C}$ over $\{0,1\}^n$. A set $\mathcal{S} = \{s_1, \ldots, s_t\} \subseteq \{0,1\}^n$ is said to be *shattered* by a concept class $\mathscr{C}$ if $\{(c(s_1), \ldots, c(s_t)) : c \in \mathscr{C}\} = \{0,1\}^t$. In other words, for every labeling $\ell \in \{0,1\}^t$, there exists a $c \in \mathscr{C}$ such that $(c(s_1), \ldots, c(s_t)) = \ell$. The VC dimension of a concept class $\mathscr{C}$ is the size of the largest $\mathcal{S} \subseteq \{0,1\}^n$ that is shattered by $\mathscr{C}$.

2.3. Classical learning models

In this paper we will be concerned mainly with the PAC (Probably Approximately Correct) model of learning introduced by Valiant (1984), and the agnostic model of learning introduced by Haussler (1992) and Kearns et al. (1994). For further reading, see standard textbooks in computational learning theory such as Kearns and Vazirani (1994); Anthony and Bartlett (2009); Shalev-Shwartz and Ben-David (2014).

In the classical PAC model, a learner $\mathcal{A}$ is given access to a *random example oracle* $\mathrm{PEX}(c, D)$ which generates labeled examples of the form $(x, c(x))$ where x is drawn from an unknown distribution $D : \{0,1\}^n \to [0,1]$ and $c \in \mathscr{C}$ is the *target concept* that $\mathcal{A}$ is trying to learn. For a concept $c \in \mathscr{C}$ and hypothesis $h : \{0,1\}^n \to \{0,1\}$, we define the error of h compared to the target concept c, under D, as $\mathrm{err}_D(h, c) = \Pr_{x \sim D}[h(x) \neq c(x)]$. A learning algorithm $\mathcal{A}$ is an *(ε, δ)-PAC learner* for $\mathscr{C}$, if the following holds:

> For every $c \in \mathscr{C}$ and distribution D, given access to the $\mathrm{PEX}(c, D)$ oracle:
> $\mathcal{A}$ outputs an h such that $\mathrm{err}_D(h, c) \leq \varepsilon$ with probability at least $1 - \delta$.

The *sample complexity* of $\mathcal{A}$ is the maximum number of invocations of the $\mathrm{PEX}(c, D)$ oracle which the learner makes, over all concepts $c \in \mathscr{C}$, distributions D, and the internal randomness of the learner. The *(ε, δ)-PAC sample complexity* of a concept class $\mathscr{C}$ is the minimum sample complexity over all (ε, δ)-PAC learners for $\mathscr{C}$.

Agnostic learning is the following model: for a distribution $D : \{0,1\}^{n+1} \to [0,1]$, a learner $\mathcal{A}$ is given access to an $\mathrm{AEX}(D)$ oracle that generates examples of the form (x, b) drawn from the distribution D. We define the error of $h : \{0,1\}^n \to \{0,1\}$ under D as $\mathrm{err}_D(h) = \Pr_{(x,b) \sim D}[h(x) \neq b]$. When h is restricted to come from a concept class $\mathscr{C}$, the minimal error achievable is $\mathrm{opt}_D(\mathscr{C}) = \min_{c \in \mathscr{C}}\{\mathrm{err}_D(c)\}$. In agnostic learning, a learner $\mathcal{A}$

needs to output a hypothesis h whose error is not much bigger than $\mathrm{opt}_D(\mathscr{C})$. A learning algorithm $\mathcal{A}$ is an (ε,δ)-*agnostic learner* for $\mathscr{C}$ if:

> For every distribution D on $\{0,1\}^{n+1}$, given access to the $\mathrm{AEX}(D)$ oracle:
> $\mathcal{A}$ outputs an $h\in\mathscr{C}$ such that $\mathrm{err}_D(h)\leq \mathrm{opt}_D(\mathscr{C})+\varepsilon$ with probability at least $1-\delta$.

Note that if there is a $c\in\mathscr{C}$ which perfectly classifies every x with label y for $(x,y)\in\mathrm{supp}(D)$, then $\mathrm{opt}_D(\mathscr{C})=0$ and we are in the setting of proper PAC learning. The *sample complexity* of $\mathcal{A}$ is the maximum number of invocations of the $\mathrm{AEX}(c,D)$ oracle which the learner makes, over all distributions D and over the learner's internal randomness. The (ε,δ)-*agnostic sample complexity* of a concept class $\mathscr{C}$ is the minimum sample complexity over all (ε,δ)-agnostic learners for $\mathscr{C}$.

2.4. Quantum information theory

Throughout this paper we will assume the reader is familiar with the following quantum terminology. An n-dimensional *pure state* is $|\psi\rangle=\sum_{i=1}^n\alpha_i|i\rangle$, where $|i\rangle$ is the n-dimensional unit vector that has a 1 only at position i, the α_i's are complex numbers called the *amplitudes*, and $\sum_{i\in[n]}|\alpha_i|^2=1$. An n-dimensional *mixed state* (or *density matrix*) $\rho=\sum_{i=1}^n p_i|\psi_i\rangle\langle\psi_i|$ is a mixture of pure states $|\psi_1\rangle,\ldots,|\psi_n\rangle$ prepared with probabilities $p_1,\ldots,p_n$, respectively. The eigenvalues $\lambda_1,\ldots,\lambda_n$ of ρ are non-negative reals and satisfy $\sum_{i\in[n]}\lambda_i=1$. If ρ is pure (i.e., $\rho=|\psi\rangle\langle\psi|$ for some $|\psi\rangle$), then one of the eigenvalues is 1 and the others are 0.

To obtain classical information from ρ, one could apply a POVM (positive-operator-valued measure) to the state ρ. An m-outcome POVM is specified by a set of positive semidefinite matrices $\{M_i\}_{i\in[m]}$ with the property $\sum_i M_i=\mathrm{Id}$. When this POVM is applied to the mixed state ρ, the probability of the j-th outcome is given by $\mathrm{Tr}(M_j\rho)$.

For a probability vector $(p_1,\ldots,p_k)$ (where $\sum_{i\in[k]}p_i=1$), the entropy function is defined as $H(p_1,\ldots,p_k)=-\sum_{i\in[k]}p_i\log p_i$. When $k=2$, with $p_1=p$ and $p_2=1-p$, we denote the binary entropy function as $H(p)$. For a state ρ_{AB} on the Hilbert space $\mathcal{H}_A\otimes\mathcal{H}_B$, we let ρ_A be the reduced state after taking the partial trace over $\mathcal{H}_B$. The entropy of a quantum state ρ_A is defined as $S(\mathbf{A})=-\mathrm{Tr}(\rho_A\log\rho_A)$. The mutual information is defined as $I(\mathbf{A}:\mathbf{B})=S(\mathbf{A})+S(\mathbf{B})-S(\mathbf{AB})$, and conditional entropy is defined as $S(\mathbf{A}|\mathbf{B})=S(\mathbf{AB})-S(\mathbf{B})$. Classical information-theoretic quantities correspond to the special case where ρ is a diagonal matrix whose diagonal corresponds to the probability distribution of the random variable. Writing ρ_A in its eigenbasis, it follows that $S(\mathbf{A})=H(\lambda_1,\ldots,\lambda_{\dim(\rho_A)})$, where $\lambda_1,\ldots,\lambda_{\dim(\rho_A)}$ are the eigenvalues of ρ. If ρ_A is a pure state, $S(\mathbf{A})=0$.

2.5. Quantum learning models

The quantum PAC learning model was introduced by Bshouty and Jackson (1999). The quantum PAC model is a generalization of the classical PAC model, in which instead of having access to random examples $(x,c(x))$ from the $\mathrm{PEX}(c,D)$ oracle, the learner now has access to superpositions over all $(x,c(x))$. For an unknown distribution $D:\{0,1\}^n\to[0,1]$ and

concept $c\in\mathscr{C}$, a *quantum example oracle* $\mathrm{QPEX}(c,D)$ acts on $|0^n,0\rangle$ and produces a *quantum example* $\sum_{x\in\{0,1\}^n}\sqrt{D(x)}|x,c(x)\rangle$ (we leave QPEX undefined on other basis states). A quantum learner is given access to some copies of the state generated by $\mathrm{QPEX}(c,D)$ and performs a POVM where each outcome is associated with a hypothesis. A learning algorithm $\mathcal{A}$ is an (ε,δ)-*PAC quantum learner* for $\mathscr{C}$ if:

> For every $c\in\mathscr{C}$ and distribution D, given access to the $\mathrm{QPEX}(c,D)$ oracle:
> $\mathcal{A}$ outputs an h such that $\mathrm{err}_D(h,c)\leq\varepsilon$, with probability at least $1-\delta$.

The *sample complexity* of $\mathcal{A}$ is the maximum number invocations of the $\mathrm{QPEX}(c,D)$ oracle, maximized over all $c\in\mathscr{C}$, distributions D, and the learner's internal randomness. The (ε,δ)-*PAC quantum sample complexity* of a concept class $\mathscr{C}$ is the minimum sample complexity over all (ε,δ)-PAC quantum learners for $\mathscr{C}$.

We define quantum agnostic learning now. For a joint distribution $D:\{0,1\}^{n+1}\to[0,1]$ over the set of examples, the learner has access to an $\mathrm{QAEX}(D)$ oracle which acts on $|0^n,0\rangle$ and produces a quantum example $\sum_{(x,b)\in\{0,1\}^{n+1}}\sqrt{D(x,b)}|x,b\rangle$. A learning algorithm $\mathcal{A}$ is an (ε,δ)-*agnostic quantum learner* for $\mathscr{C}$ if:

> For every distribution D, given access to the $\mathrm{QAEX}(D)$ oracle:
> $\mathcal{A}$ outputs an $h\in\mathscr{C}$ such that $\mathrm{err}_D(h)\leq\mathrm{opt}_D(\mathscr{C})+\varepsilon$ with probability at least $1-\delta$.

The *sample complexity* of $\mathcal{A}$ is the maximum number invocations of the $\mathrm{QAEX}(D)$ oracle over all distributions D and over the learner's internal randomness. The (ε,δ)-*agnostic quantum sample complexity* of a concept class $\mathscr{C}$ is the minimum sample complexity over all (ε,δ)-agnostic quantum learners for $\mathscr{C}$.

2.6. Pretty Good Measurement

Consider an ensemble of d-dimensional states, $\mathcal{E}=\{(p_i,|\psi_i\rangle)\}_{i\in[m]}$, where $\sum_{i\in[m]}p_i=1$. Suppose we are given an unknown state $|\psi_i\rangle$ sampled according to the probabilities and we are interested in maximizing the average probability of success to identify the state that we are given. For a POVM specified by positive semidefinite matrices $\mathcal{M}=\{M_i\}_{i\in[m]}$, the probability of obtaining outcome j equals $\langle\psi_i|M_j|\psi_i\rangle$. The average success probability is defined as

$$P_{\mathcal{M}}(\mathcal{E})=\sum_{i=1}^m p_i\langle\psi_i|M_i|\psi_i\rangle.$$

Let $P^{opt}(\mathcal{E})=\max_{\mathcal{M}}P_{\mathcal{M}}(\mathcal{E})$ denote the optimal average success probability of $\mathcal{E}$, where the maximization is over the set of valid m-outcome POVMs.

For every ensemble $\mathcal{E}$, the so-called *Pretty Good Measurement* (PGM) is a specific POVM (depending on the ensemble $\mathcal{E}$), which we shall define shortly, that does *reasonably* well against $\mathcal{E}$.

Theorem 1 *Let $\mathcal{E}=\{(p_i,|\psi_i\rangle)\}_{i\in[m]}$ be an ensemble of d-dimensional states. Suppose $P^{PGM}(\mathcal{E})$ is defined as the average success probability of identifying the states in $\mathcal{E}$ using the PGM, then we have that*

$$P^{opt}(\mathcal{E})^2\leq P^{PGM}(\mathcal{E})\leq P^{opt}(\mathcal{E}).$$

Proof The second inequality in the theorem follows because $P^{opt}(\mathcal{E})$ is a maximization over all valid POVMs and the first inequality was shown by Barnum and Knill (2002). For completeness we give a simple proof of $P^{opt}(\mathcal{E})^2 \leq P^{PGM}(\mathcal{E})$ below (similar to Montanaro (2007)). Let $|\psi'_i\rangle = \sqrt{p_i}|\psi_i\rangle$, and $\mathcal{E}' = \{|\psi'_i\rangle : i \in [m]\}$ be the set of states in $\mathcal{E}$, renormalized to reflect their probabilities. Define $\rho = \sum_{i\in[m]} |\psi'_i\rangle\langle\psi'_i|$. The PGM is defined as the set of measurement operators $\{|\nu_i\rangle\langle\nu_i|\}_{i\in[m]}$ where $|\nu_i\rangle = \rho^{-1/2}|\psi'_i\rangle$ (the inverse square root of ρ is taken over its non-zero eigenvalues). We first verify this is a valid POVM:

$$\sum_{i=1}^{m} |\nu_i\rangle\langle\nu_i| = \rho^{-1/2}\left(\sum_{i=1}^{m} |\psi'_i\rangle\langle\psi'_i|\right)\rho^{-1/2} = \mathrm{Id}\,.$$

Let G be the Gram matrix for the set $\mathcal{E}'$, i.e., $G(i,j) = \langle\psi'_i|\psi'_j\rangle$ for $i,j \in [m]$. It can be verified that $\sqrt{G}(i,j) = \langle\psi'_i|\rho^{-1/2}|\psi'_j\rangle$. Hence

$$\begin{aligned} P^{PGM}(\mathcal{E}) = \sum_{i\in[m]} p_i|\langle\nu_i|\psi_i\rangle|^2 &= \sum_{i\in[m]} |\langle\nu_i|\psi'_i\rangle|^2 \\ &= \sum_{i\in[m]} \langle\psi'_i|\rho^{-1/2}|\psi'_i\rangle^2 = \sum_{i\in[m]} \sqrt{G}(i,i)^2. \end{aligned}$$

We now prove $P^{opt}(\mathcal{E})^2 \leq P^{PGM}(\mathcal{E})$. Suppose $\mathcal{M}$ is the optimal measurement. Since $\mathcal{E}$ consists of pure states, by a result of Eldar et al. (2003), we can assume without loss of generality that the measurement operators in $\mathcal{M}$ are rank-1, so $M_i = |\mu_i\rangle\langle\mu_i|$ for some $|\mu_i\rangle$. Note that

$$\begin{aligned} 1 = \mathrm{Tr}(\rho) &= \mathrm{Tr}\Big(\sum_{i\in[m]} |\mu_i\rangle\langle\mu_i|\rho^{1/2} \sum_{j\in[m]} |\mu_j\rangle\langle\mu_j|\rho^{1/2}\Big) \\ &= \sum_{i,j\in[m]} |\langle\mu_i|\rho^{1/2}|\mu_j\rangle|^2 \geq \sum_{i\in[m]} \langle\mu_i|\rho^{1/2}|\mu_i\rangle^2. \end{aligned} \tag{5}$$

Then, using the Cauchy-Schwarz inequality, we have

$$\begin{aligned} P^{opt}(\mathcal{E}) = \sum_{i\in[m]} |\langle\mu_i|\psi'_i\rangle|^2 &= \sum_{i\in[m]} |\langle\mu_i|\rho^{1/4}\rho^{-1/4}|\psi'_i\rangle|^2 \\ &\leq \sum_{i\in[m]} \langle\mu_i|\rho^{1/2}|\mu_i\rangle\langle\psi'_i|\rho^{-1/2}|\psi'_i\rangle \\ &\leq \sqrt{\sum_{i\in[m]} \langle\mu_i|\rho^{1/2}|\mu_i\rangle^2}\sqrt{\sum_{i\in[m]} \langle\psi'_i|\rho^{-1/2}|\psi'_i\rangle^2} \\ &\overset{\text{Eq. (5)}}{\leq} \sqrt{\sum_{i\in[m]} \langle\psi'_i|\rho^{-1/2}|\psi'_i\rangle^2} = \sqrt{P^{PGM}(\mathcal{E})}. \end{aligned}$$

■

The above shows that for all ensembles $\mathcal{E}$, the PGM for that ensemble is not much worse than the optimal measurement. In some cases the PGM *is* the optimal measurement. In particular, an ensemble $\mathcal{E}$ is called *geometrically uniform* if $\mathcal{E} = \{U_i|\varphi\rangle : i \in [m]\}$ for some Abelian group of matrices $\{U_i\}_{i\in[m]}$ and state $|\varphi\rangle$. Eldar and Forney Jr (2001) showed $P^{opt}(\mathcal{E}) = P^{PGM}(\mathcal{E})$ for such $\mathcal{E}$.

2.7. Known results and required claims

The following theorems characterize the sample complexity of classical PAC and agnostic learning.

Theorem 2 (Blumer et al. (1989); Hanneke (2016)) *Let $\mathscr{C}$ be a concept class with VC-dim($\mathscr{C}$) $= d+1$. In the PAC model, $\Theta\Big(\frac{d}{\varepsilon} + \frac{\log(1/\delta)}{\varepsilon}\Big)$ examples are necessary and sufficient for a classical (ε,δ)-PAC learner for $\mathscr{C}$.*

Theorem 3 (Vapnik and Chervonenkis (1974); Simon (1996); Talagrand (1994)) *Let $\mathscr{C}$ be a concept class with VC-dim($\mathscr{C}$) $= d$. In the agnostic model, $\Theta\Big(\frac{d}{\varepsilon^2} + \frac{\log(1/\delta)}{\varepsilon^2}\Big)$ examples are necessary and sufficient for a classical (ε,δ)-agnostic learner for $\mathscr{C}$.*

We will use the following well-known theorem from the theory of error-correcting codes (which follows immediately from the Gilbert-Varshamov bound):

Theorem 4 *For every sufficiently large integer n, there exists an integer $k \in [n/4, n]$ and a matrix $M \in \mathbb{F}_2^{n\times k}$ of rank k, such that the associated $[n,k,d]_2$ linear code $\{Mx : x \in \{0,1\}^k\}$ has minimal distance $d \geq n/8$.*

We will need the following claims later

Claim 5 *Let $f : \{0,1\}^m \to \mathbb{R}$ and let $M \in \mathbb{F}_2^{m\times k}$. Then the Fourier coefficients of $f \circ M$ are $\widehat{f\circ M}(Q) = \sum_{S\in\{0,1\}^m : M^tS = Q} \widehat{f}(S)$ for all $Q \subseteq [k]$ (where M^t is the transpose of the matrix M).*

Proof Writing out the Fourier coefficients of $f \circ M$

$$\begin{aligned} \widehat{f\circ M}(Q) &= \mathop{\mathbb{E}}_{z\in\{0,1\}^k}[(f\circ M)(z)(-1)^{Q\cdot z}] \\ &= \mathop{\mathbb{E}}_{z\in\{0,1\}^k}\Big[\sum_{S\in\{0,1\}^m} \widehat{f}(S)(-1)^{S\cdot(Mz)+Q\cdot z}\Big] && \text{(Fourier expansion of } f\text{)} \\ &= \sum_{S\in\{0,1\}^m} \widehat{f}(S) \mathop{\mathbb{E}}_{z\in\{0,1\}^k}[(-1)^{(M^tS+Q)\cdot z}] && \text{(using } \langle S, Mz\rangle = \langle M^tS, z\rangle\text{)} \\ &= \sum_{S:M^tS=Q} \widehat{f}(S). && \text{(using } \mathbb{E}_{z\in\{0,1\}^k}(-1)^{(z_1+z_2)\cdot z} = \delta_{z_1,z_2}\text{)} \end{aligned}$$

■

Claim 6 $\max\{(c/\sqrt{t})^t : t \in [1, c^2]\} = e^{c^2/(2e)}$.

Proof The value of t at which the function $\Big(c/\sqrt{t}\Big)^t$ is the largest, is obtained by differentiating the function with respect to t,

$$\frac{d}{dt}\Big(c/\sqrt{t}\Big)^t = (c/\sqrt{t})^t\Big(\ln(c/\sqrt{t}) - 1/2\Big).$$

Equating the derivative to zero we obtain the maxima (the second derivative can be checked to be negative) at $t = c^2/e$. ■

Fact 7 *For all $\varepsilon \in [0, 1/2]$ we have $H(\varepsilon) \leq O(\varepsilon \log(1/\varepsilon))$, and (from the Taylor series)*

$$1 - H(1/2 + \varepsilon) \leq 2\varepsilon^2/\ln 2 + O(\varepsilon^4).$$

Fact 8 *For every positive integer n, we have that $\binom{n}{k} \leq 2^{nH(k/n)}$ for all $k \leq n$ and $\sum_{i=0}^{m}\binom{n}{i} \leq 2^{nH(m/n)}$ for all $m \leq n/2$.*

The following facts are well-known in quantum information theory.

Fact 9 *(Kaye et al., 2006, Appendix A.9) Let binary random variable $\mathbf{b} \in \{0, 1\}$ be uniformly distributed. Suppose an algorithm is given $|\psi_{\mathbf{b}}\rangle$ (for unknown b) and is required to guess whether $\mathbf{b} = 0$ or $\mathbf{b} = 1$. It will guess correctly with probability at most $\frac{1}{2} + \frac{1}{2}\sqrt{1 - |\langle\psi_0|\psi_1\rangle|^2}$.*

Note that if we can distinguish $|\psi_0\rangle$ and $|\psi_1\rangle$ with probability $\geq 1 - \delta$, then $|\langle\psi_0|\psi_1\rangle| \leq 2\sqrt{\delta(1-\delta)}$.

Fact 10 *(Subadditivity of quantum entropy): For an arbitrary bipartite state ρ_{AB} on the Hilbert space $\mathcal{H}_A \otimes \mathcal{H}_B$, it holds that $S(\rho_{AB}) \leq S(\rho_A) + S(\rho_B)$.*

3. Information-theoretic lower bounds

Upper bounds on sample complexity carry over from classical to quantum PAC learning, because a quantum example becomes a classical example if we just measure it. Our main goal is to show that the *lower* bounds also carry over. All our lower bounds will involve two terms, one that is independent of $\mathscr{C}$ and one that is dependent on the VC dimension of $\mathscr{C}$. In Section 3.1 we prove the VC-independent part of the lower bounds for the *quantum* setting (which also is a lower bound for the classical setting), in Section 3.2 we present an information-theoretic lower bound on sample complexity for PAC learning and agnostic learning which yields optimal VC-dependent bounds in the classical case. Using similar ideas, in Section 3.3 we obtain near-optimal bounds in the quantum case.

3.1. VC-independent part of lower bounds

Lemma 11 (Atıcı and Servedio (2005)) *Let $\mathscr{C}$ be a non-trivial concept class. For every $\delta \in (0, 1/2)$, $\varepsilon \in (0, 1/4)$, a (ε, δ)-PAC quantum learner for $\mathscr{C}$ has sample complexity $\Omega(\frac{1}{\varepsilon}\log\frac{1}{\delta})$.*

Proof Since $\mathscr{C}$ is non-trivial, we may assume there are two concepts $c_1, c_2 \in \mathscr{C}$ defined on two inputs $\{x_1, x_2\}$ as follows $c_1(x_1) = c_2(x_1) = 0$ and $c_1(x_2) = 0, c_2(x_2) = 1$. Consider the distribution $D(x_1) = 1 - \varepsilon$ and $D(x_2) = \varepsilon$. For $i \in \{1, 2\}$, the state of the algorithm after T queries to $\mathrm{QPEX}(c_i, D)$ is $|\psi_i\rangle = (\sqrt{1-\varepsilon}|x_1, 0\rangle + \sqrt{\varepsilon}|x_2, c_i(x_2)\rangle)^{\otimes T}$. It follows that $\langle\psi_1|\psi_2\rangle = (1-\varepsilon)^T$. Since the success probability of an (ε, δ)-PAC quantum learner is $\geq 1-\delta$, Fact 9 implies $\langle\psi_1|\psi_2\rangle \leq 2\sqrt{\delta(1-\delta)}$. Hence $T = \Omega(\frac{1}{\varepsilon}\log\frac{1}{\delta})$. ■

Lemma 12 *Let $\mathscr{C}$ be a non-trivial concept class. For every $\delta \in (0, 1/2)$, $\varepsilon \in (0, 1/4)$, a (ε, δ)-agnostic quantum learner for $\mathscr{C}$ has sample complexity $\Omega(\frac{1}{\varepsilon^2}\log\frac{1}{\delta})$.*

Proof Since $\mathscr{C}$ is non-trivial, we may assume there are two concepts $c_1, c_2 \in \mathscr{C}$ and there exists an input $x \in \{0,1\}^n$ such that $c_1(x) \neq c_2(x)$. Consider the two distributions D_- and D_+ defined as follows: $D_\pm(x, c_1(x)) = (1 \pm \varepsilon)/2$ and $D_\pm(x, c_2(x)) = (1 \mp \varepsilon)/2$. Let $|\psi_\pm\rangle$ be the state after T queries to $\mathrm{QAEX}(D_\pm)$, i.e., $|\psi_\pm\rangle = (\sqrt{(1 \pm \varepsilon)/2}|x, c_1(x)\rangle + \sqrt{(1 \mp \varepsilon)/2}|x, c_2(x)\rangle)^{\otimes T}$. It follows that $\langle\psi_+|\psi_-\rangle = (1-\varepsilon^2)^{T/2}$. Since the success probability of an (ε, δ)-agnostic quantum learner is $\geq 1 - \delta$, Fact 9 implies $\langle\psi_+|\psi_-\rangle \leq 2\sqrt{\delta(1-\delta)}$. Hence $T = \Omega(\frac{1}{\varepsilon^2}\log\frac{1}{\delta})$ ■

3.2. Information-theoretic lower bounds on sample complexity: classical case

3.2.1. Optimal lower bound for classical PAC learning

Theorem 13 *Let $\mathscr{C}$ be a concept class with VC-dim$(\mathscr{C}) = d+1$. Then for every $\delta \in (0, 1/2)$ and $\varepsilon \in (0, 1/4)$, every (ε, δ)-PAC learner for $\mathscr{C}$ has sample complexity $\Omega\Big(\frac{d}{\varepsilon} + \frac{\log(1/\delta)}{\varepsilon}\Big)$.*

Proof Consider an (ε, δ)-PAC learner for $\mathscr{C}$ that uses T examples. The d-independent part of the lower bound, $T = \Omega(\log(1/\delta)/\varepsilon)$, even holds for quantum examples and was proven in Lemma 11. Hence it remains to prove $T = \Omega(d/\varepsilon)$. It suffices to show this for a specific distribution D, defined as follows. Let $\mathcal{S} = \{s_0, s_1, \ldots, s_d\} \subseteq \{0,1\}^n$ be some $(d+1)$-element set shattered by $\mathscr{C}$. Define $D(s_0) = 1 - 4\varepsilon$ and $D(s_i) = 4\varepsilon/d$ for all $i \in [d]$.

Because $\mathcal{S}$ is shattered by $\mathscr{C}$, for each string $a \in \{0,1\}^d$, there exists a concept $c_a \in \mathscr{C}$ such that $c_a(s_0) = 0$ and $c_a(s_i) = a_i$ for all $i \in [d]$. We define two correlated random variables $\mathbf{A}$ and $\mathbf{B}$ corresponding to the concept and to the examples, respectively. Let $\mathbf{A}$ be a random variable that is uniformly distributed over $\{0,1\}^d$; if $\mathbf{A} = a$, let $\mathbf{B} = \mathbf{B}_1 \ldots \mathbf{B}_T$ be T i.i.d. examples from c_a according to D. We give the following three-step analysis of these random variables:

1. $I(\mathbf{A} : \mathbf{B}) \geq (1-\delta)(1 - H(1/4))d - H(\delta) = \Omega(d)$.
   Proof. Let random variable $h(\mathbf{B}) \in \{0,1\}^d$ be the hypothesis that the learner produces

(given the examples in $\mathbf{B}$) restricted to the elements $s_1, \ldots, s_d$. Note that the error of the hypothesis $\mathrm{err}_D(h(\mathbf{B}), c_{\mathbf{A}})$ equals $d_H(\mathbf{A}, h(\mathbf{B})) \cdot 4\varepsilon/d$, because each s_i where $\mathbf{A}$ and $h(\mathbf{B})$ differ contributes $D(s_i) = 4\varepsilon/d$ to the error. Let $\mathbf{Z}$ be the indicator random variable for the event that the error is $\leq \varepsilon$. If $\mathbf{Z} = 1$, then $d_H(\mathbf{A}, h(\mathbf{B})) \leq d/4$. Since we are analyzing an (ε, δ)-PAC learner, we have $\Pr[\mathbf{Z} = 1] \geq 1 - \delta$, and $H(\mathbf{Z}) \leq H(\delta)$. Given a string $h(\mathbf{B})$ that is $d/4$-close to $\mathbf{A}$, $\mathbf{A}$ ranges over a set of only $\sum_{i=0}^{d/4} \binom{d}{i} \leq 2^{H(1/4)d}$ possible d-bit strings (using Fact 8), hence

$$H(\mathbf{A} \mid \mathbf{B}, \mathbf{Z} = 1) \leq H(\mathbf{A} \mid h(\mathbf{B}), \mathbf{Z} = 1) \leq H(1/4)d.$$

We now lower bound $I(\mathbf{A} : \mathbf{B})$ as follows:

$$\begin{aligned} I(\mathbf{A} : \mathbf{B}) &= H(\mathbf{A}) - H(\mathbf{A} \mid \mathbf{B}) \\ &\geq H(\mathbf{A}) - H(\mathbf{A} \mid \mathbf{B}, \mathbf{Z}) - H(\mathbf{Z}) \\ &= H(\mathbf{A}) - \Pr[\mathbf{Z} = 1] \cdot H(\mathbf{A} \mid \mathbf{B}, \mathbf{Z} = 1) - \\ &\qquad \Pr[\mathbf{Z} = 0] \cdot H(\mathbf{A} \mid \mathbf{B}, \mathbf{Z} = 0) - H(\mathbf{Z}) \\ &\geq d - (1 - \delta)H(1/4)d - \delta d - H(\delta) \\ &= (1 - \delta)(1 - H(1/4))d - H(\delta). \end{aligned}$$

2. $I(\mathbf{A} : \mathbf{B}) \leq T \cdot I(\mathbf{A} : \mathbf{B}_1)$.

   Proof. This inequality essentially appeared in (Jain and Zhang, 2009, Lemma 5), we include the proof for completeness.

$$\begin{aligned} I(\mathbf{A} : \mathbf{B}) = H(\mathbf{B}) - H(\mathbf{B} \mid \mathbf{A}) &= H(\mathbf{B}) - \sum_{i=1}^{T} H(\mathbf{B}_i \mid \mathbf{A}) \\ &\leq \sum_{i=1}^{T} H(\mathbf{B}_i) - \sum_{i=1}^{T} H(\mathbf{B}_i \mid \mathbf{A}) = \sum_{i=1}^{T} I(\mathbf{A} : \mathbf{B}_i), \end{aligned}$$

   where the second equality used independence of the $\mathbf{B}_i$'s conditioned on $\mathbf{A}$, and the inequality uses Fact 10. Since $I(\mathbf{A} : \mathbf{B}_i) = I(\mathbf{A} : \mathbf{B}_1)$ for all i, we get the inequality.

3. $I(\mathbf{A} : \mathbf{B}_1) = 4\varepsilon$.

   Proof. View $\mathbf{B}_1 = (\mathbf{I}, \mathbf{L})$ as consisting of an index $\mathbf{I} \in \{0, 1, \ldots, d\}$ and a corresponding label $\mathbf{L} \in \{0, 1\}$. With probability $1 - 4\varepsilon$, $(\mathbf{I}, \mathbf{L}) = (0, 0)$. For each $i \in [d]$, with probability $4\varepsilon/d$, $(\mathbf{I}, \mathbf{L}) = (i, \mathbf{A}_i)$. Note that $I(\mathbf{A} : \mathbf{I}) = 0$ because $\mathbf{I}$ is independent of $\mathbf{A}$; $I(\mathbf{A} : \mathbf{L} \mid \mathbf{I} = 0) = 0$; and $I(\mathbf{A} : \mathbf{L} \mid \mathbf{I} = i) = I(\mathbf{A}_i : \mathbf{L} \mid \mathbf{I} = i) = H(\mathbf{A}_i \mid \mathbf{I} = i) - H(\mathbf{A}_i \mid \mathbf{L}, \mathbf{I} = i) = 1 - 0 = 1$ for all $i \in [d]$. We have

$$I(\mathbf{A} : \mathbf{B}_1) = I(\mathbf{A} : \mathbf{I}) + I(\mathbf{A} : \mathbf{L} \mid \mathbf{I}) = \sum_{i=1}^{d} \Pr[\mathbf{I} = i] \cdot I(\mathbf{A} : \mathbf{L} \mid \mathbf{I} = i) = 4\varepsilon.$$

Combining these three steps implies $T = \Omega(d/\varepsilon)$. ∎

3.2.2. Optimal lower bound for classical agnostic learning

Theorem 14 *Let $\mathscr{C}$ be a concept class with VC-dim$(\mathscr{C}) = d$. Then for every $\delta \in (0, 1/2)$ and $\varepsilon \in (0, 1/4)$, every (ε, δ)-agnostic learner for $\mathscr{C}$ has sample complexity $\Omega\left(\frac{d}{\varepsilon^2} + \frac{\log(1/\delta)}{\varepsilon^2}\right)$.*

Proof The d-independent part of the lower bound, $T = \Omega(\log(1/\delta)/\varepsilon^2)$, even holds for quantum examples and was proven in Lemma 12. For the other part, the proof is similar to Theorem 13, as follows. Assume an (ε, δ)-agnostic learner for $\mathscr{C}$ that uses T examples. We need to prove $T = \Omega(d/\varepsilon^2)$. For shattered set $\mathcal{S} = \{s_1, \ldots, s_d\} \subseteq \{0,1\}^n$ and $a \in \{0,1\}^d$, define distribution D_a on $[d] \times \{0, 1\}$ by $D_a(i, \ell) = (1 + (-1)^{a_i + \ell} 4\varepsilon)/2d$.

Again let random variable $\mathbf{A} \in \{0,1\}^d$ be uniformly random, corresponding to the values of concept c_a on $\mathcal{S}$, and $\mathbf{B} = \mathbf{B}_1 \ldots \mathbf{B}_T$ be T i.i.d. samples from D_a. Note that c_a is the minimal-error concept from $\mathscr{C}$ w.r.t. D_a, and concept $c_{\tilde{a}}$ has additional error $d_H(a, \tilde{a}) \cdot 4\varepsilon/d$. Accordingly, an (ε, δ)-agnostic learner has to produce (from $\mathbf{B}$) an $h(\mathbf{B}) \in \{0,1\}^d$, which, with probability at least $1 - \delta$, is $d/4$-close to $\mathbf{A}$. Our three-step analysis is very similar to Theorem 13; only the third step changes:

1. $I(\mathbf{A} : \mathbf{B}) \geq (1 - \delta)(1 - H(1/4))d - H(\delta) = \Omega(d)$.

2. $I(\mathbf{A} : \mathbf{B}) \leq T \cdot I(\mathbf{A} : \mathbf{B}_1)$.

3. $I(\mathbf{A} : \mathbf{B}_1) = 1 - H(1/2 + 2\varepsilon) = O(\varepsilon^2)$.

   Proof. View the D_a-distributed random variable $\mathbf{B}_1 = (\mathbf{I}, \mathbf{L})$ as index $\mathbf{I} \in [d]$ and label $\mathbf{L} \in \{0, 1\}$. The marginal distribution of $\mathbf{I}$ is uniform; conditioned on $\mathbf{I} = i$, the bit $\mathbf{L}$ equals $\mathbf{A}_i$ with probability $1/2 + 2\varepsilon$. Hence

$$\begin{aligned} I(\mathbf{A} : \mathbf{L} \mid \mathbf{I} = i) = I(\mathbf{A}_i : \mathbf{L} \mid \mathbf{I} = i) &= H(\mathbf{A}_i \mid \mathbf{I} = i) - H(\mathbf{A}_i \mid \mathbf{L}, \mathbf{I} = i) \\ &= 1 - H(1/2 + 2\varepsilon). \end{aligned}$$

   Using Fact 7, we have

$$\begin{aligned} I(\mathbf{A} : \mathbf{B}_1) = I(\mathbf{A} : \mathbf{I}) + I(\mathbf{A} : \mathbf{L} \mid \mathbf{I}) &= \sum_{i=1}^{d} \Pr[\mathbf{I} = i] \cdot I(\mathbf{A} : \mathbf{L} \mid \mathbf{I} = i) \\ &= 1 - H(1/2 + 2\varepsilon) = O(\varepsilon^2). \end{aligned}$$

Combining these three steps implies $T = \Omega(d/\varepsilon^2)$. ∎

In the theorem below, we optimize the constant in the lower bound of the sample complexity in Theorem 14. In learning theory such lower bounds are often stated slightly differently. In order to compare the lower bounds, we introduce the following. We first define an *ε-average agnostic learner* for a concept class $\mathscr{C}$ as a learner that, given access to T samples from an AEX(D) oracle (for some unknown distribution D), needs to output a hypothesis $h_{\mathbf{XY}}$ (where $(\mathbf{X}, \mathbf{Y}) \sim D^T$) that satisfies

$$\mathop{\mathbb{E}}_{(\mathbf{X}, \mathbf{Y}) \sim D^T} [\mathrm{err}_D(h_{\mathbf{XY}})] - \mathrm{opt}_D(\mathscr{C}) \leq \varepsilon.$$

Lower bounds on the quantity $(\mathbb{E}_{(\mathbf{X},\mathbf{Y})\sim D^T}[\mathrm{err}_D(h_{\mathbf{XY}})] - \mathrm{opt}_D(\mathscr{C}))$ are generally referred to as *minimax lower bounds* in learning theory. For concept class $\mathscr{C}$, Audibert (2008, 2009) showed that there exists a distribution D, such that if the agnostic learner uses T samples from $\mathrm{AEX}(D)$, then

$$\mathop{\mathbb{E}}_{(\mathbf{X},\mathbf{Y})\sim D^T}[\mathrm{err}_D(h_{\mathbf{XY}})] - \mathrm{opt}_D(\mathscr{C}) \geq \frac{1}{6}\sqrt{\frac{d}{T}}.$$

Equivalently, this is a lower bound of $T \geq \frac{d}{36\varepsilon^2}$ on the sample complexity of an ε-average agnostic learner. We obtain a slightly weaker lower bound that is essentially $T \geq \frac{d}{62\varepsilon^2}$:

Theorem 15 *Let $\mathscr{C}$ be a concept class with VC-dim$(\mathscr{C}) = d$. Then for every $\varepsilon \in (0, 1/10]$, there exists a distribution for which every ε-average agnostic learner has sample complexity at least $\frac{d}{\varepsilon^2} \cdot \left(\frac{1}{62} - \frac{\log(2d+2)}{4d}\right)$.*

Proof The proof is similar to Theorem 14. Assume an ε-average agnostic learner for $\mathscr{C}$ that uses T samples. For shattered set $\mathcal{S} = \{s_1, \ldots, s_d\} \subseteq \{0,1\}^n$ and $a \in \{0,1\}^d$, define distribution D_a on $[d] \times \{0,1\}$ by $D_a(i,\ell) = (1 + (-1)^{a_i+\ell}\beta\varepsilon)/2d$, for some constant $\beta \geq 2$ which we shall pick later.

Again let random variable $\mathbf{A} \in \{0,1\}^d$ be uniformly random, corresponding to the values of concept c_a on $\mathcal{S}$, and $\mathbf{B} = \mathbf{B}_1 \ldots \mathbf{B}_T$ be T i.i.d. samples from D_a. Note that c_a is the minimal-error concept from $\mathscr{C}$ w.r.t. D_a, and concept $c_{\tilde{a}}$ has additional error $d_H(a,\tilde{a}) \cdot \beta\varepsilon/d$. Accordingly, an ε-average agnostic learner has to produce (from $\mathbf{B}$) an $h(\mathbf{B}) \in \{0,1\}^d$, which satisfies $\mathbb{E}_{\mathbf{A},\mathbf{B}}[d_H(\mathbf{A}, h(\mathbf{B}))] \leq d/\beta$.

Our three-step analysis is very similar to Theorem 14; only the first step changes:

1. $I(\mathbf{A} : \mathbf{B}) \geq d(1 - H(1/\beta)) - \log(d+1)$.

   Proof. Define random variable $\mathbf{Z} = d_H(\mathbf{A}, h(\mathbf{B}))$, then $\mathbb{E}[\mathbf{Z}] \leq d/\beta$. Note that given a string $h(\mathbf{B})$ that is ℓ-close to $\mathbf{A}$, $\mathbf{A}$ ranges over a set of only $\binom{d}{\ell} \leq 2^{H(\ell/d)d}$ possible d-bit strings (using Fact 8), hence

   $$H(\mathbf{A} \mid \mathbf{B}, \mathbf{Z} = \ell) \leq H(\mathbf{A} \mid h(\mathbf{B}), \mathbf{Z} = \ell) \leq H(\ell/d)d.$$

   We now lower bound $I(\mathbf{A} : \mathbf{B})$:

   $$\begin{aligned}
   I(\mathbf{A} : \mathbf{B}) &= H(\mathbf{A}) - H(\mathbf{A} \mid \mathbf{B}) \\
   &\geq H(\mathbf{A}) - H(\mathbf{A} \mid \mathbf{B}, \mathbf{Z}) - H(\mathbf{Z}) \\
   &= d - \sum_{\ell=0}^{d+1} \Pr[\mathbf{Z} = \ell] \cdot H(\mathbf{A} \mid \mathbf{B}, \mathbf{Z} = \ell) - H(\mathbf{Z}) \\
   &\geq d - \mathop{\mathbb{E}}_{\ell \in \{0,\ldots,d\}}[H(\ell/d)d] - \log(d+1) && \text{(since } \mathbf{Z} \in \{0,\ldots,d\}\text{)} \\
   &\geq d - dH\Big(\frac{\mathbb{E}_\ell[\ell]}{d}\Big) - \log(d+1) && \text{(using Jensen's inequality)} \\
   &\geq d - dH(1/\beta) - \log(d+1), && \text{(using } \mathbb{E}[\mathbf{Z}] \leq d/\beta\text{)}
   \end{aligned}$$

   where for the third inequality we used the concavity of the binary entropy function to conclude $\mathbb{E}_\ell[H(\ell/d)] \leq H(\mathbb{E}_\ell[\ell]/d)$, and for the fourth inequality we used that $\beta \geq 2$.

2. $I(\mathbf{A} : \mathbf{B}) \leq T \cdot I(\mathbf{A} : \mathbf{B}_1)$.

3. $I(\mathbf{A} : \mathbf{B}_1) = 1 - H(1/2 + \beta\varepsilon/2) \overset{\text{Fact 7}}{\leq} \beta^2\varepsilon^2/\ln 4 + O(\varepsilon^4)$.

Combining these three steps implies

$$T \geq \frac{d \ln 4}{\varepsilon^2} \cdot \Big(\frac{1 - H(1/\beta)}{\beta^2 + O(\varepsilon^2)} - \frac{\log(d+1)}{\beta^2 d + O(d\varepsilon^2)}\Big).$$

Using $\varepsilon \leq 1/10$, $\beta = 4$ to optimize this lower bound, we obtain $T \geq \frac{d}{\varepsilon^2} \cdot \left(\frac{1}{62} - \frac{\log(2d+2)}{4d}\right)$. ■

3.3. Information-theoretic lower bounds on sample complexity: quantum case

Here we will "quantize" the above two classical information-theoretic proofs, yielding lower bounds for quantum sample complexity (in both the PAC and the agnostic setting) that are tight up to a logarithmic factor.

3.3.1. Near-optimal lower bound for quantum PAC learning

Theorem 16 *Let $\mathscr{C}$ be a concept class with VC-dim$(\mathscr{C}) = d + 1$. Then, for every $\delta \in (0, 1/2)$ and $\varepsilon \in (0, 1/4)$, every (ε,δ)-PAC quantum learner for $\mathscr{C}$ has sample complexity $\Omega\Big(\frac{d}{\varepsilon \log(d/\varepsilon)} + \frac{\log(1/\delta)}{\varepsilon}\Big)$.*

Proof The proof is analogous to Theorem 13. We use the same distribution D, with the $\mathbf{B}_i$ now being quantum samples: $|\psi_a\rangle = \sum_{i\in\{0,1,\ldots,d\}} \sqrt{D(s_i)}|i, c_a(s_i)\rangle$. The $\mathbf{AB}$-system is now in the following classical-quantum state:

$$\frac{1}{2^d} \sum_{a\in\{0,1\}^d} |a\rangle\langle a| \otimes |\psi_a\rangle\langle\psi_a|^{\otimes T}.$$

The first two steps of our argument are identical to Theorem 13. We only need to re-analyze step 3:

1. $I(\mathbf{A} : \mathbf{B}) \geq (1 - \delta)(1 - H(1/4))d - H(\delta) = \Omega(d)$.

2. $I(\mathbf{A} : \mathbf{B}) \leq T \cdot I(\mathbf{A} : \mathbf{B}_1)$.

3. $I(\mathbf{A} : \mathbf{B}_1) \leq H(4\varepsilon) + 4\varepsilon \log(2d) = O(\varepsilon \log(d/\varepsilon))$.

   Proof. Since $\mathbf{AB}$ is a classical-quantum state, we have

   $$I(\mathbf{A} : \mathbf{B}_1) = S(\mathbf{A}) + S(\mathbf{B}_1) - S(\mathbf{AB}_1) = S(\mathbf{B}_1),$$

   where the first equality follows from definition and the second equality uses $S(\mathbf{A}) = d$ since $\mathbf{A}$ is uniformly distributed in $\{0,1\}^d$, and $S(\mathbf{AB}_1) = d$ since the matrix $\sigma = \frac{1}{2^d}\sum_{a\in\{0,1\}^d} |a\rangle\langle a| \otimes |\psi_a\rangle\langle\psi_a|$ is block diagonal with 2^d rank-1 blocks on the diagonal.

It thus suffices to bound the entropy of the singular values of the reduced state of $\mathbf{B}_1$, which is

$$\rho = \frac{1}{2^d} \sum_{a\in\{0,1\}^d} |\psi_a\rangle\langle\psi_a|.$$

Let $\sigma_0 \geq \sigma_1 \geq \cdots \geq \sigma_{2d} \geq 0$ be its singular values. Since ρ is a density matrix, these form a probability distribution. Note that the upper-left entry of the matrix $|\psi_a\rangle\langle\psi_a|$ is $D(s_0) = 1-4\varepsilon$, hence so is the upper-left entry of ρ. This implies $\sigma_0 \geq 1-4\varepsilon$. Consider sampling a number $\mathbf{N} \in \{0,1,\ldots,2d\}$ according to the σ-distribution. Let $\mathbf{Z}$ be the indicator random variable for the event $\mathbf{N} \neq 0$, which has probability $1-\sigma_0 \leq 4\varepsilon$. Note that $H(\mathbf{N} \mid \mathbf{Z} = 0) = 0$, because $\mathbf{Z} = 0$ implies $\mathbf{N} = 0$. Also, $H(\mathbf{N} \mid \mathbf{Z} = 1) \leq \log(2d)$, because if $\mathbf{Z} = 1$ then $\mathbf{N}$ ranges over $2d$ elements. We now have

$$\begin{aligned} S(\rho) &= H(\mathbf{N}) = H(\mathbf{N},\mathbf{Z}) = H(\mathbf{Z}) + H(\mathbf{N} \mid \mathbf{Z}) \\ &= H(\mathbf{Z}) + \Pr[\mathbf{Z}=0]\cdot H(\mathbf{N} \mid \mathbf{Z}=0) + \Pr[\mathbf{Z}=1]\cdot H(\mathbf{N} \mid \mathbf{Z}=1) \\ &\leq H(4\varepsilon) + 4\varepsilon\log(2d) \\ &= O(\varepsilon\log(d/\varepsilon)). \qquad \text{(using Fact 7)} \end{aligned}$$

Combining these three steps implies $T = \Omega\Big(\frac{d}{\varepsilon\log(d/\varepsilon)}\Big)$. ■

3.3.2. Near-optimal lower bound for quantum agnostic learning

Theorem 17 *Let $\mathscr{C}$ be a concept class with VC-dim($\mathscr{C}$) = d. Then for every $\delta \in (0,1/2)$, $\varepsilon \in (0,1/4)$, every (ε,δ)-agnostic quantum learner for $\mathscr{C}$ has sample complexity $\Omega\Big(\frac{d}{\varepsilon^2\log(d/\varepsilon)} + \frac{\log(1/\delta)}{\varepsilon^2}\Big)$.*

Proof The proof is analogous to Theorem 14, with the $\mathbf{B}_i$ now being quantum samples for D_a, $|\psi_a\rangle = \sum_{i\in[d],\ell\in\{0,1\}} \sqrt{D_a(i,\ell)}|i,\ell\rangle$. Again we only need to re-analyze step 3:

1. $I(\mathbf{A}:\mathbf{B}) \geq (1-\delta)(1-H(1/4))d - H(\delta) = \Omega(d)$.
2. $I(\mathbf{A}:\mathbf{B}) \leq T\cdot I(\mathbf{A}:\mathbf{B}_1)$.
3. $I(\mathbf{A}:\mathbf{B}_1) = O(\varepsilon^2\log(d/\varepsilon))$.

   Proof of step 3. As in step 3 of the proof of Theorem 16, it suffices to upper bound the entropy of

   $$\rho = \frac{1}{2^d} \sum_{a\in\{0,1\}^d} |\psi_a\rangle\langle\psi_a|.$$

   We lower bound the largest singular value of ρ. Consider $|\psi\rangle = \frac{1}{\sqrt{2d}} \sum_{i\in[d],\ell\in\{0,1\}} |i,\ell\rangle$.

$$\langle\psi|\psi_a\rangle = \frac{1}{d}\sum_{i\in[d]} \frac{1}{2}\Big(\sqrt{1+4\varepsilon} + \sqrt{1-4\varepsilon}\Big) = \frac{1}{2}\Big(\sqrt{1+4\varepsilon} + \sqrt{1-4\varepsilon}\Big) \geq 1 - 2\varepsilon^2 - O(\varepsilon^4),$$

where the last inequality used the Taylor series expansion of $\sqrt{1+x}$. This implies that the largest singular value of ρ is at least

$$\langle\psi|\rho|\psi\rangle = \frac{1}{2^d}\sum_{a\in\{0,1\}^d} |\langle\psi|\psi_a\rangle|^2 \geq 1 - 4\varepsilon^2 - O(\varepsilon^4).$$

We can now finish as in step 3 of the proof of Theorem 16:

$$I(\mathbf{A}:\mathbf{B}_1) \leq S(\rho) \leq H(4\varepsilon^2) + 4\varepsilon^2\log(2d) \overset{\text{Fact 7}}{=} O(\varepsilon^2\log(d/\varepsilon)).$$

Combining these three steps implies $T = \Omega\Big(\frac{d}{\varepsilon^2\log(d/\varepsilon)}\Big)$. ■

4. A lower bound by analysis of state identification

In this section we present a tight lower bound on quantum sample complexity for both the PAC and the agnostic learning settings, using ideas from Fourier analysis to analyze the performance of the Pretty Good Measurement. The core of both lower bounds is the following theorem.

Theorem 18 *For $m \geq 10$, let $f : \{0,1\}^m \to \mathbb{R}$ be defined as $f(z) = (1-\beta\frac{|z|}{m})^T$ for some $\beta \in (0,1]$ and $T \in [1, m/(e^3\beta)]$. For $k \leq m$, let $M \in \mathbb{F}_2^{m\times k}$ be a matrix with rank k. Suppose $A \in \mathbb{R}^{2^k\times 2^k}$ is defined as $A(x,y) = (f\circ M)(x+y)$ for $x,y \in \{0,1\}^k$, then*

$$\sqrt{A}(x,x) \leq \frac{2\sqrt{e}}{2^{k/2}}\Big(1-\frac{\beta}{2}\Big)^{T/2} e^{11T^2\beta^2/m + \sqrt{Tm\beta}} \qquad \text{for all } x \in \{0,1\}^k.$$

Proof The structure of the proof is to first diagonalize A, relating its eigenvalues to the Fourier coefficients of f. This allows to calculate the diagonal entries of $\sqrt{A}$ exactly in terms of those Fourier coefficients. We then upper bound those Fourier coefficients using a combinatorial argument.

We first observe the well-known relation between the eigenvalues of a matrix P defined as $P(x,y) = g(x+y)$ for $x,y \in \{0,1\}^k$, and the Fourier coefficients of g.

Claim 19 *Suppose $g : \{0,1\}^k \to \mathbb{R}$ and $P \in \mathbb{R}^{2^k\times 2^k}$ is defined as $P(x,y) = g(x+y)$, then the eigenvalues of P are $\{2^k\widehat{g}(Q) : Q \in \{0,1\}^k\}$.*

Proof Let $H \in \mathbb{R}^{2^k\times 2^k}$ be the matrix defined as $H(x,y) = (-1)^{x\cdot y}$ for $x,y \in \{0,1\}^k$. It is easy to see that $H^{-1}(x,y) = (-1)^{x\cdot y}/2^k$. We now show that H diagonalizes P:

$$\begin{aligned} (HPH^{-1})(x,y) &= \frac{1}{2^k}\sum_{z_1,z_2\in\{0,1\}^k} (-1)^{z_1\cdot x + z_2\cdot y} g(z_1+z_2) \\ &= \frac{1}{2^k}\sum_{z_1,z_2,Q\in\{0,1\}^k} (-1)^{z_1\cdot x + z_2\cdot y}\widehat{g}(Q)(-1)^{Q\cdot(z_1+z_2)} \quad \text{(Fourier expansion of } g) \\ &= \frac{1}{2^k}\sum_{Q\in\{0,1\}^k} \widehat{g}(Q) \sum_{z_1\in\{0,1\}^k} (-1)^{(x+Q)\cdot z_1} \sum_{z_2\in\{0,1\}^k} (-1)^{(y+Q)\cdot z_2} \\ &= 2^k\widehat{g}(x)\delta_{x,y}, \end{aligned}$$

where we used $\sum_{z\in\{0,1\}^k}[(-1)^{(a+b)\cdot z}] = 2^k\delta_{a,b}$ in the last equality. The eigenvalues of P are the diagonal entries, $\{2^k\widehat{g}(Q) : Q \in \{0,1\}^k\}$. ■

We now relate the diagonal entries of $\sqrt{A}$ to the Fourier coefficients of f:

Claim 20 *For all $x \in \{0,1\}^k$, we have*

$$\sqrt{A}(x,x) = \frac{1}{2^{k/2}} \sum_{Q\in\{0,1\}^k} \sqrt{\sum_{S\in\{0,1\}^m : M^tS=Q} \widehat{f}(S)}.$$

Proof Since $A(x,y) = (f\circ M)(x+y)$, by Claim 19 it follows that H (as defined in the proof of Claim 19) diagonalizes A and the eigenvalues of A are $\{2^k\widehat{f\circ M}(Q) : Q\in\{0,1\}^k\}$. Hence, we have

$$\sqrt{A} = H^{-1}\cdot \mathrm{diag}\Big(\Big\{\sqrt{2^k\widehat{f\circ M}(Q)} : Q\in\{0,1\}^k\Big\}\Big)\cdot H,$$

and the diagonal entries of $\sqrt{A}$ are

$$\sqrt{A}(x,x) = \frac{1}{2^{k/2}} \sum_{Q\in\{0,1\}^k} \sqrt{\widehat{f\circ M}(Q)} \overset{\text{Claim 5}}{=} \frac{1}{2^{k/2}} \sum_{Q\in\{0,1\}^k} \sqrt{\sum_{S\in\{0,1\}^m : M^tS=Q} \widehat{f}(S)}.$$

■

In the following lemma, we give an upper bound on the Fourier coefficients of f, which in turn (from the claim above) gives an upper bound on the diagonal entries of $\sqrt{A}$.

Lemma 21 *For $\beta \in (0,1]$, the Fourier coefficients of $f : \{0,1\}^m \to \mathbb{R}$ defined as $f(z) = (1-\beta\frac{|z|}{m})^T$, satisfy*

$$0 \le \widehat{f}(S) \le 4e\Big(1-\frac{\beta}{2}\Big)^T\Big(\frac{T\beta}{m}\Big)^q e^{22T^2\beta^2/m}, \quad \textit{for all } S \textit{ such that } |S| = q.$$

Proof In order to see why the Fourier coefficients of f are non-negative, we first define the set $U = \{u_x^{\otimes T}\}_{x\in\{0,1\}^m}$ where $u_x = \sqrt{1-\beta}|0,0\rangle + \sqrt{\beta/m}\sum_{i\in[m]}|i,x_i\rangle$. Let V be the $2^m\times 2^m$ Gram matrix for the set U. For $x,y\in\{0,1\}^m$, we have

$$\begin{aligned} V(x,y) = (u_x^*u_y)^T &= \Big(1-\beta+\frac{\beta}{m}\sum_{i=1}^m\langle x_i|y_i\rangle\Big)^T \\ &= \Big(1-\beta+\frac{\beta}{m}(m-|x+y|)\Big)^T = \Big(1-\beta\frac{|x+y|}{m}\Big)^T = f(x+y). \end{aligned}$$

By Claim 19, the eigenvalues of the Gram matrix V are $\{2^m\widehat{f}(S) : S\in\{0,1\}^m\}$. Since the Gram matrix is psd, its eigenvalues are non-negative, which implies that $\widehat{f}(S)\ge 0$ for all $S\in\{0,1\}^m$.

We now prove the upper bound in the lemma. By definition,

$$\begin{aligned} \widehat{f}(S) &= \mathop{\mathbb{E}}_{z\in\{0,1\}^m}\Big[\Big(1-\beta\frac{|z|}{m}\Big)^T(-1)^{S\cdot z}\Big] \\ &= \mathop{\mathbb{E}}_{z\in\{0,1\}^m}\Big[\Big(1-\frac{\beta}{2}+\frac{\beta}{2m}\sum_{i=1}^m(-1)^{z_i}\Big)^T(-1)^{S\cdot z}\Big] \qquad (\text{since } |z| = \textstyle\sum_{i\in[m]}\frac{1-(-1)^{z_i}}{2}) \\ &= \sum_{\ell=0}^T\binom{T}{\ell}\Big(1-\frac{\beta}{2}\Big)^{T-\ell}\Big(\frac{\beta}{2m}\Big)^\ell \mathop{\mathbb{E}}_{z\in\{0,1\}^m}\Big[\sum_{i_1,\ldots,i_\ell=1}^m(-1)^{z\cdot(e_{i_1}+\cdots+e_{i_\ell}+S)}\Big] \\ &= \sum_{\ell=0}^T\binom{T}{\ell}\Big(1-\frac{\beta}{2}\Big)^{T-\ell}\Big(\frac{\beta}{2m}\Big)^\ell \sum_{i_1,\ldots,i_\ell=1}^m 1_{[e_{i_1}+\cdots+e_{i_\ell}=S]}, \end{aligned}$$

using $\mathbb{E}_{z\in\{0,1\}^m}[(-1)^{(z_1+z_2)\cdot z}] = \delta_{z_1,z_2}$ in the last equality.

We will use the following claim to upper bound the combinatorial sum in the quantity above.

Claim 22 *Fix $S\in\{0,1\}^m$ with Hamming weight $|S| = q$. For every $\ell\in\{q,\ldots,T\}$, we have*

$$\sum_{i_1,\ldots,i_\ell=1}^m 1_{[e_{i_1}+\cdots+e_{i_\ell}=S]} \le \begin{cases} \ell!\cdot m^{(\ell-q)/2}\Big/\Big(2^{(\ell-q)/2}((\ell-q)/2)!\Big) & \textit{if } (\ell-q) \textit{ is even} \\ 0 & \textit{otherwise} \end{cases}$$

Proof Since $|S| = q$, we can write $S = e_{r_1}+\cdots+e_{r_q}$ for distinct $r_1,\ldots,r_q\in[m]$. There are $\binom{\ell}{q}$ ways to pick q indices in $(i_1,\ldots,i_\ell)$ (w.l.o.g. let them be $i_1,\ldots,i_q$) and there are $q!$ factorial ways to assign $(r_1,\ldots,r_q)$ to $(i_1,\ldots,i_q)$. It remains to count the number of ways that we can assign values to the remaining indices $i_{q+1},\ldots,i_\ell$ such that $e_{i_{q+1}}+\cdots+e_{i_\ell} = 0$. If $\ell-q$ is odd then this number is 0, so from now on assume $\ell-q$ is even. We upper bound the number of such assignments by partitioning the $\ell-q$ indices into pairs and assigning the same value to both indices in each pair.

We first count the number of ways to partition a set of $\ell-q$ indices into subsets of size 2. This number is exactly $(\ell-q)!\Big(2^{(\ell-q)/2}((\ell-q)/2)!\Big)^{-1}$. Furthermore, there are m possible values that can be assigned to the pair of indices in each of the $(\ell-q)/2$ subsets such that $e_i+e_j = 0$ within each subset. Note that assigning m possible values to each pair of indices in the $(\ell-q)/2$ subsets overcounts, but this rough upper bound is sufficient for our purposes.

Combining the three arguments, we conclude

$$\sum_{i_1,\ldots,i_\ell=1}^d 1_{[e_{i_1}+\cdots+e_{i_\ell}=S]} \le \binom{\ell}{q}q!\cdot(\ell-q)!\cdot m^{(\ell-q)/2}\Big/\Big(2^{(\ell-q)/2}((\ell-q)/2)!\Big).$$

which yields the claim. ■

Continuing with the evaluation of the Fourier coefficient and using the claim above, we have

$$\begin{aligned}
\widehat{f}(S) &= \sum_{\ell=0}^{T}\binom{T}{\ell}\Big(1-\frac{\beta}{2}\Big)^{T-\ell}\Big(\frac{\beta}{2m}\Big)^{\ell}\sum_{i_1,\ldots,i_\ell=1}^{m} 1_{[e_{i_1}+\cdots+e_{i_\ell}=S]} \\
&\le \sum_{\ell=q}^{T}\binom{T}{\ell}\Big(1-\frac{\beta}{2}\Big)^{T-\ell}\Big(\frac{\beta}{2m}\Big)^{\ell}\ell!\cdot m^{(\ell-q)/2}\Big/\Big(2^{(\ell-q)/2}\Big(\frac{\ell-q}{2}\Big)!\Big) && \text{(by Claim 22)} \\
&= \Big(1-\frac{\beta}{2}\Big)^{T}\Big(\frac{2}{m}\Big)^{q/2}\sum_{\ell=q}^{T}\binom{T}{\ell}\ell!\Big(\frac{\beta}{m(2-\beta)}\Big)^{\ell}\Big(\frac{m}{2}\Big)^{\ell/2}\Big/\Big(\frac{\ell-q}{2}\Big)! \\
&\le \Big(1-\frac{\beta}{2}\Big)^{T}\Big(\frac{2}{m}\Big)^{q/2}\sum_{\ell=q}^{T}\Big(T\cdot\frac{\beta}{m}\cdot\sqrt{\frac{m}{2}}\Big)^{\ell}\Big/\Big(\frac{\ell-q}{2}\Big)! && \text{(since } \beta<1 \text{ and } \tbinom{T}{\ell}\ell!\le T^{\ell}\text{)} \\
&= \Big(1-\frac{\beta}{2}\Big)^{T}\Big(\frac{2}{m}\Big)^{q/2}\Big(\frac{T\beta}{\sqrt{2m}}\Big)^{q}\sum_{r=0}^{T-q}\Big(\frac{T\beta}{\sqrt{2m}}\Big)^{r}\frac{1}{(r/2)!} && \text{(substituting } r\leftarrow(\ell-q)\text{)} \\
&\le \Big(1-\frac{\beta}{2}\Big)^{T}\Big(\frac{T\beta}{m}\Big)^{q}\sum_{r=0}^{T-q}\Big(\frac{T\beta}{\sqrt{2m}}\Big)^{r}\frac{e^{r/2}}{(r/2)^{r/2}} && \text{(using } n!\ge(n/e)^{n}\text{)} \\
&= \Big(1-\frac{\beta}{2}\Big)^{T}\Big(\frac{T\beta}{m}\Big)^{q}\sum_{r=0}^{T-q}\Big(\frac{\sqrt{e}T\beta}{\sqrt{mr}}\Big)^{r} \\
&\le \Big(1-\frac{\beta}{2}\Big)^{T}\Big(\frac{T\beta}{m}\Big)^{q}\sum_{r=0}^{T}\Big(\frac{\sqrt{e}T\beta}{\sqrt{mr}}\Big)^{r} && \text{(since the summands are } \ge 0\text{)} \\
&= \Big(1-\frac{\beta}{2}\Big)^{T}\Big(\frac{T\beta}{m}\Big)^{q}\Big(\sum_{r=0}^{\lceil e^3T^2\beta^2/m\rceil}\Big(\frac{\sqrt{e}T\beta}{\sqrt{mr}}\Big)^{r}+\sum_{r=\lceil e^3T^2\beta^2/m\rceil+1}^{T}\Big(\frac{\sqrt{e}T\beta}{\sqrt{mr}}\Big)^{r}\Big).
\end{aligned}$$

Note that by the assumptions of the theorem, $T^2e^3\beta^2/m \le T\beta \le T$, which allowed us to split the sum into two pieces in the last equality. At this point, we upper bound both pieces in the last equation separately. For the first piece, using Claim 6 it follows that $\Big(\frac{\sqrt{e}T\beta}{\sqrt{mr}}\Big)^{r}$ is maximized at $r=\lceil T^2\beta^2/m\rceil$. Hence we get

$$\sum_{r=0}^{\lceil e^3T^2\beta^2/m\rceil}\Big(\frac{\sqrt{e}T\beta}{\sqrt{mr}}\Big)^{r} \le \Big(2+\frac{e^3T^2\beta^2}{m}\Big)e^{\lceil T^2\beta^2/m\rceil/2} \le 2e^{22T^2\beta^2/m+1}, \tag{6}$$

where the first inequality uses Claim 6 and the second inequality uses $2+x\le 2e^{x}$ for $x\ge 0$ and $e^3+1/2\le 22$. For the second piece, we use

$$\sum_{r=\lceil e^3T^2\beta^2/m\rceil+1}^{T}\Big(\frac{\sqrt{e}T\beta}{\sqrt{mr}}\Big)^{r} \le \sum_{r=\lceil e^3T^2\beta^2/m\rceil+1}^{T}\Big(\frac{1}{e}\Big)^{r} \le \sum_{r=1}^{T}\Big(\frac{1}{e}\Big)^{r} = \frac{1-e^{-T}}{e-1} \le 2/3. \tag{7}$$

So we finally get

$$\begin{aligned}
\widehat{f}(S) &\le \Big(1-\frac{\beta}{2}\Big)^{T}\Big(\frac{T\beta}{m}\Big)^{q}\Big(2e^{22T^2\beta^2/m+1}+2/3\Big) && \text{(using Eq. (6), (7))} \\
&\le 4e\Big(1-\frac{\beta}{2}\Big)^{T}\Big(\frac{T\beta}{m}\Big)^{q}e^{22T^2\beta^2/m} && \text{(since } 22T^2\beta^2/m>0\text{)}
\end{aligned}$$

■

The theorem follows by putting together Claim 20 and Lemma 21:

$$\begin{aligned}
\sqrt{A}(x,x) &= \frac{1}{2^{k/2}}\sum_{Q\in\{0,1\}^k}\sqrt{\sum_{S\in\{0,1\}^m:M^tS=Q}\widehat{f}(S)} && \text{(using Claim 20)} \\
&\le \frac{1}{2^{k/2}}\sum_{Q\in\{0,1\}^k}\sum_{S\in\{0,1\}^m:M^tS=Q}\sqrt{\widehat{f}(S)} && \text{(using lower bound from Lemma 21)} \\
&= \frac{1}{2^{k/2}}\sum_{S\in\{0,1\}^m}\sqrt{\widehat{f}(S)} && (\cup_Q\{S: M^tS=Q\}=\{0,1\}^m \text{ since rank}(M)=k) \\
&= \frac{1}{2^{k/2}}\sum_{q=0}^{m}\sum_{S\in\{0,1\}^m:|S|=q}\sqrt{\widehat{f}(S)} \\
&\le \frac{2\sqrt{e}}{2^{k/2}}\Big(1-\frac{\beta}{2}\Big)^{T/2}e^{11T^2\beta^2/m}\sum_{q=0}^{m}\binom{m}{q}\Big(\frac{T\beta}{m}\Big)^{q/2} && \text{(using Lemma 21)} \\
&= \frac{2\sqrt{e}}{2^{k/2}}\Big(1-\frac{\beta}{2}\Big)^{T/2}e^{11T^2\beta^2/m}\Big(1+\sqrt{\frac{T\beta}{m}}\Big)^{m} && \text{(using binomial theorem)} \\
&\le \frac{2\sqrt{e}}{2^{k/2}}\Big(1-\frac{\beta}{2}\Big)^{T/2}e^{11T^2\beta^2/m+\sqrt{Tm\beta}}. && \text{(using } (1+x)^t\le e^{xt} \text{ for } x,t\ge 0\text{)}
\end{aligned}$$

■

4.1. Optimal lower bound for quantum PAC learning

We can now prove our tight lower bound on quantum sample complexity in the PAC model:

Theorem 23 *Let $\mathscr{C}$ be a concept class with VC-dim($\mathscr{C}$) $= d+1$, for sufficiently large d. Then for every $\delta\in(0,1/2)$ and $\varepsilon\in(0,1/20)$, every (ε,δ)-PAC quantum learner for $\mathscr{C}$ has sample complexity $\Omega\Big(\frac{d}{\varepsilon}+\frac{1}{\varepsilon}\log\frac{1}{\delta}\Big)$.*

Proof The d-independent part of the lower bound is Lemma 11. To prove the d-dependent part, define a distribution D on a set $\mathcal{S}=\{s_0,\ldots,s_d\}\subseteq\{0,1\}^n$ that is shattered by $\mathscr{C}$ as follows: $D(s_0)=1-20\varepsilon$ and $D(s_i)=20\varepsilon/d$ for all $i\in[d]$.

Now consider a $[d,k,r]_2$ linear code (for $k\ge d/4$, distance $r\ge d/8$) as shown to exist in Theorem 4 with the generator matrix $M\in\mathbb{F}_2^{d\times k}$ of rank k. Let $\{Mx: x\in\{0,1\}^k\}\subseteq\{0,1\}^d$ be the set of codewords in this linear code; these satisfy $d_H(Mx,My)\ge d/8$ whenever $x\ne y$. For each $x\in\{0,1\}^k$, let c^x be a concept defined on the shattered set as: $c^x(s_0)=0$ and

$c^x(s_i) = (Mx)_i$ for all $i \in [d]$. The existence of such concepts in $\mathscr{C}$ follows from the fact that $\mathcal{S}$ is shattered by $\mathscr{C}$. From the distance property of the code, we have $\Pr_{s\sim D}[c^x(s) \neq c^y(s)] \geq \frac{20\varepsilon}{d}\frac{d}{8} = 5\varepsilon/2$. This in particular implies that an (ε,δ)-PAC quantum learner that tries to ε-approximate a concept from $\{c^x : x \in \{0,1\}^k\}$ should successfully *identify* that concept with probability at least $1-\delta$.

We now consider the following state-identification problem: for $x \in \{0,1\}^k$, denote $|\psi_x\rangle = \sum_{i\in\{0,\ldots,d\}} \sqrt{D(s_i)}|s_i, c^x(s_i)\rangle$. Let the (ε,δ)-PAC quantum sample complexity be T. Assume $T \leq d/(20e^3\varepsilon)$, since otherwise $T \geq \Omega(d/\varepsilon)$ and the theorem follows. Suppose the learner has knowledge of the ensemble $\mathcal{E} = \{(2^{-k}, |\psi_x\rangle^{\otimes T}) : x \in \{0,1\}^k\}$, and is given $|\psi_x\rangle^{\otimes T} \in \mathcal{E}$ for a uniformly random x. The learner would like to maximize the average probability of success to identify the given state. For this problem, we prove a lower bound on T using the PGM defined in Section 2.6. In particular, we show that using the PGM, if a learner successfully identifies the states in $\mathcal{E}$, then $T = \Omega(d/\varepsilon)$. Since the PGM is the optimal measurement[6] that the learner could have performed, the result follows. The following lemma makes this lower bound rigorous and will conclude the proof of the theorem.

Lemma 24 *For every $x \in \{0,1\}^k$, let $|\psi_x\rangle = \sum_{i\in\{0,\ldots,d\}} \sqrt{D(s_i)}|s_i, c^x(s_i)\rangle$, and $\mathcal{E} = \{(2^{-k}, |\psi_x\rangle^{\otimes T}) : x \in \{0,1\}^k\}$. Then*

$$P^{PGM}(\mathcal{E}) \leq \frac{4e}{2^{d/4+T\varepsilon}} e^{8800T^2\varepsilon^2/d+4\sqrt{5Td\varepsilon}}.$$

Before we prove the lemma, we first show why it implies the theorem. Since we observed above that $P^{opt}(\mathcal{E}) = P^{PGM}(\mathcal{E})$, a good learner satisfies $P^{PGM}(\mathcal{E}) = \Omega(1)$ (say for $\delta = 1/4$), which in turn implies (by taking logarithms) that $\Omega(d + T\varepsilon) \leq O(T^2\varepsilon^2/d + \sqrt{Td\varepsilon})$. Hence, it follows that

$$\Omega(\max\{d, T\varepsilon\}) \leq O(\min\{T^2\varepsilon^2/d, \sqrt{Td\varepsilon}\}).$$

Note that if $T\varepsilon$ maximizes the left-hand side, then $d \leq T\varepsilon$ and hence $T \geq \Omega(d/\varepsilon)$. The remaining cases are $\Omega(d) \leq T^2\varepsilon^2/d$ and $\Omega(d) \leq \sqrt{Td\varepsilon}$. Both these statements give us $T \geq \Omega(d/\varepsilon)$.[7] Hence the theorem follows, and it remains to prove Lemma 24:

Proof Let $\mathcal{E}' = \{2^{-k/2}|\psi_x\rangle^{\otimes T} : x \in \{0,1\}^k\}$ and G be the $2^k \times 2^k$ Gram matrix for $\mathcal{E}'$. As we saw in Section 2.6, the success probability of identifying the states in the ensemble $\mathcal{E}$ using the PGM is

$$P^{PGM}(\mathcal{E}) = \sum_{x\in\{0,1\}^k} \sqrt{G}(x,x)^2.$$

6. For $x \in \{0,1\}^k$, define unitary $U_{c^x} : |s_i, b\rangle \to |s_i, b + c^x(s_i)\rangle$ for all $i \in \{0,\ldots,d\}$. The ensemble $\mathcal{E}$ is generated by applying $\{U_{c^x}\}_{x\in\{0,1\}^k}$ to $|\varphi\rangle = \sum_{i\in\{0,\ldots,d\}} \sqrt{D(s_i)}|s_i, 0\rangle$. View $c^x = (0, Mx) \in \{0,1\}^{d+1}$ as a concatenated string where Mx is a codeword of the $[d,k,r]_2$ code. Since the 2^k codewords of the $[d,k,r]_2$ code form a linear subspace, $\{U_{c^x}\}_{x\in\{0,1\}^k}$ is an Abelian group. From the discussion in Section 2.6, we conclude that the PGM is the optimal measurement for this state-identification problem.

7. We made no attempt to optimize the constants here. Also, we remark that this tight lower bound on sample complexity implies that Lemma 21 is tight up to constant factors in the exponent.

For all $x, y \in \{0,1\}^k$, the entries of the Gram matrix G can be written as:

$$\begin{aligned} G(x,y) = \frac{1}{2^k}\langle\psi_x|\psi_y\rangle^T &= \frac{1}{2^k}\Big((1-20\varepsilon) + \frac{20\varepsilon}{d}\sum_{i=1}^{d}\langle c^x(s_i)|c^y(s_i)\rangle\Big)^T \\ &= \frac{1}{2^k}\Big((1-20\varepsilon) + \frac{20\varepsilon}{d}(d - d_H(Mx, My))\Big)^T \\ &= \frac{1}{2^k}\Big(1 - \frac{20\varepsilon}{d}d_H(Mx, My)\Big)^T, \end{aligned}$$

where Mx, $My \in \{0,1\}^d$ are codewords in the linear code defined earlier. Define $f : \{0,1\}^d \to \mathbb{R}$ as $f(z) = (1 - \frac{20\varepsilon}{d}|z|)^T$, and let $A(x,y) = (f \circ M)(x+y)$ for $x, y \in \{0,1\}^k$. Note that $G = A/2^k$. Since we assumed $T \leq d/(20e^3\varepsilon)$, we can use Theorem 18 (by choosing $m = d$ and $\beta = 20\varepsilon$) to upper bound the success probability of successfully identifying the states in the ensemble $\mathcal{E}$ using the PGM.

$$\begin{aligned} P^{PGM}(\mathcal{E}) &= \sum_{x\in\{0,1\}^k} \sqrt{G}(x,x)^2 \\ &= \frac{1}{2^k}\sum_{x\in\{0,1\}^k} \sqrt{A}(x,x)^2 && \text{(since } G = A/2^k\text{)} \\ &\leq \frac{4e}{2^k}\Big(1 - \frac{\beta}{2}\Big)^T e^{22T^2\beta^2/d+2\sqrt{Td\beta}} && \text{(using Theorem 18)} \\ &= \frac{4e}{2^k}\Big(1 - 10\varepsilon\Big)^T e^{8800T^2\varepsilon^2/d+4\sqrt{5Td\varepsilon}} && \text{(substituting } \beta = 20\varepsilon\text{)} \\ &\leq \frac{4e}{2^{k+T\varepsilon}} e^{8800T^2\varepsilon^2/d+4\sqrt{5Td\varepsilon}} && \text{(using } (1-10\varepsilon)^T \leq e^{-10\varepsilon T} \leq 2^{-\varepsilon T}\text{)} \end{aligned}$$

The lemma follows by observing that $k \geq d/4$. ■

■

4.2. Optimal lower bound for quantum agnostic learning

We now use the same approach to obtain a tight lower bound on quantum sample complexity in the *agnostic* setting.

Theorem 25 *Let $\mathscr{C}$ be a concept class with VC-dim$(\mathscr{C}) = d$, for sufficiently large d. Then for every $\delta \in (0, 1/2)$ and $\varepsilon \in (0, 1/10)$, every (ε,δ)-agnostic quantum learner for $\mathscr{C}$ has sample complexity $\Omega\Big(\frac{d}{\varepsilon^2} + \frac{1}{\varepsilon^2}\log\frac{1}{\delta}\Big)$.*

Proof The d-independent part of the lower bound is Lemma 12. For the d-dependent term in the lower bound, consider a $[d,k,r]_2$ linear code (for $k \geq d/4$, distance $r \geq d/8$) as shown to exist in Theorem 4, with generator matrix $M \in \mathbb{F}_2^{d\times k}$ of rank k. Let $\{Mx : x \in \{0,1\}^k\} \subseteq$

$\{0,1\}^d$ be the set of 2^k codewords in this linear code; these satisfy $d_H(Mx,My) \geq d/8$ whenever $x \neq y$. To each codeword $x \in \{0,1\}^k$ we associate a distribution D_x as follows:

$$D_x(s_i,b) = \frac{1}{d}\Big(\frac{1}{2} + \frac{1}{2}(-1)^{(Mx)_i+b}\alpha\Big), \qquad \text{for } (i,b) \in [d]\times\{0,1\},$$

where $\mathcal{S} = \{s_1,\ldots,s_d\}$ is a set that is shattered by $\mathscr{C}$, and α is a parameter which we shall pick later. Let $c^x \in \mathscr{C}$ be a concept that labels $\mathcal{S}$ according to $Mx \in \{0,1\}^d$. The existence of such $c^x \in \mathscr{C}$ follows from the fact that $\mathcal{S}$ is shattered by $\mathscr{C}$. Note that c^x is the minimal-error concept in $\mathscr{C}$ w.r.t. D_x. A learner that labels $\mathcal{S}$ according to some string $\ell \in \{0,1\}^d$ has additional error $d_H(Mx,\ell)\cdot\alpha/d$ compared to c^x. This in particular implies that an (ε,δ)-agnostic quantum learner has to find (with probability at least $1-\delta$) an ℓ such that $d_H(Mx,\ell) \leq d\varepsilon/\alpha$. We pick $\alpha = 20\varepsilon$ and we get $d_H(Mx,\ell) \leq d/20$. However, since Mx was a codeword of a $[d,k,r]_2$ code with distance $r \geq d/8$, finding an ℓ satisfying $d_H(Mx,\ell) \leq d/20$ is equivalent to *identifying* Mx, and hence x.

Now consider the following state-identification problem: for $x \in \{0,1\}^k$, let $|\psi_x\rangle = \sum_{(i,b)\in[d]\times\{0,1\}} \sqrt{D_x(s_i,b)}|s_i,b\rangle$. Let the (ε,δ)-agnostic quantum sample complexity be T. Assume $T \leq d/(100e^3\varepsilon^2)$, since otherwise $T \geq \Omega(d/\varepsilon^2)$ and the theorem follows. Suppose the learner has knowledge of the ensemble $\mathcal{E} = \{(2^{-k},|\psi_x\rangle^{\otimes T}) : x \in \{0,1\}^k\}$, and is given $|\psi_x\rangle^{\otimes T} \in \mathcal{E}$ for uniformly random x. The learner would like to maximize the average probability of success to identify the given state. For this problem, we prove a lower bound on T using the PGM defined in Section 2.6. In particular, we show that using the PGM, if a learner successfully identifies the states in $\mathcal{E}$, then $T = \Omega(d/\varepsilon^2)$. Since the PGM is the optimal measurement[8] that the learner could have performed, the result follows. The following lemma makes this lower bound rigorous and will conclude the proof of the theorem.

Lemma 26 *For $x \in \{0,1\}^k$, let $|\psi_x\rangle = \sum_{(i,b)\in[d]\times\{0,1\}} \sqrt{D_x(s_i,b)}|s_i,b\rangle$, and consider the ensemble $\mathcal{E} = \{(2^{-k},|\psi_x\rangle^{\otimes T}) : x \in \{0,1\}^k\}$. Then*

$$P^{PGM}(\mathcal{E}) \leq \frac{4e}{e^{(d\ln 2)/4+25T\varepsilon^2}} e^{220000T^2\varepsilon^4/d+20\sqrt{Td\varepsilon^2}}.$$

Before we prove the lemma, we first show why it implies the theorem. Since we observed above that $P^{opt}(\mathcal{E}) = P^{PGM}(\mathcal{E})$, a good learner satisfies $P^{PGM}(\mathcal{E}) = \Omega(1)$ (say for $\delta = 1/4$), which in turn implies

$$\Omega(\max\{d, T\varepsilon^2\}) \leq O(\min\{T^2\varepsilon^4/d, \sqrt{Td\varepsilon^2}\}).$$

Like in the proof of Theorem 23, this implies a lower bound of $T = \Omega(d/\varepsilon^2)$ and proves the theorem. It remains to prove Lemma 26:

8. For $x \in \{0,1\}^k$, define unitary $U_{c^x} = \sum_{i\in[d]} |s_i\rangle\langle s_i| \otimes X^{(Mx)_i}$, where X is the NOT-gate, so $X^{(Mx)_i}|b\rangle = |b+(Mx)_i\rangle$ for $b \in \{0,1\}$. The ensemble $\mathcal{E}$ is generated by applying $\{U_{c^x}\}_{x\in\{0,1\}^k}$ to $|\varphi\rangle = \frac{1}{\sqrt{d}}\sum_{(i,b)\in[d]\times\{0,1\}} \sqrt{\frac{1}{2}+\frac{1}{2}(-1)^b\alpha}|s_i,b\rangle$. Since the 2^k codewords of the $[d,k,r]_2$ code form a linear subspace, $\{U_{c^x}\}_{x\in\{0,1\}^k}$ is an Abelian group. From the discussion in Section 2.6, we conclude that the PGM is the optimal measurement for this state-identification problem.

Proof Let $\mathcal{E}' = \{2^{-k/2}|\psi_x\rangle^{\otimes T} : x \in \{0,1\}^k\}$ and G be the $2^k \times 2^k$ Gram matrix for the set $\mathcal{E}'$. As we saw in Section 2.6, the success probability of identifying the states in the ensemble $\mathcal{E}$ using the PGM is

$$P^{PGM}(\mathcal{E}) = \sum_{x\in\{0,1\}^k} \sqrt{G}(x,x)^2.$$

For all $x,y \in \{0,1\}^k$, the entries of G can be written as:

$$\begin{aligned}
2^k\cdot G(x,y) &= \langle\psi_x|\psi_y\rangle^T \\
&= \Big(\sum_{(i,b)\in[d]\times\{0,1\}} \sqrt{D_x(i,b)D_y(i,b)}\Big)^T \\
&= \Big(\frac{1}{2d}\sum_{(i,b)\in[d]\times\{0,1\}} \sqrt{(1+10\varepsilon(-1)^{(Mx)_i+b})(1+10\varepsilon(-1)^{(My)_i+b})}\Big)^T \\
&= \Big(\frac{1}{2d}\sum_{\substack{(i,b):\\(Mx)_i=(My)_i}} (1+10\varepsilon(-1)^{(Mx)_i+b}) + \frac{1}{2d}\sum_{\substack{(i,b):\\(Mx)_i\neq(My)_i}} \sqrt{1-100\varepsilon^2}\Big)^T \\
&= \Big(\frac{d-d_H(Mx,My)}{d} + \frac{\sqrt{1-100\varepsilon^2}}{d} d_H(Mx,My)\Big)^T \\
&= \Big(1 - \frac{1-\sqrt{1-100\varepsilon^2}}{d} d_H(Mx,My)\Big)^T.
\end{aligned}$$

where we used $\alpha = 20\varepsilon$ in the third equality.

Let $\beta = 1-\sqrt{1-100\varepsilon^2}$, which is at most 1 for $\varepsilon \leq 1/10$. Define $f : \{0,1\}^d \to \mathbb{R}$ as $f(z) = (1-\frac{\beta}{d}|z|)^T$, and let $A(x,y) = (f\circ M)(x+y)$ for $x,y \in \{0,1\}^k$. Then $G = A/2^k$. Note that $T \leq d/(100e^3\varepsilon^2) \leq d/(e^3\beta)$ (the first inequality is by assumption and the second inequality follows for $\varepsilon \leq 1/10$ and $\beta \leq 1$). Since we assumed $T \leq d/(100e^3\varepsilon^2)$, we can use Theorem 18 (by choosing $m = d$ and $\beta = 1-\sqrt{1-100\varepsilon^2}$) to upper bound the success probability of identifying the states in the ensemble $\mathcal{E}$:

$$\begin{aligned}
P^{PGM}(\mathcal{E}) &= \sum_{x\in\{0,1\}^k} \sqrt{G}(x,x)^2 \\
&= \frac{1}{2^k}\sum_{x\in\{0,1\}^k} \sqrt{A}(x,x)^2 && \text{(since } G = A/2^k\text{)} \\
&\leq \frac{4e}{2^k}\Big(1-\frac{\beta}{2}\Big)^T e^{22T^2\beta^2/d+2\sqrt{Td\beta}} && \text{(using Theorem 18)} \\
&\leq \frac{4e}{2^k}\Big(1-\frac{\beta}{2}\Big)^T e^{220000T^2\varepsilon^4/d+20\sqrt{Td\varepsilon^2}} && \text{(using } \beta = 1-\sqrt{1-100\varepsilon^2} \leq 100\varepsilon^2\text{)} \\
&\leq \frac{4e}{2^k}\Big(1-25\varepsilon^2\Big)^T e^{220000T^2\varepsilon^4/d+20\sqrt{Td\varepsilon^2}} && \text{(using } \sqrt{1-100\varepsilon^2} \leq 1-50\varepsilon^2\text{)} \\
&\leq \frac{4e}{e^{k\ln 2+25T\varepsilon^2}} e^{220000T^2\varepsilon^4/d+20\sqrt{Td\varepsilon^2}}. && \text{(using } (1-x)^t \leq e^{-xt} \text{ for } x,t \geq 0\text{)}
\end{aligned}$$

The lemma follows by observing that $k \geq d/4$. ■

■

4.3. Additional results

In this section we mention two additional results that can also be obtained using Theorem 18.

4.3.1. Quantum PAC sample complexity under random classification noise

In the theorem below, we show a lower bound on the quantum PAC sample complexity under the random classification noise model with noise rate η. Recall that in this model, for every $c \in \mathscr{C}$ and distribution D, $\varepsilon, \delta > 0$, given access to copies of the η-noisy state,

$$\sum_{x \in \{0,1\}^n} \sqrt{(1-\eta)D(x)}|x, c(x)\rangle + \sqrt{\eta D(x)}|x, 1-c(x)\rangle,$$

a (ε, δ)-PAC quantum learner is required to output an hypothesis h such that $\mathrm{err}_D(c,h) \leq \varepsilon$ with probability at least $1-\delta$.

Theorem 27 *Let $\mathscr{C}$ be a concept class with VC-dim$(\mathscr{C}) = d+1$, for sufficiently large d. Then for every $\delta \in (0, 1/2)$, $\varepsilon \in (0, 1/20)$ and $\eta \in (0, 1/2)$, every (ε, δ)-PAC quantum learner for $\mathscr{C}$ in the PAC setting with random classification noise rate η, has sample complexity $\Omega\Big(\frac{d}{(1-2\eta)^2\varepsilon} + \frac{\log(1/\delta)}{(1-2\eta)^2\varepsilon}\Big)$.*

One can use exactly the same proof technique as in Lemma 11 and Theorem 23 to prove this, with only the additional inequality $1 - 2\sqrt{\eta(1-\eta)} \leq (1-2\eta)^2$, which holds for $\eta \leq 1/2$. We omit the details of the calculation.

4.3.2. Distinguishing codeword states

Ashley Montanaro (personal communication) alerted us to the following interesting special case of our PGM-based result.

Consider an $[n,k,d]_2$ linear code $\{Mx : x \in \{0,1\}^k\}$, where $M \in \mathbb{F}_2^{n \times k}$ is the rank-k generator matrix of the code, $k = \Omega(n)$, and distinct codewords have Hamming distance at least d.[9] For every $x \in \{0,1\}^k$, define a *codeword state* $|\psi_x\rangle = \frac{1}{\sqrt{n}} \sum_{i \in [n]} |i, (Mx)_i\rangle$. These states form an example of a *quantum fingerprinting* scheme considered earlier by Buhrman et al. (2001): 2^k states whose pairwise inner products are bounded away from 1. How many copies do we need to identify one such fingerprint?

Let $\mathcal{E} = \{(2^{-k}, |\psi_x\rangle) : x \in \{0,1\}^k\}$ be an ensemble of codeword states. Consider the following task: given T copies of an unknown state drawn uniformly from $\mathcal{E}$, we are required to identify the state with probability $\geq 4/5$. From Holevo's theorem one can easily obtain a lower bound of $T = \Omega(k/\log n)$ copies, since the learner should obtain $\Omega(k)$ bits of information (i.e., identify k-bit string x with probability $\geq 4/5$), while each copy of the codeword state gives at most $\log n$ bits of information. In the theorem below, we improve that $\Omega(k/\log n)$ to the optimal $\Omega(k)$ for constant-rate codes.

Theorem 28 *Let $\mathcal{E} = \{|\psi_x\rangle = \frac{1}{\sqrt{n}} \sum_{i \in [n]} |i, (Mx)_i\rangle : x \in \{0,1\}^k\}$, where $M \in \mathbb{F}_2^{n \times k}$ is the generator matrix of an $[n,k,d]_2$ linear code with $k = \Omega(n)$. Then $\Omega(k)$ copies of an unknown state from $\mathcal{E}$ (drawn uniformly at random) are necessary to be able to identify that state with probability at least $4/5$.*

9. Note that throughout this paper $\mathscr{C}$ was a concept class in $\{0,1\}^n$ and d was the VC dimension of $\mathscr{C}$. The use of n, d in this section has been changed to conform to the convention in coding theory.

One can use exactly the proof technique of Theorem 23 to prove the theorem. Suppose we are given T copies of the unknown codeword state. Assume $T \leq n$, since otherwise $T \geq n \geq \sqrt{kn}$ and the theorem follows. Observe that the Gram matrix G for $\mathcal{E}' = \{2^{-k/2}|\psi_x\rangle^{\otimes T} : x \in \{0,1\}^k\}$ can be written as $G(x,y) = \frac{1}{2^k}\Big(1 - \frac{|M(x+y)|}{n}\Big)^T$ for $x, y \in \{0,1\}^k$. Using Theorem 18 (choosing $\beta = 1$ and $m = n$) to upper bound the success probability of successfully identifying the states in the ensemble $\mathcal{E}$ using the PGM, we obtain

$$P^{PGM}(\mathcal{E}) \leq \frac{4e}{2^{k+T}} e^{22T^2/n + 2\sqrt{Tn}}.$$

As in the proof of Theorem 23, this implies the lower bound of Theorem 28. We omit the details of the calculation.

5. Conclusion

The main result of this paper is that quantum examples give no significant improvement over the usual random examples in passive, distribution-independent settings. Of course, these negative results do not mean that quantum machine learning is useless. In our introduction we already mentioned improvements from quantum examples for learning under the uniform distribution; improvements from using quantum membership queries; and improvements in time complexity based on quantum algorithms like Grover's and HHL. Quantum machine learning is still in its infancy, and we hope for many more positive results.

We end by identifying a number of open questions for future work:

- We gave lower bounds on sample complexity for the rather benign random classification noise. What about other noise models, such as *malicious* noise?
- What is the quantum sample complexity for learning concepts whose range is $[k]$ rather than $\{0,1\}$, for some $k > 2$? Even the *classical* sample complexity is not fully determined yet (Shalev-Shwartz and Ben-David, 2014, Section 29.2).
- In the introduction we mentioned a few examples of learning under the *uniform* distribution where quantum examples are significantly more powerful than classical examples. Can we find more such examples of quantum improvements in sample complexity in fixed-distribution settings?
- Can we find more examples of quantum speed-up in *time* complexity of learning?

Acknowledgments

We thank Shalev Ben-David, Dmitry Gavinsky, Robin Kothari, Nishant Mehta, Ashley Montanaro, Henry Yuen for helpful comments and pointers to the literature. We thank Ashley Montanaro for suggesting the additional remark in Section 4.3.2. We also thank the anonymous referees from QIP, CCC, and JMLR for their helpful comments.

Abstract

scikit-multiflow is a framework for learning from data streams and multi-output learning in Python. Conceived to serve as a platform to encourage the democratization of stream learning research, it provides multiple state-of-the-art learning methods, data generators and evaluators for different stream learning problems, including single-output, multi-output and multi-label. scikit-multiflow builds upon popular open source frameworks including scikit-learn, MOA and MEKA. Development follows the FOSS principles. Quality is enforced by complying with PEP8 guidelines, using continuous integration and functional testing. The source code is available at `https://github.com/scikit-multiflow/scikit-multiflow`.

Keywords: Machine Learning, Stream Data, Multi-output, Drift Detection, Python

1. Introduction

Recent years have witnessed the proliferation of Free and Open Source Software (FOSS) in the research community. Specifically, in the field of Machine Learning, researchers have benefited from the availability of different frameworks that provide tools for faster development, allow replicability and reproducibility of results and foster collaboration. Following the FOSS principles, we introduce scikit-multiflow, a Python framework to implement algorithms and perform experiments in the field of Machine Learning on Evolving Data Streams. scikit-multiflow is inspired in the popular frameworks scikit-learn, MOA and MEKA.

scikit-learn (Pedregosa et al., 2011) is the most popular open source software machine learning library for the Python programming language. It features various classification, regression and clustering algorithms including support vector machines, random forest, gradient boosting, k-means and DBSCAN, and is designed to inter-operate with the Python numerical and scientific packages NumPy and SciPy.

MOA (Bifet et al., 2010) is the most popular open source framework for data stream mining, with a very active growing community. It includes a collection of machine learning algorithms (classification, regression, clustering, outlier detection, concept drift detection and recommender systems) and tools for evaluation. Related to the WEKA project (Hall et al., 2009), MOA is also written in Java, while scaling to more demanding problems.

The MEKA project (Read et al., 2016) provides an open source implementation of methods for multi-label learning and evaluation. In multi-label classification, the aim is to predict multiple output variables for each input instance. This different from the 'standard' case (binary, or multi-class classification) which involves only a single target variable.

As a multi-output streaming framework, scikit-multiflow serves as a bridge between research communities that have flourished around the aforementioned popular frameworks, providing a common ground where they can thrive. scikit-multiflow assists on the democratization of Stream Learning by bringing this research field closer to the Machine Learning community, given the increasing popularity of the Python programing language. The objective is two-folded: First, fills the void in Python for a stream learning framework which can also interact with available tools such as scikit-learn and extends the set of available

* Depending on the base learner.
† We have only listed incremental methods for data-streams; MEKA and scikit-learn have many other batch-learning models available. MEKA in particular, has many problem-transformation methods which may be incremental depending on the base learner (it is able to use those from the MOA framework).

state-of-the-art methods on this platform. Second, provides a set of tools to facilitate the development of stream learning research, an example is (Montiel et al., 2018).

It is important to notice that scikit-multiflow complements scikit-learn, whose primary focus is batch learning, expanding the set of free and open source tools for Stream Learning. In addition, scikit-multiflow can be used within Jupyter Notebooks, a popular interface in the Data Science community. Special focus in the design of scikit-multiflow is to make it friendly to new users and familiar to experienced ones.

scikit-multiflow contains stream generators, learning methods, change detectors and evaluation methods. Stream generators include: Agrawal, Hyperplane, Led, Mixed, Random-RBF, Random-RBF with drift, Random Tree, SEA, SINE, SEA, STAGGER, Waveform, Multi-label, Regression and Concept-Drift. Available evaluators correspond to Prequential and Hold-Out evaluations, both supporting multiple performance metrics for *Classification* (Accuracy, Kappa Coefficient, Kappa T, Kappa M), *Multi-Output Classification* (Hamming Score, Hamming Loss, Exact Match, Jaccard Index) *Regression* (Mean Squared Error, Mean Absolute Error) and *Multi-Output Regression* (Average Mean Squared Error, Average Mean Absolute Error, Average Root Mean Squared Error). Learning methods and change detectors are listed in Table 1. This table also serves to outline the position of scikit-multiflow with respect to other open source frameworks.

2. Stream Data Mining Notation and Background

Consider a continuous stream of data $A = \{(\vec{x}_t, y_t)\}|t = 1, \ldots, T$ where $T \to \infty$. Input $\vec{x}_t$ is a feature vector and y_t the corresponding target where y is continuous in the case of regression and discrete for classification. The objective is to predict the target y for an unknown $\vec{x}$. In traditional single-output models, we deal with a single target variable for which one corresponding output is produced per test instance. Multi-output models can produce multiple outputs to assign to multiple target variables $\vec{y}$ for each test instance.

Different to batch learning, where all data (X, y) is available for training; in stream learning, training is performed incrementally as new data $(\vec{x}_i, y_i)$ is available. Performance P of a given model is measured according to some loss function that evaluates the difference between the set of expected labels Y and the predicted ones $\hat{Y}$. Hold-out evaluation is a popular performance evaluation method for batch and stream settings, where tests are performed in a separate test set. Prequential-evaluation (Dawid, 1984) or interleaved-test-then-train evaluation, is a popular performance evaluation method for the stream setting only, where tests are performed on new data before using it to train the model.

3. Architecture

The base class in scikit-multiflow is StreamModel which contains the following abstract methods to be implemented by its subclasses:

- fit — Trains a model in a batch fashion. Works as an interface to batch methods that implement a fit() function such as scikit-learn methods.
- partial_fit — Incrementally trains a stream model.
- predict — Predicts the target's value in supervised learning methods.
- predict_proba — Calculates per-class probabilities in classification problems.

A StreamModel object interacts with two other objects: a Stream object and (optionally) a StreamEvaluator object. The Stream object provides a continuous flow of data on request. The StreamEvaluator performs multiple tasks: queries the stream for data, trains and tests the model on the incoming data and continuously tracks the model's performance. The sequence to train a Stream Model and track its performance using prequential evaluation in scikit-multiflow is outlined in Figure 1.

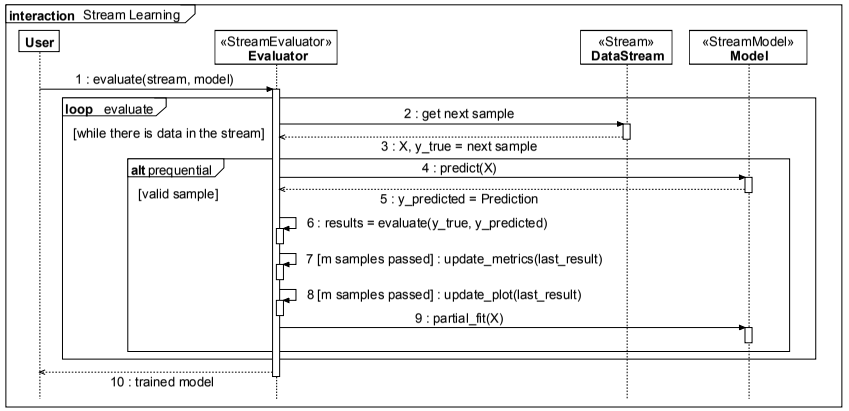

Figure 1: Training and testing a stream model using scikit-multiflow. This sequence corresponds to prequential evaluation.

4. Development

The scikit-multiflow package is distributed under the BSD License. Development follows the FOSS principles and encompasses:

- A webpage, `https://scikit-multiflow.github.io/`, including documentation and user guide. Both, documentation and user guide, are living documents that are continuously updated to reflect the current stage of scikit-multiflow.
- Version control via git. The source code of the package is publicly available on Github at `https://github.com/scikit-multiflow/scikit-multiflow`
- Package deployment and software quality are enforced via continuous integration and functional testing, `https://travis-ci.org/scikit-multiflow/scikit-multiflow`

Abstract

In 1984, Johnson and Lindenstrauss proved that any finite set of data in a high-dimensional space can be projected to a lower-dimensional space while preserving the pairwise Euclidean distances between points up to a bounded relative error. If the desired dimension of the image is too small, however, Kane, Meka, and Nelson (2011) and Jayram and Woodruff (2013) proved that such a projection does not exist. In this paper, we provide a precise asymptotic threshold for the dimension of the image, above which, there exists a projection preserving the Euclidean distance, but, below which, there does not exist such a projection.

Keywords: Johnson-Lindenstrauss transformation, Dimension reduction, Phase transition, Asymptotic threshold

1. Introduction

In 1984, Johnson and Lindenstrauss (1984), in establishing a bound on the Lipschitz constant for the Lipschitz extension problem, proved that any finite set of data in a high-dimensional space can be projected into a lower-dimensional space while preserving the pairwise Euclidean distance within any desired relative error. In particular, for any finite set of vectors $x_1, \ldots, x_N \in \mathbb{R}^d$ and for any error factor $0 < \epsilon < \frac{1}{2}$, there exists an absolute constant c such that for all $k \geq c\epsilon^{-2} \log N$, there exists a linear map $A : \mathbb{R}^d \to \mathbb{R}^k$ such that for all pairs $1 \leq i, j \leq N$,

$$(1-\epsilon)\|x_i - x_j\|_2 \leq \|Ax_i - Ax_j\|_2 \leq (1+\epsilon)\|x_i - x_j\|_2,$$

where $\|\cdot\|_2$ denotes the Euclidean norm. These inequalities are implied by the following theorem (by setting $\delta = \frac{1}{N^2}$ and using the union bound):

Theorem 1 (Johnson and Lindenstrauss (1984)) *For any real numbers $0 < \epsilon, \delta < \frac{1}{2}$, there exists an absolute constant $c > 0$ such that for any integer $k \geq c\epsilon^{-2} \log \frac{1}{\delta}$, there exists a probability distribution $\mathcal{D}$ on $k \times d$ real matrices such that for any fixed $x \in \mathbb{R}^d$,*

$$\text{Prob}_{A \sim \mathcal{D}} \left[(1-\epsilon)\|x\|_2^2 \leq \|Ax\|_2^2 \leq (1+\epsilon)\|x\|_2^2 \right] > 1 - \delta, \tag{1}$$

where $A \sim \mathcal{D}$ indicates that the matrix A is a random matrix with distribution $\mathcal{D}$.

Note that, in order to project a large number of vectors, δ must be sufficiently small. For instance, suppose we wish to project a set of $N = 2^{20}$ vectors to a smaller dimensional space. To apply the union bound to Inequality (1), we use any $\delta < 2^{-39}$. In this case, Inequality (1) implies that the probability of preserving all pairwise distances between N points (up to a relative error of ϵ) is at least $1 - \delta N^2/2 > 0$. Since the probability is nonzero, such a projection exists.

A probability distribution $\mathcal{D}$ satisfying Inequality (1) is called an (ϵ, δ)-JL distribution, or simply a JL distribution. Since these transformations are linear, without loss of generality, we assume for the rest of the paper that $\|x\|_2 = 1$. When a JL distribution is specified via an explicit construction, we may call a random projection $x \mapsto Ax$ generated in this way a JL transformation.

Since the introduction of JL distributions, there has been considerable work on explicit constructions of JL distributions, see, e.g., Johnson and Lindenstrauss (1984); Frankl and Maehara (1988); Indyk and Motwani (1998); Achlioptas (2003); Ailon and Chazelle (2006); Matousek (2008); Dasgupta et al. (2010); Kane and Nelson (2014); and the references therein. A simple and easily described JL distribution is that of Achlioptas (2003). In this construction, the entries of A are distributed as follows:

$$a_{ij} = \begin{cases} k^{-1/2}, & \text{with probability } 1/2, \\ -k^{-1/2}, & \text{with probability } 1/2. \end{cases}$$

The recent constructions in Ailon and Chazelle (2006); Matousek (2008); Dasgupta et al. (2010); Kane and Nelson (2014) have focused on the complexity of computing a projection for the purpose of applications. We note that the ability to project a vector to a smaller dimensional space, independent of the original dimension, while preserving the Euclidean norm up to a prescribed relative error, is highly desirable. In particular, dimension reduction has applications in many fields, including machine learning (Arriaga and Vempala (2006); Weinberger et al. (2009)), low rank approximation (Clarkson and Woodruff (2013); Nguyen et al. (2009); Ubaru et al. (2017)), approximate nearest neighbors (Ailon and Chazelle (2006); Indyk and Motwani (1998)), data storage (Candès (2008); Cormode and Indyk (2016)), and document similarity (Bingham and Mannila (2001); Lin and Gunopulos (2003)).

For both practical and theoretical purposes, it is important to know the smallest possible dimension k of a potential image space for any given ϵ and δ. Note that, for any $d_1 < d$, each (ϵ, δ)-JL distribution $\mathcal{D}$ on $\mathbb{R}^{k \times d}$ induces an (ϵ, δ)-JL distribution $\mathcal{D}_1$ on $\mathbb{R}^{k \times d_1}$ in a natural way: the matrices of $\mathcal{D}_1$ are obtained from $\mathcal{D}$ by deleting the last $d - d_1$ columns of a random matrix, together with the induced probability distribution. This construction is a JL distribution since $\mathbb{R}^{d_1}$ can be naturally embedded into $\mathbb{R}^d$ by extending a vector in $\mathbb{R}^{d_1}$ by $d - d_1$ zeros. Hence, if there exists an (ϵ, δ)-JL distribution on $\mathbb{R}^{k \times d}$, then there is an (ϵ, δ)-JL distribution on $\mathbb{R}^{k \times d_1}$ for all $1 \leq d_1 \leq d$. Similarly, if an (ϵ, δ)-JL distribution does not exist on $\mathbb{R}^{k \times d}$, then, for any $k_1 < k$, there cannot be an (ϵ, δ)-JL distribution on $\mathbb{R}^{k_1 \times d}$. In particular, since $\mathbb{R}^{k_1}$ can be naturally embedded into $\mathbb{R}^k$ by extending a vector in $\mathbb{R}^{k_1}$ by $k - k_1$ zeros, if an (ϵ, δ)-JL distribution existed for $\mathbb{R}^{k_1 \times d}$, it could be extended to an (ϵ, δ)-JL distribution for $\mathbb{R}^{k \times d}$.

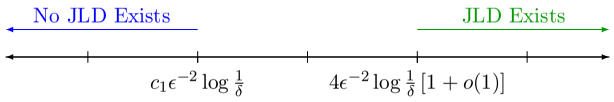

Figure 1: For fixed ϵ and δ, there exists a JL distribution for $k \geq 4\epsilon^{-2}\log(1/\delta)\,[1+o(1)]$. For $k < c_1\epsilon^{-2}\log(1/\delta)$, for some absolute constant $c_1 > 0$, there is no JL distribution. In this paper, we close this gap in the limit.

For any ϵ and δ, we define

$$k_0(\epsilon,\delta) = \min\{k : \text{there exists an } (\epsilon,\delta)\text{-JL distribution on } \mathbb{R}^{k\times d} \text{ for every } d \geq 1\}.$$

By our definition, $k_0 = k_0(\epsilon,\delta)$ is independent of d, and, by Theorem 1, we have that $k_0 \leq c\epsilon^{-2}\log(1/\delta)$ for some absolute constant $c > 0$. Frankl and Maehara (1988) show that $c \leq 9$. Achlioptas (2003) further improves this bound by providing a JL distribution with

$$k > 2\log(2/\delta)\left(\frac{\epsilon^2}{2} - \frac{\epsilon^3}{3}\right)^{-1},$$

resulting in the following upper bound:

$$k_0 \leq 2\log(2/\delta)\left(\frac{\epsilon^2}{2} - \frac{\epsilon^3}{3}\right)^{-1} = 4\epsilon^{-2}\log(1/\delta)\,[1+o(1)]\,,$$

where $o(1)$ approaches zero as both ϵ and δ approach zero.

A lower bound on k_0 was not given until 2003 when Alon (2003) proved that

$$k_0 \geq c\epsilon^{-2}\log(1/\delta)\Big/\log(1/\epsilon)$$

for some absolute constant $c > 0$. Improving Alon's work, Jayram and Woodruff (2013) and Kane et al. (2011) showed, through different methods, that, for some absolute constant $c_1 > 0$, there is no (ϵ,δ)-JL distribution for $k \leq c_1\epsilon^{-2}\log\frac{1}{\delta}$. Hence, there is a lower bound of the form $k_0 \geq c_1\epsilon^{-2}\log\frac{1}{\delta}$. This situation is summarized in Figure 1.

The goal of the current paper is to close the gap between the upper and lower bounds in the limit. In particular, we prove an optimal lower bound that asymptotically matches the known upper bound when ϵ and δ approach 0, see Theorem 2. This means that $4\epsilon^{-2}\log(1/\delta)$ is an asymptotic threshold for k_0 where a phase change phenomenon occurs. The main result of this paper is captured in the following theorem:

Theorem 2 *For ϵ and δ sufficiently small, $k_0 \approx 4\epsilon^{-2}\log(1/\delta)$. More precisely,*

$$\lim_{\epsilon,\delta\to 0} \frac{k_0(\epsilon,\delta)}{4\epsilon^{-2}\log(1/\delta)} = 1.$$

The rest of the paper is organized as follows: To prove Theorem 2, we follow the approach of Kane et al. (2011). To make their constant c_1 explicit, however, we must use a more careful argument. In Section 2, we provide explicit conditions under which we prove the main result, Theorem 2. We delay the proofs of these conditions until Section 3 in order to make the main result more accessible, since only the statements of these results are needed and not their more technical proofs. In Section 3, we prove probabilistic bounds on $s = x_1^2 + \cdots + x_k^2$ where $x = (x_1, \cdots, x_k, \cdots, x_d)$ is a random variable uniformly distributed on S^{d-1}. These bounds explicitly determine the hidden constants in the bounds on $\text{Prob}\,[s < s_0(1-\epsilon)]$ and $\text{Prob}\,[s > s_0(1+\epsilon)]$ from (Kane et al., 2011, Theorem 20). These bounds can be viewed as explicit bounds for concentration theorems for laws of large numbers from probability theory. In the Appendix, we provide an alternate proof of a result in Kane et al. (2011), showing that if $d\Omega_{d-1}$ is the surface area for the $(d-1)$-dimensional sphere S^{d-1}, then for any $1 \leq k \leq d$,

$$d\Omega_{d-1} = \frac{1}{2}f(s)ds\,d\Omega_{k-1}d\Omega_{d-k-1},$$

where $s \in [0,1]$ and $f(s) = s^{\frac{k-2}{2}}(1-s)^{\frac{d-k-2}{2}}$.

2. Asymptotic Threshold Bound

In this section, we prove the asymptotic threshold bound for JL transformations. In particular, we provide specific conditions that result in the asymptotic threshold bound of $4\epsilon^{-2}\log(1/\delta)$. In Section 3, we prove that these conditions hold, but the details of these proofs are more technical and are unnecessary to understand the main results of this paper.

2.1. The Uniform Distribution on S^{d-1}

There is a unique probability distribution, called the uniform distribution, on the $(d-1)$-dimensional sphere S^{d-1} that is invariant under the orthonormal group. We express the uniform distribution on S^{d-1} in terms of the surface area differential form $d\Omega_{d-1}$, which means that, for any measurable subset $V \subset S^{d-1}$, the $(d-1)$-dimensional surface area of V is equal to the integral with respect to $d\Omega_{d-1}$, i.e., $\text{Vol}_{d-1}(V) = \int_V d\Omega_{d-1}$.[1] Thus, the uniform distribution on S^{d-1} corresponds to the measure $d\Omega_{d-1}/\text{Vol}_{d-1}\left(S^{d-1}\right)$.

As we are interested in reducing a d-dimensional vector to a k-dimensional vector for $1 \leq k < d$, we derive a relationship between the uniform distribution on S^{d-1} and the uniform distributions on S^{k-1} and S^{d-k-1}. Following the approach of Kane et al. (2011), for $1 \leq k < d$, we define an injective map

$$\Psi : S^{d-1} \to [0,1] \times S^{k-1} \times S^{d-k-1}$$

as follows: For any $x = (x_1, x_2, \ldots, x_d)^t \in S^{d-1}$, we define s in $\Psi(x) = (s,u,v)$ as $s = x_1^2 + \cdots + x_k^2$. In the case where $0 < s < 1$, we define

$$u = (x_1, \ldots, x_k)^t/\sqrt{s} \quad \text{and} \quad v = (x_{k+1}, \ldots, x_d)^t/\sqrt{1-s}.$$

1. In this paper, we suppress the pullback maps on equalities for differential forms since there is a unique (almost) bijective map under consideration in each case. We leave the details to the interested reader.

When $s = 0$, i.e., $x_1 = \cdots = x_k = 0$, we define $u = (1, 0, \ldots, 0)^t$ (or any point in S^{k-1}) and $v = (x_{k+1}, \ldots, x_d)^t$. Similarly, for $s = 1$, we define $u = (x_1, \ldots, x_k)^t$ and $v = (1, 0, \ldots, 0)^t$ (or any point in S^{d-k-1}). It is straight-forward to check that Ψ is injective. In addition, the complement of the image of Ψ is a subset of $\{0, 1\} \times S^{k-1} \times S^{d-k-1}$, which has, in turn, $(d-1)$-dimensional surface area equal to 0. Therefore, when convenient, we assume that $s \in (0, 1)$.

For $s \in [0, 1]$, we define

$$f(s) = s^{\frac{k-2}{2}}(1-s)^{\frac{d-k-2}{2}}.$$

In the Appendix, we provide alternative proof to the computation in Kane et al. (2011) which shows that, via the map Ψ,

$$d\Omega_{d-1} = \frac{1}{2} f(s) ds \, d\Omega_{k-1} d\Omega_{d-k-1}.$$

Equivalently, in term of probability distributions,

$$\frac{d\Omega_{d-1}}{\mathrm{Vol}_{d-1}\left(S^{d-1}\right)} = Bf(s)ds \frac{d\Omega_{k-1}}{\mathrm{Vol}_{k-1}\left(S^{k-1}\right)} \frac{d\Omega_{d-k-1}}{\mathrm{Vol}_{d-k-1}\left(S^{d-k-1}\right)}, \tag{2}$$

where

$$B = \frac{1}{2} \frac{\mathrm{Vol}_{k-1}\left(S^{k-1}\right) \mathrm{Vol}_{d-k-1}\left(S^{d-k-1}\right)}{\mathrm{Vol}_{k-1}\left(S^{k-1}\right)} = \frac{\Gamma(\frac{d}{2})}{\Gamma(\frac{k}{2})\Gamma(\frac{d-k}{2})}.$$

is an appropriate scaling constant, depending on the gamma function, for more details, see the Appendix. Moreover, in this situation, we observe that $Bf(s)$ is a probability distribution on $[0, 1]$. This implies that the uniform distribution on S^{d-1} is a direct product of the distributions on the factors. In other words, a uniformly distributed random variable X_{d-1} on S^{d-1} can be decomposed into three random variables $\Psi(X_{d-1}) = (S, X_{k-1}, X_{d-k-1})$ with the following properties:

(i) S is a random variable on $[0, 1]$ with density function $Bf(s)$,

(ii) X_{k-1} and X_{d-k-1} are uniformly distributed on S^{k-1} and S^{d-k-1}, and

(iii) The random variables S, X_{k-1}, and X_{d-k-1} are *independent*.

The independence of these three random variables is a key property in our proof as it allows us to study the three spaces separately.

2.2. Upper Bound: Explicit JL Distribution

We recall that Achlioptas (2003) proved that

$$k_0(\epsilon, \delta) \leq 2\log(2/\delta) \left(\frac{\epsilon^2}{2} - \frac{\epsilon^3}{3}\right)^{-1} = 4\epsilon^{-2}\log(1/\delta)\left[1 + o(1)\right].$$

In this section, we give an alternate proof of this result using the approach and bounds from this paper.

We recall the following construction by Dasgupta and Gupta (2003): A distribution $\mathcal{D}$ on $k \times d$ matrices is formed by picking a $d \times d$ orthonormal matrix $V = (v_1, \ldots, v_d)^t$ uniformly

at random with respect to the Haar measure on orthonormal matrices and then letting $A = \frac{1}{\sqrt{s_0}}(v_1, \ldots, v_k)^t$, where $s_0 = k/d$. The following proposition shows that $k_0(\epsilon, \delta) \leq 4\epsilon^{-2}\log(1/\delta)\left[1 + o(1)\right]$, which, in turn, implies that the limit appearing in Theorem 2 (if it exists) is at most 1:

Proposition 3 *Let $0 < \epsilon, \delta < \frac{1}{2}$ and $s_0 = k/d$. Suppose that there is some constant C so that*

$$\max\{\mathrm{Prob}_{x\sim S^{d-1}}\left[s < s_0(1-\epsilon)\right], \mathrm{Prob}_{x\sim S^{d-1}}\left[s > s_0(1+\epsilon)\right]\} \leq Ce^{-\frac{k-2}{4}\epsilon^2\left(1-\frac{2}{3}\epsilon\right)},$$

where $s = x_1^2 + \cdots + x_k^2$ is defined as in $\Psi(x) = (s, u, v)$. Then, there exists an $o(1)$ function, which approaches zero as both ϵ and δ approach zero so that if $k > 4\epsilon^{-2}\log\left(\frac{1}{\delta}\right)\left[1 + o(1)\right]$, then the distribution on $k \times d$ random matrices defined as above is an (ϵ, δ)-JL distribution, that is, for any $w \in S^{d-1}$,

$$\mathrm{Prob}_{A\sim\mathcal{D}}\left[\left|\|Aw\|_2^2 - 1\right| < \epsilon\right] \geq 1 - \delta.$$

Proof Let V be the random orthogonal matrix as defined above, and let $x = (x_1, \ldots, x_d)^t = Vw$. Then $Aw = \sqrt{s_0^{-1}}(x_1, \ldots, x_k)^t$, and

$$||Aw||_2^2 = \frac{1}{s_0}(x_1^2 + \cdots + x_k^2).$$

Since V is orthonormal and $||w||_2 = 1$, we have that $||x||_2 = 1$, and, hence, $x \in S^{d-1}$. We observe that since V is a random orthogonal matrix, for fixed $w \in S^{d-1}$, $x = Vw$ is a random variable, uniformly distributed on S^{d-1}. Hence,

$$\mathrm{Prob}_{A\sim\mathcal{D}}\left[\left|\|Aw\|_2^2 - 1\right| > \epsilon\right] = \mathrm{Prob}_{x\sim S^{d-1}}\left[\left|\frac{1}{s_0}\sum_{i=1}^{k} x_i^2 - 1\right| > \epsilon\right],$$

where $x \sim S^{d-1}$ means that x is a random variable uniformly distributed on S^{d-1}. Let $s = \sum_{i=1}^{k} x_i^2$. Then, $s \in [0, 1]$ and the probability above becomes

$$\mathrm{Prob}_{x\sim S^{d-1}}\left[s < s_0(1-\epsilon)\right] + \mathrm{Prob}_{x\sim S^{d-1}}\left[s > s_0(1+\epsilon)\right] \leq 2Ce^{-\frac{k-2}{4}\epsilon^2\left(1-\frac{2}{3}\epsilon\right)}, \tag{3}$$

by assumption. We observe that when

$$k > 4\epsilon^{-2}\log\left(\frac{1}{\delta}\right)\left[1 + \frac{2\epsilon}{3-2\epsilon} + \frac{\log(2C)}{\log\left(\frac{1}{\delta}\right)}\frac{1}{1-2\epsilon/3} + \frac{2\epsilon^2}{4\log\left(\frac{1}{\delta}\right)}\right] = 4\epsilon^{-2}\log\left(\frac{1}{\delta}\right)\left[1 + o(1)\right], \tag{4}$$

the right-hand-side of Inequality (3) is less than δ. In this case, the $o(1)$ term needed in the theorem statement appears in Inequality (4). Therefore, when $k > 4\epsilon^{-2}\log\left(\frac{1}{\delta}\right)\left[1 + o(1)\right]$, the distribution $\mathcal{D}$ is an (ϵ, δ)-JL distribution. ■

We observe that this result also follows from work in Dasgupta and Gupta (2003). In particular, (Dasgupta and Gupta, 2003, Lemma 2.2) can be used to derive bounds similar to the assumed bounds in this statement.

2.3. Lower Bound for Arbitrary Distributions

In this section, we prove an optimal lower bound on the limit in Theorem 2 that matches the upper bound from the previous section. The proof of this lower bound is the main challenge in this paper. We begin with the following key lemma:

Lemma 4 *Let $x = (x_1, \ldots, x_d)^t$ be a random variable, uniformly distributed on S^{d-1}, $\Psi(x) = (s, u, v)$, and $s_0 = k/d$. Suppose that for a fixed $\epsilon > 0$,*

$$\min\{\text{Prob}\left[s > s_0(1+\epsilon)\right], \text{Prob}\left[s < s_0(1-\epsilon)\right]\} \geq L,$$

where s is a random variable with probability distribution $Bf(s)$ on $[0,1]$. For any function $c(u,v) > 0$ depending only on $u \in S^{k-1}$ and $v \in S^{d-k-1}$ (i.e., independent of s), we have

$$\text{Prob}_{x \sim S^{d-1}}\left[|sc - 1| > \epsilon\right] \geq L.$$

Proof By the equality of differential forms in Equation (2),

$$\begin{aligned}\text{Prob}\left[|sc-1| > \epsilon\right] &= \int_{|sc-1|>\epsilon} Bf(s)ds \frac{d\Omega_{k-1}}{\text{Vol}_{k-1}\left(S^{k-1}\right)} \frac{d\Omega_{d-k-1}}{\text{Vol}_{d-k-1}\left(S^{d-k-1}\right)} \\ &= \int_{S^{k-1}\times S^{d-k-1}} \left(\int_{|sc-1|>\epsilon} Bf(s)ds\right) \frac{d\Omega_{k-1}}{\text{Vol}_{k-1}\left(S^{k-1}\right)} \frac{d\Omega_{d-k-1}}{\text{Vol}_{d-k-1}\left(S^{d-k-1}\right)}.\end{aligned}$$

Our goal is to find a lower bound on the integral $\int_{|sc-1|>\epsilon} Bf(s)ds$. Due to the independence of u, v, and s, $c(u,v)$ is a fixed positive constant within this integral. We observe that $|sc-1| > \epsilon$ consists of two intervals, $s < (1-\epsilon)/c$ and $s > (1+\epsilon)/c$, and we consider two cases depending on the value of c.

We begin by recalling that

$$\text{Prob}\left[s > s_0(1+\epsilon)\right] = \int_{s>s_0(1+\epsilon)} Bf(s)ds \quad \text{and} \quad \text{Prob}\left[s < s_0(1-\epsilon)\right] = \int_{s<s_0(1-\epsilon)} Bf(s)ds.$$

If $c \geq s_0$, then $(1+\epsilon)/c \leq (1+\epsilon)/s_0$, and, hence

$$\int_{|sc-1|>\epsilon} Bf(s)ds \geq \int_{s>(1+\epsilon)/c} Bf(s)ds \geq \int_{s>(1+\epsilon)/s_0} Bf(s)ds \geq L.$$

On the other hand, if $c < s_0$, then $(1-\epsilon)/s_0 < (1-\epsilon)/c$, then

$$\int_{|sc-1|>\epsilon} Bf(s)ds \geq \int_{s<(1-\epsilon)/c} Bf(s)ds \geq \int_{s<(1-\epsilon)/s_0} Bf(s)ds \geq L.$$

Therefore, the integral $\int_{|sc-1|>\epsilon} Bf(s)ds$ is bounded from below by L, and

$$\text{Prob}\left[|sc-1| > \epsilon\right] \geq \int_{S^{k-1}\times S^{d-k-1}} L \frac{d\Omega_{k-1}}{\text{Vol}_{k-1}\left(S^{k-1}\right)} \frac{d\Omega_{d-k-1}}{\text{Vol}_{d-k-1}\left(S^{d-k-1}\right)} = L. \quad \blacksquare$$

We now show that when $k \leq \eta\epsilon^{-2}\log(1/\delta)$ with $\eta < 4$, and ϵ and δ are sufficiently small, there does not exist an (ϵ,δ)-JL distribution on $\mathbb{R}^{k\times d}$. This fact, combined with the results in Section 2.2, shows that the limit appearing in Theorem 2 exists and equals 1. In order to show this, we consider the following related problem: By definition, for a probability distribution $\mathcal{D}$ on $\mathbb{R}^{k\times d}$ to be an (ϵ,δ)-JL distribution, the following inequality must hold for every $w \in S^{d-1}$:

$$\text{Prob}_{A\sim\mathcal{D}}\left[\left|\|Aw\|_2^2 - 1\right| > \epsilon\right] < \delta.$$

Hence,

$$\text{Prob}_{A\sim\mathcal{D},\ w\sim S^{d-1}}\left[\left|\|Aw\|_2^2 - 1\right| > \epsilon\right] < \delta, \tag{5}$$

where $w \in S^{d-1}$ is a random variable distributed uniformly on S^{d-1}. Following the approach of Kane et al. (2011), our goal is to prove that, for every $A \in \mathbb{R}^{k\times d}$,

$$\text{Prob}_{w\sim S^{d-1}}\left[\left|\|Aw\|_2^2 - 1\right| > \epsilon\right] > \delta. \tag{6}$$

When Inequality (6) holds for all A, then Inequality (5) cannot hold for any distribution $\mathcal{D}$ on $\mathbb{R}^{k\times d}$. Therefore, an (ϵ,δ)-JL distribution does not exist. We make this precise in the following theorem:

Theorem 5 *Suppose that $\eta < 4$ and let $k(\epsilon,\delta) = \left\lfloor \eta\epsilon^{-2}\log\left(\frac{1}{\delta}\right)\right\rfloor$. Let $s_0 = k/d$, and suppose that, for every ϵ, δ, and s_0 sufficiently small (to make s_0 sufficiently small, d must be sufficiently large),*

$$\min\{\text{Prob}\left[s > s_0(1+\epsilon)\right], \text{Prob}\left[s < s_0(1-\epsilon)\right]\} \geq C\delta^{\frac{\eta}{4}\gamma},$$

where $C > 0$ is an absolute constant, and γ approaches 1 as ϵ, δ, and s_0 approach 0. Then, by decreasing ϵ, δ, and s_0 as needed, for every matrix $A \in \mathbb{R}^{k(\epsilon,\delta)\times d}$,

$$\text{Prob}_{w\sim S^{d-1}}\left[\left|\|Aw\|_2^2 - 1\right| > \epsilon\right] > \delta.$$

Proof We assume that A has rank $k = k(\epsilon,\delta)$ since, if not, we may reduce k (and decrease η correspondingly) to the rank of A. Let $A = U\Sigma V^t$ be the singular value decomposition of A where U is a $k\times k$ orthonormal matrix, $V = (v_1,\ldots,v_d)$ is a $d\times d$ orthonormal matrix, and Σ is a $k\times d$ diagonal matrix with $\lambda_i > 0$ its entry at $\Sigma_{i,i}$ for $1 \leq i \leq k$. Let

$$x = (x_1,\ldots,x_d)^t = V^t w.$$

Since V is orthonormal, we have $x \in S^{d-1}$. We observe that since w is a uniformly distributed random variable on S^{d-1}, $V^t w$ is also a uniformly distributed random variable on S^{d-1}. Therefore, since U is orthonormal, we have

$$\|Aw\|_2^2 = \|U\Sigma x\|_2^2 = \|\Sigma x\|_2^2 = \sum_{i=1}^k \lambda_i^2 x_i^2.$$

We recall the definition of the function $\Psi(x) = (s,u,v)$ where $s = x_1^2 + \cdots + x_k^2$. Moreover, we restrict our attention to the case where $s \in (0,1)$ since the complement has zero measure. Let

$$c = \sum_{i=1}^k \lambda_i^2 x_i^2/s = \|\Sigma_{k\times k} u\|_2^2,$$

where $\Sigma_{k\times k}$ denotes the $k \times k$ principal submatrix of Σ, then

$$\text{Prob}_{w\sim S^{d-1}}\left[\left|\|Aw\|_2^2 - 1\right| > \epsilon\right] = \text{Prob}_{x\sim S^{d-1}}\left[|sc - 1| > \epsilon\right].$$

Due to the independence of u, v, and s, it follows that c depends only on u. Therefore, by Lemma 4, it follows that

$$\text{Prob}_{w\sim S^{d-1}}\left[\left|\|Aw\|_2^2 - 1\right| > \epsilon\right] \geq C\delta^{\frac{\eta}{4}\gamma}.$$

It follows that for ϵ, δ, and s_0 sufficiently small, $C\delta^{\frac{\eta}{4}\gamma} > \delta$. ■

Therefore, by selecting ϵ, δ, and s_0 sufficiently small, it follows from Theorem 5 that there is no (ϵ, δ)-JL distribution when $k < \eta\epsilon^{-2}\log\left(\frac{1}{\delta}\right)$ for $\eta < 4$. Therefore, $k_0(\epsilon, \delta) \geq \eta\epsilon^{-2}\log\left(\frac{1}{\delta}\right)$. We collect the results of Proposition 3 and Theorem 5 in the following corollary:

Corollary 6 *Assume the hypotheses on* $\text{Prob}\left[s > s_0(1+\epsilon)\right]$ *and* $\text{Prob}\left[s < s_0(1-\epsilon)\right]$ *from Proposition 3 and Theorem 5 hold.*

(a) There exists an $o(1)$ *function that approaches* 0 *as* ϵ *and* δ *approach zero such that if* $k > 4\epsilon^{-2}\log\left(\frac{1}{\delta}\right)[1 + o(1)]$*, then there exists a JL distribution.*

(b) If $k(\epsilon, \delta) = \left\lfloor \eta\epsilon^{-2}\log\left(\frac{1}{\delta}\right)\right\rfloor$*, then, by decreasing* ϵ *and* δ*, and increasing* d*, there is no* (ϵ, δ)*-JL distribution for any* $k' \leq k(\epsilon, \delta)$*.*

This proves the main result in the paper. In the following section, we provide the more technical results that verify the assumptions in Proposition 3 and Theorem 5.

3. Explicit Concentration Bounds

Throughout this section, we assume that s is a random variable with probability distribution $Bf(s)$. We define $s_0 = \frac{k}{d}$, and we further assume that $0 \leq \epsilon, \delta \leq 1/2$, $k - 4 \geq \epsilon^{-2}$ and $s_0 < 0.4$. We derive lower and upper bounds for the following probabilities:

$$\text{Prob}\left[s > s_0(1+\epsilon)\right] \quad \text{and} \quad \text{Prob}\left[s < s_0(1-\epsilon)\right],$$

using the probability density $Bf(s)$ for s and $f(s) = s^{(k-2)/2}(1-s)^{(d-k-2)/2}$. These probabilities appear in (Kane et al., 2011, Theorem 20) without the explicit constants that are derived in this paper. These bounds are instances of explicit concentration theorems (or explicit laws of large numbers) from probability theory. Our goal is to formulate these bounds as precisely as possible so that the lower and upper bounds are asymptotically the same when ϵ and δ approach 0.

3.1. Bounds for B

We recall that $\Gamma(1/2) = \sqrt{\pi}$, $\Gamma(1) = 1$, and $\Gamma(1+z) = z\Gamma(z)$. Hence

$$\Gamma\left(\frac{d}{2}\right) = \left(\frac{d}{2} - 1\right)! \text{ if } d \text{ is even, and } \Gamma\left(\frac{d}{2}\right) = \left(\frac{d}{2} - 1\right)\left(\frac{d}{2} - 2\right)\cdots\frac{3}{2}\frac{1}{2}\sqrt{\pi} \text{ if } d \text{ is odd.}$$

In this section, we derive lower and upper bounds for B, see Equation (38), by using the following form of Stirling's approximation of $n!$ due to Robbins (1955):

$$\sqrt{2\pi}n^{n+1/2}e^{-n}e^{\frac{1}{12n+1}} < \Gamma(n+1) = n! < \sqrt{2\pi}n^{n+1/2}e^{-n}e^{\frac{1}{12n}}.$$

Since we are interested in the asymptotic behavior, we focus on the case where d is even. This choice does not affect the asymptotic results of our paper, but the calculations are more straight-forward in this case. We leave the details for the case where d is odd to the interested reader.

Lemma 7 *Suppose* k *and* d *are both even. Then we have the following inequality:*[2]

$$\frac{e^{-2}}{2\sqrt{\pi}}\frac{(d-2)^{(d-1)/2}}{(k-2)^{(k-1)/2}(d-k-2)^{(d-k-1)/2}} \leq B \leq \frac{e^{-1}}{2\sqrt{\pi}}\frac{(d-2)^{(d-1)/2}}{(k-2)^{(k-1)/2}(d-k-2)^{(d-k-1)/2}}.$$

Proof Using the bound on $n!$ from Robbins (1955), we obtain

$$C_0\frac{(d-2)^{(d-1)/2}}{(k-2)^{(k-1)/2}(d-k-2)^{(d-k-1)/2}} \leq B \leq C_1\frac{(d-2)^{(d-1)/2}}{(k-2)^{(k-1)/2}(d-k-2)^{(d-k-1)/2}},$$

where

$$C_0 = \frac{1}{2\sqrt{\pi}}e^{-1}e^{\frac{1}{6(d-2)+1}}e^{\frac{-1}{6(k-2)}}e^{\frac{-1}{6(d-k-2)}} \geq \frac{e^{-2}}{2\sqrt{\pi}}, \quad \text{and}$$

$$C_1 = \frac{1}{2\sqrt{\pi}}e^{-1}e^{\frac{1}{6(d-2)}}e^{\frac{-1}{6(k-2)+1}}e^{\frac{-1}{6(d-k-2)+1}} \leq \frac{e^{-1}}{2\sqrt{\pi}}.$$ ■

Corollary 8 *With* $s_0 = k/d$*, we have*

$$\frac{e^{-2}}{2\sqrt{\pi}}\sqrt{k} \leq Bs_0f(s_0) \leq \frac{9e^{-1}}{\sqrt{2\pi}}\sqrt{k}.$$

Proof By evaluating f at s_0 and replacing B by its lower bound found in Lemma 7, we obtain the lower bound

$$Bs_0f(s_0) \geq \frac{e^{-2}}{2\sqrt{\pi}}\sqrt{k}\left(\frac{d-2}{d-k}\right)^{\frac{1}{2}}\left(\frac{k(d-2)}{d(k-2)}\right)^{\frac{k-1}{2}}\left(\frac{(d-k)(d-2)}{d(d-k-2)}\right)^{\frac{d-k-1}{2}} \geq \frac{e^{-2}}{2\sqrt{\pi}}\sqrt{k}.$$

Similarly, by using the upper bound in Lemma 7, we obtain the upper bound

$$Bs_0f(s_0) \leq \frac{e^{-1}}{2\sqrt{\pi}}\sqrt{k}\left(\frac{d-2}{d}\right)^{\frac{d-1}{2}}\left(\frac{k}{k-2}\right)^{\frac{k-1}{2}}\left(\frac{d-k}{d-k-2}\right)^{\frac{d-k-1}{2}}\frac{\sqrt{d}}{\sqrt{d-k}} \leq \frac{9e^{-1}}{\sqrt{2\pi}}\sqrt{k},$$

where the last inequality follows from $\frac{d}{d-k} \leq 2$ since $s_0 < 0.4$, and $\left(\frac{x}{x-2}\right)^{\frac{x-1}{2}} \leq 3$ for $x \geq 3$. ■

2. Throughout this section, it is possible to derive tighter bounds on constants in the following inequalities, but the ones appearing here are sufficient for our proofs. We leave the details of the tighter bounds to the interested reader.

3.2. Bounds on Prob $[s > s_0(1+\epsilon)]$

We begin by mentioning the following inequalities which are used in our arguments below:

$$\log(1+x) \geq x - \frac{x^2}{2} \quad \text{for } 0 < x < 1, \tag{7}$$

$$\log(1-x) \geq -x - x^2 \quad \text{for } 0 < x < 0.68, \tag{8}$$

$$\log(1+x) \leq x \quad \text{for } x > -1, \quad \text{and} \tag{9}$$

$$\log(1+x) \leq x - \frac{x^2}{2} + \frac{x^3}{3} \quad \text{for } x > -1. \tag{10}$$

These bounds can be verified by employing basic calculus techniques (e.g., derivatives and Taylor expansions) as well as sufficiently accurate approximations. Using these inequalities, we derive the following bounds:

Lemma 9

$$\text{Prob}\left[s > s_0(1+\epsilon)\right] \geq \frac{e^{-2}}{4\sqrt{\pi}} e^{-\frac{1}{4}(\sqrt{k}\epsilon+1)^2 \frac{1+s_0}{1-s_0}}.$$

Moreover, when $k < \eta\epsilon^{-2}\log\frac{1}{\delta}$,

$$\text{Prob}\left[s > s_0(1+\epsilon)\right] \geq \frac{e^{-2}}{4\pi}\delta^{\frac{\eta}{4}\gamma_1},$$

where

$$\gamma_1 = \left(1 + (\eta\log(1/\delta))^{-1/2}\right)^2 \left(\frac{1+s_0}{1-s_0}\right).$$

Additionally, γ_1 *approaches* 1 *as* ϵ, δ, *and* s_0 *approach* 0.

Proof Note that

$$\text{Prob}\left[s > s_0(1+\epsilon)\right] = B\int_{s>s_0(1+\epsilon)} f(s)ds = Bs_0\int_{\epsilon}^{\frac{1}{s_0}-1} f(s_0(1+x))dx, \tag{11}$$

via the substitution $s = s_0(1+x)$.

Let $g(s) = s^{k/2}(1-s)^{(d-k)/2}$, then $f(s_0(1+x))$ can be expressed in terms of $g(s)$, namely,

$$f(s_0(1+x)) = \frac{g(s_0(1+x))}{s_0(1+x)\left(1-s_0(1+x)\right)}. \tag{12}$$

To find a lower bound on Prob $[s > s_0(1+\epsilon)]$, we compute a bound on $g(s_0(1+x))$ from below. Taking the logarithm of $g(s_0(1+x))$, we find

$$\log\left(g(s_0(1+x))\right) = \log g(s_0) + \frac{d}{2}\left(s_0\log(1+x) + (1-s_0)\log\left(1 - \frac{s_0}{1-s_0}x\right)\right). \tag{13}$$

Restricting x to the interval $0 \leq x < 1$, it then follows that $0 < \frac{s_0}{1-s_0}x < 0.68$ from the assumption that $s_0 < 0.4$. We now bound the second term in Equation (13) using Inequalities (7) and (8), as follows:

$$s_0\log(1+x) + (1-s_0)\log\left(1 - \frac{s_0}{1-s_0}x\right) \geq -\left(\frac{s_0(1+s_0)}{2(1-s_0)}\right)x^2. \tag{14}$$

Hence, by substituting Inequality (14) into Equation (13) and exponentiating, we obtain the following lower bound for $g(s_0(1+x))$:

$$g(s_0(1+x)) \geq g(s_0)e^{-\frac{k}{4}x^2\frac{1+s_0}{1-s_0}}. \tag{15}$$

We also observe that since $s_0 < 0.4$ and $0 \leq x < 1$, the denominator of Equation (12) is bounded from below as follows:

$$\frac{1}{s_0(1+x)(1-s_0(1+x))} \geq \frac{1}{2s_0(1-s_0)}. \tag{16}$$

Therefore, by substituting Inequalities (15) and (16) into Equation (12) when $0 \leq x < 1$, we have

$$f(s_0(1+x)) \geq \frac{g(s_0)}{2s_0(1-s_0)}e^{-\frac{k}{4}x^2\frac{1+s_0}{1-s_0}} = \frac{1}{2}f(s_0)e^{-\frac{k}{4}x^2\frac{1+s_0}{1-s_0}}. \tag{17}$$

Since $s_0 < 0.4$, we observe that $\frac{1}{s_0} - 1 = \frac{d-k}{k} > 1.5$. Since we assumed that $\epsilon < \frac{1}{2}$ and $k \geq 4 + \epsilon^{-2} > 4$, it follows that $\epsilon + k^{-1/2} < 1$ and so $\epsilon + k^{-1/2} < 1 < \frac{1}{s_0} - 1$. Therefore, we further restrict x to the interval $(\epsilon, \epsilon + k^{-1/2})$ and observe that Inequality (17) applies in this range. Therefore, since f is a positive function,

$$Bs_0\int_{\epsilon}^{\frac{1}{s_0}-1} f(s_0(1+x))dx \geq Bs_0\int_{\epsilon}^{\epsilon+k^{-1/2}} f(s_0(1+x))dx \geq \frac{1}{2}Bs_0f(s_0)\int_{\epsilon}^{\epsilon+k^{-1/2}} e^{-\frac{k}{4}x^2\frac{1+s_0}{1-s_0}}dx. \tag{18}$$

Replacing $Bs_0f(s_0)$ with its lower bound given in Corollary 8 and observing that the integrand is decreasing over an interval of width $k^{-1/2}$, Inequality (18) is bounded from below by

$$\frac{1}{2}Bs_0f(s_0)\int_{\epsilon}^{\epsilon+k^{-1/2}} e^{-\frac{k}{4}x^2\frac{1+s_0}{1-s_0}}dx \geq \frac{e^{-2}}{4\sqrt{\pi}}e^{-\frac{1}{4}(\sqrt{k}\epsilon+1)^2\frac{1+s_0}{1-s_0}},$$

which completes the first inequality. The second inequality follows by replacing k by the given upper bound and simplifying. ■

Lemma 10

$$\text{Prob}\left[s > s_0(1+\epsilon)\right] \leq \frac{27e^{-1}}{\sqrt{2\pi}}e^{-\frac{k-2}{4}\epsilon^2(1-\frac{2}{3}\epsilon)}.$$

Proof To derive an upper bound, we start with the expression for Prob $[s > (1+\epsilon)s_0]$ from Equation (11). We first find an upper bound on $f(s_0(1+x))$. Then, we bound $f(s_0(1+x))$ using the inequality $1 - x \leq e^{-x}$ for all x as follows:

$$f(s_0(1+x)) = f(s_0)(1+x)^{\frac{k-2}{2}}\left(1 - \frac{s_0}{1-s_0}x\right)^{\frac{d-k-2}{2}} \leq f(s_0)(1+x)^{\frac{k-2}{2}}\left(e^{\frac{-s_0}{1-s_0}x}\right)^{\frac{d-k-2}{2}}, \tag{19}$$

Moreover, since $s_0 < 0.4$,

$$\frac{s_0}{1-s_0}\frac{d-k-2}{2} = \frac{k}{d-k}\frac{d-k-2}{2} > \frac{k-2}{2}. \tag{20}$$

By applying Inequality (20) to Inequality (19), we derive the upper bound

$$f(s_0)(1+x)^{\frac{k-2}{2}}e^{-\frac{k-2}{2}x}.$$

Therefore, by extending the region of integration in Inequality (11), we find the following upper bound on the probability:

$$Bs_0\int_\epsilon^{\frac{1}{s_0}-1} f(s_0(1+x))dx \le Bs_0 f(s_0)\int_\epsilon^\infty (1+x)^{\frac{k-2}{2}}e^{-\frac{k-2}{2}x}dx. \tag{21}$$

By integrating by parts, we observe that for any ℓ and m with $1 \le \ell \le m$,

$$\int_\epsilon^\infty (1+x)^\ell e^{-mx}dx \le \frac{1}{m}(1+\epsilon)^\ell e^{-m\epsilon} + \int_\epsilon^\infty (1+x)^{\ell-1}e^{-mx}dx. \tag{22}$$

Applying Inequality (22) $\frac{k-2}{2}$ times to the integral in Inequality (21) and bounding the resulting geometric series from above gives

$$\int_\epsilon^\infty (1+x)^{\frac{k-2}{2}}e^{-\frac{k-2}{2}x}dx \le \frac{2e^{-\frac{k-2}{2}\epsilon}}{k-2}\sum_{i=0}^{\frac{k-2}{2}}(1+\epsilon)^i \le \frac{2(1+\epsilon)}{\epsilon(k-2)}(1+\epsilon)^{\frac{k-2}{2}}e^{-\frac{k-2}{2}\epsilon}.$$

By applying Inequality (10) to $(1+\epsilon)^{\frac{k-2}{2}} = e^{\frac{k-2}{2}\log(1+\epsilon)}$, we obtain the upper bound

$$\frac{2(1+\epsilon)}{\epsilon(k-2)}(1+\epsilon)^{\frac{k-2}{2}}e^{-\frac{k-2}{2}\epsilon} \le \frac{2(1+\epsilon)}{\epsilon(k-2)}e^{-\frac{k-2}{4}\epsilon^2(1-\frac{2}{3}\epsilon)}.$$

Since $k-4 \ge \epsilon^{-2}$, it follows that $\frac{(k-2)^2}{k} \ge k-4 \ge \epsilon^{-2}$, and, hence, that $\epsilon(k-2) \ge \sqrt{k}$. Therefore, we can further simplify our bound to

$$\frac{2(1+\epsilon)}{\epsilon(k-2)}e^{-\frac{k-2}{4}\epsilon^2(1-\frac{2}{3}\epsilon)} \le \frac{2(1+\epsilon)}{\sqrt{k}}e^{-\frac{k-2}{4}\epsilon^2(1-\frac{2}{3}\epsilon)}. \tag{23}$$

By combining Inequalities (21) and (23), we find an upper bound on the probability as follows:

$$Bs_0\int_\epsilon^{\frac{1}{s_0}-1} f(s_0(1+x))dx \le Bs_0 f(s_0)\frac{2(1+\epsilon)}{\sqrt{k}}e^{-\frac{k-2}{4}\epsilon^2(1-\frac{2}{3}\epsilon)}.$$

Applying the upper bound on $Bs_0f(s_0)$ from Corollary 8 and the assumption that $\epsilon \le \frac{1}{2}$ completes the inequality. ■

3.3. Bounds on Prob $[s < s_0(1-\epsilon)]$

We begin this section by including the following two additional inequalities on $\log(1-x)$:

$$\log(1-x) \ge -x - \frac{x^2}{2} - x^3 \quad \text{for } 0 < x < 0.815, \tag{24}$$

$$\log(1-x) \le -x - \frac{x^2}{2} \quad \text{for } 0 \le x < 1. \tag{25}$$

These bounds can be justified using a similar approach as for Inequalities (7-10). Using these inequalities, we derive the following bounds:

Lemma 11

$$\text{Prob}\left[s < s_0(1-\epsilon)\right] \ge \frac{e^{-2}}{2\sqrt{\pi}}e^{-\frac{1}{4}\left(\frac{(\sqrt{k}\epsilon+1)^2}{1-s_0}+2(\sqrt[3]{k}\epsilon+k^{-1/6})^3\right)}.$$

Moreover, when $k < \eta\epsilon^{-2}\log\frac{1}{\delta}$,

$$\text{Prob}\left[s < s_0(1-\epsilon)\right] \ge \frac{e^{-2}}{2\sqrt{\pi}}\delta^{\frac{\eta}{4}\gamma_2},$$

where

$$\gamma_2 = \frac{1}{1-s_0}\left(1+\frac{1}{\sqrt{\eta\log\frac{1}{\delta}}}\right)^2 + 2\left(\epsilon^{1/3}+\frac{1}{\sqrt[3]{\eta\log\frac{1}{\delta}}}\right)^3.$$

Additionally, γ_2 *approaches* 1 *as* ϵ, δ, *and* s_0 *approach* 0.

Proof The proof of this lemma is very similar to the proof of Lemma 9, so we focus on the new details. The probability can be rewritten, using the substitution $s = s_0(1-x)$, as

$$\text{Prob}\left[s < (1-\epsilon)s_0\right] = B\int_{s<s_0(1-\epsilon)} f(s)ds = Bs_0\int_\epsilon^1 f(s_0(1-x))dx. \tag{26}$$

Using $g(s)$ as in Lemma 9, it follows that

$$f(s_0(1-x)) = \frac{g(s_0(1-x))}{s_0(1-x)(1-s_0(1-x))} \tag{27}$$

and

$$\log g(s_0(1-x)) = \log g(s_0) + \frac{d}{2}\left(s_0\log(1-x) + (1-s_0)\log\left(1+\frac{s_0}{1-s_0}x\right)\right). \tag{28}$$

Since $0 < x \le 1$, it follows that $0 < \frac{s_0}{1-s_0}x < 0.68$ from the assumption that $s_0 < 0.4$. Therefore, we can bound the second term in Equation (28) using Inequalities (7) and (24), as follows:

$$s_0\log(1-x) + (1-s_0)\log\left(1+\frac{s_0}{1-s_0}x\right) \ge \frac{-s_0}{2(1-s_0)}x^2 - s_0x^3. \tag{29}$$

Substituting Inequality (29) into Expression (28) and exponentiating, we get

$$g(s_0(1-x)) \ge g(s_0)e^{-\frac{k}{4}\left(\frac{x^2}{1-s_0}+2x^3\right)}. \tag{30}$$

Since $s_0 < 0.4$, it follows that $\frac{s_0}{1-s_0} < 1$, and, hence, that $(1-x)\left(1+\frac{s_0}{1-s_0}x\right) < 1$. Therefore, the denominator in Equation (27) can be bounded from above by

$$s_0(1-x)\left(1-s_0(1-x)\right) = s_0(1-s_0)(1-x)\left(1+\frac{s_0x}{1-s_0}\right) \le s_0(1-s_0). \tag{31}$$

Therefore, by substituting Inequalities (30) and (31) into Expression (27), when $\epsilon < x < 1$, we have

$$f(s_0(1-x)) \geq f(s_0)e^{-\frac{k}{4}\left(\frac{x^2}{1-s_0}+2x^3\right)}. \tag{32}$$

Since $\epsilon < \frac{1}{2}$ and $k \geq 4+\epsilon^{-2} > 4$, it follows that $\epsilon + k^{-1/2} < 1$. Therefore, we restrict x to the interval $(\epsilon, \epsilon + k^{-1/2})$, and observe that Inequality (32) applies in this range. Therefore,

$$Bs_0 \int_\epsilon^1 f(s_0(1-x))dx \geq Bs_0 f(s_0) \int_\epsilon^{\epsilon+k^{-1/2}} e^{-\frac{k}{4}\left(\frac{x^2}{1-s_0}+2x^3\right)}dx. \tag{33}$$

Replacing $Bs_0 f(s_0)$ with its lower bound given in Corollary 8 and observing that the integrand is decreasing on an interval of width $k^{-1/2}$, Inequality (33) is bounded from below by

$$Bs_0 f(s_0) \int_\epsilon^{\epsilon+k^{-1/2}} e^{-\frac{k}{4}\left(\frac{x^2}{1-s_0}+2x^3\right)}dx \geq \frac{e^{-2}}{2\sqrt{\pi}} e^{-\frac{1}{4}\left(\frac{(\sqrt{k}\epsilon+1)^2}{1-s_0}+2(\sqrt[3]{k}\epsilon+k^{-1/6})^3\right)},$$

which completes the first inequality. The second inequality follows by replacing $k \geq 1$ by the given upper bound and simplifying. ■

Lemma 12

$$\text{Prob}\left[s < s_0(1-\epsilon)\right] \leq \frac{18\sqrt{2}e^{1/2}}{\sqrt{\pi}} e^{-\left(\frac{k}{4}\right)\epsilon^2} \leq \frac{18\sqrt{2}e^{1/2}}{\sqrt{\pi}} e^{-\left(\frac{k-2}{4}\right)\epsilon^2\left(1-\frac{2}{3}\epsilon\right)}.$$

Proof The proof of this lemma is very similar to the proof of Lemma 10, so we focus on the new details. To prove an upper bound, we start with the bound on $\text{Prob}\left[s < s_0(1-\epsilon)\right]$ from Equation (26). We first observe that

$$f(s_0(1-x)) = f(s_0)(1-x)^{\frac{k-2}{2}} \left(1 + \frac{s_0}{1-s_0}x\right)^{\frac{d-k-2}{2}}. \tag{34}$$

We now bound the logarithm of the second and third factors in Equation (34) using Inequalities (9) and (25) as follows:

$$\log\left((1-x)^{\frac{k-2}{2}} \left(1 + \frac{s_0}{1-s_0}x\right)^{\frac{d-k-2}{2}}\right) \leq \frac{k-2}{2}\left(-x - \frac{x^2}{2}\right) + \frac{d-k-2}{2}\left(\frac{s_0}{1-s_0}x\right) \tag{35}$$

Since $\frac{s_0}{1-s_0} = \frac{k}{d-k}$ and $\epsilon < x < 1$, Inequality (35) further simplifies to

$$\frac{k-2}{2}\left(-x - \frac{x^2}{2}\right) + \frac{d-k-2}{2}\left(\frac{k}{d-k}x\right) \leq x - \left(\frac{k-2}{4}\right)x^2 \leq \frac{3}{2} - \left(\frac{k}{4}\right)x^2.$$

Hence, for $\epsilon \leq x < 1$, we have

$$f(s_0(1-x)) \leq f(s_0)e^{3/2}e^{-\left(\frac{k}{4}\right)x^2} \leq f(s_0)e^{3/2}e^{-\left(\frac{k}{4}\right)\epsilon x}. \tag{36}$$

Substituting Inequality (36) into the integral of Equation (26), we find

$$\begin{aligned} Bs_0 \int_\epsilon^1 f(s_0(1-x))dx &\leq Bs_0 f(s_0)e^{3/2} \int_\epsilon^1 e^{-\left(\frac{k}{4}\right)\epsilon x}dx \\ &\leq Bs_0 f(s_0)e^{3/2} \int_\epsilon^\infty e^{-\left(\frac{k}{4}\right)\epsilon x}dx \leq Bs_0 f(s_0)\frac{4e^{3/2}}{k\epsilon}e^{-\frac{k}{4}\epsilon^2}. \end{aligned} \tag{37}$$

Since $k \geq \epsilon^{-2}$, Inequality (37) can be further simplified to

$$Bs_0 f(s_0)\frac{4e^{3/2}}{\sqrt{k}}e^{-\frac{k}{4}\epsilon^2}$$

Applying the upper bound on $Bs_0 f(s_0)$ from Corollary 8 completes the first inequality of the proof. The final inequality follows from the fact that $k \geq (k-2)\left(1-\frac{2}{3}\epsilon\right)$. ■

This completes the proof all of the conditions in Section 2, and, therefore, completes the proof of our main theorem, Theorem 2.

Appendix A. Uniform Distributions on Unit Spheres in High Dimensions

In this section, we study uniform distributions and surface areas (or hypervolumes) on high-dimensional spheres. More precisely, for any $d \geq 1$, let S^{d-1} denote the unit sphere of dimension $d-1$ and $d\Omega_{d-1}$ denote the surface area measure for S^{d-1}. We show that, for any $1 \leq k \leq d$,

$$d\Omega_{d-1} = \frac{1}{2}f(s)ds\, d\Omega_{k-1}d\Omega_{d-k-1},$$

where $s \in [0,1]$ and $f(s) = s^{\frac{k-2}{2}}(1-s)^{\frac{d-k-2}{2}}$. This is a more precise version of a result in Kane et al. (2011), replacing an unspecified constant by 1/2. We include the proof of this result here in order to make this result more accessible to a larger population of researchers. This formula is of independent interest since it shows that the uniform distribution on S^{d-1} is a product of uniform distributions on S^{k-1} and S^{d-k-1} with a distribution on $[0,1]$.

Theorem 13 *Under the almost bijective map $\Psi : S^{d-1} \to [0,1] \times S^{k-1} \times S^{d-k-1}$, we have equality of the surface area differential forms on S^{d-1}, S^{k-1}, and S^{d-k-1}, i.e.,*

$$d\Omega_{d-1} = \frac{1}{2}f(s)ds\, d\Omega_{k-1}d\Omega_{d-k-1},$$

where $f(s) = s^{(k-2)/2}(1-s)^{(d-k-2)/2}$. Equivalently, in terms of probability distribution measures,

$$\frac{d\Omega_{d-1}}{Vol_{d-1}\left(S^{d-1}\right)} = Bf(s)ds\frac{d\Omega_{k-1}}{Vol_{k-1}\left(S^{k-1}\right)}\frac{d\Omega_{d-k-1}}{Vol_{d-k-1}\left(S^{d-k-1}\right)}.$$

Hence, the uniform distribution on S^{d-1} can be identified with the product distribution on $[0,1] \times S^{k-1} \times S^{d-k-1}$ where the distribution of s on $[0,1]$ has density function $Bf(s)$ and

$$B = \frac{1}{2} \frac{Vol_{k-1}\left(S^{k-1}\right) \; Vol_{d-k-1}\left(S^{d-k-1}\right)}{Vol_{k-1}\left(S^{k-1}\right)} = \frac{\Gamma(\frac{d}{2})}{\Gamma(\frac{k}{2})\Gamma(\frac{d-k}{2})}. \tag{38}$$

This theorem is based on the following lemma, which is well-known to experts, but is included here for completeness.

Lemma 14 *Let $x = (x_1, \ldots, x_d)$ with $x_d > 0$ be a point on the upper hemisphere of S^{d-1}. Then the surface area measure of the unit sphere S^{d-1} at x is*

$$d\Omega_{d-1} = \frac{1}{x_d} dx_1 \ldots dx_{d-1}.$$

Before we begin the proof, we recall the approach for S^2 in 3-dimensional space. We consider the upper hemisphere of S^2 as the graph of a function over D^2, where D^{d-1} denotes $(d-1)$-dimensional disk, namely

$$D^{d-1} = \left\{ \hat{x} \in \mathbb{R}^{d-1} : \sum_{i=1}^{d-1} \hat{x}_i^2 \leq 1 \right\}.$$

We then integrate over the disk D^2 to calculate the surface area of S^2. In particular, the integrand is the limit of the ratios of the area of a square in D^2 to the area of the corresponding parallelogram above the square in the tangent space of S^2 as the square shrinks a point. In the case of the sphere, the parallelogram's area is calculated using the cross product, but we must replace the use of the cross product in higher dimensions.

Proof In d-dimensional space, we consider the upper hemisphere of S^{d-1} as the graph of a function over the $(d-1)$-dimensional disk D^{d-1}. We construct a pair of $(d-1)$-dimensional parallelepipeds as follows: P^{d-1} is in the tangent space of D^{d-1} and Q^{d-1} is in the tangent space of S^{d-1}. Then, we take the limit of their $(d-1)$-dimensional volumes as P^{d-1} approaches a point. Due to complications in taking the $(d-1)$-dimensional volume in d-dimensional space, we extend both P^{d-1} and Q^{d-1} to associated, full-dimensional parallelepipeds.

Let $(\hat{x}_1, \ldots, \hat{x}_{d-1}) \in D^{d-1}$ and define $\phi : D^{d-1} \to \mathbb{R}_{\geq 0}$ as

$$\phi(\hat{x}_1, \ldots, \hat{x}_{d-1}) = \sqrt{1 - \sum_{i=1}^{d-1} \hat{x}_i^2}.$$

We observe that the graph of this function is the upper hemisphere of S^{d-1}. We now extend this map to $D^{d-1} \times \mathbb{R}$ as $\Phi_d : D^{d-1} \times \mathbb{R} \to \mathbb{R}^d$ defined by

$$(\hat{x}_1, \ldots, \hat{x}_{d-1}, \hat{x}_d) \mapsto ((1+\hat{x}_d)\hat{x}_1, (1+\hat{x}_d)\hat{x}_2, \ldots, (1+\hat{x}_d)\hat{x}_{d-1}, (1+\hat{x}_d)\phi(\hat{x}_1, \ldots, \hat{x}_{d-1})).$$

We observe that $\Phi_d|_{D^{d-1}\times\{0\}}$ maps the disk $D^{d-1} \times \{0\}$ surjectively onto the graph of ϕ, i.e., the upper hemisphere of S^{d-1}, see Figure 2.

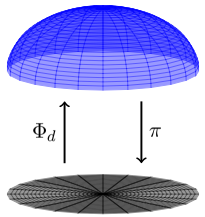

Figure 2: Φ_d maps the disk $D^{d-1} \times \{0\}$ surjectively onto the upper hemisphere of the $(d-1)$-dimensional unit sphere S^{d-1}. We observe that $(\Phi_d)^{-1} = \pi$ is the projection map onto the first $d-1$ coordinates.

We recall that, at $(\hat{x}_1, \ldots, \hat{x}_{d-1}) \in D^{d-1}$, the tangent space is $\mathbb{R}^{d-1}$ and we define the parallelepiped P^{d-1} in the tangent space by the vectors $\Delta\hat{x}_i e_i$ of length $\Delta\hat{x}_i$ in the direction of the i^{th} standard basis vector e_i of $\mathbb{R}^{d-1}$. Similarly, the tangent space at $(\hat{x}_1, \ldots, \hat{x}_{d-1}, 0) \in D^{d-1} \times \mathbb{R}$ is $\mathbb{R}^d$, and we define the parallelepiped P^d in this tangent space by the vectors $\Delta\hat{x}_i e_i$ for $1 \leq i \leq d-1$ and he_d for the final direction. Then, as the vector he_d is perpendicular to the tangent vectors of the disk D^{d-1}, the d-dimensional volume of P^d can be computed in terms of the $(d-1)$-dimensional volume of P^{d-1} and the height h, i.e.,

$$\text{Vol}_d\left(P^d\right) = h\text{Vol}_{d-1}\left(P^{d-1}\right).$$

Next, we let Q^{d-1} and Q^d be the images of P^{d-1} and P^d under the Jacobian of Φ_d, i.e., $\text{Jac}\,\Phi_d$, respectively. Note that the Jacobian of Φ_d, when restricted to $D^{d-1} \times \{0\}$, is

$$(\text{Jac}\,\Phi_d)\,|_{D^{d-1}\times\{0\}} = \left[\begin{array}{ccc|c} & & & \hat{x}_1 \\ & I & & \vdots \\ & & & \hat{x}_{d-1} \\ \hline -\frac{\hat{x}_1}{\phi(\hat{x}_1,\ldots,\hat{x}_{d-1})} & \cdots & -\frac{\hat{x}_{d-1}}{\phi(\hat{x}_1,\ldots,\hat{x}_{d-1})} & \phi(\hat{x}_1, \ldots, \hat{x}_{d-1}) \end{array}\right].$$

Since the Jacobian acts on tangent vectors, Q^{d-1} is defined by the vectors

$$\Delta\hat{x}_i \left(f_i - \frac{\hat{x}_i}{\phi(\hat{x}_1, \ldots, \hat{x}_{d-1})} f_d \right),$$

for $1 \leq i \leq d-1$, where the f_i is the i^{th} standard basis vector of $\mathbb{R}^d$. Moreover, Q^d is defined by these vectors as well as the image of he_d, i.e.,

$$h\left(\hat{x}_1, \ldots, \hat{x}_{d-1}, \phi(\hat{x}_1, \ldots, \hat{x}_{d-1})\right).$$

We observe that the vectors $\Delta\hat{x}_i \left(f_i - \frac{\hat{x}_i}{\phi(\hat{x}_1,\ldots,\hat{x}_{d-1})} f_d\right)$ for $1 \le i \le d-1$ are tangent vectors to the sphere S^{d-1}, and that $h\left(\hat{x}_1,\ldots,\hat{x}_{d-1},\phi(\hat{x}_1,\ldots,\hat{x}_{d-1})\right)$ is the outward pointing surface normal with length h. Since the tangent vectors are perpendicular to the outward pointing normal, the volumes of Q^{d-1} and Q^d have a similar relationship as the volumes of P^{d-1} and P^d, i.e.,

$$\mathrm{Vol}_d\left(Q^d\right) = h\mathrm{Vol}_{d-1}\left(Q^{d-1}\right).$$

Therefore, the ratio between the d-dimensional volumes of Q^d and P^d is the same as the ratio of the $(d-1)$-dimensional volumes of Q^{d-1} and P^{d-1}.

Since Q^d is the image of P^d under the linear map $\mathrm{Jac}\ \Phi_d\big|_{D^{d-1}\times\{0\}}$, it follows that

$$\mathrm{Vol}_d\left(Q^d\right) = \left|\det\left(\mathrm{Jac}\,\Phi_d\right)\big|_{(\hat{x}_1,\ldots,\hat{x}_{d-1},0)}\right| \mathrm{Vol}_d\left(P^d\right).$$

Therefore, the ratio of the volumes of Q^{d-1} and P^{d-1} is $\left|\det\left(\mathrm{Jac}\,\Phi_d\right)\big|_{(\hat{x}_1,\ldots,\hat{x}_{d-1},0)}\right|$. It is straight-forward to compute the determinant of $\mathrm{Jac}(\Phi_d)$ at the point $(\hat{x}_1,\ldots,\hat{x}_{d-1},0)$ via a few row reductions to eliminate the first $d-1$ entries in the last row and turn the matrix into an upper triangular matrix whose lower right corner is $\frac{1}{\phi(\hat{x}_1,\ldots,\hat{x}_{d-1})}$. Hence, the determinant of $\mathrm{Jac}(\Phi_d)$ is $\frac{1}{\phi(\hat{x}_1,\ldots,\hat{x}_{d-1})}$, which is the desired scaling factor.

Therefore, $\frac{1}{\phi(\hat{x}_1,\ldots,\hat{x}_{d-1})}$ is the local factor in the stretching of the surface area in the map from D^{d-1} to S^{d-1}. We recall that the coordinates $x_1,\ldots,x_d$ are the coordinates on the upper hemisphere and $\hat{x}_1,\ldots,\hat{x}_{d-1}$ are the coordinates on D^{d-1}. Since, under the map $\Phi_d|_{D^{d-1}\times\{0\}}$, $x_i = \hat{x}_i$ for $1 \le i \le d-1$, it follows that

$$d\hat{x}_1\ldots d\hat{x}_{d-1} = dx_1\ldots dx_{d-1} \qquad \text{and} \qquad \phi(\hat{x}_1,\ldots,\hat{x}_{d-1}) = x_d.$$

From here, the result follows directly. ■

Proof of Theorem 13 Let $(w_1,\ldots,w_d)$, $(x_1,\ldots,x_k)$, and $(y_1,\ldots,y_{d-k})$ be coordinates of points on the $(d-1)$-dimensional unit sphere, the $(k-1)$-dimensional unit sphere, and the $(d-k-1)$-dimensional unit sphere, respectively. Let $(\hat{w}_1,\ldots,\hat{w}_{d-1})$, $(\hat{x}_1,\ldots,\hat{x}_{k-1})$, and $(\hat{y}_1,\ldots,\hat{y}_{d-k-1})$ be the coordinates of points on the disks D^{d-1}, D^{k-1} and D^{d-k-1}, respectively. Let

$$\varphi : [0,1]\times D^{k-1}\times D^{d-k-1} \to D^{d-1}$$

be defined by

$$s\times(\hat{x}_1,\ldots,\hat{x}_{k-1})\times(\hat{y}_1,\ldots,\hat{y}_{d-k-1}) \mapsto \left(\sqrt{s}\hat{x}_1,\ldots,\sqrt{s}\hat{x}_{k-1},\sqrt{s}\sqrt{1-\sum_{i=1}^{k-1}\hat{x}_i^2},\sqrt{1-s}\hat{y}_1,\ldots,\sqrt{1-s}\hat{y}_{d-k-1}\right).$$

We observe that φ maps the disks D^{k-1} and D^{d-k-1} onto the half of the disk D^{d-1} whose k^{th} coordinate is nonnegative. As the measure of the image is the measure of the preimage scaled by the determinant of the Jacobian of φ, the surface area measure of the disk D^{d-1} is

$$d\hat{w}_1\ldots d\hat{w}_{d-1} = |\det\mathrm{Jac}(\varphi)|ds\,d\hat{x}_1\ldots d\hat{x}_{k-1}d\hat{y}_1\ldots d\hat{y}_{d-k-1}. \tag{39}$$

The Jacobian of φ for $s \in (0,1)$ is

$$\mathrm{Jac}\ \varphi = \left[\begin{array}{c|ccc|ccc} \frac{\hat{x}_1}{2\sqrt{s}} & \sqrt{s} & \ldots & 0 & 0 & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ \frac{\hat{x}_{k-1}}{2\sqrt{s}} & 0 & \ldots & \sqrt{s} & 0 & \ldots & 0 \\ \hline \frac{\sqrt{1-\sum_{i=1}^{k-1}\hat{x}_i^2}}{2\sqrt{s}} & \frac{-\sqrt{s}\hat{x}_1}{\sqrt{1-\sum_{i=1}^{k-1}\hat{x}_i^2}} & \ldots & \frac{-\sqrt{s}\hat{x}_{k-1}}{\sqrt{1-\sum_{i=1}^{k-1}\hat{x}_i^2}} & 0 & \ldots & 0 \\ \hline \frac{-\hat{y}_1}{2\sqrt{1-s}} & 0 & \ldots & 0 & \sqrt{1-s} & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ \frac{-\hat{y}_{d-k-1}}{2\sqrt{1-s}} & 0 & \ldots & 0 & 0 & \ldots & \sqrt{1-s} \end{array}\right].$$

Eliminating all but the k^{th} entry of the first column by adding multiples of the other columns to the first column, we obtain

$$\det\mathrm{Jac}(\varphi) = \frac{1}{2\hat{x}_k} s^{\frac{k-2}{2}}(1-s)^{\frac{d-k-1}{2}}.$$

Substituting this value into Expression (39), we have the surface area measure of D^{d-1} in terms of the disks D^{k-1} and D^{d-k-1}. That is,

$$d\hat{w}_1\ldots d\hat{w}_{d-1} = \frac{1}{2\hat{x}_k} s^{(k-2)/2}(1-s)^{(d-k-1)/2} ds\,d\hat{x}_1\ldots d\hat{x}_{k-1}d\hat{y}_1\ldots d\hat{y}_{d-k-1}. \tag{40}$$

We observe that the coordinates of the disk D^{t-1} correspond to the first $t-1$ entries of coordinates of the unit sphere S^{t-1}. Therefore, we may extend φ to the map Ψ, as defined above, where

$$\Psi^{-1} = \Phi_d \circ \varphi \circ (id_s \times (\Phi_k)^{-1} \times (\Phi_{d-k})^{-1}).$$

Employing the results of Lemma 14 in various dimensions, we rewrite the surface measure of a unit sphere in terms of the surface measure of the corresponding disks:

$$\begin{aligned} d\hat{x}_1\ldots d\hat{x}_{k-1} &= dx_1\ldots dx_{k-1} = x_k d\Omega_{k-1} \\ d\hat{y}_1\ldots d\hat{y}_{d-k-1} &= dy_1\ldots dy_{d-k-1} = y_{d-k}d\Omega_{d-k-1} \\ d\hat{w}_1\ldots d\hat{w}_{d-1} &= dw_1\ldots dw_{d-1} = w_d d\Omega_{d-1}. \end{aligned}$$

By applying the Ψ, we can substitute these three equalities into Equation (40) to obtain

$$\begin{aligned} d\Omega_{d-1} &= \frac{1}{w_d}dw_1\ldots dw_{d-1} = \frac{y_{d-k}}{2w_d} s^{(k-2)/2}(1-s)^{(d-k-1)/2} ds\,d\Omega_{k-1}d\Omega_{d-k-1} \\ &= \frac{1}{2}s^{(k-2)/2}(1-s)^{(d-k-2)/2} ds\,d\Omega_{k-1}d\Omega_{d-k-1} = \frac{1}{2}f(s)ds\,d\Omega_{k-1}d\Omega_{d-k-1}, \end{aligned}$$

where the third equality follows from the fact that $w_d = \sqrt{1-s}y_{d-k}$ by the map Ψ. Since the cases where $s = 0$ or $s = 1$ have measure 0, the result follows. ■

Abstract

Scalable machine learning over big data is an important problem that is receiving a lot of attention in recent years. On popular distributed environments such as Hadoop running on a cluster of commodity machines, communication costs are substantial and algorithms need to be designed suitably considering those costs. In this paper we give a novel approach to the distributed training of linear classifiers (involving smooth losses and L_2 regularization) that is designed to reduce the total communication costs. At each iteration, the nodes minimize locally formed approximate objective functions; then the resulting minimizers are combined to form a descent direction to move. Our approach gives a lot of freedom in the formation of the approximate objective function as well as in the choice of methods to solve them. The method is shown to have $O(\log(1/\epsilon))$ time convergence. The method can be viewed as an iterative parameter mixing method. A special instantiation yields a parallel stochastic gradient descent method with strong convergence. When communication times between nodes are large, our method is much faster than the Terascale method (Agarwal et al., 2011), which is a state of the art distributed solver based on the statistical query model (Chu et al., 2006) that computes function and gradient values in a distributed fashion. We also evaluate against other recent distributed methods and demonstrate superior performance of our method.

Keywords: Distributed learning, Example partitioning, L_2 regularization

1. Introduction

In recent years, machine learning over Big Data has become an important problem, not only in web related applications, but also more commonly in other applications, e.g., in the data mining over huge amounts of user logs. The data in such applications are usually collected and stored in a decentralized fashion over a cluster of commodity machines (nodes) where communication times between nodes are significantly large. Examples of applications involving high communication costs include: Click prediction on advertisement data where the number of examples is huge and features are words which can run in to billions, and Geo distributed data across different countries/continents where cross data-center speeds are extremely slow. In such a settings, it is natural for the examples to be partitioned over the nodes.

Distributed machine learning algorithms that operate on such data are usually iterative. Each iteration involves some *computation* that happens locally in each node. In each iteration, there is also *communication* of information between nodes and this is special to the distributed nature of solution. Distributed systems such as those based on the Map-Reduce framework (Dean and Ghemawat, 2008) involve additional special operations per iteration, such as the loading of data from disk to RAM. Recent frameworks such as Spark (Zaharia et al., 2010) and REEF (Weimer et al., 2015) avoid such unnecessary repeated loading of data from disk. Still, communication between nodes in each iteration is unavoidable and, its cost can be substantial when working with Big Data. Therefore, the development of efficient distributed machine learning algorithms that minimize communication between nodes is an important problem. The key is to come up with algorithms that minimize the number of iterations.

In this paper we consider the distributed batch training of linear classifiers in which: (a) both, the number of examples and the number of features are large; (b) the data matrix is sparse; (c) the examples are partitioned over the nodes; (d) the loss function is convex and differentiable; and, (e) the L_2 regularizer is employed. This problem involves the large scale unconstrained minimization of a convex, differentiable objective function $f(w)$ where w is the weight vector. The minimization is usually performed using an iterative descent method in which an iteration starts from a point w^r, computes a direction d^r that satisfies

$$\textbf{sufficient angle of descent: } \angle(-g^r, d^r) \leq \theta \tag{1}$$

where $g^r = g(w^r)$, $g(w) = \nabla f(w)$, $\angle(a, b)$ is the angle between vectors a and b, and $0 \leq \theta < \pi/2$, and then performs a line search along the direction d^r to find the next point, $w^{r+1} = w^r + td^r$. Let $w^\star = \arg\min_w f(w)$. A key side contribution of this paper is the proof that, when f is convex and satisfies some additional weak assumptions, the method has global linear rate of convergence (*glrc*)[1] and so it finds a point w^r satisfying $f(w^r) - f(w^\star) \leq \epsilon$ in $O(log(1/\epsilon))$ iterations. *The main theme of this paper is that the flexibility offered by this method with strong convergence properties allows us to build a class of useful distributed learning methods with good computation and communication trade-off capabilities.*

Take one of the most effective distributed methods, viz., SQM (Statistical Query Model) (Chu et al., 2006; Agarwal et al., 2011), which is a batch, gradient-based descent method. The gradient is computed in a distributed way with each node computing the gradient

1. We say a method has *glrc* if $\exists\ 0 < \delta < 1$ such that $(f(w^{r+1}) - f(w^\star)) \leq \delta(f(w^r) - f(w^\star))\ \forall r$.

component corresponding to its set of examples. This is followed by an aggregation of the components. We are interested in systems in which the communication time between nodes is large relative to the computation time in each node.[2] For iterative algorithms such as SQM, the total training time is given by

$$\text{Training time} = (T^{cmp} + T^{com})\, T^{iter} \tag{2}$$

where T^{cmp} and T^{com} are respectively, the computation time and the communication time per iteration and T^{iter} is the total number of iterations. When T^{com} is large, it is not optimal to work with an algorithm such as SQM that has T^{cmp} small and due to which, T^{iter} is large. In such a scenario, it is useful to ask: **Q1.** *In each iteration, can we do more computation in each node so that the number of iterations and hence the number of communication passes are decreased, thus reducing the total computing time?*

There have been some efforts in the literature to reduce the amount of communication. In one class of such methods, the current w^r is first passed on to all the nodes. Then, each node p forms an approximation $\tilde{f}_p$ of f using only its examples, followed by several optimization iterations (local passes over its examples) to decrease $\tilde{f}_p$ and reach a point w_p. The w_p $\forall p$ are averaged to form the next iterate w^{r+1}. One can stop after just one major iteration (going from $r = 0$ to $r = 1$); such a method is referred to as *parameter mixing (PM)* (Mann et al., 2009). Alternatively, one can do many major iterations; such a method is referred to as *iterative parameter mixing (IPM)* (Hall et al., 2010). Convergence theory for such methods is inadequate (Mann et al., 2009; McDonald et al., 2010), which prompts us to ask: **Q2.** *Is it possible to devise an IPM method that produces* $\{w^r\} \to w^\star$*?*

In another class of methods, the dual problem is solved in a distributed fashion (Pechyony et al., 2011; Yang, 2013; Yang et al., 2013; Jaggi et al., 2014). Let α_p denote the dual vector associated with the examples in node p. The basic idea is to optimize $\{\alpha_p\}$ in parallel and then use a combination of the individual directions thus generated to take an overall step. In practice these methods tend to have slow convergence; see Section 4 for details.

We make a novel and simple use of the iterative descent method mentioned at the beginning of this section to design a distributed algorithm that answers Q1-Q2 positively. The main idea is to use distributed computation for generating a good search direction d^r and not just for forming the gradient as in SQM. At iteration r, let us say each node p has the current iterate w^r and the gradient g^r. This information can be used together with the examples in the node to form a function $\hat{f}_p(\cdot)$ that approximates $f(\cdot)$ and satisfies $\nabla \hat{f}_p(w^r) = g^r$. One simple and effective suggestion is:

$$\hat{f}_p(w) = f_p(w) + (g^r - \nabla f_p(w^r)) \cdot (w - w^r) \tag{3}$$

where f_p is the part of f that does not depend on examples outside node p; the second term in (3) can be viewed as an approximation of the objective function part associated with data from the other nodes. In Section 3 we give other suggestions for forming $\hat{f}_p$. Now $\hat{f}_p$ can be optimized within node p using any method $\mathcal{M}$ which has *glrc*, e.g., Trust region method, L-BFGS, etc. There is no need to optimize $\hat{f}_p$ fully. We show (see Section 3) that, in a constant number of local passes over examples in node p, an approximate minimizer

2. This is the case when feature dimension is huge. Many applications gain performance when the feature space is expanded, say, via feature combinations, explicit expansion of nonlinear kernels etc.

w_p of $\hat{f}_p$ can be found such that the direction $d_p = w_p - w^r$ satisfies the sufficient angle of descent condition, (1). A convex combination of the set of directions generated in the nodes, $\{d_p\}$ forms the overall direction d^r for iteration r. Note that d^r also satisfies (1). The result is an overall distributed method that finds a point w satisfying $f(w) - f(w^\star) \leq \epsilon$ in $O(\log(1/\epsilon))$ time. This answers **Q2**.

The method also reduces the number of communication passes over the examples compared with SQM, thus also answering **Q1**. The intuition here is that, if each $\hat{f}_p$ is a good approximation of f, then d^r will be a good global direction for minimizing f at w^r, and so the method will move towards $w^\star$ much faster than SQM.

In summary, the paper makes the following contributions. First, for convex f we establish *glrc* for a general iterative descent method. Second, and more important, we propose a distributed learning algorithm that: (a) converges in $O(\log(1/\epsilon))$ time, thus leading to an IPM method with strong convergence; (b) is more efficient than SQM when communication costs are high; and (c) flexible in terms of the local optimization method $\mathcal{M}$ that can be used in the nodes.

There is also another interesting side contribution associated with our method. It is known that example-wise methods such as stochastic gradient descent (SGD) are inherently sequential and hard to parallelize (Zinkevich et al., 2010). By employing SGD as $\mathcal{M}$, the local optimizer for $\tilde{f}_p$ in our method, we obtain a parallel SGD method with good performance as well as strong convergence properties. This contribution is covered in detail in Mahajan et al. (2013b); we give a summarized view in Subsection 3.5.

Experiments (Section 4) validate our theory as well as show the benefits of our method for large dimensional datasets where communication is the bottleneck. We give a discussion on unexplored possibilities for extending our distributed learning method in Section 5 and conclude the paper in Section 6.

2. Basic descent method

Let $f \in \mathcal{C}^1$, the class of continuously differentiable functions[3], f be convex, and the gradient g satisfy the following assumptions.

A1. g is Lipschitz continuous, i.e., $\exists\ L > 0$ such that $\|g(w) - g(\tilde{w})\| \leq L\|w - \tilde{w}\| \quad \forall\ w, \tilde{w}$.

A2. $\exists\ \sigma > 0$ such that $(g(w) - g(\tilde{w})) \cdot (w - \tilde{w}) \geq \sigma\|w - \tilde{w}\|^2 \quad \forall\ w, \tilde{w}$.

A1 and A2 are essentially second order conditions: if f happens to be twice continuously differentiable, then L and σ can be viewed as upper and lower bounds on the eigenvalues of the Hessian of f. A convex function f is said to be σ- strongly convex if $f(w) - \frac{\sigma}{2}\|w\|^2$ is convex. In machine learning, all convex risk functionals in $\mathcal{C}^1$ having the L_2 regularization term, $\frac{\lambda}{2}\|w\|^2$ are σ- strongly convex with $\sigma = \lambda$. It can be shown (Smola and Vishwanathan, 2008) that, if f is σ-strongly convex, then f satisfies assumption A2.

Let $f^r = f(w^r)$, $g^r = g(w^r)$ and $w^{r+1} = w^r + td^r$. Consider the following standard line search conditions.

$$\textbf{Armijo:} \quad f^{r+1} \leq f^r + \alpha g^r \cdot (w^{r+1} - w^r) \tag{4}$$

$$\textbf{Wolfe:} \quad g^{r+1} \cdot d^r \geq \beta g^r \cdot d^r \tag{5}$$

3. It would be interesting future work to extend all the theory developed in this paper to non-differentiable convex functions, using sub-gradients.

where $0 < \alpha < \beta < 1$.

Algorithm 1: Descent method for f

Choose w^0;
for $r = 0, 1 \ldots$ **do**
1. Exit if $g^r = 0$;
2. Choose a direction d^r satisfying (1);
3. Do line search to choose $t > 0$ so that $w^{r+1} = w^r + td^r$ satisfies the Armijo-Wolfe conditions (4) and (5);

end

Let us now consider the general descent method in Algorithm 1 for minimizing f. The following result shows that the algorithm is well-posed. A proof is given in the appendix B.

Lemma 1. Suppose $g^r \cdot d^r < 0$. Then $\{t : (4) \text{ and } (5) \text{ hold for } w^{r+1} = w^r + td^r\} = [t_\beta, t_\alpha]$, where $0 < t_\beta < t_\alpha$, and t_β, t_α are the unique roots of

$$g(w^r + t_\beta d^r) \cdot d^r = \beta g^r \cdot d^r, \tag{6}$$

$$f(w^r + t_\alpha d^r) = f^r + t_\alpha \alpha g^r \cdot d^r, \;\; t_\alpha > 0. \tag{7}$$

Theorem 2. Let $w^\star = \arg\min_w f(w)$ and $f^\star = f(w^\star)$.[4] Then $\{w^r\} \to w^\star$. Also, we have *glrc*, i.e., $\exists\ \delta$ satisfying $0 < \delta < 1$ such that $(f^{r+1} - f^\star) \leq \delta\,(f^r - f^\star)\ \forall\ r \geq 0$, and, $f^r - f^\star \leq \epsilon$ is reached after at most $\frac{\log((f^0 - f^\star)/\epsilon)}{\log(1/\delta)}$ iterations. An upper bound on δ is $(1 - 2\alpha(1-\beta)\frac{\sigma^2}{L^2}\cos^2\theta)$.

A proof of Theorem 2 is given in the appendix B. If one is interested only in proving convergence, it is easy to establish under the assumptions made; such theory goes back to the classical works of Wolfe (Wolfe, 1969, 1971). But proving *glrc* is harder. There exist proofs for special cases such as the gradient descent method (Boyd and Vandenberghe, 2004). The *glrc* result in Wang and Lin (2013) is only applicable to descent methods that are "close" (see equations (7) and (8) in Wang and Lin (2013)) to the gradient descent method. Though Theorem 2 is not entirely surprising, as far as we know, such a result does not exist in the literature.

Remark 1. It is important to note that the rate of convergence indicated by the upper bound on δ given in Theorem 2 is pessimistic since it is given for a very general descent algorithm that includes plain batch gradient descent which is known to have a slow rate of convergence. *Therefore, it should not be misconstrued that the indicated slow convergence rate would hold for all methods falling into the class of methods covered here.* Depending on the method used for choosing d^r, the actual rate of convergence can be a lot better. For example, we observe very good rates for our distributed method, FADL; see the empirical results in Section 4 and also the comments made in Remark 2 of Section 3.

3. Distributed training

In this section we discuss full details of our distributed training algorithm. Let $\{x_i, y_i\}$ be the training set associated with a binary classification problem ($y_i \in \{1, -1\}$). Consider a

4. Assumption A2 implies that $w^\star$ is unique.

linear classification model, $y = \text{sgn}(w^T x)$. Let $l(w \cdot x_i, y_i)$ be a continuously differentiable loss function that has Lipschitz continuous gradient. This allows us to consider loss functions such as least squares ($l(s, y) = (s - y)^2$), logistic loss ($l(s, y) = \log(1 + \exp(-sy))$ and squared hinge loss ($l(s, y) = \max\{0, 1 - ys\}^2$). Hinge loss is not covered by our theory since it is non-differentiable.

Suppose the training examples are distributed in P nodes. Let: I_p be the set of indices i such that (x_i, y_i) sits in the p-th node; $L_p(w) = \sum_{i \in I_p} l(w; x_i, y_i)$ be the total loss associated with node p; and, $L(w) = \sum_p L_p(w)$ be the total loss over all nodes. Our aim is to minimize the regularized risk functional $f(w)$ given by

$$f(w) = \frac{\lambda}{2}\|w\|^2 + L(w) = \frac{\lambda}{2}\|w\|^2 + \sum_p L_p(w), \tag{8}$$

where $\lambda > 0$ is the regularization constant. It is easy to check that $g = \nabla f$ is Lipschitz continuous.

3.1. Our approach

Our distributed method is based on the descent method in Algorithm 1. We use a master-slave architecture.[5] Let the examples be partitioned over P slave nodes. Distributed computing is used to compute the gradient g^r as well as the direction d^r. In the r-th iteration, let us say that the master has the current w^r and gradient g^r. One can communicate these to all P (slave) nodes. The direction d^r is formed as follows. Each node p constructs an approximation of $f(w)$ using only information that is available in that node, call it $\hat{f}_p(w)$, and (approximately) optimizes it (starting from w^r) to get the point w_p. Let $d_p = w_p - w^r$. Then d^r is chosen to be any convex combination of $d_p\ \forall p$. Doing line search along the d^r direction completes the r-th iteration. Line search involves distributed computation, but it is inexpensive; we give details in Subsection 3.4.

We want to point out that $\hat{f}_p$ can change with r, i.e., one is allowed to use a different $\hat{f}_p$ in each outer iteration. We just don't mention it as $\hat{f}_p^r$ to avoid clumsiness of notation. In fact, all the choices for $\hat{f}_p$ that we discuss below in Subsection 3.2 are such that $\hat{f}_p$ depends on the current iterate, w^r.

3.2. Choosing $\hat{f}_p$

Our method offers great flexibility in choosing $\hat{f}_p$ and the method used to optimize it. We only require $\hat{f}_p$ to satisfy the following.

A3. $\hat{f}_p$ is σ-strongly convex, has Lipschitz continuous gradient and satisfies *gradient consistency at* w^r: $\nabla \hat{f}_p(w^r) = g^r$.

Below we give several ways of forming $\hat{f}_p$. The σ-strongly convex condition is easily taken care of by making sure that the L_2 regularizer is always a part of $\hat{f}_p$. This condition implies that

$$\hat{f}_p(w_p) \geq \hat{f}_p(w^r) + \nabla \hat{f}_p(w^r) \cdot (w_p - w^r) + \frac{\sigma}{2}\|w_p - w^r\|^2. \tag{9}$$

5. An *AllReduce* arrangement of nodes (Agarwal et al., 2011) may also be used.

The gradient consistency condition is motivated by the need to satisfy the angle condition (1). Since w_p is obtained by starting from w^r and optimizing $\hat{f}_p$, it is reasonable to assume that $\hat{f}_p(w_p) < \hat{f}_p(w^r)$. Using these in (9) gives $-g^r \cdot d_p > 0$. Since d^r is a convex combination of the d_p it follows that $-g^r \cdot d^r > 0$. Later we will formalize this to yield (1) precisely.

A general way of choosing the approximating functional $\hat{f}_p$ is

$$\hat{f}_p(w) = \frac{\lambda}{2}\|w\|^2 + \tilde{L}_p(w) + \hat{L}_p(w), \tag{10}$$

where $\tilde{L}_p$ is an approximation of L_p and $\hat{L}_p(w)$ is an approximation of $L(w) - L_p(w) = \sum_{q \neq p} L_q(w)$. A natural choice for $\tilde{L}_p$ is L_p itself since it uses only the examples within node p; but there are other possibilities too. To maintain communication efficiency, we would like to design an $\hat{L}_p$ such that it does not explicitly require any examples outside node p. To satisfy A3 we need $\hat{L}_p$ to have Lipschitz continuous gradient. Also, to aid in satisfying gradient consistency, appropriate linear terms are added. We now suggest five choices for $\hat{f}_p$.

Linear Approximation. Set $\tilde{L}_p = L_p$ and choose $\hat{L}_p$ based on the first order Taylor series. Thus,

$$\tilde{L}_p(w) = L_p(w), \qquad \hat{L}_p(w) = (\nabla L(w^r) - \nabla L_p(w^r)) \cdot (w - w^r). \tag{11}$$

(The zeroth order term needed to get $f(w^r) = \hat{f}(w^r)$ is omitted everywhere because it is a constant that plays no role in the optimization.) Note that $\nabla L(w^r) = g^r - \lambda w^r$ and so it is locally computable in node p; this comment also holds for the methods below.

Hybrid approximation. This is an improvement over the linear approximation where we add a quadratic term to $\hat{L}_p$. Since the loss term in (8) is total loss (and not averaged loss), this is done by using $(P-1)$ copies of the quadratic term of L_p to approximate the quadratic term of $\sum_{q \neq p} L_q$.

$$\tilde{L}_p(w) = L_p(w), \tag{12}$$

$$\hat{L}_p(w) = (\nabla L(w^r) - \nabla L_p(w^r)) \cdot (w - w^r) + \frac{P-1}{2}(w - w^r)^T H_p^r (w - w^r), \tag{13}$$

where H_p^r is the Hessian of L_p at w^r. This corresponds to using subsampling to approximate the Hessian of $L(w) - L_p(w)$ at w^r utilizing only the local examples. Subsampling based Hessian approximation is known to be very effective in optimization for machine learning (Byrd et al., 2012).

Quadratic approximation. This is a pure quadratic variant where a second order approximation is used for $\tilde{L}_p$ too.

$$\tilde{L}_p(w) = \nabla L_p(w^r) \cdot (w - w^r) + \frac{1}{2}(w - w^r)^T H_p^r (w - w^r), \tag{14}$$

$$\hat{L}_p(w) = (\nabla L(w^r) - \nabla L_p(w^r)) \cdot (w - w^r) + \frac{P-1}{2}(w - w^r)^T H_p^r (w - w^r). \tag{15}$$

The comment made earlier on the goodness of subsampling based Hessian for the Hybrid approximation applies here too.

Nonlinear approximation. Here the idea is to use $P-1$ copies of L_p to approximate $\sum_{q \neq p} L_q$.

$$\tilde{L}_p(w) = L_p(w), \tag{16}$$

$$\hat{L}_p(w) = (\nabla L(w^r) - P \nabla L_p(w^r)) \cdot (w - w^r) + (P-1) L_p(w). \tag{17}$$

A somewhat similar approximation is used in Sharir et al. (2014). But the main algorithm where it is used does not have deterministic monotone descent like our algorithm. The gradient consistency condition, which is essential for establishing function descent, is not respected in that algorithm. In Section 4 we compare our methods against the method in Sharir et al. (2014).

BFGS approximation. For $\tilde{L}_p$ we can either use L_p or a second order approximation, like in the approximations given above. For $\hat{L}_p$ we can use a second order term, $\frac{1}{2}(w - w^r) \cdot H(w - w^r)$ where H is a positive semi-definite matrix; for H we can use a diagonal approximation or keep a limited history of gradients and form a BFGS approximation of $L - L_p$.

Remark 2. The distributed method described above is an instance of Algorithm 1 and so Theorem 2 can be used. In Theorem 2 we mentioned a convergence rate, δ. For $\cos\theta = \sigma/L$ this yields the rate $\delta = (1 - 2\alpha(1-\beta)(\frac{\sigma}{L})^4)$. This rate is obviously pessimistic given that it applies to general choices of $\hat{f}_p$ satisfying minimal assumptions. Actual rates of convergence depend a lot on the choice made for $\hat{f}_p$. Suppose we choose $\hat{f}_p$ via Hybrid, Quadratic or Nonlinear approximation choices mentioned in Subsection 3.2 and minimize $\hat{f}_p$ exactly in the inner optimization. These approximations are invariant to coordinate transformations such as $w' = Bw$, where B is a positive definite matrix. Note that Armijo-Wolfe line search conditions are also unaffected by such transformations. What this means is that, at each iteration, we can, without changing the algorithm, choose for analysis a coordinate transformation that gives the best rate. The Linear approximation choice for $\hat{f}_p$ does not enjoy this property. This explains why the Hybrid, Quadratic and Nonlinear approximations perform so well and give great rates of convergence in practice; see the experiments in Section 4.7 and Subsection 4.9.1. Proving much better convergence rates for FADL using these approximations would be interesting future work.

In Section 4 we evaluate some of these approximations in detail.

3.3. Convergence theory

In practice, exactly minimizing $\hat{f}_p$ is infeasible. For convergence, it is not necessary for w_p to be the minimizer of $\hat{f}_p$; we only need to find w_p such that the direction $d_p = w_p - w^r$ satisfies (1). The angle θ needs to be chosen right. Let us discuss this first. Let $\hat{w}_p^\star$ be the minimizer of $\hat{f}_p$. It can be shown (see appendix B) that $\angle(\hat{w}_p^\star - w^r, -g^r) \leq \cos^{-1}\frac{\sigma}{L}$. To allow for w_p being an approximation of $\hat{w}_p^\star$, we choose θ such that

$$\frac{\pi}{2} > \theta > \cos^{-1}\frac{\sigma}{L}. \tag{18}$$

The following result shows that if an optimizer with *glrc* is used to minimize $\hat{f}_p$, then, only a constant number of iterations is needed to satisfy the sufficient angle of descent condition.

Lemma 3. Assume $g^r \neq 0$. Suppose we minimize $\hat{f}_p$ using an optimizer $\mathcal{M}$ that starts from $v^0 = w^r$ and generates a sequence $\{v^k\}$ having *glrc*, i.e., $\hat{f}_p(v^{k+1}) - \hat{f}_p^\star \leq \delta(\hat{f}_p(v^k) - \hat{f}_p^\star)$, where $\hat{f}_p^\star = \hat{f}_p(\hat{w}_p^\star)$. Then, there exists $\hat{k}$ (which depends only on σ and L) such that $\angle(-g^r, v^k - w^r) \leq \theta \ \ \forall k \geq \hat{k}$.

Lemma 3 can be combined with Theorem 2 to yield the following convergence theorem.

Theorem 4. Suppose θ satisfies (18), $\mathcal{M}$ is as in Lemma 3 and, in each iteration r and for each p, $\hat{k}$ or more iterations of $\mathcal{M}$ are applied to minimize $\hat{f}_p$ (starting from w^r) and get w_p. Then the distributed method converges to a point w satisfying $f(w) - f(w^\star) \leq \epsilon$ in $O(\log(1/\epsilon))$ time.

Proofs of Lemma 3 and Theorem 4 are given in appendix B.

3.4. Practical implementation.

We refer to our method by the acronym, FADL - Function Approximation based Distributed Learning. Going with the practice in numerical optimization, we replace (1) by the condition, $-g^r \cdot d^r > 0$ and use $\alpha = 10^{-4}$, $\beta = 0.9$ in (4) and (5). In actual usage, Algorithm 1 can be terminated when $\|g^r\| \leq \epsilon_g \|g^0\|$ is satisfied at some r. Let us take line search next. On $w = w^r + td^r$, the loss has the form $l(z_i + te_i, y_i)$ where $z_i = w^r \cdot x_i$ and $e_i = d^r \cdot x_i$. Once we have computed $z_i \ \forall i$ and $e_i \ \forall i$, the distributed computation of $f(w^r + td^r)$ and its derivative with respect to t is cheap as it does not involve any computation involving the data, $\{x_i\}$. Thus, many t values can be explored cheaply. Since d^r is determined by approximate optimization, $t = 1$ is expected to give a decent starting point. We first identify an interval $[t_1, t_2] \subset [t_\beta, t_\alpha]$ (see Lemma 1) by starting from $t = 1$ and doing forward and backward stepping. Then we check if t_1 or t_2 is the minimizer of $f(w^r + td^r)$ on $[t_1, t_2]$; if not, we do several bracketing steps in (t_1, t_2) to locate the minimizer approximately. Finally, when using method $\mathcal{M}$, we terminate it after a fixed number of steps, $\hat{k}$; we have found that, setting $\hat{k}$ to match computation and communication costs works effectively. Algorithm 2 gives all the steps of FADL while also mentioning the distributed communications and computations involved.

Choices for $\mathcal{M}$. There are many good methods having (deterministic) *glrc*: L-BFGS, TRON (Lin et al., 2008), Primal coordinate descent (Chang et al., 2008), etc. One could also use methods with *glrc* in the expectation sense (in which case, the convergence in Theorem 4 should be interpreted in some probabilistic sense). This nicely connects our method with recent literature on parallel SGD. We discuss this in the next subsection only briefly as it is outside the scope of the current paper. See our related work (Mahajan et al., 2013b) for details. For the experiments of this paper we do the following. For optimizing the quadratic approximation in (10) with (14)-(15), we used the conjugate-gradient method (Shewchuk, 1994). For all other (non-quadratic) approximations of FADL as well as all nonlinear solvers needed by other methods, we used TRON.

3.5. Connections with parallel SGD

For large scale learning on a single machine, example-wise methods[6] such as stochastic gradient descent (SGD) and its variations (Bottou, 2010; Johnson and Zhang, 2013) and dual

6. These methods update w after scanning each example.

Algorithm 2: FADL - Function Approximation based Distributed Learning. *com:* communication; *cmp:* = computation; *agg:* aggregation. $\mathcal{M}$ is the optimizer used for minimizing $\hat{f}_p$.

Choose w^0;
for $r = 0, 1 \ldots$ **do**
  1. Compute g^r (*com:* w^r; *cmp:* Two passes over data; *agg:* g^r); By-product: $\{z_i = w^r \cdot x_i\}$;
  2. Exit if $\|g^r\| \leq \epsilon_g \|g^0\|$;
  3. **for** $p = 1, \ldots, P$ *(in parallel)* **do**
    4. Set $v^0 = w^r$;
    5. **for** $k = 0, 1, \ldots, \hat{k}$ **do**
      6. Find v^{k+1} using one iteration of $\mathcal{M}$;
    end
    7. Set $w_p = v^{\hat{k}+1}$;
  end
  8. Set d^r as any convex combination of $\{w_p\}$ (*agg:* w_p);
  9. Compute $\{e_i = d^r \cdot x_i\}$ (*com:* d^r; *cmp:* One pass over data);
  10. Do line search to find t (for each t: *com:* t; *cmp:* l and $\partial l/\partial t$ *agg:* $f(w^r + td^r)$ and its derivative wrt t);
  11. Set $w^{r+1} = w^r + td^r$;
end

coordinate ascent (Hsieh et al., 2008) perform quite well. However, example-wise methods are inherently sequential. If one employs a method such as SGD as $\mathcal{M}$, the local optimizer for $\hat{f}_p$, the result is, in essence, a parallel SGD method. However, with parameter mixing and iterative parameter mixing methods (Mann et al., 2009; Hall et al., 2010; McDonald et al., 2010) (we briefly discussed these methods in Section 1) that do not do line search, convergence theory is limited, even that requiring a complicated analysis (Zinkevich et al., 2010); see also Mann et al. (2009) for some limited results. Thus, the following has been an unanswered question: **Q3.** *Can we form a parallel SGD method with strong convergence properties such as glrc?*

As one special instantiation of our distributed method, we can use, for the local optimization method $\mathcal{M}$, any variation of SGD with *glrc* (in expectation), e.g., the one in Johnson and Zhang (2013). For this case, in a related work of ours (Mahajan et al., 2013b) we show that our method has $O(\log(1/\epsilon))$ time convergence in a probabilistic sense. The result is a strongly convergent parallel SGD method, which answers **Q3**. An interesting side observation is that, the single machine version of this instantiation is very close to the variance-reducing SGD method in Johnson and Zhang (2013). We discuss this next.

Connection with SVRG. Let us take the $\hat{f}_p$ in (11). Let $n_p = |I_p|$ be the number of examples in node p. Define $\psi_i(w) = n_p l(w \cdot x_i, y_i) + \frac{\lambda}{2}\|w\|^2$. It is easy to check that

$$\nabla \hat{f}_p(w) = \frac{1}{n_p} \sum_{i \in I_p} (\nabla \psi_i(w) - \nabla \psi_i(w^r) + g^r). \tag{19}$$

Thus, plain SGD updates applied to $\hat{f}_p$ has the form

$$w = w - \eta(\nabla\psi_i(w) - \nabla\psi_i(w^r) + g^r), \tag{20}$$

which is precisely the update in SVRG. In particular, the single node ($P = 1$) implementation of our method using plain SGD updates for optimizing $\hat{f}_p$ is very close to the SVRG method.[7] While Johnson and Zhang (2013) motivate the update in terms of variance reduction, we derive it from a functional approximation viewpoint.

3.6. Computation-Communication tradeoff

In this subsection we do a rough analysis to understand the conditions under which our method (FADL) is faster than the SQM method (Chu et al., 2006; Agarwal et al., 2011) (see Section 1). This analysis is only for understanding the role of various parameters and not for getting any precise comparison of the speed of the two methods.

Compared to the SQM method, FADL does a lot more computation (optimize $\hat{f}_p$) in each node. On the other hand FADL reaches a good solution using a much smaller number of outer iterations. Clearly, FADL will be attractive for problems with high communication costs, e.g., problems with a large feature dimension. For a given distributed computing environment and specific implementation choices, it is easy to do a rough analysis to understand the conditions in which FADL will be more efficient than SQM. Consider a distributed grid of nodes in an *AllReduce* tree. Let us use a common method such as TRON for implementing SQM as well as for $\mathcal{M}$ in FADL. Assuming that $T^{\text{outer}}_{\text{SQM}} > 3.0T^{outer}_{\text{FADL}}$ (where $T^{\text{outer}}_{\text{FADL}}$ and T^{outer}_{SQM} are the number of outer iterations required by SQM and FADL), we can do a rough analysis of the costs of SQM and FADL (see appendix A for details) to show that FADL will be faster when the following condition is satisfied.

$$\frac{nz}{m} < \frac{\gamma P}{2\hat{k}} \tag{21}$$

where: nz is the number of nonzero elements in the data, i.e., $\{x_i\}$; m is the feature dimension; γ is the relative cost of communication to computation (e.g. $100 - 1000$); P is the number of nodes; and $\hat{k}$ is the number of inner iterations of FADL. Thus, the larger the dimension (m) is, and the higher the sparsity in the data is, FADL will be better than SQM.

4. Experiments

In this section, we demonstrate the effectiveness of our method by comparing it against several existing distributed training methods on five large data sets. We first discuss our experimental setup. We then briefly list each method considered and then do experiments to decide the best overall setting for each method. This applies to our method too, for which the setting is mainly decided by the choice made for the function approximation, $\hat{f}_p$; see Subsection 3.2 for details of these choices. Finally, we compare, in detail, all the methods under their best settings. This study clearly demonstrates scenarios under which our method performs better than other methods.

7. Note the subtle point that applying SVRG method on $\hat{f}_p$ is different from doing (20), which corresponds to plain SGD. It is the former that assures *glrc* (in expectation).

4.1. Experimental Setup

We ran all our experiments on a Hadoop cluster with 379 nodes and 10 Gbit interconnect speed. Each node has Intel (R) Xeon (R) E5-2450L (2 processors) running at 1.8 GHz. Since iterations in traditional *MapReduce* are slower (because of job setup and disk access costs), as in Agarwal et al. (Agarwal et al., 2011), we build an *AllReduce* binary tree between the mappers[8]. The communication bandwidth is *1 Gbps* (gigabits per sec).

Dataset	#Examples (n)	#Features (m)	#Non-zeros (nz)	λ/n
kdd2010	8.41×10^6	20.21×10^6	0.31×10^9	1.25×10^{-6}
url	1.91×10^6	3.23×10^6	0.22×10^9	0.11×10^{-6}
webspam	0.35×10^6	16.6×10^6	0.98×10^9	1.0×10^{-4}
mnist8m	8.1×10^6	784	6.35×10^9	1.0×10^{-4}
rcv	0.5×10^6	47236	0.50×10^8	1.0×10^{-4}

Table 1: Properties of datasets.

Data Sets. We consider the following publicly available datasets having a large number of examples:[9] *kdd2010*, *url*, *webspam*, *mnist8m* and *rcv*. Table 1 shows the numbers of examples, features, nonzero in data matrix and the values of regularizer λ used. The regularizer for each dataset is chosen to be the optimal value that gives the best performance on a small validation set. We use these datasets mainly to illustrate the validity of theory, and its utility to distributed machine learning. In real scenarios of Big data, the datasets are typically much larger. Note that *kdd2010*, *url* and *webspam* are large dimensional (m is large) while *mnist8m* and *rcv* are low/medium dimensional (m is not high). This division of the datasets is useful because communication cost in example-partitioned distributed methods is mainly dependent on m (see Appendix A) and so these datasets somewhat help to see the effect of communications cost.

We use the *squared-hinge loss* function for all the experiments. Unless stated differently, for all numerical optimizations we use the Trust Region Newton method (TRON) proposed in Lin et al. (2008).

Evaluation Criteria. We use the relative difference to the optimal function value and the Area under Precision-Recall Curve (AUPRC) (Sonnenburg and Franc, 2010; Agarwal et al., 2013)[10] as the evaluation criteria. The former is calculated as $(f - f^*)/f^*$ in log scale, where f^* is the optimal function value obtained by running the *TERA* algorithm (see below) for a very large number of iterations.

4.2. Methods for comparison

We compare the following methods.

8. Note that we do not use the pipelined version and hence we incur an extra multiplicative $logP$ cost in communication.
9. These datasets are available at: `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/`. For *mnist8m* we solve the binary problem of separating class "3" from others.
10. We employed AUPRC instead of AUC because it differentiates methods more finely.

- *TERA:* The Terascale method (TERA) (Agarwal et al., 2011) is the best representative method from the SQM class (Chu et al., 2006). It can be considered as the state-of-the-art distributed solver and therefore an important baseline.

- *ADMM:* We use the example partitioning formulation of the Alternating Direction Method of Multipliers (ADMM) (Boyd et al., 2011; Zhang et al., 2012). ADMM is a dual method which is very different from our primal method; however, like our method, it solves approximate problems in the nodes and iteratively reaches the full batch solution.

- *CoCoA:* This method (Jaggi et al., 2014) represents the class of distributed dual methods (Pechyony et al., 2011; Yang, 2013; Yang et al., 2013; Jaggi et al., 2014) that, in each outer iteration, solve (in parallel) several local dual optimization problems.

- *DANE:* This is the Newton based method described in Sharir et al. (2014) that uses a function approximation similar to FADL.

- *DiSCO:* This (Zhang and Xiao, 2015) is a distributed Newton method designed with communication-efficiency in mind.

- *Our method (FADL):* This is our method described in detail in Section 3 and more specifically, in Algorithm 2.

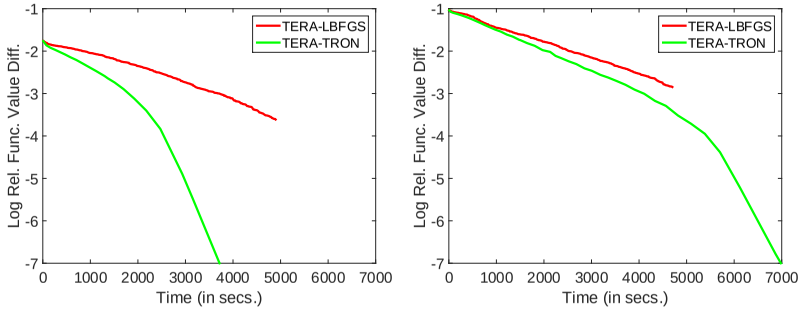
4.3. Study of TERA

A key attractive property of TERA is that the number of outer iterations pretty much remains constant with respect to the number of distributed nodes used. As recommended by Agarwal et al. (2011), we find a local weight vector per node by minimizing the local objective function (based only on the examples in that node) using five epochs of SGD (Bottou, 2010). (The optimal step size is chosen by running SGD on a subset of data.) We then average the weights from all the nodes (on a per-feature basis as explained in Agarwal et al. (2011)) and use the averaged weight vector to warm start *TERA*.[11] Agarwal et al. (2011) use the LBFGS method as the trainer whereas we use TRON. To make sure that this does not lead to bias, we try both, TERA-LBFGS and TERA-TRON. Figure 1 compares the progress of objective function for these two choices. Clearly, TERA-TRON is superior. We observe similar behavior on the other datasets also. Given this, we restrict ourselves to TERA-TRON and simply refer to it as TERA.

4.4. Study of ADMM

The ADMM objective function (Boyd et al., 2011) has a quadratic proximal term called augmented Lagrangian with a penalty parameter ρ multiplying it. In general, the performance of ADMM is very sensitive to the value of ρ and hence making a good choice for it is crucial. We consider three methods for choosing ρ.

11. We use this inexpensive initialization for FADL and ADMM too. It is not applicable to CoCoA. Because of this, CoCoA starts with a different primal objective function value than others.



(a) *kdd2010* - 8 nodes (b) *kdd2010* - 128 nodes

Figure 1: Plots showing the time efficiency of TERA methods for *kdd2010*.

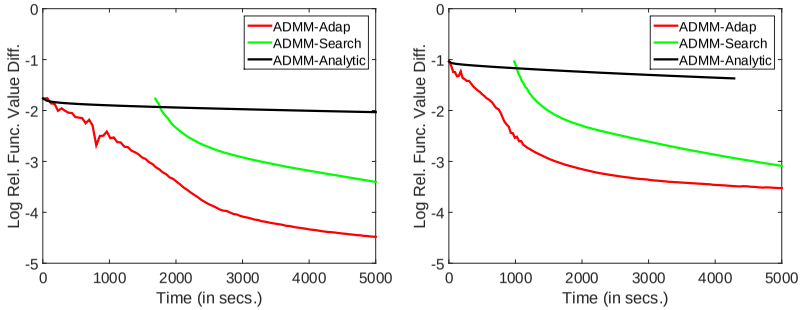
Even though there is no supporting theory, Boyd et al (Boyd et al., 2011) suggest an approach by which ρ is adapted in each iteration; see Equation (3.13) in Section 3.4.1 of that paper. We will refer to this choice as *Adap*.

Recently, Deng and Yin (2012) proved a linear rate of convergence for ADMM under assumptions A1 and A2 (see Section 2) on ADMM functions. As a result, their analysis also hold for the objective function in (8). They also give an analytical formula to set ρ in order to get the best theoretical linear rate constant. We will refer to this choice of ρ as *Analytic*.

We also consider a third choice, *ADMM-Search* in which, we start with the value of ρ given by *Analytic*, choose several values of ρ in its neighborhood and select the best ρ by running ADMM for 10 iterations and looking at the objective function value. Note that this step takes additional time and causes a late start of ADMM.

Figure 2 compares the progress of the training objective function for the three choices on *kdd2010* for $P = 8$ and $P = 128$. *Analytic* is an order of magnitude slower than the other two choices. *Search* works well. However, a significant amount of initial time is spent on finding a good value for ρ, thus making the overall approach slow. *Adap* comes out to be the best performer among the three choices. Similar observations hold for other datasets and other choices of P. So, for ADMM, we will fix *Adap* as the way of choosing ρ and refer to ADMM-*Adap* simply as ADMM.

It is also worth commenting on methods related to ADMM. Apart from ADMM, Bertsekas and Tsitsiklis (1997) discuss several other classic optimization methods for separable convex programming, based on proximal and Augmented Lagrangian ideas which can be used for distributed training of linear classifiers. ADMM represents the best of these methods. Also, Gauss-Seidel and Jacobi methods given in Bertsekas and Tsitsiklis (1997) are related to feature partitioning, which is very different from the example partitioning scenario studied in this paper. Therefore we do not consider these methods.



(a) *kdd2010* - 8 nodes (b) *kdd2010* - 128 nodes

Figure 2: Plots showing the time efficiency of ADMM methods for *kdd2010*.

4.5. Study of CoCoA

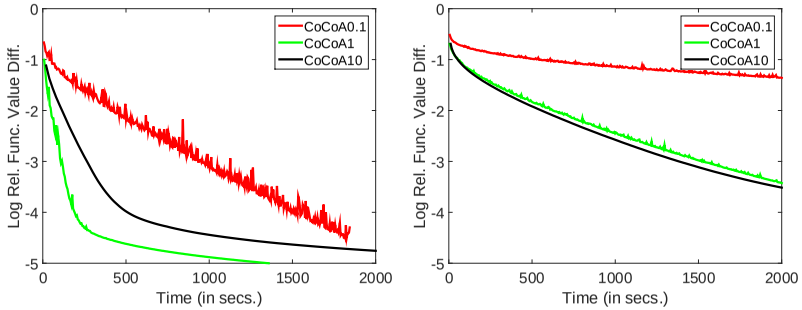
In CoCoA (Jaggi et al., 2014) the key parameter is the approximation level of the inner iterations used to solve each projected dual sub-problem. The number of epochs of coordinate dual ascent inner iterations plays a crucial role. We try the following choices for it: 0.1, 1 and 10.[12] Figure 3 compares the progress of the objective function on *kdd2010* for two choices of nodes, $P = 8$ and $P = 128$. We find the choice of 1 epoch to work well reasonably consistently over all the five datasets and varying number of nodes. So we fix this choice and refer to the resulting method simply as CoCoA. Note in Figure 3 that the (primal) objective function does not decrease continuously with time. This is because it is a dual method and so monotone descent of the objective function is not assured.[13]

4.6. Study of DANE

In our detailed comparison study later in this section, we will also include another method called DANE, which has some resemblance to FADL. This is the Newton based method described in Sharir et al. (2014). Even though this method is very different in spirit from our method, it uses a function approximation similar to our Nonlinear approximation idea; we briefly discussed this in Subsection 3.2. DANE is a non-monotone method that is based on fixed step sizes, with a probabilistic convergence theory to support it.

DANE has two parameters, μ and η in the function approximation; μ is the coefficient for the proximal term and η is used for defining the direction. Sharir et al. (2014) do not prove convergence for any possible choices of μ and η values; their practical recommendation is to use $\mu = 3\lambda$ and $\eta = 1$. The choice of μ in particular, turns out to be quite sub-optimal. We found that there was no single value of μ that is good for all datasets, and so it needs to be tuned for each dataset. So, to improve DANE, we included an initial μ-tuning step.

12. The examples were randomly shuffled for presentation. When the number of epochs is a fraction, e.g., 0.1, the inner iteration was stopped after 10% of the examples were presented.
13. The same comment holds for ADMM which is also a dual method; see for example, the jumps in objective function values for ADMM in Figures 6 and 8 for *kdd2010*.



(a) *kdd2010* - 8 nodes (b) *kdd2010* - 128 nodes

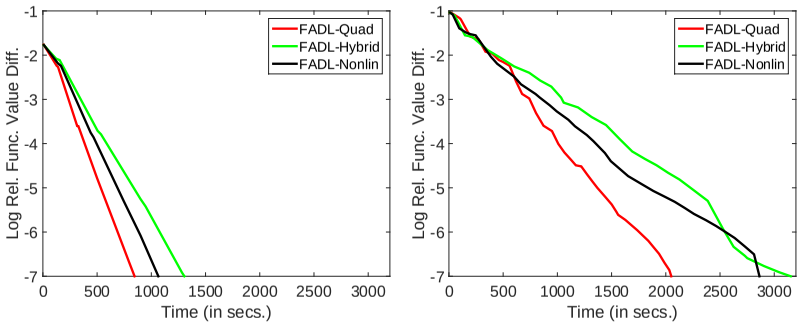
Figure 3: Plots showing the time efficiency of CoCoA settings for *kdd2010*.

We start with $\mu = 3 * \lambda$ and use an initial set of four outer iterations to choose the μ value that gives the best improvement in objective function. Starting from $\mu = 3 * \lambda$ we try several values of μ in the direction of μ change that leads to improvement. After the first four outer iterations, we fix μ at the chosen best value for the remaining iterations. (Note that the cost associated with tuning μ has to be included in the overall cost of DANE.) As we will see later in Subsection 4.9, in spite of all this tuning, DANE did not converge in several situations. Essentially, the issue is that μ has to be adaptive - DANE needs to use different choices of μ in the early, middle and end stages of one training. But then, this is nearly akin to doing a kind of line search in each outer iteration. As opposed to DANE, note that FADL is a monotone method directly based on line search, and it does not need the proximal term to restrict step-sizes. Also, unlike DANE, all the parameters of FADL are fixed to default values for all datasets.

The choice of inner optimizer for DANE is crucial for its efficiency. We tried SVRG (Johnson and Zhang, 2013) and also TRON (Lin et al., 2008). Both did well, but SVRG was better, especially for small number of nodes. So we did a more detailed study of SVRG. We tried two choices. (a) Fix the number of epochs for the local (inner) optimization to some good value, e.g., 10. (b) Always choose the number of epochs for the local (inner) optimization to be such that the cost of local computation in a node is matched with the communications cost. Choice (b) gave a better solution. So we have used it for DANE.

4.7. Study of FADL

Recall from Subsection 3.2 the various choices that we suggested for $\hat{f}_p$. We are yet to implement and study the BFGS approximation; we leave it out for future work. Our original work (Mahajan et al., 2013a) focused on the Linear approximation, but we found the Quadratic, Hybrid and Nonlinear choices to work much better. So we study only these three methods. The implementation of these methods is as described in Subsection 3.4 and Algorithm 2.



(a) *kdd2010* - 8 nodes (b) *kdd2010* - 128 nodes

Figure 4: Plots showing the time efficiency of the three function approximations of FADL for *kdd2010*.

Figure 4 compares the progress of the training objective function for various choices of $\hat{f}_p$. Among the choices, the quadratic approximation for $\hat{f}_p$ gives the best performance, although the Hybrid and Nonlinear approximations also do quite well. We observe this reasonably consistently in other datasets too. Hence, from the set of methods considered in this subsection we choose FADL-Quadratic approximation as the only method for further analysis, and simply refer to this method as FADL hereafter.

Why does the quadratic approximation do better than hybrid and nonlinear approximations? We do not have a precise answer to this question, but we give some arguments in support. In each outer iteration, the function approximation idea is mainly used to get a good direction. Recall from Subsection 3.2 that different choices use different approximations for $\tilde{L}_p$ and $\hat{L}_p$. Using the same "type" (meaning linear, nonlinear or quadratic) for both, $\tilde{L}_p$ and $\hat{L}_p$ is possibly better for direction finding. Second, the direction finding could be more sensitive to the nonlinear approximation compared to the quadratic approximation; this could become more severe as the number of nodes becomes larger. Literature shows that quadratic approximations have good robustness properties; for example, subsampling in Hessian computation (Byrd et al., 2012) doesn't worsen direction finding much.

4.8. Comparison of FADL against DiSCO

DiSCO (Zhang and Xiao, 2015) is an inexact damped Newton method, where the inexact Newton steps are computed using a distributed preconditioned conjugate gradient method. Like TERA, it belongs to the SQM class (Chu et al., 2006). The DiSCO method as described in Zhang and Xiao (2015) is not designed for squared hinge loss. Therefore, in this subsection we separately compare FADL against DiSCO using the logistic loss. With communication efficiency in mind we compare the two methods in terms of the number of communication passes. Figure 5 gives the progress in objective function as a function of the number of communication passes for the two methods. FADL is clearly better than DiSCO, the

difference being quite large on datasets such as *kdd2010*. In terms of total computing time, the superiority of FADL turns out to be even better than what is seen in the plots of communication passes. This is because DiSCO requires more extensive computational steps than FADL within one communication pass.

4.9. Comparison of FADL against TERA, ADMM, CoCoA and DANE

Having made the best choice of settings for the methods, we now evaluate FADL against TERA, ADMM, CoCoA and DANE in more detail. We do this using three sets of plots. We give details only for $P = 8$ and $P = 128$ to give an idea of how performance varies for small and large number of nodes.

1. *Communication passes.* We plot the variation of the training objective function as a function of the number of communication passes. For the x-axis we prefer the number of communication passes instead of the number of outer iterations since the latter has a different meaning for different methods while the former is quite uniform for all methods. Figures 6 and 7 give the plots respectively for the large dimensional (m large) datasets (*kdd2010*, *url* and *webspam*) and medium/small dimensional (m medium/small) datasets (*mnist8m* and *rcv*).

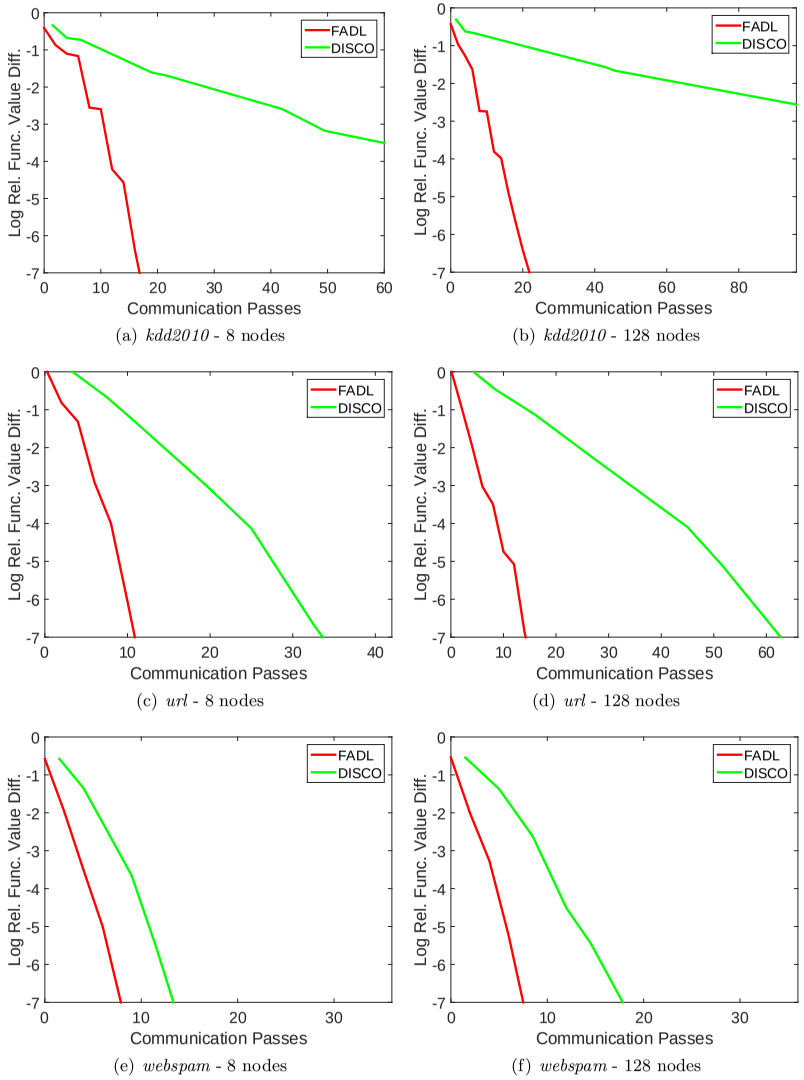
2. *Time.* We plot the variation of the training objective function as a function of the actual solution time. Figures 8 and 9 give the plots respectively for the large dimensional and medium/small dimensional datasets.

3. *Speed-up over TERA.* TERA is an established strong baseline method. So it is useful to ask how other methods fare relative to TERA and study this as a function of the number of nodes. For doing this we need to represent each method by one or two real numbers that indicate performance. Since generalization performance is finally the quantity of interest, we stop a method when it reaches within 0.1% of the steady state AUPRC value achieved by full, perfect training of (8) and record the following two measures: the total number of communication passes and the total time taken. For each measure, we plot the ratio of the measure's value for TERA to the corresponding measure's value for a method, as a function of the number of nodes, and repeat this for each method. Larger this ratio, better is a method; also, ratio greater than one means a method is faster than TERA. Figures 10 and 11 give the plots for all the five datasets.

Let us now use these plots to compare the methods. In the plots, DANE starts later than other methods due to the extra work needed for tuning the proximal parameter μ.

4.9.1. Rate of Convergence

Analysis of the rate of convergence is better done by studying the behavior of the training objective function with respect to the number of communication passes. So it is useful to look at Figures 6 and 7. Clearly, as predicted by theory, the rate of convergence is linear for all methods.

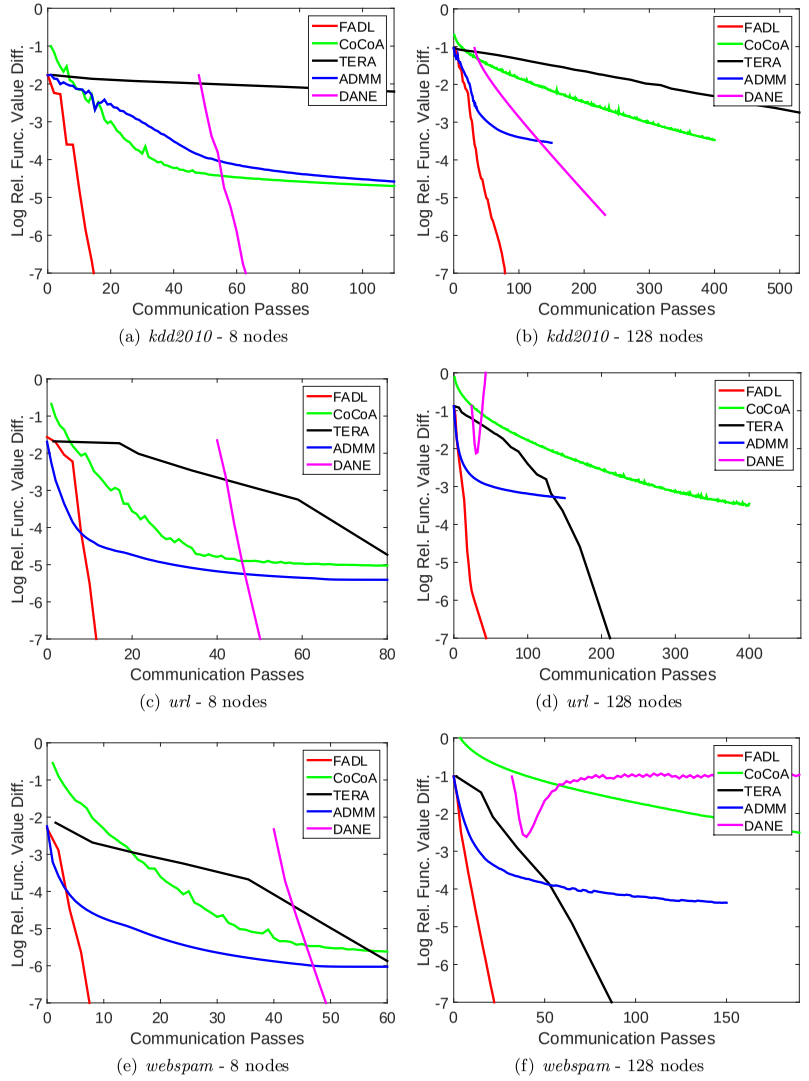


(a) *kdd2010* - 8 nodes (b) *kdd2010* - 128 nodes

(c) *url* - 8 nodes (d) *url* - 128 nodes

(e) *webspam* - 8 nodes (f) *webspam* - 128 nodes

Figure 5: Plots comparing the number of communication passes of DiSCO and FADL on three datasets.

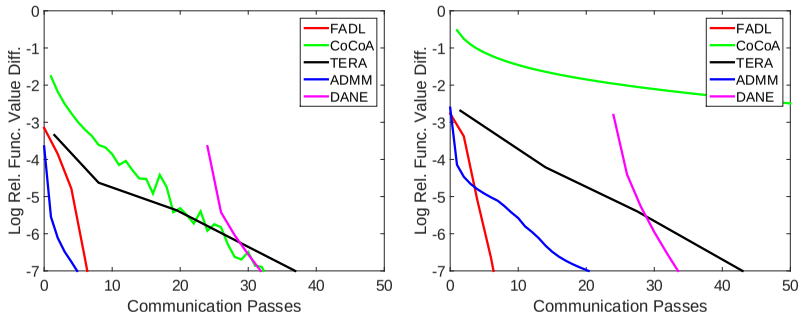


(a) *kdd2010* - 8 nodes (b) *kdd2010* - 128 nodes

(c) *url* - 8 nodes (d) *url* - 128 nodes

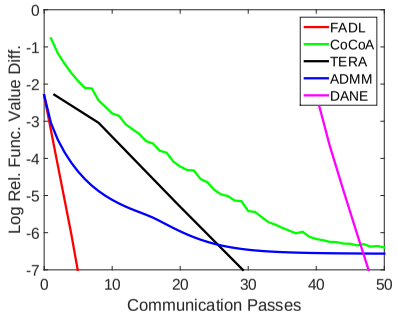
(e) *webspam* - 8 nodes (f) *webspam* - 128 nodes

Figure 6: Plots showing the rate of convergence of various methods for the three high dimensional datasets.

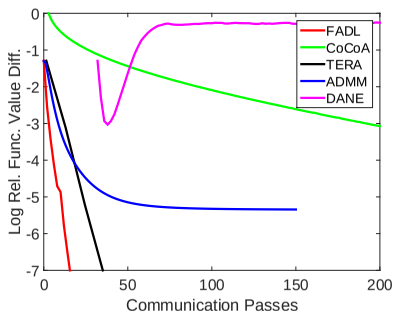


(a) *mnist8m* - 8 nodes

(b) *mnist8m* - 128 nodes



(c) *rcv* - 8 nodes



(d) *rcv* - 128 nodes

Figure 7: Plots showing the linear convergence of various methods for the two low/medium dimensional datasets.

TERA uses distributed computation only to compute the gradient and so the plots should be unaffected by P. But in the plots we do see differences between the plots for $P = 8$ and $P = 128$. This is because of their different initialization (average of one pass SGD solutions from nodes): the initialization with lower number of nodes is better due its smaller variance; note also the better starting objective function value at the start (left most point) for $P = 8$.

For FADL, the rate is steeper for $P = 8$ than for $P = 128$. This steeper behavior for lower number of nodes is expected because the functional approximation in each node becomes better as the number of nodes decreases.

Recall from Section 1 that, our main aim behind the design of the function approximation based methods is to reduce the number of communication passes significantly. The plots in Figures 6 and 7 clearly confirm such a reduction.

Even though the end convergence rate of ADMM is slow, it generally shows good rates of convergence in the initial stages of training. This is a useful behavior because generalization measures such as AUPRC tend to achieve steady state values quickly in the early stages. This usefulness is seen in Figure 10 too.

DANE has good rates of convergence when P is small ($P = 8$), but the cost associated with tuning μ makes it poor; note that, if μ is not tuned, that will affect the rate of convergence. DANE tends to be unstable for large P values.

Overall, FADL gives much better rates of convergence (both, in the early training stage as well as in the end stage) compared to TERA, CoCoA, ADMM and DANE methods.[14] FADL shows a large reduction in the number of communication passes over TERA, especially when the number of nodes is small. Against CoCoA the trend is the other way: FADL needs a much smaller number of communication passes than CoCoA especially when the number of nodes is large. These observations can also be seen from Figure 10. Clearly CoCoA seems to be very slow with increasing number of nodes.

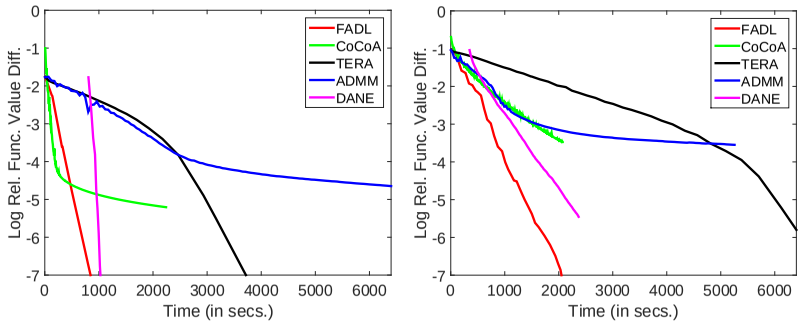
4.9.2. Time Taken

In the previous analysis we ignored computation costs within each iteration. But these costs play a key role when we analyze overall efficiency in terms of the actual time taken. We study this next. Figures 8 and 9 are relevant for this study. FADL, ADMM, CoCoA and DANE involve much more extensive computations in the inner iterations than TERA; this is especially true when the number of nodes is small because of the large amount of local data in each node. TERA fares much better in the time analysis than what we saw while studying using communication passes only. Thus the gap between TERA and other methods becomes a lot smaller in the time analysis. Compare, for example, TERA and ADMM with respect to communication passes and time. Although ADMM is much more efficient than TERA with respect to the number of communication passes, TERA catches up nicely with ADMM on the time taken.

CoCoA does well sometimes; for example, on *kdd2010* and *url*, when the number of nodes is small, say $P = 8$. But it is slow otherwise, especially when the number of nodes is large.

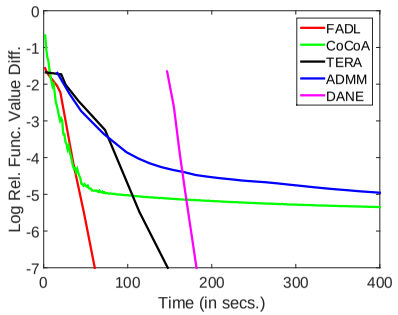
FADL is uniformly better than ADMM with respect to the total time taken. Overall, FADL shows the best performance, performing equally or much better than other methods in different situations. With medium/low dimensional datasets (see Figure 9), communication time is less of an issue and so the expectation is that FADL is less of value for them. Even on these datasets, FADL does equally or better than TERA. DANE is not competitive due to the time involved for tuning μ.

14. Here, it is useful to recall the comments made in Remark 2 of Section 3 on the goodness of the convergence rate of FADL.

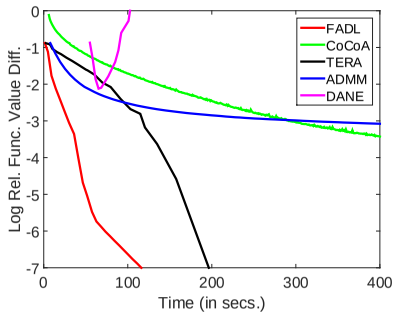


(a) *kdd2010* - 8 nodes

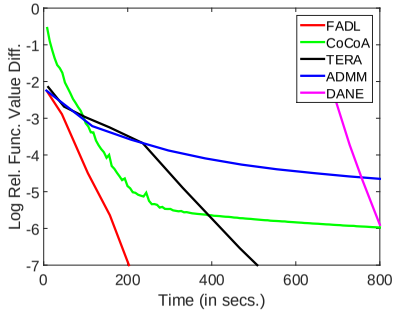
(b) *kdd2010* - 128 nodes



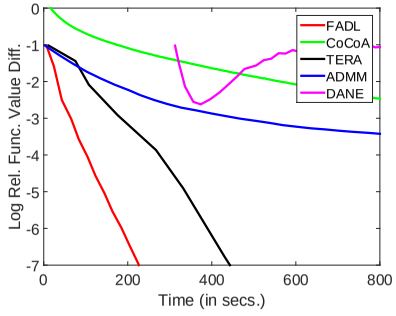
(c) *url* - 8 nodes



(d) *url* - 128 nodes

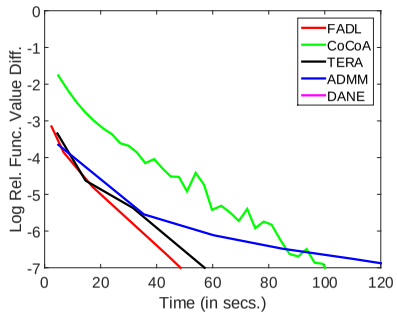


(e) *webspam* - 8 nodes

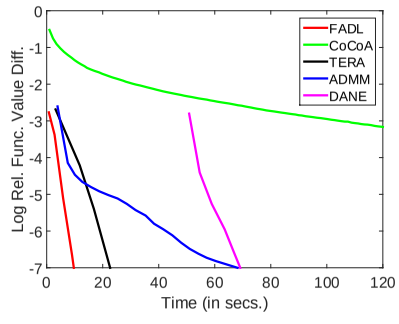


(f) *webspam* - 128 nodes

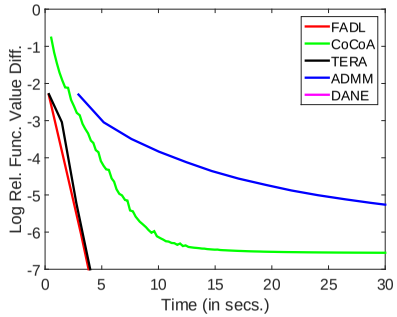
Figure 8: Plots showing the time efficiency of various methods for the three high dimensional datasets.



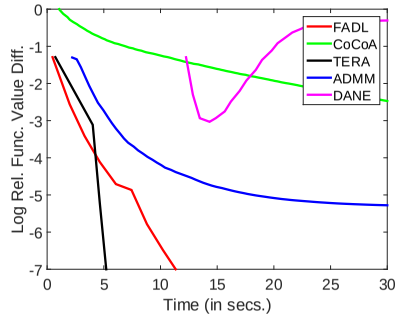
(a) *mnist8m* - 8 nodes



(b) *mnist8m* - 128 nodes



(c) *rcv* - 8 nodes



(d) *rcv* - 128 nodes

Figure 9: Plots showing the time efficiency of various methods for the two low/medium dimensional datasets. For *rcv* and *mnist8m* - 8 nodes, the plot of DANE is invisible since the time taken for tuning μ is larger than the time window displayed.

4.9.3. Relative performance of the methods

Figure 11 is relevant for this study. CoCoA shows impressive speed-up over TERA on *kdd2010* but it is much slower on all the other datasets. It is unclear why CoCoA fares so well on *kdd2010* but not on the other datasets. ADMM gives an overall decent performance when compared to TERA. FADL is consistently faster than TERA, with speed-ups ranging anywhere from 1-10. In communication-heavy scenarios where reducing the number of communication passes is most important, methods such as FADL and ADMM have great value (see Figure 10), with the possibility of getting even higher speed-ups over TERA. Except for *kdd2010* for which FADL is slower than CoCoA for small number of nodes, it is generally the fastest method. DANE does not seem to have any special scenario where it is better than others.

(e) rcv

Figure 11: Plots showing time (relative to TERA) as a function of the number of nodes. Each method was terminated when it reached within 0.1% of the steady state AUPRC value achieved by full, perfect training of (8).

4.9.4. Speed-up as a function of P

Let us revisit Figure 8 and look at the plots corresponding to *kdd2010* for FADL.[15] It can be observed that the time needed for reaching a certain tolerance, say *Log Rel. Func. Value Diff. = -3*, is two times smaller for $P = 8$ than for $P = 128$. This means that using a large number of nodes is not useful, which prompts the question: *Is a distributed solution really necessary?* There are two answers to this question. First, as we already mentioned, when the training data is huge[16] and *the data is generated and forced to reside in distributed nodes (moving data between machines is not an efficient option)*, the right question to ask is not whether we get great speed-up, but to ask which method is the fastest. Second, for a given dataset and method, if the time taken to reach a certain approximate stopping tolerance (e.g., based on AUPRC) is plotted as a function of P, it usually has a minimum at a value $P > 1$. Given this, it is appropriate to choose a P optimally to minimize training time. A large fraction of Big data machine learning applications involve periodically repeated model training involving newly added data. For example, in Advertising, logistic regression based click probability models are retrained on a daily basis on incrementally varying datasets. In such scenarios it is worthwhile to spend time to tune P in an early deployment phase to minimize time, and then use this choice of P for future runs.

4.9.5. Computation and Communication Costs

Table 2 shows the ratio of computational cost to communication cost for the three high dimensional datasets for all the methods.[17] Note that the ratio is small for *TERA* and so communication cost dominates the time for it. On the other hand, both the costs are well balanced for FADL. Note that ratio varies in the range of $0.625 - 2.845$. This clearly shows that FADL trades-off computation with communication, while significantly reducing the number of communication passes (Figures 6 and 7) and time (Figures 8 and 9).

	FADL	CoCoA	TERA	ADMM
kdd2010	1.6333	0.1416	0.1422	1.8499
url	1.3650	0.1040	0.2986	3.4886
webspam	1.2082	0.1570	0.2423	1.2543

Table 2: Ratio of the total computation cost to the total communication cost for various methods which were terminated when AUPRC reached within 0.1% of the AUPRC value for 128 nodes.

15. We choose FADL as an example, but the comments made in the discussion apply to other methods too.
16. The datasets, *kdd2010*, *url* and *webspam* are really not huge in the *Big data* sense. In this paper we used them only because of lack of availability of much bigger public datasets.
17. For the medium/low dimensional datasets *rcv* and *mnist8m*, communication latencies, line search cost etc. also play a key role and an analysis of computation cost versus communication cost does not provide any great insight.

4.10. Experiment on a much larger dataset

To verify the goodness of FADL, we also did an experiment evaluating FADL against other methods, on a large dataset that is more than an order of magnitude bigger than the largest dataset in Table 1. The dataset is the Splice site recognition dataset from the bioinformatics domain (Sonnenburg and Franc, 2010). In this dataset each example is a sequence; we considered all positional features upto 9 grams. This led to a dataset of 49 million features and 50 million examples. The size of the dataset is larger than 0.65 Terabytes. We employed a cluster of 100 nodes to solve this problem. Figure 12 compares the various methods on (a) the reduction of the objective function as a function of communication passes; (b) the reduction of the objective function as a function of time; and (c) the improvement of generalization performance (AUPRC) as a function of time. It is clear that FADL makes great reductions over other methods, on the number of communication passes. FADL is also the best performer when we measure by the time taken. On clusters with slower communication speeds and iteration set-up times, the value of FADL over other methods will be even higher. Interestingly, CoCoA comes out as the next best performer. CoCoA has slower end convergence than FADL, but it shows up equally well in plot (c) on the improvement of generalization performance. As we saw earlier with other datasets, the value of CoCoA varies a lot; for the current scenario of solving the splice site recognition on 100 nodes it seems to be well-suited. FADL, on the other hand, is uniformly good in varying scenarios of several datasets, number of nodes etc.

4.11. Summary

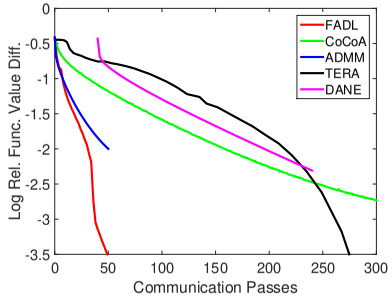
It is useful to summarize the findings of the empirical study.

- FADL gives a great reduction in the number of communication passes, making it clearly superior to other methods in communication heavy settings.
- In spite of higher computational costs per iteration FADL shows the overall best performance on the total time taken. This is true even for medium and low dimensional datasets.
- FADL shows a speed-up of 1-10 over TERA, the actual speed-up depending on the dataset and the setting.
- FADL nicely balances computation and communication costs.

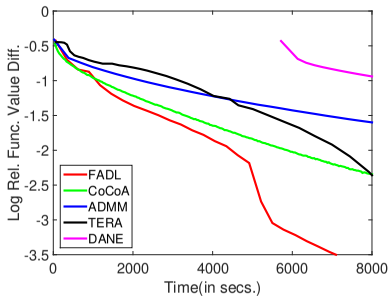
5. Discussion

In this section, we discuss briefly, other different distributed settings made possible by our algorithm. The aim is to show the flexibility and generality of our approach while ensuring *glrc*.

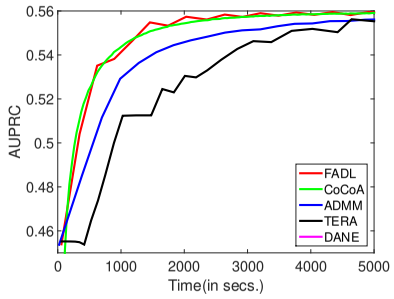
Section 3 considered example partitioning where examples are distributed across the nodes. First, it is worth mentioning that, due to the gradient consistency condition, *partitioning* is not a necessary constraint; our theory allows examples to be resampled, i.e., each example is allowed to be a part of any number of nodes arbitrarily. For example, to reduce the number of outer iterations, it helps to have more examples in each node.



(a) Communication efficiency (objective function)



(b) Time efficiency (objective function)



(c) Time efficiency (AUPRC)

Figure 12: Plots comparing various methods on the *Splice site recognition* dataset.

Second, the theory proposed in Section 3 holds for feature partitioning also. Suppose, in each node p we restrict ourselves to a subset of features, $J_p \subset \{1, \ldots, d\}$, i.e., include the constraint, $w_p \in \{w : w(j) = w^r(j) \;\; \forall r \notin J_p\}$, where $w(j)$ denotes the weight of the j^{th} feature. Note that we do not need $\{J_p\}$ to form a partition. This is useful since important features can be included in all the nodes.

Gradient sub-consistency. Given w^r and J_p we say that $\hat{f}_p(w)$ has gradient sub-consistency with f at w^r on J_p if $\frac{\partial f}{\partial w(j)}(w^r) = \frac{\partial \hat{f}}{\partial w(j)}(w^r) \;\; \forall\, j \in J_p$.

Under the above condition, we can modify the algorithm proposed in Section 3 to come up with a feature decomposition algorithm with *glrc*.

Several feature decomposition based approaches (Richtárik and Takác, 2012; Patriksson, 1998b) have been proposed in the literature. The one closest to our method is the work by Patrikkson on a synchronized parallel algorithm (Patriksson, 1998b) which extends a generic cost approximation algorithm (Patriksson, 1998a) that is similar to our functional approximation. The sub-problems on the partitions are solved in parallel. Although the objective function is not assumed to be convex, the cost approximation is required to satisfy

a monotone property, implying that the approximation is convex. The algorithm only has asymptotic linear rate of convergence and it requires the feature partitions to be disjoint. In contrast, our method has *glrc* and works even if features overlap in partitions. Moreover, there does not exist any counterpart of our example partitioning based distributed algorithm discussed in Section 3.

Recently Mairal (2013) has developed an algorithm called MISO. The main idea of MISO (which is in the spirit of the EM algorithm) is to build majorization approximations with good properties so that line search can be avoided, which is interesting. MISO is a serial method. Developing a distributed version of MISO is an interesting future direction; but, given that line search is inexpensive communication-wise, it is unclear if such a method would give great benefits.

Our approach can be easily generalized to joint example-feature partitioning as well as non-convex settings.[18] The exact details of all the extensions mentioned above and related experiments are left for future work.

Recently, a powerful divide and conquer approach Hsieh et al. (2014) has been suggested for training kernel methods. The idea is to partition the input space such that the restrictions of training on the partitioned input spaces are as decoupled as possible. If, in FADL, we had the ability to choose the parts of data that are placed in the nodes, then we would also gain by choosing decoupled partitions. However, in the distributed case, this requires pre-processing as well as shuffling of data, which are expensive.

6. Conclusion

To conclude, we have proposed FADL, a novel functional approximation based distributed algorithm with provable global linear rate of convergence. The algorithm is general and flexible in the sense of allowing different local approximations at the node level, different algorithms for optimizing the local approximation, early stopping and general data usage in the nodes. We also established the superior efficiency of FADL by evaluating it against key existing distributed methods. We believe that FADL has great potential for solving machine learning problems arising in Big data.

Appendix A: Complexity analysis

Let us use the notations of section 3 given around (21). We define the overall cost of any distributed algorithm as

$$[(c_1 \frac{nz}{P} + c_2 m) T^{\text{inner}} + c_3 \gamma m] T^{\text{outer}}, \tag{22}$$

where T^{outer} is the number of outer iterations, T^{inner} is the number of inner iterations at each node before communication happens and c_1 and c_2 denote the number of passes over the data and m-dimensional dot products per inner iteration respectively. For communication, we assume an *AllReduce* binary tree as described in Agarwal et al. (2011) with

18. For non-convex settings *glrc* is hard to establish, but proving a simpler convergence theory is quite possible.

pipelining. As a result, we do not have a multiplicative factor of $log_2 P$ in our cost[19]. γ is the relative computation to communication speed in the given distributed system; more precisely, it is the ratio of the times associated with communicating a floating point number and performing one floating point operation; γ is usually much larger than 1. c_3 is the number of m-dimensional vectors (gradients, Hessian-vector computations etc.) we need to communicate.

Method	c_1	c_2	c_3	T^{inner}
SQM	2	$\approx 5-10$	1	1
FADL	2	$\approx 5-7$	2	$\hat{k}$

Table 3: Value of cost parameters

The values of different parameters for SQM and FADL are given in Table 3. $T^{\text{outer}}_{\text{SQM}}$ is the number of overall conjugate gradient iterations plus gradient computations. $\hat{k}$ is the average number of conjugate gradient iterations (for the inner minimization of $\hat{f}_p$ using TRON) required per outer iteration in FADL. Typically $\hat{k}$ is between 5 and 20.

Since dense dot products are extremely fast $c_2 m$ is small compared to $c_1 nz/P$ for both the approaches, we ignore it from (22) for simplicity. Now for FADL to have lesser cost than TERA, we can use (22) to get the condition,

$$2.0(\hat{k}T^{\text{outer}}_{\text{FADL}} - T^{\text{outer}}_{\text{SQM}})\frac{nz}{P} \leq (T^{\text{outer}}_{\text{SQM}} - 2T^{\text{outer}}_{\text{FADL}})\gamma m \tag{23}$$

Let us ignore $T^{\text{outer}}_{\text{SQM}}$ on the left side of this inequality (in favor of SQM) and rearrange to get the looser condition,

$$\frac{nz}{m} \leq \frac{\gamma P}{\hat{k}}\frac{1}{2.0}(\frac{T^{\text{outer}}_{\text{SQM}}}{T^{\text{outer}}_{\text{FADL}}} - 2) \tag{24}$$

Assuming $T^{\text{outer}}_{\text{SQM}} > 3.0 T^{\text{outer}}_{\text{FADL}}$, we arrive at the final condition in (21).

Appendix B: Proofs

Proofs of the results in section 2

Let us now consider the establishment of the convergence theory given in section 2.

Proof of Lemma 1. Let $\rho(t) = f(w^r + td^r)$ and $\gamma(t) = \rho(t) - \rho(0) - \alpha t\rho'(0)$. Note the following connections with quantities involved in Lemma 1: $\rho(t) = f^{r+1}$, $\rho(0) = f^r$, $\rho'(t) = g^{r+1} \cdot d^r$ and $\gamma(t) = f^{r+1} - f^r - \alpha g^r \cdot (w^{r+1} - w^r)$. (4) corresponds to the condition $\gamma(t) \leq 0$ and (5) corresponds to the condition $\rho'(t) \geq \beta\rho'(0)$.

$\gamma'(t) = \rho'(t) - \alpha\rho'(0)$. $\rho'(0) < 0$. ρ' is strictly monotone increasing because, by assumption A2,

$$\rho'(t) - \rho'(\tilde{t}) \geq \sigma(t - \tilde{t})\|d^r\|^2 \;\; \forall\, t, \tilde{t} \tag{25}$$

This implies that γ' is also strictly monotone increasing and, all four, ρ, ρ', γ' and γ tend to infinity as t tends to infinity.

19. Actually, there is another communication term, $\gamma b\, log_2 P$, where b is the size of first block of communicated doubles in the pipeline. However, typically $b \ll m$ and hence we ignore it.

Let t_β be the point at which $\rho'(t) = \beta\rho'(0)$. Since $\rho'(0) < 0$ and ρ' is strictly monotone increasing, t_β is unique and $t_\beta > 0$. This validates the definition in (6). Monotonicity of ρ' implies that (5) is satisfied iff $t \geq t_\beta$.

Note that $\gamma(0) = 0$ and $\gamma'(0) < 0$. Also, since γ' is monotone increasing and $\gamma(t) \to \infty$ as $t \to \infty$, there exists a unique $t_\alpha > 0$ such that $\gamma(t_\alpha) = 0$, which validates the definition in (7). It is easily checked that $\gamma(t) \leq 0$ iff $t \in [0, t_\alpha]$.

The properties also imply $\gamma'(t_\alpha) > 0$, which means $\rho'(t_\alpha) \geq \alpha\rho'(0)$. By the monotonicity of ρ' we get $t_\alpha > t_\beta$, proving the lemma.

Proof of Theorem 2. Using (5) and A1,

$$(\beta - 1)g^r \cdot d^r \leq (g^{r+1} - g^r) \cdot d^r \leq Lt\|d^r\|^2 \tag{26}$$

This gives a lower bound on t:

$$t \geq \frac{(1-\beta)}{L\|d^r\|^2}(-g^r \cdot d^r) \tag{27}$$

Using (4), (27) and (1) we get

$$f^{r+1} \leq f^r + \alpha t g^r \cdot d^r \leq f^r - \frac{\alpha(1-\beta)}{L\|d^r\|^2}(-g^r \cdot d^r)^2 \leq f^r - \frac{\alpha(1-\beta)}{L}\cos^2\theta\|g^r\|^2 \tag{28}$$

Subtracting $f^\star$ gives

$$(f^{r+1} - f^\star) \leq (f^r - f^\star) - \frac{\alpha(1-\beta)}{L}\cos^2\theta\|g^r\|^2 \tag{29}$$

A2 together with $g(w^\star) = 0$ implies $\|g^r\|^2 \geq \sigma^2\|w^r - w^\star\|^2$. Also A1 implies $f^r - f^\star \leq \frac{L}{2}\|w^r - w^\star\|^2$ Smola and Vishwanathan (2008). Using these in (29) gives

$$\begin{aligned}(f^{r+1} - f^\star) &\leq (f^r - f^\star) - 2\alpha(1-\beta)\frac{\sigma^2}{L^2}\cos^2\theta(f^r - f^\star) \\ &\leq (1 - 2\alpha(1-\beta)\frac{\sigma^2}{L^2}\cos^2\theta)(f^r - f^\star)\end{aligned} \tag{30}$$

Let $\delta = (1 - 2\alpha(1-\beta)\frac{\sigma^2}{L^2}\cos^2\theta)$. Clearly $0 < \delta < 1$. Theorem 2 follows.

Proofs of the results in section 3

Let us now consider the establishment of the convergence theory given in section 3. We begin by establishing that the exact minimizer of $\hat{f}_p$ makes a sufficient angle of descent at w^r.

Lemma 5. Let $\hat{w}^\star_p$ be the minimizer of $\hat{f}_p$. Let $d_p = (\hat{w}^\star_p - w^r)$. Then

$$-g^r \cdot d_p \geq (\sigma/L)\|g^r\|\|d_p\| \tag{31}$$

Proof. First note, using gradient consistency and $\nabla f_p(\hat{w}^\star_p) = 0$ that

$$\|g^r\| = \|\nabla\hat{f}_p(w^r) - \nabla\hat{f}_p(\hat{w}^\star_p)\| \leq L\|d_p\| \tag{32}$$

Now,

$$-g^r \cdot d_p = (\nabla \hat{f}_p(w^r) - \nabla \hat{f}_p(\hat{w}_p^\star))^T (w^r - \hat{w}_p^\star) \geq \sigma \|d_p\|^2 = \quad \sigma \|g^r\| \|d_p\| \frac{\|d_p\|}{\|g^r\|} \geq \frac{\sigma}{L} \|g^r\| \|d_p\| \quad (33)$$

where the second line comes from σ-strong convexity and the fourth line follows from (32).

Proof of Lemma 3. Let us now turn to the question of approximate stopping and establish Lemma 3. Given θ satisfying (18) let us choose $\zeta \in (0, 1)$ such that

$$\frac{\pi}{2} > \theta > \cos^{-1} \frac{\sigma}{L} + \cos^{-1} \zeta \quad (34)$$

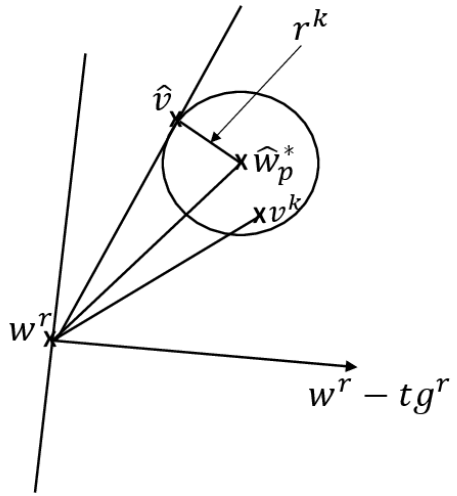


Figure 13: Construction used in the proof of Lemma 3.

By A3 and equations (3.16) and (3.22) in Smola and Vishwanathan (2008), we get

$$\frac{\sigma}{2} \|v - \hat{w}_p^\star\|^2 \leq \hat{f}_p(v) - \hat{f}_p^\star \leq \frac{L}{2} \|v - \hat{w}_p^\star\|^2 \quad (35)$$

After k iterations we have

$$\hat{f}_p(v^k) - \hat{f}_p^\star \leq \delta^k (\hat{f}_p(w^r) - \hat{f}_p^\star) \quad (36)$$

We can use these to get

$$\|v^k - \hat{w}_p^\star\|^2 \leq \frac{2(\hat{f}_p(v^k) - \hat{f}_p^\star)}{\sigma} \leq \frac{2\delta^k (\hat{f}_p(w^r) - \hat{f}_p^\star)}{\sigma} \leq \frac{\delta^k L}{\sigma} \|w^r - \hat{w}_p^\star\|^2 \stackrel{\text{def}}{=} (r^k)^2 \quad (37)$$

For now let us assume the following:

$$\|v^k - \hat{w}_p^\star\|^2 \leq \|w^r - \hat{w}_p^\star\|^2 \quad (38)$$

Using (37) note that (38) holds if

$$\frac{\delta^k L}{\sigma} \leq 1 \quad (39)$$

Let S^k be the sphere, $S^k = \{v : \|v - \hat{w}_p^\star\|^2 \leq (r^k)^2\}$. By (37) we have $v^k \in S^k$. See Figure 6. Therefore,

$$\phi^k \leq \max_{v \in S^k} \phi(v) \quad (40)$$

where ϕ^k is the angle between $\hat{w}_p^\star - w^r$ and $v^k - w^r$, and $\phi(v)$ is the angle between $v - w^r$ and $\hat{w}_p^\star - w^r$. Given the simple geometry, it is easy to see that $\max_{v \in S^k} \phi(v)$ is attained by a point $\hat{v}$ lying on the boundary of S^k (i.e., $\|\hat{v} - \hat{w}_p^\star\|^2 = (r^k)^2$) and satisfying $(\hat{v} - \hat{w}_p^\star) \perp (\hat{v} - w^r)$. This geometry yields

$$\cos^2 \phi(\hat{v}) = \frac{\|\hat{v} - w^r\|^2}{\|\hat{w}_p^\star - w^r\|^2} = \frac{\|\hat{w}_p^\star - w^r\|^2 - (r^k)^2}{\|\hat{w}_p^\star - w^r\|^2} = 1 - \frac{(r^k)^2}{\|\hat{w}_p^\star - w^r\|^2} = 1 - \frac{\delta^k L}{\sigma} \quad (41)$$

Since $\phi^k \leq \phi(\hat{v})$,

$$\cos^2 \phi^k \geq 1 - \frac{\delta^k L}{\sigma} \quad (42)$$

Thus, if

$$1 - \frac{\delta^k L}{\sigma} \geq \zeta^2 \quad (43)$$

then

$$\cos \phi^k \geq \zeta \quad \forall k \geq \hat{k} \quad (44)$$

holds. By (34) this yields $\angle(-g^r, v^k - w^r) \leq \theta$, the result needed in Lemma 3. Since $\zeta > 0$, (43) implies (39), so (38) holds and there is no need to separately satisfy it. Now (43) holds if

$$k \geq \hat{k} \stackrel{\text{def}}{=} \frac{\log(L/(\sigma(1 - \zeta^2)))}{\log(1/\delta)} \quad (45)$$

which proves the lemma.

Proof of Theorem 4. It trivially follows from a combination of Lemma 3 and Theorem 2.

Abstract

We consider a model selection problem in high-dimensional binary Markov random fields. The usefulness of the Ising model in studying systems of complex interactions has been confirmed in many papers. The main drawback of this model is the intractable norming constant that makes estimation of parameters very challenging. In the paper we propose a Lasso penalized version of the Monte Carlo maximum likelihood method. We prove that our algorithm, under mild regularity conditions, recognizes the true dependence structure of the graph with high probability. The efficiency of the proposed method is also investigated via numerical studies.

Keywords: Ising model, Monte Carlo Markov chain, Markov random field, model selection, Lasso penalty

1. Introduction

A Markov random field is an undirected graph (V, E), where $V = \{1, \ldots, d\}$ is a set of vertices and $E \subset V \times V$ is a set of edges. The structure of this graph describes conditional independence among subsets of a random vector $Y = (Y(1), \ldots, Y(d))$, where a random variable $Y(s)$ is associated with a vertex $s \in V$. Finding interactions between random variables is a central element of many branches of science, for example biology, genetics, physics or social network analysis. The goal of the current paper is to recognize the structure of a graph on the basis of a sample consisting of n independent observations. We consider the high-dimensional setting, i.e. the number of vertices d can be comparable or larger than the sample size n. It is motivated by contemporary applications of Markov random fields in the above-mentioned places, for instance gene microarray data.

The Ising model (Ising, 1925) is an important example of a mathematical model that is often used to explain relations between discrete random variables. In the literature one can find many papers that argue for its effectiveness in recognizing the structure of a graph (Ravikumar et al., 2010; Höfling and Tibshirani, 2009; Guo et al., 2010; Xue et al., 2012; Jalali et al., 2011). This model also plays a key role in our paper. On the other hand, the Ising model is an example of an intractable constant model that is the joint distribution of Y is known only up to a norming constant and this constant cannot be calculated in practice.

Thus, there are two main difficulties in the considered model. The first one is the high-dimensionality of the problem. The second one is the intractable norming constant. To overcome the first obstacle we apply a well-known Lasso method (Tibshirani, 1996). The properties of this method in model selection are deeply studied in many papers that mainly investigate linear models or generalized linear models (Bickel et al., 2009; Bühlmann and van de Geer, 2011; Huang and Zhang, 2012; van de Geer, 2008; Ye and Zhang, 2010; Zhao and Yu, 2006; Zhou, 2009). However, it is not difficult to find papers that describe properties of Lasso estimators in more complex models, for instance Markov random fields (Banerjee et al., 2008; Bühlmann and van de Geer, 2011; Ravikumar et al., 2010; Höfling and Tibshirani, 2009; Guo et al., 2010; Xue et al., 2012) that are considered in this paper.

There are many approaches trying to overcome the second obstacle that is the intractable norming constant. For instance, in Ravikumar et al. (2010) one proposes to perform d regularized logistic regression problems. This idea is based on the fact that the norming constant reduces, if one considers the conditional distribution instead of the joint distribution in the Ising model. This simple fact is at the heart of the pseudolikelihood approach (Besag, 1974) that is replacing the likelihood (that contains the norming constant) by the product of conditionals (that do not contain the norming constant). This idea is widely applied in the literature (Höfling and Tibshirani, 2009; Guo et al., 2010; Xue et al., 2012; Jalali et al., 2011) to study model selection properties of high-dimensional Ising models. However, this approach works well only if the pseudolikelihood is a good approximation of the likelihood. In general, it depends on the true structure of a graph. Namely, if this structure of the graph is sufficiently simple (examples of different structures can be found in section 5.1), then the product of conditionals should be close to the joint distribution. However, in practice this knowledge is unavailable. Another approach is described in Banerjee et al. (2008). It adapts the method that estimates the precision matrix in gaussian graphical models to the binary case. In the current paper we propose the approach to the norming constant problem that relates to Markov chain Monte Carlo (MCMC) methods. Namely, the norming constant is approximated using the importance sampling technique. This method is independent of the unknown complexity of the estimated graph. It is sufficient that the size of a sample used in importance sampling is sufficiently large to have good approximation of the likelihood.

The MCMC method is a well-known approach to overcome the problem with the intractable norming constant in classical (low-dimensional) estimation of graphs. For instance, its properties are investigated in influential papers Geyer and Thompson (1992); Geyer (1994). In the high-dimensional Ising model these algorithms were also studied. For

example, Honorio (2012) and Atchadé et al. (2017) analyzed stochastic versions of proximal gradient algorithms. Both papers derive nonasymptotic bounds between the output of the algorithm and the true minimizer of the cost function. However, in the current paper we focus on model selection properties of MCMC methods. We investigate them in the high-dimensional scenario and compare to the existing methods that are mentioned above. Model selection for undirected graphical models means finding the existing edges in the "sparse" graph that is a graph having relatively few edges (comparing to the total number of possible edges $\frac{d(d-1)}{2}$ and the sample size n).

The paper is organized as follows: in the next section we describe the Ising model and our approach to the problem that relates to minimization of the penalized MCMC approximation of the likelihood. The literature concerning this topic is also discussed. In section 3 we state main theoretical results. Details of efficient implementation are given in section 4, while the results of numerical studies are presented in section 5. The conclusions can be found in section 6. Finally, the proofs are postponed to appendices A and B.

2. Model description and related works

In this section we introduce the Ising model and the proposed method. It also contains a review of the literature relating to this problem.

2.1. Ising Model and undirected graphs

Let (V, E) be an undirected graph that consists of a set of vertices V and a set of edges E. The random vector $Y = (Y(1), Y(2), \ldots, Y(d))$, that takes values in $\mathcal{Y}$, is associated with this graph. In the paper we consider a special case of the Ising model that $Y(s) \in \{-1, 1\}$ and the joint distribution of Y is given by the formula

$$p(y|\theta^\star) = \frac{1}{C(\theta^\star)} \exp\left(\sum_{r<s} \theta^\star_{rs} y(r) y(s)\right), \tag{1}$$

where the sum in (1) is taken over such pairs of indices $(r, s) \in \{1, \ldots, d\}^2$ that $r < s$. The vector $\theta^\star \in \mathbb{R}^{d(d-1)/2}$ is a true parameter and $C(\theta^\star)$ is a norming constant, i.e.

$$C(\theta^\star) = \sum_{y \in \mathcal{Y}} \exp\left(\sum_{r<s} \theta^\star_{rs} y(r) y(s)\right).$$

The norming constant is a finite sum but it consists of 2^d elements that makes it intractable even for a moderate size of d.

For convenience, we denote $J(y) = (y(r)y(s))_{r<s}$, so

$$p(y|\theta^\star) = \frac{1}{C(\theta^\star)} \exp\left[(\theta^\star)' J(y)\right].$$

Remark 1 *The model* (1) *is a simplified version of the Ising model, for instance we omit an external field in* (1). *We have decided to restrict to the model containing only parameters* $\theta^\star_{rs}$, *because interactions between random variables is what we focus on in the current paper. However, our results can be relatively easy extended.*

The Ising model has the following property: vertices r and s are not connected by an edge (i.e. $\theta^\star_{rs} = 0$) means that variables $Y(r)$ and $Y(s)$ are conditionally independent given the other vertices. Therefore, we recognize the structure of the graph (its edges) by estimating the parameter $\theta^\star$. Assume that $Y_1, \ldots, Y_n$ are independent random vectors from the model (1). Then the negative log-likelihood is

$$\ell_n(\theta) = -\frac{1}{n} \sum_{i=1}^n \theta' J(Y_i) + \log C(\theta). \tag{2}$$

The second term in (2) contains the norming constant so we cannot use (2) to estimate $\theta^\star$. To overcome this problem one usually replaces the negative log-likelihood by its approximation and estimates $\theta^\star$ using the minimizer of this approximation. In the current paper the approximation of (2) is based on Monte Carlo (MC) methods. Suppose that $h(y)$ is an importance sampling distribution and note that

$$C(\theta) = \sum_{y \in \mathcal{Y}} \exp\left[\theta' J(y)\right] = \sum_{y \in \mathcal{Y}} \frac{\exp\left[\theta' J(y)\right]}{h(y)} h(y) = \mathbb{E}_{Y \sim h} \frac{\exp\left[\theta' J(Y)\right]}{h(Y)} \tag{3}$$

for each θ. An MC approximation of the norming constant is

$$\frac{1}{m} \sum_{k=1}^m \frac{\exp\left[\theta' J(Y^k)\right]}{h(Y^k)}, \tag{4}$$

where $Y^1, \ldots, Y^m$ is a sample drawn from h or, which is more realistic and is considered in the current paper, $Y^1, \ldots, Y^m$ is a Markov chain with h being a density of its stationary distribution. Thus, the MCMC approximation of (2) is

$$\ell^m_n(\theta) = -\frac{1}{n} \sum_{i=1}^n \theta' J(Y_i) + \log\left(\frac{1}{m} \sum_{k=1}^m \frac{\exp\left[\theta' J(Y^k)\right]}{h(Y^k)}\right). \tag{5}$$

A natural choice of the importance sampling distribution is $h(y) = p(y|\psi)$ for some parameter ψ. It leads to

$$\ell^m_n(\theta) = -\frac{1}{n} \sum_{i=1}^n \theta' J(Y_i) + \log\left(\frac{1}{m} \sum_{k=1}^m \exp\left[(\theta - \psi)' J(Y^k)\right]\right) + \log(C(\psi)). \tag{6}$$

The last term in (6), that contains the unknown constant $C(\psi)$, does not depend on θ, so it can be ignored while minimizing (6).

Our goal is selecting the true model (recognizing edges of a graph) in the high-dimensional setting. It means that the number of vertices d can be large. In fact, it can be greater than the sample size, i.e. $d = d_n \gg n$. To estimate the vector $\theta^\star$ we use penalized empirical risk minimization. The natural choice of the penalty would be the l_0-penalty, but it makes the procedure nonconvex and computationally expensive even for moderate values of d. To avoid such problems, we use the Lasso penalty and minimize a function

$$\ell^m_n(\theta) + \lambda^m_n |\theta|_1, \tag{7}$$

where $|\theta|_1 = \sum_{r<s} |\theta_{rs}|$ and $\lambda_n^m > 0$ is a smoothing parameter, that is a balance between minimizing the MCMC approximation and the penalty. We denote the minimizer of (7) by $\hat{\theta}_n^m$. Notice that the function (7), that we minimize, is convex in θ, because the Lasso penalty as well as the MCMC approximation (6) are convex function in θ. The latter follows from the fact that the Hessian of $\ell_n^m(\theta)$, that is given explicitly in (19), is a weighted covariance matrix with positive weights that sum up to one. Convexity of the problem is important from the practical and theoretical point of view. First, every minimum of a convex function is the global minimum, so there are no local minimum problems. Second, convexity is also utilized in the proofs of the results contained in the paper. In further parts of the paper we study properties of $\hat{\theta}_n^m$ in model selection.

2.2. Related works

Model selection in the high-dimensional Ising model is a popular topic and many papers investigating this problem using different methods can be found in the literature (Banerjee et al., 2008; Bresler et al., 2008; Lee et al., 2006; Ravikumar et al., 2010; Höfling and Tibshirani, 2009; Guo et al., 2010; Xue et al., 2012; Jalali et al., 2011). The significant part of them uses the pseudolikelihood approximation with the Lasso penalty. For instance, Ravikumar et al. (2010) applies it by considering d logistic regression problems. They prove that this algorithm is model selection consistent, if some regularity conditions are satisfied. These conditions are similar to the "irrepresentable conditions" (Zhao and Yu, 2006), that are sufficient to prove an analogous property in the linear model. The pseudolikelihood method with the Lasso as a "joint" procedure is proposed in Höfling and Tibshirani (2009). Moreover, in the same paper one also proposes an "exact" algorithm, that minimizes the negative log-likelihood with the Lasso penalty. However, this procedure also bases on the pseudolikelihood approximation. Model selection consistency of the latter algorithm has not been studied yet. The former procedure has this property, that is showed in Guo et al. (2010) provided that conditions similar to Ravikumar et al. (2010) are satisfied. In Xue et al. (2012) the Lasso penalty is replaced by the SCAD penalty (Fan and Li, 2001) and theoretical properties of this algorithm are studied. In Jalali et al. (2011) one replaces restrictive irrepresentable conditions by weaker restricted strong convexity and smoothness conditions (Negahban et al., 2009) and proves model selection consistency of an algorithm that joints ideas from Ravikumar et al. (2010) and Zhang (2009). Namely, it performs d separate logistic regression problems with the forward-backward greedy approach. The algorithm described in Banerjee et al. (2008) is also based on the likelihood approximation with the Lasso penalty. However, it does not apply the pseudolikelihood method. Using the determinant relaxation (Wainwright and Jordan, 2006) it treats the problem of model selection in discrete Markov random fields analogously to the continuous case.

In the current paper we apply the MCMC method to overcome the intractable norming constant problem. Our experimental study (presented in section 5) confirms that estimators based on the MCMC approximation usually perform comparably or better in model selection than their competitors from Banerjee et al. (2008); Höfling and Tibshirani (2009); Ravikumar et al. (2010). Our theoretical results are similar to those described in the previous paragraph, that is we prove model selection consistency. But, in general, our assumptions

are weaker than their analogs from the above-mentioned papers. The detailed comparison is given after Corollary 3 in section 3.

Moreover, the advantage of our algorithm is that the MCMC approach allows us to approximate the norming constant with an arbitrary precision. The approximation error of other methods is given by the problem/data. It depends on the unknown structure of a graph and a user cannot improve it. In our approach a user can improve approximation by increasing the length of simulation, using the MCMC algorithm tailored to the problem. The obvious drawback of our approach is the need of additional simulations to obtain the MCMC sample. It makes our procedure computationally more complex, but at the same time more accurate in selecting the true model.

2.3. Notation

In further parts of the paper we need few notations. Most of them are collected in this subsection.

For simplicity, we write $\hat{\theta}$ and λ instead of $\hat{\theta}_n^m$ and λ_n^m, respectively. Besides, we denote the number of estimated parameters in the model by $\bar{d} = d(d-1)/2$. Nonzero coordinates of $\theta^\star$ are collected in the set T, and T^c is a completion of T. Besides, $\bar{d}_0 = |T|$ denotes the number of elements in the set T.

For a vector a we denote its l_∞-norm by $|a|_\infty = \max_k |a_k|$ and $a^{\otimes 2} = aa'$. The vector a_T is the same as the vector a on T and zero otherwise. The l_∞-norm of a matrix Σ is denoted by $|\Sigma|_\infty = \max_{k,l} |\Sigma_{kl}|$.

Let us consider a Markov chain on a space $\mathcal{S}$ with a transition kernel $P(x, \cdot)$ and a stationary distribution π. We define the Hilbert space $L^2(\pi)$ as a space of functions that $\pi(f^2) < \infty$ and the inner product is given as $\langle f, g \rangle = \int_{\mathcal{S}} f(x) g(x) \pi(dx)$. The linear operator P on $L^2(\pi)$ associated with the transition kernel $P(x, \cdot)$ is defined as follows

$$Pf(x) = \int_{\mathcal{S}} f(y) P(x, dy) \,.$$

We say that the Markov chain has a spectral gap $1 - \kappa$ if and only if

$$\kappa = \sup\{|\rho| \colon \rho \in Spec(P) \setminus \{1\}\} \,,$$

where $Spec(\cdot)$ denotes the spectrum of an operator in $L^2(\pi)$. For reversible chains the spectral gap property is equivalent to geometric ergodicity of the chain (Kontoyiannis and Meyn, 2012; Roberts and Rosenthal, 1997).

In the paper we focus on the Gibbs sampler for the Ising model. However, theoretical results remain true for other MCMC algorithms as long as the spectral gap property is satisfied. The random scan Gibbs sampler for the Ising model with a joint distribution $p(y|\psi)$ is defined as follows: given Y^{k-1}, first we sample uniformly index r and we draw $Y^k(r)$ from the distribution

$$\mathbb{P}(Y^k(r) = 1) = \frac{\exp\{\psi' J(Y^+)\}}{\exp\{\psi' J(Y^+)\} + \exp\{\psi' J(Y^-)\}} \,, \tag{8}$$

where $Y^+(s) = Y^-(s) = Y^{k-1}(s)$ for $s \neq r$ and $Y^+(r) = 1$, $Y^-(r) = -1$. For $s \neq r$ we set $Y^k(s) = Y^{k-1}(s)$.

Suppose that $Y^1, \ldots, Y^m$ is a Markov chain on $\mathcal{Y}$ generated by a random scan Gibbs sampler defined as above. By construction the chain is irreducible, aperiodic and $h(y) = p(y|\psi)$ is the density of its stationary distribution. Therefore, the stationary distribution is defined uniquely and the chain is ergodic for any initial measure ν with the density q. Moreover, there exists a spectral gap $1-\kappa$, because the state space is finite and the chain is reversible. Actually, κ is the second greatest absolute value of eigenvalues of the transition matrix. We will need three quantities related to this Markov chain :

$$\beta_1 = \sqrt{\sum_{y\in\mathcal{Y}} \frac{q^2(y)}{h(y)}}, \quad \beta_2 = \frac{1-\kappa}{1+\kappa}, \quad M = \max_{y\in\mathcal{Y}} \frac{\exp((\theta^\star)' J(y))}{h(y) C(\theta^\star)}\,. \tag{9}$$

Roughly speaking, these three values can be viewed as: β_1 – how close the initial density is to the stationary one, β_2 – how fast the chain "mixes", M – how close the importance sampling density is to the true density (1).

3. Main results

In this section we state key results of the paper. In the first one (Theorem 2) we show that the estimation error of the minimizer of the MCMC approximation with the Lasso penalty can be controlled. In the second result (Corollary 3) we prove model selection consistency for the thresholded Lasso estimator (Zhou, 2009).

First, we introduce the cone invertibility factor that plays an important role in investigating properties of Lasso estimators. It is defined analogously to Ye and Zhang (2010); Huang and Zhang (2012); Huang et al. (2013) that concerns linear regression, generalized linear models and the Cox model, respectively. It is also closely related to the compatibility condition (van de Geer, 2008) or the restricted eigenvalue condition (Bickel et al., 2009). Thus, for $\xi > 1$ and the set T we define a cone as

$$\mathcal{C}(\xi, T) = \{\theta : |\theta_{T^c}|_1 \le \xi |\theta_T|_1\}\,.$$

For a nonnegative definite matrix Σ the cone invertibility factor is

$$F(\xi, T, \Sigma) = \inf_{0\neq\theta\in\mathcal{C}(\xi,T)} \frac{\theta'\Sigma\theta}{|\theta_T|_1 |\theta|_\infty}\,.$$

Cone invertibility factors of Hessians of two functions are crucial in our argumentation. The first function is the expectation of the negative log-likelihood (2), i.e.

$$\mathbb{E}\ell_n(\theta) = -\theta'\mathbb{E}J(Y) + \log C(\theta) \tag{10}$$

and the second one is the MCMC approximation (5). We denote them as

$$F(\xi, T) = \inf_{0\neq\theta\in\mathcal{C}(\xi,T)} \frac{\theta'\nabla^2 \log C(\theta^\star)\theta}{|\theta_T|_1 |\theta|_\infty} \tag{11}$$

and

$$\bar{F}(\xi, T) = \inf_{0\neq\theta\in\mathcal{C}(\xi,T)} \frac{\theta'\nabla^2 \ell_n^m(\theta^\star)\theta}{|\theta_T|_1 |\theta|_\infty}\,, \tag{12}$$

respectively. Notice that only the values of $\nabla^2 \log C(\theta)$ and $\nabla^2 \ell_n^m(\theta)$ at the true parameter $\theta^\star$ are taken into consideration in (11) and (12).

Now we can state main results of the paper.

Theorem 2 *Let $\varepsilon > 0, \xi > 1$ and $\alpha(\xi) = 2 + \frac{e}{\xi - 1}$. If*

$$n \ge \frac{8(1+\xi)^4\, \alpha^2(\xi)\, \bar{d}_0^2\, \log(2\bar{d}/\varepsilon)}{F^2(\xi, T)}\,, \tag{13}$$

$$m \ge \frac{64(1+\xi)^4\, \alpha^2(\xi)\, \bar{d}_0^2\, M^2\, \log\left[2\bar{d}(\bar{d}+1)\beta_1/\varepsilon\right]}{F^2(\xi, T)\beta_2}\,, \tag{14}$$

then with probability at least $1 - 4\varepsilon$ we have the inequality

$$\left|\hat{\theta} - \theta^\star\right|_\infty \le \frac{2e\,\xi\,\alpha(\xi)\lambda}{(\xi+1)[\alpha(\xi)-2]F(\xi, T)}\,, \tag{15}$$

where

$$\lambda = \frac{\xi+1}{\xi-1} \max\left(2\sqrt{\frac{2\log(2\bar{d}/\varepsilon)}{n}}, 8M\sqrt{\frac{\log\left[(2\bar{d}+1)\beta_1/\varepsilon\right]}{m\beta_2}}\right)\,. \tag{16}$$

Corollary 3 *Suppose that conditions (13) and (14) are satisfied. Let $\theta^\star_{min} = \min_{(r,s)\in T} |\theta^\star_{rs}|$ and R_n^m denote the right-hand side of the inequality (15). Consider the Lasso estimator with a threshold $\delta > 0$ that is the set of nonzero coordinates of the final estimator is defined as $\hat{T} = \{(r,s) : |\hat{\theta}_{rs}| > \delta\}$. If $\theta^\star_{min}/2 > \delta \ge R_n^m$, then*

$$P\left(\hat{T} = T\right) \ge 1 - 4\varepsilon\,.$$

The main results of the paper describe properties of estimators, that are obtained by minimization of the MCMC approximation (5) with the Lasso penalty. Theorem 2 states that the estimation error of the Lasso estimator can be controlled. Roughly speaking, the estimation error is small, if the initial sample size and the MCMC sample size are large enough, the model is sparse and the cone invertibility factor $F(\xi, T)$ is not too close to zero. The influence of the model parameters $(n, d, \bar{d}_0)$ as well as Monte Carlo parameters (m, β_1, β_2, M) on the results are explicitly stated. It is worth to emphasize that our results work in the high-dimensional scenario, i.e. the number of vertices d can be greater than the sample size n provided that the model is sparse. Indeed, the condition (13) is satisfied even if $\bar{d} \sim O\left(e^{n^{c_1}}\right)$, $\bar{d}_0 \sim O(n^{c_2})$ and $c_1 + 2c_2 < 1$. The condition (14), that relates to the MCMC sample size, is also reasonable. The number β_1 depends on the initial and stationary distributions. In general, its relation to the number of vertices is exponential. However, in (14) it appears with the logarithm. Moreover, β_1 is also reduced using so called burn-in time, i.e. the beginning of the Markov chain trajectory is discarded. Next, the number β_2 is related to the spectral gap of a Markov chain. Under mild conditions the inverse of β_2 depends polynomially on d, and under strong regularity conditions it can be reduced to $O(d \log d)$ as in Mossel and Sly (2013). Finally, there is also the number M in the condition (14) that relates to the distance between the stationary distribution $h(\cdot)$ and $p(\cdot|\theta^\star)$. Stating

the explicit relation between M and the model seems to be difficult. However, the algorithm, that we propose to calculate $\hat{\theta}$, is designed in such a way to minimize the impact of M on the results. The detailed implementation of the algorithm is given in section 4.

The estimation error of the Lasso estimator in Theorem 2 is measured in l_∞-norm. Similarly to Huang et al. (2013), it can be extended to the general l_q-norm, $q \geq 1$. We omit it, because (15) is sufficient to obtain the second main result of the paper (Corollary 3). It states that the thresholded Lasso estimator is model selection consistent, if, additionally to (13) and (14), the nonzero parameters are not too small and the threshold is appropriately chosen. It is a consequence of the fact, which follows from Theorem 2, that the Lasso seperates significant parameters from irrelevant ones, i.e. for each $(r,s) \in T$ and $(r',s') \notin T$ we have $|\hat{\theta}_{rs}| > |\hat{\theta}_{r's'}|$ with high probability. However, Corollary 3 does not give a way of choosing the threshold δ, because both endpoints of the interval $[R_n^m, \theta^\star_{min}/2]$ are unknown. It is not a surprising fact and has been already observed, for instance, in linear models (Ye and Zhang, 2010, Theorem 8). In section 4 we propose a method of choosing a threshold, that relates to information criteria.

We have already mentioned that there are many approaches to the high-dimensional Ising model. Now we compare conditions, that are sufficient to prove model selection consistency in the current paper to those basing on the likelihood approximation. If we simplify regularity conditions in Theorem 2, Corollary 3 and forget about Monte Carlo parameters in (14), then we have:

(a) the cone invertibility factor condition is satisfied,

(b) the sample size should be sufficiently large, that is $n > \bar{d}_0^2 \log d$,

(c) the nonzero parameters should be sufficiently large, that is $\theta^\star_{min} > \sqrt{\frac{\log d}{n}}$.

In Ravikumar et al. (2010, Corollary 1) one needs stronger irrepresentable condition in (a). Their analog of (b) is $n \geq v^3 \log d$, where v is the maximum neighbourhood size. Since v is smaller than $\bar{d}_0$, their condition is less restrictive. However, in (c) they require the minimum signal strength to be higher than ours, because it has to be larger than $\sqrt{\frac{v \log d}{n}}$ as distinct from $\sqrt{\frac{\log d}{n}}$ in our paper.

Assumptions in Guo et al. (2010, Theorem 2) are stronger than ours. Indeed, they need irrepresentable condition in (a), $\bar{d}_0$ in the third power in (b) and additional factor $\sqrt{\bar{d}_0}$ in (c).

In Xue et al. (2012, Corollary 3.1 (2)) model selection consistency of Lasso estimators is also proved with more restrictive conditions than ours. Namely, they are similar to Ravikumar et al. (2010) and Guo et al. (2010) but $\bar{d}_0$ is reduced in the condition (c). Moreover, they also consider the pseudolikelihood approximation with the SCAD penalty and shows that the condition (a) seems to be superfluous in this case, see Xue et al. (2012, Corollary 3.1 (1)). However, using the SCAD penalty they minimize a nonconvex function to obtain an estimator, so they have to prove that the computed (local) minimizer is the desired theoretic local solution. Their approach can be viewed as a sequence of weighted Lasso problems, so they need auxiliary Lasso procedures to behave well. Therefore, the irrepresentable condition is assumed (Xue et al., 2012, Corollary 3.2).

The conditions sufficient for model selection consistency that are stated in Jalali et al. (2011, Theorem 2) are comparable to ours but also more restrictive. Instead of the condition (a) they consider a similar requirement called the restricted strong convexity condition. It is completed by the restricted strong smoothness condition. Moreover, in the the lower bound in the condition (c) they need an additional factor $\sqrt{\bar{d}_0}$ as well as the upper bound for $\theta^\star_{min}$.

In the proof of Theorem 2 we use methods that are well-known while investigating properties of Lasso estimators as well as some new argumentation. The main novelty (and difficulty) is the use of the Monte Carlo sample, that contains dependent vectors. The first part of our argumentation consists of two steps:

(i) the first step can be viewed as "deterministic". We apply methods that were developed in Ye and Zhang (2010); Huang and Zhang (2012); Huang et al. (2013) and strongly exploit convexity of the considered problem. These auxiliary results are stated in Lemma 5 and Lemma 6 in the appendix A,

(ii) the second step is "stochastic". We state a probabilistic inequality that bounds the l_∞-norm of the derivative of the MCMC approximation (5) at $\theta^\star$, that is

$$\nabla \ell_n^m(\theta^\star) = -\frac{1}{n}\sum_{i=1}^n J(Y_i) + \frac{\sum_{k=1}^m w_k(\theta^\star) J(Y^k)}{\sum_{k=1}^m w_k(\theta^\star)} \tag{17}$$

where

$$w_k(\theta) = \frac{\exp\left[\theta' J(Y^k)\right]}{h(Y^k)}\,, \quad k = 1, \ldots, m\,. \tag{18}$$

Notice that (17) contains independent random variables $Y_1, \ldots, Y_n$ from the initial sample and the Markov chain $Y^1, \ldots, Y^m$ from the MC sample. Therefore, to obtain the exponential inequalities for the l_∞-norm of (17), which are given in Lemma 7 and Corollary 8 in the appendix A, we apply the MCMC theory. In particular, we frequently use the following Hoeffding's inequality for Markov chains (Miasojedow, 2014, Theorem 1.1).

Theorem 4 *Let $Y^1, \ldots, Y^m$ be a reversible Markov chain with a stationary distribution with a density h and a spectral gap $1-\kappa$. Moreover, let $g : \mathcal{Y} \to \mathbb{R}$ be a bounded function and $\mu = \mathbb{E}_{Y\sim h} g(Y)$ be a stationary mean value. Then for every $t > 0, m \in \mathbb{N}$ and an initial distribution q*

$$P\left(\left|\frac{1}{m}\sum_{k=1}^m g(Y^k) - \mu\right| > t\right) \leq 2\beta_1 \exp\left(-\frac{\beta_2 m t^2}{|g|_\infty^2}\right)\,,$$

where $|g|_\infty = \sup_{y\in\mathcal{Y}} |g(y)|$ and β_1, β_2 are defined in (9).

The next part of our argumentation relates to the fact that the Hessian of the MCMC approximation at $\theta^\star$, that is

$$\nabla^2 \ell_n^m(\theta^\star) = \frac{\sum_{k=1}^m w_k(\theta^\star) J(Y^k)^{\otimes 2}}{\sum_{k=1}^m w_k(\theta^\star)} - \left[\frac{\sum_{k=1}^m w_k(\theta^\star) J(Y^k)}{\sum_{k=1}^m w_k(\theta^\star)}\right]^{\otimes 2}, \tag{19}$$

is random variable. Similar problems were considered in several papers investigating properties of Lasso estimators in the high-dimensional Ising model (Ravikumar et al., 2010; Guo et al., 2010; Xue et al., 2012) or the Cox model (Huang et al., 2013). We overcome this difficulty by bounding from below the cone invertibility factor $\bar{F}(\xi, T)$ by nonrandom $F(\xi, T)$. Therefore, we need to prove that Hessians of (10) and (5) are close. It is obtained again using the MCMC theory in Lemma 9 and Corollary 10 in the appendix A.

Finally, the proofs of Theorem 2 and Corollary 3 are stated in the appendix B.

4. Details of implementation

In this section we describe in details practical implementation of the algorithm analyzed in the previous section.

The solution of the problem (7) depends on the choice of λ in the penalty term and the parameter ψ in the instrumental distribution. Finding "optimal" λ and ψ is difficult in practice. To overcome this problem we compute a sequence of minimizers $(\hat{\theta}_i)_i$ such that $\hat{\theta}_i$ corresponds to $\lambda = \lambda_i$ and the sequence $(\lambda_i)_i$ is decreasing. In the second step we use the Bayesian Information Criterion (BIC) to choose the final penalty λ. More precisely, we start with the greatest value λ_0 for which the entire vector $\hat{\theta}$ is zero. For each value of λ_i, $i \geq 1$, we set $\psi = \hat{\theta}_{i-1}$ and use the MCMC approximation (7) with $Y^1, \ldots, Y^m$ given by a Gibbs sampler with the stationary distribution $p(\cdot|\hat{\theta}_{i-1})$. This scheme exploits warm starts and leads to more stable algorithm. Next, the estimator $\hat{\theta}$ is chosen using BIC that is a popular method of choosing λ in the literature, for instance in Xue et al. (2012). Notice that the function $\ell_n^m(\theta)$ is convex, so we can use proximal gradient algorithms to compute $\hat{\theta}_i$ as a solution of (7) for a given λ_i and ψ. In the current paper we use the FISTA algorithm with backtracking from Beck and Teboulle (2009). The whole procedure is summarized in Algorithm 1.

Algorithm 1 MCMC Lasso for Ising model

Let $\lambda_0 > \lambda_1 > \cdots > \lambda_{100}$ and $\psi = 0$.
for $i = 1$ to 100 **do**
Simulate $Y^1, \ldots, Y^m$ using a Gibbs sampler with the stationary distribution $p(y|\psi)$.
Run the FISTA algorithm to compute $\hat{\theta}_i$ as

$$\arg\min_\theta \left\{\ell_n^m(\theta) + \lambda_i |\theta|_1\right\}.$$

Set $\psi = \hat{\theta}_i$.
end for
Next, set $\hat{\theta} = \hat{\theta}_{i^*}$, where

$$i^* = \arg\min_{1 \leq i \leq 100} \left\{ n\ell_n^m(\hat{\theta}_i) + \log(n)\|\hat{\theta}_i\|_0 \right\}$$

and $\|\theta\|_0$ denotes the number of non-zero elements of θ.

In Algorithm 1 we use 100 values of λ uniformly spaced on the log scale, starting from the largest λ, which corresponds to the empty model. We use $m = 10^3 d$ iteration of the Gibbs sampler. To compute $\ell_n^m(\hat{\theta}_i)$ for $i = 1, \ldots, 100$ in BIC we generate one more sample of the size $m = 10^4 d$ using the Gibbs sampler with the stationary distribution $p(\cdot|\hat{\theta}_{50})$.

The important property of our implementation is that the chosen $\psi = \hat{\theta}_{i-1}$ is usually close to $\hat{\theta}_i$, because differences between consecutive λ_i's are small. In our studies the final estimator $\hat{\theta}$ is the element of the sequence $(\hat{\theta}_i)_i$, that recognizes the true model in the best way, i.e. it minimizes the MCMC approximation and is sparse simultaneously. One believes that the final estimator $\hat{\theta} = \hat{\theta}_i$ is close to $\theta^\star$, therefore the chosen $\psi = \hat{\theta}_{i-1}$ should be also similar to $\theta^\star$, that makes M in (9) close to one. Finally, notice that conditionally on the previous step our algorithm fits to the framework described in subsection 2.1.

Note that in the first iteration in Algorithm 1 we use an uniform distribution on $\{-1, +1\}^d$ as an instrumental distribution and we can use i.i.d sample $Y^1, \ldots, Y^m$. Therefore, for λ_1 we get $\beta_1 = \beta_2 = 1$. When we compute estimators for λ_i with $i \geq 2$ we use the last sample from the previous step as an initial point, so since the Markov chain generated by the Gibbs sampler is ergodic its initial distribution should be close to $p(y|\hat{\theta}_{i-2})$. Therefore, even without the burn-in time β_1 should be approximately equal to the L^2-distance between $p(y|\hat{\theta}_{i-1})$ and $p(y|\hat{\theta}_{i-2})$, which seems to be small, because differences between consecutive λ_i's are small. So, after discarding initial iterations β_1 is further reduced. Our choice of stationary distributions also leads to relatively small variances of importance sampling weights given in (18).

The bounds on β_2 are challenging problem itself and the sharp bounds are available only in very specific cases. Due to that, we do not have the explicit control on β_2. However, in our procedure the stationary distributions are typically given by sparse Ising models and by Mossel and Sly (2013) the spectral gap depends mostly on the number of existing edges in the graph. Therefore β_2 should not vanish to rapidly with dimensionality of the problem.

Finally, the thresholded estimator is obtained using the Generalized Information Criterion (GIC). For a prespecified set of thresholds Δ we calculate

$$\delta^* = \arg\min_{\delta\in\Delta}\left\{n\ell_n^m(\hat\theta^\delta) + \log(\bar d)\|\hat\theta^\delta\|_0\right\},$$

where $\hat\theta^\delta$ is the Lasso estimator $\hat\theta$ after thresholding with the level δ. To compute $\ell_n^m(\hat\theta^\delta)$ for $\delta\in\Delta$ in GIC we generate the last sample of the size $m = 10^4 d$ using the Gibbs sampler with the stationary distribution $p(\cdot|\hat\theta)$. To find the optimal threshold we apply GIC that uses larger penalty than BIC. Choosing the threshold in this way should be better in model selection and is recommended, for instance, in Pokarowski and Mielniczuk (2015).

In the rest of this section we discuss computational complexity of our method. The computational cost of a single step of the Gibbs sampler is dominated by computing probability (8), which is of the order $O(r)$, where r is the maximal degree of vertices in a graph related to the stationary distribution. In the paper we focus on estimation of sparse graphs, so the proposed λ_i's have to be sufficiently large to make $\hat\theta_i$'s sparse. Therefore, the degree r is rather small and the computational cost of generating $Y^1,\dots,Y^m$ is of order $O(m)$. Next, we need to compute $\ell_n^m(\theta)$ and its gradient. For an arbitrary Markov chain the cost of these computation is of the order $O(d^2m)$. But when we use single site updates as in the Gibbs sampler we can reduce it to $O(dm)$ by remembering which coordinate of Y^k where updated. Indeed, if we know that only the r coordinates are updated in the step $Y^k\to Y^{k+1}$, then

$$\theta' J(Y^{k+1}) = \theta' J(Y^k) + \sum_{s:\ s<r}\Big(\theta_{sr}[Y^{k+1}(s)Y^{k+1}(r) - Y^k(s)Y^k(r)]\Big) + \sum_{s:\ s>r}\Big(\theta_{rs}[Y^{k+1}(s)Y^{k+1}(r) - Y^k(s)Y^k(r)]\Big).$$

Finally, it is well-known that FISTA (Beck and Teboulle, 2009) achieves accuracy ϵ in $O(\epsilon^{\frac12})$ steps. So, the total cost of computing the solution for single λ_i with precision ϵ is of order $O(\epsilon^{\frac12} md)$. The further reduction of the cost can be obtained using sparsity of $\hat\theta_{i-1}$ in computing $\ell_n^m(\theta)$ and its gradient, and introducing active variables inside the FISTA algorithm.

5. Numerical experiments

In this section we present efficiency of the proposed method via numerical studies. First, we compare our method to three algorithms, which we have mentioned previously, using simulated data sets. Next we apply our method to the real data example.

5.1. Simulated data

To illustrate the performance of the proposed method we simulate data sets in two scenarios:

M1: The first 6 vertices are correlated, while the remaining vertices are independent: $\theta^\star_{rs} = \pm 2$ for $r<s$ and $s = 2,3,4,5,6$, other $\theta^\star_{rs} = 0$. Thus, the model dimension in this problem is 15. The signs are chosen randomly.

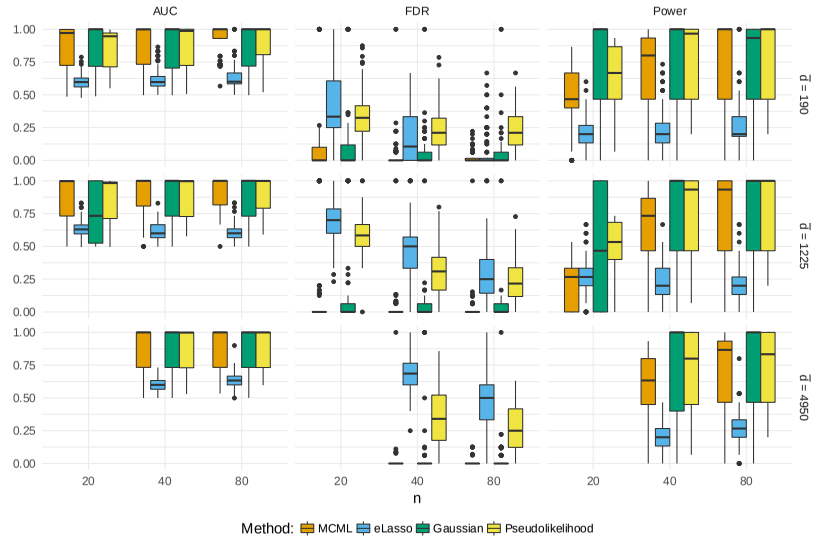

Figure 1: The results for $M1$ model

M2: The first 20 vertices have the "chain structure" and the rest are independent: $\theta^\star_{r-1,r} = \pm 1$ for $r\le 20$. Again the signs are chosen randomly and the model dimension is 19.

The model $M1$ corresponds to a dense structure on a small subset of vertices. The model $M2$ is a simple structure which involves relatively large subset of vertices.

We consider the following cases: $d = 20, 50, 100$. So, the considered number of possible edges (parameters of the model) is $\bar d = 190, 1225, 4950$, respectively. For $\bar d = 190, 1225$ we use $n = 20, 40, 80$ and for $\bar d = 4950$ we use $n = 40, 80$.

For each configuration of the model, the number of vertices d and the number of observation n we sample 100 replications of data sets. For sampling a data set we use a final configuration of independent Gibbs samplers of the length 10^6.

In simulation study we compare our methods to the following methods: the pseudo-likelihood approach, eLasso proposed by van Borkulo et al. (2014) and the Gaussian approximation from Banerjee et al. (2008). The eLasso method is based on separate logistic models and it is similar to the method proposed by Ravikumar et al. (2010). For all methods except eLasso we use two stage procedures, which are analogous to Algorithm 1. Namely, we choose λ by BIC and in the second step we choose the threshold δ by GIC. For the Gaussian approximation we use the same approximate likelihood as in Viallon et al. (2013). For eLasso for every node we use BIC as in van Borkulo et al. (2014).

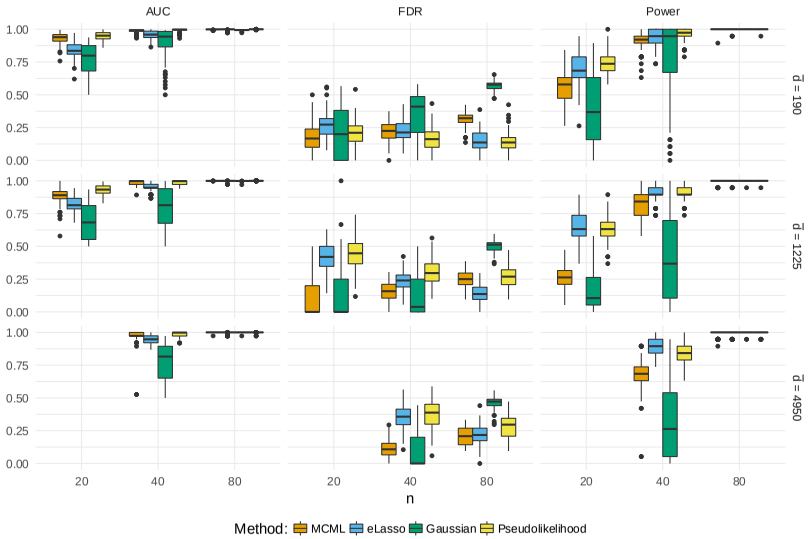

Figure 2: The results for $M2$ model

In the comparison we use the following measures of the accuracy. First, to observe the ability of methods to separate true and false edges we compute AUC, where the ROC curve is computed as the threshold δ varies. The estimates are also compared using the false discovery rate (FDR) and the ability of recognizing true edges (denoted by "Power"). The results are summarized in Figure 1 and Figure 2 for models $M1$ and $M2$, respectively.

In the first model we can observe that our algorithm and the Gaussian approximation work very well and comparably. The latter has slightly larger power, but at the price of slightly larger FDR. The dominance of these two methods over the pseudolikehood estimator and eLasso is evident. The pseudolikelihood method finds well true edges, but is not able to discard false edges. eLasso works very poorly in this model.

The second model has a simple structure, so both methods based on the pseudolikelihood approach work much better than in $M1$. The accuracy of the Gaussian approximation is weak in this model. It has substantial problem with finding true edges, especially when d is large and n small. For $n = 20, 40$ our estimator has relatively small FDR and large Power. In this model we can observe that FDR increases as n increases for the Gaussian approximation and for $n = 80$ it reaches about 0.5. The MCML approximation has also "increasing FDR", but this behaviour is less conspicuous. In fact, for $n = 80$ FDR of our algorithm is still comparable to those of eLasso and Pseudolikelihood.

Summarizing, it is difficult to indicate the winner algorithm. We can observe that the quality of our algorithm in selecting the true model is satisfactory. Moreover, only this procedure works on a good level in both models and avoids making noticeable mistakes. The Gaussian approximation works well in $M1$, but seems to be the weakest in $M2$. The eLasso completely fails in $M1$, but its quality in $M2$ is high, especially for large sample sizes. The pseudolikelihood approach in all examples well separates true and false edges, has good power but in comparison with other methods its FDR is too high, so models that it chooses contains many irrelevant edges.

Clearly, by construction the computational cost of our method is larger than its three competitors. However, the whole time that is needed to compute our estimator is reasonable. For instance, for a single data set and $n = 40$ computing the estimator on 3.4 GHZ CPU takes about 15 seconds for $\bar{d} = 190$, 60 seconds for $\bar{d} = 1225$ and 5 minutes for $\bar{d} = 4950$. Since our algorithm uses only sufficient statistics the dependence on n of its computational cost is negligible. Thus, the computational times for $n = 80$ are almost the same.

5.2. CAL500 dataset

We apply our method to "CAL500" dataset (Turnbull et al., 2008). Working with a real data set we consider the Ising model (1) with a linear term (an external field). This modification is motivated by the fact that in practice marginal probabilities of $Y(s)$ being $+1$ or -1 are unknown and should be estimated. The adaptation of our algorithm to this case is straightforward.

For model selection in the Ising model there are no natural measures of the quality of estimates. One would try to compare the prediction ability of obtained estimators, but prediction for the Ising model is challenging itself and results will be biased by the method used to approximate predicted states. Moreover, all considered methods optimize different loss functions, so these loss functions also cannot be used to the honest comparison of the methods. Due to that, we decide to show only the results of our method for the real data example.

The considered data set consists of 174 binary features and 68 numeric features for 502 songs. We skipped the numeric features and apply our method to find the dependence structure between labels. These labels concerning genre, mood or instrument are annotated to songs. We run our algorithm analogously to the case of simulated data and as the result we obtain a sparse graph with 181 edges, see Figure 3. We observe that founded edges are rather intuitive. For instance, among the most positively correlated labels we have labels denoted by 3 and 14 (,,Emotion-Arousing-Awakening" and ,,Emotion-Exciting-Thrilling"), 57 and 61 (,,Song-Like" and ,, Song-Recommend") or 22 and 34 (,,Emotion-Loving-Romantic" and ,,Emotion-Touching-Loving"). On the other hand, the most negatively correlated labels are: 44 and 45 (,,Instrument-Female Lead Vocals" and ,,Instrument - Male Lead Vocals") or 63 and 64 (,,Song-Texture Acoustic" and ,,Song-Texture Electric").

6. Conclusions

In the paper we consider a problem of structure learning for binary Markov random fields. We base estimation of model parameters on the Lasso penalized Monte Carlo approximation of the likelihood. In the theoretical part of the paper we show that the proposed procedure

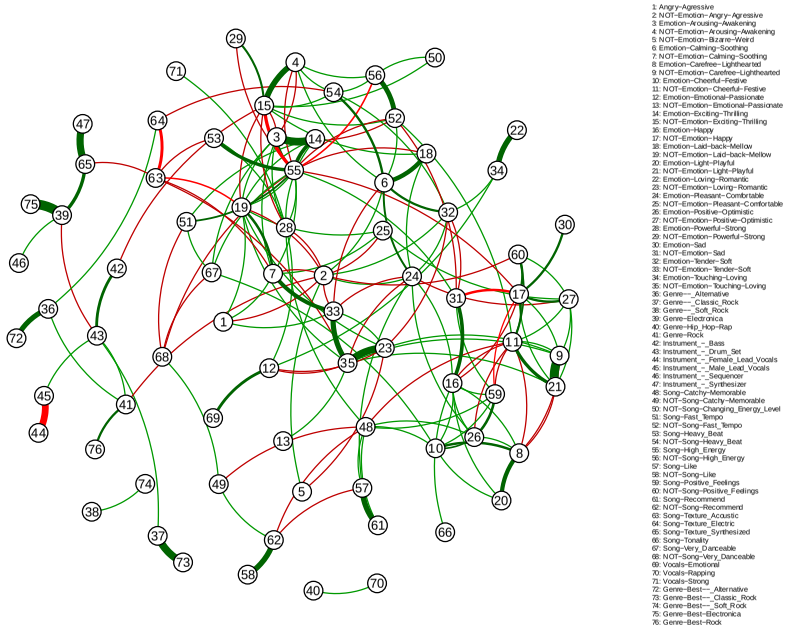

Figure 3: The obtained graph for CAL500 dataset. The width of the edges corresponds to the magnitude of $|\hat{\theta}^{\delta^*}_{rs}|$. The edges with higher absolute value are wider. The color denotes the sign of $\hat{\theta}^{\delta^*}_{rs}$: green – positive, red – negative. To improve clarity we do not show edges corresponding to $|\hat{\theta}^{\delta^*}_{rs}| < 0.001$.

reveals the true dependence structure with high probability. The regularity conditions that we need are not restrictive and are weaker than assumptions used in the other approaches based on the likelihood approximation. Moreover, the theoretical results are completed by numerical experiments. They confirm that the MCMC approximation is able to find the true model in a satisfactory way and its quality is comparable or higher than competing algorithms.

The results of the current paper can be easily extended to other discrete Markov random fields. There are also some non-trivial issues that are not discussed in the paper, for instance

investigating the model (1) with predictors (covariates). The evaluation of the prediction error of the procedure is also a difficult task. Clearly, these problems need detailed studies.

Appendix A. Auxiliary results

In this section we formulate lemmas that are needed to prove main results of the paper. The roles, that they play, are described in detail at the end of section 3. The first lemma is borrowed from Huang et al. (2013, Lemma 3.1).

Lemma 5 *Let* $\tilde{\theta} = \hat{\theta} - \theta^\star$, $z^* = |\nabla \ell^m_n(\theta^\star)|_\infty$ *and*

$$D(\hat{\theta}, \theta) = (\hat{\theta} - \theta)' \left[\nabla \ell^m_n(\hat{\theta}) - \nabla \ell^m_n(\theta) \right] .$$

Then

$$(\lambda - z^*)|\tilde{\theta}_{T^c}|_1 \leq D(\hat{\theta}, \theta^\star) + (\lambda - z^*)|\tilde{\theta}_{T^c}|_1 \leq (\lambda + z^*)|\tilde{\theta}_T|_1 . \tag{20}$$

Besides, for arbitrary $\xi > 1$ *on the event*

$$\Omega_1 = \left\{ |\nabla \ell^m_n(\theta^\star)|_\infty \leq \frac{\xi - 1}{\xi + 1} \lambda \right\} \tag{21}$$

the random vector $\tilde{\theta}$ *belongs to the cone* $\mathcal{C}(\xi, T)$.

Proof The proof is the same as the proof of Huang et al. (2013, Lemma 3.1). It is quoted here to make the paper complete.
Convexity of the MCMC approximation $\ell^m_n(\theta)$ easily implies the first inequality in (20). The same property combined with convexity of the Lasso penalty gives us that zero has to belong to the subgradient of (7) at the minimizer $\hat{\theta}$, i.e.

$$\begin{cases} \nabla_{rs} \ell^m_n(\hat{\theta}) = -\lambda \text{sign}(\hat{\theta}_{rs}), & \text{if } \hat{\theta}_{rs} \neq 0 \\ |\nabla_{rs} \ell^m_n(\hat{\theta})| \leq \lambda, & \text{if } \hat{\theta}_{rs} = 0 , \end{cases} \tag{22}$$

where we use $\nabla \ell^m_n(\theta) = \left(\nabla_{rs} \ell^m_n(\hat{\theta}) \right)_{r<s}$ and $\text{sign}(t) = 1$ for $t > 0$, $\text{sign}(t) = -1$ for $t < 0$, $\text{sign}(t) = 0$ for $t = 0$. Using (22) and properties of the l_1-norm we obtain that

$$\begin{aligned} D(\hat{\theta}, \theta^\star) &= \sum_{(r,s) \in T} \tilde{\theta}_{rs} \nabla_{rs} \ell^m_n(\theta^\star + \tilde{\theta}) + \sum_{(r,s) \in T^c} \hat{\theta}_{rs} \nabla_{rs} \ell^m_n(\theta^\star + \tilde{\theta}) - \tilde{\theta}' \nabla \ell^m_n(\theta^\star) \\ &\leq \lambda \sum_{(r,s) \in T} |\tilde{\theta}_{rs}| - \lambda \sum_{(r,s) \in T^c} |\hat{\theta}_{rs}| + |\tilde{\theta}|_1 z^* \\ &\leq \lambda |\tilde{\theta}_T|_1 - \lambda |\tilde{\theta}_{T^c}|_1 + z^* |\tilde{\theta}_T|_1 + z^* |\tilde{\theta}_{T^c}|_1 \\ &= (\lambda + z^*)|\tilde{\theta}_T|_1 + (z^* - \lambda)|\tilde{\theta}_{T^c}|_1 . \end{aligned}$$

Thus, the second inequality in (20) is also established. To prove the last claim of the lemma notice that on the event Ω_1 we obtain from (20)

$$|\tilde{\theta}_{T^c}|_1 \leq \frac{\lambda + z^*}{\lambda - z^*}|\tilde{\theta}_T|_1 \leq \xi|\tilde{\theta}_T|_1 \,.$$

■

The second lemma is an adaptation of Huang et al. (2013, Theorem 3.1) to our problem.

Lemma 6 *Let $\xi > 1$. Moreover, let us denote $\tau = \frac{(\xi+1)\bar{d}_0\lambda}{\bar{F}(\xi,T)}$ and an event*

$$\Omega_2 = \left\{\tau < e^{-1}\right\} \,. \tag{23}$$

Then $\Omega_1 \cap \Omega_2 \subset A$, where

$$A = \left\{|\hat{\theta} - \theta^\star|_\infty \leq \frac{2\xi e^\eta \lambda}{(\xi+1)\bar{F}(\xi,T)}\right\} \,, \tag{24}$$

where $\eta < 1$ is the smaller solution of the equation $\eta e^{-\eta} = \tau$.

Proof Suppose we are on the event $\Omega_1 \cap \Omega_2$. Denote again $\tilde{\theta} = \hat{\theta} - \theta^\star$ and notice that $\theta = \frac{\tilde{\theta}}{|\tilde{\theta}|_1} \in \mathcal{C}(\xi, T)$ by Lemma 5. Consider the function

$$g(t) = \theta' \nabla \ell_n^m(\theta^\star + t\theta) - \theta' \nabla \ell_n^m(\theta^\star)$$

for each $t \geq 0$. This function is nondecreasing, because $\ell_n^m(\cdot)$ is convex. Thus, we obtain $g(t) \leq g(|\tilde{\theta}|_1)$ for every $t \in (0, |\tilde{\theta}|_1)$. On the event Ω_1 and from Lemma 5 we have that

$$\theta' \left[\nabla \ell_n^m(\theta^\star + t\theta) - \nabla \ell_n^m(\theta^\star)\right] + \frac{2\lambda}{\xi+1}|\theta_{T^c}|_1 \leq \frac{2\lambda\xi}{\xi+1}|\theta_T|_1 \,. \tag{25}$$

In further argumentation we consider all nonnegative t satisfying (25), that is an interval $[0, \tilde{t}]$ for some $\tilde{t} > 0$. Proceeding similarly to the proof of Huang et al. (2013, Lemma 3.2) we obtain

$$t\theta' \left[\nabla \ell_n^m(\theta^\star + t\theta) - \nabla \ell_n^m(\theta^\star)\right] \geq t^2 \exp(-\gamma_{t\theta})\theta' \nabla^2 \ell_n^m(\theta^\star)\theta \,, \tag{26}$$

where $\gamma_{t\theta} = t \max_{k,l} |\theta' J(Y^k) - \theta' J(Y^l)| \leq 2t$, because $J(Y^k) = \left(Y^k(r)Y^k(s)\right)_{rs}$ and $|\theta|_1 = 1$. Therefore, the right-hand side in (26) can be lower bounded by

$$t^2 \exp(-2t)\theta' \nabla^2 \ell_n^m(\theta^\star)\theta \,. \tag{27}$$

Using the definition of $\bar{F}(\xi, T)$, the fact that $\theta \in \mathcal{C}(\xi, T)$, the bound (27) and (25) we obtain

$$\begin{aligned} t\exp(-2t)\frac{\bar{F}(\xi,T)|\theta_T|_1^2}{\bar{d}_0} &\leq t\exp(-2t)\theta' \nabla^2 \ell_n^m(\theta^\star)\theta \\ &\leq \theta' \left[\nabla \ell_n^m(\theta^\star + t\theta) - \nabla \ell_n^m(\theta^\star)\right] \\ &\leq \frac{2\lambda\xi}{\xi+1}|\theta_T|_1 - \frac{2\lambda}{\xi+1}|\theta_{T^c}|_1 \\ &\leq \lambda(\xi+1)|\theta_T|_1^2/2 \,. \end{aligned}$$

So, every t satisfying (25) has to fulfill the inequality $2t\exp(-2t) \leq \tau$. In particular, $2\tilde{t}\exp(-2\tilde{t}) \leq \tau$. We are on Ω_2, so it implies that $2\tilde{t} \leq \eta$, where η is the smaller solution of the equation $\eta\exp(-\eta) = \tau$. We know also that $|\tilde{\theta}|_1 \leq \tilde{t}$, so

$$\begin{aligned} |\tilde{\theta}|_1 \exp(-\eta) \leq \tilde{t}\exp(-2\tilde{t}) &\leq \frac{\tilde{t}\exp(-2\tilde{t})\theta' \nabla^2 \ell_n^m(\theta^\star)\theta}{\bar{F}(\xi,T)|\theta_T|_1|\theta|_\infty} \\ &\leq \frac{\theta'\left[\nabla \ell_n^m(\theta^\star + \tilde{t}\theta) - \nabla \ell_n^m(\theta^\star)\right]}{\bar{F}(\xi,T)|\theta_T|_1|\theta|_\infty} \\ &\leq \frac{2\lambda\xi}{(\xi+1)\bar{F}(\xi,T)|\theta|_\infty} \,, \end{aligned}$$

where we have used bounds (27) and (25). Using the equality $|\theta|_\infty = \frac{|\tilde{\theta}|_\infty}{|\tilde{\theta}|_1}$, we finish the proof. ■

Lemma 7 *For every natural n, m and positive t*

$$P\left(|\nabla \ell_n^m(\theta^\star)|_\infty \leq t\right) \geq 1 - 2\bar{d}\exp\left(-nt^2/8\right) - \beta_1 \exp\left(-\frac{m\beta_2}{4M^2}\right) - 2\bar{d}\beta_1 \exp\left(-\frac{t^2 m\beta_2}{64M^2}\right) \,.$$

Proof We can rewrite $\nabla \ell_n^m(\theta^\star)$ as

$$\nabla \ell_n^m(\theta^\star) = -\left[\frac{1}{n}\sum_{i=1}^n J(Y_i) - \frac{\nabla C(\theta^\star)}{C(\theta^\star)}\right] + \frac{\frac{1}{m}\sum_{k=1}^m w_k(\theta^\star)\left[J(Y^k) - \frac{\nabla C(\theta^\star)}{C(\theta^\star)}\right]}{\frac{1}{m}\sum_{k=1}^m w_k(\theta^\star)} \tag{28}$$

Notice that the first therm in (28) depends only on the initial sample $Y_1, \ldots, Y_n$ and is an average of i.i.d random variables. The second term depends only on the MCMC sample $Y^1, \ldots, Y^m$. We start the analysis with the former one. Using Hoeffding's inequality we obtain for each natural n, positive t and a pair of indices $r < s$

$$P\left(\left|\frac{1}{n}\sum_{i=1}^n J_{rs}(Y_i) - \frac{\nabla_{rs} C(\theta^\star)}{C(\theta^\star)}\right| > t/2\right) \leq 2\exp\left(-nt^2/8\right) \,.$$

Therefore, by the union bound we have

$$P\left(\left|\frac{1}{n}\sum_{i=1}^n J(Y_i) - \frac{\nabla C(\theta^\star)}{C(\theta^\star)}\right|_\infty > t/2\right) \leq 2\bar{d}\exp\left(-nt^2/8\right) \,. \tag{29}$$

Next, we investigate the second expression in (28). Its denominator is an average that depends on the Markov chain. To handle it we can use Theorem 4 in section 3. Notice that $\frac{\exp[(\theta^\star)' J(y)]}{h(y)} \leq MC(\theta^\star)$ for every y and $\mathbb{E}_{Y\sim h}\frac{\exp[(\theta^\star)' J(Y)]}{h(Y)} = C(\theta^\star)$. Therefore, for every n, m

$$P\left(\frac{1}{m}\sum_{k=1}^m w_k(\theta^\star) \geq C(\theta^\star)/2\right) \geq 1 - \beta_1 \exp\left(-\frac{m\beta_2}{4M^2}\right) \,. \tag{30}$$

Finally, we bound the l_∞-norm of the numerator of the second term in (28). We fix a pair of indices $r < s$. It is not difficult to calculate that

$$\mathbb{E}_{Y\sim h}\left[\frac{\exp\left[(\theta^\star)'J(Y)\right]}{h(Y)}\left(J_{rs}(Y)-\frac{\nabla_{rs}C(\theta^\star)}{C(\theta^\star)}\right)\right]=0$$

and for every y

$$\frac{\exp((\theta^\star)'J(y)}{h(y)}\left|J_{rs}(y)-\frac{\nabla_{rs}C(\theta^\star)}{C(\theta^\star)}\right|\le 2MC(\theta^\star)\,.$$

From Theorem 4 we obtain for every positive t

$$\left|\frac{1}{m}\sum_{k=1}^m w_k(\theta^\star)\left[J_{rs}(Y^k)-\frac{\nabla_{rs}C(\theta^\star)}{C(\theta^\star)}\right]\right|\ge tC(\theta^\star)/4$$

with probability at least $1-2\beta_1\exp\left(-\frac{t^2m\beta_2}{64M^2}\right)$. Using union bounds we estimate the numerator of the second expression in (28). This fact and (30) imply that for every positive t and natural n, m with probability at least $1-\beta_1\exp\left(-\frac{m\beta_2}{4M^2}\right)-2\bar{d}\beta_1\exp\left(-\frac{t^2m\beta_2}{64M^2}\right)$ we have

$$\left|\frac{\frac{1}{m}\sum\limits_{k=1}^m w_k(\theta^\star)\left[J(Y^k)-\frac{\nabla C(\theta^\star)}{C(\theta^\star)}\right]}{\frac{1}{m}\sum\limits_{k=1}^m w_k(\theta^\star)}\right|_\infty\le t/2\,. \tag{31}$$

Taking (29) and (31) together we finish the proof. ■

Corollary 8 *Let* $\varepsilon>0, \xi>1$ *and*

$$\lambda=\frac{\xi+1}{\xi-1}\max\left(2\sqrt{\frac{2\log(2\bar{d}/\varepsilon)}{n}}, 8M\sqrt{\frac{\log\left[(2\bar{d}+1)\beta_1/\varepsilon\right]}{m\beta_2}}\right)\,.$$

Conditions (13) *and* (14) *imply*

$$P(\Omega_1)\ge 1-2\varepsilon\,.$$

Proof We take $t=\frac{\xi-1}{\xi+1}\lambda$ in Lemma 7. ■

Lemma 9 *For every* n, m *and positive* t

$$\begin{aligned}P\left(\left|\nabla^2\ell_n^m(\theta^\star)-\nabla^2\log C(\theta^\star)\right|_\infty\le t\right) &\ge 1-2\beta_1\exp\left(-\frac{m\beta_2}{4M^2}\right)\\ &- 2\bar{d}(\bar{d}+1)\beta_1\exp\left(-\frac{t^2m\beta_2}{256M^2}\right)\,.\end{aligned} \tag{32}$$

Proof To estimate the l_∞-norm of the matrix difference in (32) we bound l_∞-norms of two matrices:

$$\frac{\sum\limits_{k=1}^m w_k(\theta^\star)J(Y^k)^{\otimes 2}}{\sum\limits_{k=1}^m w_k(\theta^\star)}-\frac{\nabla^2C(\theta^\star)}{C(\theta^\star)}=\frac{\frac{1}{m}\sum\limits_{k=1}^m w_k(\theta^\star)\left[J(Y^k)^{\otimes 2}-\frac{\nabla^2C(\theta^\star)}{C(\theta^\star)}\right]}{\frac{1}{m}\sum\limits_{k=1}^m w_k(\theta^\star)} \tag{33}$$

and

$$\left[\frac{\frac{1}{m}\sum\limits_{k=1}^m w_k(\theta)J(Y^k)}{\frac{1}{m}\sum\limits_{k=1}^m w_k(\theta)}\right]^{\otimes 2}-\left[\frac{\nabla C(\theta^\star)}{C(\theta^\star)}\right]^{\otimes 2}\,. \tag{34}$$

The denominator of the right-hand side of (33) has been estimated in the proof of Lemma 7, so we bound the numerator. We can calculate that

$$\mathbb{E}_{Y\sim h}\left[\frac{\exp\left[(\theta^\star)'J(Y)\right]}{h(Y)}\left(J(Y)^{\otimes 2}-\frac{\nabla^2C(\theta^\star)}{C(\theta^\star)}\right)\right]=0$$

and for every y and two pairs of indices $r<s, r'<s'$ we have

$$\frac{\exp((\theta^\star)'J(y)}{h(y)}\left|J_{rs}(y)J_{r's'}(y)-\frac{\nabla^2_{rs,r's'}C(\theta^\star)}{C(\theta^\star)}\right|\le 2MC(\theta^\star)\,.$$

Using the union bound and (30) we upper-bound the l_∞-norm of the right-hand side of (33) by $t/2$ with probability at least

$$1-\beta_1\exp\left(-\frac{m\beta_2}{4M^2}\right)-2\bar{d}^2\beta_1\exp\left(-\frac{t^2m\beta_2}{64M^2}\right)\,.$$

The last step of the proof is handling with the l_∞-norm of (34). This expression can be upper-bounded by

$$\left|\frac{\sum\limits_{k=1}^m w_k(\theta)J(Y^k)}{\sum\limits_{k=1}^m w_k(\theta)}-\frac{\nabla C(\theta^\star)}{C(\theta^\star)}\right|_\infty\left(\left|\frac{\sum\limits_{k=1}^m w_k(\theta)J(Y^k)}{\sum\limits_{k=1}^m w_k(\theta)}\right|_\infty+\left|\frac{\nabla C(\theta^\star)}{C(\theta^\star)}\right|_\infty\right)_\infty\,. \tag{35}$$

The first term in (35) has been bounded with high probability in the proof of Lemma 7. The remaining two can be easily estimated by one. Therefore, for every positive t the l_∞-norm of (34) is not greater than $t/2$ with probability at least

$$1-\beta_1\exp\left(-\frac{m\beta_2}{4M^2}\right)-2\bar{d}\beta_1\exp\left(-\frac{t^2m\beta_2}{256M^2}\right)\,.$$

Putting together this fact and the bound of (33) we finish the proof. ■

Corollary 10 *If* (14)*, then for every* $\varepsilon > 0$ *the following inequality*

$$\bar{F}(\xi, T) \geq F(\xi, T) - 16\bar{d}_0(1+\xi)^2 M\sqrt{\frac{\log\left[2\bar{d}(\bar{d}+1)\beta_1/\varepsilon\right]}{m\beta_2}}$$

has probability at least $1 - 2\varepsilon$*.*

Proof We take

$$t = 16M\sqrt{\frac{\log\left[2\bar{d}(\bar{d}+1)\beta_1/\varepsilon\right]}{m\beta_2}}$$

in Lemma 9 and use Huang et al. (2013, Lemma 4.1 (ii)). ■

Appendix B. Proofs of main results

Proof [Proof of Theorem 2] Fix $\varepsilon > 0, \xi > 1$ and denote $\gamma = \gamma(\xi) = \frac{\alpha(\xi)-2}{\alpha(\xi)} \in (0,1)$. First, from Corollary 8 we know that $P(\Omega_1) \geq 1 - 2\varepsilon$. Using the condition (14) we obtain that

$$F(\xi, T) - 16\bar{d}_0(1+\xi)^2 M\sqrt{\frac{\log\left[2\bar{d}(\bar{d}+1)\beta_1/\varepsilon\right]}{m\beta_2}} \geq \gamma F(\xi, T)\,.$$

Therefore, from Corollary 10 we have that $P(\bar{F}(\xi, T) \geq \gamma F(\xi, T)) \geq 1 - 2\varepsilon$. It is not difficult to calculate that

$$\frac{(1+\xi)\bar{d}_0\lambda}{\gamma F(\xi, T)} \leq e^{-1}\,,$$

so we have also $P(\Omega_2) \geq 1 - 2\varepsilon$. To finish the proof we use Lemma 6 (with $\eta = 1$ for simplicity) and again bound $\bar{F}(\xi, T)$ from below by $\gamma F(\xi, T)$ in the event A defined in (24). ■

Proof [Proof of Corollary 3] The proof is a simple consequence of the uniform bound (15) obtained in Theorem 2. Indeed, for an arbitrary pair of indices $(r, s) \notin T$ we obtain

$$|\hat{\theta}_{rs}| = |\hat{\theta}_{rs} - \theta^\star_{rs}| \leq R^m_n\,,$$

so $(r, s) \notin \hat{T}$. Analogously, if we take a pair $(r, s) \in T$, then

$$|\hat{\theta}_{rs}| \geq |\theta^\star_{rs}| - |\hat{\theta}_{rs} - \theta^\star_{rs}| > 2\delta - R^m_n \geq \delta\,.$$

Abstract

Learning a low-rank matrix from missing and corrupted observations is a fundamental problem in many machine learning applications. However, the role of *side information* in low-rank matrix learning has received little attention, and most current approaches are either ad-hoc or only applicable in certain restrictive cases. In this paper, we propose a general model that exploits side information to better learn low-rank matrices from missing and corrupted observations, and show that the proposed model can be further applied to several popular scenarios such as matrix completion and robust PCA. Furthermore, we study the effect of side information on sample complexity and show that by using our model, the efficiency for learning can be improved given sufficiently informative side information. This result thus provides theoretical insight into the usefulness of side information in our model. Finally, we conduct comprehensive experiments in three real-world applications—relationship prediction, semi-supervised clustering and noisy image classification, showing that our proposed model is able to properly exploit side information for more effective learning both in theory and practice.

Keywords: Side information, low-rank matrix learning, learning from missing and corrupted observations, matrix completion, robust PCA

1. Introduction

Learning a low-rank matrix from noisy, high-dimensional complex data is an important research challenge in modern machine learning. In particular, in the recent big data era, assuming that the observations come from a model with implicit low-rank structure is one of the most prevailing approaches to avoid the curse of dimensionality. While various low-rank matrix learning problems arise from different contexts and domains, the primary challenge is rather similar: namely to reliably learn a low-rank matrix L_0 based only on missing and corrupted observations from L_0. This generic framework includes many well-known machine learning problems such as matrix completion (Candès and Tao, 2009), robust PCA (Wright et al., 2009) and matrix sensing (Zhong et al., 2015), and is shown to be useful in many important real-world applications including recommender systems (Koren et al., 2009), social network analysis (Hsieh et al., 2012) and image processing (Wright et al., 2009).

Among research related to low-rank matrix learning, one promising direction is to further exploit *side information*, or *features*, to help the learning process. [1] The notion of side information appears naturally in many applications. For example, in the famous Netflix problem where the goal is movie recommendation based on users' ratings, a popular approach is to assume that the given user-movie rating pairs are sampled from a low-rank matrix (Koren et al., 2009). However, besides rating history, profiles of users and/or genres of movies may also be provided, and one can possibly leverage such side information for better recommendation. Since such additional features are available in many applications, designing a model to better incorporate features into low-rank matrix learning problems becomes an important issue with both theoretical and practical interests.

Motivated by the above realization, we study the effect of side information on learning low-rank matrices from missing and corrupted observations in this paper. Our general problem setting can be formally described as follows. Let $L_0 \in \mathbb{R}^{n_1 \times n_2}$ be the low-rank modeling matrix, yet due to various reasons we can only observe a matrix $R \in \mathbb{R}^{n_1 \times n_2}$ which contains missing and/or corrupted observations of L_0. In addition, suppose we are also given additional feature matrices $X \in \mathbb{R}^{n_1 \times d_1}$ and/or $Y \in \mathbb{R}^{n_2 \times d_2}$ as side information, where each row $\mathbf{x}_i \in \mathbb{R}^{d_1}$ (or $\mathbf{y}_i \in \mathbb{R}^{d_2}$) denotes a feature representation of the i-th row (or column) entity of X (or Y). Then, instead of just using R to recover L_0, our hope is to leverage side information X and Y to learn L_0 more effectively. Below, we further list some important applications where the side information naturally comes in as the form of X and/or Y in this framework:

- *Collaborative filtering.* Collaborative filtering is one of the most popular machine learning applications in industry where we aim to predict the preferences of users to any products based on limited rating history (e.g. the Netflix problem we mentioned previously). A traditional approach is to complete the partial user-product rating matrix R via matrix completion. However, one could also collect per-user features x_i and per-product features y_j as possible information to leverage, and the assembled feature representation for users and products becomes X and Y in this framework.

- *Link prediction.* The link prediction problem in online social network analysis is to predict and recommend the implicit friendships of users given the current network snapshot. One approach is to think of the network snapshot as a user-to-user relationship matrix R, and thus any missing relationships in the snapshot can be inferred by conducting matrix completion on R (Liben-Nowell and Kleinberg, 2007). Similarly, if user-specific information (like user profile) is collected, these user features can be deemed as both X and Y.

- *Image denoising.* Another low-rank matrix learning application is image denoising. It is known that same types of images (e.g. images of human face, digits, or images with same scene) often share a common low-rank structure, and learning that low-dimensional space can be useful for many applications such as image recognition

1. We will use terms 'side information' and 'features' interchangeably throughout the paper.

and background subtraction. Yet in the realistic setting, images may be corrupted by sparse noise such as shadowing or brightness saturation, making the learning of that low-dimensional space much more difficult. A popular approach, known as robust PCA, is to construct an observed matrix R where each column is a vector representation of an image, and further learn the underlying low-rank subspace by separating it from the sparse noise in R. In Section 4, we will show that if features of clean images X and/or label-relevant features Y are also given, one can learn the underlying low-dimensional subspace more accurately.

Organization of the paper. To study the effect of side information in low-rank matrix learning with missing and corrupted observations, we focus on answering the following important questions in a systematical manner:

- What type of side information can benefit learning?
- What model should we use for incorporating side information?
- How can we further quantify the merits of side information in learning?

Regarding the first question, in Section 2, we start with the case of *"perfect" side information* (defined in equation 2) as an idealized case where the given features are fully informative, and further generalize to the case of *noisy side information* where the given features are only partially correlated to L_0. We will see that while information from perfect features is extremely useful, certain noisy features can also be quite effective to benefit learning.

The model for incorporating side information can also be constructed subsequently once the type of side information is identified. Precisely, in Section 2, we argue that for perfect features, one can directly transform the low-rank modeling matrix into a bilinear form with respect to features X and Y. However, the validity of such an embedding becomes questionable if features are noisy. Therefore, for noisy features, we propose to break the low-rank matrix into two parts—one that captures information from features and one that captures information outside the feature space—resulting in a general model (problem 4) that learns the low-rank matrix by jointly balancing information from noisy features and observations. In addition, we discuss the connections between our model and several well-known models, such as low-rank matrix completion and robust PCA. We also show that our proposed model can be efficiently solved by well-established optimization procedures.

Furthermore, in Section 3, we provide a theoretical analysis to justify the merits of side information in the proposed model (4). To start with, in Section 3.1, we quantify the quality of features and the noise level of corruption using Rademacher model complexity in the generalization analysis. As a result, a tighter error bound can be derived given better quality of features and/or lower noise level in observations. We further derive sample complexity guarantees for the case of matrix completion in Section 3.2 and for the case where observations are both missing and corrupted in Section 3.3. For the case of matrix completion, our sample complexity result suggests that the proposed model requires asymptotically fewer observations to recover the low-rank matrix compared to standard matrix completion, as long as the given features are sufficiently informative. This result substantially generalizes the previous study of side information in matrix completion in Jain and Dhillon (2013) which only guarantees improved complexity given perfect features. On the other hand, for

the case where observations are both missing and corrupted, our resulting sample complexity guarantee implies that better quality of side information is useful for learning missing entries of the low-rank matrix provided that the corruption is not too severe. These results thus justify the usefulness of side information in the proposed model in theory.

Finally, in Section 4, we verify the effectiveness of the proposed model experimentally on various synthetic data sets, and additionally apply it to three machine learning applications—relationship prediction, semi-supervised clustering and noisy image classification. We show that each of them can be tackled by learning a low-rank modeling matrix from missing or corrupted observations given certain additional features, and therefore, by employing our model to exploit side information, we can achieve better performance in these applications compared to other state-of-the-art methods. These results demonstrate that our proposed model indeed exploits side information for various low-rank matrix learning problems.

Here are the key contributions of this paper:

- We study the effect of side information and provide a general treatment to incorporate side information for learning low-rank matrices from missing and corrupted observations.
- In particular, given perfect side information, we propose to transform the estimated low-rank matrix to a bilinear form with respect to features. Moreover, given noisy side information, we propose to further break the low-rank matrix into a part capturing feature information plus a part capturing information outside the feature space, and therefore, learning can be conducted efficiently by balancing information between features and observations.
- We theoretically justify the usefulness of side information in the proposed model in various scenarios by first quantifying the effectiveness of features and then showing that the sample complexity can be asymptotically improved provided sufficiently informative features.
- We provide comprehensive experimental results to confirm that the proposed model properly embeds both perfect and noisy side information for learning low-rank matrices more effectively compared to other state-of-the-art approaches.

Parts of this paper have previously appeared in Chiang et al. (2015) and Chiang et al. (2016), in which we exclusively studied the effect of noisy side information in matrix completion and the effect of perfect side information in robust PCA, respectively. In this paper, we consider a much more general setting and propose a general model to exploit side information for a broader class of low-rank matrix learning problems. In particular, given this general model, we can further exploit noisy side information for the robust PCA problem and for the case where observations are *both* missing and corrupted as we will discuss in Section 2.3. We also provide much more comprehensive theoretical and experimental results to demonstrate the effectiveness of the proposed treatment.

2. Exploiting Side Information for Learning Low-Rank Matrices

In this section, we discuss how to incorporate side information for learning low-rank matrices from missing and corrupted observations. We first introduce the problem formulation in Section 2.1. We then start with exploiting perfect, noiseless side information in Section 2.2 and introduce the proposed model which can further exploit noisy side information in Section 2.3. We finally describe the optimization for solving the proposed model in Section 2.4.

2.1. Learning from Missing and Corrupted Observations

The problem of learning a low-rank matrix from missing and corrupted observations can be formally stated as follows. Let $L_0 \in \mathbb{R}^{n_1 \times n_2}$ be the underlying rank-r matrix where $r \ll \min(n_1, n_2)$ so that L_0 is low-rank, and S_0 be a noise matrix whose support (denoted as Ω) and magnitude is unknown but the structure is known to be *sparse*. Furthermore, let Ω_{obs} be a set of observed entries with cardinality m, and $\mathcal{P}_{\Omega_{obs}}$ be the orthogonal projection operator defined by:

$$\mathcal{P}_{\Omega_{obs}}(X)_{ij} = \begin{cases} X_{ij}, & \text{if } (i,j) \in \Omega_{obs}, \\ 0, & \text{otherwise.} \end{cases}$$

Then, given the observed data matrix R which is in the form of:

$$R = \mathcal{P}_{\Omega_{obs}}(L_0 + S_0) = \mathcal{P}_{\Omega_{obs}}(L_0) + S_0',$$

the goal is to accurately estimate the underlying matrix L_0 given R. Without loss of generality, we assume that S_0 is supported on Ω_{obs}, i.e. $\Omega \subseteq \Omega_{obs}$ and $S_0' = S_0$. Note that this problem can be viewed as an extension of the matrix completion problem, which only assumes the given observations to be undersampled yet noiseless (Ω is the empty set).

An intuitive way to approach this problem is to estimate the low-rank matrix based on the given structural information of the problem. Specifically, Candès et al. (2011) proposed to solve this problem via the following convex program:

$$\min_{L,S} \ \|L\|_* + \lambda \|S\|_1 \quad \text{s.t.} \quad L_{ij} + S_{ij} = R_{ij}, \ \forall \ (i,j) \in \Omega_{obs}, \tag{1}$$

where $\|L\|_*$ is the nuclear norm of L defined by the sum of singular values of L, and $\|S\|_1 := \sum_{i,j} |S_{ij}|$ is the element-wise one norm of S. These two regularizations are known to be useful for enforcing low rank structure and sparse structure, respectively.

Although problem (1) has been shown to enjoy theoretical and empirical success (Candès et al., 2011), it cannot directly leverage side information for recovery if it is provided. A tailored model is thus required to resolve this issue.

2.2. Idealized Case: Perfect Side Information

Suppose in addition to the data matrix R, we are also given features of row and column entities $X \in \mathbb{R}^{n_1 \times d_1}$ and $Y \in \mathbb{R}^{n_2 \times d_2}$, $d_1 < n_1$ and $d_2 < n_2$ as side information. Then, the goal of low-rank matrix learning with side information is to exploit X and Y in addition to the observations R to better estimate L_0. A concrete example is the Netflix problem where R corresponds to the partial user-movie rating matrix and, X and Y correspond to user and movie features; the hope is to further leverage additional features X and Y along with rating history R to better predict the unknown user-movie ratings.

In principle, not all types of side information will be useful. For instance, if the given X and Y are simply two random matrices, then there is no information gain from the provided side information, and therefore, *any* method incorporating such X and Y is expected to perform the same as methods only using structural information. That being said, to explore the advantage of side information, a condition on side information to ensure its informativeness is required. To begin with, we consider an ideal scenario where the side information is "perfect" in the sense that it implicitly describes the full latent space of L_0.

Definition 1 (Perfect side information) *The side information X and Y is called perfect side information, or noiseless side information, w.r.t. L_0 if X and Y satisfy:*

$$col(X) \supseteq col(L_0), \quad col(Y) \supseteq col(L_0^T), \tag{2}$$

where $col(X)$ and $col(Y)$ denotes the column space of X and Y.

Then, consider $L_0 = U\Sigma V^T$ to be the SVD of L_0, a set of perfect side information will also satisfy $\text{col}(X) \supseteq \text{col}(U)$ and $\text{col}(Y) \supseteq \text{col}(V)$, which further indicates that there exists a matrix $M_0 \in \mathbb{R}^{d_1 \times d_2}$ such that $L_0 = XM_0Y^T$. This fact leads us to expressing the target low-rank matrix as a bilinear form with respect to features X and Y, and as a result, one can cast problem (1) with features as:

$$\min_{M,S} \ \|M\|_* + \lambda \|S\|_1 \quad \text{s.t.} \ \mathbf{x}_i^T M \mathbf{y}_j + S_{ij} = R_{ij}, \ \forall \ (i,j) \in \Omega_{obs}, \tag{3}$$

in which the problem is reduced to learning a smaller $d_1 \times d_2$ low-rank matrix M. The bilinear embedding with respect to perfect features for the low-rank matrix has already been proposed in matrix completion. Indeed, by casting $L = XMY^T$ as matrix completion, one can obtain a so-called "inductive matrix completion" (IMC) model which is able to learn the underlying matrix with much fewer samples given perfect side information (Jain and Dhillon, 2013; Xu et al., 2013; Zhong et al., 2015). We will discuss the improved sample complexity result of IMC in detail in Section 3.2.

However, an obvious weakness of the bilinear embedding in problem (3) is that it assumes the given side information to be perfect. Unfortunately, in real applications, most given features X and Y will not be perfect, and could be in fact noisy or only weakly correlated to the latent space of L_0. In such cases, L_0 can no longer be expressed as XMY^T and thus the translated objective (3) becomes questionable to use. This weakness will also be empirically shown in Section 4 in which we observe that the recovered matrix XM^*Y^T of problem (3) will diverge from L_0 given noisy side information in experiments. Nevertheless, it is arguable that certain noisy features should still be helpful for learning L_0. For example, given the SVD of $L_0 = U\Sigma V^T$, a small perturbation of a single entry of U (or V) makes the perturbed U, V to be imperfect features, yet such U and V should still be very informative. This observation thus motivates us to design a more general model to exploit noisy side information.

2.3. The Proposed Model: Exploiting Noisy Side Information

We now introduce an improved model to further exploit imperfect, noisy side information. The key idea of our model is to balance both feature information and observations when learning the low-rank matrix. Specifically, we propose to learn L_0 jointly in two parts, one part captures information from the feature space as XMY^T, and the other part N captures the information outside the feature space. Thus, even if the given features are noisy and fail to cover the full latent space of L_0, we can still capture missing information using N learned from pure observations.

However, there is an identifiability issue if we simply learn L_0 with the expression XMY^T+N, since there are infinitely many solutions of (M,N) that satisfy $XMY^T+N=L_0$. Although in theory they all perfectly recover the underlying matrix, some of the solutions shall be more preferred than others if we further consider the efficiency of learning. Intuitively, since the underlying L_0 is low-rank, a natural thought is to prefer both XMY^T and N to be low-rank so that the L_0 can be recovered with fewer parameters. This preference leads us to pursue a low-rank M as well, which conceptually means that only a small subspace of X and a subspace of Y are expected to be effective in jointly forming a low-rank estimate XMY^T. Pursuing low-rank solutions of M and N enables us to accurately estimate L_0 with fewer samples because fewer parameters need to be learned compared to other solutions. This advantage will be formally justified later in Section 3.

Therefore, putting this all together, to incorporate noisy side information and learn the low-rank matrix L_0 from missing and corrupted observations, we propose to solve the following problem:

$$\min_{M,N,S} \sum_{(i,j)\in\Omega_{obs}} \ell((XMY^T+N+S)_{ij}, R_{ij}) + \lambda_M\|M\|_* + \lambda_N\|N\|_* + \lambda_S\|S\|_1 \qquad (4)$$

with some convex surrogate loss ℓ, and the underlying matrix L_0 can be estimated by $XM^*Y^T+N^*$, where (M^*,N^*,S^*) is the optimal solution of problem (4). Note that to force M and N to be low-rank, in the proposed objective we add nuclear norm regularization on *both* variables M and N. It is known that nuclear norm regularization is one of the most popular heuristic to pursue low-rank structure as it is the tightest convex relaxation of the rank function (Fazel et al., 2001). In particular, given a low-rank matrix $\text{rank}(R)\le r$ and $\max_{ij}|R_{ij}|\le C_L$, we always have:

$$\|R\|_* \le \sqrt{r}\|R\|_F \le C_L\sqrt{rn_1n_2},$$

and thus, a nuclear norm regularized constraint $\|R\|_*\le t$ can be thought of as a relaxed condition of $\text{rank}(R)\le r$ and $\max_{ij}|R_{ij}|\le t/\sqrt{rn_1n_2}$.

The proposed problem (4) is also a general formulation to better exploit side information for learning low-rank matrices from missing and corrupted observations. This fact can be seen by considering the following equivalent form of problem (4) which converts the loss term to hard constraints:

$$\min_{M,N,S} \alpha\|M\|_* + \beta\|N\|_* + \lambda\|S\|_1 \quad \text{s.t. } (XMY^T+N+S)_{ij} = R_{ij}, \forall (i,j)\in\Omega_{obs}. \qquad (5)$$

Then, it is easy to see that by setting $\alpha=\infty$ or $\beta=\infty$, problem (5) will become problem (1) or problem (3), which learns the low-rank matrix from missing and corrupted observations

either without any side information or using perfect side information, respectively. This suggests that our model (4) is more general as it can exploit both perfect and noisy side information in learning.

The parameters λ_M, λ_N and λ_S of the model are crucial for controlling the contributions from features, observations and corruption. Intuitively, λ_S controls the ratio of corrupted observations. The relative weight between λ_M and λ_N further controls the contributions from XMY^T and N in forming the low-rank estimate. Therefore, with an appropriate ratio between λ_M,λ_N, the proposed model can leverage a (informative) part of the features XMY^T, yet also be robust to feature noise by learning the remaining part N from pure observations. Below, we further discuss the connections between our model (4) and other well-known models for solving various low-rank matrix learning problems.

2.3.1. Connections to models for matrix completion

First, consider the matrix completion case where the partially observed entries are not corrupted. Then, λ_S can be set to ∞ to force $S^*=0$, and therefore, our proposed problem (4) reduces to the following objective:

$$\min_{M,N} \sum_{(i,j)\in\Omega_{obs}} \ell((XMY^T+N)_{ij}, R_{ij}) + \lambda_M\|M\|_* + \lambda_N\|N\|_*, \qquad (6)$$

which is a general model for solving matrix completion problem. For example, when $\lambda_M=\infty$, M^* will be forced to 0 so features are disregarded, and problem (6) becomes a standard matrix completion objective. On the other hand, when $\lambda_N=\infty$, N^* will be forced to 0 and problem (6) becomes the IMC model (Jain and Dhillon, 2013; Xu et al., 2013) where the estimation of the low-rank matrix is completely from XM^*Y^T. However, problem (6) is more general than both problems, since by appropriately setting the weights of λ_M and λ_N, it can better estimate the low-rank matrix jointly from (noisy) features XM^*Y^T and pure observations N^*. Therefore, problem (6) can be thought of as an improved model which exploits noisy side information in matrix completion problem. We thus refer to problem (6) as "IMC with Noisy Features" (IMCNF) and will justify its effectiveness for matrix completion in Section 4.

2.3.2. Connections to models for robust PCA

Another special case is to consider the well-known "robust PCA" setting, in which Ω_{obs} is assumed to be the set of all $n_1\times n_2$ entries, i.e. observations are full without any missing entries but few of them are corrupted. In this scenario, our proposed problem (4) can be used for solving robust PCA problem with side information by again converting the loss term to hard constraints:

$$\min_{M,N,S} \alpha\|M\|_* + \beta\|N\|_* + \lambda\|S\|_1 \quad \text{s.t. } XMY^T+N+S=R. \qquad (7)$$

Problem (7) can be further reduced to several robust PCA models. For example, if $\alpha=\infty$, problem (7) will be equivalent to the well-known PCP method (Candès et al., 2011) which solves robust PCA problem purely using a structural prior. On the other hand, suppose side information is perfect, then one can set $\beta=\infty$ in (7) to derive the following "PCP

Model	Corresponding setting in our proposed model (4)
problem (1) (Candès et al., 2011)	$\lambda_M = \infty$
problem (3)	$\lambda_N = \infty$
MC	$\lambda_S = \infty, \lambda_M = \infty$
IMC (Jain et al., 2013)	$\lambda_S = \infty, \lambda_N = \infty$
IMCNF	$\lambda_S = \infty$
LRR (Liu et al., 2013)	Ω_{obs} = all entries, $\lambda_N = \infty$, $Y = I$
PCP (Candès et al., 2011)	Ω_{obs} = all entries, $\lambda_M = \infty$
PCPF	Ω_{obs} = all entries, $\lambda_N = \infty$
PCPNF	Ω_{obs} = all entries

Table 1: Settings of several low-rank matrix learning models in the form of our proposed problem (4).

with (perfect) Features" (PCPF) objective:

$$\min_{M,S} \ \alpha\|M\|_* + \lambda\|S\|_1 \quad \text{s.t. } XMY^T + S = R, \tag{8}$$

in which L_0 can be directly estimated by the bilinear embedding XM^*Y^T as discussed in Section 2.2. However, problem (7) is more general than both PCP and PCPF as it can exploit noisy side information for recovery. We thus refer to (7) as "PCP with Noisy Features" (PCPNF) and will examine its effectiveness to leverage noisy side information in robust PCA in Section 4.

Table 1 summarizes several well-known low-rank matrix learning models in terms of the proposed model (4). [2] From the above discussion, it shall be convincing that problem (4) is a general treatment for solving various matrix learning problems with side information. In particular, we have provided sufficient intuitions on how parameters λ_M, λ_N and λ_S play important roles in learning under various circumstances. In Section 3, we will further analytically show that by properly setting these parameters based on the quality of features and noise level of corruption, the proposed model is able to achieve more efficient learning. As a remark, in practical applications, feature quality and noise level may not be known a priori. Therefore, in this case, we recommend to set these parameters via validation, i.e. choosing parameters such that the learned low-rank model best estimates the entries in the validation set.

2.4. Optimization

We propose an alternative minimization scheme to solve the proposed problem (4). The algorithm is shown in Algorithm 1 in which we alternatively update one of the variables (M, N or S) by fixing the others in each iteration, [3] and update of each variable can thus be done via solving a single variable minimization (sub)problem. This algorithm can be viewed as applying a block coordinate descent algorithm on a convex and continuous function, and in

2. Some models are originally proposed in hard-constrained forms, yet their equivalent forms in soft constraints become instances of our proposed problem (4).
3. For simplicity, we choose $\ell(t, y) = (t - y)^2$ to be the squared loss.

Algorithm 1: Alternative Minimization for Problem (4) with Squared Loss

Input: R: observed matrix, X, Y: feature matrices, t_{max}: max iteration
Output: L^*: estimated low-rank matrix
$M \leftarrow 0, \quad N \leftarrow 0, \quad S \leftarrow 0, \quad t \leftarrow 0$
do
  $M \leftarrow \arg\min_M \sum_{(i,j)\in\Omega_{obs}} ((XMY^T)_{ij} - (R - N - S)_{ij})^2 + \lambda_M \|M\|_*$.
  $N \leftarrow \arg\min_N \sum_{(i,j)\in\Omega_{obs}} (N_{ij} - (R - XMY^T - S)_{ij})^2 + \lambda_N \|N\|_*$.
  $S \leftarrow \arg\min_S \sum_{(i,j)\in\Omega_{obs}} (S_{ij} - (R - XMY^T - N)_{ij})^2 + \lambda_S \|S\|_1$.
  $t \leftarrow t + 1$.
while *not converged* **and** $t < t_{\max}$
$L^* \leftarrow XMY^T + N$

such case the cyclic block coordinate descent algorithm is guaranteed to converge to global minimums (see Tseng, 2001). The condition required in Tseng (2001) is that the level set has to be compact, which is satisfied when $\lambda_M, \lambda_N, \lambda_S > 0$.

We now briefly discuss the optimization for solving three subproblems in Algorithm 1. Let $\mathcal{S}_x(A) := \text{sign}(A) \circ \max(|A| - x, 0)$ be the soft thresholding operator on elements of A, where $\circ$ denotes the element-wise product. Similarly, let $\mathcal{D}_x(A)$ be the thresholding operator on singular values of A, i.e. $\mathcal{D}_x(A) := U_A S_x(\Sigma_A) V_A^T$ where $U_A \Sigma_A V_A^T$ is the SVD of A. Then, when fixing N and S, the minimization problem over M becomes a standard IMC objective with observed matrix to be $R' := R - N - S$. We then solve for M using typical proximal gradient descent update $M \leftarrow \mathcal{D}_{\lambda_M}(M - \eta X^T(R' - XMY^T)Y)$, where η is the learning rate. Notice that in our setting, feature dimensions (d_1, d_2) are much smaller than number of entities (n_1, n_2). Therefore, it is relatively inexpensive to compute a full SVD for a $d_1 \times d_2$ matrix in each proximal step.

On the other hand, when fixing M and S, the subproblem of solving over N becomes standard matrix completion problem where the observed matrix is $R - XMY^T - S$. In principle, any algorithm for matrix completion with nuclear norm regularization can be used to solve this subproblem (e.g. the singular value thresholding algorithm (Cai et al., 2010) using proximal gradient descent). In our experiment, we apply the active subspace selection algorithm (Hsieh and Olsan, 2014) to solve the matrix completion problem more efficiently.

Finally, the solution of minimizing over S given fixed M, N can be written in a simple closed form, $\mathcal{S}_{\lambda_S}(\mathcal{P}_{\Omega_{obs}}(R - XMY^T - N))$. The resulting S^*, therefore, will be always supported on Ω_{obs}.

3. Theoretical Analysis on the Effect of Side Information

In this section, we provide a theoretical analysis to justify the usefulness of side information in our model (4). We will focus on the *sample complexity* analysis of the model, in which we aim to show that by exploiting side information, learning can be accomplished with fewer number of (possibly corrupted) observations. The high-level idea of the analysis is to consider the generalization error of the estimated entries, which is associated to both

number of samples and a model complexity term. We further show that model complexity can be related to the quality of features and the noise level of sparse error, and as a result, better feature quality will lead to a smaller generalization error and also a better sample complexity guarantee, provided a small enough noise level. To concentrate on the whole picture of the analysis, we leave detailed proofs of theorems, corollaries and lemmas in Appendix A.

3.1. Generalization Bound of the Proposed Model

To begin with, we consider the equivalent hard-constrained form of problem (4):

$$\min_{M,N,S} \sum_{(i,j)\in\Omega_{obs}} \ell((XMY^T + N + S)_{ij}, R_{ij}), \quad s.t.\ \|M\|_* \le \mathcal{M}, \|N\|_* \le \mathcal{N}, \|S\|_1 \le \mathcal{S}. \quad (9)$$

In the analysis, we assume that each entry $(i,j) \in \Omega_{obs}$ is sampled i.i.d. from an *unknown* distribution $\mathcal{D}$ with index set $\{(i_\alpha, j_\alpha)\}_{\alpha=1}^m$, [4] and each entry of L_0 is upper bounded by a constant C_L (so $\|L_0\|_* = O(\sqrt{n_1 n_2})$). Such a circumstance is consistent with real scenarios such as Netflix problem where users can rate movies with scale up to 5. Let $\theta := (M, N, S)$ be any feasible solution and $\Theta := \{(M,N,S) \mid \|M\|_* \le \mathcal{M}, \|N\|_* \le \mathcal{N}, \|S\|_1 \le \mathcal{S}\}$ be the set of feasible solutions. Also, let $f_\theta \in [n_1] \times [n_2] \to \mathbb{R}$, $f_\theta(i,j) := \mathbf{x}_i^T M \mathbf{y}_j + \mathbf{e}_i^T N \mathbf{e}_j + \mathbf{e}_i^T S \mathbf{e}_j$ be the estimation function (parameterized by θ) where $\mathbf{e}_t$ is the unit vector on the t-th axis, and let $F_\Theta := \{f_\theta \mid \theta \in \Theta\}$ be the set of feasible functions. We are interested in both expected and empirical "ℓ-risk" quantities, $R_\ell(f)$ and $\hat{R}_\ell(f)$, defined by:

$$R_\ell(f) := \mathbb{E}_{(i,j)\sim\mathcal{D}}\big[\ell(f(i,j), \mathbf{e}_i^T(L_0 + S_0)\mathbf{e}_j)\big], \qquad \hat{R}_\ell(f) := \frac{1}{m}\sum_{(i,j)\in\Omega_{obs}} \ell(f(i,j), R_{ij}).$$

Under this context, our model (problem 9) is to solve for θ^* that parameterizes $f^* = \arg\min_{f\in F_\Theta} \hat{R}_\ell(f)$. Classic generalization error bounds have shown that the expected risk $R_\ell(f)$ can be controlled by $\hat{R}_\ell(f)$ along with a measurement on the complexity of the model. The following lemma is a typical result to bound $R_\ell(f)$:

Lemma 2 (Bound on Expected ℓ-risk, Bartlett and Mendelson, 2003) *Let ℓ be a Lipschitz loss function and is bounded by $\mathcal{B}$ with respect to its first argument, and δ be a constant where $0 < \delta < 1$. Let $\mathfrak{R}(F_\Theta)$ be the Rademacher model complexity of the function class F_Θ (w.r.t. Ω_{obs}) defined by:*

$$\mathfrak{R}(F_\Theta) := \mathbb{E}_\sigma\big[\sup_{f\in F_\Theta} \frac{1}{m}\sum_{\alpha=1}^m \sigma_\alpha \ell(f(i_\alpha, j_\alpha), R_{i_\alpha j_\alpha})\big],$$

where each σ_α takes values $\{\pm 1\}$ with equal probability. Then with probability at least $1-\delta$, for all $f \in F_\Theta$ we have:

$$R_\ell(f) \le \hat{R}_\ell(f) + 2\mathbb{E}_{\Omega_{obs}}\big[\mathfrak{R}(F_\Theta)\big] + \mathcal{B}\sqrt{\frac{\log\frac{1}{\delta}}{2m}}.$$

4. In other words, we consider the observations to be sampled under a sampling with replacement model which is similar to Recht (2011); Shamir and Shalev-Shwartz (2014). There are also studies that consider other sampling procedures such as Bernoulli model (Candès and Tao, 2009; Candès and Recht, 2012).

Therefore, to guarantee a small enough R_ℓ, not only $\hat{R}_\ell$, but also the Rademacher model complexity $\mathbb{E}_{\Omega_{obs}}\big[\mathfrak{R}(F_\Theta)\big]$ has to be carefully controlled. We further introduce a key lemma to show that the model complexity is related to both the feature quality and the sparse noise level, where better quality of features and lower noise level will lead to a smaller model complexity. The intuition of the goodness of feature quality can be motivated as follows. Consider any imperfect side information which violates (2). One can imagine such a feature set is perturbed by some misleading noise which is not correlated to the true latent space. However, features should still be effective if noise does not weaken the true latent space information too much. Thus, if a large portion of true latent space lies on the informative part of the feature spaces X and Y, they should still be somewhat informative and helpful for recovering the matrix L_0.

More formally, for F_Θ in problem (9), its model complexity $\mathbb{E}_{\Omega_{obs}}\big[\mathfrak{R}(F_\Theta)\big]$ can be bounded in terms of $\mathcal{M}$, $\mathcal{N}$ and $\mathcal{S}$ by the following lemma:

Lemma 3 *Let $\mathcal{X} = \max_i \|\mathbf{x}_i\|_2$, $\mathcal{Y} = \max_i \|\mathbf{y}_i\|_2$, $n = \max(n_1, n_2)$ and $d = \max(d_1, d_2)$. Suppose ℓ is a convex surrogate loss satisfying conditions in Lemma 2 with the Lipschitz constant L_ℓ. Then for F_Θ in problem (9), its model complexity $\mathbb{E}_{\Omega_{obs}}\big[\mathfrak{R}(F_\Theta)\big]$ is upper bounded by:*

$$2L_\ell\mathcal{M}\mathcal{X}\mathcal{Y}\sqrt{\frac{\log 2d}{m}} + \min\left\{2L_\ell\mathcal{N}\sqrt{\frac{\log 2n}{m}}, \sqrt{\frac{9CL_\ell\mathcal{B}\mathcal{N}(\sqrt{n_1}+\sqrt{n_2})}{m}}\right\} + L_\ell\mathcal{S}\sqrt{\frac{2\log(2n_1n_2)}{m}},$$

where L_ℓ and $\mathcal{B}$ are constants appearing in Lemma 2.

Thus, from Lemma 2 and 3, one should carefully construct a feasible solution set (by setting $\mathcal{M}$, $\mathcal{N}$ and $\mathcal{S}$) such that both $\hat{R}_\ell(f^*)$ and $\mathbb{E}_{\Omega_{obs}}\big[\mathfrak{R}(F_\Theta)\big]$ are controlled to be reasonably small. We now suggest a witness setting of $(\mathcal{M}, \mathcal{N}, \mathcal{S})$ as follows. Let $\mathcal{T}_\mu(\cdot) : \mathbb{R}^+ \to \mathbb{R}^+$ be the thresholding operator where $\mathcal{T}_\mu(x) = x$ if $x \ge \mu$ and $\mathcal{T}_\mu(x) = 0$ otherwise. In addition, let $X = \sum_{i=1}^{d_1}\sigma_i\mathbf{u}_i\mathbf{v}_i^T$ be the reduced SVD of X, and $X_\mu = \sum_{i=1}^{d_1}\sigma_1\mathcal{T}_\mu(\sigma_i/\sigma_1)\mathbf{u}_i\mathbf{v}_i^T$ be the "μ-informative" part of X. The ν-informative part of Y, denoted as Y_ν, can also be defined similarly. We then propose to set:

$$\mathcal{M} = \|\hat{M}\|_* \qquad \mathcal{N} = \|L_0 - X_\mu\hat{M}Y_\nu^T\|_* \qquad \mathcal{S} = \|S_0\|_1, \quad (10)$$

where $\hat{M} := \arg\min_M \|X_\mu M Y_\nu^T - L_0\|_F^2 = (X_\mu^T X_\mu)^\dagger X_\mu^T L_0 Y_\nu (Y_\nu^T Y_\nu)^\dagger$ is the optimal solution for approximating L_0 under the informative feature spaces X_μ and Y_ν. The following lemma further shows that the trace norm of $\hat{M}$ will not grow as a function of n.

Lemma 4 *Fix $\mu, \nu \in (0, 1]$, and let γ be a constant defined by*

$$\gamma := \min\left(\frac{\min_i\|\mathbf{x}_i\|}{\mathcal{X}}, \frac{\min_i\|\mathbf{y}_i\|}{\mathcal{Y}}\right)$$

where $\mathcal{X}, \mathcal{Y}$ are constants defined in Lemma 3. Then the trace norm of $\hat{M}$ is upper bounded by:

$$\|\hat{M}\|_* \le \frac{C_L d^2}{\mu^2\nu^2\gamma^2\mathcal{X}\mathcal{Y}},$$

where $C_L \ge \max_{i,j}|\mathbf{e}_i^T L_0 \mathbf{e}_j|$ is the constant upper bounding the entries of L_0.

Therefore, by combining Lemma 2-4, we derive a generalization error bound on $R_\ell(f^*)$ of problem (9) as follows.

Theorem 5 *Suppose ℓ is a convex surrogate loss function with Lipschitz constant L_ℓ bounded by $\mathcal{B}$ with respect to its first argument and assume that $\ell(t,t) = 0$. Consider problem (9) where the constraints $(\mathcal{M}, \mathcal{N}, \mathcal{S})$ are set as (10) with some fixed $\mu, \nu \in (0,1]$. Then with probability at least $1-\delta$, the expected ℓ-risk of the optimal solution $R_\ell(f^*)$ is bounded by:*

$$R_\ell(f^*) \le \min\left\{4L_\ell\mathcal{N}\sqrt{\frac{\log 2n}{m}}, \sqrt{36CL_\ell\mathcal{B}\frac{\mathcal{N}(\sqrt{n_1}+\sqrt{n_2})}{m}}\right\} + 2L_\ell\mathcal{S}\sqrt{\frac{2\log(2n_1n_2)}{m}} + \frac{4L_\ell C_L d^2}{\mu^2\nu^2\gamma^2}\sqrt{\frac{\log 2d}{m}} + \mathcal{B}\sqrt{\frac{\log\frac{1}{\delta}}{2m}},$$

where C, C_L and γ are constants appearing in Lemma 3 and 4.

As a result, Theorem 5 leads us to deem $\mathcal{N}$ and $\mathcal{S}$ in (10) to be the measurement of feature quality and noise level respectively, where features with better quality (or observations with less corruption) lead to a smaller $\mathcal{N}$ (or $\mathcal{S}$) and thus a smaller risk quantity. Note that the measurement $\mathcal{N}$ is consistent with the stated intuition of feature quality, since given a good feature set such that most true latent space of L_0 lies on the informative part of the feature spaces, $X_\mu\hat{M}Y_\nu^T$ will absorb most of L_0, resulting in a small $\mathcal{N}$. Given Theorem 5, we can further discuss the effect of side information in the proposed model (9) on the sample complexity in several important scenarios. To make the comparison more clear, we fix $d = O(1)$ so the feature dimensions do not grow as a function of n in the following discussion.

3.2. Sample Complexity for Matrix Completion

First, consider the matrix completion case where the observations are partial yet not corrupted, i.e. $S_0 = 0$. Then, as mentioned, our model can be further reduced to IMCNF (problem (6), or equivalently problem (9) with $\mathcal{S} = 0$) which exploits noisy side information to solve the matrix completion problem. In addition, from Theorem 5, we can derive the sample complexity of IMCNF as follows.

Corollary 6 *Suppose we aim to (approximately) recover L_0 from partial observations $R = \mathcal{P}_{\Omega_{obs}}(L_0)$ in the sense that $\mathbb{E}_{(i,j)\sim\mathcal{D}}\left[\ell((XM^*Y^T+N^*)_{ij}, \mathbf{e}_i^TL_0\mathbf{e}_j)\right] < \epsilon$ given an arbitrary $\epsilon > 0$. Then by solving problem (9) with constraints to be set as (10), $O(\min(\mathcal{N}\sqrt{n}, \mathcal{N}^2\log n)/\epsilon^2)$ samples are sufficient to guarantee that the estimated low-rank matrix $XM^*Y^T+N^*$ recovers L_0 with high probability, provided a sufficiently large n.*

Corollary 6 suggests that the sample complexity of IMCNF can be lowered with the aid of (sufficiently informative) noisy side information. The significance of this result can be further explained by comparing with the sample complexity of other models. First, if features are perfect ($\mathcal{N} = O(1)$), Corollary 6 suggests that our IMCNF model only requires $O(\log n)$ samples for recovery. This result coincides with the sample complexity of IMC, in which researchers have shown that given perfect features, $O(\log n)$ observations are enough

for exact recovery (Xu et al., 2013; Zhong et al., 2015). However, IMC does not guarantee recovery when features are not perfect, while Corollary 6 suggests that recovery is still attainable by IMCNF with $O(\min(\mathcal{N}\sqrt{n}, \mathcal{N}^2\log n)/\epsilon^2)$ samples.

On the other hand, our analysis suggests that sample complexity of IMCNF is at most $O(n^{3/2})$ given any features by applying the following inequality to Corollary 6:

$$\mathcal{N} \le \|L_0\|_* \le C_L\|E\|_* \le C_L\sqrt{\text{rank}(E)}\|E\|_F = C_L\sqrt{n_1n_2} = O(n),$$

where $E \in \mathbb{R}^{n_1\times n_2}$ is the matrix with all entries to be one. To explain the result, we compare this result to the sample complexity of standard matrix completion where no side information is considered. At the first glance, it may appear that the result is worse than pure matrix completion in the worst case, since many well-known matrix completion guarantees showed that under certain spikiness and distributional conditions, one can achieve $O(n\,\text{polylog}\,n)$ sample complexity for both approximate recovery (Srebro and Shraibman, 2005; Negahban and Wainwright, 2012) and exact recovery (Candès and Recht, 2012). However, all of the above $O(n\,\text{polylog}\,n)$ results require additional distributional assumptions on observed entries, while our analysis does not make distributional assumptions. To make a fairer comparison, Shamir and Shalev-Shwartz (2014) have shown that for pure matrix completion, $O(n^{3/2})$ entries are sufficient for approximate recovery without any distributional assumptions, and furthermore, the bound is *tight* if no further distributional assumptions on observed entries is allowed. Therefore, Corollary 6 indicates that IMCNF is at least as good as pure matrix completion even *in the worst case* under the distribution-free setting. Notice that it is reasonable to meet the matrix completion lower bound $\Omega(n^{3/2})$ even given features, since for completely useless feature case (e.g. X, Y are random matrices), the given information is exactly the same as that in standard matrix completion, so any method cannot beat the matrix completion lower bound even by taking features into account.

However, in most applications, the given features are expected to be far from random, and Corollary 6 provides a theoretical insight to show that even noisy features can be useful in matrix completion. Indeed, as long as features are informative enough such that $\mathcal{N} = o(n)$, sample complexity of the IMCNF model will be asymptotically lower than standard matrix completion. Here we provide a concrete example for such a scenario. We consider the rank-r matrix L_0 to be generated from random orthogonal model (Candès and Recht, 2012) as follows:

Corollary 7 *Let $L_0 \in \mathbb{R}^{n\times n}$ be generated from random orthogonal model, where $U = \{\mathbf{u}_i\}_{i=1}^r$, $V = \{\mathbf{v}_i\}_{i=1}^r$ are random orthogonal bases, and $\sigma_1 \dots \sigma_r$ are singular values with arbitrary magnitude. Let σ_t be the largest singular value such that $\lim_{n\to\infty}\sigma_t/\sqrt{n} = 0$. Then, given the noisy features X, Y where $X_{:i} = \mathbf{u}_i$ (and $Y_{:i} = \mathbf{v}_i$) if $i < t$ and $X_{:i}$ (and $V_{:i}$) be any basis orthogonal to U (and V) if $i \ge t$, $o(n)$ samples are sufficient for IMCNF to achieve recovery of L_0.*

Corollary 7 suggests that, under random orthogonal model, if features are not too noisy in the sense that noise only perturbs the true subspace associated with smaller singular values, the sample complexity of IMCNF can be asymptotically lower than the lower bound of standard matrix completion (which is $\Omega(n^{3/2})$).

All in all, for the matrix completion case where observations are partial yet uncorrupted, our proposed problem (4) reduces to the IMCNF model (6) and moreover, Corollary 6

suggests that it can attain recovery more efficiently than other existing models by exploiting noisy yet informative side information.

3.3. Sample Complexity given Partial and Corrupted Observations

We now further consider the case where observations are *both* missing and corrupted. In the presence of corruption, Theorem 5 results in the following Corollary 8 which shows that the learned matrix $XM^*Y^T + N^* + S^*$ will be close to $L_0 + S_0$ with sufficient observations, where the number of required samples depends on both the quality of features and the noise level of sparse error. Since there always exists a solution of problem (9) with $\mathcal{P}_{\Omega_{obs}^{\perp}}(S^*) = 0$ and the generalization bound in Theorem 5 holds for any solution, the result in Corollary 8 implies that $XM^*Y^T + N^*$ is close to L_0 on *missing entries* $(i,j) \notin \Omega_{obs}$, which means we can recover the missing entries of the underlying low-rank matrix with small error. Moreover, if we apply the proposed Algorithm 1 to solve the soft-constrained form (4), the solution S^* will satisfy $\mathcal{P}_{\Omega_{obs}^{\perp}}(S^*) = 0$ automatically. In the following, we formally state the recovery guarantee for partial and corrupted observations:

Corollary 8 *Suppose we are given a data matrix $R = \mathcal{P}_{\Omega_{obs}}(L_0 + S_0)$ containing both missing and corrupted observations of L_0 along with side information X, Y. Then for problem* (9) *with constraints to be set as* (10)*, if we apply Algorithm 1 to solve its equivalent form in* (4)*, $O(\{\min(\mathcal{N}\sqrt{n}, \mathcal{N}^2 \log n) + \mathcal{S}^2 \log n\}/\epsilon^2)$ samples are sufficient to guarantee that with high probability, $\mathbb{E}_{(i,j)\sim\mathcal{D}}\big[\ell((XM^*Y^T + N^* + S^*)_{ij}, R_{ij})\big] < \epsilon$ for any $\epsilon > 0$ provided a sufficiently large n, where S^* satisfies $\mathcal{P}_{\Omega_{obs}^{\perp}}(S^*) = 0$.*

Corollary 8 suggests that if observations are both missing and corrupted, then to guarantee the learned low-rank matrix $XM^*Y^T + N^*$ is accurate on missing entries, the number of required samples depends not only on the quality of features $\mathcal{N}$, but also on the noise level of corruption $\mathcal{S}$. In addition, larger $\mathcal{S}$ results in a higher complexity guarantee. The reasoning behind this result is intuitive: compared to the matrix completion setting in Section 3.2, allowing observed samples to be corrupted makes the problem harder, and therefore may increase sample complexity. However, suppose the corruption is not too severe as the total magnitude of error $\mathcal{S}$ is in the order of $o(n/\sqrt{\log n})$, Corollary 8 still provides a non-trivial bound on required samples for learning the missing entries accurately. Furthermore, better quality of features becomes helpful for faster learning if corruption is small enough. For example, suppose the allowed corruption budget is upper bounded as $\mathcal{S} = O(1)$, then the sample complexity will again be $O(\min(\mathcal{N}\sqrt{n}, \mathcal{N}^2 \log n)/\epsilon^2)$. As discussed, it implies that the number of samples can be $o(n^{3/2})$ provided sufficiently good features, while the required samples will be $O(n^{3/2})$ if no features are given.

Remark. Overall, we provide sample complexity analysis to justify that our model (4) is able to learn the missing information of L_0 more effectively by leveraging side information. The analysis is based on the generalization bounds of the missing values, where more informative side information (and less corruption) results in fewer required samples for accurate estimation, justifying the usefulness of side information.

Again, we emphasize that our results are relatively loose compared to those exact recovery guarantees in both matrix completion (Candès and Tao, 2009; Candès and Recht, 2012) and robust PCA (Chandrasekaran et al., 2011; Candès et al., 2011) as we only consider an approximate recovery on missing entries. However, it is important to note that those stronger recovery guarantees require additional assumptions, such as incoherence of the underlying low-rank matrices and distributional assumptions, to ensure the sampled observations are sufficiently representative. On the other hand, our analysis does not require distributional or incoherence assumptions, since in generalization analysis we only need to ensure the average loss of the missing entries are sufficiently small, and therefore, the average loss can still be controlled even if few spots are wrongly estimated in a high incoherence L_0.

However, in some circumstances, it is in fact possible to provide a stronger argument to justify the usefulness of side information in the exact recovery context. For example, in the robust PCA setting where observations are grossly corrupted yet full, one can further show that by exploiting perfect side information, a large amount of low-rank matrices L_0, which cannot be recovered by standard robust PCA without features, can be exactly recovered using our proposed model. Interested readers can consult Chiang et al. (2016) for such a result in detail. A theoretical analysis on how much the side information can improve the exact recovery guarantees in general low-rank matrix learning would be an interesting research direction to explore in the future.

4. Experimental Results

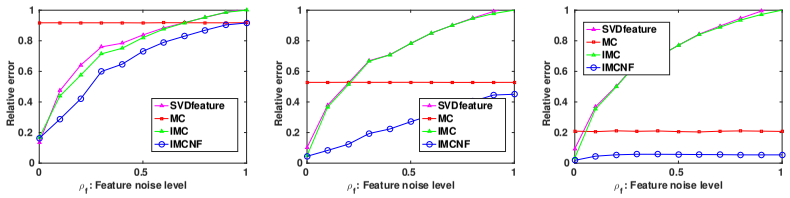
We now present experimental results on exploiting side information using the proposed model (4) for various low-rank matrix learning problems. For synthetic experiments, we show that our model performs better with the aid of side information given observations are either only missing (i.e. matrix completion setting), only corrupted (i.e. robust PCA setting) or both missing and corrupted. For real-world applications, we consider three machine learning applications—relationship prediction, semi-supervised clustering and noisy image classification—and show that each of them can be viewed as a problem of learning a low-rank modeling matrix from missing/corrupted entries with side information. As a result, by applying our model, we can achieve better performance compared to other state-of-the-art methods in these applications.

4.1. Synthetic Experiments

To begin with, we show the usefulness of (both perfect and noisy) side information in our model under different synthetic settings.

4.1.1. Experiments on Matrix Completion Setting

We first examine the effect of side information in our model in the case of matrix completion. We create a low rank matrix $L_0 = UV^T$ where the true latent row/column space $U, V \in \mathbb{R}^{200\times 20}$, $U_{ij}, V_{ij} \sim \mathcal{N}(0,1)$. We then randomly sample ρ_{obs} of entries Ω_{obs} from L_0 to form the observed matrix $R = \mathcal{P}_{\Omega_{obs}}(L_0)$. In addition, we construct perfect side information $X^*, Y^* \in \mathbb{R}^{200\times 40}$ satisfying (2), from which we generate different quality of features X, Y with a noise parameter $\rho_f \in [0,1]$, where X and Y are derived by replacing ρ_f of bases



(a) $\rho_{obs} = 0.1$ (b) $\rho_{obs} = 0.25$ (c) $\rho_{obs} = 0.4$

(d) $\rho_f = 0.1$ (e) $\rho_f = 0.5$ (f) $\rho_f = 0.9$

Figure 1: Performance of various methods for matrix completion under certain fixed sparsity of observations ρ_{obs} (upper figures) and fixed feature quality ρ_f (lower figures). We observe that all feature-based methods perform better than standard matrix completion (MC) given perfect features ($\rho_f = 0$). However, IMCNF is less sensitive to feature noise as ρ_f increases, indicating that it better exploits information from noisy features.

in X^* (and Y^*) with bases orthogonal to X^* (and Y^*). We then consider recovering the underlying matrix L_0 given R, X and Y.

In this experiment, we consider the proposed IMCNF model (problem 6) which is an instance of the general problem (4) for exploiting noisy side information in matrix completion case. We compare IMCNF with standard trace-norm regularized matrix completion (MC), IMC (Jain and Dhillon, 2013) and SVDfeature (Chen et al., 2012). The recovered matrix L^* from each algorithm is evaluated by the standard relative error:

$$\frac{\|L^* - L_0\|_F}{\|L_0\|_F}. \tag{11}$$

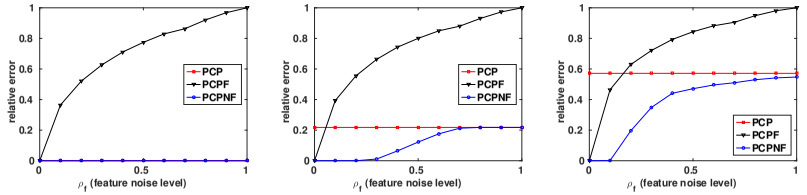
For each method, we select parameters from the set $\{10^\alpha\}_{\alpha=-3}^{2}$ and report the one with the best recovery. All results are averaged over 5 random trials.

Figure 1 shows results of each method under different $\rho_{obs} = 0.1, 0.25, 0.4$ and $\rho_f = 0.1, 0.5, 0.9$. We can first observe in upper figures that IMC and SVDfeature perform similarly under each ρ_{obs}, and moreover, their performance mainly depends on feature quality and will not be affected much by the number of observations. Although their performance is comparable to IMCNF given perfect features ($\rho_f = 0$), their performance quickly drops when features become noisy. This phenomenon is more clear in figure 1c and 1f where we see that given noisy features, IMC and SVDfeature will be easily trapped by feature noise and perform even worse than pure MC. Another interesting finding is that even if feature quality is as good as $\rho_f = 0.1$ (Figure 1d), IMC (and SVDfeature) still fails to achieve 0 relative error as the number of observations increases, suggesting that IMC is sensitive to feature noise and cannot guarantee recoverability when features are not perfect. On the other hand, we see that performance of IMCNF can be improved by both better features and more observations. In particular, it makes use of informative features to achieve lower error compared to MC and is also less sensitive to feature noise compared to IMC and SVDfeature. These results empirically support the analysis presented in Section 3.

4.1.2. Experiments on Robust PCA Setting

In this experiment, we examine the effect of both perfect and noisy side information in the proposed model for robust PCA as follows. We create a low-rank matrix $L_0 = UV^T$, where $U, V \in \mathbb{R}^{n\times 40}$, $U_{ij}, V_{ij} \sim N(0, 1/n)$ with $n = 200$. We also form a sparse noise matrix S_0 where each entry will be a non-zero entry with probability ρ_s, and each non-zero entry will take values from $\{\pm 1\}$ with equal probability. We then construct noisy features $X, Y \in \mathbb{R}^{n\times 50}$ with a noise parameter ρ_f using the same construction in the previous experiment, i.e. features X/Y will only span $40 \times (1 - \rho_f)$ true bases of U/V. We then consider to recover the low-rank matrix given the fully observed matrix $R = L_0 + S_0$ along with noisy side information X and Y.

We consider the following three methods: PCP (Candès et al., 2011) which does not exploit features, PCPF (problem 8) which theoretically exploits perfect features using bilinear embedding, and PCPNF (problem 7) for incorporating noisy side information. Note that PCPF and PCPNF are instances of our proposed model (4) that exploits side information for robust PCA problem as discussed in Section 2.3. The same relative error criterion (11) is used for evaluation.



(a) $\rho_s = 0.1$ (b) $\rho_s = 0.2$ (c) $\rho_s = 0.3$

Figure 2: Performance of various methods for robust PCA given different feature noise level ρ_f and sparsity of corruption ρ_s. These results show that PCPNF can make use of noisy yet informative features for better recovery.

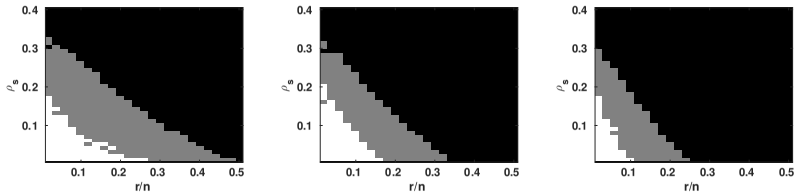
Figure 2 shows the performance of each method given different feature quality under $\rho_s = 0.1, 0.2, 0.3$. We first see that when features are perfect ($\rho_f = 0$), both PCPF and PCPNF can exactly recover the underlying matrix, while pure PCP fails to recover L_0 if $\rho_s \geq 0.2$. This result confirms that both PCPNF and PCPF can leverage perfect features for better recovery. However, as features become noisy (larger ρ_f), we see that PCPF quickly performs worse as it is misled by noise in features, while PCPNF can better exploit noisy features for recovery. In particular, in Figure 2b, we observe that PCPNF still recovers L_0 given noisy yet reasonably good features ($0 < \rho_f < 0.4$), whereas PCP and PCPF fail to recover L_0. These results show that PCPNF can take advantage of noisy side information for learning L_0 given corrupted observations.

4.1.3. Experiments on Learning with Missing and Corrupted Observations

We now further examine to what extent can side information help the learning using our model when observations are both missing and corrupted. We consider the same construction of L_0 and S_0 as in the previous experiment, and generate perfect feature matrices $X, Y \in \mathbb{R}^{n \times d}$ with $d = r + 10$. We then form the observation set Ω_{obs} by randomly sampling ρ_{obs} of entries from all n^2 indexes, and take $R = \mathcal{P}_{\Omega_{obs}}(L_0 + S_0)$ as the observed matrix. The goal is therefore to recover L_0 given R along with side information X and Y.

To exploit the advantage of side information, we consider the proposed model in form (5) where we further set $\alpha = 1$ and $\beta = \infty$ to force N^* to be zero for better exploiting perfect features, and compare it with the problem (1) which tries to recover L_0 only using structural information. Notice that when $\rho_{obs} = 1.0$, the given problem becomes a robust PCA problem where R is a fully observed matrix, in which case problem (1) reduces to PCP method and our model reduces to PCPF objective (problem 8), respectively. From this aspect, we refer to problem (1) as "PCP with partial observations" (PCP-part) and our model as "PCPF with partial observations" (PCPF-part). The relative error criterion (11) is again used to evaluate the recovered matrix. Here, we regard the recovery to be successful if the error is less than 10^{-4}. The parameter λ in both methods are set to be $1/\sqrt{\rho_{obs} n}$.

We compare the recoverability of PCP-part and PCPF-part by varying rank of L_0 (r) and sparsity of S_0 (ρ_s) under different $\rho_{obs} = 1.0, 0.7$ and 0.5. For each pair of (r, ρ_s),



(a) $\rho_{obs} = 1.0$ (b) $\rho_{obs} = 0.7$ (c) $\rho_{obs} = 0.5$

Figure 3: Performance of PCP-part and PCPF-part with perfect features for recovering L_0 from missing and corrupted observations (controlled by ρ_{obs} and ρ_s respectively). Both methods achieve recovery in white region and fail in black region, yet there is a gray region where only PCPF-part achieves recovery. This shows that by leveraging perfect features, PCPF-part can recover a much larger class of L_0 given both missing and corrupted observations are present.

we apply both methods to obtain the estimated low-rank matrix L^*. We then mark the grid point (r, ρ_s) to be white if recovery is attained by both methods and black if both fail. We also observe that in several cases recovery cannot be attained by PCP-part but can be attained by PCPF-part, and these grid points are marked as gray. The results are shown in Figure 3. We observe that for each ρ_{obs}, there exists a substantial gray region where matrices in such a region can be recovered only by PCPF-part. This result shows that in the case where both missing and corrupted entries are present, by exploiting side information, the proposed model is able to further recover a large amount of matrices which cannot be recovered if no side information is provided.

4.2. Real-world Applications

We now consider three applications—relationship prediction in signed networks, semi-supervised clustering and noisy image classification—which can be cast to problems of low-rank matrix learning from missing/corrupted entries with additional side information. As a consequence, we show that by learning the low-rank modeling matrix using our proposed model, we can achieve better performance compared to other methods for these applications as our model can better exploit side information in learning.

4.2.1. Relationship Prediction in Signed Networks

We first consider relationship prediction problem in an online review website Epinions (Massa and Avesani, 2006), where people can write product reviews and choose to trust or distrust others based on their reviews. Such a social network can be modeled as a *signed network* where each person is treated as an entity and trust/distrust relationships between people are modeled as positive/negative edges between entities (Leskovec et al., 2010). The relationship prediction problem in signed network is to predict unknown relationship between any two users given the current network snapshot. While several methods

Method	IMCNF	IMC	MF-ALS	HOC-3	HOC-5
Accuracy	**0.9474**±0.0009	0.9139±0.0016	0.9412±0.0011	0.9242±0.0010	0.9297±0.0011
AUC	**0.9506**	0.9109	0.9020	0.9432	0.9480

Table 2: Relationship prediction on Epinions network. We see that given noisy user features, IMC performs worse even than methods without features (MF-ALS and HOCs), while IMCNF outperforms others by successfully exploiting noisy features.

are proposed, a state-of-the-art approach is the low-rank model (Hsieh et al., 2012; Chiang et al., 2014) which first conducts matrix completion on the adjacency matrix and then uses the sign of the completed matrix for prediction. However, these methods are developed based only on network structure. Therefore, if features of users are available, we can also extend the low-rank model by incorporating user features in the completion step.

The experiment setup is described as follows. In this data set, there are about $n = 105$K users and $m = 807$K observed relationship pairs where 15% relationships are distrust. In addition to the who-trust-to-whom information, we are also given a user feature matrix $Z \in \mathbb{R}^{n\times 41}$ where for each user a 41-dimensional feature is collected based on the user's review history, such as number of positive/negative reviews the user gave or received. We consider the following prediction methods: walk and cycle-based methods including HOC-3 and HOC-5 (Chiang et al., 2014), and the original low-rank model with matrix factorization for the completion step (LR-ALS) (Hsieh et al., 2012). These methods make the prediction based on network structure without considering user features. We further consider the extended low-rank model where the completion step is replaced by IMCNF and IMC (Jain et al., 2013), both of which thus incorporate user features implicitly for prediction. Since row and column entities are both users, $X = Y = Z$ is set for both IMCNF and IMC methods. We randomly divide the edges of the network into 10 folds and conduct the experiment using 10-fold cross validation, in which 8 folds are used for training, one fold for validation and the other for testing. Parameters for validation in each method are chosen from the set $\sqcup_{\alpha=-3}^{2}\{10^\alpha, 5\times 10^\alpha\}$.

The averaged accuracy and AUC of each method are reported in Table 2. We first observe that IMC performs worse than LR-ALS even though IMC takes features into account. It is because these user features are only partially related to the relationship matrix, and IMC is misled by such noisy features. On the other hand, IMCNF performs the best among all prediction methods, as it performs slightly better than LR-ALS in terms of accuracy and much better in terms of AUC. This result shows that IMCNF can exploit weakly informative features to make better prediction without being trapped by feature noise.

4.2.2. Semi-supervised Clustering

Semi-supervised clustering is another application which can be translated to learning a low-rank matrix with partial observations. Given a feature matrix $Z \in \mathbb{R}^{n\times d}$ of n items and m pairwise constraints specifying whether item i and j are similar or dissimilar, the goal is to find a clustering of items such that most similar items are within the same cluster.

First, note that the problem can be sub-optimally solved by dropping either constraint or feature information. For example, traditional clustering algorithms (such as k-means) can solve the problem based purely on features of items. On the other hand, one can also

obtain a clustering purely from the pairwise constraints using matrix completion as follows. Let $S \in \mathbb{R}^{n\times n}$ be the (signed) similarity matrix constructed from the constraint set where $S_{ij} = 1$ if item i and j are similar, -1 if dissimilar and 0 if similarity is unknown. Then finding a clustering of n items becomes equivalent to finding a clustering on the signed graph S, where the goal is to put items (denoted as nodes) into k groups so that most edges within the same group are positive and most edges between groups are negative (Chiang et al., 2014). As a result, one can apply a matrix completion approach proposed in Chiang et al. (2014) to solve the signed graph clustering problem, which first conducts matrix completion on S and runs k-means on the top-k eigenvectors of completed S to obtain a clustering of nodes.

Apparently, either dropping features or constraint set is not optimal for semi-supervised clustering problem. Thus, many algorithms are proposed to take both item features and constraints into account, such as metric-learning-based approaches (Davis et al., 2007), spectral kernel learning (Li and Liu, 2009) and MCCC algorithm (Yi et al., 2013). Among many of them, MCCC algorithm is a cutting edge approach which essentially solves semi-supervised clustering using IMC objective. Observing that each pairwise constraint can be viewed as a sampled entry from the matrix $L_0 = UU^T$ where $U \in \mathbb{R}^{n\times k}$ is the clustering membership matrix, MCCC tries to complete L_0 back as ZMZ^T using IMC objective. Furthermore, since the completed matrix is ideally L_0 whose subspace spans U, it thus conducts k-means on the top-k eigenvectors of the completed matrix to obtain a clustering.

However, since MCCC is based on IMC, its performance thus heavily depends on the quality of features. Therefore, we propose to replace IMC with IMCNF in the matrix completion step of MCCC, and then run k-means on the top-k eigenvectors of the completed matrix to obtain a clustering. Both X and Y are again set to be Z as the target low-rank matrix describes the similarity between items. This algorithm can be viewed as an improved version of MCCC to handle noisy features Z.

We now compare our algorithm with k-means, signed graph clustering with matrix completion (Chiang et al., 2014) (SignMC) and MCCC (Yi et al., 2013) on three real-world data sets: Mushrooms, Segment and Covtype. [5] All of them are classification benchmarks where features and ground-truth labels of items are both available, and the ground-truth cluster of each item is defined by its ground-truth label. The statistics of data sets are summarized in Table 3. For each data set, we randomly sample $m = [1, 5, 10, 15, 20, 25, 30]\times n$ clean pairwise constraints and input both constraints and features to each algorithm to obtain a clustering π, where π_i is the cluster index of item i. We then evaluate π using the following pairwise error:

$$\frac{n(n-1)}{2}\left(\sum_{(i,j):\pi_i^*=\pi_j^*} \mathbf{1}\left[\pi_i \neq \pi_j\right] + \sum_{(i,j):\pi_i^*\neq\pi_j^*} \mathbf{1}\left[\pi_i = \pi_j\right]\right)$$

where π_i^* is the ground-truth cluster of item i.

Figure 4 shows the clustering result of each method given various numbers of constraints on each data set. We first see that for the Mushrooms data set where features are perfect (100% training accuracy can be attained by a linear-SVM for classification), both MCCC

5. All data sets are available at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/`. For Covtype, we subsample from the entire data set to make each cluster has balanced size.

	number of items n	feature dimension d	number of clusters k
Mushrooms	8124	112	2
Segment	2319	19	7
Covtype	11455	54	7

Table 3: Statistics of semi-supervised clustering data sets.

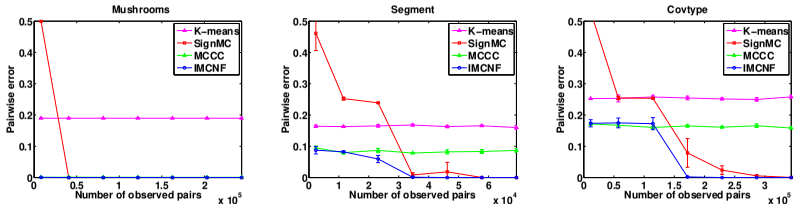


Figure 4: Performance of various semi-supervised clustering methods on real-world data sets. For the Mushrooms data set where features are perfect, both MCCC and IMCNF can output the ground-truth clustering with 0 error rate. For Segment and Covtype where features are more noisy, IMCNF model outperforms MCCC as its error decreases given more constraints.

and IMCNF can obtain the ground-truth clustering with 0 error rate, which indicates that MCCC (and IMC) is indeed effective with perfect features. For the Segment and Covtype data sets, we observe that the performance of k-means and MCCC is dominated by feature quality. Although MCCC is still benefited from constraint information as it outperforms k-means, it clearly does not make the best use of constraints since its performance is not improved even if number of constraints increases. On the other hand, the error rate of SignMC can always decrease down to 0 by increasing m; however, since it disregards features, it suffers from a much higher error rate than other methods when constraints are few. Finally, we see that IMCNF combines advantages from both MCCC and SignMC, as it not only makes use of features when few constraints are observed, but also leverages constraint information to avoid being trapped by feature noise. Therefore, the experiment shows that by carefully handling side information using IMCNF model, we can further improve the state-of-the-art semi-supervised clustering algorithm.

4.2.3. Noisy Image Classification

Finally, we consider noisy image classification problem as an application of low-rank matrix learning with corrupted observations. In this problem, we are given a set of correlated images in which a few of pixels are corrupted, and the task is to denoise the images so that one can classify the images correctly. Since the underlying clean images are correlated and thus share an implicit low-rank structure, standard robust PCA could be used to identify sparse noise and recover the (low-rank approximation of) clean images. However, in certain cases, low-dimensional features of images may also be available from other sources. For example, suppose the set of images are human faces, then the principal components of

	linear SVM classifiers					kernel SVM classifiers			
ρ_s	Clean	Noisy	PCP	PCPF	ρ_s	Clean	Noisy	PCP	PCPF
0.1		59.63	86.33	**87.88**	0.1		18.47	94.85	**95.89**
0.2	91.96	38.16	85.94	**87.48**	0.2	98.33	10.32	94.55	**95.48**
0.3		25.63	78.52	**79.84**	0.3		10.32	87.00	**87.78**

Table 4: Digit classification accuracy of PCP and PCPF with Eigendigit features. The column Clean shows the accuracy on L_0 and the column Noisy shows the accuracy on R. Denoised images from both PCP and PCPF achieve much higher accuracy than noisy images, and PCPF further outperforms PCP by incorporating Eigendigit features.

general human faces—known as Eigenface (Turk and Pentland, 1991)—could be used as features, and such features could be helpful in the denoising process.

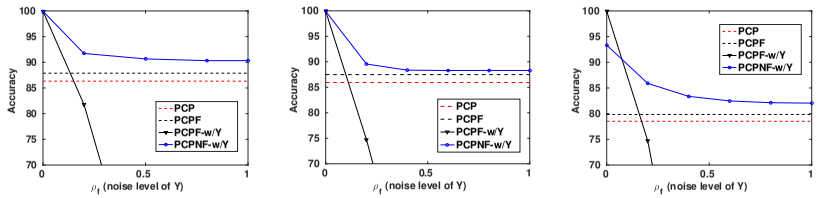
Motivated by the above realization, here we consider multiclass classification on a set of noisy images from the MNIST data set. The data set includes 50,000 training images and 10,000 testing images, and each image is a 28×28 handwritten digit represented as a 784-dimensional vector. We first pre-train both multiclass linear and kernel SVM classifiers on the clean training images, and perturb the testing image set to generate noisy images R. Precisely, let $L_0 \in \mathbb{R}^{784\times 10000}$ be the set of (clean) testing images, where each row denotes a pixel and each column denotes an image. We then construct a sparse noise matrix $S_0 \in \mathbb{R}^{784\times 10000}$ where ρ_s of entries are randomly picked to be corrupted by setting their values to be 255. The observed noisy images is thus given by $R = \min(L_0 + S_0, 255)$. In the following, we show that by exploiting features of row and column entities in this problem, we can better denoise the noisy images for classification.

Exploiting Eigendigit Features. We first exploit "Eigendigit" features to help denoising. We take the training image set to produce the Eigendigit features $X \in \mathbb{R}^{784\times 300}$ using PCA and simply set $Y = I$ as we do not consider any column features here. We then input R into PCP to derive a set of denoised images L^*_{pcp} and input R, X and Y (which is I) into PCPF (problem 8) to derive another set of denoised images $L^*_{pcpf} = XM^*$. Both L^*_{pcp} and L^*_{pcpf} will be low rank approximations of the clean images. Note that although the Eigendigit features X will not satisfy (2) which is assumed in the derivation of PCPF, we could heuristically incorporate it using PCPF in this circumstance because X is still expected to contain unbiased information of the low-rank approximation of the clean digits. [6]

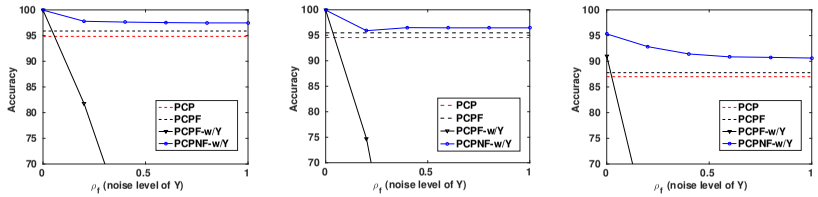
To compare the quality of denoised images of PCP and PCPF, we input L^*_{pcp} and L^*_{pcpf} to pre-trained SVMs for digit classification and report the results in Table 4. Both methods are somehow effective for denoising sparse noise, since accuracies achieved by the denoised images are much closer to the clean images compared to the noisy images. Furthermore, PCPF consistently achieves better accuracies than PCP under different ρ_s, showing that incorporating Eigendigit features using PCPF is helpful on denoising process for classification.

Exploiting both Eigendigit and Label-relevant Features In addition to the Eigendigit features X, now we further exploit features for column entities. Ideally, the

6. Rigorously speaking, the ground-truth L_0 is not even low-rank, but only approximately low-rank.



(a) Linear SVM, $\rho_s = 0.1$ (b) Linear SVM, $\rho_s = 0.2$ (c) Linear SVM, $\rho_s = 0.3$



(d) Kernel SVM, $\rho_s = 0.1$ (e) Kernel SVM, $\rho_s = 0.2$ (f) Kernel SVM, $\rho_s = 0.3$

Figure 5: Digit classification accuracy of various methods with both Eigendigit and label-relevant features. For each ρ_s, we construct the label-relevant features Y with different quality by varying ρ_f. The results show that PCPNF-w/Y is able to better exploit noisy label-relevant features Y.

column features Y may describe the relevant information between images, which could be extremely useful for classification. Thus, we generate the "label-relevant" features Y for column entities as follows. Let $Y^* \in \mathbb{R}^{10000\times 10}$ be a perfect column feature matrix where the i-th column of Y^* is the indicator vector of digit $i-1$ (so Y^* contains ground-truth label information). We then randomly pick ρ_f of rows in Y^* and shuffle these rows to form $\tilde{Y}$, which correspondingly means that $10,000 \times \rho_f$ images have noisy relevant information in $\tilde{Y}$. Finally, we form the column feature $Y \in \mathbb{R}^{10000\times 50}$ which spans $\tilde{Y}$. Thus, the quality of Y depends on the parameter $\rho_f \in [0,1]$ and smaller ρ_f results in better label-relevant features.

We consider four approaches for denoising in the following experiment. The first two baseline methods are PCP and PCPF with only Eigendigit features X. Both methods are the ones we considered in the previous experiment which do not take label-relevant features into account. Moreover, we consider using PCPF and PCPNF to incorporate *both* the Eigendigit features X and the label-relevant features Y for denoising, and we name them as "PCPF-w/Y" and "PCPNF-w/Y" to emphasize that they embed the label-relevant features Y. We apply each method to denoise noisy images under different ρ_f and ρ_s and examine the quality of denoised images by testing the accuracies they achieve in pre-trained SVMs.

The results are shown in Figure 5. In each figure, we fix the sparsity of noise ρ_s and try to recover the clean images using each method with different quality of Y. We can see that the perfect label-relevant features are extremely useful, as when $\rho_f = 0$, recovered images

from both PCPF-w/Y and PCPNF-w/Y achieve even much higher accuracies compared to the clean images (reported in Table 4). However, once ρ_f increases, PCPF-w/Y quickly fails as its accuracy drops drastically (accuracies become much lower than 70 for $\rho_f > 0.5$ and thus are not shown in figures). On the other hand, we see that PCPNF-w/Y performs much better than PCPF-w/Y on exploiting noisy label-relevant features, as it still achieves better accuracies compared to both PCPF and PCP when $\rho_f > 0$. The results again demonstrate the effectiveness of our proposed model on exploiting noisy side information.

5. Related Work

Learning a low-rank matrix from imperfect observations is an expansive domain in machine learning including many fundamental problems, such as Principal Component Analysis (PCA) (Hotelling, 1933), matrix completion (Candès and Tao, 2009), low-rank matrix sensing (Zhong et al., 2015) and robust PCA (Wright et al., 2009). While each of the above topics is an independent research area burgeoning in recent years, our main focus is to study the usefulness of side information in low-rank matrix learning where the observations are partial and/or corrupted in both theoretical and practical aspects.

Learning a low-rank matrix from partial observations is well-known as matrix completion problem, which has been successfully applied to many machine learning tasks including recommender systems (Koren et al., 2009), social network analysis (Hsieh et al., 2012; Chiang et al., 2014) and clustering (Chen et al., 2014). Several theoretical foundations have also been established. One of the most striking results is the exact recovery guarantee provided by Candès and Tao (2009) and Candès and Recht (2012) where the authors showed that $O(n \operatorname{polylog} n)$ observations are sufficient for exact recovery with high probability, provided that entries are uniformly sampled at random. Several works also study recovery under non-uniform distributional assumptions (Negahban and Wainwright, 2012), distribution-free settings (Shamir and Shalev-Shwartz, 2014) and noisy observations (Keshavan et al., 2010; Candès and Plan, 2010).

A few research papers also consider side information in the matrix completion setting (Menon and Elkan, 2011; Chen et al., 2012; Natarajan and Dhillon, 2014; Shin et al., 2015). Although most of them found that features are helpful in certain applications (Menon and Elkan, 2011; Shin et al., 2015) and in the cold-start setting (Natarajan and Dhillon, 2014), they mainly focus on the non-convex matrix factorization formulation without any theoretical analysis on the effect of side information. More recently, Jain et al. (2013) studied Inductive Matrix Completion (IMC) objective to incorporate side information, and several follow-up works also consider IMC with trace norm regularization (Xu et al., 2013; Zhong et al., 2015). All of them showed that recovery can be achieved by IMC with much lower sample complexity provided perfect features. However, as we have discussed in the paper, given imperfect features, IMC cannot recover the underlying matrix and may even suffer from poor performance in practice. This observation leads us to further develop an improved model which better exploits noisy side information in learning (see Section 2.3).

Robust PCA is another prominent instance of low-rank matrix learning from imperfect observations, where the goal is to recover a low-rank matrix from a full matrix in which a few of entries are arbitrarily corrupted by sparse noise. This sparse structure of noise is common in many applications such as image processing and bioinformatics (Wright et al.,

2009). Researchers have also investigated several approaches to robust PCA with theoretical guarantees (Chandrasekaran et al., 2011; Candès et al., 2011). Perhaps the most remarkable milestone is the strong guarantee provided by Candès et al. (2011), in which the authors showed that under mild conditions, low-rank and sparse structure are exactly distinguishable. Several extensions of robust PCA have also been considered, such as robust PCA with column-sparse errors (Xu et al., 2010), with missing data (Candès et al., 2011; Chen et al., 2013) and with compressed data (Ha and Barber, 2015).

However, unlike matrix completion, there is little research that directly exploits side information in the robust PCA problem, leaving the advantage of side information in robust PCA unexplored. Though it may appear that one can extend the analysis of side information in matrix completion to robust PCA as both problems share certain similarities, the robust PCA problem is still essentially different—in fact harder—from matrix completion in many aspects. In particular, matrix completion has been mostly used for *missing value estimation*, where the emphasis is to accurately recover the missing entries given trustable, partial observations, while robust PCA is a *matrix separation problem* where one has to identify the corrupted entries given full yet untrustable observations. This difference naturally precludes a direct extension from the analyses of matrix completion to robust PCA. Nevertheless, Chiang et al. (2016) has recently shown that given perfect features, exact recovery of higher-rank matrices becomes attainable in the robust PCA problem, indicating that side information in robust PCA can be exploited. In this paper, we extend Chiang et al. (2016) and develop a more general model which can further exploit noisy side information to help solve the robust PCA problem.

Another model that shares certain similarities to robust PCA with side information is Low-Rank Representation (LRR), which emerged from the subspace clustering problem (Liu et al., 2010, 2013). Given that the observed data matrix is corrupted by sparse errors, LRR model assumes that the underlying low-rank matrix can be represented by a linear combination of a provided dictionary. Interestingly, LRR can be thought of as a special case of the proposed PCPF model (see Section 2.3) where the given dictionary serves as the row features X. Our problem setting is also more general than LRR as we consider incorporating both row and column features to help recovery.

6. Conclusions

In this paper, we study the effectiveness of side information for low-rank matrix learning from missing and corrupted observations. We propose a general model (problem (4)) which incorporates both perfect and noisy side information by balancing information from features and observations simultaneously, from which we can derive several instances of the model, including IMCNF and PCPNF, that better solve matrix completion and robust PCA by leveraging side information. In addition, we provide a formal analysis to justify the effectiveness of side information in the proposed model, in which we quantify the quality of features and show that the sample complexity of learning can be asymptotically improved given sufficiently informative features, provided a small enough noise level. This analysis therefore quantifies the merits of side information in our model for low-rank matrix learning in theory. Finally, we verify our model in several synthetic experiments as well as in real-world machine learning applications including relationship prediction, semi-supervised

clustering and noisy image classification. By viewing each application as a low-rank matrix learning problem from missing or corrupted observations given certain additional features, we show that employing our model results in competitive algorithms whose performance is comparable to or better than other state-of-the-art approaches. All of our results consistently demonstrate that the proposed model learns the low-rank matrix from missing and corrupted observations more effectively by properly exploiting side information.

Appendix A. Proofs

Preliminary Lemmas

We first introduce two lemmas required in the proof of Lemma 3. These two lemmas provide bounds on the Rademacher complexity of the function class with bounded trace norm and $\ell 1$ norm respectively.

Lemma 9 *Let* $S_w = \{W \in \mathbb{R}^{n\times n} \mid \|W\|_* \leq \mathcal{W}\}$ *and* $\mathcal{A} = \max_i \|A_i\|_2$, *where each* $A_i \in \mathbb{R}^{n\times n}$, *then:*

$$\mathbb{E}_\sigma\big[\sup_{W\in S_w} \frac{1}{m}\sum_{i=1}^{m} \sigma_i \text{trace}(WA_i)\big] \leq 2\mathcal{A}\mathcal{W}\sqrt{\frac{\log 2n}{m}}.$$

Proof This Lemma is directly from the Lemma 3 in Hsieh et al. (2015). ■

Lemma 10 *Let* $S_w = \{W \in \mathbb{R}^{n_1\times n_2} \mid \|W\|_1 \leq \mathcal{W}\}$, *and each* E_i *is in the form of* $E_i = \mathbf{e}_x\mathbf{e}_y^T$, *where* $\mathbf{e}_x \in \mathbb{R}^{n_2}$, $\mathbf{e}_y \in \mathbb{R}^{n_1}$ *are two unit vectors. Then:*

$$\mathbb{E}_\sigma\big[\sup_{W\in S_w} \frac{1}{m}\sum_{i=1}^{m} \sigma_i \text{trace}(WE_i)\big] \leq \mathcal{W}\sqrt{\frac{2\log(2n_1n_2)}{m}}.$$

Proof This Lemma is a special case of Theorem 1 in Kakade et al. (2008) with the fact that $\|E_i\|_\infty := \max_{a,b} |(E_i)_{ab}| = 1$. ■

Proof of Lemma 3

Proof First, we can use a standard Rademacher contraction principle (e.g. Lemma 5 in Meir and Zhang, 2003) to bound $\mathfrak{R}(F_\Theta)$ to be:

$$\begin{aligned}\mathfrak{R}(F_\Theta) \leq & L_\ell \mathbb{E}_\sigma\big[\sup_{\theta\in\Theta}\frac{1}{m}\sum_{\sigma=1}^{m}\sigma_\alpha(XMY^T+N+S)_{i_\alpha j_\alpha}\big]\\ =& L_\ell\mathbb{E}_\sigma\big[\sup_{\|M\|_*\leq\mathcal{M}}\frac{1}{m}\sum_{\alpha=1}^{m}\sigma_\alpha \mathrm{trace}(M\mathbf{y}_{j_\alpha}\mathbf{x}_{i_\alpha}^T)\big]+L_\ell\mathbb{E}_\sigma\big[\sup_{\|N\|_*\leq\mathcal{N}}\frac{1}{m}\sum_{\alpha=1}^{m}\sigma_\alpha\mathrm{trace}(N\mathbf{e}_{j_\alpha}\mathbf{e}_{i_\alpha}^T)\big]\\ &+L_\ell\mathbb{E}_\sigma\big[\sup_{\|S\|_1\leq\mathcal{S}}\frac{1}{m}\sum_{\alpha=1}^{m}\sigma_\alpha\mathrm{trace}(S\mathbf{e}_{j_\alpha}\mathbf{e}_{i_\alpha}^T)\big]\\ \leq & 2L_\ell\mathcal{M}\max_{i,j}\|\mathbf{y}_j\mathbf{x}_i^T\|_2\sqrt{\frac{\log 2d}{m}}+2L_\ell\mathcal{N}\sqrt{\frac{\log 2n}{m}}+L_\ell\mathcal{S}\sqrt{\frac{2\log(2n_1n_2)}{m}}\end{aligned}$$

where the last inequality is derived by applying Lemma 9 and Lemma 10. Moreover, since $\max_{i,j}\|\mathbf{y}_j\mathbf{x}_i^T\|_2=\max_j\|\mathbf{y}_j\|_2\max_i\|\mathbf{x}_i\|_2$, we can thus upper bound $\mathfrak{R}(F_\Theta)$ by:

$$\mathfrak{R}(F_\Theta)\leq 2L_\ell\mathcal{M}\mathcal{X}\mathcal{Y}\sqrt{\frac{\log 2d}{m}}+2L_\ell\mathcal{N}\sqrt{\frac{\log 2n}{m}}+L_\ell\mathcal{S}\sqrt{\frac{2\log(2n_1n_2)}{m}}. \tag{12}$$

However, in some circumstances, the above bound (12) is too loose for sample complexity analysis. To deal with these cases, we follow Shamir and Shalev-Shwartz (2014) to derive a tighter bound on the trace norm of residual (i.e. $\mathcal{N}$). To begin with, we rewrite $\mathfrak{R}(F_\Theta)$ as:

$$\mathfrak{R}(F_\Theta)=\mathbb{E}_\sigma\big[\sup_{f\in F_\Theta}\frac{1}{m}\sum_{\alpha=1}^{m}\sigma_\alpha\ell(f(i_\alpha,j_\alpha),R_{i_\alpha,j_\alpha}))\big]=\mathbb{E}_\sigma\big[\sup_{f\in F_\Theta}\frac{1}{m}\sum_{(i,j)}\Gamma_{ij}\ell(f(i,j),R_{ij})\big],$$

where $\Gamma\in\mathbb{R}^{n_1\times n_2}$, $\Gamma_{ij}=\sum_{\alpha:i_\alpha=i,j_\alpha=j}\sigma_\alpha$. Now, using the same trick in Shamir and Shalev-Shwartz (2014), we can divide Γ based on the "hit-time" of each $(i,j)\in\Omega_{obs}$, with some threshold $p>0$ whose value will be set later. Formally, let $h_{ij}=|\{\alpha:i_\alpha=i,j_\alpha=j\}|$, and let $A,B\in\mathbb{R}^{n_1\times n_2}$ be defined by:

$$A_{ij}=\begin{cases}\Gamma_{ij}, & \text{if } h_{ij}>p,\\ 0, & \text{otherwise.}\end{cases}\qquad B_{ij}=\begin{cases}0, & \text{if } h_{ij}>p,\\ \Gamma_{ij}, & \text{otherwise.}\end{cases}$$

By construction, $\Gamma=A+B$. Therefore, we can separate $\mathfrak{R}(F_\Theta)$ to be:

$$\mathfrak{R}(F_\Theta)=\mathbb{E}_\sigma\big[\sup_{f\in F_\Theta}\frac{1}{m}\sum_{(i,j)}A_{ij}\ell(f(i,j),R_{ij})\big]+\mathbb{E}_\sigma\big[\sup_{f\in F_\Theta}\frac{1}{m}\sum_{(i,j)}B_{ij}\ell(f(i,j),R_{ij})\big]. \tag{13}$$

For the first term in (13), since $|\ell(f(i,j),R_{ij})|\leq\mathcal{B}$, it can be upper bounded by:

$$\mathbb{E}_\sigma\big[\sup_{f\in F_\Theta}\frac{1}{m}\sum_{(i,j)}A_{ij}\ell(f(i,j),R_{ij})\big]\leq\frac{\mathcal{B}}{m}\mathbb{E}_\sigma\big[\sum_{(i,j)}|A_{ij}|\big]\leq\frac{\mathcal{B}}{\sqrt{p}}$$

where the last inequality is derived by applying Lemma 10 in Shamir and Shalev-Shwartz (2014). Now consider the second term of (13). Again, by Rademacher contraction principle, it can be upper bounded by:

$$\begin{aligned}&\frac{L_\ell}{m}\mathbb{E}_\sigma\big[\sup_{f\in F_\Theta}\sum_{(i,j)}B_{ij}f(i,j)\big]\\ =&\frac{L_\ell}{m}\mathbb{E}_\sigma\big[\sup_{\|M\|_*\leq\mathcal{M}}\sum_{(i,j)}B_{ij}\mathbf{x}_i^TM\mathbf{y}_j\big]+\frac{L_\ell}{m}\mathbb{E}_\sigma\big[\sup_{\|N\|_*\leq\mathcal{N}}\sum_{(i,j)}B_{ij}N_{ij}\big]+\frac{L_\ell}{m}\mathbb{E}_\sigma\big[\sup_{\|S\|_1\leq\mathcal{S}}\sum_{(i,j)}B_{ij}S_{ij}\big].\end{aligned} \tag{14}$$

We can again upper bound the first and third term of (14) using Lemma 9 and Lemma 10. Precisely, the first term can be upper bounded by:

$$\frac{L_\ell}{m}\mathbb{E}_\sigma\big[\sup_{\|M\|_*\leq\mathcal{M}}\sum_{\alpha=1}^{m}\sigma_\alpha\mathbf{x}_{i_\alpha}^TM\mathbf{y}_{j_\alpha}\big]=L_\ell\mathbb{E}_\sigma\big[\sup_{\|M\|_*\leq\mathcal{M}}\frac{1}{m}\sum_{\alpha=1}^{m}\sigma_\alpha\mathrm{trace}(M\mathbf{y}_{j_\alpha}\mathbf{x}_{i_\alpha}^T)\big]\leq 2L_\ell\mathcal{M}\mathcal{X}\mathcal{Y}\sqrt{\frac{\log 2d}{m}},$$

and the third term of (14) is upper bounded by:

$$L_\ell\mathbb{E}_\sigma\big[\sup_{\|S\|_1\leq\mathcal{S}}\frac{1}{m}\sum_{\alpha=1}^{m}\sigma_\alpha\mathrm{trace}(S\mathbf{e}_{j_\alpha}\mathbf{e}_{i_\alpha}^T)\big]\leq L_\ell\mathcal{S}\sqrt{\frac{2\log(2n_1n_2)}{m}}.$$

In addition, by applying Hölder's inequality, the second term of (14) is upper bounded by:

$$\frac{L_\ell}{m}\mathbb{E}_\sigma\big[\sup_{\|N\|_*\leq\mathcal{N}}\sum_{(i,j)}B_{ij}N_{ij}\big]\leq\frac{L_\ell}{m}\sup_{N:\|N\|_*\leq\mathcal{N}}\|B\|_2\|N\|_*=\frac{L_\ell\mathcal{N}}{m}\mathbb{E}_\sigma\big[\|B\|_2\big]\leq\frac{2.2CL_\ell\mathcal{N}\sqrt{p}(\sqrt{n_1}+\sqrt{n_2})}{m},$$

where the last inequality is derived by applying Lemma 11 in Shamir and Shalev-Shwartz (2014). Therefore, putting all of the above upper bounds to (13) and choosing p to be $m\mathcal{B}/(2.2CL_\ell\mathcal{N}(\sqrt{n_1}+\sqrt{n_2}))$, we obtain another upper bound on $\mathfrak{R}(F_\Theta)$ as:

$$\mathfrak{R}(F_\Theta)\leq 2L_\ell\mathcal{M}\mathcal{X}\mathcal{Y}\sqrt{\frac{\log 2d}{m}}+\sqrt{\frac{9CL_\ell\mathcal{B}\mathcal{N}(\sqrt{n_1}+\sqrt{n_2})}{m}}+L_\ell\mathcal{S}\sqrt{\frac{2\log(2n_1n_2)}{m}}. \tag{15}$$

Lemma 3 thus follows by combining (12) and (15). ■

Proof of Lemma 4

Proof To begin with, we have:

$$\|X_\mu^TL_0Y_\nu\|_2\leq\|X_\mu\|_2\|L_0\|_2\|Y_\nu\|_2\leq\sigma_x\sigma_y\|L_0\|_*,$$

where σ_x (or σ_y) is the largest singular value of X_μ (or Y_ν). Therefore, by the definition of $\hat{M}$, we have:

$$\|\hat{M}\|_*\leq d\|\hat{M}\|_2=d\|(X_\mu^TX_\mu)^\dagger X_\mu^TL_0Y_\nu(Y_\nu^TY_\nu)^\dagger\|_2\leq\frac{\sigma_x\sigma_yd\|L_0\|_*}{\sigma_{xm}^2\sigma_{ym}^2}, \tag{16}$$

where σ_{xm} (or σ_{ym}) is the smallest non-zero singular value of X_μ (or Y_ν). Furthermore, by the construction of X_μ and Y_ν, we have $\sigma_{xm} \geq \mu\sigma_x$ and $\sigma_{ym} \geq \nu\sigma_y$. We can further lower bound σ_x (and σ_y) by:

$$\sigma_x^2 = \|X_\mu\|_2^2 = \|X\|_2^2 \geq \frac{\|X\|_F^2}{d} \geq \frac{n \min \|\mathbf{x}_i\|^2}{d} \geq \frac{n\gamma^2\mathcal{X}^2}{d}.$$

Therefore, from (16), we can further bound $\|\hat{M}\|_*$ by:

$$\|\hat{M}\|_* \leq \frac{d\|L_0\|_*}{\mu^2\nu^2\sigma_x\sigma_y} \leq \frac{d^2\|L_0\|_*}{\mu^2\nu^2\gamma^2\mathcal{X}\mathcal{Y}\sqrt{n_1 n_2}}.$$

The lemma is thus concluded by the fact that $\|L_0\|_* \leq C_L\sqrt{n_1 n_2}$. ■

Proof of Theorem 5

Proof The claim is directly proved by plugging Lemma 3 - 4 to Lemma 2, in which $\hat{R}_\ell(f^*) = 0$ because $(\hat{M}, L_0 - X\hat{M}Y^T, S_0) \in \Theta$ and such an instance makes $\hat{R}_\ell = 0$. ■

Proof of Theorem 6

Proof Note that since $S_0 = S^* = 0$ in matrix completion case, we have:

$$R_\ell(f^*) = \mathbb{E}_{(i,j)\sim\mathcal{D}}\big[\ell(XM^*Y_{ij}^T, \mathbf{e}_i^T L_0 \mathbf{e}_j)\big].$$

The claim therefore directly follows from Theorem 5 by setting $R_\ell(f^*) < \epsilon$. ■

Proof of Theorem 7

Proof By the construction of X and Y, we can rewrite them as follows:

$$X = \sum_{i=1}^{t-1} \mathbf{u}_i\mathbf{e}_i^T + \sum_{i=t}^{d} \tilde{\mathbf{u}}_i\mathbf{e}_i^T, \qquad Y = \sum_{i=1}^{t-1} \mathbf{v}_i\mathbf{e}_i^T + \sum_{i=t}^{d} \tilde{\mathbf{v}}_i\mathbf{e}_i^T, \tag{17}$$

where for each $\tilde{\mathbf{u}}_i$, $\tilde{\mathbf{u}}_i^T\mathbf{u}_j = 0, \forall j$. Therefore, we can upper bound $\mathcal{N}$ by:

$$\begin{aligned}\|L_0 - X\hat{M}Y^T\|_* &= \|\tilde{U}\tilde{U}^T L_0 + L_0\tilde{V}\tilde{V}^T - \tilde{U}\tilde{U}^T L_0\tilde{V}\tilde{V}^T\|_* \\ &\leq 2\|\tilde{U}\tilde{U}^T U\Sigma V^T\|_* + \|U\Sigma V^T\tilde{V}\tilde{V}^T\|_* \\ &\leq 3\sum_{i=t}^{k}\sigma_i,\end{aligned}$$

where $\tilde{U}$, $\tilde{V}$ are the second term of X and Y in (17). Moreover, we have $\sigma_i = o(\sqrt{n})$ for all $i \geq t$. To see this, suppose $\sigma_p = \Omega(\sqrt{n})$ for any $t \leq p \leq k$, then:

$$\lim_{n\to\infty}\frac{\sigma_t}{\sqrt{n}} \geq \lim_{n\to\infty}\frac{\sigma_p}{\sqrt{n}} > 0,$$

leading a contradiction to the definition of σ_t. Therefore we can conclude:

$$\mathcal{N} = \|L_0 - X\hat{M}Y^T\|_* \leq 3\sum_{i=t}^{k}\sigma_i \leq 3k \times o(\sqrt{n}) = o(\sqrt{n}),$$

and the Theorem is thus proved by plugging the above bound on $\mathcal{N}$ to Theorem 6. ■

Proof of Theorem 8

Proof The sample complexity claim directly follows from Theorem 5 by setting $R_\ell(f^*) < \epsilon$, and the claim of $\mathcal{P}_{\Omega_{obs}^\perp}(S^*) = 0$ is directly from the construction of Algorithm 1 as discussed in Section 2.4. ■

Abstract

Given matrices $X, Y \in \mathbb{R}^{n\times K}$ and $S \in \mathbb{R}^{K\times K}$ with positive elements, this paper proposes an algorithm `fastRG` to sample a sparse matrix A with low rank expectation $E(A) = XSY^T$ and independent Poisson elements. This allows for quickly sampling from a broad class of stochastic blockmodel graphs (degree-corrected, mixed membership, overlapping) all of which are specific parameterizations of the generalized random product graph model defined in Section 2.2. The basic idea of `fastRG` is to first sample the number of edges m and then sample each edge. The key insight is that because of the the low rank expectation, it is easy to sample individual edges. The naive "element-wise" algorithm requires $O(n^2)$ operations to generate the $n \times n$ adjacency matrix A. In sparse graphs, where $m = O(n)$, ignoring log terms, `fastRG` runs in time $O(n)$. An implementation in `R` is available on github. A computational experiment in Section 2.4 simulates graphs up to $n = 10,000,000$ nodes with $m = 100,000,000$ edges. For example, on a graph with $n = 500,000$ and $m = 5,000,000$, `fastRG` runs in less than one second on a 3.5 GHz Intel i5.

Keywords: Random Dot Product Graph, Edge exchangeable, Simulation

1. Introduction

The random dot product graph (RDPG) model serves as a test bed for various types of clustering and statistical inference algorithms. This model generalizes the Stochastic Blockmodel (SBM), the Overlapping SBM, the Mixed Membership SBM, and the Degree-Corrected SBM (Holland et al., 1983; Latouche and Ambroise, 2011; Airoldi et al., 2008; Karrer and Newman, 2011). Under the RDPG, each node i has a (latent) node feature $x_i \in \mathbb{R}^K$ and the probability that node i and j share an edge is parameterized by $\langle x_i, x_j\rangle$ (Young and Scheinerman, 2007).

While many network analysis algorithms only require $O(m)$ operations, where m is the number of edges in the graph, sampling RDPGs with the naive "element-wise" algorithm takes $O(n^2)$ operations, where n is the number of nodes. In particular, sparse eigensolvers compute the leading k eigenvectors of such graphs in $O(km)$ operations (e.g. in ARPACK Lehoucq et al. 1995). As such, sampling an RDPG is a computational bottleneck in simulations to examine many network analysis algorithms.

The organization of this paper is as follows. Section 2 gives `fastRG`. Section 2.1 relates `fastRG` to xlr, a new class of edge-exchangeable random graphs with low-rank expectation. Section 2.2 presents a generalization of the random dot product graph. Theorem 4 shows that `fastRG` samples Poisson-edge graphs from this model. Then, Theorem 7 in Section 2.3 shows how `fastRG` can be used to approximate a certain class of Bernoulli-edge graphs. Section 2.4 describes our implementation of `fastRG` (available at `https://github.com/karlrohe/fastRG`) and assesses the empirical run time of the algorithm.

1.1. Notation

Let $G = (V, E)$ be a graph with the node set $V = \{1, \ldots, n\}$ and the edge set E contains edge (i, j) if node i is connected to node j. In a directed graph, each edge is an ordered pair of nodes while in an undirected graph, each edge is an unordered pair of nodes. A multi-edge graph allows for repeated edges. In any graph, a self-loop is an edge that connects a node to itself. Let the adjacency matrix $A \in \mathbb{R}^{n\times n}$ contain the number of edges from i to j in element A_{ij}. For column vectors $x \in \mathbb{R}^a$, $z \in \mathbb{R}^b$ and $S \in \mathbb{R}^{a\times b}$, define $\langle x, z\rangle_S = x^T S z$; this function is not necessarily a proper inner product because it does not require that S is non-negative definite. We use standard big-O and little-o notations, i.e. for sequence x_n, y_n; $x_n = o(y_n)$ when y_n is nonzero implies $\lim_{n\to\infty} x_n/y_n = 0$; $x_n = O(y_n)$ implies there exists a positive real number M and an integer N such that $|x_n| \le M|y_n|$, $\forall n \ge N$.

2. `fastRG`

`fastRG` is motivated by the wide variety of low rank graph models that specify the expectation of the adjacency matrix as $E(A) = XSX^T$ for some matrix (or vector) X and some matrix (or value) S.

Types of low rank models	$X \in$	In each row...
SBM	$\{0,1\}^{n\times K}$	a single one
Degree-Corrected SBM	$\mathbb{R}^{n\times K}$	a single non-zero positive entry
Mixed Membership SBM	$\mathbb{R}^{n\times K}$	non-negative and sum to one
Overlapping SBM	$\{0,1\}^{n\times K}$	a mix of 1s and 0s
Erdős-Rényi	$\{1\}^n$	a single one
Chung-Lu	$\mathbb{R}^n$	a single value

Table 1: Restrictions on the matrix X create different types of well known low rank models. There are further differences between these models that are not emphasized by this table.

Given $X \in \mathbb{R}^{n\times K_x}$, $Y \in \mathbb{R}^{d\times K_y}$ and $S \in \mathbb{R}^{K_x\times K_y}$, `fastRG` samples a random graph. Define A as the $n \times d$ matrix where A_{ij} counts the number of times edge (I,J) was sampled by `fastRG`. In expectation A is XSY^T. Importantly, `fastRG` requires that the elements of X,Y, and S are non-negative. This condition holds for all of the low rank models in the above table. Each of those models set $Y = X$ and enforce different restrictions on the matrix X.

As stated below, `fastRG` samples a (i) directed graph with (ii) multiple edges and (iii) self-loops. After sampling, these properties can be modified to create a simple graph (undirected, no repeated edges, and no self-loops); see Remarks 5 and 6 in Section 2.2 and Theorem 7 in Section 2.3.

Algorithm 1 `fastRG`(X,S,Y)

Require: $X \in \mathbb{R}^{n\times K_x}$, $S \in \mathbb{R}^{K_x\times K_y}$, and $Y \in \mathbb{R}^{d\times K_y}$ with all matrices containing non-negative entries.
  Compute diagonal matrix $C_X \in \mathbb{R}^{K_x\times K_x}$ with $C_X = diag(\sum_i X_{i1}\ ,\ \ldots\ ,\ \sum_i X_{iK_x})$.
  Compute diagonal matrix $C_Y \in \mathbb{R}^{K_y\times K_y}$ with $C_Y = diag(\sum_i Y_{i1}\ ,\ \ldots\ ,\ \sum_i Y_{iK_y})$.
  Define $\tilde{X} = XC_X^{-1}$, $\tilde{S} = C_X S C_Y$, and $\tilde{Y} = YC_Y^{-1}$.
  Sample the number of edges $m \sim Poisson(\sum_{u,v}\tilde{S}_{uv})$.
  for $\ell = 1 : m$ **do**
    Sample $U \in \{1,\ \ldots,\ K_x\}, V \in \{1,\ \ldots,\ K_y\}$ with $\mathbb{P}(U = u, V = v) \propto \tilde{S}_{uv}$.
    Sample $I \in \{1,\ \ldots,\ n\}$ with $\mathbb{P}(I = i) = \tilde{X}_{iU}$.
    Sample $J \in \{1,\ \ldots,\ d\}$ with $\mathbb{P}(J = j) = \tilde{Y}_{jV}$.
    Add edge (I,J) to the graph, allowing for multiple edges (I,J).
  end for

An implementation in `R` is available at `https://github.com/karlrohe/fastRG`. As discussed in Section 2.4, in order to make the algorithm more efficient, the implementation is slightly different from the statement of the algorithm above.

There are two model classes that can help to interpret the graphs generated from `fastRG` and those model classes are explored in the next two subsections. Throughout all of the discussion, the key fact that is exploited by `fastRG` is given in the next Theorem.

Theorem 1 *Suppose that $X \in \mathbb{R}^{n\times K_x}$, $Y \in \mathbb{R}^{d\times K_y}$ and $S \in \mathbb{R}^{K_x\times K_y}$ all contain non-negative entries. Define $x_i \in \mathbb{R}^{K_x}$ as the ith row of X. Define $y_j \in \mathbb{R}^{K_y}$ as the jth row of Y. Let (I,J) be a single edge sampled inside the for loop in `fastRG`(X,S,Y), then*

$$\mathbb{P}((I,J) = (i,j)) \propto \langle x_i, y_j\rangle_S.$$

Proof

$$\begin{aligned}\mathbb{P}\big((I,J) = (i,j)\big) &= \sum_{u,v}\mathbb{P}((I,J) = (i,j)|(U,V) = (u,v))\,\mathbb{P}((U,V) = (u,v)))\\ &= \frac{\sum_{u,v}\tilde{X}_{iu}\tilde{Y}_{jv}\tilde{S}_{uv}}{\sum_{u,v}\tilde{S}_{u,v}} = \frac{\sum_{u,v}X_{iu}Y_{jv}S_{uv}}{\sum_{u,v}\tilde{S}_{u,v}} = \frac{x_i^T S y_j}{\sum_{a,b}x_a^T S y_b}\end{aligned}$$

■

2.1. `fastRG` samples from xlr: a class of edge-exchangeable random graphs

There has been recent interest in edge exchangeable graph models with blockmodel structure (e.g. Crane and Dempsey 2016; Cai et al. 2016; Herlau et al. 2016; Todeschini and Caron 2016). To characterize a broad class of such models, we propose xlr. For notational simplicity, the rest of the paper will suppose that $Y = X \in \mathbb{R}^{n\times K}$ and `fastRG`(X,S) = `fastRG`(X,S,X).

Definition 2 *[xlr] An xlr graph on n nodes and K dimensions is generated as follows,*

1. *Sample $(X,S) \in \mathbb{R}^{n\times K}\times\mathbb{R}^{K\times K}$ from some distribution and define x_i as the ith row of X.*
2. *Initialize the graph to be empty.*
3. *Add independent edges $e_1, e_2, \ldots$ to the graph, where*

$$\mathbb{P}(e_\ell = (i,j)) = \frac{\langle x_i, x_j\rangle_S}{\sum_{a,b}\langle x_a, x_b\rangle_S}.$$

From Theorem 1, `fastRG` samples the edges in xlr.

An xlr graph is both (i) edge-exchangeable as defined by Crane and Dempsey (2016) and (ii) conditional on X and S, its expected adjacency matrix is low rank. By sampling X to satisfy one set of restrictions specified in Table 1, xlr provides a way to sample edge exchangeable blockmodels. xlr stands for *edge-exchangeable and low rank* because it characterizes all edge-exchangeable and low rank random graph models on a finite number of nodes. In particular, by Theorem 4.2 in Crane and Dempsey (2016) if a random undirected graph with an infinite number of edges is edge exchangeable, then the edges are drawn iid from some randomly chosen distribution on edges f. Moreover, let B be the adjacency matrix of a single edge drawn from f. Under the assumption that $E(B|f)$ is rank K, there exist matrices $X \in \mathbb{R}^{n\times K}$ and $S \in \mathbb{R}^{K\times K}$ that are a function of f and give the eigendecomposition $E(B|f) = XSX^T$. This implies that $\mathbb{P}(e_1 = (i,j)|f) \propto \langle x_i, x_j\rangle_S$, where x_i is the ith row of X.

2.2. `fastRG` samples from a generalization of the RDPG

Under the RDPG as described in Young and Scheinerman (2007), the expectation of the adjacency matrix is XX^T for some matrix $X \in \mathbb{R}^{n\times K}$. This implies that the expected adjacency matrix is always non-negative definite (i.e. its eigenvalues are non-negative). However, some parameterizations of the SBM (and other blockmodels) lead to an expected adjacency matrix with negative eigenvalues (i.e. it is not non-negative definite); for example, if the off-diagonal elements of S are larger than the diagonal elements, then XSX^T could have negative eigenvalues. Moreover, even if the elements of X and S are positive, as is the case for the low rank models in Table 1 and as is required for `fastRG`, it is still possible for XSX^T to have negative eigenvalues. By modifying the RDPG to incorporate a matrix S, the model class below incorporates all types of blockmodels.

Definition 3 *[Generalized Random Product Graph (gRPG) model] For n nodes in K dimensions, the gRPG is parameterized by $X \in \mathbb{R}^{n\times K}$ and $S \in \mathbb{R}^{K\times K}$, where each node i is assigned the ith row of X, $x_i = (X_{i1},\ \ldots,\ X_{iK})^T \in \mathbb{R}^K$. For $i,j \in V$, define*

$$\lambda_{ij} = \langle x_i, x_j\rangle_S = \sum_k^K\sum_l^K X_{ik}S_{kl}X_{jl}.$$

Under the gRPG, the adjacency matrix $A \in \mathbb{R}^{n\times n}$ contains independent elements and the distribution of A_{ij} (i.e. the number of edge from i to j) is fully parameterized by $f(\lambda_{ij})$, where f is some mean function.

Below, we will use the fact that the gRPG only requires that the λ_{ij}s specify the distribution of A_{ij}, allowing for A_{ij} to be non-binary (as in multi-graphs and weighted graphs) or to have edge probabilities which are a function of λ_{ij}.

Theorem 4 *For $X \in \mathbb{R}^{n\times K}$ and $S \in \mathbb{R}^{K\times K}$, each with non-negative elements, if $\tilde{A}$ is the adjacency matrix of a graph sampled with `fastRG`(X,S), then $\tilde{A}$ is a Poisson gRPG with $\tilde{A}_{ij} \sim Poisson(\langle x_i, x_j\rangle_S)$.*

The proof is contained in the appendix.

Remark 5 (Simulating an undirected graph) *As defined, both the gRPG model and `fastRG` generate directed graphs. An "undirected gRPG" should add a constraint to Definition 3 that $A_{ij} = A_{ji}$ for all i, j. To sample such a graph with `fastRG`, input $S/2$ instead of S, then after sampling a directed graph with `fastRG`, symmetrize each edge by removing its direction (this doubles the probability of an edge, hence the need to input $S/2$). Theorem 4 can be easily extended to show this is an undirected gRPG.*

Remark 6 (Simulating a graph without self-loops) *As defined, both the gRPG model and `fastRG` generate graphs with self-loops. A "gRPG without self-loops" should add a constraint to Definition 3 that $A_{ii} = 0$ for all i. A graph from `fastRG` can be converted to a gRPG without self-loops by simply (1) sampling $m \sim Poisson(\sum_{u,v}\tilde{S}_{uv} - \sum_i \langle x_i, x_i\rangle_S)$ and (2) resampling any edge that is a self-loop. The proof of Theorem 4 can be extended to show that this is equivalent.*

2.3. Approximate Bernoulli-edges

To create a simple graph with `fastRG` (i.e. no multiple edges, no self-loops, and undirected), first sample a graph with `fastRG`. Then, perform the modifications described in Remarks 5 and 6. Then, keep an edge between i and j if there is at least one edge in the multiple edge graph; define the threshold function, $t(A_{ij}) = \mathbb{1}(A_{ij} > 0)$, where $t(A)$ applies element-wise.

If $\tilde{A}$ is a Poisson gRPG, then $t(\tilde{A})$ is a Bernoulli gRPG with mean function $f(\lambda_{ij}) = 1 - exp(-\lambda_{ij})$. Let B be distributed as Bernoulli gRPG(X,S) with identity mean function,

$$B_{ij} \sim Bernoulli(\lambda_{ij}).$$

Theorem 7 shows that in the sparse setting, there is a coupling between $t(\tilde{A})$ and B such that $t(\tilde{A})$ is approximately equal to B. The theorem is asymptotic in n; a superscript of n is suppressed on $\tilde{A}, B$ and λ.

Theorem 7 *Let $\tilde{A}$ be a Poisson gRPG and let B be a Bernoulli gRPG using the same set of λ_{ij}s, with $\tilde{A}_{ij} \sim Poisson(\lambda_{ij})$ and $B_{ij} \sim Bernoulli(\lambda_{ij})$. Let $t(\cdot)$ be the thresholding function for $\tilde{A}$.*

Let α_n be a sequence. If $\lambda_{ij} = O(\alpha_n/n)$ for all i, j and there exists some constant $c > 0$ and $N > 0$ such that $\sum_{ij}\lambda_{ij} > c\alpha_n n$ for all $n > N$, then there exists a coupling between $t(\tilde{A})$ and B such that

$$\frac{E\|t(\tilde{A}) - B\|_F^2}{E\|B\|_F^2} = O(\alpha_n/n).$$

For example, in the sparse graph setting where $\lambda_{ij} = O(1/n)$ and $\sum_{ij}\lambda_{ij} = O(n)$, $\alpha_n = 1$. Under this setting and the coupling defined in the proof, all of the $O(n)$ edges in $t(\tilde{A})$ are contained in B and B has an extra $O(1)$ more edges than $t(\tilde{A})$.

The condition $\alpha_n = o(n)$ implies that all edge probabilities decay. If one is interested in models where some λ_{ij}'s are constant (e.g. certain models with heavy tailed degree distributions), then there are three possible paths forward.

1. Segment the pairs i, j into two sets (large and small λ_{ij}'s) and use two different sampling techniques on each set.

2. Use `fastRG` as a proposal distribution for rejection sampling (if for some $\varepsilon > 0$, $\lambda_{ij} < 1 - \varepsilon$ for all i, j, then rejection sampling would still be $O(m)$ operations).

3. Use `fastRG` and expect edge attenuation (no greater than 37%) for high probability edges.

Regarding the third point, consider the coupling in the proof of Theorem 7 without any condition on λ_{ij}. The coupling ensures that every edge in $t(\tilde{A})$ is also contained in B. Conversely, conditioned on edge i, j appearing in B, then the probability that this edge is included in $t(\tilde{A})$ is a greater than $1 - exp(-\lambda_{ij}) \geq 1 - exp(-1) > .63$.

2.4. Implementation of `fastRG`

Code at `https://github.com/karlrohe/fastRG` gives an implementation of `fastRG` in `R`. It also provides wrappers that simulate the SBM, Degree-Corrected SBM, Overlapping SBM, and Mixed Membership SBM. The code for these models first generates the appropriate X and then calls `fastRG`. In order to help control the edge density of the graph, `fastRG` and its wrappers can be given an additional argument avgDeg. If avgDeg is given, then the matrix S is scaled so that `fastRG` simulates a graph with expected average degree equal to avgDeg. Without this, parameterizations can easily produce very dense graphs.

To accelerate the running time of `fastRG`, the implementation is slightly different than the statement of the algorithm above. The difference can be thought of as sampling all of the (U,V) pairs before sampling any of the Is or Js. In particular, the implementation samples $\varpi \in R^{K\times K}$ as multinomial$(m, \tilde{S}/\sum_{u,v}\tilde{S}_{uv})$. Then, for each $u \in \{1,\dots K\}$, it samples $\sum_v \varpi_{u,v}$-many Is from the distribution $\tilde{X}_{u\cdot}$. Similarly, for each $v \in \{1,\dots K\}$, it samples $\sum_u \varpi_{u,v}$-many Js from the distribution $\tilde{X}_{v\cdot}$. Finally, the indexes are appropriately arranged so that there are $\varpi_{u,v}$-many edges (I,J) where $I \sim X_{u\cdot}$ and $J \sim X_{\cdot v}$. Recall that the statement of `fastRG` above allows for X and Y, where those matrices can have different numbers of rows and/or columns; the implementation also allows for this.

Under the SBM, it is possible to use `fastRG` to sample from the Bernoulli gRPG with the *identity* mean function instead of the mean function $1 - \exp(-\langle x_i, x_j\rangle_S)$ that is created by the thresholding function t from Section 2.3. The wrapper for the SBM does this by first transforming each element of S as $-\ln(1 - S_{ij})$ and then calling `fastRG`. The others models are not amenable to this trick; by default, they sample from the Poisson gRPG with identity mean function.

3. Experiments

3.1. Running time of `fastRG` on large and sparse graphs

To examine the running time of `fastRG`, we simulated a range of different values of n and $E(m)$, where $E(m)$ is the expected number of edges. In all simulations $X = Y$ and $K = 5$. The elements of X are independent $Poisson(1)$ random variables and the elements of S are independent $Uniform[0,1]$ random variables. To specify $E(m)$, the parameter avgDeg is set to $E(m)/n$. The values of n range from $10,000$ to $10,000,000$ and the values of $E(m)$ range from $100,000$ to $100,000,000$. The graph was taken to be directed, with self-loops and multiple edges. Moreover, the reported times are only to generate the edge list of the random graph; the edge list is not converted into a sparse adjacency matrix, which in some experiments would have more than doubled the running time. Each pair of n and $E(m)$ is simulated one time; deviations around the trend lines indicate the variability in run time.

In Figure 1, the vertical axes present the running time in `R` on a Retina 5K iMac, 27-inch, Late 2014 with 3.5 GHz Intel i5 and 8GB of 1600 MHz DDR3 memory. In the left panel of Figure 1, each line corresponds to a single value of n and $E(m)$ increases along the horizontal axis. In the right panel of Figure 1, each line corresponds to a single value of $E(m)$ and n increases along the horizontal axis. All axes are on the log_{10} scale. The solid black line has a slope of 1. Because the data aligns with this black line, this suggests that `fastRG` runs in linear time.

The computational bottleneck is sampling the Is and Js. The implementation uses Walker's Alias Method (Walker, 1977) (via `sample` in `R`). To take m samples from a distribution over n elements, Walker's Alias Method requires $O(m + \ln(n)n)$ operations (Vose, 1991). However, the log dependence is not clearly evident in the right plot of Figure 1; perhaps it would be visible for larger values of n.

3.2. Comparison to a previous technique

Previously, Hagberg and Lemons (2015) studied a fast technique to generate sparse random kernel graphs. Under the random kernel graph model, nodes i and j connect with probability $\kappa(i/n, j/n)$, where the function κ is non-negative, bounded, symmetric, measurable, and almost surely continuous. This model class includes the SBM and the Degree-Corrected SBM. It is difficult to see how a more general low rank model could be parameterized as a random kernel graph with an almost surely continuous κ. For example, we suspect that Mixed Membership SBMs could not be parameterized as such.

The algorithm proposed in Hagberg and Lemons (2015) is fast when it is fast to compute (i) the integral $F(y,a,b) = \int_a^b \kappa(x,y)dx$ and (ii) its roots, that is for any y,a,r, solve for $F(y,a,b) = r$. Their software, which we will refer to as *fast*-κ is in python and generates a NetworkX graph.

For a simple benchmark to compare the running times of `fastRG` and *fast*-κ, Figure 2 repeats the run time experiment that was performed in Hagberg and Lemons (2015). This simulation is for an Erdős-Rényi graph with expected degree 10, for n ranging between $5,000$ and $5M$. Speed comparisons are troubled by the fact that our code returns an edge list in `R` and *fast*-κ returns a NetworkX graph in python. Converting from an edge list to other data types takes longer than sampling the edge list with `fastRG`. For example, converting the edge list to a sparse matrix (a type that is convenient for spectral estimators) takes about as long as sampling the edge list with `fastRG`. Converting the edge list to an igraph takes about 10x longer than sampling the edge list

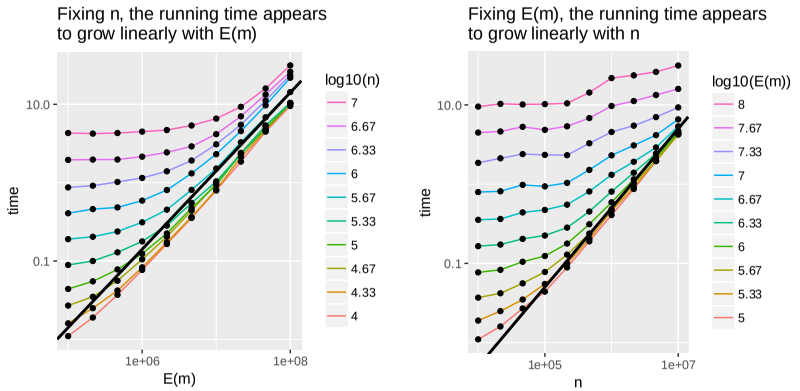

Figure 1: Both plots present the same experimental data. In the left plot, each line corresponds to a different value of n and they are presented as a function of $E(m)$. In the right plot, each line corresponds to a different value of $E(m)$ and they are presented as a function of n. On the right side of both plots, the lines start to align with the solid black line, suggesting a linear dependence on $E(m)$ and n.

with `fastRG`. There are three lines in Figure 2 for `fastRG`, one line for each data type (edge list, sparse adjacency matrix, and igraph). The speed comparison in Figure 2 corresponds to the average running time over 10 simulations performed on a 2015 MacBook Pro, 2.8 GHz Intel Core i7, with 16 GB 1600 MHz DDR3 running Python 3.5.2 and `R` 3.3.2. The slope of the blue line corresponds to the running time $O(n \log n)$. While none of these packages have been optimized for speed, they are all sufficiently fast for a wide range of purposes.

3.3. Simulating small and dense graphs with `fastRG`

This section investigates the graph density at which `fastRG` becomes slower than simulating each element A_{ij} as a Bernoulli random variable. In Figure 3, the reported time to compute this naive (element-wise) algorithm includes both (i) the time it takes to compute the probabilities `eA = X%*%B%*%t(X)` and (ii) sample the edges `z = rbinom(length(eA), 1, eA)`. The time for `fastRG` is for a directed graph, represented as a sparse matrix. The time to compute `fastRG` also includes the time it takes to construct X and B.

Figure 3 compares these two approaches on a set of Stochastic Blockmodels for values $K \in \{2,5,10\}$, $n \in \{500,1000,5000,10000\}$, and graph density $\rho = n^{-2}E(m)$ varying between .02 and .35. In all simulations, the S matrix is proportional to $I_K + J_K \in \mathbb{R}^{K \times K}$, where I_K is the identity matrix and J_K is the matrix of ones. The scale of S is adjusted to ensure the correct density ρ. For each model, both `fastRG` and the naive simulation are used to simulate two graphs. The line is a quadratic fit with ordinary least squares. In each panel, the vertical line is at $\rho = .25$, which is

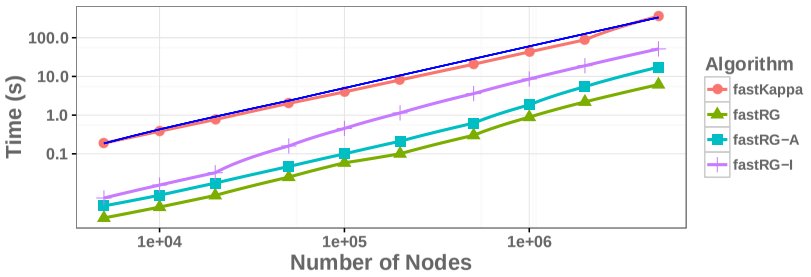

Figure 2: As the number of nodes increases (horizontal axis), all of the running times increase in parallel to the solid blue line which gives the rate $O(n \log n)$. The bottom three lines all correspond to `fastRG`, outputting three different graph types (edge list, sparse adjacency matrix, and igraph). For example, in roughly 8 seconds, *fast-*κ generates a graph with 20k nodes and `fastRG` generates an igraph with 1M nodes. To generate the random edge list on 1M nodes with `fastRG` takes less than 1 second

approximately the crossover point in all simulations. For scale, $\rho = .25$ corresponds to expected degrees 125, 250, 1250, and 2,500 respectively for n values 500, 1000, 5000, and 10000.

Appendix A. Proofs

For an integer d, define $1_d \in \mathbb{R}^d$ as a vector of ones. The proof of Theorem 4 requires the following lemma, which says that a vector (or matrix) of independent Poisson entries becomes multinomial when you condition on the sum of the vector (or matrix).

Lemma 8 *Let $A \in \mathbb{R}^{n \times n}$ be the random matrix whose i,jth element $A_{ij} \overset{i.d.}{\sim} Pois(\lambda_{ij})$ $i,j = 1, \ldots, n$. Then conditioned on $\sum_{i,j} A_{ij} = 1_n^T A 1_n = m$,*

$$(A_{11}, A_{12}, \ldots, A_{nn}) \sim Multinomial(m, \lambda / \sum_{ij} \lambda_{ij})$$

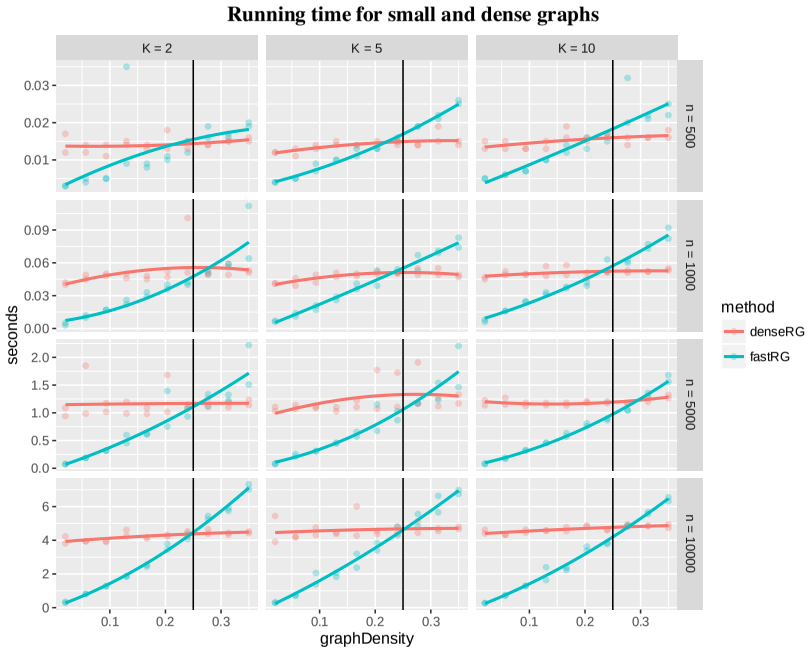

Figure 3: This figure compares the run time of `fastRG` to the run time of simulating each A_{ij} as a Bernoulli random variable (`denseRG` in the legend). Note that the number of edges grows quadratically with the edge density. So, as the density of the graph increases (horizontal axis), the running time of `fastRG` grows quadratically, whereas the running time of the naive algorithm does not depend on the density of the graph. In this simulation, the crossover is around $\rho = .25$ (black line). This figure shows that even for relatively small n and in the dense regime, `fastRG` has potential to be faster than the naive approach.

where $\lambda = (\lambda_{11}, \lambda_{12}, \ldots, \lambda_{nn})$. *That is, let* $a \in \mathbb{R}^{n\times n}$ *be a fixed matrix of integers with* $1_n^T a 1_n = m$, *then*

$$\begin{aligned}\mathbb{P}(A = a | 1_n^T A 1_n = m) &= \mathbb{P}(A_{11} = a_{11}, A_{12} = a_{12}, \ldots, A_{nn} = a_{nn} | 1_n^T A 1_n = m) \\ &= \frac{m!}{\prod_{i,j} a_{ij}!} \prod_{i,j} \left(\frac{\lambda_{ij}}{\lambda_{11} + \lambda_{12} + \cdots + \lambda_{nn}} \right)^{a_{ij}}.\end{aligned}$$

For completeness, a proof of this classical result is given at the end of the paper. The next proof is a proof of Theorem 4.

Proof Let A come from the Poisson gRPG with X and S and identity mean function. Let $\tilde{A}$ be a sample from `fastRG`. For any fixed adjacency matrix a, we will show that $\mathbb{P}(A = a) = \mathbb{P}(\tilde{A} = a)$.

Define $m = 1_n^T a 1_n$ and decompose the probabilities,

$$\mathbb{P}(A = a) = \mathbb{P}(1_n^T A 1_n = m)\mathbb{P}(A = a | 1_n^T A 1_n = m) \quad (1)$$
$$\mathbb{P}(\tilde{A} = a) = \mathbb{P}(1_n^T \tilde{A} 1_n = m)\mathbb{P}(\tilde{A} = a | 1_n^T \tilde{A} 1_n = m). \quad (2)$$

The proof will be divided into two parts. The first part shows that $\mathbb{P}(1_n^T A 1_n = m) = \mathbb{P}(1_n^T \tilde{A} 1_n = m)$ and the second part will show that $\mathbb{P}(A = a | 1_n^T A 1_n = m) = \mathbb{P}(\tilde{A} = a | 1_n^T \tilde{A} 1_n = m)$.

Part 1: The sum of independent Poisson variables is still Poisson,

$$\sum_{ij} A_{ij} \sim Poisson(\sum_{ij} \lambda_{ij}).$$

So, we must only show that $1_n^T A 1_n$ and $1_n^T \tilde{A} 1_n$ have the same Poisson parameter:

$$\sum_{ij} \lambda_{ij} = 1_n^T X S X 1_n = 1_n^T X C C^{-1} S C^{-1} C X 1_n = 1_n^T \tilde{X} \tilde{S} \tilde{X} 1_n = 1_n^T \tilde{X} \tilde{S} \tilde{X} 1_n = 1_K^T \tilde{S} 1_K = \sum_{u,v} \tilde{S}_{uv}.$$

Part 2: After conditioning on $1_n^T A 1_n = m$, Lemma 8 shows that A has the multinomial distribution. In `fastRG`, we first sample $1_n^T \tilde{A} 1_n$ and then add edges with the multinomial distribution. So, we must only show that the multinomial edge probabilities are equal for A and $\tilde{A}$. From Lemma 8, the multinomial edge probabilities for A are $\lambda_{ij} / \sum_{a,b} \lambda_{ab}$. To compute the multinomial edge probabilities for $\tilde{A}$, recall that (I, J) is a single edge added to the graph in `fastRG`. By Theorem 1,

$$\mathbb{P}(\tilde{A}_{ij} = 1 | 1_n^T \tilde{A} 1_n = 1) = \mathbb{P}\big((I, J) = (i, j)\big) = \frac{\langle x_i, x_j \rangle_S}{\sum_{a,b} \langle x_a, x_b \rangle_S} = \frac{\lambda_{ij}}{\sum_{a,b} \lambda_{ab}}$$

This concludes the proof. ■

Proof [Proof of Theorem 7] Let $U_{ij} \overset{i.i.d}{\sim} Uniform(0,1)$. Define $\mathscr{A}$ and $\mathscr{B}$:

$$\mathscr{A}_{ij} = \mathbf{1}(U_{ij} > 1 - e^{-\lambda_{ij}}),$$
$$\mathscr{B}_{ij} = \mathbf{1}(U_{ij} > \lambda_{ij}).$$

Note that $\mathscr{A}$ and $\mathscr{B}$ are equal in distribution to $t(\tilde{A})$ and B respectively. By Taylor expansion,

$$E\|\mathscr{A} - \mathscr{B}\|_F^2 = \sum_{i,j} (\lambda_{ij} - (1 - e^{-\lambda_{ij}})) = \sum_{i,j} \sum_{k=2}^{\infty} (-\lambda_{ij})^k / k! = \sum_{i,j} O(\lambda_{ij}^2) = \sum_{i,j} O((\alpha_n / n)^2) = O(\alpha_n^2).$$

Then, $E\|B\|_F^2 = \sum_{ij} \lambda_{ij} > c\alpha_n n$. So, defining $t(\tilde{A})$ and B with the above coupling yields the result. ■

Proof [proof of Lemma 1]

$$\begin{aligned}\mathbb{P}(A = a | 1_n^T A 1_n = m) = \frac{\mathbb{P}(A = a)}{\mathbb{P}(1_n^T A 1_n = m)} &= \frac{\prod_{i,j} \frac{\lambda_{ij}^{a_{ij}}}{a_{ij}!} e^{-\lambda_{ij}}}{\frac{(\lambda_{11} + \lambda_{12} + \cdots + \lambda_{nn})^m}{m!} e^{-(\lambda_{11} + \lambda_{12} + \cdots + \lambda_{nn})}} \\ &= \frac{m!}{\prod_{i,j} a_{ij}!} \prod_{i,j} \left(\frac{\lambda_{ij}}{\lambda_{11} + \lambda_{12} + \cdots + \lambda_{nn}} \right)^{a_{ij}}\end{aligned}$$

Abstract

In many applications involving large dataset or online learning, stochastic gradient descent (SGD) is a scalable algorithm to compute parameter estimates and has gained increasing popularity due to its numerical convenience and memory efficiency. While the asymptotic properties of SGD-based estimators have been well established, statistical inference such as interval estimation remains much unexplored. The classical bootstrap is not directly applicable if the data are not stored in memory. The plug-in method is not applicable when there is no explicit formula for the covariance matrix of the estimator. In this paper, we propose an online bootstrap procedure for the estimation of confidence intervals, which, upon the arrival of each observation, updates the SGD estimate as well as a number of randomly perturbed SGD estimates. The proposed method is easy to implement in practice. We establish its theoretical properties for a general class of models that includes linear regressions, generalized linear models, M-estimators and quantile regressions as special cases. The finite-sample performance and numerical utility is evaluated by simulation studies and real data applications.

Keywords: Bootstrap, Interval estimation, Generalized linear models, Large datasets, M-estimators, Quantile regression, Resampling methods, Stochastic gradient descent

1. Introduction

Big datasets arise frequently in clinical, epidemiological, financial and sociological studies. In such applications, many classical optimization methods for parameter estimation such as Fisher scoring, the EM algorithm or iterated reweighted least squares (Hastie et al. 2009, Nelder and Baker 1972) do not scale well and are computationally less attractive. Due to its computational and memory efficiency, stochastic gradient descent (Robbins and Monro 1951)[SGD] is a scalable algorithm for parameter estimation and has recently drawn a great deal of attention. Unlike other classical methods that evaluate the objective function involving the entire dataset, the SGD method calculates the gradient of the objective function using only one data point at a time and recursively updates the parameter estimate. This is also numerically appealing and particularly useful in online updating settings such as streaming data where it may not even be feasible to store the entire dataset in memory. Wang et al. (2016) gave a nice review on recent achievements of applying the SGD method to big data and streaming data.

The asymptotic properties of SGD estimators such as consistency and asymptotic normality have been well established; see, for example, Ruppert (1988) and Polyak and Juditsky (1992). However, statistical inference such as confidence interval estimation for SGD estimators has remained largely unexplored. Traditional interval estimation procedures such as the plug-in procedure and the bootstrap are often numerically difficult in the presence of big datasets. The bootstrap repeatedly draws samples from the entire dataset. The plug-in procedure requires an explicit variance-covariance formula. Since the classical bootstrap is not directly applicable if the data are not stored in memory, using the deal from the weighted bootstrap (Rubin 1981), we propose an online bootstrap procedure for the estimation of confidence intervals.

There are only a few papers considering the statistical inference of the SGD method. Chen et al. (2016) proposed a method called the batch-mean procedure. Although computationally efficient and theoretically sound, the batch-means procedure substantially underestimates the variance of the SGD estimator in finite-sample studies, because of the correlations between the batch means. Li et al. (2017) presented a new method for statistical inference in M-estimation problems, based on SGD estimators with a fixed step size. However, this method is limited to M-estimation and fixed step size. Su and Zhu (2018) proposed a new method called HiGrad, short for Hierarchical Incremental GRAdient Descent, which estimates model parameters in an online fashion and provides a confidence interval for the true population value. This method is also computationally efficient and theoretically sound, but it is not applicable to vanilla SGD estimators.

In this paper, we propose an online bootstrap resampling procedure to approximate the distribution of a SGD estimator in a general class of models that includes linear regressions, generalized linear models, M-estimators and quantile regressions as special cases. Our proposal, justified by asymptotic theories, provides a simple way to estimate the covariance matrix and confidence regions. Through numerical experiments, we verify the ability of this procedure to give accurate inference for big datasets.

The rest of the article is organized as follows. In Section 2, we introduce the proposed online bootstrap procedure for constructing confidence regions. In Section 3, we theoretically justify the validity of our proposal for a general class of models, along with some special cases. In Section 4, we demonstrate the performance of the proposed procedures in finite samples via simulation studies and three real data applications. Some concluding remarks are given in Section 5 and all the technical proofs are relegated to the Appendix.

2. The proposed resampling procedure

Parameter estimation by optimizing an objective function is often encountered in statistical practice. Consider the general situation where the optimal model parameter $\theta_0 \in \mathcal{R}^p$ is defined to be the minimizer of the expected loss function,

$$\theta_0 = \underset{\theta \in \Theta}{\operatorname{argmin}} \left\{ L(\theta) \triangleq \mathbb{E}[\ell(\theta; Z)] \right\}, \tag{1}$$

where $\ell(\theta; z)$ is some loss function and Z denotes one single observation and Θ is the domain on which the loss function is defined, which is assumed to be open. Suppose that the data consist of independent and identically distributed (i.i.d.) copies of Z, denoted by $\mathcal{D}_N = \{Z_1, \ldots, Z_N\}$. Under mild conditions, θ_0 can be consistently estimated by

$$\widetilde{\theta}_N = \underset{\theta \in \Theta}{\operatorname{argmin}} \left\{ \frac{1}{N} \sum_{i=1}^{N} \ell(\theta; Z_i) \right\}. \tag{2}$$

However, the minimization problem (2) for large-scale datasets pose numerical challenges. Furthermore, for applications such as online data where each sample arrives sequentially (e.g., search queries or transactional data), it may not be necessary or feasible to store the entire dataset, leaving alone evaluating the minimand in (2).

As a stochastic approximation method (Robbins and Monro 1951), stochastic gradient descent is a scalable algorithm for parameter estimation with large-scale data. Given an initial estimate $\widehat{\theta}_0$, the SGD method recursively updates the estimate upon the arrival of each data point Z_n, $n = 1, 2, \ldots, N$,

$$\widehat{\theta}_n = \widehat{\theta}_{n-1} - \gamma_n \nabla \ell(\widehat{\theta}_{n-1}; Z_n), \tag{3}$$

where the learning rates are $\gamma_n = \gamma_1 n^{-\alpha}$ with $\gamma_1 > 0$ and $\alpha \in (0.5, 1)$. As suggested by Ruppert (1988) and Polyak and Juditsky (1992), we consider the averaging estimate,

$$\overline{\theta}_n = \frac{1}{n} \sum_{i=1}^{n} \widehat{\theta}_i, \tag{4}$$

which can also be recursively updated given that $\overline{\theta}_n = (n-1)\overline{\theta}_{n-1}/n + \widehat{\theta}_n/n$.

In order to conduct statistical inference with the averaging SGD estimator $\overline{\theta}_n$ at any stage, we propose an online bootstrap resampling procedure, which recursively updates the SGD estimate as well as a large number of randomly perturbed SGD estimates, upon the arrival of each data point. Specifically, let $\mathcal{W} = \{W_i, i = 1, \ldots, N\}$ be a set of i.i.d. non-negative random variables with mean and variance equal to one. In parallel with (3) and (4), with $\widehat{\theta}_0^* \equiv \widehat{\theta}_0$, upon observing data point Z_n, we recursively updates randomly perturbed SGD estimates,

$$\widehat{\theta}_n^* = \widehat{\theta}_{n-1}^* - \gamma_n W_n \nabla \ell(\widehat{\theta}_{n-1}^*; Z_n), \tag{5}$$

$$\overline{\theta}_n^* = \frac{1}{n} \sum_{i=1}^{n} \widehat{\theta}_i^*. \tag{6}$$

We will show that $\sqrt{n}(\overline{\theta}_n - \theta_0)$ and $\sqrt{n}(\overline{\theta}_n^* - \overline{\theta}_n)$ converge in distribution to the same limiting distribution. In practice, these results allow us to estimate the distribution of $\sqrt{n}(\overline{\theta}_n - \theta_0)$ by generating a large number, say B, of random samples of $\mathcal{W}$. We obtain $\overline{\theta}_n^{*,b}$ by sequentially updating perturbed SGD estimates for each sample, $b = 1, \ldots, B$,

$$\widehat{\theta}_n^{*,b} = \widehat{\theta}_{n-1}^{*,b} - \gamma_n W_{n,b} \nabla \ell(\widehat{\theta}_{n-1}^{*,b}; Z_n), \tag{7}$$

$$\overline{\theta}_n^{*,b} = \frac{1}{n} \sum_{i=1}^{n} \widehat{\theta}_i^{*,b}, \tag{8}$$

and then approximate the sampling distribution of $\overline{\theta}_n - \theta_0$ using the empirical distribution of $\{\overline{\theta}_n^{*,b} - \overline{\theta}_n, b = 1, ..., B\}$. Specifically, the covariance matrix of $\overline{\theta}_n$ can be estimated by the sample covariance matrix constructed from $\{\overline{\theta}_n^{*,b}, b = 1, ..., B\}$. Estimating the distribution of $\sqrt{n}(\overline{\theta}_n - \theta_0)$ based on the distribution of $\sqrt{n}(\overline{\theta}_n^* - \overline{\theta}_n)|\mathcal{D}_n$ leads to the construction of $(1-\alpha)100\%$ confidence regions for θ_0. The resulting inferential procedure retains the numerical simplicity of the SGD method, only using one pass over the data. The proposed inferential procedure scales well for datasets with millions of data points or more, and its theoretical validity can be justified for a general class models with mild regularity conditions as shown in the next section.

3. Theoretical Results

3.1. Main theorems

In this section, we derive some theoretical properties of $\overline{\theta}_n^*$, justifying that the conditional distribution of $\overline{\theta}_n^* - \overline{\theta}_n$ given data $\mathcal{D}_n = \{Z_1, Z_2, \ldots, Z_n\}$ can approximate the sampling distribution of $\overline{\theta}_n - \theta_0$, under the following assumptions. Let $\|\cdot\|$ be the Euclidean norm for vectors and the operator norm for matrices. The proofs are presented in the Appendix.

(A1). The objective function $L(\theta)$ is convex, continuously differentiable over $\theta \in \Theta$, and twice continuously differentiable at $\theta = \theta_0$, where θ_0 is the unique minimizer of $L(\theta)$.

(A2). The gradient of $L(\theta)$, $R(\theta) = \nabla L(\theta)$, is Lipschitz continuous with constant $L_1 > 0$; that is, for any θ_1 and θ_2, $\|R(\theta_1) - R(\theta_2)\| \le L_1 \|\theta_1 - \theta_2\|$.

(A3). The Hessian matrix of $L(\theta)$, $S(\theta) = \nabla^2 L(\theta)$, exists and is positive definite at θ_0 with $S_0 = S(\theta_0) > 0$ and is Lipschitz continuous at θ_0 with constant $L_2 > 0$.

(A4). Let $V_0 = \mathbb{E}\{[\nabla \ell(\theta_0; Z)][\nabla \ell(\theta_0; Z)]^{\mathrm{T}}\}$. Assume $\mathbb{E}\|\nabla \ell(\theta; Z)\|^2 \le C(1 + \|\theta\|^2)$ for some C and $\mathbb{E}\|\nabla \ell(\theta; Z) - \nabla \ell(\theta_0; Z)\|^2 \le \delta(\|\theta - \theta_0\|)$ for some $\delta(\cdot)$ with $\delta(x) \to 0$ as $x \to 0$.

(A5). The learning rates are chosen as $\gamma_n = \gamma_1 n^{-\alpha}$ with $\gamma_1 > 0$ and $\alpha \in (0.5, 1)$.

(A6). The perturbation variables, $W_1, W_2, \ldots$, are non-negative i.i.d. random variables satisfying that $\mathbb{E}(W_n) = \mathrm{Var}(W_n) = 1$.

Following similar arguments in Ruppert (1988) and Polyak and Juditsky (1992), we can prove the asymptotic normality of the SGD estimator $\overline{\theta}_n$ under the above assumptions.

Lemma 1 *If Assumptions A1-A5 are satisfied, then we have*

$$\sqrt{n}(\overline{\theta}_n - \theta_0) \Rightarrow \mathcal{N}\left(0, S_0^{-1} V_0 S_0^{-1}\right), \text{ in distribution, as } n \to \infty. \tag{9}$$

From Lemma 1, we can conduct statistical inference based on $\overline{\theta}_n$ provided that we can estimate the covariance matrix $S_0^{-1} V_0 S_0^{-1}$, or we can use some resampling procedure to approximate the sampling distribution of $\sqrt{n}(\overline{\theta}_n - \theta_0)$. We first derive the asymptotically linear representation of $\overline{\theta}_n^*$ for any perturbation variables that are i.i.d. random variables satisfying that $\mathbb{E}(W_n) = 1$.

Theorem 2 *If Assumptions A1-A5 hold, and the perturbation variables, $W_1, W_2, \ldots$, are non-negative i.i.d. random variables satisfying that $\mathbb{E}(W_n) = 1$, then we have,*

$$\sqrt{n}(\overline{\theta}_n^* - \theta_0) = -\frac{1}{\sqrt{n}} S_0^{-1} \sum_{i=1}^{n} W_i \nabla \ell(\theta_0; Z_i) + o_p(1). \tag{10}$$

By Theorem 1, letting $W_n \equiv 1$, we derive the following representation for $\overline{\theta}_n$,

$$\sqrt{n}(\overline{\theta}_n - \theta_0) = -\frac{1}{\sqrt{n}} S_0^{-1} \sum_{i=1}^{n} \nabla \ell(\theta_0; Z_i) + o_p(1). \tag{11}$$

Then, considering the difference between (2) and (11), we have

$$\sqrt{n}(\overline{\theta}_n^* - \theta_n) = -\frac{1}{\sqrt{n}} S_0^{-1} \sum_{i=1}^{n} (W_i - 1) \nabla \ell(\theta_0; Z_i) + o_p(1). \tag{12}$$

Let $\mathbb{P}^*$ and $\mathbb{E}^*$ denote the conditional probability and expectation given the data. Starting from (12), we derive the following theorem.

Theorem 3 *If Assumptions A1-A6 hold, then we have*

$$\sup_{v \in \mathcal{R}^p} \left| \mathbb{P}^* \left(\sqrt{n}(\overline{\theta}_n^* - \overline{\theta}_n) \le v \right) - \mathbb{P}\Big(\sqrt{n}(\overline{\theta}_n - \theta_0) \le v \Big) \right| \to 0, \textit{in probability.} \tag{13}$$

By Theorem 2, the Kolmogorow-Smirnov distance between $\sqrt{n}(\overline{\theta}_n^* - \overline{\theta}_n)$ and $\sqrt{n}(\overline{\theta}_n - \theta_0)$ converges to zero in probability. This validates our proposal of the perturbation-based resampling procedure for inference with SGD. In the next section, we consider some special cases where Assumptions A1-A4 are satisfied.

3.2. Special cases

3.2.1. Cases where $\ell(\theta; Z)$ is twice differentiable

If the loss function $\ell(\theta; Z)$ is twice differentiable, we can use the plug-in procedure to estimate the asymptotic covariance matrix of $\sqrt{N}(\overline{\theta}_N - \theta_0)$, $S_0^{-1} V_0 S_0^{-1}$. That is, at the final step, S_0 and V_0 can be estimated respectively by

$$\widehat{S}_N = \frac{1}{N} \sum_{i=1}^{N} \nabla^2 \ell(\overline{\theta}_N; Z_i) \ \text{ and } \ \widehat{V}_N = \frac{1}{N} \sum_{i=1}^{N} [\nabla \ell(\overline{\theta}_N; Z_i)][\nabla \ell(\overline{\theta}_N; Z_i)]^{\mathrm{T}}. \tag{14}$$

However, the above final-step plug-in estimation is impractical for large-scale data or streaming data, because it requires that the whole dataset be stored. To overcome this problem, in practice we can estimate S_0 and V_0 recursively, for $n = 1, 2, \ldots$, using

$$\widehat{S}_n = \frac{1}{n} \sum_{i=1}^{n} \nabla^2 \ell(\overline{\theta}_i; Z_i) \ \text{ and } \ \widehat{V}_n = \frac{1}{n} \sum_{i=1}^{n} [\nabla \ell(\overline{\theta}_i; Z_i)][\nabla \ell(\overline{\theta}_i; Z_i)]^{\mathrm{T}}. \tag{15}$$

In the following, we examine two examples where $\ell(\theta; Z)$ is twice differentiable. Example 1 is linear regression, where the loss function $\ell(\theta; Z)$ is twice differentiable and the objective

function $L(\theta)$ is strongly convex. Example 2 is logistic regression, where $\ell(\theta; Z)$ is twice differentiable but $L(\theta)$ is non-strongly convex. They are two examples of generalized linear models, one for quantitative outcome and the other for binary outcome. In these two examples, both the plug-in procedures and the proposed perturbation resampling procedure are robust to model mis-specification.

Example 1 (Linear regression) Suppose that $Z_n = (Y_n, X_n)$, $n = 1, 2, \ldots$, are i.i.d. copies of $Z = (Y, X)$, where Y is quantitative and X is p-dim with $\mathbb{E}\|X\|^2 < \infty$. Let

$$\theta_0 = \arg\min_{\theta \in \mathcal{R}^p} \mathbb{E}\left(Y - X^{\mathrm{T}}\theta\right)^2, \tag{16}$$

where $\ell(\theta; Z) = (Y - X^{\mathrm{T}}\theta)^2$ is twice differentiable and $L(\theta) = \mathbb{E}\left(Y - X^{\mathrm{T}}\theta\right)^2$ is strongly convex. Moveover, $\nabla \ell(\theta; Z) = -2(Y - X^{\mathrm{T}}\theta)X$, $\nabla^2 \ell(\theta; Z) = 2X^{\mathrm{T}}X$, $\nabla L(\theta) = 2\mathbb{E}\{XX^{\mathrm{T}}\}\theta - 2\mathbb{E}\{XY\}$, and $\nabla^2 L(\theta) = \mathbb{E}\{\nabla l(\theta; Z)\} = 2\mathbb{E}\{XX^{\mathrm{T}}\}$. Letting $V_0 = 4\mathbb{E}\{(Y - X^{\mathrm{T}}\theta_0)^2 XX^{\mathrm{T}}\}$ and $S_0 = 2\mathbb{E}\{XX^{\mathrm{T}}\}$, we can easily verify that Assumptions A1-A4 hold. The SGD and perturbed SGD updates for θ_0, as defined in (3) and (5) respectively, are

$$\widehat{\theta}_n = \widehat{\theta}_{n-1} + 2\gamma_n (Y_n - X_n^{\mathrm{T}} \widehat{\theta}_{n-1}) X_n, \tag{17}$$

$$\widehat{\theta}_n^* = \widehat{\theta}_{n-1}^* + 2\gamma_n W_n (Y_n - X_n^{\mathrm{T}} \widehat{\theta}_{n-1}^*) X_n. \tag{18}$$

Example 2 (Logistic regression) Suppose that $Z_n = (Y_n, X_n)$, $n = 1, 2, \ldots$, are i.i.d. copies of $Z = (Y, X)$, where $Y = \pm 1$ and X is p-dim with $\mathbb{E}\|X\|^2 < \infty$. Let

$$\theta_0 = \arg\min_{\theta \in \mathcal{R}^p} \mathbb{E}\left\{ -\log\left(\frac{1}{1 + \exp(-YX^{\mathrm{T}}\theta)} \right) \right\}, \tag{19}$$

where $\ell(\theta; Z) = \log\left(1 + \exp(-YX^{\mathrm{T}}\theta)\right)$ is twice differentiable and $L(\theta) = \mathbb{E}\{\ell(\theta; Z)\}$ is non-strongly convex. Moveover, $\nabla \ell(\theta; Z) = -\frac{1}{1+\exp(YX^{\mathrm{T}}\theta)} XY$, $\nabla^2 \ell(\theta; Z) = \frac{\exp(YX^{\mathrm{T}}\theta)}{[1+\exp(YX^{\mathrm{T}}\theta)]^2} XX^{\mathrm{T}}$, $\nabla L(\theta) = \mathbb{E}\left\{\nabla \ell(\theta; Z)\right\}$, and $\nabla^2 L(\theta) = \mathbb{E}\left\{\nabla^2 \ell(\theta; Z)\right\}$. Letting $V_0 = \mathbb{E}\left\{ \frac{1}{[1+\exp(YX^{\mathrm{T}}\theta)]^2} XX^{\mathrm{T}} \right\}$ and $S_0 = \mathbb{E}\left\{ \frac{\exp(YX^{\mathrm{T}}\theta)}{[1+\exp(YX^{\mathrm{T}}\theta)]^2} XX^{\mathrm{T}} \right\}$, we can easily verify that Assumptions A1-A4 hold. The SGD and perturbed SGD updates for θ_0, as defined in (3) and (5) respectively, are

$$\widehat{\theta}_n = \widehat{\theta}_{n-1} + \gamma_n XY / [1 + \exp(YX^{\mathrm{T}} \widehat{\theta}_{n-1})], \tag{20}$$

$$\widehat{\theta}_n^* = \widehat{\theta}_{n-1}^* + \gamma_n W_n XY / [1 + \exp(YX^{\mathrm{T}} \widehat{\theta}_{n-1}^*)]. \tag{21}$$

We conclude this subsection with some discussion on the strong convexity of objective function $L(\theta)$, which is strongly convex in Example 1 and is non-strongly convex in Example 2. If $L(\theta)$ is strongly convex, i.e. there exists $\mu > 0$ such that $L(\theta_1) \ge L(\theta_2) + \nabla L(\theta_2)^{\mathrm{T}}(\theta_1 - \theta_2) + \mu\|\theta_1 - \theta_2\|^2$ for any θ_1 and θ_2, Moulines and Bach (2011) derived a non-asymptotic bound for $(\mathbb{E}\|\overline{\theta}_n - \theta_0\|)^{1/2}$. The bound of $(\mathbb{E}\|\overline{\theta}_n - \theta_0\|)^{1/2}$ has several terms; the leading term is of order $O(n^{-1})$ and the next two leading terms have order $O(n^{\alpha-2})$ and $O(n^{-2\alpha})$, suggesting the setting $\alpha = 2/3$ to make them equal. If $L(\theta)$ is non-strongly convex, Moulines and Bach (2011) derived a non-asymptotic bound for $\mathbb{E}[L(\widehat{\theta}_n) - L(\theta_0)]$ and a non-asymptotic bound for $\mathbb{E}[L(\overline{\theta}_n) - L(\theta_0)]$. The bound of $\mathbb{E}[L(\widehat{\theta}_n) - L(\theta_0)]$ is $O(\max\{n^{\alpha-1}, n^{-\alpha/2}\})$, also suggesting the setting $\alpha = 2/3$ to achieve optimal rate $O(n^{-1/3})$. Using the Polyak-Ruppert averaging has allowed the bound of $\mathbb{E}[L(\overline{\theta}_n) - L(\theta_0)]$ to go from $O(\max\{n^{\alpha-1}, n^{-\alpha/2}\})$ to $O(n^{-\alpha})$. Therefore, we use $\alpha = 2/3$ in the numerical results.

3.2.2. Cases where $\ell(\theta; Z)$ is not twice-differentiable

If the loss function $\ell(\theta; Z)$ is not twice-differentiable, neither the final-step plug-in estimation (14) nor the recursive plug-in estimation (15) is applicable. Fortunately, our proposal of scalable inference based on perturbation resampling is still applicable because it only depends on the first order derivative $\nabla\ell(\theta; Z)$. To understand this explicitly, consider the following example of robust regression via ψ-type M-estimator where the loss function may be not twice-differentiable.

Example 3 (Robust regression via ψ-type M-estimator) Suppose that $Z_n = (Y_n, X_n)$, $n = 1, 2, \ldots$, are i.i.d. copies of $Z = (Y, X)$, where Y is quantitative and X is p-dim with $\mathbb{E}\|X\|^2 < \infty$. Let $\rho(\cdot)$ be some convex function with $\rho(0) = 0$ and we attempt to estimate

$$\theta_0 = \arg\min_{\theta\in\mathcal{R}^p} \mathbb{E}\rho\left(Y - X^{\mathrm{T}}\theta\right), \tag{22}$$

where $\ell(\theta; Z) = \rho(Y - X^{\mathrm{T}}\theta)$ and $L(\theta) = \mathbb{E}\rho\left(Y - X^{\mathrm{T}}\theta\right)$. This is robust regression via ρ-type M-estimator. If $\rho(\cdot)$ is differentiable with derivative $\dot\rho(\cdot) = \psi(\cdot)$, we can solve it via ψ-type M-estimator, solving the following equation,

$$\mathbb{E}\left\{\psi\left(Y - X^{\mathrm{T}}\theta_0\right) X\right\} = 0, \tag{23}$$

where $\nabla\ell(\theta; Z) = -\psi(Y - X^{\mathrm{T}}\theta)X$ and $\nabla L(\theta) = -\mathbb{E}\left\{\psi\left(Y - X^{\mathrm{T}}\theta\right) X\right\}$. Hence, the SGD and perturbed SGD updates for θ_0, as defined in (3) and (5) respectively, are

$$\widehat\theta_n = \widehat\theta_{n-1} + \gamma_n\psi(Y_n - X_n^{\mathrm{T}}\widehat\theta_{n-1})X_n, \tag{24}$$
$$\widehat\theta_n^* = \widehat\theta_{n-1}^* + \gamma_n W_n\psi(Y_n - X_n^{\mathrm{T}}\widehat\theta_{n-1}^*)X_n. \tag{25}$$

If $\psi(\cdot)$ is not differentiable, neither the final-step plug-in estimation (14) nor the recursive plug-in estimation (15) is applicable. However, if the corresponding $\ell(\theta; Z)$ and $L(\theta)$ satisfy Assumptions A1-A4, the perturbation resampling procedure is applicable. Next we consider a special setting where the following Assumptions B1-B4 hold.

(B1). Assume that $\rho(u)$ is a convex function on $\mathcal{R}$ with the right derivative being $\psi_+(u)$ and left derivative being $\psi_-(u)$. Let $\psi(u)$ be a function such that $\psi_-(u) \le \psi(u) \le \psi_+(u)$. There exists constant $C_1 > 0$ such that $|\psi(u)| \le C_1(1 + |u|)$.

(B2). Let $\varepsilon_n = Y_n - X_n^{\mathrm{T}}\theta_0$. Assume that (X_n, ε_n), $n = 1, 2, ...$, are i.i.d. copies of (X, ε), with $\mathbb{E}\|X\|^4 < \infty$ and $\mathbb{E}\|\varepsilon\|^2 < \infty$. Let $V_0 = \mathbb{E}\{\psi^2(\varepsilon)XX^{\mathrm{T}}\} > 0$.

(B3). Let $\phi(u|X) = \mathbb{E}\{\psi(u + \varepsilon)|X\}$. Assume that $\phi(0|X) = 0$, $u\phi(u|X) > 0$ for any $u \ne 0$, and $\phi(u|X)$ has a derivative at $u = 0$ with $\dot\phi(0|X) \ge \sigma > 0$ uniformly over X. Let $S_0 = \mathbb{E}\{\dot\phi(0|X)XX^{\mathrm{T}}\} > 0$.

(B4). Assume that $\dot\phi(u|X)$ is uniformly Lipschitz at $u = 0$. That is, there exist constants $C_2 > 0$ and $\delta > 0$ such that $\left|\dot\phi(u|X) - \dot\phi(0|X)\right| \le C_2|u|$ for $|u| \le \delta$ uniformly over X.

We derive the asymptotic properties of the ψ-type M-estimator as follows.

Lemma 4 *If Assumptions B1-B4 and A5 are satisfied, then we have*

$$\sqrt{n}(\overline\theta_n - \theta_0) \Rightarrow \mathcal{N}\left(0, S_0^{-1}V_0S_0^{-1}\right), \text{ in distribution, as } n \to \infty. \tag{26}$$

Theorem 5 *If Assumptions B1-B4 and A5-A6 are satisfied, then we have*

$$\sqrt{n}(\overline\theta_n^* - \theta_0) = \frac{1}{\sqrt{n}}S_0^{-1}\sum_{i=1}^n W_i\psi(\varepsilon_i)X_i + o_p(1). \tag{27}$$

From Lemma 2 we see that the plug-in procedures are not applicable for estimating the asymptotic covariance matrix, because although they are applicable for estimating V_0, they are not applicable for estimating S_0, which involves $\dot\phi(0|X)$. Moreover, by Theorem 3, we can show that the Kolmogorov-Smirnov distance between $\sqrt{n}(\overline\theta_n^* - \overline\theta_n)$ and $\sqrt{n}(\overline\theta_n - \theta_0)$ converges to zero in probability, as stated in Theorem 2. This validates our proposal of the perturbation-based resampling procedure for robust regression. To further understand Assumptions B1-B4, we examine the following example of quantile regression, which is a special case of the above robust regression.

Example 4 (Quantile regression). Assume the τ-quantile of Y given X is $X^{\mathrm{T}}\theta_0$, with

$$\theta_0 = \arg\min_{\theta\in\mathcal{R}^p} \mathbb{E}\rho_\tau(Y - X^{\mathrm{T}}\theta), \tag{28}$$

where $\rho_\tau(u) = u(\tau - I(u < 0))$ with a given $0 < \tau < 1$. Let $\varepsilon = Y - X^{\mathrm{T}}\theta_0$ and $\psi_\tau(u) = \tau - I(u < 0)$. Thus $\mathbb{E}\{\psi_\tau(\varepsilon)|X\} = \tau - F_\varepsilon(0|X) = 0$, where $F_\varepsilon(u|X)$ is the conditional distribution function of ε. Let $p_\varepsilon(u|X)$ be the conditional density function of ε. Note that $\phi(u|X) = \mathbb{E}\{\psi_\tau(u + \varepsilon)|X\} = \tau - F_\varepsilon(-u|X)$, $\dot\phi(0|X) = p_\varepsilon(0|X)$, $V_0 = \mathbb{E}\{\psi_\tau^2(\varepsilon)XX^{\mathrm{T}}\} = \tau(1-\tau)\mathbb{E}\{XX^{\mathrm{T}}\}$ and $S_0 = \mathbb{E}\{p_\varepsilon(0|X)XX^{\mathrm{T}}\}$. Therefore, we can easily verify that if $p_\varepsilon(0|X)$ is uniformly bounded away from 0 and $p_\varepsilon(u|X)$ is uniformly Lipschitz continuous at $u = 0$, then Assumptions B1-B4 hold. Thus, the SGD and perturbed SGD updates for θ_0, as defined in (3) and (5) respectively, are

$$\widehat\theta_n = \widehat\theta_{n-1} + \gamma_n\left\{\tau - I(Y_n - X_n^{\mathrm{T}}\widehat\theta_{n-1} < 0)\right\}X_n, \tag{29}$$
$$\widehat\theta_n^* = \widehat\theta_{n-1}^* + \gamma_n W_n\left\{\tau - I(Y_n - X_n^{\mathrm{T}}\widehat\theta_{n-1}^* < 0)\right\}X_n, \tag{30}$$

and the asymptotic results stated in Lemma 2 and Theorem 3 follow directly.

4. Numerical results

4.1. Simulation studies

To assess the performance of the proposed online bootstrap resampling procedure (a.k.a. random weighting procedure; RW) for SGD estimators, we conduct simulation studies for those four examples discussed in Section 3. We compare the proposed procedure with the recursive plug-in procedure (RPI).

Setting 1 (Linear regression): Consider linear regression (16), where covariates $X^{(j)}$, $j = 1, \ldots, p$, and residual $\varepsilon = Y - X^{\mathrm{T}}\theta_0$, are independently generated from standard normal

$N(0,1)$. Here $X^{(j)}$ indicates the j-th dimension of X. Let $\theta_0 = (\mu \mathbf{1}_{q/2}^{\mathrm{T}}, -\mu \mathbf{1}_{q/2}^{\mathrm{T}}, \mathbf{0}_{p-q}^{\mathrm{T}})^{\mathrm{T}}$ (same for the other three settings). Consider the corresponding SGD estimators (17) and (18).

Setting 2 (Logistic regression): Consider logistic regression (19), where covariates $X^{(j)}$ are independently from $N(0,1)$ and response Y from Bernoulli distribution with $\mathrm{logit}\{P(Y=1|X)\} = X^{\mathrm{T}}\theta_0$. Consider the corresponding SGD estimators (20) and (21).

Setting 3 (LAD regression): Consider least absolute deviation (LAD) regression, which is a special case of robust regression (22) with $\rho(x) = |x|$ and quantile regression (28) with $\tau = 0.5$, where covariates $X^{(j)}$, $j = 1, \ldots, p$, are i.i.d. with $N(0,1)$ and residual ε, defined as $Y - X^{\mathrm{T}}\theta_0$, is independently from double exponential distribution $DE(0,1)$. Consider the corresponding SGD estimators (29) and (30) with $\tau = 0.5$.

Setting 4 (LAD regression for data with outliers): Consider LAD regression for the data generated from Setting 1 but contaminated with 10% outliers. The contaminated data are obtained by transforming the outcome variable in the data generated from Setting 1 using $Y \leftarrow Y + 10$ if $|X^{(1)}| \geq 1.96$ and $|X^{(2)}| < 1.96$; and $Y \leftarrow Y - 10$ if $|X^{(1)}| < 1.96$ and $|X^{(2)}| \geq 1.96$. In this setting, covariate vector X and residual $\varepsilon = Y - X^{\mathrm{T}}\theta_0$ are not independent, but $\mathrm{median}\{\varepsilon|X\} = 0$. Consider the corresponding SGD estimators defined in (29) and (30) with $\tau = 0.5$.

For each simulation setting, we consider four scenarios, as described by (N, p, q, μ), where sample size $N = 10,000$ or $20,000$, number of covariates $p = 10$ or 20, number of informative covariates $q = 6$, and effect size $\mu = 0.1$ or 0.2. For each example, we repeat the data generation 1000 times. For each data repetition, we use $W_{nb} \sim \exp(1)$ as random weights and generate $B = 200$ copies of random weights whenever a new data point is read. Then, for each data repetition, we obtain the SGD estimate (4), and apply the following procedures to construct 95% confidence intervals: the proposed random weighting procedure to obtain 2.5% and 97.5% quantile (RW-Q), the proposed random weighting procedure to estimate its standard error (RW-σ) and then construct "estimate $\pm$ 1.96 $\times$ $\widehat{\mathrm{SE}}$", and the recursive plug-in procedures (RPI), if applicable, to estimate its standard error. We consider the learning rate $\alpha = 2/3$. When we calculate the average SGD estimators (4) and (6), the first 2000 and 4000 estimates are excluded for $N = 10,000$ and $N = 20,000$, respectively. We also obtain the empirical standard error based on 1000 repeated SGD estimates, as a benchmark approximation to the true standard error.

The coverage probabilities of the 95% confidence interval estimates are summarized in Table 1 for linear regression (Setting 1), Table 2 for logistic regression (Setting 2) and Table 3 for LAD regression (Settings 3-4), respectively. We only report results corresponding to the first, fourth and seventh covariates (that is, $X^{(1)}$, $X^{(q/2+1)}$ and $X^{(q+1)}$). The plug-in procedures are not applicable for LAD regression in Settings 3-4.

From Tables 1 and 2, we see that, for linear regression and logistic regression, the coverage probabilities using the RW-Q, RW-σ and RPI are close to 95%. Therefore, the proposed random weighting procedures (both RW-Q and RW-σ) perform well for linear regression and logistic regression, and if we choose to use the plug-in procedure, which involves matrix inverse, we can use RPI. Since the point estimate is $\sum_{i=N_0+1}^{N} \widehat{\theta}_i/(N - N_0)$, where N_0 is the number of excluded estimates and which involves a pass of SGD estimates, its standard error should also involve a pass of SGD estimates, instead of involving only the final-step estimate or the true parameter value. We can understand this clearer if we see the "SE" column, where the standard errors from RW-σ and RPI are close to the empirical standard error. Moveover, from Table 3, we see that, for LAD regression and for both Settings 3 and 4, the coverage probabilities using either of the two proposed random weighting procedures are close to 95%, and the standard errors using RW-σ are close to the empirical standard errors.

4.2. Real data applications

In this section, we apply the proposed procedures to conduct inference for linear regression analysis for the individual household electric power consumption data (POWER) and logistic regression analysis for the skin segmentation dataset (SKIN) and gas sensors for the home Activity monitoring data (GAS). All the three datasets are publicly available on UCI machine learning repository.

The POWER dataset contains 2,075,259 observations and we fit a linear model to investigate how the time of a day influences the response variable "sub-metering-1", the energy sub-metering No. 1, in watt-hour of active energy corresponding to kitchen. The observations with missing value are deleted, and the time of a day is divided into 8 categories, "*Time 0-2*", "*Time 3-5*", ..., and "*Time 21-23*". The SKIN dataset contains 245,057 observations, out of which 50,859 is the skin samples and 194,198 is non-skin samples. We fit a logistic model to examine the relationship between the indicator of skin and three predictors, B, G and R. The GAS dataset contains 919,438 observations and we only use a subset containing 652,024 observations with response variable being either "banana" or "wine". We fit a logistic model to examine the association between the response variable and 11 explanatory variables, *Time*, *R1* to *R8*, *Temperature* and *Humidity*.

Although standard softwares such as SAS and R can fit linear and logistic regression to such datasets without difficulty, for the illustration purpose, we use the SGD as in Examples 1 and 2 to fit linear and logistic regression and use the proposed online boostrap procedure to construct confidence intervals. The point estimates and the 95% confidence intervals of the coefficients are showed in Table 4. From the left-top panel of Table 4, we see that the electronic power consumption from kitchen is relatively high in the evening and night. From the left-bottom panel of Table 4, we see that variable B is positively associated with the response while the other two variables G and R are negatively associated. From the right panel of Table 4, we see that all the variables but *R4* are statistical significantly associated with the response. Furthermore, we display the histogram of $B = 1000$ perturbation-based SGD estimates for each coefficient in Figures 4.2-4.2 for the POWER data, the SKIN data and the GAS data, respectively. The blue triangle in each figure indicates the corresponding point estimate the red triangles indicate 2.5 and 97.5 quantiles. From these figures, we see the the perturbation-based procedure can be used to approximate the sampling distribution of the corresponding SGD estimator, which might be skewed. For example, for the GAS data, the sampling distributions are very skewed, and therefore the proposed resampling procedure is able to display such skewness.

5. Discussion

Online updating is a useful strategy for analyzing big data and streaming data, and recently stochastic gradient decent has become a popular method for doing online updating. Although the asymptotic properties of SGD have been well studied, there is little research

on conducting statistical inference based on SGD estimators. In this paper, we propose the perturbation-based resampling procedure, which can be applied to estimate the sampling distribution of an SGD estimator. The offline version of perturbation-based resamping procedure was first proposed by Rubin (1981) and was also discussed in Shao and Tu (2012).

The proposed resampling procedure is in essence an online version of the bootstrap. Recall that the data points, $Z_1, Z_2, \ldots, Z_N$, are arriving one at a time and an SGD estimate updates itself from $\widehat{\theta}_{n-1}$ to $\widehat{\theta}_n$ whenever a new data point Z_n arrives. If we are forced to apply the bootstrap, then we should have many bootstrap samples; the data points of each bootstrap sample, $Z_1^*, Z_2^*, \ldots, Z_N^*$, are assumed to be arriving one at a time and the bootstrapped SGD estimate updates itself from $\widehat{\theta}_{n-1}^*$ to $\widehat{\theta}_n^*$ whenever a new data point Z_n^* arrives. Of course such bootstrap is impractical here because in online updating we will not obtain and store all the data points and then generate bootstrap samples. Now if we rearrange hypothetical bootstrap sample $Z_1^*, Z_2^*, \ldots, Z_N^*$ as

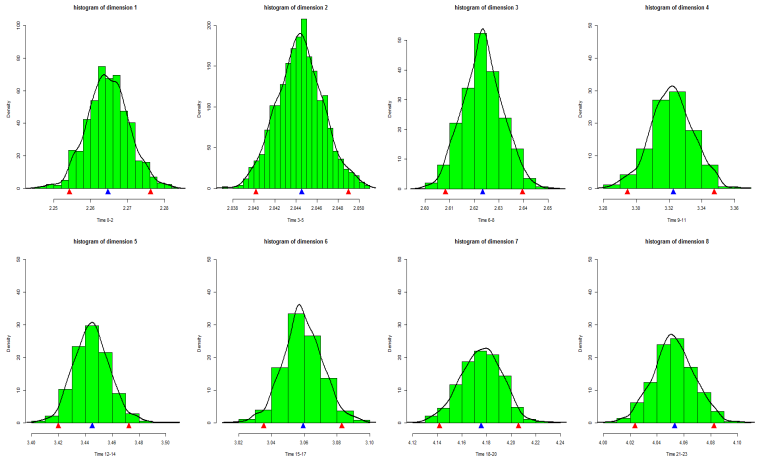

Figure 1: Histograms of $B = 1000$ perturbation-based SGD estimates for the POWER data.

$\{K_1$ copies Z_1, K_2 copies $Z_2, \ldots, K_N$ copies $Z_N\}$, where K_n follows binomial distribution $B(N, 1/N)$, then the SGD estimator updates itself from $\widehat{\theta}^*_{n-1}$ to $\widehat{\theta}^*_n$ whenever a new batch of data points, K_n copies of Z_n, arrives. Noting that binomial distribution $B(N, 1/N)$ approximates to Poisson distribution $P(1)$ as $N \to \infty$, we see that the aforementioned hypothetical

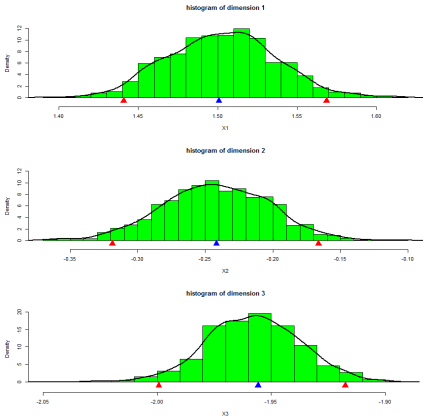

Figure 2: Histograms of $B = 1000$ perturbation-based SGD estimates for the SKIN data.

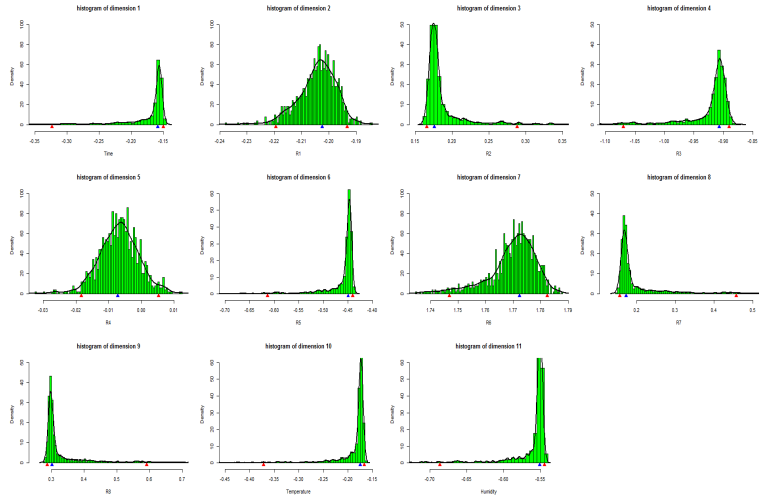

Figure 3: Histograms of $B = 1000$ perturbation-based SGD estimates for the GAS data.

bootstrap is equivalent to our proposed online bootstrap procedure with $W_n \sim P(1)$, whose mean and variance are both equal to one.

Finally, the SGD method considered in this paper is actually the explicit SGD, in contrast with the implicit SGD considered in Toulis et al (2017). We are working on extending

the proposed perturbation-based resampling procedure for conducting statistical inference for the implicit SGD.

Appendix A. technical proofs

For ease exposition of establishing asymptotic normality of SGD and perturbed SGD estimates, we present the following Proposition 1, adapted from Theorem 2 of Polyak and Juditsky (1992; pp.841). Let $R(\theta) : \mathcal{R}^p \to \mathcal{R}^p$ be some unknown function and $R(\theta_0) = 0$. The dataset consists of $Z_n, n = 1, 2, \ldots,$ which are i.i.d. copies of Z. Stochastic gradients are $\widehat{R}(\theta; Z_i)$ and $\mathbb{E}\{\widehat{R}(\theta; Z_i)\} = R(\theta)$. With an initial point $\widehat{\theta}_0$ and learning rates γ_n, the SGD estimate is defined as

$$\widehat{\theta}_n = \widehat{\theta}_{n-1} - \gamma_n \widehat{R}(\widehat{\theta}_{n-1}; Z_n) = \widehat{\theta}_{n-1} - \gamma_n \left(R(\widehat{\theta}_{n-1}) - D_n \right), \tag{31}$$

where $D_n = R(\widehat{\theta}_{n-1}) - \widehat{R}(\widehat{\theta}_{n-1}; Z_n)$ is a martingale-difference process; that is, $\mathbb{E}\{D_n | \mathfrak{F}_{n-1}\} = 0$, where $\mathfrak{F}_{n-1} = \sigma(\mathcal{D}_{n-1})$. The regularity conditions for Proposition 1 are listed as follows.

(C1). There exists a function $U(\theta) : \mathcal{R}^p \to \mathcal{R}$ such that for some $\lambda > 0$, $\delta > 0$, $l_0 > 0$, $L_0 > 0$, and all $\theta, \theta' \in \mathcal{R}^p$, the conditions $U(\theta) \geq \lambda \|\theta\|^2$, $\|\nabla U(\theta) - \nabla U(\theta')\| \leq L_0 \|\theta - \theta'\|$, $U(0) = 0$, $\nabla U(\theta - \theta_0)^{\mathrm{T}} R(\theta) > 0$ for $\theta \neq \theta_0$ hold true. Moreover, $\nabla U(\theta - \theta_0)^{\mathrm{T}} R(\theta) \geq l_0 U(\theta - \theta_0)$ for all $\|\theta - \theta_0\| \leq \delta$.

(C2). There exists a positive definite matrix $S_0 \in \mathcal{R}^{p \times p}$ such that for some $C > 0$, $0 < \varrho \leq 1$, and $\delta > 0$, the condition $\|R(\theta) - S_0(\theta - \theta_0)\| \leq C\|\theta - \theta_0\|^{1+\varrho}$ for all $\|\theta - \theta_0\| \leq \delta$ holds true.

(C3). $\{D_n\}_{n \geq 1}$ is a martingale difference process with $\mathbb{E}\{D_n | \mathfrak{F}_{n-1}\} = 0$, and for some $C > 0$,

$$\mathbb{E}\left\{ \|D_n\|^2 \,|\, \mathfrak{F}_{n-1} \right\} + \|R(\widehat{\theta}_{n-1})\|^2 \leq C \left(1 + \|\widehat{\theta}_{n-1}\|^2 \right) \text{ a.s.},$$

for all $n \geq 1$. Consider decomposition $D_n = D_n(0) + E_n(\widehat{\theta}_{n-1})$, where $D_n(0) = R(\theta_0) - \widehat{R}(\theta_0; Z_n)$ and $E_n(\widehat{\theta}_{n-1}) = D_n - D_n(0)$. Assume that $\mathbb{E}\{D_n(0) | \mathfrak{F}_{n-1}\} = 0$ a.s.,

$$\mathbb{E}\{D_n(0) D_n(0)^{\mathrm{T}} | \mathfrak{F}_{n-1}\} \xrightarrow{P} V_0 > 0,$$
$$\sup_{n \geq 1} \mathbb{E}\left\{ \|D_n(0)\|^2 I(\|D_n(0)\| > \eta) | \mathfrak{F}_{n-1} \right\} \xrightarrow{P} 0, \text{ as } \eta \to \infty,$$

and there exists $\delta(x) \to 0$ as $x \to 0$ such that, for all n large enough,

$$\mathbb{E}\left\{ \|E_n(\widehat{\theta}_{n-1})\|^2 \,|\, \mathfrak{F}_{n-1} \right\} \leq \delta(\|\widehat{\theta}_{n-1} - \theta_0\|) \text{ a.s..}$$

(C4). It holds that $(\gamma_n - \gamma_{n+1})/\gamma_n = o(\gamma_n)$, $\gamma_n > 0$ for all n, and $\sum_{n=1}^{\infty} \gamma_n^{(1+\varrho)/2} n^{-1/2} < \infty$.

Assumptions C2 and C4 are implied by the following Assumptions C2′ (i.e. Assumption C2 with $\varrho = 1$) and C4′ (i.e. Assumption A5):

(C2′). There exists a positive definite matrix $S \in \mathcal{R}^{p \times p}$ such that for some $C > 0$ and $\delta > 0$, the condition $\|R(\theta) - S_0(\theta - \theta_0)\| \leq C\|\theta - \theta_0\|^2$ for all $\|\theta - \theta_0\| \leq \delta$ holds true.

(C4′). The learning rates are chosen as $\gamma_n = \gamma_1 n^{-\alpha}$ with $\gamma_1 > 0$ and $\alpha \in (0.5, 1)$.

Proposition 1. *If Assumptions C1-C4 are satisfied, then we have* $\overline{\theta}_n \to \theta_0$, *a.s.; and*

$$\sqrt{n}(\overline{\theta}_n - \theta_0) = \frac{1}{\sqrt{n}} S^{-1} \sum_{i=1}^{n} D_i + o_p(1), \tag{32}$$

which implies $\sqrt{n}(\overline{\theta}_n - \theta_0) \Rightarrow \mathcal{N}\left(0, S_0^{-1} V_0 S_0^{-1}\right)$, *in distribution.*

A1. Proof of Lemma 1

Proof. By Proposition 1, it suffices to show that Assumptions C1-C4 hold under Assumptions A1-A5. Because C2 and C4 are implied by C2′ and C4′, it suffices to show that Assumptions C1, C2′, C3 and C4′ hold under Assumptions A1-A5.

Verification of Assumption C1: Recall that $R(\theta) = \nabla L(\theta)$ and $\widehat{R}(\theta; Z_i) = \nabla \ell(\theta; Z_i)$. Define $U(\theta) = L(\theta_0 + \theta) - L(\theta_0) + \lambda\|\theta\|^2$ for a given $\lambda > 0$. By definition of $U(\theta)$ and Assumption A1, we have $U(\theta) \geq \lambda\|\theta\|^2$ and $U(0) = 0$. For any θ and θ', since $\nabla U(\theta) - \nabla U(\theta') = R(\theta + \theta_0) - R(\theta' + \theta_0) + 2\lambda(\theta - \theta')$, letting $L_0 = L_1 + 2\lambda$ and by Assumption A2, we have $\|\nabla U(\theta) - \nabla U(\theta')\| \leq L_1\|\theta - \theta'\|$. Since $\nabla U(\theta - \theta_0)^{\mathrm{T}} R(\theta) = \|R(\theta)\|^2 + \lambda(\theta - \theta_0)^{\mathrm{T}} R(\theta)$, by Assumption A1, we have $\nabla U(\theta - \theta_0)^{\mathrm{T}} R(\theta) > 0$ for any $\theta \neq \theta_0$. Last, it remains to verify there exist $l_0 > 0$ and $\delta > 0$ such that $\nabla U(\theta - \theta_0)^{\mathrm{T}} R(\theta) \geq l_0 U(\theta - \theta_0)$ for all $\|\theta - \theta_0\| \leq \delta$. Noting that $U(\theta - \theta_0) = L(\theta + \theta_0) + \lambda\|\theta - \theta_0\|^2$, by Taylor expansion and Assumption A3, we see that there exist $l_1 > 0$ and δ_1 such that $U(\theta - \theta_0) \leq l_1\|\theta - \theta_0\|^2$ for all $\|\theta - \theta_0\| \leq \delta_1$. On the other hand, noting that $\nabla U(\theta - \theta_0)^{\mathrm{T}} R(\theta) = \|R(\theta)\|^2 + \lambda(\theta - \theta_0)^{\mathrm{T}} R(\theta)$, by Assumption A3 also, we see that there exist $l_2 > 0$ and δ_2 such that $(\theta - \theta_0)^{\mathrm{T}} R(\theta) \geq l_2\|\theta - \theta_0\|^2$ for all $\|\theta - \theta_0\| \leq \delta_2$. Selecting $\delta = \min(\delta_1, \delta_2)$ and $l_0 = \lambda l_2 / l_2$, we show that $\nabla U(\theta - \theta_0)^{\mathrm{T}} R(\theta) \geq l_0 U(\theta - \theta_0)$ for all $\|\theta - \theta_0\| \leq \delta$.

Verification of Assumption C2′: Recall that $R(\theta) = \nabla L(\theta)$, $S(\theta) = \nabla R(\theta)$, and $S_0 = S(\theta_0) > 0$. By Assumption A3, there exists $\delta > 0$ such that for any $\|\theta - \theta_0\| < \delta'$, $\|S(\theta) - S(\theta_0)\| < L_2\|\theta - \theta_0\|$. By mean-value theorem, $\|S(\theta) - S_0(\theta - \theta_0)\| = \|S(\widetilde{\theta})(\theta - \theta_0) - S_0(\theta - \theta_0)\|$, where $\widetilde{\theta}$ lies between θ and θ_0. Hence $\|S(\theta) - S_0(\theta - \theta_0)\| \leq L_2\|\theta - \theta_0\|^2$, for any $\|\theta - \theta_0\| \leq \delta$. Letting $C = L_2$, we have verified Assumption C2′.

Verification of Assumption C3: $D_n = R(\widehat{\theta}_{n-1}) - \widehat{R}(\widehat{\theta}_{n-1}; Z_n)$. Consider decomposition $D_n = D_n(0) + E_n(\widehat{\theta}_{n-1})$, where $D_n(0) = -\nabla \ell(\theta_0, Z_n)$ and $E_n(\widehat{\theta}_{n-1}) = [R(\widehat{\theta}_{n-1}) - R(\theta_0)] - [\nabla \ell(\widehat{\theta}_{n-1}; Z_n) - \nabla \ell(\theta_0; Z_n)]$. By Assumption A2, $\|R(\widehat{\theta}_{n-1})\|^2 \leq L_1^2 \|\widehat{\theta}_{n-1} - \theta_0\|^2$. In addition, Cauchy-Schwartz inequality implies that $\mathbb{E}\left\{ \|\nabla \ell(\theta; Z_n) - \nabla \ell(\theta_0; Z_n)\|^2 \right\} = 2\mathbb{E}\|\nabla \ell(\theta; Z_n)\|^2 + 2\mathbb{E}\|\nabla \ell(\theta_0; Z_n)\|^2$; we have $\mathbb{E}\left\{ \|\nabla \ell(\widehat{\theta}_{n-1}; Z_n) - \nabla \ell(\theta_0; Z_n)\|^2 \,| \right\} \leq C'(1 + \|\theta\|^2)$ for some $C' > 0$ by Assumption A4, . Together, we have $\mathbb{E}\left\{ \|D_n\|^2 \,|\, \mathfrak{F}_{n-1} \right\} + \|R(\widehat{\theta}_{n-1})\|^2 \leq C\left(1 + \|\widehat{\theta}_{n-1}\|^2\right)$ for some $C > 0$. Moreover, because $D_n(0)$'s are i.i.d., we have $\mathbb{E}\{D_n(0) D_n(0)^{\mathrm{T}} | \mathfrak{F}_{n-1}\} = V_0 > 0$ and $\sup_{n \geq 1} \mathbb{E}\left\{ \|D_n(0)\|^2 I(\|D_n(0)\| > \eta) | \mathfrak{F}_{n-1} \right\} \xrightarrow{P} 0$, as $\eta \to \infty$. Finally, note that $\mathbb{E}\|E_n(\theta)\|^2 \leq L_1^2\|\theta - \theta_0\|^2 + \mathbb{E}\|\nabla \ell(\theta; Z_n) - \nabla \ell(\theta_0; Z_n)\|^2$. By Assumption A3, $\mathbb{E}\|\nabla \ell(\theta; Z_n) - \nabla \ell(\theta_0; Z_n)\|^2 \leq \delta'(\|\theta - \theta_0\|)$ for some $\delta'(\cdot)$ with $\delta'(x) \to 0$ as $x \to 0$. Define $\delta(x) = L_1^2 x^2 + \delta'(x)$, we show $\mathbb{E}\|E_n(\theta)\|^2 \leq \delta(\|\theta - \theta_0\|)$. This complete the verification of Assumption C3.

Obviously Assumption A5 is the same as Assumption C4′. Therefore, we have verified that Assumptions A1-A5 imply Assumptions C1, C2′, C3 and C4′. By Proposition 1, we complete the proof of Lemma 1. □

A2. Proof of Theorem 1

Proof. Rewrite $\widehat{\theta}_n^*$ as

$$\widehat{\theta}_n^* = \widehat{\theta}_{n-1}^* - \gamma_n R(\widehat{\theta}_{n-1}^*) + \gamma_n D_n^*, \tag{33}$$

where $D_n^* = R(\widehat{\theta}_{n-1}^*) - W_n \nabla \ell(\widehat{\theta}_{n-1}^*; Z_n)$. Then let $\mathfrak{F}_{n-1}^*$ be the Borel field generated by $\{(Z_i, W_i), i \le n-1\}$. Since $\mathbb{E}\{W_n|\mathfrak{F}_{n-1}^*\} = 1$ and $R(\theta) = \mathbb{E}\{\nabla \ell(\theta; Z_n)\}$, we have $\mathbb{E}\{D_n^*|\mathfrak{F}_{n-1}\} = 0$. Thus D_n^* is a martingale-difference process. Let $D_n^*(\theta) = R(\theta) - W_n \nabla \ell(\theta; Z_n)$. Consider decomposition $D_n^* = D_n^*(0) + E_n^*(\widehat{\theta}_{n-1}^*)$, where

$$D_n^*(0) = -W_n \nabla \ell(\theta_0; Z_n) \tag{34}$$

and

$$E_n^*(\theta) = [R(\theta) - R(\theta_0)] - W_n[\nabla \ell(\theta; Z_n) - \nabla \ell(\theta_0; Z_n)]. \tag{35}$$

Noting that $\mathbb{E}\{D_n^*(0)\} = 0$ and $\mathbb{E}(W_n^2) = 2$ under Assumption A6, by Assumption A4, we have

$$\mathbb{E}\{[D_n^*(0)][D_n^*(0)]^{\mathrm{T}}\} = 2\mathbb{E}\left\{[\ell(\theta_0; Z_n)][\ell(\theta_0; Z_n)]^{\mathrm{T}}\right\} = 2V_0. \tag{36}$$

By Cauchy-Schwartz inequality and Assumptions A2 and A4, we have

$$\mathbb{E}\{\|E_n^*(\theta)\|^2\} \le 2\|R(\theta)\|^2 + 4\mathbb{E}\left\{\|\nabla \ell(\theta, Z) - \nabla \ell(\theta_0, Z)\|^2\right\} \le \delta'(\|\theta - \theta_0\|), \tag{37}$$

where $\delta'(x) = 2L_1^2 x^2 + 2\delta(x)$ satisfying that $\delta'(x) \to 0$ as $x \to 0$. Also by Cauchy-Schwartz inequality, $\mathbb{E}\{\|E_n^*(\theta)\|^2\} \le 2\|R(\theta)\|^2 + 2\mathbb{E}\{\|\nabla \ell(\theta, Z)\|^2\}$. Further, by Assumptions A2 and A4,

$$\mathbb{E}\{\|D_n^*\|^2|\mathfrak{F}_{n-1}\} + \|R(\widehat{\theta}_{n-1}^*)\|^2 \le 3L_1^2\|\widehat{\theta}_{n-1}^* - \theta_0\|^2 + 2C\|\widehat{\theta}_{n-1}^*\|^2 \le C'(1 + \|\widehat{\theta}_{n-1}^* - \theta_0\|^2), \tag{38}$$

for some large enough $C' > 0$. Combining results (36)-(38), we have verified Assumption C3. Moreover, noting that $\mathbb{E}W_n = 1$, we can easily verify that Assumptions A1 and A2 imply that Assumption C1 holds, and Assumption A3 implies that Assumption C2 holds. By Proposition 1, we show that $\widehat{\theta}_n^* \to \theta_0$ almost surely, and

$$\begin{aligned}\sqrt{n}(\overline{\theta}_n^* - \theta_0) &= \frac{1}{\sqrt{n}} S_0^{-1} \sum_{i=1}^n D_i^* + o_p(1) \\ &= -\frac{1}{\sqrt{n}} S_0^{-1} \sum_{i=1}^n W_i \nabla \ell(\theta_0; Z_i) + \frac{1}{\sqrt{n}} S_0^{-1} \sum_{i=1}^n E_n^*(\widehat{\theta}_{n-1}^*) + o_p(1). \end{aligned} \tag{39}$$

Note that $\mathbb{E}\{\|E_n(\widehat{\theta}_{n-1}^*)\|^2|\mathfrak{F}_{n-1}\} \le \delta'(\|\widehat{\theta}_{n-1}^* - \theta_0\|)$, following (37). Since $\widehat{\theta}_n^* \to \theta_0$ a.s., we have $\delta(\|\widehat{\theta}_{n-1}^* - \theta_0\|) \to 0$ a.s.. Thus, $S_0^{-1} \sum_{i=1}^n E_n(\widehat{\theta}_{n-1}^*)/\sqrt{n} = o_p(1)$. Therefore, by (39), this completes the proof of Theorem 1. □

A3. Proof of Theorem 2

Proof. Let

$$V_n = -\frac{1}{\sqrt{n}} S_0^{-1}(W_i - 1)\nabla \ell(\theta_0, Z_i). \tag{40}$$

By Theorem 1, we have $\sqrt{n}(\overline{\theta}_n^* - \overline{\theta}_n) = V_n + o_p(1)$. We first show that, for any $\beta \in \mathbf{B} \triangleq \{\beta \in \mathcal{R}^p : \|\beta\| = 1\}$ and $u \in \mathcal{R}$,

$$\mathbb{P}^*\left(\beta^{\mathrm{T}} V_n \le u\right) \to \Phi(u/\sigma_\beta), \text{ in probability}, \tag{41}$$

where $\Phi(u)$ is the distribution of $\mathcal{N}(0,1)$ and $\sigma_\beta = \beta^{\mathrm{T}} S_0^{-1} V_0 S_0^{-1} \beta$. In fact,

$$\beta^{\mathrm{T}} V_n = \frac{1}{\sqrt{n}} \sum_{i=1}^n (W_i - 1)\xi_i, \tag{42}$$

where $\xi_i = -\beta^{\mathrm{T}} S_0^{-1} \nabla \ell(\theta_0, Z_i)$. Note that, by Assumption A6, $\mathbb{E}W_i = \mathrm{Var}(W_i) = 1$. Hence

$$s_n = \frac{1}{n} \sum_{i=1}^n \mathrm{Var}^*\{(W_i - 1)\xi_i\} = \frac{1}{n} \sum_{i=1}^n \xi_i^2 \to \sigma_\beta^2, \text{ in probability}, \tag{43}$$

and for any $\epsilon > 0$,

$$\frac{1}{n s_n} \sum_{i=1}^n \mathbb{E}^*\left\{(W_i - 1)^2 \xi_i^2 I\left[|(W_i - 1)\xi_i| > \sqrt{n} s_n \epsilon\right]\right\} \to 0, \text{ in probability}. \tag{44}$$

Therefore, the Lindeberg's condition is satisfied. By the central limit theorem, (41) holds, which implies that for any $\beta \in \mathbf{B}$,

$$\sup_{u \in \mathcal{R}} |\mathbb{P}^*\left(\beta^{\mathrm{T}} V_n \le u\right) - \Phi(u/\sigma_\beta)| \to 0, \text{ in probability}. \tag{45}$$

Consider $\mathbf{B}_0 \triangleq \{\beta \in \mathcal{R}^p : \|\beta\| = 1, \text{the components of } \beta \text{ are rational}\}$, which contains only countable many β and is a dense subset of $\mathbf{B}$. For any subsequence $\{n_1\}$, by Cantor's "diagonal method" used in Rao and Zhao (1992), we can show that there exists a subsequence $\{n_2\} \subset \{n_1\}$ such that, with probability one,

$$\sup_{u \in \mathcal{R}} |\mathbb{P}^*\left(\beta^{\mathrm{T}} V_{n-1} \le u\right) - \Phi(u/\sigma_\beta)| \to 0, \text{ for any } \beta \in \mathbf{B}_0. \tag{46}$$

Hence, we show that

$$\sup_{v \in \mathcal{R}^p} \left|\mathbb{P}^*\left(\sqrt{n}(\overline{\theta}_n^* - \overline{\theta}_n) \le v\right) - \mathbb{P}(\zeta \le v)\right| \to 0, \text{ in probability}, \tag{47}$$

where $\zeta \sim \mathcal{N}(0, S_0^{-1} V_0 S_0^{-1})$. By Lemma 1, we can also show that

$$\sup_{v \in \mathcal{R}^p} \left|\mathbb{P}\left(\sqrt{n}(\overline{\theta}_n - \theta_0) \le v\right) - \mathbb{P}(\zeta \le v)\right| \to 0. \tag{48}$$

Combining (47) and (48), we complete the proof of Theorem 2. □

A4. Proof of Lemma 2

Proof. By Proposition 1, it suffices to show that Assumptions C1, C2′ and C3 hold under Assumptions B1-B4.

Verification of Assumption C1: Define $\Delta = \theta - \theta_0$. Let $R(\Delta) = \mathbb{E}\{\phi(\Delta^{\mathrm{T}}X|X)X\}$ and $\widehat{R}(\Delta; Z_n) = \psi(\Delta^{\mathrm{T}}X_n+\varepsilon_n)X_n$. Define $U(\Delta) = \Delta^{\mathrm{T}}\Delta$. By definition of $U(\Delta)$, $U(\Delta) \geq \lambda\|\Delta\|^2$ with $\lambda = 1$, $U(0) = 0$ and $\nabla U(\Delta)$ is Lipschitz continuous. Since $\Delta^{\mathrm{T}}\mathbb{E}\{\phi(\Delta^{\mathrm{T}}X|X)\Delta^{\mathrm{T}}X\} > 0$ by Assumption B3, we see that $\nabla U(\Delta)^{\mathrm{T}}R(\Delta) > 0$. By the mean-value theorem and by Assumption B3, there exists δ such that $\Delta^{\mathrm{T}}\mathbb{E}\{\phi(\Delta^{\mathrm{T}}X|X)\Delta^{\mathrm{T}}X\} \geq \Delta^{\mathrm{T}}\mathbb{E}\{\dot{\phi}(0|X)XX^{\mathrm{T}}\}\Delta/2 \geq \lambda_{\min}(S_0)\|\Delta\|^2/2$, for any $\|\Delta\| \leq \delta$, where $\lambda_{\min}(S_0)$ is the minimum eigenvalue of S_0. Hence $\nabla U(\Delta)^{\mathrm{T}}R(\Delta) \geq \lambda_{\min}(S_0)\|\Delta\|^2$ and we have verified Assumption C1.

Verification of Assumption C2′: Note that

$$\|R(\Delta) - S_0\Delta\| = \|\mathbb{E}\phi(\Delta^{\mathrm{T}}X|X) - \mathbb{E}\dot{\phi}(0|X)XX^{\mathrm{T}}\Delta\|.$$

By the mean-value theorem and Assumption B4, there exists δ such that, for any $\|\Delta\| \leq \delta$, $\|\mathbb{E}\{\phi(\Delta^{\mathrm{T}}X|X)X\} - \mathbb{E}\{\dot{\phi}(0|X)XX^{\mathrm{T}}\Delta\}\| \leq C_2\lambda_{\max}(S_0)\|\Delta\|^2$. This implies Assumption C2′.

Verification of Assumption C3: Let $\widehat{\Delta}_n = \widehat{\theta}_n - \theta_0$. Then $D_n = R(\widehat{\Delta}_{n-1}) - \widehat{R}(\widehat{\Delta}_{n-1}; Z_n)$. Consider decomposition $D_n = D_n(0)+E_n(\widehat{\Delta}_{n-1})$, where $D_n(0) = \psi(\varepsilon_n)X_n$ and $E_n(\widehat{\Delta}_{n-1}) = \mathbb{E}\{\psi(\widehat{\Delta}_{n-1}^{\mathrm{T}}X+\varepsilon_n)X_n\}-[\psi(\widehat{\Delta}_{n-1}^{\mathrm{T}}X+\varepsilon_n)X_n-\psi(\varepsilon_n)X_n]$. By Assumption B1 and the Cauchy-Schwartz inequality, we can show that $\mathbb{E}\left\{\|D_n\|^2 \mid \mathfrak{F}_{n-1}\right\}+\|R(\widehat{\Delta}_{n-1})\|^2 \leq 2C_1\left(1 + \|\widehat{\Delta}_{n-1}\|^2\right)$. Moreover, by Assumption B2, $D_n(0)$'s are i.i.d., so $\mathbb{E}\{D_n(0)D_n(0)^{\mathrm{T}}|\mathfrak{F}_{n-1}\} = V_0 > 0$ and $\sup_{n\geq 1}\mathbb{E}\left\{\|D_n(0)\|^2 I(\|D_n(0)\| > \eta)|\mathfrak{F}_{n-1}\right\} \to 0$, as $\eta \to \infty$. Finally, by Cauchy-Schwartz inequality and Assumptions B2-B3, we can show that $\mathbb{E}\|E_n(\Delta)\|^2 \leq \delta(\|\Delta\|)$ for some $\delta(\cdot)$ with $\delta(x) \to 0$ as $x \to 0$. This complete the verification of Assumption C3.

Obviously Assumption A5 is the same as Assumption C4′. Therefore, we have verified that Assumptions B1-B4 and A5 imply Assumptions C1, C2′, C3 and C4′. By Proposition 1, we complete the proof of Lemma 2. □

A5. Proof of Theorem 3

Proof. Recall that $R(\Delta) = \mathbb{E}\{\phi(\Delta^{\mathrm{T}}X|X)X\}$ and $\widehat{\Delta}_n = \widehat{\theta}_n - \theta_0$. Rewrite $\widehat{\theta}_n^*$ as

$$\widehat{\theta}_n^* = \widehat{\theta}_{n-1}^* + \gamma_n R(\widehat{\Delta}_n) + \gamma_n D_n^*, \tag{49}$$

where $D_n^* = W_n\psi(\widehat{\Delta}_n^{\mathrm{T}}X_n+\varepsilon_n)X_n - R(\widehat{\Delta}_n)$ is a martingale-difference process by Assumption B3 and that $\mathbb{E}\{W_n|\mathfrak{F}_{n-1}\} = 1$. Let $D_n^*(\Delta) = W_n\psi\left(\Delta^{\mathrm{T}}X_n + \varepsilon_n\right)X_n - R(\Delta)$ and $D_n^*(\Delta) = D_n^*(0) + E_n^*(\Delta)$, where

$$E_n^*(\Delta) = W_n\left[\psi(\Delta^{\mathrm{T}}X_n + \varepsilon_n) - \psi(\varepsilon_n)\right]X_n - R(\Delta). \tag{50}$$

Since $D_n^*(0) = W_n\psi(\varepsilon_n)X_n$, $\mathbb{E}\{D_n^*(0)\} = 0$ and $\mathbb{E}\{[D_n^*(0)][D_n^*(0)]^{\mathrm{T}}\} = (1 + \mathrm{Var}(W_1))V_0$ by Assumption B2. By Cauchy-Schwartz inequality and Assumptions B2-B3, we can show that $\mathbb{E}\|E_n^*(\Delta)\|^2 \leq \delta(\|\Delta\|)$ for some $\delta(\cdot)$ with $\delta(x) \to 0$ as $x \to 0$. Therefore, using the similar arguments as those in the proof of Lemma 2, we can verify that, under Assumptions B1-B4, Assumptions C1-C4 are satisfied. By Proposition 1, it follows that $\widehat{\theta}_n^* \to \theta_0$ almost surely, and

$$\sqrt{n}(\overline{\theta}_n^* - \theta_0) = \frac{1}{\sqrt{n}}S_0^{-1}\sum_{i=1}^{n} D_i^* + o_p(1). \tag{51}$$

By the decomposition of D_i^*, we have

$$\sqrt{n}(\overline{\theta}_n^* - \theta_0) = \frac{1}{\sqrt{n}}S_0^{-1}\sum_{i=1}^{n} W_i\psi(\varepsilon_i)X_i + \frac{1}{\sqrt{n}}S_0^{-1}\sum_{i=1}^{n} E_n^*(\widehat{\theta}_{n-1}^* - \theta_0) + o_p(1). \tag{52}$$

By the definition of $\delta(\|\Delta\|)$, $\mathbb{E}\{\|E_n^*(\widehat{\theta}_{n-1}^* - \Delta)\|_2^2|\mathfrak{F}_{n-1}\} = \delta(\|\widehat{\theta}_{n-1}^* - \theta_0\|)$. Since $\widehat{\theta}_n^* \to \theta_0$ a.s., we have $\delta(\|\widehat{\theta}_{n-1}^* - \theta_0\|) \to 0$ a.s.. Thus, $\sum_{i=1}^n E_n^*(\widehat{\theta}_{n-1}^* - \theta_0)/\sqrt{n} = o_p(1)$. By (52), we complete the proof of Theorem 3. □

Abstract

This article provides an original understanding of the behavior of a class of graph-oriented semi-supervised learning algorithms in the limit of large and numerous data. It is demonstrated that the intuition at the root of these methods collapses in this limit and that, as a result, most of them become inconsistent. Corrective measures and a new data-driven parametrization scheme are proposed along with a theoretical analysis of the asymptotic performances of the resulting approach. A surprisingly close behavior between theoretical performances on Gaussian mixture models and on real data sets is also illustrated throughout the article, thereby suggesting the importance of the proposed analysis for dealing with practical data. As a result, significant performance gains are observed on practical data classification using the proposed parametrization.

Keywords: semi-supervised learning, kernel methods, random matrix theory, high dimensional statistics

1. Introduction

Semi-supervised learning consists in classification schemes combining few labelled and numerous unlabelled data. With the advent of the big-data paradigm, where supervised learning implies the impossible pre-labelling of sometimes millions of samples, these so-far marginal methods are attracting a renewed attention. Its appeal also draws on its providing an alternative to unsupervised learning which excludes the possibility to exploit known data. We refer to Chapelle et al. (2006) for an overview.

An important subset of semi-supervised learning methods concerns graph-based approaches. In these, one considers data instances $x_1, \cdots, x_n \in \mathbb{R}^p$ as vertices on a graph with edge weights W_{ij} encoding their similarity, which is usually defined through a kernel function f, as with radial kernels of the type $W_{ij} = f(\|x_i - x_j\|^2/p)$ which we shall focus on in this article. The motivation follows from one's expectation that two instances with a strong edge weight tend to belong to the same class and thus vertices of a common class tend to aggregate. Standard methods for recovering the classes of the unlabelled data then consist in various random walk (Jaakkola and Szummer, 2002) or label propagation (Zhu and Ghahramani, 2002) algorithms on the graph which softly allocate "scores" for each node to belong to a particular class. These scores are then compared for each class in order to obtain a hard decision on the individual unlabelled node class. A popular, and widely recognized as highly performing, example is the PageRank approach (Avrachenkov et al., 2011).

Many of these algorithms also have the particularity of having a closed-form and quite interrelated expression for their stationary points. These stationary points are also often found to coincide with the solutions to optimization problems under constraints, independently established. This is notably the case of Zhu et al. (2003) under equality constraints for the labelled nodes or of Belkin et al. (2004) where a relaxation approach is used instead to allow for modifications of the value of labelled nodes – this ensuring that erroneously labelled data or poorly informative labelled data do not hinder the algorithm performance. As is often the case in graph-related optimization, a proper choice of the matrix representative of the inter-data affinity is at the core of scientific research and debates and mainly defines the differences between any two schemes. In particular, Joachims et al. (2003) suggests the use of a standard Laplacian representative, where Zhou et al. (2004) advises for a normalized Laplacian approach. These individual choices correspondingly lead to different versions of the label propagation methods on the graph, as discussed in Avrachenkov et al. (2011).

There also exists another branch of manifold based semi-supervised learning (Belkin and Niyogi, 2004; Goldberg et al., 2009; Moscovich et al., 2016). In contrast to the methods discussed in this paper, these approaches involve a step of manifold learning, which plays a decisive role in the success of the learning task. While there exist many articles providing theoretical analyses for such methods (Wasserman and Lafferty, 2008; Bickel et al., 2007; Moscovich et al., 2016; Globerson et al., 2017), a comprehensive comparison to the graph-based methods presently discussed is beyond current analytical reach. This being said, while the Gaussian-mixture data model under study in the present article violates the manifold assumption, given appropriate feature (kernel function) mapping, there exists a low dimensional manifold where data demonstrate a clustering behavior, as shown by Couillet and Benaych-Georges (2015); as such, when the classes are very well separated and sufficient data are available to estimate the manifold, manifold-based methods in this setting should lead to competitive performance. While clearly out of our present scope, future investigations might allow for a comparative study of manifold versus graph approaches. Another recent line of alternative works consider SSL from a graph signal processing perspective (Narang et al., 2013a,b; Gadde et al., 2014; Anis et al., 2015), where the classification scores are viewed as smooth signals on the similarity graph and the learning task then consists in recovering a bandlimited (understood in the graph Fourier transform domain) graph signal from its known sample values.

Returning to graph-based SSL, a likely key reason for the open-ended question of a most natural choice for the graph representative arises from these methods being essentially built upon intuitive reasoning arising from low dimensional data considerations rather than from mostly inaccessible theoretical results. Indeed, the non-linear expression of the affinity matrix W as well as the rather involved form assumed by the algorithm output (although explicit) hinder the possibility to statistically evaluate the algorithm performances for all finite n, p, even for simple data assumptions. The present article is placed instead under a large dimensional data assumption, thus appropriate to the present big-data paradigm,

and proposes instead to derive, for the first time to the best of the authors' knowledge, theoretical results on the performance of the aforementioned algorithms in the large n, p limit for a certain class of statistically distributed data $x_1, \ldots, x_n \in \mathbb{R}^p$. Precisely due to the large data assumption, as we shall observe, most of the intuition leading up to the aforementioned algorithms collapse as $n, p \to \infty$ at a similar rate, and we shall prove that few algorithms remain consistent in this regime.

Specifically, recall that the idea behind graph-based semi-supervised learning is to exploit the similarity between data points and thus expect a clustering behavior of close-by data nodes. In the large data assumption (i.e., $p \gg 1$), this similarity-based approach suffers a curse of dimensionality. As the span of $\mathbb{R}^p$ grows exponentially with the data dimension p, when p is large, the data points x_i (if not too structured) are in general so sparsely distributed that their pairwise distances tend to be similar regardless of their belonging to the same class or not. The Gaussian mixture model that we define in Subsection 3 and will work on is a telling example of this phenomenon; as we show, in a regime where the classes ought to be separable (even by unsupervised methods as shown by Couillet and Benaych-Georges 2015), the normalized distance $\|x_i - x_j\|/\sqrt{p}$ of two random different data instances x_i and x_j generated from this model converges to a constant *irrespective of the class of* x_i *and* x_j in the Gaussian mixture and, consequently, the similarity defined by $W_{ij} = f(\|x_i - x_j\|^2/p)$ is asymptotically the same for all pairs of data instances. This behavior should therefore invalidate the intuition behind semi-supervised classification, hence likely render graph-based methods ineffective. As a direct consequence, the scores are *flat* in the sense that they have the same asymptotic values, irrespective of the class. Nonetheless, we will show that sensible classification on data sets generated from this model can still be achieved provided that appropriate amendments to the classification algorithms are enforced, due to the small fluctuations around these flat asymptotic limit of scores. This flat limit is reminiscent of the work by Nadler et al. (2009) where the authors show that the scores indeed share the same limit, irrespective of the class, in the presence of infinitely many unlabelled samples but for $p \geq 2$ fixed. Yet, despite the scores flatness, the authors experimentally observed non-trivial classification in binary tasks thanks to the small difference between scores; they however did not provide any theoretical support for such behavior, for they analysis failed to recover the small fluctuations.

Inspired by Avrachenkov et al. (2011), we generalize here the algorithm proposed in Zhu et al. (2003) by introducing a normalization parameter α in the cost function in order to design a large class of regularized affinity-based methods, among which are found the traditional Laplacian- and normalized Laplacian-based algorithms. The generalized optimization framework is presented in Section 2.

The main contribution of the present work is to provide a quantitative performance study of the generalized graph-based semi-supervised algorithm for large dimensional Gaussian-mixture data and radial kernels, technically following the random matrix approach developed by Couillet and Benaych-Georges (2015). Our main findings are summarized as follows:

- Irrespective of the choice of the data affinity matrix, the classification outcome is strongly biased by *the number of labelled data from each class* and unlabelled data tend to be classified into the class with most labelled nodes; we propose a normalization update of the standard algorithms to correct this limitation.

- Once the aforementioned bias corrected, the choice of the affinity matrix (and thus of the parameter α) strongly impacts the performances; most importantly, within our framework, both *standard Laplacian* ($\alpha = 0$ here) and *normalized Laplacian-based* ($\alpha = -\frac{1}{2}$) methods, although widely discussed in the literature, fail in the large dimensional data regime. Of the family of algorithms discussed above, only the *PageRank* approach ($\alpha = -1$) is shown to provide asymptotically acceptable results.

- The scores of belonging to each class attributed to individual nodes by the algorithms are shown to asymptotically follow a *Gaussian distribution* with mean and covariance depending on the statistical properties of classes, the ratio of labelled versus unlabelled data, and the value of the first derivatives of the kernel function at the limiting value τ of $\frac{1}{p}\|x_i - x_j\|^2$ (which we recall is irrespective of the genuine classes of x_i, x_j). This last finding notably allows one to *predict the asymptotic performances* of the semi-supervised learning algorithms.

- From the latter result, three main outcomes unfold:
  - when three classes or more are considered, there exist Gaussian mixture models for which classification is shown to be *impossible*;
  - despite PageRank's consistency, we further justify that the choice $\alpha = -1$ is not in general optimal. For the case of 2-class learning, we provide a method to approach the optimal value of α; this method is demonstrated on real data sets to convey sometimes *dramatic improvements* in correct classification rates.
  - for a 2-class learning task, necessary and sufficient conditions for asymptotic consistency are: $f'(\tau) < 0$, $f''(\tau) > 0$ and $f''(\tau)f(\tau) > f'(\tau)^2$; in particular, Gaussian kernels, failing to meet the last condition, cannot deal with the large dimensional version of the "concentric spheres" task.

Throughout the article, theoretical results and related discussions are confirmed and illustrated with simulations on Gaussian-mixture data as well as the popular MNIST data (LeCun et al., 1998), which serves as a comparison for our theoretical study on real world data sets. The consistent match of our theoretical findings on MNIST data, despite their departing from the very large dimensional and Gaussian-mixture assumption, suggests that our results have a certain robustness to these assumptions and can be applied to a larger range of data. We indeed believe that, while only the limiting behavior of Gaussian mixture inputs is characterized in this article (mostly for technical reasons), the analysis reveals certain properties inherent to graph-based SSL methods, which extend well beyond the Gaussian hypothesis.

Notations: $\boldsymbol{\delta}_a^b$ is a binary function taking the value of 1 if $a = b$ or that of 0 if not. 1_n is the column vector of ones of size n, I_n the $n \times n$ identity matrix. The norm $\|\cdot\|$ is the Euclidean norm for vectors and the operator norm for matrices. The operator $\mathrm{diag}(v) = \mathrm{diag}\{v_a\}_{a=1}^k$ is the diagonal matrix having $v_1, \ldots, v_k$ as its ordered diagonal elements. $O(\cdot)$ is the same as specified in the work of Couillet and Benaych-Georges (2015): for a random

variable $x \equiv x_n$ and $u_n \geq 0$, we write $x = O(u_n)$ if for any $\eta > 0$ and $D > 0$, we have $n^D \mathrm{P}(x \geq n^\eta u_n) \to 0$. When multidimensional objects are concerned, for a vector (or a diagonal matrix)v, $v = O(u_n)$ means the maximum entry in absolute value is $O(u_n)$ and for a square matrix M, $M = O(u_n)$ means that the operator norm of M is $O(u_n)$.

2. Optimization Framework

Let $x_1, \ldots, x_n \in \mathbb{R}^p$ be n data vectors belonging to K classes $\mathcal{C}_1, \ldots, \mathcal{C}_K$. The class association of the $n_{[l]}$ vectors $x_1, \ldots, x_{n_{[l]}}$ is known (these vectors will be referred to as *labelled*), while the class of the remaining $n_{[u]}$ vectors $x_{n_{[l]}+1}, \ldots, x_n$ ($n_{[l]} + n_{[u]} = n$) is unknown (these are referred to as *unlabelled* vectors). Within both labelled and unlabelled subsets, the data are organized in such a way that the $n_{[l]1}$ first vectors $x_1, \ldots, x_{n_{[l]1}}$ belong to class $\mathcal{C}_1$, $n_{[l]2}$ subsequent vectors to $\mathcal{C}_2$, and so on, and similarly for the $n_{[u]1}, n_{[u]2}, \ldots$ first vectors of the set $x_{n_{[l]}+1}, \ldots, x_n$. Note already that this ordering is for notational convenience and shall not impact the generality of our results.

The affinity relation between the vectors $x_1, \ldots, x_n$ is measured from the weight matrix W defined by

$$W \equiv \left\{ f\left(\frac{1}{p} \|x_i - x_j\|^2 \right) \right\}_{i,j=1}^n$$

for some function f. The matrix W may be seen as the adjacency matrix of the n-node graph indexed by the vectors $x_1, \ldots, x_n$. We further denote by D the diagonal matrix with $D_{ii} \equiv d_i = \sum_{j=1}^n W_{ij}$ the degree of the node associated to x_i.

We next define a score matrix $F \in \mathbb{R}^{n \times K}$ with F_{ik} representing the evaluated score for x_i to belong to $\mathcal{C}_k$. In particular, following the conventions typically used in graph-based semi-supervised learning (Chapelle et al., 2006), we shall affect a unit score $F_{ik} = 1$ if x_i is a labelled data of class $\mathcal{C}_k$ and a null score for all $F_{ik'}$ with $k' \neq k$. In order to attribute classes to the unlabelled data, scores are first affected by means of the resolution of an optimization framework. We propose here

$$\begin{aligned} F &= \mathrm{argmin}_{F \in \mathbb{R}^{n \times k}} \sum_{k=1}^K \sum_{i,j=1}^n W_{ij} \left\| d_i^\alpha F_{ik} - d_j^\alpha F_{jk} \right\|^2 \\ \text{s.t. } F_{ik} &= \begin{cases} 1, & \text{if } x_i \in \mathcal{C}_k \\ 0, & \text{otherwise} \end{cases}, \; 1 \leq i \leq n_{[l]}, \; 1 \leq k \leq K \end{aligned} \tag{1}$$

where $\alpha \in \mathbb{R}$ is a given parameter. The interest of this generic formulation is that it coincides with the standard Laplacian-based approach for $\alpha = 0$ and with the normalized Laplacian-based approach for $\alpha = -\frac{1}{2}$, both discussed in Section 1. Note importantly that Equation (1) is naturally motivated by the observation that large values of W_{ij} enforce close values for F_{ik} and F_{jk} while small values for W_{ij} allow for more freedom in the choice of F_{ik} and F_{jk}.

By denoting

$$F = \begin{bmatrix} F_{[l]} \\ F_{[u]} \end{bmatrix}, \; W = \begin{bmatrix} W_{[ll]} & W_{[lu]} \\ W_{[ul]} & W_{[uu]} \end{bmatrix}, \text{ and } D = \begin{bmatrix} D_{[l]} & 0 \\ 0 & D_{[u]} \end{bmatrix}$$

with $F_{[l]} \in \mathbb{R}^{n_{[l]}}$, $W_{[ll]} \in \mathbb{R}^{n_{[l]} \times n_{[l]}}$, $D_{[l]} \in \mathbb{R}^{n_{[l]} \times n_{[l]}}$, one easily finds (since the problem is a convex quadratic optimization with linear equality constraints) the solution to (1) is explicitly given by

$$F_{[u]} = \left(I_{n_u} - D_{[u]}^{-1-\alpha} W_{[uu]} D_{[u]}^\alpha \right)^{-1} D_{[u]}^{-1-\alpha} W_{[ul]} D_{[l]}^\alpha F_{[l]}. \tag{2}$$

Once these scores are affected, a mere comparison between all scores $F_{i1}, \ldots, F_{iK}$ for unlabelled data x_i (i.e., for $i > n_{[l]}$) is performed to decide on its class, i.e., the allocated class index $\hat{\mathcal{C}}_{x_i}$ for vector x_i is given by

$$\hat{\mathcal{C}}_{x_i} = \mathcal{C}_{\hat{k}} \text{ for } \hat{k} = \mathrm{argmax}_{1 \leq k \leq K} F_{ik}.$$

Note in passing that the formulation (2) implies in particular that

$$F_{[u]} = D_{[u]}^{-1-\alpha} W_{[uu]} D_{[u]}^\alpha F_{[u]} + D_{[u]}^{-1-\alpha} W_{[ul]} D_{[l]}^\alpha F_{[l]} \tag{3}$$

$$F_{[l]} = \{ \boldsymbol{\delta}_{x_i \in \mathcal{C}_k} \}_{\substack{1 \leq i \leq n_{[l]} \\ 1 \leq k \leq K}} \tag{4}$$

and thus the matrix F is a stationary point for the algorithm constituted of the updating rules (3) and (4) (when replacing the equal signs by affectations). In particular, for $\alpha = -1$, the algorithm corresponds to the standard label propagation method found in the PageRank algorithm for semi-supervised learning as discussed in Avrachenkov et al. (2011), with the major difference that $F_{[l]}$ is systematically reset to its known value while in the study of Avrachenkov et al. (2011), $F_{[l]}$ is allowed to evolve (for reasons related to robustness to pre-labeling errors).

The technical objective of the article is to analyze the behavior of $F_{[u]}$ in the large n, p regime for a Gaussian mixture model for the data $x_1, \ldots, x_n$. To this end, we shall first need to design appropriate growth rate conditions for the Gaussian mixture statistics as $p \to \infty$ (in order to avoid trivializing the classification problem as p grows large) before proceeding to the evaluation of the behavior of W, D, and thus F.

3. Model and Theoretical Results

3.1. Model and Assumptions

In the remainder of the article, we shall assume that the data $x_1, \ldots, x_n$ are extracted from a Gaussian mixture model composed of K classes. Specifically, for $k \in \{1, \ldots, K\}$,

$$x_i \in \mathcal{C}_k \Leftrightarrow x_i \sim \mathcal{N}(\mu_k, C_k).$$

Consistently with the previous section, for each k, there are n_k instances of vectors of class $\mathcal{C}_k$, among which $n_{[l]k}$ are labelled and $n_{[u]k}$ are unlabelled.

As pointed out above, in the regime where $n, p \to \infty$, special care must be taken to ensure that the classes $\mathcal{C}_1, \ldots, \mathcal{C}_K$, the statistics of which evolve with p, remain at a "somewhat constant" distance from each other. This is to ensure that the classification problem does not become asymptotically infeasible nor trivially simple as $p \to \infty$. Based on the earlier work (Couillet and Benaych-Georges, 2015) where similar considerations were made, the behavior of the class means, covariances, and cardinalities will follow the prescription below:

Assumption 1 (Growth Rate) *As* $n \to \infty$, $\frac{p}{n} \to c_0 > 0$ *and* $\frac{n_{[l]}}{n} \to c_{[l]} > 0$, $\frac{n_{[u]}}{n} \to c_{[u]} > 0$. *For each* k, $\frac{n_k}{n} \to c_k > 0$, $\frac{n_{[l]k}}{n} \to c_{[l]k} > 0$, $\frac{n_{[u]k}}{n} \to c_{[u]k} > 0$. *Besides,*

1. For $\mu^\circ \triangleq \sum_{k=1}^K \frac{n_k}{n}\mu_k$ and $\mu_k^\circ \triangleq \mu_k - \mu^\circ$, $\|\mu_k^\circ\| = O(1)$.
2. For $C^\circ \triangleq \sum_{k=1}^K \frac{n_k}{n} C_k$ and $C_k^\circ \triangleq C_k - C^\circ$, $\|C_k\| = O(1)$ and $\mathrm{tr} C_k^\circ = O(\sqrt{p})$.
3. As $n \to \infty$, $\frac{2}{p}\mathrm{tr} C^\circ \to \tau \neq 0$.
4. As $n \to \infty$, $\alpha = O(1)$.

It will also be convenient in the following to define

$$t_k \equiv \frac{1}{\sqrt{p}} \mathrm{tr}\, C_k^\circ$$
$$T_{kk'} \equiv \frac{1}{p} \mathrm{tr}\, C_k C_{k'}$$

as well as the labelled-data centered notations

$$\tilde{\mu}_k \equiv \mu_k - \sum_{k'=1}^K \frac{n_{[l]k'}}{n_{[l]}} \mu_{k'}$$
$$\tilde{C}_k \equiv C_k - \sum_{k'=1}^K \frac{n_{[l]k'}}{n_{[l]}} C_{k'}$$
$$\tilde{t}_k \equiv \frac{1}{\sqrt{p}} \mathrm{tr}\, \tilde{C}_k$$
$$\tilde{T}_{kk'} \equiv \frac{1}{p} \mathrm{tr}\, \tilde{C}_k \tilde{C}_{k'}.$$

A few comments on Assumption 1 are in order. First note that, unlike in the previous works (Nadler et al., 2009; Globerson et al., 2017) where the number of labelled data $n_{[l]}$ and data dimension p are considered fixed and the number of unlabelled data $n_{[u]}$ is supposed to be infinite, we assume a regime where $n_{[l]}, n_{[u]}$ and p are simultaneously large. Letting p large allows us to investigate SSL in the context of large dimensional data. Further imposing that $n_{[l]}, n_{[u]}$ grow at a controlled rate with respect to p (here at the same rate) allows for an *exact characterization* of the limiting SSL performances, as a function of the hyperparameters α, f and data statistics μ_k, C_k, in non-trivial classification scenarios (i.e., when classification is neither asymptotically perfect nor impossible), instead of solely retrieving consistency bounds as a function of growth rates in $p, n_{[l]}, n_{[u]}$. This in turn allows for possible means of precise parameter setting to reach optimal performances (which is not possible with results based on bounds). While it may be claimed that SSL in practice often handles scenarios where $n_{[u]} \gg n_{[l]}$, assuming that $n_{[u]}, n_{[l]}$ are of the same order but that $n_{[u]}$ is multiple times $n_{[l]}$ actually maintains the validity of our results so long that $n_{[l]}$ is not too small. To be more exact, our results are still valid in the limit where $c_{[l]} \to 0$, but then become trivial, as numerically confirmed by Figure 5. To consider the setting where

$n_{[l]}$ is fixed while $p, n_{[u]}$ grow large would demand a change in the statistical assumptions of the input data sets, which goes beyond the scope of the present investigation.

Item 3. of Assumption 1 is mostly a technical convenience that shall simplify our analysis, but our results naturally extend as long as both liminf and limsup of $\frac{2}{p}\mathrm{tr} C^\circ$ are away from zero or infinity. The necessity of Item 1. only appears through a detailed analysis of spectral properties of the weight matrix W for large n, p, carried out later in the article. As for Item 2., note that if $\mathrm{tr}\, C_k^\circ = O(\sqrt{p})$ were to be relaxed, it is easily seen that a mere (unsupervised) comparison of the values of $\|x_i\|^2$ would asymptotically provide an almost surely perfect classification.

As a by-product of imposing the growth constraints on the data to ensure non-trivial classification, Assumption 1 induces the following seemingly unsettling implication, easily justified by a simple concentration of measure argument

$$\max_{1 \leq i,j \leq n} \left| \frac{1}{p}\|x_i - x_j\|^2 - \tau \right| \xrightarrow{\text{a.s.}} 0 \tag{5}$$

as $p \to \infty$. Equation (5) is the cornerstone of our analysis and states that all vector pairs x_i, x_j are essentially at the same distance from one another as p gets large, *irrespective of their classes*. This striking result evidently is in sharp opposition to the very motivation for the optimization formulation (1) as discussed in the introduction. It thus immediately entails that the solution (2) to (1) is bound to produce asymptotically inconsistent results. We shall see that this is indeed the case for all but a short range of values of α.

This being said, Equation (5) has an advantageous side as it allows for a Taylor expansion of $W_{ij} = f(\frac{1}{p}\|x_i - x_j\|^2)$ around $f(\tau)$, provided f is sufficiently smooth around τ, which is ensured by our subsequent assumption.

Assumption 2 (Kernel function) *The function* $f : \mathbb{R}^+ \to \mathbb{R}$ *is three-times continuously differentiable in a neighborhood of* τ.

Note that Assumption 2 does not constrain f aside from its local behavior around τ. In particular, we shall not restrict ourselves to matrices W arising from nonnegative definite kernels as standard machine learning theory would advise (Schölkopf and Smola, 2002).

The core technical part of the article now consists in expanding W, and subsequently all terms intervening in (2), in a Taylor expansion of successive matrices of *non-vanishing operator norm*. Note indeed that the magnitude of the individual entries in the Taylor expansion of W needs not follow the magnitude of the operator norm of the resulting matrices;[1] rather, great care must be taken to only retain those matrices of non-vanishing operator norm. These technical details call for advanced random matrix considerations and are discussed in the appendix and in Couillet and Benaych-Georges (2015).

We are now in position to introduce our main technical results.

3.2. Main Theoretical Results

In the course of this section, we provide in parallel a series of technical results under the proposed setting (notably under Assumption 1) along with simulation results both on a

1. For instance, $\|I_n\| = 1$ while $\|1_n 1_n^\mathrm{T}\| = n$ despite both matrices having entries of similar magnitude.

2-class Gaussian mixture data model with $\mu_1 = [4; 0_{p-1}]$, $\mu_2 = [0; 4; 0_{p-2}]$, $C_1 = I_p$ and $\{C_2\}_{i,j} = .4^{|i-j|}(1 + \frac{3}{\sqrt{p}})$, as well as on real data sets, here images of eights and nines from the MNIST database (LeCun et al., 1998), for $f(t) = \exp(-\frac{1}{2}t)$, i.e., the classical Gaussian (or heat) kernel. For reasons that shall become clear in the following discussion, these figures will depict the (size n) vectors

$$\left[F^\circ_{[u]}\right]_{\cdot k} \equiv \left[F_{[u]}\right]_{\cdot k} - \frac{1}{K}\sum_{k'=1}^{K}\left[F_{[u]}\right]_{\cdot k'}$$

for $k \in \{1, 2\}$. Obviously, the decision rule on $F^\circ_{[u]}$ is the same as that on $F_{[u]}$.

Our first hinging result concerns the behavior of the score matrix F in the large n, p regime, as per Assumption 1, and reads as follows.

Proposition 1 *Let Assumptions 1–2 hold. Then, for $i > n_{[l]}$ (i.e., for x_i an unlabelled vector),*

$$F_{ik} = \frac{n_{[l]k}}{n}\left[1 + \underbrace{(1+\alpha)\frac{f'(\tau)}{f(\tau)}\frac{t_k}{\sqrt{p}} + z_i}_{O(n^{-\frac{1}{2}})} + O(n^{-1})\right] \tag{6}$$

where $z_i = O(n^{-\frac{1}{2}})$ is a random variable, function of x_i, but independent of k.

The proof of Proposition 1 is given as an intermediary result of the proof of Theorem 5 in the appendix.

Proposition 1 provides a clear overview of the outcome of the semi-supervised learning algorithm. First note that $F_{ik} = c_{[l]k} + O(n^{-\frac{1}{2}})$. Therefore, irrespective of x_i, F_{ik} is strongly biased towards $c_{[l]k}$. If the values $n_{[l]1}, \ldots, n_{[l]k}$ differ by $O(n)$, this induces a systematic asymptotic allocation of every x_i to the class having largest $c_{[l]k}$ value. Figure 1 illustrates this phenomenon, observed both on synthetic and real data sets, here for $n_{[l]1} = 3n_{[l]2}$.

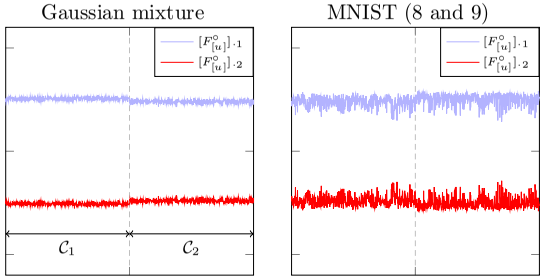

Figure 1: $[F^\circ_{[u]}]_{\cdot 1}$ and $[F^\circ_{[u]}]_{\cdot 2}$ for 2-class data, $n = 1024$, $p = 784$, $n_l/n = 1/16$, $n_{[u]1} = n_{[u]2}$, $n_{[l]1} = 3n_{[l]2}$, $\alpha = -1$, Gaussian kernel.

Pursuing the analysis of Proposition 1 by now assuming that $n_{[l]1} = \ldots = n_{[l]K}$, the comparison between $F_{i1}, \ldots, F_{iK}$ next revolves around the term of order $O(n^{-\frac{1}{2}})$. Since z_i only depends on x_i and not on k, it induces a constant offset to the vector $F_{i\cdot}$, thereby not intervening in the class allocation. On the opposite, the term t_k is independent of x_i but may vary with k, thereby possibly intervening in the class allocation, again an undesired effect. Figure 2 depicts the effect of various choices of α for equal values of $n_{[l]k}$. This deleterious outcome can be avoided either by letting $f'(\tau) = O(n^{-\frac{1}{2}})$ or $\alpha = -1 + O(n^{-\frac{1}{2}})$. But, as discussed in the study of Couillet and Benaych-Georges (2015) and later in the article, the choice of f such that $f'(\tau) \simeq 0$, if sometimes of interest, is generally inappropriate.

The discussion above thus induces two important consequences to adapt the semi-supervised learning algorithm to large data.

1. The final comparison step *must* be made upon the normalized scores

$$\hat{F}_{ik} \equiv \frac{n}{n_{[l]k}}F_{ik} \tag{7}$$

   rather than upon the scores F_{ik} directly.

2. The parameter α *must* be chosen in such a way that

$$\alpha = -1 + O(n^{-\frac{1}{2}}).$$

Under these two amendments of the algorithm, according to Proposition 1, the performance of the semi-supervised learning algorithm now relies upon terms of magnitude $O(n^{-1})$, which are so far left undefined. A thorough analysis of these terms allows for a complete understanding of the asymptotic behavior of the normalized scores $\hat{F}_{i\cdot} = (\hat{F}_{i1}, \ldots, \hat{F}_{iK})$, as presented in our next result.

Theorem 2 *Let Assumptions 1–2 hold. For $i > n_{[l]}$ (i.e., x_i unlabelled) with $x_i \in \mathcal{C}_b$, let $\hat{F}_{ia}$ be given by (7) with F defined in (2) and $\alpha = -1 + \frac{\beta}{\sqrt{p}}$ for $\beta = O(1)$. Then,*

$$p\hat{F}_{i\cdot} = p(1 + z_i)1_K + G_i + o_P(1) \tag{8}$$

where $z_i = O(\sqrt{p})$ is as in Proposition 1 and $G_i \sim \mathcal{N}(m_b, \Sigma_b)$, $i > n_{[l]}$, are independent with

$$[m_b]_a = -\frac{2f'(\tau)}{f(\tau)}\tilde{\mu}_a^\mathsf{T}\tilde{\mu}_b + \left(\frac{f''(\tau)}{f(\tau)} - \frac{f'(\tau)^2}{f(\tau)^2}\right)\tilde{t}_a\tilde{t}_b + \frac{2f''(\tau)}{f(\tau)}\tilde{T}_{ab} + \frac{\beta}{c_{[l]}}\frac{f'(\tau)}{f(\tau)}t_a \tag{9}$$

$$[\Sigma_b]_{a_1a_2} = 2\left(\frac{f''(\tau)}{f(\tau)} - \frac{f'(\tau)^2}{f(\tau)^2}\right)^2 T_{bb}t_{a_1}t_{a_2} + 4\frac{f'(\tau)^2}{f(\tau)^2}\left[\mu_{a_1}^{\circ\mathsf{T}}C_b\mu_{a_2}^\circ + \boldsymbol{\delta}_{a_1a_2}\frac{c_0T_{b,a_1}}{c_{[l]}c_{[l]a_1}}\right]. \tag{10}$$

Besides, there exists $\mathcal{A} \subset \sigma(\{\{x_1, \ldots, x_{n_{[l]}}\}, p = 1, 2, \ldots\})$ (the σ-field induced by the labelled variables) with $P(\mathcal{A}) = 1$ over which (8) also holds conditionally to $\{\{x_1, \ldots, x_{n_{[l]}}\}, p = 1, 2, \ldots\}$.

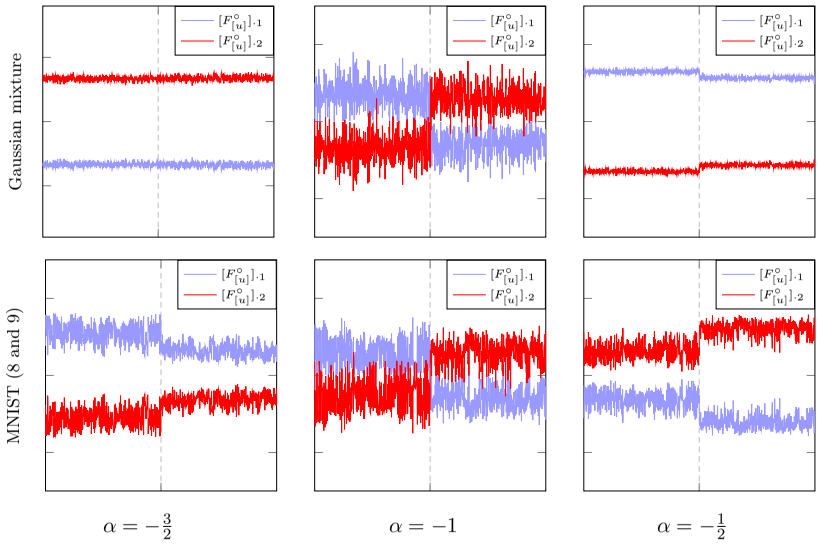

Figure 2: $[F^\circ_{[u]}]_{\cdot 1}$, $[F^\circ_{[u]}]_{\cdot 2}$ for 2-class data, $n = 1024$, $p = 784$, $n_l/n = 1/16$, $n_{[u]1} = n_{[u]2}$, $n_{[l]1} = n_{[l]2}$, Gaussian kernel.

Note that the statistics of G_i are independent of the realization of $x_1, \ldots, x_{[l]}$ when $\alpha = -1 + O(\frac{1}{\sqrt{p}})$. This in fact no longer holds when α is outside this regime, as pointed out by Theorem 5 in the appendix which provides the asymptotic behavior of $\hat{F}_{i\cdot}$ for all values of α (and thus generalizes Theorem 2).

Since the ordering of the entries of $\hat{F}_{i\cdot}$ is the same as that of $\hat{F}_{i\cdot} - (1 + z_i)$, Theorem 2 amounts to saying that the probability of correctly classifying unlabeled vectors x_i genuinely belonging to class $\mathcal{C}_b$ is asymptotically given by the probability of $[G_i]_b$ being the maximal element of G_i, which, as mentioned above, is the same whether conditioned or not on $x_1, \ldots, x_{[l]}$ for $\alpha = -1 + O(\frac{1}{\sqrt{p}})$. This is formulated in the following corollary.

Corollary 3 *Let Assumptions 1–2 hold. Let $i > n_{[l]}$ and $\alpha = -1 + \frac{\beta}{\sqrt{p}}$. Then, under the notations of Theorem 2,*

$$\mathbb{P}\left(x_i \to \mathcal{C}_b | x_i \in \mathcal{C}_b, x_1, \cdots, x_{n_{[l]}}\right) - \mathbb{P}\left(x_i \to \mathcal{C}_b | x_i \in \mathcal{C}_b\right) \to 0$$
$$\mathbb{P}\left(x_i \to \mathcal{C}_b | x_i \in \mathcal{C}_b\right) - \mathbb{P}\left([G_i]_b > \max_{a \neq b} \{[G_i]_a\} | x_i \in \mathcal{C}_b\right) \to 0.$$

In particular, for $K = 2$, and $a \neq b \in \{1, 2\}$,

$$\mathbb{P}\left([G_i]_b > \max_{a \neq b} \{[G_i]_a\} | x_i \in \mathcal{C}_b\right) = \Phi(\theta_b^a), \quad \text{with } \theta_b^a \equiv \frac{[m_b]_b - [m_b]_a}{\sqrt{[\Sigma_b]_{bb} + [\Sigma_b]_{aa} - 2[\Sigma_b]_{ab}}}$$

where $\Phi(u) = \frac{1}{2\pi} \int_{-\infty}^{u} e^{-\frac{t^2}{2}} dt$ is the Gaussian distribution function.

With G_i being independent, Corollary 3 allows us to approach the empirical classification accuracy as it is consistently estimated by the probability of correct classification given in the corollary. As with Theorem 2 which can be appended to Theorem 5 for a large set of values of α, Corollary 3 is similarly generalized by Corollary 6 in the appendix. Using both corollaries, Figure 3 displays a comparison between simulated accuracies from various pairs of digits from the MNIST data against our theoretical results; to apply our results, a 2-class Gaussian mixture model is assumed with means and covariances equal to the empirical means and covariances of the individual digits, evaluated from the full 60 000-image MNIST database. It is quite interesting to observe that, despite the obvious inadequacy of a Gaussian mixture model for this image database, the theoretical predictions are in strong agreement with the practical performances. Also surprising is the strong adequacy of the theoretical prediction of Corollary 3 beyond the range of values of α in the neighborhood of -1.

4. Consequences

4.1. Semi-Supervised Learning beyond Two Classes

An immediate consequence of Corollary 3 is that, for $K > 2$, there exists a Gaussian mixture model for which the semi-supervised learning algorithms under study necessarily fail to classify at least one class. To see this, we consider $K = 3$ and let $\mu_3 = 3\mu_2 = 6\mu_1$, $C_1 = C_2 = C_3$, $n_1 = n_2 = n_3$, $n_{[l]1} = n_{[l]2} = n_{[l]3}$. First, it follows from Corollary 3 that,

$$\mathbb{P}(x_i \to \mathcal{C}_2 | x_i \in \mathcal{C}_2) \leq \mathbb{P}([G_i]_2 > [G_i]_1 | x_i \in \mathcal{C}_2) + o(1) = \Phi(\theta_2^1) + o(1)$$
$$\mathbb{P}(x_i \to \mathcal{C}_3 | x_i \in \mathcal{C}_3) \leq \mathbb{P}([G_i]_3 > [G_i]_1 | x_i \in \mathcal{C}_3) + o(1) = \Phi(\theta_3^1) + o(1)$$

Then, under Assumptions 1–2 and the notations of Corollary 3,

$$\theta_2^1 = \text{sgn}(f'(\tau)) \frac{\mu_1^2}{\sqrt{(\Sigma_2)_{22} + (\Sigma_2)_{11} - 2(\Sigma_2)_{12}}}$$
$$\theta_3^1 = -\text{sgn}(f'(\tau)) \frac{15\mu_1^2}{\sqrt{(\Sigma_3)_{33} + (\Sigma_3)_{11} - 2(\Sigma_3)_{13}}}$$

so that $f'(\tau) < 0 \Rightarrow \theta_2^1 < 0$, $f'(\tau) > 0 \Rightarrow \theta_3^1 < 0$, while $f'(\tau) = 0 \Rightarrow \theta_2^1 = \theta_3^1 = 0$. As such, the correct classification rate of elements of $\mathcal{C}_2$ and $\mathcal{C}_3$ cannot be simultaneously greater than $\frac{1}{2}$, leading to necessarily inconsistent classifications.

It is nonetheless easy to check that this kind of inconsistency cannot occur if μ_1, μ_2 and μ_3 are mutually orthogonal (which is often bound to occur with large dimensional data). Indeed, note that all first three terms at the right-hand side of (9) can be viewed as products of

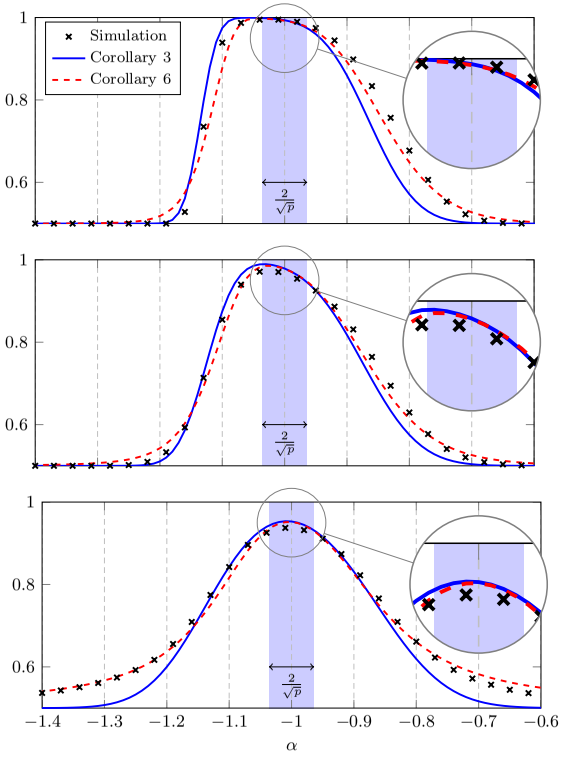

Figure 3: Theoretical and empirical accuracy as a function of α for 2-class MNIST data (top: digits (0,1), middle: digits (1,7), bottom: digits (8,9)), $n = 1024$, $p = 784$, $n_{[l]}/n = 1/16$, $n_{[u]1} = n_{[u]2}$, Gaussian kernel. Averaged over 50 iterations.

some centered vectors $\tilde{v}_k = v_k - \sum_{k'=1}^K \gamma_{k'} v_{k'}$ where $\sum_{k'=1}^K \gamma_{k'} = 1$.[2] Inconsistency occurs to class k if there exist $a, b \neq k$ such that $\tilde{v}_k^T \tilde{v}_b > \tilde{v}_k^T \tilde{v}_k > \tilde{v}_k^T \tilde{v}_a$. To better understand the cause of this inconsistency, let us consider two extreme scenarios: (i) the v_k differ by 'intensity', i.e., $v_k = r_k v$ for $k \in \{1, \cdots, K\}$, or (ii) the v_k differ by 'direction', i.e, $v_k = v + u_k$ with orthogonal u_k's. In scenario (i), let $s_{\min} = \operatorname{argmin}_{k \in \{1,\cdots,K\}} r_k$ and $s_{\max} = \operatorname{argmax}_{k \in \{1,\cdots,K\}} r_k$; then, for $k \neq \{s_{\min}, s_{\max}\}$, $\min\{\tilde{v}_k^T \tilde{v}_{s_{\min}}, \tilde{v}_k^T \tilde{v}_{s_{\max}}\} < \tilde{v}_k^T \tilde{v}_k < \max\{\tilde{v}_k^T \tilde{v}_{s_{\min}}, \tilde{v}_k^T \tilde{v}_{s_{\max}}\}$ and inconsistency is thus observed for classes $k \neq \{s_{\min}, s_{\max}\}$. Contrarily, in scenario (ii), for all

2. The third term of (9) can be seen in this way since for any two symmetric matrices $A = \{a_{ij}\}_{i,j=1}^m$ and $B = \{b_{ij}\}_{i,j=1}^m$ of same dimensions, $\operatorname{tr} AB = \sum_{i,j}^m a_{ij} b_{ij} = a_v^T b_v$ with $a_v = [a_{11}, \cdots, a_{1m}, \cdots, a_{m1}, \cdots, a_{mm}]$, $b_v = [b_{11}, \cdots, b_{1m}, \cdots, b_{m1}, \cdots, b_{mm}]$.

$k \neq k' \in \{1, \cdots, K\}$, $\tilde{v}_k^T \tilde{v}_k \geq \tilde{v}_k^T \tilde{v}_{k'}$ since $\tilde{v}_k^T \tilde{v}_k \geq 0$ and $\tilde{v}_k^T \tilde{v}_{k'} \leq 0$. As such, inconsistency is less likely to occur if the v_k's have very different directions.

4.2. Choice of f and Suboptimality of the Heat Kernel

As a consequence of the previous section, we shall from here on concentrate on the semi-supervised classification of $K = 2$ classes. In this case, it is easily seen that,

$$(K = 2) \quad \forall a \neq b \in \{1, 2\}, \ \|\tilde{\mu}_b\|^2 \geq \tilde{\mu}_b^{\mathsf{T}} \tilde{\mu}_a, \quad \tilde{t}_b^2 \geq \tilde{t}_a \tilde{t}_b, \quad \tilde{T}_{bb} \geq \tilde{T}_{ab}$$

with equalities respectively for $\mu_a = \mu_b$, $t_a = t_b$, and $\operatorname{tr} C_a C_b = \operatorname{tr} C_b^2$. This result, along with Corollary 3, implies the necessity of the conditions

$$f'(\tau) < 0, \quad f''(\tau) f(\tau) > f'(\tau)^2, \quad f''(\tau) > 0$$

to fully discriminate Gaussian mixtures. As such, from Corollary 3, by letting $\alpha = -1$, semi-supervised classification of $K = 2$ classes is always consistent under these conditions.

Since only the first three derivatives of f are involved, one may design a simple kernel for any desired values of $f'(\tau)$, $f''(\tau) f(\tau) - f'(\tau)^2$ and $f''(\tau)$ with a second degree polynomial $f(t) = at^2 + bx + c$ in such a way that $a\tau + b = f'(\tau)$, $a(a\tau^2 + b\tau + c) - (a\tau + b)^2 = f''(\tau) f(\tau) - f'(\tau)^2$ and $a = f''(\tau)$, i.e.,

$$a = f''(\tau) \quad b = f'(\tau) - f''(\tau)\tau \quad c = (f''(\tau) f(\tau) - f'(\tau)\tau^2)/f''(\tau).$$

Since τ can be consistently estimated in practice by (11) (see the discussion in Subsection 5.1), so can a, b, and c.

A quite surprising outcome of the necessary conditions on the derivatives of f is that the widely used Gaussian (or heat) kernel $f(t) = \exp(-\frac{t}{2\sigma^2})$, while fulfilling the condition $f'(t) < 0$ and $f''(t) > 0$ for all t (and thus $f'(\tau) < 0$ and $f''(\tau) > 0$), only satisfies $f''(t) f(t) = f'(t)^2$. This indicates that discrimination over $t_1, \ldots, t_K$, under the conditions of Assumption 1, is asymptotically *not* possible with a Gaussian kernel. This remark is illustrated in Figure 4 for a discriminative task between two centered isotropic Gaussian classes only differing by the trace of their covariance matrices. There, irrespective of the choice of the bandwidth σ, the Gaussian kernel leads to a constant $1/2$ accuracy, where a mere second order polynomial kernel selected upon its derivatives at τ demonstrates good performances. Since p-dimensional isotropic Gaussian vectors tend to concentrate "close to" the surface of a sphere, this thus suggests that Gaussian kernels are not inappropriate to solve the large dimensional generalization of the "concentric spheres" task (for which they are very efficient in small dimensions). In passing, the right-hand side of Figure 4 confirms the need for $f''(\tau) f(\tau) - f'(\tau)^2$ to be positive (there $|f'(\tau)| < 1$) as an accuracy lower than $1/2$ is obtained for $f''(\tau) f(\tau) - f'(\tau)^2 < 0$.

Another interesting fact lies in the choice $f'(\tau) = 0$ (while $f''(\tau) \neq 0$). As already identified by Couillet and Benaych-Georges (2015) and further thoroughly investigated by Couillet and Kammoun (2016), if $t_1 = t_2$ (which can be enforced by normalizing the data set) and $\tilde{T}_{bb} > \tilde{T}_{ba}$ for all $a \neq b \in \{1, 2\}$, then $\Sigma_b = 0$ while $[m_b]_b > [m_b]_a$ for all $b \neq a \in \{1, 2\}$ and thus leading asymptotically to a perfect classification. As such, while Assumption 1 was

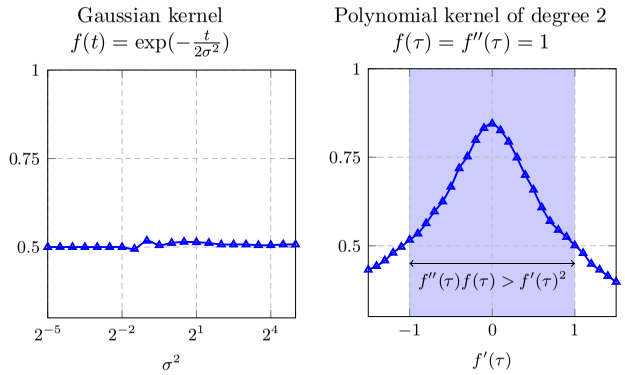

Figure 4: Empirical accuracy for 2-class Gaussian data with $\mu_1 = \mu_2$, $C_1 = I_p$ and $C_2 = (1 + \frac{3}{\sqrt{p}})I_p$, $n = 1024$, $p = 784$, $n_l/n = 1/16$, $n_{[u]1} = n_{[u]2}$, $n_{[l]1} = n_{[l]2}$, $\alpha = -1$.

claimed to ensure a "non-trivial" growth rate regime, asymptotically perfect classification may be achieved by choosing f such that $f'(\tau) = 0$, under the aforementioned statistical conditions. One must nonetheless be careful that this *asymptotic result* does not necessarily entail outstanding performances in practical finite dimensional scenarios. Indeed, note that taking $f'(\tau) = 0$ discards the visibility of differing means $\mu_1 \neq \mu_2$ (from the expression of $[m_b]_a$ in Theorem 2); for finite n, p, cancelling the differences in means (often larger than differences in covariances) may not be compensated for by the reduction in variance. Trials on MNIST particularly emphasize this remark.

4.3. Impact of Class Sizes

A final remark concerns the impact of $c_{[l]}$ and c_0 on the asymptotic performances. Note that $c_{[l]}$ and c_0 only act upon the covariance Σ_b and precisely on its diagonal elements. Both a reduction in c_0 (by increasing n) and an increase in $c_{[l]}$ reduce the diagonal terms in the variance, thereby mechanically increasing the classification performances (if in addition $[m_b]_b > [m_b]_a$ for $a \neq b$). In the opposite case of few labeled data, i.e., $c_{[l]} \to 0$, the variance diverges and the performance tends to that of random classification, as shown in Figure 5.

5. Parameter Optimization in Practice

5.1. Estimation of τ

In previous sections, we have emphasized the importance of selecting the kernel function f so as to meet specific conditions on its derivatives at the quantity τ. In practice however, τ is an unknown quantity. A mere concentration of measure argument nonetheless shows

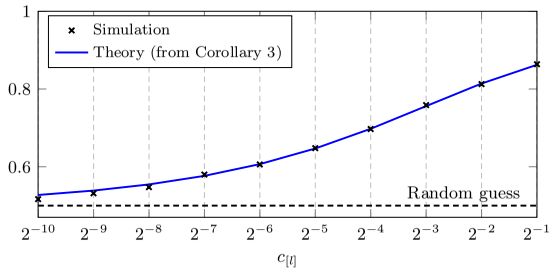

Figure 5: Theoretical and empirical accuracy as a function of $c_{[l]}$ for 2-class Gaussian data with $\mu_2 = 2\mu_1 = [6, 0, \cdots, 0]$, $C_1 = I_p$ and $\{C_2\}_{i,j} = .4^{|i-j|}$, $p = 2048$, $c_0 = 1$, $n_{[u]1} = n_{[u]2}$, $n_{[l]1} = n_{[l]2}$, $\alpha = -1$, Gaussian kernel. Averaged over 50 iterations.

that

$$\hat{\tau} \equiv \frac{1}{n(n-1)} \sum_{i,j=1}^{n} \frac{1}{p} \|x_i - x_j\|^2 \xrightarrow{\text{a.s.}} \tau. \tag{11}$$

As a consequence, the results of Theorem 2 and subsequently of Corollary 3 hold verbatim with $\hat{\tau}$ in place of τ. One thus only needs to design f in such as way that its derivatives at $\hat{\tau}$ meet the appropriate conditions.

5.2. Optimization of α

In Section 4.2, we have shown that the choice $\alpha = -1$, along with an appropriate choice of f, ensures the asymptotic consistency of semi-supervised learning for $K = 2$ classes, in the sense that non-trivial asymptotic accuracy (> 0.5) can be achieved. This choice of α may however not be optimal in general. This subsection is devoted to the optimization of α so as to maximize the average precision, a criterion often used in absence of prior information to favor one class over the other. While not fully able to estimate the optimal $\alpha^\star$ of α, we shall discuss here a heuristic means to select a close-to-optimal α, subsequently denoted α_0.

As per Theorem 2, α must be chosen as $\alpha = -1 + \frac{\beta}{\sqrt{p}}$ for some $\beta = O(1)$. In order to set $\beta = \beta^\star$ in such a way that the classification accuracy is maximized, Corollary 3 further suggests the need to estimate the θ_b^a terms which in turn requires the evaluation of a certain number of quantities appearing in the expressions of m_b and Σ_b. Most of these are however not directly accessible from simple statistics of the data. Instead, we shall propose here a heuristic and simple method to retrieve a reasonable choice β_0 for β, which we claim is often close to optimal and sufficient for most needs.

To this end, first observe from (9) that the mappings $\beta \mapsto [m_b]_a$ satisfy

$$\frac{d}{d\beta}([m_b]_b - [m_b]_a) = \frac{f'(\tau)}{f(\tau)c_{[l]}}(t_b - t_a) = -\frac{d}{d\beta}([m_a]_a - [m_a]_b).$$

Hence, changes in β induce a simultaneous reduction and increase of either one of $[m_b]_b - [m_b]_a$ and $[m_a]_a - [m_a]_b$. Placing ourselves again in the case $K = 2$, we define β_0 to be the value for which both differences (with $a \neq b \in \{1, 2\}$) are the same, leading to the following Proposition–Definition.

Proposition 4 *Let $K = 2$ and $[m_b]_a$ be given by (9). Then*

$$\beta_0 \equiv \frac{f(\tau)}{f''(\tau)} \frac{c_{[l]1} - c_{[l]2}}{t_1 - t_2} \Delta m \tag{12}$$

where

$$\Delta m = -\frac{2f'(\tau)}{f(\tau)} \|\mu_1 - \mu_2\|^2 + \left(\frac{f''(\tau)}{f(\tau)} - \frac{f'(\tau)^2}{f(\tau)^2} \right) (t_1 - t_2)^2 + \frac{2f''(\tau)}{f(\tau)} (T_{11} + T_{22} - 2T_{12})$$

is such that, for $\alpha = -1 + \frac{\beta_0}{\sqrt{p}}$, $[m_1]_1 - [m_1]_2 = [m_2]_2 - [m_2]_1$.

By choosing $\alpha = \alpha_0 \equiv -1 + \frac{\beta_0}{\sqrt{p}}$, one ensures that $\mathbb{E}_{x_i \in \mathcal{C}_1}[\hat{F}_{i1} - \hat{F}_{i2}] = -\mathbb{E}_{x_i \in \mathcal{C}_2}[\hat{F}_{i1} - \hat{F}_{i2}] + o(1)$ ($i > n_{[l]}$), thereby evenly balancing the *average* "resolution" of each class. An even balance typically produces the desirable output of the central displays of Figure 2 (as opposed to the largely undesirable bottom of top displays, there for very offset values of α). Obviously though, since the variances of $\hat{F}_{i1} - \hat{F}_{i2}$ for $x_i \in \mathcal{C}_1$ or $x_i \in \mathcal{C}_2$ are in general not the same, this choice of α may not be optimal. Nonetheless, in most experimental scenarios of practical interest, the score variances tend to be sufficiently similar for the choice of α_0 to be quite appealing.

This heuristic motivation made, note that β_0 is proportional to $c_{[l]b} - c_{[l]a}$. This indicates that the more unbalanced is the labelled data set, the more deviated from zero is β_0. In particular, for $n_{[l]1} = n_{[l]2}$, $\alpha_0 = -1$. As we shall subsequently observe in simulations, this remark is of dramatic importance in practice where taking $\alpha = -1$ (the PageRank method) in place of $\alpha = \alpha_0$ leads to significant performance losses.

Of utmost importance here is the fact that, unlike θ_0^a which are difficult to assess empirically, a consistent estimate of β_0 can be obtained through a rather simple method, which we presently elaborate on.

While an estimate for t_a and T_{ab} can be obtained empirically from the labelled data themselves, $\|\mu_1 - \mu_2\|^2$ is not directly accessible (note indeed that $\frac{1}{n_{[l]a}} \sum_{\mathcal{C}_a} x_i = \mu_a + \frac{1}{n_{[l]a}} \sum_{\mathcal{C}_a} w_i$, for some $w_i \sim \mathcal{N}(0, C_a)$, and the central limit theorem guarantees that $\|\frac{1}{n_{[l]a}} \sum_{\mathcal{C}_a} w_i\| = O(1)$, the same order of magnitude as $\|\mu_a - \mu_b\|$). However, one may access an estimate for Δm by running two instances of the PageRank algorithm ($\alpha = -1$), resulting in the method described in Algorithm 1. It is easily shown that, under Assumptions 1–2,

$$\hat{\beta}_0 - \beta_0 \xrightarrow{\text{a.s.}} 0.$$

Figure 6 provides a performance comparison, in terms of average precision, between the PageRank ($\alpha = -1$) method and the proposed heuristic improvement for $\alpha = \alpha_0$, versus the oracle estimator for which $\alpha = \alpha^\star$, the precision-maximizing value. The curves are here

Algorithm 1 Estimate $\hat{\beta}_0$ of β_0.

1: Let $\hat{\tau}$ be given by (11).
2: Let

$$\widehat{\Delta t} = \frac{1}{2\sqrt{p}} \left(\frac{\sum_{i,j=1}^{n_{[l]1}} \|x_i - x_j\|^2}{n_{[l]1}(n_{[l]1} - 1)} - \frac{\sum_{i,j=n_{[l]1}+1}^{n_{[l]}} \|x_i - x_j\|^2}{n_{[l]2}(n_{[l]2} - 1)} \right)$$

3: Set $\alpha = -1$ and define $J \equiv p \sum_{i=n_{[l]}+1}^{n} \hat{F}_{i1} - \hat{F}_{i2}$.
4: Still for $\alpha = -1$, reduce the set of labelled data to $n'_{[l]1} = n'_{[l]2} = \min\{n_{[l]1}, n_{[l]2}\}$ and, with obvious notations, let $J' \equiv p \sum_{i=n'_{[l]}+1}^{n} \hat{F}'_{i1} - \hat{F}'_{i2}$.
5: Return $\hat{\beta}_0 \equiv \frac{c_{[l]} f(\hat{\tau})}{f'(\hat{\tau}) \widehat{\Delta t}} \frac{J' - J}{n_{[u]}}$.

snapshots of typical classification precision obtained from examples of $n = 4096$ images with $c_{[l]} = 1/16$. As expected, the gain in performance is largest as $|c_{[l]1} - c_{[l]2}|$ is large. More surprisingly, the performances obtained are impressively close to optimal. It should be noted though that simulations revealed more unstable estimates of $\hat{\beta}_0$ for smaller values of n.

Note that the method for estimating β_0 provided in Algorithm 1 implicitly exploits the resolution of two equations (through the observation of J, J' obtained for different values of $n_{[l]1}, n_{[l]2}$) to retrieve the value of Δm defined in Proposition 4. Having access to Δm further allows access to $\|\mu_1 - \mu_2\|^2$, for instance by setting f so that $f''(\tau) = 0$ and $f''(\tau) f(\tau) = f'(\tau)^2$. This in turn allows access to all terms intervening in $[m_b]_a$ (as per (9)), making it possible to choose f so to maximize the distances $|[m_1]_1 - [m_1]_2|$ and $|[m_2]_2 - [m_2]_1|$. However, in addition to the cumbersome aspect of the induced procedure (and the instability implied by multiple evaluations of the scores F under several settings for f and $c_{[l]a}$), such operations also alter the values of the variances in (10) for which not all terms are easily estimated. It thus seems more delicate to derive a simple method to optimize f in addition to α.

6. Concluding Remarks

This article is part of a series of works consisting in evaluating the performance of kernel-based machine learning methods in the large dimensional data regime (Couillet and Benaych-Georges, 2015; Liao and Couillet, 2017; Couillet and Kammoun, 2016). Relying on the derivations of Couillet and Benaych-Georges (2015) that provide a Taylor expansion of radial kernel matrices around the limiting common value τ of $\frac{1}{p}\|x_i - x_j\|^2$ for $i \neq j$ and $p \to \infty$, we observed that the choice of the kernel function f merely affects the classification performances through the successive derivatives of f at τ. In particular, similar to the earlier analyses (Couillet and Benaych-Georges, 2015; Liao and Couillet, 2017; Couillet and Kammoun, 2016), we found that the case $f'(\tau) = 0$ induces a sharp phase transition on normalized data by which the asymptotic classification error rate vanishes. However, unlike the works (Couillet and Benaych-Georges, 2015; Liao and Couillet, 2017), the exact

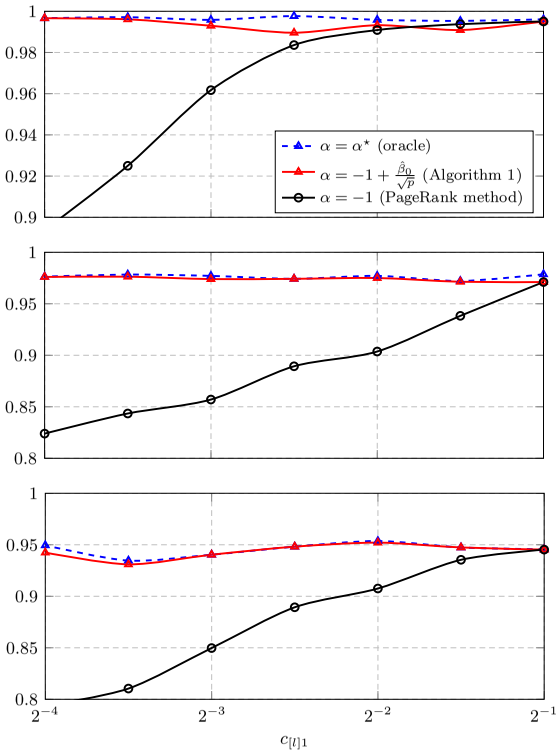

Figure 6: Average precision varying with $c_{[l]1}$ for 2-class MNIST data (**top:** digits (0,1), **middle:** digits (1,7), **bottom:** digits (8,9)), $n = 4096$, $p = 784$, $n_{[l]}/n = 1/16$, $n_{[u]1} = n_{[u]2}$, Gaussian kernel.

expression at the core of the limiting performance assumes a different form. Of importance is the finding that, under a heat kernel assumption $f(t) = \exp(-\frac{t}{2\sigma^2})$, the studied semi-supervised learning method fails to classify Gaussian mixtures of the type $\mathcal{N}(0, C_k)$ with $\operatorname{tr} C_k^\circ = O(\sqrt{p})$ and $\operatorname{tr} C_k C_{k'} - \operatorname{tr} C_k^2 = o(p)$, which unsupervised learning or LS-SVM are able to do (Couillet and Benaych-Georges, 2015; Liao and Couillet, 2017). This paradox may deserve a more structural way of considering together methods on the spectrum from unsupervised to supervised learning.

The very fact that the kernel matrix W is essentially equivalent to the matrix $f(\tau)1_n 1_n^\mathsf{T}$ (the $n \times n$ matrix filled with $f(\tau)$ values), thereby strongly disrupting with the expected

natural behavior of kernels, essentially follows from the Gaussian mixture model we assumed as well as from the decision to compare vectors by means of a mere Euclidean distance. We believe that this simplistic (although widely used) method explains the strong coincidence between performances on the Gaussian mixture model and on real data sets. Indeed, as radial functions are not specially adapted to image vectors (as would be wavelet or convolutional filters), the kernel likely operates on first order statistics of the input vectors, hence similar to its action on a Gaussian-mixture data. It would be interesting to generalize our result, and for that matter the set of works (Couillet and Benaych-Georges, 2015; Liao and Couillet, 2017; Couillet and Kammoun, 2016), to more involved data-oriented kernels, so long that the data contain enough exploitable degrees of freedom.

It is also quite instructive to note that, from the proof of our main results, the terms remaining after the expansion of $D_{[u]}^{-1-\alpha} W_{[uu]} D_{[u]}^{\alpha}$ appearing in (2) almost all vanish, strongly suggesting that similar results would be obtained if the inverse matrix in (2) were discarded altogether. This implies that the intra-unlabelled data kernel $W_{[uu]}$ is of virtually no asymptotic use. Also, the remark of Section 4.3 according to which $c_{[l]} \to 0$ implies a vanishing classification rate suggests that even the (unsupervised) clustering performance obtained by Couillet and Benaych-Georges (2015) is not achieved, despite the presence of possibly numerous unlabelled data. This, we believe, is due to a mismatched scaling in the SSL problem definition. A promising avenue of investigation would consist in introducing appropriate scaling parameters in the label propagation method or the optimization (1) to ensure that $W_{[uu]}$ is effectively used in the algorithm. Early simulations do suggest that elementary amendments to (2) indeed result in possibly striking performance improvements.

These considerations are left to future works.

Appendix A. Preliminaries

We begin with some additional notations that will be useful in the proofs.

- For $x_i \in \mathcal{C}_k$, $\omega_i \equiv (x_i - \mu_k)/\sqrt{p}$, and $\Omega \equiv [\omega_1, \cdots, \omega_n]^\mathsf{T}$
- $j_k \in \mathbb{R}^n$ is the canonical vector of $\mathcal{C}_k$, in the sense that its i-th element is 1 if $x_i \in \mathcal{C}_k$ or 0 otherwise. $j_{[l]k}$ and $j_{[u]k}$ are respectively the canonical vectors for labelled and unlabelled data of $\mathcal{C}_k$.
- $\psi_i \equiv \|\omega_i\|^2 - \mathrm{E}[\|\omega_i\|^2]$, $\psi \equiv [\psi_1, \cdots, \psi_n]^\mathsf{T}$ and $(\psi)^2 \equiv [(\psi_1)^2, \cdots, (\psi_n)^2]^\mathsf{T}$.

With these notations at hand, we introduce next the generalized version of Theorem 2 for all $\alpha = O(1)$ (rather than $\alpha = -1 + O(1/\sqrt{n})$).

Theorem 5 *For $x_i \in \mathcal{C}_b$ an unlabelled vector (i.e., $i > n_{[l]}$), let $\hat{F}_{ia}$ be given by (7) with F defined in (2) for $\alpha = O(1)$. Then, under Assumptions 1–2,*

$$p\hat{F}_{i\cdot} = p(1+z_i)1_K + G_i + o_P(1)$$
$$G_i \sim \mathcal{N}(m_b, \Sigma_b)$$

where z_i is as in Theorem 2 and

(i) for $F_{i\cdot}$ considered on the σ-field induced by the random variables $x_{[l]+1}, \ldots, x_n$, $p = 1, 2, \ldots$,

$$[m_b]_a = H_{ab} + \frac{1}{n_{[l]}}\sum_{d=1}^{K}(\alpha n_d + n_{[u]d})H_{ad} + (1+\alpha)\frac{n}{n_{[l]}}\left[\Delta_a + \frac{p}{n_{[l]a}}\frac{f'(\tau)}{f(\tau)}\psi_{[l]}^T j_{[l]a} - \alpha\frac{f'(\tau)^2}{f(\tau)^2}t_a t_b\right] \tag{13}$$

$$[\Sigma_b]_{a_1a_2} = \left(\frac{(-\alpha^2-\alpha)n - n_{[l]}}{n_{[l]}}\frac{f'(\tau)^2}{f(\tau)^2} + \frac{f''(\tau)}{f(\tau)}\right)^2 T_{bb}t_{a_1}t_{a_2} + \boldsymbol{\delta}_{a_1}^{a_2}\frac{f'(\tau)^2}{f(\tau)^2}\frac{4c_0 T_{ba_1}}{c_{[l]a_1}} + \frac{4f'(\tau)^2}{f(\tau)^2}\mu_{a_1}^\circ C_b \mu_{a_2}^\circ \tag{14}$$

where

$$H_{ab} = \frac{f'(\tau)}{f(\tau)}\|\mu_b^\circ - \mu_a^\circ\|^2 + \left(\frac{f''(\tau)}{f(\tau)} - \frac{f'(\tau)^2}{f(\tau)^2}\right)t_a t_b + \frac{2f''(\tau)}{f(\tau)}T_{ab} \tag{15}$$

$$\Delta_a = \frac{\sqrt{p}f'(\tau)}{f(\tau)}t_a + \frac{\alpha f'(\tau)^2 + f(\tau)f''(\tau)}{2f(\tau)^2}\left(2T_{aa} + t_a^2\right) + \frac{1}{n_{[l]}}\left(\frac{f'(\tau)}{f(\tau)}\right)^2\left(\sum_{d=1}^{K} n_{[u]d}t_d\right)t_a. \tag{16}$$

(ii) for $F_{i\cdot}$ considered on the σ-field induced by the random variables $x_1, \ldots, x_n$,

$$[m_b]_a = H_{ab} + \frac{1}{n_{[l]}}\sum_{d=1}^{K}(\alpha n_d + n_{[u]d})H_{ad} + (1+\alpha)\frac{n}{n_{[l]}}\left[\Delta_a - \alpha\frac{f'(\tau)^2}{f(\tau)^2}t_a t_b\right]$$

$$[\Sigma_b]_{a_1a_2} = \left(\frac{(-\alpha^2-\alpha)n - n_{[l]}}{n_{[l]}}\frac{f'(\tau)^2}{f(\tau)^2} + \frac{f''(\tau)}{f(\tau)}\right)^2 T_{bb}t_{a_1}t_{a_2} + \boldsymbol{\delta}_{a_1}^{a_2}\frac{f'(\tau)^2}{f(\tau)^2}\left(\frac{(1+\alpha)^2}{c_{[l]}^2}\frac{2c_0 T_{aa}}{c_{[l]a_1}} + \frac{4c_0 T_{ba_1}}{c_{[l]a_1}}\right) + \frac{4f'(\tau)^2}{f(\tau)^2}\mu_{a_1}^\circ C_b \mu_{a_2}^\circ$$

with H_{ab} given in (15) and Δ_a in (16).

Let $P(x_i \to \mathcal{C}_b | x_i \in \mathcal{C}_b, x_1, \cdots, x_{n_{[l]}})$ denote the probability of correct classification of $x_i \in \mathcal{C}_b$ unlabelled, conditioned on $x_1, \ldots, x_{n_{[l]}}$, and $P(x_i \to \mathcal{C}_b | x_i \in \mathcal{C}_b)$ the unconditional probability. Recall that the probability of correct classification of $x_i \in \mathcal{C}_b$ is the same as the probability of $\hat{F}_{ib} > \max_{a \neq b}\hat{F}_{ib}$, which, according to the above theorem, is asymptotically the probability that $[G_i]_b$ is the greatest element of G_i. Particularly for $K = 2$, we have the following corollary.

Corollary 6 *Under the conditions of Theorem 1, and with $K = 2$, we have, for $a \neq b \in \{1, 2\}$,*

(i) Conditionally on $x_1, \cdots, x_{n_{[l]}}$,

$$\mathbb{P}\left(x_i \to \mathcal{C}_b | x_i \in \mathcal{C}_b, x_1, \cdots, x_{n_{[l]}}\right) - \Phi(\theta_b^a) \to 0$$
$$\theta_b^a = \frac{[m_b]_b - [m_b]_a}{\sqrt{[\Sigma_b]_{bb} + [\Sigma_b]_{aa} - 2[\Sigma_b]_{ab}}}$$

where $\Phi(u) = \frac{1}{2\pi}\int_{-\infty}^{u}\exp(-t^2/2)dt$ and m_b, Σ_b are given in (i) of Theorem 5.

(ii) Unconditionally,

$$\mathbb{P}\left(x_i \to \mathcal{C}_b | x_i \in \mathcal{C}_b\right) - \Phi(\theta_b^a) \to 0$$
$$\theta_b^a = \frac{[m_b]_b - [m_b]_a}{\sqrt{[\Sigma_b]_{bb} + [\Sigma_b]_{aa} - 2[\Sigma_b]_{ab}}}$$

where here m_b, Σ_b are given in (ii) of Theorem 5.

The remainder of the appendix is dedicated to the proof of Theorem 5 and Corollary 6 from which the results of Section 3.2 directly unfold.

Appendix B. Proof of Theorems 5

The proof of Theorem 5 is divided into two steps: first, we Taylor-expand the normalized scores for unlabelled data $\hat{F}_{[u]}$ using the convergence $\frac{1}{p}\|x_i - x_j\|^2 \xrightarrow{\text{a.s.}} \tau$ for all $i \neq j$; this expansion yields a random equivalent $\hat{F}_{[u]}^{\text{eq}}$ in the sense that $p(\hat{F}_{[u]} - \hat{F}_{[u]}^{\text{eq}}) \xrightarrow{\text{a.s.}} 0$. Proposition 1 is directly obtained from $\hat{F}_{[u]}^{\text{eq}}$. We then complete the proof by demonstrating the convergence to Gaussian variables of $\hat{F}_{[u]}^{\text{eq}}$ by means of a central limit theorem argument.

B.1. Step 1: Taylor expansion

In the following, we provide a sketch of the development of $F_{[u]}$; most unshown intermediary steps can be retrieved from simple, yet painstaking algebraic calculus.

Recall from (2) the expression of the unnormalized scores for unlabelled data

$$F_{[u]} = (I_{n_u} - D_{[u]}^{-1-\alpha}W_{[uu]}D_{[u]}^{\alpha})^{-1}D_{[u]}^{-1-\alpha}W_{[ul]}D_{[l]}^{\alpha}F_{[l]}.$$

We first proceed to the development of the terms $W_{[ul]}$, $W_{[uu]}$, subsequently to $D_{[l]}, D_{[u]}$, to then reach an expression for $F_{[u]}$. To this end, owing to the convergence $\|x_i - x_j\|^2/p \xrightarrow{\text{a.s.}} \tau$

for all $i \neq j$, we first Taylor-expand $W_{ij} = f(\|x_i - x_j\|^2/p)$ around $f(\tau)$ to obtain the following expansion for W, already evaluated by Couillet and Benaych-Georges (2015),

$$W = W^{(n)} + W^{(\sqrt{n})} + W^{(1)} + O(n^{-\frac{1}{2}}) \tag{17}$$

where $\|W^{(n)}\| = O(n)$, $\|W^{(\sqrt{n})} = O(\sqrt{n})$ and $\|W^{(1)}\| = O(1)$, with the definitions

$$\begin{aligned}
W^{(n)} &= f(\tau) 1_n 1_n^\mathsf{T} \\
W^{(\sqrt{n})} &= f'(\tau) \left[\psi 1_n^\mathsf{T} + 1_n \psi^\mathsf{T} + \left(\sum_{b=1}^K \frac{t_b}{\sqrt{p}} j_b \right) 1_n^\mathsf{T} + 1_n \sum_{a=1}^K \frac{t_a}{\sqrt{p}} j_a^\mathsf{T} \right] \\
W^{(1)} &= f'(\tau) \left[\sum_{a,b=1}^K \frac{\|\mu_a^\circ - \mu_b^\circ\|^2}{p} j_b j_a^\mathsf{T} - \frac{2}{\sqrt{p}} \Omega \sum_{a=1}^K \mu_a^\circ j_a^\mathsf{T} + \frac{2}{\sqrt{p}} \sum_{b=1}^K \mathrm{diag}(j_b) \Omega \mu_b^\circ 1_n^\mathsf{T} \right. \\
&\quad \left. - \frac{2}{\sqrt{p}} \sum_{b=1}^K j_b \mu_b^{\circ\mathsf{T}} \Omega^\mathsf{T} + \frac{2}{\sqrt{p}} 1_n \sum_{a=1}^K \mu_a^{\circ\mathsf{T}} \Omega^\mathsf{T} \mathrm{diag}(j_a) - 2\Omega\Omega^\mathsf{T} \right] \\
&\quad + \frac{f''(\tau)}{2} \left[(\psi)^2 1_n^\mathsf{T} + 1_n [(\psi)^2]^\mathsf{T} + \sum_{b=1}^K \frac{t_b^2}{p} j_b 1_n^\mathsf{T} + 1_n \sum_{a=1}^K \frac{t_a^2}{p} j_a^\mathsf{T} \right. \\
&\quad + 2 \sum_{a,b=1}^K \frac{t_a t_b}{p} j_b j_a^\mathsf{T} + 2 \sum_{b=1}^K \mathrm{diag}(j_b) \frac{t_b}{\sqrt{p}} \psi 1_n^\mathsf{T} + 2 \sum_{b=1}^K \frac{t_b}{\sqrt{p}} j_b \psi^\mathsf{T} + 2 \sum_{a=1}^K 1_n \psi^\mathsf{T} \mathrm{diag}(j_a) \frac{t_a}{\sqrt{p}} \\
&\quad \left. + 2\psi \sum_{a=1}^K \frac{t_a}{\sqrt{p}} j_a^\mathsf{T} + 4 \sum_{a,b=1}^K \frac{T_{ab}}{p} j_b j_a^\mathsf{T} + 2\psi\psi^\mathsf{T} \right] + (f(0) - f(\tau) + \tau f'(\tau)) I_n.
\end{aligned}$$

As $W_{[ul]}$, $W_{[uu]}$ are sub-matrices of W, their approximated expressions are obtained directly by extracting the corresponding subsets of (17). Applying then (17) in $D = \mathrm{diag}(W 1_n)$, we next find

$$D = n f(\tau) \left[I_n + \frac{1}{n f(\tau)} \mathrm{diag}(W^{(\sqrt{n})} 1_n + W^{(1)} 1_n) \right] + O(n^{-\frac{1}{2}}).$$

Thus, for any $\sigma \in \mathbb{R}$, $(n^{-1}D)^\sigma$ can be Taylor-expanded around $f(\tau)^\sigma I_n$ as

$$\begin{aligned}
(n^{-1}D)^\sigma &= f(\tau)^\sigma \left[I_n + \frac{\sigma 1}{n f(\tau)} \mathrm{diag}((W^{(\sqrt{n})} + W^{(1)}) 1_n) + \frac{\sigma(\sigma-1)}{2n^2 f(\tau)^2} \mathrm{diag}^2(W^{(\sqrt{n})} 1_n) \right] \\
&\quad + O(n^{-\frac{3}{2}})
\end{aligned} \tag{18}$$

where $\mathrm{diag}^2(\cdot)$ stands for the squared diagonal matrix. The Taylor-expansions of $(n^{-1}D_{[u]})^\alpha$ and $(n^{-1}D_{[l]})^\alpha$ are then directly extracted from this expression for $\sigma = \alpha$, and similarly for $(n^{-1}D_{[u]})^{-1-\alpha}$ with $\sigma = -1-\alpha$. Since

$$D_{[u]}^{-1-\alpha} W_{[ul]} D_{[l]}^\alpha = \frac{1}{n} (n^{-1} D_{[u]})^{-1-\alpha} W_{[ul]} (n^{-1} D_{[l]})^\alpha$$

it then suffices to multiply the Taylor-expansions of $(n^{-1}D_{[u]})^\alpha$, $(n^{-1}D_{[l]})^\alpha$, and $W_{[ul]}$, given respectively in (18) and (17), normalize by n and then organize the result in terms of order $O(1)$, $O(1/\sqrt{n})$, and $O(1/n)$.

The term $D_{[u]}^{-1-\alpha} W_{[uu]} D_{[u]}^\alpha$ is dealt with in the same way. In particular,

$$D_{[u]}^{-1-\alpha} W_{[uu]} D_{[u]}^\alpha = \frac{1}{n} 1_{n_{[u]}} 1_{n_{[l]}} + O(n^{-\frac{1}{2}}).$$

Therefore, $(I_{n_{[u]}} - D_{[u]}^{-1-\alpha} W_{[uu]} D_{[u]}^\alpha)^{-1}$ may be simply written as

$$\left(I_{n_{[u]}} - \frac{1}{n} 1_{n_{[u]}} 1_{n_{[u]}} + O(n^{-\frac{1}{2}}) \right)^{-1} = I_{n_{[u]}} + \frac{1}{n_{[l]}} 1_{n_{[u]}} 1_{n_{[u]}} + O(n^{-\frac{1}{2}}).$$

Combining all terms together completes the full linearization of $\hat{F}_{[u]}$.

This last derivation, which we do not provide in full here, is simpler than it appears and is in fact quite instructive in the overall behavior of $F^{[u]}$. Indeed, only product terms in the development of $(I_{n_{[u]}} - D_{[u]}^{-1-\alpha} W_{[uu]} D_{[u]}^\alpha)^{-1}$ and $D_{[u]}^{-1-\alpha} W_{[ul]} D_{[l]}^\alpha F^{[l]}$ of order at least $O(1)$ shall remain, which discards already a few terms. Now, in addition, note that for any vector v, $v 1_{n_{[l]}}^\mathsf{T} F^{[l]} = v 1_k^\mathsf{T}$ so that such matrices are non informative for classification (they have identical score columns); these terms are all placed in the intermediary variable z, the entries z_i of which are irrelevant and thus left as is (these are the z_i's of Proposition 1 and Theorem 2). It is in particular noteworthy to see that *all* terms of $W_{[uu]}^{(1)}$ that remain after taking the product with $D_{[u]}^{-1-\alpha} W_{[ul]} D_{[l]}^\alpha F^{[l]}$ are precisely those multiplied by $f(\tau) 1_{n_{[u]}} 1_{n_{[l]}}^\mathsf{T} F^{[l]}$ and thus become part of the vector z. Since most informative terms in the kernel matrix development are found in $W^{(1)}$, this means that the algorithm under study shall make little use of the *unsupervised* information about the data (those found in $W_{[uu]}^{(1)}$). This is an important remark which, as discussed in Section 6, opens up the path to further improvements of the semi-supervised learning algorithms which would use more efficiently the information in $W_{[uu]}^{(1)}$.

All calculus made, this development finally leads to $F_{[u]} = F_{[u]}^{\mathrm{eq}}$ with, for $a, b \in \{1, \ldots, K\}$ and $x_i \in \mathcal{C}_b$, $i > n_{[l]}$,

$$\begin{aligned}
\hat{F}_{ia}^{\mathrm{eq}} &= 1 + \frac{1}{p} \left[H_{ab} + \frac{1}{n_{[l]}} \sum_{d=1}^K H_{ad} (\alpha n_d + n_{[u]d}) \right] + (1+\alpha) \frac{n}{p n_{[l]}} \left[\Delta_a - \alpha \frac{f'(\tau)^2}{f(\tau)^2} t_a t_b \right] \\
&\quad + \left(\frac{(-\alpha^2 - \alpha) n - n_{[l]}}{n_{[l]}} \frac{f'(\tau)^2}{f(\tau)^2} + \frac{f''(\tau)}{f(\tau)} \right) \frac{t_a}{\sqrt{p}} \psi_i + \frac{2 f'(\tau)}{f(\tau) \sqrt{p}} \mu_a^\circ \omega_i \\
&\quad + \frac{f'(\tau)}{f(\tau)} \left(\frac{(1+\alpha) n}{n_{[l]} n_{[l]a}} \psi_{[l]}^\mathsf{T} j_{[l]a} + \frac{4}{n_{[l]a}} j_{[l]a}^T \Omega_{[l]} \omega_i \right) + z_i
\end{aligned} \tag{19}$$

where H_{ab} is as specified in (15), Δ_a as in (16), and $z_i = O(\sqrt{p})$ is some residual random variable only dependent on x_i. Gathering the terms in successive orders of magnitude, Proposition 1 is then straightforwardly proven from (19).

B.2. Step 2: Central limit theorem

The focus of this step is to examine $\mathcal{G}_i = p(\hat{F}_i^{\mathrm{eq}} - (1 + z_i) 1_K)$. Theorem 5 can be proven by showing that $\mathcal{G}_i = G_i + o_P(1)$.

First consider Item (i) of Theorem 5, which describes the behavior of $\hat{F}_{[u]}$ conditioned on $x_1, \ldots, x_{n_{[l]}}$. Recall that a necessary and sufficient condition for a vector v to be a Gaussian vector is that all linear combinations of the elements of v are Gaussian variables. Thus, for given $x_1, \ldots, x_{n_{[l]}}$ deterministic, according to (19), $\mathcal{G}_i$ is asymptotically Gaussian if, for all $g_1 \in \mathbb{R}$, $g_2 \in \mathbb{R}^p$, $g_1\psi_i + g_2^T\omega_i$ has a central limit.

Letting $\omega_i = \frac{C_b^{\frac{1}{2}}}{\sqrt{p}} r$, with $r \sim \mathcal{N}(0, I_p)$, $g_1\psi_i + g_2\omega_i$ can be rewritten as $r^\mathsf{T} A r + br + c$ with $A = g_1\frac{C_b}{p}$, $b = g_2\frac{C_b}{p}$, $c = -g_1\frac{\mathrm{tr} C_b}{p}$. Since A is symmetric, there exists an orthonormal matrix U and a diagonal Λ such that $A = U^\mathsf{T}\Lambda U$. We thus get

$$r^\mathsf{T} A r + br + c = r^T U^T \Lambda U r + bU^T U r + c = \tilde{r}^T \Lambda \tilde{r} + \tilde{b}\tilde{r} + c$$

with $\tilde{r} = Ur$ and $\tilde{b} = bU^\mathsf{T}$. By unitary invariance, we have $\tilde{r} \sim \mathcal{N}(0, I_p)$ so that $g_1\psi_i + g_2\omega_i$ is thus the sum of the independent but not identically distributed random variables $q_j = \lambda_j \tilde{r}_j^2 + \tilde{b}_j\tilde{r}_j$, $i = 1, \ldots, p$. From Lyapunov's central limit theorem (Billingsley, 1995, Theorem 27.3), it remains to find a $\delta > 0$ such that $\frac{\sum_j \mathbb{E}|q_j - \mathbb{E}[q_j]|^{2+\delta}}{\left(\sum_j \mathrm{Var}[q_j]\right)^{1+\delta/2}} \to 0$ to ensure the central limit theorem. For $\delta = 1$, we have $\mathbb{E}[q_j] = \lambda_j$, $\mathrm{Var}[q_j] = 2\lambda_j^2 + \tilde{b}_j^2$ and $\mathbb{E}\left[(q_j - \mathbb{E}[q_j])^3\right] = 8\lambda_j^3 + 6\lambda_j\tilde{b}_j^2$, so that $\frac{\sum_j \mathbb{E}\left[|q_j - \mathbb{E}[q_j]|^3\right]}{\left(\sum_j \mathrm{Var}[q_j]\right)^{3/2}} = O(n^{-\frac{1}{2}})$.

It thus remains to evaluate the expectation and covariance matrix of $\mathcal{G}_i$ conditioned on $x_1, \ldots, x_{n_{[l]}}$ to obtain (i) of Theorem 5. For $x_i \in \mathcal{C}_b$, we have

$$\begin{aligned}
\mathbb{E}\{[\mathcal{G}_i]_a\} &= H_{ab} + \frac{1}{n_{[l]}} \sum_{d=1}^{K} (\alpha n_d + n_{[u]d}) H_{ad} \\
&\quad + (1+\alpha)\frac{n}{n_{[l]}} \left[\Delta_a + \frac{p}{n_{[l]a}} \frac{f'(\tau)}{f(\tau)} \psi_{[l]}^T j_{[l]a} - \alpha \frac{f'(\tau)^2}{f(\tau)^2} t_a t_b \right] \\
\mathrm{Cov}\{[\mathcal{G}_i]_{a_1}[\mathcal{G}_i]_{a_2}\} &= \left(\frac{(-\alpha^2 - \alpha)n - n_{[l]}}{n_{[l]}} \frac{f'(\tau)^2}{f(\tau)^2} + \frac{f''(\tau)}{f(\tau)} \right)^2 T_{bb} t_{a_1} t_{a_2} \\
&\quad + \boldsymbol{\delta}_{a_1}^{a_2} \frac{f'(\tau)^2}{f(\tau)^2} \frac{4c_0 T_{ba_1}}{c_{[l]a_1}} + \frac{4f'(\tau)^2}{f(\tau)^2} \mu_{a_1}^\circ C_b \mu_{a_2}^\circ + o(1).
\end{aligned}$$

From the above equations, we retrieve the asymptotic expressions of $[m_b]_a$ and $[\Delta_b]_{a_1 a_2}$ given in (13) and (14). This completes the proof of Item (i) of Theorem 5. Item (ii) is easily proved by following the same reasoning.

Abstract

Robust PCA is a widely used statistical procedure to recover an underlying low-rank matrix with grossly corrupted observations. This work considers the problem of robust PCA as a nonconvex optimization problem on the manifold of low-rank matrices and proposes two algorithms based on manifold optimization. It is shown that, with a properly designed initialization, the proposed algorithms are guaranteed to converge to the underlying low-rank matrix linearly. Compared with a previous work based on the factorization of low-rank matrices Yi et al. (2016), the proposed algorithms reduce the dependence on the condition number of the underlying low-rank matrix theoretically. Simulations and real data examples confirm the competitive performance of our method.

Keywords: principal component analysis, low-rank modeling, manifold of low-rank matrices.

1. Introduction

In many problems, the underlying data matrix is assumed to be approximately low-rank. Examples include problems in computer vision Epstein et al. (1995); Ho et al. (2003), machine learning Deerwester et al. (1990), and bioinformatics Price et al. (2006). For such problems, principal component analysis (PCA) is a standard statistical procedure to recover the underlying low-rank matrix. However, PCA is highly sensitive to outliers in the data, and robust PCA Candès et al. (2011); Chandrasekaran et al. (2011); Clarkson and Woodruff (2013); Frieze et al. (2004); Bhojanapalli et al. (2015); Yi et al. (2016); Chen and Wainwright (2015); Gu et al. (2016); Cherapanamjeri et al. (2016); Netrapalli et al. (2014) is hence proposed as a modification to handle grossly corrupted observations. Mathematically, the robust PCA problem is formulated as follows: given a data matrix $\mathbf{Y} \in \mathbb{R}^{n_1 \times n_2}$ that can be written as the sum of a low-rank matrix $\mathbf{L}^*$ (signal) and a sparse matrix $\mathbf{S}^*$ (corruption) with only a few nonzero entries, can we recover both components accurately? Robust PCA has been shown to have applications in many real-life applications

including background detection Li et al. (2004), face recognition Basri and Jacobs (2003), ranking, and collaborative filtering Candès et al. (2011).

Since the set of all low-rank matrices is nonconvex, it is generally difficult to obtain an algorithm with theoretical guarantee since there is no tractable optimization algorithm for the nonconvex problem. Here we review a few carefully designed algorithms such that the theoretical guarantee on the recovery of underlying low-rank matrix exists. The works Candès et al. (2011); Chandrasekaran et al. (2011) consider the convex relaxation of the original problem instead:

$$\min_{\mathbf{L},\mathbf{S}} \|\mathbf{L}\|_* + \|\mathbf{S}\|_1, \text{ s.t. } \mathbf{Y} = \mathbf{L} + \mathbf{S}, \tag{1}$$

where $\|\mathbf{L}\|_*$ represents the nuclear norm (i.e., Schatten 1-norm) of $\mathbf{L}$, defined by the sum of its singular values and $\|\mathbf{S}\|_1$ represents the sum of the absolute values of all entries of $\mathbf{S}$. Since this problem is convex, the solution to (1) can be solved in polynomial time. In addition, it is shown that the solution recovers the correct low-rank matrix when $\mathbf{S}^*$ has at most $\gamma^* = O(1/\mu^2 r)$ fraction of corrupted non-zero entries, where r is the rank of $\mathbf{L}^*$ and μ is the incoherence level of $\mathbf{L}^*$ Hsu et al. (2011). If the sparsity of $\mathbf{S}^*$ is assumed to be random, then Candès et al. (2011) shows that the algorithm succeeds with high probability, even when the percentage of corruption can be in the order of $O(1)$ while the rank $r = O(\min(n_1, n_2)/\mu \log^2 \max(n_1, n_2))$, where μ is a coherence parameter of the low-rank matrix $\mathbf{L}^*$ (this work defines μ slightly differently compared to Candès et al. (2011) and (16) in this work, but the value is comparable).

However, the aforementioned algorithms based on convex relaxation have a computational complexity of $O(n_1 n_2 \min(n_1, n_2))$ per iteration, which could be prohibitive when n_1 and n_2 are very large. Alternatively, some faster algorithms are proposed based on nonconvex optimization. In particular, the work by Kyrillidis and Cevher (2012) proposes a method based on the projected gradient method. However, it assumes that the sparsity pattern of $\mathbf{S}^*$ is random, and the algorithm still has the same computational complexity as the convex methods. Netrapalli et al. (2014) proposes a method based on the alternating projecting, which allows $\gamma^* \le \frac{1}{\mu^2 r}$, with a computational complexity of $O(r^2 n_1 n_2)$ per iteration. Chen and Wainwright (2015) assumes that $\mathbf{L}^*$ is positive semidefinite and applies the gradient descent method on the Cholesky decomposition factor of $\mathbf{L}^*$, but the positive semidefinite assumption is not satisfied in many applications. Gu et al. (2016) factorizes $\mathbf{L}^*$ into the product of two matrices and performs alternating minimization over both matrices. It shows that the algorithm allows $\gamma^* = O(1/\mu^{2/3} r^{2/3} \min(n_1, n_2))$ and has the complexity of $O(r^2 n_1 n_2)$ per iteration. Yi et al. (2016) applies a similar factorization and applies an alternating gradient descent algorithm with a complexity of $O(r n_1 n_2)$ per iteration and allows $\gamma^* = O(1/\kappa^2 \mu r^{3/2})$, where κ is the condition number of the underlying low-rank matrix. There is another line of works that further reduces the complexity of the algorithm by subsampling the entries of the observation matrix $\mathbf{Y}$, including Mackey et al. (2011); Li and Haupt (2015); Rahmani and Atia (2017); Cherapanamjeri et al. (2016) and (Yi et al., 2016, Algorithm 2), which will also be discussed in this paper as the partially observed case.

The common idea shared by Gu et al. (2016) and Yi et al. (2016) is as follows. Since any low-rank matrix $\mathbf{L} \in \mathbb{R}^{n_1 \times n_2}$ with rank r can be written as the product of two low-rank

matrices by $\mathbf{L} = \mathbf{U}\mathbf{V}^T$ with $\mathbf{U} \in \mathbb{R}^{n_1 \times r}$ and $\mathbf{V} \in \mathbb{R}^{n_2 \times r}$, we can optimize the pair $(\mathbf{U}, \mathbf{V})$ instead of $\mathbf{L}$, and a smaller computational cost is expected since $(\mathbf{U}, \mathbf{V})$ has $(n_1 + n_2)r$ parameters, which is smaller than $n_1 n_2$, the number of parameters in $\mathbf{L}$. In fact, such a re-parametrization technique has a long history Ruhe (1974), and has been popularized by Burer and Monteiro Burer and Monteiro (2003, 2005) for solving semi-definite programs (SDPs). The same idea has been used in other low-rank matrix estimation problems such as dictionary learning Sun et al. (2017), phase synchronization Boumal (2016), community detection Bandeira et al. (2016), matrix completion Jain et al. (2013), recovering matrix from linear measurements Tu et al. (2016), and even general problems Chen and Wainwright (2015); Wang et al. (2017); Park et al. (2016); Wang et al. (2017); Park et al. (2017). In addition, the property of associated stochastic gradient descent algorithm is studied in De Sa et al. (2015).

The main contribution of this work is a novel robust PCA algorithm based on the gradient descent algorithm on the manifold of low-rank matrices, with a theoretical guarantee on the exact recovery of the underlying low-rank matrix. Compared with Yi et al. (2016), the proposed algorithm utilizes the tool of manifold optimization, which leads to a simpler and more naturally structured algorithm with a stronger theoretical guarantee. In particular, with a proper initialization, our method can still succeed with $\gamma^* = O(1/\kappa\mu r^{3/2})$, which means that it can tolerate more corruption than Yi et al. (2016) by a factor of κ. In addition, the theoretical convergence rate is also faster than Yi et al. (2016) by a factor of κ. Simulations also verified the advantage of the proposed algorithm over Yi et al. (2016). We remark that while manifold optimization has been applied to robust PCA in Cambier and Absil (2016), our work studies a different algorithm and gives theoretical guarantees. Considering the popularity of the methods based on the factorization of low-rank matrices, it is expected that manifold optimization could be applied to other low-rank matrix estimation problems. In addition, we implement our method in an efficient and user-friendly R package `morpca`, which is available at `https://github.com/emeryyi/morpca`.

The paper is organized as follows. We first present the algorithm in Section 2, and explain how the proposed algorithms are derived in Section 3. Their theoretical properties are studied and compared with previous algorithms in Section 4. In Section 5, simulations and real data analysis on the `Shoppingmall` dataset show that the proposed algorithms are competitive in many scenarios and have superior performances to the algorithm based on matrix factorization. A discussion about the proposed algorithms is then presented in Section 6, followed by the proofs of the results in Appendix.

2. Algorithm

In this work, we consider the robust PCA problem in two settings: fully observed setting and partially observed setting. The problem under the fully observed setting can be formulated as follows: given $\mathbf{Y} = \mathbf{L}^* + \mathbf{S}^*$, where $\mathbf{L}^*$ is a low-rank matrix and $\mathbf{S}^*$ is a sparse matrix, then can we recover $\mathbf{L}^*$ from $\mathbf{Y}$? To recover $\mathbf{L}^*$, we solve the following optimization problem:

$$\widehat{\mathbf{L}} = \underset{\text{rank}(\mathbf{L})=r}{\arg\min}\ f(\mathbf{L}), \text{ where } f(\mathbf{L}) = \frac{1}{2}\|F(\mathbf{L}-\mathbf{Y})\|_F^2, \tag{2}$$

where $F : \mathbb{R}^{n_1 \times n_2} \to \mathbb{R}^{n_1 \times n_2}$ is a hard thresholding procedure defined in (3):

$$F_{ij}(\mathbf{A}) = \begin{cases} 0, & \text{if } |\mathbf{A}_{ij}| > |\mathbf{A}_{i,\cdot}|^{[\gamma]} \text{ and } |\mathbf{A}_{ij}| > |\mathbf{A}_{\cdot,j}|^{[\gamma]} \\ \mathbf{A}_{ij}, & \text{otherwise.} \end{cases} \tag{3}$$

Here $\mathbf{A}_{i,\cdot}$ represents the i-th row of the matrix $\mathbf{A}$, and $\mathbf{A}_{\cdot,j}$ represents the j-th column of $\mathbf{A}$. $|\mathbf{A}_{i,\cdot}|^{[\gamma]}$ and $|\mathbf{A}_{\cdot,j}|^{[\gamma]}$ represent the $(1-\gamma)$-th percentile of the absolute values of the entries of $\mathbf{A}_{i,\cdot}$ and $\mathbf{A}_{\cdot,j}$ for $\gamma \in [0, 1)$. In other words, what are removed are the entries that are simultaneously among the largest γ-fraction in the corresponding row and column of $\mathbf{A}$ in terms of the absolute values. The threshold γ is set by users. If some entries of $\mathbf{A}_{i,\cdot}$ or $\mathbf{A}_{\cdot,j}$ have the entries with identical absolute values, the ties can be broken down arbitrarily.

The motivation is that, if $\mathbf{S}^*$ is sparse in the sense that the percentage of nonzero entries in each row and each column is smaller than γ, then $F(\mathbf{L}^* - \mathbf{Y}) = F(-\mathbf{S}^*)$ is zero by definition thus $f(\mathbf{L}^*)$ is zero. Since f is nonnegative, $\mathbf{L}^*$ is the solution to (2). To solve (2), we propose Algorithm 1 based on manifold optimization, with its derivation deferred to Section 3.3.1.

Algorithm 1 Gradient descent on the manifold under the fully observed setting.

Input: Observation $\mathbf{Y} \in \mathbb{R}^{n_1 \times n_2}$; Rank r; Thresholding value γ; Step size η.
Initialization: Set $k = 0$; Initialize $\mathbf{L}^{(0)}$ using the rank-r approximation to $F(\mathbf{Y})$.
Loop: Iterate Steps 1–4 until convergence:
1: Let $\mathbf{L}^{(k)} = \mathbf{U}^{(k)}\mathbf{\Sigma}^{(k)}\mathbf{V}^{(k)T}$.
2: Let $\mathbf{D}^{(k)} = F(\mathbf{L}^{(k)} - \mathbf{Y})$.
3(a): (Option 1) Let $\mathbf{\Omega}^{(k)} = \mathbf{U}^{(k)}\mathbf{U}^{(k)T}\mathbf{D}^{(k)} + \mathbf{D}^{(k)}\mathbf{V}^{(k)}\mathbf{V}^{(k)T} - \mathbf{U}^{(k)}\mathbf{U}^{(k)T}\mathbf{D}^{(k)}\mathbf{V}^{(k)}\mathbf{V}^{(k)T}$, and let $\mathbf{U}^{(k+1)} \in \mathbb{R}^{n_1 \times r}$, $\mathbf{\Sigma}^{(k+1)} \in \mathbb{R}^{r \times r}$, and $\mathbf{V}^{(k+1)} \in \mathbb{R}^{n_2 \times r}$ be matrices consist of the top r left singular vectors/singular values/right singular vectors of $\mathbf{L}^{(k)} - \eta\mathbf{\Omega}^{(k)}$.
3(b): (Option 2) Let $\mathbf{Q}_1, \mathbf{R}_1$ be the QR decomposition of $(\mathbf{L}^{(k)} - \eta\mathbf{D}^{(k)})^T\mathbf{U}^{(k)}$ and $\mathbf{Q}_2, \mathbf{R}_2$ be the QR decomposition of $(\mathbf{L}^{(k)} - \eta\mathbf{D}^{(k)})\mathbf{V}^{(k)}$. Then $\mathbf{U}^{(k+1)} = \mathbf{Q}_2$, $\mathbf{V}^{(k+1)} = \mathbf{Q}_1$ and $\mathbf{\Sigma}^{(k+1)} = \mathbf{R}_2[\mathbf{U}^{(k)T}(\mathbf{L}^{(k)} - \eta\mathbf{D}^{(k)})\mathbf{V}^{(k)}]^{-1}\mathbf{R}_1^T$.
4: $k \coloneqq k + 1$.
Output: Estimation of the low-rank matrix $\mathbf{L}^*$, given by $\lim_{k\to\infty} \mathbf{L}^{(k)}$.

Under the partially observed setting, in addition to gross corruption $\mathbf{S}^*$, the observed matrix $\mathbf{Y}$ has a large number of missing values, i.e., many entries of $\mathbf{Y}$ are not observed. We denote the set of all observed entries by $\mathbf{\Phi} = \{(i,j)|\mathbf{Y}_{ij} \text{ is observed}\}$, and define $\tilde{F} : \mathbb{R}^{n_1 \times n_2} \to \mathbb{R}^{n_1 \times n_2}$

$$\tilde{F}_{ij}(\mathbf{A}) = \begin{cases} 0, & \text{if } |\mathbf{A}_{ij}| > |\mathbf{A}_{i,\cdot}|^{[\gamma,\mathbf{\Phi}]} \text{ and } |\mathbf{A}_{ij}| > |\mathbf{A}_{\cdot,j}|^{[\gamma,\mathbf{\Phi}]} \\ \mathbf{A}_{ij}, & \text{otherwise.} \end{cases} \tag{4}$$

Here $|\mathbf{A}_{i,\cdot}|^{[\gamma,\mathbf{\Phi}]}$ and $|\mathbf{A}_{\cdot,j}|^{[\gamma,\mathbf{\Phi}]}$ represent the $(1-\gamma)$-th percentile of the absolute values of the observed entries of $\mathbf{A}_{i,\cdot}$ and $\mathbf{A}_{\cdot,j}$ of the matrix $\mathbf{A}$ respectively.

As a generalization of Algorithm 1, we propose to solve

$$\underset{\text{rank}(\mathbf{L})=r}{\arg\min}\ \tilde{f}(\mathbf{L}), \quad \tilde{f}(\mathbf{L}) = \frac{1}{2}\sum_{(i,j)\in\mathbf{\Phi}} \tilde{F}_{ij}(\mathbf{L}-\mathbf{Y})^2, \tag{5}$$

Algorithm 2 Gradient descent on the manifold under the partially observed setting.

Input: Observation $\mathbf{Y} \in \mathbb{R}^{n_1 \times n_2}$; Set of all observed entries by $\mathbf{\Phi}$; Rank r; Thresholding value γ; Step size η.
Initialization: Set $k = 0$; Initialize $\mathbf{L}^{(0)}$ using the rank-r approximation to $\tilde{F}(\mathbf{Y})$.
Loop: Iterate Steps 1–4 until convergence:
1: Let $\mathbf{L}^{(k)}$ be a sparse matrix with support $\mathbf{\Phi}$, with nonzero entries given by the corresponding entries of $\mathbf{U}^{(k)}\mathbf{\Sigma}^{(k)}\mathbf{V}^{(k)\,T}$.
2: Let $\mathbf{D}^{(k)} = \tilde{F}(\mathbf{L}^{(k)} - \mathbf{Y})$.
3(a): (Option 1) Let $\mathbf{\Omega}^{(k)} = \mathbf{U}^{(k)}\mathbf{U}^{(k)\,T}\mathbf{D}^{(k)} + \mathbf{D}^{(k)}\mathbf{V}^{(k)}\mathbf{V}^{(k)\,T} - \mathbf{U}^{(k)}\mathbf{U}^{(k)\,T}\mathbf{D}^{(k)}\mathbf{V}^{(k)}\mathbf{V}^{(k)\,T}$, and let $\mathbf{U}^{(k+1)} \in \mathbb{R}^{n_1 \times r}$, $\mathbf{\Sigma}^{(k+1)} \in \mathbb{R}^{r \times r}$, and $\mathbf{V}^{(k+1)} \in \mathbb{R}^{n_2 \times r}$ be matrices consists of the top r left singular vectors/singular values/right singular vectors of $\mathbf{L}^{(k)} - \eta\mathbf{\Omega}^{(k)}$.
3(b): (Option 2) Let $\mathbf{Q}_1, \mathbf{R}_1$ be the QR decomposition of $(\mathbf{L}^{(k)} - \eta\mathbf{D}^{(k)})^T\mathbf{U}^{(k)}$ and $\mathbf{Q}_2, \mathbf{R}_2$ be the QR decomposition of $(\mathbf{L}^{(k)} - \eta\mathbf{D}^{(k)})\mathbf{V}^{(k)}$. Then $\mathbf{U}^{(k+1)} = \mathbf{Q}_2$, $\mathbf{V}^{(k+1)} = \mathbf{Q}_1$ and $\mathbf{\Sigma}^{(k+1)} = \mathbf{R}_2[\mathbf{U}^{(k)\,T}(\mathbf{L}^{(k)} - \eta\mathbf{D}^{(k)})\mathbf{V}^{(k)}]^{-1}\mathbf{R}_1^T$.
4: $k \coloneqq k + 1$.
Output: Estimation of the low-rank matrix $\mathbf{L}^*$, given by $\lim_{k\to\infty} \mathbf{L}^{(k)}$.

which is similar to (2) but only the observed entries are considered. The implementation is presented in Algorithm 2 and its derivation is deferred to Section 3.3.2.

For Algorithm 1, its memory usage is $O(n_1 n_2)$ due to the storage of $\mathbf{Y}$. For Algorithm 2, storing $\mathbf{Y}$ and $\mathbf{L}^{(k)}$ requires $O(|\mathbf{\Phi}|)$ and storing $\mathbf{U}^{(k)}$ and $\mathbf{V}^{(k)}$ requires $O(r(n_1+n_2))$. Adding them together, the memory usage is $O(|\mathbf{\Phi}| + r(n_1 + n_2))$.

For both Algorithm 1 and Algorithm 2 with Option 1, the singular value decomposition is the most computationally intensive step and as a result, the complexity per iteration is $O(rn_1n_2)$. For Algorithm 1 and Algorithm 2 with Option 2, their computational complexities per iteration are in the order of $O(rn_1n_2)$ and $O(r^2(n_1 + n_2) + r|\mathbf{\Phi}|)$ respectively.

3. Derivation of the Proposed Algorithms

This section gives the derivations of Algorithms 1 and 2. Since they are derived from manifold optimization, we first give a review of manifold optimization in Section 3.1 and the geometry of the manifold of low-rank matrices in Section 3.2.

3.1. Manifold optimization

The purpose of this section is to review the framework of the gradient descent method on manifolds. It summarizes mostly the framework used in Vandereycken (2013); Shalit et al. (2012); Absil et al. (2009), and we refer readers to these work for more details.

Given a smooth manifold $\mathcal{M} \subset \mathbb{R}^n$ and a differentiable function $f : \mathcal{M} \to \mathbb{R}$, the procedure of the gradient descent algorithm for solving $\min_{x\in\mathcal{M}} f(x)$ is as follows:

Step 1. Consider $f(x)$ as a differentiable function from $\mathbb{R}^n$ to $\mathbb{R}$ and calculate the Euclidean gradient $\nabla f(x)$.

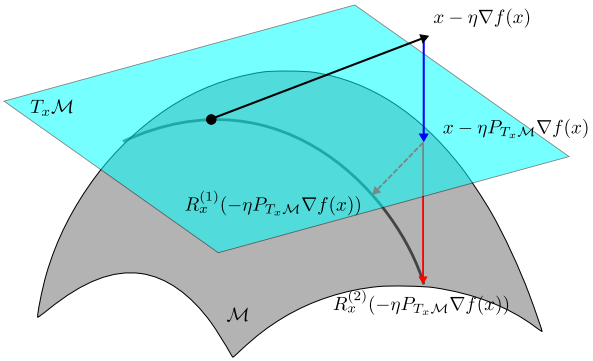

Figure 1: The visualization of gradient descent algorithms on the manifold $\mathcal{M}$. The black solid line is the Euclidean gradient. The blue solid line is the projection of the Euclidean gradient to the tangent space. The red solid line represents the orthographic retraction, while the red dashed line represents the projective retraction.

Step 2. Calculate its Riemannian gradient, which is the direction of steepest ascent of $f(x)$ among all directions in the *tangent space* $T_x\mathcal{M}$. This direction is given by $P_{T_x\mathcal{M}}\nabla f(x)$, where $P_{T_x\mathcal{M}}$ is the projection operator to the tangent space $T_x\mathcal{M}$.

Step 3. Define a *retraction* R_x that maps the tangent space back to the manifold, i.e. $R_x : T_x\mathcal{M} \to \mathcal{M}$, where R_x needs to satisfy the conditions in (Vandereycken, 2013, Definition 2.2). In particular, $R_x(0) = x$, $R_x(y) = x + y + O(\|y\|^2)$ as $y \to 0$, and R_x needs to be smooth. Then the update of the gradient descent algorithm x^+ is defined by

$$x^+ = R_x(-\eta P_{T_x\mathcal{M}}\nabla f(x)), \tag{6}$$

where η is the step size.

We remark that in differential geometry, the standard "retraction" is the exponential map from the tangent space to the manifold. However, in this work (as well as many works on manifold optimization) it is used to represent a generic mapping from the tangent plane to the manifold. As a result, the definition of retraction is not unique in this work. In Figure 1, we visualize the gradient descent method on the manifold $\mathcal{M}$ with two different kinds of retractions (orthographic and projective). We will discuss the details of those two retractions in Section 3.2.

3.2. The geometry of the manifold of low-rank matrices

To apply the gradient descent algorithm in Section 3.1 to the manifold of the low-rank matrices, the projection $P_{T_x\mathcal{M}}$ and the retraction R_x need to be defined. In this section, we let $\mathcal{M}$ be the manifold of all $\mathbb{R}^{n_1\times n_2}$ matrices with rank r and $\mathbf{X}\in\mathcal{M}$ be a matrix of rank r and will find the explicit expressions of $P_{T_x\mathcal{M}}$ and R_x.

The tangent space $T_{\mathbf{X}}\mathcal{M}$ and the retraction $R_{\mathbf{X}}$ of the manifold of the low-rank matrices have been well-studied Absil and Oseledets (2015): Assume that the SVD decomposition of $\mathbf{X}$ is $\mathbf{X}=\mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$, then the tangent space $T_{\mathbf{X}}\mathcal{M}$ can be defined by $T_{\mathbf{X}}\mathcal{M}=\{\mathbf{A}\mathbf{V}\mathbf{V}^T+\mathbf{U}\mathbf{U}^T\mathbf{B}\ :\ \text{for } \mathbf{A}\in\mathbb{R}^{n_1\times n_1},\mathbf{B}\in\mathbb{R}^{n_2\times n_2}\}$ according to Absil and Oseledets (2015). The explicit formula for the projection $P_{T_{\mathbf{X}}\mathcal{M}}$ is given in (Absil and Oseledets, 2015, (9)):

$$P_{T_{\mathbf{X}}\mathcal{M}}(\mathbf{D})=\mathbf{U}\mathbf{U}^T\mathbf{D}+\mathbf{D}\mathbf{V}\mathbf{V}^T-\mathbf{U}\mathbf{U}^T\mathbf{D}\mathbf{V}\mathbf{V}^T,\qquad \mathbf{D}\in\mathbb{R}^{n_1\times n_2}. \tag{7}$$

For completeness, a proof of (7) is presented in Appendix.

There are various ways of defining retractions for the manifold of low-rank matrices, and we refer the reader to Absil and Oseledets (2015) for more details. In this work, we consider two types of retractions. One is called the *projective* retraction Shalit et al. (2012); Vandereycken (2013), Given any $\delta\in T_{\mathbf{X}}\mathcal{M}$, the retraction is defined as the nearest low-rank matrix to $\mathbf{X}+\delta$ in terms of Frobenius norm:

$$R^{(1)}_{\mathbf{X}}(\delta)=\underset{\mathbf{Z}\in\mathcal{M}}{\arg\min}\|\mathbf{X}+\delta-\mathbf{Z}\|_F. \tag{8}$$

The solution is the rank-r approximation of $\mathbf{X}+\delta$ (for any matrix $\mathbf{W}$, its rank-r approximation is given by $\sum_{i=1}^r\sigma_i\mathbf{u}_i\mathbf{v}_i^T$, where $\sigma_i,\mathbf{u}_i,\mathbf{v}_i$ are the ordered singular values and vectors of $\mathbf{W}$).

In order to further improve computation efficiency, we also consider the *orthographic* retraction Absil and Oseledets (2015). Denoted by $R^{(2)}_{\mathbf{X}}(\delta)$, it is the nearest rank-r matrix to $\mathbf{X}+\delta$ that their difference is orthogonal to the tangent space $T_{\mathbf{X}}\mathcal{M}$:

$$R^{(2)}_{\mathbf{X}}(\delta)=\underset{\mathbf{Z}\in\mathcal{M}}{\arg\min}\|\mathbf{X}+\delta-\mathbf{Z}\|_F,\ \text{ s.t. }\ \langle R^{(2)}_{\mathbf{X}}(\delta)-(\mathbf{X}+\delta),\mathbf{Z}\rangle_F=0\ \text{ for all }\ \mathbf{Z}\in T_{\mathbf{X}}\mathcal{M}, \tag{9}$$

and its explicit solution of (9) is given in (Absil and Oseledets, 2015, Section 3.2),

$$R^{(2)}_{\mathbf{X}}(\delta)=(\mathbf{X}+\delta)\mathbf{V}[\mathbf{U}^T(\mathbf{X}+\delta)\mathbf{V}]^{-1}\mathbf{U}^T(\mathbf{X}+\delta), \tag{10}$$

and a proof is given in Appendix.

3.3. Derivation of the proposed algorithms

3.3.1. Derivation of Algorithm 1

The gradient descent algorithm (6) for solving (2) can be written as

$$\mathbf{L}^{(k+1)}=R_{\mathbf{L}^{(k)}}(-\eta P_{T_{\mathbf{L}^{(k)}}}\nabla f(\mathbf{L}^{(k)})), \tag{11}$$

where $P_{T_{\mathbf{L}^{(k)}}}$ is defined in (7) and $R_{\mathbf{L}^{(k)}}$ is defined in (8) or (10). To derive the explicit algorithm, it remains to find the gradient ∇f.

If the absolute values of all entries of $\mathbf{A}$ are different, then we have

$$\nabla f(\mathbf{L})=F(\mathbf{L}-\mathbf{Y}). \tag{12}$$

The proof of (12) is deferred to Appendix. When some entries of $\mathbf{A}$ are equivalent and there is a tie in generating $F(\mathbf{L}-\mathbf{Y})$, the objective function could be non-differentiable. However, it can be shown that by arbitrarily breaking the tie, $F(\mathbf{L}-\mathbf{Y})$ is a subgradient of $f(\mathbf{L})$.

The corresponding gradient descent method (or subgradient method when f is not differentiable) with projective retraction can be written as follows:

$$\mathbf{L}^{(k+1)}:=\text{rank-}r\text{ approximation of }\left[\mathbf{L}^{(k)}-\eta P_{T_{\mathbf{L}^{(k)}}}F(\mathbf{L}^{(k)}-\mathbf{Y})\right], \tag{13}$$

where the rank-r approximation has been defined after (8). This leads to Algorithm 1 with Option 1.

For the orthographic retraction, i.e., $R_{\mathbf{L}^{(k)}}$ defined according to (10), by writing $\mathbf{D}=F(\mathbf{L}^{(k)}-\mathbf{Y})$, the update formula (11) can be simplified to

$$\mathbf{L}^{(k+1)}:=(\mathbf{L}^{(k)}-\eta\mathbf{D})\mathbf{V}^{(k)}[\mathbf{U}^{(k)T}(\mathbf{L}^{(k)}-\eta\mathbf{D})\mathbf{V}^{(k)}]^{-1}\mathbf{U}^{(k)T}(\mathbf{L}^{(k)}-\eta\mathbf{D}), \tag{14}$$

where $\mathbf{U}^{(k)}\in\mathbb{R}^{n_1\times r}$ is any matrix such that its column space is the same as the column space of $\mathbf{L}^{(k)}$; and $\mathbf{V}^{(k)}\in\mathbb{R}^{n_2\times r}$ is any matrix such that its column space is the same as the row space of $\mathbf{L}^{(k)}$. The derivation of (14) is deferred to Appendix, and it can be shown that the implementation of (14) leads to Algorithm 1 with Option 2.

3.3.2. Derivation of Algorithm 2

By a similar argument as in the previous section, we can conclude that when all entries of $|\mathbf{L}-\mathbf{Y}|$ are different from each other, then applying the same procedure of deriving (12), we have

$$\nabla\tilde{f}(\mathbf{L})=\tilde{F}(\mathbf{L}-\mathbf{Y});$$

and $\tilde{F}(\mathbf{L}-\mathbf{Y})$ is a subgradient when $\tilde{f}(\mathbf{L})$ is not differentiable. Based on this observation, the algorithm under the partially observed setting is identical to (13) or (14), with F replaced by $\tilde{F}$. This gives the implementation of Algorithm 2.

3.3.3. Basic convergence properties of Algorithms 1 and 2

An interesting topic is that, can we still expect the algorithm to have reasonable basic properties, such as convergence to a critical point? Unfortunately, it is impossible to have such a theoretical guarantee if a fixed step size η is chosen: in general, the subgradient method with fixed step size does not have the convergence guarantee if the objective function is non-differentiable. However, if we choose step size with line search, then any accumulation point of $\mathbf{L}^{(k)}$, $\widehat{\mathbf{L}}$, would have the property that either the objective function is not differentiable at $\widehat{\mathbf{L}}$, or it is a critical point in the sense that its Riemannian gradient is zero. For example, the line search strategy for Algorithm 1 can be described as follows: start the step size η_k with a relatively large value, and repeatedly shrinks it by a factor of $\beta\in(0,1)$ such that the following condition is satisfied: for $\mathbf{L}^{(k+1)}=R_{\mathbf{L}^{(k)}}(-\eta_k P_{T_{\mathbf{L}^{(k)}}}\nabla f(\mathbf{L}^{(k)}))$,

$$f(\mathbf{L}^{(k)})-f(\mathbf{L}^{(k+1)})>c\eta_k\|P_{T_{\mathbf{L}^{(k)}}}\nabla f(\mathbf{L}^{(k)})\|^2,$$

where $c \in (0,1)$ is prespecified. The argument for convergence follows from the same argument as the proof of (Absil et al., 2009, Theorem 4.3.1).

3.4. Prior works on manifold optimization

The idea of optimization on manifolds has been well investigated in the literature Vandereycken (2013); Shalit et al. (2012); Absil et al. (2009). For example, Absil et al. Absil et al. (2009) give a summary of many advances in the field of optimization on manifolds. Manifold optimization has been applied to many matrix estimation problems, including recovering a low rank matrix from its partial entries, i.e., matrix completion Keshavan et al. (2010); Vandereycken (2013); Wei et al. (2016) and robust matrix completion in Cambier and Absil (2016). In fact, the problem studied in this work can be reformulated to the problem analyzed in Cambier and Absil (2016). In comparison, our work studies a different algorithm and gives additional theoretical guarantees.

In another aspect, while Wei et al. (2016) studies matrix completion, it shares some similarities with this work: both works study manifold optimization algorithms and have theoretical guarantees showing that the proposed algorithms can recover the underlying low-rank matrix exactly. In fact, Wei et al. (2016) can be considered as our problem under the partially observed setting, without corruption $\mathbf{S}^*$. It proposes to solve

$$\underset{\mathbf{L}\in\mathbb{R}^{n_1\times n_2},\mathrm{rank}(\mathbf{L})=r}{\arg\min} \sum_{(i,j)\in\Phi} (\mathbf{Y}_{ij} - \mathbf{L}_{ij})^2,$$

which can be considered as $\tilde{f}$ in (5) when $\gamma = 0$.

4. Theoretical Analysis

In this section, we analyze the theoretical properties of Algorithms 1 and 2 and compare them with previous algorithms. Since the goal is to recover the low-rank matrix $\mathbf{L}^*$ and the sparse matrix $\mathbf{S}^*$ from $\mathbf{Y} = \mathbf{L}^* + \mathbf{S}^*$, to avoid identifiability issues, we need to assume that $\mathbf{L}^*$ can not be both low-rank and sparse. Specifically, we make the following standard assumptions on $\mathbf{L}^*$ and $\mathbf{S}^*$:

Assumption 1 *Each row of $\mathbf{S}^*$ contains at most $\gamma^* n_2$ nonzero entries and each column of $\mathbf{S}^*$ contains at most $\gamma^* n_1$ nonzero entries. In other words, for $\gamma^* \in [0,1)$, assume $\mathbf{S}^* \in \mathcal{S}_{\gamma^*}$ where*

$$\mathcal{S}_{\gamma^*} \coloneqq \left\{ A \in \mathbb{R}^{n_1\times n_2} \mid \|A_{i,\cdot}\|_0 \le \gamma^* n_2, \text{ for } 1 \le i \le n_1; \|A_{\cdot,j}\|_0 \le \gamma^* n_1, \text{ for } 1 \le j \le n_2 \right\}. \tag{15}$$

Assumption 2 *The low-rank matrix $\mathbf{L}^*$ is not near-sparse. To achieve this, we require that $\mathbf{L}^*$ must be μ-coherent. Given the singular value decomposition (SVD) $\mathbf{L}^* = \mathbf{U}^*\mathbf{\Sigma}^*\mathbf{V}^{*T}$, where $\mathbf{U}^* \in \mathbb{R}^{n_1\times r}$ and $\mathbf{V}^* \in \mathbb{R}^{n_2\times r}$, we assume there exists an incoherence parameter μ such that*

$$\|\mathbf{U}^*\|_{2,\infty} \le \sqrt{\frac{\mu r}{n_1}}, \ \ \|\mathbf{V}^*\|_{2,\infty} \le \sqrt{\frac{\mu r}{n_2}}, \tag{16}$$

where the norm $\|\cdot\|_{2,\infty}$ is defined by $\|\mathbf{A}\|_{2,\infty} = \max_{\|\mathbf{z}\|_2=1} \|\mathbf{A}\mathbf{z}\|_\infty$ and $\|\mathbf{x}\|_\infty = \max_i |\mathbf{x}_i|$.

4.1. Analysis of Algorithm 1

With Assumption 1 and 2, we have the following theoretical results regarding the convergence rate, initialization, and stability of Algorithm 1:

Theorem 1 (Linear convergence rate, fully observed case) *Suppose that $\|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F \le a\sigma_r(\mathbf{L}^*)$, where $\sigma_r(\mathbf{L}^*)$ is the r-th largest singular value of $\mathbf{L}^*$, $a \le 1/2$, $\gamma > 2\gamma^*$ and $C_1 = \sqrt{4(\gamma + 2\gamma^*)\mu r + 4\frac{\gamma^*}{\gamma-\gamma^*} + a^2} < \frac{1}{2}$, then there exists $\eta_0 = \eta_0(C_1, a) > 0$ that does not depend on k, such that for all $\eta \le \eta_0$,*

$$\|\mathbf{L}^{(k)} - \mathbf{L}^*\|_F \le \left(1 - \frac{1-2C_1}{8}\eta\right)^k \|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F.$$

Remark 2 *(Choices of parameters). It is shown in the proof that η_0 can be set to the solution of the equation*

$$\eta_0(1+C_1)^2\left[\frac{1}{2} + \frac{a^2}{1-\eta_0(1+C_1)a}\right] = \frac{1}{8}(1-2C_1).$$

Since the LHS is an increasing function of η_0 and is zero when $\eta_0 = 0$, and its RHS is a positive number.

While $C_1 < 1/2$ requires $\sqrt{4\gamma^*/(\gamma-\gamma^*)} < 1/2$, i.e., $\gamma > 17\gamma^*$. In practice a much smaller γ can be used. In Section 5, $\gamma = 1.5\gamma^*$ is used and works well for a large number of examples. It suggests that some constants in Theorem 1 might be due to the technicalities in the proof and can be potentially improved.

Remark 3 *(Simplified choices of parameters) There exists c_1 and c_2 such that if $a < c_1$, $\gamma^*\mu r < c_2$ and $\gamma = 65\gamma^*$, then one can choose $\eta_0 = 1/8$. In this sense, if the initialization of the algorithm is good, then the algorithm can handle γ^* as large as $O(1/\mu r)$. In addition, it requires $O(\log(1/\epsilon))$ iterations to achieve $\|\mathbf{L}^{(k)} - \mathbf{L}^*\|_F / \|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F < \epsilon$.*

Since the statements require proper initializations (i.e., small a), the question arises as to how to choose proper initializations. The work by Yi et al. (2016) shows that if the rank-r approximation to $F(\mathbf{Y})$ is used as the initialization $\mathbf{L}^{(0)}$, then such initialization has the upper bound $\|\mathbf{L}^{(0)} - \mathbf{L}^*\|$ according to the proofs of (Yi et al., 2016, Theorems 1 and 3) (we borrow this estimation along with the fact that $\|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F \le \sqrt{2r}\|\mathbf{L}^{(0)} - \mathbf{L}^*\|$).

Theorem 4 (Initialization, fully observed case) *If $\gamma > \gamma^*$ and we initialize $\mathbf{L}^{(0)}$ using the rank-r approximation to $F(\mathbf{Y})$, then*

$$\|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F \le 8\gamma\mu r\sqrt{2r}\sigma_1(\mathbf{L}^*).$$

The combination of Theorem 1, 4 and the fact that $\gamma = O(\gamma^*)$ implies that under the fully observed setting, the tolerance of the proposed algorithms to corruption is at most $\gamma^* = O(\frac{1}{\mu r\sqrt{r}\kappa})$, where $\kappa = \sigma_1(\mathbf{L}^*)/\sigma_r(\mathbf{L}^*)$ is the condition number of $\mathbf{L}^*$. We also study the stability of Algorithm 1 in the following statement.

Theorem 5 (Stability, fully observed case) *Let $\mathbf{L}$ be the current value, and let $\mathbf{L}^+$ be the next update by applying Algorithm 1 to $\mathbf{L}$ for one iteration. Assuming $\mathbf{Y} = \mathbf{L}^* + \mathbf{S}^* + \mathbf{N}^*$, where $\mathbf{N}^*$ is a random Gaussian noise i.i.d. sampled from $N(0, \sigma^2)$, $\gamma > 10\gamma^*$ and $(\gamma + 2\gamma^*)\mu r < 1/64$, then there exist $C, a, c, \eta_0 > 0$ such that when $\eta < \eta_0$,*

$$P\left(\|\mathbf{L}^+ - \mathbf{L}^*\|_F \le (1 - c\eta)\,\|\mathbf{L} - \mathbf{L}^*\|_F \text{ for all } \mathbf{L} \in \Gamma\right) \to 1, \quad \text{as } n_1, n_2 \to \infty, \tag{17}$$

where

$$\Gamma = \{\mathbf{L} \in \mathbb{R}^{n_1 \times n_2} : \text{rank}(\mathbf{L}) = r, C\sigma\sqrt{(n_1 + n_2)r\ln(n_1 n_2)} \le \|\mathbf{L} - \mathbf{L}^*\|_F \le a\sigma_r(\mathbf{L}^*)\|,$$

Since $1 - c\eta < 1$, and Theorem 5 shows that when the observation $\mathbf{Y}$ is contaminated with a random Gaussian noise, if $\mathbf{L}^{(0)}$ is properly initialized such that $\|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F < a\sigma_r(\mathbf{L}^*)$, Algorithms 1 will converge to a neighborhood of $\mathbf{L}^*$ given by

$$\{\mathbf{L} : \|\mathbf{L} - \mathbf{L}^*\|_F \le C\sigma\sqrt{(n_1 + n_2)r\ln(n_1 n_2)}\}$$

in $[-\log(\|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F) + \log(C\sigma\sqrt{(n_1 + n_2)r\ln(n_1 n_2)})]/\log(1 - c\eta)$ iterations, with probability goes to 1 as $n_1, n_2 \to \infty$.

4.2. Analysis of Algorithm 2

For the partially observed setting, we assume that each entry of $\mathbf{Y} = \mathbf{L}^* + \mathbf{S}^*$ is observed with probability p. That is, for any $1 \le i \le n_1$ and $1 \le j \le n_2$, $\Pr((i, j) \in \mathbf{\Phi}) = p$. Then we have the following statement on convergence:

Theorem 6 (Linear convergence rate, partially observed case) *There exists $c > 0$ such that for $n = \max(n_1, n_2)$, if $p \ge \max(c\mu r \log(n)/\epsilon^2 \min(n_1, n_2), \frac{56}{3}\frac{\log n}{\gamma \min(n_1, n_2)})$, then with probability $1 - 2n^{-3} - 6n^{-1}$,*

$$\begin{aligned}\frac{\|\mathbf{L}^{(k)} - \mathbf{L}^*\|_F}{\|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F} \le &\Big[\sqrt{1 - p^2(1-\epsilon)^2\left(2\eta\left(1 - \tilde{C}_1 - \frac{ap(1+\epsilon)}{2(1-a)}(1 + \tilde{C}_1)\right) - \eta^2(1 + \tilde{C}_1)^2\right)} \\ &+ \frac{\eta^2 a^2 (p + p\epsilon)^2 (1 + \tilde{C}_1)^2}{1 - \eta a(p + p\epsilon)(1 + \tilde{C}_1)}\Big]^k\end{aligned} \tag{18}$$

for

$$\tilde{C}_1 = \frac{1}{p(1-\epsilon)}\Big[6(\gamma + 2\gamma^*)p\mu r + 4\frac{3\gamma^*}{\gamma - 3\gamma^*}(\sqrt{p(1+\epsilon)} + \frac{a}{2})^2 + a^2\Big].$$

Remark 7 *(Choice of parameters) Note that when η is small, the RHS of (18) is in the order of*

$$1 - p^2(1-\epsilon)^2\left(1 - \tilde{C}_1 - \frac{ap(1+\epsilon)}{2(1-a)}(1 + \tilde{C}_1)\right)\eta + O(\eta^2).$$

As a result, to make sure that the RHS of (18) to be smaller than 1 for small η, we assume that

$$1 - \tilde{C}_1 - \frac{ap(1+\epsilon)}{2(1-a)}(1 + \tilde{C}_1) > 0. \tag{19}$$

For example, when $ap(1 + \epsilon) = 4(1 - a)$, it requires that $\tilde{C}_1 < 1/3$. If (19) holds, then there exists $\eta_0 = \eta_0(\tilde{C}_1, p, \epsilon, a)$ such that for all $\eta \le \eta_0$, the RHS of (18) is smaller than 1.

The practical choices of η and γ will be discussed in Section 5.

Remark 8 *(Simplified choice of parameters) There exists $\{c_i\}_{i=1}^4 > 0$ such that when $\epsilon < 1/2$, $a < c_1 p$, $\gamma^*\mu r < c_2$ and $\gamma = c_3\gamma^*$, then when $\eta < 1/8$,*

$$\frac{\|\mathbf{L}^{(k)} - \mathbf{L}^*\|_F}{\|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F} \le (1 - c_4\eta p^2)^k.$$

Compared with the result in Theorem 1, the addition parameter p appears in both the initialization requirement $a < c_1 p$ as well as the convergence rate. This makes the result weaker, but we suspect that the dependence on the subsampling ratio p could be improved through a better estimation in (39) and the estimation of $\tilde{C}_1$ in Lemma 16, and we leave it as a possible future direction.

We present a method of obtaining a proper initialization in Theorem 9. Combining it with Theorem 6, Algorithm 2 allows the corruption level γ^* to be in the order of $O(\frac{p}{\mu r\sqrt{r\kappa}})$.

Theorem 9 (Initialization, partially observed case) *There exists $c_1, c_2, c_3 > 0$ such that if $\gamma > 2\gamma^*$, and $p \ge c_2(\frac{\mu r^2}{\epsilon^2} + \frac{1}{\alpha})\log n/\min(n_1, n_2)$, and we initialize $\mathbf{L}^{(0)}$ using the rank-r approximation to $F(\mathbf{Y})$, then*

$$\|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F \le 16\gamma\mu r\sigma_1(\mathbf{L}^*)\sqrt{2r} + 2\sqrt{2}c_1\epsilon\sigma_1(\mathbf{L}^*)$$

with probability at least $1 - c_3 n^{-1}$, where $\sigma_1(\mathbf{L}^*)$ is the largest singular value of $\mathbf{L}^*$.

4.3. Comparison with Alternating Gradient Descent

Since our objective functions are equivalent to the objective functions of the alternating gradient descent (AGD) in Yi et al. (2016), it would be interesting to compare these two works. The only difference of these two works lies in the algorithmic implementation: our methods use the gradient descent on the manifold of low-rank matrices, while the methods in Yi et al. (2016) use alternating gradient descent on the factors of the low-rank matrix. In the following we compare the results of both works from four aspects:

1. **Accuracy of initialization.** What is the largest value t that the algorithm can tolerate, such that for any initialization $\mathbf{L}^{(0)}$ satisfying $\|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F \le t$, the algorithm is guaranteed to converge to $\mathbf{L}^*$?

2. **Convergence rate.** What is the smallest number of iteration steps k such that the algorithm reaches a given convergence criterion ϵ, i.e. $\|\mathbf{L}^{(k)} - \mathbf{L}^*\|_F/\|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F < \epsilon$?

3. **Corruption level (perfect initialization).** Suppose that the initialization is in a sufficiently small neighborhood of $\mathbf{L}^*$ (i.e. there exists a very small $\epsilon_0 > 0$ such that $\mathbf{L}^{(0)}$ satisfies $\|\mathbf{L}^{(0)} - \mathbf{L}^*\|_F < \epsilon_0$), what is the maximum corruption level that can be tolerated in the convergence analysis?

4. **Corruption level (proper initialization).** Suppose that the initialization is given by the procedure in Theorem 4 (for the partially observed case) and 9 (for the fully observed case), what is the maximum corruption level that can be tolerated?

These comparisons are summarized in Table 1. We can see that under the full observed setting, our results remove or reduce the dependence on the condition number κ, while keeping other values unchanged. Under the partially observed setting our results still have the advantage of less dependence on κ, but sometimes require an additional dependence on the subsampling ratio p. The simulation results discussed in the next section also verify that when κ is large our algorithms have better performance, while that the slowing effect of p under the partially observed setting is not significant. As discussed after Theorem 6, we suspect that this dependence could be removed after a more careful analysis (or more assumptions).

Criterion	Accuracy of initialization	Convergence rate	Max corruption (perfect init.)	Max corruption (proper init.)
Algorithm 1	$O(\sigma_r(\mathbf{L}^*))$	$O(\log(\frac{1}{\epsilon}))$	$O(\frac{1}{\mu r})$	$O(\frac{1}{\mu r^{1.5}\kappa})$
APG (full)	$O(\frac{\sigma_r(\mathbf{L}^*)}{\sqrt{\kappa}})$	$O(\kappa\log(\frac{1}{\epsilon}))$	$O(\frac{1}{\kappa^2\mu r})$	$O(\frac{1}{\max(\mu r^{1.5}\kappa^{1.5},\kappa^2\mu r)})$
Algorithm 2	$O(\sqrt{p}\sigma_r(\mathbf{L}^*))$	$O(\log(\frac{1}{\epsilon})/p^2)$	$O(\frac{1}{\mu r})$	$O(\frac{\sqrt{p}}{\mu r^{1.5}\kappa})$
APG (partial)	$O(\frac{\sigma_r(\mathbf{L}^*)}{\kappa})$	$O(\kappa\mu r\log(\frac{1}{\epsilon})$	$O(\frac{1}{\kappa^2\mu r})$	$O(\frac{1}{\max(\mu r^{1.5}\kappa^{1.5},\kappa^2\mu r)})$

Table 1: Comparison of the theoretical guarantees in our work and the alternating gradient descent algorithm in Yi et al. (2016). The four criteria are explained in details in Section 4.3.

Here we use a simple example to give some intuition of why our proposed methods work better than gradient descent method based on factorization. Let us consider the following simple optimization problem:

$$\arg\min_{\mathbf{z}\in\mathbb{R}^m} f(\mathbf{z}),\ \text{ where } \mathbf{z}=\mathbf{A}\mathbf{x}+\mathbf{B}\mathbf{y},$$

where $\mathbf{x},\mathbf{y}\in\mathbb{R}^n$ and $\mathbf{A},\mathbf{B}\in\mathbb{R}^{m\times n}$. In this example, $(\mathbf{x},\mathbf{y})$ can be considered as the "factors" of $\mathbf{z}$. The gradient descent method on the factors $(\mathbf{x},\mathbf{y})$ is then given by

$$\mathbf{x}^+=\mathbf{x}-\eta\mathbf{A}^Tf'(\mathbf{z}),\ \ \mathbf{y}^+=\mathbf{y}-\eta\mathbf{B}^Tf'(\mathbf{z}). \tag{20}$$

Writing the update formula (20) in terms of $\mathbf{z}$, it becomes

$$\mathbf{z}^+=\mathbf{A}\mathbf{x}^++\mathbf{B}\mathbf{y}^+=\mathbf{z}-\eta(\mathbf{A}\mathbf{A}^T+\mathbf{B}\mathbf{B}^T)f'(\mathbf{z}).$$

As a result, the "gradient descent on factors $(\mathbf{x},\mathbf{y})$" has a direction of $-(\mathbf{A}\mathbf{A}^T+\mathbf{B}\mathbf{B}^T)f'(\mathbf{z})$. In comparison, the gradient descent on the variable $\mathbf{z}$ has a direction of $-f'(\mathbf{z})$, which is the direction that f decreases fastest. If $\mathbf{A}\mathbf{A}^T+\mathbf{B}\mathbf{B}^T$ is a matrix with a large condition number, then we expect that the gradient descent method on factors $(\mathbf{x},\mathbf{y})$ would not work well. This example shows that generally, compared to applying the gradient descent method to the factors of a variable, it is better to apply it to the variable itself. Similar to this example, our method applies gradient descent on the $\mathbf{L}$ itself while Yi et al. (2016) applies gradient descent to the factors of $\mathbf{L}$.

4.4. Comparison with other robust PCA algorithms

In this section we compare our result with other robust PCA methods and summarize them in Table 2. Some criterion in Table 1 are not included since they do not apply. For example, (Netrapalli et al., 2014, Alternating Projection) only analyzes the algorithm with specific initialization, and the criterion 1 and 3 in Table 1 do not apply to this work. As a result, we only compare the maximum corruption ratio that these methods can handle, and the computational complexity per iteration in Table 2. As for the convergence rate, it depends on assumptions on parameters such as the coherence parameter, rank, and the size of the matrix: The alternating projection Netrapalli et al. (2014) requires $10\log(4n_1\mu^2r\|\mathbf{Y}-\mathbf{L}^{(0)}\|_2/\epsilon\sqrt{n_1n_2})$ iterations to achieve an accuracy ϵ, under the assumptions that $\gamma^*<1/512\mu r^2$ and a tuning parameter is chosen to be $4\mu^2r\sqrt{n_1n_2}$. The alternating minimization method Gu et al. (2016) have the guarantee that if $\|\mathbf{L}^{(1)}-\mathbf{L}^*\|_2\le\sigma_1(\mathbf{L}^*)$, then

$$\|\mathbf{L}^{(k+1)}-\mathbf{L}^*\|_F\le\sigma_1\left(\frac{96\sqrt{2}\nu\mu\sqrt{r}(s^*/d)^{3/2}\kappa\sigma_1}{1-24\sqrt{2}\nu\mu\sqrt{r}(s^*/d)^{3/2}\kappa\sigma_1}\right)^k\|\mathbf{L}^{(1)}-\mathbf{L}^*\|_F,$$

where ν is a parameter concerning the coherence of $\mathbf{L}^*$, s^* is the number of nonzero entries in $\mathbf{S}^*$, $d=\min(n_1,n_2)$. As a result s^*/d is approximately $\gamma^*\max(n_1,n_2)$ in our notation. If ν is in the order of $O(1)$, then this results requires that $\mu\sqrt{r}\kappa\sigma_1\max(n_1,n_2)^{3/2}\gamma^{*3/2}\le O(1)$, which is more restrictive than our assumption in Theorem 1 that $\gamma^*\mu r\le O(1)$. Convex methods usually have convergence rate guarantees based on convexity, for example, the accelerated proximal gradient method Toh and Yun (2010) has a convergence rate of $O(1/k^2)$. While it is a slower convergence rate compared to the result in Theorem 1 in this work or the results in Netrapalli et al. (2014); Gu et al. (2016) and it does not necessarily converge to the correct solution, this result does not depend on any assumption on the low-rank matrix and the corruption ratio.

Criterion	Maximum corruption level	Complexity per iteration
Algorithm 1	$O(1/\kappa\mu r^{3/2})$	$O(rn_1n_2)$
Convex methods	$O(1/\mu^2r)$	$O(n_1n_2\min(n_1,n_2))$
Netrapalli et al. (2014)	$1/512\mu^2r$	$O(r^2n_1n_2)$
Gu et al. (2016)	$O(1/\mu^{2/3}r^{2/3}\min(n_1,n_2))$	$O(r^2n_1n_2)$
Yi et al. (2016)	$O(1/\kappa^2\mu r^{3/2})$	$O(rn_1n_2)$

Table 2: Comparison of the theoretical guarantees in our work and some other robust PCA algorithms.

The stability in Theorem 5 is comparable to analysis in Netrapalli et al. (2014) (the works Gu et al. (2016) and (Yi et al., 2016, Alternating Gradient Descent) do not have stability analysis). The work Netrapalli et al. (2014) assumes that $\|\mathbf{N}^*\|_\infty<\sigma_r(\mathbf{L}^*)/100n_2$ and proves that the output of their algorithm $\widehat{\mathbf{L}}$ satisfies

$$\|\widehat{\mathbf{L}}-\mathbf{L}^*\|_F\le\epsilon+2\mu^2r\left(7\|\mathbf{N}^*\|_2+\frac{8\sqrt{n_1n_2}}{\sqrt{r}}\|\mathbf{N}^*\|_\infty\right),$$

where ϵ is the error of the algorithm when there is no noise. If $\mathbf{N}^*$ is i.i.d. sampled from $N(0,\sigma^2)$, this result suggests that $\|\widehat{\mathbf{L}}-\mathbf{L}^*\|_F$ is bounded above by $\epsilon + O(\mu^2\sqrt{rn_1n_2}\sigma)$. In comparison, Theorem 5 suggests that after a few iterations, $\|\mathbf{L}^{(k)}-\mathbf{L}^*\|_F$ is bounded above by $C\sigma\sqrt{(n_1+n_2)r\ln(n_1n_2)}$ with high probability, which is a tighter upper bound.

5. Simulations

In this section, we test the performance of the proposed algorithms by simulated data sets and real data sets. The MATLAB implementation of our algorithm used in this section is available at `https://sciences.ucf.edu/math/tengz/`. For simulated data sets, we generate $\mathbf{L}^*$ by $\mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$, where $\mathbf{U}\in\mathbb{R}^{n_1\times r}$ and $\mathbf{V}\in\mathbb{R}^{n_2\times r}$ are random matrices that i.i.d. sampled from $N(0,1)$, and $\mathbf{\Sigma}\in\mathbb{R}^{n_1\times r}$ is an diagonal matrix. As for $\mathbf{S}^*\in\mathbb{R}^{n_1\times n_2}$, each entry is sampled from $N(0,100)$ with probability q, and is zero with probability $1-q$. That is, q represents the level of sparsity in the sparse matrix $\mathbf{S}^*$. It measures the overall corruption level of $\mathbf{Y}$ and is associated with the corruption level γ^* (γ^* measures the row and column-wise corruption level). For the partially observed case, we assume that each entry of $\mathbf{Y}$ is observed with probability p.

5.1. Choice of parameters

We first investigate the performance of the proposed algorithms, in particular, the dependence on the parameters η and γ. In simulations, we let $[n_1,n_2]=[500,600]$, $r=3$, $\mathbf{\Sigma}=\mathbf{I}$, and $q=0.02$. For the partially observed case, we let $p=0.2$.

The first simulation investigates the following questions:

- Should we use the Algorithms 1 and 2 with Option 1 or Option 2?
- What is the appropriate choice of the step size η?

The simulation results for Option 1 an 2 with various step sizes are visualized in Figure 2, which show that the two options perform similarly. Usually the algorithms converge faster when the step size is larger. However, if the step size is too large then it might diverge. As a result, we use the step size $\eta=0.7$ for Algorithm 1 and $0.7/p$ for Algorithm 2 for the following simulations.

The second simulation concerns the choice of γ. We test $\gamma=c\gamma^*$ for a few choices of c (γ^* can be calculated from the zero pattern of $\mathbf{S}$). Figure 5.1 shows that if γ is too small, for example, $0.5\gamma^*$, then the algorithm fail to converge to the correct solution; and if γ is too large, then the convergence is slow. Following these observations, we use $\gamma=1.5\gamma^*$ as the default choice of the following experiments, which is also used in Yi et al. (2016).

5.2. Performance of the proposed algorithm

In this section, we analyze the convergence behavior as the parameters (overall ratio of corrupted entries q, condition number κ, rank r, subsampling ratio p) changes and visualized the result in Figure 4.

Figure 4(a) shows the simulation for corruptions level q, we use the setting in Section 5.1, but replace the corruption level q by $q=0.1,0.2,0.3,0.4$. Figure 4 shows that the algorithm

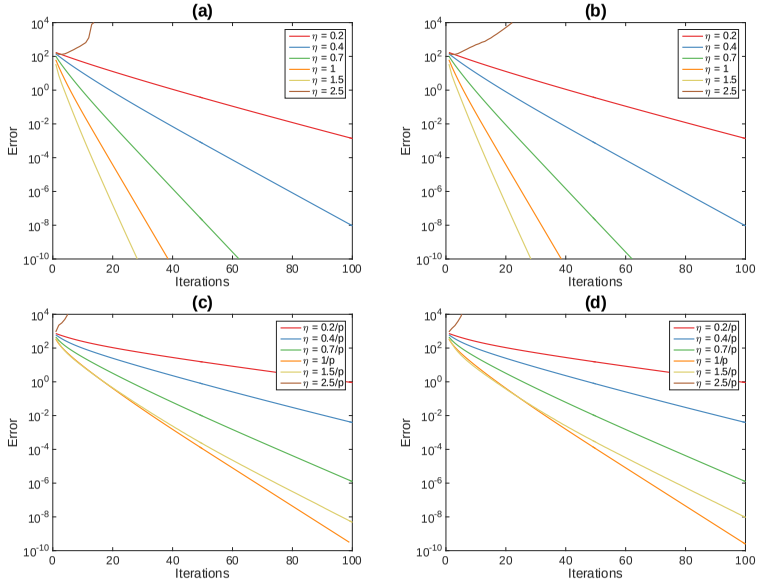

Figure 2: The dependence of the estimation error on the number of iterations for different step sizes η (a) Algorithm 1 (Option 1); (b) Algorithm 1 (Option 2); (c) Algorithm 2 (Option 1); (d) Algorithm 2 (Option 2).

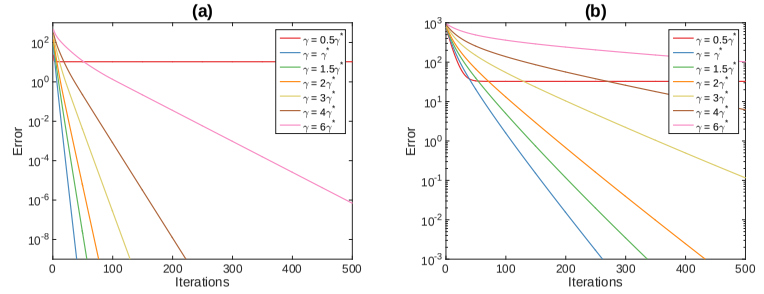

Figure 3: The convergence of the algorithm depending on the choice of γ. (a) fully observed setting; (b) partially observed setting.

converges slower with more corruption, which is expected since there is fewer information available. However, the algorithm still converges even with an overall corruption level at 0.4.

Figure 4(b) shows the simulation for rank r, we use the setting in Section 5.1, but replace r by $r = 3, 10, 30, 100, 300$ respectively. Simulations show that the algorithm works fine for rank $r = 3, 10, 30, 100$ and it converges slower for rank $r = 300$.

Figure 4(c) shows the simulation for condition number κ of $\mathbf{L}$, we use the setting in Section 5.1, but replace Σ by $\Sigma = \mathrm{diag}(1, 1, 1/\kappa)$ and try various values of κ. While the algorithm converges for κ up to 30 in the simulation, for larger κ the algorithm converges slowly at the beginning, and then decreases quickly to zero. We suspect that the initialization is not sufficiently good and it takes a while for the algorithm to reach the "local neighborhood of convergence". We also remark that $\mathbf{L}$ with a very large condition number, e.g. $\kappa = 100$, is generally challenging for any nonconvex optimization algorithm, as shown in Figure 5, Setting 4. It is because that when κ is large, the solution is close to a matrix with rank less than r – a singular point on the manifold of the matrices of rank r, which gives a geometry of manifold that is not "smooth" enough. We observe that when $\kappa = 100$, our algorithm performs well if the rank r is set to 2 (instead of the true value 3)—in fact, when $\kappa = 100$, the underlying matrix is approximately of rank 2 since the third singular value is very small.

We test the algorithm with various matrix sizes using the setting in Section 5.1 and set $[n_1, n_2] = [1000, 1200], [5000, 6000], [10000, 12000]$. Figure 4(d) shows that Algorithm 1 converges quickly for all of the choices within a few iterations.

In the last simulation, we test Algorithm 2 under the setting in Section 5.1 with various choices of the subsampling ratio p. Figure 4(e) shows suggest that the algorithm converges for p as small as 0.1, though the convergence rate is slow for small p.

5.3. Comparison with other robust PCA algorithms

In this section, we compare our algorithm with the accelerated proximal gradient method (APG) and the alternating direction method of multiplier (ADMM) based on convex relaxation (1); the robust matrix completion algorithm (RMC) Cambier and Absil (2016) based on manifold optimization problem

$$\underset{\mathrm{rank}(\mathbf{L})=r}{\arg\min} \sum_{(i,j)\in\Phi} \|\mathbf{L}_{ij} - \mathbf{Y}_{ij}\| + \lambda \sum_{(i,j)\notin\Phi} \mathbf{L}_{ij}^2,$$

as well as the alternating gradient descent method (AGD) in Yi et al. (2016) that solves the same optimization as this work, but with an implementation based on matrix factorization rather than manifold optimization. We use the implementation of APG from Toh and Yun (2010) and the implementation of ADMM from `https://github.com/dlaptev/RobustPCA`. In these two algorithms, we use the choice of parameter $\lambda = 1/\sqrt{\max(n_1, n_2)}$, which is the default choice in the implementation Toh and Yun (2010) and the theoretical analysis in Candès et al. (2011). For ADMM, the augmented Lagrangian parameter is set by default as 10λ. For RMC and GD, we use their default setting of parameters. Since the setting of Algorithm 2 does not apply to the implementations of APG/ADMM, we compare them under the fully observed setting. We compare them in the following four settings:

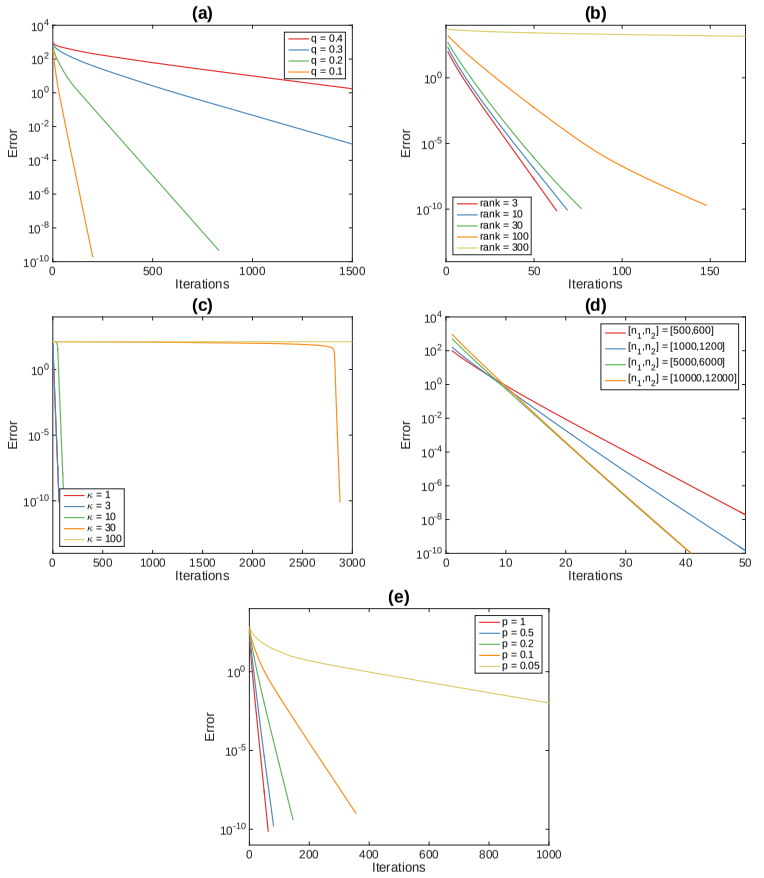

Figure 4: Dependence of the estimation error on the number of iterations for different (a) Overall ratios of corrupted entries q (Algorithm 1); (b) Ranks r (Algorithm 1); (c) Condition numbers κ (Algorithm 1); (d) Matrix sizes $[n_1, n_2]$ (Algorithm 1); (e) Subsampling ratio p (Algorithm 2).

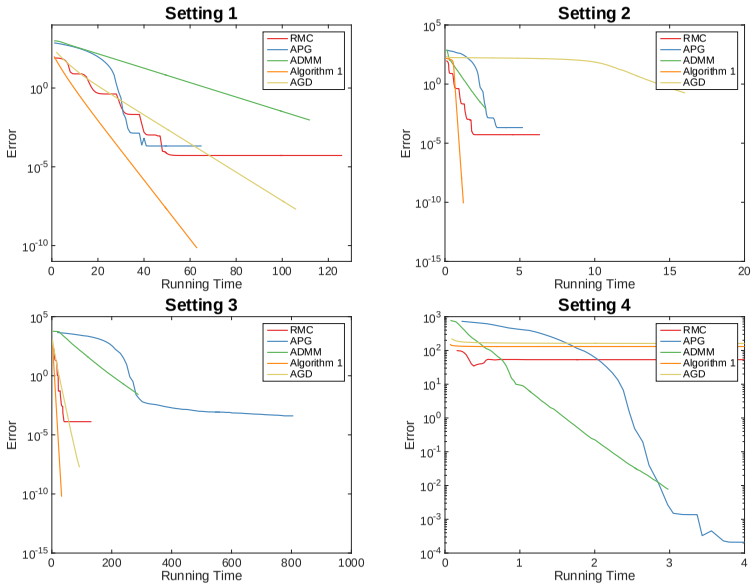

Figure 5: The comparison of the performance of the algorithms under the fully observed setting. The running time is measured in seconds.

- Setting 1: same setting as in Section 5.1.
- Setting 2 (large condition number): replace Σ by $\mathrm{diag}(1, 1, 0.1)$ in Setting 1.
- Setting 3 (large matrix): replace n_1 and n_2 by 3000 and 4000 in Setting 1.
- Setting 4 (large condition number): replace Σ by $\mathrm{diag}(1, 1, 0.01)$ in Setting 1.

Figure 5 shows that under Setting 1, 2 and 3, Algorithm 1 converges faster than other algorithms. In particular, the advantage over the AGD algorithm is very clear under Setting 2, where the condition number is larger. This verifies our theoretical analysis, where the convergence rate is faster than the analysis in Yi et al. (2016) by a factor of $\sqrt{\kappa}$. In Setting 3, the algorithms RMC, AGD and Algorithm 1 converge much faster than APG and ADMM, which verifies the computational advantage of nonconvex algorithms when the matrix size is large. However, in Setting 4, the convex algorithms converge to the correct solution while the nonconvex algorithms converge to a local minimizer that is different than the correct solution. This is due to the fact that the nonconvex algorithms have more than one minimizer, and if it is not initialized well then it could get trapped in local minimizers. In

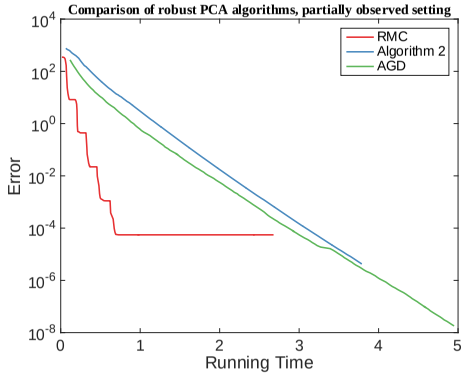

Figure 6: The comparison of the performances of the algorithms under the partially observed setting. The running time is measured in seconds.

practice, we observed that if the initialization is well chosen and close to the true $\mathbf{L}^*$, then Algorithm 1 converges quickly to the correct solution.

We also compare the performance of RMC, AGD and Algorithm 2 under the partially observed setting. We use Setting 1 with $p = 0.3$ and visualize the result in Figure 6. The results are similar to that of the fully observed setting: AGD and Algorithm 2 are comparable and RMC converges faster at the beginning, but then does not achieve higher accuracy, possibly due to their choice of the regularization parameter.

We also test the proposed algorithms in a real data application for video background subtraction. We adopt the public data set `Shoppingmall` studied in Yi et al. (2016),[1] A few frames are visualized in the first column of Figure 7. There are 1000 frames in this video sequence, represented by a matrix of size 81920×1000, where each column corresponds to a frame of the video and each row corresponds to a pixel of the video. We apply our algorithms with $r = 3$ and $\gamma^* = 0.1$, $p = 0.5$ for the partially observed case, the step size $\eta = 0.7$. We stop the algorithm after 100 iterations. Figure 7 shows that our algorithms obtain desirable low-rank approximations within 100 iterations.

In Figure 8, we compare our algorithms with APG in terms of the convergence of the objective function value. In this figure, the relative error is defined as $\|F(\mathbf{L}-\mathbf{Y})\|_F/\|\mathbf{Y}\|_F$, a scaled objective value. A smaller relative error implies a better low-rank approximation. Figure 8 shows out that our algorithms can obtain smaller objective values within 100 iterations under both fully observed and partially observed cases.

1. The data set is originally from `http://perception.i2r.a-star.edu.sg/bk_model/bk_index.html`, and is available at `https://sciences.ucf.edu/math/tengz/`.

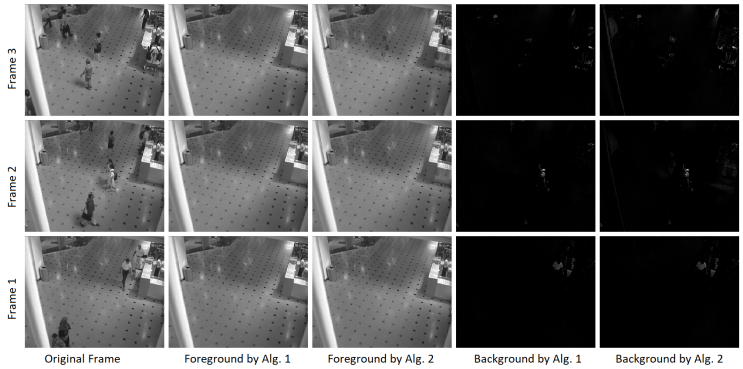

Figure 7: The performance of Algorithms 1 and 2 in video background subtraction, with three rows representing three frames in the video sequence. For Algorithm 2, a subsampling ratio of $p = 0.5$ is used.

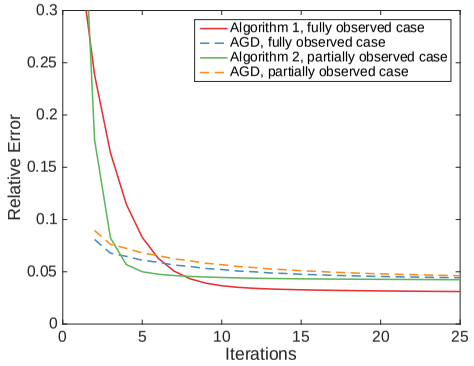

Figure 8: The relative error of Algorithms 1, 2, and AGD with respect to the iterations, for both fully observed case and partially observed case in the experiment of background subtraction.

6. Conclusion

This paper proposes two robust PCA algorithms (one for fully observed case and one for partially observed case) based on the gradient descent algorithm on the manifold of low-rank matrices. Theoretically, compared with the gradient descent algorithm with matrix factorization, our approach has a faster convergence rate, better tolerance of the initialization accuracy and corruption level. The approach removes or reduces the dependence of the algorithms on the condition number of the underlying low-rank matrix. Numerically, the proposed algorithms performance is less sensitive to the choice of step sizes. We also find that under the partially observed setting, the performance of the proposed algorithm is not significantly affected by the presence of the additional dependence on the observation probability. Considering the popularity of the methods based on matrix factorization, it is an interesting future direction to apply manifold optimization to other low-rank matrix estimation problems.

Appendix for "Robust PCA by Manifold Optimization"

A. Technical Derivations in Section 3

Verification of (7). Formula (7) can be verified as follows. Let $\langle\cdot\rangle_F$ be the Frobenius inner product of two matrices, then

$$\begin{aligned}&\langle \mathbf{D} - P_{T_{\mathbf{X}}\mathcal{M}}(\mathbf{D}), \mathbf{A}\mathbf{V}\mathbf{V}^T\rangle_F = \langle (\mathbf{I}-\mathbf{U}\mathbf{U}^T)\mathbf{D}(\mathbf{I}-\mathbf{V}\mathbf{V}^T), \mathbf{A}\mathbf{V}\mathbf{V}^T\rangle_F\\ =&\langle (\mathbf{I}-\mathbf{U}\mathbf{U}^T)\mathbf{D}(\mathbf{I}-\mathbf{V}\mathbf{V}^T)\mathbf{V}\mathbf{V}^T, \mathbf{A}\rangle_F = \langle \mathbf{0}, \mathbf{A}\rangle_F = 0\end{aligned}$$

and similarly $\langle \mathbf{D} - P_{T_{\mathbf{X}}\mathcal{M}}(\mathbf{D}), \mathbf{U}\mathbf{U}^T\mathbf{B}\rangle_F = 0$. As a result, $\langle \mathbf{D} - P_{T_{\mathbf{X}}\mathcal{M}}(\mathbf{D}), \mathbf{A}\mathbf{V}\mathbf{V}^T + \mathbf{U}\mathbf{U}^T\mathbf{B}\rangle_F = 0$ for all $\mathbf{A}\in\mathbb{R}^{n_1\times n_1}$ and $\mathbf{B}\in\mathbb{R}^{n_2\times n_2}$, which verifies formula (7) by showing that $\mathbf{D} - P_{T_{\mathbf{X}}\mathcal{M}}(\mathbf{D})$ is orthogonal to $T_{\mathbf{X}}\mathcal{M}$.

Verification of (10). It is clear that $R^{(2)}_{\mathbf{X}}(\delta)$ defined in (10) has rank r; and to show that $\langle R^{(2)}_{\mathbf{X}}(\delta) - (\mathbf{X}+\delta), \mathbf{Z}\rangle_F = 0$ for all $\mathbf{Z}\in T_{\mathbf{X}}\mathcal{M}$, we first write this property as $[R^{(2)}_{\mathbf{X}}(\delta) - (\mathbf{X}+\delta)] \perp T_{\mathbf{X}}\mathcal{M}$ for simplicity, and since $T_{\mathbf{X}}\mathcal{M} = \{\mathbf{A}\mathbf{V}\mathbf{V}^T + \mathbf{U}\mathbf{U}^T\mathbf{B} : \text{for } \mathbf{A}\in\mathbb{R}^{n_1\times n_1}, \mathbf{B}\in\mathbb{R}^{n_2\times n_2}\}$, we just need to show that $\langle R^{(2)}_{\mathbf{X}}(\delta) - (\mathbf{X}+\delta), \mathbf{A}\mathbf{V}\mathbf{V}^T + \mathbf{U}\mathbf{U}^T\mathbf{B}\rangle_F = 0$ for all $\mathbf{A}\in\mathbb{R}^{n_1\times n_1}$ and $\mathbf{B}\in\mathbb{R}^{n_2\times n_2}$. This is easy to verify, because we have $R^{(2)}_{\mathbf{X}}(\delta)\mathbf{V} = (\mathbf{X}+\delta)\mathbf{V}$,

$$\langle R^{(2)}_{\mathbf{X}}(\delta) - (\mathbf{X}+\delta), \mathbf{A}\mathbf{V}\mathbf{V}^T\rangle_F = \langle (R^{(2)}_{\mathbf{X}}(\delta)\mathbf{V} - (\mathbf{X}+\delta)\mathbf{V})\mathbf{V}^T, \mathbf{A}\rangle_F = \langle \mathbf{0}, \mathbf{A}\rangle_F = 0, \quad (21)$$

Similarly, we can easily verify that $\mathbf{U}^T R^{(2)}_{\mathbf{X}}(\delta) = \mathbf{U}^T(\mathbf{X}+\delta)$, we have $\langle R^{(2)}_{\mathbf{X}}(\delta) - (\mathbf{X}+\delta), \mathbf{U}\mathbf{U}^T\mathbf{B}\rangle_F = 0$, and therefore $[R^{(2)}_{\mathbf{X}}(\delta) - (\mathbf{X}+\delta)] \perp T_{\mathbf{X}}\mathcal{M}$. As a result, there exists a unique $R^{(2)}_{\mathbf{X}}$ such that $\text{rank}(R^{(2)}_{\mathbf{X}}) = r$ and $[R^{(2)}_{\mathbf{X}}(\delta) - (\mathbf{X}+\delta)] \perp T_{\mathbf{X}}\mathcal{M}$.

Verification of (12). We first define the operator $S:\mathbb{R}^{n_1\times n_2}\to\mathbb{R}^{n_1\times n_2}$ such that $F(\mathbf{A}) = \mathbf{S}(\mathbf{A})\circ\mathbf{A}$ ($\circ$ represents the elementwise product), i.e.,

$$\mathbf{S}(\mathbf{A}) = \begin{cases}0, & \text{if } |\mathbf{A}_{ij}| > |\mathbf{A}_{i,\cdot}|^{[\gamma]} \text{ and } |\mathbf{A}_{ij}| > |\mathbf{A}_{\cdot,j}|^{[\gamma]},\\ 1, & \text{otherwise.}\end{cases}$$

Then if the absolute values of all entries of $\mathbf{A}$ are different, the sparsity pattern does not change under a small perturbation, i.e., $\mathbf{S}(\mathbf{A}) = \mathbf{S}(\mathbf{A}+\mathbf{\Delta})$. Then by definition of $f(\cdot)$,

$$\begin{aligned}&f(\mathbf{L}+\mathbf{\Delta}) - f(\mathbf{L}) = \frac{1}{2}\|\mathbf{S}(\mathbf{L}-\mathbf{Y}+\mathbf{\Delta})\circ(\mathbf{L}-\mathbf{Y}+\mathbf{\Delta})\|_F^2 - \frac{1}{2}\|\mathbf{S}(\mathbf{L}-\mathbf{Y})\circ(\mathbf{L}-\mathbf{Y})\|_F^2\\ =&\frac{1}{2}\|\mathbf{S}(\mathbf{L}-\mathbf{Y})\circ(\mathbf{L}-\mathbf{Y}+\mathbf{\Delta})\|_F^2 - \frac{1}{2}\|\mathbf{S}(\mathbf{L}-\mathbf{Y})\circ(\mathbf{L}-\mathbf{Y})\|_F^2\\ =&\langle \mathbf{S}(\mathbf{L}-\mathbf{Y})\circ(\mathbf{L}-\mathbf{Y}), \mathbf{\Delta}\rangle_F + O(\|\mathbf{\Delta}\|_F^2),\end{aligned}$$

where $\circ$ represents the Hadamard product, i.e., the elementwise product between matrices.

Verification of (14). It is sufficient to prove the case where $\mathbf{U}^{(k)}$ and $\mathbf{V}^{(k)}$ are given by the SVD decomposition $\mathbf{L}^{(k)} = \mathbf{U}^{(k)}\mathbf{\Sigma}^{(k)}\mathbf{V}^{(k)T}$. Denote $\mathbf{D} = \nabla f(\mathbf{L}^{(k)}) = F(\mathbf{L}^{(k)} - \mathbf{Y})$. Set $\mathbf{X} = \mathbf{L}^{(k)}$ and $\delta = -\eta P_{T_{\mathbf{L}^{(k)}}\mathcal{M}}(\mathbf{D})$ in (10), we have

$$\begin{aligned}\mathbf{L}^{(k+1)} \;:=\; &(\mathbf{L}^{(k)} - \eta P_{T_{\mathbf{L}^{(k)}}\mathcal{M}}(\mathbf{D}))\mathbf{V}^{(k)}[\mathbf{U}^{(k)T}(\mathbf{L}^{(k)} - \eta P_{T_{\mathbf{L}^{(k)}}\mathcal{M}}(\mathbf{D}))\mathbf{V}^{(k)}]^{-1} \quad (22)\\ &\mathbf{U}^{(k)T}(\mathbf{L}^{(k)} - \eta P_{T_{\mathbf{L}^{(k)}}\mathcal{M}}(\mathbf{D}))\end{aligned}$$

On the other hand, from (7) we have the projection

$$P_{T_{\mathbf{L}^{(k)}}\mathcal{M}}(\mathbf{D}) = \mathbf{U}^{(k)}\mathbf{U}^{(k)T}\mathbf{D} + \mathbf{D}\mathbf{V}^{(k)}\mathbf{V}^{(k)T} - \mathbf{U}^{(k)}\mathbf{U}^{(k)T}\mathbf{D}\mathbf{V}^{(k)}\mathbf{V}^{(k)T}.$$

As a result

$$\begin{aligned}&P_{T_{\mathbf{L}^{(k)}}\mathcal{M}}(\mathbf{D})\mathbf{V}^{(k)} = [\mathbf{U}^{(k)}\mathbf{U}^{(k)T}\mathbf{D} + \mathbf{D}\mathbf{V}^{(k)}\mathbf{V}^{(k)T} - \mathbf{U}^{(k)}\mathbf{U}^{(k)T}\mathbf{D}\mathbf{V}^{(k)}\mathbf{V}^{(k)T}]\mathbf{V}^{(k)}\\ &= \mathbf{U}^{(k)}\mathbf{U}^{(k)T}\mathbf{D}\mathbf{V}^{(k)} + \mathbf{D}\mathbf{V}^{(k)}\mathbf{V}^{(k)T}\mathbf{V}^{(k)} - \mathbf{U}^{(k)}\mathbf{U}^{(k)T}\mathbf{D}\mathbf{V}^{(k)}\mathbf{V}^{(k)T}\mathbf{V}^{(k)} = \mathbf{D}\mathbf{V}^{(k)} \quad (23)\end{aligned}$$

and similarly,

$$\mathbf{U}^{(k)T}P_{T_{\mathbf{L}^{(k)}}\mathcal{M}}(\mathbf{D}) = \mathbf{U}^{(k)T}\mathbf{D}. \quad (24)$$

Combining (23), (24) with (22), the update formula (14) is verified.

B. Proof of Theorem 1

In this proof, we will investigate $\|\mathbf{L}^+ - \mathbf{L}^*\|_F$, where

$$\mathbf{L}^+ = R_{\mathbf{L}}(-\eta P_{T_{\mathbf{L}}}F(\mathbf{L}-\mathbf{Y})).$$

It is sufficient to prove that when $\|\mathbf{L}-\mathbf{L}^*\| \le a\sigma_r(\mathbf{L}^*)$ with the value a satisfying the conditions in Theorem 1, then

$$\|\mathbf{L}^+ - \mathbf{L}^*\|_F \le \Big(1 - \frac{1-2C_1}{8}\eta\Big)\|\mathbf{L}-\mathbf{L}^*\|_F. \quad (25)$$

To prove (25), we first introduce three auxiliary lemmas.

Lemma 10 **(a)** *Let* $\mathbf{D} = \mathbf{L}-\mathbf{L}^* - F(\mathbf{L}-\mathbf{Y}) = \mathbf{L}-\mathbf{L}^* - F(\mathbf{L}-\mathbf{L}^*-\mathbf{S}^*)$, *then*

$$\|\mathbf{D}\|_F^2 \le C_1^2\|\mathbf{L}-\mathbf{L}^*\|_F^2. \quad (26)$$

(b) *For the noisy setting where* $\mathbf{Y} = \mathbf{L}^* + \mathbf{S}^* + \mathbf{N}^*$, *and* $\mathbf{D}' = \mathbf{L}-\mathbf{L}^*-\mathbf{N}^* - F(\mathbf{L}-\mathbf{Y})$, *we have*

$$\|\mathbf{D}'\|_F^2 \le 2C_1^2\|\mathbf{L}-\mathbf{L}^*\|_F^2 + 2(\gamma+5\gamma^*)N_1, \quad (27)$$

where $N_1 = n_2\sum_{i=1}^{n_1}|\mathbf{N}^*_{i,\cdot}|^{\max} + n_1\sum_{j=1}^{n_2}|\mathbf{N}^*_{\cdot,j}|^{\max}$.

Lemma 11 *If* $\|\mathbf{L}-\mathbf{L}^*\|_F \le a\sigma_r(\mathbf{L}^*)$ *and* $a\le 1$, *then*

$$\|(\mathbf{L}-\mathbf{L}^*) - \mathbf{P}_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\|_F \le \frac{a}{2(1-a)}\|\mathbf{L}-\mathbf{L}^*\|_F, \quad (28)$$

$$\|(\mathbf{L}-\mathbf{L}^*) - \mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)\|_F \le \frac{a}{2}\|\mathbf{L}-\mathbf{L}^*\|_F. \quad (29)$$

Lemma 12 *For* $\mathbf{X}\in T_{\mathbf{L}}\mathcal{M}$, *then*

$$\|R^{(i)}_{\mathbf{L}}(\mathbf{X}) - (\mathbf{L}+\mathbf{X})\|_F \le \frac{\|\mathbf{X}\|_F^2}{2(\sigma_r(\mathbf{L}) - \|\mathbf{X}\|)}, \text{ for either } i=1 \text{ or } 2.$$

To prove (25), first we note that

$$\begin{aligned}
&\|\mathbf{L}-\mathbf{L}^*\|_F^2-\|\mathbf{L}-\eta P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})-\mathbf{L}^*\|_F^2\\
=&\|\mathbf{L}-\mathbf{L}^*\|_F^2-\|\mathbf{L}-\mathbf{L}^*\|_F^2+2\eta\langle\mathbf{L}-\mathbf{L}^*,P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\rangle_F-\|\eta P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\|_F^2\\
=&2\eta\langle\mathbf{L}-\mathbf{L}^*,P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\rangle_F-\|\eta P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\|_F^2\\
=&2\eta\langle\mathbf{L}-\mathbf{L}^*,P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*)-P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*-F(\mathbf{L}-\mathbf{Y}))\rangle_F-\eta^2\|P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\|_F^2\\
=&2\eta\langle P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*),P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*)-P_{T_\mathbf{L}}\mathbf{D}\rangle_F-\eta^2\|P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\|_F^2\\
\geq&2\eta(\|P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*)\|_F^2-\|\mathbf{D}\|_F\|P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*)\|_F)-\eta^2(\|\mathbf{L}-\mathbf{L}^*\|_F+\|\mathbf{D}\|_F)^2. \qquad (30)
\end{aligned}$$

The fourth line is obtained by $P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*-F(\mathbf{L}-\mathbf{Y}))=\mathbf{L}-\mathbf{L}^*-P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\rangle_F$. The fifth line is because $\mathbf{L}-\mathbf{L}^*=P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*)+P_{T_\mathbf{L}}^\perp(\mathbf{L}-\mathbf{L}^*)$. The last line uses Cauchy-Schwarz inequality $\langle P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*),P_{T_\mathbf{L}}\mathbf{D}\rangle_F\leq\|\mathbf{D}\|_F\|P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*)\|_F$ and triangular inequality $\|P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\|_F\leq\|\mathbf{L}-\mathbf{L}^*\|_F+\|P_{T_\mathbf{L}}(\mathbf{D})\|_F\leq\|\mathbf{L}-\mathbf{L}^*\|_F+\|\mathbf{D}\|_F$. Lemma 11 and the assumptions $\|\mathbf{L}-\mathbf{L}^*\|_F\leq a\sigma_r(\mathbf{L}^*)$ and $\sqrt{1-(\frac{a}{2(1-a)})^2}>\frac{1}{2}$ imply

$$\|P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*)\|_F\geq\frac{1}{2}\|\mathbf{L}-\mathbf{L}^*\|_F. \qquad (31)$$

Combining it with the estimation of $\|\mathbf{D}\|_F$ in Lemma 10, we have

$$\begin{aligned}
&\|\mathbf{L}-\mathbf{L}^*\|_F^2-\|\mathbf{L}-\eta P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})-\mathbf{L}^*\|_F^2\\
\geq&\eta(\frac{1}{2}-C_1)\|\mathbf{L}-\mathbf{L}^*\|_F^2-\eta^2(1+C_1)^2\|\mathbf{L}-\mathbf{L}^*\|_F^2. \qquad (32)
\end{aligned}$$

When ths RHS of (32) is positive (i.e., when $(1-2C_1)\geq2\eta(1+C_1)^2$), (32) implies $\|\mathbf{L}-\mathbf{L}^*\|_F>\|\mathbf{L}-\eta P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})-\mathbf{L}^*\|_F$ and

$$\begin{aligned}
&\|\mathbf{L}-\mathbf{L}^*\|_F-\|\mathbf{L}-\eta P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})-\mathbf{L}^*\|_F\\
\geq&\frac{\eta(\frac{1}{2}-C_1)\|\mathbf{L}-\mathbf{L}^*\|_F^2-\eta^2(1+C_1)^2\|\mathbf{L}-\mathbf{L}^*\|_F^2}{\|\mathbf{L}-\mathbf{L}^*\|_F+\|\mathbf{L}-\eta P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})-\mathbf{L}^*\|_F}\\
\geq&\frac{1}{2}\left(\eta(\frac{1}{2}-C_1)-\eta^2(1+C_1)^2\right)\|\mathbf{L}-\mathbf{L}^*\|_F. \qquad (33)
\end{aligned}$$

In addition,

$$\|P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\|_F\leq\|F(\mathbf{L}-\mathbf{Y})\|_F=\|\mathbf{L}-\mathbf{L}^*\|_F+\|\mathbf{D}\|_F\leq(1+C_1)\|\mathbf{L}-\mathbf{L}^*\|_F \qquad (34)$$

and Lemma 12 give

$$\begin{aligned}
&\|\mathbf{L}^+-\mathbf{L}^*\|_F-\|\mathbf{L}-\eta P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})-\mathbf{L}^*\|_F\leq\|\mathbf{L}-\eta P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})-\mathbf{L}^+\|_F\\
\leq&\frac{\eta^2\|P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\|_F^2}{\sigma_r(\mathbf{L}^*)-\eta\|P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\|_F}\leq\frac{\eta^2a^2(1+C_1)^2}{1-\eta a(1+C_1)}\|\mathbf{L}-\mathbf{L}^*\|_F. \qquad (35)
\end{aligned}$$

Combining (33) and (35),

$$\frac{\|\mathbf{L}-\mathbf{L}^*\|_F-\|\mathbf{L}^+-\mathbf{L}^*\|_F}{\|\mathbf{L}-\mathbf{L}^*\|_F}\geq\frac{1}{4}\eta(1-2C_1)-\eta^2(1+C_1)^2\left[\frac{1}{2}+\frac{a^2}{1-\eta(1+C_1)a}\right].$$

Therefore, Theorem 1 is proved when $C_1<1/2$, and η_0 is chosen such that

$$\eta_0(1+C_1)^2\left[\frac{1}{2}+\frac{a^2}{1-\eta_0(1+C_1)a}\right]\leq\frac{1}{8}(1-2C_1).$$

C. Proof of Theorem 5

The proof of the noisy case also follows similarly from the proofs of Theorem 1 and 6. Note that

$$F(\mathbf{L}-\mathbf{Y})=\mathbf{L}-\mathbf{L}^*-\mathbf{N}^*-\mathbf{D}',$$

and define $\mathbf{Q}=P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*)$, then following the proof of Theorem 1 and applying Lemma 10 (b), we have

$$\begin{aligned}
&\|\mathbf{L}-\mathbf{L}^*\|_F^2-\|\mathbf{L}-\eta P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})-\mathbf{L}^*\|_F^2\\
=&2\eta\langle\mathbf{L}-\mathbf{L}^*,P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\rangle_F+O(\eta^2)=2\eta\langle P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*),P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})\rangle_F+O(\eta^2)\\
=&2\eta\langle P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*),P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*-\mathbf{N}^*-\mathbf{D}')\rangle_F+O(\eta^2)\\
\geq&2\eta\left(\|\mathbf{Q}\|_F^2-\langle\mathbf{N}^*,\mathbf{Q}\rangle_F-\|\mathbf{Q}\|_F\sqrt{2C_1^2\|\mathbf{L}-\mathbf{L}^*\|_F^2+2(\gamma+5\gamma^*)N_1}\right)+O(\eta^2).
\end{aligned}$$

In addition, (35) gives

$$\left|\|\mathbf{L}^+-\mathbf{L}\|_F-\|\mathbf{L}-\eta P_{T_\mathbf{L}}F(\mathbf{L}-\mathbf{Y})-\mathbf{L}^*\|_F\right|=O(\eta^2).$$

Combining it with the estimation of C_1, N_1, and $\langle\mathbf{N}^*,\mathbf{Q}\rangle_F$ in Lemma 13 and the fact that $(1-\frac{a}{2(1-a)})\|\mathbf{L}-\mathbf{L}^*\|_F\leq\|\mathbf{Q}\|_F\leq(1+\frac{a}{2(1-a)})\|\mathbf{L}-\mathbf{L}^*\|_F$ (which follows from Lemma 11), the Theorem is proved.

Lemma 13 *If $\mathbf{N}^*\in\mathbb{R}^{n_1\times n_2}$ is elementwisely i.i.d. sampled from $N(0,\sigma^2)$, then*
(a) with probability $1-\frac{4}{n_1^7n_2^7}$, $\sum_{i=1}^{n_1}(|\mathbf{N}^*_{i,\cdot}|^{\max})^2\leq16\sigma^2n_1\ln(n_1n_2)$, and $\sum_{j=1}^{n_2}(|\mathbf{N}^*_{\cdot,j}|^{\max})^2\leq16\sigma^2n_2\ln(n_1n_2)$, and as a result, $N_1\leq32\sigma^2n_1n_2\ln(n_1n_2)$.
(b) There exists $C_6>0$ such that as $n_1+n_2\to\infty$, the probability that

$$\langle\mathbf{N}^*,P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*)\rangle_F\leq\frac{1}{4}\|P_{T_\mathbf{L}}(\mathbf{L}-\mathbf{L}^*)\|_F^2 \qquad (36)$$

holds for all $\{\mathbf{L}:C_6\sigma\sqrt{(n_1+n_2)r\ln(n_1n_2)}\leq\|\mathbf{L}-\mathbf{L}^*\|_F\leq a\sigma_r(\mathbf{L}^*)\}$ converges to 1.

D. Proof of Theorem 6

This proof borrows two lemmas from (Yi et al., 2016, Lemmas 9, 10) as follows.

Lemma 14 *(Yi et al., 2016, Lemma 9) There exists $c>0$ such that for all $0<\epsilon<1$, if $p\geq c\mu r\log(n)/\epsilon^2\min(n_1,n_2)$, then with probability at least $1-2n^{-3}$, for all $\mathbf{X}$ in the tangent plane $T_{\mathbf{L}^*}$, i.e., all $\mathbf{X}$ that can be written as $\mathbf{L}^*\mathbf{A}+\mathbf{B}\mathbf{L}^*$, where $\mathbf{A}\in\mathbb{R}^{n_2\times n_2}$ and $\mathbf{B}\in\mathbb{R}^{n_1\times n_1}$,*

$$(1-\epsilon)\|\mathbf{X}\|_F^2\leq\frac{1}{p}\|P_\mathbf{\Phi}\mathbf{X}\|_F^2\leq(1+\epsilon)\|\mathbf{X}\|_F^2.$$

Lemma 15 *(Yi et al., 2016, Lemma 10) If $p\geq\frac{56}{3}\frac{\log n}{\gamma\min(n_1,n_2)}$, the with probability at least $1-6n^{-1}$, the number of entries in $\mathbf{\Phi}$ per row is in the interval $[pn_2/2,3pn_2/2]$, and the number of entries in $\mathbf{\Phi}$ per column is in $[pn_1/2,3pn_1/2]$.*

Then we introduce the following lemma parallel to Lemma 10:

Lemma 16 *When the events in Lemmas 14 and 15 hold, for* $\tilde{\mathbf{D}} = P_{\mathbf{\Phi}}[\mathbf{L} - \mathbf{L}^* - \tilde{F}(\mathbf{L} - \mathbf{Y})]$ *we have*

$$\|\tilde{\mathbf{D}}\|_F^2 \leq \tilde{C}_1^2 \|\mathbf{L} - \mathbf{L}^*\|_F^2, \tag{37}$$

with

$$\tilde{C}_1 = \frac{1}{p(1-\epsilon)}\Big[6(\gamma + 2\gamma^*)p\mu r + 4\frac{3\gamma^*}{\gamma - 3\gamma^*}(\sqrt{p(1+\epsilon)} + \frac{a}{2})^2 + a^2\Big].$$

The proof of Theorem 6 is parallel to the proof of Theorem 1, with $\mathbf{L}^+$ defined slightly differently by

$$\mathbf{L}^+ = R_{\mathbf{L}}(-\eta P_{T_{\mathbf{L}}}\tilde{F}(\mathbf{L} - \mathbf{Y})).$$

Defining $P_{\mathbf{\Phi}} : \mathbb{R}^{n_1 \times n_2} \to \mathbb{R}^{n_1 \times n_2}$ by

$$[P_{\mathbf{\Phi}}\mathbf{X}]_{ij} = \begin{cases} \mathbf{X}_{ij}, \text{ if } (i,j) \in \mathbf{\Phi}, \\ 0, \text{ if } (i,j) \notin \mathbf{\Phi}. \end{cases}$$

Then $\tilde{F}(\mathbf{L} - \mathbf{Y}) = P_{\mathbf{\Phi}}\tilde{F}(\mathbf{L} - \mathbf{Y})$. Following a similar analysis as (30),

$$\begin{aligned}
&\|\mathbf{L} - \mathbf{L}^*\|_F^2 - \|\mathbf{L} - \eta P_{T_{\mathbf{L}}}P_{\mathbf{\Phi}}\tilde{F}(\mathbf{L} - \mathbf{Y}) - \mathbf{L}^*\|_F^2 \\
=&2\eta\langle \mathbf{L} - \mathbf{L}^*, P_{T_{\mathbf{L}}}P_{\mathbf{\Phi}}\tilde{F}(\mathbf{L} - \mathbf{Y})\rangle_F - \|\eta P_{T_{\mathbf{L}}}P_{\mathbf{\Phi}}\tilde{F}(\mathbf{L} - \mathbf{Y})\|_F^2 \\
\geq&2\eta\langle P_{\mathbf{\Phi}}P_{T_{\mathbf{L}}}(\mathbf{L} - \mathbf{L}^*), P_{\mathbf{\Phi}}\tilde{F}(\mathbf{L} - \mathbf{Y})\rangle_F - \|\eta P_{\mathbf{\Phi}}\tilde{F}(\mathbf{L} - \mathbf{Y})\|_F^2 \\
\geq&2\eta\langle P_{\mathbf{\Phi}}(\mathbf{L} - \mathbf{L}^*) - P_{\mathbf{\Phi}}P_{T_{\mathbf{L}}}^{\perp}(\mathbf{L} - \mathbf{L}^*), P_{\mathbf{\Phi}}(\mathbf{L} - \mathbf{L}^*) - \tilde{\mathbf{D}}\rangle_F - \eta^2(\|P_{\mathbf{\Phi}}(\mathbf{L} - \mathbf{L}^*)\|_F + \|\tilde{\mathbf{D}}\|_F)^2,
\end{aligned} \tag{38}$$

here $P_{T_{\mathbf{L}}}^{\perp}$ represents the projector to the subspace orthogonal to $T_{\mathbf{L}}$. Lemma 11 and Lemma 14 imply

$$\frac{\|P_{\mathbf{\Phi}}P_{T_{\mathbf{L}}}^{\perp}(\mathbf{L} - \mathbf{L}^*)\|_F}{\|P_{\mathbf{\Phi}}(\mathbf{L} - \mathbf{L}^*)\|_F} \leq \frac{\|P_{T_{\mathbf{L}}}^{\perp}(\mathbf{L} - \mathbf{L}^*)\|_F}{\|P_{\mathbf{\Phi}}(\mathbf{L} - \mathbf{L}^*)\|_F} \leq \frac{ap(1+\epsilon)}{2(1-a)}, \tag{39}$$

and combining it with the estimation of $\tilde{\mathbf{D}}$ in Lemma 16, the RHS of (38) is larger than

$$\|P_{\mathbf{\Phi}}(\mathbf{L} - \mathbf{L}^*)\|_F^2\left(2\eta\left(1 - \tilde{C}_1 - \frac{ap(1+\epsilon)}{2(1-a)}(1+\tilde{C}_1)\right) - \eta^2(1+\tilde{C}_1)^2\right). \tag{40}$$

In addition, Lemma 14 implies

$$\begin{aligned}
\|P_{\mathbf{\Phi}}\tilde{F}(\mathbf{L} - \mathbf{Y})\|_F &\leq \|P_{\mathbf{\Phi}}(\mathbf{L} - \mathbf{L}^*)\|_F + \|P_{\mathbf{\Phi}}\tilde{\mathbf{D}}\|_F \\
&\leq (1 + \tilde{C}_1)\|P_{\mathbf{\Phi}}(\mathbf{L} - \mathbf{L}^*)\|_F, \\
&\leq (1 + \tilde{C}_1)p(1+\epsilon)\|\mathbf{L} - \mathbf{L}^*\|
\end{aligned}$$

and combining it with Lemma 12,

$$\|\mathbf{L}^+ - \mathbf{L}^*\|_F - \|\mathbf{L} - \eta P_{T_{\mathbf{L}}}P_{\mathbf{\Phi}}\tilde{F}(\mathbf{L} - \mathbf{Y}) - \mathbf{L}^*\|_F \leq \frac{\eta^2 a^2(p+p\epsilon)^2(1+\tilde{C}_1)^2}{1 - \eta a(p+p\epsilon)(1+\tilde{C}_1)}\|\mathbf{L} - \mathbf{L}^*\|_F.$$

Combining it with (40) and Lemma 11, we have

$$\begin{aligned}
\frac{\|\mathbf{L}^+ - \mathbf{L}^*\|_F}{\|\mathbf{L} - \mathbf{L}^*\|_F} \leq&\sqrt{1 - p^2(1-\epsilon)^2\left(2\eta\left(1 - \tilde{C}_1 - \frac{ap(1+\epsilon)}{2(1-a)}(1+\tilde{C}_1)\right) - \eta^2(1+\tilde{C}_1)^2\right)} \\
&+\frac{\eta^2 a^2(p+p\epsilon)^2(1+\tilde{C}_1)^2}{1 - \eta a(p+p\epsilon)(1+\tilde{C}_1)},
\end{aligned}$$

and Theorem 6 is proved.

E. Proof of Lemmas

Lemma 10(a) Proof By the definition of F, for any matrix $\mathbf{A}$, $\mathbf{A} - F(\mathbf{A})$ is a sparse matrix, therefore

$$\mathbf{D} = \mathbf{L} - \mathbf{L}^* - \mathbf{S}^* - F(\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*) + \mathbf{S}^*$$

is a sparse matrix. Denote the locations of the nonzero entries of $\mathbf{D}$ by $\mathcal{S}$, and divide it into two sets $\mathcal{S}_1 \cup \mathcal{S}_2$ defined as follows:

$$\mathcal{S}_1 = \{(i,j) : |[\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*]_{ij}| > |[\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*]_{i,\cdot}|^{[\gamma]} \text{ and } |[\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*]_{ij}| > |[\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*]_{\cdot,j}|^{[\gamma]}\},$$

and

$$\mathcal{S}_2 = \{(i,j) \notin \mathcal{S}_1 : \mathbf{D}_{ij} = [\mathbf{L} - \mathbf{L}^*]_{ij} - F(\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*)_{ij} \neq 0\}.$$

For $(i,j) \in \mathcal{S}_1$, $[F(\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*)]_{ij} = 0$. As a result, $\mathbf{D}_{ij} = [\mathbf{L} - \mathbf{L}^*]_{ij}$. In addition, by definition of $F(\cdot)$, each row or column of $\mathbf{D}$ has at most γ percentage of points in $\mathcal{S}_1$.

For $(i,j) \in \mathcal{S}_2$, since $[F(\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*)]_{ij} = [\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*]_{ij}$, we have $\mathbf{D}_{ij} = \mathbf{S}^*_{ij} \neq 0$. By Assumption 1, therefore, for each row or column of $\mathbf{D}$, at most γ^* percentage of points lie in $\mathcal{S}_2$.

Combine the results

$$|[\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*]_{i,\cdot}|^{[\gamma]} \leq \{|[\mathbf{L} - \mathbf{L}^*]_{i,\cdot}| + |[\mathbf{S}^*]_{i,\cdot}|\}^{[\gamma]} \leq |[\mathbf{L} - \mathbf{L}^*]_{i,\cdot}|^{[\gamma - \gamma^*]},$$

$$|[\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*]_{j,\cdot}|^{[\gamma]} \leq \{|[\mathbf{L} - \mathbf{L}^*]_{j,\cdot}| + |[\mathbf{S}^*]_{j,\cdot}|\}^{[\gamma]} \leq |[\mathbf{L} - \mathbf{L}^*]_{j,\cdot}|^{[\gamma - \gamma^*]},$$

with $[F(\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*)]_{ij} = [\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*]_{ij}$, we have for $(i,j) \in \mathcal{S}_2$

$$\begin{aligned}
|\mathbf{D}_{ij}| =&|[\mathbf{L} - \mathbf{L}^* - F(\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*)]_{ij}| \\
\leq&|[\mathbf{L} - \mathbf{L}^*]_{ij}| + |F(\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*)]_{ij}| \\
\leq&|[\mathbf{L} - \mathbf{L}^*]_{ij}| + \max(|[\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*]_{i,\cdot}|^{[\gamma]}, |[\mathbf{L} - \mathbf{L}^* - \mathbf{S}^*]_{\cdot,j}|^{[\gamma]}) \\
\leq&|[\mathbf{L} - \mathbf{L}^*]_{ij}| + \max(|[\mathbf{L} - \mathbf{L}^*]_{i,\cdot}|^{[\gamma - \gamma^*]}, |[\mathbf{L} - \mathbf{L}^*]_{\cdot,j}|^{[\gamma - \gamma^*]}).
\end{aligned}$$

Applying the estimations above, and repeatedly use the fact that $(x+y)^2 \leq 2x^2 + 2y^2$, we have

$$
\begin{aligned}
\|\mathbf{D}\|_F^2 =& \sum_{(i,j)\in\mathcal{S}} \mathbf{D}_{ij}^2 = \sum_{(i,j)\in\mathcal{S}_1} \mathbf{D}_{ij}^2 + \sum_{(i,j)\in\mathcal{S}_2} \mathbf{D}_{ij}^2 \le \sum_{(i,j)\in\mathcal{S}_1} [\mathbf{L}-\mathbf{L}^*]_{ij}^2 \\
&+ \sum_{(i,j)\in\mathcal{S}_2} \Big\{ |[\mathbf{L}-\mathbf{L}^*]_{ij}| + \max(|[\mathbf{L}-\mathbf{L}^*]_{i,\cdot}|^{[\gamma-\gamma^*]}, |[\mathbf{L}-\mathbf{L}^*]_{\cdot,j}|^{[\gamma-\gamma^*]}) \Big\}^2 \\
\le& \sum_{(i,j)\in\mathcal{S}_1} [\mathbf{L}-\mathbf{L}^*]_{ij}^2 + 2\sum_{(i,j)\in\mathcal{S}_2} [\mathbf{L}-\mathbf{L}^*]_{ij}^2 + 2\sum_{(i,j)\in\mathcal{S}_2} \max\{|[\mathbf{L}-\mathbf{L}^*]_{i,\cdot}|^{[\gamma-\gamma^*]}, |[\mathbf{L}-\mathbf{L}^*]_{\cdot,j}|^{[\gamma-\gamma^*]}\}^2 \\
\le& \sum_{(i,j)\in\mathcal{S}_1} [\mathbf{L}-\mathbf{L}^*]_{ij}^2 + 2\sum_{(i,j)\in\mathcal{S}_2} [\mathbf{L}-\mathbf{L}^*]_{ij}^2 + 2\sum_{(i,j)\in\mathcal{S}_2} \{|[\mathbf{L}-\mathbf{L}^*]_{i,\cdot}|^{[\gamma-\gamma^*]} + |[\mathbf{L}-\mathbf{L}^*]_{\cdot,j}|^{[\gamma-\gamma^*]}\}^2 \\
\le& \sum_{(i,j)\in\mathcal{S}_1} [\mathbf{L}-\mathbf{L}^*]_{ij}^2 + 2\sum_{(i,j)\in\mathcal{S}_2} [\mathbf{L}-\mathbf{L}^*]_{ij}^2 + 4\sum_{(i,j)\in\mathcal{S}_2} \{|[\mathbf{L}-\mathbf{L}^*]_{i,\cdot}|^{[\gamma-\gamma^*]}\}^2 + \{|[\mathbf{L}-\mathbf{L}^*]_{\cdot,j}|^{[\gamma-\gamma^*]}\}^2 \\
\le& \sum_{(i,j)\in\mathcal{S}} [\mathbf{L}-\mathbf{L}^*]_{ij}^2 + \sum_{(i,j)\in\mathcal{S}_2} [\mathbf{L}-\mathbf{L}^*]_{ij}^2 + 4\frac{\gamma^*}{\gamma-\gamma^*}\|\mathbf{L}-\mathbf{L}^*\|_F^2 \\
\le& 2\sum_{(i,j)\in\mathcal{S}} [\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)]_{ij}^2 + 2\sum_{(i,j)\in\mathcal{S}_2} [\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)]_{ij}^2 + 4\frac{\gamma^*}{\gamma-\gamma^*}\|\mathbf{L}-\mathbf{L}^*\|_F^2 \\
&+ 2\sum_{(i,j)\in\mathcal{S}} [\mathbf{L}-\mathbf{L}^*-\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)]_{ij}^2 + 2\sum_{(i,j)\in\mathcal{S}_2} [\mathbf{L}-\mathbf{L}^*-\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)]_{ij}^2 \\
\le& 2\sum_{(i,j)\in\mathcal{S}} [\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)]_{ij}^2 + 2\sum_{(i,j)\in\mathcal{S}_2} [\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)]_{ij}^2 + 4\frac{\gamma^*}{\gamma-\gamma^*}\|\mathbf{L}-\mathbf{L}^*\|_F^2 \\
&+ 4\|\mathbf{L}-\mathbf{L}^*-\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)\|_F^2. \qquad (41)
\end{aligned}
$$

Note that from line 5 to line 6, we used the fact that for $\mathbf{x}\in\mathbb{R}^n$, and $k\le n$

$$k(x_{(k)})^2 \le (x_{(k)})^2 + (x_{(k+1)})^2 + \cdots + (x_{(n-1)}) + (x_{(n)}) \le (x_{(1)}) + \cdots + (x_{(n)}) = \|x\|_F^2,$$

where $x_{(k)}$ is the k-th order statistics of $x_1,\ldots,x_n$, i.e. the k-th smallest value. This gives us

$$(\gamma-\gamma^*)n_2|[\mathbf{L}-\mathbf{L}^*]_{i,\cdot}|^{[\gamma-\gamma^*]} \le \|[\mathbf{L}-\mathbf{L}^*]_{i,\cdot}\|_2^2; \quad (\gamma-\gamma^*)n_2|[\mathbf{L}-\mathbf{L}^*]_{\cdot,j}|^{[\gamma-\gamma^*]} \le \|[\mathbf{L}-\mathbf{L}^*]_{\cdot,j}\|_2^2.$$

Therefore

$$\sum_{(i,j)\in\mathcal{S}_2} |[\mathbf{L}-\mathbf{L}^*]_{i,\cdot}|^{[\gamma-\gamma^*]} \le \frac{\gamma^* n_2}{(\gamma-\gamma^*)n_2}\|[\mathbf{L}-\mathbf{L}^*]_{i,\cdot}\|_F^2; \qquad (42)$$

$$\sum_{(i,j)\in\mathcal{S}_2} |[\mathbf{L}-\mathbf{L}^*]_{\cdot,j}|^{[\gamma-\gamma^*]} \le \frac{\gamma^* n_1}{(\gamma-\gamma^*)n_1}\|[\mathbf{L}-\mathbf{L}^*]_{\cdot,j}\|_F^2. \qquad (43)$$

The values $\gamma^* n_2$ and $\gamma^* n_1$ in the numerator of the right hand sides in 42 and 43 are due to the fact that, in each row or column of $\mathbf{D}$, at most γ^* percentage of points lie in $\mathcal{S}_2$.

On the other hand, Lemma 11 implies

$$\|\mathbf{L}-\mathbf{L}^*-\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)\|_F \le \frac{a}{2}\|\mathbf{L}-\mathbf{L}^*\|_F. \qquad (44)$$

In addition, using the fact that there exists $\mathbf{A}\in\mathbb{R}^{n_1\times r}$ and $\mathbf{B}\in\mathbb{R}^{n_2\times r}$, such that $\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*) = \mathbf{A}\mathbf{V}^T + \mathbf{U}\mathbf{B}^T$ and $\|\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)\|_F^2 = \|\mathbf{A}\mathbf{V}^T\|_F^2 + \|\mathbf{U}\mathbf{B}^T\|_F^2$, and that for each row or column, at most $\gamma+\gamma^*$ percentage of points lie in $\mathcal{S}$, we have

$$
\begin{aligned}
&\sum_{(i,j)\in\mathcal{S}} [\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)]_{ij}^2 \le 2\sum_{(i,j)\in\mathcal{S}} [\|(\mathbf{A}\mathbf{V}^T)_{ij}\|^2 + \|(\mathbf{U}\mathbf{B}^T)_{ij}\|^2] \\
\le& 2(\gamma+\gamma^*)\mu r \sum_{1\le i\le n_1, 1\le j\le n_2} [\|(\mathbf{A}\mathbf{V}^T)_{ij}\|^2 + \|(\mathbf{U}\mathbf{B}^T)_{ij}\|^2] = 2(\gamma+\gamma^*)\mu r\|\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)\|_F^2 \\
\le& 2(\gamma+\gamma^*)\mu r\|\mathbf{L}-\mathbf{L}^*\|_F^2. \qquad (45)
\end{aligned}
$$

Similarly, $\|\mathbf{A}\|_{2,\infty} = \max_{\|\mathbf{z}\|_2=1}\|\mathbf{A}\mathbf{z}\|_\infty$

$$\sum_{(i,j)\in\mathcal{S}_2} [\mathbf{P}_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)]_{ij}^2 \le 2\gamma^*\mu r\|\mathbf{L}-\mathbf{L}^*\|_F^2, \qquad (46)$$

Combining (41)-(46), (26) is proved. ■

Lemma 10(b) Proof Let $\mathbf{L}' = \mathbf{L}-\mathbf{N}^*$, then applying the fact that for any $\mathbf{x},\mathbf{y}\in\mathbb{R}^n$,

$$|[\mathbf{x}+\mathbf{y}]|^{[\gamma]} \le |[\mathbf{x}]|^{[\gamma]} + |[\mathbf{x}]|^{\max},$$

where $|[\mathbf{x}]|^{\max}$ represents the largest value of $|[\mathbf{x}]|$. We have

$$
\begin{aligned}
\|\mathbf{D}'\|_F^2 \le& \sum_{(i,j)\in\mathcal{S}} [\mathbf{L}'-\mathbf{L}^*]_{ij}^2 + \sum_{(i,j)\in\mathcal{S}_2} [\mathbf{L}'-\mathbf{L}^*]_{ij}^2 \\
&+ 2\sum_{(i,j)\in\mathcal{S}_2} \{(|[\mathbf{L}'-\mathbf{L}^*]_{i,\cdot}|^{[\gamma-\gamma^*]})^2 + (|[\mathbf{L}'-\mathbf{L}^*]_{\cdot,j}|^{[\gamma-\gamma^*]})^2\} \\
\le& 2\left(\sum_{(i,j)\in\mathcal{S}} [\mathbf{L}-\mathbf{L}^*]_{ij}^2 + |\mathbf{N}_{ij}^*|^2 + \sum_{(i,j)\in\mathcal{S}_2} [\mathbf{L}-\mathbf{L}^*]_{ij}^2 + |\mathbf{N}_{ij}^*|^2\right) \\
&+ 4\sum_{(i,j)\in\mathcal{S}_2} \{(|[\mathbf{L}'-\mathbf{L}^*]_{i,\cdot}|^{[\gamma-\gamma^*]})^2 + (|\mathbf{N}_{i,\cdot}^*|^{\max})^2 + (|[\mathbf{L}'-\mathbf{L}^*]_{\cdot,j}|^{[\gamma-\gamma^*]})^2 + (|\mathbf{N}_{\cdot,j}^*|^{\max})^2\} \\
\le& 2C_1^2\|\mathbf{L}-\mathbf{L}^*\|_F^2 + 2(\gamma+5\gamma^*)N_1,
\end{aligned}
$$

where the last inequality follows from the proof of part (a) and the definition of N_1. ■

Lemma 11 Proof Let the SVD decomposition of $\mathbf{L}^*$ be $\mathbf{L}^* = \mathbf{U}\mathbf{\Sigma}\mathbf{V}$, $\mathbf{U}^\perp$ and $\mathbf{V}^\perp$ be orthogonal matrices of sizes $\mathbb{R}^{n_1\times(n_1-r)}$ and $\mathbb{R}^{n_2\times(n_2-r)}$ such that $\mathrm{Col}(\mathbf{U}^\perp)\perp\mathrm{Col}(\mathbf{U})$ and $\mathrm{Col}(\mathbf{V}^\perp)\perp\mathrm{Col}(\mathbf{V})$ (here $\mathrm{Col}(\mathbf{U})$ represents the subspace spanned by the columns of $\mathbf{U}$). Let

$$\mathbf{L}_{(1,1)}^* \equiv \mathbf{U}^T\mathbf{L}^*\mathbf{V}, \qquad \mathbf{L}_{(1,2)}^* \equiv \mathbf{U}^T\mathbf{L}^*\mathbf{V}^\perp,$$

$$\mathbf{L}_{(2,1)}^* \equiv \mathbf{U}^{\perp T}\mathbf{L}^*\mathbf{V}, \qquad \mathbf{L}_{(2,2)}^* \equiv \mathbf{U}^{\perp T}\mathbf{L}^*\mathbf{V}^\perp.$$

Since $\text{rank}(\mathbf{L}^*) = r$, we have

$$\mathbf{L}^*_{(2,2)} = \mathbf{L}^*_{(2,1)}{\mathbf{L}^*_{(1,1)}}^{-1}\mathbf{L}^*_{(1,2)}.$$

Since all singular values of $\mathbf{L}^*_{(1,1)}$ are larger than $(1-a)\sigma_r(\mathbf{L}^*)$, if the singular value decomposition of ${\mathbf{L}^*_{(1,1)}}^{-1}$ is given by

$${\mathbf{L}^*_{(1,1)}}^{-1} = \mathbf{U}_0\mathbf{\Sigma}_0\mathbf{V}_0^T,$$

then the $\|\mathbf{\Sigma}_0\| \le 1/(1-a)\sigma_r(\mathbf{L}^*)$. Applying

$$\|\mathbf{AB}\|_F^2 \le \|\mathbf{A}\|_F^2\|\mathbf{B}\|_F^2$$

and the fact that for a square, diagonal matrix Σ, $|[\mathbf{X\Sigma}]_{ij}| = |\mathbf{X}_{ij}\mathbf{\Sigma}_{jj}| \le \|\mathbf{\Sigma}\||\mathbf{X}_{ij}|$, we have

$$\begin{aligned}
\|\mathbf{L}^*_{(2,2)}\|_F &= \|\mathbf{L}^*_{(2,1)}\mathbf{U}_0\mathbf{\Sigma}_0\mathbf{V}_0^T\mathbf{L}^*_{(1,2)}\|_F \\
&\le \|\mathbf{L}^*_{(2,1)}\mathbf{U}_0\mathbf{\Sigma}_0\|_F\|\mathbf{V}_0^T\mathbf{L}^*_{(1,2)}\|_F \\
&\le \frac{1}{(1-a)\sigma_r(\mathbf{L}^*)}\|\mathbf{L}^*_{(2,1)}\mathbf{U}_0\|_F\|\mathbf{V}_0^T\mathbf{L}^*_{(1,2)}\|_F \\
&\le \frac{1}{(1-a)\sigma_r(\mathbf{L}^*)}\|\mathbf{L}^*_{(2,1)}\|_F\|\mathbf{L}^*_{(1,2)}\|_F \\
&\le \frac{1}{(1-a)\sigma_r(\mathbf{L}^*)}\Big(\frac{\|\mathbf{L}^*_{(2,1)}\|_F^2 + \|\mathbf{L}^*_{(1,2)}\|_F^2}{2}\Big) \\
&\le \frac{1}{(1-a)\sigma_r(\mathbf{L}^*)}\Big(\frac{a^2\sigma_r(\mathbf{L}^*)^2}{2}\Big) \\
&\le \frac{a^2}{2(1-a)}\sigma_r(\mathbf{L}^*), \qquad (47)
\end{aligned}$$

and (28) is proved. The proof of (29) is similar. ■

Lemma 12 **Proof** Let the SVD decomposition of $\mathbf{L}$ be $\mathbf{L} = \mathbf{U\Sigma V}$, and

$$\begin{aligned}
\mathbf{L}_{(1,1)} &= \mathbf{U}^T(\mathbf{X}+\mathbf{L})\mathbf{V}, \mathbf{L}_{(1,2)} = \mathbf{U}^T(\mathbf{X}+\mathbf{L})\mathbf{V}^\perp \\
&= \mathbf{U}^T\mathbf{X}\mathbf{V}^\perp, \mathbf{L}_{(2,1)} = \mathbf{U}^{\perp T}(\mathbf{X}+\mathbf{L})\mathbf{V} = \mathbf{U}^{\perp T}\mathbf{X}\mathbf{V},
\end{aligned}$$

then it is clear that

$$R^{(2)}_{\mathbf{L}}(\mathbf{X}) = \mathbf{L} + \mathbf{X} + \mathbf{U}^\perp\mathbf{L}_{(2,1)}{\mathbf{L}_{(1,1)}}^{-1}\mathbf{L}_{(1,2)}\mathbf{V}^{\perp T},$$

and using the same argument as in (47),

$$\begin{aligned}
\|\mathbf{L}_{(2,1)}{\mathbf{L}_{(1,1)}}^{-1}\mathbf{L}_{(1,2)}\|_F \le& \frac{1}{\sigma_r(\mathbf{L}^*_{(1,1)})}\|\mathbf{L}_{(1,2)}\|_F\|\mathbf{L}_{(2,1)}\|_F \\
\le& \frac{1}{\sigma_r(\mathbf{L}) - \|\mathbf{X}\|}\Big(\frac{\|\mathbf{L}_{(2,1)}\|_F^2 + \|\mathbf{L}_{(1,2)}\|_F^2}{2}\Big) \\
\le& \frac{1}{\sigma_r(\mathbf{L}) - \|\mathbf{X}\|}\frac{\|\mathbf{X}\|_F^2}{2}.
\end{aligned}$$

So Lemma 12 is proved for $R^{(2)}_{\mathbf{L}}(\mathbf{X})$.

By definition, $R^{(1)}_{\mathbf{L}}(\mathbf{X})$ is the closest matrix to $\mathbf{L}+\mathbf{X}$ that has rank r, so $\|R^{(1)}_{\mathbf{L}}(\mathbf{X}) - (\mathbf{L}+\mathbf{X})\|_F \le R^{(2)}_{\mathbf{L}}(\mathbf{X}) - (\mathbf{L}+\mathbf{X})\|_F$ and Lemma 12 is also proved for $R^{(1)}_{\mathbf{L}}(\mathbf{X})$. ■

Lemma 13 **Proof** WLOG, we assume $\sigma = 1$ and the generic cases can be proved similarly.

(a) It follows from the estimation of the distribution of the maximum of n_1 i.i.d. Gaussian variables $\{g_i\}_{i=1}^{n_1}$:

$$\begin{aligned}
&\Pr\{\max_{1\le i\le n_1}|g_i| \le 4\sqrt{\ln(n_1n_2)}\} \ge \Big(1 - 2\exp\Big(-\frac{(4\sqrt{\ln(n_1n_2)})^2}{2}\Big)\Big)^{n_1} \\
\ge& 1 - 2n_1\exp\Big(-\frac{(4\sqrt{\ln(n_1n_2)})^2}{2}\Big) = 1 - 2n_1^{-7}n_2^{-8},
\end{aligned}$$

where the first inequality applies the estimation of the cumulative distribution function of the Gaussian distribution (Ledoux and Talagrand, 1991, pg 8).

Combining this estimation for each column of $\mathbf{N}^*$ and applying the union bound, the second inequality in part (a) holds with probability $1-2n_1^{-7}n_2^{-7}$. Similarly, the first inequality in part (a) holds with the same probability.

(b) First, we parameterize $\mathbf{L}$ by $g(\mathbf{L}) = P_{\mathbf{L}^*}(\mathbf{L}-\mathbf{L}^*)$. Then we claim that, for any $\mathbf{L}$ and $\mathbf{L}'$ such that $\|\mathbf{L}-\mathbf{L}^*\|_F, \|\mathbf{L}'-\mathbf{L}^*\|_F \le a\sigma_r(\mathbf{L}^*)$, there exists C_0 depending on a such that

$$\|P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*) - P_{T_{\mathbf{L}'}}(\mathbf{L}'-\mathbf{L}^*)\|_F \le C_0\|g(\mathbf{L}) - g(\mathbf{L}')\|_F. \qquad (48)$$

To prove (48), apply (29) and obtain

$$\|\mathbf{L}-\mathbf{L}'\|_F \le \frac{1}{1-\frac{a}{2}}\|g(\mathbf{L}) - g(\mathbf{L}')\|_F. \qquad (49)$$

Since $P_{T_{\mathbf{L}}} = \mathbf{U_L}\mathbf{U_L}^T + \mathbf{V_L}\mathbf{V_L}^T - \mathbf{U_L}\mathbf{U_L}^T\mathbf{V_L}\mathbf{V_L}^T$, and using Davis-Kahan theorem Davis and Kahan (1970) and the assumption $\|\mathbf{L}-\mathbf{L}^*\|_F \le a\sigma_r(\mathbf{L}^*)$, there exists c_1, c_2 depending on a such that

$$\|\mathbf{U_L}\mathbf{U_L}^T - \mathbf{U_{L'}}\mathbf{U_{L'}}^T\|_F \le c_1,\ \|\mathbf{V_L}\mathbf{V_L}^T - \mathbf{V_{L'}}\mathbf{V_{L'}}^T\|_F \le c_2,$$

so there exists C' depending on a such that

$$\begin{aligned}
&\|P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*) - P_{T_{\mathbf{L}'}}(\mathbf{L}'-\mathbf{L}^*)\|_F \qquad (50)\\
=&\|[P_{T_{\mathbf{L}'}}(\mathbf{L}-\mathbf{L}^*) - P_{T_{\mathbf{L}'}}(\mathbf{L}'-\mathbf{L}^*)] + [P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*) - P_{T_{\mathbf{L}'}}(\mathbf{L}-\mathbf{L}^*)]\|_F \\
\le&\|\mathbf{L}-\mathbf{L}'\|_F + C'\|\mathbf{L}-\mathbf{L}'\|_F.
\end{aligned}$$

Combining (49) and (50), (48) is proved.

Second, based on (48), we will apply an ϵ-net covering argument to finish the proof that combines probabilistic estimation for each $\mathbf{L}$ and a union bound (ϵ-net covering argument is a standard argument in probabilistic estimation Vershynin (2012)). Use the estimation of

the cumulative distribution function of the Gaussian distribution (Ledoux and Talagrand, 1991, pg 8), for any $\mathbf{L}'$,

$$\Pr\left\{\langle \mathbf{N}^*, P_{T_{\mathbf{L}'}}(\mathbf{L}'-\mathbf{L}^*)\rangle_F \geq t\|P_{T_{\mathbf{L}'}}(\mathbf{L}'-\mathbf{L}^*)\|_F\right\} \leq \frac{1}{2}\exp\left(-\frac{t^2}{2}\right).$$

For any $\mathbf{L}$ such that $\|g(\mathbf{L}')-g(\mathbf{L})\|_F<\epsilon$, applying (48),

$$\Pr\left\{\langle \mathbf{N}^*, P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\rangle_F \geq t\|P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\|_F + C_0\epsilon(\|\mathbf{N}^*\|_F+t)\right\} \leq \frac{1}{2}\exp\left(-\frac{t^2}{2}\right).$$

Using union bound, there is an ϵ-net of the set $\{g(\mathbf{L}) : \|g(\mathbf{L})\|_F = x\}$ with at most $(C_5x/\epsilon)^{n_1r+n_2r-r^2}$ points. Therefore, for all $\mathbf{L}$ such that $x-\epsilon \leq \|P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\|_F \leq x+\epsilon$,

$$\begin{aligned}&\Pr\left\{\langle \mathbf{N}^*, P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\rangle_F \geq t\|P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\|_F + 2C_0\epsilon(\|\mathbf{N}^*\|_F+t)\right\}\\ \leq&\frac{1}{2}\exp\left(-\frac{t^2}{2}\right)\cdot\left(\frac{C_5x}{\epsilon}\right)^{n_1r+n_2r-r^2}. \end{aligned} \tag{51}$$

Let $t=x/8$ and $\epsilon = x/16C_0\|\mathbf{N}^*\|_F$, then when $\|\mathbf{N}^*\|_F \geq 1$ (which holds with high probability as n_1n_2 goes to infinity), then using $C_0\geq 1$ we have $\epsilon \leq x/16$, and when $x\geq 4$,

$$\begin{aligned}&t\|P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\|_F + 2C_0\epsilon(\|\mathbf{N}^*\|_F+t) \leq \frac{x}{8}(x+\epsilon)+\frac{x}{8\|\mathbf{N}^*\|_F}(\|\mathbf{N}^*\|_F+t)\\ =&\frac{x}{8}(x+\epsilon)+\frac{x}{8}+\frac{x^2}{64\|\mathbf{N}^*\|_F} \leq \frac{x^2}{8}\frac{17}{16}+\frac{x}{8}+\frac{x^2}{64} \leq \frac{x^2}{8}\frac{17}{16}+\frac{x^2}{32}+\frac{x^2}{64} \leq \frac{1}{4}(x-\epsilon)^2\\ \leq&\frac{1}{4}\|P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\|_F^2, \end{aligned} \tag{52}$$

where the last inequality applies the assumption $x-\epsilon \leq \|P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\|_F$. Combining (51) and (52) and recall that $t=x/8$, we have that for all $\mathbf{L}$ such that $x-x/16C_0\|\mathbf{N}^*\|_F \leq \|P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\|_F \leq x+x/16C_0\|\mathbf{N}^*\|_F$,

$$\begin{aligned}&\Pr\Bigg\{\langle \mathbf{N}^*, P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\rangle_F \geq \frac{1}{4}\|P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\|_F^2,\\ &\qquad\text{for all } \mathbf{L} \text{ s.t. } \left|\|P_{T_{\mathbf{L}}}(\mathbf{L}-\mathbf{L}^*)\|_F - x\right| \leq \frac{x}{16C_0\|\mathbf{N}^*\|_F}\Bigg\}\\ \leq&\frac{1}{2}\exp\left(-\frac{x^2}{128}\right)\cdot\left(16C_5C_0\|\mathbf{N}^*\|_F\right)^{n_1r+n_2r-r^2}. \end{aligned} \tag{53}$$

Let $x_i = \sqrt{n_1+n_2+128(n_1r+n_2r-r^2)\ln(16C_5C_0\|\mathbf{N}^*\|_F)}(1+1/16C_0\|\mathbf{N}^*\|_F)^i$ with $i=1,2,...$, then

$$\begin{aligned}&\sum_{i=1}^{\infty}\exp\left(-\frac{x_i^2}{128}\right)\cdot\left(16C_5C_0\|\mathbf{N}^*\|_F\right)^{n_1r+n_2r-r^2}\\ \leq&\exp(-\frac{n_1+n_2}{128})\sum_{i=1}^{\infty}\exp(-(1+1/16C_0\|\mathbf{N}^*\|_F)^{2i})\\ \leq&\exp(-\frac{n_1+n_2}{128})\sum_{i=1}^{\infty}\exp(-1-i/8C_0\|\mathbf{N}^*\|_F)\\ =&\exp(-\frac{n_1+n_2}{128}-1)\frac{\exp(-1/8C_0\|\mathbf{N}^*\|_F)}{1-\exp(-1/8C_0\|\mathbf{N}^*\|_F)} \leq 8C_0\|\mathbf{N}^*\|_F\exp(-\frac{n_1+n_2}{128}-1), \end{aligned} \tag{54}$$

where the last inequality uses $\exp(-c)\leq 1-c$ when $c\geq 0$. Clearly, the RHS goes to 0 as $n_1+n_2\to\infty$.

Combining the estimation (53) for $\{x_i\}_{i=1}^{\infty}$, with probability $1-8C_0\|\mathbf{N}^*\|_F\exp(-\frac{n_1+n_2}{128}-1)$, the event (36) holds for all $\mathbf{L}$ such that

$$\|g(\mathbf{L})\|_F \geq \max(\sqrt{n_1+n_2+128(n_1r+n_2r-r^2)\ln(16C_5C_0\|\mathbf{N}^*\|_F)}, 4).$$

Combining it with (29), the event (36) holds for all for all $\mathbf{L}$ such that

$$\begin{aligned}a\sigma_r(\mathbf{L}^*) \geq& \|\mathbf{L}-\mathbf{L}^*\|_F\\ \geq& \frac{1}{1-\frac{a}{2}}\max(\sqrt{n_1+n_2+128(n_1r+n_2r-r^2)\ln(16C_5C_0\|\mathbf{N}^*\|_F)}, 4).\end{aligned}$$

Considering that $\sqrt{n_1+n_2+128(n_1r+n_2r-r^2)\ln(16C_5C_0\|\mathbf{N}^*\|_F)}$ is the dominant term when $n_1,n_2\to\infty$, Lemma 13(b) is proved. ■

Lemma 16 Proof Following (41) and the proof of Lemma 10[a], and note that Lemma 15 means that γ^* and γ are replaced by arbitrary numbers in the intervals $[0.5p\gamma^*, 1.5p\gamma^*]$ and $[0.5p\gamma, 1.5p\gamma]$, we have

$$\|\tilde{\mathbf{D}}\|_F^2 \leq 6(\gamma+2\gamma^*)p\mu r\|\mathbf{L}-\mathbf{L}^*\|_F^2 + 4\frac{3\gamma^*}{\gamma-3\gamma^*}\|P_{\mathbf{\Phi}}(\mathbf{L}-\mathbf{L}^*)\|_F^2 + a^2\|\mathbf{L}-\mathbf{L}^*\|_F^2.$$

Applying Lemma 11 and (44), we have

$$\begin{aligned}\|P_{\mathbf{\Phi}}(\mathbf{L}-\mathbf{L}^*)\|_F \leq& \|P_{\mathbf{\Phi}}P_{T_{\mathbf{L}^*}}(\mathbf{L}-\mathbf{L}^*)\|_F + \|P_{\mathbf{\Phi}}P_{T_{\mathbf{L}^*}}^{\perp}(\mathbf{L}-\mathbf{L}^*)\|_F\\ \leq& \sqrt{p(1+\epsilon)}\|\mathbf{L}-\mathbf{L}^*\|_F + \frac{a}{2}\|\mathbf{L}-\mathbf{L}^*\|_F.\end{aligned}$$

Combining it with the estimation of $\|P_{\mathbf{\Phi}}(\mathbf{L}-\mathbf{L}^*)\|_F$ in Lemma 11, we have $\|\tilde{\mathbf{D}}\|_F \leq \tilde{C}_1\|P_{\mathbf{\Phi}}(\mathbf{L}-\mathbf{L}^*)\|_F$ with

$$\tilde{C}_1 = \frac{1}{p(1-\epsilon)}\Big[6(\gamma+2\gamma^*)p\mu r + 4\frac{3\gamma^*}{\gamma-3\gamma^*}(\sqrt{p(1+\epsilon)}+\frac{a}{2})^2 + a^2\Big].$$

Abstract

As data sets continue to increase in size and multi-core computer architectures are developed, asynchronous parallel optimization algorithms become more and more essential to the field of Machine Learning. Unfortunately, conducting the theoretical analysis asynchronous methods is difficult, notably due to the introduction of delay and inconsistency in inherently sequential algorithms. Handling these issues often requires resorting to simplifying but unrealistic assumptions. Through a novel perspective, we revisit and clarify a subtle but important technical issue present in a large fraction of the recent convergence rate proofs for asynchronous parallel optimization algorithms, and propose a simplification of the recently introduced "perturbed iterate" framework that resolves it. We demonstrate the usefulness of our new framework by analyzing three distinct asynchronous parallel incremental optimization algorithms: Hogwild (asynchronous Sgd), Kromagnon (asynchronous Svrg) and Asaga, a novel asynchronous parallel version of the incremental gradient algorithm Saga that enjoys fast linear convergence rates. We are able to both remove problematic assumptions and obtain better theoretical results. Notably, we prove that Asaga and Kromagnon can obtain a theoretical linear speedup on multi-core systems even without sparsity assumptions. We present results of an implementation on a 40-core architecture illustrating the practical speedups as well as the hardware overhead. Finally, we investigate the overlap constant, an ill-understood but central quantity for the theoretical analysis of asynchronous parallel algorithms. We find that it encompasses much more complexity than suggested in previous work, and often is order-of-magnitude bigger than traditionally thought.

Keywords: optimization, machine learning, large scale, asynchronous parallel, sparsity

1. Introduction

We consider the unconstrained optimization problem of minimizing a *finite sum* of smooth convex functions:

$$\min_{x\in\mathbb{R}^d} f(x), \quad f(x) := \frac{1}{n}\sum_{i=1}^{n} f_i(x), \tag{1}$$

where each f_i is assumed to be convex with L-Lipschitz continuous gradient, f is μ-strongly convex and n is large (for example, the number of data points in a regularized empirical risk minimization setting). We define a condition number for this problem as $\kappa := L/\mu$, as is standard in the finite sum literature.[1] A flurry of randomized incremental algorithms (which at each iteration select i at random and process only one gradient f_i') have recently been proposed to solve (1) with a fast[2] linear convergence rate, such as Sag (Le Roux et al., 2012), Sdca (Shalev-Shwartz and Zhang, 2013), Svrg (Johnson and Zhang, 2013) and Saga (Defazio et al., 2014). These algorithms can be interpreted as variance reduced versions of the stochastic gradient descent (Sgd) algorithm, and they have demonstrated both theoretical and practical improvements over Sgd (for the *finite sum* optimization problem 1).

In order to take advantage of the multi-core architecture of modern computers, the aforementioned optimization algorithms need to be adapted to the asynchronous parallel setting, where multiple threads work concurrently. Much work has been devoted recently in proposing and analyzing asynchronous parallel variants of algorithms such as Sgd (Niu et al., 2011), Sdca (Hsieh et al., 2015) and Svrg (Reddi et al., 2015; Mania et al., 2017; Zhao and Li, 2016). Among the incremental gradient algorithms with fast linear convergence rates that can optimize (1) in its general form, only Svrg had had an asynchronous parallel version proposed.[3] No such adaptation had been attempted for Saga until Leblond et al. (2017), even though one could argue that it is a more natural candidate as, contrarily to Svrg, it is not epoch-based and thus has no synchronization barriers at all. The present paper is an extended journal version of the conference paper from Leblond et al. (2017).

The usual frameworks for asynchronous analysis are quite intricate (see Section 2.2) and thus require strong simplifying assumptions. They are not well suited to the study of complex algorithms such as Saga. We therefore base our investigation on the newly proposed "perturbed iterate" framework introduced in Mania et al. (2017), which we also improve upon in order to properly analyze Saga. Deriving a framework in which the analysis of Saga is possible enables us to highlight the deficiencies of previous frameworks and to define a better alternative. Our new approach is not limited to Saga but can be used to investigate other algorithms and improve their existing bounds.

Contributions. In Section 2, we propose a simplification of the "perturbed iterate" framework from Mania et al. (2017) as a basis for our asynchronous convergence analysis. At the

1. Since we have assumed that each individual f_i is L-smooth, f itself is L-smooth – but its smoothness constant L_f could be much smaller. While the more classical condition number is $\kappa_b := L_f/\mu$, our rates are in terms of this bigger L/μ in this paper.
2. Their complexity in terms of gradient evaluations to reach an accuracy of ϵ is $O((n+\kappa)\log(1/\epsilon))$, in contrast to $O(n\kappa_b \log(1/\epsilon))$ for batch gradient descent in the worst case.
3. We note that Sdca requires the knowledge of an explicit μ-strongly convex regularizer in (1), whereas Sag / Saga are adaptive to any local strong convexity of f (Schmidt et al., 2016; Defazio et al., 2014). The variant of Svrg from Hofmann et al. (2015) is also adaptive (we review this variant in Section 4.1).

same time, through a novel perspective, we revisit and clarify a technical problem present in a large fraction of the literature on randomized asynchronous parallel algorithms (with the exception of Mania et al. 2017, which also highlights this issue): namely, they all assume unbiased gradient estimates, an assumption that is *inconsistent* with their proof technique without further unpractical synchronization assumptions.

In Section 3.1, we present a novel sparse variant of Saga that is more adapted to the parallel setting than the original Saga algorithm. In Section 3.2, we present Asaga, a lock-free asynchronous parallel version of Sparse Saga that does not require consistent read or write operations. We give a tailored convergence analysis for Asaga. Our main result states that Asaga obtains the same geometric convergence rate per update as Saga when the overlap bound τ (which scales with the number of cores) satisfies $\tau \leq \mathcal{O}(n)$ and $\tau \leq \mathcal{O}(\frac{1}{\sqrt{\Delta}} \max\{1, \frac{n}{\kappa}\})$, where $\Delta \leq 1$ is a measure of the sparsity of the problem. This notably implies that a linear speedup is theoretically possible even without sparsity in the well-conditioned regime where $n \gg \kappa$. This result is in contrast to previous analysis which always required some sparsity assumptions.

In Section 4, we revisit the asynchronous variant of Svrg from Mania et al. (2017), Kromagnon, while removing their gradient bound assumption (which was inconsistent with the strongly convex setting).[4] We prove that the algorithm enjoys the same fast rates of convergence as Svrg under similar conditions as Asaga – whereas the original paper only provided analysis for slower rates (in both the sequential and the asynchronous case), and thus less meaningful speedup results.

In Section 5, in order to show that our improved "after read" perturbed iterate framework can be used to revisit the analysis of other optimization routines with correct proofs that do not assume homogeneous computation, we provide the analysis of the Hogwild algorithm first introduced in Niu et al. (2011). Our framework allows us to remove the classic gradient bound assumption and to prove speedups in more realistic settings.

In Section 6, we provide a practical implementation of Asaga and illustrate its performance on a 40-core architecture, showing improvements compared to asynchronous variants of Svrg and Sgd. We also present experiments on the overlap bound τ, showing that it encompasses much more complexity than suggested in previous work.

Related Work. The seminal textbook of Bertsekas and Tsitsiklis (1989) provides most of the foundational work for parallel and distributed optimization algorithms. An asynchronous variant of Sgd with constant step size called Hogwild was presented by Niu et al. (2011); part of their framework of analysis was re-used and inspired most of the recent literature on asynchronous parallel optimization algorithms with convergence rates, including asynchronous variants of coordinate descent (Liu et al., 2015), Sdca (Hsieh et al., 2015), Sgd for non-convex problems (De Sa et al., 2015; Lian et al., 2015), Sgd for stochastic optimization (Duchi et al., 2015) and Svrg (Reddi et al., 2015; Zhao and Li, 2016). These papers make use of an unbiased gradient assumption that is not consistent with the proof technique, and thus suffers from technical problems[5] that we highlight in Section 2.2.

The "perturbed iterate" framework presented in Mania et al. (2017) is to the best of our knowledge the only one that does not suffer from this problem, and our convergence analysis builds heavily from their approach, while simplifying it. In particular, the authors assumed that f was both strongly convex and had a bound on the gradient, two *inconsistent* assumptions in the unconstrained setting that they analyzed. We overcome these difficulties by using tighter inequalities that remove the requirement of a bound on the gradient. We also propose a more convenient way to label the iterates (see Section 2.2). The sparse version of Saga that we propose is also inspired from the sparse version of Svrg proposed by Mania et al. (2017).

Reddi et al. (2015) presents a hybrid algorithm called Hsag that includes Saga and Svrg as special cases. Their asynchronous analysis is epoch-based though, and thus does not handle a fully asynchronous version of Saga as we do. Moreover, they require consistent reads and do not propose an efficient sparse implementation for Saga, in contrast to Asaga.

Pan et al. (2016) proposes a black box mini-batch algorithm to parallelize Sgd-like methods while maintaining serial equivalence through smart update partitioning. When the data set is sparse enough, they obtain speedups over "Hogwild" implementations of Svrg and Saga.[6] However, these "Hogwild" implementations appear to be quite suboptimal, as they do not leverage data set sparsity efficiently: they try to adapt the "lazy updates" trick from Schmidt et al. (2016) to the asynchronous parallel setting – which as discussed in Appendix E is extremely difficult – and end up making several approximations which severely penalize the performance of the algorithms. In particular, they have to use much smaller step sizes than in the sequential version, which makes for worse results.

Pedregosa et al. (2017) extend the Asaga algorithm presented in Section 3.2 to the proximal setting.

Notation. We denote by $\mathbb{E}$ a full expectation with respect to all the randomness in the system, and by $\mathbf{E}$ the *conditional* expectation of a random i (the index of the factor f_i chosen in Sgd and other algorithms), conditioned on all the past, where "past" will be clear from the context. $[x]_v$ represents the coordinate v of the vector $x \in \mathbb{R}^d$. For *sequential* algorithms, x^+ is the updated parameter vector after one algorithm iteration.

2. Revisiting the Perturbed Iterate Framework for Asynchronous Analysis

As most recent parallel optimization contributions, we use a similar hardware model to Niu et al. (2011). We consider multiple cores which all have read and write access to a shared memory. The cores update a central parameter vector in an asynchronous and lock-free fashion. Unlike Niu et al. (2011), we *do not* assume that the vector reads are consistent: multiple cores can read and write different coordinates of the shared vector at the same time. This also implies that a full vector read for a core might not correspond to any consistent state in the shared memory at any specific point in time.

4. Although the authors mention that this gradient bound assumption can be enforced through the use of a thresholding operator, they do not explain how to handle the interplay between this non-linear operator and the asynchrony of the algorithm. Their theoretical analysis relies on the linearity of the operations (e.g. to derive (Mania et al., 2017, Eq. (2.6))), and thus this claim is not currently supported by theory (note that a strongly convex function over an unbounded domain always has unbounded gradients).

5. Except (Duchi et al., 2015) that can be easily fixed by incrementing their global counter *before* sampling.

6. By "Hogwild", the authors mean asynchronous parallel variants where cores independently run the sequential update rule.

2.1. Perturbed Iterate Framework

We first review the "perturbed iterate" framework recently introduced by Mania et al. (2017) which will form the basis of our analysis. In the sequential setting, stochastic gradient descent and its variants can be characterized by the following update rule:

$$x_{t+1} = x_t - \gamma g(x_t, i_t)\,, \tag{2}$$

where i_t is a random variable independent from x_t and we have the unbiasedness condition $\mathbf{E}g(x_t, i_t) = f'(x_t)$ (recall that $\mathbf{E}$ is the relevant-past conditional expectation with respect to i_t).

Unfortunately, in the parallel setting, we manipulate stale, inconsistent reads of shared parameters and thus we do not have such a straightforward relationship. Instead, Mania et al. (2017) proposed to distinguish $\hat{x}_t$, the actual value read by a core to compute an update, from x_t, a "virtual iterate" that we can analyze and is *defined* by the update equation:

$$x_{t+1} := x_t - \gamma g(\hat{x}_t, i_t)\,. \tag{3}$$

We can thus interpret $\hat{x}_t$ as a noisy (perturbed) version of x_t due to the effect of asynchrony.

We formalize the precise meaning of x_t and $\hat{x}_t$ in the next section. We first note that all references mentioned in the related work section that analyzed asynchronous parallel randomized algorithms assumed that the following unbiasedness condition holds:

$$\text{[unbiasedness condition]} \quad \mathbf{E}[g(\hat{x}_t, i_t)|\hat{x}_t] = f'(\hat{x}_t).\ ^{7} \tag{4}$$

This condition is at the heart of most convergence proofs for randomized optimization methods.[8] Mania et al. (2017) correctly pointed out that most of the literature thus made the often implicit assumption that i_t is independent of $\hat{x}_t$. But as we explain below, this assumption is incompatible with a non-uniform asynchronous model in the analysis approach used in most of the recent literature.

2.2. On the Difficulty of Labeling the Iterates

Formalizing the meaning of x_t and $\hat{x}_t$ highlights a subtle but important difficulty arising when analyzing *randomized* parallel algorithms: what is the meaning of t? This is the problem of *labeling* the iterates for the purpose of the analysis, and this labeling can have randomness itself that needs to be taken in consideration when interpreting the meaning of an expression like $\mathbb{E}[x_t]$. In this section, we contrast three different approaches in a unified framework. We notably clarify the dependency issues that the labeling from Mania et al. (2017) resolves and propose a new, simpler labeling which allows for much simpler proof techniques.

7. We note that to be completely formal and define this conditional expectation more precisely, one would need to define another random vector that describes the entire system randomness, including all the reads, writes, delays, etc. Conditioning on $\hat{x}_t$ in (4) is actually a shorthand to indicate that we are conditioning on all the relevant "past" that defines both the value of $\hat{x}_t$ as well as the fact that it was the t^{th} labeled element. For clarity of exposition, we will not go into this level of technical detail, but one could define the appropriate sigma fields to condition on in order to make this equation fully rigorous.
8. A notable exception is Sag (Le Roux et al., 2012) which has biased updates and thus requires a significantly more complex convergence proof. Making Sag unbiased leads to Saga (Defazio et al., 2014), with a much simpler convergence proof.

We consider algorithms that execute in parallel the following four steps, where t is a global labeling that needs to be defined:[9]

1. Read the information in shared memory ($\hat{x}_t$).
2. Sample i_t.
3. Perform some computations using $(\hat{x}_t, i_t)$.
4. Write an update to shared memory.

(5)

The "After Write" Approach. We call the "after write" approach the standard global labeling scheme used in Niu et al. (2011) and re-used in all the later papers that we mentioned in the related work section, with the notable exceptions of Mania et al. (2017) and Duchi et al. (2015). In this approach, t is a (virtual) global counter recording the number of *successful writes* to the shared memory x (incremented after step 4 in 5); x_t thus represents the (true) content of the shared memory after t updates. The interpretation of the crucial equation (3) then means that $\hat{x}_t$ represents the (delayed) local copy value of the core that made the $(t+1)^{\text{th}}$ successful update; i_t represents the factor sampled by this core for this update. Notice that in this framework, the value of $\hat{x}_t$ and i_t is unknown at "time t"; we have to wait to the later time when the next core writes to memory to finally determine that its local variables are the ones labeled by t. We thus see that here $\hat{x}_t$ and i_t are not necessarily independent – they share dependence through the assignment of the t label. In particular, if some values of i_t yield faster updates than others, it will influence the label assignment defining $\hat{x}_t$. We provide a concrete example of this possible dependency in Figure 1.

The only way we can think to resolve this issue and ensure unbiasedness is to assume that the computation time for the algorithm running on a core is independent of the sample i chosen. This assumption seems overly strong in the context of potentially heterogeneous factors f_i's, and is thus a fundamental flaw for analyzing non-uniform asynchronous computation that has mostly been ignored in the recent asynchronous optimization literature.[10]

9. Observe that contrary to most asynchronous algorithms, we choose to read the shared parameter vector *before* sampling the next data point. We made this design choice to emphasize that in order for $\hat{x}_t$ and i_t to be independent – which will prove crucial for the analysis – the reading of the shared parameter has to be independent of the sampled data point. Although in practice one would prefer to only read the necessary parameters *after* sampling the relevant data point, for the sake of the analysis we cannot allow this source of dependence. We note that our analysis could also handle reading the parameter first and then sampling as long as independence is ensured, but for clarity of presentation, we decided to make this independence explicit.

   Mania et al. (2017) make the opposite presentation choice. In their main analysis, they explicitly assume that $\hat{x}_t$ and i_t are independent, although they explain that it is not the case in practical implementations. The authors then propose a scheme to handle the dependency directly in their appendix. However, this "fix" can only be applied in a restricted setup: only for the Hogwild algorithm, with the assumption that the norm of the gradient is uniformly bounded. Furthermore, even in this restricted setup, the scheme leads to worsened theoretical results (the bound on τ is κ^2 worse). Applying it to a more complex algorithm such as Kromagnon or Asaga would mean overcoming several significant hurdles and is thus still an open problem.

   In the absence of a better option, we choose to enforce the independence of $\hat{x}_t$ and i_t with our modified steps ordering.
10. We note that Bertsekas and Tsitsiklis (1989) briefly discussed this issue (see Section 7.8.3), stressing that their analysis for SGD required that the scheduling of computation was independent from the randomness from SGD, but they did not offer any solution if this assumption was not satisfied. Both the "before read" labeling from Mania et al. (2017) and our proposed "after read" labeling resolve this issue.

	f_1	f_2		f_1	f_2		f_1	f_2		f_1	f_2
core 1	×		core 1	×		core 1		×	core 1		×
core 2	×		core 2		×	core 2	×		core 2		×
$f'_{i_0}(\hat{x}_0)$	$f'_1(\hat{x}_0)$		$f'_1(\hat{x}_0)$			$f'_1(\hat{x}_0)$			$f'_2(\hat{x}_0)$		

Figure 1: Suppose that we have two cores and that f has two factors: f_1 which has support on only one variable, and f_2 which has support on 10^6 variables and thus yields a gradient step that is significantly more expensive to compute. x_0 is the initial content of the memory, and we do not know yet whether $\hat{x}_0$ is the local copy read by the first core or the second core, but we are sure that $\hat{x}_0 = x_0$ as no update can occur in shared memory without incrementing the counter. There are four possibilities for the next step defining x_1 depending on which index i was sampled on each core. If any core samples $i = 1$, we know that $x_1 = x_0 - \gamma f'_1(x_0)$ as it will be the first (much faster update) to complete. This happens in 3 out of 4 possibilities; we thus have that $\mathbb{E}x_1 = x_0 - \gamma(\frac{3}{4}f'_1(x_0) + \frac{1}{4}f'_2(x_0))$. We see that this analysis scheme *does not* satisfy the crucial unbiasedness condition (4). To understand this subtle point better, note that in this very simple example, i_0 and i_1 are not independent. We can show that $P(i_1 = 2 \mid i_0 = 2) = 1$. They share dependency *through the labeling assignment*.

The "Before Read" Approach. Mania et al. (2017) address this issue by proposing instead to increment the global t counter just *before* a new core starts to *read* the shared memory (before step 1 in 5). In their framework, $\hat{x}_t$ represents the (inconsistent) read that was made by this core in this computational block, and i_t represents the chosen sample. The update rule (3) represents a *definition* of the meaning of x_t, which is now a "virtual iterate" as it does not necessarily correspond to the content of the shared memory at any point. The real quantities manipulated by the algorithm in this approach are the $\hat{x}_t$'s, whereas x_t is used only for the analysis – consequently, the critical quantity we want to see vanish is $\mathbb{E}\|\hat{x}_t - x^*\|^2$. The independence of i_t with $\hat{x}_t$ can be simply enforced in this approach by making sure that the way the shared memory x is read does not depend on i_t (e.g. by reading all its coordinates in a fixed order). Note that this implies that we have to read all of x's coordinates, regardless of the size of f_{i_t}'s support. This is a much weaker condition than the assumption that all the computation in a block does not depend on i_t as required by the "after write" approach, and is thus more reasonable.

A New Global Ordering: the "After Read" Approach. The "before read" approach gives rise to the following complication in the analysis: $\hat{x}_t$ can depend on i_r for $r > t$. This is because t is a global time ordering only on the assignment of computation to a core, not on when $\hat{x}_t$ was finished being read. This means that we need to consider both the "future" and the "past" when analyzing x_t. To simplify the analysis, we thus propose a third way to label the iterates that we call "after read": $\hat{x}_t$ represents the $(t+1)^{\text{th}}$ *fully completed read* (t incremented after step 1 in 5). As in the "before read" approach, we can ensure that i_t is independent of $\hat{x}_t$ by ensuring that how we read does not depend on i_t. But unlike in the "before read" approach, t here now does represent a global ordering on the $\hat{x}_t$ iterates – and thus we have that i_r is independent of $\hat{x}_t$ for $r > t$. Again using (3) as the definition of the virtual iterate x_t as in the perturbed iterate framework, we then have a very simple form for

the value of x_t and $\hat{x}_t$ (assuming atomic writes, see Property 5 below):

$$\begin{aligned} x_t &= x_0 - \gamma \sum_{u=0}^{t-1} g(\hat{x}_u, \hat{\alpha}^u, i_u)\,; \\ [\hat{x}_t]_v &= [x_0]_v - \gamma \sum_{\substack{u=0 \\ \text{u s.t. coordinate } v \text{ was written} \\ \text{for } u \text{ before } t}}^{t-1} [g(\hat{x}_u, \hat{\alpha}^u, i_u)]_v\,. \end{aligned} \tag{6}$$

This proved crucial for our Asaga proof and allowed us to obtain better bounds for Hogwild and the Kromagnon algorithm presented in Mania et al. (2017).

The main idea of the perturbed iterate framework is to use this handle on $\hat{x}_t - x_t$ to analyze the convergence for x_t. As x_t is a virtual quantity, Mania et al. (2017) supposed that there exists an index T such that x_T lives in shared memory (T is a pre-set final iteration number after which all computation is completed, which means $x_T = \hat{x}_T$) and gave their convergence result for this x_T.

In this paper, we instead state the convergence results directly in terms of $\hat{x}_t$, thus avoiding the need for an unwieldy pre-set final iteration counter, and also enabling guarantees during the entire course of the algorithm.

Remark 1 *As mentioned in footnote 9, Mania et al. (2017) choose to sample a data point first and only then read the shared parameter vector in* (5)*. One advantage of this option is that it allows for reading only the relevant dimensions of the parameter vector, although it means losing the crucial independence property between $\hat{x}_t$ and i_t.*

We can thus consider that their labeling approach is "after sampling" rather than "before read" (both are equivalent given their ordering). If we take this view, then by switching the order of the sampling and the reading steps in their setup, the "after sampling" approach becomes equivalent to our proposed "after read" labeling.

However, the framework in which they place their analysis is the "before read" approach as described above, which results in having to take into account troublesome "future" terms in (6)*. These additional terms make the analysis considerably harder and ultimately lead to worse theoretical results.*

3. Asynchronous Parallel Sparse Saga

We start by presenting Sparse Saga, a sparse variant of the Saga algorithm that is more adapted to the asynchronous parallel setting. We then introduce Asaga, the asynchronous parallel version of Sparse Saga. Finally, we state both convergence and speedup results for Asaga and give an outline of their proofs.

3.1. Sparse Saga

Borrowing our notation from Hofmann et al. (2015), we first present the original Saga algorithm and then describe our novel sparse variant.

Original Saga Algorithm. The standard Saga algorithm (Defazio et al., 2014) maintains two moving quantities to optimize (1): the current iterate x and a table (memory) of historical

gradients $(\alpha_i)_{i=1}^n$.[11] At every iteration, the Saga algorithm samples uniformly at random an index $i \in \{1, \dots, n\}$, and then executes the following update on x and α (for the unconstrained optimization version):

$$x^+ = x - \gamma\big(f_i'(x) - \alpha_i + \bar{\alpha}\big); \qquad \alpha_i^+ = f_i'(x), \tag{7}$$

where γ is the step size and $\bar{\alpha} := {}^1\!/_n \sum_{i=1}^n \alpha_i$ can be updated efficiently in an online fashion. Crucially, $\mathbf{E}\alpha_i = \bar{\alpha}$ and thus the update direction is unbiased ($\mathbf{E}x^+ = x - \gamma f'(x)$). Furthermore, it can be proven (see Defazio et al., 2014) that under a reasonable condition on γ, the update has vanishing variance, which enables the algorithm to converge linearly with a constant step size.

Motivation for a Variant. In its current form, every Saga update is dense even if the individual gradients are sparse due to the historical gradient ($\bar{\alpha}$) term. Schmidt et al. (2016) introduced an implementation technique denoted lagged updates in which each iteration has a cost proportional to the size of the support of $f_i'(x)$. However, this technique involves keeping track of past updates and is not easily adaptable to the parallel setting (see Appendix E). We therefore introduce Sparse Saga, a novel variant which explicitly takes sparsity into account and is easily parallelizable.

Sparse* Saga *Algorithm. As in the Sparse Svrg algorithm proposed in Mania et al. (2017), we obtain Sparse Saga by a simple modification of the parameter update rule in (7) where $\bar{\alpha}$ is replaced by a sparse version equivalent in expectation:

$$x^+ = x - \gamma(f_i'(x) - \alpha_i + D_i\bar{\alpha}), \tag{8}$$

where D_i is a diagonal matrix that makes a weighted projection on the support of f_i'. More precisely, let S_i be the support of the gradient f_i' function (i.e., the set of coordinates where f_i' can be nonzero). Let D be a $d \times d$ diagonal reweighting matrix, with coefficients ${}^1\!/_{p_v}$ on the diagonal, where p_v is the probability that dimension v belongs to S_i when i is sampled uniformly at random in $\{1, ..., n\}$. We then define $D_i := P_{S_i} D$, where P_{S_i} is the projection onto S_i. The reweighting by D ensures that $\mathbf{E}D_i\bar{\alpha} = \bar{\alpha}$, and thus that the update is still unbiased despite the sparsifying projection.

***Convergence Result for (Serial) Sparse* Saga.** For clarity of exposition, we model our convergence result after the simple form of Hofmann et al. (2015, Corollary 3). Note that the rate we obtain for Sparse Saga is the same as the one obtained in the aforementioned reference for Saga.

Theorem 2 *Let $\gamma = \frac{a}{5L}$ for any $a \leq 1$. Then* Sparse Saga *converges geometrically in expectation with a rate factor of at least $\rho(a) = \frac{1}{5}\min\left\{\frac{1}{n}, a\frac{1}{\kappa}\right\}$, i.e., for x_t obtained after t updates, we have $\mathbb{E}\|x_t - x^*\|^2 \leq (1-\rho)^t C_0$, where $C_0 := \|x_0 - x^*\|^2 + \frac{1}{5L^2}\sum_{i=1}^n \|\alpha_i^0 - f_i'(x^*)\|^2$.*

11. For linear predictor models, the memory α_i^0 can be stored as a scalar. Following Hofmann et al. (2015), α_i^0 can be initialized to any convenient value (typically 0), unlike the prescribed $f_i'(x_0)$ analyzed in (Defazio et al., 2014).

Proof outline. We reuse the proof technique from Hofmann et al. (2015), in which a combination of classical strong convexity and Lipschitz inequalities is used to derive the inequality (Hofmann et al., 2015, Lemma 1):

$$\mathbf{E}\|x^+ - x^*\|^2 \leq (1-\gamma\mu)\|x - x^*\|^2 + 2\gamma^2\mathbf{E}\|\alpha_i - f_i'(x^*)\|^2 + (4\gamma^2 L - 2\gamma)\big(f(x) - f(x^*)\big). \tag{9}$$

This gives a contraction term. A Lyapunov function is then defined to control the two other terms. To ensure our variant converges at the same rate as regular Saga, we only need to prove that the above inequality (Hofmann et al., 2015, Lemma 1) is still verified. To prove this, we derive close variants of equations (6) and (9) in their paper. The rest of the proof can be reused without modification. The full details can be found in Appendix A.

Comparison with Lagged Updates. The lagged updates technique in Saga is based on the observation that the updates for component $[x]_v$ need not be applied until this coefficient needs to be accessed, that is, until the next iteration t such that $v \in S_{i_t}$. We refer the reader to Schmidt et al. (2016) for more details.

Interestingly, the expected number of iterations between two steps where a given dimension v is in the support of the partial gradient is p_v^{-1}, where p_v is the probability that v is in the support of the partial gradient at a given step. p_v^{-1} is precisely the term which we use to multiply the update to $[x]_v$ in Sparse Saga. Therefore one may see the updates in Sparse Saga as *anticipated* updates, whereas those in the Schmidt et al. (2016) implementation are *lagged*.

The two algorithms appear to be very close, even though Sparse Saga uses an expectation to multiply a given update whereas the lazy implementation uses a random variable (with the same expectation). Sparse Saga therefore uses a slightly more aggressive strategy, which may explain the result of our experiments (see Section 6.3): both Sparse Saga and Saga with lagged updates had similar convergence in terms of number of iterations, with the Sparse Saga scheme being slightly faster in terms of runtime.

Although Sparse Saga requires the computation of the p_v probabilities, this can be done during a first pass throughout the data (during which constant step size Sgd may be used) at a negligible cost.

3.2. Asynchronous Parallel Sparse Saga

We describe Asaga, a sparse asynchronous parallel implementation of Sparse Saga, in Algorithm 1 in the theoretical form that we analyze, and in Algorithm 2 as its practical implementation. We state our convergence result and analyze our algorithm using the improved perturbed iterate framework.

In the specific case of (Sparse) Saga, we have to add the additional read memory argument $\hat{\alpha}^t$ to our perturbed update (3):

$$\begin{aligned} x_{t+1} &:= x_t - \gamma g(\hat{x}_t, \hat{\alpha}^t, i_t); \\ g(\hat{x}_t, \hat{\alpha}^t, i_t) &:= f_{i_t}'(\hat{x}_t) - \hat{\alpha}_{i_t}^t + D_{i_t}\left({}^1\!/_n \sum_{i=1}^n \hat{\alpha}_i^t\right). \end{aligned} \tag{10}$$

Before stating our convergence result, we highlight some properties of Algorithm 1 and make one central assumption.

Algorithm 1 ASAGA (analyzed algorithm)

1: Initialize shared variables x and $(\alpha_i)_{i=1}^n$
2: **keep doing in parallel**
3: $\quad \hat{x} =$ inconsistent read of x
4: $\quad \forall j$, $\hat{\alpha}_j =$ inconsistent read of α_j
5: $\quad$ Sample i uniformly in $\{1, ..., n\}$
6: $\quad$ Let S_i be f_i's support
7: $\quad [\bar{\alpha}]_{S_i} = 1/n \sum_{k=1}^n [\hat{\alpha}_k]_{S_i}$
8:
9: $\quad [\delta x]_{S_i} = -\gamma(f_i'(\hat{x}) - \hat{\alpha}_i + D_i[\bar{\alpha}]_{S_i})$
10: $\quad$ **for** v **in** S_i **do**
11: $\quad\quad [x]_v \leftarrow [x]_v + [\delta x]_v$ // atomic
12: $\quad\quad [\alpha_i]_v \leftarrow [f_i'(\hat{x})]_v$
13: $\quad\quad$ // '$\leftarrow$' denotes a shared memory update.
14: $\quad$ **end for**
15: **end parallel loop**

Algorithm 2 ASAGA (implementation)

1: Initialize shared x, $(\alpha_i)_{i=1}^n$ and $\bar{\alpha}$
2: **keep doing in parallel**
3: $\quad$ Sample i uniformly in $\{1, ..., n\}$
4: $\quad$ Let S_i be f_i's support
5: $\quad [\hat{x}]_{S_i} =$ inconsistent read of x on S_i
6: $\quad \hat{\alpha}_i =$ inconsistent read of α_i
7: $\quad [\bar{\alpha}]_{S_i} =$ inconsistent read of $\bar{\alpha}$ on S_i
8: $\quad [\delta\alpha]_{S_i} = f_i'([\hat{x}]_{S_i}) - \hat{\alpha}_i$
9: $\quad [\delta x]_{S_i} = -\gamma([\delta\alpha]_{S_i} + D_i[\bar{\alpha}]_{S_i})$
10: $\quad$ **for** v **in** S_i **do**
11: $\quad\quad [x]_v \leftarrow [x]_v + [\delta x]_v$ // atomic
12: $\quad\quad [\alpha_i]_v \leftarrow [\alpha_i]_v + [\delta\alpha]_v$ // atomic
13: $\quad\quad [\bar{\alpha}]_v \leftarrow [\bar{\alpha}]_v + 1/n[\delta\alpha]_v$ // atomic
14: $\quad$ **end for**
15: **end parallel loop**

Property 3 (independence) *Given the "after read" global ordering, i_r is independent of $\hat{x}_t$ $\forall r \geq t$.*

The independence property for $r = t$ is assumed in most of the parallel optimization literature, even though it is not verified in case the "after write" labeling is used. We emulate Mania et al. (2017) and *enforce* this independence in Algorithm 1 by having the core read all the shared data parameters and historical gradients before starting their iterations. Although this is too expensive to be practical if the data is sparse, this is required by the theoretical Algorithm 1 that we can analyze. The independence for $r > t$ is a consequence of using the "after read" global ordering instead of the "before read" one.

Property 4 (unbiased estimator) *The update, $g_t := g(\hat{x}_t, \hat{\alpha}^t, i_t)$, is an unbiased estimator of the true gradient at $\hat{x}_t$, i.e.* (10) *yields* (4) *in conditional expectation.*

This property is crucial for the analysis, as in most related literature. It follows by the independence of i_t with $\hat{x}_t$ and from the computation of $\bar{\alpha}$ on line 7 of Algorithm 1, which ensures that $\mathbb{E}\hat{\alpha}_i = 1/n \sum_{k=1}^n [\hat{\alpha}_k]_{S_i} = [\bar{\alpha}]_{S_i}$, making the update unbiased. In practice, recomputing $\bar{\alpha}$ is not optimal, but storing it instead introduces potential bias issues in the proof (as detailed in Appendix F.3).

Property 5 (atomicity) *The shared parameter coordinate update of $[x]_v$ on line 11 is atomic.*

Since our updates are additions, there are no overwrites, even when several cores compete for the same resources. In practice, this is enforced by using *compare-and-swap* semantics, which are heavily optimized at the processor level and have minimal overhead. Our experiments with non-thread safe algorithms (i.e. where this property is not verified, see Figure 7 of Appendix F) show that compare-and-swap is necessary to optimize to high accuracy.

Finally, as is standard in the literature, we make an assumption on the maximum delay that asynchrony can cause – this is the *partially asynchronous* setting as defined in Bertsekas and Tsitsiklis (1989):

Assumption 6 (bounded overlaps) *We assume that there exists a uniform bound, called τ, on the maximum number of iterations that can overlap together. We say that iterations r and t overlap if at some point they are processed concurrently. One iteration is being processed from the start of the reading of the shared parameters to the end of the writing of its update. The bound τ means that iterations r cannot overlap with iteration t for $r \geq t + \tau + 1$, and thus that every coordinate update from iteration t is successfully written to memory before the iteration $t + \tau + 1$ starts.*

Our result will give us conditions on τ subject to which we have linear speedups. τ is usually seen as a proxy for p, the number of cores (which lowerbounds it). However, though τ appears to depend linearly on p, it actually depends on several other factors (notably the data sparsity distribution) and can be orders of magnitude bigger than p in real-life experiments. We can upper bound τ by $(p-1)R$, where R is the ratio of the maximum over the minimum iteration time (which encompasses theoretical aspects as well as hardware overhead). More details can be found in Section 6.7.

Explicit effect of asynchrony. By using the overlap Assumption 6 in the expression (6) for the iterates, we obtain the following explicit effect of asynchrony that is crucially used in our proof:

$$\hat{x}_t - x_t = \gamma \sum_{u=(t-\tau)_+}^{t-1} G_u^t g(\hat{x}_u, \hat{\alpha}^u, i_u), \tag{11}$$

where G_u^t are $d \times d$ diagonal matrices with terms in $\{0, +1\}$. From our definition of t and x_t, it is clear that every update in $\hat{x}_t$ is already in x_t – this is the 0 case. Conversely, some updates might be late: this is the $+1$ case. $\hat{x}_t$ may be lacking some updates from the "past" in some sense, whereas given our global ordering definition, it cannot contain updates from the "future".

3.3. Convergence and Speedup Results

We now state our main theoretical results. We give a detailed outline of the proof in Section 3.3.2 and its full details in Appendix B.

We first define a notion of problem sparsity, as it will appear in our results.

Definition 7 (Sparsity) *As in Niu et al. (2011), we introduce $\Delta_r := \max_{v=1..d} |\{i : v \in S_i\}|$. Δ_r is the maximum right-degree in the bipartite graph of the factors and the dimensions, i.e., the maximum number of data points with a specific feature. For succinctness, we also define $\Delta := \Delta_r / n$. We have $1 \leq \Delta_r \leq n$, and hence $1/n \leq \Delta \leq 1$.*

3.3.1. Convergence and Speedup Statements

Theorem 8 (Convergence guarantee and rate of Asaga) *Suppose* $\tau < n/10$.[12] *Let*

$$a^*(\tau) := \frac{1}{32\left(1+\tau\sqrt{\Delta}\right)\xi(\kappa,\Delta,\tau)} \quad \text{where } \xi(\kappa,\Delta,\tau) := \sqrt{1+\frac{1}{8\kappa}\min\{\frac{1}{\sqrt{\Delta}},\tau\}} \quad \text{(note that } \xi(\kappa,\Delta,\tau)\approx 1 \text{ unless } \kappa < 1/\sqrt{\Delta}\ (\leq\sqrt{n})\text{).} \tag{12}$$

For any step size $\gamma = \frac{a}{L}$ *with* $a \leq a^*(\tau)$*, the inconsistent read iterates of Algorithm 1 converge in expectation at a geometric rate of at least:* $\rho(a) = \frac{1}{5}\min\left\{\frac{1}{n}, a\frac{1}{\kappa}\right\}$*, i.e.,* $\mathbb{E}f(\hat{x}_t) - f(x^*) \leq (1-\rho)^t \tilde{C}_0$*, where* $\tilde{C}_0$ *is a constant independent of* t *(*$\approx \frac{n}{\gamma}C_0$ *with* C_0 *as defined in Theorem 2).*

This result is very close to Saga's original convergence theorem, but with the maximum step size divided by an extra $1+\tau\sqrt{\Delta}$ factor. Referring to Hofmann et al. (2015) and our own Theorem 2, the rate factor for Saga is $\min\{1/n, a/\kappa\}$ up to a constant factor. Comparing this rate with Theorem 8 and inferring the conditions on the maximum step size $a^*(\tau)$, we get the following conditions on the overlap τ for Asaga to have the same rate as Saga (comparing upper bounds).

Corollary 9 (Speedup condition) *Suppose* $\tau \leq \mathcal{O}(n)$ *and* $\tau \leq \mathcal{O}(\frac{1}{\sqrt{\Delta}}\max\{1, \frac{n}{\kappa}\})$*. Then using the step size* $\gamma = a^*(\tau)/L$ *from* (12)*,* Asaga *converges geometrically with rate factor* $\Omega(\min\{\frac{1}{n}, \frac{1}{\kappa}\})$ *(similar to* Saga*), and is thus linearly faster than its sequential counterpart up to a constant factor. Moreover, if* $\tau \leq \mathcal{O}(\frac{1}{\sqrt{\Delta}})$*, then a universal step size of* $\Theta(\frac{1}{L})$ *can be used for* Asaga *to be adaptive to local strong convexity with a similar rate to* Saga *(i.e., knowledge of* κ *is not required).*

Interestingly, in the well-conditioned regime ($n > \kappa$, where Saga enjoys a range of step sizes which all give the same contraction ratio), Asaga enjoys the same rate as Saga even in the non-sparse regime ($\Delta = 1$) for $\tau < \mathcal{O}(n/\kappa)$. This is in contrast to the previous work on asynchronous incremental gradient methods which required some kind of sparsity to get a theoretical linear speedup over their sequential counterpart (Niu et al., 2011; Mania et al., 2017). In the ill-conditioned regime ($\kappa > n$), sparsity is required for a linear speedup, with a bound on τ of $\mathcal{O}(\sqrt{n})$ in the best-case (though degenerate) scenario where $\Delta = 1/n$.

The proof for Corollary 9 can be found in Appendix B.9.

Comparison to related work.

- We give the first convergence analysis for an asynchronous parallel version of Saga (note that Reddi et al. (2015) only covers an epoch based version of Saga with random stopping times, a fairly different algorithm).
- Theorem 8 can be directly extended to the a parallel extension of the Svrg version from Hofmann et al. (2015) which is adaptive to the local strong convexity with similar rates (see Section 4.2).
- In contrast to the parallel Svrg analysis from Reddi et al. (2015, Thm. 2), our proof technique handles inconsistent reads and a non-uniform processing speed across f_i's. Our bounds are similar (noting that Δ is equivalent to theirs), except for the adaptivity to local strong convexity: Asaga does not need to know κ for optimal performance, contrary to parallel Svrg (see Section 4 for more details).
- In contrast to the Svrg analysis from Mania et al. (2017, Thm. 14), we obtain a better dependence on the condition number in our rate ($1/\kappa$ vs. $1/\kappa^2$ on their work) and on the sparsity (they obtain $\tau \leq \mathcal{O}(\Delta^{-1/3})$), while we furthermore remove their gradient bound assumption. We also give our convergence guarantee on $\hat{x}_t$ *during* the algorithm, whereas they only bound the error for the "last" iterate x_T.

12. Asaga can actually converge for any τ, but the maximum step size then has a term of $\exp(\tau/n)$ in the denominator with much worse constants. See Appendix B.7.

3.3.2. Proof Outline of Theorem 8

We give here an extended outline of the proof. We detail key lemmas in Section 3.3.3.

Initial recursive inequality. Let $g_t := g(\hat{x}_t, \hat{\alpha}^t, i_t)$. By expanding the update equation (10) defining the virtual iterate x_{t+1} and introducing $\hat{x}_t$ in the inner product term, we obtain:

$$\begin{aligned}\|x_{t+1} - x^*\|^2 &= \|x_t - \gamma g_t - x^*\|^2 \\ &= \|x_t - x^*\|^2 + \gamma^2\|g_t\|^2 - 2\gamma\langle x_t - x^*, g_t\rangle \\ &= \|x_t - x^*\|^2 + \gamma^2\|g_t\|^2 - 2\gamma\langle \hat{x}_t - x^*, g_t\rangle + 2\gamma\langle \hat{x}_t - x_t, g_t\rangle\,. \end{aligned} \tag{13}$$

Note that we introduce $\hat{x}_t$ in the inner product because g_t is a function of $\hat{x}_t$, not x_t.

In the sequential setting, we require i_t to be independent of x_t to obtain unbiasedness. In the perturbed iterate framework, we instead require that i_t is independent of $\hat{x}_t$ (see Property 3). This crucial property enables us to use the unbiasedness condition (4) to write: $\mathbb{E}\langle \hat{x}_t - x^*, g_t\rangle = \mathbb{E}\langle \hat{x}_t - x^*, f'(\hat{x}_t)\rangle$. Taking the expectation of (13) and using this unbiasedness condition we obtain an expression that allows us to use the μ-strong convexity of f:[13]

$$\langle \hat{x}_t - x^*, f'(\hat{x}_t)\rangle \geq f(\hat{x}_t) - f(x^*) + \frac{\mu}{2}\|\hat{x}_t - x^*\|^2. \tag{14}$$

With further manipulations on the expectation of (13), including the use of the standard inequality $\|a+b\|^2 \leq 2\|a\|^2 + 2\|b\|^2$ (see Appendix B.1), we obtain our basic recursive contraction inequality:

$$a_{t+1} \leq (1 - \frac{\gamma\mu}{2})a_t + \gamma^2\mathbb{E}\|g_t\|^2 \underbrace{+\gamma\mu\mathbb{E}\|\hat{x}_t - x_t\|^2 + 2\gamma\mathbb{E}\langle \hat{x}_t - x_t, g_t\rangle}_{\text{additional asynchrony terms}} - 2\gamma e_t\,, \tag{15}$$

where $a_t := \mathbb{E}\|x_t - x^*\|^2$ and $e_t := \mathbb{E}f(\hat{x}_t) - f(x^*)$.

Inequality (15) is a midway point between the one derived in the proof of Lemma 1 in Hofmann et al. (2015) and Equation (2.5) in Mania et al. (2017), because we use the tighter strong convexity bound (14) than in the latter (giving us the important extra term $-2\gamma e_t$).

In the sequential setting, one crucially uses the negative suboptimality term $-2\gamma e_t$ to cancel the variance term $\gamma^2\mathbb{E}\|g_t\|^2$ (thus deriving a condition on γ). In our setting, we need

13. Note that here is our departure point with Mania et al. (2017) who replaced the $f(\hat{x}_t) - f(x^*)$ term with the lower bound $\frac{\mu}{2}\|\hat{x}_t - x^*\|^2$ in this relationship (see their Equation (2.4)), thus yielding an inequality too loose afterwards to get the fast rates for Svrg.

to bound the additional asynchrony terms using the same negative suboptimality in order to prove convergence and speedup for our parallel algorithm – this will give stronger constraints on the maximum step size.

The rest of the proof then proceeds as follows:

1. By using the expansion (11) for $\hat{x}_t - x_t$, we can bound the additional asynchrony terms in (15) in terms of the past updates $(\mathbb{E}\|g_u\|^2)_{u\leq t}$. This gives Lemma 10 below.
2. We then bound the updates $\mathbb{E}\|g_t\|^2$ in terms of past suboptimalities $(e_v)_{v\leq u}$ by using standard Saga inequalities and carefully analyzing the update rule for α_i^+ (7) in expectation. This gives Lemma 13 below.
3. By applying Lemma 13 to the result of Lemma 10, we obtain a master contraction inequality (27) in terms of a_{t+1}, a_t and $(e_u)_{u\leq t}$.
4. We define a novel Lyapunov function $\mathcal{L}_t = \sum_{u=0}^{t}(1-\rho)^{t-u}a_u$ and manipulate the master inequality to show that $\mathcal{L}_t$ is bounded by a contraction, subject to a maximum step size condition on γ (given in Lemma 14 below).
5. Finally, we unroll the Lyapunov inequality to get the convergence Theorem 8.

3.3.3. Details

We list the key lemmas below with their proof sketch, and pointers to the relevant parts of Appendix B for detailed proofs.

Lemma 10 (Inequality in terms of $g_t := g(\hat{x}_t, \hat{\alpha}^t, i_t)$) *For all $t \geq 0$:*

$$a_{t+1} \leq (1 - \frac{\gamma\mu}{2})a_t + \gamma^2 C_1 \mathbb{E}\|g_t\|^2 + \gamma^2 C_2 \sum_{u=(t-\tau)_+}^{t-1} \mathbb{E}\|g_u\|^2 - 2\gamma e_t\,, \tag{16}$$

$$\textit{where} \quad C_1 := 1 + \sqrt{\Delta}\tau \quad \textit{and} \quad C_2 := \sqrt{\Delta} + \gamma\mu C_1\,. \quad {}^{14} \tag{17}$$

To prove this lemma we need to bound both $\mathbb{E}\|\hat{x}_t - x^*\|^2$ and $\mathbb{E}\langle \hat{x}_t - x_t, g_t\rangle$ with respect to $(\mathbb{E}\|g_u\|^2)_{u\leq t}$. We achieve this by crucially using Equation (11), together with the following proposition, which we derive by a combination of Cauchy-Schwartz and our sparsity definition (see Section B.2).

Proposition 11 *For any $u \neq t$,*

$$\mathbb{E}|\langle g_u, g_t\rangle| \leq \frac{\sqrt{\Delta}}{2}(\mathbb{E}\|g_u\|^2 + \mathbb{E}\|g_t\|^2)\,. \tag{18}$$

To derive this essential inequality for both the right-hand-side terms of Eq. (18), we start by proving a relevant property of Δ. We reuse the sparsity constant introduced in Reddi et al. (2015) and relate it to the one we have defined earlier, Δ_r:

14. Note that C_2 depends on γ. In the rest of the paper, we write $C_2(\gamma)$ instead of C_2 when we want to draw attention to that dependency.

Remark 12 *Let D be the smallest constant such that:*

$$\mathbf{E}\|x\|_i^2 = \frac{1}{n}\sum_{i=1}^{n}\|x\|_i^2 \leq D\|x\|^2 \quad \forall x \in \mathbb{R}^d, \tag{19}$$

where $\|.\|_i$ is defined to be the ℓ_2-norm restricted to the support S_i of f_i. We have:

$$D = \frac{\Delta_r}{n} = \Delta\,. \tag{20}$$

Proof We have:

$$\mathbf{E}\|x\|_i^2 = \frac{1}{n}\sum_{i=1}^{n}\|x\|_i^2 = \frac{1}{n}\sum_{i=1}^{n}\sum_{v\in S_i}[x]_v^2 = \frac{1}{n}\sum_{v=1}^{d}\sum_{i|v\in S_i}[x]_v^2 = \frac{1}{n}\sum_{v=1}^{d}\delta_v[x]_v^2\,, \tag{21}$$

where $\delta_v := |(i \mid v \in S_i)|$. This implies:

$$D \geq \frac{1}{n}\sum_{v=1}^{d}\delta_v\frac{[x]_v^2}{\|x\|^2}\,. \tag{22}$$

Since D is the minimum constant satisfying this inequality, we have:

$$D = \max_{x\in\mathbb{R}^d}\frac{1}{n}\sum_{v=1}^{d}\delta_v\frac{[x]_v^2}{\|x\|^2}\,. \tag{23}$$

We need to find x such that it maximizes the right-hand side term. Note that the vector $([x]_v^2/\|x\|^2)_{v=1..d}$ is in the unit probability simplex, which means that an equivalent problem is the maximization over all convex combinations of $(\delta_v)_{v=1..d}$. This maximum is found by putting all the weight on the maximum δ_v, which is Δ_r by definition.

This implies that $\Delta = \Delta_r/n$ is indeed the smallest constant satisfying (19). ■

Proof of Proposition 11 Let $u \neq t$. Without loss of generality, $u < t$.[15] Then:

$$\begin{aligned}
\mathbb{E}|\langle g_u, g_t\rangle| &\leq \mathbb{E}\|g_u\|_{i_t}\|g_t\| && \text{(Sparse inner product; support of } g_t \text{ is } S_{i_t})\\
&\leq \sqrt{\mathbb{E}\|g_u\|_{i_t}^2}\sqrt{\mathbb{E}\|g_t\|^2} && \text{(Cauchy-Schwarz for expectations)}\\
&\leq \sqrt{\Delta\mathbb{E}\|g_u\|^2}\sqrt{\mathbb{E}\|g_t\|^2} && \text{(Remark 12 and } i_t \perp\!\!\!\perp g_u, \forall u < t)\\
&\leq \frac{\sqrt{\Delta}}{2}(\mathbb{E}\|g_u\|^2 + \mathbb{E}\|g_t\|^2)\,. && \text{(AM-GM inequality)}
\end{aligned}$$

All told, we have:

$$\mathbb{E}|\langle g_u, g_t\rangle| \leq \frac{\sqrt{\Delta}}{2}(\mathbb{E}\|g_u\|^2 + \mathbb{E}\|g_t\|^2)\,. \tag{24}$$

15. One only has to switch u and t if $u > t$.

Lemma 13 (Suboptimality bound on $\mathbb{E}\|g_t\|^2$) *For all $t \geq 0$,*

$$\mathbb{E}\|g_t\|^2 \leq 4Le_t + \frac{4L}{n}\sum_{u=1}^{t-1}(1-\frac{1}{n})^{(t-2\tau-u-1)_+}e_u + 4L(1-\frac{1}{n})^{(t-\tau)_+}\tilde{e}_0\,, \tag{25}$$

where $\tilde{e}_0 := \frac{1}{2L}\mathbb{E}\|\alpha_i^0 - f_i'(x^*)\|^2$.[16]

From our proof of convergence for Sparse Saga we know that (see Appendix A):

$$\mathbb{E}\|g_t\|^2 \leq 2\mathbb{E}\|f_{i_t}'(\hat{x}_t) - f_{i_t}'(x^*)\|^2 + 2\mathbb{E}\|\hat{\alpha}_{i_t}^t - f_{i_t}'(x^*)\|^2. \tag{26}$$

We can handle the first term by taking the expectation over a Lipschitz inequality (Hofmann et al. (2015, Equations 7 and 8). All that remains to prove the lemma is to express the $\mathbb{E}\|\hat{\alpha}_{i_t}^t - f_{i_t}'(x^*)\|^2$ term in terms of past suboptimalities. We note that it can be seen as an expectation of past first terms with an adequate probability distribution which we derive and bound.

From our algorithm, we know that each dimension of the memory vector $[\hat{\alpha}_i]_v$ contains a partial gradient computed at some point in the past $[f_i'(\hat{x}_{u_{i,v}^t})]_v$[17] (unless $u = 0$, in which case we replace the partial gradient with α_i^0). We then derive bounds on $P(u_{i,v}^t = u)$ and sum on all possible u. Together with clever conditioning, we obtain Lemma 13 (see Section B.3).

Master inequality. Let H_t be defined as $H_t := \sum_{u=1}^{t-1}(1-\frac{1}{n})^{(t-2\tau-u-1)_+}e_u$. Then, by setting (25) into Lemma 10, we get (see Section B.5):

$$\begin{aligned} a_{t+1} \leq & (1-\frac{\gamma\mu}{2})a_t - 2\gamma e_t + 4L\gamma^2 C_1\big(e_t + (1-\frac{1}{n})^{(t-\tau)_+}\tilde{e}_0\big) + \frac{4L\gamma^2 C_1}{n}H_t \\ & + 4L\gamma^2 C_2 \sum_{u=(t-\tau)_+}^{t-1}\big(e_u + (1-\frac{1}{n})^{(u-\tau)_+}\tilde{e}_0\big) + \frac{4L\gamma^2 C_2}{n}\sum_{u=(t-\tau)_+}^{t-1} H_u\,. \end{aligned} \tag{27}$$

Lyapunov function and associated recursive inequality. We now have the beginning of a contraction with additional positive terms which all converge to 0 as we near the optimum, as well as our classical negative suboptimality term. This is not unusual in the variance reduction literature. One successful approach in the sequential case is then to define a Lyapunov function which encompasses all terms and is a true contraction (see Defazio et al., 2014; Hofmann et al., 2015). We emulate this solution here. However, while all terms in the sequential case only depend on the current iterate, t, in the parallel case we have terms "from the past" in our inequality. To resolve this issue, we define a more involved Lyapunov function which also encompasses past iterates:

$$\mathcal{L}_t = \sum_{u=0}^{t}(1-\rho)^{t-u}a_u, \quad 0 < \rho < 1, \tag{28}$$

where ρ is a target contraction rate that we define later.

16. We introduce this quantity instead of e_0 so as to be able to handle the arbitrary initialization of the α_i^0.
17. More precisely: $\forall t, i, v\ \exists u_{i,v}^t < t$ s.t. $[\hat{\alpha}_i^t]_v = [f_i'(\hat{x}_{u_{i,v}^t})]_v$.

Using the master inequality (27), we get (see Appendix B.6):

$$\begin{aligned} \mathcal{L}_{t+1} &= (1-\rho)^{t+1}a_0 + \sum_{u=0}^{t}(1-\rho)^{t-u}a_{u+1} \\ &\leq (1-\rho)^{t+1}a_0 + (1-\frac{\gamma\mu}{2})\mathcal{L}_t + \sum_{u=1}^{t} r_u^t e_u + r_0^t\tilde{e}_0\,. \end{aligned} \tag{29}$$

The aim is to prove that $\mathcal{L}_t$ is bounded by a contraction. We have two promising terms at the beginning of the inequality, and then we need to handle the last term. Basically, we can rearrange the sums in (27) to expose a simple sum of e_u multiplied by factors r_u^t.

Under specific conditions on ρ and γ, we can prove that r_u^t is negative for all $u \geq 1$, which coupled with the fact that each e_u is positive means that we can safely drop the sum term from the inequality. The r_0^t term is a bit trickier and is handled separately.

In order to obtain a bound on e_t directly rather than on $\mathbb{E}\|\hat{x}_t - x^*\|^2$, we then introduce an additional γe_t term on both sides of (29). The bound on γ under which the modified $r_t^t + \gamma$ is negative is then twice as small (we could have used any multiplier between 0 and 2γ, but chose γ for simplicity's sake). This condition is given in the following Lemma.

Lemma 14 (Sufficient condition for convergence) *Suppose $\tau < n/10$ and $\rho \leq 1/4n$. If*

$$\gamma \leq \gamma^* = \frac{1}{32L(1+\sqrt{\Delta}\tau)\sqrt{1+\frac{1}{8\kappa}\min(\tau, \frac{1}{\sqrt{\Delta}})}} \tag{30}$$

then for all $u \geq 1$, the coefficients r_u^t from (29) are negative. Furthermore, we have $r_t^t + \gamma \leq 0$ and thus:

$$\gamma e_t + \mathcal{L}_{t+1} \leq (1-\rho)^{t+1}a_0 + (1-\frac{\gamma\mu}{2})\mathcal{L}_t + r_0^t\tilde{e}_0\,. \tag{31}$$

We obtain this result after carefully deriving the r_u^t terms. We find a second-order polynomial inequality in γ, which we simplify down to (30) (see Appendix B.7).

We can then finish the argument to bound the suboptimality error e_t. We have:

$$\mathcal{L}_{t+1} \leq \gamma e_t + \mathcal{L}_{t+1} \leq (1-\frac{\gamma\mu}{2})\mathcal{L}_t + (1-\rho)^{t+1}(a_0 + A\tilde{e}_0)\,. \tag{32}$$

We have two linearly contracting terms. The sum contracts linearly with the worst rate between the two (the smallest geometric rate factor). If we define $\rho^* := \nu\min(\rho, \gamma\mu/2)$, with $0 < \nu < 1$,[18] then we get:

$$\gamma e_t + \mathcal{L}_{t+1} \leq (1-\frac{\gamma\mu}{2})^{t+1}\mathcal{L}_0 + (1-\rho^*)^{t+1}\frac{a_0 + A\tilde{e}_0}{1-\eta} \tag{33}$$

$$\gamma e_t \leq (1-\rho^*)^{t+1}\big(\mathcal{L}_0 + \frac{1}{1-\eta}(a_0 + A\tilde{e}_0)\big)\,, \tag{34}$$

where $\eta := \frac{1-M}{1-\rho^*}$ with $M := \max(\rho, \gamma\mu/2)$. Our geometric rate factor is thus ρ^* (see Appendix B.8).

18. ν is introduced to circumvent the problematic case where ρ and $\gamma\mu/2$ are too close together.

4. Asynchronous Parallel SVRG with the "After Read" Labeling

ASAGA *vs. asynchronous* SVRG. There are several scenarios in which ASAGA can be practically advantageous over its closely related cousin, asynchronous SVRG (note though that "asynchronous" SVRG still requires one synchronization step per epoch to compute a full gradient).

First, while SAGA trades memory for less computation, in the case of generalized linear models the memory cost can be reduced to $\mathcal{O}(n)$, compared to $\mathcal{O}(d)$ for SVRG (Johnson and Zhang, 2013). This is of course also true for their asynchronous counterparts.

Second, as ASAGA does not require any synchronization steps, it is better suited to heterogeneous computing environments (where cores have different clock speeds or are shared with other applications).

Finally, ASAGA does not require knowing the condition number κ for optimal convergence in the sparse regime. It is thus adaptive to local strong convexity, whereas SVRG is not. Indeed, SVRG and its asynchronous variant require setting an additional hyper-parameter – the epoch size m – which needs to be at least $\Omega(\kappa)$ for convergence but yields a slower effective convergence rate than ASAGA if it is set much bigger than κ. SVRG thus requires tuning this additional hyper-parameter or running the risk of either slower convergence (if the epoch size chosen is much bigger than the condition number) or even not converging at all (if m is chosen to be much smaller than κ).[19]

***Motivation for analyzing asynchronous* SVRG.** Despite the advantages that we have just listed, in the case of complex models, the storage cost of SAGA may become too expensive for practical use. SVRG (Johnson and Zhang, 2013) trades off more computation for less storage and does not suffer from this drawback. It can thus be applied to cases where SAGA cannot (e.g. deep learning models, see Reddi et al., 2016).

Another advantage of KROMAGNON is that the historical gradient term $f'(\tilde{x})$ is fixed during an epoch, while its ASAGA equivalent, $\bar{\alpha}$, has to be updated at each iteration, either by recomputing if from the $\hat{\alpha}$ – which is costly – or by updating a maintained quantity – which is cheaper but may ultimately result in introducing some bias in the update (see Appendix F.3 for more details on this subtle issue).

It is thus worthwhile to carry out the analysis of KROMAGNON (Mania et al., 2017)[20], the asynchronous parallel version of SVRG, although it has to be noted that since SVRG requires regularly computing batch gradients, KROMAGNON will present regular synchronization steps as well as coordinated computation – making it less attractive for the asynchronous parallel setting.

We first extend our ASAGA analysis to analyze the convergence of a variant of SVRG presented in Hofmann et al. (2015), obtaining exactly the same bounds. This variant improves upon the initial algorithm because it does not require tuning the epoch size hyperparameter and is thus adaptive to local strong convexity (see Section 4.1). Furthermore, it allows for a cleaner analysis where – contrary to SVRG – we do not have to replace the final parameters of an epoch by one of its random iterates.

Then, using our "after read" labeling, we are also able to derive a convergence and speedup proof for KROMAGNON, with comparable results to our ASAGA analysis. In particular, we prove that as for ASAGA in the "well-conditioned" regime KROMAGNON can achieve a linear speedup even without sparsity assumptions.

4.1. SVRG Algorithms

We start by describing the original SVRG algorithm, the variant given in Hofmann et al. (2015) and the sparse asynchronous parallel adaptation, KROMAGNON.

Original* SVRG *algorithm. The standard SVRG algorithm (Johnson and Zhang, 2013) is very similar to SAGA. The main difference is that instead of maintaining a table of historical gradients, SVRG uses a "reference" batch gradient $f'(\tilde{x})$, updated at regular intervals (typically every m iterations, where m is a hyper-parameter). SVRG is thus an epoch-based algorithm, where at the beginning of every epoch a reference iterate $\tilde{x}$ is chosen and its gradient is computed. Then, at every iteration in the epoch, the algorithm samples uniformly at random an index $i \in \{1, \dots, n\}$, and then executes the following update on x:

$$x^+ = x - \gamma\big(f_i'(x) - f_i'(\tilde{x}) + f'(\tilde{x})\big)\,. \tag{35}$$

As for SAGA the update direction is unbiased ($\mathbf{E}x^+ = x - \gamma f'(x)$) and it can be proven (see Johnson and Zhang, 2013) that under a reasonable condition on γ and m (the epoch size), the update has vanishing variance, which enables the algorithm to converge linearly with a constant step size.

Hofmann's* SVRG *variant. Hofmann et al. (2015) introduce a variant where the size of the epoch is a random variable. At each iteration t, a first Bernoulli random variable B_t with $p = 1/n$ is sampled. If $B_t = 1$, then the algorithm updates the reference iterate, $\tilde{x} = x_t$ and computes its full gradient as its new "reference gradient". If $B_t = 0$, the algorithm executes the normal SVRG inner update. Note that this variant is adaptive to local strong convexity, as it does not require the inner loop epoch size $m = \Omega(\kappa)$ as a hyperparameter. In that respect it is closer to SAGA than the original SVRG algorithm which is not adaptive.

KROMAGNON. KROMAGNON, introduced in Mania et al. (2017) is obtained by using the same sparse update technique as Sparse SAGA, and then running the resulting algorithm in parallel (see Algorithm 3).

4.2. Extension to the SVRG Variant from Hofmann et al. (2015)

We introduce AHSVRG – a sparse asynchronous parallel version for the SVRG variant from Hofmann et al. (2015) – in Algorithm 4. Every core runs stochastic updates independently as long as they are all sampling inner updates, and coordinate whenever one of them decides to do a batch gradient computation. The one difficulty of this approach is that each core needs to be able to communicate to every other core that they should stop doing inner updates and start computing a synchronized batch gradient instead.

To this end, we introduce a new shared variable, s, which represents the "state" of the computation. This variable is checked by each core c before each update. If $s = 1$, then

19. Note that as SAGA (and contrary to the original SVRG) the SVRG variant from Hofmann et al. (2015) does not require knowledge of κ and is thus adaptive to local strong convexity, which carries over to its asynchronous adaptation that we analyze in Section 4.2.

20. The speedup analysis presented in Mania et al. (2017) is not fully satisfactory as it does not achieve state-of-the-art convergence results for either SVRG or KROMAGNON. Furthermore, we are able to remove their uniform gradient bound assumption, which is inconsistent with strong convexity.

Algorithm 3 Kromagnon (Mania et al., 2017)

Initialize shared x and x_0
while True **do**
  Compute in parallel $g = f'(x_0)$ (synchronously)
  for $i = 1..m$ **do in parallel (asynchronously)**
    Sample i uniformly in $\{1, ..., n\}$
    Let S_i be f_i's support
    $[\hat{x}]_{S_i}$ = inconsistent read of x on S_i
    $[\delta x]_{S_i} = -\gamma([f_i'(\hat{x}_t) - f_i'(x_0)]_{S_i} + D_i[g]_{S_i})$
    for v **in** S_i **do**
      $[x]_v = [x]_v + [\delta x]_v$ // atomic
    end for
  end parallel loop
  $x_0 = x$
end while

Algorithm 4 Ahsvrg

Initialize shared x, s and x_0
while True **do**
  Compute in parallel $g = f'(x_0)$ (synchronously)
  $s = 0$
  while $s = 0$ **do in parallel (asynchronously)**
    Sample B with $p = 1/n$
    if $B = 1$ **then**
      $s = 1$
    else
      Sample i uniformly in $\{1, ..., n\}$
      Let S_i be f_i's support
      $[\hat{x}]_{S_i}$ = inconsistent read of x on S_i
      $[\delta x]_{S_i} = -\gamma([f_i'(\hat{x}_t) - f_i'(x_0)]_{S_i} + D_i[g]_{S_i})$
      for v **in** S_i **do**
        $[x]_v = [x]_v + [\delta x]_v$ // atomic
      end for
    end if
  end parallel loop
  $x_0 = x$
end while

another core has called for a batch gradient computation and core c starts computing its allocated part of this computation. If $s = 0$, core c proceeds to sample a first random variable. Then it either samples and performs an inner update and keeps going, or it samples a full gradient computation, in which case it updates s to 1 and starts computing its allocated

part of the computation. Once a full gradient is computed, s is set to 0 once again and every core resume their loop.

Our Asaga convergence and speedup proofs can easily be adapted to accommodate Ahsvrg since it is closer to Saga than the initial Svrg algorithm. To prove convergence, all one has to do is to modify Lemma 13 very slightly (the only difference is that the $(t - 2\tau - u - 1)_+$ exponent is replaced by $(t - \tau - u - 1)_+$ and the rest of the proof can be used as is). The justification for this small tweak is that the batch steps in Svrg are fully synchronized. More details can be found in Appendix B.4.

4.3. Fast Convergence and Speedup Rates for Kromagnon

We now state our main theoretical results. We give a detailed outline of the proof in Section 4.4 and its full details in Appendix C.

Theorem 15 (Convergence guarantee and rate of Kromagnon) *Suppose the step size γ and epoch size m are chosen such that the following condition holds:*

$$0 < \theta := \frac{\frac{1}{\mu\gamma m} + 2L(1 + 2\sqrt{\Delta}\tau)(\gamma + \tau\mu\gamma^2)}{1 - 2L(1 + 2\sqrt{\Delta}\tau)(\gamma + \tau\mu\gamma^2)} < 1\,. \tag{36}$$

Then the inconsistent read iterates of Kromagnon *converge in expectation at a geometric rate, i.e.*

$$\mathbb{E} f(\tilde{x}_k) - f(x^*) \leq \theta^t (f(x_0) - f(x^*))\,, \tag{37}$$

where $\tilde{x}_k$ is the initial iterate for epoch k, which is obtained by choosing uniformly at random among the inconsistent read iterates from the previous epoch.

This result is similar to the theorem given in the original Svrg paper (Johnson and Zhang, 2013). Indeed, if we remove the asynchronous part (i.e. if we set $\tau = 0$), we get exactly the same rate and condition. It also has the same form as the one given in Reddi et al. (2015), which was derived for dense asynchronous Svrg in the easier setting of consistent read and writes (and in the flawed "after write" framework), and gives essentially the same conditions on γ and m.

In the canonical example presented in most Svrg papers, with $\kappa = n$, $m = \mathcal{O}(n)$ and $\gamma = 1/10L$, Svrg obtains a convergence rate of 0.5. Reddi et al. (2015) get the same rate by setting $\gamma = 1/20\max(1,\sqrt{\Delta}\tau)L$ and $m = \mathcal{O}\big(n(1 + \sqrt{\Delta}\tau)\big)$. Following the same line of reasoning (setting $\gamma = 1/20\max(1,\sqrt{\Delta}\tau)L$, $\tau = \mathcal{O}(n)$ and $\theta = 0.5$ and computing the resulting condition on m), these values for γ and m also give us a convergence rate of 0.5. Therefore, as in Reddi et al. (2015), when $\kappa = n$ we get a linear speedup for $\tau < 1/\sqrt{\Delta}$ (which can be as big as $\sqrt{n}$ in the degenerate case where no data points share any feature with each other). Note that this is the same speedup condition as Asaga in this regime.

Svrg theorems are usually similar to Theorem 15, which does not give an optimal step size or epoch size. This makes the analysis of a parallel speedup difficult, prompting authors to compare rates in specific cases with most parameters fixed, as we have just done. In order to investigate the speedup and step size conditions more precisely and thus derive a more general theorem, we now give Svrg and Kromagnon results modeled on Theorem 8.

Corollary 16 (Convergence guarantee and rate for serial SVRG) *Let $\gamma = \frac{a}{4L}$ for any $a \leq \frac{1}{4}$ and $m = \frac{32\kappa}{a}$. Then* SVRG *converges geometrically in expectation with a rate factor per gradient computation of at least $\rho(a) = \frac{1}{4}\min\left\{\frac{1}{n}, \frac{a}{64\kappa}\right\}$, i.e.*

$$\mathbb{E}f(\tilde{x}_k) - f(x^*) \leq (1-\rho)^{k(2m+n)}\left(f(x_0) - f(x^*)\right) \qquad \forall k \geq 0\,. \tag{38}$$

Due to SVRG's special structure, we cannot write $\mathbb{E}f(x_t) - f(x^*) \leq (1-\rho)^t\left(f(x_0) - f(x^*)\right)$ for all $t \geq 0$. However, expressing the convergence properties of this algorithm in terms of a rate factor per gradient computation (of which there are $2m+n$ per epoch) makes it easier to compare convergence rates, either to similar algorithms such as SAGA or to its parallel variant KROMAGNON – and thus to study the speedup obtained by parallelizing SVRG.

Compared to SAGA, this result is very close. The main difference is that the additional hyper-parameter m has to be set and requires knowledge of μ. This illustrates the fact that SVRG is not adaptive to local strong convexity, whereas both SAGA and Hofmann's SVRG are.

Corollary 17 (Simplified convergence guarantee and rate for KROMAGNON) *Let*

$$a^*(\tau) = \frac{1}{4(1+2\sqrt{\Delta}\tau)(1+\frac{\tau}{16\kappa})}\,. \tag{39}$$

For any step size $\gamma = \frac{a}{4L}$ with $a \leq a^*(\tau)$ and $m = \frac{32\kappa}{a}$, KROMAGNON *converges geometrically in expectation with a rate factor per gradient computation of at least $\rho(a) = \frac{1}{4}\min\left\{\frac{1}{n}, \frac{a}{64\kappa}\right\}$, i.e.*

$$\mathbb{E}f(\tilde{x}_k) - f(x^*) \leq (1-\rho)^{k(2m+n)}\left(f(x_0) - f(x^*)\right) \qquad \forall k \geq 0\,. \tag{40}$$

This result is again quite close to Corollary 16 derived in the serial case. We see that the maximum step size is divided by an additional $(1+2\tau\sqrt{\Delta})$ term, while the convergence rate is the same. Comparing the rates and the maximum allowable step sizes in both settings give us the sufficient condition on τ to get a linear speedup.

Corollary 18 (Speedup condition) *Suppose $\tau \leq \mathcal{O}(n)$ and $\tau \leq \mathcal{O}(\frac{1}{\sqrt{\Delta}}\max\{1, \frac{n}{\kappa}\})$. If $n \geq \kappa$, also suppose $\tau \leq \sqrt{n\Delta^{-1/2}}$. Then using the step size $\gamma = a^*(\tau)/L$ from (39),* KROMAGNON *converges geometrically with rate factor $\Omega(\min\{\frac{1}{n}, \frac{1}{\kappa}\})$ (similar to* SVRG*), and is thus linearly faster than its sequential counterpart up to a constant factor.*

This result is almost the same as ASAGA, with the additional condition that $\tau \leq \mathcal{O}(\sqrt{n})$ in the well-conditioned regime. We see that in this regime KROMAGNON can also get the same rate as SVRG even without sparsity, which had not been observed in previous work.

Furthermore, one has to note that τ is generally smaller for KROMAGNON than for ASAGA since it is reset to 0 at the beginning of each new epoch (where all cores are synchronized once more).

Comparison to related work.

- Corollary 16 provides a rate of convergence *per gradient computation* for SVRG, contrary to most of the literature on this algorithm (including the seminal paper Johnson and Zhang, 2013). This result allows for easy comparison with SAGA and other algorithms (in contrast, Konečný and Richtárik 2013 is more involved).
- In contrast to the SVRG analysis from Reddi et al. (2015, Thm. 2), our proof technique handles inconsistent reads and a non-uniform processing speed across f_i's. While Theorem 15 is similar to theirs, Corollary 16 and 17 are more precise results. They enable a finer analysis of the speedup conditions (Corollary 18) – including the possible speedup without sparsity regime.
- In contrast to the KROMAGNON analysis from Mania et al. (2017, Thm. 14), Theorem 15 gives a better dependence on the condition number in the rate ($1/\kappa$ vs. $1/\kappa^2$ for them) and on the sparsity (they get $\tau \leq \mathcal{O}(\Delta^{-1/3})$), while we remove their gradient bound assumption. Our results are state-of-the-art for SVRG (contrary to theirs) and so our speedup comparison is more meaningful. Finally, Theorem 15 gives convergence guarantees on $\hat{x}_t$ *during* the algorithm, whereas they only bound the error for the "last" iterate x_T.

4.4. Proof of Theorem 15

We now give a detailed outline of the proof. Its full details can be found in Appendix C.

Our proof technique begins as our ASAGA analysis. In particular, Properties 3, 4, 5 are also verified for KROMAGNON[21], and as in our ASAGA analysis, we make Assumption 6 (bounded overlaps). Consequently, the basic recursive contraction inequality (15) and Lemma 10 also hold. However, when we derive the equivalent of Lemma 13, we get a slightly different form, which prompts a difference in the rest of the proof technique.

Lemma 19 (Suboptimality bound on $\mathbb{E}\|g_t\|^2$)

$$\mathbb{E}\|g_t\|^2 \leq 4Le_t + 4L\tilde{e}_k \qquad \forall k \geq 0, km \leq t \leq (k+1)m\,, \tag{41}$$

where $\tilde{e}_k := \mathbb{E}f(\tilde{x}_k) - f(x^*)$ and $\tilde{x}_k$ is the initial iterate for epoch k.

We give the proof in Appendix C.1. To derive both terms, we use the same technique as for the first term of Lemma 13. Although this is a much simpler result than Lemma 13 in the case of ASAGA, two key differences prevent us from reusing the same Lyapunov function proof technique. First, the e_0 term in Lemma 13 is replaced by $\tilde{e}_k$ which depends on the epoch number. Second, this term is not multiplied by a geometrically decreasing quantity, which means the $-2\gamma e_0$ term is not sufficient to cancel out all of the e_0 terms coming from subsequent inequalities. To solve this issue, we go to more traditional SVRG techniques.

The rest of the proof is as follows:

1. By substituting Lemma 19 into Lemma 10, we get a master contraction inequality (42) in terms of a_{t+1}, a_t and $e_u, u \leq t$.

21. Note that similarly to ASAGA, the KROMAGNON algorithm which we analyze reads the parameters first and then samples. This is necessary in order for Property 3 to be verified at $r = t$, although not practical when it comes to actual implementation.

2. As in Johnson and Zhang (2013), we sum the master contraction inequality over a whole epoch, and then use the same randomization trick (44) to relate $(e_t)_{km \leq t \leq (k+1)m-1}$ to $\tilde{e}_k$.

3. We thus obtain a contraction inequality between $\tilde{e}_k$ and $\tilde{e}_{k-1}$, which finishes the proof for Theorem 15.

4. We then only have to derive the conditions on γ, τ and m under which we contractions and compare convergence rates to finish the proofs for Corollary 16, Corollary 17 and Corollary 18.

We list the key points below with their proof sketch, and give the detailed proof in Appendix C.

Master inequality. As in our Asaga analysis, we apply (41) to the result of Lemma 10, which gives us that for all $k \geq 0, km \leq t \leq (k+1)m-1$ (see Appendix C.2):

$$a_{t+1} \leq (1 - \frac{\gamma\mu}{2})a_t + (4L\gamma^2 C_1 - 2\gamma)e_t + 4L\gamma^2 C_2 \sum_{u=\max(km, t-\tau)}^{t-1} e_u + (4L\gamma^2 C_1 + 4L\gamma^2\tau C_2)\tilde{e}_k \,. \tag{42}$$

Contraction inequality. As we previously mentioned, the term in $\tilde{e}_k$ is not multiplied by a geometrically decreasing factor, so using the same Lyapunov function as for Asaga cannot work. Instead, we apply the same method as in the original Svrg paper (Johnson and Zhang, 2013): we sum the master contraction inequality over a whole epoch. This gives us (see Appendix C.2):

$$a_{(k+1)m} \leq a_{km} + (4L\gamma^2 C_1 + 4L\gamma^2\tau C_2 - 2\gamma) \sum_{t=km}^{(k+1)m-1} e_t + m(4L\gamma^2 C_1 + 4L\gamma^2\tau C_2)\tilde{e}_k \,. \tag{43}$$

To cancel out the $\tilde{e}_k$ term, we only have one negative term on the right-hand side of (43): $-2\gamma \sum_{t=km}^{(k+1)m-1} e_t$. This means we need to relate $\sum_{t=km}^{(k+1)m-1} e_t$ to $\tilde{e}_k$. We can do it using the same randomization trick as in Johnson and Zhang (2013): instead of choosing the last iterate of the k^{th} epoch as $\tilde{x}_k$, we pick one of the iterates of the epoch uniformly at random. This means we get:

$$\tilde{e}_k = \mathbb{E} f(\tilde{x}_k) - f(x^*) = \frac{1}{m} \sum_{t=(k-1)m}^{km-1} e_t \tag{44}$$

We now have: $\sum_{t=km}^{(k+1)m-1} e_t = m\tilde{e}_{k+1}$. Combined with the fact that $a_{km} \leq \frac{2}{\mu}\tilde{e}_k$ and that we can remove the positive $a_{(k+1)m}$ term from the left-hand-side of (43), this gives us our final recursion inequality:

$$\big(2\gamma m - 4L\gamma^2 C_1 m - 4L\gamma^2\tau C_2 m\big)\tilde{e}_{k+1} \leq \big(\frac{2}{\mu} + 4L\gamma^2 C_1 m + 4L\gamma^2\tau C_2 m\big)\tilde{e}_k \tag{45}$$

Replacing C_1 and C_2 by their values (defined in 17) in (45) directly leads to Theorem 15.

Algorithm 5 Hogwild

```
Initialize shared variable x
keep doing in parallel
    x̂ = inconsistent read of x
    Sample i uniformly in {1, ..., n}
    Let S_i be f_i's support
    [δx]_{S_i} := −γ f_i'(x̂)
    for v in S_i do
        [x]_v ← [x]_v + [δx]_v        // atomic
    end for
end parallel loop
```

5. Hogwild Analysis

In order to show that our improved "after read" perturbed iterate framework can be used to revisit the analysis of other optimization routines with correct proofs that do not assume homogeneous computation, we now provide the analysis of the Hogwild algorithm (i.e. asynchronous parallel constant step size Sgd) first introduced in Niu et al. (2011).

We start by describing Hogwild in Algorithm 5, and then give our theoretical convergence and speedup results and their proofs. Note that our framework allows us to easily remove the classical bounded gradient assumption, which is used in one form or another in most of the literature (Niu et al., 2011; De Sa et al., 2015; Mania et al., 2017) – although it is inconsistent with strong convexity in the unconstrained regime. This allows for better bounds where the uniform bound on $\|f_i'(x)\|^2$ is replaced by its variance at the optimum.

5.1. Theoretical Results

We now state the theoretical results of our analysis of Hogwild with inconsistent reads and writes in the "after read framework". We give an outline of the proof in Section 5.2 and its full details in Appendix D. We start with a useful definition.

Definition 20 *Let $\sigma^2 = \mathbf{E}\|f_i'(x^*)\|^2$ be the variance of the gradient estimator at the optimum.*

For reference, we start by giving the rate of convergence of serial Sgd (see e.g. Schmidt, 2014).

Theorem 21 (Convergence guarantee and rate of Sgd) *Let $a \leq \frac{1}{2}$. Then for any step size $\gamma = \frac{a}{L}$, Sgd converges in expectation to b-accuracy at a geometric rate of at least: $\rho(a) = a/\kappa$, i.e., $\mathbb{E}\|x_t - x^*\|^2 \leq (1-\rho)^t \|x_0 - x^*\|^2 + b$, where $b = 2\frac{\gamma\sigma^2}{\mu}$.*

As Sgd only converges linearly up to a ball around the optimum, to make sure we reach ϵ-accuracy, it is necessary that $\frac{2\gamma\sigma^2}{\mu} \leq \epsilon$, i.e. $\gamma \leq \frac{\epsilon\mu}{2\sigma^2}$. All told, in order to get linear convergence to ϵ-accuracy, serial Sgd requires $\gamma \leq \min\big\{\frac{1}{2L}, \frac{\epsilon\mu}{2\sigma^2}\big\}$. The proof can be found in Appendix D.3.

Theorem 22 (Convergence guarantee and rate of HOGWILD) *Let*

$$a^*(\tau) := \frac{1}{5\left(1+2\tau\sqrt{\Delta}\right)\xi(\kappa,\Delta,\tau)} \quad \text{where } \xi(\kappa,\Delta,\tau) := \sqrt{1+\frac{1}{2\kappa}\min\{\frac{1}{\sqrt{\Delta}},\tau\}} \quad \text{(note that } \xi(\kappa,\Delta,\tau)\approx 1 \text{ unless } \kappa < 1/\sqrt{\Delta}\ (\leq\sqrt{n})\text{).} \tag{46}$$

For any step size $\gamma = \frac{a}{L}$ with $a \leq \min\left\{a^*(\tau), \frac{\kappa}{\tau}\right\}$, the inconsistent read iterates of Algorithm 5 converge in expectation to b-accuracy at a geometric rate of at least: $\rho(a) = a/\kappa$, i.e., $\mathbb{E}\|\hat{x}_t - x^*\|^2 \leq (1-\rho)^t(2\|x_0 - x^*\|^2) + b$, where $b = (\frac{8\gamma(C_1+\tau C_2)}{\mu} + 4\gamma^2 C_1\tau)\sigma^2$ and C_1 and $C_2(\gamma)$ are defined in (17).

Once again this result is quite close to the one obtained for serial SGD. Note that we recover this exact condition (up to a small constant factor) if we set $\tau = 0$, i.e. if we force our asynchronous algorithm to be serial.

The condition $a \leq \frac{\kappa}{\tau}$ is equivalent to $\gamma\mu\tau \leq 1$ and should be thought of as a condition on τ. We will see that it is always verified in the regime we are interested in, that is the linear speed-up regime (where more stringent conditions are imposed on τ).

We now investigate the conditions under which HOGWILD is linearly faster than SGD. Note that to derive these conditions we need not only compare their respective convergence rates, but also the size of the ball around the optimum to which both algorithms converge. These quantities are provided in Theorems 21 and 22.

Corollary 23 (Speedup condition) *Suppose $\tau = \mathcal{O}(\min\{\frac{1}{\sqrt{\Delta}},\kappa\})$. Then for any step size $\gamma \leq \frac{a^*(\tau)}{L} = \mathcal{O}(\frac{1}{L})$ (i.e., any allowable step size for* SGD*),* HOGWILD *converges geometrically to a ball of radius $r_h = \mathcal{O}(\frac{\gamma\sigma^2}{\mu})$ with rate factor $\rho = \frac{\gamma\mu}{2}$ (similar to* SGD*), and is thus linearly faster than its sequential counterpart up to a constant factor.*

Moreover, a universal step size of $\Theta(\frac{1}{L})$ can be used for HOGWILD *to be adaptive to local strong convexity with a similar rate to* SGD *(i.e., knowledge of κ is not required).*

If $\gamma = \mathcal{O}(1/L)$, HOGWILD obtains the same convergence rate as SGD and converges to a ball of equivalent radius. Since the maximum step size guaranteeing linear convergence for SGD is also $\mathcal{O}(1/L)$, HOGWILD is linearly faster than SGD for any reasonable step size – under the condition that $\tau = \mathcal{O}(\min\{\frac{1}{\sqrt{\Delta}},\kappa\})$. We also remark that since $\gamma \leq 1/L$ and $\tau \leq \kappa$, we have $\gamma\mu\tau \leq 1$, which means the condition $a \leq \frac{\kappa}{\tau}$ is superseded by $a \leq a^*(\tau)$ in Theorem 22.

We note that the condition on τ is much more restrictive if the condition number is small than for ASAGA and KROMAGNON. This can be explained by the fact that both SAGA and SVRG have a composite rate factor which is not directly proportional to the step size. As a result, in the well-conditioned setting these algorithms enjoy a range of step sizes that all give the same contraction rate. This allows their asynchronous variants to use smaller step sizes while maintaining linear speedups. SGD, on the other hand, has a rate factor that is directly proportional to its step size, hence the more restrictive condition on τ.

Function values results. Our results are derived directly on iterates, that is, we bound the distance between $\hat{x}_t$ and x^*. We can easily obtain results on function values to

bound $\mathbb{E}f(\hat{x}_t) - f(x^*)$ by adapting the classical smoothness inequality:[22] $\mathbb{E}f(x_t) - f(x^*) \leq \frac{L}{2}\mathbb{E}\|x_t - x^*\|^2$ to the asynchronous parallel setting.

Convergence to ϵ-accuracy. As noted in Mania et al. (2017), for our algorithm to converge to ϵ-accuracy for some $\epsilon > 0$, we require an additional bound on the step size to make sure that the radius of the ball to which we converge is small enough. For SGD, this means using a step size $\gamma = \mathcal{O}(\frac{\epsilon\mu}{\sigma^2})$ (see Appendix D.3). We can also prove that under the conditions that $\tau = \mathcal{O}(\frac{1}{\sqrt{\Delta}})$ and $\gamma\mu\tau \leq 1$, HOGWILD requires the same bound on the step size to converge to ϵ-accuracy (see Appendix D.4).

If ϵ is small enough, the active upper bound on the step size is $\gamma = \mathcal{O}(\frac{\epsilon\mu}{\sigma^2})$ for both algorithms. In this regime, we obtain a relaxed condition on τ for a linear speedup. The condition $\tau \leq \kappa$ which came from comparing maximum allowable step sizes is removed. Instead, we enforce $\gamma\mu\tau \leq 1$, which gives us the weaker condition $\tau = \mathcal{O}(\frac{\sigma^2}{\epsilon\mu^2})$. Our condition on the overlap is then: $\tau = \mathcal{O}(\min\{\frac{1}{\sqrt{\Delta}}, \frac{\sigma^2}{\epsilon\mu^2}\})$. We see that this is similar to the condition obtained by Mania et al. (2017, Theorem 4) in their HOGWILD analysis, although we have the variance at the optimum σ^2 instead of a squared global bound on the gradient.

Comparison to related work.

- We give the first convergence analysis for HOGWILD with no assumption on a global bound on the gradient (M). This allows us to replace the usual dependence in M^2 by a term in σ^2 which is potentially significantly smaller. This means improved upper bounds on the step size and the allowed overlap.
- We obtain the same condition on the step size for linear convergence to ϵ-accuracy of HOGWILD as previous analysis for serial SGD (e.g. Needell et al., 2014) – given $\tau \leq 1/\gamma\mu$.
- In contrast to the HOGWILD analysis from Niu et al. (2011); De Sa et al. (2015), our proof technique handles inconsistent reads and a non-uniform processing speed across f_i's. Further, Corollary 23 gives a better dependence on the sparsity than in Niu et al. (2011), where $\tau \leq \mathcal{O}(\Delta^{-1/4})$, and does not require various bounds on the gradient assumptions.
- In contrast to the HOGWILD analysis from Mania et al. (2017, Thm. 3), removing their gradient bound assumption enables us to get a (potentially) significantly better upper bound condition on τ for a linear speedup. We also give our convergence guarantee on $\hat{x}_t$ *during* the algorithm, whereas they only bound the error for the "last" iterate x_T.

5.2. Proof of Theorem 22 and Corollary 23

Here again, our proof technique begins as our ASAGA analysis, with Properties 3, 4, 5 also verified for HOGWILD[23]. As in our ASAGA analysis, we make Assumption 6. Consequently, the basic recursive contraction inequality (15) and Lemma 10 also hold. As for KROMAGNON, the proof diverges when we derive the equivalent of Lemma 13.

22. See e.g. Moulines and Bach (2011).
23. Once again, in our analysis the HOGWILD algorithms reads the parameters before sampling, so that Property 3 is verified for $r = t$.

Lemma 24 (Suboptimality bound on $\mathbb{E}\|g_t\|^2$) *For all $t \geq 0$,*

$$\mathbb{E}\|g_t\|^2 \leq 4Le_t + 2\sigma^2\,. \tag{47}$$

We give the proof in Appendix D.1. To derive both terms, we use the same technique as for the first term of Lemma 13. This result is simpler than both Lemma 13 (for Asaga) and Lemma 19 (for Kromagnon). The second term in this case does not even vanish as t grows. This reflects the fact that constant step size Sgd does not converge to the optimum but rather to a ball around it. However, this simpler form allows us to simply unroll the resulting master inequality to get our convergence result.

The rest of the proof is as follows:

1. By substituting Lemma 24 into Lemma 10, we get a master contraction inequality (48) in terms of a_{t+1}, a_t, $(e_u, u \leq t)$ and σ^2.

2. We then unroll this master inequality and cleverly regroup terms to obtain a contraction inequality (49) between a_t, a_0 and σ^2.

3. By using that $\|\hat{x}_t - x^*\|^2 \leq 2a_t + 2\|\hat{x}_t - x_t\|^2$, we obtain a contraction inequality directly on the "real" iterates (as opposed to the "virtual" iterates as in Mania et al., 2017), subject to a maximum step size condition on γ. This finishes the proof for Theorem 22.

4. Finally, we only have to derive the conditions on γ and τ under which Hogwild converges with a similar convergence rate to a ball with a similar radius than serial Sgd to finish the proof for Corollary 23.

We list the key points below with their proof sketch, and give the detailed proof in Appendix D.

Master inequality. As in our Asaga analysis, we plug (47) in Lemma 10, which gives us that (see Appendix D.2):

$$a_{t+1} \leq (1 - \frac{\gamma\mu}{2})a_t + (4L\gamma^2 C_1 - 2\gamma)e_t + 4L\gamma^2 C_2 \sum_{u=(t-\tau)_+}^{t-1} e_u + 2\gamma^2\sigma^2(C_1 + \tau C_2)\,. \tag{48}$$

Contraction inequality on x_t. As we previously mentioned, the term in σ^2 does not vanish so we cannot use either our Asaga or our Kromagnon proof technique. Instead, we unroll Equation (48) all the way to $t = 0$. This gives us (see Appendix D.2):

$$a_{t+1} \leq (1-\frac{\gamma\mu}{2})^{t+1}a_0 + (4L\gamma^2 C_1 + 8L\gamma^2\tau C_2 - 2\gamma)\sum_{u=0}^{t}(1-\frac{\gamma\mu}{2})^{t-u}e_u + \frac{4\gamma\sigma^2}{\mu}(C_1+\tau C_2)\,. \tag{49}$$

Contraction inequality on $\hat{x}_t$. We now use that $\|\hat{x}_t - x^*\|^2 \leq 2a_t + 2\|\hat{x}_t - x_t\|^2$ together with our previous bound (65). Together with (49), we get (see Appendix D.2):

$$\mathbb{E}\|\hat{x}_t - x^*\|^2 \leq (1 - \frac{\gamma\mu}{2})^{t+1}2a_0 + \Big(\frac{8\gamma(C_1+\tau C_2)}{\mu} + 4\gamma^2 C_1\tau\Big)\sigma^2 + (24L\gamma^2 C_1 + 16L\gamma^2\tau C_2 - 4\gamma)\sum_{u=0}^{t}(1-\frac{\gamma\mu}{2})^{t-u}e_u\,. \tag{50}$$

To get our final contraction inequality, we need to safely remove all the e_u terms, so we enforce $16L\gamma^2 C_1 + 16L\gamma^2\tau C_2 - 4\gamma \leq 0$. This leads directly to Theorem 22.

Convergence rate and ball-size comparison. To prove Corollary 23, we simply show that under the condition $\tau = \mathcal{O}(\min\{\frac{1}{\sqrt{\Delta}}, \kappa\})$, the biggest allowable step size for Hogwild to converge linearly is $\mathcal{O}(1/L)$, as is also the case for Sgd; and that the size of the ball to which both algorithms converge is of the same order. The proof is finished by remarking that for both algorithms, the rates of convergence are directly proportional to the step size.

6. Empirical Results

We now present the results of our experiments. We first compare our new sequential algorithm, Sparse Saga, to its existing alternative, Saga with lagged updates and to the original Saga algorithm as a baseline. We then move on to our main results, the empirical comparison of Asaga, Kromagnon and Hogwild. Finally, we present additional results, including convergence and speedup figures with respect to the number of iteration (i.e. "theoretical speedups") and measures on the τ constant.

6.1. Experimental Setup

Models. Although Asaga can be applied more broadly, we focus on logistic regression, a model of particular practical importance. The associated objective function takes the following form:

$$\frac{1}{n}\sum_{i=1}^{n}\log\left(1 + \exp(-b_i a_i^\intercal x)\right) + \frac{\mu}{2}\|x\|^2, \tag{51}$$

where $a_i \in \mathbb{R}^d$ and $b_i \in \{-1, +1\}$ are the data samples.

Data sets. We consider two sparse data sets: RCV1 (Lewis et al., 2004) and URL (Ma et al., 2009); and a dense one, Covtype (Collobert et al., 2002), with statistics listed in the table below. As in Le Roux et al. (2012), Covtype is standardized, thus 100% dense. Δ is $\mathcal{O}(1)$ in all data sets, hence not very insightful when relating it to our theoretical results. Deriving a less coarse sparsity bound remains an open problem.

Hardware and software. Experiments were run on a 40-core machine with 384GB of memory. All algorithms were implemented in Scala. We chose this high-level language despite its typical 20x slowdown compared to C (when using standard libraries, see Appendix F.2) because our primary concern was that the code may easily be reused and extended for research purposes (to this end, we have made all our code available at `http://www.di.ens.fr/sierra/research/asaga/`).

Table 1: Basic data set statistics.

	n	d	density	L
RCV1	697,641	47,236	0.15%	0.25
URL	2,396,130	3,231,961	0.004%	128.4
Covtype	581,012	54	100%	48428

6.2. Implementation Details

Regularization. Following Schmidt et al. (2016), the amount of regularization used was set to $\mu = 1/n$. In each update, we project the gradient of the regularization term (we multiply it by D_i as we also do with the vector $\bar{\alpha}$) to preserve the sparsity pattern while maintaining an unbiased estimate of the gradient. For squared ℓ_2, the Sparse Saga updates becomes:

$$x^+ = x - \gamma(f_i'(x) - \alpha_i + D_i\bar{\alpha} + \mu D_i x). \tag{52}$$

Comparison with the theoretical algorithm. The algorithm we used in the experiments is fully detailed in Algorithm 2. There are two differences with Algorithm 1. First, in the implementation we choose i_t at random *before* we read the feature vector a_{i_t}. This enables us to only read the necessary data for a given iteration (i.e. $[\hat{x}_t]_{S_i}, [\hat{\alpha}_i^t], [\bar{\alpha}^t]_{S_i}$). Although this violates Property 3, it still performs well in practice.

Second, we maintain $\bar{\alpha}^t$ in memory. This saves the cost of recomputing it at every iteration (which we can no longer do since we only read a subset data). Again, in practice the implemented algorithm enjoys good performance. But this design choice raises a subtle point: the update is not guaranteed to be unbiased in this setup (see Appendix F.3 for more details).

Step sizes. For each algorithm, we picked the best step size among 10 equally spaced values in a grid, and made sure that the best step size was never at the boundary of this interval. For Covtype and RCV1, we used the interval $[\frac{1}{10L}, \frac{10}{L}]$, whereas for URL we used the interval $[\frac{1}{L}, \frac{100}{L}]$ as it admitted larger step sizes. It turns out that the best step size was fairly constant for different number of cores for both Asaga and Kromagnon, and both algorithms had similar best step sizes (0.7 for RCV1, 0.05 for URL and 5×10^{-5} for Covtype).

6.3. Comparison of Sequential Algorithms: Sparse Saga vs Lagged updates

We compare the Sparse Saga variant proposed in Section 3.1 to two other approaches: the naive (i.e., dense) update scheme and the lagged updates implementation described in Defazio et al. (2014). Note that we use different datasets from the parallel experiments, including a subset of the RCV1 data set and the Realsim data set (see description in Appendix F.1). Figure 2 reveals that sparse and lagged updates have a lower cost per iteration than their dense counterpart, resulting in faster convergence for sparse data sets. Furthermore, while the two approaches had similar convergence in terms of number of iterations, the Sparse Saga scheme is slightly faster in terms of runtime (and as previously pointed out, sparse updates are better adapted for the asynchronous setting). For the dense data set (Covtype), the three approaches exhibit similar performance.

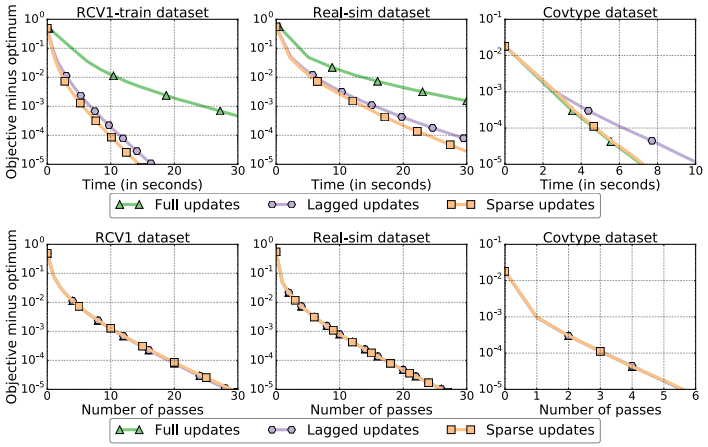

Figure 2: **Lagged vs Sparse Saga updates**. Suboptimality with respect to time for different Saga update schemes on various data sets. First row: suboptimality as a function of time. Second row: suboptimality as a the number of passes over the data set. For sparse data sets (RCV1 and Real-sim), lagged and sparse updates have a lower cost per iteration which result in faster convergence.

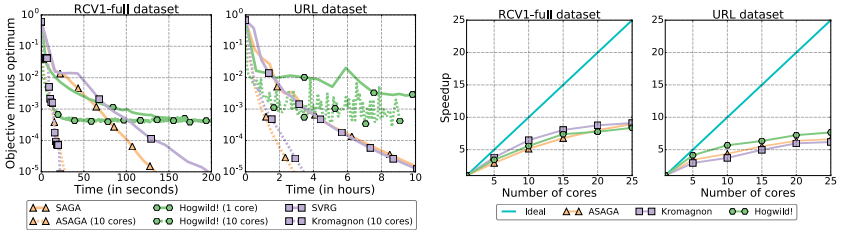

(a) Suboptimality as a function of time. (b) Speedup as a function of the number of cores

Figure 3: **Convergence and speedup for asynchronous stochastic gradient descent methods**. We display results for RCV1 and URL. Results for Covtype can be found in Section 6.6.

6.4. Asaga vs. Kromagnon vs. Hogwild

We compare three different asynchronous variants of stochastic gradient methods on the aforementioned data sets: Asaga, presented in this work, Kromagnon, the asynchronous sparse Svrg method described in Mania et al. (2017) and Hogwild (Niu et al., 2011). Each method had its step size chosen so as to give the fastest convergence (up to a suboptimality of 10^{-3} in the special case of Hogwild). The results can be seen in Figure 3a: for each method we consider its asynchronous version with both one (hence sequential) and ten processors. This figure reveals that the asynchronous version offers a significant speedup over its sequential counterpart.

We then examine the speedup relative to the increase in the number of cores. The speedup is measured as time to achieve a suboptimality of 10^{-5} (10^{-3} for Hogwild) with one core divided by time to achieve the same suboptimality with several cores, averaged over 3 runs. Again, we choose step size leading to fastest convergence[24] (see Appendix F.2 for information about the step sizes). Results are displayed in Figure 3b.

As predicted by our theory, we observe linear "theoretical" speedups (i.e. in terms of number of iterations, see Section 6.6). However, with respect to running time, the speedups seem to taper off after 20 cores. This phenomenon can be explained by the fact that our hardware model is by necessity a simplification of reality. As noted in Duchi et al. (2015), in a modern machine there is no such thing as *shared memory*. Each core has its own levels of cache (L1, L2, L3) in addition to RAM. These faster pools of memory are fully leveraged when using a single core. Unfortunately, as soon as several cores start writing to common locations, cache coherency protocols have to be deployed to ensure that the information is consistent across cores. These protocols come with computational overheads. As more and more cores are used, the shared information goes lower and lower in the memory stack, and the overheads get more and more costly. It may be the case that on much bigger data sets, where the cache memory is unlikely to provide benefits even for a single core (since

24. Although we performed grid search on a large interval, we observed that the best step size was fairly constant for different number of cores, and similar for Asaga and Kromagnon.

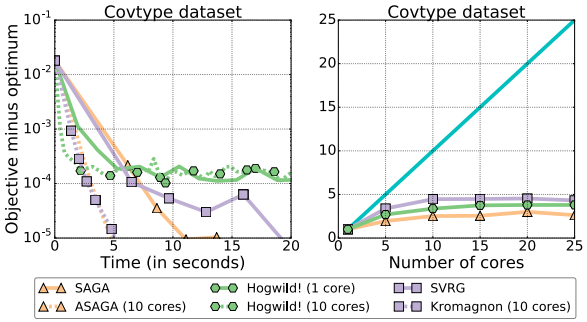

Figure 4: Comparison on the Covtype data set. Left: suboptimality. Right: speedup. The number of cores in the legend only refers to the left plot.

sampling items repeatedly becomes rare), the running time speedups actually improve. More experimentation is needed to quantify these effects and potentially increase performance.

6.5. Effect of Sparsity

Sparsity plays an important role in our theoretical results, where we find that while it is necessary in the "ill-conditioned" regime to get linear speedups, it is not in the "well-conditioned" regime. We confront this to real-life experiments by comparing the convergence and speedup performance of our three asynchronous algorithms on the Covtype data set, which is fully dense after standardization. The results appear in Figure 4.

While we still see a significant improvement in speed when increasing the number of cores, this improvement is smaller than the one we observe for sparser data sets. The speedups we observe are consequently smaller, and taper off earlier than on our other data sets. However, since the observed "theoretical" speedup is linear (see Section 6.6), we can attribute this worse performance to higher hardware overhead. This is expected because each update is fully dense and thus the shared parameters are much more heavily contended for than in our sparse datasets.

One thing we notice when computing the Δ constant for our data sets is that it often fails to capture the full sparsity distribution, being essentially a maximum: for all three data sets, we obtain $\Delta = \mathcal{O}(1)$. This means that Δ can be quite big even for very sparse data sets. Deriving a less coarse bound remains an open problem.

6.6. Theoretical Speedups

In the previous experimental sections, we have shown experimental speedup results where suboptimality was a function of the running time. This measure encompasses both theoretical algorithmic properties and hardware overheads (such as contention of shared memory) which are not taken into account in our analysis.

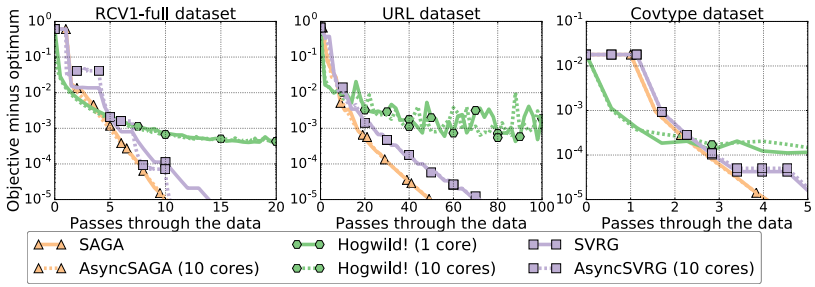

Figure 5: **Theoretical speedups**. Suboptimality with respect to number of iterations for Asaga, Kromagnon and Hogwild with 1 and 10 cores. Curves almost coincide, which means the theoretical speedup is almost the number of cores p, hence linear.

In order to isolate these two effects, we now plot our convergence experiments where suboptimality is a function of the number of iterations; thus, we abstract away any potential hardware overhead.[25] The experimental results can be seen in Figure 5.

For all three algorithms and all three data sets, the curves for 1 and 10 cores almost coincide, which means that we are indeed in the "theoretical linear speedup" regime. Indeed, when we plotted the amount of iterations required to converge to a given accuracy as a function of the number of cores, we obtained straight horizontal lines for our three algorithms.

The fact that the speedups we observe in running time are less than linear can thus be attributed to various hardware overheads, including shared variable contention – the compare-and-swap operations are more and more expensive as the number of competing requests increases – and cache effects as mentioned in Section 6.4.

6.7. A Closer Look at the τ Constant

6.7.1. Theory

In the parallel optimization literature, τ is often referred to as a proxy for the number of cores. However, intuitively as well as in practice, it appears that there are a number of other factors that can influence this quantity. We will now attempt to give a few qualitative arguments as to what these other factors might be and how they relate to τ.

Number of cores. The first of these factors is indeed the number of cores. If we have p cores, $\tau \geq p-1$. Indeed, in the best-case scenario where all cores have exactly the same execution speed for a single iteration, $\tau = p-1$.

Length of an iteration. To get more insight into what τ really encompasses, let us now try to define the worst-case scenario in the preceding example. Consider 2 cores. In the worst

25. To do so, we implement a global counter which is sparsely updated (every 100 iterations for example) in order not to modify the asynchrony of the system. This counter is used only for plotting purposes and is not needed otherwise.

case, one core runs while the other is stuck. Then the overlap is t for all t and eventually grows to $+\infty$. If we assume that one core runs twice as fast as the other, then $\tau = 2$. If both run at the same speed, $\tau = 1$.

It appears then that a relevant quantity is R, the ratio between the fastest execution time and the slowest execution time for a single iteration. We have $\tau \leq (p-1)R$, which can be arbitrarily bigger than p.

There are several factors at play in R itself. These include:

- the speed of execution of the cores themselves (i.e. clock time).
- the data matrix itself. Different support sizes for f_i means different gradient computation times. If one f_i has support of size n while all the others have support of size 1 for example, R may eventually become very big.
- the length of the computation itself. The longer our algorithm runs, the more likely it is to explore the potential corner cases of the data matrix.

The overlap is then upper bounded by the number of cores multiplied by the ratio of the maximum iteration time over the minimum iteration time (which is linked to the sparsity distribution of the data matrix). This is an upper bound, which means that in some cases it will not really be useful. For example, if one factor has support size 1 and all others have support size d, the probability of the event which corresponds to the upper bound is exponentially small in d. We conjecture that a more useful indicator could be ratio of the maximum iteration time over the expected iteration time.

To sum up this preliminary theoretical exploration, the τ term encompasses much more complexity than is usually implied in the literature. This is reflected in the experiments we ran, where the constant was orders of magnitude bigger than the number of cores.

6.7.2. Experimental Results

In order to verify our intuition about the τ variable, we ran several experiments on all three data sets, whose characteristics are reminded in Table 2. δ_l^i is the support size of f_i.

Table 2: Density measures including minimum, average and maximum support size δ_l^i of the factors.

	n	d	density	$\max(\delta_l^i)$	$\min(\delta_l^i)$	$\bar{\delta}_l$	$\max(\delta_l^i)/\bar{\delta}_l$
RCV1	697,641	47,236	0.15%	1,224	4	73.2	16.7
URL	2,396,130	3,231,961	0.003%	414	16	115.6	3.58
Covtype	581,012	54	100%	12	8	11.88	1.01

To estimate τ, we compute the average overlap over 100 iterations, i.e. the difference in labeling between the end of the hundredth iteration and the start of the first iteration on, divided by 100. This quantity is a lower bound on the actual overlap (which is a maximum, not an average). We then take its maximum observed value. The reason why we use an average is that computing the overlap requires using a global counter, which we do not want

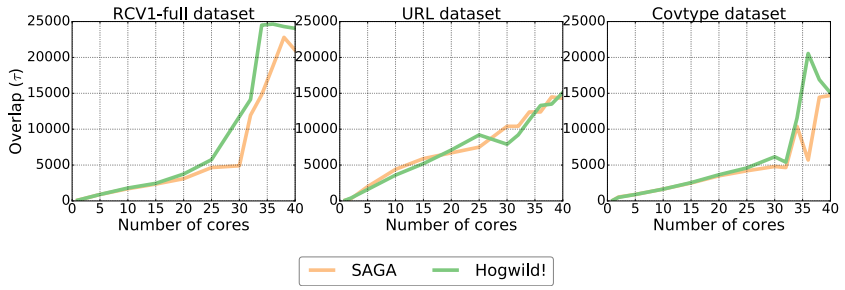

Figure 6: **Overlap**. Overlap as a function of the number of cores for both Asaga and Hogwild on all three data sets.

to update every iteration since it would make it a heavily contentious quantity susceptible of artificially changing the asynchrony pattern of our algorithm.

The results we observe are order of magnitude bigger than p, indicating that τ can indeed not be dismissed as a mere proxy for the number of cores, but has to be more carefully analyzed.

First, we plot the maximum observed τ as a function of the number of cores (see Figure 6). We observe that the relationship does indeed seem to be roughly linear with respect to the number of cores until 30 cores. After 30 cores, we observe what may be a phase transition where the slope increases significantly.

Second, we measured the maximum observed τ as a function of the number of epochs. We omit the figure since we did not observe any dependency; that is, τ does not seem to depend on the number of epochs. We know that it must depend on the number of iterations (since it cannot be bigger, and is an increasing function with respect to that number for example), but it appears that a stable value is reached quite quickly (before one full epoch is done).

If we allowed the computations to run forever, we would eventually observe an event such that τ would reach the upper bound mentioned in Section 6.7.1, so it may be that τ is actually a very slowly increasing function of the number of iterations.

7. Conclusions and Future Work

Building on the recently proposed "perturbed iterate" framework, we have proposed a novel perspective to clarify an important technical issue present in a large fraction of the recent convergence rate proofs for asynchronous parallel optimization algorithms. To resolve it, we have introduced a novel "after read" framework and demonstrated its usefulness by analyzing three asynchronous parallel incremental optimization algorithms, including Asaga, a novel sparse and fully asynchronous variant of the incremental gradient algorithm Saga. Our proof technique accommodates more realistic settings than is usually the case in the literature (such as inconsistent reads and writes and an unbounded gradient); we obtain tighter conditions

than in previous work. In particular, we show that Asaga is linearly faster than Saga under mild conditions, and that sparsity is not always necessary to get linear speedups. Our empirical benchmarks confirm speedups up to 10x.

Schmidt et al. (2016) have shown that Sag enjoys much improved performance when combined with non-uniform sampling and line-search. We have also noticed that our Δ_r constant (being essentially a maximum) sometimes fails to accurately represent the full sparsity distribution of our data sets. Finally, while our algorithm can be directly ported to a distributed master-worker architecture, its communication pattern would have to be optimized to avoid prohibitive costs. Limiting communications can be interpreted as artificially increasing the delay, yielding an interesting trade-off between delay influence and communication costs.

These constitute interesting directions for future analysis, as well as a further exploration of the τ term, which we have shown encompasses more complexity than previously thought.

Acknowledgments

We would like to thank Xinghao Pan for sharing with us their implementation of Kromagnon, as well as Alberto Chiappa for spotting a typo in the proof. This work was partially supported by a Google Research Award and the MSR-Inria Joint Center. FP acknowledges financial support from the chaire *Économie des nouvelles données* with the *data science* joint research initiative with the *fonds AXA pour la recherche*.

Appendix Outline:

- In Appendix A, we adapt the proof from Hofmann et al. (2015) to prove Theorem 2, our convergence result for serial Sparse Saga.
- In Appendix B, we give the complete details for the proof of convergence for Asaga (Theorem 8) as well as its linear speedup regimes (Corollary 9).
- In Appendix C, we give the full details for the proof of convergence for Kromagnon (Theorem 15) as well as a simpler convergence result for both Svrg (Corollary 16) and Kromagnon (Corollary 17) and finally the latter's linear speedup regimes (Corollary 18)
- In Appendix D, we give the full details for the proof of convergence for Hogwild (Theorem 22) as well as its linear speedup regimes (Corollary 23).
- In Appendix E, we explain why adapting the lagged updates implementation of Saga to the asynchronous setting is difficult.
- In Appendix F, we give additional details about the data sets and our implementation.

Appendix A. Sparse Saga – Proof of Theorem 2

Proof sketch for Hofmann et al. (2015). As we will heavily reuse the proof technique from Hofmann et al. (2015), we start by giving its sketch.

First, the authors combine classical strong convexity and Lipschitz inequalities to derive the following inequality (Hofmann et al., 2015, Lemma 1):

$$\mathbf{E}\|x^+ - x^*\|^2 \leq (1-\gamma\mu)\|x-x^*\|^2 + 2\gamma^2\mathbf{E}\|\alpha_i - f_i'(x^*)\|^2 + (4\gamma^2 L - 2\gamma)\big(f(x) - f(x^*)\big). \quad (53)$$

This gives a contraction term, as well as two additional terms; $2\gamma^2\mathbf{E}\|\alpha_i - f_i'(x^*)\|^2$ is a positive variance term, but $(4\gamma^2 L - 2\gamma)\big(f(x) - f(x^*)\big)$ is a negative suboptimality term (provided γ is small enough). The suboptimality term can then be used to cancel the variance one.

Second, the authors use a classical smoothness upper bound to control the variance term and relate it to the suboptimality. However, since the α_i are partial gradients computed at previous time steps, the upper bounds of the variance involve suboptimality at previous time steps, which are not directly relatable to the current suboptimality.

Third, to circumvent this issue, a Lyapunov function is defined to encompass both current and past terms. To finish the proof, Hofmann et al. (2015) show that the Lyapunov function is a contraction.

Proof outline. Fortunately, we can reuse most of the proof from Hofmann et al. (2015) to show that Sparse Saga converges at the same rate as regular Saga. In fact, once we establish that Hofmann et al. (2015, Lemma 1) is still verified we are done.

To prove this, we show that the gradient estimator is unbiased, and then derive close variants of equations (6) and (9) in their paper, which we remind the reader of here:

$$\mathbf{E}\|f_i'(x) - \bar{\alpha}_i\|^2 \leq 2\mathbf{E}\|f_i'(x) - f_i'(x^*)\|^2 + 2\mathbf{E}\|\bar{\alpha}_i - f_i'(x^*)\|^2 \quad \text{Hofmann et al. (2015, Eq. 6)}$$

$$\mathbf{E}\|\bar{\alpha}_i - f_i'(x^*)\|^2 \leq \mathbf{E}\|\alpha_i - f_i'(x^*)\|^2 . \quad \text{Hofmann et al. (2015, Eq. 9)}$$

Unbiased gradient estimator. We first show that the update estimator is unbiased. The estimator is unbiased if:

$$\mathbf{E}D_i\bar{\alpha} = \mathbf{E}\alpha_i = \frac{1}{n}\sum_{i=1}^n \alpha_i . \quad (54)$$

We have:

$$\mathbf{E}D_i\bar{\alpha} = \frac{1}{n}\sum_{i=1}^n D_i\bar{\alpha} = \frac{1}{n}\sum_{i=1}^n P_{S_i} D\bar{\alpha} = \frac{1}{n}\sum_{i=1}^n \sum_{v\in S_i} \frac{[\bar{\alpha}]_v e_v}{p_v} = \sum_{v=1}^d \left(\sum_{i\,|\,v\in S_i} 1\right)\frac{[\bar{\alpha}]_v e_v}{np_v} ,$$

where e_v is the vector whose only nonzero component is the v component which is equal to 1.

By definition, $\sum_{i|v\in S_i} 1 = np_v$, which gives us Equation (54).

Deriving Hofmann et al. (2015, Equation 6). We define $\bar{\alpha}_i := \alpha_i - D_i\bar{\alpha}$ (contrary to Hofmann et al. (2015) where the authors define $\bar{\alpha}_i := \alpha_i - \bar{\alpha}$ since they do not concern themselves with sparsity). Using the inequality $\|a+b\|^2 \leq 2\|a\|^2 + 2\|b\|^2$, we get:

$$\mathbf{E}\|f_i'(x) - \bar{\alpha}_i\|^2 \leq 2\mathbf{E}\|f_i'(x) - f_i'(x^*)\|^2 + 2\mathbf{E}\|\bar{\alpha}_i - f_i'(x^*)\|^2, \quad (55)$$

which is our equivalent to Hofmann et al. (2015, Eq. 6), where only our definition of $\bar{\alpha}_i$ differs.

Deriving Hofmann et al. (2015, Equation 9). We want to prove Hofmann et al. (2015, Eq. 9):

$$\mathbf{E}\|\bar{\alpha}_i - f_i'(x^*)\|^2 \leq \mathbf{E}\|\alpha_i - f_i'(x^*)\|^2. \quad (56)$$

We have:

$$\mathbf{E}\|\bar{\alpha}_i - f_i'(x^*)\|^2 = \mathbf{E}\|\alpha_i - f_i'(x^*)\|^2 - 2\mathbf{E}\langle \alpha_i - f_i'(x^*), D_i\bar{\alpha}\rangle + \mathbf{E}\|D_i\bar{\alpha}\|^2. \quad (57)$$

Let $D_{\neg i} := P_{S_i^c} D$; we then have the orthogonal decomposition $D\alpha = D_i\alpha + D_{\neg i}\alpha$ with $D_i\alpha \perp D_{\neg i}\alpha$, as they have disjoint support. We now use the orthogonality of $D_{\neg i}\alpha$ with any vector with support in S_i to simplify the expression (57) as follows:

$$\begin{aligned}
\mathbf{E}\langle \alpha_i - f_i'(x^*), D_i\bar{\alpha}\rangle &= \mathbf{E}\langle \alpha_i - f_i'(x^*), D_i\bar{\alpha} + D_{\neg i}\bar{\alpha}\rangle && (\alpha_i - f_i'(x^*) \perp D_{\neg i}\bar{\alpha}) \\
&= \mathbf{E}\langle \alpha_i - f_i'(x^*), D\bar{\alpha}\rangle \\
&= \langle \mathbf{E}\big(\alpha_i - f_i'(x^*)\big), D\bar{\alpha}\rangle \\
&= \langle \mathbf{E}\alpha_i, D\bar{\alpha}\rangle && (f'(x^*) = 0) \\
&= \bar{\alpha}^\intercal D\bar{\alpha} . && (58)
\end{aligned}$$

Similarly,

$$\begin{aligned}
\mathbf{E}\|D_i\bar{\alpha}\|^2 &= \mathbf{E}\langle D_i\bar{\alpha}, D_i\bar{\alpha}\rangle \\
&= \mathbf{E}\langle D_i\bar{\alpha}, D\bar{\alpha}\rangle && (D_i\bar{\alpha} \perp D_{\neg i}\bar{\alpha}) \\
&= \langle \mathbf{E}D_i\bar{\alpha}, D\bar{\alpha}\rangle \\
&= \bar{\alpha}^\intercal D\bar{\alpha} . && (59)
\end{aligned}$$

Putting it all together,

$$\mathbf{E}\|\bar{\alpha}_i - f_i'(x^*)\|^2 = \mathbf{E}\|\alpha_i - f_i'(x^*)\|^2 - \bar{\alpha}^\intercal D\bar{\alpha} \leq \mathbf{E}\|\alpha_i - f_i'(x^*)\|^2. \tag{60}$$

This is our version of Hofmann et al. (2015, Equation 9), which finishes the proof of Hofmann et al. (2015, Lemma 1). The rest of the proof from Hofmann et al. (2015) can then be reused without modification to obtain Theorem 2. ■

Appendix B. Asaga – Proof of Theorem 8 and Corollary 9

B.1. Initial Recursive Inequality Derivation

We start by proving Equation (15). Let $g_t := g(\hat{x}_t, \hat{\alpha}^t, i_t)$. From (10), we get:

$$\begin{aligned}\|x_{t+1} - x^*\|^2 = \|x_t - \gamma g_t - x^*\|^2 &= \|x_t - x^*\|^2 + \gamma^2\|g_t\|^2 - 2\gamma\langle x_t - x^*, g_t\rangle \\ &= \|x_t - x^*\|^2 + \gamma^2\|g_t\|^2 - 2\gamma\langle \hat{x}_t - x^*, g_t\rangle + 2\gamma\langle \hat{x}_t - x_t, g_t\rangle.\end{aligned}$$

In order to prove Equation (15), we need to bound the $-2\gamma\langle \hat{x}_t - x^*, g_t\rangle$ term. Thanks to Property 3, we can write:

$$\mathbb{E}\langle \hat{x}_t - x^*, g_t\rangle = \mathbb{E}\langle \hat{x}_t - x^*, \mathbf{E}g_t\rangle = \mathbb{E}\langle \hat{x}_t - x^*, f'(\hat{x}_t)\rangle\,.$$

We can now use a classical strong convexity bound as well as a squared triangle inequality to get:

$$\begin{aligned}-\langle \hat{x}_t - x^*, f'(\hat{x}_t)\rangle &\leq -\big(f(\hat{x}_t) - f(x^*)\big) - \frac{\mu}{2}\|\hat{x}_t - x^*\|^2 && \text{(Strong convexity bound)} \\ -\|\hat{x}_t - x^*\|^2 &\leq \|\hat{x}_t - x_t\|^2 - \frac{1}{2}\|x_t - x^*\|^2 && (\|a+b\|^2 \leq 2\|a\|^2 + 2\|b\|^2) \\ -2\gamma\mathbb{E}\langle \hat{x}_t - x^*, g_t\rangle &\leq -\frac{\gamma\mu}{2}\mathbb{E}\|x_t - x^*\|^2 + \gamma\mu\mathbb{E}\|\hat{x}_t - x_t\|^2 - 2\gamma\big(\mathbb{E}f(\hat{x}_t) - f(x^*)\big)\,. && (61)\end{aligned}$$

Putting it all together, we get the initial recursive inequality (15), rewritten here explicitly:

$$a_{t+1} \leq (1 - \frac{\gamma\mu}{2})a_t + \gamma^2\mathbb{E}\|g_t\|^2 + \gamma\mu\mathbb{E}\|\hat{x}_t - x_t\|^2 + 2\gamma\mathbb{E}\langle \hat{x}_t - x_t, g_t\rangle - 2\gamma e_t\,, \tag{62}$$

where $a_t := \mathbb{E}\|x_t - x^*\|^2$ and $e_t := \mathbb{E}f(\hat{x}_t) - f(x^*)$.

B.2. Proof of Lemma 10 (inequality in terms of $g_t := g(\hat{x}_t, \hat{\alpha}^t, i_t)$)

To prove Lemma 10, we now bound both $\mathbb{E}\|\hat{x}_t - x_t\|^2$ and $\mathbb{E}\langle \hat{x}_t - x_t, g_t\rangle$ with respect to $(\mathbb{E}\|g_u\|^2)_{u\leq t}$.

Bounding $\mathbb{E}\langle \hat{x}_t - x_t, g_t\rangle$ ***in terms of*** g_u***.***

$$\begin{aligned}\frac{1}{\gamma}\mathbb{E}\langle \hat{x}_t - x_t, g_t\rangle &= \sum_{u=(t-\tau)_+}^{t-1} \mathbb{E}\langle G_u^t g_u, g_t\rangle && \text{(by Equation (11))} \\ &\leq \sum_{u=(t-\tau)_+}^{t-1} \mathbb{E}|\langle g_u, g_t\rangle| && (G_u^t \text{ diagonal matrices with terms in } \{0,1\}) \\ &\leq \sum_{u=(t-\tau)_+}^{t-1} \frac{\sqrt{\Delta}}{2}(\mathbb{E}\|g_u\|^2 + \mathbb{E}\|g_t\|^2) && \text{(by Proposition 11)} \\ &\leq \frac{\sqrt{\Delta}}{2}\sum_{u=(t-\tau)_+}^{t-1} \mathbb{E}\|g_u\|^2 + \frac{\sqrt{\Delta}\tau}{2}\mathbb{E}\|g_t\|^2. && (63)\end{aligned}$$

Bounding $\mathbb{E}\|\hat{x}_t - x_t\|^2$ ***with respect to*** g_u Thanks to the expansion for $\hat{x}_t - x_t$ (11), we get:

$$\|\hat{x}_t - x_t\|^2 \leq \gamma^2 \sum_{u,v=(t-\tau)_+}^{t-1} |\langle G_u^t g_u, G_v^t g_v\rangle| \leq \gamma^2 \sum_{u=(t-\tau)_+}^{t-1} \|g_u\|^2 + \gamma^2 \sum_{\substack{u,v=(t-\tau)_+ \\ u\neq v}}^{t-1} |\langle G_u^t g_u, G_v^t g_v\rangle|\,.$$

Using (18) from Proposition 11, we have that for $u \neq v$:

$$\mathbb{E}|\langle G_u^t g_u, G_v^t g_v\rangle| \leq \mathbb{E}|\langle g_u, g_v\rangle| \leq \frac{\sqrt{\Delta}}{2}(\mathbb{E}\|g_u\|^2 + \mathbb{E}\|g_v\|^2)\,. \tag{64}$$

By taking the expectation and using (64), we get:

$$\begin{aligned}\mathbb{E}\|\hat{x}_t - x_t\|^2 &\leq \gamma^2 \sum_{u=(t-\tau)_+}^{t-1} \mathbb{E}\|g_u\|^2 + \gamma^2\sqrt{\Delta}(\tau-1)_+ \sum_{u=(t-\tau)_+}^{t-1} \mathbb{E}\|g_u\|^2 \\ &= \gamma^2\big(1 + \sqrt{\Delta}(\tau-1)_+\big) \sum_{u=(t-\tau)_+}^{t-1} \mathbb{E}\|g_u\|^2 \\ &\leq \gamma^2\big(1 + \sqrt{\Delta}\tau\big) \sum_{u=(t-\tau)_+}^{t-1} \mathbb{E}\|g_u\|^2. && (65)\end{aligned}$$

We can now rewrite (15) in terms of $\mathbb{E}\|g_t\|^2$, which finishes the proof for Lemma 10 (by introducing C_1 and C_2 as specified by 17 in Lemma 10):

$$\begin{aligned}a_{t+1} &\leq (1 - \frac{\gamma\mu}{2})a_t - 2\gamma e_t + \gamma^2\mathbb{E}\|g_t\|^2 + \gamma^3\mu(1 + \sqrt{\Delta}\tau) \sum_{u=(t-\tau)_+}^{t-1} \mathbb{E}\|g_u\|^2 \\ &\quad + \gamma^2\sqrt{\Delta} \sum_{u=(t-\tau)_+}^{t-1} \mathbb{E}\|g_u\|^2 + \gamma^2\sqrt{\Delta}\tau\mathbb{E}\|g_t\|^2 \\ &\leq (1 - \frac{\gamma\mu}{2})a_t - 2\gamma e_t + \gamma^2 C_1\mathbb{E}\|g_t\|^2 + \gamma^2 C_2 \sum_{u=(t-\tau)_+}^{t-1} \mathbb{E}\|g_u\|^2. && (66)\end{aligned}$$

■

B.3. Proof of Lemma 13 (suboptimality bound on $\mathbb{E}\|g_t\|^2$)

We now derive our bound on g_t with respect to suboptimality. From Appendix A, we know that:

$$\mathbb{E}\|g_t\|^2 \leq 2\mathbb{E}\|f'_{i_t}(\hat{x}_t) - f'_{i_t}(x^*)\|^2 + 2\mathbb{E}\|\hat{\alpha}^t_{i_t} - f'_{i_t}(x^*)\|^2 \tag{67}$$

$$\mathbb{E}\|f'_{i_t}(\hat{x}_t) - f'_{i_t}(x^*)\|^2 \leq 2L\big(\mathbb{E}f(\hat{x}_t) - f(x^*)\big) = 2Le_t\,. \tag{68}$$

N. B.: In the following, i_t is a random variable picked uniformly at random in $\{1,...,n\}$, whereas i is a fixed constant.

We still have to handle the $\mathbb{E}\|\hat{\alpha}^t_{i_t} - f'_{i_t}(x^*)\|^2$ term and express it in terms of past suboptimalities. We know from our definition of t that i_t and $\hat{x}_u$ are independent $\forall u < t$. Given the "after read" global ordering, $\mathbf{E}$ – the expectation on i_t conditioned on $\hat{x}_t$ and all "past" $\hat{x}_u$ and i_u – is well defined, and we can rewrite our quantity as:

$$\begin{aligned}\mathbb{E}\|\hat{\alpha}^t_{i_t} - f'_{i_t}(x^*)\|^2 = \mathbb{E}\big(\mathbf{E}\|\hat{\alpha}^t_{i_t} - f'_{i_t}(x^*)\|^2\big) &= \mathbb{E}\frac{1}{n}\sum_{i=1}^n \|\hat{\alpha}^t_i - f'_i(x^*)\|^2 \\ &= \frac{1}{n}\sum_{i=1}^n \mathbb{E}\|\hat{\alpha}^t_i - f'_i(x^*)\|^2.\end{aligned}$$

Now, with i fixed, let $u^t_{i,l}$ be the time of the iterate last used to write the $[\hat{\alpha}^t_i]_l$ quantity, i.e. $[\hat{\alpha}^t_i]_l = [f'_i(\hat{x}_{u^t_{i,l}})]_l$. We know[26] that $0 \leq u^t_{i,l} \leq t-1$. To use this information, we first need to split $\hat{\alpha}_i$ along its dimensions to handle the possible inconsistencies among them:

$$\mathbb{E}\|\hat{\alpha}^t_i - f'_i(x^*)\|^2 = \mathbb{E}\sum_{l=1}^d \big([\hat{\alpha}^t_i]_l - [f'_i(x^*)]_l\big)^2 = \sum_{l=1}^d \mathbb{E}\Big[\big([\hat{\alpha}^t_i]_l - [f'_i(x^*)]_l\big)^2\Big].$$

This gives us:

$$\begin{aligned}\mathbb{E}\|\hat{\alpha}^t_i - f'_i(x^*)\|^2 &= \sum_{l=1}^d \mathbb{E}\Big[\big(f'_i(\hat{x}_{u^t_{i,l}})_l - f'_i(x^*)_l\big)^2\Big] \\ &= \sum_{l=1}^d \mathbb{E}\Big[\sum_{u=0}^{t-1} \mathbb{1}_{\{u^t_{i,l}=u\}}\big(f'_i(\hat{x}_u)_l - f'_i(x^*)_l\big)^2\Big] \\ &= \sum_{u=0}^{t-1}\sum_{l=1}^d \mathbb{E}\Big[\mathbb{1}_{\{u^t_{i,l}=u\}}\big(f'_i(\hat{x}_u)_l - f'_i(x^*)_l\big)^2\Big].\end{aligned} \tag{69}$$

We will now rewrite the indicator so as to obtain independent events from the rest of the equality. This will enable us to distribute the expectation. Suppose $u > 0$ ($u = 0$ is a special case which we will handle afterwards). $\{u^t_{i,l} = u\}$ requires two things:

26. In the case where $u = 0$, one would have to replace the partial gradient with α^0_i. We omit this special case here for clarity of exposition.

1. at time u, i was picked uniformly at random,
2. (roughly) i was not picked again between u and t.

We need to refine both conditions because we have to account for possible collisions due to asynchrony. We know from our definition of τ that the t^{th} iteration finishes before at $t+\tau+1$, but it may still be unfinished by time $t+\tau$. This means that we can only be sure that an update selecting i at time v has been written to memory at time t if $v \leq t-\tau-1$. Later updates may not have been written yet at time t. Similarly, updates before $v = u+\tau+1$ may be overwritten by the u^{th} update so we cannot infer that they did not select i. From this discussion, we conclude that $u^t_{i,l} = u$ implies that $i_v \neq i$ for all v between $u+\tau+1$ and $t-\tau-1$, though it can still happen that $i_v = i$ for v outside this range.

Using the fact that i_u and i_v are independent for $v \neq u$, we can thus upper bound the indicator function appearing in (69) as follows:

$$\mathbb{1}_{\{u^t_{i,l}=u\}} \leq \mathbb{1}_{\{i_u=i\}}\mathbb{1}_{\{i_v\neq i\ \forall v \text{ s.t. } u+\tau+1\leq v\leq t-\tau-1\}}. \tag{70}$$

This gives us:

$$\begin{aligned}&\mathbb{E}\Big[\mathbb{1}_{\{u^t_{i,l}=u\}}\big(f'_i(\hat{x}_u)_l - f'_i(x^*)_l\big)^2\Big] \\ &\quad\leq \mathbb{E}\Big[\mathbb{1}_{\{i_u=i\}}\mathbb{1}_{\{i_v\neq i\ \forall v \text{ s.t. } u+\tau+1\leq v\leq t-\tau-1\}}\big(f'_i(\hat{x}_u)_l - f'_i(x^*)_l\big)^2\Big] \\ &\quad\leq P\{i_u = i\}P\{i_v \neq i\ \forall v \text{ s.t. } u+\tau+1 \leq v \leq t-\tau-1\}\mathbb{E}\big(f'_i(\hat{x}_u)_l - f'_i(x^*)_l\big)^2 \\ &\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad (i_v \perp\!\!\!\perp \hat{x}_u, \forall v \geq u) \\ &\quad\leq \frac{1}{n}(1-\frac{1}{n})^{(t-2\tau-u-1)_+}\mathbb{E}\big(f'_i(\hat{x}_u)_l - f'_i(x^*)_l\big)^2.\end{aligned} \tag{71}$$

Note that the third line used the crucial independence assumption $i_v \perp\!\!\!\perp \hat{x}_u, \forall v \geq u$ arising from our "After Read" ordering. Summing over all dimensions l, we then get:

$$\mathbb{E}\Big[\mathbb{1}_{\{u^t_{i,l}=u\}}\|f'_i(\hat{x}_u) - f'_i(x^*)\|^2\Big] \leq \frac{1}{n}(1-\frac{1}{n})^{(t-2\tau-u-1)_+}\mathbb{E}\|f'_i(\hat{x}_u) - f'_i(x^*)\|^2. \tag{72}$$

So now:

$$\begin{aligned}\mathbb{E}\|\hat{\alpha}^t_{i_t} - f'_{i_t}(x^*)\|^2 - \lambda\tilde{e}_0 &\leq \frac{1}{n}\sum_{i=1}^n\sum_{u=1}^{t-1}\frac{1}{n}(1-\frac{1}{n})^{(t-2\tau-u-1)_+}\mathbb{E}\|f'_i(\hat{x}_u) - f'_i(x^*)\|^2 \\ &= \sum_{u=1}^{t-1}\frac{1}{n}(1-\frac{1}{n})^{(t-2\tau-u-1)_+}\frac{1}{n}\sum_{i=1}^n\mathbb{E}\|f'_i(\hat{x}_u) - f'_i(x^*)\|^2 \\ &= \sum_{u=1}^{t-1}\frac{1}{n}(1-\frac{1}{n})^{(t-2\tau-u-1)_+}\mathbb{E}\Big(\mathbf{E}\|f'_{i_u}(\hat{x}_u) - f'_{i_u}(x^*)\|^2\Big) \quad (i_u \perp\!\!\!\perp \hat{x}_u) \\ &\leq \frac{2L}{n}\sum_{u=1}^{t-1}(1-\frac{1}{n})^{(t-2\tau-u-1)_+}e_u \qquad \text{(by Equation 68)} \\ &= \frac{2L}{n}\sum_{u=1}^{(t-2\tau-1)_+}(1-\frac{1}{n})^{t-2\tau-u-1}e_u + \frac{2L}{n}\sum_{u=\max(1,t-2\tau)}^{t-1}e_u\,.\end{aligned} \tag{73}$$

Note that we have excluded $\tilde{e}_0$ from our formula, using a generic λ multiplier. We need to treat the case $u = 0$ differently to bound $\mathbb{1}_{\{u^t_{i,l}=u\}}$. Because all our initial α_i are initialized to a fixed α^0_i, $\{u^t_i = 0\}$ just means that i has not been picked between 0 and $t-\tau-1$, i.e. $\{i_v \neq i \ \forall \ v \text{ s.t. } 0 \leq v \leq t-\tau-1\}$. This means that the $\mathbb{1}_{\{i_u=i\}}$ term in (70) disappears and thus we lose a $\frac{1}{n}$ factor compared to the case where $u > 1$.

Let us now evaluate λ. We have:

$$\begin{aligned}\mathbb{E}\Big[\mathbb{1}_{\{u^t_i=0\}}\|\alpha^0_i - f_i'(x^*)\|^2\Big] &\leq \mathbb{E}\Big[\mathbb{1}_{\{i_v\neq i \ \forall \ v \text{ s.t. } 0\leq v\leq t-\tau-1\}}\|\alpha^0_i - f_i'(x^*)\|^2\Big] \\ &\leq P\{i_v \neq i \ \forall \ v \text{ s.t. } 0 \leq v \leq t-\tau-1\}\mathbb{E}\|\alpha^0_i - f_i'(x^*)\|^2 \\ &\leq (1-\frac{1}{n})^{(t-\tau)_+}\mathbb{E}\|\alpha^0_i - f_i'(x^*)\|^2. \end{aligned} \tag{74}$$

Plugging (73) and (74) into (67), we get Lemma 13:

$$\mathbb{E}\|g_t\|^2 \leq 4Le_t + \frac{4L}{n}\sum_{u=1}^{t-1}(1-\frac{1}{n})^{(t-2\tau-u-1)_+}e_u + 4L(1-\frac{1}{n})^{(t-\tau)_+}\tilde{e}_0\,, \tag{75}$$

where we have introduced $\tilde{e}_0 = \frac{1}{2L}\mathbb{E}\|\alpha^0_i - f_i'(x^*)\|^2$. Note that in the original Saga algorithm, a batch gradient is computed to set the $\alpha^0_i = f_i'(x_0)$. In this setting, we can write Lemma 13 using only $\tilde{e}_0 \leq e_0$ thanks to (68). In the more general setting where we initialize all α^0_i to a fixed quantity, we cannot use (68) to bound $\mathbb{E}\|\alpha^0_i - f_i'(x^*)\|^2$ which means that we have to introduce $\tilde{e}_0$.

B.4. Lemma 13 for Ahsvrg

In the simpler case of Ahsvrg as described in 4.2, we have a slight variation of (69):

$$\mathbb{E}\|f_i'(x^t_0) - f_i'(x^*)\|^2 = \sum_{u=0}^{t-1}\mathbb{E}\|\mathbb{1}_{\{u^t_i=u\}}\big(f_i'(\hat{x}_u) - f_i'(x^*)\big)\|^2. \tag{76}$$

Note that there is no sum over dimensions in this case because the full gradient computations and writes are synchronized (so the reference gradient is consistent).

As in Section B.3, we can upper bound the indicator $\mathbb{1}_{\{u^t_i=u\}}$. Now, $\{u^t_{i,l} = u\}$ requires two things: first, the next B variable sampled after the u^{th} update, $\tilde{B}_u$[27], was 1; second, B was 0 for every update between u and t (roughly). Since the batch step is fully synchronized, we do not have to worry about updates from the past overwriting the reference gradient (and the iterates x_u where we compute the gradient contains all past updates because we have waited for every core to finish its current update).

However, updating the state variable s to 1 once a $B = 1$ variable is sampled is not atomic. So it is possible to have iterations with time label bigger than u and that still use an older reference gradient for their update[28]. Fortunately, we can consider the state update as any regular update to shared parameters. As such, Assumption 6 applies to it. This means that we can be certain that the reference gradient has been updated for iterations with time label $v \geq u + \tau + 1$.

This gives us:

$$\begin{aligned}\mathbb{E}\|\mathbb{1}_{\{u^t_i=u\}}\big(f_i'(\hat{x}_u) - f_i'(x^*)\big)\|^2 &\leq \mathbb{E}\Big[\mathbb{1}_{\{\tilde{B}_u=1\}}\mathbb{1}_{\{B_v=0 \ \forall v \text{ s.t. } u+1\leq v\leq t-\tau-1\}}\|f_i'(\hat{x}_u) - f_i'(x^*)\|^2\Big] \\ &\leq \frac{1}{n}\big(1-\frac{1}{n}\big)^{(t-\tau-u-1)_+}\mathbb{E}\|f_i'(\hat{x}_u) - f_i'(x^*)\|^2\,. \end{aligned} \tag{77}$$

This proves Lemma 13 for Ahsvrg (while we actually have a slightly better exponent, $(t-\tau-u-1)_+$, we can upperbound it by the term in Lemma 13). Armed with this result, we can finish the proof of Theorem 8 for Ahsvrg in exactly the same manner as for Asaga. By remarking that the cost to get to iteration t (including computing reference batch gradients) is the same in the sequential and parallel version, we see that our analysis for Corollary 9 for Asaga also applies for Ahsvrg, so both algorithms obey the same convergence and speedup results.

B.5. Master Inequality Derivation

Now, if we combine the bound on $\mathbb{E}\|g_t\|^2$ which we just derived (i.e. Lemma 13) with Lemma 10, we get:

$$\begin{aligned} a_{t+1} \leq &(1-\frac{\gamma\mu}{2})a_t - 2\gamma e_t \\ &+ 4L\gamma^2C_1e_t + \frac{4L\gamma^2C_1}{n}\sum_{u=1}^{t-1}(1-\frac{1}{n})^{(t-2\tau-u-1)_+}e_u + 4L\gamma^2C_1(1-\frac{1}{n})^{(t-\tau)_+}\tilde{e}_0 \\ &+ 4L\gamma^2C_2\sum_{u=(t-\tau)_+}^{t-1}e_u + 4L\gamma^2C_2\sum_{u=(t-\tau)_+}^{t-1}(1-\frac{1}{n})^{(u-\tau)_+}\tilde{e}_0 \\ &+ \frac{4L\gamma^2C_2}{n}\sum_{u=(t-\tau)_+}^{t-1}\sum_{v=1}^{u-1}(1-\frac{1}{n})^{(u-2\tau-v-1)_+}e_v\,. \end{aligned} \tag{78}$$

If we define $H_t := \sum_{u=1}^{t-1}(1-\frac{1}{n})^{(t-2\tau-u-1)_+}e_u$, then we get:

$$\begin{aligned} a_{t+1} \leq &(1-\frac{\gamma\mu}{2})a_t - 2\gamma e_t \\ &+ 4L\gamma^2C_1\big(e_t + (1-\frac{1}{n})^{(t-\tau)_+}\tilde{e}_0\big) + \frac{4L\gamma^2C_1}{n}H_t \\ &+ 4L\gamma^2C_2\sum_{u=(t-\tau)_+}^{t-1}\big(e_u + (1-\frac{1}{n})^{(u-\tau)_+}\tilde{e}_0\big) + \frac{4L\gamma^2C_2}{n}\sum_{u=(t-\tau)_+}^{t-1}H_u\,, \end{aligned} \tag{79}$$

which is the master inequality (27).

27. We introduce this quantity because the iterations where full gradients are computed do not receive a time label since they do not correspond to updates to the iterates.

28. Conceivably, another core could start a new iteration, draw $B = 1$ and try to update s to 1 themselves. This is not an issue since the operation of updating s to 1 is idempotent. Only one reference gradient would be computed in this case.

B.6. Lyapunov Function and Associated Recursive Inequality

We define $\mathcal{L}_t := \sum_{u=0}^{t}(1-\rho)^{t-u}a_u$ for some target contraction rate $\rho < 1$ to be defined later. We have:

$$\mathcal{L}_{t+1} = (1-\rho)^{t+1}a_0 + \sum_{u=1}^{t+1}(1-\rho)^{t+1-u}a_u = (1-\rho)^{t+1}a_0 + \sum_{u=0}^{t}(1-\rho)^{t-u}a_{u+1}\,. \tag{80}$$

We now use our new bound on a_{t+1}, (79):

$$\begin{aligned}
\mathcal{L}_{t+1} &\le (1-\rho)^{t+1}a_0 + \sum_{u=0}^{t}(1-\rho)^{t-u}\Big[(1-\frac{\gamma\mu}{2})a_u - 2\gamma e_u + 4L\gamma^2 C_1\big(e_u + (1-\frac{1}{n})^{(u-\tau)_+}\tilde{e}_0\big) \\
&\qquad + \frac{4L\gamma^2 C_1}{n}H_u + \frac{4L\gamma^2 C_2}{n}\sum_{v=(u-\tau)_+}^{u-1}H_v \\
&\qquad + 4L\gamma^2 C_2\sum_{v=(u-\tau)_+}^{u-1}(e_v + (1-\frac{1}{n})^{(v-\tau)_+}\tilde{e}_0)\Big] \\
&\le (1-\rho)^{t+1}a_0 + (1-\frac{\gamma\mu}{2})\mathcal{L}_t \\
&\qquad + \sum_{u=0}^{t}(1-\rho)^{t-u}\Big[-2\gamma e_u + 4L\gamma^2 C_1\big(e_u + (1-\frac{1}{n})^{(u-\tau)_+}\tilde{e}_0\big) \\
&\qquad\qquad + \frac{4L\gamma^2 C_1}{n}H_u + \frac{4L\gamma^2 C_2}{n}\sum_{v=(u-\tau)_+}^{u-1}H_v \\
&\qquad\qquad + 4L\gamma^2 C_2\sum_{v=(u-\tau)_+}^{u-1}(e_v + (1-\frac{1}{n})^{(v-\tau)_+}\tilde{e}_0)\Big].
\end{aligned} \tag{81}$$

We can now rearrange the sums to expose a simple sum of e_u multiplied by factors r_u^t:

$$\mathcal{L}_{t+1} \le (1-\rho)^{t+1}a_0 + (1-\frac{\gamma\mu}{2})\mathcal{L}_t + \sum_{u=1}^{t}r_u^t e_u + r_0^t\tilde{e}_0\,. \tag{82}$$

B.7. Proof of Lemma 14 (sufficient condition for convergence for Asaga)

We want to make explicit what conditions on ρ and γ are necessary to ensure that r_u^t is negative for all $u \ge 1$. Since each e_u is positive, we will then be able to safely drop the sum term from the inequality. The r_0^t term is a bit trickier and is handled separately. Indeed, trying to enforce that r_0^t is negative results in a significantly worse condition on γ and eventually a convergence rate smaller by a factor of n than our final result. Instead, we handle this term directly in the Lyapunov function.

Computation of r_u^t. Let's now make the multiplying factor explicit. We assume $u \ge 1$.

We split r_u^t into five parts coming from (81):

- r_1, the part coming from the $-2\gamma e_u$ terms;

- r_2, coming from $4L\gamma^2 C_1 e_u$;
- r_3, coming from $\frac{4L\gamma^2 C_1}{n}H_u$;
- r_4, coming from $4L\gamma^2 C_2\sum_{v=(u-\tau)_+}^{u-1}e_v$;
- r_5, coming from $\frac{4L\gamma^2 C_2}{n}\sum_{v=(u-\tau)_+}^{u-1}H_v$.

r_1 is easy to derive. Each of these terms appears only in one inequality. So for u at time t, the term is:

$$r_1 = -2\gamma(1-\rho)^{t-u}. \tag{83}$$

For much the same reasons, r_2 is also easy to derive and is:

$$r_2 = 4L\gamma^2 C_1(1-\rho)^{t-u}. \tag{84}$$

r_3 is a bit trickier, because for a given $v > 0$ there are several H_u which contain e_v. The key insight is that we can rewrite our double sum in the following manner:

$$\begin{aligned}
&\sum_{u=0}^{t}(1-\rho)^{t-u}\sum_{v=1}^{u-1}(1-\frac{1}{n})^{(u-2\tau-v-1)_+}e_v \\
&\quad= \sum_{v=1}^{t-1}e_v\sum_{u=v+1}^{t}(1-\rho)^{t-u}(1-\frac{1}{n})^{(u-2\tau-v-1)_+} \\
&\quad\le \sum_{v=1}^{t-1}e_v\Big[\sum_{u=v+1}^{\min(t,v+2\tau)}(1-\rho)^{t-u} + \sum_{u=v+2\tau+1}^{t}(1-\rho)^{t-u}(1-\frac{1}{n})^{u-2\tau-v-1}\Big] \\
&\quad\le \sum_{v=1}^{t-1}e_v\Big[2\tau(1-\rho)^{t-v-2\tau} + (1-\rho)^{t-v-2\tau-1}\sum_{u=v+2\tau+1}^{t}q^{u-2\tau-v-1}\Big] \\
&\quad\le \sum_{v=1}^{t-1}(1-\rho)^{t-v}e_v(1-\rho)^{-2\tau-1}\big[2\tau + \frac{1}{1-q}\big],
\end{aligned} \tag{85}$$

where we have defined:

$$q := \frac{1-1/n}{1-\rho}, \quad \text{with the assumption } \rho < \frac{1}{n}\,. \tag{86}$$

Note that we have bounded the $\min(t, v+2\tau)$ term by $v+2\tau$ in the first sub-sum, effectively adding more positive terms.

This gives us that at time t, for u:

$$r_3 \le \frac{4L\gamma^2 C_1}{n}(1-\rho)^{t-u}(1-\rho)^{-2\tau-1}\big[2\tau + \frac{1}{1-q}\big]. \tag{87}$$

For r_4 we use the same trick:

$$\begin{aligned}
\sum_{u=0}^{t}(1-\rho)^{t-u}\sum_{v=(u-\tau)_+}^{u-1}e_v &= \sum_{v=0}^{t-1}e_v\sum_{u=v+1}^{\min(t,v+\tau)}(1-\rho)^{t-u} \\
&\le \sum_{v=0}^{t-1}e_v\sum_{u=v+1}^{v+\tau}(1-\rho)^{t-u} \le \sum_{v=0}^{t-1}e_v\tau(1-\rho)^{t-v-\tau}.
\end{aligned} \tag{88}$$

This gives us that at time t, for u:

$$r_4 \leq 4L\gamma^2 C_2(1-\rho)^{t-u}\tau(1-\rho)^{-\tau}\,. \tag{89}$$

Finally we compute r_5 which is the most complicated term. Indeed, to find the factor of e_w for a given $w>0$, one has to compute a triple sum, $\sum_{u=0}^{t}(1-\rho)^{t-u}\sum_{v=(u-\tau)_+}^{u-1} H_v$. We start by computing the factor of e_w in the inner double sum, $\sum_{v=(u-\tau)_+}^{u-1} H_v$.

$$\sum_{v=(u-\tau)_+}^{u-1}\sum_{w=1}^{v-1}(1-\frac{1}{n})^{(v-2\tau-w-1)_+}e_w = \sum_{w=1}^{u-2}e_w \sum_{v=\max(w+1,u-\tau)}^{u-1}(1-\frac{1}{n})^{(v-2\tau-w-1)_+}\,. \tag{90}$$

Now there are at most τ terms for each e_w. If $w \leq u-3\tau-1$, then the exponent is positive in every term and it is always bigger than $u-3\tau-1-w$, which means we can bound the sum by $\tau(1-\frac{1}{n})^{u-3\tau-1-w}$. Otherwise we can simply bound the sum by τ. We get:

$$\sum_{v=(u-\tau)_+}^{u-1} H_v \leq \sum_{w=1}^{u-2}\big[\mathbb{1}_{\{u-3\tau\leq w\leq u-2\}}\tau + \mathbb{1}_{\{w\leq u-3\tau-1\}}\tau(1-\frac{1}{n})^{u-3\tau-1-w}\big]e_w\,. \tag{91}$$

This means that for w at time t:

$$\begin{aligned}
r_5 &\leq \frac{4L\gamma^2C_2}{n}\sum_{u=0}^{t}(1-\rho)^{t-u}\big[\mathbb{1}_{\{u-3\tau\leq w\leq u-2\}}\tau + \mathbb{1}_{\{w\leq u-3\tau-1\}}\tau(1-\frac{1}{n})^{u-3\tau-1-w}\big]\\
&\leq \frac{4L\gamma^2C_2}{n}\Big[\sum_{u=w+2}^{\min(t,w+3\tau)}\tau(1-\rho)^{t-u} + \sum_{u=w+3\tau+1}^{t}\tau(1-\frac{1}{n})^{u-3\tau-1-w}(1-\rho)^{t-u}\Big]\\
&\leq \frac{4L\gamma^2C_2}{n}\tau\Big[(1-\rho)^{t-w}(1-\rho)^{-3\tau}3\tau\\
&\qquad + (1-\rho)^{t-w}(1-\rho)^{-1-3\tau}\sum_{u=w+3\tau+1}^{t}(1-\frac{1}{n})^{u-3\tau-1-w}(1-\rho)^{-u+3\tau+1+w}\Big]\\
&\leq \frac{4L\gamma^2C_2}{n}\tau(1-\rho)^{t-w}(1-\rho)^{-3\tau-1}\big(3\tau+\frac{1}{(1-q)}\big)\,.
\end{aligned} \tag{92}$$

By combining the five terms together (83, 84, 87, 89 and 92), we get that $\forall u$ s.t. $1\leq u\leq t$:

$$\begin{aligned}
r_u^t \leq (1-\rho)^{t-u}\Big[&-2\gamma + 4L\gamma^2C_1 + \frac{4L\gamma^2C_1}{n}(1-\rho)^{-2\tau-1}\big(2\tau+\frac{1}{1-q}\big)\\
&+4L\gamma^2C_2\tau(1-\rho)^{-\tau} + \frac{4L\gamma^2C_2}{n}\tau(1-\rho)^{-3\tau-1}\big(3\tau+\frac{1}{1-q}\big)\Big].
\end{aligned} \tag{93}$$

Computation of r_0^t. Recall that we treat the $\tilde{e}_0$ term separately in Section B.3. The initialization of Saga creates an initial synchronization, which means that the contribution of $\tilde{e}_0$ in our bound on $\mathbb{E}\|g_t\|^2$ (75) is roughly n times bigger than the contribution of any e_u for $1<u<t$.[29] In order to safely handle this term in our Lyapunov inequality, we only need to prove that it is bounded by a reasonable constant. Here again, we split r_0^t in five contributions coming from (81):

29. This is explained in details right before (74).

- r_1, the part coming from the $-2\gamma e_u$ terms;
- r_2, coming from $4L\gamma^2C_1e_u$;
- r_3, coming from $4L\gamma^2C_1(1-\frac{1}{n})^{(u-\tau)_+}\tilde{e}_0$;
- r_4, coming from $4L\gamma^2C_2\sum_{v=(u-\tau)_+}^{u-1}e_v$;
- r_5, coming from $4L\gamma^2C_2\sum_{v=(u-\tau)_+}^{u-1}(1-\frac{1}{n})^{(v-\tau)_+}\tilde{e}_0$.

Note that there is no $\tilde{e}_0$ in H_t, which is why we can safely ignore these terms here.

We have $r_1 = -2\gamma(1-\rho)^t$ and $r_2 = 4L\gamma^2C_1(1-\rho)^t$.

Let us compute r_3.

$$\begin{aligned}
&\sum_{u=0}^{t}(1-\rho)^{t-u}(1-\frac{1}{n})^{(u-\tau)_+}\\
&\qquad= \sum_{u=0}^{\min(t,\tau)}(1-\rho)^{t-u} + \sum_{u=\tau+1}^{t}(1-\rho)^{t-u}(1-\frac{1}{n})^{u-\tau}\\
&\qquad\leq (\tau+1)(1-\rho)^{t-\tau} + (1-\rho)^{t-\tau}\sum_{u=\tau+1}^{t}(1-\rho)^{\tau-u}(1-\frac{1}{n})^{u-\tau}\\
&\qquad\leq (1-\rho)^t(1-\rho)^{-\tau}\big(\tau+1+\frac{1}{1-q}\big)\,.
\end{aligned} \tag{94}$$

This gives us:

$$r_3 \leq (1-\rho)^t 4L\gamma^2C_1(1-\rho)^{-\tau}\big(\tau+1+\frac{1}{1-q}\big)\,. \tag{95}$$

We have already computed r_4 for $u>0$ and the computation is exactly the same for $u=0$. $r_4 \leq (1-\rho)^t 4L\gamma^2C_2\frac{\tau}{1-\rho}$.

Finally we compute r_5.

$$\begin{aligned}
&\sum_{u=0}^{t}(1-\rho)^{t-u}\sum_{v=(u-\tau)_+}^{u-1}(1-\frac{1}{n})^{(v-\tau)_+}\\
&\qquad= \sum_{v=1}^{t-1}\sum_{u=v+1}^{\min(t,v+\tau)}(1-\rho)^{t-u}(1-\frac{1}{n})^{(v-\tau)_+}\\
&\qquad\leq \sum_{v=1}^{\min(t-1,\tau)}\sum_{u=v+1}^{v+\tau}(1-\rho)^{t-u} + \sum_{v=\tau+1}^{t-1}\sum_{u=v+1}^{\min(t,v+\tau)}(1-\rho)^{t-u}(1-\frac{1}{n})^{v-\tau}\\
&\qquad\leq \tau^2(1-\rho)^{t-2\tau} + \sum_{v=\tau+1}^{t-1}(1-\frac{1}{n})^{v-\tau}\tau(1-\rho)^{t-v-\tau}\\
&\qquad\leq \tau^2(1-\rho)^{t-2\tau} + \tau(1-\rho)^t(1-\rho)^{-2\tau}\sum_{v=\tau+1}^{t-1}(1-\frac{1}{n})^{v-\tau}\tau(1-\rho)^{-v+\tau}\\
&\qquad\leq (1-\rho)^t(1-\rho)^{-2\tau}\big(\tau^2+\tau\frac{1}{1-q}\big)\,.
\end{aligned} \tag{96}$$

Which means:

$$r_5 \leq (1-\rho)^t 4L\gamma^2 C_2 (1-\rho)^{-2\tau}\big(\tau^2 + \tau\frac{1}{1-q}\big). \tag{97}$$

Putting it all together, we get that: $\forall t \geq 0$,

$$r_0^t \leq (1-\rho)^t\Big[\Big(-2\gamma + 4L\gamma^2 C_1 + 4L\gamma^2 C_2 \frac{\tau}{1-\rho}\Big)\frac{e_0}{\tilde{e}_0} + 4L\gamma^2 C_1 (1-\rho)^{-\tau}\big(\tau + 1 + \frac{1}{1-q}\big) + 4L\gamma^2 C_2 \tau (1-\rho)^{-2\tau}\big(\tau + \frac{1}{1-q}\big)\Big]. \tag{98}$$

Sufficient condition for convergence. We need all $r_u^t, u \geq 1$ to be negative so we can safely drop them from (82). Note that for every u, this is the same condition. We will reduce that condition to a second-order polynomial sign condition. We also remark that since $\gamma \geq 0$, we can upper bound our terms in γ and γ^2 in this upcoming polynomial, which will give us sufficient conditions for convergence.

Now, recall that $C_2(\gamma)$ (as defined in (17)) depends on γ. We thus need to expand it once more to find our conditions. We have:

$$C_1 = 1 + \sqrt{\Delta}\tau; \qquad C_2 = \sqrt{\Delta} + \gamma\mu C_1\,.$$

Dividing the bracket in (93) by γ and rearranging as a second degree polynomial, we get the condition:

$$4L\left(C_1 + \frac{C_1}{n}(1-\rho)^{-2\tau-1}\Big[2\tau + \frac{1}{1-q}\Big] + \Big[\frac{\sqrt{\Delta}\tau}{(1-\rho)^{\tau}} + \frac{\sqrt{\Delta}\tau}{n}(1-\rho)^{-3\tau-1}(3\tau + \frac{1}{1-q})\Big]\right)\gamma + 8\mu C_1 L\tau\Big[(1-\rho)^{-\tau} + \frac{1}{n}(1-\rho)^{-3\tau-1}(3\tau + \frac{1}{1-q})\Big]\gamma^2 + 2 \leq 0\,. \tag{99}$$

The discriminant of this polynomial is always positive, so γ needs to be between its two roots. The smallest is negative, so the condition is not relevant to our case (where $\gamma > 0$). By solving analytically for the positive root ϕ, we get an upper bound condition on γ that can be used for any overlap τ and guarantee convergence. Unfortunately, for large τ, the upper bound becomes exponentially small because of the presence of τ in the exponent in (99). More specifically, by using the bound $1/(1-\rho) \leq \exp(2\rho)$[30] and thus $(1-\rho)^{-\tau} \leq \exp(2\tau\rho)$ in (99), we would obtain factors of the form $\exp(\tau/n)$ in the denominator for the root ϕ (recall that $\rho < 1/n$).

Our Lemma 14 is derived instead under the assumption that $\tau \leq \mathcal{O}(n)$, with the constants chosen in order to make the condition (99) more interpretable and to relate our convergence result with the standard SAGA convergence (see Theorem 2). As explained in Section 6.7, the assumption that $\tau \leq \mathcal{O}(n)$ appears reasonable in practice. First, by using Bernoulli's inequality, we have:

$$(1-\rho)^{k\tau} \geq 1 - k\tau\rho \qquad \text{for integers} \quad k\tau \geq 0\,. \tag{100}$$

30. This bound can be derived from the inequality $(1 - x/2) \geq \exp(-x)$ which is valid for $0 \leq x \leq 1.59$.

To get manageable constants, we make the following slightly more restrictive assumptions on the target rate ρ[31] and overlap τ:[32]

$$\rho \leq \frac{1}{4n} \tag{101}$$

$$\tau \leq \frac{n}{10}\,. \tag{102}$$

We then have:

$$\frac{1}{1-q} \leq \frac{4n}{3} \tag{103}$$

$$\frac{1}{1-\rho} \leq \frac{4}{3} \tag{104}$$

$$k\tau\rho \leq \frac{3}{40} \qquad \text{for } 1 \leq k \leq 3 \tag{105}$$

$$(1-\rho)^{-k\tau} \leq \frac{1}{1-k\tau\rho} \leq \frac{40}{37} \qquad \text{for } 1 \leq k \leq 3 \text{ and by using (100).} \tag{106}$$

We can now upper bound loosely the three terms in brackets appearing in (99) as follows:

$$(1-\rho)^{-2\tau-1}\big[2\tau + \frac{1}{1-q}\big] \leq 3n \tag{107}$$

$$\sqrt{\Delta}\tau(1-\rho)^{-\tau} + \frac{\sqrt{\Delta}\tau}{n}(1-\rho)^{-3\tau-1}(3\tau + \frac{1}{1-q}) \leq 4\sqrt{\Delta}\tau \leq 4C_1 \tag{108}$$

$$(1-\rho)^{-\tau} + \frac{1}{n}(1-\rho)^{-3\tau-1}(3\tau + \frac{1}{1-q}) \leq 4\,. \tag{109}$$

By plugging (107)–(109) into (99), we get the simpler sufficient condition on γ:

$$-1 + 16LC_1\gamma + 16LC_1\mu\tau\gamma^2 \leq 0\,. \tag{110}$$

The positive root ϕ is:

$$\phi = \frac{16LC_1(\sqrt{1 + \frac{\mu\tau}{4LC_1}} - 1)}{32LC_1\mu\tau} = \frac{\sqrt{1 + \frac{\mu\tau}{4LC_1}} - 1}{2\mu\tau}\,. \tag{111}$$

We simplify it further by using the inequality:[33]

$$\sqrt{x} - 1 \geq \frac{x-1}{2\sqrt{x}} \qquad \forall x > 0\,. \tag{112}$$

Using (112) in (111), and recalling that $\kappa := L/\mu$, we get:

$$\phi \geq \frac{1}{16LC_1\sqrt{1 + \frac{\tau}{4\kappa C_1}}}\,. \tag{113}$$

31. Note that we already expected $\rho < 1/n$.

32. This bound on τ is reasonable in practice, see Appendix 6.7.

33. This inequality can be derived by using the concavity property $f(y) \leq f(x) + (y-x)f'(x)$ on the differentiable concave function $f(x) = \sqrt{x}$ with $y = 1$.

Since $\frac{\tau}{C_1} = \frac{\tau}{1+\sqrt{\Delta}\tau} \leq \min(\tau, \frac{1}{\sqrt{\Delta}})$, we get that a sufficient condition on our step size is:

$$\gamma \leq \frac{1}{16L(1+\sqrt{\Delta}\tau)\sqrt{1+\frac{1}{4\kappa}\min(\tau, \frac{1}{\sqrt{\Delta}})}}\,. \tag{114}$$

Subject to our conditions on γ, ρ and τ, we then have that: $r_u^t \leq 0$ for all u s.t. $1 \leq u \leq t$. This means we can rewrite (82) as:

$$\mathcal{L}_{t+1} \leq (1-\rho)^{t+1}a_0 + (1-\frac{\gamma\mu}{2})\mathcal{L}_t + r_0^t\tilde{e}_0\,. \tag{115}$$

Now, we could finish the proof from this inequality, but it would only give us a convergence result in terms of $a_t = \mathbb{E}\|x_t - x^*\|^2$. A better result would be in terms of the suboptimality at $\hat{x}_t$ (because $\hat{x}_t$ is a real quantity in the algorithm whereas x_t is virtual). Fortunately, to get such a result, we can easily adapt (115).

We make e_t appear on the left side of (115), by adding γ to r_t^t in (82):[34]

$$\gamma e_t + \mathcal{L}_{t+1} \leq (1-\rho)^{t+1}a_0 + (1-\frac{\gamma\mu}{2})\mathcal{L}_t + \sum_{u=1}^{t-1} r_u^t e_u + r_0^t\tilde{e}_0 + (r_t^t + \gamma)e_t. \tag{116}$$

We now require the stronger property that $\gamma + r_t^t \leq 0$, which translates to replacing -2γ with $-\gamma$ in (93):

$$\begin{aligned} 0 \geq \Big[&-\gamma + 4L\gamma^2 C_1 + \frac{4L\gamma^2 C_1}{n}(1-\rho)^{-2\tau-1}\big(2\tau + \frac{1}{1-q}\big) \\ &+ 4L\gamma^2 C_2 \tau(1-\rho)^{-\tau} + \frac{4L\gamma^2 C_2}{n}\tau(1-\rho)^{-3\tau}\big(3\tau + \frac{1}{1-q}\big)\Big]. \end{aligned} \tag{117}$$

We can easily derive a new stronger condition on γ under which we can drop all the $e_u, u > 0$ terms in (116):

$$\gamma \leq \gamma^* = \frac{1}{32L(1+\sqrt{\Delta}\tau)\sqrt{1+\frac{1}{8\kappa}\min(\tau, \frac{1}{\sqrt{\Delta}})}}, \tag{118}$$

and thus under which we get:

$$\gamma e_t + \mathcal{L}_{t+1} \leq (1-\rho)^{t+1}a_0 + (1-\frac{\gamma\mu}{2})\mathcal{L}_t + r_0^t\tilde{e}_0. \tag{119}$$

This finishes the proof of Lemma 14. ■

34. We could use any multiplier from 0 to 2γ, but choose γ for simplicity. For this reason and because our analysis of the r_t^t term was loose, we could derive a tighter bound, but it does not change the leading terms.

B.8. Proof of Theorem 8 (convergence guarantee and rate of Asaga)

End of Lyapunov convergence. We continue with the assumptions of Lemma 14 which gave us (119). Thanks to (98), we can also rewrite $r_0^t \leq (1-\rho)^{t+1}A$ where A is a constant which depends on n, Δ, γ and L but is finite and crucially does not depend on t. In fact, by reusing similar arguments as in B.7, we can show the loose bound $A \leq \gamma n$ under the assumptions of Lemma 14 (including $\gamma \leq \gamma^*$).[35] We then have:

$$\begin{aligned} \mathcal{L}_{t+1} \leq \gamma e_t + \mathcal{L}_{t+1} &\leq (1-\frac{\gamma\mu}{2})\mathcal{L}_t + (1-\rho)^{t+1}(a_0 + A\tilde{e}_0) \\ &\leq (1-\frac{\gamma\mu}{2})^{t+1}\mathcal{L}_0 + (a_0 + A\tilde{e}_0)\sum_{k=0}^{t+1}(1-\rho)^{t+1-k}(1-\frac{\gamma\mu}{2})^k. \end{aligned} \tag{120}$$

We have two linearly contracting terms. The sum contracts linearly with the minimum geometric rate factor between $\gamma\mu/2$ and ρ. If we define $m := \min(\rho, \gamma\mu/2)$, $M := \max(\rho, \gamma\mu/2)$ and $\rho^* := \nu m$ with $0 < \nu < 1$,[36] we then get:[37]

$$\begin{aligned} \gamma e_t \leq \gamma e_t + \mathcal{L}_{t+1} &\leq (1-\frac{\gamma\mu}{2})^{t+1}\mathcal{L}_0 + (a_0 + A\tilde{e}_0)\sum_{k=0}^{t+1}(1-m)^{t+1-k}(1-M)^k \\ &\leq (1-\frac{\gamma\mu}{2})^{t+1}\mathcal{L}_0 + (a_0 + A\tilde{e}_0)\sum_{k=0}^{t+1}(1-\rho^*)^{t+1-k}(1-M)^k \\ &\leq (1-\frac{\gamma\mu}{2})^{t+1}\mathcal{L}_0 + (a_0 + A\tilde{e}_0)(1-\rho^*)^{t+1}\sum_{k=0}^{t+1}(1-\rho^*)^{-k}(1-M)^k \\ &\leq (1-\frac{\gamma\mu}{2})^{t+1}\mathcal{L}_0 + (1-\rho^*)^{t+1}\frac{1}{1-\eta}(a_0 + A\tilde{e}_0) \\ &\leq (1-\rho^*)^{t+1}\big(a_0 + \frac{1}{1-\eta}(a_0 + A\tilde{e}_0)\big), \end{aligned} \tag{121}$$

where $\eta := \frac{1-M}{1-\rho^*}$. We have $\frac{1}{1-\eta} = \frac{1-\rho^*}{M-\rho^*}$.

By taking $\nu = \frac{4}{5}$ and setting $\rho = \frac{1}{4n}$ – its maximal value allowed by the assumptions of Lemma 14 – we get $M \geq \frac{1}{4n}$ and $\rho^* \leq \frac{1}{5n}$, which means $\frac{1}{1-\eta} \leq 20n$. All told, using $A \leq \gamma n$, we get:

$$e_t \leq (1-\rho^*)^{t+1}\tilde{C}_0, \tag{122}$$

where:

$$\tilde{C}_0 := \frac{21n}{\gamma}\Big(\|x_0 - x^*\|^2 + \gamma\frac{n}{2L}\mathbb{E}\|\alpha_i^0 - f_i'(x^*)\|^2\Big)\,. \tag{123}$$

Since we set $\rho = \frac{1}{4n}, \nu = \frac{4}{5}$, we have $\nu\rho = \frac{1}{5n}$. Using a step size $\gamma = \frac{a}{L}$ as in Theorem 8, we get $\nu\frac{\gamma\mu}{2} = \frac{2a}{5\kappa}$. We thus obtain a geometric rate of $\rho^* = \min\{\frac{1}{5n}, a\frac{2}{5\kappa}\}$, which we simplified

35. In particular, note that e_0 does not appear in the definition of A because it turns out that the parenthesis group multiplying e_0 in (98) is negative. Indeed, it contains less positive terms than (93) which we showed to be negative under the assumptions from Lemma 14.

36. ν is introduced to circumvent the problematic case where ρ and $\gamma\mu/2$ are too close together, which does not prevent the geometric convergence, but makes the constant $\frac{1}{1-\eta}$ potentially very big (in the case both terms are equal, the sum even becomes an annoying linear term in t).

37. Note that if $m \neq \rho$, we can perform the index change $t+1-k \to k$ to get the sum.

to $\frac{1}{5}\min\{\frac{1}{n}, a\frac{1}{\kappa}\}$ in Theorem 8, finishing the proof. We also observe that $\tilde{C}_0 \leq \frac{60n}{\gamma} C_0$, with C_0 defined in Theorem 2. ■

B.9. Proof of Corollary 9 (speedup regimes for Asaga)

Referring to Hofmann et al. (2015) and our own Theorem 2, the geometric rate factor of Saga is $\frac{1}{5}\min\{\frac{1}{n}, \frac{a}{\kappa}\}$ for a step size of $\gamma = \frac{a}{5L}$. We start by proving the first part of the corollary which considers the step size $\gamma = \frac{a}{L}$ with $a = a^*(\tau)$. We distinguish between two regimes to study the parallel speedup our algorithm obtains and to derive a condition on τ for which we have a linear speedup.

Well-conditioned regime. In this regime, $n > \kappa$ and the geometric rate factor of sequential Saga is $\frac{1}{5n}$. To get a linear speedup (up to a constant factor), we need to enforce $\rho^* = \Omega(\frac{1}{n})$. We recall that $\rho^* = \min\{\frac{1}{5n}, a\frac{1}{5\kappa}\}$.

We already have $\frac{1}{5n} = \Omega(\frac{1}{n})$. This means that we need τ to verify $\frac{a^*(\tau)}{5\kappa} = \Omega(\frac{1}{n})$, where $a^*(\tau) = \frac{1}{32\left(1+\tau\sqrt{\Delta}\right)\xi(\kappa,\Delta,\tau)}$ according to Theorem 8. Recall that $\xi(\kappa,\Delta,\tau) := \sqrt{1 + \frac{1}{8\kappa}\min\{\frac{1}{\sqrt{\Delta}}, \tau\}}$. Up to a constant factor, this means we can give the following sufficient condition:

$$\frac{1}{\kappa\left(1+\tau\sqrt{\Delta}\right)\xi(\kappa,\Delta,\tau)} = \Omega\Big(\frac{1}{n}\Big) \tag{124}$$

i.e.

$$\left(1+\tau\sqrt{\Delta}\right)\xi(\kappa,\Delta,\tau) = \mathcal{O}\Big(\frac{n}{\kappa}\Big)\,. \tag{125}$$

We now consider two alternatives, depending on whether κ is bigger than $\frac{1}{\sqrt{\Delta}}$ or not. If $\kappa \geq \frac{1}{\sqrt{\Delta}}$, then $\xi(\kappa,\Delta,\tau) < 2$ and we can rewrite the sufficient condition (125) as:

$$\tau = \mathcal{O}(1)\frac{n}{\kappa\sqrt{\Delta}}. \tag{126}$$

In the alternative case, $\kappa \leq \frac{1}{\sqrt{\Delta}}$. Since $a^*(\tau)$ is decreasing in τ, we can suppose $\tau \geq \frac{1}{\sqrt{\Delta}}$ without loss of generality and thus $\xi(\kappa,\Delta,\tau) = \sqrt{1+\frac{1}{8\kappa\sqrt{\Delta}}}$. We can then rewrite the sufficient condition (125) as:

$$\begin{aligned}\frac{\tau\sqrt{\Delta}}{\sqrt{\kappa}\sqrt[4]{\Delta}} &= \mathcal{O}(\frac{n}{\kappa})\,;\\ \tau &= \mathcal{O}(1)\frac{n}{\sqrt{\kappa}\sqrt[4]{\Delta}}\,.\end{aligned} \tag{127}$$

We observe that since we have supposed that $\kappa \leq \frac{1}{\sqrt{\Delta}}$, we have $\sqrt{\kappa\sqrt{\Delta}} \leq \kappa\sqrt{\Delta} \leq 1$, which means that our initial assumption that $\tau < \frac{n}{10}$ is stronger than condition (127).

We can now combine both cases to get the following sufficient condition for the geometric rate factor of Asaga to be the same order as sequential Saga when $n > \kappa$:

$$\tau = \mathcal{O}(1)\frac{n}{\kappa\sqrt{\Delta}}; \quad \tau = \mathcal{O}(n)\,. \tag{128}$$

Ill-conditioned regime. In this regime, $\kappa > n$ and the geometric rate factor of sequential Saga is $a\frac{1}{\kappa}$. Here, to obtain a linear speedup, we need $\rho^* = \mathcal{O}(\frac{1}{\kappa})$. Since $\frac{1}{n} > \frac{1}{\kappa}$, all we require is that $\frac{a^*(\tau)}{\kappa} = \Omega(\frac{1}{\kappa})$ where $a^*(\tau) = \frac{1}{32\left(1+\tau\sqrt{\Delta}\right)\xi(\kappa,\Delta,\tau)}$, which reduces to $a^*(\tau) = \Omega(1)$.

We can give the following sufficient condition:

$$\frac{1}{\left(1+\tau\sqrt{\Delta}\right)\xi(\kappa,\Delta,\tau)} = \Omega(1) \tag{129}$$

Using that $\frac{1}{n} \leq \Delta \leq 1$ and that $\kappa > n$, we get that $\xi(\kappa,\Delta,\tau) \leq 2$, which means our sufficient condition becomes:

$$\begin{aligned}\tau\sqrt{\Delta} &= \mathcal{O}(1)\\ \tau &= \frac{\mathcal{O}(1)}{\sqrt{\Delta}}.\end{aligned} \tag{130}$$

This finishes the proof for the first part of Corollary 9.

Universal step size. If $\tau = \mathcal{O}(\frac{1}{\sqrt{\Delta}})$, then $\xi(\kappa,\Delta,\tau) = \mathcal{O}(1)$ and $(1+\tau\sqrt{\Delta}) = \mathcal{O}(1)$, and thus $a^*(\tau) = \Omega(1)$ (for any n and κ). This means that the universal step size $\gamma = \Theta(1/L)$ satisfies $\gamma \leq a^*(\tau)$ for any κ, giving the same rate factor $\Omega(\min\{\frac{1}{n}, \frac{1}{\kappa}\})$ that sequential Saga has, completing the proof for the second part of Corollary 9. ■

Appendix C. Kromagnon – Proof of Theorem 15 and Corollary 18

C.1. Proof of Lemma 19 (suboptimality bound on $\mathbb{E}\|g_t\|^2$)

Mania et al. (2017, Lemma 9), tells us that for serial sparse Svrg we have for all $km \leq t \leq (k+1)m-1$:

$$\mathbb{E}\|g_t\|^2 \leq 2\mathbb{E}\|f'_{i_t}(\hat{x}_t) - f'_{i_t}(x^*)\|^2 + 2\mathbb{E}\|f'_{i_t}(\hat{x}_k) - f'_{i_t}(x^*)\|^2. \tag{131}$$

This remains true in the case of Kromagnon. We can use Hofmann et al. (2015, Equations 7 and 8) to bound both terms in the following manner:

$$\mathbb{E}\|g_t\|^2 \leq 4L(\mathbb{E}f(\hat{x}_t) - f(x^*)) + 4L(\mathbb{E}f(\tilde{x}_k) - f(x^*)) \leq 4Le_t + 4L\tilde{e}_k\,. \tag{132}$$

■

C.2. Proof of Theorem 15 (convergence guarantee and rate of Kromagnon)

Master inequality derivation. As in our Asaga analysis, we plug Lemma 19 in Lemma 10, which gives us that for all $k \geq 0, km \leq t \leq (k+1)m-1$:

$$a_{t+1} \leq (1-\frac{\gamma\mu}{2})a_t + \gamma^2 C_1(4Le_t + 4L\tilde{e}_k) + \gamma^2 C_2 \sum_{u=\max(km,t-\tau)}^{t-1} (4Le_t + 4L\tilde{e}_k) - 2\gamma e_t\,. \tag{133}$$

By grouping the $\tilde{e}_k$ and the e_t terms we get our master inequality (42):

$$a_{t+1} \leq (1 - \frac{\gamma\mu}{2})a_t + (4L\gamma^2 C_1 - 2\gamma)e_t + 4L\gamma^2 C_2 \sum_{u=\max(km,t-\tau)}^{t-1} e_u + (4L\gamma^2 C_1 + 4L\gamma^2\tau C_2)\tilde{e}_k \,.$$

Contraction inequality derivation. We now adopt the same method as in the original Svrg paper (Johnson and Zhang, 2013); we sum the master inequality over a whole epoch and then we use the randomization trick:

$$\tilde{e}_k = \mathbb{E}f(\tilde{x}_k) - f(x^*) = \frac{1}{m}\sum_{t=(k-1)m}^{km-1} e_t \tag{134}$$

This gives us:

$$\begin{aligned}\sum_{t=km+1}^{(k+1)m} a_t \leq &(1 - \frac{\gamma\mu}{2})\sum_{t=km}^{(k+1)m-1} a_t + (4L\gamma^2 C_1 - 2\gamma)\sum_{t=km}^{(k+1)m-1} e_t \\ &+ 4L\gamma^2 C_2 \sum_{t=km}^{(k+1)m-1}\sum_{u=\max(km,t-\tau)}^{t-1} e_u + m(4L\gamma^2 C_1 + 4L\gamma^2\tau C_2)\tilde{e}_k \,.\end{aligned} \tag{135}$$

Since $1 - \frac{\gamma\mu}{2} < 1$, we can upper bound it by 1, and then remove all the telescoping terms from (135). We also have:

$$\begin{aligned}\sum_{t=km}^{(k+1)m-1}\sum_{u=\max(km,t-\tau)}^{t-1} e_u = \sum_{u=km}^{(k+1)m-2}\sum_{t=u+1}^{\min((k+1)m-1,u+\tau)} e_u &\leq \tau \sum_{u=km}^{(k+1)m-2} e_u \\ &\leq \tau \sum_{u=km}^{(k+1)m-1} e_u \,.\end{aligned} \tag{136}$$

All told:

$$a_{(k+1)m} \leq a_{km} + (4L\gamma^2 C_1 + 4L\gamma^2\tau C_2 - 2\gamma)\sum_{t=km}^{(k+1)m-1} e_t + m(4L\gamma^2 C_1 + 4L\gamma^2\tau C_2)\tilde{e}_k \,. \tag{137}$$

Now we use the randomization trick (134):

$$a_{(k+1)m} \leq a_{km} + (4L\gamma^2 C_1 + 4L\gamma^2\tau C_2 - 2\gamma)m\tilde{e}_{k+1} + m(4L\gamma^2 C_1 + 4L\gamma^2\tau C_2)\tilde{e}_k \,. \tag{138}$$

Finally, in order to get a recursive inequality in $\tilde{e}_k$, we can remove the positive $a_{(k+1)m}$ term from the left-hand side of (138) and bound the a_{km} term on the right-hand side by $2e_{km}/\mu$ using a standard strong convexity inequality. We get our final contraction inequality (45):

$$(2\gamma m - 4mL\gamma^2 C_1 - 4mL\gamma^2\tau C_2)\tilde{e}_{k+1} \leq (\frac{2}{\mu} + 4mL\gamma^2 C_1 + 4mL\gamma^2\tau C_2)\tilde{e}_k \,.$$

■

C.3. Proof of Corollary 16, Corollary 17 and Corollary 18 (speedup regimes)

***A simpler result for* Svrg.** The standard convergence rate for serial Svrg is given by:

$$\theta := \frac{\frac{1}{\mu\gamma m} + 2L\gamma}{1 - 2L\gamma} \,. \tag{139}$$

If we define a such that $\gamma = a/4L$, we obtain:

$$\theta = \frac{\frac{4\kappa}{am} + \frac{a}{2}}{1 - \frac{a}{2}} \,. \tag{140}$$

Now, since we need $\theta \leq 1$, we see that we require $a \leq 1$. The optimal value of the denominator is then 1 (when $a = 0$), whereas the worst case value is $1/2$ ($a = 1$). We can thus upper bound θ by replacing the denominator with $1/2$, while satisfied that we do not lose more than a factor of 2. This gives us:

$$\theta \leq \frac{8\kappa}{am} + a \,. \tag{141}$$

Enforcing $\theta \leq 1/2$ can be done easily by choosing $a \leq 1/4$ and $m = 32\kappa/a$. Now, to be able to compare algorithms easily, we want to frame our result in terms of rate factor per gradient computation ρ, such that (38) is verified:

$$\mathbb{E}f(\tilde{x}_k) - f(x^*) \leq (1 - \rho)^{k(2m+n)}\left(\mathbb{E}f(x_0) - f(x^*)\right) \qquad \forall k \geq 0 \,.$$

We define $\rho_b := 1 - \theta$. We want to estimate ρ such that $(1 - \rho)^{2m+n} = 1 - \rho_b$. We get that $\rho = 1 - (1 - \rho_b)^{\frac{1}{2m+n}}$. Using Bernoulli's inequality, we get:

$$\rho \geq \frac{\rho_b}{2m+n} \geq \frac{1}{2(2m+n)} \geq \frac{1}{4}\min\left\{\frac{1}{2m}, \frac{1}{n}\right\} \geq \frac{1}{4}\min\left\{\frac{a}{64\kappa}, \frac{1}{n}\right\} . \tag{142}$$

This finishes the proof for Corollary 16. ■

***A simpler result for* Kromagnon.** We also define a such that $\gamma = a/4L$. Theorem 15 tells us that:

$$\theta = \frac{\frac{4\kappa}{am} + \frac{a}{2}C_3(1 + \frac{\tau}{16\kappa})}{1 - \frac{a}{2}C_3(1 + \frac{\tau}{16\kappa})} \,. \tag{143}$$

We can once again upper bound θ by removing its denominator at a reasonable worst-case cost of a factor of 2:

$$\theta \leq \frac{8\kappa}{am} + aC_3(1 + \frac{\tau}{16\kappa}) \,. \tag{144}$$

Now, to enforce $\theta \leq 1/2$, we can choose $a \leq \frac{1}{4C_3(1+\frac{\tau}{16\kappa})}$ and $m = \frac{32\kappa}{a}$. We also obtain a rate factor per gradient computation of: $\rho \geq \frac{1}{4}\min\{\frac{a}{64\kappa}, \frac{1}{n}\}$. This finishes the proof of Corollary 17. ■

Speedup conditions. All we have to do now is to compare the rate factors of Svrg and Kromagnon in different regimes. Note that while our convergence result hold for any $a \leq 1/4$ Svrg (or the slightly more complex expression in the case of Kromagnon), the best step size (in terms of number of gradient computations) ensuring $\theta \leq \frac{1}{2}$ is the biggest allowable one – thus this is the one we use for our comparison.

Suppose we are in the "well-conditioned" regime where $n \geq \kappa$. The rate factor of Svrg is $\Omega(1/n)$. To make sure we have a linear speedup, we need the rate factor of Kromagnon to also be $\Omega(1/n)$, which means that:

$$\frac{1}{256\kappa C_3 + 16\tau C_3} = \Omega(\frac{1}{n}) \tag{145}$$

Recalling that $C_3 = 1 + 2\tau\sqrt{\Delta}$, we can rewrite (145) as:

$$\kappa = \mathcal{O}(n)\,; \quad \kappa\tau\sqrt{\Delta} = \mathcal{O}(n)\,; \quad \tau = \mathcal{O}(n)\,; \quad \tau^2\sqrt{\Delta} = \mathcal{O}(n)\,. \tag{146}$$

We can condense these conditions down to:

$$\tau = \mathcal{O}(\frac{n}{\kappa\sqrt{\Delta}})\,; \qquad \tau = \mathcal{O}(\sqrt{n\Delta^{-1/2}})\,. \tag{147}$$

Suppose now we are in the "ill-conditioned" regime, where $\kappa \geq n$. The rate factor of Svrg is now $\Omega(1/\kappa)$. To make sure we have a linear speedup, we need the rate factor of Kromagnon to also be $\Omega(1/\kappa)$, which means that:

$$\frac{1}{256\kappa C_3 + 16\tau C_3} = \Omega(\frac{1}{\kappa}) \tag{148}$$

We can derive the following sufficient conditions:

$$\tau = \mathcal{O}(\frac{1}{\sqrt{\Delta}})\,; \qquad \tau = \mathcal{O}(\kappa)\,. \tag{149}$$

Since $\kappa \geq n$, we obtain the conditions of Corollary 18 and thus finish its proof. ■

Appendix D. Hogwild – Proof of Theorem 22 and Corollary 23

D.1. Proof of Lemma 24 (suboptimality bound on $\mathbb{E}\|g_t\|^2$)

As was the case for proving Lemma 13 and Lemma 19, we simply introduce $f_i'(x^*)$ in g_t to derive our bound.

$$\begin{aligned}
\mathbb{E}\|g_t\|^2 = \mathbb{E}\|f_i'(\hat{x}_t)\|^2 &= \mathbb{E}\|f_i'(\hat{x}_t) - f_i'(x^*) + f_i'(x^*)\|^2 \\
&\leq 2\mathbb{E}\|f_i'(\hat{x}_t) - f_i'(x^*)\|^2 + 2\mathbb{E}\|f_i'(x^*)\|^2 \quad (\|a+b\|^2 \leq 2\|a\|^2 + 2\|b\|^2) \\
&\leq 4Le_t + 2\sigma^2\,. \qquad \text{(Hofmann et al. (2015), Eq (7) \& (8))}
\end{aligned}$$

■

D.2. Proof of Theorem 22 (convergence guarantee and rate of Hogwild)

Master inequality derivation. Once again, we plug Lemma 24 into Lemma 10 which gives us:

$$a_{t+1} \leq (1 - \frac{\gamma\mu}{2})a_t + \gamma^2 C_1(4Le_t + 2\sigma^2) + \gamma^2 C_2 \sum_{u=(t-\tau)_+}^{t-1}(4Le_u + 2\sigma^2) - 2\gamma e_t\,. \tag{150}$$

By grouping the e_t and the σ^2 terms we get our master inequality (48):

$$a_{t+1} \leq (1 - \frac{\gamma\mu}{2})a_t + (4L\gamma^2 C_1 - 2\gamma)e_t + 4L\gamma^2 C_2 \sum_{u=(t-\tau)_+}^{t-1} e_u + 2\gamma^2\sigma^2(C_1 + \tau C_2)\,.$$

Contraction inequality derivation (x_t). We now unroll (48) all the way to $t = 0$ to get:

$$\begin{aligned}
a_{t+1} \leq (1 - \frac{\gamma\mu}{2})^{t+1}a_0 &+ \sum_{u=0}^{t}(1 - \frac{\gamma\mu}{2})^{t-u}(4L\gamma^2 C_1 - 2\gamma)e_u \\
&+ \sum_{u=0}^{t}(1 - \frac{\gamma\mu}{2})^{t-u}4L\gamma^2 C_2 \sum_{v=(u-\tau)_+}^{u-1} e_v \\
&+ \sum_{u=0}^{t}(1 - \frac{\gamma\mu}{2})^{t-u}2\gamma^2\sigma^2(C_1 + \tau C_2)\,.
\end{aligned} \tag{151}$$

Now we can simplify these terms as follows:

$$\begin{aligned}
\sum_{u=0}^{t}(1 - \frac{\gamma\mu}{2})^{t-u} \sum_{v=(u-\tau)_+}^{u-1} e_v &= \sum_{v=0}^{t-1}\sum_{u=v+1}^{\min(t,v+\tau)}(1 - \frac{\gamma\mu}{2})^{t-u}e_v \\
&= \sum_{v=0}^{t-1}(1 - \frac{\gamma\mu}{2})^{t-v}e_v \sum_{u=v+1}^{\min(t,v+\tau)}(1 - \frac{\gamma\mu}{2})^{v-u} \\
&\leq \sum_{v=0}^{t-1}(1 - \frac{\gamma\mu}{2})^{t-v}e_v\tau(1 - \frac{\gamma\mu}{2})^{-\tau} \\
&\leq \tau(1 - \frac{\gamma\mu}{2})^{-\tau}\sum_{v=0}^{t}(1 - \frac{\gamma\mu}{2})^{t-v}e_v\,.
\end{aligned} \tag{152}$$

This $(1 - \frac{\gamma\mu}{2})^{-\tau}$ term is easily bounded, as we did in (107) for Asaga. Using Bernoulli's inequality (100), we get that if we assume $\tau \leq \frac{1}{\gamma\mu}$,[38]

$$(1 - \frac{\gamma\mu}{2})^{-\tau} \leq 2\,. \tag{153}$$

38. While this assumption on τ may appear restrictive, it is in fact weaker than the condition for a linear speed-up obtained by our analysis in Corollary 23.

We note that the last term in (151) is a geometric sum:

$$\sum_{u=0}^{t}(1-\frac{\gamma\mu}{2})^{t-u}\sigma^2 = \frac{2}{\gamma\mu}\sigma^2\,. \tag{154}$$

We plug (152)–(154) in (151) to obtain (49):

$$a_{t+1} \leq (1-\frac{\gamma\mu}{2})^{t+1}a_0 + (4L\gamma^2C_1 + 8L\gamma^2\tau C_2 - 2\gamma)\sum_{u=0}^{t}(1-\frac{\gamma\mu}{2})^{t-u}e_u + \frac{4\gamma\sigma^2}{\mu}(C_1+\tau C_2)\,.$$

Contraction inequality derivation ($\hat{x}_t$). We now have an contraction inequality for the convergence of x_t to x^*. However, since this quantity does not exist (except if we fix the number of iterations prior to running the algorithm and then wait for all iterations to be finished – an unwieldy solution), we rather want to prove that $\hat{x}_t$ converges to x^*. In order to do this, we use the simple following inequality:

$$\|\hat{x}_t - x^*\|^2 \leq 2a_t + 2\|\hat{x}_t - x_t\|^2\,. \tag{155}$$

We already have a contraction bound on the first term (49). For the second term, we combine (65) with Lemma 24 to get:

$$\mathbb{E}\|\hat{x}_t - x_t\|^2 \leq 4L\gamma^2C_1\sum_{u=(t-\tau)_+}^{t-1} e_u + 2\gamma^2\tau\sigma^2\,. \tag{156}$$

To make it easier to combine with (49), we rewrite (156) as:

$$\begin{aligned}\mathbb{E}\|\hat{x}_t - x_t\|^2 &\leq 4L\gamma^2C_1(1-\frac{\gamma\mu}{2})^{-\tau}\sum_{u=(t-\tau)_+}^{t-1}(1-\frac{\gamma\mu}{2})^{t-1-u}e_u + 2\gamma^2\tau\sigma^2\\ &\leq 8L\gamma^2C_1\sum_{u=(t-\tau)_+}^{t-1}(1-\frac{\gamma\mu}{2})^{t-1-u}e_u + 2\gamma^2\tau\sigma^2\\ &\leq 8L\gamma^2C_1\sum_{u=0}^{t-1}(1-\frac{\gamma\mu}{2})^{t-1-u}e_u + 2\gamma^2\tau\sigma^2\,.\end{aligned} \tag{157}$$

Combining (49) and (157) gives us (50):

$$\begin{aligned}\mathbb{E}\|\hat{x}_t - x^*\|^2 \leq (1-\frac{\gamma\mu}{2})^{t+1}2a_0 + (\frac{8\gamma(C_1+\tau C_2)}{\mu} + 4\gamma^2C_1\tau)\sigma^2\\ + (24L\gamma^2C_1 + 16L\gamma^2\tau C_2 - 4\gamma)\sum_{u=0}^{t}(1-\frac{\gamma\mu}{2})^{t-u}e_u\,.\end{aligned}$$

Maximum step size condition on γ. To prove Theorem 22, we need an inequality of the following type: $\mathbb{E}\|\hat{x}_t - x_t\|^2 \leq (1-\rho)^t a + b$. To give this form to Equation (50), we need

to remove all the $(e_u, u < t)$ terms from its right-hand side. To safely do so, we need to enforce that all these terms are negative, hence that:

$$24L\gamma^2C_1 + 16L\gamma^2\tau C_2 - 4\gamma \leq 0\,. \tag{158}$$

Plugging the values of C_1 and C_2 we get:

$$4L\mu\tau(1+\sqrt{\Delta}\tau)\gamma^2 + 6L(1+2\sqrt{\Delta}\tau)\gamma - 1 \leq 0\,. \tag{159}$$

As in our Asaga analysis, this reduces to a second-order polynomial sign condition. We remark again that since $\gamma \geq 0$, we can upper bound our terms in γ and γ^2 in this polynomial, which will still give us sufficient conditions for convergence. This means if we define $C_3 := 1 + 2\sqrt{\Delta}\tau$, a sufficient condition is:

$$4L\mu\tau C_3\gamma^2 + 6LC_3\gamma - 1 \leq 0\,. \tag{160}$$

The discriminant of this polynomial is always positive, so γ needs to be between its two roots. The smallest is negative, so the condition is not relevant to our case (where $\gamma > 0$). By solving analytically for the positive root ϕ, we get an upper bound condition on γ that can be used for any overlap τ and guarantee convergence. This positive root is:

$$\phi = \frac{3}{4}\frac{\sqrt{1+\frac{\mu\tau}{2LC_3}}-1)}{LC_3}\,. \tag{161}$$

We simplify it further by using (112):

$$\phi \geq \frac{3}{16LC_3\sqrt{1+\frac{\tau}{2\kappa C_3}}}\,. \tag{162}$$

This finishes the proof for Theorem 22. ■

D.3. Proof of Theorem 21 (convergence result for serial Sgd)

In order to analyze Corollary 23, we need to derive the maximum allowable step size for serial Sgd. Note that Sgd verifies a simpler contraction inequality than Lemma 10. For all $t \geq 0$:

$$a_{t+1} \leq (1-\gamma\mu)a_t + \gamma^2\mathbb{E}\|g_t\|^2 - 2\gamma e_t\,, \tag{163}$$

Here, the contraction factor is $(1-\gamma\mu)$ instead of $(1-\frac{\gamma\mu}{2})$ because $\hat{x}_t = x_t$ so there is no need for a triangle inequality to get back $\|x_t - x^*\|^2$ from $\|\hat{x}_t - x^*\|^2$ after we apply our strong convexity bound in our initial recursive inequality (see Section B.1). Lemma 24 also holds for serial Sgd. By plugging it into (163), we get:

$$a_{t+1} \leq (1-\gamma\mu)a_t + (4L\gamma^2 - 2\gamma)e_t + 2\gamma^2\sigma^2\,. \tag{164}$$

We then unroll (164) until $t = 0$ to get:

$$a_{t+1} \leq (1-\gamma\mu)^{t+1}a_0 + (4L\gamma^2 - 2\gamma)\sum_{u=0}^{t}(1-\gamma\mu)^{t-u}e_u + 2\frac{\gamma\sigma^2}{\mu}\,. \tag{165}$$

To get linear convergence up to a ball around the optimum, we need to remove the $(e_u, 0 \leq u \leq t)$ terms from the right-hand side of the equation. To safely do this, we need these terms to be negative, i.e. $4L\gamma^2 - 2\gamma \leq 0$. We can then trivially derive the condition on γ to achieve linear convergence: $\gamma \leq \frac{1}{2L}$.

We see that if $\gamma = a/L$ with $a \leq 1/2$, SGD converges at a geometric rate of at least: $\rho(a) = a/\kappa$, up to a ball of radius $2\frac{\gamma\sigma^2}{\mu}$ around the optimum. Now, to make sure we reach ϵ-accuracy, we need $\frac{2\gamma\sigma^2}{\mu} \leq \epsilon$, i.e. $\gamma \leq \frac{\epsilon\mu}{2\sigma^2}$. All told, in order to get linear convergence to ϵ-accuracy, serial SGD requires $\gamma \leq \min\left\{\frac{1}{2L}, \frac{\epsilon\mu}{2\sigma^2}\right\}$.

D.4. Proof of Corollary 23 (speedup regimes for HOGWILD)

The convergence rate of both SGD and HOGWILD is directly proportional to the step size. Thus, in order to make sure HOGWILD is linearly faster than SGD for any reasonable step size, we need to show that the maximum allowable step size ensuring linear convergence for HOGWILD – given in Theorem 22 – is of the same order as the one for SGD, $\mathcal{O}(1/L)$. Recalling that $\gamma = \frac{a}{L}$, we get the following sufficient condition: $a^*(\tau) = \mathcal{O}(1)$.

Given (46), the definition of $a^*(\tau)$, we require both:

$$\tau\sqrt{\Delta} = \mathcal{O}(1)\,; \qquad \sqrt{1 + \frac{1}{2\kappa}\min\{\frac{1}{\sqrt{\Delta}}, \tau\}} = \mathcal{O}(1)\,. \tag{166}$$

This gives us the final condition on τ for a linear speedup: $\tau = \mathcal{O}(\min\{\frac{1}{\sqrt{\Delta}}, \kappa\})$.

To finish the proof of Corollary 23, we only have to show that under this condition, the size of the ball is of the same order regardless of the algorithm used.

Using $\gamma\mu\tau \leq 1$ and $\tau \leq \frac{1}{\sqrt{\Delta}}$, we get that $(\frac{8\gamma(C_1+\tau C_2)}{\mu} + 4\gamma^2 C_1\tau)\sigma^2 = \mathcal{O}(\frac{\gamma\sigma^2}{\mu})$, which finishes the proof of Corollary 23. Note that these two conditions are weaker than $\tau = \mathcal{O}(\min\{\frac{1}{\sqrt{\Delta}}, \kappa\})$, which allows us to get better bounds in case we want to reach ϵ-accuracy with $\frac{\epsilon\mu}{\sigma^2} \ll \frac{1}{2L}$. ■

Appendix E. On the Difficulty of Parallel Lagged Updates

In the implementation presented in Schmidt et al. (2016), the dense part ($\bar{\alpha}$) of the updates is deferred. Instead of writing dense updates, counters c_d are kept for each coordinate of the parameter vector – which represent the last time these variables were updated – as well as the average gradient $\bar{\alpha}$ for each coordinate. Then, whenever a component $[\hat{x}]_d$ is needed (in order to compute a new gradient), we subtract $\gamma(t - c_d)[\bar{\alpha}]_d$ from it and c_d is set to t. It is possible to do this without modifying the algorithm because $[\bar{\alpha}]_d$ only changes when $[\hat{x}]_d$ also does.

In the sequential setting, this results in the same iterations as performing the updates in a dense fashion, since the coordinates are only stale when they are not used. Note that at the end of an execution all counters have to be subtracted at once to get the true final parameter vector (and to bring every c_d counter to the final t).

In the parallel setting, several issues arise:

- two cores might be attempting to correct the lag at the same time. In which case since updates are done as additions and not replacements (which is necessary to ensure that there are no overwrites), the lag might be corrected multiple times, i.e. overly corrected.

- we would have to read and write atomically to each $[\hat{x}_d], c_d, [\bar{\alpha}]_d$ triplet, which is highly impractical.

- we would need to have an explicit global counter, which we do not in ASAGA (our global counter t being used solely for the proof).

- in the dense setting, updates happen coordinate by coordinate. So at time t the number of $\bar{\alpha}$ updates a coordinate has received from a fixed past time c_d is a random variable, which may differs from coordinate to coordinate. Whereas in the lagged implementation, the multiplier is always $(t - c_d)$ which is a constant (conditional to c_d), which means a potentially different $\hat{x}_t$.

- the trick used in Reddi et al. (2015) for asynchronous parallel SVRG does not apply here because it relies on the fact that the "reference" gradient term in SVRG is constant throughout a whole epoch, which is not the case for SAGA.

All these points mean both that the implementation of such a scheme in the parallel setting would be impractical, and that it would actually yields a different algorithm than the dense version, which would be even harder to analyze. This is confirmed by Pan et al. (2016), where the authors tried to implement a parallel version of the lagged updates scheme and had to alter the algorithm to succeed, obtaining an algorithm with suboptimal performance as a result.

Appendix F. Additional Empirical Details

F.1. Detailed Description of Data Sets

We run our experiments on four data sets. In every case, we run logistic regression for the purpose of binary classification.

RCV1 *($n = 697,641$, $d = 47,236$).* The first is the Reuters Corpus Volume I (RCV1) data set (Lewis et al., 2004), an archive of over 800,000 manually categorized newswire stories made available by Reuters, Ltd. for research purposes. The associated task is a binary text categorization.

URL *($n = 2,396,130$, $d = 3,231,961$).* Our second data set was first introduced in Ma et al. (2009). Its associated task is a binary malicious URL detection. This data set contains more than 2 million URLs obtained at random from Yahoo's directory listing (for the "benign" URLs) and from a large Web mail provider (for the "malicious" URLs). The benign to malicious ratio is 2. Features include lexical information as well as metadata. This data set was obtained from the libsvmtools project.[39]

39. http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/binary.html

Covertype *($n = 581,012$, $d = 54$).* On our third data set, the associated task is a binary classification problem (down from 7 classes originally, following the pre-treatment of Collobert et al., 2002). The features are cartographic variables. Contrarily to the first two, this is a dense data set.

Realsim *($n = 73,218$, $d = 20,958$).* We only use our fourth data set for non-parallel experiments and a specific compare-and-swap test. It constitutes of UseNet articles taken from four discussion groups (simulated auto racing, simulated aviation, real autos, real aviation).

F.2. Implementation Details

Hardware. All experiments were run on a Dell PowerEdge 920 machine with 4 Intel Xeon E7-4830v2 processors with 10 2.2GHz cores each and 384GB 1600 MHz RAM.

Software. All algorithms were implemented in the Scala language and the software stack consisted of a Linux operating system running Scala 2.11.7 and Java 1.6.

We chose this expressive, high level language for our experimentation despite its typical 20x slower performance compared to C because our primary concern was that the code may easily be reused and extended for research purposes (which is harder to achieve with low level, heavily optimized C code; especially for error prone parallel computing).

As a result our timed experiments exhibit sub-optimal running times, e.g. compared to Konečný and Richtárik (2013). This is as we expected. The observed slowdown is both consistent across data sets (roughly 20x) and with other papers that use Scala code (e.g. Mania et al. 2017, Ma et al. 2015, Fig. 2).

Despite this slowdown, our experiments show state-of-the-art results in convergence per number of iterations. Furthermore, the speed-up patterns that we observe for our implementation of Hogwild and Kromagnon are similar to the ones given in Mania et al. (2017); Niu et al. (2011); Reddi et al. (2015) (in various languages).

The code we used to run all the experiments is available at `http://www.di.ens.fr/sierra/research/asaga/`.

Necessity of compare-and-swap operations. Interestingly, we have found necessary to use compare-and-swap instructions in the implementation of Asaga. In Figure 7, we display suboptimality plots using non-thread safe operations and compare-and-swap (CAS) operations. The non-thread safe version starts faster but then fails to converge beyond a specific level of suboptimality, while the compare-and-swap version does converges linearly up to machine precision.

For *compare-and-swap* instructions we used the `AtomicDoubleArray` class from the Google library `Guava`. This class uses an `AtomicLongArray` under the hood (from package `java.util.concurrent.atomic` in the standard Java library), which does indeed benefit from lower-level CPU-optimized instructions.

Efficient storage of the α_i. Storing n gradient may seem like an expensive proposition, but for linear predictor models, one can actually store a single scalar per gradient (as proposed in Schmidt et al., 2016), which is what we do in our implementation of Asaga.

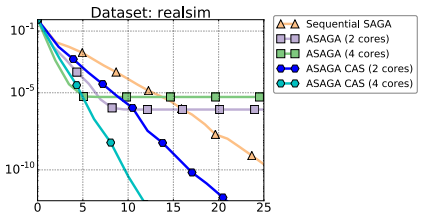

Figure 7: **Compare and swap in the implementation of Asaga.** Suboptimality as a function of time for Asaga, both using compare-and-swap (CAS) operations and using standard operations. The graph reveals that CAS is indeed needed in a practical implementation to ensure convergence to a high precision.

F.3. Biased Update in the Implementation

In the implementation detailed in Algorithm 2, $\bar{\alpha}$ is maintained in memory instead of being recomputed for every iteration. This saves both the cost of reading every data point for each iteration and of computing $\bar{\alpha}$ for each iteration.

However, this removes the unbiasedness guarantee. The problem here is the definition of the expectation of $\hat{\alpha}_i$. Since we are sampling uniformly at random, the average of the $\hat{\alpha}_i$ is taken at the precise moment when we read the α_i^t components. Without synchronization, between two reads to a single coordinate in α_i and in $\bar{\alpha}$, new updates might arrive in $\bar{\alpha}$ that are not yet taken into account in α_i. Conversely, writes to a component of α_i might precede the corresponding write in $\bar{\alpha}$ and induce another source of bias.

In order to alleviate this issue, we can use coordinate-level locks on α_i and $\bar{\alpha}$ to make sure they are always synchronized. Such low-level locks are quite inexpensive when d is large, especially when compared to vector-wide locks.

However, as previously noted, experimental results indicate that this fix is not necessary.

Abstract

In solving hard computational problems, semidefinite program (SDP) relaxations often play an important role because they come with a guarantee of optimality. Here, we focus on a popular semidefinite relaxation of K-means clustering which yields the same solution as the non-convex original formulation for well segregated datasets. We report an unexpected finding: when data contains (greater than zero-dimensional) manifolds, the SDP solution captures such geometrical structures. Unlike traditional manifold embedding techniques, our approach does not rely on manually defining a kernel but rather enforces locality via a nonnegativity constraint. We thus call our approach NOnnegative MAnifold Disentangling, or NOMAD. To build an intuitive understanding of its manifold learning capabilities, we develop a theoretical analysis of NOMAD on idealized datasets. While NOMAD is convex and the globally optimal solution can be found by generic SDP solvers with polynomial time complexity, they are too slow for modern datasets. To address this problem, we analyze a non-convex heuristic and present a new, convex and yet efficient, algorithm, based on the conditional gradient method. Our results render NOMAD a versatile, understandable, and powerful tool for manifold learning.

Keywords: K-means, semidefinite programming, manifolds, conditional gradient method

1. Introduction

In the quest for an algorithmic theory of biological neural networks, some of the authors have recently proposed a soft K-means clustering network that may model insect olfactory processing and other computations (Pehlevan et al., 2017). This network was derived by performing online optimization on the non-convex K-means objective function. Whereas the network dynamics and learning rules are biologically plausible, the nonconvexity of the objective makes it difficult to analyze the solutions and algorithm convergence.

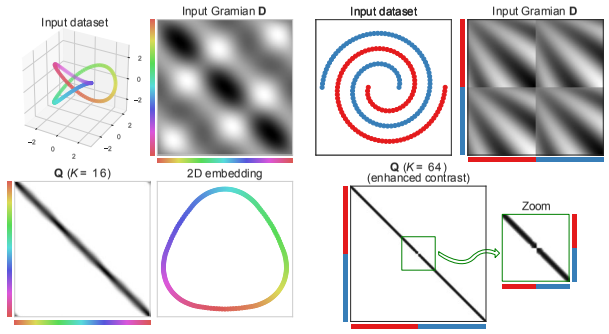
Here, to understand the solutions computed by the clustering neural network, we consider a convex SDP relaxation of K-means (Kulis et al., 2007; Peng and Wei, 2007; Awasthi et al., 2015). Given data points $\{\mathbf{x}_i\}_{i=1}^n$ we define the Gramian matrix, $\mathbf{D}$, such that $(\mathbf{D})_{ij} = {\mathbf{x}_i}^\top \mathbf{x}_j$. Then, we search for a cluster co-association matrix $\mathbf{Q}$, such that $(\mathbf{Q})_{ij} = 1$ if points i and j belong to the same cluster and $(\mathbf{Q})_{ij} = 0$ if they do not. The optimum $\mathbf{Q}_*$ can be found by solving the following optimization problem (the acronym will be explained below):

$$\mathbf{Q}_* = \underset{\mathbf{Q}\in\mathbb{R}^{n\times n}}{\operatorname{argmax}} \operatorname{Tr}(\mathbf{DQ}) \quad \text{s.t.} \quad \mathbf{Q1} = \mathbf{1},\ \operatorname{Tr}(\mathbf{Q}) = K,\ \mathbf{Q} \succeq 0,\ \mathbf{Q} \geq \mathbf{0}. \tag{NOMAD}$$

Its link with the original K-means clustering formulation is explained in Appendix A.[1]

First, we focus on the question: what does NOMAD compute? Until now, theoretical efforts have concentrated on showing that NOMAD is a good surrogate for K-means. Awasthi et al. (2015) study its solutions on datasets consisting of linearly separable clusters and demonstrate that they reproduce hard-clustering assignments of K-means. Moreover, the solution to NOMAD achieves hard clustering even for some datasets on which Lloyd's algorithm (Lloyd, 1982) fails (i.e., Iguchi et al. (2015); Mixon et al. (2016)). Related problems have been studied by Amini and Levina (2014); Javanmard et al. (2015); Yu et al. (2012).

In this work, we analyze NOMAD in a different regime than previous studies. Instead of focusing on cases and parameter settings where it approximates the original K-means formulation, we concentrate on alternative settings and discover that NOMAD is not merely a convex K-means imitator. NOMAD finds the manifold structure in the data, even discriminating different manifolds. Fig. 1 shows two examples of this unexpected behavior where NOMAD dissects the geometry of



(a) (b)

Figure 1: NOMAD, originally introduced as a convex relaxation of K-means clustering, surprisingly learns manifold structures in the data. (a) Learning the manifold of a trefoil knot, which cannot be "untied" in 3D without cutting it. NOMAD understands that this is a closed manifold, yielding a circulant matrix $\mathbf{Q}$, which can be "unfolded" in 2D. (b) Learning multiple manifolds with NOMAD. Although they are linearly non-separable, NOMAD correctly finds two submatrices, one for each manifold (for visual clarity, we enhance the contrast of $\mathbf{Q}$).

1. **Notation.** $(\mathbf{X})_{ij}$, $(\mathbf{X})_{:j}$, $(\mathbf{X})_{i:}$ denote the (i,j)-th entry of matrix $\mathbf{X}$, the j-th column of $\mathbf{X}$, and the i-th row of $\mathbf{X}$, respectively. For vectors, we employ lowercase and we use a similar notation but with a single index. We write $\mathbf{X} \geq \mathbf{0}$ if a matrix $\mathbf{X}$ is entry-wise nonnegative and $\mathbf{X} \succeq \mathbf{0}$ if it is positive semidefinite.

the data. Because of this and of the central role played by the nonnegativity constraint in the SDP we call it a NOnnegative MAnifold Disentangling (NOMAD).

The next question is: how can we compute these solutions? Despite the theoretical advantages of convex optimization, in practice, the use of SDPs for clustering has remained limited. This is mainly due to the lack of efficient algorithms to solve the convex optimization problem. We address this issue by presenting an efficient convex solver for NOMAD, based on the conditional gradient method. The new algorithm can handle large datasets, extending the applicability of NOMAD to more interesting and challenging scenarios.

Organization. We first study the behavior of NOMAD theoretically by analyzing its solution for a simple synthetic example of a regular manifold with symmetry (Sec. 2). In this context, we demonstrate how NOMAD departs from standard K-means. Building on this analysis, we suggest that NOMAD has non-trivial manifold learning capabilities (Sec. 3) and demonstrate numerically NOMAD's good performance in non-trivial examples, including synthetic and real datasets. Then, motivated by the relatively slow performance of standard SDP solvers, we focus on scaling NOMAD to large modern datasets. In Sec. 4, we study both theoretically and experimentally an heuristic non-convex Burer-Monteiro-style algorithm (Kulis et al., 2007). Finally, we present a new convex and yet efficient algorithm for NOMAD. This algorithm allows us, for the first time, to study provable solutions of NOMAD on large datasets. Our software is publicly available at `https://github.com/simonsfoundation/sdp_kmeans`.

2. Theoretical analysis of manifold learning capabilities of NOMAD

Starting with the appearance of Isomap (Tenenbaum et al., 2000) and locally-linear embedding (LLE) (Roweis and Saul, 2000), there has been outstanding progress in the area of manifold learning (e.g., Belkin and Niyogi, 2003; Hadsell et al., 2006; Weinberger and Saul, 2006; Weiss et al., 2008). For a data matrix $\mathbf{X} = [\mathbf{x}_i]_{i=1}^n$ of column-vectors/points $\mathbf{x}_i \in \mathbb{R}^d$, the majority of these modern methods have three steps:

1. Determine the neighbors of each point. This can be done in two ways: (1) keep all point within some fixed radius ρ or (2) compute κ nearest neighbors.
2. Construct a weighting matrix $\mathbf{W}$, where $(\mathbf{W})_{ij} = 0$ if points i and j are not neighbors, and $(\mathbf{W})_{ij}$ is inversely proportional to the distance between points i and j otherwise.
3. Compute an embedding from $\mathbf{W}$ that is locally isometric to $\mathbf{X}$.

For the third step, many different and powerful approaches have been proposed, from computing shortest paths on a graph (Tenenbaum et al., 2000), to using graph spectral methods (Belkin and Niyogi, 2003), to using neural networks (Hadsell et al., 2006).

However, the success of these techniques depends critically on the ability to capture the data structure in the first two steps. Correctly setting either ρ or κ is a non-trivial task that is left to the user of these techniques. Furthermore, a kernel (most commonly an RBF) is often involved in the second step, adding an additional parameter (the kernel width/scale) to the user to determine. Expectedly, the optimal selection of these parameters plays a critical role in the overall success of the manifold learning process.

NOMAD departs drastically from this setup as no kernel selection nor nearest neighbor search are involved. Yet, the solution $\mathbf{Q}_*$ is effectively a kernel which is automatically learned from the data. Because $\mathbf{Q}_*$ is positive semidefinite it can be factorized as $\mathbf{Q}_* = \mathbf{Y}^\top\mathbf{Y}$, defining a feature map from $\mathbf{X}$ to $\mathbf{Y}$.

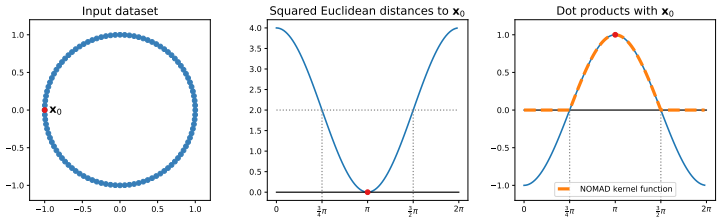


Figure 2: Correspondence between using a kernel/threshold in distance-space and nonnegativity of Gramian-based representations. In this toy example, the constraint $\mathbf{Q} \geq 0$ in NOMAD is equivalent to setting to zero distances that are greater than $\sqrt{2}$ (squared distances greater than 2). We use $\mathbf{x}_0$ as a reference but rotational symmetry makes this argument valid for all points in the dataset.

To illustrate intuitively the differences and similarities with prior work on manifold learning we use LLE (Roweis and Saul, 2000) as an example. LLE optimizes the cost function

$$\Phi(\mathbf{Y}) = \operatorname{Tr}\left((\mathbf{I}-\mathbf{W})^\top(\mathbf{I}-\mathbf{W})\left(\mathbf{Y}^\top\mathbf{Y}\right)\right), \tag{1}$$

where $\mathbf{W}$ is the adjacency matrix of a weighted nearest-neighbors graph. The key to finding a matrix $\mathbf{Y}$ that is locally isometric to $\mathbf{X}$, while unwrapping the data manifold, is to remove from $\mathbf{W}$ the connections between distant points $(\mathbf{X})_{:i}$ and $(\mathbf{X})_{:j}$. This is done with some technique to find nearest neighbors.

NOMAD also tries to align the output Gramian, $\mathbf{Q}$, to the input Gramian, $\mathbf{D}$, but discards distant data points differently. As negative entries in $\mathbf{D}$ cannot be matched because $\mathbf{Q}$ is nonnegative, the best option would be to set the corresponding element of $\mathbf{Q}$ to zero. This effectively discards pairs of input data points whose inner product is negative thus enforcing locality in the angular space (Cho and Saul, 2009), see Fig. 2. In fact, this argument can be taken further by noting that the constraint $\mathbf{Q1} = \mathbf{1}$ allows us to replace the Gramian $\mathbf{D}$ with the negative squared distance matrix,

$$-\tfrac{1}{2}\sum_{ij}\|\mathbf{x}_i-\mathbf{x}_j\|_2^2\,(\mathbf{Q})_{ij} = -\sum_i(\mathbf{D})_{ii}\sum_j(\mathbf{Q})_{ij} + \operatorname{Tr}(\mathbf{DQ}) = -\operatorname{Tr}(\mathbf{D}) + \operatorname{Tr}(\mathbf{DQ}). \tag{2}$$

Finally, the constraint $\operatorname{Tr}(\mathbf{Q}) = K$ allows further control of the neighborhood size of NOMAD (modulating the actual width of its kernel function, see Fig. 2). Next, we develop further intuition about the manifold-learning capabilities of NOMAD by analyzing theoretically the dataset in Fig. 2.

As we mentioned before, the SDP formulation of Peng and Wei (2007) was developed as a clustering algorithm. Whether this method actually delivers a clustered solution depends on the geometry of the dataset. When the dataset consists of well-segregated clusters, the resulting $\mathbf{Q}_*$ has block diagonal structure. We empirically observe that, when the dataset is sampled from a regular manifold, the solution $\mathbf{Q}_*$ does not break down the dataset into artificial clusters and actually preserves the manifold structure (see Sec. 3). In a simple example, where the manifold exhibits a high degree of symmetry, we demonstrate analytically that this behavior occurs. The following sections are devoted to this task.

2.1. Analysis of NOMAD on a 2D ring dataset

We analyze the case in which the input data to NOMAD possess rotational symmetry, i.e., data are arranged uniformly on a ring, see Fig. 2. In this case, we can write the SDP as a linear program (LP) in the circular Fourier basis. This new representation allows to visualize that NOMAD lifts the data into a high-dimensional space, with K controlling its dimensionality.

In the example in Fig. 2, the entries of $\mathbf{D}$ can be described by $(\mathbf{D})_{ij} = \mathbf{x}_i{}^\top \mathbf{x}_j = \cos(\alpha_i - \alpha_j)$, where α_i, α_j are the angles of points $\mathbf{x}_i, \mathbf{x}_j$, respectively (Fig. 2). Since the points are uniformly distributed over the ring, $\mathbf{D}$ is a circulant matrix, i.e., $\cos(\alpha_i - \alpha_j) = \cos(\alpha_{i+k} - \alpha_{k+k})$. The solution $\mathbf{Q}_*$ to NOMAD is circulant too (Bachoc et al., 2012). Being circulant matrices, $\mathbf{D}$ and $\mathbf{Q}_*$ are diagonalized by the discrete Fourier transform (DFT), i.e.,

$$\mathbf{D} = \mathbf{F}\,\mathrm{diag}(\mathbf{d})\mathbf{F}^{\mathrm{H}}, \qquad \mathbf{Q}_* = \mathbf{F}\,\mathrm{diag}(\mathbf{q})\mathbf{F}^{\mathrm{H}}, \tag{3}$$

where $\mathbf{q}, \mathbf{d} \geq \mathbf{0}$ respectively are vectors containing the eigenvalues of $\mathbf{D}$ and $\mathbf{Q}_*$, $\mathbf{F}^{\mathrm{H}}$ is a Hermitian conjugate of $\mathbf{F}$, and $\mathbf{F} \in \mathbb{C}^{n\times n}$ is the unitary DFT matrix, with entries $(p, k = 0, \ldots, n-1)$

$$(\mathbf{F})_{pk} = \tfrac{1}{\sqrt{n}} \exp\left(-i2\pi p \tfrac{k}{n}\right). \tag{4}$$

Hence, and in accord with the constraint $\mathbf{Q}_*\mathbf{1} = \mathbf{1}$, we have that $(\mathbf{F})_{0:} = \frac{1}{\sqrt{n}}\mathbf{1}$ and $(\mathbf{q})_0 = 1$.

2.2. A linear program on the data manifold

We express the objective function and the constraints of NOMAD in terms of $\mathbf{d}$ and $\mathbf{q}$, i.e.,

$$\mathrm{Tr}\,(\mathbf{D}\mathbf{Q}_*) = \mathbf{d}^\top \mathbf{q}, \tag{5}$$

$$\mathrm{Tr}\,(\mathbf{Q}) = \mathbf{1}^\top \mathbf{q} = K, \tag{6}$$

$$(\mathbf{Q})_{kk'} = (\mathbf{F})_{k:}\,\mathrm{diag}(\mathbf{q})(\mathbf{F}^{\mathrm{H}})_{:k'} = \sum_{p=0}^{n-1} \frac{(\mathbf{q})_p}{n} \cos\left(2\pi p \frac{k'-k}{n}\right) \geq 0. \tag{7}$$

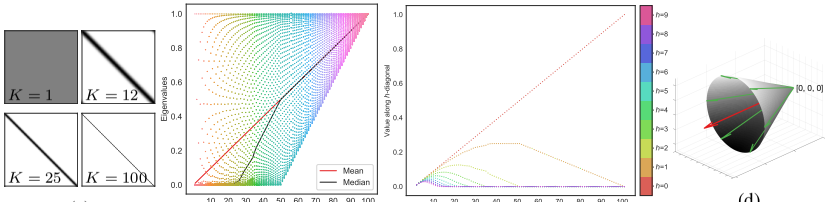
This reformulation allows us to rewrite NOMAD as a linear program

$$\max_{\mathbf{q}} \mathbf{d}^\top \mathbf{q} \quad \text{s.t.} \quad (\forall \tau)\ \mathbf{c}_\tau{}^\top \mathbf{q} \geq 0, \quad \mathbf{1}^\top \mathbf{q} = K, \quad \mathbf{q} \geq \mathbf{0}, \quad (\mathbf{q})_0 = 1, \tag{8}$$

where $(\mathbf{c}_\tau)_p = \frac{1}{n}\cos\left(2\pi p \frac{\tau}{n}\right)$.

Problem (8) sheds light on the inner workings of NOMAD. First, the constraint $\mathbf{1}^\top\mathbf{q} = K$ ensures that $\mathbf{q}$ does not grow to infinity and acts as a budget constraint. Let us assume for a moment that we remove the constraint $\mathbf{c}_\tau{}^\top\mathbf{q} \geq 0$ (the equivalent of $\mathbf{Q} \geq \mathbf{0}$). Then, the program will try to set to K the entry of $\mathbf{q}$ corresponding to the largest eigenvalue of $\mathbf{d}$; this $\mathbf{q}$ will violate as K gets bigger the removed constraint (since $(\mathbf{c}_\tau)_p$ is a sinusoid). Then the effect of this constraint is to spread the allocated budget among several eigenvalues (instead of just the largest). The experiment in Fig. 3 confirms this: the number of active eigenvalues of $\mathbf{Q}_*$ grows with K. We can interpret this as increasing the intrinsic dimensionality of the problem in such a way that only local interactions are considered.

Interpretation of K. The circulant property of $\mathbf{Q}_*$ for the 2D ring sheds further light on the meaning of K. In Fig. 3(c), we observe that the number of significant elements in each of $\mathbf{Q}_*$ is $\lceil n/K \rceil$.



(a) (b) (c) (d)

Figure 3: Evolution of the NOMAD solution for the 2D ring dataset (with 100 points, see Fig. 2) with increasing parameter K. (a) As K increases, the solution, $\mathbf{Q}_*$, concentrates more and more towards the diagonal. (b) As K increases, the number of active eigenvalues in the solution, $\mathbf{Q}_*$, grows resulting in the more uniform distribution of eigenvalues and greater mean/median (notice that the mean being linear comes from the trace constraint). (c) We define the h-diagonal of $\mathbf{Q}_*$ as the entries (i, j) for which $i - j = h$. As $\mathbf{Q}_*$ is a circulant matrix, each h-diagonal contains a single repeated value. We plot these values, assigning a different color to each h. The effect of the scaling constraint $\mathrm{Tr}\,(\mathbf{Q}) = K$ becomes evident: when one h-diagonal becomes inactive, all remaining h'-diagonals need to be upscaled. (d) The eigenvectors of $\mathbf{Q}_*$ form a high-dimensional cone (cartoon representation, cone axis in red and eigenvectors in green).

Thus, we can interpret K as a parameter that effectively sets the size of the local neighborhood on the manifold. In standard manifold learning methods this size is set by a combination of the number of nearest neighbors and the shape and scale of the kernel function. In NOMAD, all these variables are incorporated into a single parameter and balanced with the help of the remaining problem constraints.

In general, for non-symmetric and irregularly sampled manifolds, K is chosen to capture the manifold underlying the dataset: the neighborhood size needs to be small enough to capture the desired manifold features, but big enough to avoid capturing unwanted structure (e.g., noise). If sampling density differs in different areas, the size will adjust locally as needed.

2.3. Lifting the ring to a high-dimensional cone

Here, we show that NOMAD effectively embeds the data manifold into a space where its structure, i.e., rotational symmetry, is preserved. We now make use of the half-wave symmetry in $\mathbf{Q}_*$, noting that they can be fully represented with only one half of the Fourier basis. We can then decompose it with the real Fourier basis

$$\mathbf{Q}_* = \tilde{\mathbf{F}}\,\mathrm{diag}(\tilde{\mathbf{q}})\tilde{\mathbf{F}}^\top, \tag{9}$$

where $\tilde{\mathbf{q}} = [(\mathbf{q})_0, (\mathbf{q})_1, (\mathbf{q})_1, \ldots, (\mathbf{q})_{n-1}, (\mathbf{q})_{n-1}]^\top$ and $\tilde{\mathbf{F}} \in \mathbb{R}^{n\times n}$ has entries $(p, k = 0, \ldots, n-1)$

$$(\tilde{\mathbf{F}})_{pk} = \begin{cases} \frac{2}{\sqrt{n}} \cos\left(2\pi p \frac{k}{n}\right) & \text{if } k \text{ is even,} \\ \frac{2}{\sqrt{n}} \sin\left(2\pi p \frac{k-1}{n}\right) & \text{if } k \text{ is odd.} \end{cases} \tag{10}$$

Let $\tilde{\mathbf{Y}} = \mathrm{diag}(\mathbf{q})^{1/2}\tilde{\mathbf{F}}^\top$. Notice that $\langle \tilde{\mathbf{Y}}_{:i} / \left\|\tilde{\mathbf{Y}}_{:i}\right\|_F, \tilde{\mathbf{F}}_{:0}\rangle = \langle \tilde{\mathbf{F}}_{:i}, \tilde{\mathbf{F}}_{:0}\rangle = \frac{4}{n}$, meaning that the vectors $\tilde{\mathbf{Y}}_{:i}$ are the extreme rays of a right circular cone with the eigenvector $\tilde{\mathbf{F}}_{:0} = \frac{2}{\sqrt{n}}[1, 0, \ldots, 0]^\top$ as its symmetry axis, see Fig. 3(d). Thus, we can interpret the solution to NOMAD as lifting the 2D ring structure into a cone. As mentioned before, this cone is high-dimensional, with as many directions as needed to preserve the nonnegativity of $\mathbf{Q}$.

We identify the rank of the solution $\mathbf{Q}$ with the number of active eigenvalues. The bigger the K, the higher the rank. The constraint $\mathbf{Q1} = \mathbf{1}$ in NOMAD leads to a fanning-out effect in the data representation. Intuitively, this fan-out effect is key to the disentanglement of datasets with complex topologies. Spin-model-inspired SDPs for community detection (Javanmard et al., 2015) achieve a similar fanning-out by dropping the constraint $\mathbf{Q1} = \mathbf{1}$ and adding the related term $-\gamma\mathbf{1}^\top\mathbf{Q1}$ to the objective function.

With the LP framework and the geometric picture in place, we can begin to understand how the solution evolves as the parameter K increases from 1 to n. At $K = 1$, only the eigenvalue $(\mathbf{q})_0$ is active and every vector $(\tilde{\mathbf{Y}})_{:i}$ is the same with each entry equal to $1/n$. When K slightly above 1, the eigenvalue $(\mathbf{q})_1$ becomes active (nonzero), introducing the first nontrivial Fourier component. Geometrically, the vectors $\{(\tilde{\mathbf{Y}})_{:i}\}$ now open up into a narrow cone. As K increases, the cone widens and, at some point, the angle between two of the vectors reaches $\pi/2$ (this activates the nonnegativity constraint in Eq. (7)). Further increase of K necessitates use of a larger number of Fourier modes. Finally, at $K = n$ all modes are active and all vectors $\{(\tilde{\mathbf{Y}})_{:i}\}$ become orthogonal to each other. Fig. 3(b) depicts the progression with K of the number of active modes.

Summary. Previous studies (Kulis et al., 2007; Peng and Wei, 2007; Awasthi et al., 2015), focus solely on cases where NOMAD exhibits K-means-like solutions (i.e., hard-clustering). Sec. 2 provides a characterization of the NOMAD solutions on a simple example with a high degree of symmetry, showing that they are drastically different from K-means. These solutions connect neighboring points, with the neighborhood size determined by K. These neighborhoods overlap, as they would in soft-clustering, in a way that preserves global features of the manifold, including its symmetry. This is a feature sought after by manifold learning methods and help place NOMAD among reliable manifold analysis techniques.

3. Analyzing data manifolds with NOMAD: Experimental results

In the previous section, we showed that NOMAD recovers the data manifold in an idealized 2D ring dataset. Here, we extend this observation numerically to more complex datasets for which analytical form of the transformation that diagonalizes $\mathbf{Q}_*$ (nor $\mathbf{D}$) is not known, see figs. 1, 5 and 7. We visualize the solution $\mathbf{Q}_*$ by embedding it in a low-dimensional space. While our goal is not dimensionality reduction, we learn the data manifold with NOMAD, and use standard spectral dimensionality reduction to visualize the results.

Recovering multiple manifolds. K-means cannot effectively recover multiple distinct manifolds (although in some very particular cases, with well separated and linearly separable manifolds, it may group the points correctly). Interestingly, NOMAD does not inherit this limitation. Of course, if we set the NOMAD parameter K to the number of manifolds that we want to recover, there is no hope in the general case to obtain a result substantially better than the one obtained with Lloyd's algorithm (Lloyd, 1982). However, setting the NOMAD parameter K to be higher than the number of manifolds leads to a correct identification and characterization of their structures. Note that

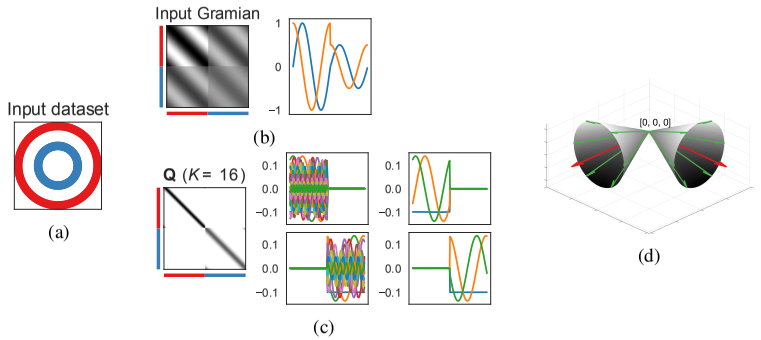


Figure 4: Solution of NOMAD on the dataset consisting of two 2D rings. (a) Two-ring dataset. (b) Input Gramian, $\mathbf{D}$, and its two eigenvectors ($\mathbf{D}$ has rank 2). Note that the eigenvectors of $\mathbf{D}$ do not segregate the rings. (c) The solution, $\mathbf{Q}$, of NOMAD contains two sets of eigenvectors with disjoint support: one set describing the points in each ring (we show all eigenvectors and a detail on the first 3 within each set). (d) The eigenvectors of $\mathbf{Q}$ form two orthogonal high-dimensional cones: one cone for each ring (cartoon representation, cone axis in red and eigenvectors in green). Notice how these cones become linearly-separable.

setting a similarly large K would not help K-means, as it is designed to partition the data, thus breaking each manifold into several pieces.

An example with two rings is presented in Fig. 4. We can expect that, as the single ring in Sec. 2 is described by Fourier modes, NOMAD describes two rings with two sets of Fourier modes with disjoint support; the solution is now arranged as two orthogonal high-dimensional cones, see Fig. 4(d). In a sense, the manifold learning problem is already solved, as there are two circulant submatrices, one for each manifold, with no interactions between them. If the user desires a hard assignment of points to manifolds, we can simply consider $\mathbf{Q}_*$ as the adjacency matrix of a weighted graph and compute its connected components.

Discussion of the experimental results. To demonstrate the manifold-learning capabilities of the NOMAD, we present several examples, both synthetic and real-world. The trefoil knot in Fig. 1(a) is a 1D manifold in 3D; it is the simplest example of a nontrivial knot, meaning that it is not possible to "untie" it in three dimensions without cutting it. However, the manifold learning procedure in Sec. 3 learns a closed 1D manifold. We also present examples using real-world high-dimensional datasets, recovering in every case structures of interest, see Fig. 6. In figs. 6(a) to 6(c), NOMAD respectively uncovers the camera rotation, the orientation of the lighting source, and specific handwriting features.

To demonstrate the multi-manifold learning and manifold-disentangling capabilities of NOMAD, we use several standard synthetic datasets, see figs. 1(b), 4 and 5. In all of these examples, NOMAD is able to disentangle clusters that are not linearly separable. We also present results for a real-world dataset (Fig. 7) which is similar to the one in Fig. 6(a) but with two objects. NOMAD

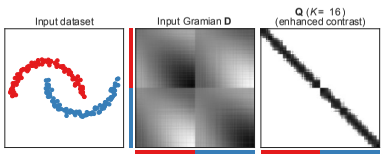

Figure 5: Learning multiple manifolds with NOMAD. The points are arranged in two semicircular manifolds and contaminated with Gaussian noise. Although the manifolds are linearly non-separable, NOMAD correctly finds two submatrices, one for each manifold (for visual clarity, we enhance the contrast of $\mathbf{Q}$).

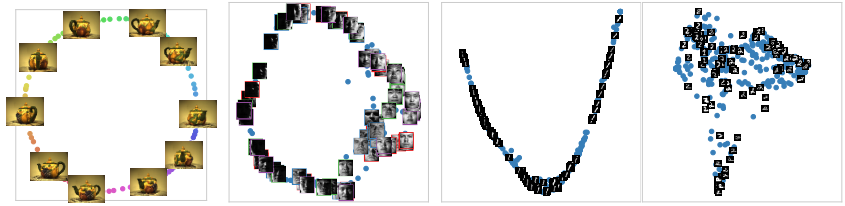

(a) Teapots ($K = 20$) (b) Yale Faces ($K = 16$) (c) MNIST digits ($K = 16$)

Figure 6: Finding two-dimensional embeddings with NOMAD. (a) 100 images obtained by viewing a teapot from different angles in a plane. The input vectors size is 23028 (76×101 pixels, 3 color channels). The manifold uncovers the change in orientation. (b) 256 images from 4 different subjects (each subject is marked with a different color in the figure), obtained by changing the position of the illumination source. The input vectors size is 32256 (192×168 pixels). The manifold uncovers the change in illumination (from frontal, to half-illuminated, to dark faces, and back). (c) 500 images handwritten instances of the same digit. The input vectors size is 784 (28×28 pixels). On the left and on the right, images of the digits 1 and 2, respectively. The manifold of 1s uncovers their orientation, while the manifold of 2s parameterizes features like size, slant, and line thickness. Details are better perceived by zooming on the plots.

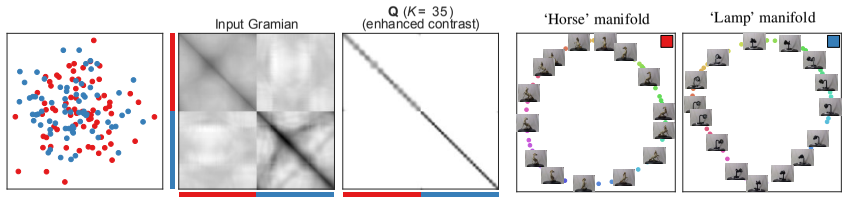

Figure 7: 144 images obtained by viewing a lamp and a horse figurine from different angles in a plane. The input vectors size is 589824 (384×512 pixels, 3 color channels). We plot the input data using a 2D spectral embedding (the points corresponding to each object are colored differently). NOMAD correctly finds two submatrices, one for each manifold (for visual clarity, we enhance the contrast of $\mathbf{Q}$); furthermore, NOMAD recovers closed manifolds.

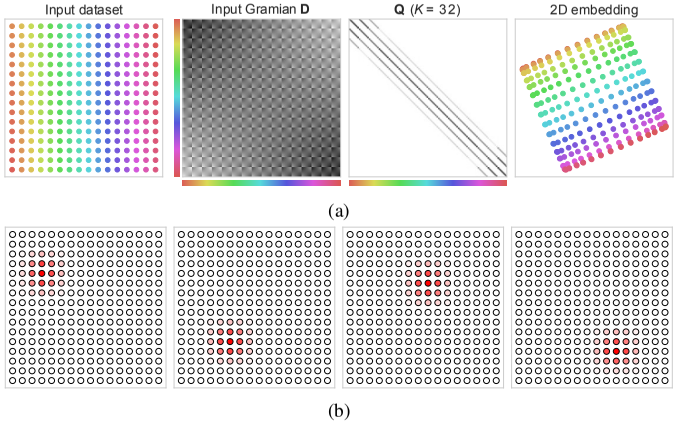

Figure 8: Learning a 2D manifold embedded in a 10-dimensional ambient space; the first two dimensions are regular samples on a 2D grid (shown on the left) and the remaining ones are Gaussian noise. (a) NOMAD recovers the right 2D structure (of course, some distortion is expected along the edges). (b) We show a few columns of $\mathbf{Q}$ on top of the data itself: the red level indicates the value of the corresponding entry in $\mathbf{Q}$ (red maps to high values, white maps to a zero). NOMAD effectively tiles the dataset with a collections of overlapping local neighborhoods centered at each data point. These patches contain all the information necessary to reconstruct the intrinsic manifold geometry.

recovers two closed manifolds, each of which containing the viewpoints of one object. The structure of the solution is similar to the one in Fig. 4(d).

Finally, we include an example in which NOMAD captures the structure of a 2D manifold living in a 10-dimensional space, see Fig. 8. NOMAD assigns a local patch to each data point (non-zero values for neighboring points, zeros elsewhere). These local patches tile the manifold with overlap (as in soft-clustering), allowing to recover its grid structure. Such tiling takes place in all of the examples included in the paper.

3.1. Manifold disentangling with multi-layer NOMAD

The recursive application of NOMAD, with successively decreasing values of K, enhances its manifold-disentangling capabilities. The pseudocode is as follows:

$\mathbf{D}_1 \leftarrow \mathbf{X}^\top \mathbf{X}$;
for $l = 1, 2, \ldots$ **do**
  Choose K_l (for all $l > 1$ we require $K_l \leq K_{l-1}$);
  Find the solution $\mathbf{Q}_l$ of NOMAD with input matrix $\mathbf{D}_l$ and parameter K_l;
  $\mathbf{D}_{l+1} \leftarrow \mathbf{Q}_l$;
return $\{\mathbf{Q}_l\}_{l=1,2,\ldots}$

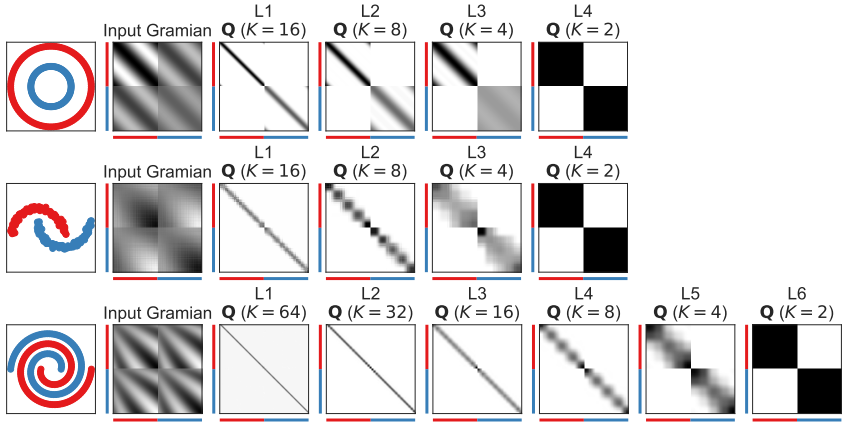

Figure 9: Results of recursive NOMAD application (multi-layer NOMAD). For each example, we show matrices $\mathbf{Q}_*$ computed by the successive application of the algorithm. Multi-layer NOMAD untangles these linearly non-separable manifolds and, in the final layer, assigns each manifold to one cluster.

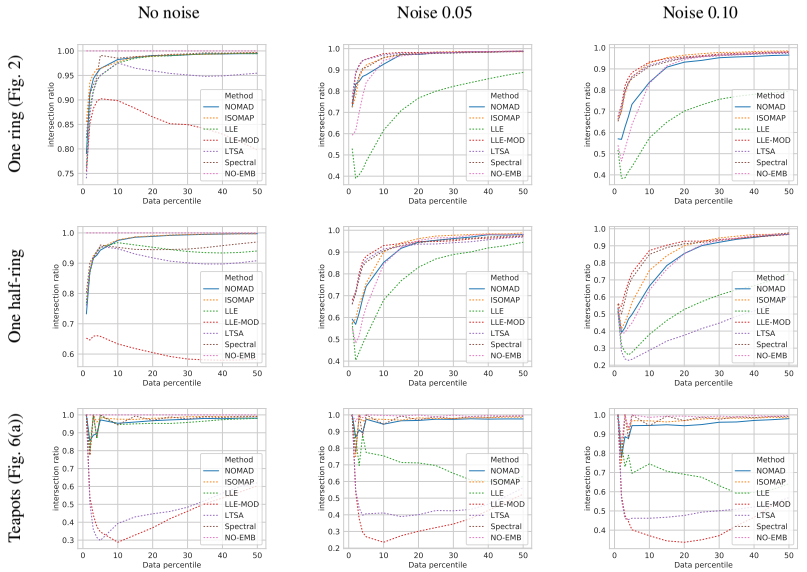
In Fig. 9, we present the evolution of successive matrices $\mathbf{Q}_l$. In all of these examples, multi-layer NOMAD is able to correctly identify clusters that are not linearly separable, something unattainable with single-layer NOMAD or with K-means clustering. Interestingly, we find that the manifolds are already segregated after one application of NOMAD in the direction of the leading eigenvectors of $\mathbf{Q}$ (see Fig. 4). The rest of the NOMAD layers little-by-little sieve out the (unwanted) smaller eigenvalues in an unsupervised fashion.

To turn this algorithm into a general data-analysis tool, we need an automated selection of the values $\{K_l\}$ which is a non-trivial task in general. Additional results, using different sequences $\{K_l\}$, can be found in Appendix C. Further research is needed to develop such algorithm and fully understand multi-layer NOMAD's interesting behavior.

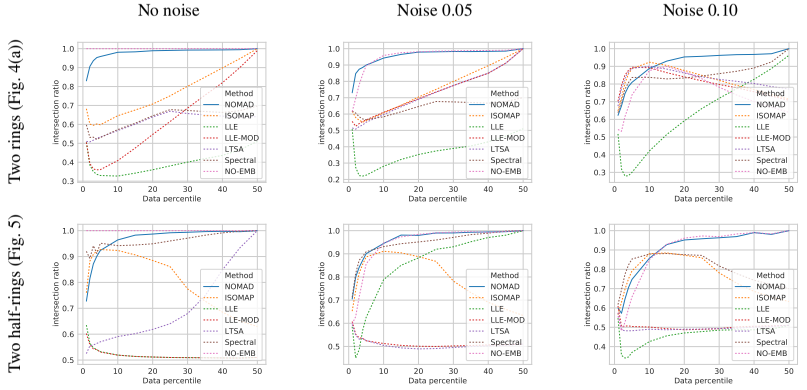
3.2. Geodesic-distance preservation: NOMAD versus existing manifold learning techniques

In order to compare different methods for manifold discovery, we need to agree upon appropriate metrics, which itself is an active area of research (e.g., Zhang et al., 2012). In particular, we want a metric that allows fair comparison among outputs of methods with very different objectives. Since our method is not explicitly geared towards dimension reduction, or towards variance maximization, we prefer metrics that emphasize the preservation of intrinsic structure of the manifold. In particular, we hope to preserve the ordering of intrinsic distances along the manifold, something that guarantees that the neighborhood structure remain similar.

Concretely, (1) we compute N nearest neighbors for each dataset point and build a weighted graph with these distances as edges; (2) we use this graph to compute geodesic distances using



(a) One manifold: NOMAD is among the best-in-class methods.



(b) Two manifolds: NOMAD outperforms all considered methods.

Figure 10: Comparison of the robustness of geodesic distances to the addition of noise for different manifold learning methods. The description of the experimental protocol is in Sec. 3.2. The method termed NO-EMB directly computes distances on the noisy data.

Dijkstra's algorithm; (3) we finally sort the distances in increasing order. We consider this ordering our ground truth.

We then add noise to the each point in the dataset. Noise was added by creating $5d$ additional dimensions that contain Gaussian noise with standard deviation 0.05 and 0.10. Using the noisy dataset, we run the geodesic-distance-sorting process on the embeddings produced by different manifold learning algorithms using N nearest neighbors. For NOMAD, instead of resorting to nearest neighbors, we set $K = n/N$ and use the non-zero entries in $\mathbf{Q}$ to determine the graph connectivity. As NOMAD yields a similarity matrix $\mathbf{Q}$, we derive distances from it with the formula $(\mathbf{Q})_{ii} + (\mathbf{Q})_{jj} - 2(\mathbf{Q})_{ij}$. Using this weighted graph, we compute and sort the geodesic distances.

For our distance-preservation measure, we use a bullseye score: for each method, we count the fraction of points in the top p percentile of distances that are also present in the top p percentile of ground truth distances.

As seen in Fig. 10, when the data is sampled from a single manifold, NOMAD performs very well, on par with the best algorithms included in our comparison. However, in the two-manifolds case, NOMAD clearly outperforms all other methods, nearly matching the performance of direct distance computations on the noisy data.

4. Heuristic non-convex solvers for large-scale NOMAD

Standard SDPs involve $O(n^2)$ variables and their resulting time complexity is often $O(n^3)$. Consequently, standard solvers (O'Donoghue et al., 2016a) will struggle with large datasets. NOMAD lends itself to a fast and big-data-friendly implementation (Kulis et al., 2007). This is done by posing a related problem

$$\max_{\mathbf{Y}\in\mathbb{R}^{r\times n}} \operatorname{Tr}\left(\mathbf{D}\mathbf{Y}^\top\mathbf{Y}\right) \quad \text{s.t.} \quad \operatorname{Tr}\left(\mathbf{Y}^\top\mathbf{Y}\right) = K,\ \mathbf{Y}^\top\mathbf{Y}\mathbf{1} = \mathbf{1},\ \mathbf{Y} \geq \mathbf{0}. \tag{11}$$

In this new problem, we have forgone convexity in exchange of reducing the number of unknowns from $O(n^2)$ to rn. For example, Kulis et al. (2007) set $r = K$. The problematic constraint $\mathbf{Y}^\top\mathbf{Y} \geq \mathbf{0}$, involving $O(n^2)$ terms, has been replaced by the much stronger but easier to enforce $\mathbf{Y} \geq \mathbf{0}$. The speed gain is shown in Fig. 15. See Appendix E for a description of the algorithm.

However, strictly speaking, the new constraint is equivalent to the old one only if $\mathbf{Q}$ is completely positive. An $n \times n$ matrix $\mathbf{A}$ is called completely positive (CP) if there exists $\mathbf{B} \geq \mathbf{0}$ such that $\mathbf{A} = \mathbf{B}^\top\mathbf{B}$. The least possible number of rows of $\mathbf{B}$ is called the cp-rank of $\mathbf{A}$. Whereas matrix $\mathbf{A}$ is doubly nonnegative (DN), i.e. $\mathbf{A} \geq \mathbf{0}$ and $\mathbf{A} \succeq 0$, not every DN matrix (with $n > 4$) is CP (Maxfield and Minc, 1962).

We are thus interested in two questions. First, is the solution $\mathbf{Q}_*$ to NOMAD completely positive? Answering this question in the affirmative would allow for theoretically sound and fast implementations of NOMAD. Whereas the set of CP matrices forms a convex cone, the problems of determining whether a matrix is inside the set and of projecting a matrix into the set are NP-hard leading us to the second question: What is the cp-rank of $\mathbf{Q}_*$? This issue is critical because it determines the number of unknowns. For example, if $\text{cp-rank}(\mathbf{Q}_*) \leq K$, (11) would be easier to solve. These questions are difficult only when NOMAD produces a soft-clustering $\mathbf{Q}_*$, as in all of the examples in this paper. Indeed, it is not hard to prove that, whenever NOMAD produces a hard-clustering $\mathbf{Q}_*$, $\mathbf{Q}_*$ is CP (see Awasthi et al., 2015, for such conditions).

Let us now go back to the example in Sec. 2 (points arranged regularly on a ring). For this example, we can establish a simple sufficient condition on K, for $\mathbf{Q}_*$ to be CP. Recall that if $\mathbf{D}$ is

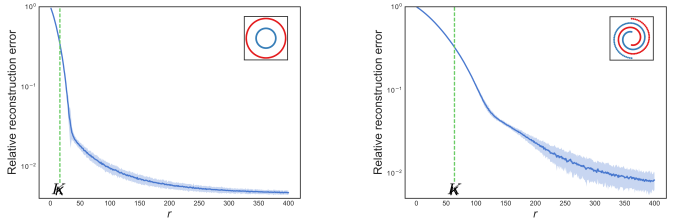


Figure 11: We empirically study the cp-rank of $\mathbf{Q}_*$. As a proxy of the exact nonnegative decomposition, we compute the rank-r symmetric NMF $\mathbf{Q}_* \approx {\mathbf{Y}_+}^\top\mathbf{Y}_+$ for different values of r. We show the mean plus/minus two standard deviations of the relative error $\left\|\mathbf{Q}_* - {\mathbf{Y}_+}^\top\mathbf{Y}_+\right\|_F / \left\|\mathbf{Q}_*\right\|_F$ computed from 50 different SNMFs for each r (their differences stem from the random initialization). Both datasets have 200 points. Clearly, setting $r = K$ is not enough to properly reconstruct $\mathbf{Q}_*$.

circulant, $\mathbf{Q}_*$ is circulant (Bachoc et al., 2012). In Proposition 2 of Appendix B, we prove that if the solution $\mathbf{Q}_*$ to NOMAD is a circulant matrix, then it is CP for every $K \leq 3/2$ or $K \geq \frac{n}{2}$. Naturally, more theory is needed to shed light onto this problem in general scenarios as it is unclear whether similar results exist.

Complementarily, we have studied the questions raised in this section from an experimental viewpoint. We use the symmetric nonnegative matrix factorization (SNMF) of $\mathbf{Q}_*$, see Appendix D, as a proxy for checking whether $\mathbf{Q}_*$ is CP. The rationale is that if the approximation with SNMF is very tight, it is highly likely that $\mathbf{Q}_*$ is CP. These experiments are presented in Fig. 11. We found that, with a properly chosen rank r, SNMF can indeed accurately approximate $\mathbf{Q}_*$. However, setting $r = K$ is in general not enough and leads to a poor reconstruction. These two facts support the idea that $\mathbf{Q}_*$ is CP, but has a cp-rank much higher than K.

Our experiments with the non-convex algorithm in Appendix E lead to similar conclusions as those with SNMF, see Fig. 12. Setting $r = K$, leads to a poor approximation of $\mathbf{Q}_*$ and, as observed by Kulis et al. (2007), to hard-clustering. Setting $r \gg K$ leads to much improved reconstructions, at the expense of speed.

5. A fast and convex algorithm for NOMAD

The Burer-Monteiro solver forgoes convexity in favor of speed. However, as discussed in the previous section, this conversion carries theoretical and practical difficulties that are not easily overcome. In this section, we propose an algorithm for NOMAD that is fast and yet convex.

5.1. Augmented Lagrangian formulation

First, we redefine the variables in NOMAD by setting $\mathbf{P} = \mathbf{Q} - \mathbf{E}_n$, where $\mathbf{E}_n = \frac{1}{n}\mathbf{1}\mathbf{1}^\top$. Then,

$$\max_{\mathbf{P}} \operatorname{Tr}(\mathbf{D}\mathbf{P}) \quad \text{s.t.} \quad \mathbf{P}\mathbf{1} = \mathbf{0}, \quad \operatorname{Tr}(\mathbf{P}) = K - 1, \quad \mathbf{P} \succeq \mathbf{0}, \quad \mathbf{P} + \mathbf{E}_n \geq \mathbf{0}. \tag{12}$$

As usual in the optimization literature, we handle this constraint with an augmented Lagrangian method. The augmented Lagrangian of Problem (12) with respect to the constraint $\mathbf{P} + \mathbf{E}_n \geq \mathbf{0}$ is

$$g(\mathbf{P}, \mathbf{\Gamma}) = -\operatorname{Tr}(\mathbf{D}\mathbf{P}) + \operatorname{Tr}(\mathbf{\Gamma}(\mathbf{P} + \mathbf{E}_n)) + \tfrac{\gamma}{2}\left\|[\mathbf{P} + \mathbf{E}_n]_-\right\|_F^2, \tag{13}$$

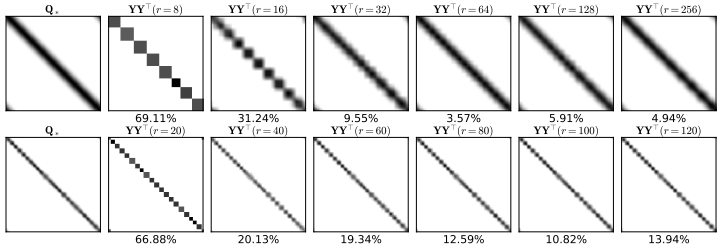

Figure 12: Comparison of the results obtained with a standard SDP solver (first column) and with a low-rank non-convex approach (remaining columns, r denotes the rank of the obtained solution). **(Top)** Dataset in Fig. 4; we set $K = 8$ in all cases. **(Bottom)** Dataset in Fig. 6(a); we set $K = 20$ in all cases. In each case, we also display the relative error between the matrix $\mathbf{Y}^\top\mathbf{Y}$ and $\mathbf{Q}_*$. Interestingly, setting $r = K$ produces hard clustering solutions (see the block diagonal structure of the matrices on the second column), while increasing r produces "softer" solutions. This suggests that the cp-rank of $\mathbf{Q}_*$ is (much) greater than K.

where $\mathbf{\Gamma} \geq \mathbf{0}$ is the associated Lagrange multiplier, and $[\cdot]_- = \min(\cdot, 0)$ is the projection operator onto the negative orthant. We can then pose Problem (12) as

$$\min_{\mathbf{P}} \max_{\mathbf{\Gamma}\geq 0} g(\mathbf{P}, \mathbf{\Gamma}) \quad \text{s.t.} \quad \mathbf{P1} = \mathbf{0}, \quad \operatorname{Tr}(\mathbf{P}) = K - 1, \quad \mathbf{P} \succeq \mathbf{0}. \tag{14}$$

We solve it using the method of multipliers, i.e.,

$$\mathbf{P}_{t+1} = \operatorname*{argmin}_{\mathbf{P}} g(\mathbf{P}, \mathbf{\Gamma}_t) \quad \text{s.t.} \quad \mathbf{P1} = \mathbf{0}, \quad \operatorname{Tr}(\mathbf{P}) = K - 1, \quad \mathbf{P} \succeq \mathbf{0}, \tag{15a}$$

$$\mathbf{\Gamma}_{t+1} = [\mathbf{\Gamma}_t + \tau(\mathbf{P}_{t+1} + \mathbf{E}_n)]_- . \tag{15b}$$

5.2. A conditional gradient method for SDPs with an orthogonality constraint

In this section, we introduce a very efficient algorithm to solve

$$\max_{\mathbf{Z}} f(\mathbf{Z}) \quad \text{s.t.} \quad \mathbf{Z} \succeq 0, \ \operatorname{Tr}(\mathbf{Z}) = s, \ \mathbf{Zb} = \mathbf{0}. \tag{16}$$

of which Problem (15a) is an instance.

To this end we modify an algorithm to efficiently solve the SDP (Hazan, 2008)

$$\max_{\mathbf{Z}} f(\mathbf{Z}) \quad \text{s.t.} \quad \mathbf{Z} \succeq 0, \ \operatorname{Tr}(\mathbf{Z}) = s, \tag{17}$$

where function f is differentiable and concave. The iterative algorithm consists, at each iteration $t = 0 \ldots$, of the following steps:

1. Let $\mathbf{v}_t$ be the largest algebraic eigenvector of $\nabla f(\mathbf{Z}_t)$.
2. $\mathbf{Z}_{t+1} = (1-\alpha)\mathbf{Z}_t + \alpha s \mathbf{v}_t\mathbf{v}_t^\top$ with $\alpha = 2/(t+2)$.

Algorithm 1: Conditional gradient algorithm for SDPs with an orthogonality constraint

input : function f to minimize, scale parameter s.
output : solution $\mathbf{Z}_{t+1} \in \mathcal{P}_s$ to Problem (17).

Initialize $\mathbf{Z}_0 = \mathbf{0}$;
for $t = 0, \ldots, \infty$ **do**
  Let $\mathbf{v}$ be the largest algebraic eigenvector of $\nabla f(\mathbf{Z})$ such that $\mathbf{v}^\top\mathbf{b} = 0$;
  $\alpha \leftarrow 2/(t+2)$;
  $\mathbf{Z}_{t+1} \leftarrow (1-\alpha)\mathbf{Z}_t + \alpha s \mathbf{v}\mathbf{v}^\top$;
  if *converged* **then** break ;

This algorithm is an instance of the Frank-Wolfe/conditional-gradient algorithm (Frank and Wolfe, 1956). As such it provides a solution without performing any projections. First, $\mathbf{Z}_{t+1}$ is a non-negative linear combination of two positive semidefinite matrices, and is thus positive semidefinite itself. Second, the iterations maintain the invariant $\operatorname{Tr}(\mathbf{Z}_t) = s$ as $\operatorname{Tr}(\mathbf{Z}_{t+1}) = (1-\alpha)\operatorname{Tr}(\mathbf{Z}_t) + \alpha s \operatorname{Tr}\left(\mathbf{v}_t\mathbf{v}_t^\top\right) = (1-\alpha)\operatorname{Tr}(\mathbf{Z}_t) + \alpha s$.

We now show how to extend this algorithm to handle an orthogonality constraint. Let $\mathcal{P}_s$ be the convex cone of positive semidefinite matrices with trace s that are orthogonal to a given vector $\mathbf{b}$, i.e.,

$$\mathcal{P}_s = \{\mathbf{Z} \succeq 0, \ \operatorname{Tr}(\mathbf{Z}) = s, \ \mathbf{Zb} = \mathbf{0}\}. \tag{18}$$

Notice that setting $\mathbf{b} = \mathbf{1}$ yields the constraints of Problem (15a). We seek to solve

$$\max_{\mathbf{Z}} f(\mathbf{Z}) \quad \text{s.t.} \quad \mathbf{Z} \in \mathcal{P}_s. \tag{19}$$

Fortunately, we can push the constraint $\mathbf{Zb} = \mathbf{0}$ into the eigenvector computation. We begin by noticing that the final solution is a weighted sum of the matrices $\mathbf{v}_t\mathbf{v}_t{}^\top$. It then suffices to require that, for every t, $\mathbf{v}_t\mathbf{v}_t{}^\top\mathbf{b} = \mathbf{0}$, which reduces to $\mathbf{v}_t{}^\top\mathbf{b} = \mathbf{0}$. This naturally yields a new iterative method, summarized in Alg. 1. This algorithm has the same performance guarantee as Hazan's (2008), given by the following proposition, which we prove in Appendix F.

Proposition 1 *Let $\mathbf{X}, \mathbf{Z} \in \mathcal{P}_s$ and $\mathbf{Y} = \mathbf{X} + \alpha(\mathbf{Z} - \mathbf{X})$ and $\alpha \in \mathbb{R}$. The curvature constant of f is*

$$C_f := \sup_{\mathbf{X},\mathbf{Z},\alpha} \tfrac{1}{\alpha^2}[f(\mathbf{X}) - f(\mathbf{Y}) + (\mathbf{Y} - \mathbf{X}) \bullet \nabla f(\mathbf{X})]. \tag{20}$$

Let $\mathbf{Z}^\star$ be the solution to Problem (19). The iterates $\mathbf{Z}_t$ of Alg. 1 satisfy for all $t > 1$

$$f(\mathbf{Z}^\star) - f(\mathbf{Z}_t) \leq \tfrac{8C_f}{t+2}. \tag{21}$$

5.3. A conditional gradient algorithm for NOMAD

Alg. 2 summarizes the proposed method of multipliers, see iterations (15a) and (15b), to solve Problem (12). The inner problem (15a) is solved using Alg. 1. A few remarks are in order:

- When using the method of multipliers, it is often not necessary (nor desirable) to solve the inner problem to a high precision (Goldstein and Osher, 2009). In our implementation we set $N_{\text{inner}} = 10$.

Algorithm 2: Conditional gradient algorithm for NOMAD

input : matrix $\mathbf{D}$, scale parameter k.
output : solution $\mathbf{Q}$ to NOMAD.

Initialize $\mathbf{P}_0 = \mathbf{0}$; $\mathbf{\Gamma} \leftarrow \mathbf{0}$; $\gamma = 1$;
for $t = 1, \ldots, \infty$ **do**
  for $t_{inner} = 1, \ldots, N_{inner}$ **do**
    Let $\nabla g(\mathbf{P}, \mathbf{\Gamma}) = -\mathbf{D} + \mathbf{\Gamma} + \gamma\,[\mathbf{P} + \mathbf{E}_n]_-$;
    Let $\mathbf{A} = (\mathbf{I} - \frac{1}{n}\mathbf{1}\mathbf{1}^\top)\nabla g(\mathbf{P}, \mathbf{\Gamma})(\mathbf{I} - \frac{1}{n}\mathbf{1}\mathbf{1}^\top)$;
    Let $\mathbf{v}$ be the smallest algebraic eigenvector of $\mathbf{A}$, such that $\mathbf{v}^\top\mathbf{1} = 0$;
    $\mathbf{H} \leftarrow (K-1)\mathbf{v}\mathbf{v}^\top$;
    $\alpha \leftarrow 2/(t + t_{\text{inner}} + 2)$;
    $\mathbf{P} \leftarrow (1-\alpha)\mathbf{P} + \alpha\mathbf{H}$;
  $\mathbf{\Gamma} \leftarrow [\mathbf{\Gamma} + \tau\,(\mathbf{P} + \mathbf{E}_n)]_-$;
  if *converged* **then** break ;
$\mathbf{Q} \leftarrow \mathbf{P} + \mathbf{E}_n$

- There is no need to need for a highly accurate eigenvector computation (Hazan, 2008). We use the Lanczos algorithm and set its accuracy to $(t+1)^{-1}$.
- Alg. 1 solves a maximization problem and requires the eigenvector with the largest algebraic eigenvalue. To solve the minimization problem (15a), we simply compute the eigenvector with the smallest algebraic eigenvalue (Jaggi, 2013).
- As $\mathbf{b} = \mathbf{1}$, we can enforce the orthogonality constraint $\mathbf{v}_t{}^\top\mathbf{1} = 0$ by computing the maximum eigenvalue of $\mathbf{A} = (\mathbf{I} - \frac{1}{n}\mathbf{1}\mathbf{1}^\top)\nabla g(\mathbf{P}, \mathbf{\Gamma})(\mathbf{I} - \frac{1}{n}\mathbf{1}\mathbf{1}^\top)$. This operation can be carried out very efficiently.

Complexity. The complexity of Alg. 1 is similar to that of Hazan's (2008), plus an additional factor to compute $\mathbf{A}$. From Proposition 1, Alg. 1 yields a solution with accuracy ε, i.e., $f(\mathbf{Z}_t) \geq f(\mathbf{Z}^\star) - \varepsilon$, in $\frac{4C_f}{\varepsilon} - 1$ iterations. Computing $\nabla g(\mathbf{P}, \mathbf{\Gamma})$, $\mathbf{A}$, and $\mathbf{H}_t$ require n^2 operations. Let T_{EIG} be the number of iterations of the eigensolver, each iteration taking $O(n^2)$ operations. Additional operations require $O(n)$ time. Then, the overall complexity of Alg. 1 is

$$O\left(\frac{C_f}{\varepsilon}\left[n + n^2 + n^2 T_{\text{EIG}}\right]\right). \tag{22}$$

For the Lanczos algorithm, and our accuracy setting of $(t+1)^{-1}$, we have $T_{\text{EIG}} = O((t+1)\log n)$. In this case, the complexity per iteration is $O(n^2 \log n)$. As a comparison, standard SDP solvers have a complexity of $O(n^3)$ per iteration. These solvers also involve significant memory usage, while our algorithm has an optimal space complexity of $O(n^2)$.

5.4. Experimental analysis

Throughout the iterations of Alg. 2, $\mathbf{P} \in \mathcal{P}_{k-1}$, see Eq. (18). Thus, we only need to keep track of the constraint $\mathbf{Q} = \mathbf{P} + \mathbf{E}_n \geq \mathbf{0}$ and of the value of the objective $\text{Tr}\,(\mathbf{DP})$.

We illustrate with two typical examples the empirical convergence of these values in Fig. 13. the convergence the objective value is clearly superlinear, while we observe a linear convergence for the nonnegativity constraint. Accelerating the latter rate is an interesting line of future research.

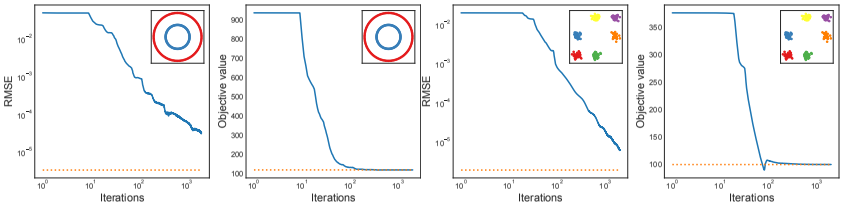

Figure 13: Prototypical examples of the behavior of the proposed conditional gradient NOMAD solver as its iterations progress. On the left plots, we show the RMSE of $[\mathbf{Q}]_- = [\mathbf{P} + \mathbf{E}_n]_-$, with the average computed over its non-zero entries. After about 10 iterations, the RMSE drops linearly, as usual for the method of multipliers. On the right plots, we display the objective value $\text{Tr}\,(\mathbf{DP})$, which usually converges in a few hundred iterations. In each case, as a reference, we show in orange the values returned by the standard SDP solver. The proposed algorithm enforces the nonnegativity constraint in NOMAD less accurately (although accurate enough for practical purposes), while exactly enforcing all the other constraints.

We can see in Fig. 13 that standard solvers enforce the nonnegativity constraint more accurately. However, they do not exactly enforce $\mathbf{P} \in \mathcal{P}_{k-1}$. There is a trade-off between what can be enforced up to which precision, making the solutions sometimes not exactly comparable.

We show the suitability of the proposed NOMAD solver in Fig. 14. In the vast majority of cases the solutions are the same. While the proposed method enforces the nonnegativity constraint less accurately than the standard solver, it enforces all the other constraints exactly. This is why in the teapot example, bottom left of Fig. 14, the solution of the proposed method looks less jagged than the one of the standard solver: the constraint $\mathbf{Q1} = \mathbf{1}$ is more accurately enforced, resulting in a more "circulant" representation.

In Fig. 15, we present the speed comparison of computing NOMAD with three different methods: two state-of-the-art SDP solvers, SCS (O'Donoghue et al., 2016b) and SDPNAL+ (Yang et al., 2015), the low-rank Burer-Monteiro solver (discussed in Sec. 4), and the proposed conditional gradient method. The Burer-Monteiro method is the fastest. Keep in mind that the latter does not guarantee convergence to the global optimal solution; this is particularly true specially in its fastest setting, i.e., by keeping r relatively small, see Sec. 4. Among solvers that solve a convex problem, for very small problems (up to 250 points), standard SDP solvers are the fastest. For larger problems the proposed solver is significantly faster. It is important to point out that, in theory, the speed difference grows significantly larger. This is hard to show in practice as standard solvers either run out of memory very quickly (SCS) or are implemented to time out for big instances (SDPNAL+); the proposed solver has a much more efficient use of memory.

We highlight the extended computational capabilities of the proposed conditional gradient method with an example that cannot be handled by standard SDP solvers. We use as input the 9603×9603 Gramian formed by all (vectorized) images of the digit zero in MNIST. The proposed algorithm is able to compute a solution to NOMAD with ease for a problem size about 100 times larger than the upper size limit for standard solvers. In the 2D embedding of the solution (see Sec. 3 for details about its computation), shown in Fig. 16, we can clearly see that the images are organized by their intrinsic characteristics (elongation and rotation).

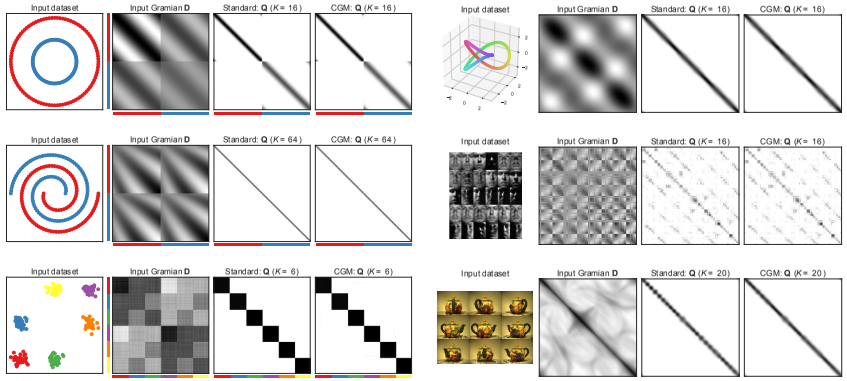

Figure 14: Comparison of the standard SDP solver with the proposed conditional gradient solver (CGM) for NOMAD on different datasets. In most cases, the results are practically indistinguishable while being delivered much faster.

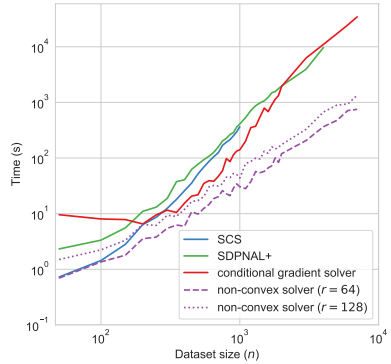

Figure 15: Running time comparison (smaller is better) of different NOMAD solvers for $K = 16$ (SCS (O'Donoghue et al., 2016b) and SDPNAL+ (Yang et al., 2015) are written in a highly optimized C/C++ code, while we use our non-optimized Python code for the others). The non-convex solver is much faster than the convex ones. Unfortunately, it may yield different results, see Fig. 12, and may not converge to the global maximum. The conditional gradient algorithm proposed in this paper is much faster than SCS and SDPNAL+ (about three times faster for $n = 10^3$) but guarantees converging to the global optimum. Additionally, the proposed algorithm handles large problems seamlessly: in our desktop with 128GB of RAM, SCS (running under CVXPY) runs out of memory with instances larger than $n = 1200$) while SDPNAL+ times out before converging for instances larger than $n = 4000$.

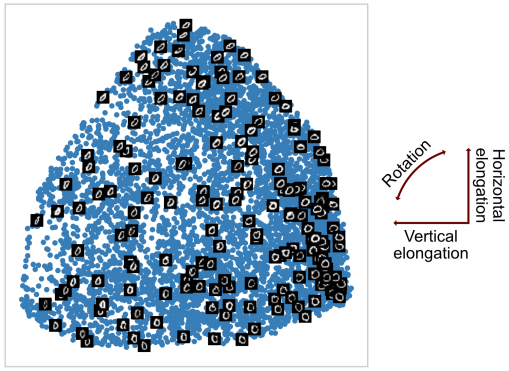

Figure 16: We show the 2D embedding of the digit 0 in MNIST, computed in the same fashion as in Fig. 6. In this case, we use all 9603 images of the digit and obtain a 9603×9603 matrix. We compute the solution of NOMAD with $K = 128$ using the proposed conditional gradient method (Alg. 2). In contrast, traditional SDP-solvers can only handle dense matrices approximately 100 times smaller. As in Fig. 6, the data gets organized according to different visual characteristics of the hand-written digit (e.g., orientation and elongation).

6. Conclusions

In this work, we showed that NOMAD can learn multiple low-dimensional data manifolds in high-dimensional spaces. An SDP instance, it is convex and can be solved in polynomial-time. Unlike most manifold learning algorithms, the user does not need to select/use a kernel and no nearest-neighbors searches are involved.

We also studied the computational performance of NOMAD. We first focused on a non-convex Burer-Monteiro-style algorithm and performed both theoretical and empirical analysis. Finally, we presented a new algorithm for NOMAD based on the conditional gradient method. The proposed algorithm is convex and yet efficient. This algorithm allows us, for the first time, to analyze the behavior of NOMAD on large datasets.

Related and future work. It has not escaped our attention that NOMAD can be considered as an instance of kernel alignment (Cristianini et al., 2002). In supervised setting, kernel alignment has been previously formulated as an SDP (e.g., Lanckriet et al., 2004; Cortes et al., 2012). Even beyond the distinction between the supervised and unsupervised scenarios, this body of work differs significantly from NOMAD. Its goal is to optimally combine pre-computed kernel matrices, whereas NOMAD learns such a matrix from scratch. Nonetheless, we find this connection with kernel learning very promising and plan to investigate it further in the future.

Appendix A. Relationship with K-means

K-means seeks to cluster a dataset $\mathcal{X} = \{\mathbf{x}_i\}_{i=1}^n$ by computing

$$\min_{\boldsymbol{\mathcal{C}}_K} \sum_{k=1}^K \sum_{\mathbf{x}_i \in \mathcal{C}_k} \left\| \mathbf{x}_i - \tfrac{1}{|\mathcal{C}_k|} \sum_{\mathbf{x}_j \in \mathcal{C}_k} \mathbf{x}_j \right\|_2^2, \tag{K-means}$$

where $\boldsymbol{\mathcal{C}}_K = \{\mathcal{C}_k\}_{k=1}^K$ is a partition of $\mathcal{X}$, i.e., $\mathcal{C}_k \cap \mathcal{C}_{k'} = \emptyset$ and $\bigcup_k \mathcal{C}_k = \mathcal{X}$. Albeit its popularity, it is known to be NP-Hard and, in practice, users employ an heuristic (Lloyd, 1982, originally developed in 1957) to find a solution. The objective function of K-means, henceforth denoted J_K, can be rewritten (dropping the terms that are constant with respect to $\mathcal{C}_k$) as

$$J_K = -\sum_{k=1}^K \tfrac{1}{|\mathcal{C}_k|} \sum_{\mathbf{x}_i, \mathbf{x}_j \in \mathcal{C}_k} \mathbf{x}_i^\top \mathbf{x}_j. \tag{23}$$

Let $\mathbf{X} \in \mathbb{R}^{d \times n}$ be the matrix formed by horizontally concatenating the vectors in $\mathcal{X}$. Let $\mathbf{z}_k \in \{0,1\}^n$ be the indicator vector of set $\mathcal{C}_k$. Let $\mathbf{Y}$ be the $k \times n$ matrix with rows $\mathbf{Y}_{k:} = |\mathcal{C}_k|^{-1/2} \mathbf{z}_k$. We have

$$\begin{aligned} J_K &= -\sum_{k=1}^K \tfrac{1}{|\mathcal{C}_k|} \sum_{i,j} \mathbf{x}_i^\top \mathbf{x}_j \cdot (\mathbf{z}_k^\top \mathbf{z}_k)_{ij} && \text{(24a)} \\ &= -\sum_{i,j} (\mathbf{X}^\top \mathbf{X})_{ij} (\mathbf{Y}^\top \mathbf{Y})_{ij} && \text{(24b)} \\ &= -\operatorname{Tr}\left(\mathbf{X}^\top \mathbf{X} \mathbf{Y}^\top \mathbf{Y}\right). && \text{(24c)} \end{aligned}$$

By construction, the matrix $\mathbf{Q} = \mathbf{Y}^\top \mathbf{Y}$ exhibits the following properties

$$\mathbf{Q}\mathbf{1} = \mathbf{1}, \tag{25}$$
$$\operatorname{Tr}(\mathbf{Q}) = K. \tag{26}$$

Let $\mathbf{D}$ be the Gramian matrix, i.e., $\mathbf{D} = \mathbf{X}^\top \mathbf{X}$. We can then re-cast K-means as the optimization problem

$$\max_{\mathbf{Y} \in \mathcal{V}_\mathbf{Y}^{K \times n}} \operatorname{Tr}(\mathbf{D}\mathbf{Q}) \quad \text{s.t.} \quad \begin{array}{c} \mathbf{Q}\mathbf{1} = \mathbf{1}, \\ \operatorname{Tr}(\mathbf{Q}) = K, \\ \mathbf{Q} = \mathbf{Y}^\top \mathbf{Y}. \end{array} \tag{27}$$

where $\mathcal{V}_\mathbf{Y} = \{0\} \cup \left\{|\mathcal{C}_k|^{-1/2}\right\}_{k=1}^K$. Seeking to apply the desirable properties of SDP to K-means, we can pose (Kulis et al., 2007; Peng and Wei, 2007)

$$\max_{\mathbf{Q} \in \mathbb{R}^{n \times n}} \operatorname{Tr}(\mathbf{D}\mathbf{Q}) \quad \text{s.t.} \quad \begin{array}{c} \mathbf{Q}\mathbf{1} = \mathbf{1}, \\ \operatorname{Tr}(\mathbf{Q}) = K, \\ \operatorname{rank}(\mathbf{Q}) = K, \\ \mathbf{Q} \succeq 0,\ \mathbf{Q} \geq \mathbf{0}. \end{array} \tag{28}$$

where mixed-integer program is relaxed into the real-valued nonnegative program, directly optimizing over $\mathbf{Q}$. NOMAD is as a relaxation of this problem, simply obtained by removing the rank constraint.

Appendix B. On the complete positivity of NOMAD solutions on circulant matrices

Proposition 2 *If the solution $\mathbf{Q}_*$ to NOMAD is a circulant matrix, then it is CP for every $K \leq 3/2$ or $K \geq \frac{n}{2}$.*

Proof For $K \leq 3/2$, plugging the constraint $\mathbf{Q}_*\mathbf{1} = \mathbf{1}$ into Corollary 2.6 in (So and Xu, 2013, p. 7) gives the desired result.

Let us address $K \geq \frac{n}{2}$. Kaykobad (1987) proved that every diagonally dominant matrix $\mathbf{A}$, i.e., $|(\mathbf{A})_{ii}| \geq \sum_{j \neq i} |(\mathbf{A})_{ij}|$ for all i, is a CP matrix. We have to prove then that $\mathbf{Q}_* \geq \mathbf{0}$ is diagonally dominant. We have $\operatorname{Tr}(\mathbf{Q}_*) = K$ and, since $\mathbf{Q}_*$ is circulant, all $(\mathbf{Q}_*)_{ii}$ have the same value. Then, $(\mathbf{Q}_*)_{ii} = K/n$. From $\mathbf{Q}_*\mathbf{1} = \mathbf{1}$, $\sum_{j \neq i} (\mathbf{Q}_*)_{ij} = 1 - (\mathbf{Q}_*)_{ii} = 1 - K/n$. Hence, $\mathbf{Q}_*$ is diagonally dominant for $K \geq \frac{n}{2}$. ■

Appendix C. Additional results

We include additional results of the multi-layer NOMAD algorithm using different values of k in each layer.

Appendix D. Symmetric NMF

In this section, we present the algorithm used to compute the symmetric NMF of a matrix $\mathbf{A} \in \mathbb{R}^{n \times n}$, defined as

$$\min_{\mathbf{Y} \in \mathbb{R}^{n \times r}} \left\| \mathbf{A} - \mathbf{Y}\mathbf{Y}^\top \right\|_F^2 \quad \text{s.t.} \quad \mathbf{Y} \geq \mathbf{0}. \tag{SNMF}$$

We use the alternating direction method of multipliers (ADMM) to solve it. In short, ADMM solves convex optimization problems by breaking them into smaller subproblems, which are individually

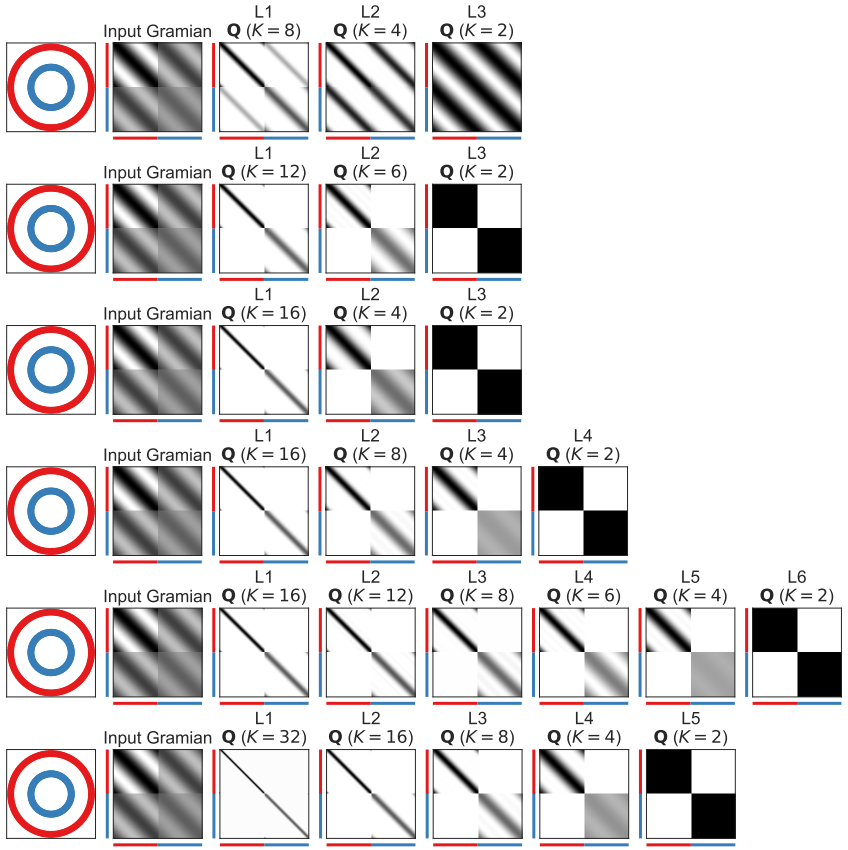

Figure 17: Additional results of multi-layer NOMAD.

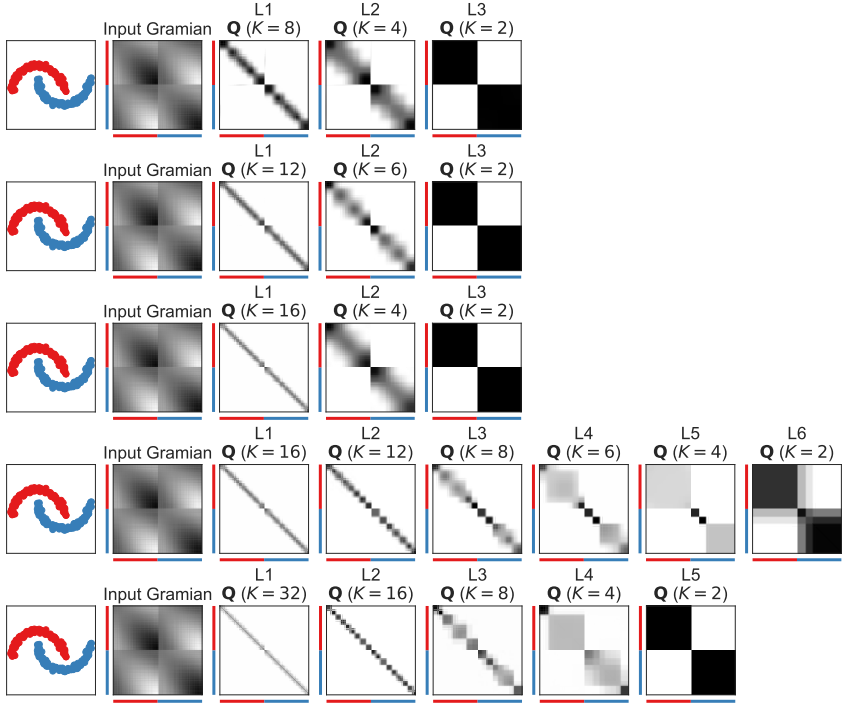

Figure 18: Additional results of multi-layer NOMAD.

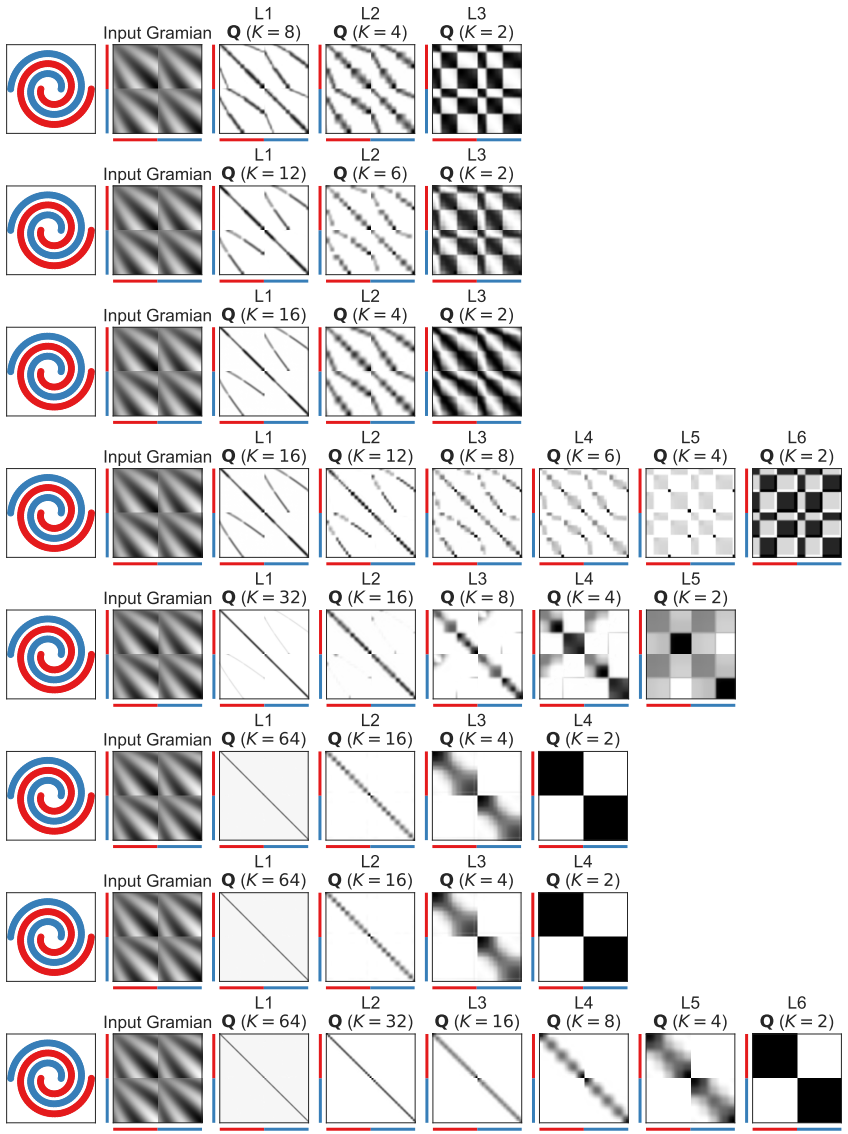

Figure 19: Additional results of multi-layer NOMAD.

easier to handle. It has also been extended to handle non-convex problems, e.g., to solve several flavors of NMF (Févotte and Idier, 2011; Xu et al., 2012; Tepper and Sapiro, 2014, 2016).

Problem (SNMF) can be equivalently re-formulated as

$$\min_{\mathbf{Y}\in\mathbb{R}^{n\times r}} \left\|\mathbf{A}-\mathbf{Y}\mathbf{X}^\top\right\|_F^2 \quad \text{s.t.} \quad \mathbf{Y}=\mathbf{X},\ \mathbf{Y}\geq\mathbf{0},\ \mathbf{X}\geq\mathbf{0}, \tag{29}$$

and we consider its augmented Lagrangian,

$$\mathscr{L}\left(\mathbf{X},\mathbf{Y},\mathbf{\Gamma}\right)=\tfrac{1}{2}\left\|\mathbf{A}-\mathbf{Y}\mathbf{X}^\top\right\|_F^2+\tfrac{\sigma}{2}\left\|\mathbf{Y}-\mathbf{X}\right\|_F^2-\operatorname{Tr}\left(\mathbf{\Gamma}^\top\left(\mathbf{Y}-\mathbf{X}\right)\right) \tag{30}$$

where $\mathbf{\Gamma}$ is a Lagrange multiplier, σ is a penalty parameter.

The ADMM algorithm works in a coordinate descent fashion, successively minimizing $\mathscr{L}$ with respect to $\mathbf{X},\mathbf{Y}$, one at a time while fixing the other at its most recent value and then updating the multiplier $\mathbf{\Gamma}$. For the problem at hand, these steps are

$$\mathbf{X}^{(t+1)}=\underset{\mathbf{X}\geq\mathbf{0}}{\operatorname{argmin}}\,\mathcal{L}\left(\mathbf{X},\mathbf{X}^{(t)},\mathbf{\Gamma}^{(t)}\right), \tag{31a}$$

$$\mathbf{Y}^{(t+1)}=\underset{\mathbf{Y}\geq\mathbf{0}}{\operatorname{argmin}}\,\mathcal{L}\left(\mathbf{X}^{(t+1)},\mathbf{Y},\mathbf{\Gamma}^{(t)}\right), \tag{31b}$$

$$\mathbf{\Gamma}^{(t+1)}=\mathbf{\Gamma}^{(t)}-\eta\sigma\left(\mathbf{X}^{(t+1)}-\mathbf{Y}^{(t+1)}\right). \tag{31c}$$

In our experiments, we fix η and σ to 1. We initialize the algorithm with a random matrix.

Appendix E. Non-convex SDP solver

We follow the algorithm proposed in Kulis et al. (2007); Hou et al. (2015) to solve Problem (11). Our approach has a small but fundamental difference: instead of setting $r=K$, we allow for $r\geq K$. We define the augmented Lagrangian of Problem (11) as

$$\begin{aligned}\mathcal{L}\left(\mathbf{Y},\mu,\lambda\right)=&-\operatorname{Tr}\left(\mathbf{D}\mathbf{Y}^\top\mathbf{Y}\right)+\tfrac{\sigma}{2}\left\|\mathbf{Y}^\top\mathbf{Y}\mathbf{1}-\mathbf{1}\right\|_2^2-\mu^\top(\mathbf{Y}^\top\mathbf{Y}\mathbf{1}-\mathbf{1})\\&+\tfrac{\varphi}{2}(\operatorname{Tr}\left(\mathbf{Y}^\top\mathbf{Y}\right)-K)^2-\lambda(\operatorname{Tr}\left(\mathbf{Y}^\top\mathbf{Y}\right)-K),\end{aligned} \tag{32}$$

where μ,λ are Lagrange multipliers, σ,φ are penalty parameters. We obtain $\mathbf{Y}$ by running the steps

$$\mathbf{Y}^{(t+1)}=\underset{\mathbf{Y}\geq\mathbf{0}}{\operatorname{argmin}}\,\mathcal{L}\left(\mathbf{Y},\mu^{(t)},\lambda^{(t)}\right), \tag{33a}$$

$$\mu^{(t+1)}=\mu^{(t)}-\eta\sigma\left(\mathbf{Y}^\top\mathbf{Y}\mathbf{1}-\mathbf{1}\right), \tag{33b}$$

$$\lambda^{(t+1)}=\lambda^{(t)}-\eta\varphi\left(\operatorname{Tr}\left(\mathbf{Y}^\top\mathbf{Y}\right)-K\right). \tag{33c}$$

This is a non-standard approach since the minimization over $\mathbf{Y}$ (the gradient $\partial\mathcal{L}/\partial\mathbf{Y}$ is given in Hou et al. (2015)) is a non-convex problem. Although there are no guarantees about the convergence of the procedure, theoretical assurances for related problems have been presented in Boumal et al. (2016). To perform the minimization with respect to $\mathbf{Y}$, we use the L-BFGS-B algorithm (Byrd et al., 1995) with bound constraints ($(\mathbf{Y})_{ij}\in[0,1]$). Finally, the initialization to the overall iterative algorithm is done with symmetric nonnegative matrix factorization, see Appendix D. In our experiments, we fix η, φ, and σ to 1 and prenormalize $\mathbf{D}$ (dividing by its Frobenius norm).

Appendix F. Proofs for the conditional gradient algorithm

This section closely follows the works of Hazan (2008) and Clarkson (2010).

Lemma 3 *The dual objective of*

$$\max_{\mathbf{Z}} f(\mathbf{Z}) \quad s.t. \quad \mathbf{Z}\mathbf{b} = \mathbf{0}, \quad \operatorname{Tr}(\mathbf{Z}) = k-1, \quad \mathbf{Z} \succeq \mathbf{0} \tag{34}$$

is

$$\min_{\mathbf{Z}} w(\mathbf{Z}), \tag{35}$$

where

$$w(\mathbf{Z}) = s\,\phi(\mathbf{Z}) + f(\mathbf{Z}) - \operatorname{Tr}\left(\mathbf{Z}\nabla f(\mathbf{Z})\right), \tag{36}$$

$$\phi(\mathbf{Z}) = \max_{\substack{\|\mathbf{v}\|_2=1 \\ \mathbf{v}^\top\mathbf{b}=0}} \mathbf{v}^\top \nabla f(\mathbf{Z})\mathbf{v}. \tag{37}$$

Proof The Lagrangian relaxation of Problem (19) is

$$\begin{aligned}\ell = -\max_{\boldsymbol{\Psi},\psi,\mathbf{y}} \min_{\mathbf{Z}} \; & -f(\mathbf{Z}) - \operatorname{Tr}(\boldsymbol{\Psi}\mathbf{Z}) \\ & + \psi(\operatorname{Tr}(\mathbf{Z}) - s) + \mathbf{y}^\top\mathbf{Z}\mathbf{b},\end{aligned} \tag{38}$$

where $\boldsymbol{\Psi} \succeq \mathbf{0}$, $\psi \in \mathbb{R}$, and $\mathbf{y} \in \mathbb{R}^n$ are Lagrange multipliers. Differentiating and equating to zero we get $\boldsymbol{\Psi} = -\nabla f(\mathbf{Z}) + \psi\mathbf{I} + \mathbf{y}\mathbf{b}^\top$. Note that $\boldsymbol{\Psi} \succeq \mathbf{0}$ implies that $\mathbf{y} = c\mathbf{b}$ for some $c \in \mathbb{R}$, yielding

$$\boldsymbol{\Psi} = -\nabla f(\mathbf{Z}) + \psi\mathbf{I} + c\mathbf{b}\mathbf{b}^\top \succeq \mathbf{0}. \tag{39}$$

Plugging Eq. (39) and $\mathbf{y} = c\mathbf{b}$ in Eq. (38) we get

$$\begin{aligned}\ell &= \max_{\psi} \min_{\mathbf{Z}} f(\mathbf{Z}) - \operatorname{Tr}\left(\left(\nabla f(\mathbf{Z}) + \psi\mathbf{I} + c\mathbf{b}\mathbf{b}^\top\right)\mathbf{Z}\right) \\ &\qquad + \psi(\operatorname{Tr}(\mathbf{Z}) - s) + c\mathbf{b}^\top\mathbf{Z}\mathbf{b} \qquad (40) \\ &= \max_{\psi\in\mathbb{R}} \min_{\mathbf{Z}} f(\mathbf{Z}) - \operatorname{Tr}\left(\nabla f(\mathbf{Z})\,\mathbf{Z}\right) + \psi s \qquad (41) \\ &= \max_{\substack{\mathbf{Z} \\ \psi\in\mathbb{R}}} f(\mathbf{Z}) - \operatorname{Tr}\left(\nabla f(\mathbf{Z})\,\mathbf{Z}\right) - \psi s. \qquad (42)\end{aligned}$$

From Eq. (39), $\psi\mathbf{I} \succeq \nabla f(\mathbf{Z}) - c\mathbf{b}\mathbf{b}^\top$, implying

$$\begin{aligned}\psi &\geq \lambda_{\max}\left\{\nabla f(\mathbf{Z}) - c\mathbf{b}\mathbf{b}^\top\right\} \qquad (43a) \\ &\geq \lambda_{\max}\left\{\nabla f(\mathbf{Z}) - d\mathbf{b}\mathbf{b}^\top\right\} \quad \forall d > c \qquad (43b) \\ &\geq \phi(\mathbf{Z}). \qquad (43c)\end{aligned}$$

The last inequality comes from taking $d \to +\infty$, thus shifting the eigenvalue associated with $\mathbf{b}$ (should there be one) away from the maximum. Without loss of generality, we set $\psi = \phi(\mathbf{Z})$, finally obtaining $\ell = \min_{\mathbf{Z}} w(\mathbf{Z})$.

Proposition 4 *Let $\mathbf{X}, \mathbf{Z} \in \mathcal{P}_s$ and $\mathbf{Y} = \mathbf{X} + \alpha(\mathbf{Z} - \mathbf{X})$ and $\alpha \in \mathbb{R}$. The curvature constant of f is*

$$C_f := \sup_{\mathbf{X},\mathbf{Z},\alpha} \tfrac{1}{\alpha^2}[f(\mathbf{X}) - f(\mathbf{Y}) + (\mathbf{Y} - \mathbf{X}) \bullet \nabla f(\mathbf{X})]. \tag{44}$$

Let $\mathbf{Z}^\star$ be the solution to

$$\max_{\mathbf{Z}} f(\mathbf{Z}) \quad s.t. \quad \mathbf{Z}\mathbf{b} = \mathbf{0}, \quad \operatorname{Tr}(\mathbf{Z}) = k-1, \quad \mathbf{Z} \succeq \mathbf{0}. \tag{45}$$

The iterates $\mathbf{Z}_t$ of Alg. 1 satisfy for all $t > 1$

$$f(\mathbf{Z}^\star) - f(\mathbf{Z}_t) \leq \tfrac{8C_f}{t+2}. \tag{46}$$

Proof Let

$$h(\mathbf{Z}) = \tfrac{1}{4C_f}[f(\mathbf{Z}^\star) - f(\mathbf{Z})]. \tag{47}$$

Proving that $h(\mathbf{Z}_t) \leq \frac{2}{t+2}$ yields the desired result. From Lemma 3, we have

$$w(\mathbf{Z}) \geq w(\mathbf{Z}^\star) \geq f(\mathbf{Z}^\star) \geq f(\mathbf{Z}). \tag{48}$$

By eqs. (36) and (37), we have

$$\begin{aligned}\mathbf{v}_t^\top \nabla f(\mathbf{Z}_t)\mathbf{v}_t &= \phi(\mathbf{Z}) \qquad (49) \\ &= w(\mathbf{Z}_t) - f(\mathbf{Z}_t) + \operatorname{Tr}\left(\mathbf{Z}\,\nabla f(\mathbf{Z}_t)\right). \qquad (50)\end{aligned}$$

Therefore,

$$\operatorname{Tr}\left((\mathbf{H}_t - \mathbf{Z}_t)\,\nabla f(\mathbf{Z}_t)\right) = w(\mathbf{Z}_t) - f(\mathbf{Z}_t). \tag{51}$$

Now, using Eq. (20)

$$\begin{aligned}f(\mathbf{Z}_{t+1}) &= f(\mathbf{Z}_t + \alpha_t(\mathbf{H}_t - \mathbf{Z}_t)) \qquad (52a) \\ &\geq f(\mathbf{Z}_t) + \alpha_t \operatorname{Tr}\left((\mathbf{H}_t - \mathbf{Z}_t)\,\nabla f(\mathbf{Z}_t)\right) + \alpha^2 C_f. \qquad (52b)\end{aligned}$$

Putting Eq. (52b) together with eqs. (48) and (51),

$$\begin{aligned}f(\mathbf{Z}_{t+1}) &\geq f(\mathbf{Z}_t) + \alpha_t(w(\mathbf{Z}_t) - f(\mathbf{Z}_t)) - \alpha_t^2 C_f \qquad (53a) \\ &\geq f(\mathbf{Z}_t) + \alpha_t(f(\mathbf{Z}^\star) - f(\mathbf{Z}_t)) - \alpha_t^2 C_f \qquad (53b) \\ &= f(\mathbf{Z}_t) + 4\alpha_t C_f h(\mathbf{Z}_t) - \alpha_t^2 C_f. \qquad (53c)\end{aligned}$$

From the definition of $h(\mathbf{Z}_t)$, this implies

$$h(\mathbf{Z}_{t+1}) \leq h(\mathbf{Z}_t) - \alpha_t h(\mathbf{Z}_t) + \tfrac{\alpha_t^2}{4}. \tag{54}$$

Finally, we prove inductively that $h(\mathbf{Z}_t) \leq \frac{2}{t+2}$. In the first iteration, $\alpha_1 = 1$ and $h(\mathbf{Z}_2) \leq \frac{1}{4}$. By taking $\alpha = \frac{2}{t+2}$, we have

$$\begin{aligned}h(\mathbf{Z}_{t+1}) &\leq h(\mathbf{Z}_t) - \alpha_t h(\mathbf{Z}_t) + \tfrac{\alpha_t^2}{4} \qquad (55a) \\ &\leq (1 - \alpha_t)h(\mathbf{Z}_t) + \tfrac{\alpha_t^2}{2} \qquad (55b) \\ &= (1 - \tfrac{2}{t+2})\tfrac{2}{t+2} + \tfrac{2}{(t+2)^2} \leq \tfrac{2}{t+3}. \qquad (55c)\end{aligned}$$

Abstract

`seglearn` is an open-source Python package for performing machine learning on time series or sequences. The implementation provides a flexible pipeline for tackling classification, regression, and forecasting problems with multivariate sequence and contextual data. Sequences and series may be learned directly with deep learning models or via feature representation with classical machine learning estimators. This package is compatible with `scikit-learn` and is listed under `scikit-learn` "Related Projects". The package depends on `numpy`, `scipy`, and `scikit-learn`. `seglearn` is distributed under the BSD 3-Clause License. Documentation includes a detailed API description, user guide, and examples. Unit tests provide a high degree of code coverage. Source code and documentation can be downloaded from `https://github.com/dmbee/seglearn`.

Keywords: Machine-Learning, Time-Series, Sequences, Python

1. Introduction

Many real-world machine learning problems e.g. voice recognition, human activity recognition, power systems fault detection, stock price and temperature prediction, involve data that is captured as sequences over a period of time (Aha, 2018). Sequential data sets do not fit the standard supervised learning framework, where each sample $(\mathbf{x}, y)$ within the data set is assumed to be independently and identically distributed (iid) from a joint distribution $P(\mathbf{x}, y)$ (Bishop, 2011). Instead, the data consist *sequences* of $(\mathbf{x}, y)$ pairs, and nearby values of $(\mathbf{x}, y)$ within a *sequence* are likely to be correlated to each other. Sequence learning exploits the sequential relationships in the data to improve algorithm performance.

2. Supported Problem Classes

Sequence data sets have a general formulation (Dietterich, 2002) as sequence pairs $\{(\mathbf{X}_i, \mathbf{y}_i)\}_{i=1}^{N}$, where each $\mathbf{X}_i$ is a multivariate sequence with T_i samples $\langle \mathbf{x}_{i,1}, \mathbf{x}_{i,2}, ..., \mathbf{x}_{i,T_i} \rangle$ and each $\mathbf{y}_i$ target is a univariate sequence with T_i samples $\langle y_{i,1}, y_{i,2}, ..., y_{i,T_i} \rangle$. The targets $\mathbf{y}_i$ can either be sequences of categorical class labels (for classification problems), or sequences of continuous data (for regression problems). The number of samples T_i varies between the sequence pairs in the data set. Time series with a regular sampling period may be treated equivalently to sequences. Irregularly sampled time series are formulated with an additional sequence variable $\mathbf{t}_i$ that increases monotonically and indicates the timing of samples in the data set $\{(\mathbf{t}_i, \mathbf{X}_i, \mathbf{y}_i)\}_{i=1}^{N}$.

Important sub-classes of the general sequence learning problem are sequence classification and sequence prediction. In sequence classification problems (eg song genre classification), the target for each sequence is a fixed class label y_i and the data takes the form $\{(\mathbf{X}_i, y_i)\}_{i=1}^{N}$. Sequence prediction involves predicting a future value of the target $(y_{i,t+f})$ or future values $\langle y_{i,t+1}, y_{i,t+2}, ..., y_{i,t+f} \rangle$, given $\langle \mathbf{x}_{i,1}, \mathbf{x}_{i,2}, ..., \mathbf{x}_{i,t} \rangle$, $\langle y_{i,1}, y_{i,2}, ..., y_{i,t} \rangle$, and sometimes also $\langle \mathbf{x}_{i,t+1}, \mathbf{x}_{i,t+2}, ..., \mathbf{x}_{i,t+f} \rangle$.

A final important generalization is the case where contextual data associated with each sequence, but not varying within the sequence, exists to support the machine learning algorithm performance. Perhaps the algorithm for reading electrocardiograms will be given access to laboratory data, the patient's age, or known medical diagnoses to assist with classifying the sequential data recovered from the leads.

`seglearn` provides a flexible, user-friendly framework for learning time series and sequences in all of the above contexts. Transforms for sequence padding, truncation, and sliding window segmentation are implemented to fix sample number across all sequences in the data set. This permits utilization of many classical and modern machine learning algorithms that require fixed length inputs. Sliding window segmentation transforms the sequence data into a piecewise representation (segments), which is particularly effective for learning periodized sequences (Bulling et al., 2014). An interpolation transform is implemented for resampling irregularly sampled time series. The sequence or time series data can be learned directly with various neural network architectures (Lipton et al., 2015), or via a feature representation which greatly enhances performance of classical algorithms (Bulling et al., 2014).

3. Installation

The `seglearn` source code is available at: `https://github.com/dmbee/seglearn`. It is operating system agnostic, and implemented purely in Python. The dependencies are `numpy`, `scipy`, and `scikit-learn`. The package can be installed using pip:

```
$ pip install seglearn
```

Alternatively, seglearn can be installed from the sources:

```
$ git clone https://github.com/dmbee/seglearn
$ cd seglearn
$ pip install .
```

Unit tests can be run from the root directory using `pytest`.

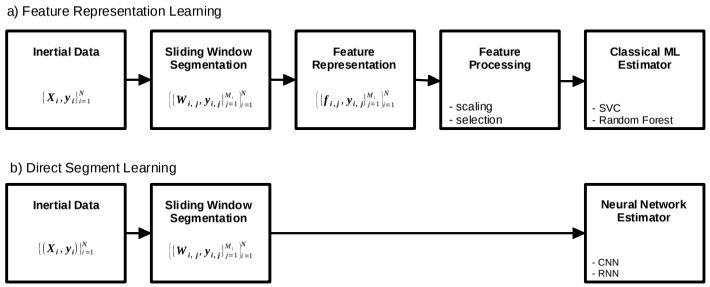

Figure 1: Example `seglearn` pipelines for a) learning segment feature representations, b) learning segments directly. $\boldsymbol{X}_i$: time series, $\boldsymbol{y}_i$: time series target, N: number of time series in the data set, $\boldsymbol{W}_{i,j}$: segment (derived from $\boldsymbol{X}_i$), $\boldsymbol{f}_{i,j}$: feature vector (calculated from $\boldsymbol{W}_{i,j}$), $\boldsymbol{y}_{i,j}$: segment target, M_i: number of segments derived from time series $\boldsymbol{X}_i$, SVC: Support Vector Classifier, CNN: Convolution Neural Network, RNN: Recurrent Neural Network.

4. Implementation

The `seglearn` API was implemented for compatibility with `scikit-learn` and its existing framework for model evaluation and selection. The `seglearn` package provides means for handling sequence data, segmenting it, computing feature representations, calculating train-test splits and cross-validation folds along the temporal axis.[1] An iterable, indexable data structure is implemented to represent sequence data with supporting contextual data.

The `seglearn` functionality is provided within a `scikit-learn` pipeline allowing the user to leverage `scikit-learn` transformer and estimator classes, which are particularly helpful in the feature representation approach to segment learning. Direct segment learning with neural networks is implemented in pipeline using the `keras` package, and its `scikit-learn` API. Examples of both approaches are provided in the documentation and example gallery. The integrated learning pipeline, from raw data to final estimator, can be optimized within the `scikit-learn model_selection` framework. This is important because segmentation parameters (eg window size, segment overlap) can have a significant impact on sequence learning performance (Burns et al., 2018; Bulling et al., 2014).

Sliding window segmentation transforms sequence data into a piecewise representation (segments), such that predictions are made and scored for all segments in the data set. Sliding window segmentation can be performed for data sets with a single target value per sequence, in which case that target value is mapped to all segments generated from the parent sequence. If the target for each is sequence is also a sequence, the target is segmented

1. Note splitting time series data along the temporal axis violates the assumption of independence between train and test samples. However, this is useful in some cases, such as the analysis of a single series.

as well and various methods may be used to select a single target value from the target segment (e.g. mean value, middle value, last value, etc.) or the target segment sequence can be predicted directly if an estimator implementing sequence to sequence prediction is utilized.

A human activity recognition data set (Burns et al., 2018) consisting of inertial sensor data recorded by a smartwatch worn during shoulder rehabilitation exercises is provided with the source code to demonstrate the features and usage of the `seglearn` package.

5. Basic Example

This example demonstrates the use of `seglearn` for performing sequence classification with our smartwatch human activity recognition data set.

```
>>> import seglearn as sgl
>>> from sklearn.model_selection import train_test_split
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.preprocessing import StandardScaler
>>>
>>> data = sgl.load_watch()
>>> X_train, X_test, y_train, y_test = train_test_split(data["X"], data["y"])
>>>
>>> clf = sgl.Pype([("seg", sgl.SegmentX(width=100, overlap=0.5)),
...                 ("features", sgl.FeatureRep()),
...                 ("scaler", StandardScaler()),
...                 ("rf", RandomForestClassifier())])
>>>
>>> clf.fit(X_train, y_train)
>>> score = clf.score(X_test, y_test)
>>> print("accuracy score:", score)

accuracy score:  0.7805084745762711
```

6. Comparison to other Software

Three other Python packages for performing machine learning on time series and sequences were identified: `tslearn` (Tavenard, 2017), `cesium-ml` (Naul et al., 2016), and `tsfresh` (Christ et al., 2018). These were compared to `seglearn` based on time series learning capabilities (Table 1), and performance (Table 2).

`cesium-ml` (v0.9.6) and `tsfresh` (v0.11.1) support feature representation learning of multi-variate time series, and currently implement more features than does `seglearn`. However, the feature representation transformers are implemented as a pre-processing step, independent to the otherwise sklearn compatible pipeline. This design choice precludes end-to-end model selection. There are no examples or apparent support for problems where the target is a sequence/time series or integration with deep learning models.

	tslearn	cesium-ml	ts-fresh	seglearn

Documentation	✓	✓	✓	✓
Unit Tests	✓	✓	✓	✓
Multivariate time series	✓	✓	✓	✓
Context data	X	✓	X	✓
Time series target	X	X	X	✓
Sliding window segmentation	X	X	X	✓
Temporal folds	X	X	X	✓
sklearn compatible model selection	X	X	X	✓
Feature representation learning	X	✓	✓	✓
Number of implemented features	N/A	58	64	20
Deep learning	X	X	X	✓
Classification	✓	✓	✓	✓
Clustering	✓	✓	✓	✓
Regression	✓	✓	✓	✓
Forecasting	X	✓	✓	✓

Table 1: Comparison of time series learning package features for `tslearn` v0.1.18.4, `cesium-ml` v0.9.6, `tsfresh` v0.11.1 and `seglearn` v1.0.2.

`tslearn` (v0.1.18.4) implements time-series specific classical algorithms for clustering, classification, and barycenter computation for time series with varying lengths. There is no support for feature representation learning, learning context data, or deep learning.

The performance comparison was conducted using our human activity recognition data set with 140 multivariate time series with 6 channels sampled uniformly at 50 Hz and 7 activity classes. The series' were all truncated to 4 seconds (200 samples). Classification accuracy was measured on 35 series' held out for testing, and 105 used for training. `seglearn`, `cesium-ml`, and `tsfresh` were tested using the sklearn implementation of the SVM classifier with a radial basis function (RBF) kernel on 5 features (median, minimum, maximum, standard deviation, and skewness) calculated on each channel (total 30 features). `tslearn` was evaluated with its own SVM classifier implementing a global alignment kernel (Cuturi et al., 2007). The testing was performed using an Intel Core i7-4770 testbed with 16 GB of installed memory, on Linux Mint 18.3 with Python 2.7.12.

Classification accuracy was identical between `cesium-ml`, `tsfresh`, and `seglearn` (as they used the same features and classifier in the evaluation) though `seglearn` significantly outperformed the other packages in terms of computation time. Classification performance of the global alignment kernel SVM (GAK-SVM) implemented in `tslearn` was poor on our data set, even following hyper-parameter optimization of gamma by grid search over the log space $[10^{-4}, 10^{4}]$. GAK-SVM is not typically applied to raw inertial data for human activity recognition in the literature, and better performance has been achieved with this algorithm in other time series applications (Cuturi and Doucet, 2011; Lorincz et al., 2013).

	tslearn	cesium-ml	ts-fresh	seglearn
Classification accuracy	0.057	**0.714**	**0.714**	**0.714**
Computation time (seconds)	0.79	62.9	0.40	**0.088**

Table 2: Comparison of time series learning package performance on our human activity recognition dataset.

DALEX: Explainers for Complex Predictive Models in R

Przemysław Biecek przemyslaw.biecek@gmail.com
Faculty of Mathematics and Information Science, Warsaw University of Technology
75 Koszykowa Street, Warsaw, Poland
Samsung Research Poland

Editor: Alexandre Gramfort

Abstract

Predictive modeling is invaded by elastic, yet complex methods such as neural networks or ensembles (model stacking, boosting or bagging). Such methods are usually described by a large number of parameters or hyper parameters - a price that one needs to pay for elasticity. The very number of parameters makes models hard to understand.

This paper describes a consistent collection of explainers for predictive models, a.k.a. black boxes. Each explainer is a technique for exploration of a black box model. Presented approaches are model-agnostic, what means that they extract useful information from any predictive method irrespective of its internal structure. Each explainer is linked with a specific aspect of a model. Some are useful in decomposing predictions, some serve better in understanding performance, while others are useful in understanding importance and conditional responses of a particular variable.

Every explainer presented here works for a single model or for a collection of models. In the latter case, models can be compared against each other. Such comparison helps to find strengths and weaknesses of different models and gives additional tools for model validation. Presented explainers are implemented in the `DALEX` package for R. They are based on a uniform standardized grammar of model exploration which may be easily extended.

Keywords: interpretable machine learning, explainable artificial intelligence, predictive modelling, model visualization

1. Introduction

Predictive modeling has a large number of applications in almost every area of human activity, starting from medicine, marketing, logistic, banking and many others. Due to the increasing amount of collected data, models become more sophisticated and complex.

It is believed that there is a trade-off between the interpretability and accuracy of a model (see Johansson et al., 2011). It comes from the observation that the most elastic models usually have higher accuracy but in turn they are also more complex. Complexity here means a large number of model parameters that affect the final prediction. That number is big enough to make the model ununderstandable for an ordinary human being.

In many areas we cannot sacrifice interpretability, either because of legal requirements (see *right to explanation* in GDPR), or because it leads to unfair decisions (see O'Neil, 2016) or because it is important for users (see Lundberg and Lee, 2017). Interpretability brings multiple benefits such as: a) helps to extract interpretable patterns from trained models; b) helps to identify reasons behind poor predictions; c) increases trust in model predictions (see Ribeiro et al., 2016); d) reduces the hidden debt in machine learning models (see Sculley et al., 2015); e) helps to detect bias in machine learning models; f) creates additional safety catch that may protect from overfitted models.

In this paper we present a consistent general framework for exploration of black-box models. This framework covers the most known approaches to interpretability and structure exploration, such as Partial Dependence Plots (Greenwell, 2017), Accumulated Local Effects Plots (Apley, 2017), Merging Path Plots (Sitko and Biecek, 2017), Break Down Plots (Staniak and Biecek, 2018), Permutational Variable Importance Plots (Fisher et al., 2018) or Cateris Paribus Plots. An unique feature of `DALEX` explainers is that they can be natively used to compare two or more models. Model comparison helps to understand differences in model responses, gives new insights that may be used to construct new, better features.

Presented framework is available as an open source package `DALEX` for R. The R language (R Core Team, 2017) is one of the most popular languages for statistical and machine learning modeling. `DALEX` works with any predictive model. The extended user documentation[1] contains examples for the most popular frameworks, such as `caret` (Kuhn, 2008), `mlr` (Bischl et al., 2016), Random Forest and Gradient Boosting Machines. The `DALEX` package is available on at CRAN and GitHub[2] along with technical documentation[3].

Example explainers presented in this paper were recorded with the `archivist` package (Biecek and Kosinski, 2017). To save space, we present only graphical explainers. Numerical explainers can be downloaded with R commands listed in footnotes.

2. Architecture

Figure 1 presents the general architecture of the `DALEX` package. This methodology is model-agnostic and works for predictive models, such as classification or regression models.

Methods for understanding of global structure of a model (a.k.a. model explainers) and for understanding of a local structure of a model (a.k.a. prediction explainers) are implemented in separate functions. We call these functions *explainers* since they are designed to explain a single feature of a model. Every explainer returns numerical summaries in a tabular format. These tables may be visualized with generic `plot` function. The `plot` function works also for multiple models and overlays model explainers in a single chart. See examples in Figure 1 panels F, I and J.

2.1. Prediction Understanding: Explainers for Variable Attribution

The most known approaches to explanations of a single prediction are *LIME* method (Ribeiro et al., 2016), for local variable importance, and *Shapley values* (Lundberg and Lee, 2017), for local variable attribution. *Break Down Plots* are fast approximations of *Shapley values*. Comparison of these methods is presented in Staniak and Biecek (2018). An example for these explainers[4] is presented in Figure 1 panels C and D.

Note, that for non additive models, the local model behaviour may be very different from global model behaviour. Consider $f(x_1, x_2) = x_1 * x_2$ around point $(0, 0)$.

1. User documentation is available at `https://pbiecek.github.io/DALEX_docs`.
2. Development version is available at `https://github.com/pbiecek/DALEX`.
3. Technical documentation is available at `https://pbiecek.github.io/DALEX`.
4. Access this explainer with `archivist::aread('pbiecek/DALEX_arepo/72b47')`.

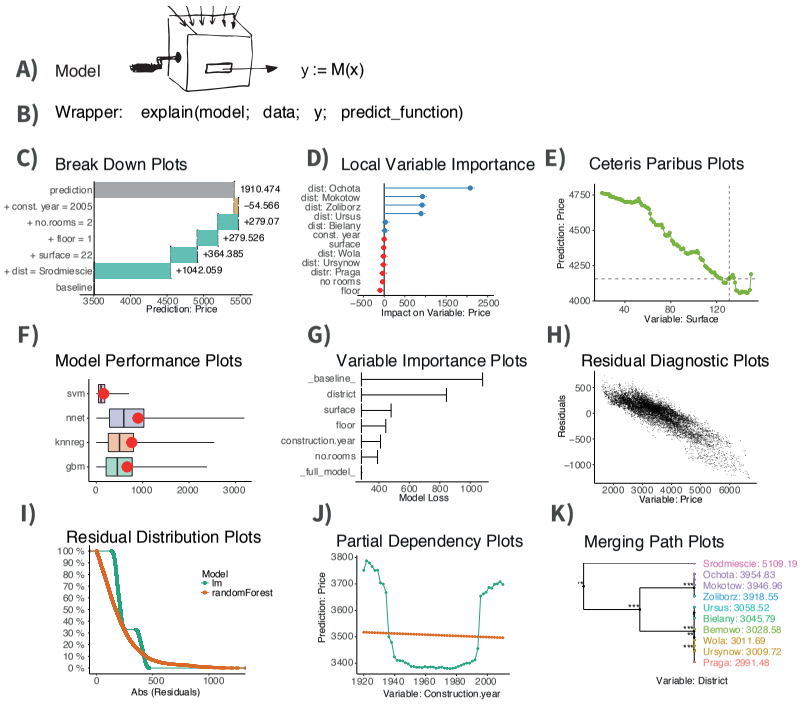

Figure 1: Architecture of the `DALEX` package is based on simple unified grammar. A) Any predictive model $M : \mathcal{R}^p \to \mathcal{R}$ may be used. B) Models are first enriched with additional metadata with the function `explain()`. Each explainer returns numerical summaries that can be plotted with generic `plot()` function. C, D, E) Explainers for a single prediction. F) Comparison of four models. G, H) Explainers for a single model, I) Comparison of residuals for two models. J, K) Explainers for a single variable, respectively continuous and categorical.

2.2. Prediction Understanding: Explainers for What-If Scenarios

Ceteris Paribus Profiles show how the model response changes as a function of a single variable. These plots recollect similarities to more known *Partial Dependency Plots*. The difference between them is that *Ceteris Paribus Profiles* are focused on a single observation.

An example for this explainer[5], is presented in Figure 1 panel E. One can read how model response will change for an altered value of a single variable.

5. Access this explainer with `archivist::aread('pbiecek/DALEX_arepo/c8989')`.

2.3. Model Understanding: Explainers for Model Performance

Model performance is often summarized with a single number such as *F1* or *accuracy*. This makes it easier to construct a ranking of models and choose the best one. However, more descriptive statistics are better when it comes to understanding of a model. The descriptive statistics most often used for classification is *ROC (Receiver Operating Characteristic)* with various extensions for regression as in Hernndez-Orallo (2013).

The `DALEX` package offers a selection of tools for exploration of model performance, see Figure 1 panels F and I[6], and model diagnostic, see Figure 1 panel H. The latter is available through the `auditor` package (Gosiewska and Biecek, 2018), closely integrated with `DALEX`.

2.4. Model Understanding: Explainers for Effect of a Single Variable

The `DALEX` package offers a selection of tools for better understanding of a conditional model's response based on a single variable. For continues variables it supports *Partial Dependence Plot* (Greenwell, 2017) as implemented in the `pdp` package and *Accumulated Local Effects Plot* (Apley, 2017) as implemented in `ALEPlot` package, see Figure 1 panel J[7]. For categorical variables it supports *Merging Path Plot* (Sitko and Biecek, 2017) as implemented in the `factorMerger` package. See Figure 1 panel K.

2.5. Model Understanding: Explainers for Variable Importance

The `DALEX` package offers a model-agnostic procedure to calculate variable importance. The model-agnostic approach is based on permutational approach introduced initially for *Random Forest* (Breiman, 2001) and then extended for other models by Fisher et al. (2018).

An example for these explainers[8] is presented in Figure 1 panel G. It's common in variable importance charts to hitch bars in 0. Charts in the `DALEX` package present not only drop in model performance but also the initial model performance. In that way one can compare variables between models with different initial performance.

3. Summary

In this article we have introduced consistent methodology and tools for model-agnostic explanations. Global explainers (for model understanding) and local explainers (for prediction understanding) are based on uniform grammar. Every explainer creates a numerical summary, visual summary and allows for comparison of multiple models. The `DALEX` package is tested with CI tools and is easy to extend[9]. Here we presented `DALEX` 0.2.5 with `R` 3.5.1.
